Cadmium-air cells have been developed that deliver 45-50 whr/lb at the C/5 rate of discharge. The major failure modes of the cadmium-air system are: loss of capacity by the cadmium anode, shorting by cadmium penetration, poisoning of the air-cathode by a soluble cadmium species, loss of electrocatalytic activity by the air-cathode during prolonged cycling, and water loss by evaporation through the cathode pores and/or cell vent. It has been determined that loss of capacity by the cadmium anode can be prevented by the addition of Fe_2O_3 or TiO_2 extender into the active structure and by the removal of CO_2 from the influent air stream. It was found that cadmium penetration through the separator wrap can be avoided by preventing carbonate build-up in the electrolyte and by placing a wettable, inert interseparator between the anode and main separator. Poisoning of the air-cathode by soluble cadmium can be overcome by saturating the electrolyte with zincate or aluminate ions. Deactivation of the air-cathode is a problem that requires further investigation, and drying out of the cadmium-air cell can be prevented by providing the cell with an electrolyte sump.

The cadmium-air battery is of interest to the battery technologist in that: 1—it has a theoretical energy density of 202 whr/lb, 2—the stability and cycle life of the alkaline cadmium anode are excellent in nickel-cadmium and silver-cadmium batteries, and 3—the cadmium anode has a very low self-discharge rate.

In order to attain maximum energy density from the cadmium-air system, sponge cadmium electrodes were developed under a USAECOM internal program. The air-cathodes were supplied by General Electric Company and Leesona Moos Laboratories. The separators were supplied by Douglas Aircraft Company, R.A.I. Research Corporation, Pellon Corporation, and E. I. du Pont de Nemours & Company. No auxiliary charging electrodes were employed since the air-cathodes were bifunctional; *i.e.*, they were charging and discharging electrodes.

Experimental Procedure

The sponge cadmium anodes were prepared in the following manner: (*a*) cadmium oxide (Fisher Certified, Cat. No. C-16) was homogeneously blended with 5% by weight of carbonyl nickel powder (International Nickel Company, Type 255) and 5-10% by weight of ferric oxide extender (Fisher Certified, Cat. No. I-116) or titanium oxide extender (Fisher Certified, Cat. No. T-315), and (*b*) 44g of the cadmium oxide mix were mold pressed into an electrode containing an Aldex paper wrap (Aldine Corporation), a 5 Ni-15-2/0 nickel Exmet grid (Exmet Corporation), and a nickel tab. The electrode dimensions were: 0.095 in. in thickness, 3½ in. in height, and 2⅜ in. in width, and the electrode porosity (in the fully charged state) was 62.5%.

The unit cadmium-air cells were constructed as follows: The sponge cadmium anode was inserted into a heat-sealed polyamide Pellon bag of 6 mils thickness (2506K, Pellon Corporation). Around this, one or two layers of main separator material were laterally wrapped. The wrapped negative was then inserted into another Pellon bag (2506K) which completed the separator system for the unit cell. The electrode pack was finally inserted into a bicell containing state-of-the-art bifunctional air-cathodes. Nylon mesh air spacers of 100 mils thickness were placed on the gas side of the air cathodes, and the complete unit cell was secured between lucite supports.

Key words: electrochemistry, energy storage, batteries, cadmium-air, cadmium electrodes, air-cathodes, extenders.

* Electrochemical Society Active Member.

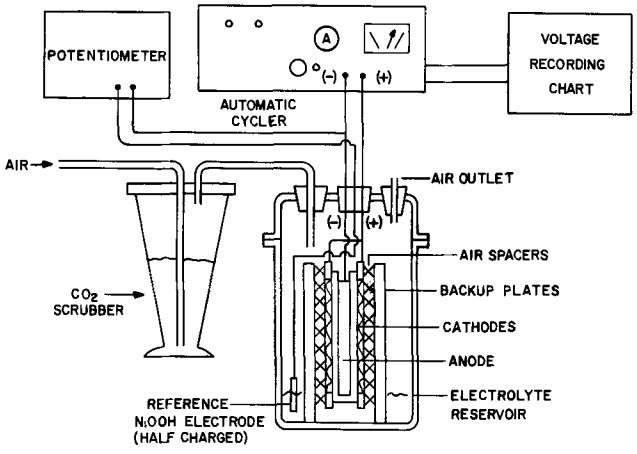

Fig. 1. Instrumentation

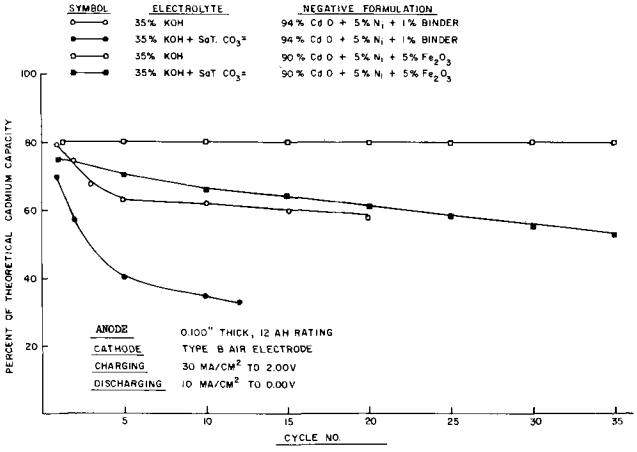

Fig. 2. Capacity maintenance as a function of cadmium mix and CO_2 exposure.

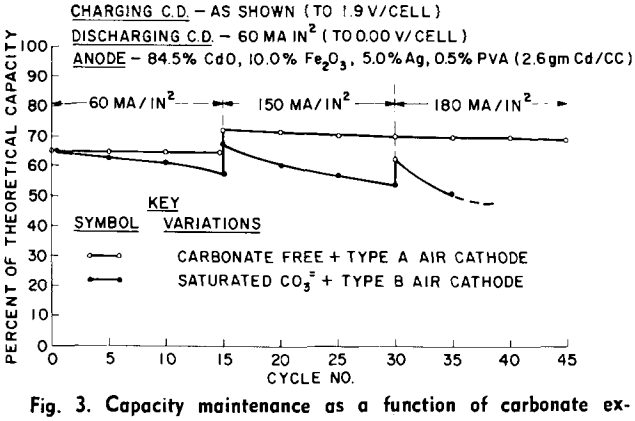

Fig. 3. Capacity maintenance as a function of carbonate exposure and charging current density.

The instrumentation employed in this program is shown in Fig. 1. The unit cadmium-air cell was contained in a reaction kettle. An electrolyte reservoir provided electrolyte to the electrodes by means of the wicking action of the Pellon wraps. The cell was cycled using an automatic cycler with the voltage cut-off set to zero volts on discharge and 1.9v on charge (C/5 rates of charge and discharge). Reference readings were taken with a potentiometer using a partially charged nickel-hydroxide reference electrode. Charge-discharge curves were automatically recorded by a Honeywell-Electronik voltage recorder. When desired, carbon dioxide was removed from the incoming flow of air by means of a scrubber which contained KOH solution. All tests in this program were run at room temperature ambient.

Results

The major failure modes of the cadmium-air system are: loss of capacity by the cadmium anode, shorting by cadmium penetration, poisoning of the air-cathode by a soluble cadmium species, loss of electrocatalytic activity by the air-cathode during prolonged cycling, and water loss by evaporation through the cathode pores and/or cell vent.

Loss of capacity by the cadmium anode.—When an alkaline cadmium electrode is continuously cycled on a deep discharge regime, it gradually loses capacity. This phenomenon is often observed with nickel-cadmium and silver-cadmium batteries when the cells become cadmium limiting on discharge.

The problem of capacity loss by the cadmium anode was to a large extent overcome by the introduction of alpha ferric oxide into the active cadmium powder and by removal of CO_2 from the influent air to the unit cell. Figure 2 shows that a control cadmium-air cell with a sponge negative containing no extender, and which was exposed to CO_2 (black circles), lost 37% of its initial capacity in 12 cycles. A test cell (open squares) with a negative containing 5% ferric oxide, and where CO_2 was removed from the unit cell, delivered 80% of theoretical capacity without any loss in capacity for 35 cycles. The combination of 5% ferric oxide extender and CO_2 exposure (black squares) resulted in the loss of 30% capacity in 35 cycles, while the combination of no extender and no CO_2 exposure (open circles) resulted in a capacity loss of 25% in 20 cycles. From these data, it is seen that the loss in capacity by the cadmium anode can be prevented by the addition of ferric oxide extender to the active cadmium powder and by the removal of CO_2 from the influent air to the unit cell. Recent test results show that 5-10% titanium dioxide also acts as an extender for the cadmium anode, the results being equivalent to that of ferric oxide.

The carbonate effect is further illustrated in Fig. 3. The figure shows the capacity of the sponge cadmium anode (containing 10% Fe_2O_3) as per cent of theoretical capacity *vs.* cycle number. The prime variables were cycling of the cell in carbonate free electrolyte (open circles) and in carbonate saturated electrolyte (solid circles). No data are available for intermediate concentrations of carbonate-KOH solutions. From the figure, it is seen that carbonate exposure decreased the capacity of the anode by 30% in 35 deep cycles, while the anode in a carbonate-free electrolyte lost only 3% of its initial capacity in the same number of cycles. Later cycling data of the test cell containing the ferric oxide extender and where the influent air was scrubbed free of CO_2 show that 75-80% of the theoretical capacity was attainable after 100 deep discharge cycles. These anode efficiencies yield energy densities of 45-50 whr/lb for optimumly designed cadmium-air unit cells of nominal 10 amp-hr capacity.

Cadmium penetration.—Cadmium, like zinc, has been known to build up crystals which can penetrate separators and cause shorting of batteries. Table I shows the effects of carbonated electrolyte, overcharge, and the separator system on shorting by cadmium penetration. Group A separator wraps were employed in a carbonate-saturated cadmium-air cell containing a sponge anode. Group B separator wraps were with a carbonate saturated cell containing a sintered cadmium anode. Group C separator wraps were with a CO_2 scrubbed cell containing a sponge anode.

From the data in Table I, it can be seen that cadmium penetration can be prevented by: (*a*) eliminating carbonate from the unit cell (compare Group C with Groups A and B), (*b*) minimizing overcharge, and (*c*) placing a layer of polyamide Pellon between the anode and main separator (compare A1 and A2). In addition, sintered-nickel cadmium anodes appear

Table I. The effect of overcharge, carbonate, and separator system on cadmium penetration

	Separator system	Cycles to short	Total amp-hr of overcharge
A	Sponge cadmium-air cell ($CO_3^=$ saturated)		
A1	(+) 1×0.001 in. Cellophane/1×0.006 in. Pellon (−)	58	48
A2	(+) 1×0.006 in. Pellon/2×0.001 in. cellophane (−)	9	5
A3	(+) 1×0.006 in. Pellon/2×0.002 in. Astroset /1×0.006 in. Pellon (−)	75	76
B	Sintered nickel cadmium-air cell ($CO_3^=$ saturated)		
B1	(+) 1×0.006 in. Pellon (−)	98	56
C	Sponge cadmium-air cell (no $CO_3^=$ in electrolyte)		
C1	(+) 1×0.006 in. Pellon/2×0.002 in. Astroset /1×0.006 in. Pellon (−)	120+ (still cycling)	180+
C2	(+) 1×0.006 in. Pellon/1×0.0015 in. RAI P300 /1×0.006 in. Pellon (−)	20+ (still cycling)	20+

more resistant to shorting than sponge anodes (compare Group B with Group A).

Cadmium poisoning of the air-cathode.—Both types of air-cathodes evaluated in this program (from General Electric and Leesona Moos) became severely polarized toward the end of discharge in cells discharged at current densities greater than 10 ma/cm². On subsequent recharge, the cathodes were reactivated and exhibited normal E-I discharge responses *vs.* fully charged cadmium anodes. However, *vs.* nearly fully discharged cadmium anodes, the air-cathodes become inactive during discharge. Even when a fresh uncycled air-cathode was discharged against a nearly fully discharged cadmium anode, the cathode became inactive.

Spectrographic analysis shows the presence of 0.1 mg/cm² cadmium in the air-cathode after cycling in a cadmium-air bicell. The poisoning of the air-cathode by the cadmium anode occurred in KOH electrolytes which were free of carbonate ions or other impurities. In these experiments, the influent air had been CO_2 scrubbed.

Figure 4 shows that when the electrolyte is saturated with carbonate ions, deactivation of the air-cathode will not occur. For comparison, the figure includes the discharge curves of the air-cathodes and cadmium anodes (*vs.* an Hg/HgO reference cell) in pure 7 normal KOH (open circles) and 7 normal KOH saturated with carbonate (solid circles). From these data, it appears that the cadmium anode forms a soluble species which poisons the air-cathode, but in the presence of carbonate ions the poisoning effect is prevented. However, as was shown in Fig. 2, carbonate severely decreases the capacity of the cadmium anode (after 20 cycles). Therefore, carbonate is not a desirable additive in a cadmium-air cell to prevent poisoning of the air-cathode. Consequently, a search was

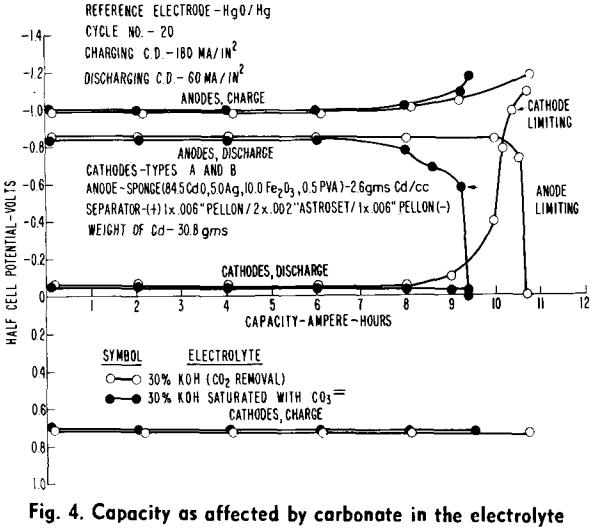

Fig. 4. Capacity as affected by carbonate in the electrolyte

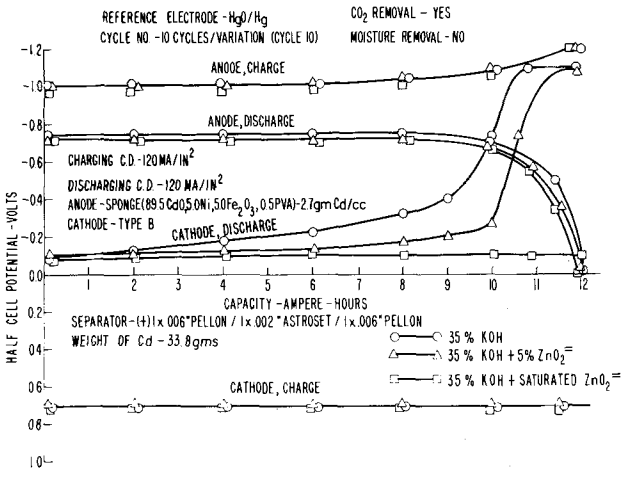

Fig. 5. Capacity as a function of zincate ion content

made for electrolyte additives which would: (*a*) prevent poisoning of the air-cathode by cadmium ions, and (*b*) be innocuous to the cadmium anode. One such additive has been found. As shown in Fig. 5, when the electrolyte was saturated with zincate ions, the air-cathode did not deactivate at the end of discharge. In addition, the electrical efficiency of the cadmium anode was not impaired after 10 deep discharge cycles. Since overcharge did not show a zinc deposition step, it apparently is safe to saturate the electrolyte with zincate in a rechargeable cadmium-air cell. It should be pointed out that aluminate ions have also been found to prevent cathode poisoning. At present, cadmium-air cells with zincate electrolyte are being life cycled and other additives are being screened in an effort to understand and better control the poisoning effect of the air-cathode.

Deactivation of the air-cathode on prolonged cycling.—Another failure mode encountered in the cadmium-air cell program was deactivation of the air-cathode after prolonged cycling. Figure 6 shows the performance of a cadmium-air cell during 300 deep discharge cycles. The air-cathode was manufactured by the Leesona Moos Laboratories in 1966 for a prototype mechanically rechargeable zinc-air battery. The anode was a sintered cadmium anode, and the influent air was *not* CO_2 scrubbed. The upper curve in the figure shows the capacity maintenance of the cell. The cell

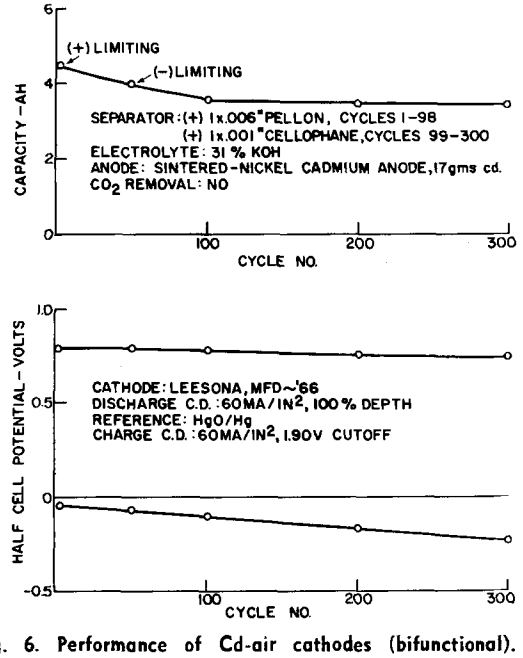

Fig. 6. Performance of Cd-air cathodes (bifunctional). (CO_2 exposure; 31% KOH.)

lost 25% of its initial capacity during the first 100 cycles and was negative-limiting in each discharge cycle. Since the electrolyte became saturated with carbonate ions, the anode lost capacity by carbonate contamination and the air-cathode never became limiting on discharge.

The lower curves in the figure show the half-cell potentials of the anode and cathode *vs.* cycle number (using an Hg/HgO reference cell). At a discharge current density of 10 ma/cm^2, the anode half cell potential decreased from 800 to 750 mv in 300 cycles, while that of the air-cathode decreased from minus 50 to minus 220 mv. The drop in anode potential is probably caused by carbonate contamination and the drop in cathode potential is attributed to a loss in electrocatalytic activity of the platinum catalyst.

Figure 7 shows the performance of cadmium-air cells which were constructed with state-of-the-art air-cathodes manufactured by General Electric and Leesona Moos Laboratories. The cells were charged at 20-ma/cm^2 to a 2.0v cutoff and discharged at 10 ma/cm^2 to a zero volt cutoff. The cells were given 50 deep discharge cycles (without overcharge); the influent air was CO_2 scrubbed; the electrolyte was pure 30% KOH; and the anodes were sponge cadmium electrodes containing 5% ferric oxide extender. From the figure, it is seen that: (*a*) the half-cell potential of the air-cathodes decreased from minus 50 to minus 100 mv in 50 cycles, (*b*) the cells were positive-limiting for each discharge cycle, (c) the electrical capacity decreased by about 10% for each cell in 50 cycles, and (*d*) the negative half-cell potential remained constant at 800 mv during the 50 cycles. In this experiment, the poisoning effect of the air-cathode by soluble cadmium again was very evident. Therefore, the deactivation effect of the cathodes was not very apparent.

To demonstrate more clearly the deactivation effect of the air-cathodes, the preceding experiment was repeated by using similar cells but employing 30% KOH electrolyte saturated with zincate ions. In this case, the cadmium poisoning effect would not be a factor. Figure 8 shows the performance of these cells during 50 deep discharge cycles. It should be noted that the cells were given large overcharges on an intermittent basis. This resulted from failure of the automatic cyclers to cut off on charge during several cycles. The following results were noted: (*a*) one cell failed by cathode flooding after overcharge on

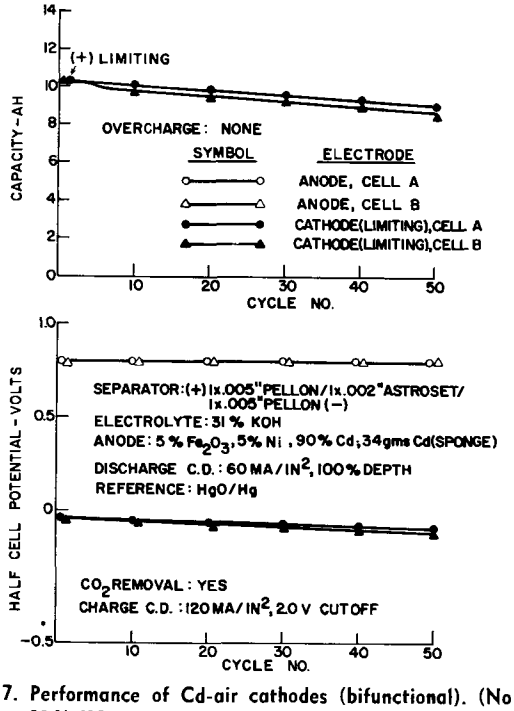

Fig. 7. Performance of Cd-air cathodes (bifunctional). (No CO_2 exposure; 31% KOH).

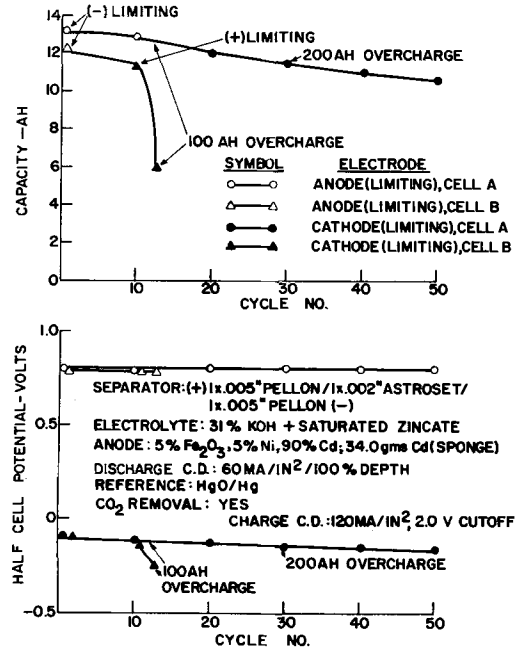

Fig. 8. Performance of Cd-air cathodes (bifunctional). (No CO_2 exposure; 31% KOH + saturated zincate.)

cycle 12, (*b*) the other cell was negative-limiting during the first 20 cycles and became positive limiting during the remaining 30 cycles, (c) the half-cell potential of the air-cathode decreased from minus 100 to minus 160 mv in 50 cycles, and (*d*) the half-cell potential of the cadmium anode remained constant at 800 mv during the 50 cycles.

The slow deactivation of the air-cathode is indicated by the test results of these experiments. The performance characteristics of these state-of-the-art air-cathodes indicate that further developmental work is required to prevent a loss in electrocatalytic activity by the platinum catalyst.

Water loss and unit cadmium-air cell design.—The 10 amp-hr unit cadmium-air cells employed in the USAECOM program lost about 0.5 cc of water per cycle at the C/5 rate of charge and discharge. This water loss primarily resulted from transpiration of water vapor through the pores of the air-cathode and cell vent. As shown in Fig. 9, an optimumly designed cadmium-air cell of nominal 10 amp-hr capacity includes a sump at the base of the cell which contains

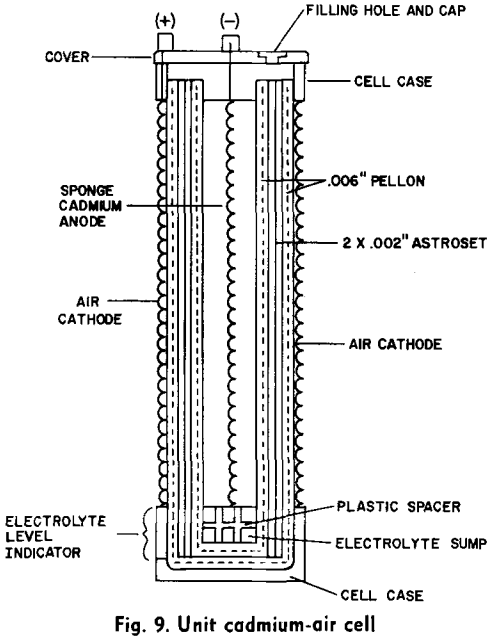

Fig. 9. Unit cadmium-air cell

5 cc of reserve electrolyte (as water). The excess water would prevent drying of the cell for approximately 10 cycles (the unit cells cycled in this program had an electrolyte reservoir of 100 cc of excess electrolyte). The cells could be watered every 10 cycles through a filling hole in the cover, after unscrewing the sealing plug. The required amount of water could be indicated by constructing the cell with a transparent or translucent plastic frame through which the electrolyte level can be seen and adjusted.

Electrolyte absorbent polyamide Pellon is placed in both the anolyte and catholyte compartments to transport electrolyte from the sump to the electrodes. The main separator consists of two layers of a nonoxidizable and nondegradable membrane, such as Astroset 3420-09 (an inorganic membrane from Douglas Aircraft Corporation) or Radiation Applications Inc. P-300 (a grafted polyethylene membrane). The cadmium anode is 100 mils thick, with an apparent porosity of 62%, and contains 5% ferric oxide extender and 5% carbonyl nickel conductor. The air-cathodes are state-of-the-art and bifunctional (with a platinum loading not exceeding 6 mg/cm^2). The electrolyte is 30% KOH saturated with zincate, and CO_2 is removed from the influent air by means of ascarite or soda-lime columns contained within the battery case.

The energy densities on the basis of weight and volume for the 10 amp-hr cadmium-air cell are tabulated in the top of Table II. The weights of the cell components are listed in the bottom of the table. From the data, it is seen that an energy density of 51 whr/lb is attainable at the C/10 rate and 43.5 whr/lb at the C/2 rate.

An actual 24v, 25 amp-hr cadmium-air battery was constructed by General Electric for the U. S. Army Electronics Command. The battery was built according to the design parameters derived from the USAECOM program. The unit test cells had an energy density of 45 whr/lb at the 2-amp rate and the battery plus case hardware had an energy density of 35 whr/lb. Unfortunately, electrolyte leakage from the cells and cathode flooding after prolonged charged stand prevented further testing of the battery. Serious as these problems are, they should not be difficult to correct in future cadmium-air battery designs.

Discussion

The loss in capacity by the cadmium anode is attributed to a loss in real surface area by the growth of cadmium crystals and by the subsequent blockage of the electrode pores (1-3). At moderate and elevated temperatures, the charge and discharge of the cadmium electrode are reported to be controlled by the reaction between a soluble cadmiate ion species [$Cd(OH)_3^-$] and the active lattice sites (4). It is believed that the function of the extender is to provide lattice sites for the formation of cadmium hydroxide and metal cadmium via the soluble cadmiate ion species. As the number of lattice sites, or nuclei, increases, there should then be a greater tendency to form finely divided metal cadmium or cadmium hydroxide. It is possible that any metal oxide, which (*a*) is insoluble in alkali, (*b*) is electrochemically inert, and (c) possesses crystal lattice dimensions similar to those of cadmium hydroxide, could serve as a beneficial extender for the cadmium electrode.

Table II. Energy density calculations for a 12 amp-hr cadmium-air cell

Energy density (cycles 1-50)

Rate	Capacity, amp-hr	CCV, v	Whr/lb	Whr/in.^{3}
C/10	13.5	0.86	51.0	4.05
C/5	12.5	0.83	47.2	3.80
C/2	11.5	0.73	43.5	3.50

Weight of cell components

Cathodes	17.5g
Anode	39.8g
Separator	3.0g
Electrolyte + 5 cc of water	22.0g
Cell case, sump, cover, and other	22.0g
Total	104.3g (0.30 lb)

Volume of cell (including 0.100 in. air spacer) 47.0 cc

The fact that carbonate increases the rate of capacity loss by the cadmium anode may be explained by (*a*) the formation of electrochemically inactive cadmium carbonate and/or (*b*) the accelerated growth of cadmium crystals by a soluble cadmium carbonate species [$Cd(CO_3)_3^{-4}$] (5, 6). The reason that carbonate causes cadmium to penetrate the separator wraps may be due to a dendritic type of electrodeposited metallic cadmium during the reduction of soluble cadmium carbonate. Finally, the fact that carbonate prevents poisoning of the air-cathode by the soluble cadmiate species [$Cd(OH)_3^-$] may be due to a preferential formation of soluble cadmium carbonate by the cadmium anode toward the end of discharge, the soluble cadmium carbonate species being innocuous to the air-cathode. Some of these phenomena are of interest in that they also relate to the performance of nickel-cadmium and silver-cadmium batteries. Basic studies of the effects of carbonate on the electrochemical performance of the cadmium anode are therefore warranted.

The effect of zincate or aluminate ions on the performance of the air-cathode in the presence of cadmiate ions is not understood. Possibly the cadmiate concentration is reduced when the electrolyte is saturated with zincate or aluminate and/or the latter ions prevent chemisorption of cadmiate ions on the electrocatalytic sites of the air-cathode. A study of this phenomenon on a fundamental basis is required.

The loss of electrocatalytic activity by the platinum catalyst after prolonged cycling of the air-cathode may be due to a recrystallization of the platinum and/or loss of hydrophobicity at the three phase interface. Further study and development of the air-cathode is undoubtedly warranted.

Conclusions

1. Loss of capacity by the cadmium anode can be prevented by the addition of ferric oxide or titanium dioxide extender into the active structure and by removal of carbon dioxide from the influent air stream to the unit cells.

2. Cadmium penetration through the separator wrap can be prevented by removal of CO_2 from the cell, minimizing overcharge and placing an inert electrolyte absorbent interseparator between the cadmium anode and main separator.

3. Poisoning of the air-cathode by soluble cadmium can be overcome by saturating the electrolyte with zincate or aluminate ions.

4. Further development work is required on the air-cathode to prevent electrocatalytic deactivation after the prolonged cycling.

5. Water loss can be compensated by providing unit cell with an electrolyte sump.

6. Unit cadmium-air cells have been developed which show a cycle life capability of 300 cycles and an energy density in the range of 45-50 whr/lb.

The Heat Capacity of Electrolytes Simulating Those Found in Silver Chloride-Magnesium Water-Activated Batteries

Duane W. Faletti

Applied Physics Laboratory, University of Washington, Seattle, Washington

and Ivan W. Herrick and Mark F. Adams

College of Engineering, Research Division, Washington State University, Pullman, Washington

ABSTRACT

The heat capacities of magnesium chloride-sea water solutions with chlorinities varying from 4.5 to 19.0 parts per thousand and with 0-70g of magnesium chloride per liter of solution were determined over a temperature range from 5° to 85°C. These solutions simulate the electrolyte conditions found in silver chloride-magnesium water-activated batteries using sea water. An empirical equation was developed which successfully predicts, within 1.5%, the heat capacities of such solutions over a range of chlorinity from 0 to 19 parts per thousand.

Work is in progress to develop an improved design technique for silver chloride-magnesium water-activated batteries based on a semiempirical mathematical model (1). To determine battery performance, heat capacity values accurate to a few per cent are required to calculate the temperature of the electrolyte circulating in flow passages and cells.

AZ61 magnesium alloy is commonly used as the anode in silver chloride-magnesium batteries and sea water is the common electrolyte (though it is possible to operate such batteries on fresh water). Since the primary effect of the battery reaction is to add magnesium chloride to the entering electrolyte, sufficiently accurate results for the purposes of battery design can be obtained from a study of the heat capacity of solutions of magnesium chloride in sea water and in water. Secondary effects include the formation of precipitates of the hydroxides of magnesium, aluminum, zinc, and manganese, and the removal of some of the salts found in the entering electrolytes by, among other things, retention in the sponge silver formed by the reduction of the silver chloride. The solutions studied cover the range of composition and temperature of interest. They were prepared by the method given in Ref. (2).

Experimental Method

The heat capacity was determined by a method commonly applied to static systems: electrical energy was converted to heat at a constant, known rate within the confines of the solution for a known length of time.

Temperature measurements were taken prior to and after the heating period for determining the temperature rise caused by the heat input. The above information plus a knowledge of the heat capacity of the calorimeter and the mass of the fluid in the calorimeter was sufficient to allow a calculation of the heat capacity using the equation

$$Cp = \frac{\dfrac{E^2 t}{4.184\, R \Delta T} - CpCal}{W_{soln}} \qquad [1]$$

Key words: heat capacity, sea water-magnesium chloride solutions, silver chloride-magnesium battery electrolytes.

where Cp is the heat capacity of the solution, Cal/g °C, E is the potential across the heater in volts, t is the length of the heating period in seconds, R is the heater resistance in ohms, ΔT is the temperature rise resulting from the heat input, CpCal is the "heat capacity" (note units) of the calorimeter in Cal/°C, and W_{soln} is the mass of the solution under study.

Apparatus.—Two types of calorimeters were used in this study. One type which worked satisfactorily at 5° and 25°C was simply a 1-liter Dewar flask capped by a cork into which the thermometer, heater, and glass stirrer were mounted, an arrangement which can be operated rapidly and easily. However, there appeared to be no effective way of heating the space in the calorimeter above the liquid while still maintaining calorimetric conditions. The resulting condensation of vapor in this space caused significant errors at temperatures above 45°C.

In order to circumvent these problems, a cavity calorimeter was constructed for use at temperatures of 45°, 65°, and 85°C (Fig. 1). Though agreement between the two calorimeters was acceptable at 45°C, only the results obtained with the cavity calorimeter arrangement are presented for temperatures above 25°C.

A Beckman differential thermometer accurate to 0.002°C was used for the temperature measurements. The heaters were glass coils filled with silicone oil with a nominal 60-ohm length of Nichrome C resistance wire running through them. The resistance wire ended below the liquid level and was connected to copper leads which extended to the outside of the calorimeter.

Electrical energy to the heater was supplied by a stable power supply of 60v. The resistance of the heater was measured immediately before and after the heating period, and the potential drop across the heater was measured during the heating period. The accuracy of the thermometer, electrical components, and balance weights was checked periodically.

Procedure.—All heat capacity determinations were made with a minimum void space above the liquid so that evaporation effects could be ignored.

To eliminate condensation on the upper portion of the calorimeter jar (which occurred at 45°C and

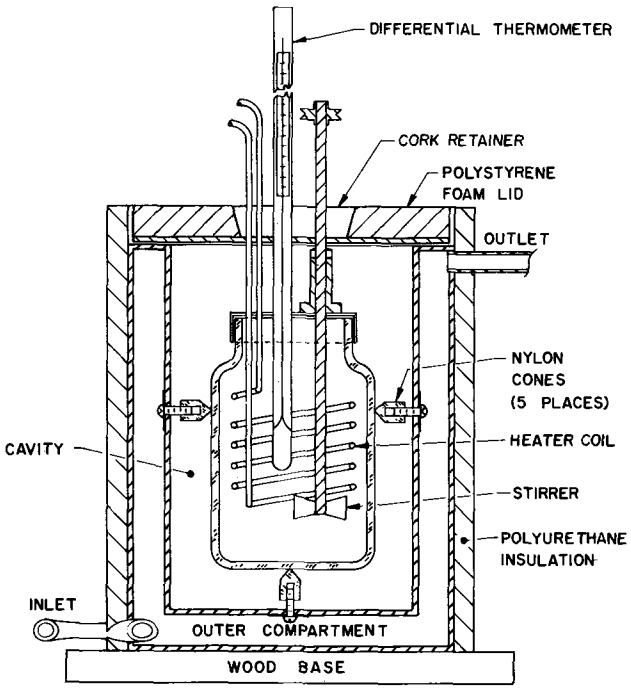

Fig. 1. Schematic of cavity calorimeter; for measuring heat capacity of electrolytes with temperatures ranging from 45° to 85°C.

above), the following procedure was used with the cavity calorimeter: Samples were preheated to about 1°C below the test temperature in a preheating bath, whereupon the top of the calorimeter jar was heated with a hot air blower to evaporate any condensate which may have accumulated there. The calorimeter jar was then placed in the calorimeter with the water circulating through the outer compartment held at 1°C above the test temperature during the entire test.

After the calorimeter was allowed to equilibrate for 20 min, seven temperature readings were taken at 50-sec intervals, whereupon the heater resistance was measured and the heater was started. The voltage of the heater (held constant to 0.01v or better) was measured at least three times during the 150-sec heating interval and the results averaged. Upon completion of the heating period, the heater resistance was measured along with an additional seven temperature readings taken at 50-sec intervals.

Data reduction and error analysis.—The temperature rise in the calorimeter was determined as follows: Separate temperature-time curves were drawn through the two sets of temperatures recorded prior to and following the heating period. This could be done with a maximum deviation of 0.002°C or less by excluding the first point taken after the end of the heating cycle. The temperature rise from the heat input was taken to be the difference of these two temperature-time curves at a time 80 sec after the start of the heating period.

The time chosen to take the temperature rise, using Challoner's Method (3), was based on (*a*) an observed 10-sec time lag between the start of the heating and the first indication of a temperature rise, and (*b*) the apparent linearity of the temperature rise with time during the heating period. This process yields temperature rises with maximum uncertainties of 0.4% (0.008°C) with about two thirds of the uncertainty resulting from the extrapolation process.

The heat capacities of both calorimeters were determined from experiments with water using the techniques described above but solving for the heat capacity of the calorimeter by rearranging Eq. [1] and adding the known value of the heat capacity of water (4). The values of calorimeter heat capacity obtained should at least partially compensate for systematic errors in temperature extrapolations, etc. Five values of calorimeter heat capacity were determined at each temperature level studied from which the average values of calorimeter heat capacity were calculated.

An error analysis based on the values of maximum uncertainties in the five parameters of the experiment (Table I) and the uncertainty values calculated for the heat capacity of the calorimeter (using the values of the same five parameters) gives a maximum uncertainty value of ± 1.25% for the heat capacity results. If the uncertainty value of the calorimeter heat capacity is excluded, a maximum uncertainty value of ± 0.7% results. The latter value is of some interest since the values of the calorimeter heat capacities were subjected to averaging.

As a check on the experimental technique, the heat capacity was determined for four solutions with known heat capacities. Two of these solutions were sea water; the agreement obtained is discussed later. Of the two remaining solutions, one was of 2.44 m/o (mole per cent) sodium chloride solutions which was run through at 45°C. The heat capacity obtained was 0.33% greater than that found by interpolating ICT data (5).

The other check was made with a 0.405 molal sodium chloride solution studied at 85°C. The heat capacity obtained was 0.55% lower than that obtained by Eigen and Wicke (6).

Presentation and Discussion of Results

Three determinations of the heat capacity were made for each solution at each temperature. These three values were averaged and are presented in Table II and Fig. 2. The total spread in the three determinations made at a given point never exceeded 0.7% and was typically 0.3%. Values of the heat capacity of solutions with zero chlorinity, *i.e.* magnesium chloride-water solutions, over a temperature range of 10°-85°C were obtained by crossplotting the results of Eigen and Wicke (6) and Rutskov (7) and are shown in Fig. 2.

An additional check on the accuracy of the results is provided by the values of heat capacity for artificial sea water solutions. The heat capacities determined at 5°C for a solution with a chlorinity of 4.5 parts per thousand (‰) and for a solution at 25°C with a chlorinity of 19.0‰ were, respectively, 0.39% and 0.27% lower than values obtained by Cox and Smith (8).

The empirical equation,

$$Cp = 0.9960 - 0.001259\ (CM) - 0.002174\ (CHL) + 0.000009526\ (CM)\ (CHL) \quad [2]$$

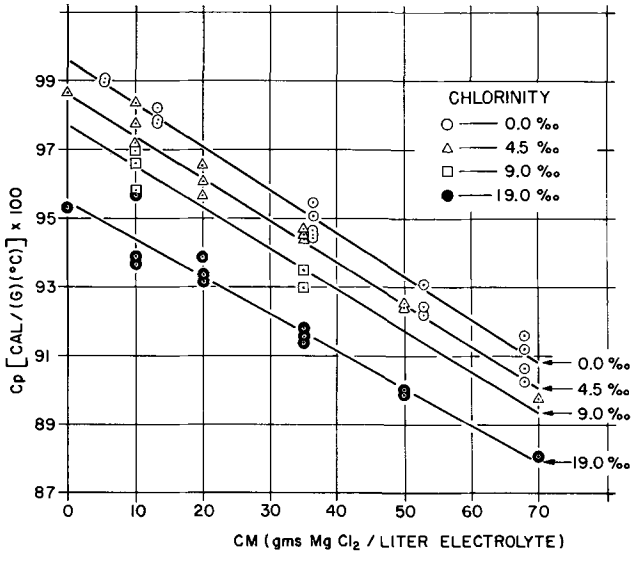

Fig. 2. Heat capacity as a function of added $MgCl_2$. Lines show values of heat capacity as predicted by Eq. [2] for the levels of chlorinity shown, in parts per thousand.

was developed where *CM* is added $MgCl_2$ in g/liter of sea water or fresh water, and *CHL* is chlorinity in parts per thousand. This equation successfully predicts the heat capacity as a function of chlorinity (0.0-0.19°/₀₀) and added magnesium chloride (0-70 g/liter) to within 1%, with two exceptions: The first is a 1.1% deviation with a solution of 4.5°/₀₀ chlorinity and 10 g/liter added magnesium chloride at 45°C; the second is a solution of 19.0°/₀₀ chlorinity and 10.0 g/liter added magnesium chloride at 45°C with a deviation of −1.4%.

The chlorinity of sea water in the world's oceans varies from about 4.5 to 22.5°/₀₀. Since Eq. [2] is based on a linear interpolation between 0.0 and 19.0°/₀₀ chlorinity, the use of Eq. [2] to extrapolate to a chlorinity of 22.5% appears justified.

The electrolyte temperatures and compositions covered in this study are typical of those found in high-drain silver chloride-magnesium sea water-activated batteries. The observed 10% variation in heat capacity (*see* Table II) indicates that corrections for this variation in heat capacity (*i.e.*, Eq. [2]) should be incorporated into design techniques which make use of material and energy balances (such as the design techniques under development at Applied Physics Laboratory, University of Washington).

Mechanisms of Oxidation of Ta-10W Alloy Coated With Tungsten Disilicide

Joan B. Berkowitz-Mattuck*

Arthur D. Little, Incorporated, Cambridge, Massachusetts

ABSTRACT

Continuous oxygen consumption measurements have been made on two commercially available W/Si type coatings, the TRW duplex coating and Solar's TNV-13, at temperatures between 1000° and 1800°C and an oxygen partial pressure of 150 Torr in helium. The coatings were applied by the vendors to small cylindrical pellets of Ta-10 a/o W. It was shown that the coated samples undergo significant changes in properties if preheated in non-oxidizing atmospheres. Although the as-received TRW and TNV-13 samples are both nominally similar, they exhibit totally different oxidation behavior under the conditions investigated. Oxidation of the TNV-13 coated samples is parabolic between 1000° and 1700°C, and the parabolic rate constant increases with temperature. Oxidation of the TRW coated samples is logarithmic, and the extent of oxidation in a 1-hr time period decreases as the temperature is increased from 1000° to 1250° to 1500°C. At 1700°C, the TNV-13 coating provides protection, while the TRW coating fails catastrophically. The results of electron microprobe analysis suggest that the basic differences in oxidation mechanism between the two coating systems may be ascribed to the presence of a small amount of titanium in the TNV-13 coating.

The poor oxidation resistance of refractory metals and alloys severely limits their usefulness in oxidizing environments at high temperature. Since the metals themselves are attractive for many projected applications due to their high melting points and good high-temperature strengths, considerable effort has been devoted in recent years to the development of oxidation-resistant coatings. This paper examines the basic oxidation mechanism of two commercial coating sys-

* Electrochemical Society Active Member.

tems, both based on tungsten disilicide, which were developed for improving the oxidation resistance of Ta-10W. The coating systems, while similar from a chemical standpoint, differ both in precise formulation and in over-all oxidation behavior.

Materials

Annealed Ta-10W rod, 0.312 in. in diameter, was supplied by National Research Corporation, Newton, Massachusetts. A certified heat analysis of the material is reproduced in Table I. The principal impurity is seen to be Nb and the W concentration is somewhat lower than the nominal 10%. The as-received rod was machined into cylindrical pellets approximately 0.3 in. in height, a size suitable for the oxidation tests described in Table I. The material analyzed 9.2 w/o (weight per cent) W with the balance Ta.

The coating systems selected for study were the Solar TNV-13 duplex coating (1) and the TRW (Thompson Ramo-Woolridge) silicon-tungsten coating (2). The coatings were applied by the manufacturers to the cylindrical test pellets described above. The basic steps in the respective coating fabrication processes are summarized in Table II. Both coating systems are duplex in nature. The TRW system has a chemically vapor deposited layer of W, applied by Westinghouse, adjacent to the Ta-10W alloy surface. The TNV-13 system starts with a slurry coat of 95W-5Ti. The silicon is diffused into the TRW coating in a vacuum pack, and into TNV-13 in a high-pressure pack. Finally, TNV-13 is impregnated with glass frit, while the TRW coating receives no further treatment.

Oxidation Kinetics Measurements and Results

For both as-received and coated samples, measurements were made of the rate total oxygen uptake as a function of time at temperature. A diagram of the oxidation apparatus is shown schematically in Fig. 1 and has been described previously (3). Briefly, a mixture of helium and oxygen of known composition flows through a thermal conductivity cell (TC-I) containing a thermistor bead detector, and over an inductively heated pellet, where some of the oxygen is lost from the stream by reaction. The oxygen depleted stream passes through a second thermal conductivity cell (TC-II) similar to the first. The two cells, TC-I and TC-II, form two arms of a Wheatstone bridge, whose recorded output at any time is directly proportional to the rate at which the sample is reacting at that time. The recorded rate curve is automatically integrated to give the net extent of reaction over a given time period. The test environment for the oxidation studies reported here was 760 Torr, with 150 Torr oxygen and the remainder helium.

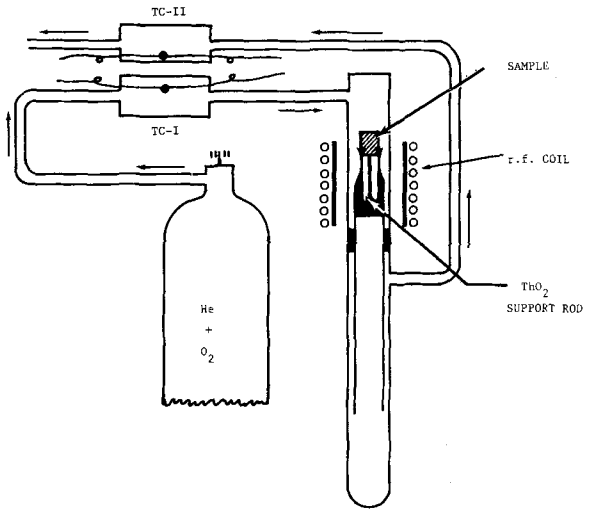

Fig. 1. Schematic drawing of apparatus for monitoring rates of oxygen depletion.

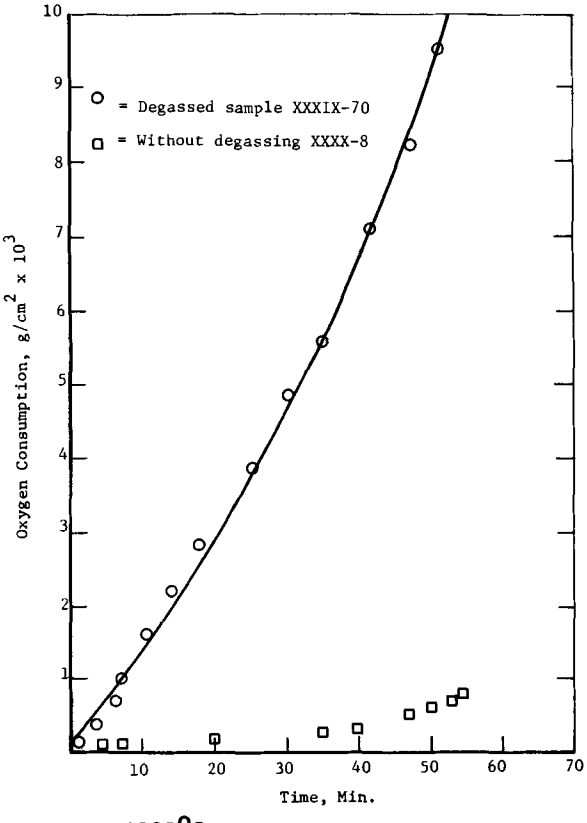
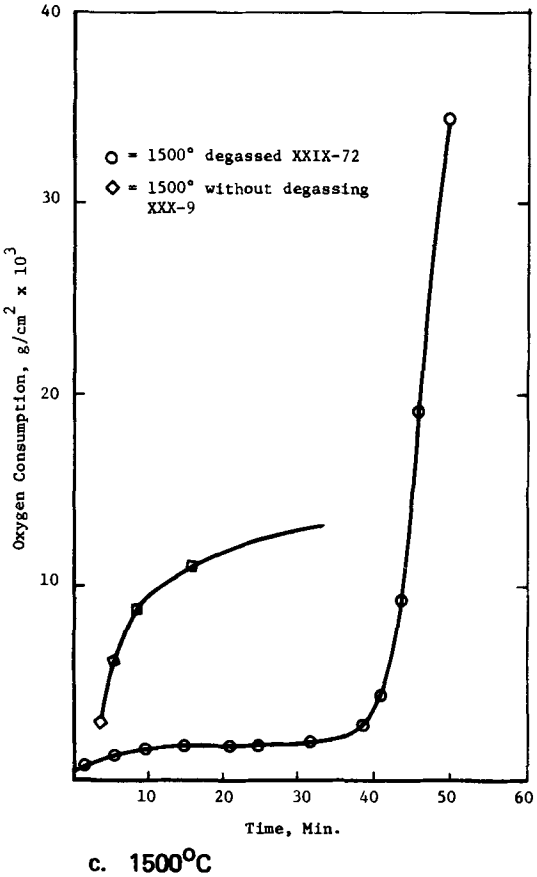
In previous oxidation studies with the present apparatus, it was routine to preheat specimens in pure helium at the planned oxidation temperature to remove any residual permanent gasses. This degassing procedure was found to degrade seriously the coated systems under investigation here, and was ultimately abandoned. Oxidation results for degassed and undegassed TRW samples are compared in Fig. 2 for temperatures of 1000°, 1250°, and 1500°C, respectively. At 1000° and 1250°C, the extent of oxidation at all times is significantly higher for the degassed samples, although the form of the oxidation *vs.* time curves is similar. At 1500°C, the oxidation mechanism may change, and the degassed sample initially oxidizes less rapidly than the undegassed one. Eventually, however, the degassed sample fails catastrophically, while the undegassed one retains excellent protective characteristics. Thus, the oxidation behavior of a coated sample is critically dependent on prior history. Furthermore, coated specimens will not tolerate prolonged exposure at high temperatures in nonoxidizing atmospheres without significant changes in properties. It may be noted that permanent gas evolution, as monitored with the thermal conductivity cell, proved to be negligible in all cases.

In Fig. 3, oxidation results for undegassed TRW coated samples are compared as a function of temperature. Over a 1-hr period, the extent of oxidation decreases as the temperature is increased from 1000° to 1250° to 1500°C. The improvement of oxidation resistance with increasing temperature over the protective range is characteristic of both monolithic molybdenum and tungsten silicides (4). The rate of formation of the protective silica film is probably more rapid at higher temperature and hence protection is established earlier. At 1700°C initial rates are exceedingly high, but a protective oxide is never established and a catastrophic oxidation failure occurs.

In contrast to the data in Fig. 3 for the TRW coating, oxygen consumption *vs.* time curves for the undegassed Solar TNV-13 coating are shown in Fig. 4 for temperatures of 1000°, 1250°, 1500°, 1700°, and 1800°C. The TNV-13 coating clearly shows a declining rate of oxidation with time, characteristic of a good oxidation-resistant material, up to the highest temperatures. Even up to 1500°C, where both the TNV-13 and the TRW coatings are protective, the fundamental mechanism of oxidation appears to be different. The curves of Fig. 4 are approximately parabolic, as seen in the plots of oxygen consumption squared (g^2/cm^4) *vs.* time in Fig. 5. Near 1500°C, where the protective properties of the TRW coating seem to be optimum, the oxidation curve is logarithmic, and the final *rate* of oxidation at long times is lower than for the paraboli-



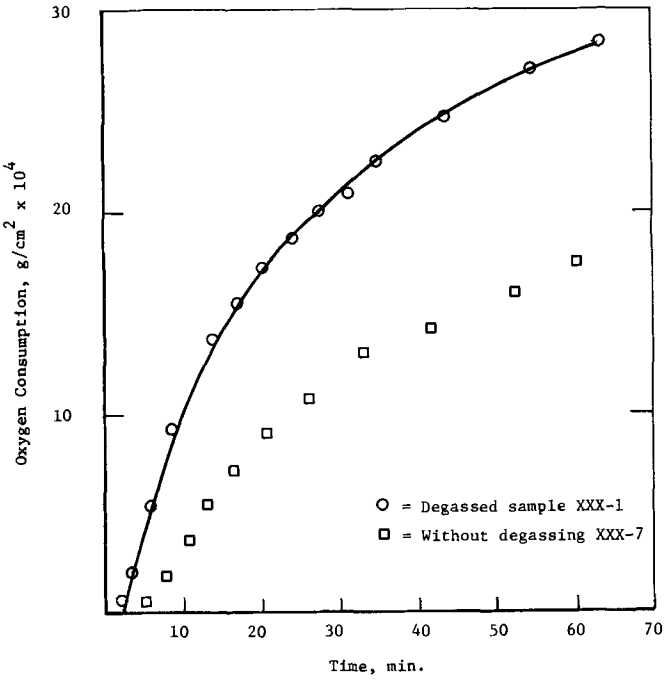
a. 1000°C



c. 1500°C

Fig. 2. Oxidation of TRW coated Ta-10W

cally oxidizing TNV-13. The total oxygen consumed in a 1-hr time period at 1500°C is also lower for the TRW than for the TNV-13 coating, 1.2 x 10^{-4} g/cm² for TRW compared to 9.4 x 10^{-4} g/cm² for TNV-13. However, at 1700°C, the TNV-13 coating is vastly superior, still retaining good protective properties with



b. 1250°C

parabolic oxidation, while the TRW coating has failed completely. At 1800°C (observed brightness temperature), the TNV-13 coating is seen to have failed catastrophically within 6 min. An experiment conducted at gradually rising temperatures with TNV-13 led to irreparable coating degradation near 1740°C.

For purposes of comparison, a number of runs were made on the uncoated alloy, previously heated in pure helium at the oxidation temperature for about ½ hr. The kinetic results for 150 Torr oxygen partial pressure are summarized in Fig. 6 for temperatures of 1000°, 1250°, 1500°, and 1700°C. At 1000°C, although the rate of oxidation decreases with time for at least 40 min, the rate law is not parabolic. The data at 1250°C show very clearly the breakaway behavior characteristic of tantalum and its alloys. If the 1000°C runs were extended to longer times, sharp increases in rate might become apparent. At 1500°C, the very rapid oxidation precluded a long run. For the first 12 min, oxidation proceeded linearly. Note that at 1250°C the total oxy-

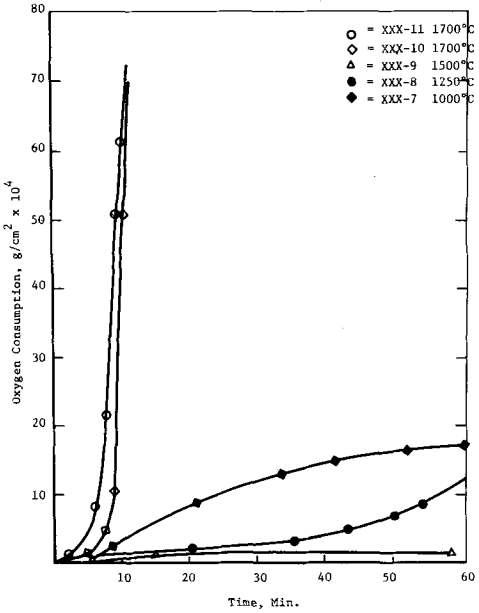


Fig. 3. Oxidation of TRW coated Ta-10W as a function of temperature.

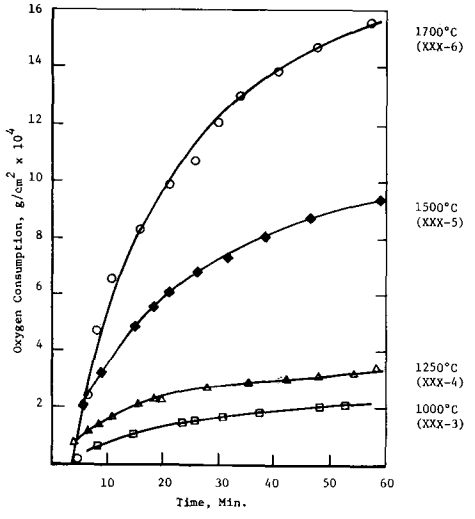

Fig. 4. Oxidation of Solar TNV-13 coated samples as a function of temperature.

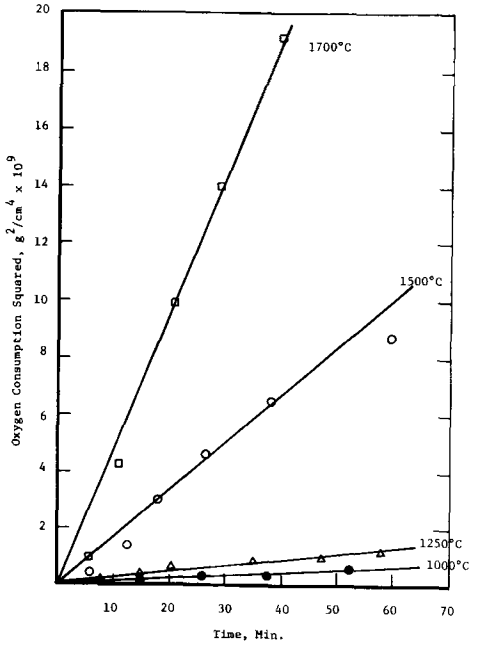

Fig. 5. Parabolic plot of oxidation data for Solar TNV-13 coated samples.

gen consumed over a 45-min period was 0.248 g/cm², with breakaway occurring at an oxygen pick-up close to 0.07 g/cm². At 1500°C, the oxygen pick-up reached 0.248 g/cm² in a period of a little over 9 min. At 1700°C, there is an abrupt increase in oxidation rate after 3 min at temperature, followed by a period of apparent decrease in rate. Thus in these experiments the total oxygen consumed, or equivalently the alloy recession, was comparable after 12 min at both 1500° and 1700°C. Further kinetic measurements for longer times on larger samples, and detailed structural analyses, would be required to determine whether different mechanisms are operative.

Metallography and Microprobe Analysis

Photomicrographs of the oxidized uncoated samples of Ta-10W are shown in Fig. 7. In Fig. 7(a) and 7(b), macrographs (magnification of 10X before reproduction) are shown for uncoated samples oxidized at 1000° and 1250°C, respectively. In Fig. 7(b), the Maltese-cross type cracks visible in the oxide layers are indicative of a highly stressed oxide film. Even at 1000°C, dissolution of oxygen into the tantalum gives rise to an extensive network of internal oxide pre-

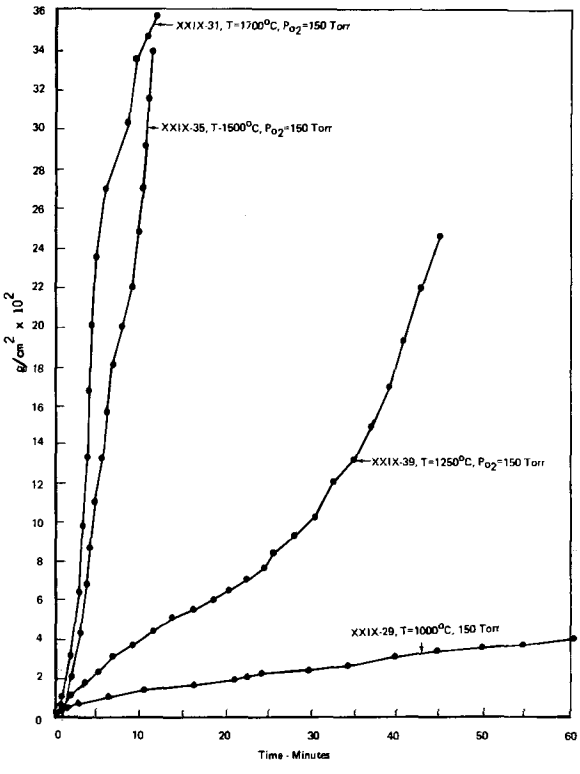

Fig. 6. Oxidation of Ta-10W

cipitate in the alloy immediately adjacent to the outer oxide film [Fig. 7(c)].

Metallographic sections of the as-received TRW coated samples are shown in Fig. 8 under normal and polarized light. The bright outermost layer that appears under polarized light for both coating systems is an artifact, probably due basically to the roughness of the coating surface. The TRW coating is described by the manufacturer as a duplex W/Si-W two-cycle coating (2). A tungsten layer is deposited by chemical vapor deposition, and a Si-W coating is then formed by a vacuum-pack process. The pack typically contains 99% Si, 0.5% W, and 0.5% NaF activator. Silicon is diffused into the tungsten precoat at temperatures near 2200°F for times of the order of 3 hr. A layer of WSi_2 purportedly grows inward from the external surface. The two layers are plainly visible in Fig. 8(a)—a grey band of tungsten adjacent to the alloy substrate, and a crystalline outer layer of silicide.

The Solar TNV-13 coating, shown in Fig. 9, is quite different from the TRW, both in method of preparation and in final microstructure. TNV-13 is described as a duplex (95W-5Ti)-Si composition. It is prepared in three steps. First, a 95W-5Ti slurry, in an organic vehicle, is applied and then sintered in vacuum at 2760°F. Second, a silicide coating is formed by high-pressure pack cementation; *i.e.*, the slurry coated alloy is imbedded in a mixture of silicon and a small amount of NaF activator, and heated in argon at pressures slightly above atmospheric for about 7 hr at 2150°F. Finally, the coating is impregnated with an aqueous slip of finely milled barium borosilicate glass frit, and air-fired for 10-14 min at 1800°F. The duplex nature of the final coating is clear in Fig. 9. A comparison of the TNV-13 coating in Fig. 9 with the TRW coating in Fig. 8 seems to suggest that the 95W-5Ti precoat, applied as the first step in fabricating TNV-13, is silicided almost completely during subsequent steps. The inner layer of TNV-13 has a similar microstructure to the outer layers of the TRW coating system, and was later shown to consist mainly of tantalum silicides. The outer layer of the TRW coating is, of course, WSi_2. Table III indicates the Ti and Ta distribution in the TNV-13 coating system, as determined by electron microprobe analysis. The Ti is seen to be concentrated

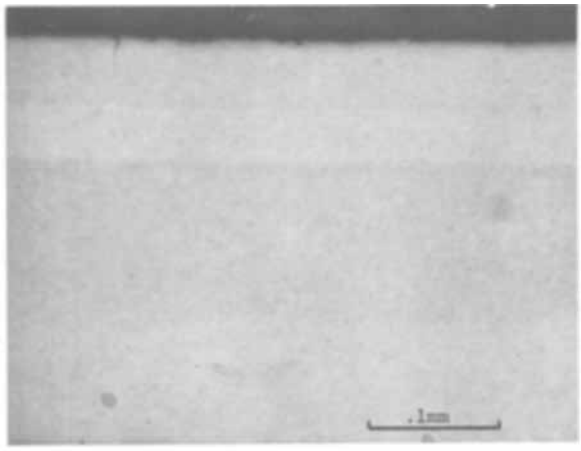
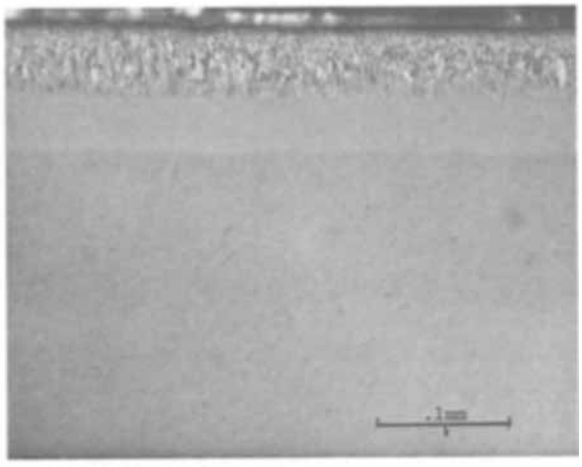
near the center of the inner crystalline tantalum silicide band [position 0.5 in Fig. 9(b)]. In this case, the analytical measurements were somewhat crude, and the absolute numbers are of less significance than the relative trends displayed.



(a) Axial Section

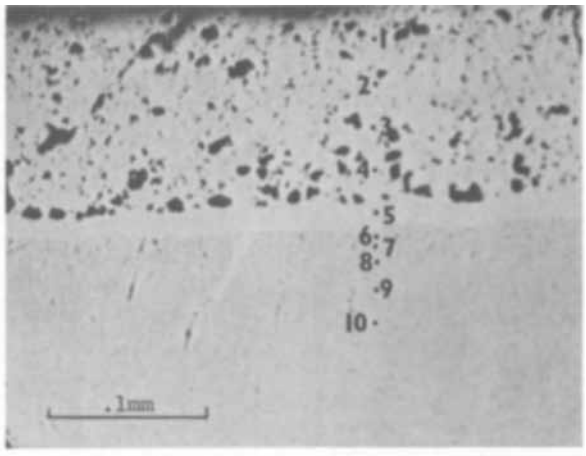


(b) Axial Section; Polarized Light

Fig. 8. TRW coated samples of Ta-10W (as received)

The microstructure of the TNV-13 and TRW coatings after oxidation for 1 hr at 1500°C are compared in Fig. 10. Both coating systems are characterized by the growth of a surface layer with a rough uneven structure at the interface with the coating. The nature of the surface layer, however, is quite different in the two cases. In the Solar coating, the surface layer that develops is a smooth dense oxide with no apparent structure. Microprobe analysis, discussed below, shows the oxide to contain silicon and titanium, but essentially no tungsten. Comparison of Fig. 10(b) with Fig. 9(b) reveals the substantial crystal growth and recrystallization of the coating that appears to occur simultaneously with high-temperature oxidation. While the coating structure of the as-received material shown in Fig. 9(b) appears to be amorphous, the structure in 10(b) after oxidation displays an equiaxed grain structure. Microprobe results for the TRW sample after oxidation at 1500°C are summarized in Table IV. The tungsten and tungsten disilicide layers are identified unambiguously. The outer layer that develops during oxidation is seen to contain both Si and W, and presumably oxygen as well. It is possible that protection is actually conferred by a very thin layer of silica which is not detected in the photomicrograph. It is interesting to note the absence of a W_5Si_3 phase at the W/WSi_2 interface, as well as the absence of interdiffusion between the chemically vapor deposited tungsten layer and the tantalum in the alloy. Unfortunately, adherence at the W/Ta-10W interface may be inadequate. Delamination, as shown in Fig. 10(e), was actually seen to have occurred over most of the surface of the oxidized sample.

In Fig. 11, photomicrographs are shown for coated samples oxidized at 1700°C and 150 Torr oxygen pres-



(a) Axial Section

Fig. 9. Solar TNV-13 coated samples of Ta-10W (as received)

sure. The TNV-13 coating is seen to be intact, with a smooth glassy outer oxide similar to that obtained at 1500°C [*cf.* Fig. 10(a) and (b)]. The oxide is also observed to bridge a crack. Comparison of Fig. 11(b) with 10(b) shows grain growth and recrystallization in the area beneath the surface oxide to have proceeded to a greater extent at 1700° than at 1500°C, as might be expected. Two bands are visible in Fig. 11(b) between the recrystallized zone and the alloy substrate, whereas only one is apparent in Fig. 10(b). Results of electron microprobe analysis of the oxidized coated structure for TNV-13 coating are summarized in Table V. The outer oxide is in all likelihood silica, containing substantial quantities of titanium, probably as the oxide. The new band at the alloy/coating interface appears

to be Ta_2Si, formed by interdiffusion of silicon from the coating. The extensively recrystallized region is WSi_2 containing some Ti. Beneath this is a band containing W_5Si_3 near the interface with WSi_2, and Ta_5Si_3 (having the same hexagonal crystal structure as W_5Si_3) near the interface with Ta_2Si. It is particularly noteworthy that Ti in the oxidized structure is concentrated in the protective oxide. The TRW sample, shown in Fig. 11(c), (d), and (e) failed at an edge *via* tungsten delamination. The attack on the unprotected substrate is similar to that discussed above for uncoated Ta-10W. The three layers visible in Fig. 10 may also be seen within the light band of Fig. 11(e)—the W, WSi_2, and W-Si-O layers. Failure therefore appears to be basically mechanical in nature.

The TNV-13 specimen that failed at 1800°C is shown in Fig. 12. The very thick oxide that covers most of the surface has the characteristics of the Ta_2O_5 that forms on the uncoated alloy. The conversion of the alloy substrate to oxide results in such a large increase in volume that the oxide grows out to envelop partly the original coating.

Discussion

Both the TRW and TNV-13 coatings have been extensively tested in other laboratories, with results that differ in several aspects from those reported here. Perhaps the most significant difference lies in the upper temperature limit of the coating systems. In this work, catastrophic failure of the TRW coating at 1700°C (3090°F) was noted in less than 10 min; protective lifetimes of 0.5-3.0 hr at 3500°F have been reported by TRW. The TNV-13 coating was found here to provide reliable protection for at least 1 hr at 1700°C, but to show signs of failure near 1730°C (3150°F). The same coating tested by TRW displayed variable edge failures at times of 0.5, 2.0, and 8.50 hr at 3000°F, and general failure after 5 min at 3500°F. Tests of the TNV-13 and TRW coatings at McDonnell are cited by Solar (1) and protective lifetimes reported are as follows: at 3200°F, 10 and 6.5 hr, and, at 3600°F, 0.8 and

1.5 hr for TNV-13 (Solar C) and TRW, respectively. On the basis of the present results, useful coating lifetimes could not be predicted above 3090°F for TRW or above 3150°F for TNV-13. The difficulty may lie in the different methods of testing, and/or inaccuracies of temperature, introduced by lack of knowledge of the proper emittance corrections for each test. Further work on temperature measurement is clearly required, and the present experiments serve to confirm the existence of a problem, rather than to provide a solution.

No quantitative data were found in the literature for comparison with results reported here on extent of oxidation as a function of temperature. At 2400°F (1315°C), weight gains of 1 and 5 mg/cm^2 are reported for TNV-13 after 50 hr in static air (5). The measurements described above are of total oxygen consumption, rather than weight gain. Since some tungsten may be lost from the coating in the form of volatile tungsten oxides, total oxygen consumption should be larger than net weight gain. Extrapolating the oxygen consumption data given above for a 1-hr time period at 1250° and 1500°C, to 50 hr on the basis of a parabolic rate equation, oxygen values of 2.4 and 6.65 mg/cm^2 are predicted at 1250° and 1500°C, respectively. While the extrapolation is certainly over too wide a range to be very reliable, the agreement with the Solar results (5) is gratifyingly good nonetheless. Since nitrogen influences the behavior of some materials, the test data reported here for helium oxygen may not be strictly comparable to air oxidation test data. This point might be checked experimentally.

Comparing the oxidation behavior of the TRW and TNV-13 coatings as shown in Fig. 3, 4, and 5, we are led to the conclusion that the oxidation mechanism must be quite different for the two coating systems, in spite of the similarity in basic chemical composition. The TNV-13 coating oxidized parabolically; the TRW coating oxidizes logarithmically. Between 1000° and 1800°C and an oxygen pressure of 150 Torr, the rate of oxidation of the TNV-13 coating increases with increasing temperature and the coating remained protective at 1700°C. In contrast, the rate of oxidation of the TRW coating decreases as the temperature is increased from 1000° to 1250° to 1500°C and then increases catastrophically at 1700°C. The metallographic and microprobe results reported above identify im-

portant structural differences in the two coating systems that may account for the very different oxidation mechanisms observed.

The protective oxide that develops on TNV-13 is a relatively thick silica glass, containing 4-10 w/o of titanium. The SiO_2-TiO_2 phase diagram is of the simple eutectic type, with a eutectic composition and temperature near 10 w/o TiO_2 and 1540°C (6). The melting point of silica is reported as 1713°C (7). No oxygen pickup was detected in the WSi_2 layer beneath the protective oxide. However, the WSi_2 layer was originally porous and extensive grain growth and recrystallization were observed as a result of the high-temperature exposure. The outer layer observed in the TRW coating was a microcrystalline W-Si-O phase, although the kinetic data suggests that an external silica skin might have been formed as well. The presence of titania in the TNV-13 coating is almost certainly beneficial. It may act as a catalyst for the rapid nucleation and growth of silica, or may improve the protective properties of the glass.

A major problem with the TRW coating is delamination of the chemically vapor deposited tungsten layer during exposure. In the TNV-13 system, although a 95W-5Ti slurry is laid down initially, siliciding is very deep and the final layer left in contact with the alloy is not tungsten but a tantalum silicide. Here, too, it may be that titanium promotes coating adherence.

The oxidation of the TRW coating in the protective range, 1000°-1500°C, is logarithmic, and oxidation resistance improved with increasing temperature. The oxidation of TNV-13 is parabolic. The parabolic rate constants for total oxygen consumption are plotted *vs.* reciprocal absolute temperature in Fig. 13. Between 1250° and 1700°C, the calculated activation energy is 42 kcal/mole. This is significantly higher than the 27 kcal/mole reported both for oxygen diffusion in silicon (8) and for parabolic oxidation of both silicon (9) and silicon carbide (10). This, too, suggests that the titania acts to modify the structure of the outer protective silica glass.

Technical Note

Contact Resistances of Several Metals and Alloys to GaAs

Haruhiro Matino and Makoto Tokunaga

Central Research Laboratory, Tokyo Shibaura (Toshiba) Electric Company, Limited, Kawasaki, Japan

Low-resistance ohmic contacts are essential in the fabrication of GaAs devices, particularly for the demands of high-frequency operation and/or small device geometry required in microwave diodes and transistors. Resistance data have been reported by several investigators on ohmic contacts to n-type GaAs using metal halide fluxes (1) and Ag-In-Ge alloys (2), and to p-type GaAs using Ag-Mn alloys (3).

It is further hoped for planar structure that the contact metals have good adherence to SiO_2 surface. However, no data on the ohmic contact between the metals Mo, Ti and Cr, and GaAs are available in the existing literature.

In this report, the specific contact resistances are quantitatively investigated for a variety of metals (Ag, Au, Mo, Cr, and Ti) and alloys (Sn-Ag, In-Ag, Sn-Ge-Ag, Ge-Au-Ag, In-Ge-Ag) on both n- and p-type GaAs of a wide resistivity range.

Most of the GaAs materials used in this investigation were boat-grown single crystals; epitaxially grown n-type crystals were used for the lower carrier concentrations of 1 to 5 x 10^{15} cm^{-3}. For the n-type studies, the carrier concentrations ranged from 1 x 10^{15} to 6 x 10^{18} carriers/cm^3 and from 1 x 10^{18} to 6 x 10^{19} carriers/cm^3 for p-type samples. All of the metals used in this investigation were of 99.99% purity. After lapping the (100)-oriented wafers, both surfaces of the wafer were chemically etched in a solution of $8H_2SO_4$:$1H_2O_2$:$1H_2O$. The thickness of the etched wafers is about 200μ. On both etched surfaces heated at 300°C, the elemental metals were evaporated to a thickness of 1000Å or more, and were further covered with gold when necessary, under background pressure of 10^{-6} mm Hg or lower. In the case of alloys, *e.g.* In-Ag, the film is formed by sequential evaporation of In and then Ag in the proportion of 25:75 w/o (weight per cent) In:Ag, to a total thickness of 3000Å or more. After evaporation, the wafer was heated to 500°C for 10 min in a hydrogen atmosphere in order to form the contact. The consecutively evaporated metals will alloy in a very short time (minutes or seconds) when exposed to temperatures near the recrystallization temperature of the metal of higher melting point or at a lower temperature (4).

On one side of the wafer, circular dots of 25 or 100μ diameter were formed by a photoengraving technique with the use of a suitable etching solution for each metal or alloy. The smaller contact was used for lower specific resistance measurements in order to raise the accuracy. When this contact of 25μ diameter was used, the error was less than 50% even for 1 x 10^{-7} ohm-cm^2 resistance contacts.

After scribing, chips were mounted on TO-5 headers. Two leads were bonded to each dot: one is for a current feed and the other is used for a voltage drop measurement. No influence of the lead resistance was introduced by this double lead method. The specific contact resistance is obtained from total resistance measured, and the resistivity and the thickness of the wafer. The contact is considered to be ohmic when I-V characteristics are completely linear over several orders of magnitude of current range.

The results obtained are listed in Table I. Ag contacts provide good ohmic contacts to both n- and p-type materials with the carrier concentrations of 1 x 10^{18} cm^{-3} or higher, and of 6 x 10^{18} cm^{-3} or higher, respectively. Au contacts are good only to n-type of 6 x 10^{18} cm^{-3} and p-type of 1 x 10^{19} cm^{-3} or higher. Mo, Ti, and Cr, which are widely known to have good adherence to SiO_2, yield good ohmic contact to p-type materials with carrier concentration of 6 x 10^{18} cm^{-3} or higher. Specific contact resistances of Mo and Cr contacts to the p-type material of 6 x 10^{19} carriers/cm^3 are both one order of magnitude lower than those reported by Nuese and Gannon on Ag-Mn contact to p-type material of 8.5 x 10^{19} carriers/cm^3 (3). The resistivity of the Ti contact was slightly less than that of Ag-Mn. These active-metal (Mo, Cr, and Ti) contacts, however, were found not to be good to n-type materials of 6 x 10^{18} carriers/cm^3, even when a sintering temperature was chosen as high as 700°C. The Ag-alloys containing In, Sn, and/or Ge provide good ohmic contacts to n-type materials with carrier concentration of 1 x 10^{15} cm^{-3} or higher as is shown in

Table I. Contact resistance in ohm-cm^2 of sintered metal contacts to GaAs[a] (300°K)

Carrier concentrations and conduction type	Ag	Au	Sn-Ag (25:75)[d]	In-Ag (25:75)	Ge-Au-Ag (10:10:80)	Sn-Ge-Ag (10:10:80)	In-Ge-Ag (10:10:80)	Mo	Cr	Ti

1×10^{19} p-type	6.2×10^{-6}	1.1×10^{-5}		1.5×10^{-5}				4.3×10^{-5}	2.7×10^{-5}	
6×10^{18} p-type	2.9×10^{-4}	Nonohmic		2.4×10^{-4}				7.3×10^{-4}	1.9×10^{-4}	
1×10^{18} p-type	Nonohmic			5.3×10^{-4}				Nonohmic	Nonohmic	

[a] The sintering was performed at 500°C for 10 min.
[b] Ohmic contacts cannot be obtained even at 700°C after 60 min sintering.
[c] 1×10^{-3} ohm-cm^2 or less was reported by Cox and Strack (2).
[d] This and other ratios shown in the case of the alloys are the mean of weight per cents.

Table I. Their magnitude is comparable with that of Ag-In-Ge contacts to 0.6-2.6 ohm-cm n-type GaAs reported by Cox and Strack (2).

It is seen in the table that the contact resistance is highly dependent on the carrier concentration. The contact resistances of Mo, Cr, and In-Ag to p-GaAs and of some alloys to n-GaAs are plotted as functions of square root of carrier concentration in Fig. 1. Following the theory of ohmic contact given by Mead (5), this suggests that carrier tunneling through a finite potential barrier of the contact is dominant in governing the contact resistance, even at room temperature. In the case of n-GaAs samples, whose carrier concentrations are relatively lower, the linearity does not hold except in the higher concentration region and, thus, another carrier transport mechanism such as thermionic emission should be present.

Metallurgical features of these contacts have been microscopically examined. Figure 2(a) shows a surface of the Mo contact to GaAs after sintering at 500°C for 10 min; the surface is seen to be extremely smooth. In contrast, the Au contact usually yields a spotty regrown region on the GaAs surface by a sintering at 341°C or higher, as is shown in Fig. 2(b). This would be because of Au-GaAs eutectic formation at 341°C (6). Note that the photograph in Fig. 2(b) was taken after the contact was formed at 500°C for 10 min and Au was etched off by Metex Aurostrip (supplied by McDermid Incorporated of Waterbury, Connecticut). We have been using the Mo or Cr contacts covered with gold in the fabrication of GaAs p^+n planar diodes with a reasonably shallow junction less than 0.5μ without any noticeable degrading of device performances.

In conclusion, Mo and Cr contacts to p-type GaAs of 1 x 10^{18} carriers/cm^3 or higher are recommended, especially for planar structures. For high-purity n-type GaAs, Ag-In-Ge and Ag-Sn-Ge alloys contacts

are good. Ag-In alloy contacts are especially recommended to both n- and p-type GaAs of 1 x 10^{18} carriers/cm^3 or higher. This is very advantageous for transistors and integrated circuits which should have both n- and p-type regions.

Addendum

The following Note was added in proof to the Technical Paper "Oxygen Doping of Solution-Grown GaP" by L. M. Foster and J. Scardefield which was published in the April 1969 issue of the JOURNAL, Vol. 116, No. 4, pp. 494-498:

In recent private communication with P. J. Dean, it was pointed out that the estimate of oxygen content from Zn-O pair emission could differ from that determined by electrical compensation by perhaps a factor of two lower, and the perfect agreement reported here is thus somewhat fortuitous. However, it was also pointed out that the local field correction that enters the formula connecting concentrations, oscillator strength, and absorption [J. D. Cuthbert, C. H. Henry, and P. J. Dean, *Phys. Rev.*, **170**, 739 (1968)] might have been sufficiently in error to restore the agreement.

Anodic Oxidation of Cyclic Hydrocarbons at Fuel Cell Electrodes

M. L. Savitz*[1] and A. L. Hubbard*[2]

U. S. Army Mobility Equipment Research & Development Center, Fort Belvoir, Virginia

ABSTRACT

The anodic oxidation of cyclohexane and benzene has been studied with potentiostatic-gas chromatographic techniques on commercially available fuel cell electrodes at 107°C in 85% H_3PO_4. The cathodic desorption products were identified and studied as a function of potential and reactant. Possible mechanisms for over-all oxidation of benzene and cyclohexane are discussed.

The practical application of fuel cell power plants is related to the performance which can be achieved at an electrode surface. Reaction paths and the rate-limiting steps must be understood for aliphatics, olefins, aromatics, naphthenes, and oxygenated compounds if versatile electrode structures are to be devised. Luksha (1) found that there was a 50 mv increase in polarization from that of pure octane when a fuel containing up to 5% olefins, 1% aromatics, 5% six-ringed naphthenes, 15% five-ringed naphthenes, and the remainder saturated normal or isooctane was reacted at a Niedrach-Alford Teflon bonded 35 mg/cm^2 platinum electrode with phosphoric acid electrolyte. Grubb (2) had shown earlier that cyclohexane and benzene were ¼ as reactive as hexane and ⅛ as reactive as the most reactive hydrocarbon, propane. Benzene was slightly less reactive than cyclohexane. Several investigators (3-6) obtained evidence for several types of intermediates adsorbed on the electrode surface when normal saturated hydrocarbons or ethylene were the reactants. Part of the adsorbate designated CH-α (3) can be cathodically desorbed and is thought to contain only C and H. Another C-H material (CH-β) is unreactive toward both reduction and oxidation at reasonable potentials and may be a polymer. The third species is a more highly oxidized material thought to contain at least one C-O bond (O-type). Previously (7) we examined the composition of the steady-state adsorbed residues on platinum wire with benzene or cyclohexane as the reactant using cathodic and anodic desorption techniques developed by Brummer (3). Much of the adsorbed species was removed at 0.01v *vs.* RHE, and this species (CH-α) for both cyclohexane and benzene appeared to be in the same state of oxidation. That part of the adsorbate which was not cathodically desorbable was in a highly oxidized state similar to O-type.

The electrochemical measurements on a wire electrode did not indicate (*i*) whether the cathodically desorbable species is a composite of several entities; (*ii*) whether the relative amounts of the possible constituent species are dependent on the potential maintained during adsorption; and (*iii*) whether these species are the same for benzene and cyclohexane. In order to clarify this situation, gas chromatographic methods were used to study the cathodically desorbable products obtained from the reaction of cyclohexane or benzene at a fuel cell electrode. In prior efforts using this type of technique with propane, Grubb (8) and Barger and Savitz (9) found that on cathodic desorption methane and ethane were identified gas chromatographically and that the relative amounts of these two constituents were very potential dependent.

Experimental

The experimental set-up was similar to that which has been described previously (9). Briefly, a commercially available American Cyanamid type AA-25 electrode, containing 25 mg/cm^2 platinum black and 25 w/o (weight per cent) Teflon pressed together on a tantalum screen with a Teflon coating on the gas side and with an active geometric area of 20.3 cm^2, was mounted into a cell wherein the Teflon backed side was exposed only to the fuel which entered through a 1/16 in. gas space milled out of Teflon block and the other side of the electrode was exposed to 85% H_3PO_4. The counter electrode, in a compartment separated from the working compartment by a glass frit, had a geometric area of 58.2 cm^2 and a platinum loading of 35 mg/cm^2. The reference electrode was the autogeneous type developed by Giner (10). The benzene or cyclohexane (Phillips Research Grade 99.91 mole per cent purity) was introduced into the cell via a liquid capillary pressure system (11) so that reactants were fed at a flow rate no greater than 0.1 cc/min. The liquid was vaporized before entering the cell which was maintained in an oven at 107°C ± 1°. The exit of the working compartment was connected with heated lines directly to the sampling valve of a dual column F&M 5750 research gas chromatograph containing flame ionization and thermal conductivity detectors. A 6 ft, ⅛ in. gas chromatographic column packed with UCON LB550-X on chromosorb W had a retention time of 2.1 min for cyclohexane and 3.2 min for benzene at 90°C. Normal hydrocarbons were retained for only a few seconds and were not well separated; therefore a Poropak T column was used in separate experiments to identify the lower boiling hydrocarbons. Standards of known compounds were run and identification accomplished by comparison of retention times.

In order to obtain a reproducible surface, potentiostatic procedures were used similar to those used by Brummer (12) and Gilman (13) for platinum wire and adapted by us (9) for porous electrodes. Figure 1 shows the schematic of the procedure used. Cyclohexane or benzene could be admitted to the system either

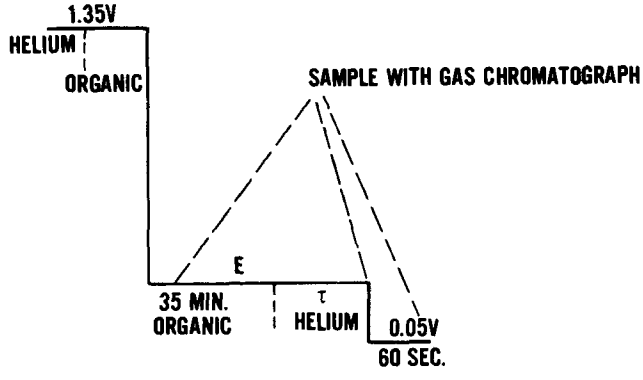

Fig. 1. Schematic of procedure used for gas chromatographic studies.

* Electrochemical Society Active Member.

[2] Present address, Rockefeller University, New York, N. Y.

at 1.35v or at the potential of adsorption with no change in the results. In most previous hydrocarbon studies, the platinum oxide formed at potentials above 1.0v was usually reduced at a more cathodic potential, *e.g.*, 0.05v, before going to the potential of adsorption. This step was omitted in these studies because in some preliminary experiments at a porous electrode with benzene as the reactant some of the benzene could be hydrogenated to cyclohexane at the more cathodic potentials. With cyclohexane, omission or inclusion of the 0.05v step did not affect the results. When the current no longer changed at the potential of interest, usually after about 35-min total adsorption time, the electrode was swept with helium (high purity 99.995%) at a flow rate of about 6 cc/min. During the helium sweep the effluent from the fuel side of the electrode was sampled periodically with the gas chromatograph. After varying lengths of time at potential under helium, the potential was stepped to 0.05v. The helium effluent was then sampled three times at 15-sec intervals after being at 0.05v for 45 to 60 sec. This time was critical since the maximum amount of desorption products appeared in this interval. The time reflects the length of the line between the cell exit and the gas chromatograph and the rate of the helium sweep. Quantitative determinations of the hydrocarbon species desorbed from the electrode were determined by calculating the area under the curve with the height times the width at half height method (14). This method of area determination gives reasonable accuracy provided the peaks are symmetrical, as was the case with the hydrocarbons on the columns used in this study. No direct normalization of areas corresponding to hydrocarbon concentrations was made. When standard solutions containing 90-10, 50-50, 10-90 mixtures of cyclohexane and benzene were injected on the column, the relative percentage of the areas under the curve corresponded to the prepared composition within ±2%. Five different sample injections of each standard solution gave similar results. Experiments at each potential and under each helium sweep with cyclohexane and benzene as reactant were repeated at least three times. For the same electrode, the value of areas or peak heights for benzene, cyclohexane and C_1 to C_6 hydrocarbons agreed to within 15% in separate experiments.

The electrode area was measured daily to determine whether the results were related to a decrease in surface area. The surface area of the electrode was determined by measuring the charge associated with galvanostatic reduction of a surface oxide formed at a fixed potential (15). Hydrogen adsorption methods could not be used due to extensive hydrogen evolution in the potential range of interest during analysis of hydrogen coverage. The electrode was held at 1250 mv *vs.* RHE for 2 min to form oxide layers. At this point, a cathodic galvanostatic pulse of 2 amp was applied to the electrode [400 μcoul = 1 cm^2 of area (16)]. Galvanostatic reduction of oxygen deposited at constant potential gave reproducible values for a particular electrode at a specific potential. Figure 2 shows how the area of the electrode decreased with time. The electrode decreased the most rapidly the first few days and then leveled off. When benzene was used on the same electrode, the decay rate of the electrode did not increase from that found with cyclohexane. When new electrolyte was added, the area increased temporarily and then decreased to its previous value. The decay of the electrode area was also followed by examining the oxidation of the electrode in the presence of helium at 0.4v. The electrode was held at 1.35v for 20 min and maintained at 0.4v for 30 min. Then the surface of the electrode was examined with an anodic galvanostatic pulse. Although the charge obtained is different by the two methods, the decay is similar. Although the area of the electrode decreases by a factor of three during a 40-day period and the absolute values for the areas corresponding to the desorbed species are different, the relative amounts of C_1 to C_6 compounds agree to within 10% regardless of the age of the electrode.

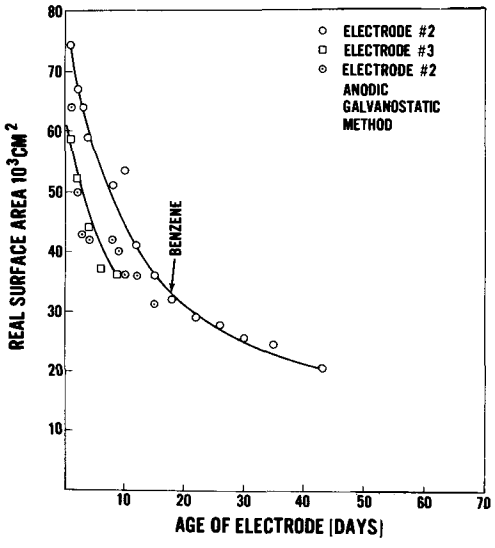

Fig. 2. Change of area of electrodes with time

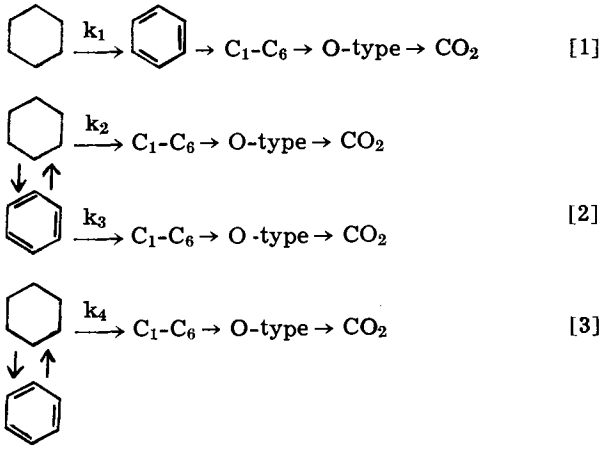
Results and Discussions

In studies with platinum wire electrodes (7), we found that when cyclohexane or benzene was adsorbed at potentials from 0.1 to 0.4v *vs.* RHE 70% (±5%) of the final adsorbate was CH-α. At 0.5 to 0.7v *vs.* RHE about 60% (±5%) of the adsorbate was CH-α. Since the residue for both cyclohexane and benzene appeared to be in the same state of oxidation, the possibility of a benzene-cyclohexane equilibrium was suggested (7). To determine whether the oxidation reaction proceeds from cyclohexane to benzene to C_1-C_6 species to O-type and CO_2 (Eq. [1], whether conversion of cyclohexane to benzene is a equilibrium reaction with each proceeding via individual paths to CO_2 (Eq. [2]), or whether conversion of cyclohexane to benzene is an equilibrium reaction with a common path to CO_2 (Eq. [3]), the adsorption and desorption of benzene and cyclohexane on a fuel cell electrode was studied at representative potentials.



In the above possible reaction paths it has been assumed that O-type is in the main reaction path. There might be parallel paths (Eq. [4]) with any one of the cyclohexane and benzene reactions from Eq. [1] to [3] to form CH-α.

Hydrocarbon → Eq. [1], [2], or [3] → CH types → CO_2
Hydrocarbon → Eq. [1], [2], or [3] → O-types → CO_2 [4]

If some of the cyclohexane is converting to benzene and parallel reaction paths are pursued, and the oxi-

Table I. Variation of benzene formation with time and potential

Time, min	0.2v Cyclohexane/ Benzene	Benzene[a] (8×10^3)[c]	0.4v Cyclohexane/ Benzene	Benzene[b] (8×10^3)[c]

16	1350	0.65	3300	0.2
27	1510	0.55	3300	0.2

[a] Cyclohexane height is constant 880 (8×10^3).
[b] Cyclohexane height is constant 660 (8×10^3).
[c] Represents attenuation of gas chromatographic area. For actual area multiply each area by 8×10^3.

dation of benzene is slow compared to cyclohexane ($k_3 < k_2$) benzene formation would be an undesirable side reaction which could reduce the over-all fuel cell performance. The dehydrogenation of cyclohexane need not necessarily lead to benzene unless there were six Pt atoms involved directly in adsorption and a planar configuration would result. If cyclohexane were to exist in planar form, there would be angle strain and instability. Stereochemically, cyclohexane can exist in a chair or boat conformation. The chair conformation is the more stable form (17) and would lead to 1 site adsorption; the boat form would lead to 4 or 2 site adsorption with preference for the former.

Cathodic desorption products with cyclohexane as reactant.—When cyclohexane was adsorbed on an electrode at a fixed potential, excess removed under helium sweep, and the potential then stepped to 0.05v to remove the cathodically desorbable species (Fig. 1), varying amounts of methane, ethane, propane, n-butane, n-pentane, n-hexane, benzene and cyclohexane were observed in the effluent gas stream.[3] No branched chain hydrocarbon or compounds containing 7 or more carbon atoms were obtained; thus there appears to be no dimerization of species. At 1.35v no material other than cyclohexane appeared in the effluent. When the potential was lowered from 1.35v to 0.05v (no intermediate adsorption potential) with cyclohexane as reactant, neither benzene nor the C_1-C_6 compounds were observed; thus the cathodic desorption step caused no cracking of cyclohexane. However, after 1 min of cyclohexane adsorption at potentials from 0.25 to 0.40v, the gas chromatographic analysis indicated the presence of benzene. The total amount of benzene decreased both with time at potential and with increasing potential as shown in Table I. The amount of benzene was reproducible within 10% for four different experiments with the same electrode. At potentials above open circuit (0.45v) no benzene was observed. Under helium sweep at the potential of adsorption, the benzene disappeared completely, and the excess cyclohexane decreased at least by a factor of 10, depending on the length of helium sweep. When the potential was stepped to 0.05v, benzene was again observed in the effluent. The fact that some benzene desorbed at adsorption potential below 0.4v and more was removed at 0.05v indicates that the benzene formed may be adsorbed in two different ways, may be adsorbed on two different types of sites or that the site energies change with potential. It also appears that benzene is not as tightly bound as has been previously thought (18), may not lose aromatic character, and may be more loosely bound than cyclohexane.

Benzene formed is also competing for sites with the cyclohexane reactant. When the electrode was lowered to 0.05v the maximum amount of benzene desorbed from the electrode was always observed on the chromatograph 15 sec before the maximum cyclohexane peak. This was true at all potentials and length of helium sweep; *e.g.*, at 0.3v adsorption, 60 min. helium sweep, maximum benzene was seen after 60 sec at 0.05v, maximum cyclohexane after 75 sec at 0.05v; at 0.5v adsorption 60-min helium sweep, maximum benzene was seen after 75 sec at 0.05v, maximum cyclohexane after 90 sec at 0.05v. This behavior was not a column effect, as when standards containing 90-10, 50-50, 10-90 mixtures of cyclohexane and benzene were injected on the column, the retention times were independent of relative amount of material in the samples. There was no conversion of benzene to cyclohexane in the 15-sec period as cyclohexane increased to a greater amount than the maximum amount of benzene decreased and there was still benzene coming off the electrode after 75 or 90 sec. If the diffusion coefficients of benzene and cyclohexane in helium were different, benzene would move from the electrode to the gas sampling valve faster. (Air-benzene at 0°C is 0.077 cm²/sec atm; air-cyclohexane at 45°C is 0.086 cm²/sec (19)).

The benzene observed at potentials of adsorption from 0.25 to 0.4v could result from initial dehydrogenation of cyclohexane to benzene (11). When the potential was changed from 1.35 to 0.4v the current became more anodic for 15 sec before becoming cathodic. At potentials anodic to 0.45v where no benzene was observed until desorption, anodic current was always observed during initial adsorption.

In Fig. 3 the cyclohexane and benzene desorbed as a function of potential are presented. Figure 3 shows the actual heights obtained for cyclohexane and benzene as a function of potential after 10- and 60-min sweeps. The cyclohexane which was still in excess in the lines after 10 or 60 min of helium sweep has been subtracted from the total amount of cyclohexane to give that quantity attributed to the cyclohexyl species on the electrode. The quantity attributed to excess cyclohexane in the line was obtained by sweeping with helium at the potential of adsorption for up to 65 min and sampling for cyclohexane at 15-sec intervals. At every potential there was more of the cyclohexyl type species than benzene. At 0.4v, the largest amount of benzene relative to cyclohexane was observed (ratio of benzene to cyclohexane at 0.4v was 1:25, at 0.3v was 1:80, and at 0.5v was 1:130). The area attributed to benzene at 0.4v accounted for only 4% of the total area attributed to desorbed six carbon ring species. The amount of cyclohexane was constant and high at 0.25 and 0.3v regardless of length of helium sweep (10 or 60 min). This is to be expected since in the region of hydrogen deposition any benzene formed could be hydrogenated. At

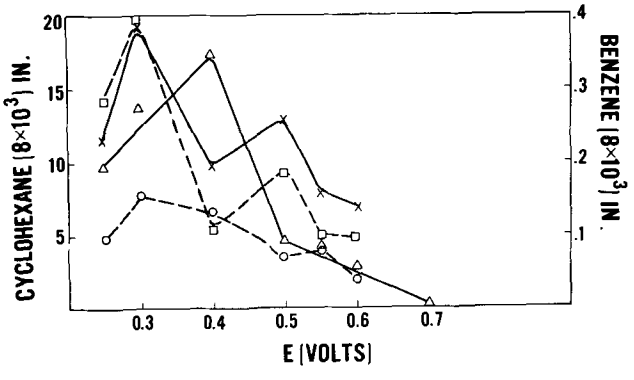

Fig. 3. Desorbed benzene and cyclohexane for 10- and 60-min helium sweeps. Area can be obtained by multiplying the height x 10^{-2} in. (width) x 8 x 10^3 (attenuation factor). Thus, the area of cyclohexane at 0.3v, 10-min sweep would be 20 x 10^{-2} x 8 x 10^3 or 1600 in.². X, Cyclohexane, 10 min He sweep; □, cyclohexane, 60 min He sweep; △, benzene, 10 min He sweep; ○, benzene, 60 min He sweep.

[3] It must be remembered that when C_1, C_2, C_3, cyclohexyl, etc., intermediates are mentioned, the methane, ethane, propane, cyclohexane, etc., are not necessarily the adsorbed compounds. The C_1 might be thought of as a methine, methylene, or methyl fragment representing three, two, or one bond between carbon and the surface. Desorption at 0.05v could hydrogenate the normal species. It does not hydrogenate all of the benzene, as evidenced by presence of benzene in effluent sampled at 0.05v.

potentials positive to open-circuit potential of 0.45v, the total amount of cyclohexane decreases with time and potential. At potentials positive to open circuit the amount of benzene rapidly decreases during the 10-min helium sweep. At 0.7v, no benzene was observed on the 0.05v step within limits of detection of flame ionization using a UCON column. The benzene which is not seen at higher potentials might be an undesirable side product at lower potentials or that which is formed might react directly to CO_2 (Eq. [2]) with k_3 and subsequent steps very fast. Reaction of benzene has been studied to clarify this and is discussed later in the paper.

In addition to benzene and cyclohexane being observed on cathodic desorption, varying amounts of normal chained C_1-C_6 hydrocarbons were observed. Table II indicates the relative amount of each species at several potentials and the total area attributed to the compounds on a gas chromatograph. At most potentials, C_3 and C_4 species were predominant. The relative amounts of C_1 and C_2 species were small although the relative amount of C_1 species increased slightly with potential. In Table II it can be seen that the total amount of C_1-C_6 hydrocarbon increased with increasing potential and was largest at the most anodic potential considered (0.7v). The areas in Table II represent those of an electrode two days old. Total areas on a 17-day old electrode were 50% less, but the relative amounts of C_1 to C_6 material were within ±8%. At all potentials, the total amount of C_1 to C_6 was greater than the benzene. At 0.3v, benzene was 26% of total material excluding cyclohexane. At 0.5v benzene was 8.5% of total material excluding cyclohexane. The amount of cyclohexane found in the desorbable mixture also decreased with potential. At 0.3v 96% of the desorbable species was cyclohexane; at 0.5v, 90%, cyclohexane and at 0.7v, 73%, cyclohexane.

Results from the adsorption of cyclohexane have indicated that any one of the paths mentioned earlier (Eq. [1]-[4]) might occur. The adsorption and desorption of benzene has been studied at representative potentials to provide additional information for choosing a specific path.

Gas chromatographic results with benzene as reactant.—Procedures for pretreatment, adsorption, and helium sweep were the same for benzene as those for cyclohexane. With cyclohexane as reactant, desorption was performed at 0.05v in order to minimize hydrogenation of benzene to cyclohexane during pulsing. When benzene was admitted to the electrode at 1.35v for 30 min, helium swept through for 10 min to remove some of the excess, potential lowered to 0.05v with sampling every 15 sec with the chromatograph, there was a 1:2500 ratio of cyclohexane to benzene after 45 sec at 0.05v, a 1:1625 ratio after 60 sec and 1:180 ratio after about 5 min at 0.05v. During a normal desorption the maximum amount of material is removed after 45 to 60 sec at 0.05v. When benzene is the reactant, hydrogenation of the excess as it passes over the electrode does not appear to occur during the time of interest. Thus any cyclohexane observed during a run would result from desorption of some 6 ring species adsorbed on the electrode and not as a result of hydrogenating excess benzene in the line. Also the amount of cyclohexane that appeared when benzene was adsorbed at potential and then removed at 0.05v was always greater than the corresponding decrease in benzene peak. Whether the cyclohexane which is seen originates from a cyclohexyl species and/or benzene on the electrode and hydrogenated at 0.05v is difficult to distinguish.

Benzene is more difficult to handle chromatographically than cyclohexane. The peaks are broader and not as well defined even though benzene remains on the column only 3 min. With cyclohexane, it was possible to continue sampling at the potential of adsorption to note how cyclohexane would decrease during the time at 0.05v. When cyclohexane was the reactant and the potential was lowered to 0.05v, the area of cyclohexane would increase; thus cyclohexane area originating from excess in line could be subtracted from that total area. When benzene was reactant, the peak after the cathodic pulse would sometimes increase and sometimes decrease.

In spite of the problems with chromatographic analysis for benzene, there were very definite trends as shown on Fig. 4. Each point was repeated at least three times. The areas of desorbed cyclohexane were reproducible to ±18%. The area of cyclohexane changed by 20% as a result of length of helium sweep (*e.g.*, 30-min sweep instead of 10 min at 0.3v). When the experiment was repeated a few days later, the area for 10-min helium sweep at 0.3v decreased 16% and the area for the 30-min helium sweep was still 20% less than the 10-min sweep performed on the same day. The total amount of cyclohexane, as determined by measuring the peak area from the chromatograph, was greatest for 0.3v regardless of time at potential under helium. After 30 min under helium sweep, the value decreased 20% and remained constant. A maximum of cyclohexane might be expected in the region of hydrogen adsorption, as adsorbed benzene could be easily hydrogenated. At 0.5 and 0.7v there was less cyclohexane. At 0.5v the amount of cyclohexane remained fairly constant with time under helium. At 0.7v there was a 40% decrease in cyclohexane during the 30-min helium sweep and then it was fairly constant. If helium was swept through for over 16 hr at the potential of adsorption, there was little benzene left in the line; however a relatively large amount of benzene desorbed at 0.05v. Figure 5 shows the area of cyclohexane and benzene. In the results shown in Fig. 5, the benzene is from the electrode with the small amount of background subtracted out. It can be seen that behavior is similar after 16 hr as 60 min. These results were obtained on

a different electrode, but the 10-min results from each electrode were similar in both cases. From the long sweep, it can be seen that there is a maximum amount of cyclohexane desorbed at 0.3v. The amount decreases at the more anodic potentials. There is less benzene at 0.2 and 0.6v than at the intermediate potentials. When cyclohexane was reactant, there was a maximum of benzene at 0.4v; with benzene there is a maximum of benzene relative to cyclohexane at this potential. This might lead to the conclusion that there was an equilibrium between the two species (Eq. [3]) with the relative amount very potential dependent. With cyclohexane, the maximum amount of benzene was still only 4% of the total material from the electrode. When benzene is reactant, at least 50% of the species is cyclohexane. This could be a result of hydrogenation of some of the adsorbed benzene during the 60 sec at 0.05v. Deuterated experiments in progress should give some information concerning this.

If the cyclohexyl species which is desorbed at 0.05v is from a cyclic intermediate species similar to that when cyclohexane is reactant and not just from hydrogenation of adsorbed benzene at 0.05v, the relative amounts of C_1-C_6 species should be similar at the various potentials to those obtained with cyclohexane (Eq. [1] or [3]). This does not prove to be the case. Even though the same C_1-C_6 hydrocarbons were observed on cathodic desorption the relative amounts were different. Table III shows relative percentage of each species at the various potentials. The relative amount was independent of time under helium sweep at potential of adsorption. At 0.3v, there was a minimum of C_1 species. This species increased with potential and was the predominant species at 0.5 and 0.7v. There was also less C_6 species at the lower potentials. At each potential, there was a relatively equal amount of C_3-C_5. It appears that at potentials above open circuit (0.45v) longer chain hydrocarbons convert to C_1 species more readily than at 0.3v. When cyclohexane was reactant, there was no relative increase of C_1 species and the total amount of C_1-C_6 species increased with potential. However with benzene as reactant, there was a maximum of lower boiling material at 0.3v and a minimum at 0.5v which is also where the maximum and minimum amount of cyclohexane is observed on desorption. The distribution of C_1-C_6 was quite different than for cyclohexane, and the total amount of C_1-C_6 was much less when benzene was reactant than when cyclohexane was reactant except at 0.3v. Also, the origin of the species appears to be quite different. Although the C_2 species appears as ethane for both cyclohexane and benzene, the amount of time for the maximum amount of C_2 species to be seen depends on the reactant. This indicates that the C_2 species may be a different C_2 species (a more unsaturated species when benzene is reactant) or bound on different types of sites. Deuterated experiments should clarify the first point.

Table III. Percentage C_1 to C_6 hydrocarbons, benzene as reactant, helium sweep for 10 min

Potential, v	Total area, in.²	C_1	C_2	C_3	C_4	C_5	C_6
0.3	101.1	2.7	19.4	22.4	24.2	20.4	10.7
0.5	22.8	20.1	10.7	15.0	23.8	19.4	10.6
0.7	53.9	26.4	11.0	15.5	15.4	14.4	16.7

The fact that the amounts of C_1-C_6 are so different for benzene and cyclohexane indicates that there is not just a simple consecutive step (Eq. [1]) or equilibrium between cyclohexane and benzene (Eq. [3]), but probably an equilibrium and then different steps to CO_2 (Eq. [2]). To further determine whether the reaction proceeds through O-type (Eq. [2]) or there are parallel paths (Eq. [4]), the rate of oxidation of the two compounds is being studied and will be reported later.

Conclusions

On the basis of gas chromatographic data, benzene and cyclohexane react via different paths. Both compounds yield methane, ethane, propane, n-butane, n-pentane, n-hexane, cyclohexane, and benzene on cathodic desorption. The amount of each species, however, depends on the reactant and potential of adsorption.

Manuscript submitted Aug. 22, 1968; revised manuscript received Feb. 20, 1969. This paper was presented at the Montreal Meeting, Oct. 6-11, 1968, as Paper 330.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

The Anodic Dissolution and Passivation of Zinc in Concentrated Potassium Hydroxide Solutions

R. W. Powers* and M. W. Breiter*

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

In this study, mainly two sets of experiments were carried out to obtain a better understanding of the tendency of the alkaline zinc electrode to passivate. Either photomicrographs of the electrode surface were taken *in-situ* at different potentials during an anodic voltage sweep or the two components of the electrode impedance were measured with a small signal of superimposed 1000 Hz A.C. The course of the passivation was found to depend strongly on the convective conditions in the electrolyte near the zinc electrode. The conditions for the formation of two different types of solid films have been defined and their effects on the current-potential curve have been determined. Type I film is white, loose, and flocculent. It forms in the absence of convection by precipitation from a supersaturated layer of zincate near the surface. When the conditions for supersaturation are largely removed by stirring, the formation of the type II film can be observed. The latter is more compact and appears to form directly at the surface rather than by precipitation. Its color can range from light gray to black depending on the potential and time of formation. The type II film is considered responsible for the transition from the active to the passive state of zinc in alkaline solution.

Three kinds of studies have been carried out in recent years on the kinetics and mechanism of the zinc electrode in alkaline media: (*a*) measurements near the equilibrium potential of the zinc electrode in solutions containing zincate or other zinc complexes (1-9); (*b*) anodic dissolution and formation of passivating layers (10-41); and (c) cathodic studies with emphasis on the morphology of the electrodeposit. The latter are outside the scope of the present paper.

In this communication, new results on the anodic dissolution and passivation of zinc in KOH solutions are described and discussed. A combination of techniques was used to supplement past work and to gain a better understanding of the processes taking place. Mainly two kinds of experiments were carried out. In one set, an anodic voltage sweep, starting at the rest potential of the zinc electrode, was applied potentiostatically at a slow constant rate and photomicrographs of the electrode surface were taken *in-situ* at different potentials. In the second set of experiments, the ohmic and capacitive components of the electrode impedance, in addition to the current-potential curve, were measured using voltammetry with superimposed 1000 Hz A.C.

Previous work.—There seems to be nearly universal agreement that at anodic potentials near the equilibrium value, the oxidation product of zinc in concentrated alkaline solutions is the soluble zincate ion. By emf measurements, Dirkse has shown that this species is the complex tetrahydroxyl anion, $Zn(OH)_4^{--}$, an interpretation supported by recent Raman and infrared, as well as NMR, studies (2, 4, 5).

Gerischer was the first to study the discharge mechanism of the zinc electrode (1). From impedance measurements on zinc amalgams he concluded that reaction [1] of the following sequence is rate-determining

$$Zn + 2\,OH^- \rightarrow Zn(OH)_2 + 2e^- \qquad [1]$$

$$Zn(OH)_2 + 2\,OH^- \rightarrow (Zn(OH)_4)^{--} \qquad [2]$$

The exchange current density of reaction [1] was about 0.1 amp/cm² in 5M KCl containing various concentrations of hydroxyl ions with a total concentration of zinc ions of 0.1M. Gerischer's results have been confirmed very recently by Farr and Hampson, using however $NaClO_4$ as the supporting electrolyte (9).

Lorenz suggested the subsequent scheme on the basis of the frequency dependence of the electrode impedance of a solid zinc electrode in 2M KCl + 0.5M $ZnCl_2$ at pH values of 7 and 1.5 (3).

$$Zn^{++}{}_{\text{bulk electrolyte}} \rightarrow Zn^{++}{}_{\text{surface}} \qquad [3]$$

$$Zn^{++}{}_{\text{surface}} + 2e^- \rightarrow Zn_{ad} \qquad [4]$$

$$Zn_{ad} \rightarrow Zn \qquad [5]$$

Zinc ions that diffuse to the surface in step [3] are discharged in step [4] to adsorbed atoms. Step [5] includes the surface diffusion of these so-called ad-atoms and their incorporation into the lattice. Surface diffusion was found to be the hindered step. The exchange current density of the discharge step was about the same as for the zinc amalgam electrode. This result suggests that the discharge steps are similar on solid zinc and on zinc amalgams.

Impedance measurements and measurements by the double-pulse technique were made on polycrystalline zinc electrodes, on the cleavage plane of zinc single crystals, *i.e.*, on (0001), and on heavily cold-worked electrodes in different alkaline solutions (6-8). The independence of the exchange current of the discharge step on the zincate concentration indicates the adsorption of intermediates. A two-step discharge mechanism was considered the most probable one

$$Zn_{kink} + OH^- \rightarrow (Zn_{ad}OH)^- \qquad [6]$$

$$(Zn_{ad}OH)^- \rightarrow Zn(OH) + e^- \qquad [7]$$

$$Zn(OH) + OH^- \rightarrow Zn(OH)_2 + e^- \qquad [8]$$

$$Zn(OH)_2 + 2\,OH^- \rightarrow (Zn(OH)_4)^{--} \qquad [9]$$

Step [6] includes the formation and surface diffusion of ad-atoms which may be stabilized by attachment of OH^- ions. It is considered the slowest step and leads to low values of the diffusion flux (6). Step [7] was suggested as the discharge step which determines the value of the exchange current in measurements with the double-pulse technique (7).

Several groups of workers have studied the passivation of zinc in concentrated alkali using the constant current technique (10-19). For a rather wide range of conditions, equations of the type

$$(i - i_l)\, t^{1/2} = k$$

* Electrochemical Society Active Member.

were found to describe the relationship between i, the applied constant current density, and t, the time required for passivation. Here the quantities, i_1 and k, are constants for a given electrolyte concentration, temperature, and convective conditions. The form of the above equation indicates the important role of diffusional processes in the passivation of zinc. However, there is a minimum amount of charge per unit area required for passivation, corresponding to at least the formation of a monolayer. This requirement leads to the replacement of the inverse square root law given above by an inverse linear law at current densities in excess of about 0.2 amp/cm^2. On the other hand, at low current densities the inverse square root law also fails to describe the experimental data if modes of mass transport, other than pure diffusion, become important. Thus, it was found that longer passivation times are required for vertical electrodes than for horizontal ones due to the onset of natural convection (13, 16, 18).

Unlike the experimentally simpler constant current technique, the potentiostatic method permits measurement of the current density at all potentials within a range of interest and hence study of intermediate stages of passivation. The first comprehensive potentiostatic study of solid zinc electrodes in alkaline solutions in both active and passive regions was carried out by Sanghi and Fleischmann (23). They observed that the concentration of zincate ion has a small effect on the dissolution rate in the active region. The maximum dissolution rate (at the peak of the potentiostatic current-potential curve) is only a fraction of the limiting diffusion current of hydroxyl ions at bulk concentrations greater than 0.01M. Stirring increases the current at a given potential in both the active and passive regions. Saturation with zincate decreases the current at a given potential in the passive region. The passivation of the zinc electrode was attributed to precipitation and formation of a new oxide phase that is less soluble than the one formed at lower anodic potentials. The outer portion of this oxide phase is nonetheless converted to a soluble species in the passive region.

Vozdvizhenskii and Kochman found that, in both 2M and 5M KOH solutions, the potentiostatic current-potential curve had two peaks before the electrode became passive (25). The relative heights of these peaks depended on the sweep rate of the voltammetric measurement. According to their visual observation of the surface, a white film, that appears almost from the start of the experiment, covers the surface at the onset of passivation. This film gradually darkens with increasing potential in the passive region, turns brown, and is finally converted to a completely black color, presumably due to the presence of finely dispersed zinc within it. The two peaks were attributed to the formation of oxides with different hydration, structure, and solubility.

The behavior of the zinc electrode in the passive region was thoroughly investigated by Kabanov and co-workers (26-28). In solutions saturated with zincate in the potential range $-1.0 < U < 0.2$v with respect to a mercury-mercuric oxide electrode, the direct dissolution reaction

$$Zn \rightarrow Zn^{++} + 2e^- \qquad [10]$$

was suggested to occur to a large extent in addition to the chemical dissolution of zinc oxide

$$ZnO + 2\,OH^- + H_2O \rightarrow (Zn(OH)_4)^{--} \qquad [11]$$

The independence of current on potential at U less than 0.2v was attributed to the limiting rate of diffusion of zinc atoms through the oxide layer.

Ashton and Hepworth established that the rate of dissolution of zinc single crystals in 0.5M NaOH in the active region decreases slightly at constant potential with an increase in the planar packing density (29). This latter quantity increases in the order

$$(0001) < (10\bar{1}0) < (11\bar{2}0)$$

for zinc and other hexagonal close-packed metals. Their polycrystalline electrodes showed a dissolution behavior similar to that for the $(10\bar{1}0)$ plane.

There is a considerable literature on the structure and properties of the solid products formed during the anodization of zinc in alkali (18, 30-38). Thus Fischer and Budiloff identified the dark, 3-4μ thick layers formed in 2% NaOH at a constant current of 50 mamp/cm^2 as zinc oxide by means of both x-ray and electron diffraction (30). Very extensive studies of anodic coatings formed at anodic potentials corresponding to oxygen evolution in NaOH solutions of various concentrations have been carried out by Huber (31-33, 35, 36). The coloration of such coatings was attributed to an excess of zinc in zinc oxide since they are bleached on heating in air and colored again on heating in zinc vapor (33). Fry and Whitaker established that anodic films formed in 0.145M NaOH + 0.027M Na_2CO_3 at potentials in excess of 3.5v against saturated calomel were white. By both chemical and x-ray diffraction analyses, these films, as well as darker films formed at lower potentials, were identified as zinc oxide (38). Hampson, Tarbox, Lilley, and Farr identified zinc oxide by electron diffraction on specimens in KOH solutions subjected to potentials slightly below that for oxygen evolution. Very weak lines due to γ-zinc hydroxide were also noted (18).

On the other hand, Huber reported that γ-zinc hydroxide and a very small amount of colorless zinc oxide precipitate on an active zinc electrode in 1M NaOH after continued electrolysis. Such findings were obtained by electron diffraction of thinner coatings and by x-ray diffraction of thicker ones (35). Nikitina made an extensive study by means of microscopy as well as by x-ray diffraction of the precipitate formed on a zinc anode as well as the product precipitated in the bulk of the electrolyte. She worked with KOH solutions from 3 to 10M and at different temperatures between —20° and 20°C (37). Prismatic γ-zinc hydroxide, rhombic ϵ-zinc hydroxide, as well as zinc oxide were identified depending on the KOH concentration and the temperature. The less stable γ form of the hydroxide was observed with lower alkali concentrations and at the lower temperatures. The most stable hydroxide, the ϵ modification, appeared under intermediate conditions. Zinc oxide, which is slightly more stable than the ϵ-hydroxide, was observed in the more concentrated KOH solutions at higher temperatures. For instance in 10M KOH, ZnO was found at 20°C, but ϵ-$Zn(OH)_2$ with a small amount of γ-$Zn(OH)_2$ at 0° and —20°C. Nikitina's results are in general agreement with those of Jofa, Mirlina, and Moiseeva (34). Vozdvizshenskii and Kochman reported that after the evolution of oxygen on a zinc anode in 2M KOH, the surface was black but coated on the outside by a white gelatinous coating which readily washed off (25).

Experimental Procedure

Two kinds of zinc electrodes were used in this study. The first was obtained by cleavage from single crystal rods grown from zinc 99.9995% pure. Specimens, about 0.3 cm thick, were produced by the rapid insertion of a needle into the crystal while it was immersed in liquid nitrogen contained in a thermally insulated box. Rewarming to room temperature was carried out in an inert atmosphere. The specimen surface so-produced lies in the (0001) plane. It is mirror-like and marred by only a few cleavage steps. Such specimens were put into the test cell without further pretreatment. Experiments were started after an equilibration time of about 10 min, during which the zinc electrode stayed at open circuit potential in a 7M KOH + 0.25M ZnO solution saturated with purified argon. Both sets of measurements (current density i *vs.* electrode potential U with photomicrographs and $i - U$ curve with determination of the components of the electrode impedance) were made on the single crystal specimens.

Polycrystalline electrodes were cut from rolled zinc sheet, designated as Mix 60 by the supplier, the New Jersey Zinc Company. It was about 99.99% pure. The polycrystalline electrodes were pretreated by dipping them for a short time in concentrated nitric acid followed by thorough rinsing in a stream of distilled water. It took about 2 min to mount an electrode and to transfer it to the test cell. A polycrystalline electrode was connected to a potentiostat and immersed in electrolyte at −1.6v in the absence of zincate and at the rest potential in the presence of zincate. Measurements were started 5 min after immersion. A cathodic current transient was observed during and after immersion of the specimen electrode in KOH solutions without zincate. This cathodic current decays with time and tends toward a steady state value.

Throughout this study, the electrode potential was measured against and is referred here to a mercury-mercuric oxide electrode in pure KOH of the same concentration as that in the test cell. In addition, a secondary potential scale, one referred to the zinc rest potential, is also shown on the various $i - U$ curves presented in this paper. Such a scale facilitates the detailed examination of the shapes of the various experimental curves, an important part of the analysis carried out in this study.

The experimental work was carried out in KOH solutions prepared from reagent grade chemicals and distilled water. The solutions were either freshly prepared before the experiments or were stored under argon with exclusion of air in special apparatus.

The viewing cell and techniques for microscopic observation of zinc electrodes under polarization as well as most of the auxiliary instrumentation were described in detail previously (42). The zinc electrode potential was controlled by a Jaissle potentiostat and was programmed using either a Type 255 or a Model 504 Exact function generator. The current was recorded as a function of potential on a Moseley Model 2D-2A X-Y recorder. In this cell, designated here as cell I, the specimen surface is positioned horizontally facing upward. Impedance measurements on both cleaved and polycrystalline electrodes were also made in it. In addition, a second Teflon vessel, designated here as cell II, was used in which a polycrystalline sheet electrode was positioned vertically. A Teflon block with a cylindrical hole, 1 cm in diameter by 1.5 cm long, was pressed against the zinc sheet to affect a uniform current distribution over the zinc electrode. A fine hole in the block, 0.3 cm from the electrode surface, led to a separate reference electrode compartment.

Both the voltage sweep and the a-c signal were applied to the test electrode by the potentiostat during the impedance measurements as described previously (43). The manually triggered voltage for the sweep was taken from a Type 255 Exact Electronics function generator. It was necessary to keep the amplitude of the a-c signal as small as possible in order not to perturb the shape of the $i - U$ curve. An amplitude of 1 mv between the test and reference electrodes was used as the $i - U$ curve was not affected by the a-c component at this low amplitude. The ohmic ($1/R_p$) and capacitive (ωC_p) components of the electrode impedance in an analog parallel circuit were obtained simultaneously. The a-c signal between test electrode and reference electrode was fed to the reference input of the circuit which resolves the two components of the impedance (44, 45). The a-c voltage across a standard resistor, through which flowed the cell current between test and counter electrodes, was applied to the other input of this circuit. Both components of impedance were recorded as a function of the electrode potential on a Moseley Model 136A X-Y-Y recorder. The d-c current was obtained by amplifying the total voltage across the standard resistor by an operational amplifier, filtering out the a-c component, and feeding the d-c voltage to the Y input of another X-Y recorder. The electrode potential was always recorded on the X axis of the recorders.

Experimental Results

The current-potential curve shown in Fig. 1 was measured on a cleaved single crystal electrode at 0.55 mv/sec in 7M KOH + 0.25M ZnO at 23°C. The photomicrographs A to J shown in Fig. 2 were taken at the corresponding points marked on the $i - U$ curve in Fig. 1. The micrographs, obtained with dark field objectives at a total magnification of 90X, show the changes in the surface structure of the same area during the anodic potential sweep. Representative traces of the two components of the electrode impedance measured in an analog parallel circuit at 1000 Hz on similar cleaved single crystal electrodes in 7M KOH + 0.25M ZnO are shown in Fig. 3. The measurements were made under similar experimental conditions of assembling, sweep rate, and quiescent electrolyte as for those shown in Fig. 1 and 2. The $1/R_p - U$ and the $\omega C_p - U$ curves display characteristic waves which are discussed in a later section.

Because of the low impedance of the zinc electrode, a correction was necessary to take account of the resistance R_{EI} of the electrolyte between the test electrode and the opening to the capillary leading to the reference electrode compartment. This resistance was determined by applying a-c voltages with frequencies between 100 and 10,000 Hz from a function generator across cell I and a multiple decade resistance box in series with this test cell. For this determination, the cell was filled with 0.1M KCl, the zinc electrode was replaced with a platinized platinum sheet, and the Hg/HgO electrode with a platinized platinum wire. Using a dual beam oscilloscope, the series resistance was adjusted so that the amplitude of the a-c signal measured between the platinum sheet and the platinum wire equalled that across the resistance box. When the two signal amplitudes were equal, the electrolyte resistance equalled that of the adjustable series resistance. The distance from the test electrode to the center of the capillary opening, measured with a microscope equipped with a filar eyepiece, amounted to 0.76 mm. This value can be compared with one, 0.77 mm, calculated from the measured electrolyte resistance, the measured cross-sectional area of the cell, and the known specific resistivity of the electrolyte. The electrolyte resistance correction for the cell filled with 7M KOH + 0.25M ZnO was computed with this information and the known specific resistivity of the

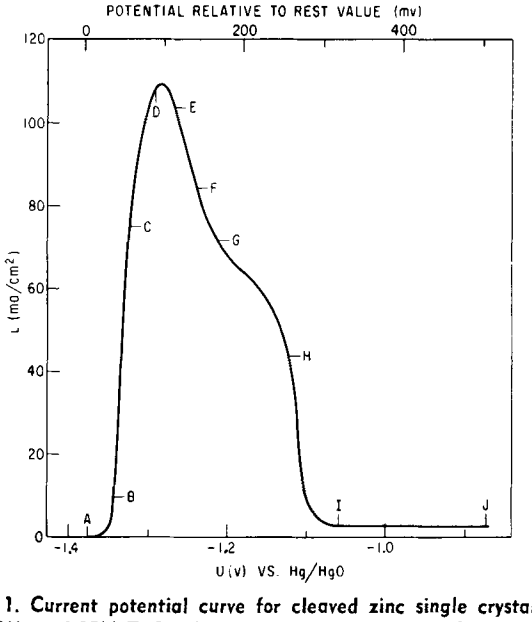

Fig. 1. Current potential curve for cleaved zinc single crystal in 7M KOH + 0.25M ZnO taken during anodic sweep at 0.55 mv/sec in cell I. Quiescent condition.

solution (46). It amounted to only 0.14 ohm cm^2. After converting the data in Fig. 3 to those for an analog series circuit, the electrolytic resistance, R_{EL}, was subtracted from the ohmic component R_s in the series circuit. Then the corrected ohmic value ($R_s - R_{EL}$) and the capacitive component $1/\omega C_s$ were used for a final conversion back to a parallel circuit consisting of the components R'_p and C'_p. This is the regular procedure for the treatment of impedance data (47, 48).

The $1/R'_p - U$, $C'_p - U$, and $i - U$ curves are plotted on Fig. 4 for the cleaved single crystal electrode and on Fig. 5 for the polycrystalline electrode in 7M KOH + 0.25M ZnO. The experimental conditions for the measurements shown on the two figures were the same except for the pretreatment of the electrodes as described in the preceding section.

A large number of voltammetric experiments were carried out on polycrystalline electrodes in cell II. Typical curves of $i - U$, $1/R_p - U$, and $\omega C_p - U$ obtained at a 1 mv/sec sweep rate in 7M KOH + 0.25M ZnO are shown on Fig. 6. Curves for the anodic sweep are represented by solid lines while those for the return cathodic sweep are indicated by broken ones. Still other $i - U$ curves and photomicrographs appear in Fig. 7-13.

Discussion

Different shapes of the i — U, $1/R_p$ — U, and ωC_p — U curves.—Probably the most interesting feature of the data presented in Fig. 1-6 is that the shapes of the i — U, $1/R_p$ — U, and ωC_p — U curves measured in cell I are very different from those measured in cell II. There is a very large peak in the i — U curve from cell I at a potential of —1.27v that is completely absent on the curve obtained in cell II. As will be discussed in more detail below, double peaks in the i — U curves

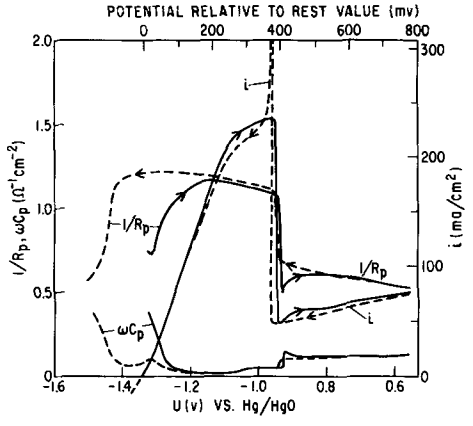

Fig. 6. Current density (i), parallel conductance ($1/R_p$), and capacitive susceptance (ωC_p) vs. U for polycrystalline zinc in 7M KOH + 0.25M ZnO taken during triangular sweep at 1 mv/sec in cell II.

were usually observed only in the former cell. The current densities measured in cell II were usually larger and the width of the active region greater by about 100 mv as can be seen on comparing Fig. 1 with Fig. 6.

The differences in data obtained in the two cells are accentuated in the resolved component measurements. The traces of the two components of the electrode impedance measured in an analog parallel circuit at 1000 Hz as shown in Fig. 3 were representative of data obtained in cell I. They were obtained under similar experimental conditions of assembling, sweep rate, and quiescent electrolyte as for those shown in Fig. 1 and 2. Similar results from numerous runs demonstrated that the characteristic shapes of the $1/R_p - U$ and $\omega C_p - U$ curves shown in Fig. 3 can be correlated with that shape of the $i - U$ curve shown in Fig. 1. When measured data such as shown in Fig. 3 were corrected for the electrolyte resistance by the method described previously, double peaks appeared in the $C'_p - U$ curves in the potential range between —1.37 and —1.07v which correspond qualitatively to the double peaks in the $i - U$ curves. These are shown in Fig. 4 and 5.

Numerous experiments showed that the characteristic shapes of the $1/R_p - U$ and $\omega C_p - U$ curves obtained in cell II, as shown on Fig. 6, are to be associated with that shape of the $i - U$ curve also shown on the same figure. Both components of impedance display a rapid change with U near the potential where the $i - U$ curve undergoes an initial rise. In contrast to data obtained in cell I, neither resolved component changes much with potential between —1.25 and —1.00v. The onset of passivation is correlated with an abrupt decrease in $1/R_p$ and a small increase in C_p. The increase of C_p with increase in potential for potentials less than —1.3v is in general agreement with recent results of Dirkse and Shoemaker (49).

While these measurements of the resolved components of impedance were very useful in pointing up differences between the two experimental cells, a quantitative study of impedance variations is very difficult because the impedance of the zinc electrode in strong alkaline solutions is so low. Even though the electrolyte resistance correction is very small by ordinary standards, amounting to only 0.14 ohm cm^2, it constituted such a relatively large correction on the measured values that presentation of data as $1/R'_p$ and C'_p over a range of potential, roughly between —1.15 and —0.9v, did not seem worthwhile. Although the resistance correction at the beginning of the experiment is probably known to within a per cent, uncertainties arise from the change of the electrolytic conductance during the potential sweep because of the enrichment of the electrolyte film near the surface with zincate as a result of the anodic zinc dissolution. Detailed correlations between the different peaks become difficult since their locations are affected by the uncertainties mentioned.

Most of the variations in the shapes of the curves measured in the two cells arose from very different hydrodynamic conditions. In cell I there was little natural convection as the test electrode was arranged horizontally facing upward. In contrast, in cell II the electrolyte near the vertical test electrode was undoubtedly stirred (50). That stirring due to natural convection is the important difference was shown by mechanically stirring the electrolyte in cell I using both single crystal and polycrystalline specimens. A lift pump operated by ultra-pure hydrogen was used for this purpose. In Fig. 7, the $i - U$ curve for a single crystal electrode with stirred electrolyte is presented and should be compared with Fig. 1 for the unstirred condition. Although these results are strong evidence of the influence of processes in the diffusion layer on some aspects of film formation, additional evidence is presented below.

Formation of a loose white coating under quiescent conditions.—The relationship between the potential and the kind of film formed will be considered first for quiescent conditions. Up to about —1.28v, under which conditions the current increases monotonically with increasing potentials, faceting of the initially very smooth single crystal surface takes place. Such facets grow coarser with time as shown in Fig. 2A-D. As no evidence of anodic film formation is seen in this region, presumably only a soluble oxidized zinc species is formed. The faceting was sufficiently coarse in this experiment that the specimen retained its mirror-like quality reasonably well. A mirror-like surface, which appears dark with dark field microscope objectives,

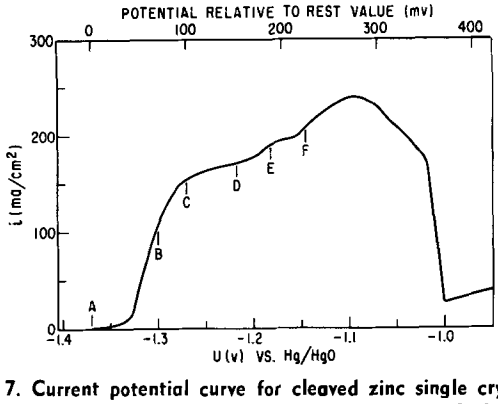

Fig. 7. Current potential curve for cleaved zinc single crystal in 7M KOH + 0.25M ZnO taken during anodic sweep at 0.50 mv/sec in cell I. Solution stirred.

is of course the most suitable background against which to view the formation of a whitish film that occurs at a slightly higher potential. In some runs, for reasons we do not yet understand, the faceting occurred on a smaller scale, with the result that the detection of the beginning of filming was made more difficult.

A coating or film on the electrode is first evident very near that potential at which the current density is maximum, *i.e.*, at about —1.27v as shown on Fig. 2E. This film spreads out and gradually covers the surface (Fig. 2F and G). Although it perhaps cannot be discerned from the photomicrographs, the film that forms near —1.27v is loose, flocculent, and white. At higher potentials, it may cover the electrode to a depth of 50-100μ in some places. This coating likely results from precipitation from a layer of electrolyte close to the electrode surface that is supersaturated with zincate ions. In "channels" between "islands" of film, it is often possible to see small white particles in motion under the microscope. This agitation is an indication of small scale convective motion associated with phase separation as precipitation should leave a less dense solution below a more dense one. This brings out the point that the word "quiescent" is used throughout this paper in a relative sense to distinguish hydrodynamic situations in which natural convection is small from others in which a solution is either pumped or subject to considerable natural convection. At still higher potentials, the anodic coating darkens as shown in Fig. 2G and H. The point I on Fig. 1 at the onset of passivation corresponds to almost complete coverage of the zinc electrode with film.

As shown on Fig. 7, the —1.27v peak in the $i - U$ curve is absent if the electrolyte is stirred. In Fig. 8, photomicrographs are presented which were taken at various potentials as indicated on Fig. 7. A white coating was not observed near —1.27v in this experiment. These results provide negative evidence that this peak is associated with a precipitated film. By stirring, the mass transfer of zincate ions is presumably increased sufficiently that a supersaturated layer of zincate does not form close to the zinc electrode.

When the potential scan rate is reduced to about one-tenth of that used to obtain Fig. 1, other experimental conditions remaining the same, a second peak in the $i - U$ curve near an anodic potential of —1.15v becomes fully developed as shown on Fig. 9. This peak appears only as an inflection point in Fig. 1. The overall reduction in the heights of the anodic peaks at the very slow scan rate should be noted. Double peaks in the anodic polarization curve for zinc in concentrated alkali were reported previously by Vozdvizhenskii and Kochman (25). These authors pointed out that the resolution of the second peak was improved by decreasing the potential scan rate, although they did not state quantitatively the scan rates used in their experiments. In our experience, very low rates of the order of a fraction of a millivolt per second are required. Vozdvizhenskii and Kochman used horizontal test electrodes as did we in cell I. It is important to point out that the horizontal electrode arrangement is not the only experimental situation in which double peaks can be observed. They also appeared with vertical electrodes in contact with a separator. We assume that the natural convection which usually occurs near a vertical zinc electrode under polarization is suppressed by the separator. This reduces sufficiently the rate of mass transport of zincate away from the electrode that the formation of a supersaturated layer of zincate occurs.

The formation of dark compact films.—The shape of the $i - U$ curve is altered greatly by stirring as shown in Fig. 6 for a vertical electrode subject to natural convection and in Fig. 7 for a horizontal electrode with forced convection. Instead of obtaining a peak near —1.27v, the current density continues to rise with increasing potential. However, the rate of rise varied considerably from run to run. In some, the current increased very slowly up to a potential of —0.97v, at which it dropped abruptly and complete passivation ensued. This behavior is very similar to that reported recently by Ashton and Hepworth for the anodization of zinc in 0.5M NaOH (29). A more rapid increase of current density with potential is shown on Fig. 6. In other runs the rise was gradual up to a potential of about —1.22v when fluctuations in the current density occurred as shown on Fig. 7. These fluctuations are often much larger than those indicated on the latter figure. At higher potentials, the current increased more steeply, passed through a maximum, and then dropped precipitously.

The stirring action permits the observation of a second, very different kind of film by preventing the formation of a supersaturated layer of zincate with subsequent precipitation of a loose white layer. The fluctuations in the current mentioned above are associated with the buckling and tearing of this second type. This behavior is shown on Fig. 8E and F. This type II film appears to be much more compact than the first type and is transparent to a greater or lesser degree. It is generally more adherent and seems to form directly on the surface of the zinc electrode. As discussed in more detail below, its color can range from very light gray to black. Other photomicrographs of buckled films, taken during a run under conditions similar to those used for Fig. 7 and 8, are shown in Fig. 10A and B.

There is another technique which facilitates the observation of type II film without interference from the first type. This involves the use of a potential jump from the rest value to a potential ranging usually from —0.5 to 0.5v in a quiescent solution. As discussed in the section on previous work, the application of a large constant current leads to passivation with a minimum, nearly constant, amount of charge per unit area and minimizes the formation of a supersaturated layer of electrolyte near the electrode. With potentiostatic experiments, after jumping the potential, for instance to 0.5v, an initially very high current density is noted which saturates the potentiostat. The current declines with time, amounting after 1 min to about 76 ma/cm^2, after 5 min to 56 ma/cm^2, and to 38 ma/cm^2 after 10 min. With time, surface features on the single crystal zinc electrode surface become obliterated due to the presence of type II film which becomes increasingly opaque. It is interesting to note however that even when the electrode is covered with film so as to appear very black to the eye, underlying surface features on the electrode surface may be viewed microscopically merely by increasing the intensity of illumination. If the potential is reduced after a certain time of formation, *e.g.*, to —0.5v after 10 min, fissures often appear in the film and some portions of the surface become denuded of film as shown on Fig. 11A. On other portions of the surface, the type II film is piled up several layers deep as shown in Fig. 11B.

Interpretation of impedance data.—As discussed previously, the general shape of the $1/R_p - U$ and $\omega C_p - U$ curves reflects the convective conditions under which the measurements were made. The gradual decrease of current with potential between —1.2 and —1.0v on the single crystal and the polycrystalline zinc surface in cell I (see Fig. 4 and 5) and the sudden decrease at about —0.95v on the polycrystalline surface in cell II (see Fig. 6) are accompanied by similar changes in the resolved components. The latter behavior is attributed to the completion of the coverage of the surface with type II film. Further conclusions of a qualitative nature may be derived from the impedance measurements in cell I for which a R_{EI} correction was made under the simplifying assumption that $R_{EI} \approx$ constant. A corresponding correction was not applied to the data obtained in cell II since the convective conditions did not guarantee a uniform current distribution.

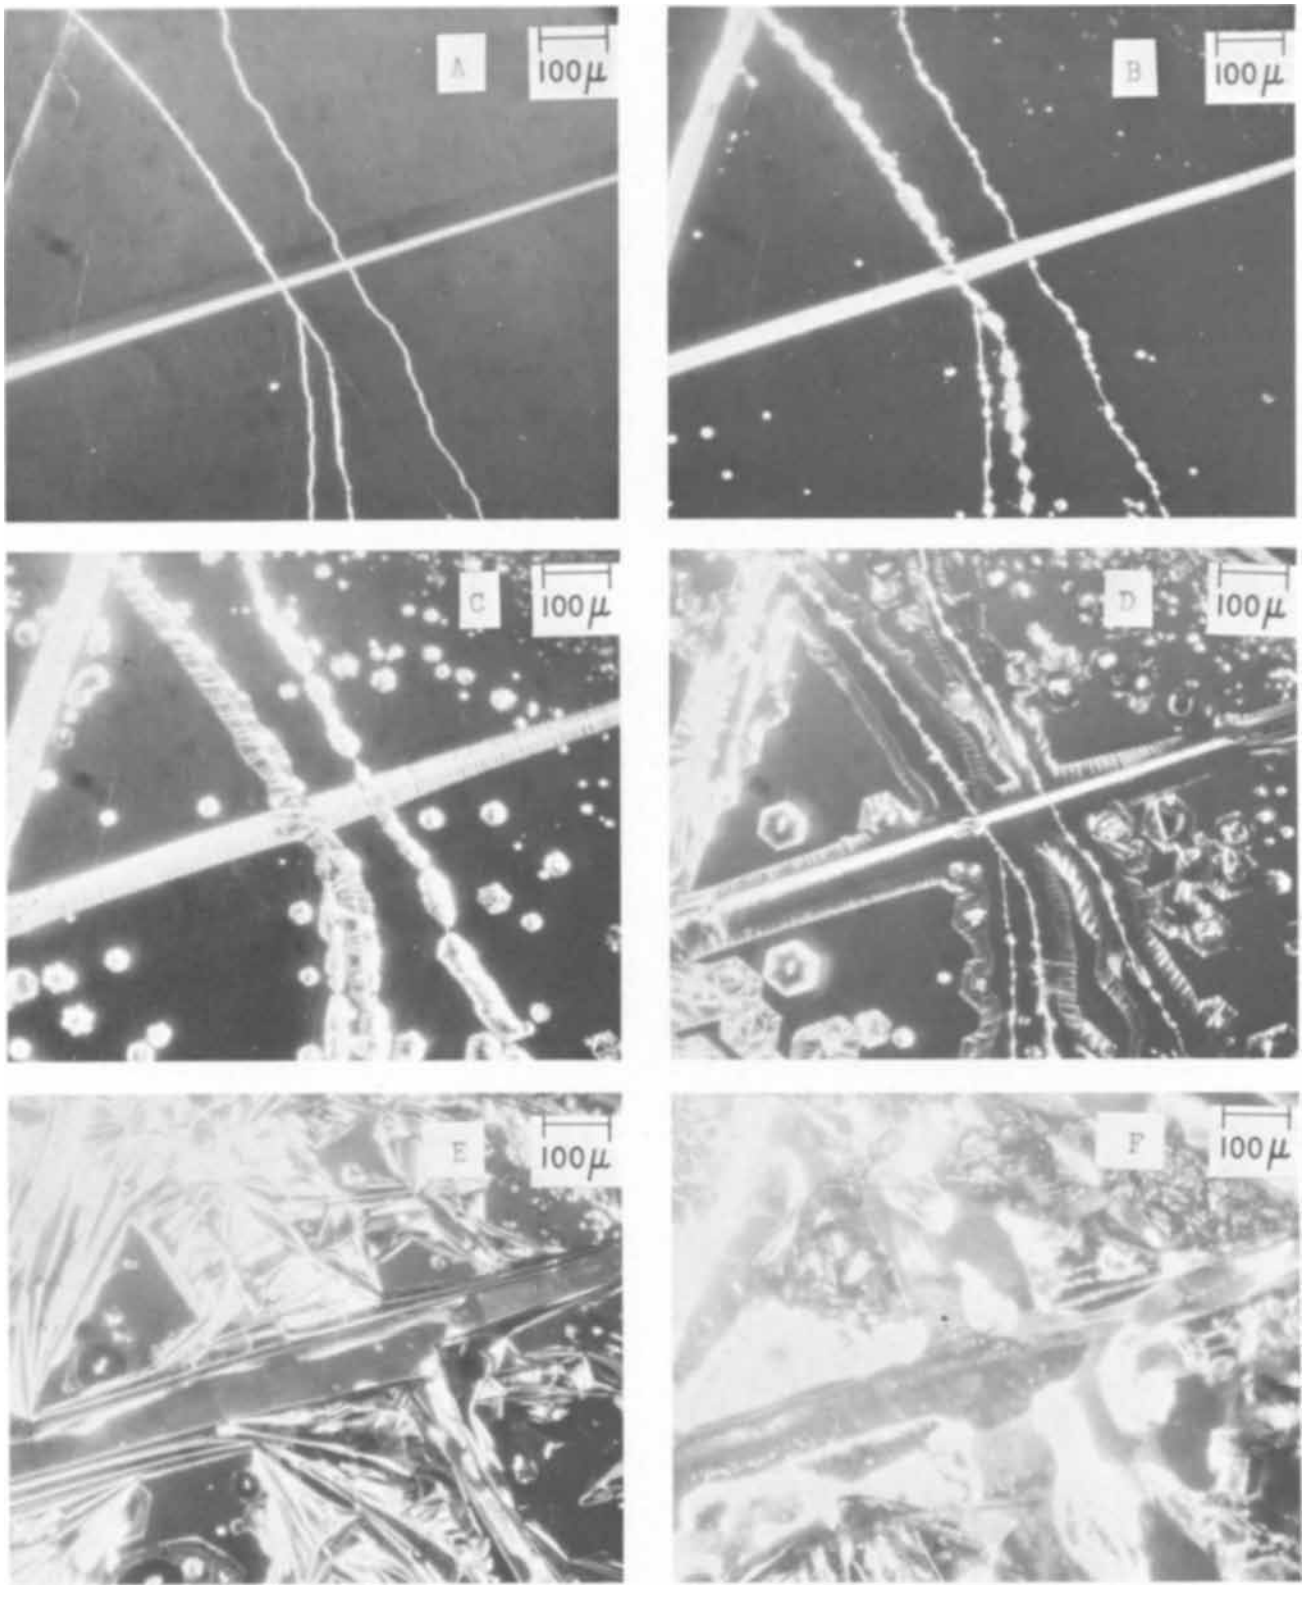

Fig. 8. Changes in the optical morphology of a zinc electrode observed during the sweep shown on Fig. 7. Dark field 90X.

The $C'_p - U$ curves in Fig. 4 and 5 show C'_p values larger than 60 $\mu F/cm^2$ between —1.35 and —1.15v and between —0.90 and —0.70v. The peak values are several hundred $\mu F/cm^2$. Such C'_p values cannot represent the double layer capacitance on zinc which is of the order of 20 $\mu F/cm^2$ (48). Large values of C'_p were also found by impedance measurements at the equilibrium potential of the zinc/zincate electrode and were attributed at high frequencies to a capacitance resulting from the presence of (Zn_{ad}-OH^-) (6). Our capacitance data in the two potential regions defined above have to be interpreted in a similar way. The adsorption reactions in question cannot be specified yet on the basis of the available data. However, it is considered likely that the formation of OH_{ad} is involved in the appearance of one or possibly of the two capacitance peaks in the region between —1.35 and —1.15v. Since the first peak is small on the single crystal plane and larger on the polycrystalline surface, the same adsorption reaction on different planes may have been observed. Since the second potential region is separated by about 0.4v from the first one, an adsorp-

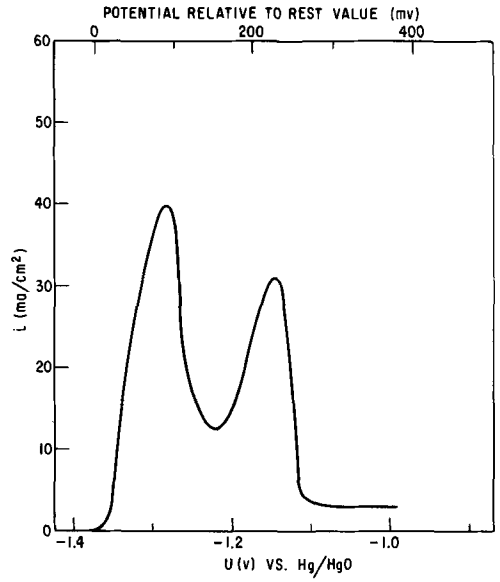

Fig. 9. Current potential curve for cleaved zinc single crystal in 7M KOH + 0.25M ZnO taken during anodic sweep at 0.05 mv/sec in cell I. Quiescent condition.

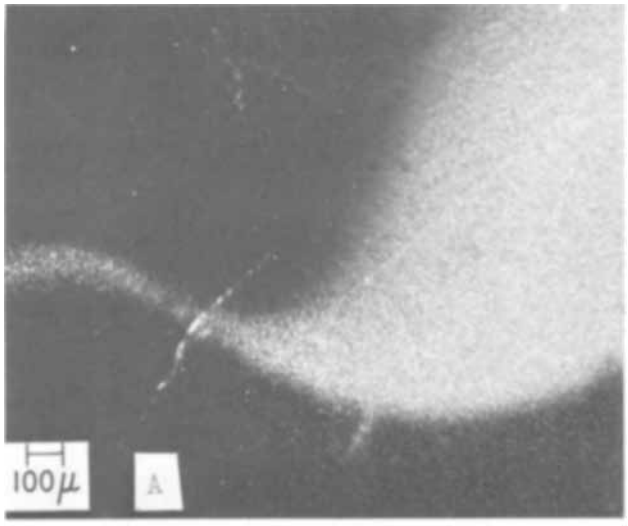
tion reaction different from that in the first region has to be postulated as the cause of the capacitance peak between —0.90 and —0.70v.



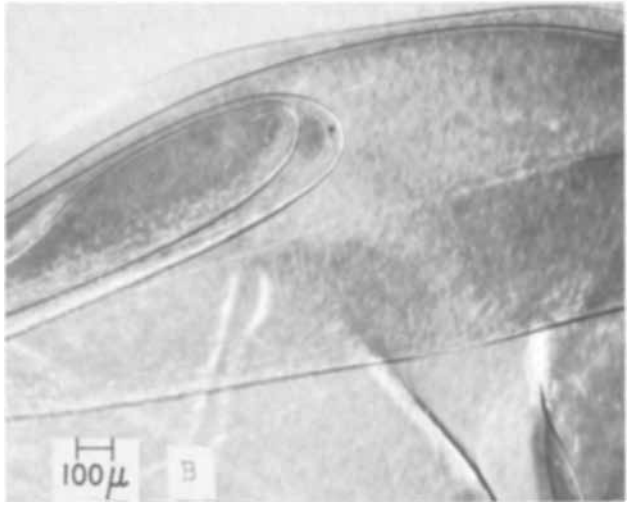


Fig. 11. Torn and piled-up type II film. Formed at 0.5v and torn by reducing potential to —0.5v. Dark field 48X.

Concluding Remarks

In the preceding sections, we have attempted to describe experimental conditions wherein one of the two different kinds of film involved in zinc passivation could be observed without interference from the other type. Both kinds of film were described previously by numerous authors. It appears likely from this prior work that type I film is either a form of zinc hydroxide or of zinc oxide while type II film is zinc oxide. An important part of the present contribution is a better delineation of the conditions for their formation. The electrode potential and the hydrodynamic conditions in the electrolyte near the zinc electrode mainly determine which film is observed.

An intriguing question, for which we have as yet no definitive answer, is the potential at which the type II film first forms. A thin, compact, nearly transparent coating that forms directly atop the surface of the zinc electrode is very difficult to detect. As shown on the photomicrographs in this report, it is probably most easily observed when buckled and torn. In our experience, the films formed by jumping the potential anodically from the rest value were capable of various shades of darkness depending largely on the forming potential and the elapsed time. Type II films formed during stirring at potentials near —1.2v are of a still lighter color. If the darkening of a filmed zinc electrode can be attributed entirely to the type II film, then the film that forms on a zinc electrode under quiescent conditions at potentials in excess of —1.22v must be of a duplex character. A porous, white precipitated film (type I) must cover type II. The dark-

ening of a filmed zinc electrode undergoing anodization under quiescent conditions is evident in that series of photomicrographs shown in Fig. 2 beginning with H, and possibly even in G. Darkening was determined quantitatively in another experiment. The potential of a single crystal zinc electrode was changed rapidly from the rest value by 200 mv in the anodic direction and the intensity of diffusely reflected light from the specimen was sensed using a photometer placed in one of the eyepiece tubes of the Leitz Ortholux microscope used to observe the zinc electrode under polarization. A recording of the intensity variation with time is shown in Fig. 12. The intensity of incident light upon the specimen was held constant throughout the experiment. There was a delay of 20-30 sec during which time the specimen retained its mirror-like character and appeared black. As type I coating formed and spread over the surface, the intensity increased. After about 110 sec, however, as the filmed electrode became dark because of adsorption of incident light, the recorded intensity fell. If the film formed after such an experiment is dissolved by stirring for 10-30 min at open circuit, a black web-like structure is observed under the microscope. It is often one of great delicacy and beauty. These so-called "zinc cobwebs," which we assume to form from an underlying compact type II film, are described elsewhere (51).

The rather different behavior of the two kinds of film substances involved in zinc passivation is brought out in yet another way on considering the curves shown on Fig. 6 and 12. Use was made of triangular sweeps wherein the potential was changed at a constant rate from the rest value to about —0.5v and then back again to the rest value. On Fig. 6, one can see that the current obtained with decreasing potential on the return part of the sweep duplicated rather well that obtained with increasing potential. This conclusion applies particularly well to data obtained at the more negative potentials. These data were obtained in cell II (vertical zinc electrode) where because of natural convection only small amounts of the first type film would be expected to form. Curves demonstrating these points have also been obtained with cell I (horizontal zinc electrode) with stirred electrolyte. In contrast, the very different behavior encountered with a horizontal electrode without stirring (quiescent condition) is brought out in the i — U curves shown on Fig. 13. Here the current at the lower potentials obtained during the cathodic sweep is very much less than that obtained during the anodic sweep. Microscopic observations readily indicate that the type I film which formed gradually with increasing potential (probably with some type II film beneath it) remained on the electrode for the entire return sweep. It thus appears that, whereas type II film substance is of predominant importance in controlling the active to passive transition between —1.07 and —0.97v, type I film can greatly influence the current level at lower potentials.

The Microstructure of Sintered Silver Electrodes

I. During Discharges at the 1-Hour Rate

Charles P. Wales*

Naval Research Laboratory, Electrochemistry Branch, Washington, D. C.

ABSTRACT

Silver electrodes that had been manufactured for Ag-Zn storage batteries were cycled in 35% KOH at 25°C. The electrodes were examined by optical microscopy. The initial Ag_2O formation during a discharge at the 1-hr rate usually occurred on the surfaces of AgO clumps at many scattered areas throughout the electrode. After discharge potential fell to the Ag_2O/Ag plateau, Ag formation occurred on the electrode surface and then gradually spread to the interior as a discharge was continued. When a slow (20-hr) discharge rate was used, however, Ag formed at the surface and at the interior of an electrode simultaneously.

The use of silver-zinc and silver-cadmium storage batteries is limited by several factors, including the gradual loss of capacity often observed with use, the short life of some models, and the difficulty of recharging the batteries to full capacity in a short time. The present investigation concerns the structure of the silver electrode that is used as positive electrodes in silver-zinc and silver-cadmium storage batteries. Microscopic examination of electrodes at various stages of charge and discharge has been of considerable value in understanding the processes which occur. The three phases Ag, Ag_2O, and AgO can be seen and differentiated from each other by using optical microscopy. The progressive decrease in capacity of a sintered silver electrode that was discharged at a low (20-hr) rate has been shown to be the result of a gradual change in electrode structure as large Ag particles formed during the slow discharges in place of the small particles originally present (1).

The present paper describes structural changes that occur during discharges of sintered silver electrodes in the first 30 cycles of an electrode. These electrodes were always discharged at the 1-hr rate and charged at the 20-hr rate. Structures present in these electrodes at the end of discharges and structural changes during charges that followed the 1-hr rate discharges are to be the subject of later papers.

Experimental Procedure

The silver electrodes used for the microscopic examination had been manufactured commercially for use in Ag-Zn storage batteries. The electrodes were all of the same size and had been designed to discharge at comparatively low rates, requiring one or more hours for a complete discharge. The electrodes consisted of sintered Ag particles with a grid of expanded sheet Ag that was close to one electrode surface. The structure of these electrodes has been illustrated (1). Electrode dimensions were 41.5 mm wide by 38.0 mm high by 0.8 mm thick. The theoretical capacity of an electrode, based on the weight of sintered Ag present, was approximately 2.9 amp-hr.

An electrode which was to be examined was charged and discharged between two other sintered Ag electrodes of the same size and construction. All three electrodes were wrapped individually with treated cellulose separator to slow the diffusion of soluble Ag species. The cell containing these electrodes, which has been described in more detail in ref. (1), was so constructed that the middle electrode could be removed readily from the separator when it was desired to cut an electrode sample for microscopic examination. The cell also contained a Ag/Ag_2O reference electrode. All work was done at approximately 25°C in an excess of 35% KOH solution.

The removable electrodes were charged at the constant current which required approximately 20 hr for

a complete charge. A charge was ended when electrode potential stopped changing rapidly after oxygen began to evolve. These electrodes were discharged at the constant current which required 1 hr for potential to drop to —500 mv *vs.* the reference electrode, a potential equivalent to an endpoint of approximately 1.0v for a typical Ag-Zn cell. Progressively lower values of charge and discharge current were used as the electrode capacity gradually declined with cycling, so that the actual hours usually varied less than 3% from the desired 20 hr for charge and 1 hr for discharge. An exception was the first two cycles of an electrode, where capacity fluctuated and variation from the desired times averaged 9.6%. Samples approximately 19 x 21 mm were cut from a removable electrode at various times, for microscopic examination. The remainder of the electrode was then returned to the cell and placed within the separator as before. Current was lowered by an amount sufficient to compensate for the removal of each sample, so that current density on the remainder of the electrode was unchanged.

Each sample from an electrode was handled separately to avoid unnecessary delay in microscopic examination. Sample treatment was changed from that used earlier (1). The wet-polishing step was omitted and a different impregnation plastic was used. Porous electrodes cannot be ground and polished successfully in preparation for microscopic examination unless the voids within the electrode are filled with a solid material. Several polyesters were tested as the impregnation material but all reacted slowly with Ag_2O and AgO before solidifying. Epoxy resins are available that are less reactive with silver oxides, but most epoxy resins have high viscosity and need to be heated for curing. A little decomposition of AgO seemed to occur even when an electrode sample was heated at the relatively low temperature of 40°C for 8 hr. This agrees with the recent report of slow AgO decomposition taking place at 25°C, while at 50° the AgO decomposition had increased greatly (2). The majority of the samples in the present work were impregnated with an epoxy resin that required several days at room temperature before the epoxy resin hardened sufficiently that it could be ground and polished successfully. The most recent samples were impregnated with a transparent epoxy resin[1] that is less viscous and will harden overnight at room temperature.

Note that an exothermic reaction takes place after the components of an epoxy resin or polyester are mixed. Dangerously high temperatures can occur when a large volume of the liquid plastic is prepared. The temperature may increase sufficiently that the plastic will ignite spontaneously. A particularly hazardous situation can occur if a large quantity of plastic is used to impregnate large battery electrodes consisting of an oxide, because the oxide will decompose when heated and the released oxygen will speed combustion of the plastic. In the present work only a small quantity of epoxy was needed for a sample. The temperature of the aluminum mold that held a sample did not rise noticeably above room temperature.

After a sample was cut from an electrode, the sample was immediately washed in 4-6 changes of distilled water to remove the KOH solution. Then the sample was dried in a vacuum for 1 hr. A dried sample was placed in the cylindrical cavity of an aluminum mold. The cavity was then filled with Lucite pellets to hold the sample upright. While under a vacuum, the sample was impregnated with the epoxy resin. Only 15-20g of epoxy were needed to fill the void spaces between the pellets and in the electrode. The impregnated sample was returned to atmospheric pressure while the plastic was still liquid, and the plastic was cured at room temperature. Then a cross section of the sample was prepared by grinding the sample successively on 120, 240, 400, and 600 mesh silicon carbide papers. Finally the sample was dry polished on a sponge rubber lap charged with 0.3μ alumina powder. The sample was then examined by optical microscopy and the appearance of significant areas recorded by photography.

Results of Microscopic Examinations

Figure 1 gives typical potentials measured during discharges at the 1-hr rate and for comparison also includes two discharges at the 20-hr rate. The potential in the first portion of a discharge was the potential of AgO being reduced to Ag_2O, and then the remainder of the discharge took place at the potential of Ag_2O being reduced to Ag. Electrodes showed the AgO/Ag_2O potential during the first 11-15% of cycle 1 discharges at the 1-hr rate. A smaller proportion of the following discharges took place at the AgO/Ag_2O potential, and from cycle 3 to cycle 30 this potential lasted for only the first 6-12% of discharges at the 1-hr rate. (No electrodes were given more than 30 cycles in the present work.) The shape and length of this higher potential portion of a discharge varied from cycle to cycle. When the 20-hr rate was used, a larger proportion of a discharge took place at the AgO/Ag_2O potential. The first discharge at the 20-hr rate showed less of this higher potential than the later cycles. After the first cycle, the higher potential plateau resembled that of E in Fig. 1. It can be seen in Fig. 1 that the total capacity delivered during discharge decreased gradually as an electrode was cycled at the 1-hr rate and capacity decreased more rapidly when the 20-hr rate was used, although the slower discharge gave a larger capacity on the first cycle.

At the end of a charge to oxygen evolution at the 20-hr rate over half of the Ag in an electrode had been oxidized to AgO, with much smaller amounts of an electrode consisting of metallic Ag or of Ag_2O. Figure 2 illustrates an electrode at the end of the first charge, as well as can be done in one photograph. This and all subsequent figures are photographs of cross sections through an electrode and, therefore, also show cross sections through individual particles or crystals of which the electrode is composed. The charged electrode had variation from one area to another. At some areas more AgO was present than was in the area shown in Fig. 2, while elsewhere larger amounts of Ag and Ag_2O were present. Large Ag particles did not oxidize completely during charge, but many of the small Ag particles had oxidized completely to AgO. It could be seen under polarized light that what appeared to be large AgO crystals actually consisted of several smaller AgO crystals that had grown together. The AgO crystals tended to fill some of the voids originally present in the unused electrode.

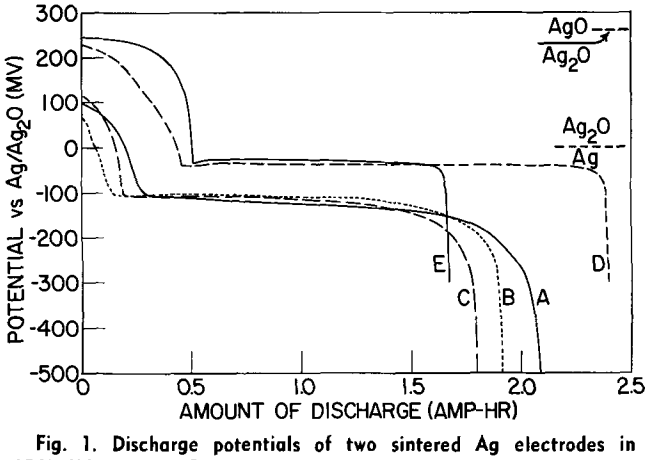

Fig. 1. Discharge potentials of two sintered Ag electrodes in 35% KOH at 25°C following charges at 20-hr rate. A, cycle 1; B, cycle 15; and C, cycle 30 of electrode always discharged at 1-hr rate. D, cycle 1; and E, cycle 6 of another electrode always discharged at 20-hr rate.

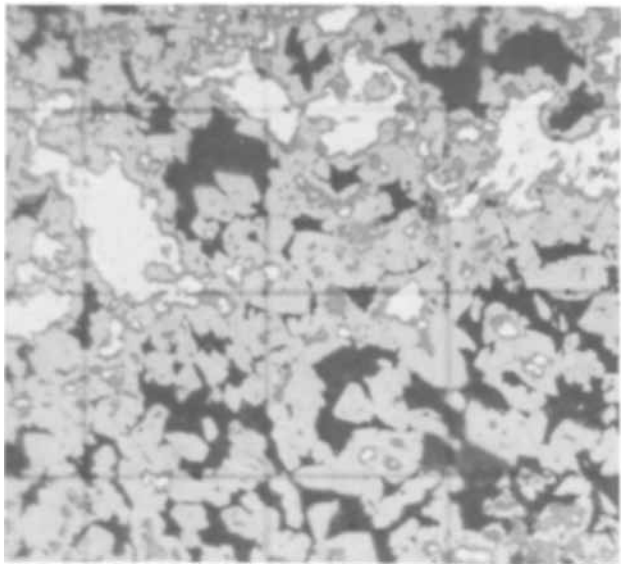

Fig. 2. Previously unused electrode at the end of the first charge to oxygen evolution. Metallic Ag particles are the lightest shade. Groups of AgO crystals are shown by the medium gray that predominates. Ag_2O (darker gray) is present in small patches within the AgO and also is present as a thin layer separating Ag particles from the AgO. Void areas are the darkest shade. Lines forming the squares are 30μ apart.

The appearance of the electrode at the end of the first charge and during the first discharge was different from the appearance when charged or discharged equivalent amounts in subsequent cycles. One area of an electrode that was discharged over 90% at the Ag_2O/Ag potential plateau using the 1-hr rate at cycle 1 is shown in Fig. 3. All areas of an electrode did not discharge simultaneously. In the area illustrated by Fig. 3, the surface of all AgO clumps had been reduced to Ag_2O during the discharge. The Ag_2O was present as very small crystals in a layer that was more porous than the AgO. The Ag present in the area shown in Fig. 3 was Ag that had not been oxidized during the initial charge of the electrode. During the partial discharge no Ag had been formed in this area. Comparison with Fig. 2 indicates the changes that had occurred as Ag_2O formed during an incomplete discharge at cycle 1. The angular shapes of AgO clumps had been retained.

Most of the Ag particles that formed during the first discharge at the 1-hr rate were much smaller than the Ag particles originally present. The formation of Ag from Ag_2O is shown in Fig. 4. During the first discharge the Ag formation took place more often below the surfaces of the small clumps of active material than at their surfaces. Comparison of Fig. 3 to Fig. 4 suggests that the Ag had nucleated from the smaller Ag particles that had remained at the end of the first charge. Ag began to form before all AgO was reduced to Ag_2O. As the Ag_2O coating on a clump of AgO was reduced to Ag, additional AgO was reduced to Ag_2O with the result that Ag never contacted AgO. Almost all of an electrode had been reduced to Ag by the end of a discharge at the 1-hr rate, although a few small areas of oxides usually remained.

The Ag particles produced by a discharge at the 1-hr rate formed into larger clumps than were present in the unused electrode. As an electrode was cycled, these clumps gradually became larger and large void spaces developed. During charge of an electrode that contained clumps of small Ag particles produced by one or more discharges at the 1-hr rate, larger AgO clumps were formed than those shown in Fig. 2 for the initial charge of a sintered Ag electrode. As discharges at the 1-hr rate and charges at the 20-hr rate were repeated, the AgO clumps in a charged electrode became larger. These large AgO clumps contained many particles of Ag that had not been oxidized during the charge. The remaining figures show structures present during discharges of electrodes that had developed clumps of active material after an electrode had been cycled. The appearance of an electrode during cycle 5 discharge will be illustrated as being typical after clumps have formed. Electrodes given 30 cycles differed only in having larger clumps, larger void spaces between the clumps, and in having slightly more Ag remaining unoxidized at the end of a charge.

During the early part of a typical discharge at the 1-hr rate, the first Ag_2O formation was on the surface of AgO clumps. This is illustrated in Fig. 5 by an electrode that was discharged until potential had just reached the Ag_2O/Ag plateau. No Ag had formed during this incomplete discharge. In some areas of this electrode, such as the area shown in Fig. 5, relatively

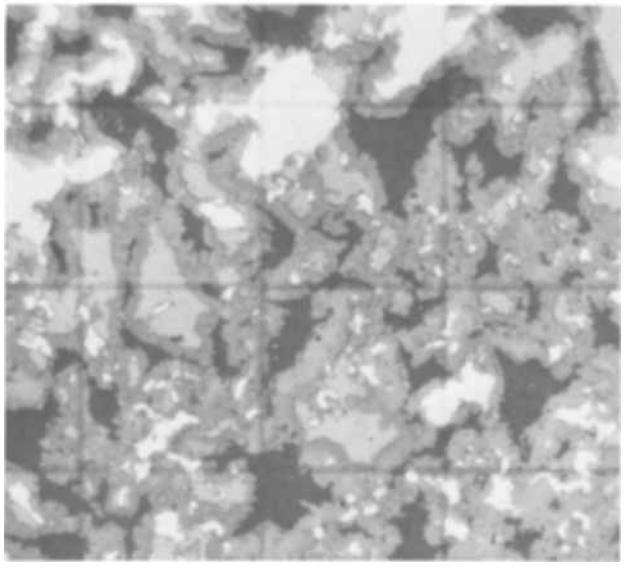

Fig. 3. Incompletely discharged electrode at cycle 1, showing an area where a thick Ag_2O layer has formed on the outside of AgO particles but where Ag has not yet formed during the discharge at the 1-hr rate. Ag present in this area was Ag that had failed to oxidize during the charge. Compare with Fig. 2 at the same magnification.

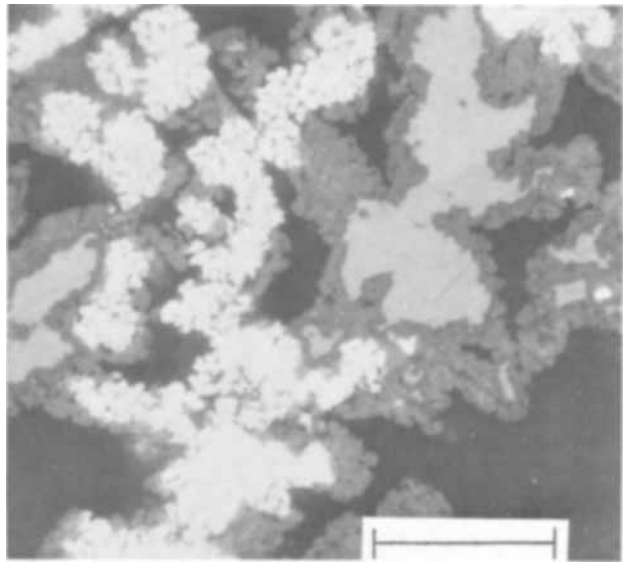

Fig. 4. Electrode incompletely discharged at cycle 1 using the 1-hr rate showing formation of small Ag particles (white). AgO is medium gray, Ag_2O darker gray, and void areas are black. Marker indicates 15μ. Compare with Fig. 3 but note different magnification.

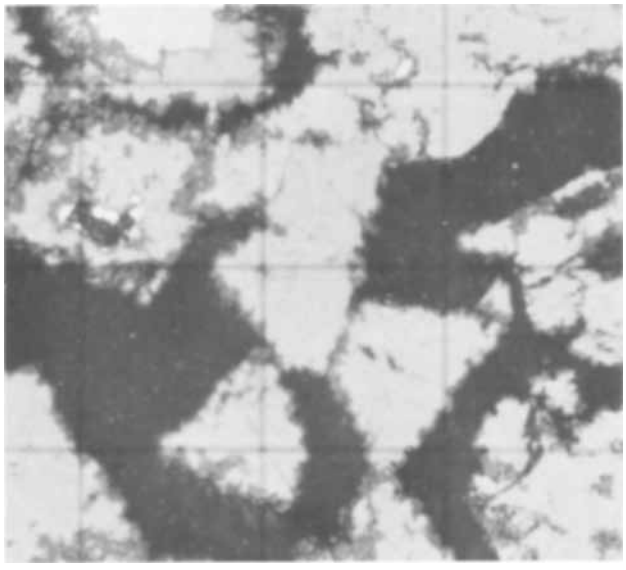

Fig. 5. Electrode discharged at the 1-hr rate just to Ag_2O/Ag potential plateau at cycle 5, illustrating that Ag_2O formed initially on the surface of AgO clumps. Approximately 11% of capacity had been removed during discharge. Most areas of this electrode had more Ag_2O present than is shown here. Lines forming squares are 15μ apart.

little Ag_2O had formed and the shape of the AgO clumps present at the end of the previous charge could be recognized despite penetration of Ag_2O at many points along the AgO surfaces. A more common area is the one shown in Fig. 6, where Ag_2O formation has been extensive in many places. Areas that were predominantly Ag_2O were scattered at random throughout areas of AgO. Ag_2O had formed at both the center and the surface of the electrode, and AgO still remained in both places. AgO remained near most of the Ag grid in the electrode, however, although Ag_2O predominated at a few of the grid members.

Ag began to form during a discharge after potential reached the Ag_2O/Ag plateau. This Ag formed first on the surface of the electrode when the 1-hr discharge rate was used, in contrast to the more random formation of Ag_2O in the earlier part of a discharge. Figure 7 illustrates this Ag formation in an electrode that had been discharged 0.50 hr. Instead of the bright-field vertical illumination used for all other photographs, oblique illumination was used for Fig. 7

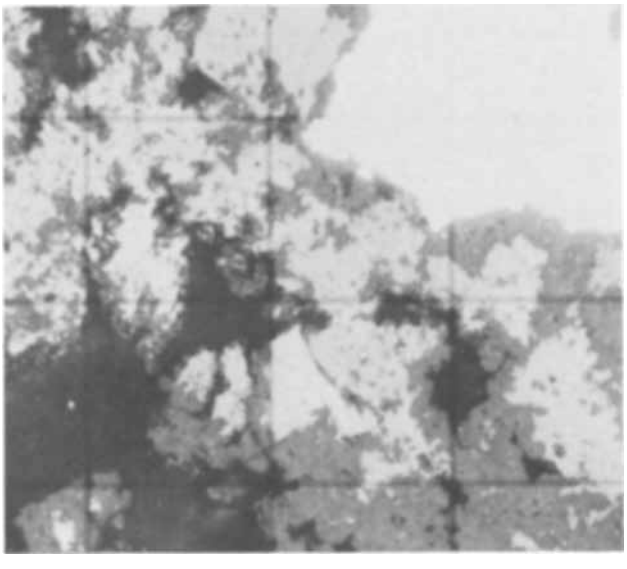

Fig. 6. Typical Ag_2O formation in the discharged electrode shown in Fig. 5. Lines forming squares are 15μ apart.

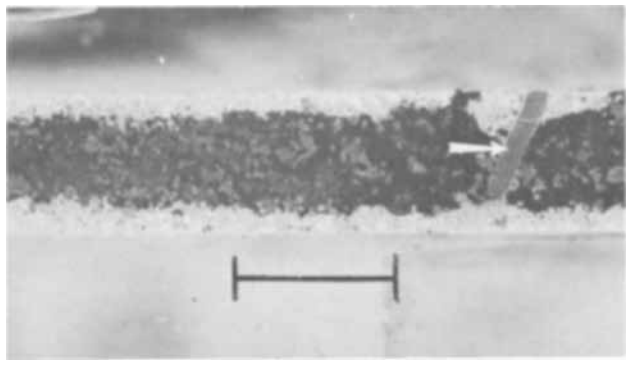

Fig. 7. Cross section of an electrode that was discharged 50% at the 1-hr rate at cycle 5, showing that Ag formed first at the surfaces. Arrow points to cross section of a grid. Large Ag particles that have been cross sectioned and polished appear as medium gray in this photograph using oblique illumination, but most Ag particles were too small to be visible at this low magnification. Reflections of light from the surfaces of Ag particles below the polished cross section appear as white. Oxide regions are the darkest shade. Marker indicates 1 mm.

in order to emphasize the areas where Ag had formed during discharge. Many small black areas remained on the surface in places where Ag had not yet formed during this partial discharge. One such area is visible in Fig. 7 at a small distance to the left of the grid. Less than 5% of the surface of this half-discharged electrode consisted of these oxide areas. The formation of Ag in the electrode is shown in Fig. 8 at higher magnification. In the center of this electrode that was 50% discharged the oxides seemed unchanged from those in an electrode 12% discharged (Fig. 5 and 6), with some areas being predominantly AgO and others Ag_2O.

Figure 9 shows Ag that had formed next to an area where AgO had already been reduced to Ag_2O. Small Ag particles that probably had been formed during the partial discharge were often found in Ag_2O areas such as the top of Fig. 9, but not in AgO areas. Ag formation next to an area that contained AgO with a coating of Ag_2O on its surface is shown in Fig. 10. Areas such as this were more common in the half-discharged electrode than areas where Ag_2O predominated, such as the one shown in Fig. 9.

By the end of a discharge at the 1-hr rate an electrode consisted almost entirely of clumps of Ag par-

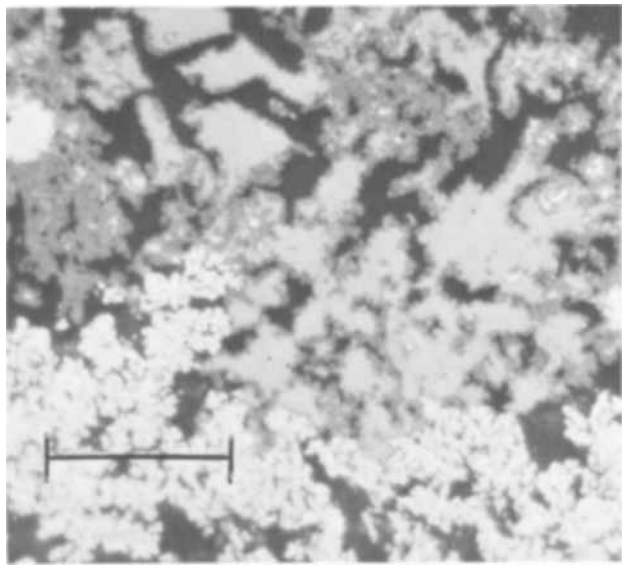

Fig. 8. Higher magnification view of electrode shown in Fig. 7. Boundary was fairly sharp between oxides in the middle of the electrode (top) and Ag that had been formed from the surface inwards (bottom) during discharge. Marker indicates 30μ.

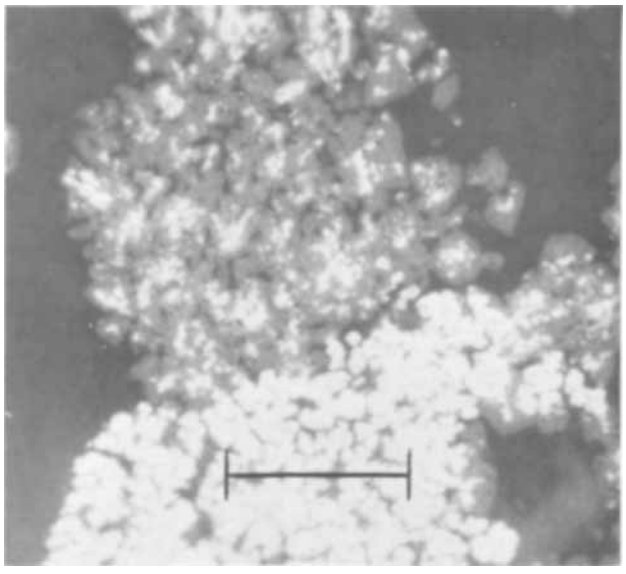

Fig. 9. Ag that formed during discharge (bottom) in a region that was predominantly Ag_2O and Ag (top). Same electrode as Fig. 7 and 8. Marker indicates 15μ.

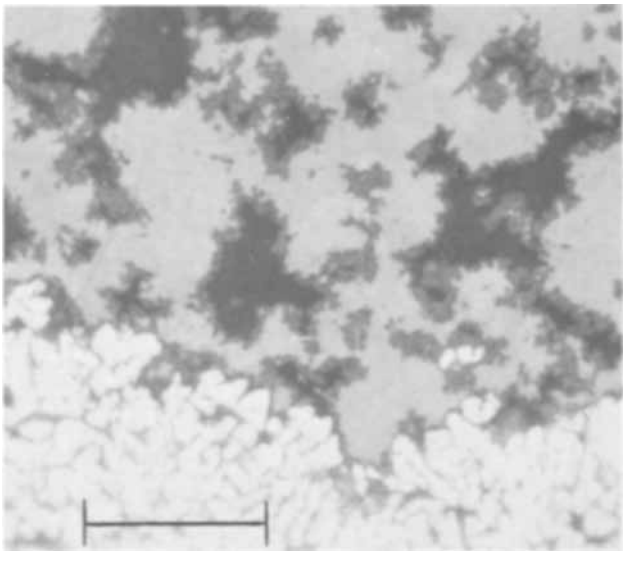

Fig. 10. Boundary between Ag that formed during discharge (bottom) and AgO clumps that were covered with Ag_2O (top). Same electrode and magnification as Fig. 9.

ticles, such as those shown at the bottom of Fig. 8-10. A few small areas of oxides were usually present also. The appearance of discharged electrodes and the gradual changes that occur with cycling will be discussed in detail in the next paper in this series.

Discussion

When the 20-hr rate of discharge was used, it has already been shown that the Ag particles which formed during this slow reduction were larger than the Ag particles originally present in an unused electrode (1). This increase in particle size was the cause of the rapid capacity decrease when slow discharges were used (compare D and E in Fig. 1) because the large Ag particles that had formed did not oxidize completely during charges. When the 1-hr rate of discharge was used, however, most of the Ag particles that formed were smaller than those originally present. Since these small particles oxidized readily during charges, the capacity did not decrease nearly as rapidly when the 1-hr discharge rate was used as when the 20-hr rate was used.

During a discharge, the first Ag_2O was usually formed at the AgO-electrolyte interface and was not formed using as nuclei the Ag_2O that separated Ag particles from AgO (Fig. 3, 5, and 6). The Ag_2O formed an uneven coating on the surfaces of AgO clumps, and penetrated at some points. This penetrating formation resembled the way that Ag_2O formed on Ag during a charge. Since 11% of the capacity had been removed from the electrode shown in Fig. 5 and 6, and this capacity all came from the reduction of AgO, over 22% of the AgO present at the end of the previous charge had been reduced to Ag_2O. The exact amount of AgO that had been reduced is uncertain, because a small part of the capacity of the charged electrode was present as Ag_2O. Judging by the photographs, the surface of all AgO clumps was covered with Ag_2O before discharge potential reached the Ag_2O/Ag plateau. When the discharge was interrupted to cut the electrode sample shown in Fig. 5 and 6, the open-circuit potential rose rapidly and reached the AgO/Ag_2O potential in 1.5 min, which was not surprising considering the large amount of AgO that remained.

Comparison showed many differences between electrodes that were discharged at the 1-hr rate until potential reached the Ag_2O/Ag plateau and electrodes discharged to the same plateau at the 20-hr rate. When the 20-hr discharge rate was used, approximately 30% of the electrode capacity was removed by the time that the Ag_2O/Ag plateau was reached, a value 3 to 5 times greater than the capacity removed when the 1-hr rate was used. As a result, much more Ag_2O was present in an electrode that was discharged slowly to the Ag_2O/Ag plateau, and areas where AgO predominated were relatively uncommon. In an electrode discharged at the 20-hr rate, in contrast to an electrode discharged at the 1-hr rate, the Ag_2O layer which separated Ag particles from AgO had thickened during a partial discharge, and Ag_2O (presumably newly formed) was present within AgO areas. The Ag_2O that was formed during a discharge at the 1-hr rate retained more of the angular shape of AgO clumps than did the Ag_2O formed at the 20-hr rate.

Although most of a discharge at the 1-hr rate took place at the Ag_2O/Ag potential plateau (Fig. 1), much AgO remained in electrodes until potential fell at the end of a discharge. Examples of this AgO were shown in Fig. 8 and 10 for an electrode discharged 50%, and in Fig. 3 and 4 for an electrode discharged over 90%. A few small patches of AgO and Ag_2O could usually be found in an electrode even after a discharge at the 1-hr rate reached the endpoint of —500 mv *vs.* the Ag/Ag_2O reference electrode. At the 20-hr discharge rate the AgO was reduced more readily, with the result that only a small amount of AgO remained by the time that a discharge was two-thirds completed. At the end of a discharge to —300 mv at the 20-hr rate it was unusual to find any AgO or Ag_2O remaining. This difference in the amount of oxide remaining at the end of a discharge was the reason for cycle 1 of an electrode giving a smaller capacity when the discharge was done at the 1-hr rate than when done at the 20-hr rate. Figures 4 and 10 show that a solid AgO clump at the end of a charge becomes a clump of Ag particles at the end of a discharge and that the Ag particles in a discharged electrode occupied less volume than the oxides.

Not only the size of Ag but also the distribution of Ag in the electrode varied with discharge current density. When an electrode was discharged part way along the Ag_2O/Ag potential plateau at approximately the 20-hr rate, some Ag had formed and some oxide remained in areas throughout the electrode, although a little more Ag was found near the surface. In contrast, during the first half of a discharge at the 1-hr rate the Ag started forming at the surface of the electrode and none was formed in the interior (Fig. 7). The width of oxide in the center of the elec-

trode shown in Fig. 7 approximately equalled the sum of the widths of areas without oxide on the surface of this electrode, confirming that the discharge was approximately 50% complete. The Ag had not formed preferentially at the Ag grid, although the grid was connected directly to the electrical leads. Conductivity, therefore, was not the factor that determined in which areas Ag would form. Diffusion in the electrolyte was probably the controlling factor. The formation of Ag_2O from AgO must occur by a different mechanism because Ag_2O areas were formed at scattered sites throughout the electrode. The reduction of AgO seems to have stopped temporarily in the central areas of an electrode after Ag began to form on the surface. The reduction reaction was then concentrated near the surfaces, moving inward after oxide nearer the surface was reduced to Ag. Since AgO areas, such as are shown in Fig. 8 and 10, were commonly found next to Ag areas while Ag_2O areas were less common (Fig. 9), probably Ag_2O areas were reduced preferentially to Ag and the formation of Ag stopped temporarily when AgO regions were reached.

Summary

Sintered Ag electrodes, that had been manufactured commercially for use in Ag-Zn storage batteries, were charged at the 20-hr rate and discharged at the 1-hr rate in 35% KOH solution at 25°C. Samples were cut from an electrode at various times and cross sections were prepared for microscopic examination.

Ag_2O was formed on the surface of AgO clumps during the early part of a discharge. The Ag_2O formation took place at many areas scattered throughout an electrode. Some AgO clumps were completely or almost completely reduced to Ag_2O, while others were only reduced on their surfaces. Discharge potential fell to the Ag_2O/Ag plateau after a coating of Ag_2O had formed on the surface of all AgO clumps. AgO was reduced much less readily at the 1-hr rate than at the 20-hr rate. Comparing discharges at the 1-hr and 20-hr rates, during the more rapid discharge the potential fell to the Ag_2O/Ag plateau after less capacity had been withdrawn from the electrode, the proportion of AgO present in an electrode discharged beyond this point was greater, and noticeable amounts of AgO remained at the end of a discharge.

Ag began to form after discharge potential fell to the Ag_2O/Ag plateau. In contrast to the formation of Ag_2O at scattered sites, Ag formed first on the surface of an electrode when the 1-hr discharge rate was used and then gradually spread from the surface to the interior. During a discharge at the 20-hr rate Ag formed at both the surface and the interior, with a slight preference being shown for areas at or near the surface. The formation of Ag must be limited by a different step in the mechanism than is the formation of Ag_2O during discharge.

Influence of Oxygen Pressure on the Oxidation Kinetics of Copper in Dry Air at Room Temperature

P. K. Krishnamoorthy and S. C. Sircar

Metallurgical Engineering Department, Indian Institute of Technology, Kharagpur, India

ABSTRACT

The effect of oxygen pressure in the range of 0.01-0.21 atm O_2 pressure on the oxidation behavior of annealed copper at room temperature was investigated. The results have been analyzed with reference to the Cabrera-Mott theory of growth of very thin oxide films on metals. The alteration in the rate of oxidation has been explained on the basis of the cationic vacancy concentration of the oxide, as it is well established that the oxygen pressure on a p-type oxide semiconductor surface has an influence on the cationic vacancy concentration of the semiconductor. A correlation of rate constant with pressure has been obtained which is in conformity with the theoretical treatment of the kinetics by Grimley and Trapnell assuming the destruction of cation vacancies at the metal oxide interface to be the rate controlling step.

It is well known that the oxygen pressure exerts a great influence on the vacancy concentration of p-type semiconductor oxides. Hence it is expected that the pressure should exert an effect on the oxidation kinetics of copper at low temperatures as the cuprous oxide is a metal deficit one. In the thin film range, *i.e.*, at temperatures above 60°C, where the logarithmic, cubic, and parabolic laws are obeyed, a pressure dependent rate has been observed by William and Hayfield (1), Lustman and Mehl (2), etc. At low temperatures, of the order of room temperature, Germer and White (3) found that the rate of oxidation at 4 and 20 mm mercury of oxygen pressure were identical. But Jennings and Stone (4) and Lanyon and Trapnell (5) observed the rates to be pressure dependent.

The present work was taken up to cover the pressure effect in the very thin film range where Cabrera and Mott's (6) inverse logarithmic law leading to a limiting thickness is obeyed. The influence of an applied field, addition of lithium, and cold working were first investigated and have been reported earlier (7-10). These studies have established quantitatively the validity of Mott's theory, and the influence of pressure was then taken up to confirm the hypothesis further.

Experimental Details

The material used contained 0.23% nickel and 0.003% silver. The specimens used were in the form of sheets 2.5 x 1 x 0.05 cm with a hole of 1 mm diameter drilled at one end for hanging purposes. All speci-

mens were thoroughly annealed at 600°C for 2 hr before exposure. Surface preparation was done first by mechanically polishing on emery papers followed by electropolishing in phosphoric acid bath under conditions suggested by Allen (11). To overcome any surface contamination by any phosphate or oxide film the specimens were cathodized in a NaH_2PO_4 and Na_2HPO_4 buffer solution at a current density of 50-100 $\mu A/cm^2$ for a few seconds. They were then thoroughly cleaned and dried in acetone before exposure. The surface obtained was reproducible. The initial air-formed film, before exposure, was the same in all the cases and was small.

Oxidation was carried out at five different pressures, *viz.*, 0.0135, 0.027, 0.068, 0.1227, and 0.21 atm O_2 partial pressure. Different pressures were obtained by first hanging the specimen in a chamber containing silica gel (for drying the air inside) provided with arrangements for evacuation. The chamber was evacuated to a pressure of a few mm of mercury, and then a controlled amount of air was admitted to the system until the desired pressure was reached. The system was quite leak proof. The fall in mercury level even during long exposures was of the order of 1-2 mm only. Only one specimen was used at a time for a particular exposure.

The thickness estimations were done electrometrically by cathodic reduction in a NaH_2PO_4-Na_2HPO_4 buffer solution at a current density of 5 $\mu A/cm^2$. This was done in a setup designed for the purpose similar to that of Mills and Evans (12) with arrangement for evacuation under reduced pressures. An accuracy of $\pm$ 1 Å could be achieved.

Results and Discussions

Results are discussed with reference to the Cabrera-Mott (6) theory of growth of very thin oxide films on metals at low temperatures. They derived their equation by considering the process as follows:

1. Adsorption of oxygen on oxide surface.
2. Ionization of this by capture of electrons from the metal by the quantum mechanical tunnel effect.
3. Creation of cationic vacancies at the oxide/gas interface.
4. Subsequent migration of cations under the action of the electric field set up or, in other words, the migration of cationic vacancies toward the metal/oxide interface.
5. Destruction of these vacancies at the metal/oxide interface.

On the above basis they arrived at an equation of the form

$$\frac{dx}{dt} = K \exp\left(\frac{x_1}{x}\right) \qquad [1]$$

where

$$K = N\Omega\nu \exp\ (-W/kT)$$

and

$$x_1 = \frac{1}{2}\frac{qa}{kT} \cdot V$$

x being the thickness at time t, where the different quantities have the usual significance.

The equation may be rewritten in the form

$$\log\frac{dx}{dt} = \log K + x_1/2.3x \qquad [2]$$

so that a plot of log dx/dt *vs.* $1/x$ should yield a straight line.

The results of oxidation at different pressures are presented in Fig. 1. The log dx/dt *vs.* $1/x$ plot computed by taking the slopes of the curve at different thickness values is shown in Fig. 2. The straight line plot of these seems to obey Mott's equation quantitatively.

Further, the parallelism of these plots indicates that the x_1 term is independent of pressure, or in other words V, the potential difference between the metal/oxide and the oxide/gas interface, stays constant as the other terms in x_1 are constants at a fixed temperature. For the atmospheric pressure case calculations have shown earlier (10) that the V term, and the K term calculated on the basis of slope and intercept on dx/dt axis, respectively, are of the same value as predicted theoretically by Mott (6).

From the plots shown in Fig. 2, it can be concluded that pressure mainly affects the N term (or K term, W being constant at a fixed temperature). This value has been computed at the different pressures and is shown in Table I. The next step, hence, was to find the nature of variation of N with pressure. For this let $K \propto p^n$, where p = partial pressure of oxygen in the system and n = constant.

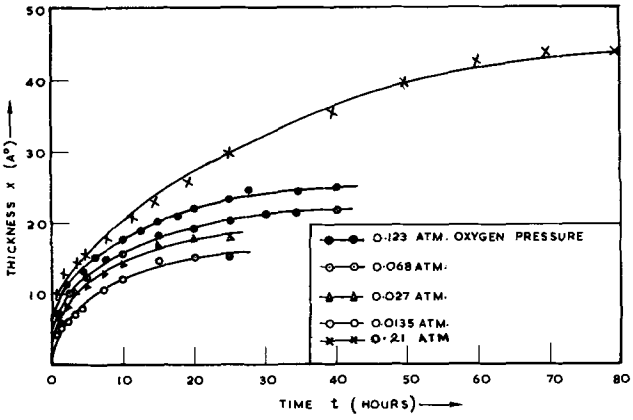

Fig. 1. Oxidation at 30°C at different oxygen pressures

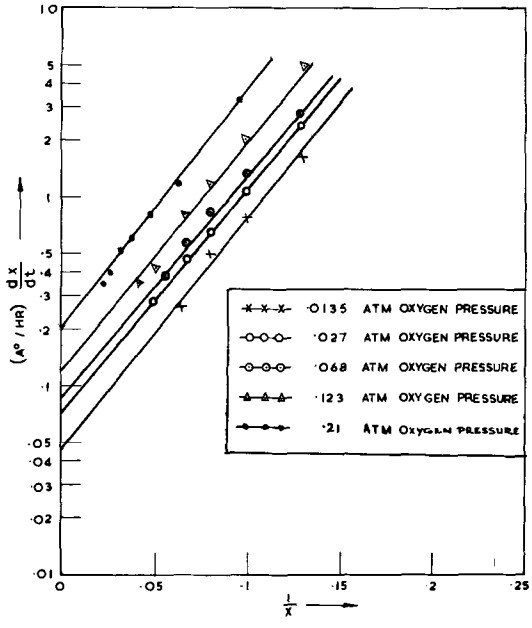

Fig. 2. Effect of oxygen pressures on oxidation at 30°C. Log $\frac{dx}{dt}$ *vs.* $\frac{1}{x}$ plot.

Table I. Variation of N (concentration of cation vacancies in the oxide) with oxygen pressure

Partial pressure of oxygen—p atm	K, A/hr.	$N\Omega\nu$, A/hr.	N, No./cm²
0.0135	0.045	0.2×10^{16}	0.32×10^{15}
0.027	0.07	0.316×10^{16}	0.51×10^{15}
0.068	0.085	0.38×10^{16}	0.608×10^{15}
0.123	0.12	0.55×10^{16}	0.88×10^{15}
0.21	0.20	0.632×10^{16}	1.01×10^{15}

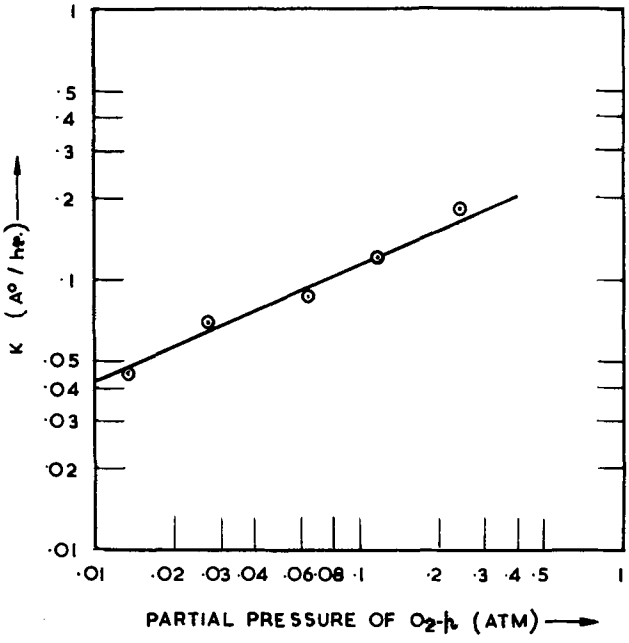

Fig. 3. Log K *vs.* log p plot at 30°C

Hence a plot of log K *vs.* log p should be a straight line with n = slope. This plot is shown in Fig. 3. The curve shows that $n = 0.3$ or $K \propto p^{1/3-1/4}$.

The term N according to Mott and Cabrera is the number of ions/unit area of the oxide ready to migrate or, in other words, the concentration of mobile species/unit area of the oxide. This can be taken equal to the cationic vacancy concentration according to Hauffe (13) that the diffusion in case of defect structures is actuated essentially by the vacancies. This has been further confirmed by the influence of addition of a little lithium to the metal which was found to block the vacancies and thus retard the rate (8).

The observed relationship can be arrived at theoretically by considering Mott's kinetics as has been done by Trapnell and Grimley (14). For very thin films they have formulated two equations for a p-type semiconductor oxide growth based on two different assumptions. According to them, if the rate-controlling step is the destruction of cation vacancies at the metal/oxide interface, then they replace the N term of Mott's equation by a new term involving the concentration of vacancies and a pressure$^{1/4}$ term, whereas if the rate-controlling step is the formation of vacancies at the oxide/gas interface, they have not included any pressure term but define N as the number of adsorption sites/unit area of the oxide surface, which is obviously dependent on pressure to the saturation value. Close observation of Grimley and Trapnell's (14) equation indicates that it is same as Mott's (6) equation with better significance of the parameters V and W. For example, the $\Delta\mu_0$ term in Grimley's equation, *i.e.*, the free energy change of the reaction forming the cationic vacancies at the oxide/gas interface is equivalent to the Wi term, *viz.*, the energy of solution of an ion in the oxide. Again this treatment shows that even though Mott has not specifically talked of pressure effect, the N term obviously includes this.

Rhodin (15) mentioned that in the thin and very thin film range the process is rather insensitive to pressure. This is presumably because he has worked in the pressure range beyond the saturation value (since adsorption dependence on pressure shows a saturation) or because that in the high-pressure range, as the rate is dependent on one-fourth power of pressure, it may be difficult to detect the effect.

The increase in the value of N with pressure is in conformity with the well-known fact that increase in oxygen pressure on a p-type semiconductor oxide surface tends to increase the vacancy concentration of the oxide.

The value of the power n (0.3) is slightly higher than 0.25. This probably shows that, in the pressure range studied, the surface is not fully saturated with oxygen ions and some of them may be present as (O^-/ads) and majority as (O_2^-/ads). At the moment, since the exact nature of the adsorbing species is not well established, the above explanation probably accounts for the deviation in the value of n from 0.25.

