The results given in Fig. 6 and 7 demonstrate that the onset of passivation is determined by flow rate and current density. The results strongly indicate that, in the systems investigated here, the onset of passivation is controlled by mass transfer. The fact that in both nitrate solutions studied (Fig. 7) passivation occurred in the same range of current density suggests that the transport of anions was not a controlling factor. An anion limited dissolution mechanism is expected if a net consumption of anions at the anode occurs, *e.g.*, by complex formation of dissolved metal ions. Such a mechanism has been reported for the dissolution of gold in chloride solutions (33) and a similar but more complex case is represented by the dissolution of copper in chloride solution, where under some conditions formation of stable cuprous chloride complexes is possible (30, 33). If noncomplexed metal ions are produced during the dissolution process, accumulation of anions in the vicinity of the anode is necessary in order to maintain electroneutrality.

At a high dissolution rate, the product of the metal ion concentration and anion concentration may exceed the solubility product. This may lead to precipitation of salt crystals. Initiation of passivity by salt precipitation has been described by Muller (31). A critical review of more recent literature dealing with the phenomena has been given by Hoar (32). The fact that, in our experiments, the onset of passivity was independent of concentration in nitrate solutions, but occurred at lower current densities in the sulfate solution, is qualitatively consistent with the above mechanism, since copper sulfate has a lower solubility than copper nitrate.

A semiquantitative test of the theory is illustrated by the results of Fig. 8, in which Nusselt numbers derived from the experimentally observed passivation current densities were compared with those predicted from the known mass transfer relations [3] and [9]. A band of possible values of the passivation current density i_p was estimated from Fig. 7. Nusselt numbers corresponding to these values were calculated by assuming a concentration driving force corresponding to the saturation concentration c_s of copper nitrate and copper sulfate, respectively. The experimental Nusselt number is then given by

$$Nu_p = \frac{i_p D_h}{2\mathbf{F} c_s D} \qquad [10]$$

The value of D was assumed to be 10^{-5} cm^2/sec. It has to be regarded as an order of magnitude estimate of an effective diffusion coefficient of copper ion including the influence of migration and of possible changes in physical properties in the vicinity of the anode. Values for the saturation concentration c_s were estimated from solubility data given in (15) and (16) to be 7 mole/liter for copper nitrate and 1.5 mole/liter for copper sulfate (25°C). The influence of the presence of potassium ions on the value of c_s was neglected, since due to migration, their concentration at the interface is much smaller than that of copper ions. A reasonable order of magnitude agreement between experimental and predicted passivation current densities was obtained (Fig. 8). The observed agreement indicates that in the systems studied here, the application of a model which considers maximum possible mass transfer rates of dissolution products leads to valid predictions of the conditions, which correspond to the onset of passivation.

Surface textures.—The results reported in the previous section indicated that the surface texture resulting from anodic dissolution depended strongly on whether dissolution occurred in the active or transpassive mode. As to which dissolution mode prevailed at a given current density depended on mass transfer conditions. The findings of the present investigation are thus comparable to results reported in recent studies about the conditions leading to electropolishing (17-20). While the detailed mechanism leading to polishing is disputed, it is well established now that passivation phenomena play a dominant role. The current density leading to passivation (sometimes referred to as limiting current density in the literature) is determined by mass transfer. Obtaining polished surfaces during ECM has been reported by various authors (21-23). The fact that, under appropriate operating conditions, a very low surface roughness can be obtained allows the application of ECM to technical surface finishing operations (24). No current potential curves indicating passivation have been reported so far for conditions corresponding to ECM. In view of the results obtained in the present study and of some findings reported in the literature (25,29), it seems very probable that passivation phenomena play an important role in practical ECM, not only with respect to dimensional accuracy (see above) but also with respect to obtainable surface finish. The present study confirms and extends a general observation (20) valid for metal dissolution at conventional current densities, that active dissolution leads to etched surfaces while transpassive dissolution often results in anodic brightening, pitting, or polishing.

Many questions remain unanswered by the present study such as, *e.g.*, why pitting is observed at all under the present experimental conditions which would seem highly unfavorable for dissolution within pits, not only from a point of view of local current distribution, but also from a point of view of mass transfer. The role of the metallurgical factors in determining

[16] The effective specific resistance ρ_i* is always smaller than ρ_i because the actual cross section of the current flux in the solution is larger than the electrode area.

[17] Such measurements are complicated by the extremely fast discharge of the double layer under the conditions employed.

how etching and pitting proceed or the influence of the chemical composition of the electrolyte on the nature of anodic films formed are other areas which need more research. A study of the dissolution of copper single crystals under conditions comparable to those of the present study has been initiated recently at this laboratory.

Conclusions

The present work demonstrates the feasibility of studying an electrochemical process proceeding at a current density of many amperes per square centimeter under controlled hydrodynamic conditions. A rectangular flow channel cell operated under fully developed turbulent flow conditions has been found to be well suited for this investigation. Steady state mass transfer rates corresponding to an equivalent diffusion layer thickness of the order of 10^{-4} cm have been realized.

A study of copper dissolution in KNO_3 and K_2SO_4 solutions has shown two distinct dissolution modes. Active dissolution resulting in etched surfaces occurred at relatively low overpotentials. Observed dissolution rates were well within the limits estimated from known mass transfer relations for the transport of cupric ions away from the surface. Transpassive dissolution proceeded at higher anode potentials, leading to pitting and brightening. Current densities applied during transpassive dissolution were up to ten times higher than the minimum current density leading to passivation; the latter is believed to correspond to the highest rate at which cupric ions may be removed from the anode by convective diffusion. It appears, therefore, that a large part of the oxidized copper was transported away from the anode in the form of solid dissolution products formed at or near the anode. It is probable that a similar transport mechanism is involved in many practical ECM operations.

Diffusion of Oxygen through a Platinum Diaphragm

James P. Hoare*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

A thin Pt foil was mounted in a cell between two compartments filled with 2*N* sulfuric acid solution. On the polarization side, the foil was anodized, and oxygen was detected on the diffusion side by observing the increase in potential *vs.* an α-Pd reference electrode in the N_2-stirred acid solution. When the foil was made a cathode, the potential on the diffusion side shifted toward less noble values. The diffusion coefficient was determined with Fick's First Law from the cathodized foil data to be 1.8×10^{-11} cm^2 sec^{-1} at 24°C and by the time lag method from the anodized foil data to be 4.4×10^{-11} cm^2 sec^{-1} at 24°C.

In a recent report (1), it was demonstrated that oxygen can penetrate Pt foil bielectrodes by migrating from the anodized side through the metal to the cathodized side. The presence of oxygen was detected on the cathodic side of the bielectrode by its effect on the hydrogen overvoltage. It was suggested (2) that additional evidence in favor of the conclusions drawn from the bielectrode studies may be obtained by anodizing the Pt foil connected as a diaphragm (1) and

* Electrochemical Society Active Member.

observing the potential on the unpolarized or diffusion side of the Pt diaphragm. The results of such an experiment are described in the following paragraphs.

Preparation of the electrodes, solutions, and Teflon cell is the same as described for the bielectrode studies (1) except that an α-Pd reference electrode (3) was placed in the cell compartment on the diffusion side of the Pt diaphragm. After preelectrolyzing all the electrodes and both sides of the foil against removable Pt wire cathodes for 24 hr, purified hydrogen was bubbled through the $2N$ H_2SO_4 solution contained in both compartments of the cell until the potential between any two Pt electrodes was zero volts and until the Pd bead electrode was converted to an α-Pd reference electrode. Then H_2-stirring was replaced with N_2-stirring at a flow rate of about 250 cc/min. All potentials are recorded against the normal hydrogen electrode (NHE).

A Pt foil (0.00127 cm thick with an apparent exposed area of 0.7 cm^2) was anodized (potential $\sim$ 2600 mV) at 24.6 mA/cm^2 against a large Pt gauze counter electrode in the polarization compartment of the cell, and the potential of the diffusion side of the foil was recorded against the α-Pd reference electrode in the N_2-stirred acid solution as a function of the time of polarization. Potentials were recorded with a Model 1230A General Radio Electrometer with an input impedance of 10^{14} ohms. The results are presented in Fig. 1 by the circles.

After an induction period of about 1.75 hr where the potential remained in the vicinity of the hydrogen potential, the potential rose relatively rapidly to a fairly steady value (increase in potential of 2 to 3 mV in 30 min) between 1050 and 1060 mV. Duplicate runs yielded similar results.

A possible explanation is as follows: The driving force of anodic polarization enables oxygen to penetrate the Pt lattice beyond the dermasorbed regions (4). This dissolved oxygen can migrate through the Pt lattice to the diffusion side of the Pt where it can react with any dermasorbed or surface adsorbed hydrogen to form water. Once the hydrogen is removed, oxygen can saturate the dermasorbed layers and migrate to the surface of the diffusion side of the Pt foil diaphragm. At this point, the potential rises rapidly to more noble potentials. Finally, a point is reached where a steady-state concentration of oxygen is maintained on the Pt surface as indicated by the steady value of 1060 mV.

It is interesting to note that in one run in which a tiny leak developed between the polarization and diffusion compartments of the cell, any polarization applied to the polarization side of the diaphragm appeared immediately on the diffusion side.

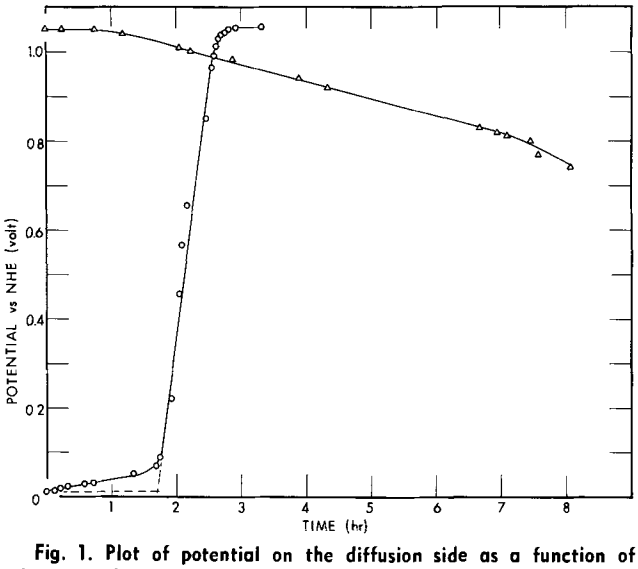

Fig. 1. Plot of potential on the diffusion side as a function of the time the Pt foil was anodized (circles) and cathodized (triangles) on the polarization side. The dotted lines indicate how the time lag was determined.

When the potential of the diffusion side of the Pt foil diaphragm had reached the steady value of 1060 mV, the polarization side of the foil was cathodized. Nitrogen-stirring was maintained. A plot of the potential of the diffusion side as a function of the length of time of cathodization at — 24.6 mA/cm^2 on the polarization side is shown in Fig. 1 by the triangles. The potential does fall with time but at an extremely slow rate.

This result is in agreement with the findings that hydrogen does not penetrate Pt foils with clean surfaces (5, 6). When H_2 is evolved on the polarization side of the Pt foil, atomic hydrogen can penetrate the Pt lattice no further than the dermasorbed region (first 2 or 3 atom layers), but oxygen can diffuse from the interior of the Pt to react with hydrogen on the polarization side of the foil setting up an oxygen concentration gradient across the Pt diaphragm. As oxygen diffuses from the diffusion side to the polarization side of the diaphragm to react with hydrogen, the surface concentration of oxygen on the diffusion side of the Pt foil decreases with time, producing a shift of the potential to less noble values. It seems, then, that the rate of diffusion of oxygen through the Pt diaphragm under the driving force of the oxygen concentration gradient set up under open-circuit conditions is much slower than the migration of dissolved oxygen through the foil under the driving force of the concentration gradient set up by anodization.

If one can assume for the case where the foil is cathodic that a steady-state removal of oxygen takes place during the second to the sixth hour of a run (triangles in Fig. 1), and that Fick's First Law applies, an estimate of the diffusion coefficient of oxygen through Pt can be made. It is likely that Fick's law holds because a thickness effect was observed in the bielectrode studies (1). It must also be assumed (*a*) that the dermasorbed layers on the polarization side of the foil are saturated with dissolved hydrogen, (*b*) that the dermasorbed layers on the diffusion side are saturated with dissolved oxygen, and (c) that an oxygen atom reaching the polarization side will be removed by the reaction with dermasorbed hydrogen atoms to form water.

The layers saturated with oxygen are kept saturated as long as surface adsorbed oxygen is present to diffuse into the dermasorbed layers. From cathodic stripping curves, it has been shown (7) that the potential of an oxygen electrode depends directly on the amount of oxygen adsorbed on the Pt surface. The rate of change of potential with surface coverage, θ, is 2.28 mV μC^{-1} cm^{-2}. In Fig. 1 (triangles), the decrease in potential is directly related to the decrease in coverage or the disappearance of oxygen.

Fick's First Law may be written as

$$P = D\, dc/dx$$

where D is the diffusion constant (cm^2 sec^{-1}), dc/dx the concentration gradient (atoms cm^{-1}), and P the permeation rate (atoms cm sec^{-1}). If the dissolved oxygen atom resides in the octahedral holes of the face centered cubic Pt lattice, there is associated ideally with each surface Pt site a dermasorbed oxygen (in the surface layer the four nearest neighbor Pt atoms are shared with four other unit cells). Since the quantity of charge associated with a monolayer of adsorbed oxygen atoms is 420 μC cm^{-2} (7, 8) and with an oxygen atom, 3.2 x 10^{-19} C, the saturated dermasorbed layer contains 1.31 x 10^{15} oxygen atoms cm^{-2}. The thickness of the foil is 1.27 x 10^{-3} cm and the concentration of oxygen atoms on the polarization side is zero. Then, dc/dx is 1.03 x 10^{18} atoms cm^{-1}.

The slope of the curve (triangles) in Fig. 1 is 38 mV hr^{-1}, and using 2.28 mV μC^{-1} cm^{-2} as the rate of change of potential with coverage along with the foil

thickness, 1.27 x 10^{-3} cm, a value of 1.85 x 10^{7} atoms cm sec^{-1} is obtained for P. From these calculated values of P and dc/dx, a value of 1.8 x 10^{-11} cm^2 sec^{-1} is obtained for D at 24°C. This value is about three orders of magnitude smaller than the D for hydrogen through iron (1.16 x 10^{-8} at 85°C) and about two orders smaller for hydrogen through nickel (2.59 x 10^{-9} at 20°C) (9). Such values for D for oxygen through Pt seem reasonable in consideration of the larger size of the oxygen atom.

The diffusion constant can also be determined from the time lag method (ref. 9, p. 217) by the equation

$$D = d^2/6t_{lag}$$

where d is the thickness of the diaphragm and t_{lag} is the time required to set up the steady state of flow after starting the run. In the case where the foil was anodized (circles in Fig. 1), an induction period was observed. From this curve, t_{lag} is 101 min, and D has a value of 4.4 x 10^{-11} cm^2 sec^{-1}, in good agreement with 1.8 x 10^{-11} cm^2 sec^{-1} calculated from the triangles in Fig. 1.

Thermodynamics of LiBr in Anhydrous Dimethyl Sulfoxide

Mark Salomon

NASA, Electronics Research Center, Cambridge, Massachusetts

ABSTRACT

The activity coefficients of LiBr in anhydrous dimethyl sulfoxide have been determined at several temperatures by the emf method. The results differ considerably from the analogous LiCl-DMSO system and it is concluded that anion solvation effects are mainly responsible for this behavior.

The properties of dipolar aprotic solvents such as dimethyl sulfoxide differ so widely from those of the protic solvents that interest in them has grown both in kinetic (1-5) and thermodynamic studies (5-9). In the present paper, the thermodynamics of LiBr in dimethyl sulfoxide (DMSO) is reported. The activity coefficients were determined at several temperatures by emf measurements on the cell

$$Li \mid LiBr - DMSO \mid TlBr, Tl\ (Hg) \qquad [1]$$

The observed emf's of cell [1] can be converted to the emf's of cell [2] for solid thallium by the relation

$$\mathcal{E}_2 = \mathcal{E}_1 - \mathcal{E}_3$$

where $\mathcal{E}_2$ and $\mathcal{E}_3$ are, respectively, the emf's of the following cells

$$Li \mid LiBr - DMSO \mid TlBr, Tl \qquad [2]$$

$$Tl \mid Tl^+ \mid Tl\ (Hg) \qquad [3]$$

The Nernst relation for cell [2] is

$$\mathcal{E}_2 = \mathcal{E}^\circ_2 - \frac{2RT}{\mathbf{F}}\{\ln m_\pm + \ln \gamma_\pm\} \qquad [4]$$

where R is the gas constant, T the absolute temperature, $\mathbf{F}$ the Faraday constant, and $m_\pm$ and $\gamma_\pm$ are, respectively, the mean molality and activity coefficient. To evaluate the standard potential $\mathcal{E}^\circ_2$ the Guggenheim approximation (10) for $\gamma_\pm$ was used; *i.e.*

$$\ln \gamma_\pm = -\frac{Am^{1/2}}{1 + m^{1/2}} + 2\beta m \qquad [5]$$

where A is the Debye-Huckel constant and β is an empirical constant. The constant β has been associated with ion-pairing effects (6, 11, 12) but can also be associated with specific hydration effects (see below) as suggested by Stokes and Robinson (13).

It is also of interest to determine the solubility product for TlBr from the relation

$$\ln Ksp\ (TlBr) = (\mathcal{E}^\circ_2 - \mathcal{E}^\circ_7)\ \mathbf{F}/RT \qquad [6]$$

where $\mathcal{E}^\circ_7$ is the standard emf of cell [7] below.

$$Li \mid Li^+ \mid Tl^+ \mid Tl \qquad [7]$$

In DMSO, $\mathcal{E}^\circ_7$ = 2.641V at 25°C (5).

Experimental

The cells, solutions, and thallium amalgams were prepared in a manner similar to that described earlier (12, 14). The solutions were prepared by weight in a dry-box from a stock LiBr-DMSO solution whose molality was determined by a potentiometric titration with standard (aqueous) 0.1*M* $AgNO_3$. The solvent (Matheson, Coleman and Bell, "Spectroquality") was dried with Linde 4A molecular sieves. Typical solvent purity as determined by gas chromatography is less than 25 ppm water and less than 25 ppm organic impurities (15).

The amalgam was prepared entirely in the dry box and one batch of 3.147% Tl (by weight) in mercury was used for all of the experiments.

The cells, which were used in earlier studies (6, 12, 14), were assembled in the dry-box and then removed and placed in a water bath regulated to ±0.02°C. Potentials were read from a Fluke model 881A differential voltmeter to ±5 μV.

Results

Emf measurements were begun almost immediately after placing the cell in solution. The initial values at 25°C became constant to within ±0.1 mV after some 3 to 5 hr. The temperature was then changed to 15°C and raised to 35° and 45°C. The experiment was usually initiated in the morning and a complete set of emf's were recorded by evening (*i.e.*, about 8-10 hr). The emf at 25°C after 8-10 hr was reproducible to within ±0.1 mV in most cases and to within ±0.3 mV in several other cases. After 48 hr at 25°C, the emf of cell [1] usually decreased by almost 1 mV. Continual decrease in emf was observed over longer times presumably due to the solubility of TlBr (see *K*sp below). After three days in the temperature bath, the Li electrodes had become discolored due to the reaction (6)

$$Li_{(s)} + TlBr\ (soln) \rightarrow Tl_{(s)} + LiBr\ (soln)$$

Similar behavior over shorter time periods were observed in the LiCl-DMSO system (6).

The physiochemical properties of DMSO used to evaluate $\mathcal{E}^\circ_2$ are listed in Table I. $\mathcal{E}_3$ values used to obtain $\mathcal{E}_2$ were taken from the work of Richards and Daniels (16). From Eq. [4] and [5] it is seen that a plot of $\mathcal{E}'$ *vs.* m should be linear with a slope proportional to β and an intercept of $\mathcal{E}^\circ_2$. Here $\mathcal{E}'$ is defined as

$$\mathcal{E}' = \mathcal{E}_2 + \frac{2RT}{F}\left\{\ln m_\pm - \frac{Am^{1/2}}{1 + m^{1/2}}\right\} \qquad [8]$$

Figure 1 shows a typical plot for 25°C. A least squares was then fitted to the data and the results are shown in Table II. In this table $\mathcal{E}^\circ_2$ values are given in terms of molarity units ($\mathcal{E}^\circ_{2,c}$) molality units ($\mathcal{E}^\circ_{2,m}$), and mole fraction units ($\mathcal{E}^\circ_{2,N}$). Also given in Table II are the standard enthalpies and entropies for cell [2] based on molal units along with the values for β (*c.f.*, Eq. [5]). The thermodynamic quantities were calculated from a least squares fit to a second order polynomial, *i.e.*

$$\Delta G^\circ_{2,c} = -60.657 + 0.02876 \cdot T - 4.9719 \cdot 10^{-6} T^2$$

$$\Delta G^\circ_{2,m} = -60.592 + 0.02970 \cdot T - 7.6290 \cdot 10^{-6} T^2$$

$$\Delta G^\circ_{2,N} = -61.286 + 0.04442 \cdot T - 1.5190 \cdot 10^{-5} T^2$$

Here ΔG°_2 is in kcal/mole and ΔH°_2 and ΔS°_2 are easily obtained by differentiating with respect to temperature.

The activity coefficients were calculated from Eq. [4] and the results are shown in Table III. A plot of $\ln\gamma_\pm$ *vs.* $m^{1/2}$ is shown in Fig. 2. In Fig. 2, the $\ln\gamma - m^{1/2}$ relation for LiBr in H_2O (13) is also shown.

Table I. Properties of DMSO*

°C	$\mathcal{E}$	d_o†	A
15	47.4	1.1050	2.7688
25	46.6	1.0960	2.6822
35	45.9	1.0867	2.6056
45	45.1	1.0770	2.5345

* The Debye-Hückel constant (A) values are based on ln (e) units and conversion to log (10) units is accomplished by dividing by 2.3026.
† The density of pure DMSO, d_o, is given in g/cc.

Table II. Free energies, enthalpies, and entropies of cell [2]*

°C	$\mathcal{E}^\circ_{2,c}$	$\mathcal{E}^\circ_{2,m}$	$\mathcal{E}^\circ_{2,N}$	β	$\Delta H^\circ_{2,m}$	$\Delta S^\circ_{2,m}$
15	2.28877	2.28381	2.15721	0.514	−59.96	−25.30
25	2.27767	2.27301	2.14201	0.485	−59.91	−25.15
35	2.26655	2.26214	2.12675	0.460	−59.87	−25.00
45	2.25526	2.25120	2.11141	0.439	−59.82	−24.84

* $\mathcal{E}^\circ$ values are in volts; ΔH° is in kcal/mole; ΔS° is in e.u.; β units are kg/mole.

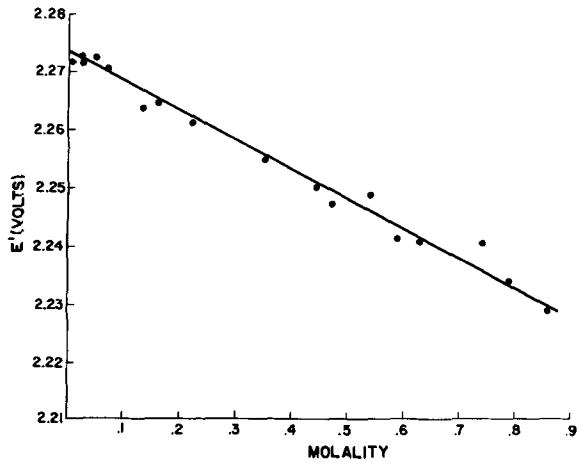

Fig. 1. Plot of E' (see Eq. [8]) vs. molality

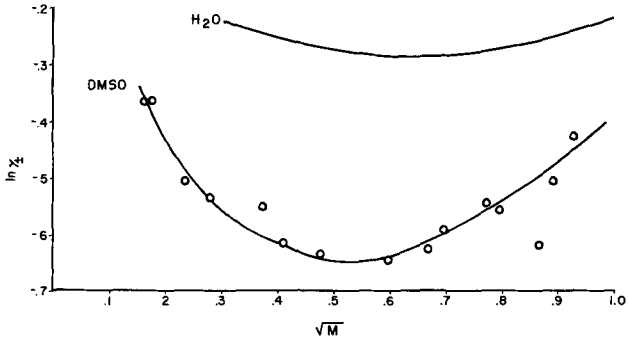

Fig. 2. Plot of $\ln\gamma_\pm$ *vs.* the square root of the molality

Finally the solubility product for TlBr at 25°C can be calculated from Eq. [6]; with $\mathcal{E}^\circ_7 = 2.641$V (5),[1] a value of $10^{-6.23}$ is obtained for *K*sp (TlBr).

Discussion

Parker (17) in a review on dipolar aprotic solvents concluded, on the basis of solubilities, conductivities, and half-wave potentials, that not only are anions poorly solvated in solvents such as DSMSO, but also that the extent of solvation by solvent molecules increases in the order

$$Cl^- < Br^- < I^-$$

Considering the emf results for LiCl in DMSO (6, 9) and LiBr in DMSO (present results), more proof of this conclusion is found. From Fig. 2, the plot of $\ln\gamma_\pm$ *vs.* $m^{1/2}$ for LiBr in DMSO shows that at about $m = 0.4$, the activity coefficient begins to increase. A similar treatment for LiCl in DMSO [using the data in ref. (6)] shows no indication of any curvature up to concentrations of 0.9M. In terms of the theory of Stokes

[1] $\mathcal{E}^\circ_7 = 2.641 \pm 0.003$V and this uncertainty is carried over to the value of *K*sp (TlBr).

Table IV. Energetics of transfer of Li salts from H_2O to DMSO at 25°C

Salt	$\Delta G°_t$	$\Delta H°_t$	$\Delta S°_t$	$\delta\Delta H°_t$	Reference
LiCl	4.865	−3.12	−26.77		6
LiBr	2.515	−2.05		3.38	1
		−5.67	−27.46		Present work
		−5.43		0.0	1
Li I		−9.07		−3.64	1

Units refer to molal scale: $\Delta H°_t$, $\Delta G°_t$ are in kcal/mole, $\Delta S°_t$ in e.u.

and Robinson (13), the curvature in plots such as Fig. 2 can be accounted for by the decreasing solvent activity. In this context then, one concludes that the chloride ion is practically unsolvated in DMSO whereas the bromide ion is solvated to a fairly large extent.

This behavior is also reflected in the energetics of solvation. Table IV lists, on the basis of molal units, the standard free energy, enthalpy, and entropy of transfer of various lithium salts from water to DMSO.

The quantity $\delta\Delta H°_t$ is a relative enthalpy of transfer defined as

$$\delta\Delta H°_t = \Delta H°_t\,(X^-) - \Delta H°_t\,(Br^-)$$

which shows that $\Delta H°_t\,(X^-)$, for halides, becomes larger (more negative) as the anion size increases. Similar behavior was found for lithium halides in propylene carbonate (18, 12, 14). The heats of solution, ΔH_{soln}, become more negative as anion size increases whereas heats of solvation, ΔH_{solv}, become less negative (1). This is analogous to aqueous solutions of lithium halides [*e.g.*, see ref. (19)]. This behavior has led Fuchs *et al.* (1) to conclude that while anions may be less solvated in the dipolar aprotic solvent, the order of increasing solvation is

$$I^- < Br^- < Cl^-$$

This conclusion is opposite to that resulting from the present work based on the activity coefficients of LiCl and LiBr and from other work discussed above (2, 3, 5, 12, 14, 17). The danger in comparing ΔH_{solv} values in this manner rather than $\delta\Delta H°_t$ or activity coefficients can be demonstrated as follows: Let us consider the Born equation

$$\Delta H_{solv}(X^-) = -\frac{e^2}{2(r+\delta)}\left\{1 - \frac{1}{\epsilon} - \frac{T}{\epsilon^2}\cdot\frac{d\epsilon}{dT}\right\} \quad [9]$$

where e is the electronic charge, ϵ is the dielectric constant, T the absolute temperature, r the Pauling anion radius, and δ is an empirical constant assumed to be independent of temperature (20). Equation [9] predicts that for transfer from the gas to solution phase, ΔH_{solv} should decrease (become less negative) as r increases which is in fact the case. The δ corrections are quite complex as it was found that in order to "predict" the correct $\Delta H°_{solv}$ for Cl^-, Br^-, I^-, from the gas phase to propylene carbonate, δ values had to be adjusted such that $\delta\,(Cl^-) = \delta\,(Br^-) = 0.67$ and $\delta\,(I^-) = 0.72$ (14). In aqueous solutions δ takes on a constant value of 0.10 for all anions (20). The δ values then take on more (complex) significance rather than simply being an empirical parameter associated with a solvent molecule radii (14). Additional support of the present conclusion can be drawn from the similarity in the solubility of TlBr ($Ksp = 10^{-6.23}$) as compared to Butler's (5) determination of the solubility of TlCl ($Ksp = 10^{-6.26}$).

The Thermal Temperature Coefficient of the Calomel Electrode Potential Between 0° and 70°C

II. Thermodynamic Results—The Moving and Transport Entropies and Heat Capacities of Aqueous Chloride Salines and Their Ions

Andre J. de Bethune*

Department of Chemistry, Bridgewater State College, Bridgewater, Massachusetts

ABSTRACT

The initial thermal temperature coefficient of the calomel electrode reported in Part I is combined with the results of thermal diffusion studies elsewhere to yield information about: the entropy of transport S^* of the aqueous electrolytes KCl, NaCl, LiCl, HCl, and $CaCl_2$; the experimentally determinable moving (transported)entropy $\overline{\overline{S}}$ of the ion constituents Cl^-, K^+, Na^+, Li^+, H^+, and Ca^{++}. A four-constant equation analogous to the Fuoss-Onsager conductance equation is developed for the concentration dependence of the entropy of transport S^* and is applied to the salts KCl and NaCl. The division of the moving entropy $\overline{\overline{S}}$ into its nonmeasurable ionic component terms: the ionic transport entropy S^* and the stationary entropy $\overline{S}$, is attempted via two postulates: the Agar postulate and the KCl-bridge postulate which give results mutually consistent within about 0.8 eu (35 μVF/deg), *e.g.*, $\overline{S}^\circ(H^+) = -5.22$ eu from our data under the Agar postulate, and −4.42 eu under the KCl-bridge postulate. These values are in good agreement with previously reported values of −4.48, −5.5, and −5.7 based on a number of alternative postulates. Values are also obtained for the transport heat capacity C^* of the electrolytes and for the measurable moving heat capacity $\overline{\overline{C}}$ of the ion constituents at 30°. A division of $\overline{\overline{C}}$ into its nonmeasurable ionic components: C^* and $\overline{C}$ is also carried out on the basis of Fales and Mudge's hydrogen thermal emf data via the KCl-bridge postulate, and yields, *e.g.*, $C^*_0 = 30$ eu (Cl^-), 5 (H^+); $\overline{C}^\circ = -24$ (Cl^-), −5 (H^+); $\overline{\overline{C}}^\circ = 6$ (Cl^-), 0 (H^+).

In Part I(1), the initial thermal emf of the calomel electrode in several aqueous chloride salines was represented between 0° and 70°C by the quadratic

$$V_t - V_{25} = A_{25}(t-25) + B(t-25)^2 \qquad [1]$$

where the A's range between +294 and +1024 μV/deg and the B's between −1.9 and −0.1 μV/deg^2. The A's measure the initial thermal temperature coefficient (thermoelectric power) $\epsilon_0 = (dV/dT)_{\text{th,initial}}$ of the corresponding calomel electrode at 25°. At constant chloride ion concentration, the difference between ϵ_0 in two different salts (2) is given by

$$\mathbf{F}[\epsilon_0(MCl) - \epsilon_0(KCl)] = t_K S^*(KCl) - t_M S^*(MCl)/z_M \qquad [2]$$

where S^* is the entropy of transport (Eastman's entropy of transfer) of the salt. S^* is related to the Soret (thermal diffusion) coefficient σ by

$$\sigma = d\ln m/dT = -S^*/[\nu RT(1 + (d\ln\gamma/d\ln m)_T)] \qquad [3]$$

S^* is the entropy transported reversibly from the hot to the cold heat reservoir by the reversible transfer of one mol of solute from the hot to the cold region of the solution, in the limit $\Delta T \to 0$.

Another quantity of interest is the final thermoelectric coefficient $\epsilon_\infty = (dV/dT)_{\text{th,final}}$ of a thermal cell after thermal diffusion has come to a steady state. Theory (2) shows that the final thermal emf is given by the initial thermal emf plus the isothermal emf of the concentration cell created by thermal diffusion. In general

$$\epsilon_\infty = \epsilon_0 \mp t_g S^*/\nu\mathbf{F} \quad (\text{if } z_r = \pm) \qquad [4]$$

where z_r is the charge of the ion to which the electrodes are reversible, t_g the transference number of the gegenion, and ν the valence of the salt. For calomel thermal cells

$$\epsilon_\infty = \epsilon_0 + t_+ S^*/z_+\mathbf{F} \qquad [5]$$

In the present work, S^* values for KCl, and occasionally for other salts, as obtained from thermal diffusion studies elsewhere, have been used in the calculation of ϵ_∞.

Temkin and Khoroshin (3) first proved that the final thermal emf is independent of the nature of the gegenion. For a calomel thermal cell

$$\mathbf{F}(dV/dT)_{\text{th,final}} = \mathbf{F}\epsilon_\infty = \Delta\overline{\overline{S}} = S^\circ(Hg, l) - \tfrac{1}{2}S^\circ(Hg_2Cl_2, c) + \overline{\overline{S}}(Cl^-, aq) - \overline{\overline{S}}(e^-, Cu) \qquad [6]$$

where $\overline{\overline{S}}$ denotes the moving entropy [Agar's "transported" entropy (4), Temkin and Khoroshin's "Entropiya dvizhushchiksya Iona," entropy of the moving ion (3)] of a solute species, which is

$$\overline{\overline{S}} = \overline{S} + S^* \qquad [7]$$

i.e., the sum of the stationary partial molal entropy $\overline{S}$ [also known, for an ion constituent, as the absolute ionic entropy (4) or the entropy of electrochemical

* Electrochemical Society Active Member.

Key words: calomel electrode, electrolytes, entropy of transport, heat capacity of transport, ionic entropy, ionic heat capacity, ions, thermodynamic properties of salines, thermoelectric power, transported entropy, transported heat capacity.

transport (6)] plus the transport entropy S^* [also known as the Eastman entropy of transfer (5) or the entropy of migration transport]. For ionic species, $\overline{\overline{S}}_i$ is the partial molal entropy of an ion including the ΔS of building up of that part of the solvation sheath which travels with the ion (known as Eastman's second region, the first region is the ion itself). On the other hand, S^*_i as originally defined by Eastman (5), is the ΔS of disintegration of that portion of the ionic solvation sheath which is left behind when the ion goes away. Therefore, $-S^*_i$ is the ΔS of building up of this outer solvation sheath (known as Eastman's third region). The more positive S^*_i, the more the ion is a structure maker in the third region. The sum $\overline{S}_i = \overline{\overline{S}}_i + (-S^*_i)$ is therefore the partial molal entropy of the stationary ion including the ΔS of building up of its complete solvation sheath. This sum is therefore the entropy transported across a thermal cell when an ion is transferred from one half-cell to the other by the agency of the two equal and opposite electrode reactions, a mechanism in which the ion sheds its complete hydration sheath in one half-cell (at one temperature) and forms a complete hydration sheath in the other half-cell (at a different temperature). $\overline{S}_i$ can therefore appropriately be called the ionic entropy of electrochemical transport (6, 8).

In view of Eq. [6], the moving entropy $\overline{\overline{S}}$ is experimentally measurable for a single ionic species from final thermal emf's, or from initial thermal emf's and thermal diffusion data, as was originally shown by Temkin and Khoroshin (3). On the other hand, neither the stationary entropy $\overline{S}$, nor the transport entropy S^*, are separately measurable for a single ionic species. Estimates of these quantities can be made on the basis of certain postulates, which include (*i*) the KCl-bridge postulate, (*ii*) the Agar postulate, and (*iii*) the Gurney postulate. The KCl-bridge postulate was utilized by de Bethune, Licht, and Swendeman (6) to interpret Fales and Mudge's (9) thermal emf data for the 0.1 molal HCl hydrogen electrode with a saturated KCl bridge. By assuming that the bridge potential was zero, they obtained for the standard stationary entropy of hydrogen ion

$$\overline{S}^\circ(H^+) = -4.48 \pm 0.5 \text{ eu} \qquad [8]$$

at 25°. This result can be compared with Gurney's −5.5 eu (10) from his assignment of equal viscosity *B*-coefficients to K^+ and Cl^-, also with Lin and Breck's −5.7 eu (11) based on their postulate that trichelated redox ion pairs are approximately isentropic because the large organic structures tend to shield the solvent water from the charge on the central ion. The Agar postulate selects the arbitrary value

$$S^*(Cl^-, 0.01 \text{ molal}) = 0 \qquad [9]$$

as a basis for deducing conventional ionic transport entropies so that $S^*(K^+, 0.01 \text{ molal}) = S^*(KCl, 0.01 \text{ molal}) = 1.65$ eu at 25°. The thermal diffusion potential of 0.01 molal KCl, computed from $[t_{Cl}S^*_{Cl} - t_K S^*_K]\mathbf{F}^{-1}$, is −35.1 μV/deg on the basis of the Agar postulate, as compared with the value zero assigned under the KCl-bridge postulate. The two postulates thus yield results mutually consistent within better than 1 entropy unit (43.36 microvolt-faradays per degree).

The moving entropy $\overline{\overline{S}}_i$ has a twofold concentration dependence, (*i*) that of $\overline{S}_i$ given by the ordinary mass action expression

$$\overline{S}_i = \overline{S}^\circ_i - R \ln m_i\gamma_i - RT\, d \ln \gamma_i/dT \qquad [10]$$

and (*ii*) the further concentration dependence of S^*_i which is akin to that of the activity coefficient or of the ionic conductance. In dilute solutions, the concentration dependence of S^*_i can be approximated by the Debye-Hückel theory (4, 12), and in more concentrated solutions, by equations of the Fuoss-Onsager form (12). These relationships show that, at infinite dilution, S^*_i tends to a finite limiting value S^*_{oi} which can be calculated in principle from the Eastman electrostatic model (5) quantitated by taking a temperature derivative of the Born free energy of hydration expression to yield (2)

$$S^*_{oi} = (z_i^2e^2/2D_0r_i)\, d(1/D)/dT \qquad [11]$$

where r_i is the ionic radius at the "boundary" between the Eastman second and third regions. In water, $d(1/D)/dT = 5.83 \times 10^{-5}$ deg^{-1} at 25° (2). Equation [11] takes the form $S^*_{oi} = +9.68\, z_i^2/r_i(\text{Å})$ eu, which shows that conventional ionic transport entropies, generally between 0 and 3 eu, are reasonable for r_i values of a few angstroms.

The moving entropy $\overline{\overline{S}}_i(m)$ at molality m is transformed, by addition of the mass action terms $R \ln m_{i,\gamma} + RT\, d \ln \gamma/dT$, to the quantity

$$\overline{\overline{S}}^{\circ\prime}(m) = \overline{S}^\circ_i + S^*_i(m) \qquad [12]$$

which is a first approximation to the limiting standard value $\overline{\overline{S}}^\circ = \overline{S}^\circ + S^*_{oi}$. Here the measurable mean ion activity coefficient γ of the salt is substituted for the unmeasurable single ion activity coefficient γ_i in 1,1 salts (in binary salts of multiply charged ions, an extension of the Debye-Hückel theory (2) suggests taking the single ion activity coefficient as $\gamma_i = \gamma^{-z_i/z_j}$).

Reference Values for Salt Transport Entropies

Potassium and sodium chlorides at 25°.—The transport entropies of potassium and sodium chlorides have been investigated experimentally up to 0.05 molal by Agar and Turner (15) and Snowdon and Turner (16, 17) by a conductimetric method based on unbalancing a Wheatstone bridge by applying a thermal gradient to a conductance cell, and, between 0.5 and 4 molal by Longsworth (18) and Chanu and Lenoble (19) by optical methods based on the tilting of interference fringes in a thermal field. From their reported Soret coefficient data, S^* values for aqueous KCl and NaCl at 25° were computed. de Bethune (12) showed that these S^*'s can be well fitted from 0 to 4 molal by a four-constant equation analogous to the Fuoss-Onsager (20) conductance equation

$$S^* = A + Bm^{1/2} + Cm + Dm \log m \qquad [13]$$

The least squares values for the constants are listed in Table I and fit the data almost everywhere within better than ±0.1 eu. The four constant equation can therefore be used to calculate S^* at infinite dilution and at 0.1 molal where no direct experimental data are available. The results of this calculation are given in Table II.

Other reference values.—Other experimental values of the salt transport entropy as based on measured Soret coefficients have been adopted as listed in Table III.

Salt Transport Entropies and Final Thermoelectric Coefficients of Calomel Electrodes

The results at 25° are given in Table IV. The second column gives ϵ_0 from Part I (1). The third column

Table I. Least squares constants used to fit the four constant Eq. [13] to the transport entropies of potassium and sodium chlorides at 25°C

	S^* in calories · degree^{-1} · mol^{-1} Range: 0 to 4 molal	
Constant	KCl	NaCl
A	2.2400	2.9698

Table II. Transport entropies of potassium and sodium chlorides in water at 25° calculated from the four constant equation

Molality	S^* (KCl)	S^* (NaCl)
	calories · degree^{-1} · mol^{-1}	
0	2.240	2.970
0.01	1.647	2.362
0.1	0.829	1.553
1.0	0.373	1.277

lists the cation transference numbers utilized [Daley (25)]. The fourth column gives the salt transport entropies S^*/z_M in eu·eq^{-1}. Reference values from Tables II and III are given in parentheses. Other values are calculated from the thermoelectric data as described below. The fifth column gives ϵ_x calculated from ϵ_0 and the reference values of S^* via Eq. [5]. The last column gives values of S^* taken from the literature and based on either thermal diffusion or thermoelectric studies.

The salt transport entropies listed in the fourth column were calculated from the observed ϵ_0 and the mean final $\langle\epsilon_x\rangle_{avg}$ via Eq. [5]. The results of Table IV are extended to 35° for KCl, the only salt for which reference S^*'s were available (Table III) or could be estimated.

Moving Entropy of Chloride Ion and Related Quantities at 25°

The final thermoelectric coefficient ϵ_∞ from Table IV can be used in Eq. [6] to compute the moving entropy $\overline{\overline{S}}$ of chloride ion in 0.01, 0.1, and 1.0 molal solutions. Standard entropy data used are $S^\circ(Hg,l) = 18.5$ eu, $S^\circ(Hg_2Cl_2, c) = 46.8$ eu, Latimer (29), $\overline{\overline{S}}(e^-, Cu) = -0.045$ eu, Khoroshin and Temkin (3), Agar (4). The results of the computation are given in Table V, line 1. The mass action correction $R \ln m_{Cl}\gamma_{Cl} + RT\, d \ln \gamma_{Cl}/dT$, with γ_{Cl} set equal to γ_{KCl}, is introduced

[a] KCl values, de Bethune, Licht, and Swendeman (6).

next to convert $\bar{\bar{S}}$(Cl⁻) to $\bar{\bar{S}}^{o\prime}$(Cl⁻), the preliminary standard value (line 5). By introduction of $\bar{S}^o$ from Latimer (29) or NBS Circular 500 (30): KCl 37.7, NaCl 27.6, LiCl 16.6, HCl 13.17, ½$CaCl_2$ 6.6 eu·eq^{-1}, and S^* from Tables II, III, and IV, $\bar{\bar{S}}^{o\prime}$ is calculated next for these salts including the limiting value $\bar{\bar{S}}^o$ at infinite dilution (lines 6, 8, 10, 12, 14). From these it is possible to compute $\bar{\bar{S}}^{o\prime}$ for the cations (lines 7, 9, 11, 13, 15).

To obtain the standard values $\bar{\bar{S}}^o$ for the individual ions, it is necessary to split the experimental difference $S^*_o - S^*_{0.01m} = 0.60$ eu (Table II) for KCl and NaCl between their respective ions. Electrostatic theory (4, 12) suggests that this difference should be equally divided between the two ions of a 1,1 salt, *i.e.*, $S^*_o - S^*_{0.01m} = 0.30$ eu for a univalent ion. The same differences are also applied to LiCl and HCl and to their ions (lines 10-13).

For $CaCl_2$, the above differences of S^* values must be adjusted to the valence pattern of a 1,2 salt. Electrostatic theory suggests a limiting law of the form $dS^*_i/d\mu^{1/2} \sim -z_i^2$. This yields $S^*_o - S^*_{0.01m\ Cl^-} = 2.20$ eu·mol^{-1} or 1.10 eu·eq^{-1} for a divalent chloride. Values of $\bar{\bar{S}}^{o\prime}$ including $\bar{\bar{S}}^o$ are calculated in this manner for ½$CaCl_2$ (line 14) and for ½Ca^{++} (line 15).

Lines 16-21 in Table V give the single-ion transport entropies S^*_i based on the data of Table II-IV, calculated from Eq. [12] from the Agar postulate. These values are consistent with a standard stationary entropy of hydrogen ion $\bar{S}^o(H^+) = -5.22$ eu, a value which compares well with the set of alternative values of −4.48, −5.5, and −5.7 discussed above.

Lines 22-27 give single-ion transport entropies S^*_i based on the KCl-bridge postulate. These values lead to $\bar{S}^o(H^+) = -4.42$ eu, showing excellent agreement with de Bethune, Licht, and Swendeman's (6) −4.48 eu and with the large volume of thermal emf data satisfactorily correlated therewith (6). The thermal diffusion potentials (*tdp*) of the various salts, relative to KCl = 0, are given in lines 28-31. The *tdp*'s according to the two postulates would differ by an amount proportional to the shift of S^*(Cl⁻) under the two postulates

$$tdp'' - tdp' = [S^*(Cl^-)'' - S^*(Cl^-)']\mathbf{F}^{-1} \quad [14]$$

The KCl-bridge postulate gives values of S^*(Cl⁻) about 0.7 to 0.8 eu (30 to 35 μV**F**/deg) higher than the Agar postulate, and its *tdp*'s would be consistently higher algebraically by the same amount. For single ionic values of S^*_i and $\bar{S}^o_i$, the following conversion rules hold among the several postulates

to convert	*from*	*to*	*add*
$S^*_\mp$ and $\bar{S}^o_\pm$	Agar postulate	Gurney postulate	$\mp$0.3 eu · eq^{-1}
$S^*_\mp$ and $S^o_\pm$	Gurney postulate	KCl-bridge postulate	±1.0/±1.1 eu · eq^{-1}
$S^*_\mp$ and $S^o_\pm$	Agar postulate	KCl-bridge postulate	±0.7/±0.8 eu · eq^{-1}

The mutual consistency of these three postulates, within about 1 eu, is interesting but does not *per se* justify adopting any one of them as an "absolute" basis for ionic entropies (34). The Gurney (10) postulate is based on his division of the viscosity *B*-coefficient of KCl at 25° into equal ionic terms: $B(K^+) = B(Cl^-) = -0.0070$, both coefficients being small as compared with other ionic terms (on this basis) ranging from $B(Li^+) = +0.147$ to $B(I^-) = -0.080$. If the KCl-bridge value $\bar{S}^o(H^+) = -4.5$ eu were adopted instead of the Gurney value of −5.5, a satisfactory Gurney plot could be prepared on the basis of ionic viscosity *B*-values shifted by only $\mp$0.007 (for ± ions). The entries of Table V, usually given to the nearest 0.01 eu·eq^{-1}, are generally valid to within a few tenths of an entropy unit.

Salt Transport Heat Capacities

The transport heat capacity of a salt has been defined by Agar (14) as $C^* = T(dS^*/dT)_p$. Temperature differentiation of Eq. [2], neglecting any temperature dependence of t_i, yields

$$\mathbf{F}T[d\epsilon_0(MCl)/dT - d\epsilon_0(KCl)/dT] = 2\mathbf{F}T[B(MCl) - B(KCl)] = t_K C^*(KCl) - t_M C^*(MCl)/z_M \quad [15]$$

where the *B*'s are the quadratic coefficients of Eq. [1]. The reference values of C^*(KCl) in Table VI are based, at 0.01 and 1.0 molal, on direct thermal diffusion observations of S^* at 25° and 35° as summarized in Table II and III. For 0.1 molal, use was made of a graphically interpolated value of S^* at 35° which may be uncertain by ± 0.1/0.2 eu, the corresponding uncertainty in C^* would amount to ± 3/6 eu. An uncertainty in *B* of ± 0.1 μV/deg^2 would correspond to a little more than ± 4 eu in C^*/z_M for LiCl to a little less than ± 2 eu for HCl.

The data are summarized in Table VI. The first three columns give the salt, concentration, and quadratic *B*-coefficients from Part I (1). The fourth column gives C^*/z_M in eu·eq^{-1} as calculated from the KCl reference values at 30° via Eq. [15]. The uncertainty of these values amounts to several calories per degree·equivalent. They can be compared with in-

dependent determinations from other observers, sometimes at other concentrations and temperatures, as listed in the last column. The values for 0.01 molal LiCl and ½$CaCl_2$ appear to be high. The fifth column lists the partial molal heat capacity of the salt $\overline{C}_p$ at 25° as calculated from constants given by Harned and Owen (22) from their equation

$$\overline{C}_p(m) = \overline{C}_p{}^o + \overline{J}(m) = \overline{C}_p{}^o + Sm^{1/2} \qquad [16]$$

where the slope S is valid up to 3 molal. Values for calcium chloride were calculated from Pitzer and Brewer (35, p. 653). The sixth column gives the moving heat capacities of the salts defined by

$$\overline{\overline{C}}(m) = \overline{C}_p(m) + C^*(m) \qquad [17]$$

The partial molal heat capacity of these electrolytes is large and negative, becoming less negative at increasing concentrations, according to Eq. [16]. This expresses the influence of the addition of ions to water in ordering the surrounding water structure in the Eastman second and third regions both, and in thus depriving the water structure of some of its ability of absorbing energy as its temperature is raised. C^* on the other hand measures the increase in the heat capacity of the water structure in the third region when the ions are removed. This quantity is large and positive, becoming less positive as the concentration increases. Their sum, the moving (transported) heat capacity $\overline{\overline{C}}$ of the salt is then given by a much smaller quantity, usually positive, which decreases slowly with increasing concentration. Agar (14) suggested that $\overline{\overline{C}}_i$ should equal the Dulong and Petit value of 6 eu for the vibration of the center of mass of each monatomic ion. This would make $\overline{\overline{C}}$ = 12 eu for 1,1 salts and 18 eu·mol^{-1} or 9 eu·eq^{-1} for 1,2 salts, an expectation which is only roughly verified by the $\overline{\overline{C}}$ values listed in the sixth column.

The Eastman-Born electrostatic model, given in Eq. [11], permits an evaluation of the ionic transport heat capacity as

$$C^*{}_{oi} = TdS^*{}_{oi}/dT = (z_i{}^2e^2/2D_or_i)\,d^2(1/D)/dT^2 \qquad [18]$$

if r_i is not a function of temperature. In water, Gurney (10) has suggested the empirical formula $D(T)$ = 305.7 exp(−T/219) which leads to

$$C^*{}_{oi} = (T/219)S^*{}_{oi} = 13.4\,z_i{}^2/r_i(\text{Å})\ \text{eu} \qquad [19]$$

at 303°K. If ionic crystal radii (10) are substituted into Eq. [19], theoretical ionic transport heat capacities are obtained as follows: Cl^- 7.4, K^+ 10.1, Na^+ 13.7, Li^+ 17.2, ½Ca^{++} 25.3 eu. These theoretical transport heat capacities are of the right order, but yield salt values smaller than the experimental ones (Table VI, col. 4). As in the case of the transport entropy $S^*{}_o$, the correlation between the electrostatic model and observations is only approximate and does not lead to any useful results regarding the radius r_i at the boundary between the Eastman second and third regions.

Moving Heat Capacity of Chloride Ion and Related Quantities at 30°

The final thermoelectric coefficients ϵ_∞ at 25° and 35° permit calculation of the second derivative of the final thermal emf (Table VII, line 1) for which the thermodynamic equation is

$$\mathbf{F}T(d^2V/dT^2)_{\text{th,final}} = \mathbf{F}T(d\epsilon_\infty/dT) = Td\Delta\overline{\overline{S}}/dT = \Delta\overline{\overline{C}}$$
$$= C_p{}^o(\text{Hg, l}) - \tfrac{1}{2}C_p{}^o(Hg_2Cl_2, \text{c})$$
$$+ \overline{\overline{C}}(Cl^-, \text{aq}) - \overline{\overline{C}}(e^-, \text{Cu}) \qquad [20]$$

Standard heat capacity data are $C_p{}^o$(Hg, l) = 6.65 eu, $C_p{}^o$ (Hg_2Cl_2, c) = 24.3 eu, NBS(30), and $\overline{\overline{C}}(e^-$, Cu) = −1.5 μVF/deg = −0.034 eu, Temkin and Khoroshin (3).

The moving heat capacity $\overline{\overline{C}}(Cl^-)$ at 0.01, 0.1, and 1.0 molal is given in Table VII, line 2, and is close to the Dulong and Petit value of 6 eu. From the data of Table VI, $\overline{\overline{C}}_i$ is then calculated for the cations at the three concentrations (lines 3 to 7), the values for 0.01 molal Li^+ and ½Ca^{++} appear to be high. The other values are probably reliable within several eu·eq^{-1}. Values at infinite dilution, where given, are obtained from a $\sqrt{m}$-extrapolation.

The attempt to split $\overline{\overline{C}}_i$ into its constituent terms $C^*{}_i$ and $\overline{C}_i$ was made, via the KCl-bridge postulate, by assuming that the saturated KCl-bridge in Fales and Mudge's 0.1 molal HCl-H_2 thermal cell (9) did not contribute to the second derivative of their observed thermal emf's, for which deBethune, Licht, and Swen-

[a] Based on KCl values at 25° and 35° (Table IV).
[b] From a $\sqrt{m}$-extrapolation.

deman (6) calculated +1.286 μV/deg^2, after correction to unit activity of hydrogen gas. By setting $FT(d^2V/dT^2) = 384\ \mu VF/\text{deg} = 8.8$ eu $= \frac{1}{2}C_p^\circ(H_2, g) - \overline{C}(H^+, 0.1m) - \overline{\overline{C}}(e^-, Cu)$, with $C_p^\circ(H_2, g) = 6.892$ eu (30), one gets

$$\overline{C}(H^+, 0.1 \text{ molal}) = -5.4 \text{ eu} \qquad [21]$$

(line 8). This value can be used, in conjunction with $\overline{\overline{C}}$ values above and $\overline{C}_p$(HCl, 0.1 molal) (Table VI) to obtain $\overline{C}$ and C^* for 0.1 molal H$^+$ and Cl$^-$ (lines 9-11). To extend these values to other concentrations, use was made of the postulate that $\overline{J}(Cl^-) = \overline{J}(K^+) = \frac{1}{2}\overline{J}(KCl)$. Values of $\overline{C}$ and C^* for H$^+$, Cl$^-$, K$^+$, Na$^+$, Li$^+$, and ½Ca^{++} based on these postulates are given in lines 8-19. In lines 20 and 21, the heat capacity of water, 18 eu, is added to the H$^+$ values for $\overline{\overline{C}}$ and $\overline{C}$ to convert them to the H$_3$O$^+$ basis. C^* is the same for H$^+$ and H$_3$O$^+$ since this represents the heat capacity loss of the solvent in the third region resulting from the presence of the hydrated ion.

The single ion values generally present the following picture: $\overline{C}$ for Cl$^-$, K$^+$, and ½Ca^{++} is negative at infinite dilution, and increases (algebraically) with increasing concentration, becoming positive for K$^+$ by 1.0 molal. $\overline{C}$ for Na$^+$ is close to zero at infinite dilution and increases with increasing concentration. $\overline{C}$ for H$^+$ is negative, for Li$^+$ positive, both approximately independent of concentration. A negative value for $\overline{C}$ suggests that the ion becomes a more pronounced structure maker with increasing temperature in the combined second and third Eastman regions.

The transport heat capacity C^* is large and positive for Cl$^-$ and decreases with increasing concentration. C^* is smaller but still positive for the cations, in the order (at 0.1 molal) Na$^+$ > Li$^+$ > ½Ca^{++} > K$^+$ > H$^+$, and comes close to zero or even negative at 1.0 molal in the order K$^+$ > Na$^+$ > Li$^+$ > H$^+$ > ½Ca^{++}. A positive value of C^* is associated with an increase in structure making tendency with increasing temperature in the Eastman third region. Thus all ions appear to become more pronounced structure makers in the third region with increasing temperature in dilute solutions, but the tendency reverses for Na$^+$, Li$^+$, H$^+$, and Ca^{++} in concentrated solutions.

The role played by the ion in the second region appears to be twofold. A negative value of $\overline{\overline{C}}$ (H$^+$, Ca^{++} except for its high value) suggests a marked increase in structure making tendency with increasing temperature in the Eastman second region. On the other hand, a value of $\overline{\overline{C}}$ in excess of the Dulong and Petit value of 6 eu/g-ion (Na$^+$, Li$^+$, K$^+$) suggests an inverse effect in which the ion contributes an increase in the ability of its entourage of tightly bound waters to absorb energy.

Conclusion

An interpretation of the results presented above will be developed in Part III to follow, and will be based on modern theories of the water structure, and on a simplified form of the partition function of water which will be extended to hydronium ion (36, 37)

Manuscript submitted Dec. 2, 1968; revised manuscript received *ca.* June 19, 1969. This paper is based in part on the Ph.D. dissertation of Henry O. Daley, Jr., at Boston College. Grateful acknowledgement is made to the Office of Saline Water, U.S. Department of the Interior, for support of this investigation under Grants No. 14-01-0001-389 and -1466 at Boston College. ABSTRACT

The moving (transported) ionic properties $\overline{\overline{S}}$ and $\overline{\overline{C}}$ are partial molal properties of the ion itself and include the effect of its electrical charge on that portion of the solvation layer which travels with the ion (Eastman first and second regions). The negatives of the ionic transport properties $-S^*$ and $-C^*$ measure the influence of the ion (plus its tightly bound waters if any) on the remainder of the solvent (Eastman third region). A positive value of S^* identifies the ion as a structure maker in the third region. The sums $\overline{X} = \overline{\overline{X}} + (-X^*)$, where $X = S$ or C, measure the partial molal properties of the stationary ion, including the effect of the ionic charge on both Eastman second and third regions of the solvent. Observed values of $\overline{C}$ suggest a twofold effect of the ionic charge on its entourage of water molecules: a loosening of the O-H covalent bonds coupled with a stiffening of the O . . . H hydrogen bonds. The moving entropy and heat capacity of hydronium ion can be understood in terms of the hydrogen-bonded model of water structure, in which every H_2O or H_3O^+ can be 4-, 3-, 2-, 1-bonded to its neighbors or unbonded. By ascribing both bond and vibrational energy levels on this model, an approximate partition function is constructed for H_2O and H_3O^+, which can be made to fit our data for the unitary entropy and heat capacity of H_3O^+ at 25° and standard data for the entropy and heat capacity of H_2O between 0° and 100°. This model predicts the following fraction of hydrogen bonds broken in liquid H_2O at 0°, 25°, and 100°: 0.183, 0.218, and 0.310; in H_3O^+ at 25°, 0.094. The addition of H^+ to H_2O thus introduces a distinct amount of structure to the $H_3O^+ \ldots (H_2O)_4$ complex since it reduces the number of hydrogen bonds broken at 25° to a level, 9.4%, equal to half the number of hydrogen bonds broken in the liquid $H_2O \ldots (H_2O)_4$ complex at the melting point. The need to break about 12% more hydrogen bonds when the proton moves away at 25° is consistent with a calculated heat of transport of 3530 cal/mol, which compares favorably with the observed heat of transport of around 3000 cal/mole (on the Agar postulate). The single-ion stationary heat capacities $\overline{C}$ for K^+, Na^+, Li^+, and Cl^- obtained experimentally in the present study via the KCl-bridge postulate compare very favorably with theoretically calculated values of $\overline{C}_v$ for these ions based on the statistical model of Scheraga-Griffith.

A summary of the results of Part II (1a) is provided in Table I where the standard moving (transported) entropy $\overline{\overline{S}}^o$ of chloride ion, and related quantities, at 25°, are compared with data from previous observers (lines 1 to 5). For all the ions, our values of $\overline{\overline{S}}^o_i$ agree within 0.5 eu with Agar's (1), ours being smaller for chloride and larger for the cations. The values of Breck and Lin (2), and Haase, Hoch, and Schönert (3) are also given, as are also the earlier values of Khoroshin and Temkin (4) which are to-

day largely of historical interest. The bottom three sections of Table I represent three different divisions of $\overline{\overline{S}}^o_i$ into its constituent terms $\overline{S}^o_i$ and S^*_{oi} according to the Agar, KCl-bridge, and Gurney viscosity postulates, which yield, for $S^o(H^+)$, values of −5.2, −4.4, and −5.5 eu, respectively. Mention must also be made of Lin and Breck's −5.7 eu (5) based on the isentropicity of trichelated redox ion pairs.

Interest focuses on the values of $S^*_o(Cl^-)$ as deduced by the different methods. The present study gives 0.30 eu under the Agar postulate and 1.10 eu under the KCl-bridge postulate. Agar (1) had previously obtained 0.49 eu and Breck and Lin (2) 0.7 eu, both under the Gurney postulate. This concordance of values leads one to believe that the absolute value of this quantity, which still remains to be unambiguously determined (8), will probably not be significantly different from any of them. An examination of the S^*_o values of all the ions, under all postulates, identifies them as structure makers in the Eastman third region of the solvent in the order $H^+ > Na^+ > K^+ > Ca^{++}$ (?) $> Cl^- > Li^+$, lithium ion being either a very weak structure maker ($S^*_o = 0.29$, Agar postulate) or a structure breaker ($S^*_o = -0.51$, KCl-bridge postulate). At higher concentrations, Li^+ becomes a structure breaker in the third region (S^* negative, Part II, Table V, lines 19 and 25) under both postulates.

The standard moving entropy $\overline{\overline{S}}^o$, *i.e.*, the partial molal entropy of the central ion plus its tightly bound waters, of the ions K^+, Cl^-, and Na^+ ranges from 21 to 11 eu. By subtraction of the cratic entropy (7) for a standard aqueous saline, R ln 55.51 or 8.0 eu for each ion, the unitary part of the moving entropy of these ions is found to range from 13 to 3 eu, values comparable to but smaller than the molal entropy of simple liquid molecules such as H_2O, 16.7; D_2O, 18.2; HDO, 19.0; Hg 18.5 eu. This somewhat lower entropy is consistent with a degree of organization imposed by the presence of the electrostatic charge. The entropy of transports S^*_o of K^+, Cl^-, and Na^+ appears, on both Agar and KCl-bridge postulates, to be small and positive, in the range 0-3 eu. The transport entropy is the entropy loss of the solvent in the third region due to the ordering influence of the ion and its tightly bound waters. A partial freezing of vibration in the hydrogen bonds between the Eastman second and third regions would be sufficient to account for an entropy loss of this magnitude. The fundamental frequency of hydrogen-bond stretching vibrations is 175 cm^{-1} (9), about 1/20th of the frequency of the covalent O-H bond [3600 cm^{-1}, (10)]. A partial freeze-out of one such hydrogen-bond vibration by a stiffening of the bond would be sufficient to account for a loss of a significant portion of the Einstein vibrational entropy

$$S_{vib} = R[u(e^u - 1)^{-1} - \ln(1 - e^{-u})] \qquad [1]$$

equal to 1.2 R or 2.4 eu at 300°K, where $u = hc\tilde{\nu}/kT$. This is an entropy loss of the right magnitude. The standard partial molal entropy $\overline{S}^o_i$ of the stationary ion is thus positive for Cl^-, K^+, and Na^+ and slightly smaller than the moving entropy $\overline{\overline{S}}^o_i$.

For Li^+ and Ca^{++}, the moving entropy $\overline{\overline{S}}^o_i$ is negative, which suggests a highly ordered structure in the Eastman first and second regions, *i.e.*, in the ion itself and its tightly bound waters. The entropy of transport S^*_{oi} is close to zero or slightly negative for Li^+, and small and positive for Ca^{++}. The partial molal entropy $\overline{S}^o_i$ of the stationary Li^+ and Ca^{++} ions thus emerges in both cases as negative, due principally to the ordering influence of these small ions in the Eastman second region. The role of Li^+ is thus contrasted: a structure maker in the second region, and a slight structure breaker in the third region.

Hydrogen plays a unique role in this regard. Take the round numbers: $\overline{\overline{S}}^o = +5$, $S^*_o = +10$, $\overline{S}^o = -5$ eu for H^+. The addition of one water entropy, 16.7 eu, yields $\overline{\overline{S}}^o = 21.7$ eu as the partial molal moving entropy of H_3O^+. Subtraction of the cratic entropy gives the unitary part of the moving entropy of hydronium ion as $\overline{\overline{S}}^u(H_3O^+) = 13.7$ eu. This is 3.0 eu smaller than the water entropy. Thus the hydronium ion structure appears to be sufficiently stiffened by its electrostatic charge to make its unitary entropy less than the entropy of water, despite the presence of one extra atom with its three additional degrees of freedom. The entropy of transport S^* of hydrogen ion is large and positive, around +10 eu, the same value holds for H_3O^+ as for H^+, since this is an interaction negentropy between the ion (plus its tightly bound waters if any) and the surrounding solvent in the third region [negentropy (11) because it measures the amount of order created by the presence of the ion]. This large positive value indicates the particular influence of H^+ as a structure maker in the solvent through enhanced hydrogen bonding. The energy of the hydrogen bond has been estimated between 3.1 and 7 kcal/mol (9, 12). Thus an entropy of transport as high as 10 eu could be contributed by the need to break hy-

drogen bonds when the proton moves away (2) and the structure shifts from the more highly hydrogen bonded $H_3O^+ \cdot (H_2O)_x$ structure to the less hydrogen bonded $H_2O \cdot (H_2O)_x$ structure.

If one looks at hydroxyl ion, whose conventional standard entropy is $\bar{S}^o(OH^-, \text{conv.}) = -2.52$ eu (13) and entropy of transport S^* (under the Agar postulate) 13.5 eu (1, 6), one obtains $\bar{S}^o(OH^-) = +2.5$ eu, and $\bar{\bar{S}}^o(OH^-) = 16$ eu. The unitary part of the latter is $\bar{\bar{S}}^u(OH^-) = 8$ eu, *i.e.*, about half of the water entropy. The contribution of OH^- to the ordering of the solvent through enhanced hydrogen bonding is even more marked than for H^+, as measured by the comparative S^*'s for the two ions. Consider the reaction

$$H_2O + H_2O = H_3O^+ + OH^- \qquad [2]$$

for which $\Delta S^o = -19.2$ eu (13). This large negative entropy change can be visualized as the summation

$$\Delta S^o = [\bar{\bar{S}}^u(H_3O^+) + \bar{\bar{S}}^u(OH^-)] + [-S^*_o(H^*) - S^*_o(OH^-)] + 2R \ln 55.51 - 2\,S^o(H_2O) = [13.7 + 8] + [(-10) + (-13.5)] + 2(8.0) - 2(16.7) = -19.2 \qquad [3]$$

in which the unitary entropies of the ions themselves contribute 21.7 eu, a loss of 11.7 eu over the two parent waters, and the interaction negentropy of the ions with the solvent contributes a further entropy loss of 23.5 eu, while the cratic (dilution) term contributes an entropy gain of 16.0 eu.

The data on heat capacities can be visualized in terms of the expression $\bar{C}_i = \bar{\bar{C}}_i + (-C^*_i)$. The moving heat capacities of ions such as Cl^-, K^+, Na^+, Li^+ (excluding its high value) which range from 2 to 20 eu (Part II, Table VII, lines 2-5) are comparable to C_p values of simple monatomic, diatomic, or triatomic liquids such as Hg(l), 6.6; Zn(l), 7.5; Cu(l), 7.5; Xe(l), 10.7; CO(l), 14.5; Cl_2(l), 16.0; H_2O(l), 18.0; SO_2(l), 20.7 [ref. (14), pp. 63-66]. The central ion, together with its tightly bound waters if any, manifests a partial molal heat capacity $\bar{\bar{C}}_i$ comparable to the C_p of small neutral molecules. The moving hydrogen ion has a slightly negative $\bar{\bar{C}}$, *i.e.*, it transports a reduction of heat capacity wherever it goes, and this also appears to be true for Ca^{++} (excluding its high value) (lines 6, 7).

As pointed out in Part II (1a), the role of the ion on its immediate entourage of tightly bound waters appears to be twofold, according as $\bar{\bar{C}}_i$ is greater or less than the Dulong and Petit value of 6 eu for the vibrations of a monatomic ion. $\bar{\bar{C}}_i$ is the partial molal heat capacity of the ion in motion, *i.e.*, it is the change in heat capacity of the solvent system that moves with the ion on addition of the ion to this system. Any excess of $\bar{\bar{C}}_i$ above 6 eu suggests that the ion is contributing an increase in the heat capacity of its tightly bound waters, perhaps by loosening the covalent O-H bonds, and permitting a heat capacity contribution to develop from the three internal vibrations of the tightly bound H_2O's whose frequencies are normally so high that quantum restrictions ordinarily prevent them from contributing to $C_p(H_2O)$. Where $\bar{\bar{C}}$ is less than 6 eu, or even negative, the ion brings in a reduction in heat capacity in its immediate entourage. This suggests that the ordering influence of the ion, which enhances the degree of hydrogen bonding of the surrounding water structure, affects the water system that moves with the ion (second region), and causes it to lose heat capacity.

The ionic transport heat capacity C^*_i represents the gain in heat capacity of the solvent in the third region when the ion moves away, it is positive for all ions (Part II, Table VII, lines 9, 11, 13, 15, 17, 19) except Li^+, Na^+, H^+, and $\frac{1}{2}Ca^{++}$ at 1.0 molal. Therefore C^*_i measures the heat capacity squeezed out of the solvent in the third region by the introduction of the ion plus its tightly bound waters if any. This loss of heat capacity, which results from an electrostatic enhancement of the degree of hydrogen bonding in the third region, is often larger than the heat capacity $\bar{\bar{C}}_i$ of the central ion itself plus any possible effect it may have in loosening up the covalent structure of its tightly bound waters. The resultant is then a negative value for $\bar{C}_i$, the partial molal heat capacity of the stationary ion, *i.e.*, the heat capacity change of the entire solvent system (second and third regions both) on introduction of the ion.

It is interesting to note that, for Cl^-, $\bar{\bar{C}}$ is very close to the Dulong and Petit value, and that C^* is large and positive (30 eu). This suggests that Cl^- either has no tightly bound waters and the ordering effect of its charge occurs entirely in the third region or else that the two effects of the charge: loosening of the covalent O-H bonds, and enhancement of the O ... H hydrogen bond structure exactly offset each other in the second region, probably the former.

With hydrogen ion, C^* is small (Part II, Table VII, line 9). Since hydrogen ion is a pronounced structure maker in the third region, its small C^* indicates that its structure making tendency shows little variation with temperature. An extrapolation according to a $\sqrt{m}$-law gives $C^*_o = 5.1$ eu. Coupled with our KCl-bridge value of $\bar{C}^o(H^+) = -5.1$ eu (line 8), this gives $\bar{\bar{C}}^o(H^+) = 0.0$ eu. The corresponding values for hydronium ion are then $\bar{C}^o(H_3O^+) = 12.9$ eu and $\bar{\bar{C}}^o(H_3O^+) = 18.0$ eu, *i.e.*, the hydronium ion has a moving heat capacity which is the same as $C_p(H_2O)$.

The molal heat capacity of liquid water, 18.0 eu, is three Dulong and Petit values, while C_v for water vapor is only a little over 6 eu (for three translations and three rotations), and C_p for ice is a little over 9 eu. Thus the liquid water structure picks up, through intermolecular interaction (hydrogen bonding) an increment of heat capacity of close to 12 eu over that of the vapor. A crude model of the water structure could be visualized as consisting of its three atoms loosely bound in a hydrogen-bonded quasi-lattice, possessing nine fully excited vibrational degrees of freedom. Such a model would have a heat capacity of $9 \times (2/2)R = 17.9$ eu. This model is an oversimplification, however, because the internal modes of vibration of H_2O retain frequencies high enough in the liquid state [bond stretching vibrations $\nu_1 = \nu_3 = 3440$ cm^{-1}, bond bending $\nu_2 = 1645$ cm^{-1} (9) as compared with 3652, 3756, and 1595 cm^{-1} in the vapor (15)] to make as negligible a contribution to the heat capacity of the liquid as they do to that of the vapor. Recently, Scheraga and Griffith (16) proposed a model of water structure in which the three internal modes of vibration are disregarded, and are replaced by a series of five energy levels for 4-bonded (ground state) and for 3-, 2-, 1-, and unbonded water molecules (excited states) within the hydrogen bonded quasi-lattice. The remaining six vibrations are assigned as translational modes (3) and librational modes (3) of the H_2O molecule as a whole within the lattice. Griffith (16) adjusted the energy levels and frequencies to give a best fit to the experimental thermodynamic data as follows

Type of H_2O molecule	Energy level (cal/mol)	Translational vibrations (cm^{-1})	Librational vibrations (cm^{-1})
unbonded	6670	26	197
1-bonded	4970	86	374
2-bonded	3870	61	500
3-bonded	2030	57	750
4-bonded	0	210	750

For liquid water at 0°, 25°, and 100°, this model predicts the following mol-fractions: 4-bonded H_2O: 0.368, 0.278, and 0.129; 3-bonded: 0.600, 0.671, and 0.740; 2-bonded: 0.030, 0.046, and 0.105; 1-bonded: 0.0014, 0.0026, and 0.0091; unbonded: 0.0008, 0.0023, and 0.0176. The fraction of hydrogen bonds broken at these temperatures is 0.167, 0.192, and 0.266, respectively. The calculated energy of fusion is 1347 cal/mol (compared with the experimental $\Delta H_{fus}(H_2O) = 1436$ cal/mol).

The Scheraga-Griffith partition function for H_2O provides for different sets of vibrational states for each energy level. It is therefore not separable according to the two types of molecular energy: bond and vibrational, and becomes quite cumbersome for analysis. It will here be replaced by a separable approximation. This approximate partition function for H_2O and H_3O^+ takes the form (21)

$$Q = \frac{(1 + ge^{-\epsilon/kT})^4}{(1 - e^{-h\nu^T/kT})^3(1 - e^{-h\nu^L/kT})^3} \quad [4]$$

in which the five energy levels are assigned an equal spacing ϵ. These levels have the geometrical multiplicities 1, 4, 6, 4, 1 corresponding to the number of ways a given H_2O or H_3O^+ can be 4-, 3-, 2-, 1- or unbonded in the quasi-lattice. In addition to these geometrical multiplicities which naturally appear in the fourth power expansion of the binomial, the multiplicity factor g is introduced as a correction needed to compensate for the fact that the higher energy levels, with their lower vibrational frequencies, have a higher density of vibrational states in the Griffith partition function than they would have in the approximate partition function if the factor g were to be omitted. Values of g calculable from the Griffith frequency assignments range between 2 and 18. The value 3 has been determined empirically for g as described below. Unique frequencies ν^T and ν^L are assigned to the three translational and three librational modes of vibration in all energy levels for both H_2O and H_3O^+. The approximate partition function thus has four adjustable parameters for H_2O, and one more for H_3O^+, as compared with 14 parameters in the Griffith partition function for H_2O.

To determine the frequencies ν^T and ν^L, the approximate partition function Q was also applied to the ice structure at 273°K, with the numerator set equal to unity, *i.e.*, ice is assumed to be 4-bonded throughout. The experimental values for the entropy S^o (ice, 273°K) = 9.88 eu, less the residual entropy of ice: R ln 3/2 = 0.81 eu (17), and for the heat capacity C_p^o (ice, 273°K) = 9.11 eu, neglecting the small difference between C_p and C_v, were equated to the vibrational contributions from Q. A fit was found at $\nu^L = 498.1$ and $\nu^T = 153.6$ cm^{-1}, values not inconsistent with the set of Griffith frequencies and in a ratio not far from 4:1, *i.e.*, $(m_O/m_H)^{1/2}$, a result which is not surprising since the translational vibrations involve largely motions of the oxygen atom, and the librational vibrations involve largely motions of the hydrogen atoms (22).

To evaluate the hydrogen bond energies in the numerator of Q, use was made of the experimental differences at 298°K

$$S^o(H_2O) - \bar{\bar{S}}^u(H_3O^+) = 3.0 \text{ eu} \quad [5]$$

$$C_p^o(H_2O) - \bar{\bar{C}}^o(H_3O^+) = 0 \quad [6]$$

as obtained above. The residual moving entropy of H_3O^+ was evaluated by a method to be described below as R ln 4/3 = 0.57 eu. Correction for the residual entropies of H_2O and H_3O^+, together with the assumption of equal vibrational contributions for both, gives the difference in bond entropies and heat capacities as

$$S_{bond}(H_2O) - \bar{\bar{S}}_{bond}(H_3O^+) = 2.78 \text{ eu} \quad [7]$$

$$C_{bond}(H_2O) - \bar{\bar{C}}_{bond}(H_3O^+) = 0 \quad [8]$$

Values of $\epsilon(H_2O)$ and $\epsilon(H_3O^+)$ were sought that would satisfy these differences. These were found to be $\epsilon(H_2O) = 1409$ and 1540; $\epsilon(H_3O^+) = 1996$ and 2060 cal/mol, for $g = 3$ and 4, respectively. Then complete bond and vibrational entropies and heat capacities for H_2O were computed from the full partition function Q, yielding, after inclusion of the residual entropy, at 298°K: $S^o = 16.74$ and 17.53 eu, and $C_v^o = 17.11$ and 18.91 eu, for $g = 3$ and 4, respectively. Since the experimental values are $S^o = 16.716$ eu and $C_v^o = 17.81$ eu for H_2O, the choice $g = 3$ gives a closer fit and was adopted empirically together with the parameters: $\nu^T = 153.6$, $\nu^L = 498.1$ cm^{-1}, $\epsilon(H_2O) = 1408.7$, $\epsilon(H_3O^+) = 1996.4$ cal/mol. Calculated entropies and heat capacities from Q are listed in Table II together with the experimental values for comparison. The partition function does correctly give the entropy of water from 0° to 100° as well as the entropy of fusion of ice. It does follow the decreasing trend of $C_v(H_2O)$ with increasing temperature, but not so abruptly as the experimental values. This is also a characteristic of the full Griffith-Scheraga partition function which predicts, however, a steeper drop than that observed (Table II).

The residual entropy of hydrogen ion can be calculated by a method analogous to Pauling's computation for ice (17). For a tetrahedral lattice of N oxygen atoms with $2N$ hydrogen atoms distributed among the $2N$ O ... O bonds and two sites available to each hydrogen atom (at 0.99 and at 1.77Å away from any particular oxygen atom), the number of configurations is 2^{2N}. These configurations include the following arrangements of H around O: 1 H_4O^{++}, 4 H_3O^+, 6 H_2O, 4 OH^- and 1 $O^=$. Thus for each O atom, only 6/16 of all possible configurations are H_2O's, and for the entire system, $W = 2^{2N}(6/16)^N$. The residual entropy is k ln $W = R$ ln $2^2 \cdot 6/16 = R$ ln 3/2 (17).

The residual contribution to the unitary partial molal entropy of hydrogen ion is the change in residual entropy of a large mass of H_2O per H^+ added to it. Take a central H_2O molecule and add H^+ to it. The number of distributions of 3H's among two sites each is 2^3, and the fraction of possible configurations that correspond to H_3O^+ is 4/16, making $W = 2^3$ (4/16) for the central O atom. The three vicinal O's, bonded by the three H's of the central H_3O^+, have each two further H's to be distributed among two sites per bond in three bonds. The fraction of possible configurations allowed here is only 3/16, instead of 6/16, since only three, instead of four, bonds are available. This makes $W = [2^2(3/16)]^3$ for these three O's. The fourth vicinal O whose own H bonds it to the central H_3O^+, has only one further H to be distributed among two sites per bond in three bonds. Again, the fraction of allowed configurations is only 3/16, instead of 6/16, making $W = 2(3/16)$ for this fourth O. For the remaining O's further away from the central

[a] Calculated from the Griffith-Scheraga (16) partition function.

H_3O^+, W appproaches the Pauling value of $2^2(6/16)$ for pure water. The change in residual entropy resulting from the addition of one H^+ to an ice-like lattice of N H_2O's is then

$$k \ln \frac{2^3(4/16)[2^2(3/16)]^3\, 2(3/16)\, [2^2(6/16)]^{N-5}}{2^{2N}(6/16)^N} \quad [9]$$

and this is $\bar{S}^u_{resid}(H^+)$ which becomes $-R$ ln 24 = −6.32 eu on a molar basis. Now, $\bar{S}^u_{resid} = \bar{\bar{S}}^u_{resid} + (-S^*_{resid})$. The moving entropy term is the increment in residual entropy of the central H_2O itself on its transformation to H_3O^+, this is k ln $[2^3(4/16)]/[2^2(6/16)]$ which gives $\bar{S}^u_{resid}(H_3O^+) = R$ ln 4/3 = 0.57 eu. The residual entropy of transport of H^+ is then $S^*_{resid}(H^+) = R$ ln 32 = 6.89 eu. Since experimentally $S^*_o(H^+)$ is around 10 eu (Table I), this result suggests that the electrostatic part of the entropy of transport of H^+ amounts to a little over 3 eu, a value which would be consistent with the Eastman-Born equation at r_i = 2.8Å, *i.e.*, close to the O . . . O distance in the ice lattice.

The experimental values for H_2O in Table II are based on the NBS value for the entropy at 25° (18) and the NBS values for the specific heat as recorded in the "Handbook of Chemistry and Physics." C_v was computed from the observed C_p by the usual formula involving the compressibility and thermal expansion of water. Observed values for H_3O^+ are based on research reported above in the present paper.

The approximate partition function predicts the following mol fractions at 0°, 25°, and 100°: 4-bonded H_2O: 0.446, 0.375, and 0.227; 3-bonded: 0.399, 0.417, and 0.408; 2-bonded: 0.134, 0.174, and 0.274; 1-bonded: 0.020, 0.032, and 0.082; unbonded: 0.0011, 0.0022, and 0.0095, so that the fraction of hydrogen bonds broken becomes 0.183, 0.218, and 0.310 at these temperatures, i.e., about 10-16% larger than in the Griffith-Scheraga model. For H_3O^+ at 25°, Q predicts the mol fractions: 4-bonded: 0.675; 3-bonded: 0.279; 2-bonded: 0.043; 1-bonded: 0.0030; unbonded: 0.000077, for a fraction of hydrogen bonds broken of only 0.094. Thus the approximate partition function Q confirms that H_3O^+ is a strong structure maker in the solvent. The addition of H^+ to H_2O introduces a distinct amount of structure to the $H_3O^+ \ldots (H_2O)_4$ complex since it reduces the number of hydrogen bonds broken at 25°: 9.4%, to a level of half the number of hydrogen bonds broken, 18.3%, in the liquid $H_2O \ldots (H_2O)_4$ complex at the melting point. The need to break 12.4% more bonds, *i.e.*, from 9.4 to 21.8%, when the proton moves away at 25° is consistent with a heat of transport of $0.124 \times 4[\epsilon_{(H_3O^+)} + \epsilon_{(H_2O)}] + 0.782 \times 4\,[\epsilon_{(H_3O^+)} - \epsilon_{(H_2O)}]$ = 1689 + 1838 cal/mol = 3527 cal/mol, a value which is higher than but of the right order as compared with the observed heat of transport TS^* of H^+ of around 3000 cal/mol (on the Agar postulate). Lin (19, 20) has recently shown that S^* for hydrogen ion is strongly lowered by the addition of ethanol to water, where the ethanol effectively tends to hinder the proton transfer mechanism of H^+ mobility. Thus the heat of transport for proton transfer, calculated above to be 3527 cal/mol, from our present model of the H_2O and H_3O^+ structures, should be larger than the observed heat of transport, which contains a contribution from the much smaller heat of transport of the H_3O^+ migration. As the numbers quoted above show, this expectation is indeed found to be the case.

Further validation of the model is provided from the surface energy of water which is $\gamma - Td\gamma/dT$ (γ is surface tension), and is equal to 117.8 erg/cm² at 25°. Taking the surface population of water as $(\rho N_0/M)^{2/3} = 1.038 \times 10^{15}$ molecules/cm², the molar surface energy is 1634 cal, a value which compares favorably with our $\epsilon_{(H_2O)}$ of 1409 cal/mol, the energy increment when one H_2O molecule goes from a 4-bonded to a 3-bonded state, as it must when it moves into a position in the surface.

Despite its success (Table II), the approximate partition function Q has a number of defects. It overestimates the heat capacity of ice in the interval −50° to −200° by about 10-18%, but yields a satisfactory 1392 cal for the energy E-E_o of ice at 0° as compared with the experimental value of around 1310 cal. It underestimates the energy of fusion as 1031 cal as compared with the experimental 1436 cal. The calculated free energies are rather poor. The predicted ΔA(fusion) is negative at all temperatures so that the melting point of ice should then be 0°K. On the other hand, the calculated ΔA(fusion) remains small (−439 cal at 273°K) up to several hundred degrees, and then bends over sharply and drops linearly with increasing T. When this high temperature limit for ΔA(fusion) is extrapolated back to zero, it predicts a melting point of 383°K, *i.e.*, about 110° too high.

With OH^- ion, there are three translational vibrations and two librational vibrations. If the same frequencies and bond contributions are utilized as for H_3O^+, $\bar{\bar{S}}^u$ is calculated to be 13.2 eu, a value much higher than the observed 8 eu. The hydroxyl ion should be more tightly bound to the hydrogen bonded water lattice than H_3O^+, as evidenced by its higher entropy of transport. This factor alone would tend to raise the frequencies and the bond energies for OH^- and would significantly lower $\bar{\bar{S}}^u$. If the observed unitary part of the moving entropy of hydroxyl ion $\bar{\bar{S}}^u(OH^-)$ = 8 eu is arbitrarily divided into a vibrational contribution of 7 eu plus a bond contribution of 1 eu, the observed value can be fitted with the assignments: ν^T = 196, ν^L = 784 cm^{-1}, ϵ = 3000 cal/mol, all of which are about 50% higher than the corresponding values for H_3O^+, *i.e.*, the hydrogen bond $OH^- \ldots H_2O$ would seem to have about 50% greater stiffness than $H_3O^+ \ldots H_2O$. The corresponding moving heat capacity would then be, for the five vibrations: 6.9 eu, for the bonds: 3.8 eu, giving a calculated total $\bar{\bar{C}}^o(OH^-)$ of about 11 eu.

Since the conventional partial molal heat capacity is $\bar{C}_p^o(OH^-, conv.) = -32$ eu (18), it is possible from our KCl-bridge value $\bar{C}^o(H^+) = -5.1$ eu to obtain $\bar{C}^o(OH^-) = -27$ eu, and, in view of the moving heat capacity calculated above, $C^*(OH^-) \approx 38$ eu is the heat capacity loss of the third region surrounding the OH^- ion, a value comparable to and even larger than C^* for the chloride ion (Part II, Table VII, line 11).

Griffith (16) extended his statistical theory of the water structure to infinitely dilute solutions of alkali halide salts. Adjusting his statistical parameters to the experimental properties of the salts and to Breck and Lin's (2) choice of absolute partial molal ionic entropies (Table I, line 14), his theory yields values of the single ion partial molal heat capacities which can be compared with our experimental results based on the KCl-bridge postulate (Part II, Table VII). The comparison is as follows with our values given in parentheses: Li^+, 11.94 (8.5); Na^+, 0.16 (0.3); K^+, −4.37 (−4.9); Cl^-, −30.71 (−24.1). There is an interesting and close parallel between Griffith's statistical values and our experimental results in this case.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

LIST OF PRINCIPAL SYMBOLS

A Linear coefficient in thermoelectric equation, μV/deg.
A Helmholtz free energy, cal/mol.
B Quadratic coefficient in thermoelectric equation, μV/deg^2.
B Gurney's relative viscosity coefficient.
C_p, C_v Molal heat capacity at constant pressure, or constant volume, cal/deg·mol (eu/mol); cal/deg·eq (eu/eq).
$\overline{C}_p^o$ Partial molal heat capacity at infinite dilution.
C^* Transport heat capacity of a salt or an ion constituent.
C^*_o Transport heat capacity of a salt or an ion constituent at infinite dilution.
$\overline{\overline{C}}$ Partial molal moving (transported) heat capacity of a salt or an ion constituent.
$\overline{\overline{C}}^o$ Partial molal moving (transported) heat capacity of a salt or an ion constituent at infinite dilution.
$\overline{C}$ Partial molal stationary heat capacity of an ion constituent.
$\overline{C}^o$ Partial molal stationary heat capacity of an ion constituent at infinite dilution.
c Velocity of light, 2.998 x 10^{10} cm.s^{-1}
D Dielectric constant, dimensionless.
D_o Coulomb's law constant: (10^{-9}/9) a.s.v^{-1}·m^{-1}, or 1 statampere. second·statvolt^{-1}. cm^{-1}, see ref. (13), Part II.
E Molal energy, cal/mol.
E_o Molal entropy, at 0°K.
e Elemental charge, 1.602 x 10^{-19} a.s.
F The Faraday, 96487 a.s.
g Empirical multiplicity factor in approximate partition function Q.
H Molal enthalpy, cal/mol.
h Planck's constant, 6.62 x 10^{-27} erg.s.
i, j Ionic indexes.
$\overline{J}$ Relative partial molal heat capacity.
k Boltzmann constant, 1.38 x 10^{-16} erg/deg, 86.17 microvolt-electrons/deg.
m Molality: mols of solute per kilogram of solvent.
m Mass, grams.
M Molecular weight, molar mass, grams/mol.
N Number of molecules; N_o: Avogadro's number
n Number of mols.
p Pressure, dyne·cm^{-2}, atm.
Q Partition function for water and hydronium ion (dimensionless).
r Ionic radius, cm, Å.
R Gas constant, 1.98717 eu/mol, 86.17 microvolt-faradays/deg-mol.
S molal entropy, cal/deg-mol (eu/mol), cal/deg·eq (eu/eq).
$\overline{S}$ Partial molal entropy of a salt, partial molal stationary entropy of an ion constituent.
$\overline{S}^o$ Partial molal entropy of a salt in the hypothetical standard state with $m = 1$, but all other properties at infinite dilution.
S^* Transport entropy of a salt or an ion constituent.
S^*_o Transport entropy of a salt or an ion constituent at infinite dilution.
$\overline{\overline{S}}$ Partial molal moving (transported) entropy of an ion constituent.
$\overline{\overline{S}}^o$ Partial molal moving (transported) entropy of an ion constituent in the hypothetical standard state.
$\overline{\overline{S}}^{o\prime}$ $\overline{S}^o + S^*(m)$, preliminary standard value of the moving entropy for an ion constituent.
$\overline{\overline{S}}^u$ Unitary part of $\overline{\overline{S}}^o$ for an ion constituent.
T Temperature, °K; t temperature, °C.
t_+, t_-, t_i, t_r, t_g Hittorf transference numbers of + ions, − ions, ions of species i, ions of species r to which electrode is reversible, ions of species g gegenions of r.
V Electrical potential of copper electrode terminal, volts.
v Valence of a salt.
$z, z_+, z_-, z_i, z_r, z_g$ Ionic valence (with sign). See t_+ . . . for explanation of subscripts.
γ Mean ion activity coefficient of a salt; γ_i: ionic activity coefficient.
ϵ Energy level in hydrogen-bonded structure of H_2O and H_3O^+.
ϵ_o $= (dV/dT)_{th,initial}$ Initial thermoelectric coefficient, μV/deg.
ϵ_∞ $(dV/dT)_{th,final}$ Final thermoelectric coefficient, μV/deg.
μ Ionic strength; ν: number of ions per molecule of salt.
$\tilde{\nu}, \nu$ Frequency, wave number, s^{-1}, cm^{-1}.
ρ Density, g·cm^{-3}.

Electron Microprobe Study of the Active Materials in the Lead-Acid Storage Battery

Takewo Chiku and Koichi Nakajima

Toyota Central Research & Development Laboratories, Inc., Nagoya, Japan

The electrochemical processes of forming the active materials in a lead-acid storage battery have been thoroughly examined. However, the mechanism of formation is not clear as yet. Based on observations of the electrochemical polarization in a cylindrical mass of litharge, one of the present authors (1) clearly showed that the polarization was largely dependent on the potential gradient produced in the mass. Thus, it was shown that negative polarization began to develop from a region near the positive end of the cylindrical mass, while positive polarization began to develop from the interior of the mass. Simon and Jones (2, 3) have studied the structural changes occurring during the electrochemical formation of positive active material, and they showed that the microstructure depended on the condition under which the active materials were formed.

Tudor *et al.* (4) proposed the autoradiographic technique to apply to battery research, and by using this technique they have shown (5) the electrochemical behavior, especially of the Pb-Ca grid battery with the addition of phosphoric acid. However, their technique is not suitable for microanalysis of the structural change of electrode plates during the process of charge and discharge.

The present study was undertaken to elucidate with the aid of an electron probe x-ray microanalyzer the concentration changes of lead sulfate and its distribution on charge and discharge in the electrode plate.

Experimental Procedure

The samples examined were taken from automobile batteries, each cell consisting of 5 positive and 6 negative plates. Specifications of this battery are as follows: 12V, 40 Ahr at the 20-hr rate, terminal voltage 9.5-9.7V after discharge with 150A at −15°C for 5 sec, and the specific gravity of the electrolyte solution 1.260 at 20°C.

The batteries were discharged under various conditions after having been charged at 3A for 13 hr. A negative and a positive plate were taken from each stage shown in Table I. These stages are designated as A, B, C, D, E, and F. Three blocks of active material surrounded by the unit grid section were then cut out carefully from the upper, middle and lower portions of each electrode plate as shown in Fig. 1, the size of the unit section being 17 x 4 x 1.4 mm³. These blocks were then completely cleansed with distilled water until no sulfate ion was detected and finally dried at room temperature under reduced pressure.

Table I. Time of discharge or charge and terminal voltage in each stage of the electrode plate

Stage	Charge at 0.0022 A/cm² Time of charge, hr	Charge at 0.0022 A/cm² Terminal voltage, volt	Discharge at 0.003 A/cm² Time of discharge, hr	Discharge at 0.003 A/cm² Terminal voltage, volt	Discharge at 0.011 A/cm² Time of discharge, min	Discharge at 0.011 A/cm² Terminal voltage, volt
A	0.1	2.07	0.5	2.05	0.5	1.70
B	0.5	2.07	1	2.04	1	1.72
C	2	2.11	2	2.03	2	1.71
D	5	2.20	3	2.01	3.5	1.62
E	8	2.37	6	2.00	5.7	1.50
F	13	2.87	8	1.00	6.2	0.80

The intensity of Pb-Lα and S-Kα radiation was measured on these block samples along the surface or in the direction of depth from the surface by using a Shimadzu ARL electron probe x-ray microanalyzer operated at 30 kV. The area of the irradiated specimen surface was 2μ or 10μ in diameter for making a line analysis and 360 x 360 μ^2 for measuring the electron beam scanning pattern (EBS). The intensity of the characteristic radiation of each element in the sample was determined as the average value of at least twenty different measurements.

Experimental Results and Discussion

Figure 2 shows the EBS pattern of S-Kα radiation obtained from the defined portions on the surface of the discharged positive plate in which the effective depth of penetration of the electron beam into the sample was estimated to be about 2μ. Line analyses were also carried out on samples taken from each stage shown in Table I. A typical example of the analysis is shown in Fig. 3. This result shows that the electrochemical reaction which occurs on the electrode plates does not proceed homogeneously over the entire plate, but that the content of $PbSO_4$ produced during discharging varies from area to area in the samples. It is clearly seen from these figures that for a given position the slopes of the intensity curves of Pb-Lα and S-Kα radiation are opposite to each other. Thus, an increase (or decrease) of the intensity of Pb-Lα corresponds to a decrease (or increase) of that of S-Kα. This can be explained in terms of the nucleation and growth (or decomposition) of $PbSO_4$ (6), if the sources of S-Kα radiation emitted from the electrode plate are related completely to the presence of $PbSO_4$ in the region observed. The concentration of $PbSO_4$ and its distribution in the samples can be estimated on this assumption. Figure 4 shows the per cent change of

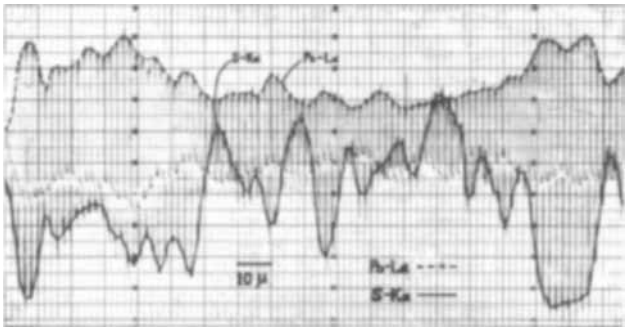

Fig. 3. Example of line analysis of S-Kα and Pb-Lα radiation across the surface of the negative plate (see Fig. 1) taken from stage D.

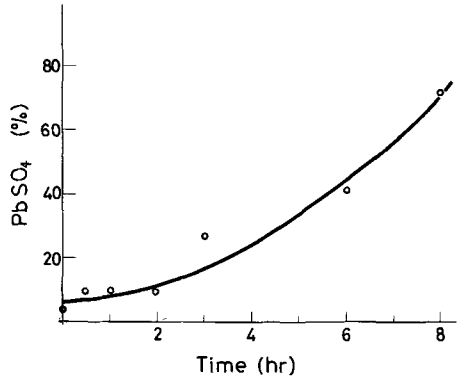

Fig. 4. Dependence of the content of $PbSO_4$ in the negative plate on the time of discharge (at 0.003 A/cm²).

the content of $PbSO_4$ in the surface of a negative plate with time of discharge: the content of $PbSO_4$ increases gradually with the time, and after 8 hr the increase attains to about 75%, which agrees with the result (6) obtained by x-ray.

It is very interesting to note that the surfaces of the electrode plates are not covered entirely with the substance containing sulfur even in the latter stage of discharge. This result enables us to suggest that some Pb crystallites must remain randomly to the final stage of discharge, and they will make nuclei for changing $PbSO_4$ into Pb during charging.

The concentration gradient of $PbSO_4$ sampled from the surface to the inner part was measured on samples which corresponded to the stages in the process of charge or discharge shown in Table I. The content of $PbSO_4$ in the positive plate had a tendency to decrease with depth from the surface for any stage of the discharge and charge, confirming the previous results (1) and also that of Tudor *et al.* (5).

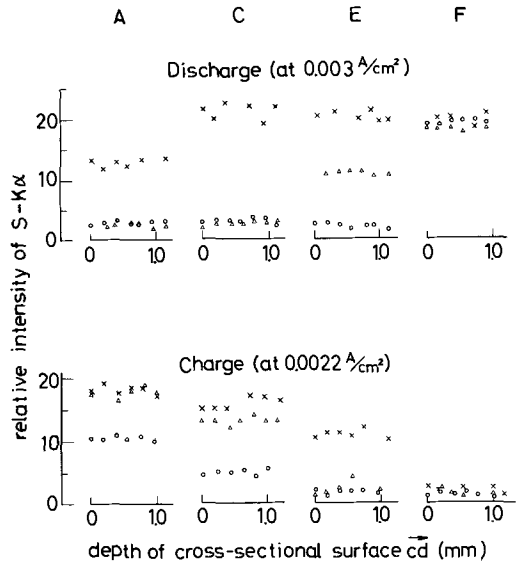

Fig. 5. Relative intensity of S-Kα radiation vs. depth from the surface of negative plate. —x— lower, —△— middle, —○— upper.

Figure 5 is the intensity change of S-Kα radiation with depth of the negative plate, showing somewhat different behavior from that of the positive plate, that is, the concentration gradient of $PbSO_4$ is almost zero for any stage of charge and discharge. The result of electron microprobe analysis shown in Fig. 4 indicates the existence of S-Kα radiation corresponding to a few per cent of $PbSO_4$ in the charged state. It will be understood by this fact that $PbSO_4$ in the electrode plate is not entirely changed into lead even in the fully charged state, and its amount increases with time of battery usage (6). It should be noted here that the total amount of $PbSO_4$ estimated from the x-ray analysis corresponds to that of crystallites a few hundred angstroms or more in size.

One of the authors (Chiku) has expected from his previous experiments (1) performed in a large quantity of the electrolyte solution without using a separator and glass mat that the electrochemical reaction occurring in the negative plate should develop from the interior to the surface for the stage of discharge, and *vice versa* for the stage of charge. The present results, however, do not coincide absolutely with the above description, suggesting that the concentration change of $PbSO_4$ and its distribution depend on the effective quantity of electrolyte solution next to the electrode plate.

It will be noted that the intensity of S-Kα radiation in both negative and positive plates becomes a maximum in the lower part of plate for any stage of the discharge and charge, showing that the electrochemical reaction proceeds first in the lower part for the stage of discharge and in the upper for the stage of charge. This may be explained as being caused by the formation of a concentration gradient of electrolyte solution along the surface of the plate (and also a temperature gradient) during the progressive reaction. An experimental confirmation of this will be given by electron microscopic observations of the morphological change of $PbSO_4$ crystallites in the lower and upper parts of the plate.

Summary

The dependence of the concentration of $PbSO_4$ and its distribution on charge and discharge in the electrode plate were examined in commercial lead-acid storage batteries by using an electron probe x-ray microanalyzer.

The concentration change of $PbSO_4$ in the negative plate during discharge was found to be stationary with

the depth from the surface. Similar distribution curves of $PbSO_4$ were also obtained for the electrode plates during charging.

Acknowledgment

The authors wish to give hearty thanks to Dr. Ninomiya for his informative discussion. Thanks are also given to Messrs. H. Haba, A. Isogai, and K. Satta for their diligent aid throughout the course of the work.

Manuscript submitted Jan. 15, 1969; revised manuscript received June 13, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

The Dissociation Pressure of Hematite

P. E. C. Bryant and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

Several determinations of the dissociation pressure for hematite to magnetite have been made during the past several years. Greig *et al.* (1) determined the temperatures at which these oxides exist in equilibrium with air and pure oxygen. Darken and Gurry (2) confirmed and expanded these results by an extensive investigation on the equilibration of these oxides in atmospheres of known oxygen potentials at several temperatures in the range 1100°-1500°C. More recently, Norton (3) and Salmon (4) measured the equilibrium pressures directly at temperatures from as low as 780° to 1362°C and, most recently, Blumenthal and Whitmore (5) and Charette and Flengas (6) have determined the dissociation pressure and standard free energy of formation at temperatures in the range 690°-1100°C using a solid state electrochemical method.

The difference is significant between the results obtained from the two electrochemical investigations. Charette and Flengas (6) used a closed cell with a nickel oxide reference electrode, the zirconia-calcia electrolyte in the form of a closed tube separating the electrode compartments. On the other hand, Blumenthal and Whitmore (5) used the open cell stacked tablet technique, the cell operating with a zirconia-calcia electrolyte tablet and iron, wustite as the reference electrode. Hematite exhibits a relatively high dissociation pressure in comparison to wustite; consequently a low mixed potential rather than an equilibrium potential may have been generated by this latter cell due to transfer of oxygen from one electrode compartment to the other through the inert gas atmosphere surrounding the stacked tablets. In this work, a different cell has been used containing copper-cuprous oxide as the reference electrode. Since the electromotive force generated by this cell is small, it should be possible to obtain equilibrium values of the potentials by the open cell stacked tablet technique.

The galvanic cell may be represented as

$$\begin{matrix} & \text{Cu} & & & \text{Pt} \\ & | & & & | \\ Cu_2O, & Cu & | \; Zr_{0.85}Ca_{0.15}O_{1.85} \; | & Fe_3O_4, & Fe_2O_3 \end{matrix} \qquad [1]$$

where Cu and Pt represent the metal leads embedded between the solid tablets in the electrode compartments. The tablets of the zirconia-calcia electrolyte containing 15 w/o (weight per cent) calcia and the metal-oxide components were prepared from Fisher C. P. reagent powders, the Cu_2O, Cu and Fe_3O_4, Fe_2O_3 electrodes containing metal and oxygen in the ratios 2.10 and 8.75, respectively. Cell construction, preparation of the electrode and electrolyte tablets, and the apparatus for potential measurements have been reported (7).

The temperature of a cell was controlled within ± 1°C and potentials were determined to a precision of 10^{-3} mV. To insure potential stability, the inert gas atmosphere flowing around the cell contained trace amounts of oxygen resulting from dissociation of cuprous oxide contained in a small silica combustion boat outside each electrode compartment and in a copper tray below the cell supporting tube. Oxygen was provided by this means to the argon atmosphere at a partial pressure below the hematite-magnetite equilibrium oxygen pressure but sufficient to prevent appreciable dissociation of hematite.

In Fig. 1, the electromotive force values produced are shown for several temperatures in the range 1060°-1323°K. The results were obtained from cycles of ascending and descending temperatures on three cells. Potential stability was excellent being steady at a specific test temperature for a period of 20 hr. Investigation of each cell at completion of the experiment showed that the reaction electrodes had plastically flowed about the copper and platinum leads, virtually encasing them in the metal-oxide mixtures, and that the electrode-electrolyte tablets were sintered together.

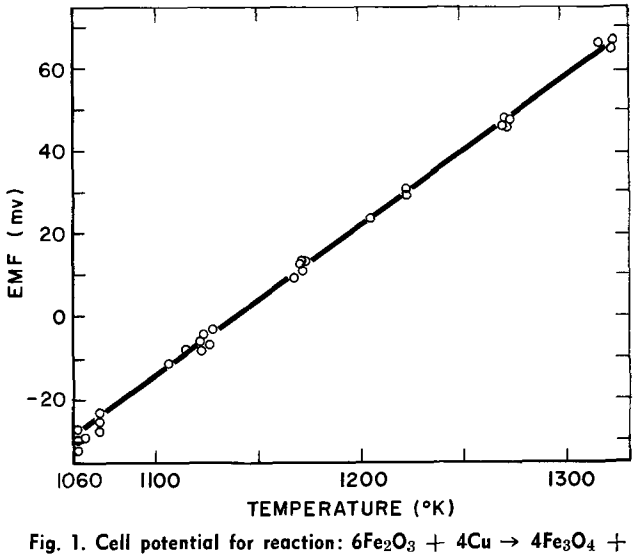

Fig. 1. Cell potential for reaction: $6Fe_2O_3 + 4Cu \rightarrow 4Fe_3O_4 + 2Cu_2O$.

* Electrochemical Society Active Member.

Table I.

Cell potential: E (mV) = A + BT (°K)
Cell Reaction: $6Fe_2O_3 + 4Cu \rightarrow 4Fe_3O_4 + 2Cu_2$

Reference	Temperature range (°K)	A	B	Standard deviation (mV)
This work	1060-1323	−413.7	0.363	±1.6
(6)	967-1373	−416.12	0.36471	±1.14

Kiukkola and Wagner (8) have expressed the thermodynamic parameter to be obtained from this type of galvanic cell involving only oxygen migration through the electrolyte. In the case of cell [1], the potential is

$$E = \frac{RT}{4F} \ln PO_2(Fe_2O_3, Fe_3O_4)/PO_2(Cu_2O, Cu) \quad [2]$$

where R is the gas constant, $\mathbf{F}$ is the Faraday, and the oxygen pressures are the dissociation pressures for the designated oxides. In turn, these dissociation pressures may be related to the standard free energies of formation of the oxide per mole of oxygen. For example, this free energy change for hematite formation from magnetite is

$$\Delta G°_T = -RT \ln PO_2\ (Fe_2O_3, Fe_3O_4) \quad [3]$$

assuming that the activities of the pure solid oxides are unity. Consequently the values of the dissociation pressure for hematite at the investigated temperatures, which may be calculated from the potential determinations and the values reported for the standard free energy of formation of cuprous oxide, may then be represented by the Van't Hoff isochore.

Since the cell potentials were linearly related to temperature, the constants of the line illustrated in Fig. 1 were evaluated by the least-squares method. These values, as illustrated in Table I, show close agreement with those calculated from the electrochemical results previously presented for the same temperature range by Charette and Flengas (6). Accordingly both the closed tube cell and the stacked tablet open cell with a suitable reference electrode have yielded values for the equilibrium potentials of the hematite-magnetite system within an accuracy better than ±2 mV.

The dissociation pressures of hematite calculated from the results of this investigation may be represented by the equation

$$\log PO_2\ (Fe_2O_3, Fe_3O_4) = \frac{-26{,}196 \pm 69}{T} + 15.124 \pm 0.003 \quad [4]$$

where T is °K and pressure is an atm. In this calculation, the expression used for the standard free energy of formation of cuprous oxide per mole oxygen is that given from two previous investigations (6, 9)

$$\Delta G°_T = -79{,}780 + 34.120T \pm 345 \text{ cal} \quad [5]$$

The above results and those reported in the literature for the temperature range 690°-1500°C are plotted in Fig. 2. It is apparent that Eq. [4] when extrapolated gives a good estimate to the higher temperature results. The least-squares line for all reported values at temperatures in the range 690°-1470°C is

$$\log PO_2\ (Fe_2O_3, Fe_3O_4) = \frac{-25{,}908 \pm 215}{T} + 14.862 \pm 0.007 \quad [6]$$

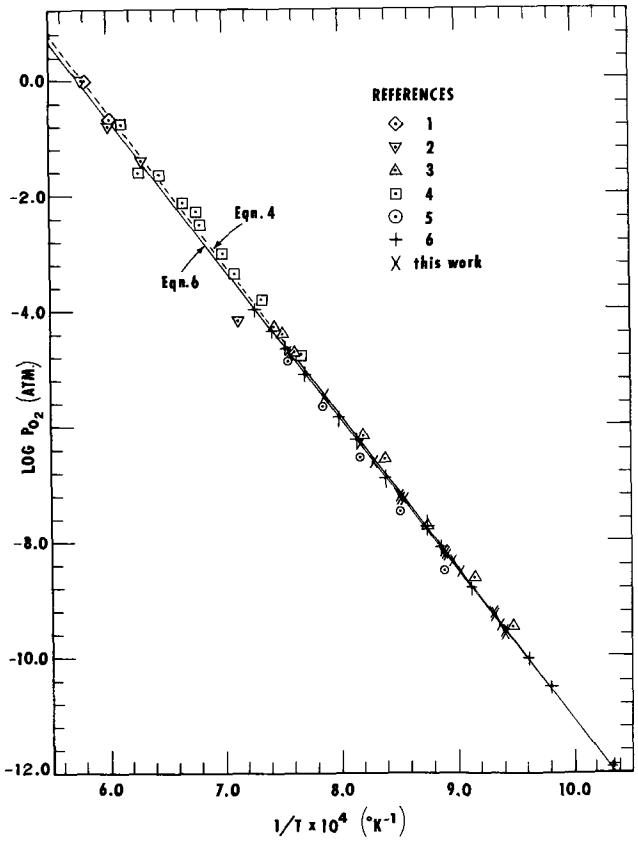

Fig. 2. Van't Hoff isochore, log p_{O_2} vs. $1/T$, for the dissociation pressure of hematite to magnetite.

This latter equation would thus appear to be the best estimate presently available for determining the dissociation pressure of hematite at temperatures where the oxides exist as solids.

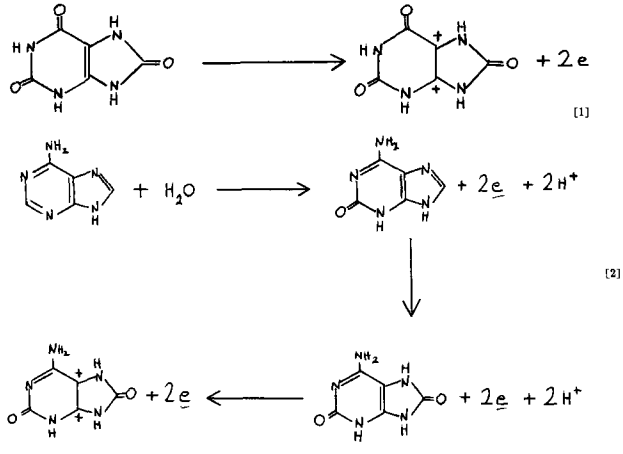
Brief Communication

Dicarbonium Ions as Products of Electrochemical Oxidation of Biologically Important Purines at the Pyrolytic Graphite Electrode

Glenn Dryhurst

Department of Chemistry, University of Oklahoma, Norman Oklahoma

Recent studies have indicated that the primary electrochemical oxidation product of uric acid (1) (2,6,8-trioxypurine) and adenine (6-aminopurine) (2) in aqueous solution at the pyrolytic graphite electrode is a dicarbonium ion; this results from removal of two electrons from the 4,5-carbon-carbon double bond of the purine ring. Uric acid is oxidized in a single rapid 2*e* process (Eq. [1]), while adenine first undergoes two 2*e* oxidations at the 2 and 8 positions to the oxy- and then dioxyadenine, the latter compound then being further oxidized to a dicarbonium ion (Eq. [2]).



Subsequent work (3) suggests that many other biologically important purines may give a similar primary electrooxidation product. Such a dicarbonium ion could not have a long lifetime and indeed many ultimate breakdown products have been observed (1-3). The oxidation waves for all purines shift positive with increasing *p*H which suggests that the primary electrochemical product results from a concerted removal of two electrons and attack by water to give a 4,5-dihydroxy species with the liberation of two protons. Nevertheless, for the purpose of this report the primary electrochemical product will be referred to as a dicarbonium ion. Purines containing exocyclic sulfur atoms do not appear to be oxidized in the purine ring, but rather at the sulfur moiety (4).

It appeared reasonable to suppose that carbonium ions of the type shown in Eq. [1] and [2] would be very readily electrochemically reducible. Accordingly a number of purine derivatives were studied by fast sweep cyclic voltammetry in the hope of detecting a short lived electrochemically reducible oxidation product. Initially pyridine was employed as solvent but the very low solubility of all the purines precluded its extensive use. Accordingly an aqueous acetate buffer solution *p*H 4.7 was utilized in which all the important purines are reasonably soluble.

Experimental

Chemicals.—Uric acid, xanthine, hypoxanthine, adenine, guanine, guanosine, adenosine were obtained from Nutritional Biochemicals, 2,8-dioxyadenine from Aldrich and isoguanine sulfate from K and K.

The *p*H 4.7 acetate buffer had an ionic strength of 0.5. Deaeration was accomplished with water saturated Linde Argon without further purification.

Apparatus.—Cyclic voltammetry was accomplished with the apparatus described by Dryhurst *et al.* (5) with the triangular voltage sweeps supplied by an Exact Electronics Model 502 function generator. Current-voltage curves were recorded on a Tektronix Model 502A dual beam oscilloscope equipped with a Model C-27 polaroid camera. A water jacketed three compartment electrochemical cell was used maintained at 25° ± 0.1°C containing a saturated calomel reference electrode (SCE) to which all potentials are referred; a platinum gauze counterelectrode in saturated KCl was employed.

The preparation of the pyrolytic graphite electrode has been described earlier (2, 4).

Results and Discussion

Uric acid was studied in the first instance because the 2*e* electrooxidation of this compound should result directly in formation of a dicarbonium ion. At scan rates below about 300 mV sec^{-1} a saturated solution of uric acid showed a well-formed oxidation peak at about 0.47V but no corresponding cathodic behavior except for a peak at around —0.8V due to parabanic acid, one of the ultimate products (1). At faster scan rates, however, a well formed cathodic peak appears at about 0.42V and with increasing scan rate, it grows in height relative to the anodic peak (Fig. 1). The separation of the anodic and cathodic peak potentials is indicative of an almost totally reversible couple; the peaks do separate somewhat with increasing scan rate.

Oxidation of xanthine appears to involve about 4*e* (3) which may indicate a two step oxidation to uric acid and then a dicarbonium ion. That this is essentially true seems to be proven by the fact that, using fast scan rates, as soon as the oxidation peak of xanthine has been scanned (E_p = 0.81V), on the reverse sweep a reduction peak is observed (E_p = 0.42V), and on the subsequent anodic sweep a new oxidation peak (E_p = 0.45V) appears before the original xanthine peak (Fig. 2). These new peaks form an almost reversible couple and, within experimental accuracy are identical to those observed for uric acid (Table I).

Similar studies on hypoxanthine, 2,8-dioxyadenine, isoguanine, adenine, and guanine (Fig. 3) reveal a similar behavior, *i.e.*, after scanning the original oxidation peak a reduction peak is observed on the reverse scan which forms a reversible couple with a new

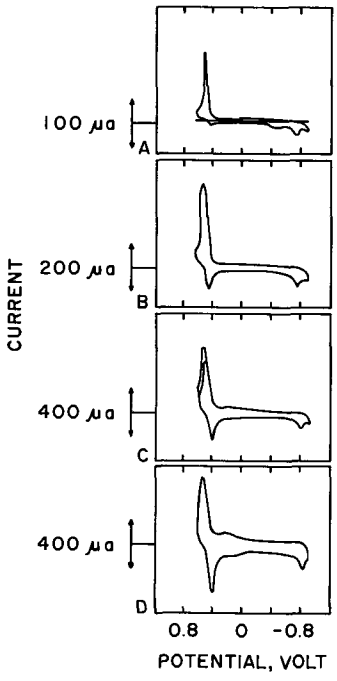


Fig. 1. Cyclic voltammograms of saturated uric acid in acetate buffer pH 4.7 at the PGE. Scan rates: A, 0.32V·sec^{-1}; B, 1.6V·sec^{-1}; C, 3.2V·sec^{-1}; D, 6.4V·sec^{-1}.

oxidation peak on the second and subsequent anodic sweeps. The very close agreement between the anodic and cathodic peak potentials for all the compounds studied (Table 1) no doubt reflects the very similar structure and nature of the intermediate species. It is noticeable (Fig. 3) that as the extent of oxygenation of the compounds decreases so the magnitude of the reversible dicarbonium ion peaks decreases. This is presumably due to the fact that at fast scan rates only a minor portion of the electroactive material at the electrode surface is completely oxidized, *i.e.*, adenine requires 6e for the complete primary oxidation reaction (2).

Complete interpretation of all the additional peaks observed for some compounds is not possible at this time but will be reported later, however, the reduction peak generally observed at about —0.8V is no doubt due to parabanic acid or its derivatives (1, 2).

Two nucleosides, adenosine and guanosine, were studied; significantly the reversible intermediate redox couple was not observed although a new oxidation peak was noted at 0.50V on all scans following the first. Final interpretation of this phenomenon will be reported soon.

Table I. Potentials for oxidation and reduction peaks observed on cyclic voltammetry of purines at the PGE

Compound	Scan rate, V · sec^{-1}	Peak potentials of intermediate species Anodic, volt	Cathodic, volt
Uric acid	3.84	0.47[a]	0.42
Xanthine	3.84	0.45	0.42
Hypoxanthine	3.84	0.44	0.40
2,8-Dioxyadenine[b]	3.88	0.45[a]	0.43
2-Oxyadenine	4.6	0.51	0.45
Adenine	3.84	0.44	0.41
Guanine	3.84	0.47	0.42
Adenosine	6.2	0.50	None
Guanosine	5.8	0.51	None

[a] These compounds are fully oxygenated and further electrooxidation probably involves direct attack at the 4,5-double bond.
[b] The numbering system is that employed in chemical abstracts and ref. (1) and (2).

Scanning Electron Microscopy and the Growth and Mechanical Properties of Cu_2O Scales

I. A. Menzies and P. Aldred

Corrosion Laboratories, Department of Chemical Engineering, University of Manchester Institute of Science and Technology, Manchester, England

ABSTRACT

The morphology of growth of Cu_2O on Cu has been studied using scanning electron microscopy. The mechanical properties of columnar Cu_2O specimens prepared by total oxidation of metallic copper have been studied as a function of bend rate and temperature. The modulus of elasticity of cuprous oxide was constant ($\sim 4 \times 10^6$ psi) from room temperature to 500°C and thereafter decreased linearly with increasing temperature to $\sim 2 \times 10^6$ psi at 800°C. The oxide exhibited a pseudo brittle-ductile transformation at 360°C and 400°-500°C when slow and fast bending rates, respectively, were used. There was also a maximum strength peak at a critical temperature related to the onset of plastic deformation. Load-deflection functions indicated large amounts of plastic deformation and in the light of fracture surface observations this can be interpreted in terms of a slow cleavage mechanism.

Although a knowledge of the mechanical properties of oxide scales is important with respect to understanding completely the mechanisms of environmental degradation and breakdown of metals and alloys, few measurements of the mechanical properties of scales formed by thermal oxidation of the metal have been made. Tylecote (1) first attempted to measure the properties of copper oxide films on copper by a hot torsion method and more recently Harrison (2) has measured the fracture strain of Fe_3O_4 films formed on steel at 316°C in 2.5M NaOH at ambient temperature by an electrochemical method. Douglass (3) also presented evidence for the plasticity of ZrO_2 films on Zr at 500°C. None of the experimental techniques were completely satisfactory and most of the available information concerning properties has been obtained for oxide specimens produced by complete oxidation of the metal. The strength (4, 5) and creep (6) of iron oxides, the strength, elasticity, and creep of NiO (4, 7, 8) and the strength of Cu_2O (1) have all been measured. In the earlier investigations little attention was given to the effects of scale structure on properties and more recent studies of NiO (8, 9) indicated that the temperature of oxide growth and hydrogen annealing of nickel prior to oxidation had a significant effect on oxide structure and hence on properties. Strafford and Gartside (10) succeeded in establishing that the mechanical behavior of CoO is markedly affected by oxide stoichiometry and in particular that plastic deformation decreased as stoichiometry was approached and the number of cation vacancies decreased.

The present study of Cu_2O has been carried out to provide detailed structural and mechanical information for totally oxidized material to provide a suitable background for future studies of the properties of films attached to the metal. Oxide growth and fracture morphology have been investigated using scanning electron microscopy and the modulus of elasticity and the yield and fracture stress and strain studied as a function of loading rate and temperature. It was of particular interest to examine the onset and mechanism of plasticity in Cu_2O. It is anticipated that in the long term, this knowledge, with additional information concerning the properties of cupric oxide will permit a better understanding of certain aspects of the oxidation of copper to be achieved.

Experimental

Copper of 99.999% purity, in the form of 0.006 in. thick sheet by Metals Research Ltd., Cambridge, was used. No metallic impurities were detected by spectrographic methods. Standard specimens 0.3 cm broad and 3 cm long were oxidized in purified air at 1030°C for the required period of time to effect partial or complete oxidation of copper to Cu_2O.

The mechanical properties of the oxide specimens were measured using a three point loading bend technique (7, 9, 11). The apparatus used in the present work (11) was fully automatic and capable of measuring the properties up to 1200°C and under controlled atmosphere conditions. The load applied to the specimen and its central deflection were measured by a load cell and displacement transducer, respectively. The electrical outputs from the load cell and displacement transducer were fed into an X-Y autoplotter from which a load-deflection function was obtained. Bending rates of 0.011 and 0.508 cm/min were used throughout the work. The load-deflection functions were carefully analyzed to determine the modulus of elasticity, yield stress and strain, or fracture stress and strain as appropriate.

The modulus of elasticity (E) was calculated from the relationship $E = PL^3/4bd^3h$ where P is the load, L is the coupon length between its supports, b and d are the specimen width and thickness, respectively, and h is the measured deflection. Individually measured values of d must be used in order to maintain accuracy of the value of E. The fracture stress (Su) of specimens exhibiting only elastic deformation is given by $Su = 3PuL/2bd^2$ where Pu is the fracture load and the other terms have the same significance as above. The fracture strain (ϵ) of coupons exhibiting only elastic deformation is given by Su/E. If however the oxide coupons exhibit elastic and plastic deformation the methods outlined above for the calculation of stress and strain cannot be used. It can, however, be shown (11) that under these conditions the fracture strain is given by $\epsilon = 8hy/L^2 red$ where y is $d/2$ and $L red \approx \sqrt{8hR}$ where R is the radius of curvature of the bent specimen. Furthermore it can be shown (12) that the stress (S) of a plastically bent rectangular section is given by

$$S = \frac{2}{bd^2}(2M + \phi\, dM/d\phi)$$

where M is the bending moment of the coupon and ϕ is half the angle subtended by two plane sections after bending. This relationship can be used to obtain the fracture stress when the coupons exhibit both elastic and plastic behavior (11).

Specimens for scanning electron microscopy were fractured either in the bend test apparatus or by hand while immersed in liquid nitrogen. The fractured samples of oxide or composite coupons were cemented to small Duralumin stubs by means of Durofix cement. The fracture surface was mounted normally to the stub and set at ~ 45° to the stub surface. In order to prevent surface charging of the specimen in the microscope the Durofix cement was coated with a thin layer of carbon black. A conducting path from the oxide sample to the Duralumin stub was also obtained using carbon black, great care being taken to avoid contamination of the fractured surface. The specimens thus prepared were examined in a Cambridge Instrument Company, Stereoscan Mk IIa. The theory of the instrument has been discussed by Oatley *et al.* (13) and will not be discussed here. The specimen detail resolution was always better than 500Å and as good as 150Å in some cases with a depth of focus at least 300 times greater than that of a normal light microscope.

Results

Morphology of oxide formation on copper.—An SCEM study was made of the nature of growth of Cu_2O. The structure of the Cu_2O film formed after 2 min at 1030°C is shown in Fig. 1a. It can be seen that a portion of the Cu_2O film has lifted straight off the Cu substrate during the fracture process. The Cu_2O film is compact and the metal-oxide interface is relatively smooth. After oxidation for 10 min at 1030°C the oxide was again compact although in one special area numerous voids were present (Fig. 1b). The pronounced markings in the Cu_2O film are cleavage steps produced by the fracture process and the points marked x in Fig. 1b are cleavage facets. The structure of a completely oxidized coupon is shown in Fig. 1c and a number of voids can be seen at the core of the coupon.

The structure of the oxide film formed at the corners of copper coupons was unusual and consisted of an outer columnar-grained layer and an inner fine-grained layer which exhibited numerous pores. The formation of this structure is shown clearly in the scanning electron micrographs in Fig. 2. The Cu-Cu_2O interface after only 2 min oxidation at 1030°C is shown in Fig. 2a. It is immediately apparent that Cu_2O crystallites (B) have grown at the interface beneath a compact columnar layer of Cu_2O and pores are associated with the crystallites. This area was found to have developed into a fine-grained porous structure after oxidation for 10 min at 1030°C (Fig. 2b). The remaining metal core is indicated in Fig. 2b and the finger-like crystallites of Cu_2O, observed in Fig. 2a, can be seen growing from this region near the corner of the Cu-Cu_2O interface. An extremely porous and confused mass of small crystals is shown in Fig. 2c. Detailed examinations of specimens after total oxidation indicated the presence of large holes and small grains of Cu_2O in the specimen center between the outer compact columnar-grained layers of Cu_2O (*cf.* Fig. 1c). It was now of interest to measure the mechanical properties of such totally oxidized coupons and to examine the fracture surfaces in some detail.

Effect of measurement temperature, atmosphere, and bending rate on the mechanical behavior of Cu_2O coupons.—The properties of the coupons were measured at temperatures ranging from ambient to 800°C in both Ar and O_2 atmospheres. Over-all the load-deflection functions and mechanical properties were found to be the same for both Ar and O_2 atmospheres. For the slow bending rate, the Cu_2O coupons exhibited elastic behavior prior to fracture at 325°C whereas at 360°C some plastic deformation was also observed (Fig. 3). The amount of plastic deformation observed at 360°C was such that some coupons were unbroken at the maximum deformation limit of the apparatus and hence the properties were not investigated at higher temperatures. For the fast bending rate elastic behavior to fracture was observed at 325°, 360°, and 400°C and plastic deformation was only observed

at temperatures > 500°C. The load-deflection functions obtained at both bending rates exhibited marked

serrations when the Cu_2O coupons were plastically deformed to an amount > 65 x 10^{-3} cm (Fig. 3).

The mechanical properties of the Cu_2O coupons were calculated from the load-deflection functions and the results are given as a function of temperature in Tables I and II for the slow and fast bending rates, respectively. The modulus of elasticity was independent of the bending rate and was constant at ~4 × 10^6 psi when the temperature was increased from ambient

Table I. Mechanical properties of Cu_2O coupons bent at 0.011 cm/min as a function of temperature

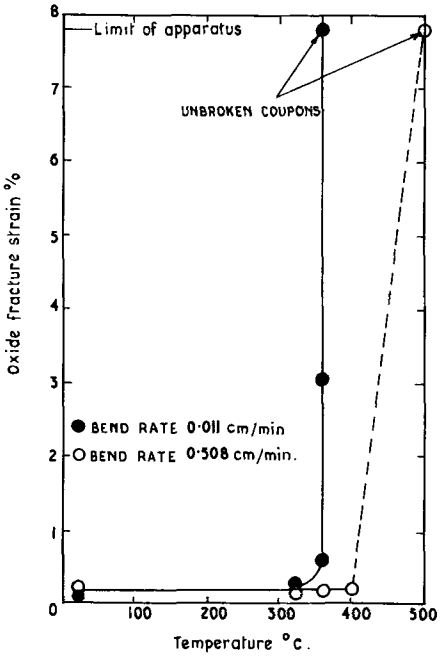

Fig. 4. Fracture strain of Cu_2O coupons as a function of the measurement temperature and bending rate.

to 500°C. Above 500°C a rapid decrease in the modulus of elasticity from $\sim 4 \times 10^6$ psi to 2×10^6 psi was observed when the temperature was increased to 800°C. The Cu_2O coupon fracture strain is shown as a function of the bending rate and temperature in Fig. 4 in order to bring out clearly the presence of a pseudo brittle-ductile transformation which was dependent on the bending rate. For the slow bending rate the transformation occurred at ~360°C, whereas for the fast bending rate the transformation was delayed to some temperature between 400° and 500°C. At temperatures above the transformation temperature Cu_2O specimens remained unbroken after 7.8% strain (apparatus limit) for both bending rates. The fracture strain of the oxide specimens at temperatures below the transformation temperature increased from 0.16 to 0.23% when the temperature was increased from ambient to just below the transformation temperature for each bending rate. In this temperature range the fracture stress remained constant at ~3-4 tsi. Finally, it is clear that the yield strain and yield stress of the Cu_2O coupons bent at the fast rate decreased from 0.065 to 0.014% and from 1.2 to 0.1 tsi, respectively, when the temperature was increased from 500° to 800°C.

Microscopic examination of mechanically deformed Cu_2O *specimens.*—A Cu_2O specimen after bending at 360°C in an argon atmosphere is shown in Fig. 5. Examination of the surface topography of such specimens indicated by the presence of numerous slip lines and few deformation bands that plastic deformation had occurred during bending. Other specimens bent to fracture at the slow rate were examined with the SCEM. A typical area of the fracture surface is shown in Fig. 6a and in more detail in Fig. 6b. A comparison of these figures shows that the nature of the crack front, commencing at point x (Fig. 6a) was complex. A separate area of the fracture surface is shown in Fig. 6c, and this provides evidence that fracture occurred at 360°C both by transgranular and intergranular crack propagation. The crack front propagated in the direction shown by the arrows. Originally the crack progressed in a transgranular manner then in the vicinity of the arrows it changed partially to an intergranular front (indicated by the solid arrows) while the remainder continued in a transgranular manner across another grain (dotted arrows).

Discussion

The SCEM study of the growth of Cu_2O on copper confirms the columnar nature of the grains and the smooth nature of the oxide-metal interface in general (Fig. 1a). The formation of isolated crystallites and oxide bridges at the corners of specimens (Fig. 2a, b) was of especial interest. This has most probably arisen due to the severe mechanical constraint at the corners which has prevented plastic flow of the oxide.

It is also clear from the present work that there was no significant difference in the properties of Cu_2O as a function of atmosphere (Tables I and II). Thus under these conditions the same results were obtained whether the measurements were made in argon or oxygen at atmospheric pressure. There was thus no indication of changes in properties of the specimens with possible changes in vacancy distribution across the scales.

There are few absolute values of elastic modulus for Cu_2O in the literature. Dankov and Churaev (14), however, suggested that a value $\sim 3 \times 10^6$ psi was typical for Cu_2O at ambient temperature. They obtained this value indirectly from internal stress measurements and the agreement with the measured value of 4×10^6 psi in the present work is satisfactory. The rapid decrease in the modulus of elasticity at a critical temperature is a common occurrence in metals and oxides, *e.g.*, in polycrystalline MgO at ~ 1000°C (15, 16), and it has been suggested (17) that this rapid decrease may be caused by grain boundary sliding. Since this can be an important deformation mechanism at temperatures > 0.5 Tm (Tm for Cu_2O ~ 460°C) the decrease in modulus of elasticity at 500°C would be in reasonable agreement with a grain boundary sliding mechanism. This will be discussed more fully later with respect to fracture.

The yield strain and stress of Cu_2O specimens decreased with increasing temperature from 500° to 800° (Table II). This is in agreement with the fact that an increase in temperature increases dislocation mobility thus facilitating plastic flow at lower stresses. The values obtained are in excellent agreement with those obtained (18) from compression experiments at similar temperatures at a crosshead speed of 0.13 cm/min, *i.e.*, between the two values used in the present work. However, Vagnard and Washburn found that yielding occurred at 200°C and not at 400°-500°C as observed for the fast bending rate in the present work. Compressional experiments are better suited for observing plastic deformation in oxide materials because the tensile stresses which develop in bending accentuate brittleness and therefore higher temperatures will be required to initiate yielding in bending.

The fracture strains of Cu_2O at temperatures below the pseudo brittle-ductile transformation temperature are in agreement with the fracture strains observed in brittle materials (19). At temperatures greater than the transition temperature the observed strains of $\geq$7.8% before fracture can be compared with previous work (1) in which Cu_2O elongations of ~12% and ~25% were observed at 500°-600°C and 700°-900°C, respectively. The observation that plastic deformation is observed at lower temperatures (~360°C) with a slow bend rate is in general agreement with observations in metals where the flow stress is increased by an increased strain rate (20). Over-all the yield stress corresponding to the onset of plastic deformation was lower at higher temperatures (*cf.* Table II), in further agreement with the mechanical behavior of metals. Since the flow stress is the stress required to initiate plastic deformation it will depend on such material factors as purity, grain size, and crystal structure. In the case of Cu_2O here this is of high purity and of large columnar grain structure. The relatively easy deformation of Cu_2O is reflected in the relatively low yield stress at all temperatures and the relatively high fracture strains. Cuprous oxide has an unusual structure (18) in that oxygen atoms are ordered on a b.c.c. lattice and the copper atoms occupy the sites of an f.c.c. lattice. The structure consists of two interpenetrating and identical networks which are not cross-connected by any primary Cu-O bonds. Slip lines have been observed on the tensile surfaces of Cu_2O but examination of specimens after fracture at 360°C (Fig. 6a) did not show any dimple formations which are characteristic of ductile fractures (21). In contrast the fracture surfaces exhibited cleavage with some isolated areas showing intergranular fracture. These observations are in contrast to the shape of the load-deflection functions (Fig. 3) which suggest extensive plastic deformation. Observations on the Cu_2O specimens strongly suggest that slow cleavage is responsible for the shape of the load-deflection functions of the type shown in Fig. 3. Surface cracks were also found in the Cu_2O specimens. This was also observed in Cu_2O by Vagnard and Washburn (18) during compressional experiments at <400°C. They found that cracks nucleated at local stress concentrations where slip bands crossed and also where they met grain boundaries. A similar type of crack nucleation has been observed in MgO (22, 23) and analyzed by Stroh (24, 25). It seems likely that cracks observed in the present work nucleated in the manner described by Vagnard and Washburn, since large local deformations were observed at slip band intersections (Fig. 7a) and also where slip lines piled up at a grain boundary (Fig. 7b). This inhomogeneity of slip observed in this system could offer a possible explanation for the complicated shape of the load-deflection function in Fig. 3. The peaks in the plastic region of the curve were observed continuously up to deformations of ~800 x 10^{-3} cm and it seems possible that these peaks are associated with the initiation of slip in grains which, up to that point, were undeformed. The increase in work hardening observed after the initial yield point will be due to grain boundary and crystallographic blockages which oppose slip. At some critical strain these blockages will be overcome and slip will be initiated in neighboring grains. When this occurs there will be an initial decrease in the work hardening rate followed by an increase as further slip becomes blocked. This process will repeat itself giving rise to the observed peaks in the load-deflection functions.

Once surface cracks have formed their rate of propagation will depend on the bending rate, temperature, and degree of plastic relaxation at the crack tip. This plastic relaxation absorbs energy and prevents rapid crack propagation (26). In fact it has been observed that cracks have propagated through Cu_2O grains which do not exhibit slip deformation and that crack propagation has been halted at the grain exhibiting extensive slip deformation. The cracks prop-

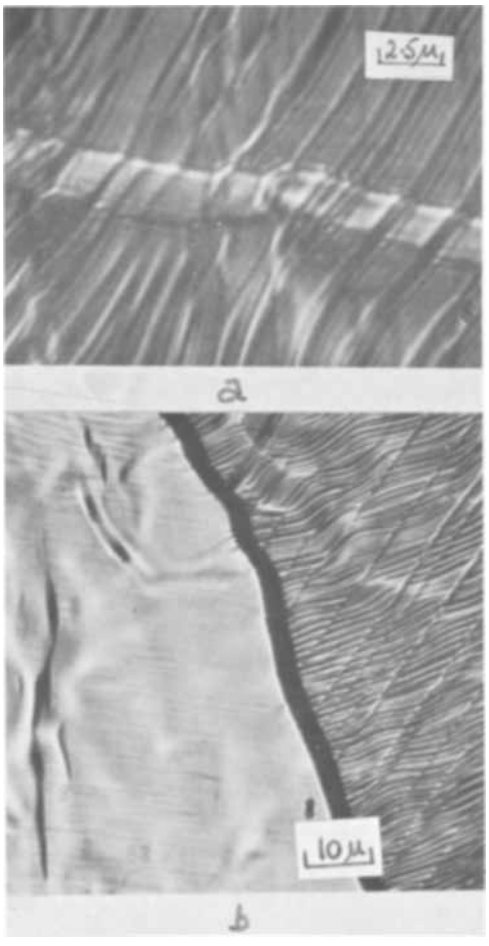

Fig. 7. Surface topography of Cu_2O specimen, formed in air at 1030°C, after bending at 360°C in argon. (a) Intersection of slip bands. (b) Intersection of slip lines with a grain boundary.

agate by repeated breaking of crystal bonds at the crack tip. In Cu_2O the {111} planes have weak bonds and cleavage occurs along them (18). During bending therefore, slow cleavage on {111} planes would be expected if most of the surface energy, created by crack formation, was absorbed by plastic deformation. Such plastic deformation during cleavage of ionic crystals has been observed even at ambient temperatures (27) and hence at the higher temperatures in the present work plastic relaxation is even more favored. The fracture surface of a Cu_2O specimen (Fig. 6a) indicates that a crack was initiated at a grain boundary marked x on the tensile side of the neutral axis. To the left of the boundary, cleavage occurred mainly on one crystal plane within the large grain, whereas to the right of the boundary a complicated crack front was observed (Fig. 6b). It would appear that this crack front could be described by two main vectors situated at 90° to each other. At the same time as the crack front was moving directly perpendicular to the neutral axis it was also moving parallel with this axis. The resultant crack front was therefore most likely situated at ~45° to the point marked x in Fig. 6a. It can be visualized that this duplex direction of crack propagation would produce a "tearing" effect resulting in a confused structure (cf. Fig. 6b). It can be seen in Fig. 6b that numerous small cleavage steps are associated with larger cleavage steps which are situated at ~90° to each other and could therefore represent cleavage on the {111} planes. It is suggested therefore that during bending cracks are nucleated on the tensile surface. These cracks are prevented from drastic propagation by plastic relaxation at the crack tip. Bending continues and the stress at the crack tip builds up until it is sufficient to cause further propagation of the crack which in turn is halted by plastic relaxation. This process will be continuous and the crack propagates slowly along the {111} planes. This intermittent crack propagation is probably responsible for the serrations in the load-deflection function. Gilman *et al.* (28) have shown that the increases in surface energy that accompany cleavage step formation in ionic crystals may cause the cracks to move more slowly than they would normally do under the same driving force. Thus the suggested crack propagation mechanism would account for the shape of the load-deflection functions and the lack of evidence in the oxide fracture surfaces for extensive ductility.

Finally the strength peak observed at a temperature immediately below that for which plastic deformation was observed (Tables I and II) requires comment. A similar phenomenon has been reported previously for Cu_2O wires (1) and for NiO wires and sheet specimens (4, 8). Silicon and germanium also exhibit such strength peaks with increasing temperatures (29). The strength will tend to rise as the heat-induced ability to deform plastically increases with temperature. Plastic deformation relieves stress concentrations and thereby promotes the full strength properties of the material. Above the temperature of maximum strength, the strength decreases with further increase in temperature, as in the case of ductile metals.

Acknowledgments

We wish to thank Professor T. K. Ross for the provision of research facilities and one of us (P.A.) wishes to thank the Science Research Council for the award of a research studentship. We also wish to thank Mrs. P. Cross of the Department of Textile Technology for her valued advice and assistance with the SCEM study.

The Free Energy of Formation of Tantalum Silicides Using Solid Oxide Electrolytes

S. R. Levine and M. Kolodney*

The City College of The City University of New York, New York, New York

ABSTRACT

A method is described for determining the standard free energies of formation of the tantalum silicides from emf measurements on cells with solid thoria-yttria electrolytes. Measurements were conducted over the temperature range 900°-1100°C in a purified argon atmosphere. Corrections for electronic conduction were established with Ta, Ta_2O_5 electrodes. Difficulties were encountered because the hard, refractory nature of the compounds prevented fabrication of dense electrodes and because silica films interfered with the measurements. At 1300°K, the measured standard free energies of formation in kcal per gram atom of silicon are: $TaSi_2$, —8.1 (+1.8/—3.7); Ta_5Si_3, —24.0 ±3; Ta_2Si, —27.2 ±3.1; $Ta_{4.5}Si$, —37.3 ±7.2.

Silicides are of interest as protective coatings for tantalum and other refractory metal alloys exposed to oxidizing conditions. Since the formation of a silica glass is essential for protection, a desirable reaction is one that produces silica and a lower silicide, as for example

$$5TaSi_2 + 7\,O_2 = 7SiO_2 + Ta_5Si_3 \qquad [1]$$

On the other hand, since the formation of the oxide of the substrate may interfere with the integrity of the silica film, the following reaction is undesirable

$$4TaSi_2 + 13\,O_2 = 2Ta_2O_5 + 8SiO_2 \qquad [2]$$

However, the refractory metal oxide may be tolerable where SiO_2 and the metal oxide form a glass or where the metallic oxide is volatile (1, 2).

In order to predict and understand the oxidation behavior of refractory metal silicides accurate free energy of formation data are required for the silicides and their oxidation products. Data for silica and for the refractory metal oxides are available (3), but data for silicides are scanty. Free energies of formation are known only for some of the rhenium silicides (4). For most other refractory metal silicides only enthalpies of formation are available. Thermodynamic information on the tantalum-silicon system, which is the subject of this study, has been collected by three classical techniques: Brewer and Krikorian (5) determined limits for the stability of refractory silicides by direct reaction of the compounds with carbides and nitrides. Robins and Jenkins (6) measured the heats of formation of some transition metal silicides from the heat evolved during formation of the compounds from their elements. In the third technique, employed by Searcy and co-workers (7-9), the dissociation pressure of silicon over the silicide of interest was measured by the Knudsen effusion method. The vapor pressure data were analyzed by a Second or Third Law approach to obtain enthalpies of formation for the silicides. Data for the tantalum silicides, obtained by these three techniques are presented in Table I. The values listed in column IV are based on an average of the Second and Third Law techniques using a value of —112 kcal for the heat of sublimation of silicon at 298°K. The values in column V are based on the same vapor pressure data as column IV but an improved value of the heat of sublimation of silicon (—108.4 kcal at 298°K) was used and the calculations were made using only the Third Law method (10, 11).

In the present work a fourth method was for the first time applied to the determination of the thermodynamic properties of the tantalum silicides. This technique employs a solid oxide electrolyte between a silicide electrode and a reference electrode. Solid electrolytes for the measurement of thermodynamic properties were brought into prominence by Kiukkola and Wagner (12), Schmalzried (13), and others. Oxide electrolytes are binary oxides which conduct almost entirely by transport of oxygen ions over a given temperature-oxygen partial pressure domain. A simple cell employing an oxide electrolyte and an iron-iron oxide (Fe_xO) reference electrode may be formulated as

$$Pt/Fe,Fe_xO//\text{oxide electrolyte}//M,MO/Pt \qquad [3]$$

where the cell reaction is

$$M + Fe_xO = MO + xFe \qquad [4]$$

If the cell is reversible, the free energy of the reaction

ΔG_R is related to the cell voltage E and to the oxygen partial pressure by

$$\Delta G_R = -nFE = RT \ln \frac{P_{O_2}\ (\text{for M,MO})}{P_{O_2}\ (\text{for Fe,Fe}_x\text{O})} \quad [5]$$

where T is the temperature (°K) and P_{O_2} refers to the oxygen partial pressures over the respective metal-metal oxide electrodes. From Eq. [4] and [5], the standard free energy of formation of MO may be obtained provided that all solid phases are pure (unit activity) and the free energy of formation of the reference oxide Fe_xO is known.

$$\Delta G^\circ_{MO} = \Delta G^\circ_{Fe_xO} - nFE \quad [6]$$

For the more complex reaction of Eq. [1] a cell using an iron-iron oxide reference electrode would be formulated as follows.

$$\text{Pt/Fe,Fe}_x\text{O//oxide electrolyte//SiO}_2, \text{TaSi}_2, \text{Ta}_5\text{Si}_3\text{/Pt} \quad [7]$$

The over-all cell reaction is

$$5TaSi_2 + 14Fe_xO = 7SiO_2 + Ta_5Si_3 + 14xFe \quad [8]$$

and the free energy of formation of the highest silicide $TaSi_2$ may be obtained from

$$5\Delta G^\circ_{TaSi_2} = 7\Delta G^\circ_{SiO_2} + \Delta G^\circ_{Ta_5Si_3} - 14\Delta G^\circ_{Fe_xO} + nFE \quad [9]$$

Obviously, success of the measurement depends on an accurate knowledge of the free energies of formation of not only SiO_2 and Fe_xO, but also of the lower silicide, Ta_5Si_3. Since the latter is unknown, it becomes necessary to establish free energies for all four of the silicides in the system. Furthermore, oxidation of a silicide to silica and the lower silicide is not the sole possibility. Instead, oxidation may yield Ta_2O_5 and a higher silicide or it may produce both SiO_2 and Ta_2O_5 as in Eq. [2]. All of the possible half-cell reactions for the four silicides of the Ta-Si system ($TaSi_2$, Ta_5Si_3, Ta_2Si, and $Ta_{4.5}Si$) are shown in Table II where they are arranged in terms of their reaction products. In addition, this table lists expected emf values *vs.* an iron-iron oxide (Fe,Fe_xO) reference electrode calculated using the enthalpy data of Searcy and Finnie (10) in lieu of free energies of the silicides. Other thermodynamic data are from Wicks and Block (3).

Examination of the estimated cell voltages of Table II indicates that the silicide pair $TaSi_2$-Ta_5Si_3 should be oxidized only to SiO_2 (compare reactions I and IV). Similarly, from the expected values for reactions II and V for the Ta_5Si_3-Ta_2Si pair, silica appears to be the preferred oxidation product. For the Ta_2Si-$Ta_{4.5}Si$ pair, tantala formation clearly gives the desired free energy minimum as indicated by the expected values for reactions III and VI of Table II.

In order to confirm these expectations, an experimental stability study was conducted. This study was performed at about 1600°C in vacuum using x-ray diffraction to follow changes in the relative amounts of phases. It confirmed the stability of silica in the presence of $TaSi_2$ and Ta_5Si_3 and the stability of tantala in the presence of Ta_2Si and $Ta_{4.5}Si$. However, for the Ta_5Si_3-Ta_2Si pair, the thermal stability study indicated that tantala rather than silica is the stable oxide.

Since each of the reactions I, V, and VI involves a pair of silicides, emf measurements for these cannot provide individual free energies of formation. However, data for a reaction from group C of Table II would yield the free energy of a single silicide and would thereby permit calculation of all. It may be shown from phase rule considerations that only one reaction in group C is permissible. Since the preferred reaction I yields Ta_5Si_3 and SiO_2, while the preferred reaction V yields Ta_5Si_3 and Ta_2O_5, it appears that reaction VIII is a possible one in group C. In any case, emf data for four cell reactions are needed to evaluate the individual free energies of formation of all four silicides in the system.

Experimental

The tantalum silicides were prepared by direct reaction of the elements. The tantalum used in the synthesis was —120 mesh powder obtained from Fansteel Metallurgical Corporation. The minimum purity was 99.9%. The silicon was —325 mesh powder of 99.99% purity obtained from United Mineral and Chemical Corporation. The tantalum and silicon were weighed out in the desired proportions and mixed in plastic vials in a high speed mixer for a minimum of 20 min. They were pressed into ½ in. diameter pellets weighing approximately 3g under a pressure of 20 tsi and were reacted in a covered alumina crucible. The crucible, containing a tantalum susceptor, was placed in an induction heated vertical tube furnace connected to a vacuum system. The pellets ignited at about 1125°C with visible evolution of heat. The reaction lasted less than 1 min and the rapid evolution of the heat of reaction brought the temperature up to about 1400°C. During the reaction period the pressure rose above 10^{-2} Torr because of silicon sublimation, but less than 0.01% of the silicon was lost. The reacted pellets were crushed and mixed with tantalum oxide and/or silica and with less than 1 w/o (weight per cent) nickel sintering aid. The tantalum oxide was a purified grade obtained from Fisher Scientific Company. Silica was also obtained from Fisher. The mixed powders were pressed into 2.5g pellets in a ½ in. diameter die under a pressure of 20 tsi. Because the silicides are extremely hard and brittle, a binder was necessary to provide strength for handling the green pellets. A 1% solution of polymethyl-methacrylate in methyl ethyl ketone was used to yield a dry pellet containing approximately 0.2% binder by weight. The pellets were presintered at about 550°C in vacuum to remove the binder and were then sintered on alumina trays in vacuum at about 1625°C for 10 min. The

* SiO_2(a) silica is amorphous as grown on silicide electrodes.

system pressure was maintained below 10^{-5} Torr. The temperature was measured with an optical pyrometer. With the exception of ($TaSi_2$-Ta_5Si_3-SiO_2) electrodes containing little silica, the electrodes sintered poorly. Those electrodes that sintered well were ground and polished to a bright metallic finish. However, the lower silicide electrodes crumbled when ground, so in order to present a dense surface to the electrolyte, these electrodes had to be used in the as-sintered condition. However, because of silicon losses their surfaces within a particular batch showed considerable variation in composition. Therefore, electrodes suitable for use in the cells were selected by x-ray diffraction analysis of the surfaces. This permitted a determination of the relative amounts of the lower silicides present.

Reference electrodes for the emf measurements were prepared from the appropriate metal and metal oxide powders by cold pressing followed by sintering in vacuum. Iron-ferrous oxide electrodes were prepared from 97.1% pure iron powder obtained from the J. T. Baker Chemical Company. The iron was oxidized in air at about 500°C until about one-third of the oxygen required to oxidize all of the iron to FeO had been gained. The powder was then pressed into 2g pellets in a ½ in. diameter die at 15 tsi and sintered in vacuo at 1250°C for 15 min. Tantalum, ditantalum pentoxide electrodes were fabricated from 99.9% pure tantalum powder and purified grade Ta_2O_5 in the ratio 4:1 by weight. The ½ in. diameter pellets weighing 2.5g were sintered in vacuum at 1650°-1700°C for 15 min. All reference electrodes were ground flat on emery papers and polished on a napless nylon cloth with 5μ levigated alumina.

Thoria-yttria electrolytes were fabricated from 99.9% pure thoria powder and 99.9% pure yttria powder obtained from A. D. Mackay, Inc. The powders were weighed out in the desired proportions and mixed for either 20 min in a high speed mixer or for 60 hr in a conventional ball mill. The mixed powder was pressed into ½ in. diameter pellets weighing from 3-6g and were sintered in vacuum for 3-36 hr at temperatures from 1900° to 2200°C. The sintered pellets were cut on a diamond wheel to remove the surface layer and any fractured areas. Opposite faces were maintained parallel to within 0.002 in. The electrolytes were also polished on a napless nylon cloth with 5μ levigated alumina abrasive. The density, as measured by water displacement, ranged from 87 to 100% of theoretical depending on sintering time, temperature, and the manner in which the thoria and yttria were mixed. The electrolytes were dark green in the as-sintered condition probably because of the trapping of electrons in defects. Heating in air at temperatures as low as 300°C caused the electrolytes to turn white in 30 min or less. They also turned white during their use in the electrochemical cells where the oxygen partial pressure was low.

The emf apparatus employed in this work was similar to the apparatus used by Kiukkola and Wagner (12). The cell, consisting of three pellets, was assembled between fused quartz rods. The platinum lead wires were brought through the end flanges of the apparatus with Teflon lead-throughs. A chromel-alumel thermocouple was used to measure the cell temperature. The cell emf was measured with a Keithley Model 610B electrometer with 10^{14} ohm input impedance on the volt scale. Part or all of the cell voltage was biased by a potentiometer in series with the electrometer. The electrometer output was recorded on a potentiometric strip chart recorder. The cell was enclosed in a Vycor tube which was closed off by brass flanges with O-ring seals. The cell was heated by a silicon carbide tube furnace and the temperature was controlled to ± 5°C. The cell was operated under argon that was purified by passing in succession over anhydrous magnesium perchlorate, zirconium-12.5 a/o (atom per cent) titanium chips at 425°C, anhydrous magnesium perchlorate, Zr-12.5 a/o Ti chips at 375°C and tantalum at 600°C. EMF measurements were made over the range of 700°-1100°C, but most satisfactory measurements were made in the 900°-1100°C region.

Results and Discussion

Test of apparatus and electrolyte.—The apparatus was tested by performing emf measurements on the cell

$$Pt/Ni,NiO//0.925ThO_2\text{-}0.075Y_2O_3//Fe,Fe_xO/Pt \quad [XI]$$

over the temperature range of 700°-1000°C. The data obtained were in good agreement with the results of other investigators (12, 14, 15).

Tests of low pressure electrodes were carried out with

$$Pt/Fe,Fe_xO//ThO_2\text{-}Y_2O_3//Ta,Ta_2O_5/Pt \quad [XII]$$

Results obtained with these cells employing dense Ta, Ta_2O_5 electrodes are summarized in Table III. Electrolyte compositions of 1 m/o (mole per cent) Y_2O_3 and 7.5 m/o Y_2O_3 in thoria were used. Electrolyte thickness was varied from 0.19 to 0.46 cm, while the argon flow rate was varied over the range of 1-3 CFH. The electrolyte composition, electrolyte thickness, and argon flow rate were found to have no effect on the results for cells employing dense Ta,Ta_2O_5 electrodes. Therefore, it was concluded that the deviations of the observed emf's from the expected values computed from the data for Fe_xO (14) and Ta_2O_5 (3) were caused by electronic conduction in the thoria-yttria electrolytes. That is, conduction in the electrolyte was not 100% ionic as assumed for Eq. [5]. However, the temperature coefficients of these cells were in excellent agreement with the expected coefficients. Such behavior should be expected if the electrodes are not appreciably polarized by the electronic exchange current. Therefore, emf data obtained under these conditions are useful if a correction for electronic conduction is made.

This correction may be made by applying an equation derived by Schmalzried (13). Since the oxygen partial pressures over silicide electrodes are not very different from those over Ta,Ta_2O_5 electrodes, the corrections will be closely applicable. The average transport number for ionic conduction, $\bar{t}_i$ is defined simply in terms of the measured and true cell voltages $E_{meas.}$ and E, by

$$\bar{t}_i = \frac{E_{meas.}}{E} \quad [10]$$

Now for the present case where the Fe,Fe_xO reference electrode possesses a high oxygen pressure relative to its Ta,Ta_2O_5 mate, $E_{meas.}$ may be expressed by

$$E_{meas.} = -\frac{mRT}{4\mathbf{F}}\left[\ln\frac{P_e^{1/m} + P_{Ta}^{1/m}}{P_{Fe}^{1/m}}\right] \quad [11]$$

Table III. Corrected emf measurements (mV)

Temperature, °C	700	750	800	850	900	950	1000	1050	1100

where P_e is an oxygen partial pressure characteristic of the electrolyte, P_{Ta} and P_{Fe} are the oxygen partial pressures over the Ta, Ta_2O_5 and the Fe,Fe_xO electrodes, and m has a theoretical value of 4.

The value of P_e may be calculated from Eq. [11] using experimental values of $E_{meas.}$ and calculated pressures for P_{Ta} and P_{Fe}. At 1300°K, the result is

$$P_e = 2.59 \times 10^{-29} \text{ atm}$$

It then becomes possible to derive $E_{meas.}$ as a function of P_{Ta} referred to a fixed P_{Fe}. The true voltage, E, is calculated for the same pressures using Eq. [5] and appropriate data (3, 14). As a matter of interest, a local ion transport number, t_i, may be calculated for the electrolyte at its interface with the low pressure electrode (13)

$$t_i = \exp\left[4\mathbf{F}(E_{meas.} - E)/mRT\right] \qquad [12]$$

The results of the calculations are presented in Table IV. This table may also be used to evaluate corrections for the silicide electrodes where electronic conduction is significant.

Examination of Table IV discloses that the thoria-yttria electrolytes were found essentially free of electronic conduction ($\bar{t}_i \geqq 0.99$) down to oxygen partial pressures of about 10^{-24} atm at 1300°K. This confirms the work of Steele and Alcock (15) and Vecher and Vecher (16), but is in substantial disagreement with the results described by Rapp (17).

Silicide electrodes.—A very large number of electrodes was prepared from pairs of silicides in each of the three phase fields. These were mixed with silica and/or tantala to correspond to the reactions of Table II and were tested in cells. Two major kinds of difficulties were encountered. First, many of the mixtures of refractory silicides and oxides did not sinter well even when activated with small amounts of nickel. Consequently, the interior structure was often porous so that the very low partial pressures of oxygen could not be maintained and cell voltages were too low. This was especially true at the lower test temperatures where the electrode-electrolyte reaction was sluggish. As previously explained, this problem was partially overcome by utilizing a dense pressed and sintered surface whose composition was determined by x-ray diffraction. A second difficulty occurred when oxidation of the silicide yielded a silica glass whose high resistivity resulted in ultimate decrease of voltage. Because of these problems, emf readings were considered reliable only when they were stable, insensitive to the flow rate of the surrounding argon, and displayed the expected small negative temperature coefficient. In all cases, corrections for electronic conduction were made using Table IV. The corrected measurements are summarized in Table III where the cell numbers correspond to the reactions given in Table II.

$TaSi_2$-Ta_5Si_3 *phase field.*—Fifteen electrodes were prepared and tested, but only two points, representing six observations were satisfactory. These are listed under cell I.

Ta_5Si_3-Ta_2Si *phase field.*—Nineteen electrodes were prepared and tested. The ratio of the two silicides was varied while the content of Ta_2O_5 was in the range of 0-25% and that of SiO_2 varied between 0-7% by weight. X-ray and microscopic examinations of the electrodes before and after use led to the conclusion that the anticipated oxidation of Ta_2Si_3 to Ta_2O_5 and SiO_2 (VIII) did not occur. Instead, electrodes that were primarily Ta_5Si_3 were oxidized to SiO_2 and the lower silicide (II). On the other hand, Ta_2Si was oxidized to Ta_2O_5 and the higher silicide, Ta_5Si_3 (V). The corrected potentials measured for these electrodes are given in Table III under the appropriate cell numbers.

Ta_2Si-$Ta_{4.5}Si$ *phase field.*—The expected reaction is VI of Table II. Four electrodes were examined and two performed satisfactorily. The average values are listed in Table III. In this case, correction was made not only for electronic conduction, but also to normalize all measurements to the slightly higher values measured at maximum argon flow rates. Hence, although the variability of the measurements was ±4 mV, the results were considered reliable to only ±10 mV.

Evaluation of free energies of formation.—The measured emf values were combined with free energy of formation data for Fe_xO (14) and for Ta_2O_5 and SiO_2 (3) to produce four linear equations which could be solved for the free energies of formation of the individual silicides. An upper bound for cell I was set by the limitation that its potential may not exceed that of Si,SiO_2 *vs.* the same reference electrode. The results of the calculations are presented in Table V.

Although the free energies are given at three temperatures because measurements were made in the vicinity of these temperatures, it is obvious that the estimated errors are too large to permit calculation of entropy changes. It is worth noting that nearly one-half of the uncertainty in the data for the silicides is attributable to uncertainties in the free energy data for the oxides of iron, tantalum, and silicon. This sets a limit on the accuracy that may be achieved.

The free energies of formation may be compared with little error to the enthalpies of formation given in Table I. Since by the Neumann-Kopp rule the formation of a compound from its elements involves no change in heat capacity, then

$$\Delta G^\circ_T \cong \Delta H^\circ_{298} - T\Delta S^\circ_{298} \qquad [13]$$

Furthermore, for the formation of ordered solids from the solid elements, ΔS°_{298} is very close to zero (4). Hence

$$\Delta G^\circ_T \cong \Delta H^\circ_{298} \qquad [14]$$

Comparison of the values in Tables I and V shows that for the three lower silicides the results obtained by the emf method are in substantial agreement with those obtained by effusion. Some improvement in the confidence interval for Ta_5Si_3 and Ta_2Si has been achieved in this work. Furthermore, the results obtained in this investigation are thermodynamically consistent in that the activity of silicon must increase monotonically from the lower to the higher silicides, while the activity of tantalum must decrease. Therefore, emf's of electrodes where SiO_2 is the oxidation product must increase from the lower to higher silicides, while those where Ta_2O_5 is the oxidation product must fall. This requirement is obeyed by the present results but not by results inferred from earlier data.

Table IV. Transport properties for thoria-yttria electrolytes at 1300°K with an Fe, Fe_xO reference electrode

1400		−23.1 ± 3	−26.1 ± 3.1	−35.3 ± 7.2

Summary

It has been demonstrated that solid oxide electrolytes may be successfully employed for the measurement of the free energies of formation of refractory silicides. Problems were encountered because the electrode pellets consisted of mixtures of high melting hard compounds that could not be readily fabricated with low porosities. Consequently, it was difficult to maintain low oxygen partial pressures at the electrode-electrolyte interface. This drawback was overcome by using as-sintered surfaces, but may be overcome by hot-pressing of electrodes or by improved sealing techniques. Another difficulty caused by the formation of silica films of low conductivity may be solved by performing measurements at much higher temperatures.

A fundamental limitation of the method is the uncertainty in the free energies of formation of the oxides employed as reference electrodes and the oxide products of reaction. In the present study this represented nearly one-half of the total uncertainty of the measurements.

Acknowledgments

The authors thank the Lewis Research Center of the National Aeronautics and Space Administration for its support under grant No. NGR 33-013-017 and Mr. R. Oldrieve who monitored the grant. They are especially grateful to Professor R. A. Graff for numerous discussions and to J. Bodnaruk and D. Marden for assistance with the equipment.

Vapor Growth of High Resistivity ZnTe

A. S. Jordan and L. Derick

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

High resistivity crystals of ZnTe, essentially free of the usual Te precipitates, have been vapor grown from a powdered ZnTe charge, containing a small amount (8×10^{-3} a/o) of In, by a modification of the Piper and Polich technique. Attempts to incorporate larger amounts of In in the charge resulted in negligible vapor transport rates which are qualitatively related by means of the transport theory of Lever and Jona to the p-T and the solidus diagrams of ZnTe. The observed Te precipitation is consistent with the retrograde solidus of ZnTe and with the diffusion coefficient of Te in the crystal.

ZnTe, a group II-VI wide band-gap semiconductor, has been considered a potentially useful electroluminescent and electrooptic material for some time (1, 2). There are several feasible methods for the growth of pure and doped ZnTe crystals. Fischer *et al.* (3) have successfully grown n-type ZnTe in an autoclave from Zn-rich melts, containing 20 m/o (mole per cent) excess Zn, under 30-50 atm of argon pressure. Solution growth of ZnTe crystals from Te-rich melts has been reported by Title *et al.* (4).

It is a well-established fact that ZnTe crystals doped with group III impurities are generally high resistivity p-type due to self-compensation (4). Usually the impurities, such as Al, are introduced by diffusion into the II-VI compounds (5, 6). However, Title *et al.* (4) have prepared Al-doped solution grown ZnTe by the addition of Al to the Te-rich liquid. Tubota (7) and Nahory and Fan (8) have grown In-doped ZnTe crystals in graphite reinforced quartz capsules according to a modified Bridgman technique originated by Fischer (9).

In the present study we report on the vapor growth of pure and In-doped ZnTe utilizing a vertical modification of the Piper and Polich (10) technique.

Experimental

Piper and Polich (10) have grown single crystals of undoped CdS by condensing Cd(g) and S_2(g) escaping from a dissociating source of powdered CdS. According to Piper and Polich, Aven has utilized their method to grow ZnTe crystals by the reversible reaction

$$ZnTe(s) \rightleftarrows Zn(g) + \tfrac{1}{2} Te_2(g) \qquad [1]$$

In the present study their method was modified to permit the use of evacuated sealed tubes. Figure 1 illustrates the vertical vapor transport furnace and its temperature profile. The heating element was a platinum-20% rhodium resistance wire wound on a 12 in. long high purity alumina core. The furnace temperature was controlled to better than ± 0.5°C by the use of a saturable core reactor in conjunction with a Leeds and Northrup Speedomax H controller, providing an ap-

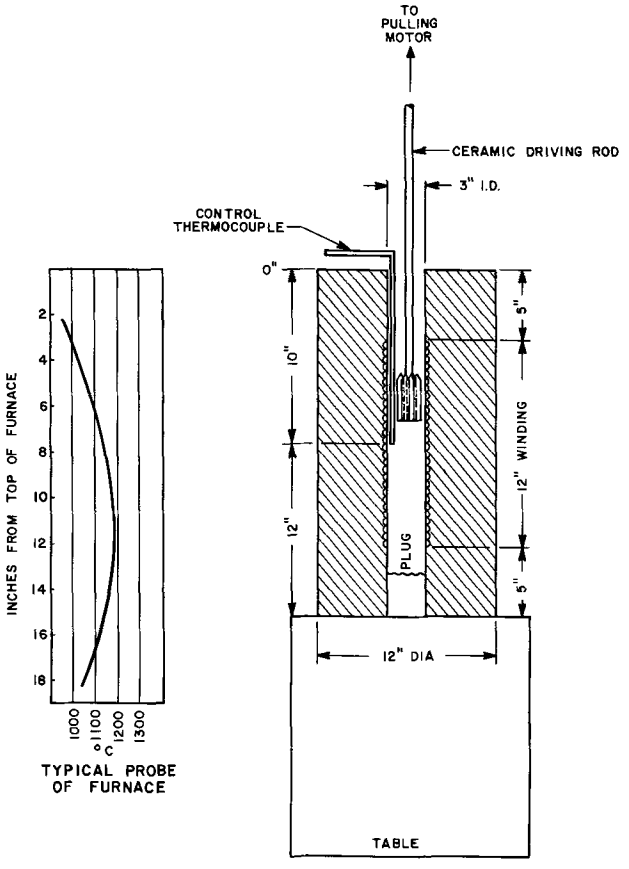

Fig. 1. ZnTe vapor transport furnace and temperature profile

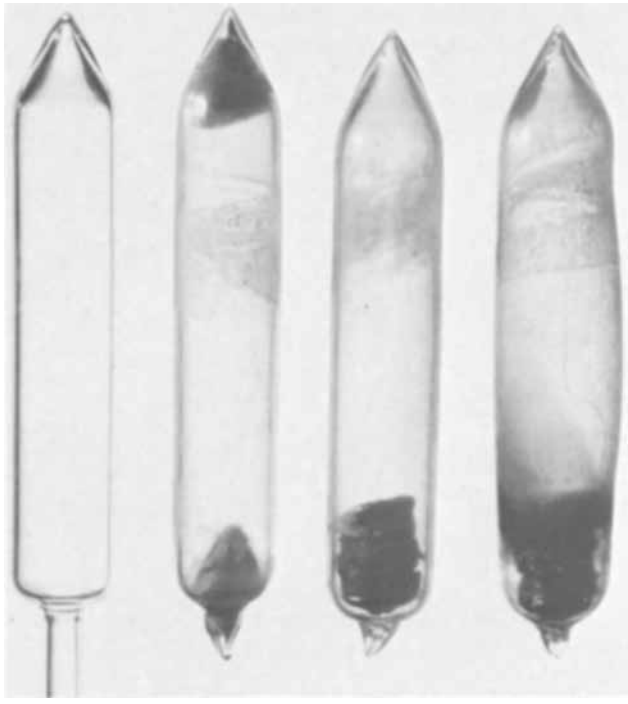

Fig. 2. Expansion of ampoules after vapor growth. A clean ampoule, 105 mm long by 18 mm OD, is shown on the left of the photograph. Three other ampoules after the completion of a simultaneous run are shown on the right. The following amounts of In were added to the charge in these ampoules (left to right): 1, 8×10^{-3} a/o; 2, 8×10^{-2} a/o; 3, 9×10^{-1} a/o. Note the expansion of ampoules 2 and 3.

proximately 2 in. long uniform temperature zone. Outside this zone the temperature gradient was found to be $\approx$ 15°C/in.

It was possible to load up to four ampoules containing powdered ZnTe into the furnace. Figure 1 indicates a cluster of four ampoules, held together by platinum straps, suspended from a Pt wire to a ceramic driving rod which was connected by a chain to a variable speed motor. A clean ampoule is shown in Fig. 2.

Usually three thermocouples were attached by wire to the cluster. One was near the tip, another approximately 1 in. away from the tip, and the third was in the vicinity of the charge. The temperatures corresponding to these locations were continuously monitored on a multipoint recorder.

In a typical experimental run between 12-20g ZnTe powder, supplied by Harshaw Chemical Corporation, was charged into the conical part of the ampoule for subsequent evacuation and sealing at approximately 10^{-7} Torr pressure. The furnace, loaded with the cluster of ampoules, was slowly heated in about 2 hr to approximately 1160°C. Initially, the tip of the ampoule was positioned approximately 11 in. from the top of the furnace (Fig. 1). This facilitated the cleaning of the tip by sublimation of some adhering ZnTe powder. After a few hours the ampoule was raised to a position where the tip and the charge were at the same temperature. This took place, as seen in Fig. 1, when the tip was 9 in. from the top of the furnace. Then, the variable speed motor drive was connected and the ampoules were pulled upwards at approximately 0.2 mm/hr. Usually, at the completion of a run the tip was at 1140°C and the source at 1160°C, corresponding to a minimum total pressure of 98 Torr and 125 Torr (11), respectively. A typical run lasted from five to eight days and yielded an ingot about 20-30 mm long and 8-13 mm in diameter. The ampoules were slowly withdrawn from the cooling furnace to avoid cracking. In many runs a pyrolytic BN liner with a conical tip was placed inside the quartz ampoule.

Results and Discussion

Perfection of crystals.—All the crystals grown by vapor transport were p-type, as indicated by a thermoelectric probe. A typical boule is illustrated in Fig. 3. From this boule it was possible to obtain cubes of single crystals with sides as large as 0.6 cm. When the growth was interrupted after a short time, say 1 hr, one could see that two or three triangular shaped nuclei had already formed near the tip of the cone. Recently, Lind (12) was able to eliminate spurious nucleation in some II-VI compounds by a periodic reversal of the temperature gradient during growth, resulting in the re-evaporation of the unstable nuclei. Often the monocrystalline regions were twinned which we could minimize by the use of BN inserts in the ampoules.

Suppression of vapor transport.—In the present study, in order to prepare high resistivity ZnTe, In, a relatively volatile impurity, was added to the ZnTe charge in the ampoule. It was anticipated that In would vaporize and codeposit with ZnTe since at 1150°C, the usual growth temperature, the vapor pressure of In is approximately 0.5 Torr.

Fig. 3. Boule of vapor grown ZnTe crystal

Initially, 0.9 a/o (atom per cent) In was added to the charge. However, after a five day run no vapor transport was observed and the ampoule diameter had increased. In a subsequent experiment a cluster of three ampoules was placed in the furnace with 0.9, 8×10^{-2}, and 8×10^{-3} a/o In added to the source material. By simultaneously growing in several ampoules, uncertainties which might be inherent in consecutive runs could be eliminated. Figure 2 illustrates the three ampoules together with an unused ampoule after the completion of this run. A sizable (6g) crystal grew in the ampoule with 8×10^{-3} a/o In addition. In the two other ampoules vapor transport was negligible except for several minute crystallites which had an approximate total weight of 10 mg. In addition, considerable expansion of the ampoules was observed when the amount of In was over 8×10^{-3} a/o.

Further experiments have shown that the expansion of the ampoules and the suppression of the vapor transport was neither due to the excessive pressure of some volatile species of In and Te nor particularly to the specific presence of In. On the one hand, heating InTe in an ampoule for a day at 1150°C did not cause any change in the geometry of the ampoule. On the other hand, an addition of Sn or Ga to the charge also led to negligible vapor transport rates. Moreover, the effect of excess Zn in the charge was similar to that of 0.9 a/o In. However, when InTe, In_2Te_3, or SnTe were added to the ZnTe source, significant vapor transport was observed. In Fig. 4 all the starting compositions containing ZnTe and Sn, Ga, SnTe, InTe, In_2Te_3, In + Te, excess Te, or excess Zn expressed in a/o are plotted using triangular coordinates. The reported solid solubility of In_2Te_3 in ZnTe (13) is also included.

It was possible to separate the region of compositions where vapor transport was observed from the region where vapor transport was negligible. It is noticeable in Fig. 4 that starting compositions in the direction of the Zn-rich side of the diagram were not favorable to vapor transport.

Interpretation.—A qualitative interpretation of the suppression of vapor transport rates is possible in terms of thermodynamic and kinetic arguments. When a pure solid compound such as ZnTe evaporates in a closed container at a constant temperature, the composition of the solid changes due to the preferential volatilization of one or the other of the components. However, by continuously removing the vapor phase from the vicinity of the subliming solid, eventually an equilibrium state is reached in which the solid and the vapor have the same composition (congruent vaporization). In this state the total pressure is at a minimum and the congruent vapor composition for solids with a narrow range of departures from stoichiometry is nearly that of the stoichiometric vapor ($p_{Zn} = 2p_{Te_2}$). It is expected that the eventual vapor composition resulting from the high purity ZnTe source is not too different from the composition of congruently subliming ZnTe. However, when impurities such as In, Sn, or Ga are added to the ZnTe charge the vapor compositions and pressures change from their values corresponding to congruent vaporization, *i.e.*, $p_{Zn} \neq 2p_{Te_2}$.

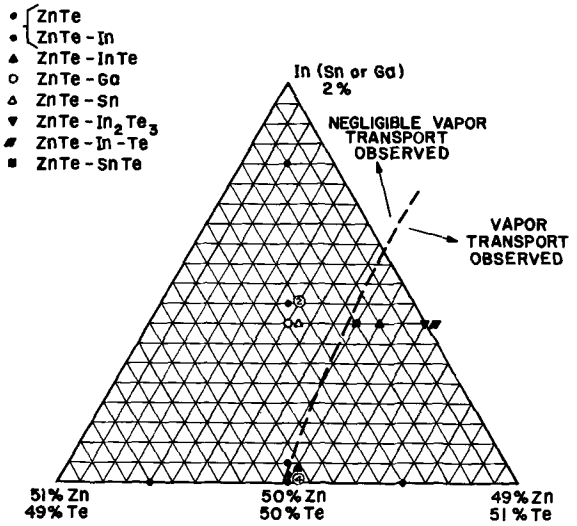

Fig. 4. Dependence of vapor transport on charge composition. The initial charge compositions, expressed in a/o, are plotted on an expanded triangular composition diagram. The ○ shown outside the diagram at 47.7 a/o Zn and 50.5 a/o Te represents the solid solubility of In_2Te_3 in ZnTe at 1150°C.

The equilibrium constant, $K = p_{Zn}\sqrt{p_{Te_2}}$, for reaction [1] is thought to remain essentially constant when small amounts of impurities are present in the charge. At the same time the pressure ratio p_{Zn}/p_{Te_2} may significantly change by the addition of an impurity because at the run temperature ($\approx$ 1150°C) the charge composition moves from a point in the binary solidus phase field (11), characterized by $p_{Zn}/p_{Te_2} \approx 2$, into a ternary solidus (*i.e.*, solid solutions of ZnTe + In or ZnTe + Ga) or solid and liquid phase field. There seems to be no thermodynamic or diffusional limitation to ternary solid solution formation in the systems under consideration.[1] Since the solidus isotherms in these ternary systems are not presently available, it is necessary to make some qualitative remarks about their probable shapes.

It has been previously reported (11) that the solidus curve of pure ZnTe is retrograde and lies entirely in the Te-rich region of the phase diagram. This suggests, if one assumes that excess Zn is insoluble for example in the ZnTe + In solid solution, and if the relatively large solid solubility of In_2Te_3 in ZnTe (13) is taken into account,[2] that the ternary Zn-Te-In solidus isotherm is offset toward Te and In rich concentrations ($x_{Zn}/x_{Te} < 1$). Accepting this tentative model for the ternary solidus isotherm, one concludes that at a constant initial impurity concentration, say 0.8-0.9 a/o in Fig. 4, the range of compositions where vapor transport was observed most probably corresponds to compositions within the ternary solidus isotherm at the run temperature. This view is strongly supported by the chemical analysis of some crystals which indicates that the In concentration in the vapor grown ZnTe crystals is nearly that of the respective initial charges. It has been found by atomic absorption spectroscopy that the addition to the charge of 8×10^{-3} a/o In and 0.8 a/o In (in the form of In_2Te_3) resulted in crystals containing 6.9×10^{-3} a/o and 0.66 a/o In, respectively.

One can readily show that in the ternary solid solution which consists of ZnTe and an impurity, say In, p_{Zn} is related to the atom fraction of In in the solid, x_{In}. The work of Thomas and Sadowski (16) has established that the major defect in ZnTe is a doubly ionized Zn vacancy. Furthermore, it is known that group III impurities are donors, substituting on Zn sites. Based on this information, taking into account the charge neutrality condition for p-type ZnTe and the simultaneous equilibria for the creation of Zn vacancies and the incorporation of In donors, one obtains for the relation of p_{Zn} to x_{In} the following equation

$$k_1 x_{In} + p_{Zn} = k_2/[\dot{h}] \qquad [2]$$

where $[\dot{h}]$ is the hole concentration and k_1 and k_2 are proportional to the two equilibrium constants.

[1] The relatively large solid solubilities of In and Ga in ZnTe have been well-established (13, 14). Lacking the appropriate diffusion coefficients for ZnTe, one can estimate the diffusion coefficient of In at 1150°C from the measurements of Kato and Takanayagi (15) for CdTe. A relatively large coefficient (10^{-7} cm^2/sec) is obtained, consistent with solid solution formation within the time available for crystal growth.

[2] According to Mason and O'Kane (13), 2 m/o In_2Te_3 can be dissolved in ZnTe at 1150°C.

In general, ZnTe changes from a low resistivity p-type ($[\dot{h}]$ large) to a high resistivity p-type ($[\dot{h}]$ small) semiconductor when doped with a group III element. Therefore, p_{Zn} changes with the addition of In. As the relationship $K = p_{Zn}\sqrt{p_{Te_2}}$ is still expected to hold, the ratio $p_{Zn}/p_{Te_2} = 2$ is necessarily upset.

One would intuitively expect the rate of transport to be proportional to the lowest partial pressure in the system. Indeed it is demonstrated in the Appendix by an application of the vapor transport theory of Lever and Jona (17) that the transport rate is at a maximum when $p_{Zn}/p_{Te_2} = 2$, hence, any change in this ratio would result in a decrease in the transport rate. Moreover, as p_{Zn} or p_{Te_2} approaches zero, the rate also approaches zero. The experimental transport rates were not uniform in the solid solution region, the region in Fig. 4 where vapor transport was observed. For example, in a simultaneous run the ratio between the yields for an ampoule with 8×10^{-3} a/o In added to ZnTe and for one with pure ZnTe was 0.58, indicating a decrease in the transport rate by approximately a factor of 2.

It is thought that the addition of 1.6 a/o In, 0.9 a/o In, 8×10^{-2} a/o In, 0.8 a/o Sn, or 0.8 a/o Ga similar to the addition of 0.5 a/o excess Zn moved the over-all charge composition into the two phase liquid and solid solution region. As seen in Fig. 4, the vapor transport rate was negligible for all of the above compositions. Moreover, in all these cases an expansion of the ampoules was observed.

The effect of Zn addition can be completely explained in terms of the p-T diagrams for the Zn-Te system proposed by Jordan and Zupp (11). According to their results, $p_{Zn} = 7.9$ atm, $p_{Te_2} = 10^{-5}$ atm, and $p_{Zn}/p_{Te_2} = 7.9\times10^{5}$ in the Zn-rich binary two phase region and also on the solidus boundary at 1150°C. Consequently, in view of the high values of p_{Zn} in the vicinity of the Zn-rich side of the solidus isotherm, the expansion of the quartz ampoules is not surprising. Furthermore, as the values of p_{Zn}/p_{Te_2} are large, the vapor transport rates, as observed, become negligible. The ratio p_{Zn}/p_{Te_2} is expected to change along the ternary solidus isotherm.[3]

Moderate suppression of vapor transport rates is also expected near the Te-rich solidus boundary. In fact, an approximate calculation given in the Appendix indicates that the ratio of transport rates on the Zn-rich side to the Te-rich side is of the order of 10^{-4}. Although only few crystals have been grown near the Te-rich boundary due to the large density of Te precipitates resulting from growth in this region, in all cases diminished vapor transport rates have been observed.[4]

Te *precipitates*.—Tellurium precipitates have been previously observed in solution and vapor grown ZnTe crystals (18). Figures 5 and 6 are photomicrographs of precipitates, viewed in transmitted light, in undoped crystals grown from a Te-rich solution and from the vapor phase, respectively. The precipitates are tetrahedral in shape, separated by 30-70μ, having 2-6μ long edges. Sometimes, as illustrated in Fig. 7 and 8, a dislocation network or a grain boundary is decorated by the precipitates.

According to Reynolds (18), the relative x-ray and electron back-scatter intensities from the matrix and the precipitates indicated that the precipitates were rich in Te. However, Reynolds was unable to determine the Te content of the precipitates more quantitatively by electron microprobe or by x-ray diffraction analysis.

[3] On the Te-rich side of the binary solidus $p_{Zn}/p_{Te_2} = 4\times10^{-2}$ at 1150°C (11). The partial pressures are the following: $p_{Zn} = 2.8\times10^{-2}$ atm and $p_{Te_2} = 7.1\times10^{-1}$ atm.

[4] For instance, when 0.5 a/o excess Te was added to the charge, the resulting small crystal weighed only 0.5g, corresponding to an approximately twenty-fold rate reduction, compared to the crystal grown from a pure ZnTe charge.

A consideration of the liquidus and solidus curves (11) in the Zn-Te system clearly demonstrates that Te precipitation in the solid is possible. The solidus of ZnTe is retrograde with an excess of Te. At approximately 1200°C, the maximum solubility of Te in the crystal is

$$\frac{4.6\times10^{-5}\text{ mole excess Te}}{\text{mole ZnTe}}\left(\text{or}\ \frac{1.48\times10^{-4}\text{g Te}}{\text{cc ZnTe}}\right)$$

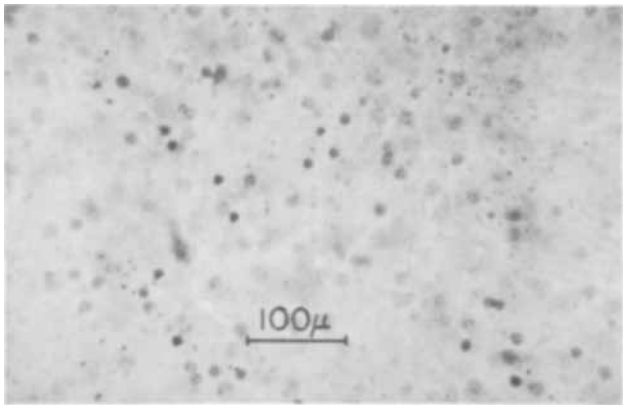

Fig. 5. Transmission photomicrograph of Te precipitates in undoped solution grown ZnTe.

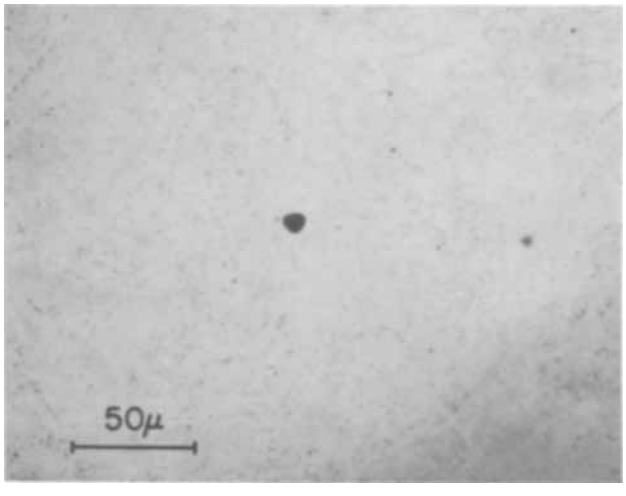

Fig. 6. Transmission photomicrograph of Te precipitates in undoped vapor grown ZnTe. Some precipitates are not in focus.

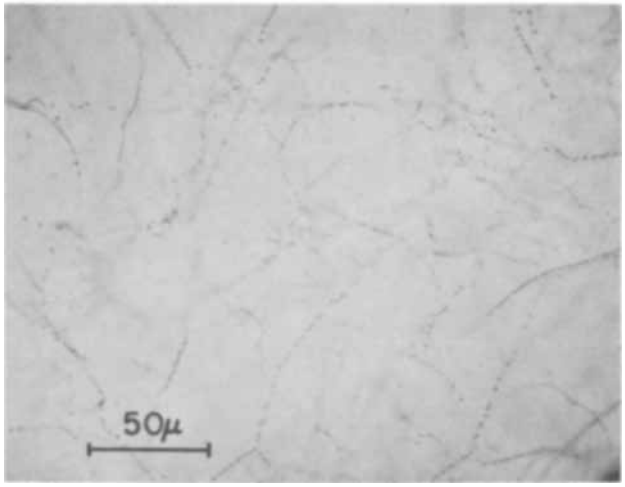

Fig. 7. Transmission photomicrograph of a dislocation network in undoped vapor grown ZnTe.

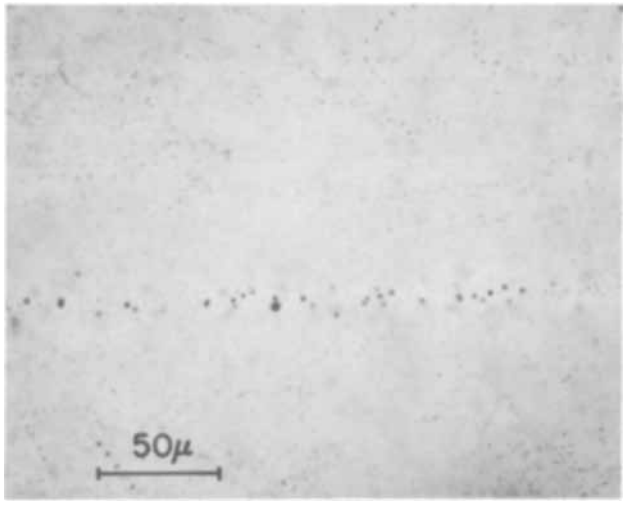

Fig. 8. Transmission photomicrograph of a decorated grain boundary in undoped vapor grown ZnTe.

If a crystal grown from either a Te-rich solution of the vapor phase is cooled to room temperature, the phase diagram requires separation into a nearly stoichiometric compound and a solid Te phase.

One can readily estimate the mean separation of the precipitates by an order of magnitude calculation[5] and obtain $\approx 67\mu$. This is in good agreement with the experimentally observed separation of 30-70μ.

Moreover, it can also be shown that there is no kinetic limitation to precipitation. The average distance, $\overline{X}$, the Te atoms move during the cooling of a crystal in t minutes can be estimated by the graphical integration of the function

$$\overline{X} = \int \sqrt{6D}\, d\sqrt{t} \qquad [3]$$

where the integrand is the three dimensional random walk formula of Shewmon (19) and D is the temperature dependent self-diffusion coefficient of Te in ZnTe obtained from the data of Reynolds (18). Integrating Eq. [3] between room temperature and 1150°C and using an estimated cooling rate of 50°C/min, one has $\overline{X} = 18\mu$.[6] Accordingly, during cooling each precipitate can be formed from the surrounding crystal volume which, if assumed to be spherical, has an 18μ radius. The resulting mean separation of precipitates is 36μ, in reasonable agreement with the experimental and thermodynamic estimates, thus demonstrating that precipitation is consistent with the known diffusional and thermodynamic behavior of Te in ZnTe.

Precipitation has also been observed in vapor grown In-doped crystals. Figures 9 and 10 are photomicrographs of ZnTe crystals grown from a charge with an addition of In_2Te_3, resulting in an over-all composition with 0.8 a/o In and 0.2 a/o excess Te. The high density of Te precipitates, shown in Fig. 9, is due to the relatively large amount of Te present in the charge. Figure 10 illustrates a grain boundary decorated with precipitates and a parallel depletion region.

Usually, Te precipitates have been removed from ZnTe by annealing after growth in a Zn atmosphere (18, 20, 21). However, Fig. 11 shows the microstructure of a crystal, vapor grown from a charge containing 8×10^{-3} a/o In, which is essentially free of precipitates, virtually featureless, with a lightly decorated dislocation network in view. The starting composition of this charge was near the region in Fig. 4 where vapor transport was suppressed. This composition is in the solid solution region, probably in the vicinity of the solidus line separating the two condensed phases Zn-rich liquid and ZnTe from ZnTe. A consideration of the solidus (11) of ZnTe indicates that precipitation of Te should not be expected in a crystal which was vapor grown from a charge composition near the Zn-rich boundary.

Electrical and optical properties.—The electrical and optical properties of vapor grown ZnTe were strongly effected by In-doping. The room temperature resistivity of the crystals was measured by the four point probe method. A Ga-In amalgam served as a contact for the crystals. The resistivity of undoped ZnTe was 2 ohm-cm. The addition of 8×10^{-3} a/o In to the charge increased the resistivity to 740,000 ohm-cm, due to self-compensation via the incorporation of 1.2×10^{18} In atoms/cc in the crystal. To the best of our knowledge, this was the first successful attempt to grow high resistivity In-doped ZnTe crystals by a static vapor transport technique. The resistivity is in good agreement with the previously reported value of Tubota (7) which was about 300,000 ohm-cm for an In-doped sample grown by Bridgman's method.

Figure 12 illustrates the dependence of the absorption coefficient, α, on energy for ZnTe. The curves were derived from spectrometric data taken at 30°K. According to the measurements of Nahory and Fan (8),

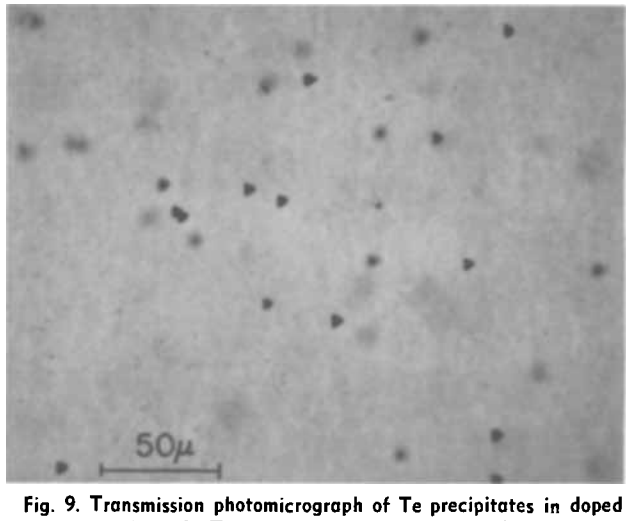

Fig. 9. Transmission photomicrograph of Te precipitates in doped vapor grown ZnTe. In_2Te_3 was added to the charge. Over-all composition of the charge: 0.8 a/o In, 50.2 a/o Te, 49 a/o Zn. In content of crystal: 1.15×10^{20} atoms/cc.

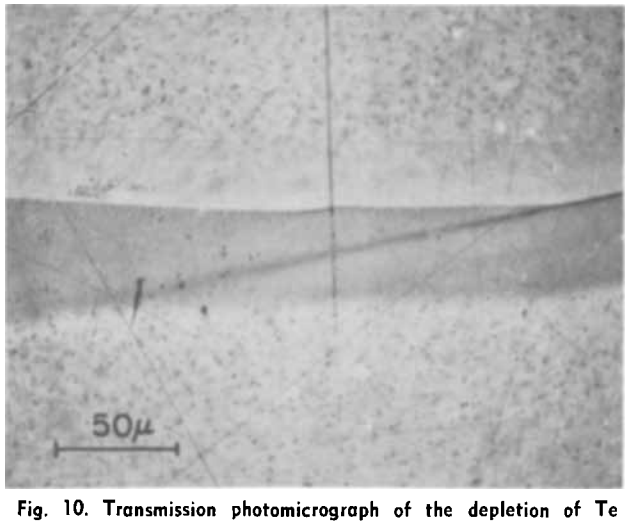

Fig. 10. Transmission photomicrograph of the depletion of Te precipitates near a grain boundary in the crystal shown in Fig. 9.

[5] The approximate volume of a tetrahedral precipitate, using an average edge length of 4μ, is 7.5×10^{-12} cc, weighing 4.5×10^{-11}g Te/precipitate. Assuming that an amount corresponding to the retrograde maximum of Te precipitates out during cooling, the density of precipitates, ρ, is 3.3×10^{6}/cc ZnTe. The mean separation of precipitates is given by $3\sqrt{1/\rho}$.

[6] The integrand in Eq. [3] can be readily transformed into a function of T if the cooling rate, r, is given by $r = (T_{\text{initial}} - T)/t$. Then, $d\sqrt{t} = dt/2\sqrt{t} = -dT/2\sqrt{r(T_{\text{in}} - T)}$.

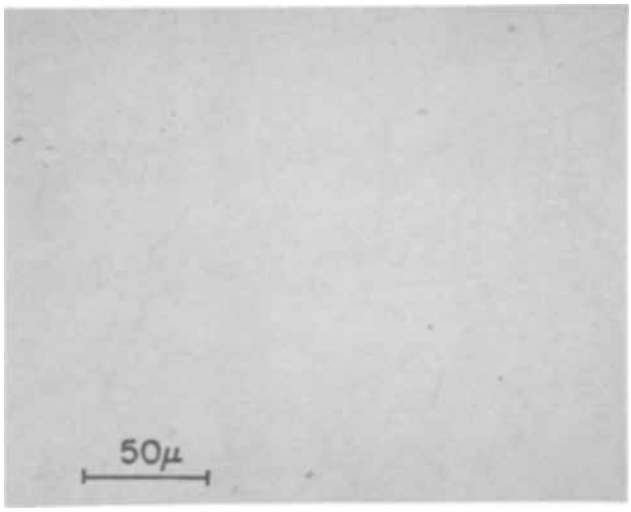

Fig. 11. Transmission photomicrograph of doped vapor grown ZnTe. 8×10^{-3} a/o In was added to the charge. In content of crystal: 1.2×10^{18} atoms/cc. This crystal is essentially free of precipitates.

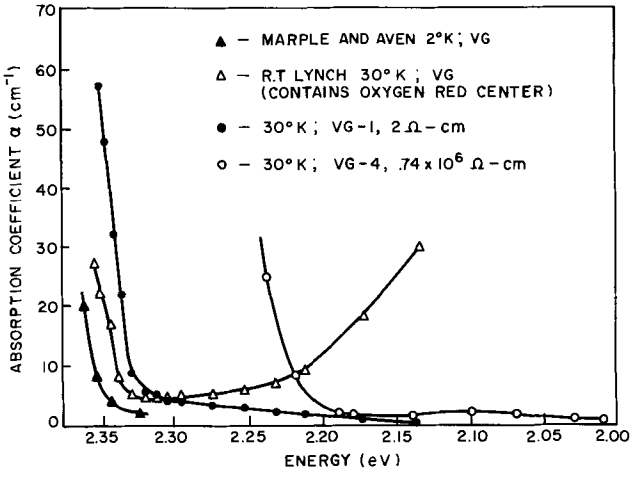

Fig. 12. Absorption coefficient vs. energy for doped and undoped ZnTe crystals.

the energy gap of ZnTe is at 2.385 eV. It can be seen in Fig. 12 that the 2°K results of Marple and Aven (20) extrapolate to this value. However, the absorption edge between 2.33-2.35 eV observed in the undoped vapor grown crystal does not correspond to the true energy gap of this material. In fact, Nahory and Fan have suggested that the edge located below $\alpha = 100$ cm^{-1} near 2.33 eV at 1.7°K was due to electron transitions to the conduction band from a level 0.05 eV above the valence band. This level is probably produced by Zn vacancies.

It can be observed in Fig. 12 that the incorporation of In in the lattice causes the absorption edge to rise at a lower energy, at about 2.2 eV. Nahory and Fan (8) found the position of the In donor level at 0.2 eV from the conduction band. Therefore, the edge observed in the doped crystal is associated with the In donor level.

Usually the color of undoped ZnTe is orange. Crystals containing In or O centers are red. The change in color caused by the addition of impurities can be readily understood on the basis of the absorption curves in Fig. 12.

Conclusions and Summary

High resistivity p-type crystals of ZnTe were grown by transporting powdered ZnTe with In added in a closed, evacuated ampoule. Only certain special charge compositions yielded appreciable vapor transport rates. It was possible to grow 740,000 ohm-cm ZnTe, free of Te precipitates, by the addition of 8×10^{-3} a/o In to the charge.

Acknowledgments

The authors are grateful to Dr. F. A. Trumbore and Dr. C. D. Thurmond for stimulating discussions, Dr. J. Merz for the absorption data, Dr. S. Wemple for the electrical measurements, Dr. R. Saul for taking some of the photomicrographs, and to Dr. R. Buckley and Dr. R. Curran for their help in the initial phases of the work. Mr. T. Y. Kometani performed the chemical analysis of the crystals. Thanks are also due to Dr. A. Strauss of M.I.T. Lincoln Laboratories for supplying InTe.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

APPENDIX

According to the theory of Lever and Jona (17) for chemical transport in nonconvective systems, the deposition rate, J, can be written as

$$J = \frac{\Delta \ln K - \delta}{\xi \Delta z} \qquad [A\text{-}1]$$

where Δz is the separation between source and seed, δ is the supersaturation over the solid surface not in equilibrium with the vapor, and $\Delta \ln K$ is the difference in equilibrium constant between source and seed temperatures for the volatilization reaction; *i.e.*, $ZnTe(s) = Zn(g) + \frac{1}{2}Te_2(g)$. One can evaluate ξ for the present system by a combination of Eq. [28] and [29] of ref. (17) to yield

$$\xi = \frac{(p_{Te_2} - \frac{1}{2}p_{Zn})^2}{p_{Zn}p_{Te_2}ND_{Zn\text{-}Te_2}} + \xi_i \qquad [A\text{-}2a]$$

where

$$\xi_i = \frac{p_A}{p_{Zn}ND_{Zn\text{-}A}} + \frac{p_A}{4p_{Te_2}ND_{Te_2\text{-}A}} \qquad [A\text{-}2b]$$

p_A is the partial pressure of a residual inert gas A (present in the container), N is the total gas density in moles/cc, $D_{Zn\text{-}Te_2}$, $D_{Zn\text{-}A}$, and $D_{Te_2\text{-}A}$ represent the gaseous interdiffusion coefficients.

It is possible to evaluate $\xi - \xi_i$ in terms of $\alpha = p_{Zn}/p_{Te_2}$ and obtain

$$\xi - \xi_i = \frac{\left(\frac{\alpha}{2} - 1\right)^2}{\alpha ND_{Zn\text{-}Te_2}} \qquad [A\text{-}3]$$

A combination of Eq. [A-3] and [A-1] shows that for $\alpha = 2$, *i.e.*, for congruent vaporization, ξ is at its minimum and J is at its maximum value. Furthermore, $\xi - \xi_i$ is proportional to $\alpha/4$ when $\alpha >> 2$; hence, J is at a minimum for very large α. Similarly, $\xi - \xi_i$ approaches $1/\alpha$ as $\alpha << 2$ and J again reaches a minimum at $\alpha = 0$. In the Zn-rich two phase region $\alpha = 7.9 \times 10^5$ and in the Te-rich two phase region $\alpha = 4 \times 10^{-2}$ at 1150°C. Therefore, J is small in both instances. The transport rate near the Te-rich side is approximately 10^4 higher than in the vicinity of the Zn-rich side. This estimate is based on the ratio of Eq. [A-3] for the two sides using the known values of α.

The Effect of Oxygen Pressure on the Oxidation of Iron at 350° and 400°C

M. J. Graham and M. Cohen*

Division of Applied Chemistry, National Research Council, Ottawa, Ontario, Canada

ABSTRACT

A kinetic study has been made of the effect of oxygen pressure (10^{-6} to 60 Torr) on the oxidation of Ferrovac E iron at 350° and 400°C. The initial rate of oxidation is found to increase with increasing oxygen pressure, while after 180 min the weight gain is independent of pressure (for pressures greater than 10^{-5} Torr). Initially Fe_3O_4 forms on the surface, and once this is covered by a continuous layer of αFe_2O_3 the oxidation rate is markedly reduced. The lower the oxygen pressure, the longer the time before αFe_2O_3 starts to nucleate, and no αFe_2O_3 is observed after oxidation at very low pressures (5×10^{-6} and 1×10^{-6} Torr). An induction period is observed for the oxidation at 5×10^{-6} Torr.

The literature contains a great number of papers on the oxidation of iron [*e.g.*,(1)], but few studies have considered the effect of oxygen pressure on the oxidation kinetics. Recently Boggs and co-workers (2) have reported a study of the oxidation of zone-refined iron in the temperature range 220°-450°C, using pressures of 10^{-2} to 100 Torr. These authors find that for oxidation up to 350°C the oxide film thickness, after a given oxidation time, increases as the oxygen pressure is lowered. At 450°C, the oxidation appears to be independent of oxygen pressure. The present work examines more closely the low pressure oxidation of iron at 350° and 400°C, also extending the pressure range down to 10^{-6} Torr. The weight gains were measured using a vacuum microbalance (except for the very low pressure oxidation). The oxide phases present were identified by reflection electron diffraction and some oxide surfaces were replicated for examination by electron microscopy.

Experimental

Apparatus.—The oxidation apparatus is shown schematically in Fig. 1. A Cahn R. G. Electrobalance was mounted in a stainless steel chamber of an all metal U.H.V. system. After an overnight bake at 100°C (the maximum permissible temperature for the balance), pressures of less than 5×10^{-8} Torr were obtained, the outgassing rate of molecules from the walls, balance, etc. being $\sim 8 \times 10^{-8}$ Torr·l·sec^{-1}. The background gas as determined by a partial pressure analyzer (an A.E.I., M.S. 10 spectrometer) was mainly water vapor. To improve the vacuum capabilities of the system, all the original soldered connections in the balance were replaced by spot-welded platinum joints.

The electrobalance was used either on the 0.4 mg or 1.0 mg Recorder Range (weight change corresponding to recorder full scale deflection), with a total noise level of about 3 μg.

Low oxygen pressures were measured using Varian ionization gauges; a U.H.V. gauge for pressures below 10^{-5} Torr and a milli-Torr gauge in the range 10^{-5} to 10^{-1} Torr. These pressures were controlled by a Granville-Phillips Automatic Pressure Controller, using the ion gauges as transducers. Higher oxygen pressures were measured using an Edwards capsule dial gauge, which was installed in the gas-handling section of the apparatus.

Materials purity.—Ferrovac E[1] iron, analyzed to contain the following impurity concentrations (in ppm); Mn, 24; Si, 10; Cr, 5; O_2, 200; Ni, 11; Al, 26; Cu, 10; Co, 5; and C, 70 was used. In some of the experiments 99.997% iron (zone-refined material from the Battelle Memorial Institute[2]) was also used.

[1] Ferrovac E is the trade name of a high purity iron produced by Vacuum Metals Corporation, Division of Crucible Steel Company of America.

[2] This material was supplied through the American Iron and Steel Institute.

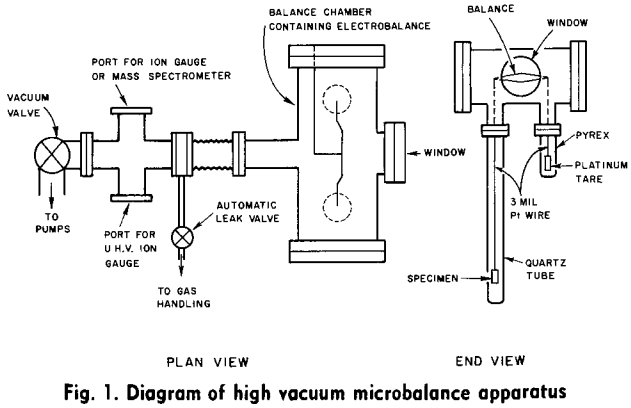

Fig. 1. Diagram of high vacuum microbalance apparatus

* Electrochemical Society Active Member.

Spectroscopically standardized oxygen and hydrogen, supplied by Baker Chemical Company were used. The oxygen contained <70 ppm total impurity and the hydrogen < 14 ppm.

Specimen preparation.—Iron coupons, 5 × 1 cm, were cut from a 9 mil thick cold-rolled sheet. They were degreased, abraded with 600 grit silicon carbide, and electropolished for 1 min in a 95% glacial acetic acid-5% perchloric acid (70%) solution (3). The specimens were then annealed in vacuum at 700°C for 2 hr and finally re-electropolished for a further minute. This method of preparation resulted in a flat surface with about 20-30Å of oxide.

Oxidation procedure.—Specimens prepared as above were first weighed on a Mettler analytical microbalance before loading into the oxidation apparatus. (The weighing of specimens on the Mettler balance before and after oxidation provided a check on the weight gain measured by the Cahn electrobalance and a small drift usually encountered with the electrobalance could be compensated for by adjusting the Cahn weight change to that given by the Mettler balance). After the system had cooled following an overnight bake, and when the pressure was $<10^{-7}$ Torr, the specimen was reduced at 600°C in about 10 Torr of hydrogen for 1 hr. After this time the hydrogen was pumped out of the system and fresh hydrogen admitted. After a few minutes this hydrogen was removed and a further dose of fresh hydrogen admitted. The system was finally evacuated and the temperature was adjusted to the value at which the oxidation experiment was to be performed. Originally, hydrogen reductions were performed at 400°C, but oxidations following reductions at this temperature gave nonreproducible results. The problem was resolved by raising the reduction temperature to 600°C.

Following the removal of hydrogen from the system, oxygen was admitted when the pressure was $<8 \times 10^{-8}$ Torr. Extra pumping time was used to reduce the background to $\sim 3 \times 10^{-8}$ Torr before oxidations were performed at the very low pressures (10^{-6}-10^{-5} Torr). At the end of an oxidation, the system was again evacuated and the weight gain was found from the difference between the initial and final weights of the specimen at the temperature of the experiment and in high vacuum. This procedure corrected for the so-called thermomolecular effect (4) which is pressure and temperature dependent and gives rise to the largest spurious mass changes encountered with the vacuum microbalance. The exact magnitude of this pressure effect was determined at the end of an oxidation experiment by re-admitting oxygen a number of times and noting the apparent mass change from the reading in vacuum. Knowing the variation of the pressure effect with time, it is then possible to accurately define the initial portion of the oxidation curve.

Oxide examination.—Reflection electron diffraction was carried out in a G. E. Diffraction Apparatus, using an accelerating voltage of 45 kV and a camera length of 50 cm. Two-stage formvar platinum-carbon replicas of the oxide surfaces were examined in the electron microscope.

Results

Kinetic data.—A comparison was first made of the oxidation of Ferrovac E iron with zone-refined iron, and the weight gain-time curves for the two materials, oxidized at 350°C and 10^{-3} Torr oxygen pressure, are shown in Fig. 2. It is observed that both materials oxidize in a similar manner for the first 10 min, after which time the rate of oxidation of Ferrovac E slows markedly while the zone-refined material continues to oxidize at a fairly rapid rate. After 2 hr, the oxide is nearly twice as thick on the zone-refined iron as on the Ferrovac E. This difference in oxidation behavior may possibly be accounted for in terms of different grain size and different crystal orientations present in

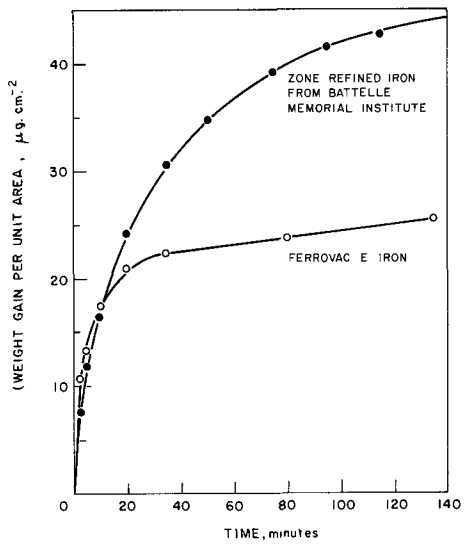

Fig. 2. Comparison of the oxidation of iron supplied by the Battelle Memorial Institute with Ferrovac E iron; 10^{-3} Torr oxygen at 350°C.

the two materials. Following the 700°C vacuum anneal, the grain size of the Battelle iron is about 2-3 mm in diameter, compared with a few microns for the Ferrovac E, and as the oxidation rate is strongly dependent on crystallographic orientation (5-7), larger grains present in the zone-refined material exposing planes with high oxidation rates may be responsible for the observed enhanced oxidation over Ferrovac E iron. Also, the time to formation of αFe_2O_3 varies with crystal plane (5), and the continued rapid oxidation observed with the zone-refined material may be taking place on large grains of such orientation that αFe_2O_3 has not yet formed a continuous film over the magnetite. The statement that a continuous outer layer of αFe_2O_3 slows the reaction rate will be discussed later. The reproducibility of oxidation runs on zone-refined iron was found to be not as good as with Ferrovac E. A series of oxidations, performed at 350°C and 10^{-3} Torr oxygen pressure on seven zone-refined iron specimens, annealed under similar conditions but some of them at different times, were reproducible to within about 10%. Specimens annealed together yielded results in closer agreement, presumably due to a more similar grain growth and grain size. Oxidations of Ferrovac E iron, under similar conditions, were reproducible to about 5%, irrespective of whether specimens were annealed at the same time or not. Because of this better reproducibility it was decided to use the Ferrovac E iron in the study of the effect of pressure on the oxidation kinetics, despite its inferior purity as compared to the zone-refined material. Also, the smaller grain sized Ferrovac E is more typical of the polycrystalline material.

The weight gain-time curves obtained for the oxidation of Ferrovac E at 350° and 400°C and oxygen pressures of 10^{-6} to 10^{-2} Torr are shown in Fig. 3 and 4, and oxidation curves for the higher pressure oxidation (10^{-2}, 35, and 60 Torr), are given in Fig. 5. In Fig. 6, a comparison is made of the very low pressure oxidation (10^{-6}, 5 x 10^{-6}, and 10^{-5} Torr), at 350° and 400°C.

Considering Fig. 3 to 6, the effect of oxygen pressure on the kinetics is clearly evident, particularly in the pressure range 10^{-6}-10^{-2} Torr. As the oxygen pressure is increased from 10^{-6} through to 35 or 60 Torr, the initial rate of oxidation is increased. The position and extent of turnover of the curves to a reduced oxidation rate is also pressure dependent. At 10^{-5} Torr and below only a small, if any, reduction in the oxidation rate is observed (with the exception of the oxidation at 10^{-5} Torr and 350°C) after 3 hr of oxidation. Although the initial rate of oxidation in-

creases with increasing oxygen pressure in the range 10^{-4} to 35 or 60 Torr of oxygen, the weight gain after 3 hr is essentially pressure independent, as summarized in Table I. After 3 hr oxidation at 350°C, the average weight gain for this pressure range is about 26 μg

Table I. Weight gain per unit area after 3 hr oxidation

Pressure, Torr	Weight gain (μg cm⁻²) after 3 hr (a) 350°C	(b) 400°C
10^{-6}	~0.5	~0.1
5 x 10^{-6}	17.0	14.2
10^{-5}	22.6	37.0
10^{-4}	24.8	53.2
10^{-3}	27.3	51.0
10^{-2}	25.8	53.0
35	—	50.9
60	25.1, 25.0, 25.8	—

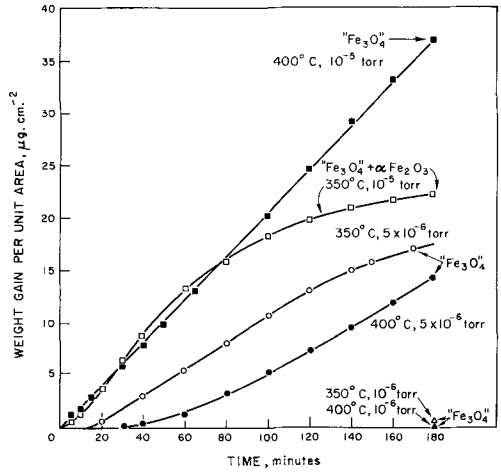

Fig. 6. Comparison of the low pressure oxidation of Ferrovac E iron at 350° and 400°C.

cm^{-2}, compared with a value of about 52 μg cm^{-2} at 400°C. An induction period is observed for oxidations at 5 x 10^{-6} Torr at both 350° and 400°C.

The weight gains after 3 hr of oxidation at 10^{-6} Torr were obtained by difference from the weight of the specimen before and after oxidation, as determined by the Mettler analytical microbalance, (taking into account the removal of the oxide film resulting from the electropolishing), the Cahn electrobalance being not sufficiently stable to identify this small weight change.

The kinetic data from oxidations at 10^{-4}, 10^{-3}, and 10^{-2} Torr oxygen at 350° and 400°C is plotted in a parabolic manner in Fig. 7 and 8, respectively. Another parabolic plot of the data from the oxidation at 35

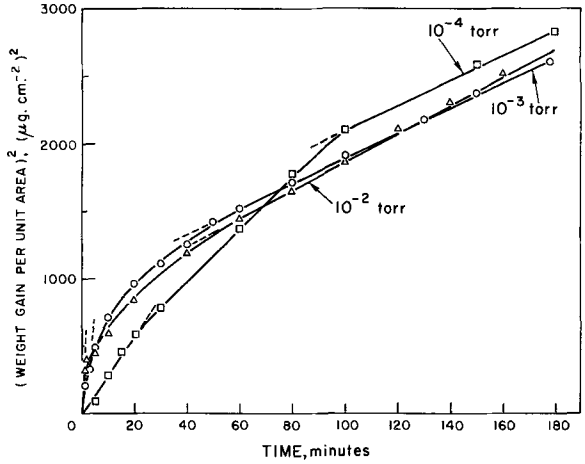

Fig. 8. Parabolic plot of data from the oxidation at 400°C; 10^{-4}, 10^{-3}, and 10^{-2} Torr oxygen pressure.

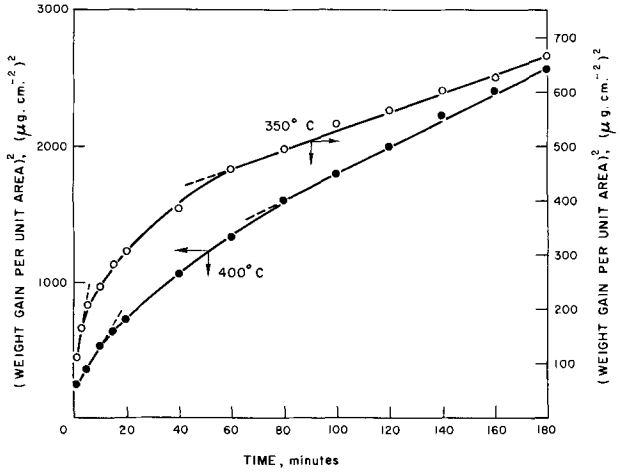

Fig. 9. Parabolic plot of data from the high pressure oxidation at 350° and 400°C.

Torr and 400°C; 60 Torr and 350°C, is shown in Fig. 9. In all cases, the initial oxidation conforms to a parabolic rate law, the duration of this period becoming shorter as the pressure is increased. The slower oxidation rate at 350°C makes the initial data for this temperature more reliable than the data at 400°C, and the time scale is expanded in Fig. 7 to show more clearly the first parabolic agreement. At the end of the first stage, the oxidation proceeds through an intermediate range before entering a second parabolic region of lower rate. It was found that the data did not fit a single logarithmic plot.

Electron diffraction.—The oxides present after oxidation, at various pressures and times at both 350° and 400°C, were identified by reflection electron diffraction and the results are summarized in Table II. "Fe_3O_4" in the table represents a cubic oxide, either Fe_3O_4 or γFe_2O_3, or both. Where αFe_2O_3 was detected (with the exception of the oxidation at 10^{-5} Torr and 350°C), this layer was too thick to permit reflections from the underlying Fe_3O_4 layer.

It can be seen from Table II that only a cubic oxide is formed at oxygen pressures below 10^{-5} Torr for both 350° and 400°C, while after 3 hr of oxidation at 10^{-4} and above, an outer layer of αFe_2O_3 is formed at both temperatures. For short time oxidations at 10^{-3} Torr and 350° and 400°C, only a cubic oxide is found to be present. An interesting finding is that αFe_2O_3 (in addition to cubic oxide), is detected after 3 hr of oxidation at 350°C and 10^{-5} Torr oxygen, while no αFe_2O_3 is found after the corresponding oxidation at 400°C.

Electron microscopy.—Electron photomicrographs of replicas of metal and different oxide surfaces are shown in Fig. 10 (a to i); the average thickness of the oxide is given in parenthesis.

Figures 10 (a) and (b) show the nature of the metal surface immediately prior to oxidation, *i.e.*, after the specimen had been hydrogen reduced at 600°C, and then held at 400°C for a few hours while the background pressure was reduced to $\sim 3 \times 10^{-8}$ Torr, it was quenched to room temperature. A smooth area of the surface is illustrated in Fig. 10 (a), compared with one of the roughest areas in Fig. 10 (b). The observed thermal facetting is similar to that found by Sewell *et al.* (8) on iron surfaces hydrogen annealed at 800°C.

Table II. Summary of electron diffraction analysis

Pressure and time of oxidation	Phases observed 350°C	400°C
10^{-6} Torr, 3 hr	"Fe_3O_4"	"Fe_3O_4"
5×10^{-6} Torr, 31 min	"Fe_3O_4"	"Fe_3O_4"
5×10^{-6} Torr, 3 hr	"Fe_3O_4"	"Fe_3O_4"
10^{-6} Torr, 3 hr	αFe_2O_3 + "Fe_3O_4"	"Fe_3O_4"
10^{-4} Torr, 3 hr	αFe_2O_3	αFe_2O_3
10^{-3} Torr, 2¼ min	—	"Fe_3O_4"
10^{-3} Torr, 5 min	"Fe_3O_4"	—
10^{-2} Torr, 3 hr	αFe_2O_3	αFe_2O_3
35 Torr, 3 hr	—	αFe_2O_3
60 Torr, 3 hr	αFe_2O_3	—

Oxide nuclei present after the oxidation at 10^{-6} Torr for 3 hr at 400°C are observed in Fig. 10 (c), and the growth of these nuclei appears to be completely random. Replicas of specimens oxidized for 31 min at 5×10^{-6} Torr at both 400° and 350°C are shown in Fig. 10 (d) and (e); this was after the induction period when a noticeable weight increase could be observed with the Cahn microbalance (see Fig. 6). The influence of substrate structure on the oxidation is shown in Fig. 10 (e) where the outer texture of the oxide on the two grains is different. Large oxide nuclei are seen in Fig. 10 (d), and triangular shaped nuclei ~200Å in height are present near the grain boundary.

Surfaces of thicker oxides are shown in Fig. 10 (f to i). Figures 10 (f) and (g) show the variation of the degree of roughness of the oxide outer surface with the underlying crystal plane of the metal. The height of oxide facets on the upper left grain in Fig. 10 (f) range up to 300-400Å. The ridged structure of the αFe_2O_3 surface, found after oxidation for 3 hr at 10^{-3} Torr and 400°C [Fig. 10 (h) and (i)], is similar to that observed by Boggs *et al.* (2, 5) for oxidations under similar conditions.

Discussion

The marked effect of oxygen pressure on the oxidation of iron at 350° and 400°C is clearly shown in Fig. 3, 4, and 5. As the pressure is increased from 10^{-6} to 60 Torr the initial rate of oxidation is increased. This period of high oxidation rate is, in general, followed by one of much lower oxidation rate.

The proposed mechanism to explain the different initial rates is as follows; initially Fe_3O_4 forms on the surface and the oxide layer grows as iron ions diffuse outward through cation vacancies in the oxide. The cation vacancies are formed at the outer surface of the oxide when oxygen is incorporated into the lattice. The concentration of vacancies and hence the concentration of iron ions diffusing to the O_2/Fe_3O_4 interface depends on the availability of oxygen at the outer surface. Thus, as the oxygen pressure is increased, the concentration of vacancies is increased and so the flux of iron ions is increased leading to an increased oxidation rate. This assumes that in the low pressure region the incorporation of oxygen into the lattice to form oxygen ions is pressure dependent.

The lowering of the oxidation rate may be due to either the formation of a continuous layer of αFe_2O_3, over the Fe_3O_4, or loss of contact between the oxide and the metal. Taper sections of these thin oxides did not yield conclusive evidence of oxide separation from the metal. Moreover, the electron diffraction data, summarized in Table II, supports the argument that the formation of a continuous hexagonal oxide layer reduces the oxidation rate. At pressures below 10^{-5} Torr, where no marked reduction in oxidation rate was observed, only cubic oxide was found to be present after 3 hr of oxidation (Table II). Also specimens which were removed before the decrease in rapid rate observed at higher pressures showed only "Fe_3O_4" by electron diffraction. In all cases where a marked decrease in oxidation rate had already occurred, electron diffraction showed only an outer layer of αFe_2O_3. These observations would indicate that in the rapid rate region, diffusion, probably of cations, through magnetite is the rate controlling process, while in the low rate region, diffusion, probably of oxygen ions, through αFe_2O_3 is the controlling process. This was partially confirmed by an experiment in which iron had been oxidized into the αFe_2O_3 region and then annealed, in vacuo, to convert all the oxide to Fe_3O_4 (9). On readmitting oxygen a rapid "magnetite-type" rate was initially observed, with again a later falling off in rate characteristic of control by αFe_2O_3.

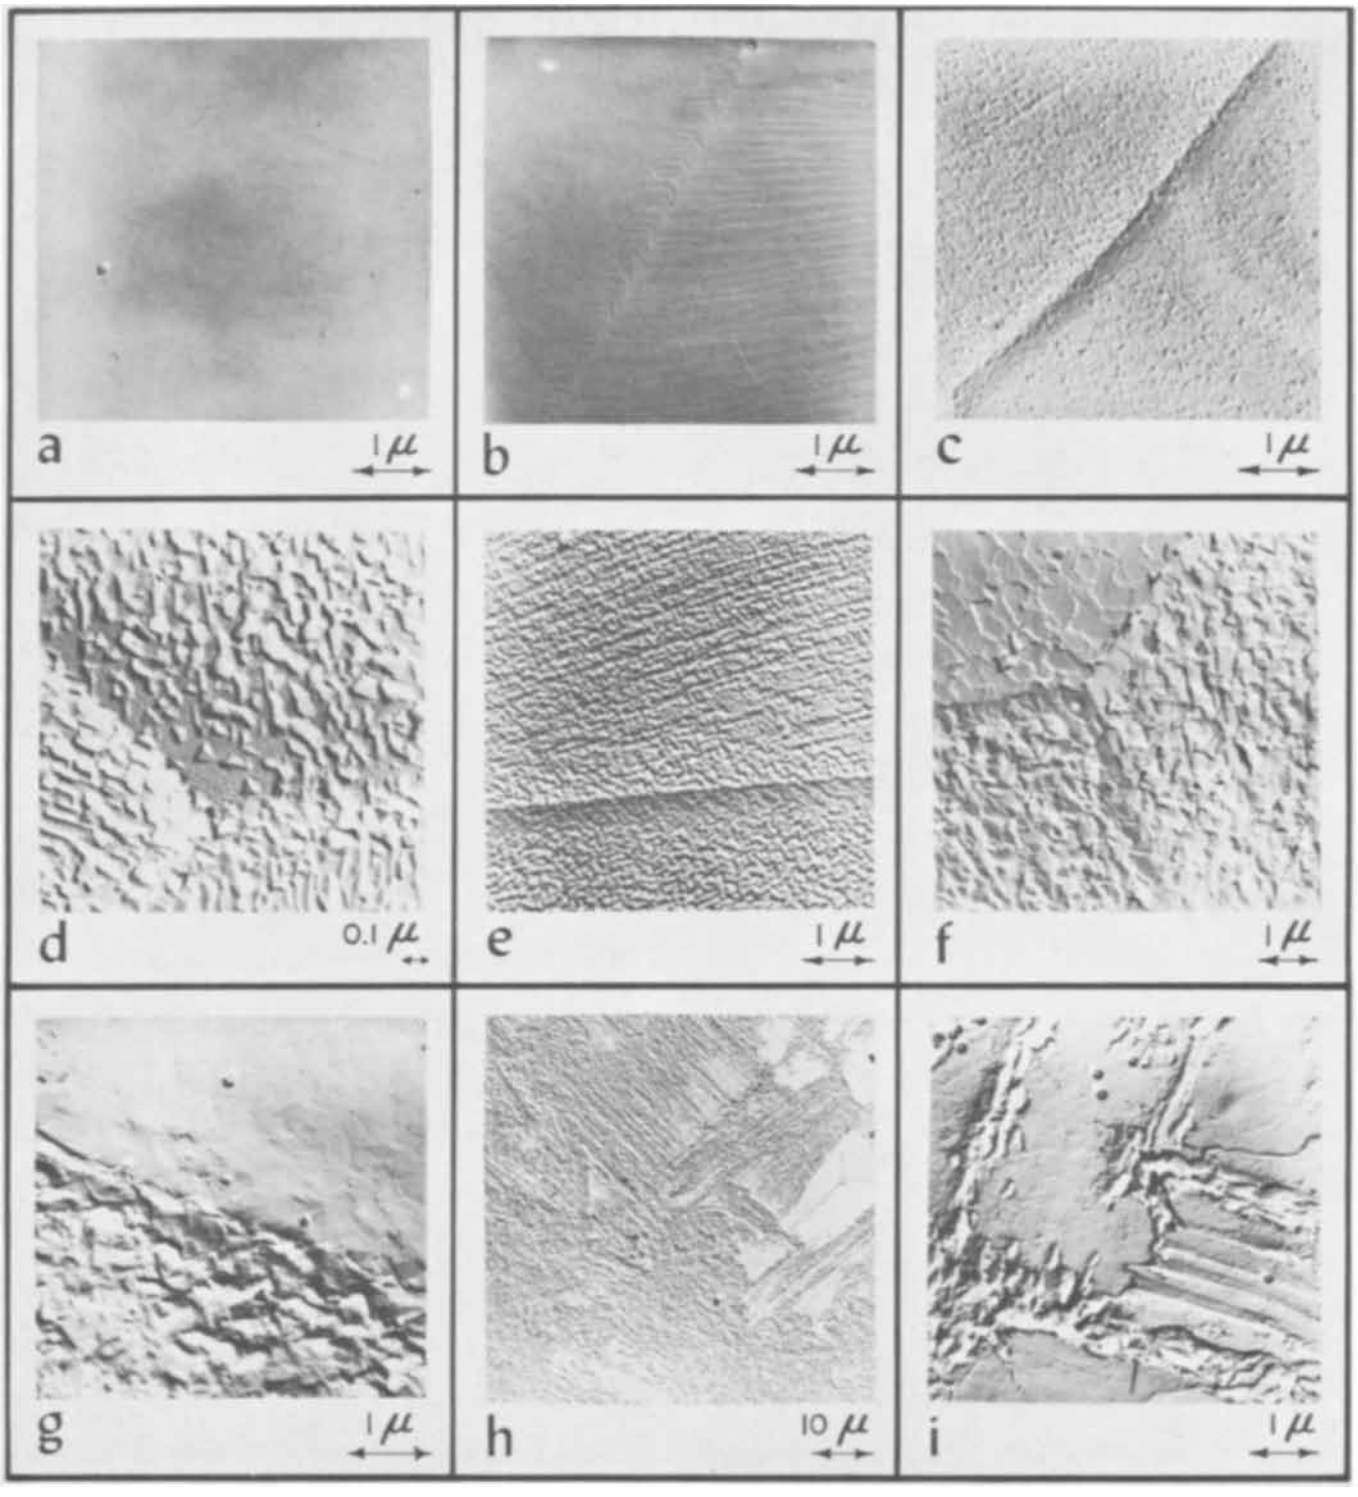

Fig. 10 (a) to (i). Electron photomicrographs of replicas of metal and different oxide surfaces; the oxide thicknesses are given in parenthesis. (a) and (b) metal immediately prior to oxidation; (c) oxidized at 10^{-6} Torr, 400°C for 3 hr (~70Å); (d) oxidized at 5 x 10^{-6} Torr, 400°C for 31 min (~50Å); (e) oxidized at 5 x 10^{-6} Torr, 350°C for 31 min (~60Å); (f) oxidized at 5 x 10^{-6} Torr, 400°C for 3 hr (900Å); (g) oxidized at 10^{-5} Torr, 400°C for 3 hr (2200Å); (h) and (i) oxidized at 10^{-3} Torr, 400°C for 3 hr (3100Å).

The time to formation of αFe_2O_3 will depend on the temperature, oxygen pressure, and crystallographic orientation of the underlying metal. The kinetic stability of an αFe_2O_3 film depends on a balance between its reduction to Fe_3O_4 by diffusing iron and the oxidation of Fe_3O_4 to αFe_2O_3 by oxygen. Thus, at 10^{-5} Torr, the higher diffusion of iron through Fe_3O_4 at 400°C leads to continuous reduction of any αFe_2O_3 to Fe_3O_4, while at 350°C a presumably slower flux of iron allows, after some time, the formation of a continuous layer of αFe_2O_3 (Fig. 6). At lower oxygen pressures only Fe_3O_4 is observed. As the pressure is increased between 10^{-5} and 10^{-2} Torr the time to formation of αFe_2O_3 is decreased. At above 10^{-2} Torr the oxidation rates are essentially pressure independent, but, of course, temperature dependent. At these high pressures αFe_2O_3 nucleates after a short time, accounting for the early turnover of the oxidation curves.

The similarity between the oxidation at 10^{-2} Torr and 35 or 60 Torr is in disagreement with the results of Boggs *et al.* (2) who report that at 350°C the oxidation rate is strongly pressure dependent over this pressure range. Although Boggs finds the initial rate of oxidation to increase as the pressure is increased,

and the present results confirm this finding over a very wide pressure range, after 150 min of oxidation he reports the weight gain with 100 Torr oxygen pressure to be about only one quarter of the weight gain found at 10^{-2} Torr. It is difficult to explain the discrepancy between the two sets of data. Part of the discrepancy may be due to the different compositions of iron used and different methods of preparation.

The reason for the induction period observed at 5×10^{-6} Torr for both 350° and 400°C is probably either to a slow nucleation process (10) taking place or the removal of oxidizable impurities, most likely carbon from the specimen. Micrographs of replicas of oxide surfaces at the end of the induction period are shown in Fig. 10 (d) and (e), where the growth of nuclei into a continuous film is taking place. As seen in Fig. 6, the induction period appears to be longer at 400°C than at 350°C, but the times involved are not sufficiently reproducible to unequivocably make such a distinction. Sewell (11) using an x-ray technique to study the kinetics of oxidation has also observed an induction period for the oxidation of (100) iron at 400°C and 3×10^{-6} Torr oxygen. It is also noteworthy that the oxide thickness determined using this new technique correlates well with the present microbalance data.

The parabolic plots shown in Fig. 7, 8, and 9 indicate two distinct regions of conformity; an initial good parabolic fit of the data, the oxidation rate increasing with increasing pressure and the duration of the agreement becoming shorter as the pressure is increased from 10^{-4} to 60 Torr. The initial parabolic behavior is followed by an intermediate stage before a second parabolic region is reached where the plots are approximately parallel, signifying that this second region is essentially independent of pressure. The two distinct parabolic rates are most clearly observed in Fig. 7, and the values of the rate constants derived from the data in this figure are the most accurate obtained; the actual values of the initial rate constants at 10^{-4}, 10^{-3}, and 10^{-2} Torr oxygen pressure and 350°C are 1.9×10^{-13}, 4.3×10^{-13}, and 1.35×10^{-12} g^2cm^{-4} sec^{-1}, respectively. In this parabolic region at 350°C and during the initial parabolic region at 400°C (Fig. 8), we are probably dealing solely with the growth of Fe_3O_4. The electron diffraction analysis of oxides formed after short times of oxidation at 10^{-3} Torr shows only Fe_3O_4 to be present (Table II), supporting this view. Thus, if initially we are only concerned with the growth of magnetite, then the rate of oxidation as given by the parabolic rate constant should be proportional to the concentration of cation vacancies at the oxide-oxygen interface, which in turn is proportional to the (oxygen pressure)$^{1/2}$. As the pressure is increased more oxygen is incorporated into the oxide and so more cation vacancies are formed, leading to enhanced diffusion of iron through these cation vacancies giving rise to an increased oxidation rate. It may be seen in Fig. 11 that for the oxidation at 10^{-4}, 10^{-3}, and 10^{-2} Torr and 350°C, the parabolic rate constant, taken from the initial slopes of the curves in Fig. 7, is proportional to the (pressure)$^{1/2}$.

Linear behavior is observed for part of 5×10^{-6} Torr at 350°C and at 10^{-5} Torr at 400°C (Fig. 3 and 4). If it is assumed that under these conditions the oxidation rate is controlled by a combination of the rate of impingement of oxygen on the surface and the sticking factor of oxygen on the oxide, a sticking factor of 0.03 at 350°C and 0.025 at 400°C can be calculated.

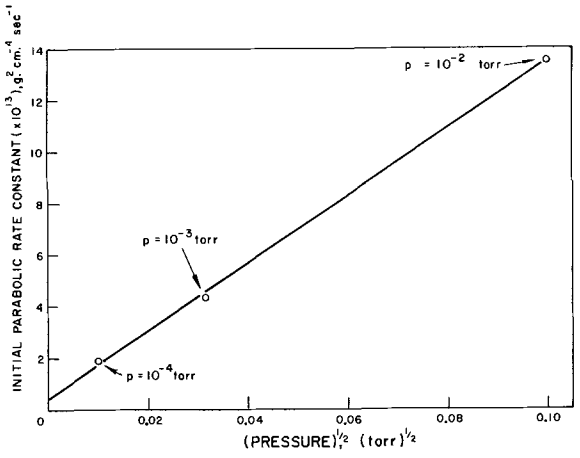

Fig. 11. Initial parabolic rate constant for the oxidation at 350°C and oxygen pressures of 10^{-4}, 10^{-3}, and 10^{-2} Torr plotted against the square root of the pressure.

Activation energies derived from the initial K_p values at 350° and 400°C, and 10^{-4}, 10^{-3}, 10^{-2} Torr are 15, 17, and 22 kcal · $mole^{-1}$, respectively. The values are obviously not too reliable as oxidation rates were only measured at two temperatures, but they are of some significance. No comparable data for oxidations under similar conditions exists in the literature but higher values of 33 kcal · $mole^{-1}$ (12), for composite oxide formation in the temperature range, 500°-900°C and 45 kcal · $mole^{-1}$ (13) for the growth of magnetite in the range 400°-570°C, are quoted for higher temperature oxidations.

The Chalcogenide Semiconductor System: As_2Se_3-Sb_2Se_3

N. S. Platakis, V. Sadagopan,* and H. C. Gatos*

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

The glass formation region of the system As_2Se_3-Sb_2Se_3 and the vitreous-crystalline transformation were investigated. Electrical and optical properties in the vitreous and in the polycrystalline state were studied as a function of composition on homogeneous and geometrically well defined samples prepared by a new method. Activation energies obtained from electrical and optical measurements were in excellent agreement and were found to decrease with increasing content of Sb_2Se_3. For a given composition, the activation energy in the vitreous state was greater than in the crystalline state by 0.2-0.4 eV. Excepting the absorption edge, no absorption or reflection bands were observed in all of the compositions studied in the ranges of 0.7-1.7 and of 2.5-50μ.

Chalcogenide glasses have been extensively investigated in recent years. As photoconductors they have found applications in vidicon type camera tubes (1-4). Since their properties are relatively unaffected by the presence and variation of impurities (5-9) these materials are of interest for this type of application or electronic applications in general. Infrared optics and xerography are further areas of research and development where the role of vitreous semiconductors is very important.

The over-all behavior of vitreous semiconductors is not nearly as well understood as that of the crystalline semiconductors. For example, electrical conduction in the vitreous materials is still a poorly understood process (5, 9-18).

The present study examines the pattern of property changes as a function of composition in the pseudobinary system As_2Se_3-Sb_2Se_3. It is also concerned with the extension of the glass formation region and the corresponding effects on the electrical and optical properties. The stability of the vitreous state and the parameters affecting it are of considerable interest particularly in view of the encouraging results reported (4) on the pseudobinary Sb_2Se_3-Bi_2S_3.

Experimental

The compounds As_2Se_3 and Sb_2Se_3 were prepared individually from their elements which were of high purity (semiconductor grade, 99.999+%). For each compound nominally stoichiometric amounts were placed in a quartz ampule which was repeatedly evacuated, flushed with argon and finally evacuated to 10^{-6} Torr before sealing off. Each sealed ampule was heated for about 5 hr at 350°C, whereupon the temperature was raised to 750°C and maintained for about 5 hr.

The resulting As_2Se_3 and Sb_2Se_3 were placed, in the desired proportions, in a quartz ampule which, in turn, was flushed, evacuated, and sealed off. The ampule was fitted to a horizontal shaft of a motor and positioned in a horizontal furnace. While under rotation (about 25 rpm) the ampule was held for about 1 hr at 750°C. It was then withdrawn from the furnace and quenched in air while still under rotation. This technique, described in more detail elsewhere (18), allowed the preparation of hollow cylinders of uniform wall thickness and uniform composition. Typical dimensions of the cylinders employed were: length 3 cm, thickness 0.07 cm, and ID 1 cm.

Appropriate lengths of the samples were cut with ordinary cutting wheels while still in the quartz ampule from which they were separated by simply immersing in acetone. The hollow-cylinder samples exhibited no porosity or other macroscopic defects. Electron probe analysis along the cylinders and across their thickness revealed no detectable variation in chemical composition. Visual examination and x-ray diffraction techniques were employed for confirming the vitreous state of the alloys.

Electrodes for electrical measurements were attached to the inner and outer surface of each sample after immersing it first in silver paste. The silver paste shorting the inner and outer electrodes was removed by grinding the two ends of the cylinders. The ohmic behavior of the contacts was tested over a wide range of current and temperature (0-600V, 293°-520°K). The possibility of current leakage through the edges of the samples was examined by an electrode arrangement recommended by the American Society for Testing Materials (ASTM Designation, D257-1961): During the silver paste coating of the cylinders two bands one near each edge of the outer surface of the sample were masked and left uncoated. Thus, one electrode could be attached to the main outer silver-paste covered portions of the outer surface and another (common) electrode to the outer areas near the edges of the cylinder. In this way the resistance of the sample could be measured between the inner electrode and the main outer electrode, while the third electrode was grounded or was kept at the same potential with the main outer electrode. No difference in resistance between the inner and the main outer electrode was found in these cases. This result indicates that no fringing effect nor leakage were present.

Resistivity measurements as a function of temperature were carried out in a vertical furnace under argon atmosphere. The temperature was controlled to within ±0.5°C. Before each measurement the samples were allowed to equilibrate for 15 to 40 min. Unless the vitreous samples underwent crystallization during heating, the resistivity measurements were reproducible on temperature recycling (within 5%) and exhibited no hysteresis (9). The d-c potential employed was less than 100V.

For the optical measurements (absorption and reflection) the samples were cut from the same cylinders as the samples for the electrical measurements. They were mechanically polished down to 20-800μ. A copper cold-finger cryostat was used for the low temperature measurements. Standard commercial instruments were employed to study the optical properties in the ranges of 0.7-1.7 and 2.5-50μ.