The present study also confirms the importance of the interface reaction rate-determining step for very thin film growth as suggested by Grimley and Trapnell (14), Hauffe (13) etc.

Acknowledgment

The authors are grateful to Professor P. R. Dhar, Head, Department of Metallurgical Engineering, Indian Institute of Technology, Kharagpur, for his keen interest and lively discussions.

Manuscript submitted Sept. 19, 1968; revised manuscript received *ca.* Feb. 17, 1969. This paper is part of a Ph.D. thesis submitted by one of the authors (P.K.K.) to the Indian Institute of Technology.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

ABSTRACT

The dissolution processes involved in the formation of porous films in sulfuric acid have been studied by suddenly lowering the formation voltage and observing changes in the current flowing and the barrier layer capacitance as steady-state conditions are re-established. It was found that current changes always follow capacitance changes, and that the dissolution processes involved are (*a*) initially a short time region of chemical dissolution is found up to some point where the minimum electric field strength required for ionic migration is approached, and (*b*) a second stage dissolution assisted by the presence of this electric field. The change from one dissolution rate to the other is continuous as this minimum electric field is approached. On the basis of the Keller model, the required pore base orientation is proposed to occur during the second stage field-assisted process.

The structure of porous anodic oxide films on aluminum has been investigated for many years, the results of which have produced essentially two main proposals: (a) the classical structure of the cylindrical pore proposed by Keller *et al.* (1), this cylindrical pore generally being regarded as being an ideal structure. Proposed variations have included the truncated cone-shaped pore (2), the slanting pore axis (3), twisting and distortion of the pores (4), and the fibrous (5) rather than the regular porous structure. The second model (b) was proposed by Murphy and Michelson (6, 7) in which the structure is seen as a combination of submicrocrystallites of alumina and hydrated alumina, the ratio of the latter to the former increasing as the distance from the metal surface increases (this model has been described as the triple layer model consisting essentially of layers of low, moderate, and high degree of hydration moving from metal outwards).

Model (b), however, lacks the presence of discrete pores, unlike the Keller model (1), and consequently lacks experimental verification since the presence of pores appears to be well established, especially from the excellent photographs of Wood, O'Sullivan, and Vaszko (8). Despite the apparent validity of the Keller model, several phenomena associated with the behavior of porous films have yet to be explained satisfactorily. This paper is concerned with one of these phenomena, *i.e.*, the behavior of the porous films when the anodizing steady-state conditions are changed, particularly when the voltage of formation is reduced.

Since the dimensions of the Keller model are controlled largely by the voltage of formation (the oxide cell size increasing with increasing voltage), changes in the voltage during anodizing would seemingly require a re-orientation of the film dimensions, *i.e.*, as the voltage is reduced new pores should be initiated and the oxide cell size should decrease. Some evidence has been presented to show that this re-orientation takes place (8). The role played by the barrier layer during this re-orientation process is, as yet, uncertain, and it is with this specific problem that this paper is concerned.

From a study of this voltage decrease phenomenon, Michelson (9) has shown that, initially, the processes involved do not produce any significant changes in barrier layer capacitance before substantial current begins to flow. This, it was argued, indicated the barrier layer re-orientation was initially a matter of proton space charge rearrangement (which produces no capacitance change); only later did dissolution occur and, therefore, produce changes in current. It was concluded that the Keller model was incapable of accounting for these experimental observations, which were in agreement with the triple layer model. However, the center of the argument lies in the observation that no barrier layer capacitance, *i.e.*, the thickness, changes were observed before the current began to increase. In the present study, the authors have examined the voltage decrease phenomenon by measuring the rate of reattainment of steady-state thickness for the barrier layer, and the rate of reattainment of the steady-state current density, as functions of the voltage decrease increment and the recovery temperature of the electrolyte.

Experimental

A suitable length of 99.98% superpurity grade fully annealed aluminum in the form of ⅛ in. diameter wire was chemically polished in a solution containing 125 ml concentrated sulfuric acid, 350 ml orthophosphoric acid, and 25 ml concentrated nitric acid at 90°-95°C for 5 min [this time being chosen as that necessary to produce a reproducible surface finish (15)]. Following this treatment, the specimen was washed in distilled water for 1 min, rinsed in acetone and air-blown dry and immediately immersed in 15% w/w sulfuric acid in a cell thermostated at the required temperature. Anodizing was performed by applying the required voltage of formation between the specimen anode and a large area aluminum cathode. Capacitance values were obtained by applying a 100 Hz

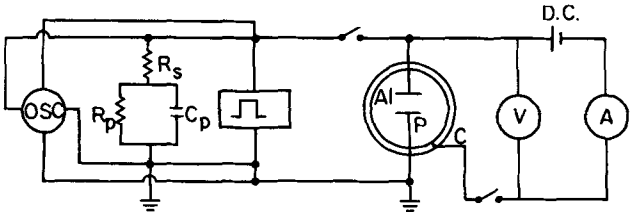

Fig. 1. Circuit, cell and analogue circuit used in this study. Al, aluminum anode; P, platinum gauze subsidiary electrode; C, aluminum cathode; D.C. is stabilized voltage supply, A, a micro-milliammeter, and V is a voltmeter measuring cell voltage.

square wave signal (amplitude < 5 mv) to the test anode and a reference capacitance electrode (25 times the test area platinum gauze electrode) and to an R-C parallel analogue (10) circuit simultaneously. The responses of the two systems were displayed on a twin beam oscilloscope, and a balance obtained by selecting the correct values of R_s, R_p, and C_p (see Fig. 1). The values of R_p and C_p are then taken as being representative of the resistance and capacitance of the barrier layer lying adjacent to the metal surface (after Hoar and Wood) (11).

Following the immersion of the specimen in the 15% w/w sulfuric acid, the capacitance value increased to a constant value (10 μf cm^{-2}). A formation voltage of 5v was then applied from a constant d-c stabilized voltage supply and steady state was allowed to be attained. C_p and the current i, were then measured and noted. The formation voltage was then increased to either 10 or 15v, and steady-state conditions were again allowed to be attained. Following this, the formation voltage was reduced to 5v, and the reattainment of the 5-volt values of C_p and i were observed with respect to time. This procedure was repeated for the 15 to 5v and the 10 to 5v reductions as a function of electrolyte temperature and the mode of change of the formation voltage; the effect of the voltage change mode was studied on a single electrode, and the effect of voltage reduction increment on separate electrodes.

Results

As observed previously by Michelson (9) the rate of reattainment of the 5v values of C_p and i from either the 15 or 10v voltage was strongly dependent on the mode of voltage change; this, itself, suggests some field-assisted dissolution process is involved in the dissolution processes being studied. Consequently, two modes of voltage change were adopted:

(*a*) A relatively slow change in voltage, the current density being maintained above an arbitrary minimum of 1 ma cm^{-2}, *i.e.*, the current flowing was maintained at ionic magnitudes and hence the electric field was maintained about the minimum field required for ionic motion (*ca.* 7.2 $\times$ 10^6 v-cm^{-1}).

(*b*) An instantaneous decrease in voltage in order to induce a large instantaneous decrease in the field strength. The current decreases suddenly to those values typical of electronic magnitude, and hence further oxide growth ceases.

Table I shows the times required for the reattainment of the steady-state cell current and capacitance values for 5v for the voltage change 10 to 5v, as a function of the sulfuric acid electrolyte temperature and the voltage mode of change.

Table II shows the same times for the 10 to 5v compared with times for a 15 to 5v change, employing voltage change mode (b) in each case.

Figure 2 shows the behavior of the cell current with respect to time, during the reattainment process for the voltage change 10-5v employing voltage change mode (b), as a function of electrolyte temperature. Figure 3 shows the change in the cell current correlated to the changes in capacitance for the 10 to 5v change employing voltage change mode (b) at 26°C. This figure clearly shows that a substantial change in capacitance does occur before an appreciable current increase is observed, in exact opposition to that reported by Michelson.

Table I. Reattainment times for the voltage decrease 10-5v as a function of electrolyte temperature and voltage mode of change

Voltage change, v	Electrolyte temperature, °C	Reattainment time, sec, employing the voltage change mode (a)	(b)
10-5	26	45	1080
	35	22	600
	45.5	9	150

Table II. Comparison of the reattainment times for the two voltage changes 10-5v and 15-5v using voltage change mode (b) as a function of electrolyte temperature

Voltage change, v	Electrolyte temperature, °C	Reattainment time, sec, employing voltage change mode (b)
10-5	26	1080
	35	600
15-5	26	3840
	35	1620

Figure 4 illustrates the corrrelation of current and capacitance changes for the two voltage changes 15-5v and 10-5v employing voltage change mode (b) at 35°C electrolyte temperature; the conclusion concerning which parameter changes first, current or capacitance, obtained from Fig. 3, is confirmed in this figure.

Discussion

It would appear from Table II, when comparing the reattainment times required for the 10 to 5v and 15 to 5v changes that, whatever the mechanism of barrier layer dissolution, it does not seem chemical in nature. However, this conclusion is not new. Novakovsky (12, 13) first in a general discussion of passivity and then in a mechanistic study of the passivation of iron has indicated that the film theory of passivity taken with a chemical dissolution process is untenable with the known facts concerning passivating oxide phenomena. Engell (14) has reported that the dissolution of oxides can be strongly potential dependent, *e.g.*, the dissolution rate of oxides of iron falls exponen-

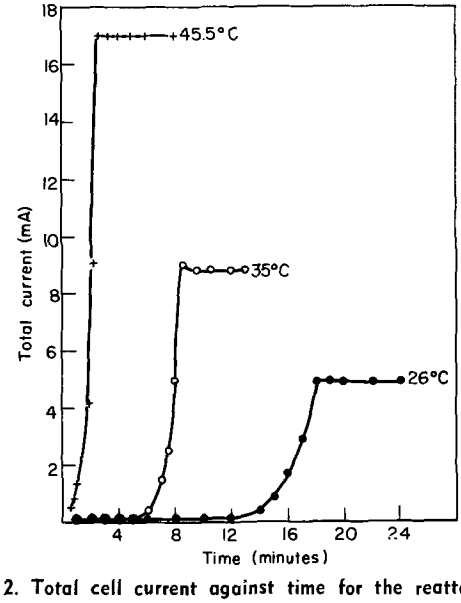

Fig. 2. Total cell current against time for the reattainment of steady-state anodizing conditions for the 10 to 5v change employing voltage change mode (b), as a function of the electrolyte temperature.

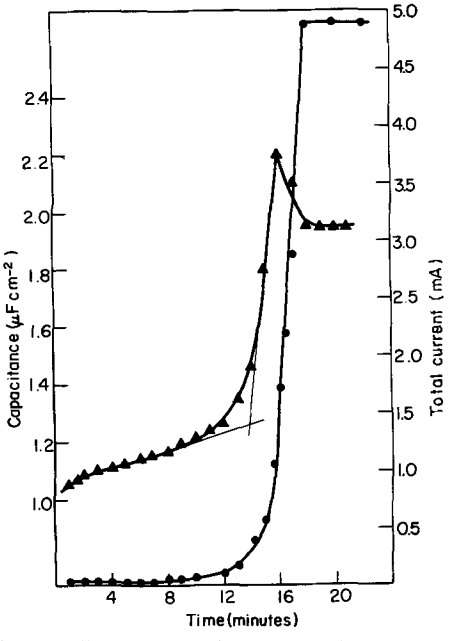

Fig. 3. Total cell current (circles) and barrier layer capacitance (triangles) changes following the voltage reduction 10 to 5v employing voltage change (b) at 26°C electrolyte temperature.

tially with increasingly positive potentials. Engell concluded from this that anions, in the oxide lattice, leave the lattice more easily than cations.

If purely chemical dissolution of the barrier layer were involved, and assuming that such dissolution follows zero order kinetics, as has been previously reported (15), then the time of dissolution of 100Å would be double that required for 50Å. However, Table II shows that 100Å required 3.6 times that required for the 50Å dissolution. Figures 3 and 4, which effectively show the change in barrier layer thickness with time, indicate that the rate of dissolution undergoes a sharp increase following a linear C-t change. This may indicate that the nature of the dissolution process changes during the course of dissolution, and consequently a time-basis comparison with purely chemical kinetics would be invalid (Table IV).

Table I provides further apparent evidence that simple chemical dissolution is not involved. When the electric field is maintained above the minimum field required for ionic motion, the reattainment times are between 15 and 25 times less than that required when the field is instantaneously decreased to below the minimum field. Nagayama and Tamura (16) have deduced that the temperature increase due to local Joule heating, in the presence of current flow, is very small (< 1°C) and therefore it can be concluded that the presence of a passage of current cannot account for the wide difference in the dissolution times between voltage change modes (a) and (b).

The influence of the electrolyte temperature can also be seen from Table I as being in the ratio 5:2.5:1 for increasing temperature with voltage change mode (a), and 7:4:1 for increasing temperature with voltage change mode (b). These ratios can be compared with work reported by Hunter and Fowle (17) in which the dissolution action of 15% w/w sulfuric acid was doubled for every 8.5°C rise in temperature, and increased fivefold by a 10°-20°C rise in temperature.

Michelson (9) has proposed the barrier layer dissolution to be the result of the passage of current, and not the cause of the passage of current; however, Fig. 2 and 3 clearly show that initially the capacitance increases rapidly, this rapid increase being followed by an appreciable linear region of increase which, in turn, is followed by a second very rapid increase leading to capacitance overshoot. The greatest change in capacitance and the capacitance overshoot occurs approximately at the point at which the greatest change in the current occurs; this is to be expected if the current is the result of barrier layer dissolution.

If the barrier layer has to dissolve to a thickness which corresponds to the presence of the minimum field required for ionic motion before any appreciable current increase can occur, can one calculate this thickness and perhaps obtain proof of this statement from Fig. 3 and 4? From Table I it was concluded that the presence of a field, in excess of the minimum field, produced a 15-25 times increase in the dissolution rate; therefore, as the field increases from an instantaneously low field to the minimum field, appreciable changes in the dissolution rate should occur and this should be reflected by a rapid change in capacitance at some point. Figures 3 and 4 show this to be true; extrapolation of the linear region to the intersection of the extrapolation of the rapid increase slope produces the capacitance value, at which this minimum field is established, of 1.25 μf cm^{-2} for the three cases reproduced here.

A simple calculation shows that, if the minimum field is assumed as 7.2×10^6 v-cm^{-1}, the thickness of barrier film across which 5v is applied will be 70Å when this minimum field is achieved. The capacitance value of this 70Å film is assumed to be given by the parallel-plate condenser equation, *i.e.*, $\epsilon A/4\pi d$, where ϵ is the dielectric constant [assumed as 10 from the work of Hoar and Wood (11) and Vermilyea (18)], A is the barrier layer surface area [assumed as equal to the metal surface area and not the pore base area, following Dekker and Urquhart (19)], and where d = 70Å. Calculation shows the capacitance to be equal to 1.26 μf cm^{-2}, in excellent agreement with the experimental value.

Therefore, it would appear that the minimum electric field is present at the point the current begins to increase above ionic magnitudes; prior to this point substantial changes in the barrier layer thickness do occur, being the greater the higher the initial voltage of formation.

Table III shows an analysis of the reattainment times from Fig. 3 and 4. The time required up to the minimum field is dependent on the thickness that has to be dissolved, and on the electrolyte temperature for any one voltage change. The dissolution rates above and below the minimum field can now be calculated (Table IV). The dissolution time above the minimum field was corrected for time spent in, and recovering from, barrier layer thickness overshoot.

Table III. Reattainment times from Table II divided into the time spent above and below the minimum electric field strength required for ionic migration

Voltage change, v	Electrolyte temperature, °C	Reattainment time, sec Below minimum field	Above minimum field
10-5	26	840	240
	35	270	330
15-5	35	1080	540

Table IV. Mean dissolution rates calculated above and below the minimum field

Voltage change, v	Electrolyte temperature, °C	Dissolution rate, A min^{-1} Below minimum field: Time averaged	Below minimum field: From linear C-t section	Above minimum field
10-5	26	2.2	1.1	20.0
	35	6.7	3.1	40.0
15-5	35	4.4	1.8	10.0

Prior to the attainment of the minimum electric field, the dissolution rate is a function of temperature and appears to be a function of the voltage change at the temperature of 35°C, being the smaller the greater the voltage decrease to 5v involved, *i.e.*, the lower the instantaneous new field at 5v. However, the rates reported in Table IV, prior to the attainment of the minimum field required for ionic migration, are strictly mean values calculated over the time required to reach this point, and thus may be invalid, as mentioned earlier. Figures 3 and 4 show that initially the capacitance changes rapidly, then is relatively linear for a short while, then changing rapidly finally to produce the overshoot. This observation indicates that a time-averaged dissolution rate is invalid. Applying the equations from an earlier paper (15) to the initial capacitance changes, the rates of dissolution derived from 1/C-time plots were calculated (column 4, Table IV). Values obtained at 25° and 35°C can be compared with the values of 1 and 2Å min^{-1}, respectively, previously reported (15, 17) for dissolution of alumina films in sulfuric acid. Thus, although the first indications were that chemical dissolution was not involved in these steady-state reattainment processes, on closer examination there would appear to be a chemical dissolution process for a short interval below the minimum field. As the minimum field is approached, the dissolution rate increases progressively in an exponential manner, *i.e.*, dissolution rate is field-assisted approaching and exceeding the minimum field. The exponential nature of the increasing dissolution rate, and the fact that when the barrier layer reaches 50Å, insufficient oxide is being produced to balance dissolution, capacitance overshoot occurs. The formation rate of the oxide, *i.e.*, the current, continues to increase, and, at some point during overshoot, exceeds the dissolution rate, thereby producing a decrease in barrier layer capacitance. Finally, balance between the oxide formation rate and the dissolution rate is attained; thus, the barrier layer capacitance remains constant.

Conclusions

The dissolution processes occurring at barrier layer surfaces, following voltage reductions, are seen as processes in which current changes follow capacitance changes, *i.e.*, the opposite to that reported previously (9). The nature of the dissolution process is seen as essentially chemical (apart from some initial unexplained phenomenon) for a short period up to a point where the minimum electric field for ionic migration is approached; following this, dissolution increases exponentially and is seen as a field-assisted process. It is during this latter period that reorientation of the pore base structure is considered to occur. Since this period is not totally taken up with barrier layer dissolution, but with the regrowth of barrier layer following overshoot during dissolution, reorientation of the pore base structure is seen as a process requiring a few minutes when the minimum electric field is achieved (the greater this reorientation, the longer the time that is required).

This evidence concerning the processes which occur when voltage reductions are performed during anodizing can, it is considered, be explained most easily in terms of a model derived from the "ideal" Keller model (1), or one of its derivatives (2). It is further suggested that the capacitance overshoot and the barrier layer regrowth serve to demonstrate the "dynamic equilibrium:" which exists between barrier oxide formation and the ensuing dissolution processes leading to a conversion of barrier to porous oxide. Whenever these two processes, *i.e.*, formation and dissolution, are in nonequilibrium, some phenomenon will occur in an attempt to regain the "equilibrium," *e.g.*, reduction of voltage reduces the formation to a negligible level, and, therefore, the dissolution will predominate (the barrier layer will become thinner) until an "equilibrium" is achieved.

Analysis of Gold Foils and Electroplating Solutions for Metallic and Anionic Impurities

H. Graham Silver[1]

Bell Telephone Laboratories, Inc., Reading, Pennsylvania

ABSTRACT

A comparison made between an "acid" citrate gold electroplating solution and an alkaline free potassium cyanide-containing gold electroplating solution demonstrates that both are susceptible to metallic impurity contamination. However, except for silver which is also codeposited from the alkaline electroplating solution, only the acid solution readily releases these impurities to codeposit with the gold. The alkaline solution, on the other hand, immediately becomes contaminated with anionic impurities, such as the formate and carbonate ions, which rapidly build up to a high concentration.

Potassium gold cyanide electroplating solutions containing free KCN are subject to contamination not only by $H.COO^-$ and $CO_3^=$ anionic impurities (1), but also by a brown polymeric material (2) of formula $[HCN]_4$. This polymer is generated at a soluble gold anode when the *p*H in its vicinity is reduced on the occasional anodic evolution of oxygen. The polymer codeposits with the gold, discoloring the latter, and is the agent responsible for the major proportion of the gaseous impurities evolved from the gold deposit on subsequent heating (3). However, gold deposits obtained from electroplating solutions containing no free KCN, for example, the dibasic ammonium citrate/$KAu(CN)_2$ electroplating solution, contain only low levels of gaseous impurities.

It is widely known that, even with careful periodic maintenance, the extended use of all types of $KAu(CN)_2$ electroplating solutions (4, 5) often results in a deterioration of the color, purity, and other physical properties of the gold deposit. Thus, it was deemed instructive to observe and directly compare the increase in metallic and anionic contaminants, by suitable analysis, in heavily used dibasic ammonium citrate/$KAu(CN)_2$ and KCN/$KAu(CN)_2$ electroplating solutions and in the gold foils obtained therefrom. The choice of these particular electroplating solutions was made owing to their immediate availability and the fact that the former solution, as opposed to the latter solution, did not contain free KCN and was operated at a *p*H below 7.

Experimental

A gold foil was plated on a stainless steel substrate[2] from a dibasic ammonium citrate/$KAu(CN)_2$ electroplating solution of formulation (6)

(68% min Au)	$KAu(CN)_2$	20 g/l	± 0.1 g/l
dibasic ammonium citrate		50 g/l	± 0.1 g/l
	*p*H	5.5	
Anodes	Platinized titanium (insoluble)		

which had been used steadily for a period of about six months with periodic maintenance. The foil was analyzed by emission spectroscopy for metallic impurities. Two 50-ml samples of the electroplating solution were withdrawn, one of which was analyzed for total metallic impurities by emission spectroscopy, while the other was analyzed for the following components: (*a*) Free CN^-; (*b*) $CO_3^=$; (*c*) *p*H; (*d*) CNO^-; (*e*) $H.COO^-$ formate; (*f*) $C_2O_4^=$ oxalate; (*g*) $CO(NH_2)_2$ urea.

Key words: electrodeposition, gold electroplating, metallic impurities, anionic impurities.

[1] Present address: General Telephone & Electronics Laboratories Incorporated, Bayside, New York.

[2] All stainless steel substrates, used for this purpose in this experiment, were degreased in the vapor of boiling trichloroethylene for 5 min, immersed in acetone for 15 min, acid-cleaned in hot 1:1 HCl for 1 min, and finally rinsed in deionized water.

A gold foil was plated on a stainless steel substrate from a KCN/$KAu(CN)_2$ electroplating solution of formulation:

(68% min. Au)	$KAu(CN)_2$	9 g/l	± 0.1 g/l
	KCN	45 g/l	± 0.1 g/l
	KOH	3 g/l	± 0.1 g/l
	*p*H	13	
Anodes		Gold (99.99%)	

which had been used continually for a period of about six weeks with periodic maintenance. The foil was analyzed by emission spectroscopy for metallic impurities. In the same manner as above, two 50-ml samples of the electroplating solution were withdrawn and analyzed for total metallic, anionic, and organic impurities.

Finally, in order to act as a reference point, two solid samples of $KAu(CN)_2$, one obtained from Engelhard Industries, 68.31% gold, and one obtained from Technic Inc., 68.2% gold, were analyzed for the following components, (*a*) metallic impurities, (*b*) free CN^- ion, and (*c*) $H.COO^-$ ion.

Results and Discussion

A comparison of the metallic and anionic impurities present in the two solid samples of $KAu(CN)_2$ is shown in Tables I and II.

The results indicate that both the Engelhard and Technic $KAu(CN)_2$ salts have a somewhat high level of silver contamination, which is rather to be expected, owing to the close chemical similarity between silver and gold. However, compared with the results reported below for the heavily used electroplating solutions, the concentration of other metallic impurities and anionic contaminants in the $KAu(CN)_2$ salts is indeed very low and may be considered negligible for most electroplating purposes. This is also true for the metallic impurities present in the soluble gold anodes (99.99%) used in the KCN/$KAu(CN)_2$ electroplating solution.

Table I. Comparison of metallic impurities

Metallic impurity	Fe	Cu	Ag	Si	Pb	Pd	Al	Mg	Ca

g/l	0.6	0.4	0.4	0.4	<0.2	<0.5	5.7

The gold foil plated from the six-month-old dibasic ammonium citrate/$KAu(CN)_2$ electroplating solution contained the metallic impurities listed in Table III. The dibasic ammonium citrate/$KAu(CN)_2$ electroplating solution contained the metallic impurities shown in Table IV after the sample was heated to dryness, and the same solution contained the anionic and organic impurities given in Table V. Of the metallic impurities present in the gold foil, copper and cadmium appear to be the ones most easily plated out of the electroplating solution. It is instructive to note that cadmium, although present at a concentration of 30 ppm in the solution, occurs in the foil at a concentration of 500 ppm. Although such a comparison between the concentration of metallic impurities within both the electroplating solution and the gold foil is not strictly valid and quantitative, it is commonly stated that a "concentration" effect has taken place, in that the cadmium appears to be preferentially plated out of the electroplating solution. The same observation applies to the behavior of copper. On the other hand, iron and nickel, present at a concentration of 400 and 900 ppm, respectively, in the solution, occur in the foil at a concentration of only 50 and 40 ppm, respectively.

Presumably, the concentration of the metallic contaminants Cd and Cu within the solution would be even higher if they were not so easily plated out with the gold. In fact, metallic contamination of a dibasic ammonium citrate/$KAu(CN)_2$ electroplating solution is very easily detected, since its color changes to yellow on the dissolution of small amounts of iron (7). This color deepens as the concentration of iron increases, which also usually signifies that other metallic contaminants, such as nickel, cobalt, and copper present in Rodar[3] and copper parts, are also increasing.

Contrary to the ease with which metallic contamination of a dibasic ammonium citrate/$KAu(CN)_2$ electroplating solution can occur, the level of anionic impurity remains remarkably low considering the length of time, about six months, that the solution was used. This is true, even if it is assumed that the levels detected now are no different from those present at the solution make-up, which is unlikely. The pH of the solution, 5.7, precludes too great an increase in concentration, within the solution, of the free CN^- ion, obtained on the electrodeposition of the gold, since HCN is evolved in acidic solution. There is the possibility that some polymerization of the HCN will occur at this pH (2), but owing to the low concentration of HCN present in the solution, the amount of polymer produced is very small and may readily be removed by treating the electroplating solution with activated carbon, upon which the polymer is adsorbed, and filtering. Thus, with a low concentration of the CN^- ion present at any one time, its reaction products with water and air (1), the $CO_3^=$, $H.COO^-$, CNO^- ions, etc., do not form at any appreciable rate.

The gold foil plated from the six-week-old KCN/$KAu(CN)_2$ electroplating solution contained the metallic impurities listed in Table VI.

The KCN/$KAu(CN)_2$ electroplating solution contained the metallic impurities listed in Table VII after the sample was heated to dryness; and the same solution contained the anionic and organic impurities listed in Table VIII. Of the metallic impurities present in the gold foil, silver and iron appear to be the ones most easily plated out of the electroplating solution. All the other impurities are effectively held at a concentration of < 10 ppm within the gold foil. The low concentration of silver in the electroplating solution, on the other hand, may be due to a "concentration" effect, which preferentially plates silver out of the solution. The free KCN present in the electroplating solution combines with many of the metallic impurities to form complex anions, *e.g.*, $Fe(CN)_6^{3-}$, $Cu(CN)_2^-$, $Ni(CN)_3^{2-}$, $Cr(CN)_6^{3-}$, etc., thus altering the redox potentials of the metal ions sufficiently to prevent their codeposition with the gold. This complexation mechanism effectively keeps the metallic impurities dissolved in the electroplating solution, which also slowly turns yellow as the concentration of several of the impurities, notably iron, nickel, and chromium, increases. This color change may be difficult to distinguish from that due to an increase in concentration of the HCN polymer within the electroplating solution (2). Thus, care should be taken in ascribing such a color change exclusively to a polymeric or metallic impurity.

Contrary to the low level of metallic impurities present in the gold foil obtained from a KCN/$KAu(CN)_2$ electroplating solution, the increase of anionic impurities, particularly the $CO_3^=$ and $H.COO^-$ ions, within the electroplating solution, over the period of about six weeks that it had been used, is rather disturbing. The drop in pH of the electroplating solution from 13 to 10.6 is probably partly due to the absorption of CO_2 from the atmosphere, but mainly due to the electrolytic propagation within the solution of CO_2, as will be explained shortly. Thus, an electroplating solution containing free KCN readily

[3] Rodar: 29% Ni, 17% Co, 0.3% Mn, balance Fe.

becomes contaminated with anionic impurities, derived mainly from the side reactions of the KCN with water and air. Moreover, a comparison of the results of this work and those of a previous work (1) would indicate that electrolysis has an effect on the relative concentrations of the $H.COO^-$ and $CO_3^=$ ions present within a $KCN/KAu(CN)_2$ electroplating solution.

The ratio of $CO_3^=$ ion to $H.COO^-$ ion in Table VIII is approximately 0.65. Yet, in an aqueous KCN solution maintained at 70°C and exposed to air (1), in which no electrolysis is being conducted, the ratio is closer to 0.2. The higher $CO_3^=/H.COO^-$ ratio observed for the used electroplating solution probably results from the electrolytic oxidation of the $H.COO^-$ ion at the anode to CO_2 (8, 9), which is retained in the alkaline KCN solution.

Conclusion

Dibasic ammonium citrate/$KAu(CN)_2$ and $KCN/KAu(CN)_2$ electroplating solutions are both susceptible to metallic impurity contamination. These impurities do not plate out of the $KCN/KAu(CN)_2$ solution with the gold as readily as they do from the dibasic ammonium citrate/$KAu(CN)_2$ solution. However, the $H.COO^-$ and $CO_3^=$ ionic impurities build up to a high concentration in the $KCN/KAu(CN)_2$ electroplating solution, but are barely present in the dibasic ammonium citrate/$KAu(CN)_2$ electroplating solution. There is evidence that some of the $H.COO^-$ ion is oxidized at the anode to CO_2, which is retained in the alkaline electroplating solution.

Electrolytic Reductive Coupling

XVI. A Study of 1,2-Diactivated Olefins. Part I, Voltammetry

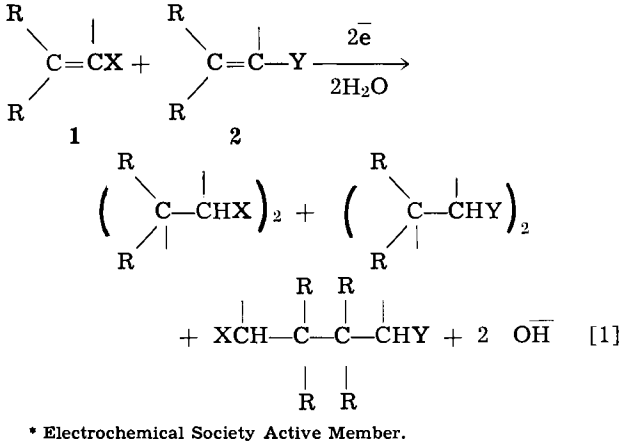
John P. Petrovich, Manuel M. Baizer,* and Morris R. Ort

Central Research Department, Monsanto Company, St. Louis, Missouri

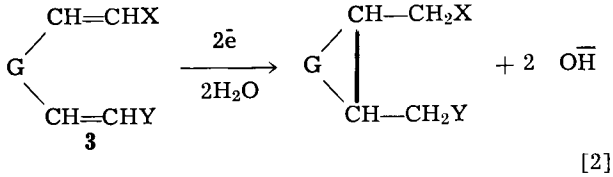
ABSTRACT

Representative 1,2-diactivated olefins XCH=CHY, in which X and Y are electron-withdrawing groups not themselves reduced in the course of the electrolyses, were studied in polarography, cyclic voltammetry, electron spin resonance spectroscopy, and macroelectrolyses. This first of three papers deals with the voltammetry of these compounds and the evidence it affords that a major pathway to the cathodic formation of reduced dimeric products at the first reduction wave is the nucleophilic attack of the intermediate anion radical on starting material rather than radical dimerization of the anion radicals. The rates of disappearance of the anion radicals were measured as a function of olefin concentration as well as the concentration of proton source and Michael-type acceptor. In each case a linear dependence of observed rate on concentration was noted. The implications for directed synthesis and for anionic polymerization are discussed.

Previous papers in this series (1) have been concerned mainly with delineating the scope of electrolytic reductive coupling of activated olefins as a method for synthesizing bifunctional compounds (2). Within the limits discussed previously the generality of the reactions summarized in Eq. [1] and [2] has been demonstrated when R = H or



[1]



[2]

alkyls, X and Y are electron-withdrawing groups, not themselves reduced under the conditions of the electrolysis, and G is a bridging group, *e.g.*, $(CH_2)_n$. When X = Y (Eq. [1]), the process has been called electrohydrodimerization; the process of [2] is electrohydrocyclization (3).

A working hypothesis which has been very useful in rationalizing the synthetic results previously obtained and, indeed, in predicting the scope of the method has been the proposal (4) that an anionic intermediate is formed by electroreduction of **1** or **2** (depending on which is more easily reduced) and that this intermediate nucleophically attacks the β-position of the unreduced but polarized acceptor molecules to form the coupled product(s) (5). Mechanistic studies (8) relating to Eq. [1] have been concerned mainly with one or another aspect of acrylonitrile hydrodimer-

* Electrochemical Society Active Member.

ization (Eq. [3]) and have not thus far resulted in a

$$2CH_2{=}CHCN \xrightarrow[2H_2O]{2\bar{e}} NC(CH_2)_4CN + 2\,O\bar{H} \quad [3]$$

completely satisfactory detailed elucidation of the reaction. Concerning process [2] evidence has been presented (9) in support of the proposal that concerted one-electron transfer-ring closure occurs followed by a second reduction step

Now olefins **1** and **2** show only one polarographic wave; the limiting diffusion current corresponds to two or fewer electrons per molecule depending on the concentration and type of proton donor available (10). The major mechanistic problems concerning the reactions of **1** and **2** arise then from the fact that the presumed anion radical intermediate reacts with monomer, proton source, or possibly another anion radical before its presence can be verified by available instrumental methods.

The 1,2-diactivated olefins XCH=CHY **4**, however, possess two electron-withdrawing groups and do produce observable (11) anion radicals on one-electron reduction. While the nature of the first intermediate formed from **4** is, within certain limitations, more definable than that from **1**, the analysis of the subsequent steps by which **4** is converted to products via **5** is complex (Chart I) because several reasonable alternate pathways may be

CHART I

$$\underset{\mathbf{4}}{XCH{=}CHY} + \bar{e} \rightarrow \underset{\mathbf{5}}{(XCHCHY)^{\cdot-}}$$

$$\xrightarrow[\text{dimerization}]{k_d} \text{Prod. ec}$$

$$\xrightarrow[\text{olefin}]{k_o} \text{Prod. ece}$$

$$\xrightarrow[\text{water}]{k_H} \text{Prod. ec or ece}$$

$$\xrightarrow[\text{acrylonitrile}]{k_{AN}} \text{Prod. ece}$$

formulated. Processes may be encountered that are ec (an electrochemical step followed by a chemical step, *e.g.*, radical anion formation and dimerization, k_d), eec (formation of a dianion followed by reaction of this species with substrates), ecc (radical anion protonation, k_H, followed by dimerization of neutral radicals), ece (radical anion attack upon substrate followed by a second reduction, k_o and k_{AN}, and ecec. . .c (polymerization). The first objectives therefore, after proving the intermediacy of **5**, were to determine by established electrochemical techniques the most probable modes of decomposition of **5** through chemical reactions with each of the several components of the substrate under electrolysis conditions.

On a microscale olefins **4** were examined by polarography, cyclic voltammetry, and electron spin resonance spectroscopy. On a macroscale olefins **4** were reduced at the first polarographic wave in a divided cell either alone or in the presence of **1** at different levels of proton donor concentration. The polarographic and cyclic voltametric results are reported in this paper. The electron spin resonance spectroscopy and macro electrolysis will be given in subsequent papers.

Experimental

Materials.—Solvent. Dimethylformamide (Dupont, technical grade) was stored at least 24 hr over potassium carbonate, distilled at atmospheric pressure from barium oxide (lumps), distilled under reduced pressure from anhydrous copper sulfate, passed through Linde Type 4A molecular sieve, and stored under nitrogen until used.

Tetraethylammonium perchlorate (Southwestern Analytical Chemicals) was recrystallized from water and dried in a vacuum oven.

Activated Olefins.—Cinnamonitrile, fumaronitrile, ethyl cinnamate, diethyl fumarate, stilbene, and ethyl α-cyanocinnamate were obtained commercially and used without further purification.

Dibenzoylethylene (29), β-benzoylacrylonitrile (30), ethyl β-benzoylacrylate (31, 32), benzalacetophenone (33), β-carbethoxyacrylonitrile (34), 3-(4-pyridyl) acrylonitrile (35), ethyl 3-(4-pyridyl) acrylate (36), N,N-dimethyl β-carbethoxyacrylamide (34), N,N,N',N'-tetramethylfumaramide (37), ethyl 4,4,4-trifluorocrotonate (38), ethyl 4,4,4-trifluoro-3-trifluoromethylcrotonate (39, 40), and ethyl α-cyanosorbate were prepared by minor modifications (41) of literature methods.

N,N-dimethylcinnamamide was prepared from cinnamoyl chloride (185g, 1.11m, Eastman) and dimethylamine (100g, 2.22m). Three recrystallizations of the solid from benzene gave 104g of the desired amide, mp 99°-101°.

Anal. Calcd. for $C_{11}H_{13}NO$: C, 75.32; H, 7.48; N, 8.00. Found: C, 75.43; H, 7.42; N, 8.03.

Ethyl β-trifluoromethylcrotonate. A solution of β-trifluoromethylcrotonic acid (32.8g, 0.21m, Aldrich Chemical Company), 200 ml of ethanol and 0.5 ml of concentrated sulfuric acid was refluxed for 8 hr. The reaction mixture was poured into water, dissolved in dichloromethane, washed with dilute sodium bicarbonate, water, dried over anhydrous sodium sulfate, and the solvent was removed by distillation. The liquid residue was distilled to give 21.5g of ethyl β-trifluoromethylcrotonate, bp 128°, $n^{25}D$ 1.3746.

Anal. Calcd. for $C_7H_9F_3O_2$: C, 46.16; H, 4.98; F, 31.29. Found: C, 46.25, 46.36; H, 5.01, 5.39; F, 31.33, 31.65.

Polarography.—All polarograms were obtained with a Sargent Model XXI polarograph. The dropping mercury electrode constants were m = 1.58 mg/sec., t = 4.20 sec., $m^{2/3}t^{1/6}$ = 1.725. Standard polarographic H cells were used throughout. The polarograms were recorded against a saturated calomel electrode as the reference using 0.1*M* tetraethylammonium perchlorate in dimethylformamide as solvent. Cell resistances were around 1000 ohms and no correction was made for i_r drop in the cell.

Cyclic voltammetry.—The cyclic voltammograms were obtained using a Wenking Model 66TA1 potentiostat and an Exact Model 505 function generator. Recording of the current-voltage curves was accomplished with a Tektronix 502-A Dual Beam Oscilloscope and a C-27 camera attachment. The cell used for these experiments was a three-compartment cell; the reference and auxiliary electrode compartments were separated from the working electrode compartment by glass frits. The working electrode was a mercury drop suspended on a mercury-coated platinum wire. The reference electrode was a saturated calomel electrode connected to the electrolysis vessel by a cotton-plugged glass capillary. The auxiliary electrode was a platinum wire. The solutions analyzed were 1. to 5. x $10^{-3}M$ depolarizer with 0.1*M* tetraethylammonium perchlorate in dimethylformamide as solvent. Typical peak-to-peak separations were between 0.06 and 0.15v for scan rates of between 3 and 360 v/min.

Results and Discussion

Polarography.—The polarograms of a series of diactivated olefins, Tables I and II, were obtained in dimethylformamide (DMF) solution containing 0.1*M* tetraethylammonium perchlorate (TEAP). Both anhydrous DMF and DMF containing 1*M* water were used. Among this group of olefins two distinctive behaviors were observed. For olefins XIII and XVII two one-electron waves were obtained which coalesced into a single two-electron wave with the addition of a sufficient amount of water. This type of polarographic behavior has frequently been reported (12). On the other hand, for olefins III, VI, IX, and X only a single reduction wave was observed using anhydrous DMF as solvent. In these cases a decrease in the limiting current is observed in approximately the expected position for the second reduction wave, and the limiting current (I_d) for the first wave is very small, *e.g.*, 0.80 for olefin III.

With olefins I, V, VII, XIII the second wave is considerably smaller than expected for a one-electron process. From the measured rate constants, *vide infra*, it is clear that the generated anion radicals **5** react with incoming depolarizer within the lifetime of the mercury drop.

Under the anhydrous conditions employed here, the reaction can form trimers or higher oligomers as well as dimers, thereby exhibiting a diffusion current somewhat less than one electron per molecule (10, 26). Since the dianion **7** has two negative charges in the same molecule, it would be expected to react even more rapidly with incoming depolarizers than the anion radical **5**, initiating oligomerization and thereby causing the observed decrease in the limiting current at the potential of the second reduction (13). The addition of 1*M* water to these systems affects the first wave only slightly, but eliminates the oligomerization initiated by the dianion, thereby increasing the diffusion current. The second wave is then observed at a slightly more positive potential than the potential at which the decrease in the limiting current is observed in the anhydrous system; *e.g.*, for olefin III in anhydrous DMF the decrease is at −1.8v, and in aqueous DMF the second wave is at −1.72v (Fig. 1). These observations again point out the caution which must be observed in interpreting polarographic data on active systems, especially when proton sources are absent.

The reaction of **5** with sufficient water yields a neutral radical α to an activating group. Since no additional polarographic wave is observed under conditions where this reaction occurs, this radical must be reduced either at the same or at a more positive potential than the olefin (14). Further, no additional reduction waves are observed using conditions under which **5** reacts with the olefin. The product of this reaction is a dimeric anion radical in which the radical site is insulated from the negative charge by a two-carbon bridge. This dimeric anion radical must also consequently be reduced at the same or at a more positive potential than the original olefin. It is clear, therefore, that attempts to trap a dimeric anion radical of this type by chemical methods (15) are difficult since the intermediate is unstable to reduction by the reducing agent, such as an alkali metal, and even the monomeric anion radical.

It is interesting, incidentally, to compare the polarograms of olefin VI, Table I, and olefin XIX, Table II. These two olefins have the same two activating groups, carbethoxy and nitrile, but in 1,2 and 1,1 positions, respectively. The effect of placing both activating groups on the same carbon atom shifts the first wave slightly in the anodic direction and also completely eliminates the second wave below —2.5v. This points

out the importance of charge separation in the formation of a dianionic species.

Several attempts were made to correlate these polarographic $E_{1/2}$ values with published σ values. Numerous successful correlations for other classes of compounds have appeared in the literature (16). However, the diactivated olefins discussed here do not lend themselves to such treatment.

A qualitative order can be drawn from our data for the stabilizing effects as measured by $E_{1/2}$ values of the activating groups on the anion radical intermediates:

$$\phi CO > CN \geq CO_2C_2H_5 > 4\text{-Py} > CF_3 > CON(CH_3)_2 > \phi > H$$

The most easily reduced diactivated olefin of those studied is dibenzoylethylene (I); the most difficult to reduce is stilbene (XVI).

Attempts to correlate polarographic $E_{1/2}$ values for monoactivated olefins with reactivity as measured by anionic polymerizability have had limited success (17). The rates of polymerization of these olefins depend importantly on the steric requirements of the propagation step. It is clear from the data in Table I that the polarographic data depend overwhelmingly on the number and nature of the electron-withdrawing groups in conjugation with the olefin and only slightly if at all on the bulkiness of the groups, *cf.* I and IX.

The high I_d value for compound XXI is probably due to fluoride ion elimination followed by reduction. Fluoride elimination has been observed in the bulk electrolysis of ethyl β-trifluoromethylcrotonate.[1]

Cyclic voltammetry.—The cyclic voltammograms of a series of diactivated olefins were obtained in anhydrous DMF solution containing 0.1M TEAP. The dependence of the peak current, i_p, on the voltage scan rate was obtained. Representative data are given in Table III. Two types of behavior were noted (Fig. 2). Curve 1, Fig. 2, is typical of the behavior observed for olefins II, III, IV, VI, VII, IX, *i.e.*, olefins which are very reactive and easily polymerizable, while curve 2 was typical of the behavior of the other olefins studied, *i.e.*, I, V, VIII, X, XI, XII, XIII, XV, XVI, XVII. Neither of these curves corresponds to the "linear" dependence of $ip/V^{1/2}$ with $V^{1/2}$ expected for an ec mechanism (18). Curve 2 is, however, typical of the behavior expected for a reversible electron transfer followed by a fast chemical reaction and a subsequent electron transfer (ece) (18). Curve 1 probably corresponds to an ece

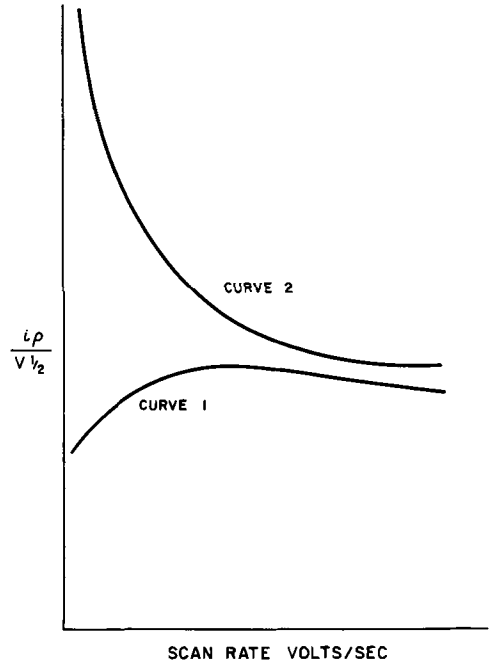

Fig. 2. Plot of $i_P/V^{1/2}$ *vs.* scan rate for curve 1, ethyl cinnamate and curve 2, ethyl β-cyanoacrylate.

mechanism when the slow scan region is complicated by a polymerization reaction. In all cases a 20-40 mv shift in peak voltage was noted for a ten-fold change in sweep rate.

In order to gain some knowledge of the nature of the chemical reaction involved, the rate constants for the decomposition of the electrochemically generated anion radicals were calculated from the cyclic voltammograms using the simplified method of Nicholson (19), Eq. [8], and a numerical plot of $k_f \tau$ *vs.* i_r/i_f as given by Nicholson and Shain (20); where i_r/i_f is the ratio of the reverse to the forward

$$i_r/i_f = \frac{i_{ap}}{i_{cp}} + \frac{0.485\ (i_{sp})}{i_{cp}} + 0.086 \qquad [8]$$

current, i_{ap} is the anodic peak current, i_{cp} is the cathodic peak current, i_{sp} is the current at the switching potential, τ is the time from $E_{1/2}$ to the switching potential and k_f is the first-order rate constant for the disappearance of the intermediate ion radical. When there is no further electron exchange, a plot of $k\tau$ *vs.* τ has been shown to be linear and to pass through zero (21).

For the diactivated olefins, a plot of $k\tau$ *vs.* τ deviates from linearity significantly for values of i_r/i_f of <0.75, but is fairly linear above this value. The region of the curve representing 5-20% chemical reaction was used for all of the rate constants reported here. In this region the contribution from the second electron transfer to i_{cp} and i_{sp} is small. Therefore, the equation derived for an ec mechanism would also apply to an ece mechanism. The rate constants calculated in this manner, Tables IV, V, and VI, were reproducible to $\pm$ 10%.

The half-lives, $^{0.69}/_{k_{obs}}$, varied from 15 sec for dibenzoylethylene to 0.0096 sec for ethyl β-cyanoacrylate at 2 x $10^{-3}M$ depolarizer. In general, the symmetrically substituted olefins are the least reactive indicating that the ground-state dipole contributes to the reactivity. It is interesting to note that the nitrile function contributes significantly more to the reactivity of the anion radical than does the benzoyl function, *e.g.*, the intermediate from olefin VI reacts nearly 30 times as rapidly as does the corresponding intermediate from olefin III. The anion radical from cinnamonitrile (VIII) reacts 9 times as fast as the anion radical from ethyl cinnamate (XII).

The rate constants for the disappearance of the anion radicals by any route were determined for six

Table VI. Rate constants for the reactions of anion radicals electrochemically generated from diactivated olefins with diactivated olefins, k_o, water, k_w, and acrylonitrile, k_{AN} at 25°C

Compound	k_o	k_w	k_{AN}
III	690	2.8	0
VI	40,000	0	0
X	101	0.96	0.12
XI	230	3.1	—
XII	69	4.2	—
XIII	82	2.2	1.2

of the olefins, III, VI, X, XI, XII, XIII, as a function of the bulk concentration of the olefin. The effect of adding water and acrylonitrile to the system was also examined. For each diactivated olefin studied, a plot of the observed rate constant, k_{obs}, *vs.* the bulk concentration of olefin was linear but did not pass through zero. This is the type of behavior expected for competitive reactions following Eq. [9]. The quantity used to calculate k_o

$$k_{obs} = k + k_o\,[\text{olefin}] \qquad [9]$$

was the bulk concentration of olefin. This introduces an error in the calculation of k_o since, under electrolysis conditions, the concentration of the olefin in the area of the electrode is less than but proportional to the bulk concentration. However, since all of the diffusion coefficients for the olefins studied are probably of similar magnitude, the relative values of k_o are sufficiently accurate for comparisons. Since one of the activating groups for each of the olefins studied is a carbethoxy group, the relative reactivity of these olefins is a measure of the contribution to the over-all reactivity from each of the other activating groups. The order and relative reactivity is C_6H_5, 1 ≤ CON$(CH_3)_2$, 1.2 < $CO_2C_2H_5$, 1.5 < 4-pyridyl, 3.3 < C_6H_5CO, 10 < CN, 580.

Three possible reaction paths can be written for the disappearance of these anion radical intermediates **5**, Eq. [10], [11], and [12]. The measured rate constants for the reaction of the anion

$$\underset{\mathbf{4}}{XCH{=}CHY} + e^- \rightarrow \underset{\mathbf{5}}{XCH(\dot{-})\text{—}CHY}$$

$$\mathbf{5} + \text{proton source} \rightarrow \underset{\mathbf{7}}{(XCHCHY)(\cdot)}H \rightarrow \text{dimer} \qquad [10]$$

$$\mathbf{5} + XCH{=}CHY \rightarrow \text{dimeric anion radical} \qquad [11]$$

$$\mathbf{5} + \mathbf{5} \rightarrow \text{dimeric dianion} \qquad [12]$$

radical **5** of representative olefins, Table V, with water clearly indicate that Eq. [10] is not a major path for the reaction of the anion radicals and, therefore, for the formation of dimeric products, *e.g.*, for olefin X, k_o/k_w = 105. The yield of dimeric products is, however, dependent on the concentration of water in the electrolysis mixture (9). In general, the more water present in the electrolysis mixture, the lower the yield of dimeric products and the higher the yield of saturated monomer. It is hard to explain how or why water would interfere with a free radical reaction. Water is an extremely poor free-radical inhibitor. If the formation of dimer products involved the dimerization of the free radicals **7**, Eq. [10], an increase in the water concentration should result in an increase in dimeric products, in contrast to what is observed experimentally.

In addition, the protonation of the anion radical **5** would most likely lead to the resonance stabilized, secondary α-radical, rather than the primary β-radical. The α-radical would lead to branched-chain dimers rather than the linear dimers that are observed. In special cases, small yields of α, β coupled dimers have been observed (7), but no α, α dimers have been obtained.

Concerning the second and third paths, our interpretation of the data obtained in studying cyclic polarograms of **4** at several concentrations and sweep rates as well as the determination of the effect of water on the rate of disappearance of **5** leads to the conclusion that [11] rather than [12] is the major route to the dimeric species.

It is clear that the observed rate constant for the reaction of the electrochemically generated anion radical **5** with the olefin (Eq. [11]) should be a linear function of the bulk concentration of the olefin. On the other hand, the dependence of the observed rate constant for anion radical dimerization (Eq. [12]) on the bulk concentration of olefin is not easily determined. It may also be linear. A rigorous mathematical solution for this kind of system has not been accomplished (22), so that an argument for [10] and [11] based on concentration dependence alone is not at present unequivocal. However, our data (Table V), when coupled with the observed dependence of $i_p/V^{1/2}$ and the peak potential on the sweep rate (Table III), argue strongly in favor of an ece mechanism (Eq.

[11]) rather than an ec mechanism (Eq. [12]). The coupling reaction, therefore, does not involve the dimerization of two electrochemically generated anion radicals to any appreciable extent. In certain nonelectrochemical systems this same conclusion based on electrostatic considerations has been stated by Szwarc (23) in a general discussion of anion radical dimerization. Calculated equilibrium constants (24) for the dimerization of two anion radicals for 1,2-diactivated systems highly favors the monomeric species, *e.g.*, for stilbene anion radicals, log $K = -53$.

The rate constants for the reaction of the anion radicals with water, k_w, as well as with acrylonitrile, k_{AN}, were calculated assuming a simple kinetic expression for competitive pseudo-first-order reaction paths, Eq. [13]. The reactivity of

$$k_{obs} = k + k_o[\text{olefin}] + k_w[H_2O] + k_{AN}[\text{acrylonitrile}] \quad [13]$$

these anion radicals toward the parent olefin was found to be much greater than toward either water or acrylonitrile. In particular, the relative rates for the reactions of the anion radicals from diethyl fumarate (X) and from N,N-dimethyl β-carbethoxyacrylamide (XIII) with the parent olefin, water, and acrylonitrile are 840:8:1 and 39:2:1. In a typical homogeneous reaction, one would expect from polymerization data and their effectiveness as Michael acceptors (25) the relative reactivities toward an anion to be water > acrylonitrile > parent olefin. The apparent "low reactivity" of water in the electrohydrodimerization reaction has been rationalized (26) on the basis of a large difference in the concentration of water in the bulk of the solution and at the electrode surface due to the hydrophobic nature of the tetraalkylammonium ion. Let us examine the result, however, of analyzing the situation from the point of view of electric field effects alone.

Just prior to electron transfer when the depolarizer is oriented in the electric field, one would expect it to have a very strong induced dipole, almost to the extreme of charge separation. All of the molecules in the vicinity of the electrode would be subjected to some kind of polarization. The degree of the polarization at a given electrode potential should be different from each reactant, *e.g.*, diethyl fumarate, acrylonitrile and water, depending on its individual polarizability. The net effect of this polarization should be an "induced reactivity" which may be very different from the respective "normal" reactivity in nonelectrochemical systems (27). This induced reactivity would be quite similar to induced electron density discussed by Hoijtink (28) to rationalize the reduction products of polynuclear hydrocarbons as a function of the applied electric field. The extent of the polarization of the olefins in question should be qualitatively related to their polarographic reduction potentials.

From the rate constants measured for olefins X and XIII an interesting trend is apparent. At their respective reduction potentials (—1.54 and —1.76v) the two anion radicals show similar reactivities toward their respective olefins and yet show different reactivities toward water and acrylonitrile. The reactivities of both water and acrylonitrile are higher at the higher electrode potential. The reactivity of water changes by a factor of 2, while that for acrylonitrile shows a tenfold increase. Extrapolating these very limited data, which is always dangerous, to couplings occurring in similar electrolyte systems, one would predict that the reactivity of acrylonitrile would be about 15 times that of water toward an anion radical generated at ca. —2.0v, the reduction potential of acrylonitrile.

Conclusions Concerning Mechanisms

From the above results as well as the observed rate constants, Tables III and IV, we conclude that the initial chemical step in the electrolytic reduction of activated olefins occurs at the electrode surface. A

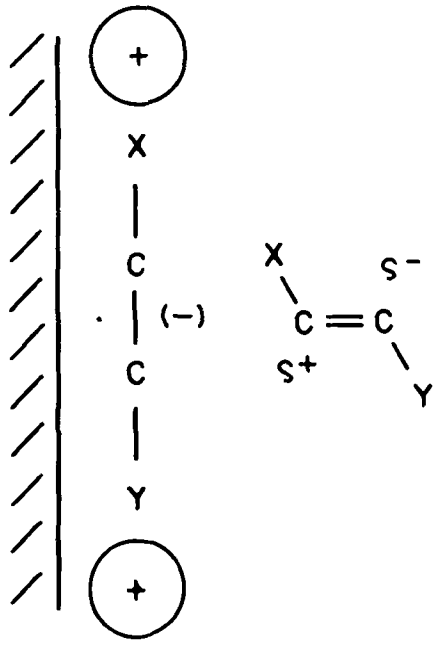

Fig. 3. Mechanistic picture of results

mechanistic picture consistent with these results presents the anion radical lying on the electrode surface within the plane of the adsorbed tetraalkylammonium ions and reacting with a polarized acceptor molecule or proton source as depicted in Fig. 3. The results of the reaction with an acceptor is a coupled species with an anionic site outside of the polarizing field and a radical site at the electrode surface. This radical probably reduces rapidly either by the electrode or by relay through a monomeric anion radical, thus yielding a new anion which is repelled from the electrode surface. Once the final reduction product, either the dimeric or monomeric anion, leaves the influence of the electric field, normal solution reactions can occur. This mechanism is consistent with the mechanism proposed previously for the electrohydrocyclization reaction (9) since the upper limit of a rapid reaction is a concerted process. It is also consistent with the basic suggestions as to the mechanism of the electrohydrodimerization of monoactivated olefins (8) with the exception that the relatively low reactivity of water may be due at least partially to polarization effects rather than exclusively to concentration effects. These three systems, monoactivated olefins, diactivated olefins, and bisactivated olefins, give the full spectrum of reactivities for the electrolytic reductive coupling reaction. The diactivated olefins show the lowest reactivity, *i.e.*, the anion radicals are observable. The bisactivated olefins react by a concerted path, and the monoactivated olefins are intermediate in reactivity.

Electrolytic Reductive Coupling

XVII. A Study of 1,2-Diactivated Olefins. Part II. Macro-electrolyses

John P. Petrovich, Manuel M. Baizer,* and Morris R. Ort

Central Research Department, Monsanto Company, St. Louis, Missouri

ABSTRACT

The electrolytic reductive coupling of a variety of diactivated olefins, XCH=CHY, has been studied. The reduced dimeric products have been isolated and carefully identified. Both symmetrical and unsymmetrical dimers were observed. The dimeric products are formed by two paths: the first involves the attack of the electrochemically generated anion radical on unreduced olefin; the second involves the protonation of the anion radical followed by reduction to an anion and subsequent attack on the olefin. The isomer distribution in the dimeric product obtained by the first route is rationalized on the basis of the relative anion stabilizing ability of the activating groups in the acceptor molecule and the relative ability toward stabilizing a radical site in the donor molecule. The possibility of forming cross-coupled products (between a diactivated olefin and a Michael acceptor) is limited to systems in which the electrochemically generated anion radical is relatively stable toward its parent olefin or in which the reduction potentials of the pair are similar, *i.e.*, $\Delta E_{1/2} < 0.4$v.

Part I (1) described the voltammetric study of olefins XCH=CHY, **1**, in which X and Y are electron-withdrawing groups not themselves reduced under the conditions of electrolysis. It was established that anion radicals **2**, were the intermediate species produced by

$$\underset{\mathbf{1}}{\text{XCH—CHY}} \xrightarrow{\bar{e}} \underset{\mathbf{2}}{(\text{XCH—CHY})^{-}}$$

* Electrochemical Society Active Member.

the first one-electron reduction. Strong evidence was presented that **2** reacts anionically at the electrode surface with **1**, water, or nonreduced electrophiles added to the catholyte. The results of macroelectrolyses (at the first reduction wave) designed to obtain simple coupled products are reported here. The interpretation of the results is complicated (Charts I and II) because (*a*) each of the above initial ec reactions initiates a separate route to products; (*b*) water or some other proton donor must be included in the

catholyte lest the **1** oligomerize/polymerize; (c) as a consequence of (*b*), some e-water-e contribution to the total reaction scheme will lead to products formed from anions reacting not in the vicinity of the electrode (Eq. [4]); and (*d*) symmetrical as well as unsymmetrical hydrodimeric products may be formed. From a careful analysis of the coupled products obtained and a consideration of the facts summarized in Part I a rational scheme is proposed for the routes (Chart II) whereby **1** leads to products. A conclusion concerning the most probable path(s) leading to each coupled product is included in the presentation of the Results; the supporting arguments are presented in the Discussion.

Chart I: Over-all reduction coupling reactions of $XCH{=}CHY$

$$2 + 1 \xrightarrow[H_2O]{} \underset{\mathbf{3}}{XCHCH_2Y\ \ XCHCH_2Y} + \underset{\mathbf{4}}{XCHCH_2Y\ \ YCHCH_2X} + \underset{\mathbf{5}}{XCH_2CHY\ \ XCH_2CHY} \quad [1]$$

$$2 + R_2C{=}CHZ \xrightarrow[H_2O]{1} (3,4,5,6) + \underset{\mathbf{7}}{XCHCH_2Y\ \ R_2CCH_2Z} + \underset{\mathbf{8}}{XCH_2CHY\ \ R_2CCH_2Z} \quad [2]$$

Chart II: Reaction paths for reductive couplings of $XCH{=}CHY$

$$\mathbf{1} \xrightarrow{1e^-} \mathbf{2}$$

Path A $2 + \text{olefin} \rightarrow \text{dimer} \xrightarrow[2H_2O]{e^-} \text{hydrodimers}$ [3]

Path B $2 + H_2O \rightarrow (XCHCHY)H \xrightarrow{e^-} (XCHCHY)H \xrightarrow{-H_2O} XCH_2CH_2Y$ [4]

Path C $2 + CH_2CHCN \rightarrow (XCHCHY)CH_2\overset{-}{C}HCN \xrightarrow[H_2O]{e^-} \text{cross-coupled products}$ [5]

Experimental

Materials.—Solvent.—Dimethylformamide (Dupont, technical grade) was stored at least 24 hr over potassium carbonate, distilled at atmospheric pressure from barium oxide (lumps), distilled under reduced pressure from anhydrous copper sulfate, passed through Linde Type 4A molecular sieve, and stored under nitrogen until used.

Electrolytes.—Tetraethylammonium p-toluenesulfonate (Aldrich Chemical Company) was recrystallized twice from acetone and dried in a vacuum oven.

Activated Olefins.—Cinnamonitrile, ethyl cinnamate, and diethyl fumarate were obtained commercially and were used without further purification. Dibenzoylethylene (19), β-benzoylacrylonitrile (20), ethyl β-benzoylacrylate (21), β-carbethoxyacrylonitrile (24), N,N-diethyl β-carbethoxyacrylamide (22), N,N-dimethyl β-carbethoxyacrylamide (22), N,N-dimethylcinnamide (1), and ethyl 4,4,4-trifluorocrotonate (23) were prepared by literature methods.

α,β-Disubstituted ethanes.—Hydrocinnamonitrile, ethyl hydrocinnamate and diethyl succinate were obtained commercially and used as vpc standards without further purification.

β-Benzoylpropionitrile (24), ethyl β-benzoylpropionate (25), ethyl β-cyanopropionate (26), and dibenzoylethane (27) were prepared by adaptations of literature methods.

N,N-dimethylhydrocinnamamide was prepared from dimethylamine and hydrocinnamoyl chloride, bp 110°-112° (0.8m), $n^{25}D$ 1.5308.

Anal. Calcd. for $C_{11}H_{13}NO$: C, 74.50; H, 8.54; N, 7.89. Found: C, 74.22; H, 8.51; N, 7.65.

N,N-dimethyl β-carbethoxypropionamide.—A suspension of N,N-dimethyl β-carbethoxyacrylamide (23g, 0.134m), 0.5g of 10% palladium on charcoal and 100 ml of ethanol was treated for 30 min with hydrogen at 40 psi in a Parr shaker at room temperature. The solvent was removed by distillation at reduced pressure. Distillation of the oily residue at reduced pressure gave 18.9g of the desired compound, bp 90°-91° (0.1 mm), $n^{25}D$ 1.4527.

Anal. Calcd. for $C_8H_{15}NO_3$: C, 55.50; H, 8.73; N, 8.07. Found: C, 55.03; H, 8.85; N, 8.40.

N,N-Diethyl β-carbethoxypropionamide was prepared by hydrogenation of the olefin as described above, bp 95°-96° at 0.6 mm, $n^{25}D$ 1.4502 [lit. (28) bp 102°-104° (0.8 mm)].

Preparative electrolysis.—The apparatus used for the preparative electrolysis has been described previously (29). A mercury cathode, area 55 cm^2, was used throughout.

General electrolysis method.—The anolyte consisted of a saturated aqueous solution of tetraethylammonium p-toluene-sulfonate. The catholyte consisted of 0.1-0.2m of the depolarizer, 20g of tetraethylammonium p-toluenesulfonate, and 3-20g of water depending on the reactivity of the depolarizer. This mixture was diluted to 150 ml total volume with a cosolvent, either dimethylformamide or acrylonitrile. The electrolysis was conducted to about 80% conversion, assuming 1 electron per mole of depolarizer. The pH of the catholyte was maintained around 8 by the addition of acetic acid. When the electrolysis was completed, the catholyte was diluted, poured into methylene chloride, washed with water, and the organic phase was dried over anhydrous sodium sulfate. The solvent was removed by distillation and the product distribution (olefin, saturate and dimer) was estimated by vpc on appropriate columns.

Electrolysis of ethyl β-cyanoacrylate.—The catholyte contained 16g of water, 24.0g depolarizer with DMF as solvent. A 6-ft XE-60 on Chromosorb W column was used for product identification. It was programed from 120° to 240°. The yields were 16% ethyl β-cyanopropionate and 84% hydrodimers. Two hydrodimeric products were apparent by vpc: peak A 95%, peak B 5%. The hydrodimer was distilled at reduced pressure, 21.0g, bp 159°-160° at 0.4 mm, $n^{25}D$ 1.4535.

Anal. Calcd. for $C_{12}H_{16}N_2O_4$: C, 57.13; H, 6.39; N, 11.11; mol wt 252. Found: C, 56.82; H, 6.70; N, 11.36; mol wt 250.

The nmr spectrum of this mixture had a triplet at τ 8.67, a slightly split doublet at τ 7.12, multiplet at τ 6.51, and a quartet at τ 5.73, a very small triplet at τ 8.65, and a very small quartet at τ 5.68 in a ratio of 3:2:1:2.

The copper I chloride complex (30).—Sulphur dioxide was bubbled for 5 min through a solution of 2.52g (0.01m) of the hydrodimers and 1.34g (0.01m) of copper II chloride in 20 ml of 95% ethanol. The reaction mixture was placed in a refrigerator for 2 days, during which time the product separated from solution. The product was isolated by filtration under nitrogen, washing on the filter with ethanol and drying under vacuum. The product, 1.15g, had an indefinite mp. The original dimer could be regenerated with hydrochloric acid.

Anal. Calcd. for $C_{12}H_{16}CuClN_2O_4$: C, 41.03; H, 4.59; Cu, 18.09. Found: C, 40.49, 40.55; H, 4.43, 4.17; Cu, 17.97, 17.96.

The nmr spectrum of the complex in d_6 acetone as solvent had a single triplet at τ 8.63, a slightly split doublet at τ 6.94, a multiplet at τ 6.27 and a quartet at τ 5.68.

The saponification of the hydrodimer with 10% sodium hydroxide gave quantitatively a dicarboxylic acid, mp 173°-174°.

3,4-Dicyanoadipic acid.—cis-4-Cyclohexene-1,2-diamide was prepared as described by Ficken and Linstead (31). This diamide was dehydrated to form cis-1,2-dicyano-4-cyclohexene by the action of p-toluenesulfonyl chloride by the method of Stephens, Biance, and Pelgrim (32). The 1,2-dicyano-4-cyclohexene was oxidized to 3,4-dicyanoadipic acid (mp 174°-175°) by $KMnO_4$ in acetone solution. The nmr spectrum of this

material was identical to that of the acid isolated from the saponification of the electrolysis product of ethyl β-cyanoacrylate. Diethyl 3,4-dicyanoadipate was prepared from the acid, and it was found to have the same vpc retention time as the electrolysis product.

Electrolysis of ethyl β-benzoylacrylate.—The catholyte contained 10 ml of water and acrylonitrile as solvent. Only 5g of the ethyl β-benzoylacrylate was added to the catholyte at the start of the run. The remainder was added dropwise as necessary to maintain the working electrode potential below —1.0v *vs.* sce (total 20.4g, 0.1m). After electrolysis and extraction, the low-boiling materials, ethyl β-benzoylacrylate and ethyl β-benzoylpropionate, were removed by distillation at reduced pressure. The 13.0g of residual dimeric products was chromatographed on aluminum oxide (Taylor Company 80-200 mesh). Two main fractions were isolated; the first product was a yellowish oil which was washed with hexane and recrystallized from ethanol, 2.9g, mp 105°-115°.

Anal. Calcd. for $C_{24}H_{26}O_6$: C, 70.23; H, 6.39; mol wt 410. Found: C, 70.32; H, 6.23; mol wt 416.

The second major fraction diluted was a white solid which was recrystallized from ethanol, 1.2g, mp 119°-120°.

Anal. Calcd. for $C_{24}H_{26}O_6$: C, 70.23; H, 6.39; mol wt 410. Found: C, 69.90; H, 6.07; mol wt 408.

The nmr spectrum of the first sample, mp 105°-115°, with carbon tetrachloride as solvent had 2 triplets at τ 8.82 and 8.76 in a ratio of 1:10, a poorly defined multiplet at τ ~ 7.2 (very small), a slightly split singlet at τ 6.32, a quartet at τ 5.78, a multiplet at τ 2.4, and a multiplet at τ 1.95 in a ratio of 3:6:2:3:2 for the major signals. The second isolated solid, mp 119°-120°, had a much cleaner nmr spectrum with only the major peaks listed above in a ratio of 3:6:2:3:2. The mother liquors from all of the recrystallizations were combined and analyzed by nmr. The presence of an unsymmetrical isomer was indicated by a triplet at τ 8.91, a doublet at τ 7.36, a multiplet at τ 6.6, and considerable broadening of the phenyl hydrogens.

Electrolysis of β-benzoylacrylonitrile.—The catholyte contained 20 ml of water and acrylonitrile as solvent. The olefin was dissolved in acrylonitrile, 23.5g diluted to 100 ml, and 10 ml of this solution was added to the catholyte at the start of the run. The remainder was added dropwise as necessary to maintain the working electrode potential below —1.0v *vs.* SCE. The organic extract was concentrated by distillation and cooled. A white solid separated, was filtered and washed with methylene chloride. Recrystallization from acetonitrile gave 6.1g of a white solid, mp 197°-198°.

Anal. Calcd. for $C_{20}H_{16}N_2O_2$: C, 75.93; H, 5.09; N, 8.86; mol wt 316. Found: C, 75.62; H, 4.86; N, 8.99; mol wt 314.

The nmr spectrum of this material in d_6-dimethylsulfoxide showed a singlet at τ 6.66, a multiplet at τ 2.13, and a multiplet at τ 1.80 in a ratio of 3:3:2. The mother liquor from above was concentrated, triturated with hot ethanol to remove the β-benzoylpropionitrile, 13.1g, (compared to an authentic sample by nmr and vpc) and the residue was recrystallized from acetonitrile, 4.8g, mp 183°-193°. The nmr spectrum of this material was identical to that of the isomer, mp 197°-198°. These two isomers are meso and dl 1,4-dibenzoyl-2,3-dicyanobutane.

Electrolysis of dibenzoylethylene.—The catholyte contained 3 ml of water, 23.6g dibenzoylethylene (0.1m) and dimethylformamide as solvent. The electrolysis products were chromatographed on alumina with methylene chloride as eluant. Four compounds were isolated, dibenzoylethane (10.2g), mp 144°-145°, from ethanol [lit. (33) mp 144°-145°]; dl 1,2,3,4-tetrabenzoylbutane (6.1g), mp 164°-165°, from ethanol [lit. (33) mp 167°-168°]; meso 1,2,3,4-dibenzoylbutane (1.8g), mp 198°-201°, [lit. (33) mp 202°-203°], and the hydrotrimer, 1,2,3,4,5,6-hexabenzoylhexane (2.4g), mp 285°-286°, probably dl and meso mixtures.

Anal. Calcd. for $C_{48}H_{38}O_6$: C, 81.10; H, 5.38; mol wt 710. Found: C, 81.56; H, 5.42; mol wt 690.

Electrolysis of N,N-dimethyl β-carbethoxyacrylamide.—The catholyte contained 3 ml of water, dimethylformamide, and 44g of depolarizer. The crude electrolysis product was analyzed by vpc. Five hydrodimeric products were observed on 2% silver nitrate, 18% Carbowax 4000, on Chromosorb W 6-ft column at 225°. One of the isomeric products was quantitatively precipitated by treating the oily mixture with acetone, 6.5g, mp 146°-148°.

Anal. Calcd. for $C_{16}H_{28}N_2O_6$: C, 55.79; H, 8.19; N, 8.14; mol wt 344. Found: C, 55.89; H, 8.32; N, 8.21; mol wt 330.

Distillation of the thick, oily residue gave 2.8g, bp 85°-87°, (0.1 mm) of N,N-dimethyl β-carbethoxypropionamide and 26.3g, bp 177°-191°, (0.15-0.3 mm) of a mixture of hydrodimeric products.

Anal. Calcd. for $C_{16}H_{28}N_2O_6$: C, 55.79; H, 8.19; N, 8.14. Found: C, 55.71; H, 8.31; N, 8.52.

A second electrolysis of N,N-dimethyl β-carbethoxyacrylamide was run using 10g of water and dimethylformamide as solvent. The electrolysis products were analyzed as above.

Electrolysis of N,N-diethyl β-carbethoxyacrylamide.—The catholyte contained 20g of water and dimethylformamide as the solvent. The electrolysis products were distilled at reduced pressure. The product distribution based on distilled material was 34% N,N-diethyl β-carbethoxypropionamide, bp 96°-104°, (0.3-0.5 mm) and 66% of a mixture of hydrodimers, bp 162°-171°, (0.3-0.4 mm). The hydrodimer fraction was found to contain about 3% of N,N,N′,N′-tetraethyl-3,4-dicarbethoxyadipamide by vpc comparison with an authentic sample prepared as described below.

N,N,N′,N′-tetraethyl-3,4-dicarbethoxyadipamide.—To a solution of 1,2,3,4-butanetetracarboxylic acid anhydride (158g, 0.8m) in 200 ml of acetone was added dropwise diethylamine (116g, 1.6m) at 25°-35°. The mixture was stirred at room temperature for 2.5 hr, and the solvent was removed. To the residue was added 200 ml of acetic anhydride and the mixture was refluxed for 4 hr. The acetic acid and the excess acetic anhydride were removed by distillation. The residue was taken up in acetone, cooled and 19.6g of 1,2,3,4-butanetetracarboxylic dianhydride was recovered. The filtrate was concentrated and cooled. The desired product crystallized out. Recrystallization from acetone gave 29.6g of 3,4-bis(N,N-diethylcarbamoylmethyl) succinic anhydride, mp 115°-116°. Infrared bands at 1850-1780 cm^{-1} are consistent with a 5-membered anhydride.

Anal. Calcd. for $C_{16}H_{26}N_2O_5$: C, 58.87; H, 8.03. Found: C, 58.34, 58.11; H, 7.84, 7.92.

A solution of 17.7g (0.05m) of this anhydride in 150 ml of ethanol and 0.5 ml of concentrated sulfuric acid was refluxed for 4 hr. The reaction mixture was cooled, poured into water, extracted with benzene, and the organic layer washed with water. The benzene was removed by distillation and the product isolated by preparative vpc. A 12% silicone grease on Chromosorb W column, 8 ft x ¾ in., at 275° was used for the isolation, $n^{25}D$ 1.4728.

Anal. Calcd. for $C_{20}H_{36}N_2O_6$: C, 59.97; H, 9.06; N, 7.00. Found: C, 59.19; H, 9.01; N, 6.78.

Electrolysis of cinnamonitrile.—The catholyte contained 0.25m of depolarizer, 5g of water, 37g depolarizer, and DMF as solvent. The electrolysis products were analyzed by vpc (6-ft 5% XE-60 cm Chromosorb W column programed from 125°-250°) and found to contain 20% hydrocinnamonitrile and 80% hydrodimeric products (7 and 28.2g, respectively). Of the hydrodimeric products, 4 components (A, B, C, and D) were apparent in a ratio of 9:22:57:12%. The crude electrolysis product was treated with methylene chloride whereupon a white solid crystallized. The solid contained only components B and C (vpc). The solid was chromatographed on alumina and the components were separated, B, mp 165°-167° from acetone and C, mp 214°-215° from acetone. The nmr spectrum of C in a 1:1 mixture of methylene chloride and d_6-benzene has a multiplet at τ 8.13, a multiplet at τ 7.08, and a broad singlet at τ 2.80. Therefore C is 3,4-diphenyladiponitrile, lit. (18) mp 215°. The nmr spectrum of B in 1:1 methylene chloride and d_6-benzene has two doublets at τ 7.91 and 7.88, a broad multiplet at τ 6.86, a multiplet at τ 3.33, and a multiplet at τ 2.93. This spectrum is consistent with the expected spectrum of 2-benzyl-3-phenylglutaronitrile. The isomer A was not obtained pure but as a mixture with B. The nmr spectrum of A, eliminating the resonance due to B, showed a doublet at τ 7.75, a multiplet at τ 7.13, and

a broad singlet at τ 2.98. This isomer we believe to be 2,3-dibenzylsuccinonitrile.

Electrolysis of N,N-dimethyl cinnamide.—The catholyte contained 5g of water, 35g of depolarizer and dimethylformamide as solvent. Vpc analysis of the crude electrolysis mixture, 36.2g, 6-ft, XE-60 on Chromosorb W at 200°, showed 18% N,N-dimethyl hydrocinnamide and 82% of a single hydrodimer. Crystallization of the crude electrolysis product from benzene-hexane gave a single hydrodimer, mp 134°-136°. The nmr spectrum of this material in 1:1 d_6-benzene and d_6-acetone as solvent showed a multiplet at τ 7.35, a broad triplet at τ 6.25 and a singlet at τ 3.02. This spectrum is consistent with that expected for N,N,N',N'-tetramethyl-2,3-dibenzylsuccinamide.

Anal. Calcd. for $C_{22}H_{22}N_2O_2$: C, 79.96; H, 6.71; N, 8.48. Found: C, 74.54; H, 8.23; N, 7.92.

Electrolysis of ethyl cinnamate.—The catholyte contained 10g of water, 49.2g of depolarizer and DMF as solvent. Vpc analysis (XE-60 on Chromosorb W column programed from 150° to 225°) of the crude electrolysis mixture, 48.7g showed 41% ethyl hydrocinnamate and 59% of a hydrodimeric mixture (two isomers by vpc analysis). The ethyl hydrocinnamate and ethyl cinnamate were removed by distillation at reduced pressure, bp 65°-75° (0.1 mm). The residue was treated with ethanol and cooled. A white solid crystallized. Recrystallization from ethanol gave product A, a single compound by vpc, mp 105°-107°. The nmr spectrum of the material, in carbon tetrachloride as solvent, had a triplet at τ 9.10, a triplet at τ 8.83, a multiplet at τ 7.20, a triplet at τ 6.46, a pair of quartets at τ 5.88, and a singlet at τ 2.88, slightly split at the base. The IR spectrum of this material has 2 carbonyl frequencies at 1730 and 1700 cm^{-1}. These data are consistent with 2-carbethoxy-3,4-diphenyl cyclopentanone.

Anal. Calcd. for $C_{20}H_{20}O_3$: C, 77.90; H, 6.54. Found: C, 78.00; H, 6.74.

A second product was isolated from the residue by concentration of the ethanol solutions, mp 117°-119° from ethanol [lit. (5) mp for diethyl 3,4-diphenyl adipate 116°]. The nmr spectrum of this material in carbon tetrachloride as solvent showed a triplet at τ 8.75, a broad doublet at τ 7.30, a broad triplet at τ 6.47, a quartet at τ 6.04, and a singlet at τ 2.93. The nmr spectrum of the liquid dimer indicates the presence of a third compound, namely, diethyl 2-benzyl-3-phenylglutarate.

Electrolysis of ethyl 4,4,4-trifluorocrotonate.—The catholyte contained 36g of depolarizer, 5g of water, and DMF as solvent. The electrolysis products were distilled. The products were ethyl 4,4,4,-trifluorobutyrate, 23g, bp 110°-115° (atmospheric pressure) and a dimer fraction, 3g, bp 58°-61° (0.2 mm). The nmr analysis showed ~85% of the dimer mixture was diethyl 3,4-di(trifluoromethyl)adipate; the remaining 15% was probably the unsymmetrical isomer. The mixture was analyzed.

Anal. Calcd. for $C_{12}H_{16}F_6O_4$: C, 42.60; H, 4.73. Found: C, 42.59; H, 4.78.

Electrolysis of ethyl β-trifluoroethylcrotonate.—The catholyte contained 46g of depolarizer, 10g of water, and acetonitrile as solvent. The electrolysis products were distilled, bp 128°-130° (atmospheric pressure). This main cut, 41.6g, contained the depolarizer, 17%, ethyl 3-trifluoromethylbutyrate, 21%, and a third component, 62%. This last component was purified by preparative vpc, 5% silicone rubber on Chromosorb W, 8 ft column, and was identified as ethyl 3-difluoromethylenebutyrate by its i_r spectrum, bands at 1340 and 1760 cm^{-1} for $CF_2 = C$, and nmr spectrum.

Anal. Calcd. for $C_7H_{10}F_2O_2$: C, 51.22; H, 6.14; F, 22.62. Found: C, 50.11, 50.24; H, 6.33, 6.67; F, 23.49, 23.76.

Mixed coupling of N,N-dimethyl-β-carbethoxy acrylamide and acrylonitrile.—The catholyte had 10 ml of water and acrylonitrile as the solvent. Only 5g of the olefin was added to the catholyte at the start of the run. The additional 25g was added as needed to maintain the working electrode potential below −1.4v. The thick electrolysis products were distilled at reduced pressure. Three main cuts were separated: The first, 8.0g, bp 27° (0.6 mm), was shown to be N,N-dimethyl-β-carbethoxypropionamide by vpc comparison with an authentic sample; the second cut, 20.5g, bp 90.92° (0.5 mm), contained 2 isomers in 2:1 ratio by vpc. The infrared and nmr spectra were consistent with a 1:1, N,N-dimethyl-β-carbethoxyacrylamide, acrylonitrile addition product. The minor component was shown to be N,N-dimethyl-3-carbethoxy-5-cyanopentanamide by comparison of vpc retention times on several columns with an authentic sample prepared as described below; the third cut, 2.4g, bp 185°-191° (0.3 mm), was a mixture of hydrodimeric products as discussed above.

N,N-dimethyl-3-carbethoxy-5-cyanopentanamide.—To a solution of chloroacetyl chloride (125g, 1.11m) in 500 ml of dry benzene was added dimethylamine (*ca.* 100g). The solution was stirred for 1 hr, filtered, and the solvent was removed by distillation at reduced pressure. Distillation at reduced pressure gave 115g of N,N-dimethylchloroacetamide, bp 57°-59° (0.3 mm). To a slurry of NaH (40g, 55% dispersion in mineral oil, 0.94m) in 375 ml of dimethylformamide was added diethyl malonate (150g, 0.94m) at a sufficient rate to maintain a reaction temperature between 40° and 50°. After the addition was complete, the yellow solution was stirred until hydrogen evolution ceased. To this solution was added N,N-dimethylchloroacetamide (115g, 0.94m) at a sufficient rate to maintain a reaction temperature of 75°. The slurry was stirred overnight, poured into water, and extracted two times with methylene chloride. The organic layers were combined, dried over sodium sulfate, and the solvent was removed by distillation. Distillation at reduced pressure gave 171g of N,N-dimethyl-diethylmalonylacetamide, bp 140°-143° (0.9 mm).

Anal. Calcd. for $C_{11}H_{19}NO_5$: C, 53.86; H, 7.81; N, 5.71. Found: C, 53.25; H, 7.72; N, 5.75.

Vpc analysis on a 6-ft Ucon. W98 column at 200° showed only one peak.

To a solution of 0.4g of sodium metal in 70 ml of ethanol was added N,N-dimethyl-diethylmalonylacetamide (171g, 0.74m). To this solution was added acrylonitrile (44.5g, 0.8m) dropwise keeping the reaction temperature below 40° by means of an ice bath. The solution was then heated to 50° for 3.5 hr. Sufficient acetic acid was added to neutralize the solution. The solution was poured into water and extracted two times with ether. The ether extracts were combined, dried over anhydrous sodium sulfate, and the solvent was removed by distillation. Recrystallization of the residue from ether gave 114g of N,N-dimethyl-3,3-dicarbethoxy-5-cyanopentanamide, mp 70°-72°.

Anal. Calcd. for $C_{14}H_{22}N_2O_5$: C, 56.35; H, 7.43; N, 9.39. Found: C, 56.36; H, 7.68; N. 9.38.

N,N-dimethyl-3,3-dicarbethoxy-5-cyanopentanamide, (114g, 0.38m) was saponified in the cold with one equivalent of potassium hydroxide in 50% aqueous ethanol as solvent. The neutral solution was acidified with hydrochloric acid, and the solvent was removed by distillation at reduced pressure. The crude acid was dissolved in 750 ml of pyridine. Copper powder (40g) was added, and the slurry was refluxed for 4 hr. The solvent was removed by distillation at reduced pressure. The residue was dissolved in methylene chloride, washed with dilute hydrochloric acid, water, dried over sodium sulfate, and the solvent was removed by distillation. Several recrystallizations of the residue from hexane-ethanol gave 24g of N,N-dimethyl-3-carbethoxy-5-cyanopentanamide, mp 43°-45°.

Anal. Calcd. for $C_{11}H_{18}N_2O_3$: C, 58.39; H, 8.02; N, 12.38. Found: C, 58.36; H, 8.10; N, 12.11.

Ethyl 3,5-dicyanopentanoate was prepared as described above from ethyl bromoacetate and ethyl cyanoacetate, bp 160° (0.9 mm). This material was shown to contain about 6% of an impurity.

Anal. Calcd. for $C_9H_{12}N_2O_2$: C, 59.98; H, 6.71; N, 15.55. Found: C, 59.35; H, 6.85; N, 14.44.

Michael reaction.—The olefin (0.1m) was dissolved in 50 ml of t-butanol with 0.2m of diethyl malonate. Potassium t-butoxide (10 ml of 0.1M solution) was added, and the mixture was stirred about 72 hr. The mixture was then acidified with acetic acid, dissolved in methylene chloride, washed with water, dried over sodium sulfate, and the solvent was removed by distillation. The residue was either distilled or recrystallized to obtain the addition product.

From ethyl p-benzoylacrylate.—The product was distilled, bp 188°-192° (0.35 mm), $n^{25}D$ 1.4943. The nmr spectrum of this material had a pair of doublets at τ 2.10, a multiplet at τ 2.58, a pair of quartets at τ 5.90 and 5.94, a multiplet at τ 6.2 and 6.6, and a pair of triplets at τ 8.78 and 8.83. Vpc analysis on several columns showed only one component.

Anal. Calcd. for $C_{19}H_{24}O_5$: C, 62.65; H, 6.64. Found: C, 62.84; H, 6.60.

From benzalacetophenone.—The product was recrystallized from ethanol, mp 71°-72°. It had a single component (by vpc analysis on several columns).

Anal. Calcd. for $C_{22}H_{24}O_5$: C, 71.72; H, 6.57. Found: C, 71.49; H, 6.71.

From ethyl β-cyanoacrylate.—The product was distilled, bp 138°-140° (0.5m).

Anal. Calcd. for $C_{13}H_{19}NO_6$: C, 54.95; H, 6.37; N, 4.99. Found: C, 54.90; H, 6.37; N, 4.99.

Vpc analysis showed 2 components in a 78:22 ratio. The isomers were separated by preparative vpc. The isomers were saponified with one equivalent of sodium hydroxide and decarboxylated. The two possible products were prepared independently. Diethyl 3-cyanoglutarate was prepared by heating the reaction product of sodium salt of t-butyl cyanoacetate and ethyl chloroacetate with *p*-toluenesulfonic acid, bp 106°-110° (0.2m).

Anal. Calcd. for $C_{10}H_{15}NO_4$: C, 56.32; H, 7.09; N, 6.57. Found: C, 56.34; H, 7.10; N, 6.44.

Diethyl cyanomethylsuccinate was prepared by saponification and decarboxylation of the addition product of ethyl cyanoacetate and diethyl fumarate, bp 115°-117° (0.4m).

Anal. Calcd. for $C_{10}H_{15}NO_4$: C, 56.32; H, 7.09; N, 6.57. Found: C, 56.26; H, 7.30; N, 6.29.

From ethyl β(4-pyridyl)acrylate.—The product was distilled, bp 138°-140° (0.3m).

Anal. Calcd. for $C_{17}H_{23}NO_6$: C, 60.75; H, 6.58; N, 4.14. Found: C, 61.08; H, 7.26; N, 4.68.

Vpc analysis showed 2 components. The isomer distribution was obtained from the nmr spectra.

From N,N-dimethyl-β-carbethoxyacrylamide.—The product was distilled, bp 158° (0.05 mm).

Anal. Calcd. for $C_{15}H_{25}NO_7$: C, 54.50; H, 7.61; N, 4.23. Found: C, 54.37; H, 7.69; N, 4.21.

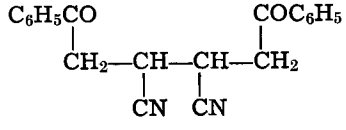
Vpc analysis showed only one component on four different columns. The material was saponified and decarboxylated. The product of this reaction showed a single ester group in the nmr.

Results

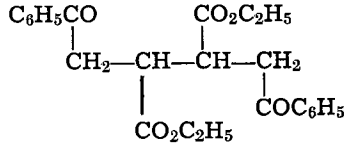
The data obtained from bulk electrolysis at the first polarographic wave of various representative diactivated olefins **1** are summarized in Table I.

The electrolysis of dibenzoylethylene **I** yields four products, dibenzoylethane, meso-1,2,3,4-tetrabenzoylbutane, dl-1,2,3,4-tetrabenzoylbutane and a small amount of 1,2,3,4,5,6-hexabenzoylhexane. In view of the relative stability of the anion radical, $t_{1/2}$ = 15.3 sec at 2 x $10^{-3}M$ toward reaction with the parent olefin (1), it is not surprising that a relatively large amount of the ethane derivative was obtained. Only 3 ml of water could be used in the catholyte in order to get even a 40% yield of the hydrodimer. The hydrodimer in this case is probably formed by a combination of paths A and B.

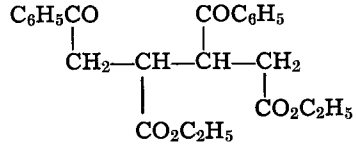
In contrast, path A is the predominant route to products from β-benzoylacrylonitrile (II). In the electrolysis of II, 20 ml of water was used, and the pH was maintained as near 7 as possible by the frequent addition of acetic acid. Under these conditions 55% of the hydrodimer was isolated. (Using less water resulted in the exclusive formation of trimers and higher oligomers of the olefin.) Two crystalline isomers were isolated from the electrolysis. The nmr spectra of these isomers were identical. The positions of the resonance of the phenyl hydrogens as well as the shape of the signal are identical for the hydrodimers and for β-benzoylpropionitrile. The most likely structure for these products are meso and dl-1,4-dibenzoyl-2,3-dicyanobutane (XI).



(XI)



(XII)



(XIII)

No cross-coupled products were obtained even when acrylonitrile was used as the solvent.

Another example which probably involves paths A and B but not C is the electrolysis of ethyl β-benzoylacrylate (III) in acrylonitrile. Two solid products and a liquid mixture were obtained. The nmr spectra of the solids were nearly identical. The position of the resonance of the phenyl hydrogens are identical for the hydrodimers and for ethyl β-benzoylpropionate.

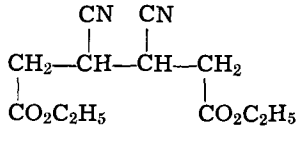
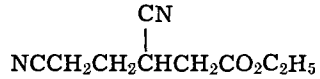
The nmr spectrum of the liquid mixture indicated the presence of *ca.* 80% of the solid isomers and *ca.* 20% of a third compound which has a carbethoxy group in a different environment. The nmr spectrum of the solid isomer is consistent with the expected spectrum from 1,4-dibenzoyl-2,3-dicarbethoxybutane (XII), while the shifted methylene and methyl resonances in the nmr spectrum of the liquid indicate an unsymmetrical structure, *i.e.*, 1,3-dibenzoyl-2,4-dicarbethoxybutane (XIII) possibly arising through path B. No cross-coupled product was obtained.

Ethyl β-cyanoacrylate on electrolysis gives through path A at least 95% diethyl 3,4-dicyanoadipate (XIV) with a small amount of the unsymmetrical isomer. The nmr spectrum of (XIV) is consistent



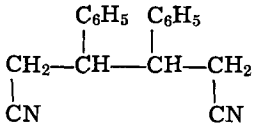
(XIV)



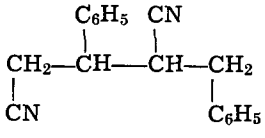
(XV)

with this structure. The nmr spectrum of the copper (I) complex of (XIV) shows the most highly shifted protons are the methylene protons. This type of complex is formed with nitrile groups and is very sensitive to the ring size being formed (2). Saponification of (XIV) gave 3,4-dicyanoadipic acid which was identified by comparison with an authentic sample synthesized from 3,4-dicyanocyclohexene.

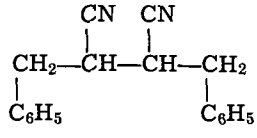
Four isomers were indicated by the vpc analysis of the electrolysis products of cinnamonitrile (V) (3). One of the isomers (22%) was the previously reported 3,4-diphenyladiponitrile (XVI). The nmr spectrum of the second isomer showed two different phenyl



(XVI)



(XVII)



(XVIII)

groups and 2 doublets for the methylene hydrogens. This spectrum is consistent with that expected for 2-benzyl-3-phenylglutaronitrile (XVII). The third isomer had a single phenyl group and a single methylene group both significantly different from the phenyl group of (XVI). It is, therefore, probably 2,3-dibenzylsuccinonitrile (XVIII). The nmr spectra of the fourth isomer showed two different phenyl groups, and therefore the compound is probably an isomer of (XVII). Paths A and B are probably used here. Path C was not tested. Similarly, paths A and B are indicated in the electrolysis of ethyl cinnamate which yielded two solid products and a liquid mixture. One of the solids is the previously reported meso-diethyl 3,4-diphenyladipate (5). The second isomer is a cyclized ketone. The nmr spectrum of this compound has a broad singlet at τ 2.91. Of the two possible ketone products, only 2-carbethoxy-3,4-diphenylcyclopentanone would be expected to have nearly equivalent phenyl groups. The nmr spectrum of the liquid mixture shows two different carbethoxy groups and a broad multiplet for the phenyl group. The mixture probably consists of some dl-diethyl 3,4-diphenyladipate (*ca.* 20%) and diethyl 2-benzyl-3-phenylglutarate.

The electrolysis of N,N-dimethylcinnamide (6) gave only N,N,N',N'-tetramethyl 2,3-dibenzylsuccinamide, probably through path A. The nmr of this material showed a single phenyl group identical to the phenyl group of N,N-dimethylhydrocinnamamide, and the amide-methyl groups were significantly shifted.

A very poor yield of dimeric products was isolated from the electrolysis of ethyl β-trifluoromethylacrylate. The dimeric product appears to be a mixture of *ca.* 85% of diethyl 3,4-trifluoromethyladipate and 15% of diethyl 2-trifluoromethyl-3-(2,2,2-trifluoroethyl) glutarate. Similarly, the electrolysis of ethyl β-trifluoromethylcrotonate gives no dimeric products, but does give the fluoride elimination product, ethyl 3-difluoromethylenebutyrate, in 70% yield. The steric effects on the dimerization reaction are apparent in this case. A methyl group in the position β to the carbethoxy group, the position through which the dimer of olefin (IX) forms, blocks the dimerization reaction and, therefore, affords the intermediate the opportunity to eliminate a fluoride ion.

All three paths are operative in the electrolysis of N,N-dimethyl β-carbethoxyacrylamide. Product analysis by vpc showed 5 hydrodimeric isomers. One solid isomer was isolated, and the nmr spectrum was consistent with diethyl 3,4-(N,N,N',N'-tetramethylcarbamoyl) adipate (XIX). The structures of other isomers were assigned by a comparison of the nmr spectrum of the mixture with the spectra of (XIX) and N,N,N',N'-tetraethyl-3,4-dicarbethoxyadipamide synthesized independently. In this case, the product distribution was sensitive to the amount of proton donor added to the catholyte (1). The second run contained 10 ml of water, while the first run contained only 3 ml of water in the catholyte. No acetic acid was added during the electrolysis. The pH was controlled as uniformly as possible for each run simply by allowing the ester to saponify.

Of the possible paths available for the reaction of the anion radical 2 only path E [Eq. (4)] is sensitive to the water concentration. The protonation of 2 yields a radical α to either X or Y depending on their individual ability to stabilize the radical. This radical is rapidly reduced, yielding the most stable anion. The attack of this anion on the parent olefin yields an unsymmetrical product since the attack would result in the most stable anion (Eq. [6]). Path B can lead to a different isomer than path A and in fact, from olefin VIII.

$$\overset{(-)}{\mathrm{YCH_2\dot{C}HX}} + \mathrm{YCH=CHX} \rightarrow \mathrm{YCH_2CHXC\dot{H}YCHX} \overset{(-)}{} \qquad [6]$$

does as evidenced by the change in isomer distribution with water concentration.

Only diethyl fumarate (—1.54v) and N,N-dimethyl-β-carbethoxyacrylamide (VIII) gave cross-coupled products with acrylonitrile in sufficient yield to be isolated. A trace of cross-coupled product between ethyl β-cyanoacrylate (—1.45v) and acrylonitrile was indicated by vpc analysis after many unsuccessful experiments. The only successful technique for obtaining the cross-coupled products was to add the depolarizer dropwise to the electrolysis solution using acrylonitrile as the solvent. Even using this technique, no cross-coupled products were obtained from olefins II (—1.11v) and III (—1.23v). The cross-coupled products from olefins (VIII) were ethyl 3-(N,N-dimethylcarbamoyl)-5-cyanopentanoate (XX) and N,N-dimethyl-3-carbethoxy-5-cyanopentanamide (XXI) in a 2:1 ratio. The cross-coupled product from olefin IV was ethyl 3,5-dicyanopentanoate (XV). These products were identified by comparison of vpc retention

times and nmr spectra with authentic samples prepared independently.

Discussion

Reaction sequences and alternate routes to products.—From consideration of the energetics and the nature of the products obtained we conclude that the attack of **2** on the substrate is nucleophilic rather than free radical. This type of reaction leaves the radical site on the electrode surface where it is available for further rapid reduction without reorientation of the molecule. Chart II outlines the detailed subsequent reaction paths. By paths A and C coupled products are formed at the electrode: A leads exclusively to hydrodimers; C leads exclusively to cross-coupled products. Path B, which involves coupling probably away from the electrode surface, can lead to hydrodimers, dihydroproduct, and cross-coupled products. The distribution of total products depends then critically on the extent of participation of reagents by path A, B (7), or C. This, in turn, depends on (*a*) the inherent reactivities of the species involved, (*b*) their availability at the electrode surface, (c) their steric requirements, and most of all (*d*) their polarizability in the electric field.

The influence of each of these factors is best illustrated by an analysis of the situation that obtains, when **1** is undergoing reduction, in the presence of an acceptor like acrylonitrile:

1. The reactivity of **2** toward **1** (path A) is roughly proportional (1) to the reduction potential of **1**. (Deviations from this relationship appear to be due to steric factors.) In all types of current macrocells employed unreduced **1** is always available for reaction with **2** at the electrode. When **2** is formed at a much more positive potential (*e.g.*, —1.23v, compound III) than is required for acrylonitrile (—1.9v), the sequence through path A overwhelms any possibility of obtaining mixed coupled products.

2. The reactivity of **2** toward acrylonitrile (in the unavoidable presence of **1** at the electrode surface) increases as required potential for forming **2** (*e.g.*, —1.76v, compound VIII) becomes more negative probably due to the increased polarization of acrylonitrile at the higher potential. Simultaneously, as indicated above (1), the reactivity of **2** toward **1** decreases, so that mixed coupled products can be formed (path C competing with path A). The limit of separation of the potentials of the donor and acceptor appears to be *ca.* 0.4v. This is a similar potential spread to that observed by Höfelmann *et al.* (8), for the anionic copolymerization of activated olefins.

3. Reaction of **2** with water as the first c reaction leads to products derived from **3** (path B). The extent of participation of water to a much lesser extent than that of acrylonitrile also increases (1) with increasing negative potential requirements of **1**. The distribution of products obtained from **3** is what might be expected from a Michael reaction in which **1**, acrylonitrile, and a proton source compete for a carbanion. In particular the amount of coupled product derived from **3** is sensitive to the bulk water concentration.

Activating group effect; role in isomer distribution.—Since the initial addition products formed by path A are dimeric anion radicals [(Eq. 3)] having a complete separation of the anion and the radical sites, the distribution of the isomeric products obtained should depend on three considerations: (*a*) the relative stabilizing effect of the activating groups for an α-anion in the "acceptor" half of the dimer, (*b*) the relative stabilizing effect of the activating groups for an α-radical in the "donor" half of the dimer, and (*c*) some steric effects similar to those encountered in ordinary Michael reactions. By contrast the major factor that need be considered in rationalizing the distribution of the isomeric Michael adducts obtained from XCH=CHY **1** (9) and a typical donor such as diethyl malonate anion is the relative ability of X and Y to stabilize an adjacent anion (Table II).

By comparing the distribution of isomeric products obtained electrochemically from individual monomers, an order of relative stabilizing effects can be obtained; *e.g.*, from the structure of the dimeric product from olefin (II), it is clear that the benzoyl group is more effective at stabilizing both the anionic and radical sites than is the nitrile group. Similarly, the structure of product from olefin (IV) indicates that the carbethoxy group is more effective than the nitrile group at stabilizing both; the product from olefin (X) indicates that the phenyl group is more effective than the amide for stabilizing both the anionic and radical sites. A comparison of the products from olefins (IV), (V), and (VII) indicates that the relative stabilizing effects for an anionic site are $CO_2C_2H_5 > CN > C_6H_5$, while for the radical site they are $CO_2C_2H_5 \geq C_6H_5 > CN$. The remaining activating groups can be assigned ratings of activating influences in this series on the basis of product distribution from individual olefins. Therefore, the relative stabilizing effects are: for an anionic site, $C_6H_5CO > CO_2C_2H_5 >$ 4-pyridyl $> CN > CF_3 > C_6H_5 > CON(CH_3)_2$ (10), and for the radical site, $C_6H_5CO > CO_2C_2H_5 \geq$ 4-pyridyl $\geq C_6H_5 > CF_3 > CN > CON(CH_3)_2$. These "stabilizing" orders necessarily include steric effects since no attempt was made to eliminate them. It is not clear whether these stabilizing orders reflect kinetic or thermodynamic control of the product distribution. Since the addition of the anion radical **2** to the olefin is very rapid (Eq. [3]), the products which are formed by path A probably exhibit kinetic control. On the other hand, no conclusion on this point can be drawn with regard to the reaction of the monomeric anion with the olefin (Eq. [4]).

With this reservation in mind, some comments concerning the orders of stabilizing ability as derived from this work and its relation to reported work can be made. The predominant ability of the benzoyl group to stabilize both an anion and a radical is as expected (11). The finding that the carboxylic ester dominates over a competing nitrile group is unusual (12). However, recently, Lentz and Weiss (13) have shown that the major adduct obtained from a 1:1 mixture of acrylonitrile and ethyl acrylate catalyzed by trialkylphosphine was ethyl α-cyanoethylacrylate. This reaction has been postulated as going through a series of equilibria (14) one of which in this case would involve a direct competition between an anion α- to the carbethoxy or α- to the nitrile group. The predominance

Table II. Product distribution from the Michael reaction of selected diactivated olefins with the potassium salt of diethyl malonate in t-butanol solution

of this crossed product indicates the greater stabilizing ability of the carbethoxy group over the nitrile group for the anionic site. Both the nitrile (15) and the carbethoxy (16) groups have been shown to be better for stabilizing an anion than the phenyl group. Very limited data are available regarding the relative stabilizing effects of these activating groups on a radical. The data of Knunyants (17) from the amalgam dimerization of cinnamate derivatives in acid media and of Huang and Singh (18) from the generation of hydrocinnamate radicals by t-butyl peroxy radicals indicate that the phenyl group is better than the carbethoxy, nitrile and amide groups for stabilizing a radical. No comparisons in this regard have been reported among the latter three groups.

An attempt to obtain a quantitative reactivity order from our data was unsuccessful. As pointed out previously, the dimeric products can arise by either path A or B (Eq. [3] and [4]) probably yielding different isomeric products. It is difficult to ascertain the relative contribution of each path. Obviously, the concentration of proton source in the catholyte is critical. Hydronium ions must pass through the membrane separating the anolyte and catholyte during the electrolysis to maintain electrical neutrality. Since the porosity of the membrane can not be rigorously controlled, the concentration of proton source in the catholyte varies to a small but significant extent not only during a particular electrolysis but more importantly from one electrolysis to the next. Therefore, only a qualitative order of relative stabilizing effects under these electrochemical conditions can be drawn.

All of these conclusions are based on the use of the tetraalkylammonium cation. The effect of using an alkali metal cation on the product distributions as well as on the reactivity of anion radicals is being investigated.

Acknowledgment

The authors wish to express their appreciation to John L. Chruma for excellent technical assistance and to Dr. Donald A. Tyssee for devising and executing the synthesis of 3,4-dicyanoadipic acid.

The Electrochemical Behavior of Zinc in Alkaline Media

John P. Elder*[1]

Metals & Controls, Inc., a corporate division of Texas Instruments Incorporated, Attleboro, Massachusetts

ABSTRACT

The electrochemical behavior of horizontally disposed planar zinc in 30% (6.9M) potassium hydroxide, alone and saturated with zinc oxide at 25°C, has been investigated in a controlled manner, using both galvanostatic and potentiostatic techniques. The anodic characteristics have been interpreted in terms of a kinetically controlled process preceding a diffusion step. The cathodic behavior of oxidized zinc has been interpreted in terms of a complex two-state process, involving the formation of a bound zinc hydroxide, followed by a reduction of both the adsorbed species and the soluble zincate to zinc metal.

Of the several sophisticated energy conversion devices investigated in the last two decades, there is strong evidence of the increasing predominance of rechargeable alkaline battery systems. Within this field, there is an ever-increasing interest in the use of zinc as the favored anode material. One of the main disadvantages in the use of zinc as the negative electrode in silver-zinc and nickel-zinc cells lies in the fact that zinc hydroxide is highly soluble in the strongly alkaline aqueous electrolytes employed in these systems. Any study of the electrochemical behavior of zinc in alkaline media must consider the mechanism and kinetics of the complex electrode reactions in relation to the nature of the electrolyte at the electrode interface and in the bulk of the solution.

Potentiometric (1, 2), spectral (3) and P.M.R. (4) investigations indicate that the predominant zincate species existing in highly alkaline media is $Zn(OH)_4^{2-}$. Jost (5) and Okinada (6) do not preclude the presence of $Zn(OH)_3^-$, specially in more dilute solutions. Detailed physicochemical data pertaining to solubility (5, 7-9), conductivity (7-9), and vapor pressure (9) is available. Kober and West (10) indicate that the nature of the species present in solution is dependent on the hydroxyl ion activity, which is itself governed by the zincate ion concentration. As one approaches saturation, negatively charged colloids tend to form (2) which further complicates the situation. Under certain conditions, notably during anodization of zinc, supersaturation can occur (11). However, little is known concerning the nature of such solutions, which are localized in the anolyte layer. Practical, porous zinc battery electrodes investigated singly, or in the cell environment, in the laboratory, are normally charged and discharged under constant current conditions. Although it is argued that when such a highly active electrochemical system as this is investigated using the galvanostatic technique, certain transient features of the electrode phenomena will be overshadowed (14), there are reasons why such a technique should be employed. By studying the behavior of planar zinc under such conditions, it is hoped that the observations will assist in the interpretation of the behavior of the more complex practical system. A number of studies of the anodic behavior of planar zinc in highly concentrated aqueous alkali have been performed (12-20). As Hampson *et al.* (17) state, the common feature of galvanostatic investigations is the difficulty in obtaining reproducible results. Eisenberg *et al.* (15) emphasize the importance of considering the disposition of the zinc anode and the resulting effects of convection on passivation phenomena. Using the rotating disk electrode to control mass transfer, Popova *et al.* (18-19) have investigated the anodic dissolution of passivated zinc using both potentiostatic and galvanostatic control. Sanghi and Wynne-Jones (13) concluded that insufficient electrode pretreatment was a major cause of irreproducibility and error in such passivation experiments. Most investigations of this system have employed some form of mechanical polishing, although there is some disagreement as to the correct method. Farr and Hampson, who employed both faradaic impedance measurements (21) and the double pulse galvanostatic technique (22) in attempting to elucidate the mechanisms associated with the anodic oxidation of zinc, have stressed very high metal purity in their studies with micro-electrodes.

The relationship of anodic current density and zinc passivation time has very often been expressed by the empirical equation (12, 15-17) $i - i_{lim} = k \cdot t^{-1/2}$. The purpose of the present investigation was to test the validity of this relationship over a wider range of current densities than has hitherto been studied, with special emphasis on accuracy and reproducibility. The major part of this paper deals with the findings of the chronopotentiometric study. The anodic oxidation of horizontally disposed zinc in 30% (6.9M) potassium hydroxide, and in the zinc oxide saturated electrolyte at 25°C, and the cathodic reduction of the oxidized electrode under galvanostatic control, have been studied. The slow cyclic voltammetric technique was also employed and some of the resulting data are presented.

Experimental

Electrolytic cell.—In Fig. 1 is shown a cross-sectional diagram of the cell used in this investigation. It consists of a 6.5 x 3.5 x 3.5 in. double-walled Lucite container with two compartments. Water from a constant temperature bath is continually circulated through the double-walled spacing, maintaining the temperature at 25°±0.2°C. The mercury-mercuric oxide reference electrode system was set up in the right-hand compartment. The working-counter electrode system consists of a fixed platinum gauze disk and a 1.08 cm^2 area planar zinc disk, embedded in a removable Lucite disk, both mounted on a Lucite support.

* Electrochemical Society Active Member.
[1] Present address: Electrochemistry Department, Whittaker Corporation, 3540 Aero Court, San Diego, California.

99.999% zinc (A. D. Mackay, Inc., New York) was used throughout. The electrode support, when introduced into the major compartment, fits rigidly into a position adjacent to the compartment separating wall, in such a manner that the periphery of the zinc disk lies within 0.5 mm of a 0.4 mm diameter, 45° channel through part of the wall. This channel serves as a Luggin capillary. It opens into a wider channel packed with compressed nylon fiber, soaked with cell electrolyte, acting as a salt bridge. The continuation of the open channel as shown, allows for the escape of any gas bubbles which otherwise might become entrapped in the Luggin. A fourth platinum gauze disk electrode, suspended in a cylindrical nylon chamber with a base of compressed nylon fiber located in the major compartment, is employed during potentiostatic prebiasing of the working electrode. Solution and gas inlets and outlets and a thermometer well complete the cell.

Electrode Pretreatment.—Sanghi *et al.* (13, 14) mechanically polished zinc with alcohol-lubricated emory, followed by Selvyt cloth. Hampson *et al.* (16, 17) preferred an acid dip, followed by polishing with moist filter paper. Popova *et al.* (18-20) polished zinc with moist glass powder. It has been observed repeatedly in this laboratory that, if mechanically polished zinc is cathodically polarized in a hydrogen-saturated, concentrated aqueous alkali, finely divided zinc forms on the electrode surface. However, such a deposit, resulting from the reduction of a thin surface layer of oxide, does not form if the mechanically polished zinc is chemically polished prior to immersion in the electrolyte. Chemical polishing was chosen since the suggested laboratory electropolishing procedure for zinc is time-consuming (23). Three solutions were studied. Chromic-sulfuric acid proved unsuccessful, immersion in this solution yielded a white film. Although a 50% hydrogen peroxide—50% acetic acid solution may be used, it is not advised since one must control the temperature and immersion time rigidly and the anolyte layer must be quiescent. A 1-sec immersion in 50% nitric acid at room temperature proved very successful and was used throughout this investigation. Prior to each experiment, the following procedure was followed: The zinc disk was mechanically polished on three grades of water-lubricated silicon carbide emory, followed by a 0.3μ micropolish on Selvyt cloth. The disk, then mounted on the Lucite support, was chemically polished, washed successively in hydrogen-saturated deionized water and 30% potassium hydroxide, and then rapidly inserted into the cell. At the moment of insertion, the zinc was held at the appropriate prebias potential (see Results section) prior to initiating the charging study. Under these conditions, reproducible data were obtained.

Electrical circuitry.—Conventional circuitry was employed for the programmed charging studies. A simplified block diagram is shown in Fig. 2. The potentiostatic-galvanostatic sequence control unit incorporates time-delay circuits and the necessary mercury-wetted switching relays. Philbrick solid-state operational amplifier circuitry was used throughout. The voltage followers, VF1 and VF2, were a P.85 and a P.65AU, respectively. An SP.656 was employed for the integrator, I. P.65AU amplifiers were employed for the differentiator, D, and the voltage comparator, VC, sensitive to ± 1 mv. In conjunction with a potentiostat (Wenking, standard model #61 TRS) and two independent constant current units, of the type described by Bockris *et al.* (24), a variety of operational sequences may be applied to the working electrode system. During potentiostatic prebiasing, the Osteryoung (25) four-electrode technique was employed in order to obtain clean switching to the galvanostatic mode. Switching from the first to the second galvanostat may be accomplished either when the working electrode has attained a given potential level, VF1-VF2-VC network, or when a given charge input has been reached, VF1-I-VC network. The Wenking motor potentiometer, MP. 165, was employed to drive the potentiostat for the slow cyclic voltammetric studies. A Tektronix #565, dual-beam oscilloscope with type 2A63, differential amplifier vertical plug-in units was used to record fast charging curves. Slow chronopotentiometric and cyclic voltammetric data were recorded with a Hewlett-Packard, Moseley, 136AM, dual-pen recorder.

Results

A steady equilibrium potential is not observed when freshly polished zinc is immersed in 30% potassium hydroxide. At —1.400v (—1.302v *vs.* NHE), a very small cathodic current flows. In all subsequent studies in this media, the zinc was prebiased at this potential prior to initiating either the galvanostatic charging program or the slow linear potential sweep. In the zinc oxide saturated electrolyte, zinc initially exhibits a potential of —1.345v (—1.247v *vs.* NHE). This slowly drifts to —1.352v where it remains steady. This final value was employed in this media as the prebias potential.

In Fig. 3 is shown a tracing of an oscillographically recorded potential-time curve, typical of the electrochemical behavior of zinc in 30% potassium hydroxide at 25°C undergoing the following charging program, anodic oxidation at 500 ma (462 ma/cm^2) for 15 sec, *i.e.*, a charge input of 7.5 coulombs, followed by cathodic reduction at 100 ma (93 ma/cm^2). While the zinc was prebiased at —1.400v, the oscilloscope was triggered, point a. Approximately half a second later, anodic charging was initiated, point b. The potential jumped very quickly to point c, *circa* —1.2v where the anodic transition commences. The potential rises linearly to point d, *circa* —1.0v in 6.7 sec. Differential measurements confirmed that this transition exhibits

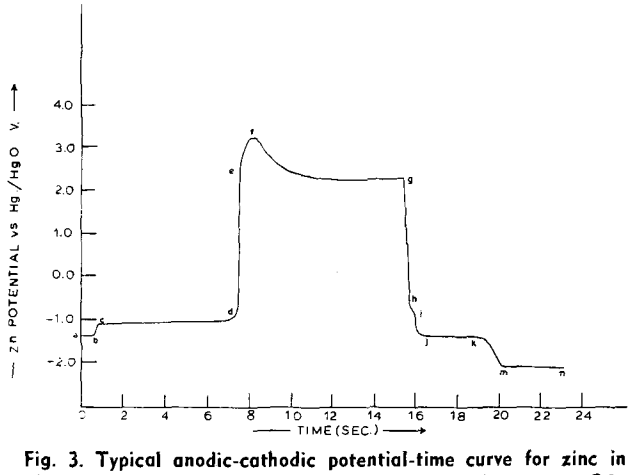

Fig. 3. Typical anodic-cathodic potential-time curve for zinc in 30% potassium hydroxide at 25°C. Prebias —1.400v, anodic C.D. 462 ma/cm^2, cathodic C.D. 93 ma/cm^2.

no discontinuities. At point d, passivation is complete, as indicated by the large increase in impedance. The potential rises extremely rapidly to point e, *circa* +2.2v, where the galvanostatic overshoot commences. The potential peaks at +3.2v, point f, and then levels at +2.25v, where oxygen evolution proceeds. Current reversal was initiated at point g. The potential falls rapidly to *circa* —0.5v, point h, where there is a relatively short-lived transition to point i, *circa* —0.9v. (The time scale of this region has been magnified in the diagram to show the transition.) The potential drops rapidly to point j, *circa* —1.35v, where a larger cathodic transition is observed. Like the anodic transition region, c-d, this transition is well-defined and shows no discontinuities, as indicated by differential measurements. The potential falls linearly to *circa* —1.37v, point k, in 2.1 sec. The potential finally falls to *circa* —1.9v, point m, where vigorous hydrogen evolution occurs. In the zinc oxide saturated electrolyte, the potential-time characteristics are very similar to that described above. Following prebias at —1.352v, on charging, a well-defined continuous passivation region is observed, followed by a galvanostatic overshoot. On cathodic polarization from the oxygen evolution potential, the first cathodic transition is observed. This is more well defined than that observed in potassium hydroxide alone. The potential then falls to the final value, —1.35v. On continuous polarization, a mossy deposit of zinc results, and the potential never falls to that indicative of the H.E.R. The anodic transition region has been studied over a wide range of current densities in both electrolyte media at 25°C. In order to study the cathodic current density-transition time characteristics, zinc was anodically oxidized under constant conditions (potassium hydroxide alone, 462 ma/cm^2, zinc oxide saturated electrolyte, 342 ma/cm^2) to 7.5 coulombic input, prior to initiating cathodic polarization. The resulting chronopotentiometric data for regions c-d, h-i and j-k are shown in Table I.

Anodic characteristics.—Zinc exhibits a steady anodic potential when charged at low current densities. As the limiting current density is approached, the potential commences to drift with time to less negative values. At any given current density in the range, 10^{-4} — 10^{-1} amp/cm^2, the anode potential is less negative in the zinc oxide saturated electrolyte than in potassium hydroxide alone. Furthermore, there is no linear Tafel region. In the zinc oxide saturated media only, two anodic transitions were observed at high current densities. The first transition was very short lived, and the potential was relatively close to the equilibrium value. The second, main transition, was of much longer duration and at a less negative potential, *e.g.*, at an anodic current density of 740 ma/cm^2, the first transition at —1.27v lasted for 3 msec, while the second transition at —0.7v lasted for 0.37 sec before passivation and the ensuing overshoot. With decrease in current density, the potential of the short-lived transition approached the equilibrium value, and the time decreased to such a value as to be extremely difficult to measure with any accuracy.

Cathodic characteristics.—The potential-time curves characteristic of the cathodic behavior of oxidized zinc were monitored in the following manner. After prebias and anodization, the oscilloscope was triggered just prior to point g (see Fig. 3). The appropriate time base was selected to study either region h-i or j-k. The first cathodic transition region h-i was observed on potential decay as well as during cathodic polarization. On potential decay in potassium hydroxide alone, the transition time was 0.72 sec. In the zinc oxide saturated media, the transition time was 5 sec. On cathodic polarization, the transition times were reduced considerably and, furthermore, the region became increasingly ill defined. In potassium hydroxide alone, it became impossible to measure transition times with any accuracy above 15 ma/cm^2. In the zinc oxide saturated electrolyte, this limit was extended to 45 ma/cm^2. This characteristic region is observed only if, in the preceding oxidation, the potential has attained a certain value. If, by means of the voltage level switch, anodic charging is interrupted at any potential between points d and e, region h-i is not observed. An example of this behavior is shown in Fig. 4. Following prebias at — 1.4v, the oscilloscope was triggered and the zinc oxidized at 462 ma/cm^2. At —0.75v, the potential decay curve was initiated. The potential fell instantaneously to —1.35v where it remained steady. If the voltage cut-off is raised from e to f, the characteristics of the first cathodic transition region become more well defined. Once the peak of the galvanostatic overshoot has been attained, region h-i characteristics remain unaffected on further anodic polarization. The second cathodic transition region j-k, which can only be studied in potassium hydroxide alone, was observed irrespective of the voltage level at which cathodic polarization was initiated.

In Fig. 5 are shown cyclic voltammograms characteristic of the behavior of zinc in 30% potassium hydroxide (full line) and the zinc oxide saturated

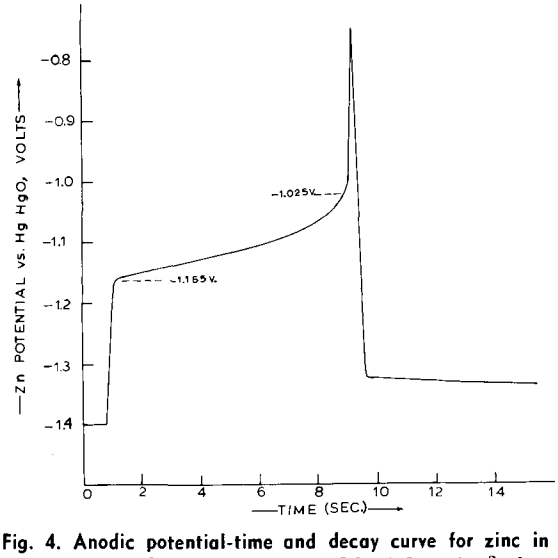

Fig. 4. Anodic potential-time and decay curve for zinc in 30% potassium hydroxide at 25°C. Anodic C.D. 462 ma/cm^2, decay initiated at 0.75v vs. Hg/HgO.

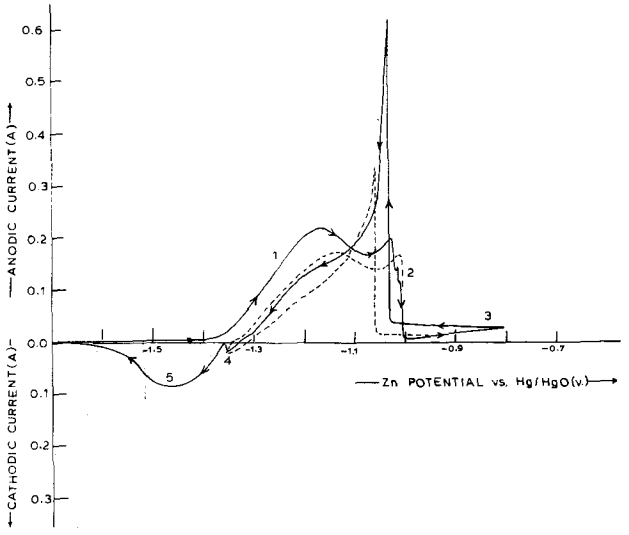

Fig. 5. Cyclic voltammograms for zinc in 30% potassium hydroxide at 25°C. Sweep rate 2.78 mv/sec; full line, potassium hydroxide alone; dashed line, zinc oxide saturated media.

electrolyte (dashed line) at 25°C. The sweep rate was 2.78 mv/sec. In potassium hydroxide alone, following an initial prebias at —1.4v, the applied potential was lowered to —1.7v and the slow linear potential sweep initiated. The sweep was reversed manually at —0.8v and continued to —1.7v. In the zinc oxide saturated media, the forward sweep was initiated from the prebias potential, —1.352v, reversed at —0.8v and stopped at —1.352v. If the sweep was continued to more negative potentials in this electrolyte, the cathodic current density increased linearly and a mossy zinc deposit resulted. At very low sweep rates, marked current oscillations were observed in region 2. Visual observation showed the growth of an oxide film in region 3. On the reverse pass, this film disappeared in region 2, with an instantaneous increase in anodic current. Irrespective of the sweep rate, this anodic spike occurred at the same potential, —1.03v in potassium hydroxide alone, —1.06v in the zinc oxide saturated media. With increase in sweep rate, the character of regions 1, 2, and 4 became less well defined, whereas region 5 remained unaffected. A study of the variation of the peak currents and potentials of regions 4 and 5 with sweep rate yielded inconclusive results. However, on the forward pass, consistent results were obtained relating the region 1 anodic peak current and potential with sweep rate. For both electrolyte media, the potential shifted to less negative values, and the current increased with increase in sweep rate. The majority of the data recorded pertained to the zinc oxide saturated electrolyte. The relevant data over the range, 0.56-139 mv/sec are summarized in Table II. The potential data was reproducible to ±5 mv and the current density to ±2 ma/cm². On continued cycling at any particular sweep rate, the over-all voltammetric character remained essentially the same. However, the anodic region 1 broadened and lost character. The peak, which became increasingly difficult to identify, tended to move to more negative potentials, and the current density decreased in value, ultimately approaching a limit. When cycling was interrupted at the conclusion of a complete pass, the system immediately reverted to its initial state, as indicated by the character of the first voltammogram recorded after the interruption. On continued cycling, the above behavior was repeated.

Discussion

The anodic polarization data obtained at low charging current densities in this study is in good agreement with that reported by Dirkse *et al.* (26). The limiting current density data obtained in this investigation is compared with selected pertinent published data in Table III. The magnitude of the values reported for differently oriented electrodes examined after various pretreatments in the several media tend to cast doubt on the value reported by Hampson and Tarbox (16). In general, a working electrode potential is a function of both the current density and the electrolyte interfacial concentration of the electroactive species (27). Since Dirkse (11) and Eisenberg *et al.* (15) have established a concentration build-up in the anolyte layer during the anodic oxidation of zinc, it is not surprising that the working potential data cannot be analyzed in terms of the charge transfer kinetic equation (28). $i - \tau$ data for the anodic oxidation of zinc in highly alkaline media has traditionally been correlated by means of Eq. [1]

$$(i - i_{lim})\tau^{1/2} = k \qquad [1]$$

The data obtained in this investigation (Tables I and III) has shown that k is a function of the current density. For both electrolyte media, with increase in current density, k increases to a maximum (KOH, k_{max} = 1 amp sec$^{1/2}$/cm² at 425 ma/cm², KOH-ZnO, k_{max} = 0.65 amp sec$^{1/2}$/cm² at 230 ma/cm²), and then gradually decreases. The conventional method of treating chronopotentiometric data, characteristic of electrochemical phenomena involving at least one electrolyte soluble species, is to study the characteristics of $i\tau^{1/2}$ *vs.* i plot. Such plots are shown in Fig. 6 for A, potassium hydroxide, B, zinc oxide saturated potassium hydroxide. When the limiting current density has been exceeded, $i\tau^{1/2}$ decreases linearly with increase in current density, ultimately attaining a limiting value. Between the linear plot current density limits, the data has been fitted to a general equation of type [2] by means of a least squares fit regression analysis program (IBM S/360 computer).

$$i\tau^{1/2} = k_0 - k_1 \cdot i^m \qquad m = 1, 2, 3, \ldots \qquad [2]$$

In Table IV are shown the calculated values of k_0 and k_1 for m = 1, and the associated statistical data. The high value of the correlation coefficient, C.C., and

the low values of the standard error, S.E., and the standard error of the estimate, S.E.E., confirm the accuracy and reproducibility of the data and the validity of Eq. [2]. With increase in m, C.C. decreases indicating that $m = 1$ is the correct value. For comparison, the data of Eisenberg *et al.* (15) in zinc oxide saturated potassium hydroxide are shown plotted in Fig. 6, Curve C, and the calculated coefficients of [2] are given in Table IV. The greater scatter in this data is mirrored in the associated statistical data. The anodic oxidation of zinc shows all the characteristics of a complex mechanism involving a kinetically controlling step preceding the diffusion of a soluble species through the boundary layer. Theory (27) indicates that, if the concentration of a soluble diffusing species is dependent on the kinetics of a preceding process, then the chronopotentiometric parameter is related to the current density by Eq. [3].

$$i^{1/2} = \frac{n\mathbf{F}(\pi D)^{1/2}\Delta C}{2} - \frac{i\pi^{1/2}}{2K(k_f + k_r)^{1/2}} \qquad [3]$$

ΔC is the concentration difference between the bulk and the interface, D is the diffusion coefficient of the soluble species. $K = k_f/k_r$ is the equilibrium constant of the preceding kinetically controlling step. This equation is valid provided that $(k_f + k_r)^{1/2}\tau^{1/2} \geq 2$. At sufficiently high current densities, when τ is small, [3] reduces to [4].

$$i\tau^{1/2} = \frac{K}{K+1} \cdot \frac{n\mathbf{F}(\pi D)^{1/2}\Delta C}{2} \qquad [4]$$

Farr and Hampson (21, 22) indicate the possibility of kinetically controlling reactions preceding a solution diffusion stage. Dirkse *et al.* (26) have summarized the possible mechanistic steps involved in the anodic oxidation. Following the stabilization of zinc adatoms by hydroxyl ion adsorption, a rapid two-electron charge transfer process is postulated with an exchange current density of 224 mA/cm² in a zinc oxide saturated 7M potassium hydroxide solution (22). The very short-lived potential plateau, observed at high current densities, may well be indicative of this step. This stage is followed by equilibria

$$Zn(OH)_{2ad} \rightleftharpoons Zn(OH)_{2diss} \qquad [5]$$

$$Zn(OH)_{2diss} + n\,OH^- \rightleftharpoons Zn(OH)_{2+n}^{n-} \qquad [6]$$

If either [5] or [6] is rate controlling, and if a first-order process, then, assuming the validity of [3] and [4], k_f and k_r may be calculated using the data of Table IV. In potassium hydroxide, $k_f = 0.98$, $k_r = 0.9$ sec^{-1}. In the zinc oxide saturated media, $k_f = 0.02$, $k_r = 0.06$ sec^{-1}. Although no great emphasis should be placed on these absolute values, relatively they appear plausible. Utilizing the values for the bulk and interfacial concentrations of zincate given by Eisenberg *et al.* (15), a value of 1.0 x 10^{-5} cm²/sec is calculated for the apparent diffusion coefficient of the zincate ion in the zinc oxide saturated media. This value is slightly greater than 0.85 x 10^{-5} cm²/sec reported by Stachurski (29) from polarographic measurements (temperature not given). Further experimentation in varying concentrations of potassium hydroxide and zincate over a range of temperatures is required before it is possible to state which of the two processes, [5] zinc dissolution or [6] the complexing step, is rate determining.

The findings of the cyclic voltammetric study qualitatively confirm the conclusions regarding the complexity of the anodic process. The region 1 anodic peak current density and IR-free peak potential data, shown in Table II, obey the relationships

$$i_p = 123.4\ V_t^{0.3}\ (\text{ma/cm}^2) \qquad [6]$$

with a correlation coefficient of 0.996. The standard error of the index is 0.002.

$$E_p = -1.177 + 0.1565 \log_{10} V_t\ (\text{volts}) \qquad [7]$$

with a correlation coefficient of 0.975. The standard error of the estimate is 24 mv.

$$E_p = -0.701 + 0.5246 \log_{10} i_p\ (\text{volts}) \qquad [8]$$

with a correlation coefficient of 0.987. The standard error of the estimate is 17 mv.

For a purely diffusion-controlled process, i_p should be a linear function of the square root of the sweep rate. Equation [8] shows that the anodic peak corresponds with the initial potential of the anodic plateau, point c, Fig. 3. Region 2 corresponds with the onset of passivation, point d. The potential at which the anodic spike is observed agrees with the peak potential reported by Popova *et al.* (18-19). These workers have been primarily concerned with the electrode phenomena associated with region 3. They have shown that, when zinc is deeply passivated, 80-90% of the total current is associated with the direct electrochemical dissolution of zinc. The remaining current is associated with the growth of the oxide film. Impedance data (20) has been employed to support the conclusion that the kinetically controlling stage in the zinc dissolution is the rate of diffusion of zinc atoms through the thickening oxide film. The situation is further complicated by the chemical dissolution of this film, the rate of which is dependent on the nature of the electrolyte. The rate decreases linearly with increase in the zincate concentration, ultimately ceasing in supersaturated solutions. It would appear, therefore, that the cathodic behavior of passivated zinc is dependent not only on the prior anodic history of the electrode, but also on the nature of the electrolyte.

It is pertinent first to consider the second cathodic transition region, j-k. The data for this region, observed in potassium hydroxide alone, have been analyzed in a manner similar to that for the anodic region, c-d. $i\tau^{1/2}$ (amp sec$^{1/2}$/cm²) increases linearly with i (amp/cm²) according to Eq. [9].

$$i\tau^{1/2} = 0.0736 + 0.602\,i \qquad [9]$$

The very high correlation coefficient, 0.98, and the low standard error of the estimate, 0.003, confirm the validity of this relationship. General theory of coupled adsorptive-diffusive phenomena (30) predicts that the chronopotentiometric parameter should increase linearly with the polarizing current density. As is often

the case, the data fits the three Lorenz models (30), (*i*) adsorbate reduced first, (*ii*) adsorbate reduced last, (*iii*) simultaneous reduction of adsorbate and diffusing species. Furthermore, quantitative estimations of the diffusion coefficient of the soluble species and of the surface concentration of the adsorbate are precluded because of the lack of knowledge of the catholyte concentration gradient and the true surface area of the electrode.

The findings of this investigation regarding the appearance and characteristics of region h-i are in general agreement with those of Popova *et al.* (18). They find that this region becomes increasingly well defined if the zinc is passivated at increasingly positive potentials. Since this region is observed on potential decay, it would appear to be a spontaneous reduction. Since it is also observed even if the anodic overshoot is incomplete, prior to the O.E.R., it is thought not to be due to the reduction of adsorbed oxygen molecules. Popova *et al.* (18) propose that this region is the result of the reduction of excess oxygen in the zinc oxide film. If this indeed is true, then one may speculate that the hydroxyl ion so produced reacts with the zinc ion, continually produced as a result of the direct electrochemical oxidation of diffusing zinc atoms, forming a surface bound zinc hydroxide. Since the growing oxide film is thicker in the zinc oxide saturated electrolyte, there is a relative increase in the amount of excess oxygen available for reduction. Therefore, the amount of charge associated with this reduction will be greater in the zinc oxide saturated media than in potassium hydroxide alone. An examination of the data pertaining to this region in Table I shows that as the cathodic current density is increased, $i\tau$ approaches a limiting value, 4 millicoulombs/cm^2 in potassium hydroxide, 8 millicoulombs/cm^2 in the zinc oxide saturated media.

A Study of the Anodic Oxidation of Tantalum Using Open-Circuit Transients

J. L. Ord*

Department of Physics, University of Alabama, University, Alabama

ABSTRACT

The anodic oxidation of tantalum in sulfuric acid has been studied by analyzing open-circuit transients applied at intervals along galvanostatic oxidation transients. The dependence of the oxidation current density, i, on the overpotential, V, is expressable in an equation of the form $i = i_o \exp(V/V_o)$, where i_o and V_o are parameters determined from the data analysis. The parameter V_o is found to vary linearly with the potential during galvanostatic oxidation, while i_o depends on the applied current density. Using this equation relating current density and potential, together with a knowledge of the behavior of the parameters i_o and V_o, one can predict both the steady-state and transient behavior of this system.

In studies of the anodic oxidation of valve metals such as tantalum, the overpotentials observed, because of their magnitude, are generally assumed to appear across the oxide layer and the parameters measured are usually expressed in terms of the electric field in the layer. In studies of the anodic oxidation of other metals, in particular the passive metals such as iron,

* Electrochemical Society Active Member.

the overpotentials observed are much lower. In these systems there is no general agreement as to whether the overpotential appears across the oxide layer, across the double layer in the electrolyte, or even whether this potential can be called a true overpotential. As a result, measurements on the anodic oxidation of the passive metals are interpreted in a wide variety of ways, thus underlining the fact that the determination of an equation relating current density to overpotential from electrical measurements is not a unique process.

A striking illustration of this fact is provided by two careful studies of anodic oxidation which used similar techniques, yielded similar data, but from which quite different conclusions were drawn: Young's study of the anodic oxidation of tantalum (1), and Sato and Cohen's study of the anodic oxidation of iron in neutral electrolyte (2). Both of these investigations yielded data on the dependence of dV/dQ on log i. This dependence, which is generally linear, may be written in the form $dV/dQ = B \log (i/A)$ by introducing the two parameters A and B. Both sets of data showed only a slight dependence of dV/dQ on log i. Sato and Cohen took what might be called the logical approach to their data and ignored this slight variation by setting $B = 0$. In their proposed model the current density depended on both the overpotential and the layer thickness, but not explicitly on the electric field in the layer. Young, following the work of Güntherschulze and Betz (3), expected the field in the layer to affect the conduction process, and hence expected dV/dQ to vary linearly with log i. He decided that the variation he detected experimentally was significant, accounted for its magnitude by making A a very small number, and concluded that the electric field in the layer controlled the current through the layer. Thus, although the experimental data obtained in these two studies were quite similar (as are most features of the anodic oxidation of iron and tantalum with the exception of the range of potentials which can be studied), the two systems were described in the literature as behaving quite differently.

Over the past few years the work carried out in our laboratory (at the University of Waterloo) has been aimed at determining which features of the anodic oxidation process are dependent on the particular substrate or electrolyte used, and which features are more characteristic of the process itself. In an earlier paper (4) data were presented which showed that if open-circuit transients (5) were used to study the anodic oxidation of iron in sulfuric acid and in neutral electrolyte, similar results were obtained. The data in both cases indicated that the current through the layer was controlled by the electric field in the layer.

In the present work we present the results of open-circuit transient measurements taken during the anodic oxidation of tantalum. The parameters arising from the analysis of open-circuit transients provide a different starting point for setting up an equation relating current density to overpotential and can be used as basic parameters to describe the response of the system to other types of transients. Perhaps the most important use of these parameters is in the comparison of the anodic oxidation of the valve metals and the passive metals.

Experimental

Electrodes were prepared from single crystals of tantalum (purchased from Semi-Elements Inc. of Saxonburg, Pennsylvania). Hollow cylindrical samples of length 0.3 in. and diameter 0.2 in. were machined from this material. The samples were then etched to remove the cold-worked layer, or to remove the anodic oxide in subsequent experiments, and then chemically polished (6). The final surface treatment consisted of a brief immersion in hydrofluoric acid (6 to 8 sec), followed by a rinse in distilled water. The sample was then dried and mounted between Teflon washers in the electrode assembly (7). All the data

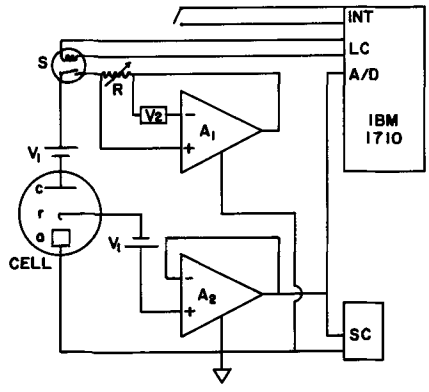

Fig. 1. Circuit schematic: A_1, A_2, operational amplifiers; SC, strip chart recorder; INT, computer interrupt switch; LC, latching contact; A/D, analog to digital data line; S, computer operated relay; V_1, blocking batteries; C, cathode; r, reference electrode; a, anode.

presented in this work were obtained using the same sample. Current densities were computed by dividing the applied current by the macroscopic surface area, assuming a roughness factor of unity.

The cell consisted of a 500 ml jacketed five-necked flask fitted with standard taper joints through which the electrode assembly, a mercurous sulfate reference electrode, a platinum cathode, a gas dispersion tube, and a thermometer were inserted, the electrode surface under study being vertical. The electrolyte used was 0.2N H_2SO_4 which was bubbled with argon for at least 12 hr prior to the beginning of an experiment in order to remove traces of other dissolved gases. The bubbling was continued throughout the course of an experiment. The cell was maintained at a temperature of 25.0° ± 0.1°C.

A schematic diagram of the circuitry used is shown in Fig. 1. High input impedance differential operational amplifiers (Philbrick SP2A) were used for the galvanostat and follower. These amplifiers normally operate over a ±10v range, therefore biasing batteries (V_1) were used to provide an operating range of 0-20v. Potentials were monitored on a strip chart recorder (Sanborn 7700), and open-circuit transients were recorded using the analog to digital converter of an IBM 1710 Process Control Computer. The computer was used rather than a fast recorder simply because our laboratory was linked to the computer and the analysis of open-circuit transients was greatly simplified by storing the data in digital form in the computer.

An open-circuit transient was initiated by closing an interrupt switch. The computer sensed the closure of this switch, recorded the potential, started an internal clock with a 4.8 msec time interval, and set a latching contact which energized a relay which opened the circuit. The potential was then sampled every 4.8 msec, and, when the sampled potential differed from the last stored potential by more than 100 mv, it was stored along with the corresponding time. The transient was terminated by a second closure of the interrupt switch. The computer then stopped sampling the potential, opened the latching contact to reclose the relay, transferred the values of potential and time to a disk memory, and was ready to record another transient.

Results

Open-circuit transients (in which the potential of the electrode was recorded as a function of time as the layer capacitance discharged through the layer) were used to determine the values of i_o and V_o in the equation

$$i = i_o \exp (V/V_o) \qquad [1]$$

which is used to relate the current density through the layer, i, to the overpotential of the electrode, V. Here i_o and V_o are parameters which have the same dimensions as i and V, respectively. Since the charge stored

on the layer capacitance is small when compared to the charge necessary to cause an appreciable change in the thickness of the layer, these transients may be considered as taking place at fixed layer thickness. The analysis of this type of transient has been described by Grahame (8), and transients of this type have been used to study the anodic oxidation of passive iron (4, 5, 9, 10).

Using Eq. [1] for the relation between the overpotential and the current density through the layer, the differential equation of the circuit under study is

$$C\,dV/dt + i_o \exp(V/V_o) = i_1 \qquad [2]$$

where C is the layer capacitance and i_1 the measured current in the external circuit. When the circuit is opened the external current immediately becomes zero and Eq. [2] takes the form

$$C\,dV/dt + i_o \exp(V/V_o) = 0 \qquad [3]$$

with the initial condition that the current flowing immediately before the circuit was opened is known.

If i_o, V_o, and C are considered constant during the open-circuit transient (or during some initial portion of the transient), then, by solving Eq. [3], the potential will have a time dependence during the transient given by

$$V = V_o \log(CV_o/i_o) - V_o \log(t + \theta) \qquad [4]$$

where $\theta = CV_o/i_1$. Thus V_o, i_o, and C can be determined directly by the analysis of such a transient.

Experimental open-circuit transients fit expressions of this form extremely well for suitably chosen values of θ. Transients were analyzed either graphically, by plotting V *vs.* log $(t + \theta)$, or with the aid of a digital computer. In either case θ was varied until the best fit to a straight line was obtained for an initial portion of the transient. The transient would not necessarily be expected to fit Eq. [4] for large values of time since complicating factors may enter as the current density becomes extremely small and Eq. [1] may no longer be valid. Experimentally, the fit to a straight line was found to be good to a point where dV/dt (or the current through the layer) had decreased by a factor of at least 25 from its initial value. From this we conclude that the exponential form of Eq. [1] is valid with constant parameters during an open-circuit transient. A typical set of data gave straight lines for V *vs.* log $(t + \theta)$ by the method of least squares with the standard deviation in the slope less than $2 \cdot 10^{-3}$ for slopes of the order of unity. For the least squares analysis points separated by equal potentials rather than equal times were used in order to have equally spaced data points on a semilogarithmic plot. The fit to a straight line is relatively insensitive to small variations in θ; hence the values found for θ cannot be considered very accurate, and the values of the capacitance found in this way may not be as accurate as those determined by other techniques.

A series of open-circuit transients was recorded at intervals along a galvanostatic oxidation transient and analyzed to determine the values of V_o and θ. In what follows we will use the term formation current density to designate the current density of the galvanostatic oxidation transient, and the term formation potential to designate the overpotential at which the circuit was opened. Figure 2 shows the values of V_o obtained from these transients as a function of the formation potential for two values of the formation current density, 3 and 100 μa/cm^2. For each value of the formation current density the plot of V_o *vs.* formation potential is linear, and both lines pass through the zero of formation potential. At 3 μa/cm^2 the slope of the straight line is 0.0938 with a standard deviation of 0.0008 and at 100 μa/cm^2 the slope is 0.0865 with a standard deviation of 0.0013. The difference between the slopes is statistically significant.

The corresponding values of the reciprocal capacitance, calculated from $1/C = V_o/(i_1 \cdot \theta)$, are shown in Fig. 3 for formation current densities of 3 and 100 μa/cm^2. This result shows that the reciprocal capacitance varies linearly with formation potential, but it does not show the slight dependence on the oxidation current density reported by others (1).

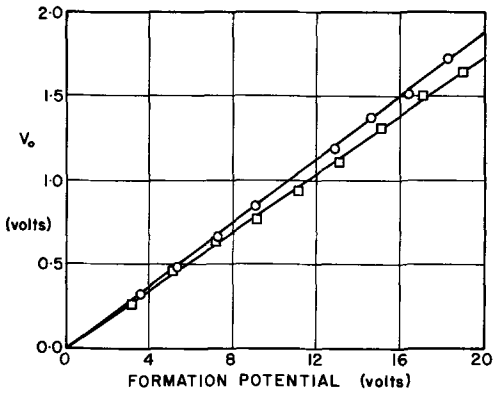

Fig. 2. Dependence of V_o on formation potential. The formation current density is 3 μa/cm^2 for the data represented by the circles and 100 μa/cm^2 for the data represented by the squares.

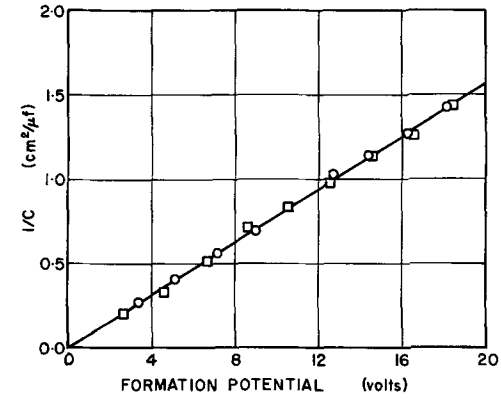

Fig. 3. Dependence of the reciprocal capacitance on formation potential. The formation current density is 3 μa/cm^2 for the data represented by the circles and 100 μa/cm^2 for the data represented by the squares.

A value for i_o can be calculated for each open-circuit transient; however, since values of V_o are proportional to the formation potential for a fixed formation current density, i_o will have the same value for all transients from the same formation current density. For example, at 100 μa/cm^2 the value of i_o may be found by setting log $(100/i_o)$ equal to 1/0.0865, giving $i_o = 93.5 \cdot 10^{-5}$ μa/cm^2. Figure 4 shows i_o plotted *vs.* formation current density, i_f, on logarithmic scales for five sets of open-circuit transients with formation current densities ranging from 3 to 300 μa/cm^2. (The straight line is a least squares fit to these points.) From this figure, assuming that the relation between log i_o and log i_f is linear over this range of formation current densities, one may write

$$i_o = k(i_f)^\alpha \qquad [5]$$

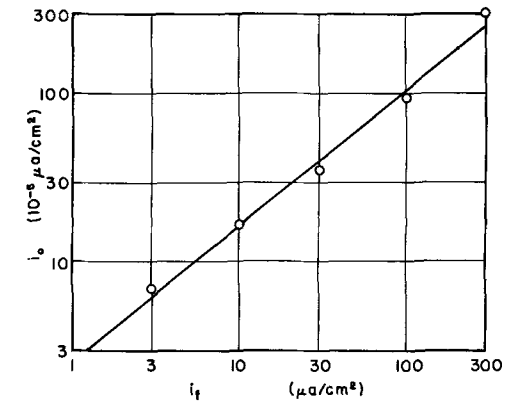

Fig. 4. Dependence of i_o on the formation current density

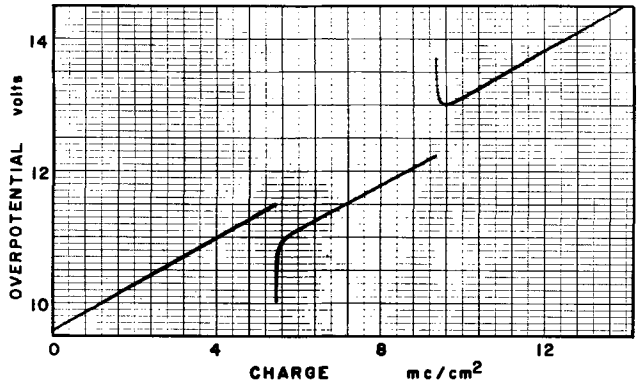

Fig. 5. Recorder trace of overpotential vs. charge for an oxidation transient in which the current density was switched from 200 to 40 μa/cm^2 and then back to 200 μa/cm^2.

The values of k and α obtained from this figure are $2.7 \cdot 10^{-5}$ and 0.8, respectively, if both i_o and i_f are expressed in μa/cm^2. The errors in k and α cannot be given quantitative estimates with any degree of confidence, but errors of 25% would not be surprising. It should be noted that if there were no dependence of the slope of V_o *vs.* formation potential on the formation current density then i_o would be directly proportional to the formation current density.

In order to facilitate the discussion of the difference between the parameters found here and those found by other methods (11,12) a transient in which the current density was switched from 200 to 40 μa/cm^2 and then back to 200 μa/cm^2 is shown in Fig. 5. The speed of the strip chart recorder was slowed by a factor of five when the current density was switched back to 200 μa/cm^2, producing a plot of potential *vs.* charge. Reference is made to this figure below.

Discussion

In general an exponential dependence of current density on overpotential can be interpreted in terms of a process controlled by an activation energy using the relation

$$i = \kappa\lambda \frac{ekT}{h} a_1 \exp(-U/kT) \exp(\beta\lambda e\eta/kT) \quad [6]$$

This expression is valid provided η, the overpotential across the barrier, is large enough to inhibit the reverse current across the barrier. Here κ is the transmission coefficient, λ the valence of the charge carriers, a_1 the activity of carriers moving across the barrier in the forward direction, U the activation energy at the reversible potential, and β the fraction of the overpotential aiding motion in the forward direction. The other symbols have their standard meanings.

The parameter V_o can be interpreted in terms of this equation using a simple Mott-Cabrera model (13). The data plotted in Fig. 2 show that V_o is proportional to the formation potential, V_f. In this model the overpotential appears across a layer of thickness D, setting up an electric field V/D in the layer. The product of this field and the half jump distance, a, gives the overpotential which aids the forward current, $\beta\eta$. Thus

$$V_o = (kT/\lambda ea)D \quad [7]$$

and is directly proportional to the layer thickness.

The experimental data strongly support a model of this type in which the electric field in the layer controls the current density through the layer. The parameter V_o varies over a wide range of values, and the fit to a linear proportionality to formation potential for fixed formation current density is quite good. Data taken at different formation current densities fall on lines with slightly (but significantly) different slopes. Since V_o and Q are both proportional to the layer thickness, dV/dQ is proportional to dV/dV_o. The difference in the slopes in Fig. 2 is essentially the experimental data from which the high-field models are deduced in the dV/dQ measurements. In terms of the open-circuit measurements, the high-field model is deduced from the first-order proportionality of V_o to V_f, and the second order dependence of the V_o *vs.* V_f slope on the formation current density is related to the behavior of the parameter i_o.

The behavior of the parameter i_o cannot be interpreted in terms of a simple Mott-Cabrera model since this model assumes that all of the factors in Eq. [6] except the exponential factor containing the overpotential are constants. The dependence of i_o on the formation current density detected experimentally can be made consistent with Eq. [6] by choosing a more complicated model in which at least one of these factors can vary. The Frenkel-defect model (14) used to interpret transient Tafel slopes in theories based on dV/dQ data is one such model in which the activity factor is given an explicit field dependence. We do not feel that we can deduce a meaningful model to account for the i_o variation from present experimental data. In Fig. 4, i_o is plotted *vs.* the formation current density, i_f, both of which parameters have the same dimensions. The data in Fig. 4 could equally have been given in terms of the formation field. Had the parameter i_o been found experimentally to be independent of the formation current density, the open-circuit parameters would have been identical to the parameters determined by dV/dQ measurements, and the dV/dQ data would have predicted transient Tafel slopes.

The data in Fig. 3 show that the reciprocal of the capacitance which is discharged through the layer during an open-circuit transient is proportional to the formation potential and, therefore, is proportional to the layer thickness. It might be expected that the reciprocal capacitance data would show the same dependence on the formation current density that is shown by V_o, a result which has been obtained by other workers (1). One explanation of the lack of dependence on formation current density found here is that the parameter θ from which the reciprocal capacitance is calculated is far less sensitive to the fitting process than is V_o. This explanation must be rejected on the basis of the experimental evidence in Fig. 3, which shows very little scatter in the reciprocal capacitance data. The explanation we propose for this behavior is based on data obtained in our laboratory (16) on the effect of the electric field in the layer on the low-frequency dielectric constant and the refractive index of the layer. It was found that at fixed layer thickness the reciprocal capacitance of the layer decreased appreciably when the current density through the layer was lowered, and it exhibited an overshoot of similar duration to the potential overshoot. The data obtained by other workers which detected the dependence of the slope of the reciprocal capacitance *vs.* formation potential on current density were taken with the formation current disconnected. We suggest that the reciprocal capacitance plotted in Fig. 3 is the reciprocal capacitance with the formation current flowing and that $1/C$ retains its initial value over the initial portion of an open-circuit transient, as does i_o. Our data on the field dependence of the dielectric constant predicts that this reciprocal capacitance should show very little dependence on the formation current density.

The equation usually used to describe the steady-state (constant growth rate) current density through the oxide layer during the anodic oxidation of tantalum is

$$i = A \exp(BE) \quad [8]$$

where E is the electric field in the layer and A and B are constants with the values $0.5 \cdot 10^{-12}$ μa/cm^2 and $5 \cdot 10^{-6}$ cm/v, respectively. The transient presented in Fig. 5 can be used to illustrate the way in which the parameter A can be determined. The slope of the curve in Fig. 5 is about 5% lower at a formation current density of 40 μa/cm^2 than it is at 200 μa/cm^2.

Since dV/dQ is proportional to E, and E is in turn proportional to log (i/A), log (i/A) must also change by 5% when the formation current density is switched between these two values, implying that $A = 2 \cdot 10^{-12}$ μa/cm^2. This estimate agrees reasonably well with the accepted value given above.

The steady-state equation (Eq. [8]) can also be obtained from the open-circuit transient data as a special case of Eq. [1]. In the steady state, Eq. [5] can be substituted into Eq. [1], giving

$$i_f = k\ (i_f)^{\alpha} \exp\ (V_f/V_o)$$

or

$$i_f = (k)^{1/(1-\alpha)} \exp (V_f/(1-\alpha)V_o) \qquad [9]$$

For the parameters in Eq. [9] to have the same values as the parameters in Eq. [8], α must have a value of 0.63. This value falls within our estimate of the error in α. (This error estimate takes into account the fact that V_o is determined from the slope of V *vs.* log $(t+\theta)$, i_o from the slope of V_o *vs.* V_f, and α from a third successive slope, the slope of log i_o *vs.* log i_f.)

The parameter α can be estimated much more accurately with the aid of Fig. 5 by extrapolating the linear portion of the potential transient at 200 μa/cm^2 back to the point where the current density was switched from 40 μa/cm^2. The potential at this point is found to be 12.9v. Thus when the current was switched the change in the formation potential (ignoring the potential overshoot) was from 12.2v to 12.9v. Using

$$V = V_o \log (i/i_o) = V_o \log (i/k(i)^{\alpha})$$

one obtains

$$\Delta V = V_o\ (1-\alpha)\Delta \log\ (i) = V_o\ (1-\alpha)\ \log\ (i_2/i_1)$$

With $i_1 = 40$ μa/cm^2, $i_2 = 200$ μa/cm^2, $V_o = 1.1$v (at $V = 12.2$v), and $\Delta V = 0.70V$ (from Fig. 5) one finds that $\alpha = 0.61$, which is consistent with the value of 0.63 necessary for the numerical comparison of Eq. [8] and [9].

We have stated that i_o is a function of the formation current density, but so far the only statement we have made about the manner in which i_o changes when the formation current density is changed is that i_o changes very little during the initial portion of an open-circuit transient. We would now like to outline briefly one way in which potential overshoot may be treated using the parameters derived from open-circuit transients.

The general equation used to relate the total current in the circuit to the currents charging the layer capacitance and flowing through the layer was given in Eq. [2]. The differential equation describing this type of galvanostatic transient can be obtained in much the same manner as Eq. [3] was obtained, with the exception that here V, C, i_o, and V_o are all functions of time. The time dependence of V_o can be taken care of quite simply by setting V_o proportional to Q. The capacitance may be considered a constant because the capacitive term is only important when dV/dQ is large. Therefore it is only necessary to specify the time dependence of i_o in order to solve the differential equation. One such time dependence is a relaxation time approximation for the change in i_o when the formation current density is changed from $i_{f,i}$ to $i_{f,f}$

$$i_o = i_{o,f} + (i_{o,i} - i_{o,f}) \exp\ (-t/\tau) \qquad [10]$$

where τ is a relaxation time. Since the experimental evidence shows that the overshoot involves an approximately constant amount of charge, the relaxation time can be made inversely proportional to the current density, the proportionality constant being the only unknown parameter which must be fit to experimental data. The foregoing discussion is in no sense an explanation of potential overshoot; it is merely one way of fitting overshoot transients using the parameters V_o and i_o determined from open circuit transients.

The discussion of overshoot given above predicts a long relaxation time for open-circuit transients for which the only current flowing through the layer is the rapidly decreasing current which discharges the layer capacitance. This prediction is consistent with our assumption based on the fitting of open-circuit transients that i_o does not change appreciably over the initial portion of an open-circuit transient. If an extended open-circuit transient is analyzed, a deviation from a log $(t + \theta)$ fit is found for large values of t. The direction of this deviation is such as to produce a slower decrease of V with t than predicted by log $(t + \theta)$. This deviation is consistent with our prediction that any change in i_o over an open-circuit transient must be a decrease produced by the decreasing current density through the layer. A deviation in the other direction is observed with poorly prepared samples with appreciable leakage currents. Reclosing the circuit produces a slight overshoot whose magnitude increases with the duration of the open-circuit transient. We interpret this overshoot as the recovery of i_o to its initial value. A larger overshoot is observed if, instead of opening the circuit, the current density is lowered by a factor of two for the same length of time before reapplying the initial current density. Greater potential changes (and hence field changes) are produced during the open-circuit transient than during this transient, but we interpret the smaller overshoot as indicating that the open-circuit transient creates a smaller perturbation of the system. It is for this reason that we prefer open-circuit transients for studying the system. We feel that they come closest to determining the true field dependence of the current density, *i.e.*, the partial derivative of the current density with respect to electric field with all other variables constant.

If an equation relating current density to overpotential, deduced from experimental data, is considered to be no more than a compact way of summarizing the experimental results, then the exact form of the equation is not important. If, on the other hand, the equation is considered to have sufficient general validity to enable it to be compared with a theoretical equation such as Eq. [6] in order to deduce a model for the conduction process, then the form of the equation becomes very important, since it is generally the model and the deduced values of parameters and not the experimental data on which they are based which are referred to when describing a system. For example, it has been stated that one of the basic differences between the behavior of the valve metals and that of the passive metals is the vast difference between the value of A quoted for the valve metals and the value of i_o quoted for the passive metals. We have shown that this vast difference between the values arises because of different approaches to the data analysis. When the two systems are studied using open-circuit transients, their behavior is found to be quite similar.

We have stated that the parameters obtained from open-circuit transients provide a basis for the comparison of the anodic oxidation of tantalum with that of iron in a neutral electrolyte. It has been previously mentioned that both of these systems show a slight dependence of dV/dQ on log i. It is also well known that both systems show potential overshoot when the current density is abruptly changed. By comparing the open-circuit transient data for iron in a neutral electrolyte presented by Ord (4), several more quantitative similarities become evident. The potential decay during an open-circuit transient fits Eq. [4] for both systems, implying that the dependence of overpotential on current density may be described by Eq. [1] for both systems. Both systems show a linear dependence of V_o on V_f at constant formation current density. The value of the slope of this line is comparable in the two systems (for tantalum it is about 0.09 while for iron it is 0.2). Both systems show a slight dependence of the slope of V_o *vs.* V_f on the formation current density; in both cases the slope increases with decreasing current density. Thus the

parameter i_o will depend on the current density in roughly the same manner for both systems. Values of i_o for comparable formation current densities are $7 \cdot 10^{-5}$ μa/cm^2 for tantalum and $5 \cdot 10^{-3}$ μa/cm^2 for iron [this latter number was calculated from data presented in ref. (4)].

Because of the many similarities between iron and tantalum it is our opinion that many general features of the anodic oxidation process may be independent of the metal involved, even when the metals are as dissimilar as iron and tantalum. Therefore we believe that any theory devised to apply to one of these systems should be equally applicable to the other. For this reason we feel that theories of the passivity of iron which place the entire overpotential across the electrical double layer are not tenable. Likewise, any theory of the anodic oxidation of tantalum should be applicable to a film only 10Å thick.

Acknowledgment

The authors are indebted to Mr. P. Freeman for his assistance in performing the experiments, and to Mr. P. Isaacs and Mr. A. Weerheim of the University of Waterloo Computing Centre for their work with the process control computer. This work received partial support from the National Research Council of Canada under Grant No. A-1151, and from the Office of Naval Research under Contract No. N00014-66-C0200.

Manuscript submitted Sept. 12, 1966; revised manuscript received Sept. 30, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Effects of Oxidizable Anion Adsorption on the Anodic Behavior of Platinum

Sigmund Schuldiner*
Naval Research Laboratory, Washington, D. C.

ABSTRACT

The retardation of the hydrogen oxidation reaction which commences at about 0.7v (NHE) in sulfuric acid solution can be modified by the presence of formate ions. Steady-state, potentiostatic measurements were made in formic acid and formic acid plus sulfuric acid solutions both in the presence and absence of hydrogen. The work showed that at potentials under 1.5v passivity was due to adsorbed anions rather than adsorbed oxygen atoms, Pt oxides, or free radicals formed by the oxidation of water. Pure formic acid solutions were not passivated below 1.5v; however, formate ion did retard hydrogen oxidation, but not as strongly as does sulfate ion. The oxidation of formic acid in solutions containing sulfuric acid was affected by adsorption of both sulfate and formate ions. The retardation of the net oxidation of hydrogen and formic acid in formic acid-sulfuric acid mixtures was less than that of hydrogen in sulfuric acid. In the presence of dermasorbed oxygen, both formate and sulfate ions strongly retard the oxidation of added species. The effect of potential on reaction rate appears to depend on the particular organic species adsorbed and may reflect the potential of zero charge.

Several recent papers (1-3) from this Laboratory have indicated that under steady-state, potentiostatic conditions, the retardation of the hydrogen oxidation reaction at potentials more anodic than 0.7v may be caused by anion adsorption rather than adsorbed oxygen atoms, oxides, or oxygen containing radicals. The possibility of this passivation being due to adsorbed oxygen atoms, oxides, or oxygen-containing free radicals was shown to be improbable because of the very rapid reaction of such oxygen species with hydrogen.

To provide further evidence to support the author's opinions concerning anion adsorption, experiments were designed to determine the effects of reactable (oxidizable) anions. Such oxidizable anions should compete with inert anions adsorbed at anodic potentials and may affect reaction rates. In addition the total replacement of an inert anion with a readily oxidizable anion should eliminate or appreciably reduce passivation due to anion adsorption.

It was felt that an ideal oxidizable anion for this work would be formate ion. This is the simplest type of organic anion. It should be easily adsorbed at positive potentials and is fairly easily oxidized. Formate ions and formic acid could be dissociated on a Pt electrode and neutral products such as atomic hydrogen, carbon monoxide, and carbon dioxide, could be formed. However, if formate ion can adsorb on the surface (or highly polarizable formic acid, free radicals or similar species), competition with inert anions are possible and information concerning the effects of such adsorbed species[1] on the rate of anodic reactions would be available.

Experimental

The experimental high-purity, gas-tight setup and conditions were the same as previously used (1, 4). The solutions were 1M formic acid, and 0.1M and 1M formic acid in 1M sulfuric acid solution. Each solution was investigated under both helium and hydrogen saturated conditions (atmospheric pressure). The formic acid was reagent grade. An initial run through the

* Electrochemical Society Active Member.

[1] No attempt was made in this work to determine the actual organic species which were adsorbed or oxidized and the terms formic acid and formate ion are not used in a strict sense.

potential range up to 2v was made before data were recorded. The concentrations of formic acid given are the initial values; losses in concentration due to electrochemical reaction, decomposition, and vaporization during each experiment did occur. Titrations of acid content after termination of a run (some lasted for over a month) showed decreases in the order of 25-40% of formic acid. However, changes in the potentiostatic current density *vs.* voltage relations were not appreciable during a series of runs. In several cases, formic acid was added during a run to approximately approach the initial concentration. This made little difference.

It should be emphasized that this work was designed to determine the steady-state potentiostatic behavior of formic acid oxidation and oxidation of hydrogen and formic acid mixtures with especial interest in the influence of the formic acid (or a derivative) on the passive behavior of platinum in the potential region above 0.7v (NHE). No attempt was made to correct for IR losses in the low conductivity, pure formic acid solutions, to conduct a mechanistic or kinetic study which involved the various by-products of formic acid, or, indeed, to determine what the reaction steps or products were. The goal was the effects of formate ion adsorption (or other oxidizable by-products), in particular the effects of such species on the adsorption of an inert anion (sulfate ion) and on the reactability of oxidizable species on a Pt anode.

The two bright Pt bead (99.99%) working electrodes used were about 0.5 cm^2 in true area (5) and the temperature was 25° ± 2°C. The gas flow into the cell was about 40 ml/min until a steady-state current density was reached. The time necessary to attain this steady-state current density varied from a few minutes to more than a day, depending on both the set potential and the previous sequence of potentials. The gas flow rate was then increased to well over 1000 ml/min, and the constant current density was recorded. Potentiostatic control was accomplished with a Pt wire reference electrode for one series of runs and with a Pd wire reference in a side arm for another series. The presence of a Pd wire made no apparent difference in the potentiostatic measurements. When hydrogen flowed either a Pt/H_2 reference electrode or a miniature glass electrode was used to monitor the potential. The results were the same in either case. In helium saturated solution the potential monitoring reference was always a miniature glass electrode. All potentials are referred to the normal hydrogen electrode (NHE) with the exception of the data in pure formic acid solutions (Fig. 2 and 3) where the reference electrode is the hydrogen electrode, same solution (HESS). To change the scale for these formic acid solutions to NHE would require a reduction of the HESS values by about 0.1v.

Cyclic current fluctuations usually ranging from about 10 to 20% were observed in the potential region between 0.3 and 1v and on the decreasing potential sequence from 1.3 to 0.9v. Values shown in the figures are average values. The scatter of points was essentially the same as found for pure hydrogen [Fig. 1, ref. (1)]. At least three increasing and decreasing potential sequences were determined and wherever critical changes occurred, many additional checks were run. Figure 1 demonstrates the current density *vs.* time relation typically found when the potential was changed in regions where slow changes occurred.

Results and Discussion

Figures 2 and 3 show the potentiostatic current density *vs.* potential relations obtained in 1M formic acid both in helium- and hydrogen-stirred solution. Figure 2 is for the increasing potential sequence, whereas Fig. 3 is for the decreasing potential sequence. The broken line in Fig. 2-7 is either the increasing or decreasing potential sequence for the oxidation of water in helium-saturated 1M sulfuric acid solution (4) and the dotted line in each figure is either the increasing or decreasing potential sequence for the oxidation of hydrogen (1) in 1M H_2SO_4.

The 1M HCOOH curve in Fig. 2 shows that although the rate of oxidation of formic acid is much slower than hydrogen oxidation there is no passivation of the Pt electrode to the formic acid oxidation below 1v. Indeed, the rate of oxidation of formic acid increases with potential or remains constant in several potential regions until a potential of 1.6v (HESS) or about 1.5v (NHE) is reached. From about 1.0 to 1.8v the rate of formic acid oxidation is about one order of magnitude faster than the rate of hydrogen oxidation in sulfuric acid solution.

The mixture of formic acid and hydrogen, as illustrated in Fig. 2, shows a great increase in the rate of oxidation at potentials below 1.0v. This shows that the primary reaction in this region is the oxidation of hydrogen. The formic acid under these potential conditions retards the hydrogen oxidation reaction. There is a retardation of the oxidation reaction at about 0.8 to 1.2v, but it is not as sharp as for pure hydrogen in sulfuric acid solution. At potentials more noble than 1.2v, the rate of oxidation of the formic acid-hydrogen mixture is essentially the same as for formic acid alone.

The data in Fig. 2 clearly show that passivation of platinum for formic acid oxidation does not occur

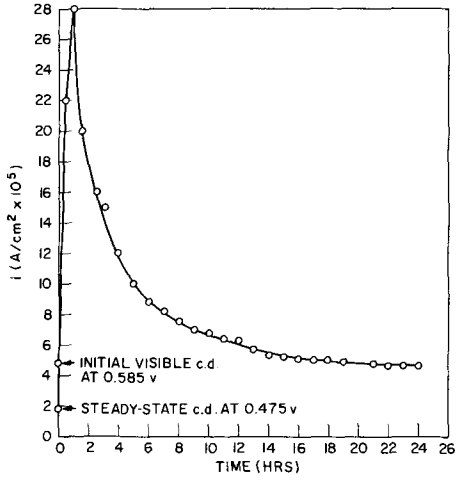

Fig. 1. Typical current density *vs.* time relation found when the potential was changed in a region where slow processes occurred. Potential was increased from 0.475 to 0.585v 0.1M HCOOH + 1M H_2SO_4.

below 1.6v. Hence the formation of either oxides or adsorbed oxygen atoms which passivate the electrode is not possible. In the case of the formic acid-hydrogen mixture, formate ion most likely is being adsorbed, which in fact retards the hydrogen oxidation reaction, even though the formate ion itself can be oxidized but at a much slower rate. Determinations of the over-all rate of oxidation of a monolayer of $Pt\text{-}O_{ad}$ with formic acid gave reaction rates of about 5×10^{-4} amp/cm². Thus the rate of reaction of adsorbed oxygen atoms with formic acid is well over two to three orders of magnitude faster than the oxidation of water in the potential range from 0.7 to 1.6v. Hence, significant amounts of oxygen cannot remain on the surface below 1.6v.

Data for the decreasing potential sequence, Fig. 3, clearly show that, from 1.7 to 0.9v, the behavior of formic acid, formic acid + hydrogen, and hydrogen in sulfuric acid solution is virtually identical. Evidently, the formation of dermasorbed oxygen decreases the catalytic activity of the platinum so much that the rate of oxidation of formic acid is identical to that of hydrogen in the presence of sulfate ion. However, the rate of water oxidation under similar potential conditions is still significantly slower. It should be mentioned that the presence of dermasorbed oxygen also considerably reduces the reaction rate of adsorbed oxygen with oxidizable species such as hydrogen (6). However, it is doubtful that adsorbed oxygen is an important factor under these conditions. This is because the reduced reaction rate between adsorbed oxygen and hydrogen or formic acid would still be well above the rate of water oxidation.

Potentiostatic polarization curves (increasing potential sequence) for a mixture of formic acid and sulfuric acid at two nominal concentrations of formic acid (0.1 and 1M) are shown in Fig. 4. Here again, even though, at lower potentials, the rate of oxidation of formic acid is considerably slower than that of hydrogen; no passivation occurs at 0.7v. Passivity is evident at about 1.6v only. Furthermore, in the potential range between 1.2 and 1.6v, the rate of oxidation of formic acid is greater than that of hydrogen. At potentials above 1.7v, where the principle reaction is the oxidation of water to oxygen, formate ions slightly increase the net oxidation current.

For the potential decreasing sequence shown in Fig. 5, in the potential range from 1.7 to 0.9v the rate of the oxidation of formic acid mixed with sulfuric acid is well below that of either formic acid, formic acid + hydrogen, or hydrogen in sulfuric acid solution (Fig. 3). This shows that sulfate ion adsorption on the Pt electrode containing dermasorbed oxygen retards the formic acid oxidation considerably more than the hydrogen oxidation. Thus under similar conditions of sulfate ion plus dermasorbed oxygen, hydrogen is more readily oxidized than is formic acid. This indicates that even though formate ions may be present, the bulk of the coverage of the electrode is with sulfate ions and that under similar surface conditions and at high positive potentials the electrostatic attraction of formate ions does not have as great a bearing on the rate of oxidation as does the presence of a neutral but more easily oxidizable species such as hydrogen. This is in contrast with the case of the increasing potential sequence (Fig. 4) where formate ions do effectively compete with sulfate ions. The difference is most likely due to the reduction in catalytic activity owing to dermasorbed oxygen. The dermasorbed oxygen affects the rate of formic acid oxidation much more than that of hydrogen.

The data shown in Fig. 6 and 7 show the potentiostatic behavior in formic acid + sulfuric acid in the presence of hydrogen for the increasing and decreasing potential sequence, respectively. Figure 6 shows that in the active low potential range, high concentrations (1M) of formic acid in the presence of sulfate ion retard the hydrogen oxidation rate considerably more than in the absence of sulfuric acid (Fig. 2). At low

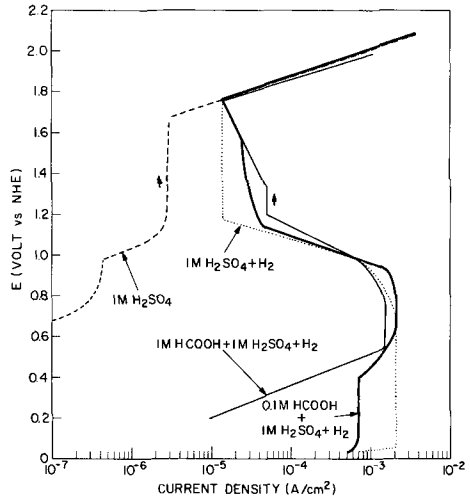

Fig. 6. Potentiostatic anodic current density *vs.* potential relation on a bright Pt electrode for increasing potential sequence. Solid lines, 0.1 and 1M HCOOH in 1M H_2SO_4 in hydrogen-saturated solution. See legend in Fig. 2 for meaning of broken and dotted lines.

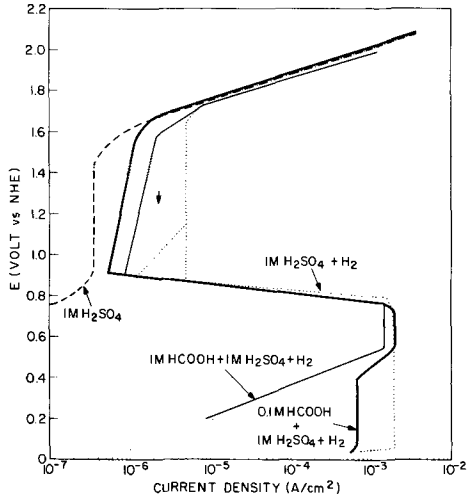

Fig. 7. Potentiostatic anodic current density *vs.* potential relation on a bright Pt electrode for decreasing potential sequence. Solid lines, 0.1 and 1M HCOOH in 1M H_2SO_4 in hydrogen-saturated solution. See legend in Fig. 2 for meaning of broken and dotted lines.

concentrations of formic acid (0.1M), however, oxidation of hydrogen is affected only moderately.

In the potential range from 0.7 to 1.6v, passivation does occur as in the case of pure hydrogen; however, the presence of formic acid has a moderating effect and significantly increases the rate of the net oxidation reaction. This is believed to be due to the competitive adsorption of formate ions which can be oxidized and can contribute to the net anodic current. Figure 7 again shows that the presence of formic acid considerably retards the hydrogen oxidation reaction when dermasorbed oxygen is present. In the low current density regions shown in both Fig. 5 and 7, water oxidation may contribute significantly to the net current density.

Investigations of formic acid oxidation [see Conway (7) and Piersma and Gileadi (8) for reviews] offer only a limited amount of information on the steady-state, potentiostatic oxidation of formic acid at potentials positive to 0.9v. Gilroy and Conway (9) refer to data from Conway's laboratory which indicate a passivation of formate ion oxidation in aqueous solution at about 1v. They attribute this passivation to the presence of a passivating "oxide." For pure formic acid-potassium formate solutions, Conway, *et al.* (10) indicated passivation by the formation of intermediates. The results reported here (Fig. 2) indicate no passivation in aqueous formic acid solution up to 1.6v. The data obtained in this investigation verify previous findings (1-3) that passivation in the vicinity of 0.7v is due to sulfate ion adsorption rather than the formation of adsorbed oxygen, an oxide, or other oxidation products of water. Water oxidation is too slow below 1.6v, and the oxidation products of water on a Pt surface react so rapidly with oxidizable species in solution that the possibility of the build-up of a passive layer by such oxygen species is most unlikely. Only at high noble potentials is the combined effects of anion adsorption and sorbed oxygen adequate to retard the oxidation of hydrogen and formic acid effectively. At sufficiently noble potentials the rate of water oxidation exceeds the rate of hydrogen and/or formic acid oxidation.

The data can therefore be reasonably explained by attributing passivity to anion adsorption. As shown in Fig. 2, formate ion can cause passivation of the hydrogen oxidation reaction, but the retardation of reaction rate is much less than for inert sulfate ions. Since formic acid is more difficult to oxidize than hydrogen it would tend to increase the retardation if oxygen passivated the Pt electrode, but the reverse is obtained.

One may argue that some formate ion attracted to the positive surface in the passive region may cause a partial breakdown of a passive oxygen layer and, thereby, increase the rate of oxidation. However, this is not borne out by the behavior observed in the decreasing potential sequence curves (Fig. 3, 5, and 7). Figure 3 shows that in the presence of dermasorbed oxygen the formate ion retards the rate of hydrogen oxidation just as much as does sulfate ion. The data in Fig. 5 and 7 show that in the presence of dermasorbed oxygen and both sulfate and formate ions, the rate of oxidation of hydrogen is less than in the presence of only sulfate or formate ion (Fig. 3). Figure 2 clearly shows that, even though formate ion does not passivate its own oxidation below 1.6v, it passivates hydrogen oxidation at 0.8v. In addition, a breakdown in passivity due to formate ion adsorption assumes a complete oxygen coverage of the Pt surface at potentials in the vicinity of 0.7v. Data previously given (2) show that such a complete oxygen film is not obtained. The 1M HCOOH + 1M H_2SO_4 curve in Fig. 4 shows that a limiting current density is reached at 0.5v and passivation does not occur until 1.5v. Contrasting this with the results for 1M HCOOH shown in Fig. 2, the initial limiting current density occurs at 0.8v. These results show that sulfate ions do play an important role in the oxidation of formic acid.

One may speculate on the potential of zero charge (pzc) and the region in which adsorption of formic acid species are at a minimum. This effect is best seen in Fig. 6 in the 0.1M HCOOH + 1M H_2SO_4 + H_2 curve. These data show a current density maximum between 0.6 and 0.8v. Below 0.6v the rate of hydrogen oxidation is moderately retarded by formic acid, but in the potential range from 0.6 to 0.8v a current density of 2×10^{-3} amp/cm^2 is reached. This is exactly the maximum current density found for pure hydrogen oxidation in high purity sulfuric acid solution (1). This may indicate that the potential of zero charge is in the vicinity of 0.6-0.8v because at the pzc the adsorption of a highly polarizable species, such as formic acid or of formate ion, should be at a minimum. The maximum current density of 2×10^{-3} amp/cm^2 does not decrease until a potential of 0.8v. Contrast this to the 1M H_2SO_4 + H_2 curve which starts decreasing at 0.7v. This also shows that formate ion does compete with sulfate ion in the passivation of the Pt surface.

Conclusions

This work verifies that, at potentials negative to 1.5v, passivation of a Pt electrode to the oxidation of hydrogen is not due to the adsorption of species from

the oxidation of water or to the formation of Pt oxides. Such passivity is caused by anion adsorption.

If the oxidizable material exists as an adsorbable anion, which can oxidize faster than water, then no passivation will occur. If a species is present which is oxidized more rapidly than the adsorbable anion, then the oxidation of that species will be retarded when the potential is noble enough to significantly adsorb such anions.

In the presence of dermasorbed oxygen, passivation in a combination of sulfuric and formic acids is much more pronounced than in the presence of either acid alone. The oxidation reaction rates may give a clue as to the potential of zero charge in the presence of an organic species which is both easily polarized and ionized.

The Electrical Properties of Lanthanum Oxide-Calcium Oxide Solid Electrolytes

T. H. Etsell and S. N. Flengas*

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

Electrical conductivity measurements have been made in the La_2O_3-CaO system as a function of composition, temperature, and oxygen pressure. At 1600°C, La_2O_3 can dissolve about 16 m/o CaO which leads to the creation of anion vacancies. These defect solid solutions behave as oxygen anion conductors below an oxygen pressure of 10^{-7} atm. Above this pressure, the appearance of p-type conductivity, proportional to $P_{O_2}^{1/4}$, produces a region of mixed conduction. No evidence of n-type conductivity was observed. Even La_2O_3 exhibits predominantly ionic conduction at intermediate oxygen pressures. Several transport numbers were verified by emf measurements. The results of this investigation are compared with those obtained previously for other oxide electrolyte systems.

For certain substitutional solid solutions of oxides having cations of different valences, the condition of electrical neutrality requires the appearance of oxygen anion vacancies. Within specified ranges of temperature and oxygen pressure, such systems exhibit exclusively ionic conduction arising from the motion of oxygen anions through lattice vacancies. However, outside these ranges, the solid solutions cease to function satisfactorily as electrolytes due to the appearance of either p- or n-type conductivity.

Most of the previous studies of the electrical conductivities of these electrolytes have dealt with mixtures of various di- and trivalent metal oxides (MgO, CaO, SrO, Sc_2O_3, Y_2O_3, and the rare earth oxides) with the group IV oxides ZrO_2 (1-9), ThO_2 (10-17), HfO_2 (5, 18, 19), and CeO_2 (20, 21). For solid solutions based on trivalent metal oxides, only a limited number of measurements have been reported (22-24), and the potentiality of such systems as solid electrolytes cannot be properly evaluated. Particularly, for the La_2O_3-CaO system, results have been given (23) for only two oxygen pressures.

In the present investigation, the electrical properties of La_2O_3-CaO solid solutions containing from 0 to 50 m/o (mole per cent) CaO have been measured over the temperature interval 400°-1100°C, under oxygen pressures varying between 1 and 10^{-21} atm at 1000°C. Care was taken to ensure that equilibrium was achieved during the preparation of the specimens since several authors (25, 26) have denied any significant solubility of CaO in La_2O_3, although Foex (27) determined that 16 m/o CaO could be dissolved during fusion in a solar furnace.

Normally, La_2O_3 has the hexagonal A-type rare earth oxide structure. The cubic C-type can only be prepared by decomposing lanthanum compounds below 550°C (28-30). Other forms may be stable above 2040°C (31), although these phases could not be retained by rapid quenching to room temperature. In A-type La_2O_3, each cation is seven-coordinated with six of the oxygen anions in an octahedral arrangement which is distorted to accommodate the seventh. The cations have four oxygen neighbors at 2.42Å and three at 2.69Å (32). Both four- and five-coordinated oxygen anions exist in the lattice.

During the formation of solid solutions in the La_2O_3-CaO system, substitution of La^{3+} ions with Ca^{2+} ions on the cation sublattice will cause the formation of either anion vacancies or cation interstitials. For the anion vacancy model, the fraction of vacant oxygen sites x_{V_O} will be given by

$$x_{V_O} = \frac{x_2}{6x_1 + 3x_2} \qquad [1]$$

where x_1 and x_2 are the mole fractions of La_2O_3 and CaO, respectively. Even for small additions of CaO,

* Electrochemical Society Active Member.

the composition-controlled vacancy concentration will far exceed that arising from thermal disorder. In a system of this kind, the ionic conductivity σ_i may be expressed as

$$\sigma_i = [V^{\cdot\cdot}_O]2eu \quad [2]$$

where $[V^{\cdot\cdot}_O]$ is the charge carrier concentration in vacancies per cubic centimeter, $2e$ is the charge in coulombs, and u is the mobility in square centimeter/volt-second. Therefore, there will be a large increase in the ionic conductivity accompanying the addition of CaO to La_2O_3 which could result in an oxygen pressure region of almost exclusively ionic conduction.

According to the theory of Kiukkola and Wagner (33), at high oxygen pressures some of the anion vacancies may dissolve gaseous oxygen according to the reaction

$$\tfrac{1}{2}\, O_{2(g)} + V^{\cdot\cdot}_O = O_O + 2h^{\cdot} \quad [3]$$

where $V^{\cdot\cdot}_O$ is a doubly ionized oxygen vacancy, O_O is an oxygen anion on a normal lattice site, and $h^{\cdot}$ is an electron hole. Assuming that the concentration of electron holes p is low, the equilibrium constant for this reaction may be written as

$$K = \frac{p^2}{P_{O_2}^{1/2}\,[V^{\cdot\cdot}_O]} \quad [4]$$

Since $[V^{\cdot\cdot}_O]$ is large and essentially unaffected by Eq. [3], the p-type conductivity σ_p will be proportional to $P_{O_2}^{1/4}$. Similarly, at low oxygen pressures, oxygen will be lost from the lattice via the reaction

$$O_O = \tfrac{1}{2}\, O_{2(g)} + V^{\cdot\cdot}_O + 2e' \quad [5]$$

where e' is an excess electron. The resulting n-type conductivity σ_n will vary as $P_{O_2}^{-1/4}$ providing that the excess electrons do not mutually interact. Equation [2] indicates that the ionic conductivity should be independent of oxygen pressure. Hence, the oxygen pressure dependence of the electrical conductivity should describe the type of charge carriers present in these oxide systems.

Experimental

The oxide mixtures were prepared by an oxalate coprecipitation method, which was found superior to both evaporation of nitrate solutions and direct mixing of the constituent oxides. Initially, appropriate amounts of 99.99% La_2O_3 and 99.95% $CaCO_3$, whose analyses are given in Table I, were dissolved in a slight excess of nitric acid. Prior to this, the "La_2O_3" had been heated to 1000°C to remove H_2O and CO_2. After neutralization with ammonium hydroxide, precipitation was effected by the rapid addition of the near-boiling nitrate solution to a boiling solution containing a 25-40% excess of ammonium oxalate. After filtering immediately, the oxalates were washed, dried at 125°C, and decomposed at 950°-1050°C in a porcelain crucible.

Subsequently, the oxides were reacted in a Pt crucible held in air for 24 hr at 1400°-1450°C. The caked products were ground to obtain —300 mesh particles. Next, the light brown oxide powders were compacted at 100,000 psi in a tungsten carbide die into disks ½ in. in diameter and about ⅛ in. thick. Most of these pellets were sintered in air for 36 hr at 1600°C in a platinum-wire-wound furnace, while being supported by prefired 1 in. diameter pellets of a similar composition. Several were treated in air for 3 hr at 1900°C in a gas-fired furnace or in vacuum (10^{-3} Torr) at 1500°C.

Table I. Impurities in La_2O_3 and $CaCO_3$

Impurity	La_2O_3 ppm	Impurity	$CaCO_3$ ppm
CeO_2	10	$SO_4^=$	70
Pr_6O_{11}	100	Ba	100
Other rare earths	20	Sr	200
Fe	1	Mg	<50
		Fe	10
		Pb	10
		K	<50
		Na	50

Prior to conductivity measurements, the faces of the samples were platinized by applying a 10% chloroplatinic acid solution which was subsequently decomposed at 600°-700°C to yield an adherent, black Pt film. They were then transferred to the high-temperature press shown in Fig. 1. The Inconel tube (76% Ni, 16% Cr, 7% Fe) was 24 in. long with an inside diameter of 1.35 in. With this apparatus, 0.002 in. Pt foil electrodes could be pressed against the samples at 12,000 psi and 1000°C. After this operation, the measured conductivities became independent of the applied pressure and, indeed, the electrodes could not be separated from the ceramic disks. A second method of electrode application consisted of pressing —200 mesh Pt powder onto the faces of the pellets before they were removed from the carbide die. These electrodes (~0.003 in. thick) adhered extremely well after sintering. Both methods effectively eliminated contact resistance. The conductivity measurements were taken in either the high-temperature press or a quartz cell, in which the samples were held between an alumina rod and the bottom of a quartz tube.

High oxygen pressures (1-10^{-5} atm) were achieved using Ar-O_2 mixtures analyzed with either a mass spectrograph or an electrochemical oxygen analyzer. Intermediate and low oxygen pressures (10^{-6}-10^{-18} atm at 1000°C) were controlled with CO-CO_2 mixtures analyzed with a gas chromatograph. In addition, highly reduced conditions (10^{-18}-10^{-21} atm at 1000°C) were obtained using H_2-H_2O mixtures. The appropriate gases were dried with either $Mg(ClO_4)_2$ or P_2O_5, passed through calibrated rotameters, and mixed in a one-liter Pyrex bulb. All of the expected oxygen pressures were verified with an oxygen concentration cell involving a commercial ZrO_2 + 10 m/o CaO closed-end tube as the electrolyte and at Pt,O_2 reference electrode. The gases were passed at a total pressure of 1 atm and room temperature linear speeds of about 0.9 cm/sec.

The two-probe a-c conductivity readings were taken at 3000 cps with a conductivity bridge equipped with

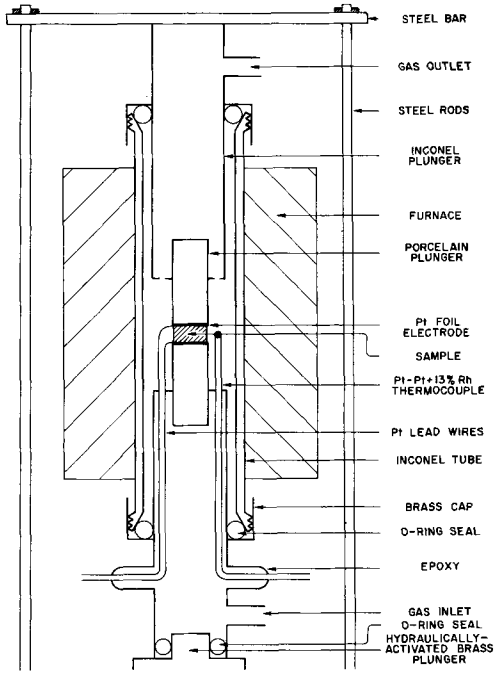

Fig. 1. High-temperature press for electrical measurements

a Wagner ground and a cathode ray oscilloscope and having an accuracy of ±0.1% in the range 500-50,000 ohms. Usually, measurements were made by holding the temperature constant until the entire oxygen pressure range had been traversed in both directions.

Emf measurements were conducted on the cells

(—) Ni,NiO/La_2O_3-CaO/Cu,Cu_2O (+)

and

(—) Fe,Fe_xO/La_2O_3-CaO/Ni,NiO (+)

at 600°-1100°C in the high-temperature press shown in Fig. 1. The metal-metal oxide electrodes were prepared by mixing the appropriate powders, pressing them at 80,000 psi, and sintering *in situ*. With this arrangement, the three pellets could be pressed tightly together in order to minimize any harmful effects from the surrounding atmosphere which could give rise to mixed potentials (34). After evacuating the system, argon, dried with $Mg(ClO_4)_2$ and P_2O_5 and deoxygenated with Cu turnings at 500°C and Ti pellets at 850°C, was admitted into the cell. Readings were taken at increasing and decreasing temperature using a Radiometer Universal *p*H meter connected to a scale expander which could be read to ±0.1 mv.

Results and Discussion

Physical properties.—Unfortunately, La_2O_3 is very hygroscopic due to weak bonding between hexagonal layers (27) and insufficiently screened cations (35). In the present study, x-ray diffraction analysis indicated the presence of only hexagonal La_2O_3 with a = 3.937Å and c = 6.130Å. If the oxide was handled in air for more than 2-3 hr, lines of $La(OH)_3$ were observed. However, the addition of CaO markedly improved the stability of La_2O_3 towards hydration. Foex (27) reported that the addition of 15 m/o CaO decreased the hydration speed by about 25 times.

Room temperature x-ray analysis indicated that about 16 m/o CaO [3.2 w/o (weight per cent)] could be dissolved in La_2O_3 at 1600°C. Sintering at 1900°C did not affect the solubility limit. The lattice parameters of La_2O_3 were almost independent of the CaO content on account of the limited solubility and the similarity of the radii of the cations (r_{La3+} = 1.14Å, r_{Ca2+} = 0.99Å). For specimens containing from 17.5 to 50 m/o CaO, lines of hexagonal La_2O_3 and CaO were observed. Therefore, no compound formation occurs in this system, a finding which is substantiated by a previous study (36) and predictable from cation field-strength considerations (37). The solubility limit was verified by gravimetric analyses on samples having more than 16 m/o CaO since the free lime could be separated from the solid solution phase by preferential dissolution in distilled water. Also, two phases could be seen under a microscope when more than 20 m/o CaO was present.

For temperatures below 1600°C, the solubility limit shifts to lower CaO contents. For instance, heating a pellet containing 15 m/o CaO at 1000°-1200°C for 20 hr resulted in the appearance of free CaO.

After sintering, the densities of the pellets were determined by carefully measuring their dimensions. All of the ceramic disks underwent a linear shrinkage of 5-7% of their original ½ in. diameters. Theoretical densities were calculated using the oxygen vacancy model for the solid solutions and the measured lattice parameters. Past the solubility limit, the theoretical densities were determined by accounting for the volume fractions of the two phases. These values are compared with the measured ones in Fig. 2. The measured densities range from 95-100% of theoretical. The agreement between the two sets of data from 10-17.5 m/o CaO, combined with an almost complete absence of porosity evidenced from observations made with a microscope, lends support to the anion vacancy model for the solid solutions. Sintering at 1900°C did not lead to any improvement in the densities of the pellets.

Although La_2O_3 pellets were white, the solid solutions were brown and reached a maximum color intensity at the solubility limit. The colors were not as intense after sintering in vacuum, indicating that color centers are created in the crystals when they are exposed to high oxygen pressures. In order to observe the microstructure of the pellets, they were etched with a hot HF + 20% HNO_3 solution. Grain sizes increased with the CaO content and were approximately 2.5-5, 10, and 25μ for samples containing 0-2.5, 5, and 15 m/o CaO, respectively. Grains in the order of 2000μ resulted from the heat treatments at 1900°C. The pressed Pt electrodes, adhering to the faces of the pellets, were never observed to penetrate to a depth greater than 25μ.

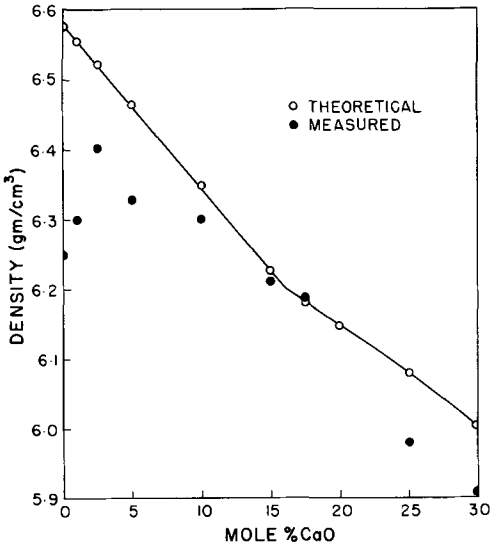

Fig. 2. Measured and theoretical densities in the La_2O_3-CaO system.

Electrical conductivity measurements.—All of the reported measurements were taken at 3000 cps. Increasing the frequency from 1000 to 3000 cps caused resistance decreases of less than 1% at high oxygen pressures and less than 2% at low pressures. Upon changing the oxygen pressure, the time required to attain equilibrium varied from 10-15 min at 1000°-1100°C to several hours at 600°-700°C.

To illustrate the oxygen pressure dependence, four conductivity isotherms for the La_2O_3 + 15 m/o CaO composition are plotted in Fig. 3. The solid lines define the oxygen pressure range covered with Ar-O_2 and CO-CO_2 mixtures, while the dotted lines continue to the lowest pressures imposed by the H_2-H_2O mixtures. An analysis of these curves indicates that the conductivity is solely ionic below 10^{-7} atm and, above this pressure, mixed p-type and ionic conductivity is present. The oxygen pressure dividing the two regions is essentially independent of temperature. No trace of n-type conductivity was detected.

The effect of the CaO content on the ionic conductivity is shown in Fig. 4. The corresponding vacancy concentrations, calculated from Eq. [1], are also given. Among nominally identical samples, the conductivity results were reproducible to about ±10%. The ionic conductivity increases rapidly up to 3 m/o CaO and is proportional to the vacancy concentration, as predicted by Eq. [2] for a dilute solution of defects. From 3 to 16 m/o CaO, the conductivity increases only slightly making any decomposition that may occur during the measurements difficult to detect. In the two-phase region past 16 m/o CaO, the conductivity decreases very little. However, in samples containing 30 and 50 m/o CaO, free CaO only occupies 7 and 20% of the volume, respectively. The conductivity at 50 m/o CaO is 25-30% lower than the maximum value. Since the conductivity of CaO is only about 10^{-6} $ohms^{-1}cm^{-1}$ at 1000°C (2, 5), a rapid decrease in con-

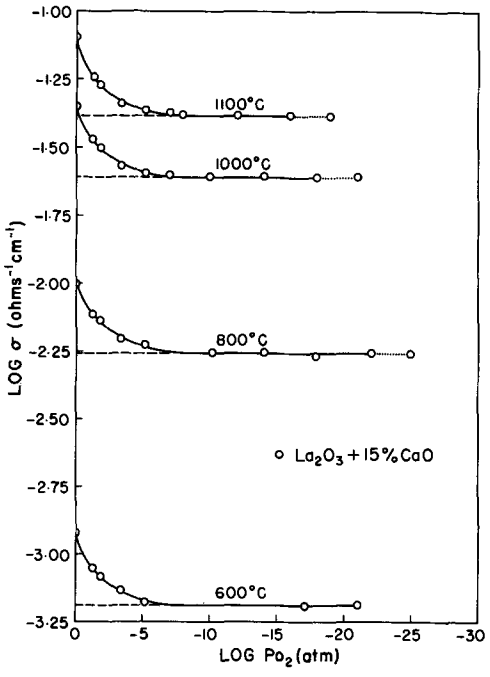

Fig. 3. Conductivity isotherms for La_2O_3 + 15 m/o CaO

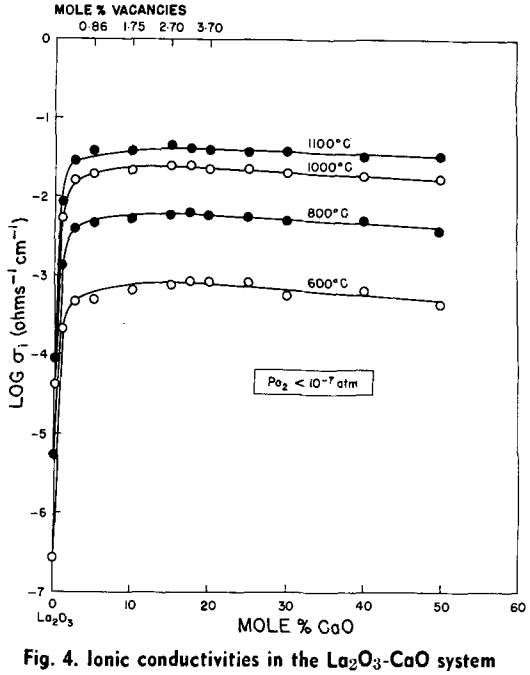

Fig. 4. Ionic conductivities in the La_2O_3-CaO system

ductivity should occur when the continuity of the solid solution phase is destroyed.

The variation of p-type conductivity with oxygen pressure and composition is presented in Fig. 5 and 6 for temperatures of 1063° and 895°C. The p-type contribution was determined by assuming that the ionic conductivity remained independent of oxygen pressure above 10^{-7} atm. The slopes are in reasonable agreement with the value of 0.250 predicted from Eq. [4]. Hence, the electron holes produced via Eq. [3] are free to conduct and the assumption of doubly ionized anion vacancies appears to be true. The reaction

$$V^{\cdot}_O = V^{\cdot\cdot}_O + e'$$

will go to the right at high oxygen pressures where the concentration of excess electrons is low. The p-type conductivity increases as the oxygen vacancy concentration increases. If the electron hole mobility and the activity coefficient for the anion vacancies are independent of the CaO concentration, Eq. [4] predicts that

$$\sigma_p \propto [V^{\cdot\cdot}_O]^{1/2}$$

at a constant oxygen pressure. This relationship, previously discussed by Bauerle (15) and Lasker and Rapp (16), was obeyed up to about 5 m/o CaO.

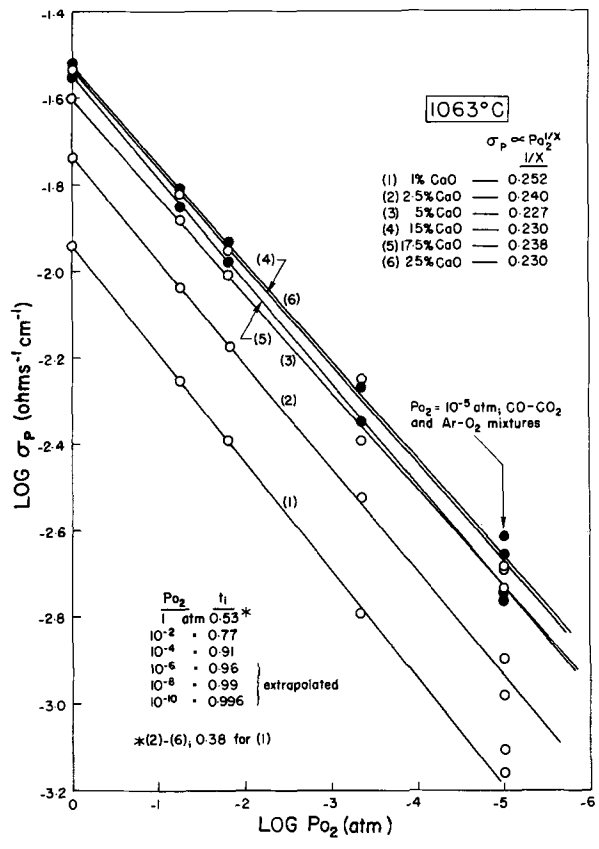

Fig. 5. P-type conductivity at 1063°C as a function of oxygen pressure and m/o CaO.

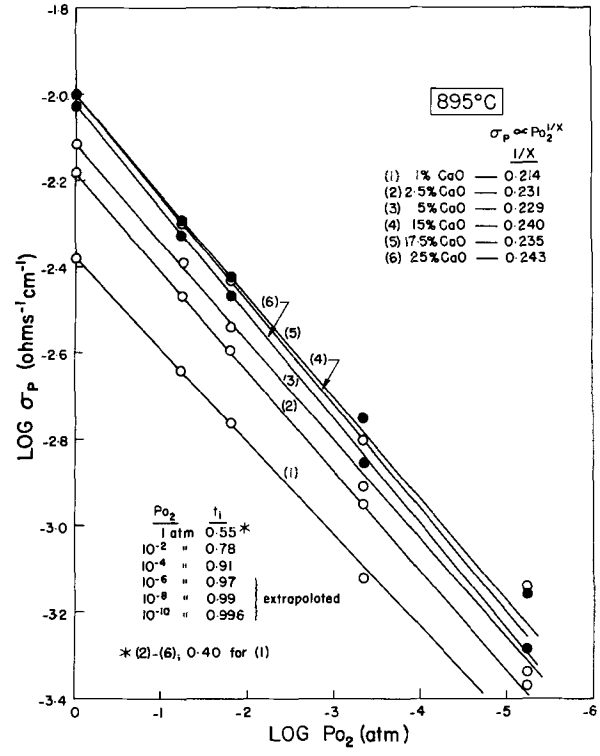

Fig. 6. P-type conductivity at 895°C as a function of oxygen pressure and m/o CaO.

Also given in Fig. 5 and 6 are several ionic transport numbers t_i, calculated from the expression $t_i = \sigma_i/\sigma$ where σ is the total conductivity. The transport numbers at oxygen pressures below 10^{-5} atm must be obtained by extrapolation of the log σ_p *vs.* log P_{O_2} plots. For compositions from 2.5 to 25 m/o CaO, the electronic contribution reaches nearly 50% at an oxygen pressure of 1 atm, while pressures below 10^{-8} atm are required to reduce it below 1%. The ionic transport numbers are somewhat lower for the 1 m/o CaO composition, in agreement with the dilute solution model proposed by Lasker and Rapp (16) for ThO_2-Y_2O_3 solid solutions. The transport numbers are approximately independent of temperature from 600°-1100°C.

The total conductivity of La_2O_3 over a much wider range of oxygen pressures than previously reported (38-42) is shown in Fig. 7 for 1032°C. A broad minimum occurs between 10^{-9} and 10^{-12} atm. The σ *vs.* $P_{O_2}^{1/4}$ plot in Fig. 8 illustrates that this minimum is essentially ionic conductivity. The intercept at $P_{O_2}^{1/4} = 0$ is in close agreement with the minimum conductivity of 4.5 x 10^{-5} ohms^{-1} cm^{-1} in Fig. 7. Assuming that the ionic conductivity is independent of oxygen pressure, both σ_p and σ_n may be determined and are also plotted in Fig. 7. Extrapolation of these lines

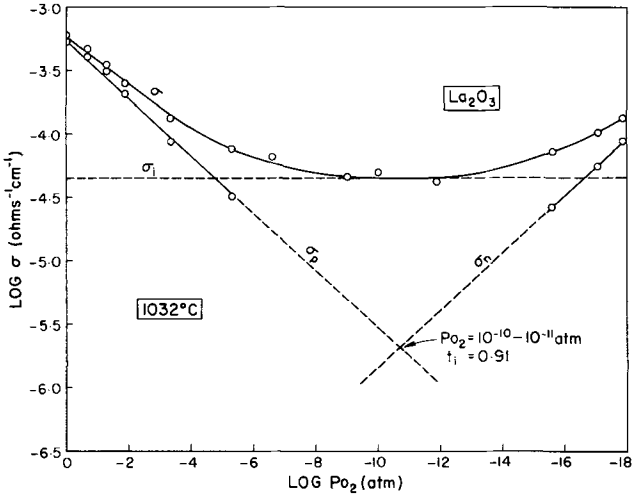

Fig. 7. Total and partial conductivities of La_2O_3 at 1032°C

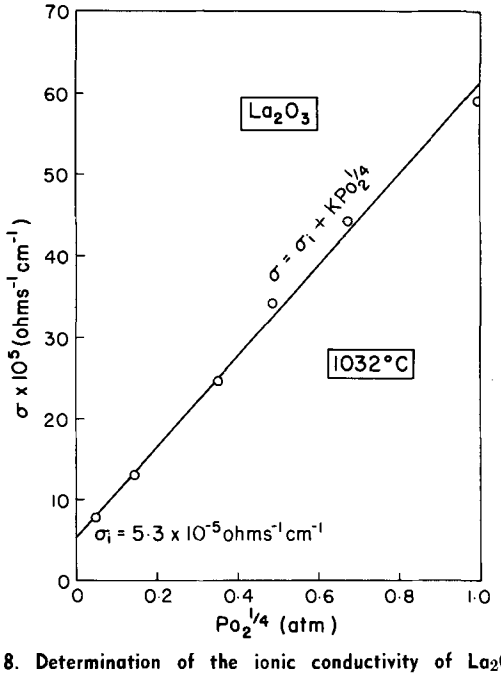

Fig. 8. Determination of the ionic conductivity of La_2O_3 at 1032°C.

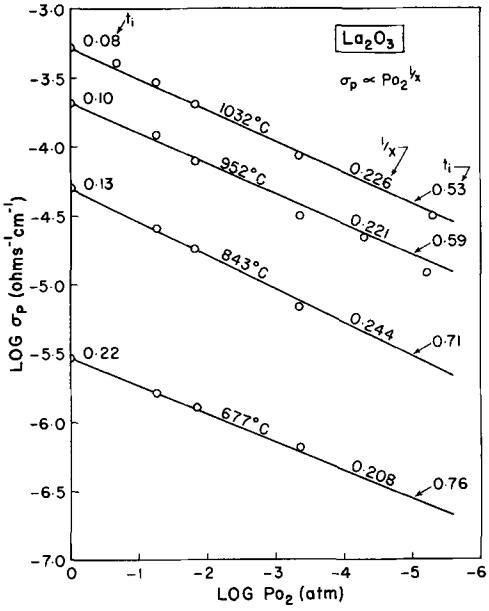

Fig. 9. P-type conductivity isotherms for La_2O_3

indicates that the smallest electronic contribution is found between 10^{-10} and 10^{-11} atm. Lower temperatures shifted the p-n transition point to somewhat lower pressures. At this point, the ionic transport number was calculated to be 0.91 at 1032°C.

Four p-type conductivity isotherms for La_2O_3 are presented in Fig. 9. Similar to the La_2O_3-CaO solid solutions, the data appear to be best represented by a $P_{O_2}^{1/4}$ dependence. The slope at 677°C may be low on account of the difficulty experienced in achieving equilibrium with the surrounding atmosphere below 700°C. Ionic transport numbers are given in Fig. 9 at oxygen pressures of 1 and 10^{-5} atm. The conduction is almost entirely electronic at 1 atm and the ionic transport numbers increase markedly with decreasing temperature.

Regarding the conduction mechanisms in La_2O_3, the questions remain as to what type of lattice defects are present and which ions (La^{3+}, $O^{=}$, or impurity ions) are transporting the ionic current. The hexagonal A-type structure of La_2O_3 is closely related to the low-temperature, cubic C-type form which, in turn, is obtained from the fluorite structure by removing ¼ of the anions and slightly rearranging the remainder. Therefore, anion interstitials might reasonably be expected. From Table I, the major impurities in the La_2O_3 used in this investigation were Pr^{4+} and Ce^{4+} cations. Their presence on the cation sublattice could also create anion interstitials. Also, the possibility of Schottky defects cannot be ignored. On account of the large charges and radii of the cations, cationic conductivity appears unlikely. Thus, the ionic conduction in La_2O_3 undoubtedly resulted from the migration of oxygen anions through either vacancies or interstitial positions. The intrinsic or extrinsic origin of these defects cannot be determined from the preceding discussion. However, the analysis of Chebotin *et al.* (43) of Rudolph's results (39) for La_2O_3 (1000 ppm impurities) indicates that the ionic transport number is 0.31 at 1000°C and an oxygen pressure of 1 atm. In the present study involving purer La_2O_3 (100 ppm impurities), the corresponding value is 0.09. This difference lends support to the possibility of impurity-controlled ionic conduction.

At high oxygen pressures, oxygen may enter the lattice by filling anion vacancies, creating cation vacancies, or occupying interstitial positions. The anion vacancy case has been treated in Eq. [4] and [5]. The cation vacancy and anion interstitial mechanisms may be represented by the reactions

$$3/4\ O_{2(g)} = 3/2\ O_o + V'''_{La} + 3h^{\cdot} \qquad [6]$$

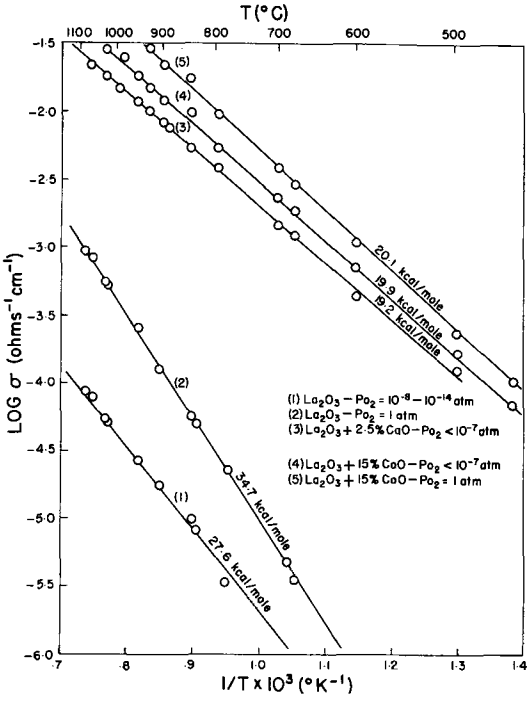

Fig. 10. Arrhenius plots of the total conductivity. Apparent activation energies are shown. Compositions are in terms of m/o CaO.

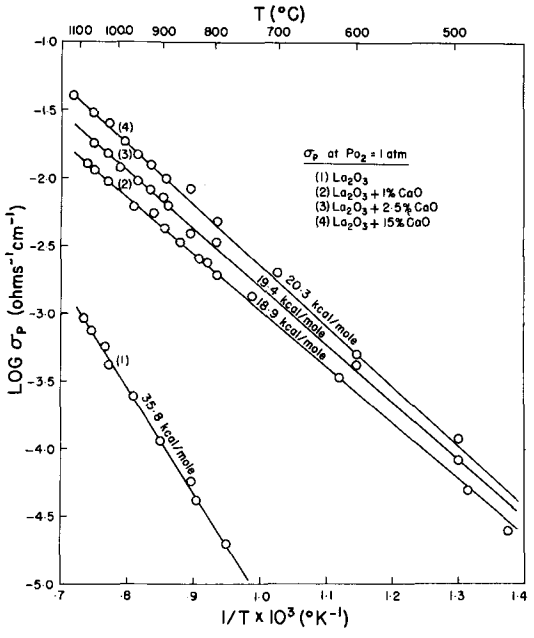

Fig. 11. Arrhenius plots of the p-type conductivity at an oxygen pressure of 1 atm. Apparent activation energies are shown. Compositions are in terms of m/o CaO.

and

$$1/2\ O_{2(g)} = O''_i + 2h^{\cdot} \qquad [7]$$

where V'''_{La} is a triply-ionized cation vacancy and O''_i is an interstitial oxygen anion. It is evident that, regardless of which mechanism is assumed, a $P_{O_2}^{1/4}$ dependence for p-type conductivity will always be derived, providing that only small deviations from stoichiometry occur. Since electronic defects are much more mobile than ionic defects, this should be true near an oxygen pressure region where $t_i \sim 1$. Equation [5] describes a possible mechanism which would lead to the appearance of n-type conductivity at low oxygen pressures. In the present instance, this onset may have been aided by the ease of reduction of the Pr^{4+} and Ce^{4+} impurity ions.

The temperature dependence of the total conductivity for both La_2O_3 and La_2O_3-CaO solid solutions is presented in the form of Arrhenius plots in Fig. 10. Curves 1, 3, and 4 represent mainly ionic conductivity, curve 2 represents mainly p-type conductivity, and curve 5 represents approximately equal amounts of both types. Arrhenius plots for p-type conductivity are given in Fig. 11. For La_2O_3, the apparent activation energy for ionic conduction Q_i and for p-type conduction Q_p are somewhat lower than the values determined by Chebotin *et al.* (43). Since $Q_p > Q_i$, ionic transport numbers increase with decreasing temperature as shown in Fig. 9. For the solid solutions, $Q_p \sim Q_i$ and both are approximately independent of composition. However, for La_2O_3 + 1 m/o CaO, $Q_i \sim 17$ kcal/mole. The apparent activation energy for p-type conduction may be related to the enthalpy change of Eq. [3].

Least squares analyses have been made on the equation

$$\log \sigma = \log A - B/T$$

where $B = Q/2.303R$ and the results are recorded in Table II. Both the conductivities and the apparent activation energies were more difficult to reproduce for solid solutions rich in CaO than for those dilute in CaO. Several times, the conductivities of samples containing more than 10 m/o CaO decreased irreversibly around 1000°C. However, two La_2O_3 + 2.5 m/o CaO samples were cycled over the temperature range 600°-1100°C for 3 weeks. During this time, no detectable changes in their Arrhenius plots were observed.

Emf measurements.—Some of the transport numbers of these electrolytes were determined by emf measurements. Results for several runs are plotted in Fig. 12. The solid lines define values recently measured with a stabilized zirconia electrolyte (34), a purely ionic conductor. Agreement to within ±1 mv was obtained with the La_2O_3-CaO electrolytes. At 1000°C, the Cu-Cu_2O, Ni-NiO, and Fe-Fe_xO electrodes impose oxygen pressures of $10^{-6.2}$, $10^{-10.3}$, and $10^{-14.8}$ atm, respectively (34). Verification has, therefore, been obtained for the assumption that the pressure-independent conductivities in Fig. 3 define a region of solely ionic conduction. The low value for the Cu/Ni cell in Fig. 12 at 1000°C may have resulted from the appearance of p-type conductivity in the electrolyte because of the relatively high oxygen pressure associated with the Cu-Cu_2O mixture. The cell

we also investigated. For an electrolyte exhibiting mixed conduction, $\bar{t}_i = E_{meas}/E_{thermodyn}$ where $\bar{t}_i$ is the average ionic transport number between the oxygen potentials defined by the electrodes and $E_{thermodyn}$ is calculated for the case where $t_i = 1$. If the electrodes do not remain reversible because of electronic conduction in the electrolyte, low values for E_{meas} will result. Application of this equation to the measurements on the above cell gave $\bar{t}_i \sim 0.9$ from 800°-1050°C, in good agreement with the results in Fig. 7.

Comparison with other oxide electrolytes.—The maximum ionic conductivities reported in several solid oxide electrolyte systems are presented in Table III. The data have been averaged where more than one reference is used. For the ZrO_2-based electrolytes, the maximum conductivities occur at compositions which coincide with the minimum amount of the additives necessary to fully stabilize the cubic phase (1, 3-7). Although the conductivity of the La_2O_3-based electrolyte is comparable to the other oxide systems, the concentration of anionic vacancies is somewhat lower. However, the shape of the curves in Fig. 4 indicates that the limited solubility of CaO in La_2O_3 has not restricted the maximum ionic conductivity to any appreciable extent.

The La_2O_3-based electrolytes can be more easily compared to ThO_2-based ones since similar vacancy concentrations can be considered. Although the ionic conductivities of La_2O_3 and ThO_2 (15, 16) are similar, the addition of CaO to La_2O_3 causes a much more rapid increase in conductivity than the addition of either Y_2O_3 or CaO to ThO_2. For instance, the ionic conductivity of La_2O_3 + 1.5 m/o CaO is one to two orders of magnitude greater than it is for ThO_2 + 0.5 m/o Y_2O_3 (12, 15, 16). These two compositions have equivalent vacancy concentrations of 0.25 m/o. In addition, the ionic conductivity of La_2O_3 + 6 m/o CaO (1 m/o vacancies) is about two orders of magnitude higher than values reported for the Sc_2O_3-CaO, Y_2O_3-CaO, and Sm_2O_3-CaO systems at a similar vacancy concentration (24). The oxygen anions are very mobile in the hexagonal A-type rare earth oxide structure of La_2O_3. Perhaps, the three large La^{3+}-$O^{=}$ interionic distances and the low coordination numbers for the anions cause them to be weakly held in their lattice positions. Also, there may be relatively large gaps between the cations through which the anions can move.

Table III. Conductivities of solid oxide electrolytes

Composition, m/o	Anionic vacancies, m/o	σ_i at 1000°C, ohms^{-1} cm^{-1}	Q_i, kcal/mole	References
ZrO_2 + 13% CaO	6.5	5.2×10^{-2}	26.2	3, 4, 6, 9
ZrO_2 + 8% Y_2O_3	3.7	11×10^{-2}	17.8	3, 7
ZrO_2 + 8% Sc_2O_3	3.7	25×10^{-2}	15.2	7
ThO_2 + 8% Y_2O_3	3.7	0.5×10^{-2}	25.4	12, 16
HfO_2 + 12% CaO	6.0	0.4×10^{-2}	33.0	5
HfO_2 + 8% Y_2O_3	3.7	2.9×10^{-2}	25.8	19
La_2O_3 + 15% CaO	2.7	2.4×10^{-2}	20.3	This study

Nevertheless, in the La_2O_3-CaO system, the conductivity-composition curves shown in Fig. 4 level off much more rapidly than they do in the ThO_2-Y_2O_3 (12, 16) or ThO_2-CaO (12) systems. Possible reasons for this include lattice distortion introduced by the Ca^{2+} cations, defect interactions between Ca^{2+} cations and anion vacancies, vacancy clustering, and vacancy ordering, a phenomenon previously found to reduce the ionic conductivity in the ZrO_2-CaO (4, 9, 44) and ZrO_2-Y_2O_3 (6) systems. Vacancy ordering might occur at relatively low defect concentrations since all the La^{3+}-$O^{=}$ interionic distances are not equal and, accordingly, all the oxygen positions are not equivalent.

The marked stability of the La^{3+} and Ca^{2+} valence states could render La_2O_3-CaO electrolytes useful to extremely low oxygen pressures. From Eq. [5], σ_n varies as $[V^{\cdot\cdot}_O]^{-1/2}P_{O_2}^{-1/4}$ at low defect concentrations. Combining this expression with the proportionality between σ_p and $[V^{\cdot\cdot}_O]^{1/2}P_{O_2}^{1/4}$ leads to the result that, at constant temperature, $\sigma_p\sigma_n$ is constant. For La_2O_3 at 1000°C, $\sigma_p\sigma_n = 7 \times 10^{-13}$ ohms^{-2} cm^{-2}. Providing that the mobilities of the electron holes and excess electrons do not change appreciably, this product may be extended to La_2O_3-CaO solutions, dilute in CaO. Application of this relationship to the La_2O_3 + 5 m/o CaO composition means that $\sigma_i = \sigma_n$ ($t_i = 0.50$) at $P_{O_2} = 10^{-35}$ atm and 1000°C.

Conclusions

Solid electrolytes, permeable only to oxygen anions below an oxygen pressure of 10^{-8} atm ($t_i > 0.99$), may be formed in the La_2O_3-CaO system. The oxalate coprecipitation method permits solid solutions to be formed at relatively low temperatures. Although 16 m/o CaO will dissolve in La_2O_3 at 1600°C, only 2 to 3 m/o CaO is required to achieve a high level of ionic conductivity. Conditions favoring ionic conduction in La_2O_3 are low temperatures, intermediate oxygen pressures, and, perhaps, the presence of impurity ions. The electrolytes are extremely resistant to reduction and may be useful for measuring the thermodynamic properties of systems which exert very low oxygen potentials.

The Effect of Overpotential on the Electrolytic Hydrogen-Deuterium Separation Factor on Bright Platinum Electrodes in 1.2*N* HCl-10% D_2O

M. Hammerli, J. P. Mislan, and W. J. Olmstead

Atomic Energy of Canada Ltd., General Chemistry Branch, Chalk River Nuclear Laboratories, Chalk River, Ontario, Canada

ABSTRACT

The electrolytic hydrogen-deuterium separation factor, S_D, was studied on bright platinum as a function of overpotential in 1.2*N* HCl-10% D_2O at 25°C. S_D increased from 4.1 ± 0.21 at —50 mv to 6.5 ± 0.35 at —400 mv, and remained virtually constant between —400 mv and —1.2v applied overpotential. Results agree with published work with H_2SO_4 but not HCl as electrolyte. Only because there is a plateau in the S_D *vs.* overpotential curve are the ohmic potential drop corrections of little significance. The high degree of reproducibility in results achieved, namely ±5%, is believed to be due to (*a*) effective exclusion of Cl_2 (anode gas) from the cathode compartment, (*b*) relatively short (1-60 min) electrolyses, and (c) removal of the large pre-electrolysis cathode from the cell prior to an electrolysis. A leaching-distillation process was also employed as the pretreatment, and is shown to be as effective as pre-electrolysis. Tafel plots obtained before and after electrolysis showed no hysteresis, and are in agreement with recent work on copper cathodes, where cathodic saturation currents are observed.

Many investigators (1-7) have studied the effect of cathode materials, current density, temperature, and the nature and concentration of the electrolyte on the electrolytic hydrogen-deuterium separation factor, S_D,[1] usually in an attempt to distinguish between different mechanisms of the hydrogen evolution reaction. More recently, several workers (8-12) have studied the separation factor as a function of the applied electrode potential.

To date, very little agreement exists between results of various workers. Thus, for example, the deuterium separation factor for platinum in acid solution has been reported as low as 2 (14) and as high as 9 (11) by different workers. Moreover, even investigators from the same laboratory have obtained different results on the same cathode-electrolyte system (12, 15). Theoretical predictions as to the magnitude of the separation factor are at present conflicting, because of the complexity of the calculations and their inherent assumptions, as Salomon and Conway (16) have pointed out.

The present work was undertaken in an attempt to obtain more consistent experimental data. Potentiostatic rather than galvanostatic control was chosen for the work reported here, because it has been shown (17, 18) that the potential at a solid metal electrode can vary with time under constant current conditions. It will be shown that we have achieved some measure of success in our aim, and that the dependence of the separation factor on overpotential is not greatly altered when the applied overpotential has been corrected for ohmic potential drop in the electrolyte.

Experimental

The cell.—The separation factor measurements were made under potentiostatic conditions in a three-compartment cell, (see Fig. 1 and 2) whose temperature was controlled to 0.1°C by a circulating water bath. Each compartment could be isolated by solution-wetted stopcocks. The reference electrode was connected to the cathode compartment by a Luggin capillary. The solution volume of the cathode compartment is about 80 ml, and the gas volume about 60 ml. The gas exit on the cathode compartment head was fitted with a water-cooled condenser for future experiments to be carried out at higher temperatures. Presaturators for the argon sweep gas were connected to the anode and cathode compartment with O-ring joints. Viton O-rings were used for all such joints.

A leak-tight fit of the electrode into the cathode holder (Teflon) was achieved with a Teflon plug which had a tapered thread and a center hole just large enough to accept the exposed stem of the electrode. The cathode holder was designed to fit into a 10 ml Pyrex syringe barrel (uniform bore) blown onto the cathode compartment head. A good seal between the

Fig. 1. Electrolysis cell; A, anode; C, cathode; R, reference electrodes.

Key words: hydrogen, deuterium, isotope separation, electrolysis, water, heavy water.

[1] S_D is defined as the H/D ratio in the evolved gas divided by the H/D ratio in the electrolyte.

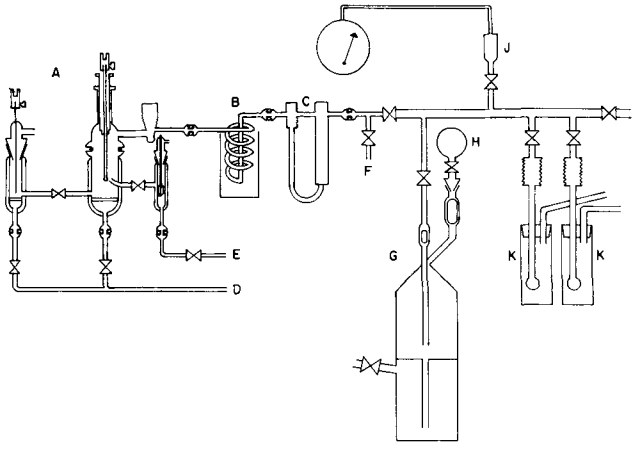

Fig. 2. Semischematic diagram of the electrolysis cell and gas collection system; A, electrolysis cell; B, solid CO_2-acetone trap; C, Cartesian manostat; D, argon inlet; E, hydrogen inlet; F, purge vent; G, Toepler pump; H, sample flask; J, Pirani gauge; K, solid N_2 trap.

barrel and Teflon holder was obtained with an O-ring, and yet the holder could readily be moved for the purpose of positioning the cathode with respect to the Luggin capillary. Later, the O-ring seal was replaced by a seal formed by expanding the polished surface of a new Teflon holder against the syringe barrel by screwing a stainless steel cylinder with a tapered thread into the holder.

Reference electrodes.—Two reference electrodes, one for potential control and the other for potential measurements, were used in the same solution at the same temperature. Apart from some early measurements which were based on quinhydrone reference electrodes with gold as the metallic phase, hydrogen reference electrodes were employed. The design of the hydrogen electrode half-cell was such that no hydrogen gas from it was ever detected in the cathode compartment. An electrolytic hydrogen generator, (Matheson of Canada Ltd., model R-152) was the source of pure hydrogen gas for the reference electrodes, and the reduction of the cathodes described later. Prior to an experiment the emfs of the hydrogen reference electrodes were checked against a saturated calomel electrode as well as each other.

Chemicals.—Analytical grade concentrated HCl was doubly distilled in an all-quartz still. The 1.2*N* (unit activity) HCl solutions containing 10% D_2O by volume were made up with triply distilled H_2O and D_2O each of which had been preirradiated with Co^{60}-γ-rays, and then refluxed with alkaline permanganate to destroy any peroxides formed before the final distillation. The distilled electrolyte was stored in a liter quartz flask.

Cathodes.—Two types of electrodes were employed as cathodes. A platinum tube electrode (diameter = 1.27 mm, wall thickness = 0.254 mm), sealed at one end in the shape of a hemisphere,[2] was used as received from Engelhard Industries Ltd. after it had been cleaned in a hot H_2SO_4-HNO_3 bath. Heat shrinkable Teflon tubing was pushed over the open end until the desired geometric surface area at the closed end remained exposed to the electrolyte. Thus, the electrolyte was in contact only with the outside of the tube electrode.

Smooth platinum bead electrodes were formed by melting the tips of 1.27 mm diameter (0.050 in.) platinum wires in a gas-oxygen flame. They were reduced in a hydrogen atmosphere for a few hours in a quartz oven either at 800° or 1050°C. The system was then evacuated through a grease free vacuum line before reducing the oven temperature. Heat shrinkable Teflon tubing, which had been treated in the hot H_2SO_4-HNO_3 bath, was then pushed over the electrode stem until only the bead and the upper part of the stem, where electrical contact was made, was exposed. As a final pretreatment the electrode was extracted with warm electrolyte overnight in a Soxhelet extractor.

Anode.—The anode consisted of a strip of platinum gauze, 15 cm long and 4.5 cm wide (Johnson, Matthey and Mallory Unimesh #Q2050, 48 mesh x 0.006 in.). This strip was wound into a roll, 0.5 cm in diameter and 4.5 cm wide, to which a platinum wire, 0.127 cm in diameter, was fastened at one end.

Pre-electrolysis pretreatment.—For all the experiments on the platinum tube electrode, the electrolyte was pre-electrolyzed, *in situ,* overnight with the aid of a platinum gauze cathode identical to the anode just described. This pre-electrolysis cathode could be raised from, or lowered into the electrolyte, by means of double O-ring seal contained in a Pyrex sleeve, which was mounted vertically on the cathode compartment head.[3] The current used was 10-15 mA. After pre-electrolysis was completed, the platinum gauze cathode was pulled out of the electrolyte, but not removed from the cathode compartment. This procedure led to difficulties which will be discussed later.

Leaching-distillation pretreatment.—For all experiments on the platinum bead cathodes, the pretreatment was as follows. Prior to a series of runs, the cell was treated in a hot H_2SO_4-HNO_3 mixture, baked in a 525°C oven overnight, and leached with freshly redistilled electrolyte for at least 24 hr. Meanwhile, the selected cathode was extracted with warm electrolyte overnight in a Soxhelet extractor as already mentioned. Another aliquot of electrolyte was then totally distilled in an all-quartz still immediately before filling the cell and mounting the bead electrode into the cathode holder.

Argon sweep gas.—Once the cell system had been assembled, argon gas entering the anode and cathode compartments at the bottom of each through glass frits, specially selected for their uniform porosity, served to sweep the hydrogen gas and/or air out of the cell. The Matheson ultra high purity argon used for this purpose received no further purification. Mass spectrometric analysis of argon samples in which the impurities had been concentrated about a thousandfold by freezing most of the argon in a solid N_2 trap, confirmed the low levels of impurities claimed by the manufacturer. The hydrogen concentration was found to be about 0.1 ppm.

Potential control.—The desired overpotential was controlled to ±2 mv by a sensitive potentiostat (Magna Corporation, model 4700M), and continuously monitored on one channel of a Moseley dual-channel strip chart recorder, (model 7100B-11-19 with two plug-in modules 17501A); the current passed between the counter (anode) and working (cathode) electrodes was continuously recorded on the other channel. The time of electrolysis varied from 1 to 60 min depending on the overpotential applied.

Temperature measurements.—For a few runs a platinum-10% rhodium 90% platinum thermocouple was placed a few millimeters from the Pt-bead electrode in order to measure possible temperature increases in the vicinity of the electrode during electrolysis, and to check on the efficiency of the thermostating facilities described previously.

Gas collection.—After completion of an electrolysis, the cathode compartment was isolated from the anode and reference compartments, and the H_2, HD, and D_2 gases swept into the collection system (see Fig. 2) with high-purity argon. The collection system consisted of a glass spiral trap cooled to —80°C with solid

[2] This electrode configuration was obtained with another experiment in mind.

[3] This particular cathode compartment head is not shown in Fig. 1.

CO_2-acetone, a Cartesian manostat (Edwards High Vacuum Canada Ltd., model 6), and a solid N_2 trap in which the hydrogen isotopes were concentrated by freezing down some of the argon. After about 15 min, the solid N_2 trap was isolated so that the gas in the rest of the system could be transferred into a gas flask with a Toepler pump without appreciably diluting the gas sample with argon (vapor pressure about 3 mm Hg, and volume of trap: volume of system ::1:60). The remaining gas in the trap was then expanded into the system, the trap isolated again, and the gas added to the flask. Experience showed that one expansion was enough to collect essentially all the hydrogen. This procedure increased the hydrogen concentration in argon sufficiently to permit accurate analyses of samples from electrolyses as short as 1 min.

H/D analyses.—All samples were analyzed mass spectrometrically. A CEC (Consolidated Electrodynamics Corporation) model 21-610 mass spectrometer was first used. Later, the work load on this instrument became too great, and a CEC model 21-130 mass spectrometer was employed. Both instruments were carefully calibrated over a range of ionizing currents and sample pressures, as well as different hydrogen to argon ratios from 30% hydrogen: 70% argon to 2% hydrogen: 98% argon. Carefully prepared heavy water standards were reduced in a uranium furnace previously equilibrated with the same standard, and the gas mixtures withdrawn at the reduction temperature (500°C). Complete reduction required several hours. An appropriate quantity of argon was then added to the hydrogen isotopes. From the equilibrium constant data (12) for the reaction

$$H_2 + D_2 \rightleftharpoons 2HD$$

at 500°C, the isotopic composition of the hydrogen was calculated and this, in turn, allowed the sensitivity factors for HD and D_2 relative to H_2 to be determined for each instrument. Each gas sample was analyzed three times with a reproducibility of ±1%.

The deuterium content of the electrolyte was determined before and after a series of runs on a Thomson-Houston model THN-202B hydrogen-deuterium mass spectrometer (13).

Ohmic potential drop measurements.—The ohmic potential drop between the tip of the Luggin capillary and the cathode was measured galvanostatically. Current supplied by a galvanostat (Northeast Scientific Corporation, model RI-234) to the cell was interrupted at the anode with a mercury relay (C.P. Clare and Company, type HG 2A-1004). The energizing current to the relay coil was also used to trigger the time base of an oscilloscope (Tektronix type 556, vertical plate amplifier type L). For meaningful measurements of the ohmic potential drop, a 50 μsec/div or faster sweep rate was necessary, but the switching time of the relay was about 5 msec or ten times slower than the required oscilloscope sweep. This problem was solved by delaying the triggering pulse from the relay coil to the oscilloscope with the variable delay time of a pulse generator (Datapulse, type 101). The change in the potential difference between the cathode and reference electrode was recorded photographically.

Tafel plots.—Steady-state Tafel plots were obtained periodically in the usual manner at both increasing and decreasing successive overpotentials before, and sometimes after a set of electrolyses.

Results and Discussion

S_D as a function of η.—The main result of our experiments concerning the relation between overpotential and the separation factor, S_D, on platinum electrodes immersed in 1.2*N* HCl-10% D_2O aqueous electrolyte is that S_D increases as the applied cathodic overpotential, $\eta_{applied}$, increases from zero to about |— 400 mv|, and then remains virtually constant with increasing overpotential.

Figure 3 shows this dependence of S_D on $\eta_{applied}$ for (*a*) the platinum tube electrode at two different exposed areas with the quinhydrone electrode as the reference electrode and pre-electrolysis as the electrolyte pretreatment, and (*b*) two platinum bead electrodes in two series of runs with the hydrogen electrode as the reference electrode and the leaching-distillation process as the pretreatment.

It must be pointed out that, although stringent precautions were taken to keep quinhydrone out of the cathode compartment, no claim is made that this aim was achieved. For this reason two experiments were carried out, one with the hydrogen reference electrode, and the other with the quinhydrone electrode plus deliberate additions of quinhydrone (approx. 10^{-3}M) to the catholyte. The values of S_D were experimentally the same in both cases, but it was observed that the hydrogen gas in the catholyte containing quinhydrone was liberated in smaller and more uniform bubbles from the electrode surface, suggesting that quinhydrone was probably adsorbed on the cathode surface.

For the S_D determinations on the platinum tube electrode several aliquots of electrolyte were used over a period of several days. For the S_D determinations on the platinum bead electrodes only one aliquot of electrolyte was used for each electrode and all electrolyses (whose corresponding S_D values are numbered in Fig. 3 in the order in which the electrolyses were obtained) were carried out over a period of about 14 hr. Because of our sensitive hydrogen isotope measurement technique, it was possible to keep the electrolysis time ≤5 min for $\eta_{applied} \geq$ |—100 mv| thereby minimizing time effects on S_D due to electrode surface aging (9, 20, 21) and/or changes in concentrations of electroactive impurities in the electrolyte with time.

As Fig. 3 shows, the data obtained on the tubular electrode system show good reproducibility contrary to expectations based on the above discussion, and are in excellent agreement with the results shown in Fig. 4 to be discussed later. While the scatter in the data obtained on the bead electrode systems is much greater, the over-all reproducibility of the results of Fig. 3 is still within that obtained by previous workers [*e.g.* see ref. (11)].

Reproducibility of S_D measurements.—The dilemma of why the more stringent electrode and electrolyte pretreatments used for the bead electrode system should yield the less reproducible results, was at least partially resolved, when it was realized that Cl_2 could reach the cathode, and that this possibility was greatly enhanced by the very time-saving techniques designed

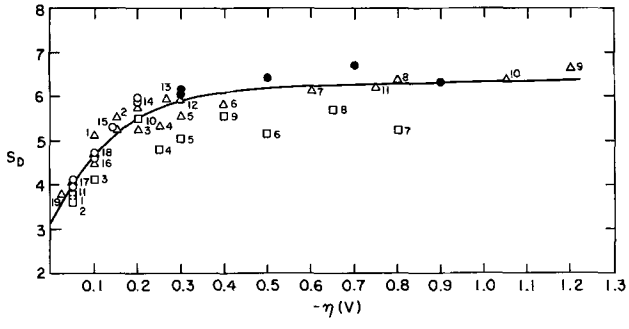

Fig. 3. Electrolytic separation factor as a function of applied overpotential for bright platinum in 1.2*N* HCl-10% D_2O at 25°C; ● and ○, hollow platinum tube electrode with geometric surface areas of 0.063 and 0.51 cm², respectively; electrolyte was pre-electrolyzed and the quinhydrone reference electrode was used. □ i and △ i, two platinum bead electrodes, each with geometric surface area = 0.06 cm²; the leaching-distillation pretreatment and the hydrogen reference electrode were used; i = i'th consecutive electrolysis on a given electrode.

(12); x and o, with galvanostatic and potentiostatic control, respectively.

to reduce impurity build-up. When some Cl_2 was deliberately added to the catholyte, the separation factor from the subsequent electrolysis was always depressed as Table I shows, although the results in Table I are qualitative only. In order to prevent chlorine contamination of the catholyte, the anode compartment was thereafter continuously purged with argon rather than only for a few minutes between successive electrolyses. S_D determinations utilizing this improvement are shown in Fig. 4.

The results in Fig. 4 were all obtained from a single electrode and one aliquot of electrolyte. Successive overpotentials were chosen at random as before. The results obtained here without pre-electrolysis are in excellent agreement with those of Fig. 3 with pre-electrolysis. Our leaching-distillation pretreatment therefore appears to be as effective as pre-electrolysis in yielding reproducible results, at least as far as S_D determinations are concerned. A pretreatment other than electrolysis is to be preferred, provided it is effective, in any system where the electrolyte concentration is being changed as a result of electrolysis (Cl_2 evolution at the anode in this work). One value of S_D was obtained under controlled current conditions and, as shown, is in good agreement with the potentiostatic data. This behavior was also observed by Yokoyama (12) and suggests that the importance of potentiostatic control may very well have been over emphasized in steady-state applications such as electrolysis at high current densities, where large ohmic potential drops cannot be avoided. Ohmic potential drop measurements are discussed in a later section.

The results presented in Fig. 4 are within a ±5% reproducibility range. This degree of reproducibility, not achieved before, is believed to be due to several factors. The relatively short duration of an electrolysis, the exclusion of Cl_2 from the cathode compartment, and the electrode and electrolyte pretreatments

have already been mentioned. Two additional factors will now be discussed.

It was observed that H-D analyses of successive aliquots of gas, removed from the cell 30 to 90 min apart following one electrolysis period, yielded different values of S_D. Typical results are shown in Table II. It is obvious that the first aliquot was relatively richer in hydrogen (S_D larger) than the mean value, and *vice versa* for the last aliquot. Under the same electrolysis conditions, a value of S_D close to the mean value was obtained from analyses made on the total gas produced. This effect disappeared entirely when the large surface area pre-electrolysis cathode was removed from the cathode compartment prior to an electrolysis. We believe the effect was due to slow effusion of absorbed hydrogen gas with an isotopic ratio significantly different from that of the electrolysis gas, and time dependent. The pre-electrolysis electrode would be expected to occlude apreciable quantities of the hydrogen isotopes after a 24-hr pre-electrolysis (22-25). Nevertheless, since the cell was always thoroughly purged with argon for at least an hour after completion of the pre-electrolysis, it was surprising to find this effect. Part of the scatter in published S_D values, where pre-electrolysis was employed, might be explained if the pre-electrolysis electrode were left in the cathode compartment and H/D analyses were based on aliquots of the electrolysis gas. All S_D measurements reported here are based on analyses of the total electrolysis gas. The pre-electrolysis electrode was removed from the cathode compartment when that technique of purification was used.

The second factor is that mass spectrometric analysis results for samples of pure hydrogen isotopes are pressure dependent due to H_3^+ formation, which is also dependent on composition and the ion source characteristics of the mass spectrometer. With our instruments the pressure effect was only about 3% over a decade change in analyzer pressure, but could be more significant in other systems. In our work this difficulty was circumvented by diluting the hydrogen isotopes with argon, and also by working over a small range of inlet pressures at a constant ionizing current of 80 μA. This resulted in analyses of such mixtures being independent of pressure.

Comparison with published results.—Our results in Fig. 4 have been compared with the AVERAGE values of S_D on platinum obtained by Salomon and Conway (11) for 1.0*N* HCl-10% D_2O at 25°C, and those obtained by Yokoyama (12) for 1.0*N* H_2SO_4-10% D_2O at 15°C. Our results agree well with Yokoyama's when his experimental error of about 25% and lower temperature are taken into account. However, our results disagree with those of Salomon and Conway who found a maximum in the curve. Lewis and Ruetschi (8) observed maxima on Pt electrodes, but in 6*N* KOH. No explanation of the disagreement can be given except that electrode surface conditions could have been different. Nevertheless, some doubt now exists as to the validity of Salomon and Conway's co-anion hypothesis (11) to explain their HCl and $HClO_4$, and Fukuda and Horiuti's (15) H_2SO_4 results.

Temperature control.—Temperature measurements with the thermocouple near the cathode during electrolysis at high overpotentials (current density approx. 2A cm^{-2}) indicated that no significant in-

crease in temperature occurred in our system and that temperature control inside the cathode compartment was within ±0.1°C. It may be significant that no decrease in S_D was observed here at the higher overpotentials. Such a decrease could conceivably be due to local heating of the electrode and solution in its immediate vicinity, for it is well established [see (26) for example] that S_D decreases with increasing temperature.

Ohmic potential-drop measurements.—A typical oscillograph of the ohmic potential drop between the cathode and the Luggin capillary is shown in Fig. 5. The ohmic potential drop was measured from the horizontal line at the top, representing $\eta_{applied}$ just before the anode circuit was broken, to the point where the intensity of the display increased sharply, but where the potential decay was still almost vertical on the 50 μsec cm^{-1} sweep rate used. Reproducible results were obtained in this manner up to $\eta_{applied} = |-500$ mv|, beyond which the relay failed to produce a sharp break, as evidenced by noise signals in the oscillographs. The magnitude of the ohmic potential drop, for electrode placements of about 1 mm from the capillary tip, is displayed in Fig. 6 and seen to be a large "correction" at the higher applied overpotentials. For example, at $\eta_{applied} = |-400$ mv| the ohmic potential drop = 107 ± 5 mv. The current density is ~0.7A cm^{-2}, and "R" is thus ~0.15 ohm cm^2.

Although the ohmic potential drop correction can be large, its effect on the dependence of S_D on overpotential is relatively small as seen in Fig. 7. Because S_D reaches a plateau at about $\eta_{applied} = -400$ mv, the ohmic potential drop correction has no further effect on the shape of the curve (Fig. 7) for $\eta_{applied} \geq |-400$ mv|. The experimental limitations of the relay are thus irrelevant for this special case. However, the importance of the ohmic potential drop correction will increase with increasing cathodic overpotential for all such curves which do not exhibit a plateau. Comparison of results of different workers must therefore be made with the ohmic potential drop correction in mind. The appropriate curve in Fig. 7 should be employed when comparing the results of our work with results of other workers. Any theoretical treatment should be based on the corrected S_D *vs.* η curve.

Tafel plots.—A typical Tafel plot, corrected for ohmic drop, is shown in Fig. 8. The data were obtained after the series of electrolyses whose corresponding S_D values are given in Fig. 4 and 7. The linear portion at the lower current densities, based on the geometric area, always had a slope of −30 ± 1.5 mv regardless of whether the data were obtained before or after S_D measurements. Moreover, the Tafel

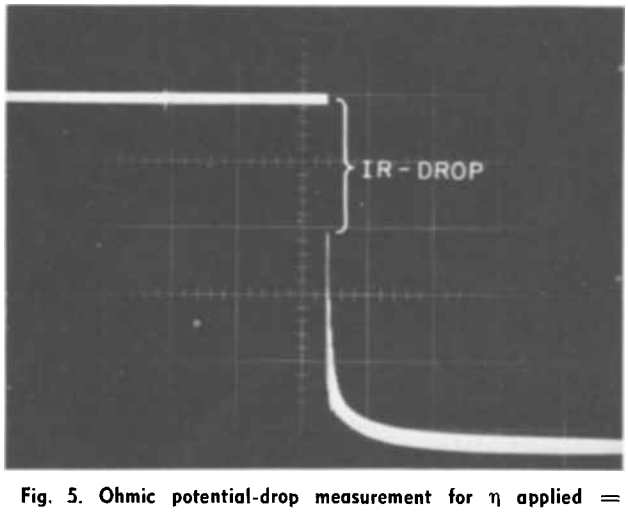

Fig. 5. Ohmic potential-drop measurement for η applied = −350 mv using the galvanostat;* IR-drop = −100 mv and η corrected = −250 mv; ordinate = 50 mv/division, abscissa = 50 μsec/division.

*The constant current was adjusted such that η applied = −350 mv just prior to an IR-drop measurement.

plot showed no hysteresis [*cf.* ref (27)]. Our Tafel plot resembles closely that recently published by Nomura and Kita (28) for the hydrogen evolution reaction on copper cathodes. They argue that the large deviation from the Tafel slope at the higher current densities is due to the existence of a cathodic saturation current, which they regard as evidence for the catalytic mechanism for the hydrogen evolution reaction; that is

$$2MH_{ads} \rightarrow 2M + H_2$$

(where M denotes the metal adsorption site) is the rate-determining step of the over-all reaction,

$$2H_3O^+ + 2e \rightarrow 2H_2O + H_2$$

Whether their arguments are applicable or not to the hydrogen evolution reaction on platinum, no evidence was obtained under the present experimental conditions for the second Tafel region of 100-120 mv (27, 29), which has been attributed (27) to a slow electrochemical atom-ion desorption step, *viz.*

$$MH_{ads} + H_3O^+ + e \rightarrow M + H_2O + H_2$$

At first sight, it appears that our Tafel data are inconsistent with those of Bockris and Azzam (27), and Schuldiner (29). This is not so for the following reasons. Although Bockris and Azzam obtained their data employing a flow technique, thereby minimizing concentration polarization effects, and they applied an IR-drop correction, their results on Pt are in some doubt. It is particularly difficult to explain the pronounced hysteresis in their Tafel plot without invoking adsorption of some inorganic impurity(ies) on their electrodes as Schuldiner (30) has pointed out. Furthermore, our results do not disagree with those obtained by Schuldiner (30) at about the same *p*H. Schuldiner observed the Tafel slope of about 110 mv only in systems of higher *p*H (>1), and in systems with added salts (29), also at higher *p*H.

Acknowledgments

The authors thank Dr. W. H. Stevens for suggesting this study and Professor B. E. Conway of the University of Ottawa for several profitable discussions and for reading the manuscript. They are also grateful to Mr. J. G. Wesanko who so willingly undertook the difficult task of constructing electrolysis cells.

Manuscript submitted Dec. 23, 1968; revised manuscript received Feb. 19, 1969. This paper was presented at the New York Meeting, May 4-9, 1969, as Paper 212.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Mechanism of the Electrochemical Reduction of Persulfates and Hydrogen Peroxide

R. Memming

Philips Zentrallaboratorium GmbH, Laboratorium Hamburg, Germany

ABSTRACT

Electrochemical studies have shown that the reduction of persulfate and hydrogen peroxide is a two step mechanism, the first step occurs by electron transfer with the conduction band and the second step by hole injection with the valence band. It could be concluded from corresponding measurements performed with a semiconductor electrode (GaP) that the electrochemical properties of these oxidizing agents have to be described by two instead of one redox (normal) potential. One normal potential is much lower (ϵ^0_1) and the other much larger (ϵ^0_2) than the theoretical value (ϵ^0) determined from thermodynamic data. These values are estimated as

$$\epsilon^0_1 \leqq 0.6\text{v};\ \epsilon^0_2 \geqq 3.4\text{v};\ \epsilon^0 = 2\text{v for } S_2O_8^{2-}$$

and

$$\epsilon^0_1 \leqq 0.6\text{v};\ \epsilon^0_2 \geqq 2.9\text{v};\ \epsilon^0 = 1.77\text{v for } H_2O_2.$$

Redox reactions with persulfates and hydrogen peroxide have been subject of several investigations. Especially the electrochemical behavior of H_2O_2 was of interest in connection with the electrochemical reduction and formation of oxygen. Bagotzky and Jablokowa (1) and Weiss (2) determined the reaction order in the reduction process of H_2O_2 on a dropping Hg-electrode and assumed a two step mechanism

$$H_2O_2 + e^- \rightarrow OH + OH^-$$

$$OH + e^- \rightarrow OH^-$$

R. and H. Gerischer (3) and Winkelmann (4) obtained the same results with a Pt-electrode and assumed also the same mechanism. Chemical properties of persulfate also are reported in the literature (5). The reaction kinetics, however, have not been studied in detail. Frumkin (5) has only postulated a possible reduction process which is similar to that of H_2O_2.

In the present paper investigations on the reduction mechanism using a semiconductor electrode (GaP) are reported. As is shown such a GaP-electrode with a large energy gap makes it possible to obtain fundamental information about the corresponding charge transfer in the reduction process.

Experimental

The electrochemical measurements were performed with single crystals of GaP as electrode material. These crystals were oriented in the <111> direction. The best results were obtained with Ga planes. In all cases the density of free carriers was about $10^{17}/cm^3$. The solutions (Merck, p.a.) were buffered to the proper pH values using standard phosphate and borate buffers. The electrodes were glued in araldit (CIBA) sockets (exposed area ~ 0.2 cm^2). A saturated calomel electrode was used as a reference electrode. (In the figures, however, values are plotted against the potential of the normal hydrogen electrode.)

All measurements were performed under potentiostatic conditions. In the medium pH range, measurements could be carried out only at cathodic potentials since $Ga(OH)_3$ layers are formed during anodic polarization (8). The interfacial capacity was determined at 250 kc by measuring the phase angle between a-c current and a-c voltage (6). The experimental arrangement for the luminescence measurements has been described previously (7).

Reduction of Simple Redox Systems

Charge transfer processes on GaP electrodes may occur via the valence or the conduction band of the crystal. As was reported (8) previously the anodic dissolution proceeds via the valence band, whereas for the cathodic hydrogen evolution conduction electrons are consumed. In the latter case a charge transfer across the interface can only occur if sufficient electrons in the conduction band are available. Consequently, in the case of n-type GaP the interfacial current rises rapidly with increasing cathodic potential, whereas with p-type GaP a very small saturation current of less than 1 μa was found (Fig. 1). Illumination of such a p-type electrode, *i.e.*, optical excitation of electrons from the valence band into the conduction band, leads to an increase of the cathodic current. The saturation current is only determined by the number of electrons excited by light. As shown in Fig. 2 it increases linearly with the light intensity.

Moreover, it was observed (8) that the charge transfer during the reduction of certain redox systems on GaP proceeds via the conduction band and in others via the valence band. This is demonstrated in Fig. 3 for ceric and ferricyanide ions in acid solutions using a p-type electrode. In the first case the current density is quite large and is not determined by the diffusion of minority carriers toward the surface, *i.e.*, the reduction of ceric ions proceeds via the valence band. In the case of ferricyanide ions the cathodic current is much smaller. Since this current may be increased by illumination of the p-type electrode it has to be concluded that electrons from the conduction band are consumed for the reduction of $[Fe(CN)_6]^{3-}$ in acid solutions.[1]

As proved by investigations with a variety of semiconductor electrodes the probability for a charge

[1] It should only be mentioned here that in alkaline solutions the reduction of $[Fe(CN)_6]^{3-}$ proceeds via the valence band. This effect is not of interest here, it was discussed elsewhere (8).

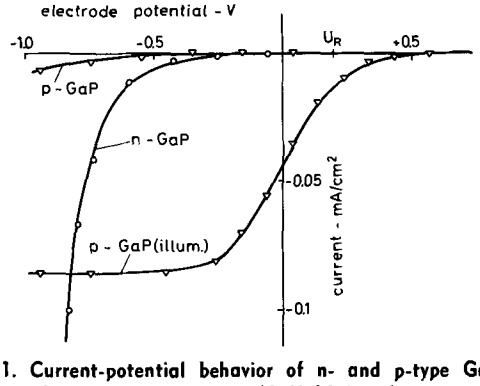

Fig. 1. Current-potential behavior of n- and p-type GaP electrodes in the cathodic region (1*N* H_2SO_4) (electrode potential against normal hydrogen electrode, NHE).

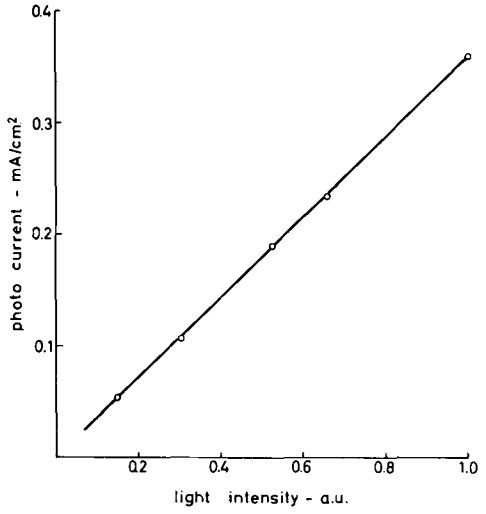

Fig. 2. Cathodic photocurrent vs. light intensity for a p-GaP electrode (1N H_2SO_4).

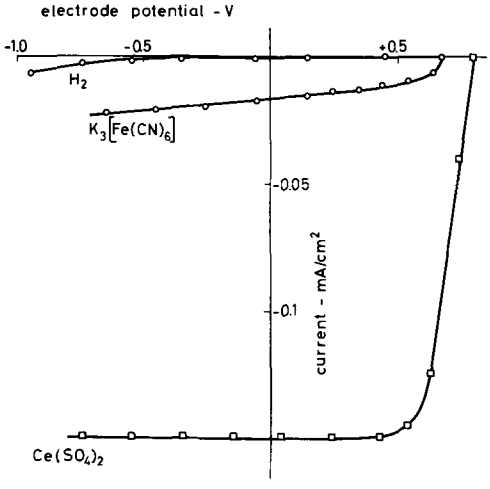

Fig. 3. Current-potential (NHE) behavior of a p-type GaP electrode in various oxidizing agents (10^{-2}M) in 1N H_2SO_4.

transfer via the conduction or the valence band depends on the redox potential of the corresponding systems (9). It was always found that the valence band process is preferred for systems with a high redox potential. This result may be qualitatively understood by the fact that an oxidizing agent is an electron acceptor. This property can be described energetically by deep lying energy levels. If we have, *e.g.*, a redox reaction of the type

$$A^{(z+1)+} + e^- \rightarrow A^{z+}$$

then the $A^{(z+1)+}$ ions represent the unoccupied and, A^{z+} the occupied electron levels. According to Gerischer's theory (10) the position of those energy levels is influenced by the solvation shell of the corresponding ions. Since the structure of the solvation shell depends on the charge of such an ion in its oxidized ($A^{(z+1)+}$) or reduced state (A^{z+}) the energy levels of $A^{(z+1)+}$ and A^{z+} differ considerably from each other. This is schematically shown in Fig. 4. According to the basic concept of this model electrons can be exchanged only between states on the same energy level (10), *i.e.*, the tunneling of an electron occurs without energy exchange with the surrounding molecules. As further shown by Gerischer the Fermi level in the semiconductor and of the redox system are equal at equilibrium conditions. Since generally we do not have an inert electrode no equilibrium is achieved, *i.e.*, one observes a corrosion potential which differs considerably from the redox potential. This

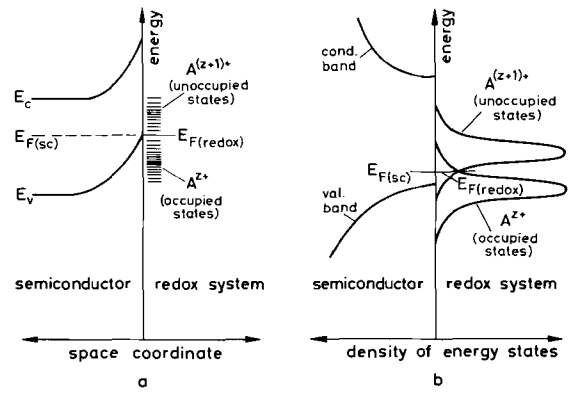

Fig. 4. Schematic energy diagram of the interface semiconductor-redox system.

model proposed by Gerischer (10) is the basis of all further considerations.

In Fig. 4 we have shown schematically a situation where the energy levels of the redox system only overlap with the valence band. In this case the electron transfer only occurs via the valence band as it was observed with ceric ions on gallium phosphide electrodes. The normal potential of this redox system amounts to 1.4v. The energy levels of redox systems with a higher normal potential have a much lower position in Fig. 4 (strong electron acceptors), *i.e.*, in this case the electron transfer is expected even more to proceed via the valence band.

We have performed corresponding measurements with persulfates and hydrogen peroxide which have a normal potential of 2.0 and 1.77v, respectively. As discussed above the reduction of these systems should occur via the valence band, *i.e.*, the reduction current should not be limited by minority carriers in p-type GaP. In contradiction to this postulation, however, we did observe a cathodic current diffusion limited by minority carriers. The results obtained with persulfates and hydrogen peroxide and the corresponding reduction mechanism are discussed next.

Reduction Mechanism of Persulfate and Hydrogen Peroxide

In Fig. 5 the current-voltage behavior is shown for a p-type GaP electrode in sulfuric acid before and after addition of $(NH_4)_2S_2O_8$ of various concentrations. It should be noted that the current scale is considerably enlarged compared with Fig. 1. As shown in Fig. 5a only a very small current increase occurs after addition of a large amount of $S_2O_8^{2-}$ ions. Similar results were also obtained with H_2O_2. As shown in Fig. 5b the cathodic current may be increased by illumination of the electrode. In this figure it is quite striking that at large cathodic potentials the current obtained for the reduction of $S_2O_8^{2-}$ is twice as large as that measured during the hydrogen evolution in H_2SO_4. As discussed in the previous section and demonstrated in Fig. 1 and 2 the saturation value of the photocurrent for the hydrogen evolution is only determined by the number of electrons excited by light from the valence band into the conduction band. Provided that this argument still holds for the reduction of persulfate we have to assume that only half of the electrons necessary for the reduction is produced by light excitation. This is possible principally because two electrons are necessary for the reduction of one persulfate ion according to

$$S_2O_8^{2-} + 2e^- \rightarrow 2SO_4^{2-} \qquad [1]$$

Actually, this result leads to a very simple model assuming that reaction [1] is a two step process. We can then assume that only for the first reaction step an electron from the conduction band is consumed, whereas an electron from the valence band is transferred across the interface in the second step. Conse-

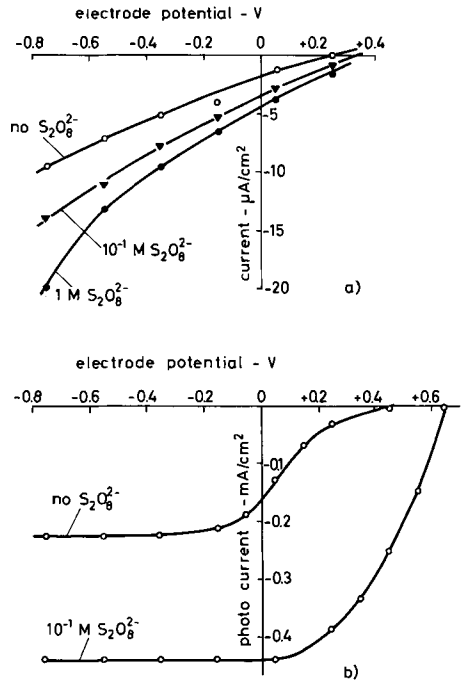

Fig. 5. Interfacial current vs. electrode potential (NHE) of p-type GaP in 1*N* H_2SO_4 with various concentration of $(NH_4)_2S_2O_8$. (a) Without illumination, (b) during illumination.

quently reaction [1] may be split up into

$$S_2O_8^{2-} + e^- \rightarrow SO_4^- + SO_4^{2-} \quad [1a]$$

$$SO_4^- \rightarrow SO_4^{2-} + p^+ \quad [1b]$$

In these equations e^- indicates an electron from the conduction band whereas p^+ is a hole injected into the valence band. Such a hole is created if an electron from the valence band is transferred to the redox system. A similar equation can be postulated for the reduction of hydrogen peroxide

$$H_2O_2 + e^- \rightarrow OH + OH^- \quad [2a]$$

$$OH \rightarrow OH^- + p^+ \quad [2b]$$

Such a current-doubling was also observed by Morrison and Freund (11, 12) for the oxidation of formic acid on ZnO. These authors also postulated a two step mechanism in which both valence and conduction band are involved. This interpretation of the current doubling, of course, is only an assumption. In the case of GaP electrodes, however, it is possible to prove this model as follows:

As mentioned above holes are injected if electrons from the valence band are consumed in the second reaction step ([1b] and [2b]). Using n-type GaP instead of p-type as the electrode material, these holes diffuse into the interior of the crystal and recombine somewhere with an electron from the conduction band. As we reported recently (7) this recombination process corresponds to a radiative transition, *i.e.*, luminescence occurs if holes are injected into an n-type GaP electrode. Such an experiment can only be performed with n-type material in order to have sufficient electrons in the conduction band for the recombination with injected holes. In the case of persulfate or hydrogen peroxide an n-type electrode has also the advantage in the luminescence experiment that the first reaction step ([1a] or [2a]) is not limited by minority carriers.

As we reported recently (7) we did observe luminescence which can only be explained by injection of holes. The same spectral distribution was also obtained with hydrogen peroxide. This result proves indeed that the second reaction step proceeds via the valence band.

pH dependence.—In a further experiment we also measured the *p*H dependence of the current doubling, as shown for hydrogen peroxide in Fig. 6 and for persulfate in Fig. 7. As a standard value we used again the cathodic photocurrent for the H_2 evolution which is independent of the *p*H value. In the case of H_2O_2 current doubling always occurs in alkaline solutions, whereas in acid solutions it depends on the H_2O_2 concentration (Fig. 6).

This *p*H dependence may obviously be related to the degree of dissociation of this molecule. Since the *p*K value of H_2O_2 is about 12 it may be concluded that the OOH^- ion is more easily reduced on a GaP electrode than the undissociated molecule itself. The *p*H dependence for $S_2O_8^{2-}$ as shown in Fig. 7 is much more difficult to understand. One possible explanation for the drop of the current doubling above about *p*H = 2 would be the assumption that hydrogen persulfate ions ($HS_2O_8^-$) exist below *p*H = 2. In general ions with a lower negative charge are more easily reduced than those with a higher charge for electrostatic reasons. Unfortunately the corresponding *p*K value is not known. Only the corresponding *p*K value for SO_4^{2-} (HSO_4^-) is tabulated which would fit to the experimental results (*p*H ~ 2). It seems to be reasonable to assume the *p*K value for persulfate to be similar. This is supported by the fact that the reduction current (saturation value) of persulfate on a Pt electrode varies in the same way in the corresponding *p*H range and remains constant at higher *p*H values. On the other hand the photocurrent on a GaP electrode increases slowly again at higher *p*H values. This may be due to the fact that $S_2O_8^{2-}$ is not very stable in alkaline solutions and decomposes partly to H_2O_2 (via Caro acid).

It would be interesting to study the *p*H dependence in the reduction of persulfate or peroxide also with n-type electrodes since then sufficient electrons are available in the conduction band. Current voltage curves have shown, however, that with n-type material practically no increase of the cathodic current

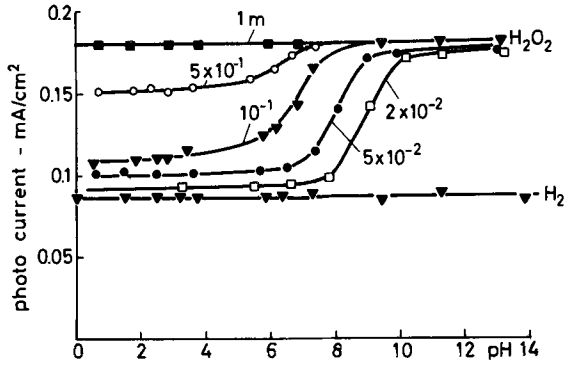

Fig. 6. *p*H dependence of the photocurrent for p-type GaP in various H_2O_2 concentrations.

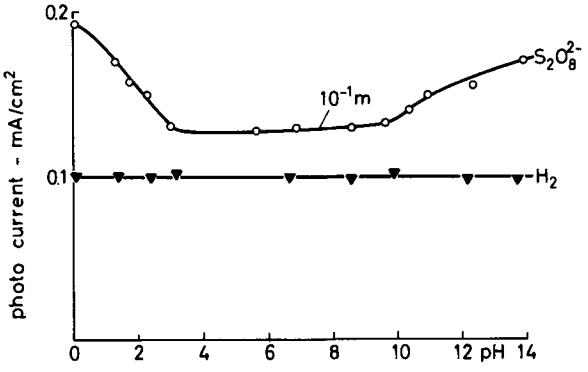

Fig. 7. *p*H dependence of the photocurrent for p-type GaP and 10^{-1}M $(NH_4)_2S_2O_8$.

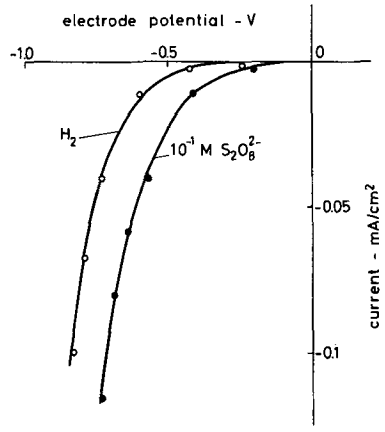

Fig. 8. Current potential (NHE) behavior of an n-type GaP electrode in 1*N* H_2SO_4 and 10^{-1}M $(NH_4)_2S_2O_8$.

occurred after addition of persulfate to H_2SO_4 (pH = 0.5) (see Fig. 8). On the other hand we did already mention in connection with the luminescence experiments that holes are injected if $S_2O_8^{2-}$ ions were present in the electrolyte. From this we may conclude that obviously the reduction of $S_2O_8^{2-}$ does occur at higher cathodic potentials than for p-type electrodes. Actually, in the case of n-type electrodes the reduction of persulfate sets in at about the same potential as the hydrogen evolution. This result implies that also with n-type electrodes the rate determining step is not determined by the redox system but by charge carriers within the electrode. This prediction may easily be proved by capacity measurements as follows:

In Fig. 9 the experimental values of the space charge capacity C_{sc} are plotted *vs.* the electrode potential for n- and p-type GaP. According to this figure $1/C_{sc}^2$ varies linearly with the electrode potential, *i.e.*, the space charge capacity follows the Schottky-Mott law

$$\frac{1}{C_{sc}^2} = \frac{2kT}{e^2\,\epsilon\epsilon_0\,N_{D(A)}}\left(\frac{e\,U_{sc}}{kT} - 1\right)$$

where U_{sc} = potential drop across the space charge layer, $N_{D(A)}$ = density of donor or acceptor states within the semiconductor, ϵ = dielectric constant, ϵ_0 = 8.854 x 10^{-12} amp·sec·v^{-1}·meter^{-1}). Such a relationship is always obtained for a depletion layer (6). Extrapolating the curves to $1/C_{sc}^2 = 0$ one obtains roughly flat band position, *i.e.*, $U_{sc} = 0$. The band bending is zero for n-type at —0.9v and for p-type at +1.2v. The difference between the two flat band positions is then 2.1v, *i.e.*, it is slightly less than the energy gap of GaP (2.25 ev). This result is expected for highly doped semiconductors provided that the potential difference applied across the interface occurs only within the space region of the electrode. From this result the band bending at the rest potential U_R = +0.35v (see Fig. 9) can be determined (13). One obtains an upward bending of 1.25v for n-type and downward bending of 0.85v for p-type as shown schematically in Fig. 10. Consequently the electron density at the surface of an n-type electrode is so small that any charge transfer from the conduction band into the electrolyte is only determined by number of electrons available at the surface. This behavior makes it also impossible to obtain any further information about the reduction of persulfate from current voltage curves with n-type GaP-electrodes.

Normal potentials of persulfate and hydrogen peroxide.—As described in the first part of our discussion in this paper it depends on the normal potential of a redox system whether the charge transfer occurs via the conduction or via the valence band. Since the reduction of $S_2O_8^{2-}$ and H_2O_2 is a two-step mechanism in which both energy bands of the electrode are involved it follows directly from Gerischer's model (10) that the properties of these redox systems can only be described by two instead of one normal potential. This can be demonstrated again by an energy diagram (Fig. 11a) which is similar to that shown in Fig. 4b. In the case of persulfate, for example, we have now three energy states. The energy position of the

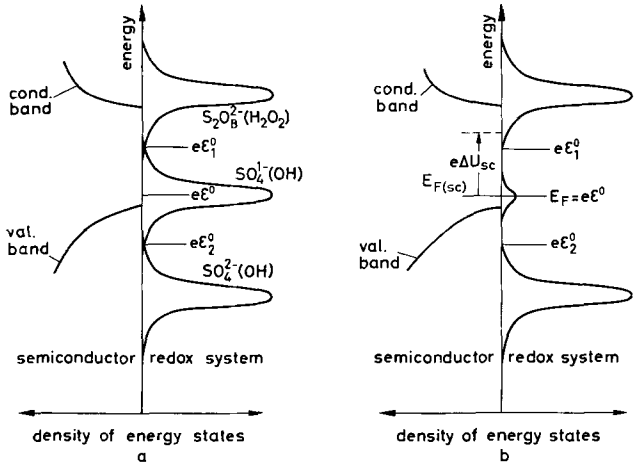

Fig. 11. Schematic energy diagram of the interface semiconductor-persulfate (hydrogen peroxide) (at equilibrium). Concentration of SO_4^{1-}: (a) large, (b) small.

intermediate state SO_4^- is just between the unoccupied $S_2O_8^{2-}$ and the occupied state SO_4^{2-}. According to Gerischer's model the density of the unoccupied ($S_2O_8^{2-}$) and of the intermediate state (SO_4^-) are equal at normal potential ϵ^0_1 for the first reaction step provided that the concentrations of $S_2O_8^{2-}$ and SO_4^- are equal. The latter condition is more or less trivial because, according to Nernst law, the redox potential is only identical with the normal potential if the concentrations are equal. In the same way also the normal potential for the second step ϵ^0_2 is determined. The effective redox potentials depend on the concentrations of the three species. The corresponding Nernst equations are given by[2]

$$e\epsilon_1 = e\epsilon^0_1 + kT \ln \frac{C_{S_2O_8^{2-}}}{C_{SO_4^-}\, C_{SO_4^{2-}}} \qquad [3]$$

$$e\epsilon_2 = e\epsilon^0_2 + kT \ln \frac{C_{SO_4^-}}{C_{SO_4^{2-}}} \qquad [4]$$

where e = elementary charge, and k = Boltzmann's constant. The free enthalpy of the complete reversible electrochemical reaction is given by $\Delta G = zF\epsilon^0$. For a two-step mechanism this free enthalpy may be split up into two values

$$zF\epsilon^0 = (z_1\epsilon^0_1 + z_2\epsilon^0_2)F \qquad [5]$$

According to [1a] and [1b] $z_1 = z_2 = 1$ and $z = 2$ so that

$$\epsilon^0 = \frac{\epsilon^0_1 + \epsilon^0_2}{2} \qquad [6]$$

i.e., the normal potential ϵ^0 of the total system is just the mean value of the normal potentials ϵ^0_1 and ϵ^0_2 defined for each reaction step (see Fig. 11a). Under equilibrium conditions the concentrations of the three species have to arrange themselves in such a way that the redox potentials are equal, *i.e.*,

$$\epsilon_1 = \epsilon_2 = \epsilon \qquad [7]$$

Since the intermediate state SO_4^- is a very unstable species its concentration is very low. Using an electrolyte containing $S_2O_8^{2-}$ and SO_4^{2-} ions in concentrations of the same order of magnitude then the effective redox potential ϵ of the complete system is almost identical with the corresponding normal potential ϵ^0 according to

$$\epsilon = \epsilon^0 + \frac{kT}{2e} \ln \frac{C_{S_2O_8^{2-}}}{C^2_{SO_4^{2-}}} \qquad [8]$$

In this case the redox potential ϵ ($\approx \epsilon^0$) is just halfway between the two normal potentials ϵ^0_1 and ϵ^0_2 and the density of energy states for the intermediate species (SO_4^{1-}) is very low as indicated in Fig. 11b.

Moreover, at equilibrium the Fermi level $E_{F(sc)}$ in the semiconductor and the Fermi level $E_{F(redox)}$ in the redox system (which is defined as $e\epsilon$) are equal (10) (Fig. 11b). Values of the normal potential ϵ^0 in this energy scale are not known. Only the corresponding normal potential ϵ^0_h relative to the hydrogen normal potential can be generally measured or calculated from thermodynamic data. In the case of persulfate $\epsilon^0_h = +2.0$v (14). Consequently, at equilibrium one would also measure an electrode potential of +2.0v provided that no corrosion etc. occurs. This is a very large potential and according to capacity measurements the energy bands even for p-type GaP would be bent upward very strongly. Consequently the electron density at the semiconductor surface would be very low, *i.e.*, at an electrode potential of +2.0v the Fermi level at the surface of the semiconductor is quite close to the valence band. This leads to the conclusion that the upward band bending has to be decreased considerably by varying the electrode potential into the cathodic direction before sufficient electrons are available in the conduction band for a charge transfer across the interface. In the energy distribution picture (Fig. 11b) this is equivalent to an upward shift of the Fermi level in the semiconductor (dotted line for $E_{F(sc)}$). According to the current voltage curves (Fig. 5b) a reduction current was actually measured below +0.75v, *i.e.*, Fermi level $E_{F(sc)}$ has to be shifted upward relative to the equilibrium value by at least 1.5v.

It is important to note that this behavior of persulfate or hydrogen peroxide not only occurs on semiconductor electrodes but exhibits a general property of these redox systems. Using a platinum instead of a semiconductor electrode a cathodic reduction current is also only observed below about +0.8v, although sufficient electrons are available even at large anodic electrode potentials. On the other hand it is also a necessary condition for a charge transfer that occupied energy states in the metal overlap with the empty states ($S_2O_8^{2-}$) in the redox system. In the case of a metal its Fermi level is also equal to that of the redox system at equilibrium. Since only energy states up to Fermi level are occupied and no higher energy levels can be filled, the overlapping between the occupied states and the $S_2O_8^{2-}$ states is very poor (Fig. 13a). Applying an external voltage ΔU the Fermi level in a metal (in contradiction to a semiconductor) cannot be shifted relative to its energy states. In this case only the potential difference across the Helmholtz double layer can be changed (Fig. 12b), *i.e.*, the energy states in the metal are shifted relative to those of the redox system as shown schematically in Fig. 13b. Since the energy difference between the unoccupied ($S_2O_8^{2-}$) and the occupied state (SO_4^{2-}) is quite large (see below) the electrode potential has to be varied considerably into the cathodic direction before a current flow is discernible.

Comparing the results obtained with $S_2O_8^{2-}$ and H_2O_2 with those of other redox systems it is possible to get a rough estimate for the values of the two normal potentials ϵ^0_1 and ϵ^0_2. This does not mean that we obtain absolute values of the potentials. We can only determine corresponding values of the normal poten-

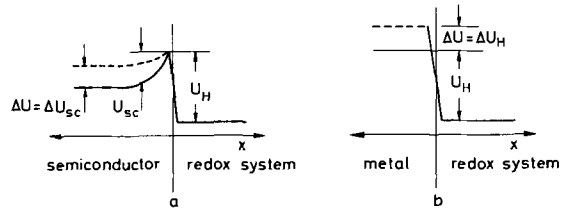

Fig. 12. Potential distribution for (a) semiconductor and (b) metal electrolyte interface. Dotted line: at cathodic polarization.

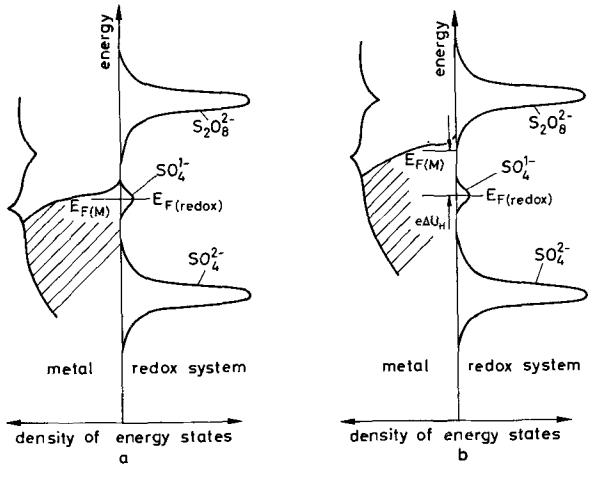

Fig. 13. Schematic energy diagram of the interface metal-persulfate. (a) At equilibrium, (b) during cathodic polarization.

[2] The reference point for the normal potentials $\epsilon^0_{1,2}$ is here not the standard hydrogen electrode. The point of zero energy is the free electron energy at infinity which is zero by definition.

tials $\epsilon^0_{1,h}$ and $\epsilon^0_{2,h}$ *vs.* a normal hydrogen electrode. As mentioned before it depends on the normal potential whether the charge transfer in a certain redox reaction occurs via the conduction or the valence band. According to Fig. 3 the reduction of Fe^{3+} proceeds already via the conduction band. Since the normal potential of the Fe^{2+}/Fe^{3+} amounts to 0.6v we have to conclude that also the normal potential $\epsilon^0_{1,h}$ for the first reaction step of persulfate and hydrogen peroxide is equal or smaller than this value. The normal potential $\epsilon^0_{1,h}$ can immediately be calculated using Eq. [6] since the normal potential of the complete system is known from thermodynamic data. One obtains for persulfate

normal potential:	ϵ^0_h	$= +2.0$v (complete system)
	$\epsilon^0_{1,h}$	$\leqq +0.6$v (1. reaction step)
	$\epsilon^0_{2,h}$	$\geqq +3.4$v (2. reaction step)
and for H_2O_2:	ϵ^0_h	$= +1.77$v
	$\epsilon^0_{1,h}$	$\leqq +0.6$v
	$\epsilon^0_{2,h}$	$\geqq +2.94$v

In the case of persulfate, *e.g.*, the difference between the two normal potentials is

$$\Delta\epsilon = |\epsilon^0_1 - \epsilon^0_2| \geqq 2.8\text{v}$$

Consequently, the energy difference between the unoccupied and occupied states is also larger than 2.8 ev.

Acknowledgments

The author is indebted to Dr. Beckmann, Dr. Möllers, and Dr. Schwandt for many helpful discussions and to Mr. G. Kürsten for performing the measurements. Thanks are also due to Ir. Peters from the Philips Laboratories in Eindhoven for supplying the single crystals of GaP.

Manuscript submitted Nov. 19, 1968; revised manuscript received Feb. 18, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Capacities of Zinc-Potassium Hydroxide Interfaces

R. A. Myers[1] and J. M. Marchello

University of Maryland, College Park, Maryland

ABSTRACT

A galvanostatic pulse current technique was employed to measure the capacitance of flat and porous zinc electrodes in 32 w/o KOH solution at 25°C. The data were obtained by operating near the hydrogen evolution potential. The electrode capacities were used to obtain the wet surface area of the zinc-KOH interface. Some exchange currents were obtained and average pore cross sections were calculated for porous zinc electrodes.

The metal-electrolyte interface exhibits a double layer capacitance which can be used to calculate the surface area. The objective of this investigation was to obtain a better understanding of the properties of the zinc electrode in the zinc-air battery. Unpublished results of investigations conducted on zinc electrodes at the Naval Ordnance Laboratory indicated that porous zinc electrodes do not seem to passivate as readily as flat zinc electrodes. Performance data is usually based on current density in terms of projected geometric area without regard for the physical structure of the surface. Since performance is dependent on the surface characteristics, the double layer capacitance technique was employed to determine the wet surface area of the zinc electrode.

Grahame (1) states that the charges (once the conditions equilibrate) do not cross the double layer because they lack the tendency to do so. The metal electrode is infinitely polarizable either (+) or (—) at the interface. The distribution of charge in the electrolyte phase at the interface may be calculated using the Gouy-Chapman theory. The original theory assumed point size charges, but this has been modified by Stern to account for finite size particles. In this theory, two double layers are assumed; the compact double layer (Helmholtz or inner double layer) is separated by the distance of closest approach from the outer or diffuse double layer.

The double layer capacity is usually measured by a galvanostatic pulse or an a-c bridge technique. The total capacitance is made up of two double layer capacitances in series. If the bulk of the capacitive nature of the interfacial system is very close to the interface then $C_{diffuse}$ is large and the total capacitance is equal to the compact capacitance. This is usually the case in strong electrolytes. It is also assumed that there is no specific adsorption of impurities which would alter the double layer. The capacitance is a function of potential. The electrode-electrolyte interface exhibits a minimum capacitance with respect to some particular potential, often referred to as the

[1] Present address: Harry Diamond Laboratory, Washington, D. C.

zero-point. This minimum usually occurs when the interface capacitance equals the compact capacitance.

The true surface area is obtained by dividing the capacitance measured by some standard capacitance density. The standard that has been used is liquid mercury for which the geometric and interfacial area are the same. Liquid mercury behaves as an ideally polarizable electrode (no charge transfer). Specific adsorption effects can be prevented by using a dropping mercury electrode (4). In strong electrolytes, mercury exhibits only a compact double layer for which the minimum capacitance is 16 μf/cm^2 (1, 2). This capacitance minimum can be used as a standard because the compact double layer is independent of metal, electrolyte, and temperature (2).

Single pulse techniques, similar to the one used in this investigation, are described theoretically and experimentally in the literature. McCallum *et al.* (2, 3) report capacitance data for the following: flat platinum, nickel, and silver; porous carbon and nickel: and nickel screen in aqueous electrolytes. They also report results for porous lithium in propylene carbonate electrolyte. Mercury-electrolyte interface capacitance techniques are reported by McMullen and Hackerman (4). They also report values for platinum, silver, copper, aluminum, and tantalum.

McCallum *et al.* (3) report an attempt to measure the capacitance of zinc electrodes in KOH. Their conclusion was that it was impossible to obtain meaningful results under the conditions they used due to faradaic effects. However, Dirkse *et al.* (5) recently report measurements for flat zinc.

Experimental

In galvanostatic pulse techniques the capacitance, C_T, or the electrode surface is calculated from the equation

$$C_T = i_p \Big/ \frac{dv}{dt} \qquad [1]$$

where i_p is the pulse current in amperes and dv/dt is the slope of the voltage response curve.

The technique used for double layer capacitance determination, Myers (6), was adapted from the work of McCallum and Hardy (3, 4). The cell used in the determination of the double layer capacitance is shown in Fig. 1. It was fabricated from Pyrex and Teflon. No grease was used in any joint because of contamination. The body was a standard tapered joint, 5 in. high, with a capacity of 250 ml. Two provisions were made for bubbling argon gas through the cell. A 2 cm gas dispersion tube rested in the bottom of the cell for deoxygenating the KOH. A surface level opening introduced an argon blanket over the KOH. These openings were connected to the gas washing bottle shown on the left. The male end of the joint was fashioned into a top for the cell. It contained four female joints for electrode connections and a ball joint and stopper for KOH addition. Teflon stoppers with a small hole down the center were used in the female joints. Two of these held the nickel wire which was connected to a 65 cm^2 platinized platinum counter electrode; one held the nickel wire connected to the working electrode, and the fourth was for optional leads to a Teflon sheathed copper-constantan thermocouple.

Fig. 1. Double layer capacitance measurement cell configuration

The reference electrode shown on the far right of Fig. 1 in a separate compartment connected to the cell by an electrolyte bridge was a saturated calomel electrode (SCE). While the mercury-mercuric oxide electrode is recommended to avoid liquid junction potentials, the SCE was found to be adequate for this study (6). Preliminary experiments gave liquid junction potentials of 3.5 mv which is well below the $\pm$ 10 mv accuracy of the electrometers used here.

A wire diagram of the double layer circuit appears in Fig. 2. It is similar to the diagram appearing in the report by McCallum (3). The circuit is divided into two sections. The right half was the polarizing circuit. The power source (battery and/or power supply) applied a voltage between the working electrode and counter electrode in the cell. The 10,000 ohm precision adjustable resistance controlled this voltage so that the desired voltage, between the working and reference electrodes, could be established. The two reversing switches allowed polarization in either direction. The milliammeter measured the faradaic current. The two 45-henry inductor coils prevented pulsing through the polarization circuit.

The left side of Fig. 2 shows the pulsing circuit. The Tektronix 160 series instruments provided a known constant square wave pulse across the working electrode and counter electrode with the pulse generator operating in "negative pulse out" mode. Pulse durations could be adjusted from 0.01 to 100 msec, pulse heights from 0.5 to 50v, and pulse repeat intervals between 0.1 and 10,000 msec, each independently. The pulse size and the voltage response of the working electrode were separately indicated on the oscilloscope through the dual-trace plug-in unit. A permanent record of these traces was obtained on polaroid film with a C-12 Polaroid Camera Unit mounted on the oscilloscope.

The pulse current was obtained by dividing the height of the pulse on the lower trace by 10,000 (R_s-series resistance). The dv/dt was measured directly on the upper trace. The capacitance of the electrode surface was calculated from Eq. [1].

An electrolyte of 32 w/o (weight per cent) KOH was used throughout. It was prepared from reagent grade KOH pellets and purified water. Distilled water was passed through an acid-leached activated carbon bed and redistilled, using a small Pyrex distillation apparatus, from an alkaline permanganate solution.

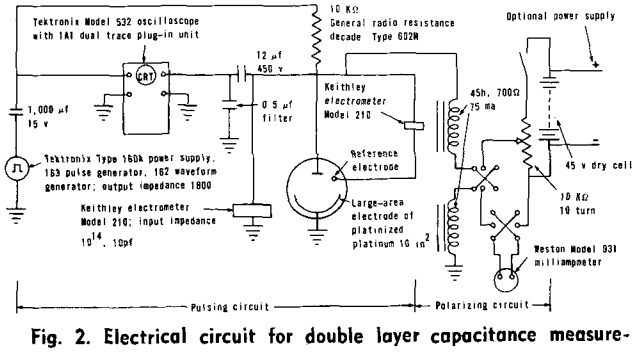

Fig. 2. Electrical circuit for double layer capacitance measurements.

Distillation was carried out at atmospheric pressure. Vapors passed through a 4 ft insulated column to prevent mechanical carry over. The final water had a conductivity of 8 x 10^{-7} mhos/cm. This water was used to make up the electrolyte. The final procedure was to pre-electrolyze the KOH solution for 48 hr at 50 ma employing two platinum electrodes just before use.

All zinc electrodes studied were less than 2 cm^2 projected area and weighed less than 0.6g. The size and weight were restricted due to limitations in detecting slopes of the dv/dt response during the double layer capacitance measurements.

Flat zinc electrodes were cut from acetone washed 99% pure zinc metal strips, 0.016 in. thick, to an area of 1 cm^2 with a 4 in. extension of the same piece of metal. Only zinc metal contacted the KOH. The area of extension that contacted the KOH was taken into account for apparent area determinations. Before making the capacitance measurement, the electrode was placed in pure KOH and cathodically cleaned at 50 ma for 30 min to remove any oxide film. The counter electrode during cleaning was a 14 cm^2 platinum electrode. At the end of the cleaning period, the electrode was rapidly transferred to the Pyrex cell for the double layer capacitance measurements.

Porous zinc electrodes were prepared by electrochemical deposition of zinc onto a silver X-mat screen from a saturated ZnO-KOH solution. The silver X-mat was pure silver, weighed 0.2 g/in.^{2} and was 0.005 in. thick. For each zinc electrode 1 cm^2 of this screen was cut out and spot-welded to a 6 in. piece of nickel wire. The rate of deposition was controlled at values between 0.1 and 0.5 amp/cm^2 for a period of 1-2 hr at about 2.0v. By knowing the rate and time of deposition, the amount of zinc on the screen was determined. Zinc is known to deposit under these circumstances at a rate of 1.1833 g/amp-hr. The electrode was then pressed to a thickness of between 0.03 and 0.05 in. and cleaned the same as the flat zinc described above. This procedure produced pure mossy type porous zinc electrodes.

The controlling parameters studied for effect on surface area were time and rate of deposition and applied pressure after deposition. A few electrodes were prepared by depositing zinc onto flat zinc to obtain surface area data between flat zinc and porous zinc. This procedure followed the same outline.

At the beginning of a capacitance measurement the cell was assembled and purged with argon for 30 min. Then the argon flow was stopped and the stopcocks closed. The polarizing switch was closed, and the polarizing voltage was applied across the cell. The voltage between the working and reference electrodes was observed until it reached the desired value. The signals on the oscilloscope were centered and a picture was taken of these signals. A series of pictures was taken at various voltages for several electrodes in order to obtain the zero-point capacitance. This was the point that corresponded to the true surface area. The minimum capacitance occurred where the response trace had a maximum slope which made it easy to find the approximate voltage range by scanning first and then working step by step across the range recording the responses. Plots of capacitance *vs.* reference voltage defined the zero-point which was used in later runs as the operating point. A slightly negative overpotential had to be established on the zinc during the argon purge to prevent zinc from going into solution. Also, the establishment of the desired zinc-reference voltage (saturated calomel electrode) on the porous electrode required a longer time than for the other electrodes.

Posey *et al.* (7) developed an expression for the charging of ideally porous structures. For charging times greater than the characteristic time constant τ, his results simplify to

$$v(x,t) = ipR_o\left[\frac{t}{\tau} + \frac{1}{3} + \frac{x}{L}\left(\frac{x}{2L} - 1\right)\right] + V_o \quad [2]$$

where $v(x,t)$ = potential in electrolyte at point x and time (v), $R_o = \rho L/A$ total axial pore resistance (ohms), A = normal pore cross sectional area (cm^2), ρ = electrolyte resistivity (ohm-cm), i_p = current pulse (amp), $\tau = R_oC_T$ time constant (sec), C_T = total capacitance (farads), L = electrode thickness (cm), t = pulse time (sec), and V_o = initial voltage on porous structure (v).

Differentiation of Eq. [2] with respect to time results in Eq. [1] which shows that for charging times greater than τ the potential response will be a constant. A preliminary estimate showed that the pulse current had to be greater than 1.0 msec to allow for the total zinc pore to be charged and less than 12 msec in order to minimize faradaic effects. Therefore, a pulse time of 5 msec was chosen for this work. The smallest setting on the vertical deflection of the oscilloscope was 0.005 v/cm. On this setting, the smallest detectable voltage deflection (which corresponded to the change in the zinc electrode potential resulting from the galvanostatic pulse) was about 0.25 mv. For a pulse current of 1.2 x 10^{-4} amp for a duration of 5 msec this would correspond to a capacitance of about 30,000 μf according to Eq. [1]. Based on the standard of 16 $\mu f/cm^2$, this capacitance would correspond to a double layer area of about 2000 cm^2. Therefore, this was the limit for the area determination on the porous electrodes.

Sixteen standard electronic capacitors with rated values in the range from 12 to 250 μf were tested on several occasions. This was done by removing the cell from the system and connecting the capacitor across the working electrode-reference electrode panel connections. The rest of the procedure was the same. Several voltages were placed on each capacitor for tests. As before, the oscilloscope traces were evaluated, and the capacitance was calculated. In all cases, the results were within 2% of the rated values, and repeated results checked within 0.5%.

Results

In the course of the experimental work, about 350 pictures were taken of the double layer responses of electrode surfaces and response of electrodes to load changes during discharge. This entailed the study of over 75 electrodes. About one half of these electrodes were of metals that were reported in the literature (1, 2, 4) and were used to establish the limitations of the procedure used here. The other half of the electrodes were either flat or porous zinc on which the experimental data were the main concern of this research. All of the data were taken in 32% KOH at a temperature between 25° and 27°C.

Before measuring zinc the values for platinum, nickel, silver, and mercury were measured to check with reported literature values. These are summarized in Table I. Sample oscilloscope traces are shown in Fig. 3.

Table I. Summary of double layer capacitance measurements on standard metals

Metal	Description	E_{min} (v)	Current (ma)	Geometric area (cm^2)	Specific capacitance ($\mu f/cm^2$)
Nickel	0.012 in. thick sheet	−0.70	0.006	12.9	20.65
		−0.70	0.004	12.9	20.60
		−0.70	0.0	12.9	26.30

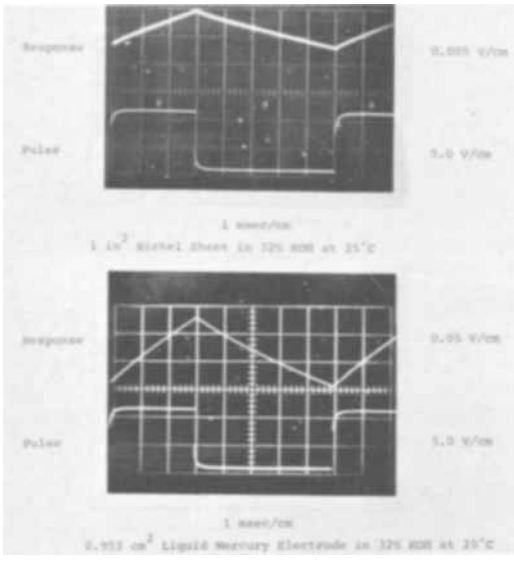

Fig. 3. Oscilloscope traces from double layer capacitance measurements on nickel and mercury.

The first successful results were obtained on flat zinc plates near the hydrogen evolution potential. With small surface areas in comparison to porous zinc, it was easier to traverse the current-voltage curve of flat zinc in KOH. The rest voltage for zinc was —1.60 *vs.* SCE. Figure 4 shows current density (based on geometric area) voltage characteristics for a flat zinc electrode under current producing conditions. However, the current producing reaction at the interface disrupts the double layer. In fact any faradaic current involving the metal ions at the surface decreases the capacitive nature of the surface so that the double layer can not be readily measured. Therefore, attempts to measure the double layer capacitance at voltage less negative than —1.60 (*vs.* SCE) were unsuccessful. As positive polarization was applied more current flowed as indicated by Fig. 4 until a current of about 375 ma/cm² was obtained. At this point passivation occurred. Passivation is the result of a zinc oxide coating forming on the surface which inhibits the flow of current. Oscilloscope traces photographed in this current-voltage region showed extreme curvature.

Thus polarization was applied to make the zinc voltage more negative. The current went to zero and then became negative below —1.64v, Fig. 5. The net current was flowing onto the zinc electrode. The oscilloscope response curve straightened at about —1.75v. More negative operating voltage caused the response to become curved again. Linear voltage responses indicate a minimum faradaic current and capacitance at the interface. Therefore, an apparent zero-point ex-

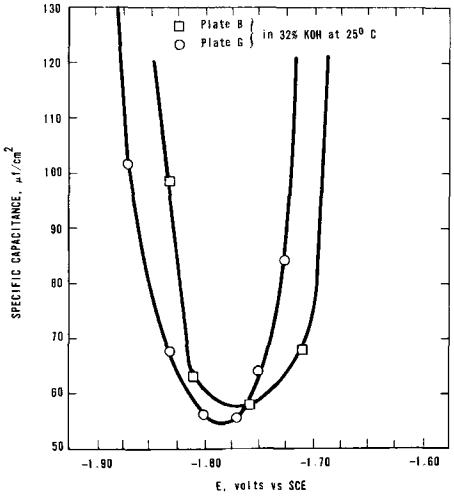

Fig. 6. Double layer capacitance measurements for flat zinc

ists in this voltage range. Several flat zinc electrodes were measured in this range to define the exact minimum. Figure 6 shows two sets of data taken to show the capacitance obtained. The zero-point is found to be at —1.76v. Figure 7 shows example oscilloscope traces for flat and porous zinc at the minimum.

The current-voltage characteristics were measured potentiostatically in the operating range on flat zinc since this data was not reported by Sanqhi and Fleischman (9). A sample of these results is shown in Fig. 5. This figure also shows production of current and a trend toward passivation which was shown in Fig. 4. More negative voltages are the results of adding current which eventually results in hydrogen evolution. There is an inflection point near the measured zero-point capacitance. The slope of this curve (di/dv) in the operating range has a smaller magnitude. The magnitude of the current is less than 0.2 ma/cm² (based on geometric area) and is not the result of the zinc electrode reaction.

Once the zero-point capacitance range and current-voltage range were obtained for zinc, the data taking procedure was simplified for the remaining electrodes studied. It was only necessary to establish the zero-point voltage on an electrode and photograph the traces at that point, since this is the only one corresponding to the double layer area.

Equation [1] was used with the oscilloscope readings to calculate the capacitance. The double layer

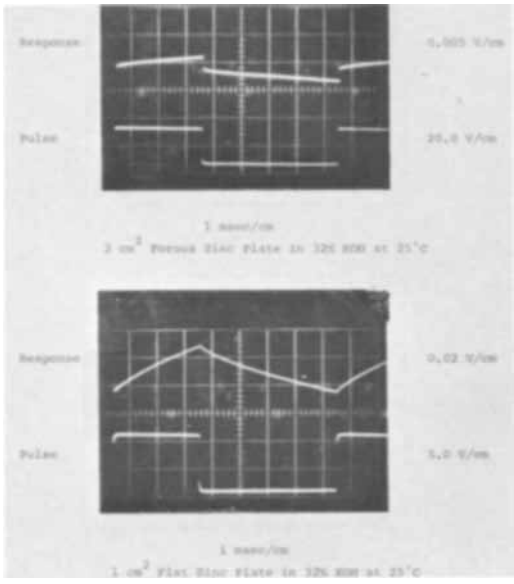

Fig. 7. Oscilloscope traces from double layer capacitance measurements on zinc electrodes.

area (DLA) in square centimeters was obtained from Eq. [3], according to ref. (2).

$$DLA = \frac{C(\mu f)}{16(\mu f/cm^2)} \quad [3]$$

where C is the capacitance measured.

Thirty-two zinc electrodes were studied in the course of experimental work. Double layer areas were measured from 3.82 cm² on flat zinc to 824.0 cm² on porous zinc. If a roughness is defined as the ratio of double layer area (DLA) to geometric areas (GA), then the range of roughness obtained was 3.0 to 212 cm²/cm². Based on the weight of zinc on the electrode, these compared to about 20.0 to 2100 cm²/g. The faradaic current effect was obtained by dividing the total current at the zero-point by the DLA. These values ranged from 0.02 to 0.17 ma/cm². A summary of results of the double layer measurements on zinc are listed in Table II.

According to McCallum (3), the oscilloscope trace data used to determine the double layer capacitance can be used to determine an exchange current according to Eq. [4].

$$I_o = \frac{nF}{RT}\left(\frac{\eta_{act}}{I}\right) \quad [4]$$

where I_o is the exchange current density. η_{act} is the voltage change due to the pulse current I. However, because of the large negative polarization (1.60 mv) the nature of the species involved in the exchange current reaction will be different. This polarization should prevent zinc from taking part in the exchange reaction.

Equation [4] held for $\eta_{act} < 50$ mv, and in most cases this voltage change was less than 5 mv. For a pulse of 5 msec duration the resulting voltage change

I_o μa/cm² based on geometric area.
I_o' μa/cm² based on double layer area.

can be assumed to be activation controlled, which is a requirement of Eq. [4]. For these calculations η_{act} was not the electrode overpotential which was equal to 1.76-1.60v or 160 mv. The I_o values obtained in this way are tabulated by the type of zinc electrode in Table III. I_o is based on geometric area, and I_o' is based on the DLA. Similar results were obtained by Farr and Hampson (8) in the potential range for zinc going to zincate.

Two electrodes of the same physical characteristics were discharged up to 95% of their theoretical capacity. One was mounted vertically and the other horizontally in the cell to study the gravitational effect. There was some zinc left on the electrodes at 95% discharge which indicated that the method used to calculate weight of zinc was accurate. The two sets of data are plotted in Fig. 8.

Equation [2] can also be solved for the response at the outside edge at the beginning of the pulse

$$V(O,O) = \frac{i_p R_o}{3} + V_o \quad [5]$$

The pore resistance according to Eq. [2] is equal to $\rho l/A$, where A is the normal average pore cross sectional area. The range of the average pore diameters obtained in this equation are reported in Table II.

Discussion

This investigation measured the surface area and pore structure of porous zinc electrodes. The area measurement was made by a single pulse galvanostatic measurement of the double layer capacitance of zinc metal in potassium hydroxide electrolyte. Extensive work has been done by McCallum *et al.* (2) on this particular approach to measuring the double layer area of metals. Their conclusion was that pH, temperature, and agitation had little effect on the capacitance values. If temperature is controlled within ±5.0°C the change in capacitance will not be detected. Graham (1) calculated that capacitance minimum only changed 1.5 μf for an 85°C change in temperature.

The effect of concentration was also considered by McCallum. The only effect occurred in dilute solutions. There are two double layers according to the theory of Gouy and Chapman: the compact and diffuse double layers. In dilute solutions, a second minimum occurred because the diffuse double layer was controlling. They recommended using concentrated electrolyte to avoid ambiguous results, since these

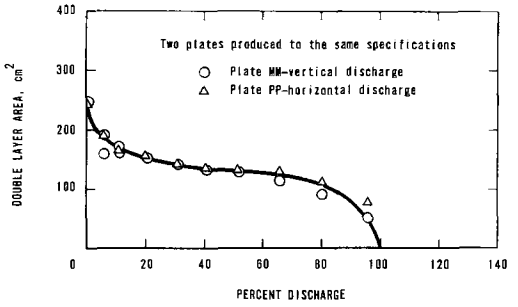

Fig. 8. Porous zinc double layer area = *f* (per cent discharge)

minima might occur very close in some cases and also to avoid high resistances in the cell that could introduce curvature in the *dv/dt* trace for the porous zinc.

The results for nickel, platinum, and silver in Table I agree well with those reported by McCallum *et al.* (2) both in the zero-point voltage and the capacitance.

Mercury in aqueous systems has received the attention of many workers. Grahame showed that theoretically the minimum should be 16 μf/cm^2. Until only recently, the best data published was about 20 μf/cm^2. Table I lists three values of mercury obtained in this work of 17.5, 18.4, and 18.4 μf/cm^2.

The oscilloscope traces in Fig. 4 and 6 show a voltage gap at the beginning of each pulse. This is the IR component of the polarization between the working and counter electrode due to the pulse. The size of the IR component depends on the relative position of these electrodes in the cell.

An operating voltage was found at which the capacitance of zinc could be measured. The approximately parabolic like curves in Fig. 5 are similar in shape to ones obtained for the other metals. The capacitance values at the minimum for the various types of zinc are consistent with the method of production. The relative areas seem reasonable. The surface of flat zinc was viewed under a microscope, and it appeared slightly more rough than the other metals. The minimum capacitance obtained on zinc was about 56-64 μf/cm^2 or a roughness of 3.5-4.0. The faradaic current was larger than it was for the other metals, and hydrogen evolution was noted at the minimum of -1.76v *vs.* SCE. But because the amount of hydrogen evolution was small and the surface area was large, the evolution was not believed to alter the double layer significantly.

Dirkse *et al.* (5) reported values for zinc which approached the values obtained in this work for the minimum capacitance. Their plots of capacitance *vs.* voltage do not show a minimum which is because they were not at the minimum voltage found in this work (6). It is felt that this point (-1.76v *vs.* SCE) is the zero point for zinc because it was the same for the three types of zinc: flat, electroplated, and porous; and the *dv/dt* response was linear in each case. In this work electrodes of about 1 cm^2 area were measured. The specific capacitance (in μf/cm^2) would not differ greatly from the total capacitance so that small errors in the area had little effect on the specific capacitance. However, Dirkse's electrodes had an area of only 0.02 cm^2 so that a small error could change the specific capacitance by 10-20 μf/cm.

The zinc reaction in KOH during discharge is

$$Zn + 4(OH)^- \rightarrow Zn(OH)_4^= + 2e^- \qquad [6]$$

For the double layer measurements, a negative overpotential was placed on the zinc which eliminates this reaction and any oxide present is converted to zinc. Current is forced in the opposite direction which results in hydrogen evolution at the zinc metal surface according to the reaction

$$2H^+ + 2e^- \rightarrow H_2 \qquad [7]$$

The current is small, in the order of μa/cm^2 at the operating voltage, and the rate of hydrogen evolution is also small.

The hydrogen reaction stabilizes the double layer. Without this reaction, the oxide and electrolyte exist in both a compact and diffuse double layer. The hydrogen reaction eliminates the effect of the diffuse layer. Hydrogen exists either as (H^+) or (H_3O^+) since this species has to exist with a positive charge in the electrolyte phase of the double layer and the chemisorbed species on zinc at the other side of the double layer. The electrons (e^-) in the zinc redistribute at the metal side of the interface. The controlling reaction is

$$H^+ + e^- \rightleftarrows Zn\,(H)_{chem} \qquad [8]$$

It is this hydrogen equilibrium reaction that stabilizes the double layer. The small current is the result of a second reaction causing the hydrogen evolution

$$2Zn\,(H)_{chem} \rightleftarrows 2Zn^o + H_2 \qquad [9]$$

The above interpretation of the double layer structure on zinc is consistent with the theory of the structure of the double layer and the particular operating point for zinc.

The determination of the exchange current from the oscilloscope pictures resulted in values that are almost constant. The exchange current should be a constant value for a metal. Values reported for other metals are usually in the order of 1 ma/cm^2 based on the geometric area. The zinc data are less than 1 ma/cm^2 and dependent on the type of zinc surface, but they are constant based on the DLA. The average values are about 34, 29, 20, ± 2 μa/cm^2. These values are not likely to be the true exchange currents for the zinc electrode as described by Eq. [6], but rather an exchange current due to Eq. [8] and [9].

Double layer measurements were attempted in KOH saturated with ZnO. As would be expected, it was not possible to obtain the proper polarization voltage for the measurement. Instead of the hydrogen evolution reaction, which was necessary to establish the compact double layer, zincate ion was being converted to zinc.

In order to confirm the fact that the double layer area was being measured in the study, several electrodes were discharged to obtain the DLA as a function of the per cent of discharge. Electrodes were discharged in a separate Lucite cell with an excess of 32% KOH in order to prevent any precipitation of ZnO. Precipitation of ZnO would result in ZnO trapped in the porous structure which could alter the capacitance measured. Then at various percentages of total discharge the electrodes were switched into the Pyrex cell containing fresh KOH that was not contaminated with zinc species for the double layer capacitance measurements. In this way, zincate ion would not be available to interfere with the capacitance determination. Two sets of data are presented in Fig. 8. The DLA drops about 40% in the first 10% of discharge, maintains a slower rate of change up to about 60% of discharge and then drops off. The initial change in DLA is due to reaction of the many small dendrites resulting from the method of electrodepositing and pressing. Once this large, rough surface is reacted, the remaining uniform internal structure reacts away slowly. Therefore, the DLA must be the total wet surface area available to the KOH, but it is not the reaction area.

Porous electrodes fail by passivation but only at much higher current densities. This is because the reaction surface is greater so that there is more space available for diffusion of $Zn(OH)_4^=$ and for saturation to occur.

Acknowledgment

The authors wish to express their appreciation to the Naval Ordnance Laboratory in Silver Spring, Maryland, for the loan of the electronic equipment and materials. R. A. Myers was an NDEA fellow during the course of this study.

Manuscript submitted Aug. 12, 1968; revised manuscript received Jan. 13, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Interfacial Electrical Effects Observed during the Freezing of Dilute Electrolytes in Water

Alan W. Cobb[1] and Gerardo Wolfgang Gross

New Mexico Institute of Mining and Technology, Socorro, New Mexico

ABSTRACT

Dilute solutions of about 50 typical salts, acids, and bases in the concentration range 10^{-6} to $10^{-3}M$ were frozen at nonequilibrium rates. The freezing potential, charge separation across the phase boundary, and chemical composition of the phases were measured. The charge separation is a function of ionic species present in the solution, their concentration, and the freezing rate. It is caused by a differential transfer of ion constituents across the phase boundary. Hydrogen and hydroxyl ions neutralize the charge as the phase boundary advances. The solution pH greatly affects the charge separation, other conditions held constant.

In 1950, Workman and Reynolds (1) suggested that thunderstorm electricity may be produced by an electrical effect that they had found to occur during controlled freezing of dilute ionic solutions. Depending on the ions present and their concentration, they measured potential differences that could exceed 200v between an electrode placed wholly within the ice and an electrode in the unfrozen solution. Workman and Reynolds showed that these potentials are not merely electrostatic in nature, that is, contact potentials, but that charge is actually transferred across the advancing phase boundary. The rate of charge transfer is dependent on the rate of phase transformation (2), and the amount of charge transferred is proportional to the mass, or volume, of the solid phase. For a given experimental configuration and freezing rate, sign and magnitude of the potential difference and rate and quantity of charge transfer depended on the kind and amount of contaminants in solution. Thus, for a $2 \times 10^{-4}M$ NaF solution, Workman and Reynolds measured a transfer of 530,000 esu or 1.8×10^{-4} coulombs/cm^3 of ice formed. Working in a helium atmosphere with a $7 \times 10^{-5}M$ NaCl solution, these investigators found that the pH of the solid phase, when melted and brought back to room temperature, was lower than that of the liquid phase. They interpreted this as being caused by selective trapping of chloride ions in the solid phase and rejection of sodium ions into the supernatant liquid. They found a rough agreement to exist between the charge transfer calculated from the pH change and that based on the electrical measurements. Workman and Reynolds suggested that the incorporation of solute ions may be a means for reducing the surface energy of a freshly formed ice surface.

Subsequently, other investigators made experimental (3, 4) and theoretical (5, 6) studies of the charge transfer mechanisms, the effects of specific solutes (7-12), the effect of electrode materials and electrode treatment on the charge separation (13), the connection between freezing rate and preferential ion incorporation (14), the relation between interface processes during ice growth and d-c conductivity characteristics of the bulk ice (15), solute partition coefficients (16), and spontaneous freezing of supercooled solutions (17). These studies have recently been discussed by one of us (18). Partial reviews are also found in ref. (19) and (20).

The purpose of the present paper is a systematic investigation of typical solutes, grouped according to their chemical characteristics and studied over a large range of concentrations. The pH effect has been investigated in detail, and charge separation measurements have been compared to the solute content of the phases.

Experimental Procedures

Aqueous solutions.—Solutions in the range 10^{-6} to $10^{-3}M$ were tested. The water was first carefully distilled and then passed through an ion exchange column of Amberlite MB-1 resin just before using. Typical resistivity range for the freshly prepared water stock was 3 to 10×10^6 ohm-cm. Control experiments with freshly distilled water of 1 to 2×10^6 ohm-cm not subjected to ion exchange yielded results indistinguishable within experimental error from those where deionized water was used. The reagents used to make up the test solutions were of the best grade commercially available. All glassware, plastic materials, and metal parts used in contact with the samples were carefully cleaned and stored in purified water.

Freezing arrangement.—A small cylindrical sleeve of Teflon (0.25-0.50 mm wall thickness, 34 mm diameter, and 52 mm height) was pressed onto a metal base, usually platinum, to make a water-tight container (see Fig. 1). This "freezing cup" was filled with approximately 35 ml of the solution to be frozen and put in contact with a heavy block of copper maintained at about −12° to −14°C (except where noted otherwise). Thermal contact was improved by having the bottom of the cup base wet as it was hand-pressed to the cold copper. With this procedure, ice forms within a few seconds on the inside surface of the metal base and grows upward with the c-axis approximately normal to the refrigerating surface. In order to avoid the formation of large concentration gradients in the ice, freezing was customarily halted when 10-15% of the solution had frozen. Typically, the initial freezing rate (after 1 sec) was of the order of $1.9\text{-}2.5 \times 10^{-2}$ cm/sec, and the average freezing rate for the first 5 min of freezing was about one-tenth of the initial

[1] Present address: California State Polytechnic College, San Luis Obispo, California.

Key words: interfacial electrical effects, ice/water system, freezing potentials, differential solute incorporation in ice, ice/water interface potentials, charge separation at the advancing ice/water interface.

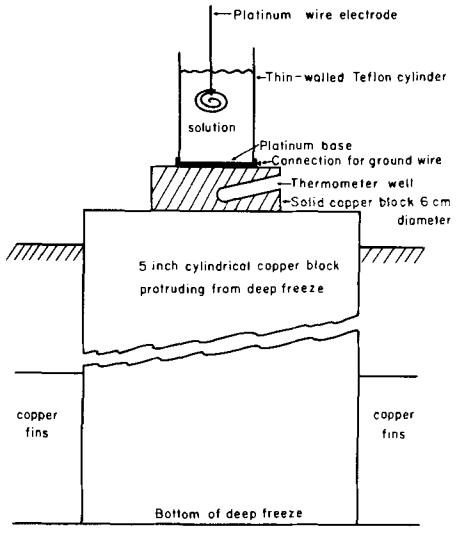

Fig. 1. Experimental arrangement used for studying electric charge separation during the freezing process.

rate. Runs were terminated after 5 to 6 min unless otherwise stated.

Electrical measurements.—The platinum base also served as the ice electrode and was electrically grounded. The solution electrode was a platinum wire with a flat Teflon-tipped spiral formed at one end. The other end was connected to the input terminal of an electrometer through a movable Lucite arm connected to a micrometer. When the Teflon tip made contact with the ice surface, the electrical continuity was interrupted, causing a deflection on the electrometer. The corresponding level of the ice surface could be read off the micrometer and recorded. In this way, it was possible to measure the freezing rate and the volume frozen.

A General Radio model 1230A d-c electrometer was used to measure either the potential difference or the charge flow between the solution and ice electrodes. Since the highest full-scale deflection of this instrument was 10v, potentials exceeding this value were measured either with a bucking potential from a dry cell connected between the solution electrode and the electrometer input or with an electrostatic voltmeter.

The input impedance of the GR 1230A electrometer is variable from zero to "infinity" ($> 10^{12}$ ohms). Freezing potentials were measured across an "infinite" input impedance called "open-circuit" arrangement in this paper. The rate of charge transfer (freezing current) was measured with an input impedance of 10,000 ohms. This effectively provided a low-resistance electrical shunt between the water and ice electrodes. Either freezing potential or current were recorded on a strip chart recorder (Varian Model G-10) running at a speed of 4 ipm. The freezing current was integrated over 5 min (unless otherwise indicated). From the total charge thus obtained, the average concentration of transferred charges was derived and compared with the chemically determined difference between solute cations and anions.

The type of material used for the cup base (and for the solution electrode) was not critical provided that comparable freezing rates could be maintained and the electrodes were not attacked by the solutions. For charge-transfer determinations, however, the metal used for the base must be resistant to electrolytic oxidation; platinum, palladium, gold, purified graphite, and stainless steel were found to be satisfactory.

The dimensions of the freezing cup, as well as the electrode distances (and shapes), did not in our experience affect freezing potentials and transferred charge concentrations, as long as comparable freezing rates were maintained. Theoretically, the interface potential is independent of the area of a flat, smooth interface (Eq. [2]).

The freezing potential was measured under experimental conditions essentially precluding charge neutralization except through the phase boundary itself which can be characterized by an "interface resistance" (6, 14). The bulk resistances of the phases had no direct effect on the measurements.

The cell resistance was estimated from the average of the ratio of a small change in freezing-cell emf to a small change in current when an external source of emf was applied in both the positive and negative directions. For many solutes, notably those yielding a larger incorporation of the negative ion constituent, this is essentially the ice resistance. To convert cell resistance to ice resistivity it would be necessary to evaluate the external circuit resistance, the two electrode resistances, the solution resistance, and the ice/solution interface resistance, subtract these from the cell resistance and multiply the result by a cell geometry factor of about 23. Data on ice resistivity and interface resistances for samples of a few solutions grown under comparable experimental conditions are found in the literature (6, 14-16).

Exclusion of atmospheric gases.—Most experiments were carried out in the normal atmosphere. Freezing of deaerated solutions under vacuum often led to supercooling and disorderly freezing and therefore was not practical as a routine. Of gases occurring in the atmosphere, carbon dioxide and ammonia were found to have specific effects which will be discussed later. No specific effect was detected from atmospheric oxygen. Since the solubility of air in ice is smaller than in water, air bubbles may form at the interface and, in escaping, cause convection. This reduces the interface concentration below the theoretical level.

Analysis methods.—After completing a freezing run, the unfrozen liquid was separated, and the ice was immediately washed several times with high-purity water. After removing excess water, the ice was melted. Analyses for alkali and alkaline earth metal ions were made with a Beckman D. U. flame photometer. The pH was determined with a Beckman model G pH meter, and the fluoride and chloride determinations were made by standard colorimetric methods (21) using a Bausch and Lomb Spectronic 20 spectrometer. For ammonium ion or ammonia determinations, the Jackson modification of Nessler's method was used (22). For a given element or radical, analysis results are expressed as concentrations (in moles per liter) of ion constituent in the melted ice at room temperature. The use of the terms "ion" or "ion transfer" does not imply judgment concerning the state of the impurities in the phases.

Freezing rate and interface concentration.—Assume that heat flow is perpendicular to and through the base only of the freezing cup (that is, the interface is horizontal, flat, and smooth), that the solute concentration far from the phase boundary remains constant, and that no convection takes place. Under these ideal conditions, the freezing rate diminishes according to the relation (Ref. 23, p. 285, Eq. [12])

$$\frac{dx}{dt} = at^{-1/2} \qquad [1]$$

a is the heat-flow parameter (see List of Symbols), which is numerically equal to the freezing rate one unit time after the beginning of freezing.

For this freezing mode, Wagner (24) has shown that the concentrations of a solute atom at the interface (on the solid and on the liquid side) are independent of freezing rate and, indeed, constant if the solute partition coefficient is constant. Thus, these concentrations are uniquely related to the concentration of the initial solution. For ionic impurities in ice, however, the distribution coefficient may be concentration-dependent (12, 18, 25, 26). While it thus appears probable that Wagner's relation is not strictly applicable to

ionized solutes in water, it is a useful first-order approximation.

Results

The Freezing Potential

The potential difference developed during the freezing of dilute ionic solutions depends in sign and magnitude on the ionic species present. The magnitude also depends on concentration and on the freezing rate. Only salts gave consistent freezing potential differences of more than 1 or 2v. The typical potential curve exhibits a relatively steep initial rise leading to a peak, and a much more gradual decline. Table I lists for a number of salts in unbuffered solutions the highest peak potential obtained and the corresponding concentration. For each salt, a considerable number of concentrations was tested, and for each concentration the data of three or more consistent freezing runs were averaged. With care, freezing potentials could be duplicated within plus or minus 10%. The major causes of variation were (*a*) poor thermal contact of the freezing cup with the cold block (potentials too low), (*b*) partial supercooling of the solution before the onset of orderly freezing (very sharp initial rise to an unusually high peak), and (*c*) insufficient recovery of the heat sink between runs (potential too low).

The effect of concentration on the magnitude of the potential peak is illustrated in Fig. 2 for solutions of five typical salts. All curves exhibit a maximum of varying sharpness. The maximum-peak concentration increases in the order: ammonium salts (except ammonium fluoride); lead salts and fluorides; chlorides; and ammonium fluoride (Table I).

The fluorides tested typically showed a maximum freezing potential of 30-45v (ice negative) at a concentration of approximately $2 \times 10^{-5}M$. Sodium salts showed a somewhat greater freezing potential than potassium salts and usually more of the sodium ions were carried into the ice.

Every pure uncontaminated hydroxide solution yielded an insignificant freezing potential (*e.g.*, 0.1v for a fresh ammonium hydroxide solution, $5 \times 10^{-6}M$), whereas the presence of carbonates, either by design or not, caused the development of high potentials (*e.g.*, 165v for a similar solution prepared from old stock and in contact with the atmosphere).

Table I. Highest freezing potentials for various salts. Concentrations given in units of 10^{-6}M. Sign of potential difference refers to the ice.

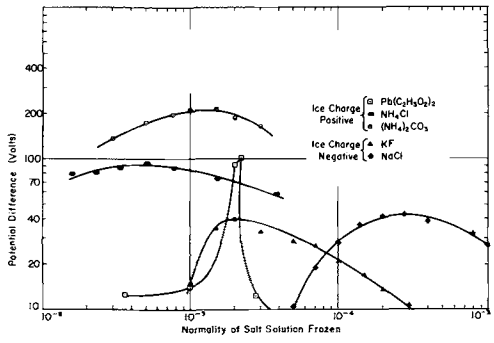

Fig. 2. Effect of solute concentration on the freezing-potential peak. The ammonium salts yield the largest potential differences. The concentration dependence is relatively weak. The ice is positively charged with respect to the liquid phase. Lead acetate also gives a positively charged ice, but the maximum potential is sharply peaked between 1 and 2 x 10^{-5}M. A less rapid decline is shown by the fluorides which (except the ammonium fluoride) also peak around 2 x 10^{-5}M. In the fluorides the ice is negatively charged.

Solutions of the acids HF, HCl, and H_2SO_4 gave insignificant potentials.

Solutions of various nitrates, oxalates, and sulfates, with a few exceptions (lead nitrate) gave maximum potential differences not exceeding 25v (ice positive) and poorly reproducible. In some cases this may have been due to a rise time exceeding the duration (typically 5-6 min) of our runs.

Qualitatively, these results are typical, but quantitatively they may differ for different investigators or for the same investigator at different times. The reasons are several: different samples of a reagent-grade salt may yield solutions of different *p*H even when made up with water of the same degree of purity; a reagent may contain traces of interfering impurities; a lack of care during the handling of a solution prior to and during freezing may cause the absorption of carbon dioxide or of ammonia from the atmosphere, or of other impurities from different sources.

Effect of pH on the freezing potential.—The maximum freezing potential of a $2 \times 10^{-5}M$ NaF solution varied from 90 to 6v as the *p*H was lowered from 7.7 to 4.8. Detailed results are presented in Table II. The optimum solution *p*H for the highest freezing potential, regardless of sign, was usually between 7 and 8. A number of the salt solutions tested, especially those containing anions of the stronger acids, were slightly acidic (*p*H near 6). An adjustment to a *p*H 7.5 in these cases would probably have resulted in a higher maximum freezing potential than shown in Table I. For example, the *p*H of a $5 \times 10^{-6}M$ NaF solution was adjusted to 7.85 by means of $1 \times 10^{-5}M$ NaOH. This solution gave successive maximum freezing potentials of 240 and 225v (ice negative); a freezing potential of under 10v was the rule when the *p*H was not adjusted.

Typically, the fluorides show a rapid decrease with concentration of the freezing-potential maximum on the low-concentration side of the peak (Fig. 2). The fluoride concentration in the ice at the point where the maximum freezing potential had fallen to 25% of the

Table II. Effect of *p*H on the freezing potential of a 2 x 10^{-5}M NaF solution

Acid or base added	*p*H Solution	Freezing potential	Cell res., 10^6 ohms	*p*H Melted ice

$2 \times 10^{-5}M$ HF	4.82	6	0.3	4.82

peak was in the narrow range of 6×10^{-7} to $1.5 \times 10^{-6}M$ for seven different fluorides tested. This was approximately the hydrogen-ion concentration of the solutions frozen. At these very low solute concentrations the availability of hydrogen ions from the solution may be sufficient to keep pace with the incorporation of solute anions, thus leading to a sharp reduction of the observed freezing potential.

In general, a reduction of the hydrogen ion concentration in a given solution reduces the slope of the potential decay curve and allows the development of much higher maximum potentials.

An increase in the hydrogen-ion content of the freezing solution invariably increases the proton content of the ice as measured by the *p*H of the melted ice or by an increased conductivity of the solid (Table II).

Effect of the freezing rate on the freezing potential.—In one series of experiments the temperature of the heat sink was varied from −47° to 0°C. This resulted in initial freezing rates (after 1 sec) of 4.2 to 0.7×10^{-2} cm/sec. The observed maximum freezing potential for a $4.3 \times 10^{-5}M$ NaF solution appeared to saturate at initial freezing rates above 2.4×10^{-2} cm/sec (Fig. 3). The saturation value lay between −45 and −50v. The impurity concentration in the ice was in direct proportion to the initial freezing rate.

Effect of ammonia and atmospheric carbon dioxide.—Ammonia may be a residue in distilled water, or it may be absorbed from tobacco smoke, floor waxes, or fertilizers. In the presence of carbon dioxide it impresses a positive potential on an advancing ice/water phase boundary and therefore tends to counteract negative potentials such as those caused by halides.

Atmospheric carbon dioxide, by itself, produces two distinct effects. In solutions of salts producing a negatively charged ice, it lowers the *p*H and therefore the freezing potential difference. In basic solutions, on the contrary, it increases the freezing potential difference. Both of these effects have been discussed above.

Volatile organics from various sources (*e.g.*, insecticides used to spray garden plants) appear to have an inhibiting effect on freezing potentials.

Location and width of the charged layer.—A freezing cup was equipped with several small wire probes imbedded horizontally in the insulated side of the cup above the base. As the advancing ice front covered a probe completely, the probe potential became the same as that of other more deeply imbedded probes, or of the base itself. Therefore, the freezing potential is generated close to the growing ice surface.

Net Charge Transport

Purpose.—Because of the specific relation, experimentally observed, between freezing potentials and

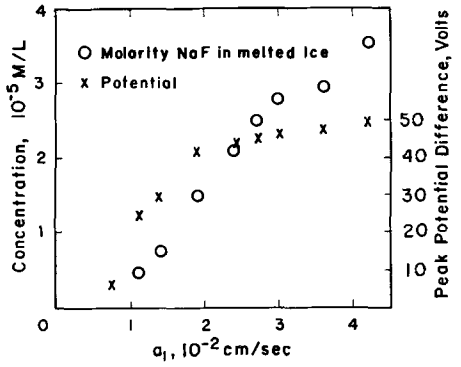

Fig. 3. Freezing-potential peak and solute concentration in the melted ice as a function of the freezing rate 1 sec after start of freezing (a_1) for a $4.3 \times 10^{-5}M$ NaF solution. The difference between solute cation and anion constituents was below the detection limit.

types of solute species present, Workman and Reynolds (1) concluded that charge transfer is related to a selective incorporation into the solid phase of ions of one sign. Actually, in many cases a considerable number of the "less favored" ion constituents are also taken into the solid, so that it is more accurate to speak of differential rates of transfer of the solute species across the phase boundary. Workman and Reynolds (1) presented evidence that, as the phase boundary advances, charge balance is being restored by hydrogen and hydroxyl ions, respectively. The charge separation ceases when the interface ceases to advance or when it advances very slowly. Theoretically, the quantity of charge transferred should be directly and simply related to the chemical composition of the phases. In practice this relation is difficult to demonstrate in a quantitative manner: the phenomenon is observed in rather dilute solutions, the solute fraction incorporated into the ice is frequently small, and differences between species are typically of second-order magnitude (Ref. 14, Table II).

For some solutes (those favoring incorporation of the anion), the charge separation effect can be demonstrated by shunting the phase boundary with an external resistance of known value. In this case a fraction of the charge transferred appears as a current that can be measured and recorded as a function of time. Workman and Reynolds (1), using shunts of 10^6 to 10^8 ohms, measured a maximum charge transfer of about 500,000 esu/cm³ of ice frozen from dilute fluoride solutions. Because this is too low for chemical detection (see Table III, Footnote), we arbitrarily chose a shunt resistance of 10,000 ohms. This is at least two orders of magnitude lower than the typical interface resistance but high enough to allow accurate electrical

measurements, and the charge separation is increased from five to thirtyfold over Workman and Reynolds' results.

Experimental.—In Table III and Fig. 4, we present data on the charge transport and differential ion transfer. Potassium fluoride solutions were frozen in a freezing cup much larger than the one described before. The base was made of stainless steel (interior diameter 11.2 cm) and the solution electrode of pure nickel. 500 ml of solution were placed into this cup and about 100-120 ml of this were frozen in about 30 min (average freezing rate about 1×10^{-3} cm/sec). Thus, enough melt water was obtained to analyze for solute cation, solute anion, and hydrogen ions. Both shunt and open-circuit data are presented. For the shunt experiments, the solute cation concentration of the melted ice is considerably smaller than the anion concentration at the most dilute concentrations. The fractional difference becomes smaller as the mother solution concentration increases. The difference between solute cations and anions is made up by hydrogen ions. There is good agreement between the hydrogen-ion transfer derived from charge transfer data and results computed from *p*H measurements. The sum of hydrogen-ion concentration and potassium-ion concentration agrees fairly well with the measured fluoride concentration. For the open-circuit runs, the differences between cations and anions are much smaller and difficult to measure accurately, therefore the agreement of the difference with the hydrogen-ion concentration is poor. At smaller freezing rates, however, larger differences were obtained (Ref. 14, Table II). NaF solutions gave similar results.

Chlorides of sodium and potassium (Fig. 5 and 6) showed trends similar in general to the fluorides, but at a given solution concentration the fraction incorporated into the ice was generally smaller for the chlorides.

The contrast in cation constituents between shunt and open-circuit samples grown from the same solutions is illustrated in Fig. 7.

The maximum charge transfer for a number of representative compounds is given in Table IV along with the concentration required for maximum transfer. The concentration dependence of the charge transfer is shown in Fig. 8. These charge transfer data were obtained with the small freezing cup (see Experimental Procedures). Typically, the solution concentration for maximum charge flow is from five to ten times the concentration that gives a maximum freezing potential. A current of more than 10 μa/cm^2 of interface surface was obtained with fluoride solutions at the concentration and at the freezing rate specified.

With the exception of ammonium fluoride (see below), all the fluorides tested (those of Cs, K, Na, Li, Mg, Ca, Ba, Ni, Zn, Ag, di- and tetraethylammonium)

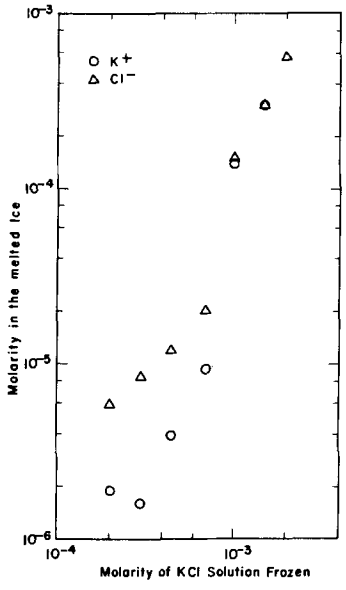

Fig. 5. Differential incorporation of the ionic constituents of potassium chloride as a function of concentration, 10 kohm shunt.

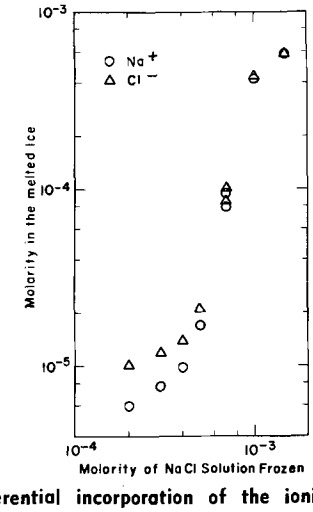

Fig. 6. Differential incorporation of the ionic constituents of sodium chloride solutions as a function of concentration, 10 kohm shunt. The difference between sodium and chloride at low concentrations is appreciably smaller than for potassium and chloride (Fig. 5).

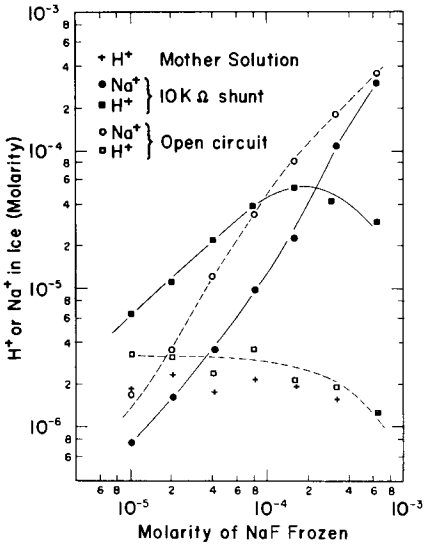

Fig. 7. Cation constituents in ice samples grown from dilute NaF solutions with and without a shunt. In the melted "shunt" ice, Na^+ content is lower, H^+ content higher than in the "open-circuit" ice. Hydrogen-ion concentration of open-circuit ice follows closely but is consistently a little higher than that of the original solutions.

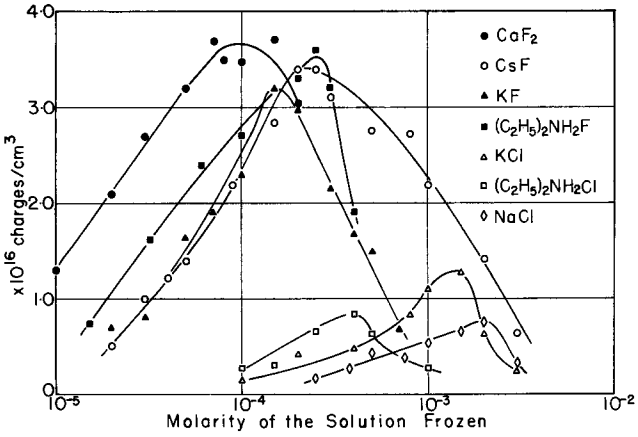

Fig. 8. Transferred charge concentration for several typical solutes (type I) as a function of concentration of the freezing solution. The curves are clustered in two groups (fluorides and chlorides, respectively) because the anion is preferentially incorporated and therefore determines the charge transfer.

showed a maximum charge transport of 3-4 x 10^{16} elementary charges per cubic centimeter of ice formed at solution concentrations of 2 to 3 x $10^{-4}M$. The nature of the positive ion (excluding ammonium) had only a small effect on the charge transfer in contrast to salts of other negative ions.

Among the potassium salts, the fluoride gave the highest interphasial charge transfer, followed by the formate, the azide, the chloride, the bromide, the nitrite, and the iodide. Solutions of salts that on freezing gave a cell resistance of more than 10^7 ohms (see Tables I and IV) showed only a small charge transfer (10^{15} or less charges/cm^3) at any concentration.

The freezing current through an external circuit is accompanied by electrolytic production of oxygen and hydrogen at the electrodes. The formation of oxygen on the base (visible as a uniform white deposit of minute bubbles) was demonstrated in a clear Lucite freezing cell with a stainless steel base. A KF solution (2 x $10^{-4}M$) within the airtight cell was first boiled under vacuum to flush the cell free of all atmospheric gases. The oxygen identity was verified by Winkler's method (27) on the gas collected on repeated freezing and melting under shunt conditions.

The charge transfer through an external circuit is greatly dependent on the condition of the metal surface on which freezing takes place (13) and can be enhanced by conditioning the metal base prior to freezing. Two methods were used: Hydrogen was electroplated onto the base by applying —3v from a battery while allowing a very thin layer of ice to form on the base. The ice was removed prior to freezing the desired solution. Alternatively, a small charge was passed through the cell applying + 1.5v to the base for a few seconds and cutting off when freezing started. These procedures assured an immediate release of hydrogen ions to the ice from the base, greatly lowering the electrical resistance of the ice as well as the ice/metal contact resistance (Fig. 9). The open-circuit freezing potential was not influenced by these preparations of the base.

As in the case of potential measurements, the hydrogen-ion content of the freezing solution has an effect on the measured charge flow since these ions provide a neutralizing or countercurrent at the interface. When the proportions of a mixture of 2 x $10^{-4}M$ KF and 2 x $10^{-4}M$ HF were adjusted to a *p*H of 4.5 and this mixture was frozen in the usual manner, no appreciable charge flow was observed through an external shunt, nor did a measurable potential develop

Table IV. Maximum charge flows obtained with a 10,000-ohm shunt, with or without treatment of the base. (Concentrations are given in units of $10^{-6}M$)

at the ice surface. The composition of the ice was the same as though a 2 x $10^{-4}M$ KF solution had been frozen under maximum charge flow conditions.

Ammonium Salts

A salt composed of ammonium and fluoride ions, both of which are preferentially incorporated into ice when they are constituents of other salts, might be expected to show a rather unusual behavior. NH_4F concentrations below 5 x $10^{-5}M$ gave freezing potentials under 1v (ice negative). Above this concentration, the potential difference increased to a maximum of —9v at 2 x $10^{-3}M$. Since other ammonium salts tested (chloride, bromide, formate) gave very high positive potentials, the ammonium radical has a greater tendency to enter the solid phase than any anion constituent except the fluoride. The quantity of NH_4F transported into the ice during the usual freezing procedure was higher than that of any other salt (Table I). The concentration for maximum freezing potential (2 x $10^{-3}M$) was 100 or more times the concentration for maximum freezing potential of any other fluoride and ammonium salt, and from 3 to 10 times higher than that of any other salt studied. Furthermore, the maximum charge transfer, of only 0.25 x 10^{16} charges/cm^3 of ice, was measured at a solution concentration more dilute, 4.5 x $10^{-4}M$, than the solution giving the maximum potential. The cell resistance during the freezing experiments was higher than that observed for other salts giving negative freezing potentials (Table I), and it passed through a minimum value for a solution concentration of 2.5 x $10^{-5}M$ [see also ref. (15), Fig. 4]. The cell resistance of ice prepared with other ammonium salts, those giving positive potentials, was always very much higher (Table I). The substituted ammonium salts, diethyl ammonium and tetraethyl ammonium fluorides, performed like the metallic fluorides, that is, they exhibited moderate negative freezing potentials and a large charge transfer.

Discussion

The experimental work discussed above leads to a broad classification of solutes into three types according to their electrochemical characteristics during freezing of an aqueous solution (18). This classification is summarized in Table V.

Differential Incorporation of Ion Constituents

The electrical effects discussed above are specifically related to ion-forming solutes. From this, it does not necessarily follow that in the solid phase these solutes exist in the ionic state, or even that they cross the phase boundary as ions. As to the first point, it has been postulated on the basis of conductivity measurements that impurities in the ice lattice ionize according to the law of mass action (28-30). If this is true, then a certain fraction must be nonionized. Seidensticker's semiconductor model of ice (31) postulates that impurities also affect the orientational and translational lattice defect states in the ice structure itself, and these states may produce a potential in addition to ionized impurities. Therefore, electrical effects could occur even if a given solute atom or radical crosses the phase boundary in a nonionized state, that is, effectively shielded by a hydrogen or hydroxyl ion. The fact, however, that dilute salt solutions may show high freezing potentials which are absent with all concentrations of either the corresponding acid or the appropriate base alone (even if solute incorporation proceeds at comparable rates) lends some justification to the view that it is indeed the ionic charge, unshielded by hydrogen or hydroxyl ions, that gives rise to the freezing potential.

The preferential inclusion of foreign atoms or radicals into the ice lattice appears to be based on size and structure so that a minimum readjustment of the ice lattice will afford accommodations. This may explain the high acceptability of the ammonium radical and the fluorine atom. The large anions, such as Cl^-, Br^-, CN^-, are less acceptable. Some of the still more complex anions (SO_4H^-, SO_4^{--}, NO_3^{--}, $C_2H_3O_2^-$) are not preferentially incorporated into the ice structure, and the same holds true of the simple cations, NH_4^+ and Pb^{++} excepted. The results obtained with ammonium fluoride and other ammonium salts (Fig. 10) indicate, however, that the acceptability of a given ion (its distribution coefficient) is coupled to that of its counterion. This greatly complicates the picture.

Variables That Determine the Freezing Potential Peak

LeFebre (6) has given an analytical expression of the freezing-potential peak as a function of the ionic incorporation rates and the neutralizing interface current. We are specifically interested in his expressions for the amplitude and time (after start of freezing) of the freezing-potential peak

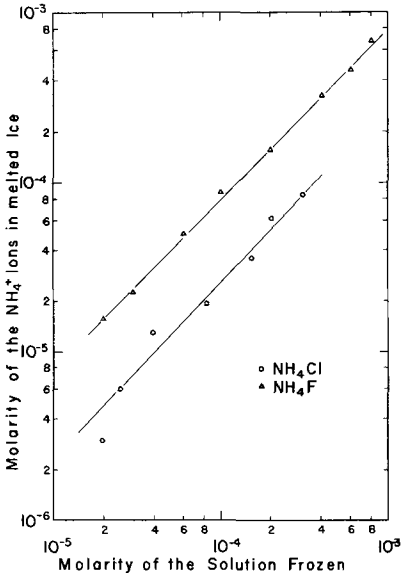

Fig. 10. Incorporation of ammonium ion constituent during the freezing of ammonium fluoride and of ammonium chloride. The incorporation of a given ion constituent is coupled to that of its counterion.

$$V_{max} = K_1 I_g' A (aR_s/C_s)^{1/2} = K_1 I_g' d_s (a\rho_s/\epsilon_s)^{1/2} \quad [2]$$

$$t_{max} = K_2 C_s R_s \quad [3]$$

K_1 and K_2 are empirical constants, depending on experimental conditions; I_g' is a parameter characterizing the charging current, defined below; A is the surface area of the interface; a is the heat-flow parameter defined in Eq. [1]; R_s, the interface resistance, and C_s, the interface capacitance, determine the discharge current; ρ_s, ϵ_s, and d_s are, respectively, the interface resistivity, dielectric constant, and thickness.

The charging parameter

$$I_g' = |z^+q^+|k^+c_l^+ - |z^-q^-|k^-c_l^- \quad [4]$$

where the superscript refers to the anion or cation respectively, z is the valence and q the effective ionic charge. The charging parameter is a function of the difference between two products involving interface concentrations (on the liquid side), c_l, and distribution coefficients, k.

This expression accounts in a general way for the concentration dependence of the maximum potential peak amplitude in different solutes. In particular, we compare KF and KCl (Table I). The maximum potential peak is of about the same amplitude but the corresponding concentrations are 2 x $10^{-5}M$ and 2.5 x $10^{-4}M$, respectively. Equation [2] gives this result if in Eq. [4] the distribution coefficient for the chloride ion is about an order of magnitude smaller than for the fluoride. The distribution coefficient for chloride is indeed smaller (16, 18) although there is no certainty at present about the magnitude of the difference. Discharge currents may also be different for these two cases and affect the potential, but this possibility is not at present experimentally verifiable.

The concentration dependence of the potential amplitude peak for the same solute can also be explained by this model through the concentration dependence of the distribution coefficients.

Since the freezing potential, according to this model, is produced by the sum of several ion currents, it is not in any simple way related to the work of building a solute into the ice lattice.

Other possible models have been reviewed elsewhere (18).

Effect of Interface Potential on the Solute Content of Ice

The relationship between interface potential and ice composition was studied for fluorides of potassium (14) and sodium. The amount of fluoride ion constituent incorporated into the ice was not appreciably affected by either the potential differences naturally present or artificially imposed during freezing. Incorporation of the cation constituent, on the other hand, was highly sensitive to the potential difference between ice and solution. Reduction of this potential difference by an external shunt resulted in a considerable reduction of solute cation incorporation into the ice (Fig. 7). The shunt permits an electrolytic reaction that produces an abundant supply of neutralizing hydrogen ions. Conversely, it has been seen that adding hydrogen ions to a freezing solution decreases the potential.

If both solute anion and cation were equally acceptable to the ice structure, the shunt should not make an appreciable difference with respect to either the cation or the anion constituents in the ice. This case is approximately realized for ammonium fluoride, and indeed results of a shunted sample differ little from the open-circuit case.

The effect of the interface potential on the solute distribution is also related to the problem of the thickness of the charged interface layer which has been discussed elsewhere (18).

Role of Hydrogen Ions in Interface Processes and Bulk Ice Conductivity

The migration of hydrogen ions into the ice as a mechanism for making possible the preferential incorporation of certain anion constituents (type I) was substantiated in this work by (*i*) the large increase of the freezing potential and of the ice resistance when the hydrogen ion content of the solution was lowered (*ii*) the rapid decline of the freezing potential when the freezing was lowered or suddenly terminated; (*iii*) the absence of a freezing potential, regardless of the kind and concentration of solute anion constituent, at high hydrogen-ion levels ($\geq 10^{-4}M$); and (*iv*) the high ice resistance when type II solutes were incorporated and therefore no "demand" existed for hydrogen ions.

With the exception of the shunt case, where the ice resistance is connected in series-parallel with the interface resistance, the bulk resistance of ice has no appreciable effect on the interface processes. The following experimental evidence supports this conclusion. First, the polarity and magnitude of the freezing potential is not affected by the conductivity of a substrate ice of different composition. Thus, when a cold type I solution is substituted for a freezing type II solution, the ice of which is characterized by a high positive potential and low conductivity, the potential difference reverses its sign and acquires the characteristics of the new solution. If a cold type II solution is poured onto a highly conductive type I (or type III) ice, a similar reversal is observed in the opposite sense (3, 18). (In performing this experiment, it is important to avoid mixing of the two solutions, or remelting of the substrate ice.)

Second, ice is grown from a type I solution at a uniform freezing rate (16). The potential curve typically exhibits a more or less pronounced peak and then declines very slowly. In this stage, the solution is briefly stirred vigorously. The potential sharply declines as new ice ceases momentarily to form but, as the freezing rate recovers, the potential sharply rises to a value considerably higher than before stirring. A slow decline begins from this new and higher value. This process may be repeated at will. The freezing potential is primarily a function of the interface concentration in the liquid but not of the bulk resistance of the ice column.

Since ice is a proton conductor (28-30), those solutes (types I and IIIa), freezing rates, and interface conditions (shunt) favoring a large hydrogen-ion transfer into the solid will also produce an ice with a high electrical bulk conductivity.

Summary and Conclusions

Experimental techniques were described to measure the charge transfer across the phase boundary during nonequilibrium freezing of dilute solutions and to relate this charge transfer to the difference between the concentrations of anionic and cationic solute constituents in the phases. The maximum measured charge transfer was of the order of 10^{16} elementary charge units per cubic centimeter of ice formed. This appears to be an upper limit.

Because hydrogen and hydroxyl ions restore the charge balance, the solution pH drastically affects the freezing-potential difference; its largest values (of more than 200v) were observed in the pH range between 7 and 8.

The charge separation effect is specific in magnitude, sign, and rates of growth and decay with respect to type (acid, base, salt), species, and concentration of solutes. It is also a function of freezing rate. For a given solute, the concentration giving the maximum charge transfer through a shunt is, in general, roughly ten times the concentration giving the highest potential difference.

Acknowledgment

This work was undertaken at the behest of Dr. E. J. Workman who also designed much of the experimental equipment and suggested some of the experiments. The authors acknowledge many valuable suggestions from Dr. R. G. Seidensticker in connection with this paper. This work was supported in part by the Office of Naval Research under contract Nonr 815(05) and by Project Themis under contract N00014-68-A-0157.

Manuscript submitted Aug. 19, 1968; revised manuscript received ca. Feb. 4, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

LIST OF SYMBOLS

a heat flow parameter, cm-sec$^{-1/2}$; $a = a_o\sqrt{\Delta T}$, in which:

$$a_o = \left(\frac{c_i K_i}{2Q}\right)^{1/2} \simeq 6.04 \times 10^{-3}\,\Delta T^{-1/2}\ \text{cm sec}^{-1/2}$$

where c_i = specific heat of ice (0.505 cal/g-C° at 0°C); K_i = thermal diffusivity of ice (0.0115 cm^2/sec; Q = latent heat of fusion (79.7 cal/g); ΔT = difference between temperature of heat sink and of ice melting point

a_1 freezing rate 1 sec after start of freezing, cm-sec^{-1}

c_1^+, c_1^- solute cation or anion concentration, respectively, on the liquid side of the phase boundary, cm^{-3} or moles 10^{-3} cm^{-3}

C_s interface capacitance, farads

D diffusion coefficient, cm^2 sec^{-1}

d_s thickness of the interface, cm

ϵ_s dielectric constant of the interface, dimensionless

I_g' charging parameter, coul-cm^{-3}

k^+, k^- distribution coefficients of a positive or negative ion constituent, respectively (ratio of solute concentration on the solid side of the phase boundary to that on the liquid side)

q^+, q^- effective charges of ions as they cross the phase boundary, coul or coul/mole

R_s interface resistance, ohms

ρ_s interface resistivity, ohm-cm

t_{max} time, after freezing begins, at which the freezing-potential difference reaches its maximum value (without regard to sign), sec

V_{max} maximum freezing-potential difference (without regard to sign), volts

The Transport Entropy of Hydrogen Ion in the Water-Ethanol System

I. The Initial Thermoelectric Powers of the Hydrogen-Hydrogen Ion Thermocell, and the Cation Transport Number of HCl in the Water-Ethanol System

J. Lin and James J. De Haven

Department of Chemistry, Boston College, Chestnut Hill, Massachusetts

ABSTRACT

The initial thermoelectric powers $\epsilon_0(X)$ of the thermocell $(T)Pt/H_2$ (1 atm)/HCl (0.01M), H_2O (100-X), $C_2H_5OH(X)/H_2$(1 atm)/$Pt(T + \Delta T)$ [X w/o (weight per cent)], and the cation transport numbers $t_{H^+}(X)$ of HCl in the H_2O-C_2H_5OH system were measured at 25°C. These experiments were undertaken in connection with a thermoelectric study of the mechanism of the transfer of hydrogen ion across a temperature gradient. The dependence of $\epsilon_0(X)$ and $t_{H^+}(X)$ on X is discussed in terms of the structure of the solvent system.

The exceptionally high mobility of the hydrogen ion under an applied electric field in water has long attracted interest. In spite of the view of Darmois (1) regarding proton mobility on the Lorenz-Drude model as an electronlike metallic conductivity involving the bare proton, existing evidence seems to suggest overwhelmingly that the small size of the proton could not itself be responsible for the high mobility, since the proton is strongly hydrated in aqueous solution as a distinct chemical species $H^+(H_2O)_n$, where n = 1,2,3. . . Since the formation of hydrogen bonds is involved, the structure of the solvent itself is particularly relevant to the problem. Indeed, the transfer of proton with help from another water molecule as a possible mechanism for the abnormally high hydrogen ion mobility, has been developed more explicitly in recent years by utilizing modern ideas concerning the structure of water and the nature of hydrogen ions in the solution (2a). The point of view here is that when water contains an acidic substance, the H_3O^+ ions that are formed may be considered to fit into the structure just as well as in pure water and that interatomic distances can be regarded as approximately unchanged. When an electric potential is applied, it is supposed that the hydrated protons migrate to some extent through the solution in the ordinary diffusion manner from one equilibrium position to another; at the same time a proton can transfer from the hydronium ion to an adjacent water molecule which is favorably oriented. This latter process can be very rapid. The exchange takes place within a hydrogen bond, and the actual distance an individual proton moves is quite small (≈1Å) (2a), but the center of charge has moved an oxygen-oxygen distance which is the order of 2.5Å (2a). In this way the positive charge will be transferred a considerable distance in a short time, and as a consequence the hydrogen ion acquires an exceptionally high mobility.

The familiar experimental data on ion mobility, conductance, transport number, conductance-viscosity product, and activation energy for ionic mobility (4) all point to the fact that the migration of the hydrated hydrogen ion through aqueous solution involves a mechanism different from that applicable to other ions. Recently in a study of the entropies of aqueous ions, Breck and Lin (3) have observed that the ionic entropies of transport for H^+ and OH^- are also exceptionally large for univalent ions. For example at infinite dilution the standard "absolute" ionic entropies of transport $S^{*\circ}_i$, as determined by these authors (3) are: (in e.u.) Cl^-, 0.7; H^+, 10.2; OH^-, 14.2; Na^+, 2.2; K^+, 1.5; Br^-, 0.6; I^-, —0.9. Since both H^+ and OH^- ions have a unique relation to the solvent, it was also suggested that the behavior of both ions under the influence of a temperature gradient might be exceptional. Thus, the alternate ordering and disordering effect of the ionic field on the water structure arising from the simple migration of these ions may not be the only contribution to the transport of entropy. There may be a much more significant contribution from the entropy of reaction as hydrogen bonds are alternately made and broken. The heats of transport involved here are of the order 3-4 kcal/mole while the experimental value of the hydrogen bond energy in water is approximately 3.1 kcal/mole (5).

The present work is motivated by the above considerations and is concerned with the mechanism of the transfer of hydrogen ion under a temperature gradient. Experimentally this may be approached by studying the solvent effect on the thermoelectric power of thermocells. For indeed, if a considerable part of the heat of transport of H^+ comes from the fact that hydrogen bonds are alternatively made and broken, then $S^*_{H^+}$ should exhibit a distinct dependence on the structure of the solvent. In fact in a recent study of the heats of transport of $CdSO_4$, $AgNO_3$, $BaCl_2$, and KI in H_2O and D_2O, Becsey and Bierlein (6) found that heats of transport in H_2O are considerably higher than in D_2O. This is attributed by the authors to the fact that D_2O has more "structure" than H_2O. A more randomly constituted liquid will experience a greater degree of orderliness while under the influence of the electrostatic field of an ion and hence will exhibit the greater heat of transport. Furthermore, by a proper choice of solvents it should be possible to diminish to a great extent the contribution from alternative formation and breakage of hydrogen bonds to the heats of transport. One good example of this solvent system is the H_2O-ROH system where R is an alkyl group. If we represent the reaction which is mainly responsible for the transfer of additional (besides the simple migration) aqueous H^+ as

$$H_3O^+ + H_2O \rightarrow H_2O + H_3O^+ \qquad [1]$$

then at a point where enough alcohol has been added to the water reaction, [1] is replaced by

$$H_3O^+ + ROH = H_2O + ROH_2^+ \qquad [2]$$

However, [2] is favored chemically in the backward

direction (equilibrium constant for the reverse reaction is ≈250 for R = C_2H_5) and therefore the additional proton transfer process should be retarded substantially. Under these circumstances, a simple migration mechanism should be operative and if the suggestion by Breck and Lin is correct, S^*_{H+} should then be of the order of magnitude of that of an ordinary univalent ion, *i.e.*, around —1 to +2 e.u.

Hydrochloric acid in the H_2O-C_2H_5OH solvent system was investigated first. The system H_2O-C_2H_5OH as a solvent is particularly convenient for present purposes. First, the physical constants of the solvent system have been studied and are fairly complete (7). Second, thermodynamic properties and the structural aspects have been reviewed admirably by Franks and Ives (8). An attractive feature of the solvent system is that, at about 20 w/o ethanol, it exhibits a very strong solvent structure quite sharply. This is very interesting, since we have found that t_{H+} shows a maximum, and ϵ_0 shows a minimum at this particular solvent composition. Detailed discussions of this observation are given in the Discussion section.

In any solvent study the problem of standard states is always a formidable one. If we wish to compare our study with the available results in aqueous solution, the results of heats or the corresponding entropies of transport obtained at each X, where X is the weight per cent of alcohol in the solvent mixture, must be converted to the same reference state as that of the aqueous solution (whether this is on a conventional or on an "absolute" basis). Therefore, in order to have quantitative results from the thermocell study, we need to know the cation transport number at a given X, $t_{H+}(X)$, for HCl in H_2O-C_2H_5OH system, initial and final thermoelectric powers[1] $\epsilon_0(X)$ and $\epsilon_x(X)$ of a thermocell of the form

$$\underset{T}{A/HCl(m),\ H_2O(100\text{-}X)\text{-}C_2H_5OH(X)/}\underset{T+\Delta T}{A} \quad [3]$$

where A is the electrode system reversible to H^+, and finally the standard partial molar entropy of H^+, $S^o_{H+}(X)$, at each solvent composition. The cation transport number $t_{H+}(X)$ at concentration greater than 0.1m has been studied by Wear, Curtiss, and Amis (9) by the Hittorf method; also at infinite dilution it is readily calculated from Spivey and Shedlovsky's (10) conductance result. However, data for $t_{H+}(X)$ at the concentration of present interest (0.01m) are lacking. Although theoretical interpolation may be used to give the desired value at 0.01m, we have preferred not to do so and we have measured $t_{H+}(X)$ at 0.01m using the moving boundary method. In this paper, we report the observed $t_{H+}(X)$ and $\epsilon_0(X)$ of cell [3] at an average temperature of 25°C (T = 20°C and ΔT = 10°) using hydrogen electrodes at m = 0.01 and X ranging from 0 to 92%. The hydrogen electrode is popular and has served as a reference electrode in isothermal cells; however, data on the hydrogen electrode in thermocell study appear to be rare. For example, the work by Goyan (11) which is frequently referred to dates back to 1937. A comparison (even though only at X = 0) with the result of Goyan would also seem interesting. Results of $\epsilon_x(X)$ of [3] and $S^o_{H+}(X)$ which may be calculated referring to $S^o_{H+}(X = 0)$ by studying the isothermal temperature coefficient of the emf of the cell Pt/H_2/HCl(m), H_2O//HCl(m), H_2O-$C_2H_5OH(X)$/H_2/Pt, where // represents a salt bridge, will be reported in a future paper.

Experimental

Preparations of the solutions.—Baker's analyzed HCl was used throughout the experiments. 95% commercial ethanol was used after distilling twice. The specific gravity of the purified ethanol was found to be d^4_{25} = 0.8058 which, by the interpolation of the density data given by the Handbook of Chemistry (7), was found to correspond to a composition of 92.0% ethanol. Solutions used in the thermocells and the transport number measurements were then prepared by mixing proper amounts of concentrated HCl and the purified ethanol to give 0.01m solution at a desired solvent composition. Densities, molality (m), and molarity (C) of the solutions along with solvent compositions are given in Table I.

[1] The initial and final thermoelectric powers ϵ_0 and ϵ_∞ refer to the thermocell before thermal diffusion has occurred and after it has reached its steady state, respectively.

Measurement of the transport numbers.—A moving boundary method described by Shoemaker and Garland (12) was used to measure the transport numbers of HCl in the H_2O-C_2H_5OH system. Fisher certified grade Cd stick was used as the anode and Ag/AgCl, prepared by the thermal method (13), as cathode. The current source used was a General Radio Type 1203B unit power supply. The graded transference cell was calibrated at 25°C so that accurate volume displacements could be obtained. The IR drop over a constant standard resistance (General Radio Type 500-A) was recorded with a Sargent MR recorder; the amount of total electricity passed through the transference cell was calculated by integrating the potential-time curve obtained in the recorder. Methyl orange was used as indicator up to X = 80. For X higher than 80% it was found necessary to use Gramacey Universal Indicator to give a better view of the boundary. The results of the measurements are given in Table I.

Measurements of $\epsilon_0(X)$.—A modified N-type cell (14) to accommodate the improved Hildebrand type hydrogen electrode (13) was used to measure $\epsilon_0(X)$. Glass joints were used where needed to prevent access of air to the electrode. As is well known the purity of the hydrogen gas used is critical to the accuracy of the measurement, and it is necessary that gas supplied to the electrode be of adequate purity. The gas used in this investigation is Matheson ultrapure hydrogen and is analyzed to contain less than 5 ppm N_2 and less than 1 ppm O_2. To avoid introducing any impurities, a stainless steel regulator (Matheson Model 18) was used. General instruction concerning the plating of the electrode given by Hills and Janz (13) was followed. The hydrogen gas was presaturated with the cell solution before supplying to the cell. A few experiments were carried to study the sensitivity of the electrode to the flow rate of the hydrogen gas. In some cases, it was found that for flow rates lower than one bubble per second, the thermal emf would fluctuate considerably (over a range of about 0.1 mv) and would almost take an hour to reach a steady value. For over two bubbles per second, the electrode was found to be quite insensitive to the flow rate and was fast to reach a steady value (≈10 min). For example, between two bubbles per second and continuous stream of hydrogen gas (approximately six bubbles per second), the thermal emf observed was in difference of about 10 μv. For the data reported here, a flow rate of about three bubbles per second was used. The electrodes so prepared were very reproducible and gave a residual emf of about 30 μv over a period of about a week. The temperature of each electrode compartment was measured by a copper-constantan thermocouple, and the emf of the thermocell was recorded

by the MR recorder. The recorded reading was frequently checked by the L&N K3-type potentiometer. A L&N constant current supply (L&N No. 0,99034) was used for the K3 potentiometer. A Guildline enclosure Type 1149 standard cell and Type 9450 galvanometer were used. Residual emf readings were taken both before and after the measurement of ϵ_o, and the average of the two readings, which was within 15 μv of each of the readings, was then subtracted from the value of the measured ϵ_o. The initial thermoelectric powers ϵ_o observed are listed in Table I.

Discussion

By virtue of the high solubility of alcohols in water, the alcohol-water system has been used frequently as a solvent. However, alcohol-water mixtures often show abnormalities which are as yet inadequately understood; for instance the viscosity-composition maxima and the negative partial molal volumes (18). Although attempts may be made to study these solvent systems directly, it may often be more profitable to use ions as a kind of internal indicator which reflect the electrochemical properties of the solvents, *e.g.*, the study of ionic Walden product of H^+ ion in ethanol-water system. Many thermodynamic, transport, and structure data (8) indicate that the addition of a small amount of simple alcohols to water initially enhances the structure of the solvent. For the case of ethanol, this structure enhancement reaches its maximum at around $X = 20\%$. Further addition of ethanol to increase its concentration tends to reduce the structure progressively. This structure-composition variation is also indicated by the sharp maximum of the ionic Walden product of H^+ ion at about $X = 20\%$. According to Spivey and Shedlovsky (10) the position of the maximum Walden product is the point where the probability of the occurrence of the hydrogen bonded path required for the hydrogen ion transfer is the highest. Thus, it is implied that the solvent has more structure at this composition.

The structure-composition variation of the solvent system seems to be also in line with our results on the transport number of H^+. It is noticed from Fig. 1 that t_{H+} also has a maximum at around $X = 20\%$. The capacity of our transference cell is 1 ml, and the unit of the graded scale is 0.01 ml; therefore, it is likely that our results may have an inherent error of about 0.5%. At around $X = 5\%$ the t_{H+} has a slight decrease, and it is not known whether this bears any significance in the ion solvent interaction or whether this is due to the experimental error. Just to see how the present measurement compares with other studies, we have calculated t_{H+} from the conductance data of Spivey and Shedlovsky obtained at infinite dilution. The equation used for this calculation comes from a simple Debye-Hückel consideration and is given by Robinson and Stokes (15). Denoting η as the viscosity

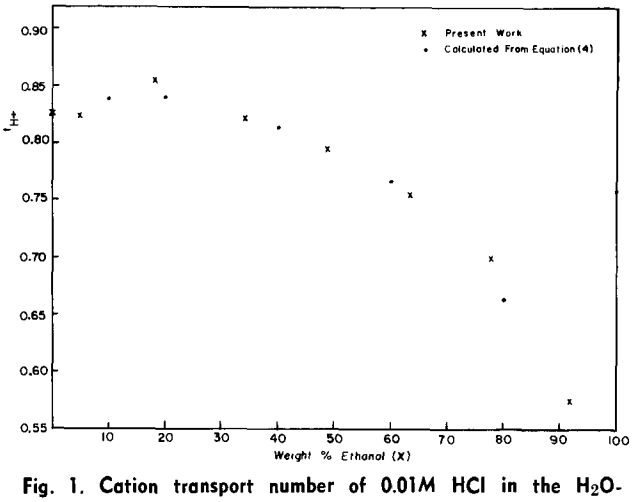

Fig. 1. Cation transport number of 0.01M HCl in the H_2O-ethanol system.

of the solvent, N the Avogadro number, e the electronic charge, and D the dielectric constant, the equation reads

$$t_{H+} = \frac{\lambda^o_{H+} - 0.5\,AC^{1/2}_{HCl}/\,(1 + \kappa\mathring{a})}{\Lambda^o_{HCl} - AC^{1/2}_{HCl}/\,(1 + \kappa\mathring{a})} \qquad [4]$$

where λ^o_{H+} and Λ^o_{HCl} are the equivalent conductance of H^+ and HCl, respectively, at infinite dilution and $A = 82.5/\eta(DT)^{1/2}$, $\kappa = (8\pi Ne^2/1000DkT)^{1/2}\ C^{1/2}_{HCl}$, and $\mathring{a}$ is the distance of closest approach which is taken from Scatchard (16) to be 4.05Å. The result of this calculation is compared with the experimental results in Fig. 1. It is interesting to see that the calculated t_{H+}'s seem to fit in well with the observed t_{H+}'s except at X around 10 ~ 20%. However, it is worth mentioning that the conductance data at $X = 10\%$ is an estimated value (10) and therefore subject to a slight uncertainty. The fact that the calculated t_{H+} at $X = 100\%$ is large, deserves some comment. If, indeed, transfer of protons occurs according to [1], then it is not surprising that t_{H+} at $X = 100\%$ should be higher than that of X around 90%. Since at about $X = 90\%$, the percentage of protons present as H_3O^+ is close to 100 (17) and therefore, $ROH_2^+ + ROH \rightarrow ROH + ROH_2^+$ at $X = 100\%$ should be more effective than the case expressed in Eq. [2]. While the general agreement of the observed and calculated points is good, the over-all shape of the curve does not as yet permit the tracing of a curve through the points especially in the domains X = 0-20% and 90-100%.

In measuring the initial thermoelectric power, instead of measuring the residual emf and applying this correction, measurements may also be done by the so-called reversal technique described by Goyan (11). For 0.01*m* HCl in aqueous solution ($X = 0$) Goyan's ϵ_o value is 0.142 mv/deg which is somewhat lower than our value, 0.150 mv/deg. Since for aqueous 0.01*m* HCl the activity coefficients λ_{HCl} and the relative partial molal heat content $\bar{L}_{HCl}$ are known it is interesting to see how the present measurement compares with other thermocell studies. The equation which governs the initial thermoelectric powers when a hydrogen electrode is used may be written as

$$\mathbf{F}\,\epsilon_o = \frac{1}{2}S_{H_2} - \bar{\bar{S}}_e - S_{H+} - t_{H+}S^*_{H+} + t_{Cl-}S^*_{Cl-} \qquad [5]$$

where $\mathbf{F}$ is the Faraday constant, $\bar{\bar{S}}_e$, the transported entropy of the electron in the metal leads (Cu leads were used in this study) and S_{H+}, the partial molal entropy of the hydrogen ion. If instead of the hydrogen electrode, other electrodes such as Ag/AgCl or Hg/HgCl are used, then the other initial thermoelectric powers ϵ'_o may be written as

$$\mathbf{F}\,\epsilon'_o = S_M - S_{MCl} - \bar{\bar{S}}_e + S_{Cl-} - t_{H+}S^*_{H+} + t_{Cl-}S^*_{Cl-} \qquad [6]$$

where M denotes the metal and MCl, its chloride. By subtracting [5] from [6]

$$\mathbf{F}(\epsilon'_o - \epsilon_o) = \left(S_M - S_{MCl} - \frac{1}{2}S_{H_2}\right) + S_{HCl}$$

$$= \left(S_M - S_{MCl} - \frac{1}{2}S_{H_2}\right) + S^o_{HCl} - 2\left(\mathrm{R}\ln m_{HCl} + \mathrm{R}\ln\gamma_{HCl} + RT\frac{\partial}{\partial T}\ln\gamma_{HCl}\right)$$

$$= \left(S_M - S_{MCl} - \frac{1}{2}S_{H_2}\right) + S^o_{HCl} - 2\mathrm{R}\ln m_{HCl} + 2S'_{HCl} \qquad [7]$$

Using the familiar expression in terms of the relative partial molal enthalpy of the solute $\bar{L}_{HCl}$, we may

S'_{H^+} (obs); In e.u., from γ_{HCl} and $\bar{L}_{HCl}$ given in ref (18).
γ^{obs}_{HCl}; From ref. (18).
$T\frac{\partial \ln D}{\partial T}$; Calculated from D at 0, 25, 35°C.
TDP; In mv/deg = $\mathbf{F}^{-1}(t_{Cl^-}S^*_{Cl^-} - t_{H^+}S^*_{H^+})$, based on conventional value $S^o_{H^+}(X) = 0$.

write the nonideal terms S'_{HCl} as

$$S'_{HCl} = -R\left(\ln \gamma_{HCl} + T\frac{\partial \ln \gamma_{HCl}}{\partial T}\right) = -R\left(\ln \gamma_{HCl} - \frac{\bar{L}_{HCl}}{2RT}\right) \quad [8]$$

Taking $\gamma_{HCl} = 0.905$ (18), $\bar{L}_{HCl} = 15.86$ cal/mole (18), for 0.01M HCl from [8] we have, $S'_{HCl} = 0.22$ e.u. With $S_{Ag} = 10.206$ e.u., $S_{AgCl} = 22.97$ e.u., $S_{Hg} = 18.5$ eu., $S_{HgCl} = 23.4$ eu., $\frac{1}{2}S_{H_2} = 15.61$ e.u., $\bar{\bar{S}}_e = -0.045$ e.u. and $S^o_{HCl} = 13.16$ e.u. we have from [7]

$$\mathbf{F}(\epsilon'_o - \epsilon_o) = \begin{cases} 3.53 \text{ e.u. for M} = \text{Ag} \\ 11.39 \text{ e.u. for M} = \text{Hg} \end{cases}$$

Since ϵ'_o for Ag/AgCl electrode at 0.01m HCl is reported to be 0.288 (19) mv/deg and that of Hg/HgCl, 0.638 mv/deg (20), we obtained the calculated initial thermoelectric powers for H_2-electrode as

$$\epsilon_o = \begin{cases} 0.135 \text{ mv/deg, based on Ag/AgCl electrode} \\ 0.144 \text{ mv/deg, based on Hg/HgCl electrode} \end{cases}$$

Thus it is seen that both Goyan's and our results seem to be consistent with other existing thermocell studies.[2]

It is worth mentioning that the thermocell studies could be an effective way of measuring the standard partial molal entropies of electrolytes. This is seen in Eq. [7] from which all thermal diffusion potentials and transport entropy have been eliminated. If one wishes to calculate the standard partial molar entropy of an electrolyte, say HCl, one could study the isothermal temperature coefficient of the cell Pt/H_2/HCl/AgCl/Ag at infinite dilution; however, in a thermocell study one would only have to measure the initial thermoelectric powers using the two electrodes at an average temperature of interest. Thus, as far as entropy is concerned, what may be accomplished by several temperature measurements in an isothermal cell may be equally well accomplished with the measurements of two thermocells at a given average temperature.[3]

There is, at present, no way of cross checking the consistency of the other $\epsilon_o(X)$ values for which X is not 0%. It is interesting to note that the variation of $\epsilon_o(X)$ values with X shows behavior opposite to that of the transport numbers. In view of the correlation between the transport numbers and the structure of the solvents, the behavior of $\epsilon_o(X)$ *vs.* X must be more than just a coincidence. However, there appears no satisfactory way of explaining the correlation between $\epsilon_o(X)$ and the solvent structure, at the present time.

Assuming that standard partial molar entropy of the hydrogen ion, $S^\circ_{H+}(X)$, is known, it is possible to compute S^*_{H+} on a conventional basis of $S^*_{Cl-} = 0$ at 0.01m provided that the nonideal contribution S'_{H+} is known. Since the solution is dilute enough, S'_{H+} may be estimated within the frame of Debye-Hückel theory. For this purpose, we have computed "ionic" activity coefficients γ_{H+} at X=0, 10, 20, 40, 60, 80, and 100% by the equation

$$\ln \gamma_{H+} = -\frac{\alpha m^{1/2}_{H+}}{1 + \kappa\mathring{a}} + \beta m_{H+} \quad [9]$$

where, using d as the density of the solvent, at 25°C, $\alpha = 816.147 \times \left(\frac{d}{D^3}\right)^{1/2}$. The constant β is known to vary with D^{-2} (16) and we have taken $\beta = 2000/D^2$. The results of this calculation are compared with experimental (18) activity coefficients of HCl at X=0, 10, 20, and 100% in Table II. By neglecting the coefficient of thermal expansion and from the dielectric constant at 0°, 25°, and 35° given by Spivey and Shedlovsky, $S'_{H+}(X)$ may finally be calculated by the following formula (21)

$$S'_{H+} = +\frac{3}{2}R\left(T\frac{\partial \ln D}{\partial T} + \frac{1}{3}\right)\ln \gamma_{H+} \quad [10]$$

Results of S'_{H+} are also entered in Table II. It is interesting to see that for X=0, the observed S'_{H+} and the calculated values are in a good agreement. Based on the calculated S'_{H+}, and taking $S^\circ_{H+}(X=0) = -5.5$ e.u. the conventional S^*_{H+} (0.01m, X=0) is found to be 9.98 e.u. The value reported by Snowdon and Turner (22) is 10.22 e.u. For other solvent compositions it is not possible to perform the same analysis since $S^\circ_{H+}(X)$ is not known. However, the thermal diffusion potential (TDP), TDP = $1/\mathbf{F}(t_{Cl}-S^*_{Cl-} - t_{H+}S^*_{H+})$ using a conventional value of $S^\circ_{H+}(X) = 0$ may be calculated and is shown in the last row of Table II. It is interesting to note that TDP's also exhibits a minimum at around X=20%. Further discussion will be reserved until the determination of $S^\circ_{H+}(X)$ and $\epsilon_\infty(X)$, to be published in another paper.

Acknowledgment

The authors wish to thank Mr. John Griffin for supplying them with the silver-silver chloride electrode used. They also wish to express their thanks to Professor Andre J. de Bethune for his interest in this work and his reading of the manuscripts. This work was supported by the Office of Saline Water, United States Department of the Interior, under Grant No. 14-01-0001-1466.

Manuscript submitted Sept. 3, 1968; revised manuscript received *ca.* Feb. 10, 1969.

[2] By making a correction on concentration from 0.01040 to 0.0100M, our result becomes 0.147 mv/deg.

[3] Equation [7] may be rewritten as $P = \mathbf{F}(\epsilon'_o - \epsilon_o) + 2R \ln M_{HCl} = \left(S_M - S_{MCl} - \frac{1}{2}S_{H_2}\right) + S^o_{HCl} + 2S'_{HCl}$. Since $S'_{HCl} = 0$ at infinite dilution S^o_{HCl} may be evaluated by extrapolating P to infinite dilution.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Technical Notes

Preparation of Uniform Pore Structures for Porous Electrode Studies

Richard C. Alkire,* Edward A. Grens II,* and Charles W. Tobias*

Lawrence Radiation Laboratory and Department of Chemical Engineering, University of California, Berkeley, California

In many experimental studies using porous materials it is desirable to have highly regular pore structures where the local porosity and specific surface area are determinable to a much greater accuracy than would be possible with random pore configurations. In these cases knowledge of the pore geometry reduces the number of unknown parameters of the system thereby permitting a more quantitative assessment of experimental results. Some investigators have used porous bodies composed of bundles of fine tubes (1) or beds of small spheres (2) to accomplish this purpose, but the former approach is limited to pores of quite large dimensions ($>300\mu$) while the latter gives structures of insufficient regularity for many purposes.

In connection with studies of anodic dissolution of porous metal electrodes a technique has been developed for fabrication of porous structures possessing highly uniform porosity and having individual pores of nearly identical and uniform size and shape (3). These structures are formed from fine wires sintered in parallel close-packed configuration.

In principle, the method may be used to fabricate porous bodies from any material which may be sintered and which is available in wire form. A bundle of straight wires is assembled in such a way that the wires lie in a hexagonal close-packed array. The bundle is then sintered under appropriate conditions of temperature and duration. The resulting mass has parallel individual pores passing through it which correspond to the original void spaces between wires. If the assembly of the bundle is carefully accomplished, all of the pores will have very nearly the same size and shape. This method of assembling wires in a hexagonal close-packed array is an extension of the work of Alexander and Balluffi (4) to the formation of porous bodies on a considerably larger scale.

Proper choice of sintering conditions will allow complete fusion of adjacent wires along lines of contact and elimination of the narrow fissures bordering these contact lines without distortion of the over-all structure. An array of straight wires can be closely approximated by sections of a large wire coil where the radius of curvature of windings is much greater than any pore length of interest. This technique has been successfully applied to fabrication of porous copper electrodes with pores of about 35μ diameter.

Experimental

Porous structures were fabricated from 0.010 in. diameter copper wire (BS No. 30, 99.9% Cu) formed in a coil of 6 5/8 in. ID. In order to promote good sintering conditions, the wire was first cleaned three times in trichloroethylene solvent. The degreased wire was wound in hexagonal close-packed array on a stainless steel spool (3 ¾ in. width). The first layer of wire was wound in such a way that on each turn the wire was in contact with the neighboring wire, wound on the previous turn. Each subsequent layer of wire was wound in the same direction and placed in the crack between wires of the preceding layer. In this manner 83 layers of wire were placed on the spool (a 1.04 cm

* Electrochemical Society Active Member.

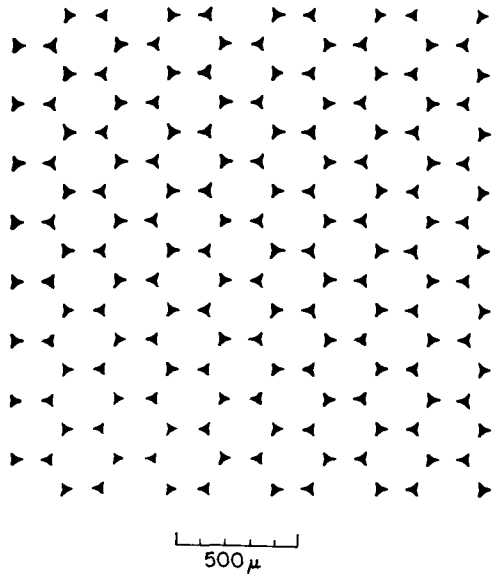

Fig. 1. Porous electrode structure; enlarged cross section parallel to electrode face.

thickness). During the winding, the tension in the wire was maintained at approximately 130g force.

After completion of winding, the air contained in the coil was evacuated and replaced with nitrogen. The coil was then stored in nitrogen until sintering. At that time the nitrogen was removed under vacuum and replaced with hydrogen. The coil was then placed in furnace with a hydrogen atmosphere and sintered for 60 hr at 1050° ± 10°C. These conditions were determined by the results of test sinterings made with small coils of the same wire for temperatures of from 980° to 1070°C and for sintering times of from 4 to 64 hr. After sintering the temperature was reduced at the approximate rate of 100°C/hr.

Individual porous blocks were cut from the sintered coil. The first cut, of two used to remove a block, was made such that the exposed surface was parallel to and about 0.04 cm off a radial plane bisecting the coil. The second cut was made parallel to the first to give a rough piece about 0.57 cm thick. The pieces were then machined to final dimension, with removal of about 0.04 cm from the faces (first and second cuts). The pores then intersected the face at approximately right angles. This machining did not damage the pore structure although it wiped or smeared a thin film of copper over the surface, largely closing over the pores. The smeared film was then removed by electrochemical dissolution in dilute sulfuric acid at current densities sufficiently high (~0.8 A/cm^2) to prevent penetration of the reaction appreciably into the pores; about 3 min of such electrolysis was required to give clean surfaces with open pores.

Results and Discussion

A typical cross section of the resulting structure is shown greatly enlarged in Fig. 1. From photographic enlargements, measurements of individual pore cross-sectional areas and perimeters yielded mean values, at the 95% level of

$$1.964\ (\pm 0.101) \times 10^{-5}\ \text{cm}^2, \text{ and}$$

$$2.22\ (\pm 0.05) \times 10^{-2}\ \text{cm}$$

respectively, and thus a specific surface area of

$$1{,}130\ \text{cm}^2/\text{cm}^3$$

based on void volume. The porosity was 3.5%.

Porous materials fabricated by the method outlined above have a highly uniform porosity. This property is particularly advantageous in such applications as the study of the rate of dissolution at various locations within porous bodies. If the porosity is initially uniform, measurement of the porosity distribution throughout the porous piece after dissolution immediately gives the time-averaged reaction rate during dissolution. This type of porous body has a further advantage. Should a large part of the sintered contact region be removed by a process such as dissolution, the material will still retain its essential structure. Further, analyses of many experiments involve a parameter which contains the product of the specific surface area and the reaction rate constant, and often neither of these is known with confidence. Thus use of porous bodies such as those described here having a known and uniform specific surface area facilitates the theoretical interpretation of experimental data. Finally, the structures formed by this method possess a regular geometry readily described mathematically. They thus lend themselves well to experimental investigation of theories based on well characterized pore configurations.

On the Formation of Growth Twins in Electrodeposited Silver

T. Kilner[1] and A. Plumtree

Materials Science Laboratory, Department of Mechanical Engineering, University of Waterloo, Waterloo, Ontario, Canada

Faust and John (1) have reported twinned boundaries in electrodeposited dendrites of aluminum, copper, gold, lead, and silver. The presence of twinned boundaries has also been reported in metals grown by vapor deposition (2) and semiconductors solidified from the melt (3). The importance of twin boundaries lies in their ability to provide re-entrant grooves or two-dimensional nucleation sites, which are self-perpetuating when two or more twin planes are present in a dendrite of a material crystallizing in

[1] Present address: Ryerson Institute of Technology, Toronto, Ontario, Canada.

the diamond-centered cubic or face-centered cubic systems.

This present investigation reports some observations on the origin of twinned boundaries in silver electrodeposited from an unstirred aqueous solution (1M $AgNO_3$ + 2M NH_4NO_3). The cathode was made from 99.98% Ag wire of 0.030 in. diameter and was subsequently melted to increase the available surface area, producing a bead of about 1/16 in. in diameter. The cathode was then annealed at 900°C for 7 hr to produce excessive grain growth, resulting in the bead containing only about 10-20 grains. To prevent deformation due to handling during x-ray work and also to ease removal from the electrolyte, the cathode was contained in an open-ended capillary tube normally used for powder pattern x-ray diffraction work. The anode was also prepared from 99.98% Ag wire.

The electrodeposition conditions ranged from 15 μA and 0.210v up to 200 μA and 0.700v a room temperature. Voltage measurements included the IR drop between cathode and anode. No reference electrode was used. The current density was estimated from the total current and the area of the cathode which showed deposition, thereby giving average values which ranged from 4 x 10^{-3} A/in.^{2} to 50 x 10^{-3} A/in.^{2} Outside this range, higher current densities produced nonadherent deposits, and lower current densities resulted in impracticably slow growth rates (0.001 in./day). Throughout the range of current densities used in this investigation, two basic growth morphologies were observed. The first consisted of a small needlelike form and the second, a thin flat angular form in the shape of a three- or six-sided lozenge[2] on which the present work was carried out.

These lozenge-shaped dendrites were studied metallographically by mounting in a cold setting resin and mechanical polishing on emery papers. Final mechanical polishing was carried out using 6 and 1μ diamond paste. The specimens were then chemically polished with the chromic acid-based solution of Gilpin and Worzala (4) and etched in the manner described by Kilner and Plumtree (5). This technique revealed that the dendrites possessed several twinned boundaries running parallel to the major flat surfaces of the dendrite as seen in Fig. 1 which shows a longitudinal cross section of a dendrite electrodeposited at 300 mv. Laue x-ray back-reflection photographs revealed that the boundaries were {111} twin planes and that the growth direction was $[2,\bar{1},\bar{1}]$. Faust and John have discussed the ramifications of the growth direction of twinned dendrites (1,6).

Careful examination showed twin boundaries appearing within the deposited metal as shown in Fig. 2, indicating that these growth twins formed out of a faulting sequence which occurred during deposition itself rather than from epitaxial growth on the substrate and also in the absence of polycrystalline growth. The presence of secondary twinning branching out from the main twinned planes was also observed, and an example is shown in Fig. 3. However, the incidence of secondary twinning was not marked. As with the main twins, growth accidents or faulted stacking sequences occurring at the re-entrant groove may well account for the origin of the secondary twins. Once this twinned region is formed, the current density or driving force for crystal growth by the secondary twinning mechanism will be the same as that for growth by the main twin boundaries and therefore both parts of the crystal will grow at the same rate. Since the main twinned bands have a greater component of growth in the growth direction, (*i.e.*, $[2,\bar{1},\bar{1}]$ direction) than the secondary twin bands, then the secondary twin bands will be outgrown, leaving the dendrite dominated by twinned boundaries lying parallel to the main growth direction (in this case, $[2,\bar{1},\bar{1}]$ direction) as seen in Fig. 1

[2] Since in cross section these logenze-shaped growth forms exhibited branching, they will be referred to as dendrites. This is in keeping with the nomenclature of previous authors (1).

The Field-Effect Transistor as a Constant Current Source in Electrochemical Investigations

R. B. Davidson and M. A. Hopper*

Department of Physics, University of Alabama, University, Alabama

The well-known application of the field-effect transistor to current control (1, 2) has received no attention in electrochemical investigations. Circuits employing the field-effect transistor are simply and inexpensively constructed, in addition offering excellent control of current. These advantages, combined with the moderate operating voltage of the device, make a field-effect transistor galvanostat more practical than the usual constant current circuit of a source of emf in series with a high impedance. In comparison to operational amplifier based galvanostats the circuits using a field-effect transistor require fewer components, thus being more economical to construct.

Electrical circuit schematics for a galvanostat using only a field-effect transistor, a resistance and a power supply (battery) are shown in Fig. 1. For the circuits shown a maximum current is maintained in the load resistance (the electrochemical cell) when the feedback resistance is small. The maximum controllable current depends on the particular transistor, but is generally between 1 and 10 mA. The load current is decreased by increasing the feedback resistance. With a feedback resistance of 10 megohms the current is reduced to about 0.1 μA. Generally, no current smaller than this is required in electrochemical applications.

The load current will be held constant provided that the voltage between the drain and source of the field-effect transistor is less than the breakdown voltage but greater than the so-called "pinch-off" voltage of the device. In our studies we have used the Motorola HEP 802 field-effect transistor (priced at under $2). This transistor has a rated breakdown voltage of 25v, but certain transistors were found to have actual breakdown voltages of almost 50v. Employing a power supply with an output slightly less than the breakdown voltage of the transistor, it was found that load currents between 0.1 μA and 5 mA could be controlled to better than 0.1% provided that the voltage drop across the transistor was greater than 3v (the "pinch-off" voltage). The current remains constant, subject to the above conditions, even though the voltage appearing across the load may vary over a fairly wide range (approximately 20v for the transistors used in this study).

As a check on the operation of the circuit of Fig. 1 the galvanostatic oxidation of bismuth in a sodium carbonate solution was studied up to an overpotential of 20v. The results obtained in this study were in excellent agreement with the investigation of the anodic oxidation of bismuth using an operational amplifier galvanostat (3).

The variable feedback resistance in Fig. 1 may be replaced by the combination of a potentiostat and a fixed resistance; a modified circuit using this technique is shown in Fig. 2. The potentiostat controls the voltage between the gate and the source of the field-effect transistor, thus controlling the load current. By varying the potentiostat output, the load current may be altered to any desired value. Replacement of the potentiostat of Fig. 2 with a potential sweep generator transforms the circuit into a current sweep generator.

The disadvantage of the simple field-effect transistor circuit (Fig. 1) is that a maximum current of the order of only 5 mA may be controlled. Many electrochemical applications require more current than this upper limit. An extension of the current range

The Field-Effect Transistor as a Constant Current Source in Electrochemical Investigations

R. B. Davidson and M. A. Hopper*

Department of Physics, University of Alabama, University, Alabama

The well-known application of the field-effect transistor to current control (1, 2) has received no attention in electrochemical investigations. Circuits employing the field-effect transistor are simply and inexpensively constructed, in addition offering excellent control of current. These advantages, combined with the moderate operating voltage of the device, make a field-effect transistor galvanostat more practical than the usual constant current circuit of a source of emf in series with a high impedance. In comparison to operational amplifier based galvanostats the circuits using a field-effect transistor require fewer components, thus being more economical to construct.

Electrical circuit schematics for a galvanostat using only a field-effect transistor, a resistance and a power supply (battery) are shown in Fig. 1. For the circuits shown a maximum current is maintained in the load resistance (the electrochemical cell) when the feedback resistance is small. The maximum controllable current depends on the particular transistor, but is generally between 1 and 10 mA. The load current is decreased by increasing the feedback resistance. With a feedback resistance of 10 megohms the current is reduced to about 0.1 μA. Generally, no current smaller than this is required in electrochemical applications.

The load current will be held constant provided that the voltage between the drain and source of the field-effect transistor is less than the breakdown voltage but greater than the so-called "pinch-off" voltage of the device. In our studies we have used the Motorola HEP 802 field-effect transistor (priced at under $2). This transistor has a rated breakdown voltage of 25v, but certain transistors were found to have actual breakdown voltages of almost 50v. Employing a power supply with an output slightly less than the breakdown voltage of the transistor, it was found that load currents between 0.1 μA and 5 mA could be controlled to better than 0.1% provided that the voltage drop across the transistor was greater than 3v (the "pinch-off" voltage). The current remains constant, subject to the above conditions, even though the voltage appearing across the load may vary over a fairly wide range (approximately 20v for the transistors used in this study).

As a check on the operation of the circuit of Fig. 1 the galvanostatic oxidation of bismuth in a sodium carbonate solution was studied up to an overpotential of 20v. The results obtained in this study were in excellent agreement with the investigation of the anodic oxidation of bismuth using an operational amplifier galvanostat (3).

The variable feedback resistance in Fig. 1 may be replaced by the combination of a potentiostat and a fixed resistance; a modified circuit using this technique is shown in Fig. 2. The potentiostat controls the voltage between the gate and the source of the field-effect transistor, thus controlling the load current. By varying the potentiostat output, the load current may be altered to any desired value. Replacement of the potentiostat of Fig. 2 with a potential sweep generator transforms the circuit into a current sweep generator.

The disadvantage of the simple field-effect transistor circuit (Fig. 1) is that a maximum current of the order of only 5 mA may be controlled. Many electrochemical applications require more current than this upper limit. An extension of the current range

Measurement of Electrical Conductivity in Molten Fluorides. A Survey[1]

G. D. Robbins*

Reactor Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

Investigation of the electrical conductivity of molten salt systems has been an area of lively research in recent years, and a number of articles have appeared which deal with this aspect of transport phenomena (1-3). It is the intent of this survey to limit itself to the subject of conductance measurements in molten fluorides. The containment problems encountered with these materials set them apart from the other molten halides with respect to experimental difficulties and consequent precision of measurement which can be expected. By considering only fused fluorides, it is hoped that sufficient details may be presented to permit workers in the field to obtain a comprehensive overview of the experimental techniques employed covering the period 1927 to 1967, to indicate possible sources of error in the light of electrode process concepts, and to present a recommended procedure for the measurement of electrical conductance in highly corrosive molten salts. To our knowledge, no such survey exists which addresses itself to these questions.

Many investigations in the past have been concerned with cryolite-containing melts because of their relevance to the aluminum industry, and a review of these systems has been given by Grjotheim and Matiasovsky (4). Renewed interest in the transport properties of fused fluorides in general has resulted from their use as fuel, blanket, and coolant materials in molten salt reactors (5).

This survey consists of a tabulation of fluoride systems investigated over the last forty years, followed by a discussion of experimental techniques noted in the tabulation and a critical analysis of their relation to the principles of measurement of electrical conductance in molten salts. Emphasis is placed on cell and electrode design and material, on measuring bridges, and on frequency ranges employed and frequency dispersion of the measured resistance. Values of specific and equivalent conductance for many of the systems reported here may be found in tabular form in Janz's "Molten Salts Handbook" (6).

Tabulation

Table I is a tabulation of electrical conductance investigations ordered by system and within each system, chronologically. Where similar experimental techniques have been employed for more than one fluoride system a cross reference is given. In the column headings, (R) and (l/a) refer to approximate values of measured resistance and cell constant, respectively. V_{pp} is the peak-to-peak value of voltage applied to the bridge. The logic of the table headings and the significance of the large number of "not stated" (abbreviated "N.S.") entries will become apparent in the discussion which follows.

Discussion

Materials.—Because of the high specific conductance of most molten salts (1-6 ohm^{-1} cm^{-1}) (7), experimental approaches have tended to fall into two groups (1): (I) use of capillary-containing cells, which results in a cell constant of several hundred cm^{-1}, the capillaries being constructed from electrically insulating materials; or (II) use of metallic cells in which the container is usually one electrode, with a second electrode positioned in the melt. The latter type of cell has cell constants of the order of a few tenths cm^{-1}, requiring quite accurate measuring bridges and determination of lead resistances. Since the value of measured resistance in such cells is less than 1 ohm, errors due to temperature gradients, changes in cell constant with temperature, and polarization become a significant problem. Hence, cells of type (I) are clearly desirable for use in molten salts. However, electrically insulating materials for capillary construction which are resistant to attack by molten fluorides are scarce.

Boron nitride (15) and single-crystal magnesium oxide (19-21) have been employed in capillary construction in cells of type I, while metallic cells of type II have been fabricated from platinum (8, 13, 14, 16-21, 26-28) and platinum-20% rhodium (9, 22, 23). Hot-pressed beryllium oxide (28), fused magnesium oxide (25), and graphite (15, 24, 32) also have been used in cell construction.

In addition to the above-mentioned metallic conductors, electrode materials have ranged from graphite (25, 32) to Inconel (11, 12), molybdenum (15, 24), and molten aluminum (25, 32).

Bridges.—Figure 1 shows the basic circuits of bridge types listed in Table I. By far the most commonly employed type of measuring bridge is some form of the basic Wheatstone bridge circuit (Fig. 1A), such as the Jones bridge (33, 34) (Fig. 1B), in which the two upper arms are matched, standard resistances, and the impedance of the cell in one lower arm is balanced by a variable impedance in the fourth arm. A sinusoidal potential source and a null detector complete the circuit. The balancing impedance is usually a variable resistance, R_p, and capacitance, C_p, connected in parallel. However, the solution resistance, R_s, and solution-electrode interfacial capacitances, C_s, in the cell are considered to be in series (35) (Fig. 2a). The capacitance resulting from the electrode leads is in parallel, across the representation shown in Fig. 2a, but at frequencies ordinarily employed, and with some care in positioning, the relatively low resistances encountered in molten salts usually permit this capacitance to be neglected.

At applied potentials sufficiently small that no electrochemical reaction occurs, the equivalent circuit of Fig. 2a is approximately valid (C_s is potential

Table I. Electrical conductance investigations of molten fluoride systems

No.	System	Ref.	Cell, (R) or (l/a)	Electrodes	Bridge (Detector)	f (kHz) of Measurement	R vs. f	Vpp (v)
1	LiF	8	Pt crucible (R) $\cong$ 0.1 Ω	Pt crucible and platinized Pt foil (3 × 4 mm)	Wheatstone (telephone)	6	N.S. = Not stated	N.S.

dependent), and the interfacial capacitance is charged and discharged during each half-cycle through the solution resistance. Substituting this equivalent circuit representation for the cell into Fig. 1B and performing a circuit analysis reveals that the two conditions which must obtain at balance are

$$\frac{R_s}{R_p} + \frac{C_p}{C_s} = \frac{R_{std}}{R_{std}} = 1 \qquad [1]$$

and

$$R_s R_p C_s C_p (2\pi f)^2 = 1 \qquad [2]$$

f is the frequency of the sine wave. Equations [1] and [2] may be combined to yield

$$R_p = R_s [1 + R_p^2 C_p^2 (2\pi f)^2] \qquad [3]$$

or

$$R_p = R_s + \frac{1}{R_s C_s^2 (2\pi f)^2} \qquad [4]$$

It is often the practice to equate R_p (the reading on the bridge dials) to R_s (the true solution resistance). (In the case of unmatched standard resistors, their ratio is used.) Yet as Eq. [4] demonstrates, this is

really an approximation in which the additive term $1/R_sC_s^2(2\pi f)^2$ has been neglected. The approximation is usually valid in dilute aqueous solutions where R_s is large. However, in molten salts, particularly in cases where capillaries are not used to increase the conducting path (such as in most fluorides), considerable error can result from the neglect of this term.

As an example, in a dilute aqueous solution reasonable values of R_s, C_s, and f might be 1000 ohms, 20 μf, and 1000 Hz, respectively. In which case the neglected term is 0.06 ohm (compared to 1000 ohms). In molten salts in cases where capillaries are not used to increase resistance, R_s is often less than 5 ohms. For such a value of resistance, and assuming values of C_s (36) and f as above, the neglected term becomes 12 ohms (compared to 5 ohms).

Although this approximation was pointed out by Jones (34) forty years ago and has been discussed more recently (37), in none of the nine groups of investigations employing this type of bridge (Table I) is it apparent that the effect of the approximation has been considered. R_s can be calculated from R_p and C_p (the resistance and capacitance readings on the bridge) via Eq. [3] provided the bridge has been demonstrated to obey Eq. [1] and [2] by first testing it with a dummy cell consisting of a known resistance and capacitance connected in series.

It is not possible to assess the extent to which neglect of the additive term in Eq. [4] may have contributed to an error in the published results (using Eq. [3]) because no author reported the values of capacitance required for bridge balance. However, such an error would be frequency dependent in magnitude, and the frequency independence of some results (15, 19-23) indicates no error from this source.

Use of Eq. [3] to calculate R_s is limited by the accuracy with which the values of the variable capacitance and the frequency are known and by the demonstrated ability of the bridge to satisfy the balance equations using dummy components. These difficulties can be avoided by employing a bridge in which the balancing components are in series (38). Then in the case of no electrochemical reaction, the value of R_s is well represented by the reading on the balanced bridge; however, this method does require the use of large capacitors.

Frequency response.—As seen in Table I, of the sixteen independent groups of investigators, over half do not state whether or how measured resistance varied with measuring frequency. Jones and Christian (39) considered this question in their investigations in aqueous electrolytes, measured resistances at a series of frequencies, and extrapolated measured resistance to infinite frequency employing the functional form $f^{-1/2}$. The theoretical basis for their experimental procedure was the work of Warburg (40, 41) and Neumann (42) who, on the basis of Fick's laws of diffusion, predicted that the polarization resistance (that part of the measured resistance due to electrode polarization) was inversely proportional to $f^{1/2}$. Thus the measured resistance, R_m, was considered to be composed of a true solution resistance, R_s, and a polarization resistance, R_z.

$$R_m = R_s + R_z \qquad [5]$$

Frequency dispersion of the measured resistance has been observed in organic solvents (43) and in molten salts. Often the form of the frequency dispersion was not $f^{-1/2}$. Nichol and Fuoss (43) observed f^{-1} frequency dependence in methanol solutions, while De Nooijer (44) reported that in molten nitrate melts plots of measured resistance *vs.* $f^{-1/2}$ were not linear, but approached linearity as the frequency approached infinity. His values of measured resistance at 20 kHz only differed from values extrapolated to infinite frequency by about 0.1%. Winterhager and Werner (13, 14) have considered frequency dispersion in molten nitrate, chloride, and fluoride melts and have mathematically (45) analyzed their results obtained with a Thomson-type bridge. They conclude that at sufficiently high frequencies measured resistance becomes independent of frequency, and they employ a measuring frequency of 50 kHz.