Results and Discussion

General characteristics.—In the vitreous system $(1-x)As_2Se_3 \cdot xSb_2Se_3$ the compositions with $x = 0, 0.1,$

* Electrochemical Society Active Member.

[1] Present address: IBM, Thomas J. Waston Research Center, Yorktown Heights, New York.

0.2, 0.3, 0.4, 0.45, and 0.5 were investigated. They exhibited a relatively high mechanical strength and no inclusions or other macroscopic heterogeneities. These characteristics are attributable to the method of preparation employed (18). All compositions were found to be chemically stable in air at room temperature and were hardly reactive in water or dilute acids. However, chemical attack was clearly observed in alkaline solutions even at room temperature. This chemical reactivity decreased with increasing Sb_2Se_3 content. At room temperature no transformation to the crystalline state was observed even after extended periods of time. At higher temperatures crystallization was observed for some compositions and is discussed below.

Region of glass formation.—A value of $x \cong 0.5$ has been reported (19) as the limit of glass formation in the system $(1\text{-}x)As_2Se_3 \cdot xSb_2Se_3$. In the present study this value was found to be reasonable. However, the values of $x = 0.45$ and 0.50 could be reached only by quenching in horizontal quartz tube under rotation as described above; the commonly used quenching techniques lead invariably to a two phase structure with the crystalline areas readily visible. It was not possible to extend usefully (in the form of single phase) the region of glass formation to higher Sb_2Se_3 content by employing higher quenching rates; the material could not sustain the thermal shock and invariably shattered so that no samples suitable for examination could be obtained.

Electrical characteristics.—The hollow cylinder samples employed had thin walls (<1 mm), were about 1 cm in diameter and 3 cm long; thus, their outer area was essentially the same as the inner area so that within experimental error the electrical resistivity ρ could be taken as

$$\rho = R\frac{A}{l}$$

where R is the total resistance, A is the outer (or inner) area of the cylinder, and l its thickness.

The resistivity was measured as a function of temperature (296°-520°K) for all of the vitreous compositions indicated above. Those with $x = 0.3$, 0.4, 0.45, and 0.5 were also studied in the crystalline state. The results are plotted in Fig. 1. It is seen that the resistivity is significantly greater in the vitreous state, consistent with the expected decreased mobility and carrier concentration as compared with the crystalline state (19). As in typical semiconductors, the resistivity is exponentially decreasing with temperature in both the vitreous and in the crystalline state. The corresponding activation energies are tabulated in Table I. A decrease in the activation energy with increasing Sb_2Se_3 content is apparent. In the compositions with $Sb_2Se_3 > 0.3$, the activation energy appears relatively insensitive to the Sb_2Se_3 content; in fact, in the crystalline state the activation energy of the compositions studied is essentially the same as that reported for crystalline Sb_2Se_3. This result is surprising and not understood. It should be noted that the resistivity in the vitreous state decreases with increasing Sb_2Se_3 content, but it increases in the crystalline state. Similar reversals in resistivity trends have been reported for other vitreous systems (20); however, the reasons for this behavior are not clear as yet.

Table I. Resistivity activation energies (E_ρ)

Material	E_ρ, eV		log ρ_0*	
	Vitreous	Crystalline	Vitreous	Crystalline

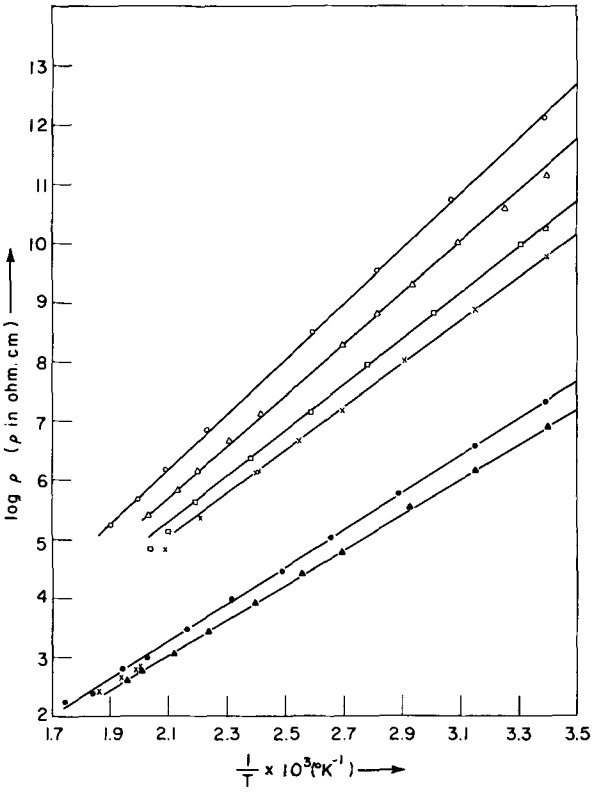

Fig. 1. Dependence of the electrical resistivity on temperature in the system $(1-x)As_2Se_3 \cdot xSb_2Se_3$. ○, $x = 0$ (vitreous); △, $x = 0.2$ (vitreous); □, $x = 0.4$ (vitreous); x, $x = 0.45$ (vitreous); ●, $x = 0.45$ (crystalline); ▲, $x = 0.4$ (crystalline). For clarity the plots for the compositions $x = 0.1$, 0.3, and 0.5 were omitted.

The deviations from the exponential dependence of the resistivity on temperature (see Fig. 1) in the vitreous compositions with $x = 0.3$, 0.4, 0.45, and 0.5 were associated with transformations to the crystalline state as confirmed by x-ray diffraction patterns; on temperature recycling, the samples exhibited the resistivity values of the crystalline state. In contrast the compositions with $x = 0$, 0.1, and 0.2 exhibited the same resistivity values on recycling and even after heating at 220°C for two days. No impurity effects (no change in slope in the activation energy curves) were observed in the present materials consistent with previous results (19) and theoretical considerations (21, 22). It is also of interest to note that in As_2Se_3 no change in the slope of the resistivity *vs.* temperature curve was observed in going through the softening point (187°C). This behavior certainly reflects the direct dependence of the electrical properties on short range order.

The difference in activation energy between the vitreous and the crystalline state is still theoretically unresolved. The presently determined higher values for the vitreous states are consistent with Banyai's views (10) that in going from the ordered to the disordered state electronic states near the band edges are strongly perturbed. They enter the forbidden energy gap and most of them become localized. The nonlocalized electronic states retreat into the energy bands. Assuming that the nonlocalized states are responsible for electrical conduction then the activation energy for conduction should be greater in the vitreous state. However, in the case of As_2Se_3 (19, 23) the activation energy in the crystalline state is greater by 0.1-0.2 eV than in the vitreous state. Although attempts have been made to account theoretically for this behavior of

Curve 1, $x = 0.45$ at $T = 296°K$ (vitreous); curve 2, $x = 0.45$ at $T = 77°K$ (vitreous); curve 3, $x = 0.1$ at $T = 296°K$ (vitreous); curve 4, $x = 0.1$ at $T = 77°K$ (vitreous). Curves 1 and 2 correspond to the left hand side ordinate and curves 3 and 4 correspond to the right hand side ordinate.

As_2Se_3 and the similar behavior of other materials, no definitive stage of understanding has been achieved as yet.

Optical measurements.—The optical absorption characteristics of the compositions discussed above were examined at 296° and 77°K. Typical results for some compositions and two temperatures are shown in Fig. 2 and 3 where the absorption coefficient α and $\sqrt{\alpha}$ are plotted against the energy of the radiation. It is seen that the absorption edge shifts to shorter wavelengths with decreasing Sb_2Se_3 content and with decreasing temperature. The absorption edges were determined from plots of the $\sqrt{\alpha}$ *vs.* the photon energy as shown for some representative cases in Fig. 3. For each absorption curve the edge is taken as the mean of the intersects with the abscissa of the two component straight lines, A and B (24, 25).

The numerical results are summarized in Tables II and III. Here also, the activation energies follow the same trends observed in the values obtained by electrical resistivity measurements. In the vitreous state the absorption edges of the compositions with $x = 0.1$, 0.45, and 0.5 were determined both at 296° and 77°K.

* E_ρ values from Table I.

Assuming that the absorption edge depends linearly on temperature in this temperature range [such a linearity has been found (26) for As_2Se_3 in the range 353°-77°K] the thermal coefficients of the absorption edge of those compositions were determined (Table II). In view of the fact that in these extreme compositions the absorption edge changed by about the same amount (0.13 to 0.15 eV) for the 220°K interval it was assumed that the temperature coefficient for the vitreous compositions with $x = 0.2$, 0.3, and 0.4 is the average of the temperature coefficients of the compositions with $x = 0.1$ and 0.45. These values are consistent with those determined in earlier investigations. Thus for vitreous As_2Se_3 and $As_2Se_3 \cdot Tl_2Te$ the values -7.3×10^{-4} eV/°K and -6.7×10^{-4} eV/°K have been found (26). In the crystalline state the absorption edges of all four compositions investigated were determined at 296° and 77°K. Making the same assumption as before the thermal coefficients of the absorption edge were calculated (Table III). It is of interest to note that the thermal coefficients are eventually the same for the vitreous and the crystalline state consistent with the results on As_2Se_3 (19). Employing the presently determined coefficients and assuming the linear dependence of the absorption edge to extend down to 0°K [such a linearity has been assumed (26) for As_2Se_3] the optical activation energies were adjusted to 0°K for comparison with the resistivity activation energies of Table I which, as determined, correspond to 0°K. The agreement between the two sets of values is very good, the maximum difference ($E_\rho - E_\lambda$) being 0.2 eV (Tables II and III).

The difference between the resistivity activation energy, E_ρ, and the optical activation energy, E_λ, is a measure of the degree of localization of the carriers; accordingly the value $E_\alpha = \frac{1}{2}(E_\rho - E_\lambda)$ is taken as the activation energy for the translational motion of the electrons (5). As seen in Tables II and III, E_α in the present case is relatively small indicating that nonlocalized electronic states are predominant in the conduction process.

In the infrared region of 2.5 to 50μ no absorption nor reflection bands were observed in any of the compositions. Both absorption and reflection remained constant throughout the range and increased somewhat as the content of Sb_2Se_3 increased.

Regarding the transformation from the vitreous to the crystalline state it was found by electrical and optical techniques that its temperature decreases and its rate increases with increasing Sb_2Se_3 content. A discussion of the transformation energetics and kinetics will be reported in a future communication.

β-Silicon Carbide Films

P. Rai-Choudhury* and N. P. Formigoni

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

β-SiC films were grown in a horizontal reactor using a flow system in either H_2 or argon carrier gas. Substrates used were silicon single crystals, hexagonal SiC platelets, and sapphire. Films were grown by three essentially different methods; namely, (*i*) reaction of pyrocarbon (from CH_4 or C_2H_2) with substrate silicon atoms, (*ii*) reaction of $SiCl_4$ and CH_4, and (*iii*) pyrolysis of $(CH_3)_2SiCl_2$. The quality and the growth mechanisms of films grown under different reaction conditions are discussed. It is inferred from the results of the pyrocarbon reaction that silicon diffuses through the initially formed SiC film and reacts with surface carbon atoms. Infrared absorption spectra indicate that the growth rate of thin films of β-SiC depends on the orientation of the silicon substrates. Electron diffraction patterns indicate ordered films of β-SiC.

The cubic form of silicon carbide (β-SiC) has a forbidden energy gap of 2.3 eV (1) and behaves as an intrinsic semiconductor up to temperatures near 1000°C. It is, therefore, an interesting material for electron devices at high operating temperatures. Films of β-SiC have been grown by several investigators either by chemical vapor deposition (2) or by reacting hydrocarbons with the surface silicon atoms (3-5). Rohan and Sampson (6) have pointed out that because of relatively large differences in both the thermal expansion coefficients and tensile strengths of β-SiC and silicon, it is not possible to grow single crystal films thicker than a few microns. They chose sapphire as a substrate and listed different planes of sapphire and the matching planes of β-SiC. The films of β-SiC grown by them from a $SiCl_4 + C_3H_8$ system were, however, neither epitaxial nor single crystal. The available literature on this subject generally points out the difficulty in obtaining good heteroepitaxy of especially refractory (high melting) materials. For many potential device applications, considerable improvement is desirable in purity as well as crystalline perfection (*e.g.*, large area single crystal films). A better understanding of the various chemical reactions involved and of the growth mechanism might aid in improving the quality of the films. In this paper we have examined: (*i*) the preparation of thin films of β-SiC using different vapor deposition reactions, (*ii*) infrared transmission spectra and electron diffraction patterns, and (*iii*) film growth mechanisms under different reaction conditions.

Experimental

The reaction chamber used was a horizontal quartz tube having a SiC-coated graphite susceptor heated externally by an rf coil. Reactions were carried out using a flow system in either H_2 or Ar ambient. The substrates used were chemically polished single crystal silicon slices, and in different experiments, hexagonal platelets of SiC and sapphire of (0001) orientation. All silicon used was boron doped. The silicon substrates were 10 ohm-cm of (100) orientation as well as 0.1 ohm-cm of (110) and (111) orientations. Predeposit etching of the silicon substrates with water vapor (7) was done in situ. A 500 to 1000 ohm-cm n-type silicon layer was grown epitaxially on the differently oriented silicon substrates prior to the growth of the SiC film. Thus, a freshly generated epitaxial silicon provided clean and comparable initial surfaces on different silicon substrates for heteroepitaxial films. In cases where α-SiC and α-Al_2O_3 substrates were used along with silicon substrates they were prepared separately and epitaxial silicon layers were not grown on the silicon wafers prior to film deposition. Four methods were used for the growth of SiC films, *viz.*, (*a*) reaction of methane with Si surface, (*b*) reaction of acetylene with Si surface, (c) reaction of methane and silicon tetrachloride, and (*d*) pyrolysis of dimethyldichlorosilane. X-ray topography, electron microscopy, and infrared spectroscopy were used to study and characterize various phases of film growth.

* Electrochemical Society Active Member.

Results

The various methods of SiC preparation, the structural perfection of the films, and the infrared absorption data are presented in this section. In the preparation of SiC films by different techniques silicon substrates of (100), (110), and (111) orientations were always used except when films were prepared above the melting point of silicon using α-Al_2O_3 and α-SiC substrates.

Preparation of the films.—Methane pyrolysis.—In the present investigation, depending on the experimental conditions, films ranging from oriented single crystals to near amorphous structure were grown. For example, it was possible to reduce the rate of nucleation to the point where growth occurred only at the dislocations as shown in Fig. 1. The layer in Fig. 1 was grown at 1200°C on a (100) substrate by pyrolysis of CH_4 ($p_{CH_4} \simeq 1.5 \times 10^{-3}$ atm). X-ray topographs indicated the presence of at least one dislocation under-

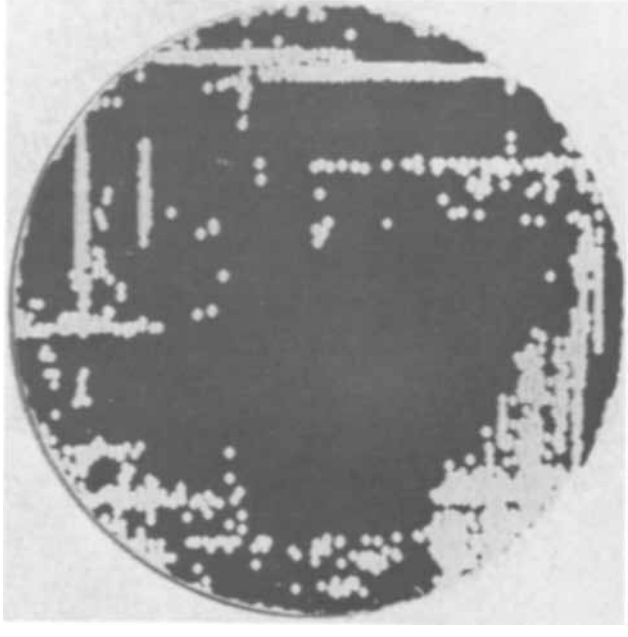

Fig. 1. Photomicrograph of β-SiC layer grown on (100) Si substrate by pyrolysis of CH_4. Magnification: 5 times.

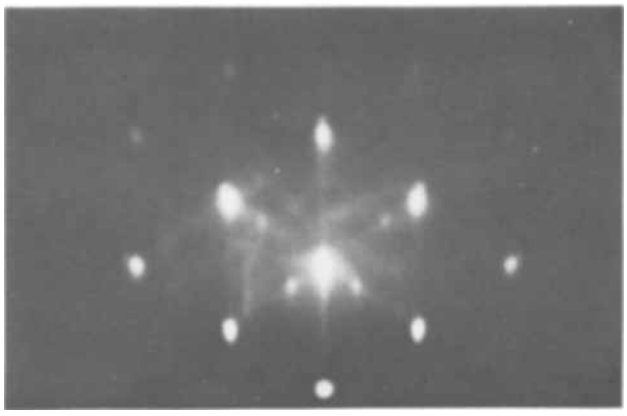

Fig. 2. Electron microprobe X-ray scan of failed test device

neath every SiC crystallite. Examination of a number of these substrates prior to film growth indicated that these dislocations were most likely present in the starting material. Figure 2 shows an electron diffraction pattern of these discontinuous films. A strong (100) orientation is represented, superimposed on the streaked Si (100) pattern of the substrate. Additional diffraction spots, two-thirds along the diagonals which connect the permitted reciprocal lattice points, are evident and indicate twinning in the β-SiC film on {111} planes. The CH_4 partial pressure was then increased in order to obtain a continuous film. Transmission electron microscopic (TEM) examination of the latter films indicated that a complete surface coverage was obtained by increasing the CH_4 partial pressure to about 1.3×10^{-2} atm. However, higher CH_4 partial pressure and consequent increased growth rate resulted in films which sometimes indicated the presence of a ring component in the diffraction pattern. In all films grown by CH_4 pyrolysis, presence of any excess carbon at the film surface could not be detected by electron microscopy. In general, β-SiC films were obtained and consisted of grains of the order of 2000Å.

Acetylene pyrolysis.—SiC films were then grown by pyrolysis of C_2H_2 ($p_{C_2H_2} \simeq 3.7 \times 10^{-3}$ atm) in the temperature range of 1100°-1200°C. No deposit was observed at temperatures of 1050°C and below. All SiC films deposited from C_2H_2 were found to be coated by a film of pyrolytic carbon which had to be removed by oxidation before a characteristic diffraction pattern could be obtained. Films grown by this method always gave diffraction patterns which consisted primarily of rings, and therefore were considerably less crystalline than those from CH_4 pyrolysis.

Silicon tetrachloride and methane reaction.—Obviously SiC films by pyrolysis of methane and acetylene can be grown only on silicon substrates. In order to deposit on substrates other than silicon, SiC films were deposited by reacting $SiCl_4$ ($p_{SiCl_4} \simeq 2.8 \times 10^{-4}$ atm) with CH_4 ($p_{CH_4} \simeq 1.3 \times 10^{-2}$ atm) at 1200°C. When silicon substrates of three different orientations were used, a continuous film was deposited indicating random nucleation, and the deposits exhibited considerable preferred orientation. It was anticipated that hexagonal SiC and α-Al_2O_3 might be suitable substrates because they permit higher deposition temperatures and provide better lattice matching (*e.g.*, for β-SiC $a = 4.36$Å; for α-Al_2O_3 $a = 4.76$Å, $c = 12.99$Å). Films of SiC were deposited on these substrates under conditions similar to those for deposition on Si except at a temperature of about 1500°C. The deposits on α-SiC substrate were of β-form having two orientations with crystallite size larger than on Si. It was not possible to obtain any deposits on α-Al_2O_3 substrates because Si deposited from the hydrogen reduction of $SiCl_4$ reacted with Al_2O_3 to form volatile aluminum suboxides, leaving an etched Al_2O_3 surface (8). Thus Si was not available to react with the carbon from the pyrolysis of CH_4.

Dimethyldichlorosilane pyrolysis.—With the hope of producing SiC directly rather than via Si and C formation, films were deposited on silicon, α-SiC as well as α-Al_2O_3 substrates by the pyrolysis of $(CH_3)_2SiCl_2$. When H_2 was used as a carrier gas the deposited film at temperatures of 1100°-1200°C always indicated presence of unreacted Si in the SiC films, whereas in an inert carrier gas, such as Ar, Si was not present. Although β-SiC films were formed on α-Al_2O_3 substrates by this method they were polycrystalline and of poor quality. Unfortunately, it was not possible to deposit at high temperatures using this organo-silane, due to the formation of excess carbon in the films. Although the SiC formation from $(CH_3)_2SiCl_2$ was much more efficient than from $SiCl_4$ and CH_4, the films on silicon and α-SiC substrates were less ordered in the former case.

In closing this section it should be mentioned that when SiC was grown and/or deposited from CH_4, $SiCl_4$, and CH_4, and from $(CH_3)_2SiCl_2$, the films on (100) silicon substrates showed a single preferred orientation. However, the films on (110) and (111) silicon displayed multiple oriented growth. As was pointed out earlier, the films from pyrolysis of C_2H_2 was of random orientation.

Infrared absorption.—The IR transmission spectra of SiC films grown onto single crystal silicon substrates of different crystal orientation were examined in the spectral range 2500 to 700 cm^{-1}. The instrument employed was a Perkin-Elmer 13 single pass double beam spectrophotometer equipped with NaCl optics. Operations in the ratio mode was chosen so that the atmospheric absorption bands were compensated within about 2%.

Figure 3 shows the spectra of the continuous films grown on (111), (110) and (100) oriented silicon substrates by the pyrolysis of CH_4 at 1200°C and a CH_4 partial pressure of 1.3×10^{-2} atm. The predominant feature of this spectrum is the band centered at 789

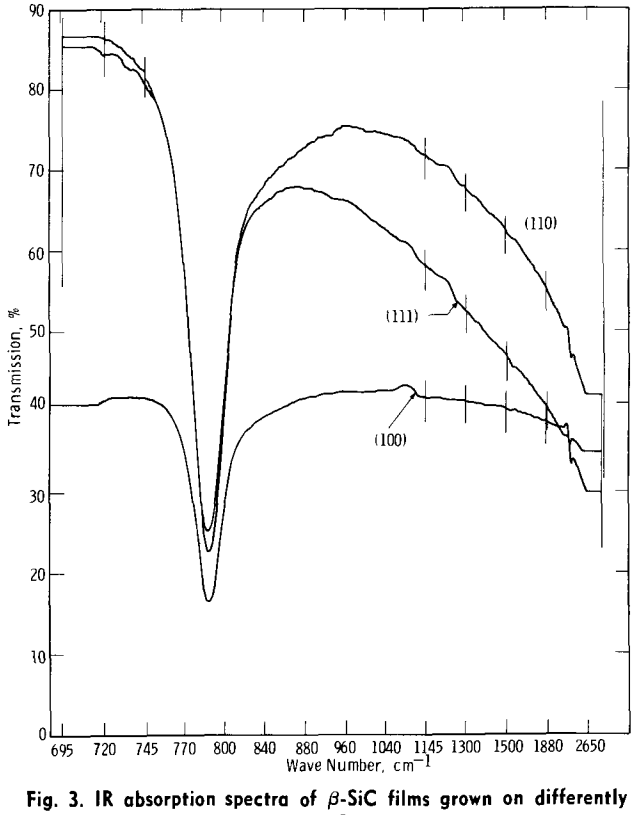

Fig. 3. IR absorption spectra of β-SiC films grown on differently oriented Si substrates by pyrolysis of CH_4.

cm^{-1}, a wave number which coincides within the experimental accuracy with the one attributed by Spitzer to the fundamental vibration of the SiC oscillator (9). The half-band width of about 30 cm^{-1} measured on this spectrum coincides very closely with the corresponding data published by Spitzer and co-workers (9). Because of the very small thickness of the SiC films examined, free carrier absorption in the grown film is not appreciable. However, two of the three spectra recorded in Fig. 3 exhibit a sloping background transmission line. This is due to unbalance between the free carrier absorption in the silicon wafer used as substrate for the film *vs.* the silicon wafer placed in the reference beam. The (100) oriented substrate shows instead excellent compensation of the free carrier absorption because the concentration of electrically active impurity in the substrate and the reference wafer were nearly identical. However, the inverted peak centered around 1070 cm^{-1} (residual-ray wavelength of the SiO_2) indicates that the reference wafer contained a larger amount of bonded oxygen than the sample wafer.

Because of the very thin films grown and the important conclusions to be drawn from these results it is necessary to examine the uniformity of these films. The β-SiC films appeared continuous and free from any pin-holes when viewed in reflection and transmission through an optical microscope after removal of various portions of the substrate by chemical etching. Optical absorption measurements of these films, after removal of the Si substrate, in the u.v. down to 2000Å leave little doubt (negligible transmission) that the films are free from any pin-holes. The coincidence of the present value of the half-band width with that of Spitzer and co-workers can be considered as another evidence in support of a continuous film. If, for example, 10% of the area examined was not covered by the film, then the half-band width would be larger because of the transmission by the uncovered portion of the Si wafer. In general the spectrometer beam covered about 50% of the wafer surface and therefore films of average thickness were examined. By deliberately changing the sampling area the optical density of the film did not change significantly. It can therefore be concluded that the films examined here were free from pin-holes and of uniform thickness.

On the basis of Spitzer and co-worker's results an estimate of film thickness was obtained from Fig. 3. The results are listed in Table I. Such extremely small thicknesses are measurable with a good degree of confidence only because the absorption of the resonance band for SiC is very intense, having an extinction coefficient roughly equal to 2.5×10^5 cm^{-1}. The film thickness measurements indicate that the growth rate is orientation dependent. Similar effects are also observed in the case when films are deposited from the reaction of $SiCl_4$ and CH_4, as well as from pyrolysis of dimethyldichlorosilane on silicon substrates. The IR spectrum is very similar to those shown in Fig. 3.

Discussion

In this study SiC has been prepared by three essentially different methods; namely, (*i*) pyrolysis of hydrocarbons (CH_4 and C_2H_2), (*ii*) reaction of $SiCl_4$ and CH_4, and (*iii*) pyroylsis of $(CH_3)_2SiCl_2$. The first method proceeds with the formation of pyrocarbon at the surface of the initially formed SiC film followed by the diffusion of either carbon or silicon through the SiC film. The reaction zone is either the C-SiC or SiC-Si interface. The second method consists of the reduction of $SiCl_4$ to elemental silicon and decomposition of CH_4 to carbon in H_2 followed by the reaction between silicon and carbon to SiC on the substrate surface (10). SiC formation by this reaction does not proceed in the absence of H_2, at least up to a temperature of 1200°C. SiC films prepared by the third method, *viz.*, by the pyrolysis of $(CH_3)_2SiCl_2$, always indicated presence of unreacted silicon when deposited in hydrogen ambient. The films deposited in an inert carrier gas such as argon did not show the presence of any excess silicon. These results can be explained by examining the over-all $(CH_3)_2SiCl_2$ reaction which can be written as follows

$$(CH_3)_2SiCl_2(g) = SiC(s) + CH_4(g) + 2HCl(g) \quad [i]$$

$$\Delta F_{1500°K} = -32.8 \text{ kcal/mole}$$

$$(CH_3)_2SiCl_2(g) + 2H_2(g) = Si(s) + 2CH_4(g) + 2HCl(g) \quad [ii]$$

$$\Delta F_{1500°K} = -14.9 \text{ kcal/mole}$$

$$CH_4(g) = C(s) + 2H_2(g) \quad [iii]$$

$$\Delta F_{1500°K} = -17.9 \text{ kcal/mole}$$

$$Si(s) + C(s) = SiC(s) \quad [iv]$$

$$\Delta F_{1500°K} = -17.9 \text{ kcal/mole}$$

In the absence of H_2, reaction [*ii*] does not proceed, and therefore elemental Si is not formed. When H_2 is present, excess Si is produced, which can form SiC according to reaction [*iv*], provided reaction [*iii*] takes place. The partial pressure of CH_4 formed by reactions [*i*] and [*ii*] is expected to be considerably less than the equilibrium CH_4 partial pressure ($p^e_{CH_4} \sim 2.6 \times 10^{-3}$ atm) required by reaction [*iii*]. Also the presence of excess H_2 (used as carrier gas) will derive reaction [*iii*] to the left. Therefore reaction [*iii*] is unlikely to proceed in spite of its negative standard free energy because of low CH_4 and high H_2 partial pressures. This probably explains why only SiC is formed directly from $(CH_3)_2SiCl_2$ in an inert ambient, whereas a mixture of SiC and silicon is formed in H_2 carrier gas.

Considering now the growth of SiC by pyrolysis of CH_4 or C_2H_2, let us assume that the growth occurs at the Si-SiC interface via diffusion of carbon through the initially formed thin SiC film as was postulated by Nakashima *et al.* (4). Using a diffusion controlled model, together with the assumption of infinite source, constant diffusivity and a capturing boundary at the SiC-Si interface, the time dependent thickness, x, of the SiC film is given by (11)

$$x = 2\alpha(Dt)^{1/2} \quad [1]$$

where α is a constant. For the present purpose it is assumed that $\alpha = 1$. In the above expressions, D is the diffusivity of C in SiC and t is the diffusion time. For a measured film thickness of 350Å grown in 1 min at 1200°C, the value of diffusivity obtained from Eq. [1] is 5×10^{-14} cm^2/sec. On the other hand, the upper limit for the diffusivity of carbon in SiC, extrapolated from the work of Ghoshtagore and Coble (12), is of the order of 10^{-18} cm^2/sec at 1200°C. Such extrapolation over large temperature (from 1850°C) is reasonable for the present purpose since there is no compositional phase change in the limits of temperatures involved and the effect of crystallographic forms on diffusivity is small. Further, the value of the diffusivity calculated from the film thickness is only intended as a guide for the determination of a possible growth mechanism. Thus, a difference of four orders of magnitude between the minimum diffusivity calculated from the film thickness and the maximum diffusivity obtained from the literature rules out the

Table I. Evaluation of film thickness using the absorption band at 790 cm^{-1} (9)

Crystal orientation of substrate	Thickness of SiC grown in 1 min deposition, Å

(110)	320
(100)	410

mechanism that C diffuses through SiC film. To further substantiate this view films grown by CH_4 pyrolysis were examined for the presence of excess carbon at the surface by a spark source mass spectrometer. A complete stoichiometry of the films (*i.e.*, C/Si ratio of unity) indicate absence of any surface carbon which could act as a diffusion source. Also, as was mentioned earlier, carbon could not be detected by transmission electron microscopy on the surface of films grown by CH_4 pyrolysis.

In the alternative growth mechanism silicon diffuses through SiC to react with the pyrocarbon at the film surface. This model is supported by the fact that the diffusivity of silicon is expected to be considerably higher than that of carbon in SiC (12, 13). However, in this case extrapolation of the diffusivity of silicon in SiC to temperatures of our interest is not possible due to inadequate data (*i.e.*, the activation energy of the process is not reported). The fact that the growth of the SiC films involves outward diffusion of Si is also supported in a recent communication by Haq *et al.* (14). The question now is whether the film growth is diffusion-limited or not.

In cubic systems such as Si and β-SiC diffusivity is independent of the direction of the flux relative to the crystallographic axes (15), and therefore in a diffusion-limiting case the film growth rate should be independent of crystal orientation. However, contrary to this, the film growth rate (experienced with all four deposition methods) was found to be orientation dependent. Therefore, although silicon diffuses through SiC film it is not the controlling step. The only rate controlling step to explain the orientation dependence of the growth rate is adsorption, desorption, and/or surface reaction.

Conclusion

Under the growth conditions used in this investigation, epitaxy of β-SiC on (100) Si has been achieved, together with multiple-oriented growth on (110) and (111) Si. The results using β-SiC substrates indicate that in order to grow β-SiC single crystal over the entire substrate area, it may be necessary to exceed the deposition temperature of 1500°C adopted in these experiments. Because of the high reactivity of silicon with Al_2O_3 films of β-SiC could not be grown on sapphire substrates by reacting CH_4 and $SiCl_4$. When pyrolysis of $(CH_3)_2SiCl_2$ was used as a deposition technique films were formed on sapphire, but, were of poor quality. It has been deduced from film thickness data that the reaction of pyrocarbon with substrate silicon atoms is preceded by the diffusion of Si through the initially formed SiC film. Orientation dependence of the growth rate appears to indicate a process controlled by surface reaction, rather than diffusion of silicon through the grown SiC film. Of course, as the film grows thicker diffusion will eventually become the controlling factor. In the pyrolytic decomposition of $(CH_3)_2SiCl_2$, SiC is formed directly when inert carrier gas is used, while excess Si is formed in H_2 carrier gas.

Acknowledgments

The authors wish to thank Dr. A. J. Noreika for the electron diffraction analysis and Mr. W. Cifone for assistance with the experimental work. The comments of Dr. W. J. Choyke and Dr. J. E. Johnson were greatly appreciated.

Manuscript submitted Sept. 5, 1968; revised manuscript received July 11, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Epitaxial Growth and Properties of Silicon on Alumina-Rich Single-Crystal Spinel

G. W. Cullen,* G. E. Gottlieb,* C. C. Wang,* and K. H. Zaininger

RCA Laboratories, Princeton, New Jersey

ABSTRACT

Mobilities similar in magnitude to bulk silicon mobilities may be realized in 1.4 to 1.6μ thick films on flame fusion magnesium aluminate spinel, for carrier concentrations greater than $\approx 2 \times 10^{16}$ cm^{-3} (p-type). The electrical properties of these films are not significantly altered by thermal oxidation at 1200°C for 1 hr. In this carrier concentration range the electrical characteristics are not highly dependent on the deposition rate within the limits investigated. For carrier concentrations between 5×10^{15} and 2×10^{16} cm^{-3} (p-type) the "as deposited" film mobilities are near bulk values, but the mobilities are degraded by the thermal oxidation. In this doping range the electrical properties of the oxidized films are critically dependent on the deposition rate. The films deposited at the higher rates are altered less on oxidation than films deposited at the lower rates. Using a growth rate of 2 μ/min, a mobility of 300 cm^2/V-sec (~80% of bulk) at $N_a = 4 \times 10^{15}$ cm^{-3} may be realized in a film oxidized 1 hr at 1100°C. Below this carrier concentration the mobility of the oxidized films decreases sharply with decreasing carrier concentrations. Minority carrier lifetimes as high as 40 nsec have been realized in 4μ thick films of silicon on spinel. The carrier concentration as a function of temperature and mobility as a function of thickness of silicon on spinel have been measured.

The semiconducting properties of silicon thin films epitaxially grown on sapphire (1-4) appear to be limited by the crystalline quality of the cubic silicon deposited on the rhombohedral sapphire (5-7), and by contamination of the silicon by aluminum from the substrate (6, 8, 9). As a result of the aluminum contamination (autodoping), the electrical properties of silicon films on sapphire change considerably during the thermal formation of oxide films for device fabrication (10). Magnesium aluminate spinel has been investigated as a substrate material for epitaxial growth of silicon because the lattice match of the cubic silicon to cubic spinel is better than the match between silicon on sapphire. Single crystal silicon has been successfully grown on spinel (11, 12), and the crystallographic nature of the silicon has been examined in detail (13). It has been demonstrated that epitaxial silicon on spinel is less contaminated by substrate constituents than silicon on sapphire (14). There has been, however, a serious drawback to the use of the spinel as a substrate material. The commercially available $MgO \cdot 3.3Al_2O_3$ single crystals are unstable at the temperatures commonly employed for device processing. The thermal stability of the single crystal spinel increases with decreasing alumina content in the range between $MgO \cdot 3.3Al_2O_3$ and $MgO \cdot 1Al_2O_3$ (14, 15), but unfortunately the difficulty of preparing good quality crystals also increases with the decreasing alumina content (15). In order to pursue further the possibility of using spinel as a substrate material, it has been necessary to prepare single crystals with alumina content less than the commercially available $MgO \cdot 3.3Al_2O_3$. In the compositional range from $MgO \cdot 1.0Al_2O_3$ to $MgO \cdot 2.5Al_2O_3$ the crystals are sufficiently stable during the device processing thermal treatments for use as substrate material (15).

Other investigators have reported on the characteristics of 20μ thick silicon on low alumina rich spinel (19). However, for many of the device geometries of interest at this time, silicon films less than 2μ in thickness are required. In the case of silicon on sapphire, the electrical properties are a strong function of the film thickness, and the properties of the thinner films ($< 2\mu$) are considerably more sensitive than the thick films ($> 7\mu$) to deposition and substrate variables (4, 10, 14).

It has previously been demonstrated that the mobilities of 2.0μ thick silicon deposited on flux grown stoichiometric spinel are higher than the mobilities of silicon on sapphire (17). In this paper we report on the properties of 1.4-1.6μ thick silicon on flame fusion spinel in the composition range $MgO \cdot 1.5Al_2O_3$ to $MgO \cdot 2.2Al_2O_3$. The hole mobility and the stability of the mobility during thermal oxidation were studied as a function of the deposition rate and carrier concentration. The carrier concentration as a function of temperature and the minority carrier lifetime of the thin films were also measured.

Deposition Methods and Apparatus

Silicon is epitaxially grown on the single crystal spinel surface by pyrolysis of silane (SiH_4) in a hydrogen atmosphere at 1100°C. The substrate is heated by direct contact with an inductively heated susceptor which is positioned in a water-cooled quartz ampoule. Since the reaction chamber walls are held at room temperature by the water-cooling, deposition occurs only on the susceptor and substrate wafer, and contamination from the quartz is minimized. The rf susceptor is a pyrolytic-carbon coated pure carbon block. The dense pyrolytic coating prevents outgassing of the pressed carbon block. This type of susceptor has been found to be more free of impurities than the silicon carbide coated carbon blocks commonly used as rf susceptors.

The gas-metering and -mixing apparatus is schematically presented in Fig. 1. The system is He leak-tight. The gases are mixed in glass bulbs before they are passed into the growth chamber. The doping gas is diluted twice in the system so that the flow meters can be used with sufficiently high gas flows to provide good accuracy. Accurate metering is necessary because, depending on the doping level desired, the dopant source gas of 10 ppm dopant in H_2 is diluted by as much as 500 to 1 before it passes into the growth chamber.

Provision has been made in the gas control system to stabilize the flows and metering valve settings before the reactants are exposed to the substrate. The

* Electrochemical Society Active Member.

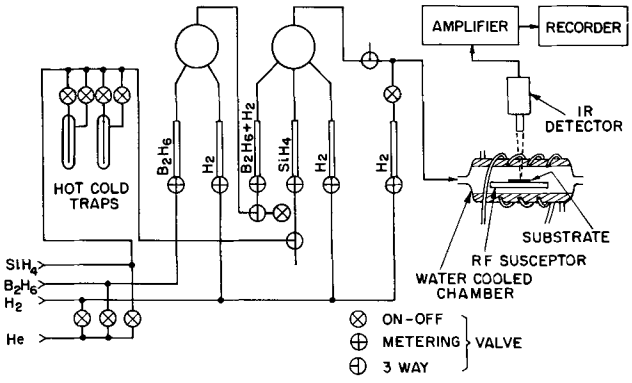

Fig. 1. Apparatus employed for the deposition of silicon on spinel

deposition chamber is flushed with H_2 while the desired flows are established in the control system. During stabilization, the SiH_4-B_2H_6-H_2 mixture is exhausted through a three-way valve immediately prior to the deposition chamber. The mixture is then suddenly switched into the growth chamber. This method is used because the total deposition time is often as brief as 45 sec, and thus the time needed to set up and to stabilize the system may be a significant portion of the deposition time.

The H_2 used as the carrier gas and diluent is purified by passing through a hot Pd-Ag membrane (Engelhard Industries, Newark, New Jersey). The silane-H_2, diborane-H_2, and arsine-H_2 gas mixtures are commercially prepared (Scientific Gas Products Company, Edison, New Jersey).

Since the deposition rate is one of the most critical parameters, the thickness of the growing film is continuously monitored by an IR detector (20) (Beckman Instruments Model 924-1230). The system is schematically shown in Fig. 1. The hot substrate acts as the IR source, and interference in the IR intensity is observed as the thickness of the silicon film increases. The growth chamber of the horizontal growth system was originally constructed to provide a sight path through the water jacket; however, it has been found that if the filter provided with the radiation pyrometer is removed, the detector is sufficiently sensitive to the radiation that passes through the water jacket to be used with the conventional horizontal growth ampoule. Since the thickness measurement is a function of the wavelength used, the method must be recalibrated when the filter is removed. Unexpected changes in the deposition conditions can be immediately observed with the IR detector. An interference pattern is shown in Fig. 2 taken during a growth run in which an accidental surge in the source gas occurred. It is also seen that the film growth started within a second of the introduction of the silane-hydrogen mixture, the growth rate was constant prior to the gas surge,

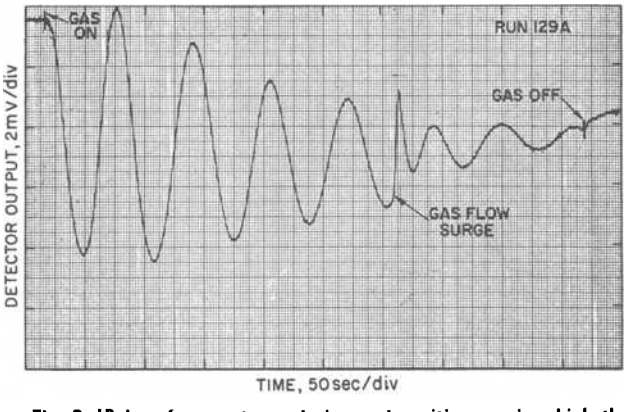

Fig. 2. IR interference trace during a deposition run in which the gas flow conditions momentarily changed.

and the growth stopped within a second of the termination of the source gas. The properties of the deposited films are remarkably sensitive to these variables in the gas flow.

Electrical Properties of Silicon on Spinel

Mobility and stability of electrical properties to thermal oxidation.—The deposition conditions for the epitaxial growth of silicon on spinel were evaluated by preparing a series of samples at various doping levels to measure the mobility as a function of the carrier concentration. Since the mobility is highly dependent on both the crystallographic structure and the impurity content of the films, this is an appropriate property for the comparison of the quality of the silicon on spinel films with silicon on sapphire and bulk silicon. The mobility is also a strong function of the film thickness and the post-deposition treatment, and thus these factors are explicitly stated when comparisons are made. The oxide of the MOS transistor structure is commonly prepared by exposure of the silicon to dry oxygen for 1 hr at temperatures between 1100° and 1200°C, and therefore it was important to examine the change in the electrical properties during this treatment. The mobility of 1.4-1.6μ thick silicon films, before and after thermal oxidation, was measured as a function of the carrier concentration at three different growth rates.

The substrates used are within the compositional range $MgO \cdot 1.5Al_2O_3$ to $MgO \cdot 2.2Al_2O_3$. All depositions were carried out on the (111) surface. The 20 mil thick substrate wafers were lapped with 30μ boron carbide and polished with alumina. The final mechanical polishing was carried out with 0.3μ alumina. The substrates then were degreased thoroughly. Immediately prior to the deposition of the silicon film, the substrates were annealed in H_2 at 1150°C for 20 min. All the depositions were carried out at 1100°C, and the rates were adjusted by control of the silane concentration. The mobilities of the as-deposited films were measured, the films were oxidized in dry oxygen for 1 hr, and the mobility measurement was repeated. Initially, the films were oxidized at 1200°C, but during the course of this study device processing procedures were developed which required a maximum oxidation temperature of 1100°C; therefore, the films deposited at 2μ/min were oxidized at 1100°C.

The mobilities as a function of carrier concentration and oxidation for films deposited at a rate of 0.4 μ/min are presented in Table IA. This rate has been commonly employed in the past for the deposition of silicon on sapphire. It is seen that for carrier concentrations greater than 2 x 10^{16} cm^{-3} (p-type) the as-deposited mobilities of the 1.4-1.6μ films are similar to the bulk mobilities. The electrical properties in this doping range are not significantly altered by thermal oxidation. These mobilities, both before and after oxidation, are at least double the mobilities of oxidized silicon on sapphire for equivalent doping levels (10). Below a doping level of 2 x 10^{16} cm^{-3} the as-deposited mobilities are nearly bulk to N_a as low as 5 x 10^{15} cm^{-3}, but the change in the mobility on thermal oxidation increases with decreasing carrier concentration below $N_a \approx 2 \times 10^{16}$ cm^{-3}. For sample 49, the μ = 350 cm^2/V-sec, which is 95% of bulk at N_a = 4.5 x 10^{15} cm^{-3}, decreased to μ = 55 cm^2/V-sec and N_a = 1.5 x 10^{15} cm^{-3} after thermal oxidation.

Doubling the deposition rate to 0.8 μ/min yields an improvement in the stability to oxidation at the low carrier concentrations (Table IB). The as-deposited μ = 335 cm^2/V-sec at N_a = 5.6 x 10^{15} cm^{-3} of sample 73 changed after oxidation to μ = 225 cm^2/V-sec at N_a = 4.2 x 10^{15} cm^{-3}. Although this represents a 33% decrease in mobility, it is appreciably more stable to oxidation than the sample 49 cited above.

Further improvement in thermal stability is realized by depositing the films at a growth rate of 2 μ/min

Table I. Silicon on spinel mobility and stability of mobility to thermal oxidation

Sample No.	Thermal treatment	N_a, cm^{-3}	Mobility cm^2/V-sec	% Decrease in μ on oxidation	% of Bulk (18), μ

Conditions for data in Table I:
Rates: ±10%
Substrate orientation: (111)
Substrate composition: x of $MgO \cdot x\ Al_2O_3$
A, 1.5 to 2.0
B, 1.7 to 2.0
C, 2.2
Thickness of deposits: 1.4 to 1.6μ
Thermal oxidation: A and B, 1 hr at 1200°C
C, 1 hr at 1100°C
Temperature of deposition: 1100°C

(Table IC). The as-deposited μ = 330 cm^2/V-sec at N_a = 4.9 x 10^{15} cm^{-3} of sample 170 changed after oxidation to μ = 300 cm^2/V-sec and N_a = 4.0 x 10^{15} cm^{-3}. This represents a decrease in mobility of less than 10%. The three samples cited, at the three growth rates, have very similar as-deposited characteristics, and therefore the effect of deposition rate on stability to thermal oxidation is clearly demonstrated. The similar as-deposited electrical characteristics also indicate that the substrate crystal quality is uniform from boule to boule. The electrical characteristics of the films have been a stronger function of the substrate surface crystallinity than the substrate composition within the compositional range employed. The effect of lowering the oxidation temperature by 100°C was checked by further oxidation of films at 1200°C. The change in mobilities after a second oxidation at the higher temperature were about equal in magnitude to the initial change, as has previously been observed for two oxidations at 1200°C. Even considering the total changes after two oxidations, the mobility degradation of the 2.0 μ/min rate samples is about half of the degradation of the 0.8 μ/min rate samples.

At carrier concentrations below 5 x 10^{15} cm^{-3}, and at a growth rate of 2 μ/min, the as-deposited mobility decreases, and the change in mobility on oxidation increases, with decreasing carrier concentration. It is interesting to note that the after-oxidation properties of two anomalous samples, 165 and 168, fall very nearly on the curve described by the other after-

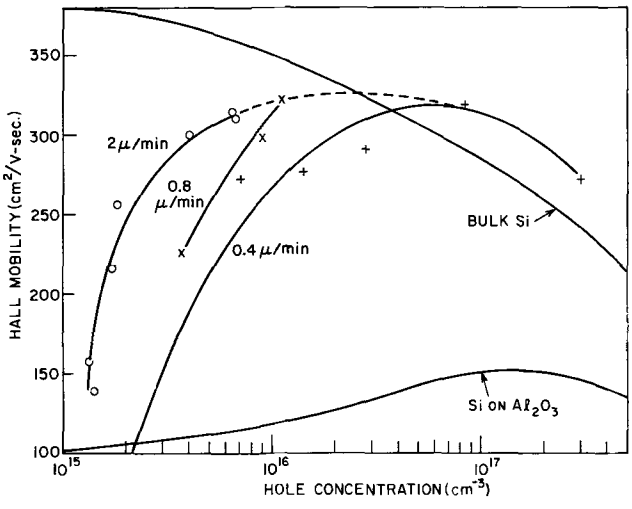

Fig. 3. Mobility as a function of hole concentration for oxidized 1.4-1.6μ thick (111) silicon on spinel, oxidized 2.0μ thick (100) silicon on sapphire, and bulk silicon.

oxidation samples deposited at the same rate (Fig. 3), even though the as-deposited mobilities are unusually low. This behavior is not understood at this time. All of the samples of Table IC were prepared from the same tank of silane-H_2, the same tank of diborane-H_2, and on substrates cut from the same spinel crystal. There is appreciable scatter in the properties of films with N_a< 5 x 10^{15} cm^{-3} because, for these doping levels, the magnitude of unintentionally added impurities is similar to that of the dopant, and therefore the quality of the deposits is critically dependent on the deposition parameters and nature of the substrate surface. Real but nonreproducible high mobilities have been obtained in a number of samples. At the lowest deposition rate an as-deposited mobility greater than 400 cm^2/V-sec was realized at a carrier concentration of 5.2 x 10^{15} cm^{-3}. This deposit was not oxidized. A mobility of 395 cm^2/V-sec was realized at N_a = 4.2 x 10^{16} cm^{-3}. The latter sample did not change significantly on oxidation.

In Fig. 3 a comparison is made between the mobility *vs.* hole concentration relationships of silicon on spinel, silicon on sapphire (10), and bulk silicon (21). The silicon films on the insulating substrates have been oxidized for 1 hr at 1200°C, with the exception of the 2.0 μ/min samples which were oxidized for 1 hr at 1100°C. The silicon on spinel films are 1.4-1.6μ in thickness, while the silicon on sapphire films are 2.0μ in thickness. The mobility *vs.* carrier concentration relationship of 2μ thick (111) silicon on (0001) sapphire has not been reported, presumably due to the difficulties involved in depositing silicon on (0001) sapphire. Therefore, it has been necessary to compare the (111) silicon on spinel with (100) silicon on sapphire. It has been shown, however, that for 2μ thick silicon on sapphire, the hole mobilities in (100) silicon are higher than in (111) silicon (22). Therefore, the data compared in Fig. 3 represent the optimum results that have been obtained to date on each of the insulating substrate materials. The bulk silicon curve included in Fig. 3 represents an average of experimental values collected from a number of sources (21). This curve has been used as a reference to calculate the per cent of bulk mobility values, for the silicon on spinel films, presented in Tables I and III.

In comparing the properties of silicon on spinel with silicon on sapphire it should also be pointed out that the hole concentrations of the silicon films on sapphire typically decrease by an order of magnitude on thermal oxidation (10) for films with as-deposited hole concentrations less than ~1 x 10^{17} cm^{-3}. The changes have been attributed to electrical deactivation during oxidation of aluminum contamination

from the substrate (22). Due to the "autodoping" effects from both spinel and sapphire, it is impractical to use as a standard of reference the electrical properties of silicon films with no dopant intentionally added.

Effect of hydrogen firing on the mobility of silicon on spinel.—The low mobilities which result from thermal oxidation of low carrier concentration films deposited at 0.4 μ/min may be driven back to at least the as-deposited value by exposure to a hydrogen atmosphere for 1 hr at 1100°C (see Table II). In both cases cited the carrier concentration increased during the hydrogen treatment. Similar characteristics have been observed in silicon films on sapphire (22).

Mobility as a function of silicon film thickness.—The mobility as a function of the Si film thickness, holding other variables as constant as possible, is presented in Table III. The carrier concentration was held in the mid 10^{16} cm^{-3} (p-type) because in this carrier concentration range the electrical properties are not so critically dependent on the deposition conditions. The deposits were grown at 1.1 μ/min. The thickness was monitored during growth by observing interference bands with an IR pyrometer, and the total deposit thickness was checked on the Cary spectrometer. The films were grown on 20 mil thick wafers cut from one $MgO \cdot 2.0Al_2O_3$ single crystal boule.

The mobility increases sharply with thickness between thicknesses of 0.6 and 3.1μ. At 3.1μ the mobility is 129% of the reference bulk silicon mobility (21) for an equivalent carrier concentration. Between 3.1 and 8.8μ the mobility does not appear to be a strong function of film thickness. The highest mobility of 430 cm^2/V-sec was obtained at a thickness of 10.5μ. The study was not carried beyond the 10.5μ thickness because silicon deposits above this value are of little interest for device applications and because the composite is fragile due to thermally induced stresses. In order to study thicker films, thicker substrates must be employed, but the values obtained using the thicker substrates are not directly comparable with values obtained using the thinner substrate because the compressive stresses (18, 19) are a function of the substrate thickness. At present the film thickness requirement for most device configurations is 1.5μ. At this thickness the mobility is approximately equal to the reference bulk mobility for the carrier concentration studied.

Table II. Effect of thermal treatment in oxidizing and reducing atmospheres on the electrical properties of low carrier concentration Si on spinel

Sample	N_a, cm^{-3}	Mobility, cm^2/V-sec	Thermal treatment
49	4.5×10^{15}	350	As-deposited
	1.5×10^{15}	50	O_2, 1200°C, 1 hr
	6.7×10^{15}	400	H_2, 1100°C, 1 hr
48	1.8×10^{15}	240	As-deposited
	ρ too high for Hall measurement		O_2, 1200°C, 1 hr
	7.7×10^{15}	280	H_2, 1100°C, 1 hr

Table III. Si on spinel mobility as a function of Si thickness

Thickness, μ	N_a, cm^{-3}	Mobility, cm^2/V-sec	% of bulk, μ
0.6	1.9×10^{16}	110	34
1.1	3.4×10^{16}	260	83
1.5	3.4×10^{16}	330	104
1.9	6.6×10^{16}	310	104
3.1	5.0×10^{16}	395	129
4.8	5.0×10^{16}	360	117
6.4	2.7×10^{16}	395	122
6.8	1.4×10^{16}	350	102
8.8	4.1×10^{16}	365	117
10.5	4.8×10^{16}	430	140

Rate of deposition: approx. 1.1 μ/min.
Substrate (111) $MgO \cdot 2.0Al_2O_3$.

The observed increase in mobility with increasing thickness between 0.6 and 3.1μ can be attributed in part to decreasing local concentrations of impurities from the substrate and increasing crystalline perfection, as the film grows away from the substrate. Charges at the surfaces, particularly at the substrate-film interface, undoubtedly exert a significant influence on the mobility. These factors are difficult to examine experimentally. If one neglects the effect of the surface charge, with a Debye length of 200Å (for a carrier concentration of 2×10^{16} cm^{-3}) and a carrier mean free path of 100Å (22), the surface scattering is confined to a maximum of $\sim$ 20% of the thinnest (0.6μ thick) film measured.

Carrier concentration as a function of temperature.—Hall measurements were made at temperatures between 77° and 300°K in a nitrogen gas ambient. The sample measured was a 1.5μ thick silicon film on (111) $MgO \cdot 1.7Al_2O_3$ spinel. The film was oxidized at 1200°C for 1 hr. The hole concentration *vs.* temperature for this film, and for comparably boron doped bulk silicon (23), is presented in Fig. 4. It is seen that the characteristics of the silicon on spinel film are in good agreement with bulk silicon. This demonstrates the absence of unknown deep level acceptors or compensating donors.

MOS capacitance vs. voltage characteristics of silicon on spinel.—Metal-oxide-semiconductor (MOS) capacitor units have been constructed and studied in silicon on spinel. The characteristics of the MOS units provide an assessment of the silicon-spinel system for various device applications.

Prior to oxidation, the sample was cleaned by a standard procedure (24) for removing organic contamination and metal ions from the surfaces. The silicon was oxidized (25) at about 1200°C to form a SiO_2 layer $\sim$ 1000Å thick, and then exposed to hydrogen at 500°C to reduce the interface states (26). Evaporated aluminum gate dots or mercury probes were used as the metal contacts of the silicon-on-spinel MOS system. The back contact was provided by etching off a part of the oxide and establishing a silver paste contact to the exposed silicon.

The capacitance (C) *vs.* bias voltage (V) characteristics (Fig. 5) of a typical sample were measured using an automatic C-V display system (27). The epitaxial silicon is 4μ thick with a carrier concentration of 3×10^{15} cm^{-3} (n-type) and an electron mobility of 1065 cm^2/V-sec. From Fig. 5 it is seen that the flatband voltage shift is less than 2V, and very little positive charge ($\sim 10^{11}$ cm^{-2}) is present in the oxide layer. The breakdown strength of the oxide film is greater than 10^6 V/cm.

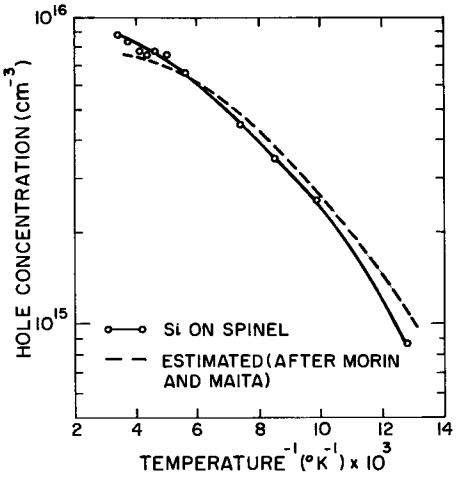

Fig. 4. Carrier concentration as a function of temperature for p-type silicon on spinel.

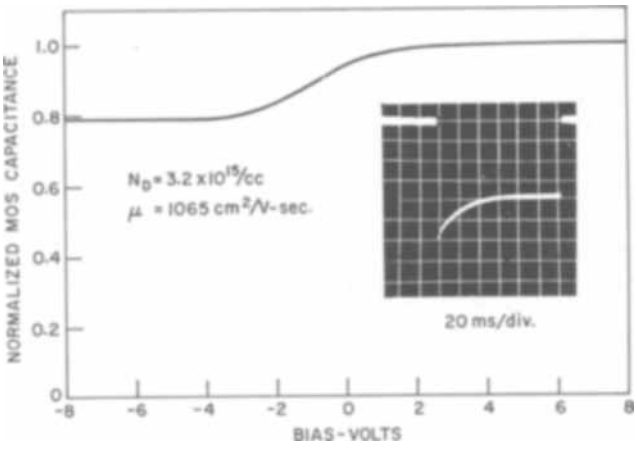

Fig. 5. Capacitance *vs.* bias characteristic and transient response of the inversion layer capacitance for an MOS capacitor in silicon on spinel.

The minority-carrier lifetime in the silicon was determined by the MOS transient response method (28). A step voltage is applied to the gate of an MOS capacitor of correct polarity to deplete the majority carriers from the semiconductor surface, and the rate at which the inversion layer forms is measured. A time constant T can be derived from measurements of the initial slope of the transient response curve, and the minority-carrier lifetime τ is related to T by

$$\tau = 1/2(Tn_i/N_A)$$

where N_A is the doping density and n_i is the intrinsic carrier density of the semiconductor. The transient response of the inversion layer capacitance is shown in the insert in Fig. 5. The time constant is $\sim$ 10 msec, giving a lifetime of over 40 nsec.

Minority carrier lifetimes of $\sim$ 0.1 nsec have been commonly measured in silicon on spinel MOS units prepared using the commercial alumina rich $MgO \cdot 3.3Al_2O_3$ spinel substrates. These low lifetimes are believed to be due to the poor crystallinity of the substrate and to heavy metal contamination (29, 30) from the substrate. The heavy metals are added to the commercial flame fusion spinel to improve the crystallinity. By using the pure low alumina rich spinel as a substrate material the minority carrier lifetime has been improved by more than a factor of 100. This also represents a considerable improvement over the 4.5 nsec lifetime (28) reported for 5μ thick 3 x 10^{16} cm^{-3} (boron doped) silicon on sapphire MOS structures.

Discussion

The mobility *vs.* hole concentration relationship in as-deposited 1.5-1.6μ thick (111) silicon films on spinel is similar to that of bulk silicon for carrier concentrations as low as 5 x 10^{15} cm^{-3}. The mobilities are considerably higher than have been obtained in 2μ thick (111) or (100) silicon on sapphire (10, 22). It is reasonable to assume that the closer silicon-substrate crystallographic match (11, 12), and the lower autodoping (14) of the silicon on spinel as compared to silicon on sapphire, are factors which contribute to the increase in the mobilities observed.

For hole concentrations greater than $\sim$ 2 x 10^{16} cm^{-3} the as-deposited mobilities are relatively insensitive to the deposition rate between rates of 0.4-2.0 μ/min, and the mobilities change insignificantly on thermal oxidation of 1 hr at 1100°C. However, below hole concentrations of $\sim$ 2 x 10^{16} cm^{-3}, the mobilities of the oxidized films decrease with decreasing carrier concentration, the magnitude of the degradation of mobility on thermal oxidation increases with decreasing carrier concentration, and after-oxidation mobilities are highly sensitive to the deposition rate. The near-bulk as-deposited mobilities and degradation induced by thermal oxidation suggest that the after-oxidation low carrier concentration mobilities are more limited by the influence of unintentionally added impurities than by the crystalline imperfections in the film. The electrical properties of the silicon deposited at the highest rate used (2.0 μ/min) are the least sensitive to thermal oxidation. This is consistent with observations that rapid coverage (31) of the substrate suppresses contamination of the growing silicon film by gaseous reaction products (32) from the substrate material.

The sharp decrease observed in the after-oxidation mobility with decreasing carrier concentration below $N_a \sim 5 \times 10^{15}$ cm^{-3} is difficult to explain since the concentration of the unintentionally added impurities is not a function of the doping level. A possible explanation is an increase in the space charge region around inhomogeneously distributed defects as the doping level is decreased for carrier concentrations less than 2 x 10^{16} cm^{-3}. Weisberg (33) has proposed this model to explain a similar decrease in mobility with decreasing carrier concentration observed in the III-V compounds. As the carrier concentration is decreased, due to an increasing space charge region, the effective radius of a heterogeneity may increase to an order of magnitude higher than the physical size of the heterogeneity. Under these circumstances, the mobility decreases with decreasing carrier concentration. In the III-V compounds the inhomogeneously distributed defects have been identified with compositional variations. In the silicon on spinel films, the heterogeneities may be impurities concentrated in lattice defects. Because of the critical dependence of the mobility on the deposition rate the effects observed are assigned to impurities from the substrate, such as aluminum, rather than impurities in the deposition gases. The decrease in mobility on thermal oxidation may then be associated with a change in oxidation state of the aluminum with a corresponding change in the space charge region around the aluminum.

It has recently been demonstrated that compressive stresses introduced into the silicon film during cooling of the silicon-spinel composite from the deposition temperature can result in significant enhancement of the hole mobility in the (111) plane (19). Thus, in addition to the good silicon-spinel lattice match and the decrease in autodoping, the stress in the film may contribute to the relatively high hole mobilities observed in the (111) silicon on spinel.

Brief Communication

Growth of Single Crystal GaP from Organometallic Sources

Robert W. Thomas

Department of Electrical Engineering, Syracuse University, Syracuse, New York

Single crystal growth of GaP on the (111) face of a silicon substrate has been achieved at atmospheric pressure by the thermal decomposition of a gas phase mixture of gallium triethyl and phosphorous triethyl at 485°C.

The system used for this experiment was designed for epitaxial growth of silicon on silicon by the pyrolysis of silicon tetrachloride. No substantial changes were made in the system with the exception that a nonchlorinated fluorocarbon grease was used throughout and extreme attention was paid to the elimination of atmospheric leaks. The system consists of a vertical flow reaction chamber, a single crystal silicon susceptor heated by rf induction, palladium purified hydrogen carrier gas, and liquid source flasks in a temperature controlled bath.

The growth was preceded by a high temperature bake-out (1260°C) in hydrogen. The proper growth mixture was obtained by electron microprobe analysis of the resulting growth layer.

Kα lines of Ga and P at 20 kV were used for the electron microprobe analysis. Sample growth was compared with a single crystalline standard under the same measurement conditions. Gallium to phosphorous ratios corrected for background only, were 3.85 to 1. This was well within the margin of error of the GaP standard crystal measurements.

The growth was transparent and showed the characteristically brilliant interference fringes commonly observed for SiO_2. Growth thickness was measured by angle lapping and shown to vary from 2700 to 4500Å over the surface area. The deposition time for this thickness was 2 hr.

Reflection electron diffraction measurements were made on the films (see Fig. 1). The results of this analysis substantiated the single crystalline nature of the film. The film was shown to be (111) in orientation and single crystalline over the entire 1 in. silicon substrate. The satellite spots occurring at approximately 1/3 the major lattice spacing are thought to be either due to some twinning or a super lattice at the surface. The exact nature of the GaP surface super lattice has not been confirmed as yet. Electrical measurements of the film showed it to be conducting with a conductivity somewhat lower than the 1 ohm-cm substrate. Although the measurements were made with a mercury probe the surface effects made an exact measurement very difficult. Mesa heterodiodes were made by selective etching using an apiezon mask. These diodes exhibited rectification with reverse breakdown knees between 15 and 50V. The absence of gallium or phosphorous diffusion into the silicon was verified by V-I measurements on the stripped silicon surface and by angle lapping and staining techniques. Electrical characterization of the film and heterojunction will be

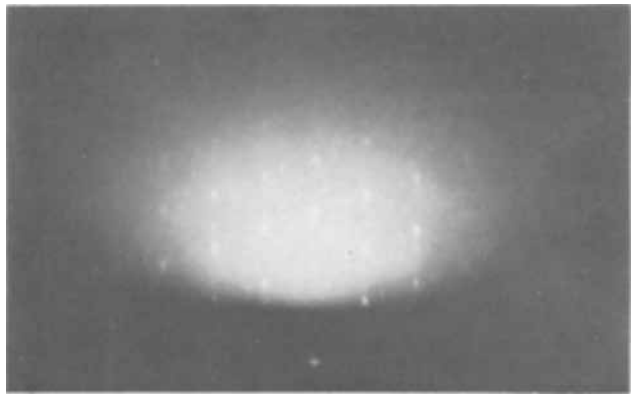

Fig. 1. Reflection electron diffraction pattern of gallium phosphide on silicon.

carried out when suitable ohmic contacts on the film are made.

A word of caution is included on the reactivity and toxicity of these organometallic compounds. Phosphorous triethyl was demonstrated to be stable in air and water but has been reported previously to react violently under certain oxygen pressures. This compound is closely related to several nerve gases and should be considered highly toxic. Gallium triethyl was demonstrated to be highly unstable in air and reacted with explosive violence. Its toxicity is not known. However, both of these compounds are highly aromatic and will give an appropriate warning to the user when inhaled in very low concentrations.

Present work on the growth of thicker films and the electrical characterization of the resulting heterojunctions are to be reported at a later date.

A High-Voltage, Solid-State Battery System

II. Fabrication of Thin-Film Cells

Charles C. Liang,* James Epstein,* and Gerard H. Boyle*

Laboratory for Physical Science, P. R. Mallory & Company Incorporated, Burlington, Massachusetts

ABSTRACT

The cell fabrication processes were studied of a high-voltage, solid-state battery system, Li/LiI/AgI. Thin-film cells were made by the following procedures: (*a*) AgI was sprayed on a Ag foil and run through a three-zone furnace to melt the AgI film on the foil; (*b*) LiI electrolyte was vacuum deposited on the AgI film; (c) Li was vacuum deposited on the electrolyte. In order to obtain a pinhole-free electrolyte layer, the thickness of the LiI film must be in excess of 5μ The yield of the thin-film cells with the expected open-circuit voltage of 2.1V was affected by the substrate temperature during Li deposition. It was found that, when the temperature of the substrate was properly controlled and the thickness of the LiI film exceeded 15μ, the yield could be as high as 95%.

The cell structure of a high-voltage, solid-state battery system Li/LiI/AgI was considered in a previous publication (1). It was concluded that, due to the high resistivity of the electrolyte and discharge product LiI, a thin-film multilayer parallel-connected cell structure must be developed if practical, interesting current-carrying capabilities are to be achieved.

One of the major tasks in the construction of a thin-film multilayer parallel-connected cell is the fabrication of the thin-film cell units. The present investigation was undertaken to study the fabrication processes for such thin-film cell units.

Experimental

Formation of the cathode.—Mallinckrodt silver iodide powder was used as the cathode material. It was blended with water in a Virtis blender to form a AgI-H_2O slurry. The slurry was sprayed on a heated (150°±10°C) 25μ thick silver foil. The silver iodide and silver foil were then passed through a 30-in. long three-zone furnace (Fig. 1) to fuse the silver iodide film onto the silver foil. Three thermocouples were mounted at points 5 in., 15 in., and 25 in. from the entrance of the furnace and the temperatures at these points were controlled by means of West model JL controllers at 200°, 600°, and 200°C, respectively. The silver iodide coated silver foil was sent through the furnace by means of a conveyor belt driven by a Bodine variable speed motor.

The silver iodide film formed by this process was tightly bonded to the silver foil and the surface of the film was reasonably smooth.

Cathodes of various sizes were stamped from the coated foil and mounted in the substrate holder (Fig. 2) for the vacuum depositions of electrolytes and anodes.

Deposition of the electrolyte.—Foote Mineral LiI · $3H_2O$ was melted at 100°C and the molten LiI · $3H_2O$ was filtered through glass wool maintained at 100°C. The filtrate was then dried in a vacuum oven at 250°C for at least 16 hr. The dried LiI was vacuum deposited on the silver iodide cathode as the electrolyte.

A Consolidated Vacuum Corporation Economy Coater type CVE-19 vacuum system was used for the deposition process. A Vacuum Atmosphere Corporation model Vac-Lab HE-233-46 vacuum box served as the vacuum chamber during the vacuum deposition process and as the inert atmosphere chamber before and after the deposition.

The deposition setup shown in Fig. 3 contained a lithium iodide deposition and a lithium deposition compartment separated by a steel shield. The evaporation sources, a tantalum boat containing lithium iodide and a cylindrical titanium crucible containing lithium, were mounted approximately 1 in. above the base plate. Lithium iodide was evaporated by passing current through the tantalum boat directly, whereas lithium was evaporated by passing current through a heating coil which in turn heated the titanium crucible. The substrate holder with the cathodes in position was installed in the slots of a cooling plate positioned 10-12 in. above the evaporation sources. At the center of the cooling plate in each compartment, a sensor head of a Sloan model OMNI-II deposit control master was installed facing the evaporation source for the purpose of controlling the deposition rate and measuring the film thickness. In the lithium deposition compartment, a mask was mounted on the cooling plate and extended below the substrate holder so that the diameter of the lithium deposit would be slightly smaller than that of the electrolyte to avoid any possibility of shorting between the two electrodes. The substrate holder could be moved from one compartment to the other by a gear controlled from the outside of the vacuum chamber.

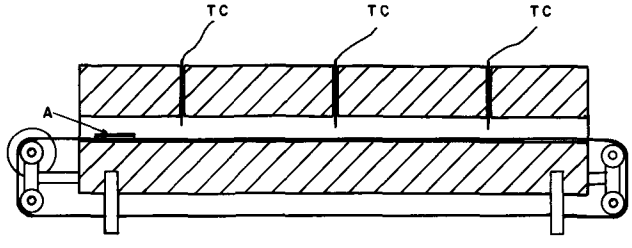

Fig. 1. Three-zone furnace: TC = thermocouple; A = Ag/AgI foil.

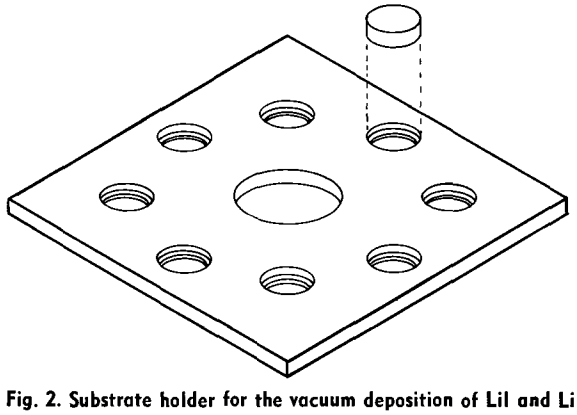

Fig. 2. Substrate holder for the vacuum deposition of LiI and Li

* Electrochemical Society Active Member.

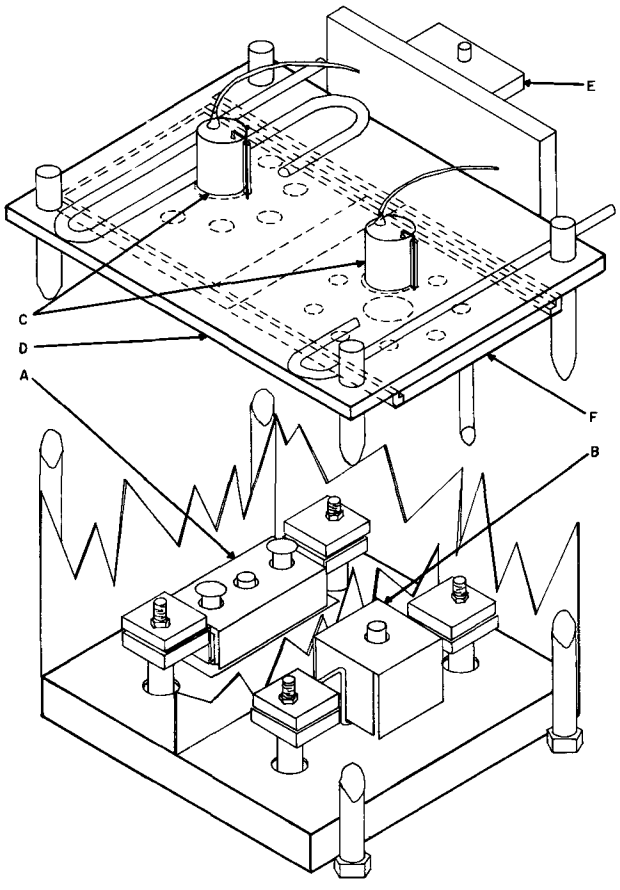

Fig. 3. Deposition setup: A—LiI source, B—Li source, C—Sloan OMNI-II Sensor Head, D—cooling plate, E—substrate position control, F—Li deposition mask.

The deposition of lithium iodide on the silver iodide cathode was carried out under a pressure of 2 to 8 x 10^{-6} mm Hg and the deposition rate was controlled at 0.03-0.08 μ/sec by means of the Sloan model OMNI-II deposit control master.

Deposition of the anode.—Foote Mineral reactor-grade lithium rods (99.983% pure) were used as the raw material for the deposition of the anodes.

After the lithium iodide deposition, the substrate holder was moved to the lithium deposition compartment and the lithium anodes were deposited at a rate of 3 ± 1 mμ/sec under a pressure of 2-5 x 10^{-6} mm Hg.

Polarization studies.—The thin-film cells were tested in the vacuum box under an argon atmosphere. Cell voltages were measured by means of a Keithly Model 610B electrometer and recorded by a Varian G14A strip chart recorder. An Electronic Measurements model C631 constant current power supply was used for the polarization of the test cells under constant current conditions. For the construction of the polarization curve, the cell voltage readings were taken after the constant current had been applied for at least 10 min to reach a steady-state condition. All the tests were carried out at temperatures of 25° ± 2°C.

Results and Discussion

The spray-melting process produced satisfactory cathode films. The adherence of the cathode film was tested by attempting to separate the silver iodide film from the silver foil by rubbing the silver iodide surface with a silver foil. In addition, the resistance of the silver iodide film was measured between the silver substrate and an amalgamated silver electrode with known surface area. It was found that the measured resistance of the cathode film agreed reasonably well (± 10%) with the expected value calculated from the conductivity of silver iodide (5). The uniformity of the film depended on the speed at which the sprayed film was passed through the three-zone furnace. At a speed of 15 in./min, the melted cathode film was very smooth and the variations in the film thickness were less than 20% of the film thickness.

The dehydration process for lithium iodide was carefully controlled to avoid hydrolysis. It was found that the upper limit of the drying temperature for the dehydration process in the vacuum oven was 250°C. At temperatures above 250°C, extensive hydrolysis would occur. In fact, even under the present experimental conditions, hydrolysis occurred to some extent as shown by the fact that a 1M LiI solution prepared from the evaporated lithium iodide exhibited a *p*H of 9 at 25°C. However, no apparent effect on the cell operation was observed by the presence of the small amount of LiOH in the electrolyte. This was shown by the fact that the discharge characteristics of the cell containing the 250°C vacuum oven dried lithium iodide was similar to that of the cell containing the 60°C vacuum oven dried lithium iodide.

One of the most critical operations in the fabrication of the thin film Li/LiI/AgI cells was the vacuum deposition of the lithium iodide electrolyte film on the cathode. The electrolyte film must be pinhole free to prevent internal shorting between the two electrodes. It was found that, in order to obtain a smooth and coherent lithium iodide film on the silver iodide cathode, the substrate should be maintained at a low temperature by circulating a refrigerant through the cooling plate, preferably below —20°C. However, more importantly, the thickness of the deposited lithium iodide film determined the effectiveness of the film as a separator between the two electrodes. It was found that, in order to obtain a pinhole-free lithium iodide film on the cathode, the thickness of the film must be greater than 5μ. This was evident as the results showed that practically all of the thin-film Li/LiI/AgI cells were short-circuited and exhibited 0V as their open-circuit voltages when the deposited lithium iodide film was less than 5μ thick.

Table I shows the effect of the electrolyte film thickness on the yield of the thin-film cells with the expected 2.1V open-circuit voltage. It was noted that an acceptable yield of 95% was obtained as the film thickness reached 15μ.

The temperature of the substrate during the lithium deposition on the electrolyte film had a distinct effect on the characteristics of the thin-film cell. Lithium was deposited on lithium iodide under the following conditions:

(*a*) No heat shield was installed between the substrate and the evaporation source. The radiative heat from the evaporation source reached the substrate and caused a temperature rise.

(*b*) A heat shield was applied to block most of the radiative heat from reaching the substrate.

(c) In addition to the heat shield, the substrate was cooled by circulating tap water through the cooling plate.

(*d*) In addition to the heat shield, the substrate was cooled by circulating a refrigerant at —20°C through the cooling plate.

Table I. The effectiveness of the LiI film as a separator as a function of film thickness*

LiI film thickness, μ	Total No. of cells fabricated	No. of cells exhibiting open-circuit voltage of 2.1V	Yield, %
1	48	0	0
2	48	0	0
5	48	2	3.6
10	48	30	62
15	56	53	95

* Temperature of the substrate was controlled as —20°C during the deposition of LiI and Li.

Table II. The effect of substrate temperature during the Li deposition on the yield of thin-film cells*

Li deposition condition	Total No. of cells fabricated	No. of cells exhibiting open-circuit voltage of 2.1V	Yield, %
No heat shield	56	0	0
With heat shield	56	0	0
Substrate was cooled by tap water	56	15	27
Substrate was cooled by refrigerant at −20°C	56	53	95

* The thickness of electrolyte = 15μ.

Table II summarizes the results from these studies. It was evident that the temperature of the substrate during the lithium deposition had a pronounced effect on the yield of the process.

The effect of the substrate temperature on the yield of the process was to be expected. It is well known (2) that, when an alkali-halide crystal is heated in the vapor of the corresponding alkali metal, it acquires a nonstoichiometric excess of alkali metal to form "color centers" which increase its electronic conductivity. If the temperature of the substrate was not properly controlled during the deposition of lithium on lithium iodide, conditions favoring the formation of color centers in lithium iodide were indeed present. Lithium iodide was heated by the radiative heat from the evaporation source and the lithium vapor was in direct contact with the heated lithium iodide. In addition, the high temperature of the substrate could also cause diffusion of lithium atoms through the electrolyte, resulting in electronic conductivity. Therefore, it was imperative to cool the substrate properly during the deposition of lithium so that the lithium iodide electrolyte would not acquire an excess of lithium to become an electronic conductor.

The geometrical area of the anode of all the test cells was 2.36 cm^2 and the thicknesses of the components of the cell were typically: silver current collector, 25μ; silver iodide cathode, 30μ; lithium iodide electrolyte, 15μ; and lithium anode, 4μ.

The thin-film cell had an open-circuit of 2.1V which agreed well with the value of 2.09V calculated from the Gibbs free energy change (3) for the reaction:

$$Li + AgI \rightarrow LiI + Ag$$

and it confirmed this to be the discharge reaction of the cell. From the linearity of the polarization curve of the Li/LiI/AgI thin film cell (Fig. 4), it was concluded that the cell impedance was ohmic in nature and the resistivity of lithium iodide was calculated to be 1.17 x 10^7 ohm-cm (4). The resistivity of silver iodide, 10^4 ohm-cm (5), was negligible in comparison with that of lithium iodide.

The discharge curves of the thin-film cells under various constant loads are shown in Fig. 5. The discharge efficiencies were approximately 50% and the current capabilities of the cells demonstrated the usefulness of the system for low rate applications especially in view of the fact that the current capability can be increased by parallel connecting such thin-film cells.

The initial voltage decay of the thin-film cell during discharge agreed well with the expected increase in cell resistance due to the production of lithium iodide. However, a more severe decrease in cell voltage occurred when the cell reached about 20% depth of discharge. The polarization characteristics of the system are sufficiently complex to deserve a separate discussion in a subsequent publication.

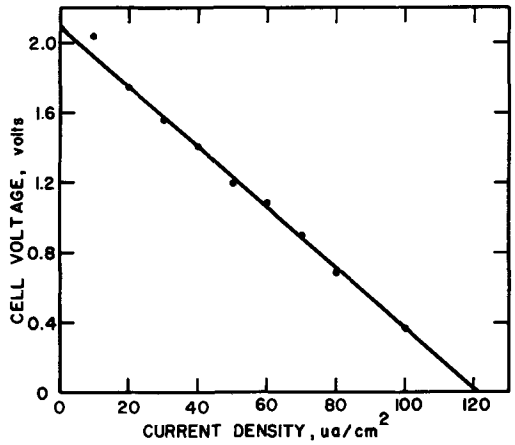

Fig. 4. Typical polarization curve of Li/LiI/AgI thin-film cell. Temperature: 25° ± 2°C. Cell dimensions: geometrical area = 2.36 cm^2, anode thickness = 0.4 x 10^{-3} cm, electrolyte thickness = 1.5 x 10^{-3} cm, cathode thickness = 3.0 x 10^{-3} cm.

Mechanism of Bonding Electroless Metal to Organic Substrates

G. V. Elmore* and K. C. Davis

International Business Machines Corporation, CD-Manufacturing Research Laboratory, Endicott, New York

ABSTRACT

The use of electroless metal bonded organic substrates has many possible applications. The present state-of-the-art is limited to a few organic substrates. Initial studies included the mechanism of bonding electroless copper to acrylonitrile-butadiene-styrene and to polysulfone. This was investigated by using a scanning electron microscope to view the interfacial surfaces of substrates subsequent to chemical processing and electroless and electrolytic plating. The examination revealed that interlocking surfaces were present which permitted mechanical interaction at the copper-organic interface. When these surfaces were replicated on epoxy, bonding between this surface and electroless copper was obtained.

This investigation was performed to examine the mechanism of bonding electroless copper to organic substrates. Previous investigators of this bonding mechanism have been divided essentially into two groups. There are those who feel the mechanism is mainly a mechanical interlocking type bond (1, 2, 5, 6, 9, 10), while others are of the opinion that the etchant chemically alters the surface of the substrate so that chemical bonding of the substrate and electroless metal takes place (3, 7). A review of the theoretical studies has been given by Saubestre (8).

Examination of Treated Surfaces

As an initial step in this investigation, a study was made of interfacial surfaces of electroless copper and treated acrylonitrile-butadiene-styrene (ABS) utilizing the scanning electron microscope (SEM). The SEM is particularly suitable for this study because replication is not required, the depth of focus is excellent, and the high magnification is very desirable. Electron microscope photographs of conditioned ABS have been previously published (1, 4, 9, 10). Also, scanning electron microscope photographs of conditioned polysulfone have been published by Ryan *et al.* (6). Zahn and Wiebusch (10) postulate that the conditioning of the surface results in a loss of butadiene that was present as dispersed spheroids in the acrylonitrile-styrene matrix. The conditioner attacks the butadiene at a faster rate than the acrylonitrile-styrene, thus leaving spheroidal voids in the surface. In this study, SEM photographs of the treated ABS were made; and, in addition, SEM photographs of the copper interface were taken.

Plating-grade ABS (obtained from Marbon Chemical Division of Borg-Warner Corporation) 0.090 in. thick, was treated for 15 min in chromic-sulfuric etchant at 65°C. The prepared sheet was subsequently plated with electroless copper and then electroplated to 0.001 in. of copper with copper pyrophosphate electrolyte. The peel strength was 5 lb/in. peel (Jacquet 90° peel test). The SEM was used to take photographs of the plastic and copper. Figure 1 illustrates the surface of the untreated ABS at 10000 magnification. Figure 2 illustrates, at 7000 magnification, the ABS surface after a conditioning treatment. Figure 2 shows, in the same manner as previously illustrated by other investigators (1, 4, 9, 10), that the treatment has preferentially etched cavities in the surface. Figure 3 illustrates, at 5000 magnification, the ABS surface after peeling of the copper. The surface of the plastic has been torn by the peeling action, indicating the fracture occurred in the ABS substrate. Figure 4 similarly illustrates, at 7000 magnification, the copper surface after peeling; the particles of ABS torn away during peeling partially cover the copper spheroids. Figure 5 illustrates, at 10000 magnification, the copper surface after the ABS particles have been removed with acetone. The spheres of copper which are clearly visible had filled the holes in the ABS left by the etchant. Thus, the interlocking mechanical bond

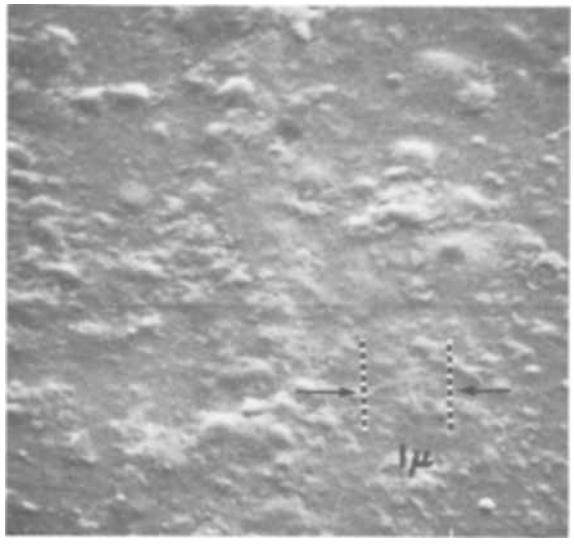

Fig. 1. Untreated ABS surface

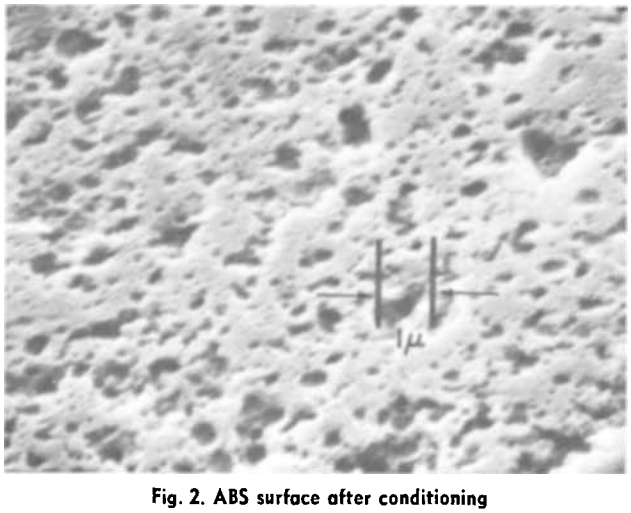

Fig. 2. ABS surface after conditioning

* Electrochemical Society Active Member.

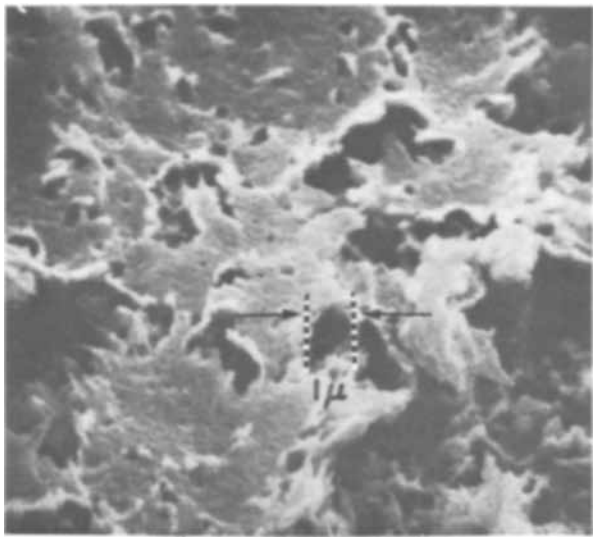

Fig. 3. Treated and plated ABS after copper has been peeled

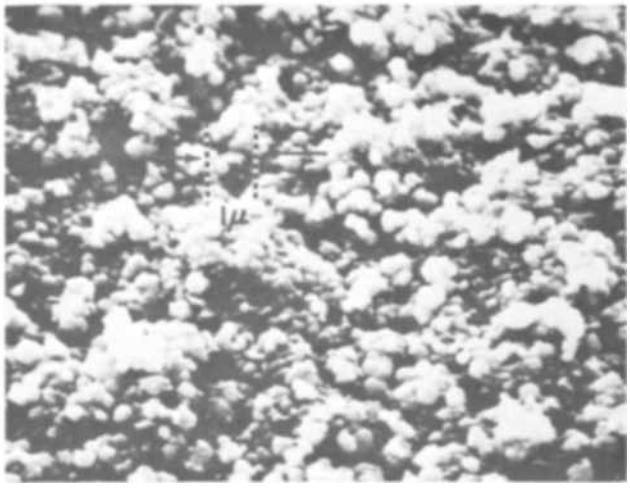

Fig. 4. Copper surface after peeling from treated ABS

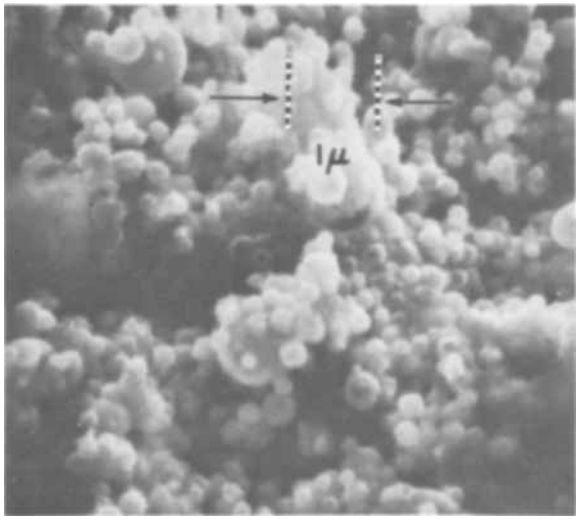

Fig. 5. Cleaned copper surface after peeling from treated ABS

formed between the copper and the treated ABS is clearly demonstrated.

Enthone and Union Carbide, in conjunction, have developed a method of treating polysulfone that yields a good bond between electroless copper and the polysulfone. Samples of copper-plated polysulfone

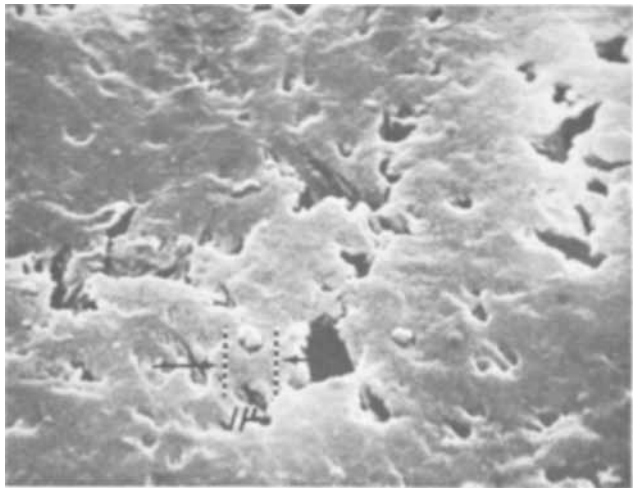

Fig. 6. Treated polysulfone surface

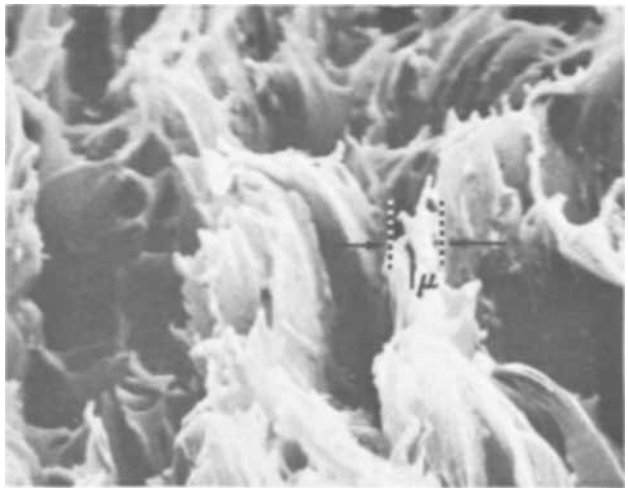

Fig. 7. Treated polysulfone after copper has been peeled

were obtained from Enthone. An additional electroplating with pyrophosphate copper was added to the samples increasing the copper thickness to 0.001 in. The resulting peel strength was 11 lb/in.

A set of SEM photographs was taken similar to those of the ABS samples. Figure 6 illustrates the treated polysulfone surfaces at 7000 magnification. Similar SEM photographs have been published by Ryan (6). Figure 7 illustrates, at 7000 magnification, the polysulfone surface after the copper has been peeled. The polysulfone has been stretched by the peeling action as the copper was removed from the crevices. Figure 8 illustrates, at 7000 magnification, the peeled copper surface with an intermingling of copper and polysulfone. Figure 9 illustrates the copper surface after cleaning with methylene chloride; the interlocking nature of the copper and polysulfone is again quite evident.

Replication of Treated Surfaces

To determine whether the nature of the substrate had an effect on the bond, assuming the same surface roughness, a copper surface treated for bonding by the Clevite Company was replicated on various substrates. A sheet of fluorinated ethylene propylene copolymer (FEP) was molded to this treated copper surface at 500 psi and 280°C. A sheet of polysulfone was molded at 500 psi and 280°C to the surface of treated Clevite copper. Lastly, an epoxy-glass laminate was molded to the surface of treated Clevite copper at 500 psi and 170°C. Then the Clevite copper was removed with ammonium persulfate copper etchant.

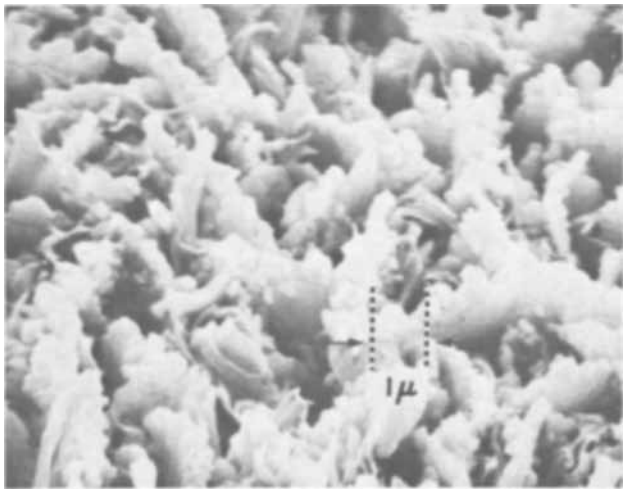

Fig. 8. Copper surface after peeling from treated polysulfone

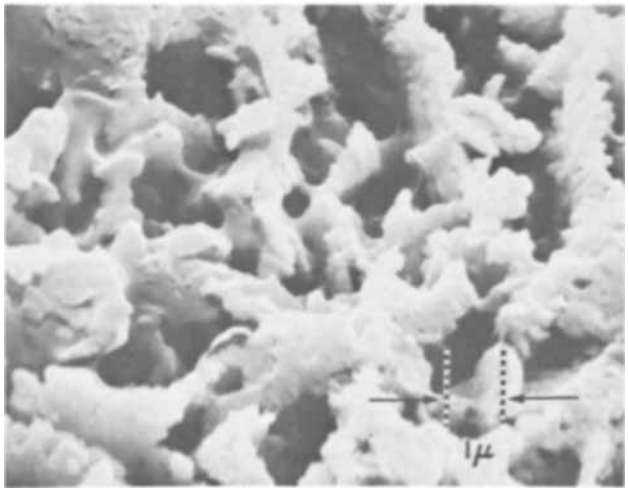

Fig. 9. Cleaned copper surface after peeling from treated polysulfone.

Figure 10 illustrates, at 2800 magnification, the surface of the epoxy after this treatment. The surface of the FEP and of the polysulfone was the same. After rinsing, the three different substrates—with a matte finish that is wetted by water—were plated with electroless and electrolytic copper to 0.001 in. in thickness. The resulting bonds after heating at 170°C for 15 min were all in the same range from ½ to ¾ lb/in. in peel strength. The copper, upon peeling, had the appearance of the original Clevite copper and did not change color in HCl, which is a characteristic of treated Clevite copper.

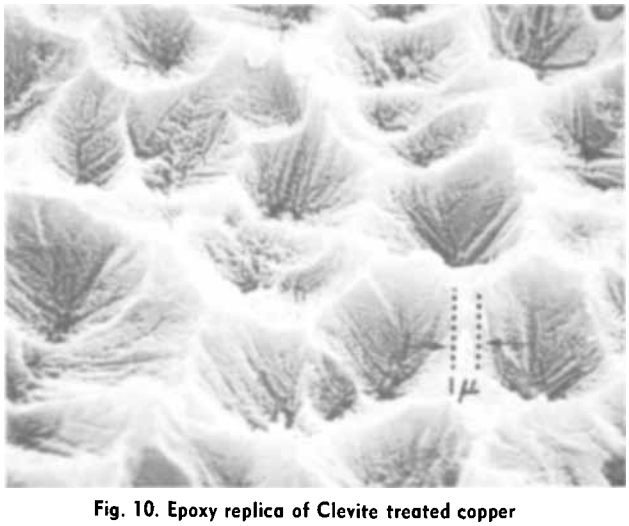

Fig. 10. Epoxy replica of Clevite treated copper

This type of roughness is sufficient for bonding molten substrate to copper but is insufficient to obtain good bonding of organic substrate to electroless copper. Logie (3) has found that a copper surface taken from conditioned ABS can be molded to ABS to yield a bond of 15 lb/in. As can be seen from Fig. 10, the microroughness of the Clevite surface is much less than either treated ABS or polysulfone. However, if the substrate is melted and processed onto the Clevite copper, different mechanisms of bonding are a factor. Not only is much more intimate contact and exact matching obtained than when electroless copper is formed on the surface but, also, when the substrate is liquid, possibilities of chemical interaction between substrate and copper are much enhanced. Thus, Clevite copper bonded to epoxy-glass by lamination produced bonds with peel strength of approximately 10 lb/in. Even when the possibility of chemical reaction is low, if a liquid substrate is contacted with the Clevite replicated surface, an excellent bond is obtained. Thus, when uncured epoxy in solvent is poured on the replicated Clevite-FEP surface, dried, and cured at 170°C, the materials could not be separated without badly tearing the FEP.

To determine if epoxy with a surface texture of treated ABS or treated polysulfone could have a good bond to electroless copper, the surfaces were replicated in epoxy. The replications were made in every case without the use of pressure because it had been found that application of pressure, while the organic substrate was liquid, flattened and distorted the copper surface that was being replicated. Logie and Rantell (3) have previously done studies with ABS replicated surfaces. For the polysulfone, the replication was accomplished by beginning with Enthone copper-clad polysulfone. The treated polysulfone was removed from the deposited copper by dissolving the polysulfone in methylene chloride. After hot alkaline-anodic-cleaning, a brominated epoxy in solvent (25% solids) was poured on the surface, dried, and cured at 170°C. This was then backed with a thick layer of 100% solid epoxy and cured. The copper was then removed with ammonium persulfate copper etchant, the board was rinsed, and electroless and electrolytic copper were applied. After aging for 1 day, the peel strength was 3 lb/in. After 5 days of aging at room temperature, the peel strength increased from 3 to 5 lb/in. The original polysulfone-copper bond of 10-12 lb/in. was not duplicated because of differences in elasticity between the polysulfone and epoxy. Higher bonds are always obtained when the substrate is flexible than when it is brittle. When smooth epoxy is treated with ammonium persulfate copper etchant and electroless and electrolytic copper is applied, there is essentially no bond.

The experiment was repeated with plating-grade ABS. In this test, the original bond of ABS copper was 10-12 lb/in. The ABS was removed with acetone; however, because of pigmentation and a nonhomogeneous nature, the last traces of ABS were much more difficult to remove than the polysulfone. After vapor degreasing and a hot alkaline anodic-cleaning, the copper was treated with concentrated H_2SO_4 for 5 min, rinsed, and dried. The brominated epoxy was applied as previously described and the same procedures were followed. Initially, the peel strength was ¾ lb/in. After heating for 15 min at 170°C, the peel strength was 4 lb/in. The ABS and polysulfone also indicated similar increased bond strength with aging either at room temperature or at elevated temperatures.

Investigation of Aging

The increase of bond with aging is caused by changes occurring in the surface of the substrate. This is indicated by the appearance of the copper when

it is peeled away. On freshly plated samples of ABS, the copper, when peeled, has no ABS on the surface of the copper. As the sample ages, more and more ABS is pulled off with the copper, indicating a gradual strengthening of the cohesive strength of the surface layers of ABS. Undoubtedly, the conditioning agent affects the acrylonitrile-styrene, weakening and altering the surface of the ABS. In this investigation, it has been found that the rate of improvement in copper-ABS bond during aging is greatly accelerated if the ABS is clad only on one side with copper compared to ABS clad on both sides with copper. It would appear that a diffusion-controlled reaction occurs which affects improvement of bond with aging. Perhaps the conditioning makes the ABS surface more susceptible to water adsorption from the solutions, thus weakening the strength. As the adsorbed water diffuses away from the surface layers, the strength of the surface layers increases. Even in substrates which have had no conditioning, a film of water solution or hydrated compounds, such as $Sn(OH)_2$, may be initially present between the copper and organic substrate, since the copper is formed from solution, thus weakening the bond until diffusion of this layer from the surface occurs. Vacuum aging of ABS samples increased rate of improvement of bond; aging in water or 100% humid air impeded the improvement of bond with aging.

From this work, it is concluded that good bonding of epoxy to electroless copper can be obtained if the epoxy has the surface roughness characteristics of ABS or polysulfone.

Conclusions

On the basis of the replication experiments and the scanning electron microscope photographs of treated samples, it may be concluded that a major factor contributing to good bonding between organic substrate and electroless copper is a mechanical interlock of the bonding surfaces. The results do not disprove that chemical bonding does not also take place; however, no significant bond has been obtained on samples that were seen to be smooth by SEM photographs.

Acknowledgments

The authors wish to acknowledge the invaluable assistance of J. B. Kurzweil and W. R. Merwarth, MRL Electron and Ion Beam Development, in obtaining the SEM photographs.

Measurement of the Throwing Power of Electrolytes Used in Electrochemical Machining

P. A. Brook and Q. Iqbal[1]

Department of Metallurgy, University of Nottingham, Nottingham, England

ABSTRACT

A method of measuring the throwing power of solutions under conditions pertinent to electrochemical machining has been developed, based on the Haring-Blum cell. Results on solutions of sodium chloride and sodium chlorate show that the latter has a lower throwing power under the present conditions in agreement with previously reported data. Additions of 0.12% potassium dichromate and of 1% benztriazole to sodium chloride solutions reduced the throwing power to values comparable to those of the chlorate solutions. The results are discussed in terms of passivation effects.

Recent advances in the technology of electrochemical machining (ECM) make increasingly stringent demands on the electrolytes used. Increased productivity calls for higher currents (and current densities) which in turn require electrolytes with greater electrical conductivities. To use the current at the optimum efficiency, the "stray cutting," *i.e.* the anodic dissolution from areas not directly opposite the cathode, must be reduced to a minimum and, for ease of tool design, a very close correspondence between the tool and the final machined anode is required. For many years, electroplaters have been concerned with a related problem and have measured the ability of a solution to give a deposit over a complex cathode by its "throwing power." Normally a uniform deposit is required, corresponding to a throwing power of 100%. In the case of ECM a low, or even negative, throwing power is required to reduce stray cutting, which could be eliminated when the throwing power approaches $-\infty$.

Thus if we want to machine a simple re-entrant (Fig. 1) using a tool EFGHJK and an anode ABDC, the current density, and hence dissolution, should be large across BD opposite GH but should be zero across

[1] On study leave from West Pakistan University of Engineering and Technology, Lahore.

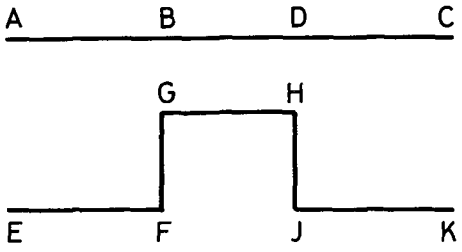

Fig. 1. Arrangement of nonuniform electrodes

AB and DC. The reverse problem of deposition onto EFGHJK requires a uniform current density over the whole surface.

The throwing power of a plating bath is normally measured in a Haring-Blum cell (1) and calculated by means of one of the following formulas (1-4):

$$TP = ((P - M)/P)\ 100 \quad [1]$$

$$TP = ((P - M)/(P - 1))\ 100 \quad [2]$$

$$TP = ((P - M)/(P + M - 2))\ 100 \quad [3]$$

where P is the linear ratio, *i.e.* the ratio of the distances of the equipotential plane parallel cathodes from the anode, and M is the metal distribution ratio, *i.e.* ratio of the weights of the metal deposited on the cathodes. The advantages and disadvantages of these formulas have been discussed frequently and it is sufficient to say that [3] is in general use in the U.K.

The arguments (4) used to support formula [3] for throwing power in electrodeposition have an equal validity when anodic processes are being discussed, and in this paper all throwing powers have been calculated on this formula with the minor alteration that the metal distribution ratio is now the ratio of weight of metal dissolved from the nearer anode/weight of metal dissolved from the farther anode.

The Haring-Blum cell itself has a number of disadvantages but it does enable throwing power to be described in a quantitative fashion.

The use of a similar cell for measuring the throwing power of ECM electrolytes seems desirable but the normal Haring-Blum cell is not immediately useful for ECM measurements because (*a*) the anode-cathode separations are of the order of inches and (*b*) it is essential to be able to measure the electrolyte flow rate in the interelectrode gap.

This paper describes a modified Haring-Blum cell suitable for ECM electrolytes and some results are reported.

Experimental

A rectangular two-compartment cell was designed and built from Perspex to take the above factors into account. A cross section (not to scale) is shown in Fig. 2 and the associated flow system in Fig. 3. This arrangement allows the flow rates in the two compartments to be controlled and measured independently. The bulk flow rate, 0.7 liter/min, was kept constant through both compartments as it was thought that this situation corresponded most closely with that obtaining during practical machining.

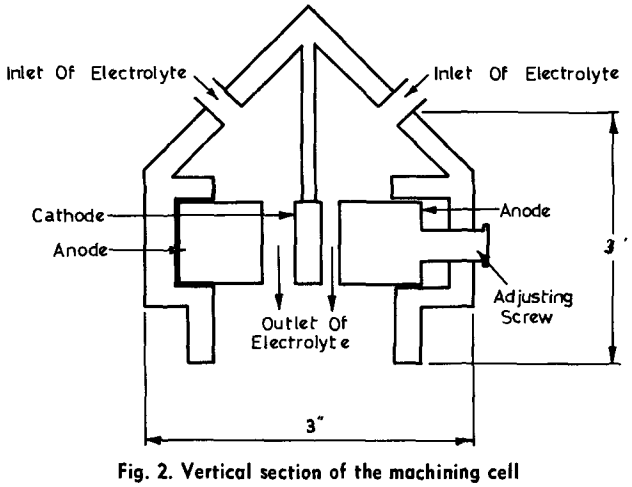

Fig. 2. Vertical section of the machining cell

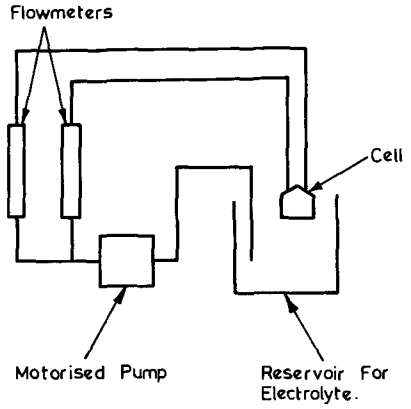

Fig. 3. Layout of the apparatus

The cell voltage required to maintain the working current density of 15 A/in.^{2} varied between 2 and 10V.

The linear ratio (the ratio of the two anode-cathode separations) was usually kept at 5:1 but, where necessary, variations from this were made by the use of insulated packing. The smaller anode-cathode separation was either 0.005 or 0.010 in. and the gap depth 0.5 in.

The cathodes, made from copper, and the anodes, from 18/8 stainless steel,[2] were ½ x ½ x 2 in. The electrodes were masked on the sides and on the working faces so that the exposed area was 1 in.^{2}. The metal distribution ratio was calculated from the weight losses of the two anodes after 2 min machining.

The electrolytes were made of A. R. material to a total volume of 8 liters and were discarded after 5 runs. Conductivities of the electrolyte were measured by means of a standard conductivity bridge.

Results and Discussion

The results are shown in Tables I and II. There is some degree of scatter but, with one or two exceptions, the results are reproducible within ~5%. A correlation was sought between throwing power and specific conductivity and, while some evidence of a positive correlation was obtained, it was not strong enough to warrant further discussion at this stage.

The results from Table I indicate that sodium chlorate has a lower throwing power than sodium chloride,

Throwing index	3.67	0.48

confirming the results of Laboda and McMillan (5). At the lower concentrations temperature increases have the effect of increasing throwing power, but at higher concentrations temperature increases produce only small changes in the case of chloride solutions or a decrease in the chlorate solutions. The effects of concentration changes are variable. The result of increasing the absolute gap width while retaining the initial linear ratio is generally to decrease the throwing power. This effect is not linearly dependent on the absolute gap width, since results reported by Cuthbertson and Turner (6) indicate that with gap width in the region of 0.05-0.15 in. the throwing power increases with increasing gap width.

The finish of all the machined anodes was that of a lightly etched surface with no marked grain boundary attack, with the exception of the nearer anodes machined in the saturated solutions of sodium chlorate which showed some regions of polishing. This would suggest that the dissolution, in the majority of the reported cases, takes place according to the prepolishing regime obtained on a typical Jacquet curve.

A few results, obtained for nitrate solutions under the same conditions, generally confirm these trends. The throwing power of nitrate solutions is intermediate between chloride and chlorate solutions, but one or two values are lower than the values for the corresponding chlorate solutions. This is not in entire agreement with Laboda and McMillan but this apparent contradiction may be a result of the different measuring techniques.

The effects of chlorate ions have been discussed in terms of passivation of the anode in the regions of low current density (7). If this is the case then the deliberate addition of suitable passivators to, for example, sodium chloride solutions should have the result of reducing the throwing power. Two such additions were made, benztriazole (BTZ), which is an efficient passivator for copper (8), and potassium dichromate. In both cases these additions, at the concentrations shown in Table I, markedly decrease the throwing power of chloride solutions; the effect in the case of potassium dichromate is very large. The additions of BTZ and sodium dichromate had no visual effect on the surface finish which were again lightly etched. The amounts of metal dissolved from the nearer anodes were not significantly altered by the presence of the two additions, but the metal dissolved from the farther anodes was reduced by a factor of ~2. Hence the metal removal rates of the nearer anodes remain virtually unchanged, while those of the farther anodes are reduced. These observations seem to confirm the hypothesis that the reduction in throwing power is associated with passivation in the low current regions. The probable consumption of BTZ at the electrodes makes it unlikely that this observation will be of practical use. A further consequence to the effect of chromate ions on the throwing power is that the throwing power of a machining electrolyte would be expected to change during its life due to a progressive build-up of chromate ions derived from the chromium present in suitable anode materials, while the presence in solution of other machining products would have related effects. Aged chloride solutions used elsewhere in our laboratory were examined for the presence, or otherwise, of chromate ions and tests indicated that chromate was present in these solutions at the same order of concentration as that used for the throwing power measurements previously. This change of throwing power could be responsible in part for the "aging" of electrolytes which occurs in practice when the machining properties change with increasing time of use.

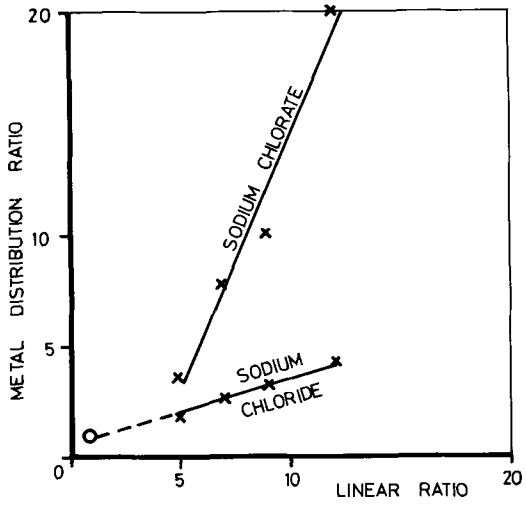

Fig. 4. Throwing index plot

The work of Jellinek and David (9) shows that some of the ambiguities associated with the use of the concept of "throwing power" can be resolved by use of the throwing index which is obtained by plotting the metal ratios against a range of linear ratios. The reciprocal of the gradient of the line is described as the "throwing index," the major advantages of which are that (a) a single number is obtained which is characteristic of a range of linear ratios, and (b) the throwing index is obtained from the number of experimental points thus reducing the effects of experimental error. The solution with a good throwing power gives a line which is nearly horizontal and one with a poor throwing characteristic will give a steeper gradient. The present work was extended to include this concept by measuring the metal ratios for linear ratios between 5 and 12 for 20% NaCl and $NaClO_3$ at 25°C. The results, shown in Table II and Fig. 4, give reasonably linear plots. All the curves should go through the point represented by the linear ratio equal to 1 and the metal distribution ratio equal to 1 and a linear extrapolation of the data for the sodium chloride solutions does indeed do so, but this is not the case for the chlorate solutions. The value for 20% sodium chloride is well in the range ~1 to 10 reported by Jellinek and David for electroplating solutions, but the result for the chlorate solution, while confirming the earlier throwing power work, is outside the range quoted. Again this confirms the results of Laboda and McMillan.

Conclusions

It has been shown that throwing power of machining electrolytes can be measured with a fair degree of reproducibility. The improvements obtained by using the $NaClO_3$ electrolyte reported elsewhere have been confirmed for the anodic material used in the present work. The mechanism of the chlorate improvement is probably due to passivation effects, in agreement with the effects of additions of other passivators such as BTZ and chromate ions.

The use of the throwing index has been investigated and shown to give reasonable results.

Multilayer Theory of Correction Factors for Spreading-Resistance Measurements

T. H. Yeh* and K. H. Khokhani

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York

ABSTRACT

The spreading-resistance technique has shown the versatility of determining either the thickness of diffused or epitaxial layers or establishing the impurity profiles for various multilayered silicon structures. However, correction factors must be applied to the measured spreading-resistance values in order to get the corrected resistivities. The calculation for the correction factors based on the unilayer step-junction theory has been reported previously by the authors. In this paper, the calculation of the correction factors based on the multilayer step-junction theory and the utilization of a computer for such calculations are presented.

The calculation of the correction factors based on the assumption of the unilayer step-junction theory, for the resistance values measured on silicon layers by the spreading-resistance technique, was presented in an earlier report (1, 2). The unilayer step-junction theory assumes that the resistivity is homogeneous throughout the thickness of each structure below the point of measurement, and that the resistivity changes at an interface are abrupt (1, 4). This assumption was used extensively to establish the impurity profile for the measurements made on N(epitaxial)/N+ (substrate) silicon structure (1, 2).

For such a structure, the measured spreading-resistance values are converted to resistivity values from the calibration curve (1, 2), and plotted against distance as shown in Fig. 1. The calculation of correction factors is based on a two-layer problem as shown in Fig. 2, according to the following equation:

$$R_{S.R.} = \frac{\Delta V}{I} = \frac{\rho_1}{4r_0}\left\{\frac{4}{\pi}\int_0^\infty \left[\frac{1 + K_1 e^{-2H_1X}}{1 - K_1 e^{-2H_1X}}\right] \sin(X) \left[\frac{J_1(X)}{X^2} - \frac{J_0\left(\frac{S}{2}X\right)}{X} + \frac{J_0(SX)}{2X}\right] dX\right\} \quad [1]$$

where

$R_{S.R.}$ = Spreading resistance

$K_1 = \dfrac{\rho_2 - \rho_1}{\rho_2 + \rho_1}$

$S = 2s/r_0$

$H_1 = h_1/r_0$

s = Probe spacing

r_0 = The effective radius of contact of the probe

X = Integration parameter

J_1, J_0 = Bessel function

The terms within the curl bracket of Eq. [1] are generally labeled as a correction factor, C.F. The corrected resistivity value is then given by the following expression:

$$\rho_{1\ \text{corrected}} = \frac{\rho_1}{\text{C.F.}} \quad [2]$$

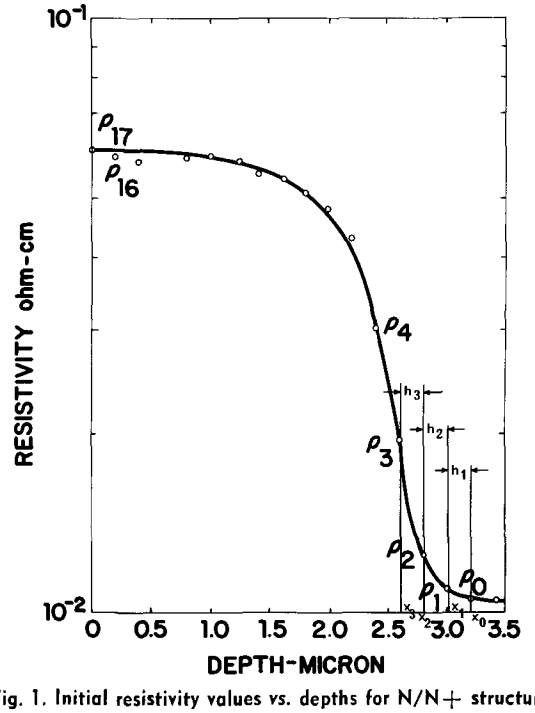

Fig. 1. Initial resistivity values vs. depths for N/N+ structure

* Electrochemical Society Active Member.

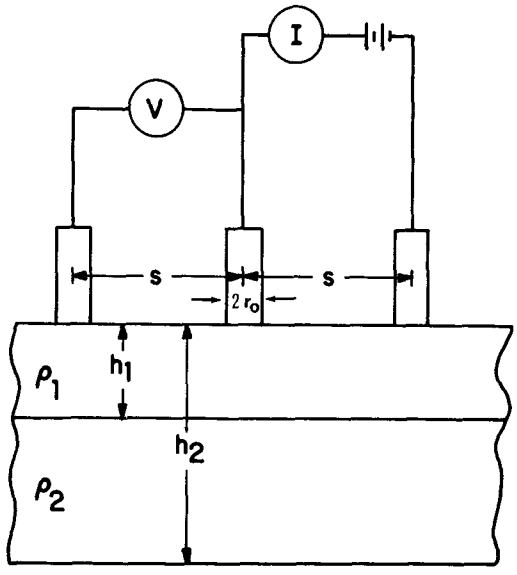

Fig. 2. Spreading resistance technique on a two-layered structure

The first measured resistivity to be corrected is labeled ρ_1, which actually is the last measurement in the N/N+ structure, and this resistivity is assumed to be uniform throughout the layer thickness of $x_0 - x_1 (= h_1)$. The resistivity change at the interface is abrupt, and the resistivity of the substrate can be assumed for ρ_0. The K_1 value in Eq. [1] for this problem is equal to $\rho_0 - \rho_1/\rho_0 + \rho_1$. Upon determining the correction factor, the resistivity is corrected using Eq. [2]. This corrected resistivity value $\rho_{1\ \text{corrected}}$ may then be used to find a new effective radius of contact, r_0, from the calibration curve (1, 2), a new correction factor, and a new corrected resistivity. This procedure is repeated to get an exact value of resistivity (*e.g.*, until either the r_0 value or the correction factor does not change), because the r_0 value initially obtained from the calibration curve for the first correction factor calculation is not necessarily exact.

Because of the unilayer step-junction assumption, neither this corrected resistivity, $\rho_{1\ \text{corrected}}$, nor its initial resistivity, ρ_1, are utilized when the second measured resistivity, ρ_2, is corrected. For correcting ρ_2, it is assumed that the resistivity, ρ_2, is homogeneous throughout its thickness $x_0 - x_2 (= h_1)$, even though we know that within its thickness one of the layers has a different resistivity value, $\rho_{1\ \text{corrected}}$. The calculation of the correction factor for ρ_2 is again evaluated by Eq. [1] using the K_1 value of $\rho_0 - \rho_2/\rho_0 + \rho_2$.

Undoubtedly, certain accuracy of the correction factor is sacrificed for each of the subsequent resistivity values, such as $\rho_3, \rho_4 \ldots \rho_{17}$ for the structure because of the unilayer step-junction assumption. This is especially true for the corrected value of ρ_{17}, because in the calculation of its correction factor this resistivity, ρ_{17}, is assumed to be uniform throughout the total thickness, even though there are 16 layers of corrected resistivity values, $\rho_{1\ \text{corrected}} \ldots \rho_{16\ \text{corrected}}$ below ρ_{17}.

Obviously, if one uses the corrected resistivity values to obtain a correction factor for any one of the measured values, *e.g.* utilizing $\rho_{1\ \text{corrected}}$ and $\rho_{2\ \text{corrected}}$ to correct ρ_3, then the value $\rho_{3\ \text{corrected}}$ should be more accurate than the one without the consideration of the values of $\rho_{1\ \text{corrected}}$ and $\rho_{2\ \text{corrected}}$.

Multilayer Theory

However, if one wants to use the preceding corrected resistivities for the calculation of the correction factor for the subsequent initial resistivity, one must use the multilayer step-junction theory to solve the problem. The geometry is shown in Fig. 3. The solution to LaPlace's equation in cylindrical coordinate

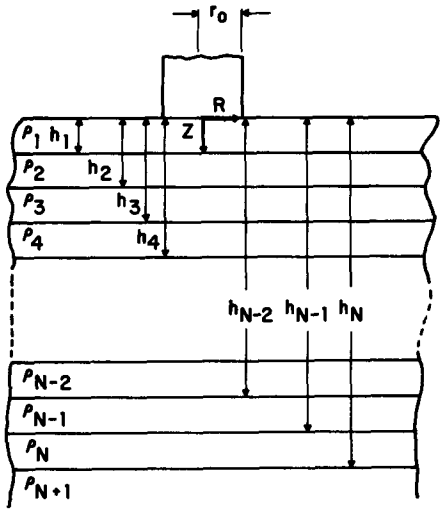

Fig. 3. Geometry for the multilayered problem

for this problem is:

$$R_n = \frac{V_n(R,Z)}{I} = \frac{\rho_n}{2\pi r_0} \left\{ \int_0^\infty \frac{e^{-XZ} \sin X\, J_0(RX)}{X}\, dX + \int_0^\infty \frac{{}_N\theta_n\,(X/r_0)\, e^{-XZ} \sin X\, J_0(RX)}{X}\, dX + \int_0^\infty \frac{{}_N\psi_n\,(X/r_0)\, e^{XZ} \sin X\, J_0(RX)}{X}\, dX \right\}$$

$$n = 1, 2, 3 \ldots N \quad [3]$$

The boundary conditions for this type of problem are relatively standard with the exception of the current distribution under the contact. These boundary conditions are:

Surface:

$$\frac{\partial V_1(R,Z)}{\partial Z} = 0 \text{ for } R > r_0,\ Z = 0 \quad [4]$$

$$\frac{\partial V_1(R,Z)}{\partial Z} = -\frac{I\rho_1}{2\pi r_0 (r_0^2 - R^2)^{1/2}} \text{ for } R \leq r_0,\ Z = 0 \quad [5]$$

These first two conditions relate to the field at the surface. Equation [4] states that there is no current flow out of the surface away from the contact. Equation [5] is developed from considerations of the current flow under a flat circular contact on an infinite geometry (5).

Region 1:

$$\lim_{R \to \infty} V_1(R,Z) = 0 \quad [6]$$

First interface:

$$\frac{1}{\rho_1}\frac{\partial V_1(R,Z)}{\partial Z} = \frac{1}{\rho_2}\frac{\partial V_2(R,Z)}{\partial Z} \quad [7]$$

$$V_1(R,Z) = V_2(R,Z) \text{ for } Z = h_1 \quad [8]$$

The equations at the interfaces state that the current density must be the same across the boundary and that the potential is continuous.

Region 2:

$$\lim_{R \to \infty} V_2(R,Z) = 0 \quad [9]$$

Second interface:

$$\frac{1}{\rho_2}\frac{\partial V_2(R,Z)}{Z} = \frac{1}{\rho_3}\frac{\partial V_3(R,Z)}{\partial Z} \quad [10]$$

$$V_2(R,Z) = V_3(R,Z) \text{ for } Z = h_2 \quad [11]$$

and similarly for Region 3, 4 . . . N.

Region N:

$$\lim_{R\to\infty} V_N(R,Z) = 0 \quad [12]$$

$$\lim_{Z\to\infty} V_N(R,Z) = 0 \quad [13]$$

These boundary conditions are then imposed on the solutions given in Eq. [3] to specify

$${}_N\theta_n\left(\frac{X}{r_0}\right) \text{ and } {}_N\psi_n\left(\frac{X}{r_0}\right)$$

The application of the boundary conditions results in a series of linear equations:

$${}_N\theta_1\left(\frac{X}{r_0}\right) - {}_N\psi_1\left(\frac{X}{r_0}\right) = 0 \quad [14]$$

$$e^{-2H_nX} \cdot {}_N\theta_n\left(\frac{X}{r_0}\right) + {}_N\psi_n\left(\frac{X}{r_0}\right) - e^{-2H_nX} \cdot {}_N\theta_{n+1}\left(\frac{X}{r_0}\right) - {}_N\psi_{n+1}\left(\frac{X}{r_0}\right) = 0 \quad [15]$$

$$-e^{-2H_nX} \cdot {}_N\theta_n\left(\frac{X}{r_0}\right) + {}_N\psi_n\left(\frac{X}{r_0}\right) + \beta_n \cdot e^{-2H_nX}\, {}_N\theta_{n+1}\left(\frac{X}{r_0}\right) - \beta_n \cdot {}_N\psi_{n+1}\left(\frac{X}{r_0}\right) = (1-\beta_n)\, e^{-2H_nX} \quad [16]$$

$${}_N\psi_{n+1}\left(\frac{X}{r_0}\right) = 0 \quad [17]$$

where N = Number of layers of different resistivity and finite thickness

n = Index, from 1 to N

$$\beta_n = \frac{\rho_n}{\rho_{n+1}}$$

$$H_n = \frac{h_n}{r_0}$$

and Region $N + 1$ is infinitely thick.

Using the simplified notation

$${}_N\theta_n\left(\frac{X}{r_0}\right) = {}_N\theta_n \quad [18]$$

$$e^{-2H_nX} = E_n \quad [19]$$

The above equations become:

$${}_N\theta_1 - {}_N\psi_1 = 0 \quad [20]$$

$$E_n \cdot {}_N\theta_n + {}_N\psi_n - E_n \cdot {}_N\theta_{n+1} - {}_N\psi_{n+1} = 0 \quad [21]$$

$$-E_n \cdot {}_N\theta_n + {}_N\psi_n + \beta_n E_n \cdot {}_N\theta_{n+1} - \beta_n \cdot {}_N\psi_{n+1} = (1-\beta_n)E_n \quad [22]$$

$${}_N\psi_{n+1} = 0 \quad [23]$$

For example, if $N = 2$, the set of linear equations becomes:

$${}_2\theta_1 - {}_2\psi_1 = 0 \quad [24]$$

$$E_1 \cdot {}_2\theta_1 + {}_2\psi_1 - E_1 \cdot {}_2\theta_2 - {}_2\psi_2 = 0 \quad [25]$$

$$-E_1 \cdot {}_2\theta_1 + {}_2\psi_1 + \beta_1 E_1 \cdot {}_2\theta_2 - \beta_1 \cdot {}_2\psi_2 = (1-\beta_1)E_1 \quad [26]$$

$$E_2 \cdot {}_2\theta_2 + {}_2\psi_2 - E_2 \cdot {}_2\theta_3 - {}_2\psi_3 = 0 \quad [27]$$

$$-E \cdot {}_2\theta_2 + {}_2\psi_2 + \beta_2 E_2 \cdot {}_2\theta_3 - \beta_2 \cdot {}_2\psi_3 = (1-\beta_2)E_2 \quad [28]$$

$${}_2\psi_3 = 0 \quad [29]$$

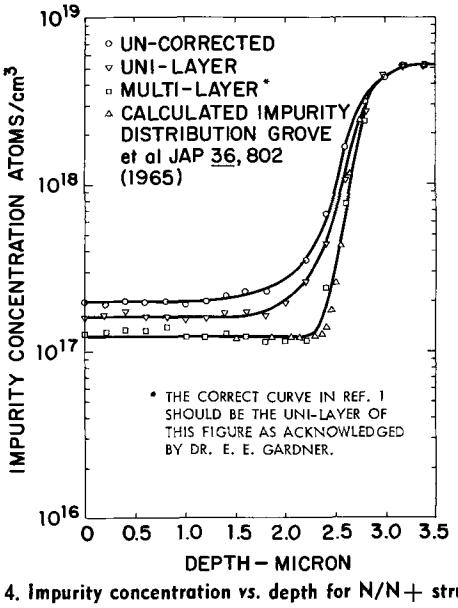

Fig. 4. Impurity concentration vs. depth for N/N+ structure

There are six equations and six unknowns. The matrix is, with the columns given by:

${}_2\theta_1$	${}_2\psi_1$	${}_2\theta_2$	${}_2\psi_2$	${}_2\theta_3$	${}_2\psi_3$	Constant
1	−1	0	0	0	0	0
E_1	1	$-E_1$	−1	0	0	0
$-E_1$	1	$\beta_1 E_1$	$-\beta_1$	0	0	$(1-\beta_1)E_1$
0	0	E_2	1	$-E_2$	−1	0
0	0	$-E_2$	1	$\beta_2 E_2$	$-\beta_2$	$(1-\beta_2)E_2$
0	0	0	0	0	1	0

Determinants may then be formed to solve for any of the θ's and ψ's. In general, the matrix will be $2N + 3$ by $2N + 2$. The determinants will be $2N + 2$ by $2N + 2$.

Prior to this paper, the multilayer theory has never been tested because, for a sample having 17 layers (as shown in Fig. 1) to be considered, one must solve an ever-increasing number of determinants by hand, starting with a 4 by 4 matrix then steadily expanding to a 37 by 36 matrix. It is almost an unthinkable task. However, with the aid of a computer, this multilayer approach is feasible. For a 17-layer problem it took an IBM 7090 computer about 10 min to obtain 17 corrected resistivities. These values were then converted to net impurity concentration according to Irvin's curve (6), and plotted against the depth as shown in Fig. 4. In the same figure, the uncorrected impurity profile and the corrected profile obtained by the unilayer step-junction approach plus the calculated impurity profile according to the method of Grove *et al.* (7) are also included for comparison. The agreement between the multilayer corrected profile and the one calculated according to Grove *et al.* is remarkably good.

A computer program for obtaining 17 corrected resistivities on a typical N(epitaxial)/N+ (substrate) structure is written in Fortran language.[1] The computer output for the sample shown in Fig. 4 is given in Table I.

Conclusion

The calculation of the correction factors for spreading-resistance probe measurements based on the multilayer step-junction theory and the utilization of a computer for such calculations are presented. A detailed computer program, written in Fortran language, for obtaining 17 corrected resistivities on a N/N+ silicon structure is also given. The advantage and the importance of using multilayer theory instead of unilayered theory for the calculation of the correction factors are discussed.

Photochromic Spiropyran Resists

M. Orlovic, E. Stone,* and I. M. Pearson*,[1]

Electronics Division, The National Cash Register Company, Hawthorne, California

ABSTRACT

Many photochromic spiropyrans form amorphous continuous films which are colored intensely by u.v. radiation. The colored and uncolored forms display marked differences in solubility in common nonpolar solvents. These properties enable the photochromic spiropyrans to be used advantageously as resists in chemical etching and RF sputter etching processes and in a novel differential adhesion process. Experimental procedures and results are given for applications of these spiropyran resist processes to thin-film pattern preparation in metals, semiconductors, and SiO.

Photochromic (PC) spiropyrans are generally colorless or lightly colored under visible or infrared light, but become intensely colored because of breaking of the bond between the spirocarbon and the pyran-oxygen, when exposed either in liquid (1, 2) or solid (3-5) solution or in amorphous solid form (6) to ultraviolet (u.v.) radiation (no polymerization occurs). The spiropyrans are soluble in polar organic solvents but the colored form is less soluble than the uncolored form in nonpolar solvents such as petroleum ether, methyl cyclohexane, and other saturated hydrocarbons. Moreover, many of these PC substances, *e.g.* the Fischer's base-salicylaldehyde condensation compounds (6) shown in Fig. 1, form continuous amorphous films when deposited either singly or in mixtures from solutions in volatile aromatic hydrocarbons such as benzene or toluene. The amorphous deposits develop persistent and uniform coloration on appropriate u.v. irradiation at ambient temperatures. Figure 2 shows the absorption spectra of the unexposed and u.v.-exposed forms of a typical spiropyran (PCI) deposit at room temperature. Both forms absorb strongly in the u.v.; however, only the colored form does so in the visible.

These film-forming, PC, and solubility properties enable numerous spiropyrans to be utilized advantageously as resists in chemical etching and RF sputter etching processes, and in a novel differential adhesion process, for making thin film patterns in metals, semiconductors, and the insulator, SiO.

Experimental Procedures and Results

Chemical etching.—The procedure for using PC spiropyran resists, similar in many respects to that employed for common photoresists, consists of the following:

1. A thin pattern-material film, approximately 0.1-0.3 μm thick, is laid down on glass (some other rigid, nonporous substrate may be used), generally by evaporation or sputtering in a vacuum system.
2. An amorphous[1] PC film is spin-coated onto the pattern material from a filtered solution in A.R.-grade

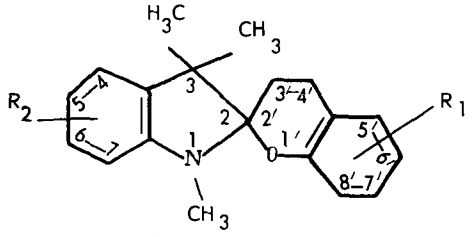
Key words: amorphous films, photochromic spiropyrans, resists, thin films, chemical etching, RF sputter etching, differential adhesion, metals, semiconductors, SiO.

[1] Crystalline films of spiropyrans tend to remain uncolored when exposed to u.v. However, the films of the PC already cited, and many others, can remain amorphous for many days. Some spiropyrans may crystallize unless mixed with a closely related derivative (6) such as PCI.



where I. R_1 = 6′-NO_2, 8′-OCH_3

benzene, preferably in a clean atmosphere, under yellow lighting (u.v. filtered out). The PC film thickness is approximately 0.6 μm when deposited from a 10 w/o (weight per cent) solution in benzene which is spin-coated at 1000 rpm.

3. A mask on a u.v.-transmissive substrate, preferably glass, is laid down on the PC film and a contact print is made using u.v. illumination (< 400 nm). Uncollimated light from a Spectroline Model B-100 BLE (Spectronics Corporation, Westbury, L.I., N.Y.) or Blak-Ray Model X-4 (Ultra-Violet Products, San Gabriel, Calif.) lamp is often satisfactory. Oxygen need not be excluded. Suitable optical densities of 1 or more are achieved with a u.v. energy of 0.5 w-sec. The exposure time can be varied considerably without appreciable effect.

Laser recording instead of contact printing with u.v. may be carried out on the PC material. A u.v. laser, such as the Kr (ion) laser which emits in the 330-360 nm region, seems suitable. Argon and He-Ne lasers which have outputs in the visible are satisfactory if the PC is colored with u.v. before recording, since the maximum absorptions in the visible of the colored forms of most PC spiropyrans of interest lie in the 470-650 nm region.

4. The pattern is washed with petroleum ether (*e.g.*, the 30°-60°C bp fraction)[2] to remove unexposed PC if a negative pattern[3] is desired.

[2] In the case of PCI, the solubility of the unexposed material is ≈0.9 mg/g of this solvent at 24°C. The exposed PCI solubility is ≈0.3 mg/g of solvent.

[3] The capability of making positive images also exists (6). For this purpose, the unexposed PC pattern is treated with conc HCl acid vapor. Both the unexposed and exposed portions of the image form a yellow complex with HCl. However, the exposed PC complex is preferentially soluble in aqueous dil. HCl and can be removed with this reagent.

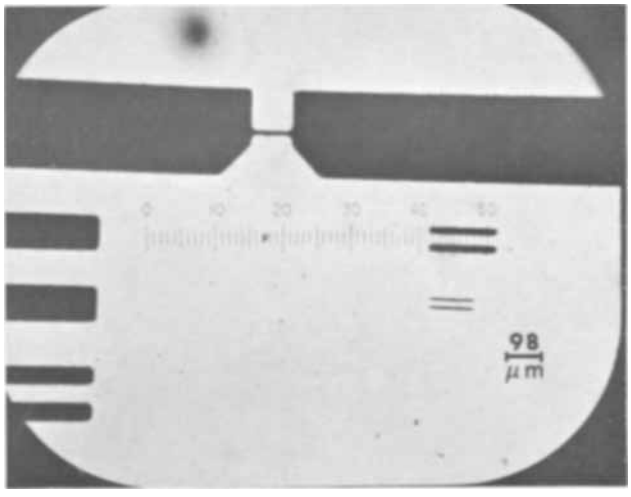

Fig. 3. Pattern etched in 1000Å-thick Cu with 42 w/o $FeCl_3$ for 20 sec. Each micrometer scale division is 19.6 μm.

5. The pattern is etched by dipping or gentle spraying with mild agents to remove the material unprotected by PC. As examples, aqueous solutions of $FeCl_3$ are used to etch Cu, Sn, and permalloy and aqueous $PdCl_2$ to etch Al; HCl vapors convert CdSe to $CdCl_2$ which is then washed off with water.

6. Exposed PC is removed by gentle spraying with acetone, leaving the pattern in the underlying material.

An application of the chemical etching process to the preparation of a Cu pole and rectangle pattern is shown in Fig. 3. The pole gap width is 18.7 μm. The smallest rectangle widths are 5-7.5 μm. The resist material was an equal-weight mixture of 1, 3, 3-trimethylindolino-5′-bromo, 6′-nitro, 8′-methoxy-benzospiropyran (PCI) and 7-phenyl, 1, 3, 3-trimethylindolino-5′-bromo, 6′-nitro, 8′-methoxy-benzospiropyran (PCII). (In general, the PC spiropyrans specific-

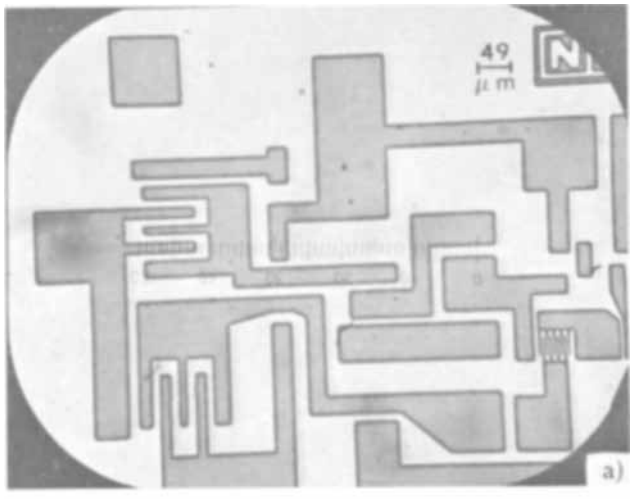
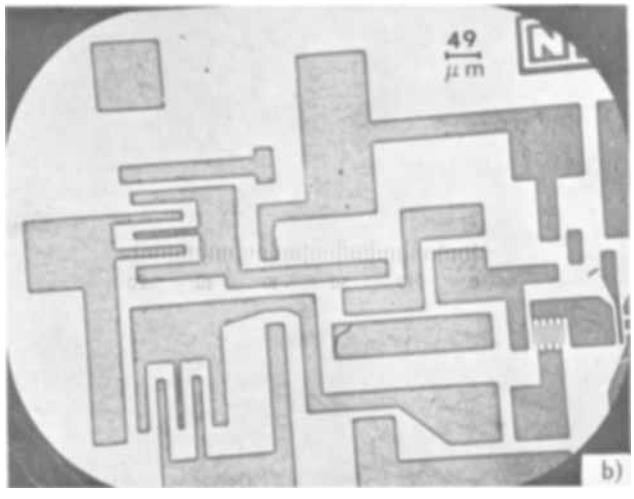
ally referred to in this paper are interchangeable in all the applications described.)

As is true for other chemical etch resist processes, undercutting and pinholing, which impair film continuity, edge acuity, and resolution capability, often occur. However, line widths of ≈8 μm are obtained readily with good feature characteristics, using PC resists.

RF sputter etching.—This PC resist process is similar to chemical etching except that the pattern material from which the unexposed PC has been washed away is not removed by chemical agents, but rather by RF sputtering (7, 8) with argon ions. Unlike chemical etching, RF sputter etching produces straight lines with sharp edges and avoids undercutting.

Plots are shown in Fig. 4 of the dependence on the RF power of the sputter etch rate for u.v.-exposed PCI and for Au films, at two suitable argon pressures (Linde high-purity dry argon, 99.99 +%, was used without further purification). The specific voltages





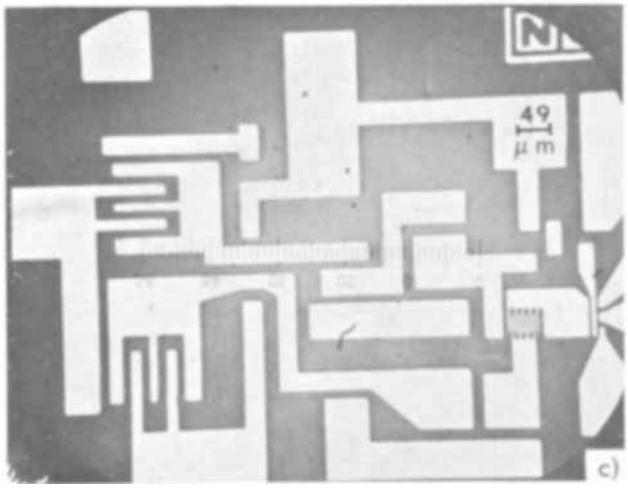


Fig. 7. Differential adhesion TTL pattern in 450Å-thick Al made using RF sputter cleaning of washed PCI image: (a) washed PC image; (b) RF sputter cleaned PC image; (c) Al pattern. Each scale division is 9.8 μm.

are indicated for each data point and other operating conditions are given, including the area of the 10.2-cm-diameter RF electrode. The RF vacuum apparatus employed is otherwise essentially similar to that described previously (7).

The rates for PCI and Au are as much as 10% higher at the lower argon pressure, and are linear functions of the RF power under our conditions. PCI etches at a considerably higher rate than Au. Consequently, the PC film used must be thicker than Au (or other basis materials). In most cases, the PC process is used to make thin-film patterns which are <0.1 μm thick. An initial PCI film thickness of ≈ 0.6 μm is employed at an RF power of 100-200w (power density of 1.2-2.5 w/cm^2).

Comparative tests indicate that, under our conditions, the rate of RF sputter etching of the well-known photoresist, KTFR, is $\approx 20\%$ higher than is the case for Au, and consequently also etches more slowly than PCI.

An application of RF sputter etching using PCI resist and contact printing is shown in Fig. 5. The interconnection pattern of a transistor-transistor logic (TTL) circuit with source and sink was made with 850Å-thick Au for the purpose of demonstration. The small interconnection fingers are 5 μm in width. A pattern in 200Å-thick Au is shown in Fig. 6. This raster was sputter etched after recording with a He-Ne laser on a u.v.-exposed PC coating of 1, 3, 3-trimethylindolino-6'-nitro, 7'-methoxy-benzospiropyran (PCIII) overlying the Au basis film on glass.

Differential adhesion.—Unlike the chemical or RF sputter etching processes, the pattern material in the differential adhesion (DA) process is deposited over the developed, *i.e.* exposed and washed, PC image pattern. Pressure-sensitive adhesive tape, *e.g.* ordinary Scotch tape, is applied to the overlying pattern material and is then pulled away. The material overlying the (exposed) PC is removed in this manner, while the material in contact with the substrate continues to adhere to the latter and delineates the pattern. Careful cleaning of the developed PC image by glow discharge or by RF sputter bombardment prior to overlaying is desirable, to remove traces of unexposed PC and thus ensure good adhesion of the overlay material to the substrate. Unlike chemical or RF sputter etching, the final pattern step in the differential adhesion method can be carried out under relatively simple conditions, well suited for automation.

The DA process works well with materials which adhere sufficiently to the substrate. Substances which are known to readily form oxygen bonds with the substrate seem particularly utilizable.

This process has been tried with both baked and unbaked films, of various thicknesses, of the negative-acting KTFR (Eastman Kodak) and the positive-acting Azoplate AZ-111 (Shipley) photoresists. In all cases, the overlay deposited over the developed photoresist patterns tended to adhere to both the resist and to the glass substrate. Consequently, the PC spiropyrans have a unique advantage over these photoresists in the DA process.

The application of the DA process to the formation of the TTL circuit in 450Å-thick Al is shown in Fig. 7. The beneficial effect of RF sputter cleaning on the PCI image of (a) is shown in (b). Note how the gaps between the interconnection fingers have been cleared. Photograph (c) shows the final evaporated Al over-

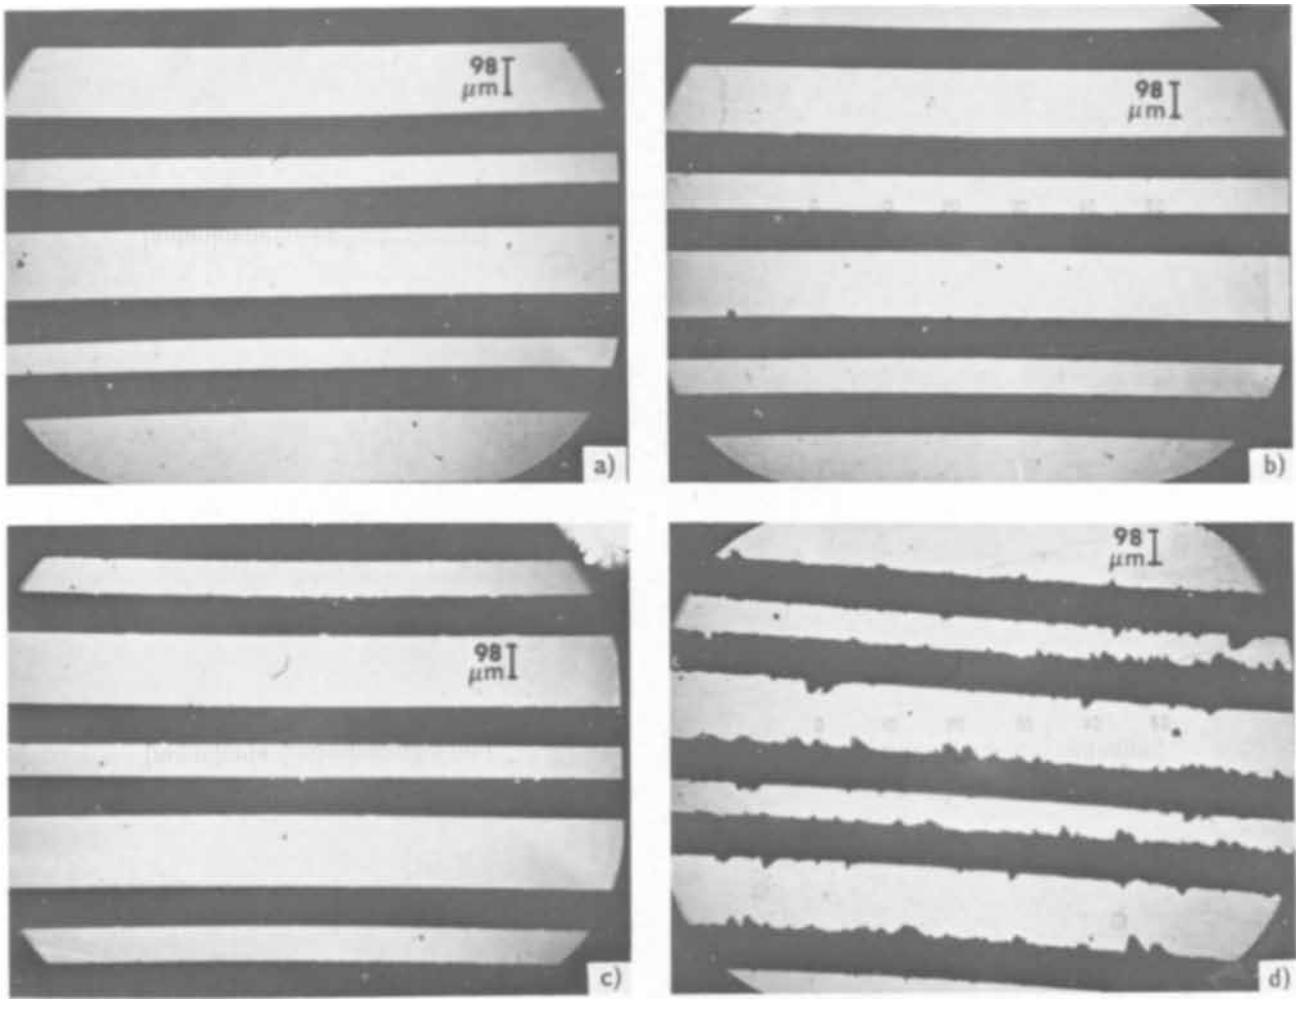

Fig. 8. Dependence of edge acuity of a differential adhesion line pattern on Al overlay thickness: (a) 600Å Al; (b) 1150Å Al; (c) 1650Å Al; (d) 3000Å Al. Each scale division is 19.6 μm.

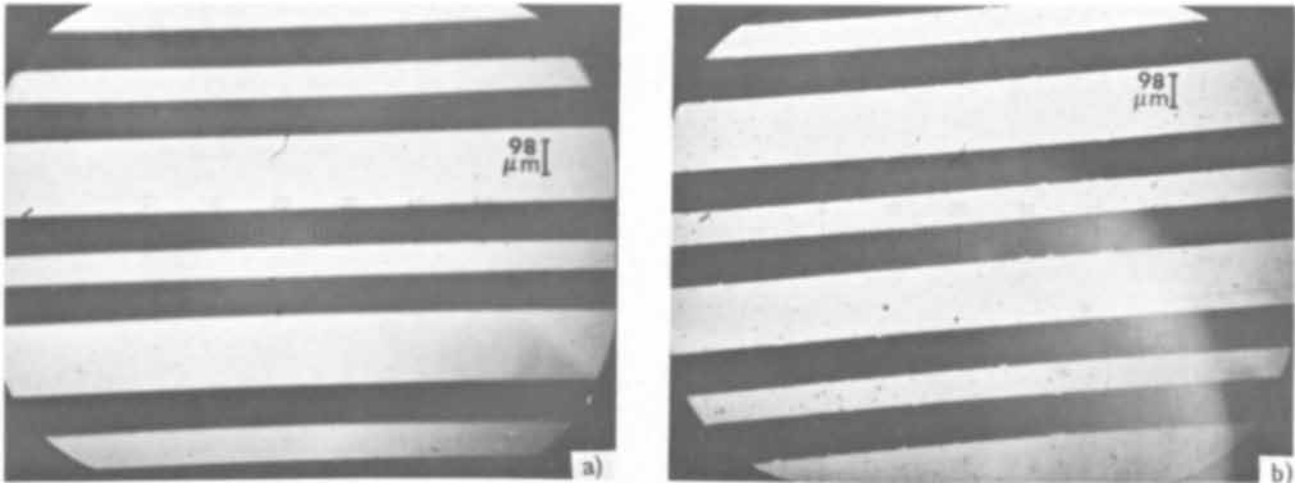

Fig. 9. Dependence of the edge acuity of a differential adhesion line pattern on Al-Ag overlay thickness: (a) 1500Å Al-1500Å Ag; (b) 1750Å Al-1750Å Ag. Each scale division is 19.6 μm.

lay pattern after pressure tape was applied and removed.

The results of a series of eight tests of the preparation by the DA process of thin-film Ta dual pole patterns (using PCIII), which are another version of the pattern shown in Fig. 3, are described in Table I. Measurements of two different pole gap widths are given for the eight samples and for the photo mask employed. Test averages and the standard deviation of a single test are also shown to illustrate the precision of the process in this application.

The dependence of the edge acuity of a DA line pattern (using PCI) on the Al overlay thickness is shown in Fig. 8. The photos were taken with reflected light. The white Al lines are 85 and 185 μm wide, respectively, and the dark spaces are 120 μm wide. The patterns in which the Al is 600 and 1150Å thick, (a) and (b), have good edge acuity. The 1650Å pattern in (c) begins to exhibit some general raggedness. The 3000Å pattern, (d), is very ragged. It thus appears that the maximum thickness of the Al overlay should be <1650Å if optimum line edge acuity is to be obtained. The maximum overlay thickness at which satisfactory edge acuity is obtained can be increased by, *e.g.*, using an Al-Ag bilayer overlay. This is illustrated in Fig. 9. The 1500Å Al-1500Å Ag bilayer (total thickness of 3000Å) shown in (a) has good edge acuity although this thickness is unsatisfactory for Al alone as previously shown. However, the 3500Å Al-Ag bilayer in (b) has some edge raggedness.

A 450Å-thick Al resolution test pattern made by the DA process using PCI is presented in Fig. 10. The photo mask which was employed is a 40:1 reduction of an NBS Microscopy Resolution Test Chart. The No. 10 group has 400 lines/mm; the actual line width in the photograph is 2.45 μm.

Discussion

In all the resist applications described, the PC spiropyrans have the following important advantages over some, or all, commercial photoresists:

Table I. Pole gap widths (in μm) of differential adhesion Ta patterns

Test No.	Pole gap I	Pole gap II
Photo mask	32.3	22.5
1	30.0	23.0
2	29.2	25.0
3	30.2	25.4
4	32.4	23.8
5	34.0	28.0
6	34.8	25.2
7	32.2	25.2
8	32.2	23.8
Test mean	32.0	24.9
Std. dev. of a single test	1.99	1.41

1. The PC exposure time to u.v. light is not critical (because the monomolecular colored material is obtained easily) and is consequently not a troublesome process parameter. Suitable coloration occurs quickly and reproducibly.
2. The PC image pattern is delineated clearly by the intensely colored exposed PC. Contrast is high.
3. Both the unexposed and exposed PC are washed away readily with volatile solvents under normal operating conditions. No mechanical aids or severe stripping procedures are ordinarily required for exposed PC removal.
4. Both the unexposed and exposed PC are recoverable from solutions in the solvents by distillation or evaporation. The exposed form can be decolored by visible or infrared light or mild heating, and may subsequently, be reusable for a number of cycles.
5. The PC solids and their solutions are stable indefinitely when protected from light and heat.

PC spiropyran resists are not as mechanically strong or as chemically inert as, *e.g.*, Kodak photoresists. Reasonable care must be taken to avoid excessive abrasion or shear of the PC films.

The chemical etching resist application is limited mostly to pattern preparation in metals such as those cited previously and bilayers thereof, which can be etched with mild agents such as aqueous $FeCl_3$, dil. HCl and HF acids.

Table II lists the materials which we have thus far utilized satisfactorily in making thin film patterns by

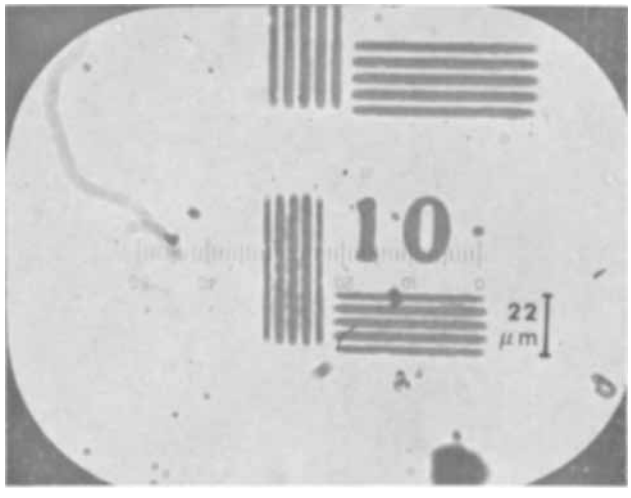

Fig. 10. Al (450Å thick) resolution test pattern made by differential adhesion process (No. 10 group has line width of 2.45 μm). Each scale division is 2.45 μm.

Table II. Materials utilized in PC resist processes

PC resist process	Metals	Semiconductors	Insulator
1. Differential adhesion	Sputtered: Ta, Cr, Cr-permalloy, Cr-Au Evaporated: Al, Ti, Sn, Al-Ag	Evaporated: Ge, CdSe	Evaporated: SiO
2. RF sputter etching	Evaporated: Au, Pb, Zn, Sn, Bi	Evaporated: Ge, CdSe	

the PC spiropyran resist RF sputter etching and DA processes. The list includes a number of substances widely used in microcircuits. Other single and composite materials seem utilizable but have not yet been studied in sufficient detail.

Acknowledgments

The authors wish to thank Dr. H. Schwab and coworkers at NCR-Dayton for providing the PC spiropyrans. We are also indebted to various NCR colleagues for the photo masks employed in this work.

Technical Note

Electron Probe Microanalysis of Discharged MnO_2 Particles in Relation to Leclanche Battery Performance

K. Miyazaki

Mitsui Mining and Smelting Company, Central Research Laboratories, Mitaka-shi, Tokyo, Japan

Many previous works (1-5) have dealt with the x-ray examination, chemical analysis, and other studies of the discharge products of MnO_2 in simplified Leclanché electrodes as well as alkaline cell systems. There are, however, only a limited number of works that focus attention on the changes in the states of MnO_2 as it functions as depolarizer in actual dry battery service. Among them are the elaborate works of pioneering authors, including Matsuno (6) reporting the existence of Mn_3O_4 in exhausted dry cells, McMurdie (7) finding $Mn_2O_3 \cdot ZnO$ and $ZnCl_2 \cdot 4Zn(OH)_2$, and Copeland and Griffith (8) also describing the formation of $Mn_2O_3 \cdot ZnO$ with the use of actually worked dry cells or the like.

No attempts have been made to examine the interiors of individual MnO_2 particles that have served in the Leclanché cathode mix during actual battery discharge. It was therefore desired to study the micro state of the interior of a very small volume of MnO_2 during discharge. In previous works of the present author (9, 10), the behavior of oxygen in MnO_2 electrodes was followed with an electron probe microanalyzer using Leclanché, as well as alkaline, type wet cells. It was shown that the oxygen atoms of the MnO_2 electrodes were actually released during discharge reactions through the solid phase. The relative concentration of oxygen after discharge was found to be markedly reduced from its initial value. This indicated that the use of microanalytical examination may possibly be a powerful tool in revealing changes in the MnO_2 phase during discharge and especially in determining how and where the discharge reaction proceeds at a thin zone to which application of other analytical means is inconvenient.

In the present paper, the behaviors of MnO_2 particles which were incorporated into Leclanché dry cells were investigated with this tool. Particular attention was given to the battery quality of the MnO_2 ores employed. Three MnO_2 ores were chosen to represent a poorly performing, a fairly well performing, and an excellently performing material, respectively. A series of D-size, pasted-type dry cells with each of these materials as the depolarizer was constructed and the change in the intrastate of the MnO_2 particles due to the discharge was examined on the basis of line profiles of manganese, oxygen, and zinc elements across the depolarizer particles. The purpose here is to observe whether a relationship exists between the discharge quality of MnO_2 and the behaviors of the elements at the inner part of the MnO_2 particle during discharge.

Experimental

Manganese dioxide materials.—Three typical battery grade manganese dioxide ores from commercial sources were available with approximate fineness of −150 mesh; one was a naturally occurring ore and the other two were electrolytically synthesized products. All were of γ-type MnO_2. The physical and chemical characteristics of these materials are listed is Table I, in which the materials are denoted as samples I, II, and III, repectively.

Table I. Characteristics of MnO_2 materials used

Sample	Origin	Physical			Chemical						
		Apparent density	True density	BET surface area, m^2/g	Mn	MnO_2	SiO_2	Fe	Ca	SO_4	Water cont., %
I	Natural	1.21	4.43	32	56.8	88.5	0.9	0.4	0.10	—	1.5
II	Electrolytic	1.39	4.25	67	59.6	91.9	—	0.03	0.13	1.15	5.1
III	Electrolytic	1.27	4.28	83	58.5	89.7	—	0.01	0.02	0.91	2.8

The failure of the analyses in Table I to add up to 100% may be due primarily to the presence of lower oxides and bound water. From the Mn and MnO_2 percentages in Table I, the n value of MnO_n for each sample is calculated as 1.97, 1.95, and 1.94, respectively, if a nonstoichiometric expression (11, 12) for γ-type MnO_2 is employed. The water content listed in Table I is the loss in weight obtained by heating any of the samples at 100°-110°C according to the definition in many practical standards including The Japanese Industrial Standards (JIS) (13).

A number of previous works have dealt with the problem of lower oxides and bound water in MnO_2, and it is interesting to note for instance that Gattow (14) defined manganese dioxide as $MnO_{1.7\text{-}2.0}$, independent of the content of H_2O and foreign ions. Sasaki and Kozawa (15) described two types of water in MnO_2; one escapes at a lower temperature and is resorptive, and the other is released at higher temperature and is not resorptive. Actually, the amount of the latter type of water, *i.e.* the bound water, was found to be about 4-5% for samples I and III, and about 1% for sample I with the standard Karl Fischer method by heating the samples from 110° up to 600°C.

Cell construction.—Each one of the ores was mixed with the cathode components and was constructed into D-size, pasted-type dry cells containing 22g of manganese dioxide per cell with the standard formulation shown in Table II.

Discharge of the cells.—Two types of discharge, relatively heavy and light, were performed with these cells to a cut-off voltage of 0.75V. Intermittent discharges were employed considering the fact that the daily usage of dry batteries is mostly intermittent. The heavy discharge was performed through 4 ohms for 30 min/day and 5 days a week, while the light discharge was performed through 40 ohms for 4 hr/day and 5 days a week, according to the test methods in JIS (16). The discharge temperature was controlled at 20° ± 1°C.

The discharged dry batteries were disassembled and the cathode mixes containing the discharged MnO_2 were washed with water and dried at 105°C in preparation for parallel examination by means of electron probe microanalysis and x-ray diffraction.

Electron probe microanalysis.—Each discharged sample was mixed with an epoxy resin and set into a shape having a well-polished surface. The mounted samples were scanned with an accelerating voltage of 25 kV, an average electron intensity of 0.15 μA, a scanning electron beam diameter of 1μ, and a magnification of 300X, to obtain the line profiles of manganese, oxygen, and zinc across transverse sections of typical discharged MnO_2 particles representing the three MnO_2 species used.

Several precautions were taken to obtain good EPMA images of the three elements under examina-

Table III. Discharge products of MnO_2 materials found by x-ray diffraction technique

Types of MnO_2	Discharge	
	Heavy	Light
Sample I	MnO_2 + Mn_3O_4 + very small amount of $ZnCl \cdot 4Zn(OH)_2$	MnO_2 + Mn_3O_4 + very small amount of $ZnCl_2 \cdot 4Zn(OH)_2$
Sample II	Mn_3O_4 + residual MnO_2 + $ZnCl_2 \cdot 4Zn(OH)_2$ intense at (003) peak	$ZnCl_2 \cdot 4Zn(OH)_2$ intense at (003) peak + a minor amount of $Mn_2O_3 \cdot ZnO$
Sample III	$Mn_2O_3 \cdot ZnO$	Well-developed $Mn_2O_3 \cdot ZnO$

tion. A thin film of carbon (100-200Å in thickness) was vacuum sputtered on surfaces of all the specimens. The carbon sputtering was run simultaneously for all the specimens in a multisample sputtering device to secure a uniform carbon thickness. When mounting each specimen thus prepared to the metallic holder of the microanalyzer, a small amount of an electrically conducting paint was applied to fill the gap between the specimen and the holder to electrically earth the specimen. This procedure provided very stable images by eliminating static charge from the specimen during operation. It also aided in the removal of heat. Care was also exercised to take the oxygen line profile first, while possible contamination, if any, from the epoxy remained minimal; the profiles of manganese and zinc then followed. The scanning operation above provided a sufficient reproducibility of line analysis to compare the relative concentrations of the three elements before and after discharge of MnO_2.

X-ray diffraction.—Each discharged sample was also examined with an x-ray diffractometer using nickel filtered FeK_α radiation.

Results

Discharge curve and x-ray diffraction.—Figure 1 shows the heavy discharge performances of the three MnO_2 materials. It is seen that sample I is a rather poorly performing MnO_2, while sample II is a fairly well-performing one. The latter is actually a most average electrolytic MnO_2, while sample III is an excellent material. The light discharge has also shown the same order of performances for the three types of MnO_2, with hours of discharge being approximately 130, 170, and 250, respectively.

In Table III are summarized the discharge products of each type of MnO_2 found by the conventional x-ray diffraction technique.

Electron probe microanalysis.—Microprobe profiles of MnO_2 particles before and after discharge are shown in Fig. 2-7. These figures illustrate how the MnO_2 particles undergo changes in their microstructures due to transport of the reacting elements during discharge.

Discussion

It would be difficult to generalize completely all of the intraparticle phenomena in conjunction with dis-

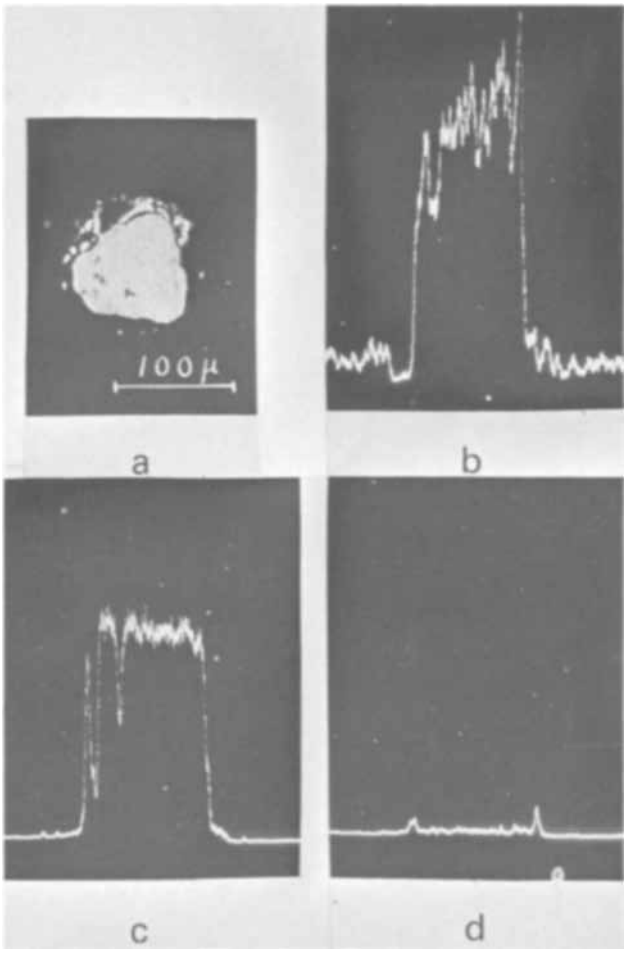

Fig. 3. Typical MnO_2 particle of sample I after heavy and light discharges: (a) cross section without generation of microcracks, (b) and (c) oxygen and manganese distributions showing minor decreases from before discharge, and (d) zinc reaching only the outermost surface but essentially not entering the inside of the particle.

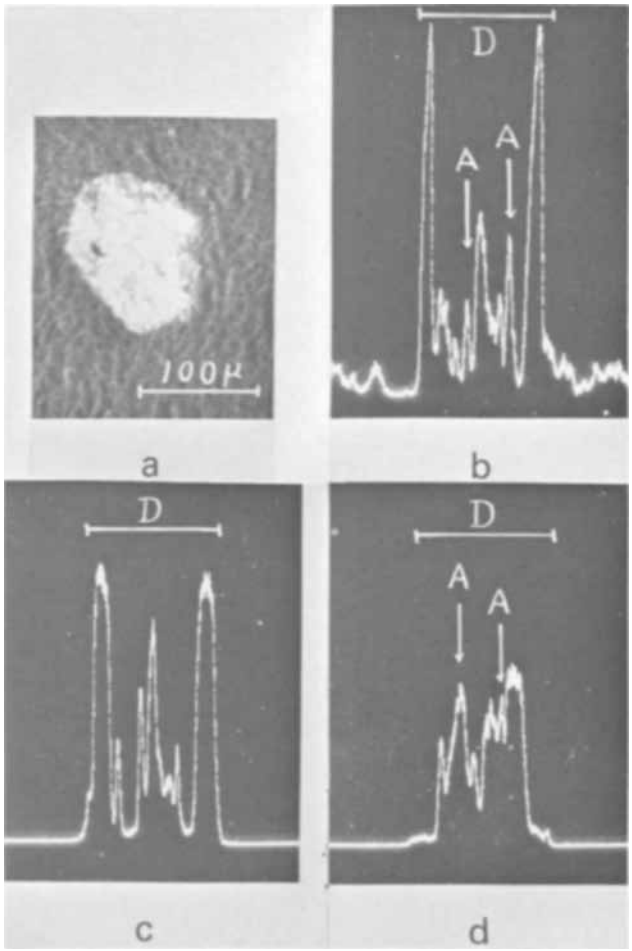

Fig. 4. Sample II particle after heavy discharge, representative of about one half in number: (a) a network of microcracks generated across the particle: (b) and (c) oxygen and manganese, having a maximum concentration at a region slightly inside of the diameter "D"; and (d) zinc replacing most of the inner sites of manganese and oxygen. Zinc coexists with a minor amount of oxygen at such points as "A" corresponding to $ZnCl_2 \cdot 4Zn(OH)_2$.

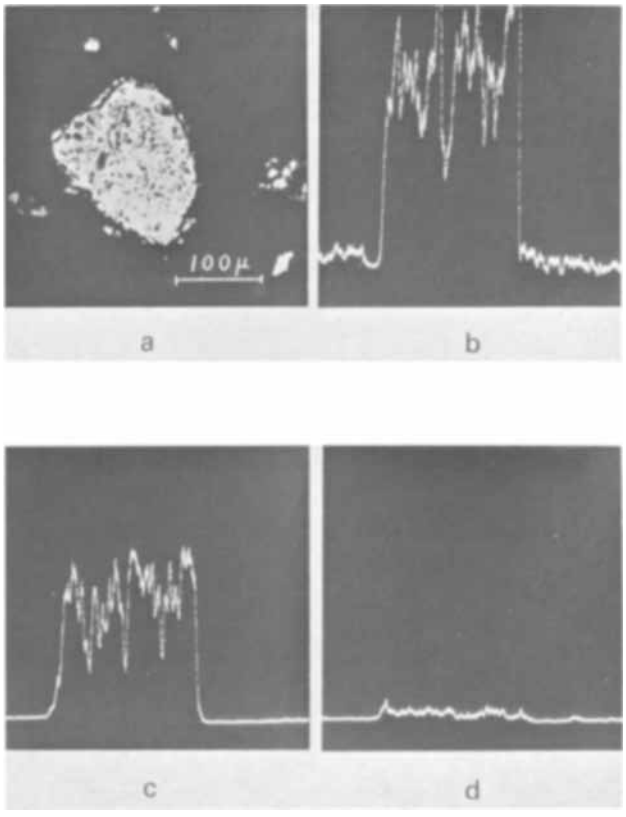

Fig. 5. Sample II particle after heavy discharge, representing the other half in number: (a) microcracks beginning to form across the particle; (b) and (c) a zigzag pattern of decreasing oxygen and manganese concentrations, yet not deeper than in Fig. 4; and (d) zinc beginning to penetrate into the particle.

charge mechanisms for MnO_2. However, it is believed that sufficient examples are presented to give an appreciation of the discharge process of MnO_2 in dry cells in terms of the behaviors of the constituent elements of the MnO_2 including the external zinc ion.

In considering how and where the discharge proceeds at individual MnO_2 particles in the dry cells, it is helpful to postulate two regions; first, the outer region near the surface, *X*, in Fig. 8, and second the inner region including the central part, *Y*, in Fig. 8. The role of the region *X* on the discharge can be taken for granted, as previous workers pointed out the importance of the surface characteristics of MnO_2 involving the surface area (5, 17) and the pore distribution (18, 19). The role of the region *Y*, the inside of the particle, must be added here, and it is apparent from the foregoing microanalytical photographs that the discharge proceeds in a competitive manner between the two regions.

In Fig. 8, which is a schematic illustration of a discharging MnO_2 particle, a proposed relationship is given between the microanalytical patterns of line profiles and the difference in the magnitudes of v_x and v_y where v_x denotes the discharge rate at *X* and v_y the one at Y in arbitrary units.

When v_x and v_y are equally small or v_y is significantly smaller than v_x in spite of a normal rate of v_x, the line profiles of manganese and oxygen may show the pattern of Fig. 8(B), which is exactly the case of Fig. 3 with sample I. In case that v_x is smaller than v_y, the pattern of distributions of manganese and oxygen may become something like Fig. 8(C), which corresponds to the line profiles in Fig. 4 with sample II. Lastly, if v_x and v_y are equally and sufficiently large, a pattern such as Fig. 8(D) may be obtained for the elements, which is equivalent to Fig. 7 with sample III. Intermediate states can be produced in between these clear-cut patterns due to various conditions including the depth of discharge even with the same samples of MnO_2 shown in Fig. 5 and 6.

The reason it is possible for v_y to become larger than v_x is attributed to an intrinsic ability of the MnO_2 material to develop a network of micropores connecting the regions *X* and *Y* as soon as the discharge reaction has initiated at the particle. It is interesting to note that sample I showed no sign of microcracks on the cross-sectional view of the particle after discharge, while samples II and III produced microcracks linking together the inner and the outer regions of the particles. The initial pore openings were not detected before discharge as in Fig. 2(a) because the magnitude of a pore diameter is too small, previously calculated to be less than 400Å by Cahoon *et al.* (19) and predominantly 180Å by Kozawa (18). However, as a result of discharge at the inner regions, *Y*, along these pores, transfer of manganese and oxygen toward the outside occurred and the invaded regions became detectable in the cross-sectional views (a) in Fig. 4, 6, and 7. Furthermore, the developed networks may be a possible path for the external zinc ions to approach into the inner part of the MnO_2 particle.

As a matter of fact, in Fig. 9 are illustrated the x-ray distribution pictures of the three elements for another typical particle of sample II which underwent the Fig. 4 type of discharge. It is seen in the pictures of Fig. 9 that a network of pores developed between the central part and the surface of the particle and the oxygen and manganese in the central region was much reduced, and that, inversely, the zinc concentrated in this region. It is to be noted here again in Fig. 9 that the residual "islets" of the oxygen and manganese are lined up at the region a little inside of

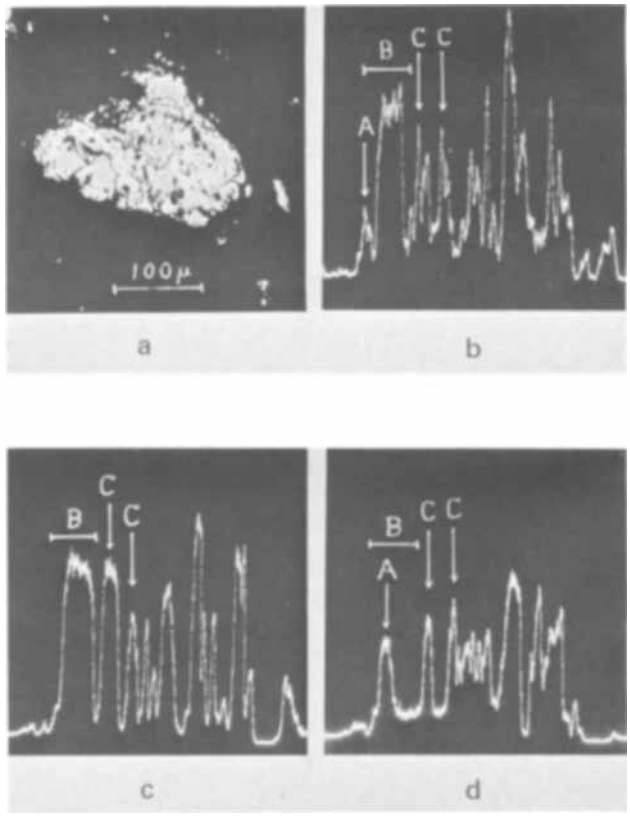

Fig. 6. Sample II particle after light discharge: (a) microcracks covering the cross section; (b), (c), and (d) oxygen, manganese, and zinc distributions, respectively, indicating that zinc replaces manganese in the region "B" on the one hand and coalesces with manganese at the region "C" on the other. At such a point as "A" even in region "B," zinc is accompanied by oxygen as in Fig. 4, showing a microstate of $ZnCl_2 \cdot 4Zn(OH)_2$ plus $Mn_2O_3 \cdot ZnO$ in the particle.

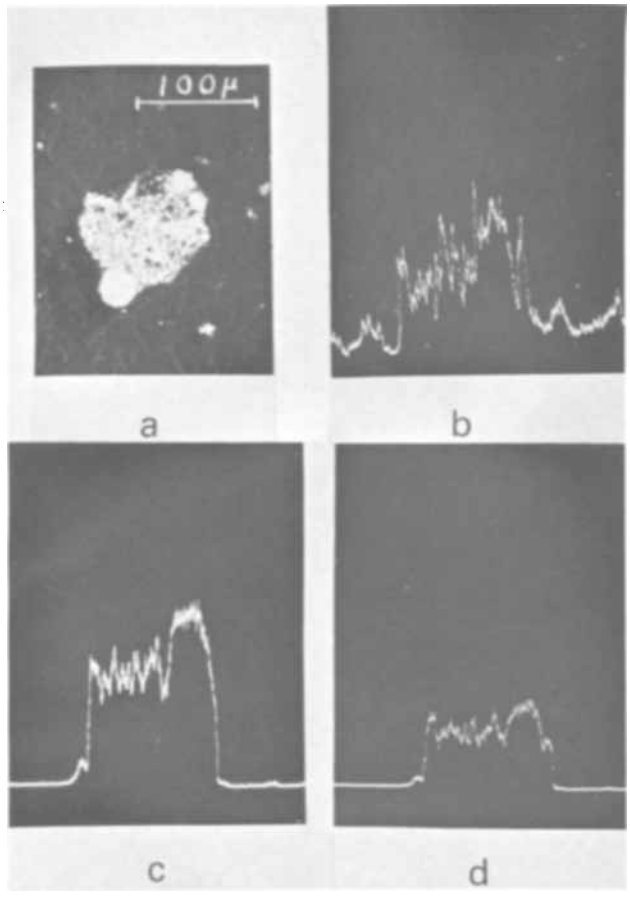

Fig. 7. Typical sample III particle after heavy and light discharges: (a) microcracks generated across the particle, (b) and (c) a noticeable reduction in oxygen and manganese distributions in a rather uniform fashion, and (d) zinc having a distribution pattern almost identical with those of oxygen and manganese, indicating that the three elements have combined into one form of compound, $Mn_2O_3 \cdot ZnO$.

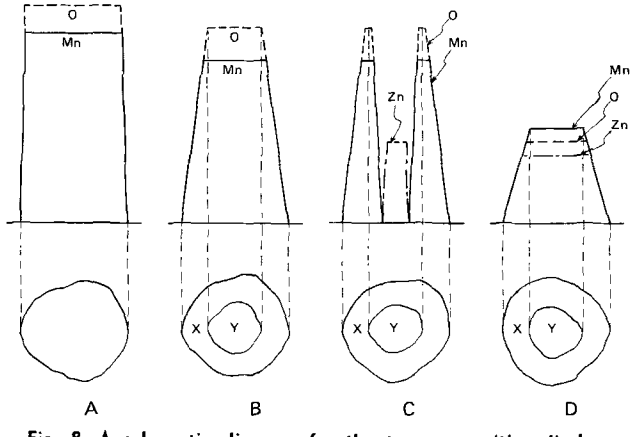

Fig. 8. A schematic diagram for the two competitive discharge reactions, one from the surface and the other from the inside of the MnO_2 particle: (A) before discharge; (B) v_x and v_y are equally small, corresponding to a poor quality MnO_2; (C) v_y is larger than v_z, corresponding to a medium-quality MnO_2; and (D) v_x and v_y are large, corresponding to a superior-quality MnO_2.

the surface of the particle. Therefore, the low concentration region at the outermost surfaces of both in Fig. 4 and 9 will invariably be attributed to the actual decrease in the existing elements. A more quantitative treatment will need to take into consideration a possible topographic effect of the specimen surface on line intensities. However, a full discussion in terms of detailed microanalytical factors is not within the scope of this paper.

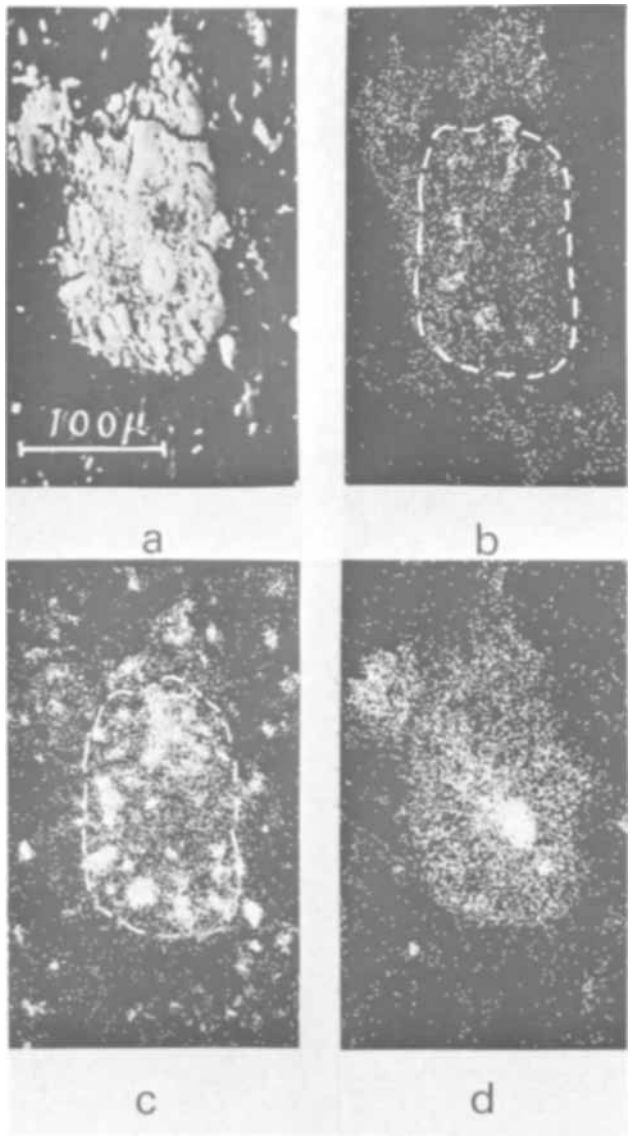

Fig. 9. A plane view of the distribution of oxygen, manganese, and zinc elements in MnO_2: (a) electron optical image of microcracks generated across the particle; (b) and (c) x-ray distribution pictures of oxygen and manganese, showing "islets" of the elements remaining along the network of the microcracks; and (d) zinc x-ray distribution profile showing this element has occupied the central sites which were occupied by manganese and oxygen before discharge.

A limitation of the geometrical model of Fig. 8 in interpreting the discharge mechanism is the fact that it will not account for the chemical affinity of elements. The entry of external zinc into the MnO_2 particles in Fig. 8(C) and (D) can be explained by the large rates of v_y in both cases to form enough geometrical room to receive the zinc ion which is migrating in along the micropores. However, it may not be straightforward as to the reason why the entering zinc remained independent of manganese in the former case, while the zinc coalesced with manganese in the latter. In this respect, the reaction velocities v_x and v_y will not directly relate to the mode of existence of zinc in the lattice, which may be governed by the intrinsic quality of the MnO_2 species itself.

However, the geometrical interpretation in terms of the competitive reaction rates v_x and v_y in Fig. 8 will lead to a clearer understanding as to how and where the discharge proceeds at a thin zone of the MnO_2 on the particle-wide basis, on which not much information was obtained by means of the conventional x-ray diffraction examination of Table III.

It is also interesting to note that the manganese has decreased in intensity in all the line profiles of Fig. 3-7, although the extent is generally smaller than that for oxygen. Dissolution of MnO_2 into Mn^{+2} ions from a discharging MnO_2 electrode was described by Brenet *et al.* (20) and Cahoon *et al.* (21-23) as being one of the possible discharge products of MnO_2, and Vosburgh *et al.* (24) identified two discharge products, an oxide with a composition of about $MnO_{1.6}$ and Mn^{+2} ions, using MnO_2 electrodes deposited on graphite rods and discharging them in NH_4Cl electrolyte. The results obtained here with the reduced oxygen and manganese line profiles after discharge may provide visual evidence for the escape of a portion of the manganese as well as the oxygen through the solid phase of MnO_2 particles during discharge of the dry cells.

Summary and Conclusions

The electron probe microanalytical techniques used in this study are useful in revealing the changes in the inside of MnO_2 particles during the cathodic reactions in the dry cell, and in supplementing the discussions of previous workers on the discharge of MnO_2.

The discharge quality of MnO_2 materials used are interpreted on the basis of manganese, oxygen, and zinc line profiles. The amounts of manganese and oxygen in MnO_2 decrease during discharge, and the release of oxygen is large in the case of MnO_2 ores with better discharge performances.

The pattern of decrease of manganese and oxygen in combination with the entrance of zinc is tentatively classified into three types according to the discharge quality of the MnO_2 ores employed. With a poor grade ore, the entrance of external zinc into the MnO_2 particles is not noticeable. However, with a fair-grade MnO_2, the zinc is observed to occupy the inner portions of the particle, where the manganese was situated before discharge. With a high-grade ore, the zinc is distributed in a rather uniform fashion in the diametrical direction of the particle together with the residual manganese and oxygen.

An intermediate between these three typical patterns for the distribution of the elements may be explained as a special case of combinations of the three cases. This implies that the discharge proceeds through two processes in a competitive manner, one from the surface and the other along the micropores or cleavages inside of the particles, the balance of which may govern the discharge quality of the MnO_2 materials.

Acknowledgments

The author wishes to thank his colleagues, N. Sasaki for the x-ray diffraction, H. Nakamura and T. Kobayashi for the electron probe microanalysis, and M. Yamamoto for helpful discussions during the course of this investigation.

The Cathodic Reduction of Oxygen on Platinum in Alkaline Solutions

K. F. Blurton[1]* and E. McMullin[2]

Leesona Moos Laboratories, Great Neck, New York

ABSTRACT

Measurements with rotating disk and ring/disk electrodes have been used to elucidate the reaction paths for oxygen reduction on platinum in concentrated alkaline electrolyte. It is concluded that oxygen is reduced to hydrogen peroxide at potentials between the open circuit voltage and 0.4V *vs.* a reversible hydrogen electrode. Between 0.4 and 0.0V *vs.* a reversible hydrogen electrode, oxygen is reduced to OH^- with peroxide as an intermediate product. The effect of hydrogen peroxide decomposition on the limiting current density for oxygen reduction at a rotating disk electrode and on the value of the ring current of a rotating ring/disk electrode is discussed.

Studies on the electrochemical reduction of oxygen have been stimulated in the last few years by the interest in fuel cells and metal/air batteries. It has been previously demonstrated that hydrogen peroxide is the product of oxygen reduction on carbon electrodes in alkaline solution (1, 2). However the role played by this species during oxygen reduction on platinum electrodes in the same electrolyte is open to more controversy and probably depends on the electrode potential and surface pretreatment. Thus it has been postulated that during oxygen reduction on platinum in alkaline electrolyte hydrogen peroxide is either an intermediate in a single reaction path (3-7) or the sole product of the reaction (8-10) or an intermediate in a path parallel to a second reaction path involving oxygen reduction directly to OH^- (11, 12). It has also been suggested (13) that oxygen is reduced directly to OH^- without peroxide being involved.

The aims of the present study were to elucidate the role of hydrogen peroxide in the reduction of oxygen on platinum, to measure the effect of the peroxide decomposition on the limiting current at a rotating disk electrode, and to analyze the effect of the peroxide decomposition on the current measured at the ring of a rotating ring/disk electrode. It was decided to perform these studies in concentrated alkaline electrolyte at elevated temperatures, *i.e.*, under conditions similar to those for the operation of fuel cells.

Experimental

The reaction cell was a one liter, glass cylindrical vessel fitted with a lucite lid. Gas inlets were positioned above and below the surface of the electrolyte and were placed as far as possible from the rotating electrode to prevent interference with the fluid flow. The counterelectrode was a platinum gauze (geometric area 23 cm^2) which was placed on the bottom of the glass vessel. The reference electrode was a reversible hydrogen electrode immersed in the test electrolyte and located in a second compartment. This compartment was connected to the main one by a Luggin capillary. The tip of the Luggin capillary was located slightly above the surface of the disk electrode again to prevent interference with the electrolyte flow and the ohmic drop was found to be less than 1 mV in the test solution at all the experimental currents.

The construction of the disk electrode was similar to that described by Blurton and Riddiford (14). The construction of the ring/disk electrode is shown in Fig. 1. The insulating material was 7/16 in. diameter Kel F. The internal and external radii of the ring electrode were 0.260 cm and 0.375 cm, respectively, and the radius of the disk electrode was 0.245 cm. Electrical contact was made by platinum wire welded onto the inner ends of the disk and ring electrodes. There was no electrolyte creep between the platinum and the shielding and these were found to be inert to the caustic potash solutions at 70°C. Both the rotating disk and ring/disk electrodes were stored in distilled water between runs.

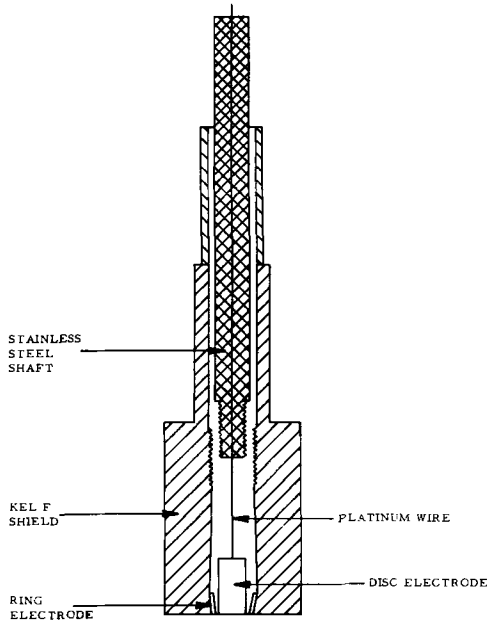

Fig. 1. Construction of rotating ring/disk electrode

Before making measurements with the ring/disk electrode a light coating of platinum was electrodeposited onto the working surface of the ring. The polarization curve on the disk was then measured by changing the disk potential in steps of 50 mV in the potential range of open circuit to 0V with a low impedance potential divider. At each disk potential, the ring current was measured at a potential of 1.3V.[3] At this potential the current due to oxygen evolution is insignificant and all the hydrogen peroxide produced at the disk, which reaches the ring, is oxidized, *i.e.*, the ring is operated in the hydrogen peroxide limiting current region.

[2] Present address: Quantachrome Corporation, Greenvale, New York.

[3] All potentials refer to the reversible hydrogen electrode in the same solution.

A solution of 6.9M KOH was prepared from Baker Analyzed Reagent grade chemical and triple distilled water. Oxygen and hydrogen were obtained from cylinders and were used without further purification. Potentials were measured with a differental voltmeter (J Fluke Model 801H) and the current was measured from the potential drop across a standard resistor. No rigorous purification schemes were used for the electrolyte for a previous study (12) showed that electrolyte impurities in alkaline electrolyte did not influence peroxide formation.

Results

The polarization curve for oxygen reduction on a rotating platinum disk electrode in 6.9M KOH solution at 70°C is given in Fig. 2. The steady state current was attained in 5-10 min. The shape of this curve was similar at all electrode rotation speeds and showed three distinct regions. At potentials between open circuit and 0.7V the current increased with increasing polarization, between 0.7 and 0.6V a limited current region was observed and between 0.6 and 0V the current again increased with increasing polarization. In agreement with the work of Tikhomirova, Luk'yanycheva, and Bagotskii (8) but in contrast to that of Müller and Nekrasov (3) no peak was observed in the current/voltage curves. Figure 2 also shows the current/voltage curve obtained by decreasing the polarization from 0V to open circuit. The currents during the reverse sweep were similar to those obtained by increasing the polarization in the potential range 0-0.5V but differed from those obtained by increasing the polarization in the potential range 0.5V to open circuit. The experimental open circuit voltage at the end of the hysteresis measurement was more cathodic than that determined initially, but it increased steadily to the original value on standing.

The value of the limiting current was found to depend markedly on electrode history and reproducible plots of i_L *vs.* (electrode rotation speed)$^{1/2}$ were only obtained when all the limiting currents were determined within a period of a few hours (Fig. 3). This was achieved by potentiostating the electrode at 0.70V and measuring the limiting current at a fixed electrode rotation speed. The electrode was then allowed to stand on open circuit until the original open circuit voltage was obtained and the limiting current at another electrode rotation speed was measured by repotentiostating at 0.70V. This procedure was repeated by potentiostating the electrode at 0.65V to check that the measured current was indeed the limiting current. Similar current/voltage curves for oxygen reduction were obtained on a lightly platinized as on the bright platinum disk electrode but the limiting currents were greater on the former electrode (Fig. 3). The platinum electrodeposit on these electrodes was sufficiently smooth so that the hydrodynamic flow was not disturbed.

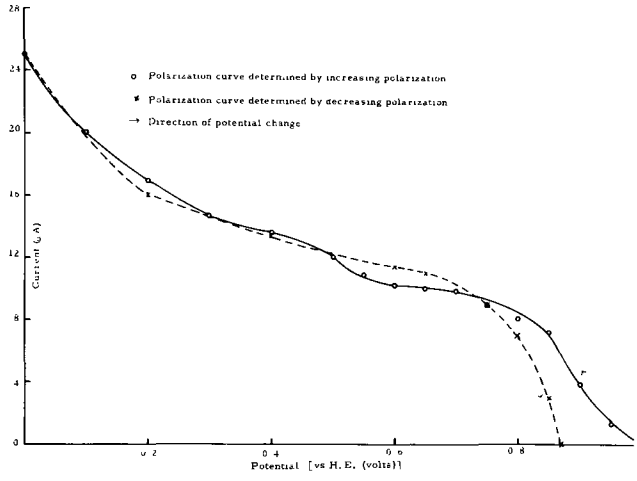

Fig. 2. Polarization curve for oxygen reduction on a rotating platinum disk electrode in 6.9M KOH solution at 70°C; electrode rotation speed 500 rpm.

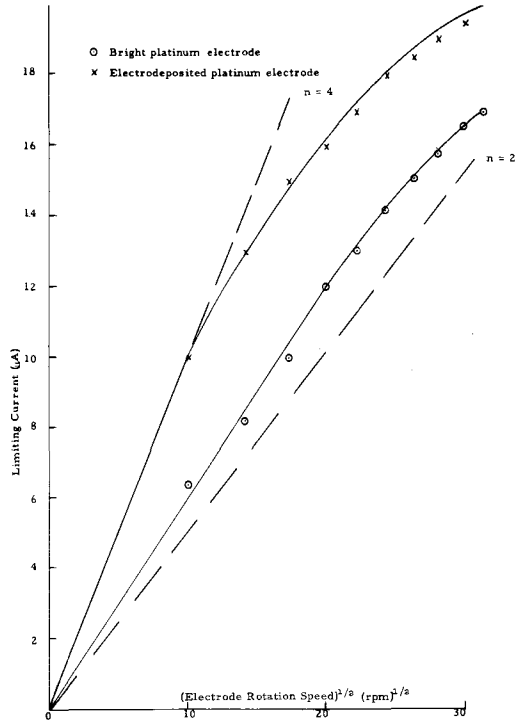

Fig. 3. Limiting current vs. (rpm)$^{1/2}$ for oxygen reduction at the rotating disk electrode. The theoretical plots for the 2 and 4 electron processes were calculated using the values of D_{O_2}, ν_{KOH}, and C_{O_2} given in the text.

The plot of the limiting current *vs.* (electrode rotation speed)$^{1/2}$ was nonlinear (Fig. 3). Now the values of the bulk concentration of oxygen (C_{O_2}), the oxygen diffusion coefficient (D_{O_2}), and the KOH solution viscosity (ν_{KOH}) have not been determined under the present experimental conditions, but extrapolation of the available data (15-17) gives $C_{O_2} = 6.1 \times 10^{-5}$ mole l^{-1}, $D_{O_2} = 1 \times 10^{-5}$ cm^2 sec^{-1}, and $\nu_{KOH} = 8.3 \times 10^{-3}$ cm^2 sec^{-1} (18). From this data it was found that the values of the experimental limiting currents were intermediate between those calculated (19, 20) for a 2 and 4 electron process (Fig. 3).

The current/voltage curve for oxygen reduction at the disk electrode in 6.9M KOH solution at 70°C with the corresponding ring current at 1.3V is given in Fig. 4 at an electrode rotating speed of 1000 rpm. The ring current reaches a maximum value at disk potentials between 0.75 and 0.45V and, in the same potential range, there is a limiting current on the disk electrode. At potentials more cathodic than 0.5V the disk current increases and the ring current decreases, *i.e.*, the hydrogen peroxide produced at the disk is further reduced to water. Similar results have been obtained at other electrode rotating speeds and Fig. 5 gives the values of the ratio of the disk current to the ring current (I_D/I_R) at these rotation speeds. The accuracy of these ratios is limited by the small values of the ring and disk currents which, in turn, are limited by the low oxygen solubility in the concentrated alkaline solution. The ratios were generally reproducible to ± 1 although larger deviations were recorded particularly at low electrode rotation speeds when the disk and ring currents are at their minimum values.

At disk potentials more cathodic than 0.4V the variation of I_D/I_R with electrode rotating speed was less reproducible due to the very small values of the ring current. However, the values of I_D/I_R were clearly dependent on the electrode rotation speed and, in gen-

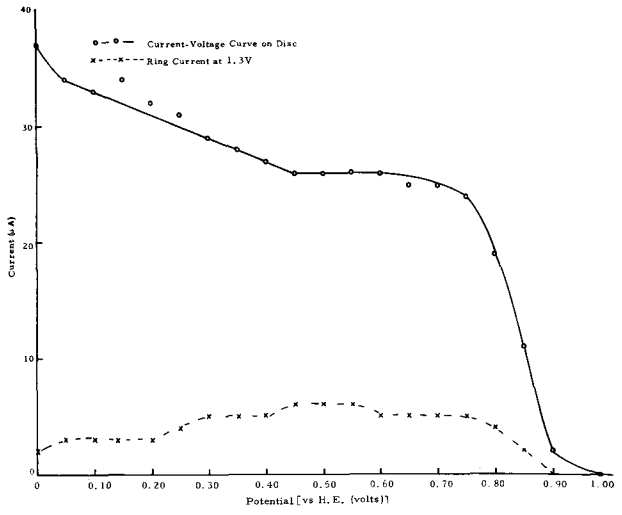

Fig. 4. Current/voltage plot for oxygen reduction at the disk of the rotating ring/disk electrode in 6.9M KOH solution at 70°C with the corresponding ring current at 1.3V; electrode rotation speed 1000 rpm.

eral, decreased as the electrode rotation speed increased.

Discussion

Comparison of the current/voltage relationship for oxygen reduction on a dropping mercury (21) with the corresponding plot obtained on a rotating platinum disk electrode (Fig. 2) suggests that, on the rotating disk electrode, oxygen is reduced to hydrogen peroxide in the potential range of open circuit to 0.6V whereas at more cathodic potentials oxygen is reduced to water probably with hydrogen peroxide as an intermediate. The low value of the open circuit voltage at the end of the potential scan also indicates that peroxide is formed by the reduction of oxygen for, in the presence of peroxide, the oxygen electrode attains the potential of $O_2 + H_2O + 2e \rightarrow HO_2^- + OH^-$ rather than that of $O_2 + 2\,H_2O + 4e \rightarrow 4\,OH^-$ (1, 22). The hysteresis observed in the polarization curves (Fig. 2) is probably due to the influence of the hydrogen peroxide. This phenomenon has been discussed by Bowen and Urbach (10) and was attributed by them to the influence of the peroxide on the platinum surface oxides.

The experimental limiting currents for the reduction of the tri-iodide ion in 0.1M potassium iodide were equal to the theoretical values for electrode rotation speeds of 100-1000 rpm inclusive. Thus the nonlinearity of the limiting current *vs.* (electrode rotation speed)$^{1/2}$ plots (Fig. 3) is due to the nature of the electrode reaction and not to an experimental deviation from the theoretical requirements. The dependence of the limiting current on the electrode surface treatment indicates that the hydrogen peroxide is decomposing by a surface chemical reaction.

McIntyre (23) has shown that plots of i_L *vs.* (electrode rotation speed)$^{1/2}$ similar to that in Fig. 3 indicate that the product formed by the electrochemical reaction decomposes by a second order surface catalyzed chemical reaction to form the reactant, *i.e.*, in the present study the reaction is represented by the equations

$$O_2 + H_2O + 2e \rightarrow HO_2^- + OH^- \qquad [1]$$

$$2\,HO_2^- \rightarrow O_2 + 2\,OH^- \qquad [2]$$

For this reaction scheme the limiting current density is given by (23)

$$\frac{i_L}{2F} = 2L_{O_2}\,\omega^{1/2}C_{O_2} - \frac{L^2_{H_2O_2}\omega}{2k_h}\left[\left(1 + \frac{4k_hL_{O_2}C_{O_2}}{L^2_{H_2O_2}\omega^{1/2}}\right)^{1/2} - 1\right] \qquad [3]$$

where ω(rad. sec^{-1}) is the angular velocity of the disk, k_h is the second order heterogeneous chemical rate constant of the regenerative reaction (*i.e.*, Eq. [2]), and L_i is given by (23, 24)

$$L_i = \frac{0.62048\,D_i^{2/3}\,\nu^{-1/6}}{1 + 0.2980\,(D_i/\nu)^{1/3} + 0.14514\,(D_i/\nu)^{2/3}} \qquad (i = O_2, H_2O_2) \qquad [4]$$

By assuming that $D_{O_2} = D_{H_2O_2}$ the values of k_h have been calculated from Eq. [3] and data given in Fig. 3 and they are reported in Table I.

The values of k_h given in Table I are based on the geometric area of the electrode and the difference between the values on bright and electrodeposited platinum is due to the difference in the true surface area of the electrode. The constancy of the values of k_h suggests that Eq. [1] and [2] do indeed represent the over-all process for the reduction of oxygen in alkaline solution and that the peroxide decomposition is occurring by a 2nd order surface catalyzed reaction. A similar reaction scheme has also been proposed by Tikhomirova, Luk'yanycheva, and Bagotskii (8) for oxygen reduction on platinum in 1*N* KOH solution.

Damjanovic, Genshaw, and Bockris (11, 12) suggested, from an analysis of plots of I_D/I_R *vs.* $\omega^{-1/2}$, that oxygen reduction on platinum in alkaline solution proceeds along two parallel reaction paths (*i.e.*, Eq. [5] and [6]) and that these reactions occur at similar rates.

$$O_2 + 2H_2O + 4e \rightarrow 4\,OH^- \qquad [5]$$

$$O_2 + H_2O + 2e \rightarrow HO_2^- + OH^- \qquad [6]$$

The relationship between I_D/I_R and $\omega^{-1/2}$ was shown to be (25)

$$\frac{I_D}{I_R} = \frac{x+1}{N} + \frac{(x+2)}{N}\,\frac{1.61 \cdot k \cdot \nu^{1/6}}{D^{2/3} \cdot \omega^{1/2}} \qquad [7]$$

where k is the rate constant for the electrochemical reduction of hydrogen peroxide to water, N is a factor dependent on the geometry of the rotating ring/disk electrode, and x is the ratio of the current for the reaction represented by Eq. [5] to that represented by Eq. [6].

For the electrode assembly used in the present study the calculated (26) value of N and the experimental value (for the redox reaction $2Br^- \rightarrow Br_2 + 2e$) were equal to 0.495 (*i.e.*, $1/N = 2.021$). The experimental value of I_D/I_R for oxygen reduction in 6.9M KOH solution was greater than $1/N$ and it was independent of electrode rotation speed and of potential between 0.8 and 0.4V (Fig. 5). Thus the treatment of Damjanovic, Genshaw, and Bockris (25) indicates that two parallel reactions are occurring during oxygen reduction (Eq. [5] and [6]) in the potential range 0.8-0.4V. Also, since the peroxide is not further reduced electrochemically (*i.e.*, $k = 0$) Eq. [7] simplifies to

$$\text{Intercept in Fig. 5} = \frac{x+1}{N} \qquad [8]$$

which gives x equal to 1.5. Thus the two parallel

processes are occurring with comparable rates and, since the value of I_D/I_R is independent of potential in the range 0.8-0.4V, the relative rates of the two reactions are independent of potential.

The inconsistency as to whether the over-all reaction is represented by Eq. [1] and [2] or by Eq. [5] and [6] may be resolved by a closer inspection of the derivation of Eq. [7]. This derivation (25) utilizes the equation

$$I_R = \frac{I_D \cdot N}{1 + k\delta/D} \qquad [9]$$

where δ is the diffusion layer thickness of the intermediate and it is applicable (19) to the electrochemical reaction at the disk electrode of a reactant to an intermediate with partial electrochemical conversion of the intermediate to a final product. Thus it is necessary to determine whether Eq. [9], and hence Eq. [7], requires modification to apply to the reactions represented by Eq. [1] and [2]. Another approach, which we propose, is to assume that Eq. [9] is correct and modify Eq. [7]. This has been achieved by determining the effect of the hydrogen peroxide concentration (and hence decomposition rate) on the disk and ring currents.

When oxygen is electrochemically reduced to hydrogen peroxide which then decomposes by a second order heterogeneous chemical reaction (*i.e.*, Eq. [1] and [2]), McIntyre (23) has shown that the disk limiting current ($I_{L,D}$) is given by

$$\frac{I_{L,D}}{2F} = J_{H_2O_2} + 2\, k_h\, [\bar{C}_{H_2O_2}]^2 \qquad [10]$$

where $J_{H_2O_2}$ is the flux of the peroxide to the uniformly accessible surface of the disk and $\bar{C}_{H_2O_2}$ is the surface concentration of hydrogen peroxide. The flux of peroxide when the oxygen surface concentration is zero is related to the peroxide surface concentration by (23)

$$J_{H_2O_2} = L_{H_2O_2}\, \omega^{1/2}\, [\bar{C}_{H_2O_2}] \qquad [11]$$

and $\bar{C}_{H_2O_2}$ is given by (23)

$$\bar{C}_{H_2O} = \frac{L_{H_2O_2}\omega^{1/2}}{2k_h}\left[\left(1 + \frac{4k_h L_{O_2} C_{O_2}}{L^2_{H_2O_2}\omega^{1/2}}\right)^{1/2} - 1\right] \qquad [12]$$

The thickness of the H_2O_2 diffusion layer, $\delta_{H_2O_2}$, at the rotating disk electrode, is given by (20)

$$\delta_{H_2O_2} = \frac{D_{H_2O_2} \cdot \omega^{-1/2}}{L_{H_2O_2}} \qquad [13]$$

and the current at the ring electrode is related to the hydrogen peroxide surface concentration (27) by

$$I_R = 2\,NF\,\frac{\bar{C}_{H_2O_2} \cdot D_{H_2O_2}}{\delta_{H_2O_2}} \qquad [14]$$

By substituting Eq. [11], [12], and [13] into the equation obtained by dividing Eq. [10] by [14]

$$\frac{I_{L,D}}{I_R} = \frac{1}{N}\left(1 + \frac{4k_h L_{O_2} C_{O_2}}{L^2_{H_2O_2}\omega^{1/2}}\right)^{1/2} \qquad [15]$$

Thus for the reaction scheme represented by Eq. [1] and [2], the rate of change of $I_{L,D}/I_R$ depends to a much lesser extent on $\omega^{-1/2}$ than that predicted by Damjanovic, Genshaw, and Bockris (25). Equation [15] may be simplified by assuming that $D_{O_2} = D_{H_2O_2}$, by assuming that $C_{O_2} = 6.1 \times 10^{-5}$ mole l^{-1} and by using the average value of k_h for the smooth electrode from Table I. Then

$$\frac{I_{L,D}}{I_R} = \frac{1}{N}\left(1 + \frac{7.7}{\omega^{1/2}}\right)^{1/2} \qquad [16]$$

In the present study $20 < \omega < 100$, so that

$$3.3 > I_{L,D}/I_R > 2.7 \qquad [17]$$

It was not possible to detect the small variation of $I_{L,D}/I_R$ with $\omega^{-1/2}$ predicted by Eq. [17] due to the small values of the ring current. However, the apparent independence of $I_{L,D}/I_R$ on ω (Fig. 5) does indicate that oxygen is electroreduced by a reaction scheme represented by Eq. [1] and [2]. Also, the values of k_h were determined on a different electrode from that used for the ring/disk electrode and this causes the discrepancy between the calculated (Eq. [17]) and experimental (Fig. 5) values of I_D/I_R since k_h depends on the electrode roughness.

Thus we suggest that the measurements with the rotating ring/disk electrode coupled with those of the limiting currents on the rotating disk electrode confirm that the reduction of oxygen on platinum in alkaline solution in the given potential range proceeds via reactions represented by Eq. [1] and [2] and that the parallel reactions do not occur. The treatment given here does show that caution must be exercised in the interpretation of I_D/I_R *vs.* $\omega^{-1/2}$ plots and that, in contrast to Nekrasov's statement (6), the catalytic decomposition of peroxide does modify the ring current. It should be stressed that the derivation of Eq. [15] is applicable only under limiting current conditions and depends on the validity of Eq. [9].

The results obtained with the rotating disk electrode (Fig. 2) suggest that peroxide electroreduction occurs at potentials more cathodic than 0.6V whereas measurements with the ring/disk electrode (Fig. 5) indicate that peroxide reduction occurs at potentials more cathodic than 0.4V. This difference is probably due to the different condition of the electrode surfaces and indicates the importance of the nature of the surface on peroxide reduction. The difference in the plots of I_D/I_R *vs.* (electrode rotation speed)$^{-1/2}$ between Fig. 5 and those of Damjanovic, Genshaw, and Bockris (11, 12) may also be due to a variation in the state of the electrode surface.

The results reported in this paper demonstrate that the catalytic decomposition of peroxide formed at a disk electrode during the reduction of oxygen influences both the value of the disk limiting current and the value of the ratio of the disk to ring current. In the limiting case, *i.e.*, $k_h \to \infty$, the disk limiting current equals the value calculated for a four electron process but for other values of k_h the disk limiting current is intermediate between that for a 2 and 4 electron process. Clearly the peroxide decomposition reaction will also affect the shape of the galvanostatic chronopotentiometric curve and the apparent number of electrons calculated from the transition time (13, 21, 28, 29).

Redox Coulometers

Joseph L. Weininger*

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

A coulometer is described which cumulatively measures periods of time, up to a preset limit, during which a repetitive event occurs. The redox couple ferrocyanide-ferricyanide is reversibly reduced and oxidized at pyrolytic graphite electrodes. An ion exchange membrane prevents the mixing of the electrolytic solutions surrounding the electrodes, thereby setting up a concentration cell with transference. The cell potential follows the Nernst relation, but depending on cell geometry and operating parameters, partial diffusion control of electrode reactions is also observed. At a given potential limit the process is reversed. This cycling is repeated for a cell life in excess of 2000 cycles with less than 1% error when interrupted for as long as 24 hr.

A coulometer measures the quantity of electricity passed through a circuit by means of the electrolysis of an electrochemical couple. The principle of its operation is based on Faraday's law. In this report a coulometer is discussed which, integrating a constant current signal, will measure the duration of time, up to a preset limit, during which a repetitive event occurs. Such timing operations are important in process controls where a fixed time limit may be divided into different time segments.

Henderson (1) has designed a variety of coulometers with battery plates as electrodes. These devices are based on and are used in battery technology. For example, two identical cadmium-cadmium hydroxide plates are operated against each other. Their predetermined states of charge and discharge, indicated by the cell voltage, time a process which in Henderson's case is the charging of a battery at high constant current density. For applications requiring extremely long life and reliability such a device may be unsuitable, because the repeated cycling of most battery plates is accompanied by noticeable evolution of gases due to the electrolysis of solvent water. Also, the mechanism of the battery operation involves the chemical transformation of solid phases of the electroactive material, for example, the interconversion of cadmium and cadmium hydroxide. Such electrodes, known as "electrodes of the second kind," experience structural changes as a result of the electrode reaction which during repeated cycling tend to reduce the capacity of the plates.

To overcome these difficulties a redox couple is used in the present coulometer, which is soluble in both its oxidized form (concentration C_O) and its reduced form (concentration C_R). The couple is chemically stable and has a potential far removed from that required for evolution of either hydrogen or oxygen from water.

Mechanism of the Coulometer

In the schematic drawing of Fig. 1 the coulometer is connected to a constant current switching circuit.[1] The direction of the current (polarity) is controlled by the cell which reverses the current at preset upper and lower voltage limits. The limits at which this switching occurs can be adjusted arbitrarily.

The cell consists of two chambers, each containing an inert electrode and each filled with a solution of composition C_O and C_R. In effect, the cell is a "concentra-

rig. 1. Schematic of redox coulometer

tion cell with transference," which implies that there is electrolytic continuity between the two half-cells. Diffusion of the redox species from one compartment to the other must be prevented. This is accomplished with an ion exchange membrane. A cation exchange membrane is used when the changing concentrations involve anions; conversely, an anion exchange membrane is required for electroactive cations.

The mechanism of the coulometer operation is illustrated by the data of Table I. The emf of the cell is given by the Nernst relation

$$E = \frac{RT}{n\mathbf{F}} \cdot \ln \frac{C_O{}^A \cdot C_R{}^B}{C_R{}^A \cdot C_O{}^B}$$

where the superscripts indicate the respective cell compartments. Either the reduced or oxidized species may be in limited supply. As the ratios C_O/C_R vary, so will the potential difference exhibited by the cell. It is this cell voltage which will reverse the current flow in the external circuit. In this manner the capacity of the coulometer, *i.e.*, the duration of time which the cell adds cumulatively and linearly, is predetermined by the concentration of the redox couple.

The time measurement occurs in the first half-cycle, also called the "timing period." The second half-cycle, the "reset period," has only the function of bringing the cell back to the original starting point so that repetitive timing can be accomplished during the first half-cycles under identical conditions.

In the examples of Table I both compartments A and B are filled with the same solution, having concentration ratio C_O/C_R of 4/1. The reduced species is oxidized at the positive electrode until a negligible amount of C_R is present in A at the start of the first half-cycle (timing or discharge). A corresponding amount of the reduced species, but one still in limiting supply, is produced at cathode B. In the following half-cycle (reset or charging) the polarity is reversed, hence cathodic and anodic processes are reversed, and so on. In Table I the ratio of 4/1 was chosen for purpose of illustration. Other values could be chosen and, similarly, the oxidized species with concentration C_O could be limiting.

Cell Design and Components

A detailed sketch of the cell is shown in Fig. 2. Each half-cell consists of a poly(methylmethacrylate) housing with a cavity 1-in. in diameter and 0.1-in. deep, in which graphite electrodes (with Pt contacts) are located. The two half-cells are separated by a cation

Table I. Concentration of redox species (Arbitrary units)

	Initial (on filling) Compartments		First half-cycle Reset (Start of timing) Compartments		Second half-cycle Timing (Completion of timing) Compartments	
	A	B	A	B	A	B
C_O	4	4	5	3	3	5
C_R	1	1	0	2	2	0

exchange membrane, are fastened together with Nylon bolts, and are sealed with Viton O-rings. The redox solution is introduced after partially evacuating the cell.

Pyrolytic graphite is used as an indicator electrode because it is cheaper than platinum and chemically as stable. Electrodes are heated in vacuum before use in order to expel reducing gases trapped in the pyrolytic graphite during its preparation.

The couple used in this coulometer is the ferrocyanide-ferricyanide couple, for which the electrode reaction is

$$Fe(CN)_6{}^{-4} \rightleftarrows Fe(CN)_6{}^{-3} + e$$

Its oxidized and reduced components are both soluble, it has a potential far removed from that required for evolution of either hydrogen or oxygen from water, it reaches a reversible equilibrium with high exchange current density, it is chemically stable above pH 3.5, provided it is stored in the absence of oxygen so as to prevent oxidation of ferrocyanide, and it is easily prepared and purified in the form of the potassium salts.

The "parent"-metal ion couple is

$$Fe^{++} \rightleftarrows Fe^{+++} + e \quad E^o = 0.771\text{V (}vs.\text{ NHE)}$$

Even in this one metal ion system, with ions of iron, there is a wide choice of couples available by complexing ferrous and ferric ions with different ions, of which the cyanide is only one example. It has a higher equilibrium potential ideally suited for the coulometer operation in a cell voltage range of +0.3 to —0.3V. In the ferrocyanide-ferricyanide case, this corresponds to a potential range of +0.16 to +0.76V (*vs.* NHE), precisely the "safe" range, in which there is no interference from either hydrogen ion reduction at the lower potential limit or oxidation of water at the upper limit.

The large size of the hydrated anions of the ferrocyanide-ferricyanide couple practically eliminates co-ion (anion) diffusion through the ion-exchange membrane charged with the same polarity. Furthermore, because this couple consists of large negative ions, it is compatible with the use of cation exchange membranes, which are commercially better developed than anion exchange membranes.

Different commercially available cation exchange membrane materials, mostly sulfonated polystyrene membranes, were satisfactory. The final choice was an oxidatively stable fluorocarbon polymer with ion exchange based on sulfonated trifluorostyrene. The ion exchange membranes, supplied in the hydrogen ion form, were stored in the coulometer redox solution. This assured exchange with potassium and sodium ions and equilibrated the ion exchange membrane with the coulometer solution before use.

Because of the small coulombic charge required for operation of the coulometer through a single half-cycle, it is necessary that the redox couple be present in dilute concentration, of the order of 1-10 mM/liter in small volumes of less than 1 ml. This requires a supporting electrolyte. Since chemical stability of the couple also requires a *p*H above 3.5, preferably near 7, the function of the buffer and supporting electrolyte is combined by the use of Sorenson's phosphate electrolyte (2) which gives a *p*H 6.67 for the mixture 0.5M KH_2PO_4 + 0.5M Na_2HPO_4. Latimer gives a rest potential of 0.48V (*vs.* NHE) for the couple with equal concentrations of negative ions (3). Our determination in a buffered solution at *p*H 6.67 is E^o = 0.475V (*vs.* NHE).

Results

The symmetrical cell had pyrolytic graphite electrodes with 5.07 cm^2 surface area. The spacing between the electrode and the ion exchange membrane was 0.0254 cm and defined a volume of 0.129 ml for each of the half-cells. Thus, a total of only 0.258 ml of the redox solution was required. Slightly more is available because of the presence of channels for filling the cell.

Figures 3 and 4 show the performance of this cell at constant current flow of 67 μA. The cell contained a solution of 0.016M $K_3Fe(CN)_6$ + 0.004M $K_4Fe(CN)_6$ + 0.5M Na_2HPO_4 + 0.5M KH_2PO_4. Figure 3 traces the voltage as a function of time for cycles 138-142 with current reversal at ± 0.3V. During cycles 168 and 169 the current was interrupted for 17 and 20 min, respectively, as shown in Fig. 4. No increase in the timing or reset periods of the cycles occurred as a result of the interruptions. The second period at open circuit, at —100 mV, when there was a difference of almost two orders of magnitude in the concentrations C_R of the two half-cells, gave the following small voltage changes

Time (min)	0	0.25	0.50	1.00	4.00	12.0	18.0	20.0
E (mV)	100	88	86	85	79	76	74	75
ΔE (mV)	0	12	14	15	21	24	26	26

Considering the S-shaped discharge curve, 100 mV is near the time limit of a half-cycle. The change of ΔE = 26 mV represents elimination of concentration polarization in the absence of current flow. When it is resumed, all or most of the voltage drop is made up as the previous partial diffusion control is reestablished.

Concentration polarization is also illustrated in an experiment with a similar cell, containing a more concentrated solution, 0.088M $K_3Fe(CN)_6$ + 0.022M $K_4Fe(CN)_6$ + 0.5M Na_2HPO_4 + 0.5M KH_2PO_4. Figure 5 shows a typical half-cycle of this cell, at a constant current of 100 μA. The curve is the experimental voltage trace; points are calculated values based on the Nernst relation with concentrations varying according to Faraday's law. Since the concentrations of the redox couple are small and that of the supporting electrolyte is large, concentrations rather than activities were used in the calculation.

Discussion

As constant current is applied to the cell, reversible electrode reactions involve two soluble species in a layer of electrolyte, in which the concentrations of reactant and product are alternately depleted and enriched. The mechanism of the coulometer can be understood as the change in Nernst potential arising from changes in concentrations. For example, starting at zero voltage, electrode reactions depend only on the redox couple. However, as reactions proceed, the limiting concentration C_R decreases in one half cell and transport phenomena alter the voltage-time relation. Depending on the magnitude of the constant current and the extent of mixing due to convection in the thin electrolyte layer, concentration polarization sets in and will result in greater than calculated voltage changes.

Figure 5 shows that diffusion limitation becomes effective and more pronounced near the end of a half-cycle, which is characterized by greater concentration changes and consequently more rapid changes in cell voltage. The nonlinear and sharp increase in the voltage response of the cell is an advantage in applications for simple binary logic circuits which require an end-of-cycle signal.

The accuracy of the coulometer's measurements can be estimated from the errors introduced by keeping the cell on open circuit for different periods of time. The errors are less than 0.1% for consecutive cycles involving at least 5 min open circuit stands, and less than 1% for 24 hr on open circuit. This stability reflects the exclusion of co-ions from the ion exchange membrane. Ion exclusion depends on the charge and size of the diffusing ion, the degree of crosslinking of the membrane, the external ionic strength (supporting electrolyte), and the electrolyte concentration. At a co-ion concentration of 0.01M, the dynamic transport number of the counter-ion (the cation in the present case), t_+, is 0.97-1.00. The diffusion of anions through the cation exchange membrane will be negligible except in the most stringent application of the redox coulometer, when extended open circuit stands near the voltage limit (large concentration differences) are involved.

Although some time may be required to charge the double layer at very low current density, this does not introduce an appreciable error. In the experiments of Fig. 3, 4, and 5, the current densities are 13.2 and 19.7 x 10^{-6} A/cm^2; hence assuming a double layer capacitance of 10 μF/cm^2 and a cell voltage of 0.6V (start of half-cycle), the charging of the double layer at the pyrolytic graphite electrode would require 0.45 and 0.30 sec.

The only long-term systematic source of error was the evaporation of water. The first cell described here was operated for more than 2000 cycles, but required addition of 0.1 ml of distilled water after about 1500 cycles in order to replenish the solution for evaporated water.

The question of accuracy and possible changes in cell capacity also arises. Although solutions can be prepared accurately, it is simpler to adjust the constant current level and so obtain the desired cycling regime. In this work the solution concentration ratio C_O/C_R was arbitrarily chosen to be 4:1. Any other ratio is suitable if it conforms to the cell mechanism. Likewise, ratios of 4:1, in one half cell, and another ratio, such as 8:2 in the other, would be feasible but would not offer any advantage in timing applications.

Conclusions

1. The redox coulometer is suitable for measuring periods of time continuously or cumulatively.
2. The cell performance is reliable and reversible over a very long lifetime provided only that the cell is hermetically sealed to prevent evaporation of solvent water.
3. The voltage limits of operation are determined by the concentration of the redox couple according to the Nernst relation. Deviation (increased voltage at constant current) occurs near the end of a half cycle due to transport phenomena.
4. Within the voltage limits, the redox couple is chosen for the most stable voltage region with regard to solvent decomposition.
5. The nature of the ion in limiting supply determines the choice of the ion exchange membrane to be used.

Acknowledgment

The author greatly appreciates discussions with F. G. Will and the use of his switching circuit. He is particularly indebted to W. L. Mowrey for his ingenious and efficient design of the coulometer cells.

Lithium Anode Properties in a Nonaqueous Cell

G. W. Jackson* and G. E. Blomgren

Union Carbide Corporation, Consumer Products Division, Research Laboratory, Cleveland, Ohio

ABSTRACT

The anode discharge characteristics for the cell system Li/1.0M $AlCl_3$ in propylene carbonate/AgCl have been studied by use of an interrupter and a constant load pulse technique called potential profile analysis. The potential profile results show a severe polarization of the concentration type. A speculation concerning the mechanism responsible for the polarization is advanced, which postulates a nonsteady-state diffusional process through an insoluble layer of LiCl reaction product. A large volume of electrolyte which dissolves the product or sufficient stirring to remove the product eliminates the severe concentration polarization of the anode.

The use of alkali and alkaline earth metals as anodic materials in combination with nonaqueous electrolytes has been of increasing interest because of the high theoretical value of the energy per unit of weight. However, most attempts to construct cells which use these materials have resulted in numerous difficulties in overcoming the considerable losses due to polarization of the electrodes. Because of this, studies were undertaken to attempt to understand the nature of these polarization problems. This paper reports on studies of anode polarization for the cell system

Li/1.0M $AlCl_3$ in propylene carbonate/AgCl

Experimental

Inert atmosphere.—All experiments were run in a Forma dry box which contained several trays of phosphorus pentoxide for scavenging moisture. To obtain a dry argon atmosphere, cylinders of 99.995%, high purity, Linde argon were used.

Measuring apparatus.—The polarization measurements were obtained at ambient temperature by the use of two current pulse techniques. The first method employed the use of the Kordesch-Marko interrupter (1). The results obtained through the use of such a technique were IR free. The second method was a current interrupted pulse technique which required an oscilloscope to measure the voltage. The cells were operated on closed circuit under a 1 mA drain and were pulsed on 1 sec open circuit and 5 sec closed circuit. From the voltage-time profiles, information about the nature of the polarization could be obtained. Figure 1 shows a block diagram of the apparatus used in the second technique.

Cells.—Information was desired under two types of cell conditions, one in which a large volume of electrolyte was present in order to better define the electrode properties and one in which a limited amount of electrolyte was present in order to simulate the conditions of a finished cell. Therefore, two types of test holders were used. For the limited electrolyte experiments, a Teflon plastic test holder was used. This test cell holder was equipped with a threaded cap to place

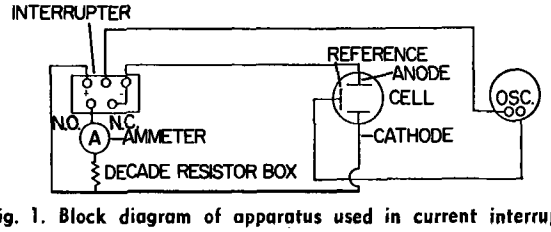

Fig. 1. Block diagram of apparatus used in current interrupted pulse technique.

* Electrochemical Society Active Member.

the electrodes under pressure to ensure contact. Two sizes of this test holder were used. One had an electrode area of 1 cm^2 and the other 6.41-cm^2 area. Figure 2A shows the cell holder.

For the experiments under electrolyte-rich environments, both a rectangular Teflon plastic test cell and a threaded cap cell were used. Figure 2B shows the rectangular cell. For the threaded cap cell the electrolyte volume was approximately 1 cm^3/cm^2 of electrode area.

Electrolyte and separators.—In every case where electrode separation was required, two pieces of nonwoven Viskon were used. This material was obtained from the Chicobee Manufacturing Company, North Little Rock, Arkansas.

The reagent grade solvent, propylene carbonate, was obtained from Fisher Scientific Company. The water content was determined to be 0.8% by Karl Fisher titration. The solvent as received from the vendor was stored over molecular seive, type 4A, and then distilled using a Podbielniak Semi-Cal distillation unit under 10 mm Hg. Only the middle third fraction was used in the experiments. The final water content according to Karl Fisher was below the lowest detectable level by this method of 0.002%.

The aluminum chloride used was anhydrous reagent grade material from Fisher Scientific Company. The lithium was 2 x 0.015 in. lithium metal ribbon obtained from Foote Mineral Company, Exton, Pennsylvania.

Reference electrode.—The reference electrode was an Ag, AgCl electrode made by anodizing a piece of silver wire. This electrode remained quite stable over the time in which the experiment was carried out. The stability was verified by checking against a calomel reference electrode every 2 hr. The Ag/AgCl reference was found to be stable ± 2 mV over the time of the experiment.

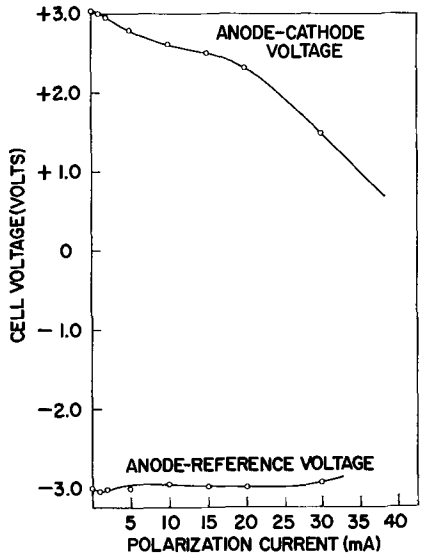

Fig. 3. IR-free polarization curves in electrolyte-rich cell (1 cm^3 electrolyte/cm^2 electrode).

Results and Discussion

Figure 3 shows an electrolyte-rich polarization curve using the Teflon plastic test holder and a Kordesch-Marko interrupter (1). The anode, which was 2.86 cm in diameter, had an apparent surface area of 6.41 cm^2. The electrolyte concentration was a 1.0M solution of $AlCl_3$ in propylene carbonate. A word might be said at this point about making electrolytes of aluminum chloride. It was found that extreme care had to be taken in order to avoid the breakdown of the solvent when aluminum chloride was added. Even when aluminum chloride was added at a very slow rate and the solution was vigorously stirred, heat was generated and the resultant solution turned straw-brown. When the solute was added more rapidly the reaction was more violent, gave off excess heat, evolved white pungent vapors, and turned dark brown to almost black in color. The IR-free readings in Fig. 3 indicated that the anode polarized very little, while the cathode showed a large polarization.

To observe time effects on the polarization occurring at the anode, a continuing 1 mA, 5 sec on-time, 1 sec off-time current pulse was applied to the cell. Figure 4 shows a series of tracings obtained using the threaded cap Teflon plastic cell having an anode of 1 cm^2 apparent surface area and containing approximately 1 cm^3 electrolyte.

Figure $4A_1$ shows that the OCV was 2.88V; Fig. $4A_2$ shows anodic and cathodic polarizations of 400 and 500 mV, respectively. The anodic polarization appeared to be equivalent to an ohmic resistance as shown in Fig. $4A_3$ by the rapid recovery to a higher voltage the instant the circuit is broken. Because the sweep time is 1 cm/sec, the ohmic and activation polarizations are not distinguishable. In Fig. $4B_1$, both anodic and cathodic tracings are shown, while Fig. $4B_2$ shows an enlarged view of the anodic polarization. In Fig. 4C, it was noted that the open-circuit voltage had begun to drop, but the anodic polarization remained about the same, although it appeared to take on some diffusional characteristics. This is indicated by the portion of the curve which slowly sweeps upward. On further discharge, the drop in open-circuit voltage continued as shown in Fig. 4D and 4E. If the circuit was opened long enough, the cell returned to an open-circuit voltage of 2.88V and remained there. Figure 4F shows an example of a slow recovery of the anode. As can be

seen, no steady state was reached in 2 sec. It could be surmised then, that the open-circuit voltages shown were not true equilibrium potentials but represented a potential which was dependent on the diffusional characteristics of the cell. A porous product was observed to build on the surface of the anode. X-ray analysis of scrapings of the surface showed that the product on the surface was LiCl. In the rectangular Teflon plastic cell where there is an abundance of electrolyte, the discharge continues much longer before concentration polarization becomes a large factor.

While the precise mechanism responsible for the polarization is undoubtedly complex, a speculation concerning the nature of the observed concentration effects can be made with the aid of a simplified model. Since the anode reaction product is observed to be LiCl, a half-cell reaction scheme can be written for the anode alternatively as

$$Li + Cl^- \rightarrow LiCl\downarrow + e \qquad [1]$$

or

$$4\ Li + AlCl_4^- \rightarrow 4\ LiCl\downarrow + Al^{3+} + 4\ e \qquad [2]$$

while the cathode reaction may proceed via the reaction

$$AgCl + e \rightarrow Ag + Cl^- \qquad [3]$$

or

$$4\ AgCl + Al^{3+} \rightarrow 4\ Ag + AlCl_4^- \qquad [4]$$

Reactions [2] and [4] would be consistent with the ionic species observed by Hon (2) in an NMR study of solutions of $AlCl_3$ in acetonitrile, which could be expected to behave similarly to propylene carbonate. Reactions [1] and [3] would require the presence of some free chloride ion, probably in equilibrium with the complex aluminum species. In the case of reactions [1] and [3] chloride ion must be transported from the cathode to the anode and for [2] and [4], $AlCl_4^-$ must be transported.

If one assumes that all of the insoluble LiCl product remains at the anode surface in the form of a somewhat porous layer, then diffusion of chloride ion or the complex aluminum chloride ion through the LiCl barrier will occur, but at a drastically reduced rate compared to diffusion through the bulk solution. The effect of this will be to define a diffusion layer which is equivalent to the thickness of the product LiCl layer and which is set up due to the passage of current. When the current is switched off, as in the transient profile technique, the ions in the solution will diffuse into the diffusion layer in such a way as to dissipate the concentration gradient, and this is observed as a gradual return of the open-circuit voltage to the equilibrium value. We can test this model of the lithium anode polarization by a solution of the linear diffusion equation for the nonsteady state

$$D\frac{\partial^2 c}{\partial x^2} = \frac{\partial c}{\partial t} \qquad [5]$$

where D is regarded as an effective diffusion coefficient for diffusion through the porous layer and c the concentration of the diffusing species. The general solution of Eq. [5] for an arbitrary concentration profile at time zero, $C_0(x)$; is given by (3)

$$C(x,t) = \frac{1}{\sqrt{\pi\ Dt}}\int_0^\infty C_0(x')\ e^{-(x-x')^2/4\ Dt}\,dx' \qquad [6]$$

We can test the model with a step concentration gradient as an initial condition where δ is the thickness of the diffusion layer, C_e is the concentration at the anode surface and C_0 the bulk concentration, *i.e.*

$$\begin{aligned} x > \delta,\ C_0(x) &= C_0 \\ 0 \leq x < \delta,\ C_0(x) &= C_e \end{aligned} \qquad [7]$$

The solution for the concentration at the electrode surface is

$$\frac{C_0 - C(0,t)}{C_0 - C_e} = \phi\left(\frac{\delta}{2\sqrt{Dt}}\right) \qquad [8]$$

where $\phi\left(\frac{\delta}{2\sqrt{Dt}}\right)$ is the error function defined by

$$\phi(y) = \frac{2}{\sqrt{\pi}}\int_0^y e^{-\zeta^2}\,d\zeta \qquad [9]$$

The problem was also solved for a linear gradient initial condition, but within the range of times studied here, no distinction could be made between the two cases. Now, using the Nernst equation to express the diffusion overpotential we have

$$\begin{aligned} \eta_d &= \frac{RT}{z_i F}\ln\frac{C(0,t)}{C_0} \\ \eta_d{}^0 &= \frac{RT}{z_i F}\ln\frac{C_e}{C_0} \end{aligned} \qquad [10]$$

where $\eta_d{}^0$ is the overpotential at the instant the current is switched off and η_d is the overpotential at any time t, which is taken in the calculations at 1 sec. Finally, the diffusion equation in terms of overpotentials is given by

$$\frac{1 - \exp(\eta_d\ z_i F/RT)}{1 - \exp(\eta_d{}^0\ z_i F/RT)} = \phi\left(\frac{\delta}{2\sqrt{Dt}}\right)_{t=1} \qquad [11]$$

The method of calculation is to measure the overpotentials at time zero and at 1 sec from the potential profiles of Fig. 4, evaluate the left hand side of Eq. [11] and find the value of the argument from error function tables. The thickness δ is then calculated from the total "on" time of the discharge and the bulk density of LiCl and thus the effective diffusion coefficient is obtained. The results are given in Table I. The order of magnitude of the diffusion coefficient obtained is about what might be expected for diffusion through a porous body, *i.e.*, at $\sim 10^{-8}$ it is between the value of solid state diffusion $\sim 10^{-12}$ or less and of solution diffusion $\sim 10^{-5}$. The lack of constancy of the effective diffusion coefficient with increasing time could be due to a number of factors which could change the value of the calculated diffusion coefficient in the direction observed. Among these factors are loss of product as a function of discharge time, increasing porosity of product with increasing discharge time or a finite, but diminishing effect of a concentration gradient in the bulk electrolyte as the porous product layer thickens. The first two factors could be reflected in a nonlinear growth rate of the porous layer with discharge time. (It should be recalled that one of the assumptions of the model is a strictly linear rate of growth of the product layer.) In fact, if the layer is assumed to grow at an arbitrary rate, *i.e.*, $\delta(T) = \delta' T^n$, where T is the

total time of current flow, the value of n can be determined from a plot of $\log(\delta/2\sqrt{Dt})_{t=1}$ *vs.* $\log T$. The log-log plot is linear within experimental error and the value of n determined in this way is $n = 0.43$. The constancy of $(\delta/2\sqrt{Dt})_{t=1}\ T^{-0.43}$ is shown in the last column of Table I where the values obtained in this way are constant to within the experimental error. In the absence of more definite information about the nature of the porous film it does not seem advisable to try to extract any further significance from these results.

The column in the table labeled η_0 is the measured combined ohmic and activation overpotential. Its constancy indicates that the electrolyte remains invariant and that there are no unusual ohmic or activation effects which further substantiates the porous layer diffusion model. Further experiments with a large volume of electrolyte containing only $AlCl_3$, in which all of the product LiCl is soluble, show no such concentration polarization but only show the effect of ohmic and activation polarizations. Also, the concentration effect is not observable in solutions which are presaturated with LiCl and stirred during the discharge (see Fig. 5). In the stirred solutions, no layer is observed on the surface of the lithium, but LiCl product does appear on the bottom of the test cell after stirring is ceased. This shows that the product is not very adherent and can be removed with even gentle stirring and its removal eliminates the severe concentration polarization.

In summary, while there are troubling questions about some of the quantitative aspects of the porous product layer diffusion model, it is believed that the qualitative description of this system is accurate and semiquantitative agreement of the theory with the observed results is obtained. Furthermore, it is believed that the technique of observation of open-circuit voltage recovery can offer a valuable diagnostic criterion for cases in which an insoluble product is formed at an electrode.

Conclusions

This study indicates that the discharge of a lithium anode in an $AlCl_3$-propylene carbonate electrolyte can be severely affected by a build-up of product LiCl at the anode surface. Sufficient electrolyte to dissolve the product or stirring of the electrolyte which mechanically removes the product from the surface, eliminates the severe polarization effect. A simplified model of diffusion through a porous product layer has been advanced to attempt to describe the observed polarization effects.

Studies of Inhibition of Magnesium Corrosion

David A. Vermilyea* and Carol F. Kirk

Research and Development Center, General Electric Company, Schenectady, New York

ABSTRACT

The corrosion of pure magnesium in aqueous solutions of various pH has been studied. The reaction product is a porous layer consisting mainly of $Mg(OH)_2$ in the absence of inhibitors, but films formed in solutions containing $NaIO_4$ are composed of substances which could not be identified. The reaction in inhibitor-free solutions proceeds by the formation and dissolution of a primary film, possibly an oxide, followed by precipitation of a film of $Mg(OH)_2$. In $NaIO_4$ solutions the reaction product is thicker and probably denser because the periodate decreases its dissolution rate, and the over-all metal removal rate is less by a factor of 10 at pH 9-10.

Recent studies (1) of the dissolution of MgO and $Mg(OH)_2$ revealed that periodate, germanate, vanadate, and tellurate ions retarded dissolution in alkaline solutions, while sodium dodecyl sulfonate was an inhibitor in acid solutions. This paper presents the results of a study of inhibition of corrosion of metallic magnesium by those substances.

Experimental

The metal specimens, cut from ingots of 99.99% Mg obtained from United Mineral and Chemical Corporation, were about 3 cm x 1 cm x 0.05 cm. We do not know what impurities were present in the magnesium. Etching for 30 sec in 10% HNO_3 followed by 10 sec in 2% HCl produced a surface which was fairly smooth on a microscopic scale. The grain size was about 0.2

cm. Surfaces prepared with other chemical etching pretreatments gave similar results.

Weight measurements made using a Cahn RG Electrobalance were repeatable to about 10^{-6} g/cm^2. Specimens were weighed before and after exposure and after a 60 sec immersion in 10% CrO_3. The latter treatment removed the reaction product with little attack on the metal; freshly prepared specimens lost 5×10^{-6} g/cm^2 after the chromic acid treatment.

The specimens were exposed at 25°C in 500 cc of solution in vessels with ground glass covers to prevent absorption of CO_2 in the alkaline solutions. It is known (2) that the corrosion rate of magnesium in water is not greatly affected by the presence of oxygen. We actually found little difference in a period of a week whether the vessel was open or closed. The solutions were not agitated.

The reaction product was examined using standard diffraction and electron microscopic techniques and also by reflection infrared spectroscopy. For the latter examination a Beckmann IR-12 spectrometer was used with a specimen holder which gave three reflections from polished magnesium sheets which were cut from the ingots, metallographically polished, and chemically etched by the procedure described above.

Results

Nature of the reaction product.—Specimens were usually exposed to solutions containing 10^{-4} M $MgSO_4$ plus the inhibitor to be studied plus KOH to pH 10.0 ± 0.2. We added the $MgSO_4$ in order that the total Mg^{+2} concentration would not change greatly during an experiment, but actually we could not detect any difference when it was absent.

Electron diffraction from samples exposed to solutions with no inhibitor revealed that $Mg(OH)_2$ and Mg were present, with no other substances giving diffraction. The lines were somewhat diffuse. Samples exposed to $NaIO_4$ solutions, on the other hand, yielded diffuse electron diffraction lines which could not be associated with any known compound.

Electron microscope studies showed that films produced in inhibitor-free solutions were composed of platelets the outer portions of which were about 300 by 3000Å. Figure 1 shows a typical example, but does not reveal the three-dimensional structure visible with stereo photomicrographs. The structure appears very similar to that observed on $Al(OH)_3$ films formed by reaction of aluminum with water (3). At least the outer portion of the layer is evidently quite porous. Presumably the platelets are $Mg(OH)_2$. Longer exposures gave similar films with slightly smaller platelets.

The platelets shown in Fig. 1 appear to have random orientations. A specimen exposed in plain water developed the film shown in Fig. 2. In that film it appears that there are some platelets oriented nearly perpendicular to the surface while a majority have their major faces parallel to the surface. Probably the platelets dissolve faster at the edges, so that platelets which nucleate with an orientation perpendicular to the surface are dissolved preferentially, leaving those oriented parallel to the surface. The somewhat higher dissolution rate in plain water as compared with the pH 10 solution is responsible for the different film morphology.

By contrast, with the above results, the outer surface of a specimen exposed in a $NaIO_4$ solution had the appearance of a mud flat, Fig. 3. In Fig. 3 the white areas are probably cracks in the replica. Evidently the periodate has caused a profound change in the character of the layer. It is not certain that this layer is porous. Shorter exposures to $NaIO_4$ solutions gave products with some platelets and some "mud flat" areas. It therefore appears that as the film grows the spaces between platelets are filled in.

Infrared spectroscopic studies over the region 800-4000 cm^{-1} of films grown in inhibitor-free solutions showed only a single intense absorption at 3700 cm^{-1} with a width of 20 cm^{-1} at half maximum intensity. Using the same spectrometer we found that this absorption, which is the OH stretching vibration, occurred at 3698 cm^{-1} in natural Brucite and at 3702 cm^{-1} in $Mg(OH)_2$ precipitated from $MgSO_4$ solution with KOH. In the latter two spectra the width at half maximum intensity was only 12 cm^{-1}. In the spectrum from the reaction product there were no bands, even weak broad ones, corresponding to liquid water or to hydroxyl ions in other crystallographic positions. It is concluded that these films are mostly reasonably well crystallized $Mg(OH)_2$.

Infrared spectra from specimens exposed in $NaIO_4$ solutions, by contrast, showed the rather more complicated structure. In addition to the band at 3700

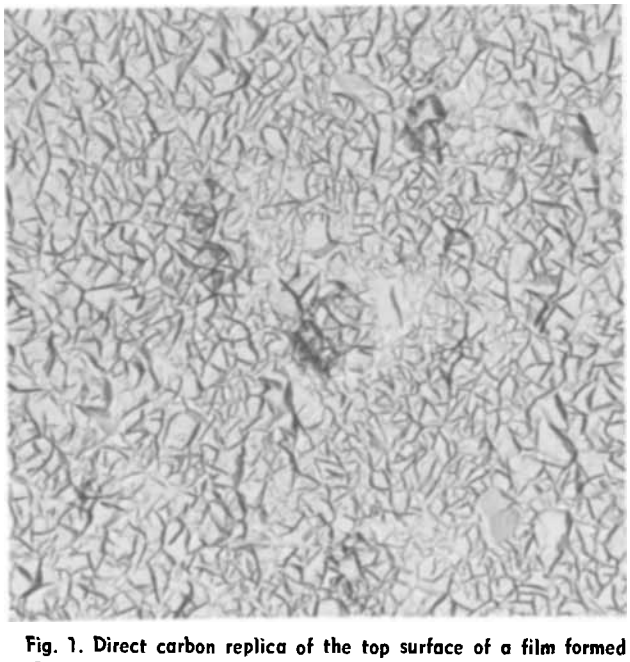

Fig. 1. Direct carbon replica of the top surface of a film formed in 294 min on magnesium in $MgSO_4$ + KOH solution, pH 10.1 Magnification 15,000X.

Fig. 2. Top surface of a film formed on magnesium in 100 min in pure water. Magnification 15,000X.

Fig. 3. Top surface of a film formed in 68 hr in a 10^{-3}M $NaIO_4$ solution, pH 10. Magnification 15,000X.

cm^{-1} there was a broad, intense absorption between 2600 and 3800 cm^{-1}, other weaker ones at 1450 cm^{-1} and 1650 cm^{-1}, and finally a broad absorption at 720 cm^{-1}. While the broad absorption at 2600-3800 cm^{-1} suggests hydroxyl ions in various binding states the interpretation of the details of this spectrum is not obvious, since the remaining bands did not correspond exactly to those for likely substances like periodate or iodate. However, the complexity of this result reinforces the conclusion from diffraction and microscopy that the product formed in periodate solutions differs substantially from that formed in inhibitor-free solutions. $Mg(OH)_2$ precipitated with KOH from a $MgSO_4$ solution containing $NaIO_4$ gave a spectrum with the same features as that from the film, except that the band at lower energy was at 680 cm^{-1}.

Corrosion rate, inhibitor-free solutions.—Figure 4 shows the weight loss after removal of the reaction product in CrO_3 for exposures in 10^{-4}M $MgSO_4$ plus KOH to *p*H 10. The unexposed specimens would lose about 5×10^{-6} g/cm^2 in CrO_3 because of the dissolution of the initial film, and extrapolation of data from longer times indicates that the initial film would be produced in about 12 min. Hence each exposure time was increased by 12 min to take account of the film initially present.

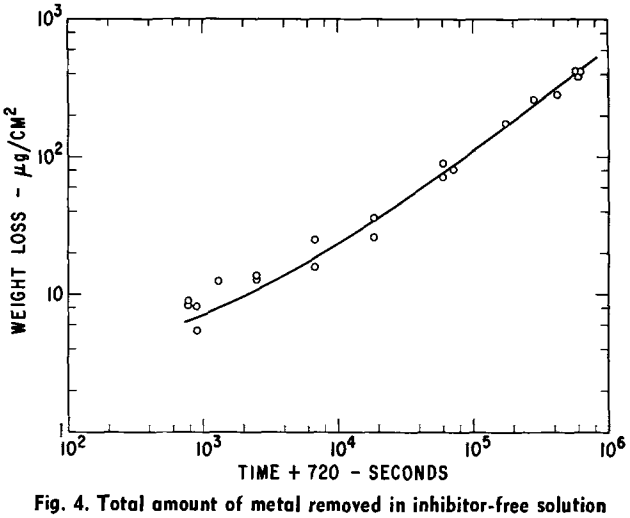

Fig. 4. Total amount of metal removed in inhibitor-free solution

Table I. Rates of various processes

Process	Time, sec	Rate, moles/cm^2-sec
Corrosion of Mg in inhibitor-free solution	6×10^3	6.6×10^{-11}
	6×10^4	3.7
	6×10^5	2.1
Formation of Mg^{+2} in inhibitor-free solution	6×10^5	1.6×10^{-11}
Corrosion of Mg in $NaIO_4$ solution	6×10^3	4.8×10^{-11}
	6×10^4	1.2
	6×10^5	0.29
Dissolution of MgO		10^{-11}
Natural brucite ($Mg(OH)_2$)		10^{-13}
High energy Mg $(OH)_2$		10^{-10}

The average slope of the log-log plot of Fig. 4 is about 2/3, so that the rate decreases with time but not as fast as if controlled by a diffusion process. The slope appears to increase somewhat at long times, suggesting an approach toward a constant rate, probably ultimately controlled by dissolution of the product. Table I gives corrosion rates calculated from the data of Fig. 4. Blanchet *et al.* (3) found a steady corrosion rate of about 11.7 mdd or 5.6 10^{-11} moles/cm^2-sec for pure magnesium in refreshed pure water at 22°C, in reasonable agreement with the results of this study. Corrosion rates in 3% NaCl are from two to ten times higher (2, 4); we have found that a solution of 10^{-4}M $MgCl_2$ plus KOH to *p*H 10 causes pitting attack and increased weight loss.

Table I also gives rates from the previous study (1) for dissolution of MgO; highly reactive, fine particle $Mg(OH)_2$ obtained from Mathieson, Coleman, and Bell and designated "high energy $Mg(OH)_2$"; and for natural Brucite, all at *p*H 10. If diffusion of dissolved $Mg(OH)_2$ away from the specimens was the controlling process the rate would be about 10^{-10} moles/cm^2-sec for a diffusion layer thickness of 10^{-2} cm. A comparison of the observed corrosion rate with these values shows the following. The rates are always less than the diffusion limited rate, especially at longer times. The rates are less than that for high energy $Mg(OH)_2$, which suggests the presence of a reasonably well crystallized product. The electron micrographs of Fig. 1 and 2 support this conclusion. The rates are much greater than the rate for natural Brucite, however.

Figure 5 shows that before the CrO_3 treatment the specimens exposed in the inhibitor-free solution showed a small weight gain at short times but a large weight loss at long times. From the data in Fig. 4 and 5 it is possible to determine the rate of dissolution to form Mg^{+2} and the rate of formation of $Mg(OH)_2$. Assuming that the reaction produces only Mg^{+2} and $Mg(OH)_2$, the following relationships are valid

$$\Delta W_I = \Delta W_1 \times 2 \times \frac{\text{mol.wt OH}}{\text{mol.wt Mg(OH)}_2} - \Delta W_2 \quad [1]$$

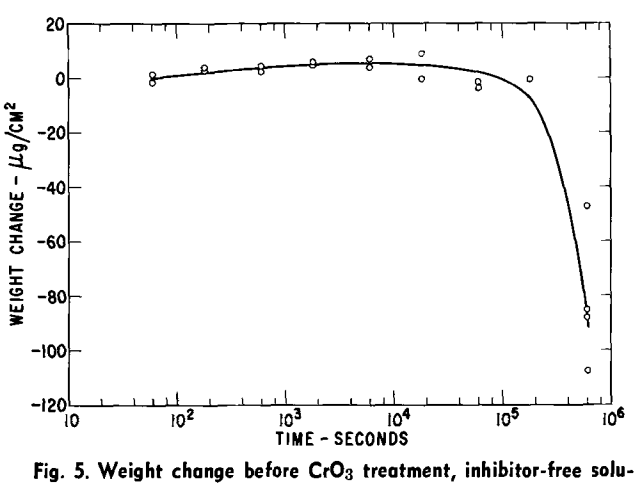

Fig. 5. Weight change before CrO_3 treatment, inhibitor-free solution.

$$\Delta W_{II} = -\Delta W_1 \times \frac{\text{mol.wt Mg}}{\text{mol.wt Mg(OH)}_2} - \Delta W_2 \quad [2]$$

In Eq. [1] and [2], ΔW_I and ΔW_{II} are the weight changes after exposure and after the removal of the product in CrO_3 respectively, and ΔW_1 and ΔW_2 are the weight of $Mg(OH)_2$ formed and the weight of Mg^{+2} dissolved. Solving for ΔW_1 and ΔW_2 gives

$$\Delta W_1 = \Delta W_I - \Delta W_{II} \quad [3]$$

$$\Delta W_2 = -0.583\,\Delta W_{II} - 0.417\,\Delta W_I \quad [4]$$

Figures 6 and 7 show log-log plots of ΔW_1 and ΔW_2; the average slopes are about 0.58 and 0.84, respectively, so that both weight change rates decrease with time. The slope of the curve for growth of $Mg(OH)_2$ suggests diffusion control while the rate of dissolution of Mg^{+2} is nearly constant. At 10^6 sec the dissolution rate is $1.6 \cdot 10^{-11}$ moles/cm^2-sec which is only slightly less than the total corrosion rate of $2.1 \cdot 10^{-11}$ moles/cm^2-sec; evidently dissolution is the most important process at long times.

Corrosion rates in $NaIO_4$ solutions.—Figure 8 presents data for specimens exposed in 10^{-3}M $NaIO_4$ plus 10^{-4}M $MgSO_4$ plus KOH to *p*H 10. The scatter of these results is very large for reasons which are not apparent. There was some pitting and also crevice corrosion where the specimen rested against a glass support; perhaps the scatter is associated with variations in the amount of local attack.

The slope of the log-log plot is only 0.38, so the rate falls off faster than for a process under diffusion control. Corrosion rates calculated from the curve and listed in Table I are initially about the same as in the absence of inhibitors but at long times are less by a factor of 10. Apparently the modifications of the corrosion product which were revealed by diffraction, microscopy, and infrared spectroscopy result in a reduced corrosion rate.

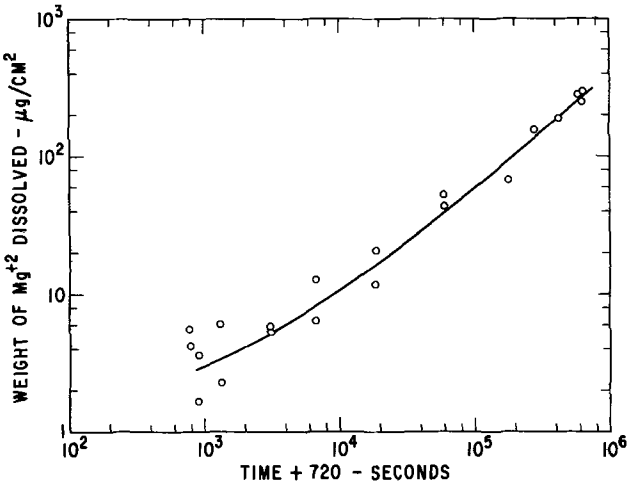

Fig. 6. Mg^{+2} dissolved in inhibitor-free solutions, calculated from Eq. [4].

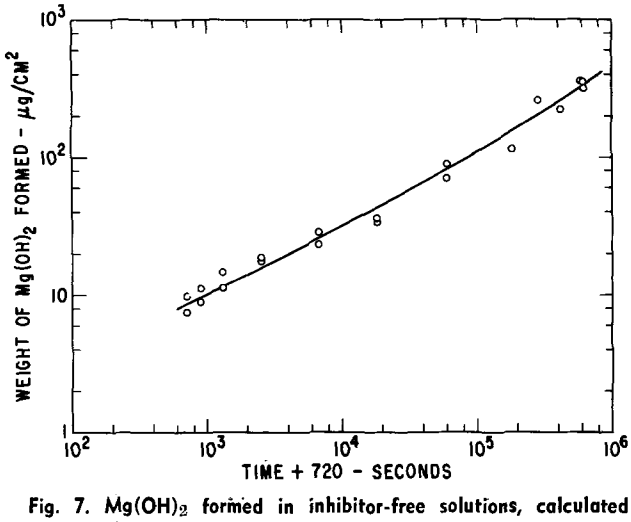

Fig. 7. $Mg(OH)_2$ formed in inhibitor-free solutions, calculated from Eq. [3].

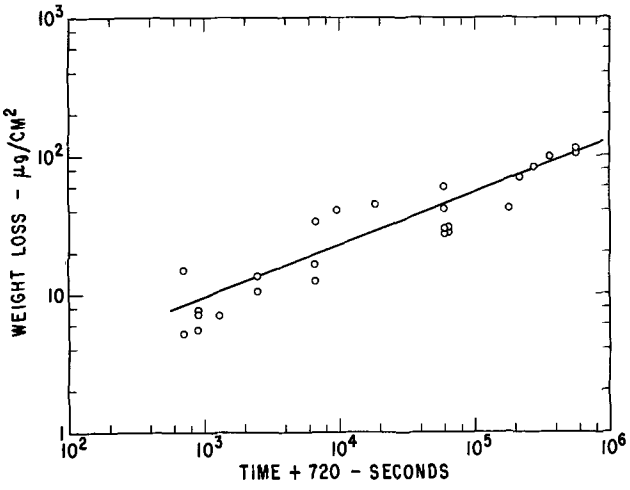

Fig. 8. Total amount of metal removed in $NaIO_4$ solutions

Figure 9 shows that the specimens gained weight when measured before the CrO_3 treatment, in contrast to the results in inhibitor-free solutions. If the assumption is again made that only $Mg(OH)_2$ and Mg^{+2} are formed as corrosion products and the results analyzed with Eq. [3] and [4], it is found that the amount of Mg^{+2} formed is less than zero for many specimens. Evidently the assumption that only $Mg(OH)_2$ and Mg^{+2} form is incorrect, a result which reinforces the conclusions from infrared spectroscopic studies.

Increasing the $NaIO_4$ concentration to 10^{-2}M did not decrease the corrosion rate much below that for 10^{-3}M, but at 10^{-4}M the specimen was pitted and the total corrosion rate was about twice as great as in inhibitor-free solutions.

Role of pH.—In inhibitor-free solutions with an initial *p*H of 10 the *p*H increased during exposure, and at 10^6 sec reached 10.5. In $NaIO_4$ solutions, on the other hand, the *p*H fell and reached 9.3 at 10^6 sec. Table II gives results of studies of the effect of *p*H on the rate of attack. In inhibitor-free solutions the total corrosion rate, the amount of $Mg(OH)_2$ formed and the amount of Mg^{+2} dissolved all decreased with increasing *p*H. In $NaIO_4$ solutions the total corrosion was least at *p*H 9, although the weight gain before CrO_3 increased continuously with increasing *p*H. The interpretation of these results will be given in the discussion.

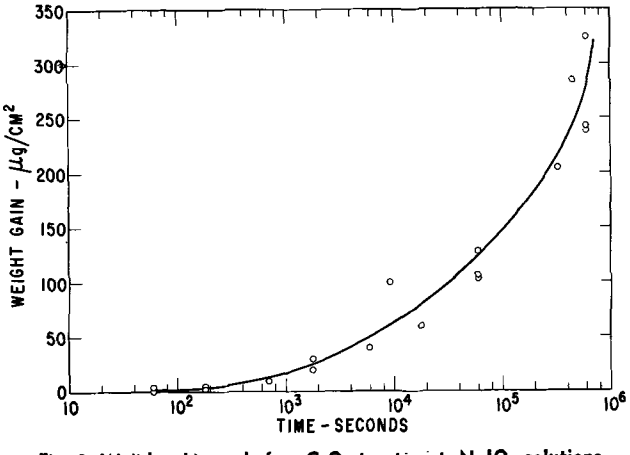

Fig. 9. Weight change before CrO_3 treatment, $NaIO_4$ solutions

Table II. Effect of pH on rates

A. Inhibitor-free solutions

Weight change at 1.8 x 10^5 sec (interpolated)

pH	Total corrosion, $\mu g/cm^2$	Before CrO_3, $\mu g/cm^2$	$Mg(OH)_2$ formed, $\mu g/cm^2$	Mg^{+2} dissolved, $\mu g/cm^2$
8	−250	−70	165	160
9	−210	−55	155	150
10	−118	−3	115	70
11	−57	+13	70	38

B. $NaIO_4$ solutions

Weight change at 3 x 10^5 sec (interpolated)

pH	Total corrosion, $\mu g/cm^2$	Before CrO_3, $\mu g/cm^2$
8	−130	+40
9	−63	+112
10	−84	+204
11	−100	+350

Other inhibitors for alkaline solutions.—Much less work was done with other inhibitors than periodate, which was found to have greatest influence on the dissolution of $Mg(OH)_2$. In other studies it was found that tellurate was reduced, evidently to tellurium, and a black deposit covered the specimen; tellurium was detected in the deposit by x-ray fluorescence. Germanates and vanadates did reduce the corrosion rate somewhat, but not by as large a factor as did periodate. Germanium and vanadium were not detected on the specimens after exposure. All inhibitors were present at 10^{-3}M.

Corrosion at low pH.—In pH 1 H_2SO_4 magnesium was found to corrode at a rate equal to that calculated on the basis of control by proton diffusion to the surface. In pH 3 H_2SO_4 and $HClO_4$ however, the rate was found to be constant at about 3.4 x 10^{-10} moles/cm^2-sec, while the rate calculated on the basis of control by proton diffusion and a stationary layer thickness of 10^{-2} cm is about 5 x 10^{-9} moles/cm^2-sec. X-ray diffraction and infrared spectroscopy disclosed the presence of $Mg(OH)_2$ on the samples, while electron microscopy revealed a structure similar to that of Fig. 1.

The reduced rates and presence of $Mg(OH)_2$ in pH 3 solutions can be understood if the effect of the diffuse double layer near the surface is considered. The point of zero change of $Mg(OH)_2$ is about pH 12 (5). At pH 3 the potential difference between the surface of $Mg(OH)_2$ and the solution could be as large as about 0.5V. In a 10^{-3}M solution the concentration of positively charged ions at the plane of closest approach is then calculated to be about 10^{-6}, so the pH in the vicinity of $Mg(OH)_2$ particles is about 6 instead of 3. The dissolution rate of the natural Brucite at pH 6 is about 10^{-10} moles/cm^2-sec. Using Eq. [3] and [4] with the observed values of $\Delta W_I = -118$ $\mu g/cm^2$ and $\Delta W_{II} = -413$ $\mu g/cm$ for a specimen exposed in pH 3 H_2SO_4 for 6 x 10^4 sec gives $\Delta W_1 = 295$ $\mu g/cm^2$ and $\Delta W_2 = 290$ $\mu g/cm^2$. Converting ΔW_2 to a rate gives 2 x 10^{-10} moles/cm^2-sec for formation of Mg^{+2}, in reasonable agreement with the calculated rate.

Confirmation of the role of the diffuse double layer was obtained by adding M Na_2SO_4 and M $NaClO_4$ to the pH 3 solutions. In M Na_2SO_4 (pH 3.0) the total corrosion rate was 3.1 x 10^{-9} moles/cm^2-sec, while in M $NaClO_4$ (pH 3.1) it was 5.2 x 10^{-10}. Using the analysis of Eq. [3] and [4] the dissolution rates were 2.1 x 10^{-9} and 3.9 x 10^{-10} for sulfate and perchlorate solutions, respectively; the expected rate for Brucite at pH 3 is 4 x 10^{-9} moles/cm^2-sec. For the perchlorate solution there is still an appreciable double layer correction which makes the surface pH 3.6 and the expected rate 2 x 10^{-9} moles/cm^2-sec. The agreement is within a factor of 2 for Na_2SO_4 and a factor of 5 for the $NaClO_4$, which is fair. It is concluded that the double layer effect is plausible.

Corrosion accelerators.—Buffer solutions at around neutral pH act as accelerators of magnesium corrosion. In carbonate solutions for example, rates of 1.6 x 10^{-7} moles cm^2-sec and 1.4 x 10^{-10} moles/cm^2-sec were measured in M $NaHCO_3$ and 10^{-3}M $NaHCO_3$, respectively; solution pH's were 7.95 and 8.35. Assuming that the process was controlled by diffusion of HCO_3^- to the surface the theoretical rates are 5 x 10^{-7} and 5 x 10^{-10} moles/cm^2-sec, in reasonable agreement with the measured values.

Corrosion in gases.—Specimens exposed in the laboratory atmosphere gained only 1 $\mu g/cm^2$ in 7 days, while at 240°C the weight gain in 18 hr was about 1.4 $\mu g/cm^2$. Other samples were exposed at 25°C in a closed vessel containing a M NaCl solution to produce an atmosphere with a humidity of about 98%. After 2.3 x 10^5 and 3.4 x 10^5 sec the weight gains were 2.4 and 9.6 $\mu g/cm^2$. After CrO_3 treatment total weight losses were 7.1 and 10.1, respectively. (It should be remembered that an unexposed specimen would lose 5 $\mu g/cm^2$.) Corrosion in gaseous environments at moderate temperatures is evidently very slow, even when the gas is nearly saturated with water vapor. For rapid corrosion liquid water is necessary.

Discussion

These studies have shown that the corrosion of pure magnesium in water has characteristics very similar to those of the aluminum-water reaction (3). For instance, the reaction does not proceed in the absence of a liquid phase; a porous product of similar appearance is produced; there is little effect of temperature (4); and the kinetics suggest control by diffusion through the porous reaction product. These similarities suggest that for magnesium as for aluminum the reaction proceeds by the formation and dissolution of a primary film, with the rate controlled by the disposition of the soluble species. The magnitude of the corrosion rate observed in these studies for inhibitor-free solutions is similar to the rate of dissolution of MgO, which suggests that the primary film may be an oxide.

A possible corrosion mechanism is then the formation of a magnesium oxide, dissolution of the oxide to form soluble species, and precipitation of an $Mg(OH)_2$ film which gradually impedes the process. At long times, when the corrosion rate is sufficiently reduced, there would be a balance of the formation and dissolution of the $Mg(OH)_2$, which would finally have a constant thickness. The corrosion rate would then be constant. The role of pH is then easy to understand, for as the pH increases the rates of dissolution of the oxide and the hydroxide decrease sharply, so that all the rates decrease.

The role of periodate is to decrease the rate of dissolution of $Mg(OH)_2$ so that more reaction product accumulates and stifles the reaction. The nature of the reaction product is substantially altered in the presence of periodate. The role of pH is slightly different in periodate solutions. As the pH increases from 8 there is first a decrease in rate because of the slower rate of dissolution of the reaction products. However, at higher pH as the point of zero charge is approached the potential of the $Mg(OH)_2$ or MgO relative to the solution decreases and the attraction of IO_4^- to the surface is less. The inhibition is then decreased and at pH 11 the rates in inhibitor-free and inhibitor-containing solutions are about the same.

Conclusions

1. Periodate ion decreases the rate of the corrosion of magnesium in the pH range 8-10 after a week's exposure by about a factor of 10.

2. The effect of periodate is to change the nature of the reaction product and retard its dissolution.

3. A mechanism comprising formation of magnesium oxide, its dissolution to form Mg^{+2}, followed by precipitation of some of the Mg^{+2} as $Mg(OH)_2$ is consistent with the observations.

Partial Currents During Anodic Dissolution of Cu-Zn Alloys at Constant Potential

H. W. Pickering* and P. J. Byrne

E. C. Bain Laboratory for Fundamental Research, United States Steel Corporation, Monroeville, Pennsylvania

ABSTRACT

The partial currents, i_{Zn} and i_{Cu}, for anodic dissolution of single phase Cu-Zn alloys in a sulfate solution are shown for the potential range $-1000 < E < 500$ mV. The results show the conditions for preferential dissolution of the less noble component and in which potential range transition to simultaneous anodic dissolution takes place. The polarization curve for Zn exhibits a potential region of low, relatively constant current and another region above a certain potential, E_c, where the current increases sharply with potential. E_c increases with increasing Cu content. Copper dissolution is observed only at the higher potentials in accord with its more noble standard potential. These results are in qualitative agreement with the dissolution behavior of Cu from Cu-Au alloy found by Gerischer and Rickert.

Over a decade ago Gerischer and Rickert (1) presented probably the first polarization curve for the less noble component of an alloy in a study of the dissolution of various Cu-Au alloys as a function of applied potential. Since Au did not dissolve for their experimental conditions the measured current was due mainly to Cu dissolution. The curves contain complex features not before observed for metals or alloys. They include a potential region where Cu dissolves at a low, potential-independent rate. Above a certain potential, referred to as the critical potential, E_c, the current increases sharply with potential. Also E_c is a function of alloy composition, increasing with increase in gold content. Gerischer and Rickert further showed that long times were required in arriving at a quasi-stationary current. The current starts out high but decreases at an ever decreasing rate; after an hour there is very little further decrease. For the potential range investigated Cu was found to dissolve at an appreciable rate only from the Cu-rich Cu-Au alloys. These results have been confirmed in our own investigations where all the above-mentioned features were observed (2).

More recently Feller (3) has shown, with the help of a rotating disk-ring electrode, that preferential dissolution of Zn from Cu-Zn alloys occurs more predominantly with the Zn-rich than with the Cu-rich alloys. Similar results have been obtained by Sugawara and Ebiko (4), as shown by metallographic examination of dissolved specimens, and by others (5). For the same rates of dissolution a higher potential was required the higher the copper content of Cu-Zn alloys. This is similar to the aforementioned behavior of Cu-Au alloys and also to the behavior of Ag-Au alloys (6) and the ternary Fe-Cr-Ni alloys (7, 8). In none of these investigations, however, was a potential region of low, constant current observed, similar to that found with Cu-Au alloys by Gerischer and Rickert. Also Graydon and co-workers (9) obtained kinetic data on the dissolution of copper from α brass during immersion in an oxygen-saturated sulfuric acid solution. Periodic polarographic measurements indicated that the rate of copper dissolution increased with time for many hours prior to the attainment of a steady value.

In order to determine the conditions for preferential and simultaneous dissolution, the partial currents for various binary alloys are being currently determined as a function of potential. These are alloys for which both components dissolve over part or all of the potential range of interest, so that one obtains for each alloy two polarization curves, one for each component. In this paper are presented the partial currents of Cu (i_{Cu}) and of Zn (i_{Zn}) as a function of potential for dissolution of three single-phase Cu-Zn alloys, which range from Cu-rich to Zn-rich.

Experimental

In order to obtain i_{Zn} and i_{Cu} during potentiostatic dissolution of Cu-Zn alloy at 23°C, the amounts of Cu and of Zn in the electrolyte were periodically determined by chemical analysis. Data were obtained for dissolution of single-phase alloys of α, γ, and ϵ brass in the buffered electrolyte (pH $\cong$ 5), 1*N* Na_2SO_4 — 0.05*N* $NaC_2H_3O_2$ — 0.05*N* $HC_2H_3O_2$.

Specimens, ~0.1 cm thick and 1.25 cm in diameter, of single-phase γ and ϵ brass were prepared as described elsewhere (10). Chemical and x-ray analysis indicated their compositions to be Cu 65 a/o (atomic per cent) Zn (Cu65Zn) and Cu 86 a/o Zn (Cu86Zn), respectively. The α brass designated as 70/30 brass was provided by American Smelting and Refining Company. It was homogenized for 2½ days at 600°C in an

* Electrochemical Society Active Member.

evacuated capsule, rolled to a thickness of 0.015 cm and then annealed at 600°C for 16 hr in an evacuated capsule. X-ray diffraction analysis indicated the composition to be approximately Cu 30 a/o Zn (Cu30Zn). Specimens of α brass were prepared with an area of ~6 cm^2. γ brass is complex bcc, ϵ brass is hcp, and α brass is fcc.

The cell of Pyrex construction is shown in Fig. 1. The Pyrex tube prevents Cu and Zn ions, formed by dissolution of the specimen, from coming in contact with the counter electrode where they may be deposited. Contact of the electrolyte between the two chambers occurs via three small (3 mm diameter) fine frits located approximately 120° apart. The electrolyte was made from reagent-grade chemicals and doubly distilled water. Prepurified helium was passed through the cell before and during dissolution in order to remove oxygen. The reference cell was a mercury-mercurous sulfate electrode. The potentials, which were maintained with a Wenking potentiostat, are all reported relative to the standard hydrogen electrode (SHE). Electrical contact to the specimen was made with a Teflon-coated copper rod which has one end slotted and fitted with a tightening screw. The small contact area between the sample and rod was sealed from the environment with polyethylene. Immediately prior to insertion at a particular potential the specimen surfaces were ground with 600 emery paper, cleaned with methanol and rinsed in water.

Quantitative chemical analysis of the electrolyte from the anode (inner) compartment of the cell provided the amounts of Cu and Zn dissolved. In an auxiliary experiment using a pure Cu specimen it was determined that negligible amounts of Cu^{2+} ion were lost from the inner compartment by transport through the frits. In the runs at high potentials (currents), however, the Pyrex tube was removed in order to be within the output of the potentiostat; Cu and Zn which deposited on the Pt counter electrode were then dissolved chemically prior to quantitative chemical analysis. For low concentrations of both copper and zinc ions, colorimetric analysis was used. Positive identification of the presence of copper and zinc ion in the electrolyte could be made for concentrations as low as 0.05 μg/cc Cu and 0.02 μg/cc Zn. Usually the concentrations of Cu and Zn ions in the electrolyte, if detectable at all, were considerably higher than this. For example, oxidation of Cu or Zn to the divalent ion at a current density of 1 x 10^{-6} A/cm^2 corresponds to a concentration in the electrolyte after 20 hr of 0.5 μg/cm^3 in the case of the γ and ϵ specimens; in the case of the α brass specimens, with their larger surface area, the same current density corresponds to a concentration of Cu or Zn ions of 1.4 μg/cm^3 after 20 hr. For high concentrations of the ions coulometric and titrimetric methods were used for copper and zinc, respectively. In order to obtain data on the partial currents as a function of time of dissolution, fresh electrolyte was placed in the cell after the initial dissolution period and dissolution was continued. This electrolyte was then drained and analyzed, and again the cell was replenished with fresh electrolyte, etc.

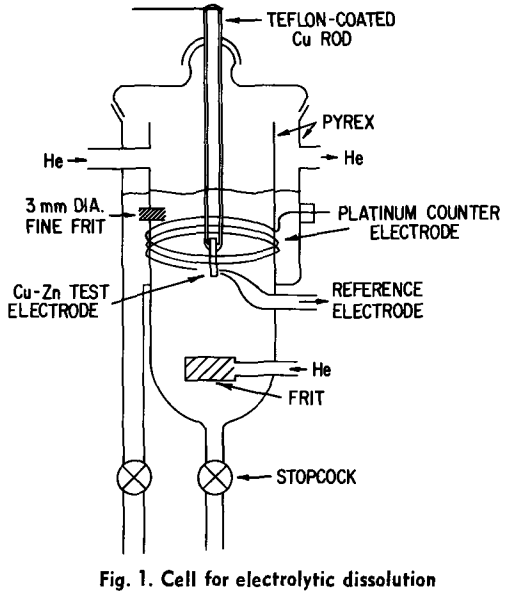

Fig. 1. Cell for electrolytic dissolution

Specimens were usually dissolved in two dissolution periods; the data obtained during the second period were used to arrive at a polarization curve. The lengths of the first and second periods were set at 1 and 20 hr, except when the quasi-stationary currents were large ($\gtrsim$10 mA/cm^2), when shorter times were used. The average current densities calculated on the basis of the geometrical area from data obtained in the second period were then plotted as a function of potential to give the polarization curves for the individual components. IR corrections were negligible since for all but the most positive potentials the net current, anodic or cathodic (measured off the meter), did not exceed 10 mA/cm^2 corresponding to an IR value of ~10 mV.

Results

Current-time behavior.—i_{Zn} for dissolution of Zn from all three alloys in 1*N* Na_2SO_4 — 0.05*N* $NaC_2H_3O_2$ — 0.05*N* $HC_2H_3O_2$ starts out high but falls at an ever decreasing rate. Most of the relatively large amount of dissolution associated with the approach to the quasi-stationary current occurs during the first hour and after many hours the rate of decrease is quite low; at the higher potentials, especially for α brass, the approach to a quasi-stationary current is much faster. Typical i_{Zn}-time behavior for Zn dissolution is shown in Fig. 2. After the 1-hr initial period, consecutive periods of 16-24 hr duration were used. In plotting the points allowance was made for the passage of a larger amount of charge during the earlier part of each dissolution period. The points accordingly lie at shorter times than the mid-times of the dissolution periods.

i_{Cu}-time behavior for dissolution of Cu is similar to that for Zn. The rate of decrease of i_{Cu} is usually less than that of i_{Zn} so that the ratio of the copper and zinc currents, i_{Cu}/i_{Zn}, increases with time; for some potentials this ratio becomes the same as the Cu/Zn atom ratio in the alloys (simultaneous dissolution). Exceptional i_{Cu}-time behavior in these investigations, but similar to that reported by Graydon and co-workers (9) for immersion of α brass in oxygen-saturated sulfuric acid, is an increase in i_{Cu} with time at the highest potentials rather than a decrease.

Current-time behavior at higher potentials than in Fig. 2 is shown in Fig. 3 where the total current due to metal dissolution ($i_{Zn} + i_{Cu}$) is plotted as a function of time of dissolution of a γ and an α brass specimen.

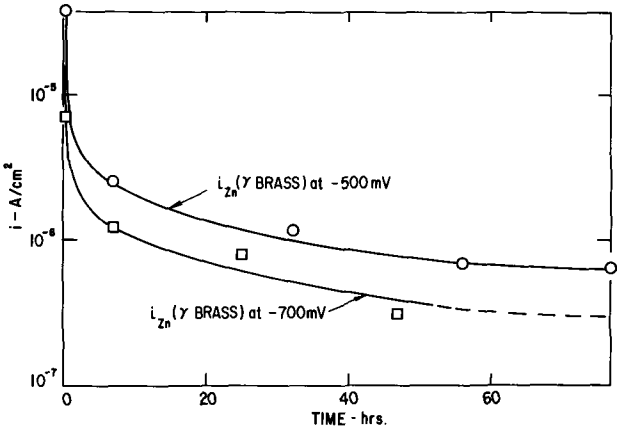

Fig. 2. i_{Zn}-time behavior for dissolution (preferential) of Zn from γ brass in 1*N* Na_2SO_4-0.05*N* $NaC_2H_3O_2$-0.05*N* $HC_2H_3O_2$.

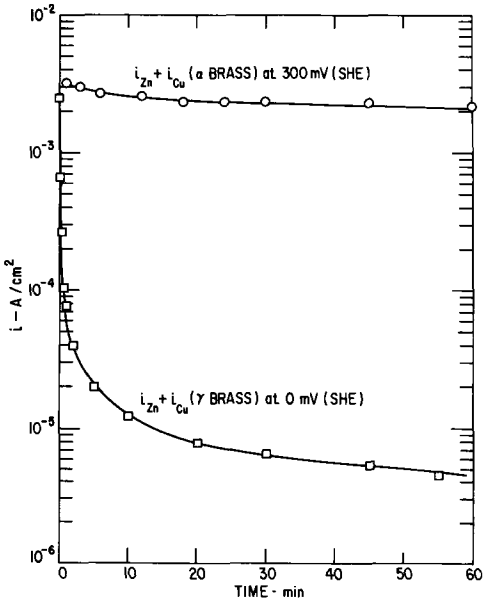

Fig. 3. ($i_{Zn} + i_{Cu}$)-time behavior for dissolution of Zn and Cu from α and γ brass.

The above-mentioned faster approach to a quasi-stationary current at high potentials is seen in the top curve for α brass. The data points are not from chemical analysis data; rather they are the directly measured currents (from the microammeter) which may be taken as the $i_{Zn} + i_{Cu}$ values since hydrogen evolution was negligible.

Partial polarization curves.—Curves of $i_{Zn} - E$ and $i_{Cu} - E$ for dissolution of Zn and Cu from single-phase Cu-Zn alloys in 1*N* Na_2SO_4 — 0.05*N* $NaC_2H_3O_2$ — 0.05*N* $HC_2H_3O_2$ are shown in Fig. 4. The polarization curves for the less noble component, Zn, exhibit complex behavior. There is a critical potential, E_c, where the rate of dissolution and its dependency on potential changes sharply. Below E_c there is a potential region of low, relatively constant current, whereas above E_c there is a potential region of rapidly increasing current, the rate of increase falling off at the higher potentials. E_c is a function of alloy composition, increasing with increasing content of the more noble component, Cu. E_c has values of roughly −950, 0, and +100 mV (SHE) for ε, γ, and α brass, respectively, although for ε brass the potential range of the low-current region is small or nonexistent in view of the proximity of the reversible potential of Zn in the electrolyte. Good agreement was observed between the Zn current calculated from the chemical analysis data and the directly measured value when conditions were such that the latter was due mainly to Zn dissolution. For example the data points in Fig. 4, ▽ at −470 mV and ◇ at 125 mV, for the i_{Zn} (ε brass) and i_{Zn} (γ brass) curves, respectively, are the directly measured currents.

Polarization curves for dissolution of Cu are shown (Fig. 4) only for γ and α brass. With ε brass no copper dissolution was detected for the potentials investigated. Cu dissolves from γ brass at $E \gtrsim 50$ mV with i_{Cu} rising rapidly to a value of ~0.1 mA/cm² at ~250 mV. Even at this potential, however, i_{Cu} is less than i_{Zn} by two orders of magnitude. The partial currents for Cu dissolution from γ brass at $E > 150$ mV are for shorter dissolution periods than the normal 1- and 20-hr periods (since i_{Zn} was so high); hence these currents are larger than they would have otherwise been and the scatter is greater.

Cu dissolves from α brass at about 50 mV with i_{Cu} rising rapidly to a value of ~16 mA/cm² at 400 mV. Above ~200 mV $i_{Cu} \cong 2i_{Zn}$.

Metallographic examination.—Cross-section metallographic examination of the specimens is revealing in the case of the higher current densities ($E > E_c$). For both ε and γ brass specimens a porous (poorly reflecting) layer is observed after appreciable dissolution. Pronounced, localized (cracklike) dissolution was also evident with γ brass, especially at the higher potentials. These features are illustrated in Fig. 5. Also at the higher potentials a (outer) scale sometimes is observed although not in Fig. 5. Cross-section metallographic examination of the dissolved α brass specimens for $E > E_c$, on the other hand, indicates that the porous-type alloy layer usually does not form; a scale, which was identified by x-ray diffraction analysis as Cu_2O, was observed at the higher potentials ($\lesssim 300$ mV). Figure 4, therefore, gives apparent current densities at $E > E_c$ for dissolution of ε and γ brass; the true current densities can be expected to be lower and to vary over the surface, being greatest at the advancing front of the porous structure. On the other hand the current densities for α brass in Fig. 3 and 4 may vary little over the surface and be close to the true value.

Discussion

The data in Fig. 4 show that two modes of dissolution may occur depending on the potential: preferential and simultaneous. Preferential dissolution changes gradually with potential from virtually no dissolution of the more noble metal to simultaneous dissolution of both components. Comparison of the Cu and Zn polarization curves for dissolution of α brass shows that preferential dissolution occurs for $E < 200$ mV, and that simultaneous dissolution occurs usually for $E \lesssim 200$ mV. Below ~50 mV virtually only Zn dissolves, and between 50 and 200 mV a gradual transi-

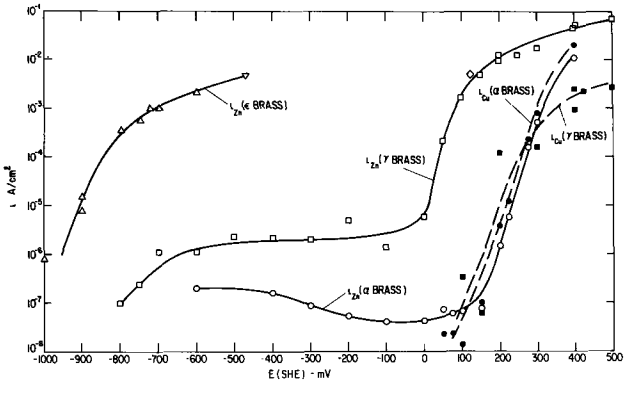

Fig. 4. i_{Zn}-E and i_{Cu}-E curves for dissolution of Zn and Cu from single-phase Cu-Zn alloys in the buffered (pH = 5) Na_2SO_4 electrolyte. Solid and dashed lines are the Zn and Cu currents, respectively.

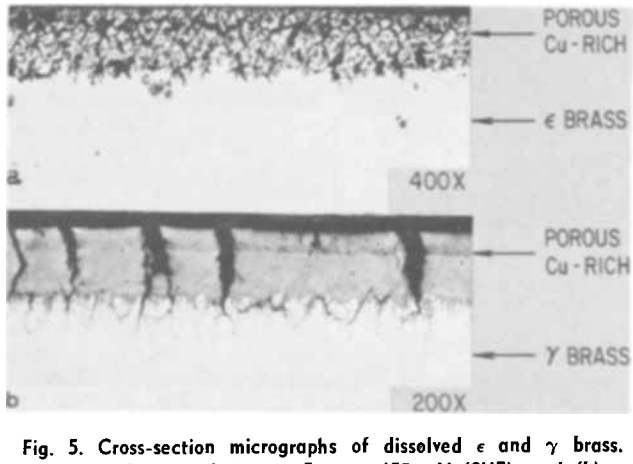

Fig. 5. Cross-section micrographs of dissolved ε and γ brass. (a) ε brass after dissolution at $E = -455$ mV (SHE), and (b) γ brass after dissolution at $E = 500$ mV (SHE).

tion occurs from Zn dissolution alone to simultaneous dissolution.

Comparison of the Cu and Zn polarization curves for dissolution of γ brass shows that preferential dissolution of Zn occurs at all potentials investigated; only Zn dissolves for potentials up to ~50 mV. Above ~50 mV Cu also dissolves, with $i_{Zn}/i_{Cu} > 10:1$. Since this ratio is much larger than the Zn/Cu ratio in γ brass, preferential dissolution of Zn occurs as well at these higher potentials; however, the degree of preferential dissolution of Zn clearly decreases with increasing potential in this region. Since it also decreases with time, it may be supposed, therefore, that at some higher potential and/or longer time, simultaneous dissolution of Zn and Cu would occur.

With ϵ brass only Zn dissolves in the potential range investigated. Since the potential was always well below the standard potential of Cu ($E_{Cu}^{\circ} = 337$ mV), the absence of significant Cu dissolution during dissolution of ϵ brass specimens is not surprising.

The potential at which Cu begins to dissolve from γ and from α brass is approximately the same as with pure Cu according to an auxiliary experiment in which pure Cu was used as the specimen. Similarly Zn dissolution commences at potentials near the reversible potential for pure Zn in the electrolyte, but the rate of Zn dissolution is suppressed by the accumulation of Cu on the surface and only becomes appreciable when a higher potential (E_c) is reached.

Pickering and Wagner (11) theorize that preferential dissolution of the less noble component may be expected when the difference between the single-electrode potentials of the two constituent metals in the electrolyte is sufficiently large, *i.e.*, several times RT/F, and when the potential of the dissolving alloy is higher than that of the less noble metal and lower than that of the more noble metal. The results presented herein for Cu-Zn alloys are in agreement with these concepts. In addition there is also the occurrence of preferential dissolution in a potential region where the free energy change for dissolution of both Cu and Zn is negative (with α and γ brass at $E \gtrsim +50$ mV). This is especially noticeable with γ brass (Fig. 4) and may be accounted for by the difference in the overpotentials (driving force) for dissolution of the components, the overpotential being far greater for Zn than for Cu.

The curves for Zn dissolution from the Zn-rich Cu-Zn alloys are qualitatively the same as those for dissolution of the less noble component, Cu, from Cu-rich Cu-Au alloys (1, 2). The similarity of the curves for the less noble metal in the two alloy systems probably extends to the alloys rich in the more noble metal, but a comparison is not possible due to the absence of data for the Cu-Au system at potentials noble of the oxygen evolution reaction. Dissolution of Cu from Au-rich alloys at higher potentials would be analogous to the dissolution of Zn from (Cu-rich) α brass (Fig. 4). For the same reason no comparison is possible of the polarization curves of the more noble components for the two alloy systems.

The formation of porous layers on ϵ and γ brass specimens during anodic dissolution is similar to the formation of porous layers during preferential anodic dissolution of Cu from Cu-Au alloys under similar conditions (11, 12) and during corrosion of Cu-Zn and Cu-Au alloys (13). The porosity is understood to be due to surface roughening. With diffusion of Zn to the surface as the controlling step in the over-all dissolution process of Cu-Zn alloy (10), a plane surface is unstable according to Harrison and Wagner (14), so that surface roughening and subsequent porosity may be expected.

The absence of porous layers on the α brass specimens is in agreement with the usual occurrence for α brass of simultaneous dissolution for $E \gtrsim 200$ mV. In its simplest form simultaneous dissolution may involve only consecutive removal of atom layers, as in the case of a pure metal. Even so one may expect that the surface atomic layer is enriched in Cu, in accord with ionization of Cu as the controlling step as suggested by others (9, 15). The situation becomes complex when appreciable preferential dissolution occurs prior to the onset of simultaneous dissolution; in this case simultaneous dissolution may occur in the presence of a Zn-depleted layer of finite depth.

Concluding Remarks

The results clearly show under which conditions preferential dissolution of the less noble component and in which potential range transition to simultaneous anodic dissolution take place. The anodic polarization behavior of Cu-Zn alloys appears to be similar to that of Cu-Au alloys. This behavior is not well understood. In particular, as Uhlig (16) has pointed out, a satisfactory understanding requires an explanation for the occurrence of a rather well-defined critical potential and insight concerning the low current region is almost totally lacking. At potentials above E_c some understanding exists. According to recent x-ray and electron diffraction investigations on Cu-Au (11, 12) and Cu-Zn (10) alloys, preferential dissolution at $E > E_c$ occurs via interdiffusion in the alloy next to the surface, accompanied by exceedingly fast surface roughening (17, 18).

A cursory examination of polarization data on alloys available in the literature gives some indication that other alloys exhibit similar polarization behavior. For example, in the practically important system, 18-8 stainless steel in hot $MgCl_2$ solution, an appreciable anodic current is observed at potentials more noble than —150 mV (SHE) according to Hoar and Hines (7) and others (8, 19, 20). Yet anodic dissolution of Fe and Cr at $E < -150$ mV may occur since the reversible potentials of Fe and Cr in the electrolyte are much lower. Further indication of a marked similarity with the Fe-Cr-Ni alloys is found in the recent data of Condit, Beauchamp, and Staehle (21). These authors show that as the Ni content is increased from 0 to 20 w/o (weight per cent) in a base alloy of fixed Cr content (20 w/o) the potential required to sustain a given rate of dissolution of the alloy becomes more noble. Ni, therefore, influences the dissolution of stainless steel in the same way as does Cu in the Cu-Zn alloys and Au in the Cu-Au alloys. For further insight it is desirable to determine the partial currents of the components, Fe, Cr, and Ni. Such data would also give information on whether or not passivation occurs for this alloy-electrolyte system at 150°C. A marked increase in metal dissolution in a potential region negative of —150 mV would indicate that passivation occurs; whereas an anodic current which is essentially independent of potential at $E < -150$ mV would indicate preferential dissolution (of Fe and/or Cr) in the absence of passivation. This is particularly important in connection with understanding stress corrosion in the austenitic stainless steels.

Acknowledgment

The authors want to record their indebtedness to Professor C. Wagner of the Max Planck Institut für physikalische Chemie for pointing out the need for data of the kind presented herein, and for his comments as well as those of Drs. R. A. Oriani, L. S. Darken, and R. P. Frankenthal on reading the manuscript. They want also to acknowledge the skillful assistance of Messrs. G. W. Momeyer and W. L. Doyle, who made the numerous chemical analyses, and of Mr. R. M. Lytle who did the metallography. All except Professor Wagner are staff members of the E. C. Bain Laboratory for Fundamental Research of the United States Steel Corporation.

Manuscript submitted April 18, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Electrodeposition of Lead Dioxide from Alkaline Solution

A. B. Gancy*

Tyco Laboratories, Inc., Waltham, Massachusetts

ABSTRACT

An investigation has been made of the properties of lead dioxide electrodeposited from dilute $Pb(NO_3)_2$ solutions made alkaline with NaOH, *i.e.*, under conditions which were expected to produce α-PbO_2. The apparent coulombic efficiency, measured gravimetrically, is strongly dependent on both the *p*H and the lead (biplumbite) ion concentration. Efficiency values encountered in this study ranged as high as 115%. A detailed composition analysis has been made on a material deposited from 5×10^{-2}M $Pb(NO_3)_2$-0.9M NaOH solution at an apparent coulombic efficiency of 112%. Analyses for water, lead, and active oxygen lead to the empirical composition

$$PbO_{1.868} \cdot 0.136\,H_2O, \text{ or its equivalent, } PbO_{1.732}(OH)_{0.272}$$

Si is the major trace contaminant, as measured by emission spectrography, but it is not present to the extent that silicate need be considered as an integral part of the electrodeposited compound. Quantitative analysis shows that nitrate is not an inclusion. Electron photomicrographs reveal a uniform fine-grained structure in which the crystal faces and boundaries are slightly curved. X-ray diffraction analysis gives an α-PbO_2 pattern. This is the same pattern reported in the literature for $PbO_{1.87}$, prepared by chemical methods. The real coulombic efficiency of plating, recalculated on the basis of the analysis for composition, is 98%. The rapid drop in the apparent coulombic efficiency as the *p*H is increased is suggested to be the result of an approach in the net lead oxidation state to 4.00.

A study has been initiated in this laboratory to investigate a report in the literature (1) that O_2 evolution on α-PbO_2 in strong acid solutions is distinctly different from that on β-PbO_2. In order to eliminate as much as possible effects arising from the known morphological differences between electrodeposited α- and β-PbO_2, an attempt was made to match the well-defined polycrystalline β-PbO_2 with a similar α modification. Inasmuch as electrodeposition from more alkaline solutions seemed to favor the α form (2), initial efforts were directed toward $Pb(NO_3)_2$-NaOH solutions. The *p*H was maintained above 9 to avoid precipitation of PbO and/or $Pb(OH)_2$ at the lead solubility minimum.

It was soon discovered that higher lead oxides could be produced from dilute, alkaline $Pb(NO_3)_2$ solutions with coulombic efficiencies far in excess of 100%, assuming the transfer of two electrons per mole of lead oxidized. Efficiencies below 100% can always be attributed to competitive anodic processes or other factors. But apparent efficiencies consistently and reproducibly far in excess of 100% require explanation. Some of the possibilities were inclusion of carbonates (absorption of atmospheric CO_2), inclusion of water, coprecipitation of PbO or $Pb(OH)_2$, and a net valence of lead in the electrodeposit appreciably lower than 4.0. The matter becomes especially interesting in light of references in the literature to the compound $PbO_{1.87}$ and to a continuous solid solution region between $PbO_{1.87}$ and PbO_2 (3).

The present paper describes the apparent plating efficiency as a function of NaOH concentration. A single electrodeposit is then studied in detail by x-ray diffraction, emission spectrography, electron microscopy, and wet chemical analysis. A knowledge of detailed composition and structure then allows a determination of the true anodic electrodeposition efficiency.

Experimental

Electrodeposition methods.—Two distinct groups of samples were prepared, one in which the deposit weighed ~ 150 mg, and the other, 1-1.5g. The former were large enough for a carbon, hydrogen microcombustion analysis, as well as for x-ray diffraction, elec-

Electrodeposition of Lead Dioxide from Alkaline Solution

A. B. Gancy*

Tyco Laboratories, Inc., Waltham, Massachusetts

ABSTRACT

An investigation has been made of the properties of lead dioxide electrodeposited from dilute $Pb(NO_3)_2$ solutions made alkaline with NaOH, *i.e.*, under conditions which were expected to produce α-PbO_2. The apparent coulombic efficiency, measured gravimetrically, is strongly dependent on both the *p*H and the lead (biplumbite) ion concentration. Efficiency values encountered in this study ranged as high as 115%. A detailed composition analysis has been made on a material deposited from 5×10^{-2}M $Pb(NO_3)_2$-0.9M NaOH solution at an apparent coulombic efficiency of 112%. Analyses for water, lead, and active oxygen lead to the empirical composition

$$PbO_{1.868} \cdot 0.136\,H_2O, \text{ or its equivalent, } PbO_{1.732}(OH)_{0.272}$$

Si is the major trace contaminant, as measured by emission spectrography, but it is not present to the extent that silicate need be considered as an integral part of the electrodeposited compound. Quantitative analysis shows that nitrate is not an inclusion. Electron photomicrographs reveal a uniform fine-grained structure in which the crystal faces and boundaries are slightly curved. X-ray diffraction analysis gives an α-PbO_2 pattern. This is the same pattern reported in the literature for $PbO_{1.87}$, prepared by chemical methods. The real coulombic efficiency of plating, recalculated on the basis of the analysis for composition, is 98%. The rapid drop in the apparent coulombic efficiency as the *p*H is increased is suggested to be the result of an approach in the net lead oxidation state to 4.00.

A study has been initiated in this laboratory to investigate a report in the literature (1) that O_2 evolution on α-PbO_2 in strong acid solutions is distinctly different from that on β-PbO_2. In order to eliminate as much as possible effects arising from the known morphological differences between electrodeposited α- and β-PbO_2, an attempt was made to match the well-defined polycrystalline β-PbO_2 with a similar α modification. Inasmuch as electrodeposition from more alkaline solutions seemed to favor the α form (2), initial efforts were directed toward $Pb(NO_3)_2$-NaOH solutions. The *p*H was maintained above 9 to avoid precipitation of PbO and/or $Pb(OH)_2$ at the lead solubility minimum.

It was soon discovered that higher lead oxides could be produced from dilute, alkaline $Pb(NO_3)_2$ solutions with coulombic efficiencies far in excess of 100%, assuming the transfer of two electrons per mole of lead oxidized. Efficiencies below 100% can always be attributed to competitive anodic processes or other factors. But apparent efficiencies consistently and reproducibly far in excess of 100% require explanation. Some of the possibilities were inclusion of carbonates (absorption of atmospheric CO_2), inclusion of water, coprecipitation of PbO or $Pb(OH)_2$, and a net valence of lead in the electrodeposit appreciably lower than 4.0. The matter becomes especially interesting in light of references in the literature to the compound $PbO_{1.87}$ and to a continuous solid solution region between $PbO_{1.87}$ and PbO_2 (3).

The present paper describes the apparent plating efficiency as a function of NaOH concentration. A single electrodeposit is then studied in detail by x-ray diffraction, emission spectrography, electron microscopy, and wet chemical analysis. A knowledge of detailed composition and structure then allows a determination of the true anodic electrodeposition efficiency.

Experimental

Electrodeposition methods.—Two distinct groups of samples were prepared, one in which the deposit weighed ~ 150 mg, and the other, 1-1.5g. The former were large enough for a carbon, hydrogen microcombustion analysis, as well as for x-ray diffraction, elec-

* Electrochemical Society Active Member.

tron microscopy, emission spectrography, and nitrate analysis. Such samples were too small, however, for a precise analysis for lead by $PbSO_4$, and 1-1.5g deposits were obtained using larger scale apparatus. This same apparatus was used to prepare the 0.5g samples for As_2O_3 titration (active oxygen analysis).

The 150 mg samples were plated onto rectangular electrodes cut from 0.030 in. platinum sheet. Platinum support wires were spot welded to the electrodes. The ~ 5 cm^2 geometric area electrode was made long and narrow so that the entire piece, including the support wire, could be inserted into microcombustion tubes. Prior to deposition the electrodes were degreased, etched to a dull finish in aqua regia, and finally heat-treated for 3 hr at 600°C, the approximate temperature used in the combustion analysis. They were then weighed to the nearest 0.1 mg. Electrodeposition was from $Pb(NO_3)_2$, NaOH solutions, prepared two liters at a time and stored in tightly sealed polyethylene bottles. A Pt mesh cylinder surrounded the anode and functioned as cathode. 500 ml of rapidly stirred solution were used per plating. The temperature was maintained at 50°-55°C. A constant current source device was used in conjunction with an electric timer. Current was read from a sensitive milliameter (Sensitive Research Instrument Corporation, 05-100 mA). Prior to weighing, the samples were washed with distilled water and air-dried.

In order to examine the reproducibility of electrodeposition, 15.00 mA (~ 3 mA/cm^2) were passed for 7200 sec in a 5 x 10^{-2}M $Pb(NO_3)_2$, 0.9M NaOH solution. The average deposit weight for eight determinations was 150 ± 0.3 mg (theoretical, 133.8 mg). This falls well within the readability of the milliameter (3 parts/1000) and is close to the indeterminate error of a deposit weight determination which requires four individual weighings. The apparent coulombic efficiency is 112.2 ± 0.2%.

The larger samples, ranging from 0.5 to 1.5g, were plated onto a 0.030 in. Pt sheet electrode having a ~ 25 cm^2 geometric area. The cathode was made of thin Pt stock and fashioned so as to produce a uniform current density on both sides of the anode plate. Five liters of vigorously stirred $Pb(NO_3)_2$-NaOH solution were used per plating. Temperature was maintained at 50°-53°C. As with the smaller samples, the electrodeposit was washed with distilled water and air dried prior to weighing.

Analytical methods.—Analysis for water.—To analyze for H_2O, samples were decomposed in a microcombustion apparatus customarily used for carbon, hydrogen analysis of organic compounds. Carbon analysis was routinely made along with the hydrogen analysis, but carbon contents were found to be negligibly low. This is evidence that the inordinately high plating efficiencies found were not not caused by CO_2 absorption.

Analysis for lead.—The method was to plate at least a gram using the 5l apparatus, to dissolve the deposit in acidic H_2O_2, and then to precipitate and weigh $PbSO_4$. A negative blank correction and a positive correction for the solubility of $PbSO_4$ in H_2SO_4 were made.

Analysis for nitrate.—According to Raub (4) metal and metal alloy electrodeposits can codeposit with certain anions present in the electrolyte such as citrate, tartrate, and nitrate. The α-naphthylamine-sulfanilic acid spot test for nitrate (5) indicated about 0.01% nitrate in the sample.

Using a colorimetric method employing brucine in perchloric acid, the nitrate content of the PbO_2 was found to be less than 0.001%. Nitrate was therefore not considered further in the composition study.

Active oxygen determination.—The postulate of the simple compound $Pb(OH)_xO_y$ requires only two knowns for the determination of x and y; these are provided by the lead and the water analyses. However, a third analysis is required as a check on the first two and also functions to reveal any possible third unknown in the form of anion inclusion or inert contaminant. This third analysis is for active oxygen or a measure of the lead oxidation state. A standard As_2O_3 titration method was used (6).

The reaction proceeds as follows

$$2PbO_a \cdot bH_2O + (a-1)\,As_2O_3 + 4H^+ = 2Pb^{++} + (a-1)As_2O_5 + 2(1+b)H_2O$$

The As_2O_3 equivalent is expressed

$$As_2O_3 \text{ equivalent} = \frac{2(a-1)\,(\text{wt sample})}{(207.2 + 16.00\,a + 18.02\,b)}$$

This result can be expressed as "oxide ion" by multiplying by $(8a/a - 1)$.

Solubility of lead dioxide.—The solubility of lead dioxide at 25°C is given by the expression (7) $\log (PbO_3^=) = 2\,pH - 31.32$. At pH = 14, the solubility of lead dioxide is predicted to be an appreciable 10^{-3} mols/l.

Weight loss measurements were made in 0.97M NaOH solutions at 50°C using the electrodeposited PbO_2 of interest in the over-all analysis. Even in the absence of $Pb(NO_3)_2$ and at a higher NaOH concentration (0.97 *vs.* 0.90M NaOH), the solubilization rate was observed to be so low as to produce a negligible effect on the gravimetric analysis.

Results and Discussion

Coulombic efficiency of lead dioxide electrodeposition.—In Fig. 1 the apparent coulometric efficiency is plotted against the NaOH concentration for three levels of $Pb(NO_3)_2$ concentration. The position of the rising portion of the curve is very much dependent on the lead concentration. The point at which the curves cross the "100%" axis has no special significance, as will become apparent from the ensuing discussion of real electrodeposition efficiencies. The rather steep drop in the 5 x 10^{-3}M $Pb(NO_3)_2$ curve at NaOH concentrations greater than 1*N* is of interest only in regards to competing processes and the effect of stirring on the electrodeposit.

The region of high apparent coulombic efficiency was considered most intriguing and was therefore chosen for closer study. Thus conditions corresponding with the highest efficiencies were examined, consistent with the avoidance of PbO or $Pb(OH)_2$ precipitation at lower *p*H's. Finally, as a matter of convenience in scaling up the electrodeposition for more precise analysis, all of the composition studies were made on a deposit plated from a 5 x 10^{-2}M $Pb(NO_3)_2$-0.9M NaOH solution. It can be seen from Fig. 1 that the apparent coulombic efficiency for this material is about 112%. The deposits were intense black, with a smooth lustrous metallic surface.

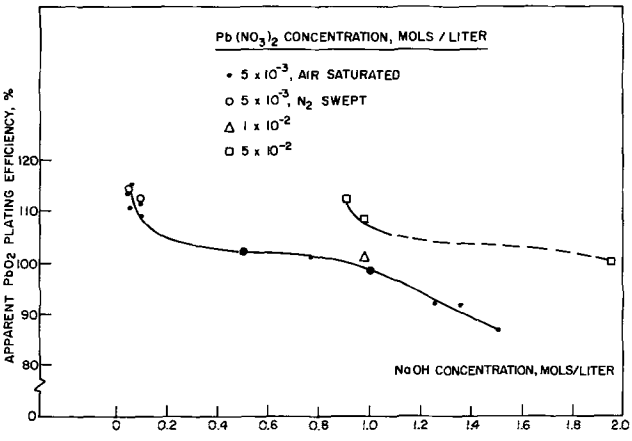

Fig. 1. Electrodeposition of lead dioxide from alkaline $Pb(NO_3)_2$ solution. T = 50°C; C.D. = 3 mA/cm^2.

Figure 1 also shows that there is no alteration in the results due to bubbling N_2 through the closed electrodeposition apparatus so as to avoid absorption of CO_2 from the atmosphere. The electrodeposition or inclusion of basic lead carbonates in the solid can therefore be ruled out as an explanation of the inordinately high efficiencies.

Water content.—Table I gives the water analyses of four separate preparations of the material picked for the composition analyses, that plated from 5 x 10^{-2}M $Pb(NO_3)_2$ to 0.9M NaOH solution at 50°C. Three were 150 mg samples, while the fourth was a 1.1g deposit. The latter was analyzed in order to check on the scaleup of the deposition procedure. All samples were plated at 3 mA/cm² geometric area.

The agreement between small and large sample analyses is good. The value 1.04% H_2O will subsequently be used in the over-all composition determination. Note that this water content is considerably higher than that of the various commercial PbO_2 powders (8).

Lead analysis.—Table II gives the Pb analyses for the electrodeposited PbO_2 under study. The overlap between small and large sample results is satisfactory. The precision of the former, however, is considered insufficient for a satisfactory composition analysis. The value 86.50% Pb is used in the composition analysis. (The theoretical amount of Pb in $PbO_{2.00}$ containing no water would be 86.62%.)

Active oxygen analysis.—The lead dioxide under study was, again, plated from a 5 x 10^{-2}M $Pb(NO_3)_2$-0.9M NaOH solution at 3 mA/cm² and 50°C. The As_2O_3 titrations gave 0.725 ± 0.004% As_2O_3 equivalents on a 0.5g sample. The error is the indeterminate error in reading the buret. (The theoretical % As_2O_3 equivalents for $PbO_{2.00}$ containing no water would be 0.836.)

A 0.5g sample of reagent grade PbO_2 was similarly analyzed to give 97.7 ± 0.5% as lead dioxide. This compared well with the manufacturer's assay of 97.5%. This analysis in itself suggests a net lead valence less than four in addition to the presence of water and other foreign constituents.

Spectrographic analysis for trace metals.—The PbO_2 electrodeposit under study was analyzed by the emission spectrograph. Silicon is the major trace constituent at a 0.03-0.3% level.

Lead dioxide composition.—Since the minimum total trace metal concentration is low enough to be ignored, there are only two unknowns to solve for in the formulation $PbO_a \cdot bH_2O$. Three independent relationships are available in the form of a water, lead, and active oxygen analysis. The approach will be to use the information in pairs, and then to examine each of the three results critically. In this analysis the following expressions are used and referred to by number:

$$\% H_2O = \frac{18.02b}{207.2 + 16.00a + 18.02b} \times 100 = 1.04 \quad [1]$$

$$\% Pb = \frac{207.2}{207.2 + 16.00a + 18.02b} \times 100 = 86.50 \quad [2]$$

Table I. Water content of electrodeposited lead dioxide

Sample wt	Apparent coulombic efficiency, %	% H_2O	
150.3 mg	112.1	1.098	average
150.0	112.0	0.96	1.04 ± 0.05
149.6	111.8	1.056	
1.1278 g	112.5	1.04 ± 0.04	(duplicate analysis)

Table II. Analysis for lead in electrodeposited PbO_2

Sample wt, g	% Pb
~0.15	86.7 ± 0.6 (average of 3 determinations)
~1.5	86.50 ± 0.04 (average of 2 determinations)

Table III. Determination of the constants in $PbO_a \cdot bH_2O$

Combination of equations	a	b	Derived quantities % O	% Pb	% H_2O	Total assay, %
[1] and [2]	1.86₅	0.138	12.50	—	—	100.04
[1] and [3]	1.85₉	0.137	—	86.55	—	100.14
[2] and [3]	1.86₈	0.136	—	—	1.02	100.00

$$\% As_2O_3 \text{ equiv} = \frac{2(a-1)}{207.2 + 16.00a + 18.02b} \times 100 = 0.725 \quad [3]$$

"Oxide ion" cannot be expressed independently since it is related to the As_2O_3 equivalent through the parameter a

$$\% O = \frac{8a}{(a-1)} \% As_2O_3 \text{ equiv}$$

Table III gives the three solutions for a and b. Also listed are the total assays obtained by adding to the two measured quantities the third component computed using the derived values of a and b. The agreement between measured and calculated quantities is very satisfactory. Relatively speaking the agreement in % H_2O is much poorer than that in % Pb. But in absolute terms, the % H_2O error is the smaller. An examination of the analytical methods and results shows that the precision of the data decreases in the order % Pb, % As_2O_3 equiv., % H_2O. Thus combination [2] and [3] would appear to be the best choice. It also happens to give the total assay closest to 100% although this is only a reflection of error accumulation in the calculations.

The lead dioxide composition is then $PbO_{1.868} \cdot 0.136$ H_2O with a net lead valence of 3.74. The good agreement between calculated and measured quantities leads to the conclusion that the formulation $PbO_a \cdot bH_2O$ is the correct one, and that silicate impurity need not be taken into account. The indicated formula is possibly incorrect only insofar as ~0.1% trace metal silicates have not been worked into the analysis.

X-ray diffraction analysis.—The x-ray diffraction pattern for the electrodeposit under discussion is that of α-PbO_2 (9) whose composition was reported as $PbO_{1.94-2.02}$. The pattern is essentially the same as that obtained for $PbO_{1.87}$, a composition prepared from PbO_2 by Katz (3).

Structure.—It must be concluded that all three compositions (*i.e.*, α-PbO_2, $PbO_{1.87}$, and $PbO_{1.868} \cdot 0.136$ H_2O) have the same basic structure. Evidently a large deficiency of oxygen atoms can occur in α-PbO_2 without changing the basic structure of the molecule, if indeed the formula $PbO_{1.87}$ is a correct one. The formula for the compound prepared in the present work can be rewritten to give

$$PbO_{1.732}(OH)_{0.272}$$

The numerical coefficients add to give 2.004, which is equal to 2.00 within the experimental error. This suggests very strongly that OH^- ions replace some of the $O^=$ ions in the α-PbO_2 lattice.

Within experimental error, the compound under discussion can be represented by the expression

$$19PbO_2 \cdot 3Pb(OH)_2$$

(expressed in terms of fractional coefficients, $PbO_{1.862} \cdot$

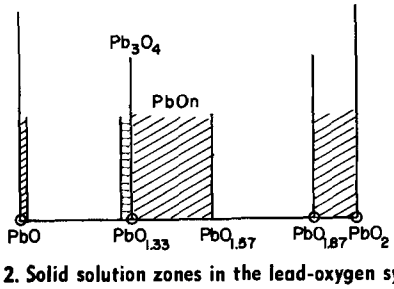

Fig. 2. Solid solution zones in the lead-oxygen system

0.136 H_2O). This can be considered to be a solid solution of lower and higher valent lead oxides. As such, it falls within the solid solution zone reported by Katz (Fig. 2). The only difference is that Katz defines the anhydrous case, while here some oxide ions are replaced by hydroxyl ions. Structurally, they are both equivalent. While it cannot be disproved, the $Pb(OH)_2$ is not believed to be present as a colloidal dispersion.

Real plating efficiency.—The compound $PbO_{1.86_8}$ · 0.136 H_2O was plated from 5 x 10^{-2}M $Pb(NO_3)_2$-0.9M NaOH solution at 50°C. The passage of 1078.6 coulombs produced 1.5030g. From this it can be determined that the real plating current efficiency was 98%. This is to be compared with the apparent coulombic efficiency of 112%. The importance of knowing the exact composition of the deposit when determining coulombic efficiency is clear.

Summary

1. PbO_2 plated from $Pb(NO_3)_2$ solutions between pH 9 and 10 has the structure of α-PbO_2 but contains, probably in solid solution, some $Pb(OH)_2$. One such deposit has the composition: $PbO_{1.73}(OH)_{0.27}$ or 19 PbO_2 · 3 $Pb(OH)_2$ and was obtained with current efficiency of 98% based on the real mean lead valence of 3.74.

2. Except for very low concentrations of lead and high concentrations of NaOH, the current efficiency from solutions with pH greater than 10 is close to 100% based on tetravalent lead.

Acknowledgment

The author is indebted to Dr. A. C. Makrides for advice and suggestions in the course of the investigation, and to Dr. S. B. Brummer and Dr. J. Giner for assistance in preparing the manuscript. Valuable discussions were also held with Dr. J. N. Butler and Dr. G. A. Wolff.

This work was made possible by the Department of the Army, Harry Diamond Laboratories, Washington, D.C., under Contract No. DA-49-186-AMC-136(D).

Manuscript received Feb. 7, 1969; revised manuscript received June 30, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Electrochemical Oxidation of Aliphatic Sulfides under Nonaqueous Conditions

Peter T. Cottrell and Charles K. Mann*
Department of Chemistry, Florida State University, Tallahassee, Florida

ABSTRACT

The anodic oxidation of aliphatic sulfides has been investigated, using cyclic voltammetry and controlled potential electrolysis. Reactions of dimethyl sulfide in acetonitrile have been studied in detail, considering the effects of variation of water content and of type of supporting electrolyte. With as much as 1% water in MeCN, dimethyl sulfide is completely oxidized to dimethyl sulfone. In anhydrous $NaClO_4$-MeCN, the products are CH_3SO_3Na and CO. It is suggested that the electrochemical reaction involves formation of protons and $CH_3SCH_2^+$, which condenses with CH_3SCH_3 to form $CH_3SCH_2^+S(CH_3)_2$. When perchlorate is present as supporting electrolyte, it is involved in a slow chemical reaction which produces Cl^-, CO, and CH_3SO_3Na. The reaction of benzyl methyl sulfide is very similar, leading to benzaldehyde and CH_3SO_3Na.

Previous investigation has shown that organic sulfides are oxidized in aqueous systems at platinum anodes to sulfones and sulfonium salts (1). Many aromatic and olefinic sulfides form cation radicals which exhibit appreciable lifetimes when they are oxidized in nonaqueous systems. Examples are tetramethylthio-, tetraethylthio-, and tetraphenylthioethylene (2); 1,2,4,5-tetramethylthiobenzene, dithiohydroquinone dimethyl ether, 1,6-bis(methylthio)pyrene and 1,4-bis(methylthio)naphthalene (3, 4). Similarly, heterocyclic sulfur compounds such as thianthrene undergo reversible one-electron reactions leading to cation radicals (5, 6). There have apparently been no studies of the anodic reactions of aliphatic sulfides in nonaqueous media. This report describes the anodic oxidation of dimethyl sulfide and benzyl methyl sulfide in acetonitrile. Special attention is paid to the influence of small amounts of water and to effects caused by variations in supporting electrolyte.

Experimental

Reagents.—Acetonitrile was purified as previously described (7); anhydrous sodium perchlorate was recrystallized from 95% ethanol and dried in a vacuum oven. Reagent grade tetramethylammonium tetrafluoborate was recrystallized from water-ethanol and similarly dried. Sulfides were purified by careful distillation of commercially available samples. Dimethyl sulfide boiled at 37°; lit. bp_{760}, 38° (8). Benzyl methyl sulfide boiled at 87° under 11 mm; lit. bp_{11}, 87°-88° (9).

Acetonitrile was dried by stirring with calcium hydride at room temperature for several hours and degassed by repeated freezing and pumping. Solutions were prepared by transferring dried solvent, protected from atmospheric contact, to a flask containing supporting electrolyte which had previously been dried by heating under a vacuum. Chlorine dioxide was prepared by the method of Atkins *et al.* (10). Dimethylmercaptomethyl sulfonium chloride was prepared from dimethyl sulfide and methylchloromethyl sulfide (11).

Procedures.—Controlled potential electrolyses were performed in closed, three-electrode, three-compartment cells, using an electronic potentiostat with platinum anodes and mercury cathodes. Details have been described (12). Cyclic voltammetry results were ob-

* Electrochemical Society Active Member.

tained using the apparatus previously described (13). Throughout the work, a silver-0.10*M* silver nitrate-acetonitrile reference electrode was used. All potentials are cited relative to this electrode, which is itself +0.30V *vs.* aqueous SCE.

Anhydrous perchloric acid was prepared by oxidizing hydrogen gas at a platinum anode at +0.8V in 0.1*M* $NaClO_4$ (14). The following columns were used for gas chromatography: dimethyl sulfide on SE 30, on Chromosorb P; dimethyl sulfide, benzyl methyl sulfide, and benzaldehyde on Dowfax 9N9-NaOH on Chromosorb W; methanesulfonyl chloride on Dow-Corning silicone grease on Chromosorb P; acetamide, dimethyl sulfoxide, dimethyl sulfone and water on Porapak Q; carbon monoxide and oxygen on 13X molecular sieves; benzaldehyde and benzyl methyl sulfide on potassium oleate on Chromosorb W. Gas chromatography was used, as will be described, for qualitative and quantitative examination. In all cases, unknown peaks were compared with those produced by valid samples, chromatographed at the same time. When GLC was used for identification of components in a mixture, this identification was supported by other types of evidence, *e.g.*, spectroscopy, and by chromatographing at more than one temperature or on more than one type of column.

Results

Cyclic voltammetry.—Cyclic voltammetry curves for a series of commercially available organic sulfides and mercaptans were obtained at a platinum wire microelectrode. Results are collected in Table I. The sulfides and mercaptans examined all showed irreversible oxidation reactions at potentials more positive than would have been true for the corresponding amines. For example, dimethyl sulfide is oxidized at a more positive potential than is trimethylamine. Some of the compounds showed two or more oxidation steps; two of them also showed reduction peaks at potentials positive relative to the reference electrode. However, none of them gave any indication of reversible oxidation. No trends or simple correlations between substituent effects and peak potentials were observed.

Controlled potential electrolysis.—Oxidation of 30 m*M* dimethyl sulfide in dry 0.4*M* $NaClO_4$-MeCN was carried out at +1.40V. After a preelectrolysis at +1.7V, during which current dropped quickly from about 10 mA to 50 μA, the potential was lowered to 1.4V, dimethyl sulfide was added and the current increased to as much as 100 mA and then dropped to approximately 50 μA within about 90 min. The current-time variation was not exponential, as would have been the case with a simple first order reaction in the apparatus used, but was instead nearly linear. Coulometric measurement, typically made with 0.3 to 3 mM of reactant, showed 0.84 ± 0.02 electrons per molecule of sulfide taken. Charge involved in the preelectrolysis amounted typically to 1% of that in the subsequent reaction.

Table I. Cyclic voltammetry for sulfides and mercaptans

Compounds[a]	Peak potential,[b] volts

[a] Voltammetry at a platinum wire electrode at 10 V/sec sweep rate, reactant 5-10 m*M* in 0.10*M* $NaClO_4$-acetonitrile.
[b] Potentials measured at ambient temperature of about 22°, Ag-0.10*M* $AgNO_3$-MeCN reference electrode.
[c] Reduction peak, all those unmarked are oxidation peaks.

The reaction of dimethyl sulfide was carried out with 0.1*M* tetramethylammonium tetrafluoborate as supporting electrolyte, but with other conditions as described above. The reaction was considerably slower than with $NaClO_4$; initial current was typically 40 mA, dropping steadily to 90 μA after 3 to 4 hr. This reaction involved 0.85 electrons per molecule of sulfide.

In order to investigate the influence of water on the reaction, an elctrolysis of 35 m*M* dimethyl sulfide was performed in 0.4*M* $NaClO_4$-MeCN with 1% of water added. This experiment was run at +1.20V, rather than at +1.40V, because of the very large currents observed. Preelectrolysis at 1.6V resulted in currents ranging from 5 to 0.09 mA. On addition of dimethyl sulfide, current increased to, typically 110 mA and dropped exponentially to about 0.110 mA. Current integration showed 4.0 ± 0.1 electrons per molecule of sulfide taken.

Benzyl methyl sulfide was oxidized in anhydrous 0.4*M* $NaClO_4$-MeCN at 1.40V. Reaction currents varied from 90 to 0.15 mA in an approximately linear fashion, similar to the dimethyl sulfide reaction. The coulometric measurement amounted to 0.82 ± 0.02 electrons per molecule of sulfide.

Product analysis—Me_2S *electrolysis.*—Immediately on conclusion of the reaction of Me_2S in dry $NaClO_4$-MeCN, starting material in an amount corresponding to approximately 25% of that originally present could be determined by GLC on the reaction mixture. Small amounts (approximately 3 m/o (mole per cent) of original sulfide) of dimethyl sulfone and dimethyl sulfoxide and a trace of acetamide could also be detected. A reaction was run during which samples were taken at intervals for dimethyl sulfide assay by GLC. A plot of Me_2S concentration *vs.* time shows an approximately linear decrease, while current is decreasing, but with little change after the current had become constant.

When the reaction mixture was allowed to stand under a nitrogen atmosphere at room temperature for 5 to 10 days, a white precipitate formed. This was identified as sodium methanesulfonate by comparison of its infrared, ultraviolet, and NMR spectra with those of a valid sample. For quantitative determination of the yield of $MeSO_3Na$, the volatile fraction of a reaction product was removed under vacuum. The residue was treated with thionyl chloride and N,N-dimethylformamide to convert any sulfonic acid or sulfonate present into methanesulfonyl chloride (15) which was determined by GLC. The indicated recovery of $MeSO_3Na$ amounted to 95 ± 5 m/o of dimethyl sulfide originally taken.

In addition to the products mentioned, the reaction mixture contained strong acid, corresponding to 58 m/o of starting sulfide. As $MeSO_3Na$ precipitated on standing, carbon monoxide was shown, by GLC identification, to be evolved. During the period after completion of the electrolysis, the reaction mixture developed a green-yellow color. Although reaction solutions did not exhibit any ESR spectra during or immediately after electrolysis, the green solutions did show a single broad band centered at $g = 2.0$.

During the precipitation of $MeSO_3Na$, uv spectra were recorded. A broad intense absorption band was found which was thought to be due to chlorine-oxygen compounds produced during the decomposition of Cl_2O_7. Chlorate, chlorite, hypochlorite, and other oxides of chlorine are known to absorb strongly in the uv (16). When the volatile fraction of the reaction mixture was removed, it exhibited a much weaker absorption which was qualitatively identical with that of ClO_2 in acetonitrile. This fraction was acidic and gave a substantial silver chloride precipitate. After separation from the volatile components, an acetoni-

trile solution of the residue showed the intense uv absorption described above.

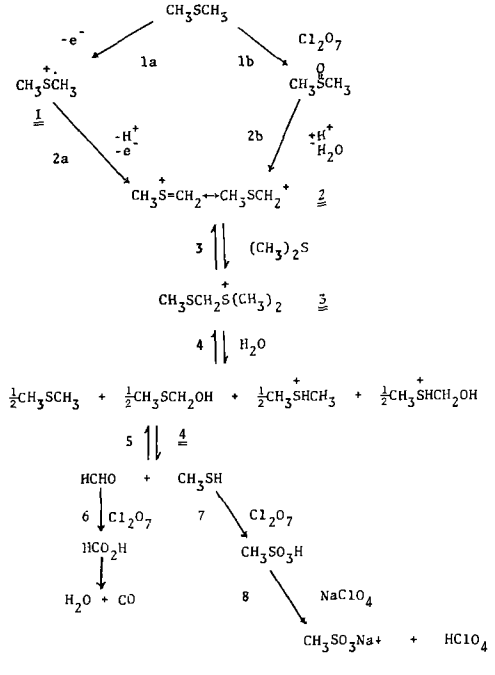
When Me_2S was oxidized in the presence of 1% water, it was apparently converted quantitatively to dimethyl sulfone. There was no evidence of participation of perchlorate or other chlorine compound. When the recation was carried out in a dry 0.1*M* tetramethylammonium tetrafluoborate-MeCN solution, approximately 30% of starting material was detectable by GLC after the electrolysis had come to a stop. However, there was no indication of any continuing chemical reaction and no evidence of oxygen-containing products. The reaction mixture showed only a very weak uv absorption at 255 mμ, in contrast to the very strong absorption observed when perchlorate was present.

Discussion

Dimethyl sulfide oxidation.—On the basis of the results which have been described, the reaction scheme outlined in Chart I is suggested for the reaction of Me_2S in dry $NaClO_4$-MeCN. It consists of a sequence of electrochemical and chemical steps, reactions 1, 2, and 3, which occur during the electrolysis to produce dimethylmethylthiomethyl sulfonium ion 3, which is thought to be the immediate major product. On standing, it is suggested that the sequences of chemical reactions 5,6,7,8 and 1b,2b,3,4,5,6,7,8 occur slowly, resulting in ultimate conversion of all of the original starting material to the sodium salt of methane sulfonic acid.

The process is initiated by electrochemical step 1 which involves removal of one electron from the substrate to produce the cation radical 1 which rapidly undergoes loss of a proton and of a second electron to form the sulfonium derivative 2. Some aromatic sulfides undergo reversible one-electron oxidations analogous to reaction 1 to produce cation radicals that are stabilized by delocalization of charge in the aromatic pi-system; since this stabilization of aliphatic cation radicals is impossible they would be expected to react too rapidly to permit step 1 to appear reversible. The sulfonium ion 2, however, would be expected to be resonance stabilized as indicated (17, 18). The hexachloroantimonate salt of 2 has been shown to react with Me_2S as indicated in step 3 to form the sulfonium derivative 3 (17).

CHART I



One observation that must be accounted for is the chromatographic detectability of Me_2S at the conclusion of the electrolysis. Presumably a compound is present which is electrochemically unreactive but which decomposes in the chromatograph to yield Me_2S. One possibility would be protonated sulfide. The reaction mixture is strongly acidic and such a salt could dissociate in the chromatograph injection port. However, a sample of $Me_2S \cdot HClO_4$ in MeCN was prepared as described above and was found not to produce a Me_2S peak.

A sample of 3 was prepared as described above and was found to show a peak for Me_2S. This corresponded to approximately 50 m/o of the sulfonium salt taken. It is suggested, therefore, that the presence of 3 at the end of the electrolysis would account for the chromatographic observations. Hydrolytic cleavage of 3 in step 4 is suggested to account for the scission of the carbon-sulfur bond. Pocker and Parker (19) reported that while trimethyl sulfonium iodide in ethanol decomposes to dimethyl sulfide and methyl iodide, the perchlorate salt yields the sulfide and methylethyl ether, as indicated in Eq. [9]. It is suggested that a similar reaction is

$$(CH_3)_3S^+ClO_4^- \xrightarrow{EtOH} (CH_3)_2S + CH_3OC_2H_5 + HClO_4 \quad [9]$$

involved in decomposition of 3, but with traces of water, rather than ethanol, as the reactant.

Step 5 is the decomposition of a hemithioacetal of formaldehyde (8, p. 330). If this occurs in the presence of a strong oxidizing agent, the formation of methane sulfonic acid, shown in step 7, would be expected. Under the conditions of these experiments, the sodium salt would precipitate because it is insoluble in MeCN. Decomposition of formic acid to give carbon monoxide would also be expected.

It is known that dimethyl sulfoxide undergoes the acid catalyzed dehydration indicated in Eq. [10] and that 2 will react with Me_2S

$$CH_3S(O)CH_3 \xrightarrow{+H^+} CH_3S(OH^+)CH_3 \rightleftarrows CH_3S^+=CH_2 + H_2O \quad (2)$$

$$2 + Me_2S \rightarrow CH_3SCH_2S^+(CH_3)_2 \quad (3) \quad [10]$$

to produce 3 (20). It should therefore be possible to produce chemically a solution very similar to that thought to exist at the end of the electrolysis by allowing stoichiometric amounts of dimethyl sulfoxide and protonated dimethyl sulfide to react in $NaClO_4$-MeCN solution. It was indeed found that, when equimolar amounts of Me_2SO and Me_2SH^+ were allowed to react, Me_2S corresponding to one half of that originally taken could be detected by GLC. Before mixing, neither the dimethyl sulfoxide nor the protonated dimethyl sulfide produced a peak. This recovery is in agreement with the stoichiometry implied in step 4 in which each mole of 3 is cleaved to produce one half mole of unprotonated Me_2S. It is also in agreement with the observed recovery of 25 m/o of the original Me_2S after electrolysis, since two moles of Me_2S are required to produce one mole of 3 electrochemically. Furthermore, on standing or after being warmed, the sodium salt of methanesulfonic acid was precipitated, carbon monoxide was generated, chloride could be detected and the uv spectrum showed the very intense end absorption described.

One significant difference was noted between the chemical and electrochemical reaction mixtures; acet-

amide was a major product in the former, but was present only in small concentrations in the latter. It is thought to be produced by acid catalyzed hydrolysis of MeCN (21). This would be possible in formation of the chemical reaction mixture because dehydration of dimethyl sulfoxide, Eq. [10], represents a major source of water. By contrast, in the electrochemical process, the major source of compound 2 is Me_2S through steps 1a and 2a which do not involve water. It was found that, on mixing anhydrous samples of dimethyl sulfoxide and protonated dimethyl sulfide, water would then be detected. After a period of time, the water content decreased and acetamide appeared.

Participation by perchlorate.—When significant yields of oxygen-containing products are formed as a result of an anodic oxidation, it is of interest to identify the oxygen source. Three reasonable possibilities exist here, elemental oxygen, water, and the perchlorate anion of the supporting electrolyte. Molecular oxygen can be eliminated from consideration because of the care taken in degassing the solutions and in protecting them from atmospheric contamination.

The results of the experiment with 1% water present show that it most certainly does enter into the reaction scheme if it is present, since an entirely different product, dimethyl sulfone, is produced. We believe that when water is present in concentrations larger than that of the sulfide, the reaction leads to formation of sulfone; however, when the water concentration is sufficiently low, this reaction path is unavailable and steps 7 and 8 occur to produce the sulfonic acid, providing perchlorate is available. In these experiments, care was taken to exclude water, including drying solvent with CaH_2, baking all glassware and supporting electrolyte in a vacuum, making all transfers out of contact with the atmosphere, and operating under a blanket of purified nitrogen or helium. Water concentrations in the electrolysis vessel typically amounted to 0.5 m*M*, compared with 30 m*M* for initial Me_2S concentration. We think that much of the water detected was introduced by the syringe used to inject samples into the chromatograph; that reaction mixtures were actually drier than our assays indicate.

We suggest, therefore, that the major source of oxygen in these experiments was perchlorate. Some was introduced from water formed by equilibration of perchloric acid, itself produced by reaction of the supporting electrolyte with electrochemically generated protons, with its anhydride. This is indicated in Eq. [11]

$$2\ HClO_4 \rightleftarrows H_2O + Cl_2O_7 \qquad [11]$$

which would be shifted to the right by uptake of water in step 4. This same reaction makes Cl_2O_7 available to react, both with methyl mercaptan in step 7 and possibly with starting material in steps 1b and 2b. We do not know the actual sequence of steps involved in Cl_2O_7 (7) reduction; however, observation of the uv spectrum of ClO_2 and recovery of chloride shows that this is occurring.

Tetrafluoborate supporting electrolyte.—If this reaction scheme is correct, elimination of perchlorate should substantially prevent the formation of oxygen-containing products. Reaction with Me_4NBF_4 supporting electrolyte, rather than perchlorate, did have this effect. No sulfonate was formed, and the product mixture showed very little uv absorption. We suggest that the reaction may have gone through steps 1a, 2a, and 3 only. Fluoborate salts similar to 3 are known to be stable (17); however, the products of the fluoborate reaction were not investigated. The similarity in coulometric results for the perchlorate and fluoborate reactions supports this suggestion, since steps 5 through 8 do not involve electrode reactions. The difference in shape of the current-time curves is not in accord with this suggestion, since perchlorate participation should not affect the rate of the anodic steps. It does not necessarily follow, however, that this rate difference indicates a different reaction mechanism, for variation in supporting electrolyte may cause appreciable changes in reaction conditions. The actual reaction potential is subject to variations with change in electrolyte because of alteration of the liquid junction potential involved in the reference probe. In addition, variation in supporting electrolyte may alter the double layer at the electrode-solution interface enough to cause significant variation in reaction rate.

Benzyl methyl sulfide oxidation.—The reaction of benzyl methyl sulfide in anhydrous $NaClO_4$-MeCN has been carried out under conditions similar to those described for Me_2S. The results were in substantial agreement. $PhCH_2SMe$ could be detected by GLC at the end of the electrolysis. On standing, $MeSO_3Na$ precipitated from solution and benzaldehyde could be detected by GLC. We suggest that this reaction may be a general one for aliphatic sulfides.

Implications for study of anodic oxidations.—It is fairly general practice to use perchlorate salts as supporting electrolytes for anodic oxidations. It has been observed by a number of workers that, at very anodic potentials in MeCN, it is possible to encounter direct reaction of perchlorate to form, among other products, ClO_2. In the present example, although considerable care has been taken to avoid the direct anodic oxidation of perchlorate, we have nevertheless produced ClO_2 as well as chlorine in other oxidation states. A possibly similar case has been reported in connection with hydrocarbon oxidation (22). An additional similar example has been observed by one of the present writers in studying the anodic oxidation of nitrate (23). It may be true that this complication should be considered whenever anodic reactions are performed in a very anhydrous medium.

The Mechanism of the Dendritic Electrocrystallization of Zinc

J. W. Diggle,*,[1] A. R. Despic,[2,]* and J. O'M. Bockris*

The Electrochemistry Laboratory, The University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

Measurements have been made of the growth rate of zinc dendrites in alkaline zincate solutions as a function of overpotential (η), concentration (c), and temperature (T). The tip radii have been measured by electron microscopy. At constant potential, an initiation time of between 5 and 100 min is observed, depending on η, c, and T. The dendrite grows linearly with time, at a rate depending on η, c, and T. The total current to base and dendrite was independent of time until a time τ_i, where $\tau_i > \tau_d$ (the time for initiation obtained from the growth rate *vs.* time relation). Thereafter, $i \propto t^2$. A critical overpotential was determined, -75 mV $> \eta_{crit} > -85$ mV. Below this η_{crit}, sponge was formed. Dendrites were observed up to $\eta = -160$ mV; above this the deposition was heavy sponge. At a given c, the growth rate of a given dendrite increased with η according to an exponential law. The growing tip is parabolic, where $10^{-5} < r_{tip} < 10^{-4}$ cm. No twinning was observed.

The basic model used depended on the increase in c.d. possible for an electrodic reaction when the diffusion current depends on a radius of curvature of the substrate, rather than the linear diffusion layer thickness, δ_0. When the tip of a dendrite-precursor attains this condition, its growth is released from the diffusion control characteristic of it in the predendrite situation, and it grows further under predominantly activation control at a rate far greater than that possible in any other direction, where the radii of curvature are much greater. The Gibbs radius-dependent overpotential term is also present, although it has a minimized influence. The initiation of the dendrite is treated in terms of growing pyramids on the substrate surface. At first the growth is linear-diffusion controlled, but it is shown that the rotation of the spiral, within the linear diffusion boundary surrounding the sphere, gives rise to a decrease of the effective radius of curvature of the dendrite tip until the value $r < 0.1\ \delta_0$ is attained, which is effectively the condition for the dendrite initiation. The theory of the propagation in terms of the activation, diffusion and Gibbs overpotential is consistent, in terms of τ_d, with experiment. A derived growth-time line is also numerically consistent with experiment. The dendrite growth rate as a function of c and η are numerically calculated with reasonable consistency. The tip radius can also be approximately calculated in terms of the present model.

Dendrite formation in electrodeposition and in the spontaneous crystallization of metals from their melts is related, respectively, to overpotential, for the former phenomenon, and to the degree of undercooling. Thus, the theory of rate determination of the growing dendrite in electrodeposition depends partly on mass transfer, while that for thermal crystallization depends on heat transfer. Correspondingly, there is an analogous response to variables, *e.g.*, if the overpotential exceeds a limit, dendritic deposition ceases (1), and if the degree of undercooling is sufficiently high, dendritic crystallization of metals does not occur (2).

Studies with silver dendrites deposited from molten salts (3) indicated that a critical overpotential η_{crit} is a necessity for dendrite initiation, and related this overpotential to a sharp increase at η_{crit}, of the dendrite radius for maximal growth. Reddy (4) has suggested that the critical overpotential may be related to the stacking fault energy of the crystal lattice (5, 6) necessary for the formation of a twin plane, through which it was proposed that the dendrite propagated. The existence of twin planes in dendrites has been reported on numerous occasions (7-9), whereas evidence for the single crystal nature of dendrites (10) has also been reported. It has yet to be shown that twin planes play a necessary part in dendrite initiation and propagation (11, 12).

The Barton and Bockris theory (3) involves a model of spherical diffusion to the dendrite tip. However, to allow for the fact that the rate of growth should then increase continuously toward zero tip radius, it was necessary to include the change of the reversible electrode potential with radius. In this way a maximum dendrite growth rate would be achieved at some optimum rip radius (3)

ABSTRACT

Measurements have been made of the growth rate of zinc dendrites in alkaline zincate solutions as a function of overpotential (η), concentration (c), and temperature (T). The tip radii have been measured by electron microscopy. At constant potential, an initiation time of between 5 and 100 min is observed, depending on η, c, and T. The dendrite grows linearly with time, at a rate depending on η, c, and T. The total current to base and dendrite was independent of time until a time τ_i, where $\tau_i > \tau_d$ (the time for initiation obtained from the growth rate *vs.* time relation). Thereafter, $i \propto t^2$. A critical overpotential was determined, -75 mV $> \eta_{crit} > -85$ mV. Below this η_{crit}, sponge was formed. Dendrites were observed up to $\eta = -160$ mV; above this the deposition was heavy sponge. At a given c, the growth rate of a given dendrite increased with η according to an exponential law. The growing tip is parabolic, where $10^{-5} < r_{tip} < 10^{-4}$ cm. No twinning was observed.

The basic model used depended on the increase in c.d. possible for an electrodic reaction when the diffusion current depends on a radius of curvature of the substrate, rather than the linear diffusion layer thickness, δ_0. When the tip of a dendrite-precursor attains this condition, its growth is released from the diffusion control characteristic of it in the predendrite situation, and it grows further under predominantly activation control at a rate far greater than that possible in any other direction, where the radii of curvature are much greater. The Gibbs radius-dependent overpotential term is also present, although it has a minimized influence. The initiation of the dendrite is treated in terms of growing pyramids on the substrate surface. At first the growth is linear-diffusion controlled, but it is shown that the rotation of the spiral, within the linear diffusion boundary surrounding the sphere, gives rise to a decrease of the effective radius of curvature of the dendrite tip until the value $r < 0.1\ \delta_0$ is attained, which is effectively the condition for the dendrite initiation. The theory of the propagation in terms of the activation, diffusion and Gibbs overpotential is consistent, in terms of τ_d, with experiment. A derived growth-time line is also numerically consistent with experiment. The dendrite growth rate as a function of c and η are numerically calculated with reasonable consistency. The tip radius can also be approximately calculated in terms of the present model.

Dendrite formation in electrodeposition and in the spontaneous crystallization of metals from their melts is related, respectively, to overpotential, for the former phenomenon, and to the degree of undercooling. Thus, the theory of rate determination of the growing dendrite in electrodeposition depends partly on mass transfer, while that for thermal crystallization depends on heat transfer. Correspondingly, there is an analogous response to variables, *e.g.*, if the overpotential exceeds a limit, dendritic deposition ceases (1), and if the degree of undercooling is sufficiently high, dendritic crystallization of metals does not occur (2).

Studies with silver dendrites deposited from molten salts (3) indicated that a critical overpotential η_{crit} is a necessity for dendrite initiation, and related this overpotential to a sharp increase at η_{crit}, of the dendrite radius for maximal growth. Reddy (4) has suggested that the critical overpotential may be related to the stacking fault energy of the crystal lattice (5, 6) necessary for the formation of a twin plane, through which it was proposed that the dendrite propagated. The existence of twin planes in dendrites has been reported on numerous occasions (7-9), whereas evidence for the single crystal nature of dendrites (10) has also been reported. It has yet to be shown that twin planes play a necessary part in dendrite initiation and propagation (11, 12).

The Barton and Bockris theory (3) involves a model of spherical diffusion to the dendrite tip. However, to allow for the fact that the rate of growth should then increase continuously toward zero tip radius, it was necessary to include the change of the reversible electrode potential with radius. In this way a maximum dendrite growth rate would be achieved at some optimum rip radius (3)

$$r_{opt} \frac{1 \pm [1 + DC_bF^2\eta/2\gamma Vi_0]^{1/2}}{F\eta/2\gamma V}$$

where D is the diffusion coefficient of the silver ion, C_b is the bulk concentration of the silver ion, V is the molar volume of silver, and i_0 is its exchange current density, and γ is the surface tension between metal and electrolyte.

Hamilton (13), assuming that the dendrite tip was a moving paraboloid, has shown that, to correlate his

equations to the results of Barton and Bockris (3), it was necessary to assume that γ and i_0 were a magnitude lower and higher, respectively, than that assumed by Barton and Bockris. The computed values of the tip radius and the growth velocity with respect to overpotential were then in good agreement with experimental observations (3). Hamilton concluded that the dendrite growth was diffusion controlled and occurred at the maximum velocity, the process having a high i_0 value due to a twin plane growth mechanism [*cf.* also Reddy (4)].

In summary, some agreement exists as to the importance of diffusive transfer in dendritic deposition; however, the details of initiation and the concept of the critical overpotential are hardly understood. This study attempts to answer the following questions: (*i*) why do silver and zinc dendrites have such widely differing apparent η_{crit} values, 3 mv and 80 mv, respectively; (*ii*) why can the initiation of single dendrites be observed for silver, yet not for zinc; (*iii*) what significance can be attached to the so-called initiation time (3), and (*iv*) what electrodic parameters control the value of the critical overpotential η_{crit}?

Experimental

Electrolyte.—The electrolye used throughout this work was a 10% w/w solution of potassium hydroxide (Baker reagent grade) in conductivity water to which was added sufficient reagent grade ZnO to produce zincate concentrations between 0.01 and 0.2 moles liter^{-1}. All electrolytes were de-aerated with purified nitrogen for 4 hr in the subsidiary cell (Fig. 1), prior to introduction into the observation cell.[3]

Electrodes.—Spherical electrodes (0.5 mm radii) were used and prepared as follows: A short length of 0.2 mm diameter platinum wire was sealed into 3 mm bore glass tubing. This platinum wire was slowly melted in a gas jet until a sphere was formed in contact with the tip of the glass tubing. The Pt sphere was cleansed in a mixture of sulfuric and nitric acids (5 min), then washed with conductivity water. The Pt surface was highly reflective and void of imperfection on 60X microscopic inspection.

The Pt sphere was immersed in a strongly agitated solution containing 1 mole liter^{-1} $ZnSO_4 \cdot 7H_2O$ dissolved in 0.01*N* H_2SO_4 and a low (< 50 mV) cathodic overpotential applied. Under such conditions, ($i_L \sim 0.5$ A-cm^{-2}), smooth compact zinc deposits were observed. The deposition was continued for 10 min, after which, assuming 100% coulombic zinc deposition efficiency, the deposit was 10^{-3} cm thick. The electrode was withdrawn from the preparation cell, washed in conductivity water, and introduced into the observation cell.

The anode and reference electrodes were prepared in a similar manner, but to a 50μ zinc thickness. Electrode reproducibility was good. Freshly prepared cathode and reference electrodes were used in each experiment, and freshly prepared anode in every other experiment.

Apparatus.—(*i*) *Cell.*—The cell (Fig. 1) allows observation of the zinc deposition process and the dendrite growth rate. The electrode assembly, E, consisted of the three electrodes in glass guide tubes clamped in position with gas-tight Teflon seals. Temperature control was maintained ±0.05°C by circulating thermostatted water through the outer jacket of the cell.

(*ii*) *Optical system.*—The optical tube (A in Fig. 1) is similar to that of Barton and Bockris (3). A real image of the spherical electrode is projected on the objective lens of a telescope-microscope system mounted horizontally. This system, which has only one optical window between the lenses and the electrode, avoids the problem of image distortion found with externally mounted optical arrangements. Therefore, the resolution and possible magnification range are extended; the magnification was up to 800 (300X was used).

(*iii*) Potentiostatic control was used (Wenking potentiostat).

Procedure.—Following the insertion of the electrodes into the observation cell, the electrolyte from the subsidiary cell was introduced and the overpotential applied immediately electrolyte contact between the electrodes occurred.

Observation of the cathode electrode was maintained until dendrites were initiated. In the dendrite growth rate experiments, the electrode assembly E was slowly rotated until the required dendrite was normal to the observation axis. Polaroid photographs were taken at intervals (minutes); alternatively, visual rate measurements were made.

The dendrite growth rate and the current changes were determined as a function of overpotential in the range −85 to −140 mV, zincate ion concentration 0.01 to 0.20 moles liter^{-1}, and temperature in the range 25°-50°C.

Results

Dendrite initiation time and morphology of the deposited zinc.—Two initiation times are distinguished. First, the time observed experimentally was found to correlate with the initiation time, τ_i, from current-time phenomenon (see Fig. 5, 7, and 8); since at this time, dendrites were clearly visible, τ_i is in excess of the true initiation time. Second, the initiation time obtained by extrapolating the dendrite length-time plot to zero dendrite length, τ_d. This is regarded as the more significant initiation time. Experimentally, $\tau_d < \tau_i$.

Dendrites were observed to be initiated at overpotentials between −85 and −140 mV. Below −85 mV the zinc morphology was spongy. Above −140 mV the zinc morphology was sponge mixed with dendrites (1) (Fig. 2). Within the range of overpotential required to initiate dendrites, the character of the deposits was dendritic, but not of the 'ideal" shape (10), and appeared dependent on the conditions of growth (Fig. 3a and 3b). In the majority of experiments the dendrite main axis and primary branches were of a swordlike nature, and the area at the tip was flat and stepped (Fig. 4). Secondary branching was rare, as

[3] No rigorous electrolyte purification was performed since it has been shown (14) that in highly purified systems the results, in terms of dendrite initiation and propagation, are essentially identical.

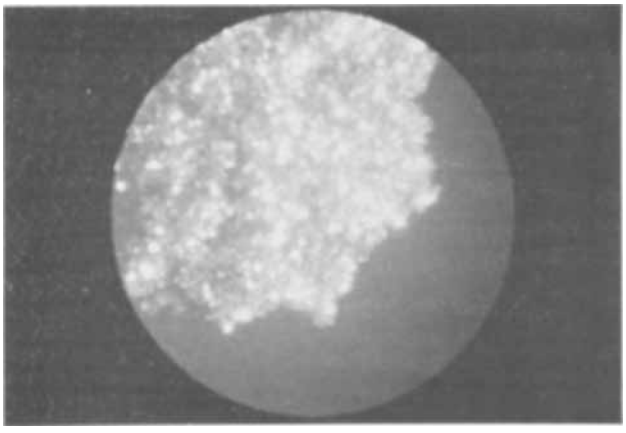

Fig. 2. Example of the zinc deposition obtained at $\eta = -200$ mV; $c_0 = 0.1$ moles liter^{-1} and $T = 35°C$. Magnification 25X.

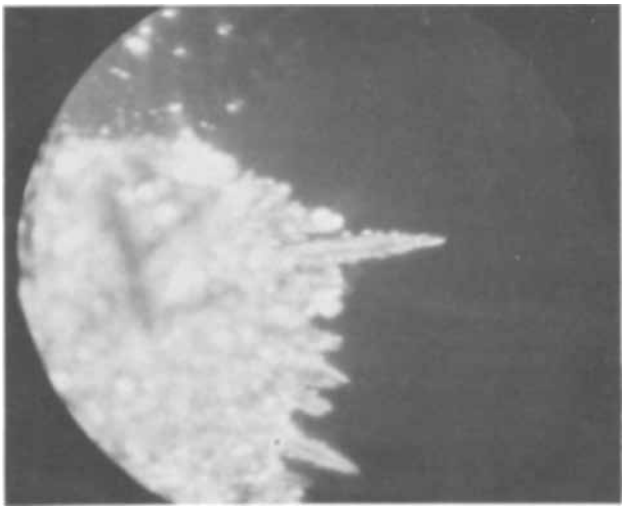

Fig. 3a. Typical dendritic growth resulting from a low propagation rate experiment. $c_0 = 0.01$ moles liter^{-1}, $\eta = -100$ mV, $T = 35°C$, where $v = 0.04$ μsec^{-1}. Magnification 100X.

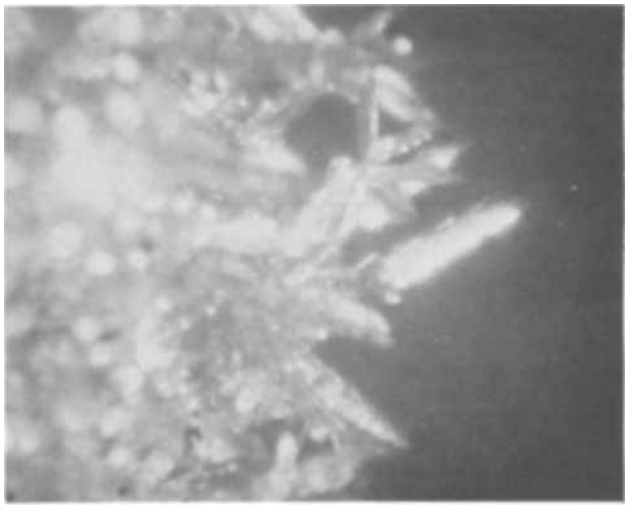

Fig. 3b. Typical dendritic growth resulting from a high propagation rate experiment. $c_0 = 0.1$ moles liter^{-1}, $\eta = -100$ mV, $T = 35°C$, where $v = 0.4$ μsec^{-1}. Magnification 75X.

has been previously reported by Powers (15) at —100 mV overpotential [Fig. 28, ref. (15)].

Examination in polarized light and by electron diffraction indicated that the dendrites were single crystals; no evidence of twinning was found.

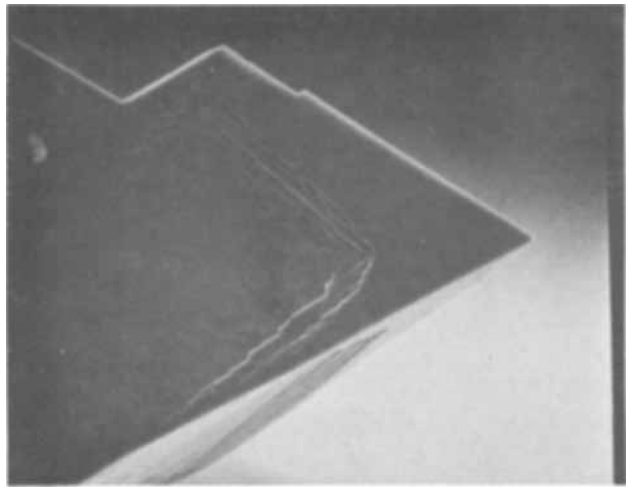

Fig. 4. Dendrite tip geometry. $c_0 = 0.1$ moles liter^{-1}, $\eta = -85$ mV, $T = 35°C$. Magnification 850X.

Change in the total current with respect to time.—The total current (Fig. 5, 7, and 8) increases according to an approximate t^2 relationship (Fig. 9). The region of sharp current change appeared to coincide with the visual appearance, under 300X magnification, of dendrites.

Total current against time as a function of zincate concentration.—Figure 5 shows the total current plotted against time as a function of zincate concentration. The time required for the appearance of dendrites, as determined from the inflection point, decreases as the zincate concentration increases. For 0.01 mole liter^{-1}

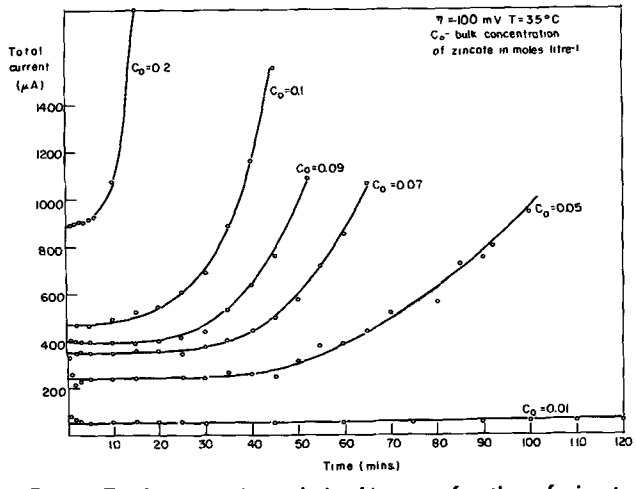

Fig. 5. Total current-time relationship as a function of zincate concentration. $\eta = -100$ mV, $T = 35°C$.

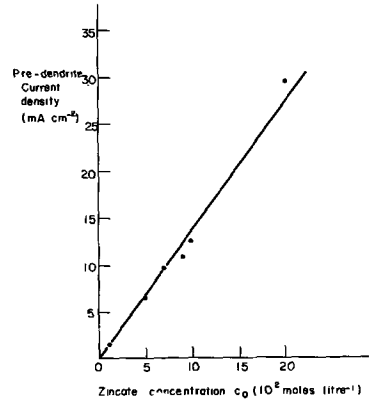

Fig. 6. Predendrite current density as a function of zincate concentration from which D/δ_0 is evaluated.

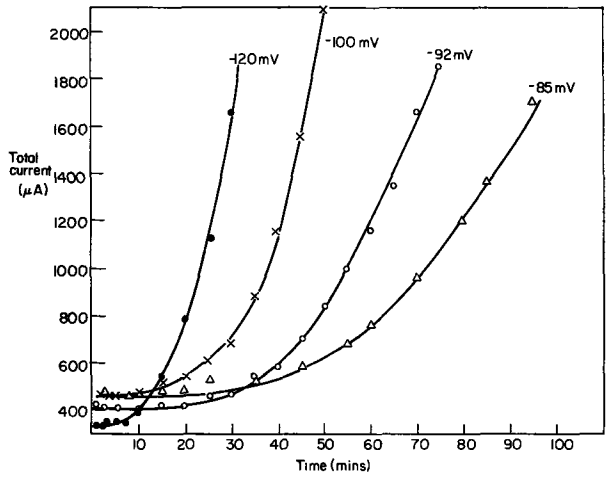

Fig. 7. Total current-time as function of overpotential. $c_0 = 0.1$ moles liter^{-1}, $T = 35°C$.

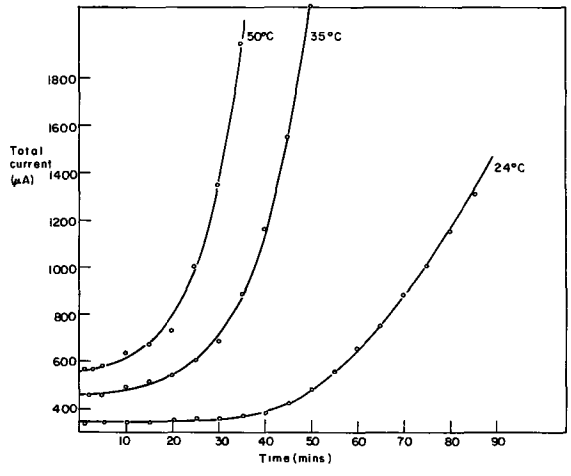

Fig. 8. Total current-time as a function of electrolyte temperature. $c_0 = 0.1$ moles liter^{-1}, $\eta = -100$ mV.

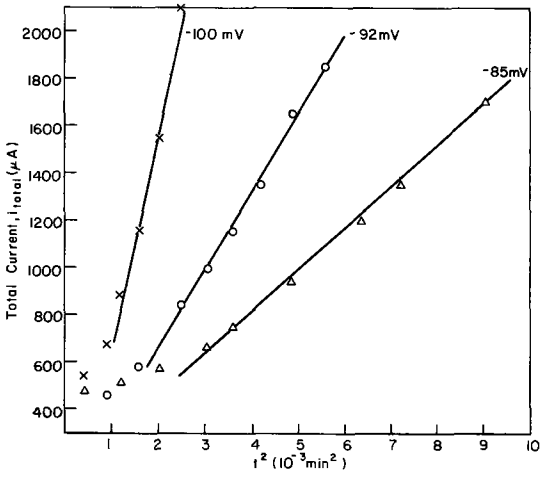

Fig. 9. Power law dependence of total current on time as a function of overpotential. $c_0 = 0.1$ moles liter^{-1}, $T = 35°C$.

zincate, the experimental initiation time τ_i was > 120 min.

The relationship between the initial predendrite current density, calculated on the geometric area, and the zincate concentration c_0 is shown in Fig. 6. From the linear slope, assuming the applicability of $i_L = (nFDc_0)/\delta_0$, the value of the term D/δ_0 was found to be 6.8×10^{-4} cm sec^{-1}. Taking the value of δ_0 as 10^{-2} cm produces $D = 6.8 \times 10^{-6}$ cm^2 sec^{-1}, a value

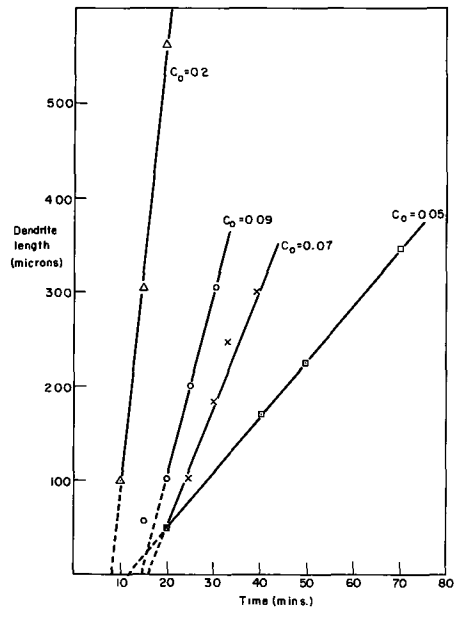

Fig. 10. Dendrite length, y, with respect to time as a function of zincate concentration. $\eta = -100$ mV, $T = 35°C$.

in excellent agreement with that reported by McBreen (16).

Total current against time as a function of overpotential.—Figure 7 shows that the value of τ_i decreases with increase of η.

Total current against time as a function of temperature.—The time required for the appearance of the first dendrites τ_i decreases as the temperature increases (Fig. 8).

Rate of dendrite propagation.—As a function of zincate concentration.—Figure 10 shows the change in observed dendrite length with respect to time (time measured from the moment of overpotential application) as a function of zincate concentration. The extrapolations from the linear regions to zero dendrite length gives the initiation times, τ_d, as defined by Barton and Bockris (3). From Table I, where the dendrite propagation rates (v) are tabulated, the rate of propagation increases as the zincate concentration increases. The value of the term dv/dc_0 is obtained as 0.43 cm^4 mole^{-1} sec^{-1}, where v is expressed in cm sec^{-1} and c_0 in moles cm^{-3}. In Table I is tabulated the dendrite tip current density (i) calculated from the propagation rate (v) assuming that no thickening occurs. Then

$$i_{tip} = v\frac{nF}{V} \qquad [1]$$

where V is the molar volume of zinc.

Figure 11 shows the relationship between log i and log c_0—the best statistical straight line is shown, the slope of which is 1.00 ± 0.14; the dotted line represents a slope of 0.75.

As a function of overpotential.—The extrapolated initiation time τ_d decreases with increasing overpotential (Fig. 12), as do the observed times, τ_i.

Table I. Experimental propagation rate (v) and dendrite tip current density (i_{tip}) as a function of zincate concentration

η, mV	T, °C	c_0, moles liter^{-1}	v, μsec^{-1}	i_{tip}, A cm^{-2}
−100	35	0.01	0.04	0.084
		0.05	0.10	0.20
		0.07	0.20	0.43
		0.09	0.31	0.66
		0.10	0.40	0.84
		0.20	0.75	1.60

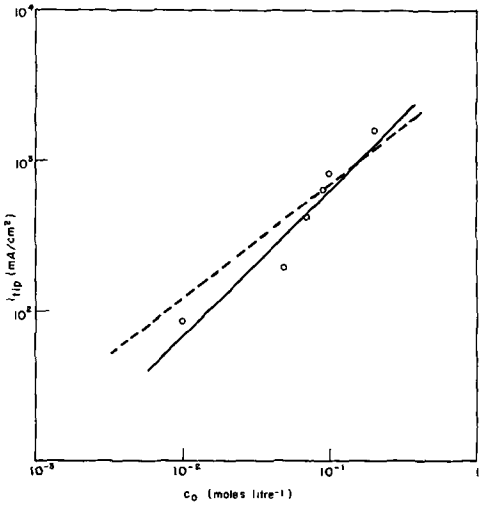

Fig. 11. Log i_{tip} as a function of log c_0. The dotted line has a theoretically significant slope of 0.75; solid line is the best statistical line through experimental points.

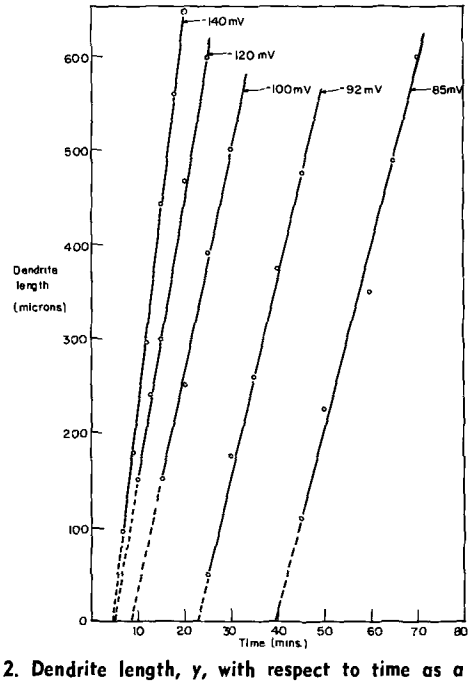

Fig. 12. Dendrite length, y, with respect to time as a function of overpotential. $c_0 = 0.1$ moles liter^{-1}, $T = 35°C$.

The dendrite propagation rate, v, increases with increasing overpotential (Table II); the $v - \eta$ slope increases with increasing η (Fig. 13). The logarithm of the tip current density when plotted against η was found to be linear (Fig. 14) where $d\eta/d \log i_{tip} = 0.17v$.

As a function of temperature.—The extrapolated times, τ_d, were observed to decrease with increasing temperature (Fig. 15).

Table III shows the propagation rate, v, and the calculated dendrite tip current density (i) as a function of temperature: the value of dv/dT being 1.3×10^{-6} cm sec^{-1} deg^{-1}.

Table II. Experimental propagation rate (v) and dendrite tip current density (i_{tip}) as a function of overpotential

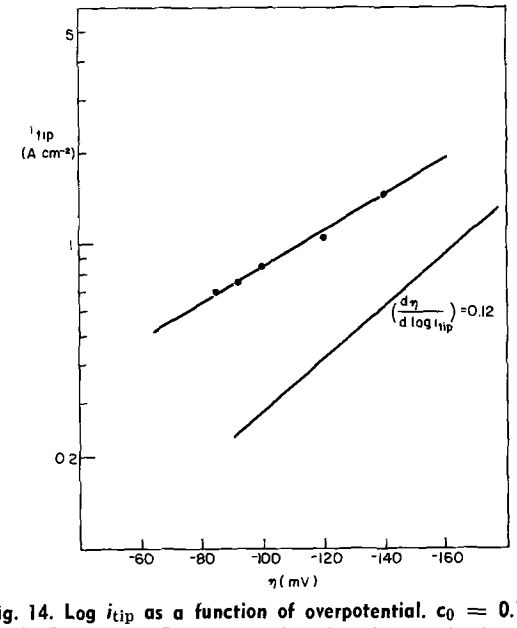

Fig. 14. Log i_{tip} as a function of overpotential. $c_0 = 0.1$ moles liter^{-1}, $T = 35°C$. Theoretical slope based on activation control, with $\alpha_c = 0.5$, is included for comparison.

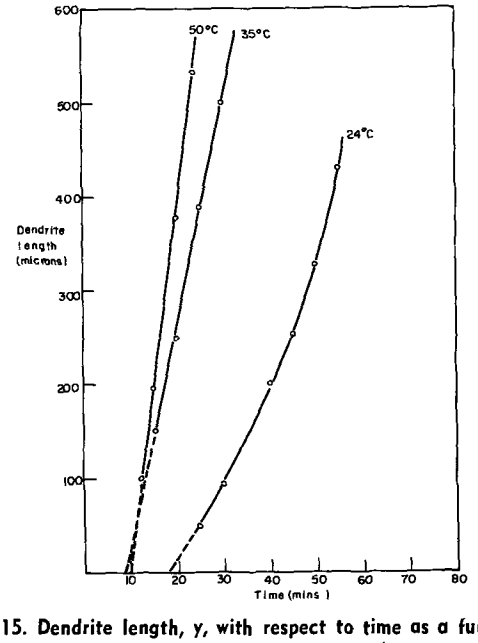

Fig. 15. Dendrite length, y, with respect to time as a function of electrolyte temperature. $c_0 = 0.1$ moles liter^{-1}, $\eta = -100$ mV.

Table III. Experimental propagation rate (v) and dendrite tip current density (i_{tip}) as a function of temperature

η, mV	c_0, moles liter^{-1}	T, °C	v, μsec^{-1}	i_{tip}, A cm^{-2}
−100	0.1	24	0.25	0.53
		35	0.40	0.84
		50	0.60	1.26

The log i_{tip} — $1/T$ plot (Fig. 16) shows a linear relationship of slope -1.25×10^3 deg. From this the electrochemical activation energy ΔH^o, at the overpotential of — 100 mV, can be calculated at 6 kcal mole^{-1}.

Initiation overpotential, η_{crit}, and initiation time, τ.— Experimentally, $-75 > \eta_{crit} > -85$ mV; below —75 mV dendrites were not observed. Extrapolation of Fig. 13 to zero propagation rate suggests that the value of η_{crit} lies below —10 mV. Dendrites were not observed at potentials more anodic than —75 mV because the initiation time is so long (Fig. 17); only black spongy zinc was observed.

Influence of dendrite propagation current on measured total current.—To relate the changes in total current flowing to a dendrite initiation process, it is necessary to show that the dendrite propagation current is negligible when compared to the current at the substrate surface. From Table I, the propagation rate of dendrites in a zincate concentration of 0.1 moles liter^{-1} at 35°C and an overpotential of —100 mV is equivalent to a dendrite tip current density of 840 mA cm^{-2}. The dendrites were *ca.* 10μ in width; assuming that the dendrite tip is a hemisphere, the current through the dendrite can be calculated as 1.2 μA. Figure 5 shows that this level of dendrite propagation current is negligible compared to the total current observed, even allowing for the simultaneous growth of 30 dendrites on an electrode area of *ca.* 3×10^{-2} cm^2. This conclusion is also valid for other zincate concentrations. This conclusion can be confirmed experimentally by initiating dendrites at, say, —100 mV and then lowering the overpotential to —50 mV. The growth rate of the dendrites eventually decreases to zero; the total current remains at a value only slightly less than that at —100 mV.

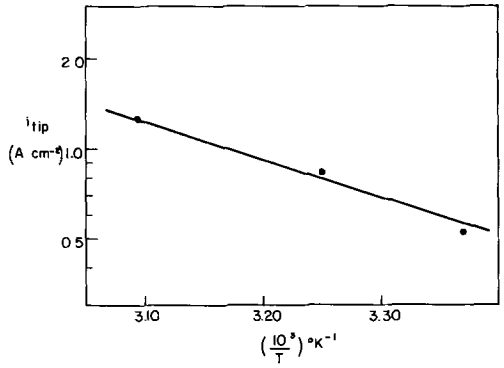

Fig. 16. Log i_{tip} as a function of reciprocal temperature. From the slope an electrochemical activation energy is evaluated.

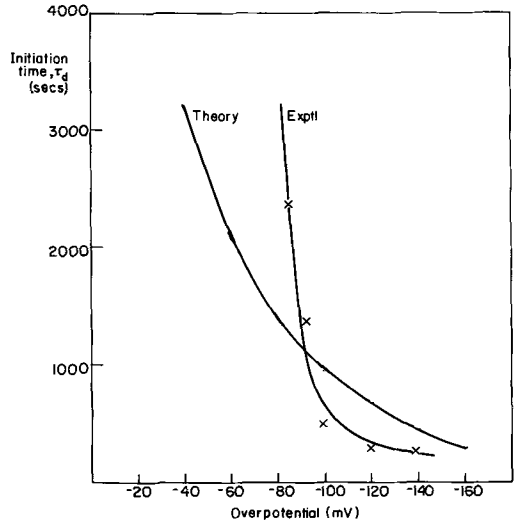

Fig. 17. Initiation time, τ_d, as a function of overpotential. $c_0 = 0.1$ moles liter^{-1}, $T = 35$°C. Theory line is calculated from an initiation theory developed in the section on Model of dendrite initiation.

Discussion

Summary of the phenomenology.—Facts are: (*i*) an initiation overpotential ($\sim$ —80 mV) is required to produce dendrites; (*ii*) two initiation times have been observed, one for dendrites, τ_d, and the other for current, τ_i, *e.g.*, Fig. 7 and 12, $\tau_d < \tau_i$. The times required for the dendrites to approach the boundary of the linear diffusion layer are in agreement with the times, τ_i; (*iii*) the growth of dendrites, beyond the initiation time, is linear with time; (*iv*) the total current increases with time such that $i \propto t^2$ (Fig. 9).

Basic model. The model is that of Barton and Bockris (3) extended to the Tafel region of overpotential. Then

$$\eta = \frac{RT}{\alpha_c \mathbf{F}} \ln \frac{i}{i_0} + \frac{RT}{z\mathbf{F}} \ln \left(\frac{i_L - i}{i_L} \right) + \frac{2\gamma V}{n\mathbf{F}r} \quad [2]$$

where

$$i_L = \frac{n\mathbf{F}D}{r} c_{tip} = i_{L(s)}$$

where subscript (*s*) indicates spherical diffusion, V is the molar volume of zinc, r is the radius of the dendrite tip at which the zincate concentration is c_{tip}, γ is the surface energy of the zinc/electrolyte interface, other parameters have their usual significance.

An optimum tip radius will exist where the growth rate is maximal and constant.

Propagation.—Equation [1] which relates the propagation rate v to the dendrite tip current density i can be rewritten as

$$\frac{dy}{dt} = \frac{M}{\rho n \mathbf{F}} i_{tip} \quad [3]$$

where y is the dendrite length. Expressing i_{tip} in terms of an irreversible activation-diffusion current density, an equation relating propagation rate to overpotential, zincate concentration and temperature can be obtained. The current density i_{tip} can be set equal to

$$i_{tip} = i_0 \left\{ \left(\frac{a_i^0}{a_e^0} \right)_c \exp \left(\frac{-\alpha_c \mathbf{F} \eta}{RT} \right) - \left(\frac{a_i^R}{a_e^R} \right)_a \exp \left(\frac{\alpha_a \mathbf{F} \eta}{RT} \right) \right\} \quad [4]$$

for the general reaction $0 + e^- \rightleftarrows R$. a_i is the activity of the oxidized (o) or reduced (R) state at the current density i_{tip}, and a_e are the activities in the equilibrium state.

Neglecting double layer effects (valid at the high ionic strength used in this work), the ratio of the activities for the cathodic reaction may be written as

$$\left(\frac{a_i^0}{a_e^0} \right) = \left(1 - \frac{i}{i_L} \right) \quad [5]$$

The ratio of the activities for the reverse anodic reaction must take into account the Kelvin term which becomes appreciable at low values of dendrite tip radii. The change in the free energy accompanying the anodic reaction at equilibrium (ΔG_e) and that accompanying the reaction at current density i_{tip} (ΔG_i) will

differ appreciably when the Kelvin term is high, *i.e.*, at low dendrite tip radii. Thus

$$\Delta G_i - \Delta G_e = RT \ln \left(\frac{a_i^R}{a_e^R} \right)_a \quad [6]$$

ΔG_i and ΔG_e differ by the Kelvin term $\frac{2\gamma V}{r}$

$$\therefore \Delta G_i - \Delta G_e = \frac{2\gamma v}{r} \quad [7]$$

Thus

$$\frac{2\gamma V}{RT \cdot r} = \ln \left(\frac{a_i^R}{a_e^R} \right)_a \quad [8]$$

or

$$\exp \left(\frac{2\gamma V}{RT \cdot r} \right) = \left(\frac{a_i^R}{a_e^R} \right)_a \quad [9]$$

From [9], [5], and [4]

$$i_{tip} = i_0 \left\{ \left(1 - \frac{i}{i_L} \right) \exp \left(\frac{-\alpha_c F \eta}{RT} \right) - \exp \left(\frac{2\gamma V}{RT \cdot r} \right) \exp \left(\frac{\alpha_a F \eta}{RT} \right) \right\} \quad [10]$$

The concentration of zincate at the tip is the bulk zincate concentration when the tip is close to or outside the outer boundary of the linear diffusion layer. The value of c_{tip} at a dendrite whose length is y, where $y < \delta$, can be obtained by linearization of the concentration profile in the diffusion layer (Fig. 18). Then

$$c_{tip} = c_0 y / \delta_0 \quad [11]$$

Therefore, substituting Eq. [11] and [10] with the equation for the spherical diffusion limiting current density, $i_{L(s)}$, into Eq. [3] one obtains ($i_{L(tip)} = i_{L(l)} y/r$ where subscript l indicates linear diffusion)

$$\frac{dy}{dt} = \frac{M}{\rho n F} \frac{n F D c_0 y / \delta_0 \, i_0 \left\{ \exp \left(\frac{-\alpha_c F \eta}{RT} \right) - \exp \left(\frac{2\gamma V}{RT \cdot r} \right) \exp \left(\frac{\alpha_a F \eta}{RT} \right) \right\}}{n F D c_0 y / \delta_0 + i_0 r \exp \left(\frac{-\alpha_0 F \eta}{RT} \right)} \quad [12]$$

which produces, when $i_{L(l)} = nFDc_0/\delta_0$

$$\frac{dy}{dt} = \frac{M}{\rho n F} \frac{i_{L(l)} y \, i_0 \left\{ \exp \left(\frac{-\alpha_c F \eta}{RT} \right) - \exp \left(\frac{2\gamma V}{RT \cdot r} \right) \exp \left(\frac{\alpha_a F \eta}{RT} \right) \right\}}{i_{L(l)} y + i_0 r \exp \left(\frac{\alpha_c F \eta}{RT} \right)} \quad [13]$$

Rearranging Eq. [13] produces

$$\frac{dy}{i_0 \left\{ \exp \left(\frac{-\alpha_c F \eta}{RT} \right) - \exp \left(\frac{2\gamma V}{RT \cdot r} \right) \exp \left(\frac{\alpha_a F \eta}{RT} \right) \right\} + \frac{r \exp \left(\frac{\alpha_a F \eta}{RT} \right)}{i_{L(l)} y}} \Bigg/ \frac{dy}{\left\{ \exp \left(\frac{-\alpha_c F \eta}{RT} \right) - \exp \left(\frac{2\gamma V}{RT \cdot r} \right) \exp \left(\frac{\alpha_a F \eta}{RT} \right) \right\}} = \frac{M}{\rho n F} dt \quad [14]$$

Taking r as a constant, and placing

$$\left\{ \exp \left(\frac{-\alpha_c F \eta}{RT} \right) - \exp \left(\frac{2\gamma V}{RT \cdot r} \right) \exp \left(\frac{\alpha_a F \eta}{RT} \right) \right\} = u \quad [15]$$

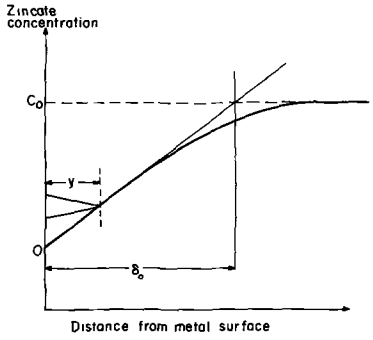

Fig. 18. Schematic representation of the calculation of the concentration at the dendrite tip.

Eq. [14] integrates to the general expression between y and y_0, where y_0 is the limit when $t = 0$

$$\frac{y}{i_0 u} + r \ln y \frac{\exp \left(\frac{\alpha_a F \eta}{RT} \right)}{i_{L(l)} u} = \frac{M}{\rho n F} t + \frac{y_0}{i_0 u} + r \ln y_0 \frac{\exp \left(\frac{\alpha_a F \eta}{RT} \right)}{i_{L(l)} u} \quad [16]$$

Two limiting cases arise: (*i*) when $\frac{y}{i_0 u} >> \frac{r \ln y}{i_{L(l)} u} \exp \left(\frac{\alpha_a F \eta}{RT} \right)$, a linear relation will exist between y and t; (*ii*) in the reverse situation, where $\frac{y}{i_0 u} << \frac{r \ln y}{i_{L(l)} u} \exp \left(\frac{\alpha_a F \eta}{RT} \right)$, an exponential relationship exists between y and t. For the present experiments, when $r/y > 10^{-3}$ at $\eta = -100$ mV, the exponential form is valid, *i.e.*

$$\frac{r \log y}{i_{L(l)} u} \exp \left(\frac{\alpha_a F \eta}{RT} \right) = \frac{M}{2 \cdot 3 \rho n F} t + \frac{r \log y_0}{i_{L(l)} u} \exp \left(\frac{\alpha_a F \eta}{RT} \right) \quad [17]$$

and when $r/y < 10^{-3}$, the linear form will be valid, *i.e.*

$$y = i_0 u \frac{M}{\rho n F} t + y_0 \quad [18]$$

Thus, the linear form will be valid ($r = 10^{-5}$ cm) from dendrite length > 100μ. This prediction is confirmed in Fig. 10, 12, 15. Below 100μ the exponential form of y and t applies.

In the linear region, the propagation rate, v, can be written from Eq. [3] and [18] as

$$v = i_0 u \frac{M}{\rho n F} \quad [19]$$

or, in terms of dendrite tip current density, as

$$i_{tip} = i_0 \left\{ \exp\left(\frac{-\alpha_c \mathbf{F}\eta}{RT}\right) - \exp\left(\frac{2\gamma V}{RT \cdot r}\right) \exp\left(\frac{\alpha_a \mathbf{F}\eta}{RT}\right) \right\} \quad [20]$$

Similarly for the exponential $y - t$ region

$$v = y_0 \frac{M}{2 \cdot 3\rho n\mathbf{F}} \frac{u}{r} i_{L(l)} \exp - \left(\frac{\alpha_a \mathbf{F}\eta}{RT}\right) \exp\left[\frac{M}{2 \cdot 3\rho n\mathbf{F}} \frac{u}{r} i_{L(l)} \exp - \left(\frac{\alpha_a \mathbf{F}\eta}{RT}\right) t\right] \quad [21]$$

and

$$i_{tip} = i_{L(l)}\, y_0 \frac{u}{r} \exp - \left(\frac{\alpha_a \mathbf{F}\eta}{RT}\right) \exp\left[\frac{M}{2 \cdot 3\rho n\mathbf{F}} \frac{u}{r} i_{L(l)} \exp - \left(\frac{\alpha_a \mathbf{F}\eta}{RT}\right) t\right] \quad [22]$$

Since the $y - t$ linear region is that for which data are available (Fig. 10, 12, and 15), differential relations for comparison with experiment will be worked out in terms of the linear condition. From Eq. [19], at high η

$$\left(\frac{dv}{d\eta}\right)_{c_0,T} = - i_0 \frac{\alpha_c \mathbf{F}}{RT} \frac{M}{\rho n\mathbf{F}} \exp\left(\frac{-\alpha_c \mathbf{F}\eta}{RT}\right) \quad [23]$$

The dependence of the propagation rate on the zincate concentration (c_0) arises so: if it can be assumed that the discharge of zinc is a 2-step, one electron per step, reaction, where the first electron transfer is reported (17-19) as rate determining, then for the cathodic direction of the rate-determining step[4]

$$Zn(OH)_4^{=} + e \overset{\vec{k}}{\rightarrow} Zn(OH)_2^{-} + 2\,OH^{-}$$

the exchange current density can be written as

$$i_0 = 2\mathbf{F}\vec{k}\, c_0 \exp\left(\frac{-\alpha_c \mathbf{F}}{RT} V_{rev}\right) \quad [24]$$

where V_{rev} is the reversible equilibrium potential for $Zn(OH)_4^{=}$ to Zn reduction.

Introducing Eq. [24] into [19]

$$v = 2\mathbf{F}\vec{k} c_0 u \frac{M}{\rho n\mathbf{F}} \exp\left(\frac{-\alpha_c \mathbf{F}}{RT} V_{rev}\right) \quad [25]$$

Differentiating with respect to c_0 at constant η and T

$$\left(\frac{dv}{dc_0}\right)_{\eta,T} = 2\mathbf{F}\vec{k} u \frac{M}{\rho n\mathbf{F}} \exp\left(\frac{-\alpha_c \mathbf{F}}{RT} V_{rev}\right) - 2\mathbf{F}\vec{k} c_0 u \frac{M}{\rho n\mathbf{F}} \frac{\alpha_c \mathbf{F}}{RT} \left(\frac{dV_{rev}}{dc_0}\right) \exp\left(\frac{-\alpha_c \mathbf{F}}{RT} V_{rev}\right) \quad [26]$$

Substituting the dependence of V_{rev} on c_0 into Eq. [26] and simplifying produces

$$\left(\frac{dv}{dc_0}\right)_{\eta,T} = \frac{v}{c_0}\left(1 - \frac{\alpha_c}{2}\right) \quad [27]$$

Since, for the mechanism assumed, $\alpha_c = \beta = 0.5$

[4] The authors recognize the possibility of the following reaction as being rate determining

$$Zn^{++} + e \rightarrow Zn^{+}$$

this step being superseded by the equilibrium chemical step

$$Zn(OH)_4^{=} \rightleftarrows Zn^{++} + 4\,OH^{-}$$

The kinetic expressions derived in either case are identical. In the absence of firm evidence as to whether the oxidized state is Zn^{++} or $Zn(OH)_4^{=}$, the anion form is assumed here.

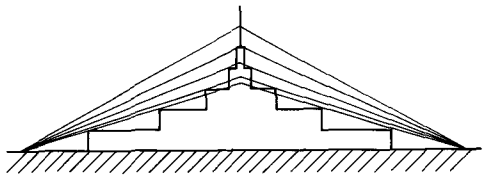

Fig. 19. Successive stages involved in the growth of a pyramid under linear diffusion control. Approximating pyramid to a cone shows how the effective radius of curvature decreases as the height increases.

$$\left(\frac{dv}{dc_0}\right)_{\eta,T} = \frac{v}{c_0} 0.75 \quad [28]$$

Expressing Eq. [19] as a dendrite tip current density

$$i_{tip} = i_0 \exp\left(\frac{-\alpha_c \mathbf{F}}{RT}\eta\right) \quad [29]$$

produces, assuming that the anodic current is negligible, the dependence of an activation current density upon overpotential and concentration of zincate.

Model of dendrite initiation.—The model proposed is that the dendrites originate from the tips of pyramids arising as the result of the rotation of a screw dislocation.

Experimentally, for all potentials above the critical initiation overpotential of about —80 mV, the current density measured during the initiation period, with respect to geometric substrates area, approaches the limiting current density for linear diffusion. Under such conditions any surface irregularity will tend to amplify according to the present, and to an earlier model (20), in an exponential manner with time, *e.g.*, Eq. [1] of ref. (20) or Eq. [17] of the present paper. There is, however, an additional effect when screw dislocation pyramids are increasing in height under linear diffusion control: since the distance between two successive steps on a spiral is given (21) by $4\pi r$, as the dendrite precursor height increases the step length distance decreases. Thus, the pyramid grows according to the model in Fig. 19, *i.e.*, the radius of curvature of the tip decreases as the pyramid height increases.

Since the radius of curvature is related to the curvature overpotential η_r by[5]

$$\eta_r = \frac{2A\gamma}{n\mathbf{F}\rho r} \quad [30]$$

where A is the atomic weight of zinc, γ is the surface energy at the spiral tip/electrolyte interface, and ρ is the density (g cm^{-3}) (for example, if η_r were 5 mV, r would be 4×10^{-6} cm).

As the spiral rotates, the concentration at the spiral apex increases since the apex is moving up the concentration gradient (Fig. 18); thus $i_{L(l)}$ at the apex increases, and therefore η_d at the apex decreases. Since the total overpotential is constant (potentiostatic control), η_d and/or η_r at the apex must increase.

As the spiral tip radius of curvature continues to decrease at some value of r, the tip becomes a point for spherical, rather than linear, diffusion. The condition for the onset of spherical diffusion at the spiral tip (see Appendix) is $r/\delta_0 << 1$. Taking $\delta_0 = 0.02$ cm and $r/\delta_0 = 0.01$, then r required for spherical diffusion is 2×10^{-4} cm. The term η_d must now be expressed in terms of the limiting current density for spherical diffusion, *i.e.*, $i_{L(s)}$.

As the dendrite precursor height increases further, η_d continues to decrease and η_r continues to increase. At some optimum value of r, where η_d is minimal and η_r is sufficient to stabilize the low radius of curvature, the

[5] Here η_r takes the place of Δe_r [Barton and Bockris (3)], the change in the reversible potential due to curvature, r. Both η_r and Δe_r are based on the same thermodynamic arguments which produce Eq. [30].

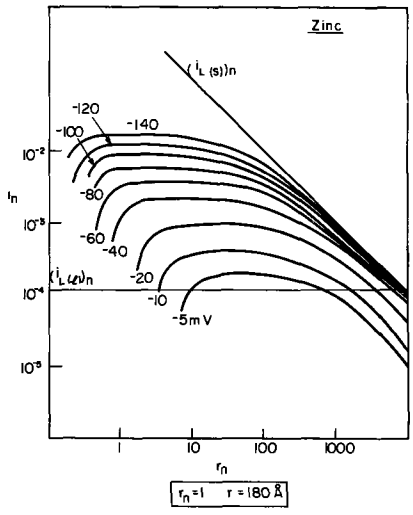

Fig. 20. i_n — r_n relationship for the zinc system from the present work.

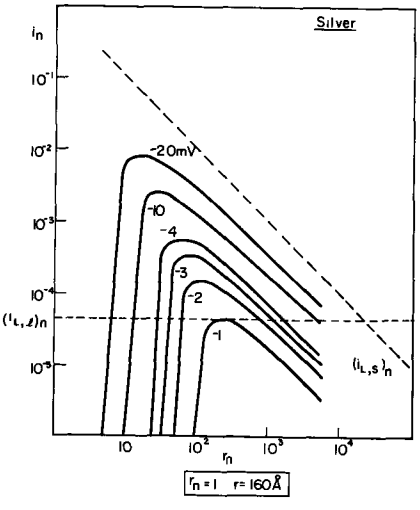

Fig. 21. i_n — r_n relationship for the silver system [Barton and Bockris (3)].

tip will have achieved a maximum growth rate under predominant activation control (this optimum value of r is clearly seen in Fig. 20 and 21 for zinc and silver, respectively).

It is our contention that this is the essence of the initiation of dendritic growth, the initiation time being that time required to attain the necessary stable radius of curvature, for spherical diffusion, due to an increase in η_r.

If the growing pyramid can be regarded as a growing paraboloid whose tip can be taken as hemispherical, then the radius of curvature at the tip is given by (22)

$$r_c = \frac{r_0^2}{2y} \qquad [31]$$

where r_0 is the radius of the pyramid base and y is the pyramid height.[6] Considering $r_0 = 2 \times 10^{-4}$ cm, which is equivalent to an original step length of 2×10^{-4} cm, which would require $\eta_r = 0.05$ mV to cause rotation, and taking y as 20μ, the radius of curvature is equal to 10^{-5} cm. Therefore, the radius of curvature at the tip has decreased from 10^{-3} to 10^{-5} cm as the pyramid height increases from 0.2 to 20μ, thereby producing an increase in η_r from 0.05 to 1 mV.

If it can be assumed that the rate control during propagation of the dendrite is entirely activation,

[6] In this derivation it is assumed that the parabola is symmetrical around the a-axis, and can be represented by the general form, $a = bx^2$.

Table IV. Initial and final conditions at the growing pyramid during the initiation period τ with respect to overpotential terms, pyramid height, and radius of curvature

Total overpotential = −100 mV, c_0 = 10^{-4} moles cm^{-3}, T = 35°C	Initial	Final
η_d	97	1
η_a	3	98
η_r	<0.1	1
Pyramid height	0.2μ	20μ
Tip radius of curvature	10μ	0.1μ

The initial overpotential terms are those terms for the initial substrate calculated at the point the potentiostatic control is applied. For example, $\eta_a = RT/n\mathbf{F} \cdot i/i_0$, where i is the initial substrate c.d., i_0 is taken as 100 mA cm^{-2}. η_r is taken as <0.1 mV (see text), then η_d is taken to be the difference between the applied overpotential and $(\eta_a + \eta_r)$. The final overpotential terms are those terms calculated from the propagation rate of the dendrite (see text).

utilizing i_0 from the literature (23) and placing i equal to the dendrite propagation rates (Fig. 10, 12, and 15), agreement is found between η_a thus calculated and the total applied overpotential. Thus, η_d and η_r are small during dendrite propagation, a result consistent with the above model. Table IV summarizes these changes which occur during initiation at the growing pyramid.

How will the attainment of the critical radius of curvature depend on exchange current density and η_{total}? Since η_a approximately equals η_{total} at time τ, then for a constant dendrite growth rate the value of this η_{total} at time τ will decrease as i_0 increases. Therefore, those metals for which i_0 is relatively low will have a larger η_{crit} than those metals for which i_0 is high, *e.g.*, zinc ($i_0 = 10^{-1}$ A cm^{-2}), $\eta_{crit} = -80$ mV, whereas silver ($i_0 = 1 - 10$ A cm^{-2}) $\eta_{crit} = -3$ mV.

Theoretical calculation of extrapolated initiation time, τ_d.—From Eq. [18] at $y = 0$, the extrapolated initiation τ_d can be expressed as

$$\tau_d = -y_0 \frac{\rho n \mathbf{F}}{i_0 u M} \qquad [32]$$

The term y_0 is the extrapolated dendrite length at zero time (a negative quantity). Values for y_0 were obtained by extraploation to $t = 0$ of Fig. 10, 12, and 15, respectively. Figure 17 and Tables V and VI show the theoretical and experimental τ_d values as a function of overpotential, zincate concentration and temperature, respectively. From Eq. [18] it can be seen mathematically that y_0 should be a constant, thus the values of τ_d were calculated from an average extrapo-

Table V. Theoretical and experimental τ_d values (from Eq. [32]) as a function of zincate concentration. η = −100 mV, T = 35°C, y_0 = −310 μ, standard exchange current density i_0^0 = 0.6 A cm^{-2} mole$^{-3/4}$ liter$^{3/4}$

Zincate concentration c_0, moles liter^{-1}	Experimental τ_d, sec	Theoretical τ_d, sec
0.2	480	470
0.1	540	800
0.09	900	870
0.07	960	1050
0.05	620	1440

Table VI. Theoretical and experimental τ_d values (from Eq. [32]) as a function of temperature. $c_0 = 10^{-1}$ moles liter^{-1}, η = −100 mV, $i_0 = 10^{-1}$ A cm^{-2}, and $(\Delta H^0)_{rev}$ = 10 kcal mole^{-1}

Temperature, °C	Experimental τ_d, sec	Theoretical τ_d, sec
24	1080	910
35	540	620
50	600	380

lated value of y_0. The agreement between experiment and theory is seen to be qualitative in the case of Fig. 17, and three results in Tables V and VI differ due to the fact that the extrapolations do not terminate at the same value of y_0. However, the agreement reported for the propagation rates (section below on Experimental test of theoretical propagation equations) indicates that Eq. [18] is valid.

Total current-time phenomenon.—The increase in the total current with time can be said to be due to one (or both) of two possible causes: (*i*) processes which occur during the initiation of a dendrite, or (*ii*) processes which occur during the propagation of a dendrite.

The former model was the subject of an earlier publication (20) which, at that time, appeared valid. Further examination of this model has, however, revealed two seemingly basic discrepancies. These are (*a*) the theoretical τ is greater than the experimental τ to the extent of 1-2 orders of magnitude (agreement being obtained only when $\delta = 10^{-3}$ cm for unstirred solutions), and (*b*) zinc deposition during the initiation time τ has been shown (24) to produce roughening of the electrode surface without any increase in the total current; such microsurface roughening, according to the former model (20) above, should have led to an exponential $i - t$ relationship.[7]

Thus, it would appear that these discrepancies, along with the observation that the total current does not increase appreciably until the dendrite length approaches the value of δ (section above on Summary of the phenonemology), indicate that the $i - t$ phenomenon is due to processes following initiation.

The dependence of total current on time has been shown to be $i = kt^2$ (Fig. 9) when $t > \tau_i$. The increase in the total current is proposed to be due to an increase in the electrode area due to the formation of the dendrites. Under such conditons, the total current is

$$i_{\text{total}} = i_{\text{subslrate}} + i_{\text{dendrites}} = i_s + A_t N_t i_d \quad [33]$$

where A_t and N_t are the area of one dendrite and the number of dendrites at time t, respectively, and i_d is the dendrite side current density. The identity of i_d is taken to the limiting current density under linear diffusion, since the sides appear essentially planar (Fig. 4).

The value of A_t can be expressed by assuming that the dendrite has a rectangular cross section with width w, thickness d, and length y at time t. Thus

$$i_d A_t = 2wyi_d + 2dyi_d + wdi_{\text{tip}} \quad [34]$$

The last term in Eq. [34] is the dendrite propagation current which is negligible (section above on Influence of dendrite propagation current on measured total current). Therefore

$$i_d A_t = 2(wy + dy)i_d \quad [35]$$

Since w and d change under a linear current flux while y changes under a spherical current flux, w and d remain constant when compared to y. Expressing the time dependence of y with respect to τ, the initiation time produces, in the linear form of $y - t$, the equation (cf. Eq. [18])

$$y = i_0 u \frac{M}{\rho n \mathbf{F}} (t - \tau) + y_\tau \quad [36]$$

Substituting Eq. [36] into [35] produces

$$i_d A_t = 2(w + d)\left\{ y_\tau + i_0 u \frac{M}{\rho n \mathbf{F}} (t - \tau) \right\} i_d \quad [37]$$

This is an expression for the side current of one dendrite as a function of time, providing that the dendrite length changes linearly with time.

How will N_t behave as a function of time (Eq. [33])? If the dendrite initiation process were instantaneous (25), N_t would be constant. Thus, i_{total} would be linear with time, contrary to the experimental results. Under galvanostatic conditions Naybour (25) found that dendrite initiation was instantaneous; however, since overpotential will decrease as initiation proceeds, the condition required for initiation outlined earlier may be lost. Under potentiostatic conditions, dendrite initiation may be continuous, as is reported by Powers (15) for so-called protrusions.

The nucleation or initiation law is assumed (26) to be first order with a low initiation constant K; thus the total number of dendrites at time t is given by

$$N_t = N_0 K t \quad [38]$$

where N_0 is the number of initiation sites on the substrate taken.

Since initiation is taken to be progressive, τ can have values between time t and $\tau_{\min}$ ($\tau_{\min}$ is the experimentally reported τ since this is the initiation time of the first dendrites). The total current due to dendrites will be the sum of all the individual currents from the dendrites initiated at a range of τ values; thus

$$i_{\text{dendrites}} = \int_{\tau_{\min}}^{t} 2(w + d)\left\{ y_\tau + i_0 u \frac{M}{\rho n \mathbf{F}} (t - \tau) \right\} i_d N_0 K d\tau \quad [39]$$

Simplifying Eq. [39] by considering $y_\tau = 0$, and integrating, produces

$$i_{\text{dendrites}} = (w + d) i_0 u \frac{M}{\rho n \mathbf{F}} i_d N_0 K (t - \tau_{\min})^2 \quad [40]$$

If, at sufficiently large t, $\tau_{\min} << t$, then Eq. [40] approximates to

$$i_{\text{dendrites}} = (w + d) i_0 u \frac{M}{\rho n \mathbf{F}} i_d N_0 K t^2 \quad [41]$$

According to Eq. [40], i_{total} against time should show a parabolic relationship. Further, when $t >> \tau_{\min}$, Eq. [41] shows i_{total} should show a t^2 dependence (Fig. 9).

The general validity of Eq. [40] can be seen by considering Fig. 7 where $\eta = -100$ mV, $c_0 = 0.1$ moles liter^{-1}, and $T = 35°$C and the total current is 850 μA after 35 min, *i.e.*, $i_{\text{dendrites}} = 400$ μA, where $i_s = 450$ μA. Assuming $i_0 = 10^{-1}$ A cm^{-2}, $u = 6.65$ (Eq. [15]) when $\eta = -100$ mV and $i_d = 10^{-2}$ A cm^{-2} (Fig. 6), a value of N_0K can be calculated providing an estimate can be made of $(w + d)$. In the section on Influence of dendrite propagation current on the measured total current, the width w of the dendrite main axis was taken as 10^{-3} cm; however, the present $(w + d)$ must include contributions due to side branches. An effective w (main axis + side branches) can be obtained from Fig. 3a where the effective width is seen to be approximately one-fifth of the dendrite length, y. In the present calculation $y = 6 \times 10^{-2}$ cm; thus w can be approximated as 1.2×10^{-2} cm. From Fig. 3b, which corresponds to the conditions of this calculation, w can be seen to be approximately 10^{-2} cm. Since it is observed experimentally that d is small compared to w, $(w + d)$ can be approximated as w. Using these experimental estimates, N_0K is calculated as 1.3 cm^{-2} sec^{-1} from [40]. Thus, on the electrode area under examination, the initiation rate of dendrites will be such that every 25 sec, beyond $\tau_{\min}$, a dendrite will be formed from the precursor pyramid.

Experimentally, it is observed that $\approx$30 dendrites are formed in 35 min under conditions of the above calculation ($\tau_{\min} = 10$ min), *i.e.*, the experimental initiation rate is 0.7 cm^{-2} sec^{-1}. This degree of agreement supports Eq. [40].

Experimental test of theoretical propagation equations.—Table VII shows the theoretical and experimental values of the terms $(dv/d\eta)_{c_0,T}$ and $(dv/dc_0)_{\eta,T}$ according to Eq. [23] and [28], respectively, for the

[7] The theory developed here is for $t >> \tau$ where $i \propto t^2$; when τ is appreciable compared to t the exponential $i - t$ relationship is probably essentially valid, where the 10^{-3} cm corresponds to the value of τ at that time.

Table VII. Experimental test of Eq. [23] and [28]

Assumed parameters	Parameter		Theory	Experiment
$i_0 = 100$ mA cm^{-2} $\eta = -100$ mV	$\left(\frac{dv}{d\eta}\right)_{c_0, T}$	cm sec^{-1} volt^{-1}	7.3×10^{-4}	5.0×10^{-4}
$c_0 = 10^{-4}$ moles cm^{-3} $\alpha_c = 0.5$	$\left(\frac{dv}{dc_0}\right)_{\eta, T}$	cm sec^{-1} mole^{-1} cm^3	0.3	0.43

conditions shown. The agreement can be seen to be consistent with the assumed model involving monoelectronic transfer steps with the redox step rate determining (section above on Propagation), *i.e.*

$$Zn(OH)_4^{=} + e \rightarrow Zn(OH)_2^{-} + 2\,OH^- \quad [42]$$

$$Zn(OH)_2^{-} + e \rightleftarrows Zn + 2\,OH^- \quad [43]$$

Figure 14 produces $(d\eta/d \log i_{tip})_{c_0,T} = 0.17$V, whereas the Tafel slope for the above mechanism where $\alpha_c = 0.5$ produces 0.12V at 35°C.

Figure 11, whose slope $(d \log i_{tip}/d \log c_0)_{\eta,T} = 1.00 \pm 0.14$, can be compared with the theoretical slope, from the above mechanism, of 0.75.

The electrode kinetic parameters obtained here from the dendrite propagation under activation control are in much closer agreement with the above mechanism than with either (*a*) a simultaneous transfer of two electrons, as proposed for zinc amalgam studies (27-29), or (*b*) a monoelectronic two-step transfer with the second step rate determining.

From Eq. [10] the current density at the dendrite tip for the condition $y > \delta_0$ is

$$i_{tip} = \frac{n\mathbf{F}Dc_0 i_0 \left\{ \exp\left(\frac{-\alpha_c \mathbf{F}\eta}{RT}\right) - \exp\left(\frac{\alpha_a \mathbf{F}\eta}{RT}\right) \exp\left(\frac{2\gamma V}{RTr}\right) \right\}}{n\mathbf{F}Dc_0 + r\, i_0 \exp\left(\frac{-\alpha_c \mathbf{F}\eta}{RT}\right)} \quad [44]$$

which, when simplified, produces

$$\frac{i_{tip}}{K} = i_n = \frac{\exp\left(\frac{-\alpha_c \mathbf{F}\eta}{RT}\right) - \exp\left(\frac{\alpha_a \mathbf{F}\eta}{RT}\right) \exp\left(\frac{1}{r_n}\right)}{\frac{K}{i_0} + r_n \exp\left(\frac{-\alpha_c \mathbf{F}\eta}{RT}\right)} \quad [45]$$

where $K = \frac{RTn\mathbf{F}Dc_0}{2\gamma V}$ and $r_n = \frac{RT}{2\gamma V} r$.

Figure 20 shows a plot of $i_n - r_n$ for the zinc system as a function of overpotential, assuming the mechanism outlined earlier. Theoretically, it may be said that dendrites should appear when $i_n > (i_{L(l)})_n$ where $i_{L(l)}$ is the limiting linear current density to the substrate surface. However, from Fig. 17 it is experimentally observed that the initiation time below —80 mV is long and hence dendrites do not appear until the overpotential lies in the region of —80 mV.

Figure 13 shows the theoretical propagation rate, as a function of overpotential, calculated from Fig. 20; the agreement with experiment is reasonable.

Figure 21 shows a theoretical $i_n - r_n$ plot for the silver system assuming the parameters of Barton and Bockris (3). Figures 20 and 21 differ considerably, in that zinc exhibits a wide range of dendrite radii which can grow at the maximum rate, whereas silver shows a small range. Such a difference can be used to account for the fact that it is easier to initiate single dendrites of silver than of zinc.

The theoretical values, or range of values, of dendrite tip radii, r, at which the propagation rate is a maximum, obtained from Fig. 20 and 21, are shown in Table VIII. The agreement with experiment for silver is satisfactory; that for the present study on zinc is somewhat less so.

Table VIII. Theoretical and experimental values of optimum dendrite tip radius required for maximum propagation rate

Metal	Overpotential, mV	Theoretical, cm	Experimental, cm
Zinc	−85	5×10^{-6} to 10^{-4}	10^{-4} to 10^{-5}
	−100	5×10^{-6} to 10^{-4}	4×10^{-4} to 10^{-4}
Silver	−5.2	5.6×10^{-5}	11.0×10^{-5}
	−8.8	4.8×10^{-5}	4.3×10^{-5}
	−16.7	3.2×10^{-5}	2.1×10^{-5}

Conclusions

(*A*) Dendrite initiation is the result of pyramidal growth under bulk diffusion control until the required radius of curvature, to give spherical flux to the propagating tip, is attained.

(*B*) Two critical overpotentials are established, the first being that required to rotate a screw dislocation, the second being that required to produce bulk-diffusion controlled deposition at a rate necessary to produce the change in tip radius required to alter diffusion from linear to spherical. It is the latter which has been identified as the critical overpotential.

(*C*) The initiation time (τ) is the time from the moment of current flow to the attainment of spherical diffusion at a stable propagating tip; this condition is established within the linear diffusion boundary layer, δ_0. τ is not identifiable with either τ_d (that from dendrite length-time extrapolation) or τ_i (that from total current-time graph), but $\tau_d < \tau < \tau_i$.

(*D*) The growth of the zinc dendrite, once initiated, is linear with time and under activation control. Therefore, the dendrite tip current density shows the usual activation current density dependences.

(*E*) The predominance of single dendrites for silver, as compared to that of zinc, is due to a much narrower range, for Ag, of tip radii which can grow at the optimum, maximum rate (Fig. 20 and 21).

(*F*) The total current increase with time, according to a second power law, is due to the increase in electrode area during dendrite growth. This law is consistent with a linear dendrite growth rate (experimentally observed) and a continuous (rather than instantaneous) initiation of dendrites while current passes.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

APPENDIX

*Condition for the Establishment of Spherical Diffusion**

The steady-state equation for diffusion states that

$$\nabla^2 c = 0 \qquad [A1]$$

which, when related to spherical coordinates and spherical symmetry, becomes

$$\nabla^2 c = \frac{1}{r^2}\frac{\partial}{\partial r}(r^2\,\partial c/\partial r) = 0 \qquad [A2]$$

General integration of [A2] produces

$$r^2\frac{dc}{dr} = \text{constant } (k) \qquad [A3]$$

Integration of Eq. [A3] between the limits r_0 and $(r_0 + \delta_0)$ gives

$$c(r_0 + \delta_0) - c(r_0) = \int_{r_0}^{r_0+\delta} \frac{k}{r^2}\,dr = \frac{k}{r_0} - \frac{k}{(r_0 + \delta_0)} \qquad [A4]$$

The constant, k, can now be written as

$$k = \frac{c(r_0 + \delta_0) - c(r_0)}{\dfrac{1}{r_0} - \dfrac{1}{(r_0 + \delta_0)}} \qquad [A5]$$

The flux at the electrode surface is given by

$$J(r_0) = -D\left(\frac{dc}{dr}\right)_{r=r_0} \qquad [A6]$$

Substituting for (dc/dr) from Eq. [A3] and then for k (Eq. [A5]) produces

$$J(r_0) = \frac{D}{r_0^2}\,\frac{c(r_0 + \delta_0) - c(r_0)}{\dfrac{1}{r_0} - \dfrac{1}{(r_0 + \delta_0)}} \qquad [A7]$$

The current density at the electrode surface is given by

$$i = \frac{2FD}{r_0^2}\,\frac{c(r_0 + \delta_0) - c(r_0)}{\dfrac{1}{r_0} - \dfrac{1}{(r_0 + \delta_0)}} \qquad [A8]$$

which, when $\delta_0 >> r_0$ reduces to

$$i = \frac{2FD[c(r_0 + \delta_0) - c(r_0)]}{r_0} \qquad [A9]$$

which is the spherical diffusion equation. Thus, the condition for spherical diffusion is $\delta_0 >> r_0$, where r_0 is the radius of curvature of the tip to which diffusion is proceeding.

* The authors are indebted to Mr. G. Razumney for this derivation.

Stress Induced Binary Diffusion in a Solid

R. J. Charles

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

Operational methods are used to describe the migration transients of two ions which respond to concentration gradients and ion space charge when a nonuniform stress is applied to a solid. The results indicate two characteristic time constants for the approach to equilibrium. The shorter time constant is related to the establishment of space charge and thus to electrical properties. The long time constant is related to an ion interchange process which depends on the sample geometry.

The application of nonuniform mechanical pressure to a bounded solid containing diffusible ions may result in ion transport and accumulation similar to that obtained by the application of an electric field. For the case where more than one ion type responds to applied stress the electric field from displaced ions is common to all diffusing species. The effects of concentration and stress gradients, however, are specific to the type

of diffusing ion. Because of electric field coupling in multiple ion diffusion, the ion flows occurring after stress application may interact with one another such that the transient leading to steady state is highly complex.

The main object of this work is to present a model which examines the transient conditions by which a steady state is achieved when a stress gradient is applied to a solid containing two diffusible ions. The problem has particular application to delayed elastic effects and internal friction in glasses containing mixed alkali ions (1) but is relevant to ion substituted crystals (2) and to some physiological materials (3).

Statement of the Problem

Single ion case.—Weber and Goldstein (4) propose an equation of the following form for the flux, J, of a single ion of concentration, C, and diffusion coefficient, D, in a solid subjected to a stress gradient, η

$$J = -D[dC/dx + CeE/(kT) + C\overline{V}\eta/(kT)] \quad [1]$$

In this equation x is the flux direction, e is unit charge, E is the electric field, $\overline{V}$ is the partial molar volume of the diffusing ion, and kT has its usual significance.

In the present work it is desirable to utilize Eq. [1] by defining diffusion coefficients and concentrations with respect to a particular diffusional process. The case treated here consists of a solid in which ions diffuse by an interstitialcy mechanism. Thus, in the following, the symbols D and C refer to the interstitial diffusion coefficient and interstitial concentration of a mobile ion. These values are related to the ion self-diffusion coefficient D_o, and total ion concentration C_o, by the relation $D\,C = D_oC_o$. If a Frenkel defect model is adopted, then C may be estimated by an equation of the form $C/C_o = \exp(-W/(2kT))$ where W is the energy of formation of such a defect.

Interstitials are produced by dissociating neutral pairs of anions and cations and locally must obey the mass action principle for such a reaction. Let us consider the sample initially under no stress or electric field and write n^o for the vacancy concentration, p^o for the interstitial concentration, and $C_o - p^o$ for the bound pair concentration. The equilibrium constant for bound pair dissociation then equals $n^op^o/(C_o - p^o)$ and generally since $p^o << C_o$ and there is no space charge

$$K \approx (p^o)^2 \quad [2]$$

where K is another constant.

If, by application of a stress, ρ cations/cm^3 accumulate in a local region of the specimen then the space charge density will be ρ but the interstitial and vacancy concentrations must adjust to maintain equilibrium. The vacancy concentration changes from n^o to n and the interstitial concentration changes from p^o (equal to n^o) to $(\rho + n)$ and, conforming to local equilibrium

$$(\rho + n)\, n \approx K \approx (p^o)^2 \quad [3]$$

Thus, by choosing the positive root, one obtains

$$n \approx ((1 + 4(p^o/\rho)^2)^{1/2} - 1)\, \rho/2 \quad [4]$$

If the space charge density, ρ, is small compared to the zero stress state interstitial concentration then

$$n \approx p^o - \rho/2 \quad [5]$$

and the interstitial concentration is given by

$$(\rho + n) \approx p^o + \rho/2 = C \quad [6]$$

The above assumption can only be proved valid by proceeding with actual calculations to see if the space charge density, for reasonable stress gradients, may always be considered small compared to interstitial concentrations. Equation [4] shows that Eq. [6] is still reasonably valid when $(p^o/\rho)^2 = 25$ or when ρ is approximately 10% of p^o. In summary, one may view Eq. [6] as stating that local equilibrium is preserved if half the ions that enter a region to produce space charge drop into the bound state and the other half remain as interstitials.

Using the previous assumptions (*i.e.* $\rho << n$ and thus $n \approx n^o \approx p^o$) Eq. [1] may be written for the interstitial case as

$$J = -D[d(\rho + n)/dx + ep^oE/(kT) + p^oV\eta/(kT)] \quad [7]$$

Differential forms of Eq. [6] and [7] may be combined with Poisson's equation (*i.e.*, $dE/dx = -e\rho/\epsilon\epsilon_0$) to give

$$J(x,t)_x = \rho(x,t)_t = D[2e^2p^o(\epsilon\epsilon_0kT)^{-1}\rho - \rho_{xx}] \quad [8]$$

where ϵ is the dielectric constant of the solid, ϵ_0 is the permittivity of free space (8.854×10^{-12} A sec volts^{-1} meters^{-1}) and the subscripted letter method is used to denote differentiation. The equation is linear, and the factor 2 results from the approximation concerning equilibrium between bound and interstitial ions.

For the single ion case Eq. [8] is to be solved subject to the conditions that the stress gradient is constant, all ions are conserved (*i.e.*, the integral excess ion density from surface to surface of the sample is zero) and that ions will not be discharged at the sample surfaces [*i.e.*, J(surface) = 0]. The solution is symmetrical and may be obtained by the method of separation of variables which yields the familiar type of diffusion equation involving an infinite sum of trigonometric and exponential terms. For sample edges at $\pm\, a/2$ and a stress gradient η along the sample length

$$\rho(x,t) = \frac{\beta \sinh(\gamma a)}{\gamma \cosh(\gamma a/2)}\left[\frac{\sinh(\gamma x)}{\sinh(\gamma a)} - \frac{2}{\pi}\sum_{n=1}^{\infty}\frac{n(-1)^n}{n^2 + (\gamma a/\pi)^2}\sin(n\pi x/a)\exp[\gamma^2 + n^2\pi^2/a^2)Dt]\right] \quad [9]$$

where $\beta = p^oV\eta/(kT)$ and $\gamma = [2p^oe^2/(\epsilon\epsilon_0kT)]^{1/2} = L^{-1}$.

The term L is a Debye length and for a material, such as a glass, of dielectric constant 4.0 containing 10^{21} mobile ions per cm^3 with an energy of defect formation of 1 eV (giving, from Eq. [2], a zero stress defect concentration of about 2×10^{12} ions per cm^3) this length calculates to be 1.2μ. Since the Debye length is small compared to normal sample dimensions it may be interpreted as that distance from the sample surface at which the excess ion concentration falls to e^{-1} times its surface value.

For usual sample dimensions ($a >> L$) the time constant to establish steady state in Eq. [9] is essentially the factor L^2/D. Since the conductivity, σ, equals $D\,p^o\,e^2/(kT)$ this time constant equals $\epsilon\epsilon_0/(2\sigma)$ or one-half of the electrical time constant for the material. On the other hand if the sample is multiphase, such that the diffusion occurs in an isolated phase having characteristic dimensions of the order of the Debye length, then a number of relaxation times, all smaller than the electrical time constant, are involved.

For a typical partial molar volume of 6Å^3 per ion (4 cm^3/mole), a stress gradient of 3×10^8 dynes/cm^3 (approximately equal to 10^4 psi/in.) and p^o equal to 2×10^{12} ions per cm^3 the stress coefficient β, for the glass at room temperature, calculates to be about 10^{11} ions cm^{-4}. Thus, from Eq. [9], the steady-state excess ion concentration at the sample surfaces calculates to be $\rho(\pm a/2, \infty) = \pm 10^{11}\ (1.2 \times 10^{-4}) = \pm 1.2 \times 10^7$ ions cm^{-3} or approximately five orders of magnitude smaller than the zero stress interstitial concentration, p^o. Thus the approximation concerning local equilibrium between bound and interstitial ion states (*i.e.*,

$\rho << p^0$) appears justified for usual applications.

For steady state the field, E, is given by

$$E(x, \infty) = \beta e(\gamma^2 \epsilon\epsilon_0)^{-1}\left[\frac{\cosh(\gamma x)}{\cosh(\gamma a/2)} - 1\right] \quad [10]$$

and the potential from end to end is

$$V = \int_{-a/2}^{a/2} E(x, \infty)\, dx = \beta e a(\gamma^2 \epsilon\epsilon_0)^{-1}\left[\frac{2\tanh(\gamma a/2)}{\gamma a} - 1\right] \quad [11]$$

A sample with the above characteristics and stress state and of a length greater than a few Debye lengths would thus develop a maximum field of about 1 mV/cm and, correspondingly, a 1 cm sample would develop about 1 mV potential.

Two ion case.—Two ions, each with a different mobility and a different response to stress, are now considered. While the solutions of the flux equations will encompass virtually all combinations of diffusion coefficients, stress response factors and concentrations, application to real cases will generally demand that the ion with the largest diffusion coefficient will exhibit the lowest partial molar volume. This results from the fact that small ions are expected to move more easily through a given lattice or structure than big ions whereas a given deformation of the structure would affect a large ion more than a small one.

Denoting the two ions by subscripts 1 and 2, two parallel flux equations may be written following Eq. [7]. We assume that the ions exhibit separate partial molar volumes, interstitial diffusion coefficients and energies of defect formation and that the conditions for local equilibrium discussed previously hold independently for each ion. Thus, following the single ion procedure (Eq. [8]) two simultaneous divergence equations may be obtained for the two ion types.

$$\left.\begin{aligned} J_1(x, t)_x = \rho_1(x, t)_t = D_1[\gamma_1^2(\rho_1 + \rho_2) - (\rho_1)_{xx}] \\ J_2(x, t)_x = \rho_2(x, t)_t = D_2[\gamma_2^2(\rho_1 + \rho_2) - (\rho_2)_{xx}] \end{aligned}\right\} \quad [12]$$

where, if i takes a value of either 1 or 2, $\gamma_i = [2\rho_i{}^0 e^2/(\epsilon\epsilon_0 kT)]^{1/2} = L_i^{-1}$.

The boundary conditions for these equations are

$$\left.\begin{aligned} \rho_i(x, o) &= 0 \\ \rho_i(\pm a/2, t)_x &= \beta_i \\ \int_{-a/2}^{a/2} \rho_i(x, t)\, dx &= 0 \end{aligned}\right\} \quad [13]$$

The equations in [12] are first reduced to ordinary differential equations by Laplace transforms of the time variable, t, in terms of the variable s. Thus, denoting a tranfsormed variable by a circumflex, one obtains for ion 1 an equation of the form

$$\hat{\rho}_1(x, s)_{xx} = (s/D_1 + \gamma_1^2)\hat{\rho}_1(x, s) + \gamma_1^2\hat{\rho}_2(x, s) \quad [14]$$

Interchanging the subscripts 1 and 2 will yield the parallel equation for ion 2.

Rearranging the above, differentiating twice with respect to x and substituting one obtains fourth order equations

$$(\hat{\rho}_i)_{4x} - A(\hat{\rho}_i)_{xx} + B\hat{\rho}_i = 0 \quad [15]$$

where i is again either 1 or 2. The constants in these equations are $A = s/D_1 + s/D_2 + \gamma_1^2 + \gamma_2^2$ and $B = s(s/(D_1D_2) + \gamma_2^2/D_1 + \gamma_1^2/D_2 + (\gamma_1\gamma_2)^2)$. Solutions of the form $\rho = \Sigma\, a_n \exp(\lambda_n x)$ are assumed yielding identical auxilliary equations for the four roots λ_n.

$$\lambda_{1-4} = \pm\,(A/2 \pm (A^2/4 - B)^{1/2})^{1/2} \quad [16]$$

and thus λ_1 equals $-\lambda_3$ and λ_2 equals $-\lambda_4$. For i equal to either one or two the boundary conditions transform to

$$\left.\begin{aligned} \hat{\rho}_i(o, s) &= 0 \\ \hat{\rho}_i(\pm a/2, s)_x &= \beta_i/s \\ \int_{-a/2}^{a/2} \hat{\rho}_i(x, s)\, dx &= 0 \end{aligned}\right\} \quad [17]$$

Applying these boundary conditions to the assumed solutions one obtains for ion one

$$\hat{\rho}_1(x, s) = \frac{[\beta_2 - \beta_1(\lambda_2^2\gamma_1^{-2}) - s(D_1\gamma_1^2)^{-1} - 1]\gamma_1^2}{s(\lambda_1^2 - \lambda_2^2)} \frac{\sinh(\lambda_1 x)}{\lambda_1 \cosh(\lambda_1 a/2)} - \frac{[\beta_2 - \beta_1(\lambda_1^2\gamma_1^{-2}) - s(D_1\gamma_1^2)^{-1} - 1]\gamma_2^2}{s(\lambda_1^2 - \lambda_2^2)} \frac{\sinh(\lambda_2 x)}{\lambda_2 \cosh(\lambda_2 a/2)} \quad [18]$$

Interchanging subscripts 1 and 2 in Eq. [18] yields the appropriate solution for ion two.

Equations of the form given in Eq. [18] may be integrated in the complex plane to yield inverse transforms by the theory of residues. Each term of these equations may be expressed in the form $q(x, s)/r(s)$, consequently by the above, the inverse transform is

$$\mathbf{L}^{-1}[q(x, s)/r(s)] = \sum_{n=1}^{\infty} q(x, s_n)/r'(s_n)\exp(s_n t) \quad [19]$$

where the prime denotes differentiation with respect to s. Examination of Eq. [18] shows that singularities or poles occur only when $s = 0$ or when $r = \cosh(\lambda_i a/2) = 0$ (there are no real values of s and thus no real singularities for $\lambda_1^2 - \lambda_2^2 = 0$). Steady-state solutions result from the pole at $s = 0$ and are obtained from

$$\rho(x, \infty) = \underset{\text{Lim. } s \to 0}{s\hat{\rho}(x, s)} \quad [20]$$

Thus

$$\rho_1(x, \infty) = \gamma_1^2(\beta_1 + \beta_2)(\bar{\gamma})^{-3}\frac{\sinh(\bar{\gamma}x)}{\cosh(\bar{\gamma}a/2)} - \frac{(\beta_2\gamma_1^2 - \beta_1\gamma_2^2)x}{(\bar{\gamma})^2} \quad [21]$$

where $\bar{\gamma} = (\gamma_1^2 + \gamma_2^2)^{1/2}$.

Interchanging subscripts yields a parallel steady-state solution for ion two.

Values of s for the remaining poles are obtained from $\gamma_i^2 = -(\pi/a)^2(2n - 1)^2$. We now write z for $(\pi/a)(2n - 1)$ and thus from Eq. [16] and the above

$$s_n^{\pm} = 1/2[-(z^2(D_1 + D_2) + D_2\gamma_2^2 + D_1\gamma_1^2) \pm [(z^2(D_1 + D_2) + D_2\gamma_2^2 + D_1\gamma_1^2)^2 - 4D_1D_2z^2(z^2 + \gamma_1^2 + \gamma_2^2)]^{1/2}] \quad [22]$$

Because of the multiplicity of signs in the quadratic expressions for λ_i^2 and s_n, care must be exercised so that sign errors and duplicate terms are avoided in the summations of Eq. [19]. As shown in Eq. [22], each value of n results in two values of s_n (*i.e.*, s_n^+ or s_n^-). Considering s_n^+, two λ^2 values are possible only one of which equals $-z^2$. The same is true for s_n^-. Let us designate the unequal root for s_n^+ as λ^+ and that for s_n^- as λ^-. The derivative of r(*i.e.*, r') is first evaluated at those values of s_n for which $\lambda^2 = -z^2$. Thus

$$r'|_{s_n} = (a/2)\sinh(z\alpha/2)\left|\frac{dz}{ds_n}\right|_{s_n} = (a(-1)^n/2)\left|\frac{dz}{ds_n}\right|_{s_n} \quad [23]$$

Differentiation of λ^2 (from Eq. [16]) yields

$$\left|\frac{dz}{ds_n}\right|_{s_n} = \frac{1}{4z}\left[\frac{1}{v} \pm \frac{(s_n/v^2 - 4s_n/(D_1D_2) + (\bar{\gamma})^2(D_2 - D_1)/(D_1D_2)}{[(s_n/v + (\bar{\gamma})^2)^2 - 4s_n(s_n + D_2\gamma_2^2 + D_1\gamma_1^2)/(D_1D_2)]^{1/2}}\right] \quad [24]$$

where the plus sign is associated with s_n^+ and the minus sign with s_n^- and $v = D_1D_2/(D_1 + D_2)$. Thus, using trigonometric expressions for hyperbolic functions of complex arguments, one obtains

$$\rho_1(x,t) = \rho_1(x,\infty) + \frac{8}{a}\sum_{n=1}^{\infty}\frac{[\beta_2 - \beta_1((\lambda^+/\gamma_1)^2 - s_n^+/(D_1\gamma_1^2) - 1)]\gamma_1^2}{s_n^+(z^2 + (\lambda^+)^2)z\left|\frac{dz}{ds_n^+}\right|_{s_n^+}}\cos(z\alpha)\exp(s_n^+t) + \frac{8}{a}\sum_{n=1}^{\infty}\frac{[\beta_2 - \beta_1((\lambda^-/\gamma_1)^2 - s_n^-/(D_1\gamma_1^2) - 1]\gamma_1^2}{s_n^-(z^2 + (\lambda^-)^2)z\left|\frac{dz}{ds_n}\right|_{s_n^-}}\cos(z\alpha)\exp(s_n^-t) \quad [25]$$

where x varies over $\pm a/2$ and $\alpha = (a/2 - n)$. Once again the interchange of subscripts 1 and 2 yields the corresponding excess ion density equation for the second ion.

Examination of Eq. [22] and [25] shows that in the binary case there exist two sets of time constants which control the stress induced diffusion processes. If we consider a sample long compared to the Debye length of either of the ions ($a >> L_1 >> L_2$) and diffusion coefficients of these ions which are appreciably different (eq. $D_2 << D_1$) then the largest and dominant time constants of each of these sets may be obtained from Eq. [22] by considering small z (*i.e.*, for $n = 1$, $z = \pi/a$ and $z^2(D_1 + D_2) << D_1\gamma_1^2 << D_2\gamma_2^2$). The first time constant is then

$$\tau_{first} \approx (D_1\gamma_1^2)^{-1} \approx L_1^2/D_1 \approx \epsilon\epsilon_0/(2\sigma_1) \quad [26]$$

which is, as in the single ion case, simply one-half of the electrical time constant for the fast diffusing species. The second time constant, which is considerably larger than the first, is approximately

$$\tau_{second} \approx \frac{a^2}{\pi^2 D_2}(\gamma_1/\bar{\gamma})^2 \approx \frac{L_2^2}{\pi^2 D_2}\left(\frac{a^2}{L_1^2 + L_2^2}\right) \approx \frac{\epsilon\epsilon_0}{2\pi^2\sigma_2}\left(\frac{a^2}{L_1^2 + L_2^2}\right) \quad [27]$$

This latter time constant is dependent not only on the electrical time constant of the slower moving species but also on the diffusion path length relative to the Debye lengths of both ions. As with the single ion this diffusion path is to be considered the sample length for a homogeneous material or the diffusion path length of conductive regions if the sample is inhomogeneous. If this latter path length is of the order of the Debye lengths, then simple reduced expressions for either time constant are not possible.

Steady-state space charge densities (or excess ion concentration) are given by Eq. [21] where, for diffusion paths long compared to the Debye lengths, an exponential form may be substituted for the hyperbolic functions. In general, for the case of differing partial molar volumes of the two ions, the solutions indicate excesses or deficiencies in ion concentrations which are linear with distance except within a few Debye lengths of the sample surfaces where the distance-concentration relationship becomes exponential.

The total space charge density at steady state is obtained from Eq. [21] and is given by

$$(\rho_1 + \rho_2) = (\beta_1 + \beta_2)(\bar{\gamma})^{-1}\frac{\sinh(\bar{\gamma}x)}{\cosh(\bar{\gamma}a/2)} \quad [28]$$

Thus the field is

$$E = \frac{(\beta_1 + \beta_2)e}{(\bar{\gamma})^2\epsilon\epsilon_0}\left[\frac{\cosh(\bar{\gamma}x)}{\cosh(\gamma a/2)} - 1\right] \quad [29]$$

and the end to end potential is

$$V = \frac{(\beta_1 + \beta_2)ea}{(\bar{\gamma})^2\epsilon\epsilon_0}\left[\frac{2\tanh(\bar{\gamma}a/2)}{\bar{\gamma}a} - 1\right] \quad [30]$$

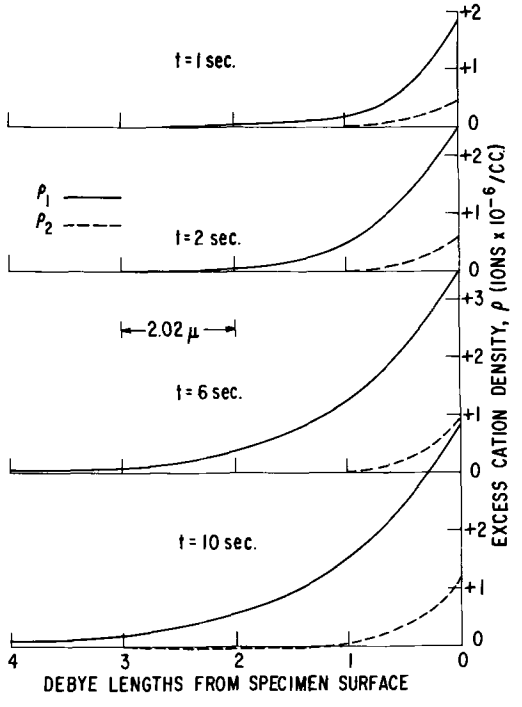
These equations are of similar form to those for the one ion case.

Interpretation

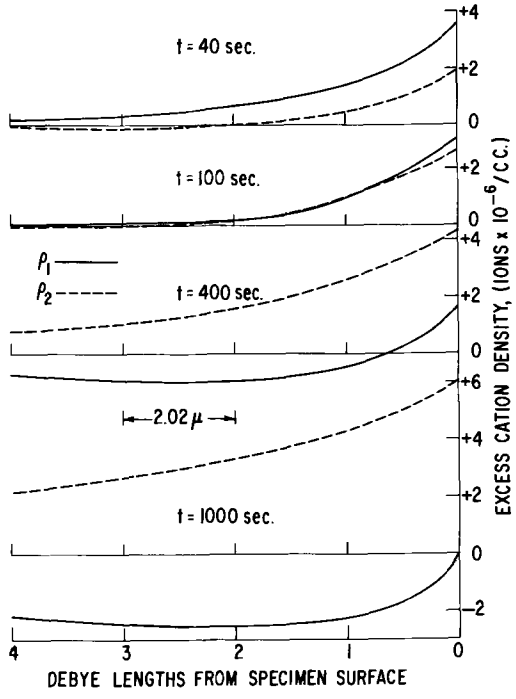
The general behavior of the stress induced diffusion of a single ion, as given by Eq. [9], is straightforward and requires little comment. After stress application a steady state is approached continuously by a unidirectional net flow of ions. Net ion flow halts when sufficient space charge is developed at a surface to produce a flux which is opposed and balanced by the flux due to the stress gradient. Two ion behavior is considerably more complex but the general ion motions, as given by forms of Eq. [25], do have a relatively simple interpretation. On application of a stress gradient the fast diffusing species move to regions of lower compressive stress, and the space charge that is initially developed hinders the motion of the slower moving species to these regions. If the activation volume $\bar{V}$ is greatest for the fast moving species (the unlikely case), then the space charge due to these ions overcomes the stress effect on the slower moving ions and these latter ions are forced to accumulate in the higher compressive stress regions until a steady state is achieved. On the other hand if the slow moving ions exhibit the greatest response to stress (the likely case), then these ions slowly accumulate in the low compressive stress regions and displace the fast moving ions which had previously migrated to these regions. Thus, the fast moving ions, which initially moved in the direction of lower compressive stress, reverse direction and flow back through the sample to regions of higher compressive stress.

At steady state a stable space charge situation arises since the excess of large ions (high stress response factor) exceeds the deficiency of small ions at the low stress end of the specimen while the deficiency of large ions exceeds the excess of small ions at the opposite end. At intermediate positions in the sample a continuous interchange of large and small ions takes place and since this interchange occurs over virtually the whole length of the sample the time to reach steady state is extremely long. If the diffusion coefficients of the two ions differ greatly, then a pseudo-steady state is first obtained when the fast moving ions accumulate sufficiently at the low stress end of the sample. The time to reach this state is relatively short since diffusion of the fast moving ions over distances of the order of only a few Debye lengths is involved.

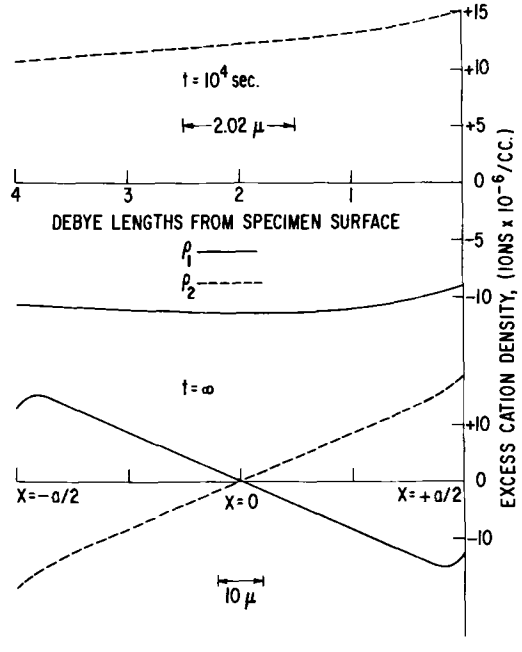
Figure 1 shows the results of a typical calculation for a thin plate (0.1 mm) containing two mobile ions



1A



1B



1C

Fig. 1. Excess ion distributions as a function of time after stress application for a bent plate having the characteristics listed in Table I.

which is bent to produce a uniform stress gradient through the plate. The characteristics of this particular problem are given in Table I and roughly correspond to those that would pertain to a mixed alkali silicate glass at room temperature.

Figure 2 compares the total space charge distribution ($\rho_1 + \rho_2$) with the steady-state distribution for times equal to one, two, and three times the time constant for the fast moving species. It is evident that appreciable space charge only occurs within a few Debye lengths of the sample surfaces for any stage of the migration process. It is also evident that equilibrium space charge is essentially established within a few multiples of the time constant of the fast moving species. We conclude that the preliminary migration of the fast moving species develops the major portion of the space charge distribution in the sample and that the subsequent long term ion interchange proceeds under virtually constant electrical field conditions.

Table I. Example data

η = 300 kg/cm³	a = 0.01 cm	T = 300°K
p^o_1 = 5 × 10¹¹ ions/cc	interstitial	
p^o_2 = 2 × 10¹¹ ions/cc		
L_1 = 2.40 × 10⁻⁴ cm	L_2 = 3.78 × 10⁻⁴ cm	
$\overline{V}_1$ = 3cc/mole	$\overline{V}_2$ = 5cc/mole	
β_1 = 1.8 × 10¹⁰ ions/cm³	β_2 = 1.2 × 10¹⁰ ions/cm³	
D_1 = 10⁻⁸ cm²/sec	D_2 = 10⁻⁹ cm²/sec	
τ_1 = 5.75 sec	τ_2 = 7100 sec	

Little experimental data exists to which the above transient theory for binary diffusion may be applied. Weber and Goldstein (4) show that for the case of nonblocking electrodes the application of a stress field to a sodium ion conducting glass produces a measurable electrical current. Comparison of this current, under short-circuit conditions, with the current obtained by a known electrical field allowed a calculation

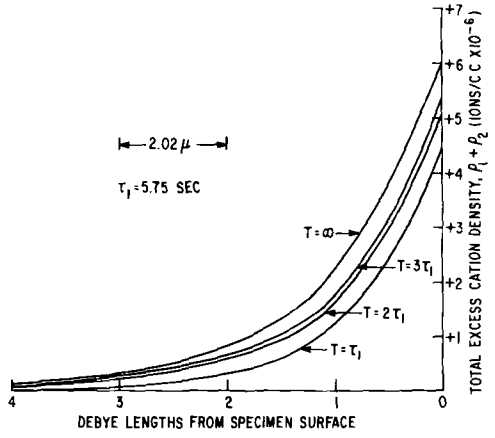


Fig. 2. Total space charge distribution for the plate in Fig. 1 at times equal to one, two, and three times the time constant for the fast moving ion.

of the volume term in Eq. [1]. This volume, having a value of 1.3 cc/mole, was interpreted as the partial molar volume of sodium ions in the glass and is of the same order of magnitude as activation volumes for sodium ion conduction under hydrostatic pressure for similar glasses (5). It would appear reasonable, therefore, that activation volumes determined from hydrostatic pressure measurements would be satisfactory data for calculating the stress response (β) factors in the present work.

Steinkamp, Shelby, and Day (1) progressively substituted K_2O for Li_2O in silicate glasses and, by the fiber technique, observed the reduction of an internal friction peak attributed to lithium ions and the growth of another peak at a very much higher temperature. The first peak was associated with the migration of lithium ions which exhibited relatively short relaxation times at room temperature. The second peak would be attributed therefore to a process involving very long relaxation times at room temperature. These observations are consistent with the present theory for the interaction and diffusion of two types of ions in a stress gradient but further confirmation would require correlation of the long relaxation times to either the macroscopic dimensions of the pendulum fiber or diffusion path lengths within the fiber as well as to the diffusional properties of K^+ ions. The above authors state that the first internal friction peak, due to Li^+ ions migration, is well correlated with the electrical behavior of Li^+ ions in the material (*i.e.*, dielectric loss and electrical conductivity) whereas no association of the second, long time constant peak with electrical properties was possible. From the present theory this result seems reasonable for the time constants for the development of an internal friction peak or a dielectric loss peak by migration of a fast moving species (*e.g.*, Li^+) involve the same parameter, namely the electrical conductivity due to the fast moving ion. On the other hand the long term ion interchange, with which would be associated a mechanical loss, would not occur in electrical measurements since the stress gradient responsible for this interchange would be absent.

Participation of Oxygen Species in Periodic Anodic Processes

Herbert F. Hunger*

Institute for Exploratory Research, United States Army Electronics Command, Fort Monmouth, New Jersey

ABSTRACT

Galvanostatic periodic potential transients of the half element Pt/1M CH_2O, 3.75M H_2SO_4 were measured. A combination of coulometric analysis of the transients and of estimates of surface coverages of the electrodes with organic and oxygen species provided a useful method to study the mechanism of the periodic anodic process over the whole oscillation domain. Three regions with marked differences in mechanism were found experimentally: (*i*) the region of the "valve" mechanism, from 0.15 to 0.92V *vs.* SHE, where anodic oxidation of formaldehyde with readsorption of the latter as the coupling step occurs; (*ii*) the region of a mixed mechanism, from 0.18 to 1.1V *vs.* SHE, where anodic oxidation of the platinum surface occurs in addition to the anodic oxidation of the organic species; chemical reduction of the surface oxide leads to readsorption of formaldehyde at the oxide free surface; and (*iii*) the region of the oxide formation-reduction mechanism, from 0.6 to 1.15V *vs.* SHE where solely anodic oxidation of the platinum surface occurs, followed by chemical reduction with formaldehyde, the coupling step. Based on mechanistic considerations the nonlinear relationship between process frequency and the process variables was established over the whole frequency domain.

The occurrence of oscillatory behavior during the anodic oxidation of organic compounds (formic acid) at noble metal electrodes in aqueous electrolytes at room temperature was observed as early as 1927 and a mechanism was postulated (1, 2). Further early observations of periodic behavior were reported by Thalinger and Volmer and by Butler and Armstrong (3, 4). Early theoretical work on conditions for periodic behavior, such as the concept of simultaneous re-

* Electrochemical Society Active Member.

actions and of coupling, was reported by Bonhoeffer (5). This was followed by work of Franck on the general theory of instable electrical states and the oscillatory behavior of the iron electrode during anodic polarization (6, 7). Franck's work resulted in an explanation of the specific phenomena and a mathematical model (8). In 1954 pertinent work on organic compounds was resumed by Pavela (9). Numerous papers on oxidation of organic compounds have appeared in the 1960's; on the subject of periodic phenomena, a recent publication by Conway and co-workers reports on oscillatory kinetics during the electrochemical oxidation of formate (10). In this work the theory of general conditions for appearance of oscillatory kinetics formulated by Higgins (11) was applied to potentiostatic oscillation data. In this specific case, the general necessity for an autocatalytic type of effect (chemical reduction of a surface oxide by organic species) was found.

In a recent paper we reported on a mechanism of oscillatory behavior during the anodic oxidation of formaldehyde at platinized platinum electrodes in sulfuric acid at room temperature (12). The mechanism could account mainly for the experimental observations in the electrode potential region below +0.8V *vs.* SHE where platinum surface oxidation was suppressed. In this paper we are extending our considerations into the potential region above +0.8V *vs.* SHE thus covering the whole oscillation region. The involvement of oxygen species in the periodic process will be discussed.

Experimental

The cell used to study the oscillation phenomena can be presented by the scheme (−)Pt/1M CH_2O, 3.75M H_2SO_4/1M CH_2O, 3.75M H_2SO_4/Pt(+). It contained a platinized platinum electrode in an anolyte consisting of 1M formaldehyde in 3.75M sulfuric acid. The electrode was placed in the center tube of a modified glass-H-cell (E. H. Sargent & Company). A dynamic hydrogen reference electrode of the type described by Giner (−26 mV *vs.* SHE) was arranged in the second leg of the cell and connected with a properly arranged Luggin capillary to the anode. The platinized platinum electrodes were made from platinum-foil (0.076 cm thickness with a geometrical cross section area of 1 cm^2). Both anode and reference electrode were platinized in a controlled manner. The third leg of the glass vessel which was separated by a fritted glass disk from the anode compartment contained a platinum counter electrode. The chemicals used to prepare the electrodes and the electrolytes were of highest purity grade commercially available. Preelectrolyzed 3.75M sulfuric acid was used as the electrolyte. All necessary connections were made with standard glass joints and purified argon gas was bubbled through the anode chamber. The temperature during experimentation was controlled with a constant temperature bath.

A precision current source (Model CS-12, North Hills, Electronics, Inc.) was used to control the current (1 μA-999 mA) between the working anode and the counterelectrode. A potentiometric recorder (Model FW 5A-3332 from Texas Instruments, Inc.) was used for measuring the stationary anode potentials and the potential transients *vs.* the reference electrode.

Different experimentation was used to study the mechanism:

(*a*) *Galvanostatic anodic stripping of adsorbed organic species with variation of the anodic stripping current.*—In the first publication we discussed adsorption-desorption experiments whereby the anodic stripping current was kept constant at 50 mA, close to the threshold current density of the oscillations to avoid anodic oxidation of the platinum surface (12). In these adsorption experiments we varied the stripping current in order to measure the pulse charge Q and the process frequency ν of periodic transients over a wider range of current densities. The following previously established procedure was followed (12). Adsorption of organic species at platinized platinum electrodes took place from 1M formaldehyde in 3.75M sulfuric acid. After adsorption the electrodes were dipped in 3.75M sulfuric acid to remove the adherent liquid and transferred immediately into the anode chamber of the cell described previously which contained in this case only 3.75M sulfuric acid as the electrolyte. A preset circuit permitted the oxidation of the absorbed organic species immediately at a preselected constant current. A defined adsorption time and defined dipping conditions, which lead to partial or complete removal of the liquid film without substantial desorption of adsorbed organic species, resulted in defined amounts of organic species at the electrode. From the potential transients observed, the amount of organics could be determined. Depending on the amount of organic species, two types of transients were found: Linear and periodic ones.

(*b*) *Galvanostatic measurements of periodic, anodic potential transients under conditions where the bulk concentration of formaldehyde in the electrolyte was controlled.*—This permitted the measurement of the potential-current density relationship over the total oscillation region, yielding data of Q, the pulse charge expressed in $\mu C/cm^2$, and the process frequency ν as a function of I, the current density, as well as of ΔV, the potential transient response.

(*c*) *Determination of the rate of the chemical reduction of platinum-oxygen species with formaldehyde.*—For that purpose platinized platinum anodes in 1M formaldehyde-3.75M sulfuric acid mixtures were treated galvanostatically. The constant current which was varied between 100 and 999 mA was interrupted when the desired upper oxidation potential was reached (0.9-1.18V *vs.* SHE). The potential transient at zero current was followed with the potentiometric recorder to the rest potential (0.1-0.2V *vs.* SHE) and compared with the corresponding transient under current. In Fig. 1 the periodic potential transients at a constant current of 400 mA are shown. τ_B is the time required for the transient under current (ΔV = 1.06 to 0.33V). The chemical reduction transient can be seen in the $i = 0$

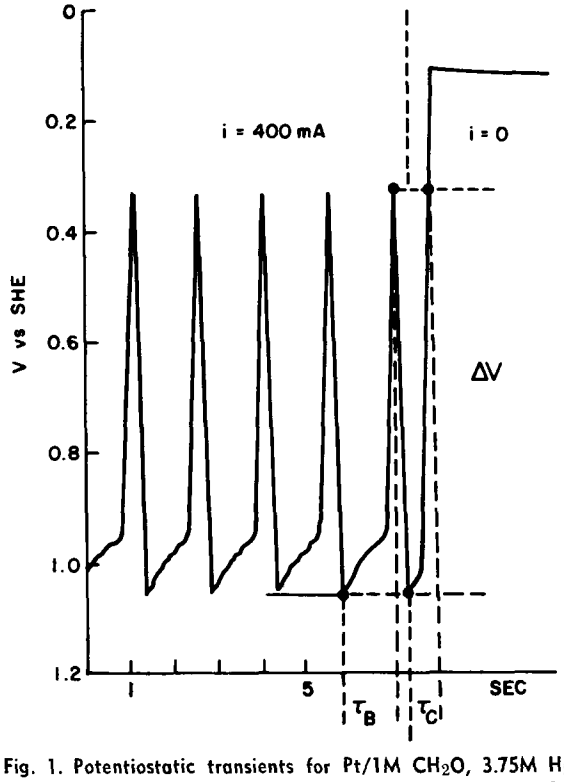

Fig. 1. Potentiostatic transients for Pt/1M CH_2O, 3.75M H_2SO_4 at 25°C. Potential measured *vs.* SHE. i =400 mA and i = 0.

region. τ_C corresponds to ΔV. The rest potential lies at about 0.12V.

(*d*) *Estimation of the real surface area of the platinum anodes.*—Before any measurements under (*a*), (*b*), or (*c*) were taken, the real surface area of the platinized platinum electrodes was determined from the anodic charging curve in sulfuric acid in accordance with established procedures (12). These procedures were based on the method used by Butler and coworkers, measuring the number of oxygen atoms deposited on the surface (13, 14). The galvanostatic anodic transients showed three regions marked by different slopes: one for the anodic oxidation of adsorbed hydrogen (0.0-0.33V *vs.* SHE), the region where charging of the double layer occurs (0.33-0.92 *vs.* SHE), and the region for build up of an oxygen monolayer (0.92-1.6V *vs.* SHE). A charge of about 420 μC/cm^2 was associated with the deposition of the oxygen monolayer (12). The length of the transient which is due to deposition of the oxygen monolayer was used to compute the area. Electrodes with real surface areas above 1000 cm^2 were used in the experimentation.

In addition, the region where charging of the double layer occurred was closely examined. From twenty transients at a constant current of 50 mA (transition time 0.95-1.6 sec), the corresponding μC/cm^2 of real surface area were computed. The double layer charging transients showed a linear relationship between potential and time. The charge Q_D between 0.33 and 0.92V *vs.* SHE was about 30 μC/cm^2. The corresponding capacitance, $C = Q_D/\Delta V$, can be computed to 51 μF/cm^2. This comes close to the double layer capacitance value reported by Schuldiner (15).

Results and Discussion

The results of (*a*) adsorption experiments with variation of the anodic stripping current are given in Table I. An adsorption time of 300 sec and a stripping current between 50 and 250 mA resulted in periodic transients. Above 250 mA linear transients were observed. The pulse charges constitute the average value over all pulsations. It is apparent from Table I that both Q and ν increase with I.

The results of (*b*) galvanostatic measurements of potential transients at constant bulk concentration of formaldehyde in the electrolyte are given in Table II.

We have found previously from adsorption-desorption experiments that the pulse charge Q close to the threshold of the oscillations is on the average 85 μC/cm^2 (range 76-94 μC/cm^2) (12). Considering the frequency dampening effect, the value observed for the very first oscillation was 46-59 μC/cm^2. This is in good agreement with the data of the first region in Table II (57-116 μC/cm^2).

Mechanisms of periodic anodic processes.—Table II can be subdivided into three regions corresponding to three different mechanisms in the periodic anodic process, discussed in more detail below.

1. *"Valve" mechanism.*—If the upper value of the potential transient remains below +0.92V *vs.* SHE no noticeable oxide formation occurs and the anodic oxidation of formaldehyde follows the "valve" mechanism path which is identical with reaction path II of the previous paper (12).

$$CH_2(OH)_{2sol} \rightarrow CH_2(OH)_{2ads} \quad (a)$$
$$CH_2(OH)_{2ads} \rightarrow A + H^+ + e^- \quad (b)$$
$$A \rightarrow B + H^+ + e^- \quad (c)$$
$$B \rightarrow C + H^+ + e^- \quad (d)$$
$$C \rightarrow CO_2 + H^+ + e^- \quad (e)$$

This mechanism postulates the stepwise anodic oxidation of formaldehyde. Step (a) is a diffusion-absorption step and steps (b) through (e) are charge transfer steps leading to anodic oxidation of organic species adsorbed during one cycle. No attempt was made in this work to determine the actual organic species which were adsorbed or oxidized. Step (e) is followed by readsorption (a), the coupling step, which is required to continue the periodic electrode process. The valve mechanism is based on the observation that adsorption of organic species becomes small at about +0.6V *vs.* SHE and above (16, 17).

It is of interest to note that there is apparently a numerical relationship between the pulse charge Q and the double layer charge Q_D of the electrode in pure sulfuric acid electrolyte. Q_D was practically zero at 0.33V *vs.* SHE and reached linearly with potential a value of 29.5 μC/cm^2 at 0.92V *vs.* SHE. Comparing Q and Q_D for any upper potential value in the region of the "valve" mechanism (0.69-0.86V *vs.* SHE) it was found that $Q_D \sim 1/4Q$ (Table III).

2. *Mixed mechanism* (valve mechanism plus anodic oxidation of platinum followed by chemical reduction of the oxide).—At current densities above 100 μA/cm^2, potential transients beyond +0.9V *vs.* SHE are observed. A second reaction path in addition to the valve mechanism accounting for the anodic oxidation of the platinum surface explains the observed increase in pulse charge Q above 100 μC/cm^2. These platinum oxygen species are formed by adsorption of water and through further anodic discharge of adsorbed OH groups (f), (g) (18, 10).

$$Pt + HOH \rightleftharpoons Pt/OH + H^+ + e^- \quad (f)$$
$$Pt/OH \rightarrow Pt/O + H^+ + e^- \quad (g)$$

Pt/O is the surface oxide formed (stoichiometric representation is purposely avoided).

* Data refer to real surface areas of electrodes $1.97 \cdot 10^3$ cm^2.
** Corresponds to about 50 mA/cm^2 geometrical cross section.

This comes close to the double layer capacitance value reported by Schuldiner (15).

It is of interest to note that there is apparently a numerical relationship between the pulse charge Q and the double layer charge Q_D of the electrode in pure sulfuric acid electrolyte. Q_D was practically zero at 0.33V *vs.* SHE and reached linearly with potential a value of 29.5 μC/cm^2 at 0.92V *vs.* SHE. Comparing Q and Q_D for any upper potential value in the region of the "valve" mechanism (0.69-0.86V *vs.* SHE) it was found that $Q_D \sim 1/4Q$ (Table III).

Table III. Comparison of pulse charge Q with Q_D

116	0.69	18
68	0.75	21
57	0.80	24
63	0.81	24
73	0.82	25
102	0.84	26
109	0.86	27

This is followed by chemical reduction of the platinum oxygen species by formaldehyde which explains the reverse of the anodic transient to less positive potentials (h) (10, 19).

$$Pt/O + 1/2CH_2O \rightarrow 1/2CO_2 + 1/2H_2O + Pt \quad (h)$$

The chemical reduction prepares the electrode for the coupling step, the readsorption of formaldehyde at the oxide free platinum surface at less positive potentials through step (a).

In order to find some proof for oxide reduction reaction (h), the rate of the chemical reduction of the platinum-oxygen species with formaldehyde was measured and compared with that of the anodic back transient. The results are shown in Table IV.

It can be seen that the time τ_C required to reach the same end potential from a defined starting potential by the chemical reduction reaction is always smaller than the time required for the back transient at current under otherwise equivalent constant current conditions. Thus it appears possible that chemical reduction of platinum oxide can occur with a sufficiently fast rate during the anodic back transient. The pulse charge Q at 600 $\mu A/cm^2$ is 300 $\mu C/cm^2$. Thus the anodic and cathodic short circuit current densities during the chemical reaction amount to 2000 $\mu A/cm^2$.

If we relate the Q values of Table II to surface coverages we come up with the following picture. Surface coverage estimates for formaldehyde and oxygen yield both about 420 $\mu C/cm^2$ for a 4 $e^-/2$ site attachment ratio at full coverage (12). In the following we use Pt as the symbol of a platinum site (surface atom) and $\Sigma \circledcirc$ to characterize the coverage. The chemisorption of formaldehyde is probably dissociative (i).

$$2Pt + CH_2O \rightarrow Pt \cdot CHO + Pt \cdot H \qquad \Sigma \circledcirc \sim 0.2 \quad (i)$$

Dissociative chemisorption is a well-established fact in the case of saturated hydrocarbons on transition metals (20). A saturated ad-layer of 180 $\mu C/cm^2$ found experimentally would mean a 43% organic coverage of the platinum surface. The average pulse charge of 85 $\mu C/cm^2$ indicates an initial coverage of about 20%, a half depleted ad-layer (12). The rest of the surface is available for other species. In accordance with the stoichiometry of the valve mechanism we can consider another adsorption step, the dissociative chemisorption of water in the presence of adsorbed organic species (j).

$$Pt \cdot CHO + 2Pt + HOH \rightarrow Pt \cdot CHO + Pt \cdot OH + Pt \cdot H \qquad \Sigma \circledcirc \sim 0.3 \quad (j)$$

With respect to adsorbed OH groups it was found in water adsorption experiments on platinum that about $6.8 \cdot 10^{14}$ water molecules are strongly adsorbed per square centimeter of real surface area (21, 22). This suggests that one water molecule attaches to two platinum sites. This chemisorption mechanism of water has been discussed by Bond (23). Equation (j) gives the maximum coverage of the electrode with reactants during one oscillation cycle as required by the stoichiometry of the valve mechanism. Thus we can see that there will always be available a minimum of 70% of the platinum surface for other occupants. Expressed in $\mu C/cm^2$ corresponding to oxide formation, this 70% rest amounts to 294 $\mu C/cm^2$. From Table II it can be noted that a maximum value of the pulse charge of 387 $\mu C/cm^2$ was measured which accounts at the given upper potential (1.1V *vs.* SHE) for both oxidation of organics and oxide formation. Considering the average value of Q for oxidation of organics (85 $\mu C/cm^2$), oxide coverage build up over one cycle at 1.1V *vs.* SHE reaches about 302 $\mu C/cm^2$. This is in good agreement with the theoretical value above for oxide formation (294 $\mu C/cm^2$), assuming a mixed mechanism.

* Data refer to real surface areas of electrodes.

3. *Oxide formation-reduction mechanism* (anodic platinum oxide formation followed by chemical reduction with formaldehyde).—In Fig. 2 the pulse charges expressed in $\mu C/cm^2$ are shown as a function of the current density. Data are from adsorption experiments, from experiments with constant bulk concentration, and from chemical reduction experiments.

The decrease in pulse charge Q (Fig. 2) above 400 $\mu A/cm^2$ can be explained by strongly diminished adsorption of organic species above +0.6V *vs.* SHE. The average value of $\overline{Q}_{org}$ of 85 $\mu C/cm^2$ agrees well with the experimentally observed drop of 96 $\mu C/cm^2$. Transients above 400 $\mu A/cm^2$ are therefore probably due purely to the formation of an oxide layer followed by chemical reduction with formaldehyde in accordance with reactions (f) through (h). Using the previous coverage data the surface oxide build-up during one cycle corresponds approximately to the composition $Pt_2O_{1.5}$.

Frequency-current density relationship.—The frequency-current density relationship was derived from experimental data such as in Table I and Table II. The relationship is nonlinear. Equation [1], which was found at first empirically, but could be derived later on basis of the mechanism, describes the relationship

$$\nu = k \cdot I \cdot \frac{Q_{org}}{Q_{org} + Q_{ox}} \quad [1]$$

The frequency ν is proportional to the anodic current density I. The deviation from initial linearity is given through the ratio $Q_{org}/Q_{org} + Q_{ox}$ (last column in Table II). Q_{org} is the pulse charge due to oxidation of the formaldehyde in accordance with the value mechanism and Q_{ox} that due to anodic oxidation of the platinum surface.

In Fig. 3 the frequency-current density relationship is shown. Data are from the experiments described previously. The frequency data from the adsorption experiments are slightly lower since they constitute averaged values and consider the frequency dampening effect observed for the pulses with higher order (12).

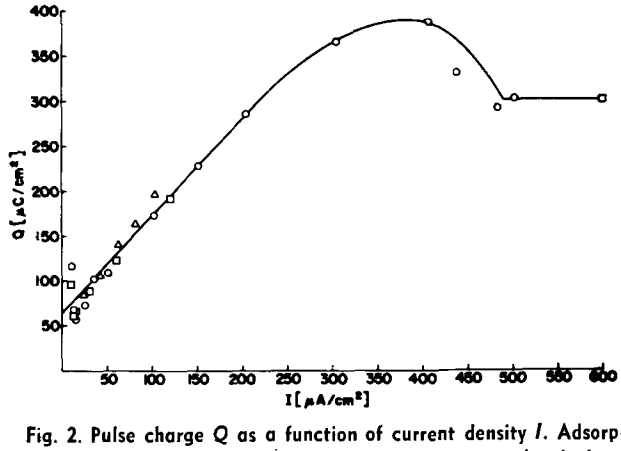

Fig. 2. Pulse charge Q as a function of current density I. Adsorption experiments △; constant bulk concentration ⊙; chemical reduction experiments ⊡.

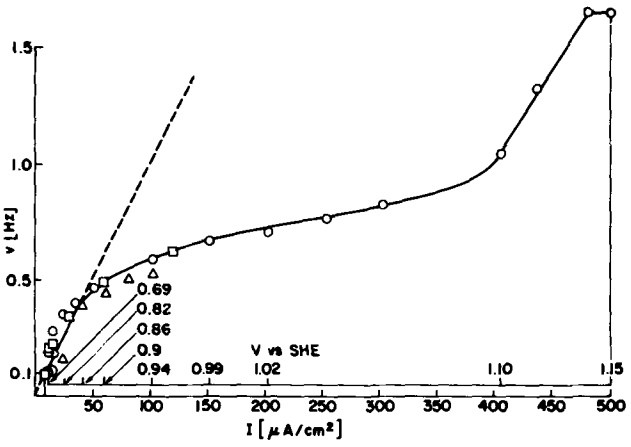

Fig. 3. Frequency-current density relationship. Adsorption experiments △; constant bulk concentration ⊙; chemical reduction experiments ⊡.

It has been observed previously that an initial linear region can be found up to about 0.5 Hz (24). This is followed by a region of deviations from the initial slope. Finally there is again a linear rise up to the limiting frequency of 1.66 Hz for the given anolyte composition and temperature.

In the initial linear region the valve mechanism prevails. There the frequency is directly proportional to the current density [2].

$$\nu = k \cdot I = k \cdot I_{org} \qquad [2]$$

Above +0.92V the formation of surface oxides in an additional reaction path to the valve mechanism has to be taken into account in the frequency computation. Since the time period τ_a for one cycle exceeding 0.92V accounts for both, the anodic oxidation of the adsorbed organic species plus the formation of the oxide, we can write [3]

$$\tau_a = \tau_{org} + \tau_{ox} \qquad [3]$$

If we compare the oxide build up at various current densities, a value of $\overline{Q}_{org} = 85\ \mu C/cm^2$ can be taken as the point of practical zero oxide coverage. If no oxides were formed, the same amount of formaldehyde adsorbed at the electrode should become oxidized twice as fast if the current density were doubled. Thus if no increase in τ is caused by an additional reaction, the frequency would be directly proportional to the current density [2]. It would be identical in this case with I_{org}, the anodic organic oxidation current density. By expanding the equation with $(I_{org} + I_{ox})$ thus taking an additional path in account we obtain [4].

$$\nu = k\ (I_{org} + I_{ox})\ \frac{I_{org}}{(I_{org} + I_{ox})} \qquad [4]$$

Multiplying Eq. [4] with the anodic transient time for one cycle we obtain [5].

$$\nu = k\ (I_{org} + I_{ox})\ \frac{\tau_a I_{org}}{\tau_a I_{org} + \tau_a I_{ox}} \qquad [5]$$

There are two ways open to relate the coulombs Q_x for anodic oxidation of a specie x to the current density and transient time [6] [7]

$$Q_x = I_a \tau_x \qquad [6]$$

$$Q_x = I_x \tau_a \qquad [7]$$

Combining Eq. [5] with Eq. [7] leads to [8]

$$\nu = k\ (I_{org} + I_{ox})\ \frac{Q_{org}}{Q_{org} + Q_{ox}} \qquad [8]$$

Since $(I_{org} + I_{ox})$ is the total anodic current density we obtain our original Eq. [1] which describes the second part of the $\nu - I$ curve with its deviation from the original slope up to about 1 Hz. Deviation from linearity is found if $Q_{org}/Q_{org} + Q_{ox} < 1$ and $\neq$ const with I, which is the experimental case.

The third region of the $\nu - I$ curve is again linear. It appears that this region falls together with that of oxide formation and chemical reduction of the oxides with formaldehyde. The oscillations are caused by the counterplay between oxide formation and reduction and are mass transport controlled. Turbulence in the electrolyte layer next to the electrode is created through the vigorous evolution of carbon dioxide. This leads to periodic changes in the thickness of the mass transport boundary layer. The frequency of such oscillations can be estimated by forming the ratio of the transport coefficient D of the specie which is controlling to the square of the thickness of the mass transport boundary layer ζ [9] (25).

$$\nu = 2D/\zeta^2 \qquad [9]$$

For a mass transport coefficient of 10^{-5} for CH_2O and a boundary layer thickness of $3.46 \cdot 10^{-3}$, a limiting frequency of 1.66 Hz can be computed. A further increase in frequency can be expected if mass transport is enhanced. This can be done by raising the temperature. At 90°C the frequency was about 10 Hz with full stability of the oscillations (ΔV = 0.74-0.77V). The frequency limitation of the half element lies around 15 Hz, due to diminishing amplitude ($\Delta V \rightarrow 0$).

The Reaction of Titanium(IV) with Hydrogen at Palladium Membranes

Thomas C. Franklin* and J. Albert McDaniel[1]**

Chemistry Department, Baylor University, Waco, Texas

ABSTRACT

A colorimetric study was made of the kinetics of the reduction of acidic titanium(IV) chloride solutions by hydrogen diffusing through a palladium membrane. The rate of this reaction was found to be first order with respect to the concentration of the titanium and was inhibited by the addition of organic poisons. The inhibition followed an adsorption isotherm leading to the conclusion that the rate of the reaction was controlled either by adsorption of titanium(IV) or by a reaction involving an adsorbed titanium(IV) species.

A number of studies have been made of the migration of electrolytically generated hydrogen through palladium membranes (1-3) and the reaction of previously hydrided palladium (4-8) with oxidizing agents. Castellan (9) has studied the reaction of cerium(IV) with hydrogen diffusing through palladium membranes. In most of the studies with oxidizing agents, it was concluded that the rate-determining step was the diffusion of the oxidizing agent to the hydrided surface (6, 9). If this is the rate-determining step, the addition of poisons should have no effect on the rate of the reaction; therefore, a study was initiated to determine whether poisons did affect the rate of reduction of titanium(IV) by hydrogen diffusing through a palladium membrane.

Experimental Methods and Procedures

Figure 1 shows the cell used. Hydrogen was electrolytically generated from the 2*N* sulfuric acid on the interior wall of the palladium tube and then diffused through the palladium to the exterior wall. The exposed palladium tube was 11 cm long and approximately 5 mm in diameter. In the exterior chamber the hydrogen diffusing out reacted with titanium(IV) reducing it to colored titanium(III). The rate of the chemical reduction was followed by pulling samples of the solution and analyzing them spectrophotometrically for titanium(III).

At the same time the potential of the exterior of the palladium was measured against a reference calomel electrode using a Luggin capillary.

The exterior solution was a 30% sulfuric acid solution which in different experiments contained different amounts of titanium(IV). The solution was stirred by bubbling with nitrogen. The exterior of the palladium tube was palladized lightly between each series of runs.

Hydrogen was generated on the interior at 67.39 mA until the potential measured between the exterior of the assembly and the saturated calomel electrode became constant. A measured quantity of a titanium(IV) stock solution, prepared by adding titanium(IV) chloride to 30% sulfuric acid, was added to the reaction vessel. Then at 1 or 2 min intervals the potential of the outside of the palladium electrode was measured, and a sample was removed and analyzed spectrophotometrically for titanium(III). After each analysis, the sample was returned to the cell. At no time did the volume of added solutions or removed samples exceed 2% of the total volume. Thus, the addition or removal of solution did not appreciably alter the rate of reaction. After about 14 min a measured amount of an organic additive was rapidly injected into the solution, and the progress of the reaction was followed for another period of time; at regular time intervals additional amounts of additive were introduced into the solution. The additives studied were sodium 2-propene-1-sulfonate, thiourea, 1, 3-diethyl-2-thiourea, 1-ethylquinolinium iodide, and sodium 2-propanesulfonate. All experiments were performed at 25°C using the purest grade of chemicals commercially available.

Results and Discussion of Results

Figure 2 shows typical data for the initial rate of reaction with two different concentrations of titanium (IV), one twice that of the other. As can be seen, the initial rate of reduction at the higher concentration is approximately double that of the lower concentration, showing that the reaction is first order with respect to titanium(IV). The average first order rate constant obtained for 29 different runs was 2.02 x 10^{-3} min^{-1} with a standard deviation of ± 0.30 x 10^{-3}. As seen in Fig. 2, the deviation was small when the only change was a change in the concentration of titanium(IV). The observed deviations were attributed primarily to a lack of reproducibility of the palladized surface.

The fact that the reaction is first order with respect to the titanium(IV) is in agreement with other studies on different oxidizing agents (5, 6, 9). In these studies the first order kinetics was attributed to a diffusion limited process. However, in this study changing the rate of stirring by changing the nitrogen bubbling rate did not appreciably alter the rate of the reac-

tion which was contrary to what was expected if the rate was controlled by the rate of diffusion of the titanium(IV).

Much more damaging to the concept of a diffusion controlled process was the effect of poisons on the rate of the reaction. Figure 3 shows the effect of 1, 3 diethyl-2-thiourea on the rate of reduction. Each organic additive tried gave similar results in that the addition of the organic compound decreased the rate of the reaction. This shows that the rate-determining step involves neither the diffusion of hydrogen through the metal nor diffusion of titanium(IV) to the surface. Diffusion processes depend on the geometrical surface area and not the real surface area (10).

From the poisoning data, it was concluded that the rate of the reaction was a function of the real area and that the poison blocked the surface area. That the poison is being adsorbed on the electrode is indicated by examining the effect of different concentrations of additive on the rate of reduction. Unfortunately, one can introduce only two concentrations of an additive such as thiourea before the electrodes become almost completely poisoned, but it can be seen in Fig. 4 that the effect looks very much like an adsorption isotherm. In the case of the propenesulfonate, a number of different concentrations can be used, and it can be seen in Fig. 5 that one can fit the data to a Freundlich-type adsorption isotherm.

It is possible that the poison could act by decreasing the amount of adsorbed hydrogen. The potential of the electrode should be a measure of the amount of hydrogen (11, 12) in the neighborhood of the electrode surface. Figure 6 shows definitely that the potential decreases sharply after the introduction of the titanium(IV) indicating that the rate of diffusion

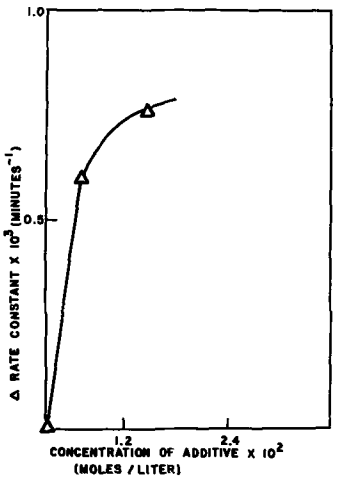

Fig. 4. Apparent adsorption isotherm from rate data for the additive thiourea.

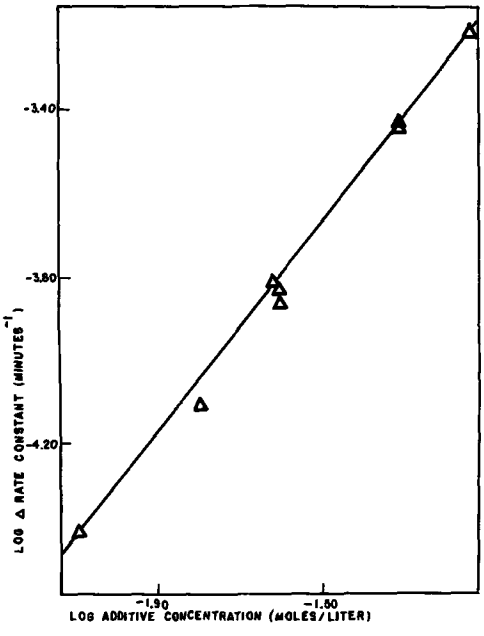

Fig. 5. Freundlich isotherm for the additive sodium 2-propenesulfonate.

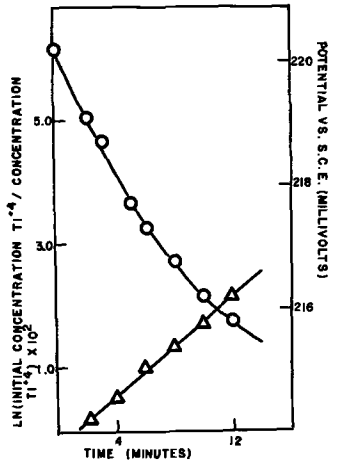

Fig. 6. Potential-time (○) and first order rate constant plots (△) for the reduction of titanium(IV) with hydrogen.

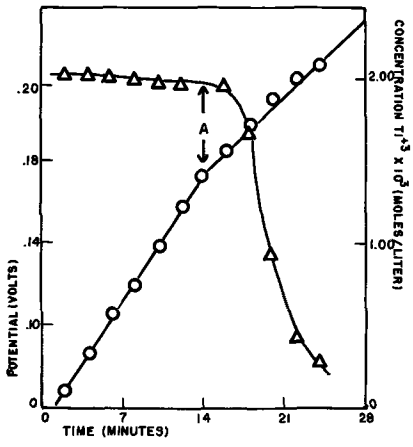

Fig. 7. Effect of 1-ethylquinolinium on the rate of reaction and potential change. A, Time of addition of ethyl quinolinium iodide; △, potential; ⊙ concentration of titanium(III).

of hydrogen is not as rapid as the rate of reaction of the hydrogen with titanium. Eventually, the potential approaches a limiting value indicating a new steady-state condition for the adsorbed hydrogen. During this entire process, however, the rate of reaction is constant. This effect is much more pronounced in the presence of additives (Fig. 7). In the presence of thiourea, 1-ethylquinolinium iodide and 1, 3 diethyl-2-thiourea the rate of reaction stayed constant while the potential changed approximately 0.1V. This indicates first of all that under the conditions of these experiments the rate of the reaction is independent of the electrode potential and, second, that it is independent of the amount of hydrogen at the surface.

A generalized mechanism for this process could be written as follows:

$$H_{\text{evolution side}} \rightarrow H_{\text{metal}} \rightarrow H_{\text{reaction side}} \quad \text{(A)}$$

$$Ti(IV)_{\text{soln}} \rightarrow Ti(IV)_{\text{electrode}} \quad \text{Diffusion} \quad \text{(B)}$$

$$Ti(IV)_{\text{electrode}} \rightarrow Ti(IV)_{\text{adsorbed}} \quad \text{Adsorption} \quad \text{(C)}$$

$$Ti(IV)_{\text{adsorbed}} \rightarrow Ti^*(IV)_{\text{adsorbed}} \quad \text{Rearrangement} \quad \text{(D)}$$

$$Ti(IV) \text{ or } Ti^*(IV) + H_{\text{reaction side}} \rightarrow \text{Products} \quad \text{(E)}$$

It would appear from the poisoning data that neither reactions (A) or (B) can be rate determining. Since the rate of reaction was independent of the potential, no electron transfer step was included in the mechanism. Also, since the potential depends on the amount of hydrogen at the surface, reaction (E) was regarded as being nonrate determining. Reaction (E), of course, since it is beyond the rate-determining step, could easily be made up of a series of electron transfer steps.

It was thus concluded that either reaction (C), the adsorption of the Ti(IV) complex, or (D), the rearrangement of the complex to some more reactive form, was thus concluded to be the rate-determining step.

The Mechanism of Oxygen Evolution on Nickel, Platinum, and Other Metals and Alloys

Robert F. Scarr*

Union Carbide Corporation, Consumer Products Division, Research Laboratory, Cleveland, Ohio

ABSTRACT

The oxygen evolution reaction in 1M KOH has been studied by low speed linear sweep voltammetry of several metals including: Ni, Pt, Co, Fe, NiFe, NiPt, and Ni_3Pt. The Tafel slope for all these metals at early stages of the oxygen evolution wave was found to be about 46 mV/dec. For nickel and its alloys, dual Tafel regions were observed wherein, at even lower current densities, the slope was 34 mV/dec. A recently proposed theory for interpreting Tafel slopes is applied to these results, and a mechanism involving a three-step formation of adsorbed hydrogen peroxide is given. The exchange current density for several of these steps is evaluated, and the results are found to be consistent with the properties of the metals.

The process of oxygen evolution has been studied extensively over the years to the point where there seems to be general agreement on certain aspects of the reaction (1). For example, the rate-determining step (rds) is usually accepted as being the electrochemical adsorption of hydroxide radical, while the substrate is suspected of playing more than just a passive role. There is enough disparity in the results, however, to forestall general acceptance of a more detailed understanding of oxygen evolution.

In order to study this reaction, investigators have used, for the most part, steady-state galvanostatic or potentiostatic techniques to measure kinetic param-

* Electrochemical Society Active Member.

Key words: oxygen evolution mechanism; oxygen evolution on nickel, platinum, and alloys; potential sweep of oxygen evolution.

eters, and high-speed linear sweep voltammetry to characterize the electrode surface. Each of these techniques is applicable to only a limited aspect of the entire problem. In order to obtain further information, one must study the reaction under somewhat different experimental conditions, either at very short times or at very low currents where ultimate conditions do not yet prevail.

One technique which may offer some advantages is linear sweep voltammetry (LSV) at low sweep rates. At scan speeds between 0.2 and 100 mV/sec, the electrode can be investigated both at low currents and at stages early in the chronology of electrode surface change. At these sweep rates, nonfaradaic double layer charging currents are negligible, although care must be taken to ascertain the influence of convective forces.

This paper describes a study of oxygen evolution in alkaline electrolyte using LSV on several metals including nickel, platinum, cobalt, iron, and three alloys of nickel corresponding to NiFe, NiPt, and Ni_3Pt.

Experimental

Apparatus and materials.—The cell for this investigation was a three-compartment cell, about 100 ml in total volume, made from Lucite plastic which had been leached with caustic for several years prior to use. Nickel foil counterelectrodes were placed in each of the two outer compartments. The test electrode and reference electrodes were contained in the center section. The reference electrode was situated aside and in the plane of the test electrode, and about 1 mm away at its closest point. The center compartment was isolated from the counterelectrode compartments by separators of fine mesh Teflon gauze whose purpose was to minimize convective transfer of counterelectrode reaction products. The chamber above the electrolyte surface was continually flushed with deoxygenated nitrogen. Although the cell materials may normally be regarded as a source of contaminants, their influence on the electrode reaction was diminished by frequent changes of electrolyte. Due to the nature of the experimental procedure and in view of the reproducibility of results, the effect of impurities is considered to be negligible in this work.

Test electrodes were made from spectrographically pure metal obtained from Johnson and Matthey, Ltd. Single metal electrodes were used in the form of wire, foil, or rods. Parts of these electrodes which were not intended to contact the electrolyte were coated with several protective layers of Miccrotex masking lacquer from Michigan Chemical Corporation. Alloy samples, which were produced in the form of large beads, were made into electrodes by trimming the bead to the desired shape, attaching a current collector wire with silver epoxy, and then potting the bead in epoxy resin. The final finish was achieved by polishing with 600 grit silicon carbide paper. Apparent area of all electrodes was controlled and known. The surfaces of the foil electrodes were mounted vertically in the cell while those of the alloy beads were horizontal.

The reference electrode for all measurements was mercury-mercuric oxide. All potentials given in this paper are reported with respect to this electrode. The electrolyte was 1M KOH which had been preelectrolyzed under nitrogen between a nickel anode and a mercury pool cathode of about 3 cm^2. Preelectrolysis was conducted at controlled current while the solution was agitated by the nitrogen stream. As the potential of the cathode became increasingly negative, the magnitude of the current was progressively reduced from 2 mA/cm^2 toward the final stage, an overnight run at 2 $\mu A/cm^2$. The potential of the mercury pool during this period approached —1.2V *vs.* mercury-mercuric oxide. Teflon vessels were used for preparation and storage of the electrolyte.

The potential of the test electrode in the linear sweep experiments was controlled with a Wenking potentiostat. The sweep signal was electronically synthesized using conventional operational amplifier circuitry. Current-voltage curves were recorded on an Electro Instruments Model 520 X-Y recorder.

Alloys were made from mixtures of spectrographic grade wire or metal powder which were fused in magnesia crucibles under argon in an induction furnace. The stoichiometric composition of the alloys corresponded to NiPt, Ni_3Pt, and NiFe. Nickel is continuously soluble in platinum or iron, with no compound formation. Some "ordering" in the solid structure is believed to occur in the nickel-platinum alloys at the particular atomic ratios used (2). As a consequence of using induction heating, sample beads were quite homogeneous due to agitation by eddy currents. At the conclusion of the heating period, such rapid cooling occurred as to essentially quench the melt, thus preserving uniformity. Metallographic examination of the specimens revealed quite homogeneous surface composition with rather large grain size.

Procedure.—At the beginning of the experimental investigation of each metal, the electrode was scrubbed with Alconox detergent, rinsed thoroughly with distilled water, and placed in the cell. After the potential had become reasonably stable on open circuit, an anodic linear sweep voltamogram was obtained at 1 mV/sec beginning at the open-circuit potential and sweeping (forward) toward more positive potentials. At this slow sweep rate, the characteristic peaks, if any, for the oxidation of the metal would appear followed by the onset of oxygen evolution. Thereafter, during forward and reverse sweep cycling, the potential was never carried more negative than the foot of the anodic oxygen wave, that is, about 0.4V. An exception to this procedure occurred with the nickel electrode where the negative extreme was 0.2V. It was expected that this measure would render the surface of the electrode fairly stable and reproducible with respect to the formation of metal oxides themselves.

At the termination of each forward half-cycle, the potential was held only a few seconds in the oxygen evolution region before reversing the sweep. At the conclusion of the reverse sweep, the potential was held at the foot of the oxygen wave for longer periods of time, *i. e.*, at least 10 min. Additional sweeps were made at other scan rates between 0.2 and 100 mV/sec. Consecutive runs at each sweep speed showed the current-voltage curves to be reproducible.

Results and Discussion

A typical linear sweep voltamogram for nickel metal is given in Fig. 1. This plot was obtained at 1 mV/sec, and it shows both the forward and reverse sweeps. The peak for the oxidation of the substrate is quite prominent and is limited to a narrow range of potential preceding oxygen evolution. The evolution of oxygen was visually confirmed at potentials positive to 0.55V. The featureless increase in current at potentials positive to 0.55V and the near coincidence of forward and reverse sweeps in the oxygen evolution region indicate that (*a*) the nature of the surface has remained unchanged during gassing, and (*b*) the oxygen evolution reaction is at least momentarily at steady state.

The area of the electrode did increase from cycle to cycle, however, due to oxidation of the metal in the region of the peak. This effect was evaluated at fixed sweep rate in two ways which yielded roughly the same results. First, the area under the nickel oxidation peak was measured graphically and found to increase about 5% per cycle. Second, the current at a given potential in the oxygen evolution region also increased at nearly 5% per cycle.