It should be emphasized that, while one can measure resistance at a series of frequencies and extrapolate to infinite frequency, one cannot make measurements at frequencies which approach infinity. In fact, very high-frequency measurements (in the megahertz range) are to be avoided because of the increased admittance of the leads and the fact that at very high frequencies one ceases to measure a property associated with ionic mobility and observes properties associated with dipole moments and polarizabilities. Hence the question of concern is what functional form of the frequency should be employed to extrapolate the measured resistance to infinite frequency.

Applying the concepts resulting from electrode process studies (46-48), when a sufficiently large a-c potential is impressed on the cell that charge is transferred across the solution-electrolyte interfaces during part of each half-cycle, corresponding to an electrochemical reaction, one may envision the equivalent circuit shown in Fig. 2b. Z_r represents the impedance associated with the reaction, which is in parallel with the solution-electrode interfacial capacitance. Under the exacting assumptions of faradaic admittance theory, Z_r may be represented by a frequency-independent resistance, θ, in series with a frequency-dependent impedance, $-W-$, the Warburg impedance (Fig. 2c). The latter is conveniently represented as a resistance and capacitance in series, R_r and C_r, at constant frequency, while both are predicted to vary as $f^{-1/2}$. Although this is the functional form sometimes observed in conductance measurements, the assumptions on which faradaic admittance theory are based are sufficiently restrictive (*e.g.*, that the amplitude of the sine wave approach zero) as to render equivalent circuit 2c of marginal applicability to most conductance apparatus. However, during that part of each half-cycle in which reaction is occurring at the electrodes, equivalent circuit 2b is a useful concept, and it is interesting to examine this representation in the light of experimental practices commonly employed to eliminate R_z (Eq. [5]). In the practice of extrapolating the measured resistance to infinite frequency, it can be seen that at very high frequencies the impedance of the capacitance path across the interface decreases relative to that of the reaction path, so that the equivalent circuit approaches that of Fig. 2a. The practice of platinizing the electrodes results in greatly increasing their surface area, increasing C_s and the relative admittance of this path. Thus, the effect of R_z is diminished.

Robinson and Stokes (49) have considered the question of frequency dispersion in terms of electrode process concepts as applied to aqueous media and give balance equations for a bridge with a parallel-component balancing arm, assuming various relative magnitudes for R_s, θ, and R_r. Under the conditions employed by Jones and Christian (39), $f^{-1/2}$ dependence is predicted. Hills and Djordjevic (50) analyzed frequency response in terms of an equivalent circuit representation similar to that of Fig. 2c and demonstrated possible errors which may result from extrapolation *vs.* $f^{-1/2}$. The largest error encountered in molten salts was 0.04 ohm. Robinson and Stokes conclude that one should measure resistance as a function of frequency and extrapolate to infinite frequency in accordance with the observed behavior. This is also the conclusion of Nichol and Fuoss (43), who had observed a f^{-1} frequency dependence of resistance in methanol solutions. Buckle and Tsaoussoglou (51) have found that measured resistance *vs.* frequency plots show a plateau in the range 10-100 kHz in aqueous potassium chloride and molten potassium bromide. They suggest that extrapolation of resistance *vs.* $f^{-1/2}$ would lead to erroneous conductances and

that one should study frequency dispersion in a particular apparatus and select a frequency-independent region for performing conductivity experiments.

Thus, it seems clear that *a priori* prediction of the functional form which should be employed for elimination of polarization resistance (via Eq. [5]) is not possible, and one must determine experimentally the frequency response with a particular apparatus and under a given set of experimental conditions. However, before resorting to this empirical approach, there are several steps which may be taken to reduce frequency dependence of the measured resistance: 1. A test of the bridge circuit by substituting a calibrated resistance and capacitance, connected in series, having values similar to those expected from the conductance cell indicates within what limits the bridge reading represents the series resistance (cf. Eq. [4]). 2. Reduction of the sine wave amplitude to the smallest possible value compatible with the detector (preferably below 100 mv) reduces effects associated with any electrode reactions. That over half of the investigators represented in Table I do not address themselves to the question of frequency dispersion justifies, the author feels, the foregoing discussion.

The lower the applied voltage, the less should be the contribution from any electrochemical reaction since during each half-cycle the time during which reaction occurs is less. The last column of Table I lists the peak-to-peak voltage applied to the bridge. Two authors (13-14, 16-17) contributed this information.

Summary

A survey of electrical conductivity measurements in molten fluoride systems covering the period 1927 to 1967 has been presented. Particular emphasis is placed on cell and electrode material and design, on measuring bridges, and on the frequency dispersion of the measured resistance. It is pointed out that the common practice of measuring resistance with a Wheatstone-type bridge having a parallel resistance and capacitance, R_p and C_p, in the balancing arm can result in considerable error if the relation $R_p = R_s[1 + R_p^2C_p^2 (2\pi f)^2]$ is not employed in determining the solution resistance R_s. The frequency dependence of the measured resistance and the practice of extrapolating measured resistances to infinite frequency *vs.* $f^{-1/2}$ is examined in terms of electrode process concepts. Recommendations are presented for reducing frequency effects, and a summary of experimental approaches of 16 groups of investigators for 56 molten fluoride systems is given.

Manuscript submitted April 22, 1968; revised manuscript received *ca.* Feb. 10, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

DISCUSSION SECTION

The Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 115, No. 4, 5, 6, 9, (April, May, June, and September), and in Vol. 116, No. 6 (June 1969).

The Alkaline Manganese Dioxide Electrode II. The Charge Process

David Boden, C. J. Venuto, D. Wisler, and R. B. Wylie
(pp. 333-338, Vol. 115, No. 4)

S. Ghosh[1]: In understanding the mechanism of the charge process in the alkaline medium of the manganese dioxide cell system, a basic question has remained unanswered: whether alkali will dissolve MnO_2 to form manganate solution. During the discharge of the MnO_2 electrode in the alkaline media, it is susceptible to the formation of solution in liquid phase near the electrode. At the time of charging, the quantitative reformation of MnO_2 could not be obtained resulting in loss of initial electrode material. In our study of the depolarization mechanism of gamma MnO_2, we observed that high *p*H was not conducive to obtaining the proper charge and discharge capacity relation with that of the theoretically calculated value, whereas in the acidic range the coulometric capacity has some comparable relations.

In Fig. 5, 7, and 8, the charge and discharge curves were drawn on the basis of constant current charge and discharge. I feel, instead, if the discharge were carried out through a standard resistance and similarly the coulometric values obtained during the charge, it would have been useful for comparison with the theoretical coulometric capacity for a closer understanding of the practical utility of the system. To date a reversible cell system with manganese dioxide electrode has not been a practical proposition. Your study is most enlightening; I hope you will explore further and will be able to establish the proper condition for a reversible alkaline managanese dioxide cell.

Before I close my observations, I would like to inform you about my unpublished work in which I have tried to form a reversible system with manganese dioxide as positive electrode and cadmium as negative. I observed that the alkali was reacting with the stationary electrode and a liquid layer was formed in the neighborhood of it; a considerable dissolution of MnO_2 was observed after a few cycles of charge and discharge. The initial cycling was, no doubt, hopeful but we were restricted by the problem of dissolution and other side reactions, which occurred in the system. In the study on the depolarization mechanism of gamma MnO_2, we observed that high *p*H was not conducive to getting the proper coulometric discharge capacity compared with the medium in acidic or neutral range. It was observed that, if discharge is carried out to the point beyond breakdown of the structure of manganese dioxide, it was difficult to obtain MnO_2 again for discharge process. Up to the point where the lattice dilution of the oxide occurred it was possible to bring them back to the charge condition. In our study we examined those progressively discharged samples of MnO_2 by x-ray diffraction, electron diffraction, and electron microscopy, and found that discharge products of progressively discharged samples are mixtures of manganese dioxide with lower oxide of manganese, and the preparation of lower oxide progressively increased with the discharge.

[1] Indian Standards Institution, Manak Bhavan, 9 B. S. Zafar Marg, New Delhi 1, India.

I am giving the above comments in the hope that they will help to reveal the actual mechanism of this charge and discharge process which is, no doubt, still an open question.

Field Ion Microscopical Studies of Exchange Current Density on Iridium

Leonard Nanis and Philippe Javet
(pp. 509-511, Vol. 115, No. 5)

D. A. Smith[2]: The contrast to be expected from field-ion images of dislocated surfaces has recently been quantified in detail (Pashley, 1965[3]; Ranganathan, 1966[4]; Smith *et al.*, 1968[5]; Brandon and Perry, 1967[6]; Sanwald and Hren, 1968[7]). It is generally agreed that a dislocation will be visible when the component of the dislocation Burgers vector along the normal to the surface where it emerges is not equal to zero. Dislocations are visible as a characteristic spiral contrast which may arise from both edge and screw dislocations. Almost all observations of dislocations can be analyzed in terms of this model. The authors reference to the absence of "spiral dislocations" is imprecise. More importantly, it is worth emphasizing that the perpetual steps postulated in theories of growth both from the vapor phase and by electrodeposition may be produced at emergent edge and mixed dislocations, not just screw dislocations. Any dislocation converts a crystal into a continuous helical ramp (Cottrell, 1964[8]). The geometrical situation in the surface is illustrated in Fig. 1 of Smith *et al.*[5] It may be that consideration of the surface topology around emergent stacking faults can add to knowledge of the reasons for the different behavior of various substrates in growth processes.

It is not justified to suggest that the absence of dislocation spirals in the small image shown as Fig. 5 suggests a growth mechanism which does not involve dislocations; a field-ion tip and the deposit which was observed to develop contain a multitude of the kink sites required for nucleation. Furthermore dislocations might emerge in the areas of the specimen which did not contribute to the image. Dr. G. D. W. Smith of this laboratory has pointed out that the occurrence of only two "spikes" around the tetrad axis of the specimen casts doubt on the crystallographic nature of the build up.

Some Properties of Electroless Cobalt

Allen S. Frieze, Richard Sard, and Rolf Weil
(pp. 586-591, Vol. 115, No. 6)

P. Cavallotti and **G. Salvago**[9]: Interesting information is supplied by Messrs. Frieze, Sard, and Weil on the nucleation and growth of chemically deposited cobalt. The explanation given of their results in terms of growth inhibition by codeposited phosphorus is, however, in contrast with some experimental results obtained in the course of the systematic research work carried out in this Laboratory on the chemical plating

of nickel and cobalt. As a matter of fact, x-ray and electron diffraction patterns of the chemical deposits obtained in different conditions showed different preferred orientations corresponding to the most densely packed planes parallel to the base: <0001>, <10$\bar{1}$0> and <11$\bar{2}$0>.[10]

Further experiments were carried out varying the parameters of a bath assumed as standard, of the following composition

$$[CoSO_4] = 0.3 \text{ m/l}$$

$$[NaH_2PO_2] = 0.6 \text{ m/l}$$

$$[C_6H_6O_7^{2-}]/[Co^{2+}] = 1$$

$$[NH_4^+]/[Co^{2+}] = 2$$

$$[NH_2CH_2COOH]/[Co^{2+}] = 1$$

pH = 10.5 adjusted with NaOH.

The deposition usually was carried out at 80°C, on copper specimens chemically plated with acid nickel baths containing $[NiCl_2]$ = 0.15 m/l; $[CH_3CHOHCOOH]$ = 0.5 m/l; $[NaH_2PO_2]$ = 0.3 m/l, at pH = 3.5 and 90°C. Therefore the deposition occurred on a nickel-phosphorus alloy of very high phosphorus content, which could be considered an "amorphous" substrate.[11]

All our deposits were examined to determine possible preferred orientations by taking electron reflection diffraction patterns, as well as by x-ray diffraction, with the method of Clark and Simonsen, mentioned by Frieze, Sard, and Weil, or with a North American Philips Geiger counter x-ray spectrometer.

Results obtained by the three techniques were in agreement; except that the <0001> fiber texture was more markedly observed by x-ray diffraction techniques in the deposits of low phosphorus content.

Deposits from the standard bath showed a strong <10$\bar{1}$0> fiber texture. Varying the operating conditions, by lowering $[NaH_2PO_2]$ to 0.225 m/l or increasing the pH up to incipient precipitation of basic salts or hydroxides in the solution (corresponding to a pH value of about 11.5 at room temperature), we noticed a <0001> fiber texture perpendicular to the base, as we did when the thickness of the deposit was 10μ.

At variance with the results of Frieze, Sard, and Weil a strong <11$\bar{2}$0> preferred orientation was observed varying four different operating conditions:

1. Increasing $[NaH_2PO_2]$ up to 1.5 m/l;
2. Using solutions not containing ammonium ions;
3. Increasing the molar ratio $[C_6H_6O_7^{2-}]/[Co^{2+}]$ up to 2.4;
4. Decreasing the pH value to 8.

Figure 1 shows the electron diffraction patterns obtained from deposits in the above mentioned conditions with <10$\bar{1}$0>, <0001> and <11$\bar{2}$0> fiber axes.

According to the theory followed by Frieze, Sard, and Weil the <11$\bar{2}$0> fiber axis corresponds to the least inhibited outgrowth. If the growth inhibition was to be attributed to codeposited phosphorus, as in those authors' opinion, the occurrence of a <11$\bar{2}$0> fiber axis would correspond to a decrease of the phosphorus content in the deposit. This is not, however, the case, because for deposition at increased $[NaH_2PO_2]$, which lead to the development of a strong <11$\bar{2}$0> preferred orientation, the phosphorus content obviously increased from about 4%, in the deposits from the standard bath with <10$\bar{1}$0> fiber axis, to about 5%. Moreover, the deposits with <11$\bar{2}$0> preferred orientation had different phosphorus content depending on the conditions under which they were obtained.

So, when we increased $[NaH_2PO_2]$ the phosphorus content increased too, as already noted, but deposits

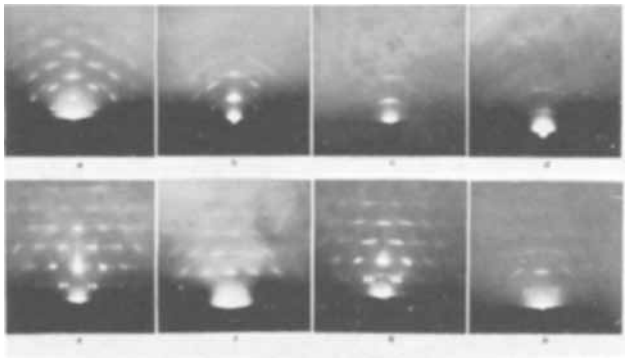

Fig. 1. Electron reflection diffraction patterns of chemical cobalt deposits. Bath conditions: a—$[CoSO_4]$ = 0.3 m/l; $[NaH_2PO_2]$ = 0.6 m/l; $[C_6H_6O_7^{2-}]/[Co^{2+}]$ = 1; $[NH_4^+]/[Co^{2+}]$ = 2; $[NH_2CH_2COOH]/[Co^{2+}]$ = 1; pH = 10.5 adjusted with NaOH; T = 80°C, deposit thickness, 50 μ; b, *idem* a, except pH = 11.7 adjusted with NaOH, deposit thickness: 3μ; c, *idem* b, deposit thickness: 30μ; d, *idem* a, except $[NaH_2PO_2]$ = 0.225 m/l, deposit thickness: 10μ; e, *idem* a, except $[NaH_2PO_2]$ = 1.5 m/l, deposit thickness: 30μ; f, *idem* a, except no ammonium ions in the solution, deposit thickness, 30μ; g, *idem* a, except $[C_6H_6O_7^{2-}]/[Co^{2+}]$ = 2.4, deposit thickness: 10μ; h, *idem* a, except pH = 8 adjusted with NaOH, deposit thickness: 10μ.

from solutions not containing ammonium ions showed nearly the same phosphorus content as in the deposits obtained from the standard solution, and deposits from bath at pH 8 showed a decreased phosphorus content of about 3.5%. An increase in the phosphorus content to about 5% was also observed for deposition from baths at a molar ratio $[C_6H_6O_7^{2-}]/[Co^{2+}]$ value of 2.4. Examining the phosphorus content in the deposits with <0001> fiber axes, a more striking evidence arises of the consequential character of obtaining of the preferred orientations in the deposits on the plating conditions; the phosphorus content does not appear as the cause of the development of preferred orientations but rather as a consequence of the operating conditions. In fact, while the deposits from baths of low $[NaH_2PO_2]$ = 0.225 m/l contain about 2% of phosphorus, the deposits obtained in severe conditions of precipitation at very high pH, with the same <0001> fiber texture of the preceding deposit, contain about 5% of phosphorus, conditions in which the inhibition would be severe according to the above mentioned authors, who affirm that "the {0001} plane should tend to be perpendicular to the surface." Considering the chemical deposition of nickel, it has been shown that only a <111> fiber texture could be observed in most deposits with phosphorus content up to 7%.[12]

According to the theory of Reddy, as reported by Frieze, Sard, and Weil, the {111} plane should tend to be perpendicular to the surface when growth is inhibited. This is in sharp contrast with the experimental evidence, which shows a more marked lamellar structure (*i.e.*, lateral growth according to Reddy) when the phosphorus content increases.

In the case of cobalt chemical deposition a similar tendency toward a more lamellar structure is shown when $[NaH_2PO_2]$ in the solution is increased, and consequently the phosphorus content in the deposits increases; the preferred orientation, however, changes from <0001>, through <10$\bar{1}$0> to a <11$\bar{2}$0> fiber axis. This sequence of preferred orientation is at variance with the explanation given by Frieze, Sard, and Weil. Moreover, Gutzeit[11] attributed the lamellar structure to periodic variations of the phosphorus content in the coating. This would lead, increasing the phosphorus content in the deposited cobalt, to a disorientation of the deposit, as a consequence of the different preferred orientations depending on the amount of

[10] L. Cadorna, P. Cavallotti, and G. Salvago, *Electrochim. Metallorum*, 1, 177 (1966).
[11] G. Gutzeit, *Plating*, 46, 1158 (1959).
[12] A. H. Graham, R. W. Lindsay, and H. J. Read, *This Journal*, 112, 401 (1965); L. Cadorna and P. Cavallotti, *Electrochim. Metallorum*, 1, 93 (1966).

phosphorus codeposited, variable in each lamella. The very strong <11$\bar{2}$0> fiber axis obtained at higher [NaH_2PO_2] is at variance with this conclusion. According to the theory proposed by Reddy[13] to explain the different preferred orientations obtained in the electrodeposition of nickel, the coverage of different faces with adsorbed hydrogen atoms on the cathode is a decisive factor in the development of a preferred orientation. Trying to explain the experimental results by assuming the adsorbed atomic hydrogen as a growth inhibitor, we would observe only the most inhibited fiber textures because of the very high hydrogen concentration on the surface, since a marked hydrogen evolution was always observed in the chemical plating of nickel and cobalt. This, however, is contradicted by the obtainment of several preferred orientations, among which also the <0001> and <11$\bar{2}$0> fiber texture for chemical deposits of cobalt, corresponding to the less inhibited lateral and outgrowth according to Reddy, as well as the <111> fiber texture for chemical deposits of nickel. Also the sequence <0001>, <10$\bar{1}$0>, <11$\bar{2}$0> of fiber textures, which was observed when increasing [NaH_2PO_2] in the cobalt solutions for chemical plating, with consequent increase of hydrogen evolution, cannot be explained by this theory.

Frieze, Sard, and Weil have also underlined the similarity between the microstructures of chemical and electrodeposited cobalt with <10$\bar{1}$0> fiber axes. An analogous relationship is valid between electrodeposits and some chemical deposits with <11$\bar{2}$0> fiber axes, *viz.*, from baths without ammonia or at low *p*H. When [NaH_2PO_2] or [$C_6H_6O_7^{2-}$]/[Co^{2+}] are increased to a high value with corresponding development of a <11$\bar{2}$0> fiber axis, the coating shows a mamelonar structure, typical of deposits containing inclusions. It may be concluded that phosphorus affects the morphology and the grain size of the deposits, without inhibiting the formation of a crystalline structure in the case of cobalt deposits.

Deposits with <0001> fiber axes were observed at low [NaH_2PO_2] and high *p*H, *i.e.*, in a range of possible inhibition conditions, with a decrease of the deposition rate. These conditions can be related to a too great stabilization of the hydrated and hydrolyzed cobalt ions in the layer adjoining the surface, on which the reaction occurs.

Deposits with <0001> fiber axes were also obtained in our laboratory by electrodeposition.[14] In this case the <0001> fiber texture is favored by high temperature, high c.d., and eventual presence of surface-active substances. This is substantially in agreement with the results of several authors.[15] The addition of boric acid has a negative influence on the development of this preferred orientation; *e.g.*, from a bath containing [$CoSO_4$] = 1 m/l, at *p*H = 5.5, T = 80°C, c.d. = 1500 amp/m^2, the deposits presented strong <0001> fiber axis.

As in the preceding case, the <0001> preferred orientation can be related to the formation of highly stabilized hydrolyzed species at the cathode. A certain relationship between the microstructures of chemical and electrodeposited coatings with the same preferred orientation can be observed. These results are at variance with the theory of Reddy, which is followed by Sard, Schwartz, and Weil,[16] because, in the given conditions, corresponding to inhibition by hydroxides or basic salts, the less inhibited lateral growth according to Reddy can be observed. If one attributes the inhibition to the hydrogen atom coverage of the surface, the already mentioned objection arises on the possibility of obtaining this preferred orientation in the chemical plating, when the surface coverage by hydrogen atoms is always very high.

The microhardness of the deposits with <0001> fiber axes presented a characteristic behavior for indentation on the cross section: the hardness changed with direction and was greater for indentation parallel to the base (300 HV for electrodeposits, 260 for chemical deposits from baths at low [NaH_2PO_2], while in the perpendicular direction it was 250 for electrodeposits and 230 for the corresponding chemical ones).

Deposits with <11$\bar{2}$0> and <10$\bar{1}$0> fiber axes behaved in the opposite way: indentation parallel to the base was 350 HV from the standard bath, 200 HV from baths without ammonia, 450 HV from baths with high [NaH_2PO_2], while in the perpendicular direction it was 400 HV, 270 HV and the same of that in the parallel direction for baths at high [NaH_2PO_2]. This behavior is in agreement with the crystallographic structure and with the results of the micrographs of the surface and of the cross section of the deposits.

In our last paper on chemical plating of nickel and cobalt by reduction with hypophosphite,[17] we examined the characteristics of the process and evidenced the importance of hydrolysis phenomena in the process. The reactions, by which nickel or cobalt are reduced, involves hydrolyzed species, but with hydroxyl ions not too tightly bonded to the nickel or cobalt ion, and the possibility of bridged intermediates.

The importance of the hydrolysis phenomena cannot be misunderstood taking into account the interpretative scheme of the obtainment of the different preferred orientation. In fact, to obtain a determinate preferred orientation we must consider the possible influence of the substrate and of the particular bath conditions, at which the reactions occur at the surface. We have deposited cobalt on a surface of "amorphous" chemical nickel of high phosphorus content,[11] searching to eliminate the first effect. Examining the conditions at which deposits with <11$\bar{2}$0> fiber axes obtained: low *p*H, high [NaH_2PO_2], high relative citrate concentration, no ammonia in the solution, it appears that all these conditions can be related to a decreased interaction of the hydrolyzed species with the surface, caused either by an increase in the concentration of the concurrent hypophosphite, or, when the *p*H or the complexing agents in the solution are decreased, by a decrease in the concentration of the hydrolyzed species, or else by a decrease of their degree of reactivity in respect to the considered reduction reactions. It is not possible to extend the consideration on the chemical plating to the electrodeposition without taking into account the differences between the two processes. The intervention of the hydrolyzed species on the anodic dissolution as well as on the cathodic deposition of the iron-group metals has been outlined in a number of papers (*e.g.*, [18]). This influence can also be acknowledged, when considering the modes of electrocrystallization of cobalt. As a matter of fact, by increasing the c.d. some influence may be observed toward changing the preferred orientation from <11$\bar{2}$0> to <10$\bar{1}$0>. The influence of increasing chloroanions concentration is the opposite.[16] The influence of the *p*H is complicated by the possible formation of cubic cobalt, which favors the <110> + <11.0> fiber axes.[14]

By obtaining a <11$\bar{2}$0> fiber axis, rather than a <10$\bar{1}$0> fiber texture, the substitution of the hydroxyl ions in the coordination sphere of the metal ions by

chlorides, and more precisely in the hydrolyzed layer adjoining the surface, may be considered. By increasing the concentration of the hydrolyzed species in this layer, the preferred orientation of the deposit would change to the $<10\bar{1}0>$ fiber axis and to the $<0001>$ in the most pronounced conditions, where hydroxides or basic salts begin to precipitate. This suggestion, although still lacking decisive experimental evidence, allows one to explain and predict several results, while by "using the concepts of free and inhibited outgrowth" this "was not possible."

A. S. Frieze, R. Weil, and **R. Sard:** We fail to see where our experimental results are "at variance" with those of Cavallotti and Salvago, when the fact is considered that their bath compositions, plating conditions, and deposit thicknesses were considerably different from ours. We did not observe the $<11\bar{2}0>$ fiber axis because the conditions under which it occurs were not investigated.

Cavallotti and Salvago seem to feel that, because the $<11\bar{2}0>$ fiber axis was observed in deposits with higher phosphorus contents than those where $<10\bar{1}0>$ was found, the whole concept of free and inhibited growth is negated. We disagree with this conclusion. Deposits with both fiber axes have the most densely packed plane perpendicular to the surface. The difference between the axes is that the $<11\bar{2}0>$ direction is more closely packed. As the plane is the governing factor, there is, therefore, not a significant difference in the degree of inhibition between the deposits with the two fiber axes. The work of Pangarov and Vitkova[19] illustrates this fact. The phosphorus contents reported by Cavallotti and Salvago is probably the average over the entire thickness. It is conceivable that in deposits as thick as those used by them, the phosphorus content near the surface where the electrodiffraction patterns were taken was considerably different from the average. Therefore, it is necessary to show that the phosphorus content in the surface layer, where the $<11\bar{2}0>$ fiber axis was determined, was higher than where the grains have the $<10\bar{1}0>$ preferred orientation.

The statement "it may be concluded that phosphorus affects the morphology and the grain size of the deposits, without inhibiting the formation of a crystalline structure in the case of cobalt deposits," appears to be a contradiction. Also, Cavallotti and Salvago appear not to have performed the necessary experiments to determine grain size, which obviously[20] cannot be done by optical microscopy.

We also disagree that a lamellar structure constituted lateral growth. Earlier work[21] has shown that lamellar structures consist of alternating layers of columnar and more equiaxed crystallites. A columnar structure is outgrowth.

Cavallotti and Salvago criticized the lateral and outgrowth concepts, claiming that they do not predict the results. The theory put forth by them is also a phenomenological one and gives no reason why certain plating variables should produce a certain order of crystallographic orientations. Their interpretation follows from a different point of view, namely, that of chemists, while ours is that of physical metallurgists. The argument that hydrolysis at the surface accounts for all observations is far from compelling. It appears that the chemical and metallurgical approaches must be reconciled if a satisfactory understanding of electroless deposits is to be reached.

Charge-Transfer Complexes and Electrochemical Cells—Coal Batteries

R. A. Friedel
(pp. 614-615, Vol. 115, No. 6)

F. Gutmann,[22] A. M. Hermann,[23] and A. Rembaum[24]: With reference to the recent paper by R. A. Friedel, we wish to offer the following comment.

Dr. Friedel maintains that the operation of the solid-state primary cells based on charge transfer complexes reported by us[25,26] is based on the presence of liquid water which acts as a reactant and not merely as a catalyst. He substantiates this by experiments using Mg anodes.

We wish to point out that his experiments, as well as his conclusion regarding the presence of water, agree with our own work as long as magnesium anodes are employed. A parasitic corrosion reaction between Mg and I_2 which occurs without drawing current causes the poisoning of the Mg surface with insulating MgI_2 and thus stops the reaction unless sufficient water is present to dissolve it. The presence of water, of course, then causes the evolution of gaseous hydrogen, as reported by Dr. Friedel.

However, we have already pointed out[26] that water as such is by no means essential, even using Mg anodes, and have shown that a number of nonaqueous, organic liquids, serve at least equally well. Moreover, later, so far unpublished experiments using Ag anodes in place of the Mg, support our above contention that the presence of water is associated with a parasitic reaction of the Mg: primary cells were prepared and assembled in a dry box under dry argon, using a 1:2 phenothiazine:iodine complex, and Ag anodes. Some of these were then assembled in nickel formers, spot-welded together, and potted in epoxy while still in the dry box. A further coat of epoxy was then applied immediately after removal from the dry box. These cells gave open-circuit voltages of 0.65-0.68v and short circuit currents of the order of 100 $\mu a/cm^2$, so far for about 4 weeks after preparation.

Other cells were assembled in a Teflon insulated C-clamp and then sealed, still in the dry box, in a glass jar containing P_2O_5. These cells gave the same voltage and a short circuit current density of about 8 ma/cm^2 and thus far have lasted for several weeks under the above conditions. The higher current densities are probably due to a better mechanical contact between the cell components; in the case of the Ni-formers it is very difficult to maintain sufficient positive pressure to ensure uniform contact over the entire electrode area.

Still other cells prepared under like dry conditions, using a highly iodinated ionene[27] complex salt behaved likewise: no significant current with Mg anodes, and 0.8 ma/cm^2 sealed over P_2O_5 thus far for several days.

As to the merits of containing the iodine in the form of a charge transfer complex rather than in its elemental form, it might be apposite to point out that the current obtainable from a cell is determined *inter alia* by the cell's effective internal series resistance. Room temperature resistivity of commercial, chemically pure, iodine is usually about 10^5 to 10^6 ohm-cm; zone refined iodine has a resistivity[28] of 1.3 x 10^9 ohm-cm, while, *e.g.*, the phenothiazine:iodine complex has a resistivity of 3-10 ohm-cm at room temperature. The resulting improvement by 5 to 6 orders of magnitude

in the ohmic series resistance of the cell caused by storing the iodine in the form of a charge transfer complex, is thus by no means negligible.

R. A. Friedel: With reference to the discussion by Gutmann *et al.* I wish to offer the following comment:

The above discussion principally concerns new work and work that had not been published at the time of my paper. I wish to congratulate the authors on the development of their new Ag-anode charge-transfer battery that operates without any trace of water or other high permittivity solvents.

There is only one point that perhaps needs clarification, the degree of importance of having a charge-transfer complex as the source of iodine. In the above discussion Gutmann *et al.* state that the storing of iodine in the form of a charge-transfer complex is important because the effective internal resistance of a cell is thereby lowered to a practicable range of values. But the preparation of complexes by mechanical grinding was reported in the original paper to be as good as a chemically prepared complex.[25] The two "complexes', must differ greatly; it seems questionable, therefore, whether a *bona fide* charge-transfer complex is vitally important. Perhaps the new battery with Ag anode requires a true, chemically prepared complex. In any case the batteries with Mg anodes apparently attain low resistance values in the first few moments of operation, for the uptake of water or solvent vapors and the production of MgI_2 and probably other compounds must lower drastically the internal resistance of chemically pure iodine and thus reduce the importance of having a charge-transfer complex.

We are indebted to Gutmann, Hermann, and Rembaum for their discovery of these batteries which led to our use of coals as battery components. Work on coal-iodine batteries will continue; water will be involved as it is a constituent of all coals. Work will be carried out also on anthracite batteries; pieces of some anthracites as the cathode, with a magnesium anode, produce open-circuit voltages under one volt and short-circuit current densities in the range of 100 $\mu a/cm^2$.

The Direct Observation of Barrier Layers in Porous Anodic Oxide Films

G. C. Wood, J. P. O'Sullivan, and B. Vaszko
(pp. 618-620, Vol. 115, No. 6)

A. La Vecchia,[29] **G. Piazzesi,**[30] **F. Siniscalco**[29]: The beautiful electron micrographs of the anodic oxide cross section presented by the authors improve our knowledge about oxide morphology and restrict the very subtle discussions grown up on this subject to a sound model supported by the most complete evidence.

Regarding Fig. 1, we observe that the lack of details in the cell section does not allow one to discover fine structure such as those observed by other experimenters[31] and ourselves.[32]

We systematically found a sort of graininess on cell surface, both from the Al and the oxide side, working with different replica techniques such as two-stage cellulose acetate-carbon or direct carbon replicas. Even with the purest single crystal samples such irregularities were discovered, and this fact led us to think of a probable subpore mechanism of ion transfer in the barrier layer. Instead of considering the barrier layer as a bulk homogeneous material, one may imagine a further subpore structure consisting of microchannels spreading radially from the pore bottom toward the cell surface. Those channels may not be considered as ordinary pervious channels, but

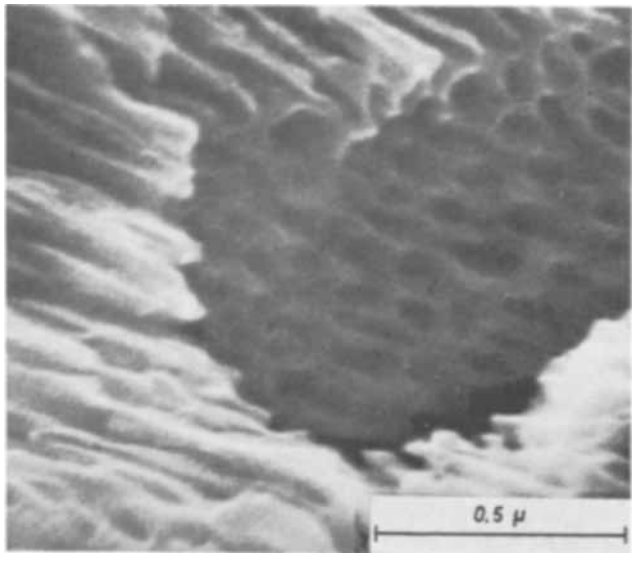

Fig. 1. Electron scanning micrograph of a fracture surface

rather as easy paths of peculiar structure, such as chains of more hydrated nearly amorphous alumina, in which charge carriers flow preferentially. So we arrive to a sort of Murphy-type mechanism confined in the barrier layer. A more detailed observation of the layer morphology will give useful contribution to support or to disregard this hypothesis.

Observing oxide microfractographs we found that pore channels grow up approximately perpendicular to the mean metal surface, but with a memory of the previous metal crystal structure and orientation; very often the fracture surface does not contain pore axes but is slightly tilted giving a low angle section of pore channels. For this reason we could not make extensive observations along single pore sections that appeared limited in length, such as those shown by the authors in Fig. 3.

An Electron Scanning Microscope Stereoscan II[33] enabled us to remove doubts: there was no artifact introduced by the replica technique and fracture surfaces appeared highly irregular and not everywhere parallel to pore axes such as shown in Fig. 1. For this reason, we would ask the authors if they used a particular technique to obtain fracture surfaces or if they have further experimental evidence supporting the proposed mechanism for redistribution of pores and cells during transient assessment of the barrier layer after having changed the external electrical conditions.

Transient electrical response constitutes another important source of information about the oxide formation processes, although in our experience such results must be handled with great care. We performed several tests on samples of various purity (from commercial grade to 99.9995% Al single crystals) anodized in sulfamic acid baths (7.5% Hσ) at different temperatures, and we noted the essential influence on such behavior of the actual time-gradient of the imposed electrical variable and of the stirring of the bath. The electrical transient behavior of our layers was rather complicated, and we could observe three essential stages: a very rapid departure from the stationary value of one of the electrical parameters depending on the time-gradient imposed to the other; the layer behaves as a condenser with a large apparent capacity, the major contribution to which may be ascribed to the electrical space charge build up by protons. The second stage consists in a slower subsequent recovery toward the stationary values, mainly due to thermal and diffusional phenomena and strongly

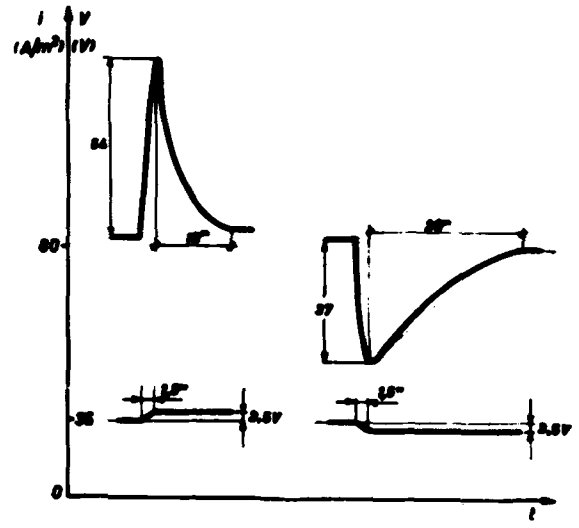

Fig. 2. Current transient response to a linear voltage variation

influenced by the amount of stirring or by the rate at which fresh solution can be supplied at the anode. Finally, depending on the magnitude of the impressed variation, there may be a slow drift toward final values of the observed electrical parameter determined by the actual value at which the other electrical variable is constrained. In this stage we recognize a plausible change in the oxide geometrical structure to fit the imposed electrical conditions. We studied systematically the effects of small linear variations around steady-state values, acting with an anodization cell already described.[34] An example of recorded curves is shown in Fig. 2. Detailed description, results and discussion will be given in a later paper.

Observing the curves reported by the authors in Fig. 2, we wonder, because we never found that behavior, that, after a voltage change, current always increases reaching the steady value.

This fact seems to us very interesting; unfortunately, more information about the experimental conditions is needed to evaluate the importance of such results, and we also would ask to the authors if they have formulated some thermodynamical interpretation. Clearly, in both cases the system is evolving, through a transient structure, toward a more organized state showing an increase in energy dissipation.

A tentative explanation, based on the theory of the local potential of Prigogine and Glansdorff[35] in analogy with the work done for other organized structures such as the cell pattern arising in the Bénard convection, will be of remarkable interest.

G. C. Wood, J. P. O'Sullivan, and **B. Vaszko:** We thank the authors of the discussion for their kind remarks on our electron micrographs and for their interesting comments.

The lack of "graininess" in oxide sections shown in our paper was reproducible throughout the experiments described and also in subsequent extensive work. Replicas taken from the metal after removal of the oxide film, as well as those from the cell bases themselves, showed even less structure, apart from the cell arrangement itself. It is our experience that simple scanning electron micrographs add little information in this area although it is conceivable that careful experimentation, *e.g.*, special precautions to avoid "charging up" of the specimen in the electron beam, might improve the situation. It should be noted that to draw conclusions concerning the chemical or electrical nature of the barrier oxide from electron microscopical data alone is not advisable, without reference to other techniques. Without necessarily denying the existence of hydrogen bonding, anion incorporation, proton space charges, etc., in anodic films we consider that their use in explaining the development of pores, etc., has been overemphasized. Our results support a very simple model which we intend to publish shortly.

Concerning the nature of the fracture surfaces, the observation that fracture often occurs at an angle to the direction of pore growth is in line with our experience, although occasionally the two planes correspond. No special technique was used to achieve this.

Our transient electrical measurements are different from those by the discussors, our changes being much greater. Thus the system is removed much further from equilibrium in our case. Generally, we find that the changes observed were much less reproducible at smaller values of the change in the applied voltage. We have formulated an explanation showing the importance of the general film structure prior to the voltage change in determining the nature of the electrical fluctuations observed. This explanation does not involve thermodynamics directly.

Analysis of the Uhlig Defect Model of Oxidation Kinetics

A. T. Fromhold, Jr.
(pp. 882-890, Vol. 115, No. 9)

Dennis B. Matthews[36]: The recent paper by Fromhold in this journal analyzes the kinetics of electron tunneling processes in a way which fails to take into account several factors which significantly affect the conclusions reached.

It is fundamental that the rate of a reaction is controlled by the activation energy rather than the energy change accompanying the reaction, but it is not obvious that under certain circumstances the two may be equal. Such a situation can occur when the reaction involves electron tunneling. The word "involves" is important because, in general, the actual tunneling process is preceded by an activation process, wherein the electron in its ground state absorbs energy which raises the electron to some excited energy level. The need for such an activation process is brought about by the fact that the electron in its ground state is not always in a state conducive to tunneling owing to the absence of empty acceptor states at the same energy level. To undergo a radiationless transition the electron often has to undergo thermal excitation. For an electron in a metal this thermal excitation is described by the Fermi distribution function. The mechanism under discussion is best described as "thermally excited electron tunneling." Such a mechanism cannot, within the framework of absolute rate theory, be divided into two steps, thermal excitation and tunneling, one of which becomes rate determining, just as one cannot divide other reactions into distinct steps comprising thermal excitation to the top of a barrier and electronic arrangement to form the product nuclei.

Utilizing the Uhlig model as given in Fig. 2(c) of Fromhold's paper it is seen that in order for electron transfer to occur the electron has to be thermally excited either to the level of the oxide conduction band (top of the barrier) or to the O^- energy level which then permits electron tunneling with nonzero probability to the O^- site. For thin films where the electron tunneling probability is high, the latter mechanism is more probable while for very thick films the former mechanism is the more probable. Naturally, for intermediate thicknesses both mechanisms will be operative, and in general the rate is proportional to $\int n(E) \cdot W(E) \cdot dE$ where $n(E)$ is the number of elec-

[36] Union Carbide Australia Ltd., Research and Development Laboratories, Marquet St., Rhodes, N. S. W., Australia.

[37] But *c.f.* below for a corrected version of this Uhlig model.

trons at the energy level E, $W(E)$ is the probability of electron tunneling at the energy level E, and integration is over all energy levels E. The possibility of an absence of O^- sites at the energy level E is accounted for by $W(E)$, which would then be zero. $W(E)$ is a function of oxide film thickness.

The concept of electron tunneling described above does not necessarily result in a fast electron transfer step (*i.e.*, nonrate determining) since the thermal activation term $n(E)$ still remains even if $W(E)=1$. Under conditions of easy electron tunneling the activation energy of the electron transfer step is given by footnote 37 Φ-A where Φ is the metal/oxide electronic work function and A is the electron affinity of oxygen at the oxide-oxygen interface.

Thus it is seen that there is a distinctive feature of electron transfer during oxide formation as compared to electron emission, namely, the availability of acceptor states, which introduces a thermal excitation term into the rate expression. The distinction is actually not so clear cut when one considers that, in order to measure the number of electrons emitted, we need a collector electrode biased with respect to the emitter electrode in such a way as to provide an electron sink for all the emitted electrons. In this sense then the adsorbed oxygen acts like an electron sink or as a collector of the emitted electrons.

Regarding the relative energies of the metal and O^- electron levels, one must take into account all energy terms. Thus if the reaction step under consideration is

$$O\ (ads.) + e^-\ (M) \rightarrow O^-\ (ads.) \qquad [1]$$

then the standard enthalpy change is given by

$$\Delta H_o = \Delta H_o\ (O^-\ ads.) - \Delta H_o\ (O\ ads.) + \Phi\text{-}A \qquad [2]$$

where ΔH (O^- ads.) and ΔH (O ads.) are the standard enthalpies of O^- and O adsorption, respectively. The electronic work function is potential dependent according to

$$\Phi = \Phi(V = 0) + V \qquad [3]$$

so that when the metal/oxide interface is positively charged with respect to the oxide-air interface then V is positive and $\Phi > \Phi(V = 0)$.

The energy change ΔH_o defines the differences in energy of the O^- and metal electron states. For the thermally excited electron tunneling mechanism the standard enthalpy of activation ΔH_o is equal to $\Delta H_o^{\neq}$ hence from Eq. [2] and [3]

$$\Delta H_o = \Delta H_o\ (O^-\ ads.) - \Delta H_o\ (O\ ads.) + \Phi \qquad [4]$$

$$= \Delta H_o^{\neq}\ (V = 0) + V \qquad [5]$$

and a linear dependence of log (rate) on potential, V, is predicted.

As a concluding remark, it is noted that if one allows for the thermal distribution of electrons in the metal, one should also allow for the thermal distribution of adsorbed oxygen states, *i.e.*, the oxide — O^- bond can have a Boltzmann distribution of vibrational-rotational energy levels. At first sight, for thin films this will lead to an approximately equal distribution of current between all energy levels extending from just above the Fermi level up to the O^- level.

A. T. Fromhold, Jr.: Dr. Matthews makes a statement in his opening paragraph which is entirely unsupported by the remainder of his discussion. The principal point of the discussion appears to be that rate processes limited by tunneling can have activation energies equal to the energy change accompanying reaction, a point that is made explicitly in the section "On the Possibility of Obtaining the Direct-Logarithmic Law" of the paper which he says does not consider this factor. That the tunneling process is not in actuality directly relevant to the Uhlig theory[38] is a fact which has apparently missed his attention also; no attempt is made in his discussion to explain the relevance of the equations to any theory of metal oxidation.

It should be pointed out that Eq. [3] underlying the derivation of the final result embodied in Eq. [5] in his discussion is valid only when the potential V is impressed over a barrier thickness so thin ($\simeq$ 50 or 100Å) that electron tunneling has a nonnegligible probability of occurring. In addition, a positively charged metal-oxide interface, such as mentioned by Dr. Matthews, clearly precludes electronic emission processes (including thermally-activated tunneling) from being rate limiting in thermal oxidation; instead, this would generally indicate that ionic transport is rate limiting. Furthermore, no attempt is made in his discussion to deduce the film thickness dependence of V, which is the critical step in ascertaining the resulting kinetics of thermal oxidation.

It thus appears that my recent paper serves as an opportunity for Dr. Matthews to present his views on the complexities of thermally activated tunneling whenever no single step is completely rate limiting. For an authoritative account of this matter, the reader is referred to the excellent article by Murphy and Good[39] entitled "Thermionic Emission, Field Emission, and the Transition Region", which is ref. (26) in the paper Dr. Matthews uses as a basis for his remarks.

Effects of Oxidizable Anion Adsorption on the Anodic Behavior of Platinum

Sigmund Schuldiner

(pp. 767-771, Vol. 116, No. 6)

K. J. Vetter and **J. W. Schultze**[40]: Schuldiner's assumption that the retardation of hydrogen oxidation on platinum at potentials above 1v is due to adsorbed anions[41, 42] rather than to adsorbed oxygen atoms or platinum oxides is essentially based on the following experimental results and hypotheses: (*i*) The unstationary rate of the reaction of platinum oxide with dissolved hydrogen, measured on open circuit, is adequate to a current density of $0.4\text{-}8\cdot10^{-3}$ amp/cm^2.[43] During this reduction of the platinum oxide the coverage of PtO and the potential decrease, whereas the reaction rate remains constant.[43] From this Schuldiner concludes that this reaction is a potential independent reaction of zero (or first) order in the PtO-coverage.[42, 43] The reaction rate of the platinum oxide with formic acid is stated to be $5\cdot10^{-4}$ amp/cm^2.[41] (*ii*) The rate of the electrochemical formation of the oxide layer is assumed by Schuldiner to be equal to or less than the stationary measured current density of 10^{-7} to 10^{-6} amp/cm^2 in the absence of hydrogen (see Fig. 2, footnote[41] curve 1M H_2SO_4). Since the rate of the reaction of PtO with H_2 or HCOOH according to hypothesis (*i*) at potentials below 1.6v is much more rapid than the rate of the electrochemical formation of PtO as given by hypothesis (*ii*), Schuldiner concludes that significant amounts of oxygen cannot remain on the surface below 1.6v.[41]

Hypotheses (*i*) and (*ii*) are not compatible with other experimental results. As shown below, the chemical reaction

$$PtO + H_2 \rightarrow Pt + H_2O \qquad (I)$$

has to be subdivided into an anodic reaction

$$H_2 \rightarrow 2H^+ + 2e^- \qquad (Ia)$$

and a cathodic reaction of equal rate

$$PtO + 2H^+ + 2e^- \rightarrow Pt + H_2O \qquad (Ib)$$

The current densities of reactions (Ia) and (Ib) as a function of potential E and coverage θ are plotted in

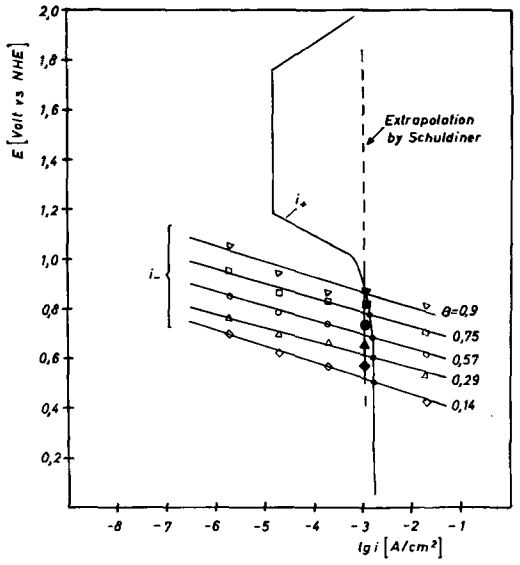

Fig. 1. i_+ anodic current density of reaction (Ia); i_- (open symbols) cathodic current density of reaction (Ib);[44] θ = coverage of PtO. Full symbols, experimental rate of over-all reaction (I) by Schuldiner and Warner.[43] Full circles, estimated values of the rate of over-all reaction (I) obtained from partial current densities i_+ and i_-.

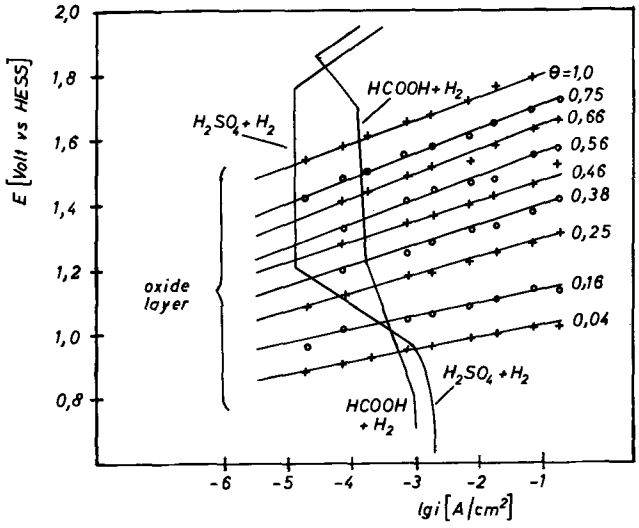

Fig. 2. Anodic current density of the oxide layer formation[44] and the current-potential curves of the systems $H_2SO_4 + H_2$ and HCOOH + H_2 (41, 42). θ = coverage of PtO. HESS = hydrogen electrode same solution.

Fig. 1. The anodic current density i_+ of reaction (Ia) is taken from Fig. 1 of Schuldiner's paper.[42] The cathodic current density i_- of the reaction (Ib) was determined by Vetter and Schultze[44] through galvanostatic pulse experiments as a function of θ, E, and pH. In Fig. 1 the current-potential curves are shown for different values of coverage of PtO at pH 0.3 (1N H_2SO_4). The experimental values of footnote[44] are given by the open symbols. From these measurements follows

$$i_- = k_- \cdot c_{H^+} \cdot \exp\left(a_-\theta - \frac{2.3\,E}{b_-}\right) \qquad [1]$$

with a_- = 13.8, b_- = 60 mv, k_- = constant, c_{H^+} = concentration of hydrogen ions. If reaction (I) is a combination of reactions (Ia) and (Ib), the rate of (I) on open circuit is given in Fig. 1 by the points of intersection of the curves of i_+ and of i_-. i_+ is independent of the potential in the range of 0.4v < E < 0.9v, whereas i_- is dependent on E and θ. It can be seen that the resulting rate given by the full circles in Fig. 1 is nearly constant and independent of E and θ because a drop in θ is compensated by a decreasing potential. This conclusion can be verified by the experimental results obtained by Schuldiner and Warner.[43] The mean value of the reaction rate is stated to be $1.2 \cdot 10^{-3}$ amp/cm^2,[42,43] Potential E related to this current density and coverage θ, stated in Fig. 1, are taken from Fig. 4 of the paper by Schuldiner and Warner.[43] These points are shown in Fig. 1 by full symbols. The agreement of the intersection points (dots) estimated from [42] and [44] and the experimental points (full, large symbols) taken from [43] is excellent. Hence, the reaction of PtO with H_2 is an electrochemical process combining (Ia) and (Ib). This conclusion is in agreement with conceptions of Breiter.[45] An extrapolation of the reaction rate constant in the range of 0.4v < E < 0.9v, to higher potentials E > 0.9v as shown by the dotted line of Fig. 1 is not allowed. The same conclusion may be valid for the reaction of PtO with formic acid; for this reaction Schuldiner does not give any experimental details.[41]

If chemical reaction (I) would take place besides the electrochemical oxidation of hydrogen, the reaction rate should be equal to or less than the current density of $1.5 \cdot 10^{-5}$ amp/cm^2 in the potential range 1.2v < E < 1.7v. In this case an equivalent current density is consumed to substitute the PtO which has been reduced by chemical reaction. To calculate the resulting coverage, the anodic current density of the oxide formation as a function of θ and E must be given. This was measured by Vetter and Schultze[44] and is shown in Fig. 2. The resulting equation is

$$i_+ = k_+ \cdot c_{OH^-} \cdot \exp\left(-a_+\theta + \frac{2.3\,E}{b_+}\right) \qquad [2]$$

In the case of pure chemical oxidation of the hydrogen, the coverage of PtO is determined by the intersection points of the current-potential curves of the oxide-layer formation and the current-potential curve of the system $H_2SO_4 + H_2$ measured by Schuldiner. The PtO-coverage is 0.4 for a potential of 1.2v, and 1 for 1.5v. These are minimum values for a pure chemical oxidation mechanism which is not proved. In the case of minor participation of the chemical reaction, the coverage values are higher, i.e. about 0.6 and > 1 for the pure electrochemical mechanism.

As for formic acid solutions with or without hydrogen, it can be seen from Fig. 2 that the minimum coverage of PtO is 0.36 at 1.2v and 1.0 at 1.6v provided that the chemical reaction of PtO with formic acid is rate determining. If not, even higher coverages of 0.6 and > 1 result.

These values of PtO coverages are sufficient to change the electrochemical and electronic[46] properties of the platinum surface and to cause the retardation of the hydrogen oxidation reaction.

Stress Generation during High-Temperature Oxidation

I. Oxygen Solution Effects[1]

R. E. Pawel* and J. J. Campbell

Metals and Ceramics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

The flexure of thin rectangular specimens of tantalum and niobium oxidizing on one side at 800°C was measured at several oxygen pressures. In these experiments, the oxygen pressure and oxidation time were generally kept small enough to prevent excessive oxide formation, and the oxygen diffusion distances were of the same order as the specimen thickness. For both oxidation and annealing experiments, the observed flexure behavior under these conditions could be correlated with that predicted on the basis of changes in the oxygen concentration gradients in the specimen. The results have helped to establish further some of the important characteristics of stress generation due to the dissolution of oxygen into the surface layers of a metal during oxidation.

The influence of mechanical stresses during gaseous oxidation has been a subject of intuitive importance for some time. However, the measurement and characterization of these effects have only recently been attempted on a quantitative and systematic basis. Stress systems which arise as a consequence of the oxidation process itself have now been shown in several instances to be the primary trigger for dramatic kinetic and morphological responses. Events such as wrinkling, cracking, and spalling of comparatively thick oxide films on either a macro- or microscopic scale furnish the more obvious bases for several types of changes in reaction rates. However, especially in the thin-film stage of oxidation, stresses may act in less spectacular ways while still playing a large role in the determination of the reaction kinetics and mechanism. For example, studies of the first stages of gaseous oxidation of copper (1) and nickel (2, 3) emphasize the importance of structural defects in such films on the rate of oxidation. It follows that the existence of stresses within the films may in large measure determine the extent of such defects as well as their behavior during continuing film growth.

In systems where the solution of oxygen into the metal is an important factor during oxidation, it has been predicted (4, 5) and shown (6, 7) that large stresses (of the order of the yield stress) in the surface layers of the metal can arise from this source. There are several ways in which these stresses in the metal might be expected to affect the oxidation rate. Although few definitive experiments have been made, a clear example where the normal reaction sequence has been drastically changed by the presence of stress in the metal is furnished in the initial stages of the gaseous oxidation of tantalum at temperatures in the range of 350°-550°C, where platelets of oxide grow into the metal along certain crystallographic planes. The unusual morphology in this particular case is very probably a result of a shear or martensitic type of transformation (8, 9), a process which would take place more readily under the influence of the high biaxial stress which exists.

The refractory metals tantalum and niobium are cases where stresses due to both oxygen solution and film effects might be expected to arise. Our previous work with these metals has shown that in the temperature range 350°-550°C the stress system is initially dominated by oxygen solution effects which give way later in the process (after the "breakaway" increase in the oxidation rate) to film effects. We are continuing our investigation of the details of stress generation in these metals a higher temperatures where it appears more feasible to separate the two major stress sources by varying the oxygen pressure. The present paper presents data for oxidation at 800°C under conditions which emphasize oxygen solution effects and further establishes some of the important phenomena during the dissolution of a reactant into the surface layers of a solid.

Experimental Procedure

We have continued to use the flexure technique (6) to follow stress development during oxidation. In this method, the curvature exhibited by a thin rectangular specimen is measured as it oxidizes on one side only. Thus, if the dimensions and physical properties of the specimen are known, the elastic bending stresses which exist can be computed. While the measurement is basically a simple one, its accuracy depends critically on maintaining pure cylindrical elastic bending of the specimen, a condition requiring specimen uniformity and very close tolerances on dimensions.

The equipment and procedures for these basic measurements have been described in detail previously (6, 7). Tantalum and niobium coupons approximately 1 x 4 cm were cut from 0.020, 0.030, and 0.050 in. sheet and annealed in vacuum at 1600° and 1000°C, respectively.[2] They were carefully mechanically and electrolytically polished and furnished with a Nichrome support yoke to facilitate mounting in the oxidation apparatus. Finally, a thin layer of a protective material was deposited on one side of each specimen by vacuum evaporation. Aluminum proved to be effective for this purpose for oxidation temperatures up to 550°C; however, for experiments at 800°C, a 2 parts gold, 1 part aluminum alloy was used. The specimen was affixed to the support in the apparatus and brought to the oxidation temperature in vacuum. The oxygen pressure was then adjusted to the desired value by a controlled leak, and the flexure of the specimen followed as a function of time by measuring the deflection of a fiber "transducer" with a cathetometer. The amount of flexure exhibited by the specimen per unit of strain energy supplied by the oxidation reaction depends on the thickness of the specimen. Thus, some additional degree of control was available with respect to the sensitivity of the measurements as well as the ability to insure that the bending stresses remained within the elastic limit throughout most of the experiments. The maximum elastic bending stress was computed from the simple beam formula

$$\sigma_s = \pm \frac{Eh}{2\rho_x} \qquad [1]$$

[2] Nominal analysis: 99.8-99.9 w/o with Ta, Nb, Fe, and W major metallic impurities; typical oxygen content after anneal was about 200 ppm.

where E is Young's modulus for the metal, h is the specimen thickness, and ρ_x is the radius of curvature of the specimen in its long dimension. It is recognized that the equation is an approximation which, for coupon-shaped specimens, generally yields slightly conservative bending stress values (6).

Results

It is important to remember that the flexure of the specimen is the mechanical result of a process that takes place on one side of the specimen. Thus, in order to be able to use bending stress values to determine the complete stress distribution in a quantitative fashion, it is necessary to establish either the mechanism of stress generation and/or the general shape of the stress-distance curve. If such information is not immediately available, it is possible to use the bending stress data themselves to point out or to evaluate the consistency of a given model.

In our present work, the flexure of tantalum and niobium specimens was followed during oxidation at 800°C at oxygen pressures from about 10 to 100μ. A few experiments were conducted at higher pressures in order to observe the influence of film stresses on the total strain behavior. Additionally, strain measurements made during annealing after short oxidation periods were useful in corroborating the oxidation model.

Method of analysis.—Previous work (10) has indicated that under the conditions of our experiments, the solution of oxygen into the metal would be expected to account for a significant fraction of the total oxygen consumed, at least during the first stages of the reaction. Thus, since an oxygen concentration gradient exists, a corresponding stress gradient will also exist.[3] The relation between the surface stress and the measured bending stress can then be determined by employing the conditions of mechanical equilibrium; that is, the sum of the forces and moments for the system must be equal to zero. The stress in the reaction layer is assumed to be a function of depth, x, and time, t, given by

$$\sigma_1(x, t) = K[C(x, t) - C_o] \quad [2]$$

where $C(x, t)$ is the oxygen concentration as a function of position and time, C_o is the residual oxygen concentration, and K is a proportionality constant, the form of which depends on the boundary conditions of the experiment. This stress, (σ_1), on one side of the specimen, will result in a set of bending stresses given by

$$\sigma_2(x, t) = \sigma_B + \left[\frac{2\sigma_s(t)}{h}\right]x \quad [3]$$

where σ_B is the component of bending stress at the reacting surface, $\sigma_s(t)$ is the measured maximum bending stress as a function of time from Eq. [1], and h is the specimen thickness. Thus, the equilibrium equations are

$$\int_o^h K[C(x, t) - C_o]dx + \int_o^h \left[\sigma_B + \left(\frac{2\sigma_s}{h}\right)x\right]dx = 0 \quad [4]$$

and

$$\int_o^h K[C(x, t) - C_o]x\,dx + \int_o^h \left[\sigma_B + \left(\frac{2\sigma_s}{h}\right)x\right]x\,dx = 0 \quad [5]$$

In our earlier paper, it was shown that, for conditions where the surface oxygen concentration quickly reached its final value, and the depth of oxygen penetration was small compared to the thickness of the specimens, an approximate "working equation" could be derived by simultaneous solution of Eq. [4] and [5]. For these conditions

$$\sigma_1(x, t) = \sigma_I\frac{C(x, t) - C_o}{C_s - C_o} = \sigma_I \operatorname{erfc}\frac{x}{2\sqrt{Dt}} \quad [6]$$

where σ_I is the surface stress due to oxygen solution, D is the diffusivity of oxygen in the specimen, and C_s is the oxygen concentration at the surface. For the steep concentration gradients which existed, the complementary error function could be approximated by a linear function of x, resulting in a simple relationship between the surface stress and the measured maximum bending stress

$$\sigma_I = 2\sigma_s(t)\frac{h^2}{d(3h - 2d)} \quad [7]$$

where d is the effective penetration distance, $2.3\sqrt{Dt}$. Similarly, when other simple boundary conditions are applicable along with semi-infinite geometry, analytical expressions can be used to obtain the stress distribution parameters under the terms of the model. However, the rate of oxygen diffusion is sufficiently high at 800°C so that for most specimens the condition of a limited diffusion zone is met only for the very early stages of reaction. When diffusion distances begin to approach the specimen thickness, the relation between total stress and bending strain is not direct, and particular attention must be paid to differences in stress behavior between free specimens, constrained specimens, or specimens oxidizing on both sides.

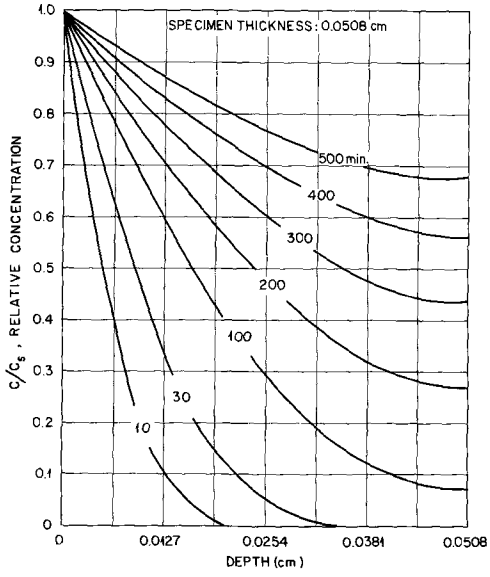

Fig. 1. Oxygen concentration profiles for diffusion at 800°C in 0.020 in. (0.0508 cm) thick tantalum sheet.

Data and interpretation.—In order to interpret flexure data in terms of oxygen-solution effects, it is necessary to define the oxygen concentration profiles in the specimen as a function of time.[4] A typical set of such profiles for a simple oxidation experiment on a 0.020 in. (0.0508 cm) thick tantalum specimen is shown in Fig. 1. Since the specimen thickness must be considered finite rather than semi-infinite when solving the diffusion equation in this case, these profiles, and the others used in this work, were obtained from distance-time arrays produced by a computer program based on finite-difference techniques. This approach was sufficiently accurate for the purposes of these experiments and, in addition, furnished an exceptional versatility in allowing us to vary the boundary conditions to test several details of the oxygen solution model. These tests would have been virtually impossible to make by analytical means. The profiles in Fig. 1 were computed on the assumption that a constant

[3] Unless the concentration gradient is completely linear and the specimen is not constrained.

[4] Diffusion coefficients based on the expressions $D = 0.019 \exp(-27{,}500/RT)$ for diffusion of oxygen in tantalum and $D = 0.015 \exp(-26{,}300/RT)$ for diffusion of oxygen in niobium were used in this work (11).

surface oxygen concentration, C_s, existed during the diffusion time. While this assumption is probably incorrect in detail for short diffusion times, the computer results obtained by the methods referred to above indicated that the shape of the profiles would not be altered significantly for diffusion times greater than about 20 or 30 min. As is seen in the figure, oxygen penetrates rapidly and after about 100 min the oxygen level on the protected side of the specimen starts to increase. According to the oxygen-solution model for stress generation, this behavior should result in flexure or bending stress components that should first increase, then decrease as the specimen "fills up" with oxygen. The resulting "ideal" behavior of the maximum bending stress, expressed as a fraction of the surface stress developed, was computed on this basis and is presented in Fig. 2. The bending stresses are seen to increase to a maximum and then to decrease at a slower rate. Unlike the case for which the reaction is limited to a shallow region, it is noticed that for experiments in which the thickness of the diffusion zone is comparable to the specimen thickness, the maximum bending stress will be a significant fraction of the surface stress, σ_I. However, it must be remembered that for specimens undergoing flexure, the stress at the surface due to oxygen solution will be reduced by the component of the bending stress at the reacting surface. Thus, the resultant stress at the surface may approach zero even as the specimen goes through its maximum flexure.

The measured maximum bending stresses for a tantalum specimen being oxidized on one side at 800°C at a pressure of approximately 10μ are shown in Fig. 3. Metallographic examination at the conclusion of the experiment did not reveal any significant changes in the appearance of the polished specimen surface, indicating that little, if any, oxide film or platelet formation occurred. The behavior is similar enough to the ideal to lead us to believe that oxygen is indeed the principal stress source under these conditions. However, the behavior of the apparent surface stress, computed via Eq. [7], in the initial stages of flexure show that the ideal model, which assumes a constant surface oxygen concentration, is not sufficiently accurate to permit quantitative values to be obtained. The most probable reason for this is that the effective oxygen concentration at the surface is increasing with time during this part of the reaction. For example, if it is assumed in this experiment that the surface oxygen concentration increases to its maximum value at a decreasing rate (parabolically) over the first 30 min, a more consistent result is obtained which correlates the oxygen concentration with stress very closely. Values of the surface stress thus computed for this

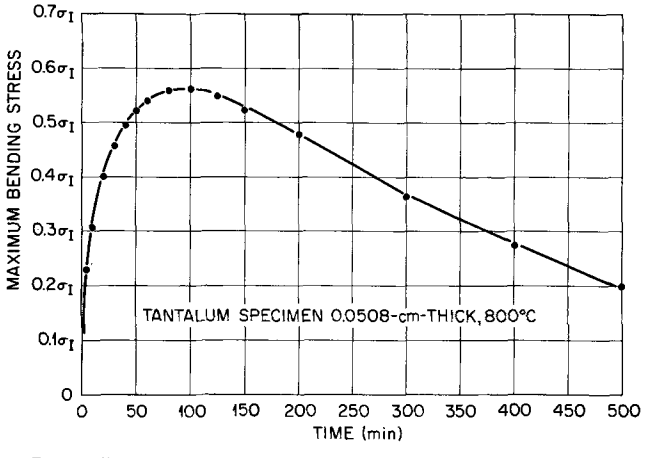

Fig. 2. "Ideal" flexure behavior for 0.020 in. (0.0508 cm) thick tantalum specimen computed from concentration profiles shown in Fig. 1. The maximum bending stress is expressed here as a fraction of the surface stress due to oxygen solution, σ_I, assumed to be a constant.

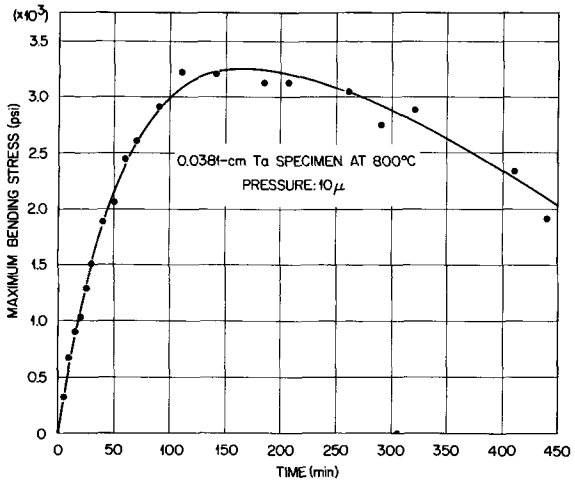

Fig. 3. Experimental flexure behavior for 0.0381 cm thick tantalum specimen at 800°C at an oxygen pressure of approximately 10μ.

experiment reached approximately 4000 psi. Such computations necessitate the use of Eq.[4] and [5], including computer solutions for $C(x,t)$ for the unusual conditions imposed to obtain surface stress values.

An interesting sidelight which was made evident from such experiments was the possibility of using flexure behavior to estimate diffusion coefficients for oxygen in the metal in a manner which does not require quantitative strain measurements. To a first approximation, the specimen should start to "unbend" during a flexure experiment shortly after the effective penetration distance equals the specimen thickness. Thus, for these conditions

$$D \cong \frac{h^2}{5.3\, t_m} \qquad [8]$$

where D is the diffusion coefficient, h is the specimen thickness, and t_m is the time at which the specimen flexure starts to decrease. For the experiment represented by the data of Fig. 3, the flexure reversal occurred at approximately 150 min. Thus, Eq. [8] leads to a diffusion constant for oxygen in tantalum at 800°C of 3×10^{-8} cm²/sec, a value which compares very favorably with the accepted value of 4.75×10^{-8} cm²/sec (11). A similar experiment with a niobium specimen yielded $D = 8 \times 10^{-8}$ cm²/sec which also compares well with the accepted value of 6.6×10^{-8} cm²/sec. This agreement is taken as additional evidence that volume diffusion rather than grain boundary diffusion controls the strain effects observed in these specimens.

At intermediate pressures for tantalum and niobium specimens, flexure effects due to both oxygen solution and oxide film sources are seen. However, if the oxygen is pumped out of the system before large quantities of oxide have formed, the unbending of the specimen observed during the anneal can then be correlated satisfactorily with the changes in the oxygen concentration gradient alone. Figure 4 shows maximum bending stress data for a niobium specimen held at 800°C. For the first 16 min, the oxygen pressure was maintained at about 15μ; then the oxygen was removed and the specimen allowed to anneal in vacuum at the same temperature. The measured bending stresses (solid circles) are seen to have increased to about 16,000 psi during the oxidation period, and then to have virtually disappeared after an hour's vacuum anneal. The oxygen concentration profiles pertinent to this experiment are presented in Fig. 5. Linear approximations of these profiles were then used in the mechanical equilibrium equations (Eq. [4] and [5]) to obtain bending stress changes during annealing. These computed bending stresses, normalized with

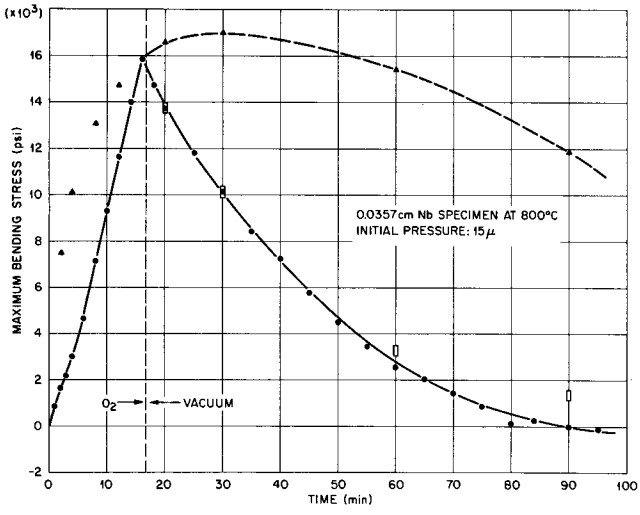

Fig. 4. Flexure behavior for 0.0357 cm thick niobium specimen held at 800°C. respect to the measured value at t = 16 min, are shown by the open rectangles in Fig. 4. The agreement with the actual values is good. The flexure behavior that would be expected if the oxygen concentration at the surface of the specimen were maintained constant, perhaps by dissolving oxide, is shown in this figure by the solid triangles. Clearly, in this experiment, the latter case does not apply, oxide dissolution was a slow step, or insufficient oxide was present. Metallographic examination of this specimen after the experiment revealed only a few isolated small patches of NbO with a limited superficial film, which may have formed during cooling. A similar result was obtained for flexure of tantalum specimens as shown in Fig. 6. In this case, the specimen was held for 65 min at about 45μ O_2 pressure before starting the anneal. The bending stresses during annealing, computed on the basis of oxygen redistribution, again

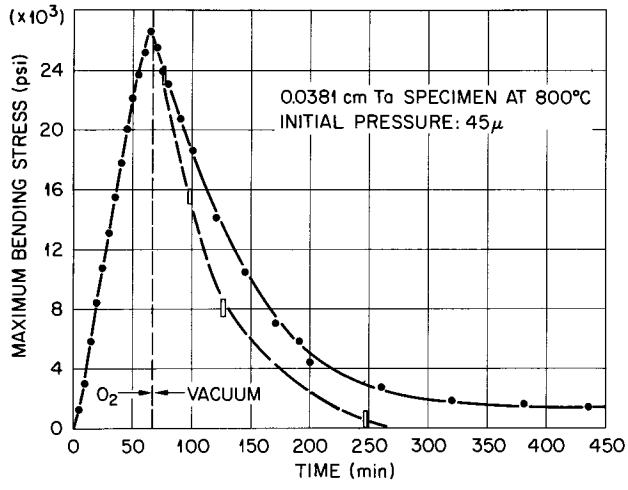

Fig. 6. Flexure behavior for 0.0381 cm thick tantalum specimen held at 800°C. For the first 65 min, the oxygen pressure was held at about 45μ. • Experimental values; □ calculated values (normalized at t = 65 min) on the basis of oxygen redistribution by volume diffusion during anneal.

agreed reasonably well with the observed values. The divergence between the observed and predicted values, as well as the residual curvature of the specimen is thought to be due mainly to the presence of a small amount of plastic strain induced during the oxidation period, since virtually no film or platelet growth could be found at the conclusion of the experiment. Surface stresses of about 20,000 psi due to oxygen solution were estimated in the manner discussed previously, allowing for a finite time over which the surface oxygen concentration increased.

At still higher pressures, the formation of oxide products along with oxygen dissolution led to a very rapid stress build-up which resulted in extensive plastic bending and distortion unless the oxidation time was limited. Of course, if plastic deformation occurs, the maximum bending stresses calculated from the observed flexure by Eq. [1] will be excessive by an amount proportional to the depth in the specimens over which the yield stress was exceeded. Figure 7 illustrates flexure behavior for a tantalum specimen under such conditions. In only a few minutes, a maximum bending stress of over 20,000 psi was indicated. The oxygen was removed from the apparatus, but then instead of unbending in strict accordance to oxy-

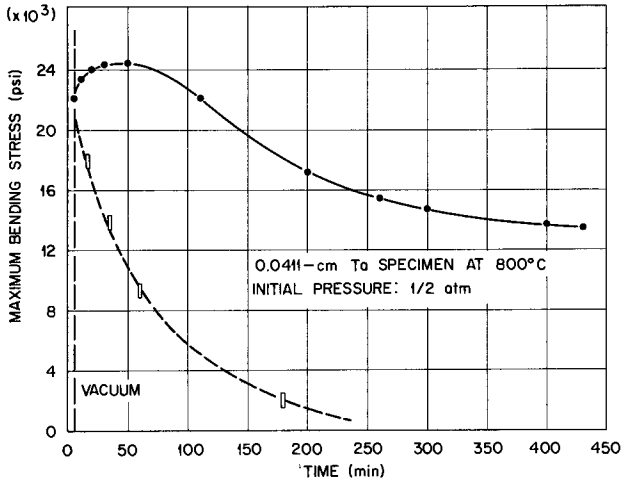

Fig. 7. Flexure behavior for 0.0411 cm thick tantalum specimen held at 800°C. For the first 5 min, the oxygen pressure was held at 0.5 atm. • Experimental values; □ calculated values (normalized at t = 5 min) on the basis of oxygen redistribution by volume diffusion during anneal.

gen redistribution effects, the specimen continued to bend. Finally, the maximum bending stresses were observed to decrease sluggishly to some constant value. There are several possible explanations for this behavior; however, it seems reasonable to postulate that oxygen from dissolving oxide is responsible for the postoxidation time flexure changes which are similar to those shown by the dashed curve in Fig. 4. The tendency for the maximum bending stresses to approach a constant value is probably due to a combination of (*i*) stresses which exist in the remaining thin oxide film and (*ii*) plastic deformation which occurred as the bending stresses went through their maximum.

Summary

The flexure of tantalum and niobium specimens oxidizing at 800°C on one side was measured at several oxygen pressures. The large mechanical strains observed in these experiments during the early stages of the oxidation reaction were found to be due to the presence of oxygen concentration gradients, in agreement with both prediction (4, 5) and previous results (6, 7). Annealing experiments, in which the changes in bending stresses were correlated directly with the redistribution of the oxygen which was present were particularly definitive in this respect. Since the effective oxygen concentration at the surface of an oxidizing specimen changed as a function of both time and oxygen pressure, the exact form of the oxygen concentration gradient, and thus the stress gradient, was difficult to compute. However, reasonable approximations regarding this behavior permitted at least semiquantitative values of the surface stresses to be obtained. For example, for the experiment depicted in Fig. 3, the component of stress at the tantalum surface due to oxygen reached a maximum of only 4000 psi; at higher pressures, *e.g.*, Fig. 6, the stress values reached about 20,000 psi.

These experiments have shown the usefulness of the flexure technique to test models for stress development during oxidation and, despite the approximations involved, have contributed to a more complete characterization of the nature and extent of these effects.

Rare Earth Bismuth Titanates

R. W. Wolfe and R. E. Newnham

Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania

ABSTRACT

Ferroelectric compounds in the family $Bi_{4-x}R_xTi_3O_{12}$ (R = rare earth) have been prepared as ceramics and single crystals. The solid solution limit increases with ionic radius: x_{max} exceeds 2 for La^{3+} and Pr^{3+} and approaches zero for the smaller Yb^{3+} and Lu^{3+} ions. The larger rare earth ions also stabilize the paraelectric phase. The dielectric properties and crystal chemistry of the bismuth titanates are discussed with reference to related structures, and the results of preliminary optical and electrical measurements are given.

Twenty years ago Aurvillius (1) discovered a family of mixed bismuth oxides with composition $M_{n+1}R_nO_{3n+3}$ where M = Bi^{3+}, Pb^{2+}, Na^+, K^+, Sr^{2+}, Ca^{2+}, Ba^{2+}; R = Ti^{4+}, Nb^{5+}, Ta^{5+}, Fe^{3+}, Ga^{3+}; and n = 2, 3, 4, 5. The crystal structures consist of Bi_2O_2 layers interleaved with $M_{n-1}R_nO_{3n+1}$ layers containing n perovskite-like units. The pseudotetragonal unit cell of $Bi_4Ti_3O_{12}$, with n = 3, is illustrated in Fig. 1.

Most, if not all, of these compounds are ferroelectric (2-5) with high transition temperatures and large spontaneous polarizations. X-ray patterns indicate orthorhombic symmetry, but recent electrical and optical measurements on $Bi_4Ti_3O_{12}$ (5) show that the true symmetry is monoclinic, point group m. A change in the sense of polarization produces a large change in the optical properties of bismuth titanate, making it unique among ferroelectrics and stimulating several device proposals (6). Bismuth titanate has a high transition temperature (675°C) resulting in large switching fields; to lower the voltages, it is desirable

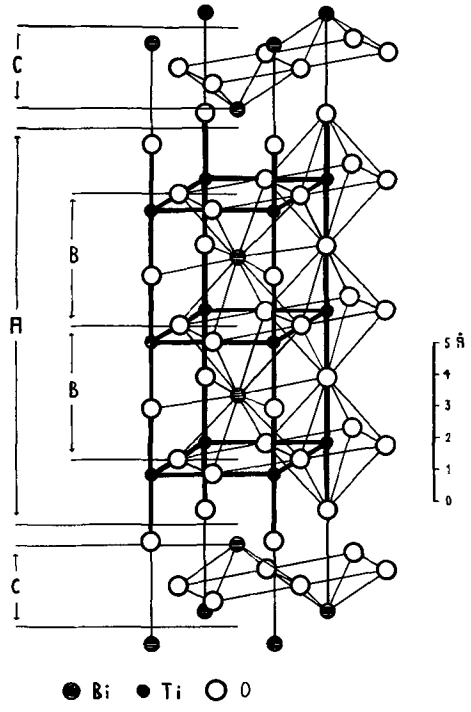

Fig. 1. Crystal structure of $Bi_4Ti_3O_{12}$ after Aurvillius (1). Dimension A delineates the $Bi_2Ti_3O_{10}$ layers with its three perovskite units, B, and C denotes the bismuth oxide layers.

to lower T_c. We have attempted to do this by substituting trivalent rare earth ions for bismuth, forming the solid solution series $Bi_{4-x}R_xTi_3O_{12}$.

Ceramic specimens of the rare earth-bismuth titanates were prepared by sintering reagent grade oxides in air at 1150°C. Weight losses never exceeded 1%. Solid solution limits were determined to an accuracy of 3%, using x-ray diffractometer patterns and the disappearing phase method. In all cases the major exsolved phase was a rare earth pyrochlore ($R_2Ti_2O_7$), possibly containing bismuth in solid solution. The results of these experiments are shown in Fig. 2, where the maximum value of x in $Bi_{4-x}R_xTi_3O_{12}$ is plotted against rare earth ionic radius. The larger ions from La to Eu fill 50% or more of the Bi sites; Gd substitutes 35%, and x_{max} descends rapidly to near zero for the smallest ions, Yb and Lu.

X-ray intensity calculations showed that the rare earth ions do not substitute randomly for bismuth. There are two different bismuth positions in the unit cell: half are coordinated to twelve oxygens in the perovskite layers, while the remainder are closely bonded to four oxygens in the bismuth oxide layer. Possible ordered configurations for composition $Bi_2R_2Ti_3O_{12}$ are illustrated in Fig. 3. Structure factors

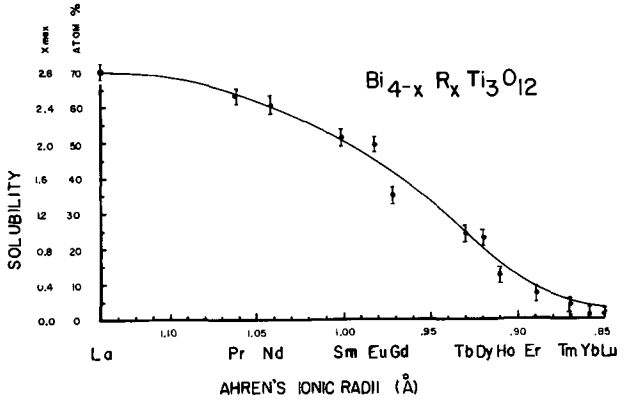

Fig. 2. Solubility of the rare earth elements in bismuth titanate at 1150°C.

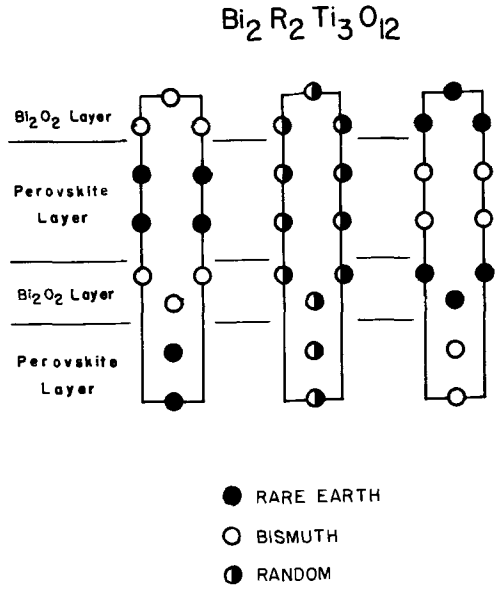

Fig. 3. Possible ordered configurations for the rare earth bismuth titanates of composition $Bi_2R_2Ti_3O_{12}$. The large cation sites in the perovskite and Bi_2O_2 layers are equal in number. ●, Rare earth; ○, bismuth; ◑, random.

were computed for the three models and compared with the structure amplitudes measured from x-ray diffractometer patterns. The results for $Bi_2La_2Ti_3O_{12}$ given in Table I are typical of the rare earth-bismuth titanates. The rare earth ions show marked preference for the perovskite-layer position, with bismuth in the more asymmetric interlayer site. Similar results have been reported for $CaBi_2Nb_2O_9$ (1) and $Na_{0.5}Bi_{4.5}Ti_4O_{15}$ (7).

The observed ordering explains the stability ranges presented in Fig. 4 for the $Bi_{4-x}R_xTi_3O_{12}$ solid solution series. $Bi_2R_2Ti_3O_{12}$ compositions are stable for R^{3+} ions larger than Gd^{3+}. Since rare earth ions occupy perovskite sites up to $x = 2$, their ionic radii must satisfy the requirements for twelve-coordination. In divalent-ion titanates (M TiO_3), the perovskite structure forms when the M^{2+} radius exceeds that of Cd^{2+}, with ilmenite structures predominating for smaller cations. Since the ionic radii of Gd^{3+} and Cd^{2+} are identical on the Ahrens' scale, it appears that the same stability criteria apply. Compounds such as $Bi_2Lu_2Ti_3O_{12}$ are unstable because the Lu^{3+} ion is too small for the perovskite layer site. For larger ions like La^{3+}, the Bi_2O_2 layer limits substitution. Only an atom with an asymmetric electron cloud, such as the lone-pair configuration of Bi^{3+} or Pb^{2+}, will promote the stability of the bismuth oxide layer. Hence x_{max} never exceeds 2 by very much.

Lattice parameters were determined from x-ray diffractometer patterns using CuKα radiation and a silicon standard. The pattern of pure $Bi_4Ti_3O_{12}$ was indexed on an orthorhombic unit cell out to $2\theta = 120°$. Having observed no monoclinic splitting in appropriate high-angle reflections, we conclude that the angle β differs from 90° by less than 0.15°.

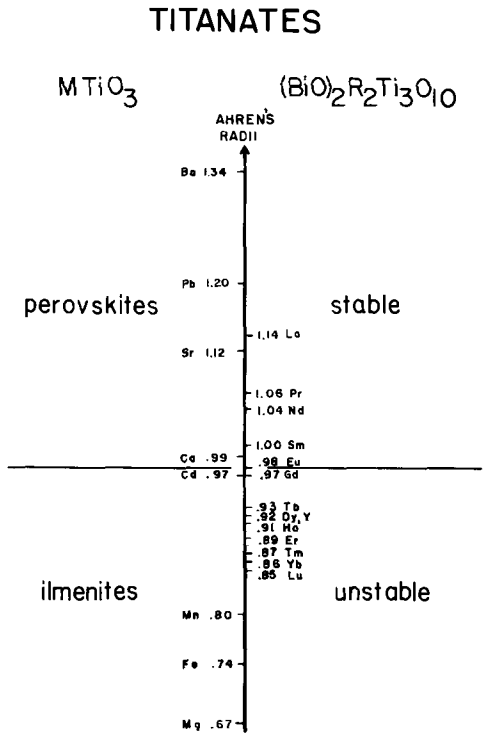

Fig. 4. Stability fields of the divalent-ion titanates and the rare earth bismuth titanates of composition $Bi_2R_2Ti_3O_{12}$.

Orthorhombic cell dimensions for a few rare earth bismuth titanates are given in Table II. Comparing cell volumes, it appears that the radii of Bi^{3+} and La^{3+} are nearly equal, contrary to the Ahrens' scale which gives Bi^{3+} 0.93Å, and La^{3+} 1.14Å. The axial ratio b/a is a measure of the orthorhombic distortion; b/a decreases when any rare earth is substituted for bismuth, suggesting that the ferroelectric transition temperature is lowered.

Curie temperatures of the rare earth bismuth titanates were determined by differential thermal analysis using Al_2O_3 as a reference material, and the α- to β- quartz transition as a calibrant. As shown in Fig. 5, T_c decreases linearly with increasing rare earth concentration x. The effect is more pronounced with large ions like La^{3+}, showing that T_c depends on rare earth ion radius r as well as composition x. Analytically, the straight lines in Fig. 5 are given by

$$T_c = 660° - A(r)x$$

To determine the dependence of T_c on radius r, the slopes $-A(r)$ are plotted against r in Fig. 6. This too yields a straight line

$$-A(r) = M(r - r_o)$$

where $M = 5.47°C$ and $r_o = 0.83Å$. Thus the transition temperature depends linearly on the product $(r - r_o)x$

$$T_c = 660° - 5.47\ (r - 0.83)x \qquad [1]$$

This equation is plotted in Fig. 7 along with a number of experimental points. The agreement verifies that Eq. [1] is valid for any rare earth R and any composition $Bi_{4-x}R_xTi_3O_{12}$.

The one-dimensional models shown in Fig. 8 can be used to explain the dependence of T_c on x and r.

Figure 8a shows a polar chain which is schematically representative of bismuth and oxygen atoms in ferroelectric $Bi_4Ti_3O_{12}$. Because of its nonspherical electron configuration, Bi^{3+} prefers an asymmetric arrangement of oxygen neighbors. This is true in many oxides of trivalent bismuth and isoelectronic Pb^{2+}. In $Bi_4Si_3O_{12}$, for example, each bismuth is coordinated to six oxygens, three on one side at 2.15Å and three on the other at 2.62Å, a marked difference in bonding.

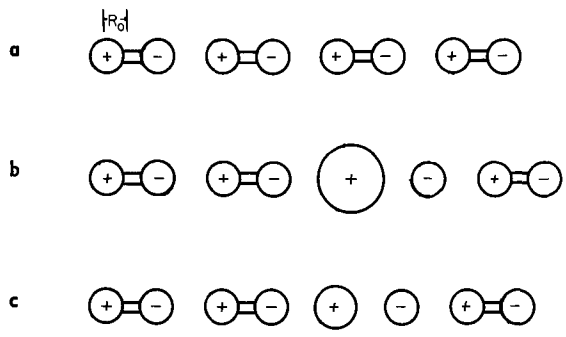

Fig. 8. One-dimensional model of bismuth and oxygen atoms in $Bi_4Ti_3O_{12}$ showing the effects of rare earth substitution.

Using 1.32Å as the ionic radius of oxygen, the shortest distance yields a Bi^{3+} radius of 0.83Å, very close to the critical radius r_o in Eq. [1].

Figure 8b shows the polar chain with a large rare earth atom replacing a bismuth atom. The substitution has two effects on the polar chain. First, the introduction of a symmetrical atom into the chain weakens the ferroelectric interactions of the bismuth atoms simply by reducing their number; this is the compositional dependence. Second, the large effective size of the substituting atom separates the bismuth atoms even further; this is the radius effect. Figure 8c shows a polar chain in which a small rare earth ion has replaced a bismuth atom. The compositional effect is the same, but the radius contribution to the depression of T_c is decreased. Ultimately, as r approaches r_o (the effective bismuth radius in the direction of its shortest bond length), the radius contribution goes to zero, and T_c becomes independent of composition.

Permittivity measurements as a function of temperature were made on ceramic disks of the rare earth bismuth titanates as a check on the Curie points determined by DTA.

Figure 9 shows some typical curves. The transition temperature observed for ceramic $Bi_4Ti_3O_{12}$ was 676°C, with a peak dielectric constant of 375, slightly lower than the value reported by Subbarao (8). Peak dielectric constants for all the compositions tested were in the range 300-500. The dielectric measurements consistently yielded T_c values 20° higher than those observed by DTA.

Single crystal measurements were needed to determine the true symmetry of the solid solutions since x-ray powder patterns are insensitive to the monoclinic distortion in $Bi_4Ti_3O_{12}$. The crystals were grown by the flux growth technique in which titania, rare earth oxide, and excess Bi_2O_3 were melted in a platinum crucible, brought to a peak temperature of 1250°C for 8 hr, and then cooled at a programmed rate of 2°-5°C/hr. The crystals were removed from the flux with a platinum sieve suspended in the melt. The largest plates measured 7 mm on edge and 0.5 mm thick. Crystals of composition $Bi_{3.4}La_{0.6}Ti_3O_{12}$ were chosen for optical and electrical studies.

The technique devised by Cummins and Cross (5) was used to prepare thin sections of $Bi_{3.4}La_{0.6}Ti_3O_{12}$ with the a or b axis normal to the thin section. When the crystal sections were viewed under polarized light, both a and b sections showed uniform parallel extinction. This observation strongly suggested that the

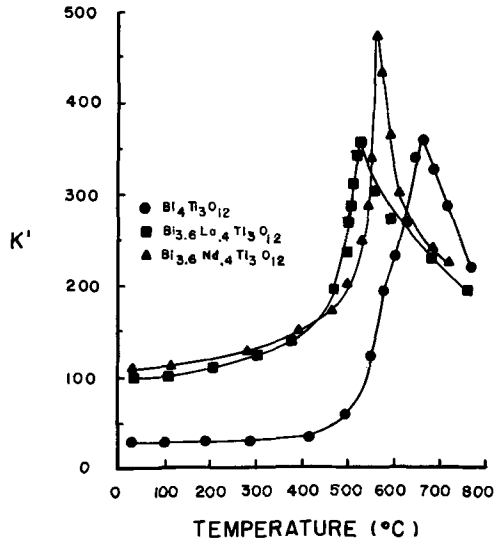

Fig. 9. Dielectric constant as a function of temperature for some rare earth bismuth titanates.

crystals possessed orthorhombic symmetry, point group mm2. Hysteresis measurements in the c direction supported this conclusion. Fields as high as 150 kv/cm failed to produce a noticeable hysteresis loop for a small single crystal; if a spontaneous polarization along c does exist it must be smaller than 0.4 $\mu C/cm^2$. This result is unfortunate since it is the component of polarization along the c direction that gives rise to the interesting electrooptical properties of $Bi_4Ti_3O_{12}$.

When the same crystal was subjected to an alternating current pyroelectric test, a small but definite signal was observed, an indication that the crystal symmetry may yet be monoclinic. Further work is underway in an attempt to determine the true symmetry of the rare earth bismuth titanates.

Effect of Polarizing Temperature on the Characteristics of SR_{10} Vinyl (PVC) Electrets

P. K. C. Pillai, V. K. Jain, and G. K. Vij

Department of Physics, Indian Institute of Technology, New Delhi, India

ABSTRACT

The results of an experimental investigation on the charge formation and decay characteristics of SR_{10} vinyl (PVC) electrets prepared at different temperatures are presented in this paper. The results show that the polarity of the final charge on either side of the electrets is positive irrespective of the polarizing conditions. It is also shown that polarizing temperature has a major influence on the behavior of vinyl electrets.

A permanently polarized dielectric, which exhibits electrical charges of opposite sign on its sides, is known as an electret (1). Recently there has been a considerable increase in the study of electret effect in solids, because of its various applications in electronics and electrical devices (2-5). The literature on electrets has been reviewed by Gutmann (6), Johnson (7), and Gross (8). Properties of electrets are known to be dependent on the properties of the electret material and also on the polarizing conditions under which the sample is fabricated (9-14).

Experimental Details

The object of this paper is to describe the effect of polarizing temperature on the decay characteristics of SR_{10} vinyl electrets. SR_{10} vinyl is a PVC compound (manufactured by Rajasthan Vinyl & Chemical Industries, Kota, India) which is found to be a good electret-forming material. This material is available in powder form. Although it does not show any definite melting point, most of the ingredients of this compound are molten at about 140°C. Above 140°C it becomes reddish in color, and at about 210°C it becomes very brittle and completely carbonized.

A special technique has been developed for the preparation of plastic electrets (9). A small quantity of this plastic powder was kept in a mica cavity of 1.0 cm^2 area and 1.0 mm thickness between two aluminum electrodes. This electret gadget with the sample was then kept in a regulated thermostat for thermal and electrical treatment. A polarizing field of 10 kv/cm was applied for 6 hr. After 3 hr of heating, the sample was allowed to cool down to room temperature while under the influence of the polarizing field. The electret molded in the mica cavity in this way was then taken out for charge measurement. The surface charge measurement was carried out by means of a Lindemann electrometer using the method of induction. After measurement the sample was short circuited by means of metallic foil and preserved in a desiccator for further studies.

Results and Discussions

The charge decay characteristics of the electrets prepared at different temperatures (30°-170°C), but with all other parameters constant, have been studied for about 30 days and the charge decays of these samples are shown in Fig. 1 to 6. It can be seen that, for the anode side of the samples prepared in the temperature range 30°-110°C, the initial charge was hetero, which reversed to homo in a few days' time except for those electrets prepared at 30° and 80°C. For the cathode sides of those samples prepared at 30°-110°C, the initial charge was hetero, which gradually decayed to a more or less permanent value in about a month without showing any charge reversal. In the second temperature range (120°-170°C), the anode side initially showed a high homocharge which gradually decayed to a constant value in about 30 days without showing any reversal of charge. But it is interesting to note that the cathode sides of these samples first possessed a homocharge which eventually reversed to a final heterocharge unlike many other electret forming materials.

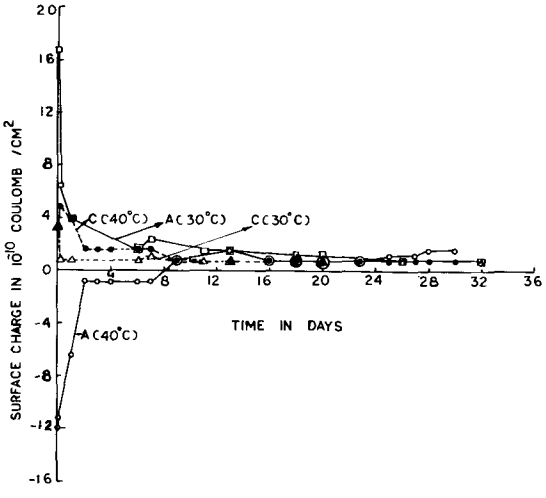

Fig. 1. Surface charge density vs. time for SR_{10} vinyl electrets prepared at 30° and 40°C with 10 kv/cm field strength in 6 hr time. Symbols used: A means anode side, and C means cathode side.

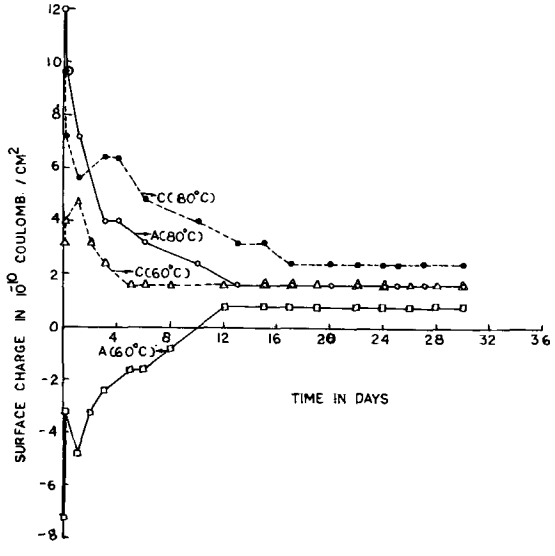

Fig. 2. Surface charge density vs. time for SR_{10} vinyl electrets prepared at 60° and 80°C with 10 kv/cm field strength in 6 hr time.

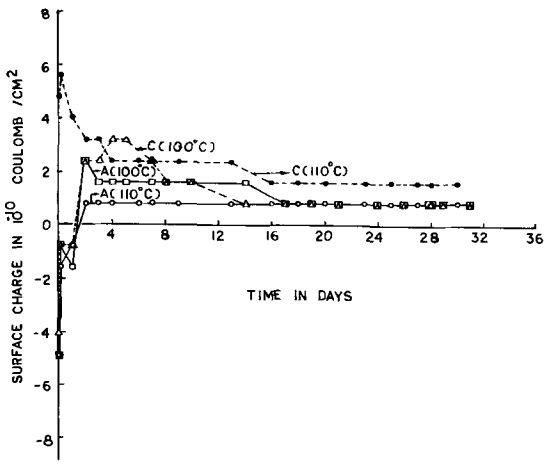

Fig. 3. Surface charge density vs. time for SR_{10} vinyl electrets prepared at 100° and 110°C with 10 kv/cm field strength in 6 hr time.

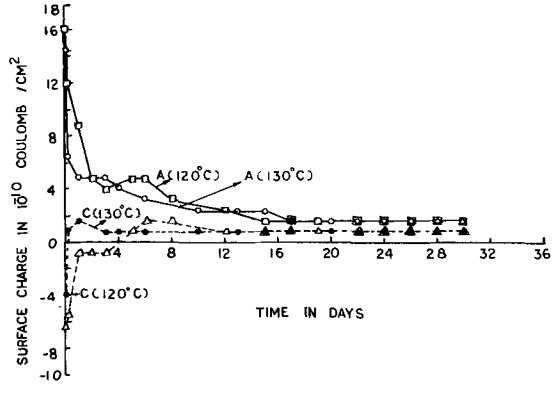

Fig. 4. Surface charge density vs. time for SR_{10} vinyl electrets prepared at 120° and 130°C with 10 kv/cm field strength in 6 hr time.

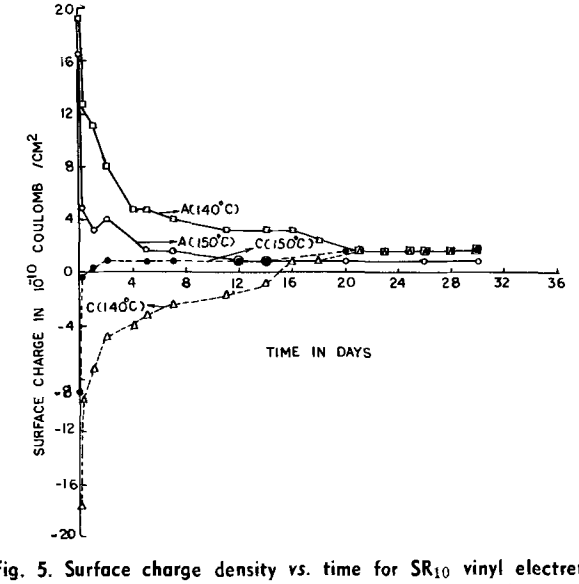

Fig. 5. Surface charge density vs. time for SR_{10} vinyl electrets prepared at 140° and 150°C with 10 kv/cm field strength in 6 hr time.

Figure 7 shows the final charge after 30 days *vs.* polarizing temperatures. These curves indicate that the final charge on either side of the various electrets has the same polarity (positive) irrespective of the forming conditions. In most of the electret forming materials, the final charges on either side are found to have opposite polarity.

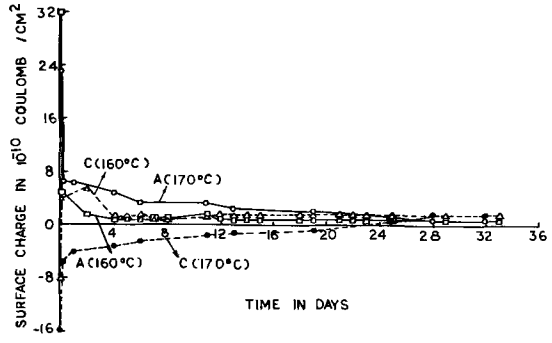

Fig. 6. Surface charge density vs. time for SR_{10} vinyl electrets prepared at 160° and 170°C with 10 kv/cm field strength in 6 hr time.

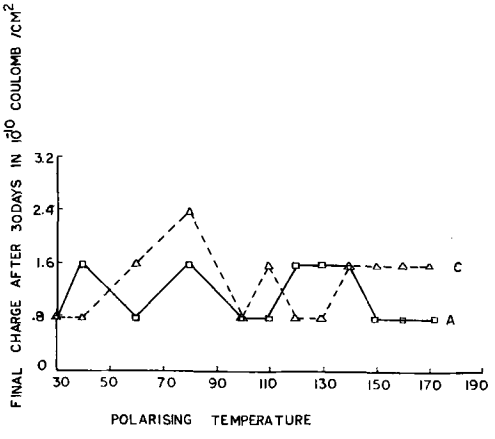

Fig. 7. Final charge density after 30 days vs. polarizing temperatures for SR_{10} vinyl electrets prepared with 10 kv/cm field strength in 6 hr time.

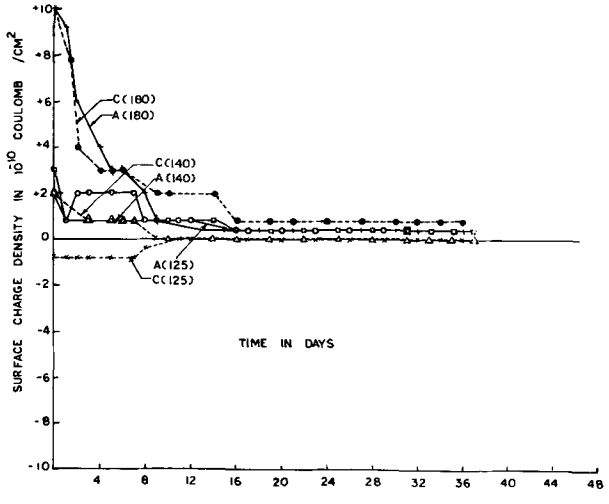

Fig. 8. Surface charge density vs. time for SR_{10} vinyl electrets formed without polarizing voltage at 180°, 140°, and 125°C.

Figure 8 shows the charge decay curves of dummy samples prepared at 125°, 140°, and 180°C without the application of polarizing field. The sample prepared at 180°C gives an initial charge of 10×10^{-10} coul/cm^2 on either side which gradually decays to a constant value of about 1.0×10^{-10} coul/cm^2 in about 15 days. The sample prepared at 140°C shows only a smaller value of about 2 to 3×10^{-10} coul/cm^2 initially and decays to about 0.75 coul/cm^2 in 15 days. But the sample prepared at 125°C did not show a permanent charge. The anode side of this sample initially showed about 2.0×10^{-10} coul/cm^2 which decayed to zero in 10 days' time. But the cathode side showed an initial homocharge of about 1.0×10^{-10} coul/cm^2 which also decayed to zero in about eleven days without any reversal of

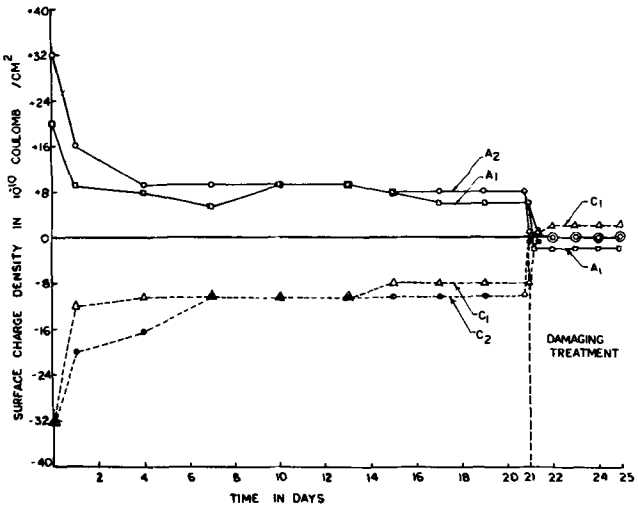

Fig. 9. Surface charge density vs. time for SR_{10} vinyl electrets prepared directly from powder at 200°C with the application of 12 kv/cm field strength. Damaging treatment *(i)* by heating and *(ii)* by dipping in water for 2 min were done on the 21st day. □ A_1, △ C_1 } corresponds to heat-treated sample; ⊙ A_2, ⊗ C_2 } corresponds to water-treated sample.

charge. It has also been noted that samples prepared at 100° and 80°C exhibited no stripping charge from the very beginning. This may be due to the lack of close contact between the dielectric and the electrode below the softening point of the electret material. These results thus show that stripping charge phenomena is temperature dependent and the magnitude is more at higher temperatures particularly above the molten state of the material.

Figure 9 shows the charge decay curves for two electrets prepared from SR_{10} vinyl. The samples were prepared directly from the powder by heating at 200°C for 3 hr under an electric field of 12 kv/cm, and then cooled down to room temperature in about 3 hr. When the charge becomes permanent, the following two types of damaging treatments were performed on the 21st day to see whether the SR_{10} electrets are good at recovering their charge after damaging treatment.

One of the samples was heated for an hour in a thermostat at 140°C and, when the sample cooled down to room temperature, the charge on either side was measured for a few days. The charges on either side were found to be reversed, and the magnitudes of charge were also reduced considerably. With time the charges gradually increased to about $2.0\text{x}10^{-10}$ coul/cm^2 after reversal (Fig. 9).

The second electret was dipped in water for 2 min, and then it was allowed to dry. On measurement for a few days, no surface charge was obtained from this sample (Fig. 9). It indicated that penetration of water into the sample damaged the electret almost permanently without regaining either hetero or homocharge. The same result was obtained with another sample after performing the same type of damaging treatment.

The above experiments show that recovery of heterocharge is possible at least partially for the sample treated at high temperature. But for the other sample, water penetration seems to have spoiled both the internal and the external polarizations, and no recovery of charge was detected for four days.

Dummy samples were also prepared without any metallic electrode and without the application of polarizing field at 145°C, and it was found that such samples did not show any charge. These experiments indicate that the presence of a metallic electrode is highly essential for obtaining a molding charge and also for the formation of an electret.

Comparing the charge decay characteristics of the zero field samples to those with field at low and high temperatures, it can be seen that polarizing field has played a major role in the formation and characteristics of SR_{10} vinyl electrets. Charge formation below 100°C is mainly due to the influence of polarizing field as zero field samples did not show any final charge at these low temperatures. However, contribution due to molding charge plays an important role at and above the molten state of the electret material.

It can be seen from Fig. 5 that the anode side of electret prepared at 140°C with 10 kv/cm field gives an initial charge of $18\text{x}10^{-10}$ coul/cm^2 in comparison to $3\text{x}10^{-10}$ coul/cm^2 of the dummy sample (Fig. 8) prepared without field. The zero field sample gives a final charge of about $0.75\text{x}10^{-10}$ coul/cm^2 after 30 days whereas the other one gives about $2.0\text{x}10^{-10}$ coul/cm^2. But the cathode side of the sample without field gives an initial heterocharge of $2\text{x}10^{-10}$ coul/cm^2 whereas the sample with field shows about $18\text{x}10^{-10}$ coul/cm^2 homocharge initially which reversed to hetero with time and assumes the final value of about $2.0\text{x}10^{-10}$ coul/cm^2. But the anode side does not show such reversal of charge. This indicates that the polarizing field and polarizing temperature have major influence on the formation and characteristics of SR_{10} vinyl electrets. It also shows that the charge obtained with both zero field samples and the samples with field are not merely due to the contact electrification between the induction electrode and the dielectric surface as indicated by Donald (16) during measurement.

The curves in Fig. 7 again show that the cathode side always gives a final heterocharge whereas the anode side shows a final homocharge. It would be difficult to explain these typical charge formation characteristics of the SR_{10} vinyl electrets on the basis of the two-charge theory of Gross (15) alone. Since the cathode side always shows a final heterocharge, it can be assumed that this material contains more positive ions which under the influence of the electric field must have collected on the cathode side and produced an excessive positive charge on that surface. Charge due to dielectric polarizations as well as various mechanisms for transferring charge across the electret-electrode gap may also be simultaneously existing and the observed charge may be the resultant of all these contributions. Thus the effective charge of electret at any instant can be expressed analytically by the following equation.

$$\sigma_E = \sigma_D + \sigma_i + \sigma_{\text{Homo}} + \sigma_M$$

where σ_E is the effective surface charge of the electret; σ_D is the contribution of charge due to dipolar orientation; σ_i is the component due to ionic polarization produced by opposite displacements of positive and negative ions in the material; σ_{Homo} is the contribution of charge due to external polarizations; and σ_M is the charge due to molding and stripping. The sign, magnitude, and the time constants of each of these components decides the magnitude and sign of the effective charge of an electret.

Summary and Conclusions

From this investigation the following conclusions can be drawn.

(i). SR_{10} vinyl is found to be suitable for electret preparation.

(ii). 80° and 140°C are found to be good polarizing temperatures for the fabrication of vinyl electrets with stable surface charge characteristics.

(iii). The cathode sides of all the electrets prepared above 120°C give an initial homocharge which eventually reverses to a permanent heterocharge, a fact which is not observed normally with other electret forming materials. But the cathode sides of all the samples prepared below 120°C show a high initial heterocharge which slowly decays to a permanent value without any reversal of charge. This result indicates the influence of polarizing temperature on the

behavior of electrets, especially in determining the polarity of the final charge.

(*iv*). The initial charge on the anode side of all the samples is found to be more than that of the cathode side. This may be due to the fact that charge measurements on the anode side was carried out first, and, as the charge decay is very rapid initially, some charge on the cathode side must have been decayed before the actual measurement on that surface has been made. This effect could also be partially due to contact electrification which can occur when the polarizing electrode is removed from the electret.

(*v*). The polarity of the final charge on either side of all the electrets is found to be positive irrespective of the polarizing conditions.

(*vi*). The charge decay characteristics of electrets prepared directly from powder under an electric stress (Fig. 9) is found to be very much different from those prepared from a molded sample (Fig. 1-6).

(*vii*). It is again shown in Fig. 8 that charged samples can be prepared by thermal treatment alone without the application of a polarizing field. But the magnitude and stability of charges of these samples are not as good as those obtained from the electrets prepared with a forming field. This result thus clearly shows that polarizing field plays an important role in the formation of a stable electret.

Characteristics of $Ba_2NaNb_5O_{15}$ for Optical Switching and Harmonic Generation

R. R. Rice,[1] H. Fay, H. M. Dess,[2]* and W. J. Alford

Union Carbide Corporation, Electronics Division, Crystal Products Department, San Diego, California

ABSTRACT

The optical quality of large single crystals of $Ba_2NaNb_5O_{15}$ grown by the Czochralski process has been studied. Crystals pulled along the a axis appear more attractive than those pulled along the c axis for both electrooptic and nonlinear applications. The 0.528μ second-harmonic beam divergence is slight in a-axis crystals, but is severe in c-axis crystals. Using a-axis crystals, extinction ratios of 13-17 db were obtained over apertures on the order of 1 mm. The extinction is limited by inhomogeneity in the passive birefringence due to slight gradients in the refractive indices.

Several ferroelectric niobates of the tungsten bronze structure have been synthesized as single crystals by Rubin, Van Uitert, and Levinstein (1). Compositions such as $Ba_2NaNb_5O_{15}$ that have filled A-sites are said to be resistant to the type of optical damage observed in $LiNbO_3$. The properties of $Ba_2NaNb_5O_{15}$ have been investigated by Geusic and co-workers, and it was reported that $Ba_2NaNb_5O_{15}$ crystals suffered no optical damage even under intense irradiation at 0.53μ (2). The useful nonlinear coefficients of $Ba_2NaNb_5O_{15}$ crystals are approximately twice those of $LiNbO_3$. The conversion efficiency for second harmonic generation has been found to approach 100% under optimum conditions, and continuous parametric oscillation has also been observed (3-5). The half-wave retardation voltage for optical switching was found to be conveniently low, the field distance product being about 1500v in the optimum direction (6).

Since $Ba_2NaNb_5O_{15}$ ideally has such interesting properties, a great deal of effort at various laboratories has been devoted to its growth, characterization, and improvement. This paper describes the authors' efforts to grow and characterize single crystal $Ba_2NaNb_5O_{15}$. The most serious problem in the growth and application of $Ba_2NaNb_5O_{15}$ has been that of obtaining good optical quality. The authors have attempted to improve the optical quality of this material by using various growth procedures and to characterize the performance of optical components fabricated from existing material.

Growth and Preparation

Large single crystals of $Ba_2NaNb_5O_{15}$ can be grown from the melt by the Czochralski technique. The melting point is approximately 1450°C (uncorrected pyrometer reading) and is essentially unaffected by slight changes in melt composition or gross changes in ambient atmosphere. The melt can be established and maintained in platinum crucibles by inductive coupling of the crucible to an r-f generator. Single crystals are grown by nucleation on a seed crystal and pulling the seed from the melt. In a typical growth run, the crystal is pulled into a neutral or oxidizing atmosphere at a rate of 5-15 mm/hr with a rotation rate of about 30 rpm. An electrically heated afterheater is located over the melt so that the crystal can be cooled slowly after termination of the growth, in order to reduce cracking. Crystals can be pulled along either the a or c direction by approximately the same technique, although the a-axis crystals have a somewhat greater tendency to crack. Figure 1 shows two representative a-axis and c-axis boules. Typical boule dimensions are 1 x 5 cm.

Boules of $Ba_2NaNb_5O_{15}$ consist of many ferroelectric domains as shown by the earlier studies (7). The domain structure in both a- and c-axis crystals consists of stacked concave disks in which the polarization is oppositely directed. The domain structure in c-axis $Ba_2NaNb_5O_{15}$ can be readily observed by polishing or lightly etching with HF normal to the growth direction. The domains may be detected similarly in a-axis boules, but they are more difficult to observe. The domain thickness in both a- and c-axis crystals varies from approximately two to ten microns. To be useful as an active optical component a crystal must first be converted to a single ferroelectric domain by an appropriate poling procedure. Both a- and c-axis crystals can be completely poled by the same procedure which consists of applying a field in excess of 100 v/cm along the c direction near the Curie temperature. The field can be applied a few degrees below the Curie point for a sufficient period, or the crystal can be cooled through the Curie point under field. The authors prefer the latter procedure.

Since $Ba_2NaNb_5O_{15}$ is an orthorhombic crystal (2 mm) below about 300°C, it becomes finely twinned whenever the boule is cooled below this temperature. Detwinning is accomplished after poling by applying a compressive mechanical stress along one of the principal orthorhombic directions (a or b) perpendicular to the tetragonal c direction, to reorient the undesired twins. As in the case of $LaAlO_3$ (8), detwinning can be accomplished at room temperature by the application of sufficient stress. It can also be accomplished by the application of a milder stress at elevated temperatures. Typical stress requirements are 30,000 to 50,000 psi at 25°C, 10,000 psi at 175°C, or less than 100 psi at 300°C. The detwinned crystal is sufficiently stable so that it can be subsequently cut and polished without reintroducing the twins. However, reheating the crystal to 300° will cause the twins to recur.

Characteristics

The dielectric properties of many $Ba_2NaNb_5O_{15}$ boules have been measured from room temperature to 600°C. The real part of the dielectric constant along the c direction rises from about 50 at 25°C to as high as 70,000 at the Curie point, as shown in Fig. 2. The imaginary part also rises with temperature and attains a maximum at the Curie point. There appears to be no dielectric anomaly at the orthorhombic-tetragonal transition near 300°C. Figure 2 shows the dielectric constant at 10 kHz along the c direction as a function of temperature for one particular specimen. The reciprocal is also plotted to show how well the Curie-Weiss law is obeyed above T_c. The value of T_c can be reproduced to within 1°C and is probably accurate to within a few degrees.

The Curie point was found to be sensitive to composition. When spectroscopic grade $Ba(NO_3)_2$ and $NaNO_3$ were used as starting materials, the authors found the Curie point to be near 560°C, as reported by Van Uitert. However, when reagent grade nitrates were used, the Curie point rose to 580°C. In both cases, the same source of Nb_2O_5 was used. Analysis of the powders used are reported in the Appendix.

The effects of doping stoichiometry and growth orientation were studied. Ta_2O_5 was added up to 5 w/o, and excesses of up to 10 a/o Na_2O, BaO, and Nb_2O_5 were made in various melts. The Curie point is depressed about 8° per m/o Ta_2O_5 added to the melt, indicating the formation of a continuous solid solution as in the case of KTN. The Curie point was found to be slightly depressed in crystals pulled from off-stoichiometry melts. Chemical analyses did not reveal any significant variations in the stoichiometry of crystals pulled from melts of different compositions. This is similar to the results found for $LiNbO_3$ (10).

There are four types of optical aberration in $Ba_2NaNb_5O_{15}$ which tend to restrict the usefulness of crystals for electrooptic or nonlinear applications. The most persistent defects are growth striations which appear to some extent in all crystals. A second more subtle optical defect is a refractive index variation parallel to the growth direction which is observable as bands parallel to the growth axis. A third type of defect is a slow variation of refractive index which produces interference fringes when a crystal with flat and parallel faces is used as a Fabry-Perot etalon in a laser beam. A fourth type of defect, seen only occasionally, is a gross localized refractive index anom-

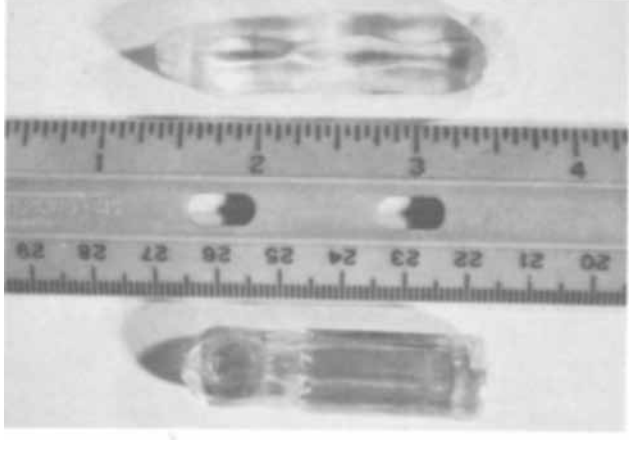

Fig. 1. Typical boules of Czochralski-grown $Ba_2NaNb_5O_{15}$ pulled along the a axis (top) and along the c axis (bottom).

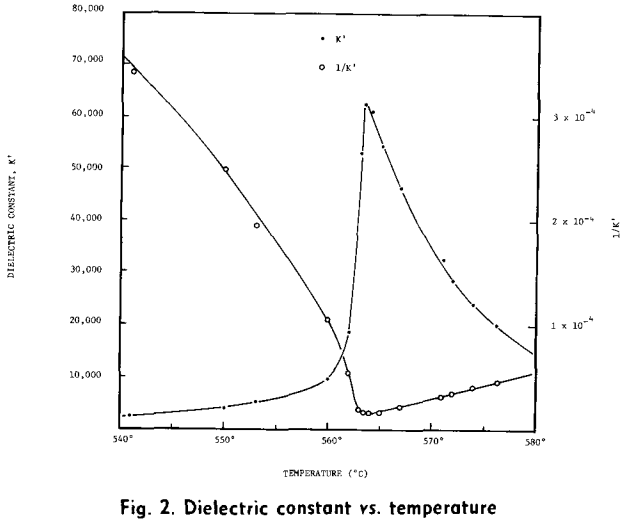

Fig. 2. Dielectric constant vs. temperature

aly which may appear quite different when viewed under different polarizations.

The growth striations are periodic variations of refractive index normal to the growth direction. Under certain growth conditions, the spacing of the striations is perfectly regular and is usually between 5 to 10μ. The growth striations appear to be identical in crystals pulled along either the a axis or the c axis. The appearance of the growth striations and other refractive anomalies in the crystal is strongly dependent on the polarization of the transmitted light. The striations appear in sharpest relief when the light is propagating along the a or b axis and is polarized along the c axis. The striations nearly vanish when viewed in light propagating along a, polarized along b, or *vice versa*.

In both electrooptic and nonlinear applications the incident beam is directed normal to the c axis. This requires that the light pass along or between the growth striations in a c-axis crystal and normal to the striations in an a-axis crystal. Light is refracted and diffracted by these index variations, and the aberration can be appreciable in a c-axis crystal when the beam passes parallel to the striations. This may cause a deleterious affect on the performance of an optical component. In an a-axis crystal, the beam passes normal to the striations, and the aberration is much less severe.

Optical defects cause an increase of beam divergence when a collimated beam of light is transmitted through the crystal. The beam divergence introduced by a-axis crystals differs markedly from that produced by c-axis crystals. Figure 3 shows the effect of inserting optically finished crystals of both orientations into a He-Ne laser beam. In all cases the light was propagated perpendicular to the c axis. For the c-axis crystal this direction is along the striations, and the beam is degraded appreciably by diffraction in the crystal. In the a-axis crystal the beam is propagated in the growth direction, thus, normal to the striations, and the beam divergence is much less. The incident light is polarized along c on the right, at 45° to c in the center, and along a on the left. The photographic plate was at a distance of 3m from the crystal. The most severe effect is seen for light polarized along c, which is the polarization direction of the harmonic wave in second-harmonic-generation experiments when the incident wave is polarized normal to c. Figure 4 shows actual 0.528μ second-harmonic spots obtained with a- and c-axis crystals at a distance of 3m from the crystal with a lens after the crystal to collimate the harmonic beam. The harmonic beam generated by the c-axis crystal suffers severe distortion, and the spot is degraded into a line. The spot obtained with the a-axis crystal shows some loss of definition, but the effect is not nearly so severe as in the c-axis crystals.

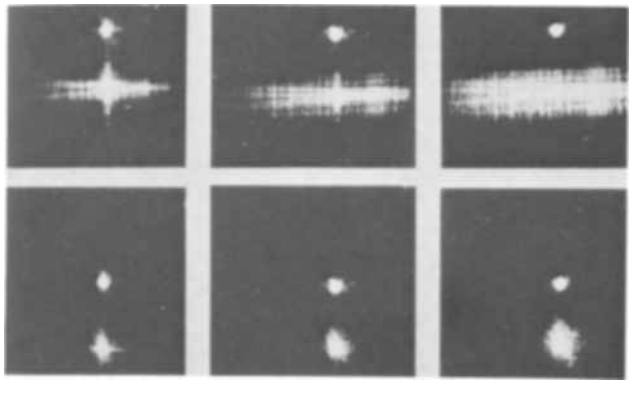

Fig. 3. Distortion of He-Ne laser beam by transmission through c-axis crystals (upper) and a-axis crystals (lower) of $Ba_2NaNb_5O_{15}$. The uppermost spot in all photographs is that produced by the laser alone; the lower image is the beam after passing through the crystal. The c axis is horizontal. The incident light is polarized parallel to c (right), at 45° to c (center), and normal to c (left).

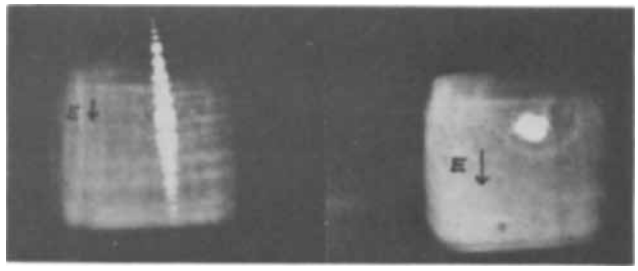

Fig. 4. Photographs of 0.53μ harmonic beam generated by passing 1.06μ laser beam into c-axis (left) and a-axis (right) crystals of $Ba_2NaNb_5O_{15}$. A lens was used to collimate the harmonic beam. The distortion of the spot indicates the beam divergence at the plane of the lens.

Crystals of $Ba_2NaNb_5O_{15}$ are very good harmonic generators for 1.06μ Nd:YAG laser radiation. About 20 mw of 0.528μ second harmonic radiation was produced in an early experiment using a rather poor a-axis crystal without antireflection coatings. No optical damage was induced in the crystal at this power level, nor was damage reported by Geusic for the much higher power levels obtained with selected crystals. Some differences have been observed in the phase-matching temperature (PMT) of crystals studied at this laboratory. Some crystals have a PMT as high as 125°C, while others grown from purer melts have a PMT as low as 80°C. The PMT and the Curie point show a definite correlation. Crystals having a Curie point near 580°C have a PMT near 80°C. The precise PMT obtained for a given crystal is very sensitive to the presence of slight impurities in the starting materials.

In a typical electrooptic experiment the incident collimated light propagates down the a or b axis polarized at 45° to the c axis, and the switching field is applied along the c axis. The field distance product for half wave retardation has been reported as 1570 and 1720v for light propagating along a and b, respectively (2). This compares favorably to the 2800-3000v obtained with $LiNbO_3$ and $LiTaO_3$. The authors have obtained a lowest value of about 1250v for light propagating down the a axis for the best crystals examined.

To be useful for electrooptic applications, $Ba_2NaNb_5O_{15}$ crystals must show a high extinction ratio over a reasonable aperture. An indication of the useful aperture can be obtained by an examination of the passive interference patterns observed when an optically finished crystal is illuminated by parallel coherent light between polarizing prisms. Figure 5 shows three such interference patterns obtained for a typical a-axis crystal. The b axis, which

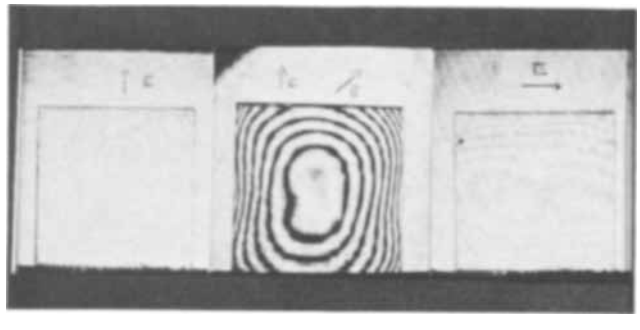

Fig. 5. Interference patterns produced by a crystal of $Ba_2NaNb_5O_{15}$ illuminated by parallel coherent light between polarizing prisms. The direction of the E field and the c axis are indicated. The outer images show etalon fringes due to variations in n_z and n_x, respectively. The central image shows fringes due to variations in the birefringence, n_z-n_x.

for this crystal is the growth direction, is the direction of light propagation for the three cases shown. On the left the prisms are set parallel to c, and the interference pattern results from a spatial variation in n_z. On the right the prisms are set parallel to a, and here the interference pattern is the result of a spatial variation in n_x. The variations in n_x and n_z combine to produce a net spatial variation in birefringence B_y across the face of the crystal, which is observed directly when the prisms are set at 45° to c, as shown in the center photograph.

The birefringence interference pattern shows high contrast, but the interference patterns due to variations of n_x and n_z are faint. This is because the birefringence pattern is formed by waves which make a single transit through the crystal, whereas the interference patterns observed for polarizations along a and c are formed by waves which are incompletely reflected from the crystal faces an odd number of times. The wave amplitude decreases with each reflection, hence complete cancellation does not occur. The crystal is a Fabry-Perot resonator or "etalon." The interference patterns shown in Fig. 5 are rather typical of good a-axis crystals viewed down the growth axis. Note that, while the spatial variation in n_z and n_x is different, the birefringence exhibits a nearly radial variation. The birefringence patterns observed for c-axis crystals, viewed normal to the growth axis, show fringes which are broken up by the growth striations.

The electric field dependence of n_x and n_y can be measured directly. The intensity an etalon fringe will go from maximum to minimum as the optical length of the crystal changes by one-quarter wavelength. The applied field necessary to change the optical length of the crystal by $\lambda/4$ can be easily calculated from the crystal dimensions and the electrooptic coefficients. When the light propagates down b polarized parallel to c, one has

$$2\epsilon_o n_z^3 z_{33}^o = \lambda_o/(E_3 \cdot l_2) \quad [1]$$

Likewise, when the light propagates down b polarized parallel to a, one has

$$2\epsilon_o n_x^3 z_{13}^o = \lambda_o/(E_3 \cdot l_2) \quad [2]$$

Here z_{ij}^o is defined as $\partial\beta_i/\partial E_j$, where β_i is a principal optical impermeability coefficient, λ_o is the free space wavelength of the light, and l_2 is the length of the crystal in the b direction. The quantity $(E_3 \cdot l_2)$ is the field-distance product that induces a change in optical length of $\lambda/4$. A change in relative retardation of one halfwave is required to change the intensity of the fringes in the birefringence interference pattern from maximum to minimum and *vice versa*. For light propagating down b polarized at 45° to c, the halfwave field-distance product obeys the equation

$$\epsilon_o(n_z^3 z_{33}^o - n_x^3 z_{13}^o) = \lambda_o/(E_3 \cdot l_2) \quad [3]$$

By measuring these three different values of $(E_3 \cdot l_2)$ one can independently determine z_{13}^o and z_{33}^o from Eq. [1] and [2] and determine their relative signs from Eq. [3].

The three values of $(E_3 \cdot l_2)$, for a particular crystal of $Ba_2NaNb_5O_{15}$, have been measured to be 535, 1400, and 1600v, respectively. The corresponding electrooptic coefficients are

$$\begin{aligned} \epsilon_o n_x^3 z_{13}^o &= 2.3 \times 10^{-10} \text{ m volt}^{-1} \\ \epsilon_o n_z^3 z_{33}^o &= 5.9 \times 10^{-10} \text{ m volt}^{-1} \\ \epsilon_o(n_z^3 z_{33}^o - n_x^3 z_{31}^o) &= 3.9 \times 10^{-10} \text{ m volt}^{-1} \end{aligned} \quad [4]$$

The latter value has been determined from Eq. [3] but can be computed using the results of applying Eq. [1] and [2]. This procedure leads to a value of 3.7 x 10^{-10} m volt^{-1}, which agrees well with the directly measured value and shows that z_{13}^o and z_{33}^o have the same relative sign. The values given in Eq. [4] agree within the limits of experimental uncertainty with those reported by Geusic *et al.* (2) on crystals of $Ba_2NaNb_5O_{15}$ synthesized by them.

The extinction ratio for electrooptic switching has been measured for a number of crystals. The values obtained depend strongly on the aperture used for the measurement. The highest values are obtained when the beam passes through the central region of the passive birefringence pattern shown in Fig. 5. With an effective aperture of 1 mm^2, extinction ratios of 13-17 db have been measured in this central region. When larger apertures are used, or the aperture is moved to a different region of the crystal, the extinction ratio degrades rapidly due to the nonuniformity of the passive birefringence. By observing the entire crystal with the d-c halfwave voltage applied, or by applying an a-c signal with a peak-to-peak voltage corresponding to a full wave of retardation, it may be shown that the electrically induced birefringence is essentially homogeneous throughout the crystal. The extinction ratio is determined by the inhomogeneity of the passive birefringence and thus could be improved greatly if these variations could be compensated by special wave plates or other means.

Summary

The quality of $Ba_2NaNb_5O_{15}$ crystals produced by Czochralski pulling along the crystallographic a- and c-axis directions has been compared. Both types of crystal exhibit striations and slight variations in index of refraction, Curie temperature, and phase-matching temperature. The optical behavior of a-axis crystals is superior to c-axis crystals since the light is propagated normal to the striations and thus suffers less beam divergence. The Curie and phase-matching temperatures and the electrooptic coefficients have been measured and found to agree with previously reported values. With a 1 mm^2 aperture extinction ratios of 13 to 17 db have been measured in the central region of the interference pattern. The extinction is limited by the inhomogeneity of the passive birefringence.

The Epitaxy of ZnSe on Ge, GaAs, and ZnSe by an HCl Close-Spaced Transport Process

H. J. Hovel* and A. G. Milnes*

Carnegie-Mellon University, Pittsburgh, Pennsylvania

ABSTRACT

The epitaxial growth of ZnSe is described on (111) oriented substrates of Ge, GaAs, and ZnSe, using a close-spaced HCl transport process. Single-crystal layers of 1-350μ in thickness were obtained at growth rates of 0.5-160 μ/hr and substrate temperatures of 550°-680°C. Both the surface appearance and the growth rate were found to depend strongly on the substrate material. For ZnSe layers grown on Ge, cracking caused by temperature coefficient differences may occur, but can generally be suppressed by using a slow cooling process. Resistivities of 10^3 ohm-cm were obtained using Ga as the n-type dopant accompanied by a zinc-rich ambient.

Description of the Growth System

Several vapor phase processes have been used for the epitaxy of ZnSe, including open tube transport in pure H_2 (1) and iodine disproportionation (2). An open tube HCl process has also been described (3); however, relatively large HCl concentrations (10-15%) were required to produce the desired growth rates, while secondary constituents such as iodine were used to prevent substrate etching.

A close-spaced epitaxy technique (4) using HCl was chosen for this work because of its inherent high efficiency and flexibility. A diagram of the growth system is shown in Fig. 1. The "close-spaced" term refers to the area encircled at the lower center, where the source and substrate are held rigidly between oxidized Si blocks and separated by a quartz spacer of 10-12 mils. The upper and lower blocks are heated independently by infrared lamps and the temperatures regulated by thermocouples, enveloped inside quartz fingers, which are inserted into the blocks and lead out to SCR (Thyristor) controllers. During growth, 620°-760°C is established at the source and 550°-680°C at the substrate, with a maximum obtainable temperature difference of approximately 120°C.

High-purity HCl (Precision Gas Company) and palladium-diffused H_2 are mixed at flow rates of about 20 and 1000 cc/min, respectively. A large fraction (98-99%) of this mixture is "dumped" (exhausted out of the system) and the remainder admitted into the growth tube, bypassing the zinc to prevent reaction with the HCl. (The zinc is used in the doping procedure after the layer has been grown.) A second H_2 input introduces H_2 at 100-200 cc/min, diluting the final mixture in the tube to HCl concentrations of 0.01%; even lower concentrations are possible at the cost of higher flow rates. Low HCl concentrations were necessary to prevent etching of Ge substrates. The system was run at just slightly greater than atmospheric pressure, as determined by the height of H_2SO_4 and H_2O in the exhaust line.

In order to eliminate possible sources of contamination resulting from reaction with HCl, all parts of the system coming into contact with it were constructed of Pyrex, quartz, and inert plastics, such as Teflon and Kel-f. Many of the glass connections were made into solid pieces by glass working techniques, and the remaining intersections were made with Teflon fittings (Beckman Company). The use of H_2O, H_2SO_4, and a cold trap in the output sections prevented the diffusion of contaminants into the system from the atmosphere

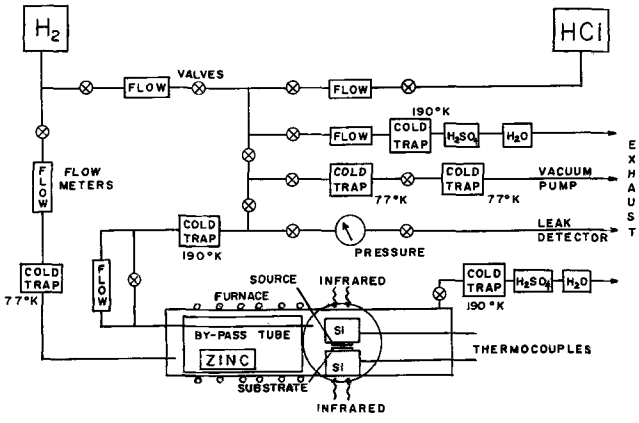

Fig. 1. ZnSe growth system

* Electrochemical Society Active Member.

and eliminated the corrosive gases from the exhaust line. Just prior to growth, all connections were checked for leaks using helium leak detection techniques. H_2 was then passed through the system at high flow rates, while heating the quartz reaction tube and zinc to 350°C, to eliminate water vapor and oxygen. These precautions minimized the possibility of unwanted impurities in the growths.

Source Preparation

The ZnSe used as the source material was purchased in the form of high resistivity (10^8-10^9 ohm-cm) ingots of large crystal grain size (Eagle-Picher Company). Doping of the sources was performed by cutting the ingot to 0.050-in. thick slices and sealing these under vacuum (10^{-6} mm Hg) in an ampoule containing zinc and an n-type dopant such as high-purity aluminum, gallium, or indium. (Contact with molten zinc during doping suppresses zinc vacancies and may also getter metallic impurities from the ZnSe.) The ampoule was then held at a temperature in the range 900°-1050°C for a period of 4-7 days. After cooling to 700°C the sealed ampoule is tipped upside down to pour off the zinc and allowed to cool. Any traces of zinc remaining on the ZnSe may be etched off with HCl.

For aluminum as the dopant the ZnSe showed electron concentrations in the low 10^{18} cm^{-3} and mobilities (300°K) in the range 100-200 cm^2/volt-sec. For gallium the concentrations were typically from 2 x 10^{16} to 10^{17} cm^{-3}, depending on the doping temperature, and the mobilities were 300-500 cm^2/volt-sec; the lower mobilities were associated with the higher doping densities. For indium the concentrations were usually about 2 x 10^{16} cm^{-3} and the mobilities about 400 cm^2/volt-sec. Zinc with no Al, Ga, or In present produced electron concentrations of just under 10^{16} cm^{-3} with mobilities of 350-550 cm^2/volt-sec.

For use as a source the ZnSe slice was mechanically lapped, followed by cleaning in acetone and methanol. Just prior to loading the slice was etched for several minutes in bromine-methanol solution and quenched in methanol.

Substrate Preparation

Germanium substrates were cut and mechanically lapped to a 1μ finish, then mounted on quartz disks and polished to scratch-free, mirror smoothness using an NaOCl process (5). The samples were then cleansed in boiling trichloroethylene, acetone, and methanol and finally etched in modified Superoxol (1HF: $1H_2O_2$: $4H_2O$): (20 H_2SO_4) in a rapidly rotating beaker in order to remove several microns from the Ge surface, removing any shallow surface damage and providing an initially clean surface.

Substrates of GaAs were polished satisfactorily by mechanical lapping to 0.05μ, then heating in 10 H_2O: 1NaOCl for 1 hr at 60°-70°C, removing about 0.5 mils of material and producing mirror smooth surfaces. ZnSe substrates were prepared by the same mechanical lapping followed by a 10-15 min etch in a rapidly rotating beaker of bromine-methanol solution. The amount of material removed by this etch is determined by the bromine concentration, and can be varied over a wide range.

ZnSe *Epitaxial Layers*

Single-crystal layers of ZnSe have been grown on (111) oriented substrates of ZnSe, GaAs (B face), and Ge using both pure H_2 and H_2-HCl atmospheres. Strong dependence of the growth rate on the substrate material was observed; the rates were typically 10-40 times higher on Ge than on either of the other two materials. This can probably be attributed to a chemical reaction occurring between the Ge and the reaction products from the ZnSe etching.

Figure 2A shows the surface of a 15μ ZnSe layer grown under "fast" conditions, *i.e.*, high growth rates and high HCl concentrations. A large density of irregular stacking faults is apparent. The reason for this

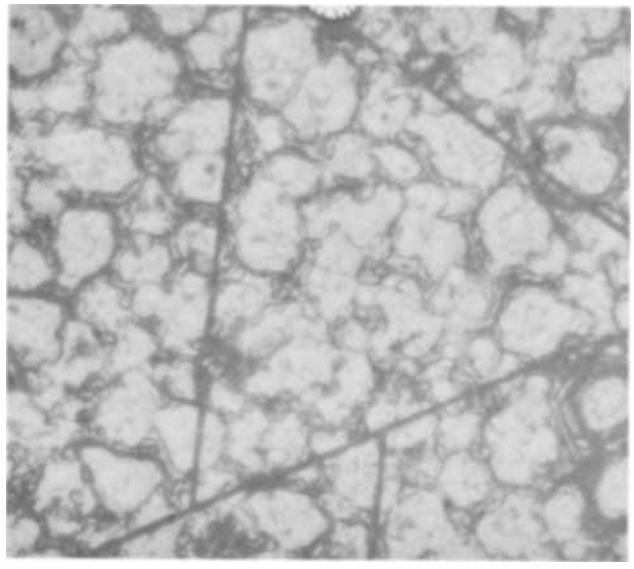

Fig. 2A. ZnSe surface under fast growth conditions: source temperature 640°C; substrate temperature 570°C; 15 μ/hr; 0.2% HCl; Magnification 300X.

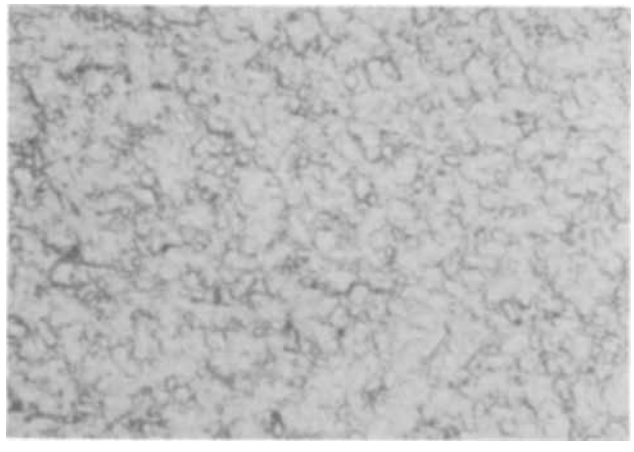

Fig. 2B. Ge surface after removal of ZnSe layer in Fig. 2A, showing deteriorated surface. Magnification 300X.

is revealed in Fig. 2B, which shows the Ge surface after removal of the ZnSe layer by bromine-methanol solution, which does not affect the Ge. The Ge has been severely etched (½ mil, roughly, in depth) by the simultaneous action of HCl and H_2Se (one of the ZnSe-HCl reaction products) during the initial stages of the ZnSe growth.

The situation is greatly improved by lowering the concentrations of these etching gases. Figure 3A shows the surface of a ZnSe layer grown under "slow" conditions, an order of magnitude reduction in both the growth rate and HCl concentration. The layer is well oriented, single-crystal material, although a relatively high density of triangular stacking faults is observed. The Ge surface after removal of the ZnSe is shown in Fig. 3B; the surface has been unaffected by the epitaxial growth, and retains the mirror smooth polish with which it started.

Figure 4 shows the surface of a ZnSe layer on GaAs (B face), in which a Ge substrate was also present (adjacent to the GaAs) during the growth in order to obtain reasonable growth rates. The surface has a cobblestone appearance, 4A, made by a high density of triangular pyramids. In 4B the same surface is shown at a different position, demonstrating larger pyramids extending about 2μ out of the surface. The GaAs surface beneath the ZnSe layer generally retained the high polish (comparable to Fig. 3B) with which it started. Occasionally however, slight pre-

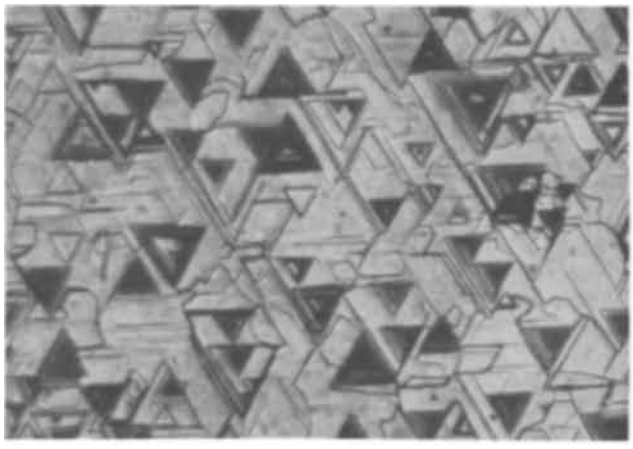

Fig. 3A. ZnSe surface under slow growth conditions: source temperature 700°C; substrate temperature 580°C; 2 μ/hr; 0.02% HCl; Magnification 300X.

Fig. 3B. Ge surface after removal of ZnSe layer in Fig. 3A, showing that the original mirror polish is retained. Magnification 300X.

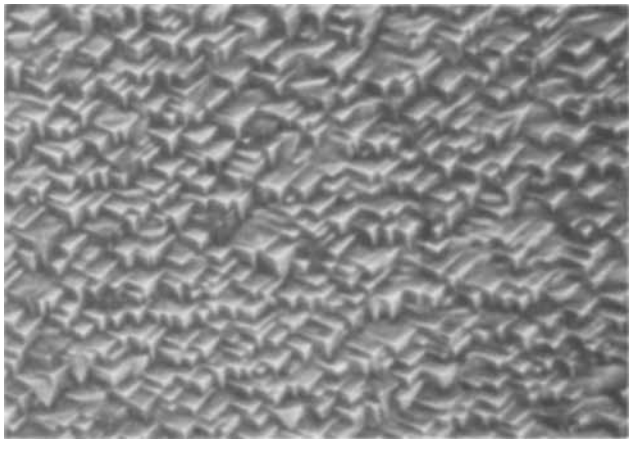

Fig. 4A. ZnSe grown on GaAs under slow conditions, with Ge substrate also present: ZnSe surface; source temperature 700°C; substrate temperature 580°C; 1 μ/hr; 0.02% HCl; Magnification 300X.

growth etching was noted; this etching occurred whenever leakage was introduced into the system either intentionally or unintentionally, and is presumably due to reaction with oxygen or water vapor. This slight etching did not occur whenever such leaks were reduced to their practical minimum, roughly 10^{-8} cc/sec per fitting.

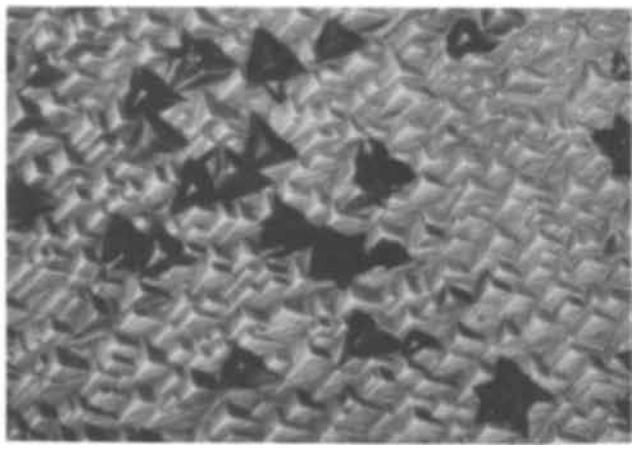

Fig. 4B. Same surface as in Fig 4A, different position, showing growth irregularities.

ZnSe layers grown on ZnSe substrates had mirror smooth surfaces over most of the grown region. The presence of twin bands usually found in ZnSe single crystals allowed an orientation dependence to be observed; the growth rate on one twinned region was 3 or 4 times that on the other twin, giving alternately high and low plateaus, each with mirror finishes.

The quantitative results for the growth of ZnSe on ZnSe, Ge, and GaAs under various operating conditions are presented in Table I. For a given substrate temperature and HCl concentration, the growth rate increased with increasing source temperature; however, there was no appreciable change in the nature of the epitaxial layers. (The efficiency, defined as the amount of ZnSe grown divided by the amount etched from the source, was 45-60% and was independent of the substrate and growth rate.) Rows 1 and 2 describe the results for relatively high HCl concentrations; the growth rate on Ge seeds is seen to be many times higher than on ZnSe substrates for essentially equal conditions. Rows 3 and 4 demonstrate similar enhancement with Ge for growth in pure H_2 atmosphere. A comparison of 1 and 2 with 3 and 4 demonstrates the much higher growth rates using HCl as the transport agent instead of pure H_2. Rows 5 through 7 describe the situation using low HCl concentrations; the rates on GaAs substrates were approximately the same as on ZnSe ones. When ZnSe-GaAs devices grown at low substrate temperatures (560°-580°C) were desired, adjacent Ge and GaAs substrates were used simultaneously; the presence of Ge increased the ZnSe growth rate on GaAs to a practical value.

The enhanced rates of growth on Ge substrates are probably caused by a chemical reaction between the Ge and the ZnSe reaction products

$$2HCl + ZnSe \rightleftarrows ZnCl_2 + H_2Se \qquad [1]$$

Table I. Growth of ZnSe on ZnSe, Ge, and GaAs

All substrates were (111) oriented, with total flow rate of 200 cc/min (reaction tube 43 mm diameter). Source to substrate spacing is 12 mils.

	Growth conditions	Source temp, °C	Substrate temp, °C	Growth rate, μ/hr
1.	ZnSe upon ZnSe	760	660	8
	0.2% HCl	620	580	0
2.	ZnSe upon Ge	760	620	160
	0.2% HCl	620	570	8
3.	ZnSe upon ZnSe pure H_2	760	660	0.05
4.	ZnSe upon Ge pure H_2	760	660	0.3
5.	ZnSe upon Ge 0.02% HCl	680	570	1
6.	ZnSe upon GaAs (B)	750	640	0.5
	0.02% HCl	700	590	0
7.	ZnSe upon GaAs (B) (0.02% HCl with Ge seed also present)	700	580	1.0 on GaAs 3.0 on Ge

$$Ge + xH_2Se \rightleftarrows GeSe_x + xH_2 \quad [2]$$

The Ge vapor species then produces a feedback effect by greatly increasing the etch rate at the ZnSe source. It is not known, however, whether the Ge acts as a catalyst for reaction [1] or produces a second reaction at the ZnSe source. Since the upper Ge surface is gradually covered by the growing ZnSe layer, less Ge surface is available for reaction [2]. The sides and bottom of the wafer, however, do not become covered and remain available for the reaction.

A second possibility, reaction between the Ge and HCl

$$y\,HCl + Ge \rightleftarrows GeCl_y + \frac{y}{2}H_2 \quad [3]$$

to produce the chloride as the feedback species, can be largely ruled out. When layers of GaAs were grown on Ge in an identical system at the same HCl concentration, temperature, and growth rate, no etching of the Ge substrate comparable to Fig. 2B was ever observed (6). The surface in Fig. 2B is therefore attributed to reaction of the Ge with H_2Se rather than HCl.

A Laue back-reflection pattern of a 20μ ZnSe layer grown on Ge at 5μ/hr is seen in Fig. 5. Since the ZnSe layer is relatively thin, a certain portion of the pattern may be due to the Ge beneath. The fraction F of the scattered beam intensity contributed by a layer of thickness x is given by (7)

$$F = 1 - e^{-\alpha x[1+1/\sin(2\theta-90°)]} \quad [4]$$

where α is the x-ray absorption coefficient at a particular wavelength, and 2θ is the angle between the incident and back-reflected beams. Since tungsten targets yield a variety of wavelengths, an exact analysis of the scattering would take into account an integration over all the wavelengths present. Values of α range from 300 to 1500 cm^{-1} for ZnSe; taking 800 cm^{-1} as an example, and using $x = 20\mu$ and $\theta = 75°$, the fraction [4] of the scattering due to the ZnSe is 0.97 at this wavelength. The pattern of Fig. 5 therefore demonstrates the single crystallinity and (111) orientation of the ZnSe layer and is typical of all the patterns taken.

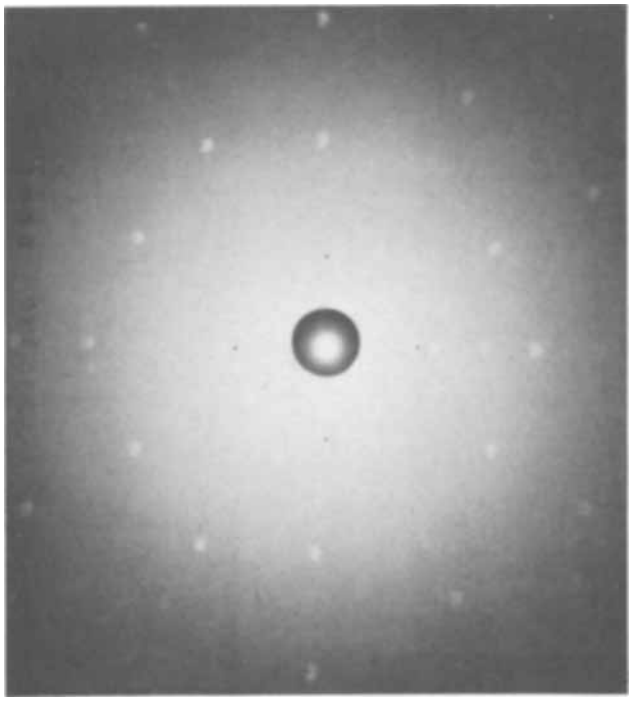

Fig. 5. Laue x-ray back reflection pattern of a 20μ ZnSe layer on Ge (tungsten target).

Fig. 6A. Cracks in ZnSe layers grown on Ge: layer 30μ thick, cooled from growth temperature at 10°C/min, showing crack formation. Magnification 300X.

Fig. 6B. Layer 3μ thick, cooled from growth temperature at 0.8°C/min, showing absence of cracks. Magnification 100X.

Crack Formation

After heterojunction layers have been grown, problems may arise from the thermal expansion mismatch of the two materials. Figure 6A shows a 30μ layer on Ge which was cooled from the growth temperature of 600°C at the rate of 10°C/min. Severe cracking has resulted, extending completely through the ZnSe and partly into the Ge. Such cracking has been observed in other heterojunction structures, notably Ge-Si where the lattice mismatch at room temperature is about 4%. The thermal expansion coefficient of ZnSe has been measured (8) up to 520°C; the lattice mismatch between ZnSe and Ge at the growth temperature is approximately 0.6% compared to 0.15% at room temperature. Although this is considerably less than the 4% of Ge-Si, it is apparently sufficient to cause cracking.

By restriction of the ZnSe growth to thinner layers however, and cooling from the growth temperature at very slow rates, a process of annealing is introduced. Figure 6B shows a 3μ ZnSe layer cooled at 0.8°C/min; under these conditions cracking apparently does not occur. For ZnSe-GaAs the lattice and expansion mismatches are higher, and here also no cracking is observed for thin layers and slow cooling.

Doping of ZnSe *Layers*

Difficulties are encountered in doping II-VI compounds such as ZnSe because of the self-compensation which occurs. For each intentionally added n-type impurity a corresponding zinc vacancy may be formed, which being acceptor-like, compensates the donor. Such compensation may be almost exact (9), so that

the number ($N_d - N_y$ (Zn)) is orders of magnitude less than N_d. It is therefore necessary to provide Zn atoms to the crystal ambient in order to control the Zn vacancy density and allow the donors to become electrically active.

The best method available is to surround the ZnSe with liquid Zn at temperatures of 800°-1100°C for times dependent on the size of the sample (10). In addition to reducing Zn vacancies, this has the additional advantage of gettering other p-type impurities from the ZnSe. It cannot be used for ZnSe on Ge directly, however, since the Ge dissolves completely in Zn at these temperatures. This problem does not arise with ZnSe on GaAs, since the GaAs does not dissolve, but Zn is a fast diffuser in GaAs and drastically changes its resistivity, therefore leading to poor control.

The method adopted here is the diffusion of Zn from the vapor phase. A zinc-filled quartz boat is placed near the input end of the tube (see Fig. 1) and kept at room temperature during the growth period. The zinc is therefore inactive during the growth, but is heated to temperatures of 700°-800°C after the growth has finished, establishing a Zn partial pressure of 10-150 mm Hg in the vicinity of the grown layer. Zinc may then diffuse into the layer from the vapor while the Ge or GaAs is protected by its contact with the SiO_2-covered Si block.

The donor impurity itself can be added in a variety of ways. The most successful method has been to use source ZnSe material heavily doped with Ga or Al, prepared by heat-treating in liquid Zn-Ga or Zn-Al alloy (10). The dopant contained in the source is presumably transported to the growing ZnSe layer. In this way 10^3-10^4 ohm-cm layers were obtained from 5 x 10^{16} Ga doped sources and 10^5-10^6 ohm-cm from 10^{18} Al doped sources, in conjunction with the Zn diffusion step mentioned above. These low substrate-to-source doping ratios are probably due to dopant transport factors, rather than inefficiencies in the Zn step, since consistent differences are observed in the use of Ga doped versus Al doped source material.

Doping was also attempted by adding elemental Ga or Al into the bypass tube (see Fig. 1) and heating it to 300°-500°C, so that all the HCl is converted to Ga or Al chloride. The etching reaction at the ZnSe source then proceeds via this chloride, releasing large amounts of Ga or Al in the growth region. Although there was some evidence that more highly doped layers were obtained by this method (about 500 ohm-cm), the ZnSe layers tended to be of poor quality and the conditions (growth rate, surface appearance, etc.) could not be well controlled. It is thought, however, that this method of doping holds promise of success with the use of Ga if better steps are developed to introduce the $GaCl_x$. The use of Al is less promising because of reactions between the $AlCl_x$ and quartz.

The Hall mobility was measured for a number of Ga doped ZnSe layers (10^3-10^4 ohm-cm) grown on Ge, and generally ranged between 50 and 100. Since the electron mobility of bulk material is 300-400 $cm^2v^{-1}s^{-1}$, this does not represent a serious difference between the bulk and epitaxial materials. Lower mobilities are expected for such epitaxial layers because of the stacking faults, twin bands, and other defects which can occur. It is also possible that a significant amount of Ge could be incorporated in the growing layer due to the presence of the Ge vapor species. The resulting Ge scattering centers would then have the effect of lowering the mobility of the epitaxial material.

The V-I characteristic of an nZnSe (10^3 ohm-cm)-p^+Ge heterojunction is shown in Fig. 7 (ohmic contact is made to both materials by the alloying of pure In). In the forward direction the conduction is moderate with most of the voltage dropped across the bulk

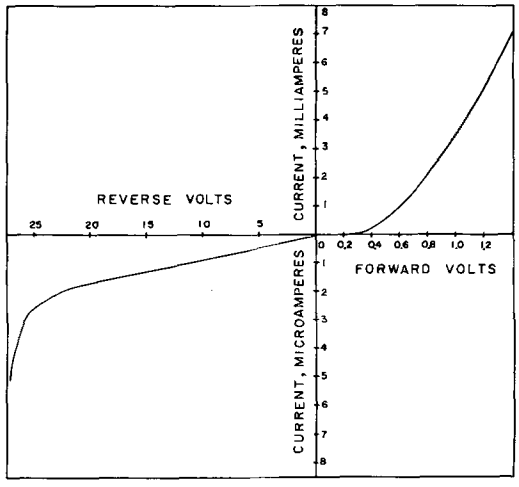

Fig. 7. Volt-ampere characteristics of an nZnSe-p^+Ge heterodiode

ZnSe. The reverse currents are quite low, and rectification ratios of several thousand are common. The diode action involves injection of electrons from the ZnSe into the Ge, and transistors with ZnSe emitters and Ge base-collector junctions with common emitter current gains of 50, or more, have been fabricated (11).

Conclusions

An HCl close-spaced transport process has been described suitable for the growth of single crystal epitaxial layers of ZnSe on several types of semiconductor substrates. The growth rates were found to be considerably higher on Ge than on GaAs or ZnSe, and rates of several mils per hour were easily achieved; however, in order to prevent unwanted etching of the Ge and maintain flat metallurgical interfaces for useful device fabrication, low HCl concentrations and subsequent low growth rates (1-10 μ/hr) were necessary. The cracking due to lattice mismatch was eliminated by growing thin layers and cooling very slowly. Resistivities of 10^3 ohm-cm were routinely achieved using Ga and a zinc over-pressure after the growth to eliminate compensating zinc vacancies.

Diffusion of Nickel and Chlorine into Lead Telluride

II. Diffusion at the Phase Limits

T. D. George[1] and J. B. Wagner, Jr.*

Department of Materials Science, Northwestern University, Evanston, Illinois

ABSTRACT

The diffusion of nickel and chlorine has been studied at the limit of solid solubility of both lead and tellurium in PbTe at 700°C. When nickel and chlorine are diffused simultaneously in a lead atmosphere there is an interaction between chlorine and the lattice such that the concentration profile of nickel exhibits a minimum. The same type of minimum in the nickel distribution is produced when lead is diffused under a lead concentration gradient into or out of a nickel-doped crystal. No minimum in the concentration of nickel was observed when a tellurium atmosphere is maintained above the crystal. The diffusion of chlorine indicates that there are anti-Frenkel defects on the anion sublattice.

Recently we reported (1) on the diffusion of nickel and chlorine into p-type lead telluride at 700°C. In that paper all of the diffusion anneals were carried out on material initially containing approximately 2×10^{18} holes/cm^3. A mechanism was suggested by which nickel redistributed in p-type PbTe during the in-diffusion of chlorine. The nickel was said to redistribute behind the advancing front of chlorine because the chlorine disturbed the local electronic equilibrium necessitating an increase in the lead vacancy concentration.

It is the purpose of the present paper to report further studies on the diffusion of nickel and chlorine into lead telluride pre-equilibrated at both of the limits of solid solubility of PbTe. At the lead telluride/lead phase limit PbTe contains excess lead and is n-type with an electron concentration of 9.7×10^{17} electrons/cm^3. With excess tellurium PbTe is p-type and contains 6.4×10^{18} holes/cm^3 at the phase limit.

Experimental

Single crystals of lead telluride were grown by the Bridgman technique from the melt. Wafers 2-3 mm thick were sawed from the ingot with a jewelers saw and lapped on 500 A silicon carbide paper and polished using 0.1μ alumina on felt.

Wafers were equilibrated either at the lead telluride-lead phase boundary or at the lead telluride/tellurium phase boundary. Several wafers were encapsulated together with powdered lead telluride and an excess of either lead or tellurium and annealed for at least 100 hr at 700°C. They were quenched by allowing the capsule to drop directly out of the vertical furnace into a bath of ice and water. Hall measurements indicated carrier concentrations of 9.7×10^{17} electrons/cm^3 at the lead phase boundary and 6.4×10^{18} holes/cm^3 at the tellurium phase boundary. The respective absolute Seebeck coefficients were -285 and $+150$ μv/°C. The carrier concentration of the lead phase boundary is in agreement with that of Brebrick and Gubner (2). The carrier concentration at the tellurium phase boundary is lower (6.4×10^{18}/cc compared to 8×10^{18}/cc) than that reported by Brebrick and Gubner. From etch pit counts we estimate the dislocation density of these crystals to be 2×10^5/cm^2.

Before applying the radiotracer, each wafer was again polished with alumina on felt to remove surface roughness produced during equilibration. Both the nickel-63 and chlorine-36 were obtained as acid solutions (pH $\sim$ 1) of $NiCl_2$ and contained 2.8×10^{-2} mg Ni/ml. The tracer was applied to one face of the wafer as before (1) with one exception. It was found experimentally that if nickel-63 was deposited on the wafer by allowing an acid solution of $^{63}NiCl_2$ (pH $\sim$ 1) to evaporate to dryness on the surface of a wafer, instead of using a neutralized solutions (pH $\approx$ 7), the diffusion results were identical with those in which nickel-63 was electroplated onto one surface. That is, the chlorine atoms from the $NiCl_2$ did not appear to diffuse into the crystal. As a further test, $Ni^{36}Cl_2$ was deposited from an acid solution. Virtually all of the chlorine evaporated. Whereas the initial surface activity of chlorine-36 was approximately 80,000 counts/min when evaporated from a neutralized solution, the initial surface activity dropped to about 80 counts/min when an acid solution of $Ni^{36}Cl_2$ was used. Crystals left in HCl for 24 hr showed no surface attack. When the behavior of nickel in the absence of chlorine from the $NiCl_2$ was to be studied, a drop of $^{63}NiCl_2$ acid solution was placed on one face of a wafer and allowed to evaporate to dryness. When the wafer was dry, the surface remained bright and there was no evidence of attack. It is suggested that nickel may be chemisorbed from the acid solution in a manner similar to that observed for a number of other metals with gallium arsenide (3).

When the effect of chlorine on the diffusion and distribution of nickel was to be studied, $^{63}NiCl_2$ was deposited from a neutralized solution onto one face of a PbTe wafer. This provided a source of both nickel and chlorine atoms which diffused into the crystal simultaneously. Chlorine-36 was always deposited onto one face of a wafer from a neutralized solution of $Ni^{36}Cl_2$.

Diffusion anneals were carried out at 700°C in sealed quartz ampoules of about 2 cm^3 total volume. When it was desired to establish the composition corresponding to one of the phase limits, the appropriate two-phase mixture of lead telluride/tellurium or lead telluride/lead was added to the ampoule with the diffusion specimen. For some experiments the wafer was sealed without the two-phase mixture.

The counting and grinding procedures were identical with those previously described (1) A semiquantitative determination of the nickel concentration was made by comparing the count rate of our samples with calibrated standards of nickel-63. Three nickel-63 standard sources were obtained from New England Nuclear Corporation. The activity of the sources covered the range of count rates encountered here, and the standard sources were approximately the same size as the diffusion wafers. Each standard source was mounted in a stainless steel ring identical to those used for mounting the diffusion samples (1). From the relationships given by Libby (4, 5), the linear absorption coefficient for the β-radiation of nickel-63 (E_{max} = 0.067 mev) in PbTe has been calculated as 18,700 cm^{-1}. This value of the linear absorption coefficient gives a half-thickness of 0.38μ. That is, half of the

* Electrochemical Society Active Member.
[1] NASA Trainee. Present address, Central Analysis and Characterization Laboratory, Texas Instruments, Incorporated, Dallas, Texas.

radiation is absorbed in passing through 0.38μ of PbTe. It has been assumed that the radiation reaching the detector comes from a depth of twice the half-thickness or 0.76μ. Taking this value and the diameter of the wafers (5.34 mm), the volume giving rise to the detected radiation was computed. Calibration curves were constructed for the nickel-63 solution used, and these were used to convert count-rate to nickel concentrations. No determinations have been made for the chlorine concentrations.

Results

Diffusion in crystals initially equilibrated at the PbTe/Pb phase limit.—The following series of experiments employed PbTe wafers pre-equilibrated at the lead telluride/lead phase limit. The crystals were initially n-type having an electron concentration of 9.7 x 10^{17} electrons/cm^3.

If nickel alone is allowed to diffuse into these crystals, nickel penetrates the crystals completely in a very short time. Based on the shortest diffusion time used, 1 hr, we estimate that the diffusion coefficient of nickel must be at least 16^{-6} cm^2/sec at 700°C. When the diffusion of nickel was carried out in the presence of excess lead, the crystal remained n-type at the end of the diffusion anneal. If the diffusion anneal was carried out in an evacuated ampoule without a lead reservoir, the crystal converted to p-type in from 3 to 5 hr. In both cases the concentration of nickel was higher near both the source surface and also the surface of the opposite side of the crystal analogous to the behavior reported previously (1). In the present studies the nickel concentration in the bulk was 2 x 10^{17}/cc. Crystals pre-equilibrated at the lead telluride/lead phase boundary and annealed in an evacuated ampoule at 700°C with no tracer also showed a conversion from n-type to p-type conductivity. Depending on the crystal size, conversion to p-type conductivity was again noted in from 3 to 5 hr.

When nickel and chlorine were diffused into the crystal simultaneously, the nickel concentration profile again contained a minimum. The results of two sets of experiments are shown in Fig. 1 and 2. The profiles for chlorine-36 are also shown in these figures. If the diffusion anneal was carried out in the presence of a lead atmosphere, the results shown in Fig. 1 were obtained. The minimum in the nickel concentration corresponds to about 1 x 10^{17} nickel at./cm^3, while the

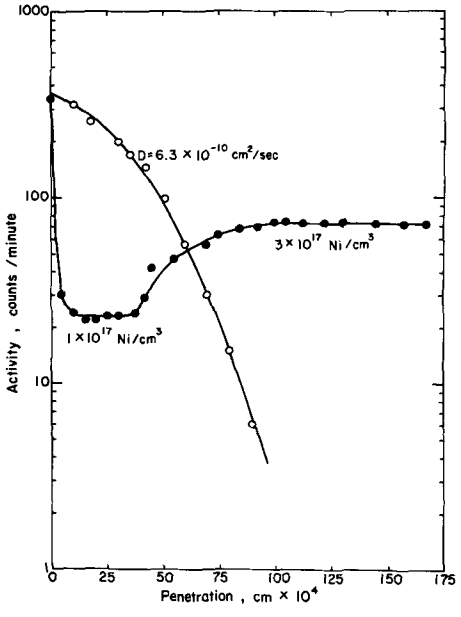

Fig. 1. Simultaneous diffusion of nickel and chlorine into a crystal pre-annealed at PbTe/Pb and diffusion annealed under the same conditions for 2 hr. —○— Chlorine-36 (determined in a separate experiment); —●— nickel-63.

constant region beyond the minimum corresponds to about 3 x 10^{17} nickel at./cm^3.

If the same experiment was repeated without the lead reservoir, typical results as shown in Fig. 2 were obtained. The minimum in the nickel concentration profile is much deeper in this case, and there appears to be an appreciable region containing no nickel at all. An n-type layer was found near the surface of these crystals, but the bulk of the crystal was p-type. As already noted, crystals pre-equilibrated at the lead phase boundary and annealed in an evacuated ampoule turn p-type in a few hours. The n-type layer at the surface must be produced by the in-diffusing chlorine. The p-n junction migrates linearly with the square root of time. However, plots of $x_{p\text{-}n}$ *vs.* $\sqrt{t}$ do not extrapolate back to the origin (see Fig. 3). In these experiments a similar nickel distribution profile was found near the opposite face of the wafer, and the nickel concentrations were the same as near the plated surface.

In order to investigate the effect of lead on the distribution of nickel, the following experiment was conducted. A crystal was pre-equilibrated at the lead tel-

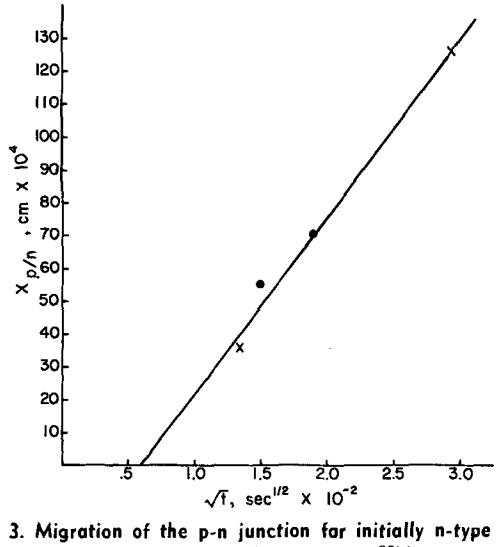

Fig. 3. Migration of the p-n junction for initially n-type crystals diffused in an evacuated ampoule. ● From ^{63}Ni curves; x from ^{36}Cl curves; corresponding to Fig. 2.

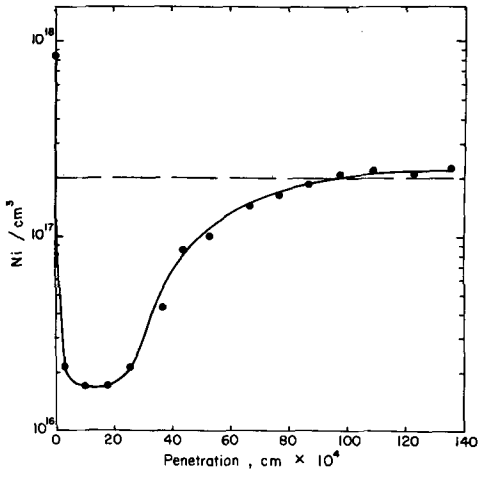

Fig. 4. Redistribution experiment. The effect of diffusing lead into an initially p-type nickel-doped crystal. - - - Nickel concentration before re-anneal in Pb atmosphere; –●– nickel distribution after 5 hr in Pb atmosphere.

luride/lead phase boundary. Next, nickel tracer (without chlorine) was applied to the wafer, and it was annealed in an evacuated quartz ampoule for 5 hr during which time the crystal converted from n- to p-type. The crystal was counted and lapped on both faces until the concentration of nickel was the same (2×10^{17} Ni/cm³). It was then placed in an evacuated ampoule containing excess lead but no additional nickel tracer and again annealed for 5 hr. The results are shown in Fig. 4. The nickel concentration increased at the surface, and there is a deep minimum located 15μ below the surface. In addition, the crystal turned n-type again indicating that lead had diffused into the lattice.

The reverse of this experiment was also carried out. Nickel was diffused into n-type PbTe in the presence of a lead reservoir. Nickel completely penetrated the crystal, and the crystal remained n-type. This crystal was lapped on both faces until the concentrations were the same on each face. The crystal was reannealed for 5 hr in a closed vacuum. The crystal was converted to p-type, and the nickel redistributed in a manner similar to that of Fig. 4 although the minimum in the nickel profile was not as deep.

Diffusion in crystals initially equilibrated at the PbTe/Te *phase limit.*—The results of diffusion experiments on crystals pre-equilibrated at the lead telluride/tellurium phase limit can be divided into two categories. The first series of experiments were carried out in the presence of excess tellurium to maintain the partial pressure over the crystal. When nickel alone was allowed to diffuse into PbTe, the resulting profile could be fit to the plane source solution of the diffusion equation

$$C(x) = C_o \exp(-x^2/4Dt) \qquad [1]$$

where C_o is the nickel concentration at the surface following the diffusion anneal, $C(x)$ is the concentration at distance x below the surface, D is the diffusion coefficient, and t is the time of the diffusion anneal. These results are shown in Fig. 5. The value of C_o shown in Fig. 5 is the one obtained by extrapolating the ln C *vs.* x^2 plot to the surface. The actual C_o measured at the surface at the end of the diffusion anneal was usually 5 or 6 times this extrapolated value. The diffusion coefficient for nickel is 4.5×10^{-10} cm²/sec.

When this experiment was repeated using $^{63}NiCl_2$ as the source of nickel, so that nickel and chlorine simultaneously diffused into the crystal, similar results were obtained, but the apparent diffusion coefficient for nickel was 2×10^{-11} cm²/sec. These results are also shown in Fig. 5. The diffusion time of

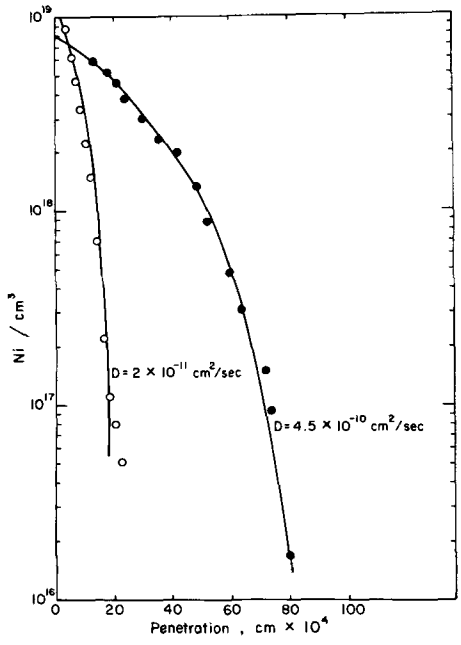

Fig. 5. Diffusion of nickel into crystals pre-annealed at PbTe/Te and diffusion annealed under the same conditions. –●– Nickel-63, 2 hr; –○– nickel-63 simultaneously diffused with chlorine, 23 hr (plotted on a reduced scale).

this experiment was 23 hr. In plotting the data, the curve has been normalized to correspond to a 2-hr anneal. This was accomplished by taking each data point and applying the relation

$$\frac{x}{t^{1/2}} = \frac{x[23]}{(8.28 \times 10^4)^{1/2}} = \frac{x[2]}{(7.2 \times 10^3)^{1/2}}$$

where x is the penetration distance, t the time, and the numbers in brackets denote the different annealing times in hours. The normalization was done so that the differences in the diffusion coefficients would be more obvious.

If nickel and chlorine are simultaneously diffused into a crystal in the absence of a tellurium reservoir, the nickel profile again exhibits a minimum, and nickel completely penetrates the crystal in a matter of 6 hr, the shortest diffusion time used. The nickel profile and corresponding chlorine profile are shown in Fig. 6. The minimum in the nickel profile is nearer the surface for equivalent diffusion times in crystals pre-equilibrated at the tellurium phase limit (6.4 x

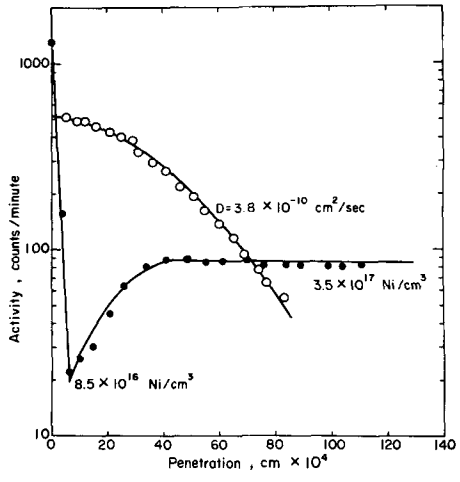

Fig. 6. Simultaneous diffusion of nickel and chlorine into a crystal pre-annealed at PbTe/Te and diffusion annealed in an evacuated ampoule for 6 hr. –○– Chlorine-36 (determined in a separate experiment); –●– nickel-63.

10^{18} holes/cm^3) than for crystals treated at the minimum total pressure (2 x 10^{18} holes/cm^3).

There was no conversion to n-type conductivity in any of the crystals pre-equilibrated at the tellurium phase limit. All of the crystals were p-type at the end of the diffusion anneal whether or not a tellurium reservoir was used during the diffusion anneal. Several crystals were annealed without radiotracer in evacuated sealed ampoules for times up to 26 hr. No change was noted in either the carrier concentration as determined from Hall measurements or in the Seebeck coefficient.

The effect of tellurium on the distribution of nickel was established in the following way. A crystal pre-equilibrated at the tellurium phase limit was simultaneously diffused with nickel and chlorine for 6 hr in an evacuated ampoule without a tellurium reservoir. Both surfaces were ground down and counted until the nickel activity was the same on both surfaces. This was beyond the depth where any chlorine activity could be detected. The crystal was then sealed in an evacuated ampoule containing excess tellurium but no additional radiotracer and annealed at 700°C for 5 hr. The resulting nickel distribution is shown in Fig. 7. The dashed line represents the nickel concentration before the crystal was subjected to the tellurium treatment. There is a general increase in nickel concentration near the surface with a very sharp increase at the surface.

Diffusion of chlorine.—In those experiments where chlorine from the $NiCl_2$ entered the crystal, the penetration profiles of chlorine were also determined. These have already been presented with the appropriate nickel profiles. The diffusion coefficients for chlorine have been measured, and the results are tabulated in Table I along with the crystal characteristics. These diffusion coefficients represent those obtained under thermodynamically stable conditions. That is, the partial pressure of one of the components was fixed during the experiment. It should be noted, however, that nickel was always present in these crystals. A graph of D_{Cl} *vs.* log P_{Te_2} is shown in Fig. 8. The diffusion coefficient for chlorine appears higher at both phase limits than under conditions of minimum total pressure. The tellurium partial pressure corresponding to the minimum total pressure was obtained from the relation given by Fujimoto and Sata (6)

$$P_{Te_2}(\min) = 2^{-2/3}K^{-2/3} \qquad [2]$$

where K is the equilibrium constant for the formation of PbTe from monatomic Pb and diatomic Te_2 vapor. At 700°C $1/K = 1.6 \times 10^{-9}$ (atm)$^{3/2}$.

Discussion of Results

The diffusion of nickel and chlorine, their interaction with each other and with the lattice have now been examined at the extremes of solid solubility of both lead and tellurium in lead telluride. The results are summarized in Table II. This study, combined with a similar investigation at an intermediate composition defined by the minimum total pressure over lead telluride (1), provides a more complete picture of the interaction of nickel and chlorine with PbTe.

Two limiting cases are to be considered, one in which only nickel is diffusing and the other in which both nickel and chlorine are diffusing simultaneously. In the previous paper (1), it was shown that when nickel alone was diffused into a p-type crystal of fixed composition [pre-annealed under an inert atmosphere corresponding to p(min) and then diffusion-annealed under the same conditions], there was no minimum in the resulting penetration profile for the concentration of nickel. On the other hand, the re-arrangement studies of both the previous study [Fig. 7 of ref. (1)] and of the present work (Fig. 4) show that when nickel is distributed homogeneously in a crystal and this crystal is then annealed under conditions to change the stoichiometry, a minimum in the nickel concentration is formed near the surface of the wafer. These data lead to the first conclusion that the production of a minimum is associated with crystals whose composition or concentration of lattice defects is changing during the migration of nickel.

When chlorine diffuses simultaneously with nickel, more pronounced minima are found in the penetration profiles. These findings confirm the first conclusion because chlorine diffuses into the lead telluride, acts as a donor, and creates cation vacancies. These newly created cation vacancies disturb the local defect equi-

Table II. Summary of diffusion studies

Diffusion elements	Prediffusion conditions	Diffusion conditions	Summary of results
1. Lattice defects in PbTe. No tracer.	Equilibrated at PbTe/Pb. n = 9.7 × 10^{17}/cc	Annealed in evacuated ampoule without lead reservoir [corresponding to p(min)].	Crystals, 2-3 mm thick, convert from n- to p-type [p = 2 × 10^{18}/cc] in 3 to 5 hr. Chemical or interdiffusion coefficient, $\tilde{D} \cong 10^{-6}$ to 10^{-7} cm²/sec estimated from time to equilibrate.
2. Nickel (alone). Thin source on surface.	Same as 1.	Same as prediffusion anneal.	Complete penetration of crystal by nickel. $D_{Ni} \geq 10^{-6}$ cm²/sec. Crystal remains n-type.
3. Nickel (alone). Thin source on surface.	Same as 1.	Annealed in an evacuated ampoule without a lead reservoir.	Complete penetration of crystal by nickel. Crystal converts to p-type.
4. Nickel and chlorine. Thin source on surface.	Same as 1.	Same as prediffusion anneal.	Minimum in nickel profile. Crystal remained n-type (Fig. 1).
5. Nickel and chlorine. Thin source on surface.	Same as 1.	Annealed in an evacuated ampoule without a lead reservoir.	Minimum in nickel profile. Crystal exhibits n-p boundary (Fig. 2). Bulk of crystal remains n-type.
6. Nickel (alone) homogeneously distributed in crystal.	p-type crystal lapped until uniform nickel concentration = 2 × 10^{17}/cc	Annealed in evacuated ampoule containing excess lead. Redistribution experiment.	Nickel concentration increases at surface and minimum in profile found near surface. Crystal converts to n-type (Fig. 4).
7. Nickel (alone) homogeneously distributed in crystal.	n-type crystal lapped until uniform nickel concentration = 2 × 10^{17}/cc	Annealed in evacuated ampoule without excess lead.	Nickel concentration increases at surface and minimum in profile found near surface. Crystal converts from n to p type. [p = 2 × 10^{18}/cc].
8. Nickel (alone). Thin source on surface.	Equilibrated at PbTe/Te. p = 6.4 × 10^{18}/cc	Same as prediffusion anneal.	"Conventional" penetration profile $D_{Ni} = 4.5 \times 10^{-10}$ cm²/sec crystal remains p-type (Fig. 5).
9. Nickel and chlorine. Thin source on surface.	Same as 8.	Same as prediffusion anneal.	"Conventional" penetration profile $D_{Ni} = 2 \times 10^{-11}$ cm²/sec crystal remains p-type (Fig. 5).
10. Nickel and chlorine. Thin source on surface.	Same as 8.	Annealed in an evacuated ampoule without excess tellurium.	Minimum in nickel profile. Crystal remains p-type (Fig. 6).
11. Nickel (alone) homogeneously distributed in crystal.	p-type crystal lapped until uniform nickel concentration = 2 × 10^{17}/cc	Annealed in evacuated ampoule containing excess Te. Redistribution experiment.	Nickel concentration increases at surface with no minimum in profile near surface. Crystal remains p-type.

librium, and the lead atoms from the sites where the cation vacancies were created must migrate out. In the previous paper (1) it was suggested that the cause of these minima in the penetration profiles was due to the "pile up" of the lead atoms trying to migrate outward to the surface while the chlorine front moved inward. Because the diffusion coefficient of chlorine (in the presence of nickel) is of the order of 10^{-10} cm²/sec (see Table I) while the diffusion of cation vacancies is estimated to be of the order of 10^{-6} to 10^{-7} cm²/sec from the time necessary to equilibrate the specimens in an inert atmosphere (see Table II), this explanation is not correct. Nevertheless, the migration of atoms must occur as stated, *i.e.*, the chlorine ions move in creating cation vacancies while the lead atoms move in the opposite direction.

It is assumed that the nickel migrates interstitially (except under high tellurium pressures as will be discussed below) and that it meets and occupies lead vacancies in accord with the mechanism first suggested by Bloem and Kröger (8) for nickel diffusing into lead sulfide. The minima in the penetration profiles of nickel observed in the present study must therefore be a direct consequence of a low concentration of available cation vacancies and correspondingly a high concentration of interstitial lead atoms ($K_F = [V'_{Pb}][Pb_i^{\bullet}]$) so that the sites available for nickel atoms are decreased from the concentration of sites in the bulk crystal.

Next consider the production of the p to n boundary within the crystal. Because minima in the nickel penetration profiles occur both with and without a corresponding apparent change in carrier, the second conclusion is that a change from p to n type, or conversely, is not necessary for the migration of nickel nor for the formation of the minima. However, there is an interaction between the electrons and the migration of the minima because the defect equilibrium must be preserved.

The position of the minimum in the nickel concentration profile is displaced further from the surface of the crystal as the hole concentration decreases or as the electron concentration increases for equal diffusion times. The region of the minimum in the nickel concentration profile is wider, or extends further into the crystal, in PbTe containing excess lead than in material containing excess tellurium. The region of the minimum in the nickel concentration is expected to be wider the slower the out-diffusion of lead or the faster the in-diffusion of chlorine. In other words the greater the difference in the diffusion coefficients of lead and chlorine, the wider will be the region where a nonequilibrium defect concentration exists. The chlorine diffusion coefficient is higher at both phase limits than at an intermediate composition (see Fig. 8). If all other parameters were fixed, then it is to be expected that the minimum in the nickel profile would be the widest and be found farthest into the crystal in highly n-type material. Furthermore, the minimum should be the narrowest and lie closest to the surface at the intermediate composition studied, because the chlorine diffusion coefficient is lowest here. As already noted, however, this trend is not the one observed. The trend from broad minima well away from the surface of the crystal on the lead rich side to narrow minima located nearer the surface on the tellurium rich side suggests that the diffusion coefficient of lead changes continuously and in the same direction across the phase field.

While no quantitative arguments can be made because of the changing chlorine diffusion coefficient across the phase field, it appears that the diffusion coefficient of lead increases in going from the lead telluride/lead phase boundary to the lead telluride/tellurium phase boundary. The faster the out-diffusion of lead when chlorine is diffusing into the lattice, the more narrow will be the region where there is a transient excess of lead relative to the equilibrium value. A simple cation defect structure which has the property of increasing the cation diffusion coefficient with increasing hole concentration is vacancies on the cation sub-lattice. The cation vacancy concentration would be expected to increase in going from the lead rich side of the phase field to the tellurium rich side.

When crystals pre-equilibrated at the tellurium phase limit were diffused with nickel in the presence of a tellurium atmosphere, the nickel penetration profiles were unlike those obtained under any other experimental conditions (see Fig. 5). In the absence of chlorine the penetration profile of nickel could be fit to Eq. [1] with $D = 4.5 \times 10^{-10}$ cm²/sec, with the exception that C_o obtained from a plot of ln C *vs.* x^2 was only about one-fifth of the observed value of the nickel concentration at the surface after the diffusion anneal. When nickel and chlorine were simultaneously diffused under the same conditions, similar results were obtained except that the apparent diffusion coefficient of nickel was 2×10^{-11} cm²/sec. Again the

value of C_0 obtained from a plot of ln C *vs.* x^2 was considerably less than the observed value.

The fact that the observed C_0 was always higher than the extrapolated value implies that nickel is being trapped on the surface. Such behavior is indicative of some sort of surface reaction. Since nickel appears to diffuse very rapidly in the absence of a tellurium atmosphere, the data suggest that nickel reacts at the surface to form nickel telluride. This reactive behavior of tellurium was confirmed by exposing a nickel-doped crystal of PbTe to a tellurium atmosphere. Nickel is withdrawn from the crystal with the nickel concentration increasing near the surface and decreasing in the bulk of the crystal (see Fig. 7). There is almost a discontinuity in the nickel concentration profile very near the surface. Such a concentration profile can be explained if the chemical potential of nickel at the surface of the crystal is less than that in the bulk as was first suggested by Bloem and Kröger (8) for the behavior of nickel in lead sulfide. This would be the case if nickel reacted with tellurium vapor at the surface of the crystal to form a second phase of nickel telluride. Nickel is known to form several compounds with tellurium. (7).

It is possible to speculate why the nickel concentration profiles obtained in tellurium atmospheres show completely different characteristics than otherwise found. If reaction at the surface were simply trapping part of the nickel, then one would expect that only a small amount of nickel would enter the crystal, but nickel would diffuse rapidly as observed under other experimental conditions. Instead, the diffusion of nickel itself appears to be much slower. It may be that the concentration profiles of nickel obtained under tellurium atmospheres are not representative of nickel diffusing into the lattice but may be instead a measure of some interpenetration of nickel telluride and lead telluride.

This same sort of behavior is observed with nickel in lead sulfide. Bloem and Kröger (8) found nickel diffusion coefficients in PbS on the order of 7×10^{-6} cm^2/sec at 500°C under inert atmospheres, whereas Seltzer and Wagner (9) found nickel diffusion coefficients on the order of 3×10^{-13} cm^2/sec at 700°C in sulfur atmospheres. Further, it was found (9) that the diffusion coefficient at 700°C was not particularly affected by varying the partial pressure of sulfur between 0.1 and 3×10^{-6} atm, and that in the region 200°-500°C nickel diffused out of PbS when nickel-doped PbS was exposed to an H_2S atmosphere (8). Both of these results suggest that nickel reacts with sulfur at the surface of PbS to form nickel sulfide.

In the present study an additional effect has been observed, however. When nickel and chlorine are simultaneously diffused into PbTe at 700°C under a tellurium atmosphere, the apparent diffusion coefficient of nickel is much smaller than when nickel alone is diffused under the same experimental conditions. If nickel is forced to diffuse via a vacancy mechanism when a tellurium atmosphere is present, the results can be explained in terms of the availability of cation vacancies. Under a tellurium atmosphere nickel appears to have a diffusion coefficient of 4.5×10^{-10} cm^2/sec in the absence of any chlorine. This value is about the same as found for chlorine under the same conditions, 4.2×10^{-10} cm^2/sec. Since it is believed that chlorine creates lead vacancies, the out-diffusing excess lead should affect the diffusion of nickel in the manner observed, *i.e.*, decrease the apparent diffusion coefficient. While the data suggest a definite interaction between nickel, chlorine and the crystal under tellurium atmospheres, it has not been possible to ascertain the exact mechanism. It is suggested that the diffusing nickel species is different in an oxidizing atmosphere (tellurium) than in an inert or reducing atmosphere (vacuum or lead), and is thereby forced to diffuse via a vacancy mechanism rather than interstitially.

While the behavior of nickel under various experimental conditions has been the main focus of this investigation, some information has been collected on the diffusion of chlorine. Even though the diffusion of chlorine has always been carried out in the presence of nickel, certain trends seem apparent. The diffusion coefficient of chlorine varies across the phase field of lead telluride in a manner which suggests a Frenkel defect structure on the anion sublattice. The diffusion coefficient of chlorine is higher at both phase limits than at the intermediate composition studied (see Fig. 8). Anion vacancy migration should predominate on the lead rich side of the phase field, while interstitial migration will predominate near the tellurium rich phase limit.

The change in the diffusion coefficient with a change in tellurium partial pressure on the lead rich side of the phase field can be given by

$$D_{Cl} \propto P_{Te_2}{}^{-0.245} \cong P_{Te_2}{}^{-1/4} \qquad [3]$$

This value is calculated on the basis of only two experimental points and, therefore, is only an approximation. Nevertheless, a $-\frac{1}{4}$ dependence on the tellurium partial pressure is the dependence one would expect if anion migration occurred via a singly charged anion vacancy, $V^{\bullet}_{Te}$. The line through the point located at the lead telluride/tellurium phase boundary has been drawn with a $+\frac{1}{4}$ slope. While there is no experimental verification of this dependence, this is the expected dependence for diffusion via singly charged interstitials.

The suggestion made here that a Frenkel disorder is present on the anion sublattice of lead telluride is in agreement with most of the anion diffusion work on the lead chalcogenides and on the II-VI compounds (10-12). The first indication that anion diffusion in compound semiconductors was of sufficient magnitude to be of importance was made by Seltzer and Wagner (10) in their study of sulfur-35 diffusion into PbS. Their results indicated that not only was anion migration an appreciable component of diffusion in PbS, but also that the predominant disorder on the anion sublattice was a Frenkel defect, anion vacancies in lead rich PbS and anion interstitials in sulfur rich PbS. The anion Frenkel disorder has also been inferred for PbSe by diffusion of Se-75 into PbSe (11). Woodbury (12) has established that an anion Frenkel disorder also exists in II-VI compounds, although anion migration in chalcogenide rich materials seems to occur via a neutral interstitial.

Summary and Conclusions

The diffusion of nickel and chlorine has been studied at the limit of solid solubility of both lead and tellurium in lead telluride at 700°C, and the results compared with those previously reported (1) on PbTe equilibrated at the minimum total pressure composition. With the exception of diffusion anneals in a tellurium atmosphere, the diffusion of nickel at 700°C is very rapid. We estimate D_{Ni} to be greater than 10^{-6} cm^2/sec.

The minimum which is produced when chlorine is diffused into nickel-doped lead telluride or is simultaneously diffused with nickel is also produced when lead is diffused into or out of nickel-doped PbTe. Any condition which causes the migration of lead through the lattice of a nickel-doped crystal produces a minimum in the nickel distribution. This supports our earlier conclusion concerning the minima in the nickel concentration profile (1). Contrary to the interpretation by Peart *et al.* (13) and by Larrabee and Osborne (14) in their studies of impurity interaction in GaAs, it is not believed that amphoteric behavior of nickel in PbTe is the reason for the minimum. For such to be the case, it seems likely that there would be only one combination of crystal stoichiometry and electronic state which would yield a solubility minimum. Instead we observe the phenomena in both n- and p-type PbTe.

The results of diffusion experiments carried out in a tellurium atmosphere suggest that nickel reacts with tellurium vapor forming a second phase at the surface. The effects on the distribution of nickel in PbTe on exposure to a tellurium atmosphere confirm this result as do diffusion studies in the absence of a tellurium atmosphere. These results also suggest an explanation for differences observed in the diffusion of nickel into PbS at low temperatures (8) in an inert atmosphere and those obtained in the 700°C region under sulfur atmosphere (9). It is also suggested that the diffusing nickel species is different in a tellurium atmosphere than under inert or reducing conditions.

The implications of these results on general doping experiments and practice in the lead salts are also of interest. If other impurities in the lead salts behave to change in the crystal stoichiometry as does nickel, methods of doping the lead salts must be reinvestigated. Changes in the crystal composition brought about by changes in the atmosphere above the crystal could induce changes in an impurity distribution which will not return to equilibrium in the time normally assumed reasonable to properly equilibrate crystals. The result will be a nonuniform doping concentration which will obviously affect other measurements.

The analysis of the chlorine diffusion data suggest that migration on the anion sublattice occurs via a Frenkel defect, anion vacancies being responsible for motion in lead rich PbTe and anion interstitials in tellurium rich material.

Doped Oxides as Diffusion Sources

I. Boron into Silicon

M. L. Barry* and P. Olofsen*

Fairchild Semiconductor Research and Development Laboratory, Palo Alto, California

ABSTRACT

A model is presented describing the diffusion of dopants from a deposited oxide into a semiconductor substrate, and simple methods are developed for measuring directly the physical constants required to describe the diffusion. Experimentally determined values of these constants for the case of boron diffusing into silicon are given for wide ranges of temperature and concentration.

Diffusion of dopants into semiconductors, particularly silicon, from a doped oxide which has been deposited at low temperatures appears to hold several advantages over standard high-temperature predeposition and diffusion processes; these advantages include better over-all process control and increased flexibility in choosing diffusion schedules, doping levels, and device configurations. Diffusion from deposited doped oxides has been reported (1-7), but these reports deal primarily with device applications and the stress effects from low-level doping. Owen and Schmidt (8) described diffusion of phosphorus from thin doped anodic oxides, but their analysis is complicated by uncontrolled experimental conditions in their early work with these oxides. In this paper, we first develop a simple model for diffusion from a doped oxide into a semiconductor, use this model to interpret experimental data for the case of boron diffusing into silicon, and then discuss improvements to the model in light of these data. Subsequent reports will treat the cases of other dopants diffusing into silicon.