Typical sweeps at each sweep rate in the positive direction are plotted on a semilogarithmic scale in Fig. 2. The combined ohmic resistance of the electrode and the solution was of the order of 1 ohm; measured

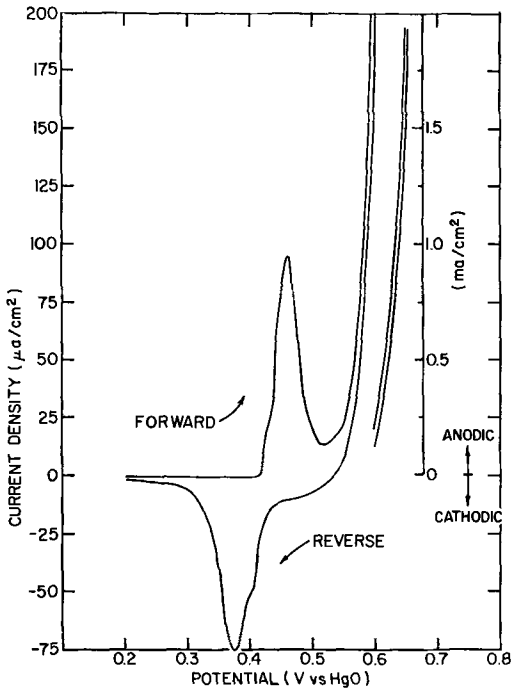

Fig. 1. Typical linear sweep voltamogram of nickel metal in 1M KOH taken at 1 mV/sec scan rate.

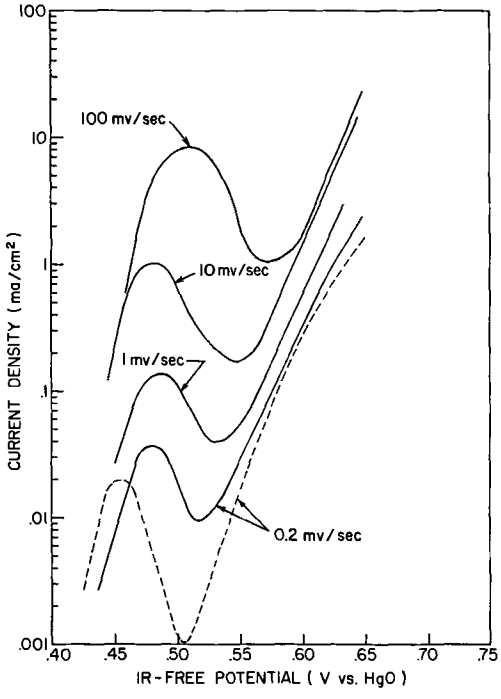

Fig. 2. Linear sweep voltamograms of nickel metal at various scan rates. Slope of the Tafel region for solid curves is 45 ± 2 mV/dec; that for the dashed curve is 34 mV/dec. In ascending order, the solid curves represent the 17th, 16th, 10th, and 11th cycles, respectively. The dashed curve is for the 7th cycle of another electrode.

potentials were corrected graphically for ohmic drop. In the oxygen evolution region, the log plots for all sweep rates exhibit a linear section whose slope ($d\eta/d \log i$) is 45 ± 2 mV/dec. The effect of stirring was investigated by bubbling nitrogen through the cell. In the region of the linear log plot, stirring had a noticeable effect on the magnitude of the current, indicating some dependence on mass transport, but the slopes of the current-voltage curves were unaffected. The existence of a linear section indicates that the electron transfer process is rate controlling.

At potentials higher than those shown, the current is no longer linear with potential due to the onset of some other limiting process, possibly mass transport, increasing ohmic polarization, or attainment of limiting coverage by the particular rate-determining intermediate. Of the several nickel electrodes used in this study, there was one for which the nickel oxidation peak was small enough and sufficiently separated from oxygen evolution so that very small currents could be detected in the interjacent region. In this one case, a second linear section was found. This region, as is shown by the dashed line in Fig. 2, had a slope of 34 mV/dec. With repeated cycling, as the surface gradually changed, the voltamograms of this electrode became more like the other electrodes.

In the linear region, the differences in current at a given potential are not wholly accounted for by area changes, but are to a great extent dependent on sweep rate below 10 mV/sec. The dependence of current as a function of potential and sweep rate has been discussed by Srinivasan and Gileadi (3) for both reversible and irreversible first order processes where an insoluble product is formed. Their findings are applicable in the present case as the reaction step under consideration will be shown later to be pseudo-first order. According to their analysis, when current at a given potential is dependent on sweep rate, the rate-controlling process may be considered to have some kinetic reversibility. By the same token, at sweep rates above 10 mV/sec, the reaction is found to be irreversible since the current becomes dependent on potential alone. Under these conditions, the exchange current for the rds may be evaluated by extrapolation of the customary log plot to the equilibrium potential.

The same experimental procedure was repeated with platinum metal. Except for the first sweep which began at the initial open-circuit potential of −0.03V, the platinum electrode was never carried more negative than 0.4V. At low sweep rates, a shoulder often appeared at about 0.75V in both forward and reverse sweeps such as those shown in Fig. 3. This voltamogram was obtained at 0.2 mV/sec and constitutes the fourth cycle for that electrode. This shoulder might be considered an indication of further platinum oxide formation. At these potentials and at this point in treatment, however, the electrode should be fully covered with PtO_2. There is some evidence in the literature for even higher oxides of platinum (1),

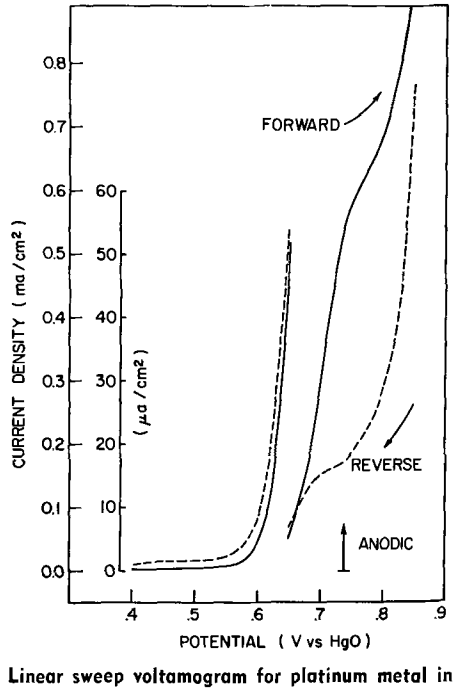

Fig. 3. Linear sweep voltamogram for platinum metal in 1M KOH taken at 0.2 mV/sec scan rate.

but these species are unstable with respect to oxygen evolution in aqueous systems. If platinum is indeed oxidized beyond PtO_2, such species might well be regarded as metastable intermediates in the process of oxygen evolution. In any case, it would be difficult to make even a conceptual distinction between higher oxide formation and oxygen evolution intermediates.

An even more pertinent argument against the oxide theory may lie in quantitative considerations. The quantity of charge represented by the shoulder, over and above an imaginary base line for oxygen evolution, is at least an order of magnitude greater than that expected for oxide formation. Such behavior can only be explained by continual removal of the reaction product as in the case of an intermediate in the oxygen evolution process.

In view of the foregoing, the shoulder is regarded as the attainment of its limiting rate by an oxygen evolution reaction step whose linear region immediately precedes the shoulder. This hypothesis is substantiated by the marked change, in contrast to nickel, in the current between forward and reverse sweeps. Growth of the electrode area, as estimated by changes in current from cycle to cycle under otherwise identical conditions, amounted to about 5% per cycle.

Typical voltamograms at several sweep rates are given on a semilogarithmic scale in Fig. 4. With the exception of the sweep at 100 mV/sec, the slope of the linear region is 48 ± 2 mV/dec, a value very close to that for nickel. The slope for the 100 mV/sec sweeps is 68 mV/dec, but a small peak due to oxidation of the substrate appears to overlap this region. The voltamograms shown are not corrected for the change in area but represent the 4th, 15th, 18th, and 19th cycles in order of increasing sweep rate. Again, the differences in the linear regions are not wholly accounted for by area change.

Several other metals also showed Tafel slopes of approximately 46 mV including cobalt, iron, and all three nickel alloys. In addition, at slow sweep rates, both of the nickel-platinum alloys exhibited at low currents a second Tafel region with a slope of 35 ± 2 mV/dec. This dual linear region is illustrated in Fig. 5 for NiPt at 0.2 mV/sec. Such behavior is in agreement with that observed in the earlier instance with nickel metal.

In accordance with the treatment of Damjanovic *et al.* (4), the existence of a dual linear log plot may be interpreted to indicate a change in the rate-determining step within a single reaction path. Dual linear regions have been reported by other investigators using galvanostatic techniques for platinum as well as other noble metals. In the case of platinum, the usually reported values of $d\eta/d \log i$ are about 60 mV/dec (5) or both 60 and 115 mV/dec (4). Values in the vicinity of 45 mV/dec such as those found in the present investigation have not been previously reported for platinum but were obtained for rhodium, iridium, and a Pt-Rh alloy by Damjanovic *et al.* (6). Similar values for nickel have been reported by Lukovtsev and Malandin (7), and by Sato and Okamoto (8) in sulfate electrolyte at high *p*H.

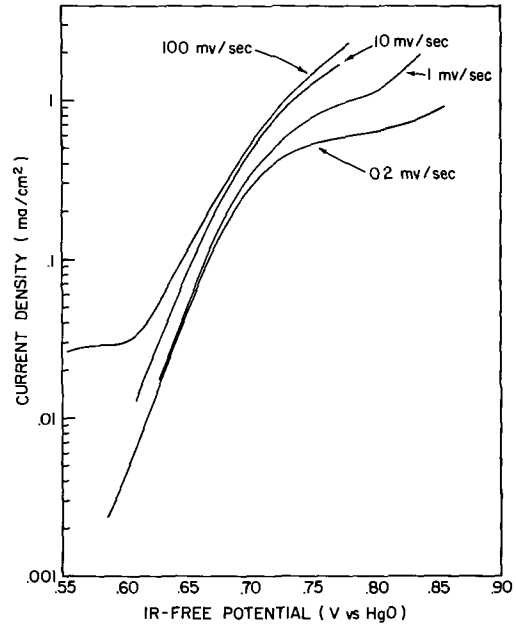

Fig. 4. Linear sweep voltamograms of platinum metal at various scan rates. Slope of the Tafel region for all but the 100 mV/sec curve is 48 ± + mV/dec.

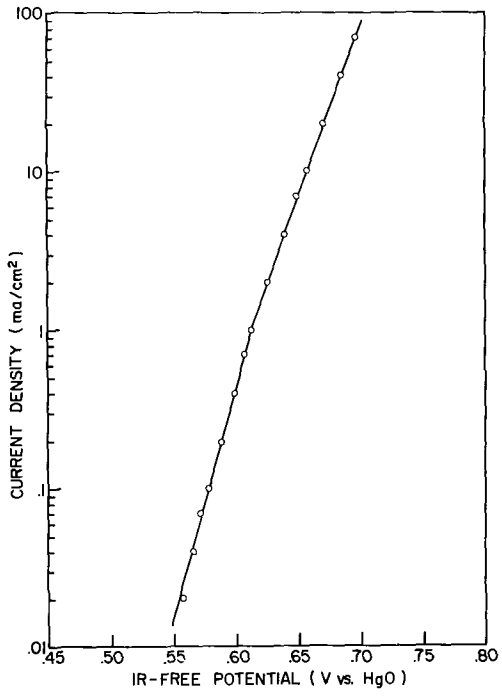

Fig. 5. Linear sweep voltamogram for NiPt alloy in 1M KOH taken at 0.2 mV/sec scan rate.

Current voltage curves obtained at constant current represent the steady state; consequently, the electrode surface has achieved the ultimate coverage of adsorbed intermediates. Linear sweep voltammetry, on the other hand, is essentially a relaxation technique, and it reflects the electrode behavior before the reaction intermediates have achieved their final distribution. The rate-determining steps under these circumstances are associated with the formation of a set of intermediates earlier in the reaction sequence than for the steady-state case. Thus, present and literature values of $d\eta/d \log i$ for platinum can be expected to be different. Had the sweep continued without encountering limiting conditions or at higher sweep rates (hence higher initial currents), a slope of 120 mV/dec would be expected. The difference between the sweeps at 10 and 100 mV/dec for platinum indicate the initial stages of the case where a different rds becomes effective.

Taking into account the value $2.3RT/\mathbf{F} = \rho$ for the present experimental conditions (58.7 mV), $d\eta/d \log i$ for the two linear log current regions may be expressed as $4\rho/7$ and $4\rho/5$ for the lower and upper overvoltage regions, respectively. The equation customarily used to predict Tafel slopes has been given by several authors (4, 5, 9) as

$$b_a = \frac{\nu}{n_p + (1 - \alpha) \cdot n_r} \cdot \rho \qquad [1]$$

where b_a is the anodic Tafel slope,
ν, the stoichiometric number,

α, the cathodic transfer coefficient,
n_p, the number of electrons transferred prior to the rds and,
n_r, the number of electrons transferred during the rds.

It can be shown that, if α is assigned the usual value of 0.5, it is impossible to obtain values of $4\rho/5$ or $4\rho/7$ using this expression. For example, if $\nu = 2$, then n_r must be an even number; therefore, the term $(1 - \alpha) \cdot n_r$ cannot be fractional. Thus the observed Tafel slope cannot be explained by Eq. [1].

McDonald and Conway (10), who obtained a value of $4\rho/5$ for gold electrodes in KOH electrolyte, have interpreted their findings on the basis of a twin barrier model. Here, the formation of an ohmic film alters the potential distribution at the electrode surface so that only a part (one-half) of the applied potential is effective in charge transfer. This theory cannot be applied to platinum since ohmic films are not known to form on this metal.

Gnanamuthu and Petrocelli (9) have recently proposed a similar theory which considers the effect of the potential gradient on reaction intermediates as a consequence of their position in the interfacial region. The potential between the metal and the bulk of the solution is considered to be divided into two regions at the inner Helmholtz plane where reside adsorbed reaction intermediates. In cases where these adsorbed intermediates are involved in charge transfer with either the electrode or the bulk alone, they are acted upon only by that portion of the potential associated with the respective region. As a first approximation it is assumed that the inner Helmholtz plane marks the halfway point in the potential gradient, hence the fraction of the total potential applicable to either region is one-half.

The following expression has been given for this theory

$$b_a = \frac{\nu}{\Sigma_i Z_i f_i + (1 - \alpha) Z_r f_r} \cdot \rho \qquad [2]$$

where Z_i is the number of charges transferred in a given step prior to rds,
f_i, the fraction of the total potential difference which is effective in the ith charge transfer.
Z_r and f_r, which refer to the rds, have meanings similar to their counterparts above.

Tafel slopes calculated using this equation will be referred to as "corrected" values.

Consider the generalized electrode process (M = metal electrode)

$$1.\ M + A^- \rightarrow MA + e^-$$

$$2.\ MA + A^- \rightarrow MB^-$$

in which an electrochemical adsorption step is followed by a chemical reaction to form an adsorbed ion. If step 1 were the rds, the predicted Tafel slope using Eq. [2] would be 2ρ, the same as that obtained with the conventional Eq. [1]. Step 2, on the other hand, involves charge transfer only between species in the solution and the adsorbed state; hence a part, and only a part of the applied potential is effective in this exchange. Applying Eq. [2] to this step with $\nu = 1$, $Z_1 = 1$, $f_1 = 1.0$, $Z_r = 1$, $f_r = 0.5$, we find a corrected Tafel slope of $4\rho/5$, whereas the conventional method gives ρ.

While there is no direct evidence to support the assumption that $f_r = 0.5$, it would appear that the experimentally observed Tafel slope, $4\rho/5$, is adequately predicted by an electrode process of the above form in conjunction with the theory of Gnanamuthu and Petrocelli. Several mechanisms have appeared in the literature which conform to the generalized scheme given above. Three of these suggested reaction paths are listed in Table I along with the expected Tafel slope for each step rate-determining as calculated both by Eq. [1] and [2].

Table I. Previously suggested reaction paths for oxygen evolution

		Tafel slope	
		Corrected	Conventional
I.	"Alkaline" path of Hoar (9)		
	$M + OH^- \rightarrow MOH + e^-$	2ρ	2ρ
	$MOH + OH^- \rightarrow MH_2O_2^-$	$4\rho/5$	ρ
	$2MH_2O_2^- \rightarrow M + MO_2^{=} + 2H_2O$	$\rho/3$	$\rho/2$
	$MO_2^{=} \rightarrow M + O_2 + 2e^-$	$2\rho/7$	$\rho/3$
II.	Krasil'shchikov path (11)		
	$M + OH^- \rightarrow MOH + e^-$	2ρ	2ρ
	$MOH + OH^- \rightarrow MO^- + H_2O$	$4\rho/5$	ρ
	$MO^- \rightarrow MO + e^-$	$2\rho/7$	$2\rho/3$
	$2MO \rightarrow O_2 + 2M$	$\rho/4$	$\rho/4$
III.	Damjanovic, Dey, and Bockris path (4)		
	$M + OH^- \rightarrow MOH + e^-$	2ρ	2ρ
	$MOH + OH^- \rightarrow MO\text{-}H\text{-}OH^-$	$4\rho/5$	ρ
	$MO\text{-}H\text{-}OH^- \rightarrow MO\text{-}H\text{-}OH + e^-$	$4\rho/7$	$2\rho/3$
	$MO\text{-}H\text{-}OH \rightarrow MO + H_2O$	$\rho/2$	$\rho/2$
	$MO + OH^- \rightarrow MO_2H + e^-$	$2\rho/5$	$2\rho/5$
	$MO_2H + OH^- \rightarrow M + O_2 + H_2O + e^-$	$2\rho/7$	$2\rho/7$
	or,		
	$2MO \rightarrow O_2 + 2M$	$\rho/4$	$\rho/4$

These various mechanisms may be further differentiated by considering the rate-determining step next in order, that is the one likely to prevail at lower current densities. Experimentally, at least for nickel metal and its platinum alloys, this step was found to have a Tafel slope of $4\rho/7$. Of the mechanisms given, a slope of this value occurs in only one, path III, which has been proposed by Damjanovic *et al.* (4). Two alternative routes have been given involving the adsorbed atomic oxygen species, MO. The first represents the electrochemical discharge of MO, and the second, atomic recombination to give O_2. Verification of this mechanism cannot be carried past the third step without further experimental information.

In view of Rozental's and Veselovskii's results with O^{18} tracers (12), the involvement of the MO species in this reaction may not be likely. These investigators, using platinum which had been preanodized in acid solution at potentials cathodic to oxygen evolution, found that the layer of adsorbed oxygen did not participate in the gassing reaction. Oxygen adsorbed at these potentials is known to have the stoichiometry PtO (1), and if it is not in fact identical to the species MO, then the two should be equivalent through an exchange process. Since none of this oxygen is found in the product gas, it is doubtful that MO is a reaction intermediate.

A reaction sequence which does not incorporate the species MO, yet whose Tafel slopes predicted with Eq. [2] conform to experimental observations is given as follows:

		Corrected Tafel slope
1. $M + OH^-$	$\rightarrow MOH + e^-$	2ρ
2. $MOH + OH^-$	$\rightarrow MO_2H_2^-$	$4\rho/5$
3. $MO_2H_2^-$	$\rightarrow MO_2H_2 + e^-$	$4\rho/7$
4. $MO_2H_2 + OH^-$	$\rightarrow MO_2H^- + H_2O$	$4\rho/9$
5. MO_2H^-	$\rightarrow MO_2H + e^-$	$4\rho/11$
6. $MO_2H + OH^-$	$\rightarrow M + O_2 + H_2O + e^-$	$2\rho/7$

This mechanism differs from those proposed by most other investigators in that the oxygen-oxygen bond is formed very early in the reaction sequence, no later than step 3. Although step 2 is shown as the formation of an adsorbed hydrogen peroxide radical ion, a species such as that proposed by Damjanovic *et al.* (4), MO-H-OH$^-$, is not ruled out. In this case the species then rearranges to give an adsorbed hydrogen peroxide molecule upon extraction of an electron in step 3.

Because of the relatively high concentration of electrolyte in these experiments, step 2 acts as a pseudo-first order process. The slight dependence on stirring can be expected, however, due to the involvement of the soluble OH^-. The remaining steps

which consist of the consecutive removal of hydrogen atoms from this species are purely speculative. Steps 4 and 5 which differentiate the processes of hydrogen removal and charge transfer might very reasonably be combined to give a single step whose Tafel slope would then be $2\rho/5$.

According to this mechanism, that oxygen which is destined to be evolved as gas remains completely unique from the oxide film oxygen; that is, it is quickly bound to another oxygen atom which serves to distinguish it from the oxide type. Hence the substrate M in this discussion may be interpreted to include both bare and oxide covered metal. Furthermore, the formation of adsorbed hydrogen peroxide itself, as opposed to peroxide free radical or other related species less stable in solution, seems reasonable since hydrogen peroxide is found (13) on reduction of oxygen. If it is true that the forward and reverse reaction paths are identical, formation of H_2O_2 would precede the slow step in the cathodic direction. Hence its presence in solution would be expected.

Approximately the same value of the Tafel slope has now been obtained for a number of metals in alkaline electrolyte: for gold by MacDonald and Conway (10), for rhodium and iridium by Damjanovic *et al.* (6), and for nickel, platinum, cobalt, and iron in the present work. Therefore, it is suggested that the rds, and probably the mechanism, is identical for all these metals.

It might be postulated that differences in over-all behavior of various metals, as well as slow variation of single electrodes over their lifetime, can be attributed to the presence of impurities. In the absence of impurities, however, such behavior may be due to the influence of the state of the surface, as determined by the history of the electrode, on the relative rates of specific steps.

The results of Damjanovic *et al* (6) who obtained a value of 40 mV/dec for the Tafel slope on both iridium and a Pt-Rh alloy, may therefore be interpreted in terms of the presently given mechanism. If the state of the electrode surface in their experiments were such that the rates of steps 2 and 3 were nearly equivalent, then a mixed rate-determining process would result. Application of Eq. [2] to the combined steps gives an expected Tafel slope of 40 mV/dec in agreement with the results obtained. In a similar fashion, the Tafel slope of 60 mV/dec found for platinum by several workers (4, 5) may be attributed to a combination of steps 1 and 2.

Referring to the totally irreversible current-voltage curves at 100 mV/sec for nickel and platinum in Fig. 6, it may be seen that the rate of step 2 on platinum is considerably below that for nickel. As a result, rate-determining step 3 is not observed on platinum. The experimentally determined apparent exchange current for step 2, evaluated at the standard potential for the over-all process, is given in Table II for these and other metals.

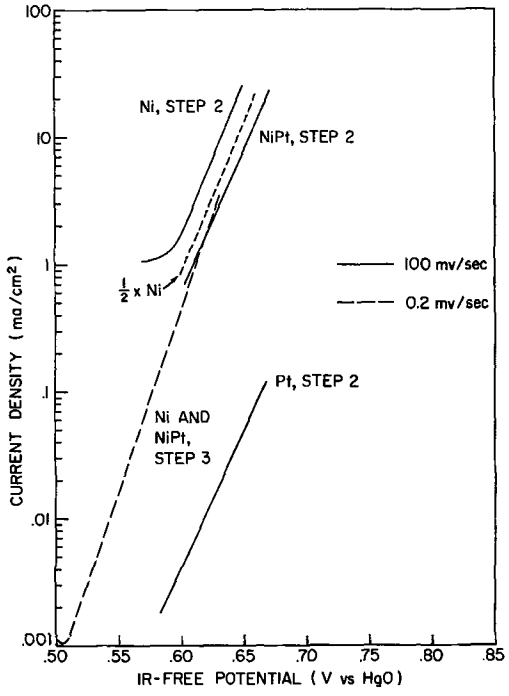

Fig. 6. Comparison of current voltage curves obtained by LSV for various reaction steps for nickel, platinum, and NiPt.

Step 2 may be expected to be faster on nickel than on platinum because the bonding energy of hydroxide ion is much greater on nickel metal. This is known to be true because nickel forms lower valent hydroxides at quite cathodic potentials. Cobalt, another metal which easily forms surface hydroxides, also has a moderately high exchange current for step 2.

Since step 2 is faster on nickel than on platinum, it is to be expected, for alloys of the two metals, that the rate for step 2 might be diminished in proportion to the platinum content. Indeed, this is found to be the case by comparing the position of the current-voltage curve for NiPt in Fig. 6 with the plot for pure nickel diminished by a factor of one-half. The two curves agree within experimental error. Correspondingly, if the rate for step 3 is likewise significantly different on the two metals, the alloy curve for step 3 will be shifted from that of pure metal. Experimentally, no such shift was found since, as shown in Fig. 6, the current voltage plots for the two metals are exactly colinear. Therefore, although the current-voltage curve for rate-determining step 3 on platinum could not be obtained experimentally, it may be inferred that it is kinetically identical with that for nickel.

Summary

It has been shown that linear sweep voltammetry at slow scan rates is a useful tool for studying kinetically complex electrochemical processes. Similar Tafel slopes have been found for several metals indicating that the same rate-determining step is involved. An additional rate-determining step which is effective at lower current levels has been observed for nickel and nickel-platinum alloys.

A mechanism based on these findings has been proposed which suggests that following the electrochemical adsorption of hydroxide ion, the formation of adsorbed hydrogen peroxide radical ion, $MO_2H_2^-$, occurs. This species is then discharged and successively dehydrogenated to give the product oxygen. The formation of $MO_2H_2^-$ is faster on nickel than on platinum, but the discharge of this species to an adsorbed hydrogen peroxide molecule seems to occur at the same rate on the two metals.

Technical Notes

Electrocapillary Measurements at the Interface Insulator-Electrolytic Solution

H. Dahms[1]

IBM Thomas J. Watson Research Center, Yorktown Heights, New York

Our present knowledge of the electrical double layer is almost exclusively based on investigations of the conductor-solution interface, with the bulk of the information being derived from studies of mercury-solution systems (1). There are no equivalent investigations of the insulator-solution interface, due mainly to the lack of experimental methods.

Here, an apparatus for obtaining electrocapillary data at an insulator surface is described. Results for the systems polyethylene/0.1M KCl + n-butanol and polyethylene/0.1M NaI are reported.

Figure 1 shows a schematic diagram of the apparatus. A tube of the insulator material, A, containing the solution to be investigated is inserted into vessel B. Vessel B is filled with an electrolytic solution. A d-c voltage is applied across the insulator by means of electrodes C and D. The difference, h, of the liquid levels in the tubing and the communicating vessel, E, is recorded with a cathetometer. The surface tension, γ, is then derived from the capillary depression, h. At contact angles approaching 0° or 180° the surface tension is given by the well-known equation

$$\gamma = \frac{r \cdot h \cdot \Delta\rho \cdot g}{2} \qquad [1]$$

where γ is the surface tension in dynes cm^{-1}, r the radius of capillary in cm, h the capillary depression (or rise) in cm, $\Delta\rho$ the difference in density between liquid and gas phase in g cm^{-3}, g the acceleration due to gravity (980 cm sec^{-2}). It should be noted that for

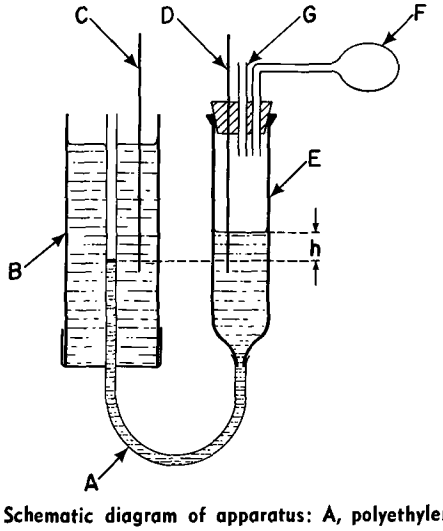

Fig. 1. Schematic diagram of apparatus: A, polyethylene tubing; B, E, glass tubing; C, D, silver wire; F, rubber bulb; G, outlet.

[1] Present address: 22 Lakeview Road, Ossining, New York 10562.

small values of capillary depression correction terms have to be applied to Eq. [1] (2).

The surface tension is related to parameters of the electrical double layer by Gibb's equation (3) which can be written for our purposes as

$$d\gamma = q\,dE - \Gamma_{Cl^-}\,d\mu_{KCl} - \Gamma_A\,d\mu_A \qquad [2]$$

where γ is surface tension, q the total charge of the interface, Γ_{Cl^-} the surface excess of Cl^- ions, μ_{KCl} the chemical potential of KCl in the solution, Γ_A the surface excess of neutral species, and μ_A the chemical potential of neutral species in the solution.

Charge and surface excesses are derived on the basis of Gibb's equation

$$q = \left(\frac{d\gamma}{dE}\right)_{\mu_{KCl},\,\mu_A} \qquad [3]$$

$$\Gamma_{Cl^-} = \left(\frac{d\gamma}{d\mu_{KCl}}\right)_{E,\,\mu_A} \qquad [4]$$

$$\Gamma_A = \left(\frac{d\gamma}{d\mu_A}\right)_{E,\,\mu_{KCl}} \qquad [5]$$

Experimental

A polyethylene tubing of 0.039 in. ID and 0.059 in. OD was used (Medical Grade Polyethylene Tubing PX 039, Becton, Dickinson and Company, Rutherford, New Jersey). Teflon tubing was also used in some experiments, giving less reproducible results probably because the diameter appeared to vary slightly along the tubing, while that of the polyethylene tubing seemed to be more constant. The ID of both glass vessels B and E was 0.75 in. Tubing A was inserted into vessel B through a rubber serum cap. It should be noted that the solution to be investigated is contacting only glass surfaces. Electrodes C and D were silver wires. F is a small rubber bulb which is briefly compressed to vary the liquid level in order to prevent sticking of the meniscus, as recommended for capillary measurements (4). Tubing G is open to the atmosphere. The meniscus height was measured with a cathetometer with an accuracy of ± 0.01 mm. At voltages higher than 600V the meniscus had a tendency to "stick," *i.e.*, to remain at a constant level regardless of the voltage applied.

Results and Discussion

Figure 2 shows the experimental data for the system polyethylene/0.1M KCl + xM n-butanol; $x = 0, 3\cdot10^{-3}, 10^{-2}, 3\cdot10^{-2}, 10^{-1}$. The adsorption isotherms for n-butanol resulting from the data are shown in Fig. 3. The potential dependence of adsorption is shown in Fig. 4. The maximal adsorption for n-butanol can be calculated from molecular models (5). The values are $4.6\cdot10^{-10}$ moles/cm² for a planar position and 7.9 for a perpendicular position. On mercury the maximum butanol adsorption is at least $6.5\cdot10^{-10}$ moles/cm², indicating a perpendicular orientation (5). The fact that the experimental data on polyethylene point to a saturation value in the range of $4\text{-}5\cdot10^{-10}$ mole/cm² is noteworthy. However, definite conclusions can be drawn only after investigations of a homologous series of alcohols or other hydrocarbons. If the polyethylene surface had a considerable roughness factor the actual coverage would be even lower.

Another interesting problem which can be approached by the present technique is the controversy over the causes of "specific adsorption" on metal surfaces (1). Graham and co-workers (6, 7) suggested that this involves a certain covalent bond between the adsorbed ion and the metal surface. More recently, however, it has been proposed that electrical image energy (8), or the degree of solvation (9), are the main factors. Figure 5 shows an electrocapillary curve

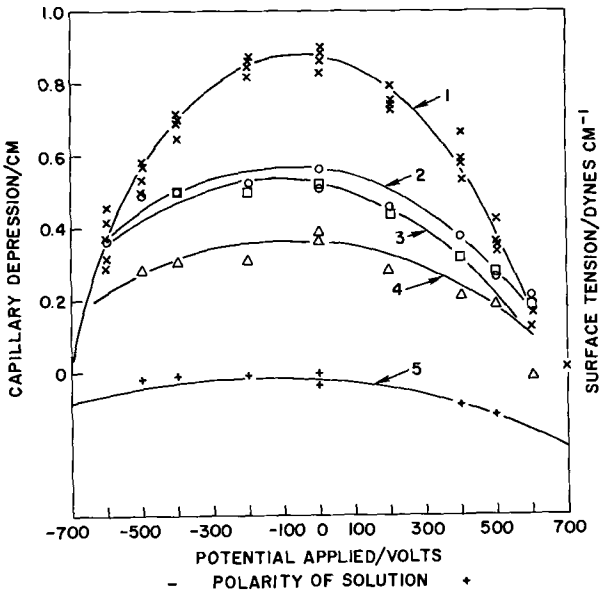

Fig. 2. Electrocapillary curves in polyethylene tubing of aqueous solutions containing 0.1M KCl and xM n-butanol. Curve 1, $x = 0$; curve 2, $x = 3\cdot10^{-3}$; curve 3, $x = 10^{-2}$; curve 4, $x = 3\cdot10^{-2}$; curve 5, $x = 10^{-1}$.

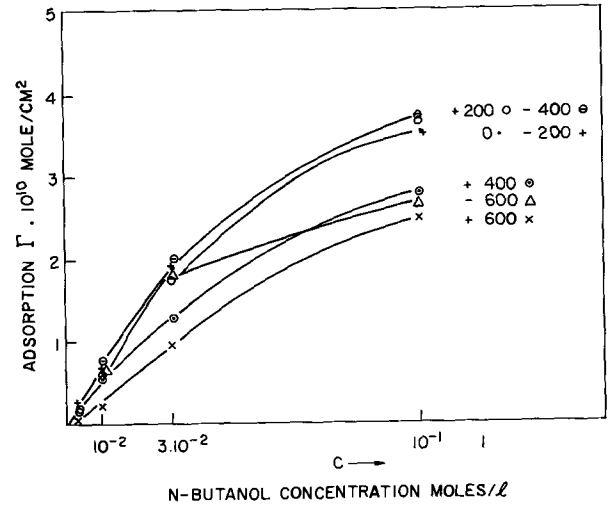

Fig. 3. Adsorption isotherms of the system polyethylene/0.1M KCl + n-butanol. Numbers in plot indicate voltage applied. For example, + 200 is 200V applied with polarity of solution being positive.

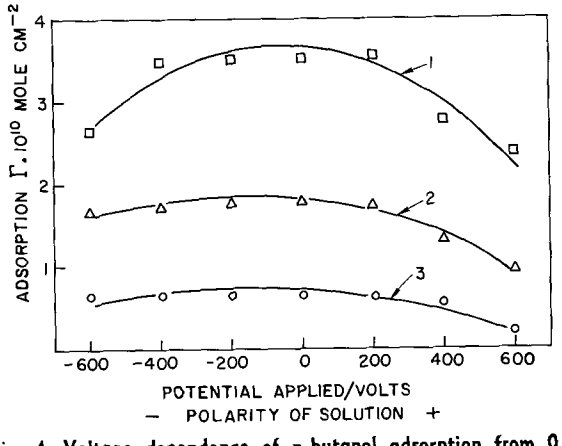

Fig. 4. Voltage dependence of n-butanol adsorption from 0.1M KCl solution. Curve 1, 10^{-1} M n-butanol; curve 2, $3\cdot10^{-2}$ M n-butanol; curve 3, 10^{-2} M n-butanol.

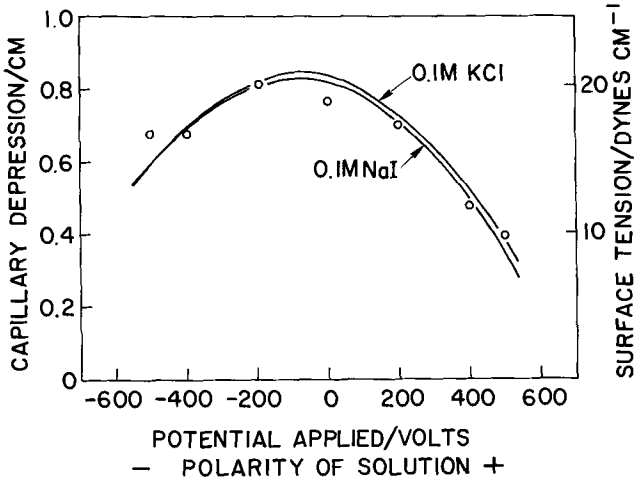

Fig. 5. Electrocapillary curves of polyethylene 10.1M NaI and polyethylene 10.1M KCl.

taken at the interface polyethylene/0.1M NaI. For comparison, the electrocapillary curve in 0.1M KCl is also plotted. Although there is admittedly a considerable scatter of the data, it can be seen that the curves coincide rather well. Similar electrocapillary curves on mercury (10, 11) show a strong decrease of surface tension in the case of iodide when the iodide ions are attracted to the surface, *i.e.*, on the left side of our plot (polarity of solution negative). It should be noted that such a rapid decrease cannot be seen in Fig. 5. This preliminary result seems to indicate that the main cause of strong specific adsorption, such as found in the case of iodide on mercury (10, 11), is due to covalent metal-ion bonding since the specific adsorption is absent at the polyethylene surface. However, more systematic measurements are needed.

Data obtained with the present method do not presently have the same high precision achieved in mercury-solution studies which have been refined for nearly a century. Many experimental aspects such as the application of adjustable hydrostatic pressure to keep the position of the solution meniscus in the capillary constant, can be directly applied to the present apparatus.

Acknowledgments

This investigation was sparked by the idea of J. N. Cole who suggested to move droplets on an insulating surface by applying an electrostatic field. Z. Kovac gave experimental advice.

Manuscript received June 9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Electroosmotic Transport in Mixed Solvents, the γ-Butyrolactone-Water System

P. Bro* and A. N. Dey*

P. R. Mallory & Company, Inc., Laboratory for Physical Science, Burlington, Massachusetts

Investigations have shown that the trace amounts of water contained in organic electrolyte solutions are bound to the cation, *e.g.*, the lithium ion (1), and that the transference number of the lithium ion through suitable cation exchange membranes is close to unity (2). These observations suggested that the residual water would be transferred selectively during electroosmosis, and experiments confirmed our conjecture (3). A description of the electroosmotic process is given here, and we present a set of equations for electroosmotic transfer in mixed solvents.

Experimental Techniques

The cell used for the electroosmotic measurements was similar to the one described earlier (3), except that each electrode compartment was provided with calibrated capillaries for the measurement of the volume changes. No corrections were introduced for the volume changes associated with the electrode reactions. They were estimated to be less than 10% of the reported values, but there is a basic uncertainty in this value because of the unknown partial molar volume of lithium chloride in butyrolactone-water solutions. All the experiments were performed with a cation exchange membrane (AMF No. C-60) in the lithium form. The voltage drops between the electrodes at 3% water level were 0.25V at 0.05 mA/cm^2 and 2.70V at 0.50 mA/cm^2.

The γ-butyrolactone (BL, Eastman Organic Chemicals) was purified by vacuum distillation at 61°-65°C and 1.0 mm Hg in a 90 cm long vacuum jacketed column using a reflux ratio of 2 to 1. The 2.5 cm ID column was packed with 0.4 cm Berl saddles. The water concentration in the purified solvent was less than 10^{-3}M as determined by gas chromatographic analysis (Perkin-Elmer chromatograph, Model 801). The 6-ft long stainless steel column had a diameter of ⅛ in. and it was packed with 50-80 mesh Porapack Type Q. We used a hot wire detector with automatic integration of

* Electrochemical Society Active Member.

the output. Calibrations with known BL/H_2O mixtures indicated an accuracy of ± 2% for the analyses.

In order to determine the H_2O/BL ratio in the membranes, they were equilibrated with known volumes of 0.10M LiCl solutions in specified mixtures of water and butyrolactone. The membranes were weighed, after superficial drying, before and after equilibration and the solution compositions were determined gas chromatographically. The membranes were finally vacuum dried at 60°C to remove water and butyrolactone and were weighed again. The amounts of water and butyrolactone sorbed by the membranes were calculated by making a material balance over the system.

Experimental Results

The passage of current through the cell resulted in the enrichment of water in the catholyte, Table I. The associated volume changes given in Table II showed that the catholyte volume increased as well. Although the specific solution transport decreased with an increase in the concentration of water, Fig. 1, the specific water transport increased. At water concentrations above 5% (vol.) the water transport became nearly constant. The composition of the membrane solutions was calculated from the data in Tables III and IV and the results are shown in Fig. 2. A molar enrichment factor of about ten was obtained for the enrichment of water in the membrane.

Discussion

The enrichment of water in the cathodic exudate may be examined from an equilibrium and a transport point of view.

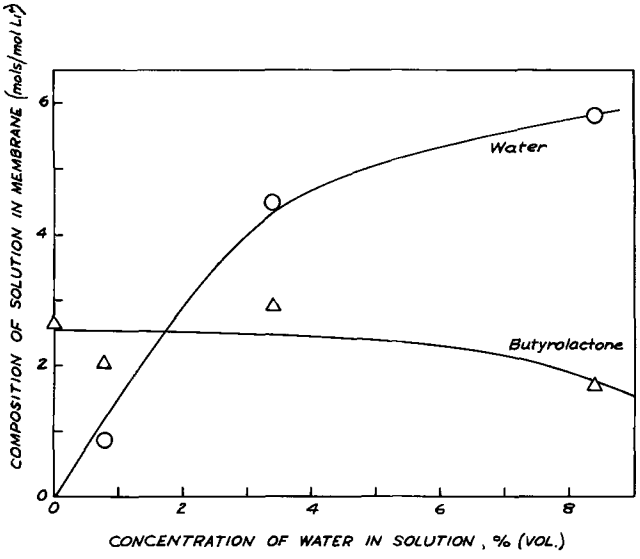

Fig. 3. Membrane/solution equilibrium

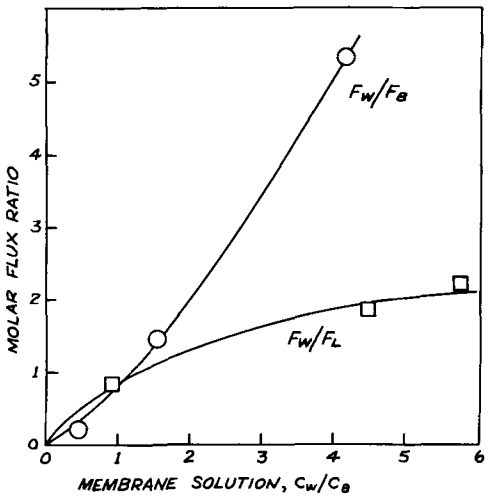

Fig. 4. Electroosmotic flux ratios

However, the calculated osmotic pressures were far in excess of the values reported for ion exchange membranes (4), and this approach was rejected.

An analysis in terms of a Langmuir sorption process gave a more credible result. The Langmuir isotherm is based on localized sorption with a constant binding energy and no interactions between the sorbed species (5). The experimental data agreed with the Langmuir model and gave a binding energy of 0.5 kcal/mole (1 mole/liter was used as a reference state for water) and a saturation value of 33 moles/liter for the water in the membrane. The absence of any noticeable swelling of the membrane suggested the reasonableness of the low binding energy. However, we do not attach any significance to the precise values reported because of the paucity of our data.

In regard to the transfer process we note that the rates of transfer were independent of the current density (3) which indicated that the membrane maintained its equilibrium composition during the process.

No mathematical description is available in the literature of the preferential electroosmotic transfer of a solvent component in a mixed solvent system, and we developed a set of equations for this process based on the friction coefficient formalism. Our equations represent an extension of Spiegler's treatment (6), and they reduce to his equations as a limiting case.

A force balance over a unit volume of the membrane leads to the basic equations

$$C_L G_L = C_A K_{LA}(u_L - u_A) + C_W K_{LW}(u_L - u_W) + C_B K_{LB}(u_L - u_B) + C_L K_{LM} u_L \quad [1]$$

$$C_A G_A = C_L K_{AL}(u_A - u_L) + C_W K_{AW}(u_A - u_W) + C_B K_{AB}(u_A - u_B) + C_A K_{AM} u_A \quad [2]$$

$$C_W G_W = C_L K_{WL}(u_W - u_L) + C_A K_{WA}(u_W - u_A) + C_B K_{WB}(u_W - u_B) + C_W K_{WM} u_W \quad [3]$$

$$C_B G_B = C_L K_{BL}(u_B - u_L) + C_A K_{BA}(u_B - u_A) + C_W K_{BW}(u_B - u_W) + C_B K_{BM} u_B \quad [4]$$

from which we obtain

$$\frac{F_W}{F_B} = \frac{C_W}{C_B} \frac{C_L K_{WL} K_{BL} + C_W K_{WL} K_{BW} + C_B K_{BL} K_{WB} + C_B K_{WL} K_{BM}}{C_L K_{WL} K_{BL} + C_W K_{WL} K_{BW} + C_B K_{BL} K_{WB} + C_W K_{BL} K_{WM}} \quad [5]$$

for the molar electroosmotic flux ratios.

- G_i = generalized force on one mole of i
- F_i = molar flux of i = $u_i C_i = \Sigma L_{ij} G_j$ (this defines L_{ij})
- C_i = molar concentration of i in the membrane solution
- K_{ij} = frictional force on i due to one mole of j in a unit velocity gradient of i and j
- W, B, L, A, M designate water, butyrolactone, lithium ions, chloride ions, and membrane, respectively.

The experimental flux ratios have been plotted in Fig. 4 and it may be seen that the flux ratio F_W/F_B was approximately equal to the concentration ratio C_W/C_B, which with Eq. [5] leads to

$$C_W K_{WM}/K_{WL} = C_B K_{BM}/K_{BL} \quad [7]$$

This equality would hold identically if $K_{WM} = 0$ and $K_{BM} = 0$, *i.e.*, if the frictional interactions between the solvent components and the membrane matrix vanish. Such an hypothesis is not unreasonable since the interaction energy for water sorption was found to be small and the membrane did not swell in any of the solutions.

If the frictional interactions between water and butyrolactone are negligible, *i.e.*, $K_{WB} = 0$, we find from [6] that

$$\frac{F_W}{F_L} = \frac{C_W}{C_L} \frac{1}{1 + \frac{C_W}{C_L}\frac{K_{WM}}{K_{WL}}} \quad [8]$$

and the flux ratio of water and lithium should be increasingly less than their concentration ratio as the water concentration increases. The experimental results did exhibit this behavior, Fig. 4, and we find that $K_{WM}/K_{WL} = 0.3$ under the stated assumption. This result in conjunction with [7] shows that K_{BM}/K_{BL} increased from 0 to 1.2 as the water/butyrolactone concentration ratio increased from 0 to 4. Since there are no reasons for believing that the interactions between the butyrolactone and the membrane should change with the water concentration, the increase of K_{BM}/K_{BL} is probably due to a decrease of K_{BL} with an increase in the water concentration, *i.e.*, the friction between the butyrolactone and the lithium ions decreases as the water concentration increases. Since the lithium ions and the water interact strongly, this means

$$\frac{F_W}{F_L} = \frac{C_W K_{WL}(C_L K_{BL} + C_W K_{BW} + C_B K_{BM}) + C_W C_B K_{BL} K_{WB}}{(C_L K_{BL} + C_W K_{BW} + C_B K_{BM})(C_L K_{WL} + C_W K_{WM} + C_B K_{WB}) - C_W C_B K_{WB} K_{BW}} \quad [6]$$

that as the water concentration increases and the lithium ions become increasingly shielded by the water, the interactions between the lithium ions and butyrolactone should decrease, *i.e.*, K_{BL} should decrease, as would be expected if $K_{WB} = 0$, and the electroosmotic equations appear to provide a consistent description of this effect.

Conclusions

The electroosmotic transfer of water-butyrolactone-lithium chloride solutions in a cation exchange membrane led to an appreciable enrichment of water in the cathodic exudate. Equilibrium studies showed that the water was sorbed preferentially by the membrane, and a molar enrichment factor of about ten was obtained for the transfer of the water.

The electroosmotic transfer was analyzed in terms of a new set of equations derived for mixed solvent systems, and the equations indicated that the electroosmotic process was dominated by the water-lithium ion interactions.

Manuscript submitted March 26, 1969; revised manuscript received July 2, 1969. This was Paper 166 presented at the New York Meeting, May 4-9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

A Theoretical Equation for the Mobility of an Ion in an Electromagnetic Field

David S. Newman,* Carl Schober, and Cyrus Lawyer

Department of Chemistry, Bowling Green State University, Bowling Green, Ohio

The total current density in an ionic conductor can be described by Eq. [1]

$$\vec{J} = \sum_{k=1}^{n} \rho_k Z_k \vec{v}_k \qquad [1]$$

where ρ_k is the charge density, Z_k the charge, and $\vec{v}_k$ the average drift velocity of the k'th ion. Limiting the discussion to 1:1 electrolyte systems for the sake of simplicity, Eq. [1] can be rewritten

$$\vec{J} = \rho^+ Z^+ \vec{v}^+ + \rho^- Z^- \vec{v}^- \qquad [2]$$

From Eq. [2] it is obvious that an experimental measurement of $\vec{J}$ gives the difference between the average drift velocities of the positive and negative ions. A second measurement, to be combined with the first, must be made in order to evaluate the velocities of the positive or negative ions separately. In practice a conductance measurement, combined with a transference number measurement, is usually employed to arrive at average drift velocities, or average mobilities. An alternative and more general method, however, is available for calculating mobilities which makes use of the ionic Hall effect (2, 3) in conjunction with conductivity data.

The force acting on a charged particle in a combined electric and magnetic field is given in MKS units by the equation

$$\vec{F} = Z_k (\vec{E} + \vec{v} \times \vec{B}) \qquad [3]$$

where $\vec{F}$ is the Lorentz force, $\vec{E}$ is the electric field, $\vec{v}$ is the average drift velocity of the particle, and $\vec{B}$ is the magnetic field. If the direction of the magnetic field is perpendicular to the direction of the electric field, as is the case in a conventional Hall effect experiment, Eq. [3] shows that the magnetic field does not change the magnitude of the average drift velocity of ions that are moving in the direction of the electric field. This concept makes it possible to calculate the average drift velocity of an ion in an ionic conductor.

* Electrochemical Society Active Member.

The equations

$$\vec{F}^+ = Z^+ \rho^+ (\vec{E} + \vec{v}^+ \times \vec{B}) \qquad [4a]$$

$$\vec{F}^- = Z^- \rho^- (\vec{E} + \vec{v}^- \times \vec{B}) \qquad [4b]$$

are next introduced where $\vec{F}^+$ and $\vec{F}^-$ are the Lorentz forces experienced by the plus and minus ions, respectively, in the combined electromagnetic field. The positive and negative ions will react to this force in an opposite sense, but since they are already moving on the average in opposite directions the two kinds of ions will move in the same direction at right angles to both the electric and magnetic fields.

If $\vec{v}^+$ were equal to $\vec{v}^-$, there would be no observable macroscopic effect due to the Lorentz force acting on the ions, but since in general $\vec{v}^+$ is not equal to $\vec{v}^-$, a Hall voltage will develop. This Hall voltage will reflect the difference between the average drift velocities (or mobilities) since it can be considered to be the electric field necessary to reduce the transverse ionic current to zero.

Under these conditions, for a current density $\vec{J}$, Eq. [4] becomes

$$0 = \rho^+ Z^+ \vec{E} + \rho^+ Z^+ (\vec{v}^+ \times \vec{B}) \qquad [5a]$$

$$0 = \rho^- Z^- \vec{E} + \rho^- Z^- (\vec{v}^- \times \vec{B}) \qquad [5b]$$

and the Hall voltage is written as

$$\vec{V} = \rho^+ Z^+ \vec{E} - \rho^- Z^- \vec{E} \qquad [6a]$$

$$= (\rho^+ Z^+ |\vec{v}^+| - \rho^- Z^- |\vec{v}^-|) |\vec{B}| \qquad [6b]$$

Dividing both sides of Eq. [6] by unit field gives

$$\vec{V}_H = (\rho^+ Z^+ u^+ - \rho^- Z^- u^-) |\vec{B}| \qquad [7]$$

where u^+ and u^- are the usual symbols for the mobilities of the plus and minus ions, respectively, and $\vec{V}_H$

is the Hall voltage for unit field. Equation [7] should be compared with a similar equation derived by Wendhausen (4) which does not indicate that the measured Hall voltage is, in fact, current dependent.

The usual scalar form of the conductance equation

$$\sigma = Z^+\rho^+u^+ + Z^-\rho^-u^- \qquad [8]$$

is then combined with Eq. [7] and u^+ and u^- are solved for.

This leads to the equations

$$u^+ = \sigma/2\rho^+Z^+ + [V_H/2(\rho^+Z^+ \mid \vec{B} \mid)] \qquad [9a]$$

$$u^- = \sigma/2\rho^-Z^- - [V_H/2(\rho^-Z^- \mid \vec{B} \mid)] \qquad [9b]$$

It can be seen that all quantities on the right hand side of Eq. [9] are measurable, in principle. Assuming the proton to be more mobile than say, Cl^- in HCl solution, Eq. [9] qualitatively is seen to have the correct sign in front of the term containing the Hall voltage.

As a test of the validity of Eq. [9], the mobilities of the carriers in a 0.01M HCl solution were calculated using Friedman's value of 3 x 10^{-7}V (2) for the Hall voltage. The specific conductivity for the HCl was taken as 4.2 x 10^{-3} ohm^{-1} cm^{-1} and a field of 10 kilogauss was assumed present (the units for magnetic field used in the calculation are volt sec/cm^2). Using these numbers a value of 4 x 10^{-3} cm^2/volt sec was calculated for the proton mobility and a value of 7 x 10^{-4} cm^2/V-sec was calculated for the chloride mobility. These numbers compare quite favorably with literature values (5) considering the nature of the approximations involved.

Alternatively, this calculation is an excellent check on Friedman's estimated value for the Hall voltage based on a "Brownon" model.

Discussion

Experimental problems.—The major experimental difficulty is measuring the very low Hall voltage, approximately 0.2 μV, in the presence of a low signal to noise ratio. Several methods for improving the signal to noise ratio have been used to study metal-liquid ammonia systems (6) and liquid mercury systems (7), and are applicable to ionic systems. The best results should be obtained from an a-c, a-c technique (6, 8) in which the Hall voltage is measured at the sum and difference frequencies.

Temperature gradients and magnetohydrodynamic effects must be minimized. Magnetoresistance has to be accounted for and the external magnetic field should be homogeneous and on the order of 10 kilogauss. It is estimated that with present instrumentation and considerable effort Hall voltages can be measured to $\pm$ 10%.

Justification for the use of the scalar form of the conductance equation in the presence of an external magnetic field.— For a system in an external magnetic field at constant temperature and pressure, Ohm's law can be generalized in the form [9]

$$\vec{J} = \sigma_E \vec{E} + \sigma_B \vec{B} \times \vec{E} \qquad [10]$$

where σ_E and σ_B are the electric and magnetic components of the conductance tensor. σ_E and σ_B are related to each other by the equation

$$\text{Tan}\,\Phi = \vec{B}\,\sigma_B/\sigma_E \qquad [11]$$

where Φ is the Hall angle. From Eq. [10] it is obvious that $\vec{J}$ is affected by the magnetic field. However, the effect is very small and can either be neglected or, in principle, measured. The change in $\vec{J}$ due to the magnetic field changing the distribution of ionic velocities in directions not parallel to the electric field, approaches zero. This is the same result predicted for the free electron model of a metal. In this model both the transverse and longitudinal components of the magnetoresistance vanish.

The change in $\vec{J}$ due to a Hall current, while not being zero, will be on the order of 1 x 10^{-6} times the electric current for magnetic fields of 10 kilogauss and will also be negligible. Therefore, the total decrease in the conductance due to the magnetic field (the second term on the right-hand side of Eq. [10]) is usually very small and the scalar form of the conductance equation is applicable.

For very large magnetic fields, on the order of 300 kilogauss, the "magnetoresistance" will probably no longer be negligible, and a more general form of the conductance tensor will have to be used.

Generality of the method.—The Hall effect-conductance technique for measuring mobilities is closer to being completely general than any other technique now in use. Any ionic system, including fused salts and solids, is accessible to Hall effect experiments because the limitations, while formidable, are all experimental. This is not the case with transference number experiments. For example, there are at least two theoretical limitations on the Hittorf technique. One of the electrode reactions must be reversible, and it is not always possible to correct for differences in solvation between anion and cation. Similar kinds of problems limit the number of systems accessible to either moving boundary or emf measurements.

Conclusion

The equations derived form the basis of a potentially useful method for studying transport properties of ionic solutions. Extension of the method to incorporate fused salts represents a fertile area for future investigation. In fused salt systems the problem of reference frames would be virtually eliminated.

On the Breakdown of Passivity on Stainless Steels in Halide Media

B. E. Wilde* and E. Williams

Applied Research Laboratory, U. S. Steel Corporation, Monroeville, Pennsylvania

This note presents some observations made in a program to develop an alloy resistant to pitting by studying passivity breakdown during potentiodynamic anodic polarization. The concept of "critical breakdown potential for passivity," E_c, as a means of screening alloys for pitting resistance has been described by Brennert (1), Mahla and Nielsen (2), Pourbaix *et al.* (3), and many others. Further, a large number of experimental and environmental factors that influence E_c have also been presented by Leckie and Uhlig (4), and Horvath and Uhlig (5). Recent findings at U. S. Steel's Applied Research Laboratory, however, have indicated another environmental variable not previously reported, which in the opinion of the writers, lends strong support to the concept of competitive adsorption in passivity breakdown proposed by Tamman (6), Uhlig and Wulff (7), Kolotyrkin (8), and Brauns and Schwenk (9).

Experiments were conducted on two steels having the chemical composition shown in Table I. Cylindrical electrodes were machined from solution-annealed stock and were polarized from the steady-state corrosion potential, E_{corr}, in the noble direction. An electronic potentiostat[1] was used along with auxiliary equipment and preparation procedures described elsewhere (10, 11). The corrosive was 1M reagent-grade sodium chloride, dissolved in distilled water (6.3 meg ohm cm^{-1}), with a final *p*H of 6.3 at 25°C. The atmosphere inside the cell was maintained by bubbling any one of four gases through the solution at a rate of 1 to 1.5 l/min. The four gases used were hydrogen, nitrogen, argon, and oxygen, drawn from high-pressure gas cylinders. The residual oxygen levels in the corrodent, after it was purged with the above gases for 24 hr, were measured with a Beckman polarographic oxygen analyzer.[2]

Results of polarization experiments are shown in Fig. 1 and 2. Clear breakdown potentials were observed on both alloys, which increased in nobility in the order $H_2 < N_2 < A < O_2$, as shown in Table II. Each value of E_c was found to be reproducible to ± 10 mV on triplicate runs. These data clearly indicate that the stability of the "passive film" to localized breakdown (pitting), as measured by the relative nobility of E_c, is related to the presence of nonionic, nonelectroactive constituents in the corrodent. It is possible, however, that H_2 may be electroactive in that it could be involved in electrochemical oxidation on the electrode surface, and similarly, oxygen may be reduced at local cathode sites, but to our knowledge, no electrochemical reactions, involving N_2 and argon can occur. The possible influence of dissolved oxygen on E_c was discounted, from inspection of Table III, where it is clear that argon with the lowest oxygen content gave next to the most noble E_c on both steels. Because of the above data, we must

turn to physical adsorption processes to explain the dependence of E_c on nonionic species in solution.

Without specifying the primary passivation mechanism (other than some type of film formation either adsorbed O_2 or nonstoichiometric phase oxides), one may view the localized breakdown of the passive state as the displacement of any adsorbed or bound species on the surface by Cl^- ions at a specific electrode potential, leading to accelerated anodic dissolution (12) and autocatalysis (13). The resistance to displacement from the film presumably must depend, in the case of N_2 and argon, on the relative polarizability of the molecule. The above data form the basis for a future publication explaining the reasons for the reported lack of agreement between electrochemical and chemical pitting tests (14).

Oxidation of Co-25 w/o Cr at High Temperatures

P. K. Kofstad[1] and A. Z. Hed

Metal Science Group, Battelle Memorial Institute, Columbus Laboratories, Columbus, Ohio

ABSTRACT

Studies of the oxidation behavior of Co-25 w/o Cr at temperatures between 900° and 1300°C and oxygen pressures in the range 0.2-760 Torr are reported and analyzed. The oxidation behavior of this alloy is complex and does not follow a single mechanism. The parabolic rate constant at high oxygen pressures ($p_{O_2} > 100$ Torr) in the temperature range of 900°-1300°C is about two orders of magnitude larger than that at low oxygen pressures ($p_{O_2} < 10$ Torr). The scales formed at high oxygen pressures have a duplex structure, the outer layer being virtually pure CoO as in Co-10 w/o Cr (1, 2), and the inner layer being mainly the spinel $CoCr_2O_4$ with small amounts of CoO and Cr_2O_3 (Cr_2O_3 is concentrated near the alloy-scale interface). At low oxygen pressures, the morphology of the scale is dependent on the radius of curvature of the specimen; at the edges where this radius is small, the structure is similar to the structure developed at high oxygen pressures; on the large surfaces, Cr_2O_3 is the dominant oxide.

The mechanism of parabolic oxidation of Co-25 w/o Cr at high oxygen pressures involves cobalt-ion diffusion through a CoO network in the inner layer. Initial oxidation under these conditions is nonparabolic and this is due to selective oxidation of chromium to Cr_2O_3 which takes place when the specimens are exposed to the "vacuum" of the reaction furnace prior to the start of the actual oxidation run. The transition from the high- to low-pressure oxidation is due to a transition to selective oxidation of chromium. The oxidation is then governed by diffusion of the reacting ions (probably chromium) through the Cr_2O_3 scales.

This paper is part of an extended study of the high-temperature behavior of binary Co-Cr alloys. Previous papers have covered oxidation kinetics and microstructures of oxide scales in high-temperature oxidation of Co-10 w/o Cr (1,2). A literature survey pertaining to the oxidation behavior of Co-Cr alloys has been given in ref. (1).

Materials and Methods

An alloy with the nominal composition Co-25 w/o (weight per cent) Cr was prepared in a vacuum furnace and cast in a tapered zirconite sand mold. The dimensions of the mold were: top, 6.3 x 6.3 cm; bottom, 3.0 x 3.8 cm; length, 24.5 cm. Subsequent chemical analysis showed that the alloy composition was Co-24.6 w/o Cr.

After sandblasting, the ingots were heat treated at 1125°C for 2 hr and then forged at high temperatures to the size 2.2 x 6.3 x 43.1 cm. The optimum forging temperatures for this alloy appeared to be 1150°-1200°C.

The forged plates were then hot rolled to a 0.22-cm thickness and subsequently cold rolled to a thickness of about 0.18 cm. After rolling, the sheets were again sandblasted. The sheets were than cut into specimens measuring 2.5 x 1.9 cm; these specimens were subsequently ground on emery paper and diamond polished. The polishing procedure removed some 50-100μ of the alloy. The final thickness of the specimens varied between 0.15 and 0.165 cm. The specimens were then measured and washed in water and trichlorethylene. A metallographic inspection of these specimens revealed a small amount of Cr_2O_3 inclusions in the alloy; these are probably due to oxygen contamination during casting, forging, and hot rolling.

Oxidation rates in controlled oxygen atmospheres were measured with an automatic Cahn R-H electrobalance enclosed in a high-vacuum system. The balance had a sensitivity of 100 μg and the weight gain was continuously recorded on an AZAR Leeds and Northrup recorder. Temperature in the mullite tube reaction chamber was controlled by an on-off Barber-Coleman controller to within 3°C, and was measured with a Pt/Pt-10 Rh thermocouple placed 10-15 mm from the specimen. The system was pumped down with a 450-liter CVC diffusion pump and an Edwards mechanical pump. Pressures down to 10^{-5} Torr were achieved, as measured on the CVC ionization and thermocouple gauges.

The specimens were connected to the balance with an annealed Pt-10 Rh wire and placed in a cold sidetube of the apparatus, and then the system was evacuated. After the furnace was temperature equilibrated and while the furnace was still under the high vacuum (10^{-4}-10^{-5} Torr), specimens were lowered into the hot zone by a magnetic device. Oxygen was then admitted to the system through a Granville-Phillips metering needle valve. One to two minutes generally elapsed from the time the specimens were loaded into the hot zone until the desired oxygen pressure in the system was reached. Zero time for the oxidation was taken as the instant when the desired oxygen pressure was attained. At the lower oxygen pressures ($\leq$ 10 Torr), oxygen was continuously pumped through the system during the oxidation.

After the specimens had been oxidized to the desired extent, they were raised out of the hot zone. The system was backfilled with oxygen, and the specimens were taken out and immersed in a molten lead bismuth alloy, which in turn was rapidly cooled and solidified. In this manner, retention of the oxide scales was accomplished.

A limited number of oxidized specimens were chosen for further examination and characterization by means of metallographic techniques, x-ray diffraction, and electron-microprobe analysis.

Results

Thermogravimetric studies.—The rate of oxidation of diamond-polished Co-25 w/o Cr alloy was studied in the temperature range 900°-1300°C. The oxidation was carried out in pure oxygen in the pressure range 0.2-760 Torr.

In Fig. 1 through 3, the weight gain of Co-25 w/o Cr alloy during oxidation is plotted *vs.* time at different oxygen partial pressures at temperatures of 1000°, 1100°, and 1300°C, respectively. Parabolic plots of the oxidation at 900°, 1100°, and 1300°C are given in Fig. 4 to 7.

[1] Present address: Central Institute for Industrial Research, Blindern, Oslo 3, Norway.

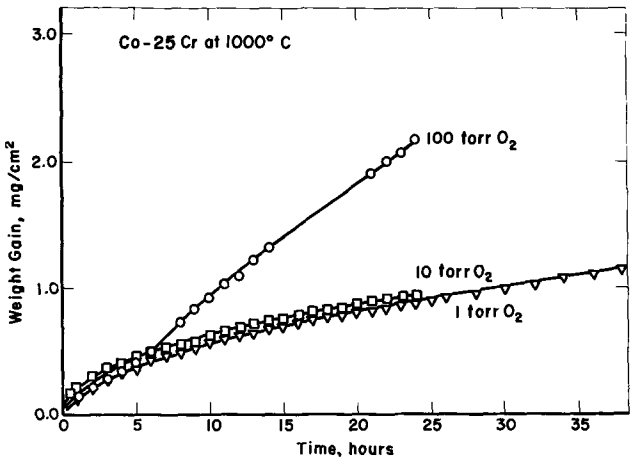

Fig. 1. Oxidation of Co-25Cr alloy at 1000°C in oxygen at pressures from 1 to 100 Torr oxygen.

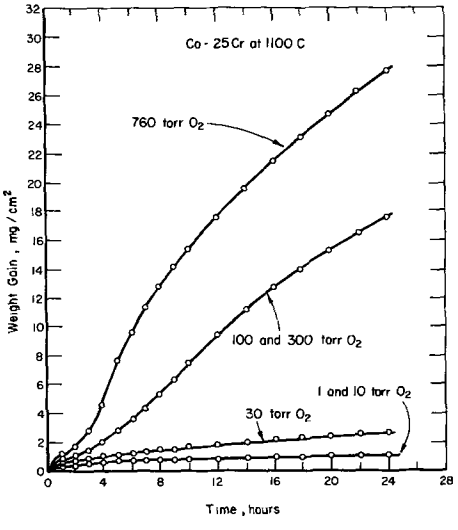

Fig. 2. Oxidation of Co-25Cr alloy at 1100°C in oxygen at pressures from 1 to 760 Torr oxygen. The experimental points of 100 and 1 Torr are not given since they fell very close to those of 300 and 10 Torr, respectively.

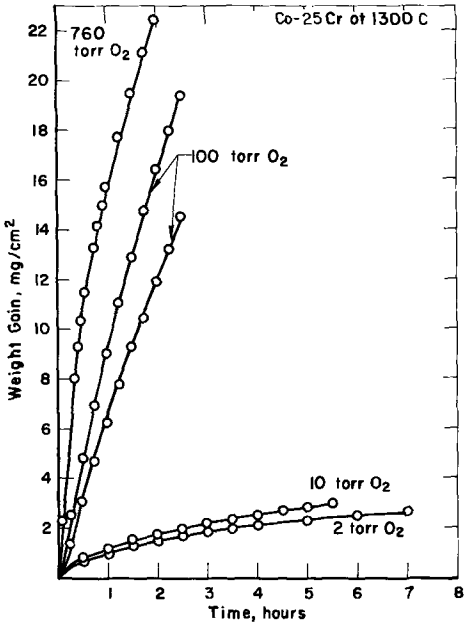

Fig. 3. Oxidation of Co-25Cr alloy at 1300°C in oxygen at pressures from 2 to 760 Torr oxygen.

A significant feature of the results is a marked decrease in the rate of oxidation when the ambient partial pressure is decreased below approximately 100 Torr. This feature is particularly evident from the results at 1100° and 1300°C (Fig. 2, 3, 5-7).

The oxidation kinetics at and above 100 Torr may be divided into two main parts: (*i*) an initial stage during which the oxidation is difficult to characterize in terms of simple rate equations, and (*ii*) a parabolic oxidation after more extended reaction. These features may particularly be noted from Fig. 5 and 7.

At low oxygen pressures the oxidation tends to a more parabolic behavior during the whole reaction period. However, at both 900° and 1100°C (Fig. 4 and 6), the results also indicate small changes in the kinetics after an initial period of oxidation.

Parabolic rate constants, k_p, evaluated from the later oxidation stages are plotted in Fig. 8 as a function of p_{O_2} at different temperatures. The sharp decrease in the oxidation at an oxygen pressure of about 50-100 Torr may be noted. At low oxygen pressures

(below 10 Torr), k_p is approximately independent of oxygen pressure. The scatter at 900°C in Fig. 8 is partially due to experimental error and partially due to a real effect that will be mentioned later. At high oxygen pressures it is difficult to evaluate an accurate oxygen-pressure dependence of k_p, but the results suggest a small increase of k_p with oxygen pressure, which is not incompatible with a relation $k_p \propto p_{O_2}^{1/3}$ or $p_{O_2}^{1/4}$, as found for the oxidation of pure cobalt and Co-10 w/o Cr (1, 2).

In Fig. 9 the parabolic rate constant at 760 and 10 Torr is plotted as a function of $1/T$. The activation energy at 10 Torr is approximately 50 kcal/mole, while at 760 Torr it changes with temperature.

During at least part of the oxidation, evaporation of oxide occurred. This was evidenced by deposits of Cr_2O_3 on the hangdown wire, and in the upper cool part of the reaction chamber. The oxide evaporation was more pronounced at high oxygen pressures, which is expected if the evaporating oxide is CrO_3. It was not possible to estimate the amount of oxide evaporation during any single run. However, the presence of an outer CoO layer on the Co-25 w/o Cr alloy at high oxygen pressures leads us to assume that this evaporation occurs only during the initial stages of oxidation under these conditions.

Metallographic studies.—The scales on oxidized Co-25 w/o Cr alloys almost invariably spalled off during cooling to room temperature. When the specimens were oxidized at high oxygen pressures, the scales would just disjoint from the substrate and could be collected as relatively large chips of oxide. When the specimens were oxidized at low oxygen pressures, the spalling was violent and collection of scale chips was very difficult. In an attempt to retain the scales with their correct orientation relative to the substrate, oxidized specimens were quenched into a liquid lead-bismuth alloy which expands under cooling. The alloy is softer than the specimen, and this results in rounded edges of the metallographically polished specimens.

In Fig. 10 a cross section of a Co-25 w/o specimen oxidized at 1100°C in 300 Torr O_2 for 14 hr is given.

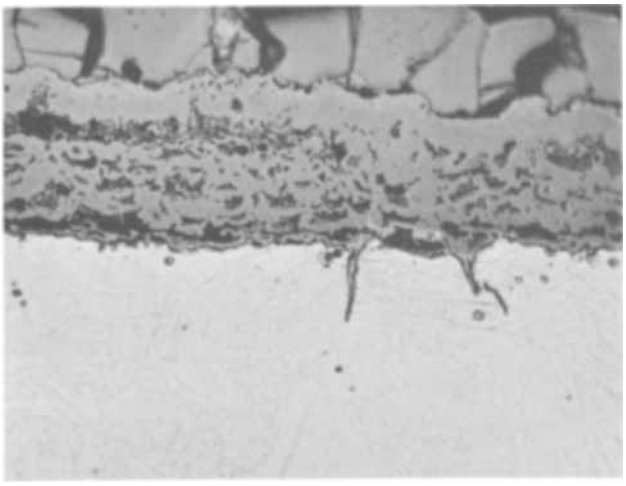

Fig. 10. Metallographic cross section of Co-25Cr alloy oxidized for 14 hr at 1100°C and 300 Torr oxygen. 350X.

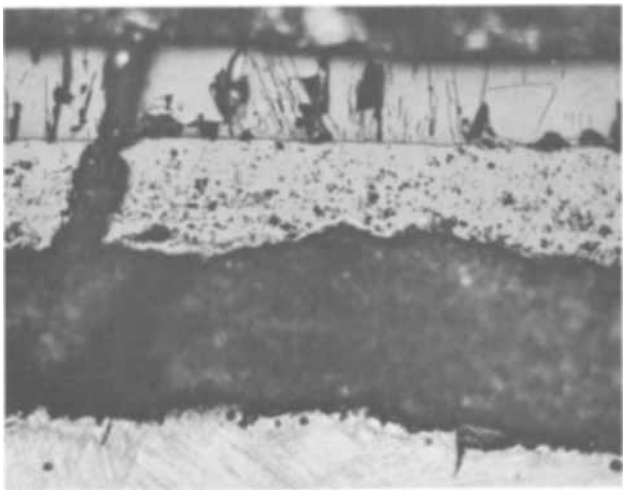

Fig. 11. Metallographic cross section of Co-25Cr alloy oxidized for 2 hr at 1300°C and 760 Torr oxygen. 200X.

Figure 11 shows the cross section of a sample oxidized at 1300°C in 760 Torr O_2 for 2 hr. The scales produced on other specimens oxidized in the region of high oxidation rates (see Fig. 8 where the k_p's are given) are similar to the ones shown in Fig. 10 and 11.

In all these cases, the scales have a duplex structure similar to that found on Co-10 w/o Cr (1) alloys. The outer layer consists of columnar CoO and the inner layer is porous. A major difference is that the inner layer consists mainly of the spinel $CoCr_2O_4$, while on Co-10 w/o Cr alloys, spinel occurred in the inner layer as a dispersion within a predominantly CoO matrix.

To provide better insight into the structure of the scale formed during oxidation at high pressures, a taper of a spalled scale has been prepared. In Fig. 12, a low magnification of the scale is shown, and in Fig. 13(a) through 13(d), different portions of Fig. 12 have been magnified. The curvature of the inner-outer layer interface is due to the bending of the scale after spalling. In Fig. 13(a), a portion of the outer layer is shown. The appearance is very similar to the appearance of the outer layers of scales found in Co-10 w/o Cr alloys (see ref. (1), Fig. 14). This part of the scale is virtually pure CoO. The cracks probably occurred during cooling, and the small precipitates are Co_3O_4.

Figure 13(b) shows the inner-outer layer interface, and Fig. 13(c) and (d) show sections of the inner

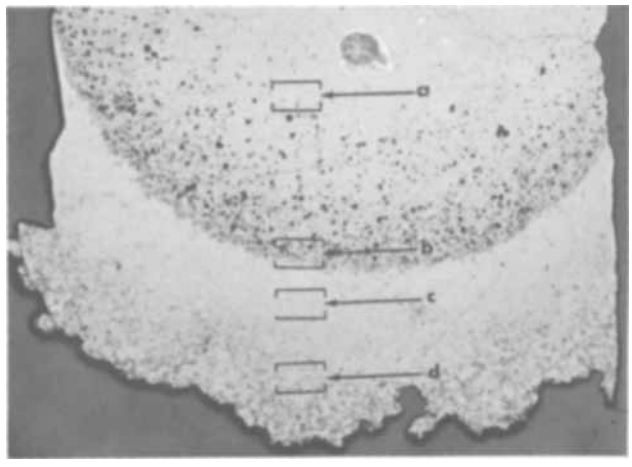

Fig. 12. Metallographic tapered cross section of scale of Co-25Cr alloy oxidized for 3 hr at 1300°C and 300 Torr oxygen. 15X.

layer. Electron-microprobe analysis (described below) shows that the inner layer is mainly spinel with CoO and Cr_2O_3 inclusions. From Fig. 13(c) and (d), one can see that the amount of these inclusions increases as the alloy/oxide interface is approached.

The microstructure of the oxidized specimen at low oxygen pressures (below 10 Torr) differs greatly from the behavior observed at high pressure.

X-ray analysis of the spalled scales reveals the presence of CoO, Cr_2O_3, and $CoCr_2O_4$. However, metallographic examination of the quenched specimen shows that CoO and $CoCr_2O_4$ are present only at the edges of the specimen. In Fig. 14, a specimen oxidized at 1300°C in 30 Torr O_2 for 7 hr is given. One can easily observe the duplex structure of the edge, and its similarity to the scales developed at high oxygen pressures. The thin layer on the large surface was identified by its optical activity and by microprobe analysis as Cr_2O_3; however, it is not known whether or not an additional outer layer spalled off. We were not able to find remnants of such a layer in the quenching alloy, and we therefore conclude that the CoO and $CoCr_2O_4$, identified by x-ray diffraction, originated from the edges of the specimens only.

Electron-microprobe analyses.—Electron-microprobe analyses have been made on some of the specimens to determine the composition of the different constituents of the scale. A scale from the specimen represented in Fig. 12 and 13 has been used for the high-pressure range.

In Fig. 15(a) through (c), some traces of the chromium content in the scale are shown, together with a micrograph of the actual trace on the scale. Trace "a" begins near the alloy oxide interface. The first 50μ of the trace show a large concentration of chromium in an erratic manner. This is due to the fact that the Cr_2O_3 at the alloy-scale interface is very powdery and is partially lost during polishing. The specimen shown in this figure has been slightly repolished and etched to remove the carbon layer deposited for the tracing, and to accentuate the scale features. This treatment caused further deterioration of the high chromium part of the scale as seen in the micrograph. At the points marked A, B, and C, the trace passes through relatively large CoO inclusions, and accordingly the chromium concentration is decreased. The bright area marked D has been probed separately and contained less than 10% chromium, which indicates CoO. The brightness and the 10% chromium observed are due to the fact that in this area the CoO inclusion is very thin and reflection from below is observed optically, as well as with the electron beam. The points marked E are typical CoO inclusions, while the points marked F are voids partially filled with Cr_2O_3. The dashed line on the trace is at about 46% chromium which corresponds to a spinel with the stoichiometric composition

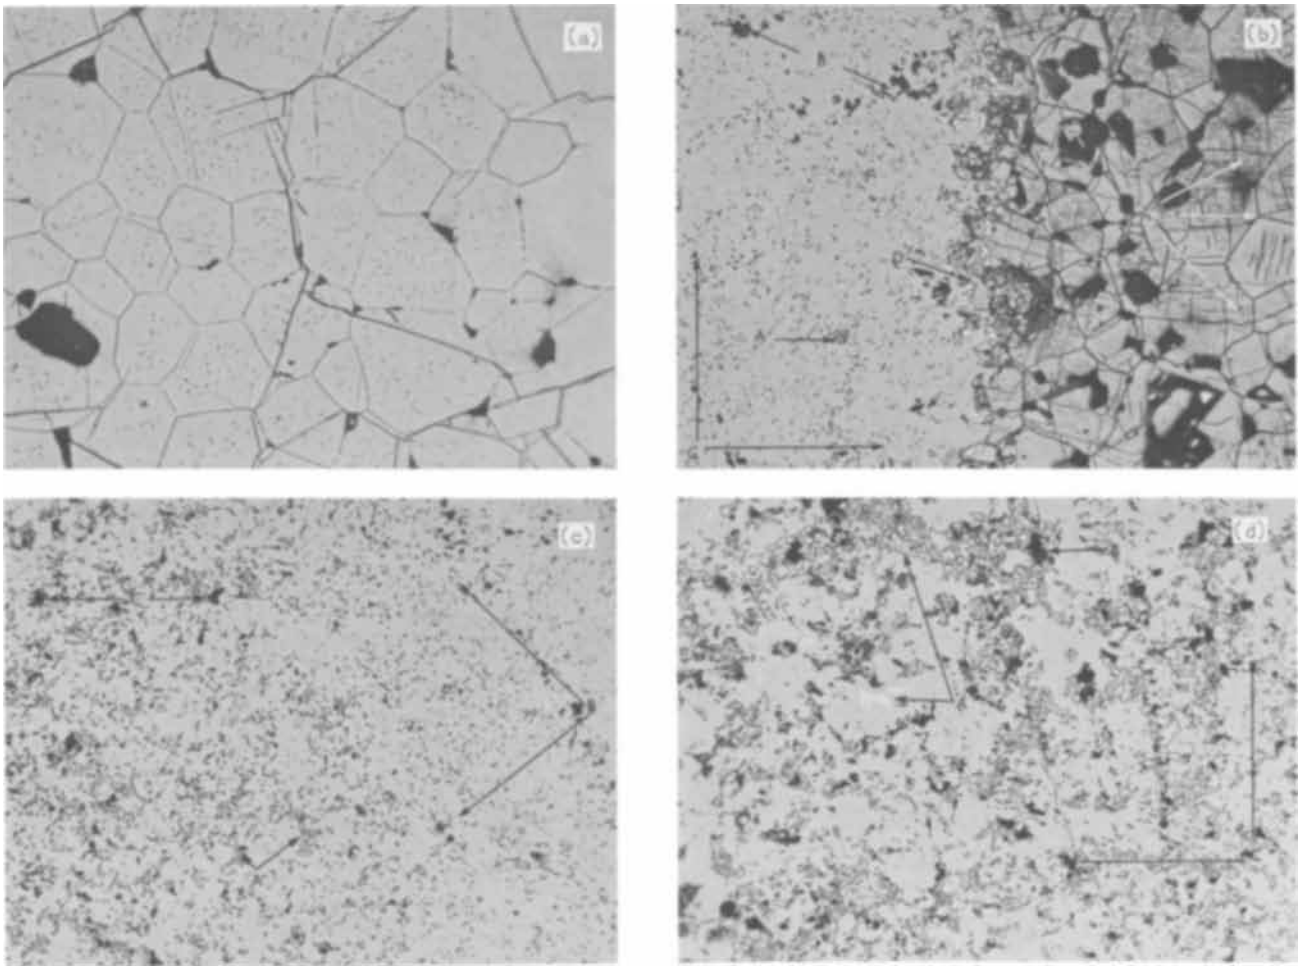

Fig. 13. Portions of Fig. 12. 200X. (a) Outer CoO layer. (b) Inner layer/outer layer interface. A, CoO inclusion; B, Cr_2O_3 and pores; C, $CoCr_2O_4$ layer; D, $CoCr_2O_4$ enclosed by CoO; E, CoO outer layer. (c) Inner layer. A, CoO inclusion; B, Cr_2O_3 and pores; C, $CoCr_2O_4$ body. (d) Inner layer close to the alloy scale interface. A, CoO channels; B, Cr_2O_3; C, $CoCr_2O_4$.

$CoCr_2O_4$. Trace "b" shows the chromium content somewhere in the middle of the inner layer and three well-marked decreases in chromium corresponding exactly to three small inclusions of CoO. One can note that the general size of the CoO inclusions has been markedly decreased relative to trace "a." Trace "c" has been taken at the inner layer-outer layer interface. The shallowness of the decrease in the chromium content at the interface, point B, is due to the tapering of the specimen, where the probe is "seeing" part of the inner layer below the outer layer. Point A corresponds to a very small CoO inclusion. The mean value of chromium content in the inner layer here is about 40%, corresponding to a spinel with the composition $Co_{1.3}Cr_{1.8}O_4$. The sudden increase of chromium in the outer layer, point C, corresponds to a void in the outer layer where the underlying inner layer is exposed to the probe beam.

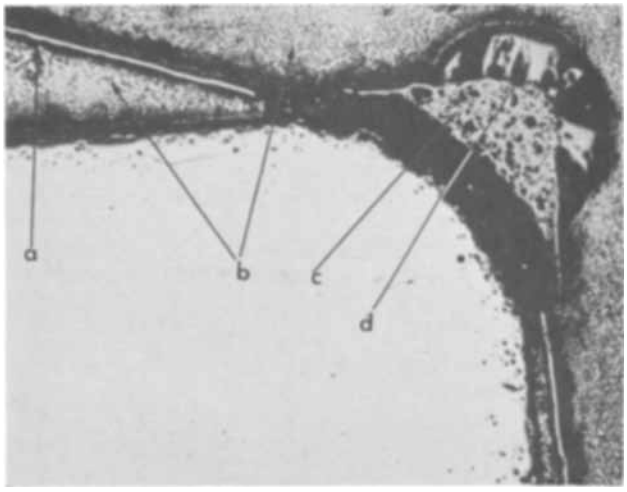

Fig. 14. Metallographic cross section of Co-25 w/o Cr alloy oxidized for 7 hr at 1300°C and 30 Torr oxygen. 70X. a, Cr_2O_3 scale; b, quenching alloy; c, spinel; d, CoO.

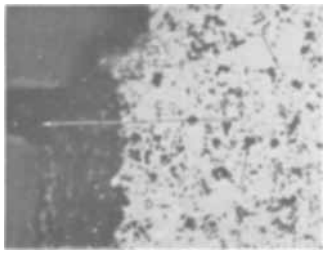
An analysis of a similar perpendicular cross section supported the conclusions that the outer layer is virtually pure cobalt oxide.

An electron-microprobe analysis was also made on a specimen oxidized at low oxygen pressures. Since it was impossible to retain a spalled section for shallow taper mounting, samples were prepared in two different ways. One of the samples was quenched in a liquid lead bismuth alloy and a perpendicular trace was made; another sample was left to spall, and a shallow taper of 4 degrees was prepared.

In Fig. 16, a trace through a quenched specimen oxidized at 1300°C in 2 Torr O_2 for 19 hr is shown. The area B in the micrograph is the quenching alloy and has been deleted from the trace. A and C are the traces through the alloy and scale, respectively. The sudden decrease in chromium content in the scale corresponds to a void. A trace through an adherent part of the scale on the large surface (after spalling) and a trace through the edge of the same specimen (oxidized at 1300°C in 10 Torr O_2 for 149.5 hr) are given in Fig. 17(a) and (b), respectively. In Fig. 17(a), which is a very shallow taper (4 degrees) only Cr_2O_3 is pres-

ent in the scale. The alloy is strongly depleted in chromium; however the size of the depleted region is not determined here due to the tapering. From both specimens it appears that the scale developed on the flat surfaces consists of pure Cr_2O_3. (This is in accordance with the optical observation, namely, green color and optical activity.) Owing to the violent spalling of these scales, one may question whether additional oxide was present in the scale. However, no remnants of an outer spalled layer could be found in the surrounding quenching alloy, and this leads us to conclude that the large surfaces of these specimens consist of single-layered Cr_2O_3.



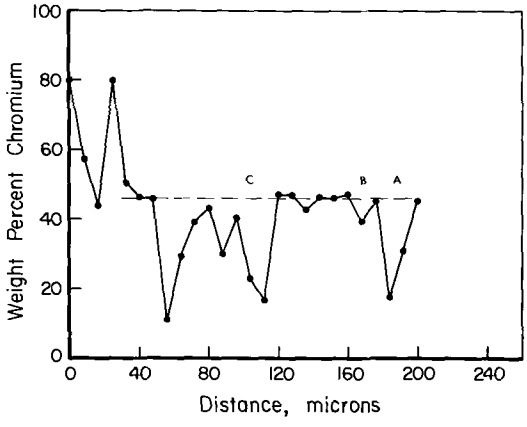


Fig. 15(a). Chromium concentration in part of the inner layer of the scale shown in Fig. 12 and 13, and corresponding micrograph. Trace near the alloy/scale interface. A, B, and C are CoO inclusions on the trace. D and F are other CoO inclusions. E are voids containing Cr_2O_3. 155X.

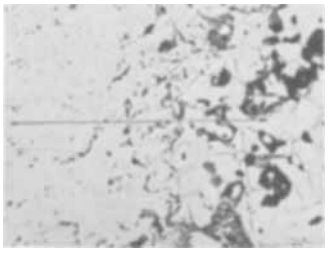

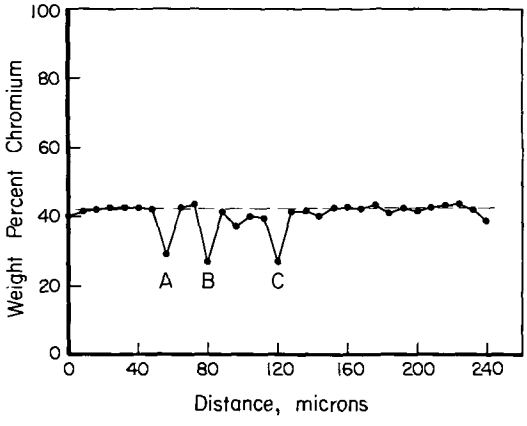

Fig. 15(b). Chromium concentration in part of the inner layer of the scale shown in Fig. 12 and 13, and corresponding micrograph. A trace in the middle of the inner layer. A, B, and C are small CoO inclusions on the trace. 155X.

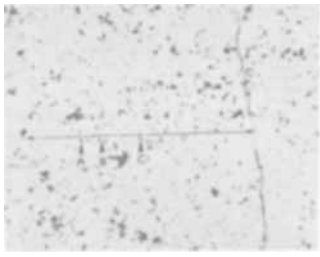

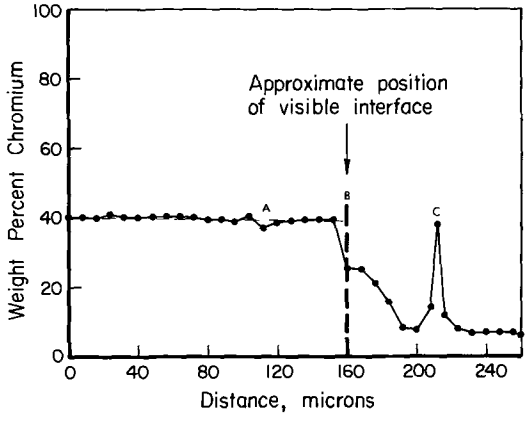

Fig. 15(c). Chromium concentration in part of the inner layer of the scale shown in Fig. 12 and 13, and corresponding micrograph. A trace near the inner/outer layer interface. A, a small CoO inclusion; B, the inner/outer layer interface; C, a void in the outer layer through which the inner spinel layer is seen. 155X.

From Fig. 17(b) we see that a structure is present at the edges which is similar to that found on the specimen oxidized at high oxygen pressure. In the alloy phase of the trace, the probe passed through two large internal Cr_2O_3 particles, A and B, and immediately at the alloy's edge a semicontinuous Cr_2O_3 layer is present. A small separation or void line is crossed at C. Then we penetrate the inner spinel layer marked D (some CoO inclusions are present in this part of the scale) until we reach the outer CoO layer (marked E), which in this case is sometimes mixed with spinel (like at F). From the metallographic cross-sections one can see that at some places the base of the scale contains metallic inclusions.

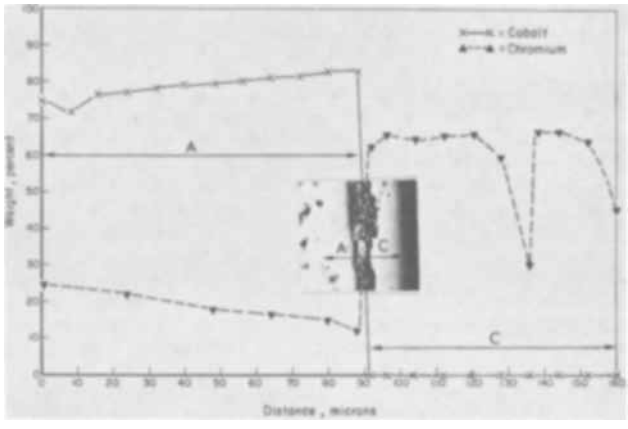

Fig. 16. A trace through the scale of a Co-25 w/o Cr alloy oxidized for 19 hr at 1300°C and 2 Torr oxygen, and a corresponding micrograph. 230X. A and C are correspondingly the alloy and the scale, B is a separation gap filled with the quenching alloy and is deleted from the trace.

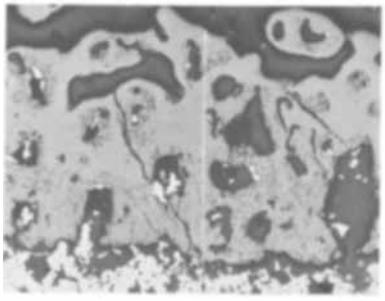

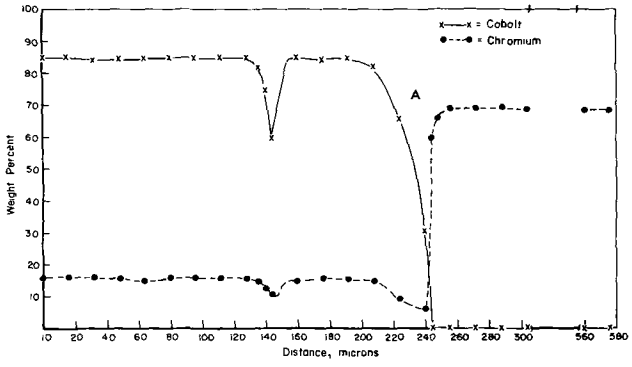

Fig. 17(a). Metallographic cross-section and electron microprobe trace of a tapered Co-25Cr alloy oxidized for 149.5 hr at 1200°C and 10 Torr oxygen. Flat surface taper (taper angle ~ 4 deg). The scale starts at A. 40X.

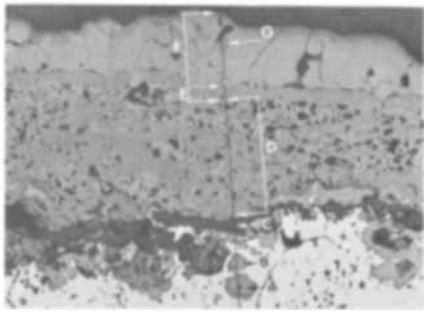

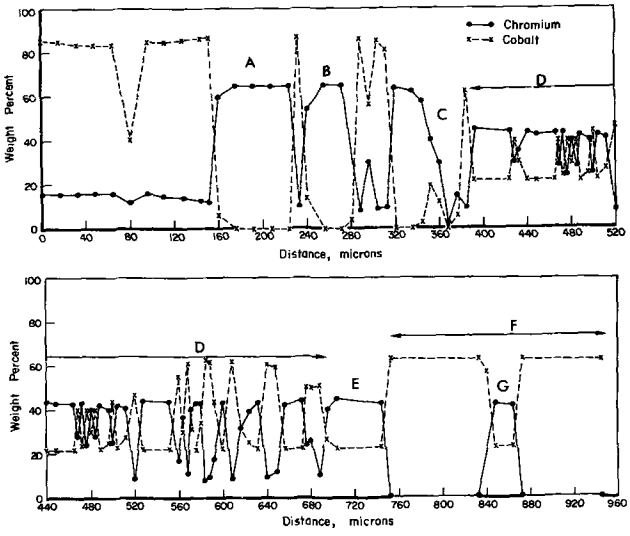

Fig. 17(b). Metallographic cross section and electron microprobe trace of a tapered Co-25Cr alloy oxidized for 149.5 hr at 1200°C and 10 Torr oxygen. Edge taper (taper angle ~ 86 deg). A and B are internal Cr_2O_3 particles, C is a separation of the scale and alloy. D is the spinel layer with CoO inclusions. F is the outer CoO layer, and G is a spinel inclusion in the outer CoO layer. E is a fairly continuous spinel layer without CoO inclusions. 50X.

This oxide structure at the edges is probably responsible for the CoO and $CoCr_2O_4$ x-ray line found in the powder collected from spalled specimens.

In Fig. 16, one can see the extent of the chromium-depleted region in the alloys; this supports the observation that at these pressures chromium oxidizes preferentially. (This is not well demonstrated in Fig. 17(a) because of the tapering.)

Discussion

The experimental evidence suggests that oxidation of Co-25 w/o Cr is governed by two oxidation mechanisms depending on the partial pressure of oxygen. At and above about 100 Torr O_2, the oxide scale has a duplex structure with an outer layer of CoO and an inner layer consisting predominantly of the Co-Cr spinel and with minor amounts of CoO. The scale has qualitatively the same microstructure as that found on Co-10 w/o Cr, but the spinel content is correspondingly higher in the inner layer of the scale on the Co 25 w/o Cr alloy. When the oxygen pressure is reduced below 100 Torr a drastic change in the composition and morphology takes place. Except at the edges of the specimens, the surface oxide consists of Cr_2O_3, and the oxidation thus involves a selective oxidation of chromium. The transition from the "high"- to "low"-pressure-oxidation regions is accompanied by a large, almost abrupt decrease in the oxidation rate.

Oxidation at high partial pressures.—Table I lists values of the thickness of the inner and outer layers on specimens oxidized in air at 1100°C for different periods of time. The ratio of layer thicknesses remains essentially constant during oxidation. This means that the mechanism must account for a continuous transport of cobalt through the inner layer and a resultant growth of the outer CoO layer.

Table I. Thickness of layers of specimens

	Oxidation period, hr		
	1	6.5	19
Thicknesses of inner layer, mm	0.01	0.034	0.1
Thicknesses of outer layer, mm	0.006	0.02	0.06
Ratio of layer thicknesses, inner/outer	1.67	1.7	1.67

This cobalt transport could conceivably take place by a diffusion through the spinel phase. However, the measured diffusion rate through the spinel is much too low (3) to account for the oxidation rates. Furthermore, the electron-microprobe analysis indicates that the spinel composition changes from approximately $CoCr_2O_4$ next to the alloy/oxide interface to $Co_{1.3}Cr_{1.8}O_4$ at the interface between the inner and outer layers [Fig. 15(a), (b), and (c)]. On this basis, a cobalt transport through the spinel phase is also highly improbable, as it would involve diffusion against the concentration gradient.

The inner layer also contains the CoO phase, and by analogy with the oxidation behavior of Co-10 w/o Cr (1, 2), we conclude that the CoO phase in the inner layer is present as a network which provides a continuous path for the outward migration of cobalt. As the diffusion coefficient of cobalt ions in CoO is 10^3 times higher than in the spinel, the fractional cross section of these channels need be only of the order of 0.001 of the total cross section to allow faster transport of Co cations than in the surrounding spinel.

In addition to the outward cobalt-diffusion, the over-all oxidation involves a continuous formation of Cr_2O_3 in the alloy phase (internal oxidation) or at the alloy/oxide interface. This leads to an enrichment of cobalt in the very outer layer of the metal phase; the cobalt is oxidized to CoO, which in turn reacts to form the spinel. As a result of the outward diffusion of cobalt and the growth of the outer CoO layer, appreciable porosity is formed in the inner layer. As described elsewhere (1, 2), oxygen is probably transported across the pores in the gaseous state, and the

porosity serves to partially short circuit the solid-state diffusion through the scale. The spinel phase, on the other hand, inhibits the oxidation by decreasing the effective CoO diffusion area in the inner scale.

In the previous considerations of the oxidation mechanism of Co-10 w/o Cr, the short-circuiting effect of the pores and the blocking effect of the spinel have been incorporated in the ideal expression for the parabolic growth of compact scales (1, 2). The resultant expression for the oxidation rate is given by (2)

$$\frac{dx}{dt} = k_p \frac{\left(1 - \frac{S_o}{A}\exp\frac{Q}{RT}\right)}{x(1-\gamma)} = \frac{k_p''}{x} \qquad [1]$$

k_p is the parabolic rate constant for growth of a compact scale, S_o/A is a parameter related to the relative blocking cross section of the spinel, Q is the activation energy associated with the increase in the radius of the spinel particles with temperature, and γ is a constant which expresses the fractional reduction in the total diffusion length, x.

Equation [1] gives an approximate phenomenological description of parabolic oxidation of Co-10 w/o Cr (1, 2). At high partial pressures of oxygen, Co-25 w/o Cr yields oxide scales with the same type of microstructure, but with a higher spinel content in the inner layer. It is believed that Eq. [1] similarly applies to the parabolic oxidation of Co-25 w/o Cr after extended oxidation. However, the spinel is, in this case, the major oxide, in contrast to the situation in Co-10 w/o Cr, and the expression $(S_o/A)\exp(Q/RT)$ should be replaced by a single parameter A describing the fractional cross section of the CoO phase. The pressure and temperature dependence of A are not easily predicted, and the activation energy at high oxygen pressures in Fig. 9, cannot be simply interpreted.

In accordance with this interpretation, the parabolic rate constant for the oxidation at the high oxygen pressures suggests a pressure dependence $k_p \propto p_{O_2}^{1/n}$, where n has the value of approximately 3. This is the same as that observed for unalloyed cobalt and Co-10 w/o Cr.

In contrast to cobalt and Co-10 w/o Cr, the oxidation of Co-25 w/o Cr exhibits a marked deviation from parabolic behavior during the initial oxidation stages. As a clue to the origin of this behavior, it was noted that exposure of specimens to the "vacuum" of the reaction furnace before introduction of oxygen resulted in thin films of Cr_2O_3. Thus the short vacuum treatment ($\sim 10^{-5}$ Torr) before the actual oxidation runs resulted in selective oxidation of chromium. In order to further study this aspect, specimens were exposed to the "vacuum" for different lengths of time before introducing the oxygen. The results at 1300°C are shown in Fig. 18. An increasing "vacuum" exposure drastically decreased the initial oxidation rate. We conclude that this is due to the formation of increasingly thicker films of Cr_2O_3.

If these Cr_2O_3 films are compact and assuming an unlimited supply of chromium from the alloy, one would expect the Cr_2O_3 films to continue their growth and the formation of the duplex scale would in this case not take place. However, the initial protective film of Cr_2O_3 will probably be broken down for two main reasons: (*i*) the alloy phase next to the oxide phase will be depleted in chromium; the rate of Cr_2O_3 growth will correspondingly be reduced and, eventually, formation of CoO and spinel will begin to take place beneath the outer Cr_2O_3 layer; (*ii*) the outer Cr_2O_3 layer will continuously evaporate, probably as CrO_3. These combined effects plus a change in the effective diffusional area through the solid-state reaction of CoO + Cr_2O_3 to the spinel will yield an initial nonparabolic behavior. After evaporation of the initial Cr_2O_3 film, the characteristic duplex scales will eventually be formed and the oxidation will then follow an approximately parabolic rate. The thicker the initial Cr_2O_3 film (Fig. 18) is, the longer the duration of the initial stage will be. This critical dependence of the pretreatment of the specimens will also significantly affect the reproducibility of parallel runs unless the experimental procedure is exactly the same from run to run. Such differences in vacuum exposure are partially responsible for the large scatter observed in k_p at 900°C in Fig. 8. The actual values of A and their pressure and temperature dependence will also be affected by the initial conditions. The deviation from parabolic behavior during the initial oxidation period may be rationalized on the basis of a time-dependent A. A more detailed model for the initial oxidation period will be published soon (4).

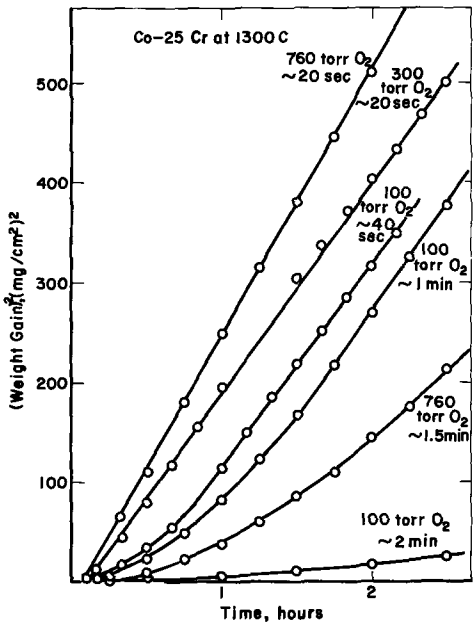

Fig. 18. Oxidation of Co-25Cr alloys at 1300°C in oxygen at pressures from 100 to 760 Torr. The various vacuum exposure periods are given by each line.

Oxidation at low partial pressures.—The abrupt decrease in the rate of oxidation in going from the high- to low-pressure regions is due to a transition to selective oxidation of chromium to Cr_2O_3 at low pressures. When neglecting the edge effects, the difference in oxidation rates reflects the improved oxidation resistance of Cr_2O_3 scales compared with the duplex scales.

An accurate analysis of the kinetic data is made difficult by the fact that part of the total weight gain is due to the edge oxidation. Furthermore, some evaporation of chromium oxide takes place, although this may be relatively small at the reduced pressures.

The oxidation at low pressures is, as a first approximation, independent of oxygen pressure. This is consistent with the fact that the main part (the flat surfaces) of the surfaces is covered with Cr_2O_3 and that oxidation of unalloyed chromium to Cr_2O_3 is also independent of oxygen pressure. A slight tendency toward increased net weight gain with decreasing oxygen pressure may possibly reflect an effect of decreased oxide (CrO_3) evaporation with decreased oxygen pressure. However, this must be confirmed by additional measurements.

The approximate parabolic rate constant at 10 Torr O_2 yields an activation energy of about 50 kcal/mole. This may be compared with the value of 59 kcal/mole for high-purity chromium (5). It has been concluded that growth of Cr_2O_3 is governed by chromium diffusion through the scale (5).

The reason for the edge effects is not clear. It may be speculated that they are due to the large surface-to-bulk ratio at the edges. This will result in a fast depletion of chromium in the alloy phase at the edges

and correspondingly make conditions favorable for CoO and subsequent spinel formation.

Magnetochemistry of Manganese in Fluorapatite and Chlorapatite

J. A. Parodi

General Electric Company, Lighting Research Laboratory, Nela Park, Cleveland, Ohio

ABSTRACT

Magnetic susceptibility determinations were made on apatites of the composition, $Ca_{10-\alpha}Mn_\alpha X_2(PO_4)_6$, where α varies from 0.1 to 5.0 and X is Cl or F. Values of the effective magnetic moment close to 5.92 are evidence for all of the manganese being divalent, and linear change of lattice parameters and refractive indices with manganese concentration indicate complete solid solution of manganese. For both chlorapatite and fluorapatite the Weiss constant varies linearly with manganese concentration, with the magnetic interaction being somewhat larger for the former. The linear variation of the Weiss constant is interpreted as indicating a constant distribution ratio of manganese between the two cation sites in the apatite structure.

Knowledge of the environment of manganese in halophosphate phosphors is important to an understanding of its function as an activator. While it is true that this problem has been the object of a moderate amount of research, the question of the crystalline environment of manganese and its interaction with its surroundings is still not settled. It is clear from electronic paramagnetic resonance (EPR) studies (1-3) that manganese preferentially occupies cation sites of trigonal symmetry in fluorapatite, the Ca(I) sites, when its concentration is roughly two orders of magnitude less than amounts used in lamp phosphors. EPR studies by Piper and Prener on single crystals of chlorapatite (4) show that manganese is distributed among the four Ca(I) and six Ca(II) sites. Ohkubo and Mizuno (5) interpret EPR spectra of synthetic polycrystalline "$3[Ca_3(PO_4)_2]$ · $Ca(F_{1-x}, Cl_x)$: Mn (ratio of Mn- to Ca-ion is 1:200)" as indicating that Mn^{++} gradually shifts from the Ca(I) site to the Ca(II) site as x increases from 0 to 0.18. Johnson (6) has interpreted polarized luminescence experiments, as well as EPR measurements, as indicating that luminescent Mn^{++} is at Ca(I) positions in fluorapatite and at Ca(II) positions in chlorapatite. Johnson's crystals contained two or four orders of magnitude less manganese than commercial halophosphate phosphors.

Unfortunately all of the above researchers investigated materials with very low manganese content, so that one cannot with confidence extrapolate their conclusions to halophosphates containing much higher concentrations of manganese. The distribution of manganese between the two cation sites may be a function of manganese concentration. For a given paramagnetic ion the value of the Weiss constant, Δ, determined by magnetic susceptibility measurements, is dependent on the crystalline environment of the ion (7). Thus, a determination of Δ for Mn^{++} would be expected to yield information not only on the distribution of manganese between the Ca(I) and Ca(II) positions, but, hopefully, also on the manner in which manganese interacts with its surroundings. The following work is concerned with the magnetic susceptibility of $Ca_{10-\alpha}Mn_\alpha X_2(PO_4)_6$, where X is F or Cl and α varies from 0.1 to 5.0.

Experimental

Preparation of materials.—Calcium, manganese chlorapatites were produced from appropriate mixtures of manganous orthophosphate, calcium orthophosphate, calcium carbonate, and ammonium chloride in 50% excess. The mixtures were fired for 1 hr in telescoping fused silica crucibles in a stream of nitrogen passed over NH_4Cl at 300°. Firing temperature ranged from 1000° for low manganese content to 850° for high manganese concentration.

Fluorapatites were prepared from similar mixtures except that stoichiometric proportions of calcium fluoride were used in place of ammonium chloride. They were fired two times for 1 hr in a purging atmosphere of CO/CO_2 = 1/10 at temperatures ranging from 950° to 1100°.

The resulting apatites were pure white to cream colored depending on manganese concentration. They sintered, but the chlorapatites were easily converted to free flowing powders by heating in water. Presumably a little calcium chloride cement was produced during firing. The fluorapatites were ground by mortar and pestle and passed through a 100 mesh silk screen.

$Mn_3(PO_4)_2$ was prepared by firing a mixture of $MnNH_4PO_4 \cdot H_2O$ and $MnCO_3$ two times at 850° in a nitrogen atmosphere. $Ca_3(PO_4)_2$ was prepared by firing a mixture of phosphor grade $CaHPO_4$ and $CaCO_3$ in nitrogen at 1000°.

Magnetic susceptibility.—The Faraday method (8), with a Mettler microbalance and pole caps after the design of Heyding, Taylor, and Hair (9), was used

for the magnetic susceptibility determinations. Mercury tetrathiocyanatocobaltate, $HgCo(CNS)_4$, and trisethylenediamine nickel thiosulfate, $Nien_3S_2O_8$, were used as calibration standards (10, 11). The sample container, which was made of fused silica, was a cylindrical bucket (7 mm ID x 8 mm) attached to a rod (20 cm x 2 mm diameter) by means of a stirrup. During measurement the sample container was surrounded by an atmosphere of nitrogen. As no trace of ferromagnetism was evident in any of the samples measured, the susceptibilities reported here are averages of determinations at several different values, usually ten, of the magnetic field. Susceptibility determinations were made at four different temperatures: room temperature and the boiling points of nitrogen, ethane, and dichlorodifluoromethane. The boiling points at 1 atm pressure are 77.3°, 184.6°, and 243.4°K, respectively.

Analytical.—Unit cell dimensions were determined by a standard x-ray diffraction technique.

Refractive indices were determined with the aid of a microscope by immersion in standard refractive index oils.

Manganese was determined either volumetrically by the bismuthate method (12), or spectrophotometrically after oxidation to permanganate by potassium periodate (13).

For the few chlorapatites subjected to complete compositional analysis, calcium was determined gravimetrically as the oxide after a double precipitation as the oxalate (14), phosphate was determined gravimetrically as magnesium pyrophosphate after a molybdate separation and a double precipitation as magnesium ammonium phosphate (14, 15), and chloride was determined by the Volhard method (16).

Results and Discussion

Refractive index as a function of manganese concentration is given in Fig. 1. It is seen that the refractive index increases linearly with manganese content. Figure 2 shows that the unit cell volume for the chlorapatites decreases regularly with increasing manganese concentration. In Fig. 3 it is seen that the spacing of the (211) plane of fluorapatite decreases progressively with increasing manganese concentration. Chemical analyses of the calcium manganese chlorapatites (Table I) show only small deviations from stoichiometry, indicating the presence of only minor proportions of impurity phases. It is, thus, reasonable to conclude that, for the purpose of magnetic susceptibility determinations, all of the manganese is in solid solution in a single apatite phase.

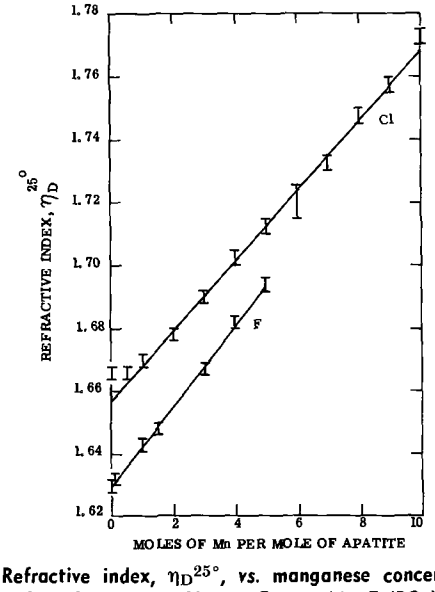

Fig. 1. Refractive index, $\eta_D^{25°}$, *vs.* manganese concentration in $Ca_{10-\alpha}Mn_\alpha Cl_2(PO_4)_6$, curve Cl, and $Ca_{10-\alpha}Mn_\alpha F_2(PO_4)_6$, curve F.

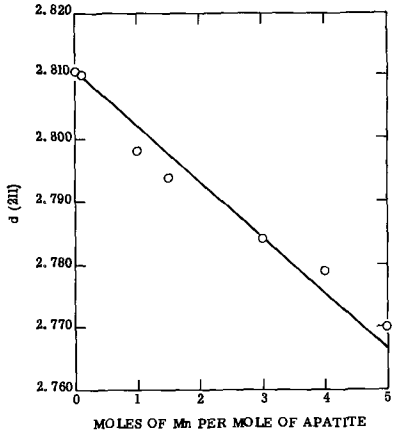

Fig. 3. Distance between (211) planes of $Ca_{10-\alpha}F_2(PO_4)_6$ *vs.* concentration of manganese.

Magnetic susceptibilities are listed in Tables II and III. The average standard deviation of a single measurement is 0.2%.

The temperature dependence of the magnetic susceptibility for these apatites follows the Curie-Weiss law, which has the form

$$\chi = \frac{C}{T+\Delta} + A \qquad [1]$$

Here C is the Curie constant, Δ is the Weiss constant which is expressed as an additive correction to the temperature, and A is the experimentally determined diamagnetic susceptibility of the apatite: —0.3604 x 10^{-6} cgs units for chlorapatite and —0.3406 x 10^{-6} for fluorapatite. A rearrangement of the above equation gives

$$T = -\Delta + \frac{C}{\chi + A} \qquad [2]$$

so that Δ is determined experimentally by plotting the absolute temperature against the reciprocal of the paramagnetic susceptibility. A best fit of the data to a straight line is easily and most accurately done by a least squares calculation on a computer. This was done

for the data in Tables II and III, and the results are given in Table IV and Fig. 4.

Before discussing the significance of the Weiss constant determination, it is necessary to ascertain the oxidation state of the manganese. From the method of preparation and the color of the samples, as well as the fact that manganese substitutes for divalent calcium in apatite, one might assume with reasonable certainty that all of the manganese is divalent. However, the value of the effective magnetic moment is the best indication of the oxidation state of manganese. We have seen that the experimental susceptibilities obey a Curie-Weiss law, which, substituting fundamental constants for the Curie constant, C, can be written

$$\chi_M = \frac{N\beta^2\mu_{eff}^2}{3k(T + \Delta)} = \frac{4N\beta^2 S(S + 1)}{3k(T + \Delta)} \qquad [3]$$

where χ_M is the temperature dependent molar paramagnetism. Rearranging and putting in numerical values for the constants, the effective magnetic moment is expressed in terms of experimentally determined parameters

$$\mu_{eff}^2 = 8.060\ (T + \Delta)\ \chi_M \qquad [4]$$

Results of this calculation appear in Tables V and VI. From equation [3], $\mu_{eff}(Mn^{+2}) = 5.92$ and $\mu_{eff}(Mn^{+3}) = 4.90$, so that, therefore, the experimental magnetic moments of Tables V and VI establish the fact that all of the manganese is divalent. Further, we see that,

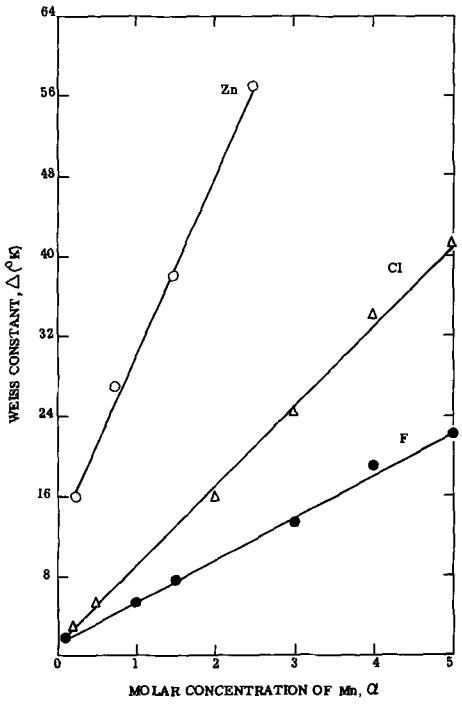

Fig. 4. Weiss constant of manganese in fluorapatite and chlorapatite, $Ca_{10-\alpha}Mn_\alpha X_2(PO_4)_6$, curves F and Cl, and in zinc silicate, $Zn_{12-\alpha}Mn_\alpha(SiO_4)_6$, curve Zn, vs. molar manganese concentration α.

Table V. Effective magnetic moment of manganese in $Ca_{10-\alpha}Mn_\alpha Cl(PO_4)_6$

α	Wt. % Mn	μ_{eff}	$100\dfrac{5.92 - \mu_{eff}}{5.92}$
0.1	0.48	5.83	1.5
0.2	0.92	5.94	0.3
0.5	2.48	5.77	2.5
1.0	4.8	5.97	0.8
2.0	9.68	5.91	0.2
3.0	14.66	5.93	0.2
4.0	19.39	5.93	0.2
5.0	23.8	5.93	0.2

$\mu_{eff}^2 = \dfrac{3k}{N\beta^2}(T + \Delta)\ \chi_M = 8.060\ (T + \Delta)\ \chi_M$.

$\chi_M = \dfrac{54.94}{N_1}(\chi + 0.3604 \times 10^{-6})$ where N_1 is the weight fraction of Mn in the apatite.

Table VI. Effective magnetic moment of manganese in $Ca_{10-\alpha}Mn_\alpha F_2(PO_4)_6$

α	Wt. % Mn	μ_{eff}	$100\frac{5.92-\mu_{eff}}{5.92}$
0.1	0.56	5.78	2.4
1.0	5.32	5.92	0.0
1.5	8.15	5.92	0.0
3.0	15.81	5.93	0.2
4.0	20.63	5.93	0.2
5.0	25.50	5.87	0.8

$\mu_{eff}^2 = \frac{3k}{N\beta^2}(T + \Delta)\chi_M = 8.060\ (T + \Delta)\chi_M$.

$\chi_M = \frac{54.94}{N_1}(\chi + 0.3406 \times 10^{-6})$ where N_1 is the weight fraction of Mn in the apatite.

as is to be expected for an S state transition metal ion, the "spin-only" formula [3] is obeyed very closely.

Van Vleck (7) interprets the Weiss constant as primarily a manifestation of distortions by interatomic forces. It is not an atomic property as is clear from the fact that it varies markedly from one compound to another of a given paramagnetic ion, whereas μ_{eff} is relatively constant. Its origin can be twofold: Δ can arise from (*i*) Heisenberg exchange interaction (direct or super-) between magnetic dipoles and/or (*ii*) interaction of the orbital angular momentum with asymmetric crystalline electric fields. In the case of S state ions such as Mn^{++} and Fe^{+++}, which have no orbital angular momentum, Δ is due only to exchange interaction and should approach zero at infinite magnetic dilution. It is clear that spin-spin interaction will be a function of the kinds and arrangements of intervening diamagnetic ions. To be specific, differences in the crystalline environment of Mn^{++} between fluorapatite and chlorapatite should appear as different values of the Weiss constant.

Inspection of Fig. 3, which is a plot of Δ against manganese concentration, reveals that there is indeed a difference in the exchange interaction between the two structures. The interaction of Mn^{++} in chlorapatite is substantially greater than in fluorapatite. In both cases, Δ is a linear function of manganese concentration and its sign is positive.

In the apatite structure there are four calcium ions of one kind, Ca(I), and six of another, Ca(II), per unit cell (17-19). The first of these, which is the same in both fluor- and chlorapatite, is a site of trigonal symmetry in which Ca^{++} is in the center of a skewed triangular prism of oxygen ions. In the second site each calcium ion is in a reflection plane perpendicular to the trigonal axis and is surrounded by an irregular polyhedron of one halide and five oxygen ions. In fluorapatite the fluoride ion is at the center of a regular triangle of calcium ions of the second kind, whereas in chlorapatite the chloride ion is shifted along the C_0 axis to a position somewhat less than half the distance from one mirror plane of calcium ions to the next.

From the crystal structure it is clear that differences in Δ can only be caused by interactions of Mn^{++} in locations near the halide ions. The larger values of the Weiss constant in chlorapatite are, therefore, caused by the presence of manganous ions at Ca(II) positions. From geometrical considerations one would expect Mn^{++} ions at the Ca(II) sites to be less well shielded from one another by intervening anions in chlorapatite and, therefore, to interact more strongly. Although there are six Ca(II) locations available in both apatites for occupation by Mn^{++}, it is extremely unlikely that, at the higher concentrations especially, all of the manganese would preferentially seek out these positions. On the other hand it is not possible at the highest concentration for all of the manganous ions to be in Ca(I) sites. It is, therefore, more reasonable to assume a distribution between the two sites in both chlorapatite and fluorapatite. From the observation that Δ is a linear function of manganese concentration from $\alpha = 0.1$ to 5.0, it is concluded that the distribution ratio of Mn^{++} between Ca(I) and Ca(II) sites is constant with change in manganese content. It is not possible to determine, from the data presented here, the numerical value of the distribution ratio, nor whether it differs from fluorapatite to chlorapatite.

The conclusion that manganese substitutes for both types of calcium ions is in agreement with the EPR results of Piper and Prener for much lower manganese concentration in chlorapatite (4), but it does not agree with the EPR studies on fluorapatite (1-3) which place Mn^{++} at Ca(I) positions. It would appear that manganese shifts from Ca(I) positions to a distribution between Ca(I) and Ca(II) as its concentration in fluorapatite increases from about Mn/Ca = 10^{-3} to 10^{-1}.

The positive sign of Δ indicates that the exchange interaction is antiferromagnetic. Griffith (20) considers the case of direct exchange between ions of a pair, the interaction given by $-J\bar{S}_1\cdot\bar{S}_2$. J is a constant commonly called the "exchange integral" and $\bar{S}_1$ and $\bar{S}_2$ are the spin vectors for the two ions. He obtains a spin Hamiltonian for the pair

$$H = -\tfrac{1}{2}JS(S+1) + 2\beta\bar{H}\cdot\bar{S} + \tfrac{3}{4}J$$

which shows that in zero magnetic field there are a singlet and a triplet state with energy separation, J. For positive J the triply degenerate state lies lower and the interaction is ferromagnetic, whereas for negative J the spin multiplet is inverted and the exchange interaction is antiferromagnetic. Griffith derives an expression for the magnetic susceptibility

$$\chi = \frac{N\beta^2}{k\,[T - (J/4k)]}$$

which is equivalent to the Curie-Weiss law

$$\chi = \frac{N\beta^2\mu^2}{3k(T+\Delta)}$$

so that $\Delta = -J/4k$. Thus, Δ is positive for antiferromagnetic and negative for ferromagnetic direct exchange.

Interaction via an intervening anion between two cations with half filled d-orbitals, *i.e.*, superexchange, is always antiferromagnetic (21, 22). This is readily understood if we consider the linear combination, $Mn^{++}-O^{=}-Mn^{++}$. There is an overlap of a $p\sigma$ orbital of $O^{=}$ with the d-orbitals of the Mn^{++} ions. The transfer of a p-electron to one Mn^{++} ion must be into an empty half of a d-orbital, so that by the Pauli exclusion principle, the p-electron left behind must have a spin parallel to those of the Mn^{++} d-electrons. In order for the remaining p-electron to transfer to the Mn^{++} ion on the opposite side, therefore, the spins of the latter must be opposed to the spins of the first Mn^{++} and the exchange is antiferromagnetic. When the angle made by Mn-O-Mn is 90° rather than 180° as in the above example, it should be clear from geometrical considerations that direct cation-cation exchange is more significant and cation-anion-cation exchange is less significant. The over-all effect is still antiferromagnetic and is greater for oxides than chlorides because of the shorter cation-cation distance in the former (23).

It is clear that the greater the overlap of the ligand wave function with the paramagnetic cation wave function, *i.e.*, the more covalent the bond, the greater is the superexchange. On this basis one would expect superexchange between Mn^{++} ions to be greater through chloride ions than through fluoride ions. In the two apatites, however, by virtue of the fact that the fluoride and chloride ions occupy different posi-

tions relative to Ca(II), the cation-anion overlap is probably greater for the former. This might be sufficient to create at the halide site more superexchange in fluorapatite, and the geometrical factors will almost certainly cause greater direct exchange in chlorapatite. The net effect, as we have seen, is a substantially larger antiferromagnetic exchange interaction for Mn^{++} in chlorapatite.

It is of interest to compare the magnetic interaction of manganese in the apatites with that of manganese in zinc silicate. For this purpose the results of Larach and Turkevich (24) are plotted, together with the present data on apatites, in Fig. 3. It is seen that Δ for Mn^{++} is much larger in zinc silicate than in the apatites. The stronger interaction can be explained on the basis of a difference in bonding.

The bonding between Ca^{++} ions and coordinating anions in apatite has more ionic character than Zn-O bonds in zinc silicate. Cation to anion distances in the apatites are very close to the sums of the corresponding ionic radii of Goldschmidt (25) and Pauling (26). Further, the value of the hyperfine splitting constant for Mn^{++} in the Ca(I) position, about 93 oersteds for an X-band EPR spectrometer, indicates relatively strong ionic bonding (1-3). Van Wieringen (27) has shown that the hyperfine splitting of Mn^{++} is large in ionic compounds, 99 and 91 oersteds in CaF_2 and CaO, and relatively small in covalent compounds, 65 and 59 oersteds in ZnSe and CdTe. In zinc silicate a hyperfine splitting of 84 oersteds (28) indicates that the bonding is intermediate between that of compounds that are usually considered strongly ionic and strongly covalent. Also the Zn-O distance of 1.92Å (29) corresponds more closely to the sum of the covalent radii (30) than to the sum of the ionic radii. The result of this difference in character of bonding is a larger Weiss constant for Mn^{++} in zinc silicate: greater superexchange because of greater overlap of the wave functions and greater direct exchange because of smaller intervening anions.[1]

It would be of interest to determine Δ for Mn^{++} in apatites containing both F^- and Cl^-. In halophosphate phosphors a relatively low concentration of Cl^- has a profound effect on the wavelength of Mn^{++} emission. For example Apple and Ishler (31) report a Mn^{++} emission peaking at 5720Å in calcium fluorophosphate phosphor, 5860Å in calcium chlorophosphate, and 5830-5850Å[2] in calcium chlorofluorophosphate in which about 10% of the fluoride has been replaced by chloride. One wonders whether a similar disproportionate effect on the exchange interaction of manganese would occur. Apple and Ishler (31) have interpreted changes in the luminescence emission of Mn^{++} in chlorophosphates and chlorofluorophosphates quenched from 1150° as due to possible redistribution of Mn^{++} between the Ca(I) and Ca(II) sites. In view of the above discussion one might expect to see a change in Δ for quenched samples. Also it is not inconceivable that the presence of antimony would cause a change in Δ, either by creating a difference in manganese distribution between the two cation sites and/or causing an environmental change which would disturb the exchange interaction.

Crystal Growth and Ferroelectric Properties of Single Crystals from the Ternary Systems of $KNbO_3$-$NaNbO_3$-$BaNb_2O_6$ and $RbNbO_3$-$NaNbO_3$-$BaNb_2O_6$

ABSTRACT

Good optical quality single crystals with a tungsten bronze crystal structure were grown by the Czochralski method from melts in the ternary systems of $(KNbO_3)_x$ $(NaNbO_3)_y$ $(BaNb_2O_6)_z$ and $(RbNbO_3)_x$ $(NaNbO_3)_y$ $(BaNb_2O_6)_z$, where $x < 0.34$, $y < 0.34$, and $z > 0.66$. X-ray, chemical, and differential thermal analyses were performed on the pulled crystals. The dielectric properties and twin structure of the crystals have been examined. Some compositions contain no microtwins while retaining the favorable electrooptic properties associated with $NaBa_2Nb_5O_{15}$.

A number of new electrooptic materials, such as $KSr_2Nb_5O_{15}$ (1) and $NaBa_2Nb_5O_{15}$ (2, 3), with a tungsten bronze structure have been reported to have improved linear electrooptic coefficients and are capable of efficient second harmonic generation. These materials do not suffer laser damage as has been the case with $LiNbO_3$, and some compositions can be grown as large optically homogeneous single crystals. In particular, $NaBa_2Nb_5O_{15}$ shows a great deal of promise, but a severe problem results from the presence of microtwins (4) which are difficult to remove and tend to degrade the optical quality.

The ferroelectric and electrooptic properties of tungsten bronze-type ferroelectric crystals pulled from melts of $K_xNa_{1-x}Ba_2Nb_5O_{15}$ have been reported (5). These compositions have many of the favorable properties of $NaBa_2Nb_5O_{15}$, including relative ease of growth. When $x \geq 0.7$ the difficulties of microtwinning are eliminated, resulting in better optical quality crystals. At $x = 0.8$, the ferroelectric transition temperature is 420°C, the room temperature dielectric constant is 55, and the electrooptic coefficient is 4.0×10^{-11} m/V. The latter value is 10% higher than $NaBa_2Nb_5O_{15}$. Laser induced optical inhomogeneities cannot be observed after extended exposure.

The present study is an extension of the work on $K_xNa_{1-x}Ba_2Nb_5O_{15}$ to include other compositions in the ternary system of $KNbO_3$-$NaNbO_3$-$BaNb_2O_6$ and to examine the effect of substituting $RbNbO_3$ for $KNbO_3$. We have studied single crystals pulled from melts of $(KNbO_3)_x$ $(NaNbO_3)_y$ $(BaNb_2O_6)_z$ and $(RbNbO_3)_x$ $(NaNbO_3)_y$ $(BaNb_2O_6)_z$ where $x < 34$, $y < 34$, and $z > 66$. These limits represent the approximate location of the ferroelectric tungsten bronze structures in the ternary systems. The two ternary systems are shown in Fig. 1 and 2. The compositions of interest melt in the range of 1390°-1460°C.

A knowledge of the ternary phase diagrams is necessary to understand what compositions can be expected by pulling crystals from a melt. There are three binary systems which are important to the behavior of the two ternary systems. These are the $NaNbO_3$-$BaNb_2O_6$, $KNbO_3$-$BaNb_2O_6$, and $RbNbO_3$-$BaNb_2O_6$ systems. Scott *et al.* (6) have examined the $NaNbO_3$-$BaNb_2O_6$ phase diagram and found an orthorhombic tungsten bronze structure which extends from 62 to 83 m/o (mole per cent) $BaNb_2O_6$ and eutectics at 23 and 85 m/o $BaNb_2O_6$. The maximum melting (1438°C) bronze composition was near 66.7 m/o $BaNb_2O_6$($NaBa_2Nb_5O_{15}$). Giess *et al.* (5) reported tetragonal tungsten bronze structures at 66.7 m/o $BaNb_2O_6$ in the $KNbO_3$-$BaNb_2O_6$ and $RbNbO_3$-$BaNb_2O_6$ systems. The compounds, $KBa_2Nb_5O_{15}$ and $RbBa_2Nb_5O_{15}$, decompose peritectically at 1391° and 1395°C, respectively.

Experimental Procedures

The starting materials were K_2CO_3, Na_2CO_3, $BaCO_3$, and Nb_2O_5 from the Johnson-Matthey Company, Grade

* Electrochemical Society Active Member.

I, with less than 10 ppm impurities, except for Nb_2O_5 which contained less than 0.03 w/o (weight per cent) Ta. The Rb_2CO_3 (99%) from Alfa Inorganics was found to contain Na, Al, Mg, Si, and Ca in quantities of less than 100 ppm. In some cases the Rb_2CO_3 was dried in CO_2 before using. Differential thermal analysis (DTA) was used to establish the freezing points of various compositions and to examine the melting and freezing behavior of pulled single crystals. Two gram powder samples of the pulled crystals or annealed powder samples were loaded in platinum capsules containing a thermocouple well in the bottom. The sample and alumina reference material were heated and cooled at 5°C/min.

Each composition was prepared by heating stoichiometric quantities of the starting materials to 1400°-1500°C in a 100 ml platinum crucible. A Czochralski type crystal pulling system (8) was used to obtain single crystals. A 23 kw r.f. generator supplied power to melt the charge in the platinum crucible, which was insulated by alumina pellets. Oxygen was passed into the system at 0.3 liters/min to avoid reduction of the crystals, which would result in a blue discoloration. Crystal growth was started with a seed crystal mounted on the pulling shaft. In many cases the seed was a single crystal of $NaBa_2Nb_5O_{15}$ with the c-axis oriented along the direction of crystal growth. Pull rates were about 2-6 mm/hr with a rotation rate of 40-60 rpm. The temperature gradient above the melt surface was about 18°C/mm for the first 5 mm and 1°C/mm for the next 50 mm. The system was usually cooled at 5°C/hr for the first 300°C and then at 15°C/hr to room temperature. Thus, the crystals were well annealed after growth, and cracking was not a serious problem. Rapid cooling did cause cracking normal to the c-axis.

Crystal growth of single phase ternary compositions was no more difficult than the growth of $NaBa_2Nb_5O_{15}$. The growth rates that were used appeared to be adequate to establish equilibrium conditions between the melt and freezing crystal, although none of the ternary compositions studied was found to be congruently melting; the crystal compositions always differed from the starting melt compositions. Some estimate of the change in composition can be seen in Fig. 3 and 4 which show the melt and pulled crystal compositions. The pulled crystal composition is the analyses obtained on the first 30g or less of crystal pulled from a 400g melt. These data are also listed in Tables I and II. The melt compositions with 66.7 m/o $BaNb_2O_6$ are part of the $K_xNa_{1-x}Ba_2Nb_5O_{15}$ or $Rb_xNa_{1-x}Ba_2Nb_5O_{15}$ pseudo-joins in the ternary systems. The evaporation of K_2O and Na_2O from melts of $K_xNa_{1-x}Ba_2Nb_5O_{15}$, where x = 0.7, 0.8, was not found to be significant. Pulled crystals from compositions held above the melting point for 20 to 430 hr showed no significant difference in chemical composition or Curie temperature. Also, the same shift in composition as shown in Fig. 3 was found

The dashed line indicates the approximate location of the phase boundary between the $BaNb_2O_6$ and bronze phases. The shaded area is the region with a tetragonal bronze structure.

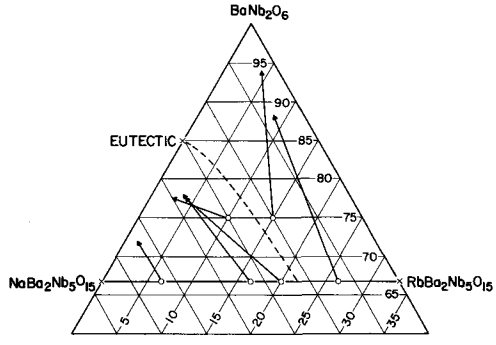

Fig. 4. Section of the ternary system of $RbNbO_3$-$NaNbO_3$-$BaNb_2O_6$ showing the melt compositions (⊙) and the compositions of pulled crystals (←) from each melt. The dashed line indicates the approximate location of the phase boundary between the $BaNb_2O_6$ and bronze phases.

for crystals grown by slowly cooling melts in sealed crucibles where no evaporation could take place.

Three Bridgman crystal growth runs were made to determine the phases present in particular compositions, the order in which the phases freeze out, and the lattice parameters and chemical composition of the first to freeze material. Two 300g samples of $(KNbO_3)_{16}$ $(NaNbO_3)_{11}$ $(BaNb_2O_6)_{73}$ and $Rb_{0.7}Na_{0.3}Ba_2Nb_5O_{15}$ and one 36g sample of $K_{0.85}Na_{0.15}Ba_2Nb_5O_{15}$ were loaded in platinum tubes which were lowered at 3 mm/hr through a platinum resistance heated furnace from a uniform zone at 1480°C into a colder zone with a gradient of 1.2°C/mm. Below 1200°C, the tubes were cooled at 50°C/hr. This method did not produce single crystals greater than 1 mm (3).

* Crystal from the frozen melt.
‡ Major phase was $BaNb_2O_6$.

Lattice constants were determined by the powder method with a silicon internal standard on a Guinier x-ray focusing camera with copper K_α radiation. The standard deviation of sine squared theta values was about 0.1%. Thus, the 3σ limits are 0.02 and 0.006Å for a_o and c_o, respectively. A Buerger precision camera with filtered molybdenum radiation was used in single crystal studies.

The pulled crystals were oriented by x-ray methods to within a ½ degree of the c-axis and cut on a diamond saw. The polished c-plane surface was examined for strain and microtwins on a Leitz polarizing microscope. The temperature (T_W) at which the microtwins disappear was measured on a microscope hot stage. For the orthorhombic crystals, microtwins were removed by cooling 5 x 5 x 5 mm^3 or smaller crystals through the tetragonal to orthorhombic phase transition with pressure applied along the [100] axis of the orthorhombic cell. The pressure was applied by a stainless steel vise which was mounted on a Leitz heating stage. The crystal surface was observed under the microscope during cooling.

The symmetry of the crystals was examined optically at 20°C on a microscope with convergent plane-polarized light and a Bertrand lens. The interference patterns established the uniaxial (tetragonal) or biaxial (orthorhombic) symmetry of the crystals.

The pulled crystals were analyzed for Rb or K, Na, Ba, and Nb using the methods shown in Table III. The weight per cent of each element was converted to the mole per cent of the niobates. The analysis for Nb served as a check on the assumption that the elements were in the niobate form.

The crystals pulled from melts of $K_{0.8}Na_{0.2}Ba_2Nb_5O_{15}$ were poled by applying an electric field of 3000 V/cm along the c-axis of the tetragonal structure at 100°C.

The small signal dielectric constants were measured on poled, oriented, single crystals at 10^4 Hz. The temperature was measured continuously from room temperature to a point above the Curie temperature. Figure 5 shows a circuit diagram of the system used. It has proved to be reliable, simple, and convenient. The voltage across R is proportional to C if $R << 1/\omega C$, which is easy to arrange. A Princeton Applied Research JB6 is used as a narrow band amplifier-oscillator and the y-scale of the x-y recorder is calibrated with known capacitors. The arrangement is similar to that described by Triebwasser (9).

Temperatures of −113° and −80°C were needed for 90° phase matched second harmonic generation with a 1.06μ Nd YAG laser for crystals from melts of $K_xNa_{1-x}Ba_2Nb_5O_{15}$ where $x = 0.8$ and 0.7. Crystals from melts of $K_{0.2}Na_{0.8}Ba_2Nb_5O_{15}$ and $Rb_{0.2}Na_{0.8}Ba_2Nb_5O_{15}$ phase matched near 80°C.

Table III. Chemical analyses

Element	Dissolution	Method	Accuracy
Na	$HF-HNO_3$	Flame photometry	±5%
Rb	$HF-HNO_3$	Atomic absorption	±3%
K	$HF-HNO_3$	Atomic absorption	±3%
Ba	$Li_2B_4O_7$ fusion	Precipitated as $BaSO_4$	±1%
Nb	KOH fusion	Polarographic reduction of Nb^{+5} to Nb^{+4}	±2%

Results and Discussion

$KNbO_3$-$NaNbO_3$-$BaNb_2O_6$ *system.*—Czochralski pulled tungsten bronze crystals were obtained from 12 different compositions in the $KNbO_3$-$NaNbO_3$-$BaNb_2O_6$ system. The maximum crystal diameter was 20 mm while the average crystal diameter and length were 8 and 30 mm, respectively. A single crystal pulled from a melt of $K_{0.2}Na_{0.8}Ba_2Nb_5O_{15}$ is shown in Fig. 6. The pulled crystals appeared to be chemically homogeneous based on Curie temperature measurements along the crystal length and the use of the crystals for electro-optic measurements. The small size of the crystals (30g or less) in relation to the melt (400g) minimized compositional changes in the crystal.

The section of the ternary system of $(KNbO_3)_x$ $(NaNbO_3)_y$ $(BaNb_2O_6)_z$ where $x < 34$, $y < 34$, and $z > 66$ is shown in Fig. 3. This shows the composition of the starting melts and the pulled crystals obtained from these melts. After the crystals were pulled, three phases were usually found in the frozen melts; these were the tungsten bronze, $BaNb_2O_6$, and the perovskite $KNbO_3$. Freezing points determined from DTA cooling curves on seeded samples along the pseudo-join between $NaBa_2Nb_5O_{15}$ and $KBa_2Nb_5O_{15}$ are shown in Fig. 7. These show a discontinuity at $K_{0.65}Na_{0.35}Ba_2Nb_5O_{15}$ and a minimum at $K_{0.825}Na_{0.175}Ba_2Nb_5O_{15}$. Above $x = 0.825$

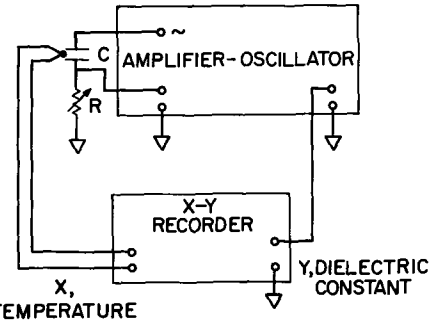

Fig. 5. Circuit diagram for the continuous measurement of dielectric constant vs. temperature. A Princeton Applied Research JB6 is used as a narrow band amplifier-oscillator. The voltage across R is proportional to C if $R << 1/\omega C$.

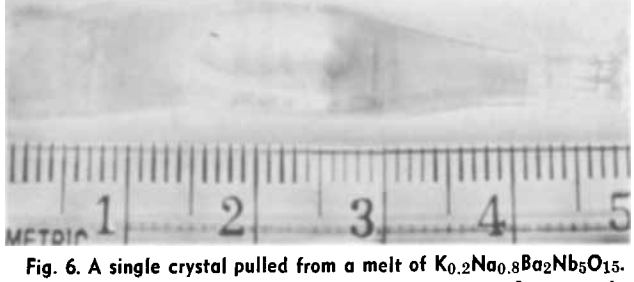

Fig. 6. A single crystal pulled from a melt of $K_{0.2}Na_{0.8}Ba_2Nb_5O_{15}$. Growth was along the c-axis. The small divisions are 1 mm each.

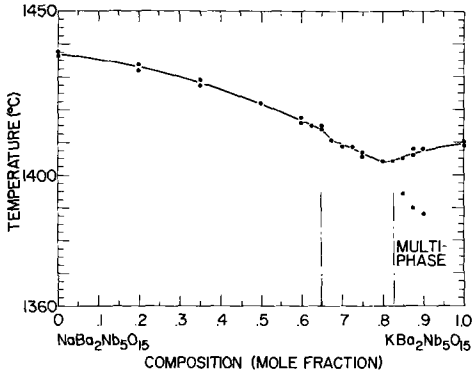

Fig. 7. Liquidus temperature vs. composition for DTA samples on the pseudo-join of $K_xNa_{1-x}Ba_2Nb_5O_{15}$. Two samples were run for most compositions. In the multiphase region a transition occurred below the liquidus temperature.

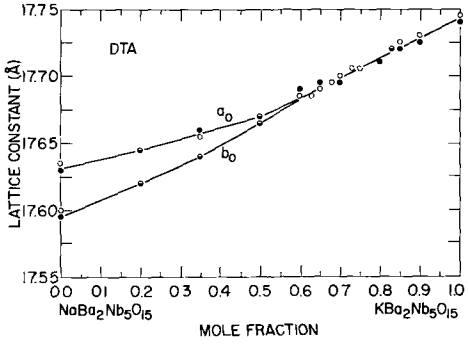

Fig. 8. Lattice constants for frozen melts of DTA samples on the pseudo-join of $K_xNa_{1-x}Ba_2Nb_5O_{15}$. Measurements were made on material from the top (●) and bottom (○) of the DTA tube.

in $K_xNa_{1-x}Ba_2Nb_5O_{15}$ the frozen DTA samples were multiphase. However, it was still possible to pull single phase bronze crystals from melts with $x \leq 0.9$. At room temperature, the pulled bronze crystals were tetragonal when the melt had $0.6 < x \leq 0.9$ and orthorhombic for $x \leq 0.6$. The chemical analysis data on the pulled crystals show that the melts become richer in $KNbO_3$ during crystal growth. Crystal growth from a 400g melt of $(KNbO_3)_{15.5}$ $(NaNbO_3)_{8.7}$ $(BaNb_2O_6)_{75.7}$ produced a tetragonal tungsten bronze phase in the initial 30g and then a $BaNb_2O_6$ rich phase. This indicated that the melt was very close to the phase boundary between the bronze and $BaNb_2O_6$ phases. A $BaNb_2O_6$ rich phase was found in crystals pulled from melts of $x = 10$, $y = 10$, $z = 80$ and $x = 25$, $y = 5$, $z = 70$.

Figure 3 shows that the pulled crystals from the tungsten bronze region were higher in $BaNb_2O_6$ and lower in $KNbO_3$ than the melt, while the $NaNbO_3$ content changed only slightly. We attempted to locate a maximum melting composition in the ternary system in order to obtain more homogeneous crystals and to operate under more favorable growth conditions. However, only small differences are believed to exist between the melting points of all compositions containing more than 66 m/o $BaNb_2O_6$. The melting behavior of some pulled crystals is described in Table IV. The melting points of pulled crystals exceed the peritectic decomposition temperature of $KBa_2Nb_5O_{15}$ (1391°C) and are less than the melting point of $BaNb_2O_6$ (1459°C). None of the crystals melted as sharply as the $NaBa_2Nb_5O_{15}$, indicating some difference between the liquidus and solidus temperatures.

Lattice parameter data for the tungsten bronze crystals are shown in Table I. Pseudo-tetragonal parameters are tabulated for crystals with slight orthorhombic splittings. Figure 8 shows the lattice constants (a_o and b_o) for frozen melts of DTA samples on the pseudo-join of $K_xNa_{1-x}Ba_2Nb_5O_{15}$. Only small differences are observed between material from the top and bottom of the DTA tube. Above $x = 0.6$ the room temperature structure is tetragonal. In this region, the lattice constant (a_o) is based on the orthorhombic cell which is $\sqrt{2}$ times larger than the tetragonal a_o. These results along with the chemical analyses on the tetragonal crystals pulled from melts with $x > 0.6$ define the approximate region of the tetragonal bronze structure in the ternary system (Fig. 3).

Table IV. Melting ranges for K-Na-Ba and Rb-Na-Ba niobate crystals

—	2.4	20.0	77.6	1425-1436
$NaBa_2Nb_5O_{15}$				1438

Additional data on the ternary phase diagrams were obtained from x-ray and chemical analysis data on the Bridgman ingots. The Bridgman cooling of $(KNbO_3)_{16}$ $(NaNbO_3)_{11}$ $(BaNb_2O_6)_{73}$ resulted in a bronze and a $KNbO_3$ rich phase in the frozen ingot. The first to freeze material (orthorhombic bronze structure) had the same composition and lattice parameters (Table V) as a Czochralski pulled crystal from a melt of the same composition (Table I). The last to freeze section in the Bridgman tube had about 95% of a $KNbO_3$ rich phase with a blue color. The Bridgman growth from the $K_{0.85}Na_{0.15}Ba_2Nb_5O_{15}$ melt resulted in the initial freezing of a tetragonal bronze crystal which had a composition lower in $NaNbO_3$ content than that predicted from the location of the phase boundary between the bronze and $BaNb_2O_6$ phases. The last to freeze section had approximately equal quantities of the bronze and $KNbO_3$ rich phases. These results and the data on pulled crystals indicate that the phase boundary between the $BaNb_2O_6$ and tungsten bronze regions extends from the eutectic at $(NaNbO_3)_{15}$ $(BaNb_2O_6)_{85}$ in that binary over to $x > 0.90$ on the $K_xNa_{1-x}Ba_2Nb_5O_{15}$ pseudo-join.

$RbNbO_3$-$NaNbO_3$-$BaNb_2O_6$ *system.*—Six compositions from the $(RbNbO_3)_x$ $(NaNbO_3)_y$ $(BaNb_2O_6)_z$ ternary system were examined in the region of $x < 34$, $y < 34$, and $z > 66$. The melt compositions and pulled crystals are shown in Fig. 4. The results of chemical analyses on each pulled crystal are summarized in Table II.

The solubility of $RbNbO_3$ in the tungsten bronze structure is considerably less than that of $KNbO_3$. The highest concentration of $RbNbO_3$ was found in a crystal of $(RbNbO_3)_{5.1}$ $(NaNbO_3)_{19.1}$ $(BaNb_2O_6)_{75.8}$ which was taken from a frozen melt of $Rb_{0.5}Na_{0.5}Ba_2Nb_5O_{15}$. Pulled material from a melt of $Rb_{0.8}Na_{0.2}Ba_2Nb_5O_{15}$ contained primarily $BaNb_2O_6$. The first to freeze section from the $Rb_{0.7}Na_{0.3}Ba_2Nb_5O_{15}$ ($x = 23.3$, $y = 10.0$, $z = 66.7$) Bridgman sample had a $BaNb_2O_6$ structure with the composition shown in Table V. The phase boundary between the bronze and $BaNb_2O_6$ phases probably extends from the 85 m/o $BaNb_2O_6$-15 m/o $NaNbO_3$ eutectic to about $Rb_{0.65}Na_{0.35}Ba_2Nb_5O_{15}$. All the tungsten bronze pulled crystals containing Rb were orthorhombic at room temperature. Their lattice parameters are listed in Table II. If the tetragonal structure exists at room temperature, it is in a much smaller region of the ternary system than the corresponding $KNbO_3$ system.

Microstructure.—Optical examination at 20°C showed interference figures characteristic of uniaxial symmetry for all crystals grown from melts of $K_xNa_{1-x}Ba_2Nb_5O_{15}$ where $0.6 < x \leq 0.9$ and from melts near $(KNbO_3)_{16}$ $(NaNbO_3)_{11}$ $(BaNb_2O_6)_{73}$. Other bronze crystals from

Table V. Chemical analyses and lattice parameters of Bridgman crystals

Melt composition, m/o				First material to freeze: Composition from chemical analyses, m/o				First material to freeze: Tungsten bronze lattice parameters		Last material to freeze

* Pseudo-tetragonal parameter, optical interference pattern indicates biaxial symmetry.

the $KNbO_3$-$NaNbO_3$-$BaNb_2O_6$ and $RbNbO_3$-$NaNbO_3$-$BaNb_2O_6$ systems were biaxial.

The typical appearance of the microtwins in pulled crystals is shown in Fig. 9. The lines are parallel to the [110] and [110] directions of the orthorhombic cell. Microtwinning results from the tetragonal to orthorhombic phase transformation and has been described for $NaBa_2Nb_5O_{15}$ (4). Table I shows that higher $KNbO_3$ concentrations in the bronze structured crystals from the $KNbO_3$-$NaNbO_3$-$BaNb_2O_6$ system cause a shift in the orthorhombic transformation (T_W) below 77°K and the resulting absence of microtwins. Although microtwins in $NaBa_2Nb_5O_{15}$ can be removed by applying pressure along the [100] axis of the orthorhombic cell while cooling below 300°C, it is not easily accomplished and can produce strain and cracking of the crystal. For example, Byer (10) describes the improvement in optical quality of detwinned $NaBa_2Nb_5O_{15}$ above 300°C. In the case of the $RbNbO_3$-$NaNbO_3$-$BaNb_2O_6$ system, the transformation (T_W) was lowered to 85°C in a crystal from a melt of $Rb_{0.6}Na_{0.4}Ba_2Nb_5O_{15}$. Results on other compositions are shown in Table II. The microtwins in the crystal from the melt of $Rb_{0.2}Na_{0.8}Ba_2Nb_5O_{15}$ are shown in Fig. 9. The microtwins were removed from this crystal by heating to 300°C and then cooling under pressure. The orthorhombic tungsten bronze crystals containing K or Rb appear to be easier to detwin that $NaBa_2Nb_5O_{15}$. Fewer crystals cracked, possibly because less pressure was required to detwin the K and Rb crystals. Also, the difference between the lattice parameters, a_o and b_o, decreases as the K and Rb concentrations increase.

Sensitivity to laser damage.—There are 10 possible cation (A^+, A^{+2}) sites available in the tungsten bronze type structure (11). These are: two α sites which have 12 oxygen ions coordinating the site; four β sites with 15 oxygen ions; and four γ sites with 9 oxygen ions. In the case of $NaBa_2Nb_5O_{15}$ (4), the β sites are believed to be filled by Ba, the smaller α sites are occupied by Na, and the smallest sites (γ) are unoccupied. Concentrations of more than 66.7 m/o $BaNb_2O_6$ in all the pulled crystals means there are more than 4 Ba ions per unit cell in the tungsten bronze structure. The extra Ba ions, which number as high as 0.41/cell for the $(KNbO_3)_{9.9}$ $(NaNbO_3)_{11.2}$ $(BaNb_2O_6)_{78.9}$ crystal, are believed to occupy the α sites along with the A^+ cations (Na, K, or Rb). For each Ba ion on an α site, there is a corresponding vacant α site. On this basis the crystals cannot be considered filled since there are some vacant α sites and completely vacant γ sites. The maximum number of Ba ions per unit cell in the tungsten bronze Rb crystals was 4.38 for the crystal of $(RbNbO_3)_{3.8}$ $(NaNbO_3)_{18.4}$ $(BaNb_2O_6)_{77.8}$.

A crystal of $(KNbO_3)_{16.3}$ $(NaNbO_3)_{8.3}$ $(BaNb_2O_6)_{75.4}$ grown from a melt of $K_{0.8}Na_{0.2}BaNb_5O_{15}$ was examined for laser damage (5) with a one-half watt argon laser (4880Å) focused with a 30 mm lens. When the electric field of the laser beam was directed along the c- and a-axes in separate runs, no optically induced inhomogeneities were observed after 15 min of exposure. Under the same conditions, $LiNbO_3$ damaged within seconds.

Dielectric properties.—The dielectric constant, ϵ, *vs.* temperature, T, and $10^4/\epsilon$ *vs.* T data for the crystals of $(KNbO_3)_{5.6}$ $(NaNbO_3)_{16.1}$ $(BaNb_2O_6)_{78.3}$ and $(RbNbO_3)_{3.8}$ $(NaNbO_3)_{18.4}$ $(BaNb_2O_6)_{77.8}$ are shown in Fig. 10 and 11. The data above the transition temperature, T_c, can be fitted to the Curie-Weiss expression, $\epsilon = (2\pi/A)(T - T_o)^{-1}$ where $2\pi/A$ is the Curie constant, c, and T_o is the paraelectric Curie temperature. The slopes, c, obtained from plots of T *vs.* $1/\epsilon$ above T_c are shown in Table VI for the two crystals. The T *vs.* $1/\epsilon$ data below T_c also give an intercept, T_o, which is approximately equal to the intercept obtained from the data above T_c. This suggests that the transition is second order. Also, thermal hysteresis which is characteristic of first order transitions was not observed in the ϵ *vs.* T curves for any of the crystals listed in Tables I and II. In the perovskite ferroelectrics, $BaTiO_3$ and $KNbO_3$, which undergo a first order transition, T_o is below T_c and thermal hysteresis in T_c is observed on heating and cooling. The A values for the two bronze crystals in Table IV are 2.2 x 10^{-5}/°C and 0.8 x

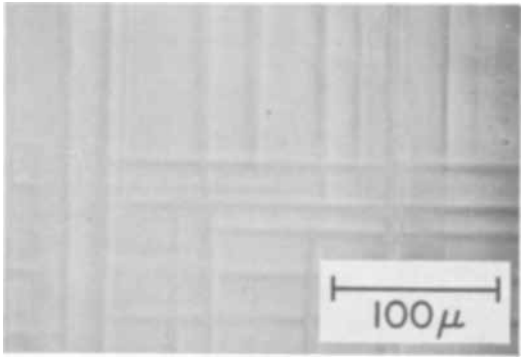

Fig. 9. Twin structure in crystals pulled from melts of $K_xNa_{1-x}Ba_2Nb_5O_{15}$ ($x \leq 0.6$) and $Rb_xNa_{1-x}Ba_2Nb_5O_{15}$ ($x \leq 0.6$) viewed along the c-axis. Lines are parallel to the [110] directions of the orthorhombic cell.

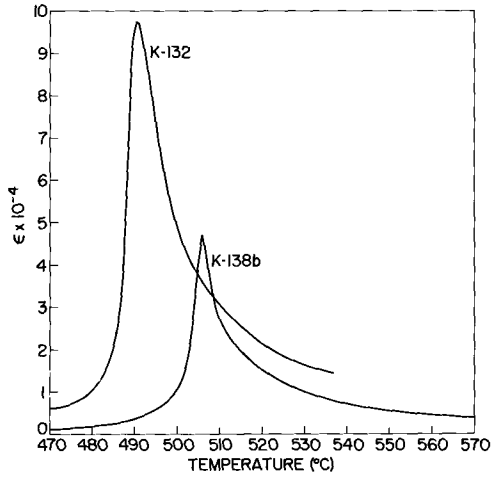

Fig. 10. Dielectric constant along the c-axis *vs.* temperature for crystals K-132 $(KNbO_3)_{5.6}$ $(NaNbO_3)_{16.1}$ $(BaNb_2O_6)_{78.3}$ and K-138b $(RbNbO_3)_{3.8}$ $(NaNbO_3)_{18.4}$ $(BaNb_2O_6)_{77.8}$.

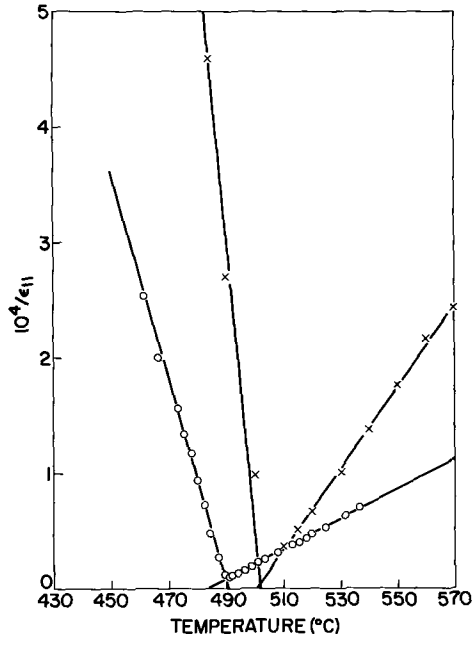

Fig. 11. $10^4/\epsilon_{11}$ *vs.* temperature for crystals K-132 $(KNbO_3)_{5.6}$ $(NaNbO_3)_{16.1}$ $(BaNb_2O_6)_{78.3}$ and K-138b $(RbNbO_3)_{3.8}$ $(NaNbO_3)_{18.4}$ $(BaNb_2O_6)_{77.8}$.

10^{-5}/°C, which are approximately the same as for the perovskites and other tungsten bronze compositions (12). Increasing the concentrations of K or Rb in the bronze crystals caused a lowering of the ferroelectric transition temperature (Tables I and II).

Burns (13) has described the effects on T_c of the quenching of $NaBa_2Nb_5O_{15}$ and also of crystals pulled from melts of $K_xNa_{1-x}Ba_2Nb_5O_{15}$. Smaller changes in T_c were observed for compositions containing more K. An ordering effect dependent on the ionic size was suggested as a possible explanation. The ionic sizes of the cations are: Ba^{++} = 1.35Å, Na^+ = 0.95Å, K^+ = 1.33Å, and Rb^+ = 1.48Å. The substitution of K^+ for Na^+ could be expected to produce less ordering.

Summary

Single crystals with an orthorhombic tungsten bronze structure were grown from a range of solutions in the ternary systems of $(KNbO_3)_x$ $(NaNbO_3)_y$ $(BaNb_2O_6)_z$ and $(RbNbO_3)_x$ $(NaNbO_3)_y$ $(BaNb_2O_6)_z$. A small solid solution region with a tetragonal bronze structure at room temperature was found in the former system. Chemical analyses of the pulled crystals indicated the approximate location of the phase boundary between the bronze and $BaNb_2O_6$ structures in each system.

Microtwins were absent at 20°C in the tetragonal bronze crystals near $(KNbO_3)_{14}$ $(NaNbO_3)_{12}$ $(BaNb_2O_6)_{74}$. These crystals also had the best optical quality. Other bronze compositions in the two ternary systems had lower tetragonal to orthorhombic transformation temperatures than $NaBa_2Nb_5O_{15}$. The microtwins in the K and Rb orthorhombic bronze crystals were less difficult to remove than those present in $NaBa_2Nb_5O_{15}$.

For the systems studied in this paper efficient phase matched second harmonic generation for 1.06-0.53μ above room temperature was obtained only in crystals with an orthorhombic bronze structure, such as those from melts of $Rb_{0.2}Na_{0.8}Ba_2Nb_5O_{15}$ and $K_{0.2}Na_{0.8}Ba_2Nb_5O_{15}$. The tetragonal bronze phase matched below room temperature.

Substitution of K or Rb for Na resulted in a lowering of the Curie temperature and a retention of the sharp transition at the Curie temperature. Analysis of the ϵ *vs.* T data for two representative crystals indicated second order transitions at the ferroelectric to paraelectric transition.

Table VI. Curie temperatures and ferroelectric constants for K-Na-Ba and Rb-Na-Ba niobate crystals

Crystal composition	T_c, °C	Above T_c $c \times 10^{-5}$, °C	Above T_c $A \times 10^5$, °C
$(KNbO_3)_{5.6}$ $(NaNbO_3)_{10.1}$ $(BaNb_2O_6)_{78.3}$	492	7.7	0.8
$(RbNbO_3)_{3.8}$ $(NaNbO_3)_{18.4}$ $(BaNb_2O_6)_{77.8}$	506	2.8	2.2

Silicon Epitaxial Layers with Abrupt Interface Impurity Profiles

Dinesh C. Gupta* and Roy Yee

General Telephone and Electronics Laboratories, Inc., Woburn, Massachusetts

ABSTRACT

Silicon epitaxial layers of good quality have been deposited on silicon substrates by the pyrolysis of silane at low temperatures. Studies to minimize the degradation of the impurity profile of an epitaxial silicon layer caused by various sources or processes are reported. Auto doping and system doping during deposition have been minimized by using techniques such as sealing the backsides of the substrates, sealing the susceptor, and using two-temperature cycle depositions. Impurity profiles of the layers deposited by the above methods are compared with the profiles of the layers obtained from more conventional deposition conditions.

The use of hyperabrupt junctions is becoming increasingly important for the fabrication of fast variable capacitive diodes and integrated circuits. This requires obtaining and controlling sharp impurity gradients at the substrate-epitaxial layer interface. The doping sources that tend to degrade the interface impurity gradient can be categorized as follows (1):

1. Impurities originating from the reaction chamber, *i.e.*, its walls, fixtures, gas lines, etc.
2. Impurities present in the silicon epitaxial growth source, *e.g.*, $SiCl_4$, $SiHCl_3$, or SiH_4.
3. Impurities originating from autodoping, *i.e.*, the inclusion of impurities within the epitaxial layer that are obtained from the substrate etching.
4. Impurities originating from the hot susceptor, if r.f. heating is used.
5. Impurities due to out-diffusion from the substrate, or the buried layers, during high temperature epitaxial growth.

The investigation reported here seeks to minimize each impurity source by using special techniques or procedures.

Apparatus and Techniques

Apparatus.—The furnace arrangement used to achieve the epitaxial deposition of silicon from the pyrolysis of silane is depicted in Fig. 1. The system uses only gaseous sources for the dopants as well as the silicon source, excluding, of course, the comparison source, silicon tetrachloride. The gases are spectroscopically analyzed for impurity content and concentrations. The dopant gases are controlled by a pneumatically pulsed gas chromatography sampling valve, however, in the results presented here, no intentional doping from dopant sources was used. The reaction chamber is a multiple slice, cold wall, vertical gas flow system capable of handling six 1-in. diameter slices (2). In the investigations reported here, however, only three slices plus a control slice were used for each run. All runs, whether using SiH_4 or $SiCl_4$, were made in the same reaction chamber to maintain identical geometric conditions. The susceptor on which the slices were placed, was fabricated from n-type, arsenic-doped, 0.5 ohm-cm silicon, and was heated by a 4 MHz r.f. coil located externally to the reaction chamber. As a precautionary measure the system was kept moisture-tight using stainless steel gas lines, fittings, etc., since traces of water vapor can cause etching of silicon at epitaxial growth temperatures (3) which may produce autodoping effects.

Silicon epitaxy source.—A widely used process to deposit epitaxial silicon layers is the hydrogen reduction of silicon tetrachloride (4). The hydrogen reduction of trichlorosilane has also been investigated (5). In both cases, however, the deposition temperatures are quite high, and achieving abrupt impurity gradients becomes difficult. Efforts have been made therefore to deposit layers at reduced temperatures using the pyrolysis of SiH_4 (6-8) and improved impurity gradients have been achieved using substrate resistivities as low as 0.007 ohm-cm (7).

The use of SiH_4 as the silicon source is well suited for minimizing autodoping and out-diffusion, for the following well-known reasons. First, silane has no HCl as a decomposition product, and consequently the amount of autodoping should be considerably reduced as compared to the hydrogen reduction of the silicon halides. Second, it is possible to reduce out-diffusion effects by lowering the epitaxial growth temperature to more than compensate in the diffusion length for the increase in diffusion time required to deposit a given layer thickness at the reduced temperature. To take advantage of this fact, the silicon source must be capable of being efficiently decomposed at the lower growth temperature. The decomposition of silane is indeed more favorable thermodynamically than silicon tetrachloride in the temperature range used here, namely, 900°-1000°C. The heat of formation for silane at these temperatures is about one order of magnitude lower than that for silicon tetrachloride (8, 9).

Control of autodoping.—We propose here that the autodoping can be controlled by back-sealing the substrates prior to deposition by using an insulating, etch-resistant film, *e.g.*, silicon oxide, silicon nitride, etc., on the back side of the silicon slices. In these studies, a 15,000Å thick layer of thermally grown silicon dioxide was used for back-sealing.

Control of susceptor doping.—The susceptor is heated and etched by HCl prior to the deposition cycle and during conventional H_2-$SiCl_4$ deposition.

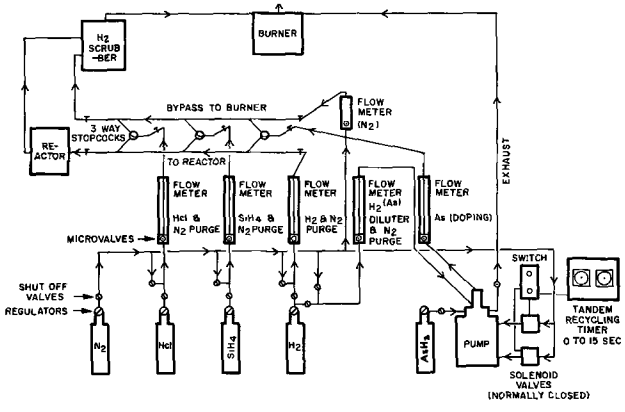

Fig. 1. Schematic of silane system

* Electrochemical Society Active Member.

Therefore, it becomes a source for impurities, especially since its resistivity is usually relatively low for efficient r.f. coupling. By sealing its surface with an epitaxially deposited layer of high purity silicon, or with an insulating etch-resistant film, a reduction of impurities from this source can be achieved.

Out-diffusion.—The resistivity of the substrate, or of buried layers, is controlled by the device design so that out-diffusion from these sources during epitaxial deposition can be controlled effectively only by maintaining the deposition temperature as low as possible to achieve good quality epitaxial layers.

The choice of SiH_4 as the silicon epitaxy source permits lower deposition temperatures, and consequently a reduction in the amount of out-diffusion from the substrates. In fact, depositing at about 1000°C compared to 1175°C will decrease the diffusion constant of the substrate dopant (in this case, arsenic) by about an order and a half in magnitude (10).

High-Low Temperature Cycle Depositions

A completely different approach for achieving good quality epitaxial layers with reduced redistribution of doping impurities is to carry out the initial nucleation growth at high temperatures and complete the deposition at a reduced temperature. This method is called the coating technique (11), or the high-low temperature cycle technique.

By this technique, a reduction in growth temperature to 850°C for silane depositions is possible, while still maintaining good quality layers with abrupt doping profiles at the interface.

Analysis and Discussion of Results

Using the special techniques described above to enhance the abruptness of impurity gradients, silicon n/n^+ epitaxial layers were deposited at temperatures of 900°-1000°C using silane as the silicon source. The impurity distributions are compared with those obtained in layers deposited using more conventional deposition conditions, namely, silicon tetrachloride as the silicon source, and the deposition temperatures in the range of 1175°-1250°C.

The quoted temperatures are optical pyrometer temperatures, emissivity uncorrected; however, the pyrometer was calibrated against a Pt + 10% Rh thermocouple, as described in the Appendix.

The substrates used for these studies were (111) oriented, mechanically and chemically polished, and had dislocation counts of less than 100 dislocations/cm^2. The arsenic concentration in the substrates was approximately 3.5×10^{19} atoms/cc.

To achieve good quality epitaxial layers, it was necessary to *in-situ* HCl etch the slices prior to deposition. After etching, the system was purged with hydrogen for a time sufficiently long to adequately remove any HCl vapors remaining in the system.

Impurity profiles were determined by diode voltage-capacitance measurements (12) on diffused or Schottky barrier diode structures. The values of the impurity concentrations reported for the surface of the layers were obtained by the spreading resistance probe measurements (13).

Deposition rate.—The dependence of the deposition rate on the growth temperature for various volume percentages of SiH_4 in H_2 is shown in Fig. 2. As the temperature is lowered, the percentage of SiH_4 should be lowered to achieve good quality epitaxial layers. The activation energy of the system is found to be 30 kcal/mole from 850° to 1100°C. Joyce and Bradley (3) have reported a value of 37 ± 1 kcal/mole as the activation energy from 950° to 1100°C. At temperatures higher than 1100°C, the reaction is found to be independent of the SiH_4 concentration, indicating that the pyrolysis of SiH_4 is complete, and a constant growth rate results. Figure 3 gives the dependence of the deposition rate at 1000°C on the volume per cent of SiH_4 in H_2.

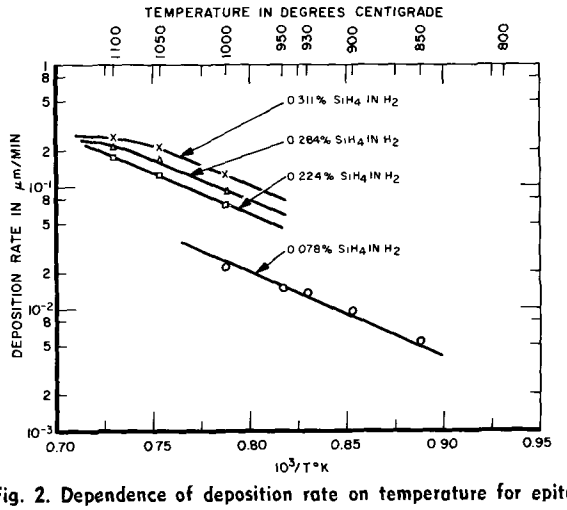

Fig. 2. Dependence of deposition rate on temperature for epitaxial layers using silane.

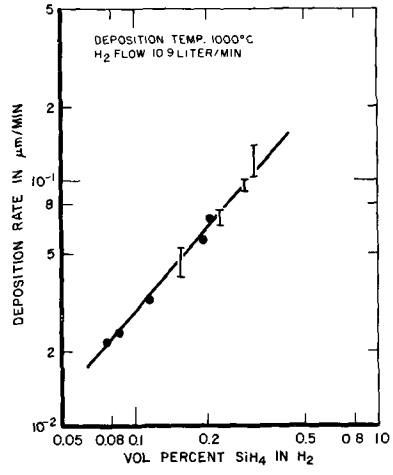

Fig. 3. Effect of SiH_4-H_2 ratio on deposition rate

Impurity profiles resulting from use of special techniques.—The effect of the back side sealing of the substrates on the impurity profiles of the layers is shown in Fig. 4 through 6. Figure 4 gives the impurity profiles of two epitaxial layers obtained by the de-

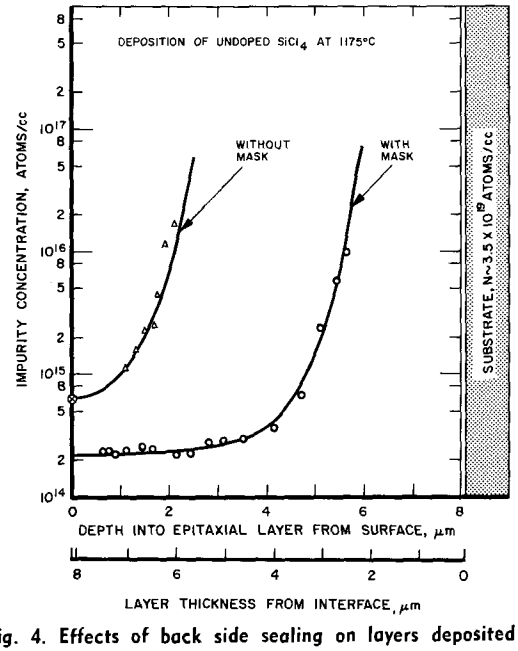

Fig. 4. Effects of back side sealing on layers deposited by the decomposition of silicon tetrachloride.

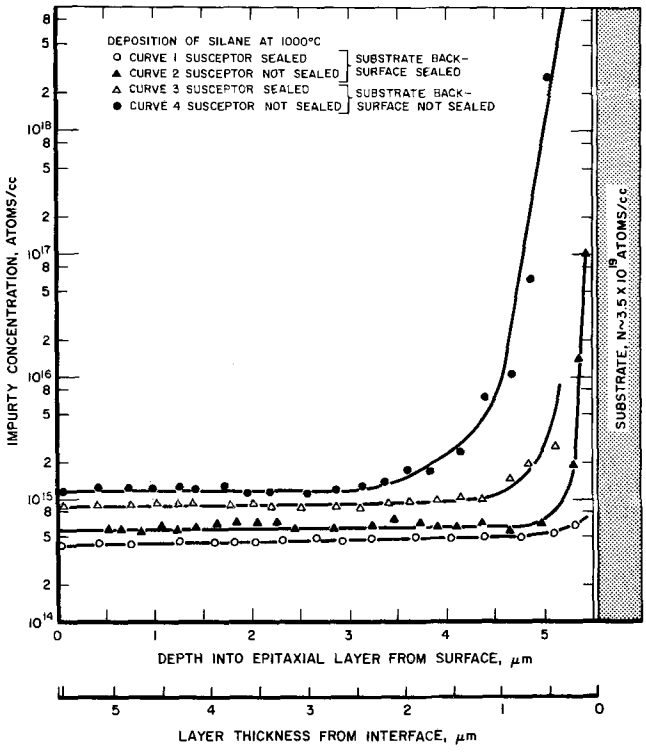

Fig. 5. Effects of substrate back-surface and susceptor sealing on layers deposited by the pyrolysis of silane.

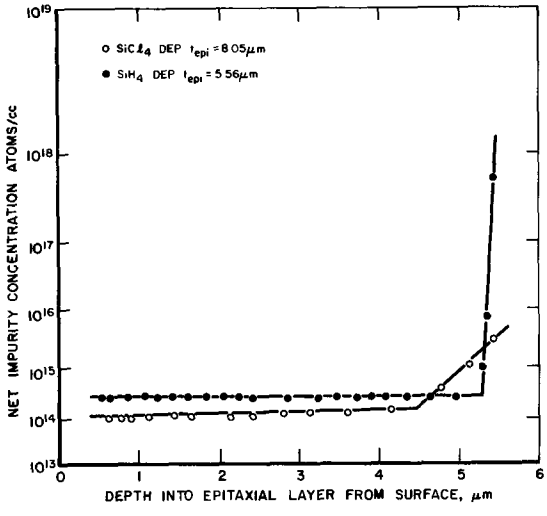

Fig. 7. Arithmetic probability plot of the impurity profiles shown in Fig. 6.

composition of $SiCl_4$. Curve 1 had the back side of the substrate sealed while in curve 2 the back side was not sealed.

In Fig. 5, the impurity profiles of the two epitaxial layers deposited with the silane process are depicted. Curve 2 had the back side of the substrate sealed, while in curve 4 the back side was not sealed.

It is clear from these results that back-sealing the slices reduces the amount of impurity doping at the interface significantly. These impurity profiles, improved as they are, still reflect the two remaining impurity sources, namely, autodoping from the susceptor and out-diffusion from the substrates. The effect of autodoping from the susceptor has been determined from two runs deposited under the condition of having the susceptor sealed as well as having the slices back-sealed in one run, and not back-sealed in the other. These two profiles are shown in Fig. 5, denoted by curves 1 and 3, respectively. Some improvement in the impurity profiles are noted over runs made without susceptor sealing, but this improvement is not as significant as that due to back-sealing. The extra doping near the interface can be accounted for by out-diffusion from the substrate. The diffusion length for the silane layers is about 0.3 μm as discussed below.

The effect of out-diffusion is also shown in Fig. 6, where comparison is made of the impurity profiles of the layers deposited by $SiCl_4$ process at 1175°C and SiH_4 process at 1000°C with the substrate back-surface sealed. The increase in the abruptness of the impurity gradient is attributed to not only the reduction of autodoping from the front side due to the nonexistence of HCl vapors in the silane system, but also to the decrease in the arsenic diffusion constant by about one and a half orders of magnitude that results from the reduction in growth temperature from 1175° to 1000°C. The layer deposited from silane also has a higher impurity concentration near the layer's surface, which shows that even though less impurity doping occurs near the interface using the silane process, the silane source used here is less pure than the silicon tetrachloride source.

Figure 7 shows an arithmetic probability plot of the impurity profiles of the layers shown in Fig. 6. Complementary error function diffusion processes, *e.g.*, out-diffusion, are readily identifiable from this type of plot since they appear as straight lines on the graph (14). One obtains a diffusion length of 1.8 μm for the deposition at 1175°C with $SiCl_4$ while for the deposition from SiH_4 at 1000°C, a diffusion length of only 0.3 μm is obtained. These results reflect the decrease in the diffusion constant of arsenic as mentioned previously. The change in the slope in the lines can be explained in terms of the model suggested by Kahng *et al.* (15) in which the impurity doping from the back side, in their case, and from the front side, in our case, is redeposited from the gas phase to give an exponential distribution. A net profile similar to the plots of Fig. 7 can be obtained by the addition of the exponential distribution for autodoping, represented by

$$N = N_o^* \exp(-x/L_2)$$

and the error function distribution for the out-diffusion during the deposition, represented by

$$N = (N_s/2)\ \mathrm{erfc}\ (x/L_1)$$

These distributions are shown in Fig. 8.

High-low cycle epitaxy.—Using a high-low temperature cycle as discussed earlier, the deposition temperature can be reduced further, *e.g.*, it was possible to deposit good quality epitaxial silicon at temperatures as low as 1000°C using the decomposition

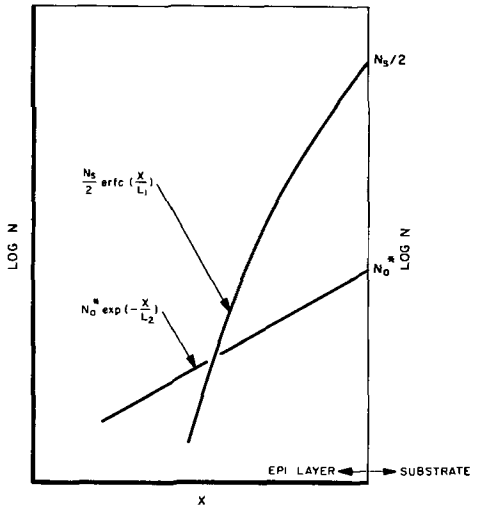

Fig. 8. Theoretical net impurity distribution of layers with autodoping and out-diffusion.

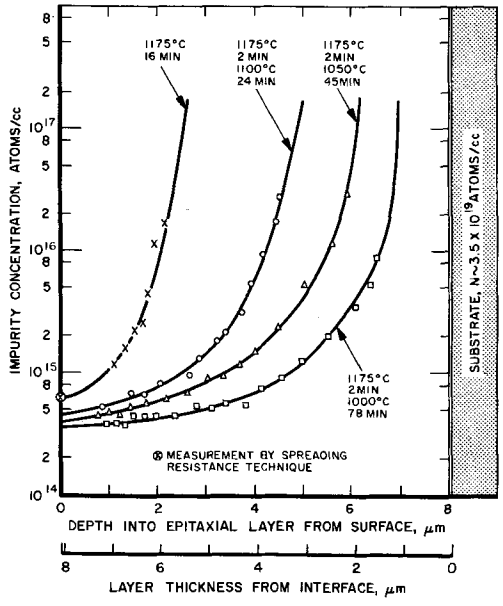

Fig. 9. Impurity profiles of the layers deposited in $SiCl_4$ system using high-low temperature cycle.

of silicon tetrachloride and this technique. The impurity profiles on the layers are shown in Fig. 9. The coating was performed at 1175°C for 2 min in each case. Note the improvement in the impurity gradient of the layers with the reduction in temperature of the low cycle. The back sides of the substrates in these cases were not sealed. Using the same technique, it was possible to deposit good quality layers at a temperature as low as 850°C with the pyrolysis of silane. Coating in the latter case was performed at 1000°C. Figure 10 shows the results. The back sides of the substrates were not sealed. It is interesting to note that the abruptness of the gradient is very nearly the same for depositions carried out at 1000°C with substrate back-surface sealed as it is for depositions at 850°C with an initial coating for 2 min at 1000°C but without the back side sealed.

Surface quality.—The surface quality of silicon deposited by the pyrolysis of silane has been found to be quite good for deposition temperatures as low as 950°C and it is possible to obtain mobilities in the layers approaching that of bulk silicon (16). Below 950°C the surfaces contain nuclei of different orientations. At temperatures below 850°C, nucleation was found to be incomplete and polycrystalline growths were obtained as shown in Fig. 11. The density of nuclei on the surface of the layer was about thirty

times less for layers deposited at 900°C than that deposited at 850°C.

Conclusions

In conclusion, a sharp transition between the doping levels of the substrate and the epitaxial layer can be achieved by low temperature epitaxial depositions using the pyrolysis of silane. Most suitable temperatures for this type of deposition are found to be in the range of 950°-1000°C where the film quality is good and the times of deposition are reasonable. Using the coating technique the deposition temperature can be lowered to 850°C without deteriorating the film quality. An even sharper transition between the doping concentration of the substrate and the layer can be obtained regardless of silicon source, *i.e.*, $SiCl_4$ or SiH_4, if autodoping from the substrate is controlled by sealing its back surface. Additional abruptness is possible if the surface of the susceptor is sealed using a film of high purity silicon or some etch-resistant dielectric material, *e.g.*, silicon oxide, silicon nitride, etc.

APPENDIX

The deposition temperature in the above studies was measured by an optical pyrometer (emissivity uncorrected), however, the optical pyrometer was calibrated by obtaining, at the pyrometer, the radiation which was dependent on the silicon ingot's surface emissivity with a platinum, platinum +10% rhodium thermocouple as follows:

A 5 ft long muffle furnace was used as a heat source to heat an ingot of silicon placed at one end of the furnace tube. Contacting the face of this silicon ingot was the thermocouple, while at the other end of the furnace tube the optical pyrometer was placed and focused onto the same silicon face to which the thermocouple was attached. An inverted cone was used as a lens shade to minimize stray radiation entering the optical pyrometer.

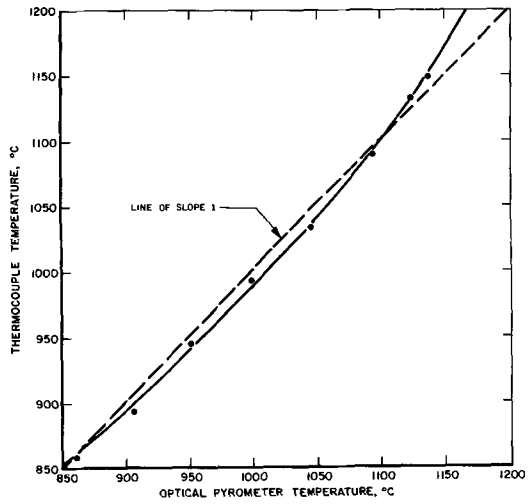

Fig. 12. Calibration of optical pyrometer with platinum, platinum +10% rhodium thermocouple.

The furnace temperature was allowed to stabilize at various temperature values, as measured on the thermocouple, within the range of 800°-1150°C, and the corresponding measurements were taken by the optical pyrometer. The results are plotted in Fig. 12. It can be seen that the optical pyrometer temperatures quoted are probably correct to within ±15°C, and for the range of temperatures most pertinent to this work tend to be actually lower than the quoted temperatures. This result is not necessarily in conflict with the results normally reported, viz., that the optical pyrometer temperature is usually lower than the actual temperature, since as can be seen in Fig. 12, deviations at the higher temperatures do indicate this condition. In most cases reported with regard to epitaxial growth, the temperatures are in this higher temperature range.

Studies in the Adamantine Family of Semiconductors

IV. The $Zn_xCd_{1-x}SnAs_2$ Semiconducting Alloy System: Phase Diagram and Preparation

B. R. Pamplin and J. S. Shah[1]

School of Physics, Bath University of Technology, Claverton Down, Bath, England

ABSTRACT

The results of a DTA study of the alloy system $Zn_xCd_{1-x}SnAs_2$ are presented and a pseudobinary phase diagram is deduced showing the liquidus, solidus, and order-disorder transition lines as a function of Cd content. The use of zone refining techniques to prepare single phase samples for further study is also described.

The II IV V_2 compounds are closely related structurally and electronically to the well known tetrahedrally bonded, diamond and sphalerite structure group IV and III V semiconducting compounds. They have been the subject of several reviews (1-3). $CdSnAs_2$ is isoelectronic and isomorphous with InAs from which it may be derived by cross-substitution (4) and to which it has similar electronic properties [*i.e.*, a room temperature electron mobility of 22,000 $cm^2/V.s$ at $n = 10^{17}$ per cc (5)]. It has a markedly lower lattice thermal conductivity [70 mw/cm°C (6)], and thus it and its solid solutions are of technological interest as thermoelectric materials.

Most pairs of isostructural II IV V_2 compounds are expected to be isomorphous in the solid state provided the electronegativities and atomic sides of corresponding atoms differ by not more than 10-15%, especially if one or two of the atomic species are the same. Previous papers in this series (7, 8) reported the x-ray evidence for complete solid solution between $ZnSnAs_2$ and $CdSnAs_2$ and also for the pseudoternary system $InAs-ZnSnAs_2-CdSnAs_2$.

This paper reports our study of the phase diagram $Zn_xCd_{(1-x)}SnAs_2$ and techniques evolved for the preparation of single phase samples at different compositions in this alloy system with a brief mention of the ternary alloys.

Properties of the End-Component Compounds

Several papers have reported relevant work on the components of the pseudobinary phase diagram $ZnSnAs_2$ (1-4, 9-14) and $CdSnAs_2$ (4, 5, 9, 10, 15, 16).

[1] Present address: H. H. Wills Physics Laboratory, The University, Bristol, England.

Early work on $ZnSnAs_2$ by Pfister and Folberth (11, 14) established that it may exist at room temperature in two forms. The stable form has the chalcopyrite structure EI_1 (space group $D_{2d}^{12} - I\bar{4}2d$) in which the diamond structure pattern of atomic sites is readily recognized, subject to a slight tetragonal distortion. The other, metastable, form has the sphalerite structure B3 (space group $T_d^2 - F\bar{4}3m$). This is derived from the first by disordering or randomizing the Zn and Sn atomic sublattices and thus restoring cubic symmetry. The fcc As atomic sublattice is substantially unaffected by the order-disorder transition occurring between these two structures. Most reported values for the temperature of the order-disorder transition lie in the range 532°-650°C (12-15). Russian work (1) indicates that it may be as high as 700°C; there may be a certain degree of hysteresis resulting in a slightly lower disorder-order transition temperature. At 778°± 3°C the compound melts incongruently, probably through a peritectic transition (13). Thus, this end of the phase diagram cannot properly be represented as a single component of exact composition $ZnSnAs_2$. But we feel that the difficulty is really a small perturbation and that to a first approximation it may be overlooked.

$CdSnAs_2$ is usually assumed to be a straightforwardly chalcopyrite structure compound which melts and freezes congruently at 595°±2°C. However some recent Russian work is mentioned (1) in which a disorder temperature 10°-20°C below the melting point is suggested because quenched $CdSnAs_2$ was observed to have a sphalerite structure.

Differential Thermal Analysis Techniques

In the DTA technique a differential temperature measurement compares the specimen with a standard substance whose properties are well behaved in the temperature range studied. Because our compounds are decomposed by heating in air, we kept our powdered sample in a vacuum-sealed quartz ampoule. Our standard, silver, was similarly encapsulated. Both ampoules were mounted close together in a cylindrical pyreofilite holder and the required signals derived from a chromel-alumel differential thermocouple and a sample thermocouple. The differential signal was recorded using a solid state chopper preamplifier. The sample temperature was recorded to an absolute accuracy of better than ±3°C.

The specially constructed tube furnace in which the holder fitted snugly had a 5 in. zone of temperature uniform to ±2°C. It was controlled by a saturable reactor with a programmed proportional temperature controller. Heating rates from 1°C/min to 10°C/min were used and 4°C/min was found to be the best compromise. The accuracy of the arrangement was tested by finding the melting points of Ag, Sb, InSb, $ZnSnAs_2$, and $CdSnAs_2$. Our measurements gave 965°, 630°, 528°, 778°, and 595°C, respectively. The value for Ag is about 4°C higher than the accepted value but the other results are in good agreement with the accepted values so no correction has been applied to our subsequent observations.

The samples used were for the most part the same annealed powders used in the x-ray lattice parameter work (7). These were chosen to lie at compositions $x = n/8$ ($n = 0, 1, 2, \ldots 8$) through the system because these are the compositions expected to show further ordering of the disordered chalcopyrite phase (17).

Results and Discussions

Typical heating and cooling curves are presented in Fig. 1 and the arrest temperatures recorded in Table I. The differential thermocouple line on the chart shows a clear but wide peak, arrest C on heating and F on cooling, coresponding to the solidus and liquidus, respectively, and one or two small peaks. Reading the arrest temperatures from the chart is necessarily rather subjective. Where possible we have followed the recommendation of Partridge *et al.* (18) and taken the temperature corresponding to the maximum rate of deflection on the rising side of the peak. Where this does not give a clear value we have erred toward lower temperatures for the heating curves and higher temperatures for cooling curves.

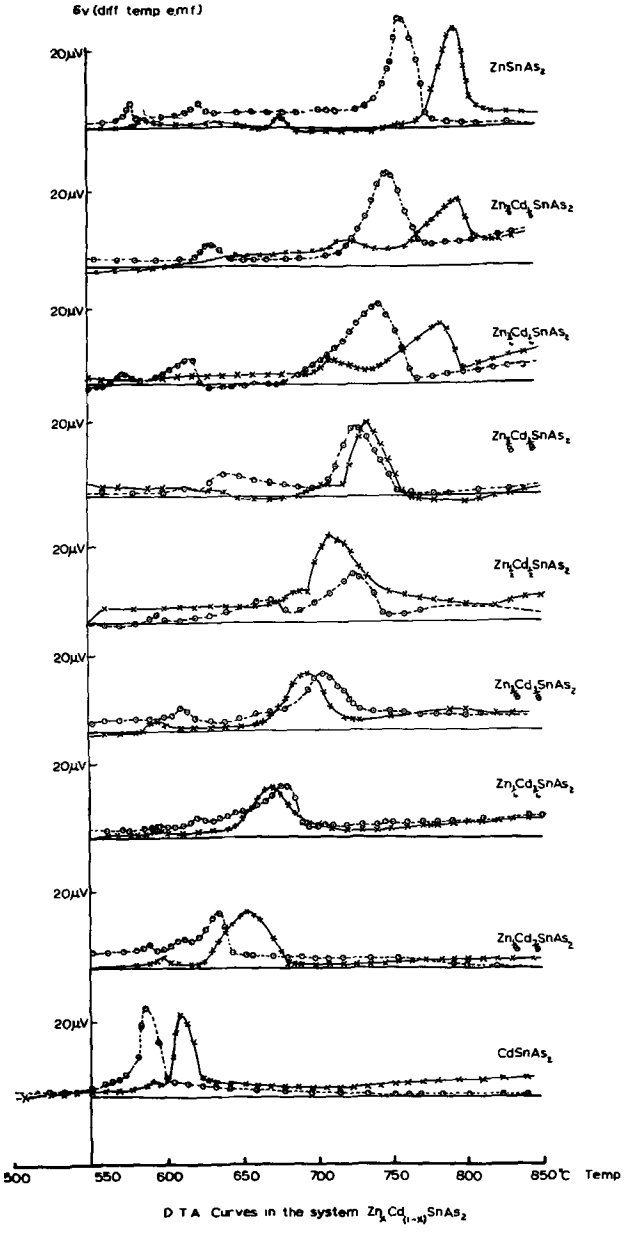

Fig. 1. Differential thermal analysis heating and cooling curves in the system $Zn_xCd_{1-x}SnAs_2$. —x—, Points while heating at 4°C/min; - - ○ - -, points while cooling at 7°C/min.

Arrest B is taken to be due to the order-disorder transition. Arrests A and D, which are often larger in area than B, are supposed, following the suggestion of Gasson *et al.* (12), to be due to SnAs and SnAs + As

phases. Electron probe microanalysis of directionally frozen and zone refined ingots confirmed the presence of these phases.

In Fig. 2 we show a proposed equilibrium diagram for $Zn_xCd_{1-x}SnAs_2$ alloys. Its general character is the same as for mixed III V alloys (such as InAs-GaAs). The two phase region between the solidus and liquidus is 50°C deep and 20 a/o (atomic per cent) wide in the middle of the system. The liquidus is taken from arrest F on cooling and the solidus from arrest C on heating. The extra line, from arrest B, divides the chalcopyrite phase region from the sphalerite structural region. This phase supposes the alloys are pseudobinary, which, since $ZnSnAs_2$ does not melt congruently, cannot be exactly true. However, we feel that the analysis of these results in terms of a two component system is basically sound and is supported by the growth studies reported in the next section.

Arrest B for $ZnSnAs_2$ itself may be attributed to the disorder-order transition but the same conclusion cannot fairly be made for the alloys which by virtue of the phase diagram we propose must freeze at best to give a graded composition ingot and at worst a non-equilibrium mixture of phases. Thus no disorder-order line is drawn in Fig. 2.

It is noted that arrests and transition temperatures observed by other workers (12, 13, 15, 16) on $ZnSnAs_2$ and $CdSnAs_2$ are generally in good agreement with our results and consistent with this phase diagram.

Preparation of Single Phase Specimens

The proposed phase diagram indicates that complete solid solution exists between the two chalcopyrite structure components below the order-disorder temperature and solid solution with the sphalerite structure between this line and the solidus for zinc rich alloys. The diagram also implies that the tie lines in the two phase region between the solidus and liquidus lie in the plane of the diagram. This would mean that an alloy of composition x frozen directionally (or zone refined) under equilibrium growth conditions would be graded from a first to freeze zinc rich composition to a last to freeze cadmium rich tail.

It is well known that alloy material with a phase diagram like that proposed must be frozen very slowly indeed if inhomogeneity due to constitutional supercooling is to be avoided. Dismukes and Ekstrom (19) have extended the conventional analysis of constitutional supercooling to the Ge-Si alloy system. They find the maximum permissible growth rate v cm/sec for a temperature gradient G °C/cm is given by

$$v = \frac{G \cdot D}{m(c_l - c_s)}$$

where m = the slope of the liquidus, c_l = solute concentration (*i.e.*, concentration of one of the components of the solid solution) in liquid, c_s = solute concentration in solid, and D = diffusion coefficient for solute in solution.

We have applied this formula to our system; taking m, c and c_s from our phase diagram, G = 20°C/cm (measured value) and assuming $D = 10^{-4}$ cm²/sec (as a typical figure in the absence of data) we find v must not exceed $5 \cdot 10^{-5}$ cm/sec or 1 mm/hr for alloys near the middle of the alloy system.

During the course of this work we made fifty ingots of these alloys. Some were quenched, some directionally frozen (DF), and some zone refined (ZR), but all on x-raying contained an adamantine phase which, judging by the relative intensities of the x-ray powder photograph lines, accounted for the majority of the material. This adamantine phase always had a variable composition, the powder photograph lines were blurred in quenched specimens and showed a graded ingot in DF and ZR ingots. These facts strongly support the main features of the proposed phase diagram. However, all ingots contained at least a trace of impurity phase. Arsenic condensed in the colder portions of the sealed tube. SnAs and SnAs + As phases were found on electron probe microanalysis of the latter portions of DF and ZR ingots. Surprisingly neither Zn_3As_2 or Cd_3As_2 (or their alloys) were ever found.

In the early stages of the work it was felt that a slight excess of As should be added to provide a gaseous atmosphere over the hot solid and liquid. However the best results were obtained when about 2% excess zinc was added to react with the SnAs phase. ZR and DF ingots containing excess zinc had a higher percentage of single phase graded composition chalcopyrite structure material. But unfortunately none of these ingots was near being a single crystal.

Several other growth techniques were tried in an attempt to produce single crystals. All, including halogen assisted vapor transport, failed. Liquid encapsulated zone refining using KI + 2LiI produced material similar to the ZR material described above.

The best material obtained, which was used in the electrical measurements (20) was produced by ZR in a vitreous carbon boat in a sealed tube kept at an ambient temperature of 570°C to inhibit sublimation of arsenic. The zone speed was 0.1 mm/hr. Figure 3 shows a photomicrograph confirming the disappearance of SnAs rich second phase material when the zone speed was reduced from 10 to 0.1 mm/hr. The boundary is quite sharp indicating that constitutional undercooling due to poling up of impurity rejected by the growing crystal is severe enough to cause the growth interface to reach a eutectic in the four components (Zn, Cd, Sn, As) phase field at just about the growth rate predicted above.

In view of the ease with which the alloys in the $InAs\text{-}ZnSnAs_2\text{-}CdSnAs_2$ system anneal from as quenched powdered alloys to a single sphalerite phase condition (7), hot and cold pressing was also used to prepare specimens for electrical measurements. The most successful technique involved the addition of 0.1% by weight of camphor to the compact before pressing under 5000 psi at 250°C for 10 min pumping at the same time to drive out the camphor binder. These pressed disks were 16 mm diameter and 3 mm thick and after sintering at 550°C for a few hours were suitable for cutting into 10 x 3 x 2 mm specimens. The electrical properties of the compressed powders compared consistently with the ingot material.

Conclusion

We are confident that the proposed phase diagram, Fig. 2, represents correctly the gross features of the $Zn_xCd_{1-x}SnAs_2$ system. The existence plane of this adamantine phase in the proper four component phase field is thought to be quite narrow and to deviate from the line given by the formula by about 2% toward the

Fig. 3. Photomicrograph of the surface of a zone refined ingot of nominal composition $ZnCdSn_2As_4$ showing that the second phase present when the zone speed was 10 mm/hr and disappeared when the speed was reduced to 0.1 mm/hr. Magnification approx. 150X.

zinc rich side for the maximum melting point composition near the zinc end of the line.

Marker Techniques for Studying the Mechanism of Scaling of Metals Based on the Use of the $O^{18}(p,n)F^{18}$ Nuclear Reaction[1]

J. B. Holt and L. Himmel

Lawrence Radiation Laboratory, University of California, Livermore, California

ABSTRACT

A general mechanistic approach to the study of scaling reactions is proposed which dispenses with the conventional inert marker. Instead, radioisotopes of the reacting components are used to establish the nature of the diffusing species in the solid reaction products formed on metal surfaces at high temperatures. For investigating the mechanism of oxidation of metals, O^{18} is employed as a tracer and the stable isotope is subsequently activated by proton bombardment *via* the nuclear reaction $O^{18}(p,n)F^{18}$. The basis for the technique is outlined and its application to the scaling of iron and of zirconium is described. The experiments with iron establish conclusively that, at temperatures up to 1050°C, iron is the only diffusing component in the dense, adherent wüstite layer which forms adjacent to the metal. Direct evidence is also presented for the vapor phase transport of oxygen by a dissociative mechanism during the growth of porous, non-adherent wüstite scales on iron in H_2/H_2O atmospheres. It is shown that oxygen is mobile in thick ZrO_2 scales formed on Zr in a water vapor atmosphere at 1200°C; however, the unusual form of the O^{18} distribution in the scale indicates that open channels must have existed in the outer portion of the scale during oxidation which allowed direct penetration of oxygen to levels deep within the ZrO_2 layer. The advantages and limitations of the present technique are discussed with particular reference to conventional marker methods. Major sources of difficulty in the interpretation of inert marker experiments are identified and a set of experimental requirements is given which, if satisfied, should permit reliable transport information to be obtained using conventional marker techniques.

The mechanism of a heterogeneous chemical reaction, such as the oxidation of a metal, can be considered established, at least in principle, if the rate-determining step in the reaction is known and if the manner in which the reactants are transported to and from the various phase boundaries in the system can be specified. Information of this kind cannot generally be obtained from kinetic studies alone. In fact, even under conditions where diffusion-controlled kinetics are observed, it is often not possible to decide, unambiguously, whether the reaction is sustained by the outward migration of metal ions through the scale, or by the inward diffusion of the nonmetallic component. The dominant or faster diffusing species can, of course, be predicted if self-diffusion or ionic conductivity data are available for both components over the entire stability range of the product phase. Unfortunately, reliable data of this type currently exist for only a few oxide and sulfide systems (1-3).

When the necessary transport data are not available, inert marker techniques are customarily employed to determine the nature of the mobile component in the growing scale. Marker methods were first introduced by Pfeil (4) in 1929 in his classic work on the scaling of iron, and they have been applied subsequently to a great many gas-solid (1) and solid-solid reactions (5-7) but often, as experience has demonstrated, with puzzling or conflicting results. Although several sources of difficulty in the conduct and interpretation of inert marker experiments have now been recognized (8-13), the feeling persists that the results of marker studies may not be trustworthy and should not be accepted without caution. The present work was undertaken in an attempt to develop a generalized marker technique that circumvents some of the problems encountered with conventional marker methods. The results have also permitted us to define in detail the experimental conditions that must be met in order to obtain reliable transport information from inert marker studies.

Instead of employing inert markers which, ideally, do not take part in the reaction, the technique described below utilizes radioactive isotopes that are themselves components of the product scale layer. For oxygen, which does not have a suitably long-lived radioisotope, the stable isotope O^{18} is used and this is subsequently activated by proton bombardment *via* the nuclear reaction $O^{18}(p, n)F^{18}$. The approach is, in essence, equivalent to carrying out a simultaneous transport experiment for both the metallic and nonmetallic component under the actual conditions encountered during the growth of the scale layer. It differs from the conventional marker technique in that the relative mobilities of the two components are determined not simply from the position or location of the marker, but from the distribution of the radioactive species in the product phase. Additional information concerning the mode of transport of the reactants may also be obtained from an analysis of these distributions. Specifically, it now becomes possible to determine whether the transport of oxygen (or other components) takes place by normal lattice diffusion, by migration along grain boundaries or other structural discontinuities in the scale, or as a result of transport through the vapor phase. Such information is not directly obtainable from conventional marker experiments but is frequently of vital importance in the interpretation of marker studies, as we shall demonstrate.

First, we briefly discuss conventional or inert marker techniques, following which the basis for the present method is outlined. Application of the technique is illustrated with reference to two scaling reactions, the oxidation of iron to wüstite, in which the cation is the mobile component, and the oxidation of zirconium, in which the growth of the ZrO_2 layer is generally considered to proceed by the inward transport of oxygen ions.

[1] Work performed under the auspices of the U.S. Atomic Energy Commission.

Inert Marker Techniques

The basic principle involved in a conventional marker experiment is quite straightforward (1, 8). It is assumed that the original gas/solid interface between two reacting materials can be marked in such a manner that it remains distinguishable after reaction has occurred. The position of the original marked interface is then located with respect to the final boundaries of the product phase. This establishes directly the fraction of the total amount of reaction product formed at the respective phase boundaries. Two limiting situations may immediately be recognized: (*a*) the metallic component is the faster diffusing species, in which case the reaction occurs exclusively at the scale/gas interface, and as a consequence the inert marker is located at the metal/scale boundary; (*b*) the nonmetallic component is much more mobile, reaction takes place entirely at the metal/scale phase boundary, and the marker is therefore found at the scale/gas interface. In both instances, the final position of the marker coincides with the original marked interface between the solid and the gas.

It might be thought that the intermediate situation in which both components have roughly comparable mobilities would be even more general. If such were the case, the marker would be found imbedded in the scale part way between the scale/gas and metal/scale boundaries. In nonstoichiometric oxides (sulfides, nitrides, *etc.*), however, the defect concentrations in the metal ion sublattice generally far exceed those in the anion sublattice or *vice versa*, and hence the rates of mass transport of the two components frequently differ by orders of magnitude. The likelihood that this intermediate situation would often be encountered in practice must therefore be considered quite remote.

Nevertheless, the literature abounds with apparent examples of this type. Even in such a well-documented system as the oxidation of iron to wüstite, for which evidence from many different sources overwhelmingly favors the cation as being the faster diffusing species (2, 14-16), markers have been found within the wüstite layer, often at a considerable distance from the iron/wüstite boundary (11, 17-20). Markers have also been observed within the NiO scale formed on nickel (21, 22), the FeS layer on iron (10), and the Ag_2S scale grown on silver (9, 23, 24). In each of these systems, it is definitely known from self-diffusion or other transport measurements that the mobility of the cation in the bulk oxide or sulfide is much greater than that of the corresponding anion (1, 2, 25, 26). These few examples illustrate the need for considerable care, not only in the planning and execution but especially in the interpretation of inert marker experiments.

It now seems clear, in fact, that the location of the marker may not be determined solely by the relative mobilities of the two constituents in the scale, but that the marker position is often strongly influenced by other conditions which arise during the growth of the scale (1, 8-12). Whenever inert markers have been observed within the reaction product formed on a metal substrate, the scale, almost without exception, has been found to consist of two physically distinct but crystallographically identical layers, an inner porous region adjacent to the metal and an outer layer, in contact with the gas phase, which is dense and compact. In duplex scales of this type, the inert marker is always found at or near the boundary between the porous and compact regions of the scale. The conclusion that has frequently but erroneously been drawn in such instances is that the dense outer portion of the scale is formed by the outward migration of metal ions and that the inner porous layer grows as a result of the inward diffusion of the nonmetallic component through the scale. In other words, comparable mobilities are assigned to both constituents in the scale lattice.

As noted previously, simple interpretations such as this are often found to be in direct conflict with theoretical predictions or with the results of self-diffusion measurements. While there can be little doubt that transport of the nonmetallic constituent has indeed taken place during the growth of the inner porous layer in duplex scales, no justification exists for assuming that this transport has occurred by normal lattice diffusion. A far more satisfactory interpretation may be given which not only explains the origin of the duplex scale but is also consistent with evidence obtained from other sources. This alternate interpretation, due to Meussner and Birchenall (10), Mrowec and Rickert (27), and others (9, 28-30), is briefly as follows.

It is assumed that the dense outer portion of the scale is formed by the outward migration of metal ions while the scale is still relatively thin and in intimate contact with the metal. As the scale continues to thicken, however, it becomes increasingly difficult for adherence between the scale and the metal to be maintained, and at some critical stage the scale may become partially detached from its substrate. The actual stage at which this happens depends on many factors, including the nature and magnitude of the stresses that originate in the scale during growth, the plasticity of the scale, and the purity of the metal. Nevertheless, should the compact scale become physically separated from the metal, the inert marker, which is surrounded by the scale, may be carried off along with it. Dissociation of the detached scale will then take place until the equilibrium partial pressure of the reacting gas is established within the void created at the interface. As a consequence, the nonmetallic component will be transported from the separated portion of the scale to the underlying metal through the vapor phase, and a new scale layer may then form beneath the marker. Certain details of this process remain to be clarified, but it is not difficult to visualize how repeated detachment of the scale, along with dissociative vapor transport, could lead eventually to the formation of an inner porous scale layer, thereby offering an explanation for why the marker is found near the junction between the porous and compact segments of the scale. According to this latter interpretation, the cation is the diffusing species in the scale lattice; transport of the nonmetal, which is indicated by the position of the marker, is thought to occur not by normal lattice diffusion but, rather, through the vapor phase.

Evidence will be presented which lends further support to this interpretation. It thus appears that, whenever porous or nonadherent scales are formed, the possibility that a dissociative mode of transport may be operative should not be overlooked in interpreting the results of marker studies. As long as the scale remains dense and adherent, however, the position of the marker will generally give a true reflection of the relative mobilities of the two reacting species in the scale layer (1, 8, 10). To avoid complications introduced by the formation of porous, nonadherent scales it is always advisable, in carrying out marker experiments, to adjust the experimental conditions so that compact, adherent scales are obtained. A full discussion of the various experimental factors involved will be postponed until the results of the present work have been described.

Techniques Utilizing Radioactive Components of the System as Markers

The inert marker can be eliminated entirely from the experimental procedure if use is made of radioactive isotopes of the two chemical constituents involved in the reaction. The theoretical and experimental basis for this approach was first outlined by Bardeen *et al.* (31) in their study of the oxidation of copper using radioactive Cu^{64}. Bardeen *et al.* plated a thin film of Cu^{64} on a copper disk, partially oxidized it to Cu_2O, and then removed successive layers of the oxide by etching, measuring the activity of Cu^{64} in each layer. They showed that the concentration of Cu^{64}

was highest at the Cu_2O/gas interface and decreased progressively toward the Cu/Cu_2O boundary. They also demonstrated, using the Wagner theory of oxidation (2, 32), that this was the distribution to be expected if the growth of the oxide were sustained by the diffusion of vacant Cu^+ ion sites from the outer surface of the oxide toward the Cu_2O/Cu interface, or, equivalently, by the outward migration of Cu^+ ions. On the other hand, had oxygen been the mobile constituent, the distribution of Cu^{64} would have remained sharp, being confined to a narrow zone at the metal/scale interface.

Although the primary purpose of their work was to provide experimental confirmation for the Wagner theory, it is clear that the method employed by Bardeen *et al.* also serves as a valuable marker technique. This has been recognized by several investigators. Using basically the same experimental approach, for example, Schnizlein and co-workers (33) have established that oxygen is the mobile component in the oxide layer formed on uranium metal at 200°C. Similarly, Jarry *et al.* (34) have shown that Ni is the faster diffusing species in the NiO scale grown on Ni at 1000°C, but that, in the reaction between fluorine and Ni at 600°-700°C, F appears to be the migrating species.

In most experiments of this kind thus far reported which involve the growth of thick scales on metals, only the distribution of the radioactive cation has been investigated (31, 33-38). In a few cases, however, the radioactive isotope S^{35} has been utilized in studying the mechanism of sulfidization (39-41) of metals and alloys. There are, as we shall see, a number of advantages in using both components of the system as tracers, particularly since this should provide a rigid cross-check on the consistency of the results. In Fig. 1, the distributions of the radioactive components which would be expected in the scale layer are illustrated schematically for the two limiting situations mentioned above, namely: (*a*) the cation is the mobile species (Fig. 1a and 1b); and (*b*) the anion is mobile (Fig. 1c and 1d). The expected positions of inert markers are indicated in both cases.

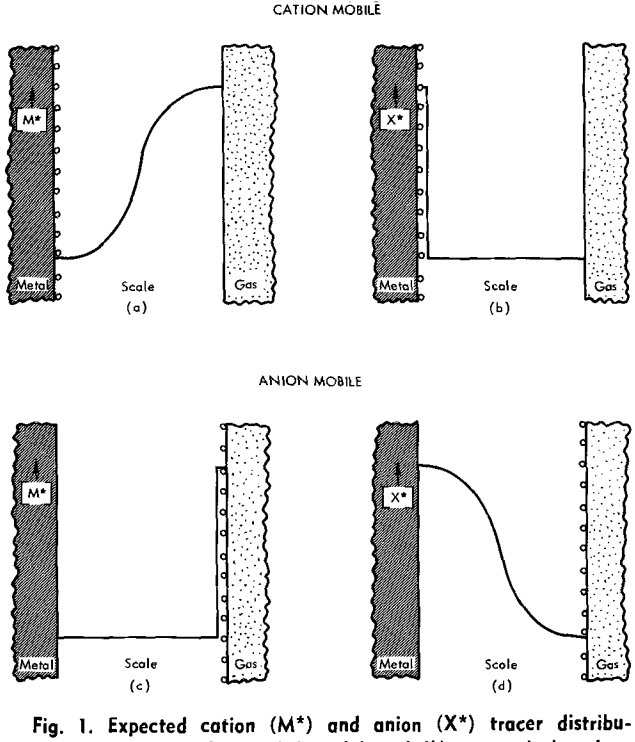

Fig. 1. Expected cation (M*) and anion (X*) tracer distributions in the scale under conditions (*a*) and (*b*), respectively, where the cation is the diffusing component. The corresponding distributions in situations where the anion is the mobile species are indicated by (*c*) and (*d*), respectively. The open circles represent the expected positions of inert markers in each case. Schematic.

Consider first the commonly encountered situation in which the mobility of the cation in the scale far exceeds that of the nonmetallic constituent. If a thin deposit of the radioactive metal is applied to the surface of the sample before oxidation, it will subsequently be found distributed throughout the scale in essentially the manner shown by Bardeen *et al.* (Fig. 1a). On the other hand, if a thin reaction layer containing a radioisotope of the nonmetal is first formed on the surface to mark the original interface and the reaction is then allowed to continue in a normal or inactive environment, the final distribution of the radioactive anion will be that shown in Fig. 1b. In this case the radioactive nonmetal functions as a truly inert marker; its distribution therefore remains sharp and its location, at the metal/scale interface, coincides with that of a more conventional Pt wire marker.

The corresponding tracer distributions in circumstances where the anion is the mobile component are given in Fig. 1c and 1d. Here, the radioactive cation behaves as a inert marker and remains at the scale/gas interface, while the anionic component is distributed continuously throughout the scale, its activity being greatest at the metal/scale phase boundary and lowest at the external surface. The point which bears emphasis is that the diffusing species in any given system is readily and unambiguously identified by the fact that it is distributed in a predictable manner over a major portion of the thickness of the scale. It should be noted, however, that when only one radioactive marker is employed, say the nonmetallic component, its distribution must be determined fairly accurately since the concentration of the radioactive anion in the scale will always be greatest at the metal/scale interface, regardless of which component is the mobile species (*see* Fig. 1b and 1d). Thus, it would not be sufficient merely to detach the scale mechanically from the metal substrate and count the activity on both its surfaces, as has been the practice in previous work in which the radioisotope S^{35} was used as a marker in sulfidization studies (39-41).

Because a suitable radioisotope of oxygen is lacking, some modification in technique is required in order to determine the anion tracer distribution in oxide scales. The method proposed here is based on the use of the nuclear reaction $O^{18}(p, n)F^{18}$ and represents an extension of the charged-particle activation technique previously developed by Condit and Holt (42-44). In effect, the stable isotope O^{18} is used as a marker in precisely the same manner as would a radioactive component, except that the tracer is activated after reaction with the metal has been completed. This is accomplished by proton bombardment of the O^{18} which yields the radioactive isotope F^{18}. The latter has a half life of 110 min and decays with the emission of a 0.67-MeV positron. These characteristics permit the O^{18} distribution in the scale to be determined by simple autoradiographic procedures.

Other charged-particle activation techniques have been employed for this same purpose. Amsel and Samuel (45), for example, have utilized the nuclear reaction $O^{18}(p, \alpha)N^{15}$ to study the mechanism of anodic oxidation of aluminum, while Cox and Roy (46) and their colleagues (47) have used the $O^{17}(He^3, \alpha)O^{16}$ reaction in similar fashion to explore the transport of oxygen in thin ZrO_2 films formed on Zr. Application of these reactions involves measurement of the energy spectrum of the α-particles produced during the nuclear reaction when the oxide, which contains O^{18} or O^{17}, is bombarded with monoenergetic protons or He^3-particles, respectively. Since the depth below the surface down to which activation occurs is limited, these reactions cannot be used to determine the stable tracer distribution in thick oxide scales unless a multiple sectioning technique is employed (48-50). However, great sensitivity can be achieved and hence these activation reactions are ideally suited to the study of the mechanism of growth of thin oxide films on metals. Using

the $O^{18}(p, \alpha)N^{15}$ reaction, Amsel and Samuel have been able to determine the concentration of O^{18} as a function of depth with a spatial resolution of 60Å in anodic oxide films on Al. The resolution claimed by Cox and Roy is about 300Å.

The two scaling reactions which we have chosen to illustrate the application of the present technique were selected because the relative mobilities of metal and oxygen ions in the respective oxides, wüstite (Fe_xO) and ZrO_2, were believed to be sufficiently well established that little doubt should have arisen concerning the interpretation. Actually, the system we chose initially as being representative of a scaling reaction in which oxygen diffusion predominates was the conversion of magnetite (Fe_3O_4) to hematite (Fe_2O_3) (14, 15). It soon became apparent, however, that the migrating species in the Fe_2O_3 layer formed on magnetite is iron and not oxygen. A detailed report of this investigation will be published elsewhere (51).

Experimental Procedure

Iron samples were machined from an ingot of zone-refined iron obtained from Battelle Memorial Institute through the courtesy of the American Iron and Steel Institute. These specimens had the form of a rectangular parallepiped approximately 2 cm × 1 cm × 2 mm thick. All surfaces of each specimen were metallographically polished, cleaned and degreased ultrasonically, and then "marked" with O^{18}. This was done by oxidizing in an atmosphere ($P_{O_2} \cong 130$ Torr) enriched to 30% in O^{18} for roughly 1 min at about 1050°C. The thin ($\sim 20\mu$) oxide layer formed during this period constituted the O^{18} marker. The O^{18} was then pumped out of the system and replaced by normal O^{16}; oxidation was then allowed to continue at the same temperature and pressure as before.

One of the O^{18} marked iron specimens was oxidized for roughly 45 min; this produced a compact, adherent scale about 300μ thick. After slowly cooling to room temperature, one of the surfaces of this specimen was beveled at a shallow angle by shimming up one edge and grinding on 600-grit Carborundum paper. The entire cross section of the scale was thus exposed on the beveled surface, giving an effective magnification of about 30. Similarly marked specimens were oxidized under the same conditions for considerably longer periods in an attempt to produce porous scales. Instead of beveling, cross sections of these samples were prepared by slicing with a string saw and polishing on a vibratory diamond-impregnated lap.

Zirconium specimens about 1.5 cm × 1.0 cm × 2 mm thick were cut from a piece of high-purity crystal-bar Zr sheet supplied by the Wah Chang Corporation. These specimens were marked by exposing them to an atmosphere enriched to 30% O^{18} for roughly 20 min at 750°C ($P_{O_2} \cong 120$ Torr). Subsequent oxidation in a normal environment was carried out at about 1200°C in a flowing water vapor atmosphere using argon as a carrier gas. Under these conditions, in 1 hr a dense, black, adherent layer of ZrO_2 about 180μ thick was produced. The scale was beveled prior to irradiation in the same manner as described above.

The 90-in. cyclotron at the Lawrence Radiation Laboratory was used to irradiate the samples with 2.7-MeV protons at a beam current of about 5 μA for times of the order of 30-45 min. At this beam energy, which is only slightly above the threshold energy (2.59 MeV) for the $O^{18}(p, n)F^{18}$ reaction, the O^{18} is preferentially activated to F^{18} and there are no interfering or competing reactions. This was confirmed by monitoring the decay of the radiation emitted by the samples, which showed that: (*a*) only a single radioactive species was present, and (*b*) the half life (110 min) corresponded to that of F^{18}. During irradiation the samples were mounted in a water-cooled target holder which was oscillated back and forth across the stationary proton beam in order to ensure that all portions of the specimen received the same total integrated exposure. Other details of the irradiation procedure have been described previously (42-44). Within about 30 min to an hour after irradiation, contact autoradiographs were prepared using Kodak Type A autoradiographic plates or, when greater resolution was desired, Type AR-10 stripping emulsion.

A number of other experiments have been carried out in order to obtain direct evidence for possible vapor phase transport of oxygen during the growth of wüstite scales on iron. For this purpose, high-purity iron specimens of both rectangular and cylindrical geometry have been employed, as well as an iron alloy containing 1 a/o (atomic per cent) Pt. These specimens were polished, degreased, and then marked with O^{18} by heating them for about 2 min at 800°C in a 30% enriched O^{18} atmosphere ($P_{O_2} \cong 120$ Torr). Preoxidation in O^{18} was deliberately carried out at a temperature below the α-γ transformation in iron in order to reduce the possibility of spalling of the oxide film during subsequent cooling; in addition, the samples were cooled relatively slowly by gradually reducing the furnace power. The marked specimens were then transferred to another system where they were oxidized either partially or completely to wüstite in a flowing H_2O/H_2 atmosphere which contained only the natural abundance of O^{18} (0.23%). The pertinent oxidizing conditions were: temp = 1015°C, $P_{H_2O}/P_{H_2} = 3.2$. In all cases the samples were slowly heated to furnace temperature in high-purity argon before the H_2O-H_2 gas mixture was admitted, and, at the conclusion of each run, the specimens were furnace cooled in argon. Cross sections of the samples were prepared by cutting them with a string saw, after which the specimens were given a standard metallographic polish.

Results and Their Interpretation

Cation migration in adherent oxide scales formed on iron.—The compact adherent scale produced on rectangularly shaped, zone-refined iron specimens in an oxygen atmosphere at 1050°C was found to consist almost entirely of wüstite; the thin surface layers of Fe_3O_4 and Fe_2O_3 which were also present represented only about 5% of the total thickness of the scale. The wüstite layer in contact with the metal was also free of porosity except near the extreme edges and corners of the specimen. A low-power photograph of the beveled surface of this specimen is shown in Fig. 2, together with the corresponding autoradiograph obtained after proton activation. It is immediately apparent that the O^{18} originally incorporated at the surface of the metal has remained fixed in this position during the subsequent thickening of the scale in a normal O^{16} environment.

This offers convincing proof that the growth of the wüstite layer is occasioned by the outward transport of Fe ions, or, in this case, by the migration of vacant Fe^{++} ion sites from the Fe_3O_4/Fe_xO phase boundary toward the Fe/Fe_xO interface. The O^{18}, being immobile, behaves precisely like an inert marker and is therefore concentrated in a sharply defined band at the Fe/wüstite interface (*see* Fig. 1b). Further verification of the sharpness of the O^{18} distribution is provided by the microdensitometer profile, also reproduced in Fig. 2, which was obtained by scanning the original autoradiographic plate in a direction normal to the metal/scale boundary on an Ansco recording densitometer. The abrupt cutoff in activity at both boundaries of the O^{18}-marked zone allows us to conclude with confidence that the mobility of oxygen ions in the rocksalt-type wüstite lattice must be at least two orders of magnitude smaller than that of iron at 1050°C. It follows that, in previous investigations in which Pt wires or other types of inert markers have been found imbedded within the wüstite layer (11, 17-20), the transport of oxygen past the marker must have occurred by some mechanism other than lattice diffusion. Additional

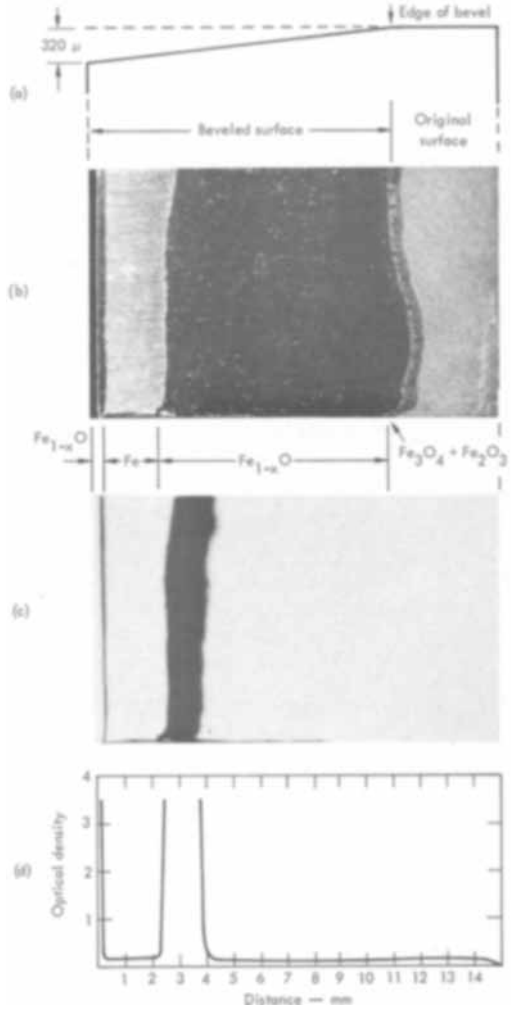

Fig. 2. O^{18} distribution in marked zone-refined iron specimen oxidized for 45 min at 1050°C in 1 atm O_2. (*a*) Plan view of beveled specimen; (*b*) low-power photograph of beveled surface; (*c*) corresponding autoradiograph after proton activation; (*d*) microdensitometer scan of autoradiograph.

experiments are described below which indicate that a vapor transport mechanism was operative.

Oxygen transport in ZrO_2 scales formed on Zr.—The 180μ-thick scale formed on high-purity Zr in a water vapor atmosphere at 1200°C had the characteristic black color usually associated with reduced or oxygen-deficient ZrO_2. Traces of the white stoichiometric oxide could be seen only at the extreme corners and edges of the specimen. The structure of the scale and the underlying metal is shown in cross section in Fig. 3a. Three distinct layers may be noted. The outermost (dark gray) layer is ZrO_2, the intermediate layer is the oxygen-stabilized α-Zr(O) solid solution (h.c.p.) and the innermost zone corresponds to the β-Zr(O) solid solution (b.c.c.) which has undergone transformation to α-Zr on cooling. Although no cracks or fissures were observed on examining the external surface of the scale under a low-power microscope, many elongated voids appear on a polished cross section (Fig. 3a), particularly in the outer portion of the scale. However, careful examination has revealed that a true diffusion barrier does exist at the metal/scale boundary. This is evident from Fig. 3b which shows that the oxide in contact with the oxygen-stabilized α-Zr(O) layer is perfectly adherent and free from any porosity.

Despite great care taken during metallographic preparation, many of the voids which are seen in Fig. 3a are believed to be artifacts. They represent areas within which small crystallites have mechanically broken out of the scale during polishing, thus giving an exaggerated appearance to the size and shape of the voids. Nonetheless, it must be presumed that the outer portion of the scale is not completely dense, and that relatively open channels which would have permitted direct access of oxygen probably existed in the outer part of the scale while oxidation was proceeding.

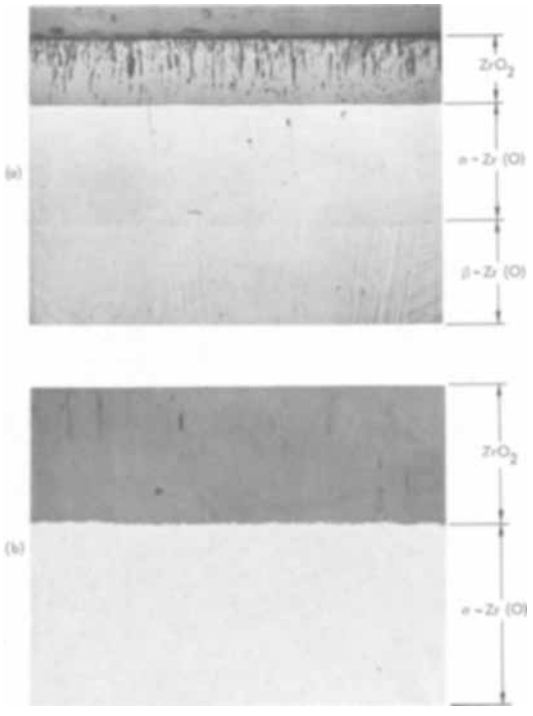

Fig. 3. Cross section of scale formed on crystal-bar Zr sheet at about 1200°C in a water vapor atmosphere. (*a*) Over-all structure showing the separate layers of ZrO_2, α-Zr(O), and β-Zr(O), 50×; (*b*) appearance of ZrO_2/α-Zr(O) interface, 250×. Unetched. Polarized light.

The autoradiograph obtained from an O^{18}-marked specimen after beveling and irradiation is presented in Fig. 4b. Included in this figure is a matching photograph of the beveled surface (Fig. 4a) and a microdensitometer profile (Fig. 4c) showing the optical density of the autoradiographic plate as a function of distance measured along the beveled surface. This particular specimen has been beveled in such a manner that only a portion of the intermediate oxygen-stabilized α-Zr(O) layer has been exposed on the beveled surface near the extreme left-hand edge of the sample.

The features of major interest here are the following: (*a*) the O^{18} tracer, initially confined to a thin ($\sim 2\mu$) layer on the metal surface, is now spread out along the bevel over a distance of about 3.5 mm from the α-Zr/ZrO_2 interface, corresponding to a distance of about 100μ in the direction normal to the interface, which is slightly over one half the total thickness of the scale; (*b*) down to a depth of about 80μ below the external surface of the scale, the O^{18} concentration is constant at a level corresponding to the natural abundance (0.23%) of O^{18}. The O^{18} distribution in the apparently dense portion of the scale near the metal interface is thus seen to be qualitatively similar to the distribution shown in Fig. 1d. This clearly establishes that the growth of the oxide layer involves the inward migration of oxygen through the ZrO_2 lattice. The actual form of the O^{18} profile in the ZrO_2 layer is unusual, however, in that, on proceeding toward the external surface, the O^{18} concentration falls off much more rapidly with distance than would be expected if oxygen were the only mobile constituent, or if oxygen transport through the scale took place only by normal solid-state diffusion processes.

The defect structure and extent of the departure from stoichiometry in ZrO_2 are still not well estab-

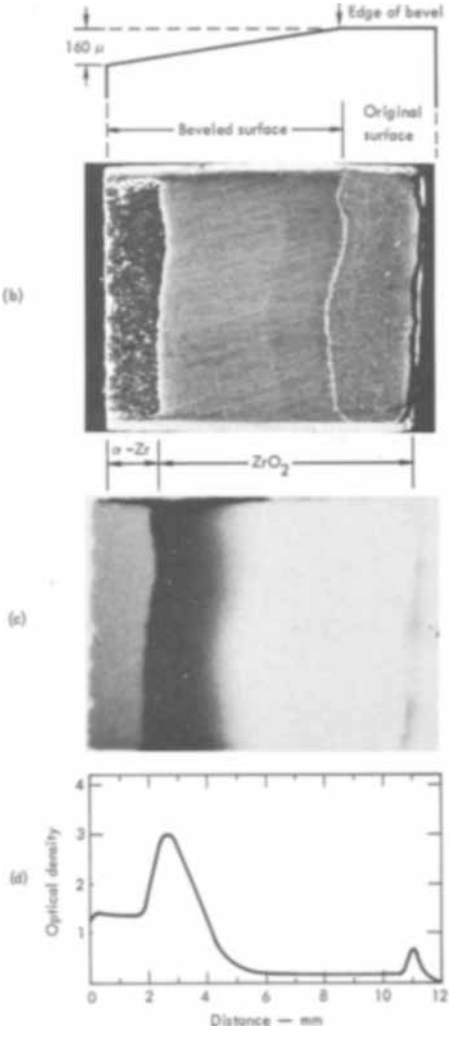

Fig. 4. O^{18} distribution in marked crystal-bar Zr specimen oxidized for 1 hr at about 1200°C in water vapor. (*a*) Plan view of beveled specimen; (*b*) low-power photograph of beveled surface; (*c*) matching autoradiograph after irradiation; (*d*) microdensitometer trace of autoradiograph.

lished (2, 52-55) either for the monoclinic form, which is stable below about 1200°C, or the tetragonal and cubic modifications, which are stable at higher temperatures. Although Madeyski and Smeltzer (56) have recently measured the self-diffusion coefficient of oxygen in pure monoclinic ZrO_2 between 800° and 1000°C using the gaseous exchange technique, comparable tracer self-diffusion data for Zr are not available, nor have the partial ionic conductivities for both components been determined. The possibility that the transport of Zr ions may make some contribution to the growth of the scale at high temperatures therefore cannot be dismissed *a priori* (2, 53, 57). It can easily be demonstrated, however, that, in order to account for the anomalous O^{18} distribution shown in Fig. 4 on a model involving counter-current diffusion of both ion species, the mobility of Zr ions in ZrO_2 must be even greater than that for oxygen. The available evidence (1) argues against such an interpretation. The inert marker experiments of Chirigos and Thomas (58) and Mallett and Albrecht (59) imply, for example, that, in oxygen at temperatures up to 950°C, the growth of ZrO_2 scales on Zr proceeds by the inward migration of oxygen without any noticeable participation on the part of cations. Had we carried out marker experiments using radioactive Zr as well as O^{18}, it could have been established whether or not the same holds true for the growth of the scale in a water vapor atmosphere, as appears probable.

The structural characteristics of the scale provide another and perhaps more reasonable explanation for the unusual form of the O^{18} distribution. When examined in polarized light, the ZrO_2 layer is found to consist of tiny lath-shaped crystallites, each oriented with their long axes parallel to the growth direction. The ease with which many of these crystallites seem to be dislodged during metallographic preparation suggests that they may not be firmly joined to one another; in fact, judging from the voids seen in cross section (Fig. 3a), it appears that more or less continuous channels exist along crystallite boundaries, especially in the outer portion of the scale. If so, normal O^{16} in the gas phase may penetrate deeply into the interior of the scale along these channels and exchange with the O^{18} which is present in the dense scale layer near the α-Zr/ZrO_2 interface. This, in turn, could lead to a rapid depletion of the O^{18} content in the outer scale layer and give rise to a tracer profile of the general form shown in Fig. 4. Comparison of Fig. 3a and Fig. 4 indicates that the region below the external surface within which voids are most apparent does indeed correspond, at least roughly, to the zone of constant background activity on the autoradiograph.

It is worth mentioning at this point that a simple and direct test of this proposed scaling mechanism could be obtained experimentally by reversing the order of oxidation, *i.e.* by oxidizing first in H_2O^{16} to produce a thick scale and then admitting H_2O^{18} shortly before cooling the sample. If channels or fissures which allow direct access of oxygen are present in the scale during growth, radioactivity produced by the $O^{18}(p, n)F^{18}$ reaction will be observed to a considerable depth below the surface; on the other hand, if the scale is truly dense and compact, the O^{18} will be confined to the extreme surface of the scale layer. By systematically varying the thickness of the scale layer formed in normal oxygen, the exact stage in the oxidation process at which mechanical breakdown on the scale occurs could also be determined. Such experiments might prove highly instructive, particularly if correlated with the results of weight gain measurements.

The mechanism by which oxygen is transported through the supposedly dense portion of the scale adjacent to the metal remains open to speculation. It has frequently been suggested in the past (46, 57, 59-64) that grain or crystallite boundaries may provide preferred paths for oxygen diffusion even in completely compact ZrO_2 scales grown on Zr. We had hoped that the autoradiographs themselves might furnish some basis for distinguishing between a grain boundary and a volume diffusion mechanism; however, the maximum resolution obtainable was not nearly sufficient to discern individual crystallite boundaries. In principle, the dominant transport mode could also be deduced from the shape of the O^{18} concentration *vs.* distance profile. The O^{18} concentration in the scale, c, relative to that at the metal/scale boundary, c_0, can easily be determined from the microdensitometer trace (Fig. 3c) by calibrating the original autoradiographic film. The resulting c-x curve is presented in Fig. 5.

It may be observed from Fig. 5a that, within a distance of about 25μ from the metal/scale boundary, the data can be fitted reasonably well by a straight line on a plot of $\ln c/c_0$ *vs.* x, which is suggestive of a line or short-circuiting diffusion process. A clear-cut distinction between a grain boundary and a bulk transport mechanism cannot be made, however, inasmuch as a rather good straight line is also obtained on a probability plot (Fig. 5b). This ambiguity may have arisen because: (*a*) the O^{18}-marked layer originally applied to the metal surface was not sufficiently thick to maintain a constant O^{18} concentration at the metal/scale interface throughout the experiment so that the appropriate boundary conditions were not satisfied; (*b*) no account has been taken of the fact that the diffusion

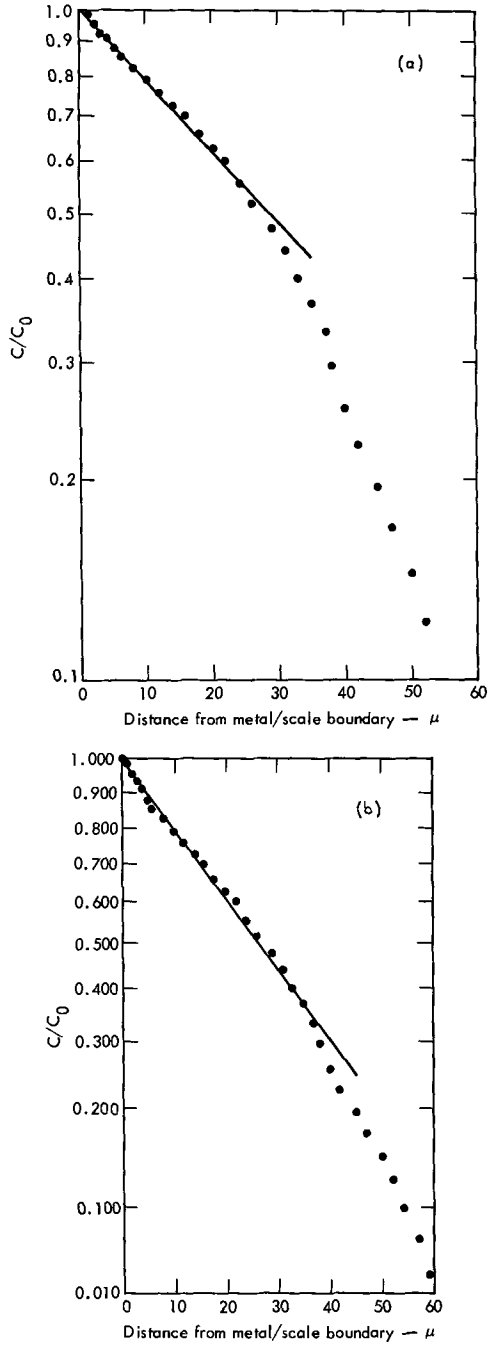

Fig. 5. The O^{18} concentration in the ZrO_2 layer as a function of the distance from the ZrO_2/α-Zr(O) interface: (*a*) ln c/c_0 *vs.* x; (*b*) probability plot of the data shown in (*a*).

of the O^{18} tracer into the growing scale layer is occurring at a moving rather than a stationary boundary; (*c*) the diffusion coefficient may be a sensitive function of the composition or stoichiometry; and (*d*) the O^{18} distribution was perturbed by exchange with gaseous O^{16} in deep-lying channels or fissures. It is evident that a more thorough study will be required in order to identify the operative transport mode decisively.

Although definite proof is lacking, the available evidence seems to suggest that most of the oxygen which eventually reaches the metal is transported through the dense part of the scale along short-circuiting paths of high diffusivity rather than by a volume diffusion process. The oxide scale formed at 1200°C in a water vapor atmosphere exhibits an average grain or crystallite size of the order of 1μ. If the structure of the scale is idealized by assuming it to consist of a columnar array of uniformly sized crystallites each 1μ × 1μ on a side, nearly one oxygen ion in every 10^3 would be located at a crystallite boundary. This means that virtually all of the mass transport needed to account for the observed rate of growth of the scale could be supplied by diffusion along crystallite boundaries if the grain boundary diffusion coefficient were as small as 10^4 times the volume diffusion coefficient of oxygen ions in ZrO_2. Considering that 1200°C is still a relatively low temperature compared to the melting point of ZrO_2 ($T_M \approx 3000$°C; $T/T_M \approx 0.49$), a ratio of the grain boundary to the lattice diffusivity of 10^4 is not at all unreasonable.

The conditions favoring grain boundary transport are greatly improved at lower temperatures, particularly in view of the marked reduction in the average crystallite size which is noted below about 1000°C. According to Lightstone and Pemsler (64), for example, the average grain diameter in ZrO_2 scales produced by oxidizing Zr in pure O_2 at 800°C is only about 300Å. These same authors investigated the transport of O^{18} in ZrO_2 scales formed on Zr at temperatures between 600° and 900°C using an argon ion beam to sputter oxygen atoms from the scale into a mass spectrometer where they could be analyzed directly. Their results were shown to be consistent with a short-circuit diffusion mechanism for oxygen transport. By making use of the $O^{17}(He^3, \alpha)O^{16}$ nuclear reaction, Cox and Roy (46) determined the distribution of O^{17} in relatively thin (<4μ) ZrO_2 scales formed by oxidizing first in O^{16} and then in O^{17} at 400° and 500°C. They, too, concluded that oxygen transport through the scale could not have been controlled by a simple volume diffusion process, and that grain or crystallite boundaries may provide the most likely paths for oxygen diffusion.

This raises some question regarding the interpretation to be placed on the values for the diffusion coefficient of oxygen which have been derived from an analysis of the diffusion-controlled oxidation kinetics of Zr at temperatures between 400° and 1050°C (65-67). Along with Cox and Roy (46), we believe that these derived or calculated values do not represent bulk diffusion coefficients; instead, they probably correspond to the product of the grain boundary diffusion coefficient and the effective cross-sectional area of high-diffusivity paths in the scale. Significantly, the calculated coefficients yield an activation energy for oxygen diffusion of only 28-31 kcal/mole, whereas the activation energy reported by Maydeski and Smeltzer (56) for relatively large-grained ZrO_2 is 56 kcal/mole. Furthermore, in the temperature range between 800° and 1000°C, the derived oxygen diffusion coefficients are between 3 and 4 orders of magnitude larger than the self-diffusion coefficients measured directly by Maydeski and Smeltzer. Cox and Roy have pointed out still another discrepancy, *viz.* that the calculated diffusion coefficients are in fortuitously good agreement with oxygen self-diffusion data for calcia-stabilized zirconia; since the latter contains nearly 15% oxygen ion vacancies and since the maximum departure from stoichiometry in pure ZrO_2 appears to be of the order of 0.1% or less (1, 55), no such agreement would be expected if oxygen diffuses by the same mechanism in both materials.

Evidence for Vapor Phase Transport of Oxygen during Growth of Wüstite on Iron in H_2-H_2O Atmospheres

Oxidation of high-purity iron samples with rectangular geometry.—Iron samples having rectangular or platelike geometry may be completely converted to wüstite without developing extensive internal porosity except near corners and edges; generally, a thin porous zone is also observed in the exact midplane of the specimen, as indicated in Fig. 6a. The O^{18} distribution in a wüstite sample which had been marked in the usual fashion prior to oxidation is shown in Fig. 6b. In regions well removed from the corners and edges, the O^{18} distribution is sharp and is confined to the midplane of the specimen, thus again confirming that iron is the diffusing species. Close inspection of the auto-

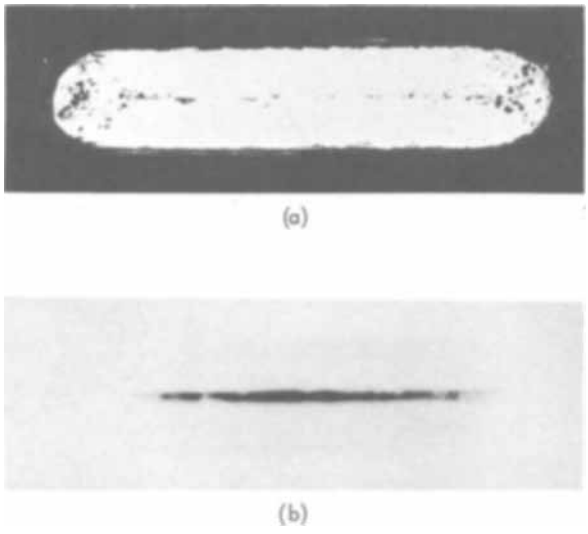

Fig. 6. O^{18} marker experiment on a rectangularly shaped zone-refined Fe specimen completely converted to wüstite by oxidizing at 1015°C in an H_2/H_2O atmosphere. (*a*) Cross section of oxidized specimen; (*b*) matching autoradiograph after proton activation of O^{18}.

radiograph (Fig. 6b) reveals that there are, in fact, two separate but parallel zones on either side of the midrib in which the O^{18} is concentrated. Apparently, the O^{18}-marked layers initially present on the two large flat faces of the iron sample did not quite meet in the center when the metal was entirely consumed.

The O^{18} distribution in the porous regions of the scale near the specimen edges is significantly different. This is evident from the autoradiograph in Fig. 7, which shows that the O^{18} tracer is spread out over a considerably greater area near the outside (right-hand) edge of the sample than it is in the denser central portion of the scale. Enhanced transport of oxygen must, therefore, have occurred at the corners and edges. This could not have been produced by the migration of some type of oxygen defect—either oxygen vacancies or interstitials—in the wüstite lattice since the relative mobilities of iron and oxygen ions in wüstite cannot be appreciably different near the corners and edges than in other regions of the scale. Furthermore, the average wüstite grain diameter is about 2-3 mm so that, if enhanced penetration of oxygen took place along grain boundaries, this would undoubtedly have been detected on the autoradiograph. No evidence for preferential grain boundary migration was found, however. We are thus led to the conclusion that the most likely mode of transport of oxygen in the porous regions of the scale is through the vapor phase *via* a dissociative mechanism (29, 30, 68).

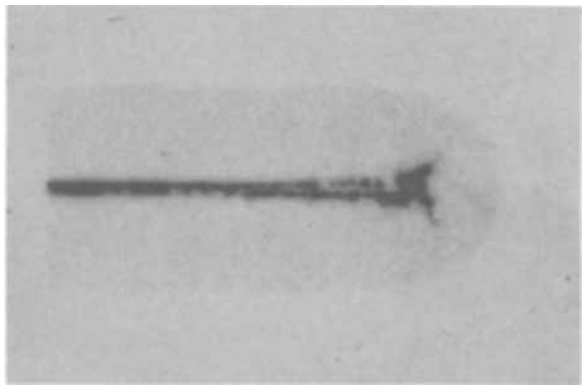

Fig. 7. Same as Fig. 6 except that the autoradiograph now shows the O^{18} distribution near the extreme (right-hand) edge of the sample.

Oxidation of high-purity iron samples having cylindrical geometry.—The local loss of adherence that occurs at the corners and edges of platelike specimens results in partial relief of stresses which are set up in the scale during growth. This, combined with the inherent plasticity of wüstite, allows the oxide formed on the large flat faces of the specimen to remain in good contact with the receding metal surfaces. Thick, compact, adherent wüstite layers, may, therefore, be produced on rectangularly shaped specimens. In samples having cylindrical form, the scale is under greater lateral constraint, but, more importantly, stresses cannot be relieved by edge cracking. As a consequence, rupture and partial separation of the scale from the metal are observed at isolated points around the circumference of the specimen at a much earlier stage in oxidation process. This sequence of affairs is illustrated in Fig. 8, which shows cross sections of the scale formed on O^{18}-marked, 7-mm-diam × 2.5-cm-long iron specimens at several intermediate stages during com-

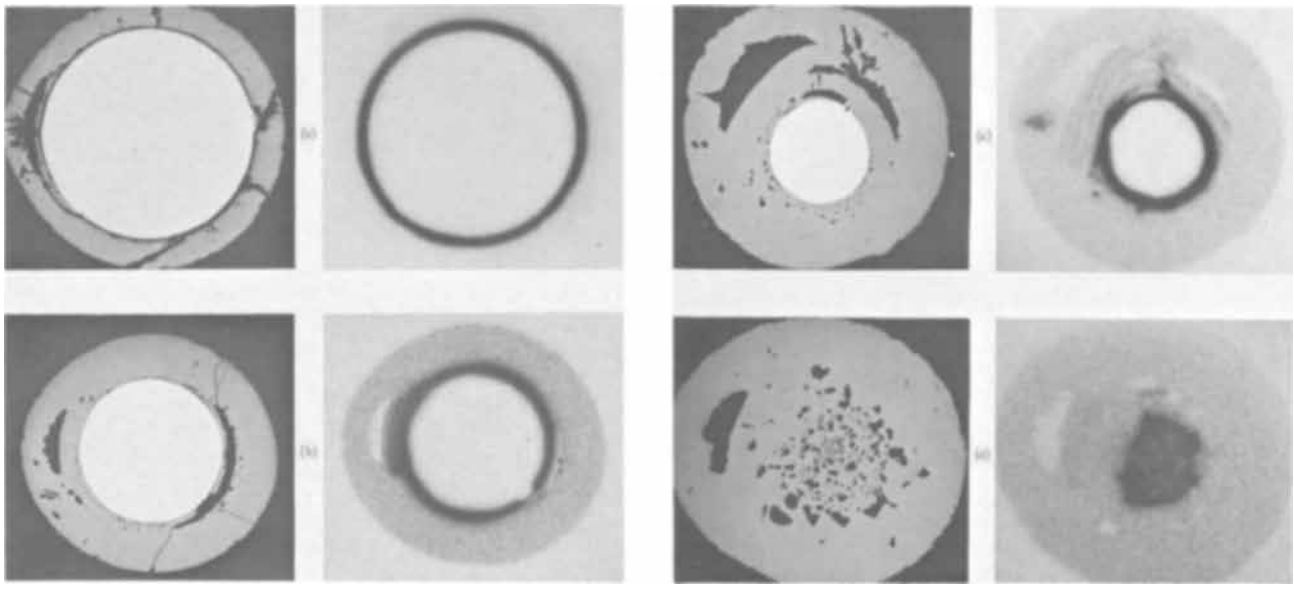

Fig. 8. Oxidation of O^{18}-marked 7-mm-diam, zone-refined iron cylinders at 1015°C in H_2/H_2O. Cross sections of the specimens and the corresponding autoradiographs are shown at various stages of oxidation to wüstite. (*a*) Oxidation time 4½ hr; (*b*) 17 hr; (*c*) 44 hr; (*d*) 90 hr.

plete reaction to wüstite at about 1000°C; the corresponding autoradiographs obtained after proton activation are also presented for comparison.

In general, the internal porosity developed in cylindrical specimens is far more extensive than that found in rectangularly shaped samples (compare, for example, Fig. 6b and 8d). The appearance of porosity in the scale is often accompanied by a smearing out of the O^{18} distribution near the metal/scale interface, and a rough correlation seems to exist between the amount of internal porosity and the extent of broadening of the O^{18} distribution. In completely oxidized cylindrical specimens, the central region over which the O^{18} tracer is distributed may occupy as much as 30% of the total volume of the oxide. The relative size of this centrally activated region increases with increasing specimen diameter and is greater near the ends of the cylinder than near the center, depending, no doubt, on the exact stage at which loss of adherence occurs between the scale and the metal. Similarly, the shape of this activated region also varies since separation of the scale from the metal does not take place simultaneously at all points around the circumference. These observations can be explained satisfactorily only by assuming that oxygen is transported through the vapor phase from detached portions of the scale to the underlying metal.

It should be pointed out that no O^{18} is observed in the vicinity of many of the large internal voids seen near the external surfaces of the scale (Fig. 8). This is somewhat puzzling. In order to be able to detect the vapor phase transport of O^{18}, however, the marked oxide must be detached cleanly from the surface of the metal along with the contiguous portion of the scale. This may not happen if the bond between the metal and the oxide is sufficiently strong. Instead, cracks may propagate through the oxide rather than along the metal/scale interface and the O^{18} may then remain bound to the metal. Indications that the detachment of the scale may actually occur in this manner can be found in Fig. 8. Juenker *et al.* (11) have proposed a similar method of scale detachment based on their metallographic observations.

Oxidation of an Fe-1 *a/o* Pt *alloy.*—Highly porous wüstites are obtained when dilute Fe-Pt alloys are oxidized to completion under the same conditions as those employed for zone-refined iron. The appearance of a completely oxidized Fe-1 a/o Pt specimen of rectangular shape is shown in cross section in Fig. 9a. (compare with Fig. 6a). In addition to the voluminous porosity, the interior portion of scale contains a fairly uniform dispersion of elemental Pt particles about 10μ in diameter. Proton activation of this sample yielded the autoradiograph shown in Fig. 9b, which reveals that the O^{18} distribution is spread out to a much greater extent on both sides of the midplane than it is in the dense, pure wüstite specimen illustrated in Fig. 6b. It is also evident that the interior portion of the scale over which the O^{18} is distributed coincides roughly with the zone of fine porosity shown in the accompanying photograph.

Solid-state diffusion of oxygen in the Pt-containing wüstite may be ruled out as a possible means of oxygen transport on the basis of the following argument. Platinum is believed to be virtually insoluble in wüstite and hence it should have little or no influence on the defect structure of the oxide. If dissolved, however, the substitution of Pt ions for iron in the wüstite lattice would either increase the concentration of iron ion vacancies or leave this concentration unchanged since the normal valence states of Pt are +2 or +4. The failure to detect even the slightest evidence for the preferential transport of oxygen along grain boundaries in high-purity, coarse-grained wüstite makes it reasonable to dismiss such a mechanism in this case as well, despite the fact that the average size of the wüstite grains in the highly porous region of the Pt-bearing

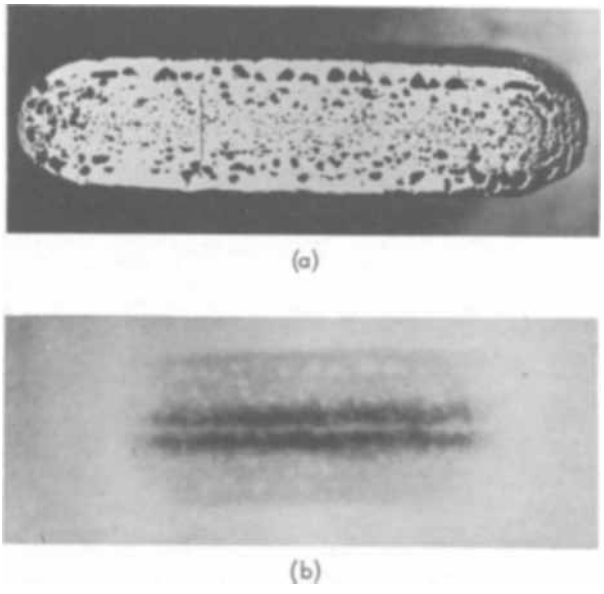

Fig. 9. O^{18} marker experiment on a rectangularly shaped Fe-1 a/o Pt alloy completely converted to wüstite in a H_2/H_2O atmosphere at 1015°C. *(a)* Cross section of oxidized specimen; *(b)* matching autoradiograph after irradiation.

scale is perhaps an order of magnitude smaller than that in the pure wüstite. Hence, by analogy with preceding examples, we again conclude that the major transport of oxygen took place through the vapor phase. Dissociative transport mechanisms thus appear to play an even more significant role in the oxidation of alloys than with pure metals, partly because impurities in the metal exert a strong influence on the degree of adherence of the scale.

Thick, non-adherent scales formed on iron in air.—The morphology of the scale produced by oxidizing a rectangularly shaped iron specimen for a relatively long time in air at about 1000°C after marking with O^{18} is shown in cross section in Fig. 10a. Complete separation of the scale from the metal has occurred along one of the large faces of the sample, thus allowing the scale on the opposite surface to grow without constraint and maintain contact with the metal. Detach-

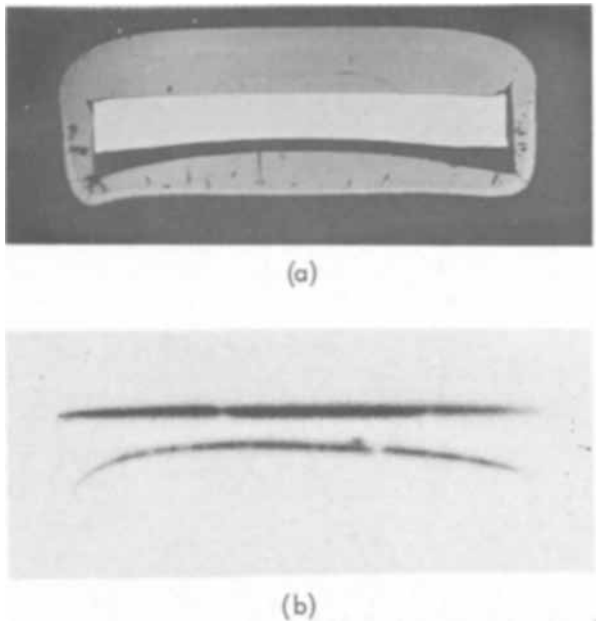

Fig. 10. O^{18} marker experiment on a rectangularly shaped zone-refined iron specimen partially oxidized in air at about 1000°C. (a) Cross section; (b) corresponding autoradiograph.

ment of the scale along this (bottom) surface apparently took place in step-wise fashion during growth as a result of the inward propagation of cracks originating at corners and edges (10, 11). It is significant, however, that, although the scale formed on the bottom surface is completely nonadherent, no internal porosity is seen except near the very edges. The nonadherent portion of the scale consists mostly of Fe_3O_4 and Fe_2O_3, which establishes that detachment of the scale occurred at temperature and not during subsequent cooling (15, 17).

The autoradiograph obtained when this specimen was activated is presented in Fig. 10b. Somewhat surprisingly, the O^{18} distribution is sharp even on the nonadherent side, where the tracer is concentrated at the surface of the oxide adjacent to the metal; faint vestiges of activity can also be found on the metal itself. It is clear that extensive transport of oxygen through the vapor phase did not occur in this experiment. Detachment of the scale from the metal is therefore not the only condition that must be met in order for a dissociative transport mechanism to operate. A suitable vapor species must also be present. Since vapor phase transport is observed when iron is oxidized to wüstite in H_2/H_2O atmospheres but not in dry air, it appears that some vapor species involving both oxygen and hydrogen, *e.g.* H_2O, is responsible. Fujii and Meussner (70) had earlier reached this same conclusion based on a detailed study of the mechanism of oxidation of Fe-Cr alloys in water vapor.

Discussion

The general approach outlined in earlier sections of this report involves study of the radioisotopic distributions of both chemical components in the growing scale layer. This approach has been illustrated here only by employing one of the two constituents, *viz.* oxygen, as a tracer. Wherever possible, however, it is suggested that both chemical species be utilized in order to provide a check on the internal consistency of the results. Establishing the distribution of the metallic as well as the nonmetallic component becomes particularly important when working with reaction products whose defect structures are unknown and for which little or no ionic transport data are available. In studying the oxidation of Zr at high temperatures, for example, the possibility that the diffusion of Zr ions may make some contribution to the growth of the scale could not be ruled out with certainty based only on consideration of the O^{18} distribution in the ZrO_2 layer.

Suitable radioisotopes exist for nearly all metals, the most notable exceptions being Ti and Al. Conveniently long-lived radioisotopes are also available for most nonmetallic elements of interest such as sulfur, carbon, phosphorus, boron, silicon, the halogens, *etc.* The only important exception, aside from oxygen, is nitrogen. Condit *et al.* (69) have recently shown, however, that the $N^{15}(\alpha,n)F^{18}$ nuclear reaction can be employed to study the distribution of nitrogen in solids in exactly the same way as the $O^{18}(p,n)F^{18}$ reaction has been utilized here. It is evident, therefore, that the use of the components of the system itself as markers constitutes a perfectly general technique which can be applied to virtually every class of scaling reactions on metals. With little modification, the same approach can also be used to study the mechanism of solid-liquid and solid-solid reactions (70), as well as such processes as the conversion of a lower to a higher oxide, sulfide, *etc.* (51). Application of the technique of the scaling of alloys may prove to be somewhat more difficult, however, because of the complex morphology of the oxide scales formed in alloy systems.

Judging from the examples presented above, the use of the $O^{18}(p,n)F^{18}$ nuclear reaction to study the mechanism of oxidation of metals offers a number of advantages over conventional marker techniques. In dense, adherent scales, for example, not only can the diffusing species be identified unambiguously but, in systems in which oxygen is the mobile component, valuable information concerning the mode of transport may also be deduced from the shape of the O^{18} concentration profile. This is illustrated by the work on the oxidation of Zr which, although not conclusive, indicates that oxygen may be transported through the compact portion of the scale along grain or crystallite boundaries. The unusual form of the O^{18} distribution in thick ($\sim 200\mu$) scales produced on Zr in a water vapor atmosphere has also furnished evidence that cracks or fissures which allow oxygen to penetrate deeply into the scale must have been present in the outer portion of the ZrO_2 layer. So detailed a picture of the transport processes that occur during the oxidation of Zr under the particular conditions employed in these experiments could hardly have been derived simply by observing the location of an inert marker.

The utilization of O^{18} as a tracer which can be detected by autoradiographic methods through subsequent proton activation thus provides the unique capability of determining whether the transport of oxygen takes place by diffusion through the solid reaction product or by some other means. In this respect, the $O^{18}(p,n)F^{18}$ nuclear reaction is definitely to be preferred over other charged-particle activation techniques such as those developed by Amsel and coworkers at the Ecole Normale in Paris (45, 48-50, 71) or by Cox and his collaborators at Chalk River, Ontario (46, 47). The experiments dealing with the growth of wüstite on iron in H_2/H_2O atmospheres dramatically illustrate this point. We have shown, for example, that oxygen is practically immobile in the wüstite lattice itself but that it is transported to the underlying metal at a rapid rate through the vapor phase under conditions which lead to the formation of porous scales. It is precisely because information of this type cannot be obtained from inert marker studies that the interpretation of conventional marker experiments must be carried out with great care. In fact, the failure to give due recognition to vapor phase transport processes is no doubt responsible for many of the incorrect conclusions which have been drawn from the results of inert marker experiments.

Certain limitations of the proton activation technique should also be noted (42, 50). Since autoradiographic procedures are employed, the accuracy with which the O^{18} distribution in the scale can be measured is partly determined by the resolution obtained on the film. This, in turn, is dependent on the thickness of the radioactive source, *i.e.* the depth of activation at the surface of the sample, the intimacy of contact between the emulsion and the sample, the characteristics of the film itself, and various other factors (72, 73). By controlling the energy of the proton beam just above the threshold energy for the $O^{18}(p,n)F^{18}$ reaction and irradiating with the beam at a grazing angle to the surface of the specimen, the depth of activation can be held to within 1μ; using the best stripping emulsions, it is possible, under these conditions, to obtain a resolution of the order of 5μ. This means that such features as the preferential transport of oxygen along grain boundaries would not be distinguishable unless the average grain diameter in the scale were greater than about 10μ.

The half life of F^{18} (110 min) is sufficiently long to make sectioning procedures practicable. However, the cross section for the $O^{18}(p,n)F^{18}$ reaction does not vary smoothly with energy but instead exhibits a number of sharp resonances (74). As a result, the activity measured at different depths below the surface cannot be related in a simple manner to the concentration of O^{18} at each level. Since sectioning methods are less satisfactory than might be supposed, the use of autoradiographic procedures becomes almost mandatory. A lower limit is thus imposed on the thickness of the oxide scale which can be employed in marker studies of this kind. Even if 100% enriched O^{18} were used, enough activity for proper autoradiographic detection

would probably not be obtained if the thickness of the O^{18}-marked layer initially formed on the metal surface were much less than 1μ. To establish the distribution of O^{18} in the scale with sufficient reliability, the final or over-all thickness of the oxide layer would have to be about an order of magnitude greater, *i.e.* roughly 10μ. The technique is therefore not nearly as well suited for investigating the early stages of oxidation of metals, as are the activation methods developed by Amsel *et al.* or Cox and co-workers.

By employing a radioisotope of the metallic component as a marker, it should not only be possible to check the interpretation of the O^{18} marker experiments but, in systems in which the cation is the faster diffusing component, supplementary information concerning the transport mechanism may also be obtained. The wüstite scales formed on iron at high temperatures are sufficiently coarse grained, for example, that preferential migration of iron along grain boundaries should be discernible on an autoradiograph if it contributes significantly to the growth of the scale. The scale may also be sectioned to determine the tracer distribution, analysis of which should reveal whether a bulk or a short-circuiting diffusion mechanism is operative. If normal lattice transport is indicated and there are no other complications, the cation diffusion coefficient calculated from the slope of the ln c *vs.* x^2 plot should agree reasonably well with the self-diffusion coefficient measured by more conventional techniques (35, 36, 38). This would provide still another check on the assumed transport mechanism. Complications may arise, however, as was shown by Carter and Richardson (37), who studied the oxidation of Co using Co^{60} as a tracer. They observed an anomalous distribution of Co^{60} near the metal/scale interface; Birchenall (75) later suggested that this may be associated with the development of porosity in the scale. It may be interesting, therefore, to compare the Fe^{55} or Fe^{59} distribution in an apparently dense pure wüstite scale with the distribution seen in the porous wüstite scales obtained by oxidizing dilute Fe-Pt alloys under the same conditions.

Based on our observations and those of others, it would seem that the proper approach to the conduct of inert marker studies is to choose the experimental conditions in such a way that complications introduced by the formation of porous scales are avoided or at least minimized. Although the factors which govern the loss of adherence between the scale and the metal, as well as the development of porosity in the scale, are still not fully understood, enough experience has been gained to permit several working rules to be set down. These are as follows:

1. Metal specimens with rectangular or platelike geometry should be employed and their lateral dimensions should preferably be of the order of ten times the thickness or greater.

2. The highest purity metals available should be selected since even trace amounts of impurities may have a deleterious effect on the adherence between the scale and the metal.

3. The surfaces of the specimens should be polished and scrupulously cleaned before the inert marker is applied.

4. High-melting noble metals such as Pt or Ir, vapor deposited on the surface of the sample in the form of thin discontinuous films, appear to provide the most satisfactory markers (8, 76). Radioisotopes of these metals (*i.e.*, Pt^{197} or Ir^{192}) are also suitable (37). If Pt wires are used, these should be lightly sintered or spot-welded to the metal so that they are in intimate contact with the surface. The wires should also be of sufficiently small diameter ($<25\mu$) that they do not interfere with normal diffusional flow during the growth of the scale (10).

5. Preliminary experiments should be carried out on unmarked specimens of identically the same size, shape, and purity in order to establish the range of conditions, *i.e.* time, temperature, oxygen pressure, *etc.*, under which compact, adherent scales are produced. The actual marker studies should be performed under these same conditions and the expectation that the scale grown on the marked samples is, in fact, free from internal porosity should be verified by metallographic examination.

6. In working with metals which undergo phase transformations at temperatures below those employed in the actual marker experiments, it is advisable to bring the metal specimen to the desired temperature in an inert (or reducing) atmosphere before admitting oxygen into the system. This will avoid any possibility that the scale formed during warmup, and the marker along with it, becomes detached from the metal surface due to volume changes accompanying the phase transformation in the metal. The same applies to systems whose oxides exhibit crystallographic transformations.

7. Temperature fluctuations in the oxidation furnace should be kept to a minimum to avoid introducing thermal stresses which could lead to premature rupture or loss of adherence of the scale. Whenever possible, the specimens should also be cooled in such a way as to prevent excessive spalling of the scale.

8. Since the presence of water vapor may accelerate vapor transport, steps should be taken to ensure that the reacting gases are dry.

By taking these simple precautions it should be possible, in most instances, to obtain a reliable measure of the relative mobilities of the metallic and nonmetallic components in the scale from inert marker experiments. These same precautions should also be observed when using O^{18} as a marker, if the objective is simply to establish the nature of the mobile constituent in the pure, dense product phase. On the other hand, if it is desired to investigate the details of the scaling mechanism over as wide a range of conditions as possible, including those which lead to the formation of porous or nonadherent scales, a somewhat different approach is called for. The physical characteristics of the scale now assume overriding significance; in this connection, the importance of good metallography as an essential aid in the interpretation of marker experiments can hardly be overestimated. It will also be appreciated that, by making proper use of O^{18} as a tracer, much may be learned concerning the physical nature of the scale as it exists at the oxidizing temperature. For example, to determine whether or not rupture of the scale has occurred in a manner which allows direct access of oxygen to the underlying metal, O^{18} may be admitted to the system shortly before the specimen is cooled to room temperature. Any cracks into which O^{18} had penetrated will then be revealed on the resulting autoradiograph by the presence of activity along their borders; these cracks should therefore be distinguishable from those which might have originated on cooling.

In conclusion, it should be mentioned that in addition to its usefulness in studying the mechanism of oxidation processes, the $O^{18}(p, n)F^{18}$ nuclear reaction may also be employed to advantage in many other types of investigations, *e.g.* in the determination of metal-oxygen phase diagrams, studies of the solubility and diffusivity of oxygen in metals, measurement of oxygen self-diffusion coefficients in bulk oxides (44, 77), and in studying the preferential segregation and mobility of oxygen along grain boundaries or other structural discontinuities (43).

Acknowledgments

The authors wish to thank the entire staff of the 90-in. cyclotron at the Lawrence Radiation Laboratory for their help in carrying out these experiments. In all phases of this work, we have profited greatly from discussions and useful comments offered by R. H. Condit. The assistance of F. Vanderhoofen and M. Y. Almassy in the preparation of specimens is also gratefully acknowledged.

Manuscript submitted March 17, 1969; revised manuscript received *ca.* July 23, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Technical Notes

Reaction Kinetics of Partially Decomposed Barium Titanyl Oxalate

Thomas S. Montgomery

Robert McCullough Research Center, Ling-Temco-Vought, Inc., Dallas, Texas

The intermediates formed from partially decomposed barium titanyl oxalate tetrahydrate, $BaTiO(C_2O_4)_2 \cdot 4H_2O$ have been studied. Several thermal decomposition mechanisms have been previously proposed by several investigators (1-5). Gallagher and Thomson (4) proposed that an anhydrous compound decomposes between 300° and 400°C producing barium carbonate and titanium(IV) oxide which, in turn, reacts at 600°-700°C to form barium titanate. Infrared analyses of compositions similar to these proposed intermediates and reaction products have been obtained previously (6-11).

In this investigation the solid state reaction kinetics between the intermediates, $BaCO_3 + TiO_2$ was examined in the 400°-700°C range. The reaction rate data was analyzed using equations corresponding to reaction mechanisms of several types. The equations representing differing models have been reviewed (12).

Experimental Procedure

Barium titanyl oxalate tetrahydrate was prepared by the method of Clabaugh *et al.* (13, 5), and heated to selected temperatures. The partially decomposed phases were analyzed by infrared spectrophotometry using the double beam mode over the range 400-4000 cm^{-1}. Isothermogravimetric analyses (TGA) were obtained at selected temperatures over the 400°-700°C range.

Isothermal analyses of weight loss *vs.* time were obtained from material calcined to 400°C, pressed at 10,000 psi and the pellets stabilized at 400°C. The pellets were elevated to the desired isothermal temperature within 10 min and the extent of the solid state reaction was monitored by per cent weight loss. The complete reaction of $BaCO_3 + TiO_2 \rightarrow BaTiO_3 + CO_2\uparrow$ requires 15.9% weight loss. The pellets were weighed immediately after being thermal stabilized at 400°C and immediately after the run. Close correlation between calculated and observed weight loss was noted for the higher temperature evaluations where the material obviously was completely reacted.

Results and Discussion

Infrared analysis.—The infrared spectra was evaluated for the barium titanyl oxalate which had been calcined at several temperatures in the 400°-700°C range. The spectra in the 200°-400°C range was considered only qualitatively so as to observe the change in spectra up to the 400°C region. It was observed that the major change in absorption peak positions occurs at 400°C, and that above this temperature the peak positions are established and only the intensity changes (Fig. 1).

The absorption peaks observed in the 400°-700°C region near 1430, 1020, 860, and 695 cm^{-1} are associated with the V_3, V_1, V_2, and V_4 vibrations, respectively, which have been previously assigned to $BaCO_3$ (6, 7). An absorption peak near 540-560 cm^{-1} may be compared both to the V_1 (or Ti-O stretch frequency) of $BaTiO_3$ (10) or the unassigned frequency of TiO_2 (11). For cubic and tetragonal $BaTiO_3$ the asymmetric absorption band V_1 extends from about 800 to 475 cm^{-1}, with a center of 540 cm^{-1}, and a half width of 165 cm^{-1} (10).

The area under the V_3 (1430 cm^{-1}) $BaCO_3$ peak decreases as the calcining temperature is increased. This correlates with the thermogravimetric data (4) showing the reaction is proceeding and the amount of the carbonate present is decreasing. The amount of TiO_2 decrease or $BaTiO_3$ increase could not be related as the only vibration mode observed for both phases

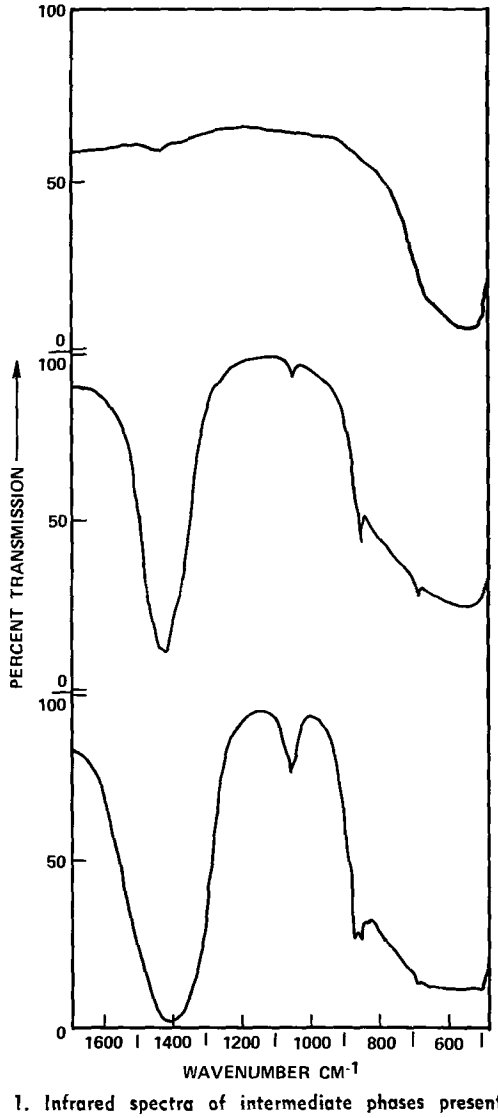

Fig. 1. Infrared spectra of intermediate phases present. Note the decrease in relative intensity of the $BaCO_3$ peaks (in text) with increasing temperature. Upper-700°C, middle-550°C, lower-450°C.

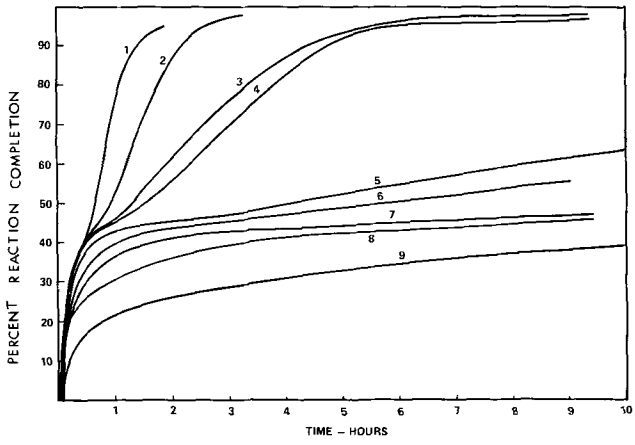

Fig. 2. Decomposition curves of $BaCO_3$ and TiO_2 phases reacting to form $BaTiO_3$. 1, 680°C air; 2, 680°C vacuum; 3, 650°C air; 4, 650°C vacuum; 5, 600°C air; 6, 600°C vacuum; 7, 550°C air; 8, 550°C vacuum; 9, 500°C air.

is near 500 cm^{-1}. The broad absorption peak in the 500-700 cm^{-1} region is retained as the temperature is increased toward 700°C. [Remaining fundamental modes for TiO_2 occur at 388 and 183 cm^{-1} and for $BaTiO_3$ at 400, 183, 12 cm^{-1} (6, 7, 10).] X-ray diffraction analysis of the phases present for heating at 550°C for 20 hr to 50% reaction completion showed only a major $BaTiO_3$ peak and four lines to match $BaCO_3$.

Reaction kinetics.—The relation between per cent reaction completion, temperature, environment, and duration of run until no further weight loss was observed is shown in Fig. 2. The 100% reaction completion represents the 15.9% weight loss for the reaction $BaCO_3 + TiO_2 \rightarrow BaTiO_3 + CO_2\uparrow$. The isothermal decomposition or reaction completion data were subjected to diffusion controlled equations. Rate constants calculated from the equations showed a drift with time (14).

The reactants, viz., $BaCO_3$, TiO_2 (anatase), and/or TiO_2 (rutile), have densities which are 4.31, 3.9, and 4.18-4.25, respectively. The presence of either anatase or rutile and $BaCO_3$ reacting to form a final phase, $BaTiO_3$ ($\rho = 6.02$), having lower molar volume may undergo contraction; and the formation of a discontinuous product layer. Laidler (15) proposes that reaction at a phase boundary may be the rate-determining step when a discontinuous product phase occurs. The relation between the fraction reaction completed and time for a phase boundary controlled reaction is

$$k_{PB}t = 1 - (1 - X)^n$$

where $n = 1/3$ for spherical shaped grains, and X is the amount of reaction completion. The rate constant data obtained for the phase boundary equation represented by the contracting sphere model ($n = 1/3$) is plotted in Fig. 3 and shows constancy of the rate constant after 40 and 55% reaction completion of the 680° and 650°C air runs, respectively.

The kinetics of the anatase-rutile transformation have been extensively studied (16, 17). In a 2-hr period, conversion of anatase to rutile is 60% completed at 680°C, whereas it is only 15% completed at 650°C (16). This may then be related to the reaction between $BaCO_3$ and TiO_2 to form $BaTiO_3$. The initial 2-hr period shows that the reaction is nearly (95%) completed at 680°C, whereas only 60% of the reaction is completed at 650°C in air. The per cent rutile formed at 600°C is negligible and the per cent $BaTiO_3$ formed

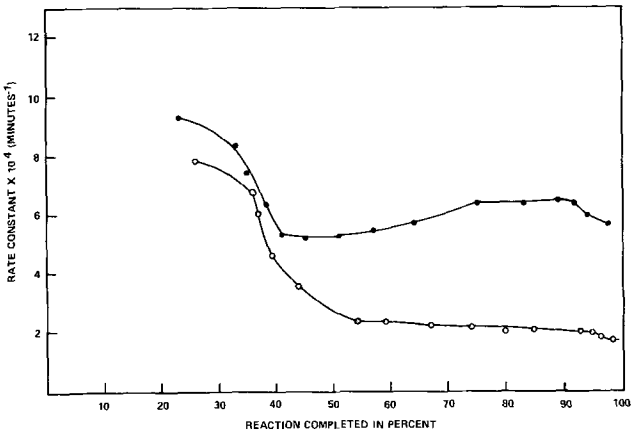

Fig. 3. Analysis of the rate constants using the phase boundary model, $[1 - (1 - \alpha)^{1/3}] = kt$, for the reaction of $BaCO_3$ and TiO_2 to form $BaTiO_3$ in air, ●, 680°C; ○, 650°C.

in the solid state reaction at 600°C is considerably less (<50%) than at the higher temperatures. This suggests that the reaction shows the Hedvall effect (18) and is controlled in part by the kinetics of the anatase-rutile conversion.

Manuscript submitted May 27, 1969; revised manuscript received July 17, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Stability of Aluminum Oxide Films on Germanium Devices

S. Krongelb

IBM Watson Research Center, Yorktown Heights, New York

Recent work has indicated that Al_2O_3 films can be deposited and used as insulating layers on semiconductor surfaces (1-3). This material can meet the need for an insulator deposited at relatively low temperatures, for, as Aboaf (2) has shown, Al_2O_3 can be formed at 420°C by the pyrolysis of aluminum isopropoxide. The present work will demonstrate that Al_2O_3 deposited by pyrolysis or by sputtering is superior to SiO_2 made at a comparable temperature by the reaction of tetraethyl orthosilicate (TEOS) and oxygen (4) in that the Al_2O_3 is far less susceptible to water pickup and much more stable under bias-temperature stressing than the SiO_2. The combination of Al_2O_3 deposited over SiO_2 will be shown to have particularly desirable characteristics for germanium device technology.

Sample Preparation

The SiO_2 films were made at 450°C by the reaction of TEOS and oxygen (4). Al_2O_3 was formed either pyrolytically from $Al(OC_3H_7)_3$ at 420°C in a nitrogen ambient as described by Aboaf (2), or by r.f. sputtering from a 99.9% pure Al_2O_3 cathode in an argon atmosphere. The substrate temperature in the latter process was estimated to be about 400°C.

Fixed-charge and surface-state densities were determined from C-V measurements made and interpreted as described by Sedgwick (5). These properties on single-layer insulators were evaluated on a structure consisting of a 2-5 ohm-cm n- or p-type (110) Ge substrate on which about 2200Å of the desired oxide had been deposited. A 30-mil diameter evaporated Al dot completed the device. The insulating film for the double-layer measurements consisted of about 1000Å of SiO_2 deposited directly on the germanium and covered with about 1500Å of the appropriate Al_2O_3. Electrical stability was evaluated on the basis of the change in fixed-charge density after a 1 hr bias-temperature stress at 150°C with fields up to 10^6 V/cm under both positive and negative bias. Charge transport during stress was measured as described by Kerr (6).

Moisture resistance was appraised by comparing the water content of the films before and after temperature-humidity (T & H) stressing at 85°C and 85% relative humidity. The amount of water in the films was determined from the infrared absorption in the 3μ region by the methods of Pliskin and Lehman (7), using films deposited on infrared transparent (high resistivity) silicon substrates. The single-oxide films were about 5000Å thick while the double-layer samples consisted of about 4000Å of SiO_2 covered by 1500Å of the appropriate Al_2O_3. The latter structure was designed primarily to determine the effectiveness of Al_2O_3 in preventing water absorption by the highly susceptible SiO_2. All spectra were obtained on a Beckman IR-10 spectrometer operated in the double-beam mode. With the above samples, an absorption corresponding to an optical density of 0.004 or greater per micron of oxide could readily be measured.

Results and Discussion

Electrical properties.—Sedgwick (5) has shown that the Ge-insulator interface is characterized by the presence of both fixed charges and fast acceptor states. These parameters are given in Table I for the various insulating films under consideration. It is noted that, except for pyrolytic Al_2O_3 directly on Ge, all the films give rise to a positive fixed charge and moderate surface-state densities. (Sputtered Al_2O_3 directly on Ge is not included because the sputtering process introduces excessive surface state densities which leads to an uninterpretable MOS characteristic.) The presence of negative fixed charge in Al_2O_3 on Ge and the reduction in fixed charge when Al_2O_3 is deposited over SiO_2 have been previously reported (2, 8). It should be noted that the fixed charges cited in Table I are effective values calculated from C-V data on the assumption that all the charge lies at the Ge-insulator interface. This effective charge describes the effect of the real charges in the insulating film on the semiconductor surface, but the actual charges, especially for the two-layer structures, are very likely not all located at the semiconductor interface.

Changes in the electrical surface properties as a result of bias-temperature stressing are given in the last column of Table I. The shifts for most samples fall within a factor of two of the values cited, and for the SiO_2 films are in a direction indicating ion motion. The magnitude of the shift for the +10V stress on SiO_2 may be greater than for −10V, but the difference is generally within the factor-of-two spread of the data. More significantly we have found that the observed C-V shift on a given SiO_2 device represents only a half to a quarter of the charge transport which was actually measured on that device during stressing. Our hypothesis, based on work currently in progress, is that the C-V shift represents the net effect of the transported charge combined with partial neutralization and trapping at the SiO_2-Ge interface. In fact, a smaller stress field can actually cause larger apparent C-V shifts. This behavior is attributed to the fact that while essentially complete ion transport still takes place at lower fields, the trapping effect is reduced. The C-V data cited here probably understate the instability inherent in this SiO_2 film deposited on germanium.

With Al_2O_3, either directly on the semiconductor or applied over SiO_2, the C-V shift is significantly reduced. These small shifts can occur is either direction for either polarity of applied stress so that the C-V data still represent a combination of effects, probably ion motion, trapping, and annealing (small shifts of comparable magnitude have been noted on heating without bias). However, ion motion in the presence of Al_2O_3 is markedly reduced as has been verified by direct measurement of charge transport during the stressing of Al_2O_3 and Al_2O_3-SiO_2 structures. The observed transport is small and comparable to or less than the C-V shifts. The C-V data thus do provide a valid evalua-

Table I. Typical electrical interface properties of various oxide films

Oxide	Fixed charge per cm²	Surface states per cm²	Change under stress in fixed charge per cm²
SiO_2 by TEOS and oxygen at 450°C	3×10^{12} pos	1.5×10^{12}	2×10^{12}
Al_2O_3 by pyrolysis in N_2 at 420°C	2×10^{12} neg (variable)	Up to 12×10^{12}	0.4×10^{12}
Pyrolytic Al_2O_3 over 450°C SiO_2	0.7×10^{12} pos	1.0×10^{12}	0.3×10^{12}
Sputtered Al_2O_3 over 450°C SiO_2	1.2×10^{12} pos	1.4×10^{12}	0.3×10^{12}

Table II. Water content of various films before and after temperature and humidity exposure

Material	Initial O.D./μ* SiOH	Initial O.D./μ H_2O	After T & H O.D./μ SiOH	After T & H O.D./μ H_2O	Days in T & H environment

* Optical density per micron of film.

tion of the stability of these films, and the magnitude of the shift is at a level which is acceptable for bipolar devices. While the single layer of Al_2O_3 does have good electrical stability, the two-layer structures are more attractive for device applications because of the lower surface-state densities associated with them.

Water pickup.—The water content of the various films before and after T & H exposure is summarized in Table II. Water content is expressed in terms of infrared optical density per micron of film; where SiOH and H_2O absorption can be resolved, both optical densities are given. [A convenient rule of thumb is that the weight fraction of water in SiO_2 is approximately equal to the optical density of the SiOH absorption per micron of oxide (9).]

The results show that SiO_2 deposited by the reaction of oxygen and TEOS has a high water content initially and readily picks up additional water during the T & H stressing. These findings are consistent with previously reported adverse effects resulting from room-temperature exposure to high humidity (4). The pyrolytic Al_2O_3 films, on the other hand, contain relatively little water initially and are only slightly affected by T & H exposure. The water content of the sputtered films is below the detectability limit of the Beckman IR-10 spectrometer even after stressing. In comparing the effects of T & H exposure on SiO_2 and Al_2O_3, it should further be noted that the SiO_2 films become saturated with water after only a few days of stressing, whereas the data for the Al_2O_3 films represent the effects of a month or more of T & H exposure.

Low water content in a film after T & H stressing has generally been taken as an indication that the film will protect the underlying materials from the effects of ambient moisture. This passivating property of the Al_2O_3 films can be seen directly from the last two entries in Table II. These samples consist of 4000Å of SiO_2 which is covered over by 1500Å of the indicated Al_2O_3. The dominant contribution to the I-R absorption in these structures comes from water in the SiO_2, and the data accordingly are expressed as the optical density per micron of SiO_2. The fact that there is no increase in water content after T & H stressing is attributed to the passivating qualities of the Al_2O_3. A slight decrease in water content is in fact noted, but the difference is close to the reproducibility limit of our measurements and further work is required to establish whether the change is really significant. The data in Table II also show that SiO_2 which is covered by Al_2O_3 has a lower initial water content than does unprotected SiO_2. This difference is probably real and may be explained by noting that some water is driven off under the conditions of the Al_2O_3 deposition. Subsequent exposure to the atmosphere does not result in reabsorption of moisture because the SiO_2 is now protected.

Conclusion

The two-layer structure of Al_2O_3 over SiO_2 deposited on germanium has been shown to have a relatively stable semiconductor interface under bias-temperature stressing. Superior moisture resistance, when compared to a single SiO_2 layer deposited at comparable temperatures, has also been demonstrated for the two-layer structure. While Al_2O_3 alone also exhibits good electrical stability and moisture resistance, it has drawbacks in that (*i*) Al_2O_3 cannot be sputtered directly onto the semiconductor surface without excessive surface damage, and (*ii*) pyrolytic deposition of Al_2O_3 on Ge results in a high and variable density of surface states. The two-layer structure overcomes these problems and appears promising for device work.

Brief Communication

Making Formed Contacts to Semiconductors Using a Programmable Power Supply

T. M. Baleshta*[1]

Surface Science Group, Mineral Sciences Division, Mines Branch, Department of Energy, Mines and Resources, Ottawa, Ontario, Canada

An effective way of obtaining good ohmic contacts is by the formed (welded)-contact method. A formed contact can be made either by discharging a capacitor, with a series resistance to provide constant current characteristics through a point contact (1), or by applying a succession of current pulses through a point contact from a high-impedance power source (2). For those workers who do not have access to commercial bonding equipment, the following contact forming technique may be useful.

A programmable d-c power supply, having both constant voltage and constant current regulation, with automatic crossover from constant voltage to constant current, is an ideal high-impedance current source that can be used to make formed contacts. A power supply with these characteristics is, for example, the Lambda Electronics Corporation Model No. LH125. This power supply is capable of supplying a voltage from 0 to 40V and a current from 0 to 3A, and has a voltage-to-current crossover delay of 1 msec. The contact-forming procedure is to use the power supply in place of the capacitor in the capacitor-discharge technique, but without the series resistance since the constant-current mode of the power supply provides this feature. The output voltage of the power supply is set to a value which will give an initial current pulse (thermal transient) that starts the contact-forming process, and the output current of the power supply (current limiting) is set to provide post heating of the contact. Postheating allows the contact area to remain molten for a short time (a few seconds) resulting in a stable and reproducible contact. When the lead wire touches the semiconductor, the power supply will hold its programmed voltage for 1 msec before automatically crossing over to the current-limiting mode.

A number of formed contacts were successfully made to low-resistance (1-ohm) samples of FeS_2 and PbS. The voltage of the power supply was set so that an initial current pulse of approximately 10A started the forming of the contacts; then a postcurrent of 1A was maintained through the contact for a few seconds to complete the forming. The lead wires used were gold and copper, both having diameters of 0.005 in. The resulting contacts were mechanically strong and voltage-current characteristics showed them to be ohmic.

Anodes for Refuelable Magnesium-Air Batteries

R. P. Hamlen,* E. C. Jerabek, J. C. Ruzzo, and E. G. Siwek

Physical Chemistry Laboratory, General Electric Company, Research & Development Center, Schenectady, New York

ABSTRACT

The aim of this work was to select a suitable anode and electrolyte combination for the operation of a replaceable anode magnesium-air battery. Various combinations were considered from the standpoint of cell voltage, parasitic consumption of metal, and the volume of reaction product sludge formed. Packaging materials were also tested to prevent the sludge from falling to the bottom of the cells and to minimize magnesium hydroxide formation on the cathodes. The anode package selected consisted of AZ61 magnesium alloy covered on each surface with Vexar expanded polyethylene and glycerinated cellulose. Sodium chloride solutions, between 7 and 18%, were satisfactory electrolytes, the latter being superior as a result of a lower resistive drop in the electrolyte and a shorter voltage transient on changing current densities.

The purpose of this work was to select an anode alloy and an electrolyte-separator system for use with magnesium-air cells. The cells are to be employed in a battery with replaceable anodes and electrolyte (1, 2). This system differs from the silver chloride-magnesium sea water cell in that the product is primarily a hydroxide rather than a chloride, and all of the magnesium hydroxide (or hydroxychloride) product must be contained within the cell rather than being flushed out. The over-all pH in the cell is higher, although at the magnesium electrode it may be lower as a result of the poorer circulation in the cells.

Since the product sludge must remain within the cell, the total ampere-hour discharge between refuelings is determined by the volume of sludge per ampere-hour and by the total cell volume available for containment of the sludge. The arrangement of the cell must be such that the bottom portion of the magnesium is not completely masked by fallen reaction product. In addition, the cell must be such that the depleted anode and the reaction products can be conveniently removed from the cell without damaging the cathodes. The voltage should be as high as possible, consistent with a reasonable coulombic efficiency, and the voltage transient on increasing from a low to a high current density should be minimized and the time interval over which it occurs should be as short as possible. The experiments described below were aimed at selecting an appropriate anode, electrolyte, and separator combination.

Experimental

Voltage and gassing behavior.—Several different magnesium alloys were selected for testing, based on previous air cell work and on the recommendations of the Dow Chemical Company. In addition to these, two samples of aluminum were obtained from the Metals Research Laboratories of the Olin Mathieson Chemical Company. These had been formerly recommended for use as a substitute for magnesium in silver chloride-magnesium torpedo batteries, and had been found to operate with slightly lower voltages, but with higher efficiencies. The various metals were compared using a small cell of 10 cm^2 active area arranged as shown in Fig. 1. A platinum-Teflon Niedrach-Alford [Ref. (3)] cathode was used, the gap between the magnesium and the cathode was ¼ in., and a flow meter was arranged so that the gas flow out of the cell could be measured. A calomel reference electrode was connected to the cell through a side arm halfway between the electrodes. A mercury-wetted 60 Hz on-off switch was placed in series with the load as a means of measuring the resistance of the whole cell and of the magnesium half cell. This resistance was measured by measuring the initial voltage recovery using an oscilloscope when the load was removed. The oscilloscope was also used for evaluation of the transient behavior of the magnesium when switching current levels. Otherwise the cell was operated at constant current. For these tests, the electrolyte was 7% sodium chloride solution. Electrolyte pumped through the cell due to gas evaluation was returned to the cell *via* the electrolyte recirculation arm shown in Fig. 1.

Figure 2 gives the polarization curves for the various alloys. The aluminum was Type A-6 alloy from the Olin Metals Laboratory. The voltage for the Gemag alloy (Magnesium Elektron, Limited) was the highest over the whole range. However, the gassing results, shown in Fig. 3, show that at relatively low current densities the gassing rate is higher than that for any of the other alloys. This means that at low current drains of a few milliamperes per square centimeter large fraction of the magnesium would be consumed in self-discharge. The dashed line in Fig. 3 represents the

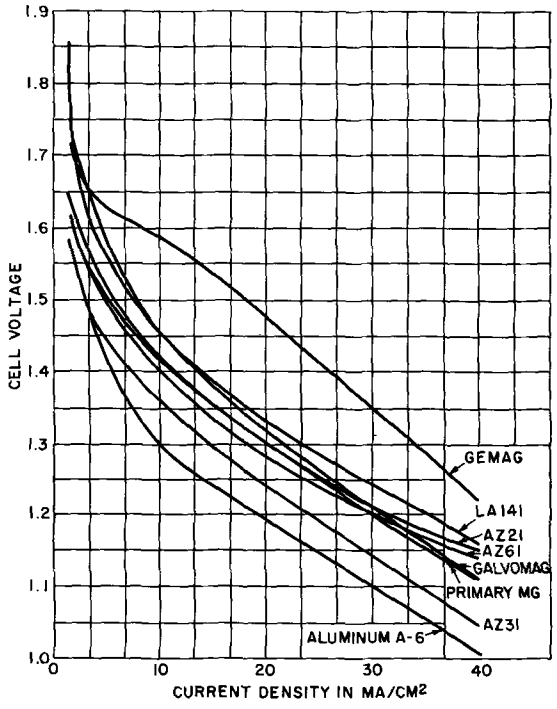

Fig. 2. Voltage vs. current density for various alloys

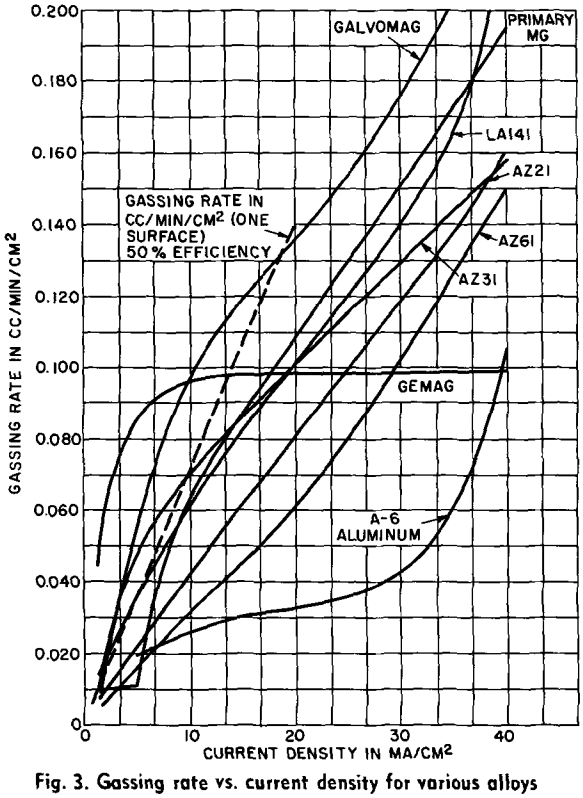

Fig. 3. Gassing rate vs. current density for various alloys

gassing rate at which 50% of the metal would be consumed in the self-discharge reaction. The farther below this line the curve for a sample is, the higher its efficiency should be. The aluminum sample should be better than the others on the basis of efficiency in the intermediate current density range, although its voltage is lower than the others. During these experiments, it was observed that the gassing rate at a given current density was somewhat dependent on the prior operation of the cell, possibly as a result of changes in surface area or electrolyte concentration. This may account for some of the irregularities of the curves in Fig. 3.

Of the magnesium samples, AZ61 represents a good compromise between voltage and gassing behavior, and is one of the readily available alloys. This is the alloy which is used in water-activated magnesium-silver chloride torpedo batteries.

Sludge volume measurements.—The volume of sludge produced for a given alloy and electrolyte system was determined as follows. A sample of alloy was operated in a small cell between air electrodes 5.7 cm high and 7.6 cm wide (43 cm^2). The thicknesses of the alloy samples ranged from 10 to 80 mils, and the gap between the electrodes was about ¼ in. The volume of liquid contained was about 14 cc. The cell was operated at constant current at ambient temperature for a specified time, and then the residual matter was washed out of the cell and off the anode into graduated centrifuge tubes. The volume of sludge was measured after centrifugation. This sludge was frequently observed to be nonhomogeneous, consisting of layers of light-colored hydroxide or hydroxychloride, and dark-colored matter containing fine particles of unreacted metal. In addition to measuring the sludge volume, observations were also made on the nature of the reaction product (tightly or loosely packed within the cell) and on the ease of removal of the magnesium anode.

Results and Discussion

Table I summarizes the results of some of the tests, which were conducted primarily with AZ31 and AZ61 magnesium alloys. The table gives the sludge volumes in cubic centimeters per ampere-hour. It was desired to find the combination giving the minimum sludge volume, since this would yield the maximum number of ampere-hours for a given cell size. The results for AZ31 in 7% sodium chloride show that there is considerable variation in results obtained from tests conducted under similar conditions. There does not appear to be any large change in sludge volume with increased sodium chloride concentration. However, the average for AZ61 in 7% sodium chloride, 3.8 cc/A-hr, is lower than that for AZ31, 4.7 cc/A-hr.

Various electrolytes and additives were employed during these tests. Some of the observations follow.

Magnesium ion in solution.—When a solution of a salt containing magnesium ion, such as magnesium chloride or bromide, was used as the electrolyte, magnesium hydroxide precipitated in and on the cathode. This caused a rapid decrease in cell output.

Calcium chloride.—With a solution of calcium chloride, the magnesium rapidly passivated. This probably resulted from the deposition of a layer of calcium hydroxide on its surface.

Thickeners.—Two per cent Jaguar gum (Stein, Hall and Company, Incorporated) was added to 7% sodium chloride solution to observe the effect of drastically in-

creasing the electrolyte viscosity. When the cell was operated, the hydrogen evolved from the magnesium carried most of the viscous electrolyte out of the top of the cell.

Precipitation aids.—Separan NP10 (Dow Chemical Company) and polyacrylic acid added to 7% sodium chloride each caused the formation of tightly packed sludge. This is a disadvantage form the standpoint of the removal of spent anodes.

Chelating agents.—Versene (the sodium salt of ethylenediamine tetraacetic acid) and Versene Fe-3 [the sodium salt of N-N-di (2-hydroxy-ethyl) glycine—both from Dow Chemical Company], potential chelating agents for magnesium ion, were considered because of the possible effect on sludge volume. There does appear to be a slight advantage using Versene Fe-3 (2%, plus 7% NaCl), the sludge volume being 3.3 cc/A-hr on AZ61 (average of 6 tests) compared to 3.8 cc/A-hr in 7% sodium chloride alone. However, the presence of Versene Fe-3 caused increased corrosion of copper and nickel cell components.

During these experiments, it was observed that magnesium hydroxide was precipitated in and on the cathode after a few hours of operation. This caused the performance to deteriorate with time. The precipitation results from the fact the hydroxyl ion is formed at the cathode, and therefore the solubility for magnesium ion is lowest at this point. In order to reduce the problem, samples of microporous filters and cellophane were placed between the anode and the cathode during cell operation. The original intent was to place a single permanent layer over the face of the cathode in contact with the solution. However, it was found that the magnesium hydroxide layer precipitated on the electrolyte side of this filter caused an increase in the internal resistance of the cell. Because of this, it was decided that each anode should be bagged in the appropriate separator material.

The bagging materials considered were: Acropor AN-200 microporous filter (Gelman Company), glycerinated and unglycerinated cellulose, and glycerinated and unglycerinated fibrous casing (all from Union Carbide Corporation). Cellulose and fibrous casing were both superior to the microporous filter medium from the standpoint of keeping magnesium hydroxide precipitate off of the cathode. Glycerinated cellophane was the least expensive of the separator materials considered and is recommended for this system.

An additional problem pertaining to the sludge was the manner in which it distributed itself vertically in the cell. If nothing was introduced to keep the sludge from dropping to the bottom of the cell, the bottom of the cell would not discharge due to increased electrolytic resistance where the sludge would fill the electrolyte gap. To compensate for this situation, various large-pore materials were introduced between the cellophane and the magnesium anode. The materials employed were cellulose felt (Kendall Company, Grade EU 101), open-cell polyurethane foam (Scott Paper Company), and various grades of Vexar expanded polyethylene (Du Pont). The material finally selected was a grade of Vexar, 30ADS49, having a thickness of 0.1 cm and diamond-shaped openings about 0.8 cm across. It was found that with felt the escape of the hydrogen gas generated was somewhat cut off, so that the internal resistance of the cell was increased by the resulting gas pockets. One of the grades of Scott foam performed as satisfactorily as the Vexar, but it was less convenient to handle and to assemble into anode packages.

Electrical contact.—Electrical contact between cells was achieved by means of a clip attached to the top of each magnesium anode. This clip had two U-shaped ears which fitted into mating contacts attached to the adjacent cathode. Clips of tin-plated nickel were found to be satisfactory. The clip was riveted to the top of each anode using brass rivets. A coating of neoprene paint (Adhesive Products Corporation) was applied over the whole clip, except for the U-shaped part, and over an adjacent ¼-in. strip of magnesium. A completed anode package is shown in Fig. 4.

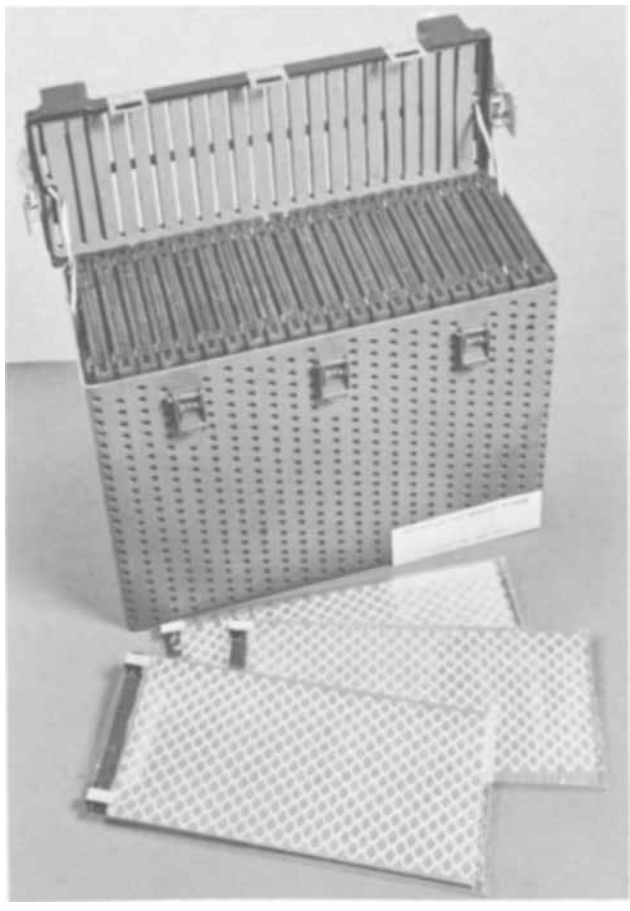

Fig. 4. Complete anodes and battery

Transients.—One of the problems usually encountered with cells having magnesium anodes is the temporary drop in voltage observed when the current is increased. This has been studied by Robinson and King [Ref. (4)] and results from the nature of the film formed on magnesium in basic solutions.

AZ61 alloy had a shorter transient time than AZ31 alloy, and each of these was considerably shorter than that for the A6 aluminum alloy. The alloy with the shortest transient time of any was the GEMAG alloy, which also showed the highest voltage. This high voltage and short transient time result from a very high rate of self-discharge, which keeps the surface relatively free of magnesium hydroxide. Because of this, the coulombic efficiency was found to be very low at the relatively low average drain rates under consideration, so that this alloy could not be used in the present application. Similar behavior was observed for the LA141 alloy. The load was resistive, so that the current reached the new value gradually. The duration of the voltage transient can be anywhere from a fraction of a second to a minute or more, depending on the relative currents before and after switching, the *p*H, the temperature, electrolyte concentration, and the extent of discharge of the anode. The *p*H at the anode can be lowered drastically when the magnesium hydroxide builds up in the cell. With *p*H paper, it has been found immediately after discharge to be as low as 8.0. Figures 5 and 6 show the transient behavior of anodes at various states of discharge using 7% sodium chloride when an initially low level was switched first to an intermediate current level, and second to a high current level. The figures show that when switching

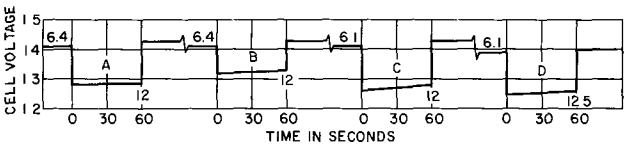

Fig. 5. Transient behavior in 7% NaCl solution—low to intermediate current—2.3A (6.4 mA/cm²) to 4.3A (12.0 mA/cm²)—after: A, 6 A-hr; B, 12 A-hr; C, 18 A-hr; D, 24 A-hr. The numbers indicate current densities in mA/cm².

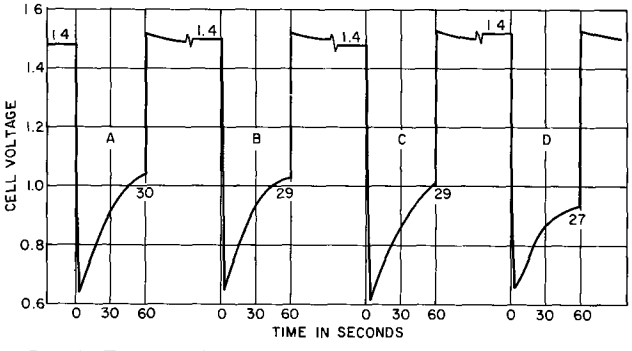

Fig. 6. Transient behavior in 7% NaCl solution—low to high current—0.5A (1.4 mA/cm²) to 10.9A (30 mA/cm²)—after: A, 6 A-hr; B, 12 A-hr; C, 18 A-hr; D, 24 A-hr. The numbers indicate current densities in mA/cm².

between intermediate current levels there is relatively little effect, but that when switching to a high load near the end of discharge there can be a major effect.

Anode thickness and life.—In these cells, it was desired to employ an anode 9.2 cm wide and 21.3 cm high, which would fit into a 0.5-cm gap between two air electrodes. It was necessary to select the thickness of the anode such that it would deliver the proper life but not allow the formation of so much product sludge that the anode could not be removed from the cell at the end of discharge. On the basis of the sludge volume measurements and life tests on thinner electrodes, a thickness of 35 mils was selected. Figures 7 and 8 give polarization curves for these large AZ61 electrodes, spaced ⅛ in. from a cathode, in various sodium and lithium chloride solutions. These data show that the voltage is highest in 18% lithium chloride, primarily as a result of the lower resistance of the electrolyte. In 7% lithium chloride the voltage at higher current densities is higher than for 7% sodium chloride, while in 18% lithium chloride the voltage drops appreciably. This probably results from the relatively low solubility

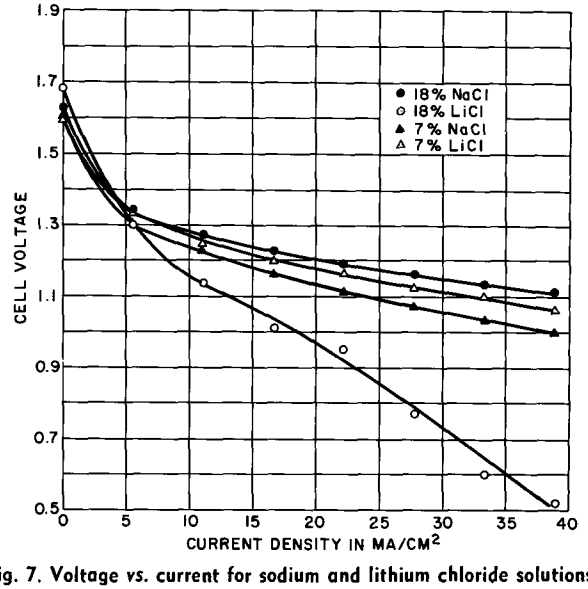

Fig. 7. Voltage vs. current for sodium and lithium chloride solutions

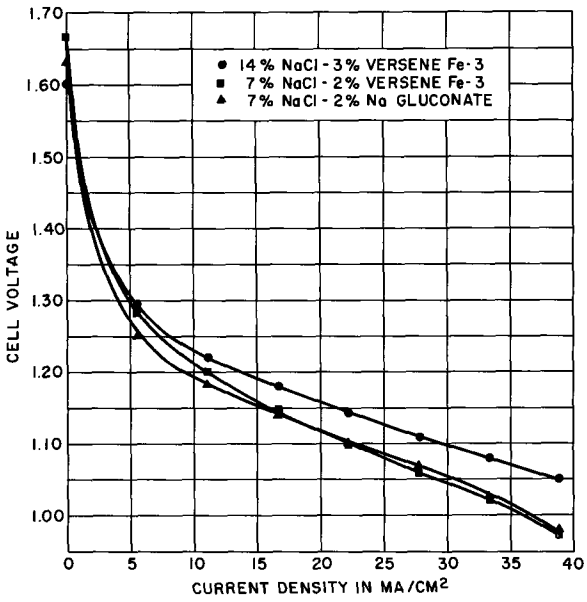

Fig. 8. Voltage vs. current using additives

of lithium hydroxide, which may precipitate on the air electrode. Figure 8 gives the results in solutions of sodium chloride containing Versene Fe-3 and sodium gluconate, each of which might be expected to chelate the magnesium to some extent. Each of these resulted in a slight decrease in voltage. In these tests the data for each of the curves were obtained from the averages of five different tests.

A series of 35-mil thick AZ61 anodes were packaged with Vexar and glycerinated cellulose and were operated in double-faced cathode compartments at a current of 2A (5.6 mA/cm²). The maximum number of ampere-hours obtained was slightly over 30, at which point the magnesium was completely consumed and the cell was solidly packed with sludge. In order to allow for removal of the depleted anode package, it was necessary to stop at about 24 A-hr of operation. At this point the anode package could be removed with less difficulty. During operation it was necessary to add about 45 cc of electrolyte over the 12-hr period to keep the voltage above 1V. When water, rather than a sodium chloride solution, was added to the cell during operation, the output voltage (on a resistive load) was decreased rather than increased. The same effect was observed when drying. There appears to be an osmotic effect relating to the fact that hydroxyl ion is produced inside the cathode during operation and, when the cell is rinsed with water rather than electrolyte, some of this water is imbibed by the electrode and causes it to be partially flooded. If the electrode is dried after rinsing, the performance on a second charge is restored to near the initial level.

Battery operation.—Figure 4 is a photograph of a 23-cell magnesium-air battery employing these anodes. It was designed for a ½A, 28V load for 9 min, and a 12A, 22V load for the following 1 min. This cycle would repeat itself continuously for 12 hr, at which time the anode would be replaced. After the initial electrolyte charge, the voltage on the first few cycles is usually low during the high current drain period until the electrolyte temperature increases. After the temperature reaches 120°F, the voltage during the high current period reaches 22V in about 3 sec using 18% sodium chloride. It was found that the duration of this transient was shorter with 18% rather than 7% sodium chloride. In the latter, the duration of this transient could be as long as 1 min near the end of discharge.

During operation a portion of the water evaporates and is carried out of the cell by the air circulating through it. As was mentioned above, this necessitates the addition of a total of about 45 cc of electrolyte to

each cell during the 12-hr operating period. The amount of water necessary varies with the operating temperature, since at higher ambient temperature more water will be lost by evaporation. If water is not added, the magnesium is not consumed uniformly and the cell voltage falls because of the greater demand on the bottom portion of the magnesium. Starting at an ambient temperature of about 80°F, it was sufficient to add about 15 cc of water to each cell at 3-hr intervals.

Determination of the Water Vapor Permeability and Continuity of Ultrathin Parylene Membranes

M. A. Spivack and G. Ferrante

Union Carbide Corporation, Bound Brook, New Jersey

ABSTRACT

A method has been developed to determine the water vapor permeability of very thin dielectric films over a large range of thicknesses. It is shown that the permeability of poly(chloro-*p*-xylylene) unsupported thin films is the same throughout the range of thicknesses tested: 292-73,388Å. The results agree with values reported on 2 x 10^{-3} cm thick samples under similar test conditions and with 8 x 10^{-3} cm thick samples obtained by standard flow methods. The results also compare favorably with the water vapor permeability of other polymeric materials. Since the permeability obtained [2.0 x 10^{-9} cm^3 (STP)-cm/sec-cm^2-cm Hg] indicates that thick (8 x 10^{-3} cm) films are structurally continuous, then ultrathin (<300Å) films of poly(chloro-*p*-xylylene) must also be free of voids. In addition, the method is sensitive enough to detect discontinuities as small as 1μ in diameter.

An important function of an encapsulating coating in electronic assemblies is to provide a moisture and gas barrier which prevents corrosion of construction materials or alteration of device parameters. At the same time it also should afford electrical insulation. All materials absorb and are permeable to moisture and gases to some extent and cannot be considered truly hermetic; however, the rates at which these processes occur may be low enough so that ideality can be approached. It is generally agreed that the major volatile contaminant is water vapor (1, 2).

This paper describes a method of determining the permeability of a dielectric film, poly(chloro-*p*-xylylene) (parylene C), to water vapor over a wide range of film thicknesses. The method involves producing free-standing membranes of the material and determining the water vapor transmission (WVT) rate at the particular film thickness. Since parylene C is nonwetting, the permeability should be the product of the WVT rate and the membrane thickness (3). Previous work with hydrophobic polymer films as thick as 70 x 10^{-3} cm (4) and as thin as 4 x 10^{-3} cm (5) has validated this assumption. No reference was found where films of less than 4 x 10^{-3} cm in thickness were used.

Deviations from this predicted behavior indicate discontinuities in the film's structure (6); therefore, by comparing the calculated permeability over a range of film thicknesses, this technique can also be used to determine whether the film contains pinholes at any particular thickness level.

Experimental

Permeability cell.—The method for determining the WVT rate had to be sensitive enough to allow accurate measurements and yet had to be nondestructive to the sensitive membranes. The simplest, most reliable, and most reproducible method was thought to be a weighed cell technique (7) with water contained inside the membrane sealed cell.

This reversed Payne Cup (water inside, desiccant outside) was modified by attaching a manometric sidearm to the cell which was completely sealed with mercury, except for a capillary bleed tube threaded through the mercury seal. The purpose of the sidearm was to provide a means of equalizing the *total* pressure across the membrane without appreciably affecting the WVT rate. (If a few millimeters of pressure differential is allowed to exist, the thinner membranes buckle to an appreciable extent.)

One can then determine permeability (P) from

$$P = \frac{q\tau}{At\,(VP_1 - VP_2)} = Q_f\tau \qquad [1]$$

where q is the quantity of gas diffusing through a film of surface area A and thickness τ, in time t with a difference $(VP_1 - VP_2)$ between the partial pressures of the diffusing gas on the two sides of the membranes (8). The usual units associated with this type of measurement are cm^3 (STP)-cm/sec-cm^2-cm Hg.

The procedure used to prepare the cell is as follows. The membrane is prepared and attached to the cell with a silicone adhesive *after* water has been inserted but *before* the sidearm is sealed with mercury. The ensemble is then allowed to come to thermal equilibrium (usually overnight, which also allows the adhesive to set). The bleed tube is inserted into the sidearm and the cell is then completely sealed (except for the bleed) with mercury. The sealed cell is placed into a desiccator which in turn is in a temperature-controlled room (23.0° ± 0.5°C). At periodic intervals

Key words: encapsulation, membrane, parylene, passivation, permeability, pinholes, polymers, thin films, water vapor.

(from 1 to 10 days), the entire cell is weighed on a balance (accurate to 0.1 mg) to measure the loss of water.

To determine the total driving force across the cell, two relative humidity monitors were used. The first was inserted into the desiccator with the various permeation cells. The second, an electrohydrometer, was used to check the relative humidity *inside* the permeation cell by sealing the hygrometer probe within the cell. The relative humidity was always found to be 100% inside and 0% outside the cell. Therefore, the pressure difference of Eq. [1] was always ~21 mm Hg.

From 6 to 12 individual cells were checked for WVT rate per membrane thickness. Usually, five weighings were taken per population sample, ranging from 1- to 10-day intervals after the start of testing to insure that a steady state has been achieved.

Membrane preparation.—The dielectric film used in these studies was poly(chloro-*para*-xylylene) or parylene C. The unsupported membranes were prepared by a vacuum process as described by Gorham (9). By this method films were deposited onto glass substrates which had been previously treated with a parting agent, such as a vacuum-evaporated alkali halide. (The results obtained were found to be independent of the parting agent used.) Following deposition of the polymer, the parting agent was activated by dissolving in water and the membrane was lifted from the substrate *via* an annular mount.

Membrane thickness.—The methods used to measure the membrane thickness were interferometry and optical absorbance. Interference fringes were used in the bulk of this work (10, 11); however, below about 800Å thickness, no fringes are discernible and, therefore, optical absorbance methods were used.

Discussion and Results

True film permeability.—The value of interest is the WVT through the film only, independent of other parallel and series diffusion pathways. In the permeability cell previously described, the escape of vapor from the cell is controlled not only by the resistance of the membrane but also by the air spaces within the cell and the surrounding desiccator. In addition, there are parallel escape routes such as through the capillary bleed tube and possible leakage through the seal used to attach the membrane to the cell.

To determine the WVT due solely to the thin membrane (Q_f, see Eq. 1), an equivalent electrical conductance analog may be made which yields

$$Q_f = \frac{Q_o\,(Q_{obs} - Q_x)}{Q_o + Q_x - Q_{obs}} \qquad [2]$$

Q_f is the conductance through the film and is the quantity of interest. Q_o is the series conductances controlled by the geometry of the system and can be measured by observing the WVT rate using a "zero" thickness film (open cell). Q_x is the conductance through all parallel diffusion routes, measurable by using a film of infinite thickness (10-mil aluminum foil). With a membrane on the cell, the quantity actually measured is Q_{obs} (observed).

Thickness variation effects.—WVT rates were measured on sample populations ranging from 292 to 78,388Å in thickness. In all cases it was observed that steady state was reached in less than a day (the shortest measuring time used) and that the rate of loss of water vapor remained constant throughout the length of the test (up to 3 weeks).

Table I shows the results obtained for each membrane thickness, including the open (zero thickness) and closed cell (infinite thickness) "end points." Also shown in Table I is the true WVT rate through the films (Q_f) as calculated from Eq. [2] and the permeability (P) as determined from Eq. [1]. The errors indicated on both Q_f and P are standard deviations.

Table I. Permeability constant for various thicknesses of parylene C films

Film thickness (Angstroms)	Observed flux, Q_{obs} (grams/day)	Film flux, Q_f (grams/day	Permeability constant, $P \times 10^9$ [cm³ (STP)-cm/sec-cm²-cm Hg]

Table II. Water vapor permeability constants of various polymers

Polymer	Permeability constant, P* cc(STP)-cm / sec-cm²-cm Hg	Reference
Cellulose acetate	1.2-3.1 × 10^{-6}	(8, 14)
Polystyrene	1.2 × 10^{-7}	(8)
Silicones	2.4-4.3 × 10^{-8}	(1)
Polyurethanes	1.3-4.7 × 10^{-8}	(1)
Polyethylene (low density)	1.1-1.8 × 10^{-8}	(8, 14, 16)
Epoxies	1.0-1.3 × 10^{-8}	(1)
Poly(ethylene terephthalate)-(Mylar)	1.0 × 10^{-5}	(1)
Polypropylene	3.8-4.0 × 10^{-9}	(1, 8)
Poly(tetrafluoroethylene)-(Teflon)	3.5 × 10^{-9}	(16)
Poly(vinylidene chloride)-(Saran)	3.1 × 10^{-9}	(17)
Poly(chloro-*p*-xylylene)-(parylene C)	2.0 × 10^{-9}	This work
Polyethylene (high density)	1.6-1.8 × 10^{-9}	(8, 16)

* At 23°C on 3-8 × 10^{-3} cm thick films.

It is seen (Table I) that the permeability, within error limits, is the same for the 292Å film as it is for the 78,388Å film. The average value from all the thicknesses is 2.03 ± 0.17 x 10^{-9} cm³ (STP)-cm/sec-cm²-cm Hg. This value agrees exactly with the results obtained by Lee (12) on 2 x 10^{-3} cm thick samples in similar ambients. This value also agrees with results obtained from 5-8 x 10^{-3} cm thick samples measured by a flow technique (ASTM-E96-63T) at a temperature of 38°C if an activation energy of 17 kcal/mole is assumed for the diffusion process.[1]

The greatest error in permeability (P) is seen to occur at the extremities of thickness. For the very thin films, the thickness uncertainty and Q_o values contribute to the large error; the end point substantially contributes in the case of the thicker films. Even with the larger uncertainties at the two thickness extremes, the permeability at each thickness deviates from the over-all average by only ± 8.5%.

Comparison with other polymers.—The water vapor permeabilities of various polymers are shown in Table II. All the values indicated were either measured at, or corrected to, 23°C and were measured on films 5-8 x 10^{-3} cm thick. Cellulose acetate is given as an example of a water-permeable polymer having a permeability constant of about 10^{-6} (units as previously defined). Polystyrene, which is a good insulator, is shown to be a poor water barrier. The common encapsulating material (silicones, urethanes, epoxies) have permeabilities in the low 10^{-8} range while poly(vinylidene chloride) exhibits a constant of about 3.1 x 10^{-9}. The water vapor permeability of parylene C is shown to be low and about the same as for very high density polyethylene.

Induced faults.—To test the sensitivity of these measurements in detecting film discontinuities, a hole of a particular size was mechanically induced into a given thickness population sample. Different sizes were in-

[1] A value of 19.2 kcal/mole is reported for poly(ethylene), 16.4 kcal/mole for poly(propylene), and 15 kcal/mole for poly(vinyl acetate) (13).

duced into different populations. The smallest hole was about 33μ in diameter (8.8 x 10^{-4} mm^2); the actual areas were measured by a planimeter on photomicrographs.

In all cases, the films with holes showed a marked increase in permeability over structurally continuous control samples.

The rate of water vapor loss through a unit area of induced hole was then compared to the size of the hole. Extrapolation of this data has shown that a discontinuity of about 1μ in diameter should be detectable within the error limits of the method.

Summary and Conclusions

A modified Payne Cup has been used to measure the water vapor permeability and continuity of thin parylene C films over relatively large surface areas. Free-standing films less than 300Å in thickness and more than 10 cm^2 in area can be tested by this method.

It was found that the permeability of parylene C unsupported thin films is the same throughout the range of thicknesses tested, 0.03-7.34 μm. The value of permeability obtained by this static method, 2.0 x 10^{-9} cm^3 (STP)-cm/sec-cm^2-cm Hg, agrees with other investigations using 2 x 10^{-3} cm thick films and with the value measured by standard flow methods on 8 x 10^{-3} cm thick films if an activation energy of 17 kcal/mole is assumed for the diffusion process.

In comparison to other polymeric materials, thick films of poly(chloro-*p*-xylylene) are shown to have a water vapor transmission rate about equivalent to very high density polyethylene and are somewhat superior to commonly accepted good water barrier films such as poly(vinylidene chloride), poly(ethylene terephthalate), and poly(tetrafluoroethylene).

Based on the hypothesis that these thick films (2-8 x 10^{-3} cm) are structurally continuous, then ultrathin ($<$ 300Å) films of parylene C must also be free of voids. Furthermore, extrapolation of data obtained from mechanically induced holes shows that voids of about 1μ in diameter should be detectable by this technique.

The combination of low water vapor permeability, structural continuity, and the vapor deposition nature of its application indicates that poly(chloro-*p*-xylylene) should be suitable for the protective dielectric in semiconductor devices or as an encapsulant for larger circuit board modules.

Manuscript submitted July 19, 1968; revised manuscript received July 24, 1969. This was Paper 473 presented at the Montreal Meeting, Oct. 6-11, 1968.

Development of an Electrochemical Acid Generator

Lloyd H. Shaffer[*,1] **and R. A. Knight**[*]

American Machine & Foundry Company, Stamford, Connecticut

ABSTRACT

Acidification of the feed streams to desalination plants is often desirable. To provide for this, an electrochemical system has been developed, combining both fuel cell and electrodialysis technology. The heart of the system is a cell which produces dilute streams of acid and base, and the whole apparatus is referred to as an "acid generator." The acid generator is a self-contained system, and requires only electricity and the desalination plant feed stream as inputs. As developed, it produces an acidified sea water stream (product), a partly desalted stream, and an alkaline stream. The anode hydrogen supply for the catalytic membrane electrode is evolved at the cathode. The acid produced is used in the prevention of scale in water processing equipment such as evaporators. Acidification of the saline feed stream releases carbon dioxide. The carbon dioxide released is used along with the alkaline cathode effluent to prepare a softened sea water for an intermediate or "buffer" stream. A small amount of product water (1%) from the evaporator is used to maintain the cathode NaOH concentration at approximately 0.1-0.3*N*. The power requirements for the cell are quite modest, about 0.5 kwhr/1000 gal for the acidification of sea water to a level of 100 ppm, and the device is readily adapted to automatic operation.

Acidification of the feed streams to desalination plants is often desirable. The reasons for this in the case of a plant designed to distill sea water are illustrated by the equations below.

$$Ca^{++} + 2HCO_3^- = CaCO_3\downarrow + CO_2\uparrow + H_2O \quad [1]$$

$$HCO_3^- = CO_2\uparrow + OH^- \quad [2]$$

$$Mg^{++} + 2OH^- = Mg(OH)_2\downarrow \quad [3]$$

Normal sea water (19 parts per thousand Cl^-) contains small but significant quantities of calcium, magnesium, and carbonate (Table I). When sea water is heated, CO_2 is driven off, and as a result the water becomes more alkaline. As bicarbonate ion decreases the carbonate ion concentration increases, and $CaCO_3$ and $Mg(OH)_2$ coprecipitate on the intake or first-stage heat transfer surfaces. The problem can be avoided through a replacement of HCO_3^- by mineral acid. The quantity of mineral acid needed is small, 0.0835 parts per thousand as HCl or 0.1112 parts per thousand as H_2SO_4. However, either because of a remote location or the particular size of a given operation, mineral acid may not always be conveniently or economically available. For example, a 1.25 million gal/day (GPD) plant, built in the early 1960's, required roughly a tank car of sulfuric acid per month for scale control. Delivery of this quantity of acid to a test site near San Diego was easily arranged but, when the plant was reassembled on an island in the Caribbean, acid pretreatment was abandoned. This necessitated a lower operating temperature and, as a result, the capacity of the plant was downgraded to 750,000 GPD (1). To provide for the replacement of HCO_3^- by mineral acid, an "acid generator" has been developed (2, 3).

The acid generator (Fig. 1) requires as inputs: electricity, about 0.5 kwhr/1000 gal, and the desalination plant feed stream. The device combines both fuel cell technology and electrodialysis techniques. The various interior compartments in the acid generator are separated by ion exchange membranes, and the cathode hydrogen is consumed on a catalytically active anode. This union of the two technologies is responsible for the rather modest amount of electrical energy, 0.05 kwhr, needed to produce an equivalent of acid and base. A summary of estimated power requirements and operating costs based on present technology is given in Table II.

Table I. Scale-forming constituents in sea water

Sea water: Cl^- = 19 g/kg, ρ_{20} = 1.0243	
Ca^{++}	0.4001 g/kg = 0.0100 m/liter
Mg^{++}	1.2720 g/kg = 0.0523 m/liter
HCO_3^-	0.1397 g/kg = 0.00229 m/liter (100.7 ppm as CO_2)
$SO_4^=$	2.649 g/kg = 0.02755 m/liter

NOTE: Oceanographer's Normal S.W., Cl^- = 19.381 g/kg (Sverdrup, Johnson & Fleming); Millstone Pt. S.W., Cl^- ~ 16.5-17.0 g/kg, CO_2 ~ 80 ppm.

Table II. Power requirements and costs

Acid
85 ppm (as HCl)
1000 gal = 1.0243 × 8.345 × 10^3 = 8550 lb
85 × 10^{-6} × 8550 = 0.726 lb HCl
= 9.03 g-equiv./1000 gal

Current
9.03 equiv./1000 gal = 10.08 A-day/1000 gal

Power
volt/cell @ 20 asf ≃ 3.0
10.08 A-day × 3.0V × 24 hr/day = 0.725 kwhr/1000 gal
Requirement, allowing for losses and auxiliaries:
0.5-1.0 kwhr/1000 gal

Estimated cost
0.5 ¢/1000 gal

During operation of the acid generator, hydrogen is oxidized on the catalytic anode and hydrogen ions are introduced into the anode stream through the ion exchange membrane portion of the catalytic membrane electrode (Fig. 2). The anode compartment is separated from the buffer (saline) stream by an anion permeable membrane. Negative ions migrate through it to maintain electrical neutrality in the anode compartment. The buffer compartment serves two purposes: it helps isolate the anode and cathode systems; it acts as the source for the ions that must be supplied to the electrode compartments to make up for the charge introduced by the electrode reactions. When the acid generator is used in conjunction with sea water processing plants, a saline stream suitable for use in the buffer compartment is obtained by treating a portion of the main feed with alkali from the cathode compartment. The cathode compartment is separated from the buffer stream by a cation exchange membrane. The cathode alkalinity is controlled by feeding a small amount, about 1%, of the product fresh water to the cathode stream. The cathode hydrogen is circulated to the anode. To make up for the inevitable small losses, an auxiliary anode was added so that excess hydrogen could be generated at the cathode. Provisions were made for operating the auxiliary anode in two modes: low, 1% of main anode current, for normal operation; and high, 10-20 times normal, for start-up.

A variety of systems were tried during the development of a functional automatic acid generator. The problems encountered have been: electrode design and materials of construction, separation of hydrogen from the cathode stream, method of circulating hydrogen through a series of cells, and methods to soften sea water for use in the buffer stream. After investigating these problems on a small scale in 450-6000 GPD units, a 30,000 GPD unit was designed and constructed to be compatible with a Maxim[2] high-pressure tube bundle evaporator. The 450 GPD unit was rectangular in design, with a 3- x 14-in. working area. The 6000 and the 30,000 GPD units were constructed from rings of PVC 9.5 in. and 11.4 in. ID, respectively.

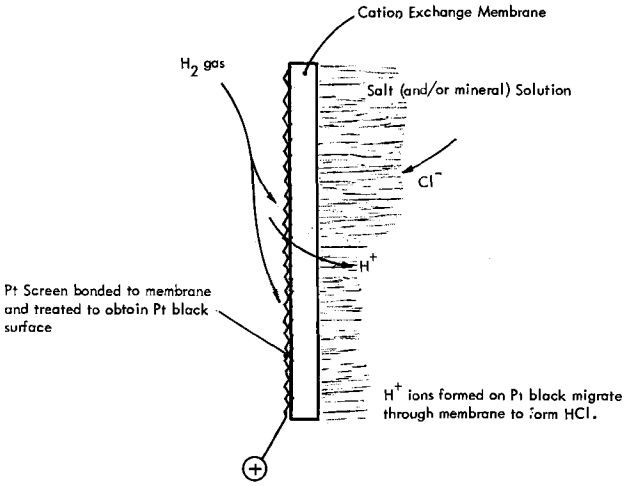

Fig. 2. Catalytic membrane electrode

Experimental

Catalytic membrane electrode.—The catalytic membrane electrode (CME) illustrated in Fig. 2 was prepared by bonding a platinized platinum/10% rhodium, 80 x 80 mesh screen to a cation permeable membrane which had been precoated with a slurry of platinum black powder (1.4 mg/cm²). The cation permeable membrane used here was a thermoplastic material prepared by first grafting styrene to a polyethylene base and then sulfonating the styrene. The chemical principles involved have been given by Chen and Mesrobian (4). A review of the principal electrochemical characteristics of leading commercial membranes is found in "Principles of Desalination" (5). The electrode was activated by cathodic reduction in 10% H_2SO_4, replatinization in 3% chloroplatinic acid, and a final cathodic reduction in 10% H_2SO_4. Electrodes prepared in this manner are capable of operating at 25-30 mA/cm² (3 x 10^{-7} equiv./sec/cm²) without excessive overvoltage or oxidation of chloride. Typical polarization curves are given in Fig. 3. In the short term, the curves are linear and reversible up to 40 mA/cm². However, at any current above ~25 mA/cm², a gradual and irreversible increase in voltage is noticeable after a few hours. The somewhat poorer polarization obtained on the large electrodes is thought to be due to the difficulties in obtaining a uniform platinum black deposit. Higher current densities are possible at higher platinum loadings. CME's were also constructed using as the current collector platinized titanium in the form of woven screen and expanded mesh. Tantalum in both forms was also used. A titanium electrode proved to be satisfactory, and was successfully tested in excess of 500 hr without degradation of performance. The tantalum was easier to handle and to bond than the titanium and, further, it appeared to give slightly better electrode performance. These electrodes were used only in the 450 GPD unit. The reason for this was that at the time of construction the only suitable electrode material available in large sizes was the platinum/10% rhodium mesh.

The elements of the catalytic membrane electrodes: the cation permeable membrane, the platinum black, and the platinized screen current collector, were bonded with a laboratory press. The conditions for bonding were 350°F at 800 psi. Electrodes for the three units mentioned above were prepared using these conditions. After the original construction was completed, it was found that lower temperatures could be used if the membrane was first equilibrated in formamide instead of distilled water. It is obvious that at the high-temperature condition the membrane loses its gel water, causing shrinkage and possible separation of the bond between current collector and membrane. The formamide has about the same dielectric constant as water and has a boiling point compatible to the bonding temperature. The net result of equilibrating the membrane in formamide is that the membrane is dimensionally stable during the heating cycle. Best re-

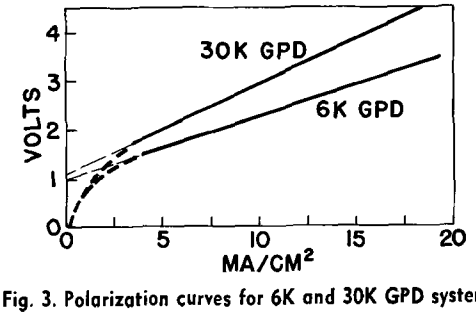

Fig. 3. Polarization curves for 6K and 30K GPD systems

sults were obtained when the bonding was done by placing the membrane electrode assembly between Pyrex plate glass platens.

Auxiliary hydrogen circuit.—To operate the acid generator, it is necessary to supply hydrogen in excess of the anode demands. This replaces hydrogen lost because of the solubility of the gas in the cathode effluent and also compensates for losses due to leakage. Provision was made for the hydrogen evolution at the cathode to exceed the rate of consumption in the main cell by adding an auxiliary anode to the system. The auxiliary anode was separated from the main cathode by a porous polyethylene plastic battery separator material. This is necessary to prevent the oxygen generated at the anode from mixing with the hydrogen generated in the adjacent cathode. The oxygen generated at the auxiliary anode was discarded. The excess hydrogen was controlled by adjustment of the current circulating in the auxiliary circuit. Hydrogen was recovered from the cathode effluent by passing the foaming liquor into a closed stilling chamber. The excess hydrogen generated was controlled so that a minimum amount of power was used to make up losses due to leakage and the solubility of hydrogen in the cathode effluent. Solubility losses depend on catholyte compartment normality (reciprocal of liters of cathode fresh water per Faraday) and they can in principle be quite small. The solubility of hydrogen in water is 1.54 ppm at 25°C and 760 mm; and, if the catholyte were maintained at 0.1*N*, the loss due to solubility would be 0.77%.

Buffer stream system.—In order for the acid generator to function, the anode must be separated from the cathode. This was accomplished by placing a cation permeable membrane in front of the cathode and an anion permeable membrane in front of the anode (CME)—*see* Fig. 1. The central compartment or "buffer" is required only to conduct electricity and to supply appropriate ions to the anode and cathode compartments. To avoid the complications that might have arisen due to the use of sea water, for example the precipitation of magnesium and calcium compounds, much of the early testing of the 450 GPD generator was performed using 0.5-1.0*N* NaCl. However as soon as the original system had been debugged, a precipitation system to soften the sea water was designed. This system used the sodium hydroxide produced at the cathode as follows: sea water and the sodium hydroxide were mixed in a heated precipitation tank at about 115°F and, simultaneously, the solution was saturated with carbon dioxide (available from the acidified sea water stream). This treatment resulted in the rapid and near total precipitation of both magnesium and calcium as magnesium hydroxide and calcium carbonate, respectively. The resulting solution (including precipitate) was allowed to overflow into a holding tank where it was permitted to cool to 90°F before passing through the buffer compartment. The system is shown schematically in Fig. 4. It was found after a short time that hydroxyl ion in the buffer stream (conc. $\sim 10^{-3}$ m/liter) was migrating into and through the anion membrane and causing the precipitation of alkaline earth metals carried by the untreated anode stream. This difficulty was circumvented by raising the product hydrochloric acid concentration from 0.003*N* (100 ppm) to 0.1-0.15*N*. This was accomplished by recirculating a part of the product stream in a feed and bleed arrangement. The high acidity introduces a current efficiency loss which depends on the selectivity of the anion membrane. The matter is discussed more fully in the Results and Discussion section. The complete system, shown in Fig. 4, was tested for 460 hr on sea water without signs of membrane fouling.

450 GPD cell.—Much of the initial testing of the acid generator was done on a unit sized for 450 GPD. The cells in this unit had tapered ends to facilitate fluid distribution and the working portions were 3- x 14-in. rectangles. The individual compartments had a thickness of ½ in. Figure 5 is a perspective view of the 450 GPD unit; it shows both the electrochemical cell and its relationship to the auxiliary liquid/gas system. Operating data, obtained both in preliminary tests on the cell and during extended tests on the entire system, are given in Table III.

6000 GPD cell.—In addition to the 450 GPD cell, two very much larger units were built and tested. Rectangular cells would also have been preferred for these; but, due to limitations of materials available for construction, sections of plastic pipe were selected for the larger unit. The first multiple unit consisted of six cells, featuring common hydrogen and cathode compartments as shown in Fig. 6. The initial compartment components were thick rings of polyethylene pipe. This was not satisfactory: the pipe sections had a tendency to cut the membranes and catalytic membrane electrodes at the inner circumference of the sealing edge, and the forces necessary to hold the unit together caused distortion of the cross sections of the polyethylene rings. It seemed desirable to avoid having the CME flex over a sharp edge and further to make sure that sealing would take place at a low total applied force. A gasket having the following features (Fig. 7) was evolved: (*a*) a filled (hard) PVC spacer ring, (*b*) beveled inner edges, (*c*) O-ring sealing surfaces.

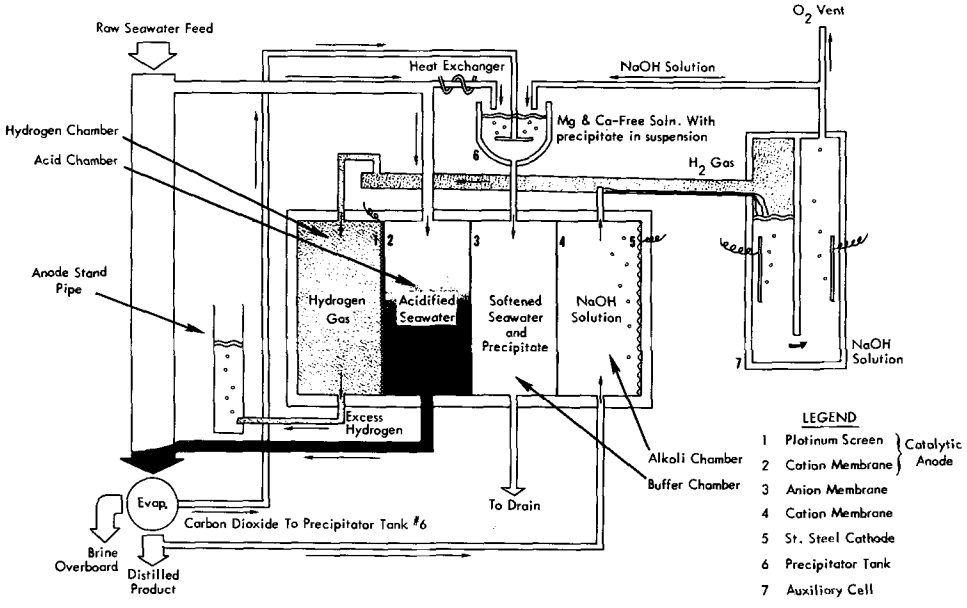

Fig. 4. Acid generator flow scheme.

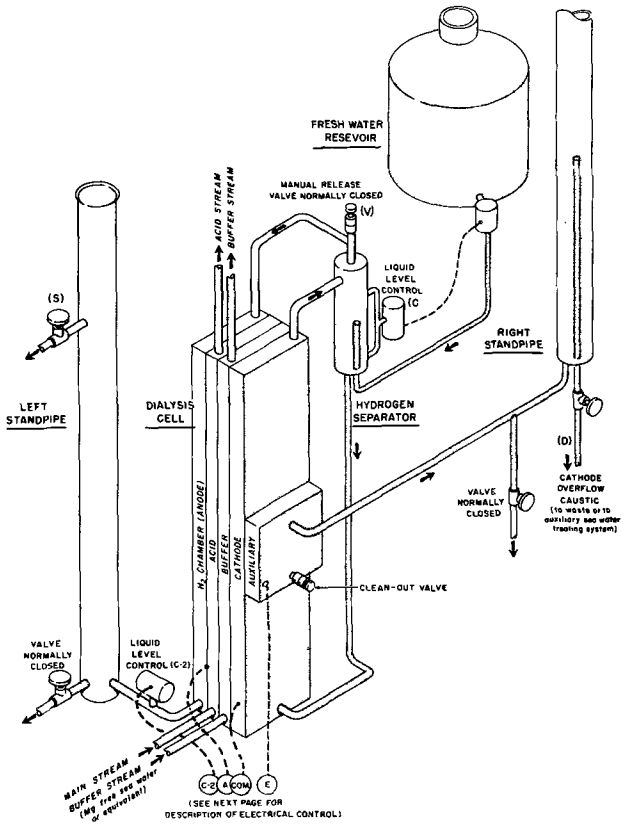

Fig. 5. Single-cell acid generator hydraulic system (450 GPD)

Experimentation with the new ring design showed that a pressure of 100-150 psi was sufficient to seal the electrodes and membranes. A six-cell multiple unit (Fig. 6) was constructed using these PVC-O-ring spacers. Calibrated deflection load springs were used to seal the cell to the desired pressure. No electrical, hydraulic, or mechanical difficulties were experienced during a total of 530 hr of testing. Relevant electrochemical data are summarized in Table III.

30,000 GPD cell.—A still larger unit, 30,000 GPD capacity, was built using the principles developed in the construction of the two small acid generators. The larger unit used ½-in. PVC spacers rather than ¾ in. as in the 6000 GPD device and it was a larger diameter, 11.4 in. instead of 9.5 in. The large unit contained 22 cells arranged as 11 pairs in series. The complete unit was tested over an extended period of time during a Navy-sponsored test of an acid-fed system. There were some minor electrical and mechanical difficulties which appeared to be due to the large round cell section; however, these did not cause any system shutdowns during the 2200-hr test period. Typical electrochemical operating data are also given in Table III.

Results and Discussion

Typical operating data for the cells described above are given in Table III. To facilitate comparison between the various units, all data have been reduced to terms based on one cell and/or the operating unit area as appropriate. The minimum power, tabulated in column 6, represents the main cell kwhr required to treat 1000 gal of feed water (9.03 equiv. of HCl at current and voltage conditions stated). The estimated total power includes an allowance for the pumps and auxiliaries actually used.

Preliminary tests on the 450 GPD acid generator cell were made with all compartments filled with 1.0*N* NaCl (Table III—line 1). Later, to simulate operation on sea water, the anode and buffer compartments were filled with 0.5*N* NaCl (Table III—line 2), and a more dilute saline fluid, 0.171*N*, was used in the cathode compartment to simulate 0.1*N* NaOH. After the com-

pletion of these tests of cell performance, a semi-automated system such as is shown in Fig. 5 was set up and operated at AMF's Millstone Point Test Station, using sea water feed to the anode compartment.

The early sea water tests were designed to be essentially equivalent to the saline water test, line 2, Table III, and an indication of the approximate operating conditions has been entered for comparison (line 3). The data available on these tests do not permit a meaningful calculation of current efficiency; however, given the physical and chemical conditions prevailing in the test cell, it is certain that it was near 100%. The somewhat lower efficiency figures recorded for the larger-scale runs are related to the high product acidity and to the fact that the anion membrane is less than 100% selective. During the first 750 hr of actual sea water operation, the buffer stream circulated from a reservoir whose salinity was maintained at 0.47*N* by daily additions of 0.6 lb of NaCl. However, during a subsequent 1000 hr, a variety of cycles for using the cathode alkali to prepare a softened sea water for buffer feed were investigated. The net result has already been described (Fig. 4). It was impossible to achieve steady long-term operation unless the buffer Ca and Mg were held to extremely low levels, 1 and 4 ppm, respectively. And at the high *p*H, ~11.5, necessary to maintain these low concentrations, ~2% of the negative ion current between buffer and product will be carried by OH^- rather than Cl^-. Hydroxyl ion migration must be prevented. In exploratory tests, long before these was any indication of electrical difficulties, visual observations showed precipitate formation in and on the anion exchange membrane. This is due primarily to the reaction between OH^- transported and Mg^{++} in the unsoftened anode stream. A 50-100 fold increase in the product acidity avoids the problem but introduces a modest electrical inefficiency. Based on published data (6), it was calculated that, in the highly acid saline product (approx. the equivalent of 0.15*N* HCl and 0.47*N* NaCl), up to 2/3 of the positive ion current will be carried by H^+; and, if the anion membrane selectivity is 82%, the apparent current efficiency of the acid generating cell will be, at best, 88%. Efficiency results for the tests conducted on the two larger devices are in agreement with this expectation.

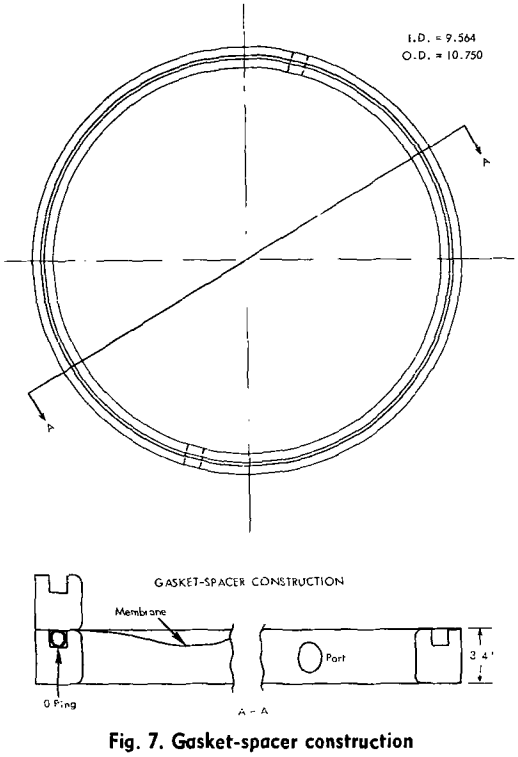

Fig. 7. Gasket-spacer construction

The almost total removal of Mg and Ca that is required introduces, in addition, another kind of electrical penalty. Mg and Ca between them account for 21% of the positive charge in sea water. Whenever current sufficient to generate the equivalent amount of alkali is passed through the cell, 21% of the original positive and negative ions will be removed from the circulating buffer stream because the buffer is set up as a desalting compartment. It had been expected that the feed and bleed buffer loop, if carefully adjusted, could be made to deliver to the cell a softened stream that was about 80% of sea water strength. In practice, there was a 70% loss in buffer salinity and a corresponding increase in power consumption. The buffer compartment ordinarily accounted for about 1/3 the total cell resistance and the large reduction in salinity therefore was equivalent to an increase of 67% in power consumption. This fact, perhaps more than any other, was responsible for the increase in minimum required power in going from the smaller to the two larger systems tested. Clearly, the buffer stream system or an alternative to it should receive a great deal of attention in any future acid generator designs.

The operating data reported for the 6000 GPD unit were derived from a set of current efficiency measurements that were made near the beginning of a 500-hr run. The high estimated total power is the result of the use of oversize pumps in assembling the 6000 GPD

configuration. When the same pumps were used in an even larger unit, a slightly lower total power figure was obtained. The data recorded for the 30,000 GPD unit are representative of conditions at the end of over 2000 operating hours. The data fairly represent the running record with two exceptions. First, during 90% of the operating time the apparent stack resistance was 15% lower than at the end and, second, the current efficiency average over 2000 hr was 85.6 ± 2%. Allowing for these two factors brings the estimated minimum power to 1.00 kwhr/1000 gal in good agreement with the figure found in operations with the 6000 GPD unit.

Conclusions and Recommendations

A self-contained device for the acidification of desalination plant feed streams has been developed. The acid generator requires as inputs electricity and the desalination plant feed stream. Substantial units of 6000 and 30,000 GPD have operated at a total power level of 2.5 kwhr/1000 gal. There are indications that this could be cut in half. The large systems tested suffer from two correctable defects. First, the cells in future units should be long thin rectangles or lozenges to get better flow distribution and to avoid problems associated with buffer precipitate settling in the quiescent portions of the round cell sections used here. And, second, further work on the catholyte/buffer system is required. Flow rates, stream ratios, and the like must be readjusted to produce a high salinity buffer stream before any significant cell power reduction is possible. Further, if the pH of the buffer can be lowered by only 1 unit, additional improvements in power requirements can be realized.

Manuscript submitted Nov. 22, 1968; revised manuscript received Aug. 11, 1969. This was Paper 223 presented at the Boston Meeting, May 5-9, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

ABSTRACT

The paper describes results of preliminary experimental observations on a fluidized bed electrode. This consists of a bed of electrically conducting spherical particles fluidized by electrolyte flow. The present results are confined to the cathodic reduction of m-nitro benzene sulfonic acid to metanilic acid in aqueous sulfuric acid. The investigations have demonstrated that charge is dispersed throughout the bed such that an electrochemical reaction takes place at the particulate surface. Results show that the fluidized electrode is capable of scaling up electrode processes having low exchange currents to give high over-all currents in relatively small cell volumes.

The electrochemical industry, in terms of output, is a large and expanding one, due more to an increasing demand for its conventional products, however, rather than to their diversification. The field of organic chemicals manufacture for instance still lies almost wholly outside the industry and, to a large extent, this is due not so much to the unwillingness of manufacturers to break new ground as to the lack of commercial cells of sufficiently high capacity to make the majority of interesting organic reactions economically attractive.

The range of specific surface area of working electrode offered by industrial electrochemical cell design at the present time is between 1 and 30 ft^2/ft^3 of cell volume, and this has proved quite adequate for those reactions, such as chloride ion discharge, which take place at current densities of between 100-1000 A ft^{-2}. On this basis, the cells operate at 1000-3000 A ft^{-3}. Many organic electrode reactions of industrial significance, however, take place at current densities of only 1-10 A ft^{-2} and at this level the present generation of cells would operate with an intensity of only 3-10% of current practice. The higher investment necessary to offset the reduced performance of each cell is usually unrealistic. One solution of this difficulty lies in new cell designs of higher specific area.

Such problems are not confined to electrochemical engineering; they are met, and in many cases have been overcome, in every branch of chemical engineering. Many of the solutions which have been found have now become well-established techniques and their translation to the electrochemical case could well prove fruitful. In this context, the fluidized bed concept is particularly attractive in that it has been immensely successful in the closely analogous field of heterogeneous catalysis. The analogy, however, is only partial and is unable to anticipate the ability of a fluidized bed system to perform the function of an elec-

trode. The necessary experimental evidence for this was the first objective of the work described in the present paper and, once demonstrated, a series of experiments of a somewhat probing nature was carried out on a sufficiently broad basis to enable a tentative evaluation of the possibilities of fluidized bed electrodes to be made.

Observations have been made on the reduction of m-nitrobenzene-sulfonic acid to metanilic acid in a fluidized cathode of copper and copper-coated glass particles. Several parameters have been probed, including particle size, bed expansion, location of the current feeder, and bed geometry. The beds used were capable of supporting currents of up to about 5000 A ft^{-3} at an electrode potential corresponding to a current density of 5 A ft^{-2} at a plane electrode. This represents a reaction intensity equal to current industrial practice despite the much lower current density value.

Experimental

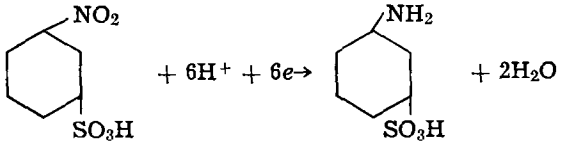
A series of experiments was designed to discern the broad pattern of behavior of the fluidized bed electrode with variation in the many physical and geometrical factors which might influence it. Of these, the following were thought to have priority of investigation: (i) bed dimension both parallel and perpendicular to the direction of current flow, (ii) particle size, (iii) bed voidage, (iv) electrode potential.

Although it is accepted that the nature of the electrode reaction and electrode surface will also determine the behavior of the bed, it was decided to limit the investigation initially to one system and extend the work to others in the light of the results obtained.

Choice and investigation of test reaction.—The cathodic reduction of m-nitrobenzene sulfonic acid was used throughout the experimental investigation because:

(a) it does not suffer markedly from side reactions;
(b) it has been extensively investigated and documented (1-5);
(c) it is associated with current densities (1-50 A ft^{-2}) appropriate to the context of the investigation;
(d) it occurs in aqueous solution and, with proper choice of electrode potentials, in the absence of gas evolution;
(e) it takes place on a variety of metal surfaces (4), and in particular in the case of copper is unaffected by the metal grade (1).

The reaction can be represented by



In order to compare the gain in performance of the fluidized bed electrode over conventional planar systems, an initial examination of the reaction was made to provide data on current density and current efficiency.

Polarization curves for the reaction were obtained with a spherical solid copper cathode, 1.2 in. diameter, arranged centrally in a vertically cylindrical Vyon diaphragm, of internal diameter 2.0 in., which was concentric with a cylindrical lead anode. Both catholyte and anolyte were of composition 0.125M m-nitrobenzene sulfonic acid and 1M sulfuric acid. Observations were made using a potentiostat, which, by adjusting the cell terminal voltage, maintained the copper sphere at any selected electrode potential. The value of the potential was measured with respect to a saturated calomel reference electrode connected to a Luggin capillary probe, the tip of which was located at the equator of the copper sphere. An examination of the contours of electrode potential over the rest of the sphere using a second Luggin probe and saturated calomel reference electrode revealed that deviations from the equatorial value were negligible. Results for both static and flowing electrolytes are shown in Fig. 1 which represent the average values obtained from a large number of experiments including some carried out subsequently on sheet copper electrodes. The polarization curves presented are of the same form as those reported by other workers (1).

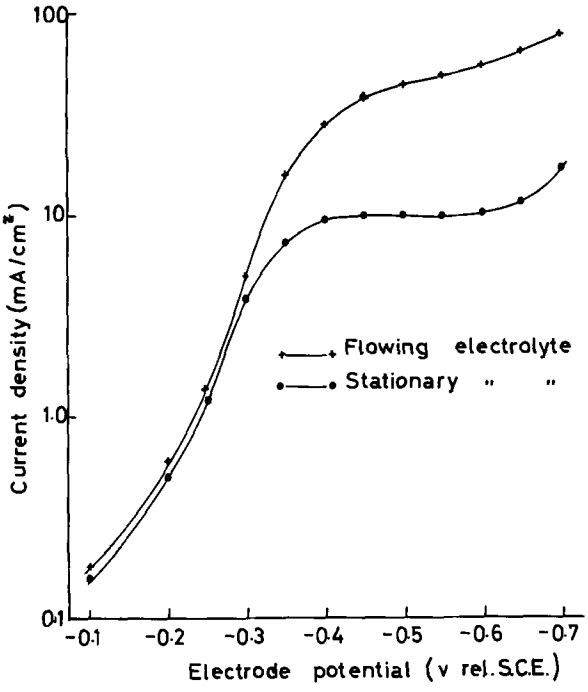


Fig. 1. Polarization data for the reduction of m-nitrobenzene sulfonic acid at a copper electrode.

The limiting current density in Fig. 1 may be identified with a region controlled by the rate of diffusion of m-nitrobenzene sulfonic acid to the electrode surface, since approximate calculation based on a diffusion layer thickness of 5 x 10^{-3} cm and a diffusivity of 0.7 x 10^{-5} cm^2 sec^{-1} gives a limiting current density of the same order of magnitude as that observed. Values presented by the Russian workers, however, are low by a factor of ten on this basis. In the present study, no explanation is offered for this discrepancy; in relation to later discussion, it is important only to remark that in this region currents are enhanced by efficient mass transfer.

The current efficiency of the reaction was also examined, the metanilic acid being determined by potentiometric titration with sodium nitrite in the presence of potassium bromide as an accelerator. The titrations were carried out directly on samples of catholyte at ambient temperature. Details of the procedure have been described by Khomutov and Filippova (2). The results are given in Table II and are in general agreement with Russian work.

At negative potentials exceeding 0.70V (SCE) the current efficiency falls off rapidly since the predominating reaction at higher potentials is increasingly that of hydrogen production. It should be pointed out that, although it is appreciated that higher current efficiencies are attainable at elevated temperatures, since the emphasis of the study was on the physical form of the electrode rather than on the chemistry of the reaction, it was felt more convenient to conduct the work at ambient temperatures.

Electrode materials.—A particulate copper cathode comprising either solid copper, copper-coated glass, or copper-coated polystyrene spheres was used throughout the investigation. Details of the particles are given in Table I.

The plated particles served two purposes. First, they allowed the particle size range to be extended beyond

Table I. Specifications of spherical particles used in the fluidized bed cathodes

Material	Size range, microns	Mean particle size, microns	Density, g cm^{-3}	Geometric surface area of material
Solid copper	75-90	82.5	8.9	81.2 cm^2 g^{-1}
	90-105	97.5	8.9	68.7 cm^2 g^{-1}
	125-150	137.5	8.9	48.6 cm^2 g^{-1}
Copper-coated glass	176-249	212	3.0	94.1 cm^2 g^{-1}
	452-520	486	3.0	41.0 cm^2 g^{-1}
Copper-coated polystyrene	355-420	387	1.2	76 cm^2 cm^{-3}
	850-1000	925	1.2	32 cm^2 cm^{-3}

150μ, the limit of availability of solid copper particles of acceptable sphericity, and, second, and more important, they provided experimental data on the performance of a supported form of electrode material which would show obvious, and in some cases essential, economies if the fluidized bed electrode were to be exploited commercially.

The plating of the glass and polystyrene beads was carried out by a method due to Shorokhova (6).

When not in use, the batches of particles were kept under water to prevent their oxidation.

In all cases, the anodes were made from lead sheet.

Fluidized bed cells.—Experimental observations were made on two forms of cell, one in which the electrical connection to the bed, henceforth called the current feeder, and the counterelectrode were concentric, and one in which they could be considered plane-parallel. They were both in essence research tools and were not considered to be prototypes of an industrial design. The details of construction of the cells are as follows:

(*i*) *Concentric configuration.*—The cell, henceforth referred to as cell I, is shown in Fig. 2. It was constructed from a flanged glass tube, 12 in. in length and 2 in. OD, the ends of which were closed by two circular perspex plates, thickness 3/8 in. The space was divided into anode and cathode compartments by a cylindrical diaphragm made from the flanged Vyon tubes, wall thickness 0.08 in. and outside diameter 1 in., bolted together at the flange with a flow distributor, also of Vyon, thickness 1/16 in., clamped between them. The fluidized bed, which was contained by the diaphragm and supported by the distributor, was introduced into the cell by removing the upper perspex plate.

The current feeder, which consisted of an 1/8-in. diameter copper rod mounted axially in the diaphragm, was supported by the lower perspex plate, into which it was cemented, and further located by the distributor through which it passed as a tight fit.

The electrode potential of the fluidized bed, which in terms of individual particles could well be extremely complex in nature, is given a characteristic value which was chosen to be that of the feeder with reference to electrolyte below the distributor. For this purpose a Luggin capillary was located as shown in Fig. 2, and readings were taken against a saturated calomel electrode. All potentials in this paper are expressed relative to a saturated calomel electrode.

A second cell of this type (cell II) was made in which the diaphragm, and hence the bed, diameter was increased to 3 in. These cells were particularly useful for calculating bed performance outside the entrance region, and, by maintaining separation of the anolyte and catholyte, for investigating current efficiency in terms of $-NO_2$ reduction. Another modification was introduced into a third cell, of diaphragm diameter 1 in., by fitting two distributors, one above the other, so that two beds, arranged in series with respect to catholyte flow, and parallel with current flow, could be examined. The reason for such a system will be made clear later.

(*ii*) *Plane parallel configuration.* The cell (cell III) is shown in Fig. 3. The internal diameter of the cell was 3 cm, and the length of tube available to the fluidized beds was approximately 12 cm. The flow distributor, which also supported the bed, was a sintered disk of porosity 3. The upper portion of the cell was constructed from a standard Quickfit B55 cone and socket joint. Two of the three nozzles it carried allowed insertion of the electrical leads to the current feeder and counterelectrode, and the third provided a gas

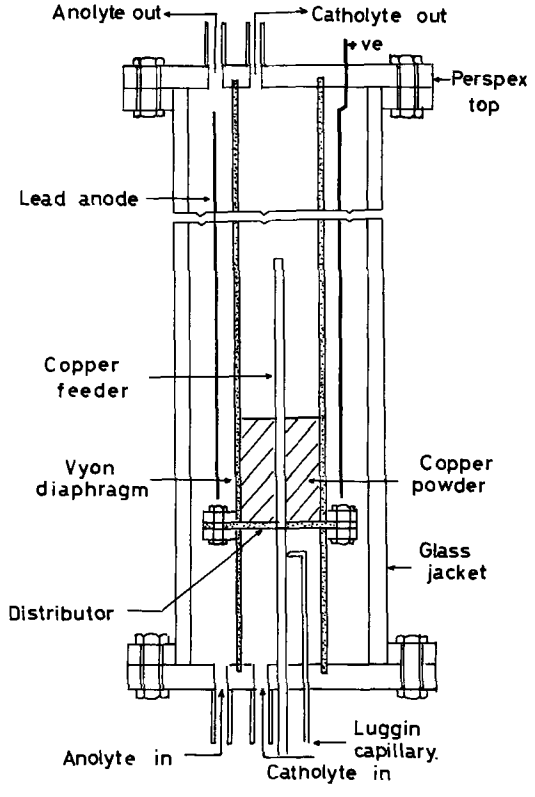

Fig. 2. Diagrammatic section of the cylindrical fluidized bed cell. Cell I.

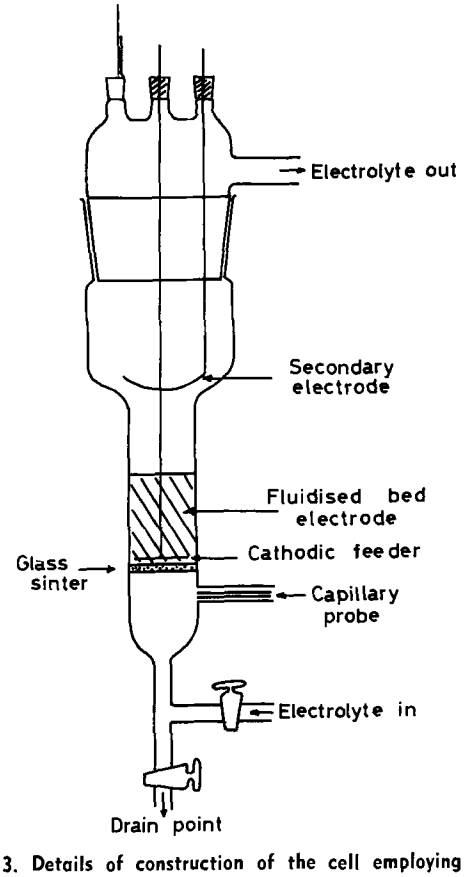

Fig. 3. Details of construction of the cell employing a plane-parallel electrode configuration. Cell III.

vent. In addition, the gas vent was used for the insertion of a Luggin capillary probe connected externally to a SCE by means of which the potential profile in the electrolyte could be observed relative to the potential of the current feeder. For this purpose the probe was supported such that its position in a vertical sense could be adjusted at will. The feeder was a flat spiral of 16 s.w.g. copper wire to which electrical connection was made by an insulated length of copper wire passing into the cell as shown in Fig. 3. When in position the plane of the feeder was perpendicular to the axis of the cell, but its axial location could be varied continuously. The counterelectrode consisted of lead sheet, shaped into a hemispherical shell, and was located above the free surface of the fluidized electrode.

The electrode potential of the bed was again characterized by the electrode potential of the feeder measured against that of the electrolyte below the distributor using a saturated calomel reference electrode.

In this form of cell the anolyte and catholyte compartments were not separated, the therefore current efficiencies could not be assessed owing to degradation of the cathodic product at the anode. Its main function was to provide information on the effect of current feeder location on electrode performance, and to enable an examination of the potential profile in the electrolyte to be made, for which purpose the visual observation afforded by the design, but not possible in the concentric configuration, simplified experimentation considerably.

(iii) The double concenrtic fluidized bed cell. The cell, cell IV, is shown in Fig. 4. It was constructed from a perspex tube of internal diameter 1.25 in. A sintered glass disk acted as a combined flow distributor and bed support. A Vyon tube of outside diameter 0.75 in. was sealed down onto the sinter such that a cathodic bed was supported in the annulus and an anodic bed of platinum coated glass particles was located inside the Vyon tube, the same electrolyte stream fluidizing both compartments.

The current feeders were coarse mesh cylindrical gauzes of copper and platinum wire for the cathodic and anodic beds, respectively. They were located adjacent to the Vyon diaphragm in a position corresponding to the top surface of the bed in the plane-parallel configuration.

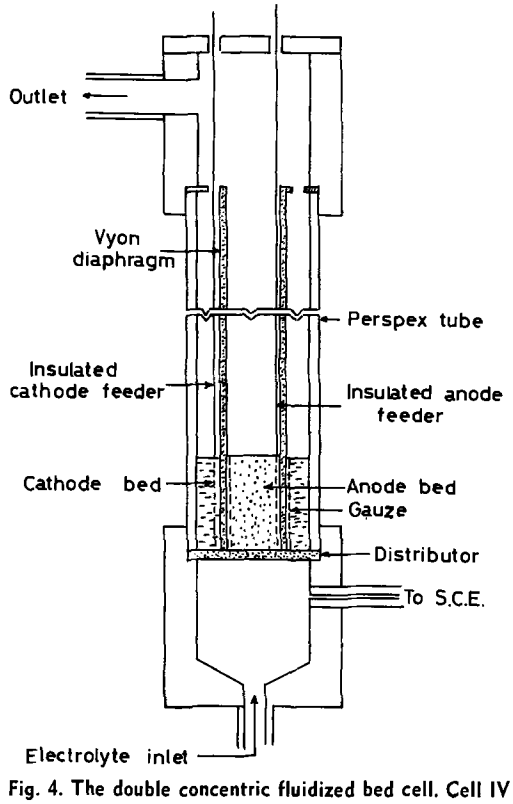

Fig. 4. The double concentric fluidized bed cell. Cell IV

The same method of electrode potential measurement was employed as in cell III, *i.e. via* a capillary located underneath the distributor. The cell was used to investigate the effect of bed expansion on electrode performance using copper-coated glass particles in the size range 450-520μ

Electrolyte circulation system.—The flow circuit was designed so that cells of either form could be inserted without modification. A diagram of the circuit is shown in Fig. 5.

The electrolyte was contained in the reservoir, capacity 5 liters, from which it was circulated through the cell by a peristaltic pump. Flow pulsations were reduced by an air vessel sealed by a mercury leg. The flow to the cell was indicated by a rotameter with a titanium float, and flow control was exercised manually by adjusting the supply and bypass valves 1 and 2. Effluent from the cell passed back to the reservoir along the return line. During extended runs with the concentric fluidized bed cell for the purpose of establishing current efficiencies, product oxidation was eliminated by running the system with a stagnant anolyte. Used electrolyte was discarded and replaced by fresh material sufficiently frequently to avoid significant depletion of the concentration of m-nitrobenzene sulfonic acid by reduction. The temperature of the electrolyte was maintained at 25°C, within acceptable limits, by means of a "Variac" transformer supplying an electric heating tape wrapped around the lower part of the reservoir.

Electrical supply.—The electrical power supply was taken directly from a rectifier. Two types were used according to the magnitude of the current load required. These were a "D-C Mobile" with maximum output 10A at 100V, and a Westinghouse silicon rectifier rated at 150A and 12V. Both were capable of continuous manual control within their ranges of current and potential.

Results and Discussion

Bed voidage.—A detailed investigation of the effect of bed voidage on the behavior of a fluidized bed electrode was carried out in cell IV, with the feeder located adjacent to the Vyon diaphragm. Observations for copper-coated glass particles in the size range 450-520μ are exemplified in Fig. 6 taken from a 40-g bed over a range of feeder potentials. The general shape of these curves has been confirmed subsequently by other workers (7). The form of the curves is not yet explained but an intensive examination of a proposed mechanism for current distribution in the bed now in progress shows early promise of doing so.

In drawing conclusions from these results, it should be borne in mind that the total current supported by the electrode reflects only the rate of reaction and not the type. The key factor in determining the latter is

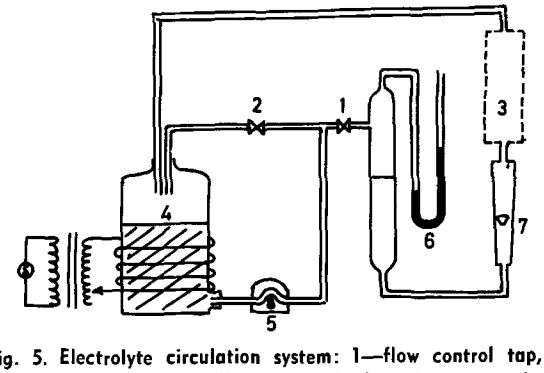

Fig. 5. Electrolyte circulation system: 1—flow control tap, 2—by-pass control tap, 3—cell, 4—heated electrolyte reservoir, 5—peristaltic pump, 6—"smoothing" vessel for electrolyte flow and manometer, 7—flowmeter.

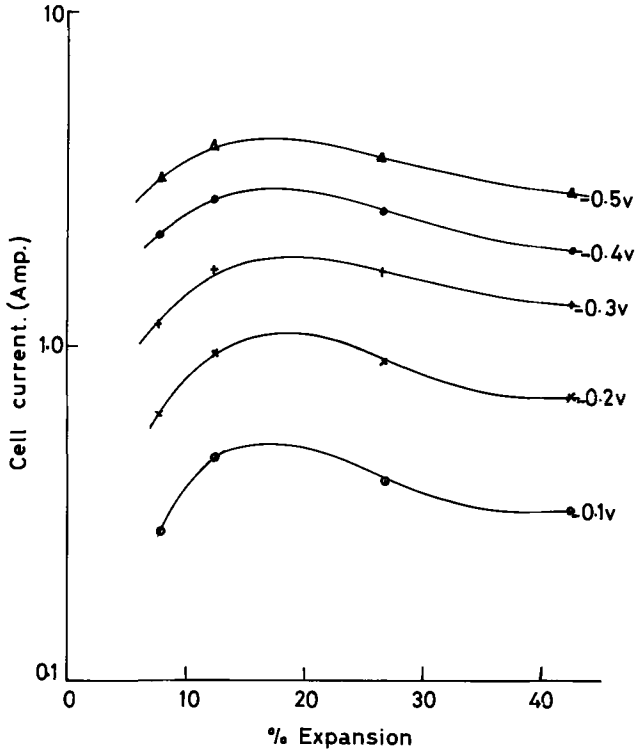

Fig. 6. Variation of cell current with expansion in the double concentric fluidized bed cell.

the potential distribution in the system and it does not therefore follow that the maximum current condition necessarily offers the best electrode performance in terms of desired reaction, although measurement of current efficiency has shown that in this particular case they do occur identically. In this connection it is also important to note that the potential distribution in the bed will show a strong dependence on the method adopted to characterize it. In the present work, it will be remembered, this was chosen to be the difference in potential between the feeder and the electrolyte prior to entry to the bed. If another method were adopted, by making reference, for example, to the electrolyte at some point within the bed, the variation of current or current efficiency with bed voidage could assume an entirely different form. Similar arguments may account for the fact that semiqualitative observations made with the concentric configurations displayed more pronounced maxima than those of the curves in Fig. 6.

From a practical point of view, however, the experimental results serve to draw attention to the importance of bed voidage in establishing the maximum operating performance of a fluidized bed electrode, and investigations so far indicate that this would be achieved with a voidage in the vicinity of 0.50-0.58 (5-25% expansion).

Scale-up.—From an electrical point of view the dimensions of the bed can be scaled up in two ways, either parallel to the direction of current flow in the cell or at right angles to it. Both cases have been investigated using cells of concentric configuration.

The effect of increasing the bed dimension at right angles to current flow was investigated in cell I and the results are presented in Fig. 7(a), (b), and (c) in terms of the variation of total cell current with static height of bed over a range of particle size and electrode potential. In general, the curves show that the total current supported by the bed scales up linearly with height except over an initial region, corresponding to low bed height, where the relationship takes on a nonlinear form. This initial region may well reflect a hydrodynamic entrance effect, since this would explain not only why the region is not typical of the

bulk of the bed but also the fact that its extent is independent of the electrode potential of the feeder and apparently only determined by physical characteristics of the particles.

The data of Fig. 7(a), (b), and (c) have also been used to determine the performance of the fluidized bed electrode in terms of specific current. Specific current, i_s, is defined as the current supported by the fluidized electrode per unit of volume it would occupy if it were in the static state, and it is therefore related to point values of the slope, dI/dh, of the curves in Fig. 7(a), (b), and (c) by

$$i_s A = dI/dh$$

where A is the cross-sectional area of the bed in a plane at right angles to its axis. By inserting values of dI/dh appropriate to the linear portion of the curves only, values of i_s were obtained from which entrance effects were eliminated.

The data obtained in this way have been divided by the specific area of the particles to produce a "pseudo current density" and are presented in Fig. 8, where they are plotted against the equivalent plane electrode current density. This latter term is defined here as the current density which is observed at a plane electrode operating at a potential equal to that chosen to characterize the fluid bed potential. This presentation of results takes account of the variation of the superficial area of the particulate electrodes and therefore makes comparison between different particle sizes and electrode dimensions more meaningful. It should be emphasized again, however, that strictly there can be no direct comparison made between a continuous electrode surface and a particulate form on the basis of a single value of potential since in general the latter will exhibit a potential distribution of varying complexity. A detailed investigation of the potential distribution is at present in progress, but at this stage the simple comparison made in Fig. 8, bearing in mind its somewhat qualitative nature, serves to give a feeling of the intensity of the performance of the fluidized bed electrode.

As a general comment, the specific current of the fluidized bed is seen to increase nonlinearly with the plane electrode current density, and is an indication that the bed is not uniformly active. The nature of the nonuniformity, however, cannot be deduced at this stage owing to the somewhat complex form of the polarization curves of the test reaction.

Considering the copper-coated glass spheres, it is seen from Fig. 8 that in the low current density region, roughly corresponding to the Tafel region, a performance significantly superior to the solid copper spheres is attained.

The effect of scaling up in a direction parallel to the current flow was determined by comparing the performance of cell I, of electrode diameter 1 in., with that of cell II, electrode diameter 3 in., for solid copper particles of size 125-150μ.

The relevant results again appear in Fig. 8, where it appears that the performance of cell II is better than cell I. However, similar weight beds were used in each cell so that comparable bed heights in cell II are approximately 1/9 of those in cell I. The effect of this is that the values of dI/dh have not reached a steady value as all the bed heights considered have been in the entrance region. For this reason, no definite conclusions may be drawn about the performance of cell II.

The data obtained from copper-coated glass particles in cells I and IV and those from solid copper powder on cells I and II have been interpreted in terms of the activity of the fluidized bed electrode by plotting the effective specific area against the plane electrode current density and in this form are shown in Fig. 9. On this basis, Fig. 9 shows that the performance of the copper-coated glass particles is superior to the solid copper powder within the range of parameters investigated.

Emphasis must again be made regarding the effect on the plotted results of the measured value of electrode potential. While in cells I and II the measured potential may be expected to approximate the true value of electrode potential, this is certainly not the case in cells III and IV. With special regard to the latter cells, the reading taken as electrode potential, and used subsequently to determine the plane electrode current density, will incorporate an IR drop through the bed which may become significant at higher potential values. For example, an IR drop of 0.025V incorporated at an observed reading of 0.35V effectively reduces the equivalent plane electrode current density from 16.5 to 9.3 A/ft^2. The effect at higher observed readings, corresponding to higher currents, would have a similar effect since, although the variation of current density with electrode potential is not so great at higher potentials, the IR drop will be greater in this case. The net effect of these considerations is to raise the effective specific areas for all points greater than an approximate plane electrode current density of 10 A/ft^2.

Potential distribution.—Potential distribution in the electrolyte in the fluid bed cathode was examined using cell III by means of a movable Luggin capillary probe connected to a SCE. Potentials were measured

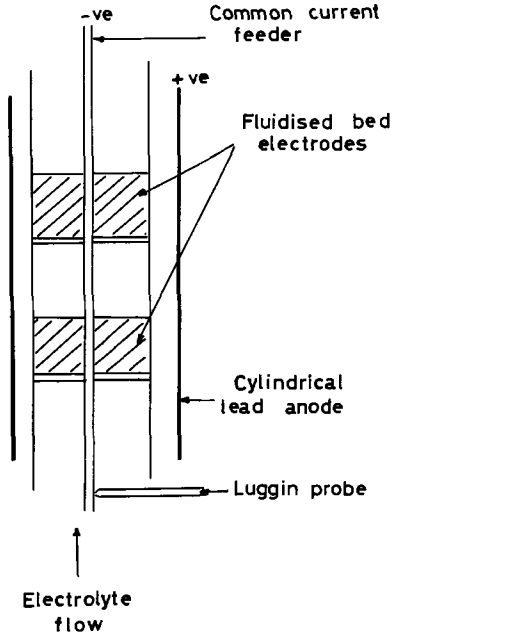

Fig. 11. Diagrammatic representation of a two-tier fluidized bed electrode. Bed diameter = 1 in.

with respect to the feeder. The results plotted in Fig. 10 correspond to three different feeder locations. As would be expected, an increase in potential in all three cases were observed in passing upward through the bed toward the anode. The rate of increase, however, is markedly different in the three cases, and in particular the total potential drop across the bed with the current feeder located in the center is greater than that with the feeder at the surface of the bed by an order of magnitude although the total cell current, 0.7A, was the same in both cases. This observation indicates that the bed is much more active in the proximity of the feeder than at points removed from it under the particular electrochemical and physical conditions obtaining. It may well imply after further investigation that, in good fluid bed electrode design, power consumption may be reduced, without in general impairing cell performance, by locating the feeder on that side of the bed nearer the counterelectrode.

The curve describing potential distribution with the feeder located near the distributor, although corresponding to the same feeder potential (0.3V) as the other two, is not strictly comparable to these since the total cell current in this case was 8.0A, some ten times greater than that observed in the other two. Although the difference in feeder location would be predicted to cause an increase in current with the feeder in this position, as well as a larger drop in potential, this change in location of the feeder cannot by itself explain the whole effect, as otherwise one would expect some significant difference between the performance with the feeder in the other two locations. It is felt, and there is more evidence to support this point of view, that the behavior of the bed in this region is of a localized nature due to an entrance effect. This has not been fully explored as yet, but its investigation is of some importance because of the obvious implications in improved electrode design. Supporting evidence was obtained from a two tier cell design shown diagrammatically in Fig. 11. The total cell current observed at all potentials examined was higher when a given weight of bed was distributed between the tiers than when it comprised a single bed. In addition, and already given mention, Fig. 7(a), (b), and (c) show typical entrance region behavior in that the performance of the bed, in terms of total cell current, increases uniformly with bed height except for a small region near the distributor which is characterized by abnormally high performance.

Current efficiency.—A series of current efficiency tests were carried out in cell I over a range of current feeder potentials using solid copper spheres, of size range 125-150μ in a bed of static height 4.9 cm (80g of bed material). The results are given in Table II, together with those for a single sphere electrode in flowing electrolyte for ease of comparison.

It is to be expected that the bed in all probability displays a complex spatial distribution of electrode potential, or, in other words, that every particle will not be operating on the same part of the plane electrode polarization curve no matter how well one attempts to control the potential of the current feeder. This is a natural consequence of the requisite potential gradients necessary to drive current through the dispersed and continuous phases. It could well be expected, however, that under the conditions of shallow potential gradients expected at relatively low total cell currents a better approach to a uniform working potential would exist than at high total currents. The data of Table II bear this out in a qualitative way in that they show, within experimental error, that at low current feeder potentials, approximating to the Tafel region, the current efficiency obtained in the bed is identical to that on the plane electrode. At higher negative potentials, within the limiting current region and where there is an onset of hydrogen evolution,

Table II. Variation of current efficiency with potential in the reduction of 0.125M m-nitrobenzene sulfonic acid in 1M H_2SO_4 at a fluidized bed cathode of solid copper particles and at a solid copper, single sphere electrode

Cathodic potential, volts	Current efficiency, % Fluidized electrode	Single sphere electrode
−0.20	78	77
−0.25	74	75
−0.30	70	70
−0.40	67	68
−0.50	62	65
−0.60	57	61
−0.70	50	57

the bed shows a significant drop in efficiency compared to the plane electrode. Assuming that hydrogen is the only other product, this suggests that parts of the bed are operating further into the hydrogen evolution region than the control potential indicates. This is not unreasonable at high currents since, in the electrode configuration under consideration, the potential profiles in the dispersed and continuous phases could diverge somewhat in regions removed from the feeder, depending on their relative conductivities. Investigations in progress tend to support this explanation. The current efficiency values quoted in the present paper have also been confirmed by other workers (7).

Electrode materials.—In the previous sections it has been noted that results are not quoted for copper-coated polystyrene beads. In general it was found that the behavior of a fluidized bed constituted of such particles had poor hydrodynamic qualities, the reason for which could be traced to their low over-all density. The movement of these particles within the bed had a "lethargic" quality which could have serious disadvantages in the application of the fluidized bed electrode in the broadest sense. One means of imparting a high density to the particles would be to give them a heavier coating of electrode material or base metal, but this to some extent would lose the advantage of using cheap nonconducting spheres as electrode carriers.

On the other hand, the solid metal spheres and coated glass beads were both satisfactory, and indications are that a minimum over-all density of 2.8 g/cm^3 is desirable.

Conclusions

The investigations have demonstrated the ability of a fluidized bed of conducting particles in contact with a current feeder to disperse charge throughout the bed such that an electrochemical reaction takes place at the particulate surface. In this way, the fluidized bed electrode is capable of scaling up electrode processes having low exchange currents so as to give high over-all currents in commercially reasonable cell volumes. As would be expected, the performance of such an electrode depends on the degree of fluidization and shows a maximum in the vicinity of 5-25% expansion (0.50-0.58 voidage). Within this region a bed of copper-coated glass beads, particle size 452-520μ, supported a specific current some 20 and more times greater than that expected of a typical commercial cell when operating at a current density of the order of 7 A ft^{-2}.

Of the materials used in the bed, coated glass beads appear to be superior in performance to solid metal particles, although the reason for this is not clear. This observation has important implications when considering the use of expensive electrode materials and in selecting over-all particle densities suitable for optimum process flow conditions.

Scale up of the bed in a direction perpendicular to current flow in the cell gives a linear increase in cell capacity, but in a direction parallel to the current flow falls short of a linear relationship, and hence size in this direction appears to be limited to about 1 in. for the types of cell considered. It is questionable, however, whether there is any need to scale up beyond this value in a parallel direction; otherwise the problem of ohmic losses in the electrolyte and diaphragm may become crucial. For instance, a bed of cross section 1 ft^2 and depth 1 in. constituted of copper-coated particles already supports a current in excess of 300A under conditions where a plane electrode would support less than 10 A/ft^2. It would probably be better therefore to think in terms of multiple cells or their equivalent rather than the scaling up of a single electrode.

It is realized that the conclusions drawn apply strictly only to the particular reaction investigated, namely the reduction of an aromatic nitro group at room temperature at a copper cathode. Other forms of cathodic and anodic reactions are under investigation, however, and observations made so far are in accord with the present conclusions.

Acknowledgments

One of the authors (J. R. B.) wishes to express his thanks to the Science Research Council for the award of an Advanced Course Studentship under which this work was carried out. The authors also wish to thank Dr. D. B. Chambers for some confirmatory experimental work carried out prior to the submission of this paper, and to all their colleagues for invaluable discussion on the subject matter of this paper.

The Oxidation of Water-Soluble Organic Fuels Using Platinum-Tin Catalysts

K. J. Cathro

Division of Mineral Chemistry, C.S.I.R.O., Port Melbourne, Victoria, Australia

ABSTRACT

Electrodeposited platinum-tin mixtures show enhanced activity toward the oxidation of methanol, formaldehyde, and formic acid when compared with platinum black. This increased activity is particularly noticeable with formaldehyde, the anode polarization being decreased by 0.4V at a current density of 100 mA/cm^2.

The use of platinum-rhenium electrodeposits as an anode catalyst for the oxidation of methanol has been described (1-3). It was suggested (2, 3) that the improvement in performance over a platinum black catalyst was due to the direct reaction of an oxide of rhenium with chemisorbed fuel residues, followed by electrolytic reoxidation of the reduced rhenium oxide. After reviewing the standard oxidation potentials of several metal-metal oxide systems, it seemed likely that other platinum-metal oxide combinations would give enhanced activity toward methanol oxidation. Several elements were codeposited electrolytically with platinum, and the mixed deposits tested, in the first instance, for catalytic activity toward the oxidation of methanol and formaldehyde in 0.5M sulfuric acid. The more active catalysts were examined also for their ability to oxidize formic acid, for, although this is not an economical fuel, it can occur in actual battery systems as a partial oxidation product of formaldehyde (4). Of the combinations tested, platinum-tin was the most promising catalyst.

The addition of tin to platinum to improve its performance as an oxidation catalyst has been patented (5, 6), but little detailed information is given as to the characteristics of these catalysts. The present study gives results for the oxidation of methanol, formaldehyde, and formic acid over a range of temperature and fuel concentration.

Experimental

The cells used were those described previously (3), but in this series of tests polarization curves were obtained galvanostatically, using a stabilized power supply and suitable ballast resistors. Cyclic voltammetry was employed on a few occasions, using a potentiostat and waveform generator made in these laboratories, the curves being recorded on an X-Y plotter. Electrode potential was measured by means of a voltage follower/precision voltmeter combination, while current was measured on a suitable multirange ammeter. A mercury-mercurous sulfate reference electrode was used throughout: its potential was checked frequently against a calomel reference. The magnitude of the *IR* correction was estimated by noting the initial change in potential when a current pulse was applied to the system.

The methanol, formic acid, and sulfuric acid used were of analytical reagent grade. Reagent-grade formaldehyde is stabilized with methanol, so a methanol-free formaldehyde solution was prepared by refluxing paraformaldehyde with water. The fuel concentration was held at 1M and the temperature at 60°C unless stated otherwise: the sulfuric acid concentration was 0.5M in all cases. Electrode performance was sufficiently stable for all tests at a given tin composition to be run on the one electrode. Oxygen-free nitrogen was bubbled through all test solutions (except for the 1000-hr endurance test) before and during polarization runs.

Electrode preparation.—Catalysts were prepared by electrodeposition at controlled potential from mixed solutions of chloroplatinic acid and stannic chloride, the deposition potential being, in most cases, +0.05V to the standard hydrogen electrode (NHE). The initial platinum concentration in the plating solution was 10 g/liter; this would have decreased by less than 5% during a platinum run. The deposit composition was controlled by varying the tin concentration between zero and 12.8 g/liter and the deposits were gray to black in color. Iridium and rhodium substrates of 1 cm^2 foil were used; these metals were chosen to permit the stripping of the deposit in *aqua regia* without dissolution of the substrate. With platinum foil there is danger of attack on the substrate, especially as platinum-tin deposits dissolve more slowly than the platinum-rhenium catalysts described previously.

Platinum analyses were made using the stannous chloride method (7), while tin determinations were made polarographically after hydrolytic separation of tin using an aluminum hydroxide carrier.

Results

The polarization observed when methanol, formaldehyde, and formic acid are oxidized on a platinum deposit is reduced by the inclusion of tin in the deposit, as shown in Fig. 1(a), 1(b), and 1(c), together with the data for platinum-rhenium (3). The improvement in catalytic activity of the deposits over that of platinum black is quite clear, as is the superiority of platinum-tin codeposits (over platinum-rhenium) for the oxidation of formaldehyde and formic acid.

Some of the factors affecting catalyst activity were studied in more detail, with the results set out below.

Catalyst loading.—The loading was varied from 0.09 to 6.2 mg/cm^2 by variation of the plating time between 1 and 30 min. It is possible to get heavier deposits by plating for a longer time, but the adhesion of such deposits is poor, and they tend to crack and fall off the substrate. The thinner deposits show good adhesion.

The effect of catalyst loading on activity is shown in Fig. 2, the current density at fixed potential (0.3V *vs.* NHE for methanol, 0.15V for formaldehyde, 0.2V for formic acid) being plotted against loading. For methanol and formaldehyde the current density is proportional to $L^{0.85}$, where L is the catalyst loading in mg/cm^2. The results for formic acid scatter more, but show a similar trend. The near proportionality of activity to catalyst loading indicates that the deposits are porous and only a small decrease in available area results from increasing the thickness of the deposit.

Catalyst composition.—The composition of the deposit was varied by changing the tin concentration as described above. The fraction of tin in the deposit was proportional to the tin in solution up to approximately 3 g/liter, but thereafter became independent of the tin concentration—*see* Fig. 3.

The effect of catalyst composition on activity is shown in Fig. 4. There is an optimum composition at approximately 5% tin by weight [8 a/o (atom per cent)] for the catalyst loading of 5 mg/cm^2 used. This

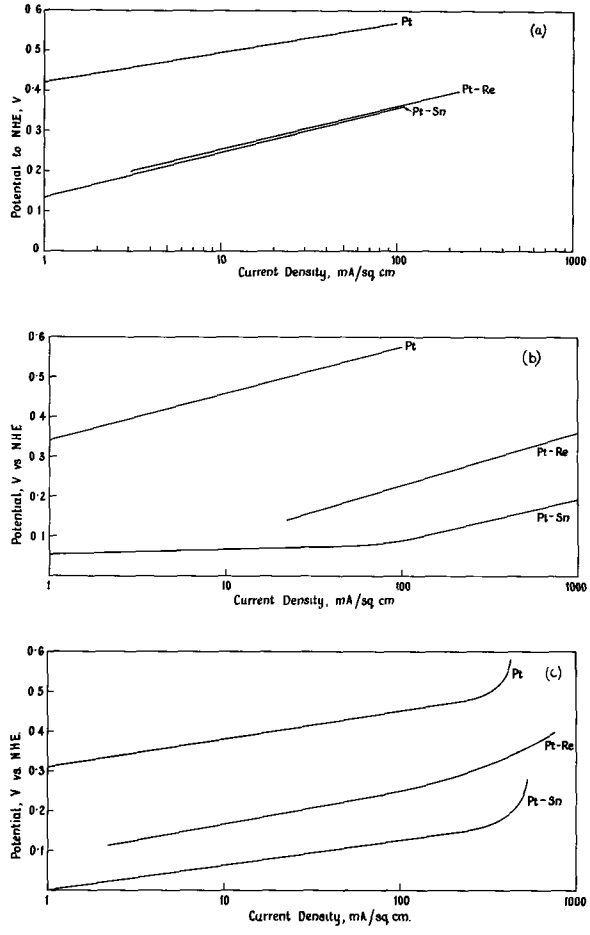

Fig. 1. Polarization curves for a platinum-tin catalyst. At 60°C, catalyst loading 7±1 mg/cm^2; platinum-tin catalyst: 6.2% Sn. (a) For 1M methanol, (b) for 1M formaldehyde, (c) for 1M formic acid.

is similar to the optimum of 11% by weight (11.4 a/o) observed for the platinum-rhenium system (3).

A further effect of an increasing fraction of tin is shown in Fig. 5. It can be seen that the electrode tends to become passive at a potential of approximately 0.3V to NHE if it contains an appreciable percentage of tin. Generally similar results are observed with formaldehyde and formic acid, except that the passivation potential is approximately 0.25V.

Deposition potential.—Catalyst deposits were made at potentials of +0.25, +0.05, zero, and −0.1V to NHE, the plating solution *p*H being 0.7, and tin concentration of 3.2 g/liter. Hydrogen was evolved freely at −0.1V. The effect of deposition potential on activity is shown in Table I.

The primary effect of a decrease in potential, all other factors being held constant, is to increase the

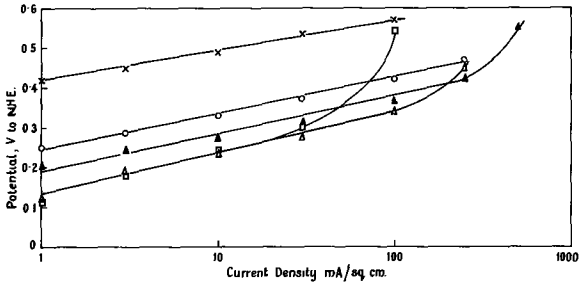

Fig. 5. Effect of catalyst composition on passivity. For 1M methanol, 60°C, 4.7 mg/cm^2. ×, No tin. ○, 0.7% Sn. ▲, 1.7% Sn. △, 4.8% Sn. □, 7.9% Sn.

Table I. Effect of deposition potential on catalyst activity

Plating potential volts to NHE	Catalyst		Current density, mA/cm², at stated potential		
	Loading, mg/cm²	Tin, %	Methanol at 0.3V	Formaldehyde at 0.15V	Formic acid at 0.20V
+0.25	2.5	6.8	13	650	78
+0.05	6.2	6.2	38	500	440
zero	11.2	2.7	38	200	300
−0.1	18.3	2.1	38	450	340

catalyst loading, but decrease the fraction of tin in the deposit. These variations of loading and composition make interpretation of the results more difficult, but if activity is assumed to be proportional to $L^{0.85}$ over the whole range of loadings, and if the effect of tin composition on activity is taken as that shown in Fig. 4, an approximate correction for these variations can be made. If this is done it is clear that there are not any large (order of magnitude) changes in specific activity with change in plating potential.

Electrolyte temperature and fuel concentration.—At fixed potential, current density increases with increase of both temperature and fuel concentration, as shown in Fig. 6 and 7.

Operating time.—One long-term run of 1000 hr duration has been made using methanol as fuel, the electrode potential at a current density of 20 mA/cm² being shown as a function of time in Fig. 8. There is a fairly rapid decay over the first hundred hours, followed by a period of nearly steady performance, with only a slight further loss in activity.

Platinum-tin deposits can be polarized to high potentials—of the order of 1.5V to NHE—at least for short periods, without significant loss in activity when returned to the normal working potential of 0.2-0.3V. This is in contrast to the platinum-rhenium system, where operation at potentials more positive than 0.5V leads to a rapid and irreversible loss in activity, probably due to loss of rhenium from the catalyst (3).

Discussion

It has been suggested that the mixed catalysts which show increased activity toward the oxidation of methanol gain their activity from the direct reaction of metal oxide with chemisorbed fuel residues, the reduced oxide then being electrolytically reoxidized (2, 3, 8, 9). The $Sn(OH)_2/Sn(OH)_4$ couple has a standard potential of + 0.075V to NHE at 25°C in acid solution (10) so it could act in this way.

It could be objected that the improvement in activity is due to the tin modifying the platinum black

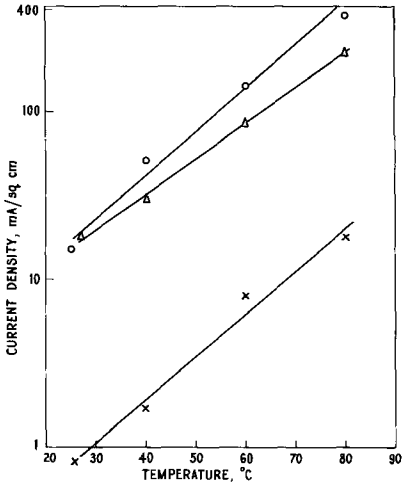

Fig. 6. Effect of electrolyte temperature on performance. At 1.7 mg/cm² catalyst, 5.3% Sn, 1M fuel. ×, Methanol at +0.3V to NHE. △, Formaldehyde at +0.15V to NHE. ○, Formic acid at +0.2V to NHE.

so as to produce an increase in surface area. The maximum possible surface area for platinum black would be for the case where every atom was a surface atom. This area can be calculated from the relation $1/A = S/N \cdot n$ where A is the specific surface in m²/g, S is the site density in atoms/m², N is Avogadro's number, and n is the atomic weight of platinum. If a value of 1.1 x 10^{19} atoms/m² is assigned to S (11), A is 270 m²/g. The surface area of a typical electrodeposited platinum black can be estimated from the charge necessary to oxidize adsorbed hydrogen, and is 18 m²/g. Now the increase in catalytic activity may be seen (from Fig. 1) to be approximately three orders of magnitude, whereas the maximum possible increase in specific surface is a factor of 15. It is unlikely, then, that the improved activity of these catalysts is due to an increase in the specific surface area of the platinum black.

Some further evidence in favor of the redox mechanism was obtained from potential-time curves made at a constant current for platinum-tin electrodes in 0.5M sulfuric acid. Two of these are shown in Fig. 9. The curve for the platinum-tin deposit shows a large

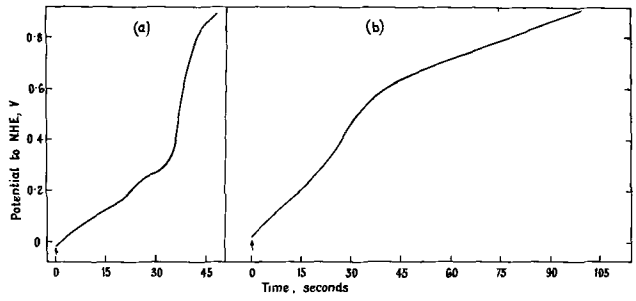

Fig. 9. Chronopotentiometry on platinum and platinum-tin: (a) 8.3 mg/cm² Pt black, (b) 9.6 mg/cm² Pt-Sn (3.3% Sn). Both in 0.5M sulfuric acid at 60°C. Current density = 10 mA/cm².

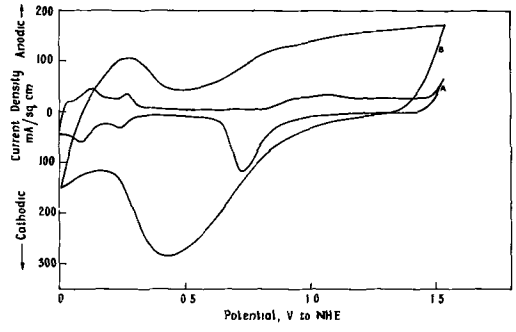

Fig. 10. Cyclic voltammetry on platinum and platinum-tin. In 0.5M sulfuric acid at 60°C, sweep rate 0.2V/sec. Curve A: 3.1 mg/cm² Pt. Curve B: 3.6 mg/cm² Pt-Sn (4.5% Sn).

increase in the charge necessary to oxidize the electrode, especially at potentials below 0.6V, while that used to oxidize the adsorbed hydrogen has decreased. The differences between platinum black and platinum-tin are even more clearly visible in the cyclic current-voltage curves of Fig. 10. These curves, representing the current flowing to a 1 cm² electrode cycled between zero and +1.6V to NHE show that oxide formation and reduction appears to extend to lower potentials on the platinum-tin electrode. These results give some support to the postulate that a redox oxide system is the cause of improved catalyst activity.

It is clear from Fig. 1 that the platinum-tin deposit is able to catalyze the oxidation of formaldehyde and formic acid more effectively than does a platinum-rhenium deposit. This could be related to the more favorable redox potential of the tin oxide system, as compared to the rhenium oxides. However, it is clear also that the rate of oxidation of methanol is very similar on both catalysts. To account for this it may be suggested that the rate of oxidation of methanol is limited by the rate of chemisorption rather than the rate of oxidation of the chemisorbed residues. Alternatively, the different compounds may give rise to different chemisorbed species, that for methanol being more difficult to oxidize.

Biegler and Koch (12) measured the adsorption rates of methanol on smooth platinum, and calculations based on the initial value of the rate show that it should be possible to chemisorb methanol sufficiently rapidly to achieve a current density of about 100 mA/cm², using 0.2M methanol at 25°C, with a catalyst loading of 1.7 mg/cm². The measured current density is 3 mA/cm² under these conditions, which makes it unlikely that chemisorption is the rate-limiting step. Breiter (13) has shown that the adsorbed intermediate has the same oxidation state in each case, but this does not prove that the species are identical. It is suggested that the chemisorbed methanol is less easily oxidized than the intermediates from formaldehyde and formic acid.

In terms of stability and activity, platinum-tin electrodeposits are effective catalysts for the oxidation of methanol, formaldehyde, and formic acid. The only property that might cause difficulty is the tendency to become passive at potentials of 0.2-0.3V. This can be overcome by the use of a ternary platinum-rhenium-tin deposit, and catalysts of this type have been used with some success in fuel cell systems operated on methanol or formaldehyde.

Acknowledgment

Helpful discussion with Dr. R. Woods in regard to the maximum possible surface area of platinum black is acknowledged.

Phase Equilibrium Studies of Lithium Halide-Containing Electrolytes

Carl E. Johnson and Melvin S. Foster

Chemical Engineering Division, Argonne National Laboratory, Argonne, Illinois

The application of fused-salt mixtures as electrolytes in electrochemical cells has resulted in increased interest in their physical and chemical properties. A knowledge of these properties is important in selecting appropriate electrolytes since the choice depends on a variety of factors. For example, cells having low-melting cathode materials require low-melting electrolytes. Also, electrolytes with high electrical conductivities are needed to reduce ohmic losses within the cell. Fused alkali halides generally meet these requirements. Because thermodynamic stability with respect to the anode material is also an important consideration, electrolytes generally have been sought from among low-melting halide salts of the anode metal.

The electrochemical data of Hamer *et al.* (1) indicate, however, that under certain circumstances a mixed-cation electrolyte could be used in a galvanic cell. These data show that if the operating temperature of the cell or battery is restricted to temperatures below 500°C, it should be possible to use mixtures of alkali halides (lithium, potassium, rubidium, or cesium, but not sodium) as electrolytes for cells having lithium as the anode metal. Galvanic cells with lithium anodes are of particular interest because of their advantages of higher cell voltages and lower metal solubility in fused salts.

For a specific salt system, it would be highly advantageous to have a method of locating the minimum temperature, its corresponding chemical composition, and the general topological characteristics of the system with a minimum of effort. Such knowledge would greatly facilitate the choice of appropriate electrolytes for the electrochemical cells of interest. Although a more detailed investigation of the electrolyte composition in the region immediately surrounding the minimum-temperature composition would also be needed to ascertain the effects of slight compositional changes on the solidus temperature, such an investigation would be expedited by having a general knowledge of the characteristics of the system.

Accordingly, a study was undertaken to evaluate the usefulness of a perturbation theory, the conformal ionic solution theory (2), in calculating the complete liquidus surface of reciprocal salt systems, *i.e.* systems having two anions and two cations. This theory requires only limited information: the melting point, the heat of fusion, and the standard Gibbs free energy of formation of each component, and the eutectic temperature of each of the four nonreciprocal pairs in the system. The theory of conformal ionic solutions as applied to this problem has been outlined by Blander and Topol (3); a brief summary is given here.

For a reciprocal system

$$AC + BD \rightleftarrows AD + BC \qquad [1]$$

the excess free energy of mixing, $\Delta G_M{}^E$, for the three salts AC, BC, and BD necessary to define the system is given by

$$\Delta G_M{}^E = X_A X_D \Delta G^\circ + X_D \Delta G_{12}{}^E + X_C \Delta G_{34}{}^E + X_A \Delta G_{13}{}^E + X_B \Delta G_{24}{}^E + X_A X_B X_C X_D \Lambda \qquad [2]$$

where the X's are ion fractions and ΔG° is the standard Gibbs free energy change for Reaction [1]. The cation fraction of B is $X_B = n_B/(n_A + n_B)$ and the anion fraction of D is $X_D = n_D/(n_C + n_D)$ where n_A, n_B, n_C, n_D are the numbers of moles of the ions indicated. The expression for the excess free energy of mixing of the binary mixture of the salts i and j ($\Delta G_{ij}{}^E$), where AD is salt 1, BD is 2, AC is 3, and BC is 4, has been truncated to include only second-order terms, so that

$$\Delta G_{12}{}^E = X_A X_B \lambda_{12} \qquad [3]$$

and

$$\Delta G_{34}{}^E = X_A X_B \lambda_{34} \qquad [4]$$

The mixing parameters, λ_{ij}, depend only on the properties of the binary systems. The term Λ is approximated from quasi-lattice theory by

$$\Lambda = -(\Delta G^\circ)^2/2 \; ZRT \qquad [5]$$

where Z is a coordination number between 4 and 6. With the relation

$$RT \ln \gamma_i = \frac{\partial(n_k + n_e)}{\partial n_i} \Delta G_M{}^E = \frac{\partial(n_k + n_e)}{\partial n_k} \Delta G_M{}^E + \frac{\partial(n_k + n_e)}{\partial n_e} \Delta G_M{}^E \qquad [6]$$

where k and e are the constituent ions of component salt i, the activity coefficients, γ_i, of any component may be calculated from Eq. [2].

The liquidus temperature, T, is the temperature at which a solid component such as AD is in equilibrium with a solution in which the component has an activity, a. If we assume that the heat of fusion, L_i, for any component, i, is independent of temperature, then

$$R \ln a_i = -L_i (1/T - 1/T_{oi}) = R \ln X_k X_e \gamma_i \qquad [7]$$

where T_{oi} is the melting point of the pure salt.

Values of λ_{ij} are calculated from the known phase diagrams of the four nonreciprocal binary systems. For a given binary system, ij, the simplified assumption was made that

$$RT \ln \gamma_i = \lambda_{ij} N_j{}^2 \qquad [8]$$

and

$$RT \ln \gamma_j = \lambda_{ij} N_i{}^2 \qquad [9]$$

where N_i, N_j are mole fractions. Equations [8] and [9] were used with Eq. [7] to yield the following:

T (eutectic)

$$= [\lambda_{ij}(1 - N_i)^2 + L_i]/[(L_i/T_{oi}) - R \ln N_i] \qquad [10]$$

$$= (\lambda_{ij} N_i{}^2 + L_j)/[(L_j/T_{oi}) - R \ln (1 - N_i)] \qquad [11]$$

Using the measured eutectic temperature and the heats of fusion and melting points of the pure components as fixed points, Eq. [10] and [11] were solved simultaneously for λ_{ij} and the eutectic composition.

To derive the liquidus temperatures, Eq. [5], [6], and [7] were solved for the precipitation tempera-

Table I. Crystallization temperatures for the LiCl-LiI-KI system

Series I mole ratio LiCl:LiI 1:1		Series II mole ratio LiCl:LiI 3:7		Series III mole ratio LiI:KI 6:4	
m/o KI	Temp (°C)	m/o KI	Temp (°C)	m/o LiCl	Temp (°C
30.0	399.5	20.0	341.3	20.0	330.0
35.0	392.1	25.0	338.0		
47.3	436.8	31.5	330.0		
		38.3	346.1		

tures, T_i, of solid AD (component 1) to yield:

$$T_1[(L_1/T_{oi}) - R \ln X_A X_D] = L_1 + (1 - X_B X_C)\Delta G^\circ = X_B(X_B X_D + X_A X_C)\lambda_{12} + X_B X_C(X_B - X_A)\lambda_{34} + X_C(X_B X_D + X_A X_C)\lambda_{13} + X_B X_C(X_C - X_D)\lambda_{24} + X_B X_C(X_B X_D + X_A X_C - X_A X_D)\ [-(\Delta G^\circ)^2/2ZRT_1] \quad [12]$$

The liquid-solid equilibrium temperature for each of the components can be similarly calculated. For a given composition, that component with the highest liquidus temperature was selected as the component precipitating at the calculated liquid-solid equilibrium temperature. If this precipitation temperature is higher than the normal melting point for that specific component, the presence of a liquid-liquid miscibility gap is indicated. Equation [12] was solved with the aid of a CDC-3600 computer (program available on request), and the output data were fed to a Calcomp-580 incremental plotter for display.

One of the salt systems being considered for use as an electrolyte in lithium-anode galvanic cells is LiCl-LiI-KI. This system was chosen for investigation after a preliminary examination had indicated that it had a minimum melting point of 264°C, one of the lowest observed for ternary alkali halide mixtures. This ternary system, which consists of the binary eutectic systems LiCl-LiI, LiCl-KI, and LiI-KI, forms one half of the reciprocal LiCl-KI system. Therefore, it afforded an opportunity to test the usefulness of the conformal ionic solution theory for obtaining the required information with a minimum of experimental effort.

The theoretical calculations for the LiCl-LiI-KI system indicated a minimum temperature of 276°C at a composition of 6 m/o (mole per cent) LiCl, 62 m/o LiI, 32 m/o KI. This information was used to design eight thermal analysis experiments. These experiments, which were performed using apparatus and techniques that have been described elsewhere (4), provided solid-liquid equilibrium data for three pseudo-binary mixtures (Table I) which traversed the predicted minimum temperature-compositional regime.

A contour diagram of the liquidus isotherms for the LiCl-LiI-KI system, given in Fig. 1, was constructed

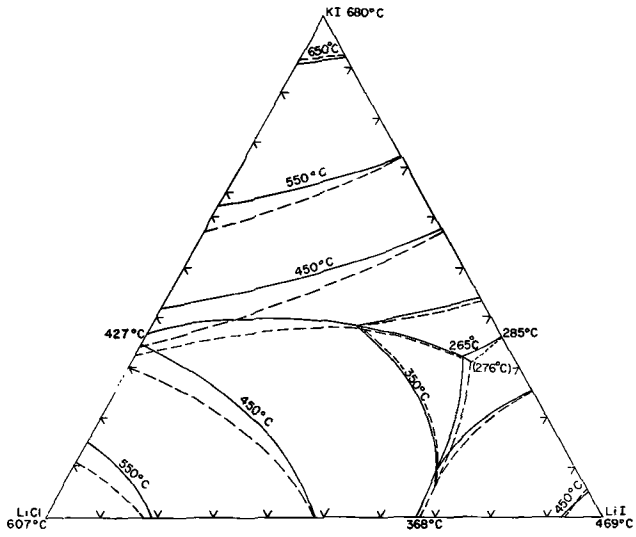

Fig. 1. LiCl-LiI-KI ternary system

from the pseudo-binary data of Table I and data for the three binary component systems. Superimposed on the figure, as dashed lines, are the isotherms predicted by the conformal ionic solution theory. It should be pointed out that the lack of agreement between calculation and experiment for the LiCl-KI binary is principally the result of the very limited experimental data available for this system. The experimental data indicated a eutectic composition of 8.5 m/o LiCl, 59 m/o LiI, 32.5 m/o KI; subsequent chemical analysis confirmed this composition. A single thermal analysis experiment at this composition showed no breaks other than a minimum at 265°C.

The good agreement between the calculated and experimental values and the few experiments required to obtain the necessary data make it clear that the conformal ionic solution theory offers significant saving of experimental effort in the selection of low-melting electrolyte mixtures.

Heat Balances in Mercury-Cathode Chlorine Cells

Scott Lynn*

Department of Chemical Engineering, University of California, Berkeley, California

Substantial quantities of heat are released in both the electrolyzer and the decomposer of a mercury-cathode chlorine cell. Because the mercury stream leaving the one usually enters the other with little change in temperature, the two are not thermally independent. Nevertheless, it is generally convenient to treat the heat balances in the two pieces of equipment separately, with the matching of the mercury temperatures being the final constraint on the problem.

Many papers have appeared in recent years in which various commercially available mercury cells are described in detail. Sommers (8, 9) has described many cells for the purpose of comparison and Gardiner (2) has discussed at length the application of design principles to the development of a specific cell in re-

* Electrochemical Society Active Member.

cent years. The reader is referred to their work for a description of specific design features or operating conditions which may be imperfectly approximated by the generalized treatment of heat balances which follows.

Electrolyzer

In the electrolyzer, part of the sodium chloride in the brine stream is being continuously converted by electrolysis into chlorine and sodium amalgam.

$$NaCl(aq) + Hg \rightarrow Na(Hg) + \frac{1}{2}Cl_2(g) \qquad [1]$$

The enthalpy change of this endothermic reaction, ΔH_E, is +327.0 kj/mole Na. In typical commercial practice, the brine enters the cell nearly saturated (~0.26 w.f. NaCl) and at a temperature of 50°-70°C. It leaves the cell depleted by 10-20% and heated to 70°-90°C. The mercury enters the cell containing virtually no sodium, at 100°-125°C. It leaves the cell at the same temperature as the exiting brine with a sodium content of 0.15-0.45 w/o (weight per cent).

The heat balance for the electrolyzer may be written

$$E\bar{I}A_c = \frac{\bar{\epsilon I}A_c}{nF}\left[\Delta H_E + Cp_B M_{NaCl}\left(\frac{1-x_2}{x_1-x_2}\right)(t_2-t_1) + Cp_{Hg}M_{Na}\left(\frac{t_2'-t_1'}{x_2'-x_1'}\right) + \frac{\Delta H_v}{2}\left(\frac{p_{H_2O}}{\pi-p_{H_2O}}\right)\right] + A_o U_{av}(t_{av}-t_s) \qquad [2]$$

The symbols are listed in the Nomenclature and the value of the various physical properties and other quantities are given in Table I.

It is convenient to divide Eq. [2] by $\epsilon\bar{I}A_c/n\mathbf{F}$ and to evaluate the resulting terms individually:

$$\frac{n\mathbf{F}}{\epsilon}E = \Delta H_E + F_1(x, \Delta t) + F_2(x', \Delta t') + F_3(t_2) + F_4(t, t_s) \qquad [3]$$

where

$$F_1 = Cp_B M_{NaCl}\left(\frac{1-x_2}{x_1-x_2}\right)(t_2-t_1)$$

$$F_2 = Cp_{Hg}M_{Na}\left(\frac{t_2'-t_1'}{x_2'-x_1'}\right)$$

$$F_3 = \frac{\Delta H_v}{2}\left(\frac{p_{H_2O}}{\pi-p_{H_2O}}\right)$$

and

$$F_4 = \frac{n\mathbf{F}}{\epsilon\bar{I}A_c}A_o U_{av}(t_{av}-t_s)$$

The term F_1 corresponds to the increase in sensible heat of the brine. This quantity is a function of the temperature rise and the flow rate. The latter varies inversely with the change of sodium chloride content from cell inlet to outlet. F_2 corresponds to the change in sensible heat of the mercury stream and is directly analogous to F_1. F_3 is the heat required to saturate the chlorine leaving the cell with water vapor. F_4 is the rate of heat loss to the surroundings by natural convection and radiation.

In evaluating these terms, assumptions about the magnitudes of the quantities used must be made. Many of these are arbitrary and may be at variance with known data for a given cell. They are discussed in detail in the Appendix.

The functions F_1-F_4 are plotted in Fig. 1A-D for various values of the temperature and composition parameters. To determine the outlet temperature for operation of a cell, one must know the cell voltage, current efficiency, current density, the inlet temperatures of brine and mercury, and the change in com-

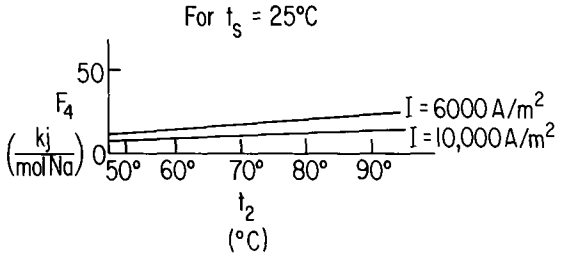

Fig. 1D. Heat effects in electrolyzer: heat loss to surroundings

position which will occur in both streams. By trial and error, one then finds the outlet temperature which satisfies Eq. [3].

Decomposer

In the decomposer, sodium amalgam reacts with water to form sodium hydroxide and hydrogen:

$$Na(Hg) + H_2O \rightarrow NaOH + \frac{1}{2}H_2 + Hg \qquad [4]$$

When enough additional water is supplied to make 50% caustic, the enthalpy change, ΔH_D, of this exothermic reaction is —122.6 kj/mole Na. In most modern cells, the decomposer is a packed bed of graphite chunks having dimensions in the range of 5-15 mm. The volume of the packing varies from 0.005 to 0.010 m³/kA of cell current.

The heat balance in the decomposer may be written

$$-\Delta H_D = F_5(\Delta x', \Delta t') + F_6(x_{NaOH}, t_o') + F_7(x_{NaOH}, t_o') + F_8(t_o', t_s') \qquad [5]$$

where

$$F_5 = Cp_{Hg}M_{Na}\left(\frac{t_o' - t_2'}{x_2' - x_1'}\right)$$

$$F_6 = Cp_{H_2O}M_{NaOH}\left(\frac{1 - x_{NaOH}}{x_{NaOH}}\right)(t_o' - t_s)$$

$$F_7 = \frac{\Delta H_v'}{2}\left(\frac{p'_{H_2O}}{\pi - p'_{H_2O}}\right)$$

$$F_8 = \frac{n\mathbf{F}}{\epsilon \bar{I} A_c}A_o'U_o'(t_o' - t_s) = \frac{n\mathbf{F}}{\epsilon}\left(\frac{4K}{D}\right)U_o'(t_o' - t_s)$$

Equation [5] equates the heat of reaction to the sum of F_5, the increase in sensible heat of the mercury; F_6, the increase in sensible heat of the water; F_7, the heat required to saturate the hydrogen with water vapor; and F_8, the heat lost to the surroundings by convection and radiation.

Because of the stirring effect of the hydrogen and the very long residence time of the caustic solution, there is very little variation in either temperature or caustic concentration in a decomposer. For purposes of calculation both may be assumed constant at the values at the outlet. The assumptions made in making the calculations are given in the Appendix. The functions F_5-F_8 are plotted in Fig. 2A and B as functions of the concentration and temperature parameters. Knowing the temperature of the entering amalgam and its change in sodium content, one finds by trial and error a value of t_2' which satisfies Eq. [5].

Example

Danna (1) cites the data in Table II as being typical of the Olin E-11 mercury cell.

From the data in Table II, one may find the values of F_5-F_8 listed in Table III by trial and error from Fig. 2A and B.

Danna (1) reports the temperature of the mercury leaving the decomposer to be 125°C. Lowering the value of t_1' would increase the difference between the

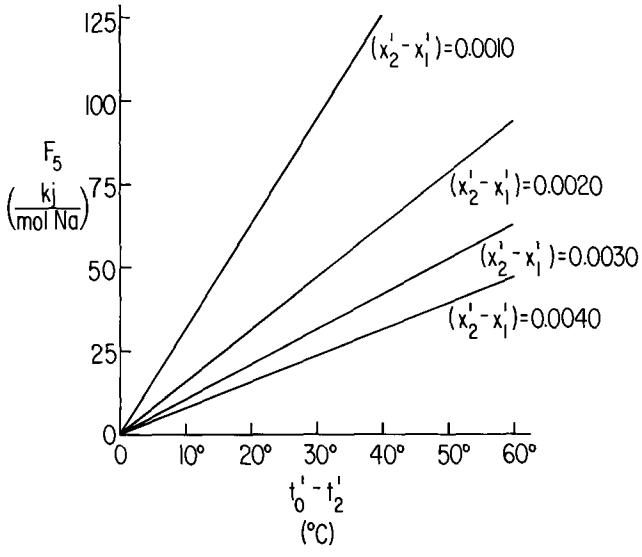

Fig. 2A. Heat effects in decomposer: heat content of mercury

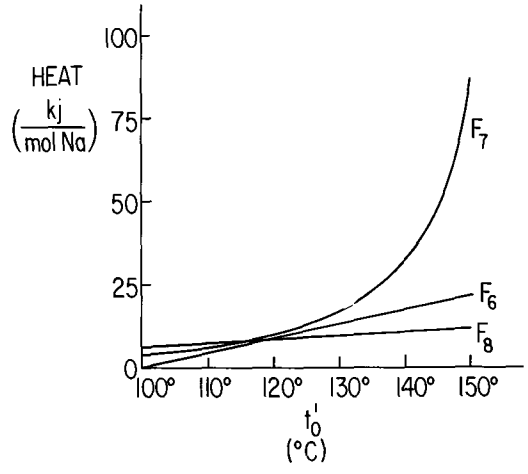

Fig. 2B. Heat effects in decomposer: F_6—heat content of caustic, F_7—heat to vaporize water, F_8—heat loss to surroundings.

heat leaving the cell $\left(\Delta H_E + \sum_{i=1}^{4} F_i\right)$ and the power input $(n\mathbf{F}E/\epsilon)$. The discrepancy may be due to a loss of heat by the amalgam stream between the cell outlet and the decomposer inlet or to the manner in which the data were averaged.

Conclusions

The calculations tabulated in Table III show that in the decomposer of this mercury-cathode chlorine

Table II. Typical operating data for the Olin E-11 mercury cell (1)

Table III. Example of heat balance calculations using data from Table II

Let t_o' = 132°C	Let t_1' = 132°C
F_5 = 77 kj/mole Na	F_1 = 153 kj/mole Na
F_6 = 18	F_2 = −77
F_7 = 18	F_3 = 24
F_8 = 10	F_4 = 14
123 kj/mole Na	ΔH_E = 327
	441 kj/mole Na

$\frac{n\mathbf{F}E}{\epsilon}$ = 434 kj/mole Na for E = 4.26V and ϵ = 95%.

cell about 63% of the heat of reaction is carried out by the mercury stream. The mercury will in general be well above 100°C, a fact which must be taken into account in the design of the mercury pump and piping system. The sensible heat of the mercury stream (F_2) entering the electrolyzer adds significantly (about 72%) to the heat ($n\mathbf{F}E/\epsilon - \Delta H_E$) which is dissipated there. Heat losses to the surroundings play a small role in either balance, being less than 10% of the energy released in the decomposer and also less than 10% of the sensible heat of the brine (F_1) in the electrolyzer.

APPENDIX

In deriving Eq. [3] and [5], a number of simplifying assumptions were made, some arbitrarily and some to facilitate the calculations. In calculations for a specific cell, the reader may wish to change them to fit his own case.

The heats of reaction and all physical properties were assumed constant over the range of temperatures considered. The heats of vaporization were calculated for 75°C for brine and 120°C for caustic using the enthalpy data of Keenan and Keyes (4) and the vapor pressure data of MacMullin (5). In writing the expression for F_3, it is assumed that the water vapor leaving the cell is in equilibrium with the exit brine with respect to temperature. The variation of vapor pressure with brine composition is not large in the range of interest, so a constant ratio of $p_{H_2O}/p^o_{H_2O}$ was taken. The vapor pressure of 50% caustic was calculated in a similar manner.

The external area, A_o, of the electrolyzer was arbitrarily assumed to be 2.2 times the area of the cathode, A_c. Half of this area was assumed to be covered with rubber 8 mm thick and to have the heat-transfer characteristics of a horizontal plate facing up (6). The other half was assumed to be a horizontal plate facing down (6). The heat-transfer coefficients due to convection and radiation, and the thermal resistance of the rubber covering were the only factors considered to be of importance in estimating the heat loss from the cell. The surroundings were assumed to be at 25°C. A more extensive treatment was not considered justified in view of the small fraction of the total heat balance which is represented by F_4.

The decomposer was assumed arbitrarily to be a vertical cylinder with a diameter of 0.8m. Only the sides were considered in the heat-transfer area, but transfer by both radiation and convection was assumed to occur (6). K, the ratio of the volume of the decomposer to the cell current, was taken arbitrarily to be 0.0075 m^3/kA.

NOMENCLATURE

A_c	Area of cathode
A_o	Area of electrolyzer (assumed to be 2.2 A_c)
A_o'	Area of decomposer
Cp	Heat capacity
D	Diameter of decomposer (assumed to be 0.8m)
E	Cell voltage, anode stem to cathode plate
F	Function from Eq. [3] or [5]
$\mathbf{F}$	Faraday, 96,500 A-sec
ΔH	Enthalpy change of Eq. [1] or [4]
ΔH_v	Heat of vaporization of water
$\bar{I}$	Cathodic current density
K	Ratio of decomposer volume to cell current
M	Molecular weight
n	Electrons exchanged in reaction [1] or [4]
p_{H_2O}	Vapor pressure of water over brine
$p^o_{H_2O}$	Vapor pressure of pure water
p'_{H_2O}	Vapor pressure of water over caustic
t_1, t_2	Brine temperature at inlet and outlet of electrolyzer
t_1', t_2'	Mercury temperature at inlet and outlet of electrolyzer
t_{av}	$(t_1 + t_2)/2$
t_o'	Temperature decomposer
t_s	Temperature of surroundings
U	Over-all heat transfer coefficient
x_1, x_2	Weight fraction NaCl at inlet and outlet of electrolyzer
x_1', x_2'	Weight fraction Na in mercury at inlet and outlet of electrolyzer
ϵ	Current efficiency
π	Atmospheric pressure

Erratum

In the paper "β-Silicon Carbide Films" by P. Rai-Choudhury and N. P. Formigoni which was published on pp. 1440-1443 of the October 1969 issue of the JOURNAL, Vol. 116, No. 10, the caption for Fig. 2, p. 1441, should read as follows: "Electron diffraction pattern of a β-SiC film grown on (100) Si substrate; the film is discontinuous showing a strong (100) orientation."

Electrochemical Dissociation of Water Vapor in Solid Oxide Electrolyte Cells

I. Thermodynamics and Cell Characteristics

H. S. Spacil* and C. S. Tedmon, Jr.*

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

This paper describes the dissociation of water vapor in high-temperature, solid oxide electrolyte cells. The characteristics of these cells are related to a composition-dependent open-circuit voltage, which can be obtained from thermodynamic considerations, to ohmic resistance, and to mass transport overvoltages. The problem of maintaining a heat balance in a system consisting of such cells is considered in terms of the heat loss through the leads connecting the cells with the surroundings. A conclusion is that the electrical energy requirement for dissociation can be reduced substantially by series connection of individual cells within the high-temperature region of the system, but that ohmic resistance limits the optimized current density through the electrolyte to values well below the maximum values that are feasible.

A recent development in the science and technology of solid oxide electrolyte cells is the application of such cells for the electrochemical dissociation of water vapor (1-3). The practical motivation for this application is the generation of inexpensive and pure hydrogen (3-4). It is the purpose of this paper to provide a definitive quantitative description of the thermodynamic and electrochemical characteristics of these cells for the various possible modes of operation. In a subsequent paper (5), the authors discuss materials, design, and fabrication problems of such cells, in the contexts of both single cells, and also multicell batteries, or "stacks."

In the first section of this paper, a generalized thermodynamic treatment of a high-temperature electrochemical cell system is presented. The analysis, subject only to the restrictions that it applies to electrochemical cells with invariant electrolytes and gaseous reactants and products, yields relationships between cell parameters in a form that is especially useful for consideration of steady-state systems which show large composition changes in going from reactants to products. In addition, this approach, in its general form, is independent of the nature of the electrode reactions. This feature is useful in dealing with water vapor dissociation cells, since these can be operated in various modes, each having different restrictions on the electrode reactions. It should be noted that this treatment would also be applicable to high-temperature fuel cell systems, but, due to the specialized nature of these, a different and more detailed analysis has been shown to be useful (6).

In succeeding sections, appropriate parameters for characterization of gas compositions at the cathode and anode are presented. Then these are used to apply the thermodynamic analysis specifically to water vapor dissociation cells employing oxygen ion electrolytes; two possible anode reactions are treated separately. Predictions of cell characteristics are compared with experimental results.

The final section of this paper presents a quantitative analysis of system heat balance. The general problem here is closely related to that of any high-temperature electrochemical, thermoelectric, or thermionic system, namely, the transmission of electric power between the high-temperature portion of the system and the ambient temperature surroundings while minimizing heat losses through the transmission leads. Results are presented for a representative system and used to demonstrate the necessity for achieving intercell connections in the high-temperature region, as well as for optimizing lead geometry.

Key words: dissociation, water vapor, oxide electrolyte.

General Thermodynamics

A generalized high-temperature electrochemical cell system is shown schematically in Fig. 1. A single cell will be considered initially. Gaseous reactants, with molar flow rates $\dot{m}_{in}$ and temperatures T_{in} react electrochemically in an isothermal zone at temperature T to form gaseous products with molar flow rates $\dot{m}_{out}$ and temperatures T_{out} and to generate heat at a net rate $\dot{Q}$. A current I is supplied to the cell at a voltage E; with this convention, positive values of I and E represent a consumption of energy at a rate $\dot{W} = EI$, in watts, by the cell. The electrolyte composition is assumed to be invariant, as will be the case with solid oxides, and the gases are assumed to be thermally perfect so that their enthalpy contents are independent of pressure.

The net flow rate of some substance, or combination of substances, into or out of the system will be of interest. For the specific case of water vapor dissociation, this will be the net flow rate of water vapor which is dissociated at the cathode. In the general case, this substance can be termed the critical component, and its molar flow rate denoted by $\dot{m}^*$. This flow rate then provides a base to which other mass and energy flow rates can be referred. This steady-state approach is useful when considering the effects of irreversible phenomena, such as heat loss, as is shown subsequently.

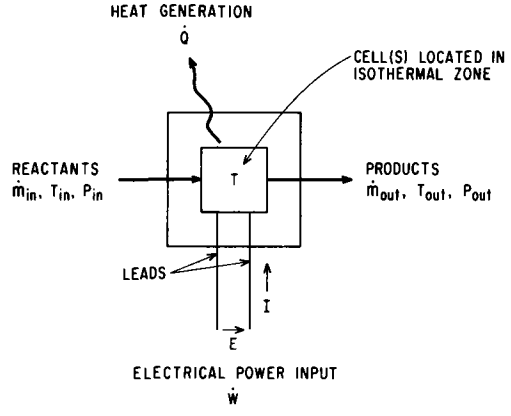

Fig. 1. Generalized high-temperature electrochemical system

Gibbs free energy change.—For the electrochemical reaction at temperature T, the rate of Gibbs free energy change for the system is $\dot{G}_T$. The partial molar Gibbs free energies of the species present can be summed to give this quantity relative to $\dot{m}^*$ as

$$\dot{G}_T/\dot{m}^* = \Delta G^{o*}{}_T + \sum_{out} [RT \sum_{s} x_s \ln (x_s P_{out})] \dot{m}_{out}/\dot{m}^* - \sum_{in} [RT \sum_{s} x_s \ln (x_s P_{in})] \dot{m}_{in}/\dot{m}^* \quad [1]$$

where $\Delta G^{o*}{}_T$ is the difference between the standard Gibbs free energies of formation of the products and reactants at temperature T, per mole of the critical component entering or leaving the cell. The summation over the index s is a summation of the product of the mole fraction x_s of each molecular species present in the product and reactant streams, and the logarithm of the same mole fraction multiplied by the total pressure, P_{out} or P_{in}, of each stream. The factor R is the gas constant per mole. The two summations are obviously entropy terms and, for equal total pressures on both sides of the electrolyte, will represent the entropy of mixing each reactant and product stream.

By neglecting frictional energy losses in the gas streams, an extension of the usual expression for the reversible electrical work obtainable in an isothermal process (7) allows an average open-circuit voltage for the cell to be obtained as

$$\overline{E}_o = (\dot{G}_T/\dot{m}^*)/z^*\mathbf{F} \quad [2]$$

where z^* is the equivalents per mole (in terms of electrons transferred through the external circuit) of the critical component, and $\mathbf{F}$ is the Faraday constant in coulombs per equivalent; $\dot{G}_T/\dot{m}^*$ must be expressed in consistent units of joules/mole. This voltage is a purely thermodynamic quantity since cell geometry and flow directions do not enter into its definition. We have termed it an average voltage since it applies to a cell in which finite changes occur in the composition of the gases passing through the cell. This composition change results from a finite cell current so that $\overline{E}_o$ varies with cell current for given reactant flow rates. Thus only the static value of $\overline{E}_o$ at zero current will be equal to the open-circuit voltage due to unchanged reactants as introduced into the cell. Appendix I shows that the value of $\overline{E}_o$ given by [2] is that of a cell with uniform current density, and which is so large that end effects can be neglected. The first of these conditions applies approximately to real single cells in which electrolyte resistivity causes the major voltage drop across the cell, and to "stacks" of series-connected cells of equal area with the same current flowing through each cell. The second condition applies to cells whose linear dimension perpendicular to the electrolyte surface is small compared to the linear dimension parallel to the direction of gas flows; this criterion is generally satisfied by the geometry of real cells. To the extent that $\overline{E}_o$ represents the average open-circuit voltage of a real cell, it could be measured experimentally in the absence of mass transport or adsorption effects by a current interruption technique. Also, with the polarity conventions used, $\overline{E}_o$ is a minimum voltage that must be overcome in order to drive current through the cell; a negative value for $\overline{E}_o$ thus indicates a cell that will operate spontaneously.

Enthalpy change.—The rate of enthalpy change for the system is $\dot{H}$, which can be expressed relative to $\dot{m}^*$ as

$$\dot{H}/\dot{m}^* = \Delta H^{o*}{}_T + \sum_{out} [x_s (H^o{}_{T_{out}} - H_T{}^o)_s] \dot{m}_{out}/m^* - \sum_{in} [x_s (H^o{}_{T_{in}} - H_T{}^o)_s] \dot{m}_{in}/\dot{m}^* \quad [3]$$

where $\Delta H^{o*}{}_T$ is the difference between the standard enthalpies of formation of the products and reactants at temperature T, per mole of the critical component entering or leaving the cell. The summation over the index s is a summation of the product of the mole fraction x_s of each molecular species present in the product and reactant streams, and the difference in standard molar enthalpy content for that species. The latter is the difference between the enthalpy content at the stream temperature, $H^o{}_{T_{out}}$ or $H^o{}_{T_{in}}$, and the enthalpy content at the cell temperature, $H^o{}_T$.

By analogy with $\overline{E}_o$, the rate of enthalpy change can be related to a voltage, for convenience in formulation of the expression for the net heat generation rate, by

$$\overline{E}_H = (\dot{H}/\dot{m}^*)/z^*\mathbf{F} \quad [4]$$

where $\dot{H}/\dot{m}^*$, like $\dot{G}_T/\dot{m}^*$, must be expressed in consistent units of joules/mole. Reactant and product stream temperatures must be specified to evaluate $\overline{E}_H$. If these temperatures were the same as the cell temperature, then the last two terms on the right-hand side of Eq. [3] vanish, and the resultant value of $\dot{H}/\dot{m}^*$ applies to the electrochemical reaction at temperature T. Under these conditions, the value of $\overline{E}_H$ from Eq. [4] can be denoted by $\overline{E}_H(T)$; a positive value of $\overline{E}_H(T)$ indicates an endothermic cell reaction, while a negative value indicates an exothermic cell reaction. While the value of $\overline{E}_H(T)$ does not apply to the complete cell system with reactants and products at temperatures which differ from the cell temperature, this value does provide a guide to heat effects in the cell itself.

Electrical and thermal characteristics.—The total current I through the cell is the product $z^*\dot{m}^*\mathbf{F}$. Denoting the total active electrolyte area by A, the average current density $\bar{j}$ is I/A. Neglecting lead resistances for the moment, and with the sign convention of Fig. 1, the total cell voltage can be written in terms of $\bar{j}$ as

$$E = \overline{E}_o + r\bar{j} \quad [5]$$

where r is the apparent specific resistance of the cell. This quantity is the resistance of a hypothetical cell of unit area which has the same electrical characteristics as the actual cell. It will, in general, include contributions from electrode resistance and nonohmic overvoltages, but in many high-temperature cells the latter are often small or negligible (6). The energy input to the cell, per mole of the critical component, is $\dot{W}/\dot{m}^*$, which can be rewritten as $z^*\mathbf{F}E$. Thus the energy input is directly proportional to E, and will be influenced by both $\overline{E}_o$ and r. Finally, neglecting energy losses due to friction in gas flow, the net heat generation rate, $\dot{Q}$, will be the sum of $-\dot{H}$ and $\dot{W}$. This rate can be then expressed per unit of cell area in terms of $\bar{j}$ as

$$\dot{Q}/A = (-\overline{E}_H + \overline{E}_o + r\bar{j})\bar{j} \quad [6]$$

Equations [2], [4], [5], and [6] have been presented for a single cell. If the system of Fig. 1 were extended to include several cells in parallel, these same equations would apply to each cell. If several cells in series are considered, the equations still apply on the average to each cell, even though no one particular cell would necessarily have the voltage and heat generation rates given by these equations which are based on over-all compositional changes. The energy input per mole of the critical component will likewise be given by $z^*\mathbf{F}E$ regardless of the actual cell arrangement.

Water Vapor Dissociation in Oxide Electrolyte Cells

Taking the amount of water vapor dissociated at the cathode as the critical component, z^* is 2 for an electrolyte conducting by O^{--} ions, so that the electri-

cal energy requirement per mole of water vapor dissociated is then 2 $\mathbf{F}E$. This will be true regardless of the nature of the anode reaction.

Solid oxide electrolytes based on stabilized zirconia having a cubic fluorite structure typically exhibit resistivities (due to O^{--} conduction) of the order of 10 ohm-cm at temperatures of 1000°C; the energy of activation for the conduction process is about 20 kcal/mole (8). These electrolytes can readily be fabricated in thicknesses down to about 0.5 mm; the electrolyte contribution to the specific resistance is the product of resistivity and thickness, and thus should be of the order of 0.5 ohm-cm^2 for the conditions quoted. Current densities in the range of 1-2 A/cm^2 should then cause the $r\bar{j}$ term in Eq. [5] to contribute about 1V to the value of E. The exact value of $\bar{E}_0$ can therefore be expected to have a significant influence on the total cell voltage. Theoretical and experimental values for $\bar{E}_0$ are presented in the following sections. Heat balance considerations, however, can strongly affect system performance; a detailed discussion is presented in a subsequent section, and continued in Part II (5).

Characterization of cathode gas.—Since water vapor and hydrogen are the only species present at the cathode, the mole fraction of water vapor at the cathode, y_C, can be used to describe the composition of the gas mixture at this electrode. Superscripts i and f are used to denote the initial (entering) and final (exiting) compositions, respectively. The flow rate of reactants to the cathode can conveniently be described in terms of the average current density that would be required to dissociate all of the water vapor entering the cell, plus the amount of water vapor that would be present if the hydrogen entering the cathode side of the cell (to prevent cathode oxidation) were in the form of water vapor. Denoting this current density by J_C, the value of $\bar{j}$ can be expressed as

$$\bar{j} = J_C(y_C{}^i - y_C{}^f) = J_C y_C{}^i x_C \qquad [7]$$

where x_C is the fraction of entering water vapor dissociated in the cell. Since x_C cannot exceed unity, the maximum value of $\bar{j}$ is thus $J_C y_C{}^i$.

Since $y_C{}^i$ and x_C characterize the initial composition and the composition change taking place in the cathode gas, the value of $\bar{E}_0$ for an oxygen anode cell will depend on these two quantities. The factor J_C cancels from Eq. [1], as it should if $\bar{E}_0$ is a purely thermodynamic quantity, when molar flow rates are expressed in [1] in terms of J_C, $y_C{}^i$, and either x_C or $y_C{}^f$. Appendix II indicates the nature of this substitution.

Oxygen Anode Dissociation Cell

The most straightforward type of dissociation cell is one in which the anode reaction involves the formation of O_2, and is

$$O^{--}\ (\text{electrolyte}) \rightarrow \frac{1}{2}O_2(\text{gas}) + 2e^-\ (\text{electrode})$$

Calculated voltages.—The value of $\bar{E}_0$ for an oxygen anode cell at a given temperature will depend on the initial composition of the cathode gas. Figures 2 and 3 show the variation of $\bar{E}_0$ as a function of x_C for this type of cell, calculated using Eq. [1] and [2] for three different initial compositions of the cathode gas at a single temperature, and for four different temperatures at the same initial composition, and a total anode pressure of 1 atm. The values at the left side of each plot, where x_C is zero, are the static open-circuit voltages that would be observed with no current flow. Figure 3 clearly shows the advantages of dissociation at higher temperatures as regards decreasing the open-circuit voltage. The value of $E_H(T)$ is about 1.29V for operating temperatures around 1000°C. This is of course due to the endothermic nature of the dissociation of water vapor to its elements, which is the overall cell reaction in this case. Since $\bar{E}_H(T)$ is greater in magnitude than $\bar{E}_0$, reference to Eq. [6] shows that at low current densities the cell itself is endothermic.

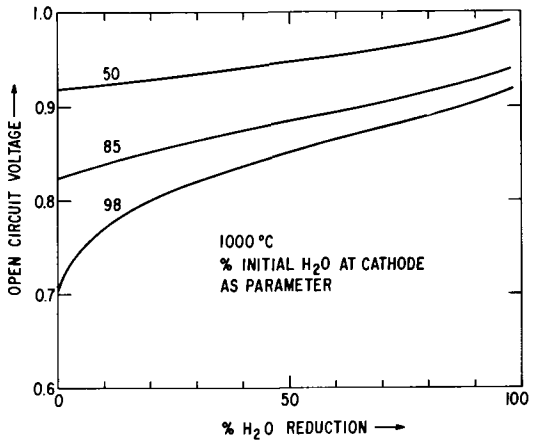

Fig. 2. Computed average open-circuit voltages for water vapor dissociation in an oxygen anode cell at various initial H_2O concentrations.

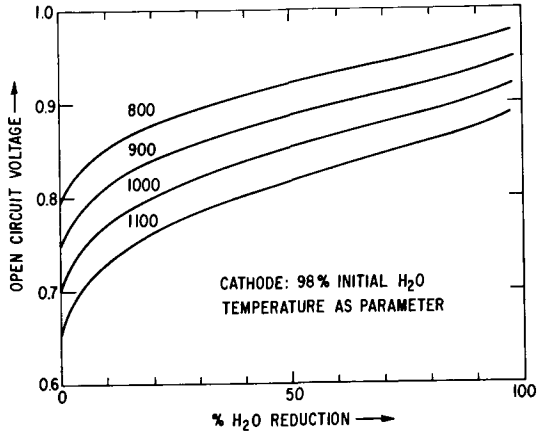

Fig. 3. Computed average open-circuit voltages for water vapor dissociation in an oxygen anode cell at various cell temperatures.

Depolarized Anode Dissociation Cell

The open-circuit voltage of a dissociation cell can be reduced by introducing a reducing fuel gas to the anode so that the anode reaction becomes

$$O^{--}\ (\text{electrode}) + \text{fuel (gas)} \rightarrow \text{oxidized fuel (gas)} + 2e^-\ (\text{electrode})$$

The low oxygen potential of the fuel in this type of cell will obviously reduce $\bar{E}_0$, as compared to an oxygen anode cell, and can thus reduce the energy required for dissociation.

Characterization of anode gas.—Fuels derived from hydrocarbons are of the most interest. Two parameters useful to describe such fuels in high-temperature cells are the normalized hydrogen-to-carbon ratio, and the relative oxidation. These quantities, denoted by h and y_A, respectively, can be most simply expressed in terms of the atom fractions of total carbon, hydrogen, and oxygen content in the fuel gas. Representing the latter by f_C, f_H, and f_O, the values of h and y_A as fractions are given by

$$h = f_H/(f_C + f_H) \qquad [8]$$

$$y_A = 2(f_O - f_C)/(2f_C + f_H) \qquad [9]$$

The relative oxidation can thus be considered as a normalized quantity that is proportional to the extent that CO and H_2 in a fuel gas have been converted to

CO_2 and H_2O. Neither of these parameters, nor the resulting open-circuit voltage, is sensitive to the presence of an inert diluent in the fuel gas. Any diluent present, however, may affect mass transport in the gas phase. The flow rate of reactants to the anode, exclusive of diluent, can then be conveniently described in terms of the current density that would be required to oxidize all of the carbon plus hydrogen entering the anode side of the cell if this carbon and hydrogen were in the form of CO and H_2. Denoting this current density by J_A, the value of $\bar{j}$ can be expressed as

$$\bar{j} = J_A(y_A{}^f - y_A{}^i) = J_A(1 - y_A{}^i)x_A \qquad [10]$$

where superscripts i and f indicate initial (entering) and final (exiting) compositions, respectively, and x_A is the fraction of the entering fuel oxidized in the cell. Diluent flow rates can be expressed relative to J_A in any desired fashion, such as a ratio of diluent to entering fuel. Since x_A cannot exceed unity, an additional constraint on the cell in this case is that the value of $\bar{j}$ cannot exceed $J_A(1 - y_A{}^i)$. The value of $\bar{E}_0$ will now depend on $y_A{}^i$ and x_A as well as on $y_C{}^i$ and x_C.

Calculated voltages.—The value of $\bar{E}_0$ at a given temperature will now depend on the initial compositions of both the cathode and anode gases, including the value of h for the fuel. Figure 4 shows the *loci* of values of constant $\bar{E}_0$ values, obtained using Eq. [1] and [2], in the x_C-x_A plane for specific initial gas compositions at 1000°C employing a substitution similar to that outlined in Appendix II. The value of −0.365V at the origin, where x_C and x_A are both zero, is the static open circuit that would be observed with no current flow.

The value of $\bar{E}_H(T)$ for a depolarized anode cell will be much smaller in magnitude than for an oxygen anode cell; the over-all cell reaction involves simultaneous fuel oxidation as well as water vapor dissociation, and the enthalpy changes at cathode and anode nearly cancel. There is a slight dependence of the enthalpy change on x_C; typical values of $\bar{E}_H(T)$ for the same conditions as given in Fig. 4 are from −0.05 to −0.06V. Thus the over-all cell reaction is slightly exothermic, but the effect is generally overshadowed by the enthalpy content changes of reactants and products if these enter and leave the cell system at different temperatures.

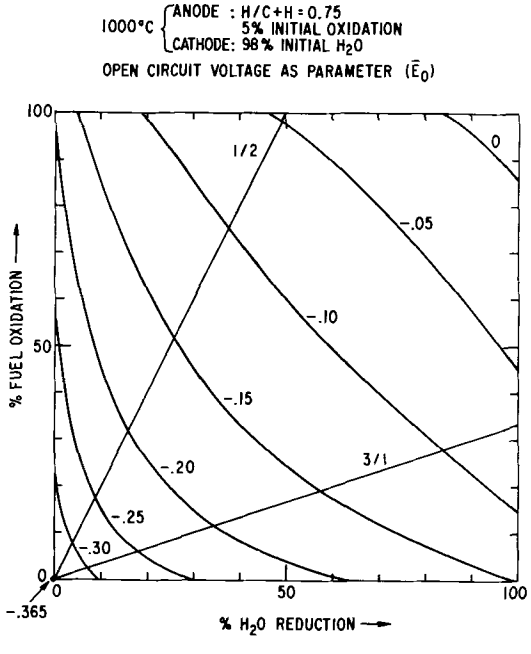

Fig. 4. Computed average open-circuit voltages for water vapor dissociation in a depolarized anode cell. Operating lines at fuel/water vapor flow rate ratios of 1/2 and 3/1 are superimposed.

Operating lines.—Equations [7] and [10] must describe the same current density. They can thus be combined to give the relation

$$J_C y_C{}^i x_C = J_A(1 - y_A{}^i)x_A \qquad [11]$$

This is a straight line in the x_C-x_A plane, and can be superimposed on a plot of $\bar{E}_0$ values as shown in Fig. 4 to give an operating line that will be followed by the cell with a constant ratio of fuel to water vapor flow rates. For a slope of unity, the operating line will describe cell operation which can simultaneously dissociate all the water vapor and oxidize all the fuel; generally either water vapor or fuel will be a limiting reactant. Figure 4 illustrates operating lines for fuel/water vapor flow rate ratios of 1/2 (fuel oxidation limiting at 50% water vapor reduction) and 3/1 (water vapor reduction limiting at 33% fuel oxidation).

Self-driven dissociation cells.—The cell voltage E of a short-circuited depolarized anode cell will obviously be zero. Applying this conditon to Eq. [5] and combining [5] and [7] yields the condition for x_C in this mode of operation as

$$-\bar{E}_0/x_C = rJ_C y_C{}^i \qquad [12]$$

Since $\bar{E}_0$ can be negative for a depolarized anode cell, the left-hand side of [12] can be positive. This self-driven mode of operation has been observed experimentally; the cell becomes, in effect, a fuel cell with water vapor as the oxidant. The operating line specified by Eq. [11] can be used to solve [12] graphically. But, even without following such an approach in detail, it is apparent that the low open-circuit voltages limit this type of operation to small current densities with the electrolytes generally available. Hence these cells are not discussed further here.

Experimental Results

Figure 5 is a schematic cross section through the active portion of a dissociation cell. Details of the construction and fabrication of such cells are presented in Part II (5). Yttria-stabilized zirconia 0.5-0.6 mm thick was normally used as the electrolyte. Cathodes were made from porous nickel, while anodes consisted either of various porous electronically conducting oxides for oxygen anode cells, or porous nickel for depolarized anode cells. Cells were operated in electrically heated furnaces, with control thermocouples attached to the outer electrode.

Cell measurements.—The cell voltage was measured by potential probes attached to the electrodes, eliminating voltage drops in the current leads. Although Fig. 5 shows current leads attached only to one end of the electrodes, most experimental cells had current leads at both ends of the electrodes. Materials for current leads, and contact resistances between these and electrodes, are discussed elsewhere by the authors (9). The auxiliary electrodes allow measurements of open-circuit voltages $E_0{}^i$ and $E_0{}^f$ that are related to the cathode and anode gas compositions at the entrance

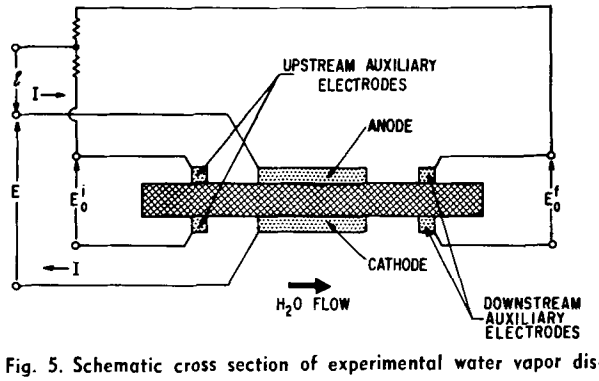

Fig. 5. Schematic cross section of experimental water vapor dissociation cell.

and exit ends of the cell. A simple resistance network, as shown, provided a linear average of these two voltages; this average is very nearly $\bar{E}_0$. Thus the difference between this experimentally measured value of $\bar{E}_0$ and E is the total overvoltage $\mathcal{E}$. In the absence of nonohmic overvoltages, the value of $\mathcal{E}$ will be equal to $r\bar{j}$, so that the slope of a plot of $\mathcal{E}$ against $\bar{j}$ should yield r.

Typically, E, ϵ, and either E_0^f or the average value of E_0^i and E_0^f were measured while the current was automatically swept from zero to a preset maximum (limiting ϵ to a maximum of 1.5-2V to prevent electrolysis of the zirconia), and back to zero over a time of about 25 min. Negligible hysteresis to the voltages was observed, and cell temperature remained constant to better than 5°C.

The value of $\mathcal{E}$ was, in general, not a linear function of current density, as it should be if it represented only a resistive voltage drop. In these cells, this can be ascribed primarily to mass transport overvoltages in the gas phase, within the pores of the electrodes. These effects, which are also encountered in measurements of high-temperature fuel cells, are detailed elsewhere in this context, as well as a discussion of the effects of electrode resistances (6). A conclusion of the cited study is that a value of r can be derived by suitably processing data on the variation of $\mathcal{E}$ with current density. The resultant value of specific resistance will contain an averaged contribution from mass transport effects. This is typically of the order of 0.05 ohm-cm² for the 0.15-mm thick electrodes generally employed, and is not a strong function of temperature since gaseous diffusion is not a thermally activated process.

Additional measurements were made on selected cells. These included leakage rate at operating temperatures, and electrode specific resistivity, as discussed in connection with high-temperature fuel cells (6). Leakage rates were of the order of 25 mA/cm² when expressed as an equivalent current density and can be neglected in comparison to the imposed current density. These leakage tests could also be used to show that electronic conductivity in the electrolyte was less than 1% of the total conductivity. Nickel electrodes showed specific resistivities of about 0.05 ohm/sq, and various oxide anodes exhibited specific resistivities of about 0.15 ohm/sq for 0.15-mm thicknesses. The contributions due to mass transport and electrode specific resistivity (which depend on cell geometry) were taken into account when calculating the cell specific resistances employed in subsequent sections.

Oxygen anode cells.—Figure 6 shows typical voltage/current density characteristics for an oxygen anode cell operated with an excess water vapor flow. The value of $J_C y_C{}^i$ was about 3 A/cm², so that at most only about 35% of the entering water vapor was dissociated at maximum current. The entering cathode gas nominally contained 50% water vapor so that the cell could be operated in a reverse direction (negative current density, with the sign convention used) while oxygen was supplied to the anode side; under these conditions, the cell becomes a hydrogen/oxygen fuel cell. The sign of the total overvoltage must then be reversed, but its significance remains the same.

The value of E at zero current is about 0.88V; this is close to the static value of $\bar{E}_0$ that would be expected from Fig. 2. The discrepancy is most probably due to deviations of the cathode feed from the nominal composition. Figure 2 also indicates that for the operating conditions of this cell, $\bar{E}_0$ should increase by only about 0.03V at most from the static value. Thus the shape of E with current density should closely parallel that of $\mathcal{E}$ for operation in the forward direction, with a constant separation for the two curves not varying by more than 0.03V. This can be verified by direct measurement in Fig. 6.

Although E is not symmetric with current density about the zero current point, $\mathcal{E}$ is symmetric about this point to within about 0.02V at 1 A/cm². The causes of the nonlinearity of $\mathcal{E}$ have already been mentioned. The symmetry of this voltage about the zero current point demonstrates that activation-type overvoltages are small, compared to resistive voltages, since these would not be symmetric with respect to direction of current flow if large. On the other hand, mass transport overvoltages at the cathode would arise primarily from water vapor/hydrogen interdiffusion, and would be expected to be symmetric. There should, of course, be no such overvoltage at the oxygen anode in the absence of a diluent, and comparison of the properties of the O_2 anode with those computed for a porous Cl_2 electrode shows that the anode pore sizes are sufficiently large to rule out any mass transport overvoltage due to viscous drag forces (10).

The asymmetry of E in Fig. 6 can then be ascribed chiefly to the fact the $\bar{E}_0$ is not symmetric with respect to the direction of current flow. This is most likely due in this case to deviations of the initial cathode gas composition from its nominal value.

Depolarized anode cells.—Figure 7 presents typical voltage/current density characteristics for a depolarized anode cell operated with limited water vapor and fuel flows. The value of $y_C{}^i$ was 0.85, and hydrogen was used as the fuel with a value for $y_A{}^i$ of 0.03. Flow rates were adjusted so that both $J_C y_C{}^i$ and $J_A(1 - y_A{}^i)$ were

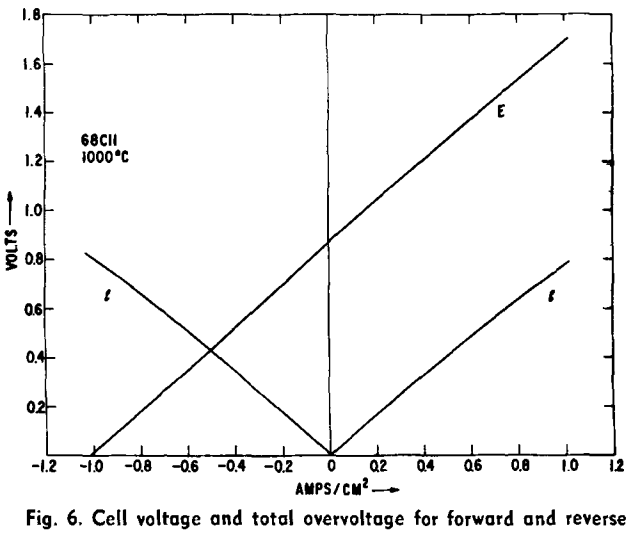

Fig. 6. Cell voltage and total overvoltage for forward and reverse operation of an oxygen anode cell with excess water vapor.

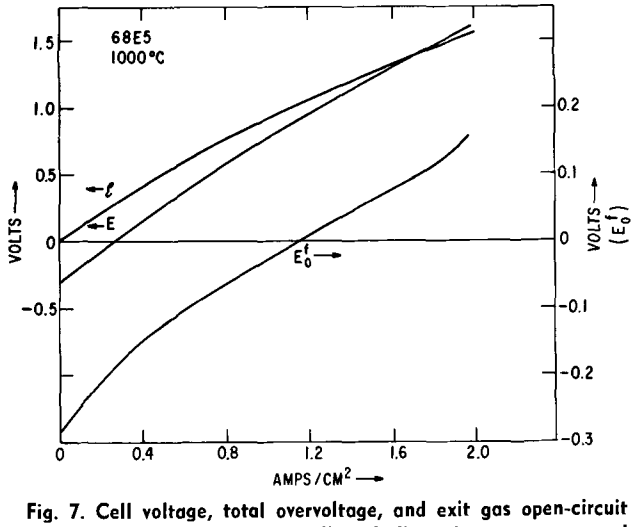

Fig. 7. Cell voltage, total overvoltage, and exit gas open-circuit voltage for depolarized anode cell with limited water vapor and fuel.

about 2.6 A/cm². Thus, at maximum current, about 75% of the entering water was dissociated and a similar amount of the entering fuel oxidized. Water vapor and fuel flows were in the same direction along the length of the tubular cell. Thus E_o^f could be measured to provide an indication of the change in water vapor dissociation, relative to fuel oxidation, at the exit end of the cell where both cathode and anode gases had their final composition. The value of E_o^i will be constant and equal to the static value of E_o^f, about —0.28V (this can be verified by direct measurement). Thus the value of $\overline{E}_o$ can be obtained by averaging the value of E_o^f with this static value.

The static value of E is negative at about —0.3V, which is generally consistent with Fig. 4 even though initial gas compositions are not identical. The static value of E in this cell is about 1.2V below that of the oxygen anode cell just described; this is a specific demonstration of the generalization that the low oxygen potential of the fuel in a depolarized anode cell reduces the amount of electrical energy (other factors being equal) required to dissociate a mole of water vapor.

Also, in contrast to the oxygen anode cell, Fig. 4 indicates that, for the depolarized anode cell being considered here, $\overline{E}_o$ should increase at maximum current by about 0.25V. Thus E should increase more rapidly with current density than $\mathcal{E}$. This is clearly shown in Fig. 7, which also shows that $\overline{E}_o$ (as measured by the average value of E_o^f) increases from —0.28 to —0.06V at 2 A/cm². Further, the change in sign of E_o^f at current densities above 1.2 A/cm² is direct evidence of the fact that the water vapor/hydrogen ratio in the exiting cathode gas is lower than the same ratio in the exiting hydrogen-base fuel gas at the anode side of the cell as a result of O^{--} transfer through the electrolyte.

It is apparent from Fig. 7 that $\mathcal{E}$ is more nonlinear for the present cell than for the oxygen anode cell with the characteristics of Fig. 6, even taking into account the different voltage scales of these two figures. The depolarized anode cell, however, has two electrodes at which mass transport overvoltages can occur, while the oxygen anode has only one. A greater degree of nonlinearity would therefore be expected for the former type of cell. It should be noted that the magnitude of mass transport overvoltages is fairly sensitive to electrode structure since these have connected porosities of only 15-30%.

System Heat Balance

It has been demonstrated that the characteristics of dissociation cells can be accounted for in terms of their average open-circuit voltage, specific resistance (ohmic), and mass transport overvoltage. Although the last is nonlinear in current density, its effect can be approximated by adding a constant to the specific resistance, provided this constant is small compared to the ohmic portion of r.

The determination of the actual system performance, *i.e.* the value of $\dot{W}/\dot{m}^*$, cannot be carried out unless the system satisfies some heat balance criterion. Consider again the system of Fig. 1. In this system, the reactant and product flows are depicted as completely separate from the leads. A real system may not have this separation, since gas and current flows may follow the same path to the cells, but the separation is useful to allow a first approximation to a heat balance which is informative as to effect of cell characteristics and lead materials on system performance. This approximation consists of the assuming that (*a*) the net heat generation rate is given by Eq. [6], which from Eq. [3] and [4] contains the effects of reactant and product temperatures as well as the enthalpy change at the cell temperature, and (*b*) the only heat loss from the cells is through the leads themselves, since in principle the thermal insulation and radiation shielding around the cells can be made sufficiently good to reduce all other heat losses to an arbitrarily low value. The latter assumption will be increasingly valid as system size increases, but the leads will always remain as a relatively high thermal conductivity path to the surroundings since they must in general be fabricated from metals or alloys exhibiting high electrical conductivity at all temperatures between that of the cells and the surroundings.

The question of multicell systems also arises. Without losing generality, any such system can be considered to consist of a set of "stacks," each containing N cells connected in series both electrically and chemically; the set of stacks are in parallel chemically and either in series or parallel electrically. The total area of all cells is still represented by A, and all intercell electrical connections must be made entirely within the hot zone at the cell temperature.

Thermal effects in leads.—Figure 8a represents a single lead of length L_l and cross section A_l extending through the thermal insulation around the cells. The thermal conductivity K of the lead material will be much higher than that of the thermal insulation, so that heat flow through the latter can be neglected, resulting in a one-dimensional problem. The lead carries the total current I which causes Joulean heating of the lead itself. The temperature T_l of the lead must be evaluated as a function of position x along the lead from a value of T at the inner (hot) end to a value of T_o at the outer (ambient) end. Then the heat loss from the cells into each lead will be proportional to A_l and to the product of K and the temperature gradient dT_l/dx in the lead at the inner end, denoted by a subscript (0). As indicated in Fig. 8a, K is a function of temperature, and thus of position along the lead.

Figure 8b shows the heat flows into and out of a thin slice of the lead, and the heat generation rate in the slice due to Joulean heating. The latter will be proportional to the square of the current and the lead resistivity ρ, which like K is a function of temperature. In the steady state, the net heat flow out of the slice must be equal to the heat generation rate in the slice, allowing a differential equation for T_l to be obtained as

$$A_l \frac{d}{dx}\left(K\frac{dT_l}{dx}\right) + \frac{I^2\rho}{A_l} = 0 \qquad [13]$$

Electrical and thermal conductivities in metals.—At ambient temperatures and higher, free electrons are responsible for both electrical and thermal conductivity in metals; in contrast to nonmetals, very little contri-

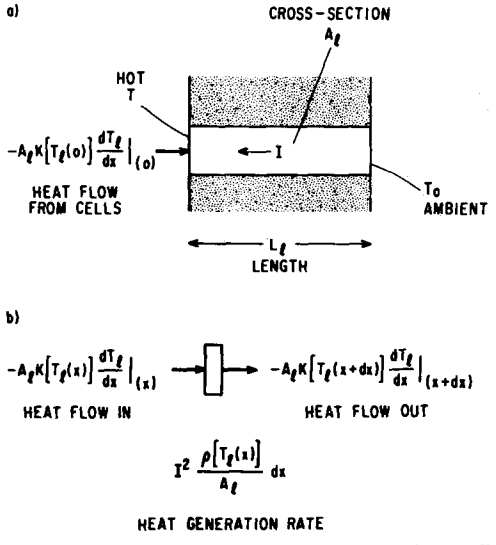

Fig. 8. (a): Schematic representation of lead, and heat flow from cells into inner end of lead. (b): Differential heat flows within lead.

bution is made to thermal conductivity by the metal atoms. As a result, a simple treatment (11) based on free electron mean path lengths in a metal predicts that electrical and thermal conductivity should be related by

$$K = \lambda\sigma T \qquad [14]$$

where λ is the Lorenz Number, with a value of 2.45 x 10^{-8} (V/°K) (2). In this treatment, the electrical conductivity itself is inversely proportional to $T + \theta$, where θ is a temperature characteristic of the metal. Two limiting cases are then possible, and are described briefly.

Pure metals.—For pure metals, θ/T is generally much less than unity as a consequence of free electron mean path length being determined primarily by thermal vibrations of the metal atoms. Then it can be shown that, for these materials, the product of the thermal coefficient of resistivity α and the resistivity ρ should be constant, independent of temperature. Available data show that this product has an average value of from about 6 x 10^{-9} ohm-cm/°K for silver to 6 x 10^{-8} ohm-cm/°K for nickel.

Alloys.—In alloys, free electron mean path length is influenced mainly by the spacing between solvent and solute atoms, causing θ/T to be much greater than unity. Then for, such materials, the resistivity ρ should be constant and independent of temperature. Many alloys based on ferrous metals or copper which contain substantial amounts of alloying additions (20% or more) have resistivities of the order of 1 x 10^{-4} ohm-cm over a fairly wide temperature range.

These electrical characteristics of pure metals and alloys as just described are approximations but are not grossly in error. For example, the resistivity of an alloy may vary by a factor of 1.5 from room temperature to 1000°C. In contrast, the resistivity of a pure metal can change by a factor of 5 or 6 over the same temperature range while its temperature coefficient-resistivity product remains constant to within 25%. The value of these approximations is that they allow relatively simple solutions of Eq. [13] in closed form, simplifying the problem of examining the effects of these two classes of lead materials on the operating point of a cell system as determined by heat balance criteria.

Heat loss and power loss in leads.—The pure metal and alloy approximations can each be introduced in turn into Eq. [13], along with the relationship of Eq. [14]. Solutions to [13] are then possible which allow evaluation of the rate of heat loss through each lead. For simplicity, two identical leads can be considered; the total heat loss from the cells through both leads will be denoted by $\dot{Q}_l$. The heat balance criterion is then

$$\dot{Q}/A = \dot{Q}_l/A \qquad [15]$$

where $\dot{Q}/A$ is given by Eq. [6].

Solutions for T_l as a function of x also allow the lead resistance R_l to be evaluated by integration of ρ over the length of the lead. The total power dissipation in each lead is then I^2R_l, and the power dissipation in two identical leads, denoted by P_l, is twice this value. The energy input to the system per mole of water vapor dissociated is now no longer given by $2\mathbf{F}E$, but must include this power dissipation. Then $\dot{W}/\dot{m}^*$ is

$$\dot{W}/\dot{m}^* = 2\mathbf{F}E + P_l/\dot{m}^* \qquad [16]$$

where E is given by Eq. [5].

The results of the solution of Eq. [13], transformed into a form appropriate for use in [15] and [16], contain a single geometrical parameter which involves total cell area, lead length, and lead cross section. This parameter, s, is given by

$$s = A/(A_l/L_l) \qquad [17]$$

In terms of s, expressions for $\dot{Q}_l/A$ and $P_l/\dot{m}^*$ can then be obtained as

$$\dot{Q}_l/A = 2\lambda^{1/2}TJ_C y_C{}^i x_C \frac{\cos\left(\frac{1}{\lambda^{1/2}}\alpha\rho\frac{s}{N}J_C y_C{}^i x_C\right) - T_o/T}{\sin\left(\frac{1}{\lambda^{1/2}}\alpha\rho\frac{s}{N}J_C y_C{}^i x_C\right)} \qquad [18]$$

$$= \lambda\frac{1}{\rho}s(T^2 - T_o{}^2) - \rho\frac{s}{N^2}(J_C y_C{}^i x_C)^2 \qquad [18b]$$

and

$$P_l/\dot{m}^* = 4\mathbf{F}\lambda^{1/2}(T + T_o)\frac{1}{N}\frac{1 - \cos\left(\frac{1}{\lambda^{1/2}}\alpha\rho\frac{s}{N}J_C y_C{}^i x_C\right)}{\sin\left(\frac{1}{\lambda^{1/2}}\alpha\rho\frac{s}{N}J_C y_C{}^i x_C\right)} \qquad [19a]$$

$$= 4\mathbf{F}\lambda\frac{s}{N^2}J_C y_C{}^i x_C \qquad [19b]$$

where [18a] and [19a] apply to the case of pure metals, and [18b] and [19b] to alloys.

Determination of system performance.—Equations [6], [7], and [18a] or [18b] can most readily be used to find the value of J_C, *i.e.* the water vapor flow rate, that satisfies [15] for any set of operating conditions. This is a nonlinear problem that can be solved by any convenient numerical method. The resultant value of J_C can then be used in Eq. [16] with [19a] or [19b] to determine $\dot{W}/\dot{m}^*$. This process can be repeated for a number of different values of the parameter s to yield the variation of $\dot{W}/\dot{m}^*$ with s. A minimum value of $\dot{W}/\dot{m}^*$ would be expected for some value of s, representing the minimum possible energy input to the system per mole of water vapor dissociated, for the assumed conditions.

System performance at heat balance.—Heat balance calculations were made on a depolarized anode cell system with water vapor and fuel inputs similar to those noted in Fig. 4, except that the fuel was assumed to contain 46% nitrogen (from air), resulting from partial combustion of a hydrocarbon to generate the fuel. Some preheating of the input streams was assumed, as well as a small amount of heat exchange to lower the temperature of the output streams. The assumed operating conditions were 95% water vapor dissociation, with a 10% excess of fuel input relative to water vapor input. In line with experimental results, the specific resistance of the cells was taken as 0.67 ohm-cm^2 at 1000°C and as 0.44 ohm-cm^2 at 1100°C.

The quantity $(\dot{W}/\dot{m}^*)/2\mathbf{F}$ having the dimensions of volts, and denoted by $\bar{E}$, was used rather than $\dot{W}/\dot{m}^*$ to describe the energy input to the system. This is the average voltage of a single cell having the properties of a cell in the system, including the effects of power dissipation in the leads; it can also be compared directly with the cell voltage for electrolysis of liquid water. Figure 9 shows the variation of performance with s at 1100°C for three different conditions: (*a*) single cells with alloy leads ($\rho = 10^{-4}$), (*b*) 10 cell stacks with alloy leads ($\rho = 10^{-4}$), and (c) 10 cell stacks with pure metal leads ($\alpha\rho = 10^{-8}$). As expected, there is an optimum lead geometry giving rise to the lowest dissociation energy, at the bottom of a rather shallow minimum. The virtues of the multicell stack in reducing the minimum dissociation energy by about a factor of two are apparent. Also, the minimum dissociation energy for 10 cell stacks does not depend on the nature of the lead material. Although this result certainly is not apparent in view of the widely different expres-

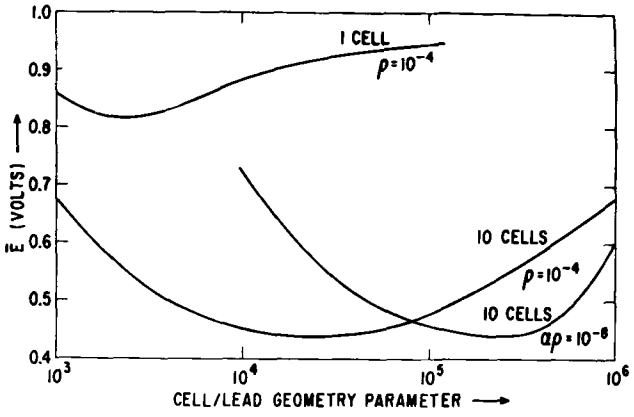

Fig. 9. Variation of average system cell voltage with cell/lead geometry parameter.

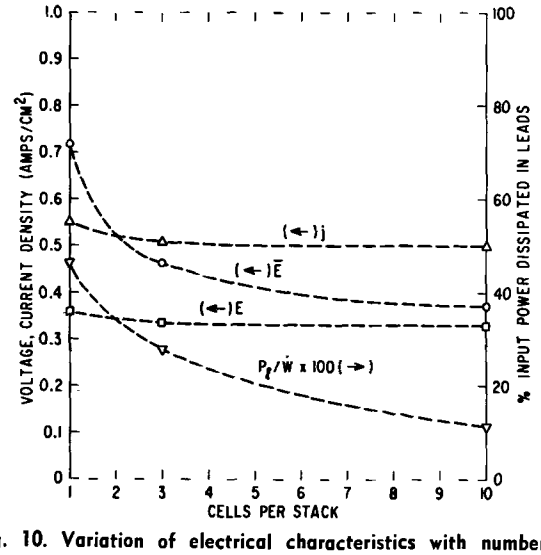

Fig. 10. Variation of electrical characteristics with number of cells per stack in a system optimized for minimum energy requirement.

sions for heat loss and power dissipation in the leads for the two cases considered, it is not unreasonable in view of the coupling between thermal and electrical conductivities. Thus there is no advantage, from an energy requirement standpoint, of preferring either type of material.

Figure 10 shows the best possible system performance, *i.e.* at the minima of curves similar to those of Fig. 9, for operation at 1000°C as a function of the number of cells per stack. Values of current density, cell voltage, and the percentage of total input power dissipated in the leads at these minima are also included. Calculation of best performance at other temperatures leads to similar results, differing primarily in the magnitude of the current density. The value of $\bar{E}_o$ is close to zero, while $\bar{E}_H$, representing mainly reactant preheating, is about 0.35V for the assumed conditions.

If minimization of energy cost is the chief criterion in dissociation, Fig. 10 illustrates the incentive for developing techniques of fabricating multicell stacks. Part II describes some of the materials problems inherent in this task. The cost of cells themselves will enter into the over-all cost of dissociation, however, and in this connection cells should be operated at as high a current density as possible to minimize the total cell area for a given system capacity. Figure 10 shows that current densities for best performance do not approach those that can safely be passed through the electrolyte as demonstrated by single-cell operation. However, the current density for best performance decreases by only 10% in going from 1 to 10 cells per stack while the energy requirement for dissociation decreases by almost 50%.

A system need not be operated at its best performance, in terms of energy requirement, if higher current densities are desirable to decrease cell area. The leads can be made larger in cross section, increasing the heat loss, effectively operating to the left of the minima shown in Fig. 9. The possible advantages of this procedure will depend on the economics of the particular system involved. Alternatively, since the value of the current density is dependent on the specific resistance of the electrolyte/electrode combinations, this parameter can be reduced to increase the current density at best performance. To some extent, increasing the cell temperature—probably with about 1150°C as an upper limit—is one way of accomplishing this reduction. Other possible approaches, and some of their limitations, are presented in Part II (5).

Manuscript submitted April 21, 1969; revised manuscript received July 17, 1969. This was Paper 356 presented at the Montreal Meeting, Oct. 6-11, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

APPENDIX I

The active area of an electrolyte can be described in terms of a normalized parameter ζ. This can be defined in terms of y_C, the fractional amount of water vapor in the gas at the cathode; the value of ζ is set at zero where $y_C = y_C{}^i$ and unity where $y_C = y_C{}^f$. Consider the area δA to be the area of electrolyte between y_C and $y_C + \delta y_C$, which in turn are associated with ζ and $\zeta + \delta\zeta$. A function a_ζ can be defined as

$$a_\zeta = \lim_{\delta\zeta \to 0} \frac{\delta A}{\delta\zeta} \qquad [I\text{-}1]$$

and the infinitesimal area dA becomes

$$dA = a_\zeta d\zeta \qquad [I\text{-}2]$$

The average current density between 0 and ζ is

$$\bar{j}(\zeta) = \frac{1}{A}\int_0^\zeta j a_\zeta d\zeta \qquad [I\text{-}3]$$

where j is the local value of current density at any point on the electrolyte. But from the definition of y_C, this same average current density is

$$\bar{j}(\zeta) = J_C(y_C{}^i - y_C) \qquad [I\text{-}4]$$

Equating these two expressions, differentiating, and re-

arranging gives

$$a_\zeta d\zeta = -AJ_C \frac{1}{j}\, dy_C \qquad [I\text{-}5]$$

Any quantity U having a local value which is a function of y_C will then have an average value $\overline{U}$ that can be expressed as

$$\overline{U} = \frac{1}{A}\int_0^A U dA = \frac{1}{A}\int_0^1 U a_\zeta d\zeta$$

$$= -J_C \int_{y_C{}^i}^{y_C{}^f} \frac{U}{j}\, dy_C \qquad [I\text{-}6]$$

This immediately gives $\overline{j}$ as

$$\overline{j} = -J_C\,(y_C{}^f - y_C{}^i) \qquad [I\text{-}7]$$

which is in agreement with Eq. [7]. Further, using [I-7] the average $\overline{U}$ can be expressed as

$$\overline{U} = \frac{1}{y_C{}^f - y_C{}^i}\int_{y_C{}^i}^{y_C{}^f} \frac{U}{(j/\overline{j})}\, dy_C \qquad [I\text{-}8]$$

Clearly, if $j/\overline{j}$ is approximately unity, the average value U is given by

$$\overline{U} \approx \frac{1}{y_C{}^f - y_C{}^i}\int_{y_C{}^i}^{y_C{}^f} U dy_C \qquad [I\text{-}9]$$

which is simply the average of U over y_C

From the Nernst equation, the local value of the open-circuit voltage, E_o, for an oxygen anode cell will be proportional to the natural logarithm of the water vapor/hydrogen ratio plus a constant, or

$$E_o \sim \ln\left(\frac{y_C}{1-y_C}\right) + k_1 \qquad [I\text{-}10]$$

Integrating [I-10] as indicated in [I-9] gives

$$\overline{E}_o \sim [y_C{}^f \ln (y_C{}^f) - y_C{}^i \ln (y_C{}^i) + (1-y_C{}^f)\ln(1-y_C{}^f)$$

$$- (1-y_C{}^i)\ln(1-y_C{}^i)]/(y_C{}^f - y_C{}^i) + k_1 \qquad [I\text{-}11]$$

But, as shown in Appendix II, substitution into Eq. [1] and [2] yields the result that $\overline{E}_o$ as defined by Eq. [2] involves terms containing $y_C{}^i$ and $y_C{}^f$ exactly the same as those of [I-11].

It can also be shown (6) that for fuel gases based on hydrocarbons, the local open-circuit voltage for a depolarized anode cell will be described approximately by

$$E_o \sim \ln\left(\frac{y_C}{1-y_C}\right) - \ln\left(\frac{y_A}{1-y_A}\right) + k_2 \qquad [I\text{-}13]$$

But y_A will be coupled to y_C by the O^{--} flow through the electrolyte in this case, so that E_o is still a function of y_C only. Thus the integration of [I-9] still applies. The mole fractions of the various species in the fuel gas can likewise be described in terms of y_A, with the result that Eq. [2] again yields a value of $\overline{E}_o$ consistent with that of the constant current density case.

APPENDIX II

The oxygen anode cell can be considered specifically to illustrate the form of the expression resulting from substituting appropriate flow rates and compositions into Eq. [1]. Using the nomenclature of the text, the molar flow rates of gases entering the cathode are

$$\dot{m}_{H_2O,\,in} = \frac{J_C A y_C{}^i}{2F} \qquad [II\text{-}1]$$

and

$$\dot{m}_{H_2,\,in} = \frac{J_C A (1-y_C{}^i)}{2F} \qquad [II\text{-}2]$$

Likewise, the molar flow rates of gases leaving the cathode are

$$\dot{m}_{H_2O,\,out} = \frac{J_C A y_C{}^f}{2F} \qquad [II\text{-}3]$$

$$\dot{m}_{H_2,\,out} = \frac{J_C A (1-y_C{}^f)}{2F} \qquad [II\text{-}4]$$

There is no reactant entering the anode, while the molar flow rate of gas leaving the anode is

$$\dot{m}_{O_2,\,out} = \frac{J_C A (y_C{}^i - y_C{}^f)}{4F} \qquad [II\text{-}5]$$

The total pressures at the cathode and anode are P_C and P_A, respectively, although P_C will cancel from the final expression. Taking the water vapor dissociated at the cathode as the critical component, the flow rate m^* is, by difference,

$$\dot{m}^* = \frac{J_C A (y_C{}^i - y_C{}^f)}{2F} \qquad [II\text{-}6]$$

With this choice for the critical component, it is apparent that ΔG^{o*}_T is the negative of the standard free energy of formation of one mole of water vapor at temperature T, or

$$\Delta G^{o*}_T = -\Delta G^o_{H_2O,\,T} \qquad [II\text{-}7]$$

The result of substituting the expressions of [II-1] through [II-7] into Eq. [1], and noting that y_C and $1 - y_C$ are the mole fractions of H_2 and H_2O, respectively, is then

$$\dot{G}_T/\dot{m}^* = -\Delta G^o_{H_2O,\,T} + RT \ln (P_A)/2$$

$$+ RT\,[y_C{}^f \ln (y_C{}^f)$$

$$+ (1-y_C{}^f)\ln(1-y_C{}^f) - y_C{}^i \ln (y_C{}^i)$$

$$- (1-y_C{}^i)\ln(1-y_C{}^i)]/(y_C{}^i - y_C{}^f) \qquad [II\text{-}8]$$

This expression can be evaluated with only a knowledge of $\Delta G^o_{H_2O,\,T}$ which can be obtained from a source of tabulated values.†

The treatment of a depolarized anode cell is similar to the preceding, but the mole fractions of the species present must be calculated taking the water gas shift reaction into account. The parameters h and y_A as defined in the text are convenient to use since the mole fractions of CO, CO_2, H_2, and H_2O in the anode gas can readily be expressed in terms of these parameters. In this case, P_A will also cancel from the final expression.