Theory

The most general one-dimensional case for diffusion of a dopant from a uniformly doped oxide into a semiconductor substrate is shown in Fig. 1. Here region I is the deposited doped oxide, with initial concentration C_o and thickness $x_o - x_B$, region II is the semiconductor substrate, and region III is an undoped barrier oxide of thickness x_B. Subscripts 1, 2, and 3 denote these regions, respectively. For normal device application of this type of diffusion, x_B is reduced to a minimum, of course, but the inclusion of a barrier oxide in the model illustrates several useful points and allows us to measure some diffusion parameters of the dopant in the oxide. The diffusion equations in each region are

$$\frac{\partial C_1(x,t)}{\partial t} = D_1 \frac{\partial^2 C_1(x,t)}{\partial x^2}, \quad -x_o < x < -x_B, \; t > 0 \qquad [1]$$

$$\frac{\partial C_2(x,t)}{\partial t} = D_2 \frac{\partial^2 C_2(x,t)}{\partial x^2}, \quad x > 0, \; t > 0 \qquad [2]$$

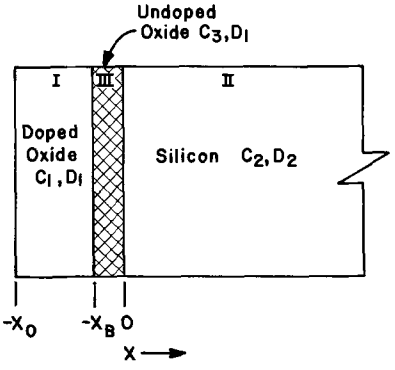

Fig. 1. Diffusion from a deposited doped oxide through a barrier oxide into a semiconductor substrate.

$$\frac{\partial C_3(x,t)}{\partial t} = D_3 \frac{\partial^2 C_3(x,t)}{\partial x^2} = D_1 \frac{\partial^2 C_3(x,t)}{\partial x^2}, \quad -x_B < x < 0, t > 0 \quad [3]$$

assuming the diffusion coefficients are not functions of concentration, and ignoring any field-aided diffusion terms operating on ionized dopants. The conditions under which these assumptions appear valid and the corrections to be made when they are not will be discussed in a later section. These equations also implicitly assume that the diffusion is a fixed-boundary problem; that is, silicon oxide is not formed at the oxide-silicon interface by oxidizing species from the ambient diffusing through the deposited oxide or by the transfer of the doping species from the oxide to the silicon (for example, boron oxide being reduced by silicon to form elemental boron and silicon oxide). The first condition can be assured either by performing the diffusion in an inert atmosphere or by using a thick deposited oxide, and it will be shown that the thickness of the oxide arising from the second factor is small compared to the diffusion length of the dopant in the oxide.

In most cases, the thickness of the substrate is very large compared to the diffusion depth in the substrate, so region II may be considered semi-infinite with little loss of generality. Other boundary conditions are

$$C_1 = C_o, C_2 = C_3 = 0 \text{ at } t = 0 \quad [4]$$

$$C_1 = 0 \text{ at } x = -x_o, t > 0 \quad [5]$$

$$C_2 \to 0 \text{ as } x \to \infty, t > 0 \quad [6]$$

$$C_3 = C_1 \text{ at } x = -x_B, t > 0 \quad [7]$$

$$D_1 \frac{\partial C_1}{\partial x} = D_1 \frac{\partial C_3}{\partial x} \text{ at } x = -x_B, t > 0 \quad [8]$$

$$C_2 = mC_3 \text{ at } x = 0, t > 0 \quad [9]$$

$$D_1 \frac{\partial C_3}{\partial x} = D_2 \frac{\partial C_2}{\partial x} \text{ at } x = 0, t > 0 \quad [10]$$

Boundary condition [5] implies that mass transfer of the dopant in the gas phase at the outer surface is very fast compared to diffusion in the oxide to the surface, and therefore, the concentration of dopant at the outside interface is vanishingly small. This assumption may not be entirely correct, but it appears physically more realizable than that of an impermeable boundary, and it is no more arbitrary than is estimating a suitable mass transfer coefficient; also, as will be shown later, under most conditions of operation this outside boundary condition is largely irrelevant. Boundary conditions [7] and [8] imply equilibrium exists at the boundary between the doped and undoped oxide, that the activity coefficients of dopant in the oxides are independent of concentration, and that all the dopant is free to diffuse, that is, there is continuity of flux at the interface. Conditions [9] and [10] again imply equilibrium and continuity of flux at the oxide-semiconductor interface, but here the segregation coefficient, m, defines the ratio of the activity coefficients of the dopant in the silicon and in the oxide; here again it is assumed that the activity coefficients in both phases are independent of concentration.

Equations [1] through [3] may be solved using boundary conditions [4] through [10], giving

$$C_1(x,t) = C_o \left[1 - \sum_o^\infty \frac{\alpha^n}{2} \left(\text{erfc} \left[\frac{2nx_o - x - x_B}{2\sqrt{D_1 t}} \right] + \alpha \text{erfc} \left[\frac{2nx_o - x + x_B}{2\sqrt{D_1 t}} \right] + 2\text{erfc} \left[\frac{(2n+1)x_o + x}{2\sqrt{D_1 t}} \right] - 2\alpha \text{erfc} \left[\frac{(2n+1)x_o - x}{2\sqrt{D_1 t}} \right] - \text{erfc} \left[\frac{(2n+2)x_o + x - x_B}{2\sqrt{D_1 t}} \right] - \alpha \text{erfc} \left[\frac{(2n+2)x_o + x + x_B}{2\sqrt{D_1 t}} \right] \right) \right] \quad [11]$$

$$C_3(x,t) = \frac{C_o}{2} \left[\sum_o^\infty \alpha^n \left(\text{erfc} \left[\frac{2nx_o + x_B + x}{2\sqrt{D_1 t}} \right] - \alpha \text{erfc} \left[\frac{2nx_o + x_B - x}{2\sqrt{D_1 t}} \right] - 2\text{erfc} \left[\frac{(2n+1)x_o + x}{2\sqrt{D_1 t}} \right] + 2\alpha \text{erfc} \left[\frac{(2n+1)x_o - x}{2\sqrt{D_1 t}} \right] + \text{erfc} \left[\frac{(2n+2)x_o - x_B + x}{2\sqrt{D_1 t}} \right] - \alpha \text{erfc} \left[\frac{(2n+2)x_o - x_B - x}{2\sqrt{D_1 t}} \right] \right) \right] \quad [12]$$

$$C_2(x,t) = \frac{C_o \sqrt{D_1/D_2}}{(1+k)} \sum_o^\infty \alpha^n \left(\text{erfc} \left[\frac{2nx_o + x_B + mkx}{2\sqrt{D_1 t}} \right] - 2\text{erfc} \left[\frac{(2n+1)x_o + mkx}{2\sqrt{D_1 t}} \right] + \text{erfc} \left[\frac{(2n+2)x_o - x_B + mkx}{2\sqrt{D_1 t}} \right] \right) \quad [13]$$

where

$$k = \frac{1}{m} \sqrt{D_1/D_2} \quad [14]$$

and

$$\alpha = \frac{1-k}{1+k} \quad [15]$$

These equations can be considerably simplified if we take the case where the doped oxide thickness is large compared to the diffusion length of the dopant in the oxide, that is, when

$$x_o - x_B \cong 4\sqrt{D_1 t} \quad [16]$$

as will be illustrated by experimental data, this condition is easily achieved for the case of boron. If inequality [16] holds, then terms containing x_o dominate the arguments of the functions in Eq. [11]-[13] and we can restrict the solutions to those terms for which $n = 0$. Then, the concentration of dopant in the silicon becomes

$$C_2(x,t) = \frac{C_o \sqrt{D_1/D_2}}{(1+k)} \text{erfc} \left[\frac{x_B + mkx}{2\sqrt{D_1 t}} \right] \quad [17]$$

For the case of no undoped barrier oxide ($x_B = 0$), this reduces to the simple case of diffusion from a semi-infinite source into a semi-infinite sink, or a complementary-error-function diffusion with an equivalent surface concentration, C_s

$$C_s = \frac{C_o\sqrt{D_1/D_2}}{(1+k)} \quad [18]$$

Thus, the surface concentration for this simple case is independent of time and depends on both the square root of the ratio of the diffusion coefficients and the segregation coefficient.

If we integrate expression [17] from $x = 0$ to $x = x_j$ (the junction depth in the semiconductor), we can determine Q, the total quantity of dopant per unit area which has diffused into the semiconductor and which is proportional to the sheet conductivity, or the inverse of the V/I commonly measured with a four-point probe:

$$I/V = 4.53Q\bar{\mu}q = 4.53\bar{\mu}q\left(\frac{2C_o\sqrt{D_1t}}{(1+k)}\left[\text{ierfc}\left[\frac{x_B}{2\sqrt{D_1t}}\right] - \text{ierfc}\left[\frac{x_B + mkx_j}{2\sqrt{D_1t}}\right]\right]\right) \quad [19]$$

where $\bar{\mu}$ is the effective mean mobility of carriers, q is the electronic charge, and 4.53 is $\pi/\ln 2$, the spreading-current factor for the 4-point probe. If the substrate resistivity is high enough (greater than 2 ohm-cm for most cases), the second term in Eq. [19] can be ignored. Then, for the simple case of no undoped barrier oxide

$$I/V = 8.15 \times 10^{-23}\bar{\mu}C_s\sqrt{D_2t} \quad [20]$$

or

$$\sqrt{D_2} = \frac{1.23 \times 10^{22}}{\bar{\mu}C_s}\frac{d(I/V)}{d(\sqrt{t})} \quad [21]$$

where $\bar{\mu}$ is in units of cm²/sec-V, C_s in atoms/cm³, I/V in mhos, t in hours, and D_2 in μ^2/hr. In addition, it can easily be shown that for this simple case the junction depth can be written

$$x_j = 2\sqrt{D_2t}\,\text{argerfc}\left[\frac{C_b}{C_s}\right] \quad [22]$$

or

$$\sqrt{D_2} = \frac{\frac{d(x_j)}{d(\sqrt{t})}}{2\text{argerfc}\left[\frac{C_b}{C_s}\right]} \quad [23]$$

where C_b is the bulk concentration of the semiconductor substrate. Thus, if we plot the sheet conductivity and the junction depth as functions of the square root of the diffusion time, we should obtain straight lines whose slopes are functions of the surface concentration[1] and are directly proportional to the square root of the diffusivity of the dopant in the semiconductor. If the surface concentration is high enough, it is possible to measure C_s independently, either by anodic oxidation profiling of the sheet conductivity (9) or by determining the plasma frequency (10, 11); when either or both of these techniques are used, it is possible to determine two independent values of D_2 from sheet conductivity and junction depth data. When the surface concentration is too low to be measured accurately, it is still possible to combine Eq. [21] and [23] and determine self-consistent values of D_2 and C_s from the above data.

Once the diffusion coefficient of the dopant in the semiconductor has been measured, it is possible to determine the diffusion coefficient, D_1, of the dopant in the oxide by comparing wafers with and without a thin undoped barrier oxide which have been coated and diffused simultaneously. If the subscript "B" refers to the wafer with a thin, undoped oxide of thickness x_B, and the subscript "N" refers to the wafer with no such barrier oxide, then manipulation of Eq. [17], [19], and [21] results in

$$\sqrt{D_1} = \frac{x_B}{2\sqrt{t}\,\text{argierfc}\left[\frac{\bar{\mu}_N(I/V)_B}{\bar{\mu}_B(I/V)_N\sqrt{\pi}}\right]} \quad [24]$$

$$\sqrt{D_1} = \frac{x_B}{2\sqrt{t}\,\text{argerfc}\left[\frac{(C_s)_B}{(C_s)_N}\right]} \quad [25]$$

$$\sqrt{D_1} = \frac{x_B\sqrt{D_2}}{(x_j)_N - (x_j)_B} \quad [26]$$

That is, if we measure the sheet conductivities, the surface concentration, and the junction depths for diffused wafers with and without a barrier oxide, we can obtain three independent measurements of the diffusivity of the dopant in the oxide.

The segregation coefficient, m, can be determined once the diffusion coefficients are known, from the following relationships derived from Eq. [17] for a wafer with no barrier oxide

$$m = \frac{1}{8.15 \times 10^{-23}\bar{\mu}(V/I)C_o\sqrt{D_2t} - \sqrt{D_2/D_1}} \quad [27]$$

$$m = \frac{1}{\frac{C_o}{C_s} - \sqrt{D_2/D_1}} \quad [28]$$

$$m = \frac{1}{\frac{C_o}{C_b}\text{erfc}\left[\frac{x_j}{2\sqrt{D_2t}}\right] - \sqrt{D_2/D_1}} \quad [29]$$

Thus, we can determine the constants of the diffusion by determining surface concentrations, sheet conductivities, and junction depths, and then, in turn, calculate concentration profiles from this model for any given diffusion time, diffusion temperature, and initial dopant concentration in the oxide.

Experimental

The substrates used in this work were all (111) silicon wafers, sliced from Czochralski-grown crystals, lapped on both sides, and mechanically and chemically polished on one side. The boron doped oxides were deposited by oxidation of silane and diborane at a substrate temperature of 400°C, and the diffusions were performed in dry nitrogen ambients. The thickness of the doped oxide was normally 0.5μ, although several experiments were done with thicker films. The boron concentration of the films was determined by flame photometric analysis of films deposited simultaneously with those used for diffusion (13). The sheet conductivity was measured with a four-point probe in an 18-position array on each wafer; earlier studies have shown that the distribution of these values across the wafer is normal; a typical standard deviation was less than 5% of the mean. Junction depths were measured using the Nomarsky interfer-

[1] Actually the slope of the sheet conductivity curve is a function of the product of the surface concentration and the mean mobility of the carriers, defined as

$$\bar{\mu} = \frac{\int_o^{x_j}\mu(C)\,C(x,t)\,dx}{\int_o^{x_j}C(x,t)\,dx}$$

It can be shown that if $C_2(x,t)$ has the form of a complementary error function, $\bar{\mu}$ is independent of diffusion time and depends on the surface concentration only. Using this assumption, we have calculated $\bar{\mu}$ as a function of C_s by numerical integration of Irvin's conductivity mobility data (12), assuming complete ionization.

ence technique after delineation by grooving and staining with a nitric-hydrofluoric acid solution (70% HNO_3:49% HF:H_2O = 0.1:50:50, by volume). The surface concentration, as mentioned above, was determined either from a profile (normal to the surface) of the sheet conductivity or from the minimum in the infrared reflection spectrum (plasma-frequency technique). Ellipsometric methods were used to measure the thickness of the barrier oxides used for measurements of the diffusivity of boron in the oxide.

Results

That these diffusions actually do follow the behavior predicted above is evidenced by Fig. 2 and 3 where the results of diffusions of boron into silicon at 1100°C from three different initial doping concentrations are shown. In addition, as predicted by Eq. [18], the surface concentrations remain constant in time, with the possible exception noted below. The concentration profile for a typical diffusion is shown in Fig. 4; the solid dots are the values measured by a sheet-conductivity profiling technique (9), and the bars are estimates of the uncertainty of the measurement, reflecting primarily a ±2% accuracy in measuring the sheet conductivity. The data follow a complementary-error-function curve satisfactorily, although at this level of accuracy it is probably impossible to distinguish between this profile and a Gaussian profile.

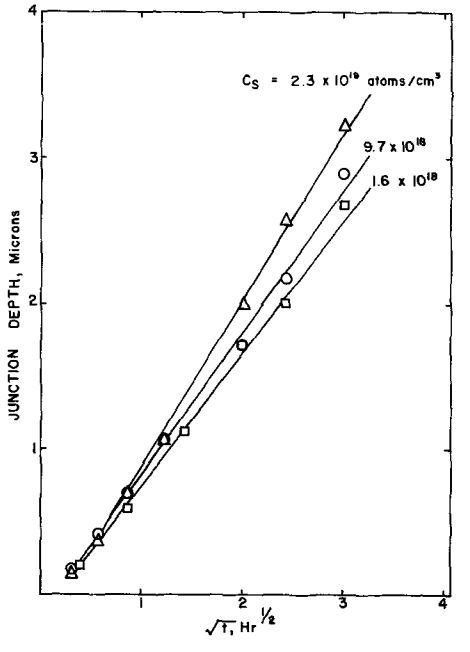

Fig. 3. Junction depths resulting from diffusion of boron into silicon at 1100°C from deposited oxides with different initial boron concentrations.

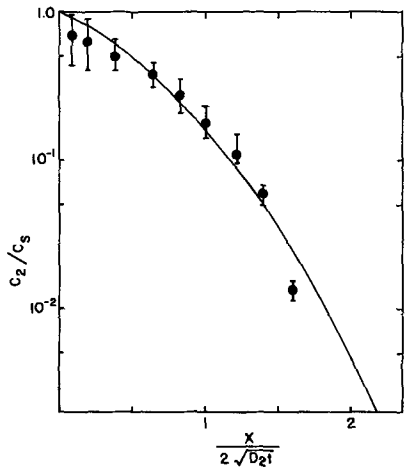

Fig. 4. Concentration profile of boron diffusing into silicon from a deposited oxide.

At temperatures below 1100°C, we find experimentally that the sheet conductivity and junction depth curves are shifted slightly along the positive time axis from the origin; we explain this as the effect of a thin, irremovable oxide which always exists at the silicon surface and which acts as a diffusion barrier. Calculations based on our diffusion model yield an estimated thickness of this oxide of about 50Å, and this is corroborated by ellipsometric measurements. At high temperatures this thickness is normally small compared to the diffusion lengths of dopant in the oxide, and the effect disappears.

At high surface concentrations (about 1 x 10^{20} at./cm³), a more serious deviation from our simple model occurs: the $I/V - \sqrt{t}$ curve becomes distinctly concave downward at diffusion times of about 2-3 hr, as shown in Fig. 5. There also may be a slight decrease in the surface concentration at this point, although the decrease is about the same size as the estimated accuracies of the measuring techniques used. At higher temperatures this behavior begins at lower

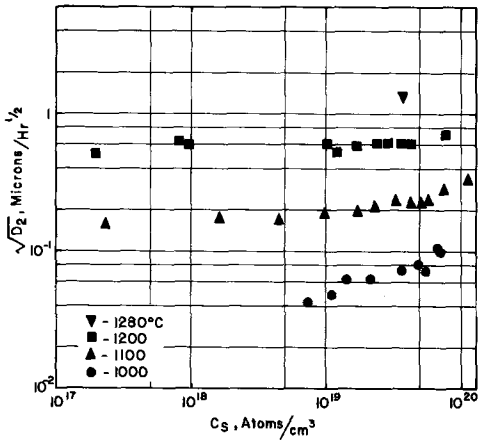

Fig. 6. Diffusion coefficients of boron in silicon at various temperatures and surface concentrations.

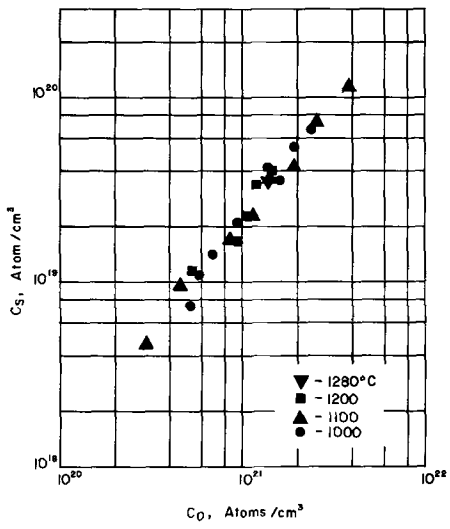

Fig. 7. Surface concentrations of boron in silicon resulting from various concentrations of boron in the deposited oxide.

surface concentrations, and conversely at lower temperatures. The junction depth remains a linear function of $\sqrt{t}$ for all conditions as is also shown in Fig. 5. This effect at high surface concentrations is quite reproducible, and effective diffusion coefficients calculated from the junction depth measurements are in agreement with predicted values.

The square roots of the diffusion coefficients of boron in silicon measured using all the above techniques at surface concentrations from 2 x 10^{17} to 1 x 10^{20} at./cm^3 and for temperatures from 1000° to 1280°C are shown in Fig. 6. Results of measurements of the diffusivity of boron in the oxide and the segregation coefficient at various temperatures are shown in Table I; the three different methods cited for the diffusivity measurements refer to Eq. [24], [25], and [26], respectively, while the values for the segregation coefficient were calculated from surface concentration data using Eq. [28].

The surface concentrations resulting from various concentrations of boron in the deposited oxide are shown in Fig. 7. Surface concentrations greater than 2.5 x 10^{19} at./cm^3 were measured using the techniques described earlier, while those less than this figure were calculated. The overlapping of the points at different temperatures reflects the relative insensitivity of the ratio of the diffusion coefficients to temperature.

Reliability of the Data

The data presented above fall into two general classifications: In some cases it has been possible to measure the same parameter with more than one technique; for example, at relatively high surface concentrations we can measure the diffusivity of boron in silicon by either the sheet-conductivity method (Eq. [21]) or by the junction-depth method (Eq. [23]). The validity of the model is then directly related to the agreement between these independent values, and these values can be legitimately compared to diffusivities and segregation coefficients measured by other techniques. Data which fall in the other class comprise those cases where independent values of one parameter are not readily measurable; then the parameters calculated can only be self-consistent and cannot be used directly to test the validity of the model, but can be used to make predictions of experimental behavior within the range of the model. In discussing the reliability of the data, then, it is important to distinguish between the accuracies involved in establishing the model as valid and the reliability which can be claimed (based on self-consistent data) for predicting experimental behavior from this model.

The reliability of the values reported above has been estimated by a geometrical combination of deviations for each of the factors entering in the calculations. For example, the diffusivity of boron in silicon as calculated by the sheet-conductivity method (Eq. [21]) is a function of the slope of the $I/V - \sqrt{t}$ curve, the effective mean mobility, and the surface concentration. The sheet conductivity data have been fitted to a least-squares straight line assuming no uncertainty in the diffusion time values; the relative standard deviations of the slopes of these lines are typically well under 5%. The uncertainty in the measured surface concentration can be as high as 25% in some cases, while the uncertainty of the mean mobility is close to 10%; these combine to yield an expected relative standard deviation in $\sqrt{D_2}$ of about 28%. In similar fashion, $\sqrt{D_2}$ calculated from junction depth measurements (Eq. [23]) has a relative standard deviation of only about 6%, primarily because argerfc (C_b/C_s) is insensitive at values of C_b and C_s normally encountered. Table II shows values of $\sqrt{D_2}$ for boron in silicon at various temperatures, as determined by these two methods. In general, there is excellent agreement between these two methods, much better than predicted from the relative accuracies of the measurements, and this agreement indicates the model is applicable under these diffusion conditions.

On the other hand, the uncertainties in the self-consistent data are much smaller than predicted above because a direct measurement of the surface concentration is not involved. For example, analyses similar to that above result in expected deviations of about 15% for $\sqrt{D_2}$ and about 12% for calculated values of

Table I. Diffusion parameters of boron in oxide

Temp, °C	C_o, at./cm^3	$\sqrt{D_1}$ ($\mu/\sqrt{hr}$), by method of: Sheet conductivity	Surface concentration	Junction depth	m
1000	1.4 x 10^{21}	—	—	0.0011	—
1100	1.4 x 10^{21}	0.01	0.01	0.006	0.2
1200	1.4 x 10^{21}	0.02	0.03	0.015	0.06
1280	1.4 x 10^{21}	0.04	0.06	0.02	0.06

Table II. Diffusion coefficients of boron in silicon by junction-depth and sheet-conductivity methods

Temp, °C	C_s	$\sqrt{D_2}$ ($\mu/\sqrt{hr}$), by method of: Sheet conductivity [21]	Junction depth [23]
1000	8 x 10^{19}	0.1	0.098
1100	5 x 10^{19}	0.2	0.22
1200	4 x 10^{19}	0.6	0.60
1280	4 x 10^{19}	1.3	1.41

C_s; in these cases, the major uncertainty is in the mobility data used.

The uncertainties in the measurements of the diffusion coefficient of the dopant in the oxide and the segregation coefficient are generally larger than those mentioned above. Normally in these calculations we are using either small differences between measured values or functions which are very sensitive to the ratios of experimentally determined values; in either case, slight errors can be magnified into large relative deviations. As a result, values of $\sqrt{D_1}$ are probably good only within ±50%, while values of m (which reflect the total of all the uncertainties listed above plus a 10% deviation in the determination of C_o, lumped into one calculation) are reliable only within a factor of 3.

Discussion of Results

Any test of the validity of a simple model such as that formulated above must indicate how well experimental data within the specified range of the model agree with its predictions and how severely the model must be modified to cover cases falling outside this specified range. With this in mind, we will discuss, first, the over-all behavior of the data and, then, in more detail, the deviations which appear at high surface concentrations.

Inspection of the results shown in Fig. 6 shows that the diffusion coefficient of boron in silicon is not strictly independent of the concentration, as is assumed in our simple model. Much of this concentration dependence can be explained by including effects of the self-induced field acting on the ionized dopants or, in other words, considering the electrochemical potential as the driving force, rather than just the chemical potential. Then an effective diffusion coefficient can be written as shown by Smits (14) and Kurtz and Yee (15):

$$D_{\text{eff}} = D_2\left(1 + \frac{C_2}{\sqrt{C_2^2 + 4n_i^2}}\right) \qquad [30]$$

where n_i is the intrinsic carrier concentration in the substrate at the diffusion temperature. The effective diffusion coefficient then varies between D_2 at low surface concentrations and twice this value at high surface concentrations. The transition regions should extend roughly from 3 x 10^{18} to 9 x 10^{19} at./cm^3 at 1000°C, from 5 x 10^{18} to 2 x 10^{20} at./cm^3 at 1100°C, and from 1 x 10^{19} to 3 x 10^{20} at./cm^3 at 1200°C. Within these concentration limits the diffusivities we have reported are actually values averaged over the range of concentration extending from the surface to the lower value of the limits given above. Since the majority of dopant atoms in these diffusions are at high concentrations near the surface, it is a reasonable approximation to report the diffusion coefficients as a function of surface concentration.

A more serious problem, both in terms of validating our diffusion model and in terms of making accurate predictions of diffusion behavior, is the divergence of the sheet conductivity $-\sqrt{t}$ curve from a straight line at high surface concentrations. The reason for this behavior is not known at the present time, but several hypotheses which have been advanced are discussed in some detail below:

1. formation of an oxide barrier at the doped oxide-silicon interface;
2. nonuniform concentration of the dopant in the oxide;
3. excessive out-diffusion of dopant from the oxide;
4. dependence of the diffusivity of the dopant in the oxide on concentration;
5. nonequilibrium at the interface.

If it is assumed that boron is transferred across the oxide-silicon interface by a reaction such as

$$2B_2O_3 + 3Si \rightarrow 3SiO_2 + 4B$$

then it can be shown that the ratio of the thickness of SiO_2 grown (x_o') to the diffusion length of boron in the oxide is

$$\frac{x_o'}{2\sqrt{D_1 t}} = \frac{1.8 \times 10^{-23} C_o}{1 + 1/m\sqrt{D_1/D_2}} \qquad [31]$$

where C_o is in units of at./cm^3. Even in heavily doped oxides, where C_o may be 3 x 10^{21} at./cm^3, the oxide formed is only a few per cent of the diffusion length of the dopant in the oxide and will not interfere significantly with the course of the diffusion.

The anomalous results shown above in Fig. 5 can also be explained by a nonuniformly doped oxide with a high surface concentration of dopant close to the oxide-silicon interface (see Appendix A). However, in our particular deposition system, a change in the deposition rate greatly magnifies any concentration gradient existing in the oxide, and we have seen no change in the anomalous behavior described above over a twentyfold deposition rate increase. Therefore we conclude that this behavior is not a result of a concentration gradient in the oxide. In addition, we have found that depositing a 1.5μ doped oxide, rather than the normal 0.5μ film, has no effect on the shape of the sheet conductivity curve at high surface concentrations. This confirms our assumption, based on the data given in Table I, that excessive out-diffusion of dopant from the oxide into the ambient is not the cause of this anomaly.

We have not been able to measure the diffusion coefficient of the dopant in the oxide accurately enough to test its independence of concentration. It is not unlikely, however, that the diffusion coefficient of boron becomes dependent on its concentration in the oxide at the relatively high levels where our discrepancies appear (16), and variations in the diffusion coefficient as large as those noted in Table I would be sufficient to cause the behavior shown in Fig. 5.

It has also been proposed that equilibrium does not always exist at the silicon-oxide interface; that in the initial stages of the diffusion, perhaps because of high stresses at the surface or because of specific boron-silicon compound formation (17), a large quantity of dopant is transferred across the interface and then diffuses normally into the substrate. At the present time, we have not been able to devise experimental means of discriminating between this behavior and that listed directly above.

It should be emphasized here that the deviations which have been discussed above occur only over a very limited range of surface concentrations, and that in the majority of cases of interest, the model presented above is quite adequate to describe the experimental behavior. A comparison is made in Fig. 8 of some of our data with that reported by other workers. Our values for the diffusivity of boron in silicon at surface concentrations near 3.5 x 10^{19} at./cm^3 are slightly lower than those of Fuller and Ditzenberger (18) at high surface concentrations, but agree well with those of Kurtz and Yee (15) and Maekawa and Oshida (19) at comparable concentrations. Our values for m agree with those estimated by Grove *et al.* (20).

Conclusions

The technique of diffusing from doped oxides deposited at low temperatures is very attractive, primarily because of complete and independent control of the surface concentration. The solution of the diffusion equations, with appropriate simplifications, predicts that the diffusion profile in the semiconductor substrate will follow a simple complementary error function if the thickness of the doped oxide is sufficient, and that the effective surface concentration depends directly on the initial concentration of dopant in the oxide, the ratio of diffusivities of the dopant in the oxide and in the semiconductor, and the segregation coefficient. The model also predicts simple techniques for measuring these parameters. We have shown ex-

perimentally that this model is followed for surface concentrations less than 1 x 10^{20} at./cm^3, and we have determined values of the diffusion coefficients of boron in silicon over wide ranges of temperature and concentration. We have not been able to explain certain deviations from this model at surface concentrations greater than 1 x 10^{20} at./cm^3, but diffusions in this range are reproducible and thus useful.

APPENDIX A

Diffusion from a continuously varying concentration of dopant in the initial deposited oxide can be approximated by the case of diffusion from a series of oxide increments parallel to the silicon interface, the dopant concentration being constant within any increment but varying from increment to increment. The first order solution[2] given here is for one increment, x_i thick, with a uniform concentration C_{oi} adjacent to the silicon, with the remainder of the oxide $x_o - x_i$ thick, having a uniform concentration C_o. The concentration in the substrate is

$$C_2(x,t) = \frac{mk}{1+k}\sum_0^\infty \alpha^n \left[C_o \left(\operatorname{erfc}\left[\frac{2nx_o + x_i + mkx}{2\sqrt{D_1 t}}\right] - 2\operatorname{erfc}\left[\frac{(2n+1)x_o + mkx}{2\sqrt{D_1 t}}\right] + \operatorname{erfc}\left[\frac{(2n+2)x_o - x_i + mkx}{2\sqrt{D_1 t}}\right]\right) + C_{oi}\left(\operatorname{erfc}\left[\frac{2nx_o + mkx}{2\sqrt{D_1 t}}\right] + \operatorname{erfc}\left[\frac{(2n+2)x_o + mkx}{2\sqrt{D_1 t}}\right] - \operatorname{erfc}\left[\frac{2nx_o + x_i + mkx}{2\sqrt{D_1 t}}\right] - \operatorname{erfc}\left[\frac{(2n+2)x_o - x_i + mkx}{2\sqrt{D_1 t}}\right]\right)\right] \quad [A\text{-}1]$$

If x_o is large, this reduces to

$$C_2(x,t) = \frac{mk}{1+k}\left(C_{oi} \operatorname{erfc}\left[\frac{x}{2\sqrt{D_2 t}}\right] - C_{oi} - C_o) \operatorname{erfc}\left[\frac{x_i + mkx}{2\sqrt{D_1 t}}\right]\right) \quad [A\text{-}2]$$

The sheet conductivity then has the form

$$I/V = 9.06\,\bar{\mu}q\left(\frac{mk}{1+k}\right)\left(\frac{C_{oi}}{\sqrt{\pi}} - (C_{oi} - C_o)\ \text{ierfc}\left[\frac{x_i}{2\sqrt{D_1 t}}\right]\right)\sqrt{D_2 t} \quad [A\text{-}3]$$

For suitable values of C_{oi} and x_i, this function has the shape of the conductivity curve given in Fig. 5.

[2] This solution and Eq. [11], [12], and [13] are by the method of LaPlace transformation (21).

Study of the Dissipation Factor of $PbZr_{0.7}Ti_{0.3}O_3$ in the Vicinity of the Curie Point

Donald F. Weirauch[1] and Victor J. Tennery[2]

Department of Ceramic Engineering, University of Illinois, Urbana, Illinois

For most ferroelectric and antiferroelectric phases possessing the perovskite structure the relative permittivity exhibits a maximum at the temperature where the material transforms to a paraelectric phase. Within the phase transformation region the measured dissipation factor or loss tangent usually exhibits an anomaly whose origin is in many cases unclear. In the case of polycrystalline $PbZr_{0.7}Ti_{0.3}O_3$, at audio frequencies the dielectric loss increases with increasing temperature except in the vicinity of the phase transformation from the rhombohedral ferroelectric phase to the paraelectric cubic phase at 340°C. At this temperature the measured loss decreases anomalously before increasing again at higher temperatures. This work reports data which indicated that for this solid solution the decrease in dissipation factor in the vicinity of the transformation temperature is primarily a consequence of the large change in the material's electrical permittivity and not due to an anomaly in the electrical resistivity.

Ceramic specimens of $PbZr_{0.7}Ti_{0.3}O_3$, 1.5 cm in diameter and 0.3 cm thick and possessing densities of 85% of theoretical, were prepared by standard techniques. Gold electrodes were applied to the flat parallel faces of the specimens by a vacuum evaporation method.

Capacitance and dissipation factor measurements were made at a frequency of 10 kHz on specimens enclosed in a small stainless steel holder whose temperature could be controlled to ± 0.2°C (1). A General Radio 1620-A capacitance measuring assembly was used for these measurements. The direct current resistivity of the same specimen was measured in the same holder with a Keithly 610A electrometer. Figure 1 shows the relative permittivity and dissipation factor of a typical specimen as a function of temperature.

It was assumed that the dielectric could be represented by an equivalent parallel circuit consisting of a capacitor in parallel with a resistor. From the measured capacitance and dissipation factor and the specimen's geometry the equivalent parallel resistivity of the specimen could be calculated from the relation

$$D = \frac{1}{2\pi fRC} = \frac{1}{\omega RC} \qquad [1]$$

which is valid for the simple parallel circuit. In this expression D = dissipation factor, f = frequency, C = parallel equivalent capacitance, R = parallel equivalent resistance, and ω = the angular frequency. If the parallel equivalent resistivity were approximately equal to the measured d-c resistivity, then the losses were all essentially conductive in nature. Also, the equivalent circuit represented the dielectric through the phase transformation region if both resistivities had the same value and the same temperature dependence through this region. Figure 2 shows that indeed these two resistivity values are very nearly equal to each other above 200°C and that they have the same temperature dependence above this temperature. Therefore, above about 200°C and at this frequency the parallel equivalent circuit was a reasonable approximation for this dielectric material. The electrical conductivity of the specimen had thus become the major source of dielectric losses in this material at these high temperatures. The observed changes in the a-c and d-c resistivities at the transformation temperature were small and, because of the demonstrated validity of Eq. [1], the decrease in the dissipation factor at the transformation temperature was due to the large observed increase in the permittivity. The rise

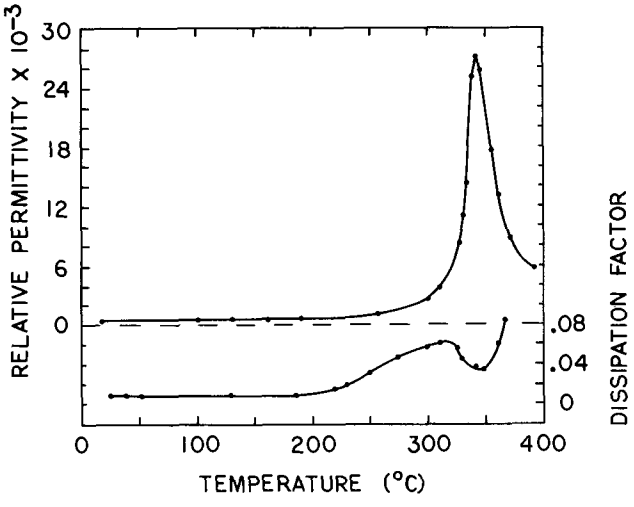

Fig. 1. Relative permittivity and dissipation factor of $PbZr_{0.7}Ti_{0.3}O_3$ as a function of temperature.

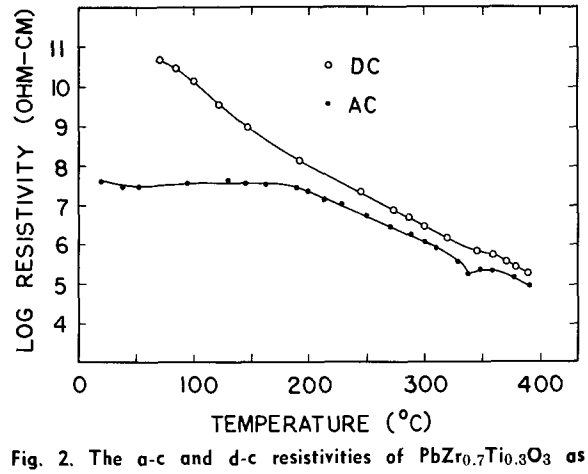

Fig. 2. The a-c and d-c resistivities of $PbZr_{0.7}Ti_{0.3}O_3$ as a function of temperature.

in dielectric loss just prior to the permittivity peak was due to the increasing conduction losses. The sharp rise in loss at temperatures just above the transformation was due to the ever increasing conduction losses and the sharp decrease in permittivity in the cubic phase region.

Solid Solution in the Silicon Nitride-Silicon Dioxide System

N. C. Tombs,[1] F. A. Sewell, Jr., and J. J. Comer[2]

Sperry Rand Research Center, Sudbury, Massachusetts

Since the description of a new insulated-gate field-effect transistor using silicon nitride as the diffusion mask and gate dielectric (1), considerable effort has been directed toward the investigation of silicon nitride for semiconductor device applications (2). This note describes investigations of the preparation and properties of the solid solution series which we were able to form between silicon nitride and silicon dioxide as end members.

We have observed that the pyrolytic reaction between silane and ammonia gases can, in the presence of certain oxygen-containing gases, yield amorphous films having compositions intermediate between those of silicon nitride and silicon dioxide (3). This has formed the basis for the controlled preparation of a series of films covering the full range of composition. It is shown by infrared absorption, electron diffraction, and optical studies that these materials are to be regarded as solid solutions rather than multiphase mixtures. The formation of the full range of solid solutions is presumably facilitated by the structural flexibility inherent in the amorphous state. Film characteristics such as etch rate in hydrofluoric acid, maximum field strength, and dielectric constant, are influenced by the solid solution composition in a manner which enables a practical compromise to be achieved for device applications.

Films were deposited on silicon substrates which had been mechanically polished and chemically etched in the conventional manner. Deposition was carried out in all-glass flow system, using an rf-heated graphite susceptor sealed in a quartz envelope. The reaction gases were silane, ammonia, and nitrous oxide at a 1% concentration in argon carrier gas. In order to obtain consistent results, it was found to be essential to minimize contamination of the reaction gases both prior to and during the reaction. Suitable deposition conditions for the entire range of films involved a substrate temperature of 900°C (uncorrected optical pyrometer reading), and a total flow rate of 18-20 liters/min, with an ammonia-silane volume ratio of 80:1.

Film thickness was determined by etching a step, evaporating a reflecting silver layer onto the surface, and measuring the fringes formed in a double-beam interferometer. A reflection spectrum was obtained over the wavelength range 0.5-1.5μ, using a Beckman DKZA spectrometer. The refractive index was obtained from the reflection minimum, the film thickness, and the instrument geometry. The film etch rate was determined at 22°C using buffered HF etch (100 ml saturated ammonium fluoride to 15 ml concentrated HF, 48%). The principal absorption band in the 5-25μ region was determined using a Perkin-Elmer Model 337 Spectrophotometer. The dielectric constant was determined from maximum capacitance *vs.* voltage measurements using 10 mil diameter aluminum electrodes evaporated onto the film.

Figure 1 shows the results obtained, on corresponding samples, for etch rate, IR absorption maximum, refractive index, and dielectric constant, *vs.* mole-per cent ammonia replaced by nitrous oxide in the reaction mixture. It is seen that the results follow a reasonably smooth curve, with the greatest effect of nitrous oxide increments occurring at the lower concentrations, as might be expected. Insofar as a direct comparison is justified, in view of the important effect of the experimental conditions, these results are consistent with other published data (4). It is not certain that these zero per cent N_2O samples do in fact represent entirely oxygen free silicon nitride, and this fact might account for the dielectric constant being close to 6, compared with values of 7 to 8 previously published. It should also be noted that the use of lower ammonia to silane ratios can yield silicon excess samples with increased dielectric constants. Concerning the refractive index, values somewhat less than

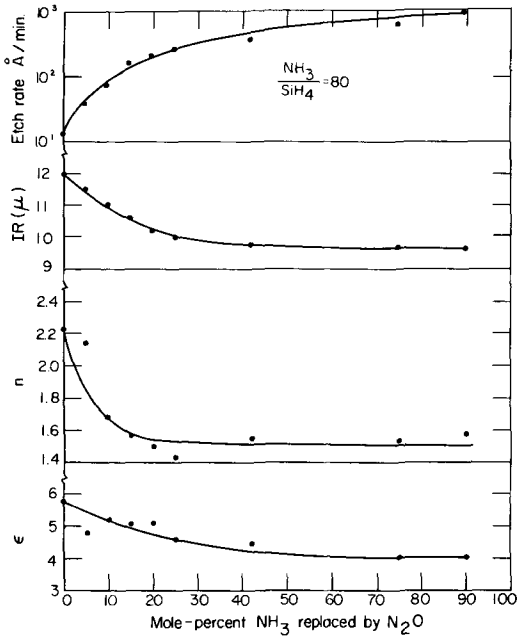

Fig. 1. Measured film properties *vs.* mole-per cent NH_3 replaced by N_2O in the reaction mixture.

[2] Present address: Air Force Cambridge Research Laboratory, Bedford, Massachusetts.

our value of 2.2 for the end member have been reported. The discrepancy is difficult to explain, especially since our corresponding dielectric constant is about 6.

Information concerning the structure of the films was obtained using selected-area transmission electron diffraction techniques (JEM 6A electron microscope, 100 kv beam). It was necessary to make windows in the silicon substrate, using the jet-chemical etching method of Booker and Stickler (5). Two specimens were usually prepared from each film sample, one film being reduced to about one half of its initial thickness (2000Å) by continuing the etching process after the silicon window had been opened. Both film thicknesses always gave similar diffraction results, so that no variations with depth through the film were apparent. However, the thinner film gave better diffraction contrast. A calibration spot-pattern for silicon could be superimposed on the amorphous film pattern by exposing a thinned edge of the silicon to the electron beam.

All the nitride and oxynitride films gave diffuse ring patterns characteristic of amorphous structures. The positions of the diffraction rings were measured on the photographic plates using a steel rule. Despite the simplicity of the technique, it is felt that the accuracy of the ring diameter measurements was ± 1%. The "d" spacings corresponding to the three most distinct diffraction rings are tabulated in Table I for films prepared using various mole-per cent replacements of ammonia by nitrous oxide. Results for a silicon dioxide film formed by thermal oxidation of silicon are also included. Figure 2 shows a plot of the outermost "d" spacing *vs.* composition. Figure 3 shows diffraction patterns for 0 and 90 m/o replacement of ammonia by nitrous oxide.

The gradual change in "d" values with composition indicates that the silicon nitride and silicon dioxide end members form a continuous series of solid solutions rather than simple mixtures. This evidence forms valuable support for that provided by the corresponding gradual change in the infrared absorption and other characteristics of the films. From the point of view of practical device applications, it is normally desirable to achieve a single-phase film in order to avoid possible inhomogeneous properties associated with mixtures. Previous reports concerning films intermediate in composition between silicon nitride and silicon dioxide (4) have not always clearly distinguished the solid solution and mixture possibilities, and electron diffraction appears not to have been applied to this problem previously. It is, in fact, possible that some preparation techniques will yield mixtures instead of solid solutions. Drum and Rand (6) have applied electron-beam microanalysis to a series of oxynitride films in connection with comparative stress measurements. They find that the atomic fraction of silicon in the various compositions is not consistent with the presence of a mixture of silicon nitride and silicon oxide.

It is of interest that Coleman and Thomas (7) have studied the structure of silicon nitride and silicon dioxide films formed by a glow discharge method. In the case of nitride, compositions ranged from silicon

to silicon nitride. Using the variation of the scattered intensity of an electron beam with angle, they have deduced the position, number, and type of atoms surrounding a given origin atom. An analogous approach might usefully be applied to the silicon nitride-silicon dioxide films we have described.

Thermal Expansion of Sputtered Silicon Nitride Films

P. J. Burkhardt* and R. F. Marvel

IBM Components Division, East Fishkill Laboratory, Hopewell Junction, New York

When silicon nitride first came into vogue in the semiconductor industry as a thin film passivating material for silicon planar devices, one of its strong selling points was that its thermal match with silicon was better than that of silicon dioxide. At that time, the best available value for the thermal expansion coefficient was that measured for the bulk crystalline material by Popper and Ruddlesden (1). This was given as 2.5×10^{-6} °C^{-1}. Bean *et al.* (2) have approximated the expansion coefficient of pyrolytically deposited silicon nitride as 4.2×10^{-6} °C^{-1} over a temperature range of 0°-1000°C by measuring the curvature of a silicon-silicon nitride wafer. More recently Tokuyama *et al.* (3) measured the expansion coefficient of pyrolytically deposited silicon nitride by measuring the curvature of a silicon-silicon nitride strip by x-ray diffraction microscopy. Their measurements were made on strips on which nitride had been deposited at 800° and 1000°C and cooled to room temperature. Rather than using the expansion coefficient of silicon, they measured equivalent strips with steam-grown SiO_2 and used the value of 5.5×10^{-7} °C^{-1} for SiO_2 as a reference. The same authors also reported the observation of cracks in the silicon nitride films. Because of the apparently good thermal match of silicon nitride and silicon, they concluded that differences in Young's modulus between silicon and silicon nitride caused the cracking.

We have developed a technique for measuring the thermal expansion coefficient of thin films such as silicon nitride directly without the use of bending beams. In this method, a cathetometer is used to measure the distance between two reference marks as a function of temperature on a freely suspended strip of film. Thus the need for a reference expansion coefficient is eliminated. Furthermore, the effect of any intrinsic interfacial stress of unknown temperature dependence, which may be present in a silicon nitride-silicon beam, is eliminated.

The silicon nitride films with which this study is concerned were produced by rf sputtering (4). This method of deposition on silicon substrates results in large intrinsic compressive stresses. These stresses are isothermally produced and would complicate a beam-type expansion coefficient measurement unless their thermal behavior is known.

For completeness the thermal expansion of a single crystal silicon wafer was also measured in the <110> direction with the same apparatus.

Experimental

Specimen preparation.—The sample films were prepared by sputtering them 1-2μ thick onto a strip of annealed molybdenum metal. The strip was ½ in. wide, 3 in. long, and 0.003 in. thick. Before cutting, the molybdenum sheet was rolled over an edge to provide a lateral curvature (Fig. 1 insert). The purpose of the curvature was to keep the stripped silicon nitride film from curling along its length.

The sequence in preparing the films was as follows: Two fiducial marks were scribed onto the molybdenum strip with a diamond scribe, at a distance no farther apart than the range of the cathetometer. The molybdenum strips were etched briefly in aqua regia. Next the silicon nitride film was deposited. Following deposition, the strips were placed into a furnace at 800°C, where commercial chlorine gas was used to etch away the molybdenum. This etching left intact the straight strips of silicon nitride film, with the scribed fiducial marks replicated on them.

Many attempts were necessary to obtain films that would remain intact after chlorine etching. Successful results were obtained by sputtering at 4μ nitrogen pressure from a Cerac[1] hot pressed silicon nitride target and by using an rf power density of 4.0 w/cm^2. The substrate temperature was 300°C.

Chemical analysis of comparable stripped silicon nitride films showed them to be about 98% Si_3N_4. Impurities detected by electron microprobe were Mo, Cl, O, Ca, and Al.

Measurement.—After stripping, the silicon nitride strips were suspended from a silica clip in a vertical silica tube furnace (Fig. 1). The furnace was wound with Kanthal A-1 wire and contained an optical silica window 4 in. long and 1 in. wide.

A chromel-alumel thermocouple was located in a well directly behind the specimen. It could be raised and lowered for measuring the temperature along the entire length of the specimen. This profiling at several temperatures showed that the variation in temperature along the length of the specimen was always less than 1°. All measurements were made in an air ambient.

The silicon strip was cut from a 2¼ in. silicon wafer and was mounted in the furnace in the same way as the silicon nitride film.

A Gaertner micrometer slide cathetometer was used to measure the distance between the two fiducial marks. The cathetometer itself was provided with aluminum foil reflectors and other heat-shielding devices to prevent expansion of the micrometer from heat radiated by the furnace. The instrument was placed about 1 ft from the furnace. The micrometer slide used

for these measurements had a range of 50 mm and a sensitivity of 0.001 mm.

Results and Discussion

The variation in distance between fiducial marks with temperature for the sputtered silicon nitride strip is shown in Fig. 2. These data points represent many temperature cycles on a single sample, to ensure that any annealing effects, at least within the temperature range of the measurements, would be observed. The data were fitted by the method of least squares (by use of an IBM 7090 computer) to the four-parameter equation

$$l = c_1 + c_2 e^{-c_3 t} + c_4 t \qquad [1]$$

where l is in millimeters and t is in degrees centigrade. The computed constants c_1, c_2, c_3, and c_4 of Eq. [1] are given in Table I for silicon and silicon nitride. The data obtained for silicon, along with the least squares fit to Eq. [1], are shown in Fig. 3. Note that over most of the range the scatter is much less than that for the

Table I. Computed constants for silicon and silicon nitride

Parameter	Silicon	Silicon nitride
c_1 (mm)	47.574	45.271
c_2 (mm)	0.3752	3.064×10^{-2}
c_3 ($°C^{-1}$)	6.834×10^{-4}	5.596×10^{-3}
c_4 (mm $°C^{-1}$)	3.745×10^{-4}	1.816×10^{-4}
a_1 ($°C^{-1}$)	-5.35×10^{-6}	-3.78×10^{-6}
a_2 ($°C^{-1}$)	6.83×10^{-4}	5.60×10^{-3}
a_3 ($°C^{-1}$)	7.81×10^{-6}	4.01×10^{-6}

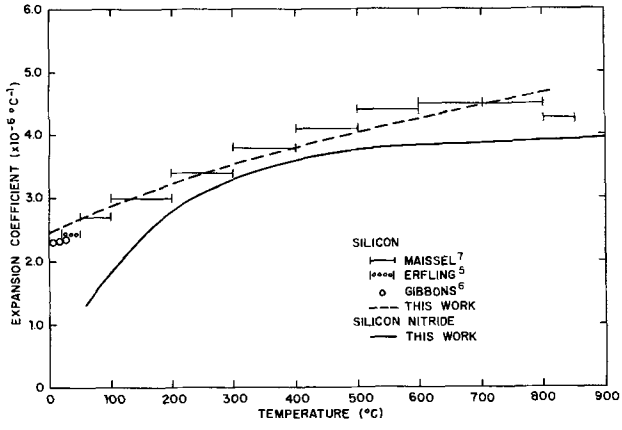

Fig. 4. Variation, with temperature, of the coefficient of thermal expansion of silicon and of a silicon nitride film.

silicon nitride films. The scatter in the thin film measurements is attributed primarily to the relative lack of rigidity of the film in spite of its lateral curvature. The thin films are therefore much more subject to distortion by room vibrations and convection than the rigid silicon strips. Both were observed.

The expansion coefficients can be expressed empirically in terms of the constants in [1] by

$$\alpha = a_1 e^{-a_2 t} + a_3 \qquad [2]$$

The constants a_1, a_2, and a_3 are simple functions of the constants in Eq. [1] and also are given in Table I.

Figure 4 shows the variation of the computed expansion coefficients with temperature, along with some data on silicon published by other authors (5-7). The curve for silicon fits fairly well with the data obtained by other authors except at the low- and high-temperature ends. It is felt that if measurements were made at lower temperatures, say down to —100°C, the fit to the data of Erfling (5), Gibbons (6), and Maissel (7) would be better.

Over the entire temperature range investigated, the thermal expansion coefficient of silicon nitride is lower than that of silicon. Above 200°C the difference between the two is very small. The thermal stresses that result from depositions at elevated temperatures will be compressive.

This result is contrary to the conclusions reached by Bean *et al.* (2). Their value of 4.2×10^{-6} in the range 0°-1000°C presumably is deduced from wafer curvature by assuming that all of the curvature is related to the thermal mismatch. Doo *et al.* (8), as did Bean *et al.*, also found wafer curvature in silicon nitride films deposited pyrolytically from silane-ammonia mixtures. The curvature has been observed to develop during deposition, *i.e.*, isothermally (9). By the same token, reverse curvature has been observed to occur during the deposition of sputtered silicon nitride films at 300°C.

Doo *et al.* (8) have suggested film densification as a possible source of tensile stress. Although this seems to be a plausible explanation for an intrinsic tensile stress, it is puzzling why such stresses could not be relieved by annealing of the silicon substrate at the temperatures of the pyrolytic depositions. In any event, an intrinsic tensile stress dependent on the deposition mechanism could conceivably account for the dependence of curvature on the silane-ammonia ratio observed by Bean *et al.* (2). Furthermore, the cracking phenomena reported by Tokuyama *et al.* (3) is probably caused by just such an intrinsic tensile stress. The inclusion of this tensile stress into the thermal component would naturally lead to an expansion coefficient higher than that of silicon.

The sputtered silicon nitride films we examined have compressive stresses of the order of 10^{10} dynes/cm^2. These are developed isothermally during deposition.

These stresses too are intrinsic and must depend on the deposition mechanism. Indeed they are dependent on the rf power density, but not noticeably on the substrate temperature.

Conclusions

The measurement of the thermal expansion coefficient of silicon nitride over a large temperature range shows it to be compatible with silicon. Efforts to relate residual stress in deposited films to thermal expansion coefficients must take into account intrinsic stresses produced during deposition. These stresses themselves may have temperature dependence that could make them difficult to separate from thermal expansion stresses.

Evidence of Phosphorus N-skin on Silicon from Vapor Transport

John R. Edwards

Department of Electrical Engineering and Materials Research Laboratory, University of Illinois, Urbana, Illinois

In surface mobility studies it was necessary to obtain diffused N^+ phosphorus doped islands for inversion layer N-channel MOS transistors. When the bulk material was 100 ohm-cm boron doped silicon, it was discovered that a diffused N-type skin layer existed in the channel region of the bulk material. This note reports the results of experiments which were designed to determine the cause of the N-skin layer. It is shown that in addition to furnace contaminations, N-skin can be created by vapor transport of phosphorus from the phosphorus-rich N^+ diffused island to the exposed silicon surface surrounding the N^+ island. The N-skin can be avoided by leaving part of the original masking oxide to protect the channel during subsequent high temperature processes.

As early as 1946, Serin (1) suggested that heat-treatment could cause a reduction in the impurity concentration near the surface of a semiconductor which was the result of a rapid evaporation of the impurity atoms from the surface. Later Lehovec *et al.* (2) presented experimental differential capacitance-voltage measurements for the impurity distribution arising by evaporation of antimony from homogeneously doped germanium.

Also using a differential capacitance-voltage method for determining doping profiles in depth in epitaxial semiconductor films, Kahng, Thomas, and Manz (3, 4) presented experimental results for a proposed model of transfer of dopant from the silicon backside (and the silicon pedestal used in the epitaxial process) into the working gas phase.

Several experiments were performed to determine the source of the N-skin caused during the fabrication of the transistors. Test wafers used were 89-91 ohm-cm boron doped, Czochralski grown silicon wafers oriented in the <111> direction. All wafers were cleaned with organic solvents, deionized water, and then etched with a mixture of 6:1:1 mixture of HNO_3:HF:-CH_3COOH as a pre-etch. Following the pre-etch a chemical-mechanical polish was performed on one side using a 13:1 HNO_3:HF solution in a rotating beaker. After polishing, the wafers were quenched in acetic acid, followed by alternate rinses in hot deionized water and a mixture of 1:1 HNO_3:H_2SO_4 (reagent grade). The deionized water for the final rinse had a resistivity greater than 10^7 ohm-cm.

The results of the experiments are summarized in Table I. Two types of silicon test wafers were used and listed as types A and B. Type A wafers were used as cleaned and placed in the furnaces after drying with blower type drying heater. Type B wafers were further processed to obtain diffused N^+ phosphorus doped islands.

The initial experiments consisted of wafers of type A which were placed in the furnace to determine whether the ambient of the furnace had caused the N skin. The furnace tubes were made of high-purity quartz and the gaseous ambients were obtained from

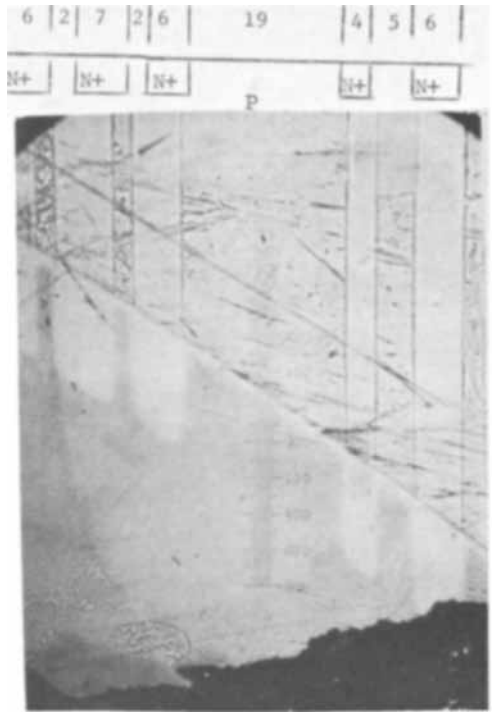

Fig. 2. Stain test result on wafer

liquid sources. The gas was transported from the liquid source through stainless steel tubing and gas purifiers into the furnace tubes with all valving made of quartz and Teflon. The ambient O_2 (wet) in Table I refers to an oxygen ambient bubbled through water whose temperature was 95°C. The results are listed in Table I as group I. These wafers were placed in the furnace under the different time, temperature and ambient conditions listed in the table. The hot-point probe measurement gave no indication of a skin layer nor was there any consistent skin indication from the stain test. (All stain tests were made using a 1:1 H_2O to HF solution with an addition of 0.1g of $Cu(NO_3)_2{:}3H_2O$ added per 100 ml of acid, water solution.)

Group II wafers had N^+ phosphorus diffused islands to allow direct electrical current measurements of the N-skin layer formed on the surface of the p-type substrate between the N islands. These wafers were cleaned and etched as those of group I, then oxidized to an oxide thickness of 9200Å in a wet O_2 ambient for 4 hr at a temperature of 1000°C.

The N^+ junctions were made using the usual photolithographic techniques. Diffusion windows were cut in the oxide and drain source islands were deposited in a two zone, P_2O_5 deposition system (5, 6) for 12 min at a temperature of 1200°C with a 500 cc/min argon carrier gas flow and a 210°C P_2O_5 source temperature.

The group of N^+ P junction wafers were tested by observing the leakage current between the drain and source of an MOS-T structure. This was given as sheet resistance in IIA. Measurements were made with the mask oxide removed using a 1:1 H_2O to HF solution in order to eliminate surface channel leakage due to oxide charge. The predeposited junction leakage resistance was greater than 10^6 ohms/square, as measured using a Tektronix 575 Transistor Curve Tracer. The practical limit of measuring the leakage resistance using the curve tracer is estimated to be about 5×10^5 ohms/square for the particular MOS-T geometry.

The wafers of group IIB were phosphorus deposited wafers which had the masking oxide completely removed by thoroughly rinsing the wafers in 1:1 H_2O to HF, followed by thorough rinsing in deionized water, a 7-min soaking in 1:1 HNO_3 to H_2SO_4, and thorough

rinsing in deionized water. These wafers were then placed in a diffusion drive-in furnace.

A 1-hr diffusion at 1200°C in an argon ambient caused the minimum N-skin leakage resistance of 20 ohms/square between the drain and source islands (II-B-1 in Table I). Under the same time and temperature conditions with oxygen as the ambient, the leakage resistance was increased by two orders of magnitude to a value 2 x 10^3 ohms/square (II-B-2). With the ambient oxygen bubbled through 95°C water, O_2 (wet), the leakage resistance was again increased by a factor of two to three to a value 5 x 10^3 ohms/square (II-B-3). These wafers showed a skin with the stain test as shown in Fig. 2. The skin was of the order of 1-2μ deep for the dry O_2 ambient and ½ to 1μ for the wet O_2 ambient. Above the photograph are the physical dimensions of the structure tested. The regions of skin close to the N^+ islands appear to have a thicker skin. The region separating structures appears to have a skin which tapers to a smaller thickness as the distances from the N^+ region increases.

Consistent with this magnitude of N-skin depth were tests made which showed the leakage considerably reduced by etching part of the silicon in a solution of 6:1:1; HNO_3:HF:CH_3COOH followed by an acetic acid rinse.

In addition a measurement of the leakage resistance which could be increased from 2 x 10^3 ohms/square for wafers II B-2 to a value of 2 x 10^{10} ohms/square (measured by an electrometer) by applying a bias voltage to a gate electrode over the oxide between the two N^+ junctions also demonstrates that the skin depth is small.

Another set of N^+P junction wafers, II-C, had the phosphorus-rich glass removed by etching in a buffered etch of NH_4F and HF, but with the layer of oxide underneath the phosphorus glass left on the silicon surface. The glass removal base solution (buffered solution) was made by dissolving 1 lb of NH_4F in 670 ml of H_2O and filtered through a 7μ millipore filter. One part HF (49%, electronic grade) was added to 20 parts buffered solution. The etching rate was determined to be about 345 Å/min. The glass thickness was determined by plotting the thickness observed optically (7) *vs.* the time left in the etching solution. The intersection of the glass etching rate and the oxide etching indicates a glass thickness of about 2400Å as shown on the etch rate curve, Fig. 1. The oxide remaining on the wafers used in this experiment was between 1500 and 3100Å which was well below the 6000Å oxide thickness indicated by the corner of the etch rate curve, indicating complete removal of the phosphorus rich glass.

The electrical tests showed that no detectable skin existed for wafers with oxide thickness of 2700-3100Å but showed a slight N-skin for the 1500Å thickness used. A stain was inconclusive on one group of devices, sometimes showing a partial skin and not at other times. It is believed that the stain test is the least conclusive and least sensitive of the tests used.

The wafer for experiment II-D had the oxide completely removed and in addition had approximately 1μ of the deposited phosphorus islands removed. This was done to explore the possibility that surface diffusion occurred, instead or in addition to vapor transport. A silicon etch composed of 6:1:1 HNO_3:HF:CH_3COOH was used. The wafer was quenched in acetic acid, rinsed in deionized water, followed by alternate rinses in deionized water and 1:1 HNO_3 to H_2SO_4 with a final rinse in deionized water. The wafer was diffused in a wet O_2 ambient for 90 min at 1000°C. The wafer showed a stain with the stain test and indicated a low leakage resistance, but measurements were probe dependent. Coupled with the absence of skin on wafers of group II-C, it is concluded that surface diffusion into the boron out-diffused region is not an important factor in the formation of the N-skin.

During the tests using N^+P junctions (type B wafers), a second group of wafers of type A were used. One group (III-A) of wafers was placed physically on top of the N^+ diffused junctions to test for vapor transport between wafers during the diffusion drive-in. Both groups were placed in the diffusion drive-in furnace at the same time. One wafer in group III-A showed an N-skin with the hot-point probe which is not completely decisive since there is the possibility of the probe breaking through the N-skin.

The final test was made in order to test the idea that removal of a phosphorus-rich glass in an acid solution might possibly cause phosphorus to plate out of the acid solution onto the bare silicon surface and cause an N-skin. The wafers of group III-B were placed in a solution of 1:1 H_2O to HF at the same time the phosphorus-rich glass was being removed from the wafers of group II. These treated wafers were rinsed thoroughly, soaked in a 1:1 solution of HNO_3 to H_2SO_4 for 7 min, then rinsed thoroughly in deionized water. The results listed in Table I show no N-skin and eliminate plating action during the phosphorous glass removal as a major cause of N-skin.

The conclusion of these experiments is that the major cause of the N-skin on an exposed Si surface must be associated with its proximity to the heavily doped N^+ regions. This can easily be interpreted by a model in which phosphorus is evaporated into the ambient at the drive-in diffusion temperature and transported in the gas phase onto the regions near the N^+ islands. The N-skin layer is formed during the diffusion drive-in cycle. This also means that any total removal of oxide in order to regrow a fresh oxide will result in an N-skin layer before the oxide can be regrown. This is in agreement with previous observations and models (1-4). A protective oxide remaining over the p-regions surrounding the N^+ island is sufficient to prevent the phosphorus from penetrating to the p-region. Since the N-skin measurements were made using channel conductance of MOS-T with the gate oxide removed, surface states and oxide charges do not enter into the interpretation. The phosphorus remaining in the furnace from previous use can also be eliminated as the major contribution since the sheet resistance of the skin was changed by orders of magnitude during tests in the same furnace.

Relations between Thermodynamics of Formation of Point Defects and Integral Thermodynamic Properties of Metal-Oxygen Systems

Per Kofstad

Central Institute for Industrial Research, Blindern, Oslo, Norway

Heats and entropies of formation of point defects in oxides and other inorganic compounds are most commonly determined from studies of the deviation from stoichiometry, electrical conductivity, and diffusion as a function of temperature and partial pressure of oxygen. When the thermodynamics of point defect formation are not known or are difficult to determine experimentally, it would be valuable to be able to correlate or to estimate such properties from other known properties of oxides. In this respect approximate empirical relations between heats of formation of fully ionized cation and oxygen vacancies and thermochemical properties of oxides have been proposed (1). Much work is also being carried out to theoretically calculate heats of formation of point defects in inorganic compounds (2), but at this stage calculations on oxides have not proved successful (3).

The purpose of this note is to point out that the thermodynamics of formation of point defects which predominate at the limits of nonstoichiometry in oxides may be related to integral thermodynamic properties of metal-oxygen systems and knowledge of the metal-oxygen phase diagrams.

Such a relation will be illustrated for an oxygen deficient oxide in which interstitial metal ions predominate at the lower limit of nonstoichiometry. The treatment may be made quite general, but for the sake of simplicity a simple hypothetical oxide system as illustrated in Fig. 1, will be considered. MO_2 is oxygen deficient, and it is assumed that interstitial ions with effective charge q, M_i, are the predominating point defects at the lower limit of nonstoichiometry. In the region at and next to this lower limit the composition of the oxide may thus be written $M_{1+y}O_2$ and the maximum value of y is termed y_m. It is further assumed that MO is essentially stoichiometric.

When the interstitial metal ions predominate, the defect equilibrium, assuming ideal behavior and that concentrations may be substituted for activities, may be written (4)

$$[M_i]\, n^q\, p_{O_2} = K_{M_i} = \exp\,(\Delta S^\circ_{M_i}/R)\, \exp\,(-\Delta H^\circ_{M_i}/RT) \qquad [1]$$

where n denotes the concentration of electrons, K_{M_i}, is the equilibrium constant, and $\Delta H^\circ_{M_i}$ and $\Delta S^\circ_{M_i}$ are the standard enthalpy and entropy terms for the formation of the defect, respectively. The standard state for M_i and the electrons is the infinitely dilute solution.

When intrinsic ionization and effects of impurities can be neglected, the electroneutrality condition requires that $n = q\,[M_i]$, and when further expressing the concentration of interstitial cations in terms of y, *i.e.*, $[M_i] = y$, Eq. [1] can be rewritten to give

$$\ln y = \frac{1}{q+1}\left(\frac{\Delta S^\circ_{M_i}}{R} - \frac{\Delta H^\circ_{M_i}}{RT} - \ln p_{O_2} - q\ln q\right) \qquad [2]$$

At maximum values of y, y_m, the MO_2 phase decomposes to MO, and the corresponding partial pressures of decomposition are $p^*_{O_2}$. In terms of y_m and $p^*_{O_2}$ Eq. [2] can be written

$$\ln y_m = \frac{1}{q+1}\left(\frac{\Delta S^\circ_{M_i}}{R} - \frac{\Delta H^\circ_{M_i}}{RT} - \ln p^*_{O_2} - q\ln q\right) \qquad [3]$$

For the decomposition of MO_2

$$MO_2 = MO + \tfrac{1}{2}\,O_2 \qquad [4]$$

the decomposition partial pressure of oxygen, $p^*_{O_2}$, can also be written

$$\ln p^*_{O_2} = \frac{2}{RT}\,(\Delta G^\circ_{MO_2} - \Delta G^\circ_{MO}) = \frac{2}{RT}\,(\Delta H^\circ_{MO_2} - \Delta H^\circ_{MO}) - \frac{2}{R}\,(\Delta S^\circ_{MO_2} - \Delta S^\circ_{MO}) \qquad [5]$$

where $\Delta G^\circ_{MO_2}$, $\Delta H^\circ_{MO_2}$, and $\Delta S^\circ_{MO_2}$ are the standard free energy, heat, and entropy of formation of MO_2, and ΔG°_{MO}, ΔH°_{MO}, and ΔS°_{MO} are the corresponding properties for MO. The standard state is 1 atm O_2. In Eq. [5] it is assumed as an approximation that the maximum deviation from stoichiometry is sufficiently small so that $\Delta G^\circ_{MO_2} \approx \Delta G^\circ_{M_{1+y_m}O_2}$.

Introducing the value of $p^*_{O_2}$ (Eq. [5]) in Eq. [3], y_m becomes

$$\ln y_m = -\frac{1}{RT(q+1)}\{2\Delta H^\circ_{MO_2} - 2\Delta H^\circ_{MO} + \Delta H^\circ_{M_i}\} + \frac{1}{R(q+1)}\{2\Delta S^\circ_{MO_2} - 2\Delta S^\circ_{MO} + \Delta S^\circ_{M_i}\} - \frac{q}{q+1}\ln q \qquad [6]$$

If the temperature dependence of y_m at the temperature where M_i predominates

$$\ln y_m = \ln A - \frac{\Delta H_{y_m}}{RT} \qquad [7]$$

can be determined from the phase diagram, it is seen by comparing Eq. [6] and [7] that $\Delta H^\circ_{M_i}$ and $\Delta S^\circ_{M_i}$ are given by

$$\Delta H^\circ_{M_i} = -2(\Delta H^\circ_{MO_2} - \Delta H^\circ_{MO}) + (q+1)\Delta H_{y_m} \qquad [8]$$

$$\Delta S^\circ_{M_i} = (q+1)R\ln A + qR\ln q - 2(\Delta S^\circ_{MO_2} - \Delta S^\circ_{MO}) \qquad [9]$$

The same procedure may be followed and relations corresponding to Eq. [8] and [9] may be derived for other defect structure situations, *e.g.*, if oxygen vacan-

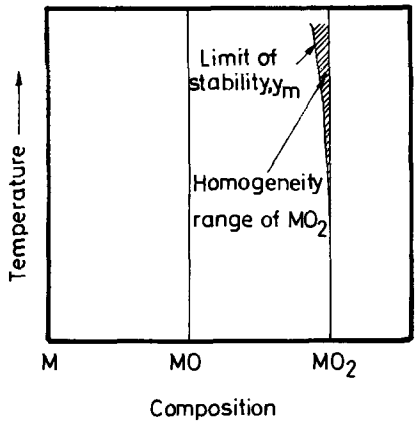

Fig. 1. Hypothetical metal-oxygen phase diagram with MO and MO_2 phases. It is assumed that the MO is essentially stoichiometric and that the MO_2 phase may be nonstoichiometric and that interstitial metal ions predominate at the lower limit of homogeneity.

cies predominate in oxygen deficient oxides or if metal vacancies or interstitial oxygen predominate at the limit of nonstoichiometry in metal deficient oxides.

Examples

Nb_2O_5.—Nb_2O_5 is oxygen deficient (5, 6), and it has been proposed that oxygen vacancies predominate at small deviations from stoichiometry and doubly charged interstitial niobium ions at and close to the lower limit of nonstoichiometry in the temperature range 900°-1200°C (6). When the interstitial niobium ions predominate, the defect equilibrium can be written

$$[Nb_i^{\cdot\cdot}]\, n^2\, p_{O_2}^{5/4} = K_{Nb_i^{\cdot\cdot}} \qquad [10]$$

By following the above procedure and considering, corresponding to Eq. [4], the reaction $Nb_2O_5 = Nb_2O_4 + \frac{1}{2} O_2$ it may be shown that

$$\Delta H^\circ_{Nb_i^{\cdot\cdot}} = -\frac{5}{4}(2\Delta H^\circ_{Nb_2O_5} - 2\Delta H^\circ_{Nb_2O_4}) + 3\Delta H_{y_m} \qquad [11]$$

For the temperature range 900°-1100°C it may be estimated that $\Delta H_{y_m} \simeq$ 6-8 kcal/mole (5, 6). At 1200°K, $\Delta H^\circ_{Nb_2O_5} = -449.2$ kcal/mole and $\Delta H^\circ_{Nb_2O_4} = -377$ kcal/mole (7) and following Eq. [11] this yields a value of $\Delta H^\circ_{Nb_i^{\cdot\cdot}} \simeq 200$ kcal/mole. The very same value of 200 kcal/mole was also estimated directly from the studies of nonstoichiometry as a function of temperature and partial pressure of oxygen (6). It may be noted that the term $-5/4(2\Delta H^\circ_{Nb_2O_5} - 2\Delta H^\circ_{Nb_2O_4})$ is much larger than $3\Delta H_{y_m}$ (Eq. [11]), and as a general trend the heat of formation of defects will increase with increased stability of the oxides.

Cu_2O.—Cu_2O is a metal-deficient oxide and Cu-vacancies are the predominating defects. Figure 2 shows the deviation from stoichiometry, x in Cu_2O_{1+x} as a function of partial pressure of oxygen as determined by Wagner and Hammen (8). (The deviation from stoichiometry may alternatively be written $Cu_{2-y}O$, and when $x << 1$, then $y = 2x$.) The values of $p^*_{O_2}$ represent the decomposition pressures of CuO according to the reaction $2CuO = Cu_2O + \frac{1}{2} O_2$.

Wagner and Hammen interpreted the oxygen pressure dependence of x as $x \propto p_{O_2}^{1/5}$, but, as shown in Fig. 2, it is not unreasonable to suggest the alternative dependence $x \propto p_{O_2}^{1/4}$. This latter relationship may be rationalized assuming that neutral copper vacancies, V^x_{Cu}, predominate. The formation of these defects in Cu_2O may be written

$$\frac{1}{4} O_2 = V^\times_{Cu} + \frac{1}{2} O_0 \qquad [12]$$

and the corresponding defect equilibrium is given by

$$V^\times_{Cu} = K_{V^\times_{Cu}} p_{O_2}^{1/4} \qquad [13]$$

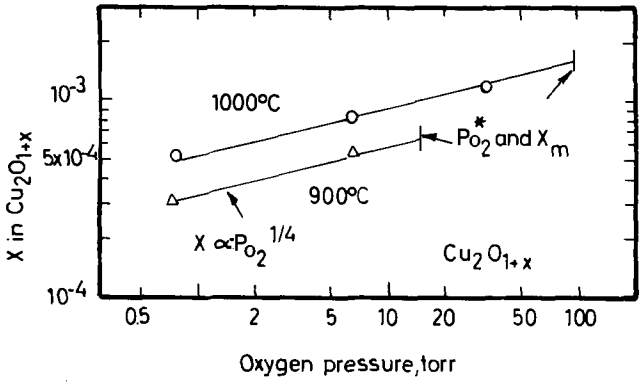

Fig. 2. Nonstoichiometry in Cu_2O (x in Cu_2O_{1+x}) as a function of partial pressure of oxygen at 900° and 1000°C. x_m indicates maximum deviation from stoichiometry and $p^x_{O_2}$ the decomposition pressure in the reaction $2CuO = Cu_2O + \frac{1}{2} O_2$. Experimental results after Wagner and Hammen (8).

When following the above procedure, it may be shown that the heat of formation of neutral vacancies, $\Delta H^\circ_{V^\times_{Cu}}$, is given by

$$\Delta H^\circ_{V^\times_{Cu}} = \Delta H^\circ_{CuO} - \tfrac{1}{2}\Delta H^\circ_{Cu_2O} + \Delta H_{x_m} \qquad [14]$$

where ΔH_{x_m} is the heat term associated with x_m ($x_m = B \exp(-\Delta H_{x_m}/RT)$).

It is, of course, not possible to obtain an accurate value of ΔH_{x_m} for the results in Fig. 2, but an estimate from the two values suggests $\Delta H_{x_m} \simeq 27$ kcal/mole. At 1100°K, $\Delta H^\circ_{CuO} = -35.8$ kcal/mole and $\Delta H^\circ_{Cu_2O} = -38.8$ kcal/mole (7), and from these values and that of ΔH_{x_m} Eq. [14] yields a calculated value of $\Delta H^\circ_{V^\times_{Cu}} \simeq 11$ kcal/mole. From the results in Fig. 2, *e.g.*, at 10 Torr O_2, $\Delta H^\circ_{V^\times_{Cu}}$ may be estimated to be approximately 12 kcal/mole.

General Remarks

The above procedure relates the thermodynamics of formation of defects predominating at limits of nonstoichiometry with integral thermodynamic properties of metal-oxygen system and the maximum deviation from stoichiometry as a function of temperature (*e.g.*, Eq. [8], [9]). The relations will be particularly useful in estimating heats of formation of defects in oxides (or correspondingly in other inorganic compounds) for which such data are lacking or for which such data are difficult to obtain experimentally. The relations are also useful in testing the internal consistency of interpretations of experimental values. Unfortunately values of maximum deviations from stoichiometry and the corresponding value of ΔH_{y_m} (Eq. [7]) are not as yet accurately known for many oxides. However, it may also be noted that for the most stable oxygen deficient oxides ΔH_{y_m} probably makes a relatively small contribution to the heat of formation of the defects (*cf.* Nb_2O_5). If the heat of formation of the defects and integral thermodynamic properties of the oxides are known, the above procedure may conversely be used to construct more accurate details of phase diagrams.

In the procedure it has been assumed that the decomposition pressure of the oxide can be determined from the free energy values of the stoichiometric oxides. This introduces no serious error for small defect concentrations (< about 2%). However, for large deviations in stoichiometry the correct chemical equation (which includes nonstoichiometry in the oxides) has to be written and the corresponding thermodynamic properties of the oxides at the limits of nonstoichiometry has to be estimated and used in evaluating $p^*_{O_2}$. Under these conditions it is also probable that ideal defect equations (*e.g.*, Eq. [1]) must be modified to take into account possible interactions or ordering of defects.

Brief Communications

The Afterglow of Some Old and New Ce^{3+}-Activated Phosphors

A. H. Gomes de Mesquita and A. Bril

Philips Research Laboratories, N.V. Philips' Gloeilampenfabrieken, Eindhoven-Netherlands

Efficient and very fast, so-called P16 phosphors with decay times of 100 nsec or less are required for some applications such as the one-gun beam-indexing television tube (1) and the flying-spot cathode-ray tube. The decay time, τ, is usually defined as the time during which the intensity of the fluorescent emission decreases from its maximum value I_o to I_o/e; this means that the expression $I = I_o\, e^{-t/\tau}$ is taken to represent the decay of the luminescence at least to a first approximation. For the above applications Ce^{3+}-activated akermanite (2) and gehlenite (3) ($Ca_2MgSi_2O_7$ and $Ca_2Al_2SiO_7$, respectively) are normally used. We found that the decay time of both phosphors is about 50 nsec, using the techniques described in ref. (3) and (4). Ropp (5) recently proposed $Y_{0.8}La_{0.1}Gd_{0.1}PO_4$:Ce ($\tau$ = 40 nsec) as an alternative phosphor.

While applying Ce^{3+}-activated gehlenite it was noticed that the fast initial decay is followed by an afterglow phenomenon of relatively long duration. This was studied on the oscilloscope screen by exciting the phosphor at a 10 kc repetition rate with 10 kev cathode-ray pulses of 20 μsec duration. The intensity of the cathodoluminescence at 80 μsec after the end of an excitation pulse (*i.e.*, just before the next pulse is initiated) was found by us to be of the order of 5-10% of the maximum intensity, I_o. We shall call this quantity δ. If the entire decay were to follow the above exponential law, δ would be 10^{-700}% instead of 5-10%.

The value of δ varies from one gehlenite sample to another. When the samples are cooled from room temperature down to the temperature of liquid nitrogen, the δ-values of some of them increase, those of others decrease. We have not been able to explain this complex behavior, or to correlate it to any known property of this phosphor material.

The afterglow adds considerably to the unwanted radiation background in the aforementioned tubes. We found that akermanite and yttrium phosphate with δ-values of 3 and 1.5%, respectively, are somewhat more suitable phosphors in this respect than gehlenite, but still far from satisfactory.

A search for phosphors with better properties has led to the discovery of the Ce^{3+}-activated yttrium silicates, Y_2SiO_5 and $Y_2Si_2O_7$, which were prepared by firing intimate mixtures of yttrium oxide, cerous oxide, and silicic acid in a slightly reducing atmosphere. The δ-values of these phosphors are an order of magnitude smaller than those of the above-mentioned phosphors, whereas their decay times are about equally short. Their high radiant efficiencies constitute a great additional advantage. In Table I the phosphor properties of the old and these new phosphors are listed together.

In the system Y_2O_3-SiO_2 several compounds occur; moreover, $Y_2Si_2O_7$ is known to exist in a number of crystalline modifications. A more detailed discussion of this complicated system and of the preparation of the desired phases will be given elsewhere.

Table I. Phosphor properties[a]

Phosphor	η, %	τ, nsec	δ, %	λ_{max}, nm
$Ca_2MgSi_2O_7$:Ce	4	45	3	370, 395[b]
$Ca_2Al_2SiO_7$:Ce	4.5	50	5-10	405[b]
YPO_4:Ce	2.5	25[b]	1.5	330[b]
$Y_{1.98}Ce_{0.02}SiO_5$	6	30	0.1	415
$Y_{1.98}Ce_{0.02}Si_2O_7$	8	40	0.1	385

[a] All values were measured by the present authors unless otherwise stated. The meaning of τ and δ is explained in the text. η stands for the radiant efficiency, λ_{max} for the wavelength at maximum emission; both were measured with 20 kev cathode-ray excitation.

Luminescence of Gallates

W. L. Wanmaker and J. W. ter Vrugt

N.V. Philips' Gloeilampenfabrieken, Eindhoven-Netherlands

A number of luminescent gallium-containing compounds of the self-activated type has been described in the literature, *e.g.*, $YGa_3B_4O_{12}$, $TbGa_3B_4O_{12}$ (1), $Sr_3(PO_4)_2$, and $Ca_3(PO_4)_2$ containing Ga (2). Gallates in the M_2O-Ga_2O_3 and MO-Ga_2O_3 systems and activated with Mn^{2+} were prepared by Hoffman and Brown (3). The same types of gallates were synthesized by us but without the addition of an activator. Luminescence was found in several of these gallates. Some properties of the most efficient of these phosphors are described in this communication.

The phosphor samples were made by standard ceramic methods, with a double firing process in air at temperatures ranging from 900° to 1400°C. Optical

Table I. Some data on gallium containing phosphors

Composition	λ_{max}(nm) Emission, room temp	Refl., %	Efficiency, % q_{UV} (254 nm)	η_{CR} (20 kv)	T_{50}, °K
$(LiGa)_{0.5}Ga_2O_4 = LiGa_5O_8$	400	44	40	8.5	340
$(LiGa)_{0.45}Mg_{0.1}Ga_2O_4$	415	27	55	7	350*
$(LiGa)_{0.36}Mg_{0.28}Ga_2O_4$	420	21	60	6	360*
$MgGa_2O_4$	415	27	35	5	360*
$(LiGa)_{0.26}Zn_{0.48}Ga_2O_4$	460	7	70	4	380*
$ZnGa_2O_4$	465	12	45	4.5	560*
$(MgZn)_{0.5}Ga_2O_4$	460	6	45	4	500*

Refl.—diffuse reflection at 254 nm.
q_{UV}—quantum efficiency (250-270 nm excitation).
η_{CR}—energy efficiency (20 kv cathode-ray excitation).
T_{50}—temperature in °K at which the light output of the phosphor has decreased to 50% of the value measured at room temperature.
* These phosphors have their maximum light output (254 nm excitation) below room temperature.

measurements were performed as previously described (4).

Like that of many phosphors of the zinc-sulfide type the efficiency of most of the gallates depends on the intensity of the exciting radiation. The excitation spectra, when measured in the usual way with a low excitation energy, therefore do not correspond to the wavelength-dependence of the excitation at high intensities. When the excitation spectra are measured with a low constant energy of the exciting radiation, most of the gallates show an excitation maximum between 220 and 250 nm.

With cathode-ray excitation the most efficient phosphors proved to be $LiGa_5O_8$, $MgGa_2O_4$, and $ZnGa_2O_4$, all with the spinel crystal structure (Table I). The energy efficiency of $LiGa_5O_8$ (8.5%) is high for an oxidic phosphor. With cathode-ray excitation the emission peak of $LiGa_5O_8$ is found at a shorter wavelength (about 380 nm) than with ultraviolet excitation (about 400 nm) (see Fig. 1). $LiGa_5O_8$ may find practical application in cathode-ray tubes, *e.g.*, in cascade screens (5). With uv excitation the emission spectrum varies with temperature as we found for $MgGa_2O_4$ and $ZnGa_2O_4$ and also for the MgLi and ZnLi gallates.

We extended the work of Hoffman and Brown (3) by preparing various mixed gallates. It was found that LiZn, LiMg, and MgZn gallates (all with the spinel crystal structure) show both a higher absorption and a higher quantum efficiency (60-70%) with 250-270 nm excitation than the unsubstituted gallates (Table I). It will be seen from Fig. 1 that the most efficient gallate phosphors have a peak height of about 80% with respect to that of a calcium halophosphate.

With cathode-ray excitation $LiGa_5O_8$ shows a non-exponential decay, the decay time depending on the pulse length of the excitation. With uv excitation a very slow rise of the fluorescence and some afterglow were observed both in $LiGa_5O_8$ and in the mixed gallates mentioned above. These phenomena might be ascribed to the presence of traps in the host lattice, *e.g.*, through a small loss of oxygen. We also found luminescence in Ga_2O_3 when it had been heated in air above 1100°C, the most intense luminescence being observed with samples fired at 1500°C (Fig. 1).

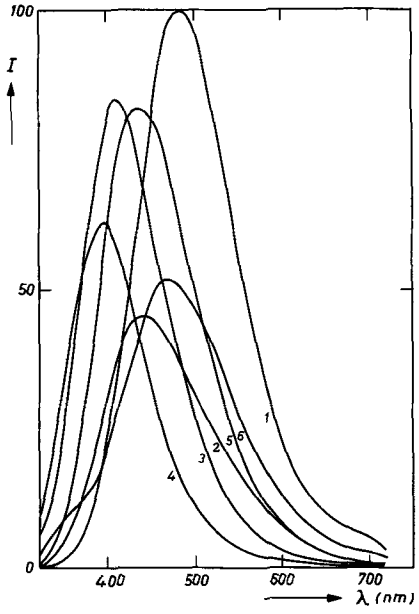

Fig. 1. Emission spectra of Ga_2O_3 and of some gallates in comparison with that of calcium halophosphate-Sb^{3+}, with mainly 254 nm excitation: curve 1, calcium halophosphate-Sb^{3+}; curve 2, Ga_2O_3 twice heated for 2 hr at 1500°C in air; curve 3, $(LiGa)_{0.45}Mg_{0.1}Ga_2O_4$; curve 4, $LiGa_5O_8 = (LiGa)_{0.5}Ga_2O_4$; curve 5, $(LiGa)_{0.45}Zn_{0.1}Ga_2O_4$; curve 6, $ZnGa_2O_4$.

The kind of luminescent center occurring in the self-activated gallates is still obscure, and more work is required in order to elucidate the mechanism of the luminescence found in the gallium compounds described above. Explaining the centers in the gallates and in Ga_2O_3, one should also consider the work of Tippins (6), who observed photoconductivity in single crystals of Ga_2O_3 grown by the Verneuil technique.

Manuscript received March 7, 1969. This was Paper 88 presented at the New York Meeting, May 4-9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Low-Temperature Epitaxial Growth of Single Crystalline Silicon from Silane

David Richman and Robert H. Arlett

RCA Laboratories, Princeton, New Jersey

Normal techniques for the growth of epitaxial silicon films by the hydrogen reduction of chlorosilane require temperatures of the order of 1200°C. Using silane pyrolysis in hydrogen allows a lowering of the temperature to the 1000°C region. Below this temperature the growth rate falls markedly if epitaxy is to be maintained. A typical reported epitaxial growth rate at 950°C in hydrogen is 0.06 μm/min (1)

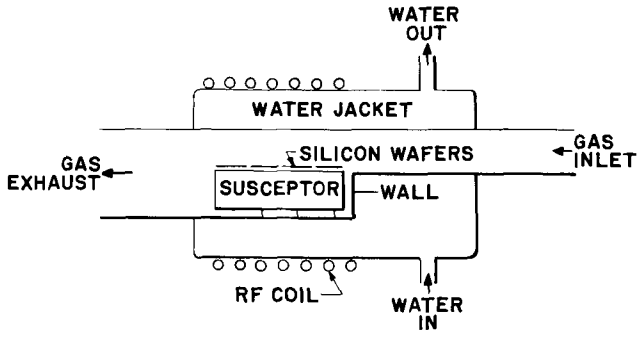

Fig. 1. Schematic diagram of epitaxial growth apparatus

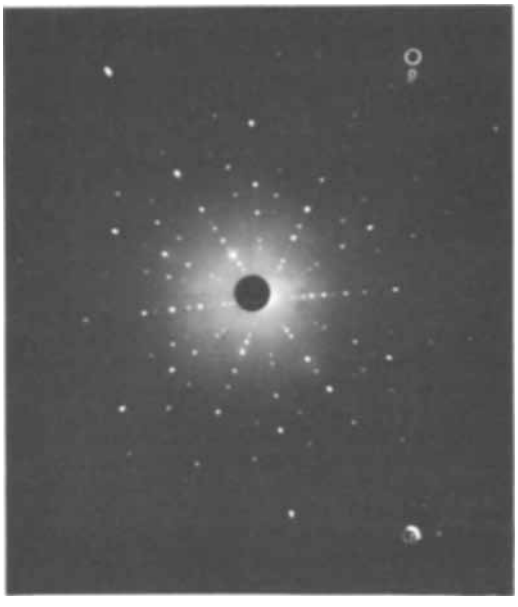

Fig. 2. Laue pattern of an 11μ silicon epitaxial layer grown at 800°C.

Low growth temperatures are of interest in order to minimize impurity diffusion effects which are appreciable at temperatures above 1000°C. However, in this regard, the very slow growth rates at temperatures below 1000°C negate the advantage of a low-temperature process.

This paper reports the results of an investigation of the pyrolysis of silane in a helium ambient. The reason for the choice of a gas other than hydrogen follows from the suggestion of Joyce and Bradley (2) that the desorption of hydrogen from the silicon surface is the rate-limiting process in the epitaxial growth of silicon from silane. It was felt that any steps taken to reduce the hydrogen pressure would increase the desorption rate and hence the epitaxial growth rate, especially at lower temperatures.

A water-cooled reaction chamber was used to prevent premature decomposition of the silane. This chamber provided a streamlined horizontal flow of the entering gas over the RF heated susceptor surface (see Fig. 1). This was intended to prevent the raining of amorphous silicon onto the substrates by minimizing heating of the gas stream away from the susceptor-gas interface thereby minimizing the homogeneous gas phase reaction.

A typical epitaxial growth experiment consisted of initially removing 5-6 μm from the (111) oriented silicon substrate wafers by etching with 1% by volume HCl gas in hydrogen at 1180°C. The temperature was then decreased to the required growth temperature, 910° or 800°C, and the hydrogen replaced by helium

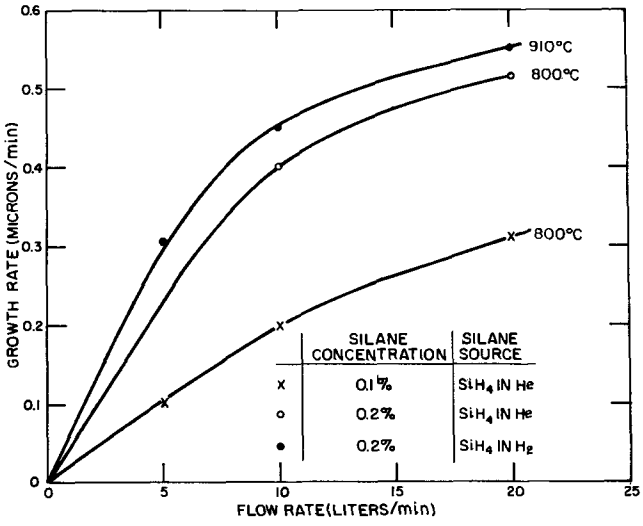

Fig. 3. Dependence of epitaxial growth rate on flow rate as a function of temperature and silane concentration.

which had been passed through two molecular sieves at 77°K and subsequently filtered through a 0.8μ filter. The silane sources were commercial mixtures of 3% silane in hydrogen or 3% silane in high-purity helium. These were mixed with the helium carrier gas to give the requisite silane concentration immediately before entering the reaction chamber. Total gas flow rates of 5, 10, and 20 liters/min were used. These correspond to linear velocities of 15, 30, and 60 cm/sec, respectively. Silane concentrations of 0.1 and 0.2% by volume were used. Growth times varied from 30 to 60 min and film thicknesses were of the order of 5-15 μm.

Using the silane in hydrogen source, epitaxial growth was obtained at 910°C for both silane concentrations and all flow rates. However at 800°C only polycrystalline deposits were obtained. Using the silane in helium source single crystal epitaxial growth was obtained at 800°C. Figure 2 shows a typical Laue pattern for a film grown at 800°C. The high quality of this pattern indicates that growth rates as high as 0.5 μm/min can be achieved at 800°C with no loss of crystallinity. Figure 3 shows the dependence of growth rate on the various experimental parameters. Electrical evaluation of these layers is presently in progress.

In conclusion, these results show that the presence of excess hydrogen inhibits the ability to obtain epitaxial growth of silicon from silane at low temperatures and high growth rates. Replacement of the hydrogen by helium has yielded epitaxy at 800°C at growth rates of 0.5 μm/min. It is noteworthy that at this high growth rate and at such a low temperature, impurity diffusion is virtually negligible.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 115, No. 4, 7, and 12 (April, July, and December, 1968).

Effect of Low Pressure on Surface Charge of Electrets

R. A. Draughn and A. Catlin
(pp. 391-394, Vol. 115, No. 4)

Bernhard Gross[1]: The authors present an interpretation of their surface charge measurements based on a formula for the field in the interface between the electret surface and the movable induction electrode and a comparison of the interface field with Paschen's law for the breakdown voltage. In this connection, reference is made to Gubkin and Skanavi.[2]

I should like to point out that I already have established an equation for the interface field of a three-layer electret in my paper "Experiencias com Eletretos, II," Fig. 1 and Eq. [4], [5], and [7].[3] The expression for the field between the dielectric surface and the lifted electrode was discussed and used extensively by me in another paper.[4] In this paper, Paschen's curve has already been used to calculate the conditions for surface breakdown exactly in the same way as now has been done by Draughn and Catlin. I was able to obtain quantitative agreement, at atmospheric pressure, between theory and experiment, which was corroborated by independent evidence from measurements of a-c effects in voids in dielectrics.

The Synthesis and Epitaxial Growth of GaP by Fused Salt Electrolysis

J. J. Cuomo and R. J. Gambino
(pp. 755-759, Vol. 115, No. 7)

R. Monnier:[5] In the discussion section of your article, Yocom's mechanism is suggested to explain the formation of P on the cathode of a cell of fused salts containing sodium metaphosphate:

$$4\ PO_3^- + 5\,e = P + 3\ PO_4^{3-}$$

Thus, this reaction is justified by the formation of sodium orthophosphate in the cathodic compartment.

It seems to me that this phenomenon is better explained by a very weak dissociation of the anion PO_3^- as in:

$$PO_3^- = P^{5+} + 3\ O^{2-}$$

followed by a direct discharge of the ion P^{5+}. Ga should then deposit according to the direct way you mention, *i.e.* Ga^{3+} ions' discharge resulting from Ga_2O_3 dissociation.

A synthesis of these two elements should follow in order to form GaP. It should be noted, however, that the order of discharge you observe during electrolysis, first P, then Ga, agrees with thermodynamics.

In order to support this interpretation, we could add that the formation of sodium orthophosphate can be easily explained. In any case, the rough equation is practically the same in both cases:

$$NaPO_3 = Na_3\,(PO_4)_2 + P + \tfrac{1}{2}\,O_2$$

With a C anode, oxygen would then give a mixture of $CO + CO_2$.

D. Shanefield[6]: The first III-V semiconductor material produced by electrodeposition was gallium arsenide.[7] Germanium crystals have also been grown by fused salt electrolysis.[8] The work of Cuomo and Gambino is certainly a great advance over earlier work because they produced doped single crystals. Their method seems broadly useful, partly because it has been demonstrated that the crystal perfection can improve as the crystal grows during electrodeposition.[9] Possibly the improvement during this process is due to the sidewise growth of dislocations observed with silicon.[10] Also, ultrapurification with respect to certain growth-affecting materials can readily be achieved by various sacrificial electrodeposition means.[11]

Electropolymer Studies, II. Electrical Conductivity of a Polystyrene Sulfonic Acid Membrane

C. S. Fadley and R. A. Wallace
(pp. 1264-1270, Vol. 115, No. 12)

J. A. Kitchener[12]: The authors have remarked that their results and theoretical calculations "disagree with a recent hypothesis that membrane inhomogeneity may seriously disrupt Grotthus conduction chains" (referring to the paper of Block and Kitchener.[13])

Unfortunately, their present argument rests on a theory of doubtful reliability. The mass of earlier work on conductivity of ion-exchange resins has demonstrated the inadequacy of any simple models. In addition to electro-osmotic flow, the universal molecular heterogeneity with even the supposedly "homogeneous" resins cannot be ignored. It must also be recalled that our suggestion of interruption of Grotthus chains in heterogeneous membranes applied to condition of strong electrical polarization.

It is a pity that the authors did not include in their paper some measurements which might well have provided direct evidence for or against the hypothesis —namely, comparative conductivities of H- and Na-form membranes at comparable water contents. It would be extremely interesting to know whether their ratio would be found equal to that of, say, the corresponding homogeneous resins, or, better, the H- and Na-forms of polystyrene sulfonic acid.

M. Block[14]: The authors assume the effect of the polyethylene matrix, constituting 75% by weight of the membrane, to have only an indirect effect on the conductivity. This assumption may be examined more closely in the light of published information on the manufacture and properties of this membrane.

Manufacture.—C.I.T.-T.N.O., The Central Technical Institute of the Organisation for Applied Scientific Research in the Netherlands, developed and marketed the TNO C-60 membrane. Despite the secrecy that obscures details of membrane manufacture,[15, 16] the following methods appear relevant.[17, 18] Commercially available, low-density polyethylene films are swollen

at 40°-50°C in styrene containing 2% divinyl benzene (DVB) and 1% benzoyl peroxide, taking up 20-30%. Immersion in saturated sodium sulfate solution at 70°C for 6 hr insures polymerization of the styrene. Sulfonate groups are subsequently introduced with sulfuric or chlorsulfonic acid. Crabtree and Glueckauf believe the chemical initiator to be stannic chloride.[19] The American Machine and Foundry Company developed similar membranes using irradiation to effect grafting in complete or partial replacement of the chemical method.[20] The similarities were so great that patent litigation ensued and A.M.F. purchased the patent rights and manufactured AMF C-60 in Holland, as well as in the U.S.A.

Substrate.—Michaels *et al.*[21] considered polyethylene film a network structure, wherein the crystalline phase serves to cross-link and immobilize chains in the amorphous phase. They point out that crystallites can be destroyed and created by changing the temperature, higher temperatures and gradual cooling favoring the growth of large crystals. Kresser[22] discussed the influence of production variables on film irregularities in greater detail. Hoffman *et al.*[23] found polyethylene films to expand in styrene more in the direction transverse than parallel to the original direction of extrusion. They pointed out that extrusion from the melt would orient polymer chains more in thinner than in thicker films, the material closest to the surface being most oriented. In the central regions of lower stress, larger crystallites could form. Styrene would diffuse first into the amorphous regions and then slowly dissolve crystallites. Antioxidants, antiblocking agents, and catalyst fragments might also be present, complicating the polymer structure.

Cross-linking.—The DVB commercially available contains 45-60% ethyl benzene, which cannot cross-link, as well as isomers of differing reactivities,[24] further complicating the structure of the final polymer. Hazenberg[18] noted that during polymerization 1-2% polyethylene may be extracted and that grafting to polyethylene occurs to a certain extent. Chen and Friedlaender[25] found that under comparable conditions 0.2% benzoyl peroxide induced 32% covalent grafting and γ-radiation 53-83%. The higher rate of grafting in thicker films was attributed to a greater number of swollen, amorphous polyethylene "micelles" but this was not proved. Some polyethylene was cross-linked further by irradiation. Whereas irradiation polymerized styrene to a molecular weight of 47,900, the same material in a polyethylene film attained a molecular weight of 178,000. Selegny[26] pointed out that these membranes largely consist of coiled chains of styrene homopolymer trapped within the interstices of the polyethylene film, corresponding to the snake-cage type.[27]

Membrane heterogeneity.—Chen *et al.*[28] found the electrical resistance 3-5 times greater across the membrane than along the direction of extrusion and believed this to be due to nonhomogeneous distribution of styrene throughout the membrane thickness. Forgacs and Scharf[29] measured the swelling of AMF C-60 in water at 30°-100°C and explained the irregularities found as transitions of the polyethylene substrate from amorphous to crystalline modifications. Arnold and Koch[30] noted an increase in electrical resistance during and just after immersion of the membrane in water in the hydrogen form. This certainly indicates nonuniformity. Arnold[31] recently used acid absorption data to confirm considerable heterogeneity.

Fig. 1. AMF C-60 stained with methylene blue. 45X

The evidence for heterogeneity, as well as large variations in reproducibility, is supported by experiments such as that illustrated in Fig. 1.[32] It shows the uneven uptake of a cationic dye of small dimensions by AMF C-60, easily visible to the naked eye. The regions of high ionic concentration are separated by large regions of different, lower ion-exchange capacities.

Jump distance.—Gregor *et al.*[33] found a volume increase of 175% to occur on transfer of this membrane from 0.1*N* KCl to 0.1*N* H_2SO_4. As this was mainly due to the PSA fraction, its volume increase must have been sevenfold. The small resistance to diffusion shown by the rapid uptake of dyes across large membrane areas[32] is a further indication of the extended nature of this material. Similarly, the doubling in volume on hydration found by Fadley and Wallace indicates an eightfold increase in volume of the PSA polymer. The square of the effective jump distance used in the paper will therefore vary by a factor of up to 16, rather than 4.

In the light of the above evidence, this membrane cannot usefully be compared with the rigid PSA resins discussed by Grubhofer.[34]

Hydration.—Oda and Yawataya[35] considered the water in a membrane to consist of three parts, namely hydration water of the fixed ion, hydration water of

the counter-ion, and solvent water filling the pores. In a PSA membrane at concentrations of 0-4*N* HCl, they found the electro-osmotic transport of H^+ to be 1 and the water of hydration of the sulfonate groups to be 1.5-3.5.[36] This is confirmed indirectly by measurements of dielectric constant and conductance by Dickel and Bunzl[37] on a PSA resin of 8-10% DVB content. They found that the hydrogen ion begins to dissociate from the sulfonate group on uptake of 2.5 moles of water per mole of valency. The lower cross-linkage of AMF C-60 would permit greater transport of water,[38-42] as indeed found by the authors. However, the fact that such a great variability exists, according to the type of membrane considered,[43] detracts from the authors' thesis that a hydration shell of about seven water molecules requires to be filled around the hydrogen ion in order to reach a maximum conductance.

Conductivity.—The factor of seven difference in conductivity between the sodium and hydrogen forms of this membrane indeed suggests that conduction by the Grotthus mechanism occurs to a considerable extent. The finding is supported by Zapior *et al.*[44] On the other hand, Cooke[45, 46] and Block and Kitchener[47] found a negligible transport of hydrogen ions during electrodialysis at current densities many times above the critical value. Similarly, although a factor of 7.8 difference in conductivity between the hydrogen and sodium forms of Amberplex C-1 was noted,[48] Grubb[49] did not and Block and Kitchener[47] failed to detect abnormal hydrogen transport.

The last-named workers found that commercial membranes containing one resin with reinforcements of different, inert materials gave rise to different electrochemical behavior. Moreover, changes were observed between batches of the same membrane.[16] Gregor *et al.*[33] noted large variations in physical properties of samples of commercial membranes, including differences in conductivity of 300%. In view of these facts and the many variants that could occur in manufacture and that can affect conductivity, it is considered likely that Fadley and Wallace were examining membranes different from those tested by Block and Kitchener under the same generic name, and that the Amberplex membranes of the latter differed from those discussed by Spiegler *et al.* one year earlier.

It could be objected that the conditions used by Block and Kitchener and the six cations tested by Cooke did not include H^+, so that the environment within the membrane was not comparable. However, the fact that anomalous conduction has been observed many times with anion-exchange membranes[16] and at least once with a cation-exchange membrane[50] shows that the appropriate alkaline or acidic loading is not essential to obtain Grotthus conduction.

In cases where anomalous conduction does not occur to an appreciable extent, it is still postulated that the Grotthus chains are interrupted, more or less frequently, by hydrophobic barriers, through which the ions have to migrate by a jump mechanism.

The existence and extent of the Grotthus mechanism of conduction across an ion-exchange membrane could be tested with the simultaneous use of deuterium or tritium and O^{18} in the diluate compartment of a two-chambered cell.[16] While the hydrogen isotope could migrate across a cation-exchange membrane as an ion or as water or both, the oxygen isotope could move only as water. Both could move as ion or solvent across anionic membranes. The simultaneous determination of ionic and electro-osmotic transport would show whether there were a complete physical transport of H^+ or OH^- ions across the membrane or if some of the charge were transferred by a chain process. In the latter case, there would be little electro-osmotic water transfer.

C. S. Fadley and R. A. Wallace: Our conclusion that abnormal conduction takes place in the hydrogen form of this membrane (AMF C-60) is based on our measurement that $\sigma_{H+}/\sigma_{Na+} \approx 7$ for ionic membranes with approximately 15 moles of water/equiv. We refer to these experimental data in our paper. The reliability of our equations for predicting conductivity as a function of water content is thus not important to this conclusion, but rather the theory is qualitatively supported by the conclusion. To further clarify this point, Fig. 1 shows the detailed variation of ionic mobility with water absorption for both sodium and hydrogen forms of the membrane. The data for sodium form are from recent work by Dr. Wallace.[51]

In effect, Fig. 1 answers Dr. Kitchener's request that we provide further experimental proof of the comparative conductivities or ion mobilities of the H- and Na-form of the polystyrenesulfonate membrane as a function of water content. Our data speak for themselves. In addition, Dr. Wallace and J. Ampaya have

recently submitted to *This Journal* a detailed experimental analysis and theoretical study of anomalous or abnormal ion conduction occurring in both cation- and anion-exchange membranes used in electrodialysis.

The two curves for H^+ correspond to the theoretical curves given in Fig. 9 of our paper. The curve for Na^+ was calculated using the empirical constants $\beta\Delta F_A^\circ = 9800$ cal/mole, $n_o = 2.75$. We have already commented that the solid H^+ curve might approximately represent "normal" (non-Grotthus) conduction. The Na^+ curve agrees quite well with the experimental data from 0 to 20 moles/equiv., and has a high water absorption limit very close to the solid curve for H^+. For approximately 1 mole of water/equiv., the experimental mobilities are equal, indicating no appreciable difference in the effects of absorbing one molecule of water for the two ionic forms.

One might also ask why the normal curve for H^+ does not agree more closely with the curve for Na^+ if transport is substantially the same for the two ions exclusive of Grotthus conduction. The answer is probably twofold. First, the sodium ion interacts less strongly with water molecules during hydration. A reflection of this is the free energy of absorption, which is greater by a factor of ~1.5 for H^+ in PSA of 10% DVB content.[52] From our equation connecting conductivity and free energy of absorption (Eq. [9] of our paper), such a difference in free energy of absorption translates qualitatively into the difference between the normal H^+ curve and the Na^+ curve between 1 and 5 moles of water/equiv. Second, abnormal conduction probably contributes to the experimental conductivity in this region and thus our solid curve overestimates normal conduction.

To be sure, the membrane we have studied has a heterogeneous molecular structure and is subject to variations in property from batch to batch. Our measurements (including those of Fig. 1 on sodium form) were made on samples from the same batch, so the latter difficulty was minimized. As to the former, several comments are in order. Heterogeneity and variations in molecular structure from surface to bulk are almost certainly present, but regardless of this the water-PSA interaction is the dominant one as far as variations in conductivity with water absorption are concerned. As Block has pointed out, PSA in the membrane probably exists as coiled chains in polyethylene interstices.

On the other hand, polyethylene crystallites will probably contain very little PSA and we are thus dealing with a quasi two-phase system. However, the PSA phases must be interconnected in order for spatially continuous conductivity to occur. With regard to the occurrence of abnormal conduction in some instances with a given commercial membrane and not in others, it is possible that the interconnections between groups of PSA molecules for some membranes are made through very dense areas of polyethylene. This spatially restricted, hydrophobic atmosphere would limit Grotthuss conduction. If conduction along the interconnecting PSA molecules is the transport-limiting process between "high-conductivity" regions dense in PSA and water, then the measured conductivity will reflect normal conduction.

For the membrane we have studied, no such hindrance of abnormal conduction was observed. Also, the conductivities at saturation are very near to those of pure phenolsulfonic acid resins of a similar exchange capacity.[53] Thus, it seems that links between any more or less condensed regions of PSA are very complete or that the membrane is more homogeneous than might be imagined from the above model.

As to phase changes of the polyethylene matrix, all our measurements with varying water absorption were made at room temperature, so it is doubtful that such changes affected our results. In view of the above, it seems reasonable to assume that for a given membrane batch at fixed temperature the polyethylene matrix has only a small effect on the variation of conductivity with water absorption.

A more precise theoretical formulation should clarify our assumption that the effective free energy of absorption ($\Delta F^{\ddagger}$) will be appreciably changed by water absorption, but not the effective jump distance (λ). In an exact treatment of conductivity based on absolute reaction rate theory, we must start with the total number of different sites for ionic carriers in the polymer matrix, each denoted by an index j. For each site, there will be various possible jump distances (λ_{ji}) and each λ_{ji} will have associated with it a free energy of activation ($\Delta F_{ji}^{\ddagger}$). The concentration of sites of type j will be denoted by c_j, such that

$$c = \sum_j c_j = \text{total concentration of counterions} \qquad [1]$$

The conductivity of each site will be given by

$$\sigma_j = \frac{c_j q^2}{h} \sum_i \lambda_{ji}^2 \exp(-\Delta F_{ji}^{\ddagger}/RT) \qquad [2]$$

and total conductivity by

$$\sigma = \sum_i \sigma_j = \frac{q^2}{h} \sum_{j,i} c_j \lambda_{ji}^2 \exp(-\Delta F_{ji}^{\ddagger}/RT) \qquad [3]$$

The effective jump distance can be related to these quantities by equating total conductivities. This yields

$$\lambda^2 \exp(-\Delta F^{\ddagger}/RT) = \sum_{j,i} f_j \lambda_{ji}^2 \exp(-\Delta F_{ji}^{\ddagger}/RT) \qquad [4]$$

where f_j = the fraction of sites which are of type j.

Since each λ_{ji} represents a *single-step* process, it is extremely unlikely that λ_{ji} will be greater than a few anion-anion distances or a few water molecule diameters. This will be reflected as a very high ΔF_{ji} for large λ_{ji} values and a correspondingly small contribution of such terms to the sums of Eq. [3]. Experimental evidence for this is indirectly given by the observation of Lapanze and Rice[54] that even PSA in aqueous solution consists of hydrated ions bound to the anionic polymer in a tight sheath. This sheath is responsible for the low effective degree of ionization observed in PSA solutions.[55] Jumps to distances much larger than the sheath diameter will thus be very unlikely upon the application of fields as low as those used in our conductivity experiments.

Therefore, the effective jump distance as we have defined it will have at most a roughly fivefold variation and the comments of Block on changes in jump distance based on macroscopic volume changes of the PSA fraction do not directly relate to this jump distance. Our mention of the work of Grubhofer[56] on PSA molecular structure was merely to indicate that intrachain λ_{ji} will remain very much the same for both wet and dry membrane. Interchain λ_{ji} will no doubt change in magnitude and relative importance, but a factor of 16 increase is very doubtful.

Equation [3] can be simplified if we assume an average site type (counterions near the PSA chain) and if the dominant terms on the right side are taken to be jumps by roughly one anion-anion distance (λ_{aa}) along the PSA chain and also jumps by λ_G due to Grotthus conduction. The conductivity will then be given by

$$\sigma = \frac{cq^2}{h} \{\lambda_{aa}^2 \exp(-\Delta F_{aa}^{\ddagger}/RT) + f_G \lambda_G^2 \exp(-\Delta F_G^{\ddagger}/RT)\} \qquad [5]$$

where f_G = the fraction of sites capable of abnormal conduction. This equation adds the effects of normal

and abnormal conduction. The quantities affected primarily by water absorption will be $\Delta F_{aa}^{\ddagger}$ and f_G, whereas λ_G and $\Delta F_G^{\ddagger}$ will be essentially constant and have been determined previously.[57] From Eq. [4] and [5], we see that for f_G small, $\lambda \approx \lambda_{aa}$, $\Delta F^{\ddagger} \approx \Delta F_{aa}^{\ddagger}$, and it is in this approximate form that we have applied Eq. [5] to normal conduction. We should also note here that the additive nature of terms in Eq. [3] and [5] is valid only when different conduction modes (*i.e.*, different λ_{ji}) exist in parallel. For the case just mentioned, this parallel nature is probably a reasonable assumption. However, the situation we have discussed of interconnecting PSA chains passing through strongly hydrophobic surroundings would represent modes in series and only the rate-limiting term(s) need be treated in such situations.

Our conclusions regarding water of hydration are based on a comparison of conductivity results and data on the net volume change per mole of water absorbed (Δv). A negative value of Δv indicates denser over-all packing of molecules in wet membranes than in the reference state of dry membrane-liquid water. Therefore, the minimum in this quantity near 10 moles of water/equiv. indicates a dense structure somehow accommodating approximately 10 molecules/HSO_3 group. The hydration estimates of 7 molecules for the H^+ ion (Stokes and Robinson[58]) and 1.5-3.5 molecules for the sulfonate group (Oda and Yawatawa[59]) would give just such a structure.

The fact that measured conductivity reaches a maximum at the same extent of water absorption probably indicates that conductivity is strongly affected by the hydration water, but only weakly affected by further absorption of essentially free solvent water. We further note that the primary hydration number for H^+ as calculated by Glueckauf[60] is only 4. Oda and Yawatawa[59] assumed this number of water molecules to be rigidly transported with the hydrogen ion as one contribution to electro-osmosis. It is not surprising, however, that some further ordering of water molecules occurs up to approximately a hydration number of 7 and that this added water interaction acts to increase conductivity.

Thin-Film Silver Halide Electrolyte Cells

Paul Vouros[1] and Joseph I. Masters

Technical Operations, Incorporated, Burlington, Massachusetts

ABSTRACT

Thin-film solid-state batteries ranging in thickness from 5 to 12μ were prepared on quartz substrates by vacuum-deposition techniques. Silver films ~1000Å thick were used in all cases as the reversible electrode, while platinum and in some cases gold films of a similar thickness were used as the counterelectrode. Electrolyte films consisted of evaporated AgI, evaporated AgBr, and a double electrolyte of AgI evaporated onto a film of AgCl or AgBr. Cells consisting of the above types of electrolytes were rechargeable, and the ones containing pure AgI or AgI + AgBr or AgCl electrolyte exhibited long shelf life. Preliminary conductivity measurements using an a-c bridge method indicate, as expected, that the electrode-electrolyte interfaces rather than the electrolyte films are the principal sources of the high internal resistance exhibited by these batteries.

The use of solid-state electrolytes in electrochemical cells was first demonstrated by Reinhold (1) during his studies of chemical equilibria between solid salts. Ionic conductivity in the solid state has since been studied by a number of workers and an extensive review of the subject has been presented by Lidiard (2). A more recent review by Raleigh (3) deals with the general aspects of solid-state electrochemical techniques and the use of solid-state galvanic cells for various thermodynamic calculations.

Silver iodide, when contained between two metallic electrodes of which one is a reversible silver anode, has long been known to act as a solid electrolyte in which the ionic current is carried almost in its entirety by Ag^+ ions (4). In recent years, several articles have appeared in the literature on the utilization of silver iodide as an electrolyte in solid-state battery applications. A bead cell developed by Weininger (5) consists of a silver anode and a platinum or tantalum cathode embedded into the solid AgI electrolyte. In the presence of iodine vapor, the cell acts as a primary battery, the iodine being reduced at the inert Pt (or Ta) electrode. Mrgudich (6, 7) has recently reported on the performance of AgI pellet batteries in which the AgI electrolyte is compressed between silver and platinum electrodes, and he also suggested that the possibility of making an all thin-film version of the system be explored. The Mrgudich batteries are rechargeable concentration cells in which the cell voltage is a function of the activity of Ag^o on the inert platinum electrode and is given by the Nernst concentration-cell equation

$$E = (RT/n\mathbf{F}) \ln \frac{a_s}{a_p} \qquad [1]$$

Here n is the valence change of silver to silver ions (*i.e.*, unity), R is the gas constant, T is the absolute temperature, $\mathbf{F}$ is the Faraday constant, a_s is the activity of Ag^o in the silver electrode which is constant and essentially unity, and a_p is the activity of Ag^o in the platinum electrode which is variable.

Aside from isolated examples such as the MAg_4I_5 electrolyte cells, where M = K, Rb or Cs (8, 9, 10, 11), a characteristic of solid-state batteries prepared to this date is their generally high d-c internal resistance, due either to the poor ionic conductivity of the electrolyte or to the high resistance of the electrochemical double layer at the electrode-electrolyte interface. The electrolyte problem may be minimized by decreasing its thickness, while a reduction in double-layer boundary effects may be achieved by increasing the interface surface area. For example, the interface structure may be altered by mixing of the electrode and electrolyte materials thus making the mixture both an electronic and an ionic conductor (6).

A solid-state cell in which the electrolyte thickness is of the order of magnitude of a micron, or as thin as possible, represents a goal in miniaturization if high resistance boundary conditions and electronic conductivity of the thin electrolyte film are not a severe limitation. A demonstration of the feasibility of an all thin-film battery produced by conventional vacuum-deposition techniques may eventually encourage a variety of low power applications in microelectronics where evaporation techniques are used, such as in integrated microcircuitry.

Thin-film solid state batteries have been reported in the past (12, 13). In those cases, they involved the use of the more complex solid electrolyte system Pb/$PbCl_2$-AgCl/Ag. We report here on a vacuum-deposited thin-film adaptation of the Mrgudich pellet format Ag/AgX/Pt or Au concentration cell system (where $X = I^-$ or Br^-).

Experimental Procedure

Film deposition and measurement techniques.—Films of silver bromide and silver iodide varying in thickness from 5 to 12μ were vapor deposited at a pressure of 5 x 10^{-5} mm Hg. A tungsten boat was operated at 632° and 560°C for the AgBr and AgI evaporations, respectively. The thickness of the transparent silver bromide film was determined by an interference measurement (14), whereas a gravimetric method based on the bulk density of opaque AgI was used to estimate the thickness of the deposited silver iodide film. The estimate given in this paper for the thickness of the AgI films may be low since the density of evaporated silver halide films is generally lower than bulk density. For example, the density of evaporated AgBr films is 4.55 g/cc as compared with a bulk density of 6.5 g/cc.

The silver metal film electrodes were deposited by evaporation using a tantalum coil source, and a CVC AST-100 sputtering unit was employed for the deposition of the platinum film electrodes. Metal film thickness varied between 700 and 1000Å, and in general the resistance of the 2.5- x 0.4-cm electrode films used (Fig. 1) was 100 ohms or less. Electrical contact with the thin metal films was established with the conductive Eccobond solder No. 56C.

To ensure against loading samples of very high internal resistance, a high input impedance Keithley 610B electrometer was used for open-circuit voltage measurement. Although the original state of charge is disturbed by a small current drain, steady-state internal resistance of charged cells can be estimated by momentarily lowering the Keithley's input impedance until the measured cell voltage is half its open-circuit value (impedance matching). The charge-discharge

[1] Present address: Baylor University, College of Medicine, Institute for Lipid Research, Texas Medical Center, Houston, Texas 77025.

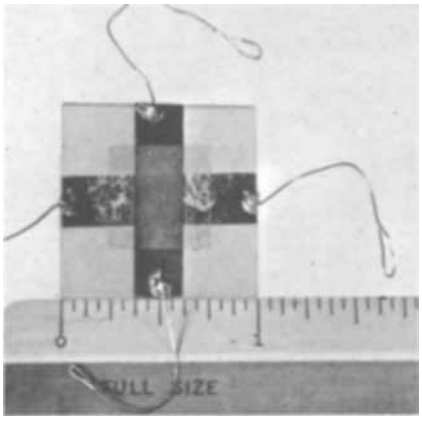

Fig. 1. Typical Pt/AgX/Ag cell in overlapping format

dynamic characteristics of the cells were also monitored by using various loads. For this work, the electrometer output was recorded with a Bausch and Lomb VOM-5 recorder. All discharge curves were taken on cells that had been charged for 1 hr at 0.5v between discharges unless otherwise specified. An a-c bridge was used to avoid polarization effects and thereby approximate (upper bound) the conductance of the electrolyte. The applied a-c voltage was small and of a variable frequency up to 600 kHz.

Cell format.—Two different cell formats were constructed: "overlapping" and "nonoverlapping." The overlapping electrode format is one in which the electrolyte is "sandwiched" between the two electrodes. The procedure used for the fabrication of a typical overlapping cell is as follows. The platinum film is sputtered on a quartz substrate. This is followed by evaporation of silver halide on portions of the substrate covered by the platinum film. Finally, the silver electrode is evaporated by masking off the platinum-covered portions of the substrate. All charge-discharge data reported below were taken with cells in which the total electrode-electrolyte overlap area was approximately 0.4 cm^2. An example of a typical overlapping cell is shown in Fig. 1.

The second, or nonoverlapping electrode format (*see* Fig. 2), is one in which the two electrode films are deposited side by side, separated by 150μ or more. The electrodes and gap between them are then coated with the evaporated silver halide. It is evident that this nonoverlapping format produces a cell of much higher electrolyte resistance than the corresponding overlapping cell because of its longer path and smaller cross-sectional area. It is not, however, subject to shorting if pinholes are present in the electrolyte film, thus allowing the study of other thin electrolyte films which may be prone to a pinhole structure.

Experimental Results

Silver iodide electrolyte thin-film cells.—Overlapping format.—The preparation of a Pt/AgI/Ag thin-film cell in an overlapping format was initially unsuccessful because of a direct short between the platinum and silver electrodes. Electron micrographs of the evaporated silver iodide film when deposited on a substrate whose temperature was 41°C indicate that the silver iodide grains [Fig. 3(a)] do not form a continuous structure and that large breaks exist between grains. Further supporting evidence [Fig. 3(b)] clearly shows that these breaks are actual voids which extend through the silver iodide layer.

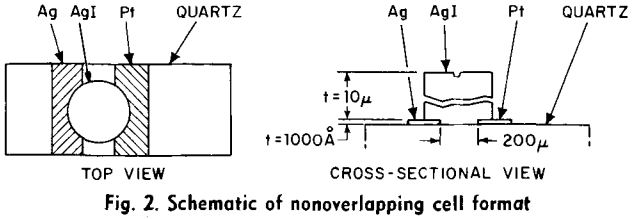

Fig. 2. Schematic of nonoverlapping cell format

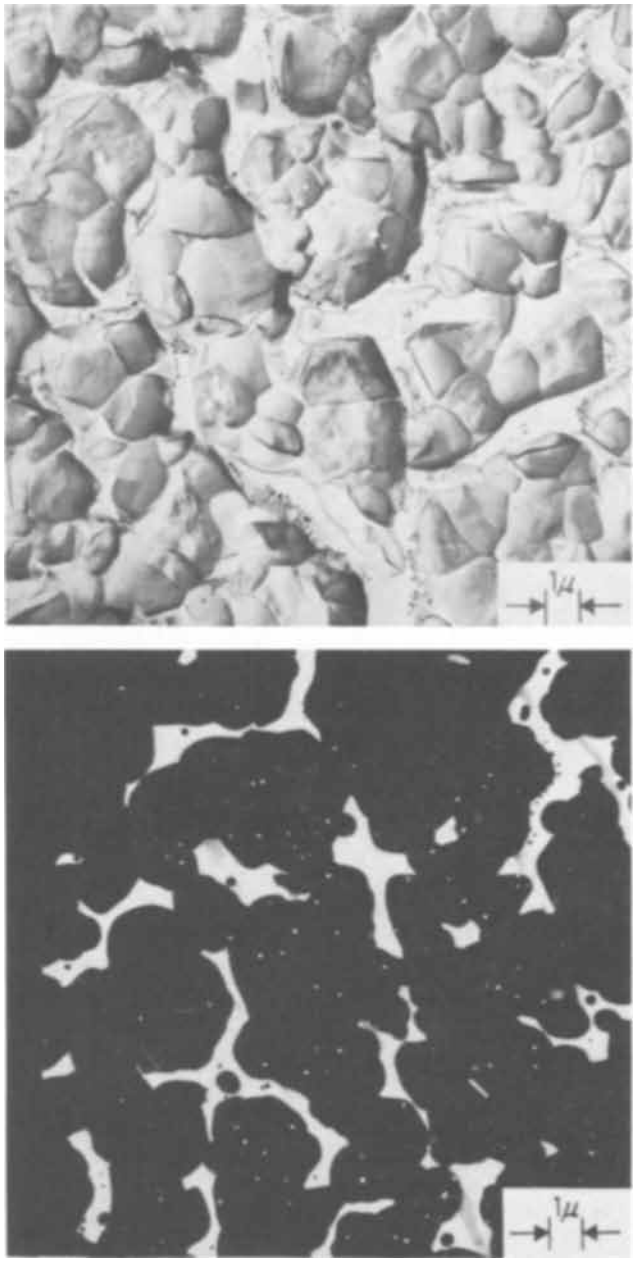

Fig. 3. Electron micrographs of evaporated AgI film deposited at a substrate temperature of 41°C: (a, top) replicated sample and (b, bottom) unreplicated sample. The electron micrographs were taken on silver iodide samples that were evaporated onto thin carbon films which were supported by nickel grids. The evaporation conditions were identical to those used for the deposition on the quartz substrate. The silver iodide film was shadowed at a 3:1 angle ratio with the platinum-imbedded carbon pellet technique. It was then coated at normal incidence with carbon, and the original halide was dissolved with a methanolic KCN solution (0.5g KCN/50 ml CH_3OH). The sample was washed gently for 5 min in three changes of distilled water.

In view of this problem, an additional step for preparation of the electrolyte was introduced, involving the chemical conversion of Ag to AgI. A strip of platinum 2.5 cm x 0.63 cm x 0.1μ was deposited by sputtering on a quartz substrate. This was followed by the deposition of a film of silver (~1000Å) directly over the center of the platinum strip. The system was then placed in an iodine chamber for ~24 hr to ensure the conversion of most of the silver to AgI. A second layer

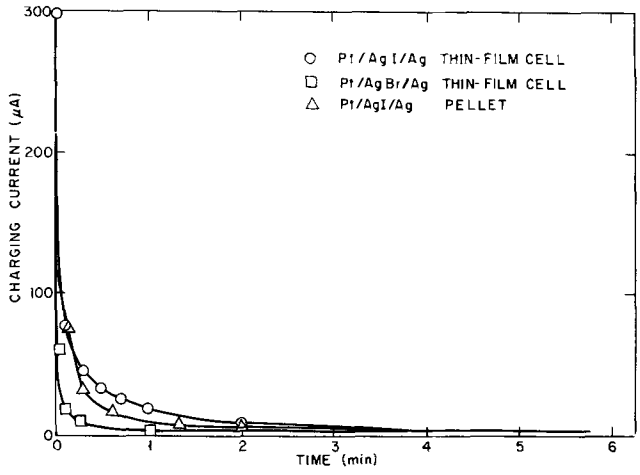

Fig. 4. Typical charging curves of various concentration cells

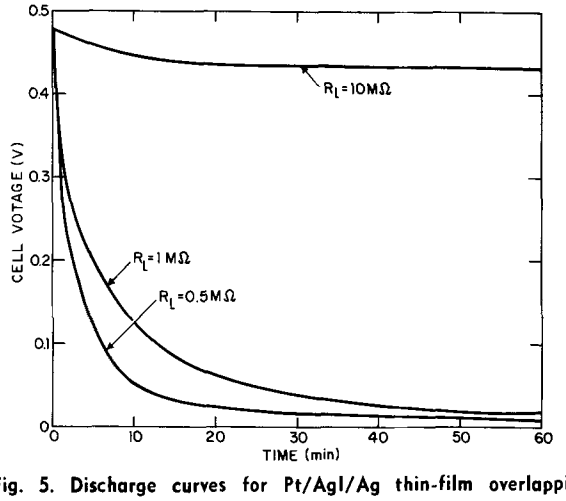

Fig. 5. Discharge curves for Pt/AgI/Ag thin-film overlapping cell using various loads.

of silver iodide was deposited by evaporation over the original ultrathin iodized silver film, which acted as the nucleus for the formation of a uniform and void-free deposit of AgI. This, in turn, was followed by the deposition by evaporation of the silver electrode.[2] The open-circuit cell voltage, which was monitored in vacuum during the deposition of the silver electrode, attained the low value of 0.06-0.10v, presumably due to the presence of some unconverted silver at the platinum electrode surface which lowers a_p in Eq. [1]. The cell was then charged at a voltage of 0.5v. A typical charging curve is shown in Fig. 4, along with those of other thin-film or pellet cells of various formats or electrolytes. Figure 5 shows a series of discharge curves for several large resistance load values. These cells showed no detectable leakage after several months of storage.

Nonoverlapping cell format.—At the outset of the AgI evaporation, the activity of Ag° at the platinum electrode starts from a minimum value, except for the activity that occurs due to diffusion and reduction of Ag^+ ions from the deposited silver iodide, to establish the equilibrium

$$Ag^+ + e^- \rightleftarrows Ag^\circ \ (a_p) \qquad [2]$$

By monitoring the cell voltage in vacuum, it is there-

[2] In addition to the chemical conversion of silver iodide to form a nucleus for the vacuum-deposited AgI film, the problem of structural voids in evaporated AgI films was also overcome by depositing a thin continuous subbing layer of AgCl or AgBr over the platinum electrode prior to the AgI evaporation. Cells consisting of Pt/AgCl or AgBr, AgI/Ag maintained the voltage to which they had been charged for several months with no detectable leakage, but suffered from a high d-c internal resistance (10^7 ohms), presumably due to the presence of high contact resistance between the halide films and the electrode interfaces.

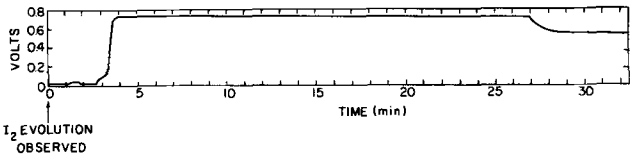

Fig. 6. Nonoverlapping cell OCV as a function of AgI evaporation

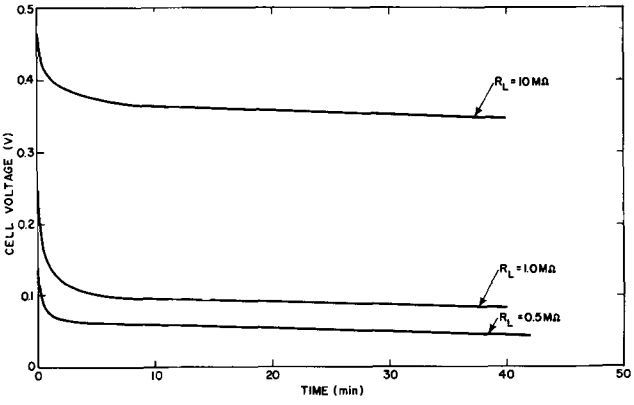

Fig. 7. Discharge curves for Pt/AgI/Ag thin-film nonoverlapping cell using various loads.

fore possible to follow the rate of AgI deposition and study the basic cell properties during the actual cell preparation. As is shown in the open-circuit voltage *vs.* time plot of Fig. 6, there is no significant increase in voltage for about 2.5 min after iodine evolution is first observed. This is followed by a rapid increase in cell voltage, which occurs when the AgI film is thick enough so that its resistance matches that of the electrometer (10^{14} ohms). The cell voltage finally reaches the high value of 0.725v where it remains constant until the evaporation is stopped (approximately 27 min). The drop in boat temperature is followed by a decrease in the cell voltage to a value of 0.550v.

The high open-circuit voltage of 0.725v can be accounted for by the operation of an I_2,Pt/AgI/Ag cell, the I_2 vapors being produced from partial decomposition of the AgI.[3] The observed value of 0.725v is higher than the theoretical value of 0.688v corresponding to the thermodynamic free energy of formation of AgI, this discrepancy occurring because of the heating of the substrate from the AgI boat. In that respect, it is consistent with the results of Weininger (5) who reported open-circuit voltage values as high as 0.75v when an I_2,Ta/AgI/Ag cell was operated at elevated temperatures. The observed voltage drop to 0.550v, typical of a Pt/AgI/Ag concentration cell (6, 7), after the source is turned off, is presumably due to the reduction of the partial pressure of I_2 and the removal of excess iodine.

The performance of a nonoverlapping Pt/AgI/Ag cell when placed under load is shown in Fig. 7. The electrode separation in this case was 750μ and the thickness of the AgI layer was about 4μ, with an overlap area of ~1.8 cm² between the electrolyte and each electrode. The cell output was generally lower than that of its overlapping counterpart which in part is due to the smaller cross-sectional area of the electrolyte and the increased internal resistance. The nonoverlapping Pt/AgI/Ag cells exhibited the same excellent voltage stability as the overlapping cells.

Silver bromide electrolyte thin-film cells.—Because of previous experience in the deposition of AgBr films for photographic applications (14), this material was tested as an overlapping cell electrolyte. Although a thin AgBr film can be deposited more readily than AgI in a continuous void-free electrolyte layer, it is

[3] The iodine evolved during the AgI evaporation is also available at the Ag electrode but it can be postulated that it reacts to form silver iodide.

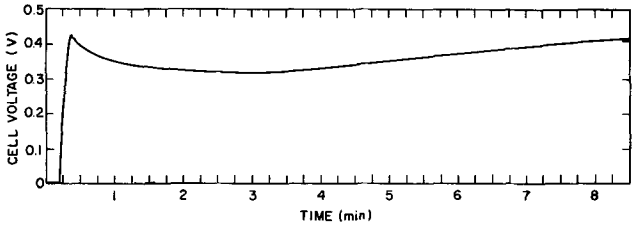

Fig. 8. Overlapping AgBr cell OCV as a function of evaporated Ag deposition.

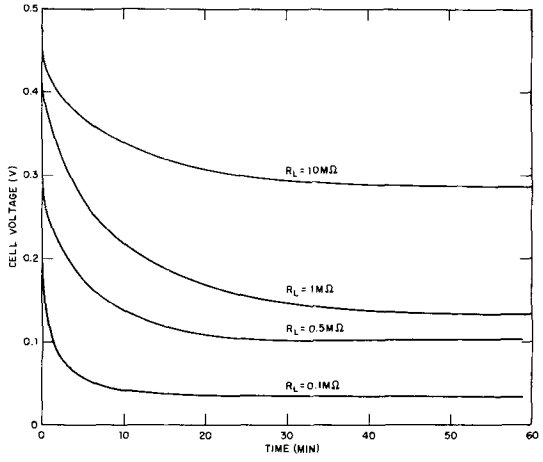

Fig. 9. Discharge curves for Pt/AgBr/Ag thin-film overlapping cell using various loads.

less desirable than AgI because of a noticeably higher electronic conductivity (causing an internal short in a cell) and lower ionic conductivity. Because of the latter, the nonoverlapping format was not considered for AgBr samples.

Silver bromide electrolyte overlapping cells were prepared, as in the case of AgI cells, by the deposition of a strip of sputtered platinum onto a quartz substrate followed by a 5-10μ thick layer of the halide. The silver electrode was then deposited so as to cover the electrolyte. As soon as a continuous layer of silver was established, the open-circuit cell voltage, which was monitored during silver deposition, increased rapidly from zero, as shown in Fig. 8,[4] and decreased gradually to a low of ~0.3v followed by an increase to about 0.4v.

The reasons for this voltage variation are not entirely clear at this point, but it may be due to heat or light radiated from the tantalum coil, the reaction of deposited silver with photolytically produced bromine, the partial diffusion of the initially deposited silver into the AgBr (15, 16), or other undetermined factors. On occasions where the evaporation became erratic, such as when the tantalum filament was overheated, high-energy silver particles or vaporized molecules penetrated through the electrolyte layer and the breakdown of the cell by an internal short was indicated by the sudden drop of the cell voltage to zero.

A typical charging curve of a Pt/AgBr/Ag thin-film cell (of thickness $t = 10\mu$) is shown in Fig. 4 and its discharge characteristics under load are given in Fig. 9. When an evaporated Au film was used as an electrode instead of sputtered platinum, the cell output was generally comparable. As anticipated, the AgBr electrolyte thin-film cells proved less stable than similar AgI cells, losing more than 30-40% of their charge in less than 1 week.

Discussion of Results

The external work done by a cell is the integral

$$W = \frac{1}{R_L}\int_0^t (E - ir)^2\, dt \qquad [3]$$

where $V = E - ir$ is the cell voltage, r is its internal resistance, R_L is the external load resistance, and i is the current. In a concentration cell, power is not delivered at a constant voltage, since during discharge E is a decreasing function of time (Eq. [1]). Therefore, capacity should be rated in terms of watt hours (whr) rather than in the more ambiguous ampere-hours. For optimum performance in such a cell, it is clear that the inert electrode should "soak up" a generous amount of material from the reversible electrode while maintaining an effectively low Ag concentration. In other words, the optimum platinum electrode in an Ag/AgI/Pt cell must have a large Ag absorptivity as well as a large effective surface. Cell output is also limited by the cell's internal resistance since the cell voltage V is reduced by the internal ir drop when under load.

The energy output of the various thin-film cells discussed earlier was roughly estimated during a 1 hr discharge into an appropriate matched load using Eq. [3]. For AgBr and AgI electrolyte overlapping cells of the dimensions discussed above, the total output is on the order of 2 x 10^{-8} whr and about half as much for a AgI electrolyte cell in the nonoverlapping format (Fig. 7). In this respect, thin-film cells had about 4-5 times less output than state-of-the-art pellet cells with thin-film electrodes (6); however, the use of the thin-film format produced approximately a threefold improvement in energy density (whr/lb) over the pellets.

An improved version of the Mrgudich pellet cell involves the replacement of the thin-film electrodes by pulverized platinum and silver compressed on either side of the silver iodide pellet, thus producing a larger overlap surface between electrode and electrolyte. This results in a hundredfold improvement in the cell output, accompanied by a corresponding increase in the amount of silver transferred to the platinum electrode (6). We believe that some improvement in cell capacity could be achieved in a similar manner for thin-film cells by depositing electrodes of larger surface area or by introducing a graded layer of electrode-electrolyte mix between the electrode and electrolyte to increase their total overlap area.

The steady-state internal resistance of the overlapping AgI electrolyte thin-film cells is on the order of 10^4 to 10^5 ohms, while it is close to 10^6 ohms for the overlapping Pt/AgBr/Ag cells and nonoverlapping Pt/AgI/Ag cells. This resistance consists basically of the sum of the resistance of the electrolyte and the resistances at the two electrode-electrolyte interfaces. The latter, however, due to an interface barrier or double layer, is capacitive in nature, and is partially shunted during current transients or during the application of a-c signals of sufficiently high frequency (16). The electrolyte resistance in various AgI and AgBr thin-film cells was thus measured using an a-c bridge with an applied voltage of 60 mv and variable frequency. The electrolyte resistance was generally found to be on the order of 10-30 ohms, depending on film thickness, and the double-layer capacitance was found to be in the 100-1000 μf range.

Table I shows the variation of cell resistance with frequency of applied a-c voltage for a Ag/AgBr/Ag thin-film overlapping system, with an electrode overlap area of 0.4 cm^2 and a AgBr film thickness of 10μ. Resistance values obtained with the same bridge for a 25-ohm resistor, run for calibration purposes, are also given. The interface capacitance appears as a significant reactance at frequencies below 1 kHz, and thus the higher frequency value of 17-18 ohms should be considered as representative of the electrolyte resistance plus any unshunted resistance. On this basis, we were able to calculate an upper bound specific ionic conductance of 1.4 x 10^{-4} ohm^{-1} cm^{-1} for evap-

[4] In addition to recording the cell voltage in vacuum, by monitoring the resistance of the silver electrode film during its deposition, the Ag evaporation may be stopped at the point where the film reaches its desired resistance value.

Table I. A-C resistance values of a Ag/AgBr/Ag system as a function of frequency*

Frequency (kHz)	Resistance (ohms)	
	25-ohm Resistor	AgBr film**
0.01	—	60-70
0.10	26	30
1.0	26	20
10	26	20
100	26	18
200	26	18
500	—	17
600	22	—

* If a cell is charged, it must be prevented from discharging with a suitable d-c bias voltage. In order to avoid the use of such a d-c bias, the measurements given in Table I were made on a symmetrical Ag/AgBr/Ag system.
** The values given in this column have been corrected for any ohmic resistances due to the silver electrode films.

orated AgBr films and 1.1 x 10^{-3} ohm^{-1} cm^{-1} for evaporated AgI films. This compares with bulk conductivities at room temperature of 2 x 10^{-5} —2 x 10^{-7} ohm^{-1} cm^{-1} for AgBr (18) and 1.65 x 10^{-6} ohm^{-1} cm^{-1} for β-AgI (19). Such a comparison, however, of bulk and thin-film conductivity values may be unrealistic at room temperature where the distribution of Frenkel defects is to a large degree a function of sample preparation techniques—unlike the randomized distribution of Frenkel defects exhibited at elevated temperatures.

The above data indicate that the main source of total cell resistance in a thin-film cell lies in the electrode-electrolyte interface and that the electrolyte resistance, as expected, is very small by comparison. Because of the large internal capacitance, discharge curves (*see* Fig. 5, 7, and 9) of thin-film cells show a large transient effect in which an appreciable fraction of the $\sim 10^{-8}$ whr of energy stored in a charged cell is involved in cell polarization or in charging and discharging the interface capacitance.

The AgI thin-film cells discussed above exhibited no detectable current leakage shown by the fact that they retained the voltage to which they had been charged for several months. The overlapping thin-film Pt/AgBr/Ag system, however, showed evidence of considerable electronic conductance after a few days of storage. Occasional failure in storage of silver iodide electrolyte cells, even when stored in the dark, was found to be due to a deterioration of the silver electrode. This may be due to reaction with atomic iodine species trapped in the AgI film during its deposition. Dense iodine vapors were in fact visible throughout the AgI heating and vaporization as stated earlier. Outgassing of the deposited silver halide film for a period of time prior to deposition of the silver film is expected to improve stability.

Improvement of the thin-film concentration cells at this early stage of their development would be expected in the area of increasing capacity and reducing internal resistance. Conductivity measurements have indicated that the principal source of internal resistance is in the electrode-electrolyte interface. Preparation of a cell in which there is a higher over-all surface of contact between electrode and electrolyte, and a greater Ag absorptivity of the blocking electrode is therefore indicated.

New Methods of Obtaining Fuel Cell Electrodes

IV. Powder Electrode Fuel Cell with Lateral Feeding

D. M. Drazić, R. R. Adzić, and A. R. Despić

Institute of Chemistry, Technology and Metallurgy, Beograd, and Faculty of Technology, University of Beograd, Beograd, Yugoslavia

ABSTRACT

A previously developed powder electrode in combination with lateral feeding with gases has been further improved. A fuel cell without gas chambers and with loose carbon powder electrodes has been constructed and tested with acid and alkaline electrolytes. 0.065 w/cm^2 of power output was achieved with a cell having an over-all thickness of 3 mm at H_2 and O_2 pressures of 0.01-0.02 atm gauge. If a battery of such cells were built, one could expect a specific power ouput of about 250 w/liter or 150 w/kg.

In most low-temperature fuel cells which have been developed in recent years, porous electrodes separating gas and electrolyte chambers have been used. In this way, the necessary gas-electrolyte-catalyst contact is readily obtained. Besides the improvements of sintered metal or porous carbon electrodes achieved up to now, efforts have been made during the last few years to develop electrodes based on some new ideas. Among the more interesting are the rotating and the laterally fed electrodes of Bonnemay *et al.* (1, 2) and Gerischer's suspension electrode (3). The so called "powder electrode", developed in our laboratory (4, 5) appeared to be very convenient for fast determinations of the electrochemical activity of powdered materials which are to be used for fuel cell electrode manufacturing. In two recent papers (6, 7), this type of electrode was used in the investigation of the influence of different kinds of treatment of active carbon on its electrochemical activity. It was shown that carbon powder properly treated and impregnated with very small quantities of platinum can be a good electrode material in powder form for oxygen reduction and hydrogen oxidation, in alkaline as well as in acid electrolytes.

In the present work, the basic concept of the powder electrode was used to develop one employing lateral feeding of the reacting gases. This was achieved by pouring the carbon powder, impregnated with the catalyst, into the approximately 0.5 mm deep hollow of the electron-conducting electrode holder and covering with the porous matrix soaked with the electrolyte. The whole cell was obtained when two such electrodes were pressed together. In Fig. 1, a schematic diagram of the cross section of such a fuel cell is presented.

A novelty of this cell is that the gases have access to carbon powder only through a few small gas feeding holes on the edge of the holder and that the usually existing gas chambers, screens, and similar gas distributing devices are completely omitted. The gas is diffused laterally from the small edge holes through the active carbon layer to the sites of the reaction. In normal type cells with gas chambers, the ratio of the projected electrode surface exposed to the electrolyte and to the gas phase is 1:1. Bonnemay *et al.* (2) realized the lateral diffusion electrode with a hydrophobic carbon powder fixed to a metallic current collector, where a greater part of the electrode was immersed in the electrolyte, while the rest was in gas phase, the reacting gas diffusing through the carbon powder to the place of consumption. The ratio of the surfaces exposed to the electrolyte and to the gas in this case was 6:1 (8). In our case, this ratio is about 1000:1, which results in considerable reduction of total volume of this fuel cell.

A second substantial feature of these electrodes—in which they differ from all other types—is the mode of current collecting. Due to the existence of gas chambers in normal cells, current collecting is often lateral. This introduces problems of great ohmic voltage drops when large electrodes are used, particularly with carbon electrodes, so that metallic nets [*e.g.*, screen electrodes (9)], or sintered metal plates (10) have to be incorporated into the electrodes, losing the substantial advantages of carbon as the electrode material: lightness and resistivity to the attack of acid electrolytes.

In our electrode, since the resistivity of carbon cannot be lowered, the mode of gas feeding and current collecting has been inverted. The gas is fed laterally, while the current is collected normally to the electrode surface (*i.e.*, the shortest way), giving rise only to the practically negligible voltage drops across the resistive carbon. This construction enables us to replace the metals as the electrode holder and electron-conducting material with other acid-resistant materials like electron-conducting plastics (*e.g.*, a polyethylene-graphite mixture produced in our laboratory with $\rho \approx 0.2$ ohm-cm) so that the average specific weight of the complete fuel cell battery can be lowered as much as 1.5 g/cm^3.

Experimental

The voltage-current characteristics of a H_2-O_2 cell were experimentally determined for two sets of electrodes. The cell with electrode area of about 20 cm^2 (diameter 5 cm) had the gas inlet and outlet at two opposite sides on the edge of the electrode. In order to decrease the distance between the inlets and outlets, and in this way the pressure drop in the battery, for the larger-area cell (440 cm^2), the electrodes

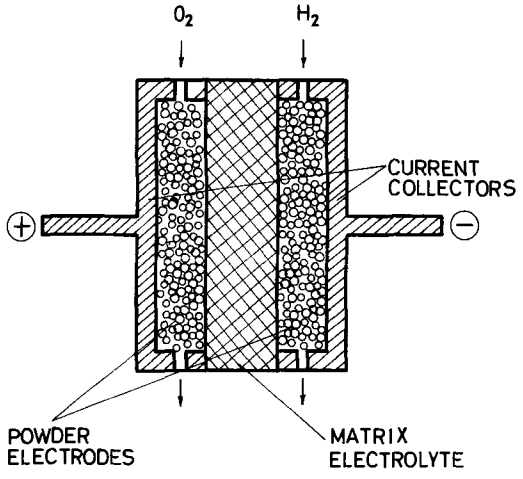

Fig. 1. Schematic cross section of a powder electrode fuel cell unit with lateral feeding.

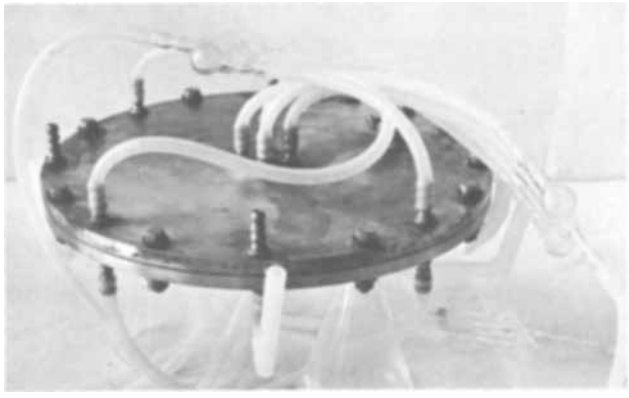

Fig. 2. Photograph of the larger experimental cell

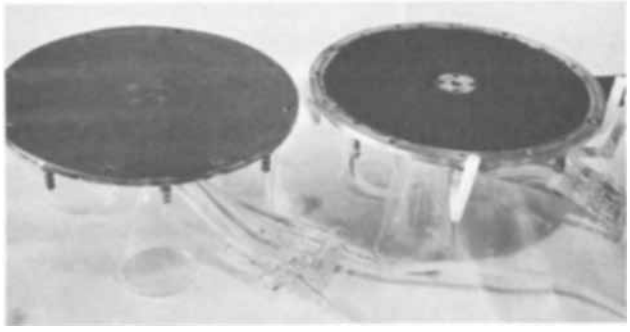

Fig. 3. Photograph of the disassembled cell. Right: electrode holder packed with active carbon. Left: electrode holder covered with porous matrix.

are made in the form of a modified annular electrode. Gases were introduced through several holes at the edge of the electrode, while the excess of gases, if necessary, was collected through the holes in the middle, as can be seen in Fig. 2. A photograph of the disassembled larger experimental cell is shown in Fig. 3. All the details of this construction are given in the patent literature (11).

The smaller cell was tested with three different electrode thicknesses: 0.25, 0.5, and 1 mm (*i.e.*, the hollow on the electrode holder was 0.25, 0.5, and 1 mm deep). Electrode material was pretreated active carbon powder (80-100μ) [for details, *see* (6, 7)] impregnated with platinum (3% by weight). After impregnation, the carbon powder was mixed with Teflon emulsion (Du Pont TFE 30B or FEP 120, 10% by weight).

Porous plastic sheets (Porvic S. Porous Plastic Ltd., England) were used as the matrix for the electrolyte. In order to eliminate the possibility of drying of the matrix, one central and several edge holes filled with electrolyte, and in contact with the porous matrix, were provided. No other gasket material was used. As the electrolytes, 5*N* H_2SO_4 or 6*N* KOH was used. The measurements were done at 25° and 60°C. Gas pressures applied were 0.01-0.02 at. gauge.

Gases used were commercial gases in cylinders. To remove the accumulated impurities and product water, an approximately 3% excess flow of gases was used and allowed to vent from the cell. No effects of water unbalance were observed. Several experiments were done with an ion-exchange membrane (Permutit C.) soaked with KOH.

Results and Discussion

Preliminary investigation of this concept in the small (20 cm^2) and large (440 cm^2) cell showed the direct parallelism between the performance of the cell and the performance of the separate powder electrodes, when the same carbon powder was used. Since in the ordinary powder electrode (4, 5) feeding with gas is normal to the electrode, this indicated

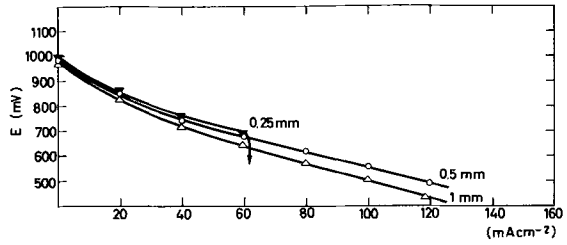

Fig. 4. Voltage-current density curves for small H_2-O_2 fuel cell (20 cm^2) with 6*N* KOH at 25°C for 1.0-, 0.5-, and 0.25-mm thick electrodes.

that practically no limitation was imposed on the cell performance by the lateral diffusion of gases through the carbon layer, at least not when the path is smaller than 15 cm. This comes out also from the fact that practically no pressure drop was achieved when the gas was passed through the electrode between the inlet and outlet holes.

In Fig. 4, voltage-current characteristics of the small cell with alkaline electrolyte at 25°C for 1-, 0.5-, and 0.25-mm thick electrodes are presented. Since in all the experiments the same carbon powder was used, the quantity of platinum, recalculated as the quantity per square centimeter of the projected electrode area was 2, 1, and 0.5 mg Pt/cm^2, respectively. From the diagrams one can conclude that the thickness of the electrode of 0.5 mm gave the best performance of the cell and therefore 0.5 mm was adopted as the optimum thickness in further experiments. The thinner electrodes obviously had much poorer gas feeding, while 1-mm thick electrodes had slightly higher overvoltages, probably due to the higher ohmic drop between the carbon particles.

In Fig. 5, voltage-current characteristics of the small cell with 0.5-mm thick electrodes are presented for acid (dotted lines) and alkaline electrolyte (solid lines) at 25° and 60°C, and power-current density characteristics at 60°C for both types. Power densities of 0.065 and 0.057 w/cm^2 at 100 ma/cm^2 for alkaline and acid types, respectively, were achieved. Since the electrode holder was made of compact nickel, when the acid electrolyte was used the edges at the holder which were in direct contact with the acid matrix were protected with an acid-resistant lacquer, while the bottoms of the hollows were unprotected (to provide the electrical contact). No trace of corrosion was observed in the course of the measurements (about 2 days), probably due to the hydrophobic properties of the carbon-Teflon mixture.

An attempt to replace the rather coarse pore size porous matrix with an ion-exchange membrane gave much poorer results. Even though in principle one can expect better results with an ion-exchange membrane, this result leads to the conclusion that at present a matrix type of fixed electrolyte is the best solution of this problem.

The large cell (440 cm^2) had 0.5-mm thick electrodes. In Fig. 6, a voltage-current curve and total

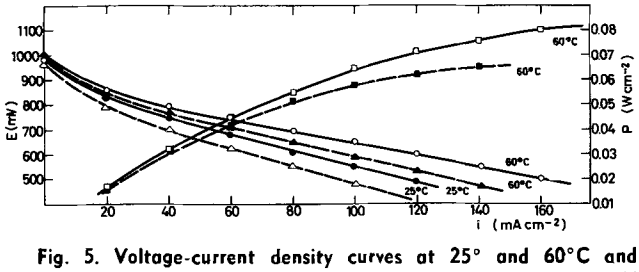

Fig. 5. Voltage-current density curves at 25° and 60°C and power-current density curves at 60°C for small H_2-O_2 cell with 5*N* H_2SO_4 (dotted lines) and 6*N* KOH (solid lines).

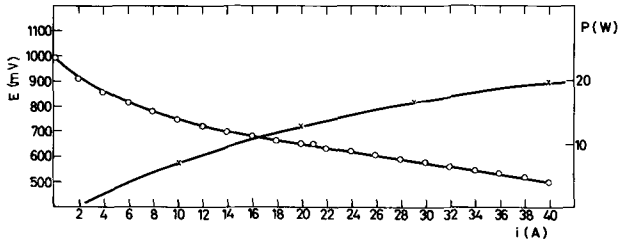

Fig. 6. Voltage-current and power-current curves for larger cell (440 cm^2) with 6N KOH at 25°C.

power-current curve for this cell are presented for 25°C as the ambient temperature.

The real temperature within the cell could not be measured but we estimated that it could not be more than 20° above the ambient temperature. Since the electrochemical activity of carbon for these electrodes can be further increased, particularly for the oxygen electrode, it is to be expected that the cell characteristics can be better than presented here.

If we take 3 mm as the total thickness of one cell, and use electron-conducting plastic for the electrode holders, it is reasonable to expect achievement of very high specific power densities of such fuel cell batteries up to 250 w/liter or 150 w/kg.

It might be concluded, finally, that the powder electrode fuel cell with lateral feeding seems to be very promising for obtaining a compact fuel cell battery.

Reactively Sputtered Thin Films in the Vanadium-Oxygen System Using Triode Sputtering

D. H. Hensler, A. R. Ross, and E. N. Fuls

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The technique of reactive triode sputtering has been employed to deposit several of the vanadium oxides in thin-film form. The resistivity, Hall coefficient, and thermoelectric power of the resulting compositions have been measured at room temperature and presented along with the partial pressure of oxygen in the sputtering gas. These data are compared with the literature when possible to categorize the observed films. It is shown that $VO_{1.87}$ and lesser oxides are metallic at room temperature as determined by a small Hall coefficient and small thermoelectric power.

The vanadium-oxygen system contains a very large number of oxide phases as determined by structural studies (1-3). Even though the existence of some of these phases seems to be in question, the occurrence of many apparently stable oxides is of particular interest to thin film investigators, since the technique of reactive sputtering of vanadium in a partial atmosphere of oxygen should readily permit the formation of some of these oxide compounds. In addition, it should be possible to form nonstoichiometric compositions of oxygen and vanadium of which little is known at present. Measurement of the electrical properties of the various oxide phases began with the work of Morin (4) who measured the conductivity of VO, V_2O_3, and VO_2 crystals. Later data on V_2O_3 was provided by Goodman (5) who measured the conductivity of single crystals, and Acket and Volger (6) who measured the resistivity, thermoelectric power, and obtained estimates of the Hall coefficient of sintered samples. The electrical conductivity and thermoelectric power of VO_2 crystals were measured by Bongers (7), and the infrared reflectivity by Barker, Verleur, and Guggenheim (8).

More recently, some studies have been made in nonstoichiometric compositions of vanadium and oxygen. Kawano, Kosuge, and Kachi (9) have measured the conductivity as a function of temperature for a series of compositions ranging from $VO_{0.8}$ to $VO_{1.25}$. These studies are especially interesting in that they indicate that a material of very low temperature coefficient of resistance may exist in this oxygen range.

Compounds in the vanadium-oxygen system have been produced in thin-film form by several techniques. Films of VO_2 have been prepared by reactive evaporation of vanadium in a residual atmosphere of oxygen gas followed by an annealing process (10). Several vanadium-oxygen compounds have been formed by sputtering vanadium and vanadium oxide films followed by suitable heat treatment (11). More recently, a reproducible single-step process for depositing good quality vanadium dioxide films by reactive sputtering was reported by Fuls, Hensler, and Ross (12), and

subsequent transport measurements have been made on these films (13). In this paper, the technique of reactive sputtering has been extended to other compositions of the vanadium-oxygen system. Hall coefficient, resistivity, and thermoelectric power data are presented in an effort to provide basic information on transport properties of these materials in thin-film form.

Experimental

The sample films were deposited on sapphire substrates by sputtering from a vanadium cathode in an atmosphere of argon and oxygen. A 24-in. metal bell jar evacuated by a 6-in. oil diffusion system was used. The amount of oxygen reacting with the vanadium to form the film depends on the partial pressure of oxygen included in the sputtering atmosphere. This was carefully controlled by means of variable leak valves on the argon and oxygen input to the bell jar. The sputtering gas was continually flushed through the bell jar at the rate of 45,000 μliters/min.

The diode sputtering apparatus used earlier to sputter VO_2 films (12) was changed to a triode system in order to increase the deposition rate while at the same time using somewhat lower argon pressure. This was done simply by adding a filament (14) and an anode to the d-c sputtering configuration as shown in Fig. 1. In this configuration, sputtering was done using an argon pressure of 18μ. The filament current was held at 250 ma, with the anode biased at 200v. The vanadium cathode had a negative potential of 4600v with the substrate holder held at ground potential.

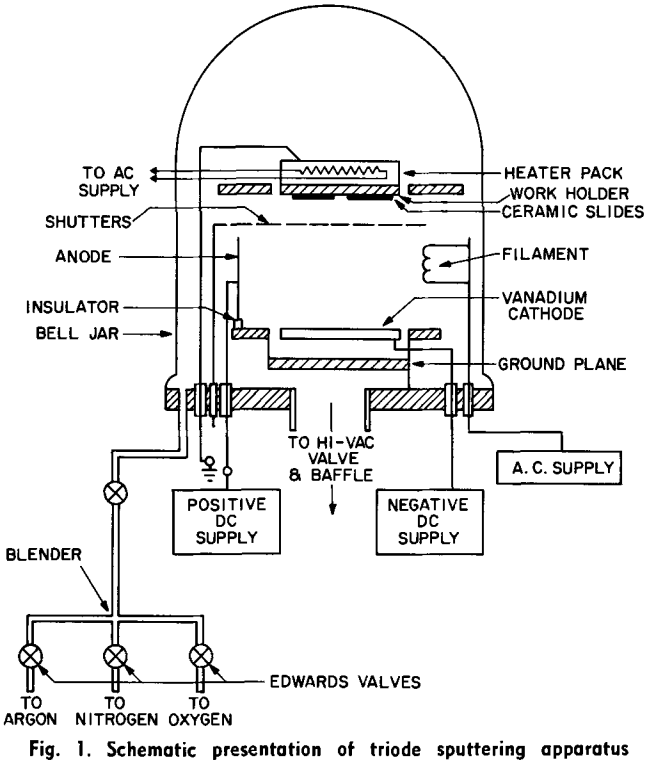

Fig. 1. Schematic presentation of triode sputtering apparatus showing position of anode and filament used to support the sputtering discharge.

The sample films were sputtered on randomly oriented sapphire substrates 0.904 cm by 2.16 cm by 0.81 mm in size after a 15-min presputter to stabilize the sputtering parameters. The substrates were held at 400°C during the sputtering process and for a 30-min postdeposition annealing in vacuum, after which they were allowed to cool slowly over several hours in vacuum.

Standard d-c techniques were used to measure the Hall effect and the resistivity. Data were taken on samples of lower resistivity using a Keithley nanovoltmeter and on higher resistivity samples using a Cary vibrating reed electrometer. Hall bridge patterns were etched in the film and leads were attached using an ultrasonic soldering device and indium solder. The thermoelectric power was measured using a technique outlined by Sidles and Danielson (15).

X-ray studies of the films were made using the Debye-Scherrer technique. Since the films were polycrystalline, Debye-Scherrer rings were obtained on film from which "d" values were measured. The crystal structure was determined by comparing the measured "d" values with those published in the literature. The chemical composition was also estimated from a comparison of the "d" values with the literature. Chemical compositions determined in this way can be considered only as approximate. The results are shown in Table I. In addition, previous studies (16) showed that films deposited on sapphire substrates at oxygen partial pressures greater than 7.0×10^{-4} Torr were highly oriented films of VO_2.

Results

Tables I and II show the variation of the resistivity, Hall coefficient, thermoelectric power, and the temperature coefficient of resistivity with oxygen partial pressure. The resistivity of vanadium sputtered without oxygen is 75 μohm-cm. This value is very close to the resistivity of evaporated vanadium films (17), but it is three times the bulk value of 25 μohm-cm (18) found in the literature. The Hall coefficient of 10.7×10^{-5} cm^3/coulomb is high compared with the value of 8.13×10^{-5} cm^3/coulomb found by Foner (19) for bulk

vanadium, and the value of 7.0×10^{-5} cm³/coulomb for evaporated vanadium films found by Chander, Howard, and Jain (17) possibly due to the inclusion of residual oxygen in the film during deposition.

The x-ray analysis of samples 3 and 4 is based on the work of Klemm and Grimm (20) and Seybolt and Sumsion (21) who identified the compositions $VO_{0.1}$ to $VO_{0.4}$ containing 13.4 to 26.2 a/o (atomic per cent) of oxygen.

Sample 5 is shown by x-ray analysis to be of the face-centered cubic type. On the basis of a comparison of the "d" values with the literature, the composition is placed at $VO_{1.2}$. Because the structure is face-centered cubic with excess oxygen atoms at interstitial sites, it is felt that comparisons with the literature are justified provided that one keeps in mind the doping effects of the excess oxygen atoms. The resistivity of this film is considerably lower than the value of 10^4 μohm-cm given by Morin (4) and somewhat lower than 2×10^3 μohm-cm given by Kawano, Kosuge, and Kachi for samples of pressed powder (9). Denker (23) has reported values of the Hall coefficient for films of the VO_x type: $x = 0.88$, $R_H = -1.1 \times 10^{-2}$ cm³/coulomb and for values of $x = 1.1$, $R_H = +2.8 \times 10^{-3}$ cm³/coulomb. He also has observed evidence of conduction by positive and negatively charged carriers. The value of $R_H = +9.2 \times 10^{-5}$ cm³/coulomb we have observed is consistent with this model for which

$$R_H = -\left(\frac{\sigma_n}{\sigma_t}\right)^2 \frac{1}{ne} + \left(\frac{\sigma_p}{\sigma_t}\right)^2 \frac{1}{pe}$$

where σ_n/σ_t is the ratio of electron conductivity to the total conductivity, σ_p is the hole conductivity, and n and p are the electron and hole densities, respectively. In the data reported here, the smaller Hall coefficient represents a more nearly equal contribution on the part of the two terms. The temperature coefficient of resistance is approximately -100×10^{-6} $(°C)^{-1}$ for this sample. These results are contrary to the findings of a positive temperature coefficient of resistance by Morin (4) for single crystals of VO. However, measurements of the temperature dependence of the resistivity of pressed powder samples with compositions in the range $VO_{0.8}$ to $VO_{1.25}$ (9) show a negative temperature coefficient of resistivity.

The temperature coefficient of resistivity is progressively more negative for samples 6 and 7. Though a direct comparison with V_2O_3 is not reasonable, it is of interest to note that both Morin (4) and Goodman (5) report a positive temperature coefficient of resistance for V_2O_3. The negative temperature coefficient of resistance in samples 6 and 7 is probably a result of structural damage inherent in the deposition process. It is also interesting to note that for sample 1 through sample 7 the Hall measurements are consistent with the estimate of $R_H < 2 \times 10^{-3}$ cm³/coulomb at 300°K by Acket and Volger (6) for V_2O_3. The composition of sample 7 is identified as $VO_{1.87}$ after the work of Anderson (22).

Conclusions

It has been shown that reactive sputtering using a triode system can be used to deposit some of the compositions in the vanadium-oxygen system. Basic room-temperature transport properties have been measured and compared with available literature. Agreement is fairly good considering the spread in the available data. Much of the data presented herein for thin films are the only data available for the compositions discussed. At oxygen partial pressures below 6×10^{-4} Torr corresponding to $VO_{1.87}$ and lesser oxides, the films are metallic as indicated by the high carrier concentration and small thermoelectric power. Between oxygen partial pressures of 1×10^{-4} Torr and 6×10^{-4} Torr, the Hall coefficient is very small indicating that both electrons and holes contribute to conduction. In our samples, the dominant carriers are holes. In the range 7×10^{-4} Torr to 2×10^{-3} Torr oxygen partial pressure, VO_2 is formed and electrons predominate. The scatter in the data for VO_2 samples is due to impurity band effects in which charge carriers of two bands contribute to conduction (13). Similarly, for $VO_{1.87}$ and lesser oxides, the thermoelectric power is small being both positive and negative, whereas, in the region where VO_2 is formed, the thermoelectric power is somewhat larger and negative.

From Table II it can be seen that a broad range of resistivities occurs in which the temperature coefficient is small. This region may be important in making resistive components in thin-film circuits. The high resistivity may make it possible to use these films as high value resistors supplementing existing thin-film technology.

Acknowledgments

The authors wish to thank Mr. N. Berlinski for his conscientious efforts in film deposition and Mrs. M. Read for performing the x-ray analysis of the films. We also wish to thank Mr. D. McNair for supplying filaments that can be used in a partial oxygen atmosphere.

Phosphorus Diffusion into Silicon Using Phosphine

M. S. R. Heynes*,[1] and P. G. G. van Loon*,[2]

ITT Semiconductors, West Palm Beach, Florida

ABSTRACT

Phosphine (PH_3) was used as a diffusion source under both reducing and oxidizing conditions. Erratic results were obtained under reducing conditions using up to 1% PH_3. In an oxidizing ambient, solid solubility limited results were reproducibly obtained from 750° to 1200°C; PH_3 concentrations from 0.1 to 2.0% were used. The presence of water resulting from the oxidation of PH_3 does not appear to be of significance. No difficulty was experienced in applying phosphine diffusion to device fabrication.

Gaseous compounds are attractive as diffusion source materials for equipment simplicity, minimum maintenance, and ease of control; the gas diborane has found widespread use in boron diffusion processes. In this work, the gas phosphine, which was shown to be a promising source material by Donovan and Smith (1), was evaluated.

Phosphine is available commercially in hydrogen and in inert carrier gases in concentrations from a few parts per million to 15% or more. In this work, source cylinders ranging from 0.1 to 5% phosphine in argon were used.

Equipment

The furnace and gas supply arrangements used are shown in Fig. 1 and 2. (The two input arrangements shown are discussed later.) Good exhaust venting was provided for the input plumbing. Total gas flow rates through the furnace were maintained at 2 liters/min. The quartz furnace tubes were of 54 mm diameter and the quartz boats were of conventional flat slab type.

Runs were made with the wafers lying flat on the boat. The test wafers were of about 1 ohm-cm resistivity boron doped and were mechanically polished. The doping gas stream was turned on 5-20 min before runs were started. If the furnace had not been used for several hours, 15-20 min were allowed but, if only say 1 hr had elapsed since the last run, just sufficient time to flush the tube with doping gas was allowed. The doping gas flowed into the furnace for the full duration of the diffusion runs and was turned off only after the diffused wafers were removed. Evaluation was by a conventional four-point probe kit and angle lapping and staining techniques.

Experimental Conditions

Diffusion experiments were carried out under both reducing and oxidizing conditions.

Under reducing conditions, thermal decomposition of the phosphine occurs above about 400°C releasing elemental phosphorus, and deposits of red phosphorus were formed at the cool ends of the furnace tube.

Experiments were run at 1000°, 1100°, and 1200°C using a source cylinder of 1% phosphine in argon with and without additions of nitrogen and hydrogen, but erratic and high sheet resistance values were obtained for all conditions tried.

It appears that the vapor pressure of phosphorus released even from the undiluted 1% source (which would be in the region of 3 Torr), is too low for much dissolution in the silicon to occur. Solid solubility limited diffusions using an elemental phosphorus source have been reported but these were sealed-tube methods in which high phosphorus vapor pressures would be expected [for example, Fuller and Ditzenberger (2)].

Coupland (3) has studied the use of elemental phosphorus as a diffusion source in a two-zone sealed system. The phosphorus was contained in a limb of the system which was outside the diffusion furnace and the vapor pressure of the phosphorus was controlled by the temperature of this limb. An extrapolation of Coupland's results indicates that a phosphorus vapor pressure of 3 Torr will give a surface concentration of about 10^{20} atoms/cm^3 which is about an order of magnitude below the solid solubility of phosphorus in silicon in the diffusion temperature range. The high sheet resistance values obtained with phosphine under reducing conditions are therefore understandable.

A long extrapolation of Coupland's results indicates that a phosphorus vapor pressure about 100 Torr is required for surface concentrations to reach solid solubility levels.

The prospect of carrying out diffusions with 30% or more of phosphine to check this estimate was unattractive and no further work was done in this direction.

Oxidizing Conditions

Good diffusion characteristics were immediately obtained with oxygen additions to the phosphine mixtures. The phosphine oxidizes immediately in the furnace to P_2O_5 plus $3H_2O$.

It is interesting to note that good results are obtained in this system when, in P_2O_5 systems, great care is taken to exclude moisture. Apparently, the composition P_2O_5 plus $3H_2O$ as formed in the hot zone of the furnace distributes well and forms a uniformly doping glass on the silicon surfaces without causing surface damage or "spiking" at the diffusion front.

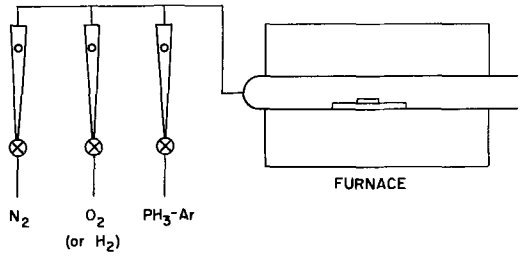

Fig. 1. Gas input and furnace arrangement

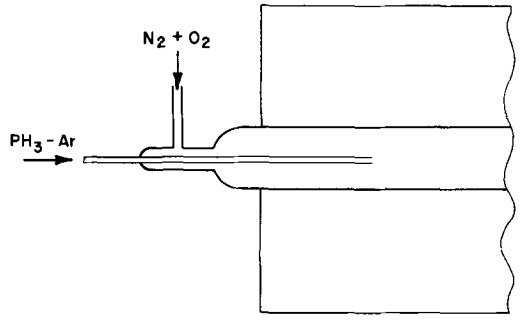

Fig. 2. Alternative gas input arrangement

Key words: phosphorus, diffusion, phosphine.

[2] Present address: Union Carbide Corporation, Electronics Division, San Diego, California.

With the simple furnace input arrangement shown in Fig. 1, a problem of premature reaction between PH_3 and O_2 soon became apparent. The input end of the furnace tube and the glassware near to it was hot enough for some oxidation of the phosphine to occur, particularly for diffusion temperatures above 1000°C. This left a messy deposit of (apparently) phosphorus oxides and acids and even some red phosphorus. In addition to the obvious maintenance problem, this reaction depletes the ingoing doping mixture.

The arrangement shown in Fig. 2 provided a way of minimizing this effect, and most of the results presented below were obtained using this arrangement.

Systematic Study of the Oxidizing System

The most convenient way of achieving uniformity and reproducibility of diffused doping is to operate with conditions which will keep the silicon surface saturated at the solubility limit of the impurity.

If this fundamental controlling factor is used, slight variations in furnace conditions will be unimportant. Only the maintenance of excess doping is required, and the oxidizing system was systematically investigated to find the range of operating conditions which would provide excess doping.

The effect of the systematic variation of phosphine concentration on sheet resistance values for 30-min diffusions at various temperatures is shown in Fig. 3. Oxygen concentrations for these runs were chosen to provide a slight excess over the amount required to oxidize the phosphine completely. (The results shown in Fig. 4 and discussed below indicate that the oxygen concentration is not critical.)

It is observed that the sheet resistance values fall to minimum levels at about 0.2, 0.4, 1, and 1.5% PH_3 at 850°, 1000°, 1100°, and 1200°C, respectively.

It should be noted that the apparent concentrations required to reach these minima depend on the construction of the input plumbing to the furnace. These results were taken with the input arrangement shown in Fig. 2 as discussed above. With the simple arrangement shown in Fig. 1, the premature reaction in the glassware resulted in a need for higher flow rates of PH_3 to achieve the minimum sheet resistances.

These minimum sheet resistance values agree within about 10% with the minimum values we have observed in P_2O_5 and $POCl_3$ diffusion systems for these times and temperatures and are assumed to be controlled primarily by the solid solubility of phosphorus in silicon.

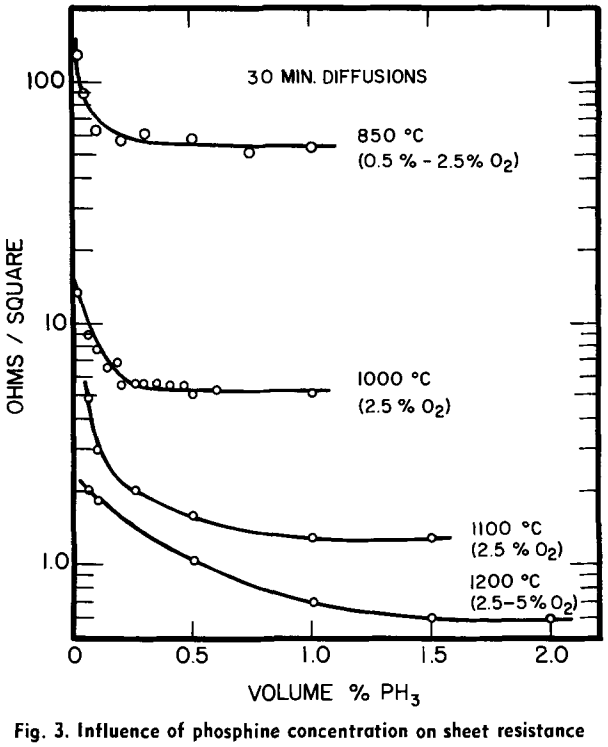

Fig. 3. Influence of phosphine concentration on sheet resistance

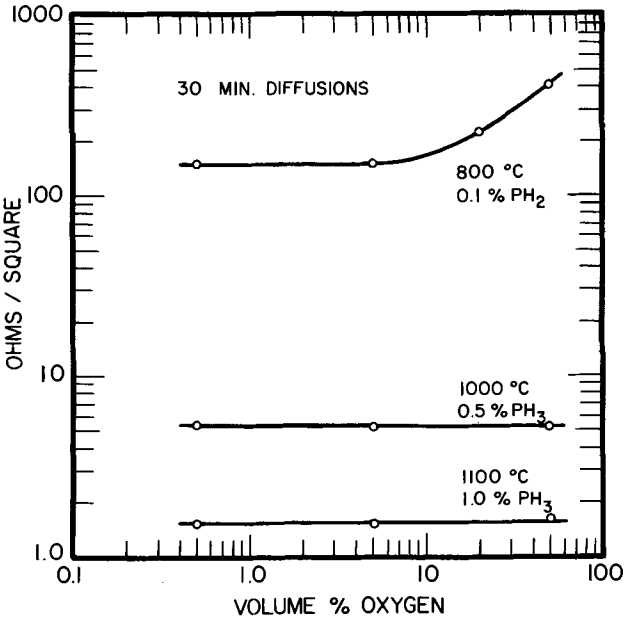

Fig. 4. Influence of oxygen concentration on sheet resistance

It is interesting to compare the concentration of phosphorus compounds present in P_2O_5 and $POCl_3$ systems with the results obtained with phosphine.

In a typical P_2O_5 emitter diffusion (carried out around 1050°C), with P_2O_5 source temperatures in the region of 220°-230°C, the concentration of P_2O_5 in the carrier gas will be in the region of 1.5% if the gas is saturated with the oxide vapor. In $POCl_3$ systems, a typical $POCl_3$ concentration in the input gas is 1% which, on oxidation, will yield a P_2O_5 concentration of 0.5%.

The present phosphine results indicate that about 1% PH_3, equivalent to 0.5% of P_2O_5, is required for solid solubility limited diffusions at 1050°C.

Not surprisingly, about the same phosphorus compound concentrations are required regardless of the particular source material.

The effect of the variation of oxygen content is shown in Fig. 4.

The phosphine concentrations used in these experiments were those found in the earlier experiments to give solid solubility controlled diffusions at relatively low oxygen concentrations.

There is no perceptible variation in sheet resistance with oxygen concentration at 1000°C and above but, at 800°C, the sheet resistance values increase from the saturation value of about 150 ohms/sq to 400 ohms/sq at 50% oxygen.

The probable explanation is that at low temperatures additional oxidation due to extra oxygen causes a significant glass dilution and masking effect but, at high temperatures, phosphorus can still diffuse through the glass rapidly enough to keep the silicon surface saturated.

Having established the conditions necessary for achieving saturation diffusions, sheet resistance and junction depth values were compiled for various times and temperatures. Figure 5 shows the sheet resistance results. These curves agreed within about 10% with those we had generated previously for $POCl_3$ and P_2O_5 diffusions (4). Figure 6 shows the junction depth results which also agree well with those from the other phosphorus systems.

The P_2O_5-H_2O System

The oxidation of PH_3 yields the composition P_2O_5: $3H_2O$. This composition will form orthophosphoric acid at low temperatures:

$$P_2O_5 + 3H_2O = 2H_3PO_4$$

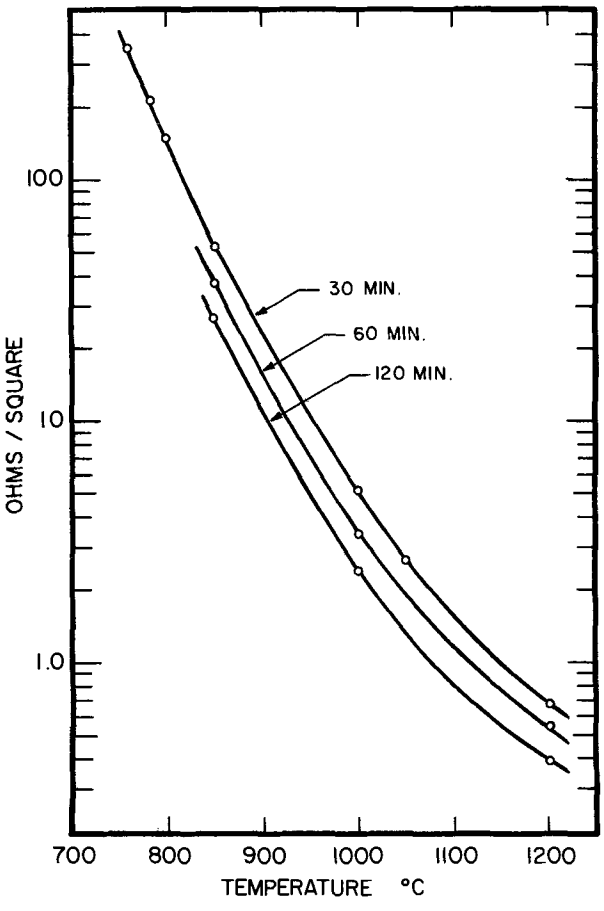

Fig. 5. Variation of sheet resistance with temperature (solid solubility-limited diffusions).

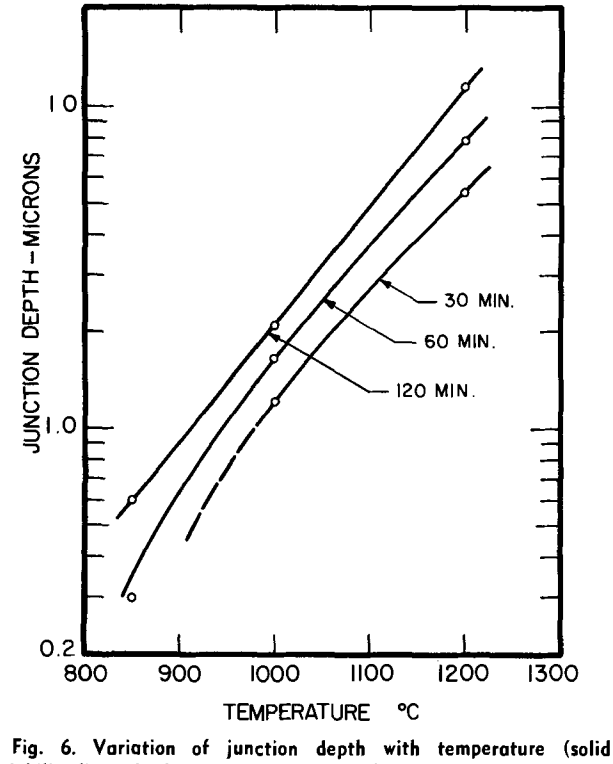

Fig. 6. Variation of junction depth with temperature (solid solubility-limited diffusions in ~ 1 ohm-cm boron-doped test wafers).

As H_3PO_4 is heated, it loses H_2O, decomposing first to pyrophosphoric acid, $H_4P_2O_7$, then at about 260°C, to metaphosphoric acid, HPO_3. At diffusion temperatures, the molecular composition of the vapor is uncertain. Apparent molecular weights for the P_2O_5-H_2O system have been measured by the vapor density method by Tarbutton and Demming (5) and, for the composition P_2O_5:$3H_2O$, the results indicated a mixture of only P_4O_{10} and H_2O molecules but the presence of low molecular weight ultraphosphoric acids was also suspected. However, for the purpose of phosphorus diffusion in silicon, it appears to be of no significance whether or not compounds are formed between P_2O_5 and H_2O. P_2O_5 and the phosphoric acids are all quite volatile and are expected to be equally reactive with a silicon surface. This is in contrast to the case of boron diffusion, where we believe that the presence of water (from doping sources such as diborane, methyl borate, and boron halides with H_2 and O_2) assists in the distribution of doping through the formation of boric acids which are much more volatile than B_2O_3 (6).

The use of what are effectively P_2O_5-H_2O systems for diffusions is not new with the use of phosphine. Lothrop (7) reported the use of the P_2O_5-H_2O azeotrope (92.4% P_2O_5:7.6% H_2O) prepared by heating metaphosphoric acid for several hours at 800°C. Lothrop concluded that reproducible diffusions could be obtained with the azeotrope which provides a source of invariant composition and whose vapor pressure is reproducibly controlled by furnace temperature.

Also, Maekawa (8) described the successful use of a source material prepared by heating orthophosphoric acid at 600°C.

The presence of water in the phosphine system will certainly contribute to oxidation of the silicon. However, with the conditions described here, the water content of the furnace atmosphere will be only 0.3-3% and only slightly more oxide growth is observed in a phosphine diffusion than in a comparable $POCl_3$ diffusion.

Device Fabrication

In the practical application of phosphine diffusion in transistor and integrated circuit fabrication, no processing difficulties were experienced in substituting the oxidizing phosphine diffusions for P_2O_5 and $POCl_3$ methods and no significant differences in device characteristics were noticed.

However, we do not favor the use of phosphine for high concentration diffusions at temperatures above 1000°C because of the high concentrations of the relatively expensive and highly toxic gas which must be used; 0.3-1.5% is required in the furnace tube in contrast to, say, the diborane system where only about 0.01% is required. Also, at these high phosphine concentrations, there is a maintenance problem. Some reaction occurs in the input glassware of the furnace and at the output end of the furnace phosphoric acid is deposited which is even more messy than the initially dry P_2O_5 from $POCl_3$ systems.

Phosphine diffusion is attractive for low temperature applications where very good control and reproducibility have been observed.

Conclusion

Good diffusion characteristics have been observed for the oxidizing phosphine system over a wide range of temperatures but because of toxicity, maintenance, and expense problems it appears unlikely that phosphine will displace existing source materials except perhaps in some low temperature-low concentration applications.

ID-Diamond-Sawing Damage to Germanium and Silicon

Ronald L. Meek and M. C. Huffstutler, Jr.

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The surface damage associated with wafering of germanium and silicon using an ID-saw has been investigated. Well-defined damage layers, which consist principally of microcracks and which have a depth of 25 $\pm 5\mu$ in germanium and 50 $\pm 10\mu$ in silicon, were observed for a range of sawing parameters. In no case was there evidence to suggest bulk damage to the materials. On the basis of vibration studies of the specimen and ID-blade, out of plane blade vibrations and periodic abrasive contact (due to noncircularity of the center hole in the blade) appear to be the important damage mechanisms.

The sophistication of present-day semiconductor device and integrated circuit technology is such that small lattice imperfections may have large enough effects on the material's transport properties and its uniformity of response to subsequent process steps to preclude satisfactory performance (1). It has been found in this laboratory that residual effects of early process steps carry over to produce defective finished devices. The present investigation is part of a continuing effort to optimize processing technology and to control or eliminate the associated defects.

While a nonmechanical method of semiconductor wafering—electrolytic shaping (2) or perhaps a laser knife—might be more desirable, at present only sawing is practical. With respect to surface damage, wire sawing is clearly superior (3) since it is essentially a lapping operation and the damage depth has been shown (4-7) to be of the order of the abrasive size; typically, a few microns. Presently available proprietary wire saws are impractical for large volumes of work, however, and inside-diameter (ID) diamond saws are usually used because of their material-savings advantage.

Little work has been reported on the nature and extent of the damage to semiconductor materials due to the wafering operation; that which is available is somewhat contradictory in that the depth of damage is reported as 12-13 or 40-70μ for what appears, superficially at least, to be the same sawing operation (8). The great depth to which mechanically sawed metal crystals are strained (9) indicates the advisability of investigating not only the surface damage but also the possible incidence of damage to the bulk of the slice.

Presumably, the vibrations of a slice being cut set up stresses analogous to fatigue tests and some of the damage may be related to this mechanism. Unfortunately, fatigue and fracture of homopolar crystals has not received the same attention as has been accorded to metals (10).

Several observations have been made while slicing silicon and germanium which deserve explanation:

1. Sometimes it is not possible to produce a whole (nonshattered), thin ($\sim 200\mu$) slice at saw settings (blade speed and feed rate) for which quite satisfactory, somewhat thicker ($\sim 300\mu$) slices are obtained. Rather, the feed rate must be increased to obtain the thin slice even though the over-all vibration level, as measured at the crystal mount, is considerably increased.

2. Sometimes, thin ($\sim 200\mu$) slices can be obtained from a certain crystal cut on the <111> plane, but the same saw settings do not permit a slice of the same thickness to be cut from seemingly equivalent material on the <100> plane.

3. Even with saw performance well within manufacturer's specifications, and with a saw blade of maximum concentricity (*i.e.*, $\sim 25\mu$ differential), no successful attempts have been made to produce slices of thickness less than about 175-200μ.

4. It appears to be possible to cut thinner germanium slices ($\sim 175\mu$) than silicon slices ($\sim 200\mu$).

These observations (No. 1 in particular) seemed to indicate the possibility of a fatigue mechanism. Although silicon and germanium (and diamond) have essentially no plastic flow domain at room temperature (11-13), the fatigue cracking of diamond has been demonstrated in a preliminary way (11). Furthermore, current information (14-16) indicates that dislocations may exist at the bottom of cracks in silicon and germanium. Repeated opening and closing of the crack might be expected to expand such networks into the bulk of the material. It seemed advisable, therefore, to ascertain not only the extent of gross surface damage but also the incidence, if any, of bulk material damage for ID-sawed semiconductor wafers.

The ID Saw

The basic configuration of the specimen and blade in an ID-saw is shown schematically in Fig. 1. (The coordinate system of Fig. 1 is used for orientation reference throughout this paper.) In principle, the support arm to which the wax-mounted ingot is fastened is an asymmetrically stiffened cantilever mounted on the feed table; y- and z-directional motions for cutting and indexing, respectively, are furnished by devices which operate at a fixed rate of speed (generally, the y- and z-drive mechanisms are powerful enough to be used on heavy-duty surface grinders, and are not equipped with a force-limiting clutch). In the process of cutting a slice, the z-motion is "locked" and the ingot moves in the y-direction at some set speed (typically, 2 cm/min). The true cutting rate is not constant, however, since there are variations due to the shape of the ingot and, what is more important, the blade edge does not move in an exact circle. When the blade edge is viewed from the frame of reference of the crystal, as a first approximation it appears that the rotation of an ellipse (with semimajor and semiminor

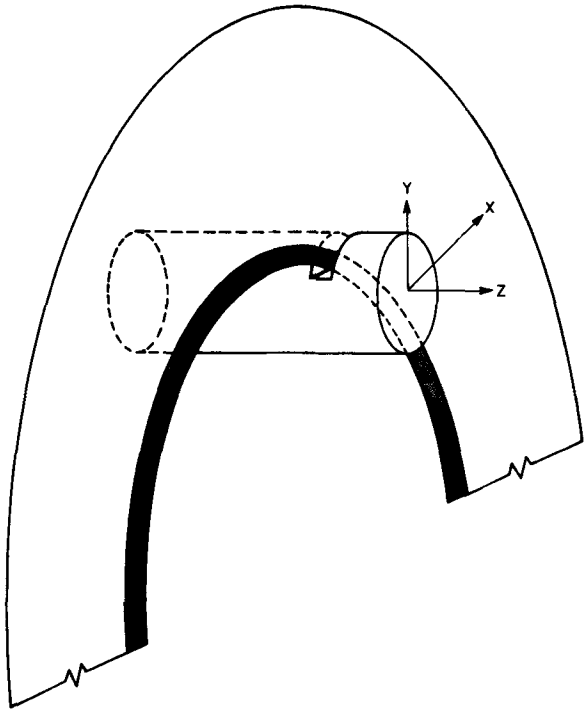

Fig. 1. ID saw schematic

axes differing by 25-50μ) is being viewed. The usual rotational blade speed is about 50 rps when a blade of 10 cm ID is used. That is, the feed rate is about 10μ per blade revolution. The lateral feed rate of the ingot being cut was measured, by means of a transducer which sensed table position as a function of time, and was found to be constant to within the uncertainty of the measurement which was estimated as less than 5%. It is clear then that large variations in cutting rate occur and that, in fact, the blade edge is not even in contact with the crystal part of the time.

In conjunction with the damage studies to be discussed shortly, vibration measurements were made in which a transducer sensitive to y-direction acceleration was placed on the crystal mount on the side opposite the kerf being cut. Frequencies of n x (wheel rotational frequency) were observed with $n = 1, 2, 3, \ldots$. The principal component appears to be at $2n$, that is about 100 Hz, and the amplitude of the vibration is about 1μ. Thus, since the crystal does not flex away from the blade edge, the large variations in cutting rate are quite real.

Typical practice in ID cutting calls for a small, low-pressure jet of water directed on the blade edge immediately before it enters the kerf. Because of the centrifugal force operating on the water film, it forms a tapered layer on the sides of the blade, being thinnest at the cutting edge. It has been found that best results are obtained if the water flow where the blade enters the kerf is sufficient only to wet the blade. The blade edge is then washed of excess cuttings with a larger water stream where it leaves the kerf. Too thick a water film where the blade enters produces tapered wafers, presumably due to ever-increasing hydrodynamic coupling between the blade and the crystal through the thickening water film.

Methodology for Damage Investigation

A number of methods are applicable to damage/defect study (4, 8, 17, 18), but the ease and speed of direct metallographic examination have been employed for the present inquiry. Some studies were carried out by alternately etching and chemically and/or mechanically polishing away the damaged material. Since all silicon/germanium etches are polish-etches, this method has the decided disadvantage that features observed after any etching step are characteristic not only of the final material surface but also the initial material surface and all the layers within the damaged layer. Mechanical polishing and then etching partially, but not totally, avoids perpetuation of the outermost surface irregularities in subsequent etches. Much better results were obtained when the slice under observation was mechanically polished on one side to a depth of about half of the slice thickness. The wafer was then mounted damaged-side-down on a glass slide with acidproof wax, after which the polished face was repeatedly etch/polished, the amount of material removed being determined (by thickness measurement) after each step. This permitted dislocations (or other etchable features) to be observed in the bulk of the material as well as any variation in their character across the slice thickness. Since the damaged surface layers are approached from beneath, their incidence is very clearly defined. The dislocation pattern in the bulk of the slice was compared to the uncut crystal's etched feature characteristics. In order to further assure that any and all flaws were revealed, two etches were used for each material and one-to-one correspondence of etched features was observed. For silicon, a modification of Dash's etch (17, 19), as well as a copper nitrate etch (20), was employed. In the case of germanium, CP-4 and the Westinghouse silver etch were utilized (20). Slices of various thickness cut on <111> and <100> planes were examined for large variations in sawing parameters.

Wafer Damage

Crystals of germanium and silicon were sawed with a stainless-steel ID-blade. The blade stock thickness was 100μ and the diamond grit (~50μ) plus blade thickness was 200μ. The kerf produced was 225μ, the average cuttings size being 2-3μ. The blade concentricity was 25-50μ.

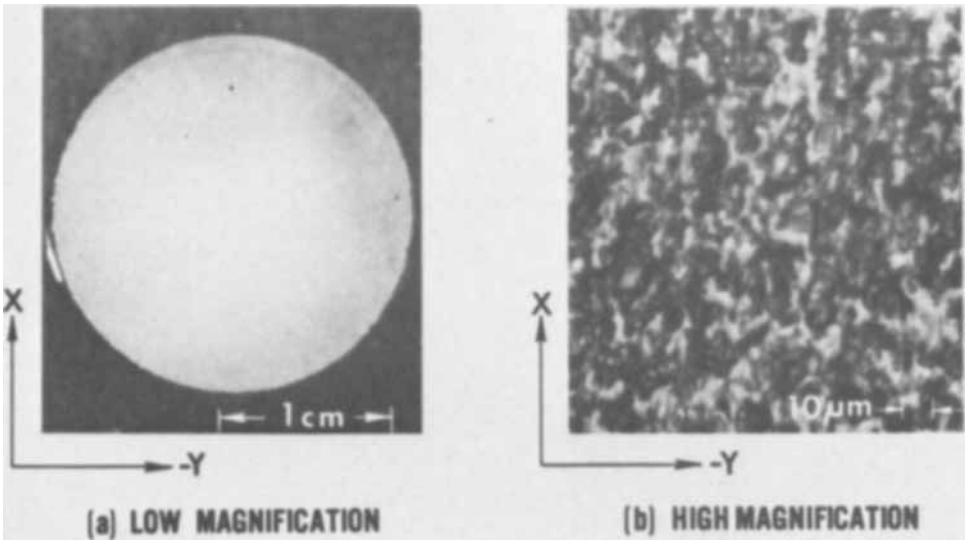
Slices, 20-30 mm in diameter, of silicon and germanium having thicknesses of 190-360μ were cut from <100> and <111> material. Blade speed settings of 50-70 rps and feed rates of 1-4 cm/min were employed. All silicon studied was initially essentially dislocation free, but one germanium sample had a grown-in dislocation density of $7(10)^4$ lines/cm^2.

As-sawed silicon surfaces appear in Fig. 2(a) and 2(b). A profilimeter survey of the surface (Fig. 3) shows it to be chipped and fractured to a depth of about a micron (the profilimeter tip diameter was about a micron). This measurement probably underestimates the surface irregularity.

A silicon wafer which was lightly Syton polished (5μ removed) and then etched appears in Fig. 4. After the polish step, the surface still appeared rough and cracked. The etched features clearly tend to lie in lines along the cutting arc of the saw. A wafer subjected to two polish/etch steps appears in Fig. 5. After the second polish (25μ total material removed) no surface defects were observed at 500 magnification. After a second etch, however, the features of Fig. 5 were revealed. The etched line has the same character and orientation as those of Fig. 5, although there are many fewer such lines. Both etches, and etching from beneath the damaged layer, revealed the same characteristics for all silicon samples studied. The total damage layer for silicon is 50 $\pm$10μ, and in no case did either etch reveal damage to the bulk of the slice beneath the damaged surface layers.

A Syton-polished germanium surface which was etched with the Westinghouse silver etch appears in Fig. 6 from which it is seen that the defect character and orientation is much the same as in silicon. The sawing-damage surface-layer for germanium is 25 $\pm$5μ, in distinction to the relative lapping-damage situation where germanium is damaged to a greater depth than silicon (8).

Examination of germanium wafers having a grown-in dislocation density of $7(10)^4$ lines/cm^2 from beneath the damaged surface is more instructive. Figure 7(a)



shows a particular slice at a depth of 25μ below the cut surface. The CP-4 etch clearly reveals the grown-in dislocations. In no case did the character or number of these dislocations indicate bulk damage to the slice center. The same slice appears in Fig. 7(b) after 5μ more material was etched away; *i.e.*, 5μ closer to the surface. The same type of features as seen in silicon are revealed. The character of these etch pits is very much different from the dislocation pits of the previous picture [Fig. 7(a)]. It is to be further noted that in the

surface layers the damage is so extensive that the dislocations characteristic of the bulk cannot be distinguished at all. Figure 8 shows a germanium sample (well into the slice center) which was first etched with CP-4, in order to reveal the dislocations, and then with the WAg etch. A pyramidal pit was formed in the bottom of each CP-4 pit, as shown in the figure, which can be contrasted to the flat-bottomed WAg pit (Fig. 6) characteristic of the damaged layers. Because of this decided difference in etched feature characteristics, we conclude that the damaged layers consist largely of microcracks rather than dislocations. In support of this position, it is again noted that room-temperature plastic deformation of germanium or silicon is not generally accepted (13). When the presence of the coolant and the total damage depth are taken into account, it is difficult to believe that the cutting action produces local heating sufficient to permit plastic deformation.

Saw Wafer Interaction

In order to gain understanding of the stresses to which the wafer is subjected during cutting, the interaction of the saw blade with the wafer is considered. At least two phenomena are apparent. First, the blade vibrates within the kerf and applies a bending force to the wafer as illustrated in Fig. 9, for which b is the radial diamond grit extent, Δ is the wafer thickness, S is the cutting rate, and t is time as measured from the start of the cut. Second, as the blade cuts into the crystal, some force F_2 is applied at a small angle β to the corner of the kerf as illustrated in Fig. 10. This tends to shear off the crystal wafer along the cleavage plane which lies at an angle α. (This shear force is much greater than that associated with F_1.)

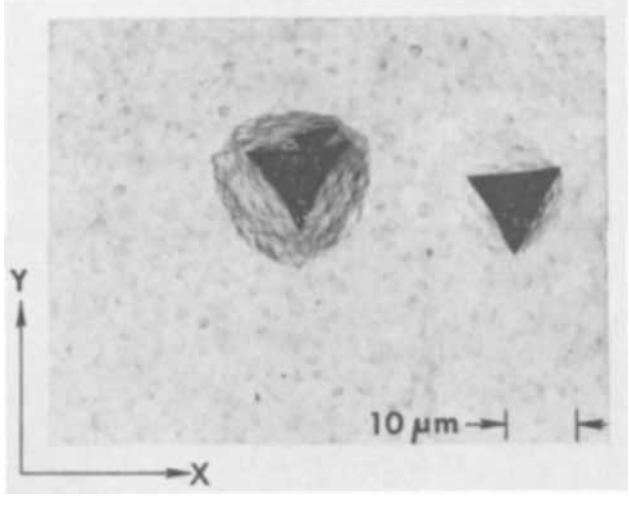

Fig. 8. Etched germanium surface (100 μm depth). Dislocations in ingot as shown by WAg etch pits (pyramidal features) formed in conical pits from previous CP-4 etch.

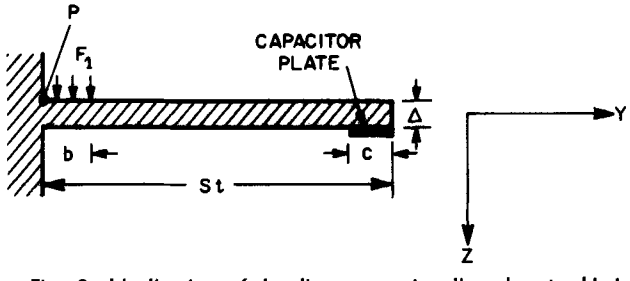

Fig. 9. Idealization of bending stress in slice due to blade vibration.

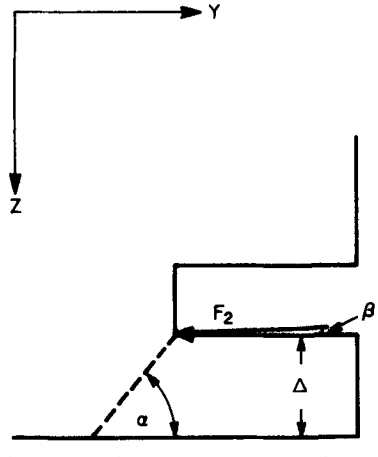

Fig. 10. Idealization of shearing stress in slice due to cutting force

The forces involved were evaluated as follows: A thin metal foil, which functioned as one plate of a capacitor, was placed on the wafer as shown in Fig. 9. A similar plate placed 50μ away was fastened to a massive aluminum support extended from the crystal mount. This capacitor then functioned as a capacitance microphone to measure the slice deflection under cutting conditions. For the situation described, elementary beam-bending theory (21) shows the deflection δ is given by

$$\delta = \frac{F_1 b^2}{2Ew\Delta^3} [4St - 2c - b]$$

where w is the slice width at the kerf and E is the appropriate Young's modulus. Experimental measurements of the slice deflection have shown that F_1/w is nearly constant at about $4(10)^5$ dynes/cm for silicon.

It is difficult to represent the deflections by any one frequency, but it appears that major deflections occur at about 500-1000 times/sec in agreement with estimates of the fundamental frequency of out-of-plane blade vibration at the relevant tension. The maximum tensile stress, at point P of Fig. 9, can then be calculated as a function of slice thickness, by use of elementary beam-bending formulas (21), from

$$\sigma_{t,\max} = \frac{3b}{\Delta^2}\left(\frac{F_1}{w}\right)$$

Values are presented in Table I. Evaluation of F_2 is somewhat more difficult. The angle β must be very small, and so will be neglected, and the cleavage plane will be assumed to intersect the cutting plane along the line of cut. Then the shear stress on the cleavage plane is

$$\sigma_s = \frac{F_2}{w\Delta} \cos\alpha \sin\alpha$$

The cleavage plane will always be a <111> plane (13), (also see later). The average cutting force per unit kerf length is easily measured and from such measurement F_2/w is estimated, with F_2 the average cutting force, as 10^7 dynes/cm when silicon is sawed. Calculated values of σ_s when the cutting plane is <111> or <100> are presented in Table II.

The tensile stress in bending necessary to break silicon and germanium wafers has been measured as illustrated in Fig. 11. The force, F, necessary to break the slice is applied slowly (over a period of about a minute) and uniformly by means of a screw feed operating against a direct-reading, spring-loaded force transducer. It was observed that the force could be maintained at about 95% of the value needed for breakage for at least 15 min without fracture of the slice. Slices were examined with the length l (the beam axis), as shown in Fig. 11, oriented along the y and x axes. In all cases, breakage was on <111> cleavage planes (as determined by observation of the angle between the breakage plane and the known surface plane) and fracture was initiated at the point where the slice entered the wax. When an appropriate cleavage plane lay within about 20° of the wall, the wafer broke along a single line. For greater angles, multiple fracture occurred, the ~25% of the slice closest to the block being shattered into several fragments. Data, in terms of the maximum tensile stress, are summarized in Table III. (The columns x and y under $\sigma_{t,\max}$ are for the beam axis along the x-, y-axes, respectively.) The germanium and all but B-silicon are from the same batches as used for depth of damage study. The B-silicon wafers were cut when saw performance was poor and scratch marks and gross surface damage were much more evident.

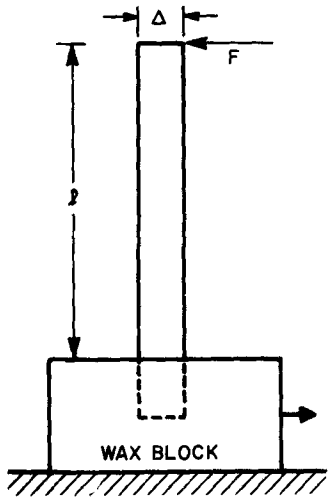

Fig. 11. Experimental slice-breakage-measurement configuration

Several observations can be made:

1. It always takes a larger stress to cause fracture when the beam axis is parallel to the damage cracks than when it is perpendicular to them. That is, the damage effect weakens the slice anisotropically.
2. The stress necessary to cause fracture is considerably increased when the damaged surfaces are removed and the breakage-stress anisotropy disappears.
3. A somewhat greater stress is necessary to break <100> than <111> slices although the difference is small for as-sawed wafers.

Comparison of the measured fracture stress with the calculations of the stresses during sawing (Tables I and II) allows plausible explanation of the observed thin slice breakage:

1. Clearly, the existing interaction stresses limit the possible slice thinness to somewhere in the range 100-

Ge	<111>	Polished	260	1.6	1.5

200μ, for Si and Ge ingots of approximately 25 mm diameter.

2. When the added effect of the shear stress due to the cutting action is taken into account, the minimum possible <100> slice thickness may be greater than for <111> slices, since the shear stress along the cleavage plane is greater for the <100> slice.

3. When a certain thickness slice cannot be cut successfully, increasing the feed rate, and consequently the shear stress, may be desirable if sufficient damping of blade vibration, and reduction of tensile stress, results.

4. Since germanium is not as hard as silicon, the blade/crystal interaction forces are expected to be smaller, and may be enough less to allow lower than critical stresses in thinner slices than is the case for silicon.

At any rate, it is clear that thinner slices having less surface damage are not likely to be produced by diamond ID-saws until devices to damp blade vibrations and smooth out variations in the cutting rate are implemented.

Finally, in support of the microcrack hypothesis, it is interesting to compare the tensile stress at a crack tip necessary to instigate fracture with that calculated from the Griffith formula (10),

$$\sigma \doteq \sqrt{\frac{E\alpha}{c}}$$

for a crack of length c in a material with specific surface energy α. If it is supposed that cracks extend from the surface to the bottom of the damaged layer, then the tensile stress at the crack tip needed to propagate the crack (fracture the slice) is easily calculated from the data in Table III. For silicon this stress is found to be 0.9-1.0 $(10)^9$ dynes/cm^2 and for germanium it is 0.7-0.8 $(10)^9$ dynes/cm^2. The specific surface energy, for the cleavage plane, is estimated (10) as 900 erg/cm^2 for silicon and 700 erg/cm^2 for germanium. Examination of the etch features for a number of slices indicates that, near the bottom of the damaged layer, the crack length is about 50μ. The calculated Griffith stress based on this crack length is 0.6 $(10)^9$ dynes/cm^2 for silicon and 0.5 $(10)^9$ dynes/cm^2 for germanium. The agreement is well within the uncertainties in the formula and the numerical values used.

Conclusions

Damage patterns in ID-sawed, thin (200-400μ) silicon wafers (2-3 cm in diameter) have been analyzed by surface etch/polishing, by material removal from the side opposite the damaged layers, by measurement of the magnitude and anisotropy of the fracture strength, and by use of specialized dislocation etches with the following conclusions:

1. The depth of surface damage as judged by the sudden appearance of etchable structural features is about 50μ.

2. The pattern of the etched damaged material can be described as dense strings of pits coincident with the abrasive path and appears to be mostly microcracks (as substantiated by a sharply decreased and anisotropic fracture strength).

3. The mechanism of damage appears to be largely out-of-plane flexural vibration of the membranelike ID-blade which produces, in turn, oscillating stresses in the wafer being cut.

Comparison studies on germanium (for which the damage depth is about 25μ) further verify that the surface damage is predominantly microcracks oriented parallel to the abrasive path. The length of these cracks is, of course, unchanged during processing so long as the wafer is not subjected to stress (at a sufficient level and appropriately directed) which would extend them. Presumably, an etch immediately after sawing would eliminate some of the most easily extended microcracks which would otherwise spread and deepen the damage during subsequent grinding and polishing operations.

Acknowledgment

The authors are pleased to acknowledge W. J. Rhines for discussions and calculations relevant to blade vibration.

Liquid Phase Epitaxial Growth of $Ga_{1-x}Al_xAs$[1]

J. M. Woodall*, H. Rupprecht, and W. Reuter

Research Division, International Business Machines Corporation, Yorktown Heights, New York

ABSTRACT

The liquid phase epitaxy method of solution growth has been applied to the ternary compound semiconductor, $Ga_{1-x}Al_xAs$, for nearly the complete solid composition range. Epitaxial deposition of this compound has been achieved on GaAs substrates. Factors which determine the metallurgical and chemical nature of the layers include: the geometry of the crystal growth apparatus, the design of the furnace and its temperature profile, the cooling schedule, the melt composition, and the residual oxygen concentration in the purging gas.

Since its development as a useful epitaxial crystal growth method for GaAs (1), the liquid phase epitaxy technique has been applied to other binary compounds, such as GaP (2). Recently (3), it was found that this method can be used for preparing efficient electroluminescent junctions in $Ga_{1-x}Al_xAs$. In this paper, we describe the necessary conditions for the successful application of the liquid phase epitaxial method to this system and report the resulting morphological and chemical characteristics of the $Ga_{1-x}Al_xAs$ epitaxial layers that are produced.

Apparatus

A vertical dip apparatus, shown in Fig. 1, was used for this study. Except for the graphite substrate holder and the Al_2O_3 crucible, the entire apparatus is made of fused quartz. The dimensions below the gas inlet and outlet ports are 12 in. by 1 in. OD. The Al_2O_3 crucible has a volume of 10 cm^3. The graphite substrate holder is hollow to allow for the insertion of dopants into the melt during growth. The substrate holder is suspended from a quartz tube which in turn is clamped to the main body of the apparatus by Teflon fittings. The quartz tube is normally covered by a gas-tight fitting which contains the dopants which are inserted in the melt during growth.

Fused quartz was found to be an unsuitable material for containing Ga-Al melts. Aluminum vapor and Al alloys react with quartz vessels causing silicon contamination at temperatures as low as 750°C (4). Both Al_2O_3 and graphite can be used for Ga-Al melts for temperatures up to 1150°C without noticeable Si contamination or other crucible and melt reactions occurring.

In order to prevent the preferential oxidation of Al in Ga-Al melts during growth, it is necessary to use an ultrapure inert purging gas. The large residual water vapor and oxygen concentrations in industrial-grade forming gas (10% H_2, 90% N_2) were found to cause nonuniform growth of uncontrolled composition. Also, during heating an oxide scum forms on Ga-Al melts, which, unlike the scum on pure Ga melts, cannot be easily reduced even in an ultrapure hydrogen ambient. This oxide layer hinders wetting between the substrate and melt in the horizontal tip method (1). However, in the vertical system the substrate is inserted through the scum into a clean liquid where wetting will occur.

Even when the purest purging gases are used, an oxide layer will form on the surface of a $Ga_{1-x}Al_xAs$ layer before its insertion into the melt and after its removal from the melt. This oxide, which is neither reduced nor dissolved when dipped into the melt, inhibits further epitaxial growth.

The furnace used for this study provided a maximum cooling rate of 30°C/min at 950°C. The temperature profile measured from the inside bottom of the furnace is shown in Fig. 2. The melt region of the apparatus is normally located between the 0- and 3-cm positions of the profile. Shifting the apparatus along this profile was found to affect the morphologi-

cal characteristics of the epitaxial layers. The temperature is controlled to ± 0.2°C.

Experimental Procedure

The experimental procedure is divided into two operations. First is the preparation of the substrate and melt. The GaAs substrate is prepared by lapping away the sawing damage with 5μ Al_2O_3 powder and then removing the lapping damage by etching in 1:3:4 HF:HNO_3:H_2O for about 45 sec. After rinsing the wafer with H_2O, the surface is blown dry with Freon gas. As is shown below, the manner in which the surface is prepared can have an effect on the quality of the resulting epitaxial growth. Wafers with both (100) and (111) faces were used in this study.

The melts are based on 20g of 99.9999% grade Ga. For all compositions studied, the melts contained at least 90 m/o (mole per cent) Ga. To saturate them with As, an excess of GaAs over that required for saturation at a given growth temperature and Al concentration is added to the melt at room temperature prior to growth. The amount of GaAs required to saturate various Ga-Al melts was determined by measuring the weight loss of a solid piece of GaAs which is soaked in a Ga-Al melt at constant temperature for 90 min. In principle, this technique (5) should not provide equilibrium values for ternary liquidus lines at constant temperature, since pure GaAs cannot equilibrate with a Ga-Al-As melt. However, the observed saturation of the Ga-Al melts with As using this technique implies that the kinetics of saturation are such that a protective layer of solid $Ga_{1-x}Al_xAs$ forms between the melt and the pure GaAs causing an apparent equilibrium to be established. Figure 3 shows the solubility of As in mole fraction as a function of 1/T°K for three melts with starting Al/Ga mole ratios of 0, 0.0097, and 0.0194. Due to the difficulty of measuring the melt temperatures during saturation, melt temperatures were approximated by averaging the furnace temperature profile at the melt region. This approximation creates a melt temperature error of ± 10°C. It is seen that the solubility of As in Ga-Al is strongly dependent on the Al concentration. For a growth temperature of 955°C, the addition of only 0.0194 mole ratio of Al to Ga reduces the solubility of As by a factor of 1/3. The information in Fig. 3 is helpful for determining the temperature ranges which should be used in order to grow epitaxial layers of the same thicknesses for different Al concentrations.

In addition to Ga, Al, and GaAs, the melt can also be charged with dopants. The addition of 0.002-0.005g of Te during initial preparation and of 0.050-0.100g of

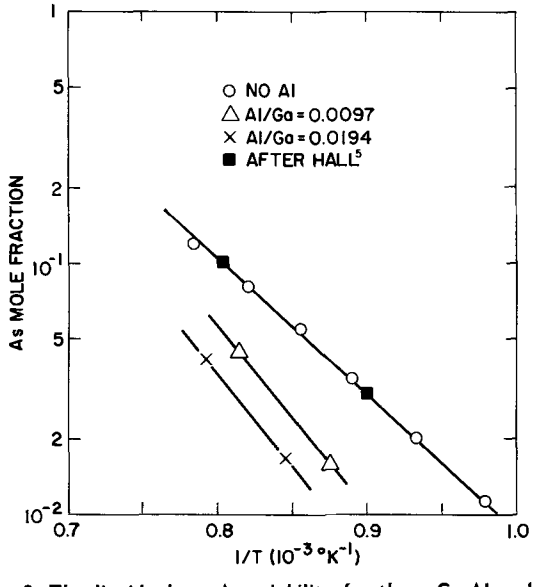

Fig. 3. The liquid phase As solubility for three Ga-Al melts vs. reciprocal absolute temperature.

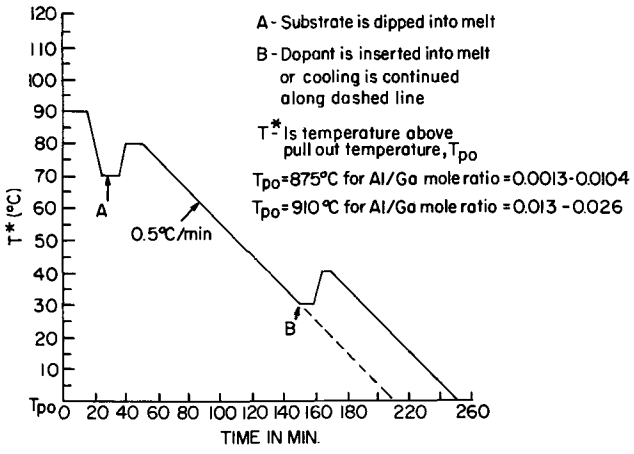

Fig. 4. Cooling and heating schedule for $Ga_{1-x}Al_xAs$ epitaxy

Zn during the middle of the growth schedule results in the formation of efficient electroluminescent p-n junctions for Al concentrations between 0 and 0.0088 mole fraction in the melt (3).

After the melt is composed, the GaAs substrate is mounted on the graphite holder. Next, the apparatus is assembled and purged with ultrapure forming gas at 3 liters/min for 30 min. The flow rate is then lowered 200 cc/min. The apparatus is then placed into the preheated furnace such that the melt region is located in the 0-3 cm position of the furnace. A typical cooling and heating schedule for the liquid phase epitaxial growth is shown in Fig. 4. The solid line is the time-temperature schedule normally used for preparing layers which contain a p-n junction, whereas the solid line to point B and dashed line after point B are the usual schedule for either undoped or singly doped layers. The shifting of the schedule to higher temperatures as the Al concentration in the melt increases compensates for the decrease in As solubility with increasing Al concentrations. Also, as the Al concentration in the melt increases, the time necessary to achieve As saturation at a given temperature increases beyond the 20 min necessary for pure Ga-GaAs melts. This longer saturation time can be effectively reduced by lowering the temperature after the 20-min period. This is the reason for the initial 20°C rapid cooling prior to dipping the substrate into the melt as shown in Fig. 4.

Ten minutes after the substrate is dipped into the melt, the temperature is raised 10°C in order to remove the growth which can occur during the dipping of the cool substrate. This 10°C rise also causes a slight etching of the substrate which assures good wetting prior to growth. The 0.5°C/min cooling rate was chosen because it was a rate below which no effect on growth composition was observed. Higher cooling rates result in lower Al concentrations in the growth. Ten minutes after point B of Fig. 4, the temperature is raised 10°C in order to remove the growth resulting from the insertion of the dopant into the melt. The growth schedule is usually terminated by first withdrawing the substrate from the melt and then removing the apparatus from the furnace. The apparatus can be withdrawn from the furnace before the substrate is removed from the melt. However, this causes the growth of a layer with a somewhat lower Al concentration than that of the layers grown during the slow-cool schedule.

Results and Discussion

Figure 5 shows photomicrographs of an n-type epitaxial layer of $Ga_{1-x}Al_xAs$ grown on the (100) face of a GaAs substrate from a melt with 0.011 mole fraction of Al and 0.050g Te. Figure 5 (top), taken at 5X magnification, shows the surface characteristics of the epitaxial growth. The surface is not as rough as the photomicrograph suggests. This becomes evi-

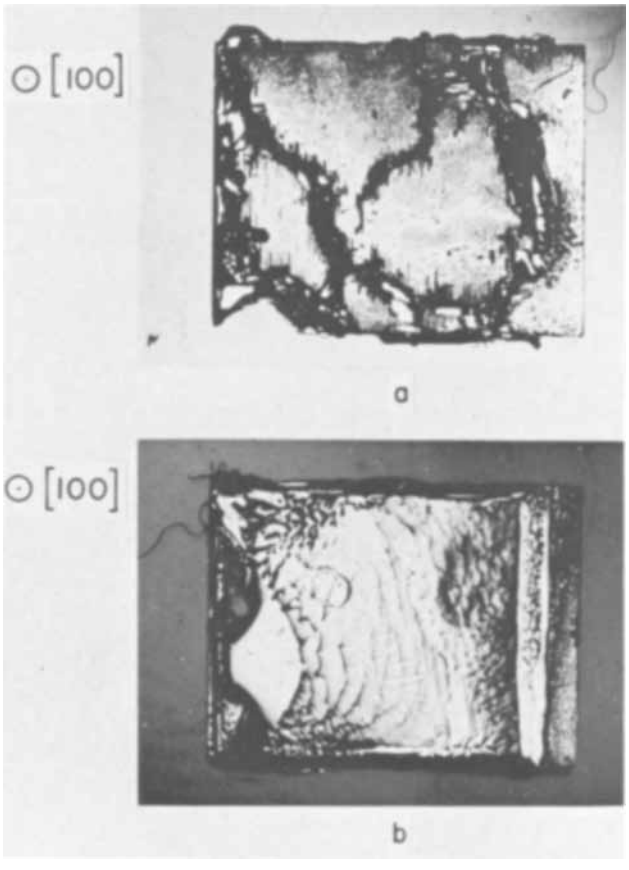

Fig. 6. Effect of wafer preparation on growth characteristics: a—H_2O:H_2O_2:H_2SO_4 1:1:3 polish; b—A lap with 5μ grit plus an etch with 1:3:4 HF:HNO_3:H_2O. Magnification 5X.

dent when viewed at higher magnification on a cleaved surface parallel to the growth axis, as in Fig. 5 (bottom) taken at 43X magnification. It should be noted that there are several areas of Fig. 5 (top) which appear as blotches. This is growth which occurs when the droplets of the melt stick to the substrate when it is removed from the melt. The composition of this layer with respect to the normal growth is discussed at the end of this section. The thickness of the epitaxial layer in Fig. 5 (bottom) is 190μ. This layer was formed by cooling from 955° to 850°C at 0.5°C/min. The epitaxial growth rate was found to be nearly constant for this temperature range and cooling rate. The epitaxial layer does not include all of the material which crystallizes from the melt during the cooling schedule. In addition to epitaxial growth, there is dendritic growth occurring simultaneously throughout the melt.

The morphology of the epitaxial layers changes drastically when the melt region of the apparatus is placed in the constant temperature zone of the furnace. When this is done, the resulting layers are highly tapered with more growth occurring on that portion of the substrate nearest the top of the melt. In addition, the layer is extremely rough with unfilled gorges extending nearly to the substrate interface. The inability to determine accurately temperature distributions of a melt with an inserted substrate holder prevents an explanation of this behavior. However, it is most likely that when the melt region is in the constant temperature zone of the furnace the melt is probably cooler at the surface than at the bottom due to heat sinking by the inserted substrate holder. This condition would be expected to produce tapered growth.

Another parameter which affects the growth of epitaxial layers is the surface preparation of (100) GaAs substrates. Figure 6 shows the effect of different etchants on epitaxial growth. The substrate in Fig. 6a was chemically polished in 1:1:3 H_2O:H_2O_2:H_2SO_4, whereas the substrate of Fig. 6b was prepared by etching 1:3:4HF:HNO_3:H_2O for 45 sec. The reagent concentrations were: HF-50%; HNO_3-70%; H_2SO_4-95%; H_2O_2-30%. Both substrates were cut from the same wafer and were used in the same growth schedule. The dark areas in Fig. 6a are caused by a small amount of fibrous growth. The rest of the wafer was not wetted by the melt. However, as seen in Fig. 6b, the entire substrate exposed to the melt is covered with good-quality epitaxial growth.

An interesting aspect of these liquid phase epitaxial layers of $Ga_{1-x}Al_xAs$ is the nature of the composition profiles along the growth axis. To obtain quantitative information about the chemical composition profiles, an x-ray fluorescent analysis was made using an electron beam probe. This proved to be a very useful technique. The resolution of the beam was such that it sampled a hemisphere of material with a diameter of about 3μ. Since the Al in the crystal matrix does not appreciably absorb the Ga and As fluorescence leaving the matrix, and since As is the constant mole fraction species, it was possible to determine the weight per cent values of each component from the Ga and As counts at each position after small corrections for the absorption due to Al in the lattice. From this, the mole fraction value x for $Ga_{1-x}Al_xAs$ was calculated as a function of position along the growth axis. Figure 7 shows a plot of composition *vs.* position for three layers grown from melts of different compositions. Positions are measured from the GaAs substrate interface. Curve A represents a layer containing a p-n junction grown from a melt with 0.0088 mole fraction Al which was cooled between 955° and 875°C. Curve B shows the profile of the layer described by Fig. 5. Curve C is an n-type layer grown from a melt with 0.017 mole fraction Al which was cooled between 990° and 910°C.

The fact that the Al concentration decreases with distance away from the substrate and that the composition gradient decreases with increasing Al concentrations can be understood in terms of the behavior of the segregation coefficient of Al, k_{Al}. If k_{Al} is defined as the ratio of the mole fraction of Al in the solid in equilibrium with the melt to the mole fraction of Al in the melt, it is found that k_{Al} is > 1 and

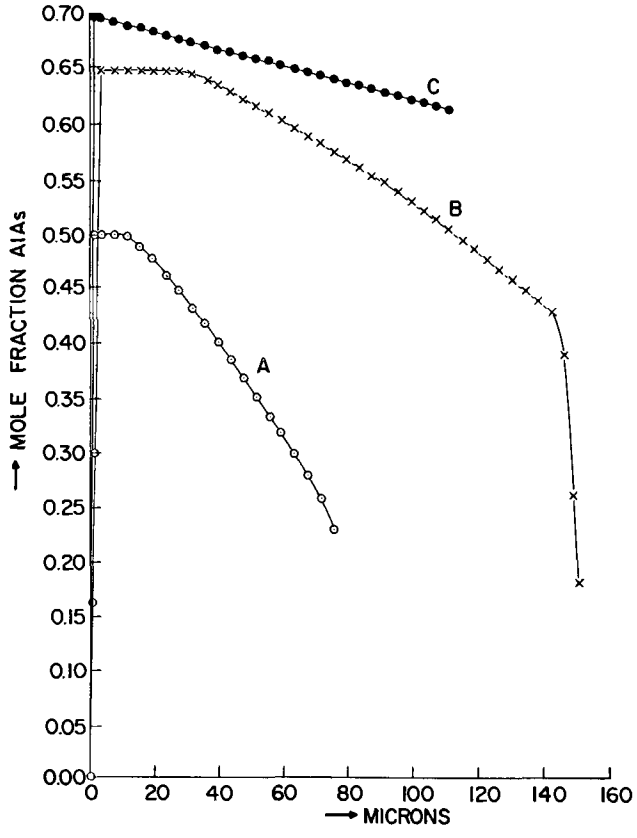

Fig. 7. Composition profiles in mole per cent AlAs along the growth axis of three layers. The zero position is the substrate-growth interface. Profiles A, B, and C represent layers grown from melts and initial growth temperature of 0.0088 mole fraction Al and 955°C, 0.011 mole fraction Al and 955°C, and 0.017 mole fraction Al and 990°C, respectively.

that it decreases with increasing Al concentration at high mole fractions of Al in the solid. Figure 8 shows the variation in k_{Al} with the Al concentration in the melt as determined by the Al concentration in first-to-freeze portions of the layers in Fig. 7 and the Al concentration in the melt. It should be noted that the points corresponding to Al mole fractions of 0.017 represent k values at 990°C, whereas the other points refer to k values at 955°C. The 955°C k value for an Al mole fraction of 0.017 would be expected to be only about 10% larger. It is not surprising that k_{Al} starts to decrease at higher Al concentrations. Since

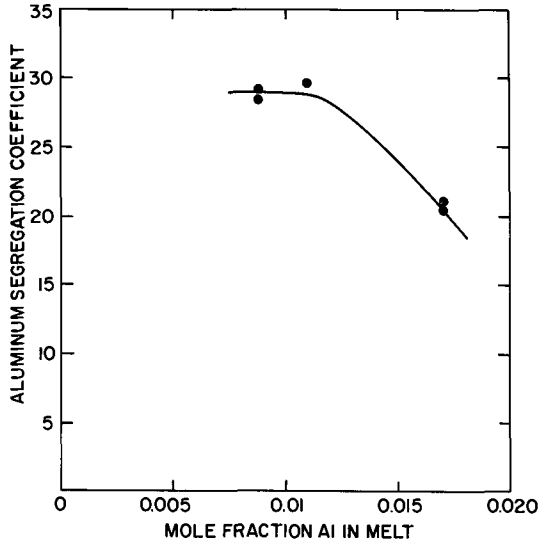

Fig. 8. Segregation coefficient for Al in Ga-Al-As melts vs. Al concentration in mole fraction in the melt.

the mole fraction of Al in the solid cannot exceed 0.5, k_{Al} must decrease as the Al concentration in the melt increases. The fact that $k_{Al} > 1$ explains qualitatively why the profiles of Fig. 7 show a decrease in the Al concentration with distance away from the substrate. The higher k_{Al}, the more melt is depleted of Al for each incremental volume element frozen, and therefore the steeper the profile. Thus, curve C ($k_{Al} = 20$) is not as steep as curve A ($k_{Al} = 28$).

The layer represented by curve A of Fig. 7 has a p-n junction 39μ from the substrate which, when forward biased, emits radiation at a peak energy of 1.83 ev at room temperature. The composition of this junction is 0.40 ± 0.02 mole fraction AlAs. This agrees well with the data of Ku and Black (4).

The electroluminescent diodes prepared from the layer described by curve A exhibit a large amount of emission passing through the surface of the n-type side when the GaAs substrate has been removed. The reason for this is easily understood from an analysis of curve A. The n-type layer extends up to 39μ, where the p-n junction is formed. The p-type layer extends from this junction to the surface. The energy of the radiation emitted at the p-n junction is greater than the band gap energy of the p-type side, since the Al concentration is continuously decreasing away from the p-n junction on the p-type side. Therefore, light traveling toward the surface of the p-type layer will be strongly absorbed. However, since the band gap energy increases (Al concentration increases) away from the p-n junction on the n-type surface, the radiation from the p-n junction traveling to the n-type surface will not be strongly absorbed. Thus, the profile of curve A permits the fabrication of efficient large area surface emitting electroluminescent diodes. To date, quantum efficiencies as high as 6% have been obtained for epoxy-domed diodes emitting at a peak energy of 1.65 ev at room temperature. The brightest visible epoxy coated diodes emit at 1.83 ev with an external quantum efficiency of 0.8%.

Finally, it should be noted that in curve B of Fig. 7 the Al concentration tends to drop rapidly near the surface. This area was formed as the result of the fast cooling of a droplet of the melt which stuck to the layer when it was withdrawn. The fact that this surface layer has a lower Al concentration is further experimental proof that segregation constants go to unity with increasing growth rate (6). This in principle should allow the formation of heterojunctions by variations in the cooling rate, providing that increasing the cooling rate does not cause an instability in the solid-liquid-interface during growth.

Summary and Conclusions

The critical parameters which affect the liquid phase epitaxial growth of $Ga_{1-x}Al_xAs$ on GaAs substrates include: substrate preparation, purity of purging gases, choice of container materials, and the temperature profile across the melt. The compositional characteristics of the layers are determined by: melt composition, growth rates, and the oxygen content of the purging gas. The composition profiles were found to be desirable for the fabrication of efficient, surface emitting electroluminescent diodes.

Environmental Factors Affecting the Critical Pitting Potential of Aluminum

H. Böhni and H. H. Uhlig*

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

The critical pitting potential determined potentiostatically of pure Al in 0.1*N* NaCl is —0.40V (SHE). This value is not greatly sensitive to temperature (0-40°C), to small alloying additions of Mn or Mg, nor to thickness of oxide film produced by anodizing. The value is more active the higher the Cl^- concentration, but becomes more noble with additions to NaCl of nitrates, chromates, acetates, benzoates, or sulfates. The latter act as pitting inhibitors which are effective in the order as listed. Dissolved Cu^{++} in trace amounts deposit on the Al surface as Cu which then acts as an efficient cathode, shifting the corrosion potential of aluminum to the critical pitting potential. Trace amounts of Fe^{+++} and Pd^{++} act similarly. Anodized surfaces effectively retard penetration of the oxide by Cu^{++} thereby delaying onset of pitting, but they are not similarly effective when Al is coupled to Cu. The mechanism of pitting is interpreted in terms of competitive adsorption of Cl^- with oxygen for sites on the metal surface. Extraneous anions compete in turn with Cl^- ions, making it necessary to shift the potential in the positive direction in order for Cl^- to adsorb followed by pit initiation. Similarities in adsorption parameters of various anions other than Cl^- on Al and 18-8 stainless steel are pointed out.

Precise determination of the critical pitting potential of Al was first carried out by Kaesche (1) using both potentiostatic and galvanostatic techniques. He found that the potential above which, but not below, Al undergoes pitting corrosion in 1*M* NaCl is —0.48V [std. H_2 scale (SHE)] which value is independent of *p*H between the interval *p*H 2-11. He also reported that the critical potential becomes more active (more negative) the higher the NaCl concentration between 0.1-4.0*M* NaCl. Bond *et al.* (2) measured the critical pitting potential for zone-refined Al in 0.5*M* NaCl in approximate agreement with the corresponding value reported by Kaesche.

Leckie and Uhlig (3) pointed out that the cathodic protection of aluminum, as usually practiced in aerated saline media, consists of polarizing Al only below the critical pitting potential and not below the open-circuit anode potential as is required for steel. In principle, therefore, zinc is a possible sacrificial anode for this purpose, but not iron. For stainless steels, on the other hand, pitting corrosion can be avoided in saline media such as sea water by coupling either iron or zinc, since either metal succeeds in polarizing the alloy below its critical pitting potential (0.21V).

In view of the importance of the critical potential to the application of Al to saline environments, data are reported herewith on the effect of temperature, of various anions and cations, of some alloying elements and of inhibiting salt concentrations on observed values. In addition, the mechanism of accelerated pitting by traces of Cu^{++} is discussed.

Experimental

For most of the measurements, 99.99% Al electrodes were employed measuring 1.5 cm long and 0.4 cm in diameter. One end of each electrode was drilled and tapped, allowing a threaded member attached to a nickel wire to hold the electrode firmly against a glass tube separated by a water-tight Teflon gasket. Only the electrode surface, totally immersed, Teflon, and glass made contact with the electrolyte. Specimens were polished to 3/0 emery paper followed by pickling in 2*N* NaOH at 80°C for 5 min and then washing in distilled water. A few measurements were also carried out on 99.4% Al and on alloys of 1.3% Mn-Al and 2.4% Mg-Al all of which were supplied by courtesy of the Aluminum Company of America.

The all-glass cell as previously described (3) was placed in an air thermostat maintained at 25° ± 0.2°C. Temperatures could also be maintained at some value above or below room temperature. At 0°C, the glass cell was placed additionally in a water-ice bath. The electrolyte was deaerated before measurements by bubbling through it purified N_2 previously passed over Cu turnings at 400°C.

The procedure was to polarize the electrode anodically within the passive region for 5 min at —0.80V *vs.* saturated calomel electrode (SCE) or —0.56V (SHE) using a Wenking potentiostat in conjunction with a chart recorder. This procedure achieved steady-state conditions before a step-by-step technique was applied by which the potential was increased 50 mV every 5 min and the corresponding current noted. The current remained relatively constant below the approximate critical potential V'_c (<1 $\mu A/cm^2$), but increased sharply above by two or more orders of magnitude. These measurements in turn were supplemented by longer time runs maintaining a given potential near the critical value for at least 12 hr. The least noble value at which pits could not be observed under a low-power microscope was taken as the steady-state critical potential V_c. Reproducibility of steady-state values was better than ±15 mV. All potentials are reported with reference to the SHE.

As a check on some of the critical pitting potentials obtained as described, immersion tests were also run using pickled specimens of 99.4% Al measuring 1½ x ½ x 0.065 in. (3.8 x 1.3 x 0.17 cm). These were suspended by means of a nylon thread through a hole drilled in one end of the specimen and then placed in closed 250 ml flasks for a period of 1-14 days. After the test period, the number of pits on the two main faces of the specimen, visible under a low-power microscope, was counted.

Results

Effect of temperature.—Temperatures between 0° and 40°C were found to have very little effect on the critical potential V_c as results of Fig. 1 show. These data are in contrast to the critical potentials for 18-8 stainless steel in 0.1*M* NaCl which are 0.6V more noble at 0°C than at 25°C (3). In other words, 18-8 stainless

* Electrochemical Society Active Member.

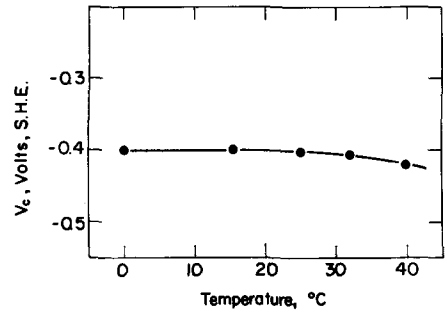

Fig. 1. Critical pitting potentials of 99.99% Al in 0.1M NaCl as a function of temperature.

steel is much more resistant to pitting corrosion at low temperatures compared to room temperature, but susceptibility of aluminum is about the same. This temperature effect refers only to initiation of pits and not to rate of pit growth. Size of pits after a given time depends on the cathodic reaction rate, the latter in turn usually proceeding more rapidly the higher the temperature.

Effect of anion concentration and alloying.—It is known that pitting of Al is pronounced in presence of chloride ions. In sulfates, on the other hand, Al electrodes can be polarized anodically without exhibiting a critical pitting potential or showing any evidence of pitting attack. In perchlorate solutions, however, pitting occurs, as well as in bromide and iodide solutions, although the pitting tendency is less pronounced than in chloride solutions.

The respective steady-state critical potentials in each environment are listed in Table I including the value in 0.5*M* NaCl reported by Bond *et al.* (2) and the nonsteady-state values reported earlier by Kaesche (1). The more active the critical potential, the greater is the tendency for pitting to occur. The effect of temperature is small in either 0.1*M* NaCl or NaBr.

Alloys of Al containing a small amount of Mg or Mn tend to pit more than does pure Al, although the shift of potential is small. For 99.4% Al, the critical potential is the same as for 99.99% Al within experimental error of the measurements. Porter and Hadden (4) reported that immersion tests in various supply waters showed that superpure Al tended to pit somewhat less than did Al alloys, although the final pit depth was almost the same.

Added anions which do not of themselves cause pitting shift the critical potential of Al in halide solutions in the noble direction corresponding to improved corrosion resistance. This was shown previously to be true for stainless steels (3, 5). If extraneous salts are added in amount sufficient to shift the critical potential above the oxygen electrode potential in air approximating 0.8V, it is obvious that aluminum will no longer pit in an aerated solution of the electrolyte mixture since the corrosion potential cannot exceed the open-circuit cathode potential. Pitting could then occur only under conditions where passivity breaks down locally, such as in a crevice due to lack of oxygen and to high concentrations of chloride ion caused by electrochemical transport, or to decrease of *p*H caused by accumulation of $AlCl_3$. Pitting otherwise would not be expected below the critical potential in any period of time for a crevice-free passive surface avoiding environmental gradients of the kind mentioned

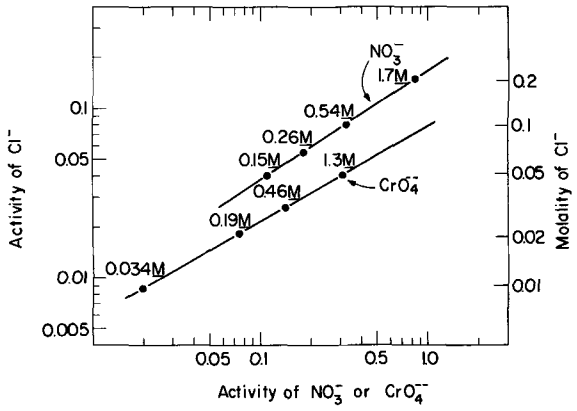

Fig. 2. Relation of minimum activities (or concentrations) of sodium nitrate or of sodium chromate required to inhibit pitting of 99.99% Al in aerated sodium chloride solutions.

It was shown earlier for stainless steels that the logarithm of the activity of an extraneous anion necessary to shift the potential to an arbitrary noble value accompanied by inhibition of pitting in aerated solutions, is linear with the logarithm of the corresponding chloride ion activity. This relation is also found to hold for Al, as is shown by data for sodium nitrate and sodium chromate additions (Fig. 2) and for sodium sulfate, sodium benzoate and sodium acetate additions (Fig. 3), where the critical potential is shifted to 0.8V (SHE) in each case. In calculating ionic activities, the corresponding activity coefficients were taken from Latimer (6) for pure sodium salts omitting corrections for total ionic strength of the solutions. Since activity coefficients for sodium acetate and sodium benzoate were not listed, they were approximated by corresponding values for rubidium acetate at and above 0.1*M* and by NaCl below. Values for Na_2CrO_4 solutions were taken from Robinson and Stokes (7) above 0.1*M* and approximated by values for Na_2SO_4 for the one lower concentration.

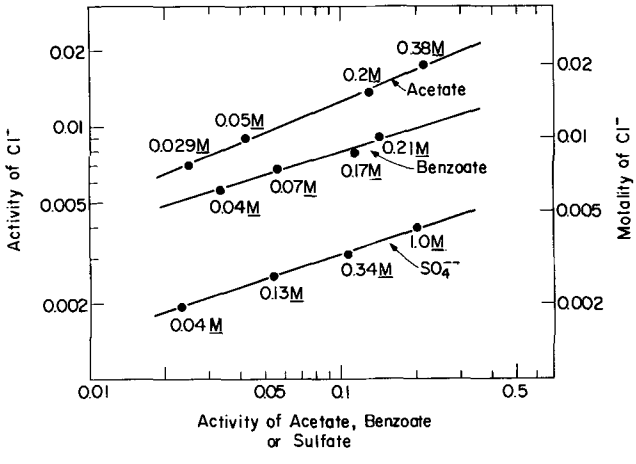

Fig. 3. Relation of minimum activities (or concentrations) of sodium acetate or sodium benzoate or sodium sulfate required to inhibit pitting of 99.99% Al in aerated sodium chloride solutions.

The mixtures of electrolytes were not adjusted to constant pH in view of the fact that both our measurements and those previously reported by Kaesche showed no appreciable effect of pH on the critical potential. Molybdates and tungstates were also tried as inhibiting anions, but these substances were probably reduced to insoluble oxides at the aluminum surface and hence led to irreproducible results. Equations representing inhibiting activities of the various successful anions are as follows:

$$\log (Cl^-) = 0.65 \log (NO_3)^- - 0.78 \quad [1]$$

$$\log (Cl^-) = 0.56 \log (CrO_4^{--}) - 1.11 \quad [2]$$

$$\log (Cl^-) = 0.41 \log (\text{acetate}^-) - 1.50 \quad [3]$$

$$\log (Cl^-) = 0.30 \log (\text{benzoate}^-) - 1.80 \quad [4]$$

$$\log (Cl^-) = 0.31 \log (SO_4^{--}) - 2.19 \quad [5]$$

Accordingly, the efficiency of inhibition within the present chloride concentration range decreases in the order: NO_3^- > CrO_4^{--} > acetate > benzoate > SO_4^{--}.

Effect of heavy metal ions.—It is well known that traces of Cu^{++} greatly accelerate the pitting of Al exposed to potable or industrial waters. Water passing through copper or brass piping, for example, picks up sufficient Cu^{++} to damage Al surfaces downstream. The mechanism of accelerated pitting is apparently, first, the deposition of metallic Cu on the Al surface by a replacement reaction, the sites of which act as pit nuclei. Second, the Cu sites become cathodes for the efficient reduction of dissolved O_2 or of any other suitably reducible species in solution, thereby polarizing Al to the critical potential at which anodic corrosion or pitting takes place. The potential reached is slightly more noble than, but does not appreciably exceed the critical value, however vigorous the pit growth, because of the small anodic polarizability of nonpassive Al within the pits (cathodic control). The time required for the shift from corrosion potential to critical potential is about 30 sec for 5 ppm Cu^{++} additions to 0.1*M* NaCl as shown by data of Fig. 4. For 5 ppm Pd^{++} addition, which behaves similarly, the time required is less, and for 5 ppm Fe^{+++} addition the time is longer, but the same critical pitting potential is reached in each case.

The above facts suggest that a suitable approach to measuring critical potentials in a given saline solution is to determine the corrosion potential in presence of a small concentration of Cu^{++}. The relevance of this technique to measuring critical potentials as a function of NaCl concentration is summarized in Fig. 5. As was shown previously for 18-8 stainless steel (3), the critical potentials for Al are linear with logarithm of Cl^- activity. Comparative data obtained by Kaesche using a different technique are included, showing good accord with present measurements. Either set of data follows the equation

$$V'_c \text{ (volts, SHE)} = -0.124 \log (Cl^-) - 0.504 \quad [6]$$

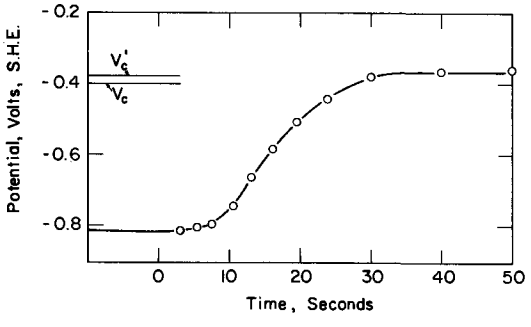

Fig. 4. Change of corrosion potential with time on immersion of 99.99% Al in 0.1*N* NaCl plus 5 ppm Cu^{++}, 25°C. Critical potentials V_c and V'_c are potentiostatic values.

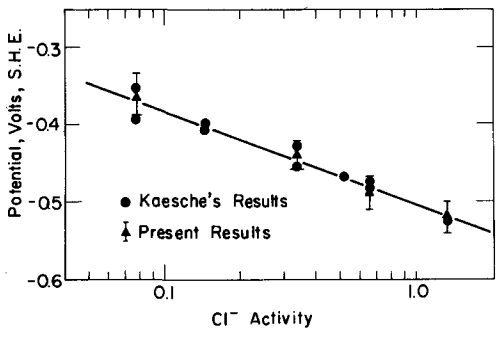

Fig. 5. Corrosion potentials of 99.99% Al in various activities of NaCl containing 5 ppm Cu^{++} in comparison with critical pitting potentials determined by Kaesche.

Since the critical potentials calculated by this equation, for reasons stated earlier, are slightly more noble than the steady state values, they more nearly accord with the continuous polarization values V'_c (continuous shift of potential to more noble values). For example, the critical potential for 0.1*M* NaCl ($\gamma = 0.78$) calculated by the equation is —0.37V compared to the steady-state value —0.40V given in Table I.

The success of the above-described method for measuring critical potentials suggested that the effect of inhibiting anions could also be investigated in like manner. In carrying out such measurements, a higher concentration of Cu^{++} (2.5 x 10^{-3}*M* or 159 ppm Cu^{++}) was found to be advisable in order to stimulate growth of pits that are nucleated at the critical potential, therefore making it easier to count their number. Figure 6, for example, shows that Na_2SO_4 additions to 0.005*M* NaCl shift the resultant critical potentials for Al, as determined potentiostatically, in the noble direction. The equilibrium potential for Cu ⇆ Cu^{++} + 2*e*, on the other hand, corresponding to 2.5 x 10^{-3}*M* $CuSO_4$ is equal to 0.337 + (0.059/2) log (2.5 x 10^{-3} x 0.7) = 0.256V where 0.7 is the approximate activity coefficient of the $CuSO_4$ solution (6). The calculated potential is relatively insensitive to the actual value chosen for the activity coefficient. Hence if the electrolyte is deaerated with nitrogen, Cu^{++} reduction is the only relevant cathodic reaction and pitting is therefore expected only below a SO_4^{--} activity of 0.02 corresponding to 0.035*M* Na_2SO_4. To check this prediction, specimens of 99.4% Al (same approx. critical potential as pure Al) were immersed in 0.005*M* NaCl containing various additions of Na_2SO_4 plus 2.5 x 10^{-3}*M* $CuSO_4$, the results of which are shown in Fig. 7. Many of the pits, when observed after an immersion period of 24 hr, were localized on the speci-

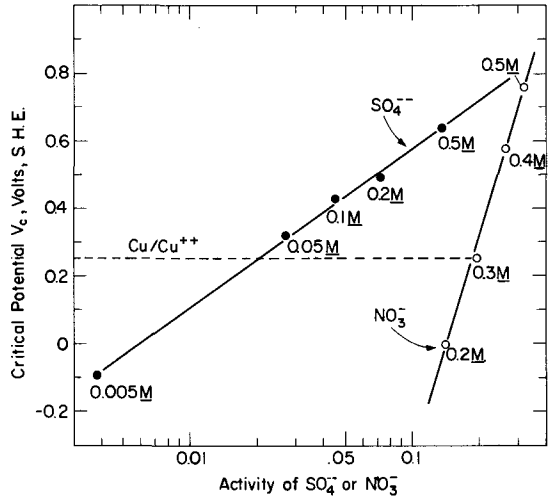

Fig. 6. Critical pitting potentials, determined potentiostatically, of Al in 0.005M NaCl with Na_2SO_4 additions, and in 0.1M NaCl with $NaNO_3$ additions, 25°C.

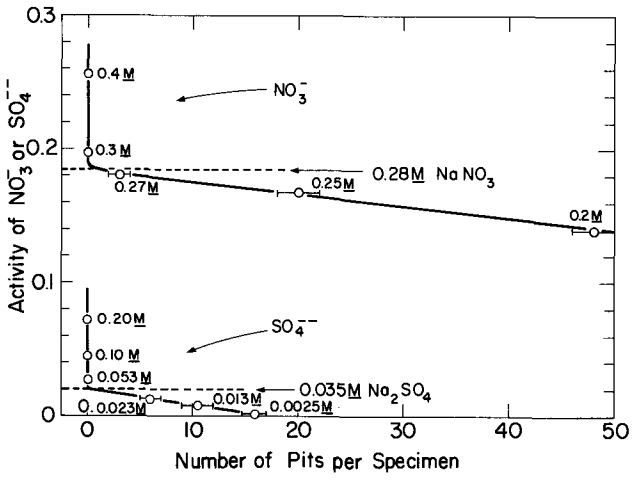

Fig. 7. Number of pits per specimen after immersing 99.4% Al in 0.005M NaCl with Na_2SO_4 additions, and in 0.1M NaCl with $NaNO_3$ additions, 24 hr, 25°C.

men edges, but for convenience only those were counted on the two main faces. When pitting was not observed on either face or edges, the test was usually continued beyond 24 hr to the order of two weeks so as to confirm that no pitting had taken place.

As the results show, the intersection of the line connecting points for the Na_2SO_4 concentrations which induce pitting, with the line for zero pitting occurs at an activity of SO_4^{--} equal to 0.02. This value agrees with the inhibiting activity predicted by data of Fig. 6. Similar good agreement was found between predicted and observed inhibiting concentrations of $NaNO_3$ added to 0.1*M* NaCl (Fig. 6 and 7).

The amount of extraneous salt needed to inhibit pitting depends on the applied potential as data of Fig. 6 show. Hence the amount of sulfate which is required to inhibit pitting in presence of Cu^{++} at a cathode potential of 0.26V is less than that required in presence of dissolved air at 0.8V. The latter situation is described by Fig. 3.

Effect of cations.—Since anions have a large effect on the critical potential, it is of interest to know whether the type and valence of cations also have an influence. The effect of calcium ion was investigated by measuring through continuous potentiostatic polarization curves the critical potentials of 99.99% Al in 5 concentrations of $CaCl_2$ from 0.05 to 1.0*M*. The dependence of the critical potential V'_c on logarithm of chloride ion activity followed the same linear equation within expected experimental variations as that derived for NaCl (Eq. [6]). Hence it is concluded that a divalent cation like Ca^{++} has no special effect on the critical potential compared to a monovalent ion like Na^+. Subsequent measurements were carried out in 0.1*N* KCl, RbCl, CsCl, $SrCl_2$, $BaCl_2$, and $LaCl_3$. Observed steady-state critical potentials corrected to the same approximate Cl^- activity, using the equation cited above, were all the same within less than 20 mV, hence only the Cl^- activity appears to be important. However, continuous polarization runs (50 mV/5 min) gave nonsteady-state critical potentials for $BaCl_2$ and CsCl which were about 70 mV more noble than for the other chlorides listed above. Although this peculiar effect of Ba^{++} and Cs^+ was not investigated further, it is perhaps caused by the double layer reaching its equilibrium structure much slower when large cations like Ba^{++} and Cs^+ are involved compared to the situation for smaller cations.

Discussion

The critical potential has been explained in terms of Cl^- penetrating an oxide film which covers the metal surface (8, 9) or in terms of competitive adsorption of Cl^- and oxygen for sites on the metal surface (3, 5). Aluminum provides an excellent opportunity to evaluate the influence of an oxide film because of the well-established procedure for increasing oxide film thickness by anodizing. The thicker the oxide film, presumably the smaller is the electric field impelling Cl^- to penetrate it and the longer is the diffusion path of Cl^- from electrolyte to metal surface. These factors, if relevant, should combine to produce a more noble critical pitting potential. On the other hand, if competitive adsorption at the metal surface is the mechanism, the thickness of any overlying oxide film would have no bearing on the steady-state potential at which Cl^- displaces adsorbed oxygen.

Aluminum specimens of 99.99% purity were anodized in 15% H_2SO_4 at 25 mA/cm² for specific times, then washed and sealed in distilled water at 90°C for ½ hr. Thickness of oxide produced by anodizing was estimated from values reported by Hoar and Wood (10). Steady-state critical potentials were determined by potentiostatic polarization in 0.1*M* NaCl. Although continuous polarization runs showed a slightly more noble value (—0.33V) for anodized electrodes, the same steady-state value —0.39V was obtained both for an oxide film 0.3 and 1.4μ thick, compared to —0.40V for aluminum not anodized. The latter values are the same within the usual experimental variations of such measurements. They support the view, therefore, that the mechanism of competitive adsorption is in better accord with the facts, and they also provide evidence that any improved resistance of anodized aluminum to pitting corrosion does not result from a shift of the critical potential.

Davies (11) reported improved resistance to pitting corrosion of anodized aluminum immersed in a solution containing 30 ppm Cl^-, 40 ppm Ca^{++}, and 0.2 ppm Cu^{++}. No pits appeared in two weeks time, contrary to unanodized specimens which pitted in a much shorter period. These results suggest that the anodized oxide film is a good diffusion barrier to Cu^{++} ions even though it is not successful in preventing diffusion of Cl^- ions. This matter was checked by anodizing 99.99% Al specimens to a film thickness of 1.4μ and sealing in H_2O at 90°C for 1 hr. They were then immersed in 0.1*M* NaCl containing 2.5 x 10^{-3}*M* Cu^{++} at 25°C. Two specimens were coupled to an equal area of copper; these showed evidence of pitting after 2 hr, with many deep pits visible after 24 hr. Two specimens not coupled were free of pits after 24 hr, in line with Davies' longer time observations.

The above results show therefore that Cu^{++} must penetrate the oxide film in order to deposit suitable cathodic sites of metallic Cu before pitting is observed in short-time tests. To this end, anodized Al is better than unanodized Al. They also show that anodized films have no particular merit in preventing pitting corrosion whenever aluminum is coupled to a more cathodic metal like Cu.

The high-temperature coefficient of the critical potential for austenitic stainless steels reported previously (3, 12) was attributed to sensitivity of the double layer structure to temperature, caused perhaps by variable hydration of the passive film and of ions located within the double layer. A negligible temperature effect for Al suggests that it is not the temperature-sensitive hydration of ions that is important so much as the temperature-sensitive hydration and structure of the passive film in the case of 18-8, and the absence of such an effect for the passive film on Al.

The role played by various cations is not important, probably because characteristically they do not adsorb at prevailing potentials, and hence their effect on the double layer and on passive film structure is minimal. The behavior of extraneous anions to inhibit pitting is similar to the behavior noted previously for 18-8 stainless steel for which inhibiting efficiency, as for Al, decreases in the order $NO_3^- > Ac^- > SO_4^{--}$. The data for inhibition of 18-8 by NO_3^- and SO_4^{--} were previously reported by Leckie and Uhlig (3); for acetates the data were presently obtained using the same

Table II. Ratios of n appearing in Freundlich adsorption isotherm

	Observed ratios			Calc. ratios		
	$n_{Cl^-}/n_{NO_3^-}$	$n_{Cl^-}/n_{SO_4^{--}}$	n_{Cl^-}/n_{Ac^-}	$n_{SO_4^{--}}/n_{NO_3^-}$	$n_{Ac^-}/n_{NO_3^-}$	$n_{SO_4^{--}}/n_{Ac^-}$
18-8	1.88	0.85	1.12	2.21	1.68	1.32
Al	0.65	0.31	0.41	2.10	1.59	1.32

potentiostatic technique and the same stainless steel as was used formerly. The equation representing activity of acetate necessary to inhibit pitting of 18-8 in a given activity of Cl^- ranging from 0.05 to 0.2M NaCl is

$$\log(Cl^-) = 1.13 \log (Ac^-) + 0.06 \quad [7]$$

The above log-log relationship was derived by Matsuda and Uhlig (13) on the basis of the Freundlich adsorption isotherm; $a_1 = k_1$ (Anion)$^{1/n_1}$ where (Anion) is the anion activity in solution, a_1 is the quantity of anion adsorbed per unit area, and k_1 and n_1 are constants. It was shown that the coefficient of the log (Ac^-) term in the above Eq. [7] is then equal to n_{Cl^-}/n_{Ac^-}. The values of this ratio are in general larger for 18-8 than for Al, corresponding to a greater tendency for Cl^- to adsorb on Al than on 18-8. Interestingly, the ratio of n's for any pair of ions not involving Cl^- are similar for both Al and 18-8. This is shown by the derived values listed in Table II. For example, $n_{SO_4^{--}}/n_{NO_3^-}$ obtained by dividing $n_{Cl^-}/n_{NO_3^-}$ by $n_{Cl^-}/n_{SO_4^{--}}$ is 2.21 for 18-8 and 2.10 for Al. The similarity of these ratios for anions other than Cl^- point to the unique adsorption behavior of Cl^- which is also the anion among those presently considered which is responsible for observed pitting corrosion.

Electrochemical Ellipsometric Study of Gold

R. S. Sirohi and M. A. Genshaw

Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

The application of ellipsometry and electrochemical techniques to the oxidation of gold reveals that a chemisorbed species is formed in the potential region 0.2-1.1V *vs.* SCE in acidic solution with gold oxide formed at more anodic potentials. In alkaline solution the chemisorbed species formed in the potential region −0.8 to +0.2V *vs.* SCE with oxide formation at more anodic potentials. Evidence supporting a change in the optical properties of the oxide film with pH and, for alkaline solution, with the presence of chloride ions, is presented.

The electrochemical oxidation of gold has been a topic of interest for many years (1-11). This oxidation leads to the formation of chemisorbed oxygen (1, 5, 7) or gold oxide (1-6, 8-10) with the initial formation of this film occurring about 1.27-1.37V (1, 3, 4, 7-10) *vs.* a reversible hydrogen electrode (RHE). Reduction of the film commences at potentials between 1.2 and 1.37V (4, 6-8, 9, 10) *vs.* RHE. The potential of oxidation and reduction varies by −2.3 RT/F (3-5, 8, 9) per unit pH. The thickness of the film is of the order of a monolayer, but at potentials more anodic than 1.8 (7, 10) −1.95V (8), a thick oxide film forms.

Inflections in charging curves, which could not be reproduced by later workers (5-10), were attributed to successive formation of Au_2O, AuO, and Au_2O_3 (4). Two arrests in film reduction have been attributed to Au_2O_3 and AuOH or AuO (2, 12).

In acidic chloride solutions passivation is observed, with the passivation time dependent on the concentration of chloride (13-17), indicating that passivation occurs when the surface concentration of chloride approaches zero.

An ellipsometric study of gold oxidation in sulfuric acid solutions, some with added oxalate, has been reported (18).

To gain further insight into the nature of the film formed at gold on electrochemical oxidation, this study, which combines optical and electrochemical measurements, was initiated.

Ellipsometry is the measurement of changes introduced in the polarization state of light by reflection from metal or metal oxide surface. The reflected light is analyzed for its polarization state, giving the relative phase retardation Δ and relative amplitude di-

minution ψ. Δ and ψ are related to the complex refractive index n^*_F and thickness L_F of film by the film optics equation (19, 20). The methods of analysis are adequately described by other authors (21-24) and need not be repeated here.

Experimental

Apparatus.—Ellipsometer.—For the steady-state measurements a Gaertner L119 Ellipsometer with horizontal plane of incidence was used along with a He-Ne laser as the source of monochromatic light. The output of the laser was converted to circularly polarized light by a waveplate prior to the polarizer. A quarter waveplate was used in the fixed 45° orientation and was positioned between the polarizer and the cell. A photomultiplier was used as the light detector.

For the transient measurements the source was changed to a 2w tungsten arc lamp (Sylvania Type C2T) filtered at 5500Å (50Å bandwidth) and a phototransistor (Motorola MRD 300) was used as a detector to maximize the signal-to-noise ratio by eliminating photomultiplier noise and minimizing the source noise. The angle of incidence at the electrode surface was 72.53°.

Cell.—The airtight cylindrical cell was made of Teflon. The light passed obliquely through synthetic quartz windows ($n = 1.457$, $\lambda = 6328$Å) which were fitted in the cell. All the connections to the cell were made through Beckman joints. Prepurified nitrogen which was further purified to get rid of organic impurities, etc., was bubbled through the electrolyte.

Electrolyte.—Acidic solutions were made from purified H_2SO_4. The H_2SO_4 was purified by adding a few drops of 30% H_2O_2 in 50 cc of H_2SO_4 and heating it for 10 min around 60°C (25). The alkaline solutions were made from NaOH, and NaCl solution was added for chloride solutions. All solutions were made from conductivity water. The acidic solutions were pre-electrolyzed by two platinized platinum electrodes with an applied potential difference of 1.35V for at least 24 hr. No pre-electrolysis was used with alkaline and chloride solutions. All experiments were carried out at room temperature.

Electrode.—The working electrode used was in the form of a block, which was polished bright and flat with different grades of emery. The counterelectrode was a smooth platinum electrode. A saturated calomel electrode was used as the reference electrode. All potentials are reported with respect to SCE.

Potential staircase measurements.—In these measurements the potential was varied in steps of 0.1V with measurements of Δ and ψ begun after 15 min.

Potential step measurements.—In these measurements the potential was varied in a single step between two values with simultaneous measurement of the intensity time and current time transient or the intensity time and charge time transients.

Potential sweep measurements.—A potential sweep generator (26) was used to vary the potential between two set potentials while the intensity-time and current-time relations were recorded on a Clevite Mark 220 dual channel recorder.

Results and Discussion

Acidic solution.—General behavior in acidic solution.—In acidic solution, the plot of Δ against potential as the potential is made more anodic in a potential staircase measurement exhibits two regions (Fig. 1): a region of slow change between 0.0 and 1.10V, and a region of rapid change anodic to 1.10V as also observed by Reid and Kruger (18). A similar trend is observed in the apparent capacity[1] of the electrode (Fig. 2).

[1] The apparent capacity was estimated from the charging current in the potential sweep measurements. It was corrected for a steady-state background current of 2 μA/cm^2 due to residual oxygen, but will include contributions due to any other faradaic processes. It should not be compared to the differential capacity measurements of other workers (12, 27, 28) whose measurements exclude any effect of faradaic processes.

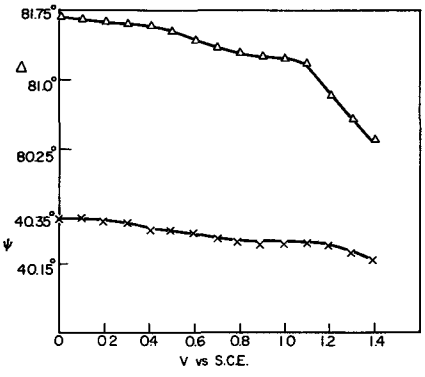

Fig. 1. Δ and ψ vs. potential for gold in 1*N* H_2SO_4 at 6328Å, potential staircase measurements.

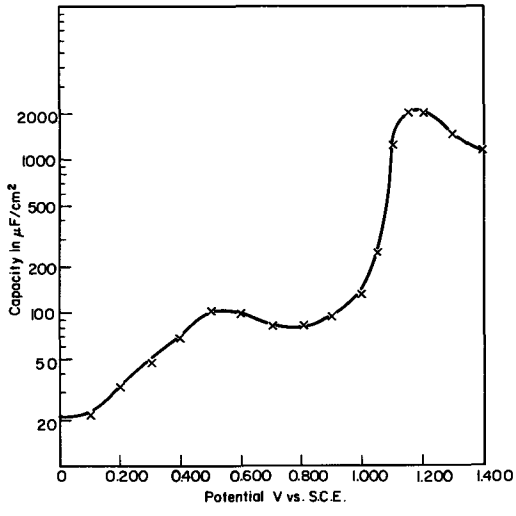

Fig. 2. Apparent capacity for gold in 1*N* H_2SO_4

Accordingly, the discussion will consider each region in turn.

The region between 0.0 and 1.1V.—At the most cathodic potentials the changes in Δ and ψ with potential are the least (cf. also Fig. 5), and the measured apparent capacity of ~20 μF/cm^2 is characteristic of the double layer capacity of a bare surface. Thus, we conclude that the bare gold surface is stable in this potential range. The optical constants calculated for gold at 6328Å are $(0.236 - 3.504i)$, which compare satisfactorily with $(0.18 - 3.48i)$ (29, 30).

As the potential is made more anodic, appreciable changes in Δ (>0.3°) occur. These changes are much greater than the experimental sensitivity (~0.02°) and so must reveal a real phenomenon. The apparent capacity (Fig. 2) shows an appreciable increase over the value observed at more cathodic potentials, indicating that charge is consumed as the potential is changed in this region.

Qualitatively similar results have been obtained in coulometry by other workers (2, 4, 8, 12) as well as changes in differential capacity (12, 27, 28). These have been attributed to the formation of AuOH or AuO (called "chemisorbed oxygen") (12, 27, 31). Thus it seems likely that a chemisorbed oxygen species is formed at gold in this potential region which is "seen" by ellipsometry.

Impurity explanations seem untenable because similar (except for kinetic effects, cf. below) results are obtained in transient and steady-state results with no evidence of diffusion control characteristic of impurities present at low concentrations.

The adsorption of anions which has been determined at other metals (32) is unlikely as a cause for the changes in Δ because the changes in Δ are larger than those characteristic of anion adsorption as observed

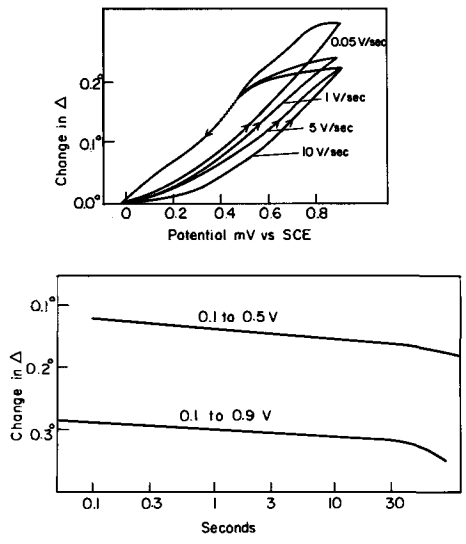

Fig. 3. Kinetics of formation of adsorbed oxygen (5500Å). Potential sweep and potential step measurements.

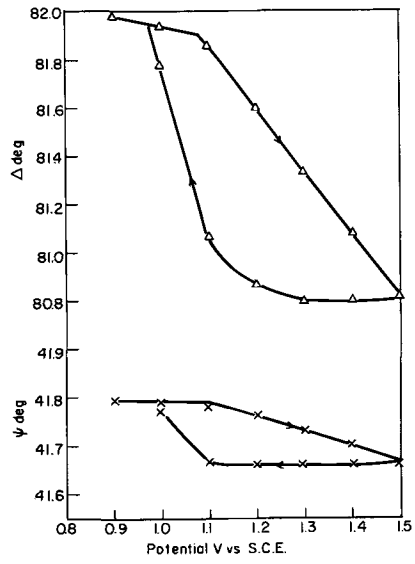

Fig. 4. Δ and ψ vs. potential in oxide region (6328Å), potential staircase measurements.

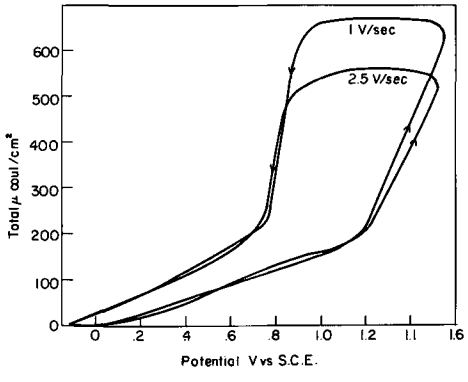

Fig. 5. Charge passed as function of potential in potential sweep measurement.

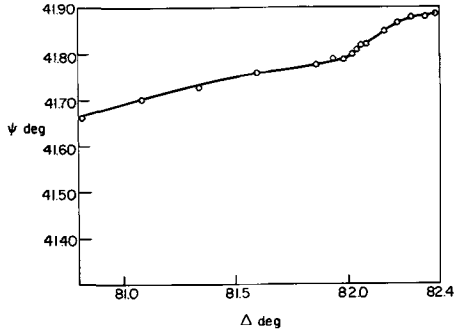

Fig. 6. ψ vs. Δ Plot. Au in H_2SO_4 at 6328Å

for Pt and Hg (32). Also, similar changes (except for a shift due to the *p*H differences) are observed at gold in 0.5*N* NaF which does not give detectable changes in Δ due to anion adsorption at platinum and mercury (32) (Fig. 3).

If one presumes the changes in Δ and ψ observed are due to "adsorbed oxygen," one can calculate the optical constants of the film by using coulometry. Using the relation between charge and potential of Fig. 5 and Δ and potential of Fig. 1, one obtains a charge of 250 μcoul/cm² to produce a change of 1° in Δ. Assuming a roughness factor of 1.7, the true amount of charge required to produce a 1° change in Δ is 150 μcoul/cm². If one takes 190 μcoul/cm² (7) as equivalent to a monolayer (univalent species), a change of 1.26° in Δ is equivalent to a monolayer. Assuming a monolayer is 3Å thick, using the exact ellipsometric equations, the only fit found is for film optical constants of about 0.3 — 0.7*i*. This value of optical constant seems improbable for any adsorbed species and would be more consistent with a metallic layer. Gold has been reported to show changes in optical constants upon application of an electric field (33) and would also be expected to be sensitive to adsorbed layers.

To attribute the observed changes in Δ and ψ solely to field induced changes in the metal optical constants is inconsistent with the observed kinetics in the Δ change. Changes occurring inside the metal should occur in the time required for double layer relaxation, $\sim 10^{-8}$ sec. The relatively slow changes observed are consistent with a slow chemisorption of a species which induces changes in the metallic optical constants producing the observed Δ and ψ changes (34).

Phase oxide growth.—At potentials anodic to 1.10V in acid and 0:200V in alkaline solution, Δ and ψ decrease linearly with potential (Fig. 4). The number of coulombs consumed in oxidation of the surface also increases linearly with potential (7-9) (Fig. 5). A hysteresis loop is observed in the graphs for film formation and reduction by both ellipsometric and coulometric methods.

This film is apparently a phase oxide. Evidence supporting this view is that more than a "monolayer" of film can be formed, that the film reduction occurs in a potential plateau characteristic of a definite phase, and that the potential for initial formation and reduction lies near that observed for the oxide Au_2O_3 (35). Also, at potentials anodic to 2.0V, a thick film forms which has been shown by chemical analysis to be Au_2O_3 or hydrated Au_2O_3 (28).

The oxide film at gold is light-absorbing, as it is not possible to fit the experimental positive slope of $d\psi/d\Delta$ (Fig. 6) for any transparent film. The absorption may arise from one of several factors. The film is probably semiconducting (11) and thus would absorb light by exciting electrons from the valence band to the conduction band. It is also possible that the absorption is due to the presence of charges in the film induced by "double layer" effects (36). It is also possible to have absorption due to the excitation of charges from the conduction band of the metal to the conduction band of the oxide.

For very thin films as observed in this work, if one assumes the film optical constants are independent of thickness, the film thickness is a linear function of Δ within the precision of the measurements. Then, from the measured values of Δ as a function of time, plots of Δ *vs.* log *t* (direct logarithmic law) (Fig. 7) and $1/\Delta$ *vs.* log *t* (inverse logarithmic law) (Fig. 8) may be made. Linearity is observed for the direct

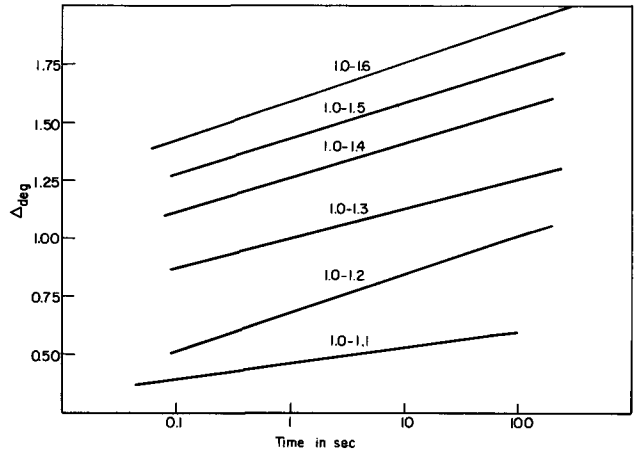

Fig. 7. Direct logarithmic plot of Δ in potential step measurement at 5500Å.

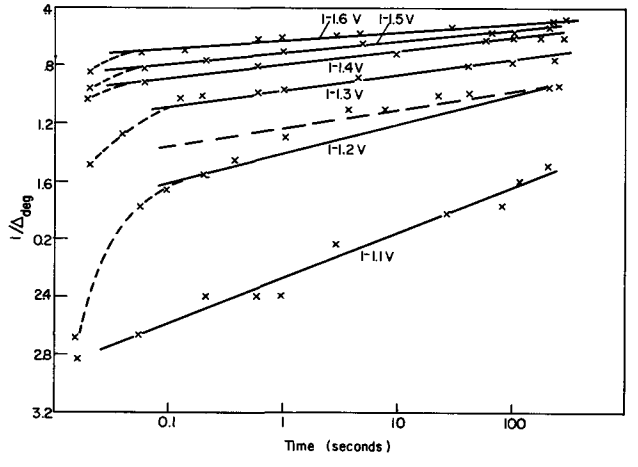

Fig. 8. Inverse logarithmic plot of Δ in potential step measurement at 5500Å.

logarithmic plot. Unfortunately, the data deviate from each growth law so that a distinction between them cannot be made (the slopes of the direct log plot decrease systematically from 0.164 deg/decade at 1.6V to 0.132 at 1.2V to 0.063 at 1.1V). Also, a plot of the value at Δ at time t (Δ_t) after the potential step is applied *vs.* V (Fig. 9) is not linear, as would be expected for mechanisms predicting the direct logarithmic law (as well as the inverse logarithmic law).

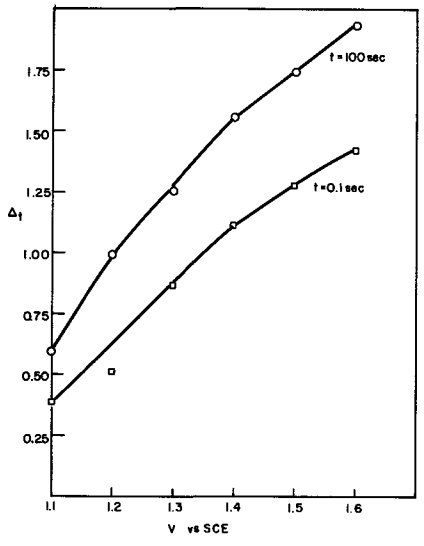

Fig. 9. Plot of Δ at constant time from potential step measurements.

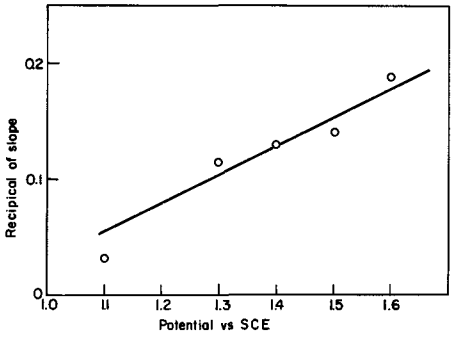

Fig. 10. Plot of the reciprocal of the slope of the inverse logarithmic plots as a function of potential.

Moreover, the fit for the inverse logarithmic law is not good at 1.2V, with considerable curvature observed. However, the reciprocal of the slopes (Fig. 10) does vary linearly with potential, as predicted from growth mechanisms producing the inverse logarithmic law; and the intercepts of Fig. 9 are scattered only 0.1 log units for 1.6-1.3V (a constant is expected for the intercept).

These measurements do not apply to the thick oxide film which forms at more anodic potentials and grows linearly with time (10).

It seems probable that for these films of only a few layers thickness, the kinetic laws suggested either do not apply or the changes in kinetics from a bare surface to a bulk oxide surface are sufficient to mask the true kinetic law.

Results in alkaline solution.—In alkaline solution the general shape of the plots of Δ and ψ against potential (Fig. 11) are similar to those in acidic solution except that the potential of oxide formation is shifted by 0.9V due to the pH change. It may be noted that this is somewhat more than expected from the usually observed change of $(2.3\ RT/\mathbf{F})/p\mathrm{H}$ (= 0.68V) for pH-dependent reactions.

The noteworthy differences are that $d\psi/d\Delta$ for the oxide region is 0.19 ± 0.02 in NaOH solution as compared to 0.12 ± 0.02 in H_2SO_4 and that $d\Delta/dV$ = 2.1 deg/volt in NaOH and 2.60 deg/volt in H_2SO_4. Also the value of $dq/d\Delta$ is not the same with 275 μcoul/deg observed in acidic solution and 170 μcoul/deg observed in alkaline. The changes in $d\Delta/dV$ may be attributed to the formation of a thicker film in alkaline solution than in acidic solution for the same change in potential. The changes in $d\psi/d\Delta$ and $dq/d\Delta$ are not explainable as a difference in film thickness alone. For a thin film with constant optical constants,

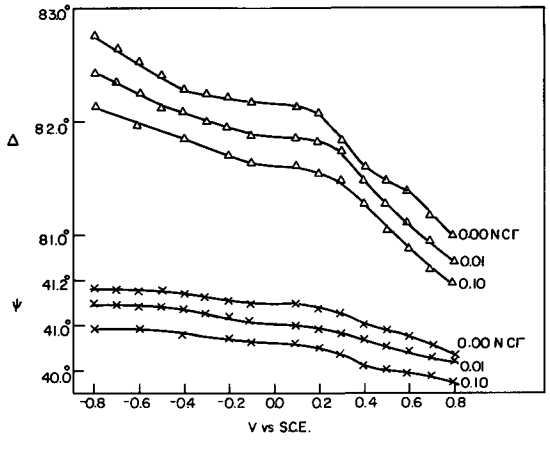

Fig. 11. Plots of Δ and ψ *vs.* potential at 6328Å in chloride containing alkaline solutions. The data in the chloride solutions is displaced vertically for greater clarity.

$d\psi/d\Delta$ is essentially independent of thickness, as shown by computer calculations using the exact ellipsometric equations. Hence, a change in $d\psi/d\Delta$ indicates a change has occurred in the film optical properties. This is supported by the observed changes in $dq/d\Delta$ as a film with constant optical properties should have a constant relation between the amount of film determined coulometrically and the optical thickness, which is not observed for the films in acidic and alkaline solution. The changes in solution refractive index are insufficient to account for the observed changes in $d\psi/d\Delta$ and $dq/d\Delta$. Probably in acid solution the film is Au_2O_3 with a change toward $Au(OH)_3$ occurring in alkaline solution, resulting in a less dense film with a lower refractive index causing a lower $dq/d\Delta$ in alkaline solution. A change in the kinetics of film formation with pH is also observed as the potential of formation is not that expected from a 59 mV/pH dependence and the relation between Δ and potential is different.

Effect of chloride.—In acid solution chloride causes gold dissolution with passivation occurring when the concentration of chloride at the surface approaches zero (13-17). Ellipsometric experiments proved unsuccessful, due to the attack on the surface destroying the reflectivity.

In alkaline solution gold is passive. The ellipsometric measurements show little effect on the trends of the plots of Δ and ψ against potential (Fig. 11). The only appreciable difference is that $d\psi/d\Delta$ for the oxide is lower (0.12) than that obtained without chloride (0.19), possibly showing a change in the optical properties of the film due to incorporation of chloride ions. There is little or no effect in $d\Delta/dV$ or in the potential of oxidation.

Study of the Lithium Oxide-Nickel Oxide System

I. Thermodynamics of Dilute Solid Solutions

S. Pizzini*, R. Morlotti, and V. Wagner

Reactor Materials Laboratory, Thermochemistry Group, EURATOM CCR, Petten, Netherlands

ABSTRACT

Emf measurements on suitable solid galvanic cells have been carried out to investigate the thermodynamics of solid solutions of Li_2O in NiO. It was shown that in the range of the dilute solutions [0.15-7 a/o (atomic per cent) Li] α — Li_2SO_4 is useful as an intermediate electrolyte. The following cell was operated

$$Pt/NiO,Li_2O(x_2)//\alpha - Li_2SO_4//NiO,Li_2O(x_1)/Pt$$

at temperatures between 570° and 800°C. Results show that the mixture is ideal to 1.5 a/o Li. Deviations from ideality at higher concentrations can be described with purely configurational energy terms.

In spite of many investigations (1-16), the thermodynamic properties of solid solutions obtained by mixing lithium oxide and nickel oxide under a convenient oxidizing gaseous environment are practically unknown. As an extension of our previous work (17) on pure NiO it was indeed felt interesting to investigate these solid solutions over the entire field of their stability.

The solid solutions of Li_2O in NiO are known to be of the substitutional type and have been treated as a binary system, where lithium enters cationic positions and electroneutrality is maintained via an equivalent amount of electron holes.

$$0.5Li_2O + 0.25\,O_2 \rightarrow Li'_{Ni} + O_O + h^{\cdot} \qquad [1]$$

As oxygen gas is needed to maintain the one-to-one ratio between the number of anions and cations, the system is better described by means of the ternary phase diagram of Fig. 1, where NiO, Ni_2O_3, and Li_2O are used as components. It is apparent that the region of the solid solutions with which we deal corresponds to the single-phase field around the line connecting pure NiO with $LiNiO_2$ that expresses a one-to-one correspondence with Li_{Ni} and $Ni^{\cdot}_{Ni}$,[1] *i.e.*, it satisfies the condition for the stoichiometry of the solution. It is also apparent from Fig. 1 and is implied by Eq. [1] that we consider NiO and $LiNiO_2$ as the components of the solid solution.[2] The structure of $LiNiO_2$ derives from that of the solid solution by the substitution of one half of the nickel ions with lithium.

On the line that expresses the stoichiometry within the homogeneity field, dissociation pressures are indicated as p^o_1, p^o_2, and p^o_n and it is apparent that by moving the system on a dissociation path (dotted line B'-B) in the B'-B direction, Li_2O is in equilibrium with the solid solution when the system becomes two phase. By moving the composition of the system in the opposite direction along the same dissociation path we enter a cation deficient region that only at temperatures lower than about 400°C eventually segregates Ni_2O_3, which is unstable at higher temperatures. At higher temperatures we will therefore consider the existence of nickel sesquioxide only fictitious.

In Fig. 1 only a guess is made on the extension of the homogeneity region, as it is only recognized that at room temperature the single phase field extends at least to 20 a/o (atomic per cent) lithium (15) whereas Bade *et al.* (18a) and Toussaint and Vos (18b) demonstrated that the single-phase region extends to at least 33 a/o lithium.

In speculating on the form and the extension of the homogeneity region,[3] we could at first imagine that on the right of the line corresponding to the stoichiometric compositions (cation deficient region) the defects should be cation vacancies and electron holes trapped at cationic positions, according to the equation

$$\tfrac{1}{2}\,O_2 \rightarrow NiO(ss) + V''_{Ni} + 2h^{\cdot} \qquad [2]$$

In the region near the NiO corner we can assume that the value of the equilibrium constant for reaction [2] does not differ greatly from that which holds for pure NiO. A quantitative estimate of the extension of the homogeneity range is therefore possible by using Mitoff's (19) equation

$$n_v = 0.11P_{O_2}^{1/6} \exp(-17800/RT) \qquad [3]$$

which gives the cation vacancy concentration (n_v) for pure NiO in terms of vacancies per ion pair. Results are given in Fig. 2, where the isobars at 760 Torr of O_2 for the vacancy concentration as well as for the equilibrium constant of reaction [2] are reported *vs.* the temperature.

From Fig. [2] it appears that positive deviations from stoichiometry are negligibly small and, therefore, the homogeneity range should be very narrow. This condition is different from that in systems containing iron, where large deviations from stoichiometry are characterisic (20). Moreover, as anion deficient NiO has not been proved to exist, guesses on the understoichiometric region of the homogeneity range are

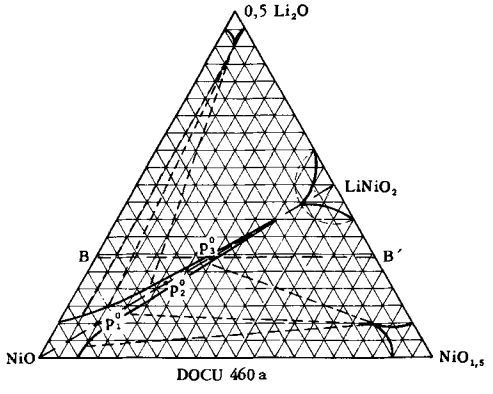

Fig. 1. Phase diagram of the system NiO, Ni_2O_3, and Li_2O (tentative). Solid lines indicate boundaries of single-phase regions. B-B' type paths indicate dissociation paths.

* Electrochemical Society Active Member.

[1] A $Ni^{\cdot}_{Ni}$ site corresponds to an electron hole trapped at a Ni site.

[2] The choice of $LiNiO_2$ as a component of the solid solution results from structural considerations. It is well known that the structure of $LiNiO_2$ is a slightly disordered rhombohedral structure, derived from a superstructure of the NaCl lattice in which the octahedral coordination is conserved (33).

[3] The phase diagram of Fig. 1 contains some symmetry elements (as the form of the homogeneity region) which are only introduced for the sake of simplicity. Actually, at the NiO corner, it is apparent that deviations from stoichiometry are much smaller than those indicated in Fig. 1, and large Li_2O excesses in the homogeneity field are unexpected over the entire composition range.

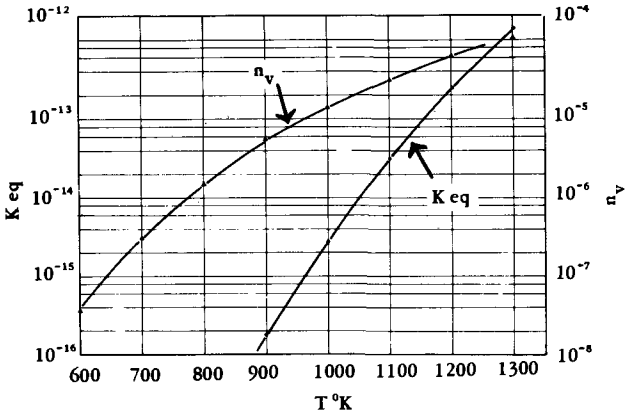

Fig. 2. Plots [from ref. (19)] of the equilibrium constant of reaction [2] and vacancy concentration n_v vs. temperature. n_v is given in terms of vacancies per ion pair and is calculated for $P_{O_2} = 1$ atm.

difficult. We suggest, however, that, in the oxygen deficient region, lithium could enter interstitial positions, the clustering of such interstitials should promote the segregation of Li_2O as the second phase, which is in fact observed when the solid solutions are investigated in reducing atmospheres. As this paper refers only to experiments carried out in the range of dilute solid solutions, we assume that an excess oxygen partial pressure does not greatly affect the composition over the stoichiometric one.

On the Measurements of Thermodynamic Activity of Dissolved Lithium Oxide

Details of the technique and generalities on the determination of thermodynamic functions via solid-state electrochemical measurements have been given recently and exhaustively by Schmalzried (21) and Steele (22), and therefore further remarks can be avoided here.

The determination of the activity ratios of Li_2O dissolved in NiO (*i.e.*, $LiNiO_2$ dissolved in NiO) was carried out by measuring the emf of a cell of the type

$$Pt/LiNiO_2(x_2) \text{ in NiO/interm. electrolyte/} LiNiO_2(x_1) \text{ in NiO/Pt} \quad [4]$$

where the atomic fractions (x_1) and (x_2) of $LiNiO_2$ correspond to those of the LiO_2 dissolved in the oxidic matrix, namely

$$x = \frac{n_{LiNiO_2}}{n_{LiNiO_2} + n_{NiO}} = \frac{n/2_{Li_2O}}{n/2_{Li_2O} + n^\circ_{NiO}} \quad [5]$$

where n_{NiO} equals the total number of moles of NiO, and $n_{NiO} = n^\circ_{NiO} - n/2_{Li_2O}$. The difficulty to be solved in the operation of these cells is the selection of a suitable intermediate electrolyte, and the problem becomes critical in the range of concentrated solutions (23).

Preliminary experiments demonstrated that the voltage of a cell fitted with (lime) zirconia or (lanthana) thoria drops with time to values near zero. Measurements of Li concentration in the solid solution after running the cell for some days at temperatures not higher than 1000°C show that the drop in emf is due to the irreversible migration of lithium from the left-hand compartment to the right-hand one, when $x_2 > x_1$.

Stable and reproducible emf values were, however, obtained when using α-Li_2SO_4 as the intermediate electrolyte, which, according to the transport number determinations of Lunden (24) is a purely cationic electrolyte.[4] Cell [4] could be written as follows

$$Pt/LiNiO_2(x_2)NiO//\alpha\text{-}Li_2SO_4//LiNiO_2(x_1)NiO/Pt \quad [4a]$$

where it is assumed that the $LiNiO_2$ in each compartment is in equilibrium with its proper partial pressure of oxygen p°_2 and p°_1, and therefore the over-all cell reaction could be written

$$LiNiO_2(x_2) + \tfrac{1}{2}\,O_2(p^\circ_1) \rightarrow LiNiO_2(x_1) + \tfrac{1}{2}\,O_2(p^\circ_2) \quad [4b]$$

With a separate experiment,[5] which will be described in a subsequent paper, we demonstrated that a partial pressure of oxygen as high as 1 atm affects neither the concentration nor the activity of $LiNiO_2$ in solid solution. Therefore, we are allowed to use the emf of the cell [4a] when measured under the same partial pressure of oxygen

$$P_{O_2} > p^\circ_1, p^\circ_2$$

at both electrodes, as a measure of the work done by the system when 1 mole of $LiNiO_2$ is transferred reversibly from the left-hand to the right-hand electrode. Thus:

$$\mathbf{F}\,E = -\,[\Delta^M G'_{LiNiO_2} - \Delta^M G''_{LiNiO_2}] \quad [6]$$

where $\Delta^M G_{LiNiO_2}$ is the relative partial molar free energy of mixing of $LiNiO_2$ in a solution of a certain composition x and $\mathbf{F}$ and E have their conventional meanings.

Since

$$\Delta^M G_i \equiv \overline{G}_i - G^\circ_i \quad [7]$$

where $\overline{G}_i$ is the partial molar free energy of mixing of a component i and G°_i is the corresponding molar free energy, the emf of cell [4a] becomes

$$\mathbf{F}\,E = -\,[\overline{G}_{LiNiO_2(x_2)} - \overline{G}_{LiNiO_2(x_1)}] \equiv RT \ln \frac{a^*_{1(LiNiO_2)}}{a^*_{2(LiNiO_2)}} \quad [8]$$

where the stars on the activity terms of Eq. [8] indicate that these activities are measured under a partial pressure of oxygen higher than the equilibrium one. Therefore we use Eq. [8] with the condition that we do not expect, according to Fig. 2, large deviations from stoichiometry when operating both electrodes of cells like [4a] at partial pressures of oxygen $P_{O_2} > p^\circ_1$, p°_2. This last condition will be assumed to hold within the range of the dilute solid solutions. The values of the partial molar free energies of mixing experimentally obtained and their differences can indeed be compared with the corresponding values calculated *a priori* with the aid of a pertinent model of the solution.

Experimental

Preparations of solid solutions.—Lithium doped nickel oxide was prepared according to the method of ref. (25) which consists of the utilization of lithium peroxide instead of lithium carbonate as the lithium dopant. Intimate mixtures of nickel oxide[6] and lithium peroxide[7] were prepared by ball-milling the weighed components in an agate mill with nickel balls. The use of nickel balls was demonstrated to be useful in avoiding contamination with oxidic materials as has been observed when harder ceramic balls were used. Pellets of ½ in. diameter were prepared with standard ceramic methods and sintered at 1000°C in closed Pt crucibles under 1 atm of oxygen. X-ray analysis proved that solid solutions are formed after some hours. It is worth noting here that lithium losses due to the vaporization of lithium oxide [quoted by some authors (16) as the main source of lithium losses during the high-temperature process] must be excluded for our conditions, as the partial pressure of lithium oxide is negligibly small (26). A source of lithium losses could

[4] Transport properties of α-Li_2SO_4 have been studied intensively by Kvist. A summary of his work on this subject is contained in ref. (24bis.).

[5] Which consisted of operating a cell like [4a] with separate compartments at different partial pressures ($0.001 < P_{O_2} < 1$ atm) of oxygen in each compartment and both electrodes at the same $LiNiO_2$ concentration.

[6] Prepared by thermal decomposition of twice-crystallized Ni_2SO_4 (Merck) and by annealing the decomposition product at 1100°C in oxygen.

[7] Obtained from Alfa Inorganics, Inc.

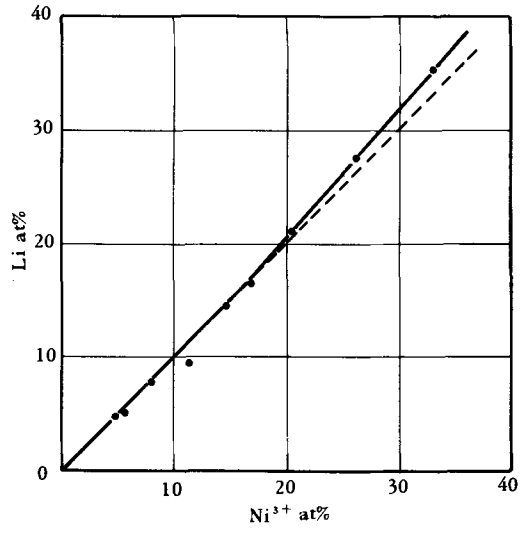

Fig. 3. Plot of the experimental values of atomic ratios of Li^+ (from photometric analysis) and of Ni^{3+} (from electrochemical analysis, see text).

be the hydrothermal decomposition of lithium oxide to lithium hydroxide which has a relatively larger vapor pressure (27).

The lithium content in the solid solution was measured by flame emission photometry as well as by measuring the lattice spacings (18b) at the Analytical Chemistry Division of the CCR EURATOM—ISPRA. The Ni^{3+} content was measured in the chloridic solution of the oxide (28) by the iodometric method and the end point determined with the dead-stop method in a cell fitted with Pt microelectrodes (29). Results are given in Fig. 3. In apparent contrast with the results of Iida and Hayashy (15), at 25 a/o lithium only a slight inflection is obtained from the line which indicates the expected one-to-one correspondence between the dissolved lithium and trivalent nickel (*i.e.*, $Ni^{\cdot}_{Ni}$.

Emf measurements.—Emf measurements on solid galvanic cells of type [4a] have been carried out on cells of conventional design, as illustrated in our previous study (17), but with α-Li_2SO_4 used as the intermediate electrolyte. Directions for the use of Li_2SO_4 in a solid galvanic cell were given in a previous paper (30). As soon as it was demonstrated that, within the range 0.155-0.522 a/o lithium, the experimental emf values fit a Nernst plot, any composition within this range was used as reference composition. The transference number determinations in α-Li_2SO_4 quoted by Lunden (24) indicate that the transport number of Li^+ is one, within the accuracy of the measurements. After a closer inspection of his data, we could quote a figure for the accuracy of about 5% over the entire range of temperature where the cubic modification is stable.

The fact that the electrolyte works as a purely ionic electrolyte was independently and indirectly demonstrated by fitting the emf values with an ideal Nernst plot (see below). Emf values were measured and recorded by a digital voltmeter and digital recorder (Hewlett Packard, Dymec System). Experiments have been carried throughout under one atmosphere of pure oxygen. Within the entire set of experiments described in this paper, the reproducibility of the emf data is better than ±5 to 10 mV.

Results and Discussion

The parameters of the equations which express the linear temperature dependence of the emf at different concentrations of lithium are given in Table I. The number of (E, T) points utilized for computing the a and b values is between 20 and 100.

Table I. Experimental results of the emf measurements

X_1/X_0	Temperature range, °C	$E = a + bT$ (V·10⁻³)
0.235/0.155	570-850	$E = -9.8 - 0.0358T$
0.365/0.155	570-850	$E = -2.0 - 0.0736T$
0.522/0.155	570-850	$E = -45.2 - 0.076T$
1.965/0.155	570-850	$E = -55.8 - 0.260T$
2.874/0.155	570-850	$E = +3.3 - 0.367T$
4.508/0.155	570-850	$E = -85.8 - 0.364T$
5.088/0.155	570-850	$E = -28.1 - 0.403T$
5.265/0.155	570-850	$E = -89.6 - 0.373T$

The equations of Table I have been used for plotting the E *vs.* x isotherms of Fig. 4, 5, and 6. The straight-line represents the Nernst plot calculated by using the equation

$$E = \frac{RT}{\mathbf{F}} \ln \frac{x_1}{x_2} \qquad [8a]$$

where x_1 and x_2 are the atomic ratios of lithium in the electrode compartments calculated according to Eq. [5].

It is apparent that, in the temperature range 600°-800°C the experimental points follow the (ideal) Nernst plot up to about 1.5 a/o lithium. Deviations from the Nernst isotherms, detectable at atomic ratios of lithium higher than 1.5%, over the entire range of temperatures, can be discussed entirely in terms of the entropy of mixing, as the Arrhenius plots of the log γ values[8] indicate negligibly small values of the heat of mixing.

Moreover, it is apparent from Fig. 7 that the plot of the isothermal temperature coefficient ϵ of the emf (from Table I) fits, in the range of the dilute solutions, the theoretical plot calculated from the purely

[8] The deviations from ideality have been computed and are reported in Table II as log γ values, where

$$\ln \gamma = (E - E^0)\, \mathbf{F}/RT \qquad [9]$$

E is the experimental value and E^0 is the Nernst value.

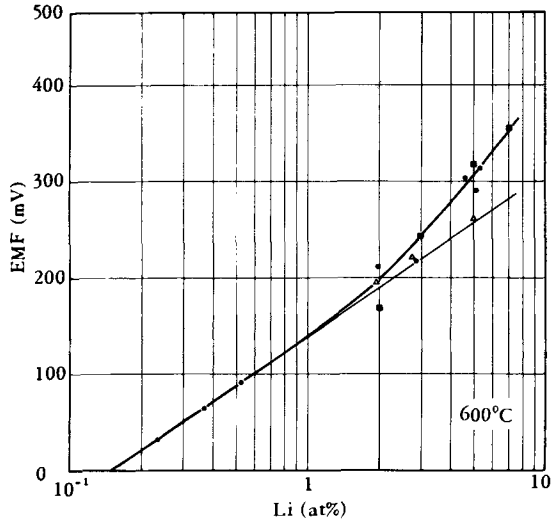

Fig. 4. Plot at 600°C of the experimental and calculated emf values as a function of the atomic ratios of Li^+. ○ Experimental points, △ from Guggenheim's formula (Eq. [11]), □ from Eq. [13]. Straight lines correspond to the Nernst plots.

configurational entropy function

$$-\epsilon\mathbf{F} = R[\ln x_2 - \ln(1-x_2) - \ln x_1 + \ln(1-x_1)] \quad [10]$$

where x_1 and x_2 are the molar ratios of $LiNiO_2$ in the cell compartments.

To discuss conveniently the experimental fitting of the emf data with Eq. [8a] and [10] in the range of the dilute solid solutions as well as the deviations from this "ideal" behavior observed at higher concentration, let us imagine that[9] between a substitutional lithium site and a positive hole trapped at a nickel position an attraction of coulombic nature exists that gives rise to a nonnegligible concentration of ion pairs $Li'_{Ni} - Ni^{\cdot}_{Ni}$. In order to look at the influence of ion pairing on the thermodynamics of the system, we consider first the mixture as an athermal solution, according to the treatment of Fowler and Rushbrooke (31) for athermal nonideal mixtures. We will, however, use Guggenheim's (32) method to calculate the configurational free energy of mixing and thereafter the log γ values, by assuming that the solution is a mixture of two kinds of molecules (strictly speaking, ions), one ($=Ni^{2+}$) which occupies one single lattice position, and a second one (*i.e.*, Li^+-Ni^{3+}) which occupies two nearest neighbor positions.

[9] So far we could assume that the lithium concentration is so low that we could exclude the presence of a lithium as nearest neighbor or next-nearest neighbor of a nickel ion of a $Ni^{\cdot}_{Ni}$-Li'_{Ni} pair chosen as the center of the system. Only the cationic sublattice is considered here.

* The triplet concentration ^{n}tr. was calculated according Eq. [13].

The absolute activities ratios which result are

$$\frac{\gamma'}{\gamma''} = \frac{N'_2(N''_2 + N''_1/2)}{N''_2(N'_2 + N'_1/2)} \left[\frac{(N'_2 + N'_1/2)}{(N''_2 + N''_1/2)} \frac{N''_2 + N''_1/2}{N'_2 + N'_1/2}\right]^{\frac{1}{2}nq} \quad [11]$$

where N_1 is the relative number of Ni^{2+} ions, N_2 is the relative number of ($Ni^{3+} - Li^+$) couples, n is the coordination number (which for a face-centered cube is 12) and q could be calculated by the following equation

$$\tfrac{1}{2}\, n(2-q) = 1$$

which strictly holds for a mixture of monomers and dimers. The triangles in Fig. 4, 5, and 6 show the calculated emf values.

It appears that at the lowest and intermediate concentrations the Nernst plot (Eq. [8a]) and the athermal mixture plot (Eq. [11]) practically coincide, whereas at the higher concentration, where the de-

Table III. Ratios of Ni ions

Li a/o	Fraction of nickel atoms having r Li atoms as nearest neighbors		
	$r = 0$	$r = 1$	$r = 2$
0.15	0.98	0.019	0.0002
2.0	0.784	0.194	0.021
3	0.693	0.260	0.043
5	0.540	0.344	0.099
7	0.418	0.381	0.157
10	0.282	0.378	0.231

viations from the "ideal" behavior appear far from negligible, the proposed model accounts only for a part of the deviation. The activity of the solution is therefore not simply determined by the configurational energy terms of Eq. [11].

A closer approach could, however, be obtained by considering that, when the solution becomes more concentrated, it is no longer possible to exclude the presence of other lithium ions as nearest neighbors of a nickel ion in a $Ni^{\cdot}_{Ni}$-Li'_{Ni} pair. To take this fact into account, we have reported in Table III the ratios of Ni ions in solution having zero, one, or two lithium ions as nearest neighbors. The calculations have been accomplished by considering that, for $n = 12$, the coordination number for a fcc structure, the fraction x_A of the nickel ions having 12 nickel ions as nearest neighbors is

$$x_A = (1 - x)^{12} \qquad [12]$$

and the fraction $x_A{}^r$ of the nickel ions having r lithium ions as nearest neighbors is

$$x_A{}^r = \frac{\dfrac{n_B!}{r!\,(n_B - r)!}\,\dfrac{(N - n_B)!}{(n - r)!\,(N - n_B - n + r)!}}{\dfrac{N!}{n!\,(N - n)}} \qquad [13]$$

where n_B is the number of lithium ions in a system of dimension N, (here $N = 1000$), $n = 12$ is the dimension of the sample removed from the system (*i.e.*, the dimension of the first coordination shell), N is obviously the sum of the elements of type A and type B, and r, as before, is the number of elements of type B which are assumed to be contained in a sample of n elements. In Fig. 4, 5, and 6 we have plotted the emf values calculated as

$$E = \frac{RT}{\mathbf{F}} \ln \frac{x'_1}{x^{o}_2} \qquad [8b]$$

where x' is the atomic ratio of the nickel ions having at least two lithium ions as nearest neighbors and x^{o} is the molar ratio of lithium in the reference compartment. It appears that the theoretical points fit the experimental curve quite well in the range of the deviations from the ideal behavior.

Moreover, in Table II, the experimental γ values are used to calculate the fraction of the electroactive species γx.

This fraction is compared with the figures for triplet concentration reported in Table III. It is apparent that there is a reasonable agreement at atomic ratios of lithium higher than 3%. We should therefore conclude that, even at higher concentrations, purely configurational energy terms describe the thermodynamics of the solution. It is out of the scope of this paper to discuss the solution in terms of nonthermodynamic properties and to define the nature of the electroactive species. It appears, however, from our results and others that the presence of Li-Ni-Li triplets affects the thermodynamics of the solution as well as the electrical conductivity and the activation energy for the electrical conductivity. Both functions, in fact, are known (4, 5, 8) to show a sharp discontinuity in the same concentration range where the emf plot deviates from the Nernst plot.

Acknowledgments

The authors are greatly indebted to C. Geel and Dr. G. Monari for skillful assistance and to Dr. G. Sternheim and Professor G. Bianchi for many stimulating discussions. We acknowledge also the contribution of Dr. G. Vos and C. J. Toussaint in the determination of the lattice spacings of the solid solutions.

Manuscript submitted Dec. 9, 1968; revised manuscript received March 3, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

APPENDIX

The use of a triplet concentration function as a measure of the $LiNiO_2$ activity does not mean that we identify a particular array of ions in the lattice with a chemical species, such as $LiNiO_2$. We may, however, show that the identity of the functional trends (the experimental emf *vs.* the concentration and that derived from introducing in the Nernst equation the concentration of the triplets) has a physical basis.

Without entering the problem of charge transport in NiO and related oxides (pure and doped), according to Heikes (34, 34bis) and Van Houten and Bosman (35) nickel sites with more than one lithium as nearest neighbor should act as trapping centers for electron holes. At high lithium concentration we quote the relative probability of the occurrence of this configuration with the activity of the solute, whereas at low lithium concentration where only isolated Li'_{Ni}-$Ni^{\cdot}_{Ni}$ pairs exist, we are allowed to quote the atomic ratio of lithium as the activity of the solute.

Diffusion of Radiotracer Ions in a Cation-Exchange Membrane

W. J. McHardy,[1] P. Meares, and J. F. Thain[2]

Chemistry Department, The University, Old Aberdeen, Scotland

ABSTRACT

The tracer diffusion coefficients of Na^+, Cs^+, Sr^{2+}, and Br^- in a homogeneous cation-exchange membrane have been measured in the homoionic counterion states over the external solution concentration range 0.005-1.0 equiv/liter and in the $Na^+ + Cs^+$ and $Na^+ + Sr^{2+}$ heteroionic counterion states over the whole equivalent fraction range at 0.02 and 0.10 equiv/liter total external concentration. Steady- and transient-state permeation and diffusion techniques have been used. The results show that the resin material is essentially uniform apart from a small volume of material of low crosslinking which forms a labyrinthine network interpenetrating the main structure. This labyrinthine network is important mainly in the diffusion of Br^- at low external concentrations. In concentrations above about 0.02 equiv/liter the diffusion coefficient D_{Br} of Br^- does not vary greatly either with concentration or with counterion type. D_{Br} is greatest in the Cs^+ state and least in the Na^+ state. These observations and the way in which D_{Br} varies with the equivalent fraction of the counterions in the heteroionic states can be explained by considering the expected frictional interactions between Br^- coions and the counterions and by the influence of the local variations in electric potential on the movements of the ions.

The diffusion coefficients of all the counterions increase as the external concentration is increased. When these diffusion coefficients are compared with the diffusion coefficients in aqueous solutions Na^+ is seen to be the least retarded in the membrane and Sr^{2+} the most retarded. The observed behavior can be understood qualitatively in terms of the relative roles of "chain" and "volume" diffusion as suggested by Jakubovic *et al.* (20). A quantitative theory of these mechanisms has not been developed, but the relevance of theoretical treatments of the effects of electric potentials on counterion mobilities in polyelectrolyte and micellar solutions is pointed out. When the membrane is in a heteroionic state the diffusion coefficients of both counterions decrease when the equivalent fraction of Na^+, the thermodynamically nonpreferred ion in each mixture, is increased. This behavior is consistent with the mechanism of diffusion discussed above and with the expected distribution of the counterions in a heteroionic state of an exchanger which has the structure deduced from the behavior of the Br^- ions.

Although several studies of the diffusion of radiotracer ions in ion-exchange membranes have been made during the past fifteen years (1) several aspects of diffusion, relevant to electrodialysis, are still incompletely understood. These include the effects of ion valency, solution concentration, and temperature. Furthermore, very few measurements have been made on membranes containing a mixture of counterions although this is the condition most often met in practice.

In the present study, in order to throw some light on these problems, the diffusion of the coions and of a series of three counterions, singly and in pairs, in a so-called "homogeneous" phenol-sulfonic cation-exchange membrane, Zeo-Karb 315, have been examined under strictly comparable conditions.

Another reason for undertaking the work was that when Spiegler (2) published his frictional treatment of transport in ion-exchange membranes he also suggested a simple, though approximate, method of estimating all the frictional coefficients from a limited amount of experimental data which included tracer diffusion coefficients. Spiegler's scheme has never been given a well-defined test although his approximations have been criticized several times (3, 4). The data given in this paper have been obtained in the course of collecting sufficient data to use Spiegler's method. Subsequent papers will deal with the measurement and interpretation of the other transport properties required and with the evaluation of the frictional coefficients.

Experimental Methods

Permeation method.—Most of the data given here were obtained by studying the rates of transfer of radiotracer ions from one solution phase through the membrane into a second solution phase of the same chemical composition as the first and initially at zero specific radioactivity. This permeation method is well known, and an early version of the authors' apparatus has been described already (5). Later developments in the apparatus and technique have also been published (1).

The entire apparatus was enclosed in an air thermostat and, in addition, water at a constant temperature was circulated continuously through coils immersed in the solution reservoirs. In this way the experimental temperature was controlled to ±0.1°C.

A flow-type Geiger-Müller tube was used as the radiation detector to monitor continuously the activity of the outgoing solution when β-emitters were being used. When γ-emitters were used the solution was circulated around an encapsulated scintillation crystal attached to a photomultiplier.

The usual circulation rate of the solutions through the diffusion cell was 1.5 liter/min. This produced a rapid flow across the membrane faces. Increasing and decreasing the flow rate between 2.0 and 1.0 liter/min had almost no effect on the ion fluxes. On this test the ion transport was apparently membrane-controlled, but experiments using several membranes which differed only in thickness showed that corrections were needed for boundary processes in order to obtain the true coefficients of homogeneous diffusion in the membrane. These corrections were made by the well-established method of treating the boundary processes as though they were due to stagnant solution films at the interfaces (6, 7). The effective thickness of the stagnant layers was found to be 16 ± 1μ in one diffusion cell and 20 ± 1μ in another. It appeared to be insensitive to the nature of the counterions and to small variations in the circulation rate of solution.

The thickness of the membrane was an appreciable fraction of its exposed diameter and an edge correction was needed to calculate the effective area available for ion transport. This correction was applied by the method of Barrer, Barrie, and Rogers (8). In our system it amounted to about 2% of the total area.

Three methods were used to evaluate diffusion coefficients from the permeation rates. Whenever possible a pseudosteady state of permeation was established. The rate of permeation was then obtained from the slope of the pen-recorder trace of the radioactivity of the outgoing solution *vs.* time, the volume of that solution and the ratio of the specific activities of the ingoing and outgoing solutions at a known time. This method was especially appropriate when using moderately concentrated solutions.

When a pseudosteady state could be obtained diffusion coefficients could also be obtained from the time-lag method. An equation for calculating D from the time lag in the presence of boundary layers is available (9). The time lag, as measured on the pen-recorder trace of the rate-meter output, was obtained directly in our experiments. This had to be corrected by subtracting from it the integrating time of the rate meter. The method was most accurate for relatively slowly diffusing ions since the time lag was then large compared with the integrating time of the rate meter and also with the operational uncertainty about the zero of time in an experiment.

When using dilute external solutions the amount of diffusate in the solution reservoirs was often smaller than the amount in the membrane on account of its relatively high exchange capacity. A steady state of permeation could not then be approached and an S-shaped permeation curve was obtained. The diffusion coefficient was evaluated from this curve by using an appropriate solution of the diffusion equation (10) which has been discussed in ref. (1). When using this nonsteady method the correction for boundary processes is less well understood. Here the method used was the same as with the steady permeation experiments.

In order to evaluate the diffusion coefficient in the membrane from the permeation rates thermodynamic equilibrium was assumed to exist between the solutions and membrane resin at the faces of contact. Extensive measurements had to be made of the sorption of coions and, in electrolyte mixtures, of the distributions of the counterions to determine these equilibrium conditions. The results of these experiments have been published elsewhere (11).

Nonstationary method.—The permeation method was not suitable for studying the diffusion of multivalent counterions when in very dilute solution and in the presence of a larger amount of univalent counterions because the multivalent ions are so strongly absorbed by the membrane. In these circumstances measurements were made by using an adaptation of the method (12) in which the movement of the tracer along a strip of membrane is followed. It had previously been established by electrical conductance measurements that the membranes were isotropic so that measurements could be made in any convenient direction.

A strip of membrane (4 x 1 x 0.1 cm) was equilibrated with the required solution and mounted on a Perspex sheet so that half of the strip was covered and sealed by plasticine and plastic tape. The edge of the Perspex sheet lay at right angles to and half way along the length of the strip of membrane. The assembly was clamped vertically with the uncovered part of the strip immersed in a beaker of the required solution until equilibrium was assured. The appropriate radiotracer was then added to the solution which was stirred for 2 hr. This was long enough to obtain a uniform distribution of tracer in the uncovered part of the strip without seriously blurring the boundary between the labelled and unlabelled halves of the strip.

The membrane strip was then removed from the Perspex sheet, rinsed quickly with unlabelled solution, blotted, and mounted in a groove in a Perspex block into which it fitted tightly. Small wells in the block at the ends of the membrane groove were filled with the inactive solution so that the ionic concentrations and water activity in the strip remained constant. The Perspex block was then covered by a thin impermeable polystyrene sheet (Polyglaze) to prevent evaporation and set in a closed plastic refrigerator box containing a little of the equilibrating solution so as to provide the correct atmosphere to prevent drying out. This box was then left in the air thermostat for the diffusion profile to develop.

At intervals the Perspex block was removed from the box and the distribution of the tracer determined by placing the block on a carriage driven by a micrometer screw under a well-screened end-window Geiger-Müller tube. Radiation from the strip entered the Geiger-Müller tube through a collimating slit 7 x 0.5 mm in a lead shield 6 mm thick (89 Sr, a pure β-emitter, was used in these experiments). Counting was carried out inside the air thermostat and the activity was determined at a series of well-defined points along the strip.

These nonstationary experiments lasted from four to seven days and a series of radioactivity determinations required about 30 min. The mean time t of the series of determinations was recorded. The spread of the activity observation times about this mean time was insignificant after the run had been in progress for about two days.

If an initially sharp boundary had existed between unlabelled (radiocount rate = 0) and labelled (radiocount rate = m_o) parts of the strip then at a subsequent time t, too short for interdiffusion to have proceeded as far as the ends of the strip, the count rate

m is given as a function of distance x from the initial boundary by

$$\frac{m}{m_o} = \frac{1}{2}\left[1 - \text{erf}\left(\frac{x^2}{4Dt}\right)^{1/2}\right] \quad [1]$$

where D is the diffusion coefficient (13).

In practice the absolute values of t and x were not known with precision. From a series of readings of m/m_o *vs.* the micrometer reading r, where

$$r = x + a \quad [2]$$

and a is a constant of the apparatus, a series of values of $(x^2/4Dt)^{1/2}$ were obtained by using error function tables. These values were plotted against r and a straight line was obtained of slope $(4Dt)^{-1/2}$ from which the apparent D at time t was obtained. As t increases the effect of the uncertainty in the zero time becomes less. Hence a graph was plotted of each apparent value of D against $1/t$ and extrapolated to the D-axis ($1/t = 0$). The intercept on this axis gave the true value of D.

Experimental accuracy.—Since transport and equilibrium data had to be combined and several corrections to be applied, it is not easy to make an estimate of the over-all accuracy of the diffusion coefficients. For various reasons radiocounting under ordinary conditions is not a highly accurate procedure. This factor probably limited the attainable accuracy of our measurements to ±1%. The desirability of keeping the integrating time of the rate meter to a minimum caused wide statistical fluctuations on the pen recorder trace. To eliminate the effect of these a set of mean points was obtained by integrating under sections of the activity *vs.* time trace with a planimeter. Steady-state slopes were determined by drawing a line through this set of mean points. The slope of this line was taken as giving the steady permeation rate relative to the activity of the ingoing solution half way through the experiment. No departure from a linear recorder trace was noticed provided the outgoing activity at the end of a run did not exceed 2% of the ingoing activity.

When the final outgoing activity was greater than 2% of the ingoing activity Crank's method (10) was used to treat the data. In the border-line region both methods of calculation were tried and they gave results which agreed to within ±2%.

The time-lag method was most useful in the study of Sr^{2+} and gave results which agreed satisfactorily with those from permeation measurements.

Measurements on Sr^{2+} in dilute mixtures of NaBr + $SrBr_2$ were mostly made by the strip method. A direct comparison between this and direct permeation measurements in pure $SrBr_2$ at 0.02 equiv/liter gave diffusion coefficients which differed by only 2%. This observation constituted evidence also for the validity of the correction for boundary processes in permeation experiments since such processes do not affect the strip method.

This correction for boundary processes was very important when studying counterions in dilute solutions. In the worst cases it amounted to 25% of D and a small error in the thickness of the hypothetical stagnant layer would have had a serious effect on the corrected value of D. Although the physical picture of stagnant liquid films at the membrane faces is inaccurate, the method of correction is valid provided the boundary regions behave as layers across which transport obeys Fick's first law of diffusion and into which sorption from the stirred solutions obeys Henry's law.

Errors in D would also arise from errors in the equilibrium data relating the composition of the membrane to that of the solution. These errors were probably most serious in measurements on coions in very dilute solutions, where spuriously high sorbed concentrations (the expected direction of any experimental error) would give low values of the diffusion coefficient. Measurements on counterions in mixed electrolytes were most liable to error when the membrane contained relatively little of one kind of counterion because the ion-exchange equilibria were then difficult to study accurately.

In comparison with the errors discussed above the uncertainties in the physical dimensions of the apparatus and membrane and in the concentrations of the solutions were unimportant. It is estimated that diffusion coefficients interpolated from smooth curves drawn through the data on any given membrane + solution system were within 3% of the true values.

Materials and Results

Membranes.—Zeo-Karb 315 (Permutit Company Ltd.) is a phenol + formaldehyde condensate membrane with fixed ions $-CH_2SO_3^-$ on a proportion (about 1/5) of the aromatic rings. The exchange capacity, water content, and swollen dimensions of the membranes were determined in each solution studied. Only a small number of membranes were used and these analytical properties agreed between different membranes to within better than 1%.

Data on the ionic equilibria between the membranes and solutions have been published (11); a few data are given in Table I.

Electrolytes.—Solutions were prepared from dried, pure NaBr, CsBr and $SrBr_2$. They were made up on the molar scale at 25°C using deionized water and regularly checked by titration against standard $AgNO_3$. The radio-tracers $^{22}Na^+$, $^{134}Cs^+$, $^{89}Sr^{2+}$, and $^{82}Br^-$ were obtained from the Radiochemical Centre, Amersham. They were converted when desirable to the appropriate salt by passing through ion-exchange columns.

Diffusion coefficients.—In calculating the diffusion coefficients from the experimental data appropriate allowances were made for dimensional and concentration changes in the membrane which resulted from changes in swelling, coion sorption, and ion-exchange equilibria with the different external solutions. The tracer diffusion coefficients are expressed in $cm^2\ sec^{-1}$ relative to the membrane as fixed reference. Corrections due to differences in mass between the inactive and tracer ions were neglected.

The diffusion of the cation and Br^- were studied with the membrane in equilibrium with NaBr between 0.005 and 1.00M, with CsBr between 0.005 and 0.10M, and with $SrBr_2$ between 0.0025 and 0.50M.

All three mobile ions were studied over the whole equivalent fraction range of mixtures of NaBr + CsBr and of NaBr + $SrBr_2$ at 0.02 and 0.10 equiv/liter total concentration.

Most measurements were made at 25°C, and a few experiments were carried out at 15° and 35°C to determine apparent activation energies for diffusion. Strictly, these were activation energies for permeation because they included also the heat of ion sorption but, within our experimental accuracy, sorption was not affected by temperature in this range (14).

Discussion

Coions.—The coions are electrostatically repelled by the fixed charges. They must be expected to make relatively few direct contacts with the polymeric matrix of the membrane and to diffuse in an environ-

Table I. Properties of Zeo-Karb 315 membranes per gram of Na^+ form fully swollen in water

Exchange capacity, m equiv	Volume, cm^3	Weight of water, g
0.486	0.887	0.665

Details of variations with solution concentration and type of counterion are given in ref. (11).

ment mainly of water molecules. However, because of the bulk and electric potential of the matrix, they may be forced to follow more tortuous paths than those taken by ions diffusing in an aqueous solution of a simple electrolyte.

The coions must also interact with the counterions by which they are electrostatically attracted. The extent of these interactions depends on the nature of the counterions through their size, charge, and degree of hydration, and also on the local concentrations of the counterions and coions. These local concentrations are controlled in part by the extent to which the counterions approach, or are bound by, the polymer chains and fixed charges and in part by the uniformity of the polymer network. The Donnan exclusion effect causes the coions to be most concentrated in those regions of the membrane where the fixed charge density and hence the counterion concentration, are lower than average.

With these considerations in mind it is possible to understand the diffusion characteristics of the coions as shown in Fig. 1-5. In Fig. 1 the diffusion coefficient D_{Br} in the membrane is plotted against the concentration of the external solution. It can be seen that at concentrations above 0.05 equiv/liter the variation of D_{Br} with increasing concentration is slight in each electrolyte and scarcely greater than the experimental uncertainty. Below 0.02 equiv/liter D_{Br} decreases in the Na^+ and Cs^+ forms of the membrane though not, apparently, in the Sr^{2+} form.

If the resin were truly homogeneous, the tortuosity of the diffusion pathways followed by the coions should be scarcely altered by the changes in the swelling of the resin which were very small over the concentration ranges studied. A simple relation between the degree of swelling and the diffusion coefficient in a homogeneous gel has been deduced earlier (15). It is

$$D = D_o \left(\frac{v_w}{2 - v_w} \right)^2 \qquad [3]$$

where v_w is the volume fraction of water in the swollen gel and D_o the diffusion coefficient of the ion in free aqueous solution. This equation takes into account only the effect of the bulk of the polymer matrix on the tortuosity of the diffusion paths. It predicts $\sim 7.5 \times 10^{-6}$ cm^2 sec^{-1} for D_{Br} in the membrane examined here.

Figure 1 shows that above 0.05 equiv/liter D_{Br} lies between 7.5 and 9.3 x 10^{-6}. This suggests that the membrane does not depart greatly from the homogeneous gel structure. The largest value of D_{Br} could be accounted for by setting v_w equal to 0.80 instead of of to its over-all average value of 0.75. This deviation may not be significant in view of the inexact theoretical basis of Eq. [3]. It is in the expected direction because the coions tend to be concentrated into those regions of the resin where the fixed charges are least

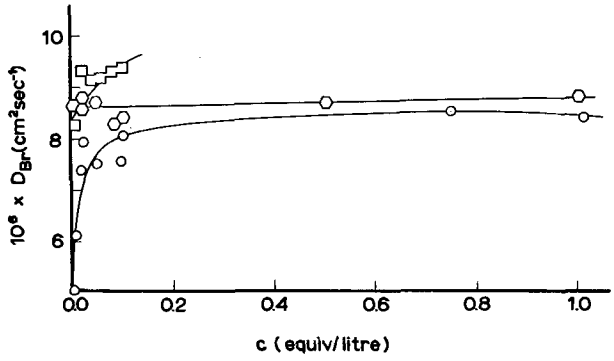

Fig. 1. Diffusion coefficient of Br^-, D_{Br}, in Zeo-Karb 315 at 25°C as a function of external solution concentration, c equiv/liter. □, membrane in Cs^+ form; ○, membrane in Sr^{2+} form; ○, membrane in Na^+ form.

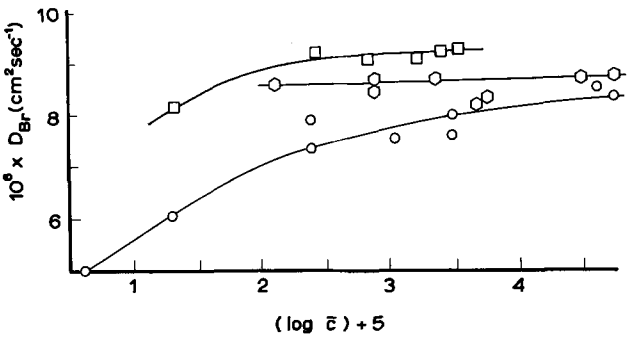

Fig. 2. Diffusion coefficient of Br^-, D_{Br}, in Zeo-Karb 315 at 25°C as a function of logarithmic bromide concentration in the membrane, $\bar{c}$ equiv/liter. □, membrane in Cs^+ form; ○, membrane in Sr^{2+} form; ○, membrane in Na^+ form.

concentrated and these are the regions least obstructed by polymer chains.

The internal concentration of the coions must be the main variable which controls the changes in D_{Br} with the concentration of the external solution. In Fig. 2 D_{Br} is plotted against the logarithm of the concentration of coions in the resin. It may be seen that D_{Br} scarcely alters over the range in which the concentration of Br^- in the resin is decreased from 5 x 10^{-1} to 5 x 10^{-3} equiv/liter. The most extended concentration range was covered with the membrane in the Na^+ form. Here, lowering the coion concentration by a further factor of a hundred from 5 x 10^{-3} to 5 x 10^{-5} equiv/liter lowers D_{Br} by about 30%.

In their cation exchanger Glueckauf and Watts (16) observed a steady decrease in D_{Br} by about fivefold over the concentration range of coions which we have studied. In a detailed analysis of the structure of their resin Glueckauf (17) showed that the distribution of fixed charge density, and hence of the coions, was very nonuniform. By comparing our data qualitatively with theirs the conclusion may be drawn that in our resin the distribution of the coions is not far from uniform and the polymer network structure basically homogeneous. However, there appears to be a small volume of material with a fixed charge density considerably lower than the average. The labyrinthine interconnection of these regions of low fixed charge density throughout the membrane creates a network of channels which interpenetrate the main structure. At low external concentrations the bromide coions are situated mainly in these regions and hence they diffuse along routes of greater than average tortuosity. This view of the resin structure is consistent also with an analysis of the bromide ion uptake data (18). At higher external concentrations the contribution of this low fixed charge density network to the coion transport is small, and its influence on the counterion transport is probably always negligible.

Figure 2 also shows that at any given coion concentration the value of D_{Br} depends on the nature of the cations. It increases in the order $Na^+ < Sr^{2+} < Cs^+$. The Na^+ form of the membrane has the largest volume and water content and the Cs^+ form the smallest. If swelling changes were causing differences between D_{Br} with the different counterions then D_{Br} would be expected to vary in the reverse direction from that observed. However this factor is probably unimportant because the variations in the water content and volume of the swollen resin with its cationic form do not exceed 2%.

It is doubtful also whether differences between the demands of the different cations on the available water for their hydration shells were important. In every case when in dilute solution there were more than seventy water molecules per counterion in the resin whereas D_{Br} scarcely changed in any given cationic form when, with the entry of the sorbed electrolyte at higher concentrations, the number of water molecules per cation was decreased from 70 to 30.

Table II. Energies of activation E for ion permeation and diffusion in Zeo-Karb 315

Ion	Concentration c (equiv/liter)	E kcal/mole
Br^-	0.05 (Na^+ form)	4.2
Br^-	1.0 (Na^+ form)	4.7
Br^-	0.005 (Sr^{2+} form)	4.1
Br^-	0.5 (Sr^{2+} form)	4.0
Na^+	0.1	5.6
Cs^+	0.05	4.8
Sr^{2+}	0.02	4.6
Sr^{2+}	0.1	4.9
Sr^{2+}	1.0	4.0

The order of the cations in which D_{Br} increases is also the order of increasing thermodynamic affinity of the resin for the counterions (11). It seems likely therefore that the frictional interaction between the coions and water does not depend on the nature of the counterions, but the interactions between the coions and counterions do so depend. These interactions produce the differences between D_{Br} in the different cationic forms of the resin.

This dependence could arise in two closely interconnected ways. The thermodynamically more preferred counterions should on the average be found closer to the polymer matrix on account of their stronger interaction with it. Thus they would offer less physical obstruction to the diffusing coions which tend to avoid the fixed charges. If the univalent counterions were paired with the fixed charges, the local electric potential in the regions most freely accessible to the coions would be more nearly uniform than if the counterions and fixed charges were largely independent in location. Such ion-pairing, even on a loose time-average basis, would therefore minimize the electrostatic energy barriers met by the diffusing coions.

Information on energy barriers is frequently sought from energies of activation. Table II lists the apparent energies of activation for diffusion calculated from the data in Fig. 3. The accuracy of these energies of activation is not better than ± 0.2 kcal/mole. The activation energy for Br^- diffusion in the Na^+ form of the membrane appears to be significantly greater than that in the Sr^{2+} form. This observation correlates satisfactorily with the suggested greater interaction between coions and counterions in the Na^+ form, especially at higher concentrations, when the counterions are interacting only weakly with the matrix. In both forms of the membrane the energy of activation for Br^- diffusion is close to that in ordinary aqueous solutions, 4.07 kcal/mole (19). This agreement emphasizes that the diffusion mechanism of Br^- ions in the membrane is essentially the same as in aqueous solutions.

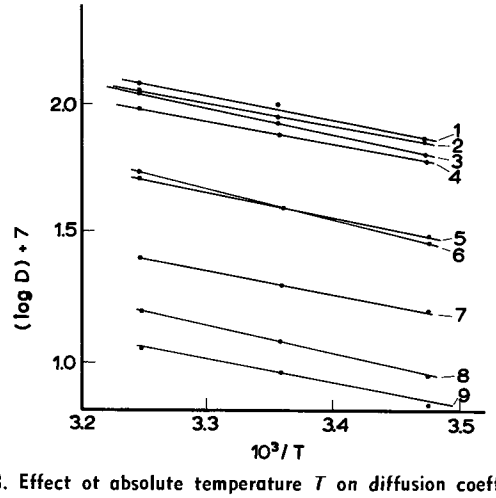

Fig. 3. Effect of absolute temperature T on diffusion coefficient D of various ions in Zeo-Karb 315. Line 1, D_{Br} in Sr^{2+} form at $c = 0.005$ equiv/liter, 2, D_{Br} in Sr^{2+} form at $c = 0.5$ equiv/liter, 3, D_{Br} in Na^+ form at $c = 1.0$ equiv/liter, 4, D_{Br} in Na^+ form at $c = 0.05$ equiv/liter, 5, D_{Cs} at $c = 0.05$ equiv/liter, 6, D_{Na} at $c = 0.1$ equiv/liter, 7, D_{Sr} at $c = 1.0$ equiv/liter, 8, D_{Sr} at $c = 0.1$ equiv/liter, 9, D_{Sr} at $c = 0.02$ equiv/liter.

The behavior of D_{Br} as Cs^+ or Sr^{2+} counterions are progressively replaced by Na^+ at two different total external solution concentrations and at 25°C is shown in Fig. 4 and 5. In each case D_{Br} fell rapidly in the more dilute solutions (0.02 equiv/liter) as the Na^+ ions were introduced. D_{Br} had reached almost its value in the pure Na^+ form by the time 50% of the counterions were Na^+. Evidently once 50% of the counterions in the resin were Na^+ the counterions which the coions met were almost exclusively Na^+. In such dilute solutions the regions of lowest fixed charge density contributed significantly to the transport of Br^-. Probably the first nonpreferred counterions, Na^+, to enter the resin were also located mainly in these more dilute regions where they balanced the few fixed charges.

At 0.10 equiv/liter the decrease in D_{Br} occurred more smoothly and gently as Cs^+ ions were replaced by Na^+. This behavior is consistent with the almost uniform distribution of the bromide ions which is believed to exist at higher external concentrations. A flat maximum was observed in the curve of D_{Br} in the Na^+/Sr^{2+} mixtures. Its height was scarcely greater than the experimental uncertainty. A real effect of this kind might however arise if a more nearly uniform electrical potential distribution in the resin were achieved once some univalent counterions were introduced in exchange for bivalent ones. This could occur because the detailed balancing and screening of the fixed charges would be more complete in the presence of some univalent counterions.

Counterions.—The diffusion coefficients of the three counterions, Na^+, Cs^+ and Sr^{2+}, are plotted in Fig. 6

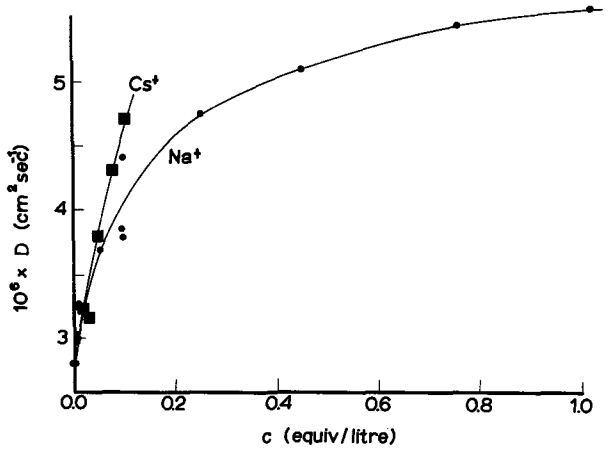

Fig. 6. Diffusion coefficients of Na^+ and Cs^+ in Zeo-Karb 315 at 25°C as functions of external solution concentration, c equiv/liter. ■ Cs^+, ● Na^+.

and 7 against the concentration of the external solutions. In every case it can be seen that the diffusion coefficient increased with increasing concentration over the whole range. This is in contrast with D_{Br} which was almost constant above 0.1 equiv/liter. The increase in D over the range 0-1 equiv/liter was about twofold for Na^+ and Sr^{2+}.

Although this pattern of behavior has been observed by many workers (1) it has not yet been explained quantitatively. The counterions are attracted by the fixed charges and as a result experience considerable frictional interaction with the polymer matrix. As well they are exposed to the electric field of the fixed charges which fluctuates from point to point in the gel. Jakubovic *et al.* (20) have suggested that the electrical influence may be so great that in a highly swollen resin and in the absence of coions the counterions migrate mainly from fixed ion to fixed ion along the polymer chains. Thus they follow paths of greater tortuosity than required by purely geometrical considerations. To jump from the ionic atmosphere around one chain into that of another involves surmounting the intervening potential barrier. This process, called "volume diffusion" by Jakubovic *et al.*, can take place more readily with counterions of low charge and high hydrated radius because they interact least with the fixed charges. Volume diffusion should be facilitated by increasing the temperature and by increasing the concentration of coions which can act as "electrical bridges" by smoothing the potential peaks between the neighboring fixed charges.

This mechanism is in qualitative agreement with the observed facts. The activation energies for diffusion of Na^+ and Cs^+ ions in the membrane (Table II) are

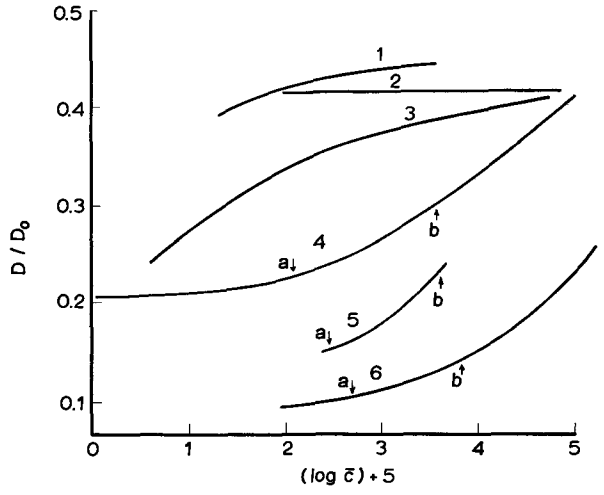

Fig. 8. Ratio of diffusion coefficients in Zeo-Karb 315 to those in dilute solution, D/D_o, as a function of logarithmic bromide concentration in the membrane, $\bar{c}$ equiv/liter. Curve 1, Br^- in Cs^+ form; curve 2, Br^- in Sr^{2+} form; curve 3, Br^- in Na^+ form; curve 4, Na^+ in Na^+ form; curve 5, Cs^+ in Cs^+ form; curve 6, Sr^{2+} in Sr^{2+} form. a, indicates external concentration c = 0.02 equiv/liter; b, indicates external concentration c = 0.10 equiv/liter.

each about 1 kcal/mole larger than in aqueous solution where the values are 4.4 and 3.9, respectively (19). The same is probably true of Sr^{2+}, but no value is available for the activation energy in free solution for comparison. The activation energy appeared to decrease at high concentrations in the Sr^{2+} state, and this would accord with the view that at high concentrations there is a more plentiful supply of coions to lower the electric potential barriers between the chains.

A clearer comparison between the three counterions is seen in Fig. 8 where, for each ion, the ratio of its diffusion coefficient in the resin to that in free solution, D/D_o, is plotted against the logarithm of the coion concentration. Also shown in Fig. 8 are the curves of D/D_o for Br^- ions in each ionic form of the membrane. It can be seen that D for each counterion increases in much the same way on increasing the coion concentration.

Cs^+ and Sr^{2+} are relatively more retarded in the resin than is Na^+. This is consistent with their stronger interactions with the matrix as indicated by the thermodynamic preferences (11). At the highest concentration D/D_o for Na^+ was close to that for Br^-. It may be concluded that at high coion concentrations the migration of highly hydrated nonpreferred counterions such as Na^+ occurs freely by volume diffusion and that the potential barriers favoring chain diffusion are unimportant. With the less hydrated Cs^+ and more highly charged Sr^{2+} counterions the situation in which there were insignificant electrical barriers to volume diffusion was not reached at the concentrations studied (21).

It can be seen that D/D_o for Sr^{2+} was less than for Cs^+ although the thermodynamic equilibrium constants showed a preference for Cs^+ over Sr^{2+} Evidently the electrical potential barriers were greater and volume diffusion less easy for the bivalent ions because a pair consisting of a fixed charge and a bivalent counterion carries a residual positive charge.

Lifson and Jackson (22) and Jackson and Coriell (23) have examined theoretically a similar electric potential barrier phenomenon which controls the diffusion coefficient of the counterions in a salt-free polyelectrolyte solution as a function of concentration. Clifford and Pethica (24) have applied this theory to the diffusion of counterions in micellar solutions and have attempted to take into account the effect of added salt. They predicted and observed an increase in D

as the added salt concentration was increased. Although the results predicted by these treatments of idealized models of polyelectrolytes and micelles are comparable with the effects observed in the ion-exchange membrane, it seems improbable that in the nonuniform and relatively randomly entangled and cross-linked network of the resin matrix the processes of chain and volume diffusion could be distinguished sufficiently clearly to enable a quantitative theory to be developed on this basis.

Data on the diffusion coefficients of the counterions in the heteroionic states of the membrane are shown in Fig. 9-12 where the diffusion coefficients are plotted against the equivalent fraction $\overline{X}_{Na}$ of Na^+ in the membrane. In every case the diffusion coefficients of both ions decreased as $\overline{X}_{Na}$ was increased (the maximum in D_{Na} in the Na^+/Sr^{2+} state at 0.1 equiv/liter seen in Fig. 12 is referred to later). The relative changes were different for the three ions; D_{Cs} was affected by composition more than D_{Na} and D_{Sr} was affected most.

In each mixture the concentration of coions decreased as $\overline{X}_{Na}$ increased and, in the light of the observations with single salts, this would shift both counterion diffusion coefficients in the observed direction. It can easily be seen from Fig. 8 that the effect of these changes in coion concentration would alone

be much too small to account for the observed decreases in the diffusion coefficients.

It must be concluded that the observed behavior was connected with the fact that Na^+ was the nonpreferred ion in both mixtures. When the membrane is loaded entirely with preferred ions (*i.e.*, the left-hand sides of Fig. 9-12) these ions take up an equilibrium distribution with respect to the fixed charges and coions. Some will be in any densely cross-linked regions of unusually high fixed charge density, others in the unusually dilute and swollen regions. At any instant some counterions will be close to and interacting strongly with the electric fields of the fixed charges, others will be far away from these charges in regions where the electric field strengths are quite low. The observed diffusion coefficient is an average of the instantaneous mobilities of all these counterions.

When a few Na^+ ions are introduced it may be inferred from the well-known variation of ion-exchange selectivity with cross-linking that these nonpreferred ions mostly will take up positions in the least dense regions of the resin. In these regions the coion concentration is higher than average, and the nonpreferred counterions spend a lower proportion of their time close to the fixed charges than they would in the denser regions. These factors contribute to the high mobility of the first Na^+ ions which enter the Cs^+ or Sr^{2+} forms of the membrane.

At 0.02 equiv/liter the limit of D_{Na} as $\overline{X}_{Na}$ tended to zero was about 4.5×10^{-6} cm^2 sec^{-1} in Na^+/Cs^+ and in Na^+/Sr^{2+} mixtures. At 0.10 equiv/liter in mixtures of Na^+/Cs^+ D_{Na} reached a limit of about 6×10^{-6} cm^2 sec^{-1}. This was slightly greater than the value in the pure Na^+ state at high external solution concentrations.

In the Na^+/Sr^{2+} mixture at 0.1 equiv/liter the behavior of D_{Na} as $\overline{X}_{Na}$ was decreased from 1.0 to 0.3 suggested that it would rise to about 6×10^{-6} cm^2

sec^{-1} as $\overline{X}_{Na}$ tended to zero. Once $\overline{X}_{Na}$ was taken below 0.2 however D_{Na} appeared to decrease. The maximum in D_{Na} did not appear to be due to errors or difficulties in the permeation experiments, and unexpectedly large errors in the equilibrium measurements would be necessary to explain the maximum in D_{Na} in this way. The decrease in D_{Na} when $\overline{X}_{Na} < 0.2$ may be due to less complete screening of the fixed charges when the resin is loaded with only multivalent counterions than is possible when some univalent counterions also are present.

Just as the first Na^+ ions to enter the membrane are concentrated into the regions where mobility is greatest so the Cs^+ and Sr^{2+} ions are displaced from these regions and their average mobilities, *i.e.*, D_{Cs} and D_{Sr}, are decreased. As more and more Na^+ ions enter they penetrate into the denser regions of the network where they spend a greater proportion of their time close to the fixed charges. Also the fixed charges are less well shielded by Na^+ than by the preferred ions. Consequently the average mobility of the Na^+ ions falls continuously as $\overline{X}_{Na}$ increases. D_{Cs} and D_{Sr} also fall continuously and the last Cs^+ and Sr^{2+} ions remaining in the resin are situated mainly in those regions where movement is most difficult.

D_{Cs} and D_{Sr} both decrease by a factor of about 2 at 0.02 equiv/liter and 2.5 at 0.10 equiv/liter when $\overline{X}_{Na}$ is changed from 0 to 1, whereas the change in D_{Na} is only about 1.5 at both concentrations. Thus that part of the membrane transport selectivity which arises from differences between the mobilities of the ions leads to a greater discriminating power when the membrane is richest in the nonpreferred ions.

The most directly comparable results of other workers are those of Ishibashi (25) who measured diffusion coefficients and electrical mobilities in a phenol sulfonic membrane containing Na^+ and Ca^{2+} ions. In agreement with our results on the $Na^+ + Sr^{2+}$ system, he observed that the mobilities of both counterions decreased as $\overline{X}_{Na}$ increased.

Soldano and Boyd (26) examined Na^+ and Cs^+ diffusion in Dowex 50 resin cross-linked with 8% and 16% divinyl benzene and observed that D_{Na} and D_{Cs} decreased as $\overline{X}_{Na}$ increased in agreement with our findings. However in the Na^++Zn^{2+} mixture on the 16% divinyl benzene resin they found that D_{Na} and D_{Zn} increased with $\overline{X}_{Na}$.

Morig and Rao (27) studied rates of exchange between Na^+ and Sr^{2+} on Dowex 50, 8% divinyl benzene, and concluded that the discrepancy between their observations and the theoretical rates of exchange (28) would be explained if D_{Na} and D_{Sr} both increased as $\overline{X}_{Na}$ increased.

The apparent disagreement between these results on Dowex 50 and ours for the $Na^+ + Sr^{2+}$ mixture is probably a consequence of the relatively large deswelling of the Dowex 50 resins when Na^+ is replaced by Zn^{2+} or Sr^{2+}.

Conclusion

It is evident from this discussion that the changes in ionic diffusion coefficients in a cation exchange resin membrane with external solution concentration and with the equivalent fractions of the different counterions in a heteroionic state of the membrane, as well as the differences between the diffusion coefficients of different kinds of ions, can all be understood in terms of the influence of the electric fields surrounding the polymer chains and fixed charges on mobility and of the existence of a few local inhomogeneities in the fixed-charge and cross-link densities. There is no need to invoke fixation of counterions by specific ion-pairing with the fixed charges nor is there any evidence of this in the system studied here.

The relative importance of the electric fields and structural dispersities in determining the observed behavior is harder to assess. If the resin network were completely homogeneous the distances between neighboring chains would average about 25-30Å. This cannot be very different from the mean distance between the fixed charges along the chains. Consequently diffusion along chains should not be greatly favored relative to diffusion across the gaps between chains. This view is consistent with the observations that at high external concentrations the diffusion of Na^+ appears to be little affected by electrostatic fields and the introduction of relatively few coions has a large effect in facilitating the diffusion of Cs^+ and Sr^{2+}. The evidence from the sorption and diffusion of the coions is that the resin consists mainly of relatively uniform material permeated by an interconnecting network of less dense regions which makes up a small part only of the total volume. This has an important function in the diffusion of coions at low external concentrations but has almost no influence on the behavior of the counterions.

Manuscript submitted Dec. 26, 1968; revised manuscript received March 24, 1969. This was Paper 226 presented at the Boston Meeting, May 5-9, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

SYMBOLS

a, an apparatus constant, cm.
c, solution concentration, equiv/liter.
$\bar{c}$, coion concentration in membrane, mole/liter.

Electrochemical Processes of the Chlorine-Chloride System on Platinum-Iridium-Coated Titanium Electrodes

G. Faita, G. Fiori, and J. W. Augustynski[1]

Laboratory of Electrochemistry and Metallurgy, University of Milan, Milan, Italy

ABSTRACT

Anodic and cathodic processes of the Cl_2/Cl^- system on Ti/Pt-Ir (30% Ir) in comparison with Ti/Pt electrodes were examined. The anodic Cl_2 evolution follows the same scheme on both the electrodes

$$Cl^- \rightarrow Cl_{ads} + e$$
$$2Cl_{ads} \rightarrow Cl_2$$

but Ti/Pt electrodes undergo a marked passivation for $\eta_{an} > 0.2V$, whereas the passivation on Ti/Pt-Ir electrodes is important only at overvoltages higher than 0.5V. Such a difference in passivation is noted also in the cathodic process: on Ti/Pt-Ir electrodes in fact, at low overvoltages, the process follows the scheme

$$Cl_2 \rightarrow 2Cl_{ads}$$
$$Cl_{ads} + e \rightarrow Cl^-$$

due to the higher catalytic activity of the surface.

The electrochemical behavior of the Cl_2/Cl^- system on Pt electrodes has been studied for 70 years (1, 2) mainly owing to interest in the electrochemical production of chlorine.

From the point of view of theoretical electrochemical kinetics the first important approach was that of Chang and Wick (3) who showed that the shapes of the polarization curves for the anodic Cl_2-evolution conform to the theory of slow discharge.

For anodic Cl_2-evolution Tedoradse (4, 5) found that the maximum kinetic current is (Cl^-)- and pH-dependent according to

$$i_{max} = K\,(Cl^-)\,(pH)^{1/2}$$

He suggested that the rate-determining-step is

$$Cl^- - e \rightarrow Cl_{ads}$$

and that the pH-dependence would be due to passivation of the electrode surface.

Difficulties caused by surface oxide layers and by possible O_2-evolution were pointed out by Toshima and Okaniwa (6), whose results agree with Tedoradse's.

Other authors considered the influence of electrode passivation (7) and its dependence on pH (8), current density (9), anode potential (10, 11), and Cl^- concentration (12).

Fewer papers are available on the cathodic Cl_2 reduction (7, 13). Frumkin and Tedoradse studied the dependence of the rate of Cl_2 ionization on a smooth Pt electrode in strongly acid solution, on the electrode rotation speed, and on Cl^- concentration. These authors interpreted the kinetic mechanism according to the scheme

$$Cl_2 + e \rightleftarrows Cl_{ads} + Cl^-$$
$$Cl_{ads} + e \rightarrow Cl^-$$

both these electrochemical steps being equally rate-determining. It is noteworthy that in the above studies strong acid solutions usually were used to reduce electrode passivation effects. Pt electrodes under these conditions undergo corrosive phenomena with possible changes in surface activity.

The aim of the present work was to investigate both the anodic Cl_2-evolution and the cathodic Cl_2-reduction on a new kind of electrode, which was obtained by thermal deposition of Pt-Ir (30% Ir) alloy on a titanium substrate. Electrodes of this type recently have aroused considerable interest from the industrial point of view as an alternative to graphite anodes in chlorine cells. Such electrodes show no corrosion phenomena even in strongly acid solutions containing Cl^- plus Cl_2 (14) and the surface passivation they may undergo is considerably less than that observed on Pt surfaces.

In the present study electrochemically platinum-coated titanium electrodes also were used to get better comparison with the previous work. Thus pH 3 was chosen because corrosion of platinized titanium takes place below this pH value. All measurements were made using a rotating disk electrode which has been described in detail elsewhere (15).

Experimental Techniques and Results

Deposition of Pt-Ir (30% Ir) alloy on titanium was performed by the thermal method (16). The titanium matrix, previously machined, was heated at 500°C in air, cooled, ground, and degreased. The electrode surface was painted with a mixture of metal chlorides ($PtCl_4 \cdot 5H_2O$ and $IrCl_4$), methanol, and lavender oil and was then dried. The sequence, painting and drying, was repeated five times, until the amount of Pt+Ir as chloride, reached 1 mg/cm^2. The Pt-Ir alloy was obtained by thermal decomposition at 500°C in air (1 hr), followed by cooling in water. The layer formed (about 1μ thick) was bright and adhered well to the support.

Three electrodes were prepared in this way which showed very reproducible behavior. The temperature used during the thermal decomposition strongly affected the catalytic properties of the alloy, the catalytic activity decreasing with increasing temperature above 500°C. An electrode, obtained by decomposition at 650°C, for example, showed a poorer behavior in

[1] Present address: Ecole Supérieure d'Electrochimie et Electrométallurgie, Grenoble, France.

the cathodic reduction of chlorine than galvanic platinum.

Platinum was electrochemically deposited on titanium according to the following procedure. The cylindrical titanium stem, after being turned, was carefully ground, then sandblasted and put into a solution of the following composition (17): 14g Pt $(NH_3)_2(NO_2)_2$, 10g $(NH_4)_2$ SO_4, 50g NH_3 per liter; pH = 10. Electrolysis was carried out at 70 mA/cm², using a Pt sheet as counterelectrode at 1-cm distance with vigorous stirring, at 80°-90°C. Electrolysis was continued until a 30μ Pt layer was obtained.

Both kinds of electrodes were then cold-pressed into polytetrafluoroethylene tubing (Algoflon-Montedison). The Pt surfaces were exposed by polishing with alumina. The diameter of the working electrode was 10 mm, the total diameter (metal + plastic) being 20 mm. Figure 1 shows the measuring circuit and the measuring technique. Required potentials were set up using a 557 AMEL potentiostat and read on a 610B Keithley electrometer. Before each set of measurements the electrodes were activated by 10 polarization cycles in the same test solution. In each cycle the electrode was potentiostated anodically at +1.7V (NHE) for 10 sec then cathodically at −0.4V (NHE) for 10 sec.

The measurements were made potentiostating the electrodes cathodically at −0.4V (NHE) for 3 sec, then at the required potentials; the polarizing current was read after 15 sec. The tip of the reference electrode was placed 10 mm under the working electrode. The ohmic drop, calculated by oscillographic methods, was always <5% of the total overvoltage (η) except for the anodic polarization on Ti/Pt-Ir electrodes, where the ohmic drop was about 10% of the total overvoltage. The question of the distribution of the current on the electrode surface was considered on the basis of Newman's theory (18). In our conditions, when η is <50 mV, the local current density shows a maximum deviation of ± 10% with respect to the average current density. When η is >>50 mV, such a deviation is very small.

Test solutions were made up with reagent grade chemicals ($NaClO_4$ from BDH, NaCl from C. Erba and triply distilled water). Solutions were saturated by Cl_2-N_2 mixtures (1 ± 0.01% to 10 ± 0.1% in Cl_2). Temperature of experiments was regulated to 30° ± 0.2°C by means of a specially designed air-thermostat.

Figure 2 shows typical cathodic polarization curves obtained, at constant rotation speed, for both types of electrodes, whose cathodic behavior was tested as a function of NaCl concentration and rotation speed. Figure 3 shows anodic polarization curves, obtained under various experimental conditions.

Discussion

Chlorine reduction.—On the basis of the rotating disk electrode theory the functional dependence of current density on rotation speed may be written as

$$1/i^{1/p} = 1/i_L^{1/p} + [i^{(p-1)/p} \times B]/\sqrt{\omega} \times C_S$$

where p is the reaction order of the surface reaction with respect to the reactant, i the current density at rotation speed ω, i_L the current density at infinite rotation speed, C_S the bulk concentration of the re-

actant, and B a factor including all constant terms derived from the analytical treatment.

Plots of $1/i^{1/p}$ against $i^{(p-1)/p}/\sqrt{\omega}$ should be straight lines only if the true value for p is used. The cathodic data were tested against various postulated values for p: a linear plot was obtained in the case $p = 1$, with the exception of the data concerning Pt-Ir electrodes at overvoltages less than 0.2V (Fig. 4 and 5). The intercepts on the $1/i^{1/p}$ axis allow the current densities at infinite rotation speed (i_L) to be computed. Data at high rotation speed (8,000 $\simeq$ 10,000 rpm) would be useful to avoid long extrapolations; unfortunately, in these extreme conditions the currents showed such instability that the accuracy of measurements was strongly affected. It seems likely that at the highest speeds, the surface roughness, although slight, might have produced turbulent conditions close to the electrode.

In order to improve the reliability of the extrapolated data, the experiments at various rotation speeds were repeated at least three times: the data used in the plots of $1/i^{1/p}$ against $i^{(p-1)/p}/\sqrt{\omega}$ for different overvoltages were the average values from the various measurements.

As regards the cathodic data of the Pt-Ir electrodes for overvoltages less than 0.2V, almost linear plots were obtained if a value of 0.5 for p was used. This remarkable result was experimentally checked by carrying out measurements at overvoltages less than 0.2V in the presence of chlorine at concentration of 1 and 10%; the ratio of the current densities, at the same electrode potentials, confirmed the reaction order to be 0.5. Electrode potentials were plotted against the log of the extrapolated i_L at various Cl^- concentrations. Since the i_L values, at the same electrode potentials, were independent of the Cl^- concentration, the reaction order with respect to Cl^- ion should be 0 (13) (Fig. 6 and 7). Experimental kinetic parameters (Tafel b-coefficient, exchange current, charge transfer resistance, stoichiometric number, reaction order) are

summarized in Table I. Taking into account the ohmic drop, current distributions, and other experimental uncertainties, the accuracy of Tafel b-coefficients and of the exchange currents was about ±5%, that of the charge transfer resistance being ±10%.

A combined knowledge of the reaction orders, stoichiometric numbers, and Tafel coefficients enable the mechanism of the electrode process to be elucidated. In Table III possible mechanisms of the cathodic Cl_2 reduction and related kinetic parameters are summarized. By comparing theoretical with experimental parameters, it is clear that the cathodic chlorine reduction on Ti/Pt-Ir electrodes follows two different schemes depending on the overvoltage range:

$\eta < 0.2V$.—The process follows path C, with C_2 rate determining step (RDS).

$0.25V < \eta < 0.5V$.—The process still follows path C, but now C_1 is the RDS, since the velocity of step C_2 increases with increasing overvoltage. A similar behavior was observed in the case of the kinetics of hydrogen evolution (19).

$\eta > 0.5V$.—Experimental results agree with the parameters theoretically required by both path A [at high overvoltages A_1 is in any case RDS (20)] and B (RDS B_1). Paths A and B have the same first electrochemical step; the second step is again electrochemical in path A, but chemical in path B.

The application of the same analysis to the data of galvanic platinum showed that the cathodic process always follows either path A (steps A_1 and A_2 comparably rate-controlling) or path B (B_1 RDS).

The main difference between the thermal Pt-Ir electrodes and galvanic platinum is described by the behavior at cathodic overvoltages less than 0.5V (Fig. 2): as a matter of fact the Pt-Ir alloy shows more favorable current-voltage characteristics owing to the higher catalytic activity of the surface. The effect of decomposition temperature on the catalytic activity has been pointed out in the section on Experimental techniques and results.

Cl_2 *evolution.*—By comparing the parameters theoretically required (Table IV) with the experimental results (Table II) on Ti/Pt-Ir electrodes, it turns out that the anodic chlorine evolution may follow both path A' (steps A'_1 and A'_2 comparably rate-controlling) and C' (C'_1 RDS), whereas path B' must be rejected because anodic currents are unaffected by P_{Cl_2}. In order to elucidate whether path A' or C' is valid a critical discussion on $(\Delta\eta/\Delta i)_{i\to 0}$ and i_o values is needed. Anodic and cathodic i_o values, obtained from the Tafel slopes, are practically identical. Furthermore, the anodic and cathodic values of $(\Delta\eta/\Delta i)_{i\to 0}$ are also identical: therefore the anodic process seems

Table III. Kinetic parameters theoretically required by different cathodic mechanisms

	Mechanism	RDS	Stoichiometric number	Reaction order with respect to Cl_2	Reaction order with respect to Cl⁻	"b" Tafel coefficient
A	1) $Cl_2 + e \rightarrow Cl_{ads} + Cl^-$	A_1	1	1	0	$RT/\alpha F$
	2) $Cl_{ads} + e \rightarrow Cl^-$	A_2	1	1	−1	$RT/(1+\alpha)F$
		$A_1 \simeq A_2$	2*	1	0	
B	1) $Cl_2 + e \rightarrow Cl_{ads} + Cl^-$	B_1	2**	1	0	$RT/\alpha F$
	2) $2Cl_{ads} \rightarrow Cl_2$	B_2	1**	2	−2	$RT/2F \leq b \leq \infty$
C	1) $Cl_2 \rightarrow 2Cl_{ads}$	C_1	—	1	0	$\rightarrow \infty$
	2) $Cl_{ads} + e \rightarrow Cl^-$	C_2	2	0.5	0	$RT/\alpha F$

Either step A_1 and B_1 could be interpreted as two-stage steps
$Cl_2 + e \rightarrow Cl_{2ads}^-$
$Cl_{2ads}^- \rightarrow Cl_{ads} + Cl^-$ (fast chemical equilibrium)

* The stoichiometric number in this case was obtained following Krishtalik's treatment (22), which requires knowledge of the ratio $\gamma = i_{oA_1}/i_{oA_2}$. This is achieved recalling that extrapolation of the anodic Tafel line to $\eta = 0$ gives $2i_{oA_2}$ as intercept, while extrapolation of the cathodic gives $2i_{oA_1}$.

** Stoichiometric numbers in the case of mechanism B were obtained following Makrides treatment (23).

Table IV. Kinetic parameters theoretically required by possible anodic mechanisms

	Mechanism	RDS	Stoichiometric number	Reaction order with respect to Cl_2	Reaction order with respect to Cl⁻	"b" Tafel coefficient
A'	1) $Cl^- - e \rightarrow Cl_{ads}$	A'_1	1	0	1	$RT/(1-\alpha)F$
	2) $Cl_{ads} + Cl^- - e \rightarrow Cl_2$	A'_2	1	0	2	$RT/[(1-\alpha)+1]F$
		$A'_1 \simeq A'_2$	2	0	1	$RT/(1-\alpha)F$
B'	1) $Cl_2 - 2Cl_{ads}$	B'_1	—	1	0	$\rightarrow \infty$
	2) $Cl_{ads} + Cl^- - e \rightarrow Cl_2$	B'_2	2	0.5	1	$RT/(1-\alpha)F$
C'	1) $Cl^- - e \rightarrow Cl_{ads}$	C'_1	2	0	1	$RT/(1-\alpha)F$
	2) $2Cl_{ads} \rightarrow Cl_2$	C'_2	1	0	2	$RT/2F$ $\theta \rightarrow 0$; $\rightarrow \infty$ $\theta \rightarrow 1$

Either step A'_2 and B'_2 could be interpreted as two-stage steps
$Cl_{ads} + Cl^- \rightarrow Cl_{2ads}^-$ (fast chemical equilibrium)
$Cl_{2ads}^- - e \rightarrow Cl_2$

to be exactly symmetrical to the cathodic process at $\eta < 0.2V$ and probably follows path C'.

For the Pt electrode, at $\eta < 0.2V$, both paths A' and C' are possible. Recalling the cathodic results on the same electrode, the more reasonable conclusions are: (*i*) cathodic and anodic processes are symmetrical (A and A') and (*ii*) the cathodic mechanism is B and the anodic one is C'.

If the anodic and cathodic processes were symmetrical, the exchange currents would fulfill the relation (20)

$$\left(\frac{\Delta\eta}{\Delta i}\right)_{i\to o} = \frac{RT}{2F}\left(\frac{1}{i_{o,an}} - \frac{1}{i_{o,cat}}\right)$$

which is not the case (Table I and II). Therefore on platinum electrodes the cathodic process probably follows path B and the anodic one path C'. This asymmetric behavior is clearly determined by the step $2Cl_{ads} \rightarrow Cl_2$, which is faster than both steps A_2 and A'_2.

The shape of the anodic polarization curves on platinum electrodes shows a surface passivation at $\eta > 0.2V$ [Cl^- diffusion current should be about 10 times higher (21)]. At high Cl^- concentration the passivation is incomplete (8), the currents, read after 15 sec, are not stationary and decrease as rotation speed increases. Such a behavior may be determined by a more efficient mass transport of the passivating species, *e.g.*, ClO^- ions. At $\eta > 0.5V$ the passivation is, however, complete and the anodic current is unaffected by Cl^- concentration and rotation speed. On Pt-Ir the oxide layer formation takes place only at $\eta > 0.4V$. This property, rather than the outstanding catalytic activity, allows the very advantageous anodic voltage current characteristic of thermal Pt-Ir electrode, which seems especially suitable for brine electrolysis. At $\eta > 0.4V$ the b-Tafel coefficients are identical for both electrodes: the surfaces are surely covered with oxide species and the anodic mechanism should then implicate the intermediate formation of oxychlorides (24). Clearly, at such overvoltages, the possibility of chlorate formation and oxygen discharge should be considered.

Conclusions

Anodic and cathodic processes of the Cl_2/Cl^- system were examined.

1. On Ti/Pt-Ir electrodes the cathodic Cl_2 reduction follows the scheme

$$\eta < 0.5V \begin{cases} Cl_2 \rightarrow 2Cl_{ads} \\ Cl_{ads} + e \rightarrow Cl^- \end{cases}$$

$$\eta > 0.5V \begin{cases} Cl_2 + e \rightarrow Cl_{ads} + Cl^- \\ Cl_{ads} + e \rightarrow Cl^- \\ 2Cl_{ads} \rightarrow Cl_2 \end{cases} \text{ concurrent steps}$$

2. On Ti/Pt electrodes the cathodic process follows the scheme

$$Cl_2 + e \rightarrow Cl_{ads} + Cl^-$$
$$2Cl_{ads} \rightarrow Cl_2$$

3. An Ti/Pt-Ir electrodes the anodic Cl_2 evolution follows the scheme (symmetric to the cathodic scheme at low overvoltages)

$$Cl^- \rightarrow Cl_{ads} + e$$
$$2Cl_{ads} \rightarrow Cl_2$$

Passivation on this electrode is important only at overvoltages higher than 0.5V.

4. On the contrary, Ti/Pt electrodes undergo a marked passivation for $\eta_{an} > 0.2V$. Such passivation is diffusion controlled at intermediate and high Cl^- concentrations. The anodic Cl_2 evolution, at $\eta_{an} < 0.2V$ on this electrode, is similar to that on Ti/Pt-Ir electrode; at higher overvoltages, passivation phenomena and formation of oxychlorides may complicate the electrode processes.

Acknowledgments

This investigation has been sponsored by the Consiglio Nazionale delle Ricerche, Rome, Italy. The authors wish to thank Dr. A. Nidola of the O. De Nora Impianti Elettrochimici, Milan, for his assistance in the electrode preparation.

Significance of Electrolyte Films for Performance of Porous Hydrogen Electrodes

I. Film Model

Fritz G. Will* and David J. BenDaniel

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

A refined analysis of the electrolyte film model is presented and evaluated on experimental polarization curves of porous hydrogen diffusion electrodes. Simultaneous diffusion and kinetic control and the existence of hydrogen surface coverage are taken into account. The effects of electrolyte film thickness and height on the shape of the polarization curves are analyzed. Polarization curves obtained on various types of partly wet-proofed porous hydrogen electrodes are in very good agreement with the computed curves. A concept of the morphology and the wetting behavior of partly wet-proofed electrodes is developed based on electron micrographs and a comparison between predicted and observed polarization curves. It is concluded that, under often prevailing conditions of diffusion control, the reaction proceeds predominantly on the wetted walls of macro pores, while the much smaller micro pores are mostly flooded and contribute little to the current.

Experiments on foil electrodes partly immersed in aqueous electrolytes have generally established the existence of stable electrolyte films[1] above the intrinsic meniscus (1-5). On electrodes with polished surfaces, films are sometimes unstable and menisci with contact angles larger than zero form (1, 6-9). Under conditions of extreme cleanliness, however, stable films have been shown to exist even on highly polished surfaces (10, 11).

Mathematical analyses of the film model have been presented (12-18) and evaluated by describing polarization curves observed on model electrodes (1, 10, 12, 13, 18). More refined geometric and kinetic models are required to describe polarization curves of actual porous gas electrodes, and very few attempts have been made in this direction (17, 19, 20). In these few cases, discrepancies up to a factor of 4 between predicted and measured curves existed (19) or unlikely kinetic equations or parameters had to be assumed to produce a curve fit.[2]

In this paper we present a refined analysis of the film model for the hydrogen oxidation reaction. We use the well established Heyrowsky-Volmer mechanism to describe the hydrogen oxidation, also taking into account the effects of hydrogen surface coverage and slow hydrogen diffusion on the reaction rate. Experimental polarization curves of actual porous hydrogen electrodes, obtained by other authors (21), are then evaluated in terms of the film model using measured structure parameters of these electrodes.

Model and Analysis

First the polarization behavior of a single pore of uniform diameter is analyzed and then a porous gas electrode as a system consisting of a large number of such pores is described.

Single pore.—The model treated is as follows: (*i*) The film meets the bulk electrolyte at right angles at the pore mouth ($x = 0$). This means that effects due to the meniscus and the electrolyte-filled part of the pore are neglected. (*ii*) The film thickness δ_o is small compared to the pore radius r and the film height H. This allows a treatment in Cartesian coordinates. (*iii*) The electric field in the film perpendicular to the surface (outside the Helmholtz layer), dE/dy, is small compared to dE/dx. (*iv*) The electrolyte concentration in the film stays approximately constant. It has been suggested (18) that water condensation and transport through the film may accomplish this. In fact, it has been shown (12) that in thick films (~1 mm) concentration gradients are very small due to water vapor transport and capillary motion.

We may write the pore current per unit perimeter $W = 2\pi r$ as

$$I/W = -(\delta_o/\rho)\, dE/dx \qquad [1]$$

where ρ is the resistivity of the electrolyte and E the local electrode polarization. The local current density i is given by

$$i = -dI/Wdx \qquad [2]$$

By differentiating Eq. [1] and substituting for dI/dx in Eq. [2] we obtain

$$\delta_o\, d^2E/dx^2 = \rho i \qquad [3]$$

subject to the boundary conditions

$$E(x) = E_a \quad \text{for } x = 0 \qquad [3a]$$

$$dE/dx = 0 \quad \text{for } x = H \qquad [3b]$$

where E_a is the total measured electrode polarization. In order to express i as a function of E, the reaction mechanism has to be known. The oxidation of hydrogen is best described by either the Heyrowsky-Volmer mechanism or the Tafel-Volmer mechanism. The former is more suitable in cases where the coverage of the metal surface with atomic hydrogen is large, the latter is preferred if the coverage is small. In the following analysis we discuss only the Heyrowsky-Volmer mechanism because hydrogen diffusion electrodes are usually made of metals which exhibit large equilibrium coverages with hydrogen and are often operated in a potential region where the coverage remains relatively large. For very small thicknesses and small polarizations, the electron transfer process (Heyrowsky-Volmer) should become rate-determining. In other cases, however, hydrogen diffusion through the film is expected to determine the rate.

* Electrochemical Society Life Member.

Key words: electrochemistry, fuel cells, porous electrodes, hydrogen oxidation, film model.

[1] A film thickness of 1.5μ and a minimum film length of 1 cm was established for the system H_2/Pt-black/8NH_2SO_4 (1, 13) using an electrochemical technique. Applying the same technique, a film of 0.18 to 0.25μ was found for KOH on Ni (3) in close agreement with values between 0.1 and 0.5μ obtained with optical techniques (11).

[2] Thus, the kinetic model assumed for O_2-reduction in (17) predicts that the local current density goes through zero and changes sign in contrast to the actual findings (4, 5). The model proposed in (20) has to assume surface diffusion coefficients 4 to 5 orders of magnitude higher than known bulk electrolyte values.

For a full description we need to consider both processes simultaneously.

The current density due to the diffusion of molecular hydrogen through the film is given by

$$i = i_l(1 - c/c_o) \quad [4]$$

$$i_l = 2FD\, c_o/\delta_o \quad [4a]$$

where **F** is the Faraday constant, D the diffusivity, c the local concentration, c_o the concentration of molecular hydrogen for standard pressure $p_o = 1$ atm, and i_l the limiting diffusion current of H_2. It is assumed that the transport of hydrogen in the gas phase and the dissolution of hydrogen in the electrolyte proceed sufficiently fast such that $c = c_o$ at the gas-electrolyte interface.

The Heyrowsky mechanism

$$H_2 \rightarrow H + H^+ + e^- \text{ (acid)} \quad [5a]$$

$$H_2 + OH^- \rightarrow H + H_2O + e^- \text{ (alkali)} \quad [5b]$$

is described by

$$i = 2i_{oH}\left[\frac{c}{c_o}\frac{1-\theta}{1-\theta_o}\exp(\alpha_H\phi E) - \frac{\theta}{\theta_o}\exp(-(1-\alpha_H)\phi E)\right] \quad [6]$$

where $\phi = \mathbf{F}/RT$ and i_{oH} and α_H are the exchange current density and the transfer coefficient for the Heyrowsky reaction, respectively. θ and θ_o are the hydrogen coverage of the surface for any voltage E and $E = 0$ ($p = p_o$), respectively. The coverage of the surface is defined as that fraction of the surface which is covered with hydrogen atoms.

The Volmer mechanism

$$H \rightarrow H^+ + e^- \text{ (acid)} \quad [7a]$$

$$H + OH^- \rightarrow H_2O + e^- \text{ (alkali)} \quad [7b]$$

is described by

$$i = 2i_{oV}\left[\frac{\theta}{\theta_o}\exp(\alpha_V\phi E) - \frac{1-\theta}{1-\theta_o}\exp(-(1-\alpha_V)\phi E)\right] \quad [8]$$

where i_{oV} and α_V are the exchange current density and the transfer coefficient for the Volmer reaction, respectively. By eliminating c/c_o and θ/θ_o from Eq. [4], [6], and [8], we obtain the current density as a function of the voltage in the form

$$i = (B - \sqrt{B^2 - 4AC})/2A \quad [9]$$

with

$$A = \theta_o \exp[(1-\alpha_V)\phi E]/2i_{oV}i_l \quad [9a]$$

$$B = \theta_o \exp(-\alpha_H\phi E)/2i_{oH} + (1-\theta_o)\exp[(1-\alpha_H)\phi E]/2i_{oH} + \theta_o \exp[(1-\alpha_V)\phi E]/2i_{oV} + (1-\theta_o)\exp(-\alpha_V\phi E)/2i_{oV} + \exp(\phi E)/i_l \quad [9b]$$

$$C = \exp(\phi E) - \exp(-\phi E) \quad [9c]$$

When Eq. [9] (together with Eq. [4a], [9a], [9b], and [9c]) is substituted into Eq. [3], a second order nonlinear differential equation in the variables E and x results. This equation cannot be solved analytically, and, therefore, was programmed in BASIC for numerical solution on a General Electric 265 computer. The output of the computer are E and I as a function of x and, hence, also the total pore current I_t as a function of the total polarization E_a.

Porous gas electrode.—We approximate the complex structure of a gas electrode of known porosity p with an array of nonintersecting macro pores of uniform diameter equal to the measured mean diameter $2r$.

Porous gas electrodes prepared from ultra-fine catalyst powders (22), exhibit a micro pore structure within the system of macro pores. Figure 1 shows an electron micrograph[3] of an electrode cross section taken at a magnification of 100,000X. The average diameter of the catalyst particles is 50Å. Large numbers of these particles form clusters with an average size of 500-2000Å. The individual particles in a cluster form micro pores with diameters between 10 and 50Å. Most of the clusters are linked together and have irregularly shaped voids (macro pores) between them. The macro pores have diameters in the 500-5000Å range and exhibit considerable surface roughness. The Teflon particles (not visible in the micrograph) range from 2000 to 5000Å (22). Since the pore volume increases with the second power of the radius while the internal surface area increases only with the first power, most of the internal pore volume, *i.e.*, the porosity, is due to the large pores, while most of the internal surface area is due to the small pores.

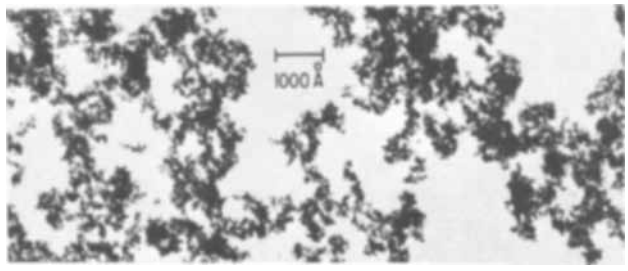

Fig. 1. Electron micrograph of electrode cross section at 100,000X (courtesy Dr. L. W. Niedrach).

We may, therefore, calculate the number of macro pores per unit of projected surface area from the measured values of the macro pore radius and the porosity, *i.e.*

$$n = p/\pi r^2 \quad [10]$$

The apparent current density i_a of the electrode (referred to the projected area) is then given by the current contributed by a single pore times the number of macro pores. In terms of the pore current per unit of circular perimeter, I_t/W, we can write

$$i_a = (2p/r)I_t/W \quad [11]$$

I_t/W contains the parameters H and δ_o which, for a porous electrode, have the significance of a mean film height and a mean film thickness. No reliable measurements of these two quantities are available.

We must also consider that the model assumes smooth pore walls exposing only catalytically active material, while in fact the pore walls are rough, contain micro pores, and expose active and inactive material. The current density referred to the projected area of the macro pore walls is, therefore, changed in proportion to the wall roughness and the catalyst fraction. Both are functions of the current density if the reaction is discharge limited, as the electric field penetrates more into the micro pores when the current density decreases. However, if the reaction is diffusion limited, the wall roughness and the catalyst fraction are constant as long as the film thickness is large compared to the micro pore radii. A treatment in two independent variables would be required to take these effects into account. This is beyond the scope of this paper. We will consider the wall roughness and catalyst fraction as constant and account for them by introducing an adjustable parameter f, changing the local current density i in Eq. [2] and [3] to fi.

Two special cases are amenable to analytical solutions and serve to illustrate the effect of f on the apparent current density of the porous electrode. For the case of diffusion control and electric field penetration $<<$ film height we obtain

$$i_a = (4p/r)\sqrt{\mathbf{F}Dc_of/\rho}\,\sqrt{E_a - (1 - \exp(-2\phi E_a))/2\phi} \quad [12]$$

[3] The loan of the relevant micrograph by Dr. L. W. Niedrach is gratefully acknowledged.

For the case of diffusion control and electric field penetration >> film height we obtain the limiting current

$$i_{al} = (4p/r)\mathbf{F}Dc_o fH/\delta_o \qquad [13]$$

which should commence at the polarization

$$E_l = \mathbf{F}Dc_o\rho f(H/\delta_o)^2 + E_H \qquad [14]$$

E_H is the polarization at the upper film end ($x = H$), and is approximately 50 mv.

Single Pore Polarization

We will now present computed polarization curves of individual pores for various film geometries. Although we have considered only the particular case of sulfuric acid electrolyte with concentrations 8-normal and 1-normal, the analysis can also be applied to other concentrations and other electrolytes.

Electrochemical parameters.—We have made use of the following values for the resistivity (23) of the electrolyte and the diffusivity (24) and solubility (24-26) of hydrogen in the electrolyte: $\rho = 1.21(8N)$ and 4.65 ($1N$) ohm cm, $D = 2.8\cdot10^{-5}$ ($8N$) and $3.7\cdot10^{-5}(1N)$ cm²/sec, $c_o = 4.2\cdot10^{-7}(8N)$ and $7.0\cdot10^{-7}(1N)$ moles/cm³. All values are for 25°C. The values for the diffusivity were extrapolated from measurements at 30°C and may be in error by 20%. The error of the solubility data should be less than 5%, that of the resistivity values less than 1%.

For the kinetic and thermodynamic parameters in Eq. [6] and [8] we have used the following values: $\alpha_V = \alpha_H = 0.5$, $i_{oV} = i_{oH} = 0.1$ A/cm² (27, 28), $\theta_o = 0.98$ (27, 29). α_V and α_H may assume values between 0.4 and 0.6, θ_o values between 0.9 and 1.0 on Pt, smaller on Ni. Depending on the "activity" of the catalyst, i_{oV} and i_{oH} on Pt may assume values an order of magnitude higher. Smaller values than 0.1 A/cm² are likely on Ni and on Pt in systems of limited purity. The effect of these parameters on the polarization curves will be discussed elsewhere.

Effect of H and δ_o.—Figure 2 shows a plot of the pore current I_t per unit perimeter $W = 2\pi r$ as a function of the applied voltage or polarization E_a, both measured at $x = 0$. The plot applies to $1N$ H_2SO_4 and shows the effect of various film heights and thicknesses on the shape of the polarization curve. We note that (*i*) a limiting current of 0.5 mA/cm is obtained for all film heights and thicknesses whose ratios $H/\delta_o = 100$ (curves 4, 5, and 6), (*ii*) the curves exhibit an inflection point

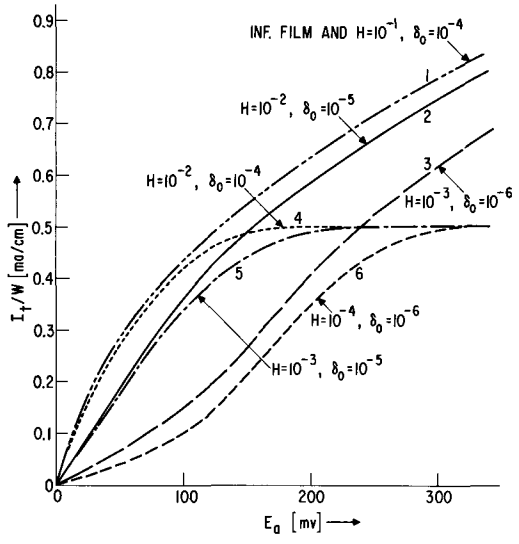

Fig. 2. Effect of film geometry on polarization curves for individual pore in $1N$ H_2SO_4, I_t/W = pore current per unit of pore perimeter, E_a = electrode polarization or applied potential, H = film height, δ_o = film thickness.

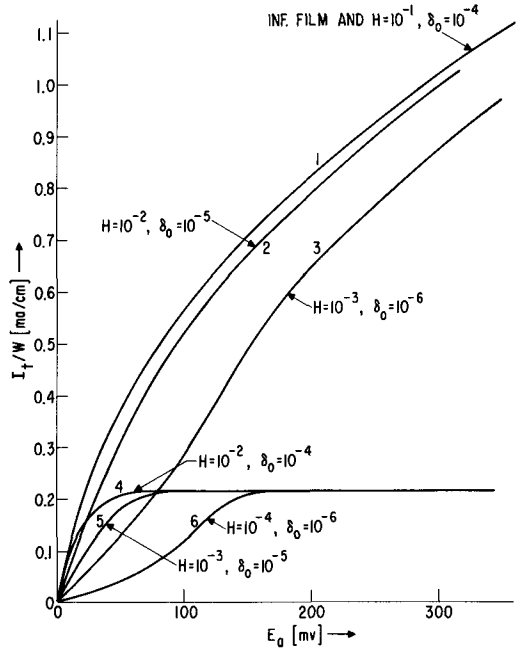

Fig. 3. Effect of film geometry on polarization curves for individual pore in $8N$ H_2SO_4.

and become increasingly concave as the film thickness decreases while for the larger thicknesses the curves are convex throughout, (*iii*) the film height has no pronounced effect on the curves for voltages $E_a < 100$ mv. In fact, in the case of $\delta_o = 10^{-4}$ cm any increase of H beyond 10^{-1} cm has no effect on curve 1 ("infinite film") throughout the voltage range.

The polarization curves for $8N$ H_2SO_4 are shown in Fig. 3. The character of the curves is very similar to that obtained for $1N$ H_2SO_4. However, the magnitude of the currents is different. Thus, the limiting current for $H/\delta_o = 100$ is 0.22 mA/cm instead of 0.5 mA/cm and starts at potentials considerably less anodic. The currents for $H/\delta_o = 1000$, on the other hand, are some 25% larger than for $1N$ H_2SO_4.

For small film thicknesses and small polarizations, the reaction rate is controlled by the charge transfer step, *i.e.*, the Heyrowsky and the Volmer mechanism (Eq. [5] and [7]), and the curves exhibit the characteristic concave shape (curves 3 and 6). As E_a and, hence, $E(x)$ increase, the rate of the transfer reactions Eq. [6] and [8] increases exponentially. Therefore, the regions of the film close to the bulk solution come under diffusion control. Since diffusion control is associated with a convex curve shape, the curves run through an inflection point. For yet larger values of E_a, even the regions of the film close to the upper end come under diffusion control, and we approach the limiting current. Curves 6 in Fig. 2 and 3 are examples for this behavior.

In accordance with Eq. [13] the limiting currents are proportional to H/δ_o and are larger in $1N$ than in $8N$ H_2SO_4. As H/δ_o increases, the onset of the limiting current is delayed according to Eq. [14]. For $\delta_o > 10^{-5}$ cm, diffusion control prevails and H hardly affects the current as long as $I_t << I_l$. For values of i_{oH} and i_{oV} larger than 0.1 A/cm², curves 2, 3, 5, and 6 would be less affected by slow discharge and, hence, approach curves 1 and 4 more closely.

Comparison with Experiments

Source of experimental data.—We have chosen the detailed experimental study of Austin and Almaula (21) with typical data for wet-proofed electrodes as the basis for comparison with our analysis. These authors obtained accurate polarization data on four porous hydrogen diffusion electrodes prepared with different known amounts of platinum, graphite, and

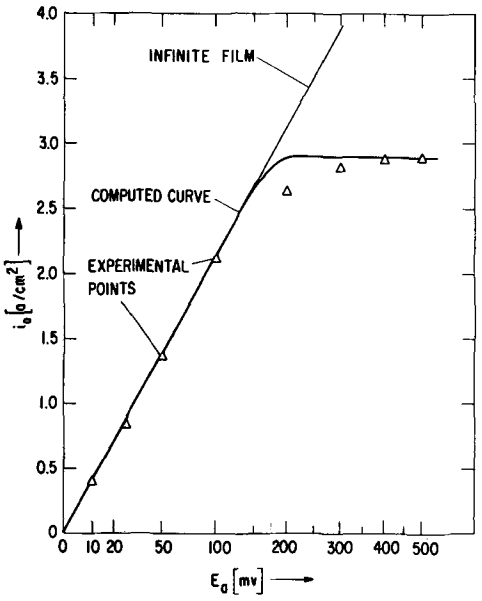

Fig. 4. The values on the abscissa have been calculated from $\sqrt{E_a - (1-e^{-2\phi E_a})/2\phi}$. Experimental data (triangles) for Teflon-bonded electrode SM1 [ref. (21)] and polarization curve computed from film model; $\phi = F/RT$, i_a = current density referred to apparent surface area, E_a = electrode polarization.

Teflon in 1N H_2SO_4. They also determined the porosity p, and the mean macro pore radius r. With the exception of one of the four electrodes, the macro pore radii lie between 0.6 and 3.2μ. This is more than two orders of magnitude larger than the micro pore radii. Hence, most of the internal pore volume is due to the macro pores, and we may calculate the apparent current density i_a from Eq. [11], substituting for p the measured total porosity and for r the macro pore radius.

For the electrochemical parameters the same values were used as for the single pore polarization except for i_{oH} and i_{oV} for which 1 A/cm² was employed. This value is reasonable for platinum electrodes in a high state of activity (27, 28).

Polarization curves of wet-proofed electrodes.— Figure 4 shows experimental points (triangles) for i_a in the case of Austin and Almaula's Teflon bonded platinum electrode SM1 as a function of $\sqrt{E_a - (1 - \exp(-2\phi E_a))/2\phi}$. Up to 100 mv the points lie on a straight line through the origin. A limiting current of 2.9 A/cm² is obtained at polarizations larger than 400 mv. This behavior is characteristic (1, 12, 13) for the existence of electrolyte films. The curve in Fig. 4 was computed by using the measured values for the porosity ($p = 0.72$) and the mean pore radius ($r = 3.2\mu$). The values $H = 11\mu$, $\delta_o = 1030$Å, and $f = 1.2$ were chosen to match the experimental values for curve slope and limiting current.

Good agreement is obtained between the computed curve and the experimental points except for the potential region 100-300 mv where the predicted currents are up to 10% too high. Curves identical to curve 1 are obtained for any set of values $H > 11\mu$, $\delta_o > 1030$Å, as long as $H/\delta_o = 107$, and for any values i_{oH} or $i_{oV} > 0.5$ A/cm². For smaller values of H and δ_o, however, the computed curves would exhibit an increasingly concave shape (looking from above) at potentials smaller than 100 mv. This behavior is not observed and, thence, $H = 11\mu$ and $\delta_o = 1030$Å constitute lower limits for the film height and film thickness for the electrode SM1.

Figure 5 shows a plot of i_a against $\sqrt{E_a - \ldots}$ for a platinized and wet-proofed carbon electrode, labeled FC100 by Austin and Almaula (21). The measured values $p = 0.2$ and $r = 0.25\mu$ (Pure Carbon Company catalogue values) along with the assumed parameters $H = 196\mu$, $\delta_o = 250$Å, and $f = 4.9 \cdot 10^{-4}$ were used for

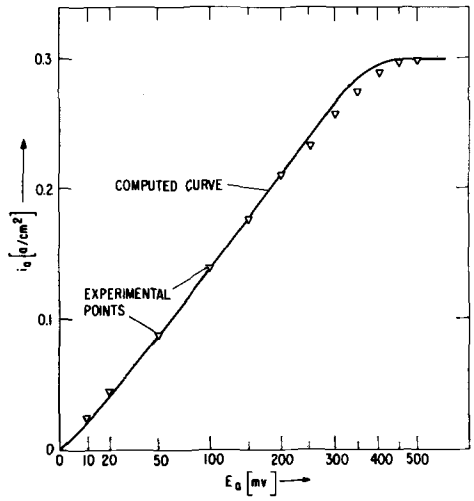

Fig. 5. The values on the abscissa have been calculated from $\sqrt{E_a - (1-e^{-2\phi E_a})/2\phi}$. Experimental data (triangles) for Teflon-bonded electrode FC100 [ref. (21)] and curve computed from film model.

the computations. An excellent fit between the data points (triangles) and the computed curves is obtained with these values. The slightly concave curve shape for $E_a < 150$ mv is an indication of some charge transfer hindrance due to the small film thickness δ_o. Apart from this small deviation, however, the curves in Fig. 4 and 5 follow the behavior predicted by Eq. [12], [13], and [14] for slow H_2 diffusion through a film.

Figure 6 summarizes experimental data (characterized by various symbols) obtained by Austin and Almaula on four different electrodes, SM1, CAA1, SM2, and FC100, in a linear plot of i_a against E_a. The curves were all computed on the basis of the film model. The structure parameters used for electrode CAA1 are $p = 0.73$, $r = 2.8\mu$, $H = 84\mu$, $\delta_o = 2800$Å, and $f = 0.135$, those for electrode SM2 are $p = 0.60$, $r = 0.65\mu$, $H = 117\mu$, $\delta_o = 650$Å and $f = 4.4 \cdot 10^{-4}$. While the curve fit is very good for electrodes FC100 and SM2, the predicted currents for CAA1 and SM1 are some 10-20% larger than observed in the potential range 100 mV $< E_a <$ 300 mV. If much smaller values for H and δ_o had been chosen, the predicted curves would have adopted a concave shape at low potentials. The observed convex shape of all four curves shows that the rate of hydrogen oxidation on these four porous electrodes is overwhelmingly determined by slow H_2 diffusion.

Conclusions

From a comparison between polarization curves predicted by the film model and curves observed on wet-proofed porous hydrogen electrodes coupled with an evaluation of electron micrographs of such electrodes we draw the following conclusions.

1. For large film thicknesses and large charge transfer rates ($\delta_o > 0.5\mu$ for $i_o > 0.1$ A/cm² or $\delta_o > 500$Å for $i_o > 1$ A/cm²) the polarization curves are determined by slow diffusion through the film.

2. For ratios film height to film thickness of several hundred or less, limiting currents are obtained. For ratios of the order of 1000 or more, the curves follow the $i - \sqrt{E_a}$ relation predicted by the infinite film model.

3. As δ_o and/or i_o decrease, charge transfer limitation is introduced, and the curves are concavely shaped at low potentials (< 50 to 150 mV).

4. Polarization curves obtained on various types of partly wet-proofed porous hydrogen electrodes are in very good agreement with the curves predicted from the film model when only the macro pores of known

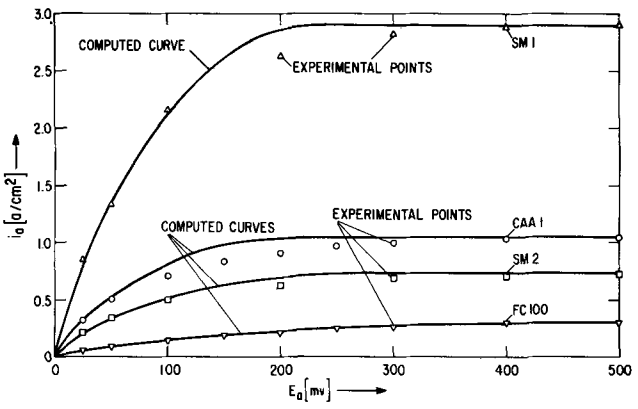

Fig. 6. Experimental data (various symbols) for four different Teflon-bonded electrodes [ref. (21)] and curves computed from film model.

diameter are considered and the micro pores are disregarded. Diffusion control prevails.

5. This indicates that the micro pores are flooded and the walls of the macro pores are covered with an electrolyte film of a thickness large compared to the micro pore diameters (10-50Å).

6. The film thicknesses range from 250 to 3000Å, the film heights from several hundred to several thousand film thicknesses.

7. The presence of hydrophobic particles of 2000-5000Å diameter prevents complete flooding of the macro pores and limits the film height.

Adsorption and Oxidation of Ethane, n-Butane, and n-Octane on Platinum Electrodes

G. Aronowitz*[1] and R. J. Flannery*

Research and Development Department, American Oil Company, Whiting, Indiana

ABSTRACT

Ethane, n-butane, and n-octane are adsorbed from aqueous sulfuric acid solutions onto platinum electrodes at 0.25-0.55V *vs.* NHE. At potentials higher than 0.30V how fast the surface coverage builds up depends on both the rate of adsorption and the rate of anodic oxidation. At 0.25-0.30V adsorption can be studied independently. Rate data show that adsorption is potential independent and first order in apparent uncovered surface area. Studies of the kinetics of anodic oxidation and studies of hydrogen codeposition indicate that the adsorbed species are similar for ethane and n-octane but differ for n-butane adsorption.

Electrooxidation of hydrocarbons is currently of interest in fuel cell technology. However, the oxidation of a complex hydrocarbon molecule occurs in many successive steps, of which one or more would be expected to involve adsorption. Consequently the development of adequate kinetic models for the process requires a detailed knowledge of the role played by the adsorption of reactants, intermediates, and products.

The build-up of intermediates has been detected during the electrooxidation of methanol and formic acid (1, 2), olefins (3), and, more recently, during the electrooxidation of saturated hydrocarbons (4, 5) on platinum electrodes. But the identities of the adsorbed species and the nature of the adsorption processes remain in doubt.

In this study the build-up of adsorbed intermediates attending electrooxidation of ethane, n-butane, and n-octane on platinum electrodes in aqueous sulfuric acid solution was observed in the potential region of interest in fuel cell technology by constant current and controlled potential methods. Studies of the kinetics of electrooxidation by a potential step method have provided a basis for analyzing the build-up process. Hydrogen codeposition studies have provided useful clues to the nature of the adsorbed species.

Experimental

A Pyrex electrolytic cell of conventional design was employed. The polarizing electrode was a 1.5-in. diameter platinum gauze basket. It was connected to a $Hg/Hg_2SO_4/Hg_2SO_4$(sat'd) + 1.0M H_2SO_4 reference electrode through a salt bridge and Luggin capillary filled with test solution. All electrode potential values cited here are given with reference to a normal hydrogen electrode.

The helium used was Bureau of Mines analytical reagent grade. The hydrocarbons were Phillips research grade.

The electrical apparatus was conventional. A Brinkman Model 61-R fast-rise potentiostat maintained the electrode potential. A galvanostat was constructed using banks of resistors and a 90V "B" battery. Mercury relays provided rapid switching between galvanostat and potentiostat and between reference potential sources. The latter were constructed from ten-turn potentiometers and batteries. The switching arrangement was sufficiently versatile for the potential step sequences employed in these studies. A Tektronix Model 531A oscilloscope with a type D preamplifer, equipped with an oscilloscope camera using Polaroid film, was used to record electrode potential *vs.* time curves.

Test electrodes were sputtered platinum film electrodes supported on bright platinum foils and were prepared following a technique developed in this laboratory (6). Electrical connection was made with a platinum wire spot welded to the foil and sealed in a soft glass tube. Electrodes were degreased in hot acetone and rinsed in conductivity water before being used. True surface areas of these electrodes were calculated from apparent areas and the charge required to strip cathodically the platinum surface oxide which was normalized to unit roughness by comparison with values reported for bright platinum (7). Roughness factors for the sputtered films varied from about 50 to 70. All results are presented on the basis of 1 cm^2 of apparent area but are normalized to an electrode having a roughness factor of 57. Thus Q and i values given per square centimeter can be divided by 57 to obtain Q and i for 1 cm^2 of real area. Twelve electrodes were used with no variation in behavior between electrodes. Electrodes were subjected to a standard activating treatment before being used on any given day. This consisted of cycling the electrode potential between 1.15 and 0.35V 6-8 times. Following this, the electrode was maintained at 1.15V for 2 min. Variation of electrode potential between 1.15 and 1.75V (mild oxygen evolution) made no differences in subsequent experimental results but treatment at potentials less positive (noble) than 1.15V resulted in a loss in activity for hydrocarbon electrooxidation and a general lack of reproducibility.

The test solution was 1.0M H_2SO_4 prepared from water obtained from a Barnstead Model E-1 conductivity water still. The conductivity of the water did not exceed 6.0×10^{-7} ohm^{-1} cm^{-1}. Test solutions were pre-electrolyzed in a separate vessel for at least 72 hr at 2.0 mA/cm^2 on bright platinum electrodes before admittance to the cell. All experiments were conducted at 65° ± 1°C. Helium was bubbled through the cell solution to provide an inert atmosphere and provision was made to switch to hydrocarbon gas flow without admitting air or impurities to the cell. Gases were washed in conductivity water before admittance to the cell and were permitted to contact only Pyrex glass or Teflon tubing to avoid contamination. In the n-octane studies, a large excess of n-octane was added to the cell solution and stirred vigorously until saturation was apparently achieved.

Rates of Build-up of Adsorbed Species

Surface species were detected by anodic charging curves. After an activation treatment, the electrode potential was stepped to a value in the range of 0.20-0.55V and maintained there to permit adsorption. After a given time a constant anodic current was applied, and the potential was followed as a function of

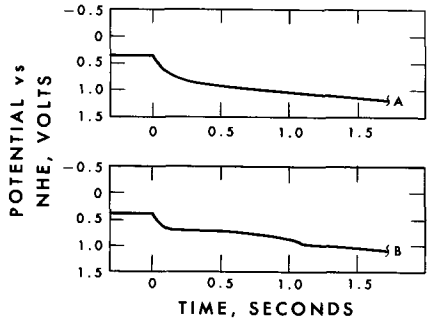

Fig. 1. Potential vs. time curves for the anodic stripping of ethane after a given time of adsorption on Pt at 65°C and 0.35V. Curve A, adsorption time = 0; curve B, adsorption time = 300 sec.

time. If the anodic current is high enough, the charge involved in the arrest is independent of the stripping current and thus reflects only the charge used in the anodic stripping of surface species. This surface charge is denoted as Q.