With expressions of the mole fractions of the various species present in the gas streams entering and leaving the cathode and anode, Eq. [3] can be evaluated with a knowledge of the various enthalpy content difference terms $H^o_{T_{out}}$-H^o_T and $H^o_{T_{in}}$-H^o_T. Since only differences in molar enthalpy content are involved, tabulated values with respect to any convenient reference temperature, such as 298°K, may be used.‡

In the preceding, the difference $y_C{}^i - y_C{}^f$ has been used to characterize the composition change in the cathode gas; this of course can be replaced by the product $y_C{}^i x_C$ (with an analogous treatment for the anode gas) to obtain expression relating $\overline{E}_o$ to x_C or x_C and x_A.

† Standard Gibbs free energy values used were from "Thermochemistry for Steelmaking," Vol. I, Elliott and Gleiser, Addison-Wesley (1960).

‡ Enthalpy content values used were obtained from the preceding source.

Electrochemical Dissociation of Water Vapor in Solid Oxide Electrolyte Cells

II. Materials, Fabrication, and Properties

H. S. Spacil* and C. S. Tedmon, Jr.*

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

Following the thermodynamic and electrochemical description of high-temperature electrolytic dissociation of water vapor discussed in Part I, this paper is concerned with materials problems, design, and fabrication of both single-cell and multicell devices. Oxygen anodes and depolarized anodes are both considered, and it is concluded that the most feasible system is that employing discontinuous electrolyte segments and depolarized anodes.

The thermodynamic and electrochemical basis for the high-temperature electrolytic dissociation of water vapor was presented in Part I of this paper (1). This part of the paper is concerned with materials problems, fabrication, and performance of both single-cell devices and multicell stacks, or batteries. Two general systems were discussed in Part I, *viz.* operation with oxygen anodes and operation with depolarized anodes. With respect to materials, each system has certain features in common and some features that are much different. Both systems have the same cathode reaction and consequently the cathode and also the electrolyte may be made from the same materials. Factors influencing the choice of cathode and electrolyte materials are discussed in the following sections. The principal differences between the two systems lie in the anode reaction and anode material. Figure 1 shows schematically the operation of a zirconia electrolyte water vapor dissociation cell operating with an oxygen anode. The dominant characteristic of this mode of operation, from a materials viewpoint, is that the anode and anode leads must be chemically and physically stable in an oxidizing environment at elevated temperatures. In many respects, the materials requirements for the oxygen anode are similar to those for zirconia fuel cell cathodes (2). This is discussed in more detail in subsequent sections of this paper. Operation of zirconia electrolyte water vapor dissociation cells with depolarized anodes is shown schematically in Fig. 2. In this mode of operation, an excess of fuel over the stoichiometric requirement is employed to maintain a reducing atmosphere over the anode. Carbon monoxide is indicated as the fuel; other fuels are also feasible. Consequently, a different set of materials requirements is involved. The effect of these parameters on the fabrication and performance of both single- and multicell devices is discussed later.

It was shown in Part I that, in order to achieve an optimal thermal balance and to minimize the energy requirements for the system, it would be necessary to utilize multicell stacks in a practical system rather than single-cell devices. The latter, however, are much easier to fabricate and test. Furthermore, the investigation and interpretation of cell reactions is more straightforward with single-cell devices. Consequently, both single-cell devices and multicell stacks have been built and tested.

Electrolytes and Cathodes

The choice of materials for the cathodes and electrolyte of the cells is largely independent of the mode of operation and the number of cells in the device. With some designs of multiple-cell stacks, it is conceivable that the choice of the cathode material could be influenced by the necessity of having to make the series connections between anode and cathode. However, this will not usually be a problem.

Electrolyte.—In cells having either oxygen anodes or depolarized anodes, the electrolyte performs the dual function of providing both oxide ion conductivity and structural strength to the device.

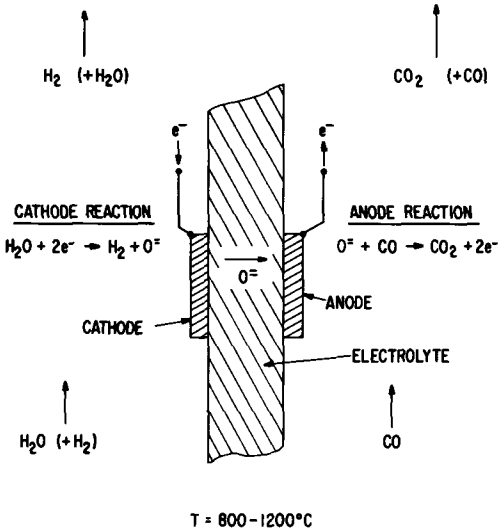

Fig. 2. Schematic illustration of solid oxide electrolyte water vapor dissociation cell with depolarized anode.

* Electrochemical Society Active Member.

Key words: dissociation, water vapor, oxide electrolyte.

The electrolyte material must satisfy several criteria. It must be fabricable into a gas-impermeable structure and possess high oxide ion conductivity and low electronic conductivity. Also, the fabrication methods used for these cells require sintering of the electrolyte to at least 95% of theoretical density at temperatures below the melting point of the electrodes (*ca.* 1450°C). Finally, the isothermal ionic conductivity should be independent of oxygen partial pressure over the wide range encountered, which may be as much as 20 orders of magnitude.

The cells which are discussed are based on a stabilized zirconia electrolyte. Other oxide ion conductors are known, such as yttria-doped thoria, or ceria-doped lanthana. The properties of zirconia are much better characterized and understood, however, and consequently it has been used. Zirconium dioxide can be stabilized into the cubic fluorite structure by the addition of various oxides such as CaO, MgO, Y_2O_3, and other rare earth oxides. In the cubic phase, the cations from the stabilizing oxide occupy sites in the zirconium cation sublattice. Since the stabilizing cation has a lower valence than the host Zr^{+4} ions, anion vacancies are created to preserve charge neutrality. As a first approximation, the oxide ion conductivity depends on the concentration of anion vacancies (3-5), and hence on the concentration and valance of the stabilizing cation. Since the concentration of vacancies is fixed by composition, it follows that at a given temperature the oxide ion conductivity is fixed by composition and therefore is substantially independent of oxygen partial pressure, at least over the range of oxygen pressures of interest here (4, 5). Figure 3 is a plot of ionic conductivity *vs.* reciprocal absolute temperature for various stabilized zirconias. Except for the case of yttria-stabilized zirconia, for which data for two compositions are presented, the curves shown for each material are for the optimal concentration of the stabilizing oxide. In each such material, lesser or greater amounts of the stabilizing oxide will result in a material with lower ionic conductivity. Thus, for the case of yttria-stabilized zirconia, 10 m/o (mole per cent) Y_2O_3 has been found to maximize ionic conductivity, while the addition of

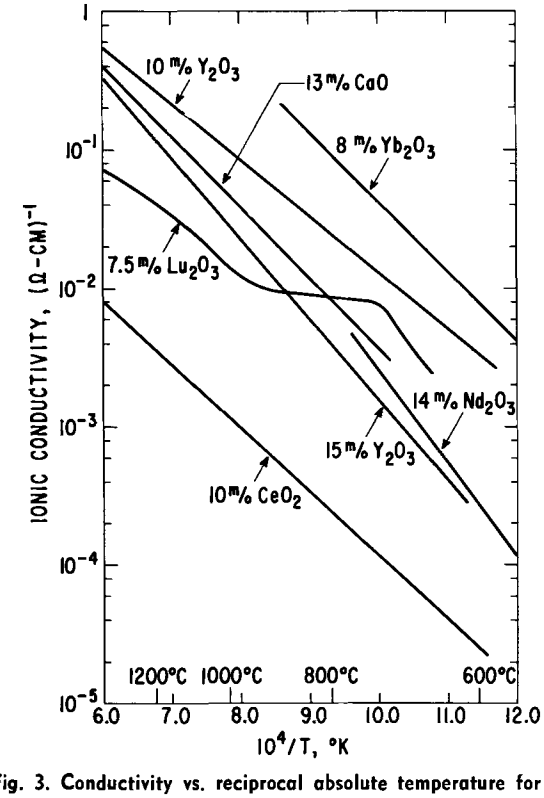

Fig. 3. Conductivity vs. reciprocal absolute temperature for various stabilized zirconias. References: ZrO_2-CeO_2 (6); ZrO_2-Y_2O_3 (7); ZrO_2-Nd_2O_3, ZrO_2-Yb_2O_3 (8); ZrO_2-Lu_2O_3 (9).

15 m/o Y_2O_3 results in decreased conductivity. The curvature in the plot for the Lu_2O_3-stabilized zirconia suggests that its conductivity may not be entirely anionic. The electronic conductivity of these stabilized zirconias is of the order of 0.1% of the ionic conductivity for oxygen partial pressures of interest.

In these experiments, zirconia stabilized with 10 m/o Y_2O_3 (termed "YSZ") was used as the electrolyte material. It is apparent from the data shown in Fig. 3 that the ytterbia-stabilized material has a higher conductivity, but cost and availability render the YSZ more practical. About 1 m/o Fe_3O_4 is added to the electrolyte to increase sinterability. This addition enables the zirconia to be sintered to about 95% theoretical density at temperatures as low as 1225°C. The addition of the iron does not measurably contribute to the electronic conductivity of the electrolyte down to oxygen partial pressures as low as 10^{-20} atm.

Details on the processing of the electrolyte material and the fabrication of cells are described subsequently; it is prepared in tubular form, about 1 cm in diameter, with a 0.5-mm wall thickness. It would be desirable, of course, to have the electrolyte as thin as possible in order to minimize total cell resistance. Leaktight tubes of YSZ with walls as thin as 0.125 mm have been prepared, but the thicker-wall tubes are a more optimal compromise between conductivity and strength.

The addition of the iron oxide as a sintering agent to the YSZ is satisfactory when the cells are operating with noncarbonaceous fuel gases. In practical application, it is likely that carbonaceous fuel gases would be used. For this purpose, the iron oxide addition is unsatisfactory; cells with Fe_3O_4-doped electrolyte show a gradual decline in performance with time, due to increased electrolyte resistance. This is apparently due to an interaction between carbon atoms from the gas and iron in the electrolyte. Cobalt oxide has been found to be an alternate sintering aid which does not interact with carbon. It can be added in about the same amounts as the iron oxide and provides sinterability in the same temperature range. Its contribution to the electronic conductivity of the electrolyte is negligible.

Cathode.—It was pointed out above that the half reaction occurring at the cathode was independent of the mode of operation, *i.e.* independent of whether depolarized anodes or oxygen anodes were used. Consequently, the choice of cathode materials is not generally going to be influenced by the mode of operation.

In both types of systems, cathodes have been made from a porous Ni-YSZ cermet, containing about 20 w/o (weight per cent) YSZ. The purpose of the latter in the electrode is to prevent sintering and growth of the Ni particles. Similar electrodes consisting of Co-20 w/o YSZ have been employed. Cell performance was found to be independent of the antisintering material in the cathode.

Both Ni and Co have the advantage of being chemically stable in H_2O/H_2 mixtures containing large amounts of H_2O. Figure 4 is a plot of the maximum H_2O content for stability of the metal indicated in an H_2O/H_2 gas mixture, as a function of temperature (10). Both Ni and Co are stable in atmospheres containing more than 90% H_2O. In contrast, for example, Fe would be severely limited as an electrode for this application. Manganese has a similar limitation, and Cu, though stable in H_2O-rich atmospheres, is limited by melting point. Consequently, Ni and Co are the only practical choices.

Details on the fabrication of the cathode on single-cell and multicell devices are discussed in a subsequent section on fabrication.

Single-Cell Devices

Single cells with oxygen anodes.—Cells operating with oxygen anodes resemble fuel cells in many respects. The electrochemical reactions occurring at the anode are effectively reversed, but the operating en-

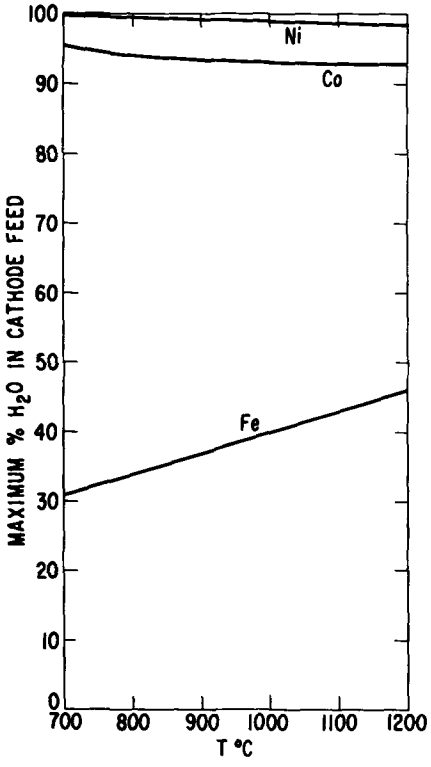

Fig. 4. Temperature dependence of the maximum water vapor content in H_2O/H_2 mixtures for stability of the metals shown.

vironment is similar, as are the criteria for chemical and mechanical stability of the anode, which would function as a cathode in a fuel cell. Basically, the anode must be made from a material which is chemically stable in air or in contact with zirconia to temperatures at least as high as 1000°C. In a previous paper (2), operational criteria were identified for fuel cell cathode materials, and quantitative relationships between cathode materials and cell operating characteristics were discussed. Many of the conclusions arrived at in that study are applicable to the problem of selection of oxygen anode materials for the zirconia electrolyte water vapor cells. It was concluded that the only practical class of materials to consider for fuel cell cathodes were the electronically conducting oxides. The same conclusion is valid for the selection of materials for anodes for these cells. Figure 5 presents conductivity data as a function of temperature for various electronically conducting oxides. The perovskite oxides—$LaCoO_3$, Sr-doped $LaCoO_3$, and $PrCoO_3$—are of particular interest because of their high values of conductivity. Unfortunately, the first two react with zirconia to form reaction products which are deleterious to cell operation; $PrCoO_3$ anodes, however, can function efficiently for long periods of operation at temperatures as high as 1000°C (2). Zirconia electrolyte water vapor dissociation cells with porous $PrCoO_3$ oxygen anodes have been built and tested. The $PrCoO_3$ is applied from an aqueous slurry to a thickness of about 0.2-0.3 mm, dried, and sintered *in situ* as the cell is heated up, resulting in a porous electrode. As was the case with fuel cells, such an electrode cannot be thermally cycled because of the large difference in thermal expansion between the $PrCoO_3$ and the zirconia.

For water vapor dissociation cells which are electrolyte limited, that is, cells in which the electrolyte resistance dominates the total resistance of the cell, the specific resistance of the cell as viewed from the terminals is given approximately by the relation

$$r = r_e + f(r_a + r_c) \qquad [1]$$

where r_e, r_a, and r_c are the specific resistances of the electrolyte, anode, and cathode, respectively, and f is a constant which takes into account the fact that the

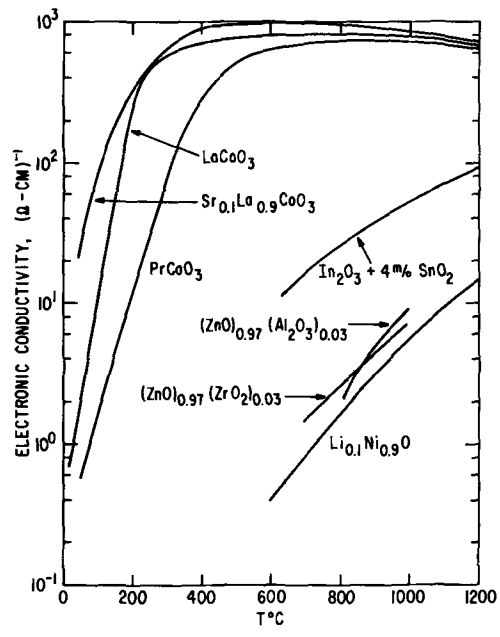

Fig. 5. Electrical conductivity vs. temperature for various electronically conducting oxides.

current distribution varies along the length of the electrodes (f = 0.08-0.3). This specific resistance, r, with units of ohm-cm^2, is the resistance of a hypothetical cell 1 cm^2 in area which has the electrical properties of the actual cell under consideration. Equation [1] can be derived by a straightforward, although tedious, analysis of a one-dimensional distributed current network (11). From a knowledge of the resistivities of the cell components and the geometry of the system, values of r can be calculated. Measurements of these resistivities have been reported elsewhere (12).

Water vapor dissociation cells with oxygen anodes have been built and tested. Satisfactory performance was obtained; up to about 95% of the incoming water vapor could be coulometrically reduced. Specific resistance of a cell can be computed from Eq. [1] and compared with experimentally determined values. The results are presented in Fig. 6, as a function of reciprocal absolute temperature. This figure presents the apparent specific resistance, which includes any contributions that may be present as a result of mass transport or activation overvoltages. Part I of this paper

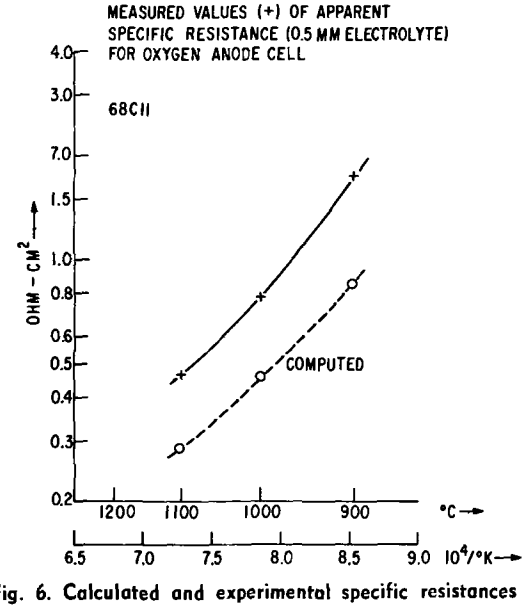

Fig. 6. Calculated and experimental specific resistances of oxygen anode cell as a function of reciprocal absolute temperature.

discussed the reasons for expecting both of these to be small compared to resistive voltage drops, at least under the usual testing conditions. This expectation is confirmed by Fig. 6 which shows that the measured value of the apparent specific resistance is approximately proportional to calculated values. The reason for the discrepancy is discussed in the following section, but, since neither mass transport nor activation overvoltages will have the same activation energy as the electrolyte resistivity, Fig. 6 shows that these effects are not significant.

Single cells with depolarized anodes.—A schematic illustration of a cell operation with a depolarized anode was presented in Fig. 2. The material requirements for cells of this type are more readily met, since the anode, as well as the cathode, is exposed to an atmosphere which is reducing to several metals, particularly Ni and Co. The anode reaction for this mode of operation is the oxidation of the fuel, such as CO. Porous Ni or porous Co electrodes, containing about 20 w/o zirconia, are acceptable anodes.

Depolarized anode cells have also been built and tested, using various fuel gases at the anode. These cells function satisfactorily, giving coulometric dissociation of the input water. Equation [1] can also be evaluated for cells of this type. Figure 7 is a plot of computed specific resistance and measured specific resistance, as a function of reciprocal absolute temperature for a typical depolarized anode cell operating on a hydrogen fuel. This figure, like Fig. 6, presents the apparent specific resistance which will include any contributions from mass transport and activation polarization effects. As with oxygen anode cells, these should be small under testing conditions. Figure 7 shows that the measured value of the apparent specific resistance is approximately proportional to the calculated value, except for a deviation at the lower temperatures (about 800°C) where activation polarizations might be expected to become significant.

The origin of the increase in measured values of specific resistance over calculated values, for both oxygen anode and depolarized anode cells, is not entirely understood, but probably lies at least in part in a form of constriction resistance at the electrode/electrolyte interfaces. Both electrodes consist of fine particles, and current flow through the electrolyte in the vicinity of the interfaces will be constricted to some region near the three-phase gas/electrode/electrolyte boundary.

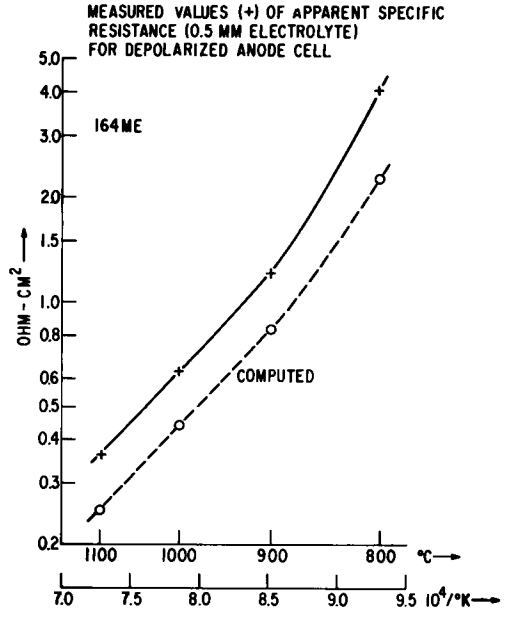

Fig. 7. Calculated and experimental specific resistances of a depolarized anode cell as a function of reciprocal absolute temperature.

This problem has been considered for solid electrolyte cells (13), and the result is that an effective thickness of the electrolyte, which will be larger than the geometrical thickness, must be used to calculate the specific resistance of the electrolyte. This in turn will result in the observed proportionality of Fig. 6 and 7.

Multicell Stacks

General design considerations.—There are two general designs for multiple-cell stacks, whether for use as fuel cells or as water vapor dissociation cells. In the first case, the electrolyte is continuous. This design is attractive because the electrolyte thus provides a convenient structural element. A schematic illustration of this type of device is shown in Fig. 8. The series connection between anodes and cathodes must be made by a lead, such as a wire, passing through the electrolyte. This connection must be made, of course, without introducing a leak.

The second general design that has been proposed for multiple-cell stacks is the case in which the electrolyte is not a continuous member. Figure 9 presents schematically several possible configurations for stacks of this type. The anode-cathode series connection may be made directly, as indicated in Fig. 9(a), and 9(c), or by means of an intermediate metal ring, or collar, as shown in Fig. 9(b).

Multicell stacks with oxygen anodes.—The continuous electrolyte design will be considered first; as was mentioned above, this design has the advantage that the electrolyte can provide structural strength. Further-

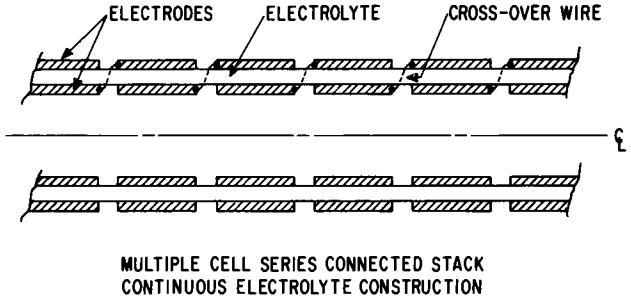

Fig. 8. Schematic illustration of a water vapor dissociation "stack" built upon a continuous electrolyte.

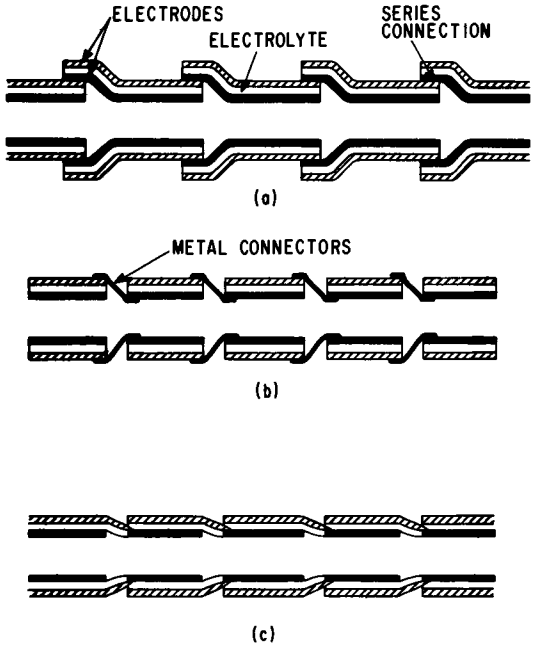

Fig. 9. Schematic illustration of various methods of construction of water vapor dissociation "stacks" built with discontinuous electrolyte.

more, the cathodes and anodes are completely separated, which allows flexibility in the choice of electrode materials. The material used for the series connection between adjacent cells, however, is exposed to an oxidizing environment on the anode side of the cell and a reducing environment on the cathode side. This condition, at temperatures of the order of 1000°C, requires the use of a noble metal such as Pt or Pd. These metals can be used as wires for the series connections. The principal problem is to bring the wire through the electrolyte without introducing leaks. Fortunately, both Pt and Pd have coefficients of thermal expansion comparable to that of stabilized zirconia. Although Pd is less costly than Pt, its use in this application imposes a substantial economic penalty, which is essentially prohibitive.

Several multicell stacks of this type have been built and tested. It was necessary to have the electrolyte be at least 0.75 mm thick in order to have no leaks at the juncture of the crossover wire. The increased electrolyte thickness increases its resistance to an unacceptable level. Consequently it is concluded that this is not a feasible approach.

Multicell stacks with oxygen anodes using a discontinuous electrolyte design, as in Fig. 9(a), are impractical because of the problem of establishing the direct series connection between anode and cathode. The oxygen partial pressure variation across the connecting section will typically be 15 orders of magnitude; the cathode must be protected against oxidation by the product oxygen, and the anode must be protected against reduction by the product hydrogen. Thus, an electronically conducting barrier would have to be interposed between the anode and the cathode of adjacent cells where these overlap. Since this barrier itself would now have to be resistant to both oxidizing and reducing conditions, again only Pt or Pd could be used. If a design like that in Fig. 9(b) is used, the collar, or ring, must be made from either Pt or Pd, which is economically unsatisfactory.

Multicell stacks with depolarized anodes.—The problems associated with multicell stacks fabricated with a continuous electrolyte are essentially the same as described above, with the exception that metals such as Ni or Co can be considered for the series connection since the anode environment will not be oxidizing to these. This alleviates the economic restriction. Both Ni and Co, however, have thermal expansion coefficients about 50% larger than that of stabilized zirconia, thus making the problem of establishing a leaktight connection more difficult.

Operation with depolarized anodes significantly relaxes conditions on materials for multicell stacks with discontinuous electrolyte segment. Either Co or Ni may be used in the anode and cathode, and a direct connection between electrodes may be established. The type of stack which has proven most satisfactory is presented schematically in Fig. 10. It is recognized that this design is a variation of that shown in Fig. 9(b). The solid Ni connections provide a leaktight series connection. The device is an integral unit. Three-cell and ten-cell stacks have been built and tested. Figure 11(a) is a photograph of a three-cell stack; a ten-cell stack is shown in Fig. 11(b). These devices

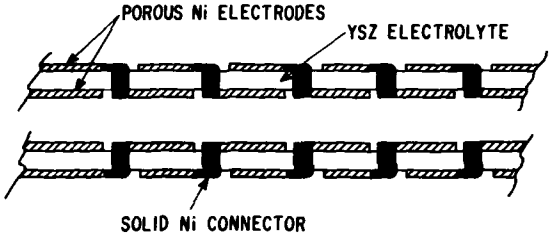

Fig. 10. Schematic illustration of water vapor dissociation "stacks" built and tested in these experiments.

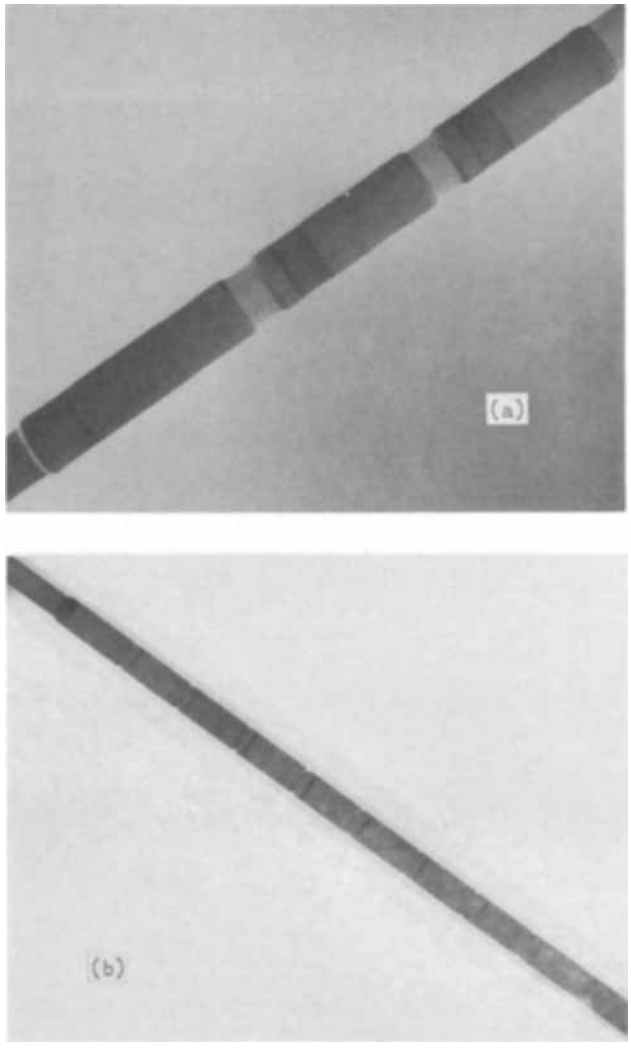

Fig. 11. (a) Photograph of typical three-cell water vapor dissociation "stack." 2/3X. (b) Photograph of typical ten-cell water vapor dissociation "stack." 3/16X.

have acceptable mechanical strength and are leaktight under pressure at room temperature.

The individual cells in multicell stacks cannot be instrumented as fully as single cells; it is not feasible to employ more than one pair of auxiliary electrodes for the entire stack, or to establish potential connections to each cell. Electrical testing is thus limited to determination of the total stack voltage, E, and, with the auxiliary electrodes, the open-circuit potential, E_o^f, at the exit end of the cell for parallel water vapor and fuel flows. The latter quantity is a single-cell measurement, as discussed in Part I.

Figure 12 is typical of the results obtained for a three-cell stack operated with H_2 fuel. Water vapor and fuel flow rates are normally expressed in terms of the current that would be required for complete dissociation of the water vapor and complete oxidation of the fuel in an equivalent single cell. The static (zero current) value of E_o^f is —0.22V, in good agreement with calculated values. The static voltage of E of —0.65V is three times the single-cell value, indicating no significant leakage at temperature under these conditions. Application of current to the stack causes E_o^f to increase and become positive at about 6.5A. At this point, the H_2O/H_2 ratios at the exit ends of the cathode and anode should be equal. Since the equivalent single-cell current is the stack current multiplied by the number of cells per stack, the observed value agrees reasonably well with the extent of water vapor dissociation and fuel oxidation that would occur at 6.5A for the given flow rates. Direct measurement of H_2 flow rates from

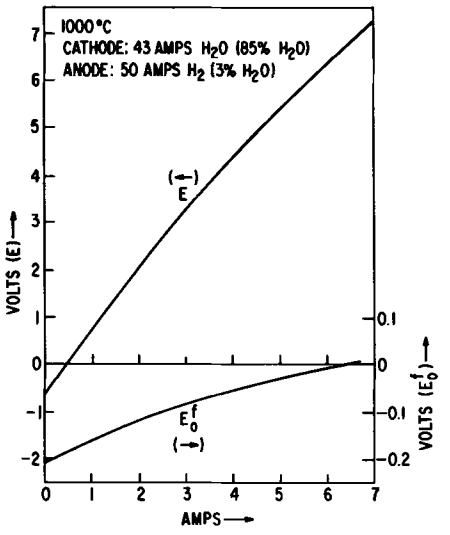

Fig. 12. Total and auxiliary electrode voltages for three-cell "stack." The active cell area is about 4 cm^2.

the cathode confirm coulometric water vapor dissociation.

Part of the nonlinearity of the stack voltage is due to the variation in average open-circuit voltage of the cells with current. The remainder is probably due to mass transport effects at the electrodes, of the type discussed elsewhere by the authors (12). An average slope, however, gives a stack resistance of about 1.0 ohms. Since the nominal cell area is 4 cm^2, the specific resistance for the device is about 1.3 ohm-cm^2, about twice that for single cells. A portion of this discrepancy can be ascribed to the different cell geometry, as well as to the interconnections and lead resistance, but the major portion cannot be accounted for at this time.

Another test of interest to stack performance is measurement of the resistance across anode-anode or cathode-cathode insulating gaps. This has been carried out, in appropriate atmospheres, on segments removed from complete stacks. The gap resistances have the proper magnitude, and show a temperature dependence paralleling that of the electrolyte. Thus any short-circuiting of adjacent cells across the gaps is due only to the electrolyte resistivity, and can be controlled by maintaining a sufficiently high value of the gap width/electrolyte thickness ratio.

The use of Ni series connections between cells allows the possibility of H_2 permeation through this material. Calculated permeation rates based on data for Ni sheet (14) are typically a few STP cc/min for current stack designs, but experimental results based on direct H_2 flow measurements indicate permeation rates an order of magnitude higher. The actual rates are undoubtedly sensitive to the structure of the Ni, and would be expected to depend on such factors as porosity and extent of grain boundaries. Although a quantitative evaluation of this effect is not possible, it must be considered in the design, fabrication, and testing of multiple cell stacks.

Fabrication Technology

For all the cells that have been described, there are two basic fabrication operations. The first is preparation of powders, and essentially involves those steps required to take the raw materials and process them into a form suitable for plasma-spraying.

The crossover leads for depolarized anode stacks were made from 99.6% purity Ni powder obtained from the Sherritt-Gordon Company. This powder, which has a particle size between 20 and 40μ, can be plasma-sprayed directly without any further preparation.

The Ni-YSZ cermet electrodes are prepared by mixing reagent-grade NiO with YSZ in the desired ratio, followed by spray-drying the powder. Spray-drying is a standard ceramic processing method which involves spraying through a nozzle a liquid-based suspension of the powder. The suspension is prepared by mixing the powders together in a water-alcohol solution to which a commercial suspending agent is added. This mixture is then fed through the nozzle on the spray-dryer into a large tank through which hot air is circulating, typically at a temperature of *ca.* 500°F. Droplets of the suspension are thus dried as they enter the tank and are subsequently size-classified. The result of this operation is agglomerated drops of very fine NiO and YSZ particles. The mix is screened to produce agglomerate particles of about 50μ size; the screened material is then calcined in air at 1325°C to impart additional strength. Following calcining, the material is ready for plasma-spraying.

Plasma-spraying is also a standard ceramic processing operation and is essentially a melting and casting operation. The prepared powders are fed into a plasma torch, in which they are rapidly melted and deposited onto a cool substrate. In these experiments, the substrate was a rotating air-cooled hollow aluminum mandrel. A Metco plasma gun was used, and a He/H_2 gas mixture was used to produce the plasma.

After plasma-spraying, the NiO in the electrode will be reduced in H_2 at about 400°C to produce a Ni-YSZ electrode. This general powder preparation procedure accomplishes several purposes. First, the use of very fine particulate NiO, rather than Ni powder, results in a fine Ni grain size in the reduced electrode. The YSZ addition prior to spray-drying affords the maximum degree of particle mixing. However, the blended mix has a particle size before spray-drying that is too small to permit satisfactory flow and melting in the plasma-spray operation. Thus the spray-drying step results in intimately mixed, very fine particles of the constituent powders bound together as a relatively coarse agglomerate suitable for plasma-spraying.

Essentially the same procedure is used for Co-YSZ electrodes.

Electrolyte powders are also prepared by spray-drying (15). Starting materials consist of unstabilized zirconia (Zircoa "A"), 99% purity Y_2O_3, and reagent-grade Fe_3O_4 powders. These powders, in the as-received condition, are all too fine for plasma-spraying, and therefore are initially spray-dried. As with the electrode powders, this operation produces an intimately mixed powder agglomerate which is then screened to a 50μ particle size. The material is calcined in air in the range of 1350°-1500°C, depending on the exact composition being prepared. It is then ready for plasma-spraying. The stabilization of the zirconia occurs during the melting and freezing of the powder in the plasma-spray operation.

For cells with oxygen anode, the $PrCoO_3$ powder is prepared by reacting Pr_6O_{11} with CoO at 1400°C in air. X-ray diffraction analysis of the products indicated essentially complete reaction. The oxide was then ground to a particle size on the order of 25μ. Oxygen anodes were applied to the cells from an aqueous slurry of the perovskite powder. $PrCoO_3$ electrodes can also be fabricated by plasma-spraying, but this procedure tends to yield an electrode that is insufficiently porous.

An important design parameter in the fabrication of water vapor dissociation cells is the electrode/electrolyte thickness ratio. The Ni-YSZ (or Co-YSZ) electrodes have thermal expansion coefficients which are characteristic of the metal; *i.e.*, $\alpha_{1000°C}$ (Ni) $\approx 15 \times 10^{-6}$ $°C^{-1}$, compared to a value of $\alpha_{1000°C}$ (YSZ) $\approx 10 \times 10^{-6}$ $°C^{-1}$ for the electrolyte. In addition, the cermet is much stronger than the pure metal (Ni or Co) at temperatures of cell operation. The electrolyte, being entirely ceramic, is also strong at elevated temperatures. Because of the differential thermal expansion, stresses arise at the electrode/electrolyte interface which can lead to mechanical failure of the cell. The

interfacial stresses can be relieved by incremental plastic flow of the electrode, if it is thin enough relative to the electrolyte. It has been empirically determined that an electrode/electrolyte thickness ratio of 1/4 is satisfactory. On cells with oxygen anodes, the $PrCoO_3$ electrode is only partially sintered and therefore quite porous. Consequently, in spite of its large coefficient of thermal expansion—$\alpha_{1000°C}$ ($PrCoO_3$) $\approx$ 28 x 10^{-6} $°C^{-1}$—interfacial stresses which arise are relieved by mechanical failure of the electrode, rather than in the electrolyte. Such failure does not occur on heating, fortunately, but cracking and spalling of the oxygen anode during cooling is a serious problem and generally these cells can be tested only once without applying a new $PrCoO_3$ anode.

A typical processing schedule for water vapor dissociation cells would then be as follows. First the metal leads (Ni) are plasma-sprayed onto a rotating aluminum mandrel. Masking is provided as required. Then the inner electrode (usually the cathode) is applied by plasma-spraying. It is reduced to a cermet in H_2. Plasma-spraying of the electrolyte then takes place; as plasma-sprayed, the YSZ is about 90% theoretical density, which is not sufficient to make it leaktight. The aluminum mandrel is removed by leaching in a KOH solution, and the cell is fired at 1225°C, which results in the YSZ sintering to about 95% theoretical density, rendering it leaktight.

The outer electrode (usually the anode) on depolarized cells or self-driven cells is applied by plasma-spraying; on cells with oxygen anodes, the $PrCoO_3$ is hand-applied.

Summary

The design, fabrication, and performance of zirconia electrolyte water vapor dissociation cells has been considered. Although not of practical value, single-cell devices are important because they provide a convenient means of evaluating cell performance and electrode reactions. Single-cell devices with both oxygen and depolarized anodes were tested.

An analysis of design and materials factors for multicell stacks led to the conclusion that the most feasible system was that employing discontinuous electrolyte segments and depolarized anodes.

The Microstructure of Sintered Silver Electrodes

II. At the End of 1-Hour Rate Discharges

Charles P. Wales*

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C.

ABSTRACT

A single discharge of a Ag electrode at the relatively fast 1-hr rate resulted in Ag particles smaller than those present in the unused sintered electrode. As an electrode was cycled in 35% KOH at 25°C, the active material tended to clump together while void spaces became larger. At the same time the average size of Ag particles gradually increased, although particle size remained small at the surface of a discharged electrode. These changes were accompanied by a gradual decrease in discharge capacity. The small Ag particles that formed during fast (1-hr) discharges could be oxidized more readily and more completely during a charge than the large Ag particles that formed during slow (20-hr) discharges. Therefore the capacity decreased more slowly when an electrode was cycled using fast discharges.

The present investigation concerns changes in the structure of silver electrodes when the electrodes were given a series of complete discharges at the 1-hr rate. The silver electrode is the positive electrode of silver-zinc and silver-cadmium storage batteries. These batteries are important as high capacity power sources and for their ability to be discharged at high current densities.

When a silver electrode is discharged at a high current density, such as the 1-hr discharge rate, electrode

* Electrochemical Society Active Member.

Key words: silver electrode; microstructure; storage batteries.

capacity is generally maintained at a higher value over a series of cycles than when a low discharge c.d. is used. The present paper shows that this difference in capacity results from changes in the microstructure of the electrodes, and that discharge c.d. has an important effect on structure. The structural changes that occurred as charged Ag electrodes were being reduced during discharge at the 1-hr rate have been described in the previous paper in this series (1). An earlier paper was concerned with the structures obtained when electrodes of the same original construction were discharged at the relatively low c.d. required for the 20-hr discharge rate (2).

Experimental Procedure

Since the experimental procedure has already been described (1), only a brief account is given here. Sintered Ag electrodes were charged individually at the 20-hr rate of constant current until oxygen began to evolve. Then an electrode was discharged at the 1-hr rate to a final potential of −500 mV *vs.* the Ag/Ag_2O reference electrode. This potential was equivalent to approximately 1.0V for a typical Ag-Zn cell. The cycling was done at 25°C in an excess of 35% KOH solution.

Samples for microscopic examination were cut from discharged electrodes that had been cycled from 1 to 30 times. After a sample had been washed and dried, it was impregnated with an epoxy resin while under a vacuum. Then a cross section of the sample was prepared by grinding and polishing. Finally a sample was examined by optical microscopy and the appearance of significant areas recorded by photography.

Results of Microscopic Examinations

Structure of unused sintered Ag electrodes.—Figure 1 shows an unused sintered Ag electrode, in order to have a base for illustrating the early changes that occur with use. All photographs in this paper are of cross sections through an electrode. The photographs, therefore, also show cross sections through the individual particles or crystals in the electrode. Since the structure of an unused electrode has already been described (2), only a brief account is given here. Ag was present in a wide range of sizes from approximately 0.5 to 100μ. Most Ag particles were small and had their smallest dimension in the range 1.5 to 2μ. It was estimated that only 5% of the active material consisted of particles that were over 15μ. The general appearance of the electrode structure was fairly uniform, although the large particles were not evenly distributed throughout the electrode. Many of the small particles were grouped together in clusters. Some clusters of small particles are shown in Fig. 1. Voids were small and well distributed in the unused electrode.

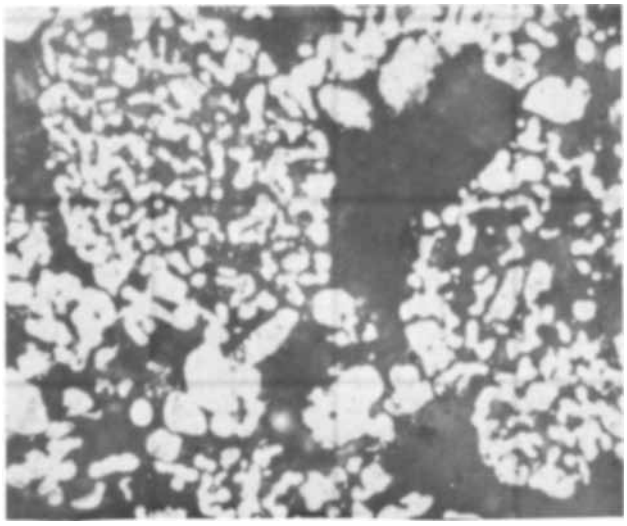

Fig. 1. Particles of Ag active material (white) in an unused sintered Ag electrode. The dark background is the impregnation plastic that has filled void areas in the electrode. Lines forming the squares are 30μ apart.

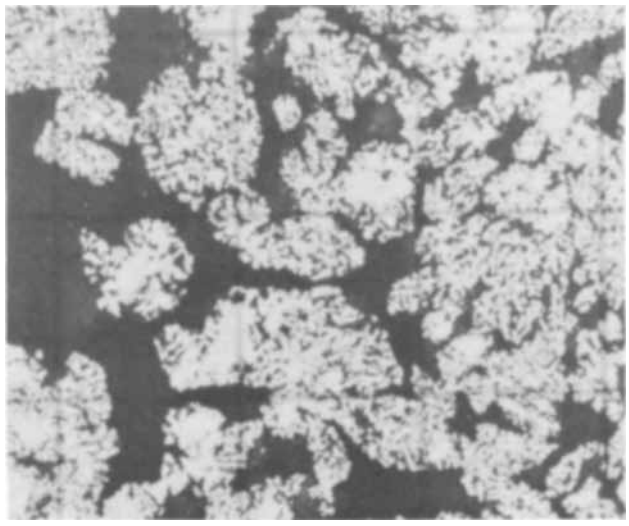

Fig. 2. Typical Ag particles present at the end of the first discharge at the 1-hr rate in 35% KOH solution. Compare with Fig. 1 at the same magnification.

Structure of discharged electrode after 1 cycle.—The average size of the Ag particles had become much smaller, and the individual particles were closer together, after charging an unused sintered electrode at the 20-hr rate to oxygen evolution and giving it a single discharge at the 1-hr rate. Figure 2 illustrates the sponge-like structure produced by the discharge at cycle 1. The changes in particle size can be seen by comparing the discharged electrode shown in Fig. 2 with the unused electrode shown in Fig. 1. Groups of particles were in larger clumps after the first discharge. (The increased size of the clumps was more apparent when the electrodes illustrated in Fig. 1 and 2 were compared at a lower magnification.) The majority of the Ag particles produced during the first discharge were quite small and had irregular, elongated shapes.

Some larger Ag particles had also formed during the first discharge, but were less common than the small particles. The area shown in Fig. 2 does not include any of these large particles that had formed during the first discharge, but it does include some even larger particles that were residual from the original electrode. These large Ag particles had failed to oxidize completely during the previous charge and were often found in the center of groups of the small particles. It is likely that some of the small Ag particles had nucleated from these large Ag particles during the discharge.

The metallic Ag grid of an unused electrode had a smooth surface, but changes occurred during the first cycle. Part of a grid member is included in Fig. 3. Small Ag particles had deposited on the surface of the grid during the discharge. Another change during the first cycle was that some penetrating attack had occurred on the grid surface. This attack probably took place during the charge, while an oxide layer was forming on the grid surface.

Deposit of small particles on surface of large particles.—Changes that took place at the grid surface resembled the changes taking place at the surface of the largest Ag particles. Figure 4 gives a full cross section through an electrode in an area that did not contain a grid member. This shows the appearance of an electrode at the end of the second consecutive discharge at the 1-hr rate, following slow charges at the 20-hr rate. The small Ag particles that formed during a fast discharge were not large enough to be seen individually at the low magnification used for Fig. 4. The bright, featureless areas included in Fig. 4 are some of the largest particles residual from the particles originally present in the unused

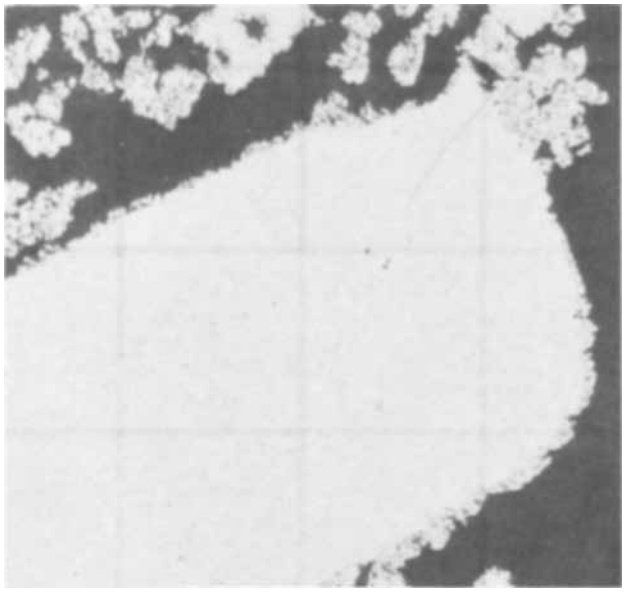

Fig. 3. Another area of the electrode shown in Fig. 2 at the end of cycle 1 discharge. Large white object is a cross section of a grid member. One electrode surface is at the right side of the photograph. Lines forming the squares are 60μ apart.

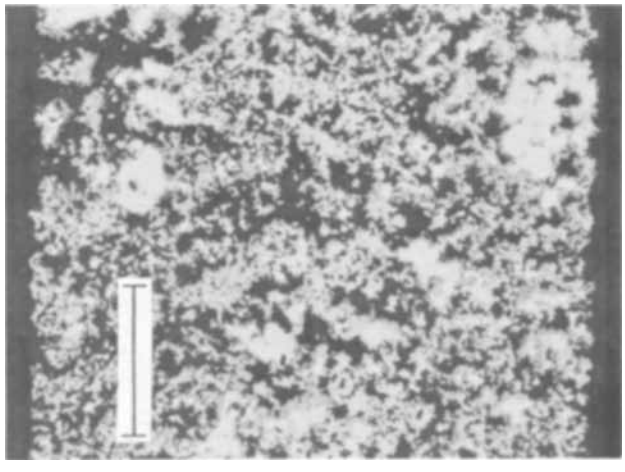

Fig. 4. Cross section of an electrode at the end of cycle 2 discharge. Electrode surfaces are at the sides of photograph. Largest Ag particles shown here had not oxidized completely during the previous two charges. Marker indicates 250μ.

electrode. As mentioned above, these very large particles were incompletely oxidized during charges. Only the surface of the largest particles was oxidized during the first charge. This surface oxide layer was reduced during the next discharge, and a layer of small Ag particles formed from the oxide layer.

The deposit of small particles gradually became thicker on the surface of large particles as an electrode was cycled. Comparison of discharged electrodes at cycles 2 and 1 showed that the number of small Ag particles present on the grid and on the large particles had increased noticeably during cycle 2. This deposit of small particles continued to grow as an electrode was cycled. Comparison of Fig. 5 with Fig. 4 shows that the deposit had become much thicker by cycle 30.

Growth of voids and clumps of particles.—The Ag particles in an electrode gradually clumped together as the electrode was cycled, and the formation of large clumps was accompanied by the development of large voids between the clumps. These changes are illustrated in Fig. 4 and 5. A comparison was made of particle distribution in discharged electrodes at cycles 1, 2, 5, 15, 27, and 30. This comparison indicated that the greatest increase in void size and in clumping of Ag particles took

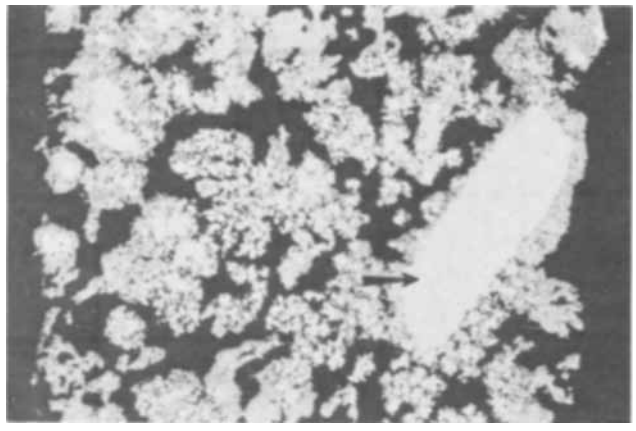

Fig. 5. Cross section of an electrode including a grid member (arrow) at the end of cycle 30 discharge at the 1-hr rate. Electrode surfaces are at the sides of photograph. Comparison with Fig. 4 at the same magnification shows changes in thickness of deposit on the grid and on the largest Ag particles. Note also the changes in voids and in Ag particle distribution.

place during the first 15 cycles. The increases were particularly evident between cycle 5 and 15. The size of voids and clumps increased more slowly from cycle 15 to 30 than from cycle 1 to 15.

Note that the discharge capacity gradually decreased when Ag electrodes were cycled using the 1-hr discharge rate (Fig. 6). This slow capacity decrease took place simultaneously with the gradual change in electrode structure. The capacity of electrodes that were discharged at the 20-hr rate has been included in Fig. 6 for comparison.

Structure of discharged electrode after 15 cycles.—The greatest change in electrode structure took place during the first cycle, with small Ag particles forming throughout the electrode during the rapid discharge. The small Ag particles were gradually replaced by larger particles when an electrode continued to be cycled, and clumps of particles gradually increased in size. The change in average particle size with cycling was less noticeable in some areas of a discharged electrode than in other areas. Figure 7 illustrates some of the Ag particles present in a discharged electrode at cycle 15. Comparison with Fig. 2 shows that the porous, sponge-like structure within the clumps of small particles was much the same in discharged electrodes at cycles 1 and 15, and that there was little change in the size of the small pores in these clumps.

A few of the larger particles that formed during discharge, gradually becoming more numerous as the number of cycles increased, are included in Fig. 7. The replacement of the small particles which formed dur-

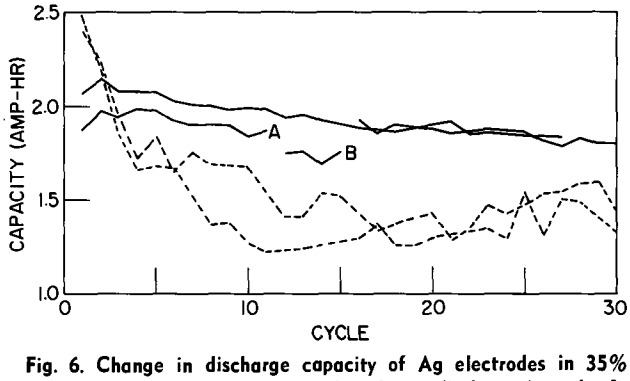

Fig. 6. Change in discharge capacity of Ag electrodes in 35% KOH at 25°C, showing two electrodes always discharged at the 1-hr rate (solid lines) and two electrodes of the same construction always discharged at the 20-hr rate (dashed lines). All charges were done at the 20-hr rate. At point A one cell stood discharged 74 days and at point B the electrolyte in this cell was replaced.

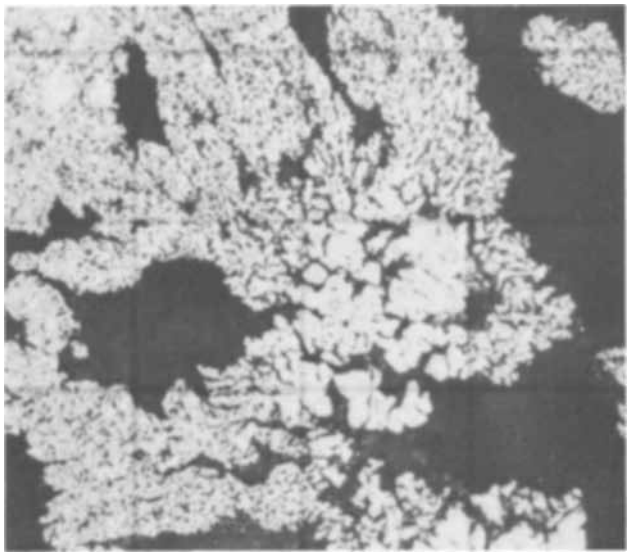

Fig. 7. Area of an electrode at the end of cycle number 15 discharge showing several sizes of Ag particles that have formed. Comparison with Fig. 2 indicates that voids have become larger as groups of Ag particles have clumped together. Lines forming squares are 30μ apart.

ing the first discharge was a slow process. The larger Ag particles were comparatively rare in the early cycles, but by cycle 15 approximately 10-15% of the active material in a discharged electrode consisted of such particles.

The large Ag particles which gradually replaced the small particles were distributed unevenly in the electrode. As much as 40-50% of some areas consisted of large particles at cycle 15, although the average for the whole electrode was only 10-15%. These larger particles were most often found in the interior of the discharged electrode and near the grid, but almost never at or near an electrode surface. These large Ag particles which formed during discharge could usually be distinguished readily from the even larger Ag particles that remained residual from the unused electrode, since there were easily recognizable differences in the structure and size of the two types.

Structure of discharged electrode after 30 cycles.—The large Ag particles occupied 30-40% of the volume of an electrode at the end of cycle 27 or 30 discharge. A typical view is shown in Fig. 8. Comparison with Fig. 7 shows that the finely divided, sponge-like structure had become less common as the number of cycles had increased. The proportion of a discharged electrode that consisted of large particles had increased by a factor of 2 or 3 in the period between cycle 15 and 30. Some of the larger Ag particles are shown at higher magnification in Fig. 9. Void space was less than usual in regions where many of these particles had clumped together. Distribution of the large particles had become very uneven. As much as 85% of some areas consisted of the large particles at the end of cycle 30, while only 10% of the other areas contained large particles.

Although many large particles had formed by the end of cycle 30 discharge, the areas near the surface of an electrode still consisted almost entirely of small Ag particles. An example of the small particles at the surface is given in Fig. 10. Small particles of this size had been found at the end of every discharge, beginning with the first discharge. As an electrode was given additional cycles, the smallest Ag particles were gradually replaced by larger particles except in areas near the electrode surface. Another change was that groups of needle-like dendrites were less common in the later cycles than they were in the early cycles. The needle-like dendrites had cross sections which were the same size as the particles shown in Fig. 10.

The average size of Ag particles increased as distance of the particles from the surface increased in electrodes that had been cycled repeatedly. The small Ag particles which were present at the surface of a discharged electrode have already been illustrated by Fig. 10. The particles which were found in regions close to the surface were larger, and some of these particles are shown in Fig. 11. The shapes of Ag particles shown in Fig. 10 and 11 were similar despite the differences in size. Although the particles shown in Fig. 11 were not of an uncommon size, it was more usual for the Ag in a discharged electrode to be present as the larger particles which were illustrated in Fig. 9.

Electrode of unusually low porosity.—There was one exception to the earlier statement that large Ag particles were almost never found at or near the electrode surface. Samples were taken from one electrode which only gave three-fourths the capacity of the other electrodes. It was found that the Ag particles were packed more closely in this electrode than was usual. The structure after five charge-discharge cycles was dif-

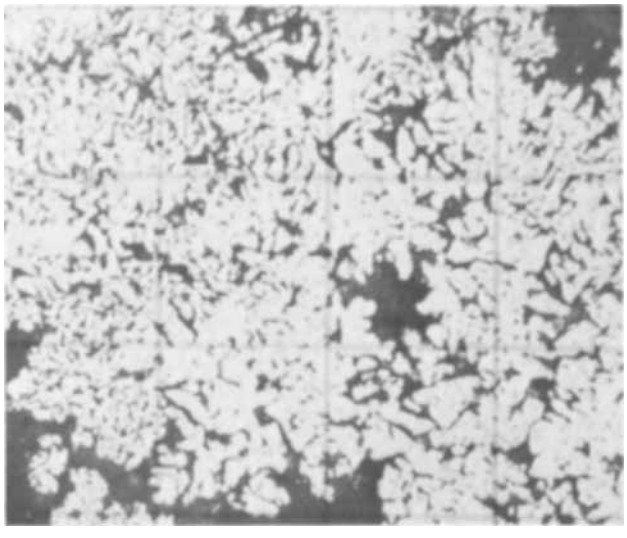

Fig. 8. Area of an electrode at the end of cycle 27 discharge including large and small Ag particles. Compare with Fig. 1, 2, and 7, all at the same magnification. Average size of Ag particles present at the end of a discharge has gradually increased with cycling.

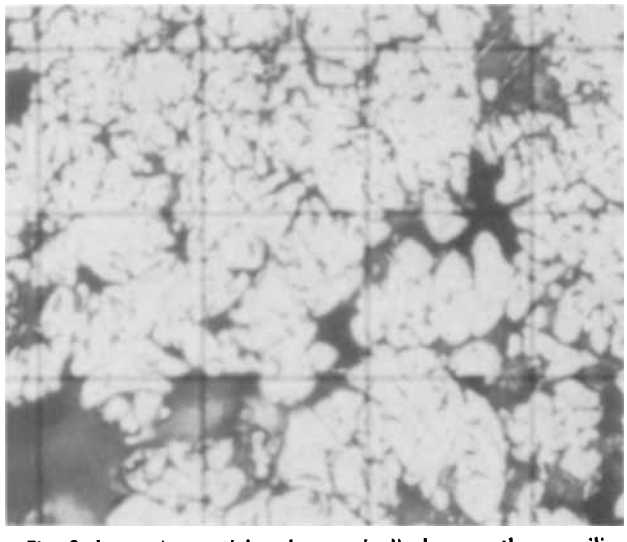

Fig. 9. Large Ag particles that gradually became the prevailing form in the interior of a discharged electrode as the number of cycles increased. A different area of the sample shown in Fig. 8 and at higher magnification. Lines forming squares are 15μ apart.

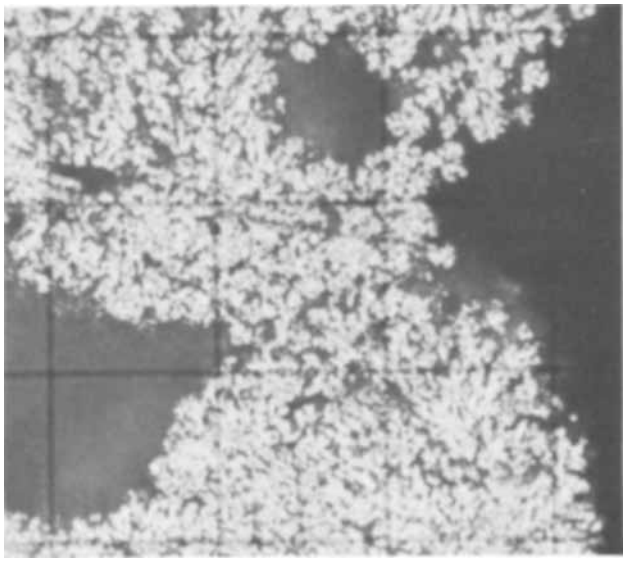

Fig. 10. Small Ag particles present at the end of cycle 30 discharge at the 1-hr rate. Right side of photograph is a surface of the electrode. Small Ag particles were always found in electrodes discharged at the 1-hr rate, but gradually became less common with cycling. Same magnification as Fig. 9.

ferent from the structure found in all other electrodes that were examined. The range of particle sizes was similar to the range found in other electrodes at cycle 5, but larger Ag particles were more numerous than smaller particles. Many of the large particles were present near the electrode surface, in contrast to the usual absence of large particles near a surface. The reason for the abnormal structure was not determined, but it is believed that the close packing of Ag particles contributed to the low capacity obtained from this electrode.

Discussion

Dependence of particle size on discharge c.d.—The present investigation of the microstructure of Ag electrodes has demonstrated that two identical electrodes can be converted by a single discharge into electrodes having structures and charge acceptance quite different from each other. These changes result from simply using different rates of discharge current. When the first discharge of a sintered Ag electrode was done at the relatively high c. d. required for the 1-hr discharge rate, the Ag particles that were produced during reduction of the oxides were smaller than the particles present in the unused electrode (Fig. 1 and 2). On the other hand, over half of the Ag that was produced during a slow discharge formed as large granular particles when the first discharge was done at the 20-hr rate (2). These large granular particles were approximately 10 times as large as the particles in the unused electrode. The results of x-ray diffraction have also indicated that Ag particle size varied inversely with the c. d. (3).

Table I summarizes the structural changes that took place during discharges. Table I is based on both the present and earlier work (1, 2).

It was concluded from the shapes of the Ag particles that a dendritic type of growth occurred during a fast discharge. Dendritic growth would be expected to occur when appreciable concentration gradients were set up in the electrolyte and when concentration of soluble Ag species was low near the surface where metallic Ag was forming. There would be more time for diffusion to take place through the electrolyte during a slow discharge. This would promote the growth of large Ag particles which lack obvious dendritic shapes when c. d. was low. Work on electrodeposition of Ag from various media, such as aqueous solutions of several different Ag salts (4, 5), or a LiCl-KCl eutectic (6), has shown that the mechanism of Ag deposition changes at high current densities. The same should be true when Ag forms in a KOH solution, as in the present work.

Dependence of capacity on particle size.—The size of the particles which were present in these electrodes was very important, since small Ag particles can be oxidized more readily and more extensively than large particles. This means that an electrode consisting of small Ag particles can be charged more rapidly and to a greater capacity than an electrode consisting of large particles. After large Ag particles had formed during a slow discharge, the original capacity of an electrode was not regained readily by using fast discharges. The central portions of large particles remained as metallic Ag at the end of a charge, instead of being oxidized. Discharge c. d. is an important factor to consider, therefore, when it is necessary to obtain a large capacity from Ag-Zn and Ag-Cd storage batteries over a period of several cycles.

The slow decrease in capacity that occurred when the Ag electrodes were discharged at the relatively fast 1-hr rate (Fig. 6) resulted mainly from the average size of Ag particles gradually growing larger as an electrode was cycled. The clumping of Ag particles into groups of increased size may also have been a factor in the slow capacity decrease, as well as loss of

Table I. Major effects of c.d. on the structures produced in Ag electrodes during discharge. Electrodes were cycled in 35% KOH at 25°C, with all charges done at the 20-hr rate

Always discharged at 1-hr rate	Always discharged at 20-hr rate
Ag_2O formed first on surface of AgO clumps during a discharge, then within clumps. Only one-fourth of the AgO was reduced to Ag_2O before Ag began to form.	Ag_2O formed on surface of AgO clumps and within AgO clumps simultaneously during a discharge. Over half of the AgO was reduced to Ag_2O before Ag began to form.
Ag formed throughout electrode at cycle 1 discharge, but in later discharges Ag formed first at electrode surface with formation gradually moving inward. Ag formed into particles smaller than those in unused electrode. Average size of Ag particles gradually increased with cycling.	Ag formed throughout electrode at scattered sites during a discharge, with a slight preference for formation at or near electrode surface. Ag formed into particles considerably larger than those in unused electrode. Size of Ag particles did not increase greatly after first discharge.
When electrode was 65% discharged more AgO was present than Ag_2O. At end of discharge some AgO and Ag_2O remained.	When electrode was 65% discharged only small amount of AgO was still present. At end of discharge no oxides were found.
There was little attack on grid during cycling.	Grid cross section decreased in size because of gradual attack during cycling.

active material through shedding or through oxides dissolving in the electrolyte and not reprecipitating back on the electrode. As the number of cycles increased, many of the larger Ag particles attained sufficient size that they did not oxidize completely during a charge. The increased size of these Ag particles may have resulted from particles growing together during a fast discharge. The first formation of metallic Ag occurred at the surfaces of an electrode during a fast discharge (1) and only small Ag particles were found in these areas.

Another indication of the relationship between capacity and particle size was that a greater capacity loss occurred during the first few cycles when the slow 20-hr discharge rate was used than when a rapid discharge rate was used (Fig. 6). Most of the Ag particles that formed during the slow discharges were at least an order of magnitude larger than the particles that formed during 1-hr rate discharges (2). The greatest change in particle size occurred during the first discharge regardless of which discharge rate was used.

Influence of discharge c. d. on grid corrosion.—The grid corrosion rate was decreased by using fast discharges instead of slow discharges. When the slow, 20-hr discharge rate was used, the grid gradually decreased in size as a result of penetrating attack at the grid surface (2). On the other hand, attack on the surface of the grid was noticeably less after using the higher c. d. of the 1-hr discharge rate for 5 cycles than it was after 5 cycles at the 20-hr rate. The average thickness of a grid member, after 30 cycles using the 1-hr discharge rate, was still approximately the same as the original thickness. Some penetrating attack had occurred, however, and the grid surface was no longer smooth.

The deposit of small Ag particles which formed on the grid surface during a discharge at the 1-hr rate gradually increased in thickness when discharges were repeated (Fig. 3 and 5). During a charge the small Ag particles in this deposit tended to be oxidized before the grid surface was oxidized. Oxidation of the deposit formed a protective oxide coating on the grid surface, so that less oxidation and, therefore, less attack of the grid occurred during a charge that followed a fast discharge.

Importance of particle size when manufacturing Ag electrodes.—Unfortunately, the mechanism which resulted in forming a protective oxide coating on the grid also formed protective coatings on the surface of the largest Ag particles present in the original sintered electrode. These oxide coatings prevented complete oxidation of large Ag particles in a charge and, therefore, prevented full utilization of the Ag active material in an electrode. The increasing thickness of the deposit of small particles that formed on the large Ag particles residual from the unused electrode was illustrated in Fig. 4 and 5.

Nothing that has been observed thus far has indicated that any advantage is obtained by including large Ag particles in the electrodes. Although the maximum thickness of the oxide layer on Ag particles was often greater than 5μ at the end of a charge, a minimum thickness of only 1-2μ was common. Therefore Ag particles having a diameter as large as 2-4μ can be expected to oxidize completely during a charge, if the particles have access to the electrolyte, and slightly larger particles should oxidize almost completely. It should be advantageous to grade particle size carefully when manufacturing sintered Ag electrodes and have a maximum particle size no larger than 3-4μ. Small changes in the size of particles present in an unused electrode will only affect the first few cycles, because the particle size of the Ag produced during a discharge is strongly dependent on discharge conditions and the particles tend to reach a limited size range when electrodes are cycled repeatedly.

Gradual clumping of particles.—Cycling was always accompanied by the slow formation of large voids as the particles clumped together into larger groups (Fig. 5, 7). The discharge rate had no apparent effect on the formation of voids and the clumping of particles. The voids and clumps seemed to grow at the same rate and to be approximately the same size, whether the 1-hr or 20-hr discharge rate was used for the same number of cycles.

Charge-discharge efficiency.—The electrodes which were discharged at the 1-hr rate gave only about 90% of charge capacity on the first discharge (not including the part of charge capacity used in evolving oxygen), since the silver oxides were not completely reduced during the fast discharge. Beginning with cycle 2, however, all discharges at the 1-hr rate gave nearly 100% of the capacity of the preceding charge. Approximately the same amount of oxide remained at the end of each discharge at the 1-hr rate. On the other hand, the electrodes which were discharged at the 20-hr rate always gave close to 100% of the capacity accepted during the previous charge.

The difference in the charge-discharge efficiency accounted for the electrodes which were discharged at the 1-hr rate giving less capacity at cycle 1 than the electrodes discharged at the 20-hr rate (Fig. 6). The electrodes which were discharged at the 1-hr rate were giving more capacity by cycle 3 than those discharged at the 20-hr rate, since capacity had decreased rapidly during the first few cycles using slow discharges. Based on a theoretical capacity of approximately 2.9 A-hr for the electrodes used in this work, it can be seen from Fig. 6 that in the first few cycles the electrodes discharged at the 1-hr rate gave 65-75% of the capacity theoretically possible, and these electrodes were giving 60-65% of theoretical capacity at cycle 30. Although the electrodes discharged at the 20-hr rate had given approximately 85% of theoretical capacity at cycle 1, they were only giving 45-55% of theoretical capacity at cycle 10.

Low capacity in impure electrolyte.—The capacity loss shown at point A of Fig. 6 was assumed to be due to carbonate content of the electrolyte becoming high during the 74 days of inactivity. Although the cell containing this electrode was closed, holes for the wire leads were not sealed tightly and CO_2 from the atmosphere could enter the cell. Carbonate could also result from the cellulosic separators reacting with the KOH solution. The electrode capacity improved markedly when the old KOH solution was replaced with fresh solution. The first discharge after replacing the electrolyte gave 113% of the capacity of the previous charge (measuring charge capacity to the beginning of oxygen evolution). An unusually large quantity of silver oxides must have remained in this electrode at the end of the preceding discharge. The concentration gradients in the electrolyte probably had become unusually high during discharges at the 1-hr rate after carbonate had increased and KOH concentration had decreased. The electrolyte has a strong influence on crystallization and should be studied in detail.

Conclusions

When sintered Ag electrodes were charged at the 20-hr rate and discharged at the 1-hr rate in 35% KOH solution at 25°C, the following changes took place:

1. As the oxides were reduced during the first discharge, the Ag particles which formed had a much smaller average size than the Ag present in the unused electrode. These small particles which formed during a fast discharge contrasted with the large granular particles of Ag, approximately 10 times as large as those in the unused electrode, which formed during a slow discharge at the 20-hr rate.

2. The capacity of an electrode decreased more slowly when electrodes were cycled using the 1-hr discharge rate than when using the 20-hr rate, because the small Ag particles which formed during a

fast discharge could be oxidized more readily and more completely during a charge.

3. Small particles of Ag formed on the surfaces of a grid during discharges at the 1-hr rate, and tended to protect a grid from serious attack. When the 20-hr discharge rate was used, however, a grid gradually decreased in size as a result of the grid surface being attacked repeatedly.

4. During the first discharge, the Ag formed into clumps of particles that were larger than the clumps originally present. As an electrode was cycled, the clumps of Ag particles gradually increased in size while large void spaces developed and small voids became less common.

5. The proportion of a discharged electrode that consisted of small Ag particles slowly decreased as larger Ag particles gradually developed in the interior of the electrode with cycling. Although the larger particles were comparatively rare in the first few cycles, approximately 30-40% of a discharged electrode consisted of the larger Ag particles at cycle 30.

Differential Capacitance and Cyclic Voltametric Studies on Smooth Lead in H_2SO_4 Solutions

Thomas F. Sharpe*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

Differential capacitance and cyclic voltametric curves for smooth lead electrodes, in the presence of organic additives, are given and discussed. The results of these experiments are compared with respect to the effectiveness of the additives as expanders in the lead-acid system.

The use of lignin and other naturally occurring organic materials as expanders for the negative plate in the lead-acid system is well known (1), and several studies have been made to correlate expander activity with organic structure. Ritchie (2) reported that the effectiveness of pure organic compounds as expanders appears to be directly related to the ease with which they can be degraded to "humic substances." The best results were obtained with carbohydrates and some homologous phenolic compounds. Other studies (3) suggested that catechol residues in the lignin molecule provide expander action. Recently the Physics Department of the Research Laboratories of General Motors Corporation tested homologs of the phthalein series and found them (4) to possess various degrees of expander activity.

Most expander studies have been based on determining their effect on the charge and discharge efficiency of experimental cells or full-size batteries (2, 3). Although such tests give little insight regarding the exact mechanism by which the expander functions, it has been suggested (5) that the expander operates by an adsorption process.

One method for studying adsorption at an electrode surface is to obtain curves showing the relationship between differential capacitance and electrode potential. The purpose of this work was to determine the extent to which organic additives, having known degrees of expander activity, alter the shape of such curves obtained with smooth lead electrodes in H_2SO_4 solutions. Also included in this study were cyclic voltametric experiments to measure the electrical current that flowed throughout the potential range at which the differential capacitance measurements were made.

Experimental

The spherical test electrodes for this study were of high-purity (99.999+%) lead and were prepared in the manner described elsewhere (6). The Pyrex measuring cell contained a glass frit to separate the counterelectrode (a portion of a lead-acid-battery positive plate) from the test electrode. The test electrode compartment of the cell was provided with ground glass openings to accommodate the test electrode assembly, pre-electrolysis electrodes, and Hg/Hg_2SO_4 reference capillary. Solutions were prepared from reagent-grade H_2SO_4 and deionized, doubly distilled water, and were pre-electrolyzed for 16 hr using platinum gauze electrodes.

The a-c impedance bridge used for the capacitance measurements is similar to that reported in the literature (7). A battery-operated potentiostat (8) was used to control the potential of the test electrode against the reference electrode, and the a-c signal was eliminated from the potentiostat circuit by means of a filter choke. Data were obtained by balancing the a-c signal (10 mV peak to peak) shown on the screen of a Tektronix Oscilloscope, Type 502-A, with the direct-reading resistance and capacitance components of the bridge.

For the cyclic voltametric experiments, the test electrodes were subjected to a voltage-time sweep by feeding a signal from a sweep generator (8) into a Wenking 63TR potentiostat. The current trace during the sweep was displayed on the screen of the oscilloscope and was recorded with a Tektronix Oscilloscope Camera.

* Electrochemical Society Active Member.

The organic materials used in this study were ammonium lignosulfonate and pure compounds of the phthalein series, and were found (4) to possess expander activity in the following order. Rhodamine B < pyrogallolsulfonephthalein < gallein < ammonium lignosulfonate < coerulein. All materials were tested at a concentration of 10 ppm and at room temperature.

Results and Discussion

Differential capacitance measurements.—Differential capacitance curves for spherical lead electrodes, obtained at a-c frequencies of 500 and 5000 Hz in 1.25 sp gr H_2SO_4, are given in Fig. 1. The capacitance measurements were started at —600 mV (*vs.* NHE), in the region of hydrogen evolution, and were made at 25-mV intervals up to about 150 mV beyond the $Pb/PbSO_4$ reversible potential (—345 mV *vs.* NHE). Steady values of the capacitance were found within a few minutes after changing the potential of the test electrode.

As evident from Fig. 1, all the organic materials lowered the capacitance values to some extent. The lowering of the capacitance can be attributed to adsorption of the organic molecules at the electrode surface. Over the potential region in which they are adsorbed, the molecules can alter the thickness of the double layer and/or the dielectric constant of the medium within it, thereby changing the values for the differential capacitance. Coerulein, the best expander of the compounds tested, appreciably lowered the capacitance throughout the entire potential region cathodic to the $Pb/PbSO_4$ reversible potential. Furthermore, the pseudocapacitance associated with the formation of $PbSO_4$ at the electrode surface was markedly suppressed and shifted to more anodic potentials. At the other extreme, rhodamine B, the poorest expander, moderately lowered the capacitance only at high cathodic potentials, thereby indicating that it is adsorbed only in this potential region.

From a practical standpoint, therefore, the results indicate that the measurement of the differential capacitance of smooth lead electrodes in the presence of organic materials can be used to select those substances that will be most effective as organic expanders for the negative plate in the lead-acid system. As expander activity increases, the differential capacitance decreases throughout the entire cathodic potential region. From a theoretical interest, however, further experiments are required to determine such factors as coverage, heats of adsorption, and orientation of the organic molecules at the electrode surface.

Cyclic voltametric experiments.—Typical oscilloscopic traces of cyclic voltametric curves for spherical lead electrodes in pure, 1.25 sp gr H_2SO_4 are given in Fig. 2. The sweeps were started at —600 mV (*vs.* NHE) after the electrodes were allowed to stand at this potential for 5 min. A new electrode was used for each sweep, and the arrows in Fig. 2-a indicate the direction of the sweep. Because of the low magnitude of the cathodic current relative to the anodic current, it was often necessary to set the oscilloscope at a higher sensitivity (Fig. 2-b) to obtain an accurate measurement of the cathodic current. Current densities at various potentials could be calculated from the areas of the lead electrodes (ranging from 0.02 to 0.05 cm^2) and the current values displayed on the traces.

In cyclic voltammetry, the question arises as to how much of the measured current is used for charging and discharging the double layer. The double-layer current (i_{dl}, in $\mu A/cm^2$) is calculated by the expression

$$i_{dl} = C\frac{dv}{dt}$$

where C is the double-layer capacitance ($\mu f/cm^2$) and dv/dt is the sweep rate (V/sec). Assuming that for a smooth Pb electrode C is close to 20 $\mu f/cm^2$, the double-

layer current, even at the highest sweep rate (62.5 x 10^{-3} V/sec) used in these studies, is only about 1 μA/cm^2. This was a negligible portion of the total current and could therefore be disregarded.

The effect of sweep rate on the shape of the cyclic voltametric curve for lead in pure H_2SO_4 is given in Fig. 3. The anodic sweep is represented by a solid line, and the cathodic sweep is given by a broken line. The peak in the anodic current corresponds to the formation of $PbSO_4$. The peak height varies linearly with sweep rate (broken line, Fig. 4), which is in agreement with theory since the $PbSO_4$ behaves as an adsorbed intermediate (9) at the electrode surface.

During the cathodic sweep, the $PbSO_4$ produced in the anodic sweep is reduced to lead, and hydrogen is evolved at the electrode surface. The current for the reduction of $PbSO_4$ appears to merge with the current for hydrogen reduction.

In the presence of the additives, the anodic current peak height, measured at a given sweep rate, varied over a wide range of experimental values (Fig. 4), and no correlation could be made between expander activity and peak height. Since the peak height is proportional to the pseudocapacitance associated with the formation of $PbSO_4$, it would be expected, from the results given in Fig. 1, that as expander activity increased, the peak height would decrease. The absence of such a trend is disconcerting, and no explanation is currently available.

There was, however, a correlation between expander activity of the organic additives and the current measured during the cathodic sweep. As expander activity increased, the current for the reduction of $PbSO_4$ and hydrogen decreased. The trend was consistent over a range of sweep rates, and typical results are shown in Fig. 5. The decrease in the cathodic current, like the lowering of the differential capacitance, is attributed to adsorption of the additives at the electrode surface.

The adsorption of an organic expander at a smooth lead electrode is undoubtedly distributed differently than that at a lead-acid battery negative plate. Because of its porous nature, the negative plate possesses reaction sites having a wide range of activity. Unlike the smooth lead electrode where the adsorption may be distributed over most of the electrode surface, adsorption at the negative plate may occur only at the most active reaction sites. The reduction of $PbSO_4$ and hydrogen would be inhibited at these sites, thereby forcing the electrochemical reaction to occur over the rest of the electrode surface. Such a mechanism would also tend to retard crystal growth which could account for

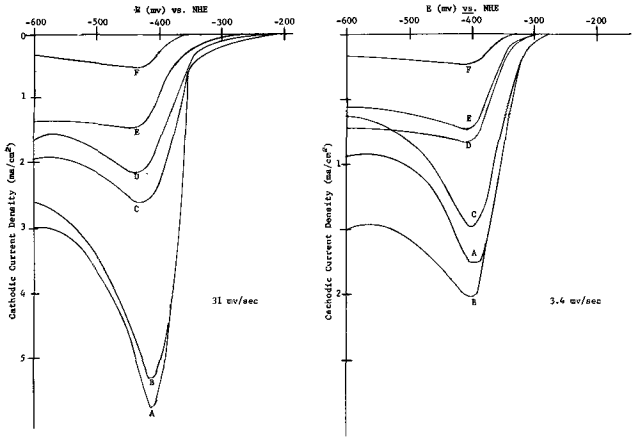

Fig. 5. Currents observed during cathodic sweep of lead electrodes in 1.25 sp gr H_2SO_4. A = no additive, B = rhodamine B, C = pyrogallolsulfonephthalein, D = gallein, E = ammonium lignosulfonate, F = coerulein. All additives were tested at 10 ppm.

the fine structure that is observed (10) when the expander is added to the negative plate.

A Reversible Solid-State Battery with $RbAg_4I_5$ as Electrolyte[1]

Mario De Rossi, Gianfranco Pistoia, and Bruno Scrosati*

Istituto Elettrotecnico, Università di Roma, Rome, Italy

ABSTRACT

A solid-state reversible cell of the type $Ag(Hg)/RbAg_4I_5/I_2$, TBAI, C, has been developed. The anodic and cathodic contact polarizations have been minimized by amalgamation of the silver electrode and the use of a suitable mixture made of tetrabutylammonium iodide (TBAI), iodine, and graphite, respectively. The cell has an open-circuit voltage of 0.56V at 25°C, a total volume of 5 cm^3, an internal resistance of 30 ohms, short-circuit current of 1.5 A/dm^2, and is rechargeable with high coulombic efficiency.

Solid-state batteries have been widely studied in recent years because they possess some remarkable advantages with respect to conventional systems such as potentiality for extreme miniaturization, large temperature ranges of operation, and long shelf life. Because of these characteristics, solid electrolyte batteries could be very profitably used in transistorized circuits, space applications, and so on.

The most serious shortcoming of this type of cell, however, has been, until very recently, the high value of the internal resistance which has limited its practical utilization to microwatt power applications (1, 2).

Silver halides, which have been considered until a short time ago to be among the best ionic conductors, have a specific conductivity which is 6-8 orders of magnitude less than that of conventional battery electrolytes (*see* Table I).

The operative possibilities of a solid-state cell were first shown by Lehovec and Broder (3) who described a cell made of a silver anode, an AgI solid electrolyte, and a cathodic mixture of iodine and graphite. This cell has an open-circuit voltage (OCV) of about 0.7V at room temperature and yields short-circuit current densities in the range of $\mu A/cm^2$. Also described is the behavior of a high-temperature cell of the type:

$$Ag/AgI/Ag_2S,C \qquad [1]$$

to take advantage of the fact that AgI is highly conductive in its high-temperature α form (4) as shown in Table II.

Cell [1] has an OCV of 0.2V at 200°C, current densities up to 0.18 A/cm^2, but very short shelf life.

In 1958 Weininger (5) described a "bead" cell made of a small bead of AgI and two electrodes, silver and tantalum wires, inserted into the electrolyte. The mini-

aturized cell yields an OCV of 0.68V and current densities of about 14 μA/cm^2. The high-temperature behavior of the cell and its recharge possibilities are also discussed.

Subsequently, Weininger (6) built the cell

$$Ag/AgI/Ta, I_2 \qquad [2]$$

working in the temperature range 150°-550°C and having as cathodic material either iodine or a chemical compound able to furnish free iodine at high temperature, such as cesium polyiodides. Cell [2] has an OCV of 0.67V, capacity of 10 mA-hr, and short-circuit currents up to 18 mA.

In 1959 Smyth (7) described a solid electrolyte cell consisting of a silver anode, an AgCl electrolyte film a few microns thick, and a cathode composed of $KICl_4$, carbon black, and grease binder. The use of $KICl_4$ as a low-pressure source of chlorine makes the cell very stable with a shelf life of ten years.

The Smyth cell has an OCV of 1.04V at 25°C and an internal resistance of about 10^5 ohms, a capacity of 2 coulombs, and short-circuit current densities of the order of 15 ÷ 30 μA/cm^2.

Recently, Foley has made a very comprehensive review of solid electrolyte galvanic cells (8).

In the cells so far described, the high internal resistance remains the most serious problem, which has been partially overcome by high-temperature and thin electrolyte film techniques.

In very recent years, several attempts have been made to improve the conductivity of silver halides and to synthesize highly conductive solid electrolytes (8).

In 1964 Takahashi and Yamamoto (9) described the cell

$$Ag/Ag_3SI/I_2, C \qquad [3]$$

The specific conductivity of Ag_3SI at 25°C is 10^{-2} ohm^{-1} cm^{-1} (10), much higher than that of the silver halides (*see* Table I). Cell [3], in fact, can yield short-circuit current densities as high as 10 mA/cm^2 at room temperature. Unfortunately, the electrolyte cannot be used for battery purposes since it has high electronic conductivity (8). In 1967 Bradley and Greene (11) and, subsequently, Owens and Argue (12), described a new group of solid electrolytes of the type MAg_4I_5, where

Table III. Specific conductivity of $RbAg_4I_5$ at 25°C

0.124	Bradley and Greene (11)
0.210	Owens and Argue (12)
0.250	This work

M is K, NH_4, Rb, and possibly Cs, having a specific conductivity, due only to silver ions, as high as 0.2 ohm^{-1} cm^{-1} at 25°C (*see* Table III).

The advantage of these electrolytes for an improved solid-state battery is obvious and in 1968 Scrosati, Boddy, and De Rossi (13) described a cell of the type

$$Ag(Hg)/RbAg_4I_5/I_2, C \qquad [4]$$

having an amalgamated silver anode, $RbAg_4I_5$ solid electrolyte, and a cathodic iodine-graphite mixture.

Cell [4] has at 25°C an OCV of 0.58V, a total volume of ~2 cm^3, short-circuit currents up to 4 mA, and a total available charge of 130 coulombs (*see* Table IV). The internal resistance of the cell is about 300 ohms. This value, even if much lower than that of the operative solid electrolyte batteries previously described, is still higher than that one would have expected on the basis of the conductivity value of the electrolyte. The relatively high value of the internal resistance in cell [4] is probably due to interfacial effects between the iodine-graphite mixture and the electrolyte.

In 1968 Argue, Groce, and Owens (14) described a solid-electrolyte battery of the type:

$$Ag/RbAg_4I_5/RbI_3, C \qquad [5]$$

formed by a mixture of silver, carbon, and $RbAg_4I_5$ as anode, $RbAg_4I_5$ as electrolyte, and a mixture of RbI_3, carbon, and $RbAg_4I_5$ as cathode.

The use in cell [5] of a polyiodide in the place of iodine seems to have overcome the contact cathodic polarization observed in cell [4], thus allowing the former to yield higher current densities (*see* Table IV).

Nevertheless, some of the performances of the cell [5] described in the paper by Argue, Groce, and Owens are rather surprising. For instance the internal resistance of a low current drain cell is reported to be (2 ± 1) ohm, while in the discharge of a battery of 5 cells in series, having an OCV of 3.30V, on 100 kohm load, load voltages ranging from 3.29 to 3.26V are reported at 25°C. From these experimental data, realistic cell resistance appears to range from 60 to 250 ohms.

In this work, a solid state reversible cell with $RbAg_4I_5$ as electrolyte and in which the cathodic polarization is minimized by the use of suitable cathodic mixture is described. Furthermore, a method to obtain an improved electrolyte and some of the electrical properties of the electrolyte are also reported.

Experimental

Materials.—All the chemicals used were reagent grade. The electrolyte, $RbAg_4I_5$, was prepared by slow

heating of a stoichiometric mixture of AgI and RbI to melting and then quenching. All these operations were performed under vacuum. Subsequently the solid product was ground and left at 165°C for about 20 hr. The powder was then compressed into pellets for the experiments. The procedure is similar to that described by Argue and Owens (12) with the difference that in the present case the melting and the quenching were done under vacuum to eliminate all the possible volatile impurities. The vacuum procedure does not change the composition of the final product, as has been proved by x-ray powder patterns, and seems to improve the $RbAg_4I_5$ conductivity (*see* Table III).

Cell structure.—The cell in its essential structure may be represented as

$$Ag/RbAg_4I_5/I_2 \qquad [6]$$

The main problems in cell [6] are the contact polarizations (13) which have been minimized in the present case by the use of an amalgamated silver disk as anode (13) and of a cathodic mixture made of powdered graphite, iodine, and tetrabutylammonium iodide (TBAI). It is known that alkylammonium salts are able to retain molecular iodine (15). The function of TBAI in the cathodic mixture is therefore to prevent tarnishing reactions by free iodine on the electrolyte when the cell is not operative. Iodine is released by TBAI during discharge and retained during charge.

In order to reduce contact resistance further, the cathodic mixture is melted, uniformly spread on the electrolyte, and allowed to solidify.

The actual cell structure is therefore

$$Ag\ (Hg)/RbAg_4I_5/I_2, TBAI, C \qquad [7]$$

Measurements.—Voltage and current determinations have been performed by a Keithley Model 610C electrometer. Conductivity measurements have been performed by the use of a cell made of two amalgamated silver disks of 1 cm diameter in contact with the electrolyte pellet. A-C conductivity was determined by a Tinsley bridge, Type 4896. Polarization studies were made by an AMEL potentiostat, Model 551.

Results

Electrolyte characteristics.—The a-c specific conductivity has been found to be 0.250 $ohm^{-1}\ cm^{-1}$ at 25°C, a value about 20% higher than that reported by Argue and Owens (12). This is probably due to the vacuum technique used in the present research in the preparation of the electrolyte.

In Fig. 1 is shown a current-voltage curve of the electrolyte obtained with two amalgamated silver electrodes at 25°C. The a-c resistance of the electrolyte sample, previously measured, was 2.9 ohms. From the data of Fig. 1, the d-c resistance appears instead to be about ten times higher, *i.e.* 27 ohms. At high current drains the polarization is much higher, thus suggesting that cells having $RbAg_4I_5$ as electrolyte should be used preferably in the low and medium current drain ranges (from μA to mA).

Figure 2 shows the typical current-voltage curve of the electrolyte obtained at 25°C with two platinum electrodes. The decomposition potential of $RbAg_4I_5$ is 0.67 ± 0.01V at 25°C.

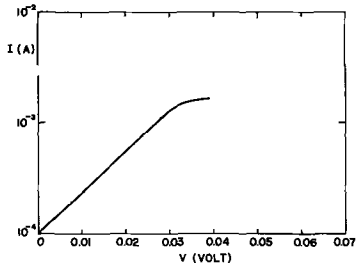

Fig. 1. Current-voltage curve for $RbAg_4I_5$ at 25°C (silver electrodes).

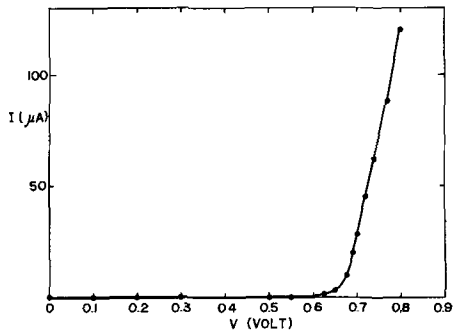

Fig. 2. Current-voltage curve for $RbAg_4I_5$ at 25°C (platinum electrodes).

Cell characteristics.—The OCV of the cell

$$Ag/RbAg_4I_5/I_2, C \qquad [8]$$

at 25°C has been found to be 0.683V (13) in good agreement with the theoretical value of 0.688V derived from the thermodynamic free energy of formation of silver iodide.

To minimize contact polarization effects, cell [7], the over-all reaction of which should be

$$Ag\ (Hg) + \tfrac{1}{2}\ I_2 \rightleftharpoons AgI \qquad [9]$$

has been taken into consideration.

The OCV of cell [7] is 0.56V at 25°C and its variation with temperature is shown in Fig. 3. The temperature dependence is 0.0006 V/°C. The cell structure is shown in Fig. 4. The cell consists of an amalgamated silver disk in contact with a pellet of $RbAg_4I_5$, ~ 2.0 cm diameter and ~ 0.15 cm thickness. The cathodic mixture is spread on the electrolyte surface. The total volume of the operative cell is ~ 5 cm^3 and the total weight ~ 10g.

From current-voltage plots at room temperature, the internal resistance was determined to be about 30 ohms (*see* Fig. 5 which applies to the initial behavior

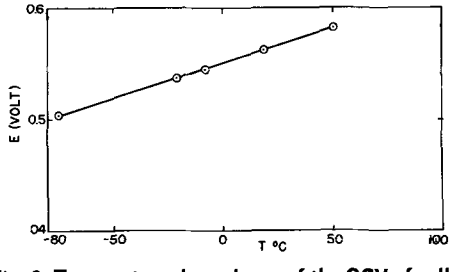

Fig. 3. Temperature dependence of the OCV of cell [7].

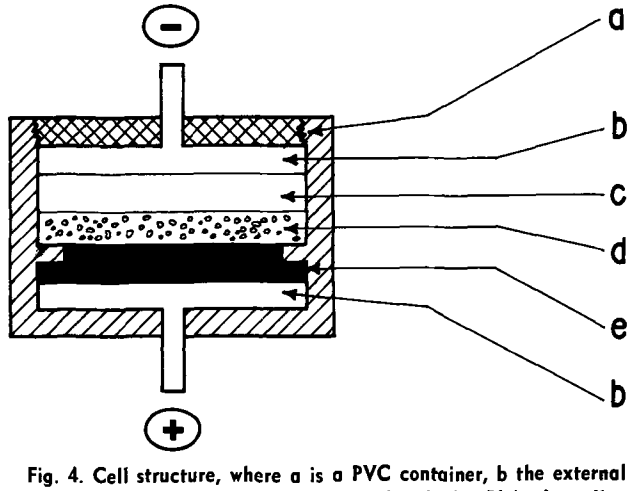

Fig. 4. Cell structure, where a is a PVC container, b the external contact, c the amalgamated silver anode, d the $RbAg_4I_5$ pellet, and e the cathodic mixture.

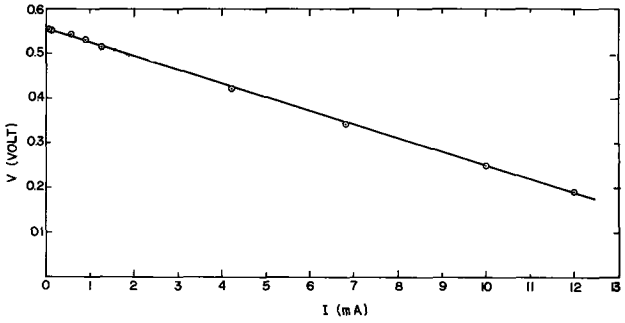

Fig. 5. Current-voltage curve for cell [7] at room temperature

of the cell). According to the a-c conductivity of $RbAg_4I_5$, the cell resistance, due to the electrolyte only, should be of the order of 0.2 ohm. The total resistance of the cell in its operative assembly is about 3 ohms, as measured by the a-c bridge. The higher value found experimentally could be explained on the basis of the data reported in Fig. 1 and of a certain residual contact resistance.

For long-time discharges, the internal resistance of the cell increases mainly because during discharge AgI, whose conductivity is very low, is formed (13).

In Fig. 6 and 7 are shown typical discharge curves at various loads and various temperatures.

Cell [7] is capable of delivering short-circuit current of ~ 50 mA (~ 1.5 A/dm²). The cell characteristics and performances at 25°C are summarized in Table IV which also gives reported data on other $RbAg_4I_5$ solid electrolyte cells.

Attempts at recharging the cell have been successful as shown in Fig. 8. The cell was discharged at 50°C through 150 ohms to 0.2V (curve a). Following this initial discharge the cell was charged at an applied voltage of 0.6V and then discharged through 1000 ohms to 0.35V (curve b). This was followed by a second charge and so on as shown in curves c and d.

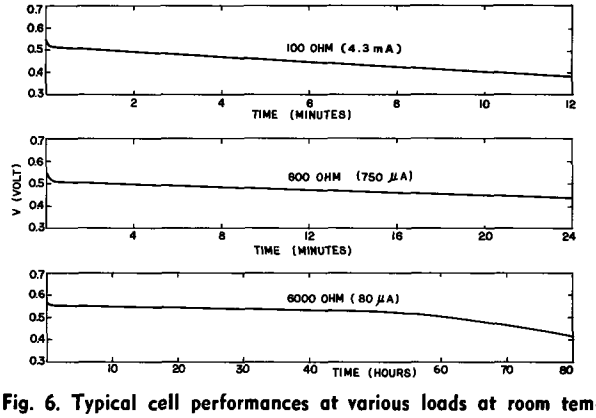

Fig. 6. Typical cell performances at various loads at room temperature.

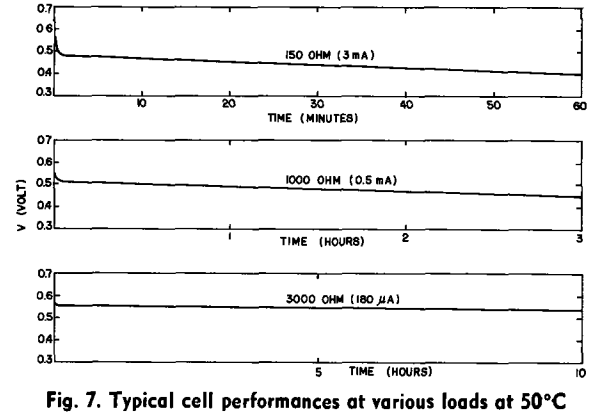

Fig. 7. Typical cell performances at various loads at 50°C

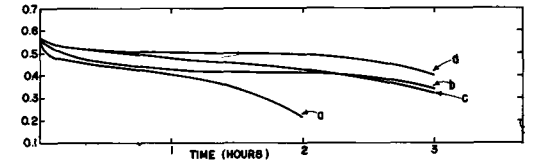

Fig. 8. Discharge curve of cell [7] charged and discharged at 50°C, where a is the first discharge at 150 ohms load and b, c, and d are the second, third, and fourth discharge curves, respectively, at 1000 ohms load.

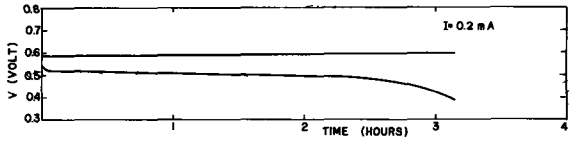

Fig. 9. Charge-discharge first cycle of cell [7] at 0.2 mA constant current and at 25°C.

The fourth charge was carried on at an applied voltage of 0.65V and the following discharge was unsatisfactory. The cell was disconnected and the negative electrode region showed a dendritic deposit of silver. This circumstance, and perhaps also the fact that the applied voltage in the fourth charge was close to the decomposition potential of the electrolyte, may explain the failure of the fifth discharge process.

This evidence indicates that the charge process preferably should be carried out at low current densities to obtain the best efficiency.

In Fig. 9 is reported a charge-discharge cycle at 25°C and at a constant current of 0.2 mA, showing a very high coulombic efficiency.

Conclusions

From the above reported data it is inferred that the cell described in this work shows clear improvements with respect to the system previously developed in our laboratory (13). Among them, the most significant is the minimization of the contact cathodic polarization.

Cell [7] also has some advantages over the battery studied by Argue, Groce, and Owens (14) at least in the low and medium current drain ranges (*see* Table IV).

Furthermore, the system described in this work shows possibilities of being recharged with high current efficiencies and, because of this and the use of iodine instead of RbI_3 in the cathodic mixture, its cost should be lower than other $RbAg_4I_5$ solid electrolyte cells.

Furthermore, cell [7] may be printed since all its components may be deposited either by evaporation (silver) or by solidification (electrolyte and cathodic mixture).

On the other hand, the cell of Argue and co-workers has a higher OCV and seems to be capable of surprisingly high current pulses, *i.e.* 90 A/dm².

On the Passivity of Iron-Chromium Alloys

III. Effect of Potential

Robert P. Frankenthal*

Edgar C. Bain Laboratory for Fundamental Research, United States Steel Corporation, Research Center, Monroeville, Pennsylvania

ABSTRACT

The kinetics of growth of the primary and of the secondary passivating films have been examined for an Fe-24% Cr alloy in 2*N* H_2SO_4 over a potential range of several hundred millivolts above the activation potential. From these data it has been possible to evaluate the effectiveness of an adsorbed film and of an oxide film in causing passivity. It is concluded that the type of film that gives rise to passivity, as well as the mechanism of anodic dissolution during the passivation process, is potential dependent: At the activation potential an adsorbed film is responsible for passivity by inhibiting the direct, activated transfer of ions from the metal surface into solution; at high potentials an oxide film acts as the passivating agent with the current limited by the rate of diffusion of ions through the film; in a 200 mV intermediate region the adsorbed film is responsible for initiating passivity, but the steady-state film is an oxide. In addition the data indicate that the rate of growth of both the primary and the secondary films is potential dependent; at sufficiently low potentials the rate constant for primary film formation is greater than that for secondary film formation, while at higher potentials the rate constant for secondary film formation becomes greater.

In the first of this series of papers (1), we showed that on an Fe-24% Cr alloy in H_2SO_4 at least two distinct, potential-dependent films are formed during the passivation process: the primary passivating film is formed reversibly at the primary activation potential, while the secondary film forms at more positive potentials, and is very stable and resistant to reduction. In subsequent work (2), we studied the kinetics of primary film growth at the primary activation potential, showed that at this potential a small fraction of a monolayer gives rise to a high degree of passivity, and presented a preferential-dissolution/adsorption mechanism for the passivation process that agreed quantitatively with the observed experimental behavior.

In this paper we extend the experimental work over a potential range of several hundred millivolts above the activation potential. Specifically we investigate the decay of the anodic current and the growth of the primary and secondary films with time at different potentials. From these data it has been possible to determine the effectiveness of a given quantity of film as a passivating agent at each potential. It is shown that none of the prevalent theories of passivity, the adsorption theory (3), the bulk oxide theory (4), or the sequential adsorption, bulk oxide theories (5, 6), is applicable over the entire potential range of passivity. Instead evidence is presented to show that at the activation potential passivity can be attributed to a film formed by an adsorption process; at high potentials an oxide is responsible; in between there exists a 200 mV region in which an initial, adsorbed film causes a large decrease in the anodic current, but is not the steady-state film which is an oxide. It is also shown that a change in the mechanism of anodic dissolution during the passivation process occurs at the same potential at which the change from passivation by an adsorbed film to passivation by an oxide film takes place. The variation of anodic current and of film growth with time and with potential is shown to be in agreement with the above conclusions.

* Electrochemical Society Active Member.

Experimental

The alloy, electrolyte solution, electrochemical cell, electrical circuitry, specimen preparation, general procedure, and justification therefore have been described in detail previously (2). Therefore, only some essential facts and procedures are summarized here.

The alloy investigated was a high-purity, vacuum-melted Fe-24% Cr ferritic alloy. The electrolyte solution was 2*N* H_2SO_4 (pH 0.02) made from reagent-grade sulfuric acid and doubly distilled water. Further purification by passing the solution over activated charcoal did not affect the results and was generally omitted.

The basic experiment consisted of the following steps: The specimen surface was cleaned by a combination of cathodic reduction and anodic dissolution, following which the specimen was put on open circuit until the steady-state corrosion potential (± 0.5 mV) was achieved; the potential was then switched to that under study and the current-time (i-t) transient was recorded; after any given time the film that had been formed could be cathodically reduced at constant

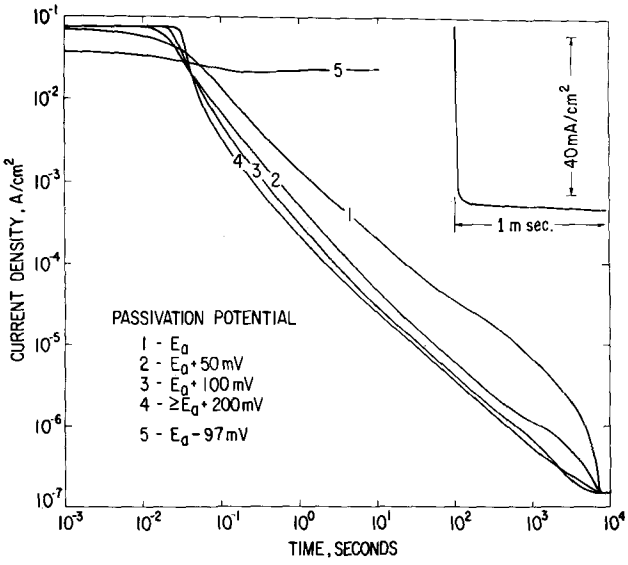

Fig. 1. Anodic current-time transients at different passivation potentials, illustrating variation with potential up to E_a + 200 mV and independence of potential at higher values. Curve 5 is the transient at the potential corresponding to the maximum current in the anodic loop; the insert is a linear plot of the first millisecond of this transient.

current (chronopotentiometry); the resulting potential-time (E-t) curve was recorded and the coulombic film thickness calculated.

All potentials are reported relative to the standard hydrogen electrode (SHE).

Results

The potentiostatically determined steady-state polarization (E-i) curve for this system has been given previously (2); the primary activation potential, E_a, was defined (1) as the potential at which the first increase in the anodic current is observed on going from the passive region to the anodic loop under conditions of reversibility. This corresponds to the minimum in the cathodic loop and lies between −0.108 and −0.109V (2).

Some typical anodic current-time transients are shown in Fig. 1. To obtain the transients at those potentials at which hydrogen evolution occurs simultaneously with the anodic reaction, it was assumed that the steady-state anodic current is the same as at potentials at which no hydrogen evolution occurs;[1] the hydrogen-evolution current, which then is equal to the difference between the measured steady-state current and the anodic steady-state current, was subtracted from the measured current at any given time to obtain the anodic current at that time. At potentials greater than E_a the initial current exceeds the capacity of the potentiostat and thus up to about 0.05 sec the transients are influenced by the characteristics of the circuit. At current densities greater than 4 mA/cm² the iR-drop correction exceeds 2 mV. At potentials more positive than E_a + 200 mV, the transients are independent of potential after about 0.05 sec. Similar observations have also been made by Nagayama and Cohen (7) for iron in borate buffer and by Rahmel and Schwenk (8) for an 18-8 austenitic stainless steel in 1N H_2SO_4 and in 0.5M Na_2SO_4. In neither case, however, did the authors report the results of any experiments within 200 mV of E_a.

A set of potential-time (E-t) curves measured during cathodic reduction after passivation at E_a has been shown previously (2). Similar curves are observed at higher potentials; for sufficiently short times

[1] This assumption is based on the observation that no discernable dissolution took place on a specimen potentiostated at E_a + 2 mV for 24 hr.

[2] Reference (2) erroneously gives the current density as 1 μA/cm²; it should be 10 μA/cm².

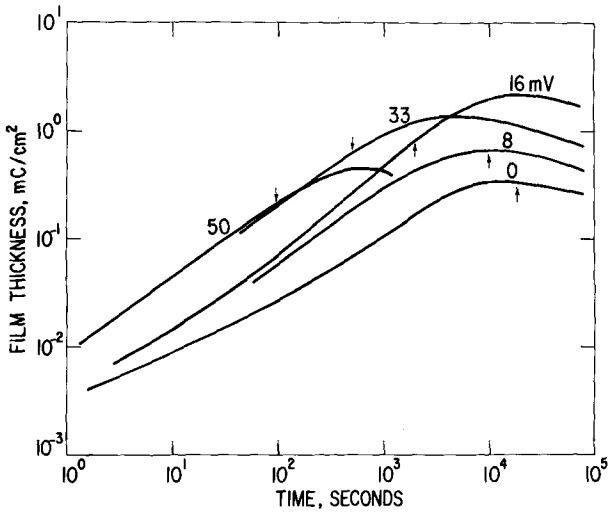

Fig. 2. Film thickness-time transients at different potentials. Passivation potential relative to E_a is given next to each curve. Time at which secondary film was first detected by an increase in the reduction potential is indicated by the arrow on each curve; at longer times true film thicknesses are greater than measured ones (see text).

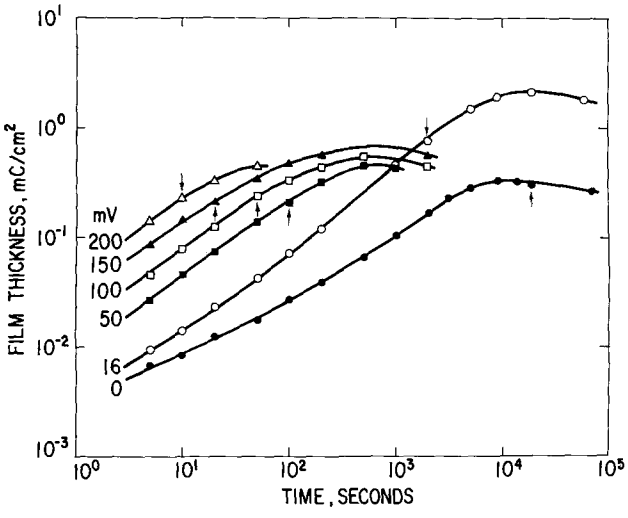

Fig. 3. Film thickness-time transients at different potentials. Passivation potential relative to E_a is given next to each curve. Time at which secondary film was first detected by an increase in the reduction potential is indicated by the arrow on each curve; at longer times true film thicknesses are greater than measured ones (see text).

the reduction potential is the same as for the primary film at E_a; the first increase in the reduction potential appears at shorter times as the passivation potential is increased (Fig. 2 and 3) and the magnitude of the change in the reduction potential increases with increasing passivation potential (Table I).

The coulombic thickness of the film is equal to the product of the time to reach the inflection point in the E-t curve and the current density for film reduction, which was 10 μA/cm².[2] To correct for hydrogen

Table. I. Effect of the passivation potential on the reduction potential. Time of passivation was 100 sec

Passivation potential, mV	Reduction potential, V
E_a	−0.123
E_a + 50	−0.124
E_a + 100	−0.128
E_a + 150	−0.131

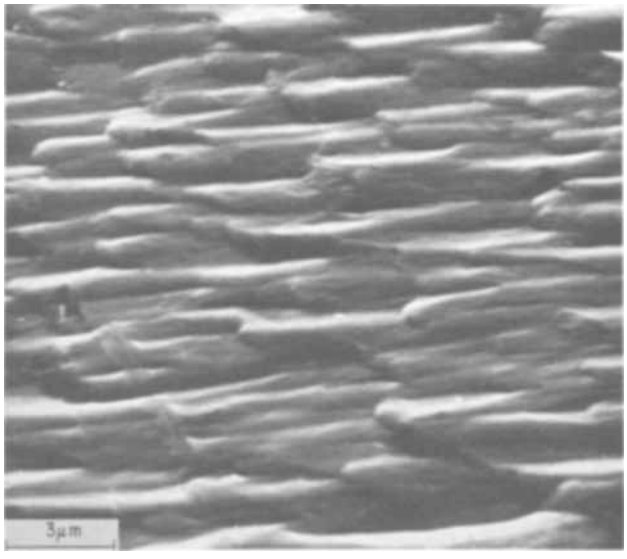

Fig. 4. Scanning electron micrograph of a surface after cleaning by anodic dissolution. Orientation-dependent etch is indicative of a film-free surface.

reduction that occurs concurrently with film reduction, 2.3 $\mu A/cm^2$, corresponding to the rate of hydrogen reduction at E_a, was added to the 10 $\mu A/cm^2$ for film reduction. Thus a current density of 12.3 $\mu A/cm^2$ was actually used. Plots of film thickness *vs.* time (Q-t curves) are shown in Fig. 2 and 3 for various potentials up to E_a + 200 mV. At more positive potentials secondary film was present before the initial point could be established.

The increase in the reduction potential is accompanied by a change in the Q-t plot for any given passivation potential (Fig. 2 and 3). At the activation potential the increase in the reduction potential does not occur until after the steady-state thickness[3] has been achieved and then this increase is accompanied by a decrease in the apparent film thickness. At higher potentials the increase in the reduction potential is detected at shorter times, before the maximum in the Q-t curve has been reached, and occurs roughly at the time at which the log Q-log t plots cease to be linear.

To determine whether the increase in the reduction potential is associated with increased difficulty of film reduction, *i.e.*, secondary film formation (1, 2), the following experiment was performed: After the film was reduced chronopotentiometrically the potential was switched to −0.205V, the potential of maximum anodic current, and the time for the current to reach its steady-state, *i.e.*, its maximum, value was monitored. This time is shortest when the reduction potential is that normally associated with the primary film; this time increases with increasing reduction potential, which in turn increases with increasing potential and time of passivation. An additional observation is that the maximum measured film thickness at E_a + 16 mV is considerably greater than that at higher potentials.

Scanning electron microscope examinations were made of many surfaces of different orientations after the specimens were anodically etched at −0.205V, the potential of maximum anodic current. A typical example of the orientation-dependent etch that is normally observed is shown in Fig. 4. This surface has been heavily etched; similar effects are also observed after lesser amounts of anodic attack.

Validity and accuracy of film thickness measurements.—Additional evidence has been obtained that strengthens the conclusions in the previous paper (2) and permits clarification of some ambiguities: (*i*) It was not possible to prove that a film formed at potentials negative of the corrosion potential was not present at all times over at least part of the surface. The orientation-dependent etch that is observed (Fig. 4) after anodic dissolution is characteristic of a film-free surface (9). Therefore, it is highly unlikely that any film initially present is not removed during the etch that is always used to clean the surface prior to each experiment. (*ii*) Cohen (10) has kindly pointed out that we had not considered the possibility of film formation at the corrosion potential after the anodic etching treatment. If after the etch the potential is switched to the corrosion potential and then back again to the etching potential, the anodic current-time transient (No. 5) shown in Fig. 1 is observed; the insert in this figure shows the first millisecond of the transient. After an initial current jump in less than 10 μsec due to charging of the double layer, the current rapidly decays to the steady-state value. If any film is formed at the corrosion potential, an increase in the current with time, rather than a decrease, would be expected as the film is removed by the etch and as is observed for an initially passivated specimen. From this it is concluded that no film is formed during the time the specimen is held at the corrosion potential. These results, as well as those presented previously (2), establish that the cathodic reduction procedure measures all the film on the surface.

The accuracy of the film-thickness measurement depends on the accuracy of the hydrogen-reduction correction. While the latter cannot be assessed quantitatively, the possible errors can be examined. Since the correction used is the experimentally determined cathodic current density, it must be the minimum correction, *i.e.*, the true cathodic current density cannot be less than the measured value. The correction perhaps should be greater for the following reasons: (*i*) If the anodic current density at E_a is greater than that assumed, the cathodic current density must also be greater in order to get the net measured current density. This error cannot be great for reasons given in the first footnote in the "Results." (*ii*) The reduction potential is about 15 mV negative of E_a; consequently the cathodic current density at this potential should be somewhat greater than at E_a. A correction for these possible errors would make the true film thickness less than that measured. Assuming that the steady-state film thickness at the activation potential cannot be appreciably less than a monolayer, the error of neglecting these additional corrections has no effect on the basic interpretation of the data. Another correction may arise from a change in hydrogen reduction kinetics in going from a filmed to a bare metal surface as the reduction proceeds. Since there is little change in the reduction potential until close to the end point, it appears that the fraction of the total current applied to hydrogen reduction remains relatively constant until close to the end point and that a significant error will occur only for very thin films.

Discussion

The purpose of this paper is to determine how the effectiveness of a given type and quantity of film as a passivating agent changes with increasing potential and the mechanism by which this film hinders anodic dissolution. In addition, it must be shown that the variations of i and Q with E and t are consistent with these findings and the resulting conclusions; the effect of potential on the i-t transients is treated in a section of this Discussion while a rate equation that accounts for the observed Q-t-E relationships is presented in an Appendix.

Effectiveness of adsorbed and of oxide films as passivators.—The primary film is the same at all passivation potentials because it exhibits the same reduction potential at each passivation potential. The data (Fig.

[3] While not easily discerned in Fig. 2 and 3, a steady state does exist over the time range from 8 to 15 ks.

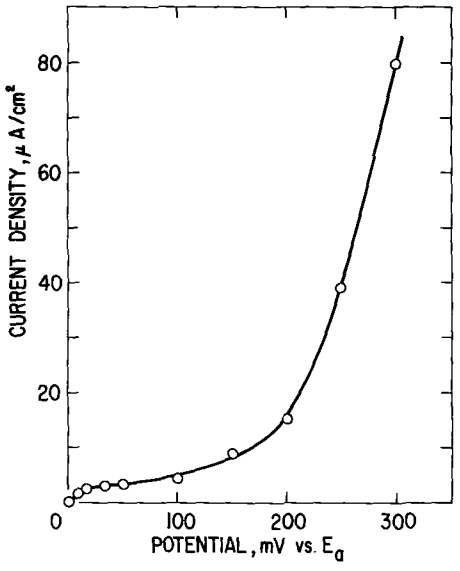

Fig. 5. Effect of a 0.36 mC/cm² film on the anodic current density at different potentials, showing the change from passivation by an adsorbed film to passivation by an oxide film at a potential of approximately E_a + 200 mV (see text).

2 and 3) show that for any given time the thickness of this film increases with potential. At the activation potential the steady-state film is 0.36 mC/cm² thick corresponding to one to three monolayers (2); we have shown (2) that the mechanism by which this film is formed and by which the decay of the anodic current can be described involves an adsorption process. At higher potentials, *e.g.*, at E_a + 16 mV, the steady-state film is many monolayers thick and it must be an oxide, because it is difficult to envision stable, separate layers of anions and cations each with a charge density of several millicoulombs/cm²; the interdiffusion of the ions to form an oxide is almost a certainty.

Although the steady-state film at potentials above the activation potential appears to be an oxide, the passivation mechanism need not necessarily involve the formation of an oxide, but may be an adsorption process such as occurs at the activation potential. To determine whether an adsorption process or the formation of an oxide film is responsible for passivity at potentials above E_a, we analyze the data in Fig. 1-3 in the following manner: At E_a the steady-state thickness of 0.36 mC/cm², corresponding to an adsorbed film, is also the minimum thickness that affords complete passivity, the anodic current density reaches its minimum value at the same time as the film thickness reaches this value; hence we arbitrarily choose this thickness as our reference. We determine the time required to reach this thickness at each potential (Fig. 2 and 3); from Fig. 1 we determine the residual anodic current density flowing at this time. This current density is plotted as a function of the potential, relative to E_a (Fig. 5) with the current normalized to zero at E_a.[4] As might be expected, the ability of this quantity of film (0.36 mC/cm²) to afford protection against anodic dissolution decreases with increasing potential. Nevertheless, over the first 200 mV this film does afford excellent protection by reducing the current density to less than 0.01% of its initial value (the value at 10^{-3} sec in Fig. 1). Above E_a + 200 mV the effectiveness of this quantity of film rapidly decreases, with the residual current at E_a + 500 mV being approximately 1 mA/cm²; thus at the higher potentials a thicker film, *i.e.*, an oxide film, is required to cause a reasonable degree of passivity.

The potential region in the neighborhood of E_a + 200 mV is most important one for this system, inasmuch as a radical change is observed in three distinct phenomena: (*i*) The film formed by the adsorption process becomes ineffective as a passivating agent above this potential; (*ii*) The preferential-dissolution/adsorption theory is not valid above this potential (2); (*iii*) The *i-t* plots become independent of potential above this potential (Fig. 1). These phenomena are consistent not only with a change in the type of film that gives rise to passivity, but also with a change in the mechanism of anodic dissolution during the passivation process. At lower potentials the preferential-dissolution/adsorption theory considers the direct, activated transfer of the ion from the metal into solution; the theory predicts a potential-dependent current-time transient (see next section) as is observed (Fig. 1). At higher potentials, at which an oxide film is required to give rise to passivity, the current-time transients are independent of potential. The latter may be explained by a mechanism involving ionic transport through a thin oxide film, the rate of which should depend only on the field across the film and not on the potential (9, 11).

We conclude that at the activation potential a film formed by an adsorption process is the primary source of passivity and that this film functions by inhibiting the direct, activated transfer of ions from the metal surface into solution. At sufficiently high potentials ($> E_a$ + 200 mV) a much thicker film, an oxide, is required; this film functions as a passivating agent by limiting the rate of anodic dissolution to the rate of diffusion of ions through the film under the influence of the field across the film. In the intermediate range ($E_a < E < E_a$ + 200 mV) the film formed by the adsorption process is responsible for lowering the current to a very small fraction of its initial value, that is it initiates passivity, while the steady-state film is an oxide and is responsible for the final decrease in the current.

Effect of potential on current-time transients.—It was stated above that the preferential-dissolution/adsorption theory predicts the effect of potential on the current-time transients for $E \leq E_a$ + 200 mV (Fig. 1); this is shown in this section.

From Eq. [3A] in the Appendix it can be seen that, if the rate of the backward reaction is sufficiently small

$$Q_j = Q_{s,j}(E)\,[1 - \exp(-k_j t^m)] \qquad [1]$$

where Q_j is the quantity of film associated with the j'th type of site[5] at any time t and potential E, $Q_{s,j}$ is the maximum or steady-state film thickness at the j'th type of site at that potential, k_j is the time-independent proportionality constants associated with film growth at that type of site and potential, and m is a constant; it is also shown in the Appendix that $k_j \sim \exp(\mathcal{K}E)$, where $\mathcal{K}$ is a constant, and that $Q_{s,j}$ is an unknown function of E.

The preferential-dissolution/adsorption theory [2] states that the anodic current density

$$i = A \exp(bE) \sum_j n_j \exp\left(-\frac{\Delta G_j^{\ddagger}}{RT}\right) \qquad [2]$$

where n_j is the number of unpassivated sites of type j per unit area, $\Delta G_j^{\ddagger}$ is the activation energy for anodic dissolution from that type of site, and A and b are constants. Since n_j is a function of both potential and time, the current density becomes a complicated function of both these variables. For less than monolayer coverage

$$n_j = n_j^{\circ}\left(1 - \frac{Q_j}{Q_j^{\circ}}\right) \qquad [3]$$

[4] Since at the higher potentials some secondary film is present at the time that 0.36 mC/cm² is measured, the true thickness is greater and the time to reach the desired thickness is actually shorter; thus the current density plotted in Fig. 5 should be greater. At E_a + 200 mV the error in the current density has been estimated to be 4 μA/cm² by extrapolating the straight line segment of the log Q – log t plot to 0.36 mC/cm².

[5] The preferential-dissolution/adsorption theory (2) considers kink, ledge, and terrace sites.

where n_j^o is the initial number of sites of type j and Q_j^o is the coulombic thickness corresponding to complete coverage of the n_j^o sites. Substituting for Q_j from Eq. [1], and rearranging

$$\frac{n_j^o - n_j}{n_j^o} = \frac{Q_{s,j}(E)}{Q_j^o}\{1 - \exp[-k_j^o t^m \exp(\mathcal{K}E)]\} \quad [4]$$

where k_j^o is the standard proportionality constant. Because of the interference of the secondary film, the function $Q_{s,j}(E)$ cannot be determined; thus the variation of n_j with E and the variation i with E cannot be calculated. It may be observed, however, that the term $\exp(bE)$ increases less rapidly with E than n_j decreases due to the term $\exp[-k_j^o t^m \exp(\mathcal{K}E)]$ in Eq. [4]. Thus for any given time, i must decrease as E increases, as is observed in this potential range, $E_a \leqq E < \sim E_a + 200$ mV. As discussed above, at higher potentials a different mechanism must apply.

Secondary film formation.—The difference between the primary and the secondary passivating films is characterized by the fact that the former is produced reversibly, while the latter is formed irreversibly and is exceedingly difficult to reduce. The existence of any secondary film can be determined sensitively by measuring the reduction potential of the film, an increase of as little as 1-2 mV being easily reproducible and indicative of irreversibility and of the presence of the secondary film. The conclusion that these changes in the reduction potential are real and due to the formation of the secondary film is in agreement with the results of the experiment in which we monitored the time for the current to reach its steady-state value at −0.205V after cathodic reduction. The slower approach to the steady state for films having higher reduction potentials is most easily explained by assuming that the reduction process did not reduce all the surface film, *i.e.*, the secondary film, and that the remainder is removed during the anodic dissolution process. Evidence for incomplete reduction is clear at the higher potentials ($E \geqq E_a + 50$ mV) at which it appears that the maximum film thickness is less than at $E_a + 16$ mV (Fig. 3); this is not only unlikely, but it clearly is not so since these maxima occur at times of less than 1000 sec while the current does not reach its steady-state value until approximately 8000 sec (Fig. 1). Since at the higher potentials secondary film formation begins before film growth has stopped, it is not possible to determine chronopotentiometrically the total film thickness at steady state. These have, however, been determined ellipsometrically at various potentials (12).

In Fig. 2 we see that the quantity of primary film present at the time that secondary film growth begins increases with potential, at least up to $E_a + 16$ mV. It is reasonable to assume that at higher potentials the total quantity of primary film formed is at least as great. Since the maximum reducible film thickness is less at higher potentials, some of the primary film must either be converted to secondary film or dissolve in the electrolyte solution. Since there is no evidence for the latter and since primary film growth always precedes secondary film formation, we conclude that the primary film undergoes a reaction to form the secondary film and that the latter is not produced directly from the metal.

The kinetic data of Fig. 2 and 3 can best be interpreted if we assume that the rate of formation of the secondary film, as well as that of the primary film, is potential dependent, and that at potentials close to the activation potential the rate constant for primary film formation is greater than the rate constant for secondary film formation, while at higher potentials ($E > E_a + 20$ mV) the rate constant for secondary film formation becomes greater. It follows that at those potentials at which the rate of growth of the primary film is greater than that of the secondary film, the apparent or measured thickness should increase until primary film growth ceases. This does happen at potentials $E_a + 8$ and $E_a + 16$ mV (Fig. 2). However, at the higher potentials at which the rate of secondary film growth is greater, the apparent thickness reaches a maximum soon after secondary film growth commences.

Because of the irreversibility of secondary film formation, the techniques employed in this study do not permit a quantitative study of the kinetics of the growth of this film. Therefore, we cannot make extensive comments on its composition and structure or suggest a mechanism for its growth.

Of interest, however, is the work of Caplan, Harvey and Cohen (13) who found for an Fe-26%Cr alloy that the film reduction potential increased sharply when the surface was subjected to highly oxidizing conditions; they attributed this to the formation of a nonstoichiometric oxide containing high valency chromium. The present work and previous work (1) are consistent with this interpretation. However, secondary film formation is detected at potentials as low as −0.108V; whether tetravalent or hexavalent chromium exist at this potential cannot be calculated since the reversible potential for the oxidation of $Cr^{III}(s)$ to Cr^{IV} or to Cr^{VI} in a $Cr^{III}(s)$ matrix, as well as the activity of the higher valent chromium species in the film, is not known.

The presence, and possibly the effect, of H and of H_2O in the passive films must also be considered (14-17). Essentially the same phenomena as those reported here have also been observed during the anodic oxidation of the noble metals (18). While variations in interpretation of the data exist, most basically involve the chemisorption of OH^- or $O^=$ followed by compound formation and oxidation to a higher valence state.

Conclusions

The kinetics of growth of the primary passivating film and of the secondary film on an Fe-24% Cr alloy in H_2SO_4 have been studied over a potential range of several hundred millivolts above the activation potential. The data have permitted a direct evaluation of the effectiveness of an adsorbed film and of an oxide film in giving rise to passivity. It is concluded that an adsorbed film is responsible for passivity at the activation potential; in the potential region $E_a < E < E_a + 200$ mV this same film is responsible for initiating passivity; however, the steady-state film is an oxide. Above $E_a + 200$ mV the adsorbed film is not an effective passivator and an oxide film is required to initiate and maintain the passive state. In the low-potential region ($E < E_a + 200$ mV) anodic dissolution during the passivation process occurs by the direct, activated transfer of the ions from the metal into solution. At higher potentials dissolution most likely occurs by the field-assisted diffusion of ions through the oxide film.

As a result of the change in the mechanism of passivity with potential, it is insufficient to state the type of film or process associated with passivity. It is necessary to define the relevant potential or potential range and the variation of film thickness, composition, structure, and mechanism of formation with potential.

The data also indicate that the rate of growth of both the primary and the secondary films is potential dependent; at potentials close to the activation potential the rate constant for primary film growth is greater than that for secondary film formation, while at higher potentials the rate constant for secondary film growth becomes greater and as a result a limiting apparent film thickness is observed before the steady state is achieved.

APPENDIX

Rate equation for primary film growth.—Previously (2) we proposed a mechanism for the passivation process at potentials below $E_a + 200$ mV in which it is assumed that dissolution occurs at different rates from different types of surface sites and that the most active

sites are passivated preferentially. Therefore, the kinetics of film growth are treated by considering each type of site and the total film as the sum of its parts, *i.e.*

$$Q = \sum_j Q_j \qquad [1A]$$

In the previous paper we restricted ourselves to three types of sites, kinks, ledges and terraces; in this paper this restriction will not be necessary. However, we restrict ourselves to the growth of no more than a monolayer of film and to the region in which no secondary film is present

We propose the following rate law for film growth at the j'th type of site at constant potential E as being consistent with the observed kinetics and with the reversibility of the film formation process

$$\left(\frac{\partial Q_j}{\partial t}\right)_E = (Q_{s,j} - Q_j)\, k_j m t^{m-1} - Q_j k_j' p t^{p-1} \qquad [2A]$$

where t is the time, $Q_{s,j}$ is the maximum or steady-state film thickness at the j'th type of site at a given potential, k_j and k_j' are time-independent proportionality constants[6] associated with film growth and film reduction, respectively, at that type of site, and m and p are constants; $Q_{s,j}$, k_j, and k_j' are potential dependent with k_j increasing and k_j' decreasing as the potential is increased. This rate equation is strictly valid only for film growth on each set of contiguous sites of the j'th type. Kinks are not likely to be contiguous; however, they occupy only 0.01% of the total sites, while terraces occupy 90% and ledges 10% of the total surface (2). This equation predicts a decreasing rate of film growth with increasing film thickness, as is observed. At sufficiently high potentials the second term on the right side of Eq. [2A] becomes negligible. Equation [2A] can be integrated analytically only when $m = p$. In that case, remembering that when $t = 0$, $Q_j = 0$, and summing over all types of sites

$$Q = \sum_j \frac{k_j Q_{s,j}}{k_j + k_j'} - \sum_j \frac{k_j Q_{s,j}}{k_j + k_j'} \exp\left[-(k_j + k_j')t^m\right] \qquad [3A]$$

For small values of the argument the exponential in Eq. [3A], may be expanded and all terms after the first in k_j, k_j' and t neglected so that Eq. [3A] reduces to

$$Q = \{\sum_j k_j Q_{s,j}\}\, t^m \qquad [4A]$$

Taking the logarithms of both sides of Eq. [4A]

$$\log Q = \log \{\sum_j k_j Q_{s,j}\} + m \log t \qquad [5A]$$

This equation predicts a linear relationship between log Q and log t as is observed for the growth of the primary passivating film (Fig. 2 and 3) with $m = 0.70 \pm 0.05$. At potentials close to E_a the linear log Q — log t relationship does not hold as well as at higher potentials. This may be either (*i*) because the constants m and p are not equal and hence Eq. [2A] cannot be integrated analytically, or (*ii*) because k_j' increases more rapidly than k_j decreases with decreasing potential. In the latter case the expansion of the exponential to obtain Eq. [4A] may not be valid for a sufficient time to observe the linear behavior predicted by Eq. [5A].

From Eq. [5A] we see that the film thickness at time 1 sec gives the time-independent apparent proportionality constant

$$k = \sum_j k_j Q_{s,j} \qquad [6A]$$

which is plotted in Fig. 6 as a function of potential. To understand completely the variation of k with E, it is necessary to know independently the variation of each $Q_{s,j}$- and each k_j-term with E. These are not known. However, it appears that at potentials well above the activation potential Q_s increases only slowly with potential (12) and hence the semilogarithmic variation of k with E is due to the variation of the k_j-terms with E. From Fig. 2 it is evident that as the potential approaches E_a, Q_s rapidly decreases, which may be the cause for the negative deviation from semilogarithmic behavior at the low potentials; the reasons given for the deviation from the linearity predicted by Eq. [5A] may also be involved.

[6] It can be shown that k_j is related to the conventional rate constant k_c by the relationship $k_c = k_j t^m$.

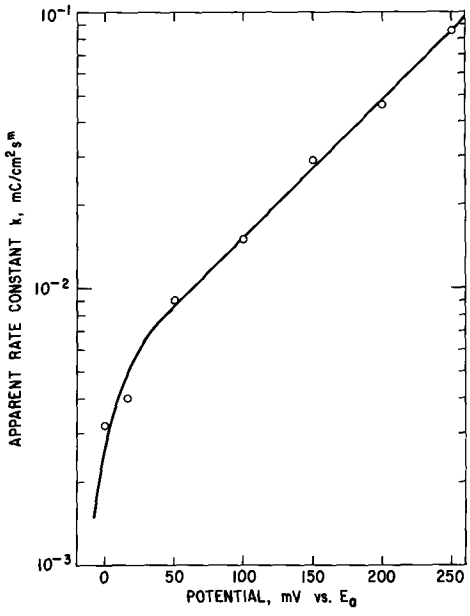

Fig. 6. Variation of the apparent rate constant k for primary film growth with potential, illustrating semilogarithmic behavior and negative deviations therefrom as the potential approaches E_a.

Acknowledgments

The author wishes to thank Mrs. A. C. Broz for skillfully performing the experimental work, C. Brickner for taking the scanning electron micrographs, and Drs. S. Barnartt, C. A. Johnson, and R. A. Oriani, all of this Laboratory, for helpful discussions.

Manuscript submitted May 16, 1969; revised manuscript received *ca.* Aug. 25, 1969. This was Paper 66 presented at the Detroit Meeting, Oct. 5-9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Anodic Films on Zinc and the Formation of Cobwebs

R. W. Powers*

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

When a zinc anode in a strongly alkaline electrolyte is observed under a microscope, two different films can be noted under appropriate conditions. Although both have been identified as zinc oxide, type I is white and forms by precipitation from a supersaturated layer of electrolyte covering the electrode. Type II, on the other hand, seems to form directly on the electrode surface. Its color can range from light gray to black. During dissolution of the type II film, entities appear which resemble spiderwebs under the microscope. These so-called cobwebs seem to form by the gathering together of the darkening agent in this film. They are mainly zinc, are electronically conducting, and can be oxidized. Cobwebs appear to have a relationship to the hydrogen evolution that occurs at potentials anodic to the zinc rest potential. They are important, in addition, because during subsequent electrodeposition they accelerate the formation of spongy zinc at low cathodic potentials and of dendritic zinc at higher ones.

When zinc is anodized under certain conditions in a strongly alkaline solution such as 7.0 Molar (M) aqueous potassium hydroxide, entities form which resemble spiderwebs under the microscope. Such structures as shown in Fig. 1 have been called zinc cobwebs. In this paper, a discussion of the relationship between the different anodic films that form on zinc and the current-potential curve is used as a basis for considering the mechanism of the formation of these cobwebs. In addition, this paper is concerned with their composition and properties as well as their effects on other phenomena that occur with the alkaline zinc electrode.

Experimental Procedure

Most of the experimental work in this study was carried out potentiostatically in a cell in which a test electrode can be observed under a microscope during the passage of an electric current. This technique is described in detail elsewhere (1). The test electrode is arranged horizontally facing upward and is viewed through a very thin glass window in the cell with a bench microscope equipped with dark field objectives. The zinc electrode potential was controlled with a Jaissle potentiostat. Ramp and triangular waveforms used in scanning the electrode potential were taken from a multiturn potentiometer driven by a clock motor. When required, a gas lift pump operated by ultrapure hydrogen circulated the electrolyte. All measurements were made at room temperature, 23° ± 1°C.

Two kinds of zinc electrodes were used. Polycrystalline ones were punched from rolled zinc sheet designated as Mix 60 by the supplier, the New Jersey Zinc Company. It is about 99.99% pure. Such specimens were electropolished in a 20% sulfuric acid bath in order to render them structureless at the beginning of an experiment. However, most test electrodes were prepared by cleavage from a single-crystal zinc rod in liquid nitrogen. This procedure produces a mirror-like surface which lies in the basal plane. Even after some etching, the single-crystal surface presents a rather uniform background against which cobwebs can be viewed in contrast to the more variegated background of polycrystalline specimens. Single crystals from two sources were used. Some were grown by the Bridgman method in graphite molds from zinc initially 99.9995% pure. Others were grown by Research Crystals, Incorporated, of Richmond, Virginia, from zinc 99.9999% pure. The latter crystals were pulled from the melt by the Czochralski technique.

The electrolyte used throughout this work was an aqueous 7.0M potassium hydroxide solution. For most experiments, 0.25 mole of zinc oxide was dissolved per liter of solution to produce a definite zinc equilib-

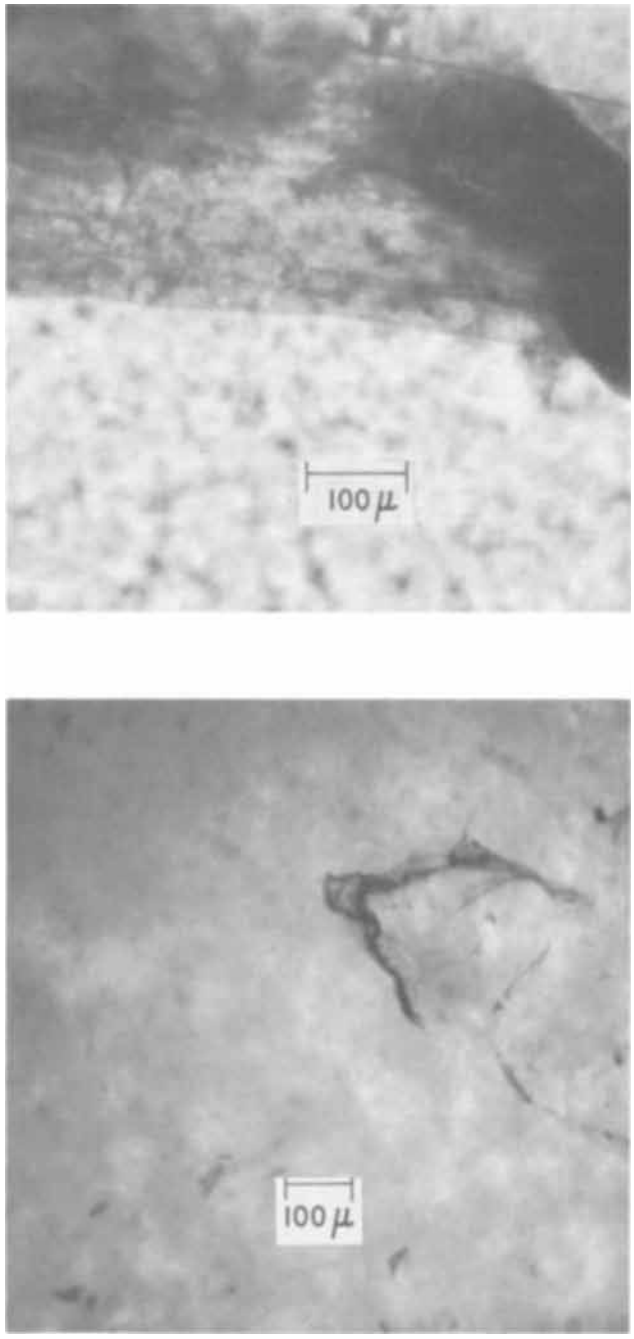

Fig. 1. Zinc cobwebs. Dark field. *Top*—100X, *bottom*—60X.

* Electrochemical Society Active Member.

rium potential and to reduce pitting of the zinc electrode surface when first exposed to electrolyte under open-circuit conditions. The occurrence of such pitting makes the interpretation of microscopic observations much more difficult. Solutions were prepared either from distilled water or from special conductivity water (2). These alkaline solutions were filtered through Gelman No. AN-200 Acropor membranes with 0.2μ pores in order to remove the larger particles of iron compounds present in reagent-grade KOH. Although atomic absorption analysis of these solutions before and after filtration indicates that only about 10% of the iron is thus removed, this treatment reduces the hydrogen evolution rate and thus makes microscopic observation easier. The filtration was carried out in a closed system in order to prevent the absorption of carbon dioxide and of oxygen. Solutions were deaerated by bubbling with purified argon.

The zinc electrode potential was measured against a mercury-mercuric oxide electrode in pure KOH of the same concentration as that used in the test cell. The electrode potentials cited in this paper are with reference to this electrode unless stated otherwise.

Experimental Results and Their Interpretation

i-U curves and the nature of the anodic films.—The conditions for the formation of zinc cobwebs are probably best understood after considering the relationship between the current-potential (*i-U*) curve and the nature of the anodic films formed under different circumstances. Some aspects of these relationships were discussed in a previous paper (3). The results to be presented confirm and extend the interpretations given there.

In Fig. 2, there is shown an *i-U* curve taken on a single-crystal specimen at the very slow potential scan rate of 0.05 mV/sec with convection nearly absent. The scan was started at the rest potential and was terminated at — 0.97V. Photomicrographs of the electrode surface were taken at the potentials indicated with capital letters beside the *i-U* curve. These are presented in Fig. 3. All were taken of the same specimen field with the same incident light intensity and exposure time. The pits produced during the dissolution of zinc at low anodic potentials (Fig. 3A-D) were usually shaped in the form of nearly regular hexagons. With increasing potential, hexagonal pits within hexagonal pits can be seen. The formation of these rather large, regularly shaped pits as shown in this series of photomicrographs constitutes an almost ideal background for viewing the initial stages of the formation of a precipitated film. The pattern of dissolution pits

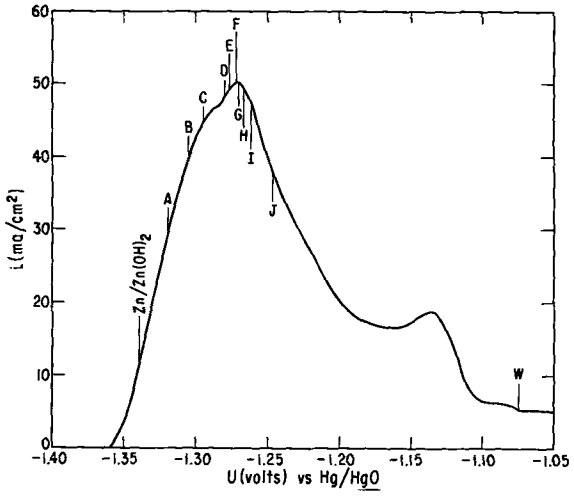

Fig. 2. Current-potential curve for cleaved zinc single crystal in 7M KOH + 0.25M ZnO taken during anodic sweep at 0.05 mV/sec under nearly convectionless conditions.

did vary somewhat from specimen to specimen. With some, highly irregular hexagonal troughs were formed over much of the electrode surface. In such instances, light scattered from the precipitated particles is difficult to distinguish from the background of light scattered off the specimen surface. As shown in a previous paper, the dissolution facets observed on specimens from still another crystal at a ten times faster potential scan rate were more uniformly developed over the entire surface (3). Here also the onset of precipitation was harder to observe than in the photographs presented in Fig. 3.

Various stages in the formation of a film by precipitation from a layer of electrolyte supersaturated with zincate are shown in Fig. 3D-G. Small white precipitate particles were noticed at potentials slightly below that at which the first maximum in the *i-U* curve occurs. They first appeared on areas of the surface where it was highly stepped or pitted. Here the local current density as well as the supersaturation are expected to be the greatest. The peak current occurred at a slightly lower potential than that previously reported where the sweep rate was ten times higher (3). This precipitated film has been called type I to distinguish it from another anodic film with very different properties (3).

The latter, called type II, appears to form directly on the electrode surface. It is more or less transparent and ranges in color from light gray to black (3). The darkening of the specimen surface, noted at potentials only slightly greater than that corresponding to the first current maximum (Fig. 3H *et seq.*), is attributed to the formation of type II beneath the type I. Corresponding to the growth of type II, the darkening increases with increasing potential or anodizing time.

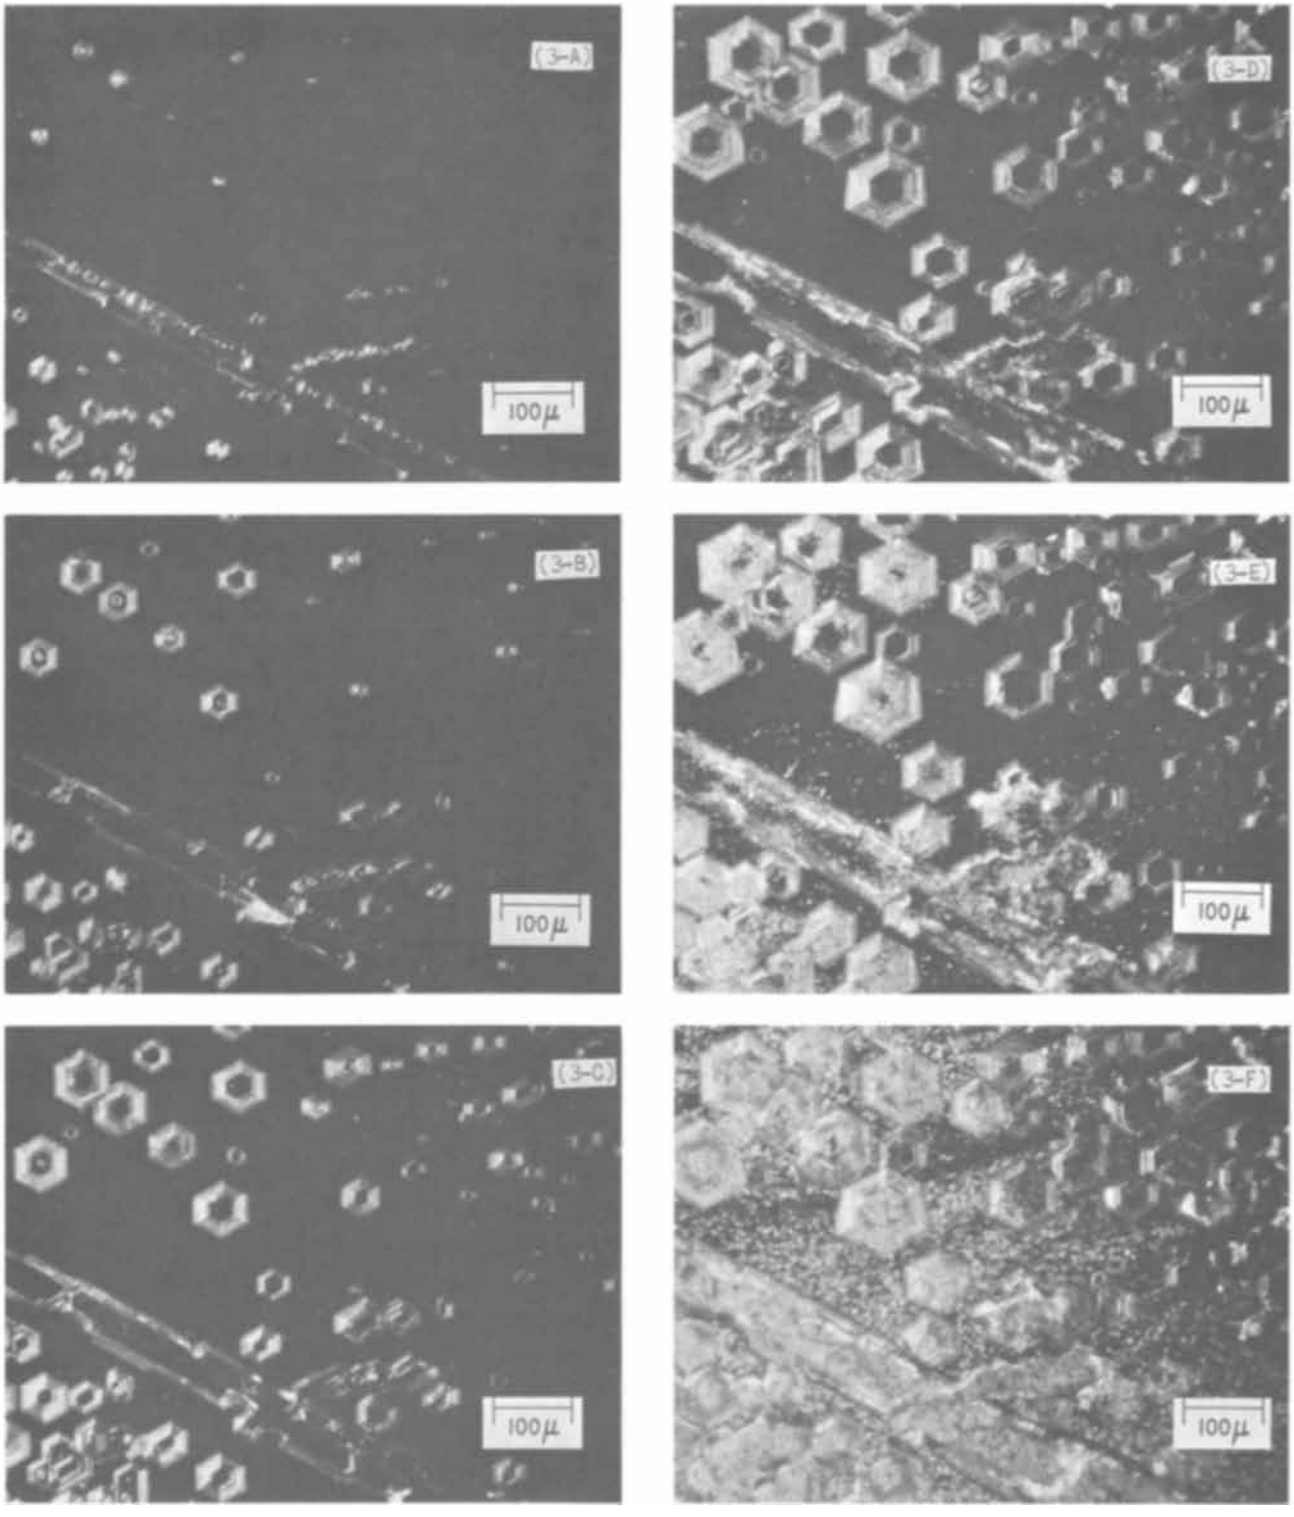
That the anodic film, formed as described above, is really duplex is shown by observation of the specimen with an intense light source. On increasing the light intensity sevenfold over that used to obtain the photographs shown in Fig. 3, to the maximum obtainable with a metal halide arc light, the outer precipitated film can readily be seen as shown on Fig. 4. This photomicrograph was obtained at the potential corresponding to W on Fig. 2. The film is somewhat porous. Holes and crevices can be seen in it. The particles are coarser and more translucent than those noted near the potential of the first current peak. The thickness of this type I film is not uniform over the surface. Consequently only a portion of the field appears in focus. Some out-of-focus areas are indicated by arrows on Fig. 4.

After placing the specimen on open circuit following the experiment described above, the electrolyte was circulated and the disintegration of the outer film was followed particle by particle. After most of it was so removed, the underlying film, where buckled and torn, was evident as shown on Fig. 5. Patches of torn film as large as those shown on this figure are not commonplace when anodizing is *followed* by stirring. As shown previously though, large areas of such film are readily noted if the electrolyte is stirred *during* the anodizing to suppress the formation of type I film (3).

In experiments similar to that described above, some dark blue pieces of film have been observed beneath the very porous outer portion during disintegration of type I. These blue particles appear to be precipitate that has been consolidated into a nearly nonporous mass and are often surrounded completely by very porous precipitate. They likely give rise to the frequently noted over-all bluish appearance of anodic films on zinc.

Type I film was identified as zinc oxide by x-ray diffraction. Concordant results were obtained on three specimens prepared under different conditions. For the preparation of one specimen, the potential applied to a single crystal was scanned from the rest value to −1.24V, slightly beyond that corresponding to the first current peak. The electrolyte was not stirred. The precipitate particles on the electrode were small and

the layer of film was very thin. An example of aged precipitate was prepared by scanning to −1.08V at 0.05 mV/sec from the rest value. The film appeared similar to that shown in Fig. 4. For the third specimen, the potential was scanned to −1.11V. Although the electrolyte was circulated in this latter case, a precipitate appeared on a small portion of the electrode surface where the stirring was not vigorous. After anodizing, electrodes were removed from the cell as rapidly as possible, immersed in 30% KOH solution to remove soluble zincate, rinsed with distilled water, and dried in a stream of nitrogen. Although the intensities of the diffraction lines were less for the first specimen, the pattern for all three corresponded to the same compound, zinc oxide. It is not likely that the diffraction patterns observed resulted from the transformation of a film of zinc hydroxide after removal of the electrode from the electrolyte. According to Dietrich and Johnston, ϵ-zinc hydroxide, the most stable modification, is kinetically stable almost indefinitely at room temperature against transformation to zinc oxide and water (4). Moreover, even though the films on these specimens were duplex, the diffraction patterns must be attributed to the outer layer as x-ray diffraction patterns were not obtained from the type II film formed under the conditions described above. The results reported here are in accord with those of Nikitina, who found that at 20°C the precipitate from a 7M KOH solution supersaturated with zincate was zinc oxide. She did report in addition that zinc hydroxide can precipitate from solutions of lower KOH concentration or even from 7M KOH at lower temperatures (5).



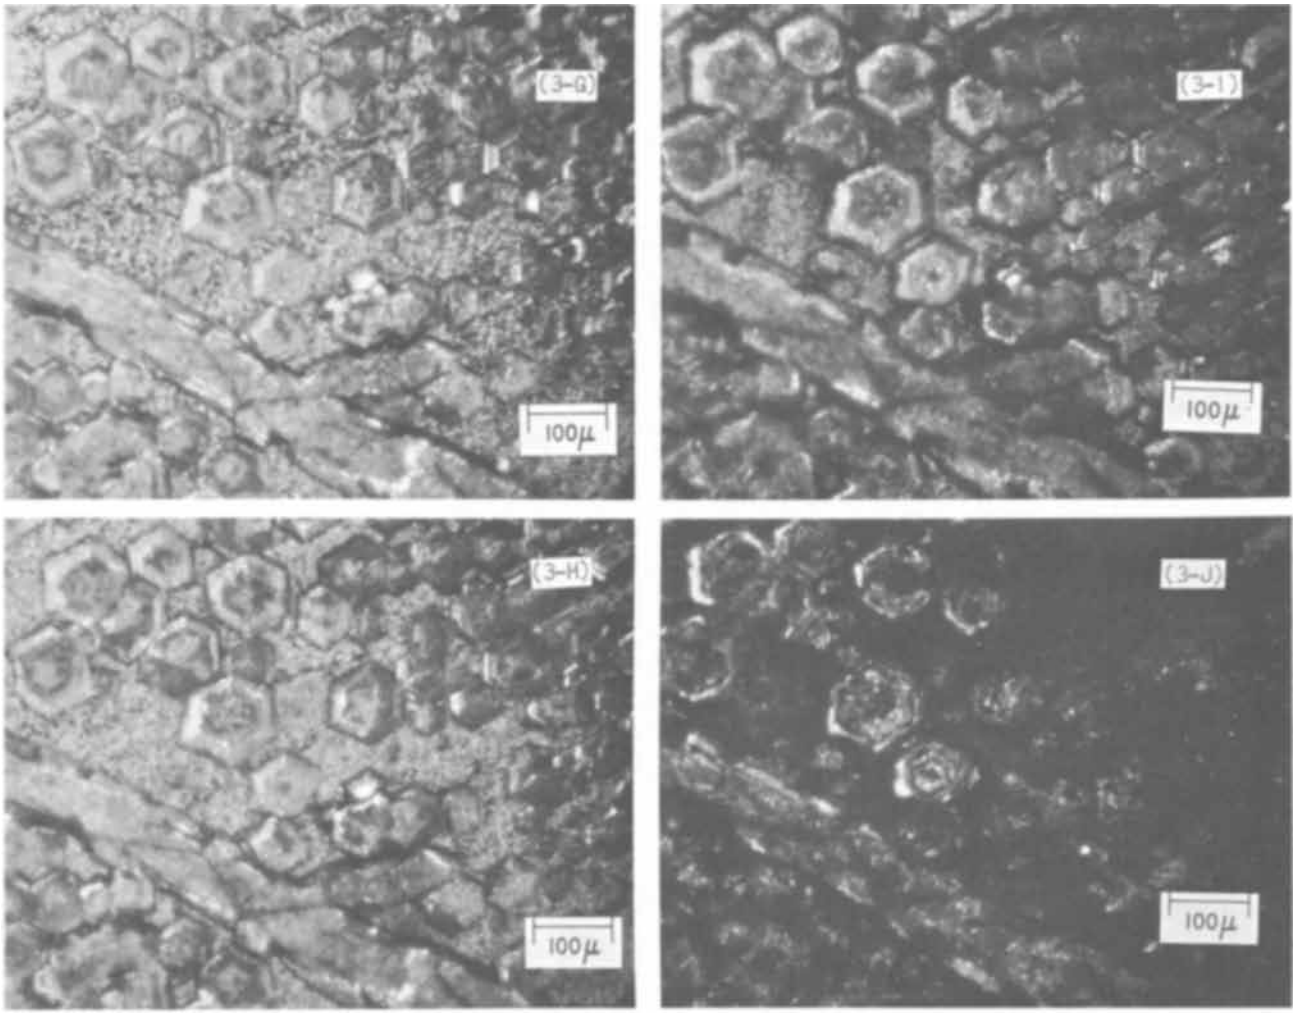


Fig. 3. Morphological changes in a zinc electrode during an anodic sweep. Dark field. 100X. Letters correspond to potentials indicated on Fig. 2 (A-J).

Type II film was also found to be zinc oxide. A single-crystal electrode, after subjection to a potential of −0.37V for 25 min, was coated with a gray film, the structure of which was established by electron diffraction. As noted previously, this procedure for preparing type II film minimizes the formation of the precipitated type (3). A reflection pattern of zinc and zinc oxide was obtained showing the presence of both epitaxial and polycrystalline zinc oxide. It was not possible to get an identifiable pattern from a rumpled type II film produced by scanning the potential of a single-crystal electrode up to −1.21V while stirring the electrolyte. This thin film may have been partially destroyed during the washing and drying operations following removal from the viewing cell.

As discussed in a previous paper, dark anodic films on zinc have been studied by a number of authors, all of whom identified them as zinc oxide (3). They were the subject of very intensive investigation by Huber who showed that the darkening was associated with the presence of excess zinc (6-9). He observed bleach-

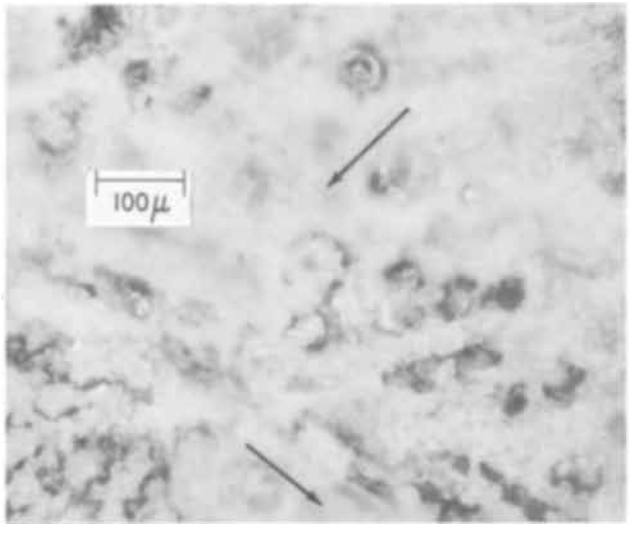

Fig. 4. Type I film. Dark field. 112X.

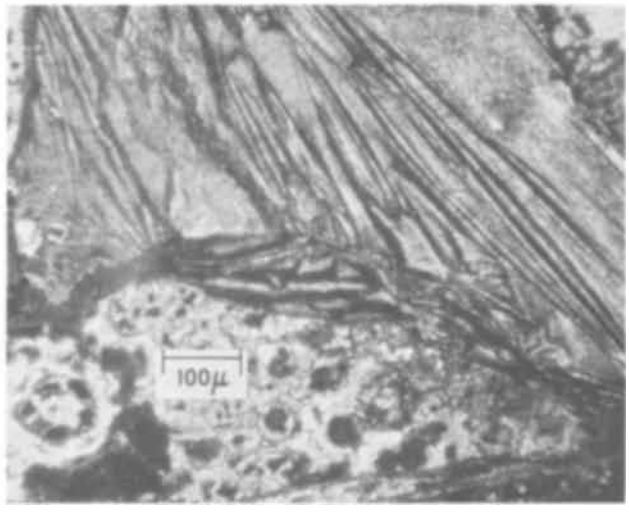

Fig. 5. Buckled type II film. Dark field. 100X.

ing on heating such films in air above 200°C and darkening again after heating in the presence of zinc vapor (8). Huber, and later Fry and Whitaker, also found the electrical conductivity of such dark zinc oxide films to be much greater than bleached ones (9, 10). The important finding of the present work is evidence for their formation at potentials close to the equilibrium value, −1.34V. The presence of a very thin layer of type II film on the zinc electrode at potentials as low as −1.30V was noted several times. During anodic potential scans with forced circulation of the electrolyte, small pieces of type II film were observed as they were partially lifted above the electrode surface and waved about by the moving electrolyte. As most previous work on dark anodic films was done at constant current, their formation was usually noticed at the oxygen evolution potential after passivation. Kaesche, however, working in dilute solutions, 1M Na_2CO_3 and 0.1M $NaHCO_3$, found evidence from constant current charging and reduction curves for the formation of an electroreducible film, presumably zinc oxide, close to the equilibrium potential (11).

The height of the second peak shown on Fig. 2, the one near −1.14V, is but 60% of that reported previously (3). The anodizing conditions were similar except that the specimens were cleaved from different single crystals. With some polycrystalline electrodes, the height was found to be nearly as great as for the first peak. Thus there is considerable variation depending on the specimen source. As this second peak occurs both in the presence as well as the absence of type I film, it likely arises from some limitation imposed by the conductivity of type II. Since zinc oxide is a semiconductor, one can speculate that small variations in the impurity content of the zinc from which the anodic film is formed may affect the degree of doping and consequently the conductivity.

Cobweb formation.—The entities called cobwebs were first observed following partial dissolution of anodic films formed during a potential scan carried to passivation. They appear to be a relatively insoluble portion of type II film and seem to form by the gathering together of the dark material in this film. Cobwebs behave as if under tension and, as the lighter-colored material is dissolved, they coalesce first into a string and then into a wad. The effect of stirring the electrolyte above them is similar to the action of a broom on spiderwebs. Some of these points can be seen from the dark field photomicrographs shown in Fig. 1. These photographs of cobwebs are unusual only as to the extent of the field lying within the same focal plane.

Probably the observation of cobwebs has been aided by the electrolyte flow pattern during stirring in the cell used for microscopic viewing (1). In this cell, the specimen caps the bottom of a hollow Teflon cylinder filled with electrolyte. A gas lift pump induces flow of electrolyte in a rectangular channel above this cylinder and parallel to the specimen surface. The flow immediately above the specimen is counter to that in the channel. This causes the dissolution of the film to be first evident on what normally would be considered the downstream side. The important point is that this circulation pattern tends to concentrate insoluble material instead of dispersing it as with most other methods of stirring.

The formation of cobwebs has been observed under a wide variety of experimental conditions. Formation occurred after anodizing at potentials ranging from −1.23 to 0.5V. However, the delicate webbing shown in Fig. 1 has been observed only on those specimens anodized at lower potentials. Cobweb formation took place on single crystals of 99.9995 and 99.9999% purity as well as on polycrystalline specimens of 99.99% purity. Formation did not appear affected by the use of lots of KOH of different purity levels or whether use was made of unfiltered KOH solutions in comparison with those filtered to remove iron compounds. Solvent purity did not appear important as both ordinary laboratory distilled water and conductivity water have been used for solution preparation without affecting cobweb formation (2). Special cleaning of the test cell in boiling concentrated nitric acid did not affect their formation. Further, it was not changed by the use of argon in place of hydrogen to operate the gas lift pump. The only positive correlation noted was with the color of the anodic film. Few cobwebs were observed if the anodizing was stopped when the film was white, *i.e.* when the electrode was covered with type I film only. However they were always seen when the film appeared dark, *i.e.* after sufficient quantity of type II film formed beneath the type I to cause the duplex film to darken. A potential scan is not required in order to form cobwebs. In fact, the most efficient procedure found for producing delicately webbed cobwebs in relatively high yield consists in stepping the potential from the rest value to −1.16V for 5-7 min, followed by circulation of the electrolyte under open-circuit conditions.

The composition and properties of cobwebs.—These facts—that a dark type II film is required for cobweb formation; that their formation is apparently not affected by changes either in the specimen purity or in the electrolyte purity; and that cobwebs can be prepared again and again on the same specimen, apparently without exhaustion, by anodizing followed by dissolution of the anodic film—suggest they are zinc and not an impurity.

Many of the experiments described above were carried out after various attempts to identify cobwebs directly by x-ray diffraction and by conventional chemical analysis failed. However, subsequent attempts using a microprobe x-ray analyzer and atomic absorption analysis were largely successful.

The specimen for microprobe analysis was prepared by anodizing at −1.16V for 5-7 min, followed by stirring the electrolyte for a couple of minutes. These steps were repeated four times so that many cobweb fragments were present on the surface of the single-crystal electrode. The microprobe gave a qualitative indication of the presence of zinc and iron only, although an effort was made to detect the presence of many other elements including copper, nickel, lead, cadmium, tin, gold, aluminum, and silicon.

Atomic absorption spectroscopy was used to get a more quantitative analysis. Specimens were anodized as described above. However, the electrolyte was stirred for a longer time in order to dislodge most of the cobwebs from the specimen surface. After 5-20 anodizing steps, the electrolyte was filtered through a Gelman Acropor membrane to collect the cobweb fragments. The membrane was washed with a 7.0M KOH solution to remove soluble zincate and then thoroughly rinsed with distilled water. One half of the filter membrane, containing no cobweb fragments, served as a control. Both this control and the other half of the membrane containing the cobwebs were placed in 5-7 ml quantities of 0.3M HCl for analysis.

The results of four different analyses for zinc and iron by atomic absorption spectroscopy are indicated in Table I. There was a considerable variation in the quantity of cobwebs available for analysis from one experiment to another—undoubtedly due in part to

Table I. Cobweb analysis by atomic absorption spectroscopy

Experiment		Quantities in μg Zn	Fe
1	Cobwebs	6.3	2.7
	Control	1.5	1.5
2	Cobwebs	16.8	1.6
	Control	10.5	0.8
3	Cobwebs	130	2.2
	Control	4.5	0.8
4	Cobwebs	41	2.1
	Control	5.3	2.1

their relatively rapid dissolution in the alkaline electrolyte. Since in all but one experiment the amount of iron in the specimen was greater than in the control, it must be inferred that cobwebs do contain some iron in agreement with the microprobe results. However in experiments 3 and 4 where the quantities analyzed were relatively large and in which therefore the accuracy should be greater, the amount of iron was but a few per cent of that for zinc. It does not seem unreasonable to assume that zinc in the cobwebs might function as a scavenger for iron compounds in the electrolyte. This would account for the presence of a small amount of iron as detected by both analytical techniques.

Cobwebs are good electronic conductors. This was documented by an adaptation of an old experiment. If a piece of pure zinc is placed in a solution of concentrated alkali, its reaction with the electrolyte to produce hydrogen will usually be slow. If, however, the zinc is touched with a platinum wire, the evolution of hydrogen from the platinum wire with simultaneous dissolution of the zinc occurs rapidly. The platinum wire need not touch the zinc directly. Another electronic conductor may be interposed between the two to yield the same result. To demonstrate the good electronic conductivity of cobwebs, a large one, formed on a cleaved single-crystal electrode, was interposed between the zinc specimen and a platinum wire. The tip of a 0.003-in. wire, the motion of which was controlled by a micromanipulator, was brought near the cobweb as shown in Fig. 6A. No hydrogen was evolved near the tip of this wire when out of contact with the cobweb. When contact was established by moving the wire in a horizontal direction, fine hydrogen bubbles were evolved from the wire in great quantity as shown in Fig. 6B. Great care was taken to avoid direct contact between the zinc specimen and the platinum wire. In these photomicrographs, only the tip of the platinum and the top of the cobweb are in focus. These results demonstrate conclusively that cobwebs are good electronic conductors.

Similar experiments may demonstrate yet another point. In Fig. 7, the photomicrograph shows that a portion of a cobweb, indicated by the arrow, disappeared after contact with a platinum wire. One interpretation of this observation is that oxidation of the cobweb has occurred. Although a cobweb mass in contact with the specimen base has considerable mechanical strength, as evidenced by difficulties in removing it with jeweler's tweezers, nonetheless there is a possibility that the disappearance was caused by mechanical dispersion associated with the evolution of hydrogen bubbles. Not all contacts with a platinum wire led to the disappearance of a cobweb at the point of contact. However, the fact that cobwebs can be oxidized was shown numerous times by another experiment. When the electrode potential of a specimen covered with cobweb fragments was stepped from the rest value to an anodic potential between −1.0 and 0V, fragments were greatly reduced in size within a few minutes. This disappearance of cobweb fragments by electrochemical oxidation is shown in Fig. 8. This experiment does not prove conclusively that cobwebs are metallic zinc as oxidation from an intermediate valence state is conceivable. However, the former interpretation seems the simpler one of this and the preceding experiment.

Some effects of cobwebs.—An important source of interest in cobwebs stems from their effects on the morphology of zinc electrodeposits. From the information presented above—that cobwebs are small pieces of electronic conductor which can protrude beyond

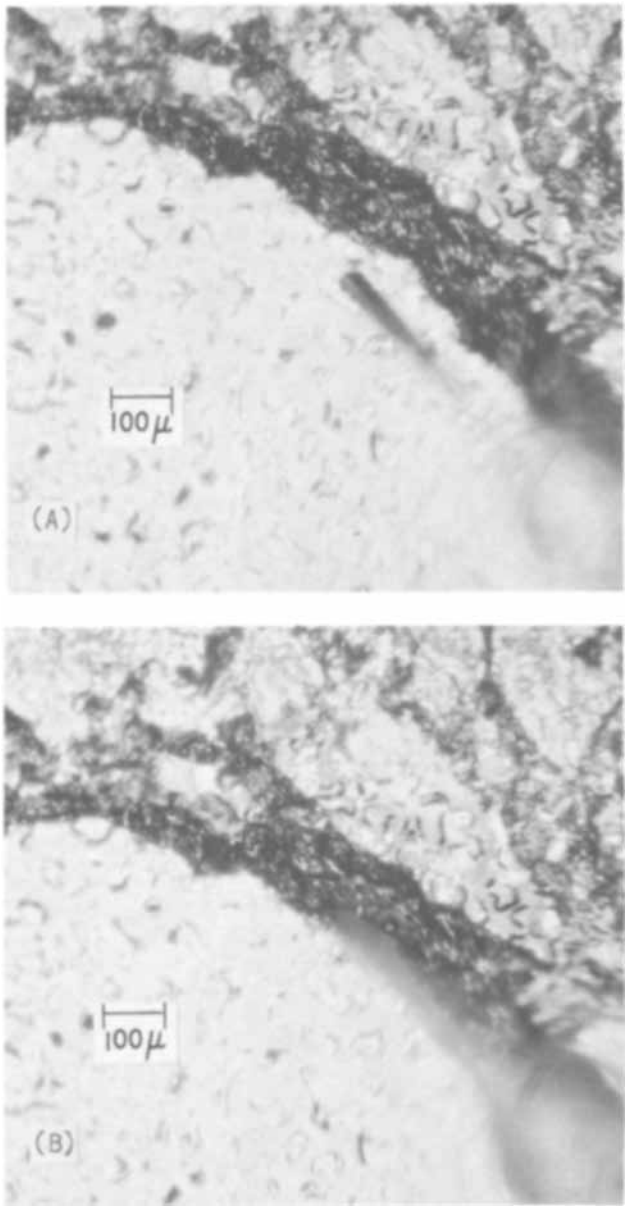

Fig. 6. Hydrogen evolution from a platinum wire touching a cobweb. Dark field. 78X. A—No contact, B—contact.

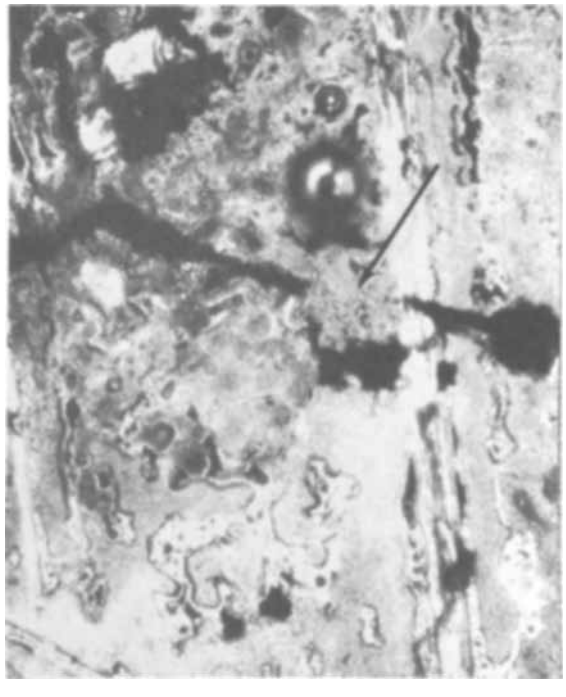

Fig. 7. Disappearance of a cobweb after contact with a platinum wire. Dark field. 90X.

the bulk of the zinc electrode into the electrolyte—it is perhaps not surprising that they should affect the early stages of the formation of both spongy and dendritic zinc during subsequent electrodeposition. However, since a satisfactory discussion of this topic would unduly lengthen this paper, information about these effects will be published elsewhere.

Nonetheless, one other phenomenon related to dark anodic layers and to cobwebs is discussed—namely, that hydrogen evolution which occurs at potentials anodic to the zinc rest potential. Several years ago, Sanghi and Fleischmann documented the strange polarization behavior of zinc in dilute KOH solutions (12). Their data for 0.1M KOH saturated with zincate showed the unusual feature of a cathodic current in the region of potential between —1.07 and —0.83V *vs.* a normal mercury-mercuric oxide electrode. They attributed this current to hydrogen discharge. Thus, in the potential range between —1.3 and 0.3V, the current is cathodic below —1.28V due to zinc deposition and hydrogen discharge. It is anodic between —1.28 and —1.07V owing to zinc dissolution and film formation. It is cathodic again in the range —1.07 and —0.83V as noted above. Finally, it is anodic again above —0.83V. Sanghi and Fleischmann speculated about the role of anodic films in catalyzing hydrogen evolution. Further, they pointed out that this hydrogen evolution should also occur in more concentrated solutions but under these conditions the cathodic reaction rate would probably be less than that for anodic dissolution. In this event, the current meter, which indicates a net current only, would register an anodic one. Similar findings were made by Kaesche, using 0.01M $NaHCO_3$ and 0.01M NaOH solutions (11).

Often during anodic scans, a large quantity of bubbles, assumed to be hydrogen, were observed to issue from the electrode at potentials around —1.0V, *i.e.* just cathodic to the equilibrium potential for hydrogen. In some cases, the rate of gas evolution appeared larger than that noted during electrodeposition at potentials 200 mV cathodic to the zinc rest potential. The rate did vary greatly from specimen to specimen though. In a number of instances, this hydrogen seemed to issue from cobweb fragments produced during a previous anodizing experiment. The evolution of hydrogen from dark anodic layers has also been noted by Oxley (13). On standing at open-circuit potential, hydrogen evolution occurs preferentially on cobweb fragments as shown in Fig. 9.

Concluding Remarks

The experiments previously cited—that cobwebs are derived from type II film, that film associated with the active to passive transition; that hydrogen is evolved from them; and that cobwebs accelerate the formation of both spongy and dendritic zinc during electrodeposition—certainly show that these entities have relationships with many of the important phenomena connected with the alkaline zinc electrode.

The observations of cobwebs and associated phenomena described in this paper have been greatly facilitated by a number of favorable circumstances. The recent availability of potentiostats of relatively high current capability permit anodic film formation under more closely controlled conditions. The use of a high-intensity light source is a great help in viewing strongly light-absorbing anodic films. A kind of stirring pattern in the test cell that tends to concentrate, rather than disperse, insoluble material is an advantage. Stirring also causes motion of small cobweb fragments that directs attention to their presence. The use of single-crystal surfaces to produce a more uniform background makes cobweb observation easier. Absence of these special conditions and techniques would have made this study much more difficult.

Acknowledgments

The author is grateful to the International Lead Zinc Research Organization, Incorporated, New York, N. Y., for partial financial support of this work. He wishes to thank V. J. DeCarlo for growing zinc single crystals used in this study. Tracy Lamanec provided a qualitative analysis of cobwebs using a

The Kinetics of Dissolution of II-VI Semiconductor Compounds in Nonoxidizing Acids

L. D. Locker*,[1] and P. L. deBruyn

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

The dissolution of ZnS, CdS, ZnSe, and $Zn_{0.85}Cd_{0.15}S$ in acid solutions has been studied under conditions where the group VI anions yield only H_2S or H_2Se. The activation energies depend on the particular compound, the acid, and the solvent. However, for ZnS the activation energy is independent of purity and crystal structure. For dissolution of high-purity compounds in aqueous H_2SO_4, the activation energies (kcal/mole) are: ZnS(9.5), CdS(14.2), ZnSe(11.7). The factors that determine nonoxidative dissolution kinetics are analyzed, and a model is presented. This case is compared to the mechanism of elemental and compound semiconductor dissolution where electron transfer occurs, and there is a relatively large change in the oxidation states between reactants and products.

The atomic processes that occur on the surface of a solid during dissolution depend on the type of bonding in the solid and on the particular species in solution (1-5). For the electrochemical dissolution of semiconductors, these processes have been studied extensively. However, little attention has been given to the mechanism of dissolution of semiconductors in nonoxidizing solutions.

The relationship of structure and bonding to the dissolution mechanism can be illustrated by several cases. For example, the dissolution of alkali halide crystals, such as LiF, is analogous to evaporation in that atoms are removed by dissociation from kink sites on the surface (1, 2). If the initial rate of dissolution in pure solvents is expressed by the equation

$$R_o = \nu \exp(-E/RT) \quad [1]$$

then for the alkali halides ν is a frequency factor that depends on the surface area and the distribution of active sites, and the activation energy E is the energy for dissociation of surface atoms. In the anodic dissolution of semiconductors, the rate is often controlled by the transport of holes from the bulk of the semiconductor to the surface. The pre-exponential term in Eq. [1] will then be a function of the bulk charge carrier concentration, the charge of the carriers, the diffusion coefficient, and the characteristic diffusion length in the solid. The activation energy will be influenced by space charge effects in the solid as well as by the bonding and structure of the particular semiconductor. All factors that have an influence on the charge carrier concentration will affect the rate of dissolution (*e.g.*, illumination, n- or p-type impurities, temperature, injection by a p-n junction, and reduction of oxidants such as ferricyanide ions on the surface).

For heavily doped n-type germanium, Gereth and Cowher (3) have reported that the rate of anodic dissolution is controlled by the supply of hydroxyl ions from the electrolyte, rather than by charge carriers in the solid. Therefore, the activation energy may depend on space charge layers in the solution rather than in the semiconductor. The pre-exponential in Eq. [1] will then be proportional to the hydroxyl ion concentration. In addition, for the spontaneous dissolution of germanium in oxygen-saturated media, Harvey and Gatos (4) found that the rate is independent of carrier concentration or illumination. In oxidative dissolution such as this, when diffusion is not rate limiting, it is bond breaking in an oxide surface complex that determines the activation energy. ν is then related to the frequency of thermal vibrations in the solid.

To distinguish between oxidative and nonoxidative dissolution, Simkovich and Wagner (5) showed for PbS and ZnO that doping of the solid and deviations from stoichiometry do not have a significant effect on the rate of dissolution in nonoxidizing acids, such as aqueous HCl. However, Ag_2S as an acceptor and Bi_2S_3 as a donor in PbS, or Li_2O as an acceptor and Al_2O_3 as a donor in ZnO do significantly affect the rate of dissolution in concentrated nitric acid. The oxidative dissolution can be characterized by the formation of elemental sulfur as a reaction product in the case of PbS.

Based on the above results, it can be concluded that in nonoxidative dissolution the rate constant and the activation energy in Eq. [1] are related to processes that occur at the solid-liquid interface. To investigate

* Electrochemical Society Active Member.
[1] Present address: Bell Telephone Laboratories, Murray Hill, New Jersey.

these processes in acid solutions, the dissolution of the II-VI compounds ZnS, ZnSe, CdS, and solid solution $Zn_xCd_{1-x}S$ has been studied as a function of both the structure and composition of the solids, and the properties of the solution. The over-all chemical reaction describing the dissolution process is

$$A_{II}B_{VI}(s) + 2H^+ = A_{II}^{++} + H_2B_{VI}(g) \quad [2]$$

with A_{II} representing the group IIB cation and B_{VI} the group VI anion. The II-VI compounds are particularly suitable for studying nonoxidative dissolution kinetics for several reasons:

1. It has already been shown that in well-agitated systems the rate is controlled by a heterogeneous surface reaction rather than by transport in the solution (6).
2. The reaction products do not form passive films that could inhibit the dissolution process.
3. The compounds can be prepared in allotropic crystalline modifications, and have a complete range of solid solubility.

Experimental

Materials.—All of the polycrystalline II-VI compounds were prepared by precipitation from a soluble salt of the group IIB cation. To produce a crystalline solid, the precipitate was dried, and annealed in H_2B gas or in an inert atmosphere. The method of preparation, impurity content, B.E.T. surface area, and crystal structure of each material are summarized in Table I. The composition of the crystallized solid solution was determined by comparing the measured lattice parameters to those reported by Ballentyne (7). In addition, chemical analyses for both zinc and cadmium were done after completely dissolving the solid in cold concentrated hydrochloric acid or in nitric acid. These two analytical methods gave results that were within 4%. The composition determined by x-ray analysis is reported in Table I. Reagent-grade chemicals and high-conductivity water (6.0×10^{-7} ohm^{-1} cm^{-1}) were used to prepare the acid solutions.

Apparatus and procedure.—Except for dissolution of ZnSe, rate measurements were made at constant pressure by continuously increasing the volume of the system as vapor was evolved. The pressure regulating system was similar to the one described by Cremer (8), although modifications were needed to keep the pressure constant to within 0.1 mm Hg while automatically recording the volume (9). The evolution of as little as 3×10^{-7} moles of vapor could be detected. This sensitivity is required in order to study the dissolution of the sparingly soluble II-VI compounds.

A 200-ml baffled Pyrex reactor flask, shown in Fig. 1, was immersed in a constant-temperature bath controlled to within 0.1°C. All experiments were carried out at a stirring speed of 1200 rpm. A 3g solid sample (± 0.1 mg) was held in a thin-walled Pyrex crucible before the start of each reaction so that it did not contact the acid in the flask. Fifty milliliters of acid

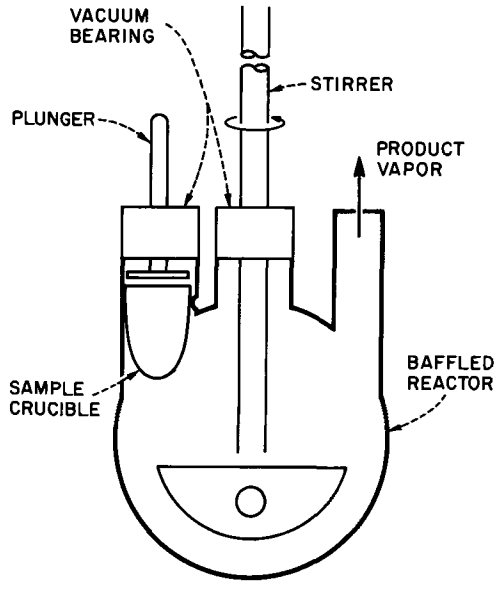

Fig. 1. Stirred reactor and sample crucible

solution were degassed by lowering the pressure until the solution boiled. The solution was then saturated by flushing the system with H_2S vapor. With the stirrer on, the reaction started instantaneously when the plunger pushed the sample crucible into the acid solution.

Dissolution experiments performed at constant pressure and temperature have definite advantages compared to experiments at constant volume. All of the vapor produced in the reaction goes into the gas phase since the solution is already saturated at a fixed constant pressure. Also, the evaluation of the constants in an empirical rate equation is easier when both temperature and pressure are constant during an experiment. In principle, the constant-pressure apparatus could have been used for the ZnSe experiments, but the large quantities of H_2Se needed to flush the system made this impractical. Although the ZnSe experiments were done at constant volume, the same reactor was used for all experiments and the sample was introduced in the same way as described above.

The concentration of acid, zinc ions, and cadmium ions was determined after equilibrium was reached in each experiment. For both zinc and cadmium, volumetric analysis was used, with ethylenediaminetetracetic acid as a complexing agent. In addition, when the cadmium ion concentration was too small to be determined by volumetric methods, analyses were done with a Jarrel-Ash flame photometer.

Results

Typical examples of the kinetic data collected in this investigation are displayed in Fig. 2 and 3. The dependence of the dissolution rate of high-purity ZnS

Table I. Preparation and properties of materials

Material	Method of preparation	Impurity content (spectroscopic analysis)	Crystal structure (observed values)	Surface area (m^2/g)
ZnS	$Zn(NO_3)_2 + H_2S$	10 ppm: Pb 3 ppm, Cu 0.2 ppm, Ni 0.3 ppm, Fe 1 ppm	Cubic $a_o = 5.38$Å	28.8

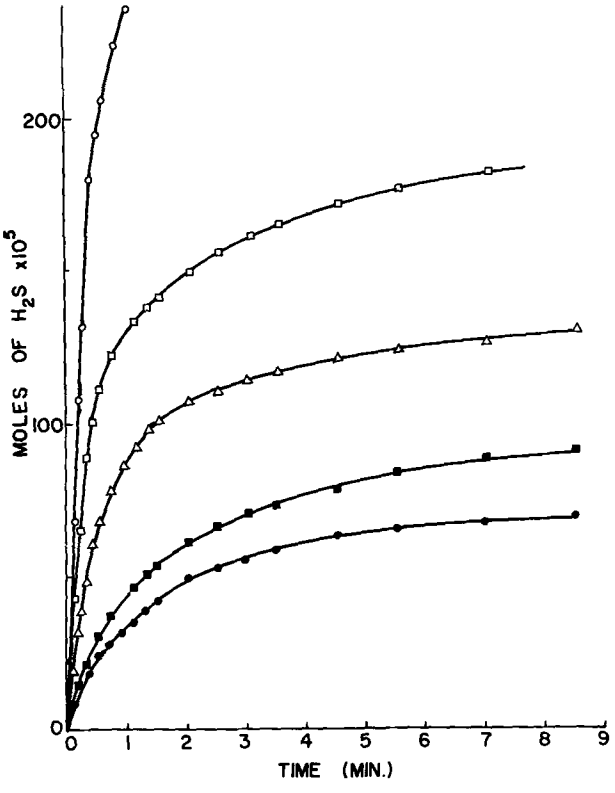

Fig. 3. Effect of temperature on the dissolution of high-purity ZnS in aqueous H_2SO_4: ● T = 0.2°C p_{H_2S} = 0.26 atm; ■ T = 10.0°C p_{H_2S} = 0.15 atm; △ T = 25.0°C p_{H_2S} = 0.27 atm; □ T = 40.0°C p_{H_2S} = 0.25 atm; ○ T = 59.0°C p_{H_2S} = 0.40 atm; [H_2SO_4] = 1.0M.

on sulfuric acid concentration at fixed temperature and hydrogen sulfide pressure is illustrated in Fig. 2. Figure 3 shows the variation of the dissolution rate with temperature at constant sulfuric acid concentration (1M). In all the investigations, the dissolution was allowed to proceed to conclusion so that information on the equilibrium state may also be obtained. This information is needed in order to determine the kinetic parameters of the reverse (precipitation) reaction. Although the general shape of the dissolution curves does not change with the composition of the leaching solution (aqueous sulfuric acid, alcoholic sulfuric acid, or aqueous hydrochloric acid), the dissolution rate in aqueous sulfuric acid is found to depend more strongly on temperature than in the other two solutions.

Our experiments confirmed the finding of Romankiw and deBruyn (6) that the dissolution process is independent of the rate of agitation of the reacting mixture beyond a critical stirring speed of 750 rpm. This experimental observation suggests that the net dissolution rate is not diffusion controlled. If we now assume that the dissolution process is controlled by a chemical reaction at the solid-liquid interface, then the rate of dissolution R (moles/m^2 sec) may be expressed as follows:

$$R = \frac{1}{A}(dn_{H_2B}dt) = k_1[H_2SO_4]^{\alpha} - k_{-1}[A_{II}SO_4]^{\beta}p^{\gamma}{}_{H_2B} \quad [3]$$

In writing Eq. [3], we assume the leaching agent to be sulfuric acid. The various symbols introduced in this expression are identified in the Nomenclature at the end of this paper. It is important to note that the formal rate constants k_1 and k_{-1} for the forward and reverse reactions, respectively, include the activity coefficients of the reacting species. The symbol A without subscript refers to the surface area (m^2) of the solid/liquid interface. The square brackets, [], imply molar concentrations of the reactants; the quantity [H_2SO_4] refers to the stoichiometric sulfuric acid concentration and not to the molar concentration of the undissociated species.

Spectrophotometric studies (10) of the composition of aqueous sulfuric acid solutions show that, except in extremely dilute solutions, the $SO_4^{=}$ ion is not a major constituent and that the concentration of undissociated H_2SO_4 is negligibly small in solutions of molarity less than 14M. At moderate concentrations, it is the HSO_4^- ion which predominates and the properties of such solutions are essentially that of a 1:1 electrolyte consisting of H^+ and HSO_4^- ions. An analysis of all pertinent thermodynamic data on this system in the temperature range 0°-50°C (11) shows that the H^+ ion concentration is proportional to the stoichiometric acid concentration in the concentration range 0.1-6M which includes the experimental concentrations (0.5-5M) used in this investigation. The sulfuric acid concentration term in Eq. [3] may therefore be replaced by the actual concentration of H^+, the proportionality constant relating [H^+] to [H_2SO_4] being approximately 0.8.

To determine the order of the forward reaction, that is, the magnitude of the constant α, we focus attention on the initial stage of the dissolution reaction. Equation [3] may now be transformed to read

$$R_o = k_f A_o[H_2SO_4]_o^{\alpha} \exp(-E_f/RT) \quad [4]$$

where R_o is the initial dissolution rate in moles/sec and is given by the initial slope of the experimental curves in Fig. 2. A check on the measured value of R_o was obtained by a numerical curve fitting technique (9). By plotting values of R_o against initial acid concentration ([H_2SO_4]$_o$), it was clearly established that α equals unity regardless of the composition of the solid phase and of the liquid phase. This first-order dependence of the dissolution rate on acid concentration was previously observed by Romankiw and deBruyn (6) for ZnS in aqueous sulfuric acid solutions. These

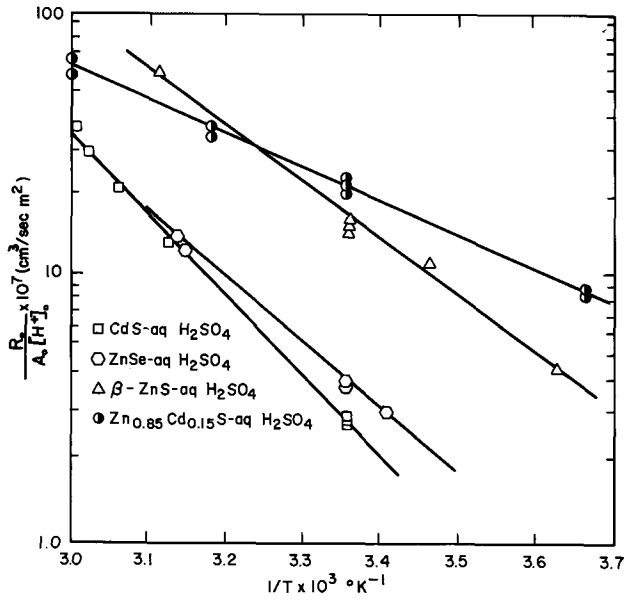

Fig. 4. Arrhenius plot for calculation of the activation energies for dissolution of II-VI compounds in aqueous H_2SO_4.

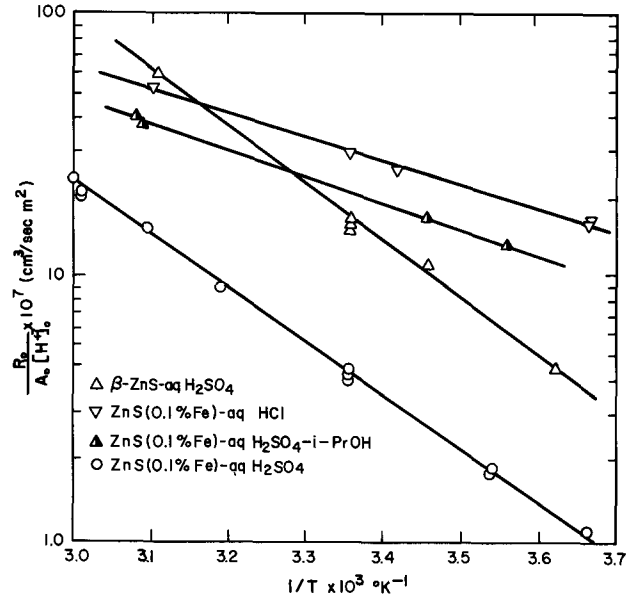

Fig. 5. Arrhenius plot for calculation of the activation energy for dissolution of ZnS in different solutions.

authors used an identical analytical procedure for evaluating α.

The activation energy E_f for the forward (dissolution) reaction was then determined by preparing plots of log $(R_o/A_o[H_2SO_4]_o)$ = log k_1 against $1/T$ as shown in Fig. 4 and 5. The magnitude of k_f, a reaction

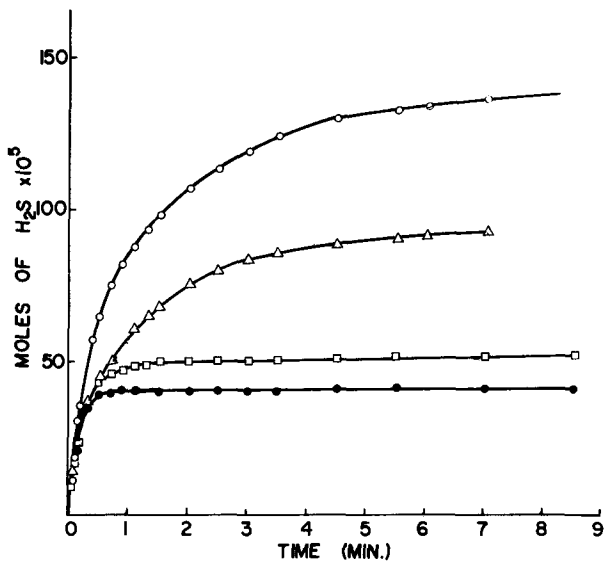

Fig. 6. Effect of H_2S pressure on the dissolution of high-purity ZnS in aqueous H_2SO_4: ● p_{H_2S} = 0.27 atm; △ p_{H_2S} = 0.32 atm; □ p_{H_2S} = 0.82 atm; ○ p_{H_2S} = 1.01 atm; T = 25°C; $[H_2SO_4]$ = 1.0M.

rate constant which is independent of temperature, may then be calculated.

At constant pressure of H_2B, it follows directly from Eq. [3] that for equilibrium conditions

$$d \log [A_{II}^{++}]_e / d \log [H^+]_e = \beta \qquad [5]$$

where the subscript e denotes that the equilibrium concentrations of the reacting species are to be used. Equation [5] shows how the constant β for the reverse (precipitation) reaction may be evaluated from experimental data such as found in Fig. 2. It also follows from Eq. [4] that, if the initial concentration of the acid is fixed in a series of experiments in which the pressure of the H_2B gas is allowed to vary, then at equilibrium, for $\alpha = 1$,

$$\log \left\{ \frac{[H_2SO_4]_o - [A_{II}SO_4]_e}{[A_{II}SO_4]_e{}^{\beta}} \right\} = \gamma \log p_{H_2B} + \log \frac{k_{-1}}{k_1} \qquad [6]$$

and therefore

$$\frac{d \log \{([H_2SO_4]_o - [A_{II}SO_4]_e)/[A_{II}SO_4]_e{}^{\beta}\}}{d \log p_{H_2B}} = \gamma \qquad [7]$$

Once β is known, the constant γ may be evaluated from the information contained in experimental rate curves such as those plotted in Fig. 6. From the appropriate plots suggested by Eq. [5] and [7], it has been established that the rate of the reverse reaction varies with the *square root* of both the concentration of the A_{II}^{++} ion in solution and the H_2B pressure. The activation

Table II. Activation energies and rate constants

Material	Solution composition	E_f (kcal/mole)	k_f (liters/sec m²)	E_r (kcal/mole)	k_r (moles liters/atm)$^{1/2}$ / sec m²
ZnS (0.1% Fe)	aq. H_2SO_4	9.9 ± 1.0*	2.7 ± 0.4 × 10^1	6.7 ± 1.0	1.9 ± 0.5 × 10^0
	aq. 20%-i-PrOH≠ 80% H_2SO_4	5.0	8.9 × 10^{-3}	1.6	5.3 × 10^{-4}
	aq. HCl	4.5	5.4 × 10^{-3}	—	—
β-ZnS	aq. H_2SO_4	9.5	3.8 × 10^0	5.8	7.5 × 10^{-2}
CdS	aq. H_2SO_4	14.2	6.8 × 10^3	6.7	1.7 × 10^1

≠ i-PrOH represents isopropanol.

energy (E_r) of the reverse (precipitation) reaction was then determined by solving Eq. [6] for k_{-1} at different temperatures and then plotting log k_{-1} against $1/T$.

All the pertinent kinetic parameters obtained by the above analysis of the experimental data are collected in Table II. It should be mentioned that in performing this analysis no correction has been made for the dependence of the activity coefficient of the reacting species on temperature. However, the stoichiometric activity coefficients for sulfuric acid and also hydrochloric acid in the concentration range 0.5*M* (Molal) to 5*M* are relatively insensitive to changes in temperature (12). The magnitudes of the activation energies E_f and E_r will therefore not be altered significantly if such corrections are made.

It is interesting to note for Table II that the values of E_r for ZnS, ZnSe, and CdS agree to within ±1 kcal/mole. During the asymptotic approach to equilibrium shown in Fig. 2, 3, and 6, the solid must form simultaneously with the dissolution. The reverse reaction involves either precipitation of new particles or growth on the already existing solid. In either case, the data suggest that the process of solid formation is not simply the reverse of the dissolution process. No attempt has been made to study the reverse reaction in detail, since the initial rate data used to calculate k_f and E_f are not affected by these complexities.

In Table II it can be seen that the activation energy E_f for dissolution in aqueous H_2SO_4 is different for each of the high-purity II-VI compounds. However, for the high-purity β-ZnS, the activation energy is almost the same as for the material containing 0.1% Fe. The latter solid also showed some wurtzite lines in its x-ray diffraction pattern which did not appear in the high-purity β-ZnS. These results indicate that the activation energy is not sensitive to impurity content or crystal structure, but the over-all rate of dissolution does depend on these factors due to changes in the number of reactive surface sites.

The dependence of the dissolution rate on the properties of the solution are also shown in Table II. For the same solid ZnS(0.1% Fe) in different solutions, there is a large change in the activation energy. Therefore, changing the solution, and with it the properties of the solid-liquid interface, influences the activation energy for the rate-controlling step.

The relatively low activation energy for dissolution of the solid solution $Zn_{0.85}Cd_{0.15}S$ may be related to other observations made on this material. For example, even after heat treatment, the x-ray diffraction peaks of the crystallized solid were not nearly as sharp as for the pure ZnS or CdS. It was found that the Zn/Cd ratio in the solution was several times higher than the ratio in the starting material. Therefore it is possible that the method of preparation sufficiently influences the surface properties of the solid to affect the activation energy for dissolution.

The results show that the rate of nonoxidative dissolution depends on both the properties of the solid and the solution. These data bear out the introductory remarks that any proposed mechanism of nonoxidative dissolution of semiconductors must account for the influence of processes at the solid-liquid interface.

Discussion

Figure 7 shows the steps that occur during dissolution of the II-VI compounds in nonoxidizing acids. Since agitation has no influence on the rate of dissolution of the II-VI compounds in aqueous H_2SO_4, and the activation energies are higher than the 3-6 kcal/mole expected for transport processes, it is unlikely that diffusion is the rate-controlling step. Furthermore, a quantitative estimate of the rate of diffusion of H^+ can be made using the equation

$$\frac{1}{A}(dn_{H_2B}/dt) = -D([H^+]_o - [H^+]_i)/d \qquad [8]$$

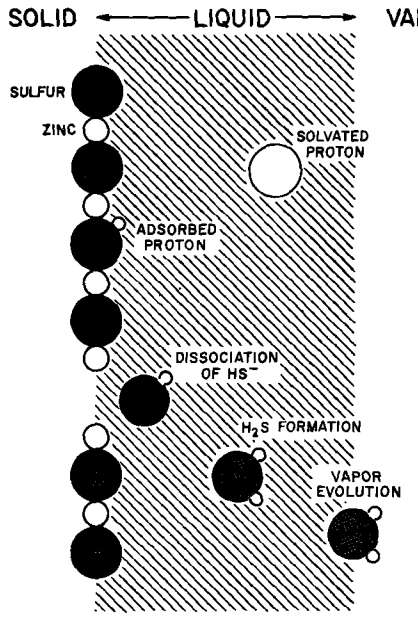

Fig. 7. The mechanism of dissolution of II-IV compounds in nonoxidizing acids.

where $[H^+]_i$ is the concentration of hydrogen ions near the solid surface. Values of $[H^+]_i = 0$, $[H^+]_o = 2$ moles/liter, $d = 10^{-3}$ cm, and $D = 10^{-5}$ cm²/sec, give a rate of 10^{-5} moles/(sec cm²). The chosen values of the effective boundary layer thickness, d, and the diffusivity, D, are likely to be within an order of magnitude for this system. Experimentally, for the II-VI compounds in aqueous H_2SO_4, the initial rates were no larger than 10^{-9} moles/(sec cm²). For the dissolution of ZnS in hydrochloric acid or in alcoholic H_2SO_4, the initial rates were approximately 10^{-5} moles/(sec cm²), so that the exclusion of diffusion control here is not as certain. However, it is the fact that the surface reaction is much slower for dissolution of ZnS in aqueous H_2SO_4 than in the other solutions, rather than the magnitude of the activation energy in the latter case, that is important. This fact is used below as evidence that a slow adsorption step is a plausible mechanism for the dissolution of the II-VI compounds in nonoxidizing aqueous H_2SO_4.

If the over-all rate of the dissolution reaction is controlled by the adsorption of hydrogen ions, or the protonated solvent, onto the surface then

$$R_o = k_f A_o [H^+]_i \exp(-E_A/RT) \qquad [9]$$

E_A is the activation energy for adsorption of the hydrogen ions at the interface. The concentration $[H^+]_i$ is related to the concentration in the bulk solution by the equation

$$[H^+]_i = [H^+]_o \exp(-\psi_\delta/RT) \qquad [10]$$

where ψ_δ is the potential of the ion at the distance of closest approach, before adsorption onto the surface. As hydrogen ions adsorb there is a change in potential equal to $(\psi_o - \psi_\delta)$, where ψ_o is the potential of the solid surface relative to the bulk solution. Also there is an energy change, Φ, when a proton interacts with the surface atoms to form some compound. This free energy change will depend on the activity of the solid surface, but it is independent of the surface charge. As shown in Fig. 7, it is assumed that the hydrogen ions adsorb preferentially on the sulfur sites, and that the surface reaction product dissociates as HS^-. This ion then reacts with a hydrogen ion to form H_2S which is transported away from the solid, and is finally evolved at the liquid-vapor interface. The observation that the H_2S/Zn^{++} mole ratio is greater than 1 is reasonable if adsorption occurs preferentially at the sulfur sites.

In terms of the adsorption theory of dissolution, where no electron transfer is involved in the rate-controlling step, the rate equation becomes

$$R_o = k_f A_o [H^+]_o \exp\left\{-\frac{\mathbf{F}}{RT}[\Phi + (\psi_o - \psi_\delta) + \psi_\delta]\right\} \quad [11]$$

The activation energy for dissolution, with the adsorption step controlling is

$$E_A = \mathbf{F}(\Phi + \psi_o) \quad [12]$$

E_A is made up of a chemical and an electrostatic contribution. The former can be related to the bonding, surface energy, and other solid properties that may effect Φ. The latter term depends on the interaction between the charged solid surface and the ions in solution. Changes in the activity of the surface due to the structure or the composition of the solid will generally be small, and Φ will not be appreciably changed. This is the reason for the small difference between the activation energies for pure β-ZnS and ZnS(0.1% Fe). The model also explains the results of Simkovich and Wagner (5), that impurities in the solid have little effect on the rate of nonoxidative dissolution. The low activation energy for $Zn_{0.85}Cd_{0.15}S$ is probably due to a state of disorder of the surface that is sufficient to affect the chemical potential for proton adsorption.

The maximum difference of about 5 kcal in the activation energies for dissolution of ZnS, ZnSe, and CdS is due primarily to the electrostatic interaction at the solid-liquid interface. This also must account for the changes in the activation energy when the same solid ZnS is dissolved in different solutions. For hydrochloric acid as the solvent, there is also the possibility that specific interactions of chloride ions occur on the surface, and alter both the surface charge and the distribution of active sites. This would lead to changes in both the rate constant and the activation energy. Although the concept of a dielectric constant for the solution near the solid surface has little meaning, the polarizability of the solvent and the potential drop across the Helmholtz layer are essential factors in the mechanism of nonoxidative semiconductor dissolution.

Conclusion

The experimental results, analyzed in terms of an activated adsorption model for the dissolution of II-VI compounds, explain why the rate of dissolution in nonoxidizing solutions is not affected by the electrical properties of the solid. It is the space charge in the solution rather than in the solid that is important.

Even in the case of oxidative semiconductor dissolution, it is known that adsorption affects the kinetics by increasing or decreasing the rate of the controlling step. For example, in the oxidative dissolution of InSb, which exhibits crystallographic polarity in the <111> direction, aliphatic amines preferentially adsorb on the Sb(111) surface and inhibit the rate by interfering with dissociation of the surface complex that controls the rate of dissolution (13). Richards and Crocker (14) found that Ag^+ reveals etch pits on the As(111) surface of GaAs for the same reason. In these two cases, it is the rate constant k_1 in Eq. [1] that is lowered. According to Harvey and Gatos (4), adsorbed halide ions catalyze the reduction of oxygen on the surface of Ge by supplying one electron. Based on the mechanism of dissolution proposed by Harvey and Gatos, this adsorption effects E as well as k_1 in Eq. [1]. Adsorbed ions can also change the rate of anodic dissolution of semiconductors when charge transfer in the solid is the rate-controlling step. The reduction of ferricyanide ($Fe(Cn_6^{-3})$ to ferrocyanide ($Fe(CN_6^{-4})$ on the germanium surface leads to an increase in the anodic dissolution rate. This is explained by Efimov (15) by the supposition that the electron required for the reduction comes from the valence band, creating an additional hole near the germanium surface. The process is analogous to the effect of illumination on the charge transfer controlled anodic dissolution.

In nonoxidative dissolution of the II-VI compounds, it is the adsorption that is the rate-controlling step. The adsorption model may be useful in explaining the results of etching studies in nonoxidizing solutions. According to this model, preferential adsorption occurs on the anion sites so that this face would be expected to dissolve faster than the corresponding cation face when the II-VI compounds are etched in the (111) orientation. Therefore, etch pits should appear on the cation faces. Studies of the adsorption kinetics of ions at the semiconductor-electrolyte interface and a more complete understanding of the changes in solvation that occur in the layer of solution near the solid surface would permit this adsorption theory of semiconductor dissolution to be developed further. These same effects are important in a broader scope of electrochemistry, such as with anodic oxide films and battery electrode behavior, so that the adsorption mechanism of nonoxidative semiconductor dissolution may be of more general importance.

Interpretation and Significance of Heats of Activation for Electrochemical Reactions Exhibiting Anomalous Tafel Slopes

B. E. Conway and D. J. MacKinnon

Department of Chemistry, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT

Heats of activation for electrochemical reactions studied over a wide range of temperatures are considered in relation to the temperature dependence of the Tafel slope factor b. Experimentally, b is found to have anomalous temperature dependence, *i.e.*, other than the classical form $RT/\alpha\mathbf{F}$, for hydrogen evolution at Hg, Cd, Pb, Ni, and Pt and the consequences of this behavior in calculation of heats of activation are evaluated. Curvature of the electrochemical Arrhenius plots is shown to arise for certain of the cases treated and is discussed in relation to the problem of detection of proton tunneling at low temperatures. Other difficulties associated with temperature dependence of coverage by atomic H and temperature-dependent structure changes in the solvent are considered.

Heats of activation in electrode processes, unlike those for gas phase and in certain cases solution reactions, cannot be easily related to the mechanism of the reaction. This arises because only an apparent energy of activation (1) is measured by such experimental derivatives as $d \ln i_0/d(1/T)$ (involving the exchange current density i_0), $(d\eta/dT)_i$, $(d\eta/d\ 1/T)_i$ or $(d\eta/d \ln T)_i$, where η is the overpotential at a current density i related to i_0 by the familiar equation $i = i_0 \exp \eta/b$, where b is the Tafel slope. However, in a number of situations, variations of heats of activation for a given reaction, *e.g.*, over a series of metals, or on account of isotopic substitution, or with temperature, can be useful as a basis for evaluation of such factors as chemisorption in relation to the electronic character of the metal (2) or the role of quantum-mechanical tunnel effects in proton transfer (3) through the estimation of frequency factor ratios.

Normally the apparent heat of activation $\Delta H^{o\neq}_R$ at the reversible potential differs from the "true," kinetically significant quantity $\Delta W^{o\neq}$ (for zero metal-solution p.d.) according to the relation (1)

$$\Delta H^{o\neq}_R = \Delta W^{o\neq} - \beta \Delta H^o \qquad [1]$$

where ΔH^o is the enthalpy change in the single (half-cell) reaction

$$H^+_{aq} + e_M \rightleftharpoons \tfrac{1}{2} H_2 \qquad [2]$$

and β is a symmetry factor. It is well known that ΔH^o, for obvious reasons, is not a thermodynamically measurable quantity, although it may be estimated with varying degrees of uncertainty depending on the value assigned to the surface potential and the basis for assignment of individual ionic free energies of hydration (4).

Usually the apparent heat of activation is evaluated at zero overpotential from the derivative $(\partial \ln i_0/\partial\ 1/T)_{\eta=0}$ or from the temperature coefficient of overpotential at a given current density (5). At finite overpotential η, the derivative $(\partial \ln i/\partial\ 1/T)_\eta$ also gives the effective heat of activation at potential η which differs from that deduced for the reversible potential by the energy $\beta\eta\mathbf{F}$. These relations which give $\Delta H^{o\neq}_R$ in terms of $\Delta W^{o\neq}$ and ΔH^o apply when the Tafel slope b of the process is given by $b = RT/\beta\mathbf{F}$ and $\beta \neq f(T)$.

In the present and other (6) recent work, we have investigated the temperature dependence of the Tafel slopes of the hydrogen (h.e.r.) and bromine evolution reactions over a wide range of temperatures (including low temperatures down to −125°C) in order to establish the correct form of the temperature dependence of b. It has been found (6) that b is rarely given by the "defining" relation quoted above and usually b is less temperature dependent than is implied by $b = RT/\beta\mathbf{F}$ with β a constant equal to approximately 0.5. Under some conditions b can be almost independent of temperature (6-9), while for other conditions b may even increase with decreasing temperature. Inspection of early papers in the literature reveals qualitatively similar observations, but the results were usually poorly reproducible and were obtained in insufficiently purified solutions. Also, the variation of b or β with T was not systematically examined.

Generally (6), when $b \neq RT/\beta\mathbf{F}$, the Tafel slope can be represented empirically by

$$b = \frac{RT}{\beta\mathbf{F}} + c \qquad [3]$$

where c is a temperature independent constant and β can be > 0.5. It appears coincidental that $b = 0.116$ at room temperature, *e.g.*, for the h.e.r. at Hg, so that b is apparently $RT/\beta\mathbf{F}$ with $\beta = 0.5$. Over a wider range of temperature, including low temperatures down to −100°C in methanol and ethanol (3, 6), and higher temperatures up to 65°C at Hg in methanol, b is not represented by the usual simple relation $b = RT/\beta\mathbf{F}$ but by Eq. [3].

The consequences of this situation with regard to the evaluation and significance of $\Delta H^{o\neq}_R$ are investi-

gated in the present paper in relation to experimental results on the kinetics of cathodic hydrogen and anodic bromine evolution measured over a wide range of temperatures. The interpretation of temperature variations of $\Delta H^{o\neq}_R$ are of interest in regard to (*a*) the role of proton tunneling (10, 11), in the h.e.r.; (*b*) the effects of solvent structure changes on $\Delta H^{o\neq}_R$ in hydrogen-bonded media as the temperature changes; and (c) the role of temperature-dependent solvent orientation (12, 13) at the electrode interface in the kinetics of the h.e.r. Hence, it is important to establish first the effect of anomalous temperature variations of *b* in relation to their effects, if any (see below), in determining the form of the temperature dependence of $\Delta H^{o\neq}_R$. Heats of activation were therefore determined for a number of metals at which the Tafel constant *b* shows (3, 6) unusual variations with temperature.

Experimental

General.—Since heats of activation were required together with Tafel slopes, steady-state, point-by-point kinetic measurements were made galvanostatically by the "rapid" procedure (14). This method has been shown to be preferable to the "slow" procedure where variations of potential over long times (up to 2 hr) are followed at each current density. The essential experimental procedure and apparatus have been adequately described elsewhere (2). The electrolysis cell for Hg was provided with glass coils in the working and reference electrode compartments, through which thermostated water could be circulated at various temperatures. Methanolic solutions of HCl were used in most of the work in order to be able to reach low temperatures. Most kinetic measurements were carried out at a series of descending temperatures but some runs were conducted at successively ascending as well as descending temperatures.

Preparation and purification of solutions.—In order to attain low temperatures, it is necessary to use either nonaqueous (3) or concentrated acid solutions (15). Tafel lines obtained in the latter media exhibit kinks associated with specific adsorption (16) but at higher concentrations (*ca.* 7.0*N* in HCl for example) linear behavior is exhibited over several decades of current density but the *b* values are higher than $2RT/F$ presumably on account of anion adsorption. In order to avoid the high concentrations of acid that are required in water to reach low temperatures, nonaqueous solutions were employed.

The solutions chosen for the present work were the following: (*i*) 0.5*N* HCl-methanol-h; 0.5*N* HCl-ethanol-h; (*ii*) 0.5*N* DCl-methanol-d for isotope effect studies; and (*iii*) 0.4M $(C_3H_7)_4NBr$ in acetonitrile for Br^- discharge. The choice of HCl and DCl was an obvious one since both could be easily prepared in the dry, gaseous state. The choice of the system 0.4M $(C_3H_7)_4NBr$-acetonitrile was governed by the desire to study a one-electron discharge process (other than that involving protons) in a nonhydrogen-bonded solvent in order to avoid anomalous changes of activation energy which can arise in H-bonded solvents due to changes of association with temperature.

Methanol-h solutions (CH_3OH) containing HCl were prepared by the procedure previously described (3). Ethanol-h (C_2H_5OH) was prepared from the undenatured material by refluxing over, and then distilling from, dried calcium oxide. The material thus obtained was then subjected to the purification treatment previously described (3) for methanol. Methanol-d (CH_3OD) was prepared from magnesium methoxide and 99.8% D_2O as described previously (3).

Gaseous DCl was prepared by the action of D_2O on redistilled benzoyl chloride, b.p. 197°C (17). Any traces of benzoyl chloride entrained in the evolution of DCl gas were removed by two traps.

For the anodic reaction of Br^- ion at graphite, spectroscopic grade acetonitrile was used as the solvent. Recrystallized and dried (18) $(C_3H_7)_4$ NBr was dissolved in the acetonitrile until a maximum concentration of 0.4M was reached.

Purification of gases.—Hydrogen gas for the reference electrode and for bubbling in the cathode compartment during the h.e.r. runs was rigorously purified before use according to previously described procedures (2, 3). N_2 used in the anode compartment was also purified (19).

Preparation of the electrodes under study.—Platinum and nickel.—These electrodes were prepared from spectroscopically pure wires of platinum and nickel by a standardized method in order to ensure the best reproducibility of the measurements. The wires were cleaned first by washing for 24 hr in thiophene-free benzene under reflux, and then sealed, after drying, in glass bulbs in a stream of the purified hydrogen gas (2, 3). The bulbs were broken just prior to the experiment in the usual way (2, 3).

Lead and cadmium.—These electrodes were prepared by melting rods of the spectroscopically pure metals in a crucible under a hydrogen flame. The molten metals, which retained brilliant oxide-free surfaces, were then drawn into 2 mm capillaries and allowed to solidify. The tubes were then cut to expose the desired metal surface.

Mercury.—Specially distilled mercury (A.C.S. grade from Johnson-Matthey and Mallory Ltd.) was used directly without further purification.

Graphite.—Pyrolytic (nonporous) ultra-pure graphite rod obtained from the General Electric Company was used for the studies on bromide discharge, and was mounted in a specially fabricated Teflon holder connected to a Tru-bore sliding glass tube which could be fitted in the head of the working electrode compartment of the cell.

Counter and reference electrodes.—Special consideration had to be given to the counterelectrode since the electrolyte used was methanolic or ethanolic HCl (or DCl); thus, in the presence of Cl^- ion, oxidation of the alcohol by Cl_2 could arise especially during the pre-electrolysis purification which was carried out for a period of at least 10 hr at a current density of 2 mA-cm^{-2}. Although a closed stopcock between the anode and cathode compartments decreased the possibility of migration of oxidation products, etc. from the anode to the cathode, it was felt that such oxidation should be eliminated.

It was found that a large silver gauze anode met this requirement satisfactorily by reacting with Cl^- ion from the solution, forming an insoluble film of silver chloride as the anode reaction. A fresh silver electrode was prepared before each run and a standardized cleaning procedure using aq. NH_3 was followed. Platinized platinum gauze over which hydrogen gas was bubbled was also tried but did not lead to satisfactory results.

The reference electrodes were a pair of platinized platinum hydrogen electrodes which operated satisfactorily in alcoholic solutions (20) and were repeatedly checked against one another. The reversibility of the hydrogen reference electrode at low temperatures (down to −90°C) was checked in a series of special experiments as follows: (*a*) Qualitatively, by bubbling nitrogen rather than hydrogen gas at one of a pair of electrodes. The electrodes recovered their initial zero potential difference within a minute or two if the nitrogen was replaced by hydrogen gas. (*b*) Quantitatively, by variation of the partial pressure of hydrogen by dilution with nitrogen at one of the electrodes.

For the anodic reaction of Br^- at graphite, the silver-silver bromide reference half-element was used. Electrodes were prepared in pairs according to the procedure given by Ives and Janz (21).

Temperature control.—For the low temperature experiments the cell was cooled by immersion in a large

Dewar flask containing a "low-boiling" (30°-60°C) petroleum ether/liquid nitrogen mixture [cf. ref. (3)]. The temperature of the cooling bath was measured by means of a pentane thermometer at the beginning and end of each run and was found to vary by no more than 1°C. As the experiments were carried out over a total temperature range of up to 160°C, this means of temperature control was considered adequate.

The shorter temperature range (24°-65°C) involved in the experiments at mercury necessitated more accurate control of the temperature [cf. ref (3)]. For these runs, thermostated water was circulated through the cell at a pre-set constant temperature in the usual way.

Potentiodynamic measurements.—These were carried out using conventional circuitry (22) at Ni and Pt at low temperatures in methanolic solutions in order to examine if quantitative H-coverage measurements could be made, as they can in aqueous solutions at noble metals. Well resolved H peaks could not be detected presumably owing to the competitive adsorption of CH_3OH (23).

Results

Exchange current densities as a function of temperature.—Linear logarithmic behavior was observed in the over-potential (η)-current density (i) relation for the h.e.r. at Ni, Pt, Cd, and Pb. Good linear Tafel relations were also observed for the Br_2 evolution reaction at graphite. At Ni, however, in the h.e.r., two linear regions were observed in the η-log i plots (Fig. 1). At the lower current densities, the slope for this part of the η-log i relation increased with increasing temperature while for the section at high i, b decreased with increasing temperature. At approximately −40°C both regions have the same slope and a single Tafel line over some 4 decades of i is observed. In CH_3OD/DCl, the isoinclinal temperature for the log i-η relation is nearer to room temperature. The activation energy behavior was evaluated by plotting the logarithm of the exchange current i_o (see below) as a function of $1/T$.

The log i_o, pertaining to the experimental region[1] of current-potential behavior actually observed, was obtained for each temperature by calculation rather than graphical extrapolation using the experimental Tafel parameters a and b which give, when $\eta = 0$, log $i_o = -a/b$.

Nickel.—In this case, two lines for log i_o *vs.* $1/T$ were obtained (Fig. 2) corresponding to the two Tafel regions of Fig. 1. The plot for the high c.d. region shows a departure from linearity at approximately −40°C and gives a mean apparent value of $\Delta H^{o\neq}_R$ of 10.4 kcal-mole^{-1} as shown in Fig. 2. The plot for the low c.d. region exhibits curvature at the high temperature end and gives limiting values of $\Delta H^{o\neq}_R$ of 7.1 in the upper region and 3.9 kcal-mole^{-1} for the lower section.

Platinum.—As in the case of the low c.d. region at nickel, the electrochemical Arrhenius plots for platinum exhibit marked curvature especially at higher over-potentials; $\Delta H^{o\neq}_R$ varies from *ca.* 8 kcal-mole^{-1} (+25° to −46°C) to *ca.* 3.5 kcal-mole^{-1} (−46° to −125°C) (Fig. 3a). The corresponding plot for the experiment conducted over a range of ascending temperatures is shown in Fig. 3b and exhibits surprisingly an apparent negative activation energy at the high temperature end.

Lead.—The kinetic results obtained at this metal give an apparent negative energy of activation at values of $1/T > 3.9 \times 10^{-3}$ °K^{-1} but normal behavior at the higher temperatures. Thus $\Delta H^{o\neq}_R$ for $1/T < 3.9 \times 10^{-3}$ °K^{-1} is + 6.3 kcal-mole^{-1}.

[1] The value of log i_o so calculated may not be identical with that actually obtaining at $\eta = 0$ in an experimentally inaccessible range (e.g., at Pb or Hg) of current densities near the reversible potential. It refers, however, correctly to the process actually occurring at higher potentials.

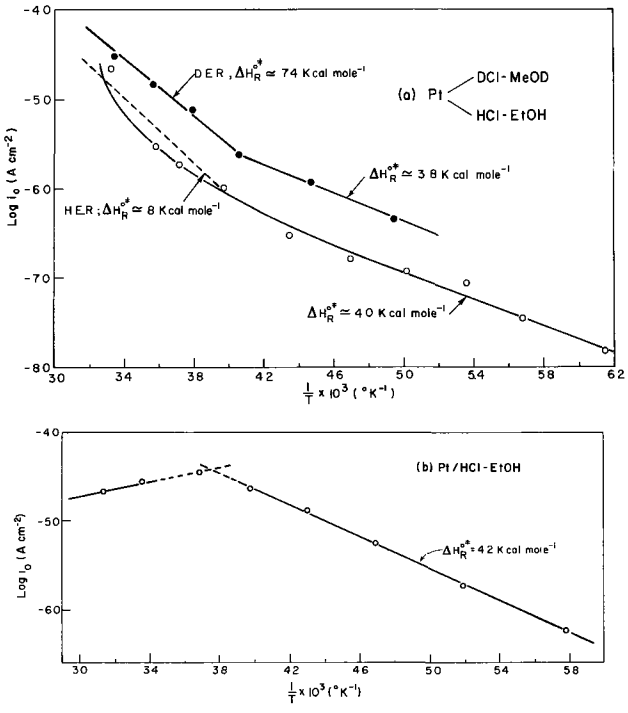

Fig. 3. (a) Electrochemical Arrhenius plots for the h.e.r. at Pt in alcoholic HCl and DCl solutions. (b) As in (a) but for a series of ascending temperatures.

Cadmium.—The log i_o *vs.* (1/*T*) plots for methanol-h and d exhibit a break at approximately 4.0 x 10^{-3} °K^{-1}, where log i_o becomes practically independent of temperature particularly in the H-solvent. The values of $\Delta H^{o\neq}_R$ calculated from the data for the h.e.r. at the high temperature end (*i.e.*, $1/T < 4.0 \times 10^{-3}$ °K^{-1}) is 7.1 kcal-mole^{-1} while that for the d.e.r. is 11.5 kcal-mole^{-1}.

Apparent activation energies as a function of η.—Values of $(\log i)_\eta$ were plotted as a function of (1/*T*) for each of the metals under consideration for various values of η. From these plots, values for $\Delta H^{o\neq}_\eta$ are obtained (5) for each η value and can then be plotted as a function of η; such relations can ideally be represented by the equation

$$\Delta H^{o\neq}_\eta = \Delta H^{o\neq}_R - \beta\eta\mathbf{F} \qquad [4]$$

where $\Delta H^{o\neq}_R$ is the value of the activation energy at zero over-potential.

Nickel; high c.d. region.—Figure 4a shows a plot of (log *i*) *vs.* (1/*T*) for η values ranging from 0 to −0.6V. $\Delta H^{o\neq}_\eta$ decreases as η increases as required by Eq. [4] and the nonlinearity of the $(\log i)_\eta$ *vs.* (1/*T*) plot gradually disappears as η increases, becoming more or less linear over the entire temperature range at the higher η values. A plot of the derived $\Delta H^{o\neq}_\eta$ *vs.* η is shown in Fig. 4b.

Nickel; low c.d. region.—The results are shown in Fig. 5, but, contrary to the above equation, $\Delta H^{o\neq}_\eta$ now increases as η increases and there is curvature in the plot which becomes more pronounced as η becomes more negative.

Platinum.—The plot of $(\log i)_\eta$ *vs.* (1/*T*) is shown in Fig. 6a; it is evident that there is some resemblance to the results for the low c.d. region at nickel shown in Fig. 5. Figure 6b shows a plot of $\Delta H^{o\neq}_\eta$ *vs.* η and indicates again an apparent negative value of β, the symmetry factor, in Eq. [4].

Lead.—Plots of $(\log i)_\eta$ *vs.* (1/*T*) were constructed as in Fig. 4, 5, and 6 and as η increases the apparent negative activation energy at the lower temperatures disappears and the relations become linear and normal at approximately −0.7V.

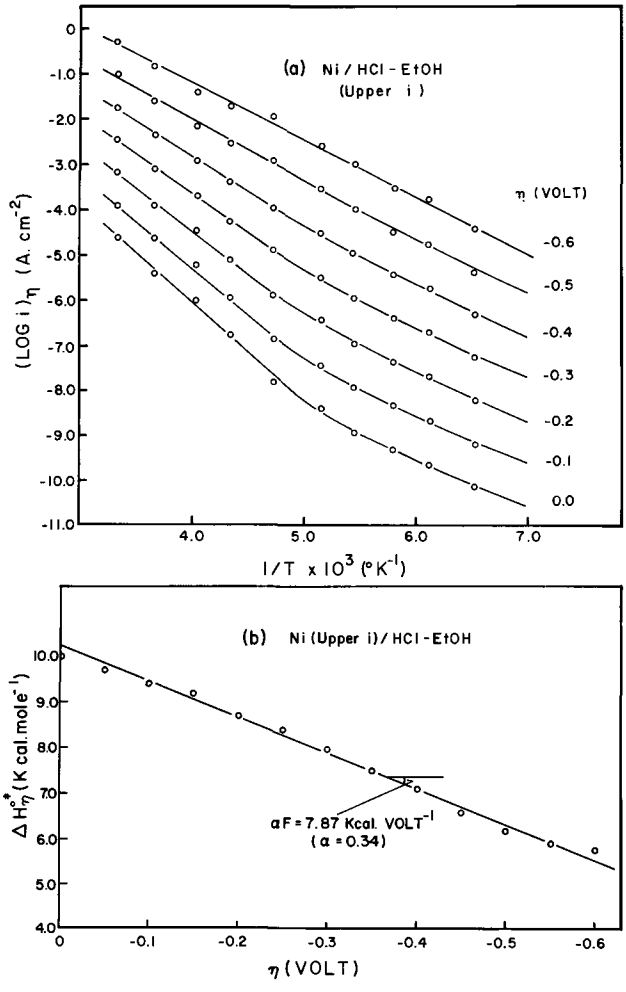

Fig. 4. (a) Plots of $(\log i)_\eta$ *vs.* 1/*T* for the upper Tafel regions in Fig. 1a. (b) Dependence of $\Delta H^{o\neq}_\eta$ (from Fig. 4a) on η (Eq. [4]).

Cadmium.—The results for this case are similar to those for lead, except that the slopes of the Arrhenius plots have, under all conditions, a normal sign.

Mercury.—The behavior of Hg was in close agreement with that evaluated previously (3) in this laboratory.

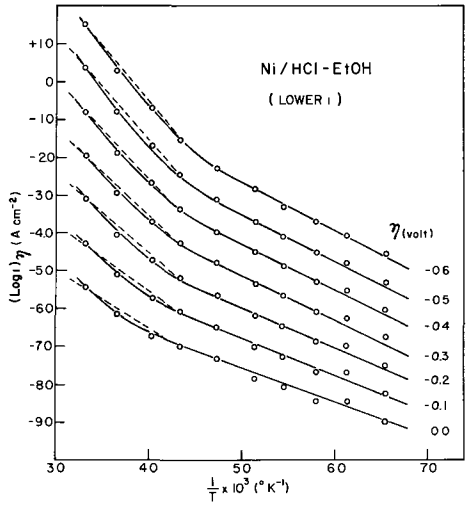

Fig. 5. Plots of $(\log i)_\eta$ *vs.* 1/*T* for the lower Tafel regions of Fig. 1a.

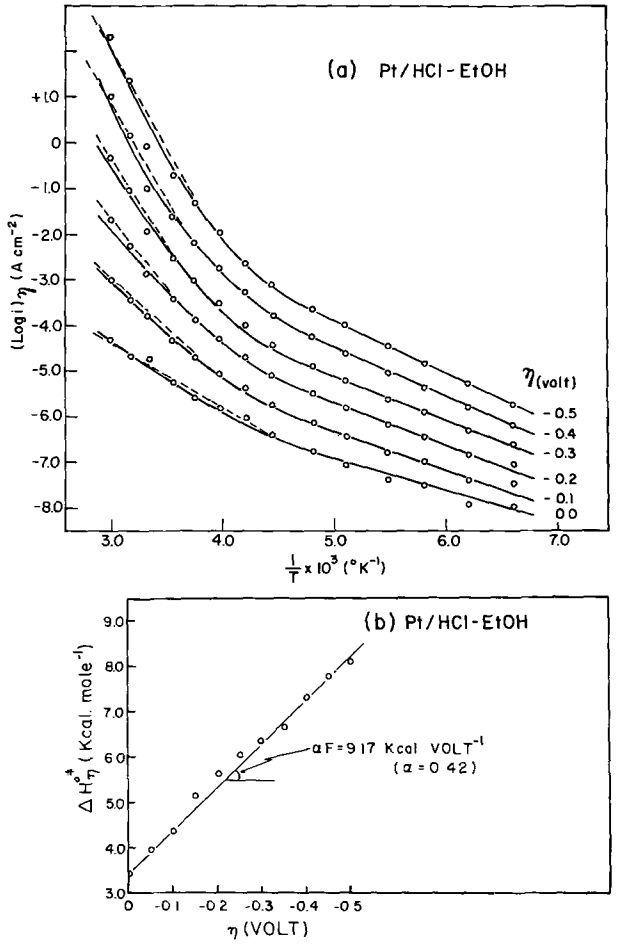

Fig. 6. (a) Plots of $(\log i)_\eta$ *vs.* $1/T$ for the h.e.r. at Pt in ethanolic HCl. (b) Dependence of $\Delta H^{o\ddagger}_\eta$ (from Fig. 7a) on η.

Corresponding data for deuterium evolution.—The polarization curves were similar to those for the h.e.r. at the above metals but b values were usually somewhat greater than the corresponding values for the h.e.r. Comparative electrochemical Arrhenius plots for the d.e.r. are shown in Fig. 7 and 3a for some of the metals referred to above.

Anodic reaction of Br^- at graphite.—The purpose of this part of the work was to provide, for comparative purposes, some results over a range of low and intermediate temperatures for a "one-electron" charge transfer process not involving reaction of H or D. After various exploratory studies, the most suitable system for this experiment was found to be 0.4M $(n\text{-}C_3H_7)_4$ NBr in spectroscopically pure acetonitrile. The Tafel slopes are found to be almost independent of T and the log i *vs.* $1/T$ plots exhibit normal behavior, giving excellent linear relations over a range of some 75°K for various η values.

Discussion

Illustrative numerical calculations of $\Delta H^{o\ddagger}_R$.—It was thought desirable to make illustrative evaluations of $\Delta H^{o\ddagger}_R$ for various situations in which complications may arise, *e.g.*, if β is $f(T)$ or if b is not simply equal to $RT/\beta\mathbf{F}$. Results are therefore presented here of numerical calculations of activation energies in which various means of expressing $\Delta H^{o\ddagger}_R$ have been used, corresponding to cases encountered experimentally. The following approach was employed: the usual relation

$$i_o = k \exp[-\Delta H^{o\ddagger}_R/RT] \qquad [5]$$

assuming a constant reactant ion concentration, was used and a value of 10.0 kcal-mole^{-1} was arbitrarily chosen for $\Delta H^{o\ddagger}_R$ and i_o values were calculated for a series of T values. These values were then put into the equation

$$\log i = \log i_o + \eta/2.3\, b \qquad [6]$$

where b was assumed to take one of the four possible forms listed below:

$b = RT/\beta\mathbf{F}$; where $\beta = 0.5 =$ const.; this is the simple form usually assumed for b, so that $\Delta H^{o\ddagger}_R$ should be recovered without complications; this is simply a "reference" case.

$b = (RT/\beta\mathbf{F}) + c$, where c was taken as a constant equal to 0.04V and $\beta = 0.71$ (to give $b = 0.116$ at $T = 298$°K; *cf.* the actual results obtained at Hg in methanol).

$b = (RT/\beta\mathbf{F}) + c$, where c was taken as a constant (*cf.* the observed experimental behavior described above for certain metals), that is, β is linear in T.

$b = c' - 2.3\ RT/\beta\mathbf{F}$; *i.e.*, b increases as T decreases, as found for example for Pt and in the low c.d. region at Ni when anion adsorption is significant.

For each of the cases listed above, $\Delta H^{o\ddagger}_R$ and $\Delta H^{o\ddagger}_\eta$ were recovered by the following methods and the calculated results were compared (Fig. 8):

(a) $d \log i_o/d(1/T) = -\Delta H^{o\ddagger}_R/2.3R$; this is the kinetically most convenient way of obtaining the heat of activation.

(b) $d(\log i)/d(1/T) = -(\Delta H^{o\ddagger}_R - \beta\eta\mathbf{F})/2.3R$ for various η values.

(c) $(d\eta/dT)_i = -\Delta H^{o\ddagger}_\eta/\beta\mathbf{F}T$.

(d) $(d\eta/d \log T)_i = -2.3\ \Delta H^{o\ddagger}_\eta/\beta\mathbf{F}$.

Case 1: $b = RT/\beta\mathbf{F}$; $\beta = 0.5$ and constant (Fig. 8 and 9). This case is trivial in that a value of $\Delta H^{o\ddagger}_R = 10.0$ kcal-mole^{-1} was chosen to calculate the i_o values from which $\Delta H^{o\ddagger}_R$ will obviously be recovered with the required starting value. However, this provides a basis for comparisons among the remaining three cases. For this case, the values of $\Delta H^{o\ddagger}_\eta$ calculated by method b are in agreement (as they must be) with values of $\Delta H^{o\ddagger}_\eta$ calculated from methods c and d.