Oscillograms obtained after adsorption of ethane at 0.35V at various adsorption times are shown in Fig. 1. Trace A is identical to traces obtained with the solution free of hydrocarbons. In trace B a potential arrest appears in the range 0.60-0.75V. The length of the arrest, τ, increases with increasing adsorption time. Solutions saturated with n-butane and n-octane show similar arrests.

Figures 2, 3, and 4 show curves of Q_{ethane}, $Q_{\text{n-butane}}$, and $Q_{\text{n-octane}}$ *vs.* adsorption time, over a range of potentials. The curves show a build-up of adsorbed species with time until steady-state conditions are achieved. The charge at steady state is denoted as Q_s. The net rate of build-up, dQ/dt, decreases with increasing Q. Both dQ/dt at a given adsorption time and Q_s decrease with increasing potential. At potentials of 0.25-0.30V the curves tend to converge, and Q_s approaches a limiting value, $Q_{s,max}$. Below 0.20V, Q declines sharply with potential, and adsorbed hydrogen can be detected. The 0.45 and 0.50V curves for n-octane are unusual. Q decreased with time after apparently attaining Q_s. No evidence for this apparent desorption appears at lower potentials even after several hours of adsorption time.

The above-described behavior strongly suggests that adsorbed species undergo electrooxidation (8). Then

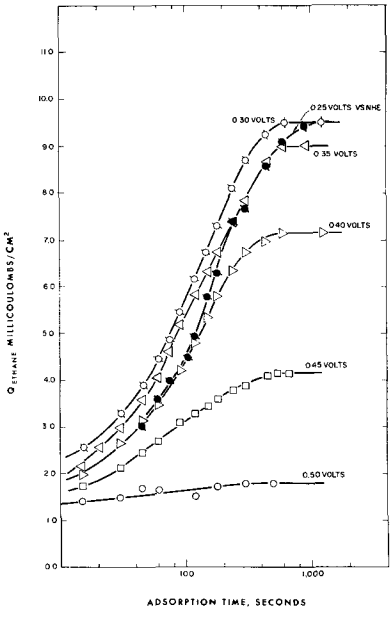

Fig. 2. Q_{ethane} vs. adsorption time

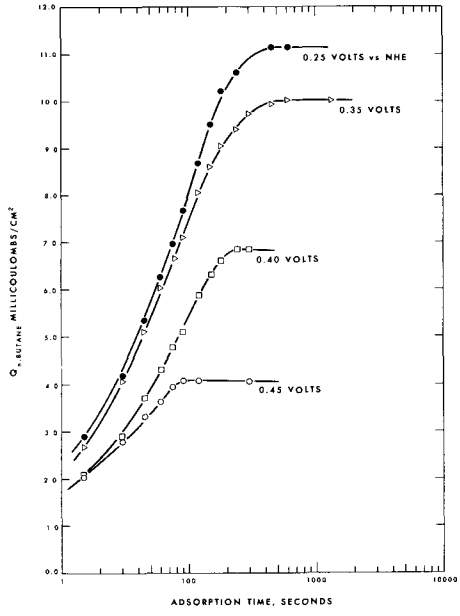

Fig. 3. $Q_{\text{n-butane}}$ vs. adsorption time

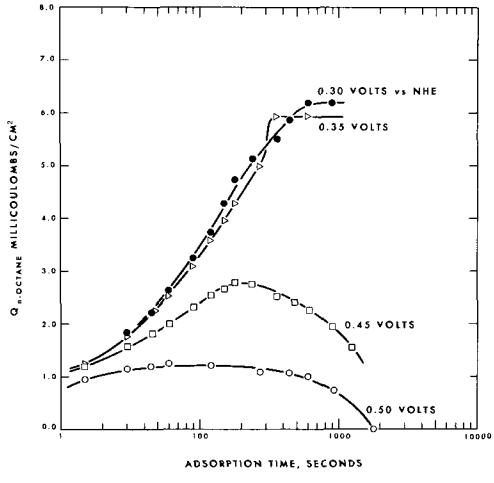

Fig. 4. $Q_{\text{n-octane}}$ vs. adsorption time

dQ/dt must depend on the rate of this electrooxidation as well as on the rate of adsorption. If adsorption occurs via a dissociation mechanism to produce partially dehydrogenated fragments and hydrogen, then recombinative desorption can be discounted because of the rapid anodic oxidation of adsorbed hydrogen in the potential range involved.

The attainment of a maximum value for Q_s at low potentials implies that saturation adsorption occurs. Consequently, $Q_{s,max}$ represents the limiting fraction of surface sites available for adsorption, and the free fraction of available surface is $(Q_{s,max} - Q)/Q_{s,max}$. Assuming that the rate of adsorption is first order with respect to this quantity, the net rate of build-up of adsorbed species can be expressed as follows

$$\frac{dQ}{dt} = k_{ad}\frac{(Q_{s,max} - Q)}{Q_{s,max}} - k_{ox}Q\, e^{\alpha nFE/RT} \qquad [1]$$

where k_{ad} and k_{ox} are constants at constant temperature and hydrocarbon concentration.

At sufficiently low values of E, where the rate of adsorption is proportional to dQ/dt, the second term on the right-hand side of Eq. [1] can be dropped. Integrating the resultant equation and taking logarithms then gives

$$\log (Q_{s,max} - Q) = \log Q_{s,max} - \frac{k_{ad}}{2.303Q_{s,max}}t \qquad [2]$$

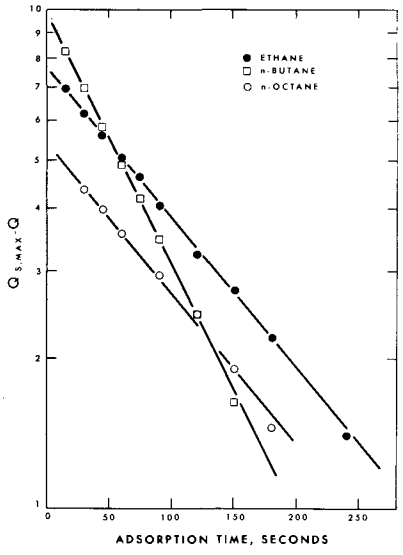

Fig. 5. Log ($Q_{s,max} - Q$) vs. adsorption time

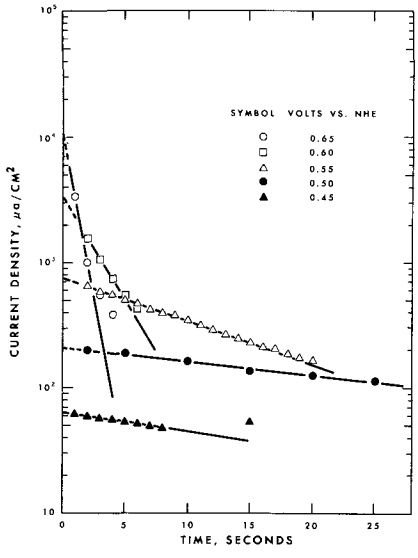

Fig 6. Log i vs. time passed during oxidation of adsorbed ethane at constant potential, E.

Figure 5 shows semilog plots of $(Q_{s,max} - Q)$ *vs.* t for ethane, n-butane, and n-octane adsorption in the range 0.25 — 0.30V. From the slopes of these curves and the values of $Q_{s,max}$, the following values of k_{ad} were computed:

Fuel	k_{ad} millicoulombs/cm²sec
ethane	0.0657
n-butane	0.1285
n-octane	0.0432

Kinetics of Electrooxidation of Adsorbed Species

Values for k_{ox} and $\alpha n\mathbf{F}/RT$, needed to test the validity of Eq. [1], were obtained by the following potential step method:

a. After activation, the electrode was maintained at an adsorption potential of 0.35V long enough to insure attainment of steady-state conditions.

b. The potential was raised to a value, E, in the range 0.425-0.650V, and the resulting anodic currents were measured simultaneously as a function of time.

c. An anodic galvanostatic pulse was applied after a fixed time at E, and Q was determined by the anodic charging curve method.

Anodic currents observed for short times during step *b* are due almost entirely to electrooxidation of adsorbed species and can be related to the instantaneous value of Q as follows

$$i = -\frac{dQ}{dt} = k_{ox}Q\, e^{\alpha n\mathbf{F}E/RT} \qquad [3]$$

The boundary condition was established in step *a*

$$Q = Q_{s,0.35} \text{ when } t = 0$$

where t now refers to the duration of step *b*. Integrating Eq. [3], substituting for Q, taking logarithms, and rearranging terms then gives

$$\log i = \log k_{ox}Q_{s,0.35} + \frac{\alpha n\mathbf{F}E}{2.303RT} - \frac{k_{ox}}{2.303}\, e^{\alpha n\mathbf{F}E/RT}\, t \qquad [4]$$

$$\log Q = \log Q_{s,0.35} - \frac{k_{ox}}{2.303}\, e^{\alpha n\mathbf{F}E/RT}\, t \qquad [5]$$

Figure 6 shows semilog plots of i *vs.* t for ethane at several values of E. Similar results were obtained for n-octane. The curves tend to become nonlinear with time probably because of readsorption of dissolved hydrocarbon and subsequent oxidation on freshly produced sites. Figure 7 shows semilog plots of the slopes $-(k_{ox}/2.303)$ exp $\alpha n\mathbf{F}E/RT$, and intercepts, log $k_{ox}Q_{s,0.35}$ + $\alpha n\mathbf{F}E/2.303\ RT$, of the curves of Fig. 6 and the corresponding n-octane curves plotted as a function of E. Figure 8 is a semilog plot of i for n-butane at t = 0.5 sec *vs.* E. These data represent approximate values of the intercepts of Eq. [4]; they could be slightly low.

Figure 9 shows semilog plots of Q *vs.* t obtained for n-octane in step c. Similar curves were obtained for ethane and n-butane. Figure 10 shows semilog plots of the slopes of the log Q *vs.* t curves, $-(k_{ox}/2.303)\exp \alpha n\mathbf{F}E/RT$, *vs.* E for ethane, n-butane, and n-octane.

The rate constant, k_{ox}, and the Tafel slope, $2.303RT/\alpha n\mathbf{F}$, computed from the data in Fig. 6-10, are shown in Table I.

In Figure 8 the data points of the log i at t = 0.5 sec *vs.* E curve for n-butane break off the Tafel plot at 0.65V. Since mass transfer limitations cannot be a factor, this behavior suggests a change in kinetics. To explore this further, an analysis was made of the anodic charging curves obtained during galvanostatic stripping. By substituting $Q_{t=0}[(\tau - t)/\tau]$ for Q in Eq. [3], integrating, taking logarithms, and using the established relationship $i\tau = Q_{t=0} = Q_{s,0.35}$, we obtain

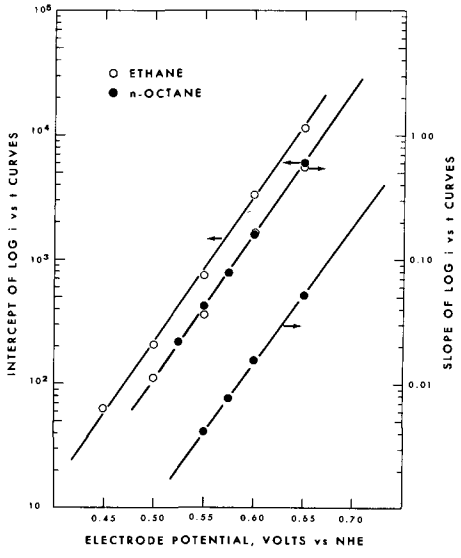

Fig. 7. Log of intercept and slope of Eq. [4] vs. E for ethane and n-octane.

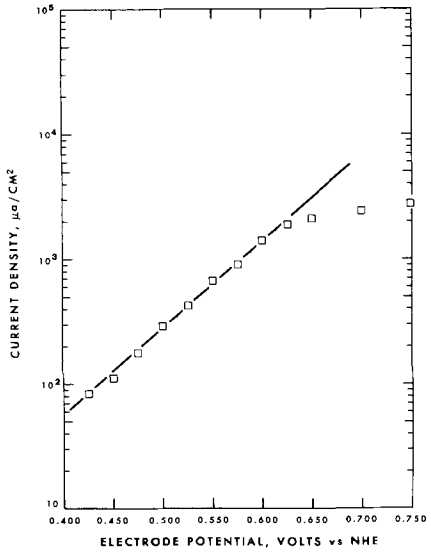

Fig. 8. Log i at $t = 0.5$ sec vs. E for n-butane

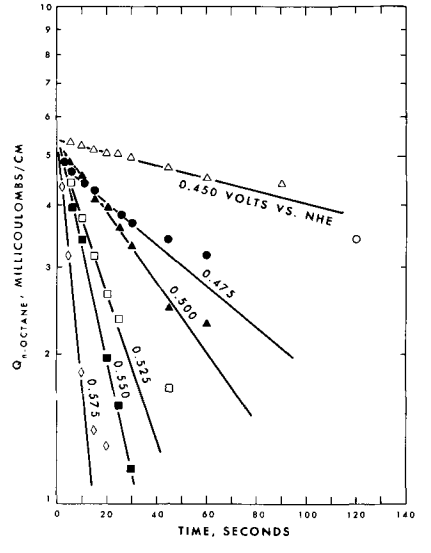

Fig. 9. Log Q vs. time of oxidation of adsorbed n-octane at constant potential, E.

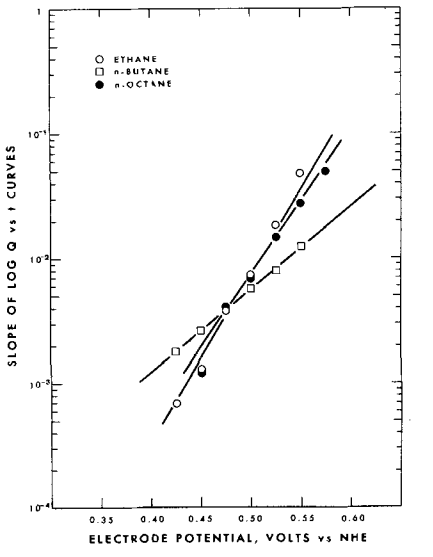

Fig. 10. Log slope of Eq. [5] vs. E for ethane, n-butane, and n-octane.

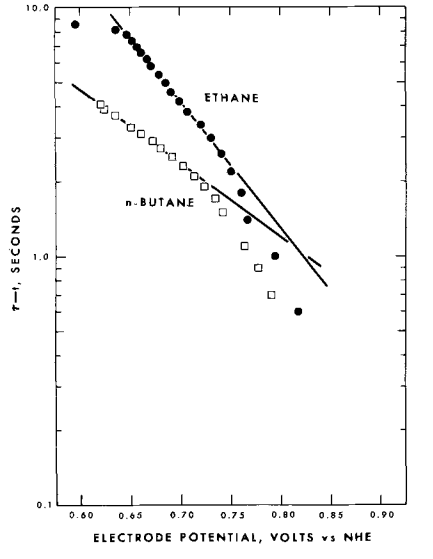

Fig. 11. Time remaining in potential arrest, τ-t vs. E during galvanostatic oxidation of adsorbed ethane and n-butane.

$$-\log(\tau - t) = \frac{\alpha n \mathbf{F} E}{2.303RT} + \log k_{ox} \qquad [6]$$

where τ = length of potential arrest in seconds, and t = time passed during the galvanostatic charging step (step c above).

Figure 11 shows semilog plots of $\tau - t$ vs. E for ethane and n-butane. Tafel slopes and k_{ox} values computed from the slopes and intercepts of the curves in Fig. 11 are

Adsorbate	k_{ox}, sec^{-1}, cm^{-2}	$2.303RT/\alpha n\mathbf{F}$
Ethane	4.00×10^{-4}	0.198
n-Butane	3.50×10^{-3}	0.337

Comparing these values with those in Table I indicates that the mechanism of anodic stripping changes at potentials higher than 0.60V.

Because knowledge of how anodic stripping affects subsequent adsorption should indicate the nature of the products of stripping, the following study was carried out. After adsorption at 0.25 or 0.30V for a time sufficient to attain $Q_{s,max}$, anodic stripping was performed by two methods: (*a*) treatment at 0.575V for 2 to 3 min; (*b*) application of an anodic galvanostatic pulse of sufficient duration just to complete the potential arrest. The electrode potential was then stepped to 0.35V for a time, t, to permit readsorption, and adsorption was measured by the anodic charging method. The Q vs. t curves so obtained were compared with the curves of Fig. 2-4. The two methods of oxidizing the surface species led to identical results. No difference was observed for ethane, but the n-butane and n-octane curves were shifted to lower Q values by some 10-15%. However, a treatment at 1.15V for 10 sec re-established the original Q vs. t behavior.

Although a partially oxidized intermediate, such as CO, would be expected to remain on the surface and block subsequent readsorption, the results suggest that

Table I. Tafel slope and k_{ox} from Eq. [4] and [5]

Fuel	Slope of Eq. [4]	Intercept of Eq. [4]	Slope of Eq. [5]
	Tafel slope, $2.303RT/\alpha$ nF		
ethane	0.086	0.086	0.073
n-butane	—	0.144	0.152
n-octane	0.086	0.086	0.086
	Rate constant, k_{ox}, sec^{-1} cm^{-2}		
ethane	3.82×10^{-8}	3.82×10^{-8}	2.51×10^{-9}
n-butane	—	9.55×10^{-6}	6.68×10^{-6}
n-octane	3.72×10^{-9}	3.02×10^{-8}	2.69×10^{-8}

complete conversion to CO_2 occurs during anodic stripping of adsorbed ethane (9). The stripping at potentials below 1.15V evidently fails to convert 100% of the adsorbed n-butane or n-octane to CO_2, and so leaves a residue which poisons a small portion of the surface available for readsorption.

Analysis of the Net Rate of Build-up of Adsorbed Species

Another limiting case arises when steady-state conditions exist. In this case the conditions $Q = Q_s$ and $dQ/dt = 0$ can be combined with Eq. [1]. Integrating the resulting equation, taking logarithms, and rearranging terms

$$-\log \frac{Q_s}{Q_{s,max} - Q_s} = \frac{\alpha n \mathbf{F} E}{2.303RT} + \log \frac{Q_s k_{ox}}{k_{ad}} \quad [7]$$

Figure 12 is a semilog plot of $Q_s/Q_{s,max} - Q_s)$ *vs.* E for ethane. Using the slope and intercept of this curve along with the previously obtained value of k_{ad}, values of 0.084V for the Tafel slope, and 3.56 x 10^{-8} sec^{-1} for k_{ox} were computed. These agree favorably with values in Table I.

Integrating Eq. [1], taking logarithms, and rearranging terms gives

$$t = -\frac{2.303}{k_{ad}\beta} \log (1 - \beta Q) \quad [8]$$

where

$$\beta = \frac{1}{Q_{s,max}} + \frac{k_{ox}}{k_{ad}} e^{\alpha n \mathbf{F} E/RT}$$

Semilog plots of $(1 - \beta Q)$ *vs.* t were constructed with values of k_{ox} and the Tafel slope averaged from all but three values from Table I. These are presented in Fig. 13 and 14 for ethane and n-octane. Curves for n-butane showed behavior similar to the n-octane curves. Values of the slope, $-2.303/k_a\beta$ were determined from the linear portions of the curves. These data are given in Table II, which also gives, for comparison, the corresponding slope values computed directly from previously calculated k_{ad} values and from the data presented in Table I.

The greatest deviation from linearity occurred at the high potentials and low ordinate values or high Q values. At 0.25 or 0.30V the slopes are nearly equal to the corresponding slope of Eq. [2]; $-2.303Q_{s,max}/k_{ad}$. This behavior is expected since when $E << \alpha n\mathbf{F}/RT$, $\beta\alpha 1/Q_{s,max}$. The ethane data fits Eq. [8] best. The readsorption studies indicate that no residue was formed during anodic stripping of adsorbed ethane. The apparent slowing of the build-up of adsorbed n-butane and n-octane above 0.35V at sufficiently long adsorption times could thus be caused by build-up of a residue which is difficult to remove by anodic treatment at potentials below surface oxide formation. Anodic oxidation could be interfering with adsorption at the more positive potentials.

Coverage of Hydrogen Adsorption Sites by Hydrocarbons

The number of hydrogen adsorption sites consumed in the adsorption of the hydrocarbons was estimated by measuring the decrease in cathodic charge required to form an adsorbed hydrogen layer after adsorption of hydrocarbon. The potential step program was used

Table II. Comparison of calculated and observed values of the slope of Eq. [8]

with one modification, after adsorption for a fixed time at 0.35V, a constant cathodic current was applied and the electrode potential measured as a function of time. The cathodic charge, Q_H, was computed from the length of the potential arrest occurring in the range 0.05-0.25V. The displaced cathodic charge, $Q_{H,t=0} - Q_{H,t}$ (t = hydrocarbon adsorption time), was compared to the charge required to strip adsorbed hydrocarbons anodically. The ratios of anodic to displaced cathodic charge were: ethane, 1.5; n-butane, 6.5; n-octane, 1.2, with an average deviation less than 6% over a broad range of adsorption times. From these ratios, $Q_{s,max}$, and $Q_{H,t=0}$, the maximum surface coverages of platinum sites, $\theta_{s,max}$, were computed: ethane, 0.44; n-butane, 0.12; n-octane, 0.37.

To determine whether codeposition of hydrogen would affect the state of the adsorbed hydrocarbon or *vice versa*, the following experiments were performed. After adsorption at 0.35V for a time sufficient to attain Q_s, the electrode potential was stepped to 0.1V and maintained for a time $t_{0.1}$, to attain hydrogen coverage free on sites. A constant anodic current was applied and an anodic charging curve obtained. For ethane and n-octane Q_s was unchanged even after a 30-min treatment at 0.1V. The ratios of $Q_{s,0.35}$ to displaced anodic charge for adsorbed hydrogen oxidation, were nearly identical to values cited above for the corresponding ratio of $Q_{s,0.35}$ to displaced cathodic charge. The behavior of n-butane differed from that of ethane and n-octane. The $Q_{n\text{-butane}}$ value obtained after treatment at 0.1V for $t_{0.1}$ = 1 min to $t_{0.1}$ = 30 min dropped to ½ $Q_{s,0.35}$, and the potential arrest for anodic stripping of adsorbed n-butane shifted to less noble values by some 100 mv.

If the potential is stepped from 0.1 to 0.35V and an anodic pulse applied after a time $t_{0.35}$, both $Q_{s,0.35}$ and the form of the arrest for adsorbed butane oxidation revert to their original state (as for no treatment at 0.1V) after $t_{0.35}$ = 5 min, indicating a complete reversal of the adsorbed hydrogen-adsorbed n-butane interaction and readsorption of material desorbed in the hydrogen adsorption region.

One possibility for error in the estimated number of sites covered by adsorbed hydrocarbon could be the occurrence of reversible hydrogenation and dehydrogenation during cathodic hydrogen deposition and subsequent oxidation steps. This would make the maximum θ values observed appear too low.

Two potential arrests of approximately equal length, corresponding to strongly and weakly bound hydrogen, appear in both the anodic and cathodic charging curves. All three hydrocarbons adsorb preferentially on sites otherwise occupied by the strongly bound hydrogen.

Discussion

The fact that only a low number of electrons per site appear to be required for oxidation of adsorbed ethane and n-octane suggests the formation of a C_1 or C_2 partially oxygenated species. The close similarity of the rate constants for electrooxidation indicates the adsorbed species are the same for both ethane and n-octane.

Support for these views is found in the observations of Niedrach (4) during anodic galvanostatic treatment of platinum electrodes in 5*N* H_2SO_4 containing ethane. The adsorbed species failed to undergo cathodic hydrogenation. Niedrach concluded from this and other observations that the adsorbed material was an oxygenated C_1 species.

The behavior of adsorbed n-butane with respect to its oxidation kinetics, its charge requirements of 6.5 electrons/site for anodic oxidation, and its response to cathodic coadsorption of hydrogen contrast markedly with that of adsorbed ethane and n-octane. The lower $Q_{n\text{-butane}}$ value observed after treatment with cathodically generated hydrogen and the readsorption at 0.35V suggest that at least part of the adsorbed butane is dehydrogenated at 0.1V and desorbed. These findings agree with a recent study of n-butane adsorption at platinum electrodes using radiolabelling techniques (6); it showed that butane preadsorbed at 0.3V was partially desorbed during treatment at 0.1V. Apparently a partially dehydrogenated species is formed during n-butane adsorption.

The attainment of maximum coverage at values substantially less than unity during adsorption of hydrocarbons on platinum electrodes was reported by Gileadi *et al.* (10) who measured maximum θ values of 0.35 to 0.45 for ethylene adsorption on platinum electrodes. This could be connected with our observation that adsorption occurs only on strongly bound hydrogen sites. Based on the observed apportionment of the two types of adsorbed hydrogen of roughly 50% of each, the observed maximum coverages of ethane and n-octane of 44% and 36%, respectively, indicate nearly complete coverage of strongly bound hydrogen sites.

The failure to detect adsorption on weakly bound sites indicates that the species adsorbed on these sites cannot be observed in the anodic charging curve. Such species may fail to undergo C-C bond breaking or a surface rearrangement to the precursors of detectable species. The hydrogen coadsorption studies however imply that such species, if they exist, are rapidly desorbed in the hydrogen deposition region with small cathodic charge requirements. The adsorption-rate studies show first-order rate dependence on free available sites over a broad range of coverage for all the hydrocarbons studied and a potential independent rate constant. Apparently a rate-determining surface process occurs between the initial adsorption step and the subsequent oxidation to detectable species.

Acknowledgment

The authors wish to express their gratitude to Mr. Ramsey White for his assistance during the electrochemical measurements. The work was financially supported by the Advanced Research Projects Agency of the Department of Defense as part of Project Lorraine under Contract Nos. DA-11-022-ORD-4023 and DA-49-186-AMC-167(X). Overvoltage of Two Stepwise-Proceeding Electrode Reactions under Transient Conditions

I. H. Plonski

Institute for Atomic Physics, Bucharest, Romania

ABSTRACT

General equations are derived for the overvoltage of two stepwise-proceeding electrode reactions for the transient regime under galvanostatic conditions. Two shapes of η-t curves have been found depending on the mechanism and i values: for $i_{o1} > i_{o2}$ and $i > i_{critical}$, the η-t curves are peak shaped; for $i_{o1} > i_{o2}$ and $i \leq i_{critical}$, the η-t curves gave the usual form of monotone increasing η toward the steady-state value. At the same time, the intermediate ion concentration increases, following an S-shape curve: for $i_{o1} = i_{o2}$ and $i_{o1} < i_{o2}$, the η-t curves have the same form as for the $i_{o1} > i_{o2}$ and $i < i_{critical}$ case, but the intermediate ion concentration remains constant and equal to the equilibrium concentration for $i_{o1} = i_{o2}$ and decreases below the equilibrium concentration for $i_{o1} < i_{o2}$. The relationships concerned are of some help in assigning a mechanism and under specific conditions in calculating the exchange currents of both steps by using them in conjunction with experimental results.

The multielectron transfer processes present the possibility of a stepwise proceeding implying a transitory existence of intermediate ion of lower valency oxidation states.

The rates of electrochemical formation and disappearance of intermediate ion are equal under steady-state conditions. The general equations for the kinetics of multielectron stepwise-proceeding electrode processes under steady-state conditions have been derived by Parsons (1), Vetter (2), and Losev *et al.* (3).

In the present paper, a general two stepwise-proceeding electrode reaction is considered and equations are derived for the transient regime under galvanostatic conditions.

In Part I, the overvoltage and intermediate ion concentration equations are discussed, under limited time conditions, that is at the very moment of switching on the current and at the steady-state. In Part II, the overvoltage-time and intermediate ion concentration-time relationships are derived assuming no simultaneous charging of the double layer or a negligible capacitive current. In Part III, the same relationships are derived taking into consideration the simultaneous charging of the double layer.

The following simplifying assumptions have been made:

(*A*) The electrochemical reaction is two stepwise-proceeding.

(*B*) During the pulse current, the final ion concentration and, of course, the metal concentration are constant; only the intermediate ion concentration is changing, but its mass transfer is neglected.

(*C*) The electrode potential and the ion concentrations are unaffected by the electric double layer potential.

(*D*) No competitive chemical or disproportionation reactions accompany the transfer process.

Equilibrium State, the Moment of Switching on the Current, and the Steady-State (Part I)

The over-all electrode reaction

$$M \underset{k_c}{\overset{k_a}{\rightleftarrows}} M^{n+} + ne^-$$

may occur through two consecutive steps

$$M \underset{k_{c1}}{\overset{k_{a1}}{\rightleftarrows}} M^{z_1+} + z_1e^- \qquad [I]$$

$$M^{z_1+} \underset{k_{c2}}{\overset{k_{a2}}{\rightleftarrows}} M^{(z_1+z_2)+} + z_2e^- \qquad [II]$$

where M is metal; M^{z_1+} is the intermediate ion; $M^{(z_1+z_2)+} \equiv M^{n+}$ is the final ion; z_1 and z_2 are the number of electrons involved in the first and second step, respectively; $n = z_1 + z_2$ is the number of electrons involved in the over-all reaction; k_a, k_c, k_{a1}, k_{c1}, k_{a2}, and k_{c2} are the rate constants in the anodic and the cathodic directions for the over-all process, the first and the second step, respectively.

The actual rates of the two steps, expressed in current density terms are given by electrochemical kinetics as

$$i_1 = i_{o1}\left(e^{\alpha_{a1}\eta} - \frac{[M^{z_1+}]}{[M^{z_1+}]_o} e^{-\alpha_{c1}\eta} \right) \qquad [1]$$

and

$$i_2 = i_{o2}\left(\frac{[M^{z_1+}]}{[M^{z_1+}]_o} e^{\alpha_{a2}\eta} - e^{-\alpha_{c2}\eta} \right) \qquad [2]$$

where i_1 and i_2 are the current densities corresponding to the first and second steps, respectively; η is the overvoltage; $[M^{z_1+}]$ and $[M^{z_1+}]_o$ are the intermediate ion concentrations at the time t and at equilibrium ($i=0$); α_{a1}, α_{c1}, α_{a2}, and α_{c2} are the transfer coefficients in anodic and cathodic directions of the two steps. The transfer coefficient expressions are

$$\alpha_{a1} = \beta_1 z_1 \mathbf{F}/RT; \alpha_{c1} = (1 - \beta_1) z_1 \mathbf{F}/RT;$$

$$\alpha_{a2} = \beta_2 z_2 \mathbf{F}/RT; \alpha_{c2} = (1 - \beta_2) z_2 \mathbf{F}/RT$$

where β_1 and β_2 are named symmetry factors, may have values ranging from zero to 1, and depend on the symmetry of the potential energy barrier, being 0.5 for a symmetrical barrier (1); $\mathbf{F}$ is the Faraday number; R is the gas constant; and T is the absolute temperature. The exchange currents of the first step, i_{o1}, and of the second step, i_{o2}, are expressed by

$$i_{o1} = z_1 \mathbf{F} k_{a1} [M] e^{\alpha_{a1}\epsilon_o} = z_1 \mathbf{F} k_{c1} [M^{z_1+}]_o e^{-\alpha_{c1}\epsilon_o}$$

and

$$i_{o2} = z_2 \mathbf{F} k_{a2} [M^{z_1+}]_o e^{\alpha_{a2}\epsilon_o} = z_2 \mathbf{F} k_{c2} [M^{(z_1+z_2)+}] e^{-\alpha_{c2}\epsilon_o}$$

where [M] and $[M^{(z_1+z_2)+}]$ are the metal and the final ion concentrations, respectively, and ϵ_o the equilibrium potential.

Under galvanostatic conditions, that is i = constant, at any moment, the corresponding current densities of the first step, i_1, and of the second step, i_2, satisfy the relation

$$i = i_1 + i_2 \qquad [3]$$

By introducing [1] and [2] into [3], the expression of the ratio $[M^{z_1+}]/[M^{z_1+}]_o$ is obtained as

$$\frac{[M^{z_1+}]}{[M^{z_1+}]_o} = \frac{i + i_{o2}e^{-\alpha_{c2}\eta} - i_{o1}e^{\alpha_{a1}\eta}}{i_{o2}e^{\alpha_{a2}\eta} - i_{o1}e^{-\alpha_{c1}\eta}} \quad [4]$$

as well as the expression of the current density, i

$$i = i_{o1}\left(e^{\alpha_{a1}\eta} - \frac{[M^{z_1+}]}{[M^{z_1+}]_o}e^{-\alpha_{c1}\eta}\right) + i_{o2}\left(\frac{[M^{z_1+}]}{[M^{z_1+}]_o}e^{\alpha_{a2}\eta} - e^{-\alpha_{c2}\eta}\right) \quad [5]$$

Under steady-state conditions, the rate of the appearance of the intermediate ion in the first step, $d[M^{z_1+}]_I/dt$, is equal to the rate of its disappearance in the second step, $d[M^{z_1+}]_{II}/dt$, that is, the rate of the appearance of the final ion, $d[M^{(z_1+z_2)+}]/dt$. This may be written, by taking into account the Faraday law, as

$$\frac{d[M^{z_1+}]_I}{dt} = \frac{i_1}{z_1\mathbf{F}} = \frac{d[M^{z_1+}]_{II}}{dt} = \frac{i_2}{z_2\mathbf{F}} = \frac{d[M^{(z_1+z_2)+}]}{dt} = \frac{i}{(z_1+z_2)\mathbf{F}} \quad [6]$$

that is

$$\frac{i_{o1}}{z_1\mathbf{F}}\left(e^{\alpha_{a1}\eta_\infty} - \frac{[M^{z_1+}]_\infty}{[M^{z_1+}]_o}e^{-\alpha_{c1}\eta_\infty}\right) = \frac{i_{o2}}{z_2\mathbf{F}}\left(\frac{[M^{z_1+}]_\infty}{[M^{z_1+}]_o}e^{\alpha_{a2}\eta_\infty} - e^{-\alpha_{c2}\eta_\infty}\right) \quad [7]$$

where $[M^{z_1+}]_\infty$ and η_∞ denoted the intermediate ion concentration and the transfer overvoltage under steady-state conditions.

By introducing [4] in [7] and rearranging the terms we obtain

$$i = \frac{z_1+z_2}{z_1z_2}i_{o1}i_{o2}\frac{e^{(\alpha_{a1}+\alpha_{a2})\eta_\infty} - e^{-(\alpha_{c1}+\alpha_{c2})\eta_\infty}}{\frac{i_{o1}}{z_1}e^{-\alpha_{c1}\eta_\infty} + \frac{i_{o2}}{z_2}e^{\alpha_{a2}\eta_\infty}} \quad [8]$$

which is the equation deduced by Vetter (2). The explicit solution of η_∞ from Eq. [8] is a rather difficult problem. It may be solved by employing the simplifying assumption of the existence of only symmetrical energy barriers, that is $\beta_1 = \beta_2 = 0.5$, which leads to the equalities: $\alpha_{a1} = \alpha_{c1} = \alpha_1$ and $\alpha_{a2} = \alpha_{c2} = \alpha_2$. For $z_1 = z_2$, then, $\alpha_1 = \alpha_2 = \alpha$, and by substituting $e^{\alpha\eta_\infty}$ by y we obtain a fourth-order algebraic equation. One of the real roots of this equation will give the expression y corresponding to $e^{\alpha\eta_\infty}$. The problem is solved in a similar way for $z_1 = 1$, $z_2 = 2$; $z_1 = 2$, $z_2 = 1$; and $z_1 = z_2 = 2$. The expressions of η_∞ as a function of i deduced in this way are very intricate. When $\beta_1 \neq \beta_2 \neq 0.5$, we must introduce into [8] the corresponding numerical values of α's and calculate η_∞ by means of a computer. It is more convenient to calculate inversely the i values corresponding to certain η_∞ values.

In discussing the following equations, we will choose the case $z_1 = z_2 = 1$; $\alpha_{a1} = \alpha_{c1} = \alpha_{a2} = \alpha_{c2} = \alpha$. In this case, Eq. [8] becomes

$$i = 2i_{o1}\frac{e^{\alpha\eta_\infty} - e^{-3\alpha\eta_\infty}}{1 + \frac{i_{o1}}{i_{o2}}e^{-2\alpha\eta_\infty}} \quad [8']$$

Two particular situations are of interest for the following discussions.

When i is sufficiently large so that the exponential terms concerning negative arguments in Eq. [8] may be neglected, this becomes (2)

$$i = \frac{z_1+z_2}{z_1}\cdot i_{o1}\cdot e^{\alpha_{a1}\eta_\infty} \quad [9]$$

Therefore

$$\eta_\infty = \frac{1}{\alpha_{a1}}\ln\frac{i}{\frac{z_1+z_2}{z_1}i_{o1}} \quad [10]$$

that is for the particular case mentioned above

$$\eta_\infty = \frac{1}{\alpha}\ln\frac{i}{2i_{o1}} \quad [10']$$

For an even more specific case, $i_{o1} = i_{o2}$, the substitution of $e^{\alpha\eta_\infty}$ by y into Eq. [8'] leads to a second-order algebraic equation, the roots of which are

$$y_{1,2} = \frac{i \pm \sqrt{i^2 + 16i_{o1}^2}}{4i_{o1}}$$

We choose for η_∞ the expression given by the positive root

$$\eta_\infty = \frac{1}{\alpha}\ln\frac{i + \sqrt{i^2 + 16i_{o1}^2}}{4i_{o1}} \quad [11]$$

(The root containing a minus sign before the square root has no physical sense because $i_{o1} > 0$, which leads to a negative value of the logarithm argument.)

At the very moment of switching on the current, that is at $t = 0+\epsilon$, where ϵ depends on the edge of the pulse transient current, the intermediate ion concentration is approximately equal to the equilibrium concentration, $[M^{z_1+}]_{0+\epsilon} = [M^{z_1+}]_o$, and Eq. [1] and [2] become

$$i_1 = i_{o1}(e^{\alpha_{a1}\eta_{(o+\epsilon)}} - e^{-\alpha_{c1}\eta_{(o+\epsilon)}}) \quad [12]$$

and

$$i_2 = i_{o2}(e^{\alpha_{a2}\eta_{(o+\epsilon)}} - e^{-\alpha_{c2}\eta_{(o+\epsilon)}}) \quad [13]$$

where $\eta_{(o+\epsilon)}$ is the overpotential value established at the very moment when the current density, i, may be considered constant.

Substitution of [3] into [12] and [13] leads to

$$i = i_1 + i_2 = i_{o1}(e^{\alpha_{a1}\eta_{(o+\epsilon)}} - e^{-\alpha_{c1}\eta_{(o+\epsilon)}}) + i_{o2}(e^{\alpha_{a2}\eta_{(o+\epsilon)}} - e^{-\alpha_{c2}\eta_{(o+\epsilon)}}) \quad [14]$$

For the case $z_1 = z_2 = 1$ and $\alpha_{a1} = \alpha_{a2} = \alpha_{c1} = \alpha_{c2} = \alpha$, we can derive from [14] the expression of $\eta_{(o+\epsilon)}$ as

$$\eta_{(o+\epsilon)} = \frac{1}{\alpha}\ln\frac{i + \sqrt{i^2 + 4(i_{o1}+i_{o2})^2}}{2(i_{o1}+i_{o2})} \quad [15]$$

The ratio of [12] and [13], for the above-mentioned case, leads to

$$\frac{i_{1(o+\epsilon)}}{i_{2(o+\epsilon)}} = \frac{i_{o1}}{i_{o2}} \quad [16]$$

from which, taking into account Eq. [3], we obtain

$$i_{1(o+\epsilon)} = \frac{i_{o1}}{i_{o1}+i_{o2}}i \quad [17]$$

and

$$i_{2(o+\epsilon)} = \frac{i_{o2}}{i_{o1}+i_{o2}}i \quad [18]$$

That is, at the very moment of switching on the current, the latter is divided between the two steps proportionally with the relative values of the corresponding exchange current densities.

Comparing [15] with [11] shows that for $i_{o1} = i_{o2}$ the expressions become identical, that is, at the very moment of switching on the current, the transfer overvoltage springs up to its steady-state value.

In this case, the value of i for which η_∞ becomes 0.01288V gives the value of i_{o1}, because, by replacing i with i_{o1} in Eq. [15] it becomes

$$\eta_\infty = \eta_{(o+\epsilon)} = \frac{1}{\alpha}\ln\frac{1+\sqrt{17}}{4} = 0.01288\text{V}$$

Table I. Comparison of $\eta_{(o+\epsilon)}$ and η_∞ for various i values

* Calculated by Eq. [34]).
† Calculated by Eq. [20].

A comparison of $\eta_{(o+\epsilon)}$, Eq. [15], with η_∞, Eq. [8'], for $i_{o1} > i_{o2}$ and $i_{o1} < i_{o2}$ at various values of i_{o1}, i_{o2} and i, is given in Table I.

It can be seen from Table I that, in the case of $i_{o1} > i_{o2}$, the $\eta_{(o+\epsilon)}$ is lower than η_∞ when the current density, i, is below a certain critical value, $i_{critical}$, denoted by i_{cr}, which is further explained; $\eta_{(o+\epsilon)}$ is equal to η_∞ for $i = i_{cr}$, and $\eta_{(o+\epsilon)}$ is higher than η_∞ for $i > i_{cr}$. With increasing i, the difference $\eta_\infty - \eta_{(o+\epsilon)}$ tends to the value corresponding to Eq. [20]. When $i_{o1} < i_{o2}$, then $\eta_{(o+\epsilon)}$ is always lower than η_∞.

When $i >> 2(i_{o1} + i_{o2})$, Eq. [15] leads to

$$\eta_{(o+\epsilon)} = \frac{1}{\alpha} \ln \frac{i}{i_{o1} + i_{o2}} \qquad [19]$$

Subtracting [19] from [10] we obtain

$$\eta_\infty - \eta_{(o+\epsilon)} = \frac{1}{\alpha} \ln \frac{i_{o1} + i_{o2}}{2\, i_{o1}} \qquad [20]$$

From Eq. [20] it should be noted that: (*a*) when $i_{o1} > i_{o2}$ and $i >> 2(i_{o1} + i_{o2})$, then $\eta_{(o+\epsilon)} > \eta_\infty$; when $i_{o1} < i_{o2}$, then $\eta_{(o+\epsilon)} < \eta_\infty$. (*b*) The maximum difference, $\eta_\infty - \eta_{(o+\epsilon)}$, should be apparent when i_{o1} is quite different from i_{o2}; when $i_{o1} > i_{o2}$, then the maximum difference is equal to $1/\alpha$ ln 1/2; when $i_{o1} < i_{o2}$, this difference may reach values as high as the i_{o2} value will allow.

Now, by substituting [8] into [4] and by rearranging the terms, we can obtain the expression of the ratio of the intermediate ion concentration under steady-state conditions, $[M^{z_1+}]_\infty$, and at the moment $t = o + \epsilon$, $[M^{z_1+}]_{(o+\epsilon)}$. The $[M^{z_1+}]_{(o+\epsilon)}$ may be considered as equal to the intermediate ion concentration at equilibrium, $[M^{z_1+}]_o$. Thus, we have

$$\frac{[M^{z_1+}]_\infty}{[M^{z_1+}]_o} = \frac{\frac{z_2}{z_1}\frac{i_{o1}}{i_{o2}} e^{\alpha_{a1}\eta_\infty} + e^{-\alpha_{c2}\eta_\infty}}{\frac{z_2}{z_1}\frac{i_{o1}}{i_{o2}} e^{-\alpha_{c1}\eta_\infty} + e^{\alpha_{a2}\eta_\infty}} \qquad [21]$$

When i is sufficiently large for neglecting the terms containing negative argument exponentials, Eq. [21] leads to

(*a*) When $z_1 = z_2 = 1$ and $\alpha_{a1} = \alpha_{a2} = \alpha_{c1} = \alpha_{c2} = \alpha$

$$\frac{[M^+]_\infty}{[M^+]_o} \to \frac{i_{o1}}{i_{o2}} \qquad [22]$$

so that the intermediate ion concentration under steady-state conditions cannot be increased by increasing i. It results from Eq. [21] and [22] that, in the special case of $z_1 = z_2 = 1$ when $i_{o1} > i_{o2}$, the steady-state intermediate ion concentration is larger than the equilibrium intermediate ion concentration. The ratio between the two limiting concentrations, $[M^+]_\infty/[M^+]_o$, increases with increasing i and tends to the limit value given by Eq. [22]. When $i_{o1} < i_{o2}$, the intermediate ion concentration under steady-state conditions is smaller than at equilibrium and their ratio tends, with increasing i, to the value given by Eq. [22].

(*b*) When $z_1 = 1$, $z_2 = 2$ and $\alpha_{a1} = \alpha_{c1} = \frac{1}{2}\alpha_{a2} = \frac{1}{2}\alpha_{c2}$, under the same conditions

$$\frac{[M^+]_\infty}{[M^+]_o} = 2\frac{i_{o1}}{i_{o2}} e^{-\frac{1}{2}\alpha_{a2}\eta_\infty} \qquad [23]$$

that is, the steady-state intermediate ion concentration decreases with increasing i.

(*c*) When $z_1 = 2$, $z_2 = 1$ and $\alpha_{a1} = \alpha_{c1} = 2\,\alpha_{a2} = 2\,\alpha_{c2}$

$$\frac{[M^{2+}]_\infty}{[M^{2+}]_o} = \frac{1}{2}\frac{i_{o1}}{i_{o2}} e^{\alpha_{a2}\eta_\infty} \qquad [24]$$

so that the steady-state intermediate ion concentration increases with increasing i. (The special case of $n = 3$ will be treated in another paper.)

The Transient Regime for C = 0 (Part II)

It has already been mentioned that the relations between the current densities corresponding to the two consecutive charge transfer steps, i_1 and i_2, and the rates of appearance, $d[M^{z_1+}]_I/dt$ (by the first step), and of disappearance, $d[M^{z_1+}]_{II}/dt$ (by the second step) of intermediate ion, M^{z_1+}, are given in accordance with the Faraday law as

$$\frac{i_1}{z_1 F} = \frac{d[M^{z_1+}]_I}{dt} \qquad [25]$$

and

$$\frac{i_2}{z_2 F} = \frac{d[M^{z_1+}]_{II}}{dt} = \frac{d[M^{(z_1+z_2)+}]}{dt} \qquad [26]$$

where $[M^{z_1+}]_I$ is the quantity of M transformed into M^{z_1+} (in concentration terms) at time t, and $[M^{z_1+}]_{II}$ is the quantity of M or of M^{z_1+} transformed into $M^{(z_1+z_2)+}$ (in concentration terms also) at time t. The quantity of intermediate ion, $[M^{z_1+}]$, existing in the system at time t, will be equal to the difference between the quantity of intermediate ion formed up to that time in the first step, $[M^{z_1+}]_I$, and the quantity of intermediate ion that disappeared up to that time in the second step, $[M^{z_1+}]_{II}$. The latter is equal to the quantity of final ion, $[M^{(z_1+z_2)+}]$, appeared as a result of the over-all reaction (not the quantity of $M^{(z_1+z_2)+}$ existing in the system, depending on the initial conditions).

The rate of accumulation of intermediate ion, $d[M^{z_1+}]/dt$, in the system will be equal to the difference in its rate of formation, $d[M^{z_1+}]_I/dt$, and its rate of disappearance $d[M^{z_1+}]_{II}/dt$. Therefore, taking into account Eq. [25], [26], [1], and [2], we obtain

$$\frac{d[M^{z_1+}]}{dt} = \frac{d([M^{z_1+}]_I - [M^{z_1+}]_{II})}{dt}$$

$$= \frac{i_{o1}}{z_1F} e^{\alpha_{a1}\eta} + \frac{i_{o2}}{z_2F} e^{-\alpha_{c2}\eta} - \frac{[M^{z_1+}]}{[M^{z_1+}]_o} \left(\frac{i_{o1}}{z_1F} e^{-\alpha_{c1}\eta} + \frac{i_{o2}}{z_2F} e^{\alpha_{a2}\eta} \right) \quad [27]$$

The substitution of [4] into [27] leads to

$$\frac{d[M^{z_1+}]}{dt} = \frac{i_{o1}}{z_1F} e^{\alpha_{a1}\eta} + \frac{i_{o2}}{z_2F} e^{-\alpha_{c2}\eta} - \frac{i + i_{o2} e^{-\alpha_{c2}\eta} - i_{o1} e^{\alpha_{a1}\eta}}{i_{o2} e^{\alpha_{a2}\eta} - i_{o1} e^{-\alpha_{c1}\eta}} \left(\frac{i_{o1}}{z_1F} e^{-\alpha_{c1}\eta} + \frac{i_{o2}}{z_2F} e^{\alpha_{a2}\eta} \right) \quad [28]$$

Also by differentiation of [4] with respect to time, we obtain

$$\frac{d[M^{z_1+}]}{dt} = [M^{z_1+}]_o \left\{ \frac{(\alpha_{c2} i_{o2} e^{-\alpha_{c2}\eta} + \alpha_{a1} i_{o1} e^{\alpha_{a1}\eta})(i_{o1} e^{-\alpha_{c1}\eta} - i_{o2} e^{\alpha_{a2}\eta})}{(i_{o2} e^{\alpha_{a2}\eta} - i_{o1} e^{-\alpha_{c1}\eta})^2} - \frac{(i + i_{o2} e^{-\alpha_{c2}\eta} - i_{o1} e^{\alpha_{a1}\eta})(\alpha_{a2} i_{o2} e^{\alpha_{a2}\eta} + \alpha_{c1} i_{o1} e^{-\alpha_{c1}\eta})}{(i_{o2} e^{\alpha_{a2}\eta} - i_{o1} e^{-\alpha_{c1}\eta})^2} \right\} \frac{d\eta}{dt} \quad [29]$$

By equating [28] to [29] we obtain

$$\frac{d\eta}{dt} = \frac{(i_{o2} e^{\alpha_{a2}\eta} - i_{o1} e^{-\alpha_{c1}\eta})[(z_1 + z_2) i_{o1} i_{o2} (e^{(\alpha_{a1}+\alpha_{a2})\eta} - e^{-(\alpha_{c1}+\alpha_{c2})\eta}) - i(z_2 i_{o1} e^{-\alpha_{c1}\eta} + z_1 i_{o2} e^{\alpha_{a2}\eta})]}{N} \quad [30]$$

where

$$N = z_1 z_2 F [M^{z_1+}]_o \{ (\alpha_{c1} + \alpha_{a1}) i_{o1}^2 e^{(\alpha_{a1}-\alpha_{c1})\eta} + (\alpha_{c2} + \alpha_{a2}) i_{o2}^2 e^{(\alpha_{a2}-\alpha_{c2})\eta} + i_{o1} i_{o2} [(\alpha_{c2} - \alpha_{c1}) e^{-(\alpha_{c1}+\alpha_{c2})\eta} + (\alpha_{a2} - \alpha_{a1}) e^{(\alpha_{a1}+\alpha_{a2})\eta}] - i(\alpha_{a2} i_{o2} e^{\alpha_{a2}\eta} + \alpha_{c1} i_{o1} e^{-\alpha_{c1}\eta}) \}$$

The solution of Eq. [30] gives the explicit form of η as a function of t, *i.e.*, $\eta(t)$. By further introduction of $\eta(t)$ into Eq. [29] and after integration of the latter we obtain the change of $[M^{z_1+}]$ with time.

By integrating [30], we obtain only the explicit form of t as a function of η, and this one only for the special case of $\beta_1 = \beta_2 = \frac{1}{2}$, when we may substitute $e^{\alpha\eta}$ by y. In other words, the explicit form of η, $\eta(t)$, and of $[M^{z_1+}]$, $M^{z_1+}(t)$, which signify the transient regime, cannot be obtained. The solutions of this kind of equation are numerical only.

One can see, from Eq. [30] that $d\eta/dt = 0$ in two cases, namely:

1. When the first round bracket is equal to zero; hence,

$$i_{o2} e^{\alpha_{a2}\eta} = i_{o1} e^{-\alpha_{c1}\eta} \quad [31]$$

that is, when the transfer overvoltage reaches the value given by the relation

$$\eta = \frac{1}{(\alpha_{a2} + \alpha_{c1})} \ln \frac{i_{o1}}{i_{o2}} \quad [32]$$

Hence, at the value of η given by Eq. (32), either the overvoltage reaches directly its steady-state value or attains a minimum or a maximum value. As the η-t curve given by Eq. [30] does not present maxima and minima, in the mentioned case, the curve reaches its steady-state from the beginning. This corresponds to the condition

$$\eta_{(o+\epsilon)} = \frac{1}{(\alpha_{a2} + \alpha_{c1})} \ln \frac{i_{o1}}{i_{o2}} \quad [33]$$

By substituting [33] into [14], it results that, at a critical value of i, denoted i_{cr}, given by the equation

$$i_{cr} = i_{o1} \left(e^{\frac{\alpha_{a1}}{\alpha_{a2}+\alpha_{c1}} \ln \frac{i_{o1}}{i_{o2}}} - e^{-\frac{\alpha_{c1}}{\alpha_{a2}+\alpha_{c1}} \ln \frac{i_{o1}}{i_{o2}}} \right) + i_{o2} \left(e^{\frac{\alpha_{a2}}{\alpha_{a2}+\alpha_{c1}} \ln \frac{i_{o1}}{i_{o2}}} - e^{-\frac{\alpha_{c2}}{\alpha_{a2}+\alpha_{c1}} \ln \frac{i_{o1}}{i_{o2}}} \right) \quad [34]$$

or, for the special case of $z_2 = z_1 = 1$, $\beta_1 = \beta_2 = \frac{1}{2}$

$$i_{cr} = (i_{o1} + i_{o2}) \left(e^{\frac{1}{2} \ln \frac{i_{o1}}{i_{o2}}} - e^{-\frac{1}{2} \ln \frac{i_{o1}}{i_{o2}}} \right) \quad [34']$$

the overvoltage springs up to its steady-state value, the very moment of switching on the current.

It is obvious that the two values, i given by Eq. [34] and η given by Eq. [33], must satisfy the steady-state equation, [8]; that is,

$$i_{cr} = \frac{z_1 + z_2}{z_1 z_2} i_{o1} i_{o2} \frac{e^{\frac{\alpha_{a1}+\alpha_{a2}}{\alpha_{a2}+\alpha_{c1}} \ln \frac{i_{o1}}{i_{o2}}} - e^{-\frac{\alpha_{c1}+\alpha_{c2}}{\alpha_{a2}+\alpha_{c1}} \ln \frac{i_{o1}}{i_{o2}}}}{\frac{i_{o1}}{z_1} e^{-\frac{\alpha_{c1}}{\alpha_{a2}+\alpha_{c1}} \ln \frac{i_{o1}}{i_{o2}}} + \frac{i_{o2}}{z_2} e^{\frac{\alpha_{a2}}{\alpha_{a2}+\alpha_{c1}} \ln \frac{i_{o1}}{i_{o2}}}} \quad [34'']$$

From Eq. [33] one can see that for $i_{o1} > i_{o2}$, the value of i at which the overvoltage reaches its steady-state value is a positive value (for anodic net current, of course); for $i_{o1} < i_{o2}$, under the same conditions, i should have a negative value; that means that by applying an external anodic current the condition of $\eta_{(o+\epsilon)} = \eta_x$ cannot be satisfied for this mechanism.

2. When the second bracket is zero, that is when

$$i = \frac{z_1 + z_2}{z_1 z_2} i_{o1} i_{o2} \frac{e^{(\alpha_{a1}+\alpha_{a2})\eta} - e^{-(\alpha_{c1}+\alpha_{c2})\eta}}{\frac{i_{o1}}{z_1} e^{-\alpha_{c1}\eta} + \frac{i_{o2}}{z_2} e^{\alpha_{a2}\eta}}$$

The latter equation is identical with Eq. [8] and signifies the steady state. In the case of $i_{o1} = i_{o2}$, it has already been shown (Eq. [11] and [15]) that $\eta_{(o+\epsilon)} = \eta_x$ for all values of current densities, so that the second bracket is zero.

The Transient Regime for $C \neq 0$ (Part III)

Therefore, if in transient regime Eq. [1], [2], and [3] were valid, Eq. [30] would mean the change of the transfer overvoltage with time under galvanostatic conditions. But, just during the transient regime the charging of the double layer, of the capacity, C, occurs. In other words, Eq. [3] becomes

$$i - C \frac{d\eta}{dt} = i_1 + i_2 \quad [35]$$

where $C\frac{d\eta}{dt}$ is the capacitive current density.

The substitution of [1] and [2] into [35] leads to

$$\frac{[M^{z_1+}]}{[M^{z_1+}]_o} = \frac{i - C\frac{d\eta}{dt} + i_{o2}\, e^{-\alpha_{c2}\eta} - i_{o1}\, e^{\alpha_{a1}\eta}}{i_{o2}\, e^{\alpha_{a2}\eta} - i_{o1}\, e^{-\alpha_{c1}\eta}} \quad [36]$$

(instead of [4]). Hence,

$$\frac{d\eta}{dt} = \frac{1}{C}\left[i + i_{o2}\, e^{-\alpha_{c2}\eta} - i_{o1}\, e^{\alpha_{a1}\eta} - \frac{[M^{z_1+}]}{[M^{z_1+}]_o}\,(i_{o2}\, e^{\alpha_{a2}\eta} - i_{o1}\, e^{-\alpha_{c1}\eta}) \right] \quad [37]$$

Equation [37] in conjunction with [27]

$$\frac{d[M^{z_1+}]}{dt} = \frac{i_{o1}}{z_1\mathbf{F}}\, e^{\alpha_{a1}\eta} + \frac{i_{o2}}{z_2\mathbf{F}}\, e^{-\alpha_{c2}\eta} - \frac{[M^{z_1+}]}{[M^{z_1+}]_o}\left(\frac{i_{o1}}{z_1\mathbf{F}}\, e^{-\alpha_{c1}\eta} + \frac{i_{o2}}{z_2\mathbf{F}}\, e^{\alpha_{a2}\eta}\right) \quad [37']$$

forms a system of two first-order differential equations which may be solved numerically.

The special case of $i_{o1} = i_{o2}$ presents the particularity of $[M^{z_1+}]/[M^{z_1+}]_o = 1$, so that Eq. [37] may be solved for the sake of simplifying assumptions of $\alpha_{a1} = \alpha_{a2} = \alpha_{c1} = \alpha_{c2} = \alpha$. The substitution of $e^{\alpha\eta}$ by y leads to a differential equation whose solution allows η to be put into an explicit form. The result is

$$\eta = \frac{1}{\alpha}\ln \frac{\left(\frac{i}{4i_{o1}} + \sqrt{\frac{i^2}{16i_{o1}^2}+1}\right)\left(1 - \frac{i}{4i_{o1}} + \sqrt{\frac{i^2}{16i_{o1}^2}+1}\right) - \left(\frac{i}{4i_{o1}} - \sqrt{\frac{i^2}{16i_{o1}^2}+1}\right)\left(1 - \frac{i}{4i_{o1}} - \sqrt{\frac{i^2}{16i_{o1}^2}+1}\right) e^{-\frac{\alpha}{C}\sqrt{i^2+16i_{o1}^2}\cdot t}}{1 - \frac{i}{4i_{o1}} + \sqrt{\frac{i^2}{16i_{o1}^2}+1} - \left(1 - \frac{i}{4i_{o1}} - \sqrt{\frac{i^2}{16i_{o1}^2}+1}\right) e^{-\frac{\alpha}{C}\sqrt{i^2+16i_{o1}^2}\cdot t}} \quad [38]$$

Limiting Conditions: $\eta_{(o+\epsilon)}$ and η_∞ Expressions

The equivalent electrical scheme of a condenser of capacity, C (representing the electric double layer), connected in parallel with a resistance (the equivalent of the transfer reaction) is currently accepted for an electrode process. This equivalent electrical scheme allows us to write Eq. [35] and means that at $t = o + \epsilon$, for $\epsilon \to o$ all the current, i, is a capacitive current; that is,

$$C\frac{d\eta}{dt} = i \quad [39]$$

Therefore, according to Eq. [35]

$$i_1 + i_2 = 0 \quad [40]$$

from which

$$\eta_{(o+\epsilon)} = 0 \quad [41]$$

The relation $[M^{z_1+}]_{(o+\epsilon)} = [M^{z_1+}]_o$ is valid in this case too.

Also, at steady state $C\frac{d\eta}{dt} = 0$; thus the equations are similar to those derived in Part II.

Discussion

On the grounds of expression [30], theoretical curves of η-t were computed for the special case of $C = 0$, $z_1 = z_2 = 1$, $\beta_1 = \beta_2 = 0.5$, $[M^+]_o = 1 \times 10^{-11}$ M/l, and arbitrary values of i_{o1}, i_{o2}, and i, by the computer CET-501, from I.C.P.U.E.C., Bucharest, Romania. The results are graphically presented in Fig. 1A, 2A, and 3A, the values of i_{o1}, i_{o2}, and i being pointed out on the figures. On figures 1B, 2B, and 3B, the theoretical curves of the case of $C = 30$ μF and the same values of i_{o1}, i_{o2}, and i as before are shown in accordance with Eq. [27] and [37].

From these curves, two observations should be noted as valid for all of the cases:

1. With the increase in time, all the curves tend to their steady-state values.
2. The time necessary to reach the steady state decreases with the increase in the i value.

The other observations will be discussed, separately, for the three particular cases.

The case of $i_{o1} > i_{o2}$—(a) $C = 0$, Fig. 1A.— When $i > i_{cr}$, the η-t curve is decreasing; when $i = i_{cr}$, the η is constant from the beginning and equals η_∞; when $i < i_{cr}$, the η-t curve is increasing. From this figure, it can be seen that for the very large values of i, the difference $\eta_\infty - \eta_{(o+\epsilon)}$ becomes constant in accordance with Eq. [20].

(b) $C \neq 0$, Fig. 1B.

Case I. $i > i_{cr}$. 1. All the curves are peak shaped.

2. The peak overvoltage increases with increasing current density. The change of the peak overvoltage with the logarithm of the current density follows a Tafel law; in this case,

$$\frac{d\eta_{peak}}{d\ln i} \simeq \frac{52.18\ \text{mV}}{\text{decade}}\left(\simeq \frac{\mathbf{F}}{RT}\right)$$

which compared with

$$\frac{d\eta_\infty}{d\ln i} = \frac{50\ \text{mV}}{\text{decade}}$$

leads to the conclusion that, at very large current densities, the Tafel slope given by the peak-overvoltage values is almost equal to the Tafel slope given by the steady-state overvoltage values. At smaller

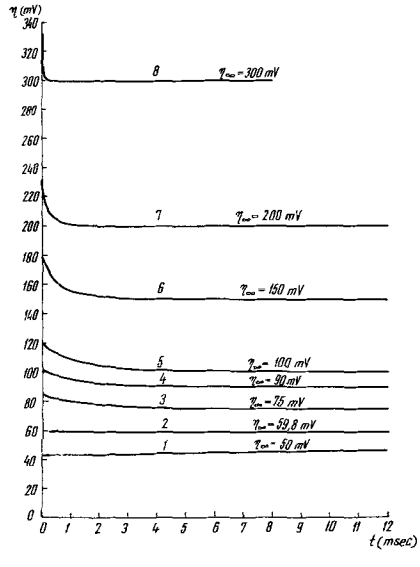

Fig. 1A. The overvoltage, η, as a function of time, t; the case of $i_{o1} = 1 \times 10^{-4}$ (A) $> i_{o2} = 1 \times 10^{-5}$ (A) for $C = 0$ and different values of i (in A).

Curve 1, $i = 2.072 \times 10^{-4}$
Curve 2, $i = 3.1262 \times 10^{-4}$
Curve 3, $i = 5.2882 \times 10^{-4}$
Curve 4, $i = 8.54 \times 10^{-4}$
Curve 5, $i = 1.1223 \times 10^{-3}$
Curve 6, $i = 3.453 \times 10^{-3}$
Curve 7, $i = 9.2591 \times 10^{-3}$
Curve 8, $i = 6.34 \times 10^{-2}$

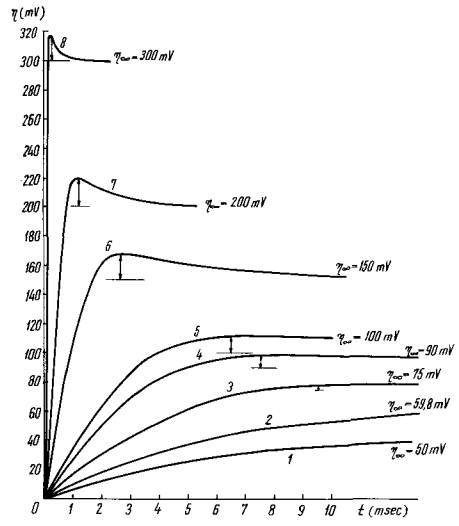

Fig. 1B. The overvoltage, η, as a function of time, t, for C = 3 x 10^{-5}F and the same values of i, i_{o1}, and i_{o2} as in Fig. 1A.

current densities

$$\frac{d\eta_{peak}}{d \ln i} = \frac{47,7 \text{ mV}}{\text{decade}}$$

and

$$\frac{d\eta_{\infty}}{d \ln i} = \frac{33.9 \text{ mV}}{\text{decade}}$$

Therefore, the Tafel slope given by the overvoltage peak values is larger than the Tafel slope given by the overvoltage steady-state values.

3. The difference $\eta_\infty - \eta_{peak}$ first increases, then tends to a constant value. It is obvious that, as C tends to zero, $\eta_\infty - \eta_{peak}$ tends to $\eta_\infty - \eta_{(o+\epsilon)}$.

4. With increasing of the current, the time corresponding to the maxima on the curves, τ peak, tends to zero. In the studied case

$$\frac{d \log \tau_{peak}}{d \log i} = -\frac{0.82}{\text{decade}}$$

Case II, $i = i_{cr}$. The curve η-t increases with increasing time, tending asymptotically to the steady-state value. Hence, the critical current density may be identified as being the maximum value of i for which the peak does not appear. The experimental determination of i_{cr} and corresponding η_∞ allows the calculation of i_{o1} and i_{o2} by means of Eq. [33] and [34], because in this case $\eta_{(o+\epsilon)} = \eta_\infty$.

Case III, $i < i_{cr}$. The curves η-t are of the same shape as in case II.

The case of $i_{o1} = i_{o2}$ (Fig. 2, curves 1-5).—(a) C = 0, Fig. 2.—For all values of i, the η springs up to the steady-state value.

(b) C ≠ 0.—The η-t curves are of the same shape as in the case of $i_{o1} > i_{o2}$ when $i \leq i_{cr}$.

The case of $i_{o1} < i_{o2}$ (Fig. 3).—(a) C = 0, Fig. 3A.

1. All the curves η-t are increasing and S shaped.

2. The time at which the inflection appears tends to zero with increasing current density.

(b) C ≠ 0, Fig. 3B.—The η-t curves are monotone increasing, tending asymptotically to their steady-state values.

The changes of intermediate ion concentration with time for the three cases, namely $i_{o1} > i_{o2}$, $i_{o1} = i_{o2}$, and $i_{o1} < i_{o2}$, and C ≠ 0 are given in Fig. 4.

From this figure it can be seen that for the case of $i_{o1} > i_{o2}$ (curves 1-7) all the curves are increasing and S shaped. The time necessary to reach the steady state as well as the time at which the inflection point appears decreases with increasing current density.

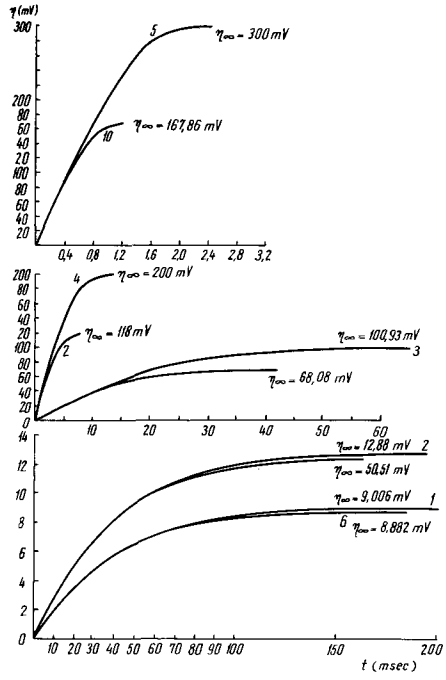

Fig. 2. The overvoltage, η, as a function of time, t, for different values of current density. The case of $i_{o1} = i_{o2} = 1 \times 10^{-5}$ (A), curves 1-5, two step-wise proceeding transfer. The case of $i_o = 1 \times 10^{-5}$ (A), curves 6-10, one step-wise proceeding transfer.
Curves 1 and 6, $i = 6.96 \times 10^{-6}$ (A)
Curves 2 and 7, $i = 1 \times 10^{-5}$ (A)
Curves 3 and 8, $i = 1.363 \times 10^{-4}$ (A)
Curves 4 and 9, $i = 9.3051 \times 10^{-4}$ (A)
Curves 5 and 10, $i = 6.34697 \times 10^{-3}$ (A)

In the case of $i_{o1} = i_{o2}$ (curve 8), the intermediate ion concentration is constant and equal to the equilibrium concentration all the time.

In the case of $i_{o1} < i_{o2}$ (curves 9-12), the intermediate ion concentrations decrease with increasing time, tending asymptotically to the steady-state values.

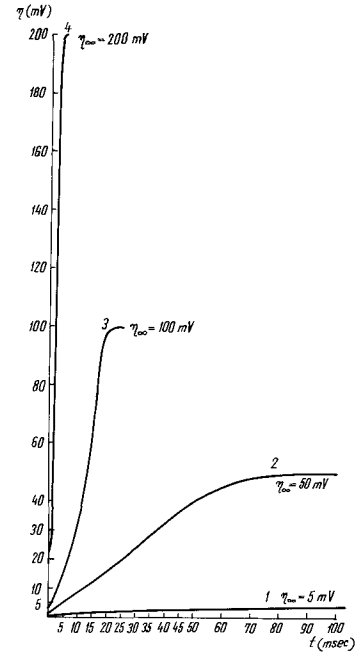

Fig. 3A. The overvoltage, η, as a function of time, t, for the case of $i_{o1} = 1 \times 10^{-5}$ (A), $i_{o2} = 1 \times 10^{-3}$ (A) for C = 0 and different values of current density.
Curve 1, $i = 6.96 \times 10^{-6}$ (A)
Curve 2, $i = 5.195 \times 10^{-5}$ (A)
Curve 3, $i = 1.363 \times 10^{-4}$ (A)
Curve 4, $i = 9.3 \times 10^{-4}$ (A)

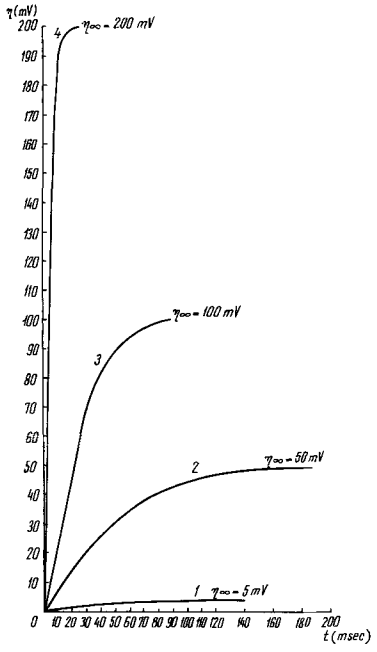

Fig. 3B. The overvoltage, η, as a function of time, t, for $C = 3 \times 10^{-5}$F, and the same values of i, i_{o1}, and i_{o2} as in Fig. 3A.

It is obvious and important that the experimental determination of the change of intermediate ion concentration with time, or at least of the ratio between the steady-state concentration and the equilibrium concentration, would give valuable information on the transfer mechanism.

We find it interesting to present, in the following, the case of the transfer of n electrons in only one step, that is

$$M \underset{k_c}{\overset{k_a}{\rightleftarrows}} M^{n+} + ne^-$$

for comparison with the cases shown before.

The expression of the current density, i, at steady state is

$$i = i_o \left(e^{\alpha_a \eta_\infty} - e^{-\alpha_c \eta_\infty}\right) \qquad [42]$$

where $\alpha_a = \beta n\mathbf{F}/RT$ and $\alpha_c = (1-\beta)n\mathbf{F}/RT$.

The substitution of α_a and α_c by α' and of $e^{\alpha'\eta_\infty}$ by y in Eq. [42] leads to a second order-algebraic equation whose positive root allows η_∞ to be put in an explicit form

$$\eta_\infty = \frac{1}{\alpha'} \ln\left(\frac{i}{2i_o} + \sqrt{\frac{i^2}{4i_o^2} + 1}\right) \qquad [43]$$

In this case, if $C = 0$, then $\eta_\infty = \eta_{(o+\epsilon)}$; that is, the overvoltage springs up readily to its steady-state value.

When $C \neq 0$, that is at transient regime, Eq. [43] becomes

$$i - C\frac{d\eta}{dt} = i_o \left(e^{\alpha'\eta} - e^{-\alpha'\eta}\right) \qquad [44]$$

By substituting $e^{\alpha'\eta}$ by y in Eq. [44] and solving the second-order equation in y, we obtain for η the expression

$$\eta = \frac{1}{\alpha'} \ln \frac{\left(\frac{i}{2i_o} + \sqrt{\frac{i^2}{4i_o^2}+1}\right)\left(1 - \frac{i}{2i_o} + \sqrt{\frac{i^2}{4i_o^2}+1}\right) - \left(\frac{i}{2i_o} - \sqrt{\frac{i^2}{4i_o^2}+1}\right)\left(1 - \frac{i}{2i_o} - \sqrt{\frac{i^2}{4i_o^2}+1}\right) e^{-\frac{\alpha'}{C}\sqrt{i^2 + 4i_o^2}\cdot t}}{1 - \frac{i}{2i_o} + \sqrt{\frac{i^2}{4i_o^2}+1} + 1 - \left(1 - \frac{i}{2i_o} - \sqrt{\frac{i^2}{4i_o^2}+1}\right) e^{-\frac{\alpha'}{C}\sqrt{i^2 + 4i_o^2}\cdot t}} \qquad [45]$$

(It may be noted that Eq. [45] is different from Eq. [38] only in the substitution of i_o by $2i_{o1}$ and n by $z_1 = z_2$ in α's expression.)

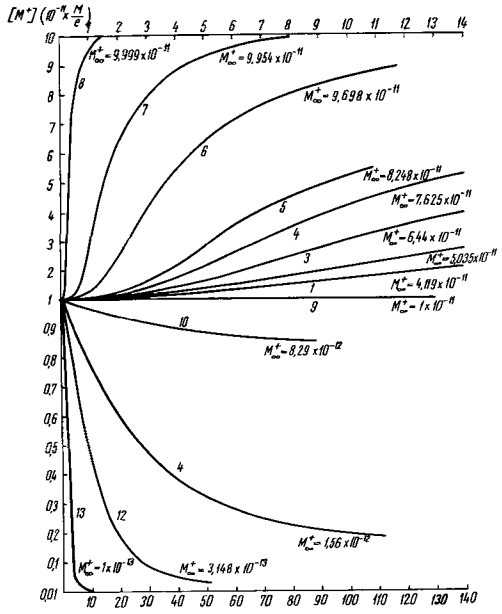

Fig. 4. The intermediate ion concentration, $[M^+]$, as a function of time, t, for the three special cases: case 1, $i_{o1} = 1 \times 10^{-4}$ (A); $i_{o2} = 1 \times 10^{-5}$ (A) (curves 1-7) for different values of current density.

Curve 1, $i = 2.172 \times 10^{-4}$ (A)
Curve 2, $i = 3.1262 \times 10^{-4}$ (A)
Curve 3, $i = 5.3882 \times 10^{-4}$ (A)
Curve 4, $i = 8.54 \times 10^{-4}$
Curve 5, $i = 1.1223 \times 10^{-3}$
Curve 6, $i = 3.453 \times 10^{-3}$
Curve 7, $i = 9.2591 \times 10^{-3}$
Curve 8, $i = 6.34 \times 10^{-2}$

Case 2, $i_{o1} = i_{o2} = 1 \times 10^{-5}$ (A) (curve 9). Case 3, $i_{o1} = 1 \times 10^{-5}$ (A); $i_{o2} = 1 \times 10^{-3}$ (A) (curves 10-13).

Curve 10, $i = 6.96 \times 10^{-6}$ (A)
Curve 11, $i = 5.095 \times 10^{-5}$ (A)
Curve 12, $i = 1.363 \times 10^{-4}$ (A)
Curve 13, $i = 9.3 \times 10^{-4}$ (A)

In Fig. 2, the η-t curves are given for the special case of $n = 2$, $\beta_a = \beta_c = 0.5$ and for the arbitrary values of i_o and i shown on the figure. It can be seen from curves 6-10 that all of them are steadily increasing, tending to the steady state. As the transfer in only one step and the transfer in two steps with $i_{o1} = i_{o2}$ are similar when $C = 0$, because η springs up to its steady-state value, both cases have been represented on the same figure. A comparison between them leads to the observation that for small values of i and the same value of exchange current the curves for both mechanisms almost coincide; with increasing of i, the η_∞ increases for the mechanism in steps more than for the mechanism in only one step, but the slopes of the η-t curves are the same for both cases.

For the sake of comparison, the time $t_{1/2}$ necessary to reach half of the steady-state values of η, denoted by $\eta_{1/2}$, for the treated cases are given in Table II.

Experimental Determination of the Double Layer Capacity

In accordance with Eq. [39]

$$C = \frac{i}{\left.\frac{d\eta}{dt}\right|_{t=o+\epsilon}}$$

the double layer capacity may be obtained from the slope of η-t curves at time t equals $o+\epsilon$. This relation is valid regardless of transfer mechanism.

Table II. Time ($t_{1/2}$) necessary to reach half of the steady-state values of η ($\eta_{1/2}$)

i (A)	i_0 (A)	i_{o1} (A)	i_{o2} (A)	η^∞ (V)	$t_{1/2}$ (sec)
6.96×10^{-6}	2×10^{-5}			4.503×10^{-3}	$13\text{-}14 \times 10^{-3}$
	1×10^{-5}			8.882×10^{-3}	27×10^{-3}
		1×10^{-5}	1×10^{-5}	9.006×10^{-3}	27×10^{-3}
		1×10^{-5}	1×10^{-3}	5×10^{-3}	33×10^{-3}
1×10^{-5}	2×10^{-5}			6.441×10^{-3}	$13\text{-}14 \times 10^{-3}$
	1×10^{-5}			1.2517×10^{-2}	24×10^{-3}
		1×10^{-5}	1×10^{-7}	1.19791×10^{-1}	1070×10^{-3}
		1×10^{-5}	1×10^{-5}	1.2882×10^{-2}	27×10^{-3}
1.363×10^{-4}	2×10^{-5}			5.046×10^{-2}	6.7×10^{-3}
	1×10^{-5}			6.8084×10^{-2}	8.5×10^{-3}
		1×10^{-5}	1×10^{-5}	1.0093×10^{-1}	$13\text{-}14 \times 10^{-3}$
		1×10^{-5}	1×10^{-3}	1×10^{-1}	21×10^{-3}
9.3051×10^{-4}	2×10^{-5}			1×10^{-1}	1.01×10^{-3}
	1×10^{-5}			1.18×10^{-1}	1.05×10^{-3}
		1×10^{-5}	1×10^{-5}	2×10^{-1}	$3.4\text{-}3.5 \times 10^{-3}$
		1×10^{-5}	1×10^{-3}	2×10^{-1}	4.5×10^{-3}
6.34697×10^{-3}	2×10^{-5}			1.5×10^{-1}	$0.36\text{-}0.37 \times 10^{-3}$
	1×10^{-5}			1.67861×10^{-1}	0.40×10^{-3}
		1×10^{-5}	1×10^{-7}	3×10^{-1}	
		1×10^{-5}	1×10^{-5}	3×10^{-1}	0.72×10^{-3}
		1×10^{-5}	1×10^{-3}	3×10^{-1}	

Far from the initial moment, it would be possible to obtain the double layer capacity value by introducing certain t and η values (preferably $t_{1/2}$ and $\eta_{1/2}$ as being more accurately determined from the curves) into the theoretical expression of the double layer capacity, which will be a function of i, i_0 (or i_{o1}, i_{o2}), and t. Unfortunately, this is possible only for the special cases where it was possible to determine η as a function of time, that is for $i_{o1} = i_{o2}$ and for the transfer reaction in only one step. From Eq. [38] we can obtain the expression of C for $i_{o1} = i_{o2}$, that is

$$C = -\frac{\alpha\sqrt{i^2 + 16i_{o1}^2}\cdot t}{\ln\dfrac{\left(e^{\alpha\eta} - \dfrac{i}{4i_{o1}} - \sqrt{\dfrac{i^2}{16i_{o1}^2}+1}\right)\left(1 - \dfrac{i}{4i_{o1}} + \sqrt{\dfrac{i^2}{16i_{o1}^2}+1}\right)}{\left(e^{\alpha\eta} - \dfrac{i}{4i_{o1}} + \sqrt{\dfrac{i^2}{16i_{o1}^2}+1}\right)\left(1 - \dfrac{i}{4i_{o1}} - \sqrt{\dfrac{i^2}{16i_{o1}^2}+1}\right)}} \qquad [46]$$

Similarly, from Eq. [45] the expression of C for transfer in one step is

$$C = -\frac{\alpha'\sqrt{i^2 + 4i_o^2}\cdot t}{\ln\dfrac{\left(e^{\alpha'\eta} - \dfrac{i}{2i_o} - \sqrt{\dfrac{i^2}{4i_o^2}+1}\right)\left(1 - \dfrac{i}{2i_o} + \sqrt{\dfrac{i^2}{4i_o^2}+1}\right)}{\left(e^{\alpha'\eta} - \dfrac{i}{2i_o} + \sqrt{\dfrac{i^2}{4i_o^2}+1}\right)\left(1 - \dfrac{i}{2i_o} - \sqrt{\dfrac{i^2}{4i_o^2}+1}\right)}} \qquad [47]$$

Of course, introducing experimental values of $t_{1/2}$ and $\eta_{1/2}$ for a stepwise-proceeding mechanism into Eq. [47] results in false capacitive values.

Conclusions

The main conclusion of this paper consists in the fact that one can obtain useful information on the transfer mechanism by studying the transient regime. The transient regime offers the possibility of identifying the existence of the step-mechanism and even of specifying the nature of the ratio between the exchange currents of the two steps. The step-mechanism dealt with above gives a new explanation of the peak-shaped η-t curves, frequently encountered in the electrode processes, and an explanation of the discordance between the double layer capacity values determined from the slope of the η-t curves at the initial moment and at a distant one, when a stepwise-proceeding transfer reaction and the over-all reaction may be confused.

Acknowledgments

The author is indebted to Dr. V. V. Losev and Dr. A. Pcelnikov from the Institute of Chemical Physics, L. I. Karpov, Moscow, for helpful criticism of this paper. The work of programming the computer CET 501 performed by Dr. E. Ciupitu, as well as fruitful discussions with several of the author's friends from the Institute of Atomic Physics, Bucharest, are gratefully recorded.

Manuscript received Dec. 27, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

The Activity Coefficient of Lithium Chloride in Anhydrous Dimethyl Sulfoxide Solutions

Gerhard Holleck, David R. Cogley,* and James N. Butler*

Tyco Laboratories, Inc., Waltham, Massachusetts

ABSTRACT

Activity coefficient measurements of LiCl in dimethyl sulfoxide have been made by the emf method and the cryoscopic method. The emf measurements are in good agreement with similar emf measurements in the literature, but not with cryoscopic measurements in the literature. By applying an empirical correction for temperature gradients resulting from heat transfer in the steady state, agreement is obtained between our cryoscopic measurements and the emf measurements. The systematic errors from heat transfer phenomena in DMSO solutions appear to have been too large thus far for accurate cryoscopic measurements.

The measurement of activity coefficients in nonaqueous solutions is of fundamental importance to a wide variety of investigations. These include the establishment of standard potentials, equilibrium constants, and other thermodynamic data; kinetic studies; and an understanding of ionic solvation and association phenomena. Solutions of lithium chloride in the dipolar aprotic solvent dimethyl sulfoxide (DMSO) have received more attention than any other similar nonaqueous system.

To evaluate the results of our studies (1) of the kinetics of the lithium amalgam-lithium ion electrode in DMSO we required values of the activity coefficient of LiCl over a wide range of concentrations. The values available in the literature at the time (2, 3) were not consistent with each other and did not cover a wide enough range of concentration. After we began our own measurements, two other studies were published (4, 5). Discrepancies between the results of three different studies by the cryoscopic method (2, 3, 5) and by the emf method (4) are much larger than their precision and no critical comparison of all these various data has been made. The LiCl-DMSO system is the only electrolyte solution in an aprotic organic solvent for which sufficient data have been obtained to allow such a critical examination.

This paper reports our measurements of the mean activity coefficient of LiCl in DMSO by both the emf and cryoscopic methods and examines critically the results of other workers.

Experimental

Materials.—Solutions were prepared from anhydrous lithium chloride (Anderson Physics Laboratories, 99.999%) and dimethyl sulfoxide (Matheson, Coleman and Bell, "Spectroquality"). The solvent was dried using molecular sieves (Linde 5-A, washed with triple-distilled water, and dried for 24 hr at 375°C in a stream of dry argon) and filtered through a 10-20μ pore-size glass frit. Analysis was performed by gas chromatography using a column of Porapak Q (Waters Associates) and thermal conductivity detection (6). Water content of the solutions was less than 25 ppm (1.5 mM) and organic impurities were less than 10 ppm.

Amalgams were prepared by weight from triple-distilled mercury (Doe and Ingalls), lithium metal (Foote Mineral Company, 99.96%), and thallium metal (American Smelting and Refining Company, 99.999%). All experiments were performed in a glove-box (Vacuum Atmospheres Corporation) using an atmosphere of argon which was recirculated through a purification train designed to remove water, oxygen, nitrogen, and organic vapors. The oxygen and water content of the atmosphere was estimated to be less than 1 ppm.

* Electrochemical Society Active Member.

Most solutions were prepared by weight, but some solutions were prepared by volume, and conversion to the molal scale was made using values interpolated from measured densities of LiCl-DMSO solutions, together with literature values for the density of pure DMSO (7). The expression

$$d = 1.0946 + 0.015\,C$$

where C is the concentration of the solution in moles/liter, was used for calculations at 25°C.

EMF measurements.—The potential of the cell

$$\mathrm{Li(Hg)/Li^+,\ Cl^-\ DMSO/TlCl(s)/Tl(Hg)}$$

was measured. A two-compartment cell with the compartments separated by a coarse glass frit, with platinum leads sealed through the glass to contact the amalgams, was used. A total of 16 cells of various LiCl concentrations were prepared. For all cells the amalgams contained 0.818 m/o (mole per cent) Li and 6.50 m/o Tl. The cells were filled by first adding approximately 5 ml of each of the amalgams to the compartments of the dry cell, sprinkling approximately 100 mg solid TlCl on top of the thallium amalgam, and then adding the LiCl-DMSO solution to the compartment containing the lithium amalgam. In this way contamination of the lithium amalgam compartment by dissolved thallium ion was reduced.

The potential of each cell was measured as a function of time, using a high impedance differential voltmeter (John Fluke), which was calibrated against a Weston Standard Cell (Eppley Laboratories) and found to be accurate to ± 0.05 mV. Potentials were steady to the nearest 0.1 mV after 1 hr and remained constant (within the uncertainty caused by temperature fluctuations in the drybox) for 24 hr afterward. Because of difficulties in thermostating the drybox, the temperature was not controlled; but it was recorded to ± 0.03°C and ranged from 22° to 26°C.

Cryoscopic measurements.—Two similar 300 ml, partially silvered Dewar flasks were covered with a single ½-in. thick, 4 x 10-in., aluminum plate, insulated with styrofoam, which served as a controlled heat sink. Figure 1 is a diagram of the apparatus. The plate temperature could be measured by copper-constantan thermocouples inserted into holes bored at four different positions. A thermoelectric cooling module (E.G. and G. Model G9-65) was mounted centrally on the aluminum plate and its low-temperature side was cooled by circulating water through a copper coil. To avoid any possible leaks of water into the drybox, the copper tube was installed in a single piece and all joints were made outside the drybox. The temperature sensor was a thermistor bead mounted on the underside of the aluminum plate, opposite the cooling module, and this was connected to an operational am-

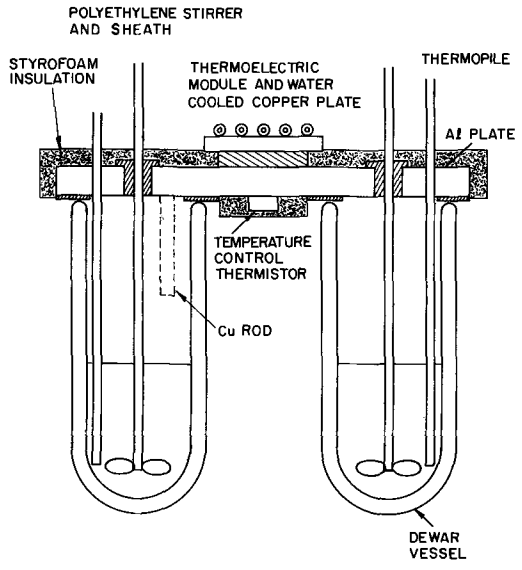

Fig. 1. Apparatus for freezing point depression measurements

plifier (Tyco) which controlled the current through the thermoelectric module so as to maintain the temperature constant (± 0.01°C) at a preset value. An attempt to use a radiative heat sink (to avoid water lines in the drybox) was not successful because of the large amount of heat generated by the resistance of the thermoelectric module. With the low-temperature side of the module cooled by tap water (7°-10°C), the temperature of the plate could be brought to below zero or controlled at temperatures as high as 30°C. At optimum conditions, approximately 7w of heat were pumped by the module.

The solutions in the Dewars were stirred with matched variable-speed stirring motors (Fisher Dyna-Mix) with polyethylene stirrers. These were normally run at approximately 100 rpm.

The temperature difference between the two vessels was measured with a 25-junction copper/constantan thermopile (Science Products Corporation) which had an output of 1.008 mv/°C (as calibrated by the manufacturer), and a resistance of 900 ohms. The thermocouple junctions were enclosed in stainless steel tubes. One arm contained a separate reference thermocouple to determine the absolute temperature. The potential of the thermopile was measured using a microvoltmeter (Keithley Model 150A), and all leads were shielded to avoid spurious currents. The output of the microvoltmeter was read on a potentiometric chart recorder as a function of time. All connections were made between pure copper leads using low thermal emf solder (Science Products Corporation). The noise level was approximately 0.001°C, but temperature differences between the thermopile elements could be estimated with a precision of ± 0.0002°C if the temperature difference was steady.

An attempt to record a simple cooling curve resulted in supercooling by as much as 3°C, which made such a freezing point determination impractical. Therefore, it was necessary to seed the solution with solid DMSO and to attempt to measure a steady-state temperature under conditions as close to equilibrium as possible. Because the mixture of liquid and solid must be stirred to achieve thermal and chemical equilibrium, a certain amount of heat is produced within the solution by the mechanical action of the stirrer. This heat must be removed by external cooling or else the seed crystals will eventually melt. Such a "melting curve" approach was taken by Garnsey and Prue (5) in their cryoscopic studies on DMSO and sulfolane. Our technique was closer to that of Dunnett and Gasser (3) in that we used as a heat sink a cover plate common to both vessels which was maintained at a temperature below the freezing point of the solution, and attempted to achieve a steady state in which a small amount of solid DMSO was present; all the heat generated by the stirrer was being absorbed by the heat sink, and the temperature did not change with time.

With the Dewar vessels each containing 100 ml pure DMSO, the effect of heat transfer on the apparent freezing point was investigated. Both vessels were cooled until solid DMSO appeared, and then the temperature of the plate was raised to approximately one degree below the freezing point of the solvent. The stirrers were operated at the lowest speed which gave a smooth time-dependence of the temperature difference between the vessels. This temperature difference was zero, but an imbalance in the heat transfer between the two vessels (*e.g.*, by changing the shape of the insulation on the aluminum plate) could affect the difference by ± 0.005°C.

We then deliberately made the heat transfer asymmetric by attaching a Teflon-covered copper rod to protrude from the plate into one vessel (this increased the cold surface in this vessel by about 1/3). With the plate temperature at 17.5°C this vessel indicated a freezing point for pure DMSO which was 0.014° ± 0.002°C (constant for at least 10 min) lower than the vessel without the copper rod. With similar Teflon-covered copper rods protruding into both vessels, the temperature difference was again zero. From these tests it was clear that the rate of cooling (even though it was small) had a substantial effect on the observed steady-state temperature of the solid-liquid mixture.

The arrangement with unsymmetrical heat transfer (copper rod protruding into one vessel but not the other) was used to evaluate the heat transfer coefficient of the system, and this coefficient was used in correcting measurements made both with the unsymmetrical arrangement and with the symmetrical arrangement, as described in the next section.

A typical measurement was made as follows: A sample of pure DMSO was placed in each vessel and the plate temperature lowered to approximately 6° or 7°C. As soon as a small amount of solid DMSO appeared, the temperature of the plate was raised until it was less than 1°C below the temperature of the vessel. The temperature difference between the vessels was recorded as a function of time and, although it was not zero, it was usually constant to within ± 0.001°C for 20 min or more.

Then measured amounts of a concentrated, precooled LiCl solution were added through an opening in the cover plate to the vessel into which the copper rod protruded and the temperature difference recorded again until equilibrium was reached. Normally there was only a small amount (less than 1%) of solid present so that this temperature corresponded closely to the freezing point of the dilute LiCl solution. If the concentrated LiCl solution warmed the DMSO too much, the seed crystals melted. The temperature of the solution could be lowered to seed it again, but this resulted in less stable temperature measurements than the method just described.

An earlier set of measurements was made by placing a sample of pure DMSO in one vessel and a solution of LiCl in DMSO in the other vessel and cooling strongly until both solvent and solution produced crystals. The temperature of the plate was then raised to approximately 1°C below the expected freezing point of the solution and the steady temperature was observed. In these experiments the heat transfer arrangement was symmetrical and, thus, this procedure corresponds exactly to that used by Dunnett and Gasser (3). In the dilute solutions this procedure produced less precise results than the addition of LiCl solution to previously seeded pure DMSO.

Results

EMF measurements.—The experimental values of the cell potential E are given in Table I for various concentrations of LiCl. The quantity

$$E^{\circ\prime} = E + 0.1183\left(\log m - \frac{1.115\sqrt{m}}{1+\sqrt{m}} + 0.282m\right) + 0.511\,(T-25)$$

where m is the molal concentration of LiCl and T is the centigrade temperature, is given for each measurement. This expression contains the Guggenheim-type concentration dependence found by Smyrl and Tobias (4) as well as a temperature coefficient calculated from known temperature coefficients of cells (4, 9).

From Table I it can be seen that $E^{\circ\prime}$ is constant within ±1 mV for concentrations below 0.5M. The average of these twelve points gives the standard potential of our cell at 25°: E° =1.3963 ± 0.001V.

From each point, then, a value of the activity coefficient $\gamma_{\pm}$ was calculated using the expression:

$$\log \gamma_{\pm} = \frac{E^{\circ} - E}{0.1183} - \log m$$

and these values are also listed in Table I.

Cryoscopic measurements.—The results of the cryoscopic experiments are summarized in Table II. $\theta_{obs} = T_{o(obs)} - T_{s(obs)}$ is the observed temperature difference between the solvent and solution at steady state. These include a set of experiments where the heat transfer arrangement was symmetrical (copper rods protruding into both vessels), and a set of experiments where the heat transfer arrangement was unsymmetrical (copper rod protruding only into the solution vessel). For this latter set of experiments the plate temperature was measured and is recorded as T_p in Table II.

[a] Data for which T_p is given were obtained with the unsymmetrical heat transfer arrangement. If T_p is not given, the heat transfer arrangement was symmetrical.
[b] Corrected for heat transfer effect using Eq. [3] if T_p is listed, and Eq. [5] if T_p is not listed.

From the experiments with unsymmetrical heat transfer it is possible to estimate the heat transfer coefficient and to correct all the measurements for the shift in temperature caused by the displacement from equilibrium. Four of the experiments listed in Table II were performed at two or more plate temperatures and in all cases it was observed that $d\theta_{obs}/dT_p$ = −0.013 ± 0.002 in agreement with our preliminary observations on pure DMSO. This relation between observed freezing point depression and plate temperature holds over a wide range of plate temperatures and concentrations. Even when the plate temperature is 6°C, which is 12.5°C below the freezing point of DMSO, θ_{obs} is 0.180 and $d\theta_{obs}/dT_p$ = −0.0144.

This remarkably consistent behavior led us to a simple empirical correction for the heat transfer effect. Assuming that the difference between the observed temperature and the true equilibrium temperature in each vessel is proportional to the exposed cold surface area of the plate and rod and to the difference between the temperature of this cold surface (T_p) and that of the liquid, we have for the solution

$$T_{s(true)} - T_{s(obs)} = 4Q(T_{s(true)} - T_p) \quad [1]$$

and for the solvent

$$T_{o(true)} - T_{o(obs)} = 3Q(T_{o(true)} - T_p) \quad [2]$$

The factors 4 and 3 are approximately proportional to the cold area in the solution vessel (with the rod) and the solvent vessel (without the rod). These equations can be combined to give an expression for the corrected freezing point depression:

$$T_{o(true)} - T_{s(true)} = \theta_{corr} = \frac{\theta_{obs} - Q(T_{o(true)} - T_p)}{1 - 4Q} \quad [3]$$

The freezing point of pure DMSO (3, 5) ($T_{o(true)}$) is 18.55°C. We have observed that the value of the derivative $d\theta_{obs}/dT_p$ is constant over a wide range of conditions. From Eq. [3] we obtain by differentiation

$$d\theta_{obs}/dT_p = -Q \quad [4]$$

and thus Q = 0.013 ± 0.002.

For the symmetrical heat transfer arrangement where a rod is projected into both vessels, the factor 3 in Eq. [2] is replaced by a factor of 4, and when combined with Eq. [1] this yields

$$\theta_{corr} = \frac{\theta_{obs}}{1 - 4Q} \quad [5]$$

with the same value of Q as derived above.

The data in Table II for which T_p is listed were obtained with the unsymmetrical heat transfer arrangement and were corrected using Eq. [3]; and those for which T_p is not listed were obtained with the symmetrical heat transfer arrangement and were corrected using Eq. [5]. An alternate set of equations, derived using $T_{s(obs)}$ and $T_{o(obs)}$ on the right-hand sides of Eq. [1] and [2], yield the same values of θ_{corr} to within the round-off errors of the table.

Osmotic coefficients were calculated from the values of θ_{corr} using the equation (5, 8)

$$\phi = \frac{T_o\theta}{2\lambda m(T_o - \theta)}$$

with T_o = 18.55°C, and with a cryoscopic constant (5) λ = 4.07°C. These osmotic coefficients are also listed in Table II.

Activity coefficients were not calculated from these cryoscopic measurements because of the large errors inherent in the smoothing and integration required. Instead the cryoscopic and electrochemical measurements were compared in terms of the integration function j, as described in the next section.

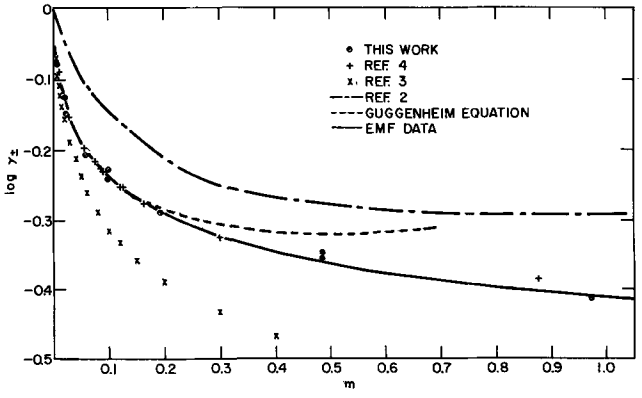

Fig. 2. Activity coefficients of LiCl in DMSO

Discussion

The activity coefficients reported in Table I are in excellent agreement with those obtained by Smyrl and Tobias (4) using the cell

$$\mathrm{Li(s)/Li^+, Cl^-, DMSO/TlCl(s)/Tl(Hg)}$$

where the thallium amalgam contained 0.967 m/o thallium. The comparison is made in Fig. 2 where it can be seen that the deviation corresponds to approximately 1 mV in the cell potential, or 0.01 in log $\gamma_\pm$. Within this same limit of error an equation of the Guggenheim form, obtained by Smyrl and Tobias,

$$\log \gamma_\pm = -\frac{1.115\sqrt{m}}{1+\sqrt{m}} + 0.282m$$

is obeyed for m less than 0.15 mole/kg. At higher concentrations the activity coefficients predicted by the equation are higher than the experimental values, but substantial ion pairing is not indicated.

The results can also be represented by the extended Debye-Hückel equation. With the parameter $B = 0.449$ [see ref. (5)] we calculate from our activity coefficients the ion size parameter $a = 3.8 \pm 0.2$Å. As with the Guggenheim form of the equation, deviations are observed for $m > 0.1$ mole/kg.

By contrast, the agreement between these measurements and those obtained by the cryoscopic method is very poor. In Fig. 2 are also plotted the activity coefficient values given by Dunnett and Gasser (3) and Skerlak *et al.* (2). These are in marked disagreement with each other and with the emf measurements. The results of Garnsey and Prue (5) were given as osmotic coefficients instead of activity coefficients, but they are quite close to those of Dunnett and Gasser. A more direct comparison can be made in terms of the function (8)

$$j = 1 - \frac{\theta}{2\lambda m}$$

which is related to the activity coefficient approximately by the equation

$$j = -\frac{1}{m}\int_0^{\ln\gamma} m\,d(\ln\gamma)$$

In Fig. 3 our results are compared with those of Dunnett and Gasser (3) and Garnsey and Prue (5). By numerical integration we also obtained j as a function of m, corresponding to the best fit to the emf data (Fig. 2 corrected to 18.5°C) and to the extended Debye-Huckel equation used by Garnsey and Prue. All calculations were made using the cryoscopic constant ($\lambda = 4.07$) determined by Garnsey and Prue. (In their paper Dunnett and Gasser used $\lambda = 4.36$.)

The most obvious feature of Fig. 3 is that the shape of the curve of j *vs.* log m is quite similar for both Dunnett and Gasser's data and Garnsey and Prue's data, but there is an almost constant difference between the two sets. This shape, however, is quite different from the shape of the curve obtained by integrating either the emf measurements or an extended Debye-Huckel equation. This discrepancy has been explained (3, 5) in terms of ion-pairing between lithium and chloride ions and both papers give association constants: Dunnett and Gasser (3), 5 kg/mole, Garnsey and Prue (5), 3 kg/mole.

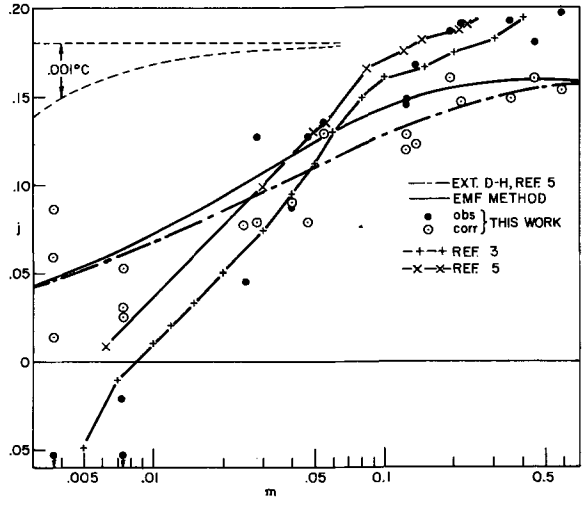

Fig. 3. Cryoscopic integration function j (see text) for LiCl-DMSO solutions.

Although ion pairing seems plausible at first glance, this explanation predicts that the cryoscopic data should approach the Debye-Huckel line at low concentration. It is quite clear from Fig. 3 that this is not the case. The cryoscopic data of Dunnett and Gasser actually give negative values for j at concentrations which are still relatively large ($0.007m$). The data of Garnsey and Prue, although sparse at low concentration, tend in the same direction. These negative values at low concentrations can be removed by adjusting the cryoscopic constant, but such adjustment only moves the data up and down on the plot of Fig. 3 and does not change its slope. No amount of adjustment can give a slope to the data which approximates that of the Debye-Huckel theory at low concentrations.

A more appropriate explanation of the difference between the previous cryoscopic measurements and the emf measurements can be found in the heat transfer phenomena inherent in the cryoscopic method. As we have pointed out in detail in this paper, even though a steady temperature may be measured, there is still heat transfer to the cooling plate from solution and crystals, and this is balanced by the heat generated from stirring the mixture of solution and crystals. Our experiments indicated that a steady temperature can be obtained for periods of up to a half hour even though the heat transfer rate is quite different and, furthermore, that the steady-state temperature of the solution depends quite strongly on the heat transfer rate. We have attempted to correct our data for this effect and, even though our results are not so precise as those of Dunnett and Gasser (3) or Garnsey and Prue (5), they appear to be in general agreement with the emf measurements at high concentrations (slightly better agreement is obtained with $\lambda = 4.12$).

In our experiments, a small quantity ($< 1\%$) of solid DMSO was present in the freezing mixture, and thus the actual concentration was about 1% greater than the value calculated from the known amount of LiCl and DMSO used to make up the solution. This error probably accounts for much of the scatter in our data and also tends to make our measured values of j too low by less than 0.01 units. Although quantitative measurements of the amount of solid DMSO present were not made, a correction for this error would place our results (without any correction for heat transfer) almost exactly in agreement with those of Dunnett and

Gasser. It should also be pointed out here that this 1% error is quite small compared to the errors resulting from the uncertainty in λ.

Our observations lead us to propose that the cryoscopic measurements on DMSO systems may suffer from an inherent systematic error. If both the solution and solvent vessels are cooled by the same heat sink, the heat transfer correction (Eq. [5]) decreases the value of j, which would bring Dunnett and Gasser's data into general agreement with the emf data. Garnsey and Prue used an absolute temperature measurement, but a similar argument could be applied to their data if a larger rate of heating was used in the determination of the freezing point of the pure solvent and dilute solutions than in the determination of the freezing point of concentrated solutions. However, such an argument must also apply to the measurements on benzoic acid solutions, which were made in the same apparatus and from which λ was determined, and thus the errors should cancel out to some extent. The striking parallelism of these two sets of measurements is not simple to explain in view of the quite different experimental setups.

We cannot make a detailed comparison of the data of Skerlak *et al.* (2), since these authors did not give any numerical results for freezing point values but only their graph of $\gamma_{\pm}$ *vs.* m. Furthermore, they did not appear to have taken any precautions to exclude moisture and the description of their experimental method is quite brief: "Beckmann apparatus with the following modifications was used for the cryoscopy. The size of the vessel containing the thermometer was about 50% narrower, wider at the (flat) bottom, and provided with a magnetic stirrer. The cooling was regulated to within 0.2 to 0.3°C with the aid of a pair of aluminum plates half immersed in the solution, suspended by constantan wires through a side arm. On cooling through 0.1°C the plates were rubbed with a thermometer against the wall of the vessel until rapid crystallization took place. Thermostated water was used in place of the cooling mixture." No mention is made of the rate of cooling or the extent to which heat transfer in the vessel was regulated. Because of the deviation of their results from those of other investigations it seems likely that the data of Skerlak *et. al.* are not of sufficient accuracy to be discussed further.

The systematic errors (resulting from heat transfer) in the cryoscopic method seem thus far to have been too great for accurate measurements of activity coefficients in DMSO solutions. To improve the accuracy, one would have to improve the heat distribution within the vessel and to eliminate virtually all heat transfer to the outside. This could probably be best achieved by modification of the apparatus described by Scatchard *et al.* (10). One would have to use a separate cover on each vessel and control its temperature carefully to correspond to that of the solution in the vessel. A metal inner container would help to obtain a more uniform temperature, but it should not be in thermal contact with the cover plate.

In performing the experiment, it would be best to have a large amount of finely distributed solid DMSO yielding a large solid-liquid interface, which would absorb the heat generated by the stirring process. This heat transfer must be minimized, but will of necessity remain at a finite value if equilibrium is to be attained even approximately. After attaining the closest approach possible to thermal and chemical equilibrium, a sample of the liquid phase should be withdrawn for analysis, since the concentration of the solution will have changed due to melting or freezing of the solid DMSO. The accuracy of the final result will depend on success in reducing heat transfer to the outside, improving heat distribution within the vessel, and minimizing the heat generated by stirring.

In conclusion, we believe that the most accurate measurements made thus far of the activity coefficients of LiCl in DMSO are those made by the EMF method. The systematic errors inherent in those measurements have been shown (4) to be negligible, and the agreement between two independent measurements is excellent.

Acknowledgments

The authors thank Dr. W. H. Smyrl for a stimulating discussion and for providing a copy of his thesis and of the translation of ref. (2). This work was supported by the Air Force Cambridge Research Laboratories, Office of Aerospace Research, under Contract No. AF 19(628)-6131, but does not necessarily constitute the opinion of that agency.

Manuscript submitted Oct. 17, 1968; revised manuscript received ca. Feb. 5, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Correction

In the paper "On the Passivity of Iron-Chromium Alloys, II. The Activation Potential" by Robert P. Frankenthal which was published in the May 1969 issue of the JOURNAL, Vol. 116, pp. 580-585, the current density for film reduction given in the first paragraph on page 581 should be 10 $\mu A/cm^2$ instead of 1 $\mu A/cm^2$.

Infrared Reflection Studies of the Oxidation of Copper and Iron

G. W. Poling[1]*

Research and Technical Department, Texaco, Inc., Beacon, New York

ABSTRACT

Infrared multiple reflectance spectra were used to record the growth of oxide films on copper and iron mirrors. Cuprous oxide and cupric oxide films were readily distinguished since they exhibit intense single bands at 640 cm^{-1} and ~560 cm^{-1}, respectively. Iron oxide films of a single composition also exhibit highly characteristic bands in the 230 to 1100 cm^{-1} region of the reflectance spectra. Spectra of mixed iron oxide films were composed of many highly overlapping bands making quantitative interpretations difficult. The intensities of the infrared bands from the copper oxide and iron oxide films were directly proportional to the oxide film thicknesses. Using a seven reflection-73° incidence optical accessory, sensitivity to detect oxide films as thin as about 5Å was achieved.

Infrared reflection spectra have been used to analyze the structure and thickness of corrosion protective films formed on metal mirrors by organic inhibitors (1). These spectra often contained bands that were attributed to metal oxide layers. The purpose of the present study was to determine whether such infrared spectra could indicate the thickness and composition of metal oxide films.

Prior use of infrared spectroscopy to characterize oxide films on metals has been scant. Hannah (2) reported that he was able to detect 10Å thick aluminum oxide films on aluminum mirrors using a four-reflection accessory. Reflection studies of Babushkin (3) indicated that copper oxide films on copper mirrors produced bands at 1055 and 610 cm^{-1}. He attributed these bands to electronic excitations rather than to lattice vibrational modes.

Interpretations of reflection spectra of surface films are usually based on comparison with transmission spectra of analogous pure compounds. Although reference spectra of several copper and iron oxide compounds are reported in the literature (4-6), most of these are nonquantitative. Therefore, reference transmission spectra of copper and iron oxides are included in this paper. These spectra often differed significantly from the oxide film-reflection spectra because the latter depend on refractive index as well as absorptivity (7, 8). These differences and the complications that they sometimes introduced in interpreting the reflection spectra are discussed.

Copper and iron mirrors were oxidized in air or in oxygen at temperatures up to 700°C. Sequences of infrared multiple reflection spectra recorded the growth of oxide films on these mirrors. Oxide film thicknesses were measured by an optical interferometer and by using interference colors. Infrared oxide band intensities were found to be directly proportional to film thickness over the range of about 0 to 5000Å.

The reflection spectra readily distinguished between cuprous and cupric oxide films on copper. Iron oxide films of a single composition also exhibited characteristic spectra. Spectra of the more common mixed iron oxide films were composed of many strongly overlapping bands that were difficult to interpret quantitatively. The reflectance spectra provided a convenient measure of the kinetics of oxidation of copper and iron.

Experimental

Recording infrared spectra.—Spectra of oxide films formed on copper and iron mirrors were recorded from 230-4000 cm^{-1} on a Beckman IR-12 spectrophotometer using multiple reflectance accessory optics. This accessory has been described in detail in a previous paper (1). To enhance sensitivity a wire-grid polarizer, oriented to transmit the parallel component, was installed in the monochromator section of the spectrophotometer (1). The accessory optics provided seven reflections at 73° incidence from two planar sample mirrors (76 x 38 x 3 mm and 51 x 38 x 3 mm). Similar optics were provided in the reference beam of the double beam spectrophotometer. Spectra of films on the sample mirrors were thereby recorded differentially against a similar set of reference mirrors. Since most spectra were recorded with the mirrors exposed to dry air, the reference mirrors were covered by a film of air-formed oxide.

The intensities of absorption bands in the reflectance spectra were measured in terms of ΔR, the fractional change in reflectivity at a band maximum; *i.e.*, $\Delta R = (R_0\text{-}R)/R_0$ where R_0 = reflectivity in absence of a film and R = reflectivity at band maximum. Spectra were recorded in a linear absorbance (A) mode or in an expanded per cent transmission ($\%T$) mode. ΔR values as low as *ca.* 0.0005 could be measured reproducibly.

Film thicknesses.—Theory predicted that the thickness (d) of an isotropic film was directly proportional to the measured ΔR values. To a good approximation the two were related by the following equation (7) (for 73° incidence angle of the parallel component)

$$d_A \simeq \left(\frac{6.38 \times 10^5 N_1^3}{\nu \cdot K_1}\right) \cdot \Delta R \qquad [1]$$

where N_1 = refractive index of the oxide, K_1 = absorption constant of the oxide = $\alpha\lambda/4\pi$ where α = absorption coefficient in cm^{-1} and λ = wavelength in cm, and ν = position of band maximum in cm^{-1}. Values of K_1 for the several oxides were determined from our reference transmission spectra (see Table I). Refractive indices were based on literature values (9, 10).

Calculations of film thicknesses using Eq. [1] were compared with independent thickness determinations. Progressions of interference colors provided approximate measures of oxide film thicknesses in the eighty to several thousand angstrom range (11-14). Checks on final oxide film thickness were made using a Bausch and Lomb interference microscope and by extracting the oxide films with concentrated mineral acids for quantitative analyses.

Materials and procedures.—Sample mirrors were prepared either by polishing OFHC copper and Armco

* Electrochemical Society Active Member.
[1] Present address: Department of Mineral Engineering, University of British Columbia, Vancouver, British Columbia.

iron plates or by vacuum deposition techniques. Most of the plate-mirrors were prepared by electropolishing the copper in 1:1 H_3PO_4:H_2O electrolyte (15, 16) and the iron in 20:1 glacial acetic acid: 70% $HClO_4$ (17). Following the electropolishing of the copper mirrors they were washed in distilled water, 10% H_3PO_4, boiling distilled water and methanol to ensure that no phosphate remained on the surfaces (16, 18). Some tests were also made on Armco iron plates that were mechanically polished using αFe_2O_3 grit.

Thin film copper and iron mirrors were vacuum deposited on top of gold films on glass flats. This enabled these metal films to be oxidized completely and the gold substrate served as mirror surfaces for recording the final spectra. The thicknesses of the Cu and Fe films were measured before and after oxidation treatments using an interference microscope. A strip along one side of each mirror was masked during film deposition. This resulted in a "step" equal to the copper or iron film thickness. Interference fringe shifts and hence film thicknesses were measured at several locations along each step.

Background reflectance spectra from the freshly prepared mirror surfaces were recorded first. The sample mirrors were then subjected to oxidation treatments and reflectance spectra were again recorded to detect absorption bands due to an oxide film. Oxide growth was monitored by recording sequences of spectra. Infrared band intensities were correlated with independent oxide film thickness determinations.

Most oxidation treatments were conducted in air in a laboratory oven. The metal mirrors were laid on a massive, preheated copper block. After the desired oxidation time the mirrors were cooled rapidly to room temperature in order to record their spectra.

Some tests were conducted with the two sample mirrors installed in a heatable (to ~450°C) infrared vacuum cell (with CsI windows) mounted on the multiple reflectance accessory. This enabled reflection spectra to be recorded continuously as a high temperature oxidation or reduction progressed. The IR-12 spectrophotometer was modified slightly so that the instrument could discriminate against the infrared radiation emitted by the hot sample mirrors. Otherwise, the emission bands from the oxide films tended to cancel out their absorption of the radiation from the instrument's source. The modification involved clutching the beam re-combining mirror of the IR-12 so that it was half way in each of the sample and reference beams. The source radiation reaching the sample mirrors was then chopped while the radiation being emitted from the hot sample mirrors was unchopped. This enabled spectra of the hot sample mirrors to be recorded while still operating in a double beam mode. Although the energy reaching the detector was halved, this did not appreciably impair the quality of the spectra.

Results and Discussion

Reference transmission spectra.—Copper oxides.— Figure 1 shows infrared spectra of (A) cuprous oxide and (B) cupric oxide in KI pellets. The 620 cm^{-1} Cu_2O band and 510 cm^{-1} CuO band were the only significant bands detected for these oxides in the 230 to 4000 cm^{-1} region. Published results indicated that the 620 cm^{-1} Cu_2O band was due to optically active lattice vibrations in this oxide (9, 19, 20). Absorption constants (K_1) for the copper oxide bands shown in Fig. 1 are presented in Table I. The anomalous dispersion effects, seen on the high frequency side of the copper oxide bands in Fig. 1, would be expected to make the observed band intensities slightly less than they should be. Identical absorption constants have however been determined from spectra of Cu_2O and CuO where such dispersion effects were all but absent. Thus the absorption constants given in Table I are thought to be accurate for the reagent grade chemicals used. Both copper oxide bands are strong infrared absorbers.

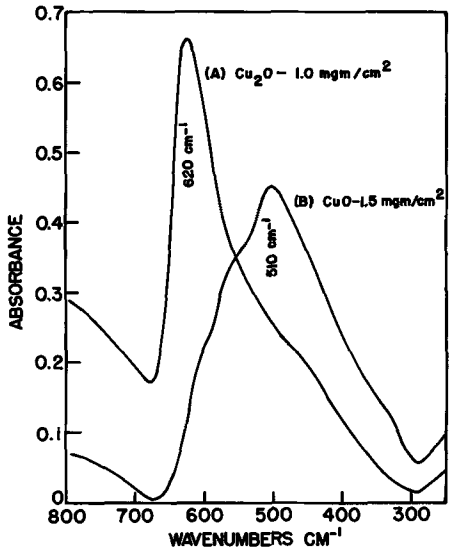

Fig. 1. Transmission spectra of Cu_2O and CuO (in KI pellets)

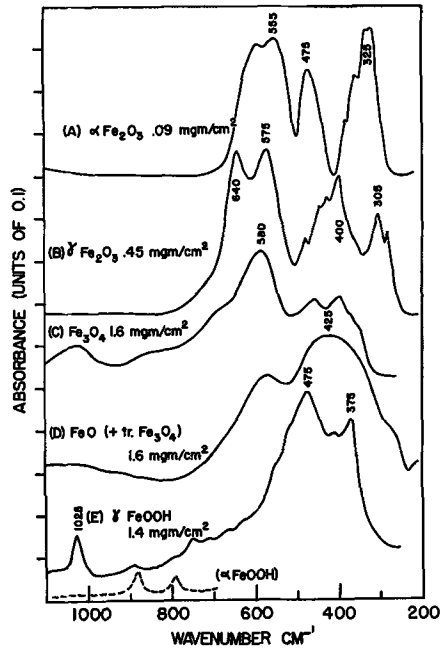

Fig. 2. Transmission spectra of iron oxides

Iron oxides.—Transmission spectra of several iron oxide compounds (in KI pellets) are shown in Fig. 2. The αFe_2O_3, γFe_2O_3, and Fe_3O_4 were all reagent grade chemicals whose compositions were checked by x-ray analysis. Wüstite (FeO) was prepared by a 700°C air oxidation of Armco iron plates. The oxidized plates were quenched in water to retain the FeO structure.

Table I. Absorption constants for copper and iron oxide infrared bands

Compound	Band position, cm^{-1}	$k^{(a)}$, cm^2/molecule	$\alpha^{(b)}$, cm^{-1}	$K_1^{(c)}$
Cu_2O	620	0.13×10^{-18}	7,600	0.93
CuO	510	0.038×10^{-18}	4,300	0.67
αFe_2O_3	555	1.00×10^{-18}	45,000	6.3
γFe_2O_3	640	0.22×10^{-18}	10,000	1.2
Fe_3O_4	580	0.066×10^{-18}	2,100	0.27
FeO	425	0.025×10^{-18}	2,800	0.53
γFeOOH	475	0.045×10^{-18}	2,800	0.46

(a) k = extinction coefficient = absorbance/C, where C = sample thickness in molecules/cm^2.
(b) α = absorption coefficient = 2.303 absorbance/path length in cm.
(c) K_1 = absorption constant = $\alpha\lambda/4\pi$.

X-ray analysis showed that a small amount of Fe_3O_4 was present in the FeO sample used to record spectrum (D) of Fig. 2. Atmospheric weathering of Armco iron plates produced the common rust (γFeOOH) whose spectrum is shown as Fig. 2(E). X-ray analysis of this sample detected a small amount of αFeOOH as well.

Each spectrum shown in Fig. 2 was sufficiently unique to identify the pure iron oxide compounds. The dissimilarities in the spectra of γFe_2O_3 (B) and Fe_3O_4 (C) were noteworthy since these compounds are not readily distinguished by x-ray or electron diffraction techniques. At the oxide thicknesses (mg/cm^2) specified in Fig. 2, no significant bands were detected in the higher wavenumber region (4000-1100 cm^{-1}) that was also scanned. Lepidocrocite (γFeOOH) and geothite (αFeOOH) were the exceptions, since these compounds exhibited O-H stretching bands at about 3400 cm^{-1}. The spectra in Fig. 2 indicate that quantitative infrared analysis of mixed iron oxides would be difficult, since the bands of each oxide overlap strongly.

Absorption constants (K_1) for the most prominent band in the spectrum of each iron oxide are given in Table I. The wide differences in these K_1 values further complicated quantitative analysis since this means that the sensitivity to detect each oxide differs markedly. The K_1 of 6.3 for the 555 cm^{-1} αFe_2O_3 band ranks it among the strongest of infrared absorbers.

Oxide films on copper.—Cuprous oxide, (a) Spectra. —Figure 3 shows a sequence of reflection spectra recorded at stages in the 140°C air oxidation of copper film mirrors. These spectra were traced from spectra recorded using a 0 to 1 absorbance range (*i.e.*, no scale expansion was required). The sample mirrors consisted of 580Å thick copper films on top of gold films on glass. Exposure times are shown on Fig. 3. Growth of the 640 cm^{-1} band terminated after about 60 min of oxidation. Spectrum (D) was typical of several spectra that were recorded after oxidation of the copper films was complete.

Comparison of the reflectance spectra in Fig. 3 with the reference spectra of Fig. 1 indicated that the oxide films were composed of relatively pure Cu_2O. This was the only oxide that was expected to form under the conditions of this oxidation (21). The observed +20 cm^{-1} shift of the absorption band from the transmission spectrum (Fig. 1A) to the reflection spectra (Fig. 3) agreed with a calculated shift. Published optical constants for Cu_2O over the 400-800 cm^{-1} region were substituted into Eq. [1] to produce a calculated reflectance spectrum. This also exhibited a +20 cm^{-1} shift in the band maximum position.

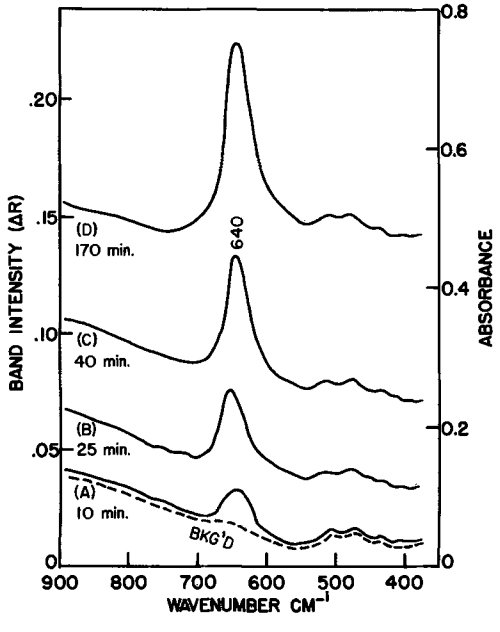

Fig. 3. Reflectance spectra from copper oxidized in air at 140°C

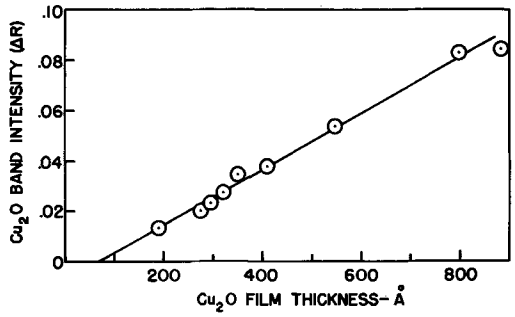

Fig. 4. Relation between Cu_2O film thickness and infrared reflectance spectra.

The reflectance spectra shown in Fig. 3 were typical of many others exhibited by both electropolished copper-plate mirrors and vacuum deposited copper films that were oxidized in air or in oxygen at 25°-200°C.

(*b*) *Film Thickness.*—Figure 4 shows that the intensity (ΔR) of the 640 cm^{-1} Cu_2O band (from Fig. 3) increased linearly with the oxide film thickness. Interference colors indicated oxide film thicknesses as oxidation progressed. The point at maximum ΔR = 0.09 and 900Å thickness represented complete conversion of the Cu film to Cu_2O (see Fig. 5). The plot extrapolated to a 70Å intercept on the abscissa. This was a reasonable value for the initial Cu_2O film thickness on the sample mirrors since they had been stored in clean air for about a month (22). The reference mirrors had been freshly prepared and were expected to have oxide films only 10-20Å thick (15). Since this oxide thickness was effectively cancelled out by recording spectra differentially, the initial films on the sample mirrors were probably *ca.* 80Å instead of 70Å.

The 900Å limiting oxide film thickness indicated in Fig. 4 was confirmed by measurements made with the interference microscope. The initial copper + air-formed oxide films were 580Å thick. These consisted of *ca.* 500Å of Cu and ~80Å of Cu_2O. Conversion of the 500Å of Cu to Cu_2O was expected to produce a Cu_2O film 500 x 1.64 + 80 = 900Å thick [1.64 is the volume ratio of Cu_2O/2Cu (21)]. The accuracy of this 900Å figure was also checked by extracting the Cu_2O from the underlying gold mirrors and analyzing quantitatively for copper.

The slope of the line in Fig. 4 was $d_A/\Delta R_{640\ cm^{-1}} \doteq$ 9000. A similar ratio was obtained from the oxidation of another set of vacuum deposited copper mirrors. Studies of rougher, electropolished copper mirrors gave $d_A/\Delta R_{640\ cm^{-1}}$ values ranging from 9500 to 11,000. Calculation of $d_A/\Delta R_{640}$ by substituting K_1 = 0.93 (Table I) and N_1 = 2.0 [at 640 cm^{-1} (9)] in Eq. [1] gave a ratio of 8600. This calculation assumed a perfectly planar surface. These results therefore suggested that the $d_A/\Delta R$ ratio increased with the roughness of the sample mirrors.

(*c*) *Oxidation kinetics.*—The kinetics of Cu_2O film growth on the copper mirrors were followed by measuring the growth in intensity of the 640 cm^{-1} infrared reflection band. Figure 5 shows results obtained from the oxidation test that resulted in the data shown in Fig. 3 and 4. Inverse logarithmic kinetics appeared to describe the oxidation better than direct logarithmic kinetics. This figure also shows that oxidation was complete after 70 min. Similar oxidation kinetics for copper have been reported in the literature (18, 23). In some of our infrared studies of the oxidation of

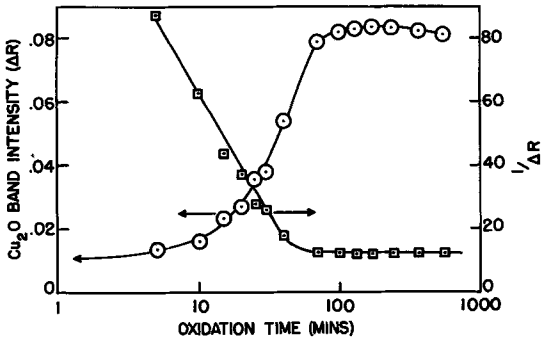

Fig. 5. Kinetics of the air oxidation of copper at 140°C

electropolished copper, linear logarithmic kinetics have provided a better fit to the data. Slight differences in the initial surface preparation are known to cause such discrepancies in the oxidation kinetics.

Cupric oxide, (a) Spectra.—When the air oxidation temperature exceeded about 200°C, CuO was found to grow on top of the Cu_2O films. Evidence for this was growth of a new band at 520-560 cm^{-1} in addition to the 640 cm^{-1} Cu_2O band in the reflectance spectra (see Fig. 1).

Relatively pure CuO films were produced by the complete oxidation of thin film copper mirrors at temperatures above 250°C (24). Figure 6 shows the reflectance spectrum that resulted from such an oxidation. The sample mirrors, consisting of 700Å Cu films on gold on glass, were first oxidized in 100 mm O_2 at 300°C for 17 hr before recording the spectrum shown in Fig. 6. An additional 22 hr oxidation in 100 mm O_2 at 400°C produced no detectable change in the spectrum. Oxidation of the copper was therefore complete when Fig. 6 was recorded.

Comparison of Fig. 6 with the reference spectra in Fig. 1 indicated that the oxide films were composed of CuO. Absence of even a shoulder at 640 cm^{-1} showed that no appreciable Cu_2O was present. The band shift of +50 cm^{-1} from the transmission (Fig. 1B) to the reflectance spectrum (Fig. 6) was in the direction expected. This resulted from the inverse dependence of ΔR on refractive index (N_1) which reached a minimum on the high frequency side of the transmission band. The magnitudes of the observed and calculated shifts could not be compared since insufficient refractive index data for CuO were available.

Comparison of the reflectance spectra shown in Fig. 3 and 6 illustrates that Cu_2O and CuO films could be readily differentiated.

(b) Film thickness.—The CuO films which exhibited the spectrum shown in Fig. 6 had an average thickness

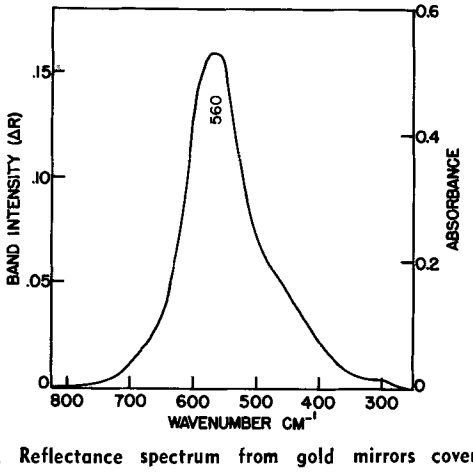

Fig. 6. Reflectance spectrum from gold mirrors covered by 1200Å of CuO.

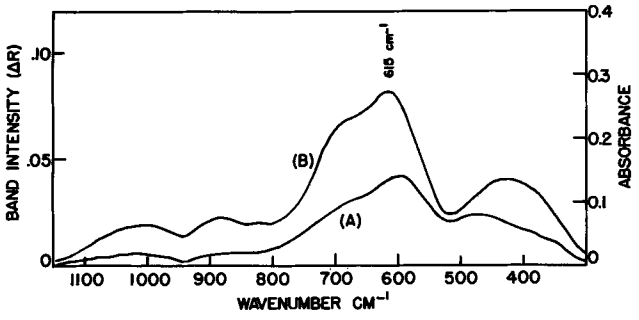

Fig. 7. Reflectance spectra from iron covered by Fe_3O_4 films formed during exposure to boiling water for (A) 21 hr (Ar purged) and (B) +6½ hr (air exposed).

of 1190Å based on measurements with the interference microscope. This checked well with the thickness expected from complete conversion of 700Å Cu films to CuO, *i.e.*, 700Å x 1.72 = 1200Å where 1.72 is the volume ratio of CuO:Cu (21). Based on this test $d_{A\ CuO} \doteq 7700\ \Delta R_{560\ cm^{-1}}$.

Oxide films on iron.—Magnetite.—Figure 7 shows reflection spectra from Armco iron mirrors covered by Fe_3O_4 films produced by exposing the iron to boiling water (25). Spectrum A was recorded after exposing freshly electropolished iron mirrors for 21 hr to boiling, argon purged distilled water. Spectrum B was recorded after an additional 6½ hr exposure to boiling H_2O at *p*H 9.0 that was open to the air. Comparison with the reference spectra in Fig. 2 shows that these reflection spectra most closely resemble the transmission spectrum of Fe_3O_4 (Fig. 2C). The +35 cm^{-1} shift of the 580 cm^{-1} band in the transmission spectrum to 615 cm^{-1} in the reflection spectrum (Fig. 7) was in the direction expected. X-ray analysis showed Fe_3O_4 to be the only iron oxide detected in these films. No correlation of Fe_3O_4 film thickness with the band intensity data was made in this test. The spectra in Fig. 7 indicated that reflection spectra could identify oxide films of a single composition on iron.

Mixed iron oxides, (a) Spectra.—A sequence of reflection spectra that resulted from the 250°C air oxidation of Armco iron mirrors is shown in Fig. 8. Oxidation times are shown with each spectrum. These mirrors were prepared by mechanically polishing the iron with αFe_2O_3. Similar spectra also resulted from the 250°C air oxidation of electropolished mirrors and from oxidation of vacuum deposited iron-film mirrors. No bands other than those shown in Fig. 8 were observed over the 4000 to 230 cm^{-1} spectral range.

The bands exhibited by the oxide films in the earlier stages of oxidation (*i.e.*, spectra A and B) are attributed to Fe_3O_4 and γFe_2O_3 (see Fig. 2). Marked enhancement of the 650 cm^{-1} bands in these spectra cannot be explained by simple additivity of the ref-

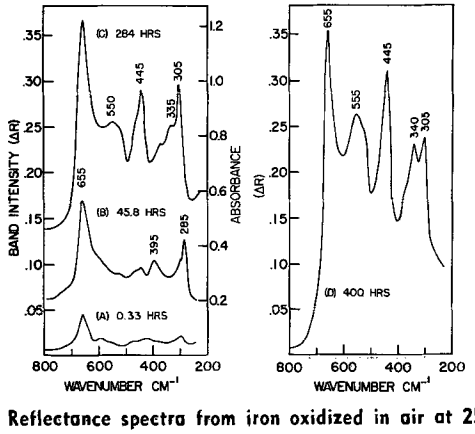

Fig. 8. Reflectance spectra from iron oxidized in air at 250°C

erence transmission spectra (B and C of Fig. 2). Instead, the additional dependence of ΔR on refractive indices (N_1) probably contributed to the intensity of this band in the reflection spectra of these "duplex" films. This is based on the fact that N_1 dips to a minimum on the high frequency side of a strong absorption band and $\Delta R \propto 1/N_1^3$ (see Eq. [1]) (7, 8).

After several hundred hours of oxidation at 250°C, bands attributed to αFe_2O_3 emerged from the reflection band envelope. These new bands are shown at ~560, 440, and 310 to 340 cm^{-1} in spectra C and D of Fig. 8. Comparison with spectrum A of Fig. 2 shows that these bands are in reasonable agreement with the reference spectrum of αFe_2O_3. Thus, the oxide appeared to be composed of Fe_3O_4, γFe_2O_3, and αFe_2O_3 films at this stage. Although the αFe_2O_3 bands became relatively intense in spectrum (D), this oxide probably composed only a small part of the films. Reference to Table I shows that αFe_2O_3 absorption was 4 to 20 times greater than γFe_2O_3 or Fe_3O_4 and Eq. [1] shows that film thickness was inversely proportional to these absorption constants. The infrared evidence for the $Fe_3O_4 + \gamma Fe_2O_3 + \alpha Fe_2O_3$ composition of such oxide films is in qualitative agreement with results in the literature (21, 26).

(b) *Film thickness.*—Oxide films formed by air oxidation of iron at 25°-300°C usually exhibited a linear relation between the intensity (ΔR) of the 650 cm^{-1} band and the film thickness. Figure 9 shows that the relation was reasonably linear from 0-1100Å for the oxide films that exhibited the spectra shown in Fig. 8. The oxide film thicknesses were determined by interference colors (12). The slope of the line in Fig. 8 is $d_A/\Delta R_{650\ cm^{-1}} = 6100$. In several other tests this ratio has varied from 5000 to 8000. Differences in surface roughness of the mirrors appeared mainly responsible for this variation as was described previously for copper mirrors.

Oxidation studies on vacuum deposited iron-film mirrors were used to check the thickness calibration of the infrared $\Delta R_{650\ cm^{-1}}$ data. An interferometer was used to determine film thicknesses as previously described for the oxidation of copper. These measurements indicated that over the range of 0-1200Å, the interference colors provided a reasonably accurate measure of the oxide film thickness.

(c) *Oxidation kinetics.*—Figure 10 shows direct logarithmic (A) and parabolic (B) plots of the infrared iron-oxide band growth from two separate tests. The solid lines show results from the 250°C air oxidation of mechanically polished iron that was also described in Fig. 8 and 9. The dashed lines show results of a similar oxidation using electropolished Armco iron mirrors. These graphs indicate that the oxidation of both sets of specimens obeyed direct logarithmic kinetics in the early stages of film growth and parabolic kinetics in the later stages. The transition occurred when the oxide films were 300-400Å average thickness. Similar transitions in the oxidation kinetics of iron have been attributed to formation of compact oxide barrier layers (21). Such layers made diffusional processes rate controlling and thus resulted in parabolic oxidation kinetics.

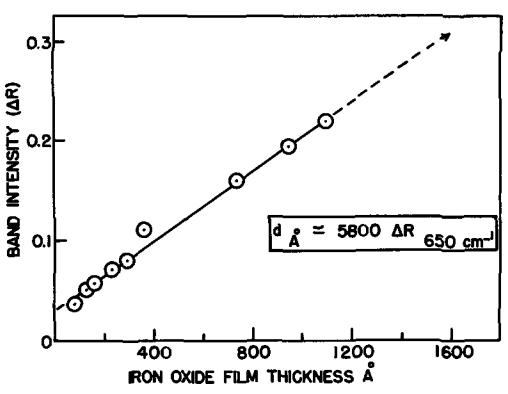

Fig. 9. Relation between iron oxide film thickness and infrared reflectance spectra.

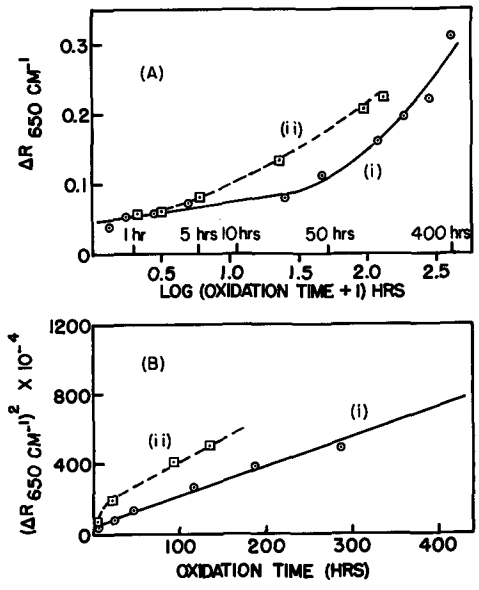

Fig. 10. Kinetics of the air oxidation of iron at 250°C. (i) Mechanically polished, (ii) electrolytically polished.

The kinetics of the oxidation of iron and subsequent hydrogen reduction of the oxide film were studied with the sample mirrors installed in a heatable vacuum cell. By recording rapid sequences of spectra over the 230 to 1100 cm^{-1} range, growth or reduction of oxide films could be followed closely while the sample mirrors were at temperature. In one experiment two 710Å iron-film mirrors were oxidized in 100 mm O_2 at 300°C for 16 hr and then at 400°C for an additional 3 hr. The appearance of the spectral sequences recorded at 300° and 400°C were similar to those shown in Fig. 8A and B. No αFe_2O_3 bands were observed. The 19 hr oxidation resulted in complete conversion of the iron films (on gold mirrors) to $Fe_3O_4 + \gamma Fe_2O_3$ films about 1500Å thick. These iron oxide films were then exposed to flowing Pd-diffused H_2 (40 cc/min) at 250°C.

Rapid sequences of reflection spectra showed that the 650 cm^{-1} iron oxide bands were reduced from a maximum ΔR of 0.30 to zero intensity in a 2 hr period. Such complete reduction of the oxide at the relatively low temperature of 250°C was surprising.

Conclusions

Infrared reflectance spectra of oxide-covered copper and iron mirrors exhibited intense metal oxide absorption bands in the 1100 to 230 cm^{-1} region. Cuprous oxide films exhibited a single strong peak at 640 cm^{-1}. They were readily distinguished from cupric oxide films which produced a slightly weaker band at 560 cm^{-1}. Reflection spectra of oxide films on iron mirrors were usually more complex and more difficult to interpret. The added complexity of these spectra was probably caused by the existence of both tetrahedral and octahedral coordinations of the iron ions in the iron oxide lattices. Thus changes in oxide composition did not produce dramatic changes in the spectra since this involved only redistribution of the iron ions between these two types of sites. In spite of their complexity, the reflection spectra did appear to distinguish between the cubic oxides (Fe_3O_4 and γFe_2O_3) and αFe_2O_3 which has a corundum structure.

The intensities of metal oxide absorption bands, in the reflection spectra, increased in direct proportion to the oxide film thickness. The following approximate relationships were observed

$$d_{A\ Cu_2O} \doteq 10{,}000\ \Delta R_{640\ cm^{-1}}$$

$$d_{A\ CuO} \doteq 7{,}700\ \Delta R_{560\ cm^{-1}}$$

$$d_{A\ Fe_xO_y(cubic)} \doteq 7{,}000\ \Delta R_{650\ cm^{-1}}$$

These linear relationships indicated that effects of any anisotropism on the spectra of the films were small. Use of polycrystalline metal mirrors probably contributed to this by randomizing the molecular orientations in the oxide films. Results using mirrors made from single crystals of metals might be quite different.

The seven reflection accessory used in these studies enabled measurement of ΔR values as low as 0.0005. This meant that copper and iron oxide films as thin as 3-5Å average thickness could be detected. By using only one reflection oxide films up to about 5000Å thickness could be studied.

Most metal oxides exhibit strong lattice bands in the 200 to 1000 cm^{-1} region (4-6). Therefore, infrared reflectance spectroscopy could provide a useful tool for studying either the growth or reduction of oxide films on most metals.

Electrical Breakdown in Thin Dielectric Films

N. Klein[1]

Bell Telephone Laboratories, Allentown, Pennsylvania

ABSTRACT

Thermal and electric breakdown processes in thin film insulators are discussed. Interpretation of the processes is greatly facilitated by using specimens with self-healing breakdowns, cleared of weak spots. Thousands of breakdown tests can be carried out on such specimens. Thermal breakdown is initiated by an increase in the electrical conductance by joule heat; breakdown occurs at a definite voltage, which can be calculated with good accuracy. Electric breakdown can be initiated by the increase of the electrical conductance in a channel by a pulse, such as an electronic avalanche. Destruction arises by discharge of the electrostatic energy stored in the specimen through the channel. The incidence of breakdown is of a statistical nature. In contrast to concepts which assume a definite breakdown field, electric breakdown can occur in certain oxides over a wide range of fields. Breakdowns occur at a rate which increases quasi-exponentially with field and also with temperature, *e.g.*, in hafnium dioxide. Experimental results are examined in the light of existing breakdown theories. It appears that further theoretical and experimental work is needed for the interpretation of the oxide results.

Investigations on breakdown are greatly facilitated in thin films because test voltages are low. Earlier work on thin films was concerned with the influence of insulator thickness on breakdown field, and dielectrics such as mica (1), NaF and KBr (2), and aluminum oxide were investigated (3). In the investigations problems were encountered with thin films which were known to arise also in thicker insulators. The specimens shorted and the breakdown voltage measured was not that of the bulk but that of the weakest spot. There was often a large spread in the breakdown properties of a batch of specimens. Breakdown caused destruction in the insulator and in the electrodes mainly by melting and by evaporation. The destruction was not only due to the breakdown event, but also due to the follow-up current. These experi-

[1] On Sabbatical Leave from TECHNION—Israel Institute of Technology, Haifa.

mental circumstances made it difficult to interpret breakdown.

Conditions are different when specimens with self-healing breakdown are tested. In such specimens one electrode at least is thinner than 1000 to 2000Å. On breakdown the thin electrode does not melt, but evaporates at the breakdown site. Shorting does not occur, and damage arising from the follow-up current is avoided. Such breakdowns were first observed nearly sixty years ago (4), and use was made of the self-healing property in the making of certain paper capacitors (5, 6).

Breakdown investigations with thin film specimens exhibiting self-healing properties were reported on mylar by Inuishi and Powers (7) and on silicon oxide by Siddall (8). Kennedy (9) observed self-healing breakdowns in aluminum oxide and Young (10) in tantalum pentoxide. It was found that hundreds and often thousands of breakdown tests could be carried out on an individual specimen. Klein and co-workers (11-17) investigated silicon oxide specimens with self-healing breakdowns and found that (*a*) distinction can be made between the properties of weak spots and those of the bulk, (*b*) the processes involved in the destruction can be identified and distinguished, (*c*) the thermal breakdown field can be measured without destruction and can be accurately calculated, (*d*) the electric breakdown can be observed with minimal destruction, and (*e*) the breakdown properties can be ascertained from measurements on one specimen. It appeared from these results that the use of thin film specimens with self-healing breakdowns offers considerable advantages over the use of shorting specimens in investigations on breakdown. This article will therefore be based mainly on experimental results obtained with self-healing breakdowns.

Breakdown can be produced by a number of processes. Several of them, such as electrochemical deterioration, dendrite formation, and gas discharges can considerably decrease the breakdown strength. These processes can be avoided with suitable care and will not be discussed here. The processes which determine the highest breakdown fields are of interest. One of them is electromechanical breakdown (18), which is due to the mechanical collapse of the insulator by the attractive forces of the electrodes. This breakdown is restricted mainly to a few soft polymers, such as polyethylene. Other breakdown processes are the thermal and the electric breakdowns. These are generally observed in insulators and the properties of these two kinds of breakdowns will be described for thin film insulators. For both kinds of breakdowns the destruction occurs mainly by melting and by evaporation. Apart from this aspect, the processes of the two kinds of breakdowns are different. The following discussion will relate to specimens from which the weak spots were eliminated by self-healing breakdowns.

Thermal breakdown has been understood since the investigations of Wagner and Hayden and Steinmetz and information on earlier work can be found in ref. (19-22). Thermal breakdown is initiated by an increase in the electrical conductance by joule heat and/or dielectric heat. In thin films without weak spots the breakdown involves the whole insulator and occurs at a definite voltage. Destruction occurs simultaneously over nearly the whole insulator. It is possible, however, to determine the breakdown voltage without destroying the specimen.

The term electric breakdown relates to events which are known in the literature under various names, such as intrinsic, avalanche, and field emission breakdown. These processes are discussed in detail in ref. (19-22). Electric breakdown in thin films can be initiated by the increase in the electrical conductance by a pulse, such as an electronic avalanche. The breakdown involves a small spot only. The incidence of breakdown is often of a statistical nature. Experimental results will be presented for oxides, showing that electric breakdown does not occur at a sharply defined field, but over a wide range of fields in each of the substances. The breakdown destroys a very small part of the insulator, and this destruction cannot be avoided on testing.

Both thermal and electric breakdown may occur in an insulator, and breakdown is produced by the process which arises at the lower field.

Thermal Breakdown

Investigations for bulk breakdown properties begin with the elimination of weak spots and with the identification of the breakdown process. The identification of the process, whether it is thermal or electric, is relatively simply achieved by measuring the d-c leakage current I *vs.* voltage V characteristic of the insulator. For this purpose the thin film specimen is connected to the power source with a series resistor larger than 10 kohms. Such a resistor is usually small relative to the specimen resistance in the vicinity of breakdown, but it is sufficiently large to prevent propagating breakdowns (11) which destroy relatively large areas at weak spots and in specimens exhibiting electric breakdown.

The following is observed on specimens exhibiting thermal breakdown in the bulk: When increasing voltage is applied, breakdowns are observed to occur at a rate which increases with voltage. When a certain voltage in maintained for a period of 5-30 min, the breakdowns stop. These breakdowns are ascribed to weak spots (11) and the destruction caused is of the single hole type illustrated by Fig. 1. After the elimination of the weak spots a V-I characteristic can be measured as shown schematically in Fig. 2 (13). This characteristic exhibits a maximum voltage V_{dm} and a negative resistance range. At point D current and thermal runaway occur and practically the whole specimen is destroyed simultaneously. This mode of destruction is in sharp contrast to the small single hole destruction which occurs at weak spots and as will be described later, occurs also on electric breakdown.

When currents are restricted to values smaller than at D, destruction is avoided. The V-I characteristic can be repeatedly measured and V_{dm} has a fixed value for a given set of conditions. V_{dm} is the maximum thermal breakdown voltage (13) and destruction arises at this voltage when the series resistance is negli-

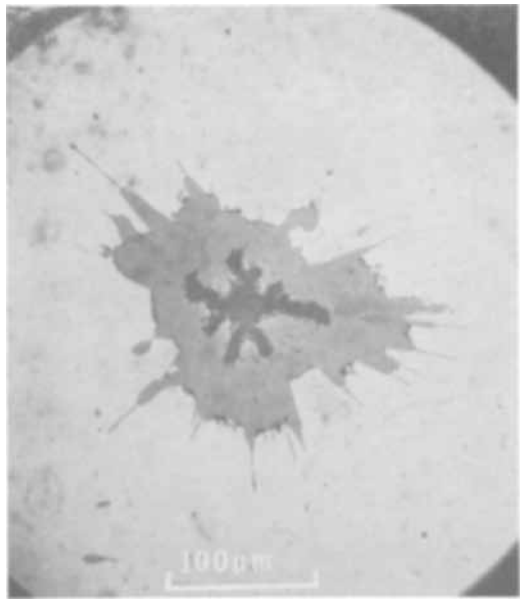

Fig. 1. Microgram of single hole breakdown in a tantalum pentoxide specimen anodized to 130V on sputtered tantalum. The top electrode is gold. The center black area is a hole through oxide and through electrodes, the gray area is oxide bared of gold.

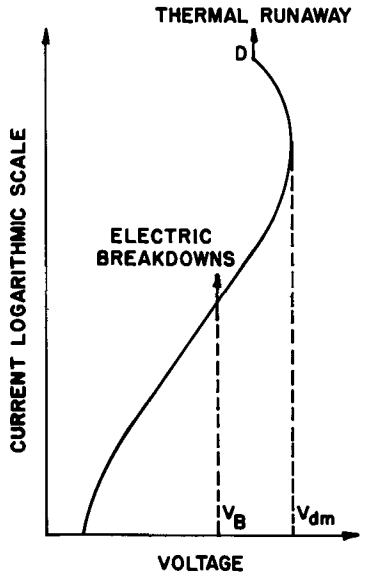

Fig. 2. Identification of the breakdown process with the *V-I* characteristic of the specimen.

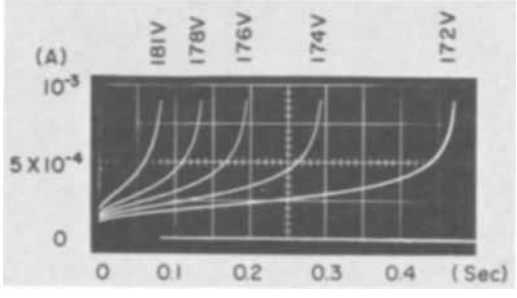

Fig. 3. Current *vs.* time oscillograms of a 5000Å thick, 4 x 10^{-3} cm^2 vapor grown silicon oxide specimen obtained on the application of voltage steps. The parameter is the applied voltage (16).

gibly small. With increasing series resistance the point of destruction D moves upward on the *V-I* characteristic. The nature of thermal runaway is well illustrated by current *vs.* time oscillograms, obtained when step shaped voltage pulses larger than V_{dm} are applied to the specimen. This is shown for a silicon oxide insulator in Fig. 3, with pulse voltage as a parameter (16). Thermal runaway is possible in insulators because above some temperature the electrical conductivity increases exponentially with temperature. An increase in temperature by joule heat increases the conductivity, which in turn increases the joule heat leading to mutual escalation. Runaway arises due to instability, when the joule heat input cannot be balanced by the heat loss of the heat transfer processes.

At the voltage V_{dm} the joule heat in the insulator is significant, a few watt per square centimeter, and the specimen temperature is a few tens of centigrades above ambient. The thermal nature of breakdown is indicated by this joule heat at the onset of the negative resistance range. It can be indicated also by showing that increased cooling increases V_{dm} (13). Negative resistance ranges with insignificant joule heat are observed sometimes in semiconductors (23). In this case, the breakdown is not thermal and may be caused by double injection. The verification of the nature of the process requires the calculation of V_{dm} on the assumption of thermal breakdown and the comparison of the calculated and the observed values of V_{dm}.

The calculation of the thermal breakdown voltage requires the solution of the equation of conduction of heat for the specimen and for the adjacent solids (19-22). For the calculations current continuity is assumed in the insulator and the thermal and electrical conductivity, K and σ are given as functions of temperature T, field F, and occasionally of time t. The equation of conduction of heat is with c the specific heat per unit volume

$$c\frac{\partial T}{\partial t} = \text{div } (K \text{ grad } T) + \sigma F^2 \qquad [1]$$

the equation for current continuity is

$$\text{div } (\sigma \vec{F}) = 0 \qquad [2]$$

and the relations for K and σ are

$$K = K(T) \text{ and } \sigma = \sigma(T,F,t) \qquad [3]$$

where σ may also be an explicit function of time. Solutions of Eq. [1]-[3] are available in thick insulators only for simple cases. Solutions are, however, relatively easily obtained for thin insulators, because use can be made of the following simplifications: the insulator temperature is assumed to be uniform and the insulator is considered as a planar source of heat. The solution of the equations yields the thermal breakdown field F_m as that field for which the temperature in the insulator rises to a destructive value T_c. $T_c \to \infty$ can often be used in the calculation of F_m without any significant error.

The possibility of obtaining simple expressions for F_m depends on the functional form of the relation $\sigma = \sigma(T,F,t)$. Various relations of exponential form were found to fit experimental observations. Sze (24) used for silicon nitride the relation

$$\sigma = \sigma_o e^{-q(\phi - dF^{1/2})/kT} \qquad [4]$$

σ_o, ϕ, and d being constants of the substance, q the electronic charge and k Boltzmann's constant. O'Dwyer used for σ an equation proposed by Hartman *et al.* (25)

$$\sigma = \frac{C_1 h}{F} e^{-(E - \alpha_1 F^{1/2})/kT + \alpha_2 F^{1/2}} \qquad [5]$$

with h the insulator thickness and C_1, E, α_1, and α_2 constants of the substance. These equations are based on an assumed physical mechanism of the electrical conduction in an insulator. The use of Eq. [4], [5] leads to relatively involved relations for the breakdown field.

It appeared that for the calculation of F_m the relation for σ need not be fundamental, but may be empirical, as long as it fits observations accurately. Such a relation is often

$$\sigma = \sigma_o e^{[bF + a(T - T_o)]} \qquad [6]$$

where σ_o, b, and a are determined from the *V-I* characteristics of the specimen, and T_o is the ambient temperature. Calculations with Eq. [6] lead to relatively simple relations for the thermal breakdown field F_m in thin insulators. Such relations for the breakdown fields on d-c F_{dm}, on a-c F_{am}, and on pulses F_{pm} are listed in Table I (13, 15, 16).

Although these relations were derived for infinitesimally thin insulations, their use can be extended to thicker insulations. Whitehead and Nethercot (26) found that for d.c. and a.c. at lower fields the error in F_m using thin film relations is 1.5%, when the thermal resistance across the insulator is one tenth of the thermal resistance from the specimen to ambient.

The use of the relations of Table I in the verification of thermal breakdown will now be illustrated. Figure 4 shows the d.c. *V-I* characteristics of a 4100Å thick, 0.06 cm^2 evaporated silicon oxide specimen with 500Å thick aluminum electrodes in the temperature range 4.2 to 515°K (14). The curves permit calculation of σ using Eq. [6] and determination of F_{dm} as function of the temperature. The observed values of F_{dm} are compared in Fig. 5 with those calculated with Eq.

Table I. Relations for the thermal breakdown field

The d.c. breakdown field F_{dm}:

$$F_{dm} = \frac{1}{b} \log \frac{\Gamma}{eaAh\sigma_0 F^2_{dm}} \quad [7]$$

b, a, and σ_0 are determined from the V-I characteristic, A is the specimen area, h is the dielectric thickness, Γ is the thermal conductance of the specimen, and e the basis of natural logarithms.

The a.c. breakdown field F_{am}:

$$B(bF_{am}) = \frac{\Gamma}{eahA\sigma_0 F^2_{am}} \quad [8]$$

where

$$B(bF_{am}) = I_0(bF_{am}) + I_2(bF_{am}) \quad [9]$$

and I_0 and I_2 are modified Bessel functions.

The pulse breakdown field F_{pm}:

$$F_{pm} = \frac{1}{b} \log \frac{K}{eah\sigma_0 HF^2_{pm}\psi(\bar{\tau})} \quad [10]$$

with

$$\bar{\tau} = K\tau/cH^2 \quad [11]$$

$$\psi(\bar{\tau}) = 1 - \frac{8}{\pi^2} \sum_{n=0}^{\infty} \frac{e^{-K(2n+1)^2\pi^2\tau/4ecH^2}}{(2n+1)^2} \quad [12]$$

where K is the thermal conductivity, c the specific heat per unit volume, and H the thickness of the substrate, respectively, and τ the pulse duration.

For $3.5h^2/\kappa < \tau < 0.5H^2/\kappa$ Eq. [10] simplifies to

$$F_{pm} = \frac{1}{b} \log \frac{\left(\frac{\pi Kc}{4e\tau}\right)^{1/2}}{ah\sigma_0 F^2_{pm}} \quad [10a]$$

For $\tau < 3.5h^2/\kappa$ heat conduction is negligible and

$$F_{pm} = \frac{1}{b} \log \frac{c_e}{a\tau\sigma_0 F^2_{pm}} \quad [10b]$$

where $c_e = (c_i h + c_m h_m)/h$, c_i and c_m being the specific heat of insulator and electrode metal, respectively, and h and h_m the thickness of insulator and of the two electrodes, respectively.

Equations [10]-[12] are based on the assumption that heat is transported from the specimen by conduction through the substrate only. Under experimental conditions heat is transported also by the electrodes and by convection. The effect of the additional heat flow paths is an increase in the value of K. This apparent value of K is calculated with Eq. [10] from one value of V_{pm} observed for one pulse duration τ.

[7]. Figure 5 also presents a curve for tantalum pentoxide obtained by anodizing tantalum sheet (22) (the tantalum was negative) and observations on silicon nitride by Sze (24). The breakdowns in silicon nitride were thermal in the temperature range, where F_{dm} decreases, but were assumed to be electric at 128°K.

Experimental results in silicon oxide on a.c. are presented in Fig. 6 (15). The ratio of the a-c peak and d-c breakdown voltage F_{am}/F_{dm} is by Eq. [7] and [8] a function of the parameter bF_{dm} only. The calculated ratio is given in Fig. 6 by the curve and the experimental results for a number of specimens at room temperature by dots. The F_{am} value of this specimen was not influenced by frequency below 1000 Hz. Above this value F_{am} decreased slowly with frequency due to the added heating associated with dielectric loss.

Breakdown test results obtained on the application of pulses to a 5000Å thick silicon oxide specimen are presented in Fig. 7, where V_{pm}, the thermal pulse breakdown voltage, is plotted *vs.* pulse duration τ (16). The small circles are measured results, and the curve was calculated. Breakdowns in this kind of specimen were observed to be thermal up to about 210-215V. However, above 195V electric breakdowns were observed as well. These occurred after a mean time lag τ_B, which decreased rapidly with increasing voltage (discussed in the following section). There was a large scatter in the time lag around τ_B. Breakdowns were electric when the time lag was less than τ, the pulse duration for thermal breakdown; in the range of 210-215V effectively all breakdowns were electric. The two kinds of breakdown can be distinguished, *e.g.*, by oscillograms, which are shown in Fig. 3 and 15 (16).

The results of Fig. 5-7 verify the thermal nature of the breakdowns in silicon oxide on d.c., a.c., and pulses of longer duration. The agreement of measured and calculated values of the breakdown field is of the order of 1%. Thermal breakdown was observed in silicon oxide in the thickness range of 2900Å to 15 μm (13). Thermal breakdown fields up to about 10^7 V/cm were observed in silicon nitride (24), in evaporated silicon dioxide kind of specimens (13), and in glass (25) 5-100 μm thick. The influence of ambient gas pressure was investigated from 2.10^{-5} Torr to atmospheric pressure (17). A small decrease in the maximum thermal

breakdown field was observed with a decrease in pressure. This was found to be caused by the decrease in the thermal conductance due to diminishing heat transport by convection.

The thermal breakdown results can be summarized in breakdown characteristics by plotting F_m *vs.* temperature with pulse duration as a parameter. This is illustrated in Fig. 8 for a 5000Å thick silicon oxide specimen (16).[2] Such results may be obtained on an individual specimen, because the tests are nondestructive.

Electric Breakdown

Experimental observations.—Recent studies on amorphous thin film oxides with self-healing breakdowns produced new results, which enlarge the information on electric breakdown available from shorting specimens. The results do not support accepted concepts and seem to be of interest for the interpretation of breakdown. The subject of this section is developed, therefore, mainly around the observations on the oxides, which were anodically grown on tantalum, hafnium, and aluminum and thermally grown on silicon.

Single hole breakdowns were observed in the oxides above a minimum voltage, the magnitude of which varied from specimen to specimen. On the application of a constant voltage larger than the minimum repetition of breakdown events was observed. The rate of the breakdown events decreased with time to a steady value, and this value was found to increase rapidly

[2] In this case the characteristics were obtained by a combination of measurements and of calculations. The upper end of the curves is presented by broken lines, because in that range the breakdowns were electric.

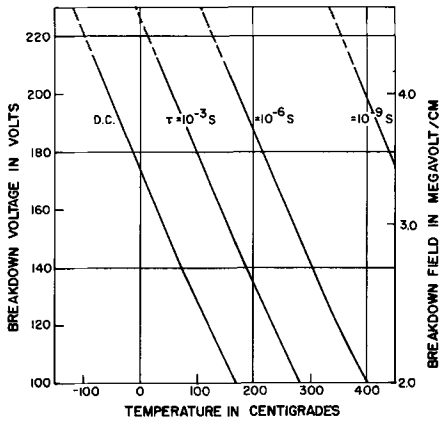

Fig. 8. Thermal breakdown characteristics of a 5000Å thick, 4 x 10^{-3} cm², vapor grown silicon oxide specimen. The parameters are the pulse duration (16)

with voltage. The rate became so large in the vicinity of a voltage V_B (see Fig. 2) that the specimen was completely destroyed by separate single hole breakdowns within a small fraction of a second.

The oxides differed from the specimens with thermal breakdown with respect to the d-c *V-I* characteristic. A maximum voltage V_{dm} and a negative resistance range were not observed (Fig. 2). The characteristic could be measured only to some voltage below V_B, for which the breakdown rate was not yet large. The average joule heat in the specimen was usually insignificant at the voltage V_B. When the maximum thermal breakdown voltage V_{dm} was calculated, it was found that $V_B < V_{dm}$. Thermal breakdown of the bulk therefore could not occur.

The oxides differed from specimens exhibiting thermal breakdown also with respect to the effect of a constant voltage. Single hole breakdowns did not settle down to a steady rate in specimens exhibiting thermal breakdown of the bulk, but stopped after some time. These single hole breakdowns were ascribed to weak spots (11). The question arose, therefore, whether the single hole breakdowns in the oxides were not due to numerous weak spots. To investigate this question the specimen was subjected to a series of breakdowns in sequential tests. In such tests the voltage rises typically within seconds to breakdown, collapses, rises again to breakdown, etc. Results of such tests are illustrated for a 2000Å thick thermally oxidized silicon dioxide specimen in Fig. 9 where the breakdown voltages *vs.* the serial number of the test are plotted (22). The first breakdown voltage at the weakest spot occurred at 38V and the breakdown voltage in the subsequent 150 breakdowns increased to a steady average value of 140V with a scatter of a

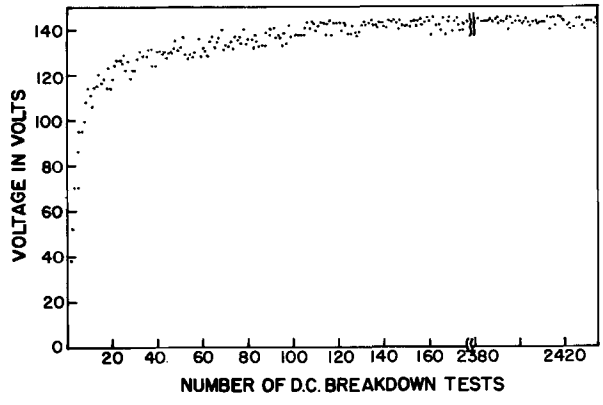

Fig. 9. Breakdown voltages of subsequent breakdown tests on a thermally grown 0.1 cm², 2000Å thick silicon dioxide specimen (22).

few per cent. The results were interpreted that the first 150 breakdowns are due to weak spots, while subsequent breakdowns are characteristic of a bulk property (22). Similar results were obtained with a number of insulators and it is believed that breakdowns at weak spots and in the bulk can be distinguished in these oxides by sequential breakdown testing. Impact ionization and field emission may be instrumental in these breakdowns and it is assumed that electric breakdowns were observed in the oxides.

Breakdowns in the bulk did not occur only at the voltages found by sequential tests, and this is illustrated here by the example of an 0.1 cm^2 tantalum pentoxide specimen with a gold electrode, anodized to 130V. The bulk breakdown voltage on sequential testing averaged 125V when the tantalum was negative. When instead of sequential testing with rising voltages, constant voltage was applied at various magnitudes, breakdowns could be observed from 80 to about 160V. The breakdowns occurred at random sites and at random time intervals. The voltage influenced the rate at which breakdowns repeated and while several hours might have elapsed between breakdowns at 80V, thousands of breakdowns occurred per second at 160V. This kind of behavior was observed also in anodic oxides of hafnium and aluminum, and in thermally grown silicon dioxide and is illustrated for aluminum trioxide in Fig. 10. The dielectric of this specimen was produced by anodization, the oxide thickness was 1700Å, the area 0.1 cm^2 and the counter-electrode was gold. In Fig. 10 the breakdown rate R_B is plotted *vs.* the voltage for room temperature, when either the aluminum, or the gold are negative and for liquid nitrogen temperature, when the aluminum is negative. The breakdown rate appears to rise quasi-exponentially with voltage. There is a very marked polarity effect, which may be related to the electrode material. The breakdown rate decreases sharply with temperature both in the oxides of aluminum and of tantalum and in hafnium dioxide the decrease was found to be quasi-exponential with temperature. It is significant that the breakdown rate usually remains constant with increasing number of breakdowns. This is illustrated for a hafnium dioxide specimen in Fig.

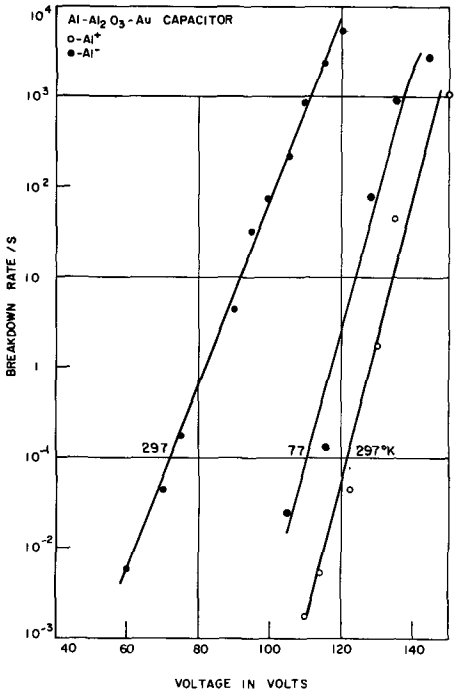

Fig. 10. Rate of breakdown R_B as function of voltage in a 0.1 cm^2 $Al-Al_2O_3-Au$ specimen. Thickness of oxide 1700Å. Curve 1 and 3 at room, curve 2 at liquid nitrogen temperature. Curve 1 and 2 the aluminum negative, curve 3 the gold negative.

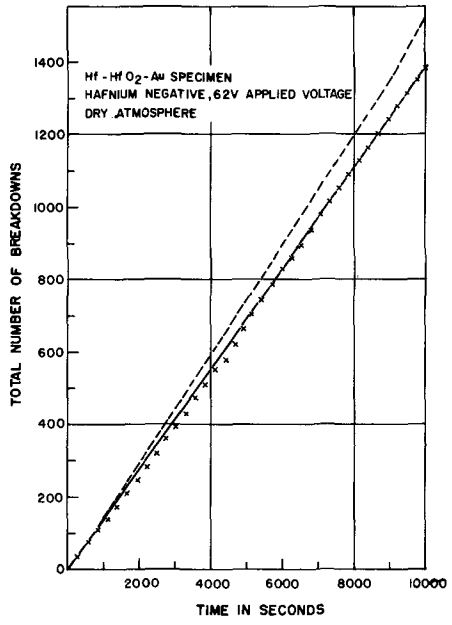

Fig. 11. Number of breakdowns *vs.* time of application of 62V to 3250Å thick, 0.1 cm^2 hafnium dioxide specimen. The hafnium was negative. Crosses indicate batches of about 40 breakdowns.

11, where the number of breakdowns is plotted *vs.* the duration of voltage application. The area of the specimen decreased in the course of this experiment. As the breakdown rate R_B is related to the undamaged specimen area of 0.1 cm^2 in Fig. 10 and 11, the full line was corrected for area decrease in Fig. 11 to the broken line. The gradient of the broken line shows that R_B is mostly constant. An increase in R_B is indicated only after 1000 breakdowns. This slight increase may be due to new breakdowns occurring at the weakened periphery of the earlier breakdowns.

The measurements of R_B extended over 6-7 decades. Extension of the measurements, however, is of interest both to lower and to higher breakdown rates. There is an indication of what happens at low breakdown rates. When fields are low at low R_B values there is a tendency for the R_B curve to bend parallel to the ordinates. This was observed with hafnium dioxide specimens. The extension of the measurement of R_B to higher values is limited by the method of determining R_B. The breakdown rate is determined by dividing the time for which full voltage was maintained by the number of breakdowns. When R_B becomes so large that the voltage rise time on the specimen becomes comparable to the average interval between breakdowns, constant voltage periods become rare, breakdowns occur while the voltage is rising and R_B cannot be determined. The limit for R_B can be increased by decreasing the voltage rise time on the specimen.

The question arises, whether there is an upper voltage limit for electric breakdowns. Evidence on this question is available only for evaporated silicon oxide specimens with self-healing breakdowns (16). A highest average electric breakdown voltage, V_B, was observed with breakdowns occurring while the voltage was rising and a breakdown rate could not be determined. Pulse rise times varied from 5×10^{-8} to 5×10^{-6}s and the peak voltage prior to breakdown was maintained for 10^{-9}s, or less. As shown in Fig. 12 for the silicon oxide specimen V_B slightly increased with decrease in the temperature but was not influenced by pulse rise time. The bars in Fig. 12 denote the standard deviations in the measurements on the specimen. The thermal pulse breakdown data of this specimen were presented earlier in Fig. 7.

The experimental results in the oxides are in conflict with assumptions of a sharply defined breakdown

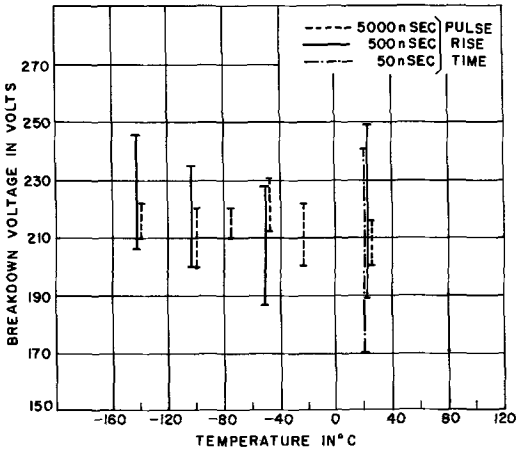

Fig. 12. Highest electric breakdown voltages in an evaporated 5000Å thick silicon oxide film as function of temperature, with voltage rise time as parameter (16). Area of specimen 4 x 10^{-3} cm^2.

field and shed new light on the significance of earlier investigations on statistical time lags. Statistical time lags between the application of voltage and the consequent breakdown have been observed in shorting specimens for a number of substances. The statistical time lag, t_s, is related to the mean interval t_B between self-healing breakdowns in the bulk. t_s is the mean interval to the first breakdown at the weakest spot. Kawamura, Ohkura, and Kikuchi (28) found for about 3 μm thick biotite mica that t_s was a strong function of the applied field. t_s increased from 6 x 10^{-8} to 8 x 10^{-5}s quasi-exponentially, while the field decreased from 8 x 10^6 to 5 x 10^6 V/cm. While these results were obtained on relatively few specimens and while they related to weakest spots in the insulations, they showed the same field dependence as was described here for the bulk of oxides. A rapid decrease in t_s with increasing field was found also in 0.01-0.07 cm thick sodium chloride in a series of detailed observations by Cooper and Smith (29).

The electric breakdown results can be summarized by plotting the electric breakdown voltage *vs.* temperature with $1/R_B = t_B$, the average interval between breakdowns as parameter. This is illustrated in Fig. 13 by the electric breakdown characteristics for a hafnium dioxide specimen.

When both thermal and electric breakdowns occur in the range of observations the thermal and electric breakdown characteristics may be superposed in one figure. This was shown earlier for glass by Vermeer (27). The glass breakdown results were obtained with shorting specimens and electric breakdowns were represented by one curve only. It remains to be ascertained for glass with self-healing specimens whether breakdowns occur over a range of voltages, as found in the oxides.

In addition to observations on breakdown voltages and rates, important information on the breakdown process are obtained from observation of the damage caused and of the voltage changes during the breakdown event. The electric breakdowns, as mentioned earlier, produce single hole type of destruction in thin films (Fig. 1) when the series resistors are larger than about 10 kohms. The magnitude of the destruction expressed by an equivalent diameter of the material removed by the breakdown increases with voltage (11, 12). This is illustrated for the destruction in the top electrode of a thermally grown silicon dioxide specimen in Fig. 14 (12). The voltage changes with time during the breakdown event are determined oscillographically, as shown in Fig. 15, for a silicon dioxide specimen (12). The traces indicate the applied voltage, the voltage collapse on breakdown and the initial phase of the recharge of the specimen from the

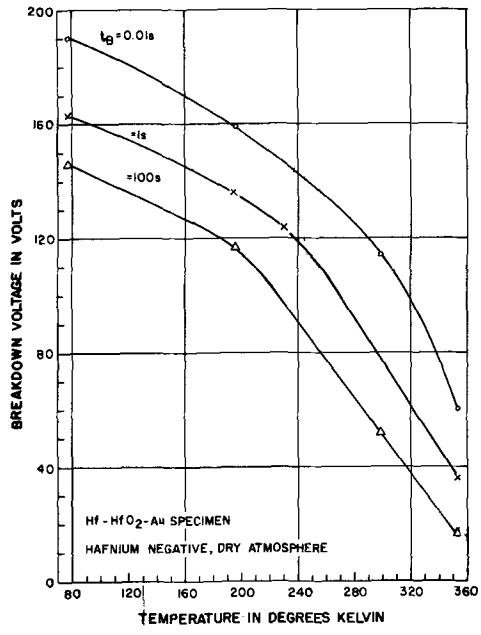

Fig. 13. Electric breakdown characteristics of an anodically grown, 0.1 cm^2 hafnium dioxide specimen. The oxide thickness was 3250Å. The parameters are the average interval between breakdowns, t_B.

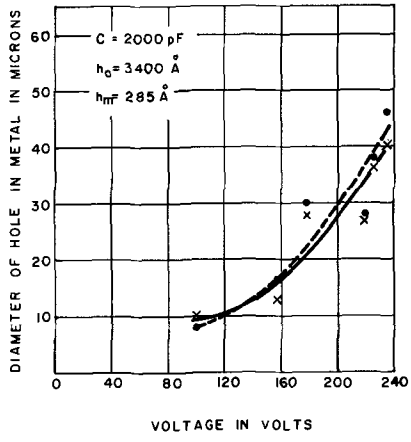

Fig. 14. Diameter of breakdown hole in counterelectrode metal *vs.* voltage in an Si-SiO_2-Al specimen (12). P-type, 1000 ohm-cm substrate, + Si. Crosses and full lines represent measurements; circles and broken lines are calculations.

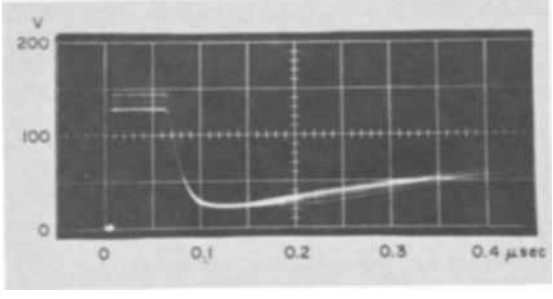

Fig. 15. Specimen voltage *vs.* time oscillogram on single hole breakdown events in a thermally grown silicon dioxide specimen (12). P-type, 0.3 ohm-cm substrate, + Si.

external supply. The voltage collapse was found to occur in thin film specimens of 10^{-10}-10^{-7}F within 10^{-8} to 10^{-5}s, while the recharge time was determined by the product of the series resistor and of the specimen capacitance.

Discussion of the observations.—The discussion of the electric breakdown process is simplified if the processes of destruction are considered first.

The voltage collapse in the oscillogram of Fig. 15 can be interpreted as discharge of the electrostatic energy stored in the specimen into the breakdown spot in a time determined by the resistance of the discharge path and by the capacitance of the specimen. Sträb (6) suggested earlier that the destruction on single hole breakdown is due to this process of discharge. The assumption as to the cause of destruction was investigated in detail in evaporated silicon oxide (11, 16) and in thermally grown silicon dioxide specimens (12). To verify the validity of the assumption, the current in the breakdown spot as function of time and the spreading resistance of the discharge path was calculated from the oscillogram (12). These data permitted the calculation of the magnitude of destruction caused by the joule heat of the discharge process. Results of such calculations were compared with observations, as illustrated by Fig. 14. Calculated and observed single hole breakdown diameters have been found to agree within 10-15% in a number of insulators. Another experimental approach to support the suggested mechanism of destruction was the determination of the temperature of the spark occurring on breakdown. This was determined independently from the rate of vaporization found from the breakdown oscillograms and from the line intensities of spectra of the breakdown events (12). In thermally grown silicon dioxide specimens breakdown temperatures of about 4000°K were ascertained by both methods. It is interesting to remark that during the discharge into the breakdown spot current densities up to 10^{10} A/cm^2 and power inputs up to 10^9 W/cm^2 were found to occur (12).

These results indicated that single hole breakdown consists of two main, consecutive stages: (*i*) a conducting channel is formed by the breakdown process in the insulator, and (*ii*) the electrostatic energy stored in the specimen discharges through the conducting channel, evaporates material and produces a hole much larger than the conducting channel.

Since it appears that the processes during the second stage of the breakdown process can be explained, the main question of electric breakdown is the identification and interpretation of the processes producing the conducting channel.

Since the work of von Hippel, Zener, and Fröhlich electronic avalanche and tunneling processes were believed to cause the conducting breakdown channels. Recently though Budenstein and Hayes (30) suggested for silicon oxide that the conducting channel is formed by decomposition of the insulator caused by the high field. Theoretical considerations based on the avalanche and tunneling processes resulted mostly in relations for a sharply defined breakdown field for insulators. The avalanche theories for single crystal insulators predicted a slow increase in breakdown field with temperature owing to increase with temperature of energy losses of the ionizing electrons by lattice vibrations. Detailed reviews of the theoretical work are given in ref. (19-21), with references to the original papers.

Most of the theories seem to be inapplicable to the interpretation of the oxide results owing to disagreement on the temperature and possible electrode dependence of the breakdown field and owing to the occurrence of breakdowns over a wide range of breakdown fields. Three theories however, Fröhlich's theory for amorphous insulators, von Hippel and Algers' assumption on space charges, and the single electron avalanche theory, predict some of the thin film oxide breakdown properties correctly, and these will be discussed now.

Fröhlich (31) assumed that an amorphous insulator has trapped a large density of electrons, n_2, in excited impurity levels separated by the energy ΔW from the bottom of the conduction band. The density of the free electrons is n_1 and $n_1/n_2 a e^{-\Delta W/kT}$. It is assumed that the free and the trapped electrons are strongly coupled by interelectronic collisions and that energy is lost to the lattice vibrations both by the free and by the trapped electrons. Energy is gained however, only by the free electrons. Breakdown arises at the field, for which the energy gain of the free electrons cannot be balanced by the losses. As the density of the free electrons increases exponentially with temperature, calculations result in

$$F_B = \frac{A}{\Delta W^{1/2}} e^{\Delta W/2kT} \qquad [13]$$

with A being a constant. The exponential temperature dependence of F_B agrees with observations in the oxides. This theory however, results in a sharply defined breakdown field, which is an intrinsic property of the insulator and independent of the electrode material, or polarity. These aspects of the theory do not agree with the observations.

It was assumed by von Hippel and Alger (32) that positive ion migration occurs in the insulator enhancing the field at the cathode. The magnitude of the effect increases with temperature and time of application of voltage. The average field for breakdown should, therefore, decrease with increasing temperature, as was observed in the oxides. On the other hand, time of application of the voltage should increase the breakdown rate, but this was not observed in the oxides.

The single electron avalanche breakdown theory developed by Fröhlich (33) and Seitz (34) has been frequently used for the interpretation of experimental results. The theory connects the formation of an avalanche with destruction. It is assumed that a single electron at the cathode starts an avalanche by impact ionization. When the avalanche reaches the anode, the number of electrons has grown to $2^{t_w/t_i}$ where t_w is the electron transit time through the insulator and t_i is the mean time between ionizing collisions. The avalanche grows to a cross section $4\pi l_p h/3$ at the anode by sideways diffusion. Here l_p is the mean free path for electron-phonon collisions and h is the insulator thickness. The phonon collisions cause a temperature increase in the insulator, and the heat produced is largest at the anode. The breakdown field is calculated with the condition that the joule heat is sufficient to start destruction of the material at the anode. According to the calculations of Seitz, the destruction in a 5000Å thick specimen would be initiated by an avalanche of about 5×10^7 electrons.

The development of a destructive single electron avalanche is a chance event. It depends on the rate of supply P_1 of a free electron in the insulator at the cathode and on the probability P_2 of an avalanche growing in excess of the size required for destruction. The breakdown is supposed to occur after a mean statistical time lag, t_s, which is a function of the field and which is

$$t_s = (P_1 P_2)^{-1} \qquad [14]$$

When many breakdowns are observed on a specimen cleared of weak spots, t_s can be identified with t_B the mean time interval between breakdowns and $t_B = 1/R_B$, the inverse of the breakdown rate.

The breakdowns observed in the oxide films are clearly chance events, both spacially and timewise, as also indicated by the constancy of R_B in Fig. 11 and agree with this aspect of the single electron avalanche theory. It is feasible to assume that many avalanche-like pulses occur constantly in the oxides. The avalanches which reach a critical size cause breakdown.

The original form of the single electron avalanche theory has been subjected to a number of criticisms. The theory assumes that the energy for destruction of the breakdown channel derives from the avalanche. This assumption is in some disagreement with the

two stage model for breakdown, discussed earlier because it was shown, that energy for the destruction is available from the energy stored in the specimen. It is believed, therefore, that the magnitude of the avalanche which causes destruction was overestimated and it was proposed that the breakdown process develops in the following way (16):

The avalanche only triggers the breakdown. It increases the temperature in the breakdown channel from the ambient temperature T_1 by a few hundred centigrades to T_2. The increase in electrical conductivity caused by the temperature rise is such as to make the channel thermally unstable at the temperature T_2. Thermal runaway arises then as shown in the oscillograms of Fig. 3, but in a time many orders of magnitude shorter. The energy for thermal runaway is supplied from the energy stored in the specimen. The avalanche and the thermal runaway produce the conducting channel and the processes of the first stage of the breakdown event. The second stage, as mentioned above, is destructive, with energy supplied by discharge of the specimen.

The number of electrons in an avalanche, N_i, triggering breakdown by increasing the channel temperature to T_2 was found (16)

$$N_i = \frac{c_e A_c}{qaF_B} \log \left[\sigma_o(T_2)/\sigma_o(T_1)\right] \qquad [15]$$

where A_c is the breakdown channel cross section and q is the electronic charge; c_e, a, and σ_o are defined in Table I. It was found also that the magnitude of the triggering charge is smallest when conduction of heat is negligible during most of the thermal runaway process.

The electric breakdown properties of a 5,000Å evaporated silicon oxide film were given in Fig. 12. The peak voltage was maintained on this specimen roughly for 10^{-9}s prior to voltage collapse on breakdown. Identifying the 10^{-9}s with the first stage of the breakdown process in this film, a minimum temperature rise in the channel of about 340°C and a minimum avalanche size of 4.5 x 10^5 electrons was calculated. This avalanche size is by more than two orders of magnitude smaller than that calculated on the earlier assumption that the avalanche has to provide the energy for destruction (34).

Serious difficulties were found recently with the original form of the single electron avalanche theory. Electroluminescence accompanies an avalanche, and the light emission is expected to be largest where the number of free electrons is largest. According to the single electron avalanche theory this should be the case at the anode. Cooper and Elliott (35) observed thick NaCl and KCl crystals between the electrodes prior to the destructive stage of the breakdown and found the largest light emission not at the anode, but at the cathode.

The original form of the single electron avalanche theory considers electrons only and the positive charges are thought to be immobile. O'Dwyer (36) calculated the field produced by the positive charges left behind in the insulator by the electron avalanche. He found that this field opposing the applied field would be 10^{11} V/cm for a destructive avalanche of the size calculated by Seitz.[3] Even the avalanche sizes postulated in ref. (16), which are smaller by two orders of magnitude imply impossible large opposing fields. Under these circumstances a single electron avalanche in its form suggested originally (33, 34) cannot develop.

Cooper and Elliott (35) and also O'Dwyer (36) suggest that the development of an avalanche is not determined by impact ionization in the insulator only but also by field emission at the cathode. When the developing avalanche leaves a positive space charge at the cathode, this space charge greatly enhances field emission of electrons from the cathode into the insulator, ensuring current continuity and making possible the development of an avalanche large enough for breakdown. O'Dwyer (25) recently further elaborated these ideas by assuming that the holes have a finite, although very small mobility and a very small ionization coefficient. These calculations result in a well-defined breakdown field.

It appears from these results that the present forms of the single electron avalanche breakdown theory do not explain yet the oxide observations. Several aspects of this theory may however be useful in interpretations. When the breakdown depends on the availability of a free electron at the cathode and the cathode insulator barrier is less than 1.5 eV, Schottky emission may explain observations. When the breakdown depends on the probability of the growth of an avalanche to a critical size, the breakdown may be explained as a chance event, which is determined by particular transport and trapping properties of the holes and by field emission at the cathode.

As the nature of the avalanche producing breakdown is not yet known, the development of a satisfactory theory requires further experimental work, mainly aimed at the identification of the processes forming a conducting channel. The first problem is, whether the occurrence of the initiating free electron, or the development of a critical size avalanche determine the breakdown event. This may be investigated by the internal photoemission of free charge carriers into the insulator from the electrodes and by observing the influence of these carriers on the breakdown rate. Preliminary experiments in thermally grown silicon dioxide showed that this method is feasible. As no large influence of photoemission on the breakdown rate was observed, the development of the avalanche was assumed to be the process determining the breakdown. When this is the case in an insulator, a second problem is whether the holes have a finite mobility at the breakdown fields. This may also be investigated with internal photoemission as shown by Goodman (37) who estimated that in silicon dioxide $\mu\tau \simeq 10^{-14}$ m²/V, μ being the hole mobility and τ the time before trapping.

[3] Earlier Kawamura *et al.* (28) made a similar observation about the single electron avalanche theory.

Influence of Bond Energies of Oxides on the Kinetics of Anodic Oxide Growth on Valve Metals

Ashok K. Vijh*

Research & Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

Average bond energy values have been calculated for the oxides of Bi, V, U, Y, Nb, Zr, Ti, W, Ta, Al, Hf, and Si from the appropriate thermochemical data. An attempt has been made to explore the influence of these bond energies on the magnitude of kinetic parameters for the anodic oxide growth on the corresponding metals. It has been concluded that, in general, with increasing bond energy, the field required for sustaining a given ionic current density tends to increase, as also does the "Tafel slope." Further, the magnitude of the "activation dipole" in Dignam's theory, both for the steady-state and the transient kinetics, tends to decrease with increase in bond energy. Interrelationship of these correlations has been briefly pointed out.

For conventional electrode processes, *e.g.*, hydrogen evolution reaction (HER) and oxygen evolution reaction (OER), M-H and M-OH bond energies, respectively, have been related quantitatively to the electrode kinetic parameters (1, 2) of the corresponding metals (represented by M). An attempt has been made here to extend similar approaches to the kinetics of oxide growth on valve metals.

The bond energies (Table I) for the various valve metal oxides have been calculated by the procedure of Howald (3). The procedure essentially involves obtaining heats of atomization per equivalent for various oxides by taking into account spin correlation stabilization energies. The quantity thus obtained is an average bond energy value. In our computations, presence of any coordinate bonds has been ignored since unambiguous estimates of their contribution are not always readily accessible, as discussed by Howald (3).

In the kinetics of HER (1), it has been suggested that the bond energies should be obtained by the procedure of Pauling (4). However, Pauling's method assumes an isolated, *e.g.*, M-H (metal hydride) bond and hence gives the bond dissociation energy (1). In the HER or OER where only a monolayer hydride or a slightly thicker surface oxide is involved, Pauling's procedure is quite valid. In the kinetics of oxide growth, however, much thicker oxides indicating phase growth reactions are involved; hence, the valid values of bond energies are those which give an average M-O (metal oxide) bond energy for the M-O bond as it exists in the environment of the bulk oxide, *i.e.*, not an isolated M-O bond. Such values are given by Howald's method and are shown in Table I and have been used in constructing the various figures in this paper.

Table I. Bond energies

Anodic oxide	Field (V cm^{-1} at an ionic current density of ca. 2 × 10^{-3} A·cm^{-2} (room temp.)	MO bond energy in eV
Bi_2O_3	1 × 10^6 (13)*	2.91
V_2O_5	3.2 × 10^6 (15)	4.56
UO_3	3.6 × 10^6 (16)	4.68
Y_2O_3	4.4 × 10^6 (17)	5.59
Nb_2O_5	4.65 × 10^6 (13, 14)	5.29
ZrO_2	4.76-5.3 × 10^6 (13, 14)	6.16
TiO_2	5 × 10^6 (14)	5.42
WO_3	5.5 × 10^6 (13, 14)	4.76
Ta_2O_5	6.2 × 10^6 (13, 14)	5.34
Al_2O_3	7.9 × 10^6 (13, 14)	5.73
HfO_2	—	6.42
SiO_2	2.6 × 10^7 (11)	5.16

* Note: The numbers in the parentheses refer to the source reference from which a given value of the field has been obtained.

* Electrochemical Society Active Member.

Correlation of Bond Energies to Kinetic Parameters

In Fig. 1 bond energies for various valve metal oxides have been plotted against the logarithm of field required to sustain a moderate value of ionic current density. In general, the higher the bond energy, the higher is the field required for a given steady-state ionic current, *i.e.*, the activation energy for oxide growth increases with the increase in the bond energy of the corresponding oxide.

It may be noted that zirconium departs noticeably from the general trend in Fig. 1. This is probably related to the fact that zirconium shows some anomalous characteristics of fundamental nature in its kinetic behavior. For example, it appears that zirconium is unique among valve metals in that its kinetic behavior depends on the thickness of the film (7), for films thicker than about 100Å. No reliable data, it seems, exist for field strength for the oxide growth on hafnium at moderate current densities, *i.e.*, in the range of mA/cm^2. It may be noted that Si does not follow the trend shown in Fig. 1 (Si as in SiO_2, solid point). The fields required for oxide growth on Si are unusually high (*ca.* 2.6 x 10^7 V cm^{-1}) and current efficiencies are extremely low from the very commencement of oxide growth, thus suggesting quite complex parallel reactions (*e.g.*, OER, dissolution) occurring concomitantly (8). It may be mentioned, however, that Si would follow the trend shown in Fig. 1, if Si-O bond energy (8 eV) as in SiO is used instead of average Si-O bond energy as in SiO_2. For a material like SiO_2 which shows rather pronounced glassy character and three-dimensional bonding network, with the consequent spectrum of melting points (hence "softening" of glass), it is not possible to decide whether the bonding behavior is determined by SiO bonds as they exist in SiO or SiO_2. Indeed, a whole spectrum of bonds would be expected (9), which would not be detected from the stoichiometric evidence on the composition of anodic oxide on Si.

Finally we note that W and Y in Fig. 1 follow the general trend only very approximately.

The intermediate value for ionic current density (*ca.* 2 mA cm^{-2}) has been purposely chosen to obtain fields used in Fig. 1. It is believed that this moderate value is more representative of the anodic behavior than the low ones (*i.e.*, μA cm^{-2}) or the high ones (*ca.* A cm^{-2}). In the microampere region, electronic currents associated with the impurity reactions from the inadvertent redox couples in the solution may vitiate the results. In the high current density region, OER, film dissolution, heating effects, sparking, and other complications may interfere with the significance of the data. Since the relation in Fig. 1 is intended to emphasize the approximate, qualitative trends only, inserting the values of field obtained at any other reasonable (*e.g.*, 1 x 10^{-5} to 1 x 10^{-2} A cm^{-2}) value of ionic current density, in Fig. 1 would not change, substantially, the general significance of the conclusions drawn here.

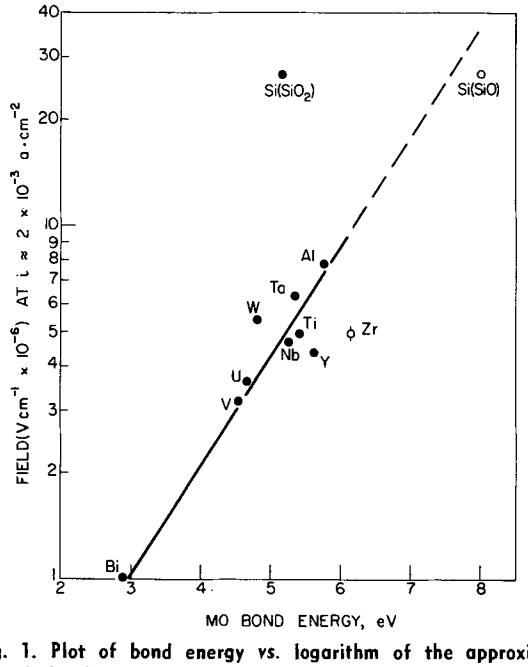

Fig. 1. Plot of bond energy vs. logarithm of the approximate value of the field required to sustain an ionic current density of 2 x 10^{-3} A·cm^{-2} for the anodic oxides of the indicated metals.

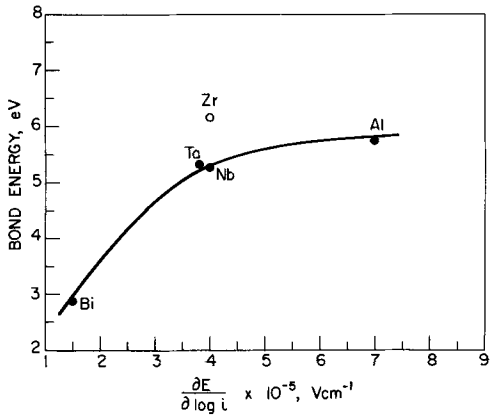

Fig. 2. Plot of Tafel slope for anodic oxide growth vs. bond energy.

In Fig. 2, the values of steady-state Tafel slopes (10-12), $\partial E/\partial \log i$, have been related to the corresponding bond energy values. Departure of Zr from the general trend may again be noted and, of course, is not entirely unexpected for the reasons outlined in the foregoing discussion. No reliable values for Tafel slopes, it seems, are available for valve metals not shown in Fig. 2. The higher the Tafel slope, the higher is the activation energy for ionic conduction since higher Tafel slopes indicate higher values of increments in overfield for given increments of ionic current density. Hence Fig. 2 corroborates the conclusions drawn from Fig. 1.

In Fig. 3, bond energies have been plotted against the corresponding values of the activation dipole (*i.e.*, μ^*), as defined in Dignam's theory, both for the steady-state and transient kinetics. Reliable values of μ^* for valve metals other than those shown in Fig. 3 are not available.

In Dignam's theory (7)

$$\frac{\mu^*}{K} \simeq \text{constant}$$

where K is the dielectric constant. Since μ^* decreases with increasing bond energy (Fig. 3), K must decrease with increasing bond energy, a result which is easily

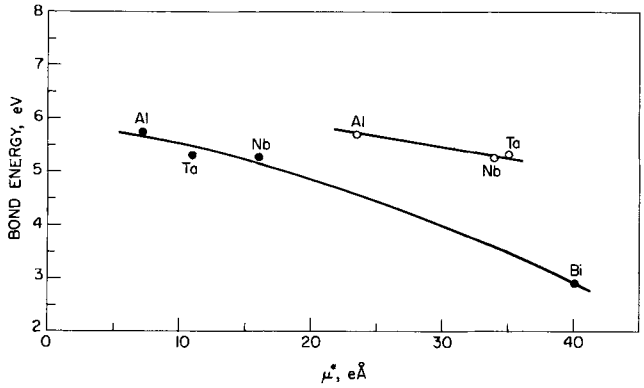

Fig. 3. Plot of bond energy vs. "activation dipole" μ^*, for ○ steady-state kinetics; ● transient kinetics.

verified as regards the rough trend, and has already been shown, directly, to be valid for a number of valve metal oxides, *viz.*, HfO_2, ZrO_2, Ta_2O_5, and Nb_2O_5 (6). Hence Fig. 3 and the related discussion constitutes some confirmation of one of the aspects of Dignam's theory, *i.e.*, $\mu^*/K \simeq$ constant.

Discussion

It follows from the preceding correlations (Fig. 1-3; Table I) that fields (for a given ionic current density) and hence activation energies for anodic growth (Fig. 1), Tafel slopes (Fig. 2), and activation dipoles (Fig. 3) may be related, at least qualitatively, to the corresponding bond energies for a number of valve metal oxides. These three quantities are among the fundamental parameters that describe the kinetics of anodic oxide growth and are, in turn, related to one another as shown below.

In the anodic growth of oxide films on valve metals, ionic current density i is related to the field E by the equation (19)

$$i = \alpha e^{\beta E} \qquad [1]$$

where α and β are constants for a given metal.

Equation [1] may also be written in the form

$$\log i = \log \alpha + 2.3\beta E \qquad [2]$$

Figure 1 illustrates that, for a given value of i, E required to sustain that i increases with increasing bond energy.

Differentiation of [2] gives

$$\frac{\partial \log i}{\partial E} = \beta' \qquad [3]$$

where

$$\beta' = 2.3\ \beta = \frac{qa}{kt}$$

or

$$\frac{\partial E}{\partial \log i} = \frac{1}{\beta'} = \text{Tafel slope} \qquad [4]$$

Figure 2 illustrates the relation of bond energy to the Tafel slope, which is the inverse of the field-coefficient in Eq. [2]. No attempt has been made here to relate α of Eq. [2] with the bond energy since the values of α reported in the literature by various workers under apparently comparable conditions differ by several orders of magnitude. It may be added that α here has the same significance as exchange current density i_o in the conventional electrode processes, *e.g.*, HER and is equivalent to, in terms of absolute reaction rate theory, the rate constant (1). The wide spread in the values of α reported by various workers tends to emphasize that the difficulties involved in obtaining reliable α values (or i_o values) are not restricted only to reactions like HER.