Case 2: $b = (RT/\beta\mathbf{F}) + c$ which is the form of the b *vs.* T plot experimentally observed at Hg where $\beta = 0.71$ and $c = 0.04$V. A plot of $(\log i)_\eta$ *vs.* $(1/T)$ is shown in Fig. 8. Unlike their counterparts in case 1, the plots exhibit curvature which is more pronounced at the higher η values. Thus $\Delta H^{o\ddagger}_\eta$ must be determined for particular values of $(1/T)$ and the derived values are hence temperature-dependent. The plots of η *vs.* log T for this case 2 are shown in Fig. 10 and values of $\Delta H^{o\ddagger}_\eta$ calculated by method b are found not to be in agreement with values of $\Delta H^{o\ddagger}_\eta$ computed by methods c and d; however, the results of c and d are

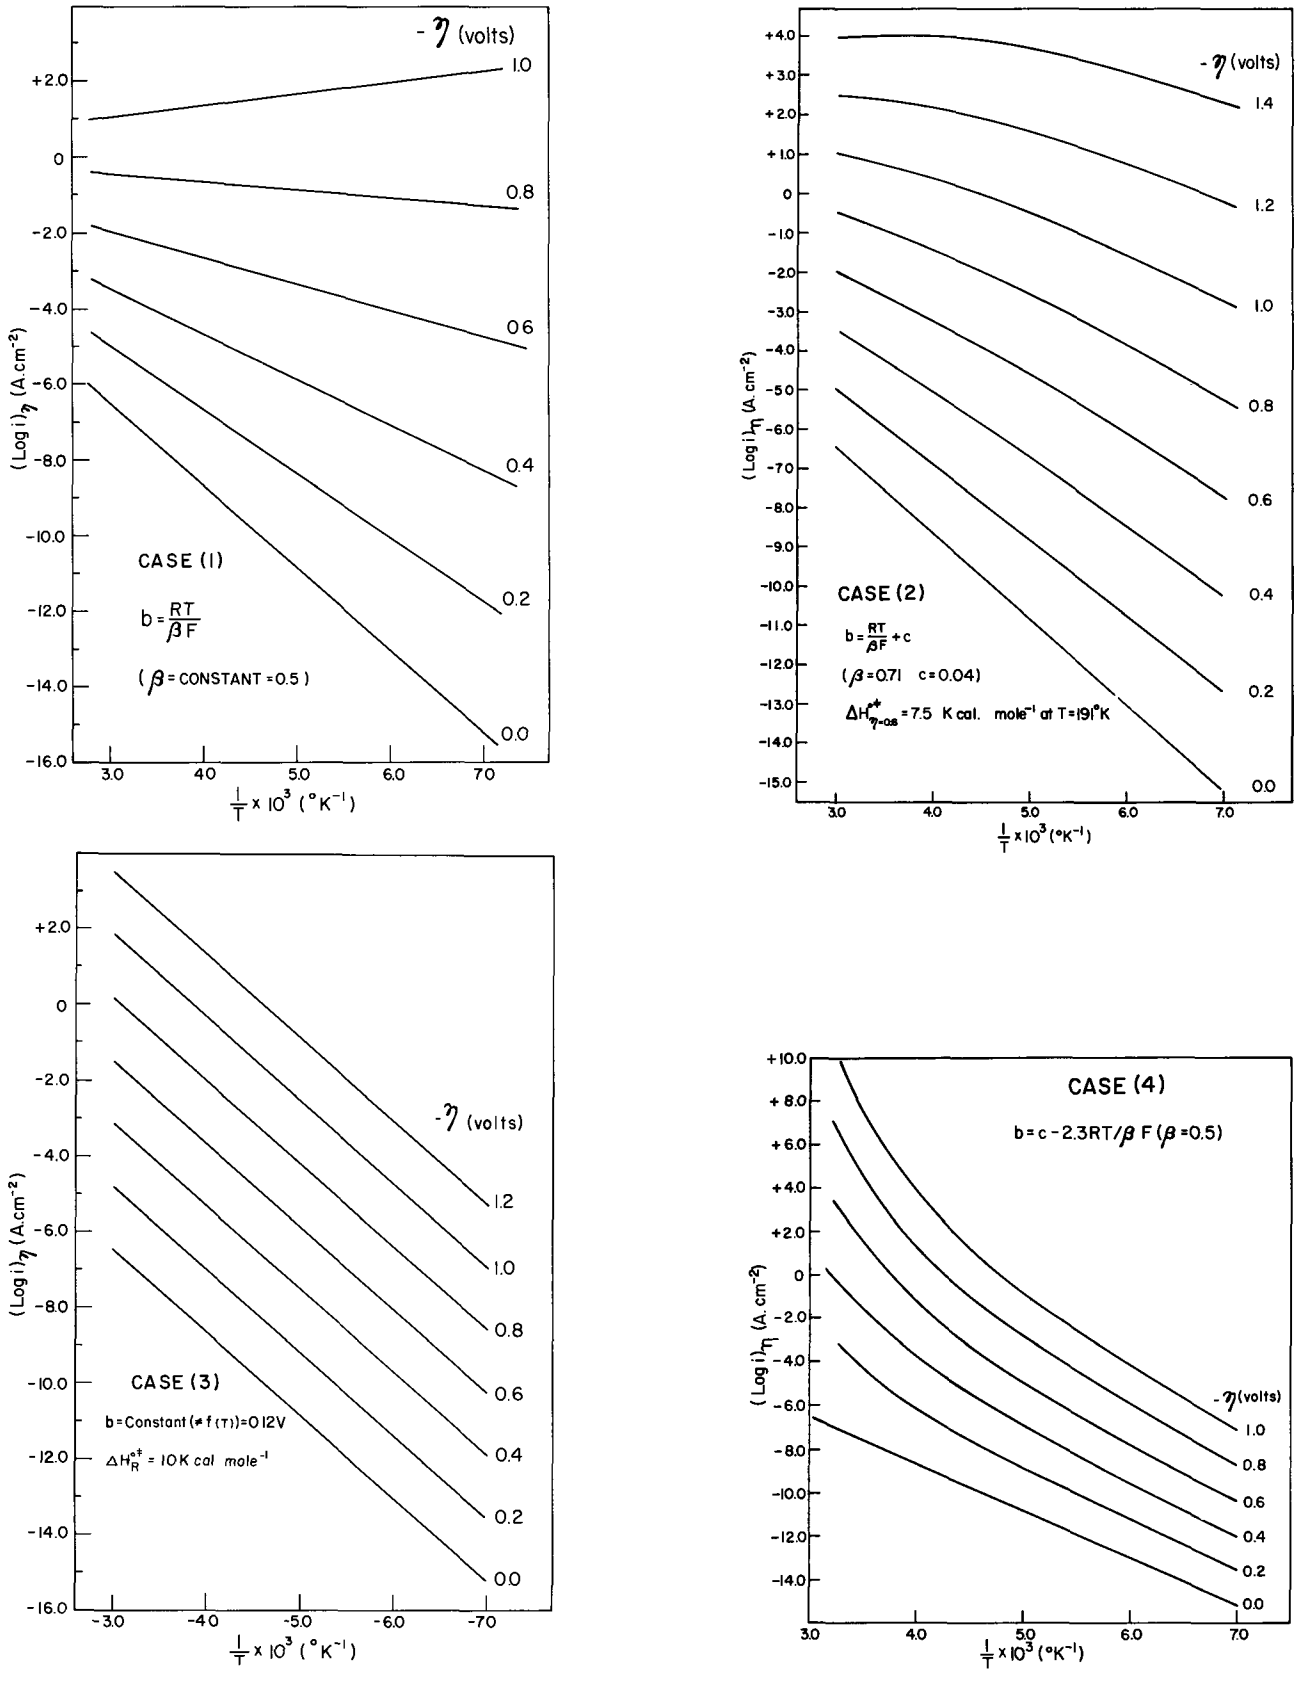

Fig. 8. Plots of (log i)$_\eta$ *vs.* $1/T$ for the four test cases examined by numerical computation

in agreement with each other.

The results derived from plots of log i_o *vs.* $1/T$ agree of course for all cases since here $\eta = 0$ (log i = log i_o at $\eta = 0$) and thus the form of b does not enter into the calculation (see lowest lines for $\eta = 0$ in Fig. 8).

Case 3: b = const. = 0.120V. Here β is changing with temperature so that $b \neq f(T)$. Thus $b = RT/\beta\mathbf{F}$ with $\beta = kT$, say.

The (log i)$_\eta$ *vs.* $1/T$ plot shown in Fig. 8 will obviously give the assumed reference value of 10.0 kcal-mole^{-1} at all η values and hence $\Delta H^{o\neq}{}_\eta$ is independent of η. When values of $\Delta H^{o\neq}{}_\eta$ are however, evaluated from the plots of $(\eta)_i$ *vs.* log T (Fig. 11), they are found to be a function of temperature (or c.d.) as follows by taking tangents to the curves in Fig. 11. Values of $\Delta H^{o\neq}{}_{\eta=0.8}$, calculated for various c.d. values, are

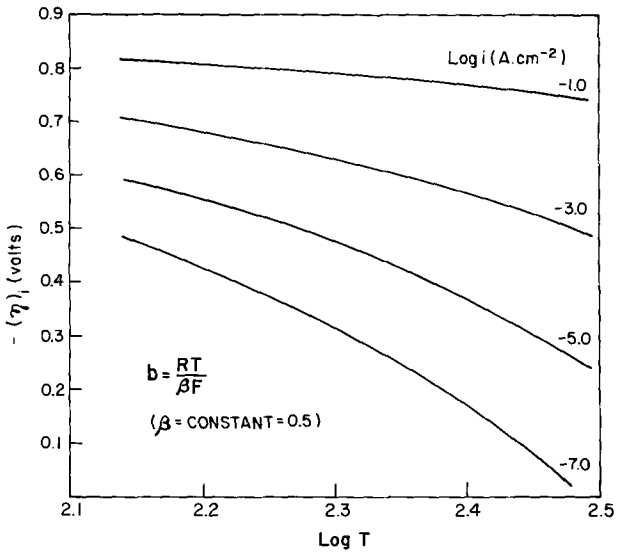

Fig. 9. Plots of $(\eta)_i$ vs. log T for case 1

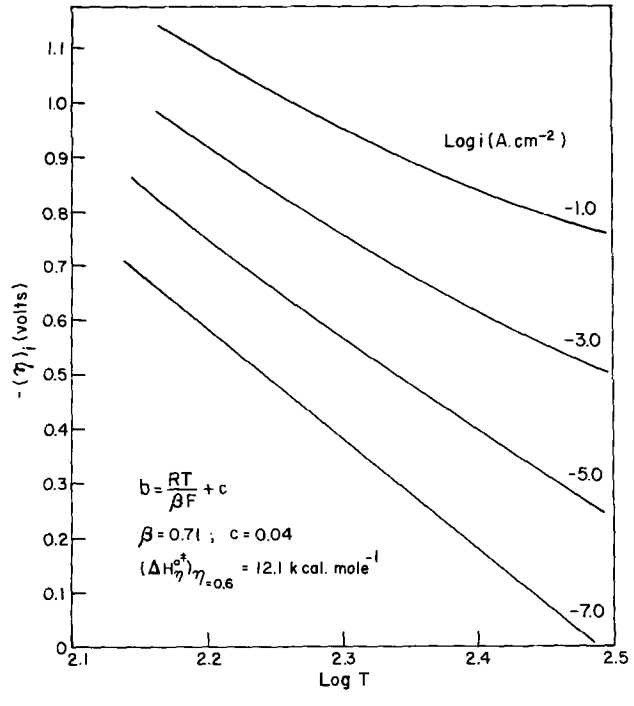

Fig. 10. Plots of $(\eta)_i$ vs. log T for case 2

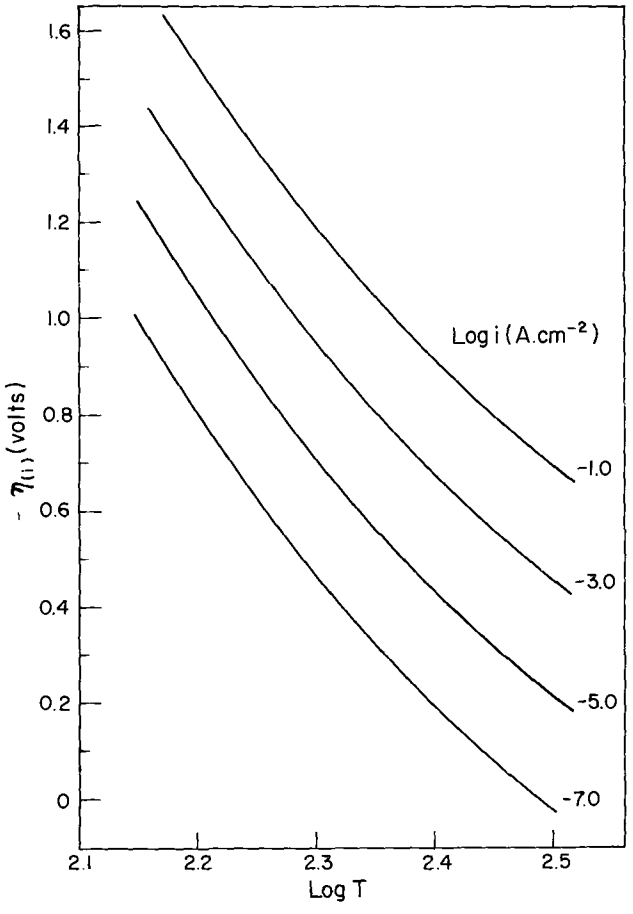

Fig. 11. Plots of $(\eta)_i$ vs. log T for case 3

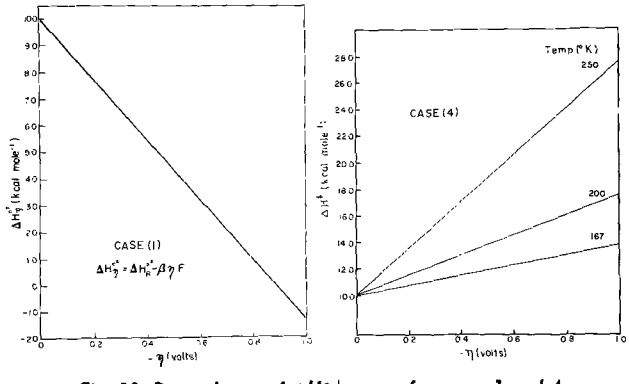

Fig. 12. Dependence of $\Delta H^{o\ddagger}_{\eta}$ on η for cases 1 and 4

found to vary by about 1 kcal-mole^{-1} when derived by methods *c* and *d*. Thus, from Fig. 11 $\Delta H^{o\ddagger}_{\eta=0.8}$ = 9.6-10.6 kcal-mole^{-1} over 7 decades of *i*.

Case 4: *b* increases with decreasing T according to a relation of the form $b = c' - 2.3\ RT/\beta\mathbf{F}$ where $\beta = 0.5$ and constant. It is shown in the present work that this case is encountered experimentally. The plots of $(\log i)_\eta$ *vs.* $1/T$ for case 4 are shown in Fig. 8 and, except for $\eta = 0$, the Arrhenius plots are curved in a manner not unlike that observed experimentally at Pt and for the low c.d. region at Ni. The curvature increases with increasing η. From Fig. 12, it can be shown that $\Delta H^{o\ddagger}_{\eta}$ increases linearly with η for a given value of T, the rate of increase becoming greater at higher temperatures. This is to be contrasted with the results for the conventional case 1, also shown in Fig. 12.

In Fig. 13, *b* is shown comparatively as a function of T for cases 1 to 4, reflecting the various cases encountered experimentally (6) for the variation of *b* with T.

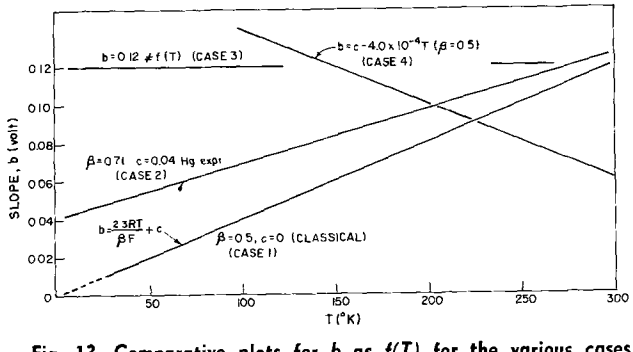

Fig. 13. Comparative plots for *b* as *f(T)* for the various cases considered and encountered experimentally [*cf.* ref. (6)].

Analytical treatment.—The above treatment based on numerical calculation has led to a number of interesting conclusions regarding the variation of $\Delta H^{o\ddagger}_{R}$ with T, so that further analytical exploration of this matter seems justified in order to examine the exact

relations between the true and apparent heats of activation for cases where $b \neq RT/\beta\mathbf{F}$.

We assume the general relation

$$\ln i = \ln i_o + \eta/b \qquad [7]$$

The conventional case, previously assumed generally applicable, is when $b = RT/\beta\mathbf{F}$ and $\beta \neq f(T)$. This gives the well known results (1, 5)

$$\frac{d \ln i_o}{d\ 1/T} = -\frac{1}{R}(\Delta W^{o\ddagger} - \beta\Delta H^o) = -\Delta H^{o\ddagger}_R/R \qquad [8]$$

where ΔH^o is the enthalpy in change reaction [2] and $\Delta W^{o\ddagger}$ is the true (but experimentally inaccessible) heat of activation when the metal-solution potential difference $\phi = 0$.

$$(\partial\eta/\partial T)_i = -\frac{1}{\beta\mathbf{F}T}[\Delta H^{o\ddagger}_\eta] = -\frac{1}{\beta\mathbf{F}T}[\Delta H^{o\ddagger}_R - \beta\eta\mathbf{F}] \qquad [9]$$

and

$$-\Delta H^{o\ddagger}_R = \beta\mathbf{F}\left(\frac{\partial\eta}{\partial \ln T}\right)_i - \beta\eta\mathbf{F} \qquad [10]$$

For a number of the experimentally investigated cases, $b = RT/\beta\mathbf{F} + c$, so that

$$\ln i = \ln i_o + \eta \Big/ \left(\frac{RT}{\beta\mathbf{F}} + c\right) \qquad [11]$$

which gives, upon differentiation

$$\left(\frac{\partial\eta}{\partial T}\right)_i = \frac{R}{\beta\mathbf{F}} \ln\frac{i}{i_o} - \left(\frac{RT}{\beta\mathbf{F}} + c\right)\frac{d \ln i_o}{dT} \qquad [12]$$

so that substituting for $\ln (i/i_o)$

$$(\partial\eta/\partial T)_i = \left(\frac{R}{RT + \beta c\mathbf{F}}\right)\cdot\eta - \left(\frac{RT}{\beta\mathbf{F}} + c\right)\left(\frac{d \ln i_o}{dT}\right) \qquad [13]$$

Expressing $\ln i_o$ in terms of a combined constant k, the true heat of activation $\Delta W^{o\ddagger}$ at $\phi = 0$ and the metal-solution p.d. ϕ_r at the reversible potential, we write

$$\ln i_o = \ln k - \frac{\Delta W^{o\ddagger}}{RT} + \phi_r \Big/ \left(\frac{RT}{\beta\mathbf{F}} + c\right) \qquad [14]$$

Then differentiating w.r.t. T and noting $\phi_r\mathbf{F} = -\Delta G^o$ and $\frac{\mathbf{F}\, d\phi_r}{dT} = \Delta S^o$ for the hydrogen half-cell reaction [2]

$$\frac{d \ln i_o}{dT} = \frac{\Delta W^{o\ddagger}}{RT^2} + \frac{\beta R}{(RT + \beta c\mathbf{F})^2}[\Delta G^o] + \frac{\beta}{(RT + \beta c\mathbf{F})}[\Delta S^o] \qquad [15]$$

which on rearrangement gives

$$\frac{d \ln i_o}{dT} = \frac{\Delta W^{o\ddagger}}{RT^2} + \frac{1}{(RT + \beta c\mathbf{F})^2}[\beta R\Delta H^o + \beta^2 c\mathbf{F}\,\Delta S^o] \qquad [16]$$

or

$$\frac{d \ln i_o}{d\ 1/T} = \frac{-\Delta W^{o\ddagger}}{R} - \frac{\beta T^2}{(RT + \beta c\mathbf{F})}\left[\frac{R\Delta G^o}{RT + \beta c\mathbf{F}} + \Delta S^o\right] \qquad [17]$$

which enables Eq. [8] to be recovered in the conventional case where $\beta c\mathbf{F} = 0$.

Returning to the evaluation of $(\partial\eta/\partial T)_i$, $d \ln i_o/dT$ can now be substituted in Eq. [13] giving, after elementary algebra

$$\left(\frac{\partial\eta}{\partial T}\right)_i = \left(\frac{R}{RT + \beta c\mathbf{F}}\right) - \left(\frac{RT + \beta c\mathbf{F}}{\beta\mathbf{F}}\right)\frac{\Delta W^{o\ddagger}}{RT^2} - \frac{1}{\beta\mathbf{F}(RT + \beta c\mathbf{F})}[\beta R\Delta H^o + \beta^2 c\mathbf{F}\Delta S^o] \qquad [18]$$

It is clear that of the two derivatives $d \ln i_o/dT$ or $d \ln i_o/d\ 1/T$ neither can give directly an apparent heat of activation which is a simple sum of $\Delta W^{o\ddagger}$ and $\beta\Delta H^o$ as is the case (Eq. [1]) when b is simply $RT/\beta\mathbf{F}$ with β constant. Similarly, $(\partial\eta/\partial T)_i$ is a complex quantity not simply related to $\Delta H^{o\ddagger}$ by Eq. [9] through $\beta\eta\mathbf{F}$, nor does it involve a sum of ΔG^o and $T\Delta S^o$ terms that can be expressed in terms of ΔH^o with $\Delta W^{o\ddagger}$. Thus when b is not simply given by the quantity $RT/\beta\mathbf{F}$, as now must be recognized to be the case experimentally under most conditions [ref. (6-9) and the present work], it cannot be expected that $\Delta H^{o\ddagger}_R$ from Eq. [8] based on $d \ln i_o/d\ 1/T$ will be identical with the quantity evaluated from $-\beta\mathbf{F}T\left(\frac{\partial\eta}{\partial T}\right)_i$ by adding $\beta\eta\mathbf{F}$ (Eq. [9]).

Bockris and Matthews (24) have again [cf. ref. (25)] referred to the question of incompatibility of activation energies of *ca.* 11 kcal · mole^{-1}, observed at mercury in alcoholic solutions, with values of $\eta > 1$V (since $\beta\eta\mathbf{F}$ is then already *ca.* 11.5 kcal · mole^{-1}). However, this value of $\Delta H^{o\ddagger}_R$ seems well authenticated (25, 27) and is also found from the results of Bockris and Parsons (26). This difficulty is only an apparent one, and is connected as we have pointed out elsewhere in discussion (25) with the question of temperature dependence of α or β, or the form of b as $f(T)$ discussed above; a general explanation was given previously (25). From the above calculations which are applicable to the case of Hg since b is experimentally (6) of the form $(RT/\beta\mathbf{F}) + c$ (with $c = 0.04$), it becomes clear how conclusions about barrier height cannot usually be made simply on the basis of the experimental derivatives $(\partial\eta/\partial T)_i$ or $d \ln i_o/d\ 1/T$, both of which evidently give complex quantities not simply related to either the apparent activation energy $\Delta H^{o\ddagger}_R$ at $\eta = 0$ or the true activation energy $\Delta W^{o\ddagger}$ at zero metal-solution p.d.

While some of the experimental results quoted (6) here involve a Tafel slope of the form $b = (RT/\beta\mathbf{F}) + c$, the possibility that $b = RT/\beta\mathbf{F}$ but with β varying with T must also be recognized (6). In such a case, the apparent activation energy is

$$\Delta H^{o\ddagger}_R + \beta\mathbf{F}\, d\phi_r/d\ 1/T + \frac{\mathbf{F}\phi_r}{T}(d\beta/d\ 1/T) \qquad [19]$$

which differs from the barrier height at $\eta = 0$ by

$$\frac{\beta\mathbf{F}}{T}(d\phi_r/d\ 1/T) + \frac{\mathbf{F}\phi_r}{T}(d\beta/d\ 1/T) \qquad [20]$$

Coverage effects in $\Delta H^{o\ddagger}_R$.—In addition to the fact that the measured value of $\Delta H^{o\ddagger}_R$ is an apparent value on account of the variation of the reference electrode potential and of b with temperature, a further complication arises with processes involving an adsorbed intermediate. In such cases, the coverage θ, *e.g.*, by H atoms, can vary with temperature and give an important contribution to the apparent heat of activation. The significance of θ in the kinetic expression for the exchange current was discussed by Devanathan and Selvaratnam (28).

For the kinetics of the h.e.r. at the reversible potential

$$i_o = k_1 C_{H^+}(1 - \theta_H)\exp[-\Delta G^{o\ddagger}_1/RT]\exp[-\phi_r/b] \qquad [21]$$

when the reaction is proceeding by a rate-determining discharge step; $\Delta G^{o\ddagger}_1$ and ϕ_r are the true free energy

of activation (corresponding to $\Delta W^{o\ddagger}$) and the metal-solution p.d. at the reversible potential. Alternatively, for an electrochemical H atom desorption step

$$i_o = k_2\,\theta_H C_{H^+} \exp\,[-\Delta G^{o\ddagger}_2/RT] \exp\,[-\phi_r/b] \quad [22]$$

or for an atom recombination step

$$i_o = k_3\,\theta_H{}^2 \exp\,[-\Delta G^{o\ddagger}_3/RT] \quad [23]$$

where k terms are combinations of constants but do not include the free energies of activation. In any of these cases, it is clear that $d \ln i_o/d\ 1/T$ will involve not only the $\Delta W^{o\ddagger}$ terms in $\Delta G^{o\ddagger}$ and $d\phi_r/d\ 1/T$ but also, depending on the type of mechanism involved, $d \ln (1-\theta_H)d\ 1/T$ or $d \ln \theta_H/d\ 1/T$. For a discharge process occurring at low coverage by H, (*i.e.*, $1-\theta_H \to 1$) no significant additional effect will arise. For the electrochemical desorption or recombination steps, however, (except at $\theta_H \to 1$) θ_H can obviously vary with temperature and in general θ_H has the form

$$\frac{K_1 C_{H^+} + \exp\,[-\phi_r \mathbf{F}/RT]}{1 + K_1 C_{H^+} \exp\,[-\phi_r \mathbf{F}/RT]} \quad [24]$$

for quasi-equilibrium in the discharge step at a "Langmuir" surface; here K_1 is the "chemical part" of the electrochemical equilibrium constant for the step $H^+_{aq} + e + M \leftrightharpoons M\,H_{ads}$ at the reversible potential ϕ_r and is related to the standard free energy of adsorption of H, ΔG^o_H in the usual way. The apparent activation energy will now be a function of the variation of θ_H with T and of ϕ_r with T, both in the kinetic term exp $-\phi_r/b$ and in the quasi-equilibrium expression for θ_H. The "chemical part" of the variation of θ_H with T obviously arises from the variation of K_1 with T, *i.e.*, from the heat of adsorption of H. Limitingly, for low θ_H at the reversible potential ϕ_r

$$\theta_H = K_1 C_{H^+} \exp\,[-\phi_r \mathbf{F}/RT]$$
$$= C_{H^+} \exp\,[-\Delta G^o_H/RT].\exp\,[-\phi_r \mathbf{F}/RT] \quad [25]$$

or

$$\ln \theta_H = \ln C_{H^+} - \Delta H^o_H/RT + \Delta S^o_H/R - \phi_r \mathbf{F}/RT \quad [26]$$

Then

$$d \ln \theta_H/d\ 1/T = -\Delta H^o_H/R - \frac{\mathbf{F}}{RT}(d\phi_r/d\ 1/T) - \frac{\mathbf{F}\phi_r}{R} \quad [27]$$

The latter two terms are the ones that also arise in the evaluation of the true activation energy of any electrode process and, as in the conventional case considered above, are together equal to $1/R$ times ΔH^o, the heat change in the half-cell process corresponding to the over-all reaction $H_3O^+ + e \to H_2O + \frac{1}{2} H_2$; the latter heat differs from ΔH^o_H since that term refers to the electrochemical discharge and adsorption partial process $H_3O^+ + M + e \to H_2O + M\,H_{ads}$. Hence

$$d \ln \theta_H/d\ 1/T = -\Delta H^o_H/R + \Delta H^o/R \quad [28]$$

Now, in the absence of any variation of coverage terms with temperature,

$$d \ln i_o/d\ 1/T = -(\Delta W^{o\ddagger}/R - \beta \Delta H^o/R) = -\Delta H^{o\ddagger}_R/R$$

so that when the variation of θ_H with temperature is allowed for in Eq. [21] for example

$$\frac{d \ln i_o}{d\ 1/T} = 1/R\,[-\Delta W^{o\ddagger} + \beta \Delta H^o - \Delta H^o_H + \Delta H^o] \quad [29]$$

$$= -1/R\,[\Delta W^{o\ddagger} + \Delta H^o_H - (1+\beta)\,\Delta H^o] \quad [30]$$

It is evident that $\Delta H^o_H - \Delta H^o$ is simply the energy of adsorption ΔH^o_{ads} of H from half a mole of H_2 so that

$$d \ln i_o/d\ 1/T = -1/R\,[\Delta W^{o\ddagger} + \Delta H^o_{ads} - \beta \Delta H^o]$$
$$= -1/R\,[\Delta H^{o\ddagger}_R + \Delta H^o_{ads}] \quad [31]$$

Since ΔH^o_{ads} is usually a negative quantity, the over-all apparent heat of activation could be negative when $\Delta H^{o\ddagger}_R + \Delta H^o_{ads} < 0$. Such a case has been observed in the present work.

Forms of electrochemical Arrhenius plots for the H.E.R.—Plots of log k *vs.* $1/T$ for the rate constant of a reaction, particularly one involving proton transfer, can deviate from linearity on account of (*a*) changes of solvent structure and hydrogen bonding with temperature; (*b*) proton tunneling; and (*c*) changes of mechanism (Fig. 14). The first two factors generally tend to produce opposite directions of deviation from linearity in the Arrhenius plots. Here we discuss qualitatively the form of the observed plots for Ni, Pt, Pb, and Cd.

The η-log i behavior at Ni shows two Tafel regions (Fig. 1); the upper one gives a Tafel slope b which initially decreases with T, while the lower region gives b values which continuously increase with decreasing T and which have high values $> 2.3 \times 2\ RT/\mathbf{F}$. This suggests that the lower region is affected by specific adsorption of anions but there is a relatively sudden desorption as η is increased. This view is supported by the fact that experiments in methanolic $HClO_4$ showed (6) only one Tafel region with b values almost equal to those for the upper region of the η-log i plots in methanolic HCl.

For the high c.d. region at Ni (Fig. 2), d log $i_o/d\ 1/T$ is progressively smaller at low temperatures than at high, *i.e.*, the relation shows "concave" curvature at the low temperature end. Also the b values for this region after falling initially with decreasing T, begin to increase again at the lowest temperatures ($<-75°C$). Both these aspects of the low temperature behavior are characteristic of participation of proton tunneling in parallel with the classical transfer process. However, the present work also shows that similar effects arise in the deuterium reaction at Ni (Fig. 7) and furthermore the Tafel slopes for the d.e.r. are higher, rather than lower, [cf. ref. (29)] than those of the h.e.r. Hence, the low temperature behavior in the log i_o *vs.* $1/T$ plots cannot be satisfactorily explained in terms of proton tunneling. We must therefore suppose that the effect arises for reasons such as preferred orientation of solvent at the lower temperatures; solvent structure change would, however, it might be supposed, lead to enthalpy effects opposite to those observed here at low temperatures, *i.e.*, $\Delta H^{o\ddagger}_R$ would tend to be larger rather than smaller.

The effects of anion adsorption are obviously of importance here, as they are in determining the Tafel slopes. Generally, at low temperatures, anion adsorption is found to be greater. For the upper lines at Ni, however, the role of anion adsorption effects must be

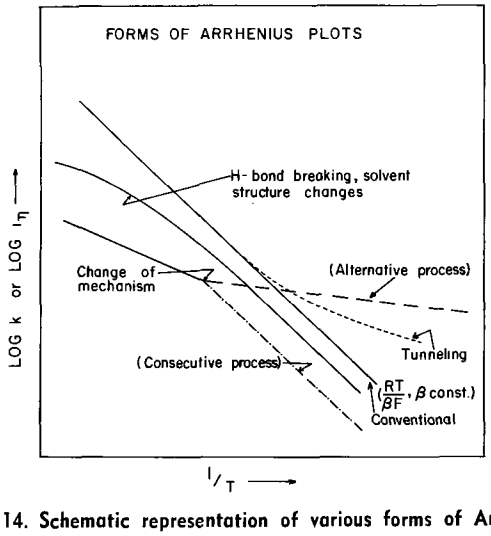

Fig. 14. Schematic representation of various forms of Arrhenius plots.

presumed absent if the change of Tafel slope is attributed to desorption of anions at high η values (*cf.* the results for the $HClO_4$ solutions; it is to be noted also that as the temperature is lowered, the potential corresponding to the change of slope is increased; this is as expected if anion desorption is involved). Under these circumstances, since tunneling has been discounted by the earlier argument, it may be suggested that the anomalous Arrhenius plots of Fig. 4 arise because of a temperature-dependent activation entropy $\Delta S^{o\neq}$ or frequency factor term of the type discussed by Caldin and Harbron (30). For the discharge step, $\Delta S^{o\neq}$ will be expected to be positive for charge neutralization and release of solvent electrostriction [*cf.* the positive (corrected) volume of activation (31)], so that with increasing solvent-structure as temperature is lowered, $\Delta S^{o\neq}$ may be expected to become relatively more positive and the rate relatively less decreased as the temperature is lowered. This would give the correct form of the curvature for the plots of Fig. 4.

A similar effect could also arise if, at lower temperatures, the methanol solvent becomes more strongly adsorbed resulting in weakening of H adsorption. In the step $H_3O^+ + MH_{ads} + e \rightarrow H_2$ this should lead to decreasing $\Delta H^{o\neq}_R$.

It may be anticipated that the behavior at Pt and Ni will be complicated by the temperature dependence of H coverage θ_H discussed above since it is well-known that the energy of adsorption of H (in Eq. [31]) can vary with θ_H and also be dependent on anion adsorption; the combination of these effects could be complex and lead to the observed temperature dependence of $d \log i_o/d\ 1/T$ for Pt and the lower Tafel regions at Ni where Cl^- adsorption effects are apparently important.

The $\log i_o$ *vs.* $1/T$ plots for Pt and for the low c.d. region of Ni (Fig. 3a and 2) exhibit curvature at the high temperature end, an effect which becomes more pronounced at high values of η. This appears to be due to the progressive desorption (15, 16) of Cl^- ions which occurs at the higher temperatures and larger η values. Such an effect is consistent with the high values of Tafel slope b and the anomalous temperature dependence of the b values (b increases with decreasing T, Fig. 1). At Pt, for increasing temperatures in the cycle of measurements, irreversible adsorption of Cl^- ion seems to be indicated (compare the two diagrams of Fig. 3).

The Arrhenius plots for Pb and Cd may also be interpreted in terms of specific adsorption of Cl^- and the apparent negative activation energy observed for Pb could receive an explanation in terms of temperature dependent H coverage in the presence of adsorbed anions. Although the activation energy for the h.e.r. at Cd falls appreciably at the lower temperatures, again similar effects set in with the d.e.r. at only slightly lower temperatures so that proton tunneling is not clearly indicated at this metal.

Split-Ring Disk Study of the Anodic Processes at a Copper Electrode in Alkaline Solution

B. Miller*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The anodic oxidation of copper in hydroxide solutions has been reexamined with the rotating ring and split-ring disk techniques. A soluble Cu(III) species has been identified in the anodic region at the onset of oxygen evolution. This species has also been generated at gold rings from disk-produced Cu(II). Passivation processes in the copper(I) and (II) oxidation regions have been analyzed by means of the corresponding ring currents.

The anodic corrosion of copper electrodes in hydroxide solutions has been variously investigated (1-12), particularly by means of galvanostatic charging curves, following Hickling and Taylor (3). Generally, two clear steps were found in the traces before oxygen was evolved, and, from the results of subsequent examinations and/or by reasonable correspondence of the measured potentials to calculated thermodynamic values, these were assigned to the electrode reactions Cu/Cu_2O and $Cu/Cu(OH)_2$ (and/or Cu/CuO). In an early work, Müller (1) concluded that a further oxidation step of copper occurred in strong base (around 0.7V *vs.* NHE in 5*N* NaOH at 12°C) to produce a higher oxide, Cu_2O_3, whose qualitative chemistry he examined.

The potential of the CuO/Cu_2O_3 couple was further measured at a platinum electrode in various hydroxide normalities by Delhez (13) at 0°C, yielding a value of 0.81V *vs.* NHE at *p*H 14. The low temperature chosen for this study is indicative of the aqueous instability of the higher oxidation state; using a solubility product prediction (14), Delhez calculated a potential for Cu^{+3}/Cu^{+2} of about 2.3V. In highly concentrated base, 13-16.8*N* NaOH, solutions of Cu(II) have yielded at Pt anodes deposits of the sodium salt of the Cu(III) anion at moderate current efficiencies (15, 16). A chemistry of Cu(III) complexes from oxidations in basic solution has been known for some time (17).

Citations of the involvement of higher oxidation states in the direct electrochemical studies (1-12) have, however, been few. For example, Ohse (7) suggested the formation of higher oxides on the basis of the potential transients he observed in cathodically current-pulsing previously anodized copper. Shams El Din and Abd El Wahab (8) found that a new step appeared on cycling copper electrodes galvanostatically (alternate full anodic and cathodic charging) and attributed this to a soluble Cu(II) product. They concluded that this material was oxidized to a film, suggested as Cu_2O_3, on which oxygen evolution then proceeded. A potential step in the subsequent cathodic current stage and the slow open-circuit decay of the copper potential from oxygen evolution levels provided the evidence for the higher oxide actually being formed since it does not appear separately from oxygen evolution in the anodic half cycle. The latter fact is apparent from the charging current studies of most workers in the 0.1-1.0M OH^- range; the anodization of a clean copper surface does not lead to a readily distinguishable step between the Cu(II) and O_2 evolution processes. On a sintered powder electrode a further step was cited (11), but attributed to "peroxide" processes. The chemical and magnetic behavior of the compounds produced by oxidation (17) is, however, in keeping with a Cu(III) formulation.

Direct observation by electrochemical current-potential measurements has not clearly settled the issue of whether the Cu(III) species is formed before or along with oxygen evolution in the more dilute alkali solutions. Both chemical and anodic oxidation of Cu(II) in concentrated base suggest that it is produced, but the detection of such processes by purely electrochemical techniques at copper anodes has been inferential because of the oxygen interference. A different approach, as exemplified by the rotating ring-disk and split-ring disk methodology applied to anodic corrosion processes at a disk (18, 19) appeared desirable. The disk, taken alone, yields results comparable to those referred to above on single electrodes. However, the use of the annular ring, detecting products transported from the disk (20-22), offers the possibility of simultaneously characterizing solubilized species, even those of relatively short lifetime ($\sim 10^{-2}$ sec). Ring currents or split-ring current ratios may be used to determine electrons transferred (18, 19).

In the present work, the transitions of a copper surface on anodization in alkali have been reexamined for the purpose of identifying the oxidation states produced and characterizing the passivation processes in each stage. Even where the transitions involve the formation of films, the ring amperometric sensitivity is sufficient to detect the soluble portion and to characterize its oxidation state by a proper combination of split-ring reactions. For example, in the case of a supposed Cu(III) species, the observation of two different reduction steps to known lower states, taking care to avoid or compensate for the ring reduction of concurrently generated oxygen, confirms the oxidation state. The oxidation behavior of anodically generated Cu(II) at noble metal rings, compared to the behavior of saturated solutions of Cu(II), supplements results from Cu(III) generation at the disk. Ring-disk conclusions on oxidation states are based on amperometric results on the electrode and the contacting solution and do not require comparison to thermodynamically calculated potentials or subsequent examination of the passive films by chemical or physical methods. In addition, the well-understood collection efficiency properties of the system (23) make feasible the quantitative determination of the electrode-solution mass distribution.

Experimental

The electrode employed was a copper disk-gold split-ring design fabricated with 99.99% copper according to procedures described elsewhere (18, 19, 24). A similar electrode with a gold disk was used to examine possible solution impurity reactions and the interference due to oxygen at ring or disk. The electrodes were polished, using 0.3μ Linde A as the final stage. Both electrodes had nominally the same dimensions, with disk, internal ring, and external ring diameters of 0.476, 0.524, and 0.642 cm, respectively. For such geometry with a conventional continuous ring, the theoretical collection efficiency, N, is 0.34 (23). The individual half-rings therefore have values (N_1 and N_2) of about 0.165, taking into account an approximate 1-2% loss

* Electrochemical Society Active Member.

of active area in the insulating ring divisions. The mechanical drive assembly (24), operating circuitry (18), and cell configuration (19) are described elsewhere. Solutions were prepared from reagent grade sodium hydroxide and showed a satisfactory absence of impurity reactions over the potential range and current sensitivities employed.

Results

The behavior of a stationary copper electrode in a controlled-potential sweep at 20 mV/sec in 1*N* NaOH is shown in Fig. 1. The first anodic peak is very much smaller than the second (by a factor of about 25). Depending on the sweep rate and cycling history, a third inflection is observed on the rise into oxygen evolution at about +0.5V *vs.* SCE and, on reversal of the sweep, a small net cathodic peak can be observed at the high potential end. The inflection, but not the net cathodic peak, is normally detectable when the electrode is rotated at speeds typical of the measurements to be cited later (600-3000 rpm).

At the current density necessary to polarize the electrode beyond 0V *vs.* SCE in a galvanostatic experiment, any process occurring in the region of oxygen evolution to the extent shown by the inflection in Fig. 1 would be obscured. On the other hand, low current reduction or open-circuit decay experiments, such as those cited earlier, would more readily detect a transition corresponding to the high potential cathodic process shown in Fig. 1.

With the copper disk rotated at 1000 rpm, the addition of potentiostated gold half-rings to the experiment produces the results shown in Fig. 2 for three ring potentials. The typical rotating disk current-potential trace corresponding to Fig. 1 is shown at the top with the three transitions of interest labeled I, II, and III. The lower traces represent a collection of half-ring currents *vs.* disk potential for runs in which a pair of such traces with different half-ring potentials was obtained in each experiment. For a half-ring held just positive of the first two disk transitions (0.00V), anodic ring current (a) is seen for I and only residual current for II. At the point of oxygen evolution, labeled III, a cathodic peak (b) is seen which is absent in blank experiments with an all-gold system and which is therefore not due to oxygen reduction. This peak is still observed at positive ring potentials of several tenths of a volt. When the half-ring is held at a high positive potential (0.55V) corresponding to the beginning of oxygen evolution, anodic ring currents (c) and (d) are seen for both disk peaks. At the other extreme, when the half-ring is held sufficiently negative (−0.90V) to reduce all copper species back to metal and oxygen to hydroxyl ions, cathodic ring currents (e) and (f) are seen for the two disk peaks. The first, (e), is not apparent at the reduced gain necessary to have (f) on scale in Fig. 2 since it is of the same magnitude as (a) which is shown on a 100× more sensitive axis. The reduction of oxygen at the −0.90V half-ring obscures any other concurrent process at the right end of the trace.

The qualitative conclusions about the ring processes consistent with the above experiments are:

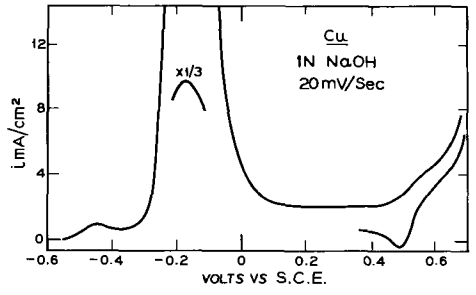

Fig. 1. Potentiodynamic sweep of a stationary copper electrode from −0.55V to oxygen evolution, then reversal to +0.35V.

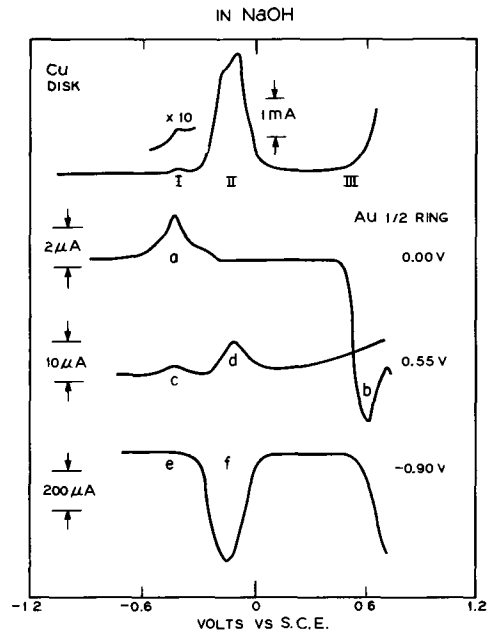

Fig. 2. Traces from top: 1, potentiodynamic sweep of copper disk in 1N NaOH, disk potential axis common to all traces; gold half-rings held at indicated potentials during disk sweeps; 2, 0.00V; 3, +0.55V; 4, −0.90V.

a,	Cu(I)	→ Cu(II)
b,	Cu(III)	→ Cu(II)
c,	Cu(I)	→ Cu(III)
d,	Cu(II)	→ Cu(III)
e,	Cu(I)	→ Cu(O)
f,	Cu(II)	→ Cu(O)

The remainder of the results to be presented is divided into two parts. The first deals with the confirmation of the above identification of species and with the measurement of the electrode-solution mass distribution in disk transitions I and II by means of the ring processes (a, e, and f). The second summarizes further evidence for the presence of a Cu(III) species and treats the current-potential characteristics of the Cu(II)-Cu(III) couple in 1*N* NaOH.

Anodic transitions I and II.—Experimentally, in a disk-ring amperometric study of a film-controlled electrode-solution mass distribution, the passive-active transitions are more readily analyzed if a constant disk anodization current is used to control the coulombs passed than if the potential is swept. This corresponds here to passivating transition I and returning to active dissolution in the rising portion of transition II where a much larger charge is required to polarize the electrode beyond the 0.0V *vs.* SCE region. Such an experiment, starting with a disk cathodically stripped immediately before anodization, is shown in Fig. 3 in which the bottom trace is the disk potential, E_d, *vs.* time at 280 μA/cm^2 (i_d = 50 μA) and the two potential plateaus (−0.49 and −0.35V) correspond to transitions I and II, respectively. The upper trace is the current, i_{r-}, through shorted half-rings operated at −0.8V, where all soluble copper species are reduced to metal, corresponding to reactions e and f. The calculated collection efficiency for the shorted half-rings is 0.33. Thus, for 50 μA i_d, the calculated current for a ring reaction which is the reverse of that at the disk is 16.5 μA, and this is the value obtained at the −0.35V plateau of II. Beyond the time scale of the trace, both i_{r-} and E_d are unchanging; currents approaching 2000 μA are required to initiate filming (see disk current peak height in Fig. 2).

If the experiment is run with shorted half-rings set at +0.3V (equivalent to *a*), the traces of Fig. 4 are obtained. Ring current is obtained only for I and is of less than 5 μA peak, the same order of magnitude as

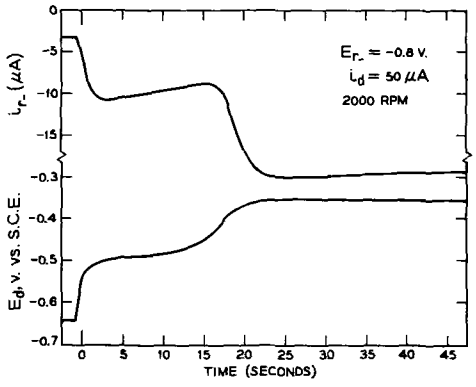

Fig. 3. Constant current anodization of Cu disk in 1N NaOH with shorted half-rings held at —0.8V. Lower trace, disk potential; upper trace, cathodic ring current.

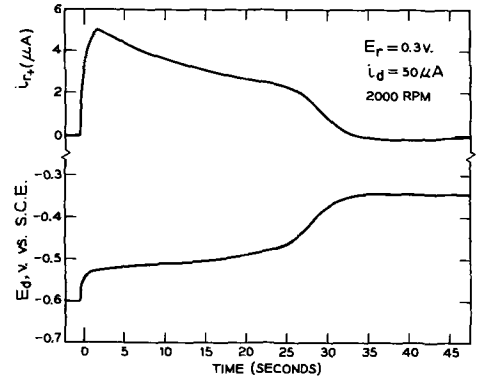

Fig. 4. As in Fig. 3, with shorted half-rings held at +0.3V. Lower trace, disk potential; upper trace, anodic ring current.

the cathodic ring maximum on the initial anodization in Fig. 3. The disk transition times for repeated constant currents are variable and depend on cycling history and initial polishing. However, the measurements which yield collection efficiencies by reflecting geometric areas, such as the cathodic ring current for II in Fig. 3, are constant and independent of the variations in the coulombs necessary to passivate I. The anodic and cathodic ring currents corresponding to I are also slightly variable, introducing some uncertainty in determining the anodic to cathodic ring current ratios so as to identify the species in the product flux. To avoid this difficulty, the split-ring experiment was run as shown in Fig. 5. The major feature is that the half-ring traces are mirror images of each other until the disk reaction II begins to contribute, at which point the cathodic half-ring current rises to that calculated from collection efficiency while the anodic half-ring current drops to the residual level. The product of I must be Cu(I) which is one-electron oxidizable and

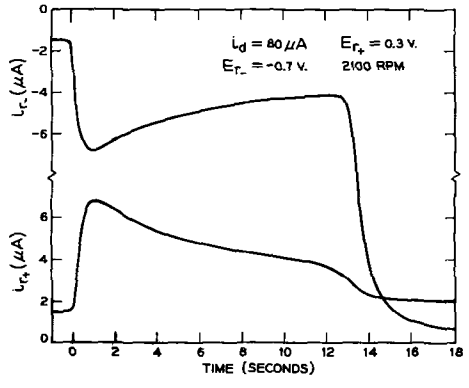

Fig. 5. Split ring anodic (i_{r+}) and cathodic (i_{r-}) limiting currents for 448 μA/cm² copper anodization in 1N NaOH.

reducible to Cu(II) and Cu(O), respectively. The Cu(I) flux never reaches the theoretical value predicted by the collection efficiency, indicating film formation, presumably Cu_2O. As soon as the double layer charging portion of the i-t plot is complete and copper current flows, the current declines from the peak, which is offset from zero time mainly by the cumulative effects of double layer capacity and the transit time from disk to ring.

Using only the data of any of the split-ring experiments as in Fig. 5, it is possible to compute additional features of the anodization process I. The product oxidation state identity has already been established above by the mirror symmetry. The cathodic ring current for II gives the electrode (geometric) collection efficiency. The time for the transition I, t_I, is given by the inflections of both traces at the 13 second region. The total coulombs at the disk for I is $i_d t_I$. For complete solubility and ring reaction involving the same number of electrons as the disk reaction producing the ring reactant, the theoretical current-time integrals at the half-rings would be $n_- i_d t_I$ and $n_+ i_d t_I$, where n_- and n_+ are the geometric collection efficiencies of the half-rings being used as cathode and anode. Thus, the fractions of disk coulombs resulting in dissolved Cu(I) and Cu_2O film are, respectively

$$\frac{\int i_{r+}\,dt}{n_+ i_d t_I} \quad \text{and} \quad 1 - \frac{\int i_{rt}\,dt}{n_+ i_d t_I}$$

all the quantities involved being controlled or measured in the single disk anodization as followed in Fig. 5. For this experiment, n_- and n_+ are 0.165, and the soluble fraction was 0.21 and the film 0.79. Conversion into a film thickness of Cu_2O using a bulk density of 6.0 g/cm³ and an electrode area of 0.178 cm² yields 57Å at the point of the disk potential polarization to reaction II.

Figures 3-5 indicate that, during constant current anodizations which would, according to the Levich equation, give Cu(I) surface concentrations of approximately 2.4-3.7 x 10^{-4}M, the measured ring peaks are actually equivalent to values of ~ 1 x 10^{-4}M. To examine whether lower disk current densities would produce Cu(I) species detectable at ring currents corresponding to the collection efficiency, *i.e.*, with no precipitation at the disk, linear anodic current scans were run as shown in the i_{r_-} and i_{r_+} *vs.* i_d traces of Fig. 6. The initial parts of the i_{r_+} and i_{r_-} traces deviate from linearity at the lowest measurable $\Delta i_r/\Delta i_d$, and no free dissolution is detectable. The region of Cu_2O formation ends at about 80 μA i_d. Free dissolution is readily seen, for example, in Ag_2O formation (25) in the same hydroxide concentration, but the solubility level of that oxide is considerably higher. The peak heights for the ring currents of Fig. 3-4 do indicate considerable supersaturations, reflecting the step current nature of the oxide formation; the maximum i_{r_+} reached in

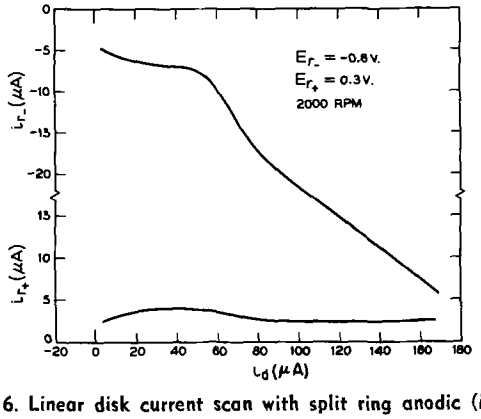

Fig. 6. Linear disk current scan with split ring anodic (i_{r+}) and cathodic (i_{r-}) limiting currents for Cu(I) → Cu(II) and Cu(I) → Cu(O) in 1N NaOH.

scans carried out as in Fig. 6 is only a fraction of the peak from the step experiment.

The transition in E_d (not shown in Fig. 6) to reaction II in the linear current scan occurs in the 70 μA i_d region. It is to be noted that when the free dissolution of the electrode occurs after this shift in reaction, the cathodic ring current *vs.* disk current trace becomes linear with a slope given by the geometric collection efficiency and with an extrapolation back to zero disk current which passes through the residual current origin of the ring trace. The oxidation state of reaction II cannot be identified by the cathodic ring behavior alone, since this reaction is always the reverse of the disk reaction and the numbers of electrons transferred cancel in the relation $i_r = \frac{n_r}{n_d} \mathrm{N} i_d$, where n_r and n_d are the numbers of electrons involved at ring and disk, respectively. Since the one electron oxidation of Cu(I) occurs in the same potential region as process II, Cu(II) can be considered to be confirmed within these experiments. Ratio experiments involving 1 and 2 electron reductions and possibly a 1 electron oxidation were not carried out for II since they were obtained for I and III, the regions of experimentally interesting uncertainty. Although structure is seen for transition II in both the ring and disk traces during disk potential scans, the possible involvement of both $Cu(OH)_2$ and CuO cannot be determined from the solution (ring) side.

Anodic transition III.—The third transition is most easily distinguished from the oxygen evolution reaction by monitoring its product at the ring, since the effect it has on the disk current during potential scan is limited to an inflection, as in Fig. 1. Moreover, the flux seen in ring reduction back to Cu(II) decays rapidly at either constant disk potential or constant disk current and thus it is not possible to obtain a ring current-potential curve of the product by sweeping ring potential for a steady state disk condition. The process appears experimentally similar to the Cu_2O step I, where film formation and passivation at the lowest accessible currents prevent the attainment of any steady-state condition except a filmed surface from which Cu(I) solubility is practically undetectable. Accordingly, the identification of the disk-produced species in III was approached by examining the peak ring or split-ring currents at various fixed ring potentials during successive disk polarizations.

After cycling the disk electrode several times, the peak ring currents at a given ring potential were found to be reproducible. The half-ring currents at different half-ring potentials during a typical charging of the disk into oxygen evolution are shown in the left oscilloscope picture of Fig. 7. The disk electrode was initially carried into oxygen evolution at a constant current ($> \sim 2$ mA) sufficient to passivate transition II. It was then allowed to decay on open circuit to a potential just above that at which it would depassivate and then charged back into oxygen evolution (E_d axis of Fig. 7) at a very much smaller current (100 μA). For E_r + 0.2V the half-ring current trace shows a cathodic peak, whereas the −0.6V cathodic half-ring current is still rising at that point. At the more positive potential oxygen reduction does not interfere, but at −0.6V it certainly does, as noted in blank studies with the all gold electrode and confirmed by the fact that the −0.6V half-ring current continues to increase while the +0.2V half-ring current drops as the copper species is passivated. Thus, at the E_d corresponding to the peak of the +0.2V trace, the ratio $i_{r-0.6}/i_{r+0.2}$ is 3.3, and for the same kind of experiment, $i_{r-0.8}/i_{r+0.2}$ is 3.8. For the traces shown, the quantity $\Delta i_{r-0.6}/\Delta i_{r+0.2}$ is 2.8 for the straight lines found between E_d of 0.56-0.58V. As will be shown, +0.2V is just negative enough to give a limiting current for product reduction to Cu(II). Therefore, at potentials of −0.6 to −0.8V where reduction to Cu(O) should be at a limiting current, the

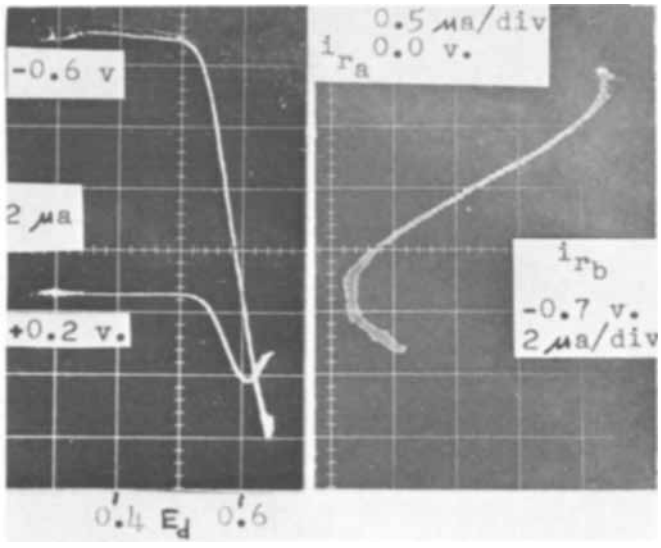

Fig. 7. Left side, split ring currents at −0.6 and +0.2V for 100 μA polarization of the disk to the positive potentials indicated; 1000 rpm in 1*N* NaOH; right side, same conditions as left side except split ring currents at 0.0 and −0.7V are plotted against each other.

contribution from oxygen makes the nominal three electron (Cu(III) → Cu(O)) to one electron (Cu(III) → Cu(II)) ratio greater than 3, especially for measurements made at the more positive disk potentials.

The same type of experiment is conducted in the right-hand portion of Fig. 7, with one half-ring current plotted *vs.* the other to improve the readability of data requiring simultaneous measure of the currents. For repeated experiments with one ring at 0.0-0.2V and the more cathodic ring at −0.7V, the slope of the linear region is 3.0 ± 0.5, the reproducibility being limited by the variable oxygen interference during the reduction of Cu(III) and the transient nature of the process. The same considerations also hold for experiments carried out by sweeping the disk potential and measuring ring current peak heights as at b, Fig. 2, for various ring potentials, where the ring currents can be made larger than in the above galvanostatic modes.

These factors make the assignment of the oxidation state as Cu(III) less certain than that for Cu(I), because in the latter case the ring reactions are free from competitive processes. A current-potential curve for the III → II reaction, if the III → II assignment is accepted, is, however, more readily derived from the galvanostatic or potentiodynamic sweep experiments described than the qualitative identification, since the relevant ring potentials are all positive of oxygen reduction.

Peak d in the survey of Fig. 2 is attributed to the oxidation reaction Cu(II) → Cu(III). Accordingly, ring current-potential curves were also obtained in the anodic direction, taking into account the oxygen evolution at the ring. The individual experimental results yielding the points used to extract the current-potential curves are next summarized and the derived behavior for the Cu(II) ⇆ Cu(III) couple then presented.

Ring oxidations.—In a saturated solution of $Cu(OH)_2$ or CuO in 1*N* NaOH, it is difficult to distinguish the oxidation wave before oxygen evolution from a blank experiment. However, the i_d peak in transition II represents a high level of supersaturation, and current levels near this value and comparably high surface concentrations of Cu(II) can be maintained at a steady state at a rotating disk. Thus, with a galvanostated disk, controlled potential sweeps of the ring may be made on concentrations of Cu(II) which are higher than those of a saturated solution by the ratio of the steady-state anodic disk current obtainable at a given rotation speed to that of a disk with a Cu(II) film (0.1

$< E_d <$ 0.4). Controlled potential ring scans from +0.4 to 0.7V, first with an open-circuited disk and then with a constant disk current about 75% of the peak transition II, are given in Fig. 8. The current-potential curve for Cu(II) → Cu(III) may be obtained by subtraction. Such a subtraction technique using a bulk saturated solution would involve differences near the experimental reproducibility, considering also that the "blank" (equivalent to i_d = 0, Fig. 8) would have to be obtained on a different solution, copper-free.

Oxidation data may be obtained, as mentioned above, by experiments yielding peak d, Fig. 2. For a 2.5M NaOH solution, in which the peak currents for transition II are approximately three times those in 1M hydroxide, some of the actual experimental traces and the point-by-point derived i-E curve are shown in Fig. 9. Two pairs of oscilloscope traces are shown, the lower of each being the disk current, whose broad peak's reproducibility is indicated by comparison of the two runs on the cycled disk. The lower ring trace gives a 0.50V E_r point on the plot; the upper ring trace, for which the residual level of oxygen evolution begins to become substantial, is at 0.70V, close to or at the limiting current region. The current-scale sensitivity ratios are 30:1 for the shorted half-rings and disk in the oscilloscope traces of Fig. 9, and it is obvious from both Fig. 8 and Fig. 9 that the collection efficiency, even accounting for a one-electron ring reaction and a two-electron disk reaction, is well below the geometric value. For example, the limiting i_r in Fig. 9 is about 0.50 mA and the disk current 9 mA, giving a collection efficiency of 2(0.5/9) = 0.11 *vs.* the 0.33 known for the electrode. The origin of the loss cannot be specified precisely. There are many possible sources of complication: for example, surface instability of Cu(III) and alteration of the anodic properties of the ring. The latter can also be affected by the possible deposition of oxide on the ring surface from the supersaturated flux of Cu(II) from the disk. There appears to be no simple relation of the ring-disk process to rotation speed, and this indicates multiple complications. However, the potential dependence of the ring current is reproducible, and, as will be seen, the independently determined oxidation and reduction currents at the ring have a sensible relation.

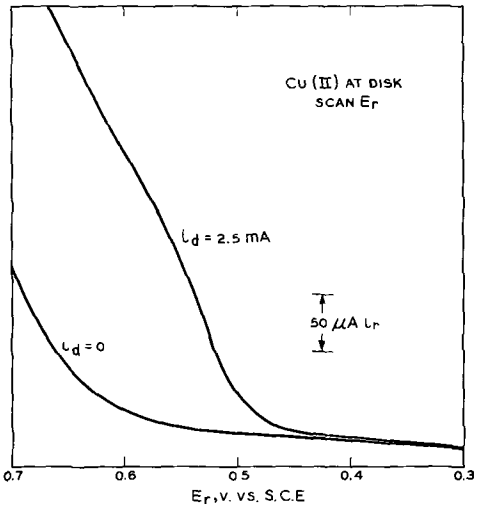

Fig. 8. Ring current-potential curves obtained by 20 mV/sec ring scan at constant disk currents in transition II region. Blank (zero disk current) scans for the 1N NaOH 1500 rpm conditions also shown.

Ring reductions.—The reduction curves were obtained by sweeping the disk potential at a fixed ring potential and by anodizing the disk at constant current with fixed ring potential as already described, the ring potentials being systematically changed for each scan. The family of curves derived from the latter approach (see also the left-hand traces of Fig. 7) is shown in Fig. 10. The ring potential was changed by 50 mV in successive runs at constant disk currents of 50 μA. The 50 μA current was chosen to give a disk-potential rate of change not appreciably greater in the region of interest than the scan rates suitable for disk potentiodynamic experiments. The passivation of Cu(III) generation at high disk potentials is clearly shown. The height of the reduction peak above the residual level was used to construct the current-potential curve.

Current-potential curves for Cu(III)-Cu(II) *in 1N* NaOH.—Figure 11 gives the curves derived from the disk potentiodynamic scans with fixed ring potentials in 1N NaOH solution. The upper curve is the collection of ring current reduction peaks as in b, Fig. 2, and the lower curve, the ring current oxidation peaks, as in d, Fig. 2. Treating the Fig. 11 curves as ring polarograms for the reduction and oxidation of constant fluxes of Cu(III) and Cu(II), respectively, $E_{1/2}$ values of +0.45 and +0.54V *vs.* SCE at 24°C are obtained.

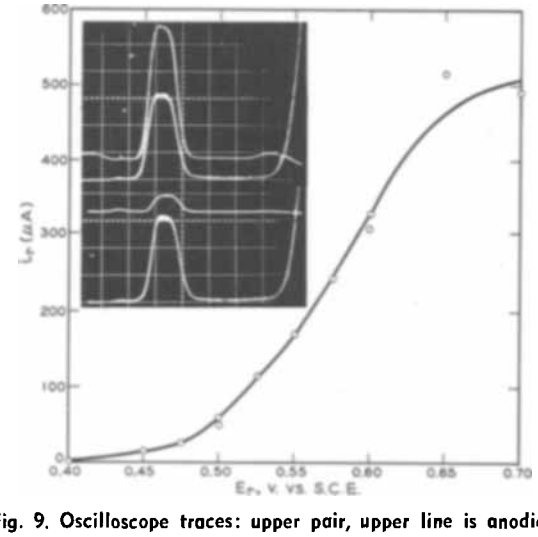

Fig. 9. Oscilloscope traces: upper pair, upper line is anodic ring current at +0.70V vs. disk potential during sweep through transition II to oxygen evolution, as shown in lower disk current line, rotation speed 1000 rpm; lower pair, identical experiment, upper line ring current at +0.50V. Plot, ring current peaks from oscilloscope traces as shown in insert plotted vs. ring potential.

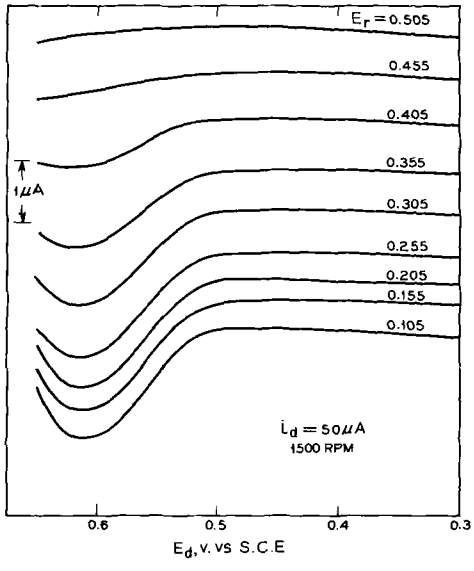

Fig. 10. Series of 280 μA/cm² constant current anodizations of the disk after zero current decays from oxygen evolution; ring currents plotted vs. disk potential for 9 constant ring potentials in 1N NaOH.

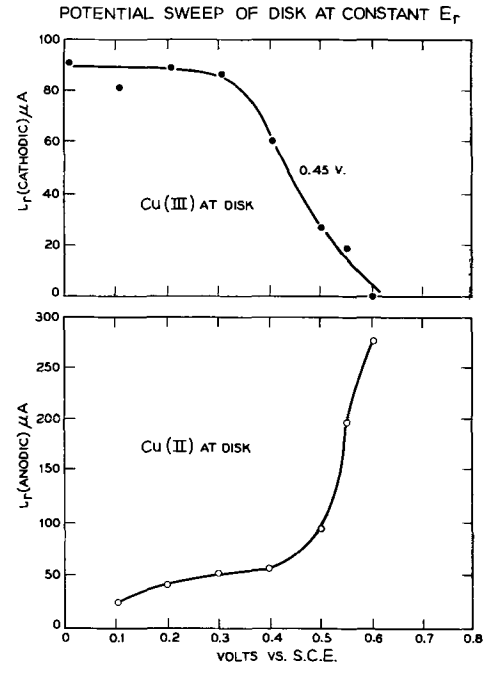

Fig. 11. Upper plot, peak cathodic currents at ring during transition III of disk potential sweep plotted against fixed ring potentials; 20 mV/sec sweep at disk, 600 rpm in 1*N* NaOH; lower plot, peak anodic currents at ring during transition II.

For the galvanostatically controlled disk, Fig. 8 and 10, the curves derived are shown in Fig. 12. $E_{1/2}$ values for reduction and oxidation are +0.40 and +0.56V *vs.* SCE, respectively. These and the values from Fig. 11 are in reasonable congruence with the value obtained potentiometrically by Delhez (13), approximately 0.48V on the present SCE scale at the lower temperature (0°C) required for stability of the Cu(III) oxide phase. In the best-defined current-potential curves, the value of $E_{3/4}$-$E_{1/4}$ is about 70-85 mV compared to the reversible 56 mV. Further speculation about kinetic parameters is not warranted by the nature of the data, accessible, as they are, only by transient or difference techniques.

Summary and Discussion

The oxidation states and corresponding electrode/solution mass distributions have been measured for the anodization of copper in 1*N* NaOH utilizing the split-ring disk technique. By means of the split-ring limiting current ratio approach, it has been possible to identify species in nonsteady reactions at the disk, a passivating surface. Successive one-electron stages have been identified, with the first and third involving film formation from their onset, while the second, or Cu(II) stage, is a solution precipitation process with a considerable range of active dissolution.

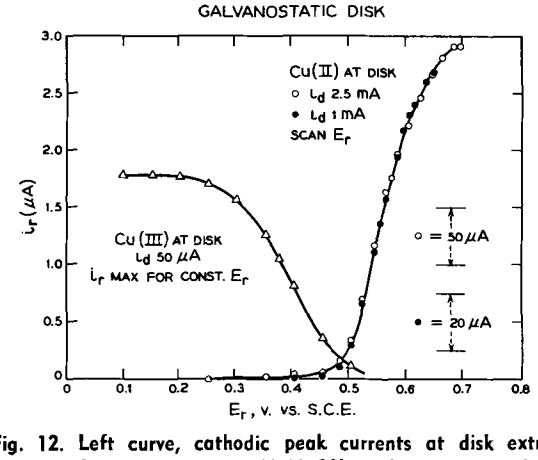

Fig. 12. Left curve, cathodic peak currents at disk extracted from Fig. 10 experiments in 1*N* NaOH; right curve; anodic ring currents from Fig. 8-type experiments representing ring current-potential curve for stated disk current corrected for blank (i_d=0) curve.

The data from a single split ring-disk anodization involving initial disk Cu_2O formation and subsequent reactivation of the electrode on polarization to Cu^{+2}-OH^- complex generation yield a variety of information. The oxidation states are identified, the passivating film thickness and the material solubilized are determined, and the time-dependence of this mass distribution between electrode and solution is measured. Cu_2O films form to a thickness of about 60Å under the anodization conditions studied, with no prefilm free dissolution detectable at the sensitivities accessible.

The high levels of supersaturation found for Cu(II) in the second stage of anodization make it possible to examine, at the ring, steady-state concentrations that could only be reached at much higher hydroxide levels under normal equilibrium conditions. This makes it possible to see the oxidation of Cu(II) distinguished from the residual level of oxygen evolution at a gold ring. Four combinations of current or potential-sweep control at the disk with static or swept potentials at the ring have yielded representative anodic and cathodic current-potential curves for the Cu(II)-Cu(III) couple. These ring-disk techniques for the identification of species and the quantitative measure of interfacial material balance appear widely applicable in the study of corrosion processes where generated species may have relatively short lifetimes in the bulk solution or passivation processes are concurrent.

Multilayer Oxide Films on Anodized Platinum

S. D. James*

Electrochemistry Division, Chemistry Research Department,
U. S. Naval Ordnance Laboratory, White Oak, Maryland

ABSTRACT

A voltammetric study is described of conditions governing the production and stability of anodically formed bulk oxide on Pt in dilute H_2SO_4. The range of anodizing conditions covered in 1 or 2*N* H_2SO_4 was: current-density, up to 10 A/cm^2; temperature, 11°-93°C; duration, up to 18 hr. The oxidizability of the Pt anode (with respect to formation of bulk oxide) was subject to considerable hysteresis. Provided a potential of about 2.15V, RHE was exceeded, electrode oxidizability seemed to be controlled largely by the amount of strain energy present in the Pt surface. The electrolytic formation and reduction of thick bulk oxide layers effected large increases in electrode roughness factor (up to 100X or more).

Superficial, monolayer-type oxide films on platinum electrodes which have been anodized in aqueous solution are very well known although far from completely characterized. The literature on this type of film which is rapidly reduced at about 0.7V, RHE has recently received thorough reviews (1).

In addition, a number of facts indicate that, as the potential or current-density of the anodization is raised, qualitative changes occur in the nature of this film. For instance several workers (2-5) have found sharp changes of slope at about 1.8V, NHE in H_2SO_4 or $HClO_4$ for plots of Q (mC/cm^2) *vs.* E (Q is the charge required for cathodic reduction of a surface oxide formed at potential E). Schuldiner and Warner (6) have also argued for the penetration of oxygen atoms at room temperature into several monolayers of a Pt anode. By examining the chemical reducibility of platinum oxides by propane, Mayell (7) obtained evidence for a potential-dependence in the nature of the oxide. Tafel plots at a Pt anode in H_2SO_4, $HClO_4$ (8-11), and NaCl (12) show two linear portions separated by a transition region where potential increases anomalously rapidly with current. This transition is associated with the incipient participation of anions in the electrode reaction (in H_2SO_4 and $HClO_4$) caused perhaps by a qualitative change in the nature of the superficial oxide film (13). The work of Kasatkin and Rakov (11) at a Pt anode in 10*N* H_2SO_4 at −60°C is particularly interesting. At this low temperature they were able to examine the polarization curve over the large range of 2-12V, NHE (10^{-6} — 1 A/cm^2). In this voltage range they found five points in the Tafel plot where radical changes in slope occurred reflecting intense passivations. To explain these results they assume the electrode substrate to be essentially unchanged as Pt/PtO while, with increasing potential, this surface is supposed to become invaded by a phantasmagoria of no fewer than eight, progressively more oxygenated, adsorbed radicals. Many studies have shown the important influence of the state of surface oxidation on the electrode kinetics of inorganic (14) and organic (15) reactants at Pt.

Somewhat more graphic evidence for the macroscopic oxidation of Pt anodes has been accumulated in various corrosion investigations (16-28).

The purpose of the present investigation was to inquire more closely, by the voltammetric technique, into the conditions influencing the production and stability of anodically formed phase oxides.

Experimental

The platinum microelectrode under study was a 0.4 mm diameter thermocouple wire of extreme purity sealed through the side of a lead-free soda lime glass tube. Internal contact was made by a spot-welded Ni wire. The electrode was ground such that Pt and glass were flush and then polished with Fisher Polishing Alumina (40μ) to a bright finish. A photomicrograph of the electrode surface at a magnification of X340 revealed it as a planar, quite well-shaped ellipse having semi-axes of 0.0220 and 0.0178 cm (±2%) *i.e.*, an apparent area of 1.23 x 10^{-3} cm^2 (±4%). This electrode was used throughout all the work reported in this paper. For the sake of simplicity, current densities are quoted as though the area were exactly 10^{-3} cm^2, *i.e.*, true current densities are 0.81 of those reported. On the other hand, surface charge densities (mC/cm^2) reported need no such correction.

Anodizations (confined to d.c.) were done in air-saturated 1 or 2*N* H_2SO_4, at constant current in a 3-electrode system. The range of anodizing conditions covered was: current density, up to 10 A/cm^2; duration, up to 18 hr; temperature, 11°-93°C. The counter-electrode was a Pt wire, and the reference electrode was a reversible hydrogen electrode in the same solution (RHE). After anodizing, the microelectrode was rinsed with water and placed in a separate cell for voltammetric study in N_2-saturated 2*N* H_2SO_4 at 25°C. The voltammograms were obtained with a Sargent XXI polarograph employing scans from 1.00 to 0.05V, RHE, at 3 mV/sec in a 2-electrode system. The counter (and reference) electrode was again the RHE which, at the currents obtaining during the cathodic scans, was completely unpolarized. All potentials are quoted *vs.* RHE on the Stockholm convention.

The use of so tiny a working electrode (10^{-3} cm^2) was very advantageous, not merely in reducing to manageable proportions the current corresponding to such high current densities but also in minimizing the associated iR drop concentrated in the solution close to the microelectrode.[1] Even so, at *e.g.*, 10 A/cm^2 in 1*N* H_2SO_4 at 25°C, $iR_c \approx 0.6$V and thus, to get a reasonably accurate idea of the working electrode's potential under these extreme conditions, the value of R_c was required with some precision. Using a General Radio impedance bridge Type 1608-A, determinations were made of the resistive component of the working electrode's impedance in roughly 2*N* H_2SO_4 ($\rho = 2.58$ ohm-cm at 25°C). This resistance, extrapolated to infinite frequency, was 30 ohms (±2). This value was then compared with that calculated from the solution resistance and the electrode dimensions, using the established formula for a constriction resistance (29). The latter quantity was 32 ohms (±1). The correct R_c in this solution was taken as 32 ohms and in other solutions it was calculated as $R_c = 12.4\rho$ (±5%). This use of a small working electrode plus the careful sub-

* Electrochemical Society Active Member.

[1] The constriction resistance R_c near a microelectrode of area A is proportional to $A^{-1/2}$ (29) while the current i corresponding to a given current-density varies directly with A. Hence the ohmic potential drop, iR_c, corresponding to a given current density, is proportional to $A^{1/2}$ and is thus ten times smaller at a 10^{-3} cm^2 than at a 10^{-1} cm^2 electrode.

* Voltammograms at 3 mV/sec in 2N H_2SO_4 at 25°C. Redn charges are mC per cm² of apparent area.

traction of ohmic potential drops made it possible to exceed the current densities of Shibata (31) and Kozawa (35) by nearly 100 fold (*vide infra*) and still know the electrode potential with fair accuracy. Neither of these authors quoted his anodization potentials.

The charge, Q, corresponding to reduction of an anodically formed film was gotten from the area under the appropriate peak in the cathodic voltammogram using that at the prereduced electrode as a base-line. The area was derived from weighing tracing paper scissored to duplicate the peak. Charges are quoted as mC/cm² of apparent area unless otherwise stated.

Results and Discussion

The voltammetric identification of phase oxides on anodically pretreated Pt appears to have begun with some experiments of Obrucheva and Nesterova mentioned by Ershler (30). They found two clear-cut arrests, at 0.7 and 0.4V, RHE, in cathodic chronopotentiograms on smooth Pt in N H_2SO_4 after preanodization at 0.1 A/cm², but only the usual 0.7V arrest after anodizing at 0.001 A/cm². They described the second, 0.4V arrest as displaying all the characteristic properties of a phase transition and attributed it to the reduction of a phase oxide. This type of study was continued by Shibata (31) who, after constant current (0.1 A/cm²) anodization in N H_2SO_4 at 25°C, inspected his oxidized electrodes chronopotentiometrically in N_2-saturated H_2SO_4. His cathodic curves displayed two well-defined arrests. The first, at about 0.6V, NHE, corresponded to a surface charge of about 4 mC/cm² and was certainly due to the reduction of the monolayer-type oxide film. Similarly, high charges have been observed previously at this potential (2, 32). The second arrest at 0.3V, NHE, lengthened with duration of the preanodization (after an induction period of about 30 min) and was 36 mC/cm² for an electrode which had been preanodized at 0.1 A/cm² for 28 hr. The only arrest previously described in the literature at this potential is that caused by monolayer hydrogen adsorption, accounting on smooth Pt for 0.5 mC/cm² at the most (33). The charge $i\tau$, for the second arrest was independent of cathodic i over at least 10 to 600 μA/cm² (34), and this arrest thus arises in a surface film of some kind. Even allowing a roughness factor of 2.5 (33) a film equivalent to 36 mC/cm² corresponds to associating at least 30 oxygen atoms with each surface Pt (2). By no possible stretching of the Pt atom oxidation number can a film of this kind be visualized as a superficial monolayer. In fact Shibata (34) later studied these films by an electron diffraction technique and concluded they were a PtO_2 phase oxide. Shibata's study of this low-potential arrest during the reduction of Pt electrodes subjected to excessive prior anodization was extended by Kozawa. After constant current anodization in 1N H_2SO_4, Kozawa recorded voltammograms in N_2-saturated 1N H_2SO_4 from 0.9 to 0.0V, NHE (35). As well as the normal cathodic peak at 0.6V, he got a second peak at 0.2V the height of which increased with the duration, current density, and temperature of the anodic pretreatment. As in Shibata's experiments, the charge corresponding to this low-potential peak, under extreme conditions, greatly exceeded that of the first peak. In Kozawa's anodizations, the upper extremities of his parametric variations were: current-density, 0.3 A/cm²; duration, 30 min; temperature, 50°C. No second cathodic peak was obtained after anodizing under similar conditions in N NaOH. Films corresponding to about 10 mC/cm² have been reported on Pt anodized in M KOH, in a somewhat obscurely presented Russian paper (36). Other voltammetric studies where phase oxides were certainly involved include those of Fleischmann *et al.* (5) and Nagel and Dietz (22).

In the present work, symbols Q_1 and Q_2 correspond to the charges involved in the voltammetric reduction of the two main films formed by the preanodization. Q_1, associated with the 0.6V peak, is due to the film formed in brief, relatively mild anodizations. This film, which will be termed the first or monolayer oxide, has been the object of most previous experimentation.

Q_2, derived from the peak at about 0.2V, is due to a film that appears only after more vigorous anodization. This film is referred to as the second or phase oxide. Under certain conditions, especially after prolonged and intense preanodization, the Q_2 peak splits and a peak at about 0.3V begins to appear. The corresponding Q's of the forked second peak are designated as Q_{2A} (0.3V) and Q_{2B} (0.2V).[2]

Hysteresis in Oxidizability (Second Oxide)

At the outset of the present work, an attempt was made to duplicate in outline the results of Kozawa (35) and Shibata (31) in dilute H_2SO_4 (1 or 2N) at 25°C. This initial attempt was strikingly unsuccessful. In spite of anodizing for much longer periods and at much higher current-densities than these workers used, the subsequent voltammograms exhibited only the usual 0.6V, first oxide peak. The most intense anodizations employed in this initial effort were those described in Table Ia as runs k_7 and k_8 at 10 A/cm²

[2] In considering the magnitude of these Q's it may be helpful to note that, if the film is a monolayer of platinum oxide, the electrode roughness factor must be $R \approx Q/0.2n$ where Q = surface charge in mC/apparent cm² and n = number of electrons withdrawn from each surface Pt during oxidation. This equation derives from an average value of 1.2×10^{15} Pt at./cm² for the three major planes of the face-centered cubic Pt lattice (2). Thus Q = 1.6 mC/cm² corresponds to R = 2 or 4 for monolayers of PtO_2 (n = 4) or PtO (n = 2) respectively.

in 1 and 2*N* H_2SO_4, respectively. In these runs, current densities greater by nearly two orders of magnitude than those successfully used by Shibata and Kozawa were fruitless, *i.e.*, $Q_2 = 0$. At this relatively early stage of the electrode's history, Q_1 was about 1.6 mC/cm^2, corresponding to a roughness factor of 2 to 4.[2] Finally, second oxide formation was obtained in run k_9 after an extremely prolonged (17 hr) anodization at 25°C in 1*N* H_2SO_4 at a potential of 2.29V, RHE. After this treatment the cathodic scan showed a sharp second peak at 0.16V with $Q_2 = 16$ mC/cm^2. In general it was found that Q_2 increased with the duration, current density, and temperature of the anodic pretreatment in agreement with Kozawa's data (35).

After the second oxide had once been formed on the electrode, it became relatively much easier to make it again. This sharply contrasting oxidizability before and after the successful run k_9 is shown in Table Ia. Before k_9, the extremely intense anodization of k_8, where the anode potential was maintained for 73 min between 3.16 and 3.35V, RHE, was fruitless. After k_9, the much milder treatment of o_2, where the potential was between 2.20 and 2.15V for only 5 min, gave a sharp second peak in the cathodic voltammogram with $Q_2 = 2.4$ mC/cm^2. Apart from the great hysteresis in oxidizability evident in Table Ia, it is obvious that the magnitude of the anode potential, provided it exceeds a certain minimum value of about 2.15V, RHE, has a relatively minor influence on second oxide formation. A hysteresis in the anodic oxidizability of Pt was briefly alluded to by Nagel and Dietz (22). They noted that during a sequence of electrolytic oxidations and reductions the anodizing time required to form a brown layer of phase oxide fell from 15 hr to 1 hr and ascribed this behavior to a gradual loosening ("Auflockerung") of the metal surface.

A pronounced hysteresis or effect of recent past history on electrode oxidizability was evident throughout the present work and introduced a strong element of irreproducibility into the data. In general, the easy formation of second oxide at the Pt electrode was favored if a thick layer of second oxide had recently been reduced to metal at this electrode. This activating effect for the anodic growth of the phase oxide was unstable and decayed at rates which varied widely according to experimental conditions. Two examples of this decay are shown in Fig. 1. The conditions applicable to these experiments are detailed in Table Ib (refers to curve A of Fig. 1) and Ic (curve B of Fig. 1). Electrode oxidizability was measured as the amount, Q_2, of second oxide formed during brief (1 or 5 min) test-anodizations in 2*N* H_2SO_4 at 25°C and 10 A/cm^2. Both the test-anodizations and the intervening periods of open-circuit storage were conducted in the same N_2-saturated 2*N* H_2SO_4 at 25°C. The time-zero of curves A and B coincides with the cathodic reduction of phase oxides equivalent to 14 mC/cm^2 (run u_5) and 40 mC/cm^2 (run u_{10}) for A and B, respectively. Halfway through curve B the test-anodization was lengthened from 1 to 5 min. In both curves, electrode oxidizability fell to zero inside 3 hr, the thicker, prior oxide of curve B being associated with an appreciably more lasting oxidizability. The procedure of characterizing electrode behavior with test-anodizations (and their associated cathodic voltammograms between 1.00 and 0.05V, RHE) seemed itself to hasten the decline in oxidizability. In one case, oxidizability survived for 48 hr in N_2-saturated 2*N* H_2SO_4 at 25°C and about 0.9V, RHE open-circuit potential, only to fall almost to zero in an hour under the influence of two test-anodizations. In another case, 67 hr of quiescence under similar open-circuit conditions sufficed to render the electrode quite inert even to the first test-anodization. Thus it would seem that after the reduction of a thick second oxide ($Q_2 >$ about 20 mC/cm^2) the Pt electrode, if undisturbed, remains oxidizable for two to three days. If, however, the electrode is subjected to the oxidation-reduction cycling involved in the procedure used to obtain Fig. 1, the oxidizability decays to zero in a matter of only several hours.

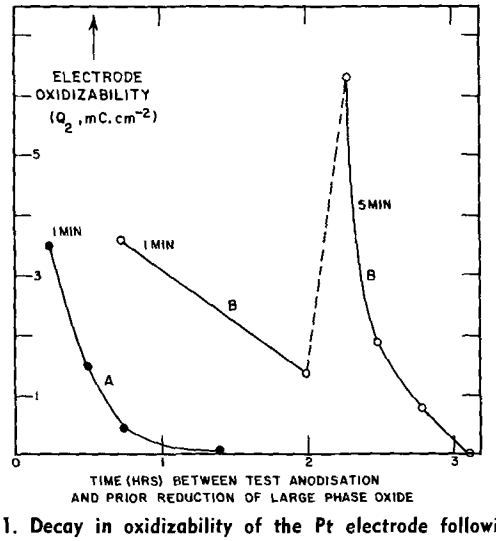

Fig. 1. Decay in oxidizability of the Pt electrode following reduction of a thick second oxide at this electrode. Q_2 is the amount of second oxide formed during brief test-anodizations at 10 A/cm^2 in 2*N* H_2SO_4 at 25°C for the labeled duration. Time zero of curves A and B was cathodic reduction of second oxides equivalent to 14 and 40 mC/cm^2, respectively.

The hysteresis in electrode oxidizability noticed in the present work was not reported in the voltammetric studies of previous workers (31, 35). An explanation of this fact and of the hysteresis itself in terms of electrode surfaces possessing varying degrees of mechanical strain can be supported by considerable evidence. Before each anodization, Kozawa (35) polished his Pt electrode with fine emery paper and rinsed it with water. This mechanical abrasion may well have introduced sufficient strain into the metal surface to act as active centers for the incipient formation of phase oxide. Shibata's pretreatments (31a) included no abrasion but just prior to anodizing, his electrodes were aged in an atmosphere of H_2 gas at 20°C for two weeks. Since Pt is subject to hydrogen embrittlement (37) Shibata's electrode surfaces also may have been significantly strained. Hence, if mechanical strain does in fact activate the Pt surface for the growth of phase oxide, it is not surprising that the oxidations of Shibata and Kozawa were both easier and more reproducible than those of the present work. This work employed no strain-producing pretreatments, and this could explain the initial failure to evoke second oxide. The first successful anodization of the present work was very prolonged (17 hr at 1 A/cm^2 in 1*N* H_2SO_4 at 25°C), and it was suggested by Schuldiner (38) that this extended period of O_2 liberation permitted considerable penetration of the Pt surface by oxygen atoms. The fact that oxygen atoms can readily reach positions below a Pt surface has been demonstrated by low-energy electron diffraction (39). Schuldiner and Warner (6, 40) have shown that such dermasorbed oxygen can strongly affect the catalytic behavior of a Pt electrode. Furthermore Hoare (41) got evidence from x-ray diffraction work, for a perceptible expansion of the lattice parameters at a Pt surface after forming a dermasorbed oxygen layer. Thus it is reasonable to suppose that the production of such a layer during extended anodization might render the electrode strained and oxidizable. It is not clear why, *e.g.*, run k_8, at 10 A/cm^2 (3.2V, RHE) for 73 min failed to activate the Pt surface since, according to Schuldiner (6) significant quantities of dermasorbed oxygen enter a Pt surface even in short anodic pulses ($\approx 10^{-3}$ sec) at potentials above 1.5V, RHE. Apparently the amount of penetration into the Pt by dermasorbed oxygen necessary to activate the surface with respect to second oxide formation is orders of magnitude greater than that acquired in short pulse

polarizations. Thus even a 73-min treatment may fail while a 17-hr treatment succeeds. From the very limited data available on the stability of dermasorbed oxygen layers on Pt electrodes (42) one would expect an oxidizability, dependent on the presence of such a layer, to persist for about two days rather than the hours illustrated in Fig. 1. However, as already stated, the imposition of test-anodizations seemed to accelerate the decline in electrode oxidizability and that of an undisturbed electrode did in fact survive for two to three days. For the persistence of oxidizability after reduction of a thick phase oxide to be due to the retention of dermasorbed oxygen for some time in surface layers, the freshly reduced Pt coating deposited during this reduction must be porous. Thus the active (containing dermasorbed oxygen) layer underneath has access to solution and is able to display its oxidizability.

There is an alternative explanation of the decay curves of Fig. 1. This again assumes the oxidizability to be caused by mechanical strain in the electrode surface but supposes this strain to arise during the reduction of the phase oxide rather than during its formation. The electrodeposition of metals is known to give catalytically active layers rich in both dislocations and point defects (43). Moreover, Piercy (44) has demonstrated that Pt can be loaded with a type of defect which anneals out at room temperature at rates not incompatible with the data of Fig. 1. Whether Pt layers electrodeposited from phase oxides under the conditions of this work could contain such defects is a moot point. That such layers are certainly different in structure from Pt black deposits obtained conventionally was shown by Shibata (34) using the electron diffraction technique. Also, for the anodic oxidation of propane, it was found that reduced PtO_2 was much more active than platinum blacks prepared by reduction from aqueous solution (49).

Structure and Stability of Anodic Films

Figure 2 shows cathodically scanned voltammograms in N_2-saturated, 2N H_2SO_4 at 25°C after the following chronological pretreatments of the Pt electrode: curve 1, prereduction in the same solution at 0.05V, RHE, *i.e.*, curve 1 shows the residual or background current; curves 2 to 6, preanodization at 93°C in 2N H_2SO_4 at 10 A/cm^2 (2.36V, RHE) for: curve 2, 5 min; 3, 30 min; 4, 1.75 hr; 5, 3.3 hr; 6, 17 hr. The splitting of the second peak, beginning in curve 4 (1.75 hr) was not observed by previous workers (31, 35) whose anodizations did not approach in severity those of the present work. Figure 3, depicting the growth of the three main films, was derived from Fig. 2 by measuring the areas under the three main peaks of this linearly scanned voltammogram to get the charges involved in forming the corresponding films. Figure 3 gives an over-all picture of film growth in a log-log plot. However, due to the successive formation and reduction of the phase oxide layers, Q_{2B}, there was a stepwise increase in electrode roughness factor, from run to run, during the experiments from which this figure is derived. In Fig. 4 an attempt was made to correct for

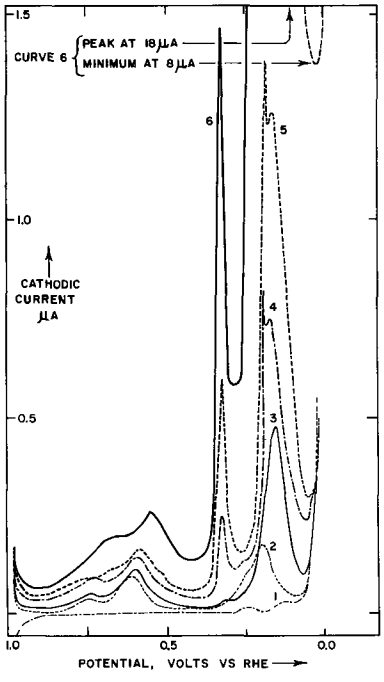

Fig. 2. Voltammetric stripping curves for the Pt electrode in N_2-saturated 2N H_2SO_4 (25°C, 3 mV/sec) after the following chronologically listed pretreatments. Curve 1, prereduction in this solution at 0.05V, RHE; curves 2 to 6, preanodization at 93°C in 2N H_2SO_4 at 10 A/cm^2 (2.36V, RHE) for: 2, 5 min; 3, 30 min; 4, 1.75 hr; 5, 3.3 hr; 6, 17 hr.

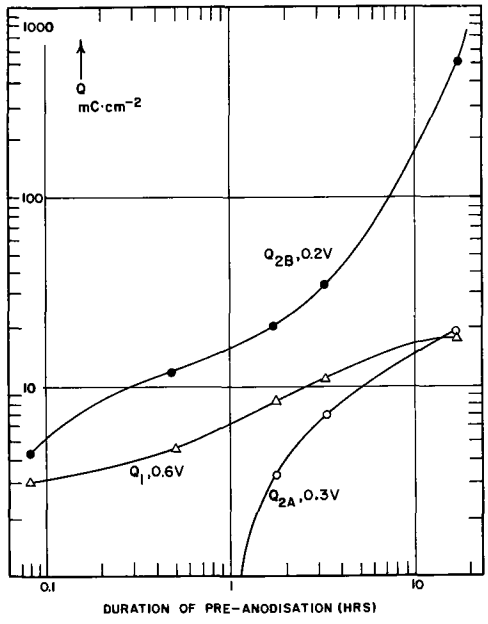

Fig. 3. Growth of anodic films on the Pt electrode vs. anodizing time. Growth curves derived from Fig. 2 are drawn for the three main peaks and labeled according to peak potential. Reduction charges Q refer to 1 cm^2 of apparent area.

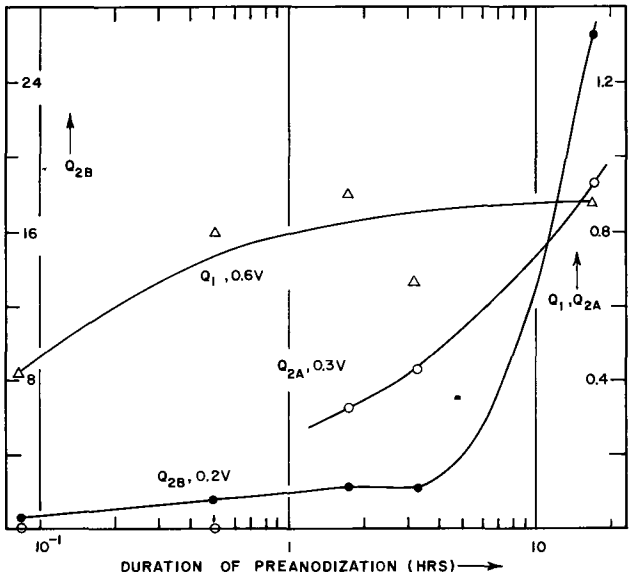

Fig. 4. Growth of anodic films on the Pt electrode vs. anodizing time. Data are those of Fig. 3 corrected for varying roughness factors, *i.e.*, reduction charges, Q, on the ordinate refer to mC/cm^2 of true area.

this varying surface area and report the Q's of Fig. 3 in terms of mC/real cm². This was done as follows. For any particular run, i, the approximate formula previously quoted,[2] *i.e.*, $R \approx Q/2n$ was applied, putting Q equal to the value of Q_1 obtained in the previous run. This gives the roughness factor appropriate to the anodization of run i. The value of R used was the average between those corresponding to monolayers of $PtO(n = 2)$ and $PtO_2(n = 4)$. Dividing the mC/apparent cm² values for run i by this value of R gives the mC/real cm² values plotted semilogarithmically in Fig. 4. The calculated values of R varied from 7.4 just before the first anodization (5 min) to 20 just before the last anodization (17 hr) of Fig. 4. Since all anodizing was done at constant current, the current density was a factor of three smaller in the last run. In spite of this variation in A/cm², the electrode potential was constant throughout this whole series of experiments (Fig. 4) at 2.36V, RHE (±0.01V).

It is evident from Fig. 3 and 4 that, after a few hours at constant potential, the rate of formation of phase oxide, Q_{2B}, increases greatly and, if continued, would have totally converted the anode to platinum oxide. In contrast Ramaley (50) in preliminary work in 1M $HClO_4$ at 25°C found that between 1.8 and 2.2V, NHE the amount of second oxide formed was determined by and varied almost linearly with the potential. This behavior seems appropriate to the formation of interfacial rather than 3-dimensional oxide.

The largest Q of Fig. 4, *viz.*, 25 mC/real cm² for Q_{2B} after 17 hr of anodizing would, if it arose from a monolayer oxide, necessitate associating about 70 oxide ions with each surface Pt. Thus Q_{2B} patently originates in a multilayer or phase oxide. While no chemical or spectral analysis of this oxide was attempted, the similarity of its appearance and mode of preparation to oxide analyzed by previous workers (25, 26) makes it highly probable that it was hydrated PtO_2. The 25 mC/real cm² oxide layer of Fig. 4 was orange-colored, amorphous looking, and very tightly adherent. After cathodic reduction of this thick film, the whole surface of the electrode was dull and pockmarked with innumerable tiny craters. An electrochemical determination of surface area at this stage gave $Q_1 = 68$ mC/apparent cm² (after a 1 min preoxidation at 2.00V, RHE in 2*N* H_2SO_4 at 27°C) corresponding to a roughness factor of 85 to 170.[2]

The Q_1 values of Fig. 3 and 4 derive from the first or monolayer oxide, the object of most previous study. Q_{2A} corresponding to the peak at about 0.3V (in Fig. 2) first observed in the present work is of comparable size to Q_1 so perhaps Q_{2A} similarly derives from a monolayer type oxide, formed at a species of external site on the Pt comparable in abundance to that responsible for Q_1 but much less easily oxidizable.

The detailed mechanism of reduction of these composite oxide films is of interest. The first reduction peak at about 0.6-0.7V in Fig. 2 is attributed to monolayer oxide. This film returns to the metallic state at the interface between bulk Pt and bulk Pt oxide. Then nothing happens until about 0.5V lower when the phase oxide starts to reduce. As pointed out by one of the referees, if this reduction begins at the oxide-acid interface it might sandwich most of the phase oxide between layers of impervious Pt metal. If this happened it is hard to see how the rest of the oxide could ever get reduced (which it does). So presumably either phase oxide reduction occurs wholly at the Pt-Pt oxide interface or reduction at the oxide-acid side deposits a highly porous metal. This latter is quite possible in view of the great roughening found in this work after such reductions.

Stability of Anodic Films

To potentiostatting at 0.5V, RHE.—The stability of the second oxide layer was examined at a controlled electrode potential of 0.5V, RHE in N_2-saturated 2*N* H_2SO_4 at 27°C. It was first established that anodizing at 10 A/cm² for 5 min in 2*N* H_2SO_4 at 93°C resulted in reproducible subsequent cathodic voltammograms such as curve 2 of Fig. 5, where $Q_2 = 7.0$ mC/cm². Curve 1, at a prereduced electrode acts as a base line for calculating the peak areas. Curve 2 was obtained in a separate cell 2-3 min after the anodization. Then curves 3 and 4 were recorded after the same anodic pretreatment. However, in recording these curves, voltage-scanning was arrested at 0.5V, RHE in order to potentiostat the electrode at this voltage. After pausing at this voltage for 104 min (curve 3) and 16.5 hr (curve 4) voltage-scanning was resumed to record the second oxide peaks. Q_2 for curves 3 and 4 was 3.8 and 1.9 mC/cm², respectively, compared with 7.0 for the normally treated electrode of curve 2. These results show that the second oxide is certainly unstable at 0.5V, RHE although its removal is still far from complete, even after 16 hr. It is apparent from Fig. 4 that the second oxide reduction regions of curves 3 and 4 were quite ill-defined[3] in comparison with those usually obtained (*c.f. e.g.* Fig. 2).

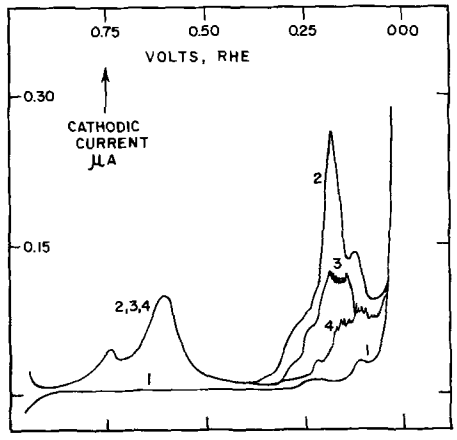

Fig. 5. Stability of second oxide layer at 0.5V, RHE exhibited by voltammetric stripping curves in N_2-saturated 2*N* H_2SO_4 (25°C, 3 mV/sec) after the following pretreatments: curve 1, prereduction in the solution at 0.05V, RHE; curve 2, anodization for 5 min at 10 A/cm² at 93°C in a separate portion of 2*N* H_2SO_4; curves 3 and 4, same as curve 2 except cathodic scanning was arrested at 0.5V, RHE to potentiostat at this value for 104 min and 16.5 hr in curves 3 and 4, respectively.

To soaking in 2N H_2SO_4 at 93°C.—It was first established that anodizing for 30 min at 10 A/cm² in 2*N* H_2SO_4 at 93°C resulted in reproducible subsequent voltammograms with $Q_1 = 5$ and $Q_2 = 17$ mC/cm². This procedure was then repeated, interposing a soaking period of 18 hr at 93°C in fresh, unelectrolyzed 2*N* H_2SO_4 between anodization and cathodic examination of the electrode. In this latter case, Q_1 had fallen to 1.7 and Q_2 to 10 mC/cm². Thus the first oxide was removed somewhat faster than the second.

Temperature Dependence of Cathodic Peak Potentials

Figure 6 shows a series of voltammograms in N_2-saturated 2*N* H_2SO_4 at 25°, 57°, and 93°C obtained in

[3] In these regions, the Sargent XXI recorder pen became subject to a "chatter" which occurred neither in curves 1 and 2 nor in those parts of curves 3 and 4 anodic to 0.25V, RHE. The origin of this effect is obscure to this author. From the experimental procedure described above, it would appear that there is a distinct difference between curve 2 on the one hand and 3, 4 on the other in that second oxide reduction in curve 2 occurred at an "anodically cleaned" electrode, i.e., one on which a monolayer oxide had been freshly reduced (45). In curves 3 and 4, 105 min and 16.5 hr, respectively of potentiostatting at 0.5V, RHE had intervened between this anodic cleaning and the resumption of voltage scanning. This is plenty of time for the electrode to have become grossly recontaminated by adsorbable solution impurities (45). To obviate this difference the electrode was given an anodic cleaning for 0.5 min at 1.7V, RHE just before continuing curves 3 and 4. However this had no effect on the pen-chatter.

that order. Each of these curves was preceded by an identical 5-min anodization in 1*N* H_2SO_4 at 10 A/cm² and 25°C. So the oxide film was similarly formed in each case but the temperature of its cathodic stripping was varied. The relative areas of the second oxide peaks in Fig. 5 are of no account. Q_2 actually fell continually in this chronological series of runs from 5.7 mC/cm² in curve 1 to 1.0 in curve 6 due presumably to the declining oxidizability discussed above. The main interest of Fig. 6 attaches to the temperature coefficient of the peak potentials. In going from 25° to 93°C, the potentials of the first and second oxide peaks became 100 and 120 mv, respectively, more positive. Both these values of peak-potential shift, of course, are relative to the unknown change of the reference electrode potential between 25° and 93°C (reference electrode was RHE, *i.e.*, reversible hydrogen electrode in the same solution). Thus the absolute magnitudes of the shifts are of little significance. It is surprising, however, that the difference between the two shifts is only 20 mv. Judging irreversibility by the potential span between onset of oxidation of the reduced electrode and incipient reduction of the oxidized electrode, one arrives at 1.0 − 0.7 = 0.3V for the first oxide and 2.1 − 0.3 = 1.8V for the second oxide. Thus it would be expected that the energy of activation and hence temperature coefficient of overvoltage should be much higher for the second than for the first oxide, giving rise to a much more substantial change in the separation of the first and second oxide peak potentials than the 20 mv actually observed in the 68°C interval.

In connection with the above discussion of the temperature dependence of oxide reduction potentials, a recent article by Marvin and Petrii (51) is of relevance. In this work galvanostatic (potential-time) curves were obtained for the cathodic reduction of PtO_2 prepared chemically by $NaNO_3$ oxidation of H_2PtCl_6 at 550°C. Chronopotentiograms were secured at different current densities (in terms of A/g of PtO_2) in 1*N* solutions of H_2SO_4 and NaOH at 20° and 95°C. Tafel plots derived from the plateau potentials of the charging curves invariably sloped by about 120 mV per decade of A/g. The only data really comparable with that of the present work were the temperature dependence of the plateau potentials. In 1*N* H_2SO_4 the plateau potential, *vs.* the respective RHE in each case, was about 330 mV higher at 95° than at 20°C. In the present work the second oxide peak potential, in 2*N* H_2SO_4 *vs.* RHE, was about 120 mV higher at 92.5° than at 25°C. Thus the data of the present work (Fig. 6) exhibits a significantly smaller temperature dependence for the second oxide reduction potential. Perhaps this reflects a significant difference in structure between chemically and anodically prepared PtO_2.

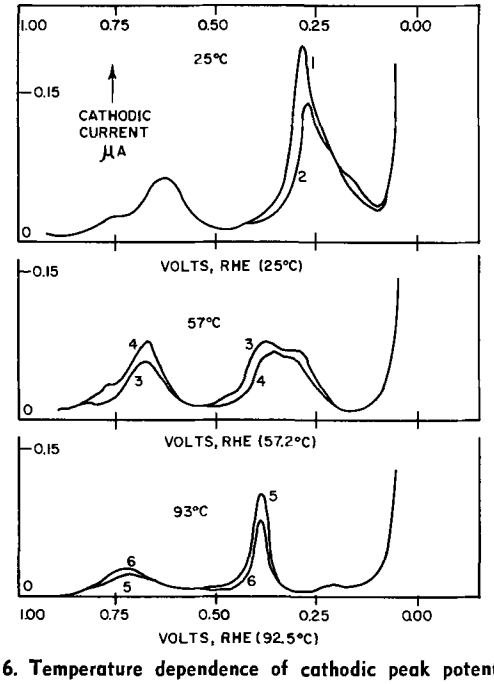

Fig. 6. Temperature dependence of cathodic peak potentials in voltammetric stripping of oxide films. Curves 1 to 6 (obtained chronologically) in N_2-saturated 2*N* H_2SO_4 (25°C, 3 mV/sec) were each preceded by an identical 5-min anodization in 1*N* H_2SO_4 at 25°C and 10 A/cm².

Low-Temperature Production of Second Oxide

Shibata's most intense anodizations (0.6 A/cm² for 60 min) failed to evoke the second oxide unless the temperature were higher than 21°C (31). He concluded that the monolayer oxide, when formed below 21°C, has a tight structure which prevents oxide growth into the interior of the metal. With the much higher anodic current densities used in the present work, it was shown that second oxide could result from anodizations as cool as 11°C, the lowest temperature at which oxidizability was studied. In one run, at 11°C in 2*N* H_2SO_4, anodizing at 10 A/cm² for 5 min (at a potential of 2.58-2.72V, RHE) yielded a sharp second oxide peak with Q_2 = 3.8 mC/cm². It was found in general that with declining anodizing temperature both the ease and reproducibility of second oxide formation was greatly diminished.

Behavior of First Oxide (0.6V Film)

The variation, in Table I of Q_1, the first oxide value, from run to run, is also of interest. This oxide is generally accepted as a monolayer-type film, and the magnitude of Q_1 is proportional to the true area of the electrode.[2] Just before run u_{10}, anodizing for 1 min at 10 A/cm² gave Q_1 = 4.5 mC/cm² (runs u_8, u_9) compared with Q_1 = 15.5 for an identical anodization immediately following u_{10}. Then, while standing in 2*N* H_2SO_4 at 25°C, Q_1 declined from this high value, falling to 3.3 mC/cm² after only 5 hr (only the early stage of this fall in Q_1 appears in Table I). The large (X3.5) increase in Q_1 caused by the reduction of the 40 mC/cm² second oxide of u_{10} is a strong indication of the phase nature of this film since the formation and dissolution of a monolayer type oxide are unlikely to effect so thoroughgoing a disruption of the surface. Thus high area Pt black catalysts for both organic hydrogenations (46) and anodic hydrocarbon oxidation (49) result from reducing PtO_2 to Pt. The fall of Q_1 from 15.5 to 3.3 mC/cm² in the 5 hr subsequent to u_{10} reflects a quite drastic reconsolidation of the disrupted Pt surface. This rate of area change seems very high by comparison with the limited data available on Pt black recrystallization in aqueous solutions (47) where, typically, 60 hr at 150°C in 90% H_3PO_4 was needed to effect 80% reduction in the electrochemically determined surface area. A major difference between the present work and the cited recrystallization study (47) lies in the storage conditions. In the latter, storage was at open-circuit while in the present work, storage was regularly punctuated by the brief anodization-cathodization treatments required to monitor the electrochemical area. It was already shown above that electrode behavior can be drastically modified by these test anodizations which greatly accelerated the decline of electrode oxidizability. Perhaps these test redox cycles have a significant effect also on the rate of consolidation of the Pt surface. Possibly Shibata's observation cited above (34), *viz.*, that a Pt surface electrodeposited from a second oxide film is more intensely strained and smaller in grain size than one prepared conventionally by deposition from chloroplatinic acid, has relevance to this point. Thus a highly strained finely divided surface should have a high recrystallization rate.

In recent work (45) it was shown that the activating effect on platinum electrodes of brief (≈1 min) anodic-cathodic cycles was due almost entirely to the impurity desorption effected by this treatment. However this was

apparently not true for the longer preanodizations of Shibata (31a). He anodized three 1 cm^2 Pt electrodes in 1*N* H_2SO_4 (25°C) at 0.1 A/cm^2 for 0.25, 1 and 28 hr, respectively, and then measured their activity by the magnitude of the hydrogen-evolution-reaction current at them for a definite small overpotential in 1*N* HCl. In each case the electrode activity fell off with time from roughly the same initial high value, but the rate of this decay was profoundly different for the three electrodes. After 30 hr in the 1*N* HCl, activity had fallen to 0.80, 0.028, and 0.018 of the initial high value for the electrodes preanodized for 28, 1, and 0.25 hr, respectively. This behavior led Shibata to discard the impurity desorption theory of electrode activation and postulate that the Pt surface had undergone a superficial structural change whose lifetime increased with the severity of the preoxidation.

The present work suggests another explanation of Shibata's data. Chronopotentiometric reduction of his electrodes showed that the preoxidations had yielded second oxide layers on them to the extent of about 0.4, 4, and 36 mC/cm^2 after the 0.25, 1, and 28-hr preanodizations, respectively. Since the present work has shown that the reduction of second oxide layers of this order of thickness can cause large increases in electrode roughness factor, it is virtually certain that the three electrodes encompassed a large spread of roughness factor (probably up to 10X). Thus the varying rates of decay in electrode activity are explained as follows. If, as is usually the case (1a, 48) contamination by adsorbing impurities from the solution was diffusion controlled, then the rate of uptake of contaminant by the electrodes was proportional to their geometrical areas which were identical. Hence percentage contamination of true area was slower for the rougher electrodes. All of Shibata's decay curves were characterized by an initial steady value of activity (the same for all three electrodes), then a more or less sudden fall, and a final slow leveling out. These curves closely resemble others obtained for the hydrogen evolution reaction at Pt under very similar conditions in 2*N* H_2SO_4 (45). In this latter work, the decay in activity was proven to arise from the adsorption of solution contaminants. It would seem that Shibata's currents started out with a measure of diffusion control, but as time (contamination) proceeded the true area diminished to the point where kinetic control predominated. With complete kinetic control the current should fall in direct proportion to the true area. This decay in current should naturally be slowest for the electrode with the highest roughness factor. Thus it would seem that Shibata's electrochemical activations comprised merely "anodic cleaning" and were not basically different from more conventional brief anodizations.

Note added in proof: Both Professor Conway himself and one of the referees of this paper considered that similarities between this work and a recent paper [Conway and Gilroy, *Can. J. Chem.*, **46**, 875 (1968)] merit further discussion. In my opinion the area of contact between the two studies is quite small. The main thrust of the present work is directed at the phase or second platinum oxide, an orange-brown layer which in extreme cases can be scraped off the metal in palpable lumps. The reduction charge (Q_{2B}) of this oxide can reach 25 mC/real cm^2 (Fig. 4). Its reduction peak potential is 0.4 to 0.5V below that of the first or monolayer oxide (Fig. 2) at a voltage scanning rate of 0.2 V/min.

Conway's Fig. 2 shows differentiated galvanostatic reduction curves for a Pt electrode in M H_2SO_4. If the prior potential exceeded 1.6V, RHE his oxide reduction curves at high current densities split into two clear peaks (OX.1 and OX.2). His total oxide reduction charge never exceeded 1.0 mC/real cm^2, *i.e.*, there is room for both OX.1 and OX.2 to coexist on the purely external surface of Pt. The scanning rate of Conway's Fig. 2 was ≈400 V/sec and OX.1/OX.2 peaks are separated by 0.1V. At lower scanning rates the peaks merged into one. This contrasts strongly with my Fig. 2 where the 1st and 2nd oxide reduction peaks differ by 0.5V at a scanning rate of 0.2 V/min, *i.e.*, X10^5 slower than Conway's.

To sum up, the following data of the present work show that a much clearer distinction exists between my 1st and 2nd oxides than between Conway's OX.1 and OX.2: (*a*) the very large mC/real cm^2 for Q_{2B} compared with Q_1; (*b*) the large voltage separation of reduction peaks for Q_1 and Q_{2B}; (c) the independent behavior of Q_1 and Q_{2B} *vs.* anodization time in my Fig. 3 and 4. I think there is little doubt that the 1st and 2nd peaks in my Fig. 2 refer to monolayer and phase oxide, respectively. On the other hand, OX.1 and OX.2 probably refer to two different energy sites on the external surface of Pt, *i.e.*, to a fine structure in the monolayer oxide. Possibly the fine structure apparent in my Fig. 2 in the 1st oxide reduction peak (*i.e.*, a small prewave at 0.7V before the main one at 0.6V) may relate to Conway's OX.1 and OX.2.

Manuscript submitted Feb. 13, 1969; revised manuscript received July 3, 1969. This paper was presented at the 19th Meeting of CITCE, Detroit, Sept. 22-27, 1968. This work was based on data obtained at Brookhaven National Laboratory, Upton, New York, in work done under the Auspices of the United States Atomic Energy Commission.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Concentration Polarization and Mass Transfer Influence on the Kinetics of Two Stepwise-Proceeding Electrode Reactions under Galvanostatic Conditions

I. H. Plonski
Institute for Atomic Physics, Bucharest, Romania

ABSTRACT

The previous system of equations derived for the kinetics of two stepwise-proceeding electrode reactions under galvanostatic conditions is extended for the case when both concentration polarization and mass transfer of the intermediate and final ion are taken into account.

In a previous paper (1) the two stepwise-proceeding electrode reactions

$$M \rightleftarrows M^{z_1+} + z_1 e \qquad \text{(I)}$$

$$M^{z_1+} \rightleftarrows M^{(z_1+z_2)+} + z_2 e \qquad \text{(II)}$$

were considered under galvanostatic conditions. Neither concentration polarization nor mass transfer were taken into account. In the reactions concerned, M is the metal, M^{z_1+} is the intermediate ion, $M^{(z_1+z_2)+}$ the final ion, and z_1 and z_2 are the number of electrons involved in the first and second step, respectively. The kinetic equations for this system are

$$\frac{d\eta}{dt} = \frac{1}{C}\left[i + i_{o2}\, e^{-\alpha_{c2}\eta} - i_{o1}\, e^{\alpha_{a1}\eta} - \frac{[M^{z_1+}]}{[M^{z_1+}]_o}\left(i_{o2}\, e^{\alpha_{a2}\eta} - i_{o1}\, e^{-\alpha_{c1}\eta}\right)\right] \qquad [1]$$

and

$$\frac{d[M^{z_1+}]}{dt} = \frac{i_{o1}}{z_1\mathbf{F}} e^{\alpha_{a1}\eta} + \frac{i_{o2}}{z_2\mathbf{F}} e^{-\alpha_{c2}\eta} - \frac{[M^{z_1+}]}{[M^{z_1+}]_o}\left(\frac{i_{o1}}{z_1\mathbf{F}} e^{-\alpha_{c1}\eta} + \frac{i_{o2}}{z_2\mathbf{F}} e^{\alpha_{a2}\eta}\right) \qquad [2]$$

Here η is the overvoltage, t the time, C the double layer capacity, i the current density, i_{o1} and i_{o2} the exchange current densities for the first and second step, respectively, $\mathbf{F}$ the Faraday number, $[M^{z_1+}]$ and $[M^{z_1+}]_o$ the intermediate ion concentration at the electrode surface during the electrolysis and at equilibrium, respectively, and $\alpha_{a1} = \frac{\beta_1 z_1 \mathbf{F}}{RT}$, $\alpha_{c1} = \frac{(1-\beta_1) z_1 \mathbf{F}}{RT}$, $\alpha_{a2} = \frac{\beta_2 z_2 \mathbf{F}}{RT}$, and $\alpha_{c2} = \frac{(1-\beta_2) z_2 \mathbf{F}}{RT}$, R the gas constant, T the absolute temperature, and β_1 and β_2 the symmetry factors for the first and second step, respectively.

The above system of equations is approximately valid under the following specific assumptions:

1. The final ion concentration is practically constant at the electrode surface; this holds for processes occurring with current densities far below the limiting diffusion current density, or for processes when the overvoltage reaches its steady state long before the end of the transition time. When the time of electrolysis is prolonged, the increase of the final ion concentration at the electrode surface will generate a concentration polarization attended by the mass transfer of the final ion into the bulk of the solution.

2. If the intermediate ion does not leave the electrode surface, because it exists only as a result of the reversible process between the surface metal and the final ion, $M \rightleftarrows M^{z_1+} \rightleftarrows M^{(z_1+z_2)+}$; in other words, there will be no intermediate ion in the bulk of the solution, and therefore no mass transfer. In this case all conclusions regarding the intermediate ion concentration refer only to the surface concentration.

3. If the diffusion current for the intermediate ion is great enough to assure a constant concentration of the intermediate ion in the whole solution. In this case the same conclusions apply to the bulk concentration, too.

4. When the intermediate ion concentration is very low and one can neglect its diffusion flux into the bulk of the solution in comparison to the rate of its further electrochemical oxidation.

With the exception of these particular cases the concentration polarization due to the change of the final ion concentration at the electrode surface and mass transport processes of both the final ion and intermediate ion must be taken into account.

The complete system of equations for this case is

$$\frac{d\eta}{dt} = \frac{1}{C}\left[i + i_{o2}\frac{[M^{(z_1+z_2)+}]}{[M^{(z_1+z_2)+}]_o} e^{-\alpha_{c2}\eta} - i_{o1}\, e^{\alpha_{a1}\eta} - \frac{[M^{z_1+}]}{[M^{z_1+}]_o}\left(i_{o2}\, e^{\alpha_{a2}\eta} - i_{o1}\, e^{-\alpha_{c1}\eta}\right)\right] \qquad [3]$$

$$\frac{d[M^{z_1+}]}{dt} = \frac{i_{o1}}{z_1\mathbf{F}}\, e^{\alpha_{a1}\eta} + \frac{i_{o2}}{z_2\mathbf{F}}\,\frac{[M^{(z_1+z_2)+}]}{[M^{(z_1+z_2)+}]_o}\, e^{-\alpha_{c2}\eta} - \frac{[M^{z_1+}]}{[M^{z_1+}]_o}\left(\frac{i_{o1}}{z_1\mathbf{F}}\, e^{-\alpha_{c1}\eta} + \frac{i_{o2}}{z_2\mathbf{F}}\, e^{\alpha_{a2}\eta}\right) + D_1\left(\frac{\partial M_1}{\partial x}\right)_{x=0} \quad [4]$$

and

$$\frac{d[M^{(z_1+z_2)+}]}{dt} = \frac{i_{o2}}{z_2\mathbf{F}}\left(\frac{[M^{z_1+}]}{[M^{z_1+}]_o}\, e^{\alpha_{a2}\eta} - \frac{[M^{(z_1+z_2)+}]}{[M^{(z_1+z_2)+}]_o}\, e^{-\alpha_{c2}\eta}\right) + D_2\left(\frac{\partial M_2}{\partial x}\right)_{x=0} \quad [5]$$

Here $[M^{(z_1+z_2)+}]$ and $[M^{(z_1+z_2)+}]_o$ are the concentrations of the final ion at the electrode surface during electrolysis and at equilibrium, respectively, D_1 is the diffusion coefficient for the intermediate ion, D_2 is the diffusion coefficient for the final ion, M_1 and M_2 are the concentrations of the intermediate and final ion, respectively, being functions of both time t and the distance from the electrode surface, x. Obviously, $M_1(0, t) = [M^{z_1+}]$ and $M_2(0, t) = [M^{(z_1+z_2)+}]$. The terms $D_1\left(\frac{\partial M_1}{\partial x}\right)_{x=0}$ in Eq. [4] and $D_2\left(\frac{\partial M_2}{\partial x}\right)_{x=0}$ in Eq. [5] represent the rate of the appearance (or disappearance) of the respective ion at the electrode surface due to mass transfer or, in other words, the diffusion currents at the electrode surface, divided by $z_1\mathbf{F}$ and $z_2\mathbf{F}$, respectively.

The mathematical problem consists in solving Fick's equation

$$\frac{\partial M_1}{\partial t} = D_1\,\frac{\partial^2 M_1}{\partial x_2} \quad [6]$$

for the initial and boundary conditions

$$M_1(x, 0) = [M^{z_1+}]_o$$

$$M_1(t, \infty) = [M^{z_1+}]_o$$

$$\left(\frac{\partial M_1}{\partial x}\right)_{x=0} \quad \text{given by Eq. [4]}$$

and also

$$\frac{\partial M_2}{\partial t} = D_2\,\frac{\partial^2 M_2}{\partial x_2} \quad [7]$$

for the initial and boundary conditions

$$M_2(x, 0) = [M^{(z_1+z_2)+}]_o$$

$$M_2(t, \infty) = [M^{(z_1+z_2)+}]_o$$

$$\left(\frac{\partial M_2}{\partial x}\right)_{x=0} \quad \text{given by Eq. [5]}$$

Equations [3]-[7] form a mixed system of equations with ordinary and partial derivatives which has only approximate numerical solution.

The solution of the first boundary problem of Fick's equation for the initial and boundary conditions

$$M_1(x, 0) = [M^{z_1+}]_o = \text{constant}$$

$$M_1(0, t) = [M^{z_1+}] = \text{function of } t$$

is

$$M_1(x, t) = \frac{1}{2\pi}\int_0^\infty \frac{1}{\sqrt{D_1 t}}\left\{e^{-\frac{(x-\xi)^2}{4D_1 t}} - e^{-\frac{(x+\xi)^2}{4D_1 t}}\right\}[M^{z_1+}]_o\, d\xi + \frac{D_1}{2\sqrt{\pi}}\int_{t_o}^{t} \frac{x}{[D_1(t-\zeta)]^{3/2}}\, e^{-\frac{x^2}{4D_1(t-\zeta)}}\, M_1(\zeta)\, d\zeta \quad [8]$$

where ξ and ζ are integral variables. Solution [8] is valid for $x \geq 0$ and $t \geq t_o$, with $-\infty < t_o < +\infty$; $M_1(x, t)$, given by Eq. [8], is differentiable once with respect to t, and twice with respect to x, and satisfies the initial and boundary conditions for $t = 0$ and $x = 0$.

Assuming a solution, $M_1(x, t)$, differentiable also at the boundary, its differential will be calculated as a limiting process. By introducing $y = (x - \xi)/2\sqrt{D_1 t}$ and $-2\sqrt{D_1 t}\, dy = d\xi$ in the first integral of Eq. [8], and $y = x/2\sqrt{D_1(t-\zeta)}$ and $(4\sqrt{D_1}(t-\zeta)^{3/2}\, dy)/x = d\zeta$ in the second integral of Eq. [8], one can obtain for $x > 0$ and $t > 0$ the differential

$$\frac{\partial M_1}{\partial x} = \frac{[M^{z_1+}]_o\, e^{-\frac{x^2}{4D_1 t}}}{\sqrt{\pi D_1 t}} + \frac{2}{x\sqrt{\pi}}\int_{\frac{x}{2\sqrt{D_1 t}}}^{+\infty} (1 - 2y^2)\, e^{-y^2}\left[M_1\left(t - \frac{x^2}{4D_1 y^2}\right)\right] dy \quad [9]$$

We define for $t > 0$ and $x = 0$

$$\left(\frac{\partial M_1}{\partial x}\right)_{x=0} = \frac{[M^{z_1+}]_o}{\sqrt{\pi D_1 t}} + \lim_{x\to 0}\left\{\frac{2}{x\sqrt{\pi}}\int_{\frac{x}{2\sqrt{D_1 t}}}^{+\infty} (1 - 2y^2)\, e^{-y^2}\left[M_1\left(t - \frac{x^2}{4D_1 y^2}\right)\right] dy\right\} \quad [10]$$

The second term of the right-hand side of Eq. [10] may be obtained numerically by computing a great enough number of integrals for decreasing values of x until its value remains constant within the desired approximation. The same route may be taken to compute $\left(\frac{\partial M_2}{\partial x}\right)_{x=0}$. Unfortunately, the computation is long and intricate.

As a good first approximation, Fick's Eq. [6] and [7] are solved by assuming $M_1(0, t)$ and $M_2(0, t)$ to be constant within a very short interval of time. In this case the solutions are

$$\left(\frac{\partial M_1}{\partial x}\right)_{x=0} = \frac{[M^{z_1+}]_o - [M^{z_1+}]}{\sqrt{\pi D_1 t}}, \quad \text{for } t > 0 \quad [11]$$

and

$$\left(\frac{\partial M_2}{\partial x}\right)_{x=0} = \frac{[M^{(z_1+z_2)+}]_o - [M^{(z_1+z_2)+}]}{\sqrt{\pi D_2 t}}, \quad \text{for } t > 0 \quad [12]$$

The same expressions [11] and [12] are then assumed to be valid also when $[M^{z_1+}]$ and $[M^{(z_1+z_2)+}]$ are time dependent. Using such an approximation, the mass transfer effect is overestimated: the real values of $[M^{z_1+}]$ and $[M^{(z_1+z_2)+}]$ which would be obtained by the correct solving of Eq. [9] and [10], respectively, will be between the values obtained by using Eq. [11] and [12] in conjunction with Eq. [3]-[5] and those obtained by assuming $\left(\frac{\partial M_1}{\partial x}\right)_{x=0} = 0$ and $\left(\frac{\partial M_2}{\partial x}\right)_{x=0} = 0$. Consequently, the following results are valid in a qualitative sense.

Equations [3] to [5] in conjunction with Eq. [11] and [12] are solved numerically for different values of the parameters concerned, given on Fig. 1 and 2.[1]

[1] Some unusual values are taken for concentrations and diffusion coefficients in order to obtain visible effects of concentration polarization and mass transfer processes in a rather convenient period of time.

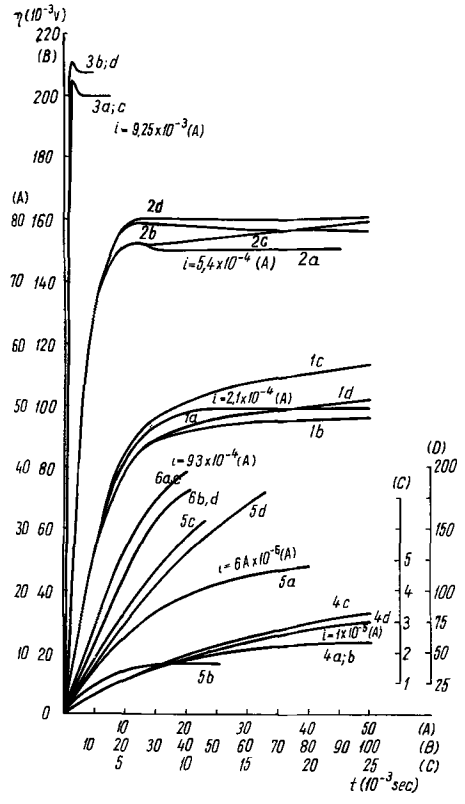

Fig. 1. Overvoltage, η, *vs.* time, *t*, for $z_1 = z_2 = 1$, $\beta_1 = \beta_2 = 0.5$, and different values of *i* pointed on the curves. Curves 1-3: $i_{o1} = 1x10^{-4}$(A), $i_{o2} = 1x10^{-5}$(A); 1-2(O_A—A_A); 3(O_C—A_C). O = ordinate, A = abscissa. Index "a": $D_1 = 0$, $\frac{d[M^{z+}]}{dt} = 0$; b: $D_1 = 1x10^4 cm^2/sec$, $\frac{d[M^{z+}]}{dt} = 0$; c: $D_1 = D_2 = 0$, $\frac{d[M^{z+}]}{dt}$ given by Eq. [5]; d: $D_1 = 1x10^4$ cm²/sec, $D_2 = 1x10^2$ cm²/sec.

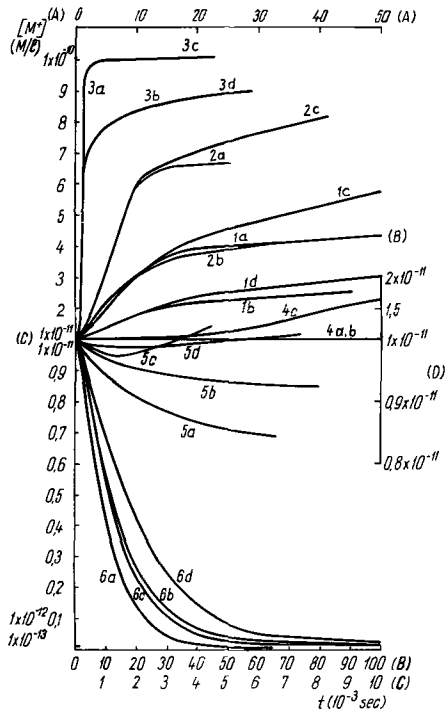

Fig. 2. Intermediate ion concentration, $[M^+]$, *vs.* time, *t*, for the same parameters as in Fig. 1. Curves: 1-3 (O_A—A_A); curve 4 (O_B—A_B); curve 5 (O_D—A_B); curve 6 (O_C—A_C).

In order to point out the effect of both the concentration polarization and the mass transfer processes, the following cases are treated first separately and then together.

(*A*). Neither concentration polarization nor mass transfer are taken into account (curves a, Fig. 1 and 2). The cases are discussed in the previous paper (1) and are given here only for comparison.

(*B*). The influence of intermediate ion mass transfer when the final ion concentration is assumed to be constant (curves b, Fig. 1 and 2).

For $i_{o1} > i_{o2}$, the mass transfer occurs from the electrode surface into the bulk of the solution. At $i < i_{cr}$, [*i* critical denoted by i_{cr} represents the value of *i* from which the $\eta - t$ curve becomes peak shaped in the absence of mass transfer influence (1)], the $\eta - t$ curve is located below the curve when no mass transfer is assumed (Fig. 1, curve 1b), and above it at $i > i_{cr}$ (Fig. 1, curves 2b and 3b). The $[M^{z_1+}] - t$ curves are located below curves a at all current density values (Fig. 2, curves b).

For $i_{o1} < i_{o2}$, the mass transfer takes place from the bulk of the solution to the electrode surface. At all current density values, both $\eta - t$ curves (Fig. 1, curves 5b and 6b) and $[M^{z_1+}] - t$ curves (Fig. 2, curves 5b and 6b) are located above curves a.

The case of $i_{o1} = i_{o2}$ is out of question because $[M^{z_1+}] = [M^{z_1+}]_o$ = constant (1).

As one can see from the represented curves, at all current density values, the mass transfer of the intermediate ion manifests its influence as a delay in the approach to the steady state. Also, as was expected, the mass transfer effect appears sooner with an increase of *i*.

It can be seen from Eq. [4] in conjunction with Eq. [11] that the corrective term for the intermediate ion mass transfer vanishes with increasing time, because after some time the gradient between the concentration at the electrode surface and in the bulk of the solution remains practically constant, but the time increases; consequently η and $[M^{z_1+}]$ will tend to their steady-state values. The physical meaning that the diffusion current at the electrode surface becomes very small is that the concentration gradient at the electrode surface and its neighborhood decreases in time, the front of diffusion being shifted toward the bulk of the solution.

(*C*). The effect of the change of final ion concentration, when no mass transfer is taken into account.

As one can see from Eq. [3] to [5], the terms containing the change of final ion concentration contain the negative exponential of the overvoltage. Hence, these terms are under two opposite influences when both $[M^{(z_1+z_2)+}]$ and η increases. Consequently, due to this fact and to the complexity of the system, it is difficult to forsee the effect of the change of final ion concentration on the behavior of η and $[M^{z_1+}]$ when *t* or *i* increase.

From the computed curves it may be noticed that for all cases $i_{o1} > i_{o2}$ (curves 1c, 2c, and 3c), $i_{o1} = i_{o2}$ (curve 4c) and $i_{o1} < i_{o2}$ (curves 5c and 6c), η surpasses its value when $[M^{(z_1+z_2)+}]$ is assumed constant, increases continuously and, as far as the computation was made, no steady state is attained. Also, it can be seen that at high current densities, that is at high values of the overvoltage (curve 3c and 6c, Fig. 1) the effect of concentration polarization on the overvoltage is not noticeable within the computed time used; this is probably due to the fact that, since the mentioned exponential term is very small, the computation (the electrolysis) must be extended to longer times in order that the final ion concentration be high enough to balance the η effect.

From Fig. 2 it can be noticed that for $i_{o1} > i_{o2}$ (curves 1c, 2c, and 3c), $i_{o1} = i_{o2}$ (curve 4c), and $i_{o1} < i_{o2}$ (curves 5c and 6c), the intermediate ion concentration is at all times greater than its value corresponding to case "a." Also, for $i_{o1} > i_{o2}$ and $i_{o1} = i_{o2}$, the $[M^{z_1+}]$ is

continuously increasing; for $i_{o1} < i_{o2}$, the $[M^{z_1+}]$ decreases at the beginning, then increases over its equilibrium value. At high current densities the same discussion is valid as for the η behavior.

The different features of $[M^{z_1+}] - t$ curves is due to the fact that for $i_{o1} > i_{o2}$ and $i_{o1} = i_{o2}$, both the increase of η and the increase of $[M^{(z_1+z_2)+}]$ lead to the increase of $[M^{z_1+}]$, so that at all times $[M^{z_1+}]$ is greater than its value corresponding to case *a*. Contrarily, for $i_{o1} < i_{o2}$, the increase of η leads to the decrease of $[M^{z_1+}]$, but the increase of $[M^{(z_1+z_2)+}]$ leads to the increase of $[M^{z_1+}]$. As a result all the curves representing the decrease of $[M^{z_1+}]$ in time are attenuated in comparison with curves a, and after some time the influence of the final ion concentration manages to balance the influence of the overvoltage, and the intermediate ion concentration begins to increase.

(*D*). The real system of equations is solved when concentration polarization and both mass transfer processes are taken into account.

As one can see from the curves d, Fig. 1 and 2, the effect of the final ion mass transfer, represented by the corrective term

$$\sqrt{\frac{D_2}{\pi t}}\,([M^{(z_1+z_2)+}] - [M^{(z_1+z_2)+}]_o) = D_2\left(\frac{\partial M_2}{\partial x}\right)_{x=0}$$

in Eq. [5], consists in attenuating the effect of concentration polarization mentioned in case c.

It can also be noticed that when the time increases, the difference between curves d and a or b becomes greater.

The fact that a steady state is not attained is valid for the times for which the computation was done. In order to see the correct behavior of $\eta - t$ and $[M^{z_1+}] - t$ curves at large values of time the computation should be extended. Anyhow, it may be proved mathematically that a steady-state will not be attained for $[M^{z_1+}]$ and $[M^{(z_1+z_2)+}]$ because the cases of $\frac{d[M^{z_1+}]}{dt} = 0$, $\frac{d[M^{(z_1+z_2)+}]}{dt} = 0$ and $\frac{d\eta}{dt} \neq 0$ and also $\frac{d[M^{z_1+}]}{dt} = 0$, $\frac{d[M^{(z_1+z_2)+}]}{dt} = 0$, and $\frac{d\eta}{dt} = 0$ lead to absurd relations. The case of $\frac{d\eta}{dt} = 0$, $\frac{d[M^{z_1+}]}{dt} \neq 0$, and $\frac{d[M^{(z_1+z_2)+}]}{dt} \neq 0$ is possible, but in order to see which of the cases, this one or the case of $\frac{d\eta}{dt} \neq 0$, $\frac{d[M^{z_1+}]}{dt} \neq 0$, and $\frac{d[M^{(z_1+z_2)+}]}{dt} \neq 0$ is true, the computation must be extended to longer times. Moreover, it is preferable to use the numerical approximate solution of Eq. [10], which is more exact (see the Appendix).

Conclusions

The main effect of intermediate ion mass transfer is to delay the reaching of the steady state, without a qualitative alteration of the shape of $\eta - t$ or $[M^{z_1+}] - t$ curves.

The influence of the concentration polarization due to the change of the final ion concentration attended by the mass transfer of the final ion consists of the fact that both the overvoltage and the intermediate ion concentration exceed their values, valid when the final ion concentration is assumed to be constant, the latter at last increasing continuously.

APPENDIX

1. Let us assume that after some time $\frac{d[M^{z_1+}]}{dt} = 0$ and $\frac{d[M^{(z_1+z_2)+}]}{dt} = 0$, *e.g.*, the rates of disappearance of the intermediate and final ion from the electrode surface by electrochemical reactions are equal to the rates of their supply at the electrode surface. Then, $[M^{(z_1+z_2)+}] \to [M^{(z_1+z_2)+}]_x$ and $[M^{z_1+}] \to [M^{z_1+}]_x$; with increasing time,

$$\frac{[M^{z_1+}]_o - [M^{z_1+}]_\infty}{\sqrt{\pi D_1 t}} \to 0;$$

$$\frac{[M^{(z_1+z_2)+}]_o - [M^{(z_1+z_2)+}]_\infty}{\sqrt{\pi D_2 t}} \to 0$$

and Eq. [4] and [5] become

$$\frac{i_{o1}}{z_1\mathbf{F}}\,e^{\alpha_{a1}\eta} + \frac{i_{o2}}{z_2\mathbf{F}}\,\frac{[M^{(z_1+z_2)+}]_\infty}{[M^{(z_1+z_2)+}]_o}\,e^{-\alpha_{c2}\eta} - \frac{i_{o2}}{z_2\mathbf{F}}\,\frac{[M^{z_1+}]_\infty}{[M^{z_1+}]_o}\,e^{\alpha_{a2}\eta} = 0 \quad [4']$$

and

$$\frac{[M^{z_1+}]_\infty}{[M^{z_1+}]_o} = \frac{[M^{(z_1+z_2)+}]_\infty}{[M^{(z_1+z_2)+}]_o}\,e^{-(\alpha_{a2}+\alpha_{c2})\eta} = \frac{[M^{(z_1+z_2)+}]_\infty}{[M^{(z_1+z_2)+}]_o}\,e^{-2\alpha\eta} \quad [5']$$

(for $\alpha_{a1} = \alpha_{a2} = \alpha_{c1} = \alpha_{c2} = \alpha$)

By introducing [5'] in [4'] we obtain $\frac{i_{o1}}{z_1\mathbf{F}}\,e^{\alpha\eta} = 0$ which is absurd for both $\frac{d\eta}{dt} = 0$ and $\frac{d\eta}{dt} \neq 0$.

2. For the case of $\frac{d\eta}{dt} = 0$; $\frac{d[M^{z_1+}]}{dt} \neq 0$; $\frac{d[M^{(z_1+z_2)+}]}{dt} \neq 0$, we have

$$\frac{[M^{z_1+}]}{[M^{z_1+}]_o} = \frac{i + i_{o2}\,\frac{[M^{(z_1+z_2)+}]}{[M^{(z_1+z_2)+}]_o}\,e^{-\alpha_{c2}\eta_\infty} - i_{o1}\,e^{\alpha_{a1}\eta_\infty}}{i_{o2}\,e^{\alpha_{a2}\eta_\infty}} \quad [3'']$$

By introducing [3''] into [4] and [5] we obtain a possible system of two equations, which may represent the increase of the intermediate ion concentration on account of the increase of the final ion concentration, for very high values of time.

$$\frac{d[M^{z_1+}]}{dt} = \frac{i_{o1}}{z_1\mathbf{F}}\,e^{\alpha_{a1}\eta_\infty} + \frac{i_{o2}}{z_2\mathbf{F}}\,\frac{[M^{(z_1+z_2)+}]}{[M^{(z_1+z_2)+}]_o}\,e^{-\alpha_{c2}\eta_\infty} - \frac{i + i_{o2}\,\frac{[M^{(z_1+z_2)+}]}{[M^{(z_1+z_2)+}]_o}\,e^{-\alpha_{c2}\eta_\infty} - i_{o1}\,e^{\alpha_{a1}\eta_\infty}}{i_{o2}\,e^{\alpha_{a2}\eta_\infty}} \left(\frac{i_{o1}}{z_1\mathbf{F}}\,e^{-\alpha_{c1}\eta_\infty} - \frac{i_{o2}}{z_2\mathbf{F}}\,e^{\alpha_{a2}\eta_\infty}\right) - \frac{[M^{z_1+}]_o}{\sqrt{\pi D_1 t}} \left[\frac{i + i_{o2}\,\frac{[M^{(z_1+z_2)+}]}{[M^{(z_1+z_2)+}]_o}\,e^{-\alpha_{c2}\eta_\infty} - i_{o1}\,e^{\alpha_{a1}\eta_\infty}}{i_{o2}\,e^{\alpha_{a2}\eta_\infty}} - 1\right] \quad [4'']$$

$$\frac{d[M^{(z_1+z_2)+}]}{dt} = \frac{i_{o2}}{z_2\mathbf{F}}\left(\frac{i_{o1}}{i_{o2}}\,e^{\alpha_{a2}\eta_\infty} - \frac{[M^{(z_1+z_2)+}]}{[M^{(z_1+z_2)+}]_o}\,e^{-\alpha_{c2}\eta_\infty}\right) - \frac{1}{\sqrt{\pi D_2 t}}\,([M^{(z_1+z_2)+}] - [M^{(z_1+z_2)+}]_o) \quad [5'']$$

Methods for Characterizing the Structure and Electrochemical Behavior of Teflon-Bonded Pt Electrodes

J. Giner,* J. M. Parry,* S. Smith, and M. Turchan

Tyco Laboratories, Incorporated, Waltham, Massachusetts

ABSTRACT

Experimental measurements designed to test a specific model of the Pt-Teflon bonded electrode are described. The model assumes that the catalyst agglomerates are filled with electrolyte and that the Teflon binder creates hydrophobic channels, providing effective gas penetration. The electrochemical measurements of surface area and distribution of adsorbed charge formed by reduction of CO_2 or oxidation of C_3H_8 were carried out for a series of electrodes of different structure. Comparisons are made with BET surface area and pore volume distribution. The results presented are consistent with the proposed model.

The Teflon-bonded electrode (1, 2) represents a very efficient structure which allows extensive utilization of the catalyst and therefore very high current densities at relatively low polarization. Although this electrode has been extensively used in fully engineered fuel cells and in many catalyst screening programs, relatively little is known about its working mechanism. In particular, the degree of utilization of the catalyst under various working conditions is an unknown factor.

Based on our experience with this type of electrode, we have developed a qualitative description of the mechanism based on a double-porosity model (3, 4). We assume that the catalyst particles form porous, electronically conductive agglomerates which under working conditions are completely flooded with electrolyte. These catalyst agglomerates are held together by the Teflon binder which also creates hydrophobic gas channels. When current is drawn from the electrode, reactant gas diffuses through the hydrophobic channels, dissolves in the electrolyte contained in the agglomerates, and reacts on available sites of the catalyst particles. The number of sites available depends on the rate of diffusion and the rate of reaction on those sites near the surface of the agglomerate. The model, of course, assumes that all the catalyst particles are in good electronic contact with the external circuit and good ionic contact with the electrolyte. Efficient utilization of the catalyst surface then is defined by mass transport rates in the agglomerate.

We can further separate (5) the utilization of the catalyst surface into a "transversal utilization" of the electrode, which depends on the internal *IR* drop, and a "radial utilization" of the flooded agglomerates, which depends on the slow diffusion of the reactant gas in electrolyte flooding the agglomerate.

In the present paper, we present details of experimental tests to assess the validity of this model and describe the development of methods to determine some of the characteristic parameters of the electrode. A mathematical treatment of the model is given elsewhere (5). We have measured (*a*) that fraction of the catalyst surface which maintains the necessary electronic and ionic contacts for normal operation; (*b*) the effect of Teflon content on the electrode structure and electrode performance; (*c*) the values of microporosity of the flooded agglomerate and macroporosity of the electrode; and (*d*) the effective size of the agglomerate (*i.e.*, the length that the reactant gas diffuses into the flooded agglomerate under the effect of a concentration gradient). We have also examined the effect of the resistance of the electrolyte from the front to the back face of the electrode.

* Electrochemical Society Active Member.

The work discussed here was carried out in the course of a program to determine the intrinsic catalytic activity of different Pt blacks for the anodic oxidation of propane. The working conditions were those under which the propane oxidation is most efficient (85% H_3PO_4 and 150°C). Although some of the results obtained are specific to these conditions, most of the conclusions should be valid in understanding those mechanisms that enable the Teflon-bonded structure to operate efficiently as a gas diffusion electrode in a fuel cell under more general conditions.

Experimental

The Teflon-bonded electrodes were prepared by sieving the commercial Pt black (Englehard Industries) through a 325-mesh screen, and mixing the desired proportions with Teflon 30 dispersion and water. The resulting paste was rolled out to a thin sheet, and pressed into gold-plated tantalum screen (50-mesh, 3-mil wire). Electrodes with 20 ± 1 mg Pt, and varying Teflon ratios (15-50% by weight PTFE), were cut out in disks of 1.13 cm^2 geometric surface area, dried for several hours under vacuum at 100°C, and finally sintered at 250°C for 5 min under N_2.

The electrochemical measurements were carried out in 85% H_3PO_4 at 150°C using the "floating electrode" technique (6) with prepurified N_2 and C_3H_8 (99.99%).

The "floating electrode" cell, as modified for this work, is shown in Fig. 1. The body of the cell consisted of a Pyrex U-tube fitted with a working electrode compartment and a counterelectrode compartment. The working electrode was supported in an electrode holder on a ring of Pt wire and kept in position by a slight downward pressure of a spring of Pt wire, which was also the electronic contact to the electrode. A Teflon collar sliding on the main support compressed the spring, keeping the electrode in position. The reference electrode was a "dynamic hydrogen electrode" (7) situated inside the main support tube. The difference between this reference and the reversible hydrogen electrode was found by calibration against a hydrogen "floating electrode" at open circuit in each experiment. It was found to be constant within a millivolt each day, with a value between 35 and 50 mV. The distance between the Luggin capillary tip and the floating electrode is fixed by the electrode holder configuration and was, therefore, identical for each test. This distance was approximately 2 mm—about twice the external diameter of the capillary.

A liquid seal filled with H_3PO_4 provided a gastight working electrode compartment.

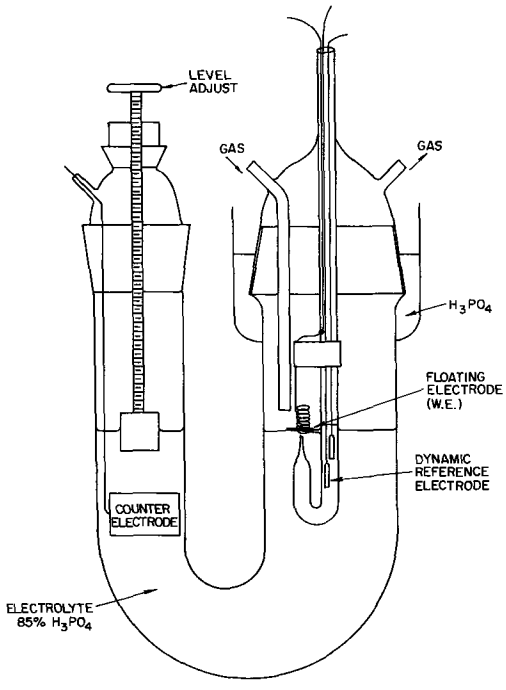

Fig. 1. Floating electrode cell

The level of the electrolyte was raised to "float" the electrode on the surface by lowering a Teflon plunger in the counterelectrode compartment.

The "floating electrode cell" was placed in an oven and maintained at 150°C. The gases (N_2, C_3H_8) were humidified over water at 93.50° ± 0.05°C (corresponding to 600 mm Hg) to keep the electrolyte concentration at its optimum value (8) of 85%.

Electrochemical measurements (described in detail below) were made using a Wenking fast rise potentiostat and a laboratory-built galvanostat. The switching from potentiostatic to galvanostatic mode was achieved with High Speed Mercury Relays. While in the galvanostatic mode, the *IR* drop between floating electrode and the tip of the Luggin capillary was determined using an interrupter technique. The voltage-time curves during galvanostatic studies were recorded on a X-Y recorder.

All quoted potential values are referred *vs.* the reversible hydrogen electrode and are corrected for *IR* drop (resistance between working electrode and Luggin capillary tip was usually about 0.6-0.9 ohm).

Effect of Teflon content on electrode performance.—Before proceeding to more detailed experiments, it was necessary to show that the Teflon content of the electrodes was at a level where the major assumptions of the model were realized in practice. Accordingly, polarization curves for the anodic oxidation of propane were measured for a series of electrodes prepared from the same batch of a commercial platinum black (using the same catalyst load of 20 mg/cm^2) but with Teflon contents varying from 15 to 50% by weight.

The measurements were carried out potentiostatically starting from 200 mV, at 50-mV increments, after waiting 5 min at each potential.

It can be seen from Fig. 2 that, in the range of 20-40% Teflon, the electrochemical activity using the current/geometric cm^2 at 400 mV *vs.* RHE as an indicator is practically identical. At both 15 and 50% Teflon, the activity has dropped off. At 15%, the electrode is "too hydrophilic" so that there are long gas diffusion paths. At 50% Teflon, the electrode is "too hydrophobic" so that there is poor electrolyte contact. The value of the peak current/geometric cm^2 increases with Teflon content in the range of 20-40% Teflon. This would indicate that the peak current is a function of electrode structure, while the current at 400 mV is more indicative of the intrinsic activity of the black. The remainder of the tests described here were carried out with 30% Teflon electrodes unless otherwise noted.

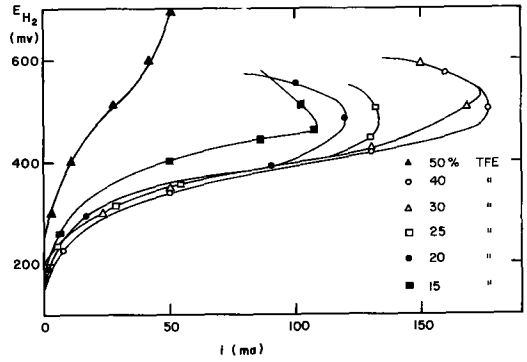

Fig. 2. Effect of Teflon content on performance of Teflon-bonded platinum electrode.

Determination of the surface area.—One of the most important factors that needs to be determined is the real surface area of the electrode that is in contact with the electrolyte and has a conductive path to the current-collecting screen under normal fuel cell operating conditions (in this case a floating electrode). For these and all the following experiments, nitrogen was used as the inert gas.

The conventional method of determining the electrochemical surface area of a Pt electrode is the determination of the extent of hydrogen adsorption (Q_H). Unfortunately, with electrodes of this type, this method gives ambiguous results due to the hydrogen evolution. As is shown in Fig. 3, hydrogen evolution can occur at potentials well above the reversible hydrogen potential. This occurs because the electrode structure permits very rapid diffusion of H_2 away from the surface so that the equilibrium H_2 partial pressure corresponding to the electrode potential is never attained. The extent of hydrogen evolution varies with the rate of nitrogen flow and the electrode structure so that the reliability of the data is affected. For this reason, we have determined the surface area by the reduction of potentiostatically chemisorbed oxygen. For these measurements, it is necessary to select a potential and adsorption time at which sizeable and reproducible chemisorption occurs, but at which no oxide formation or oxygen dissolution into the Pt lattice occurs. An adsorption potential of 1050 mV and adsorption time of 3 min were found most convenient for these measurements. The amount of charge (Q_{PtO}) determined by galvanostatic stripping at 10 mA/cm^2 was found to be very reproducible if the potential and time are well controlled, as shown in Fig. 4. The errors associated with random variation in the adsorption potential and adsorption time were carefully examined. Figure 5 shows the effect on the charge of changing the adsorption potential by a series of 20-mV increments. For convenience, the change is

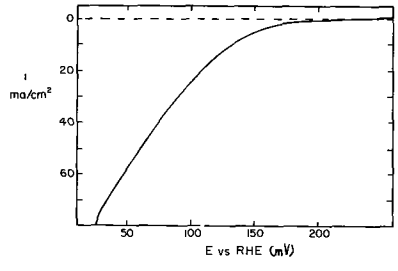

Fig. 3. H_2 evolution from PTFE-bonded Pt electrode under fuel cell conditions with N_2 flow; 85% H_3PO_4, 150°C; potential sweep: 10 mV/min.

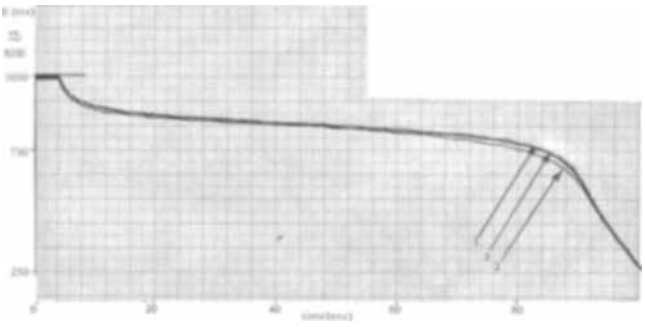

Fig. 4. Reproducibility of "electrochemical surface" determination by cathodic reduction of Pt-O. Pt-Teflon (20% TFE), 85% H_3PO_4, 150°C.

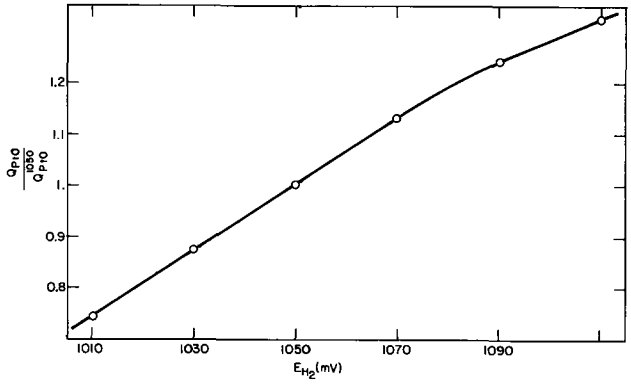

Fig. 5. Effect of potential on charge of chemisorbed oxygen

referred relative to the charge at 1050 mV. It can be seen that for a change of 10 mV (which is well above the maximum random variation to be encountered) the difference is about 7%. Figure 6 shows the effect on charge of varying the waiting time at 1050 mV. About 96% of the "steady-state" coverage is reached in 5 min, while in 3 min the coverage is 92%. In order to avoid the strongly bound oxygen which is formed after long waiting times, it was decided to measure all the charges after 3 min. Since this does not correspond to a steady-state coverage, it was necessary to control the adsorption time to better than 5 sec in order to obtain reproducible results.

A correlation between Q_{PtO} and Q_H was obtained by making measurements on the Teflon-bonded electrodes in a submerged rather than a floating position. Under these conditions, no hydrogen evolution is observed since only small quantities of dissolved H_2 are needed to satisfy the thermodynamic requirement at potentials above the reversible electrode. Table I shows that an average value for the Q_H/Q_{PtO} ratio is 0.58. Based on a saturation coverage of hydrogen on Pt of 0.21 mcoulomb/cm² of real surface, it can be concluded that 1 mcoulomb of adsorbed charge under the specified conditions of potential and time corresponds to 2.8 cm² of surface.

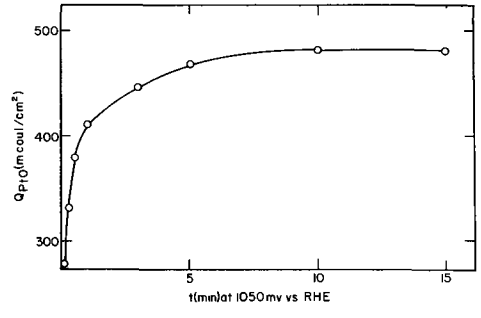

Fig. 6. Effect of waiting time at E = 1050 mV on galvanostatically determined Q_{PtO}.

Table I. Comparison of oxygen coverage formed at 1050 mV with hydrogen coverage (submerged electrode)

Electrode	% Teflon	Oxygen charge, mcoulombs/cm²	Hydrogen charge, mcoulombs/cm²	Q_H/Q_{PtO}
95C	20	484	291	0.61
94F	25	510	306	0.60
72A	30	540	297	0.55
98E	40	512	287	0.56
106D	14	532	307	0.58

Table II. Comparison of "electrochemical surface area" and BET surface area of Pt-Teflon electrodes (40% PTFE)

Electrode	Time in use (hours)	Measured Q_{PtO} (mcoulombs/cm²)	Calculated electrochemical surface (cm²/cm²)	Measured BET surface (cm²/cm²)
98B	0.5	825	2.3×10^3	2.6×10^3
98B	48	470	1.3×10^3	1.4×10^3
108E	0.5	650	1.8×10^3	3.3×10^3
108E	24	420	1.2×10^3	1.2×10^3

Long-term surface decrease.—When working at 150° in phosphoric acid, one of the problems encountered is the decay of surface area which is greatest in the first few hours, and then continues for days at a slower rate, as shown in Fig. 7. This surface decrease is due to sintering rather than loss of platinum as was shown by weighing the electrode after use. As is discussed later, this behavior was confirmed by BET measurements. X-ray diffraction measurements also showed an increase in crystallite size. All the surface measurements discussed here were carried out in a short enough period of time to be able to disregard change in area, due to sintering.

Comparison of electrochemical surface area and BET area.—By comparing the BET value of the surface with the electrochemical surface, calculated using the relationship between Q_{PtO} and real surface area of 2.8 cm²/mcoulomb, it is possible to determine the fraction of available Pt (*i.e.*, fraction of Pt which is both wet with electrolyte and in good electronic contact with the current collector). Table II shows a comparison of the electrochemical surface area and BET surface area for two 40% Teflon-bonded electrodes measured shortly after immersion and at various times up to 2 days in the electrolyte. In the case of electrode 98B, the initial and final values of the BET area and that determined electrochemically are surprisingly close. In the case of electrode 108E, the electrochemical surface area is 55% smaller than the ini-

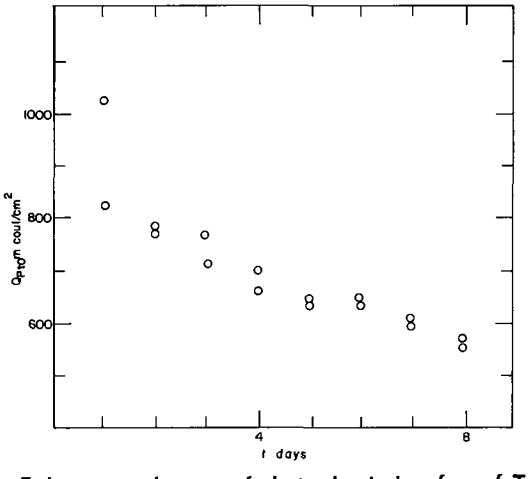

Fig. 7. Long-term decrease of electrochemical surface of Teflon-bonded electrode in 85% H_3PO_4 at 150°C.

tial BET value, but after use both surfaces are equal. This can be interpreted by saying that in good performing electrodes all the Pt surface is electrochemically available, at least at the current density of 10 mA/cm², used for the cathodic reduction of the PtO. The difference between the initial values with electrode 108E can be due to excessive wetproofing, which is highly probable since 40% Teflon content is about critical for this catalyst. For the comparisons of Table II, the surface area of the Teflon particles can be neglected since it is much smaller than that of Pt.

Comparison of electrochemical surface of completely immersed electrode under fuel cell conditions.—We have shown that the same value for the electrochemical surface area is obtained for the electrode in both the floating and fully submerged conditions. Table III shows the Q_{PtO} values for a number of electrodes with Teflon content varying from 14 to 40% under both circumstances. Complete wetting of the submerged electrode was ensured by evolving H_2 at the electrode for 2 min to remove any inert gases by a purging action; residual H_2 was readily oxidized before the surface area measurement. It can be seen that in this range of Teflon content both values are practically equal, indicating that all the Pt surface is electrochemically available in the floating electrode. This comment is strictly true only at the measuring current density of 10 mA/cm² but probably holds at significantly higher current densities, as is discussed below.

Effect of current density on cathodic stripping of chemisorbed oxygen under fuel cell conditions.—In order to study the Pt utilization at different current densities and to obtain an indication of the value of the *IR* drop in the electrolyte within the electrode structure, experiments were made in which the oxygen film formed potentiostatically at 1050 mV was reduced at a series of current densities. It can be seen from Table IV that the effect of current density on Q_{PtO} from 10-100 mA/cm² is only 3.7%. Analysis of the galvanostatic stripping curves shows no significant differences between the 10 and 100 mA/cm² curves. All these data indicate that up to 100 mA/cm² no measurable *IR* losses exist.

[1]According to our model, and using a specific conductivity of 0.55 ohm^{-1} cm^{-1} for 85% H_3PO_4 at 150°C (9), the ionic resistance between the electrolyte side and the gas side of an electrode with 50% macroporosity and 80% microporosity (as defined below) and 0.2 mm thick should be between 0.1 and 0.2 ohm-cm² depending on the tortuosity factor.

These results and calculations show again that practically 100% of the catalyst is wetted by the electrolyte. The much lower fraction of 2-5% of wetted catalyst reported by Austin and Almaula (10) can be due to the use of inefficient electrodes, in spite of the high currents obtained when used as H_2-anodes. Hydrogen oxidation can be misleading because of the very large exchange currents of this reaction on Pt, especially in acid solutions, so large that even electrodes with a very poor Pt utilization can deliver several A/cm². From this point of view, the oxidation of propane (Fig. 2) is a reaction more suited to test the utilization of a catalyst in a porous electrode structure because of its low exchange current.

The determination of microporosity and macroporosity.—For the mathematical treatment of Teflon-bonded electrodes, microporosity and macroporosity are extremely important. As microporosity we define the fraction of the flooded agglomerate, which is occupied by the electrolyte, while macroporosity can be defined as the fraction of the electrode which is not filled by the flooded agglomerate. According to the latter definition, the volumes occupied by Teflon, wire, and gas are added together, which is convenient for the mathematical treatment of Teflon-bonded electrodes when the gas transport along the unflooded pores is fast.

These definitions of macro- and microporosity are operational definitions different in general from the more frequently used concepts.

Both so defined "microporosity" and "macroporosity" can be determined by a careful gravimetric procedure involving the accurate determination of the weight of all the components of the dry electrode and of the amount of electrolyte which can be adsorbed in the electrode.

Table V shows these values for a large series of electrodes obtained with the same amount of Teflon but with different kinds of platinum black. It can be seen that microporosity changes from 80-90%, while macroporosity changes between 50 and 72%. A value of 80% for microporosity has also been reported by Horowitz (11) who also assumes the same qualitative model.

The accuracy of the gravimetric measurements on the electrode is poor due to the possible formation of droplets on the electrode surface. In order to improve the accuracy of these determinations, spheres of 0.9-cm diameter were prepared using mixtures of 30% Teflon by weight and commercial Pt black. In this way, the external surface of the mass is minimized and the error due to droplets is reduced. After sintering, the density of these spheres is the same as the calculated density of the Pt-Teflon mixture on the electrodes. Table VI shows the results obtained with two of

Table III. Comparison of "electrochemical surface area" of floating electrode and submerged electrode

#1	438.8	207.3	193.3	46	89
#2	504.6	216.2	213.1	40	90

these spheres. It can be seen that the values of microporosity and macroporosity measured on the spheres are in good agreement with the values obtained with the electrode.

Agglomerate size.—During the present work, no attempts were made to determine the agglomerate size which is an important characteristic of the Teflon-bonded electrode since it determines in part (5) the radial utilization of the catalyst in the agglomerate. However, methods have been devised to do these determinations in the immediate future. A first, direct method of determining the diameter of the agglomerate is the use of a scanning electron microscope. A second method is an indirect method based on the reduction of CO_2 which, under the conditions of the present work (85% H_3PO_4 and 150°C) can be made to occur under exclusive diffusion control. This work will be the subject of another publication.

Conclusions

From this work, the following conclusions can be reached:

1. The conventional method of determining the surface area of Pt electrodes using anodic charging curves is not appropriate to determine the area of Teflon-bonded Pt electrodes under normal fuel cell conditions, due to excessive H_2 evolution
2. A method based on galvanostatic reduction of potentiostatically chemisorbed oxygen can be developed to great precision.
3. Under normal fuel cell conditions, all the Pt surface of Teflon-bonded electrodes in good electronic contact with the current collection grid is found to be in good ionic contact with the bulk of the electrolyte, indicating that the model of the flooded agglomerate is correct.
4. The *IR* drop between the front and back of the electrode, even at 100 mA/cm^2, is negligible for an electrode with 30% Teflon.
5. The microporosity of Teflon-bonded electrodes is about 80-90%, while the macroporosity varies from 50 to 72%.
6. Under the conditions used in this work, the performance (current density at a practical potential of 400 mV *vs.* RHE) of a Pt-Teflon electrode as a propane anode in 85% H_3PO_4 and at 150°C is almost independent of Teflon content in the range 20-40%, although the peak current increases with increasing Teflon content. The performance decreases sharply for Teflon contents of 15 and 50%.
7. In 85% H_3PO_4 and at 150°C, a decrease of the Pt surface is observed which can be completely attributed to sintering. This surface decrease is accompanied by growth of crystallite size which occurs even at potentials much below those at which PtO can be formed.

Samarium, Europium, and Ytterbium Electrode Potentials in LiCl-KCl Eutectic Melt

K. E. Johnson[1] and J. R. Mackenzie[2]

Department of Chemistry, Sir John Cass College, London, England

ABSTRACT

Samarium, europium, and ytterbium displace the alkali metals from their molten chlorides, forming the divalent species Sm(II), Eu(II), and Yb(II) in solution. Progressive coulometric reduction of solutions of $SmCl_3$, $EuCl_3$, and $YbCl_3$ in LiCl-KCl at 450°C enabled the redox potentials to be measured *vs.* 1m Pt(II)-Pt(0): Sm(III)-Sm(II) −1.729 ± 0.006V; Eu(III)-Eu(II) −0.554 ± 0.007V; Yb(III)-Yb(II) −1.375 ± 0.003V. Potentials of ytterbium systems starting from both $YbCl_3$ and $YbCl_2$ were followed over a ~200°C interval and from $\partial E^{\circ\prime}/\partial T(\mathrm{Yb}) - \partial E^{\circ\prime}/\partial T(\mathrm{Ag}) = 0.66 \times 10^{-3}$V deg^{-1}, ΔS° and ΔH° for the reaction $YbCl_3 \rightarrow YbCl_2 + \frac{1}{2}Cl_2$ in LiCl-KCl at 450°C were found to be 22 cal/deg^{-1} mole^{-1} and 54.5 kcal/mole^{-1}, respectively, close to the values for pure $YbCl_3$ decomposition. No evidence of disproportionation of Sm(II), Eu(II), and Yb(II) was found but scrupulous precautions were needed to keep the solvent free from impurities which readily react with the highly reducing ions, especially Sm(II). Considerable experimental details are included.

The existence of the divalent state for some rare earth elements is evident by the formation of well-defined crystalline halides, LnX_2. The stability of LnX_2 with respect to disproportionation is given by the free energy

$\Delta G^\circ_{\mathrm{disp.}} = 2\Delta G^\circ_{f(LnX_3)} - 3\Delta G^\circ_{f(LnX_2)}$ and, using a value of $\Delta S^\circ_{\mathrm{disp.}}$ for $NdCl_2$ of −15 eu, Polyachenok and Novikov (1) estimated $\Delta G^\circ_{\mathrm{disp.}}$ for all the solid rare earth dichlorides. Their calculations suggest that $PmCl_2$, $SmCl_2$, $EuCl_2$, $TmCl_2$, and $YbCl_2$ should be stable, and $NdCl_2$ and $ErCl_2$ might also exist. It is known that all the divalent rare earth ions may be incorporated into alkaline earth fluoride crystals (2).

Instability of the species Sm(II), Eu(II), and Yb(II) in the liquid state has been postulated to account for incomplete reduction of trihalides by hydrogen (3-5), but it has been pointed out (6) that the disproportionation reaction may be augmented by reaction of the rare earth metal with the material of the reaction vessel. Recent tensimetric studies (7-9) of $SmCl_3$, $EuCl_3$, and $YbCl_3$ showed that $LnCl_3$ was unstable with respect to dissociation into $LnCl_2$ and chlorine rather than $LnCl_2$ being unstable with respect to disproportionation.

From boiling points and other thermal data Polyachenok and Novikov (10) found $\Delta G^\circ_{1400^\circ}$ for the disproportionation of $SmCl_2$ (gas) to be +30 kcal/mol $SmCl_2$. Large positive values of $\Delta G^\circ_{\mathrm{disp.}}$ were also indicated for $EuCl_2$ and $YbCl_2$ but ΔG°_{1330} for $NdCl_2$ was −14 kcal/mol in agreement with the observation that $NdCl_2$ yielded only $NdCl_3$ and Nd on sublimation.

The rare earth dichlorides are soluble in water, but all except $EuCl_2$ rapidly reduce the solvent with evolution of hydrogen. In molten chloride solvents stable solutions might be expected in the light of the thermodynamic data reviewed above. Thermographic studies (11) of the systems KCl-$SmCl_3$-$SmCl_2$ and KCl-$YbCl_3$-$YbCl_2$ indicated the formation of compounds $LnCl_2 \cdot 2KCl$ and $LnCl_3 \cdot 3KCl$ and complex ions $LnCl_4^{-2}$ and $LnCl_6^{-3}$ were postulated to exist in the melts. There was no mention of instability of $SmCl_2$ and $YbCl_2$. Contrary to this, Campbell (12) postulated disproportionation of Sm(II), Eu(II), and Yb(II) in molten LiCl-KCl eutectic. He first estimated the standard redox potentials from chronopotentiometric data. Then, after exhaustive cathodic reduction of the Ln(III) species at controlled potential, the rate of change in concentration of Ln(III) and Ln(II) was obtained by monitoring the change in redox potential with time. Chronopotentiograms for the reduction of Ln(III) were recorded after successive exhaustive reductions and reoxidations at controlled potential. The quantity $i\,\tau_{1/2}$ (i = cathode current density, τ = transition time) decreased at each cycle, and this was said to rule out an oxidation process as responsible for the slow drift of redox potential. Dark deposits, formed in the vicinity of the electrode, were tentatively identified as the rare earth metal and taken as confirmation of a disproportionation process.

Theoretical calculations of emf's of formation cells in pure chlorides (13) do not support a disproportionation of solid or liquid $SmCl_2$. The Sm(III) − Sm(II) and Sm(II) − Sm(O) potentials calculated were −1.443 and −3.891V at 450°C and −1.171 and −3.559V at 1000°C. The present study was aimed at measuring the electrode potentials of Sm, Eu, and Yb in molten LiCl-KCl eutectic. Although only the redox potentials were obtained, the stability of the divalent halides in solution in LiCl-KCl has been established. The need to maintain solvent and solute of high purity became apparent in the investigation, and it seems pertinent to include in considerable detail the means of accomplishing this and to derive the possible magnitude of errors in the formal potentials.

Basic Equipment

Vacuum manifold.—The system employed a single-stage rotary pump in conjunction with a 1½ in. mercury diffusion pump. The rotary pump was of the air ballast type, and the system was capable of maintaining pressure lower than 5 x 10^{-5} Torr. In view of the corrosive nature of the gases pumped through the system, however, particular attention was paid to trapping, and adequate protection of the pumps was only assured by the use of three liquid nitrogen traps each with a cold region some 20 cm in length. These were interposed between the manifold and pump in a "back to back" arrangement.

Measurement of pressure down to 10^{-3} Torr was made with Pirani gauges placed in the high vacuum manifolds and in the backing systems. Lower pressures entailed the use of a Penning gauge. The gauge heads

[1] Present address: Department of Chemistry, University of Saskatchewan, Regina, Saskatchewan, Canada.
[2] Present address: Department of Chemistry, The University, Southampton, England.
Key words: samarium, europium, ytterbium, redox, melt, disproportionation.

were protected from chlorine and hydrogen chloride by further trapping. In consequence all pressures quoted later in this text refer to the partial pressure of "permanent" gases in the vacuum system.

Argon purification.—The purification reagents were contained in four stainless steel tubes (¾ in. OD and 32 in. in length) assembled in pairs. One pair was charged with copper made by hydrogen reduction of cupric oxide "wire," the other with tightly packed turnings of titanium-zirconium alloy. Each tube was closed by silver-soldering stainless steel plates across the ends and was connected into the system by side arms of copper. Either 3/16 in. OD copper tube or glass was used throughout with connections made by Simplifix couplings wherever possible. Silicone rubber pressure tubing was used for connections between copper tube and glass apparatus. Pressures lower than 5×10^{-3} Torr were readily attained in the system even with the reagent tubes at 700°C.

Hydrogen chloride.—This was generated from Analar hydrochloric and sulfuric acids. The concentrated acids were allowed to drip from dropping funnels down the two arms of a Y-shaped column packed with porcelain helices. Hydrogen chloride, generated as they mixed in the vertical section, was partially dried by counter current contact with sulfuric acid, and by bubbling through the concentrated acid in a wash bottle. The latter also constituted a rough indication of the rate of flow. Final drying was effected by passage through molecular sieve cooled in a slush bath of dry ice and acetone.

Chlorine.—Tank chlorine was scrubbed with H_2SO_4, dried by passage over freshly fused $CaCl_2$, and then over anhydrous $MgClO_4$. Although $FeCl_3$ was condensed with HCl in the final drying of that gas, it possibly remained as a contaminant of Cl_2.

Furnaces.—Generally, Nichrome V in either strip or wire was wound on mullite formers, using a lathe to obtain uniform tension and spacing of turns. On smaller furnaces, where finer wire was used, turns per inch were increased near the end of each tube for a distance equal to about 1½-2 times the diameter of each tube. This helped to offset the greater loss of heat at the ends of the tube and to ensure a more uniform hot zone.

For the argon purification furnace, some 25 ft of stainless steel sheathed Pyrotenax cable, taking a total load of 2 kw at 230V, was run backwards and forwards down a 2 ft length of 2 in. diameter mullite tube and held in position by Nichrome straps.

The two vertical tube furnaces employed for melt purification and electrochemical measurement were each suspended by a pulley and counterweight system in vertical Dexion guides to enable them to be raised or lowered as required.

Temperature measurement and control.—Temperatures were measured with calibrated T1/T2 alloy thermocouples and a Cropico potentiometer, also used for electrochemical measurements.

Temperature control of the argon purification furnace was maintained by a Fielden controller of the on/off type.

A more elaborate proportional control system was used for melt purification and electrochemical measurement to attain a temperature stability within the melt better than ±0.2°C. A T1/T2 alloy thermocouple with a cold junction cooled in ice was used as sensing element and was placed close to the furnace windings. The signal actuated an A.E.I. T.C.3. Proportional Controller the output from which, after amplification by a magnetic pre-amplifier operated a 2 kw saturable core reactor (Savage Transformers). This system (Fig. 1) had the advantage of high stability over long periods and was little affected by fluctuations in supply voltage. Operating temperatures could be easily altered, and,since the slave unit was a current control device,

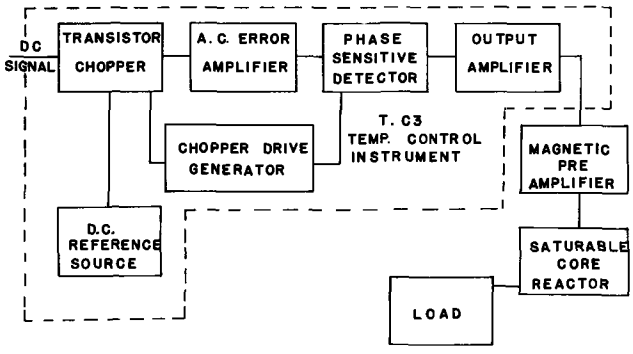

Fig. 1. Proportional temperature control system

there was little need for careful matching of load resistance to supply voltage. Heavy gauge windings could consequently be used on the furnaces without employing an intermediate matching transformer.

Coulometers.—Either a Metrohm coulometer or one of the following systems was used for the coulometric generation of solute species.

In the first system a Wadsworth Potentiostat (Southern Instruments Ltd.) was used to deliver constant current to the electrolytic cell during measured periods of time by maintaining a constant potential across a 2000 ohm potentiometer placed in the anode circuit of the cell. The current was monitored by measuring the iR drop across a 10 ohm standard resistor.

In the second system current of approximately the desired value was supplied from an H.T. battery to the cell via a resistance net-work and iR drop across a suitable resistor in series with the cell integrated over the time of generation by a mechanical integrator (Electro Methods). Calibration of this instrument was achieved by substituting a 10 ohm standard resistor for the cell and monitoring the current at short intervals over a period of an hour or more. Over narrow ranges of current a substantially linear response was observed and a precision of better than 0.2% was obtainable in the measurement of charge (14).

Preparation of Solvent

Reagents

Preliminary investigation showed that Analar KCl as supplied could contain 2-5 %ww of water removable by oven drying at 140°C, but no significant weight loss was observed on subjecting dried LiCl from freshly opened bottles to the same treatment. The entire contents of new 250g bottles of LiCl were weighed into a 5 kg jar and the calculated amount of finely powdered, oven dried, KCl added. The jar was then sealed and the contents well mixed by tumbling.

Apparatus

A filter tube containing the eutectic powder was supported inside a glass envelope by a flanged glass adaptor and provision made to collect melt either in the round bottom of the envelope for immediate electrochemical study, or in narrow, vertical, extension tubes fused to the bottom. Constrictions in the walls of these tubes enabled portions of melt each 50-70 ml in volume to be sealed off out of contact with the atmosphere. Vacuum or argon could be applied independently above or below the column and hydrogen chloride or chlorine could also be passed up the column and out to waste via a sulfuric acid guard trap.

The whole of the above assembly was supported at the flanges by a water-cooled brass annulus placed above a vertical tube furnace.

Procedure.—Hydrogen chloride treatment.—During early experiments the procedures adopted for melt purification closely followed those of Laitinen *et al.* (15). It was found, however, that extended periods of vacuum drying at room temperature did little to re-

duce the water content of the mixture. Therefore the temperature was raised slowly under vacuum immediately subsequent to charging the apparatus, while a manifold pressure of less than 10^{-3} Torr was maintained above and below the column of powder. With the onset of rapid evolution of water vapor the temperature was held steady until fluidization ceased and the pressure had returned to the above figure, when heating was resumed. At 300°C, after leaving overnight under vacuum, hydrogen chloride was admitted to the system and passed up through the powder at a pressure slightly in excess of atmospheric and the temperature again raised until sintering and finally melting took place. Under these conditions further copious evolution of water was apparent from the appearance of condensation in the upper portions of the filter tube, and the pressure above the filter was reduced to *ca.* 5×10^{-2} Torr for intervals of a few minutes to remove it.

After the greater part of the hydrogen chloride had been pumped off at pressures of the order of 10^{-3} Torr, vacuum was applied below the sinter and the melt slowly allowed to filter into the receiver. Careful admission of argon above the melt allowed the rate of filtration to be controlled.

Chlorine treatment.—The procedure adopted in the use of chlorine for melt pretreatment largely followed that already described for hydrogen chloride. Removal of dissolved chlorine prior to filtration was accomplished by evacuation above the sinter, 2-3 hr at a pressure of 5×10^{-4} Torr sufficing to remove all traces of the yellow coloration attributable to the gas in solution. Some HCl remained in Cl_2-treated melts, however.

With chlorine treatment no carbonaceous material was formed as melting occurred and it may be concluded that the heavy metal impurities, filtered off in this residue after hydrogen chloride treatment (16), were retained in solution.

Magnesium treatment.—Magnesium turnings were introduced prior to filtration while a stream of argon was bubbled through the melt in the filter. The best scavenging of the melt took place if Mg was left in contact overnight under vacuum.

Electrolysis.—Electrolysis was used as an alternative to Mg treatment.

The electrode assembly comprised a cylindrical tungsten cathode mounted in a tubular glass skirt coaxial with a graphite anode. The latter was a sliding fit in the short extension inside the skirt of the Pyrex tube supporting the assembly from a long tip cone joint (B34). This was sealed off to form a stopper to fit the top of the normal filter tube assembly used in gas pretreatment and was provided with two tungsten-to-glass seals. Molybdenum wires, one passing down the inside of the support tube, the other down the outside, welded to the tungsten lead-ins, enabled vacuum-tight electrical connection to be made with the two electrodes. Holes provided in the top of the skirt and of the support tube served the dual purpose of providing passage for these wires and of equalizing pressures throughout the assembly when in use. When in position in the filter tube the bottom of both electrodes finished about 1 cm above the sintered disk.

The glass skirt was cleaned in hot 40% perchloric acid and then well washed with distilled water before drying. The tungsten cathode was electropolished by anodization at 20V in 5*N* aqueous sodium hydroxide containing *ca.* 2 %wv of sodium nitrite. It was then well washed in distilled water and vacuum dried. New spectroscopic quality graphite rods were used as anodes, but it was necessary first to out-gas these by heating under high vacuum (10^{-5} Torr) to 500°C and then allowing them to cool in an atmosphere of chlorine.

Electrolysis of Cl_2-treated melt under a pressure of $<5 \times 10^{-3}$ Torr was carried out at 2.5V. Currents of the order of 40-60 mA were observed initially, but these decayed over periods of 6-12 hr by a factor of ten to values corresponding to cathode current densities less than 1.0 $\mu A/mm^2$.

Precautions.—All glassware was washed with hot detergent (R.B.S. 25 or Quadrilene) followed by boiling with either 30% perchloric acid or 1:1 hydrochloric acid and water, several rinses with hot distilled water and oven drying at 140°C. Water was removed from tubes by heating them with electrothermal heating tape throughout the melt pretreatment.

Preparation of Rare Earth Halides

The preparation of the trichlorides and dichlorides of Sm, Eu, and Yb has been mentioned briefly in connection with spectroscopic studies (17, 18). Details are discussed elsewhere (19).

Electrochemical Procedure

Metal ion-metal potentials.—Each electrode compartment was prepared by fusing a filter tube to the lower end of a "long tip" B19 cone, the upper end of which was joined to a B19 socket. A small hole in the wall of the compartment some 5 cm above the frit provided ingress for the argon atmosphere in the flask.

Platinum electrodes were made from 1 cm^2 foil attached to Pt wire sealed in 2 mm bore Pyrex tubing. The Pyrex sheath passed through a silicone rubber bung which served to support the electrode inside the compartment.

A samarium electrode was prepared by welding Pt to Sm with a strip of gold foil between the two metals.

A 250 ml multinecked, Quickfit flask received the HCl-treated and filtered melt which was then maintained at a temperature of 450° ± 2°C by a heating mantle controlled by an energy regulator of the Simmerstat type. Three electrode compartments were introduced, two bearing Pt and one Sm. A current of 5 mA was passed between the Pt electrodes to generate a Pt(II)-Pt(0) reference electrode.

In later experiments the third compartment was made from boron nitride[3] in the form of a blind tube which was a push fit in a short length of Pyrex tube fused to the lower end of a B19 cone assembly and was prevented from dropping through the former by a slight rim left at the open end. To permit ingress of the melt through the impermeable boron nitride a number of fine holes (0.1 mm diameter) were drilled through the blind end. The compartment, previously vacuum dried overnight at 450°-500°C, was filled by applying vacuum directly to its top.

Ytterbium electrodes consisted of pieces of ingot suspended from tungsten wire; 1 mm diameter dysprosium wire was polished with fine carborundum paper prior to use as an electrode.

Redox potentials.—The cell is depicted in Fig. 2 and the closure detailed in Fig. 3. It comprised a stainless steel center disk surrounded by a water-cooled aluminum alloy annulus and clamped to the flange of the glass envelope with an "O" ring seal forming a vacuum-tight joint. A Pyrex glass adaptor, fitted to a central tapered hole through a vacuum tight silicone rubber sleeve, enabled the apparatus to be connected to the argon and vacuum system by ball and socket joints, and a B10 cone joint at the top of the adaptor provided for the insertion of a thermocouple pocket. Additional holes accommodated Viton A "O" rings forming the seals for glass tubes passing through the disk. These tubes constituted the electrode compartments and terminated in glass frits at their lower ends, the upper ends being provided with B10 sockets. Each tube was sealed and locked into position by compression of the "O" rings by a duralumin annulus held in position by a clamping bar and set screws.

To adjust electrode height within the melt Pyrex hypodermic syringes of 2 ml capacity were used; a

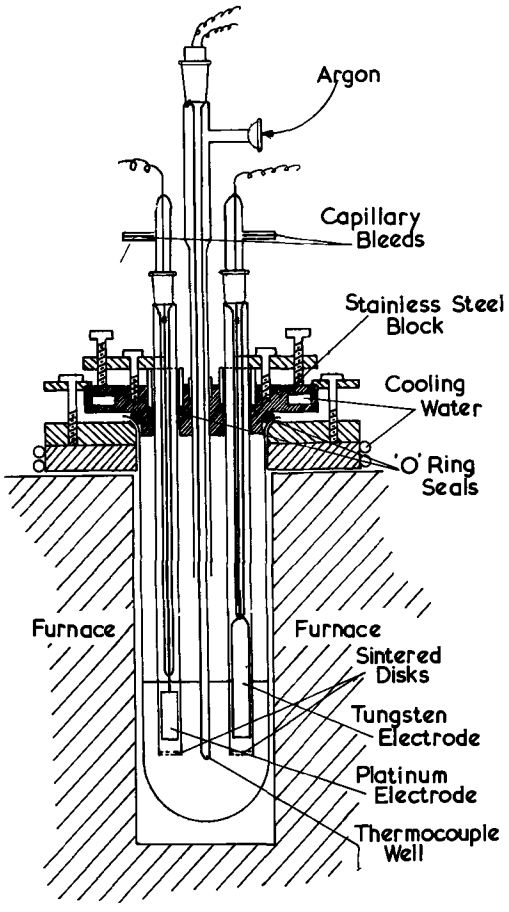

Fig. 2. Components of cell used in electrochemical measurements

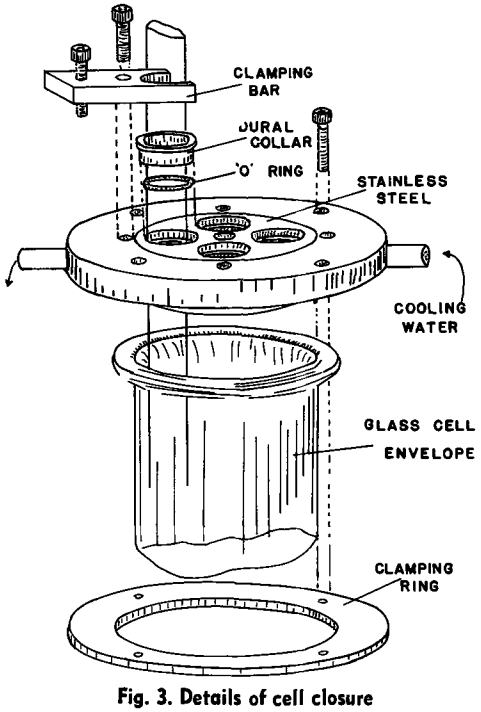

Fig. 3. Details of cell closure

B10 cone was fused to the outlet of each syringe barrel together with a short capillary side arm, while the plunger was joined to the upper end of the electrode stem.

Tungsten electrodes, made from 006-in. foil, were electropolished by anodization at 20V in 5*N* NaOH containing 1 %wv $NaNO_2$, and were vacuum dried and stored under dry argon.

Table I. Sm electrode potential vs. 1m Pt(II)-Pt(0) reference

45	0.336	−3.363
45	3.325	−3.366

Solvent was filtered into the cell envelope after the greater part of the dissolved gas had been pumped off. Argon was admitted and the filter tube assembly replaced by the electrolytic cell head with stoppered compartments above the melt level. The apparatus was then evacuated and left overnight in the furnace while the remaining hydrogen chloride was pumped off at pressure $\sim 1 \times 10^{-3}$ Torr. Argon was admitted at just above atmospheric pressure and the compartments immersed to 2-3 cm. A platinum electrode was inserted into one compartment, a tungsten one into another and solute (50-150 mg) weighed into the third before insertion of an indicator electrode (Pt or W). Throughout these operations a steady stream of argon was passed through the apparatus to prevent ingress of atmospheric oxygen and moisture.

When each compartment had filled to a depth of *ca.* 2 cm, its depth of immersion was adjusted until the level of its contents coincided with that of the bulk of the melt. Electrodes were then lowered into position and a thermocouple pocket introduced. While the temperature stabilized at 450°C, the Pt foil of the reference electrode was anodized (600 sec at 10 mA).

At the conclusion of each experiment electrodes were withdrawn from the melt and the stoppered compartments, complete with contents, were removed and allowed to cool in a dessicator. In the case of reference electrodes, solvent adhering to the outside was scraped away and the lower portion of each compartment was cut off and weighed. The contents were removed by boiling with water, dried glass reweighed, and the weight of solution obtained. Where it was more important to retain the compartment contents in an anhydrous state, cooling was carried out in a nitrogen filled drybox and the glass of the compartment carefully broken away from the solidified melt.

Results

Metal ion-metal potentials.—After anodizing for 1 min at 5 mA, a samarium electrode in a glass compartment had a potential of −2.9V[4] *vs.* a Pt(II)-Pt(0) reference electrode which decayed to −2.5V after 5 min, but could not be read again. On dismantling the apparatus, it was found that the immersed Sm was corroded, the Sm compartment had disintegrated into yellowish-green and black fragments; the flask bore heavy etches and dark brown stains; the orange color of Pt(II) in the reference compartment was lost, but the frit was covered by a gray residue; the bulk of the electrolyte was dark red and, on cooling *in vacuo*, formed a jade green solid which evolved hydrogen and left a turbid colorless solution when added to water.

Using a boron nitride compartment, a samarium electrode was inserted and anodized at 1.5 mA for various times. The consequent potentials appear in Table I.

The samarium electrode was corroded, and the melt in the compartment embrittled a piece of platinum immersed in it and, according to its persistent flame reaction, the platinum was impregnated with lithium. A silver spiral electrode, substituted for the corroded Sm electrode, assumed a stable potential which became more positive on successive anodizations. The time for stabilization after anodization decreased

[4] The IUPAC convention is used for electrode potentials.

from 50 min for the first to 15 for the fourth. Additional experimental evidence for the extreme reactivity of metallic samarium with molten alkali chlorides was provided in the following manner. Small portions of both caesium and potassium chorides (approximately 2g) were oven dried and then sintered first in a stream of dry hydrogen chloride, then under high vacuum, the temperature being finally raised until melting took place. The pellet of solidified material was transferred to a clean molybdenum boat and a bright chip of samarium ingot (*ca.* 20 mg) was placed on top. Boats were heated under a stream of pure dry argon in a clear silica combustion tube. As melting of the alkali halide occurred, the samarium metal was observed to dissolve with some violence with the formation of a very dark red to black solution. On cooling the solid product assumed a violet coloration.

Europium corroded very rapidly in the LiCl-KCl melt and a tungsten electrode inserted in the Eu compartment registered a potential of ~ -3V. Ytterbium corroded to an apple green solution and registered a potential of -3.0 to -3.5V. Dysprosium immediately blackened on immersion, then slowly corroded to give a pale violet solution containing Dy in some form and a dark solid. The Dy electrode had a potential of -2.809 ± 0.002V *vs.* 1M Pt(II)-Pt(0), and this potential was only transiently changed by anodization.

Redox potentials.—Samarium.—The potential of a tungsten indicator electrode in a solution initially containing $SmCl_3$ (at 450°C) was monitored as the Sm(III) was progressively reduced coulometrically. In two experiments out of some 30, stable potentials were measured and Nernst plots for one of these is shown in Fig. 4. Although the dark red color characteristic of Sm(II) persisted for some hours in other experiments no other reliable potential data were obtained.

Europium.—The details of four experiments in which platinum was employed as the cathode in progressive coulometric reduction of $EuCl_3$ in solution are presented in Table II.

The average of the first two experiments is an intercept of -0.554 ± 0.007V. One plot is shown in Fig. 5.

Ytterbium.—Nernst plots for four experiments at 450°C are combined in Fig. 6. Again, the concentrations were varied by progressive coulometric reduction at tungsten of vacuum sublimed $YbCl_3$ in solution. Details of these experiments appear in Table III together with two results obtained using less pure $YbCl_3$. The average of the points in Fig. 6 is a slope of 0.148V and an intercept of -1.375 ± 0.003V.

Since Ag(I) solutions are more stable at the higher temperatures than Pt(II) solutions, a Ag(I)-Ag(0) reference electrode was employed in studies of the temperature dependence of the potential. In one experiment a solution of $YbCl_3$ was partially reduced and potentials measured over a cycle from 360° to 600°C at 10° temperature intervals. Then the $YbCl_3$ was further reduced and the cycling repeated. In a second experiment a solution of $YbCl_2$ was partially oxidized, cycled, further oxidized and recycled. No hysteresis was observed in the emf *vs.* temperature relations, and the potential values observed at 450°C agreed well with those calculated from the standard potential of −1.375V as obtained above. Figure 7 and Table IV summarize the data.

Discussion

Metal ion-metal potentials.—It is clear that samarium displaces the alkali metals from their fused chlorides. The potential of the samarium electrode in the boron nitride compartment is close to the lithium potential measured by Liu (20) with a tungsten indicator electrode (−3.320V). The red solution contained Sm(II) which could be oxidized to Sm(III) at a silver anode. The lithium formed would alloy with platinum, but not silver, and be capable of vicious attack on Pyrex glass.

Europium and, less violently, ytterbium also displaced Li from LiCl-KCl to form solutions of the divalent ions. The (II)-(0) potentials of these three metals in LiCl-KCl must therefore be more negative than the lithium potential, as are the predicted reduction potentials of the pure dichlorides (6, 13). The measurements with dysprosium were inconclusive: the calculated Dy(III)-Dy(0) potential of −2.901V (13) suggests that Dy(III) may be involved but then corrosion by Li^+ oxidation becomes ruled out.

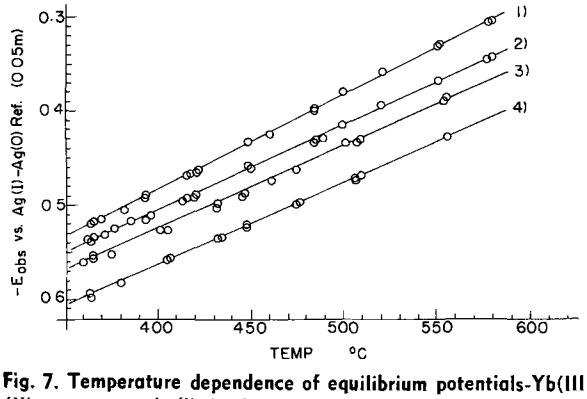

Fig. 7. Temperature dependence of equilibrium potentials-Yb(III)-Yb(II) system *vs.* Ag(I)-Ag(0) reference at the same temperature.

Redox potentials.—Stable equilibrium potentials for the three systems were linearly dependent on $\log_{10}$ Ln(III)/Ln(II) calculated on the basis of 100% current efficiency (see Appendix) for the reduction processes. Nernst slopes were close to 0.143V = 2.303 RT/F at 450°C, indicating a one electron process. Confirmation of the identity of the reduced species was provided by spectroscopic studies which showed that solutions obtained by electrolytic or magnesium reduction of the trichlorides or directly from the dichlorides had identical broad band uv-visible spectra (17) now accepted as Laporte-allowed $4f^n \rightarrow 4f^{n-1}5d$ transitions of divalent lanthanide ions.

The large number of unsuccessful experiments with samarium emphasizes that this study was at the limit of the materials and techniques adopted, primarily because one species is a highly mobile ion with the reducing power of aluminum metal. Only traces of oxidizing impurities such as hydrogen, heavy metal, or silicate ions in solution or adsorbed on the glass would upset the system, and any deterioration of the glass, once begun, appeared to proceed relentlessly.

The least difficulty was experienced with the ytterbium system but the less pure $YbCl_3$ samples (5 and 6) gave rise to curved Nernst plots and turbid green solutions. It is likely that Yb_2O_3 and YbOCl were present in such impure samples.

High-purity $EuCl_3$ was not easy to prepare and initial experiments with nominally pure material gave curved Nernst plots. All samples had mild reducing properties suggesting the presence of $EuCl_2$ as well as the expected oxide and oxychloride. One odd observation was the slight turbidity of solutions of the $EuCl_3$ in LiCl-KCl but the clarity of its aqueous solutions.

The formal potentials (on a molal scale) at 450°C are summarized in Table V together with those for some other related systems.

Thermodynamic calculations.—From the redox potentials one can calculate the free energy change for the reaction

$$LnCl_3(soln.) \rightleftharpoons LnCl_2(soln.) + \tfrac{1}{2}Cl_2(g)$$

In Table VI the results are compared with calorimetric and tensimetric data for the reaction

$$LnCl_3 \rightleftharpoons LnCl_2 + \tfrac{1}{2}Cl_2$$

The calculated differences in free energies of solution of trivalent and divalent chlorides are small and reasonable using Polyachenok's data (Line 1-Line 2) but large (Line 1-Line 3) if the calorimetric data, obtained with less pure materials and with greater errors, are employed.

Differentiation of the Nernst equation and substitution of the working concentrations of ions leads to a mean value of (0.71 ± 0.02) × 10^{-3} volt/deg^{-1} for

APPENDIX

Errors in Redox Potential Measurements

(*a*) *Restricted solubility and current efficiency.*—Where solubility of the reduced species is limited, passage of charge q_s may saturate the solvent with Ln(II) and for $q > q_s$

$$E = E^{o'} + \frac{RT}{\mathbf{F}} \ln (q_o - q) + \text{const.}$$

which means a sharp increase in Nernst slope. If Ln(III) is sparingly soluble, a similar departure from the ideal equation applies at $q < q_o - q_s$.

Where the added solute contains Δq_o of insoluble material the deviation, ΔE, of the observed potential from the expected linear relation may be written as a series

$$E = -RT\left(\frac{\Delta q_o}{q_o - q} - \frac{\Delta q_o^2}{2(q_o - q)^2} + \ldots\right)$$

Provided $q < \frac{1}{2}q_o$, linearity and slope of the E *vs.* $\ln(q_o - q)/q$ plot are little affected even at 20% contamination. The error in $E^{o'}$ can be shown to be ~ -0.6 mV per 1%.

Loss of current efficiency obeys a similar equation and introduces an error in $E^{o'}$ of +1 mV per 1% loss provided $q < \frac{1}{2}q_o$.

(*b*) *Solute impurities.*—If the solute initially contains reduced species equivalent to the passage of a charge Δq_o then

$$E = E^{o'} + \frac{RT}{\mathbf{F}} \ln \frac{q_o - (q + \Delta q_o)}{q + \Delta q_o}$$

The deviation is negative and gives rise to pronounced curvature of the E *vs.* $\ln(q_o - q)/q$ plot and the magnitude of $\Delta E^{o'}$ is much larger in this case. However, the systematic errors in $E^{o'}$ taken from linear plots appear to be less than the random errors.

Current Distribution on a Rotating Disk Electrode

Vinay Marathe and John Newman

Inorganic Materials Research Division, Lawrence Radiation Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California

ABSTRACT

The radial variation of deposit thickness on a rotating disk electrode was measured for deposition of copper from a solution 0.1*M* in $CuSO_4$ and 0.1*M* in H_2SO_4. The results confirm the theory of nonuniform current distribution on such electrodes below the limiting current.

The basic theory of the rotating disk electrode was developed by Levich in 1942. Since then, considerable work has been done to refine the theory of this electrode system. It has been widely used for the study of electrode processes and mass transfer in electrochemical systems. Measurement of diffusion coefficients and bulk concentrations and the study of moderately fast electrode reactions are some of the common applications. Theoretically predictable velocity and concentration profiles and elimination of natural convection effects due to strong forced convection make it suitable for the above-mentioned and other applications. Furthermore, the current density is uniform at the limiting current.

Recently, Newman (6) has shown that below the limiting current the current density is nonuniform and can be obtained by solving for the concentration and potential distribution simultaneously (subject to electrode kinetic boundary conditions). The convective diffusion equation for the diffusion layer can be replaced by an integral equation (7, 8, 13) relating the reactant concentration and the normal derivative of the reactant concentration at the electrode surface

$$i = \frac{n\mathbf{F}D}{1-t_+}\frac{\partial c}{\partial y}\Big|_{y=0} = \frac{n\mathbf{F}D}{1-t_+}\left(\frac{a\nu}{3D}\right)^{1/3}\sqrt{\frac{\Omega}{\nu}} \left\{ \frac{c_\infty - c_0(0)}{\Gamma(4/3)} - \frac{r}{\Gamma(4/3)}\int_0^r \frac{dc_0}{dr}\Big|_{r=x}\frac{dx}{(r^3-x^3)^{1/3}} \right\} \quad [1]$$

where i is the current density on the disk and c_0 and c_∞ are the surface and bulk concentrations of the reactant.

The potential distribution outside the diffusion layer satisfies Laplace's equation and can be expressed as a series solution, from which one obtains

$$\Phi_0 = \frac{RT}{Z\mathbf{F}}\sum_{n=0}^{\infty} B_n P_{2n}(\eta) \quad [2]$$

and

$$i = -\kappa_\infty \frac{\partial \Phi}{\partial y}\Big|_{y=0} = -\frac{\kappa_\infty}{r_0\eta}\frac{RT}{Z\mathbf{F}}\sum_{n=0}^{\infty} B_n P_{2n}(\eta) M_{2n}'(0) \quad [3]$$

Here η and ξ are rotational elliptic coordinates defined by

$$y = r_0\xi\eta \text{ and } r = r_0\sqrt{(1+\xi^2)(1-\eta^2)}$$

and Φ_0 is the ohmic drop extrapolated to the disk surface, $P_{2n}(\eta)$ is the Legendre polynomial of order $2n$, and $M_{2n}(\xi)$ is a Legendre function satisfying

$$\frac{d}{d\xi}\left[(1+\xi^2)\frac{dM_{2n}}{d\xi}\right] = 2n(2n+1)M_{2n}$$

with boundary conditions

$$M_{2n} = 1 \text{ at } \xi = 0 \text{ and } M_{2n} = 0 \text{ at } \xi = \infty$$

The disk, being metallic, should be at a uniform potential V (applied voltage), and therefore

$$V = \Phi_0 + \eta_s + \eta_c \quad [4]$$

where η_s and η_c are the surface and concentration overpotentials; these are computed from

$$\eta_c = \frac{RT}{Z\mathbf{F}}\left[\ln\left(\frac{c_0}{c_\infty}\right) + t_+\left(1-\frac{c_0}{c_\infty}\right)\right] \quad [5]$$

$$i = i_0\left(\frac{c_0}{c_\infty}\right)^\gamma\left[\exp\left\{\frac{\alpha Z\mathbf{F}}{RT}\eta_s\right\} - \exp\left\{-\frac{\beta Z\mathbf{F}}{RT}\eta_s\right\}\right] \quad [6]$$

where i_0 is the exchange current density, γ is the slope of a logarithmic plot of exchange current density *vs.* concentration, and α, β are electrode kinetic parameters.

Simultaneous solution of Eq. [1] through [6] yields the current distribution. Results obtained by iterative calculation have been described in the literature (6, 8). The current distribution depends on the parameters

$$N = -\frac{nZ\mathbf{F}^2Dc_\infty}{RT(1-t_+)\kappa_\infty}r_0\sqrt{\frac{\Omega}{\nu}}\left(\frac{a\nu}{3D}\right)^{1/3} = \Gamma(4/3)\,i_{\lim}\frac{Z\mathbf{F}}{RT}\frac{r_0}{\kappa_\infty}$$

$$\delta = i_{avg}\frac{Z\mathbf{F}}{RT}\frac{r_0}{\kappa_\infty}$$

$$J = i_0\frac{Z\mathbf{F}}{RT}\frac{r_0}{\kappa_\infty}$$

and α, β, γ, and t_+. N, δ, and J can be considered as the dimensionless limiting, average, and exchange current densities, respectively.

The aim of this work was to study the current distribution experimentally for comparison with theoretical results. Newman's theory is valid for metal deposition from a single salt and for the reaction of a minor component with excess supporting electrolyte. The metal deposition reaction from copper sulfate-sulfuric acid at copper electrodes was chosen for experimental work.

Experimental Technique

The metal deposition reaction will result in a copper deposit on the electrode surface, and this will be proportional to the current distribution if the density (g/cm^3) of the deposit is uniform. Experimental measurements of the deposit thickness would thus yield the current density distribution.

To maintain the theoretically predicted velocity profiles, the deposit thickness should be very small compared to the momentum boundary layer ($\approx 5 \times 10^{-2}$ cm). The active surface of the disk should be considerably smaller than the total surface and the cell size for approximating the assumptions of the hydrodynamic and potential distribution models. These restrictions limit the application of several thin film

measurement techniques like radiographic methods, ultrasonic testing methods, and eddy-current testing. Tolansky (12) has reported the measurement of electrodeposited films by employing interferometry. In our experiments, the deposits were found to be fairly bright but not smooth enough to give an interference pattern. Additives for obtaining bright and smooth deposits could not be employed in the present work since they could alter the transport properties and the electrode kinetic parameters of the system.

In this work, the deposit distribution was measured with a precision optical instrument by sectioning the electrode at a plane passing through its axis. The electrode was embedded in a hard epoxy resin to prevent burring of the deposit during machining.

Design of the Rotating Disk Electrode System

Disk electrodes of various shapes and designs have been used in the past. In a review on the rotating disk system, Riddiford (10) has summarized the various designs and recommended several design criteria based on theoretical and experimental considerations. These criteria attempt to attain the theoretical hydrodynamic model and concentration profile by minimizing the edge effects and ensuring laminar flow. The potential distribution is valid for a finite disk embedded in an infinite insulating plane with walls and counterelectrode at infinity. This can be achieved for a disk electrode if it satisfies the above-mentioned criteria and if the polarization is confined to the disk electrode. Angell, Dickinson, and Greef (2) have measured the potential distribution for disk electrodes satisfying Riddiford's criteria and found the results to be in qualitative agreement with Newman's theory (5, 6). The disk electrode was carefully designed (3) to meet the criteria set up by Riddiford and others. Only the central portion of the lower surface of the disk is active. A rotating disk electrode is shown in Fig. 1. The disk electrode specifications are:

Outside diameter, cm	4
Active surface diameter, cm	0.5
Disk thickness, cm	0.1
Shaft diameter, cm	0.8

The Lucite cell is 14 cm in diameter and 10 cm high. It has a circular inset in the bottom for the anode. The copper anode is 7.5 cm in diameter, *i.e.* more than 200 times larger than the cathode (this confines the polarization effects to the cathode). The electrical connection to the anode is through a screw at the bottom of the cell, and the opening is made liquid tight with a rubber ring in a groove.

The central copper portion of the rotating disk electrode is machined to dimensions and cast in epoxy resin. The epoxy, on curing, is machined to the dimensions (specified earlier) and shape shown in Fig. 1.

Experimental Set-Up and Procedure

A Lambda Model 2B regulated power supply was used as a constant current source. The current was measured with a Keithley Model 610R electrometer to an accuracy of ±2%. Electrical connection to the rotating disk electrode was achieved by means of a mercury well. The disk was mounted on a spindle with ⅜-in. 24 TPI left-handed threads. The spindle was tightly fitted in two ⅞-in. OD New Departure RC bearings. To minimize eccentricity, the bearings were mounted inside a heavy brass bearing case. The spindle was coupled to the shaft of a variable speed motor (Bodine Electric Company, Type NSE 11R, with a gear ratio of 10-1) controlled by a precision d-c voltage power supply. The speed of rotation was determined by a General Radio Type 631-BL strobotac with an accuracy of ±1%. The temperature was maintained at 25.0° ± 0.1°C by immersing the cell in a water bath.

Since the rugosity of the disk surface should be considerably less than the momentum boundary layer thickness, the disk surface was subjected to the following treatment before deposition:

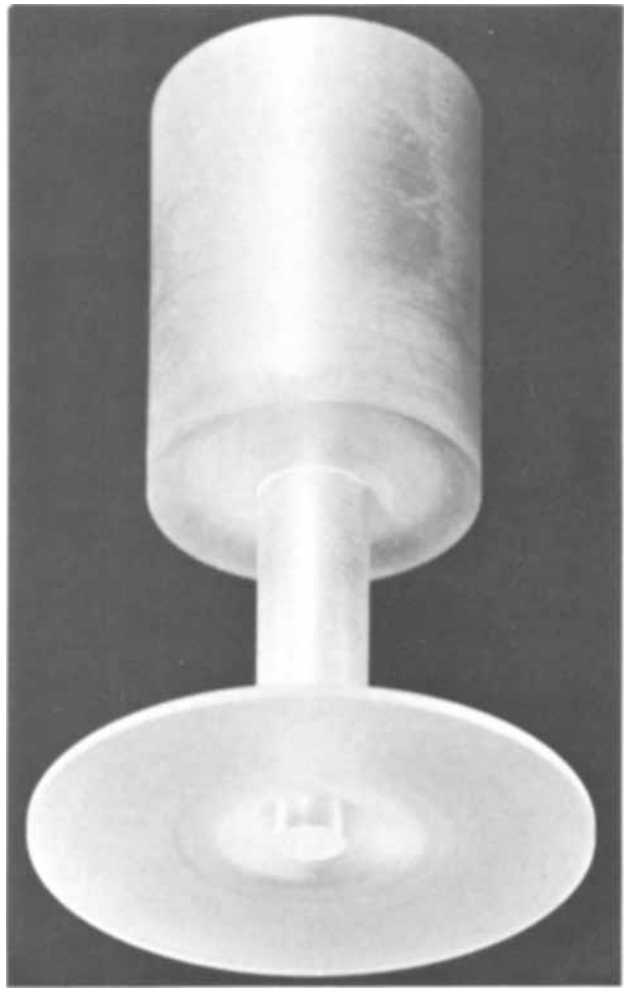

Fig. 1. The rotating disk electrode

1. The disk surface was polished successively on No. 0, 00, 000, and 0000 emery papers using kerosene as a lubricant. The last paper has a grain size of 15-20μ.
2. The electrode surface was polished on a wheel mounted with canvas cloth (Diamond Abrasive 1μ) at moderate speeds with kerosene as lubricant.
3. The surface was next polished on a wheel mounted with Microcloth using γ-alumina (0.05μ) as the grinding compound.
4. The electrode surface was cleaned with isopropyl alcohol or carbon tetrachloride.
5. The electrode was rinsed with distilled water followed by the electrolyte.

For ease and accuracy of measurement, a fairly nonuniform and smooth deposit is desirable. With copper sulfate only, the deposit was very rough and, with considerable excess of sulfuric acid, the deposit was not sufficiently nonuniform to measure the variation in deposit thickness accurately. Consequently, the electrolyte concentration chosen was 0.1*M* copper sulfate and 0.1*M* sulfuric acid. As mentioned earlier, the deposit thickness should be considerably less than the momentum boundary layer thickness ($\approx 5 \times 10^{-2}$ cm). Consequently, the time of deposition was chosen such that the maximum deposit thickness was less than 2×10^{-3} cm. Deposition times were 15-30 min.

After deposition, the disk electrode was washed with water followed by isopropyl alcohol. It was then embedded in an epoxy resin made up of:

100 parts by weight of Resin 826 (Shell Chemical Company)
10 parts by weight of LP3 (accelerator, Thiokol Chemical Company)

15 parts by weight of D40 (catalyst, Furane Plastics Company)

The embedding was done by pumping the resin down into a vacuum to eliminate bubbles and gaps at boundaries and curing at 65°C for 16 hr. One half, toward the axis, was machined off on a milling machine, leaving about 5/1000 in. for polishing and etching.

The sectioned electrode was polished as described earlier for surface treatment. It was then etched (etchant: 50 parts distilled water, 50 parts ammonium hydroxide, and 20 parts of 30% hydrogen peroxide) so that the deposit could be distinguished from the electrode due to differences in grain structure. The deposit was then observed with a metallographic microscope and microphotographs (X 1000) of the deposit layer obtained at various points by a Polaroid camera attached to the metallograph.

Results

The theoretical current distribution depends on the parameters N, J, δ, α, β, γ, and t_+ defined earlier. For computing N and J, data on ν, D, κ_x, and i_0 are needed. Kinematic viscosities (ν) and diffusion coefficients (D) were obtained from a correlation of physical properties for the copper sulfate-sulfuric acid system by Selman, Hsueh, and Newman (11). Conductivities were obtained from data reported by Richardson and Taylor (9). Data on transference numbers t_+ for the copper sulfate-sulfuric acid system were not available, so these were back-calculated from limiting current density measurements by Selman (unpublished). The exchange current density was extrapolated from the data of Mattsson and Bockris (4). The kinetic parameters α, β, and γ were also obtained from the work of Mattsson and Bockris (4) and the values used are

$$\gamma = 0.42$$
$$\alpha Z = \alpha_a = 1.5$$
$$\beta Z = \alpha_c = 0.5$$

From the microphotographs of the deposit along a disk diameter, the variation in thickness was measured. Table I gives the results of such measurements at three values of δ. These results are plotted along with the theoretical current distribution from Newman's theory (6) in Fig. 2, 3, and 4. Measurements closer to the limiting current density were rendered difficult due to powdery deposits.

Discussion and Conclusions

The experimental results are in good agreement with Newman's numerical results.

Recently, Albery and Ulstrup (1) have reported their experimental work with ring-disk electrodes in $NaBr-HClO_4$ solutions. Bromine is produced on the disk electrode, and the ring electrode is supposed to be maintained at such a potential that all the bromine reaching it is destroyed. They have developed a theoretical expression for the ring current in terms of the electrode geometry and the concentration profile at the outer edge of the disk. For some values of the concentrations and currents, the observed collection efficiencies are lower than the theoretical value for a uniform current density on the disk electrode, while a higher value would be expected if the current density were higher near the edge of the disk. Albery and Ulstrup postulate that the discrepancy may be due to the omission of the migration term in the convective diffusion equation by Newman.

Table I. Experimental values of the deposit thickness

Electrolyte: 0.1M copper sulfate – 0.1M sulfuric acid
T = 25°C, Ω = 300 rpm, r_0 = 0.25 cm
κ_x = 0.051 ohm^{-1} cm^{-1}, ν = 0.9439 × 10^{-2} cm^2/sec
Z = 2, α = 0.75, β = 0.25, γ = 0.42
N = 22.2, J = 0.382, i_0 = 1 mA/cm^2, i_{lim} = 65 mA/cm^2

r/r_0	Experimental t/t_{avg} δ = 4.82	δ = 12.3	δ = 17.12

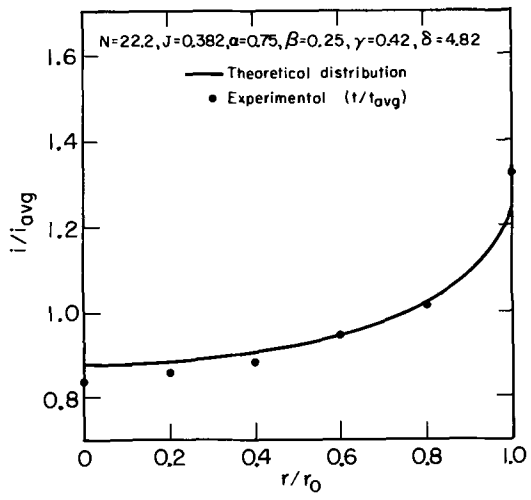

Fig. 2. Current distribution at 19.4% of the limiting current density.

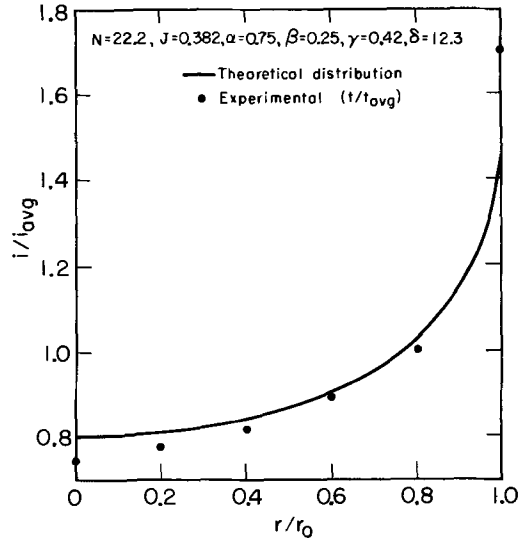

Fig. 3. Current distribution at 49.5% of the limiting current density.

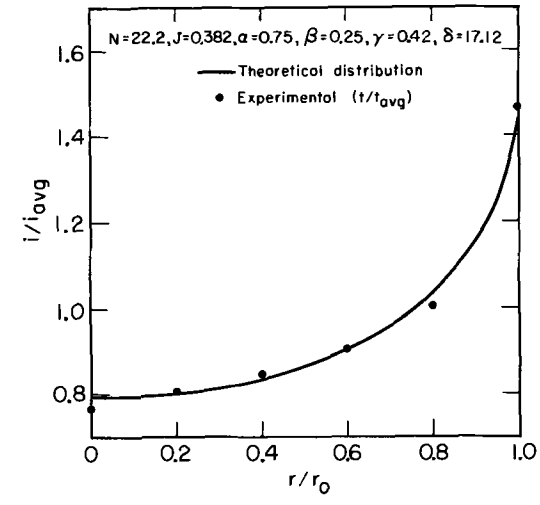

Fig. 4. Current distribution at 69% of the limiting current density.

It should be noted, however, that their system does not satisfy one of the basic requirements of Newman's theory—that the disk be embedded in an infinite, insulating plane. A straightforward way to use a ring-disk electrode for quantitative study of nonuniformities of current distribution would be to keep the two electrodes at the same potential and operate them as a sectioned electrode. The different current densities are then a measure of a nonuniform current distribution. Operation of the ring electrode as a collector for the species produced at the disk electrode would be expected to accentuate the nonuniform current distribution on the disk electrode. Further discussion of the results of Albery and Ulstrup will be submitted shortly.

The experimental method in the present work is a direct approach to testing Newman's theory, and the results seem to confirm it within the limits of experimental accuracy.

Although the theory is strictly applicable only to solutions of a single salt or solutions with an excess of supporting electrolyte, the present system is halfway between, having equal concentrations of sulfuric acid and copper sulfate. Nevertheless, the general conclusion must still apply that, below the limiting current, the current density is higher near the edge of the disk, although the appropriate values of the parameters of the theory are rendered uncertain. In this case, it appears to the authors that the parameter N is best evaluated from the experimental limiting current density.

The nonuniform current distribution arises from the nonuniform ohmic potential drop in the solution outside the diffusion layer; no approximations have been introduced in this regard. For a rotating disk electrode this tendency toward nonuniformity of the current distribution is countered, to a greater or lesser extent, by the limitations of electrode kinetics and mass transfer in the diffusion layer. In the diffusion layer, approximations were introduced appropriate to single-salt solutions or supporting-electrolyte solutions; the more general problem is formulated in Ref. (14). These approximations cannot have a drastic effect on the predicted behavior of the system; the one which first comes to mind would be that on limiting currents (15).

The observation, noted in the experimental section, that an excess of sulfuric acid led to a fairly uniform deposit is, of course, in harmony with theoretical predictions. We could still have used an excess of supporting electrolyte if we had increased the electrode radius in proportion to the increase in conductivity. This would have required redesign of the cell (there being some concern about the resulting swirling produced by the larger disk) and was decided against. For small disks used in kinetic studies with an excess of supporting electrolyte, a uniform current distribution would be expected unless the exchange current density is large. For engineering systems, nonuniformity of current distribution should not be ignored.

The Transport Entropy of Hydrogen Ion in the Water-Ethanol System

II. The Heats of Transport of HCl and the Transported Entropy of H^+

J. Lin

Department of Chemistry, Boston College, Chestnut Hill, Massachusetts

ABSTRACT

The entropy of transport of 0.01 molal HCl, S^*_{HCl}, was measured in the H_2O-C_2H_5OH system from the initial and final thermoelectric power of the quinhydrone-hydrogen ion thermocell at a mean temperature of 25°C. The variation of S^*_{HCl} with the composition of the solvent system was studied and its implication on the solvent structure and on the mechanism of H^+ ion transport across a temperature gradient is discussed. The transported entropy of H^+ ion, $\bar{\bar{S}}_{H+}$, at 25°C was also calculated from the S^*_{HCl} obtained and from the initial thermoelectric power of the hydrogen-hydrogen ion thermocell in water-ethanol mixtures given by Lin and DeHaven in Part I.

In the first paper of this work, Lin and DeHaven (1) (hereafter referred to as Part I) have suggested that studies of the solvent effect on the thermoelectric properties of thermocells may reveal interesting information concerning the structure of the solvent system and the mechanism of hydrogen ion transfer across a temperature gradient. In this connection the initial thermoelectric power of the hydrogen-hydrogen ion thermocell and the cation transport number of HCl were measured in the water-ethanol system. In the present paper we calculate the molar heat of transport of HCl and the transported entropy of hydrogen ion from the measurement of the initial thermoelectric power ϵ_0 and the final thermoelectric power ϵ_∞ of the quinhydrone (QH)-hydrogen ion thermocell at a mean temperature of 25°C, as a function of X, the weight per cent of ethanol in the H_2O-C_2H_5OH solvent mixture.

Application of the potentiometric method to study the thermal diffusion process taking place within an electrochemical cell from its initial (homogeneous) state to the final (Soret) steady state was first demonstrated successfully by Agar and Breck (2) in 1955. However, since the effect under consideration (change of thermoelectric power from the initial homogeneous state to the final steady state) is small, the electrode used must be extremely reproducible and stable and so far the electrode systems which have been studied are only a few, namely; $Tl(Hg)/Tl^+$ (3), $Cd(Hg)/Cd^{++}$ (3), $Ag/AgCl/Cl^-$ (4), $Fe(CN)_6^{-3}/Fe(CN)_6^{-4}$ (5), and QH/H^+ (6) systems. All these studies were conducted in the aqueous solvent and have given a remarkably consistent result which compared well with other independent measurements such as the conductometric method (7). In the present study, we have used the quinhydrone electrode to measure the heat of transport of 0.01 molal HCl in the water-ethanol system from 0 to 100 w/o (weight per cent) ethanol at an average temperature of 25°C.

The electrode reaction of the thermocell, $(T)\,Pt/Q, H_2Q, HCl(0.01M), H_2O(100\text{-}X), C_2H_5OH(X)/Pt(T+\Delta T)$, where Q is quinone, H_2Q hydroquinone, X ethanol weight per cent, $T = 20°C$ and $\Delta T = 10°$, is given by

$$\frac{1}{2}Q - \frac{1}{2}H_2Q + H^+ + e^- = 0 \qquad [1]$$

and following the notation of Part I, $\epsilon_0(X)$ and $\epsilon_\infty(X)$, may be written as

$$\mathbf{F}\,\epsilon_0 = \frac{1}{2}(S_{H_2Q} - S_Q) - \bar{\bar{S}}_e - S_{H+} - t_{H+}S^*_{H+} + t_{Cl-}S^*_{Cl-} \qquad [2]$$

$$\mathbf{F}\,\epsilon_\infty = -\bar{\bar{S}}_{H+} - \bar{\bar{S}}_e + \frac{1}{2}(\bar{\bar{S}}_{H_2Q} - \bar{\bar{S}}_Q) \qquad [3]$$

and

$$\mathbf{F}\,(\epsilon_\infty - \epsilon_0) = -t_{Cl-}S^*_{HCl} - \frac{1}{2}(S^*_Q - S^*_{H_2Q}) \qquad [4]$$

where the transported entropy $\bar{\bar{S}}$ is defined as $\bar{\bar{S}} = S^* + S$.

For the sake of simplicity in Eq. [2], [3], and [4] the explicit dependence of thermoelectricities, entropies, and transport numbers on X have not been shown. It is noticed in Eq. [4] that the entropy of transport of HCl may be computed from the difference of ϵ_∞ and ϵ_0 provided that the term $\frac{1}{2}(S^*_Q - S^*_{H_2Q})$ is known. Although data on the values of S^*_Q and $S^*_{H_2Q}$ are not available, since Q and H_2Q are much alike, S^*_Q and $S^*_{H_2Q}$ are expected to be not much different. Indeed, the term $\frac{1}{2}(S^*_Q - S^*_{H_2Q})$ is small and is shown to be 0.05 e.u. in aqueous solvent by Breck, Cadenhead, and Hammerli (6) (by the substitution of the molar entropy of transport of acids obtained from the Soret measurement (7) into Eq. [4]). For the case where $X \neq 0$, addition of alcohol will give rise to a different solvent structure, and both S^*_Q and $S^*_{H_2Q}$ are expected to be dependent on X. However, again due to similarity between Q and H_2Q, it is likely that both S^*_Q and $S^*_{H_2Q}$ may depend on X to much the same extent at all X. Therefore, in this study, we have also assumed that $\frac{1}{2}(S^*_Q - S^*_{H_2Q})$ is small at all X and that for all practical purposes we may rewrite Eq. [4] as

$$\mathbf{F}\,(\epsilon_\infty - \epsilon_0) = -t_{Cl-}S^*_{HCl} \qquad [5]$$

Since the left-hand side of Eq. [5] is experimentally measurable, S^*_{HCl} may be calculated by using the values of t_{Cl-} reported in Part I.

In aqueous solvents, since the isothermal temperature coefficient of the electrode system used is in most cases known, the transported entropy of the ion reversible to the electrode system may be derived by the measurement of ϵ_∞ (*e.g.*, Eq. [3]). For the present study, this is hardly the case, and it is not possible to derive $\bar{\bar{S}}_{H+}(X)$ from the present measurements alone. However, $\bar{\bar{S}}_{H+}(X)$ may still be computed by using the initial thermoelectric powers, $\epsilon_H(X)$, of the hydrogen-hydrogen ion thermocell reported in Part I. The equation which governs $\epsilon_H(X)$ may be written as

(Eq. [5] in Part I).

$$\mathbf{F}\,\epsilon_H = \frac{1}{2}S_{H_2} - \bar{\bar{S}}_e - \bar{\bar{S}}_{H^+} + t_{Cl^-}S^*_{HCl} \qquad [6]$$

Since S_{H_2} (1 atm) and $\bar{\bar{S}}_e$ are available, S^*_{HCl} and $\bar{\bar{S}}_{H^+}$ may be readily obtained. The corresponding molar heats of transfer, Q^*_{HCl} may then be calculated by the formula $Q^*_{HCl} = TS^*_{HCl}$.

Experimental

Procedures on the preparation of solutions other than $X = 100\%$ have been described in Part I. For $X = 100\%$, the solution was prepared by mixing the commercial absolute alcohol (d^{25}_4 measured = 0.7850) with an appropriate amount of 12N HCl. The exact composition was calculated to be $X = 99.9\%$ and the concentration of the solution, 0.01000M.

The initial thermoelectric powers, $\epsilon_0(X)$, were measured by the "static method" using the N-shaped cell (8) with platinum electrodes. Cell solutions were prepared by the method described by previous authors (6, 8). The quinhydrone (Fisher reagent grade) was washed several times with the acid solution prior to its addition into the cell solution. The isothermal residual emf of the cell was usually of the order of ± 50 μV and was corrected from the thermal emf readings. Results of the measurements are shown in Table I.

Measurements of final thermoelectric powers, $\epsilon_\infty(X)$, are somewhat more difficult. Mainly due to the necessity of avoiding the occurrence of convection and also to keep the measurement within reasonable bounds of time, it was always found convenient to employ a sandwich type cell with a thickness of approximately 1 cm. In the present study, the cell used is also a sandwich type cell. However, the present cell is assembled mechanically rather than like the conventional redox cell which is usually sealed together chemically using an adhesive. As shown in Fig. 1, the cell consisted of two gold disks (as electrodes) and a Plexiglass ring. In between the gold disks and the Plexiglass ring, Teflon gaskets were used to prevent leakage. The whole cell was then assembled with 4 nylon screws together with the copper jackets. There are several advantages of such a cell design. First of all, since Teflon gaskets were used to prevent leakage, the present design enables one to avoid the difficulty of finding an inert glue to seal the cell. The problem associated with this difficulty is important for the present solvent study. Not only because ethanol itself is a good solvent, but also because of the fact that quinhydrone is a strong redox agent, we have found that the cell solution interacts (especially for $X > 35\%$) with practically all the adhesives or cements that may be used to seal the cell properly. This interaction is troublesome as indicated by the fact that the thermal emf observed becomes increasingly erratic with increasing alcoholic concentration when the cell is sealed chemically (for example by the use of epoxi cement or

pliobond adhesive). Second, the copper jackets used in assembling the cell serve also as a useful "thermal blanket" for the electrodes and thus provide a more stable temperature for the electrode. Using the "temperature tower" (5, 6) along with YSI Model 71 temperature controller and Type 423 thermistors, we were able to keep the temperature of the electrode constant within 0.01° ~ 0.02° and the temperature difference to within 0.02°.

The quinhydrone electrode has been applied to many alcoholic media (9), including methanol by Ebert (10), ethanol by Larsson (11), and n-butanol by Seltz and Silverman (12). Unfortunately Larsson's reference concerning the application in ethanol media is not readily available and we were not able to consult this reference. It has been reported (10) that hydrochloric acid (especially for concentrations higher than 0.1N) has a tendency to chlorinate quinone and give rise to difficulties in emf measurements. In nonaqueous solvent systems, this chlorination reaction is perhaps even more prominent and as reported by Ebert (10), it was necessary to extrapolate his readings to "zero time." In the present study, however, we have found that electrode systems are quite stable and even for the ethanol concentration as high as 99.9% by weight, the ϵ_0 value may be reproduced within $\pm$ 7 μV/deg and the ϵ_∞ value to within $\pm$ 5 μV/deg. It is also interesting to note that no such difficulty was observed by Breck, Cadenhead, and Hammerli (6), where they have carried their thermocell measurements in aqueous solvent up to as high as 1.0N in HCl. The results of ϵ_∞ measurements are shown in Table I.

Results and Discussion

Although the initial thermoelectric powers were measured by the static method, just to see how thermocells approach their steady states, we have undertaken a few experiments to investigate the kinetic behavior of the thermocell. Figure 2 represents a result of such a study on the 34.2% alcohol solvent system. The technique used here was the same as that used in the conductance study of Sagert and Breck (13), that is first a "dummy cell" is placed in the temperature tower for thermal equilibrium (usually requiring about 2 hr) and then is quickly replaced by the working cell. The time $t = 0$ in Fig. 2 is the "hypothetical" instant (the instant when the replacement was completed) at which a temperature gradient is applied to the cell. As expected, due to the complexity of the system, the kinetic curve is not as simple as that observed in an aqueous solvent (6). Although no theory is as yet available for the description of such a kinetic curve, some qualitative explanations of Fig. 2 may be provided. It may be reasonable to assume that thermal diffusion of the acid should be more rapid and

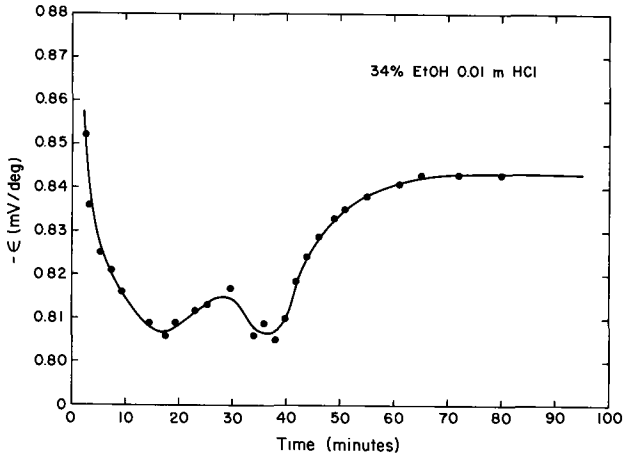

Fig. 2. Plot of the thermoelectric powers against time

thus predominate in the early stages giving rise to a smooth curve for a short time. When t is large, all the diffusion currents (over-all) approach zero and eventually the system reaches a steady state characterized by the flat portion of the curve. In between the short time and long time periods there might be a "competing" diffusion among all the species, hence a rather unusual behavior. In view of the shape of the curve, no attempt has been made to compute the effective diffusion coefficient for HCl and the over-all characteristic time of the thermocell. Also, no attempt has been made to obtain the ϵ_0 value by extrapolating the curve.

Using Eq. [5] and the $t_{Cl^-}(X)$ obtained in Part I, $S^*_{HCl}(X)$ values were computed and entered in Table I. Substituting $S^*_{HCl}(X)$ into Eq. [6], $\bar{\bar{S}}_{H^+}(X)$ may be obtained and the results are shown in Table II. Assuming that entropies of transport are additive, and also using a convention that $S^*_{Cl^-}(X) = 0$ at 0.01M, we note that $S^*_{HCl}(X)$ is just the conventional $S^*_{H^+}(X)$.

It is worth noting that the present value of $\bar{\bar{S}}_{H^+}$ at $X = 0$, which is calculated by the use of ϵ_H value from Part I agrees well with the result of Breck, Cadenhead, and Hammerli (6) who obtained $\bar{\bar{S}}_{H^+}$ at 0.01M HCl from their ϵ_∞ in water by using the isothermal temperature coefficient of the emf of the cell H_2/HCl/QH given by Harned and Wright (14). Agreement of this sort indeed is useful in cross checking the nonisothermal and the isothermal measurements.

Although studies on the solvent effect on the thermal diffusion of electrolytes, at present, are still minimal, it is nevertheless desirable to attach more importance than hitherto to the role of the solvent. The study of Becsey and Bierlein (15) should serve as an interesting example. Using the method of wave-front-shearing interferometry, Becsey and Bierlein have measured heats of transport of $CdSO_4$, $AgNO_3$, $BaCl_2$, and KI in both H_2O and D_2O and found that heats of transport observed in H_2O are substantially higher than that observed in D_2O. Their findings are indeed significant, for according to Eastman (16), heats of transport might be related to the reversible thermal effects which must occur in the vicinity of an ion as it moves through the solvent. Since a more randomly constituted solvent system will experience a greater fall in entropy while in the electrostatic field of the moving ion, the fact that entropies (or heats) of transport in H_2O are higher than D_2O is indeed consistent with the accepted concept that D_2O has more structure than H_2O (17). For the H_2O-C_2H_5OH system, although ethanol and water resemble each other fairly closely in hydrogen bonding facility (18), the structures to which these bonds can give rise are very dissimilar in the two cases and appear to be mutually exclusive. Thus, as reflected in the study of ionic Walden products (19), it is generally believed that addition of ethanol to water initially will enhance the structure of the solvent system. This structure enhancement reaches a maximum near $X = 20 \sim 30\%$ and then at a higher concentration, the structure of the solvent system is gradually reduced.

[a] Interpolated from the data given in ref. (19).
[b] Taken from Part I.

In the present study, to show how S^*_{HCl} varies with X and for the convenience of comparisons, S^*_{HCl} is plotted *vs.* X in Fig. 3 along with the limiting ionic Walden product of H^+ taken from Spivey and Shedlovsky (19). The correlation is indeed striking in spite of the fact that S^*_{HCl} takes an abrupt jump at $X = 100\%$, a phenomenon which will be discussed later. In terms of Becsey and Bierlein's findings, the decrease in S^*_{HCl} for small X value is consistent with the expectation that the addition of a small amount of ethanol would promote the structure of the solvent system. After an initial decrease, S^*_{HCl} goes to a minimum at around $X = 30\%$ and then increases to stay at a fairly small magnitude up to X is almost 100% ethanol. The exact position of the minimum of S^*_{HCl} is, however, at a higher $X(\sim 30\%)$ than that predicted by the ionic Walden product ($\sim 20\%$). According to Eastman's picture, as the ion passes by a given solvent molecule, the molecule is first oriented by the ionic field and then takes up a random orientation when the ion recedes, and so it follows that heat is liberated ahead of an ion and absorbed behind it, or as concluded by Eastman, all ionic heats (or entropies) of transport should be positive.

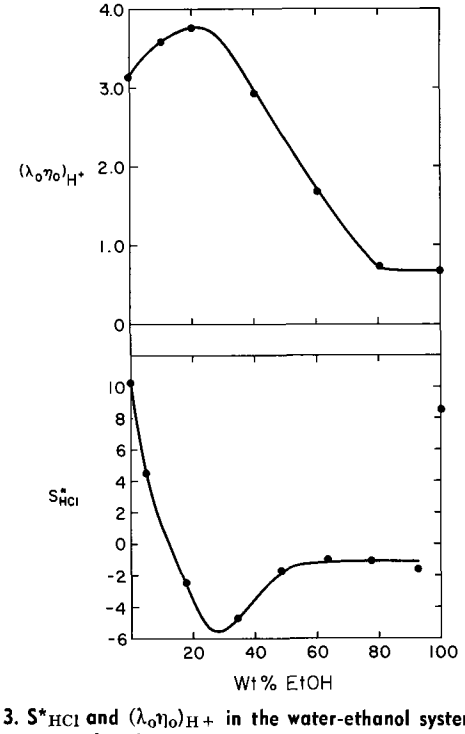

Fig. 3. S^*_{HCl} and $(\lambda_0\eta_0)_{H^+}$ in the water-ethanol system. Data on $(\lambda_0\eta_0)_{H^+}$ are taken from ref. (19).

However, negative ionic heats of transport have been observed (20) and it is now understood that for a more satisfactory interpretation of the entropy of transport, the structure-making and structure-breaking effects of the ion must be included in the consideration. For a structure-maker, there is a further reduction of the entropy of solvent molecules ahead of the ion and therefore an additional evolution of heat. But for a structure-breaker, the entropy of solvent molecules increase and may actually give rise to a negative heat of transport. The structure-breaking effect of an ion may arise if the dipole orientation by the ionic field is not compatible with the normal hydrogen-bonded structure of the solvent system and as a result some hydrogen bonds are therefore broken. Under such a circumstance the increase in the entropy of the solvent molecules due to other modes of motion may be more significant than the reduction of entropy due to dipole orientation. Chloride ions are notorious for such a structure-breaking effect in water (21) and judging from the present result it is likely that this may very well be the case in the ethanol-water system also. The S^*_{HCl}'s observed are negative for X greater than approximately 15% up to more than 90%. The large negative value for S^*_{HCl} at $X \sim 30\%$ is perhaps not unexpected since at this solvent composition the solvent system is believed to have a maximum structure (compared to the other compositions) and it is likely that the restriction imposed on the compatibility of dipole orientation may be most stringent.

As mentioned in Part I, we have anticipated that solvent study on the heat of transport may reveal interesting information concerning the mechanism of ionic transport across a temperature gradient. The fact that S^*_{HCl} increases abruptly at $X = 99.9\%$ is thus interesting and may be explained in terms of the mechanism of H^+ transport suggested by Breck and Lin (1, 20). Transport of H^+ occurs not only by a simple migration mechanism but more significantly by a chain mechanism where H^+ may be transferred from a hydronium ion to an adjacent solvent molecule which is favorably oriented, *i.e.*, by the reaction $H_3O^+ + H_2O \rightarrow H_2O + H_3O^+$ in water or its equivalent $ROH_2^+ + ROH \rightarrow ROH + ROH_2^+$ in pure alcohol. Thus, a transport of entropy may arise not only from the alternate ordering and disordering effects of the ionic field on the solvent structure, but more significantly from transport of entropies of reaction as hydrogen bonds are alternately made and broken. In an aqueous solvent, where the "absolute" ionic entropies of transport have been convincingly determined (20) this additional entropy of transport is indicated by the fact that entropy of transport of H^+ is abnormally high compared with other univalent ions.

For the present solvent system, although the convention that $S^*_{Cl^-}(X) = 0$ for 0.01*M* HCl will by no means serve the purpose of a standard state, it is nevertheless useful in judging the relative magnitude of the ionic entropy of transport at each solvent composition. Thus, the very fact that the conventional $S^*_{H^+}$'s at higher alcoholic concentrations (50-90%) are much smaller than those measured in the aqueous solvent and also in pure alcohol has indeed indicated that the suggestion by Breck and Lin may be fairly accurate, namely, that the high values of $S^*_{H^+}$ are due primarily to a proton transfer mechanism. It is true that for a large X, H^+ may be transported by the reaction, $H_3O^+ + EtOH \rightarrow H_2O + EtOH_2^+$; but it is known (18) from the equilibrium data that the rate of the reverse reaction in this case greatly exceeds that of the forward reaction. Under such circumstances only a simple migration mechanism should be operative and according to the suggested mechanism, the observed entropy of transport of H^+ would be small. In pure alcohol, H^+ may be effectively transported by the reaction $EtOH_2^+ + EtOH \rightarrow EtOH + EtOH_2^+$ and therefore a much larger ionic entropy of transport for H^+ is obtained as compared with the previous case.

Finally we discuss the transported entropy of H^+ computed in Table II. The transported entropy of an ion is the entropy carried by the moving ion under a limiting case of an isothermal condition. Following Khoroshin and Temkin (22), one may write

$$\bar{\bar{S}} = S_g + \Delta S_h + S^* = S_g + \Delta\bar{\bar{S}}_h \qquad [7]$$

where; S_g, entropy of the gaseous ion; ΔS_h, entropy of hydration of the gaseous ion; and $\Delta\bar{\bar{S}}_h$, transported entropy of hydration.

The transported entropy of hydration, $\Delta\bar{\bar{S}}_h$, which includes the contribution of the entropy of transport, was found to be better approximated by Born's model of hydration than the entropy of hydration ΔS_h in the aqueous solvent; that is, denoting Z as the ionic valence and r as the ionic radius, it was found by Breck and Lin (20) that $\Delta\bar{\bar{S}}_h$ correlates better with Z^2/r than ΔS_h. This is interesting and may be interpreted as follows. In Born's theory, apart from other approximate features, the solvent is treated as a dielectric continuum. However, in reality since a strong ionic field acts over a fairly short distance in the vicinity of the ion, the continuum model could best serve as a crude approximation. Therefore, correlations between ΔS_h and Z^2/r are in general less than satisfactory. For the case of $\Delta\bar{\bar{S}}_h$, it is slightly different since here we are considering a moving ion. A moving ion sees only an "average" dielectric medium and consequently, the continuum assumption is less critical. Thus, it is not surprising that a better correlation exits between $\Delta\bar{\bar{S}}_h$ and Z^2/r.

In the present study, S_g at 25°C may be computed from the Sackur-Tetrode equation to be 26.00 e.u. for H^+. If indeed, $\Delta\bar{\bar{S}}_h$ of H^+ may be approximated by the Born theory, it is then expected that $\Delta\bar{\bar{S}}_h$ should be proportional to $(\partial \ln D/\partial \ln T) \cdot (1/Dr)$. Thus taking $(\partial \ln D/\partial \ln T)$ and D from Part I, it is possible, within the frame of the Born theory, to estimate the relative size of H^+ as a function of the composition of the solvent system. Results of such a calculation are presented in Table II along with the pertinent parameters. It is seen that the present results predict a progressive increase (except at $X = 4.9\%$) of the ionic size when the concentration of ethanol increases. In view of the fact that ethanol molecules are larger compared with water molecules, this seems likely if r is interpreted as the "effective" radius. For it may be reasonable to expect that water molecules in the primary hydration layer will be gradually replaced by ethanol as the concentration of ethanol increases. An experimental check on this result should be interesting.

Comments

By the very nature of entropy as an "indicator" of order-disorder phenomena, it is felt that thermoelectric studies on the electrolytes in the mixed solvent system should be useful in elucidating such phenomena as ion-ion, ion-solvent, and solvent-solvent interaction. The present article does not pretend to be exhaustive, rather we hope it would be a useful example. There is a lot more remaining to be done in the immediate area; for example, to study the concentration dependence of $S^*_{HCl}(X)$ and to carry on a similar study with ions of quite different natures such as the tetraalkyl ammonium ions. Also in the present study, although the assumption that $\frac{1}{2}(S^*_Q - S^*_{H_2Q})$ is small, is hopefully a reasonable one, it is nevertheless desirable to have an experimental check on such an assumption. Work along this line is in progress in our laboratory.

To be more conclusive on the problem of the mechanism of H^+ transport across a temperature gradient, more studies on other acids will be needed. It is worth

mentioning that the mechanism suggested by Breck and Lin is sufficiently similar to the mechanism of H^+ transport under an electric field, *i.e.*, considering the transport of H^+ as a sort of "structural diffusion." In view of the fact that in these two cases the driving forces involved are quite different, this is an interesting thing to know. An electric field (for example a d-c field) will tend to align the solvent dipole and thus create more order, whereas a temperature gradient would tend to create more disorder by way of setting up a thermal energy gradient among the solvent molecules.

To evaluate the ionic entropy of transport on an "absolute" basis, a study of the problem of standard state is necessary. We plan to discuss this subject in a forthcoming article.

Acknowledgment

The author wishes to thank Professor Andre J. de Bethune for his reading of the manuscript. This work was supported by the Office of Saline Water, U. S. Department of the Interior, under Grant No. 14-01-0001-1466.

EMF and Voltammetric Measurements on the U(IV)/U(III) Couple in Molten LiF-BeF_2-ZrF_4

H. W. Jenkins,[1] G. Mamantov,* D. L. Manning, and J. P. Young

Department of Chemistry, University of Tennessee, Knoxville, Tennessee, and Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

Knowledge of the U(IV)/U(III) ratio in molten LiF-BeF_2-ZrF_4 [65.6-29.4-5.0 m/o (mole per cent)] is of considerable importance to the Molten Salt Reactor program of the Oak Ridge National Laboratory. This ratio reflects the presence of (or lack of) reducing conditions, desirable in order to minimize corrosion in the reactor. We have shown previously (1) that the reduction of uranium (IV) in molten LiF-BeF_2-ZrF_4 at 500°C is a reversible one-electron process occurring at approximately −1.5V (*vs.* Ni/NiF_2,$X_{Ni(II)}$ = 1). Other aspects of the electrochemistry of uranium in the same melt have been discussed elsewhere (2, 3). A review of electrode reactions in molten fluorides is available (4). Determination of small concentrations of U(III) in the presence of large amounts of U(IV) by direct voltammetry or chronopotentiometry (forward or current-reversal) was found to be not feasible. Spectrophotometric studies on U(IV) and U(III) in this melt (5, 6), have shown that U(IV) has analytically useful absorption bands at 640 and 1090 nm, and that U(III) absorbs strongly at 360 nm and exhibits a weaker band at 890 nm.

The emf studies on the U(IV)/U(III) couple described below were conducted as part of developing an emf series of measured potentials in molten fluorides (7). Simultaneously with the emf measurements, a simple voltammetric method was developed for the determination of the U(IV)/U(III) ratio when U(IV) >> U(III). The U(IV)/U(III) ratio in the same samples was also measured by spectrophotometry.

Experimental

The electrochemical measurements were conducted in a drybox-furnace combination that was described previously (8). The instrumentation employed and the Ni/Ni(II) reference electrode in boron nitride

* Electrochemical Society Active Member.
[1] Oak Ridge Associated Universities Fellow, University of Tennessee, Knoxville, Tennessee.

have also been described (1, 8). The melt in the reference electrode compartment consisted of anhydrous nickel fluoride (mole fraction 10^{-4}-10^{-3}) dissolved in LiF-BeF_2-ZrF_4 of the same composition as the bulk melt. It was necessary to relate the potential of each reference electrode to a common reference point since previous work (8) has shown that a junction potential exists across the boron nitride sheath. It should be emphasized that this junction potential is constant to within a few mV for periods of 1-2 weeks or longer, provided the temperature is kept constant. The common reference used in this work is the standard electrode potential of the nickel(II)/nickel couple where the standard state of nickel(II) is taken to be the hypothetical unit mole fraction solution (9). The potential of each reference electrode was determined with respect to a nickel(II)/nickel electrode in the bulk of the melt prior to the addition of solute species. A sample of the melt was taken to determine the nickel(II) concentration in the bulk of the melt. The nickel (II) in the bulk of the melt was removed by reduction with zirconium metal. The potential of the reference electrode was related to the standard electrode potential of the nickel(II)/nickel couple by means of the Nernst equation.

The potential of the U(IV)/U(III) couple was measured at a platinum wire indicator electrode. The U(IV) was added to the melt as LiF-UF_4 (73-27 m/o). The U(III) concentration was varied by the controlled reduction of U(IV) with a zirconium rod that could be immersed in the melt. It was established from stability of emf measurements and from variations in the voltammetric peak current that homogeneity of solutions was attained by waiting about 1 hr between additions and measurements; the melt was stirred periodically (either manually or mechanically) during that time. The emf measurements were recorded over a 15-30 min period to insure the stability of the values. All measurements were made at 500°C. At the time of each emf measurement, a sample of the melt was taken in a graphite windowless cell (6), allowed to solidify, and transferred to a heated spectrophotometric facility. The complete operation was performed without exposing the sample to the atmosphere; such exposure would probably alter the oxidation state of the solute. On remelting the sample in a helium atmosphere, its spectrum was obtained. The absorbance of U(IV) was determined at 640 nm and that of U(III) at 360 or 890 nm depending on its concentration level. The U(IV)/U(III) ratios determined by spectrophotometry were used in the Nernst equation to determine the standard potential of this redox couple and also for comparison with the U(IV)/U(III) ratios determined voltammetrically.

Results and Discussion

A summary of emf measurements on the U(IV)/U(III) couple *vs.* a Ni(II)/Ni reference electrode is shown in Table I, column 2. All potentials are in accordance with the Stockholm sign convention. Also given in Table I are the emf values corrected *vs.* a unit mole fraction Ni(II)/Ni electrode (column 3). A plot of the corrected emf values *vs.* the log of the U(IV)/U(III) ratio (from spectrophotometry) resulted in a straight line which exhibited the theoretical Nernstian slope of 0.153V (at 500°C). The standard electrode potential determined by extrapolation to a U(IV)/U(III) ratio of unity is -1.480 ± 0.01V. This value is in reasonably good agreement with the value of -1.517V calculated by Baes (9) from thermodynamic data obtained in a somewhat different melt, namely LiF-BeF_2 (66-34 m/o).

Values for the U(IV)/U(III) ratios determined by the new voltammetric method are shown in the last column of Table I. In the voltammetric measurements, current-voltage curves for the U(IV) → U(III) reduction are recorded *vs.* a platinum electrode which is poised at the equilibrium potential (E_{eq}) of the melt. The equilibrium potential, in turn, depends on the U(IV)/U(III) ratio. The fixed reference potential is generated internally; it is the voltammetric equivalent of the standard electrode potential (E_o), *i.e.*, the potential at which the U(IV)/U(III) ratio is unity at the electrode surface. The potential E_o is the potential corresponding to the current value that is 85% of the peak current. This holds true for a reversible couple in which the oxidized and reduced forms are soluble and the concentration of the reduced form is much smaller than that of the oxidized form (10). This is the case for the U(IV)-U(III) system in this melt (1). It follows from the Nernst equation

$$E_{eq} - E_o = \Delta E = \frac{RT}{n\mathbf{F}} \ln \frac{\text{U(IV)}}{\text{U(III)}}$$

that the difference between E_{eq} and E_o is a measure of the U(IV)/U(III) ratio. It is seen that both oxidation states may be determined from the voltammetric peak current and the position of the voltammogram on the potential scale (it is assumed that iR drop as well as polarization of the reference electrode are eliminated through the use of an auxiliary electrode).

The agreement with spectrophotometric results is quite good, considering the instability of U(III) in both experimental systems. U(III) could not be maintained for more than 24 hr. This is believed to be due in part to the diffusion of oxygen through the dry box gloves which oxidizes U(III) to U(IV).

The voltammetric method is particularly useful in nonaqueous solvents where reference electrodes are frequently not readily available, or the standard potentials may not be known. This method is being employed in highly radioactive molten salt solutions; the use of a Ni(II)/Ni reference electrode contained in boron nitride for this purpose may not be feasible.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 116, No. 1, 2, and 6, January, February, and June, 1969.

pH Changes at Anion Selective Membranes under Realistic Flow Conditions

T. R. E. Kressman and F. L. Tye
(pp. 25-31, Vol. 116, No. 1)

Allyn H. Heit[1] and **Richard Prober**[2]: Kressman and Tye's painstaking experiments provide additional insight into the mechanism for fouling of anion selective membranes in electrodialysis. Their data leave little doubt that, at conditions of high current density, organic species accelerate the functional failure of the membranes, as evidenced in practice by depressed selectivity and increased ohmic resistance. Indeed, in view of that it is surprising that OH^- transport through anion selective membranes eventually becomes stabilized (as indicated in Kressman and Tye's paper, Fig. 6 and 8).

However, in our opinion, the data do not warrant the conclusion that "the main limitation on electrodialysis is not polarization per se but poisoning of the anion-selective membranes." Even with especially purified feed solutions, high current densities could not be sustained longer than a few hours (see their Fig. 8). Thus, feed pretreatment to remove organic matter and thereby prevent membrane poisoning cannot be justified. In desalination by electrodialysis, the membranes must serve for several years; hence unpoisoned membranes are an idealization not attainable in practice over a useful fraction of the membrane lifetime.

The pH changes observed by Kressman and Tye are bulk-phase effects, and the pH at the membrane-solution interfaces may be significantly greater than in the bulk solution. For example, Kressman and Tye's data (Fig. 6) that, in NaCl solutions significant OH^- transfer began at current densities of 10 mA/cm^2, imply an average mass transfer coefficient (D/δ) of 15 cm/hr through the hydrodynamic boundary layer on the donating solution side of the anion exchange membranes (Eq. [2]). Then, assuming that the coefficient for OH^- transfer through the diffusion boundary layer on the receiving solution side of the membrane is of the same order of magnitude, we calculate that the alkalinity at the receiving solution-membrane solution interface must (on the average) have been about 0.0042*N* (pH 11.6) in order to maintain a bulk-stream alkalinity of 0.0027*N* (pH 11.4) at the stated feed-and-bleed rates.

The transport of OH^- ions through anion selective membranes at high current density brings about an undesirable side effect in electrodialysis of naturally occurring brackish waters. Sparingly soluble calcium and magnesium compounds precipitate where the OH^- concentration is greatest, that is, on the receiving stream face of the anion exchange membranes, unless the receiving stream (concentrate) feed is acidulated. We have observed such precipitation particularly with feed water of pH 7.4-7.7 and marked by 100-150 ppm of HCO_3^- ion. We have also observed that type of precipitation on the donating stream (diluate) side of the anion selective membranes with a feed stream containing 800-900 ppm (as $CaCO_3$) of hardness, despite the donating stream feed and effluent both having bulk pH values less than 7.0.

It must be remembered that pH changes occur as the result of depletion of electrolyte content in the diffusional boundary layers adjacent to the membrane surfaces. The effect is not confined to anion exchange membranes. We have observed pH changes even when the anion membrane is replaced by a nearly neutral (in fact, slightly cation selective) cellulosic membrane, as in the transport depletion process. Indeed, pH changes in electrodialysis were noted at an early period when the only material available to serve the membrane requirements of electrodialysis cells were nitrocellulose or regenerated cellulose or possibly animal tissue. Bethe and Toropoff[3] reported a passage of current through a multichambered electrodialysis stack, wherein the chambers are defined by nonselective membranes, resulted in effluents emerging from the stack at acidic or alkaline pH, depending on whether the individual stream issued, in effect, from a dilution or concentration chamber.

T. R. E. Kressman and **F. L. Tye**: Heit and Prober are not correct in inferring from our data that organic poisoning occurs only at high current densities. We believe that it happens at all current densities including zero. The effects shown in Fig. 9 resulted from poisoning runs at 5 mA/cm^2 which we would regard as a very moderate current density. The related phenomena of organic poisoning of strongly basic anion-exchange resins takes place in the absence of current and in further work[4] we have established that anion-selective membranes are also poisoned in the absence of current.

Heit and Prober should not presume that hydroxyl ion transport through the anion-selective membrane was stabilized. We state that "the apparently steady, reproducible and reversible conditions obtaining for the data on Permaplex A-20 in Fig. 6 must have occurred because the amount of organic matter accumulated by the membrane during the runs was small relative to the amount already on the membrane at the start of this series." This surely indicates that we do not regard the situation as genuinely stabilized. We have little doubt that had the experiments represented in Fig. 8 been continued for longer times that the current density necessary to maintain a receiving

stream alkalinity of 0.0027*N* would have had to be reduced. In other work[4] where operation was continued for several hundred hours conditions did not stabilize.

We have not commented on the justifiability of feedwater pretreatment as a practical procedure as inferred by Heit and Prober's second paragraph. In fact, as they admit, we have shown that organic poisoning occurs even with purified solutions.

We believe that our work shows that the attainment of higher current densities which are economically desirable in electrodialytic water treatment is not restricted by inherent hydrodynamic, mass transport, and electrical migration factors, but by the effect on them of membrane poisoning. We are at variance with nothing else that Heit and Prober write nor do we think that their remarks in any way detract from this conclusion.

An Investigation of the Difference Between NaCl and $NaClO_3$ as Electrolytes in Electrochemical Machining

James P. Hoare, Mitchell A. LaBoda, Michael L. McMillan, and Augustine J. Wallace, Jr.

(pp. 199-203, Vol. 116, No. 2)

P. J. Boden[5] and **J. M. Evans**[6]: The intensive study carried out by the authors into the behavior of electrolytes for electrochemical machining is very welcome since it is a serious attempt to solve the problems of the process via a fundamental electrochemical investigation. We have found great experimental difficulties in measuring anode potential under high flow rate conditions and were, therefore, impressed by the rotating disk technique which they employed. Our own conclusions conflict with those of the authors somewhat, and we would like to advance some of our own results.

As we have already stated,[6] we believe that the sole criterion for determining the ability of an electrolyte to produce good machining tolerances is the aggressiveness of its anion toward any passive film formed in the stray current region. Chlorate anions impose only mild attack on passive films formed in their presence, whereas the chloride anions break down the film more severely. In their paper the authors mentioned the absence of the protective γ-Fe_2O_3 in sodium chloride electrolyte. Work at Nottingham[7] seems to indicate that this film exists in chloride solutions but is almost totally pitted in the higher strength solutions (15-20% w/w).

We were surprised to read that the flow of solution has little effect on the machining rate. Turner and Cuthbertson[8] showed that the machining current varied with flow and our calculations indicate that the flow required to give polished surfaces of iron in NaCl solution varies according to the well-known empirical relationship

$$I = K(V)^n$$

where V is the velocity of the electrolyte, $n = 0.5$, and I = current density at which polishing occurs.

Since chlorates and nitrates are potential fire hazards, work has been concentrated on attempting to simulate the desirable cutting properties of these electrolytes through modification of a sodium chloride base solution. Our research has led to the conclusion that wild cutting is merely a function of heavy pitting of a passive film and, if these pits can be blocked then an improvement in machining properties may be achieved. In the case of nickel and nickel-based alloys, this has been achieved by making small additions of anions to the chloride solution so that insoluble salts can be produced in the stray current region. Additions such as carbonate, phosphate, and ferricyanide have been made to chloride solutions and the reduction in stray current attack (SCA) has been superior to that produced in chlorate electrolyte. This work is being reported in greater detail elsewhere, but it is apparent that the effectiveness of the addition is directly related to the solubility of the nickel salt it produces. Indeed, oxygen-containing anion additions, bicarbonate, sulfate, and nitrate produced a relatively small change in SCA due to the formation of soluble nickel salts. The mechanism by which these salts produce the improvement thus appears to be one of pit blocking. Also, provided that small additions are made, *i.e.*, the weight of salt added does not exceed a critical quantity, the surface finish ahead of the tool is unaffected and bright surface finishes can still be achieved at high efficiencies.

A second point which should be noted is that these additions generally increase the alkalinity of the chloride solution and should reduce corrosion of exposed parts of the E.C.M. machines.

J. P. Hoare, M. A. LaBoda, and A. J. Wallace, Jr.: We wish to thank Boden and Evans for their interest in our work, but we would like to take advantage of this opportunity to point out a number of areas in which these authors may have misinterpreted the results of our work.

In NaCl solutions, we maintain that a protective film is not present on iron specimens, although from cathodic stripping studies,[9] we also detect the presence of a nonprotective film. The important word here is "protective."

In the present paper being discussed,[10] we did not say that the metal removal rate was independent of the electrolyte flow rate. It is the steady-state polarization curve that is independent of the speed of rotation of the disk electrode. Actually, in a previous report,[11] it was pointed out that above a given flow rate, where good machining takes place, the increase in metal removal rate varies so slowly with increasing flow rates it is not economical to operate at higher rates. In this range, the metal removal rate may be considered to be approximately independent of flow rate. At the low flow rate and where the ECM properties are more strongly dependent on flow rate, interest is lacking because such experimental conditions do not give efficient ECM operation.

We would like to point out that polishing is not obtained in Cl^- ion electrolytes on most common structural metals except the 300 series stainless steels. Any polishing obtained with Cl^- ion solutions was obtained[6] in the poor ECM range of current densities (50 A/in.^{2}). Economically interesting metal-removal rates take place in the current range between 300 and 1200 A/in.^{2} (3).

Our experience has been that when the electrolyte contains high concentrations of Cl^- ion, nothing can modify the aggressive nature of such an electrolyte to the point where one obtains machining rates and excellent surface finishes on steel and nickel alloys equivalent to the results achieved with chlorate electrolytes. It may be possible to obtain bright surfaces of varying quality under certain conditions with many electrolytes, but only with the chlorate does one find the mirror-bright finish over such a large range of materials and experimental conditions.

In the absence of any detailed report of the experimental conditions, structures of cells, and experimental results, it is impossible to comment further on the work of Boden and Evans with respect to their additions of $CO_3^=$, $PO_4^=$, CrO_4^-, etc., to Cl^- ion-based electrolytes.

Effects of Oxidizable Anion Adsorption on the Anodic Behavior of Platinum

Sigmund Schuldiner
(pp. 767-771, Vol. 116, No. 6)

Sigmund Schuldiner replying to the discussion of his paper by K. J. Vetter and J. W. Schultze which appeared on page 824 of the June 1969 Discussion Section v: Vetter and Schultze[12] in a discussion of my paper on the effects of oxidizable anion adsorption on the anodic behavior of platinum have unfortunately based their analysis on a series of erroneous interpretations of data published in several papers from this Laboratory.[13-16] Their incorrect use of our data has led them to a mechanistic interpretation of the reaction of Pt-O_{ad} with dissolved H_2 which can easily be shown to be false.

In their discussion, Vetter and Schultze claim that we state [14, 16] that the mean value of the reaction rate of Pt-O_{ad} + H_2 is 1.2 mA/cm^2. In fact, we make no such statement, and the Vetter and Schultze claim that we did is not correct. In my paper[14] it was pointed out that the rate of the Pt-O_{ad} + H_2 reaction was measured on three separate Pt bead electrodes of different catalytic activity for this reaction. The actual rates for the Pt-O_{ad} + H_2 reaction for each of these electrodes was 0.4, 1.2, and 8 mA/cm^2, respectively. Warner and Schuldiner[16, 17] clearly showed that the rate of the Pt-O_{ad} + H_2 reaction is strongly dependent on the electrode thermal treatment and/or chemical etching. Platinum is a "demanding" catalyst for the reaction. However, my work[15] showed also that the steady-state hydrogen oxidation reaction is independent of the electrode history of Pt. Hence, each electrode gave the same limiting (0.04-0.7V *vs.* NHE) rate of oxidation of H_2 of 2 mA/cm^2.

If the Vetter and Schultze electrochemical mechanism for the reaction of Pt-O_{ad} + H_2 were correct, then the electrode which had a reaction rate of 0.4 mA/cm^2 for this reaction would have a limiting current density for the H_2 oxidation reaction of 0.4 mA/cm^2. Similarly, the electrode with a reaction rate of 1.2 mA/cm^2 would have an H_2 limiting oxidation current density of 1.2 mA/cm^2, and the electrode with a reaction rate of 8 mA/cm^2 would have an H_2 limiting oxidation current density of 2 mA/cm^2. The precision (within 10%) of determining both the reaction rate of the Pt-O_{ad} + H_2 reaction and the limiting H_2 oxidation rate are high enough so that the differences indicated for each electrode would be easily distinguishable in my experimental results. Since all three electrodes gave 2 mA/cm^2 limiting H_2 oxidation current density, the conclusion is that the electrochemical Pt-O_{ad} + H_2 mechanism proposed by Vetter and Schultze is incorrect.

Vetter and Schultze further err in using our data in Fig. 4,[16] by applying an incorrect relation between their supposed Pt-O_{ad} coverage (θ) and potential (E). The data in our Fig. 4[16] shows the transient relation between θ and E, whereas our potentiostatic data in footnotes 14 and 15 concerns the steady state. A steady-state relation between potential and fraction of surface covered with adsorbate can be obtained from our Fig. 2.[15] If one assumes, as does Vetter and Schultze, that this adsorbate is oxygen (or oxide) then one can obtain a relation between θ and E. Using the equation for the rate of reduction of Pt-O_{ad} proposed by Vetter and Schultze[12]:

$$i_- = k_- c_{H+} \exp(a_- \theta - 2.3\, E/b_-)$$

and using their values of $a_- = 13.8$, $b_- = 60$ mV, k_- = constant, c_{H+} = concentration of hydrogen ions, and applying this to the steady-state relation between θ and E[15] one obtains the results shown in Table I. The data for 1M H_2SO_4 shown in the last column show that i_- (k_- and c_{H+} are constants) is not constant from 0.51 to 0.87V. In fact these data show a very rapid decrease in current density from 0.51 to 0.87V. This decrease is contradictory to the data found in footnotes 14 and 15 that showed a steady-state limiting current density from 0.04 to 0.7V. The actual experimental current density decrease at 0.87V[14, 15] was one third of the 0.7V value. The calculated data shown in Table I give a decrease in current density from 0.7 to 0.87V of almost two orders of magnitude. Thus, again it is shown that the analysis used by Vetter and Schultze and their conclusion that the reaction of Pt-O_{ad} + H_2 is electrochemical is incorrect.

Table I. Steady-state relations

θ	E, V	$i_-/k_-c_{H^+}$
0.23	0.51	-7.8×10^{-8}
0.38	0.61	-1.3×10^{-8}
0.40	0.70	-5.7×10^{-10}
0.46	0.79	-4.0×10^{-11}
0.57	0.87	-8.9×10^{-12}

In their analysis of the formic acid reaction, their data (Fig. 2, footnote 12) shows that at a θ of 0.16 and E of 1V, $i \approx 10^{-4}$ A/cm^2. Not enough detail is given to indicate if these are transient or steady-state measurements. My steady-state potentiostatic measurements (Fig. 2, footnote 15) showed that at 1V the steady-state value of what Vetter and Schultze would call θ is 0.71, and i for the formation of oxygen is 5×10^{-7} A/cm^2 (Fig. 1, footnote 15). Here again, it appears that Vetter and Schultze and I are referring to two different experimental conditions. Under steady-state conditions, the rate of oxidation of water to oxygen is orders of magnitude slower than under the conditions used by Vetter and Schultze.

Vetter and Schultze have assumed that steady-state and transient θ and E relations are identical and have based their analysis on an indiscriminate use of both experimental cases. The fact is, however, that transient and steady-state values of these parameters have been shown experimentally to be quite different.

In point of fact, the Vetter and Schultze analysis demonstrates that the Pt-O_{ad} + H_2 reaction is not an electrochemical reaction. This further supports our conclusion[16] that this is a direct chemical reaction between adsorbed oxygen atoms and dissolved molecular hydrogen. This reaction is experimentally[16] independent of potential up to 0.9V, and since the reaction is chemical and independent of potential, one can reasonably predict that the reaction rate is essentially independent of potential up to at least 1.2V positive to NHE.[14, 15] In any case, at potentials below 0.9V where no extrapolation of the rate of the Pt-O_{ad} + H_2 reaction is required, I feel that Vetter and Schultze have offered strong support to my major conclusion[13-15] that the initiation of passivation of the hydrogen oxidation reaction at 0.7V *vs.* NHE is caused by anion adsorption rather than adsorbed oxygen atoms, an oxide, or another oxidation product of water.

Highly Refractive Glasses to Improve Electroluminescent Diode Efficiencies

A. G. Fischer* and C. J. Nuese

RCA Laboratories, Princeton, New Jersey

ABSTRACT

A series of low-melting arsenic-chalcogen-halogen glasses were developed, with refractive indexes between 2.4 and 2.9. Despite severe thermal expansion mismatch, it was possible to form stable glass domes on planar electroluminescent diodes by using glass compositions which permit strain relief by thermoplastic flow. By reducing internal reflection losses, external efficiencies were routinely increased by factors from 4-6 for GaAs, $GaAs_{1-x}P_x$, and $Al_xGa_{1-x}As$ diodes, resulting in external efficiencies as high as 7.2% for a solution-grown $Al_xGa_{1-x}As$ diode.

In planar-shaped electroluminescent diodes which emit near-bandgap radiation, large absorption losses and a small critical angle usually limit the external emission to a few per cent of the junction emission. In such diodes, most of the radiation is internally reflected at the crystal surface and strongly absorbed. This loss mechanism can be significantly reduced by shaping the diode to eliminate total internal reflection (*e.g.*, in the form of a hemisphere or Weierstrass sphere), or by capping the diode with a properly shaped transparent material with a refractive index as close as possible to that of the semiconductor (~3.5). An improvement in the external efficiency by a factor of up to 26 is theoretically possible (1) by either of these techniques.

In practice, a factor of 10 improvement has been attained for GaAs diodes shaped as hemispheres (1) (but not free of absorption). However this technique requires excessively thick semiconductor wafers as well as rather tedious shaping procedures, and hence is not particularly well suited for large-scale production. Furthermore, for $GaAs_{1-x}P_x$ or $Al_xGa_{1-x}As$ diodes, which are usually prepared as thin layers on thick GaAs substrates, the epitaxial layer is too thin for shaping, and the GaAs substrate strongly absorbs emission from the higher-energy-gap epitaxial layer. For these reasons, the use of a properly shaped transparent encapsulant for planar electroluminescent diodes is particularly attractive.

Transparent resin domes have been used routinely on diode light sources; however their low refractive index ($\leq$1.8) limits efficiency improvements to less than a factor of three (2). A transparent optical As-S-Br glass of high refractive index ($n = 2.4$) was used earlier by Fischer (3) as an imbedding medium for studies on ZnS electroluminescent particles. However, apart from the primary requirements for a high refractive index and low absorption, such a glass must fulfill two more conditions in order to be practical for dome fabrication on electroluminescent diodes:

(*a*) The viscosity *vs.* temperature behavior of the glass must permit it to be moldable at temperatures low enough to prevent chemical reactions between the glass and the diode, or melting of the solder contacts.

(*b*) The viscosity of the glass must be low enough at room temperature to permit thermoplastic flow. This flow can then relieve the strain caused by the large difference in the thermal expansion coefficients of the glass and the semiconductor, thereby preventing the glass dome from cracking off the crystal.

In this paper we describe a series of optical glasses consisting of various combinations of arsenic, sulfur, selenium, tellurium, bromine, and iodine, which meet the conditions discussed above. Such glasses, when used as spherical domes on planar diodes which emit near-bandgap light, have been found to increase external efficiencies by as much as a factor of 6. Through the use of these glasses, room-temperature external efficiencies were increased from 0.03 to 0.16% for vapor-grown $GaAs_{1-x}P_x$ diodes, from 0.4 to 2.1% for Zn-diffused GaAs diodes, and from 1.7 to 7.2% for a solution-grown $Al_xGa_{1-x}As$ diode. The preparation and properties of these glasses, their fabrication as domes on planar electroluminescent diodes, and the optical and electrical properties of the glass-encapsulated diodes are discussed below.

Preparation and Properties of Arsenic-Chalcogen-Halogen Glasses

Composition.—A yellow glass consisting of arsenic ($n \approx 4$), sulfur ($n \approx 1.95$), and bromine ($n \approx 1.66$) in approximately equal parts (weight per cent) has been used previously to match the refractive index of ZnS (3). However, our present studies have found that this glass is not suited for electroluminescent diode encapsulation because of a large thermal expansion mismatch between the glass and the diode, and because of the brittleness of the glass at room temperature. The purpose of our present study of arsenic-chalcogen-halogen glasses has been to overcome the thermal mismatch problem of the previous glass, and to increase the refractive index to more closely match that of $GaAs_{1-x}P_x$ ($n \approx 3.5$).

To increase the refractive index, sulfur can be replaced partly or totally by selenium ($n \approx 3$) and/or tellurium ($n \approx 4$), and bromine can be replaced by iodine ($n \approx 3.3$). But with such substitution, the absorption edge shifts to longer wave lengths, toward the red and infrared (Fig. 1), and the glasses finally become black in color. All observed properties of these glasses appear to change smoothly with changes in

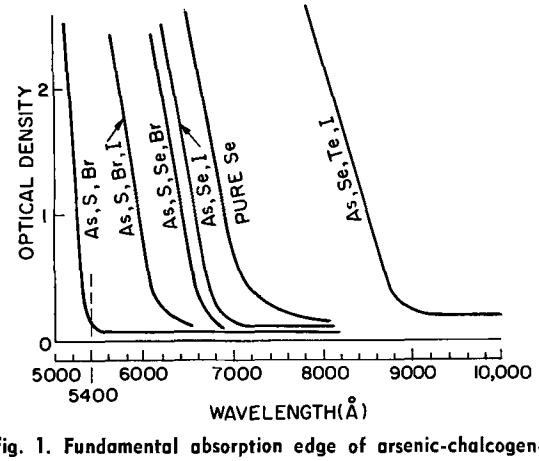

Fig. 1. Fundamental absorption edge of arsenic-chalcogen-halogen glasses.

composition. However, for the glasses to be practical for electroluminescent diode encapsulation, many ranges of composition must be avoided, as described below:

(i) Arsenic-rich compositions provide glasses with undesirably high softening temperatures (>200°C). High-temperature fabrication steps can melt ordinary solder contacts. Such glasses are also too brittle at room temperature to prevent cracking.

(ii) Halogen-rich compositions (especially those with iodine) yield glasses which are moldable at a suitably low temperature, but which solidify very rapidly upon cooling, so that they are also too brittle at room temperature. (These are labeled "short" glasses since they have a short temperature range of usable viscosity, in contrast to "long" glasses which have a long temperature range of useful viscosity). At higher halogen concentrations, these glasses are no longer brittle at room temperature, but soften at relatively low temperatures (about 50°C) which may be attained by the diodes during high-level operation. Still higher bromine content leads to glasses which are liquid at room temperature.

(iii) Compositions rich in sulfur provide desirable "long" glasses. However, too much sulfur lowers the refractive index, and also leads to devitrification upon long standing.

Because of such limitations, many different glass compositions were prepared and evaluated in order to select those best suited for electroluminescent diode encapsulation. A representative series of compositions examined for this purpose during the course of our studies is presented in Table I. Obviously, a more extensive materials-oriented study of the arsenic-chalcogen-halogen glasses would be interesting; however, the complexity of the As-S-Te-Se-Br-I glass system over wide compositional ranges precludes such a detailed investigation. Furthermore, the properties listed above were found to provide adequate guidance for the preparation of several glass compositions which were successfully used to improve electroluminescent diode efficiencies.

Two glasses in particular were found useful for diode encapsulation. A yellow glass consisting of As (10g), S (13.5g), and Br (≈2 cc) has a refractive index of 2.4 and is transparent to light with wave length greater than about 5400Å (*see* Fig. 1). A red glass consisting of As (10g), S (8g), Se (15g), and Br (≈1.8 cc), has a higher refractive index of 2.5-2.7, but transmits light only in the red and infrared spectral range. The infrared glasses which are rich in Se have a very high refractive index ($n \approx 2.9$). However they have not been successful to date because of large absorption losses due to the formation of a second phase, as observed by scanning electron microscopy.

Table I. Representative glass composition series

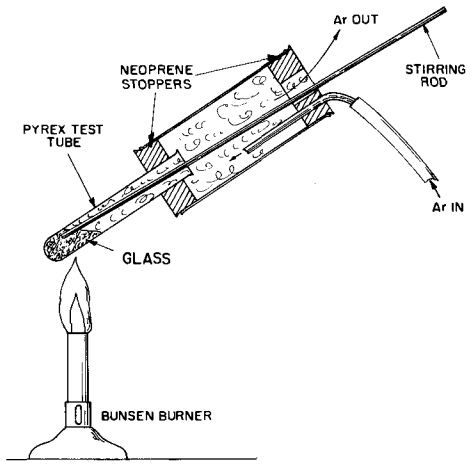

Fig. 2. Set-up for preparation of glasses.

Preparation.—The general preparation of all arsenic-chalcogen-halogen glasses proceeds basically as follows. High-purity elements[1] (99.999%) are used, and surface oxides are removed by heating in hydrogen (for Se or Te), or by heating in vacuum (for S). Bromine is dried with $CaCl_2$ or "molecular sieve," and iodine is dried by storing it in a closed vessel with P_2O_5.

Using the simple apparatus shown in Fig. 2, the arsenic is reacted with the chalcogens and iodine (when used) under argon with intense stirring. This may require heating to 600°C. The mixture is then allowed to cool to about 50°C, and bromine is added with a pipette.[2] The mixture is reheated and stirred vigorously as soon as the viscosity is low enough. At a temperature where the glass is sufficiently liquid (~200°C), one homogenizes (restirs) the composition, and lets it settle to allow bubbles to escape. Since the glass must be of high optical quality, great care is needed in this homogenization to prevent bubbles and schlieren. This preparation method is simple and inexpensive; however a small amount of bromine is always lost, the exact quantity of which depends primarily on the specific techniques of the preparer. One batch of a particular glass is sufficient to encapsulate about 100 diodes.

The reproducibility of the glasses described here could almost certainly be improved by preparation in evacuated quartz ampoules; however the danger of explosion with sealed ampoules would require careful attention.

Evaluation.—Refractive indexes were determined by the Chaulnes method (4), where the displacement of a visual image is measured with and without a plane-parallel glass plate between the sample and the observer. They ranged from 2.4 for the yellow arsenic-sulfur-bromine glasses to 2.9 for the *IR*-translucent black glasses containing Se, Te, and I.

The very important residual absorption at energies less than that of the fundamental absorption edge was monitored for each glass by measuring two large planar wafers, one 1 mm thick, the other 2 mm thick, to separate reflection from absorption losses. The absorption of a 1-mm thick wafer should not exceed 2% for useful glasses. High absorption coefficients were

[1] Suppliers: As, Se, Te: American Smelting and Refining Co., South Plainfield, N. J. S: United Mineral & Chemical Corp., 129 Hudson St., New York, N. Y. Br: Matheson, Coleman & Bell, East Rutherford, N. J.

[2] The amount of bromine required to provide adequate room-temperature thermoplasticity for any of the glass compositions is empirically determined by adding bromine in 0.2-cc increments to the molten mixture until the glass no longer cracks off the Pyrex tube upon cooling to room temperature. The final test for thermoplasticity is strong adhesion of a glass dome to a Kovar header.

found to correlate with the occurrence of small precipitated rods as seen under the scanning electron microscope, and are still excessive at present (>3%) in Se-, Te- and I-rich glasses. Suppression of this second phase by ultrasonic stirring during preparation appears to be promising.

To measure the thermal expansion curves, a very simple and inexpensive dilatometer was constructed (Fig. 3). The average expansion coefficient for the glasses was found to be 230 x 10^{-7}/°C, as compared to 48 x 10^{-7}/°C for GaAs (Fig. 4). This large mismatch in thermal expansion coefficients clearly illustrates the need for thermoplasticity of the glass at room temperature to prevent cracking.

Fabrication of Glass Domes on Diodes

To produce small manageable pieces from the large glass ingots, the test tube containing the glass is submerged in liquid nitrogen and then placed into hot water. The glass cracks into fragments several millimeters in diameter. A selection of equally sized pieces is then heated on a microscope slide until they melt into slightly flattened droplets. After cooling, the beads are carefully examined to eliminate those with flaws.

The electroluminescent diode to be dome-encapsulated is then heated in air to about 170°C under a microscope. A glass bead is lifted with vacuum tweezers and, by means of micromanipulators, placed onto the heated diode, where it rapidly melts. If it is not accurately centered on the diode, it can be gently pushed sideways to improve its positioning. If the glass is not transparent to visible light, such as the ones used on infrared-emitting diodes, an infrared image converter can be mounted on the microscope, and the infrared emission of the forward-biased diode can be used to aid in the centering procedure. After the dome is correctly placed, the diode is inverted during cooling to round the slightly flattened dome (Fig. 5).

These free-flowing glass droplets attain their shape under the influence of surface tension, gravity, viscosity, and wetting adhesion forces. The surface of the resulting dome is perfectly smooth. Domes which are formed using molds (silicone rubber molds were found best) have slightly rough surfaces and have not yielded efficiencies as high as the freely formed spheres.

Properties of Dome-Encapsulated Diodes

To evaluate the effectiveness of the glass domes for increasing the efficiency of electroluminescent diodes, numerous Zn-doped GaAs and $GaAs_{1-x}P_x$ diodes were encapsulated for each of the glass mixtures, and their external quantum efficiency was measured before and after glassing. Room-temperature external efficiencies were routinely measured with a large-area (1-in. diameter) calibrated silicon solar cell (Hoffman 2A) placed immediately adjacent to the diode. Efficiencies were also checked in an integrating sphere for several of the more successful glasses.

The room-temperature external emission *vs.* current characteristics for a representative GaAs and a $GaAs_{0.6}P_{0.4}$ electroluminescent diode, before and after encapsulation, is presented in Fig. 6 and Fig. 7. The yellow As-S-Br domes for these diodes were formed naturally, without mold, as described previously and as illustrated in Fig. 5. The hemispheres were about 0.10 in. in diameter, whereas the diodes were 0.020-0.025 in.

square. For both the GaAs and $GaAs_{0.6}P_{0.4}$ diodes of Fig. 6 and 7, external efficiencies are shown to increase by a factor of 5.1-5.3 after glassing. Removal of the glass encapsulant with methylene iodide was found to restore the efficiency to its former value, suggesting that a chemical interaction between the diode and the glass is not the cause of the efficiency increase. In general, improvements of room-temperature efficiencies varied between 4 and 6 for such diodes, which

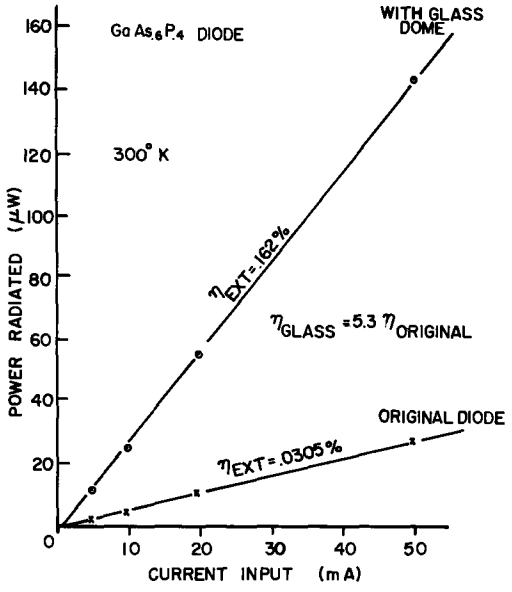

Fig. 7. Power radiated vs. input current for $GaAs_{0.6}P_{0.4}$ diode. $T = 300°K$.

are somewhat less than a value of 7 calculated for a perfectly shaped, nonabsorbing glass with a refractive index of 2.4 (2), but which are nevertheless about twice as high as values for organic resin domes. The external emission of the encapsulated diodes depends strongly on the precise shape of the dome, its centering over the diode, and the optical clarity of the glass itself.

In general, the relative efficiency improvement for encapsulated diodes depends also on the sample geometry and the optical quality of the diode prior to glassing. If a diode contains optical scattering centers, or deviations from surface planarity (*e.g.*, pits, hillocks, cleavage ridges, *etc.*), trapped light may escape *via* reflection or refraction from these inhomogeneities. However, this additional component of external emission is significant only for semiconductors with very little absorption, where the light can bounce around, such as for red-light-emitting GaP diodes. For such GaP diodes, which presently yield highest visible-light efficiencies, our glasses provide an efficiency improvement of only about a factor of 2, since the initial emission is *not* significantly limited by light trapped *via* total internal reflections. The same holds true for SiC light diodes,[3] where the index matching ($n_{SiC} \sim 2.6$) is almost perfect, but where the improvement factor (2-3) is nevertheless disappointing.

However, for the zinc-doped GaAs and $GaAs_{0.6}P_{0.4}$ diodes studied here (including those in Fig. 6 and 7), beneficial effects from optical inhomogeneities are very unlikely, since the near-bandgap radiation is readily absorbed. In particular, the GaAs substrate adjacent to the $GaAs_{1-x}P_x$ epitaxial layer would immediately absorb any of the high-energy light attempting to bounce around within the semiconductor. This is also the case for Si-compensated $Al_xGa_{1-x}As$ diodes grown from solution on GaAs substrates. The $Al_xGa_{1-x}As$ layer itself absorbs little of the light (5); however absorption in the GaAs substrate is large. Glassing of such a diode therefore resulted in an external efficiency improvement by a factor of 4.2, from 1.7 to 7.2% at room temperature (5). Our results with GaAs, $GaAs_{1-x}P_x$, and $Al_xGa_{1-x}As$ diodes suggest that large improvements will be obtained for all diodes which are initially limited by large absorption losses and a small critical angle. It should be noted that the glass domes do not provide similarly large improvements in the brightness (luminosity/area) of visible-light emitting diodes, because of magnification of the diode area by the spherical glass dome.

Besides improving diode efficiencies, an additional advantage of the glass domes is the ease with which their shape can be varied to provide different far-field emission patterns (2). For example, the small spheres which are formed naturally during cooling provide a rather broad spatial pattern not significantly unlike that of the original diode, but occasionally as broad as that shown in Fig. 8a (78° half-width). On the other hand, a large hemisphere (molded in silicone rubber) provides a somewhat more beam-like pattern due to the focussing action of the "lens" formed by the spherical glass surface (Fig. 8b). The unusual bulges in the patterns of Fig. 8 arise from irregular curvatures in the experimental glass domes examined here. Prior to glassing, the spatial emission pattern for all diodes was approximately that of a $(1\text{-}\cos^3\theta)$ distribution, with a half-width of 65°.

The current-voltage characteristics of several GaAs and $GaAs_{1-x}P_x$ electroluminescent diodes were evaluated, before and after encapsulation, in order to determine the existence of any leakage current caused by the glass or by any possible reaction of the glass with the diode surface. As shown for the representative $GaAs_{0.6}P_{0.4}$ diode in Fig. 9, there was no measurable leakage current caused by the glassing process for currents in the investigated range between 10^{-6} and 10^{-1}A. Similar results were obtained on a series of 10 different GaAs and $GaAs_{1-x}P_x$ encapsulated diodes.

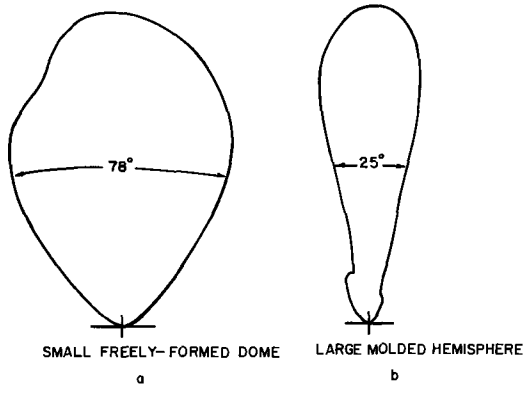

Fig. 8. a—Far-field pattern of diode with small, naturally formed dome; b—far-field pattern of large, molded hemispherical dome.

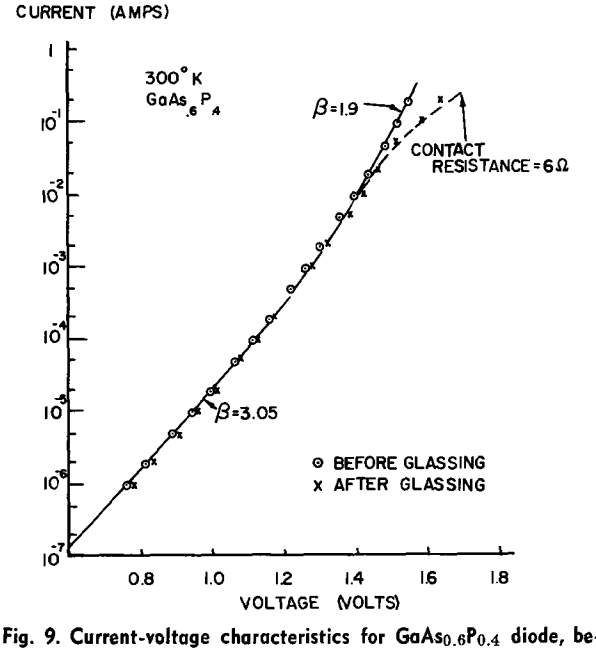

Fig. 9. Current-voltage characteristics for $GaAs_{0.6}P_{0.4}$ diode, before and after encapsulation.

[3] Supplied by General Electronic Co., Miniature Lamp Division, Cleveland, Ohio.

Note however, in Fig. 9, the deviation of the two curves at high currents. The shift to larger voltages after glassing represents an ohmic series resistance of about 6 ohms, which is almost certainly due to loosening of the current leads during the mounting of the glass dome, or by relative thermal motion during cooling. The increased contact resistance is not inherent to the glassing process itself, since diode geometries can be readily employed with current leads connected to the bottom of the diode, where they would not be weakened by the glassing process.

Conclusions

A series of arsenic-chalcogen-halogen glasses were developed with low melting temperatures and with refractive indexes between 2.4 and 2.9. The glasses are chemically stable and have absorption edges between 5400 and 9000Å. Despite the severe expansion mismatch, it was possible to form stable glass domes on planar electroluminescent diodes by employing glass compositions which permit strain relief by thermoplastic flow. Room-temperature external efficiencies were routinely increased by factors from 4 to 6 by dome-encapsulating electroluminescent diodes of GaAs, $GaAs_{1-x}P_x$, and $Al_xGa_{1-x}As$. With these glass domes, room-temperature external quantum efficiencies were increased from 0.03 to 0.16% for vapor-grown $GaAs_{1-x}P_x$ diodes, from 0.4 to 2.1% for Zn-diffused GaAs diodes, and from 1.7 to 7.2% for a solution-grown $Al_xGa_{1-x}As$ diode, close to earlier predictions (6).

Acknowledgments

The authors wish to thank H. Kressel and I. Ladany for the use of their integrating spheres and for supplying solution-grown *e-l* diodes for encapsulation. We also wish to acknowledge the capable assistance of J. J. Gannon for numerous measurements.

The Synthesis of Bulk GaP from Ga Solutions

T. S. Plaskett

IBM Research Division, Yorktown Heights, New York

ABSTRACT

The synthesis of solid ingots of high-purity GaP by reacting PH_3 with molten Ga at 1000°-1200°C is described. Actual growth parameters were measured during synthesis and compared with the values predicted from solution growth theory. Growth rates of about 1.7×10^{-5} cm/sec were possible with this system for a solution saturated with P at 1200°C. Some properties of the synthesized material are presented.

Many GaP single crystal growth techniques (1, 2) for preparing material for electronic applications require large solid starting ingots of high-purity GaP. However, most high-purity GaP is only available in granular or platelet form or as a spongy mass with considerable entrapped Ga. Solid ingots have been synthesized from the elements under high temperatures and pressures (3-5) where the melt approaches the stoichiometric composition,[1] but under these conditions there is the problem of contamination from the container material. Solid ingots of high purity have also been produced by reacting P_2 or some gaseous phosphorus compound with Ga at lower temperatures, but over an extended period of time.

In this paper a method to synthesize high-purity solid ingots of GaP at a low temperature and in a reasonable but short time is described. The growth parameters under these conditions were measured and are compared with the theoretical values predicted from constitutional supercooling considerations. Some properties of the synthesized ingot are also given.

Growth Considerations

The reaction of molten Ga with PH_3 can be described as

$$Ga + PH_3 \rightleftarrows GaP + 3/2\ H_2 \qquad [1]$$

The usual procedure is to let the GaP that is formed by the reaction dissolve into the Ga at a hot region and then precipitate at the coldest region. Essentially, the growth or precipitation is from dilute solution (at 1200°C, for example, Ga dissolves about 12% by weight of GaP). The growth of solid material without any entrapment of Ga is therefore limited by the onset of constitutional supercooling (hereafter abbreviated to cs), which is encountered at high growth rates. The conditions that are required to prevent cs during growth from dilute solutions are quite severe.

Both Hurle, *et al.* (6), and Tiller (7) have analyzed growth from solution from the standpoint of cs. Hurle *et al.* in their analysis included the effect of stirring and showed that for the growth of III-V compounds the condition for no cs can be expressed, in a slightly rearranged form, as

$$\frac{G_L}{f} \geqq -\frac{mC_L}{D} \exp \Delta \qquad [2]$$

where G_L is the temperature gradient in the liquid ahead of the solid-liquid interface

f is the growth rate

m is the slope of the liquidus curve

D is the liquid diffusion coefficient

C_L is the excess concentration of the III (or V) component in the melt and is defined as $C_L = C_{III} - 0.5$, and

[1] GaP melts at 1467°C and has a dissociation pressure at the melting point of about 35 atm.

Table I. Growth parameters

Temp, °C	Slope of liquidus m, °C/mole fraction	Excess Ga conc.* C_L, mole fraction	Theoretical G_L/f values for the onset of cs °C-sec/cm²	Measured G_L/f values at various synthesis temperatures, °C-sec/cm²
800	2.6×10^4	0.498	2.6×10^8	
900	1.2×10^4	0.493	1.2×10^8	
1000	4.5×10^3	0.480	4.3×10^7	1.4×10^7
1100	2.6×10^3	0.446	2.3×10^7	2.0×10^7
1200	1.9×10^3	0.395	1.5×10^7	2.3×10^7
1300	8.7×10^2	0.325	5.7×10^6	
1400	7.4×10^2	0.220	3.3×10^6	

* $C_L = (C_{III} - 0.5)$ where C_{III} is the concentration of the Ga in the compound and C_L is excess concentration of Ga in the Ga-P solution.

Δ is defined by the relationship, $\Delta = f\delta/D$ where δ is the thickness of the boundary layer of excess solvent at the solid-liquid interface.

If we now consider only a system where there is good stirring in the solution, then δ approaches zero and Eq. [2] reduces simply to

$$\frac{G_L}{f} \geq \frac{mC_L}{D} \qquad [3]$$

Some typical values for G_L/f for the system Ga-P are shown in Table I. The values are similar to those obtained from the analysis of Tiller (7). In both cases, the solubility data of Hall (8) and Rubenstein (9) were used to determine m and C_L. A value of 5×10^{-5} cm²/sec was used for D similar to that used by Tiller (7). From this analysis it is apparent that extremely high-temperature gradients are required if solid ingots are to be synthesized at a reasonable rate. As the concentration of the solution increases, the severity of the growth condition G_L/f decreases. At the stoichiometric composition, *i.e.*, no excess Ga, the ratio is zero since no Ga build-up would exist ahead of the interface and therefore no cs. If only partial stirring exists, the G_L/f values shown in Table I are increased by the factor exp Δ.

Experimental

The reactor used in this investigation is shown in Fig. 1. A 30g charge of Ga is placed in a pyrolytic BN crucible (1.5 cm diameter and 6 cm deep) which in turn fits into a quartz tube. The bottom of the quartz tube is cooled by a blast of air to provide the steep temperature gradient. A 10% PH_3 in Ar mixture is injected through the top of the quartz tube down to a few millimeters inside the crucible at a rate between 50-100 ml/min. A small diameter inlet tube is used to maintain a high velocity of the gas in order to prevent decomposition of the PH_3 prior to entering the hot reactor.

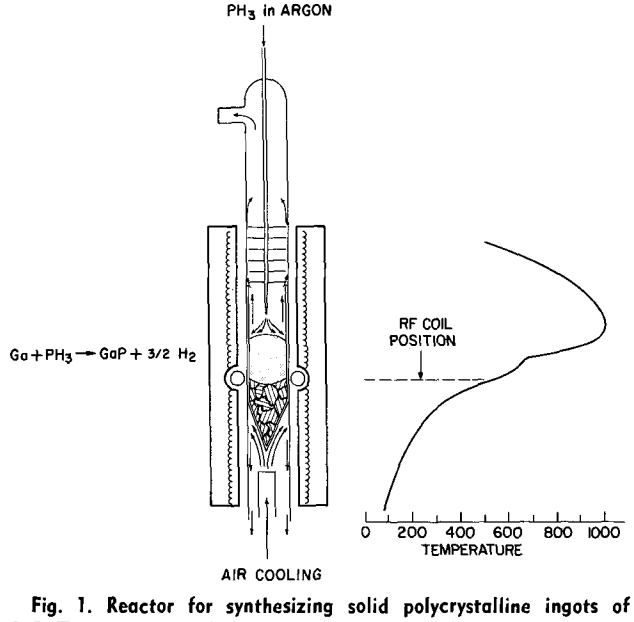

Fig. 1. Reactor for synthesizing solid polycrystalline ingots of GaP. Temperature profile in furnace shown at right.

The reactor is heated by a single turn rf coil and resistance heated furnaces are placed above and below the coil. The coil is initially positioned near the bottom of the crucible. This produces intense concentrated heat below the surface of the solution thus generating strong convective currents to provide the necessary mixing. The mixing also ensures that the GaP that is formed at the surface is dissolved throughout the solution instead of crusting over the surface and preventing further reaction. The strong blast of air at the bottom of the crucible provides the steep temperature gradient and also maintains the growing interface at a position slightly below the coil. The actual temperature profile in the furnace is shown in Fig. 1. Once a steady-state condition is reached, which takes about 6 hr, the reactor is moved through the furnace at a rate of about 1.7×10^{-5} cm/sec. The time for synthesis for the 30g charge of Ga is about 3 days.

A 10% PH_3 in Ar gas mixture was used. At concentrations lower than this, it was not possible to saturate the solution at 1200°C. An estimate of the composition required is that the partial pressure of P_2 in the gas stream must exceed the vapor pressure of P_2 over the saturated solution. For Ga-P solution at 1200°C the vapor pressure (10) is about 1×10^{-2} atm. The partial pressure of P_2 in the 10% gas mixture is 5×10^{-2} atm.

With this system, doped ingots can be synthesized either by adding the dopant to the gas stream or to the Ga prior to synthesis. GaP ingots doped with C were synthesized by adding CH_4 to the gas stream. Si, Te, Zn, Sn, and Bi doped ingots were synthesized by adding the dopant to the Ga.

A temperature exploration during synthesis was made by a thermal probe. A thin-walled quartz tube, closed at one end, was inserted down the center of the crucible. During synthesis, a thermocouple was moved through the tube. The GaP actually synthesized around the tube, and therefore the temperature profile in the solid as well as the solution was measured.

Results and Discussion

Ingot morphology.—A typical GaP ingot synthesized in this system over a period of about 3 days is shown in Fig. 2. The ingot weighs about 40g. Typical sections cut from near the top and from just above the cone of the ingot are shown. No entrapped Ga is visible. If the reactor is run at a lower temperature, some entrapped Ga is detected in the lower portion of the ingot. A typical crystalline structure of an ingot taken from the center portion is shown in Fig. 3. Occasionally near the top of the ingot a section consisted of a few large grains, but this was not reproducible. Single crystal growth would not be expected in this system because of the lack of growth stability. With the presence of convective stirring, violent growth fluctuations would be expected at the solid-liquid interface. Single crystal growth from solution requires extremely good stability, which is obtainable only at much slower growth rates. Some of the factors that determine growth stability have been discussed quantitatively by Tiller (7).

Chemical purity.—Except for Si, the impurity content was below the level of detection by emission spectrographic analysis. The impurities were best detected by photoluminescence studies. A detailed paper on the photoluminescence properties of this material is presented elsewhere (11). Briefly, the major impurities determined by photoluminescence were N, S, C, and Si. The S and C levels, as determined by electrical measurements, were below 3×10^{16} at./cc. The Si con-

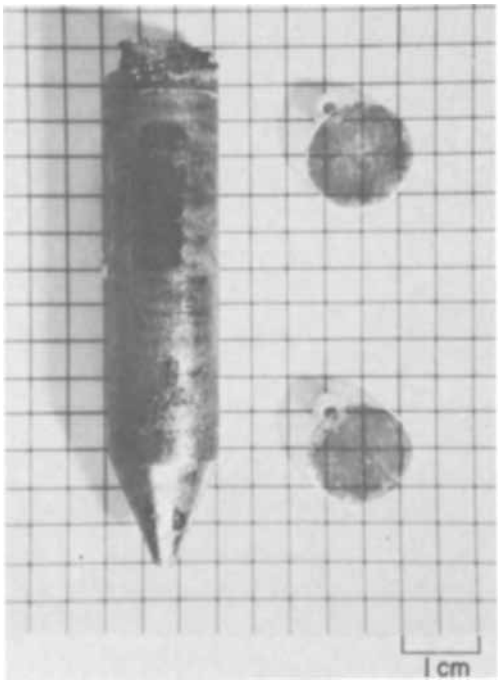

Fig. 2. Typical synthesized ingot. Polished sections shown are taken from top and bottom of another ingot.

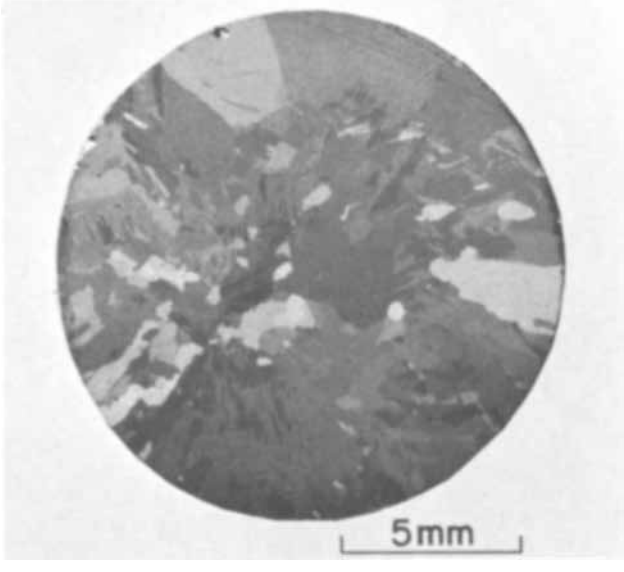

Fig. 3. Typical grain structure of an ingot. Cross section shown taken from the center portion of an ingot.

tamination is from the quartz. It was found that by operating the reactor at a lower temperature the Si could not be seen in photoluminescence. The S and C contaminations are from the PH_3-Ar gas mixture. It was possible, however, to obtain gas mixtures in which the only contaminant observed in the synthesized GaP was N (by photoluminescence) and this was probably introduced from the BN crucible. Some of the C may also be attributed to contamination from the BN crucible.

Growth conditions.—The growth conditions during synthesis were determined from the thermal probe measurements made during one run. The temperature profiles at various times after the start of synthesis, both in the ingot and solution, are shown in Fig. 4. After the start of synthesis each curve has two distinct inflection points. The lower inflection point designates the position of the solid-liquid interface while the top inflection point designates the position of the surface of the Ga solution. Some of the growth parameters

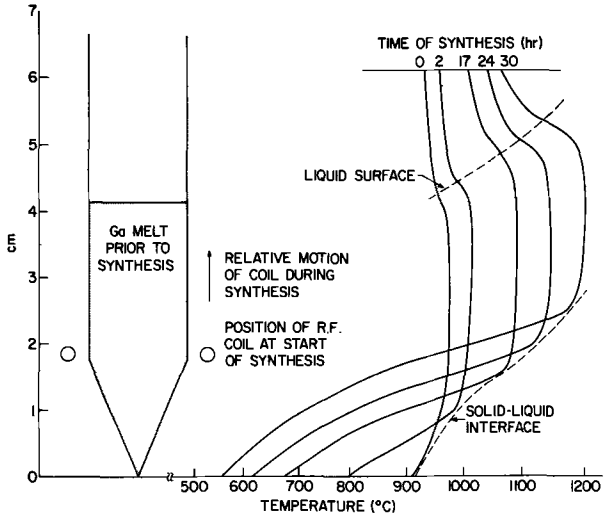

Fig. 4. Temperature profile in the solution and the ingot during synthesis.

determined from the thermal probe data are shown in Table II. The temperature of the solution increased as synthesis progressed since the rf power was not decreased proportionately to the amount of solution that was left. After the initial synthesis in the cone was complete, the growth rate and temperature gradient became essentially constant at about 1.7×10^{-5} cm/sec and about 320°-380°C/cm, respectively. If we assume that G_s, the temperature gradient obtained from the curves, is equal to G_L, the temperature gradient in the liquid at the solid-liquid interface,[2] then the G_L/f values can be calculated. Values calculated from the experimental data are shown in Table I for the temperature range used during synthesis. At the lower temperature, *i.e.*, the first quarter of the ingot to synthesize, the G_L/f values are below the predicted values for cs. This agrees quite well with the experimental evidence since entrapped Ga was occasionally observed in this region of the ingot. At the higher temperatures, *i.e.*, the remainder of the ingot, the G_L/f values are greater than the predicted value for cs and in this portion no entrapped Ga was observed.

Conclusion

A method of synthesizing high-purity GaP at reasonable rates of growth from dilute Ga solutions is described. It was demonstrated that it is possible to maintain sufficiently steep temperature gradients in a growth system to prevent cs. With the present system, the maximum temperature gradient possible was about 380°C/cm. It was found experimentally that with this gradient growth rates of about 1.7×10^{-5} cm/sec were possible for a Ga solution saturated with P at about 1200°C, without entrapping Ga. The G_L/f ratio necessary to prevent cs agrees fairly well with the theoretical value.

[2] This assumption is good for metallic crystal growth where heat transfer is only by conduction. However, for transparent materials such as GaP, heat is also transferred by radiation. O'Hara *et al.* (12) have shown that this can cause the gradient in the liquid to exceed that in the solid.

Table II. Measured growth parameters

Time after start of synthesis, hr	Interface position from cone, cm	Temperature of solid-liquid interface, °C	Temperature of reaction surface, °C	G_s °C/cm	f cm/sec
0	0	—	—	—	—
2	0.98	988	1016	210	1.7×10^{-5}
17	1.55	1080	1092	320	1.7×10^{-5}
23.5	2.01	1137	1145	380	1.7×10^{-5}
29.5	2.47	1188	1200	380	1.7×10^{-5}

The ingots were polycrystalline because of the severe growth conditions during synthesis. Considerably more growth stability would be required for single crystal growth.

The Use of Metal-Organics in the Preparation of Semiconductor Materials

I. Epitaxial Gallium-V Compounds

H. M. Manasevit and W. I. Simpson

Autonetics Division of North American Rockwell Corporation, Anaheim, California

ABSTRACT

Single-crystal GaAs, GaP, $GaAs_{1-x}P_x$ and $GaAs_{1-x}Sb_x$ films have been grown on GaAs and a number of insulating substrates by the decomposition of alkyl-gallium compounds in the presence of arsine, phosphine, arsine-phosphine, and arsine-stibine mixtures. Both triethylgallium and trimethylgallium have been used successfully in the preparation of GaAs. This process makes compound semiconductor film growth compatible with methods used for the growth of elemental semiconductors and eliminates many of the difficulties inherent in multitemperature-zone processes.

A key factor in the fabrication of many semiconductor devices is the production of single-crystal material of high purity and quality. Films of Ga-V compounds are normally harder to produce than films of elemental semiconductors. Most of the CVD methods for epitaxy already reported (1, 2) involve at least a two-temperature process: (*a*) at T_1, the formation of volatile Ga compounds by the reaction in hydrogen of metallic Ga or the Ga-V compound itself with a halide or water vapor (3) as a transporting agent; and (*b*) at $T_2 < T_1$, the deposition of the compound on a substrate in an atmosphere containing the Group V constituent. When transporting agents are used to produce high-purity epitaxial films of gallium arsenide (GaAs) on GaAs and a number of other semiconductor substrates, etching may also occur; and the early stages of epitaxial growth probably involve some doping of the growing film with impurities in the substrate or, in heteroepitaxial semiconductor systems, with the major elemental constituents of the substrate. This may result in the production of an interfacial alloyed layer in a system such as GaAs on Ge, for example.

Although the transport technique is amenable to closed-tube methods, many advantages to open-tube processes can be cited; and the latter approach is most often used. However, the nature of the reactions involved in the production of the III-V compounds necessitates that the two temperature zones be carefully controlled for reproducible growth to occur. In addition, depending on the growth technique used, it can be important to keep some of the reactants separate (1) until they reach the deposition zone, so that source materials are not affected.

This paper describes a process which requires only one hot temperature zone for the *in situ* formation and growth of the semiconductor compound directly on the heated substrate. This occurs in an atmosphere essentially free of an etching specie and is sufficient not only for growth on some semiconductors but also for growth on insulating substrates.

In this process, compound semiconductor films are produced by reacting organo-Ga compounds and Group V hydrides. Because of the use of the more volatile organo-Ga compounds, *i.e.* triethylgallium (TEG) and trimethylgallium (TMG), it has been possible to meter appreciable quantities of these room-temperature liquids into the reactor by bubbling a carrier gas through them. They can then be mixed in the reactor with different arsine (AsH_3), phosphine (PH_3), arsine-phosphine (AsH_3-PH_3), or arsine-stibine (AsH_3-SbH_3) concentrations controlled independently by simple flowmeter adjustments. Selenium or sulfur may be added as n-type dopants from tanks containing hydrogen selenide (H_2Se) or hydrogen sulfide (H_2S), respectively, diluted with a carrier gas; and p-type doping is obtained by passing the carrier gas over diethylzinc (DEZ) (4) equilibrated at 0°C in a stainless-steel container.

Experimental

Apparatus.—The apparatus consists principally of a single vertical 60-mm OD quartz tube 38 cm long containing a silicon-carbide-covered carbon pedestal which can be inductively heated; stainless-steel bubblers containing the liquid metal-organic compounds and SbH_3; appropriate flowmeters for monitoring the carrier gas,

group V hydride(s), and dopant flows; burn-off area for hydrogen; and a manifold made from ¼-in. stainless steel tubing. Provisions are made for bypassing the quartz reactor and keeping the reactants separate until the gases are equilibrated and ready to be mixed for film formation. A schematic of the apparatus is shown in Fig. 1.

Temperatures, observed on the SiC-coated pedestal, were estimated by comparing the readings of an infrared thermometer with those of an optical pyrometer at pedestal temperatures greater than 750°C, establishing an average emissivity value for the system (0.75), and then extrapolating infrared thermometer signal readings to still lower temperatures. Film thickness was determined either from measurement of an infrared reflectance interference pattern or from angle-lapping and staining multilayer structures.

Materials.—Triethylgallium (TEG) and trimethylgallium (TMG), both air- and water-sensitive liquids, were obtained commercially. The TMG was additionally purified by vacuum-trap distillation until tensiometrically homogeneous fractions were obtained [vapor pressure of TMG at 0°C = 64.5 mm, literature value = 64.5 mm (5)]. The AsH_3 concentrations were nominally 5 or 10% in H_2 and the PH_3, 10% in H_2. SbH_3 was stored under H_2 and equilibrated at −78°C. H_2Se was diluted to 500 ppm in H_2. Diethylzinc (DEZ) was purged with H_2 at −23°C for about 30 min and then stored at 0°C under H_2 until used for doping studies. During doping, the bubbling tube was kept above the liquid.

Ge (111) and GaAs semi-insulating substrates of several orientations were mechanically polished and then chemically polished just before use. Natural faces of flux-grown BeO and ThO_2 were used without polishing after being cleaned with trichloroethylene, water, and methanol rinses. Solvent-cleaned, mechanically polished, essentially scratch-free, basal-plane (0001) Verneuil sapphire (Al_2O_3) and (111), (110), and (100) slices of spinel ($MgAl_2O_4$) cut from Czochralski boules were used as substrates without further treatment.

Procedure.—In the early stages of the investigation, only TEG was commercially available, and it was used in a preliminary study to determine the feasibility of preparing GaAs films by the use of organo-Ga compounds. Thin single-crystal films of GaAs were formed on freshly etched Ge wafers by bubbling H_2 at about 1 liter/min through TEG at about 60°C for 1 hr and decomposing the gases at 700°C on the Ge wafers in an atmosphere containing AsH_3. The crystal character of the overgrowth of GaAs/Ge is shown in Fig. 2, and single crystallinity was confirmed by reflection electron diffraction.

When TMG (bp = 55.6°C at 760 mm) became available, the deposition procedure became more controllable because of its greater volatility as compared with TEG (bp = 143°C at 760 mm). Conditions now considered sufficient for growing good-quality (111) GaAs on appropriately oriented substrates of Ge, GaAs,

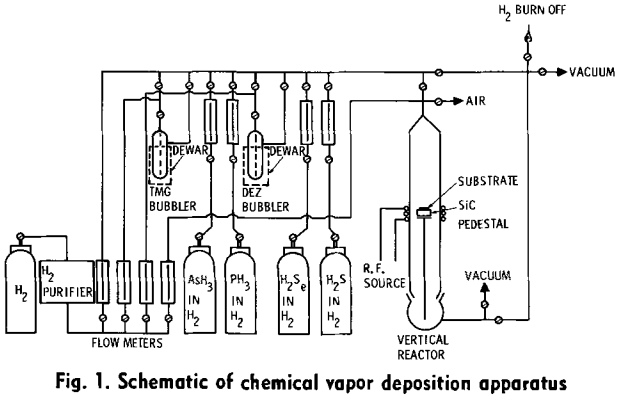

Fig. 1. Schematic of chemical vapor deposition apparatus

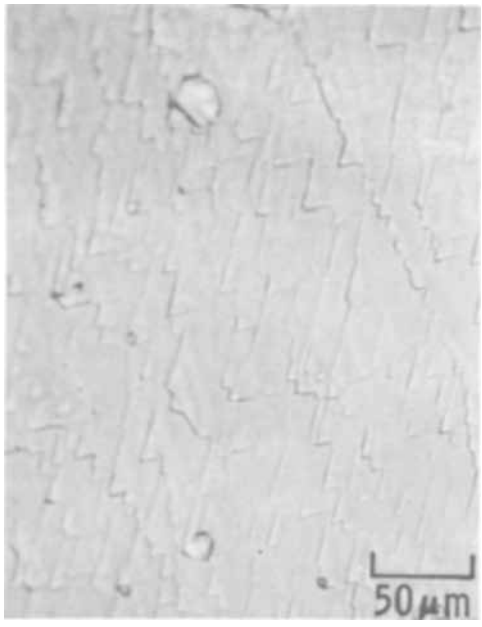

Fig. 2. Surface structure of (111) GaAs growth on (111) Ge (the film was produced from TEG and AsH_3).

and single-crystal insulators incorporate the following typical ranges of concentrations and parameters: TMG 0.2-0.8%; arsine (10%) flow rate about 100-400 ml/min; total H_2 flow rate about 1.5 liters/min; and pedestal temperature 650°-750°C. When the substrate is GaAs, the AsH_3 flow is started independently of the TMG with the pedestal at about 600°C to establish an arsenic atmosphere and help prevent decomposition of the substrate; at the desired deposition temperature, the TMG is introduced to form the GaAs deposit. It was determined for the apparatus in use that better films are produced if the group V hydrides are introduced into the reactor prior to the addition of the TMG for growth on insulating substrates also. Hydride flow is also continued when the deposition is completed and until the temperature has dropped to about 600°C.

The structural nature of the deposit, indicated by the general appearance as viewed in the optical microscope, was determined by x-ray diffraction and/or electron diffraction analysis. The presence and relative compositions of As, P, and Sb in the films were determined with the electron microprobe.

The electrical properties of the films were evaluated from measurements made on Hall samples etched in the GaAs films by standard photolithographic techniques. The carrier concentrations were deduced from the Hall coefficient R_H according to $n = 1/eR_H$, and the Hall mobility was determined from the product $\mu_H = \sigma R_H$, where σ is the electrical conductivity.

Results and Discussion

Using the aforementioned procedures, single-crystal films of GaAs, GaP, and solid solutions of gallium arsenide-phosphide ($GaAs_{1-x}P_x$) and gallium arsenide-antimonide ($GaAs_{1-x}Sb_x$) can be produced on Ge, GaAs, and/or a number of single-crystal insulating substrates.

GaAs *epitaxy.—Film orientation and crystal quality.* As described in a previous publication (6), epitaxial growth of GaAs has been achieved on a number of insulating substrates. The results from that paper are summarized in Table I. Figure 3 shows the surface of a 30-μm film on (0001) Al_2O_3 and the triangular pattern characteristic of (111) growth. The GaAs surface appears rough at thicknesses greater than about 6 μm and displays a rosette pattern, somewhat noticeable in Fig. 3 but more apparent at slightly lower magnifications. Similar growth occurs on (111) $MgAl_2O_4$ and a

natural (10$\bar{1}$1) BeO face (Fig. 4). A typical reflection electron diffraction pattern and x-ray Laue pattern for (111) GaAs growth on (0001) Al_2O_3 are shown in Fig. 5. In (a), strong Kikuchi lines are evident and support the single-crystal nature of the overgrowth; in (b), extra spots not due to the substrate can be identified and correlated with the (111) GaAs overgrowth (6).

Simultaneous growth on (0001) Al_2O_3 and on the (111)"A" and (111)"B" faces of GaAs demonstrated that the surface of the film grown on Al_2O_3 resembled the growth on the GaAs "A" face. This suggests that bonding at the Al_2O_3-GaAs interface involves an As bridge, perhaps between metal ions at the substrate surface and the succeeding Ga layer in the film. If so, one might expect different epitaxial relationships to exist between GaAs and Al_2O_3 and between Si and Al_2O_3 (7), in which bonding seemed to be related to a filling-in of metal-ion sites with bonding to the oxygen ions. Preliminary experiments involving GaAs growth on a few other sapphire orientations support the contention that different epitaxial relationships do exist in the different systems, despite the similar cubic-type structure and lattice parameters for Si (5.43A) and GaAs (5.65A).

This contention was further supported in recent studies by the observed growth of (100) GaAs on Czochralski (110) $MgAl_2O_4$,[1] a rather surprising result when compared with the GaAs-spinel relationships reported in Table I. It was also found that the epitaxy is sensitive to the quality of the spinel; for when some Verneuil spinel ($MgO \cdot 3.3Al_2O_3$) was used as a substrate, the intersection of grain boundaries with the crystal surface was readily revealed by the GaAs overgrowth (Fig. 6).

[1] This observation was made during studies being supported in part by the NASA contract No. NAS12-2010.

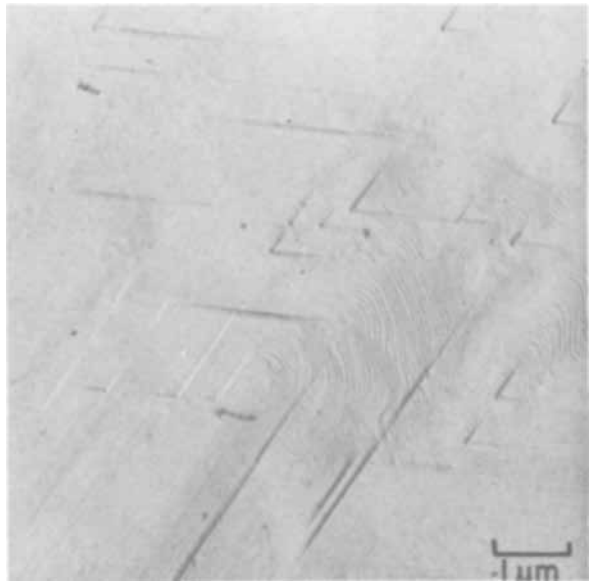

Fig. 7. Replica electron micrograph of (111) GaAs film growth on (0001) Al_2O_3.

As was observed for the silicon growth on (0001) Al_2O_3 (8), a high degree of twinning may exist in (111) GaAs films grown on (0001) Al_2O_3 if the deposition conditions are not optimized. One sample was measured as having a twin density of 7.8%. The technique for twin density measurement has been previously described (8). A replica electron micrograph for a 10-μm film is shown in Fig. 7. An indication of some twinning in the film can be seen. Growth steps in the epitaxial film are also evident. However, the reflection electron diffraction pattern for the film (similar to Fig. 5a) does not support the high twin density value. This correlates with the observation (based on measured charge carrier mobility values) that film quality can improve with film thickness. X-ray techniques provide an average value of twin density for the complete film thickness (8), while reflection electron diffraction basically reveals surface quality. With proper deposition conditions, mirror-smooth GaAs films with no detectable twins (as determined by x-ray evaluation) are being grown on (0001) Al_2O_3 and (111) $MgAl_2O_4$.

Some of the defect structure in films with microtwinning grown on insulators can be revealed by a light polishing-etch such as 1:1:4 hydrogen peroxide-water-sulfuric acid. The triangular pattern shown in Fig. 8a was produced by dipping a mechanically polished 14-μm (111) GaAs film grown on (111) $MgAl_2O_4$ for 10 sec into a freshly prepared 1:1:4 solution. Two minutes of etching (Fig. 8b) (about 2.5 μm removed) revealed a relatively uniform continuation of the defect structure. However, after 5 min of etching, only very small pyramids were evident (Fig. 8c) at the surface of the remaining 7-μm thick film. This also suggests an improvement in film quality with thickness for GaAs grown on $MgAl_2O_4$.

Studies of GaAs grown on BeO have been limited to the natural faces of flux-grown crystals. Attempts to reuse the bare natural faces of the BeO substrates without repolishing have been only partially successful. When GaAs films are etched off with HNO_3-HF mixtures, the substrates seem less amenable to (100) GaAs regrowth but slightly better for (111) GaAs growth on the $(10\bar{1}1)$ face. The $(10\bar{1}0)$ surface is apparently changed significantly by the sequence involving film growth and subsequent removal by the acid mixture.

Effects of deposition parameters on GaAs *film growth.* —At any one temperature, the growth rate of (111) GaAs on Al_2O_3 has been found to be essentially linear with TMG concentration when it is decomposed in an atmosphere containing As and at least a 10-fold excess of AsH_3 over TMG in the gas stream entering the

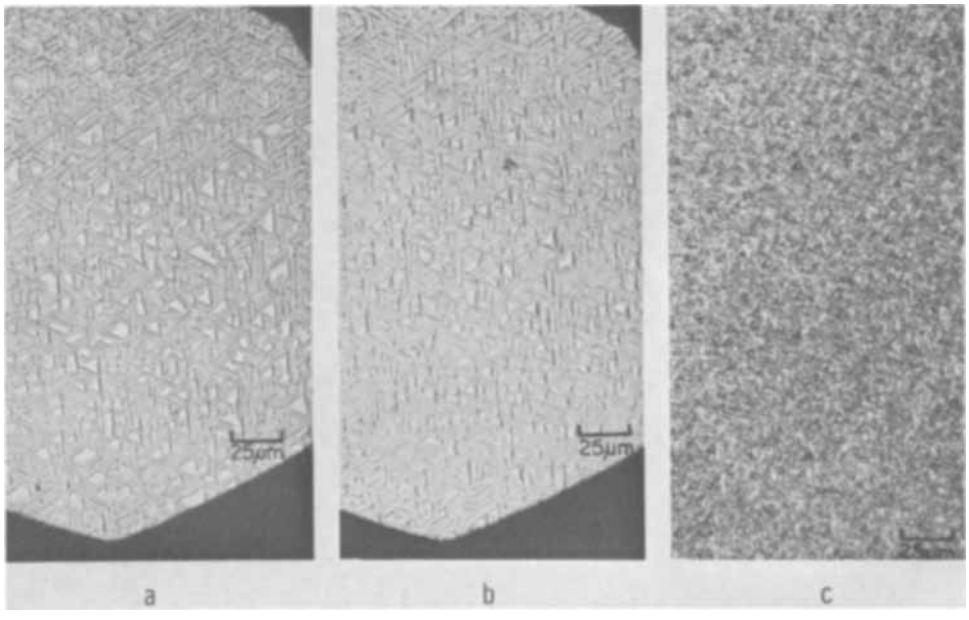

Fig. 8. Structure revealed in a 14-μm (111) GaAs growth on (111) $MgAl_2O_4$ by etching with 1:1:4 hydrogen peroxide-water-sulfuric acid mixture for a total of: a—10 sec, b—2 min, c—5 min (7 μm removed).

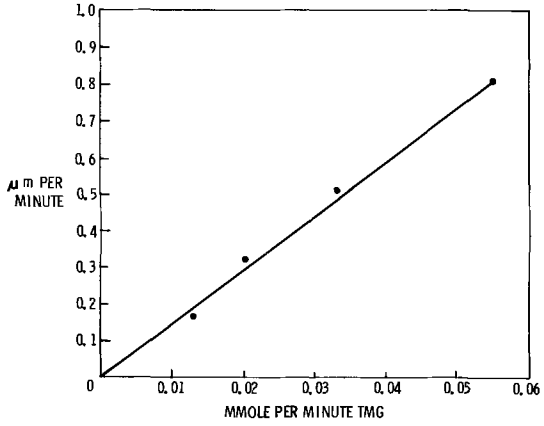

Fig. 9. Growth rate at 725°C of (111) GaAs on (0001) Al_2O_3 as a function of TMG concentration.

reactor. Typical growth rates at 725°C are depicted in Fig. 9 for different concentrations of TMG carried into the reactor per minute. With higher concentrations and temperatures, considerable turbulence is evidenced near the vicinity of the heated pedestal.

In the temperature range 600° to about 800°C, the growth rate was found to be essentially constant for TMG additions of 0.02 and 0.03 mmole/min but dropped off somewhat at about 825°C (Fig. 10). Films grown on Al_2O_3 at 800° and 825°C were less perfect than those grown at 675°C, as determined by reflection electron diffraction (Fig. 11).

Electrical properties of GaAs *films.*[2]—Hall coefficient measurements were used to examine the electrical properties of the GaAs films. Undoped specimens up to ~5 μm thick produced from one combination of TMG and AsH_3 exhibited high resistivity, about 10^3-10^5 ohm-cm. The addition of H_2Se to the gas stream containing the TMG and AsH_3 produced on pyrolysis n-type films with net carrier concentrations as high as 6.2×10^{18} electrons/cm³, obtained when the H_2Se flow rate was about 100 ml/min. The addition of "excess" H_2Se caused the electron mobility to decrease slightly and changed the appearance of the GaAs deposit. These surface changes are shown in Fig. 12(a-f). The change in crystal character may be due to the formation of another compound such as Ga_2Se_3, As_2Se_3, or an alloy, as the solubility limit of Se in GaAs is exceeded.

The addition of DEZ to the gas stream provided p-type GaAs growths with net carrier concentrations up to 2.8×10^{19} holes/cm³, resistivities of 0.003 ohm-cm,

[2] An up-to-date and more complete description of the electrical properties of GaAs films grown by the TMG-AsH_3 process will appear in a subsequent paper by A. C. Thorsen.

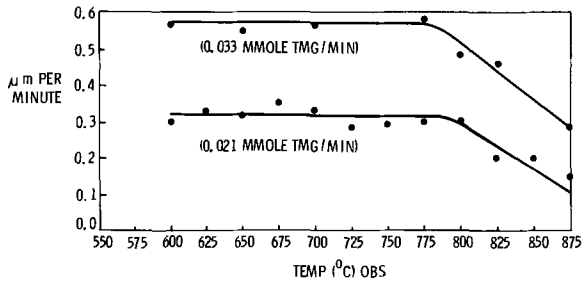

Fig. 10. Effect of substrate temperature on rate of growth of (111) GaAs on (0001) Al_2O_3.

and room temperature mobilities of about 75 cm²/V-sec. The highest doping level was reached when the H_2 flow over the DEZ was about 35 ml/min. Further additions of zinc as DEZ also caused a change in the surface character, as noted in Fig. 13(a-d).

Mobilities of Se-doped GaAs films grown on (0001) Al_2O_3 early in our studies were found to be dependent on film thickness. Films less than about 8 μm thick exhibited average mobilities usually less than 2000 cm²/V-sec, while films about 8-25 μm thick had average mobility values of about 4000 cm²/V-sec for carrier concentrations of about 4×10^{16} cm^{-3}.

Mobilities of about 5000 cm²/V-sec at $n = 1 \times 10^{16}$ cm^{-3} have recently been measured for GaAs films not intentionally doped. Experiments are also in progress to compare the properties of the growth of GaAs on GaAs with the films grown on the insulators. The effect

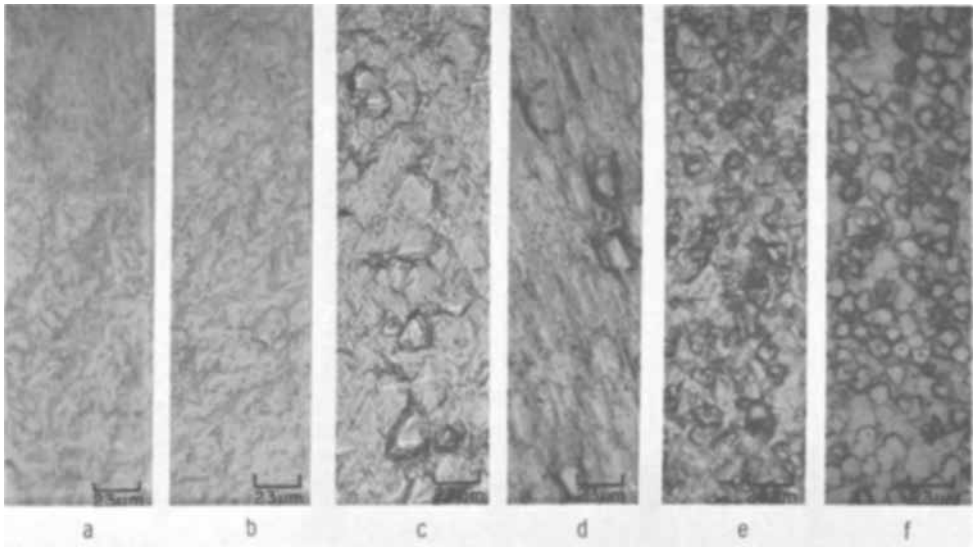

Fig. 12. Effect on appearance of GaAs growth at 725°C on (0001) Al_2O_3 of increases in H_2Se concentration. The doped H_2 flow rates were: a—10 ml/min, b—50 ml/min, c—100 ml/min, d—150 ml/min, e—200 ml/min, f—325 ml/min.

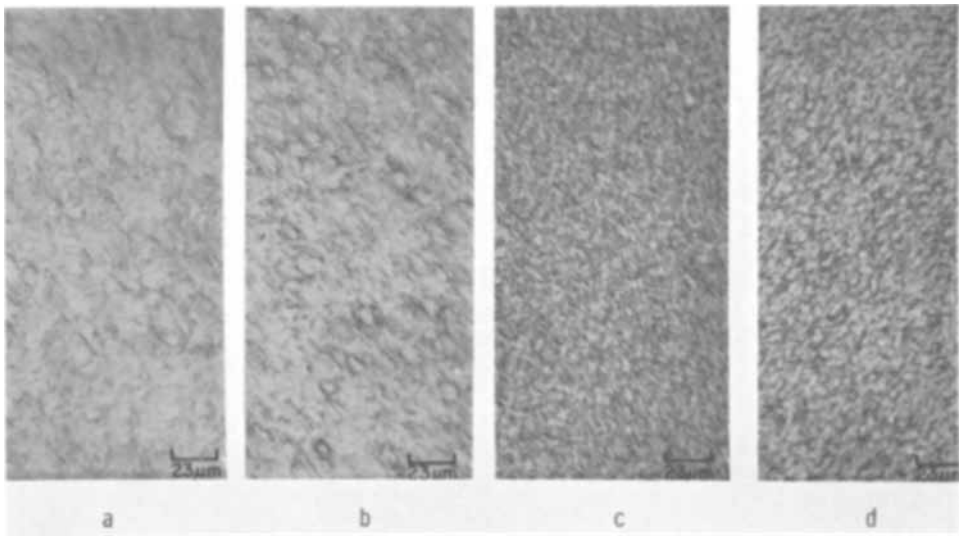

Fig. 13. Effect on appearance of GaAs growth at 725°C on (0001) Al_2O_3 of increases in DEZ concentrations. The H_2 flow rates over DEZ were: a—5 ml/min, b—25 ml/min, c—35 ml/min, d—75 ml/min.

of the purity of the starting materials on film properties is also being studied.

Films of GaAs grown on insulating substrates have been found to possess a much lower degree of residual stress than that found for Si on Al_2O_3 (9, 10) and $MgAl_2O_4$ (11). This is not unexpected, since the mean linear thermal expansion coefficients for GaAs (6.4 x 10^{-6}/°C) (12) and sapphire ($\perp$ to c-axis, 7.7 x 10^{-6}/°C, between 20°-500°C) (13) are not too far apart at room temperature. Essentially, no bowing could be observed for a 35-μm GaAs film grown on a 10-mil Al_2O_3 substrate. However, a 1-μm film did curl a 5-μm Al_2O_3 platelet concave downward, indicating that the residual stress in the GaAs is compressive. Further studies of the stresses in the films and their effect on electrical properties are in progress.

By varying the amounts and types of dopants introduced into the gas stream during crystal growth, multilayer epitaxial structures have been fabricated on Al_2O_3. A four-layer (p^+, p, n, n^+) 48-μm thick structure was grown on (0001) Al_2O_3, photolithographically processed, and etched into mesas with relatively large p-n junction areas of about 6 x 10^{-4} cm^2. An I-V characteristic of one of these "grown" diodes is shown in Fig. 14. Capacitance-voltage measurements indicated that the junctions were transitionary between graded and abrupt.

GaP *and* $GaAs_{1-x}P_x$ *epitaxy*.—Although the emphasis to date has been on the preparation of films of GaAs on insulating substrates, some experiments have been carried out with the TMG-AsH_3 and/or PH_3 reaction to prepare films of GaP and $GaAs_{1-x}P_x$ mixed compounds on GaAs and on insulating substrates.

However, it is apparent that controlling the growth of single-crystal films of GaP on insulators is more difficult than the control of GaAs film growth. Whereas GaAs films only 1 μm thick are single crystal on Al_2O_3, GaP films of the same thickness have to date exhibited only highly preferred orientation on (0001) Al_2O_3 while exhibiting single crystallinity on GaAs. However, the films on Al_2O_3 have improved in quality with additional thickness growth, producing surfaces that were identified as single-crystal (111) orientation by reflection electron diffraction. The electron diffraction pattern for the surface of such a film (7.5 μm thick) grown on (0001) sapphire is shown in Fig. 15. The pattern is sharp, and good structure is indicated.

GaP growth on a thin sapphire platelet caused curling of the platelet in a concave downward direction, which indicated the residual stress in the GaP film to be compressive.

Additions of PH_3 to the AsH_3-TMG mixtures normally used for growing GaAs films will produce thin single-crystal $GaAs_{1-x}P_x$ films on (0001) Al_2O_3. In these preliminary studies, single-crystal films with the compositions $GaAs_{0.9}P_{0.1}$ and $GaAs_{0.4}P_{0.6}$ have been grown on (0001) Al_2O_3 and (111) $MgAl_2O_4$. Additional studies are in progress.

Multilayers of single crystals of GaAs and GaP have also been fabricated on Al_2O_3. Figure 16a shows the multilayer structure revealed by a bevel section through a GaAs/GaP/GaAs/Al_2O_3 film. The order of the surface structure in Fig. 16b indicated a single-crystal com-

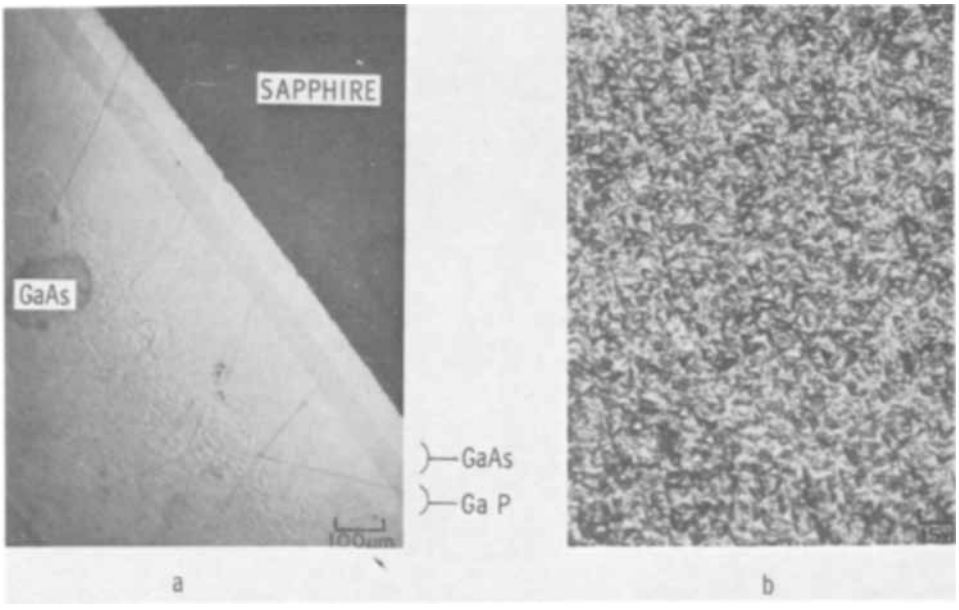

Fig. 16. a—A multilayer GaAs/GaP/GaAs/Al_2O_3 composite as revealed by angle-lapping, b—surface of the composite.

posite. This was confirmed by x-ray diffraction procedures.

$GaAs_{1-x}Sb_x$ *epitaxy*.—A few experiments relating to $GaAs_{1-x}Sb_x$ epitaxy were performed at 725°C on (100) GaAs and (0001) Al_2O_3. Single-crystal films with approximate compositions in the range $GaAs_{0.9}Sb_{0.1}$ to $GaAs_{0.7}Sb_{0.3}$ were obtained when the TMG-AsH_3-SbH_3 ratios were arbitrarily changed by either reducing the arsenic flow or increasing the flow rate of hydrogen bubbling through the liquid SbH_3. Better growth, as determined by reflection electron diffraction, was obtained on (100) GaAs than on (0001) Al_2O_3 at the higher concentrations of Sb. Epitaxial films of $GaAs_{1-x}Sb_x$ can also be achieved by using trimethylantimony in place of SbH_3 (14).

Reaction mechanisms.—The use of the metal-organic for semiconductor film formation was not without concern for the possibility of major carbon contamination. Graham (15) reported that the pyrolysis of TMG at 520°C in an argon carrier gas produced a metallic-looking film containing 8.0% carbon. Plust (16) described the production of Ga of semiconductor purity by photolysis of TEG, but Graham obtained gray-black solids containing metallic Ga using Plust's process. In order to prevent the formation of nonvolatile carbonaceous side-products, two steps were initially taken: (*a*) the use of H_2 as the carrier gas as a means for tying up free radicals that may be assumed to be involved in the mechanism for the pyrolysis of TMG; and (*b*) the use of the Group-V hydride(s) in excess over the stoichiometric amount required to react with a given amount of TMG, as represented, for example, by reaction [1] for the formation of GaAs:

$$(CH_3)_3Ga + AsH_3 \rightarrow GaAs + 3CH_4 \qquad [1]$$

The AsH_3 in excess (or other group V hydride) probably reacts with the TMG before it has a chance to pyrolyze, thus avoiding the formation of undesirable products. It also provides an As atmosphere to help prevent the dissociation at elevated temperatures. The relatively low temperatures used for GaAs formation also apparently prevent C from being a major contaminant in the GaAs films. If C were there as a minor contaminant, it would most probably be due to impure starting materials or caused by improper handling in the deposition apparatus.

Harrison *et al.* (18) performed an experiment in which TMG and AsH_3 were mixed at room temperature in 1:1 molecular proportions in the vapor state for 18 hr and then heated to about 200°C. This produced a red film which was postulated to be stoichiometric GaAs. Unfortunately, the experiment was not evaluated sufficiently. If the rate of formation and quantity of methane had been measured, then one would have more confidence in the study of the stoichiometry of reaction [1]. There may have also been a reaction between AsH_3 and a gray film which Harrison reported had formed on the walls of the tube at room temperature. This film may have been a reaction product between TMG and Pyrex, which has been previously observed (19). It was in the belief that reaction [1] was the predominant reaction that studies of reactions between the metal-organics and the hydrides were begun. Knowledge of Harrison's prior investigation at low pressures came to light afterwards.

A few experiments in our laboratories were also performed using $AsCl_3$ and TMG as the reacting materials. Epitaxy was not achieved on the insulators, and this approach was soon discarded. It may be that the reaction is complicated by the formation of HCl, produced by the reduction of $AsCl_3$ by H_2

$$2AsCl_3 + 3H_2 = 1/2As_4 + 6HCl \qquad [2]$$

Further reaction by TMG with HCl could produce in the first stage of the reaction the compound methyl gallium dichloride

$$2(CH_3)_3Ga + 4HCl \rightarrow (CH_3GaCl_2)_2 + 4CH_4 \text{ (20)} \qquad [3]$$

followed by complete dealkylation

$$(MeGaCl_2)_2 + 2HCl \rightarrow 2CH_4 + 2GaCl_3 \qquad [4]$$

HCl could also obstruct epitaxy if the growth rate of the depositing film is less than its etching rate by the HCl.

Summary

The decomposition of alkylgallium compounds (R_3Ga), *e.g.* trimethylgallium or triethylgallium, in the presence of arsine, phosphine, arsine-phosphine, or arsine-stibine has produced single-crystal growth of the corresponding Ga-V compounds on single-crystal insulating substrates as well as on GaAs, GaP, and/or Ge. A reasonable explanation for the formation of the Ga-V compound is expressed by the reaction, *e.g.* for the production of GaAs

$$(CH_3)_3Ga + AsH_3 \xrightarrow[650°\text{-}750°C]{} GaAs + 3CH_4$$

This technique obviates the use of multiple temperature zones for the CVD process, simplifies the procedure considerably, and makes compound semiconductor film growth compatible with the growth of elemental semi-

conductors, such as Si and Ge. This compatibility has made it possible to fabricate and study, *via*, CVD and appropriate masking techniques, various combinations of single-crystal compound and elemental semiconductor layers on the same insulating substrate. New degrees of freedom and new concepts in device design are now apparent which may make optimum use of the differences in the physical, electrical, and optical properties of different semiconductors.

Acknowledgments

The authors wish to thank F. M. Erdmann for assisting in the growth of the layers; Dr. R. L. Nolder, L. A. Moudy, and E. R. Goldman for electron and x-ray diffraction analyses; Dr. A. C. Thorsen for the electrical measurements; G. W. Johnson, J. L. Healy, and D. Medellin for the angle lapping and some of the photomicrographs; R. W. Stewart for electron microprobe analyses; J. P. Wendt and Dr. B. T. French for the device processing and evaluation of the 4-layer GaAs diode; S. B. Austerman for the BeO crystals; and Dr. R. P. Ruth for his most helpful discussions, encouragement, and direction in the described program.

Stresses in SiO_2 Films Obtained from the Thermal Decomposition of Tetraethylorthosilicate—Effect of Heat-Treatment and Humidity

J. A. Aboaf*

IBM Watson Research Center, Yorktown Heights, New York

ABSTRACT

The interference fringe method was used for measurement of stresses in SiO_2 films deposited on Si and Ge substrates. An attempt has been made to deduce both the amount of stress resulting from intrinsic stress and the stress arising from mismatch of temperature coefficient of expansion. From measurement at room temperature of stress in SiO_2 films deposited by thermal decomposition of tetraethylorthosilicate at 725°C in forming gas (less than 0.2 x 10^9 dynes/cm^2), or at 450°C in oxygen ($+1.5 \times 10^9$ dynes/cm^2), it is concluded that the intrinsic stress is tensile. The mechanical properties of the SiO_2 films prepared by these two methods were assumed to be similar to those of bulk vitreous silica. An explanation is offered for the observed increase in the room temperature tensile stress of the 450°C-SiO_2 film on heat-treatment to 700°C, and to the following decrease in tensile stress on heat-treatment to 800°C. A decrease in the room temperature stress in the 450°C-SiO_2 film occurs on exposure of the film to a humid ambient.

It is well known that dielectric and metal films deposited on substrates by a variety of methods are in a state of stress. Hoffman (1) in a recent review on stresses in films has dealt extensively with the measurement and origin of the stress.

The control of both the magnitude and sign (tensile or compressive) of stresses in thin film insulators deposited on semiconductors is of primary importance in the fabrication of semiconductor devices and circuits. Excessive stress in films can cause (*i*) bowing of the semiconductor substrates, with subsequent difficulty in photolithographic processes, (*ii*) the appearance of slip lines (due to plastic flow of the semiconductor) with deleterious effects in the subsequent processing of the devices, and (*iii*) cracking and peeling of the insulating films.

Stresses in thin films result from the difference in thermal coefficient between the film and substrate, from structural modifications resulting from heat treatment, and from the built-in intrinsic stress. Little is known about the intrinsic stress of films except that

* Electrochemical Society Active Member.

it is dependent on the deposition parameters and appears to be intimately related to the nucleation and growth of the film. In this study, the intrinsic stress of films has been deduced by subtracting from the experimentally measured stress, the calculated contribution resulting from the difference in thermal expansion between the film and substrate, assuming for the coefficient of expansion of the film the value of the bulk material when available.

The present investigation was undertaken to measure the room temperature stress in pyrolytic SiO_2 thin films, the changes in stress on densification of these films when heat-treated at high temperatures, and the effects on stress resulting from exposure to a humid ambient.

Experimental

Substrates.—Glang *et al.* (2) have shown that silicon wafers could be used for the measurement of stress in thin films. In the present study, <111> silicon (Monsanto Corporation) and <111> germanium (IBM Corporation) substrates were used. Wafer thicknesses were approximately 8 mils, and wafer diameters were approximately 1 in. The germanium wafers were p-type, either 0.1 ohm cm or 3-8 ohm cm and were polished on both sides; the silicon wafers 0.1 ohm cm were polished on one side. Only wafers exhibiting uniform curvatures were used. They were cleaned in 1:1 HF:H_2O prior to oxide deposition. Oxides were deposited on the concave face of the wafers (for Si, the polished face).

Film deposition.—The films were deposited by the pyrolytic decomposition of tetraethylorthosilicate in a forming gas atmosphere (10% H_2-90% N_2) at 730°C (3) (H. T. SiO_2), and in oxygen at 450°C (4) (L. T. SiO_2). Thickness uniformity was better than ± 5%.

Three deposition rates 50, 100, and 200 Å/min were used for the L. T. SiO_2. The H. T. SiO_2 was deposited at 200 Å/min. The thickness of the films used for stress measurement was approximately 4000Å.

Measurement of stress.—The method used for measurement of stresses in films and the mathematical details of the stress analysis have been described by Finegan and Hoffman (5), and consists of measuring the shape of the substrate and of the substrate film by the interference fringe technique. The change in the shape of the substrate indicates strain in the wafer, which in turn is a measure of the stress in the film.

In order to measure the stress in the films it is assumed that the substrate wafer is elastic, uniformly thick, thin compared to its radius, and that its deflection is small as compared to its thickness. This was the case in the experiments described below. However, in some cases when the thickness of the film was high and the stress at the temperature of deposition was higher than the yield stress of the substrate, the substrate deformed irreversibly (6); consequently the condition of elasticity is not met, and the theory of bending plates could not be applied.

We have used an experimental apparatus quite similar to that of Finegan and Hoffman (5). The shape of the wafers at room temperature, as determined by the Newton's ring technique, is to be parabolic. The substrate rests film side down on an optical flat and is illuminated by sodium light. The interference fringe pattern produced is photographed with a Polaroid camera (Fig. 1), and subsequently another interference fringe pattern is obtained after stripping the film from its substrate. This is the reference pattern. The relative position of the fringes on both fringe patterns (corresponding to a distance of 1.2 cm on the wafer) is measured in two perpendicular directions, making sure that the substrate film and the substrate reference data are taken in the same relative position. For each set of data, a computer program is used to fit a parabola by the method of least squares and to calculate the force per unit width in the two directions. The average of these two values, divided by the thickness of the film, is the stress in the film at room temperature.

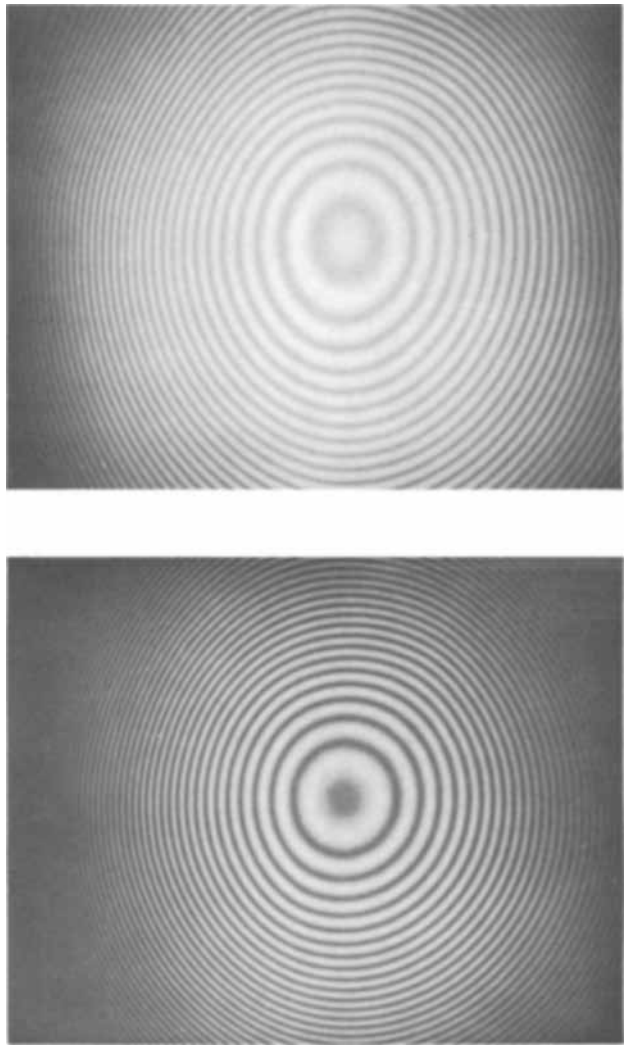

Fig. 1. Interference fringe pattern of uniformly curved silicon wafer: Top, without SiO_2 film; bottom, with 450°C SiO_2 film.

The sensitivity of the measurement is such that it is possible to detect for the wafer and film thicknesses used a minimum stress of 2.5×10^8 dynes/cm^2. The error involved in the stress measurement is dependent on the error of three independent variables: film thickness, substrate thickness, and the difference in the number of fringes. The error was calculated to be less than 15%.

The thickness of the films is measured independently either by Vamfo (7) or by double beam interferometry. Young's modulus data for the silicon and germanium substrates (necessary to calculate the room temperature stress in the films) were taken from Glang (2) and Fine (8).

Results

Wafer curvature without films.—At an early stage during this study it was found that not all wafers could be used. The interference fringe pattern of the wafers varied from well-defined (Fig. 1) to hopelessly distorted (Fig. 2) concentric rings. The yield of wafers showing a uniform circular or elliptical pattern varied from batch to batch; yields as low as zero and as high as 80% were encountered. This effect is probably due to the stresses induced during polishing. Annealing at temperatures of up to 800°C reduced yield still further.

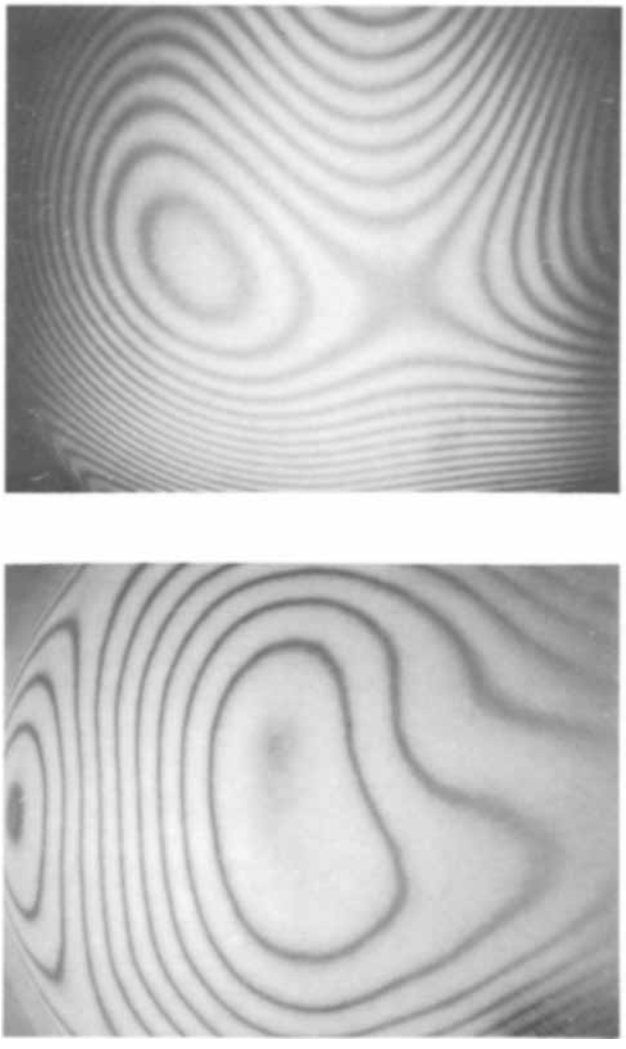

Fig. 2. Interference fringe pattern of distorted wafers

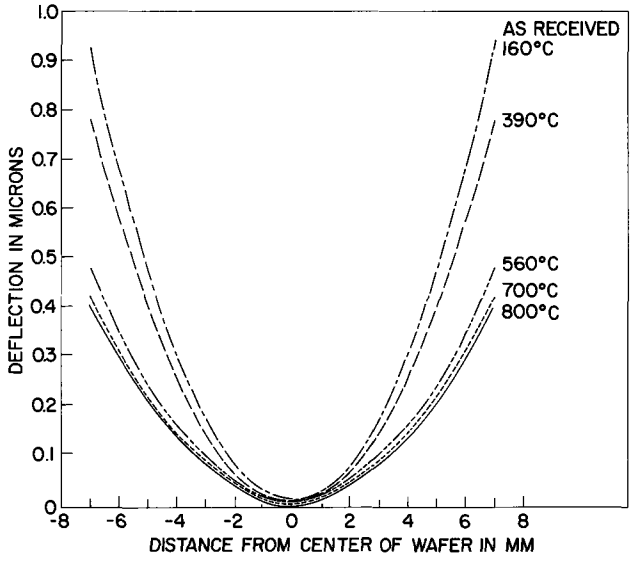

Fig. 3. Room temperature curvature of silicon wafer (Monsanto 5 ohm-cm) after heat-treatment in forming gas for ½ hr at various temperatures.

All results given in this study were obtained with wafers showing a well-defined fringe pattern of concentric rings with and without the dielectric film (Fig. 1).

The curvature of a silicon wafer is shown in Fig. 3 after several annealing treatments at different temperatures. It is seen that the wafer flattens with increasing temperature. For the measurement of stress it was not necessary to anneal every substrate. In fact, the curvature of the wafer after annealing at a certain temperature is identical to that obtained after deposition of the oxide at this temperature and successive stripping of the film. However, when heat-treatment of oxides at different temperatures were made, the wafers were annealed at 800°C for 4 hr prior to deposition of the oxide film. The change in the stress at room temperature of the oxide was then measured on basis of the same reference wafer.

Stress at room temperature of SiO_2 *films.*—A film deposited on the inner surface of a curved substrate is in tension if the film causes a decrease in the radius of curvature of the substrate, and in compression in the reverse case. In the first case, the sign of the stress is taken to be positive, and in the second case negative.

The stress at room temperature in SiO_2 films deposited on silicon and germanium is shown in Table I.

The reproducibility in the stress at room temperature is much better for the H. T. SiO_2 than for the L. T. SiO_2. It has not been possible to differentiate the stress at room temperature for L. T. SiO_2 deposited at 50, 100, 200 Å/min. The stress at room temperature for SiO_2 films deposited at 380° and 520°C fell within the range given for the 450°C-SiO_2.

Room temperature stress of SiO_2 *as a function of high-temperature annealing.*—L. T. SiO_2 films on silicon were heat-treated at 700° and 800°C in a forming gas atmosphere. The change in the room temperature stress for a typical specimen is shown in Table II.

The room temperature stress in the film increases after the 700°C heat-treatment and decreases after the 800°C treatment. Compared to the room temperature curvature at 450°C, the room temperature curvature at 700°C has increased, while that after the 800°C has decreased.

The stress at room temperature in the film reaches a plateau value rapidly after a few minutes at 700°C; at 800°C, the plateau value is reached more slowly. The thickness of the SiO_2 film after the 700°C treatment is reduced by 8%, and after the 800°C treatment by 11%, compared to that of the as-deposited sample.

L.T. SiO_2 films, 4000Å thick, on germanium crack on heat-treatment at 700°C. Films deposited on silicon do not crack after heat-treatment at 800°C.

Effect of a humid ambient on the room temperature stress of L.T. SiO_2.—L.T. SiO_2 films on silicon were treated in a humidifier at 85°C and 85% relative hu-

Table I. Stress at room temperature in SiO_2 films

	L.T. SiO_2	H.T. SiO_2
On silicon wafers	Tension $+0.9$ to $+2 \times 10^9$ dynes/cm²	Less than 0.2×10^9 dynes/cm²
On germanium wafers	Compression -0.2 to -1×10^9 dynes/cm²	Compression -1.7 to -2×10^9 dynes/cm²

Table II. Change in room temperature stress

Film treatment	Min	Room temperature stress, dynes/cm²
450°C-SiO_2 on silicon		$+1.5 \times 10^9$
Heat-treated at 700°C	5	$+2.3 \times 10^9$
Heat-treated at 700°C	15	$+2.2 \times 10^9$
Heat-treated at 700°C	30	$+2.5 \times 10^9$
Heat-treated at 800°C	5	$+1.1 \times 10^9$
Heat-treated at 800°C	15	$+0.7 \times 10^9$
Heat-treated at 800°C	30	$+0.3 \times 10^9$
Heat-treated at 800°C	60	$<0.2 \times 10^9$
Heat-treated at 800°C	90	$<0.2 \times 10^9$

midity. The change in the room temperature stress for a typical specimen is as follows:

SiO_2 as deposited	$+1.2 \times 10^9$
after 5 hr in 85°C, 85% RH	$+0.4 \times 10^9$
after 21 hr in 85°C, 85% RH	$+0.5 \times 10^9$

The decrease in room temperature stress occurs with no change in thickness of the film.

Discussion

Intrinsic stress in SiO_2 *films.*—Schwuttke and Howard (9), Blech *et al.* (10), Drum and Rand (11), and more recently Lathlaen and Diehl (12) have interpreted their stress measurements in SiO_2 films as function of various parameters (temperature, rate of deposition, etc.) as being due to various values of coefficient of expansion for SiO_2 films. A different interpretation is given below based on our experimental results.

The measurement of stress in the film at room temperature does not differentiate between stresses generated by the difference in thermal expansion between the film and substrate, and intrinsic stress. The total stress, S, as measured at room temperature is

$$S = (\alpha_{\text{film}} - \alpha_{\text{sub}}) \frac{E_f}{1 - \gamma_f} (T_2 - T_1) + \sigma_i$$

α thermal coefficient of expansion of the film or substrate
E modulus of elasticity of the film
γ_f Poisson's ratio for the film
$T_2 - T_1$ temperature of deposition of film -- room temperature
σ_i intrinsic stress.

Let us assume that the mechanical properties of the high-temperature SiO_2 films are similar to those of bulk vitreous silica. α, E, and γ for SiO_2 are taken respectively equal to 0.55×10^{-6}, 7.2×10^{11} dynes/cm^2, and 0.17 (13). The average coefficient of expansion of silicon between any two temperatures is taken from Maissel (14). Using these values, it is possible to calculate the intrinsic stress, taking for the room temperature stress in H.T.-SiO_2 films on silicon substrates, the experimental value. The intrinsic stress is tensile and its value is $\sim + 2.1 \times 10^9$ dynes/cm^2.

One can also make the assumption that the intrinsic stress in SiO_2 films is the same whether deposition occurs on silicon or on germanium wafers. Under this assumption, using the above equation and using the coefficient of expansion for germanium (15), the stress expected in SiO_2 on germanium substrates can be estimated. This stress is compressive, equal to -1.8×10^9 dynes/cm^2 and is in excellent agreement with the experimental value (Table I). The qualitative results obtained for films on germanium are in agreement with those made by x-ray diffraction by Segmuller (16).

If the above assumptions are used to estimate the room temperature stress of L.T. SiO_2 on germanium, the agreement between the calculated value and the experimental value is not as good; this is not unexpected considering the porous properties of the low-temperature oxide (4).

Annealing effects.—The room temperature stress in L.T. SiO_2 films when these are heat-treated successively to 700° and 800°C suggest that two effects occur: the first one in conjunction with the increase in tensile stress and the second one with the decrease in tensile stress to an essentially stress free film at room temperature.

The increase in tensile stress is attributed to the densification of the film because of loss of moisture contained in the film and to the closing of pores during heat-treatment to 700°C. In fact, the infrared spectra of low-temperature SiO_2 shows a water content as measured at the 3650 cm^{-1} band of 6% (0.060 optical density/micron). After the heat-treatment, the water content is 1% (0.010 optical density/micron) and the oxide is 8% thinner. It is interesting to note that this effect occurs without the shifting of the Si-O stretching band (1065 cm^{-1}) to higher frequencies.

The subsequent decrease in tensile stress as measured at room temperature after heat-treatment at 800°C may be attributed to a structural densification which results in the shifting of the 1065 cm^{-1} Si-O band to a value of 1075 cm^{-1}. The water content in the film after the 800°C treatment remains at the level reached after the 700°C treatment: the oxide thickness decreases by another 3%. Pliskin and Lehman (17) noted Si-O frequency shifts after densification of films by heat-treatment. Mackenzie (18) has interpreted volume shrinkage in bulk vitreous silica primarily to variation in the mutual orientation of SiO_4 tetrahedra.

The stress at room temperature and the intrinsic stress (stress at temperature) for low temperature SiO_2 films deposited at 450°C and annealed at 700° and 800°C are given in Table III. It is interesting to note that the intrinsic stress in the low temperature oxide is practically equal to that of the oxide which has been heat-treated at 800°C: *i.e.*, on heat-treatment at 800°C, it appears that the stress built into the films during deposition has not been released; this result cannot be explained. The intrinsic stress in the films at 450°, 700°, and 800°C was calculated as shown above on basis of the experimental values of stress at room temperature and of the mechanical properties of bulk SiO_2.

The cracking on heat-treatment of a 4000Å thick SiO_2 film deposited on germanium (this does not occur for films deposited on silicon) might be due to the large stress resulting from the larger thermal coefficient of expansion of germanium as compared to that of silicon. However, the estimated stress at temperature is almost the same for the SiO_2 film on germanium heat-treated at 700°C and for the SiO_2 film on silicon heat-treated at 800°C; only in the first case does the film crack. It does not appear thus that the high stress is the cause of cracking. It is possible, as suggested by Krongelb (4), that on heat-treating at high temperature, the moisture contained in the film tends to react as the interface between the germanium and SiO_2, forming gaseous GeO, which upon escaping would rupture the film.

Humidity effects on stress in SiO_2 *films.*—Drift of stress due to weathering for SiO_2 films deposited by the silane-NO process was reported by Drum and Rand (11). For our films, a large decrease in the room temperature stress occurs on exposure to a humid ambient. Densification (*i.e.*, decrease in the volume of the film) does not, however, occur. The Si-O absorption band shifts from 1065 to 1075 cm^{-1}. Pliskin (17) observed that increase in water content in electron gun evaporated SiO_2 film results in a shifting of the Si-O stretching band toward higher frequencies, and interpreted the phenomenon as being due to strain, varia-

Table III. Stress at room temperature and intrinsic stress for SiO_2 films

	Stress at room temperature (experimental) dynes/cm^2	Stress at* temperature (intrinsic stress) dynes/cm^2
L.T. SiO_2	$+1.5 \times 10^9$	$+2.5 \times 10^9$
L.T. SiO_2 heat-treated at 700°C for 30 min in forming gas	$+2.2 \times 10^9$	$+4.3^{**} \times 10^9$
L.T. SiO_2 heat-treated at 800°C for 1 hr in forming gas	$+0.2 \times 10^9$	$+2.5^{\dagger} \times 10^9$

* Calculated on basis of the experimental results and the assumptions made in text.
** If no densification would occur, the stress at temperature should have been $+3.4 \times 10^9$ dynes/cm^2 (experimental stress at room temperature + stress induced in heating the sample from 25° to 700°C).
† If no densification would occur, the stress at temperature should have been $+3.8 \times 10^9$ dynes/cm^2.

tion in band energy, and purity. It is suggested that the decrease in stress is related to the breakdown of the film structure as SiO_2 tetrahedra reacts with H_2O to form silanol groups (4) and a more open structure.

The presence of an intrinsic stress in vapor deposited SiO_2 films has been shown but not explained. Klokholm (19) has interpreted the intrinsic stress in metal systems as being due to the annealing and shrinkage of disordered material underneath the surface of the growing film. Unfortunately, we do not know the structure of SiO_2 films and how their structure differs according to the method of preparation. Recent experimental and theoretical advances in x-ray diffraction (20) have yielded new information on the structure of bulk SiO_2. The use of these techniques might be useful for SiO_2 films.

Conclusion

On the basis of room temperature stress measurements in SiO_2 films deposited on silicon and germanium, it has been possible to estimate the intrinsic stress in vapor deposited SiO_2 films by assuming for the values of the mechanical properties of the films deposited at high temperature those of the bulk properties of vitreous silica; the intrinsic stress derived is the same for both substrates.

The heat-treatment effects of low-temperature films occur in two stages: first, an increase in tensile stress occurring with loss of moisture contained in the film, densification, and no variation in the Si-O stretching band; second, a decrease in tensile stress occurring gradually and resulting in a shift toward higher frequencies of the Si-O band.

The room temperature stress in low-temperature films decreases sensibly on exposure to a humid ambient with no densification of the film. The intrinsic stress in these films is not explained.

Some Properties of Vapor Deposited Silicon Nitride Films Obtained by the Reaction of $SiBr_4$ and NH_3

J. A. Aboaf*

IBM Watson Research Center, Yorktown Heights, New York

ABSTRACT

Silicon nitride films, easily etchable in buffered HF (75 Å/min) and usable as gallium diffusion masks, are deposited at 800°C by the $SiBr_4$ and NH_3 reaction (ratio $SiBr_4$ to NH_3 of 1:13) in a forming gas atmosphere. The chemical composition of the films, deposited between 500° and 800°C, as measured by chemical and electron microprobe analysis, is nearer to $Si(NH)_2$ than to Si_3N_4. The 800°C films are impervious to moisture. The room temperature stress in the films deposited on silicon is very high ($+1.2 \times 10^{10}$ dynes/cm^2) and cannot be lowered by decreasing the temperature of deposition or the $SiBr_4$ to NH_3 ratio. The intrinsic stress of the films is highly tensile and is much higher than that in vapor deposited SiO_2 films: germanium wafers tend to warp with formation of slip lines. Films of Si_3N_4 composition containing —NH groups are obtained at 800°C when the ratio of $SiBr_4$ to NH_3 is 1:4.

The purpose of this study is to evaluate the reaction of $SiBr_4$ vapor and NH_3 at different temperatures in a forming gas atmosphere in view of obtaining silicon nitride films of the following characteristics: (*a*) films useful as diffusion masks against gallium at 800°C for 16 hr; (*b*) films easily etchable in buffered HF; and (*c*) films of low tensile stress or possibly compressive stress.

Silicon nitride films are prepared by various methods: reaction between silane and ammonia at temperatures above 750°C (1-3), and at low temperature

* Electrochemical Society Active Member.

by a radio frequency glow discharge reaction (4), or sputtering (5). These methods lead to silicon nitride films of Si_3N_4 composition; they are resistant to moisture and are good masks against shallow diffusion of B, P, As, and Ga (6); they are essentially insoluble in buffered HF and only slightly soluble in concentrated HF.

Mixed nitride-oxide films (7) are prepared by adding a few per cent in volume of oxygen to silane and ammonia gases. These films etch faster in HF, but this method of deposition cannot be used when the substrate is germanium because of the oxidizing atmosphere.

Silicon nitride films obtained from the reaction between $SiCl_4$ and NH_3 can be deposited on silicon at temperatures ranging between 550° and 1250°C (8, 9). A similar reaction is studied here.

Experimental

Deposition conditions.—The deposition of nitride films is carried out in a horizontal resistance furnace, 15 in. long. The furnace tube is made of quartz with an outside diameter of 59 mm; a quartz liner of 55 mm inside diameter is used and is changed every few runs. The hollow substrate holder, also of quartz, has a flat top and curved bottom and rests on the bottom of the furnace tube liner. The temperature on the top surface of the substrate (the deposition temperature) is calibrated against the temperature registered by a thermocouple placed inside. During an experimental run only the inside temperature is recorded.

A schematic of the apparatus is shown in Fig. 1. High-purity ammonia (Precision Gas Products Company) flows into the quartz tube through a nozzle situated at a distance of about 2 in. from the uniform hot zone. This geometry is necessary in order to minimize the reaction of $SiBr_4$ and NH_3 prior to reaching the hot zone. Silicon bromide, semiconductor grade (Alfa Organics Company) is kept at room temperature in a bubbler. Forming gas is used to transport the silicon bromide into the furnace and as the diluting gas. "High purity" forming gas is not satisfactory: a germanium wafer, when heated in this atmosphere at 800°C, shows a "hazy" surface resulting from an attack of the germanium. This reaction is probably due to residual H_2O in the gas. Accordingly, prior to entering into the furnace tube, the forming gas is purified by flowing it first through a platinum bed heated at approximately 400°C and then a liquid nitrogen trap (for condensation of H_2O). No etching of germanium surfaces is observed under these conditions.

Germanium nitride is found to form by the reaction of ammonia and a germanium halide between 400°-600°C (10). Electron microscopy of the surface of a <110> germanium wafer after exposure to an ammonia atmosphere for 30 min at 800°C reveals well-defined 6-facets pits. No attack of the germanium surface due to NH_3 is noticeable using the procedure described below.

The substrate wafers, silicon or germanium, are placed on the holder and the quartz tube evacuated to 20μ pressure. Purified forming gas is then introduced in the tube and the substrate holder pushed into the hot zone. When the desired temperature is reached, the ammonia is introduced in the tube and within one minute the bromide follows. As soon as the deposition is completed, the bromide and ammonia valve are closed and the substrate pulled out to the cooler zone of the furnace; subsequently, the tube is opened.

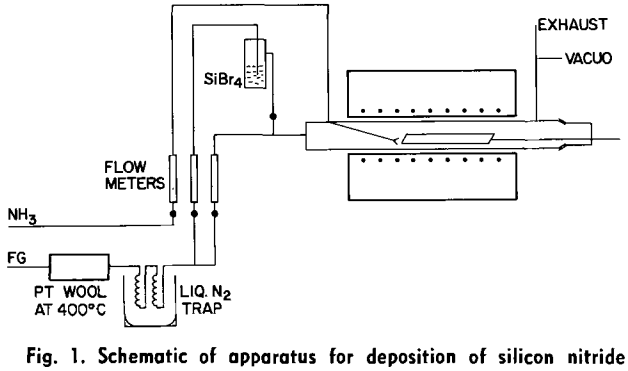

Fig. 1. Schematic of apparatus for deposition of silicon nitride ($SiBr_4$ + NH_3).

Chemical analysis.—Films, 6000-10,000Å thick deposited on germanium or platinum plates, are used for the determination of nitrogen and silicon. The nitrogen in the films is analyzed by the well-known Kjeldahl method. The silicon is determined by absorption spectrophotometry after reaction of the specimen with ammonium molybdate and subsequent reduction of the silicomolybdate.

Stress measurement.—Details of the experimental set-up of the problems regarding the choice of substrates are described elsewhere (11). Silicon wafers are used as substrate on the basis of the data reported by Glang *et al.* (12). The films are deposited on (111), n-type, 0.1 ohm cm silicon wafers, 8 mils thick. Measurements are made at room temperature using the interference technique described by Hoffman (13).

Gallium diffusion.—Lines, 2 mils wide, are made in silicon nitride films deposited at 800°C on germanium by photolithography and etching in buffered HF. A 500Å thick film of SiO_2 (deposited by the pyrolysis of tetraethylorthosilicate at 450°C in oxygen) is then deposited on the wafer. SiO_2 is not a mask against gallium diffusion, but serves to prevent the gallium from attacking the germanium surface.

The diffusion is conducted for 16 hr in a two-zone evacuated furnace with the gallium source at 750° and the specimen at 800°C; the vacuum is held at approximately 1 x 10^{-5} mm. The resulting surface concentration of gallium is 4 x 10^{18} atoms/cc.

Results

The silicon nitride films deposited on silicon or germanium are clear, transparent, and hard. Thickness variation (2000Å thick film) from one edge of a wafer to the other, and from wafer to wafer (2 wafer system) is less than 5%. The films are amorphous; electron diffraction shows only a pattern of diffuse rings. The surface of the films, as seen in electron microscopy, is particularly smooth. The refractive index of the film deposited at 800°C is 2.0.

In Fig. 2, an Arrhenius plot shows the rate of deposition of silicon nitride films for the following conditions: $SiBr_4$ 0.1 x 10^{-3} mole, NH_3 1.3 x 10^{-3} mole, forming gas as carrier gas, 5 l/min. Between 550° and 800°C there is a linear dependence of log rate *vs.* $1/T$. The slope indicates an activation energy of 19 kcal/

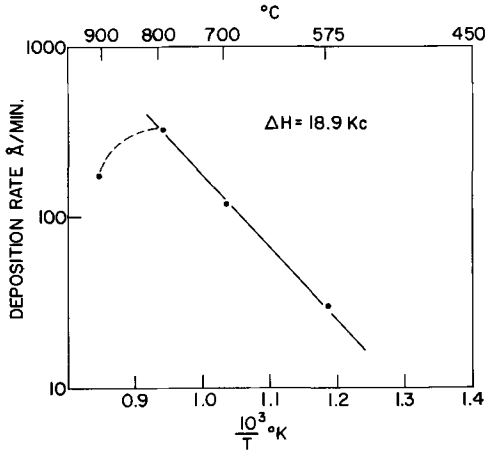

Fig. 2. Deposition rate of silicon nitride as a function of temperature. $SiBr_4$ 0.1 x 10^{-3} mole, NH_3 1.3 x 10^{-3} mole, carrier gas forming gas 5 l/min.

Table I. Etch rate of silicon nitride films

Temperature of deposition of silicon nitride films. NH_3 to $SiBr_4$ Ratio of 13:1	Etch rate in buff HF—25° Å/min	Etch rate in conc. HF—25°C Å/min
800	75	1350
700	150	—
575	1100	—

mole. The rate at 900°C decreases probably because of a depletion of the $SiBr_4$ at an upstream point, prior to reaching the deposition zone of interest.

The etch rate of the silicon nitride films ($NH_3/SiBr_4$ ratio of 13:1) is shown in Table I. It is worth noticing that in concentrated HF the etch rate is 1 order of magnitude higher than that for the nitride deposited by the silane process (1).

An MIS capacitance voltage measurement at 150 kHz made on a Ge-800°C nitride-Al sandwich results in a large density of negative fixed charge and/or surface states. The hydrogen used during deposition appears to induce surface states at the interface as was shown by Sedgwick (14). The same measurement made on a Si-800°C nitride-Al sandwich results in surface charge values of + 4 x 10^{12} charges/cm^2. The value of the dielectric constant is about 8 as computed from the maximum capacitance value of the MIS capacitance and the thickness of the oxide.

Stress measurements.—Stress measurements are made, at room temperature, on silicon wafers on which approximately 2000Å thick films are deposited. The stress at room temperature in films deposited at a $NH_3/SiBr_4$ ratio of 13:1 and at 800°C is tensile and equal to 1.3 x 10^{10} dynes/cm^2.

The stress in films deposited at different ammonia to bromide ratios is shown in Fig. 3. Films deposited at a ratio below 10:1 seem to contain an excess silicon; their etch rate is quite low, and the film cannot be totally removed with HF; consequently, they are not considered.

The room temperature stress of silicon nitride films deposited on silicon in the same apparatus by the reaction between SiH_4 and NH_3 in forming gas at 800°C, at a deposition rate of 125 Å/min, and a ratio of NH_3/SiH_4 of 20 results comparable to that of films obtained by the bromide process.

The room temperature stress in silicon nitride films on silicon deposited between 500° and 800°C at a $NH_3/SiBr_4$ ratio of 13:1 is given in Fig. 4. The stress is tensile and appears to be independent of the temperature of deposition.

The room temperature stress in silicon nitride films is one order of magnitude higher than that for SiO_2 films obtained by the pyrolytic decomposition of tetra-

ethylorthosilicate (11). While some data on the mechanical properties of single crystal silicon nitride (5) and polycrystalline silicon nitride of various porosities are available (15, 16), no data on amorphous silicon nitride can be found in the literature. Consequently, it is not possible to separate the stresses generated by the difference in thermal expansion between the film and substrate and that due to the intrinsic stress as it was done for SiO_2 films (11).

It would be interesting, however, to know at least qualitatively the sign of the intrinsic stress, or stress at temperature in the silicon nitride films. A nitride film is deposited at 800°C on a 2-mil thick, flat germanium wafer and its curvature observed *in situ* through a window situated at the end of the deposition tube. The wafer bows upward (with the nitride in the concave side). Thus, at the temperature of deposition, the intrinsic stress in the film is tensile.

Figure 5 shows the curvature (at room temperature) of a 2-mil thick (110) germanium which is coated with a 2200Å thick silicon nitride film at 800°C; for comparison that of a 2-mil thick germanium wafer on which is deposited a 7200Å thick SiO_2 film at 800°C by the thermal decomposition of tetraethylorthosilicate in forming gas is also shown. These wafers curve during deposition at 800°C and are found to be warped after being brought down to room temperature. From the large deflection brought about by the silicon nitride film, it can be concluded that the intrinsic stress in the nitride film is much higher than that estimated for SiO_2 (2.1 x 10^9 dynes/cm^2) (11). A visual inspection of the germanium wafers show that the germanium is plastically deformed; slip lines can be seen on the wafers. It is thus possible to conclude also that the intrinsic stress in both films is higher than the yield stress of germanium at 800°C. For a (110) germanium wafer, slip lines occur in the (111) plane in the <110>

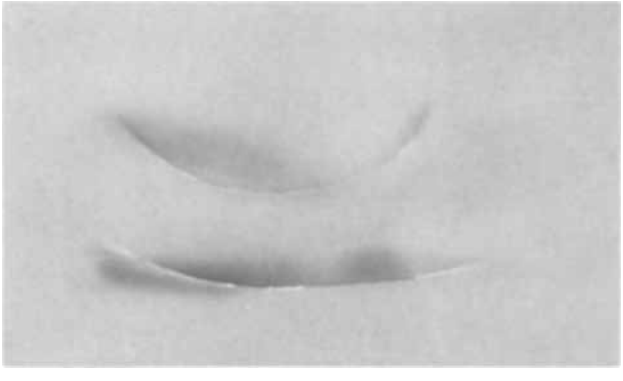

Fig. 5. Top, 2000Å thick silicon nitride film on 2-mils thick <110> germanium wafer; bottom, 7200Å thick SiO_2 film on 2-mils thick <110> germanium wafer (tetraethylorthosilicate process, 800°C).

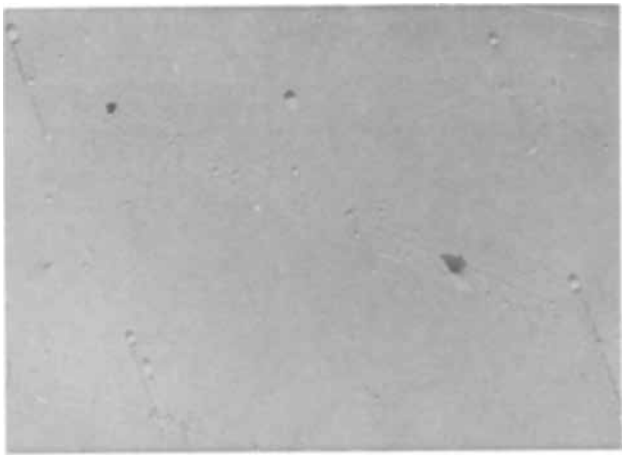

Fig. 7. Slip lines in germanium wafer <110>, direction <$1\bar{1}0$> as seen at the electron microscope. Magnification 9750X.

direction (Fig. 6). In Fig. 7, an electron microscope replica of the surface shows slip lines and a large number of pits (probably random dislocations along the length of the slip lines).

Diffusion masking.—Silicon nitride films on germanium deposited at 800°C ($SiBr_4/NH_3$ = 1/13) act as masks against gallium at 800°C for 16 hr. However, the germanium wafers covered with 1100Å thick silicon nitride + 500Å thick SiO_2 curve during the 16-hr diffusion with evidence of warping as explained in the preceding paragraph. It appears that the intrinsic stress in the silicon nitride, coupled with that of the SiO_2 film (10), are higher than the yield stress of germanium. The deformation of the wafers makes them unsuitable for device preparation.

Depositing the nitride at substrate temperatures of 700°C or less does not reduce the stress. Also, the stress is not reduced by increasing the ammonia to bromide ratio. However, a 300Å thick nitride film is a mask against gallium diffusion. This film is satisfactory; the silicon nitride + 500Å SiO_2 films do not warp the wafer during a 16-hr diffusion, and no slip lines could be found under examination with an interference microscope.

Chemical analysis.—A summary of the chemical analysis of silicon nitride films (about 8000Å thick) deposited on platinum or germanium is given in Table II. The chemical analysis is accurate to about 5% relative to the amount determined, the electron microprobe analysis to 2%.

The chemical analysis of the silicon nitride films deposited by the reaction of silane and ammonia at

*** SiH_4/NH_3 ratio = 1/20.

800°C ($NH_3/SiBr_4$ ratio of 20:1) shows that the atomic ratio of silicon to nitrogen is equal to 3/4 and agrees with that of Doo (17). For the nitride deposited by the silicon bromide and ammonia reaction at 800°C ($SiBr_4/NH_3$ = 1:13), this ratio appears to be 1/2. The only compound close to this atomic ratio described in the literature is the silicidiimide $Si(NH)_2$. It is formed in the liquid phase from $SiBr_4$ and NH_3 and is reported to be amorphous (19). Some properties of the silicidiimide and the nitride films deposited here are compared below. The infrared absorption spectra of the films (Fig. 8) shows not only the Si-N stretching vibration at 860 cm^{-1}, but also two other bands at 3350 and 1200 cm^{-1} which can be ascribed to the stretching and bending vibration of the NH group (18).

There is disagreement as to the mode of decomposition of the silicidiimide. According to Billy (19), the amorphous silicidiimide starts losing NH_3 at 80°C in a nitrogen atmosphere and is transformed into Si_3N_4 at 540°C; on the other hand, Glemser and Naumann (20), on basis of their thermogravimetric data, find the existence of two intermediate species before reaching Si_3N_4 at 1250°C, *i.e.*,

$$Si(NH)_2 \xrightarrow{300°C} Si_3N_5H_3 \xrightarrow{650°C} Si_2N_3H \xrightarrow{1250°C} Si_3N_4$$

(In these compounds, the percentage in weight in Si

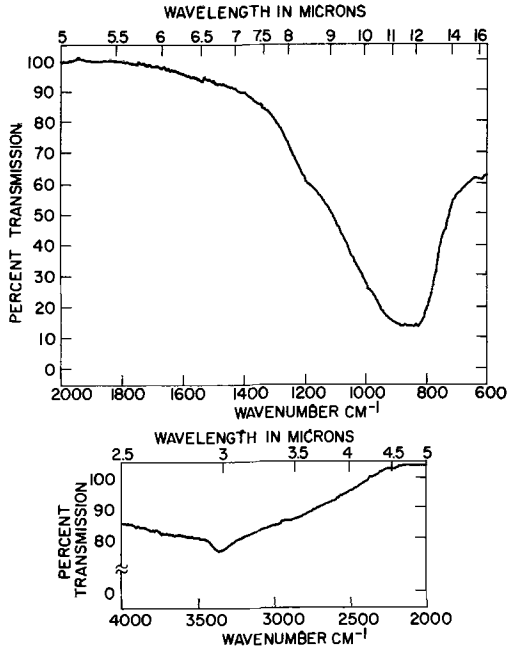

Fig. 8. Infrared absorption spectra of silicon nitride film deposited at 800°C ($SiBr_4/NH_3$ = 1:13).

is respectively 48.3, 53.4, 56.6 and 60; in N, respectively 48.3, 44.5, 42.4 and 40.)

Silicon nitride films, deposited on silicon by the bromide process at 800°C ($SiBr_4/NH_3$ = 1/13), were heat-treated in a forming gas atmosphere for 3 hr at 1300°C. The silicon composition in the films, as measured by the electron microprobe, do not change; however, the 3350 and 1200 cm^{-1} infrared absorption bands cannot be detected; accordingly, -NH groups are lost during heat-treatment. An electron diffraction study of the heat-treated films shows these films to be still amorphous.

The silicidiimide, formed in the liquid phase by the reaction of $SiBr_4$ and NH_3, absorbs water vapor readily (20). However, an infrared test of a film subjected to an 85°C and 85% relative humidity ambient, for 24 hr, shows no moisture pick up (minimum detectable 0.004 optical density per micron at 3650 cm^{-1}).

While composition and infrared properties suggest the film to be $Si(NH)_2$, other properties such as decomposition and water absorption do not confirm it. Also, it was possible to deposit at 800°C silicon nitride films of Si_3N_4 composition using a $SiBr_4$ to NH_3 ratio of 1:4. These films do not show any free silicon (electron microprobe analysis), but their infrared spectra shows -NH bands.

In conclusion, it appears that the reaction of $SiBr_4$ and NH_3 gives rise to amorphous films of various silicon, nitrogen content according to the temperature of deposition and to the ratio of $SiBr_4$ and NH_3; also, that the reaction in the vapor phase is different from that occurring in the liquid phase.

Conclusion

Silicon nitride films, readily etchable in buffered HF and usable as diffusion masks at 800°C for gallium were deposited by the $SiBr_4$ and NH_3 reaction at 800°C. The chemical composition of the films ($SiBr_4/NH_3$ = 1/13) is nearer to $Si(NH)_2$ than to Si_3N_4. It has not been possible to decrease the very high stress in the films (1.3 x 10^{10} dynes/cm^2) either by decreasing the temperature or by changing the $SiBr_4$ to NH_3 ratio.

Technical Notes

Structure of Silicon Monoxide

S. C. H. Lin and M. Joshi

IBM Burlington, Components Division, Essex Junction, Vermont

The electrical properties of silicon oxide films depend on the method of preparation, which determines the composition and the structure of the films. The structure of thin films of silicon monoxide obtained by the method of evaporation has been studied by researchers using electron diffraction (1), infrared spectroscopy (2, 3), and the electron microprobe (4). The electron diffraction and the electron microprobe studies indicate that the films consist of mixtures of Si and SiO_2. On the other hand, the infrared absorption spectroscopy results show that the films are predominantly mixtures of SiO, SiO_2, and a little Si_2O_3. All these studies are quite recent in comparison with the x-ray study (5) of bulk amorphous SiO, which is used as a source for evaporation. Brady (5) proposed, in 1958, that the bulk amorphous SiO is a material of stoichiometric mixture of SiO_2 + Si. Because of the controversy, we found it necessary to re-examine the atomic structure of SiO by x-ray diffraction.

Even after we made considerable improvement in the accuracy of the x-ray data, Brady's conclusion retains its essential validity. (Our SiO samples and Brady's samples were obtained from the same company.)

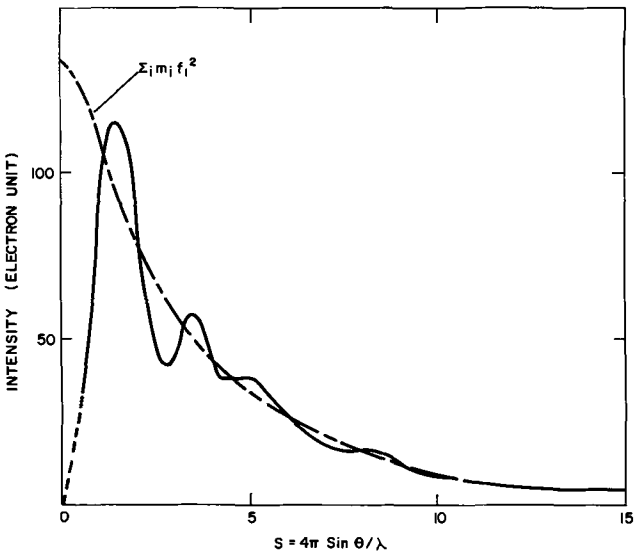

Fig. 1. X-ray intensity spectrum of silicon monoxide after correction and scaling.

Experimental

The first few peaks in the electron radial distribution function (RDF) are sensitively determined by the high angle data in the x-ray intensity curve. We took the following steps to minimize the errors in the RDF.

1. The intensity data were recorded over a considerably wider range of $S = 4\pi \sin \theta/\lambda$. $S_{max} = 15$ in our data; $S_{max} = 12$ in Brady's data.

2. Long-time step counting, 20 min/0.25° step, was performed to minimize the high angle range ($S > 5$) errors.

3. Intensity patterns were corrected only for polarization. Incoherent scattering correction was not felt necessary as the scattered x-ray entered the monochromotor before entering the counter. In our case, we have obtained in the electron unit a satisfactory normalization of the relative intensity curve throughout the total angular range. Information could not be obtained regarding this point from Brady's paper. Effective numbers of electrons $K_{Si} = 15$ and $K_O = 7$ and a sample density of 2.16 g/cm^3 were used in our radial distribution calculation.

4. The diffraction patterns were recorded with MoKα radiation. We used a scintillation counter, a monochromotor, and a pulse height analyzer for measuring scattered intensity.

Results and Discussion

The x-ray intensity curve we obtained is illustrated in Fig. 1. Curve a in Fig. 2 represents the following electron radial distribution:

$$R(r) = \sum_i \sum_j 0.5\, K_i K_j [4\pi r^2 n_{ij}(r)] = K_{Si}K_O[4\pi r^2 n_{Si-O}(r)] + 0.5\, K_{Si}K_{Si}[4\pi r^2 n_{Si-Si}(r)] + 0.5\, K_O K_O [4\pi r^2 n_{O-O}(r)]$$

Here the symbols are according to the usual notation (6). Our $R(r)$ curve is somewhat different from Brady's curve, as can be seen in Fig. 2. Peaks I and IV have almost identical positions in both curves. Peaks

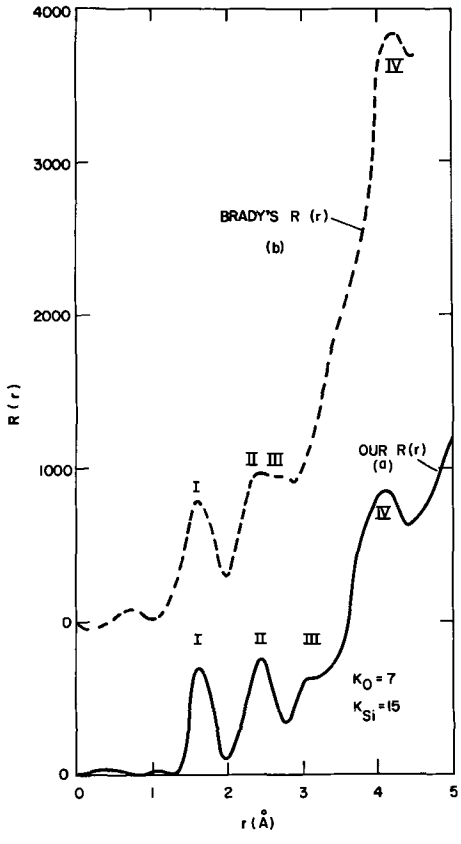

Fig. 2. Electron radial distribution curve of silicon monoxide compared with Brady's curve.

II and III are clearly separated, and are identifiable in our $R(r)$ curve. This separation gives considerable credence to Brady's model for SiO structure; namely, SiO is a mixture of amorphous Si and SiO_2.

Following Brady's line of argument, Peak I, at 1.63Å, is attributable to Si-O pairs from silica alone. The peak area is 210 e^2, which corresponds to 4 oxygen atoms around a silicon atom. Peak II has an area of 300 e^2 at 2.45Å. If this peak is due to the Si-Si pair from amorphous silicon alone, the silicon neighbor number becomes 5.3, which is large for an amorphous silicon. Since the O-O peak in vitreous silica locates at approximately 2.6Å, we would assume that this small O-O peak is hidden within the large Si-Si peak, since silicon atoms scatter twice as strongly as oxygen atoms. If half of the O-O peak area ½(0.5 x 7 x 7 x 6) = 74 is subtracted from the peak area, the rest of the area, 226 e^2 gives the correct value of 4 for the number of silicon-silicon neighbors. Peak III, at 3.05Å, is attributed to Si-Si pairs in SiO_2 and has an area approximately 240 e^2 which corresponds to 4.3 Si-Si pairs (7). Peak IV, at 3.94Å, in the radial distribution curve corresponds to the second Si-Si peak in amorphous silicon (1). The peak area calculations are summarized and compared with that of amorphous silicon and vitreous silica in Table I.

We find that the composition of the bulk SiO is a mixture of amorphous silicon and vitreous silica, as

Table I. Comparison of peak positions and areas of radial distribution function of SiO with amorphous silicon and vitreous silica

Peak	Pair distance r_{ij} (Å)	Pair I-J	Peak area A_{ij} (e^2)	No. of neighbors $n = \frac{A_{ij}}{m_i K_i K_j}$	Corresponding values in amorphous silicon		Corresponding values in vitreous silica	
					r	n	r	n
I	1.63	Si-O	210	4			1.63	4
II	2.40	O-O	(74)	(6)			2.6	6
		300 = Si-Si	(226)	(4)	2.35	4		
III	3.05	Si-Si	240	4.3			3.1	4
IV	3.95				3.85	12	4.0	

proposed by Brady. This chemical composition is not much different from the thin films of silicon monoxide as determined through electron diffraction (1) and electron microprobe (4).

Electrical Resistivity of Tungsten Films Prepared by WF_6 Reduction

A. F. Mayadas, J. J. Cuomo,* and R. Rosenberg

International Business Machines Corporation, Thomas J. Watson Research Center, Yorktown Heights, New York

This note is concerned with a study of tungsten films prepared by hydrogen reduction of tungsten hexafluoride. The observations reported here of large-area epitaxy of tungsten on sapphire are in esssential agreement with earlier structure work of the Autonetics group (1); however, we find that the very low deposition rates and high temperatures specified in the earlier work are not essential to achieving epitaxial single-crystal films. Resistivity studies for this class of films have not been previously reported; some of the present results are of particular interest in that they indicate a high degree of perfection in the single-crystal deposits.

Details of the film deposition apparatus are shown in Fig. 1. With the exception of the quartz mixing chamber and the quartz reaction tube, the system is constructed wholly of stainless steel and is completely helium leaktight, since preliminary observations had indicated that the presence of gaseous impurities is detrimental to film/substrate adhesion. Provisions were available for purging of the system with purified hydrogen, and, in order to eliminate contaminants, a hydrogen flow was maintained during periods when the system was idle. The hydrogen and WF_6 flow were controlled by a leak valve. For any one deposition, the film thickness was estimated from the WF_6 valve setting which was calibrated to W deposition rate. After each run, film thickness was measured to an estimated accuracy of $\pm 7\%$ by Tolansky interferometry.

The WF_6, obtained from the General Chemical Division of Allied Chemical Corporation, was of high-purity grade. The graphite susceptor was of spectroscopically pure graphite and prior to use it was completely coated at high temperature with tungsten to prevent outgassing during film deposition.

Oxidized silicon, sputtered Al_2O_3 on oxidized Si, and single-crystal α-Al_2O_3 (sapphire) wafers were used as substrates. These were cleaned in a hot concentrated solution of $H_2SO_4 + K_2Cr_3O_7$.

Typically, three substrates were placed in the system which was then purged for about 1 hr with hydrogen. The substrates were then preheated to 1000°C for 2 min, allowed to cool to the operating temperature, and held there for 10 min. WF_6 was controllably introduced through the leak valve. Deposition times ranged from 1 to 20 sec.

Structural determination was made by x-ray diffraction (Laue) and low angle electron diffraction techniques. Single crystal films were epitaxially grown on sapphire[1] at temperatures of 500°C or higher and rates as high as 6000 Å/sec. Most of the sapphire substrates were cut perpendicular to the normal growth direction which is approximately 70° off c-axis. A few substrates characterized by a c-axis normal were also used. The orientation relationships were similar to those reported earlier (1); that is, {111} W || {0001} Al_2O_3, and [110] W || [$2\bar{1}\bar{1}0$] Al_2O_3. A sample pattern is shown in Fig. 2A. As the deposition temperature was decreased below 450°C, the tungsten deposit became polycrystalline with a preferred {111} orientation (*see* Fig. 2B). On sputtered Al_2O_3 or oxidized silicon substrates, the tungsten deposit was polycrystalline with grain sizes of the order of 300-500Å. Above 500°C, a {111} texture was prevalent (Fig. 2C) with an increased tendency toward a random structure as the temperature was lowered (Fig. 2D).

Deposition parameters and structural observations for several films are summarized in Table I, while surface structure of some etched single-crystal films is shown in Fig. 3.

Electrical Resistivity

The electrical resistivity of several films was measured both at room temperature (296°K) and at 4.2°K, and resistivity ratios (RR $\equiv \rho_{296°K}/\rho_{4.2°K}$) computed. Measurements were of the standard 4-point in-line type.

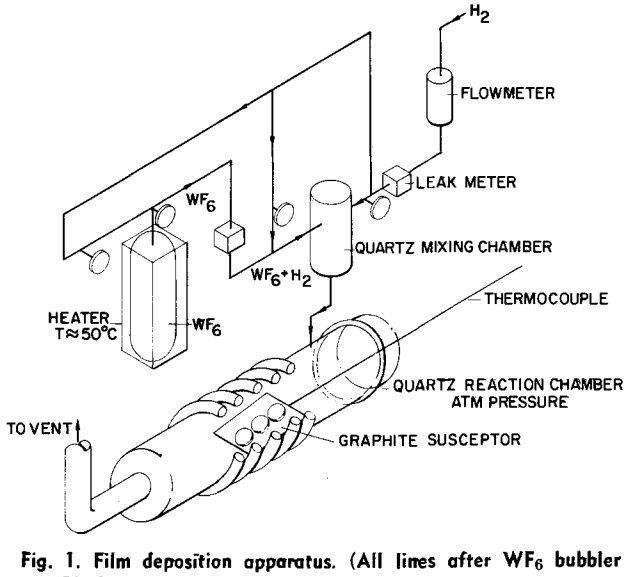

Fig. 1. Film deposition apparatus. (All lines after WF_6 bubbler are at 50°C.)

[1] A few films were also deposited on freshly cleaved MgO substrates. The cleavage planes are {100} and structure studies showed that {100} W || {100} MgO and [110] W || [100] MgO, at a substrate temperature of 500°C.

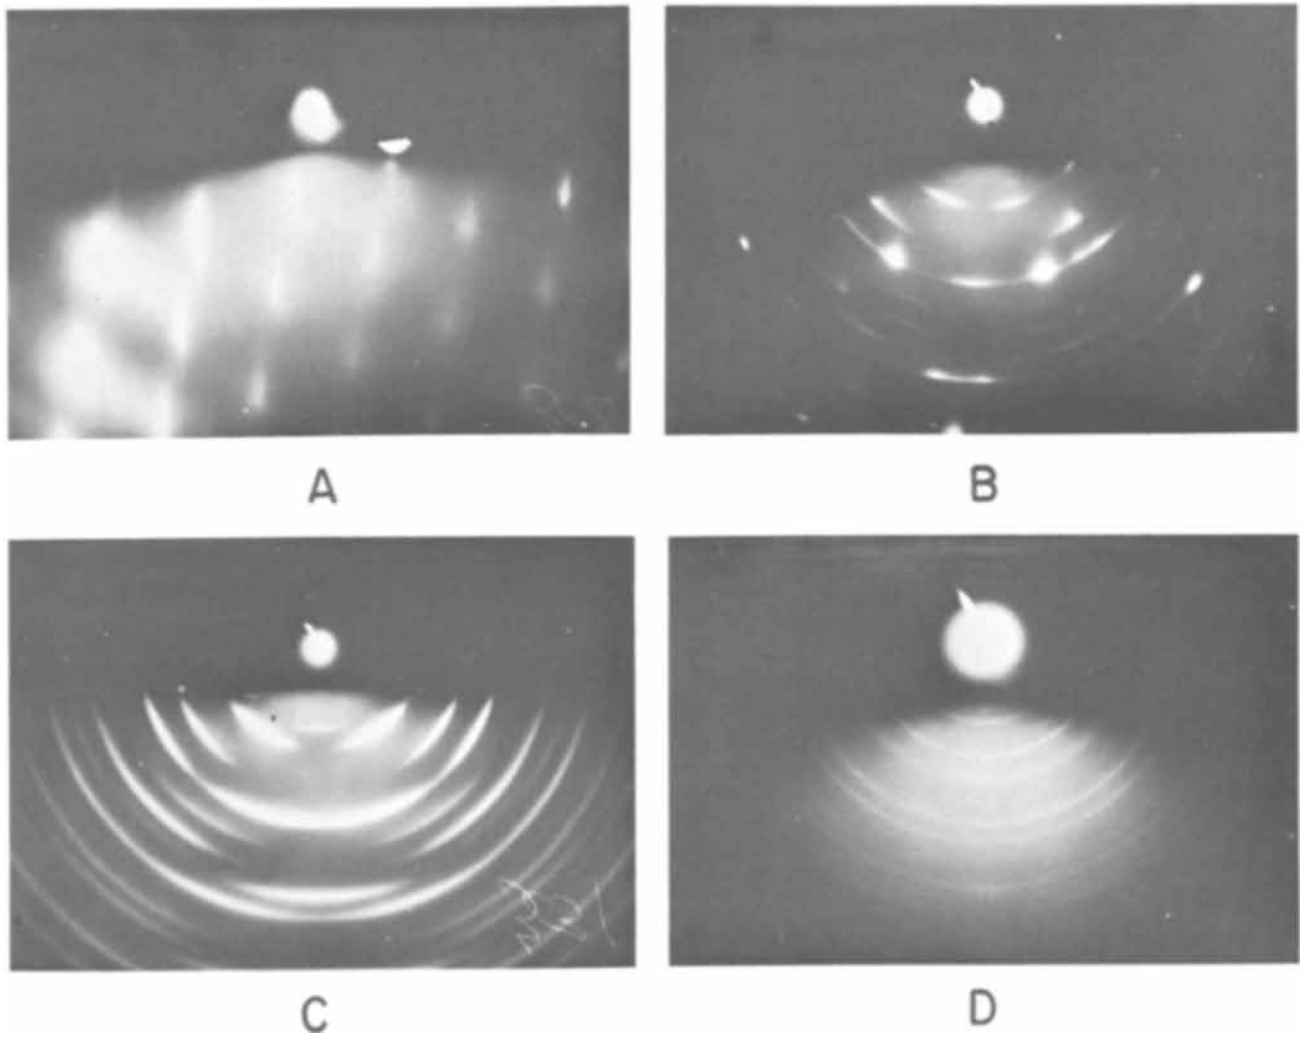

Fig. 2. A—Electron diffraction pattern from single-crystal W film (film M) on sapphire substrate (~ 70° off c-axis). Substrate temperature T_s = 510°C. B—Electron diffraction pattern from polycrystalline W film (film F) on sapphire substrate; T_s = 460°C. C—Electron diffraction pattern from polycrystalline W film (film C) on SiO_2; T_s = 520°C. D—Electron diffraction pattern from polycrystalline W film (film A) on SiO_2; T_s = 460°C.

Polycrystalline films.—Polycrystalline films, *i.e.* those deposited on thermally grown SiO_2 and sputtered Al_2O_3, exhibited room temperature resistivities, $\rho_{296°K}$, about 30-100% higher than the published bulk value of 5.3 μohm · cm (2), and low resistivity ratios: about 2-4. Substrate temperature (in the range 450°-650°C did not appear to affect these electrical characteristics. Some representative measurements are shown in Table I. In view of the fact that even the thicker polycrystalline films are characterized by such low resistivity ratios, it is safe to conclude that the (Fuchs) thickness size-effect (3) plays only a negligible role in determining the RR and virtually none in determining $\rho_{296°K}$; the poor electrical characteristics must therefore be discussed in terms of structural disorder in these films.

That the low RR's for polycrystalline films are due to grain-size effects is strikingly illustrated by the observation that samples B (polycrystalline) and J (single crystal) were deposited simultaneously with the two substrates placed side by side in the three-position susceptor (Fig 1), so that chemical impurities

Table I. Summary of Data

Film	Substrate	Substrate temp, °C	Thickness, A	ρ 296°K μohm · cm	ρ 4.2°K μohm · cm	ρ 296°K/ρ 4.2°K	Structure

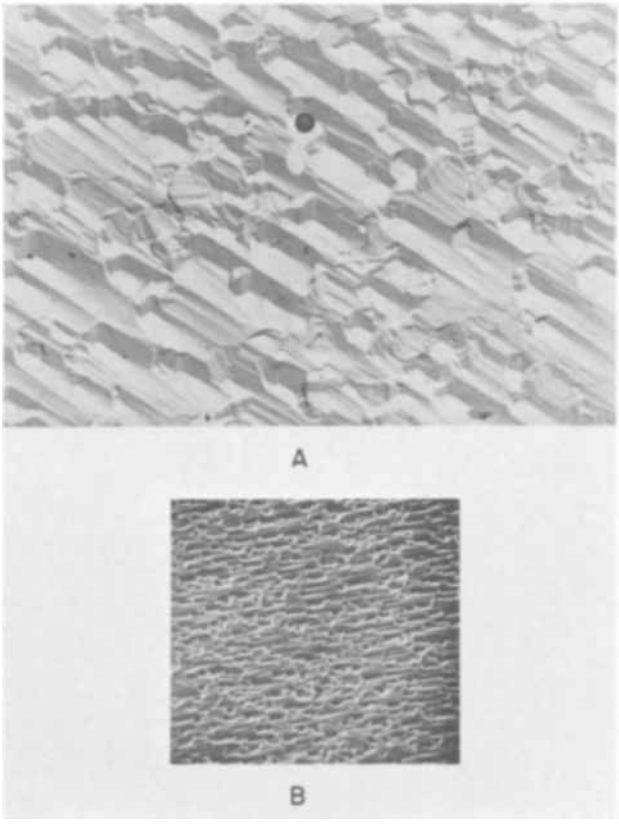

Fig. 3. A—Surface replication electron micrograph of a single-crystal W film after mild etch in potassium ferricyanide/potassium hydroxide solution. (Diameter of black sphere is 5000Å). B—Scanning electron micrograph, same film as in A. (Magnification X970).

should be present in about the same concentration in both films. Yet the RR for the polycrystalline sample is markedly lower than that for the single crystal. This difference between single-crystal and polycrystalline films deposited simultaneously was reproduced many times and was found not to depend on substrate position in the susceptor.

Epitaxial single-crystal films.—As noted in the section on film structure, a substrate temperature of about 500°C is required to obtain epitaxy. Early observations by us also indicated that the resistivities of the 500°C films were almost identical to the 600°C films, so the succeeding discussion is limited to only the 500°C films on sapphire.

Measurements of $\rho_{296°K}$ on these single-crystal films were generally within a few per cent of the bulk resistivity and were essentially independent of thickness in the range 1500-10,000Å. Measured values of $\rho_{4.2°K}$ (and hence RR), however, were strongly dependent on thickness. The RR's were generally quite high (*see* Table I, sample G through M) so that for these films the magnitude of the thickness size-effect resistivity must be estimated in order to assign a number to the intrinsic film resistivity at 4.2°K, ρ_i (*i.e.*, the resistivity the film would possess if it were infinitely thick), and intrinsic electron mean free path at 4.2°K, l_i. To extract this information by use of the Fuchs size-effect theory, the surface scattering parameter p which is the fraction of specularly reflected electrons must be known. Although available evidence indicates $p \approx 0$ is generally a good approximation, no specific data on surface scattering in tungsten are available. Furthermore, it is unlikely that the simple Fuchs theory (which postulates the existence of an isotropic scalar electron relaxation time) can quantitatively predict the thickness dependence in a complex material such as tungsten whose Fermi surface is known to consist of both a highly anisotropic electron "jack" and a hole octahedron (5). For these reasons, only qualitative estimates of ρ_i and l_i can be expected for these films.

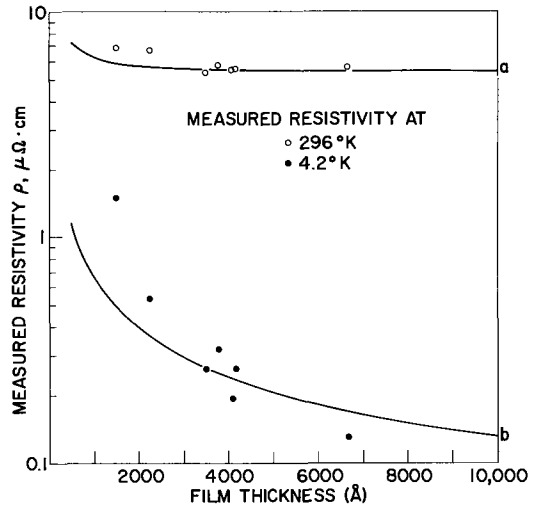

Fig. 4. Thickness dependence of measured resistivity for single-crystal films at 296° and 4.2°K. Solid lines are calculated Fuchs size-effect curves; Curve a: $p = 0$, $\rho_i = 5.3$ μohm · cm, $l_i = 413$Å; Curve b: $p = 0$, $\rho_i = 0.0437$ μohm · cm, $l_i = 50{,}000$Å.

In Fig. 4, the measured resistivities for the single-crystal films of Table I are plotted against thickness. Also shown are resistivity *vs.* thickness curves calculated[2] from the Fuchs theory for $p = 0$, with ρ_i and l_i selected to fit the data. It can be seen that, as expected, only a small size-effect is observed at room temperature and a reasonable fit can be made to the solid curve (curve a) drawn for the values $\rho_i = 5.3$ μohm · cm and $l_i = 413$Å which has previously been reported for bulk tungsten (7). At 4.2°K, a much stronger thickness dependence is found which has been fitted to the solid curve for $\rho_i = 0.0437$ μohm · cm, $l_i = 50{,}000$Å (curve b).

There seems to be a tendency for the data points corresponding to thinner films to fall above the solid curve, while those for the thicker films fall below. This may be due to the fact that thinner films getter more chemical impurities from the system and therefore have smaller l_i's; however, substantially more data points are required to study the details of the thickness dependence. It should be mentioned that x-ray topographic examination (8), sensitive to dislocations and local strain, has revealed no essential difference between our thick and thin films on sapphire (regardless of orientation): both appear to be high-quality single crystals.

A significant conclusion of the present work is that the high resistivity in the polycrystalline tungsten films is not due to impurities but to grain boundary scattering of electrons, since polycrystalline and single-crystal films deposited simultaneously have quite different resistive characteristics.

[2] The calculation scheme, which has been published earlier (6), assumes the general validity of Matthiessen's Rule at room temperature and makes use of the fact that the product $\rho_i l_i$ is a constant for any (reasonably) pure metal. The value $\rho_i l_i = 2.185 \times 10^{-11}$ ohm-cm², obtained by Fawcett and Griffiths (7) from anomalous skin-effect measurements on tungsten, was used in the calculation.

Epitaxial Gallium Arsenide from Trimethyl Gallium and Arsine

P. Rai-Choudhury*

Westinghouse Electric Corporation, Research and Development Center, Pittsburgh, Pennsylvania

Gallium arsenide is used in devices such as Gunn oscillators, high-voltage varactors, lasers, tunnel diodes, *etc.* Epitaxial techniques are being developed in which gallium arsenide with controlled doping is deposited from the vapor or liquid phase on gallium arsenide as well as sapphire substrates. Most deposition techniques reported to date use some form of transport mechanism *via* a halide (1). Relatively high volatility and the absence of any transport agents (such as HCl) make trimethyl gallium an attractive source of gallium for the vapor growth of GaAs. For instance, trimethyl gallium has a vapor pressure of 0.25 atm at room temperature, compared to 3.4×10^{-36} atm for gallium and 0.49 atm for $GaCl_3$ (2). Manasevit and Simpson (3) have reported on the use of organometallics in the preparation of III-V compounds. Manasevit has also reported on some structural aspects of the single-crystal growth of GaAs on a number of single-crystal, insulating, oxide susbtrates (4). In this communication, use of trimethyl gallium for the growth of epitaxial GaAs on gallium arsenide and sapphire substrates is reported.

A conventional horizontal rf heated reactor having a graphite susceptor was used. The substrates used were semi-insulating GaAs of (100) orientation and sapphire of (0001) orientation. The sawed GaAs substrates were lapped with 5μ alumina powder and chemically polished to remove 75μ from the depositing surface. The chemical etchants used were conc H_2SO_4: 30% H_2O_2 : H_2O :: 5:1:1. X-ray topography of the polished wafer indicated that the polished surface is damage free. Sapphire substrates were mechanically polished and annealed in H_2 for 2 hr at 1400°C prior to film growth. The trimethyl gallium [$(CH_3)_3Ga$] sources were used as received from the supplier (typical purity in ppm: Si 50 to 100; Cu, Ag, Ca, Pb, and Na < 1; Mg 1). Palladium-purified hydrogen was bubbled through the trimethyl gallium and was reacted with arsine (AsH_3) to form the epitaxial GaAs layer. The resistivity, the net carrier concentration, and the mobility of these films were measured by van der Pauw technique (5). Examination by reflection and transmission electron diffraction and microscopy was used to assess film perfection. The layers and substrates were also analyzed by a spark source mass spectrometer.

Figure 1 shows a diffraction pattern of a GaAs film grown on GaAs substrates having an (100) orientation. The film was grown at about 700°C using $(CH_3)_3Ga$ and AsH_3 with partial pressures of 7.5×10^{-4} atm and 1.0×10^{-2} atm, respectively. Depending on gas velocity, the growth rate of the films was varied from 0.69 to 0.11 μ/min. The film from which Fig. 1 was obtained was grown at 0.11 μ/min and the resulting surface of the epitaxial layer was extremely smooth and free of any visible defects. Transmission electron microscopy examinations of the films were compared to those obtained from layers grown by a conventional $AsCl_3$-Ga-H_2 system; the appearance of the deposits from the two systems is comparable. Films produced by both processes were found to contain isolated amorphous precipitates. The study of these defects is in progress and the results will be reported subsequently. Figure 2 show an electron diffraction pattern of a GaAs film grown under conditions identical to that of Fig. 1 but on a sapphire substrate. The films were epitaxial, the orientation relationship between film and substrate being

$$(111)_{GaAs} \| (0001)_{Al_2O_3} \text{ and } [1\bar{1}0]_{GaAs} \| [11\bar{2}0]_{Al_2O_3}$$

All the films grown on GaAs substrates were n-type with a net carrier concentration of 2.6×10^{17} to 9.0×10^{17} atoms/cm^3 and a mobility of 1740 to 2550 cm^2/V sec. Most of the films grown on sapphire were found to be n-type (however, hot-probe analysis was not always definitive), with one of the best films having a net carrier concentration of 6.5×10^{17} atoms/cm^3 and a mobility of 2480 cm^2/V sec. The layers were analyzed by a spark source mass spectrometer and the results are compared in Table I with those from a semi-insulating GaAs substrate as well as with epitaxial GaAs from a $AsCl_3$-Ga-H_2 system.

It should be emphasized that the impurity concentrations listed here are essentially surface concentra-

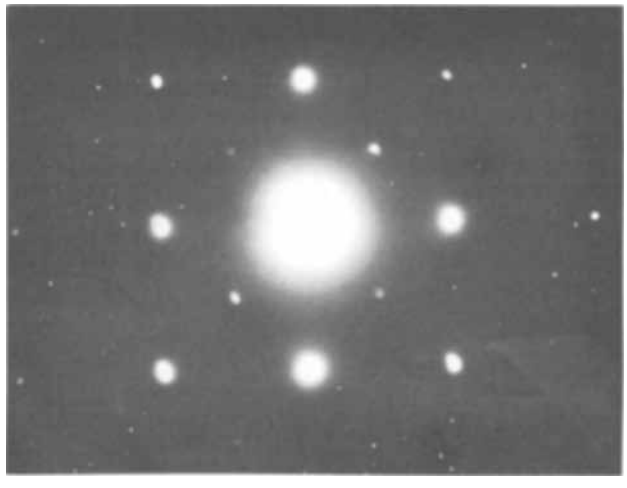

Fig. 1. Transmission electron diffraction pattern of GaAs films grown on semi-insulating GaAs substrate of (100) orientation.

* Electrochemical Society Active Member.

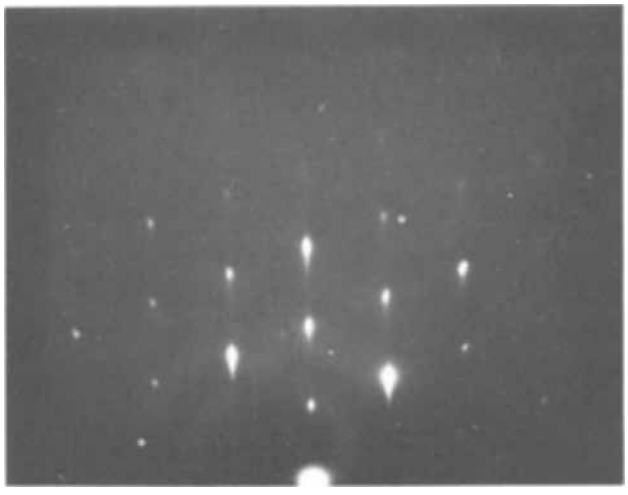

Fig. 2. Reflection electron diffraction pattern of GaAs films grown on sapphire substrate of (0001) orientation; (111)GaAs || (0001) Al_2O_3, [1$\bar{1}$0] GaAs || [11$\bar{2}$0] Al_2O_3.

tion in the case of epitaxial layers and might therefore contain some adsorbed impurities difficult to clean. The impurity concentrations in the substrate material, however, are more reliable since the entire epitaxial layer was sparked off before analysis. Since the carbon contamination level in the present system is comparable with the $AsCl_3$-Ga-H_2 system, it appears that the carbon contamination from the trimethyl gallium is probably insignificant. Metallographic examination of the surface of the epitaxial layers also supports this view. Carbon contamination from TMG is also unlikely from thermodynamic considerations. The over-all reaction may be written as

$$(CH_3)_3Ga(g) + \frac{1}{4}As_4(g) + \frac{3}{2}H_2(g) = GaAs(s) + 3\,CH_4(g)$$

The CH_4 formed may decompose to give graphite and hydrogen. At 1000°K, for example, the equilibrium partial pressure of CH_4 for the reaction

$$CH_4(g) = C(s) + 2\,H_2(g)$$

Table I. Impurity concentrations in GaAs in ppm

Element	Layers from $(CH_3)_3Ga$-AsH_3-H_2 system	Layers from $AsCl_3$-Ga-H_2 system*	Semi-insulating GaAs substrate
C	238.4	100-569	8.79
N	1.78	Not detectable	0.07
O	220.4	307-1042	0.52
Si	4.46	—	0.19
S	1.47	Not detectable	0.27
Fe	1.60	Not detectable	Not detectable
Cu	2.24	Not detectable	Not detectable
Zn	0.89	Not detectable	Not detectable

* The GaAs layer grown in the $AsCl_3$-Ga-H_2 system had a net carrier concentration of 1.1 × 10^{16} atoms/cm³ and a mobility of 3400 cm²/V sec.

is 9.7 x 10^{-2} atm which is considerably above the $(CH_3)_3Ga$ partial pressures used for growth of GaAs. Therefore, CH_4 will not decompose to graphite.

In summary, the epitaxial GaAs produced from trimethyl gallium and arsine is of good quality metallographically, but requires some improvement in purity. The electrical parameters such as mobility and net carrier concentrations of GaAs on sapphire are comparable with those of GaAs grown on semi-insulating GaAs substrates.

The Electrochemical Behavior of Titanium

Effect of pH and Chloride Ions

N. T. Thomas* and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California

ABSTRACT

The anodic and cathodic behavior of titanium in sulfuric acid in the absence and presence of chloride ions have been investigated. Two stable corrosion potentials were observed. One was in the active region, the other in the passive region. Neither corrosion potential was appreciably affected by chloride ions or pH changes between pH 0.25-2.00. The corrosion current of active titanium was not affected significantly by chloride ions up to 3.5% NaCl but decreased with increase in pH. Passivation parameters decreased with increase in pH but either remained unchanged or decreased only slightly with addition of chloride ions. The rate of the h.e.r. in the Tafel region was not appreciably affected by chloride ions. The differential capacitance of titanium in solutions of pH 0.25-2.00 ranged from 150 to 200 $\mu f/cm^2$ at the active corrosion potential and was a reasonably constant value, 25 $\mu f/cm^2$, at the passive corrosion potential. For the negative potential range a maximum capacitance, 222 $\mu f/cm^2$ at $-0.490 \pm 0.010V$ *vs.* SCE which was approximately the primary passivation potential, and a minimum capacitance, 73 $\mu f/cm^2$ at $-0.985 \pm 0.012V$, were observed. At potentials more positive than the primary passivation potential, the capacitance decreased monotonically with increase in potential and reached a value of 7 $\mu f/cm^2$ at 3.2V.

Titaninum and titanium alloys are promising new lightweight structural materials with good corrosion resistance in a number of different environments. As a result, there has been a growing literature on the corrosion and passivation behavior of titanium (1-10). This is a study of the anodic behavior of titanium in sulfuric acid solutions of pH from 0.25 to 2.00 in the absence and presence of chloride. In addition, the effect of chloride ions on the hydrogen evolution reaction has been examined.

Experimental

Electrodes made from Ti 65A (TMCA) were used for the experiments. The analysis of the impurities was given by TMCA as 0.023%C, 0.25%Fe, 0.01% N_2, 0.005% H_2, and 0.2% O_2. Cylindrical electrodes of about 1.4 cm in length were cut from 1.25-cm diameter rod. The surface area of each electrode was about 5.5 cm^2. A smooth electrode surface was obtained by slicing the surface on a lathe with a carbide cutting tool. The electrodes were degreased with hot benzene in a soxhlet column for at least 4 hr, then annealed under vacuum at 700°C for 1 hr and furnace cooled. After this, the electrodes were stored in a desiccator until use.

A description of the instrumentation, the electrochemical cell, and the electrode assembly have been given previously (11). Anodic polarization was performed potentiostatically with an Anotrol Controller (Model 4100). Galvanostatic polarization was used for the study of the h.e.r. Electrode potentials were measured with Keithley Electrometers (Model 602 and 610B). Differential capacitances were determined with the d-c pulse method.

Solutions of 1*N* H_2SO_4 were prepared by diluting reagent-grade concentrated sulfuric acid with double-distilled water. Solutions of different pH values were then obtained by adding appropriate quantities of 20*N* NaOH to the 1*N* H_2SO_4 solutions. The chloride solutions were prepared by adding appropriate amounts of sodium chloride to solutions of 1*N* H_2SO_4.

The solutions were deaerated with prepurified nitrogen for at least 12 hr before an experimental run. The electrodes were activated in 1*N* HF for 1 min, generously washed with double-distilled water, and then introduced into the deaerated solution. The electrode was rotated continuously with a tangential velocity of 6.6 cm/sec. The corrosion potential was monitored until steady state was achieved for at least 2 hr. Then, polarization of the electrode was begun. The temperature of the cell was maintained at 24° ± 1°C. Saturated calomel electrodes were used as reference electrodes.

Results and Discussion

Steady state was achieved within 2 min for anodic polarization between the corrosion potential and the primary passivation potential. Between the latter and the Flade potential, 10-20 min were required to reach steady-state conditions. In the passive region, ½-1 hr were required. For each experimental point, polarization was observed for at least an additional 5 min after steady state was observed and occasionally, as a check, polarization was maintained an additional 3 hr. For cathodic polarization, the hydrogen evolution reaction in the Tafel region reached steady state within 5 min at each polarization point.

Open-circuit behavior.—The corrosion potentials for nonactivated electrodes in 1*N* H_2SO_4 ranged between 400-700 mV *vs.* SCE indicating self-passivation when titanium was immersed in the electrolyte. A few electrodes were observed to self-activate, and a typical case is shown in Fig. 1. A similar potential-time behavior was observed by Tsvetnova *et al.* (6) for high-

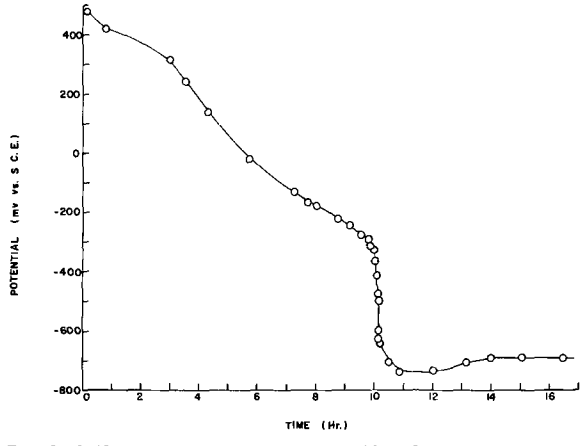

Fig. 1. Self-activation of titanium in 1*N* H_2SO_4 from the passive corrosion potential.

Table I. Effect of pH on the electrochemical behavior of titanium

pH	Active corrosion potential	Corrosion current	Passive corrosion potential	Primary passivation potential	Critical current	Passive current at 800 mV	Capacitance at active corrosion potential	Capacitance at passive corrosion potential
	mV *vs.* SCE	μA/cm^2	mV *vs.* SCE		μA/cm^2		μf/cm^2	
0.25	−680 ± 10	9.0 ± 0.7	650 ± 20	−520	22.6 ± 1.5	0.50 ± 0.02	150 ± 10	23 ± 1
0.50	−675	6.0	670	−540	12.7	0.40	195	25
1.00	−665	2.9	680	−560	3.5	0.33	202	28
1.50	−675	2.0	680	−600	2.5	0.27	205	20
2.00	−700	1.1	685	−630	0.8	0.22	198	25

purity titanium in 5*N* H_2SO_4. However, they observed an activation time which was much shorter than the ones in this investigation, indicating that the activation time increases with increase in pH.

The corrosion potentials of electrodes activated in 1*N* HF were considerably more negative than the corrosion potentials of electrodes which self-passivated. Table I gives both the active and passive corrosion potentials of titanium in solutions ranging from pH 0.25 to 2.00 and shows that there was no significant dependence of the corrosion potentials of titanium with pH. These are in accord with those of other investigators (2, 12). Peters and Myers (2), who activated their electrodes by cathodic polarization, observed a small pH dependence of the active corrosion potential.

After anodic polarization of titanium in the pH range studied, the electrode remained passive. An active corrosion potential could be obtained again by cathodic polarization. These results along with those of Schlain *et al.* (12), who obtained active corrosion potentials by conducting experiments on titanium in deaerated solutions lasting 15 days, indicate that in sufficiently acidic solutions passive titanium will eventually become active at open circuit. The activation process is accelerated by cathodic polarization, and almost instantaneous activation is achieved by a brief immersion of titanium in HF.

For pH solutions of 2.00 and above, active corrosion potentials could not be achieved within a reasonable time duration by either cathodic polarization or activation in HF. The corrosion potential of titanium (activated in HF) in pH solutions of 2.00 was approximately 50 mV above the primary passivation potential immediately after immersion. Thereafter, the corrosion potential increased slowly with time until the stable steady-state passive corrosion potential was achieved. However, active corrosion potentials for this pH could be achieved by first activating titanium in HF, immersing in 1*N* H_2SO_4, and then adjusting the pH by the addition of a concentrated solution of NaOH.

The corrosion currents of active titanium were determined by extrapolation of the Tafel line for the h.e.r. to the corrosion potential. As shown in Table I, the corrosion current decreased with increase in pH.

Anodic and cathodic behavior of titanium in the absence of chloride ions.—The anodic behavior of titanium in sulfuric acid at various pH values is shown in Fig. 2. The critical current densities, I_{cc}, the primary passivation potentials, ψ_{pp}, are shown in Fig. 3 and 4, and the passive current densities are presented in Table I. It is shown that these parameters decrease with increase in pH in accord with the results obtained by others (1-5). As shown in Fig. 3 and 4, the values of $\partial\psi_{pp}/\partial pH = -0.06V$ with $\partial \log I_{cc}/\partial pH = -0.84$, where I_{cc} is in μA/cm^2, were obtained in this investigation for the pH range between 0.25-2.00. These results were in good agreement with those of Peters and Myers (2) who obtained $\partial\psi_{pp}/\partial pH = -0.06V$ and $\partial \log I_{cc}/\partial pH = -0.77$ for titanium in sulfuric acid solutions of higher concentrations than those used in this investigation.

The primary passivation potential of titanium in 1*N* H_2SO_4 was in agreement with Tsvetnova and Krasil'shchikov (8) but their critical current was greater than that observed in this investigation. Passive currents were in agreement with the latter investigators but were lower than the values of Peters and Myers (2) since their results were not obtained at steady-state.

The cathodic polarization of titanium in 1*N* H_2SO_4 is shown in Fig. 5. The Tafel slope and exchange current density for the hydrogen evolution reaction were 150 mV and 1.7 x 10^{-8} A/cm^2, respectively. It is seen that at about −1.0V, the experimental polarization points begin to deviate from the linear Tafel curve of the h.e.r. suggesting the inception of another electrode reaction. Steady state for each experimental point at current densities exceeding the linear Tafel region was achieved in 10-15 min compared to the 5 min required within the Tafel region. The complete set of results and the analysis of the kinetics of the h.e.r. on titanium will be given elsewhere (13).

Effect of chloride ions.—Figure 5 shows the effect of chloride ions on the cathodic polarization of titanium

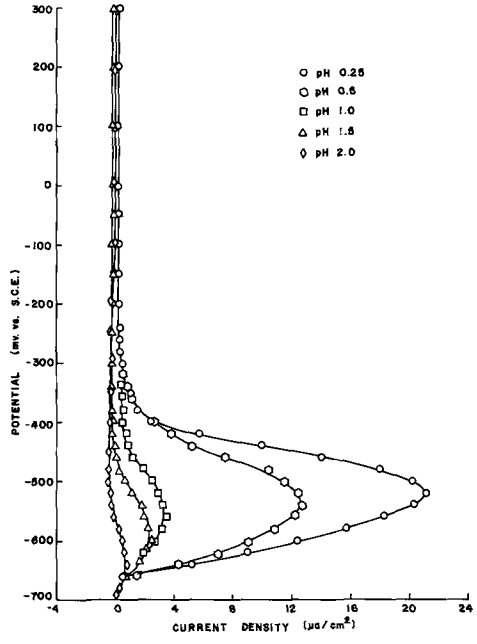

Fig. 2. Effect of pH on anodic behavior

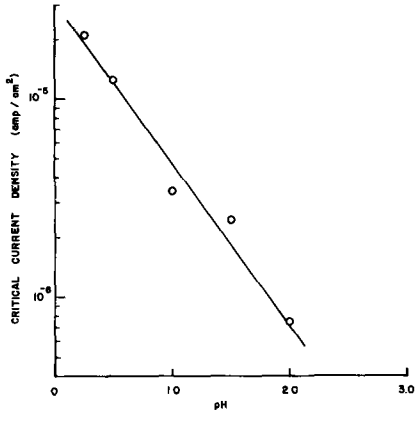

Fig. 3. Effect of pH on the critical current density

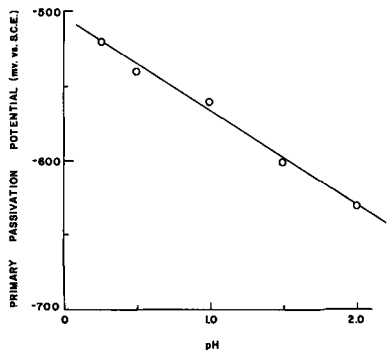

Fig. 4. Effect of pH on the primary passivation potential

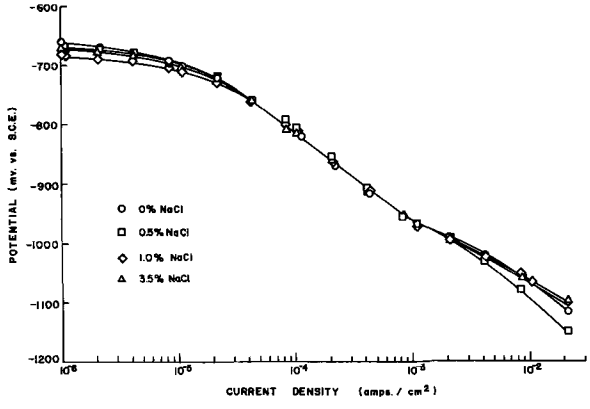

Fig. 5. The effect of chloride ions on cathodic polarization of titanium in 1*N* H_2SO_4.

in 1*N* H_2SO_4. As shown, chloride ions have no appreciable effect on the electrochemical behavior of titanium in the Tafel region of the h.e.r. However, in the low and high current density range, chloride ions have a small effect. Table II shows that the corrosion current was not affected significantly with addition of chloride ions.

The effect of chloride ions on the anodic behavior of titanium in 1*N* H_2SO_4 is shown in Fig. 6. The passivation parameters at each chloride ion concentration are presented in Table II. The active and passive corrosion potentials and the primary passivation potentials of titanium were not appreciably affected by chloride ions even for 5.8% NaCl. There was a slight decrease in the critical current density of titanium in the presence of chloride ions which was also observed by Levy (1). At the potential of 800 mV, which was well within the passive region, there was a small decrease in the passive current density with increase in chloride ions. That is, chloride ions facilitated the anodic passivity of titanium.

The above result was further substantiated by the following experiment. First, titanium in 1*N* H_2SO_4, initially at the active corrosion potential, was passivated by potentiostatically changing the potential of the electrode to 800 mV *vs.* SCE. After the steady-state passive current was attained, a small known amount of a concentrated sodium chloride solution (1*N* H_2SO_4)

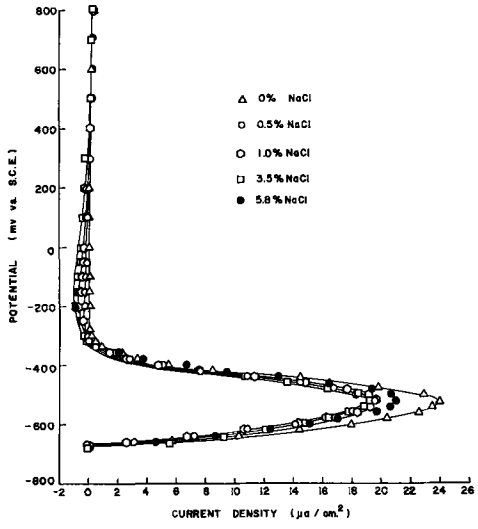

Fig. 6. Effect of chloride ions on the anodic behavior of titanium in 1*N* H_2SO_4.

was added to the electrolyte. Then, the new steady-state passive current was measured. The same procedure was followed after each incremental addition of concentrated sodium chloride solution. The result of this experiment also showed that the passive current density decreased with increase in the concentration of chloride ions.

In general, the passivation characteristics of titanium were more greatly affected by pH changes than changes in the concentration of chloride ions in accord with the results of Griess (4).

In the lower potential range of the passive region, a small cathodic current, which increased with increase in chloride ions, was observed, indicating a net reduction reaction in this potential range.

Subsequent to anodic polarization of titanium in the presence of chloride ions, the passive corrosion potential was assumed. Extensive cathodic polarization could not reactivate titanium to the active corrosion potential in contrast to the results of titanium in the absence of chloride ions.

Differential capacitance.—The capacitances of titanium at the active and passive corrosion potentials in the absence and presence of chloride ions are presented in Tables I and II. Table I shows that the capacitance of titanium in a solution of pH 0.25 was 150 ± 10 $\mu f/cm^2$ which is unusually large for the double-layer capacitance. In the pH range of 0.50-2.00, the capacitance remained essentially constant at 200 $\mu f/cm^2$. This large capacitance at the active corrosion potential may be a pseudocapacitance due to an adsorbed electroactive intermediate (*e.g.*, hydrogen atoms) (14, 15). On the other hand, the capacitance at the passive corrosion potential was approximately 25 $\mu f/cm^2$ throughout the pH range investigated.

In the presence of chloride ions up to 1% NaCl, the capacitance of titanium at the active corrosion potential, as shown in Table II, was the same as in the absence of chloride ions. However, for 3.5 and 5.8% NaCl solutions,

Table II. Effect of chloride ions on the electrochemical behavior of titanium (pH = 0.25)

% NaCl	Active corrosion potential	Corrosion current	Passive corrosion potential	Primary passivation potential	Critical current	Passive current at 800 mV	Capacitance at active corrosion potential	Capacitance at passive corrosion potential
	mV *vs.* SCE	$\mu A/cm^2$	mV *vs.* SCE		$\mu A/cm^2$		$\mu f/cm^2$	
0	−680 ± 10	9.0 ± 0.7	650 ± 20	−520	22.6 ± 1.5	0.50 ± 0.02	150 ± 10	23 ± 1
0.5	−670	10.0	650	−520	19.6	0.45	147	22
1.0	−675	11.0	640	−520	19.7	0.45	150	23
3.5	−675	11.0	665	−520	19.2	0.44	138	22
5.8	−680	—	680	−520	21.0	0.33	132	21

the capacitance of titanium decreased slightly. Table II shows that, at the passive corrosion potential, the capacitance of titanium remained essentially the same in the absence and presence of chloride ions.

The capacitance *vs.* potential behavior in the potential range from −1.15 to 3.2V *vs.* SCE is shown in Fig. 7. A capacitance maximum and minimum were observed in the negative potential range. The maximum capacitance, observed at −0.490 ± 0.010V which was approximately the primary passivation potential, was 222 μf/cm^2. The minimum capacitance, observed at −0.985 ± 0.012V, was 73 ± 2 μf/cm^2. As shown in Fig. 5, the deviation from the Tafel line for the h.e.r. commenced at approximately the potential of the capacitance minimum. It is interesting to note that this potential corresponds closely to the potential of zero charge for titanium, −0.945V *vs.* SCE, calculated by Antropov (16). However, at present, no significance is attached to the agreement between this p z c value and the potential at the capacitance minimum. Further investigation of this point is in progress.

The capacitance behavior between 0-3.2V (C = 7 μf/cm^2 at 3.2V) was in good agreement with the results of Kuznetsova *et al.* (17). As do the latter workers, it seems reasonable to attribute this decrease in capacitance in the above potential range to the increase in thickness of the oxide film. Thomashov *et al.*'s analysis of the passive film on titanium indicated that, for the passive potential range of this investigation, the surface was covered with a mixed oxide of Ti_2O_3 and TiO_2 (18).

The capacitance behavior in the neighborhood of the primary passivation potential was similar in magnitude and shape to the faradaic capacitance of titanium in 5*N* H_2SO_4 determined by Brynza *et al.* (19) with a-c impedance measurements. These investigators utilized an equivalent circuit model of the double-layer capacitance in parallel with the faradaic impedance which consisted of the faradaic capacitance and faradaic resistance in series. For the potential range in the neighborhood of the active-passive transition, Vorob'ev and Ershler (7) observed that the double-layer capacitance of titanium in sulfuric acid was reasonably constant at approximately 25 μf/cm^2. In view of this result, it seems reasonable to assume that the large capacitances observed in the active-passive transition potential range and obtained by the d-c pulse method correspond to a faradaic capacitance or, more specifically, an adsorption pseudocapacitance.

Two linear regions in the potential-time curve would be observed when a d-c current pulse is passed through a circuit equivalent to that described above for a-c impedance measurements. Since the d-c current pulse was developed by a mechanical pulser (11) with a rise time slower than 10 μsec, the initial part of the potential transient, which was the charging curve for the double-layer capacitor, could not be obtained. The second linear region, which occurs at a later time than the first, corresponds to the faradaic capacitance (pseudocapacitance, in this case). This pseudocapacitance has been surmised to result from adsorption of an electroactive species which initiates the passivation of titanium (19).

Conclusion

1. Titanium in deaerated H_2SO_4 exhibited a stable passive corrosion potential and a stable active corrosion potential.

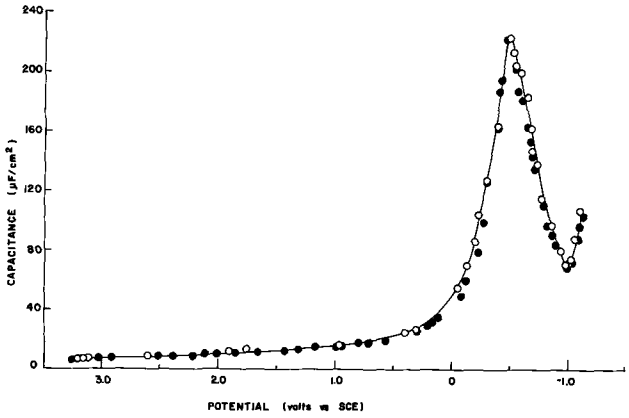

Fig. 7. Differential capacitance vs. potential for titanium in 1*N* H_2SO_4.

2. The passivation characteristics of titanium in H_2SO_4 were dependent on the pH, but did not vary appreciably with the concentration of chloride ions.

3. The capacitance-potential behavior of titanium in 1*N* H_2SO_4 showed a maximum at −0.490 ± 0.010V and a minimum at −0.985 ± 0.012V.

Orientation Dependence of the Aluminum Oxide Dielectric in Film Capacitors

Ferenc E. Rosztoczy*,[1] and Mildred H. Read

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

An investigation of the anodization of evaporated aluminum films and the reliability of aluminum oxide film capacitors made with and without a manganese oxide layer between the dielectric and the metal top electrode has been made. A correlation appears to exist between the degree of orientation of the polycrystalline aluminum film and the anodization characteristics or performance of the capacitors. The dielectrics with the highest anodization voltages or those which resulted in the highest performance capacitors were formed on the most randomly oriented aluminum films.

It has been demonstrated that the addition of a semiconducting layer of manganese oxide between the dielectric and the metal top electrode improves those properties of film capacitors which are dependent on the dielectric strength (1, 2). As a result, tantalum film capacitors with manganese oxide (TMM capacitors: Substrate—Ta-Ta_2O_5-MnO_x-Metal) show lower leakage currents and excellent performance during accelerated life testing at 50% of the formation voltage and 85°C (3). The self-healing property of the TMM capacitor structure also permits the use of larger areas and lower formation voltages, either of which results in larger capacitance values (1). It also allows the fabrication of tantalum oxide film capacitors on substrates with rough surfaces. Preliminary results indicated similar improvements in yield and life test performance when a manganese oxide layer is added to thin-film capacitor structures based on evaporated SiO or anodic Al_2O_3 dielectric (2). Aluminum oxide capacitors did occasionally exhibit low yields and poor performance (4, 5), and sometimes aluminum films could not be anodized to voltages over 100V (6). It is the purpose of this paper to describe the properties of aluminum oxide film capacitors formed on smooth glass as well as on unglazed ceramic substrates, and to show that the quality of the finished aluminum oxide film capacitors with and without the addition of manganese oxide layer between the anodic film and the counter-electrode depends to a large extent on the degree of orientation of the aluminum film.

The advantage of using aluminum instead of tantalum for thin-film capacitors would be its higher conductivity, which makes it more desirable for high-frequency applications. Its shortcoming is the significantly smaller dielectric constant [21-28 for the tantalum oxide (7, 8) *vs.* 8-11 for aluminum oxide (5, 8)].

Experimental

Figure 1 shows the 15 spot test pattern and the cross section of an AMM capacitor structure. One- by three-inch glass (Corning #7059) or unglazed high alumina ceramic slides (American Lava #614) were used as substrates. The aluminum pattern was usually generated with photoetching techniques using KMER with J100 stripper to remove the KMER without scratching the aluminum. In some cases, the aluminum pattern was evaporated through a mask. To obtain adherent aluminum films, it was important to use freshly cleaned slides and to degas them prior to the deposition of the aluminum film. The cleaning of the slides included an ultrasonic wash in a cold and then in a 75°C Igepal 710 solution (Antara Chemical Company), a boil in 10% hydrogen peroxide, and finally a rinse in overflowing, boiling, deionized water.

The aluminum films were anodized in 30% ammonium pentaborate ethylene glycol solution at room temperature. The anodization voltage was gradually increased during a 10-15 min period to the desired value which was maintained for 30 min. During anodization on certain aluminum films, slow oxygen gas formation started around 100V, which increased if the voltage was raised further. The capacitors on these slides had low breakdown voltages. Within each aluminum evaporation group, the slides tended to behave similarly during anodization.

Study of the x-ray wide-film Debye-Sherrer diffraction photographs of aluminum slides having different anodization characteristics showed that, while the aluminum oxide was amorphous in all cases, there was significant difference in the degree of (111) crystal orientation of the aluminum films. That is the degree to which the (111) plane is parallel to the substrate surface, or, alternatively, the degree to which the [111] fiber axis is normal to the substrate surface. Three typical x-ray diffraction pictures for aluminum films evaporated on glass substrates are presented in Fig. 2. Picture a represents slides where the aluminum exhibits the least orientation. Most of the lines are uniform in intensity, although the (111) line shows an arc. Picture c shows only arcs indicating a high degree of orientation, while picture b is typical for the "in between" slides. The lines are continuous but strongly arced.

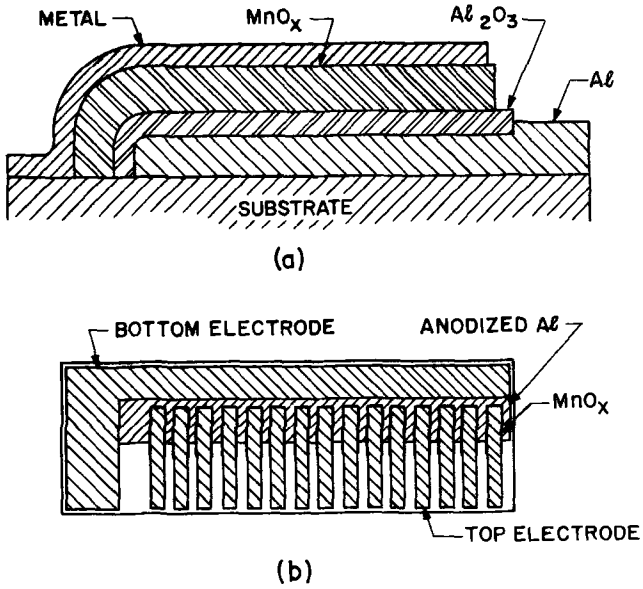

Fig. 1. (a) Cross section of AMM capacitor, (b) 15 spot capacitor pattern.

* Electrochemical Society Active Member.
[1] Present address: Varian Associates, Palo Alto, California.

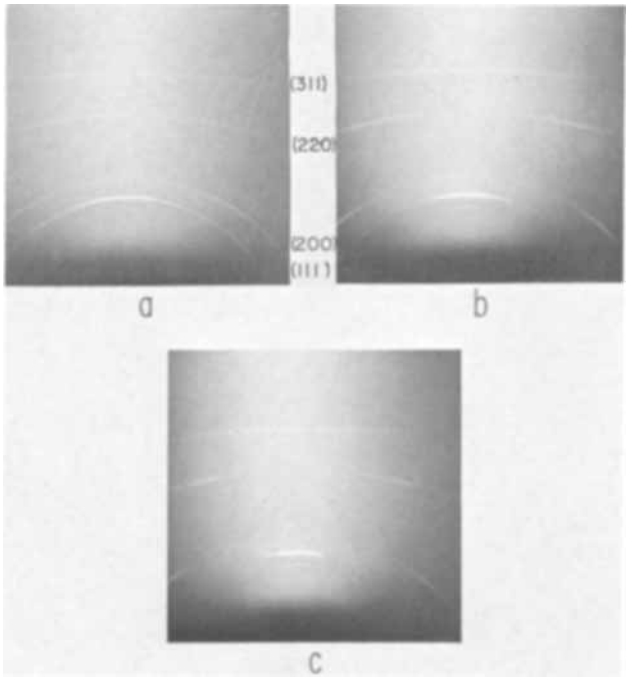

Fig. 2. X-ray photographs showing the different degree of (111) orientation in aluminum film: (a) least oriented—continuous lines with gentle arcing, (b) medium oriented—continuous lines with strong arcing, (c) most oriented—no continuous lines, only arcs.

The sharp lines would indicate a crystallite size of about 1000Å with some larger crystals giving rise to spots. In all the samples, the (111) line is stronger than expected for randomly oriented material and a certain degree of orientation appears to be present in all samples as shown by the tendency of the (111) line to appear as an arc.

Electron micrographs of platinum-carbon replicas of the aluminum film surface indicate that the crystallites are generally around 2000Å, but in each sample there are crystals about 3000-5000Å in diameter and these are much thicker than the bulk of the film (Fig. 3). The area of these larger crystals is about 1-5% of the total area. The crystallite faces tend to be parallel to the surface of the substrates. The planes on the less oriented films make larger angles to the substrate than on the more oriented films. In the case of the oriented samples, with the flattest planes, the crystallites seem to merge together in some instances (Fig. 3b).

The oxygen formation around 100V occurred on the aluminum films with the highest degree of (111) orientation, while aluminum films having a low degree of preferred orientation could be anodized to over 300V without oxygen evolution.

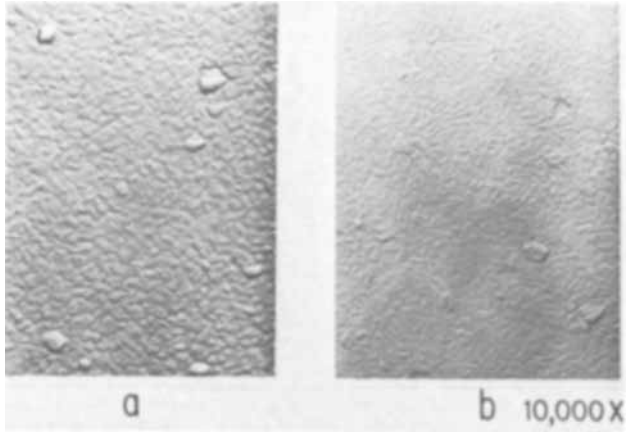

Fig. 3. Electron microscope photographs showing the effect of different degree of (111) orientation in aluminum film: (a) least oriented—planes make larger angles to substrate, (b) most oriented—planes more nearly parallel to substrate. 5500X.

A preliminary study of the evaporation conditions for aluminum films indicated that those films showing the least orientation (consequently, the most suitable ones for capacitor fabrication) were deposited in the following manner:

(a) The slides were heated to 250°C under vacuum.

(b) At a pressure in the 10^{-6} Torr range, a few hundred Angstroms of aluminum were evaporated on the hot substrate.

(c) The slides were cooled to room temperature in an argon atmosphere of about 0.2 Torr.

(d) The system was evacuated again to less than 10^{-5} Torr, and aluminum, sufficient to form 5000Å film, was evaporated on the unheated aluminum coated substrates.

A Ta_2O_5 or Ti layer on the glass substrate did not seem to affect the degree of orientation of the aluminum films.

The manganese oxide was deposited pyrolytically, by spraying an aqueous solution of 2% Mn $(NO_3)_2$ with 5% Superoxol (H_2O_2) onto the anodized aluminum-coated substrates whose temperature was maintained at about 200°C. The thickness of the resulting manganese oxide was varied between 2000 and 8000Å. The pattern of the manganese oxide was etched in HNO_3-H_2O_2 solution after the top electrodes, aluminum, gold, or nichrome-gold, had been evaporated through a mechanical mask.

Results

Yield of 15 spot AMM capacitors (AMM: Substrate—Al-Al_2O_3 MnO_x-Metal electrode).—During the preparation of the capacitors, it was found that a high degree of (111) orientation of the aluminum films seemed to limit the formation voltage. The aluminum films were, therefore, split into three groups according to the degree of orientation (*see* Fig. 2). Table I summarizes the initial yields which were obtained for 5000-pf capacitors formed at 130V on the three different types of aluminum films using the 15 spot test pattern shown in Fig. 1(b). The yield is based on the percentage of capacitors with a leakage current of less than 1 A/f at 75V. The table also lists the percentage of shorted capacitors and the average leakage current of the capacitors.

The results indicate that the degree of orientation of the aluminum films has a significant influence on the yield and the number of shorts of the aluminum oxide film capacitors. When the MnO_x was deposited at 170°C, the yield dropped from 100% found for films with a low degree of orientation to less than 50% for films with the highest degree of orientation. Raising the spraying temperature to 245°C also results in lower yields and in 4-10 times higher leakage currents, with this effect being more pronounced for capacitors formed on films showing a high degree of orientation.

Yield of 15 spot AM capacitors (AM: Substrate—Al-Al_2O_3-Metal electrode).—The observation that the

crystal orientation in the metal film has an important effect on the anodization properties of the aluminum suggested that it might be possible to use the less oriented aluminum films as determined by anodization characteristics for the development of aluminum oxide film capacitors without a layer of manganese oxide. Table II presents data for AM capacitors on glass, and on glass with either a layer of 500Å of titanium or Ta_2O_5. Both layers had initially been introduced to improve the adherence of the aluminum film to the glass substrate. The yield for the AM capacitors on glass substrates was 97% at 75V and the average leakage was about 0.7×10^{-9}A. (The slides were anodized to 130V.) Even at 100V, 90% of these capacitors had leakage currents in the 10^{-9}A range. The results were similar for AM capacitors on glass with a Ta_2O_5 layer. However, a titanium layer between the glass and the aluminum resulted in a lower yield (55% at 75V) and leakage currents which were about 10-15 times higher. This was attributed to the fact that the ammonium pentaborate-ethylene glycol used to anodize the Al is not a suitable anodizing solution for titanium at higher voltages, and the metallic titanium which was unprotected by Al_2O_3 (because of pinholes on the aluminum film) was responsible for the high leakages.

Life test performance of 15 spot AMM and AM capacitors.—AMM capacitors using the less oriented aluminum films formed at 130V with gold top electrodes were life tested at 85° and 110°C for 16 weeks. Testing voltages of 50, 65, and 70V and −20V were applied between the aluminum and the top electrode. The results of the life tests are presented in Table III. No failures occurred in 16 weeks at 50V, 85°C, or −20V, 85°C; 97% of the capacitors survived the test period at 65V, 85°C. About 7% failure occurred at 50V, 110°C, and 65V, 110°C; 90% of the capacitors survived 70V, 85°C for 16 weeks. These results are very similar to those reported for TMM capacitors formed at the same anodization voltage (9). But it should be mentioned that AMM capacitors have only about half the capacitance density (0.044 μf/cm²) as TMM capacitors (0.1 μf/cm²) if the same formation voltage is used. In the case of the reverse voltage where the aluminum was negative, the AMM capacitors survived 20V for 16 weeks at 85°C, indicating that these capacitors are less unsymmetrical than the tantalum film capacitors.

Table IV presents accelerated life test results for AM capacitors anodized at 130V. No failures were observed for 4 weeks at 50V, R.T., or at 50V and 85°C, or at 30V, 110°C for the capacitors that had no underlay. For the AM capacitors with Ta_2O_5 underlay, no failures were observed at 30V, 110°C, or at 40V, 85°C. One out of 13 capacitors failed in 4 weeks at 60V and 85°C. One out of 13 capacitors failed in 4 weeks at 50V and 85°C. The AM capacitors with titanium underlay showed similar results. No failures were observed at 30V and 85°C, or at 30V and 110°C; one out of 13 failed at 50V and 85°C.

Large AMM capacitors.—The excellent results found for the 5000-pf capacitors with an area of 0.1 cm² indicated that aluminum films showing a low degree of orientation might be suitable for the preparation of much larger capacitors by using larger areas and lower anodization voltages as for the TMM type (1, 3).

Two small groups of AMM capacitors on glass substrates and anodized to 130V, between 0.07 and 0.32 μf in size, were put on life test at 50V and room temperature for 1 week. The voltage was then raised weekly by 10V. The results presented in Fig. 4 indicate that no failures occurred below 110V. In the first group of four with an average size of 1.6 cm², 0.07 μf, corresponding to a capacitance density of about 0.044 μf/cm², the first failure occurred at 110V and two capacitors survived 140V for 3 days. In the second group of six capacitors, with an average size of 7.2 cm², 0.32 μf, no failures occurred within 8 weeks, by which time the test voltage had been increased to 120V. Four capacitors on unglazed alumina substrate which showed a 25% higher capacitance density were life tested at 50V and room temperature. All survived 16 weeks.

The possibility of using lower anodization voltages for obtaining high capacitance density AMM capacitors has also been investigated. Four AMM capacitors, between 1 and 1.5 μf in size (5-7 cm²) were prepared on glass substrates using 25V anodization. The finished capacitors were put on life test for 4 weeks at 10V and room temperature, and at 20V for an additional 4 weeks. All capacitors survived the 8 weeks of testing (*see* Fig. 5).

Effect of Anodization Voltage on the Properties of Aluminum Oxide Film Capacitors

In order to gain more information about the anodization behavior of evaporated aluminum films, a number of samples on glass substrates were anodized to 25, 130, 200, and 300V using the usual 30% ammonium pentaborate-ethylene glycol solution. In Fig. 6 the reciprocal capacitance density for the different anodization voltages has been plotted *vs.* the formation voltage. As in the case of tantalum oxide film capacitors, the reciprocal capacitance shows a linear dependence on the formation voltage.

As contrasted with the tantalum oxide film capacitors (10), the performance of the aluminum oxide film capacitors improves with increasing anodization voltage, at least up to 300V.

The results listed in Tables V and VI show how the anodization voltage affects the leakage current, the yield, and the number of shorts of AM and AMM capacitors. Analysis of the results for the AM capacitors shows that the leakage current remains below 1 A/f for all three formation voltages when the capacitors are measured at 75% of the formation voltages. For the AMM capacitors, the voltage where the current exceeds 1 A/f is lower than the AM type and it appears to be closely related to the reforming voltage which is about 70% of the formation voltage. The correlation is especially noticeable in the case of the 300V capacitors where the AMM capacitors were reformed at 210V. Below 210V the AMM type shows lower leakage currents than the AM capacitors and better yield, but at 225V the average leakage current is 200 $\times$ 10^{-9}A for the AMM *vs.* 3 $\times$ 10^{-9}A for the AM capacitors.

Frequency Dependence of Dissipation Factor and Humidity Effect

The capacitance and the dissipation factor of a number of capacitors have been measured at frequencies between 0.1 and 50 kHz. Typical results for AM and AMM capacitors are plotted in Fig. 7 and 8. The upper curve, for a 7600-pf AMM capacitor, reveals a shallow minimum of 0.022 at about 2 kHz for the dissipation factor and, above 50 kHz, the curve shows a 45° slope due to the series resistance of the manganese oxide. The dissipation factor for the AM capacitor is much lower, about 0.007 at 1 kHz, and it remains virtually unchanged because of the low series resistance of the electrodes. [When anodized to 150V, the dissipation factor of TM capacitors increased from less than 0.01 to 0.26 in the same frequency range (10), due to the series re-

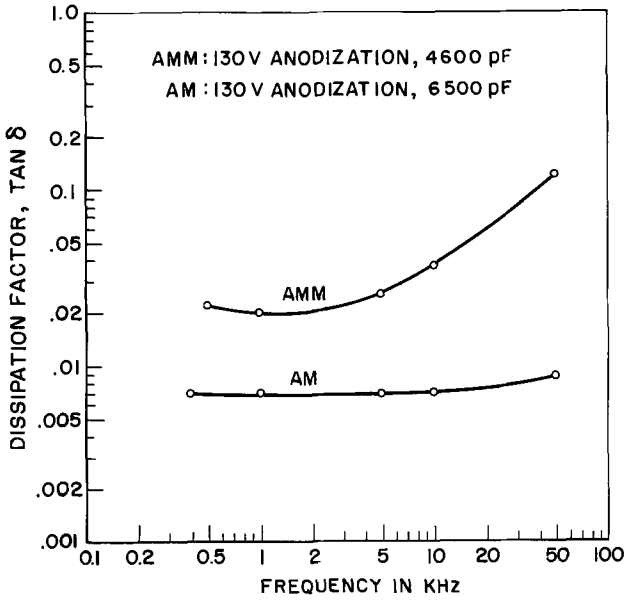

Fig. 7. Frequency dependence of tan δ for AM and AMM capacitors.

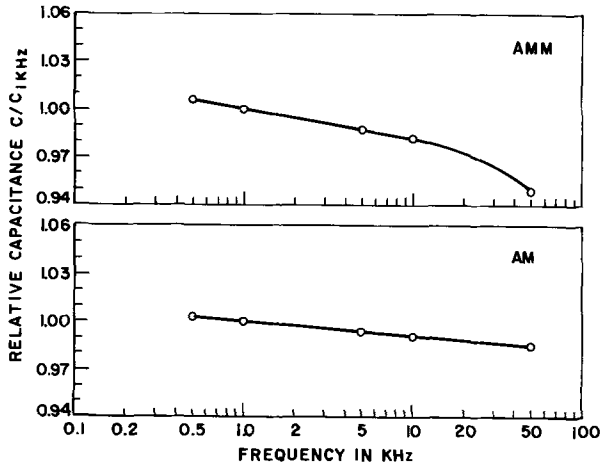

Fig. 8. Frequency dependence of capacitance for AM and AMM capacitors.

sistance of the tantalum film anode.] The capacitance of the AM capacitors decreases by about 2% between 500 Hz and 50 kHz while the AMM capacitors show a somewhat larger drop in this frequency range. [TM capacitors showed 5% decrease in the same range according to Vromen and Klerer (10).]

When measured at zero and 87% relative humidity (*see* Table VII), the AM capacitors with gold counterelectrode showed a change in capacitance of approximately 1%. For AMM capacitors it varied from 0.08 to 4%, which wide spread seems to be related to the manganese oxide. This is very similar to observations made on TMM capacitors. [With gold counterelectrode and 130V anodization, TM capacitors showed 0.79-2.46% change in capacitance by humidity according to Klerer, Orr, and Farrell (11).]

Conclusions

It was found that the quality of aluminum oxide film capacitors made either with or without a semiconducting manganese oxide layer between the dielectric and the counterelectrode depends to a large extent on the degree of the (111) orientation in the aluminum anode. The yield of AMM capacitors anodized to 130V was 100% using aluminum films with a low degree of orientation, compared to 47% for films showing a high degree of orientation.

Capacitors formed on aluminum with a low degree of orientation showed no failure during an accelerated life test period of 16 weeks at 50V, 85°C, and 97% of these capacitors survived life testing at 65V, 85°C. Aluminum oxide film capacitors prepared without a manganese oxide layer showed 97% yield, and no failure was observed during 4 weeks of life testing at 50V and 85°C. The results suggest that aluminum oxide film capacitors can be prepared which are equal in quality to tantalum oxide film capacitors; but, due to the lower dielectric constant of aluminum oxide, their capacitance density is only half that of tantalum oxide film capacitors anodized to an equivalent voltage. Aluminum oxide film capacitors offer an advantage over tantalum oxide film capacitors (12) in cases where low resistivity capacitor anodes are needed. AM capacitors have a very flat dissipation factor *vs.* frequency curve; at 50 kHz, the dissipation factor is still only 0.0085. They should be suitable for high-frequency application.

In aluminum oxide film capacitors up to 300V the breakdown voltage appears to be proportional to the anodization voltage.

The moisture effect is about 1% in AM capacitors, and it is somewhat variable in AMM capacitors. Some AMM capacitors were prepared with a moisture response of less than 0.1%.

The Effect of CO_2 on the Viscosity of Alkaline Electrolytes

T. I. Overthrow, J. N. Miller, and N. A. Hampson

Chemistry Department, Loughborough University of Technology, Leicestershire, England

Alkaline electrolytes are of general interest in many battery applications including zinc cells, fuel cells, and others. Electrolytes are frequently based on KOH (4-10M) in which the OH^- concentration may fall to about 3M at the end of discharge. CO_2 pickup is a problem in all cases. This note records a preliminary investigation of this effect.

Experimental

Measurements were made using an Ubbelohde viscometer (BS/IP/SL No. 1) in a thermostat at 59.90° ± 0.05°C. The characteristic constants of the viscometer were determined by measuring the flow times of toluene and water (1). Solutions were made up in distilled water using AnalaR grade reagents, and filtered through sintered glass disks. The flow time of each solution was measured at least three times: each mean relative viscosity value was subject to a standard error of *ca.* 2%.

Results

The relationships between the relative kinematic viscosities (ν/ν_0) of the solutions and their compositions are summarized in the figure. The three solutions represented by "0% conversion" were:

(i) NaOH (8g — 2.5M) — Na_2CO_3 (15.2g — 1.8M) — H_2O (76.8g — 53.2M)

(ii) NaOH (11.6g — 3.6M) — NaCl (16.3g — 3.5M) — H_2O (72.1g — 49.7M)

(iii) KOH (11.2g — 2.5M) — K_2CO_3 (21.3g — 1.9M) — H_2O (67.5g — 47.1M)

In each system, measurements were also made on solutions whose compositions corresponded to the progressive conversion of NaOH (KOH) to Na_2CO_3 (K_2CO_3), due allowance being made for the water which would be produced if the conversion was effected using CO_2.

Discussion

The curves in Fig. 1 indicate that the effect of CO_2 in alkaline battery electrolytes is to increase the electrolyte viscosity. It can be seen that the complete carbonation of the available OH^- in a spent electrolyte containing *ca.* 3M OH^- would be to increase the viscosity with respect to the hydroxide component by up to *ca.* 40%. The presence of an inert electrolyte (NaCl) does not eliminate the viscosity increase.

The result of this increase in viscosity would be to increase the diffusion layer thickness which in turn would decrease the limiting current density and accelerate the onset of passivation (anodic or cathodic).

The magnitude of such a reduction in the limiting current would be difficult to predict theoretically for a particular system, especially for a flowing system (2). Whatever the magnitude, however, the effect of the increase in viscosity would be undesirable.

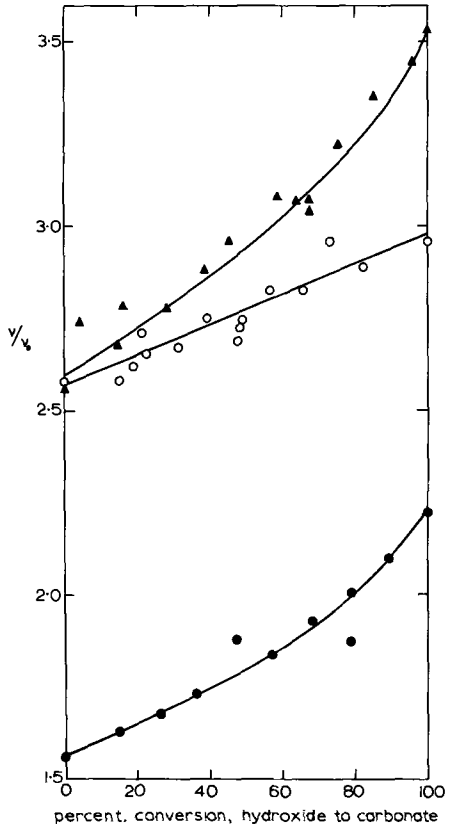

Fig. 1. Variations in the relative kinematic viscosities of aqueous solutions accompanying the conversion of NaOH (KOH) to Na_2CO_3 (K_2CO_3): ▲, system (i); ○, system (ii); ●, system (iii).

A Laboratory Cell for the Continuous Generation of Sodium Amalgam

Scott Lynn*

Department of Chemical Engineering, University of California, Berkeley, California

and H. Hunter Paalman

Research Laboratories, The Dow Chemical Company, Walnut Creek, California

The sodium amalgam produced in commercial chlorine cells is a chemically interesting commodity whose potential as a reducing agent is largely wasted when it is used to make sodium hydroxide and hydrogen. MacMullin (1) described a number of alternative uses, none of which has become widespread in the 18 years since his article appeared. However, because of the growing imbalance between caustic production and need, research in this area continues.

Sodium amalgam may be made from sodium and mercury for small-scale laboratory use, but this method becomes tedious if large quantities are required. Electrolytic generation is then preferable. However, operation of a small chlorine cell is fraught with annoyance. The chlorine must be disposed of; the anodes wear and must be frequently adjusted; chlorinated brine is corrosive, *etc.* These problems prevent a chlorine cell from being a reliable piece of laboratory equipment.

Sodium amalgam may also be generated by the electrolysis of sodium hydroxide in a cell with a flowing mercury cathode and a nickel anode. The anodic product is oxygen; the nickel electrode does not corrode and never needs adjustment. The electrolyte is relatively noncorrosive and is easily pumped. Minimal corrosion occurs when the cell is not in use.

The equipment sketched in Fig. 1 has been found by the authors to be useful for generating sodium amalgam at the rate of 3.7-5.6 g moles Na/hr (100-150A). The cell was made from two ¼- x 5- x 17-in. plates of nickel and mild steel, respectively. The active electrode area was 45 sq. in. Two 1½- x 5- x 17-in. Lucite blocks, milled out as shown in Fig. 2, formed the inlet and outlet headers. Neoprene gaskets used in assembly of the cell also served to set the spacing between the electrodes. The cell was sloped at an angle of about 10° to allow the mercury to flow by gravity; the caustic electrolyte flowed through the cell countercurrent to the mercury. The slope and caustic flow rate were sufficient to minimize blanketing of the anode by the evolving oxygen.

The caustic was pumped with an Eastern Model D-11 centrifugal pump equipped with a packing gland. A side stream was pumped through a filter to pick up scale dislodged by chemical action of the amalgam. A heat exchanger kept the operation in the temperature range of 50°-60°C. This limitation was imposed by the use of Lucite as a material of construction.

The current was supplied by a General Electric Model 6RS-945-P1 single-phase, full-wave rectifier and was unfiltered. Two rectifiers were used in parallel when higher amalgam production was required. Current was measured by using a 200A precision shunt and a null-balance potentiometer. The cell voltage was typically in the range of 3.5-4.8V.

The mercury pump was an Ingersoll-Rand ¾ KRV-B centrifugal sump pump having a capacity of 1 gpm at a head of 12 ft. To provide a constant head for the required mercury flow of 50-250 ml/min, the flow from the mercury pump was throttled with four 1/16-in. orifice plates in series (*see* Fig. 3). The larger stream of mercury flowed up through a vented, adjustable, constant-overflow standpipe and was returned to the pump. The standpipe vent line dipped into the pool

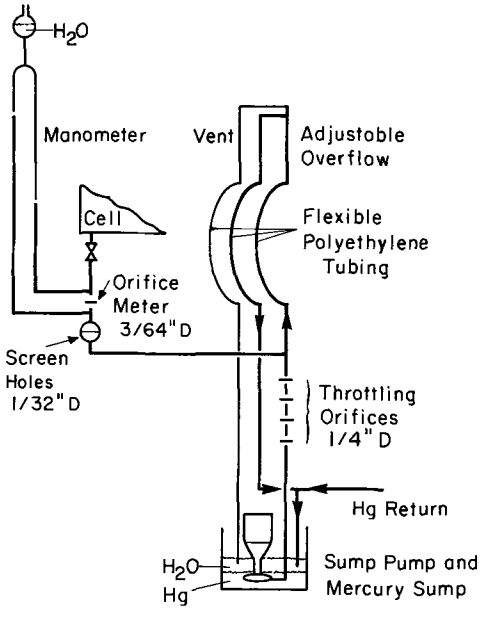

Fig. 3. Detail of mercury flow-control system.

of water covering the mercury in the sump. The downflow of mercury in the return line thereby pulled water with it, preventing the build-up of solid caustic and the discharge of mercury vapor into the room which would have resulted from venting with air. The smaller flow of mercury went to the cell through a metering orifice. The quantity of mercury flowing to the cell was varied by adjusting the height of the standpipe. This method of regulating the flow was adopted to replace a needle valve which was found to be a very unstable control device for this service.

The sodium amalgam produced could be used as desired in experimentation or could be returned to the pump through a decomposer made of a 1-ft section of 3-in. industrial glass pipe packed with granular graphite and heated with an internal steam coil to about 100°C.

The hydrogen evolved from the decomposer was measured with a soap-bubble flow meter. At steady state, this flow was a convenient method of monitoring the sodium content of the mercury stream returning to the pump. When no experimentation was in progress, the hydrogen flow could be used to determine the cell efficiency. When a reaction was being studied, the hydrogen flow was used to determine the extent of depletion of the amalgam. Oxygen containing a small amount of hydrogen was produced in the cell and was also measured with a soap-bubble flow meter. Hydrogen evolution at the cathode is the only possible side reaction in this system. The flow of oxygen could thus be used to determine the cell efficiency independently; the two methods of measurements generally agreed within 1%.

The primary variable affecting current efficiency was found to be the caustic concentration. When this was kept above 30 w/o (weight per cent) NaOH, the efficiency was consistently 97-99%. At lower electrolyte concentrations, cell performance became progressively worse. Another factor of importance in maintaining a high current efficiency was providing enough mercury to cover the cathode plate completely. This requirement set an upper limit on the amalgam concentration which could be produced at a given current and cell slope. Typical of the present system was 0.2% Na maximum at 100A. Modification of the cell design at the expense of simplicity would allow operation with a nearly level cathode and eliminate this restriction.

When the cell was first constructed, it operated at a very low current efficiency. Replacement of 316 stainless steel with mild steel in the mercury piping led to the satisfactory behavior reported above. Although the matter was not pursued, it is possible that some chromium was picked up by the mercury and caused the difficulty. Thereafter, the use of stainless steel was avoided throughout the system where possible. However, it was used in the caustic pump and other portions of the caustic piping system without trouble.

DISCUSSION SECTION

This Discussion Section contains discussion of a paper appearing in the *Journal of The Electrochemical Society*, Vol. 116, No. 3, (March 1969).

Plating Stresses from Electroless Nickel Deposition on Beryllium

R. M. Shemenski, J. G. Beach, and R. E. Maringer
(pp. 402-409, Vol. 116, No. 3)

Konrad Parker[1]: The paper presents numerous data and calculations, indicating that the internal stresses in electroless nickel deposits on beryllium can vary according to the plating conditions used by different platers. Each group of three beryllium strips plated by one of the four platers developed stress values in the nickel beryllium composite varying less than ± 10%. Nevertheless, the authors conclude that "since the resulting microstructures were similar, any effect of plating conditions should be minimal."

Recently, Baldwin and Such[2] stated: "The internal stress of the electroless deposits can be controlled by adjustment of the bath composition, particularly pH, so that it can be of any desired value between 16,000 psi (tensile) and 8000 psi (compressive). Wherever deposits having zero or compressive stress are considered beneficial, they can be produced but at a concomitantly lower plating rate."

We have started an investigation to determine the effect of the plating variables on stress in a closely controlled Kanigen® laboratory system. We have found that the masking of thin metal strips on one side can induce tensile bending prior to plating and during removal after plating. For more accurate bow-out measurements we are, therefore, plating both sides of the strips, then masking one side and stripping the deposit from the other.

Our results to date, which will be presented in detail later, show that the stress in electroless nickel deposits on beryllium and other substrates can be controlled by the plating conditions to be either tensile or compressive. Factors affecting the phosphorus content of the deposit such as pH are of primary influence in regard to the magnitude and direction of the internal stress produced. The stress in the as-plated condition is, therefore, not primarily due to differences in thermal expansion coefficients as the authors assume, but is induced to an appreciable degree during plating. It is also likely that the thermal expansion coefficient of the plate is not constant, but varies with the composition of the nickel alloy.

We confirm the authors' statement that electroless nickel deposits contract when annealed to 190°C; thus, by imparting a compressive stress in the deposit during plating, a practically stress-free state can be achieved after annealing. It would be most interesting if the authors could provide the phosphorus content of the nickel alloy coatings used in their investigation. The reason for the random variation of their stress data might then become apparent.

R. M. Shemenski, J. G. Beach, and R. E. Maringer: The authors wish to thank Mr. Parker for his remarks concerning our study on electroless nickel deposition on beryllium. It was unfortunately not within the

[1] Kanigen® & Coating Research, General American Research Division, General American Transportation Corp., 7448 North Natchez Ave., Niles, Ill. 60648.

[2] *Trans. Inst. Metal Finishing*, **46**, 73-80 (1968).

scope of this investigation to study the plating process itself. Rather, the study was designed to evaluate the product that would result in actual mirror production, not under idealized laboratory conditions. The authors are aware that plating conditions have a significant effect on the properties of an electroless nickel deposit, and in fact this is discussed in the paper. We are pleased to hear that research on the residual stresses in Kanigen® is continuing in GATX.

Each participating commercial plater was informed of the purpose of this study and was urged to use his best technology and his greatest care in plating the test specimens. The authors had no control over this phase of the study and so had to assume that these precautions were observed, just as one would expect these platers to handle an actual mirror. The reasons for feeling that this assumption was satisfactory and that gross effects due to handling or masking were minimal were also discussed in the paper.

The interpretation made by Mr. Parker of the results reported in the paper, that the residual stresses in the as-plated condition were primarily due to differences in the coefficients of thermal expansion, is not correct. It was explicitly stated that the authors recognized that: (*a*) the plating process itself, (*b*) metallurgical instability, and (c) differences in the coefficients of thermal expansion between plate and substrate, all contributed to the residual stress level attained in an electroless-nickel/beryllium substrate system. Therefore, this study acknowledged the importance of the plating process in developing residual stresses, but was limited to calculating the stress levels to be expected from present commercial practice.

The authors agree that more research on the deposition of electroless nickel is needed and that better control of the important parameters in the plating process should improve the dimensional stability of the coating. The role of phosphorus content, as discussed by Mr. Parker, is surely an important area.

Erratum

Drs. H.-E. Gumlich and U. Scherz want to point out that the review paper on "Optical Transitions in II-VI Compounds Containing Transition Elements," Paper 9 given at the Spring Meeting of The Electrochemical Society in Boston, May 5-9, 1968, by H.-E. Gumlich was based on a cooperation of H.-E. Gumlich and U. Scherz, which might not clearly enough be stated by citing U. Scherz (5). Essential parts of this paper are also contained in a review paper given by U. Scherz at the meeting of the Deutsche Physikalische Gesellschaft in Berlin, 1967. Only an abstract of this review has been printed as cited by (5) in the Boston paper by H.-E. Gumlich.

---

can be created, erased, and moved anywhere in thin sheets of magnetic material without interconnection. They may interact with one another in a controlled fashion and their presence or absence can be detected. Therefore, devices employing the new technology could be made to perform a variety of functions—logic, memory, switching, counting—all within one solid magnetic material.

The energy needed to manipulate the bubbles can be applied either by current-carrying conductors or picked up from a surrounding magnetic field by microscopic "ferromagnetic antennae" in printed patterns distributed over the surface of the material.

Physical Organic Chemist—Ph.D. 1952—Extensive industrial and contract experience in polymers, dielectrics and electrochemical technology. Highly creative and diligent. Strong interest in materials evaluation and applications. Reply Box C-22.

Physical Chemist, Ph.D. 1958—Research experience in electrodeposition, instrumentation, corrosion, metallurgy, batteries, fuel cells, organic and inorganic processes. Research or Teaching Position. Reply Box C-23.

Positions Wanted

Society members of any class may, at no cost and for the purposes of professional employment, place not more than three identical insertions per calendar year, not to exceed 8 lines each. Count 43 characters per line, including box number, which the Society will assign.

Certificates, Pins, and Keys Now Available

The Society announces the availability of the following items:

Membership Certificates	$ 3.00
Gold Membership Pin	$ 7.50
Gold Membership Key	$15.00

Those interested should send their order accompanied by check to The Electrochemical Society, Inc., 30 East 42 St., New York, N. Y. 10017.

POSITIONS WANTED

Please address replies to the box number shown, c/o The Electrochemical Society, Inc., 30 East 42 St., New York, N.Y. 10017.

Electrochemist—M.S. (1957)—seeks position in R & D. 12 years of varied battery R & D experience including alkaline secondaries, fuel cells, molten salt and metal air batteries. Patents and Publications. Reply Box C-7.

Inorganic-Physical Chemist—M.S. 1958 seeks leadership position. Experience in hydrometallurgy of Cb and Cu, electroless deposition, preparation of metal powders. Project leader in testing of electrodeposits, alumina reduction. Publications, computer programming, supervisory experience. Reply Box C-18.

Electrochemist—seeks administrative opportunity—18 years' manufacturing and R & D experience, including photochemistry, computer technology, energy conversion devices, adhesives, plastics, analysis, and technical supervision. Law training, industrial teaching, and product display experience. Reply Box C-19.

Electrochemist—Ph.D. 1962—8 years' experience in electrochemistry, electrolytic coating of polymeric materials, electrochemical processes, homogenous and heterogenous catalysis, electrokinetics, fuel cells, and batteries. Reply Box C-20.

Electrochemist—B.A. 1959—graduate studies—desires challenging position in small- to medium-size company. Ten years' basic and applied research in batteries, corrosion, electrodeposition. Reply Box C-21.