Dignam (7) defines activation dipole as

$$\mu^* = (qa)_{E \to 0} \qquad [5]$$

Ignoring for a moment the field dependence of qa, it may be observed that

$$\frac{\partial E}{\partial \log i} = \frac{kt}{qa} = \frac{kt}{\mu^*} \qquad [6]$$

It follows from Eq. [6] that the Tafel slope would change with bond energy (Fig. 2) in a manner opposite to that in which μ^* changes with bond energy (Fig. 3), a result clearly supported by Fig. 2 and 3.

It may, therefore, be stated that like the case of other electrode processes, *e.g.*, HER and OER, the magnitude of various kinetic parameters for the anodic growth on valve metals is also influenced by the bond energies of the corresponding oxides.

An attempt would now be made to explore the possible origin of the main conclusion of this paper, namely, the activation energy for anodic growth increases with increase in bond energy. For predominantly ionic compounds, *e.g.*, alkali halides, the activation energies for the formation and diffusion of point defects depend on the lattice energy (19). For predominantly covalent compounds, however, the activation energies for the formation and diffusion of point defects would be determined (5), instead, by heat of atomization, *i.e.*, bond energy. For example, if the point defect is assumed to be a hole, the foregoing argument may roughly be developed mathematically on the basis of the following considerations.

The work necessary to form a hole in an ionic crystal (*e.g.*, NaCl), W_H, is given by (19)

$$W_H = W_L - \frac{1}{2} e\phi \qquad [7]$$

where W_L is the lattice energy per ion pair; ($\frac{1}{2}\ e\phi$) factor takes into account the fact that the polarization of the surrounding medium on removal of an ion will set up at the vacant lattice point an electrostatic potential ϕ. For the case of these oxides, the lattice energies per ion pair are extremely high (6) and are the predominant term in the right hand side of Eq. [7]. Hence, Eq. [7] may be approximated as

$$W_H \simeq W_L \qquad [8]$$

The calculation of W_L may be carried out by a Madelung-type procedure based on Born's electrostatic model; alternatively, W_L may be computed by an appropriate Born-Haber cycle as follows.

$$W_L = \Delta H^o_f + \Delta H_{Sub} + \frac{1}{2}\Delta H_{diss.} + I_m + A_X \qquad [9]$$

where, ΔH^o_f is the heat of formation of the oxide;

ΔH_{Sub} is the heat of sublimation of the corresponding metal;
ΔH_{diss} is the heat of dissociation of O_2 into O atoms;
I_m is the sum of successive ionization potentials of the metal needed to produce the requisite ions;
A_X is the electron affinity of O^{-2} ion, *i.e.*, energy needed to form O^{-2} from an O atom.

All quantities in Eq. [9] must be taken as per ion pair.

For a predominantly covalent crystal (*e.g.* Ge), the lattice energy has no significance, *i.e.*, I_m and A_X in Eq. [9] disappear giving

$$W_L = \Delta H^o_f + \Delta H_{Sub} + \frac{1}{2}\Delta H_{diss.} \qquad [10]$$

or

$$W_L = \text{heat of atomization} \qquad [11]$$

or

$$W_L = \text{bond energy} \qquad [12]$$

By comparing Eq. [8] with [12], we write

$$W_L \simeq \text{bond energy} \qquad [13]$$

i.e., the work for hole formation for a covalent crystal is roughly equal to the bond energy. On the basis of similar arguments, one could show that for a covalent crystal, work for the formation or diffusion of any point defect would be determined by the bond energy.

Now we note, as has been shown elsewhere (6), that the various fundamental properties, *e.g.*, mp, bp, of several valve metal oxides increase systematically with increasing bond energy and decreasing lattice energy. These oxides, therefore (5), must be concluded to be predominantly covalent. If these oxides are assumed to be predominantly covalent, the activation energies for the formation and diffusion of point de-

fects would be expected to increase with increasing bond energy; hence, higher activation energies for anodic growth are found to be associated with oxides possessing higher bond energies (Fig. 1-3). This possible relation between bond energies and activation energies for anodic growth was first mentioned by Young (9). He did not pursue the subject in any detail, however.

It may be added that, unfortunately, the considerations developed here do not provide a basis for distinguishing the various possible mechanisms that may be involved in the anodic growth of oxides; *e.g.*, no conclusions can be drawn on the basic validity of Dignam's mosaic model (7) or on the identity of point defects mainly responsible for carrying the current during anodic growth of these oxides (9).

Manuscript submitted Dec. 26, 1968; revised manuscript received March 20, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Electrical Conductivity of Potassium Ferrite with the Beta-Alumina Structure

W. L. Roth and R. J. Romanczuk

General Electric Company, Research & Development Center, Schenectady, New York

ABSTRACT

The d-c conductivity of the beta-alumina form of potassium ferrite has been measured in crystals grown from KF flux and in crystals and polycrystalline specimens grown using solid state reactions. Both electronic and ionic conduction was observed. The former depends on the ferrous ion concentration, which can be varied by equilibration with varying partial pressures of oxygen at temperatures above 300°C. Typical conductivities ranging from $\sigma = 1.4 \exp(-3570/RT)$ to $12.3 \exp(-2420/RT)$ ohm^{-1} cm^{-1} were observed in specimens containing 0.22 and 1.6% Fe^{+2}, respectively. The electronic and ionic conductivities are comparable at 300°C and Fe^{2+} ~0.2%; the former becomes dominant at higher ferrous ion concentration and/or low temperature. Transient polarization-type phenomena were observed and tentatively explained by a model based on the coexistence of ionic conduction and electronic conduction due to the presence of Fe^{2+} and Fe^{3+} ions. Some observations are reported on the crystallography, existence range, and chemical composition of hexagonal potassium ferrite.

An isomorphous series of hexagonal compounds $A_2O \cdot nM_2O_3$, where A = Na, K, Rb and M = Al, Ga, Fe^{3+}, with n having reported values ranging from 5 to 11, crystallizes in the beta-alumina structure. The rates of exchange and self diffusion of sodium in beta-alumina (A = Na and M = Al) are very large (1) and comparable large alkali ion mobilities have been observed in hexagonal ferrites where A = Na, K and M = Fe^{3+} (2). The self diffusion coefficients of Na^+ and K^+ is hexagonal ferrites at 300°C are in the range 10^{-5} to 10^{-6} cm^2/sec, similar to ion mobilities in beta-alumina at the same temperature. The atomic arrangement of $NaAl_{11}O_{17}$ was described by Beevers and Ross (3) and Braun reported that $KFe_{11}O_{17}$ crystallized in the same structure (4). Recent investigations have shown the situation is more complex, with at least two crystallographically similar phases having been attributed to beta-alumina. X-ray and magnetic studies (5, 6) showed that the beta-alumina form of potassium ferrite was stable above 1100°C, but that between 900° and 1100° there was a potassium-rich phase with approximate composition KFe_7O_{11}. Scholder and Mannsmann (7) concluded the composition was $K_2Fe_{12}O_{19}$ and that $KFe_{11}O_{17}$ did not exist. A subsequent single crystal investigation by Rooymans *et al.* (8) suggested the formula was KFe_5O_8. It is possible that there are statistically disordered solid solutions which may exist over a broad homogeneity range.

The structure of beta-alumina may be regarded, for the present purposes, as a stack of identical "spinel-like blocks" with composition $\{Fe_{11}O_{16}\}^+$, held together by $\{KO\}^-$ layers. Since the alkali ions move

preferentially between the spinel blocks, a variable composition in the alkali containing layer may be particularly significant with respect to ionic transport.

Sample Preparation

Dense polycrystalline bars for conductivity measurements were made from cp K_2CO_3 and α-Fe_2O_3 to yield the composition $K_2O \cdot 6Fe_2O_3$. The dry powders were calcined in O_2 at 900°C, crushed and pressed into bars which measured ⅛ x ⅛ x ⅝ in. The bars were surrounded by excess powder from the prefire mix to minimize potassium loss, fired at 1400°C for ½ hr in O_2, then washed in distilled water to remove water soluble impurities. The final bars were about 93% dense, based on a theoretical x-ray density of 4.28 g/cm³ calculated for $K_2O \cdot 11Fe_2O_3$.

Single crystals suitable for conductivity measurements were produced by heating the conductivity bar specimens at 1400°C for 5 hr. The crystals were black and grew as thin hexagonal plates, 2-3 mm in diameter and up to 0.3 mm thick. X-ray photographs showed they were the beta-alumina form of potassium ferrite.

Potassium ferrite crystals also were grown from a 16KF:1Fe_2O_3 melt held in a Pt crucible at 1000°C for 4 hr, cooled at 10°/hr to 746°C, then furnace quenched to room temperature. After dissolving the excess KF in water, three types of crystalline product were found: (*a*) Black, hexagonal crystals, a few as large as 1-2 mm in diameter and 0.05 mm thick. Although x-ray photographs at first indicated they were single crystals identical to those crystallized from the oxides, long exposures revealed weak spots due to a syntactic intergrowth of a second phase, probably the rhombohedral KFe_5O_8 described by Rooymans *et al.* (8) (Fig. 1); (*b*) Transparent, extremely thin (less than 0.02 mm), red crystal plates. The x-ray photographs were of very poor quality, but the crystals appeared to be similar to KFe_5O_8 described above; (*c*) Small black crystals of α-Fe_2O_3. These crystals exhibited parasitic ferromagnetism and could be magnetically separated from the potassium ferrites.

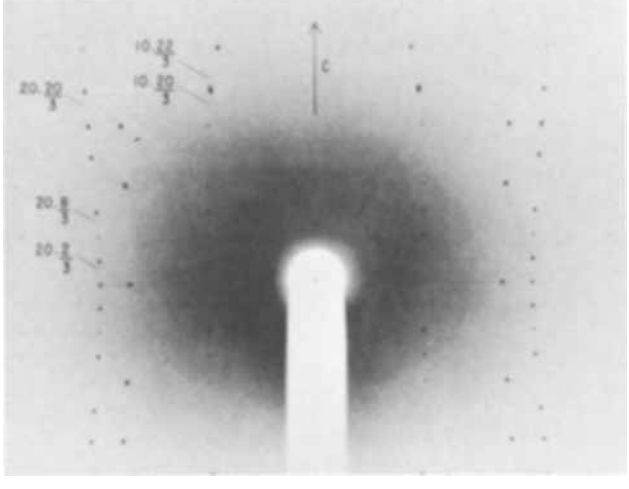

Fig. 1. X-ray photograph showing syntactic intergrowth of the "three block" phase in a "two block" crystal. The designated spots are noncoincident reflections which for convenience have been indexed on a beta-alumina cell. CoK_α rotation photograph.

Lattice Parameters and Existence Ranges

The unit cell parameters of the hexagonal potassium ferrites prepared in this work are compared in Table I with values taken from the literature. There are two structures which, if they have identical composition, may be regarded as polytypes. The unit cells are derived by stacking $N=2$ or $N=3$ hexagonal "spinel-like" blocks with dimensions A = 5.93Å and C = 11.9Å. The atomic arrangements, and consequently the free energies, of the two phases are very similar and some "crystals" contain mixed coherent regions of the $N=2$ and $N=3$ block sequences in which the A and C directions are coincident (Fig. 1). The small differences in unit cell dimensions observed in ferrites prepared in various ways may reflect differences in composition and hence the structures probably are not true polytypes.

The 2-block and 3-block structures were observed in crystals precipitated from KF, and in polycrystalline bars prepared from the oxides at temperatures below 1100°C. The 3-block phase is unstable with respect to 2-block when heated above 1100°C. If the system is open so that potassium may be lost, decomposition into a mixture of 2-block and α-Fe_2O_3 takes place in 4-5 days at temperatures as low as 650°C.

The potassium content of both 2- and 3-block phases is greater than the commonly accepted β-alumina composition $K_2O \cdot 11Fe_2O_3$. Thes chemical analyses of flux and oxide synthesized potassium ferrites are summarized in Table II. The analytical data cannot be interpreted unambiguously because the materials were not necessarily single phase. The composition derived from the analysis of flux grown 2-block crystals probably is the most reliable since α-Fe_2O_3 was separated magnetically and the x-ray patterns gave no indication of 3-block material (<5%). The potassium content of both 2- and 3-block crystals indicates an average composition near K_2O:Fe_2O_3 = 1:7, confirming the stoichiometric ratio 1:7.2 required to complete the chemical reaction.

Table II. Chemical analyses of potassium ferrites

K, %	Fe, %	Fe^{+2}, %	Source	Phases

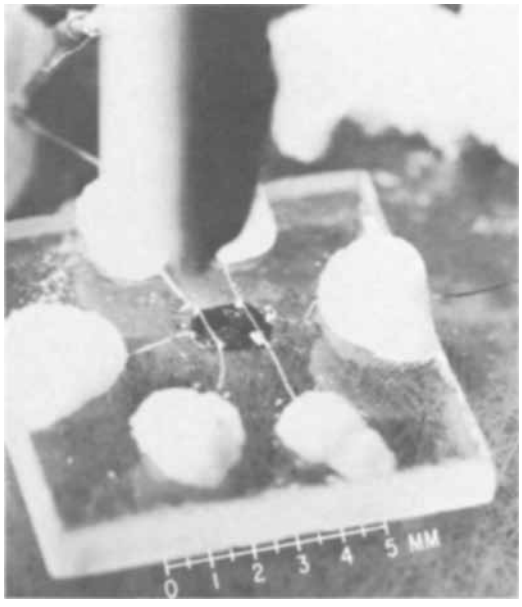

Fig. 2. Crystal-electrode assembly for 4-point conductivity measurements. The crystal is about 1.5 mm long and 0.2 mm thick. Current leads enter horizontally and the voltage probes are doubly soldered.

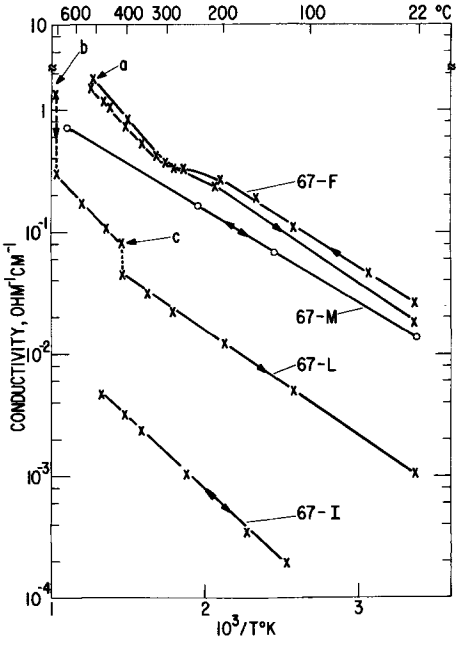

Fig. 3. Conductivity of potassium ferrite polycrystalline bars prepared from the oxides at 1400°C. 67-F, 67-M, and 67-L were fired ½ hr; 67-I for 5 hr. *(a)* Held in air at 500°C for 24 hr; *(b)* held in O_2 at 700°C for 42 hr; *(c)* held in O_2 at 400°C for 64 hr.

Conductivity Measurements

The d-c conductivities of single crystals and polycrystalline bars were measured with the 4-probe technique. Voltages were read with a Keithley model 200B electrometer and currents with an equivalent electrometer in conjunction with a Keithley decade shunt. The specimen-electrode assembly could be inserted in a 1 in. diameter cylindrical furnace.

A typical crystal-electrode assembly is shown in Fig. 2. Electrodes were either 0.002 in. Pt or Pt-Rh, attached to the crystal by In-Hg solder. The electrodes behaved satisfactorily up to 300°C but reaction with the solder occurred at higher temperatures. It was not necessary to support the larger polycrystalline specimens with the silica glass base so they were simply held in the furnace by 0.010 in. Pt wires wrapped around notches filed in the bars.

Conductivity of Polycrystalline Bars

Representative conductivity data for the polycrystalline bars are shown in Fig. 3 and summarized in Table III. At temperatures below 500°C the conductivities were reversible and described by $\sigma=\sigma_0 e^{-E/RT}$. Above 500°C the level of conductivity could be altered fairly rapidly by changing the oxygen partial pressure over the specimen.

Specimens 67-F, 67-L, and 67-M are typical of bars prepared by firing in O_2 for ½ hr at 1400°C. Specimen 67-I was prepared by firing in O_2 for 5 hr, instead of the customary ½ hr. The large decrease in σ is attributed to grain growth. Single crystal grains grew completely across the bar and these specimens were characteristically fragile and of lower density.

The shifts in σ at higher temperatures were shown to be due to oxidation-reduction reactions by isothermal experiments in which the atmosphere was changed and the conductivity then followed as a function of time (Fig. 4). Similar experiments in which the temperature was changed and the atmosphere was held constant were consistent with oxidation-reduction reactions taking place rapidly at temperatures above 450°C. The steady state conductivity depends on both the temperature and oxygen partial pressure, *i.e.*, at higher temperatures, a greater oxygen pressure is required to maintain the oxidized (low σ) state.

The changes in oxidation state were confirmed by chemical analysis. The Fe^{+2} concentration of conductivity bars equilibrated in 1 atm O_2 at 1400°C was 1.61%; after holding in O_2 at 650°C for 4½ days it decreased to 0.18%.

Single Crystal Conductivities

The potassium ferrite crystals grew as thin plates perpendicular to the C-axis and consequently four point conductivities were measured parallel to the C-face only. Representative conductivities of oxide-grown crystals, KF-flux grown crystals, and of crystals aged in O_2 are shown in Fig. 5.

Crystals 67-D and 67-Q were grown from the oxides. Both the magnitude and variation with temperature of the conductivity is the same as observed in the fine-grained polycrystalline specimens (Fig. 4) showing that the effects of grain boundaries and the solder used to attach the electrodes were negligible.

Crystals 2 and 3 were grown from KF flux. The conductivities were an order of magnitude smaller than those of oxide crystals or bars. This is consistent with the lower oxidation state of the latter which were grown at much higher temperature: the Fe^{+2} concentration in flux-grown crystals was 0.22%, compared to 1.41% in conductivity bars. The first experiment with crystal 2 was characterized by a high resistance and activation energy, but thereafter the system behaved reversibly. The same initially high resistance was observed with crystal 3, and subsequent runs indicated a discontinuity near 150°C, which decreased after the first heating cycle, and the σ-T characteristic appeared to be approaching that of crystal 2. In addition, the flux-grown crystals exhibited polarization or transient effects which are described in the next section. Several attempts to grow larger crystals from

Table III. Potassium ferrite conductivities

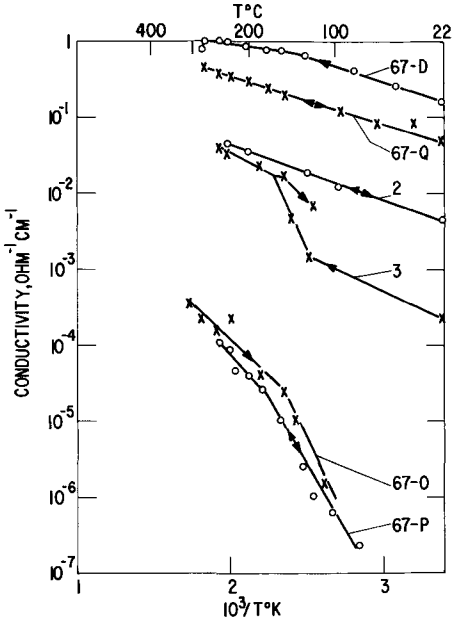

Fig. 5. Conductivity of potassium ferrite single crystals. 67-D and 67-Q, oxide grown crystals (1400°C, 5 hr); 2 and 3, fluoride flux-grown crystals; 67-O and 67-P, oxide grown crystals heated in O_2 at 650°C for 4½ days.

the flux which would be suitable for further conductivity measurements were unsuccessful and the source of these anomalies remains unresolved.

Oxide-grown crystals 67-O and 67-P were heated in oxygen at 650°C for 4½ days. The conductivity decreased as expected due to the reduction of Fe^{+2}, but in addition there was an unanticipated large increase in the activation energy. The x-ray pattern of a crushed crystal showed α-Fe_2O_3 was present, indicating the crystal had partially decomposed into K_2O and Fe_2O_3, or $KFeO_2$.

Transient Effects

The conductivities in Fig. 3, 4, and 5 are the average of instantaneous values, measured in the forward and reverse (current direction reversed) directions through the crystal, which usually agreed within a few per cent. The flux grown crystals, however, exhibited transient effects which were characterized, at constant current, by an increase to saturation, with time, in the voltage measured across the inner electrodes on the crystal.

A typical experiment illustrating this effect is shown in Fig. 6. A potential across the crystal produced an initial rapid rise ($<10^{-1}$ sec) of the probe voltage V_I which then increased to a steady-state value V_F after about 30 sec. The transient was reproducible and was observed in two crystals over a range of temperature and current density. Defining k as the reciprocal of the time t required for the voltage to rise by one-half the difference of the instantaneous value V_I and the steady state value V_F (or fall to $V_D/2$), then

$$1/t = k = k_0\, e^{-E_k/RT}\ \text{sec}^{-1}$$

with k_0 = 16.9 (±10) sec^{-1} and E_k = 4590 (±520) g-cal/mole. The steady state conductivities calculated for KF flux crystal 2 were about 30% less than the instantaneous values and had a slightly smaller activation energy. The magnitude of the voltage rise $\Delta V = V_F - V_I$ was approximately equal to V_D, and did not depend on temperature.

Discussion

The primary mechanisms to consider for electrical transport in alkali ferrites are ionic conduction through the alkali layer, or electronic semiconduction, either by hopping of electrons from Fe^{+2} to Fe^{+3} ions or 3*d* band conduction.

The ionic conductivity resulting from diffusion of potassium ions can be estimated with the Nernst-Einstein equation. According to Hever (2), the self diffusion coefficient of K^{42} in $M_2O{\cdot}7Fe_2O_3$, where M = $0.866K^+ + 0.134Na^+$, is given by $D = 1.05 \times 10^{-3}\, e^{-7210/RT}$ cm^2/sec. Assuming the same diffusion coefficient for pure potassium ferrite, two mobile K^+ per unit cell, and an average temperature 573°K

$$\sigma = D\frac{C\,Z^2\,F^2}{RT} = 9.4\, e^{-7210/RT}\ \text{ohm}^{-1}\,\text{cm}^{-1}$$

The ionic conductivity predicted by this equation at a temperature of 200°C is 4.5×10^{-3} ohm^{-1} cm^{-1}, somewhat smaller but of the same magnitude observed in flux grown crystals and in the polycrystalline bars after low temperature oxidation.

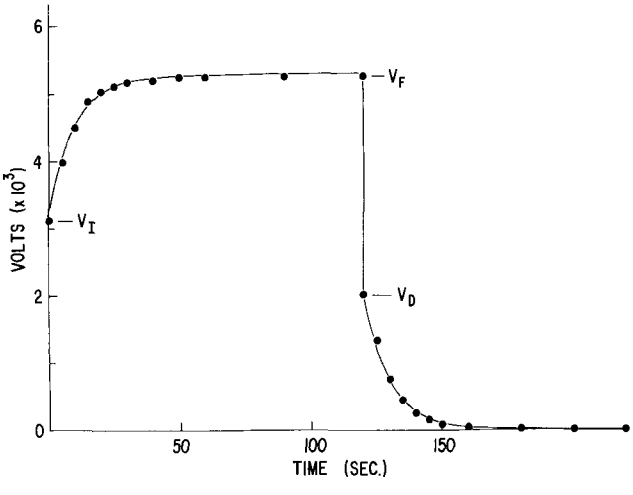

Fig. 6. Typical curve showing voltage build up and decay in fluoride flux-grown potassium ferrite. Crystal 2 at 212°C. V is voltage measured across the inner probes. Solid curve is calculated from Eq. [A], [B] in Appendix for R_1 = 1.11 x 10^4 ohms, R_2 = 6.85 x 10^3 ohms, C = 553 microfarads (see Fig. 8), and R_s = 10^7 ohms, V_0 = 7.7V.

Electronic conduction predominates at larger Fe^{+2} concentrations and the different levels of conductivity summarized in Table III can be explained if the number of carriers is proportional to the Fe^{+2} concentration.

Electrical charge neutrality requires that a reduction in the valence of iron be compensated by either a cation interstitial or an anion vacancy, so the concentration of defects responsible for ionic diffusion also may increase with the concentration of ferrous ion. The co-existence of ionic and electronic conduction suggests a possible explanation for the transients related to the proposal by Hever (2) that potassium ferrite be regarded as a parallel plate condenser in which one set of plates are the K^+ ionically conducting layers and the other set are the semiconducting spinel blocks containing Fe^{++} donors. The transient characteristics are described by the circuit shown in Fig. 7. The system is represented by the ionic resistance R_1 which is in series with capacitance C, both shunted by the parallel electronic resistance R_2. An analysis of the electrical responses for the network is given in the appendix.

The parameters derived from the transients measured in flux-grown crystals are shown in Fig. 8. The activation energy $E_1 = 6100 \pm 1000$ cal/mole determined for the ionic component is in reasonable agreement with the activation energy 7210 cal/mole measured for K^+ ion diffusion. The activation energy $E_2 = 2175$ cal/mole attributed to the electronic component may be compared with the value 2300 cal/mole obtained from the temperature dependence of the resistivity of the structurally similar hexagonal ferrite, $BaFe_2^{2+}\ Fe_{16}^{+3}\ O_{27}$ (Fe_2 IIW) [Fig. 45.5 of ref. (10)].

The apparent absence of a transient in the oxide-grown crystals is explained by R electronic $<<$ R ionic. Assuming the same values for the capacitance and the ionic resistivity, and substituting the observed values for R electronic, time constants of the order of 5 sec and voltage increments of 2×10^{-4}V would be expected. Transients of this magnitude would not have been observed in the present experiments.

The calculated equivalent capacitance of the flux grown crystal was 550×10^{-6} farads. Since the crystal volume was 1.4×10^{-4} cm^3, this corresponds to 3.9 farads/cm^3, in agreement with the capacitances of solid state batteries which ranged from 1.7 to 5.0 farads/cm^3 at 300° and 500°C (2).

The internal consistency of the transient analysis, and the agreement of the parameters derived from it with those obtained from diffusion and electrochemical

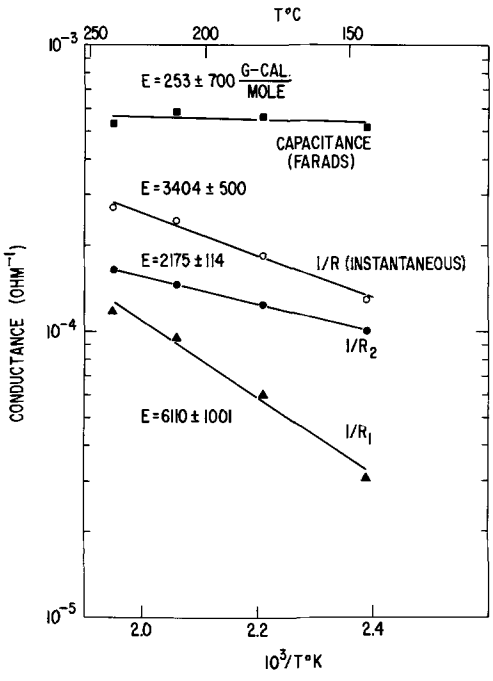

Fig. 8. Log conductance vs. $1/T$ for parameters derived from the transient analysis.

cell measurements, support the theory developed in this paper. However, there are other possible explanations for the origin of the capacitance effects, particularly those based on concentration cells in the vicinity of the electrodes. The possibility that oxide ions were partially replaced by fluoride ions cannot be excluded, although mass spectrographic analysis indicated the fluoride content of the flux grown crystals was negligible. In addition, the flux used to attach the electrodes is a potential source of electron donors, for example, by reactions of the type $Hg \rightarrow Hg^+ + e^-$. Pulse and a-c methods might be used to distinguish some of these alternatives, but such investigations would be severely limited by the size of the crystals presently available.

Conclusions

The electrical conductivity in potassium ferrite crystals with the beta-alumina structure is due to a combination of electronic and ionic conductivity. The electronic portion depends on the Fe^{2+} concentration, which in turn can be controlled by equilibration with varying partial pressures of oxygen. The ionic conductivity is due to diffusion of K^+ ions through the alkali containing layers and its magnitude and temperature dependence agree with the predictions of the Nernst-Einstein equation. At 300°C electronic semiconduction predominates when the Fe^{2+} concentration is greater than 1%, but for Fe^{2+} concentrations of about 0.2%, the electronic and ionic conductivities are comparable.

Acknowledgments

We are indebted to R. C. DeVries and J. F. Fleischer for the crystals grown from $KF\text{-}Fe_2O_3$, and to J. W. Szymaszek for the synthesis of conductivity bars and crystals from the oxides. The authors profited from helpful discussions with R. J. Charles, S. P. Mitoff, D. A. Vermilyea, and F. G. Will.

Manuscript submitted Jan. 13, 1969; revised manuscript received April 3, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

APPENDIX

Elementary circuit analysis for the network of Fig. 7 gives the following (at $t = 0$, switch S closed)

$$i_1 + i_2 - i_s = 0$$
$$V_o - i_2 R_2 - i_s R_S = 0$$
$$i_2 R_2 - \frac{q}{C} - i_1 R_1 = 0$$

Combining these equations and remembering that

$$\frac{dq}{dt} = i_1$$

Then

$$V_o = R_A\left(\frac{dq}{dt}\right) + \frac{q}{C} \quad (\Delta)$$

where

$$R_A \equiv \frac{R_1R_2 + R_1R_S + R_2R_S}{R_2}$$
$$\Delta \equiv \frac{R_2 + R_S}{R_2}$$

also

$$q = \frac{V_oC}{\Delta}\left[1 - \exp\left(-t\Delta/R_AC\right)\right]$$

and since $V_{ab} = \frac{q}{c} + i_1 R_1$

$$V_{ab}\ (\text{charging}) = \frac{V_o}{\Delta} - V_o\left[\frac{1}{\Delta} - \frac{R_1}{R_A}\right]\left[\exp\left(\frac{-t\Delta}{R_AC}\right)\right] \quad [A]$$

After the switch has been closed for a long time $\left(t >> \frac{R_AC}{\Delta}\right)$, it is opened. A similar argument yields

$$V_{ab}\ (\text{decaying}) = \frac{V_oR_2}{(R_1 + R_2)\Delta}\left[\exp\left(\frac{-t}{(R_1 + R_2)C}\right)\right] \quad [B]$$

$$V_I \equiv V_{ab}\ (\text{charging } t = 0) = V_o\left\{\frac{R_1R_2}{R_1R_2 + R_1R_S + R_2R_S}\right\} \quad [1]$$

$$V_F \equiv V_{ab}\left(\text{charging } t >> \frac{R_AC}{\Delta}\right) = V_o\left\{\frac{R_2}{R_2 + R_S}\right\} \quad [2]$$

$$V_D \equiv V_{ab}\ (\text{decaying } t = 0) = V_o\left\{\frac{R_2^2}{(R_1 + R_2)(R_2 + R_S)}\right\} \quad [3]$$

Defining time constants

$$t_{c1/2} \equiv t\left(V_{ab} = \frac{V_F + V_I}{2}\right) = \left(\frac{R_1R_2 + R_1R_S + R_2R_S}{R_2 + R_S}\right)C \ln 2 \quad [4]$$

$$t_{d1/2} \equiv t\left(V_{ab} = \frac{V_D}{2}\right) = (R_1 + R_2)\,C \ln 2 \quad [5]$$

Polymeric Electron Beam Resists

H. Y. Ku[1] and L. C. Scala

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

Crosslinking polymers may be used as negative acting resists. The product of the minimum charge dose Q required and the weight average molecular weight $\overline{M}_w$ is a constant and is a characteristic of the polymer. At an electron beam voltage of 10 kV, this Q-M product is found experimentally to be 6.3 coul-g/cm^2-mole for polystyrene, 1 coul-g/cm^2-mole for poly(vinyl chloride), and 14 coul-g/cm^2-mole for polyacrylamide. Degrading polymers may be used as positive acting resists. Their average molecular weights have only a very minor effect on their efficiency as positive resists. Their glass transition temperatures T_g are an important factor. It is recommended that these resists be prebaked at $T > T_g$, stored and developed at $T < T_g$, and postbaked at $T > T_g$.

The technology of microelectronics moved from discrete components to integrated circuits and is moving toward monolithic subsystems. The increase in packing density requires reduction in circuit size and, hence, in the component size. The decrease in component size has been limited by the resolution of conventional photoresist operation to about 2-3μ. Electron beam fabrication (1) offers much improved resolution.

Electron beam fabrication requires etch resists which are sensitive to an electron beam. Conventional photoresists, *i.e.*, the family of negative acting resists (KPR, KMER, KTFR) from Kodak and the positive acting resist AZ1350 from Shipley, were found to be exposable by electron beams (1-5). Although Kodak gives no information about the chemical composition of their resists, some of them (KPR) are believed to be vinyl polymers (6) or their derivatives with some sensitizer. Under uv light, the vinyl functions of neighboring chains crosslink forming an insoluble three-dimensional network. Others (KTFR) are believed to

[1] Present address: IBM, Thomas J. Watson Research Center, Yorktown Heights, New York.

be polymerized isoprene dimers. The composition of Shipley's AZ1350 is not revealed, and its action is not known definitely.

Because of the high sensitivity of these resists to uv and even visible light, some crosslinking or insolubilizing chemical reaction occurs on standing. They are not stable, and shelf life is short. These resists are quite satisfactory in fabricating devices of conventional size, but, since their resolution deteriorates with age and varies from batch to batch, they are not satisfactory in the fabrication of devices of very small dimensions.

Electron beam exposure of resists can be done in two ways. One way is to expose the resist with a single beam of electrons in an electron microscope or a similar instrument (1). A more recent development is to expose the complete wafer using a complete pattern of electrons employing a uv sensitive photocathode as an electron source (7). In this case the resist is exposed to the electrons with a background of strong uv light. Photoresists cannot be used and electron beam resists insensitive to uv light are needed.

Etch resists are generally high molecular weight polymers. Haller *et al.* (8) have shown that poly(methyl methacrylate) is a positive acting electron resist of superior resolution. It is not sensitive to uv light and is very stable. This paper describes the general properties of polymeric electron resists, both positive and negative, and reports some results of our investigation of electron resists that are also not sensitive to uv or visible light.

General Characteristics of Electron Resists

High polymers undergo physical and chemical change under ionizing radiation. Physical properties such as color, impact strength, elastic constants, and tensile strength are altered as the radiation dose increases. Gases are liberated indicating a change in the chemical nature of the polymer. The most important fact pertaining to their use as resists is that both crosslinking and scission of polymer chains occur. In many cases one dominates the other, and a polymer either crosslinks or degrades depending on its nature. When a polymer crosslinks, the chains link to each other forming a complex structure, and its average molecular weight increases. A polymer is degraded if the chains undergo random scission resulting in chains of decreasing molecular weights as the dose increases. Eventually, the degraded polymer may dissolve in a solvent in which the original polymer is not soluble. Polyethylene, polyacrylates, polyacrylamide, polystyrene, poly(vinyl chloride), and polysiloxanes are crosslinking polymers; polyisobutylene, polymethacrylates, poly(α-methylstyrene), and cellulose are degrading polymers. For vinyl polymers it is known that when each carbon atom of the polymer chain carries at least one hydrogen atom, the polymer crosslinks, and that if a tetrasubstituted carbon atom is present in the monomer unit, the polymer degrades.

Most of these polymers, without added light sensitizers, are insensitive to uv and visible light. They have much longer shelf life and are much more stable than conventional photoresists.

When a crosslinking polymer film coated on a surface is exposed selectively to an electron beam, the irradiated portion crosslinks. With sufficient dose the crosslinked polymer forms a three-dimensional network and becomes insoluble in the usual solvent for the polymer. The film can be "developed" by immersing it in the solvent for the polymer to dissolve away the unexposed polymer film, leaving the three-dimensional network of the polymer in the exposed area. A crosslinking polymer is a negative-acting electron resist if the crosslinked polymer is unaffected by the etching solution.

When a degrading polymer film is exposed to an electron beam, random scission occurs and the average molecular weight decreases. The film may be developed by the method of fractional solution, *i.e.*, soaking in a poor solvent which dissolves away the molecules of low molecular weight but not the ones of high molecular weight. During development the exposed film is washed away leaving the unexposed film on the wafer. If the original polymer is unaffected by the etching solution, the polymer is a positive-acting resist.

The effect of the radiation on polymer chains is usually measured in terms of the radiation chemical yield G. It is defined as the number of chemical events occurred per 100 eV of energy absorbed. The particular event occurred is usually specified within parentheses following the symbol G. Thus, the expression $G(\text{c.l.}) = 2$ means that two crosslinking events occur for every 100 eV of energy absorbed in the polymer. An electron losing E eV of energy in passing through a crosslinking polymer film will create $E \cdot G(\text{c.l.})/100$ crosslinks involving twice as many crosslinked monomers. Similarly, a scission yield is designated by $G(\text{s})$ and the number of scission events is $E \cdot G(\text{s})/100$. The energy loss E is smaller for a more energetic beam. Hence the efficiency of a 20 kV electron beam is lower than that of a 10 kV electron beam. The yield, $G(\text{c.l.})$ or $G(\text{s})$, is naturally dependent on the nature of the polymer irradiated and on the nature of the bombarding radiation. For electron energy of 10 kV or more and polymer films of 1μ or less, the energy loss may be considered uniformly distributed and the crosslinking or scission events are completely random.

While the average molecular weight $\overline{M}$ of a degrading polymer used as a positive resist has only a minor effect on the efficiency of the system, the efficiency of a crosslinking polymer used as a negative resist is greatly affected by $\overline{M}$.

When a polymer is used as a negative-acting resist, the polymer must be sufficiently crosslinked to form a three-dimensional network insoluble in the solvent for the original linear chain polymer. Assuming no intramolecular crosslinking and only single crosslinking between two molecules, Stockmayer (9) showed that for an arbitrary molecular weight distribution a three-dimensional network occurs when there is on the average one crosslinked monomer per molecule of weight average molecular weight, or one crosslink for two molecules of weight average molecular weight. For a given weight of material the number of crosslinks required is inversely proportional to the weight average molecular weight. The number of crosslinks created by each passing electron is $E \cdot G(\text{c.l.})/100$. The total number of crosslinks per square centimeter of film created by a charge dose density Q coulomb/cm^2 is $Q \cdot E \cdot G(\text{c.l.})/100q$, where q is the electronic charge. The number of weight average molecules per square centimeter is $dA/\overline{M}_w$, where d is the sheet density of the film in grams per square centimeter, A is Avogadro's number, and $\overline{M}_w$ is the weight average molecular weight of the polymer. Therefore, the minimum charge dose required for achieving a three-dimensional network is

$$Q = 50\, q\, dA/EG(\text{c.l.})\overline{M}_w \qquad [1]$$

which is inversely proportional to the crosslinking yield $G(\text{c.l.})$, the molecular weight $\overline{M}_w$, and the energy E absorbed per unit area of the film.

The significant fact is that the minimum dose required for a negative electron resist is inversely proportional to the weight average molecular weight $\overline{M}_w$ of the polymer. In other words, the Q-M product, the product of the minimum charge dose Q and of the molecular weight $\overline{M}_w$, is a constant and is a characteristic of the polymer. For better efficiency, a polymer with smaller Q-M product is preferred over one with a large Q-M product, and a polymer of high $\overline{M}_w$ is preferred over the same polymer of low $\overline{M}_w$.

The case for a degrading polymer used as positive resist is entirely different. We assume that the scission is completely random occurring at the bonds between the monomers of molecular weight M_o. Let $\overline{M}_n$ be the number average molecular weight of the polymer. The number of molecules of molecular weight $\overline{M}_n$ in a film of sheet density d g/cm^2 is $dA/\overline{M}_n$, where A is as before Avogadro's number. Each molecule has $(\overline{M}_n/M_o - 1)$ bonds and the total number of bonds is $dA(1/M_o - 1/\overline{M}_n) \cong dA/M_o$. For an electron dose of Q coul/cm^2, the number of scission events is $Q\,E\,G(s)/100\,q$. Hence the probability of scission at a bond is

$$p_s = Q\,E\,G(s)\,M_o/100\,q \cdot dA \qquad [2]$$

The number of bonds in each molecule of molecular weight of $\overline{M}_n$ is $\overline{M}_n/M_o$, and the number of scission fragments is $p_s\overline{M}_n/M_o + 1$. The number average molecular weight of these fragments is

$$\overline{M'}_n = \overline{M}_n/[p_s\overline{M}_n/M_o + 1]$$

or

$$1/\overline{M'}_n = p_s/M_o + 1/\overline{M}_n \qquad [3]$$

If $p_s\overline{M}_n/M_o >> 1$, then

$$\overline{M'}_n = M_o/p_s \qquad [4]$$

Combining [2] and [4], we get

$$\overline{M'}_n = 100\,q\,d\,A/Q\,E\,G(s)$$

If $\overline{M'}_n$ is small enough so that only the scission fragments, but not the original polymer, dissolve in a poor solvent, then the resist is developed. The value $\overline{M'}_n$ depends on the developer selected and determines the minimum electron dose Q required for exposing the resist given by the equation

$$Q = 100\,q\,d\,A/E\,G(s)\,\overline{M'}_n \qquad [5]$$

The minimum dose Q is independent of the molecular weight $\overline{M}_n$ of the original polymer. Hence, the efficiency of a positive electron resist does not depend on the average molecular weight $\overline{M}_n$ of the polymer used if $\overline{M}_n$ is sufficiently large. Furthermore, the initial molecular weight distribution is also not important. After a few scissions per molecule of $\overline{M}_n$, any distribution will approach closely the "most probable distribution" given by

$$N(x) = Np_s \exp(-p_s x)$$

$$= Np_s \exp(-M/\overline{M'}_n) \qquad [6]$$

where x is the degree of polymerization of the scission product ($x = M/M_o$) and N is the total number of molecules after scission (10). For this exponential distribution, the weight average molecular weight $\overline{M}_w$ is twice the number average $\overline{M}_n$. Equation [4] assumes the relation $p_sM/M_o >> 1$. This inequality simply means that the number of scissions per molecule is large. This is true and will be illustrated later in the case of the positive resist poly(methyl methacrylate). Equations [1] and [5] appear similar, but their meanings are quite different.

An important characteristic of a polymer is its glass transition temperature T_g. Above this temperature the polymer chains can slide over each other and the polymer is soft, pliable, and rubberlike. Below this temperature the atoms can only vibrate about their equilibrium positions at fixed distances from each other, but the chains cannot slide over each other. The polymer is hard, brittle, and glasslike. The glass transition temperature is a second order transition temperature and is usually determined by measuring the temperature at which the volume coefficient of expansion α changes. For polystyrene, α is 2×10^{-4} below T_g (100°C) and is 6×10^{-6} above T_g.

At temperatures above its glass transition temperature T_g, a polymer deforms easily under stress. An exposed and developed film will change its shape if it has some residual stress. The developed film will not maintain its definition, and the film is not suitable for high resolution application. Such loss of resolution due to creep in a polyisobutylene film ($T_g = -70$°C) was noticed by Haller *et al.* (8). The creep may be minimized by prebaking the coated film at a temperature above T_g to relax the stress created in the film during coating and by storing the film at a temperature below T_g.

The development of a resist, either positive or negative, is based on the principle of fractional solution. Flory (11) has shown that $v_1(x)$ is the volume fraction of polymer of degree of polymerization x in the solid phase and $v_2(x)$ is the corresponding volume fraction in the solution phase; then

$$v_2(x)/v_1(x) = \exp(-\sigma x) \qquad [7]$$

where σ is a function of the concentrations of the polymer in the solution, of the number average molecular weight, and of the interaction energy between the polymer molecules and the solvent molecules. The quantity σ is not calculable; however, it is important to note that the ratio $v_2(x)/v_1(x)$ is a continuous function of x. The extracted polymer fraction contains a wide range of molecular weights, with a higher concentration of molecules of low molecular weight than the solid polymer had originally. In developing an exposed positive resist, not only the polymer fragments in the exposed area will be removed but also some smaller molecules in the unexposed area, thus increasing the probability of pin-hole formation. This unwanted solution of smaller molecules from the unexposed area occurs if the development is performed at a temperature above T_g. However, below T_g the polymer chains cannot slide along each other and small molecules are not easily extracted, being held rigidly by other molecules. Similarly, if an exposed negative resist is developed at temperatures above T_g, some smaller three-dimensional network may be extracted away. This extraction will be much less likely if the film is developed at a temperature below T_g. After development, holes or discontinuities may be formed in the film and along the edge of the developed film vacated by the extracted molecules. These holes may be closed if the film is baked at temperatures above T_g. Therefore, a resist film should be prebaked at $T > T_g$, exposed, developed, and stored at $T < T_g$, and postbaked at $T > T_g$. As the resist is usually processed and stored at room temperature, the glass transition temperature of the polymer must be above the room temperature, preferably above 350°K.

The number of known polymers is large: about one thousand are listed in the "Polymer Handbook" (12). Only a small number has been examined for the effect of ionizing radiation. Among those polymers that are known to be crosslinked or degraded by scission, only a few have reasonably high glass transition temperatures. Crosslinking polymers of low T_g such as polybutadiene ($T_g = 180$°K) and polydimethylsiloxane ($T_g = 150$°K) are not good negative resists. Degrading polymers of low T_g such as polyisobutylene ($T_g = 200$°K) and poly(vinylidene chloride) ($T_g = 254$°K) are not good positive resists. The number of polymers that can be used as high resolution electron resists is therefore rather limited.

Negative Electron Resists

Crosslinking polymers have been investigated extensively. There are several known crosslinking polymers that have T_g's above room temperature. Table I lists some crosslinking polymers together with their glass transition temperatures T_g and the crosslinking yield G(c.l.).

Table I. Negative electron beam resists

Polymers	T_g, °K	G(c.l.)	Density, g/cm³
Polystyrene	370	0.04	1.05
Polyacrylamide	>350	0.02	1.06
Poly(vinyl chloride)	354	0.3	1.41

Polystyrene.—Polystyrene is resistant to all alkalis and weak acids, but is attacked slowly by strong oxidizing acids. It dissolves easily in chlorinated hydrocarbons or aromatic hydrocarbons. The density of polystyrene is 1.05 and the crosslinking yield G(c.l.) is about 0.04 (13). For a typical film of 5000Å the sheet density is 5.25×10^{-5} g/cm². The energy loss E by an electron beam passing through a thin film of polystyrene is difficult to estimate. One reason is that the energy loss mechanism is a complicated one; in addition, the dissipation is not uniform through the film. Another known factor is the back scattering of electrons from the oxidized silicon into the resist film. Ehrenberg and King (14) measured the energy loss of 10 kV electrons in bulk polystyrene as a function of penetration depth. Assuming the energy loss in a polystyrene film is the same as that in bulk polystyrene of the same depth and neglecting the difference in back scattering at the resist-substrate interface, we have $E = 800$ eV for a film of 5000Å. As shown by Eq. [1], the minimum exposure dose required is inversely proportional to the weight average molecular weight $\overline{M}_w$. Three lots of polystyrene[2] of $\overline{M}_w$ of 20,000, 35,000, and 230,000 were tested. Toluene was used as a solvent. The concentration was 5% for the highest polymer and 10% for the two lower polymers. The films were exposed by 10 kV electron beams and were developed by soaking in xylene for 30 sec and then by spraying with xylene twice for 2 sec each. The minimum exposure was found to be inversely proportional to the molecular weight $\overline{M}_w$. The experimental values were 3×10^{-4}, 2×10^{-4}, and 2.5×10^{-5} coul/cm², respectively, for the three lots of polystyrene of increasing molecular weight. The observed Q-M products are 6, 7, and 5.8 coul-g/cm²-mole, respectively, giving an average value of 6.3 under 10 kV electron beam. The Q-M product calculated by Eq. [1] is 7.9 coul-g/cm²-mole. Considering the uncertainties in the values of E and G(c.l.) and the difficulties in observing the value Q, the agreement between the observed and calculated values of the Q-M product is remarkable.

The exposed film is a three-dimensional network insoluble in xylene. It can be stripped by heating to about 100°C in the commercial stripper J100.

As stated above, polystyrene of high molecular weight is preferred over polystyrene of low molecular weight. However, the resolution of the polystyrene of $\overline{M}_w$ of 230,000 is not as good as that of $\overline{M}_w$ of 20,000. The edges of the developed polymer film pattern have a sloping bank less than 1μ wide for the polystyrene of $\overline{M}_w$ of 20,000, but they have a sloping bank of 2μ for the one with $\overline{M}_w$ of 230,000. This is due to the wider molecular weight distribution of the higher polymer with respect to that of the lower polymer.

When an electron beam penetrates into a polymer film coated on a surface, scattering increases the beam cross-sectional area in the film. Although the beam density decreases very rapidly along the normal to the edge of the irradiated area, molecules of very high molecular weight become crosslinked and remain on the surface after development, thus creating a wide sloping bank along the edges of the developed film pattern. The resolution can be improved by fractionating the polymer to attain a sharp cut-off in the high molecular weight region of the molecular weight distribution curve. This has been substantiated as follows. A dilute solution of polystyrene of $\overline{M}_w$ of 230,000 in benzene (5% solids) was prepared and ethanol was added. A 56% fraction of the dissolved solid consisting of most of the high molecular weight material was thus removed from the solution. More ethanol was added to the remaining supernatant solution, and a second fraction of 33.8% of the original polymer was separated. The viscosity of this fraction in benzene at 25°C was measured with a Cannon-Fenske viscometer and the intrinsic viscosity was found to be 0.326. Using the equation given by Orofino and Wenger (15)

$$[\eta] = 9.18 \times 10^{-5} M^{0.743}$$

we found that $\overline{M}_w = 60{,}000$. The required minimum charge dose was found to be about 1×10^{-4} coul/cm². The width of the sloping bank along the edge of the developed pattern is less than 1μ.

Molecules of molecular weight much less than M_w are also not desirable. They are less likely to get crosslinked and are dissolved away during development, thus increasing the probability of pinhole formation. Hence, polystyrene of high molecular weight but very narrow molecular weight range is recommended.

Poly(vinyl chloride).—Poly(vinyl chloride), PVC, is resistant to most acids, alkali, and common inexpensive organic solvents. Irradiation in air causes degradation, but irradiation in vacuum induces crosslinking. The crosslinking yield is estimated to be about 0.3 (16). As bought, PVC powders[2] dissolve easily in cyclohexanone. The resist solution used, 10% by weight, has excellent film-forming properties. Uniform films exhibiting brilliant colors can be easily obtained by the usual spin-coating method. The films were exposed to 10 kV electrons and developed in cyclohexanone. The minimum dose Q was found to be about 3×10^{-5} coul/cm².

Measuring the $\overline{M}_w$ by the light scattering method, Moore and Hutchison (17) found that the intrinsic viscosity of PVC in cyclohexanone at 25°C is

$$[\eta] = 174 \cdot 10^{-5} M^{0.55}$$

The intrinsic viscosity of the PVC we used was determined with Cannon-Fenske viscometer and was found to be 0.522. Hence, the average molecular weight of our PVC is $\overline{M}_w = 32{,}000$, and the Q-M product is about 1 coul/cm².

The density of PVC is 1.41 g/cm³. A 5000Å film has a sheet density of 7×10^{-5} g/cm². The energy loss of a 10 kV electron beam in passing through such a film is expected to be larger than that through a polystyrene film but lower than that through a Cu or Au film of the same sheet density. A value of $E = 1200$ eV is taken as the energy loss of 10 kV electron in passing a PVC film of 5000Å. Using [1], we found that the calculated Q-M product is 0.94 coul-g/cm²-mole, in excellent agreement with the observed Q-M product.

Polyacrylamide.—Polyacrylamide is a water soluble polymer. Its solubility in water is low, about 2%. Because of the low concentration and the low vapor pressure of the solvent water, the coating process is time consuming. Nevertheless, uniform films can be obtained. The minimum dose required was about 3×10^{-6} coul/cm². The exposed film was developed in deionized water and then rinsed in methanol, a nonsolvent. The crosslinked polyacrylamide is not soluble in water, but is swelled by aqueous solutions such as buffered HF, dilute acids, and alkalis. Hence, polyacrylamide is not an etch resist for aqueous acids or alkalis. The crosslinked polymer is resistant to concentrated phosphorous acid and is therefore a useful aluminum etch resist. It may also be used as a mask for sputtering etch.

The polyacrylamide[2] we used was not fractionated. The distribution of molecular weight is wide, and the resolution is poor. The edge of the developed re-

[2] Acquired from Monomer-Polymer Laboratories, Borden Chemical Company, Philadelphia, Pa.

sist pattern has a sloping bank of 2μ. Again, the resolution can be improved by removing the high molecular weight fraction of the polymer at the expense of slightly increased dose requirement.

The viscosity of the polyacrylamide used was measured in water at 30°C and the intrinsic viscosity was found to be $[\eta] = 13.6$. Scholtan (18) gave the following viscosity-molecular weight relation for polyacrylamide in water at 30°C

$$[\eta] = 6.31 \times 10^{-5} M^{0.80}$$

Hence, the molecular weight $\overline{M}_w$ of our polyacrylamide is 4.7×10^6 and the Q-M product is 14 coul-g/cm^2-mole.

Polyacrylamide has about the same density as polystyrene. The sheet density for a 5000Å film is 5.3×10^{-5} g/cm^2. Assuming the energy dissipation of 10 kV electrons in polyacrylamide is the same as that in polystyrene, we have $E = 900$ eV. The crosslinking yield G(c.l.) was not known. However, using the experimental values of Q and $\overline{M}_w$ and the estimated values of E, we found that the crosslinking yield of polyacrylamide under 10 kV electron is G(c.l.) = 0.02.

Positive Electron Resists

As discussed above, positive electron resists are long chain polymers which degrade by chain scission under electron bombardment. Degrading polymers have not been investigated intensively, for only a few are known to have a reasonably high glass transition temperature. Table II shows a few of the polymers that are useful as positive electron resists.

Several other styrene derivatives having tetrasubstituted carbon atoms also have high T_g. However, it is well known that a benzene ring will lower scission yield. Therefore, any styrene derivative, even if it is a positive resist, will have a low efficiency.

Poly(methyl methacrylate).—Poly(methyl methacrylate), PMMA, is very stable (unaffected by uv) and is resistant to most acids. Using 95% ethanol (5% water) as a developer, we found that the minimum exposure required for a 10 kV electron beam is 5×10^{-5} coulomb/cm^2 (19). The density of PMMA is 1.2 g/cm^3 and the molecular weight M_o of the monomer is 100.11. For a typical film of 5000Å the sheet density d is 6×10^{-5} g/cm^2. Assuming the energy loss of electron in a PMMA film is the same as that in a polystyrene film, we have $E = 1000$ eV. Assuming G(s) = 1.65 (20), we get from Eq. [2]

$$P_s = 0.014$$

For PMMA of molecular weight 100,000, $P_s\overline{M}_n/M_o = 14$. Each number average molecule has 14 scissions resulting in 15 fragments and the average weight of the scission fragments is, by [3]

$$\overline{M}_n' = 6700$$

If the initial molecular weight $\overline{M}_n$ is infinite, then the last term in [3] is zero and we have $\overline{M}_n' = 7100$. This can be reduced to 6700 by a 6% increase in the electron dose Q from 5×10^{-5} to 5.3×10^{-5} coul/cm^2, which is a very small increase. Hence, the initial molecular weight $\overline{M}_n$ of PMMA has very little effect on the final molecular weight $\overline{M}_n'$ after scission.

The number of scissions per number average molecule is large, and the molecular weight distribution follows Eq. [6]. Figure 1 shows the weight distribution

Table II. Positive electron beam resists

Polymer	T_g, °K	G(s)	M_o	Density, g/cm^3
Poly(methyl methacrylate)	378	1.65	100.11	1.20
Poly(α-methyl styrene)	373	0.25	130.18	0.906
Polymethacrylonitrile	400	1.0	67.09	1.10

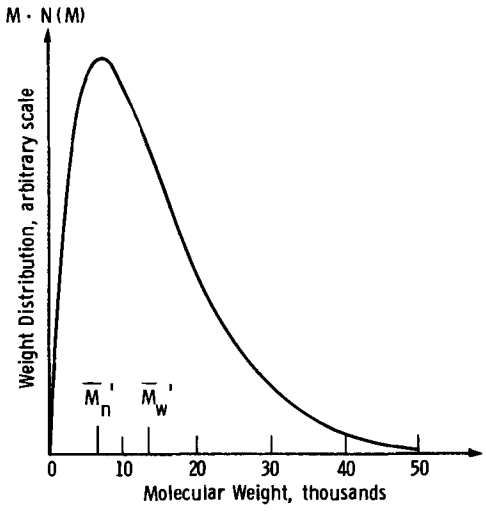

Fig. 1. Molecular weight distribution of polymethyl methacrylate (initial M.W. 100,000) after electron dose of 5×10^{-5} coul/cm^2 at 10 kV.

of PMMA as a function of the molecular weight after an electron dose of 5×10^{-5} coul/cm^2 at 10 kV. It can be seen that the tail of the distribution curve extends appreciably over 6 $\overline{M}_n'$ or 40,000. Since the developer is apparently able to dissolve molecules of such size, it is imperative that the molecular weight $\overline{M}_n$ of PMMA be relatively high, 100,000 or over, and that the fraction of molecules of $M < 50{,}000$ be very low to avoid pin-hole formation during developing. More generally, the distribution curve of the scission fragments must be well separated from that of the original polymer.

Using a 30/70 mixture of methyl ethyl ketone and isopropanol as a developer, Haller *et al.* (8) also found that the minimum exposure at 10 kV is 5×10^{-5} coul/cm^2 which corresponds to our results with ethanol as a developer. This coincidence is rather fortuitous as it is difficult to determine the minimum dose exactly. Nevertheless, it does indicate that the two different developers have about the same solvent power.

Poly(α-methyl styrene).—Poly(α-methyl styrene) has a scission yield G(s) = 0.25 (21), a monomer molecular weight of 130.18, and a density of 0.906. The sheet density of a 5000Å film is $d = 4.53 \times 10^{-5}$ g/cm^2. Assuming the energy loss in this material is the same as that in polystyrene of the same sheet density, then we have $E = 750$ eV. Using a 10/60 mixture of benzene/ethanol as a developer, Haller *et al.* (8) found that the minimum exposure at 10 kV is 1×10^{-4} coul/cm^2, hence we have from [2]

$$P_s = 7 \times 10^{-3}$$

The average molecular weight of the scission product is

$$\overline{M}_n' \approx 140\, M_o$$

$$= 18{,}000$$

For a polymer of molecular weight of 200,000, the number of scissions per molecule is about 10.

The average molecular weight $\overline{M}_n'$ is relatively large. Figure 1 and Eq. [6] imply that generally an appreciable number of the scission fragments has molecular weights over 6 $\overline{M}_n'$ or 100,000. The molecular weight $\overline{M}_n$ of the original polymer must be high, 200,000 or over, otherwise the resolution will be poor and the pin-hole count high.

Conclusion

Although the number of polymers with suitable glass transition temperature is not very large, there

are still several polymers worth investigation, even neglecting the fact that the physical and chemical properties of a polymer may be modified by copolymerization with other polymers. The general characteristics described are those of electron resists. With some modifications, they are also common to photoresists. The efficiency of a negative resist, either photoresist or electron resist, is proportional to the average molecular weight $\overline{M}_w$. Although monodispersity is not required (nor is it obtainable), a narrow range distribution in molecular weight is recommended. In the case of a positive resist, neither the average molecular weight nor its distribution is important as long as the molecular weight distribution curve is well separated from that of the scission fragments.

Cathodoluminescent $Ln_y(SiO_2)_x$:Tb Phosphors

T. E. Peters*

The Bayside Research Center of General Telephone and Electronics Laboratories, Incorporated, Bayside, New York

ABSTRACT

The synthesis of terbium-activated compounds in Ln_2O_3-SiO_2 system is described and their cathodoluminescence is compared to Zn_2SiO_4:Mn, (ZnCd)S:Ag, and other efficient Tb^{+3}-activated phosphors. The utility of the Tb^{+3} phosphors in tricolor CR tubes is also considered.

The literature affords numerous references (1) to luminescent systems in which the crystalline matricies are silicate compounds of the Group II metals. Typical activators for these systems include Pb and/or Mn, Ce^{+3}, and, more recently, Tb^{+3} (2). In phosphors containing divalent cations and trivalent rare earth activators, it is usually necessary to employ valence compensation by the introduction of a monovalent cation of the appropriate size. This generally improves the crystalline perfection and may also enhance and simplify the emission spectra. The minerals yttrialite $(Y,Th)_2Si_2O_7$ and thortveitite $(Y,Sc)_2Si_2O_7$ have been reported to contain substantial quantities of the rare earths metals as impurities (3) and therefore suggest silicate systems in which charge compensation would not be necessary to achieve maximum emission. Recent research on the phase diagrams of the Ln_2O_3-SiO_2 systems (4, 5) (where Ln = La, Y, Sc, or a rare earth) has suggested a variety of silicates of this type.

Silicates, like the sulfides, seem to be uniquely responsive to excitation by cathode rays, and therefore it was decided to investigate cathodoluminescence in several of these compounds. Of particular interest are the silicates of Y, Gd, and La since these ions possess no incomplete 4f shell, or in the case of Gd, the shell is half filled, and therefore the three are optically inert in the visible and near-ultraviolet regions of the spectrum. Trivalent terbium was chosen as the activator because it has been shown to be effective in silicate matricies, and a few efficient cathode ray phosphors based on this activator have been reported.

Experimental Procedure

The various silicate compounds are given in Table I, together with references to the reporting investigators. It may be seen that these compounds extend from SiO_2/Ln_2O_3 = 0.5 to 2.0 (where Ln = Y, Gd, La). In an effort to encompass all of the previously reported compounds, a series of silicate phosphors were synthesized over the compositional range of SiO_2/Ln_2O_3

Table I. Various silicate compounds

SiO_2/Ln_2O_3	Compound	Designation*	Ref.
0.5	Ln_4SiO_8	—	(6)
1.0	Ln_2SiO_5	Oxyorthosilicate	(4, 5)
1.5	$Ln_4(SiO_4)_3$	Orthosilicate	(4)
2.0	$Ln_2Si_2O_7$	Pyro or diorthosilicate	(4, 5)

* Designations are those used by Toropov *et al.*

* Electrochemical Society Active Member.

from 0.5 to 2.4. In the synthesis procedure, which is somewhat similar to that reported earlier for lanthanum silicate (6), a portion of the cationic oxide or nitrate was replaced by the fluoride which served as a mineralizer. Alternatively, the mineralizing action could also be accomplished by the addition of another fluoride salt such as ammonium fluoride. Pending the elucidation of the most efficient host compounds, the fluoride concentration was held constant at $LnF_3/Ln_2O_3 = 0.22$. Similarly, the terbium concentration was constant at 10 a/o (atomic per cent) of the host cation. These parameters were subsequently optimized for the best phosphors. The high-purity SiO_2 utilized in all syntheses was supplied by Cabot Corporation (Cabosil). The extremely small particle size of this material contributed to the ease of synthesis and uniformity of the product. Usually a slight excess of silica over that dictated by stoichiometry was necessary for the synthesis of the most efficient phosphors. All of the lanthanide components except Gd were of 99.9% purity or higher with respect to other rare earth elements. The principal impurity in the Gd_2O_3 was Eu_2O_3.

In a typical synthesis, the reagents were dry blended and reacted at 1300°C for 4 hr or longer in uncovered quartz crucibles. X-ray diffractometry was employed for the identification of the resulting compounds.

X-Ray Diffractometry

Crystallographically, the oxyortho and pyrosilicates each exhibit three structural subgroups, the particular structure being related to the ionic size of the lanthanide ion (5, 7). The pyrosilicates, in addition, exhibit high- and low-temperature polymorphic modifications (5) with inversion temperatures between 1200° and 1300°C.

The literature describing the orthosilicates is confusing, particularly with respect to the stability of this structure type. A temperature stability minimum has been ascribed to at least the orthosilicates of the larger lanthanides (4a, b) but more recent work indicates that this may not be the case (8). Investigators agree, however, that the orthosilicates are part of the hexagonal crystal system S. G. $P6_{3/m}$ (8, 9). Yttrium orthosilicate is apparently unique since it has been crystallized in both the hexagonal and a cubic (garnet) modification (10).

Identification of these numerous phases by x-ray diffraction was further complicated by the prolific and often conflicting lattice spacings reported by these earlier workers. In the majority of cases, identification was possible by correlating the reported data and eliminating those which were in conflict. The compounds identified in the various phosphor compositions are presented in Table II. The data presented in Table II warrant some further interpretation.

Oxyorthosilicates

All three oxyorthosilicates were obtained as pure phases. Contrary to what has been previously reported, only two structure types were observed. La_2SiO_5 and Gd_2SiO_5 were hexagonal, while Y_2SiO_5 was monoclinic. The compound Ln_4SiO_8 was not detected.

Table II. Compounds identified in various phosphor compositions

SiO_2/Ln_2O_3	Lanthanum silicates	Gadolinium silicates	Yttrium silicates
0.5	$La_2O_3 + A$	$Gd_2O_3 + A$	$Y_2O_3 + A$
1.0	A	A	A
1.2	A	—	A
1.4	A	—	$A + B$
1.6	$A + C$	$A + C^*$	$A + B + C$
1.8	$A + C$	—	$B + C$
2.0	C	C^*	$B + C$
2.4	$SiO_2 + C$	—	$B + C$

$A = Ln_2SiO_5$, $B = Ln_4(SiO_4)_3$, $C = \beta\text{-}Ln_2Si_2O_7$
* Yielded C structure when fired at 1600°C.

Orthosilicates

The orthosilicates of La and Gd were not observed. At SiO_2/Ln_2O_3 values of 1.4-1.8, corresponding to the range in which the orthosilicate might be expected to crystallize, only the oxyortho and β-pyrosilicates were detected. This seems to indicate a temperature stability minimum for these compounds as discussed earlier. Yttrium orthosilicate was observed, but never as a pure phase. Several attempts to crystallize this compound in the pure form were unsuccessful.

Pyrosilicates

Only the β-polymorphs of $La_2Si_2O_7$ and $Gd_2Si_2O_7$ were obtained as pure phases; the low-temperature α-pyrosilicate was absent, presumably because of the high synthesis temperature. The β-$Gd_2Si_2O_7$, however, was not obtained under the usual synthesis conditions; the oxyorthosilicate phase persisted over the entire range of SiO_2/Gd_2O_3 values. The reason for this was not apparent since the Gd_2SiO_5 crystal type persisted at higher flux ratios and proved to be independent of the source or chemical nature of the gadolinium employed. However, it was possible to crystallize the pyrosilicate by refiring the $SiO_2/Gd_2O_3 = 2.0$ composition at 1600°C. Yttrium pyrosilicate, on the other hand, was never obtained as a pure phase even when subjected to higher flux ratios or reaction temperatures as high as 1600°C.

Evaluation of CR Response

The cathode ray response of the phosphors was ascertained by settling them at optimum screen density on 1-in.^{2} sheets of conducting glass and exciting them at 15 kV in a demountable CR tube. A Photovolt Photometer equipped with a 1P21 phototube and a Wratten 106 filter was employed for luminosity measurements. Cathode ray performance data are reported relative to that of (Zn, Cd)S:Ag.

Typical data are presented in Table III for phosphors synthesized at a constant LnF_3/Ln_2O_3 ratio of 0.22 and a Tb^{+3} concentration of 10 a/o.

The CR response of La_2SiO_5:Tb was extremely weak, and luminosity measurements were not possible. During the syntheses of this compound and of Gd_2SiO_5:Tb, the terbium was oxidized to the tetravalent state, resulting in phosphors exhibiting brownish body color and dull green emission. In order to better evaluate these monosilicate hosts, several syntheses were conducted in reducing ambients and/or at reduced Tb^{+3} concentration levels. Under these conditions, the CR response of Gd_2SiO_5:Tb improved but that of La_2SiO_5 remained weak.

The oxyorthosilicates of yttrium and the β-pyrosilicates of lanthanum and gadolinium formed the most efficient phosphors. No attempt was made to optimize the synthesis parameters for β-$Gd_2Si_2O_7$:Tb since the temperatures at which the component oxides reacted were substantially higher than those achievable in conventional phosphor synthesis equipment. The lanthanum and yttrium phosphors, however, were op-

timized for CR performance. These data are presented in Fig. 1 and 2, and the optimum parameters are summarized in Table IV.

Cathodoluminescence Spectra

The cathode-ray-excited emission spectra of the optimized phosphors were recorded with a ¾-m Czerny-Turner spectrometer which employed an internal correction function to render the output directly in terms of relative energy. These spectra are presented in Fig. 3 and are noted to be typical of Tb^{+3} emissions in a variety of other host crystals (13). The emission spectra in all cases are dominated by a group of lines which extend from 532 to 564 nm and which are attributed to electronic transitions between $^5D_4$-

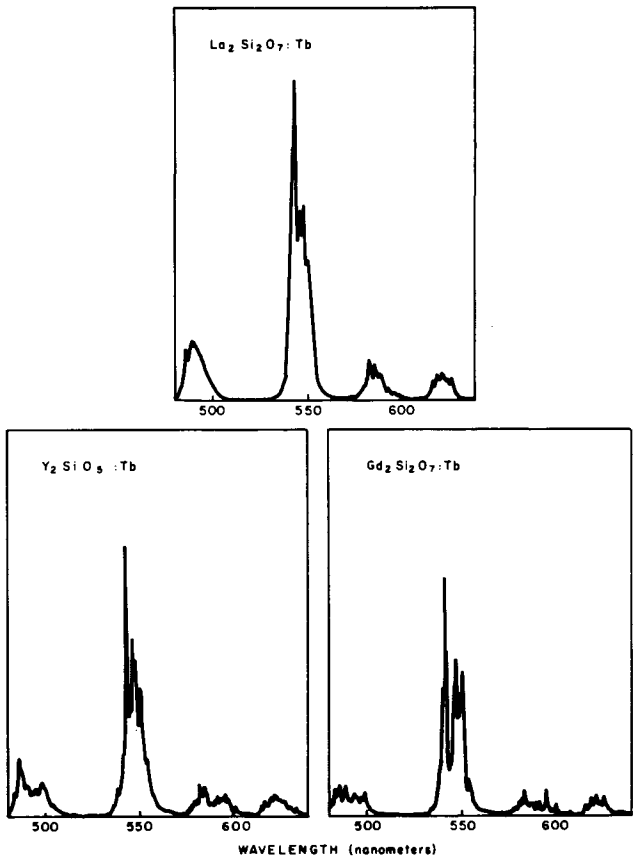

Fig. 3. Cathodoluminescence spectra of Ln silicate phosphors activated with Tb^{+3}.

$^7F_5$ levels. A smaller contribution to the luminosity arises from emissions at 480-508, 576-610, and 614-634 nm. These line groups arise from $^5D_4$-$^7F_{6,4,3}$ transitions. In general, any variation in the observed emission color of the Tb activator is usually due to differences in the relative intensities of these line groups rather than to subtle differences within the line groups. The former can result in an appreciable shift in the chromaticity coordinates on the CIE diagram as is demonstrated and discussed in the following section.

Cathode Ray Performance

The cathode ray performance data for the silicate phosphors are summarized in Table V. Data for other efficient Tb^{+3} phosphors, YPO_4:Tb and $InBO_3$:Tb, have been included for comparison (11, 12). The luminosity and conversion efficiencies for all of the phosphors have been determined relative to (Zn, Cd)S:Ag.

In terms of relative luminosity, Y_2SiO_5:Tb compares favorably with the phosphate and borate phosphors, and all three exhibit a slight improvement over Zn_2SiO_4:Mn. The silicates of La and Gd, although somewhat less efficient than the other Tb systems,

still exhibit appreciable CR performance. In their decay characteristics, the terbium-activated systems are intermediate to the Zn_2SiO_4:Mn and (Zn,Cd)S:Ag. Among the Tb^{+3} phosphors, Y_2SiO_5 and YPO_4 have the highest luminous conversion efficiency; they are exceeded only by the sulfide phosphor.

The CIE coordinates and lumen equivalents indicate a steady decrease in the saturation of the green emission color as one moves from $InBO_3$:Tb to YPO_4:Tb. This shift is accounted for by an increase in the $^5D_4$-$^7F_6$ electronic transitions relative to those of the $^5D_4$-$^7F_5$ as the symmetry of the Tb^{+3} lattice site decreases. For $InBO_3$ in which the Tb^{+3} lies in a centrosymmetric site, the $^5D_4$-$^7F_5$ magnetic dipole transitions are allowed, and these are responsible for 75% of the luminous emission. In YPO_4, where Tb^{+3} occupies a noncentrosymmetric site, electric dipole transitions are also allowed, and the contribution to the total luminosity of the $^5D_4$-$^7F_5$ line group falls to 50%. On this basis, it would appear that Tb^{+3} occupies a site of slightly higher symmetry in the silicates than in the phosphate.

Utility of Tb^{+3} Phosphors in Tricolor CR Tubes

In assessing the utility of terbium-activated phosphors in conventional tricolor cathode ray tube applications, it is necessary to consider the effect of the change in chromaticity coordinates on both color reproduction and the luminosity requirements for color mixing.

The effect on color reproduction is best assessed by substituting the chromaticity coordinates of the Tb^{+3} phosphors for those of the green primary (Zn,Cd)S:Ag and evaluating the change in the area of the triangle formed by connecting the u.v. coordinate points of the three primaries on the CIE 1960 McAdam diagram. The luminosity requirements for color mixing, such as in the reproduction of the 9300°K white point on the CIE diagram, can be obtained from a knowledge of the ratio of the lumen fractions and relative luminosities of the green primary and the phosphor under consideration. These calculations have been made for the three most efficient terbium phosphors, and the results are included in Table V. The red and blue primaries are YVO_4:Eu and ZnS:Ag, respectively. The errors encountered in the determination of the chromaticity coordinates are of necessity transmitted to the calculated areas of the resulting triangles and to the green lumen fractions. However, the presented data are sufficiently accurate to permit a qualitative appraisal of the utility of these phosphor compounds in CR tube applications.

From the standpoint of color reproduction, $InBO_3$:Tb is an acceptable replacement for the sulfide primary. Use of the silicate or phosphate, however, would result in a decrease in the gamut of obtainable colors. The silicate phosphor, as indicated, is intermediate to the borate and phosphate in this respect.

At the outset it is observed that all three of the terbium phosphors are deficient in terms of the luminosity required to reproduce the 9300°K white. The $InBO_3$:Tb phosphor appears the most promising but is still some 35% short of meeting this requirement, and the silicate and phosphate are even more deficient in this respect. Until improvements in the luminosity of these phosphor systems are obtained, their application in conventional tricolor shadow mask tubes does not appear likely.

The rare earth phosphors exhibit a distinct advantage over the green sulfide primary in their linear response at high current densities and may therefore find application in novel tube designs. This is demonstrated in Fig. 4 where the cathodoluminescent response of Y_2SiO_5:Tb and (Zn,Cd)S:Ag are presented as a function of current density. The terbium-activated silicate exhibits no saturation effect as the current density is increased while the sulfide begins to saturate and deviates from linearity almost immediately. Thus,

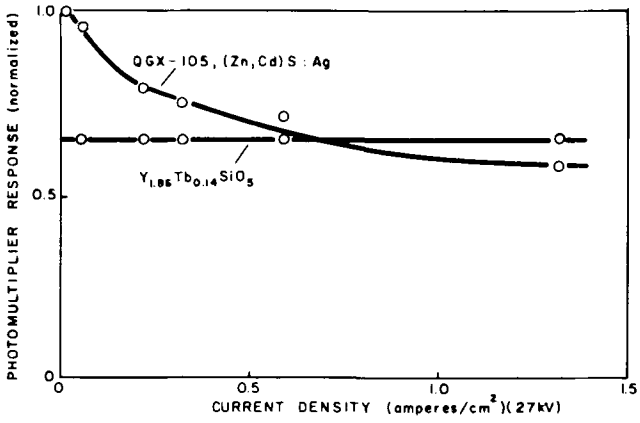

Fig. 4. Current density and CR response of $Zn_{0.72}Cd_{0.28}S$:Ag and $Y_{1.86}Tb_{0.14}SiO_5$ phosphors.

at a current density of 0.65 A/cm² the two phosphors exhibit equal luminosities. The most effective application of these rare earth phosphors, therefore, would lie in cathode ray tubes of the PDF (post deflection focusing) type where the phosphors are subjected to high current densities.

Conclusions

In summary, this investigation has shown that these terbium-activated silicates represent a new family of efficient green-emitting cathode ray phosphors. The most efficient of these, Y_2SiO_5:Tb, is equal to $InBO_3$:Tb and YPO_4:Tb in terms of relative luminosity and intermediate to the two in color and conversion efficiency.

The application of terbium-activated phosphors in tricolor shadow mask tubes has been considered and their utility was found to be limited by the brightness requirements even if some sacrifice in color could be tolerated.

The terbium phosphors were superior to (Zn,Cd)S:Ag in their performance at high current densities, indicating that the most effective application of these materials would lie in cathode ray tubes of the PDF type.

CdS-PbS Heterojunctions

Saburo Watanabe and Yoh Mita

Central Research Laboratories, Nippon Electric Company, Ltd., Shimonumabe, Kawasaki, Japan

ABSTRACT

Heterojunctions between n-type CdS and p-type PbS were prepared by chemical deposition of PbS films on CdS single crystals. The PbS films were found to grow epitaxially on CdS crystals. The cubic (111) plane of PbS was parallel to the hexagonal (002) plane of CdS and the cubic (220) plane to the hexagonal (110) plane. The heterojunctions showed a marked photovoltaic effect and distinct rectifying characteristics. The maximum open circuit voltage obtained was 0.4V under irradiation with a tungsten lamp at 0.3 w/cm^2. The spectral sensitivity of the photovoltaic effect showed a sharp maximum at the absorption edge of CdS and a flat plateau extending toward long wavelengths as far as 1μ. The junction capacitance at zero bias and diffusion voltage were measured to be 10 $\sim$ 30 nF/cm^2 and 0.4V, respectively. From these results the energy band diagram was constructed for the heterojunction.

The preparation of the p-n junction of CdS is extremely difficult. Heterojunctions with p-type Cu_2S are used for various applications (1, 2). However, as the electrical and crystallographic properties of Cu_2S are complicated, the investigation of the nature of CdS-Cu_2S heterojunction is difficult to carry out.

In this paper the heterojunction of n-type CdS and p-type PbS, which has a simple structure, is reported. It was found that the heterojunction can be prepared by chemical deposition of PbS on CdS crystals. The preparation of the heterojunctions is described and the results of the examination of crystallographic and electrical properties are given with special attention to the crystallographic structures, photovoltaic effect, and energy band diagram of the heterojunctions.

Fabrication of CdS-PbS Heterojunctions

In order to prepare CdS-PbS heterojunctions, PbS films were deposited chemically on oriented surfaces of CdS single crystals. Procedures for obtaining PbS films were similar to those reported elsewhere for PbS photoconductive films (3, 4). The solution used to grow PbS films contained 0.12 mol-NaOH, 1.2 x 10^{-2} mol-$Pb(NO_3)_2$, 4.4 x 10^{-2} mol-$CS(NH_2)_2$, and 3.4% ethyl alcohol. CdS crystals were cut parallel to their hexagonal (002) and (110) planes and were optically polished. They were immersed in the solution for 20 min at room temperature. After PbS films were formed by deposition, the crystals were taken out and washed with water and ethyl alcohol. Ohmic contacts to CdS were made prior to the growth of PbS by evaporating and alloying indium. Ohmic contacts to PbS were made by simply evaporating gold.

The thickness of the PbS films was determined by means of chemical analysis and was found to be 0.3μ. The electrical conductivity of PbS films was p-type with specific resistivity of 16 ohm-cm. The resistivity of the films decreased to 1 ohm-cm under irradiation with a tungsten lamp at an intensity of 0.3 w/cm^2. In our experiments photoconductive and semiconductive CdS crystals were used. The resistivity of the photoconductive crystals was approximately 10 kohm-cm in the dark and 500 ohm-cm under the light, and the resistivity of most semiconductive crystals was 3.0 ohm-cm.

Crystallographic Properties

Electron diffraction studies were made for several PbS films deposited on various CdS surfaces. Figure 1 (a), (b), and (c) show diffraction patterns of PbS deposited on Cd- and S-surfaces of (002) planes and on (110) planes of CdS crystals, respectively.

From the analysis of the diffraction patterns, the films were found to be cubic and epitaxial with CdS lattices. When PbS films were deposited on the (002)

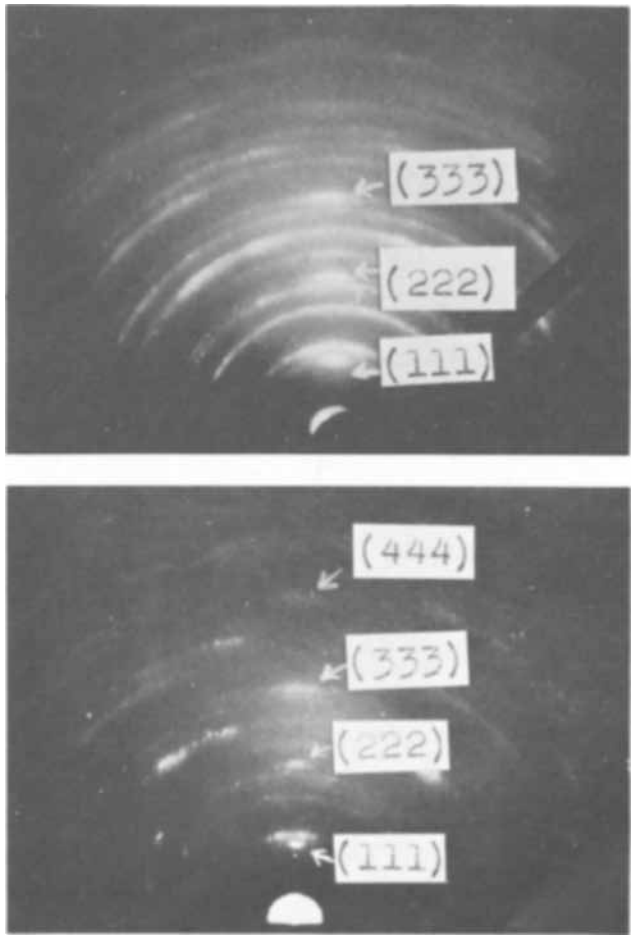

Fig. 1a (top). Electron diffraction patterns of PbS film, deposited on Cd-surface of (002) plane of CdS, Fig. 1b (bottom). deposited on S-surface of (002) plane of CdS.

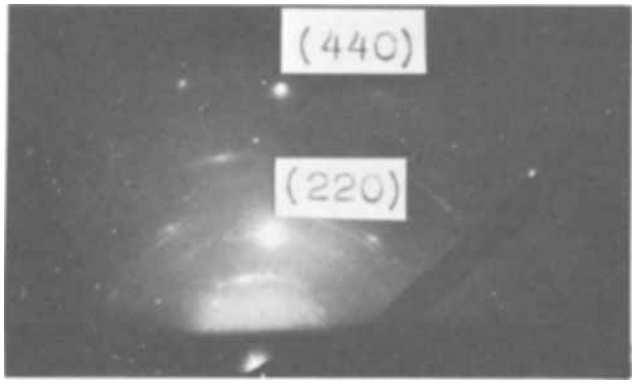

Fig. 1c. Deposited on (110) plane of CdS

planes of CdS, the films grew parallel to their (111) planes. Better crystals were obtained when grown on the S-surfaces of (002) planes than on the Cd-surfaces of the same plane. When PbS films were prepared on the (110) planes of CdS, the films grew parallel to their (220) planes. In this case the spots of the diffraction patterns are so distinct that the films are considered to be in nearly perfect orientation [Fig. 1(c)].

The electron microscope photographs of these three kinds of PbS films are shown in Fig. 2 (a), (b), and (c). It is clear that the surfaces of the films reflect the etching patterns of the CdS crystals.

Electrical and Photoelectrical Properties

The heterojunctions showed clear rectifying characteristics and marked photovoltaic effects. We have measured these properties at room temperature. Representative examples of V-I characteristics are shown in Fig. 3(a) and (b). Figure 3(a) shows the characteristics for (002) planes of semiconducting CdS crystal as the substrates, and Fig. 3(b) shows that of photoconductive CdS crystals.

The maximum values of the open circuit voltage and short circuit current are shown in Table I for various planes of CdS. The rectifying characteristics of the cells cannot be related in general to the photovoltaic effect of the cells. The spectral sensitivity of the photovoltaic effect is shown in Fig. 4, in which the output voltage was normalized with respect to the incident energy. The spectral sensitivity has a conspicuous peak at the absorption edge of CdS. In addition to this peak, there is another low and flat region extending toward longer wavelengths up to 1μ.

The photoconductive spectrum of a CdS crystal is shown in Fig. 5. It has a sharp maximum near the absorption edge and a long tail toward longer wavelength.

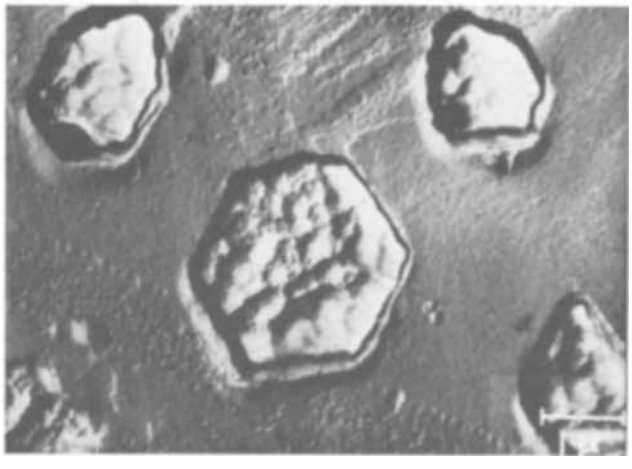

Fig. 2a. Electron microscope photograph of PbS film, deposited on Cd-surface of (002) plane of CdS.

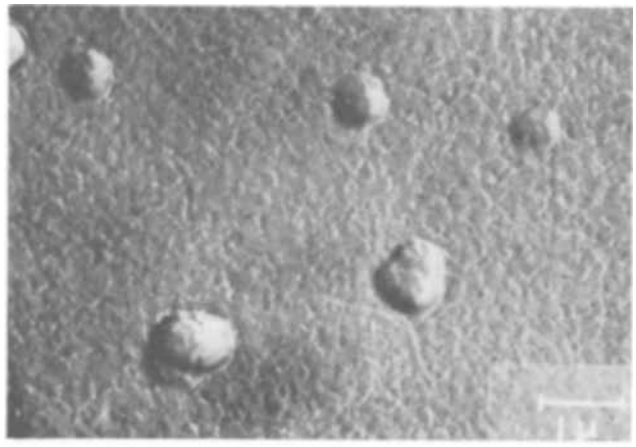

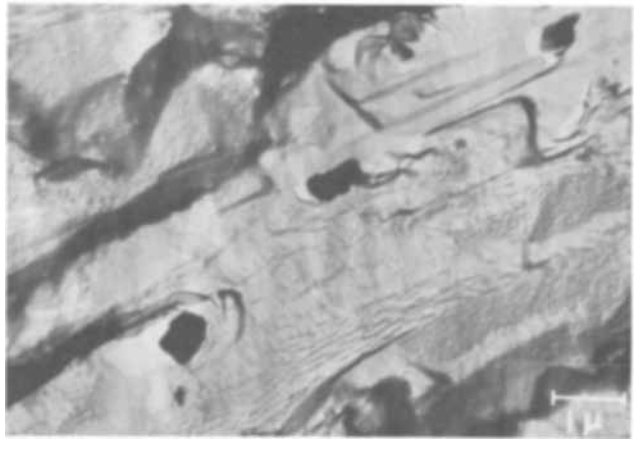

Fig. 2b (top). Deposited on S-surface of (002) plane of CdS, (c, bottom) Deposited on (110) plane of CdS.

The junction capacitance and bias dependence were measured for the heterojunctions between semiconductive CdS and PbS. The measurements were carried out at the frequency of 1 MHz, and the Q value was larger than 10. The zero-bias capacitance ranged between 10 to 30 nF/cm^2. The relation between the junction capacitance and bias voltage is given in Fig. 6. The two lines are the results of two different samples obtained on the same wafer. The inverse square of the capacitance was found to be in linear relation with applied voltage. From the lines in Fig. 6 the diffusion voltage of 0.4V was obtained. The diffusion voltage changed only slightly for different samples, but the slopes of the line differed considerably.

Discussion

PbS films deposited on amorphous substrates do not show noticeable orientations. But is has been known that they have epitaxial relations with such substrates as NaCl or Ge, which have the same or similar crystal structure as PbS (5-7). The present experiments have clearly shown that the PbS films are epitaxially oriented with respect to the hexagonal CdS lattice. The cubic (111) planes of PbS are parallel to the hexagonal (002) planes of CdS and the (220) planes of the former are parallel to the (110) planes of CdS.

In Fig. 7 (a) and (b) the arrangements of cations (or anions) of CdS and PbS are shown with respect to the (002) planes of CdS and (111) planes of PbS. The two crystal lattices closely resemble each other. The

misfit between two neighboring cations is 1.2%. Figure 8 (a), (b), and (c) show ionic arrangements of cations and anions on the (110) plane of CdS and (220) plane of PbS. Two kinds of planes are laid so that the [001] axis of CdS agrees with the [111] axis of PbS. From Fig. 8(c) it can be shown that the misfit between CdS and PbS lattices is very small in the direction perpendicular to the [111] direction of PbS and the misfit is considerably larger along the [111] direction of PbS. But, if we take a large unit cell as shown in the figure, the two lattices almost coincide. The misfit in neighboring cations (or anions) is 1.2% for the smallest interionic distance and 1.6% for the largest one. The misfit in cation-anion distance amounts to as much as 18%.

The orientations of the PbS films agree with those which are expected from crystallographic considerations. The similarity in atomic arrangement and the smaller misfit indicate that the (111) planes of PbS and (002) planes of CdS are likely to have a better epitaxial relation than another combination. Actually, however, the combination of (220) planes of PbS and

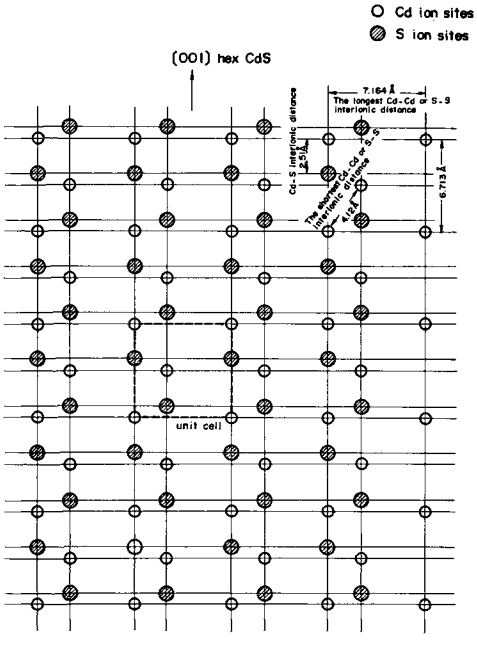

Fig. 8a. Ionic arrangement on (110) plane of CdS

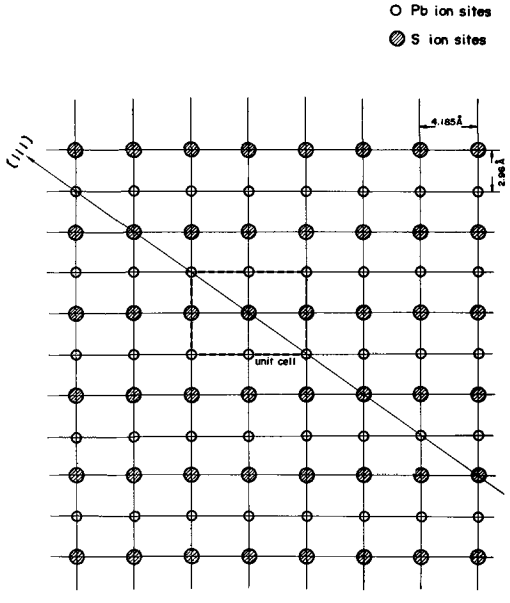

Fig. 8b. (220) Plane of PbS

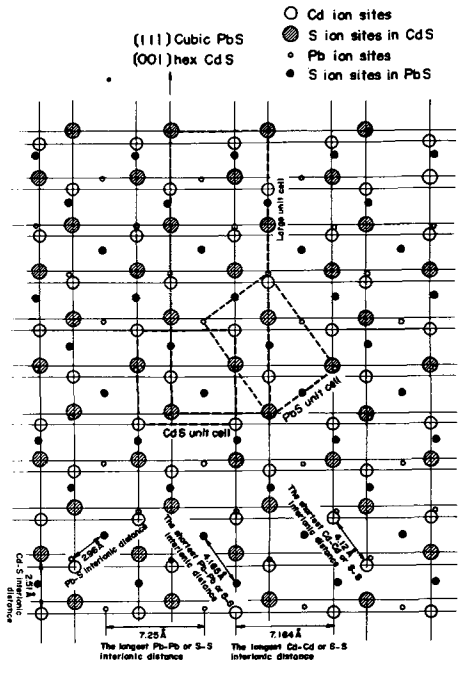

Fig. 8c. (220) Plane of PbS on (110) plane of CdS

(110) planes of CdS shows much better epitaxial growth.

The interface between PbS and CdS shows marked photovoltaic effect and rectifying characteristics. These phenomena can be interpreted as the result of the formation of p-n heterojunctions. But the heterojunctions obtained so far are not ideal. The "n" value obtained from the forward characteristics is considerably larger than 1 to 2, which is expected in an ideal diode. Clear rectifying characteristics are not always observed, particularly when photoconductive CdS crystals are used as substrates.

The heterojunctions show a photovoltaic effect under irradiation of visible and infrared light. The maximum output voltage is about the same order of magnitude as is observed in CdS solar cell. But the conversion efficiency so far obtained is considerable lower than that of the solar cell (1). This is presumably due to a lower conductivity of PbS compared with that of Cu_2S and the lack of long wavelength sensitivity of the CdS used in the experiments. The spectral sensitivity of the photovoltaic effects has a prominent peak near the absorption edge of CdS. The photovoltaic effect is almost exclusively due to intrinsic excitation of CdS and only partially due to PbS and extrinsic levels of CdS.

From the voltage dependence of the junction capacitance the junction seemed to be an abrupt junction. In Fig. 9 a schematic energy band diagram of the heterojunction on the semiconductive CdS is shown which was obtained according to a simple model (8). The interface states and intermediate levels were not taken into consideration. The position of the Fermi levels was calculated using suitable assumptions. The greater part of the diffusion voltage seemed to be supported on the CdS side because of difference in carrier concentrations and in band gaps (10^{16} cm^{-3} for CdS

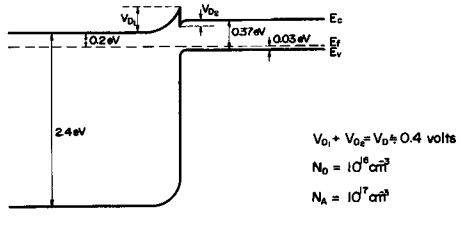

Fig. 9. Schematic energy band diagram of the heterojunction

and 10^{17} cm^{-3} for PbS; in the latter case mobility was assumed to be lower than 10 cm^2/V-sec). The measured junction capacitance was considerably smaller than that expected from the carrier concentration and the diffusion voltage. The thickness of the depletion layer obtained from zero-bias capacitance was 0.3-1μ. The donor concentration was calculated to be less than $6 \cdot 10^{15}$ cm^{-3}, which was considerably lower than that obtained from specific resistivity. So far there is no satisfactory explanation for this difference nor for the relatively large change in slopes of the lines in Fig. 6.

The energy band diagram showed the presence of large energy discontinuities at conduction and valence bands. For this reason the transfer of free electrons from PbS to CdS seemed less probable as well as the transfer of free holes in the same direction.

In conclusion the oriented growth of chemically deposited PbS films on CdS crystals was confirmed and their crystallographic relations were elucidated. The heterojunction between n-CdS and p-PbS showed a marked photovoltaic effect. The schematic energy band diagram was obtained from the results of capacitance measurements.

Gallium Phosphide Double-Epitaxial Diodes

I. Ladany

RCA Laboratories, Princeton, New Jersey

ABSTRACT

The external quantum efficiency of red EL emission in GaP diodes is studied as a function of doping in the p layer. A standardized procedure is used, consisting of liquid phase epitaxial growth of an n layer, followed by similar growth of the p layer. It is found that efficiencies up to 1.4% result from optimizing the Zn and O additions to the p melt, but that efficiencies as high as 3.4% can be obtained if the p melts are compensated by the addition of Te. Arguments are presented showing that a residual donor, probably sulfur, accounts for compensation effects in diodes made by an earlier process. Some other factors which may influence the efficiency are also discussed.

The highest efficiency so far reported for GaP red-emitting diodes was obtained by liquid phase epitaxial (LPE) growth of a Te doped layer onto a solution grown (SG) platelet doped with Zn and O. By following the growth with a heat treatment, Logan *et al.* (1) obtained efficiencies on the order of 2% at room temperature. In fabricating diodes in this way, we encountered considerable variations between platelets from the same growth run and large differences in El efficiencies of the final diodes. We have, therefore, investigated a method of fabrication consisting of successive growth of n and p layers by liquid phase epitaxy. An advantage of such a scheme is that the diode properties are less dependent on the substrate, so that similar results might be obtained for substrates obtained by various methods, such as vapor phase growth, Czochralski growth, or solution growth. All the work reported in this paper used epitaxial growth on SG platelets, however, and it is for this type of substrate that our conclusion apply directly.

Although our main concern is the double-epitaxial diode, that is a diode obtained by successive growth of two LPE layers, we shall be comparing the results to the high efficiency single-epitaxial diode mentioned above. The single-epitaxial diode we call a class I diode, and although we believe that our class I diodes compare to those made at other laboratories, the reader should bear in mind that all the data to be presented have been obtained on units made here. The double-epitaxial diode will be referred to as a class II diode.

An obvious difficulty in the formation of both p and n layers by LPE is the volatility of the dopants. One attempt to solve the doping problem involved the addition of zinc to the gas flow from a separately heated source, and the addition of gallium oxide to the melt, but gave only moderate efficiency, about one fourth of that mentioned earlier (2). Recently a method was described in which the melt is tipped onto the substrate inside a sealed quartz ampoule, which largely prevents the escape of dopants (3). Nevertheless, reported efficiencies were again below earlier values, thus hardly justifying the added complication.

In the present paper we describe a simpler method of p layer growth and discuss some properties of the resultant diodes. We also report on compensation effects in the p layer and their influence on efficiency. We begin, however, with a brief review of our efficiency measurement.

Determination of Efficiency

A vexing question in all work of this kind is the reliability of efficiency measurements. After a certain amount of experience gained using alternate methods, we have found the following to be most useful for room temperature measurements.

The GaP chip to be measured is clamped between small pressure contacts and placed in a box lined with 6 Hoffman N220CG-10L solar cells. The ratio of short circuit current of the cells connected in parallel to the current flowing in the diode is a lower limit to the efficiency. This value would be the true efficiency if the

solar cells were 100% efficient, and if 100% of the emitted light were collected. One may improve on this estimate without doing any calibration by noting that solar cell efficiencies generally run between 70% and 80%, and one may evaluate the collection efficiency by determining the portion of the solid angle not intercepted by solar cells. The estimate so arrived at is not far from the actual multiplication factor we use, equal to 1.3, which was obtained by measuring a diode in this box and in a calibrated integrating sphere.

The measured efficiency as described above is higher than the efficiency of the same chip after alloyed ohmic contacts have been applied. That this is due to absorption in the contact and not degradation can be seen from the recovery of the original efficiency if the contacts are removed by etching. This is, of course, consistent with light absorption in the contact as recently discussed by Bergh (4). If the alloy contact area is kept small, and the chip is coated with a transparent higher index material, the original efficiency is again recovered. Measurements on chips using pressure contacts therefore provide a good indication of what can be obtained from the same material in a carefully made diode. Nevertheless, the values later given in Table II were obtained from mounted diodes with alloyed ohmic contacts and a plastic or wax coating.

Determination of Optimum Doping

The Zn and O concentration required to maximize the photoluminescence efficiency of SG platelets is known (5); because of similarity of SG and LPE it might equally well apply to LPE growth. We do not expect this to be so, however, since the impurity segregation coefficients for epitaxial growth are quite different from those applying to platelet growth. Furthermore, platelet growth is carried out in a sealed crucible, whereas, in the interest of simplicity, we wish to use the standard open tube method (6). The loss of dopants under these conditions is not easily predicted, especially in the case of oxygen whose behavior in a melt is largely unknown.

To gain some idea of the loss of zinc and oxygen in LPE of class II diodes, we carried out preliminary tests using the following procedure:

We grow a Te doped layer onto a SG platelet using the optimum Te doping (7) and follow this without lapping, with the growth of the Zn and O doped p layer. Doping is accomplished by adding to the melt suitable quantities of one or another of the dopants Zn, Te, ZnO, and Ga_2O_3.

The furnace is identical to the one first described by Nelson (6). Forming gas flows over a carbon outer crucible, which is provided with a vitreous carbon liner. Tipping temperatures are in the 1050°-1070°C range, and the cooling rate varies between 20°C/min at the start of growth, and 10°C/min toward the end. About 50 μm of material is grown during one LPE run.

After the second layer is grown, the SG substrate is lapped off, the wafer cleaved into chips, and the efficiency measured.

If only zinc is added to a fresh melt (typically composed of Ga and GaP in the ratio of 10:1) we obtain very weak red emission. In the next use of the same melt, addition of oxygen alone in the P melt gives quite good efficiencies; this shows that enough zinc has remained in the melt from the previous run. If on the next run we add only zinc, the efficiency again drops to very small values, which indicates an almost complete loss of oxygen in the previous run. These observations are summarized in Table I.

Numerous runs with different additions were made in order to determine the joint dopant quantity which will maintain a high efficiency in repeated use of the same melt. The value obtained is 0.2 a/o (atomic per cent) for zinc, and 0.4 a/o for oxygen, which gives efficiencies ranging from 1 to 1.5%.

Table I. Efficiency for either O or Zn addition

Run No.	Additions, a/o		Efficiency, %
1	Zinc	0.6	0.1
2	Oxygen	0.19	0.6-0.8
3	Zinc	0.15	<0.1

Spontaneous Junctions

A noticeable difference between the structure of the p-layers grown by LPE and by SG is the occurrence of spontaneous junctions. During the growth of the p-layer by LPE, we usually obtain another junction, sometimes so close to the surface as to be hardly noticeable, but usually several microns below it. A typical photomicrograph is shown in Fig. 1, which illustrates the various junctions and layers involved.

We remove this extra junction by lapping or etching, as it might interfere with the ohmic contact to the p layer. In agreement with earlier reports (8), we never observe internal junctions in SG platelets doped with Zn and O. The implication of the occurrence of spontaneous junctions is discussed in a later section.

Compensation of the P Melt

Using the previously determined optimum doping, we have made a number of runs in which various amounts of the donor tellurium were added to the P melts. Experience with n layer growth has shown very little Te loss during a run and we therefore assume that a single addition specifies the Te concentration for all subsequent runs using that melt.

Diodes made from such material, which we call class III diodes, can show remarkably high efficiencies (Fig. 2). The scatter in efficiencies is however much greater than in uncompensated material. The spontaneous junction in the P layer is moved in deeper but in a somewhat random way, as shown in Fig. 3 where we plot the distance between the spontaneous and the optically active junction *vs.* the tellurium concentration in the melt.

Heat Treatment

Heat treatment has been shown to produce improvements in class I diodes (1). All of the class III diodes discussed have been given a heat treatment at 600°C (9), whereas class II diodes received none. Unfortunately, we found the effect of heat treatment to be uncertain. Thus, some class I and II diodes could be improved thereby but some could not, whereas some class III diodes did not change on heat treatment and others did.

Comparisons of the Three Diode Classes

Although no careful studies of the electrical properties of these diodes were made, limited measurements of the C-V, I-V, and L-I characteristics showed no clear differences between the three classes. The dependence of the total light intensity on bias has the form exp (eV/nkT) with $n \cong 1$, whereas the current dependence on bias is of the same form with $n = 1.7$. Thus radiative recombination proceeds outside the space charge region (or at shallow centers within it), whereas a good part of the current recombines in

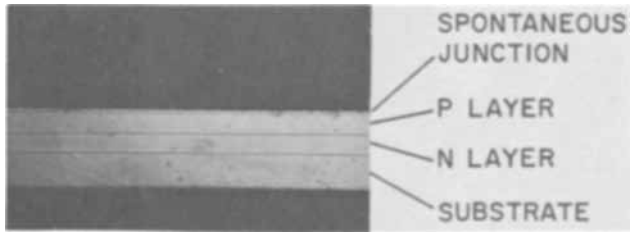

Fig. 1. Delineation of junctions occurring in double epitaxial growth on p-type SG substrates. The total thickness of the wafer is 0.19 mm.

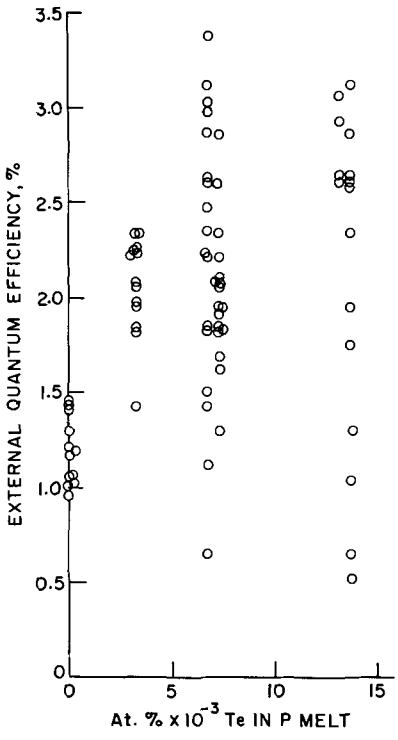

Fig. 2. Efficiencies obtained using tellurium in the p melts

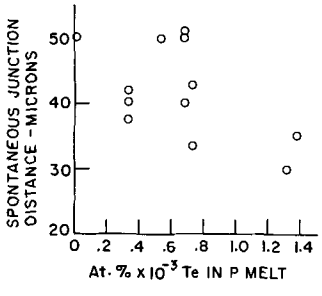

Fig. 3. Distance between the optically active and the spontaneous junction in a group of wafers grown from compensated melts.

the space charge region. This is not much different from previous findings for GaP diodes (10).

There is an indication, however, that the internal absorption in these diodes is related to the presence of the compensating donor on the p side of the junction. A convenient, if crude way of showing this connection is to measure the efficiency of a chip before and after coating it with a bead of glycol phthalate ($n \cong 1.57$), which reduces the optical mismatch to free space. In Fig. 4 we show results of such determinations, each point representing a chip from a different wafer. It can be seen that class II diodes generally show no improvement on coating, which can be taken as indicating very little absorption (11). Class I and III diodes, on the other hand, show a modest increase in efficiency.

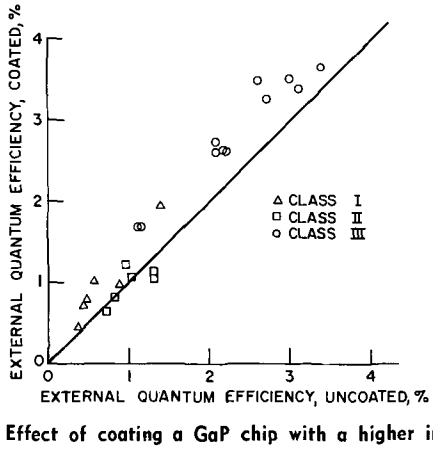

Fig. 4. Effect of coating a GaP chip with a higher index transparent wax. Each point represents a chip from a different wafer.

As mentioned before, epitaxial layers usually have a spontaneous junction near the end of growth, even if no donors are added to the melt. SG platelets grown from similar melts, however, do not yield internal junctions. This can be understood by considering the distribution coefficients for the two processes. In general, one expects impurities with large distribution coefficients such as sulfur, selenium, or tellurium (12), to be present in heavier concentrations when the growth rate is slower. Impurities with distribution coefficients less than 1, such as zinc, on the other hand require a fast growth rate in order to be incorporated into the crystal in concentrations higher than allowed by the equilibrium distribution coefficient. Since our LPE proceeds with a higher cooling rate initially, and a lower cooling rate near the end of growth, we expect to incorporate high concentrations of zinc in the early part of growth and higher concentrations of donors in the later stages. We thus see that pn junctions could arise during LPE, and we also expect a reduced donor concentration, *i.e.*, reduced compensation, in the first part of the LPE layer.

In the case of SG on the other hand, very fast growth from a supersaturated melt implies more nearly uniform doping to concentrations equal to those in the melt. (The lack of deep junctions often found by others may be due to the very high purity of currently available starting material, and the fast cooling rate used in our furnace). We therefore expect SG platelets to be evenly compensated with residual donors.

In Fig. 5 we have sketched a possible doping profile for class I and class II diodes. The left portion of each figure is the substrate (class I) or the LPE n layer (class II), and the LPE layer which defines the junction is on the right. Zinc diffusion during growth shifts the junction into the n layer but does so to a somewhat shorter distance for class II diodes since both dopants reach their maxima at the boundary.

In the case of class II diodes we have some evidence for locating the junction very close to the metallurgical boundary. In a careful search for traces revealed by etching we have seen a faint line somewhat under 1 μm away on the p side of the junction. The junction displacement is thus less than the expected location of the red emission, which may be as much as several microns away in the p layer (13). Radiative recombination in these diodes therefore occurs in the uncompensated p layer. In class I diodes, recombination will occur partly in the n layer compensated by the zinc diffusion, and partly in the p layer compensated by residual donors (7).

We review the three types of diodes in Table II. The main argument presented is that compensation is required in order to achieve the highest external effi-

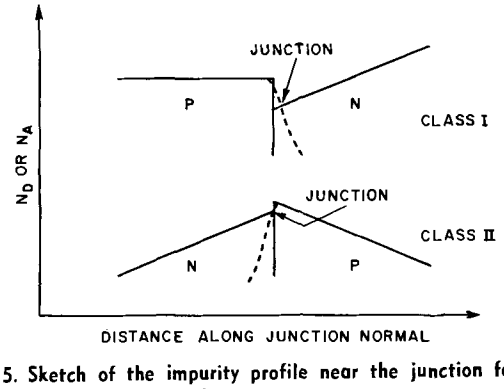

Fig. 5. Sketch of the impurity profile near the junction for two types of diodes discussed in the text.

Table II. Comparison of the three diode classes

Class	I	II	III
Fabrication	n-LPE on p-SG	p-LPE on n-LPE	p-LPE on n-LPE
Compensation	By residual donors	Little if any	Deliberate
Internal absorption	Yes	No	Yes
Maximum efficiency	2%	1.4%	3.4%

ciencies for Zn-O doped diodes. In addition, we find a difference in the internal absorption coefficient connected with the compensation. This is of considerable practical importance because class II diodes cannot be improved by index matching. If better high index coatings become available, class III diodes can be improved a great deal more. In order to arrive at an estimate of the ultimate limit, we have determined the internal efficiency by observing the change in external efficiency when the diode is surrounded by liquids of different refractive indices (11). Our best estimate for the ratio of internal to external efficiency is 3, and the maximum internal efficiency for class III diodes is therefore about 10%.

Discussion

Mass spectrometric analyses carried out at this laboratory[1] have shown the presence of sulfur and silicon in most of our GaP material. It is also found that they are difficult to remove by further recrystallization of GaP from high purity gallium. As regards the choice between the two, Hall measurements and EL spectra both suggest sulfur as the most likely donor present in class I diodes. We have made some runs using sulfur instead of tellurium, for compensation in class III diodes, and we have also fabricated some diodes with sulfur as the n layer dopant as well as the compensating donor. In both cases results were similar to those obtained with tellurium, with similar high efficiencies. Sulfur is, however, exceedingly difficult to control (its distribution coefficient is ≈ 44). Since the effects of sulfur thus are not distinguishable from those of tellurium, we have a ready explanation for the poor correlation between tellurium addition and efficiency. It must also be supposed that forming gas contains not only sulfur, but hydrocarbons as well, which introduce carbon acceptor levels in GaP (14). Uptake of these impurities from the forming gas can easily shift the spontaneous junction in a random way from run to run.

As mentioned earlier, class III diodes received a heat treatment, whereas class II diodes did not. In a number of cases, class III diodes gave high efficiencies without the heat treatment and did not improve very much afterward. Also, class II diodes generally did not improve by the same heat treatment. A few exceptions to this behavior were also noted, but in view of what has been said earlier about sulfur, it is difficult to exclude the possibility of accidental sulfur compensation. In most cases, however, heat treatment for 30 min at 600°C was effective for class III diodes, but not for class II diodes.

[1] We are indebted to W. L. Harrington and E. Botnick for the mass spectrometer studies.

We now raise the question whether structural differences other than the difference in compensation could explain the superiority of class III diodes over class I diodes. One might suppose that further reduction of dislocations by the double growth step would produce more perfect junctions. But as Saul (15) has recently shown, SG platelets are largely dislocation free, which makes this supposition unlikely. Variations between individual diodes from the same wafer, on the other hand, could be due to isolated flaws propagated from the substrate.

No doubt there are impurities besides those mentioned which may influence the Zn-O emission in GaP, some present in the starting material and others picked up from the forming gas. Better control over impurities will certainly give improved reproducibility, and possibly higher efficiency.

Acknowledgments

We are grateful to H. S. Sommers, Jr. for a critical review of the manuscript, to H. Nelson for useful discussions, to H. Kressel for spectral measurements and many helpful discussions, to N. Byer for various measurements, and to D. Redfield for clarifying several problems. The assistance of M. E. Heller, J. Alexander, and D. Marinelli in various phases of this work has been greatly appreciated.

Manuscript submitted Nov. 27, 1968; revised manuscript received *ca.* March 24, 1969. This was Recent News Paper 610 presented at the Montreal Meeting, Oct. 6-11, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Characteristics of Fast Surface States Associated with SiO_2-Si and Si_3N_4-SiO_2-Si Structures

B. E. Deal,* E. L. MacKenna,* and P. L. Castro*

Fairchild Semiconductor Research and Development Laboratory, Palo Alto, California

ABSTRACT

Characteristics of fast surface states located at the SiO_2-Si interface of thermally oxidized silicon structures (MOS) and structures incorporating vapor-deposited silicon nitride films over thermally oxidized silicon (MNOS) have been investigated. Effects of oxidation and annealing conditions on the formation or reduction of fast surface states, using MOS capacitance-voltage curves, are first discussed. The effects of silicon nitride layers over thermal oxides on the electrical properties of MNOS structures are next presented, with emphasis being placed on the ability of the nitride to prevent or mask the annihilation of fast states which normally occurs during an anneal in dry N_2 at 500°-565°C for 2-5 min after aluminum deposition. Such variables as deposition ambient, flow rate, high temperature anneals, nitride structure, and reactant type are shown to affect the masking ability of the nitride. These results, along with special experiments, help to confirm the postulate that some active species of hydrogen plays an important part in the elimination of fast surface states in MOS and MNOS structures.

Silicon nitride layers, when deposited over semiconductor device structures, have been shown to be an effective mask against the diffusion of impurity ions such as sodium (1-5). Apparently the dense nature of the nitride actually blocks the ion migration, as opposed to the phosphosilicate glass layers, also used for this purpose, which more likely getter or complex the sodium ions (6-7). The silicon nitride layers used for device passivation are generally deposited by a vapor deposition process in which NH_3 is reacted with either SiH_4 or $SiCl_4$ in the temperature range 700°-1000°C, although lower temperature processes involving sputtering or plasma excitation are also being developed (8).

Previous work in this laboratory (9) and by other investigators (8) has demonstrated that the electrical instabilities of the Si_3N_4-Si interface preclude the use of a silicon nitride layer directly on the silicon surface in most cases. On the other hand, satisfactory results have been obtained by depositing a thin nitride layer over thermally oxidized silicon (9-10). Thus, the advantage of the nitride's ability to mask against sodium migration may be combined with the excellent Si-SiO_2 interface characteristics.

It has been shown that four main types of charges are associated with the thermally oxidized silicon structure (11). These are mobile impurity ions, Q_o; fixed surface charge, Q_{ss}; radiation induced charge, N_{ot}; and fast surface or interface states, N_{st}. Of these, the fast states have been most extensively investigated but are still the least understood. However they probably affect many device electrical characteristics to the greatest degree. Examples of attempts to better understand the nature of these states and their effect on device properties, especially metal-oxide semiconductor (MOS) devices are given in ref. (12-17).

One of the interesting but puzzling characteristics of fast surface states (located at the SiO_2-Si interface) is that their density can be reduced to a relatively low level by annealing in an inert ambient such as nitrogen at low temperatures (500°-550°C) *if an active metal such as aluminum is present over the thermal oxide* (18). It has also been found (9) that this annealing or reduction of fast states is greatly retarded by the presence of a silicon nitride layer between the metal field plate and the thermal oxide. Experiments involving the nature of this phenomenon, whereby the fast state reduction is retarded in Si_3N_4-SiO_2-Si structures, are summarized in this paper. Effects of the nitride deposition process as well as subsequent thermal treatments are included. In order that the results may be more easily interpreted, characteristics of fast state formation in the thermally oxidized silicon structure (without the nitride layer) are first presented along with techniques for detecting and measuring surface state densities in MOS structures.

Experimental

Czochralski silicon, sliced and lapped to 250μ thickness, was obtained from the Wacker Chemical Company, Los Angeles, California. Dislocation count was specified to be less than 100 cm^{-2}, while doping impurity concentration was about 1.5×10^{16} cm^{-3}. The silicon slices, either p- or n-type and (111) or (100) oriented, were cleaned in organic and inorganic solvents and chemically etched to 150μ thickness in a 4 HF: 10 HNO_3 solution at 25°C.

The silicon slices were thermally oxidized immediately after etching. The standard oxidation condition was 60 min in dry oxygen at 1200°C with a very rapid cool after pulling into room ambient. This procedure provided an oxide thickness of 0.20μ, a Q_{ss}/q (fixed surface charge) value of 2×10^{11} cm^{-2}, and a medium low N_{st} (fast surface state density), *i.e.* $<5 \times 10^{11}$ cm^{-2} as oxidized. Certain samples received variations in the oxidation ambient and cooling rate as well as subsequent annealing treatments. The oxidation and annealing apparatus was similar to that used in previous work (19-20). All gases were from high purity, liquid sources.

For those structures incorporating a silicon nitride layer, the oxidized silicon slices were placed in the appropriate nitride deposition system. These systems, employing either $SiCl_4$-NH_3 or SiH_4-NH_3 reacting mixtures and H_2 or N_2 carrier gases, were in the form of horizontal, rectangular cross sectional quartz reactors. Heating was accomplished using an R.F. generator. The latter inductively heated a SiC coated graphite susceptor on which the silicon substrates were placed. Deposition temperatures were in the range 700°-1000°C. Thicknesses of the silicon nitride films were generally in the range 500-2000Å. Subsequent annealing of some of the nitride-oxide samples was carried out in nitrogen or hydrogen at temperatures in the 700°-1000°C range. Thickness measurements of both the thermal oxide and silicon nitride layers were carried out using multiple beam interferometry on mechanically polished test slices.

Most of the evaluations reported in this paper involved MOS (metal-oxide-semiconductor) or MNOS (metal-nitride-oxide-semiconductor) capacitor structures. For the metal portion of these structures, high purity aluminum (99.9999%) dots were evaporated over the oxide or nitride layer. Aluminum was also evaporated on the back side for better contact to the silicon. (Any dielectric layer remaining on the back of the slice had previously been removed using hydrofluoric acid and photoresist techniques.) After aluminum evaporation a portion of each sample was annealed in dry nitrogen at 550°C for 2-5 min.

Capacitance-voltage measurements were carried out using techniques and apparatus described earlier (9, 21). The usual measurement frequency was 100 kHz although other frequencies were also used. In addition to room temperature measurements, plots were made at lower temperatures, *i.e.*, —196°C, using encapsulated devices. The nature of these measurements is discussed later. In addition, values of surface recombination velocity, s_o, were obtained using gate-controlled diode structures which have been described earlier (9, 22).

Measurement of Fast Surface States

It will not be the purpose of this paper to determine or even speculate as to the source of fast surface states associated with thermally oxidized silicon. Rather it should be sufficient to state that these states are probably located at the SiO_2-Si interface with a density distribution through the silicon band gap. This distribution may be either discrete or continuous with energy. However, the actual case is more likely to be some combination of these two possibilities. Work at this laboratory and others (16, 23) indicates the density of states is fairly continuous through the middle of the gap with peaks near both band edges. Further, since these states adversely affect many semiconductor device properties, a minimum density is desired, *i.e.*, $<10^{10}$ cm^{-2}.

The presence of fast surface states may be detected in a variety of ways. The simplest way is by comparing an unannealed MOS capacitance-voltage curve with one having a theoretical shape. If the structure contains a relatively large number of fast states, the C-V curve will exhibit particular distortions. These may be broad slope variations (indicating a continuous distribution of states) or specific breaks (indicating single levels) or both. An example of these single levels is shown in Fig. 1. Here a typical C-V plot is shown for 2000Å SiO_2 (produced at 1200°C in dry O_2 and rapidly cooled) on 1.3 x 10^{16} cm^{-3} (111) p-type silicon. The curve is shifted along the voltage axis to compensate for Q_{ss} and ϕ_{MS}. Its shape, for both the high (H.F.) and low (L.F.) frequency cases, is compared with a curve representing no fast surface states, *i.e.*, theory. The distortion labeled Ⓐ is a result of the density of states near the valence band, that labeled Ⓑ is more related to states near the midgap, or the intrinsic level, and that labeled Ⓓ is due to states between the intrinsic level and the conduction band. The width of the low frequency type C-V curve at its midpoint is labeled Ⓒ. The broadening of this curve is a result of the states nearest the conduction band.

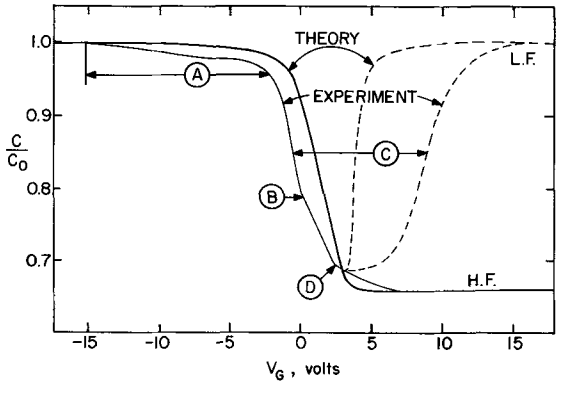

Fig. 1. Comparison of experimental and theoretical MOS C-V curves showing typical distortions in the experimental curve due to fast surface states (labeled Ⓐ, Ⓑ, Ⓒ, and Ⓓ). Unless otherwise indicated all C-V curves plotted from inversion to accumulation voltage. [p-Type (111) silicon; $C_B \cong 10^{16}$ cm^{-3}; $x_o = 0.2\mu$; $Q_{ss} = 0$, $\phi_{MS} = 0$]

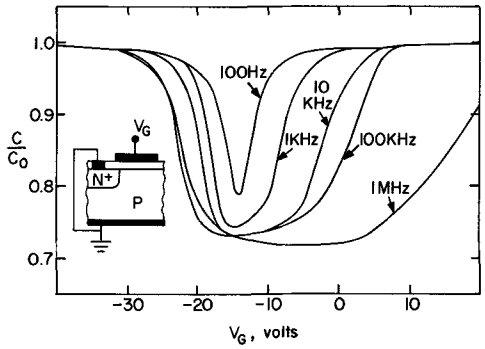

Fig. 2. Dependence of low frequency type C-V curve on measurement frequency for an MOS gate-controlled diode exhibiting medium fast state density. [p-Type (111) silicon; $C_B \cong 10^{16}$ cm^{-3}; $x_o = 0.2\mu$.]

The distortions shown in the C-V plot in Fig. 1 might be confused with nonuniform charge densities often found with contaminated structures. However it has been found through thousands of drift-free MOS runs that the distortions due to fast states are real and reproducible for a given process condition.

Some interesting observations have been made concerning the fast states as indicated in the C-V plot of Fig. 1. First, the amount of the voltage distortion labeled Ⓐ, hereafter called the Ⓐ-state voltage, is always proportional to the Ⓒ-state voltage[1] at a given frequency. As the frequency is changed, the Ⓒ-state characteristics change as indicated in Fig. 2. This effect can be attributed to the time constant required to charge and discharge the states which prevents these states from following the a-c signal as frequency increases. The Ⓐ-state voltage does not appear to vary as greatly with frequency.

Second, the number of fast states obtained in a thermally oxidized silicon structure can be varied over a wide range depending on the moisture content of the ambient used in the final high temperature treatment, *i.e.*, >600°C. As reported by other investigators (16, 17), if the oxidized silicon is cooled from a dry ambient, *i.e.*, N_2 or O_2, a high density of fast states will result. If the cooling ambient contains water (or hydrogen) the fast state density will be greatly reduced as indicated by the Ⓐ- or Ⓒ-state voltage.

A third observation is that certain device characteristics have been correlated with the states indicated in Fig. 1. For instance, the Ⓑ-state is related to noise in MOS transistors (24). Further, the amount of

[1] The low frequency type C-V curve can best be obtained by using the gate-controlled diode structure shown in the insert of Fig. 2. Here, a diffused region, extending into the edge of the MOS capacitor, of impurity type opposite to that of the silicon bulk supplies enough minority carriers to provide the low frequency type C-V curve. If the surface of p-type silicon is inverted by a large positive surface charge, low frequency type C-V curves may also be obtained for MOS capacitors, due to electrons available from the adjacent inversion layer.

Ⓑ-state distortion and thus noise can be increased by large negative fields (24, 25). The Ⓐ- and Ⓒ-states, which are undoubtedly the same as those reported by Gray and Brown (16) to be near the band edges, affect turn-on voltages, of MOS transistors. Surface recombination velocity, which is related to transistor gain, will be shown later in this paper to be correlated with several of the fast surface states. It should be noted that similar C-V curve distortions indicating fast surface states are found for n-type silicon.

Gray and Brown (16, 26) have reported that fast surface state densities may be more readily observed using low temperature (—196°C) C-V plots. As the temperature decreases, the Fermi level moves toward the band edge. Thus, the distortion in the C-V plot due to fast states near the valence band in p-type silicon becomes more pronounced at the low temperaure, resulting in a ledge or plateau in the C-V plot. The number of volts over which this ledge extends can be an indication, or relative measure, of fast state density. This effect is shown in Fig. 3. The larger the number of fast states, the further displaced the flatband voltage and the greater the ledge voltage. A considerable amount of hysteresis and other effects can occur during this low temperature plotting, but reproducible results of the type shown in Fig. 3 can be obtained if the structure is cooled under positive bias and plotted from positive (inversion) to negative (accumulation) bias. For n-type silicon the situation is just the opposite. It can be noted in Fig. 3 that the capacitance minimum of the low temperature plot is higher at the right side of the ledge than the room temperature value. This occurs once the voltage sweep is started, although it does not occur in static measurements. The phenomenon, which is not present in gate-controlled diodes or where a sufficient supply of minority carriers is present, is not completely understood but does not affect the fast state measurement.

The low temperature effect for gate-controlled diodes, where low frequency type C-V curves are obtained, is similar to the capacitors described above. An example is shown in Fig. 4 for such a structure having a medium number of fast states under the gate region. Included in the figure are the effects obtained for different conditions of voltage sweep direction and illumination. Note that if the plot is made from the accumulation side (— bias), nonequilibrium depletion characteristics prevent the measurement of the fast state ledge. Thus, as is also the case for capacitors, low temperature plots must be made from inversion to accumulation. For this plot direction the sweep rate has

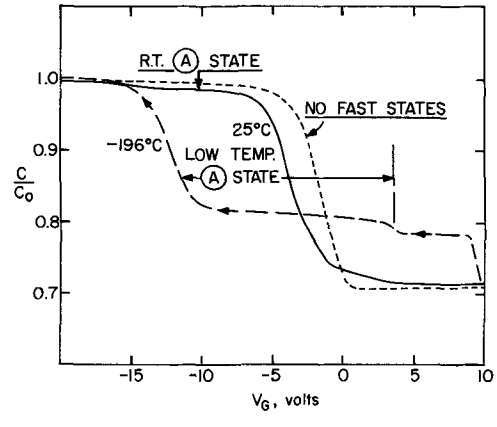

Fig. 3. Example of room temperature (25°C) and low temperature (—196°C) C-V curves for an MOS capacitor exhibiting medium-low fast state density. Thermal oxide was prepared in dry O_2 at 1200°C with rapid cool. Also shown is theoretical C-V curve for same structure with no fast states. [Silicon type, orientation and doping as well as oxide thickness same as Fig. 2 for Fig. 3-8.]

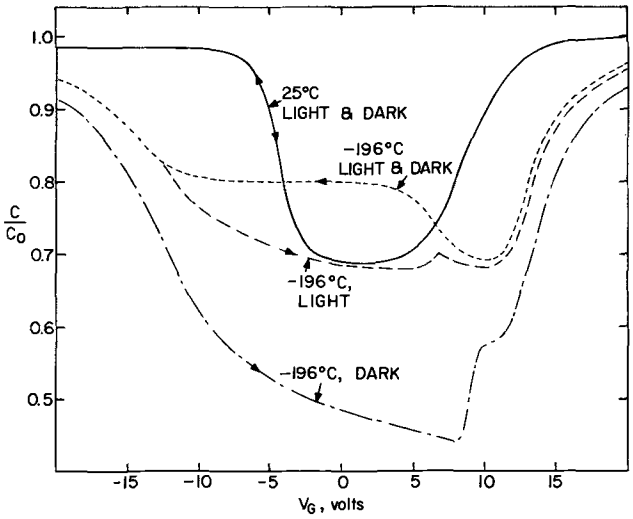

Fig. 4. Effect of plotting conditions on —196° and 25°C C-V plots for an MOS gate-controlled diode with medium fast state density.

not been found to affect the ledge or fast state measurement.

Note from Fig. 4 that the effective inversion point has been shifted to the right or more positive voltage at —196°C. Also the capacitance minimum is that predicted by theory at this temperature, *i.e.*, slightly lower than at 25°C. It should be kept in mind that for low frequency type C-V plots as obtained with gate-controlled diodes the room temperature Ⓒ-state voltage is as good a way to measure fast state density. However, this structure is more difficult to prepare and under many conditions the low temperature plots using MOS capacitors are preferred.

The change of the C-V characteristic shape with temperature is demonstrated in Fig. 5. Here a gate-controlled diode structure was cooled to —196°C. The C-V plot was made and the device allowed to slowly warm to room temperature. At various time intervals additional C-V plots were made, thus providing a series at different temperatures. The change in apparent Ⓐ-state voltage as well as the shift in inversion voltage can be noted.

Annealing of Fast Surface States

In earlier work in this laboratory (21) it was found that fast surface state densities were reduced to a level below the MOS C-V method detection point ($<5 \times 10^{10}$ cm^{-2}) during the heat treatment used to insure back side ohmic contact of aluminum to the silicon. This heat treatment is in the temperature range 500°-565°C

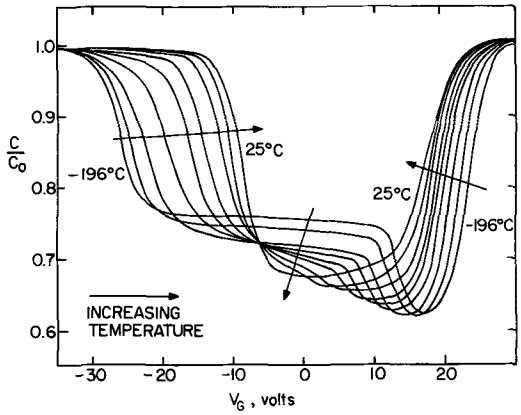

Fig. 5. Change of C-V curve shape with temperature for an MOS gate-controlled diode with medium fast state density.

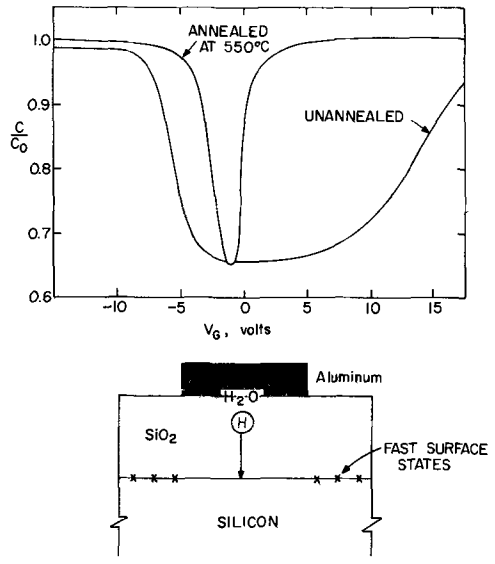

Fig. 6. Effect of post-aluminum anneal on low frequency type C-V curve for an MOS capacitor exhibiting medium fast state density. Lower portion of figure indicates proposed model for the annihilation of fast states by a hydrogen species produced by an Al-H_2O reaction.

for 2-5 min in dry nitrogen. Coincidentally, aluminum field plates are also on the oxide during this alloying step. Balk reported this fast state annealing effect (18) and proposed that during the heat treatment the aluminum reacts with minute amounts of water on the oxide surface to release a hydrogen species. This hydrogen migrates rapidly to the Si-SiO_2 interface and annihilates the fast surface states. Balk's earlier work added support to this model through hydrogen annealing experiments where a similar fast state annealing effect was noted (27).

This annealing effect when aluminum is present over the oxide is demonstrated in Fig. 6. In the upper part of the figure MOS C-V curves of gate-controlled diode structures are shown before and after a 550°C heat treatment for 2 min in dry N_2. Initially, a 0.2μ oxide structure resulted in a Ⓒ-state voltage of nearly 20V at 100 kHz. After the anneal, the theoretical curve shape is approached. If the aluminum were not present over the oxide, annealing for hundreds of hours in dry N_2 would be required to obtain this low number of fast states.

The lower part of Fig. 6 represents Balk's proposed mechanism for the annealing step. Here some hydrogen species is released to eliminate the fast states at the interface.

The effectiveness of the annealing step discussed above for minimizing fast state densities in thermally oxidized silicon structures is indicated in Fig. 7. Here, room temperature C-V plots are shown for both low and high Q_{ss} [2] oxides on p- and n-type silicon at 100 kHz. Corresponding C-V plots taken at —196°C and 100 kHz as well as data obtained at 25°C and 100 MHz are included. Either of these two measurement conditions should be a sensitive indication of fast states. As observed, the fast state density is less than 5 x 10^{10} cm^{-2}. Also, there is no dependence on the value of fixed surface charge Q_{ss}.

A more practical example of the fast state annealing effect is shown in Fig. 8. Current-voltage plots are given for an MOS n-channel transistor before and after annealing at 550°C with the aluminum field plates present on the oxide. The plots are included for three temperatures: 25°,—72°, and —196°C. Before annealing the device turn-on or threshold voltage is

[2] The relationships between N_{ss} (fast surface states) and Q_{ss} (fixed surface charge) are not discussed in this paper. While their dependence on oxidation temperature and silicon orientation are probably similar, the density of each can be independently varied.

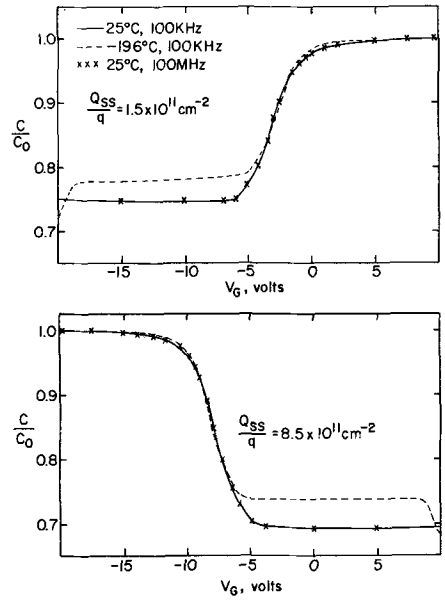

Fig. 7. Example of effectiveness of post-aluminum anneal on reducing fast state density in thermally oxidized silicon. C-V plots taken over wide frequency and temperature ranges on p-type and n-type silicon indicate less than 10^{10} cm^{-2} fast state density for low Q_{ss} (upper curves) and high Q_{ss} (lower curves) MOS capacitors.

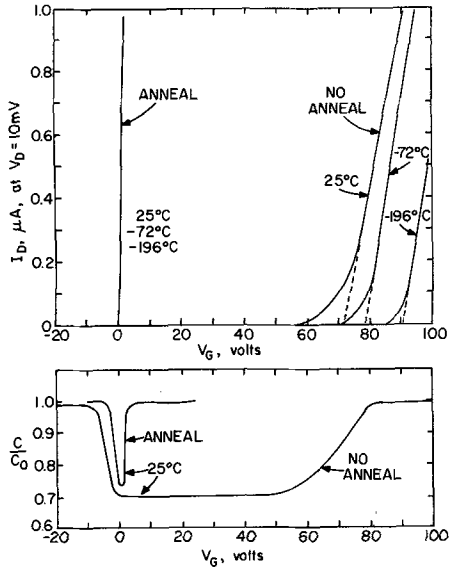

Fig. 8. Effect of temperature on turn-on voltage for an MOS transistor exhibiting a large fast state density before and after post-aluminum anneal. Note the lack of temperature dependence after the anneal. Also shown are the corresponding 25°C C-V plots.

above 70V, even at room temperature. As the temperature decreases this threshold voltage increases as predicted by Fig. 5 and also reported by Brown and Gray (26). After annealing there is no appreciable temperature effect on threshold voltage. Corresponding C-V plots are included in Fig. 8.

Effect of Silicon Nitride Films on the Annealing of Fast States

General effect.—It was reported previously that a silicon nitride layer over thermally oxidized silicon can prevent or retard the reduction of the fast surface state density which normally occurs when aluminum is present over the oxide during a low temperature (550°C) annealing treatment (9). This masking effect was first noted when the distortions of the MNOS C-V curves (attributed to fast states) were not eliminated during the 550°C anneal (see Fig. 6A). The

presence of the fast states (located at the SiO_2-Si interface) in these double-dielectric structures was confirmed by low temperature C-V plots.

Typical values of the −196°C (A)-state voltage for structures incorporating 0.1μ $SiCl_4$-NH_3-type silicon nitride layers deposited at 800°C over 0.2μ thermal oxides are listed in Table I. These values, as well as flatband voltages V_{FB} were obtained after the conventional 550°C, 5-min heat treatment with aluminum field plates present over the dielectric. This annealing treatment, as mentioned earlier, results in a −196°C (A)-state voltage of less than 0.2V for a thermal oxide of equal thickness but with no nitride layer. The data of Table I indicate that the fast state masking effect due to the nitride layer is the same for p-type and n-type silicon. Furthermore, the resulting fast state density for (100) silicon is less than that for (111) by a factor of one-third, which agrees with data previously reported by Gray and Brown (16).

Additional experiments were carried out involving the effect on fast state annealing by silicon nitride films of varying thicknesses in MNOS gate-controlled diode structures. These thicknesses were 200, 400, 700, and 900A. The reduction of the fast states due to 10 min post-aluminum anneal at 550°C was prevented in all cases except for the 200Å nitride film. It is not clear whether this thin film permitted the reduction effect through the bulk of the nitride or whether pinholes were responsible.

Carrier ambient.—Hydrogen was the carrier gas used for the nitride depositions whose results are summarized in Table I. If this ambient is changed from hydrogen to nitrogen, then an effect on resulting fast state density is obtained which is similar to that previously found for thermal oxides. In other words, a much higher fast state density results for the nitrogen carrier ambient. A typical example of this large increase in fast state density is shown in Fig. 9, where a −196°C C-V plot is compared with that obtained at room temperature for a 0.1μ $SiCl_4$ silicon nitride/0.2μ

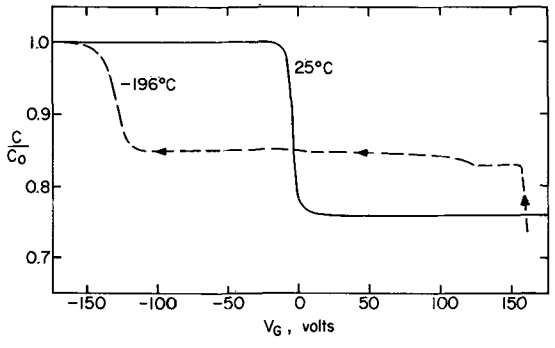

Fig. 9. Room temperature and low temperature (−196°C) C-V plots showing large fast state density induced by postnitride deposition, high temperature anneal in N_2 for 0.1μ Si_3N_4/0.2μ SiO_2 MNOS capacitor. Note that the post-aluminum anneal does not annihilate these fast states.

Table II. Relative values of fast surface states for MNOS gate-controlled diode structures* as a function of nitride deposition carrier ambient

(After low temperature, post-aluminum nitrogen anneal)

Dielectric	−196°C (A)-state voltage (V)	25°C (C)-state voltage (V)	Surface Recombination velocity, s_0 (cm/sec)
Thermal oxide	0.2	3.1 (0.1)	1-5

thermal oxide MNOS capacitor. It was also found that if a small percentage of hydrogen (*i.e.*, 5%) is included in the nitrogen carrier ambient, an intermediate value for the fast state density will be obtained.

Data typifying the above findings using gate-controlled diode structures are summarized in Table II, where values of −196°C (A)-state voltages, (C)-state voltages, and surface recombination velocity are listed. In the case of the (C)-state voltages, the theoretical width of the C-V curves is subtracted, leaving the excess value due to fast states in parentheses. The table provides an indication of the very good correlation among (A)-state and (C)-state voltages and s_0.

Subsequent high temperature annealing treatment.—Samples of the same depositions listed in Table I were subjected to an additional annealing treatment in nitrogen at 1000°C for 15 min prior to metallization. Values of flatband voltage and −196°C (A)-state voltages (obtained after the post-aluminum, 550°C nitrogen anneal) are given in Table III. These results indicate the large increase in fast state density due to this nitrogen treatment and demonstrate the ability of the nitride layer to prevent post-aluminum reduction of the fast states. It should be kept in mind that similar processing of thermal oxide structures alone will result in (A)-state voltages of less than 0.2V after post-aluminum anneal, even though very high fast state densities result after the 1000°C treatment in nitrogen.

Other experiments involved treatment of MNOS structures in 100% hydrogen at 700°-1000°C for 30 min, the structures having previously been deposited using a nitrogen carrier ambient. The very high density of fast states resulting from the deposition process was apparently reduced by the hydrogen to the same value obtained using hydrogen as the carrier ambient during deposition, *i.e.*, an (A)-state voltage of 7-10V for (111) silicon.

Table III. Values of V_{FB} and (A)-state voltage for MNOS capacitors*

(After 1000°C nitrogen anneal and subsequent low temperature post-aluminum nitrogen anneal)

* Same process conditions as for Table I.
Silicon type: p-type, (111), $C_B = 1 \times 10^{16}$ cm^{-3}.

The similarity between the results due to the carrier ambient and subsequent anealing treatments is summarized in Table IV. Ranges in values are tabulated for a number of depositions and samples. It is apparent that for the conditions of these experiments involving $SiCl_4$-NH_3 nitrides, hydrogen results in medium-low values of fast state densities while nitrogen gives high densities, either during the deposition or subsequent anneals. The nitride layer does not permit these states to be annealed or annihilated by the post-aluminum treatment in any case.

It was also shown that when high densities of fast states were produced in $Si_3N_4/SiO_2/Si$ structures incorporating SiH_4-NH_3 nitrides, these states also could not be annealed by the post aluminum 550°C treatment. The nature of differences due to the SiH_4 deposition process will be discussed later.

Structure variations in silicon nitride.—Changes in the structure of the silicon nitride film might be expected to affect its ability to mask against the fast state annealing. It has been reported that several deposition variables such as temperature, reactant compositions, and flow rates can result in nitride films of varying structure or composition (8). These differences can in turn be reflected by variations in etch rates.

Effects of film composition or structure on fast state density are presented in Table V, where three different deposition temperatures resulted in varying etch rates (in concentrated HF) and varying fast state densities after the post-aluminum anneal. For the depositions used to prepare the structures reported in Table V, flow and reactant composition conditions were maintained constant.

Another way to change the silicon nitride structure is to vary total flow rate, *i.e.*, the slower the flow rate, the faster the etch rate. Experiments were carried out in which fast state densities of nitride/thermal oxide structures were determined as a function of etch rate, the latter varied by flow rate changes. Results of these experiments, for $SiCl_4$ nitrides deposited at 900°C, are given in Fig. 10. The correlation between etch rate and fast state density is readily apparent, and results correlate very closely with the values listed in Table V. Thus, the relationship between fast state density and silicon nitride structure (indicated by etch rate) is clearly established.

Table V. Dependence of Ⓐ-state voltage of MNOS capacitors* on nitride etch rate and deposition temperature

Deposition temperature (°C)	Etch rate (conc. HF) (Å/sec)	−196°C Ⓐ-state voltage (V)

Silicon nitride type ($SiCl_4$ *vs.* SiH_4).—Most of the results reported thus far have been concerned with silicon nitride films deposited using the $SiCl_4$-NH_3 reaction. While these nitrides prevent the post-aluminum annealing of fast states, they cause a minimum amount of polarization in the MNOS structure either as deposited or after 300°C stress tests.

Differences have been noted, however, for silicon nitride films deposited using the SiH_4-NH_3 reaction as compared with the $SiCl_4$-NH_3 reaction. While similar etch rates in concentrated HF are observed (1 to 10 Å/sec), very low fast state densities are observed for the silane nitride structures even before the post-aluminum anneal. These low values are obtained whether the deposition carrier ambient is nitrogen or hydrogen and over a wide temperature range. If these structures are given a subsequent high temperature anneal in nitrogen, large fast state densities are obtained as is the case for $SiCl_4$ nitrides.

The silane nitrides also cause much more polarization (9) in the MNOS structures both before and after 300°C stress tests. Examples of differences in fast state densities and polarization for the two nitride types are shown in Fig. 11. The C-V curves for the SiH_4 nitrides are of the low frequency type due to inversion of the surrounding silicon for the examples shown. This in-

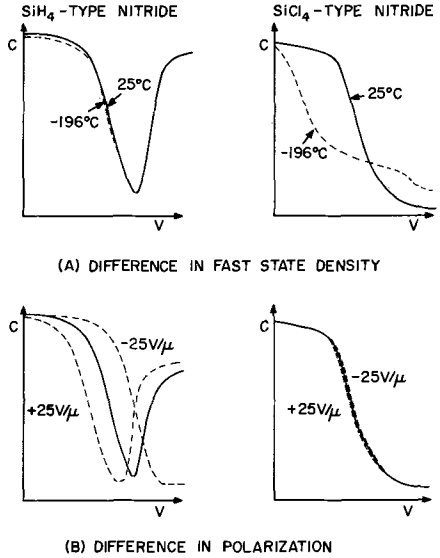

Fig. 11. Difference in electrical characteristics after post-aluminum anneal of MNOS capacitors incorporating either $SiCl_4$ or SiH_4 type silicon nitride layers.

version is prevented in the $SiCl_4$ nitride samples by the fast states.

Fast State Annealing Mechanism

The results reported thus far concerning the ability of certain silicon nitride films deposited over thermal oxides to prevent reduction of fast state densities at the SiO_2-Si interface generate some interesting questions. The first is: How does the silicon nitride film prevent the fast state annealing? In fact, what is the mechanism of post-aluminum annealing of fast states in thermal oxides?

If we accept Balk's proposed mechanism (18) that the fast state reduction in oxides occurs by the action of a hydrogen species produced by the reaction of the metal, *i.e.*, aluminum, with water on the oxide surface, then two possibilities exist for the nitride case: Either the nitride surface prevents the Al-water reaction, or the nitride prevents the migration of the hydrogen species to the SiO_2-Si interface where the fast states are located. The following experiment was conducted to establish the more likely possibility. MIS capacitors were fabricated which included four different combinations of dielectrics. As shown in Fig. 12, they were: I. Si_3N_4 only, II. Si_3N_4 over thermal SiO_2, III. vapor-deposited SiO_2 over Si_3N_4 over thermal SiO_2, and IV. vapor-deposited SiO_2 over thermal SiO_2. All nitrides were deposited using the $SiCl_4$-NH_3-H_2 reaction. The silicon in all cases was p-type (111) and aluminum field plates were deposited on each structure. After the 550°C nitrogen treatment, C-V plots were obtained at 25° and —196°C and are indicated in Fig. 12. Note that for the Si_3N_4-only structure, the high surface charge associated with the nitride-silicon interface results in a low frequency type C-V curve.

If the nitride merely prevents some surface reaction with the aluminum, then structure No. III of Fig. 12 with vapor deposited oxide should allow this reaction to occur and the fast states should be annihilated as happens in structure No. IV (no nitride). However, this did not occur. Thus we assume, as is indicated in the figure, that the hydrogen species is produced by the reaction of aluminum and possibly water, and that the dense Si_3N_4 (structures I, II, III) blocks the hydrogen migration as it also blocks Na^+ ion migration at temperatures up to 550°C. At higher temperatures (700°-1000°C) some amount of hydrogen can penetrate the nitride (28), thus resulting in a decrease of fast states (see Table IV).

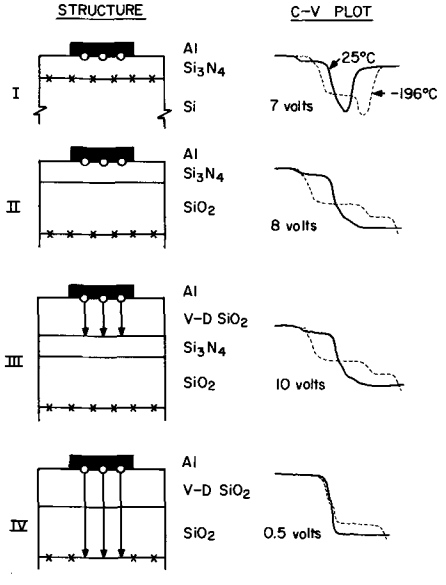

Fig. 12. Results of experiment designed to determine mechanism for nitride masking of fast state annihilation during post-aluminum anneal. Conclusion is that the silicon nitride layer prevents migration of a hydrogen species to the fast states.

A further indication that Balk's model of a metal-water reaction is responsible for fast state annealing was obtained from the results of comparing the effect of a number of metals used as field plates over thermal oxides. The over-all trend for the same postmetallization treatment (550°C, 2 min, N_2) was that the more active metals such as aluminum and magnesium resulted in very low fast state densities, while the less active metals such as gold and platinum permitted very little reduction of fast state densities.

Another question posed by these results concerns the difference between silicon nitrides produced by $SiCl_4$ or SiH_4. While the SiH_4 nitride structures over thermal oxides exhibit much lower fast state densities as deposited than $SiCl_4$ nitrides, very large densities of fast states can be induced by subsequent high temperature annealing of both nitride types in nitrogen. These fast states cannot be annihilated by post-aluminum annealing. Thus, the structural aspects of the two types of nitrides are considered similar, with the probable cause of fast state variations as well as differences in amount of polarization being due to the reactants $SiCl_4$ and SiH_4.

The main difference between SiH_4 and $SiCl_4$ is the hydrogen. However, both processes can involve hydrogen as a carrier gas. Thus, this indicates that a special form of hydrogen, *i.e.*, active or atomic, is produced in the SiH_4 reaction and this is what is required for fast state reduction. An experiment was designed to test out the active or atomic hydrogen theory. Special MNOS structures incorporating a $SiCl_4$ nitride were prepared using palladium field plates. These structures, along with nonmetallized controls, were treated in hydrogen at 800°C for 5 min. Aluminum was then deposited over the palladium for better contact and —196°C C-V plots were obtained. Results indicating relative values of fast state densities as well as amount of polarization are tabulated in Table VI.

It is well known that molecular hydrogen will dissociate into an atomic species on a palladium surface at elevated temperatures (29). This atomic hydrogen will then diffuse through the palladium if the hydrogen pressure is reduced on the other side. This is the basis for one type of hydrogen purifier. The results given in Table VI are remarkable in that the higher fast state density and low polarization of the $SiCl_4$-type silicon nitride/thermal oxide structure has been converted to the SiH_4-type silicon nitride/thermal oxide structure exhibiting no fast states but considerably more polarization. Apparently at 800°C the atomic species of hydrogen produced by a reaction with palladium diffused through the silicon nitride layer and into the silicon oxide. Here this species is free to annihilate the fast states at the SiO_2-Si interface, but at the same time can migrate back and forth in the oxide (30, 31). These results thus lead to the conclusion that the electrical difference between the two types of nitrides might be explained on the basis of atomic or active hydrogen produced by the SiH_4-NH_3

Table VI. Effect of palladium field plate and 800°C hydrogen anneal on electrical properties of MNOS capacitors*

Palladium field plate	Hydrogen anneal	−196°C Ⓐ-state voltage (V)	Polarization ΔV (V)
No	No	5-6	<0.2

Silicon type: p-type, (111), $C_B = 1 \times 10^{16}$ cm^{-3}.

reaction. This type of hydrogen, not present to any extent in the $SiCl_4$-NH_3 process, reduces the number of fast states but causes polarization in the nitride/oxide structure. It was interesting to note that the medium-low density of fast states in thermal oxide controls (no field plates) was not reduced by the hydrogen annealing at 800°C.

The above experiment involving palladium field plates and hydrogen was also carried out at 550°C. At this temperature no changes in electrical characteristics of the $SiCl_4$-type nitride/oxide structure occurred. This was undoubtedly due to the inability of any hydrogen species to diffuse through the nitride layer and is in agreement with the main finding of this paper, *e.g.*, fast states are not annihilated during the 550°C postmetallization anneal process in Si_3N_4/SiO_2 structures.

Conclusions

The characteristics of fast surface states associated with thermally oxidized silicon structures have been studied using the MOS capacitance-voltage method of analysis along with other device measurements. Process conditions for induction and annihilation of fast states have been established. While the initial fast state density of thermal oxides may be related to the fixed charge Q_{ss}, the presence or absence of a hydrogen-containing species during the cooling process or subsequent thermal treatments may determine the final fast state density. If a hydrogen species is present, a low fast state density results. Furthermore, the common low temperature (550°C), post-aluminum anneal has also been shown to be very effective in reducing fast state densities to low levels in thermal oxide structures.

Thin, silicon nitride layers have been shown to prevent or retard the annihilation of fast states in underlying, thermally oxidized silicon during the post-aluminum annealing treatment. The following effects of process variations on this phenomenon have been noted.

1. The masking or retardation of the fast state annihilation in $Si_3N_4/SiO_2/Si$ structures due to the silicon nitride layer is not dependent on silicon impurity type, concentration, or silicon orientation. Nitride layers thicker than 200Å are effective in retarding fast state reduction.

2. The final density of fast states is a function of the carrier and cooling ambient during silicon nitride deposition where $SiCl_4$ is the reactant. A nitrogen ambient will result in a large fast state density, hydrogen in a medium-low density.

3. Postdeposition annealing treatments at 700°-1000°C in nitrogen will induce large densities of fast states in MNOS structures which will not be reduced by the post-aluminum anneal treatment. A subsequent high temperature anneal in hydrogen at 700°-1000°C of a $Si_3N_4/SiO_2/Si$ structure with a high fast state density will reduce this value back to that originally obtained in $SiCl_4$-NH_3-type deposition involving a hydrogen carrier ambient.

4. The structure of the silicon nitride layer as reflected by its etch rate will influence its ability to mask against fast state annihilation. The faster the etch rate in concentrated HF, the less effective the masking. Deposition variables (such as reactant compositions, flow rates, and temperature) which affect nitride structure also affect the fast state masking property.

5. The type of nitride, $SiCl_4$ or SiH_4, has a very important effect on the fast state densities. Nitrides produced by the $SiCl_4$-NH_3-H_2 reaction result in medium-low fast state densities (5-10 x 10^{11} cm^{-2}). Those nitrides produced by the SiH_4-NH_3-H_2 reaction, on the other hand, provide very low fast state densities (<2 x 10^{10} cm^{-2}) but do cause significant polarization. Neither type of nitride permits fast states induced by post-deposition anneals to be subsequently annihilated by post-aluminum treatments.

From the above results, it is believed that for thermally oxidized silicon MOS structures some type of hydrogen species is produced during postmetallization anneals at 500°-565°C by the reaction of the field plate metal, *i.e.*, aluminum, with water adsorbed on the oxide surface. This hydrogen then migrates to the SiO_2-Si interface where it somehow annihilates the fast states. Silicon nitride layers deposited over the thermal oxide retard this hydrogen migration, however, and any fast states remaining after the nitride deposition or subsequent high temperature annealing treatments are not annihilated by the post metallization anneal. A similar hydrogen species is produced during the deposition of silane-type nitrides which, at the temperatures of deposition, can migrate through the nitride layer. This causes a reduction in fast state density, but also results in a polarization-type of instability.

Thermal Diffusion of Sodium in Silicon Nitride Shielded Silicon Oxide Films

T. E. Burgess, J. C. Baum,[1] F. M. Fowkes,*[2] R. Holmstrom,[3] and G. A. Shirn*

Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

The ability of silicon nitride layers deposited on silicon oxide-passivated silicon to act as contamination barriers has been measured through the use of a radioisotope, sodium-22. Transport studies at 500°C have shown that the concentration of sodium reaching the silicon oxide-silicon interface was reduced one thousandfold when a 1000Å shield of silicon nitride was present. These nitride films which may be deposited by any one of several techniques act not only as mechanical barriers against sodium penetration, but also as sodium getters. The amount of sodium retained by the silicon nitride film depends mainly on the film deposition temperature. For example, silicon nitride films deposited at 850°C trap more sodium than those deposited at 1100°C. The presence of moisture in the ambient atmosphere during any annealing process of a silicon nitride shielded silicon oxide film will release some of the sodium trapped in the nitride layer and allow it to move to the silicon oxide-silicon interface.

With the change to plastic packages for silicon transistors and microcircuits, silicon dioxide passivated surfaces are more subject than ever before to degradation of insulating properties by mobile charges arising from the incursion of moisture and sodium or similar impurities. Junctions are softer, gain decreases, and nearly all MOS transistor characteristics are degraded (1-3). One potential remedy for these ills is to shield the passivating oxide from moisture and sodium by covering it with an impermeable shielding layer of silicon nitride, which can be deposited by a variety of techniques (4-6). The effectiveness of silicon nitride shields has been assessed and compared by measuring the amount of thermal diffusion of sodium-22 through silicon nitride shielded silicon oxide films. As will be shown, the amount of sodium entering the passivating oxide from the nitride shield is not proportional to the concentration of sodium in the nitride, so simple diffusion studies in nitride films (7) do not necessarily predict their relative effectiveness as contamination shields. This method consists of the deposition of a measured amount of sodium-22 chloride solution on the surface of the film followed by indiffusion of the sodium for 2 hr at 500°C. The sodium-22 concentration profile in the film is used as a measure of the shielding ability of the film.

Experimental

Silicon wafers cut from (100) or (111) single crystal material were oxidized in dry oxygen at 1150°C to produce 2000Å silicon oxide films. The 1000Å silicon nitride films were deposited on this silicon oxide layer by either a pyrolytic chemical vapor deposition (PCVD) (3, 4) or by a RF-reactive sputtering technique (6). The PCVD films were prepared in 1:10, 1:100, or 1:200 silane-ammonia mixtures with the substrate temperature at 850°, 1000°, or 1100°C. The carrier gas in all cases was hydrogen. The RF sputtered silicon nitride films were deposited by reactive sputtering of a silicon target in a nitrogen atmosphere.

A carrier-free sodium-22 chloride solution which contained about 0.03 mc/ml of sodium-22 was used for the indiffusion. The specific activity of such a solution was around 5 x 10^{10} Na atoms/count/minute in the NaI well-type scintillation detector used in this work. This solution was added drop-wise from a dropping pipet to the surface of the sample film and dried at 90°C for 15 min. It was not necessary to cover the entire surface of the film with an even distribution of the radiotracer in this type experiment since comparisons were made between similarly indiffused samples. However, it was important that the same amount of sodium-22 was deposited on each surface. Five drops (approx. 0.25 mil) of the sodium-22 chloride solution gave a significant activity in most films after diffusion, and this amount of the solution was easily and reproducibly deposited on the surface of the films. Autoradiographs of indiffused samples showed that five drops covered about one tenth of the total surface area of the sample. If more sensitivity is desired, then additional sodium-22 could be deposited on the surface; however, this increase in sodium-22 must be taken into account when comparing these samples with those containing smaller amounts of the radiotracer.

After deposition of the sodium-22 chloride on the surface of the film the samples were placed on a quartz boat and annealed at 500°C in a flowing dry nitrogen atmosphere for 2 hr. The sodium-22 contaminated surface was covered during the annealing process with a clean silicon wafer to reduce the loss of sodium-22 by evaporation.

Successive layers of the films were dissolved in an appropriate solvent after indiffusion of the radiotracer was completed. Concentrated hydrofluoric acid (49%) was used as the etchant for the PCVD silicon nitride while a 10:1 solution of water-hydrofluoric acid was used to etch the silicon oxide. Silicon oxide films dis-

solve in this solution at a rate of about 300 Å/min. The solubility of PCVD silicon nitride in concentrated hydrofluoric acid depends on the method of preparation. The etch rate of this film varies betwen 40 to 200 Å/min depending on the density of the film. In order to obtain a sharp boundary in the sodium concentration profile between the silicon nitride and silicon oxide layers the final 400Å of the silicon nitride were always dissolved in hot phosphoric acid. This etchant will not attack silicon dioxide appreciably, but will dissolve PCVD silicon nitride at a rate of about 50 Å/min. The sodium-22 content of each etch solution was determined directly by the well scintillation detector.

Results and Discussion

These sodium transport studies show that a 1000Å silicon nitride film effectively shields an underlying silicon oxide film against sodium indiffusion at temperatures up to 500°C. Table I shows the average value of sodium-22 concentration found at silicon nitride-silicon oxide and silicon oxide-silicon interfaces for several samples indiffused with sodium-22 at 500°C for 2 hr in a dry nitrogen atmosphere. The PCVD silicon nitrides were deposited at three different substrate temperatures 850°, 1000°, and 1100°C using silane-ammonia gas mixtures of 1:10, 1:100, or 1:200. The density of the silicon nitride film deposited by the pyrolytic process depends on the substrate temperature and is greater for films deposited at higher temperatures. The density effects the solubility of these films with the etch rate in concentrated hydrofluoric acid being the slowest for the films prepared at 1100°C. The shielding abilities of the silicon nitride films are demonstrated by comparing the sodium concentration measured at the silicon oxide-silicon interfaces.

Since device performance is influenced by ionic impurities in the oxide film near the silicon surface, sodium concentrations in the oxide within about 300Å of the silicon surface are most important. If in Table I a comparison is made between the unshielded silicon oxide samples and those protected by a silicon nitride layer, it is seen that the presence of a nitride film reduced the amount of sodium-22 reaching the silicon oxide-silicon interfaces by as much as one thousandfold. The RF-sputtered silicon nitride films did not give the protection against the sodium penetration afforded by the PCVD silicon nitride films probably because these films were less dense than the PCVD layers.

Typical sodium-22 concentration distributions in the silicon nitride-silicon oxide films are shown in Fig. 1. The most striking feature of this figure is the shielding ability of the silicon nitride film when compared with the unshielded silicon oxide sodium-22 concentration curve. Further consideration of this figure and the data in Table I brings out another interesting feature of the silicon nitride film. In all of the samples except those prepared by RF sputtering the sodium-22 concentrations in the nitride films after indiffusion are ten to one hundred times larger than the sodium-22 concentrations in the adjacent oxide layers. This sodium distribution indicates that silicon nitride may act not only as a mechanical barrier against sodium penetration, but also as a getter for sodium. In this

Table I. Average values of sodium-22 concentrations at silicon nitride-silicon oxide and silicon oxide-silicon interfaces. Indiffusion at 500°C, 2 hr, N_2 atmosphere, 1000Å Si_3N_4 over 2000Å SiO_2

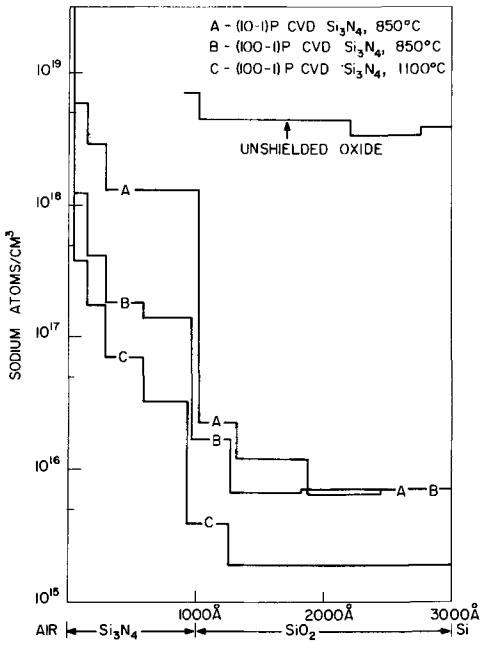

Fig. 1. Concentration of sodium-22 in silicon nitride shielded silicon oxide films after 2-hr indiffusion at 500°C in dry nitrogen.

case it should be possible for sodium originally present in the underlying silicon oxide film to out-diffuse into the silicon nitride layer under the conditions used for deposition of this film. This reaction is demonstrated in Fig. 2. Here, an 850°C PCVD 1:100 silicon nitride film was deposited over a silicon oxide film which contained indiffused sodium-22. After the deposition of the nitride film the sodium-22 originally present in the silicon oxide film was found distributed throughout the silicon nitride-silicon oxide layers. Measurements also showed that the sodium concentration was at least tenfold larger in the silicon nitride layer.

The results indicate that silicon nitride films act as both getters for sodium and physical barriers against sodium penetration. These characteristics are strongly influenced by the method of preparation. Although the physical characteristics of all the silicon nitride films were almost identical, the films produced at the higher temperatures were more dense and prohibited sodium penetration by acting as simple mechanical barriers. However, as Table I and Fig. 1 show, the sodium

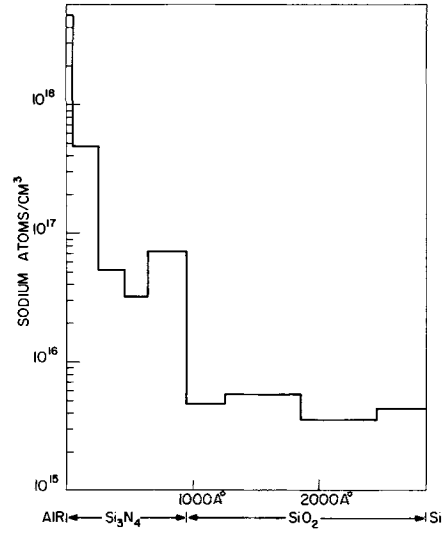

Fig. 2. Gettering of sodium-22 by pyrolytic CVD (100-1) silicon nitride deposited at 850°C on sodium-22 contaminated silicon oxide.

concentration at the silicon nitride-silicon oxide interface was lower in the higher temperature PCVD films, and these films were not as active sodium getters. In fact, the RF sputtered silicon nitride film which had the lowest density of all films listed in Table I and was deposited at the lowest temperature seemed to be the best sodium getter. Although this film retained a large concentration of sodium, considerable amounts of this ion managed to penetrate the low density silicon nitride layer. The sodium-22 profiles observed in all the silicon nitride films are probably related to the structural defects (vacancies) and their ability to immobilize sodium ions by an electron trapping mechanism. A similar sodium mechanism is reported for silicon oxide films (10).

The diffusion of sodium in silicon oxide films is strongly influenced by the presence of water (8). Water neutralizes the E'_1 centers, associated with oxygen vacancies in SiO_2 (9), that tend to trap electrons and immobilize sodium (10). Figure 3 shows that in the presence of water the sodium has less of a tendency to be trapped in the bulk oxide and is more concentrated next to the silicon. The presence of water vapor in the annealing atmosphere was also found to have a considerable effect on the sodium concentration profile in silicon nitride-shielded silicon oxide films. Sodium concentrations at the silicon oxide-silicon interfaces were increased at the expense of the sodium levels at the air-silicon oxide or air-silicon nitride interfaces. Figures 4 and 5 compare the distribution of sodium-22 in the films after annealing sodium-22 indiffused films in either dry or wet nitrogen. For these measurements samples containing these films were indiffused with sodium-22 for 2 hr at 500°C in a dry nitrogen atmosphere. Each wafer was cut in half and one half was annealed for two hours at 500°C in dry nitrogen while the second half was annealed under the same conditions except in an atmosphere of nitrogen saturated with water (at 25°C). The sodium-22 concentration at the silicon oxide-silicon interface increased in all cases when the annealing was done in an atmosphere containing water vapor. This shift occurred even at a temperature of 200°C.

The immobilizing of sodium in silicon nitride films can be attributed to the presence of electron traps (probably nitrogen vacancies) similar to those found in silicon oxide layers. The fact that the sodium gettering ability of these films varies inversely with the film deposition temperature indicates that silicon nitride layers deposited by the PCVD method at 850°C (or by RF sputtering at lower temperatures) contain larger concentrations of these electron traps than those deposited at 1000° or 1100°C. Release of the trapped sodium through the neutralization of these electron trapping centers by moisture would occur in the same manner as it does in the silicon oxide films, and would permit the sodium to move into the underlying silicon oxide film (Fig. 4 and 5). This mechanism suggests that sodium penetration of the silicon oxide layer would be more likely to occur under conditions of high ambient temperature and humidity when the protecting silicon nitride film was a good sodium getter.

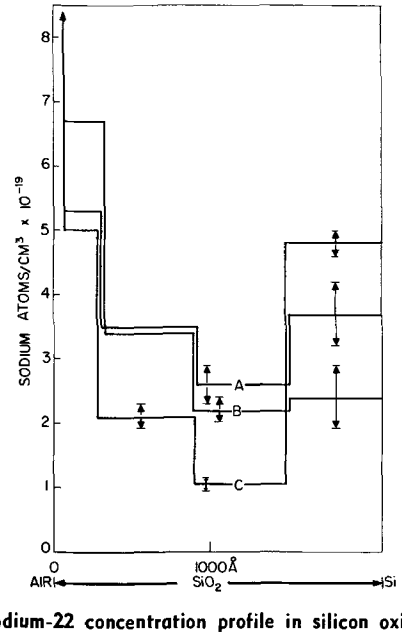

Fig. 3. Sodium-22 concentration profile in silicon oxide film annealed at 500°C: (A) 4 hr, dry nitrogen; (B) 2 hr, dry nitrogen; (C) 2 hr, dry nitrogen plus 2 hr wet nitrogen.

Summary

Silicon nitride films deposited over silicon oxide layers may be used to shield the passivating oxide film against sodium penetration. These films, deposited

by a variety of techniques, act not only as sodium barriers but also as sodium getters. The film deposition temperature strongly influences the sodium gettering characteristic of the silicon nitride layer. Films pyrolytically deposited at the lower temperature (~850°C) are always better sodium getters than those produced at 1000° or 1100°C, but all the PCVD films give equal protection to the silicon oxide layer against sodium penetration. This fact indicates that the films produced at 1000° or 1100°C are better mechanical barriers than those prepared at 850°C.

The presence of moisture in an annealing atmosphere causes sodium to move into the silicon oxide-silicon interface from the silicon nitride layer. This effect is more pronounced in systems that contain the better sodium gettering silicon nitride films. Consideration must be given for this effect for any test of sodium penetration in either silicon oxide or silicon nitride-silicon oxide film systems.

Preliminary Investigations of Reactively Evaporated Aluminum Oxide Films on Silicon

E. Ferrieu and B. Pruniaux[1]

Laboratoire d'Electronique et de Technologie de l'Informatique, Centre d'Etudes Nucleaires de Grenoble, France

ABSTRACT

Amorphous films of aluminum oxide have been vacuum deposited on silicon substrates by reactive evaporation through a highly localized partial pressure of water vapor. The properties of these films, such as density, dissolution rate, dielectric constant, and electrical breakdown, were determined as a function of deposition parameters. Values of the refractive index and of the infrared absorption of the layers are also reported. Aluminum-aluminum oxide-n-type silicon structures were prepared in various deposition conditions and were characterized by either positive or negative values for flat band voltage. Preliminary investigations of the stability of the structures under thermal, electrical, and radiation stresses are reported. Typical memory behavior of the MIS structure is also reported, which is assumed to be a consequence of a transfer of charges from the semiconductor to trapping levels in the insulator.

For several years, thermally grown silicon dioxide has been used to fabricate MOS (metal-oxide-silicon) structures. However silica films are structurally porous and their permeability toward impurities and ion migration is detrimental in device application (1, 2). Thus, it is desirable to find new amorphous dielectric films, and many investigations on pyrolytic deposition of silicon dioxide and silicon nitride on silicon and gallium arsenide have been reported (3, 4); the silicon dioxide-silicon nitride mixture has also been studied (1). Conduction phenomena in these insulators are beginning to be understood theoretically (5, 6).

The first results concerning preparation and properties of aluminum oxide films were published by Aboaf (7), using thermal decomposition of aluminum alkoxide at 420°C, and by Waxman (8) and Waxman and Zaininger (9) using plasma anodized aluminum. Amorphous alumina was found to be more dense than silica and resulted in electrically stable structures under radiation and thermal stressing. The high dielectric constant of alumina ($\epsilon_r \simeq 8$) allows lower operating voltages or thicker gate insulators than for SiO_2 ($\epsilon_r \simeq 4$) or even Si_3N_4 ($\epsilon_r \simeq 6$).

[1] Present address: Bell Telephone Laboratories, Murray Hill, New Jersey.

Few results of vacuum deposition of alumina have been reported (10-12), and we have found no reference of its use in MIS (metal-insulator-semiconductor) structures. Reactively evaporated "alumina" films, deposited on glass substrates at low temperatures ($\leq$ 300°C) have been used as a dielectric for thin film capacitors (13): ϵ_r ranging from 7 to 8, dielectric strength 3×10^6 V/cm, loss tangent $3 \cdot 10^{-3}$ measured at 55 kHz. In the reactive evaporation process, the substrate may be maintained at a low temperature. This makes the method attractive for the deposition of the insulating film of multilayered structures or of MIS structures on temperature sensitive semiconductors. This paper reports the results of preliminary experiments which have been carried out in order to evaluate the suitability of reactively evaporated alumina films for field effect devices.

Experimental

Experimental process.—(111) surfaces of n-type silicon, 0.5 ohm-cm resistivity, were used in the experiments. The slices were circular, 25 mm diameter. Just prior to deposition of the alumina films, the silicon wafers were cleaned using successive baths of trichlorethylene, methanol, nitric acid, hydrofluoric acid, and deionized water.

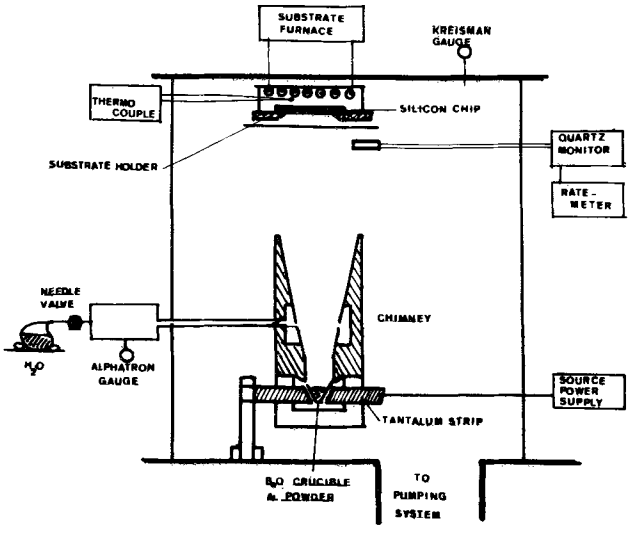

Fig. 1. Schematic of the vacuum deposition system

The silicon wafer was then placed at the top of the vacuum jar (Fig. 1) and outgased under vacuum at 400°C for 2 hr, using a radiative furnace placed above it. The substrate temperature, for deposition of the insulating film, has been varied between room temperature and 300°C and measured using a thermocouple fixed between the silicon slice and the heating furnace. The reactive evaporation of aluminum oxide was performed as follows:

1. Very pure aluminum powder (99.999%) was evaporated from a beryllia crucible heated by a tantalum strip. (The pressure during this preliminary step was better than 5×10^{-6} Torr.)

2. Then, water vapor was injected into the vacuum system through a needle valve.[2] The reaction between evaporated aluminum particles and water vapor was confined in a chimney in order to maintain a high concentration of water vapor molecules only in the evaporation field. Effectively a highly localized water vapor partial pressure was obtained: the pressure measured in the chimney was 2.6×10^{-1} Torr (NRC Alphatron gauge), while pressure in the vacuum system remained at 4×10^{-4} Torr (Ultek Kreisman gauge).

3. Then a shutter was open, and the oxidized aluminum was allowed to deposit on the silicon substrate. Deposition rates (V_{dep}) of aluminum oxide were measured using a quartz crystal monitor from 4 to 20 Å/sec. After deposition, the layer was annealed ½ hr at 300°C.

A number of electrical evaluations involved MIS structures. These were prepared by depositing on the nonheated substrate 5000Å thick aluminum field plates over the insulator. It was done in the same vacuum run, in order to lower the contamination at the Al-Al_2O_3 interface. MIS capacitors (the diameters of the field electrode being 800, 400, and 200μ) were obtained by etching aluminum using conventional photoresist techniques. Seventy-five samples of each area were obtained and tested, on the same silicon wafer, in order to establish the precision of the reported results.

The thickness of the films was measured using a Talysurf (Taylor-Hobson) which gives a ±50Å accuracy down to 200Å thickness. The dielectric constant was measured at 10 kHz with a general radio capacitance bridge. The infrared transmittance curve was taken using a Model 317 Perkin Elmer infrared spectrophotometer. The refractive index of the insulating layer was estimated using a Brewster angle technique. The C(V) curves were recorded using an MOS meter [ref. (25)] at a frequency of 10 kHz.

Discussion.—Defects in the insulating layer can be due either to the reactive process itself or to the materials of the evaporation source. Without claiming any assumptions concerning the reactive process, we can assume that two kinds of defects can be encountered in the as-made films: either noncomplete oxidation (nonstoichiometry) or formation of hydroxides. Contamination by H_2O molecules can also be a consequence of the 4×10^{-4} Torr water vapor environment, close to the substrate (H_2O molecules being adsorbed by the freshly deposited layer).

Contamination can proceed from the source materials, although the source arrangement is such that the substrate can only "see" the molten aluminum part of the source. Reaction between Ta and BeO which forms gaseous TaO, and reaction between Be and H_2O forming volatile BeOH are not believed to be an important source of contamination of the deposits. Furthermore there is no evidence of Be inclusions in the layers from the infrared measurements (Fig. 2) (but only the absence of the 7.2μ absorption peak of BeO can be significant for the 11.8 and 13.7 peak of BeO fall within the broad absorption peak of alumina). Thus, we consider, in the following, that the deposits can contain only two kinds of defects: (*i*) excess of aluminum, or oxygen vacancies, or H^+ ions which are named "positive contamination," and (*ii*) excess of [OH^-] ions which are named "negative contamination."

Results

Physical properties.—Examination of the infrared spectrum (transmission) of the aluminum oxide films (Fig. 2) indicated a broad absorption peak from 11 to 20μ, which is in good agreement with reported values for pure alumina (14).

The refractive index of the deposited alumina was typically 1.71 ± 0.03 (it is 1.765 for pure α-alumina (15)). It is of particular interest to evaluate the homogeneity of the Al_2O_3 layers as a function of deposition parameters. A compactness factor r can be defined as being the ratio

$$r = \frac{d_f}{d_a}$$

where d_f = density of reactively evaporated alumina and d_a = density of pure crystalline alumina ($\simeq$3.97).

The density d_f has been measured: (*i*) by weighing the silicon slice before and after deposition of the alumina layer, using a sensitive microbalance (accuracy for d_f equal to ±5%), and (*ii*) using the quartz crystal monitor. The relation which gives the frequency shift ΔF of the quartz when ΔM material is deposited on it, is

$$\Delta F = k\Delta M$$

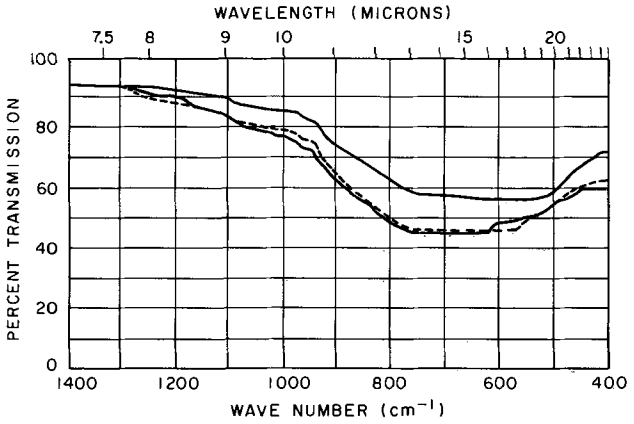

Fig. 2. Infrared absorption spectrum of three Al_2O_3 films deposited on silicon.

[2] Using pure oxygen as the oxidant instead of water vapor, makes the deposition process much more difficult to control. Furthermore the aluminum oxide films obtained were found to be less homogeneous and stable.

Table I. Deposit homogeneity as a function of deposition rate, substrate temperature 300°C

Density						
Quartz monitor	3.49	3.56	3.69	3.81	3.91	3.0
Weight	3.43	3.56	3.72	3.85	3.89	3.55
Average r value	0.87	0.89	0.925	0.967	0.982	0.82
Relative dielectric constant	7.5	7.9	7.95	8	8.05	Not measurable
Deposition rate, Å/sec	3	4	5	7	10	14

so $\Delta F_1 = kd_{al}e$ for pure aluminum deposit of thickness e and $\Delta F_2 = kd_fe$ for aluminum oxide deposit of thickness e. Thus

$$d_f = d_{al} \times \frac{\Delta F_2}{\Delta F_1}$$

This method for measuring d_f gives an accuracy of ±2%. The mechanical homogeneity of the aluminum oxide films can also be evaluated from its dielectric constant ϵ_f (24). If r is the compactness factor defined above and ϵ_a the dielectric constant of pure alumina, then

$$\epsilon_f = \frac{1}{1 - r + r/\epsilon_a}$$

The measured aluminum oxide film densities are reported in Table I. An average value of the compactness factor is given for each deposition rate. The dielectric constant is given for comparison. It can be seen from Fig. 3 that the higher the deposition rate, the better the compactness factor. But, when the deposition rate is increased further (higher than 15 Å/sec), the density strongly decreases indicating that the layer is no longer a pure dielectric film, but contains nonoxidized aluminum particles. The dielectric constant of such a deposit is not measurable, the layer being a cermet (Al_2O_3 + Al) rather than an insulator (13). Similar results are obtained from Fig. 4 where the etching rate of the layers is plotted against the deposition rate.

In order to evaluate the uniformity in depth of the films, a special arrangement was used to prepare nine steps of increasing alumina thickness on the same silicon wafer and in the same vacuum run. The etching rate of the steps was found to be constant (Fig. 5), indicating that the Al_2O_3 films are homogeneous throughout their thickness.

Adhesion of the alumina layers to the silicon substrates was excellent, up to 20,000Å thick films, operating at a substrate temperature higher than 100°C.

Electrical properties.—A reproducible ohmic contact on the silicon wafer was difficult to obtain. Best measurements were made using silver paste at the back of the silicon slice; otherwise a contact diode exists which strongly distorts C-V and dielectric constant measurements.

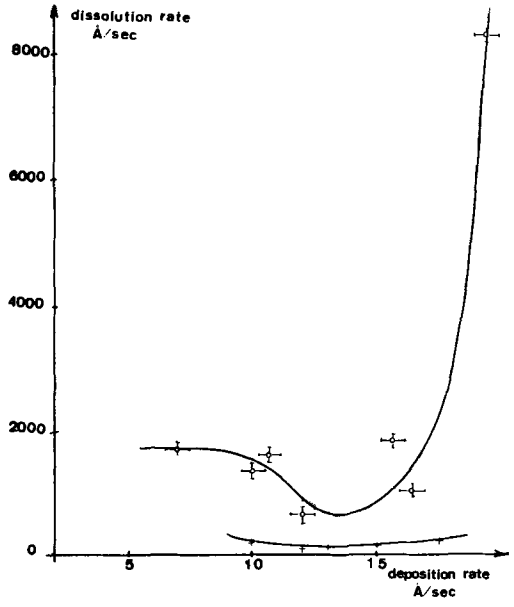

Fig. 4. Dissolution rate of alumina layers vs. deposition rate: + PO_4H_3 etch 55°C, O PO_4H_3 etch 70°C.

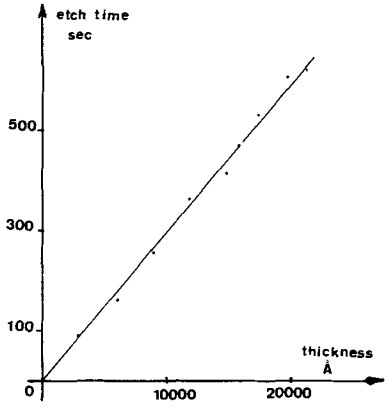

Fig. 5. Etch time vs. deposit thickness

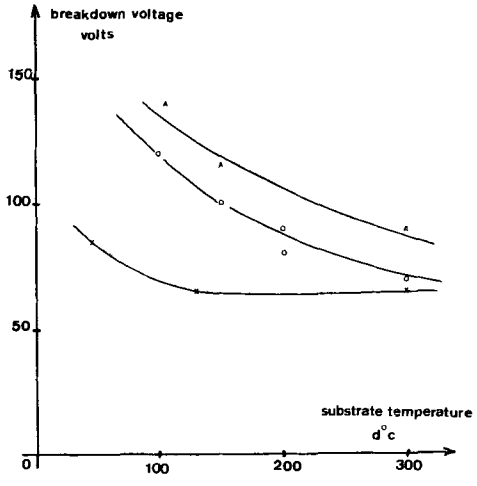

Fig. 6. Breakdown voltage of MIS structures as a function of substrate temperature during deposition (1500Å thick films): + 15 Å/sec deposition rate, O 10 Å/sec deposition rate, △ 7 Å/sec deposition rate.

Figure 6 reports the variation with deposition parameters of breakdown voltage for 1500Å thick alumina films.[3] Highest dielectric strength is obtained for low substrate temperature and deposition rate.

[3] Breakdown voltage was defined as being the voltage at which the current through the insulator was 10 μA (readings were made using a Tektronix I-V tracer); accuracy ±5%.

Unfortunately layers deposited under 100°C are poorly adherent.

Figure 7 shows that, for small probing areas (dot diameter = 200μ), the dielectric strength is constant over all the thickness of the layer. For larger probing areas, the pinhole density (due to surface roughness of the wafer or to particles in the insulating layer) is such that a short occurs for a thickness of the order of 400Å. A similar effect is observed when the dielectric constant is plotted *vs.* the thickness of the insulator (Fig. 8): the decrease of ϵ_r with thickness for large testing areas can be a consequence of mechanical defects in the insulating layer.

C-V measurements on the MIS structures indicate (Fig. 9 and 10) that the best alumina layers (lower flat band voltage) are obtained for low substrate temperatures and low deposition rates. It is evident also that, by changing these two deposition parameters, the flat band voltage can be varied from positive to negative values.

From all the results reported above, we have been able to assume that the insulator is homogeneous throughout its thickness, and to choose the following values for the deposition parameters: substrate temperature = 150°C and deposition rate ranging from 7 to 12 Å/sec (in order to study the positive and negative flat band voltage MIS structures).

MIS Structures

C-V measurements.—Typical C-V curves are shown in Fig. 11. For both curves, hysteresis is "abnormal" with respect to ion migration. According to Snow and Deal (16) this is a result not of the drift of fast ions,

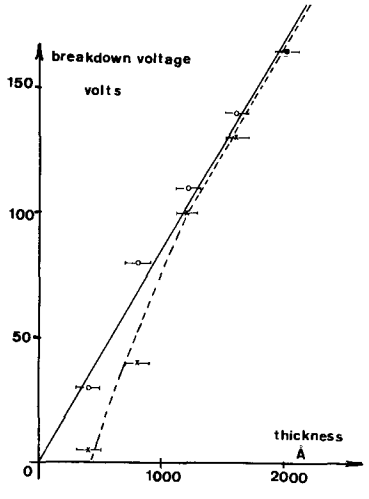

Fig. 7. Breakdown voltage of MIS structures *vs.* thickness of the Al_2O_3 layer: O ϕ = 200μ probe electrode, + ϕ = 400μ probe electrode.

but indicates a dominancy of a "trapping polarization" process. The flat band voltages V_{FB}, representative of the total amount of electrical states at the Al_2O_3-Si interface, were calculated using the Goetzberger (18) and Whelan (19) theoretical curves.

It is interesting to note (Fig. 12) that for both positive and negative flat band voltage MIS structures, V_{FB} decreases with alumina thickness. Extrapolating to a zero thickness, for both structures, leads to a limiting positive flat band voltage, ranging between +1 and +5v (the uncertainty being due to the hysteresis effect of the C(V) curves). As a consequence, the structure which shows a negative flat voltage for large oxide thicknesses, goes through a zero flat band voltage for a thickness around 1000Å. The flat band volt-

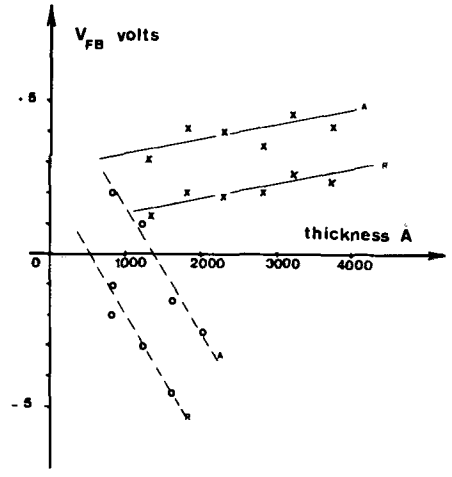

Fig. 12. Flat band voltage vs. Al_2O_3 thickness: O V_{dep} = 7 Å/sec, X V_{dep} = 12 Å/sec. Curve A, bias voltage is applied from positive to negative values; Curve B, bias voltage is applied from negative to positive values.

age can be given by the relation

$$V_{FB} = -\phi_{MS} - \frac{Q_T}{C_o} \quad Q_T = Q_{OX} + Q_{SS}$$

where Q_{OX} stands for the oxide charges (assumed to be at the semiconductor oxide interface) and Q_{SS} for the silicon pure surface charges (assumed usually to be positive charges, due to Na^+ ions).

ϕ_{MS} is the difference between the work function of the metal and the electron affinity of the silicon; in our case $\phi_{MS} = -0.25$V (17).

C_o is the capacitance per square centimeters of the insulator. Thus

$$V_{FB} = 0.25 - \frac{Q_T}{\epsilon_o \epsilon_r} t_{ox}$$

where ϵ_r is the relative dielectric constant of the insulator of thickness t_{ox}.

As shown on Fig. 12, the variation of V_{FB} with t_{ox} seems to be effectively linear. (The limiting value for $t_{ox} = 0$ is greater than 0.25V, because for very low oxide thicknesses a uniform field in the insulator can no longer be assumed, due to the fact that the ratio between the oxide thickness and the extent of the space charge in the oxide approaches one. Thus, the simple expression of V_{FB} given above is no longer valid.)

Both straight lines on Fig. 12 can be interpreted assuming that Q_{OX} are negative charges such that: $Q_{OX} << Q_{SS}$ for V_{dep} = 7 Å/sec and $Q_{OX} >> Q_{SS}$ for V_{dep} = 12 Å/sec. The dominancy of Q_{SS} over Q_{OX} (or Q_{OX} over Q_{SS}) results in a negative (or positive) value for the dV_{FB}/dt_{ox} slopes of the lines. Thus, the purest films, as expected from density and etching rate measurements, are those deposited at the lower deposition rate. "Negative contamination" appears to be the most important defect encountered, and an inversion (p-type) layer was found most of the time at the silicon surface [a similar observation is reported by Aboaf (7)].

Drift of the MIS structures under electrical and radiation stressing.—Figures 13 and 14 show the drift of the C-V curves under various applied bias, before and after annealing (30 min at 410°C, under N_2 gas flow). Annealing of the structure results in a large improvement, *i.e.*, lower drifts and saturation times.

The drifts under positive and negative bias are due to very different phenomena: regardless of the sign of the applied bias V_P, the resulting drift ΔV is positive. Thus, for positive V_P, the product $V_P \cdot \Delta V$ is positive, which [according to (16) and (21)] is now assumed to be the characteristic of carrier injection

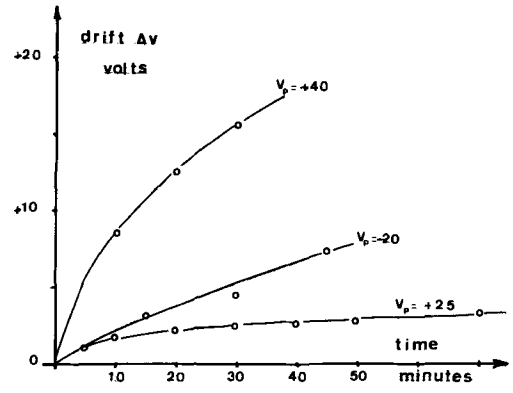

Fig. 13. Drift of C(V) curves with time under various bias voltages, before annealing of the structure.

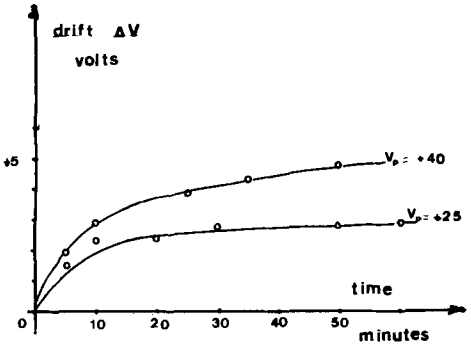

Fig. 14. Drift of C(V) curves with time under various bias voltages, after annealing of the structure 30 min at 410°C under N_2 gas flow.

from the silicon surface toward trapping levels in the insulator. On the other hand, for negative applied bias, $V_P \cdot \Delta V$ being negative, this may indicate a migration of slow negative ions in the insulator ("negative contamination") toward the silicon-insulator interface.

When cycling the structures between —40 and +40V, (after annealing) one obtains the typical hysteresis drift curve of Fig. 15; similar curves have also been reported for Si_3N_4 layers (23) and vapor deposited SiO_2-Si_3N_4 mixtures. This effect is also assumed to be a consequence of trapping effects at the Si-insulator interface.

Figure 16 reports the effect of radiation stressing on the MIS structures. Electrons of 1 mev were used, and the field electrode of the structure under test was shorted. The C(V) curves were measured after each dose. The total induced drift is less than 5V, lower than the drift observed in SiO_2 MOS structures (20)

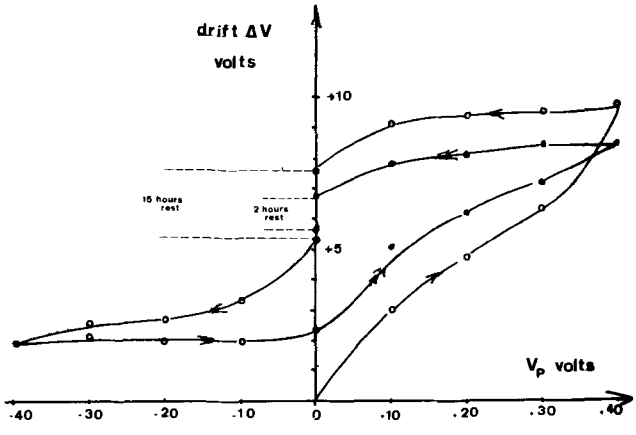

Fig. 15. Drift of C(V) curve as a function of applied bias. Each reported point on the curve was measured after 15 min applied voltage.

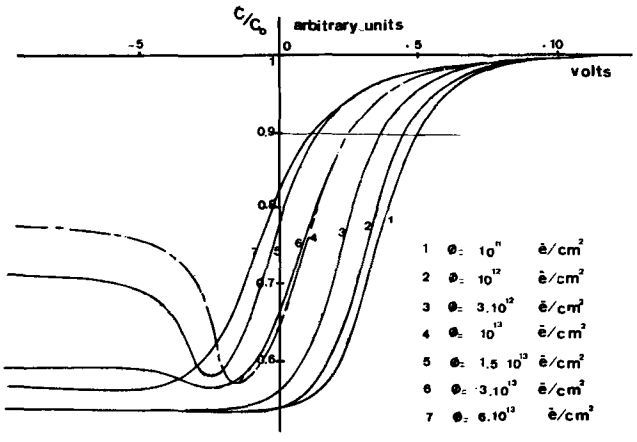

Fig. 16. Drift of C(V) curve for a 1600Å thick Al_2O_3 layer, under irradiation. The measuring frequency is 10 kHz. Each curve is drawn after each reported dose has been applied to the structure.

but similar to that obtained when Si_3N_4 was used as the insulating layer (22).

Table II reports typical observations on the stability of Al_2O_3 MIS structures, after various treatments. The drift is quite low (after annealing) as shown by the "after 6000 hr" measurements. But, it can be seen that the structures are not yet fully stabilized.

Conclusion

More detailed information of the aging behavior of the C-V curves as a function of temperature, time, and frequency are needed to fully identify the processes taking place in the structures. Nevertheless, the results obtained during this preliminary work can lead to the assumption that "negative contamination" (*i.e.*, $[OH]^-$ ions) is the main defect encountered in reactively evaporated alumina films, and to the conclusion that these insulating layers are physically homogeneous and suitable for multilayered structures. We think that a "trapping polarization" process has been identified, which can be in full or in part hidden by ion migration.

Further experiments are being carried out, for a better understanding of the phenomena involved, and to decide whether or not, reactive evaporated alumina is more suitable for field effect devices than the other well known insulators.

The Preparation and Properties of Silica Films Deposited from Silane and Carbon Dioxide

R. C. G. Swann* and A. E. Pyne

ITT Semiconductors, West Palm Beach, Florida

ABSTRACT

Silicon dioxide has been deposited from a reaction involving silane and carbon dioxide. Hydrogen and argon were used as carrier gases. Growth rates were measured from 700° to 1100°C. The choice of carrier gas had a pronounced effect on the growth rate at low temperatures. Etch rates, dielectric loss, and infrared spectra are reported. Interface charge properties are shown under certain conditions to be stable and hysteresis free with typical N_{FB} values of 1-3 x 10^{11} charge/cm^2.

The introduction of large-scale integrated MOS circuits has resulted in increased interest in chemical vapor deposition systems. At this time, silicon dioxide remains the most useful dielectric for interfacing with silicon. The advantages of deposited silicon dioxide over thermal or bulk grown oxides are well known. They include the ability to deposit thick layers at high growth rates and low temperatures to avoid movement of diffusion fronts as well as the ability to form oxides on foreign substrates. Many silicon dioxide deposition systems have been investigated, for example, the direct oxidation of silane (1), decomposition of ethyl-triethoxy-silane (2), the reaction of silicon halides with carbon dioxide (3-5), as well as sputtering (6, 7) and glow discharge reactions (8). The literature, however, contains no reference to the investigation of the silane/carbon dioxide reaction.

This system was investigated because silane and carbon dioxide do not react spontaneously at room temperature as, for instance, silane and oxygen do. Furthermore, by using prediluted silane, and argon as carrier gas, no hazardous gases are involved. The system is also highly compatible with the silane/ammonia reaction for the deposition of silicon nitride (9). With the addition of an ammonia source, the authors have deposited sequential layers of silicon dioxide and silicon nitride without removal of the wafer from the reactor.

The silicon oxide-silicon nitride structure is particularly useful as a gate insulator in MOST's because the nitride, in this context, is a poor interfacing material but an excellent sodium barrier. In the field region, thick oxides are often employed to alleviate channeling or inversion under metallizations. Ideally, for P-channel devices, such an insulator needs a high fixed charge as contrasted with the low fixed charge required for the gate regions. The field region therefore could be a layer of silicon nitride over which silicon dioxide is deposited. Because of the slow etch rate of silicon nitride and its higher dielectric constant, only a thin layer (<1000Å) would be used. The film thickness is then built up to typically 10,000Å with silicon dioxide which is also a convenient mask to use for the phosphoric acid etching of the nitride. A suitable gate dielectric would consist of 500Å of silicon dioxide over which is deposited 500Å of silicon nitride.

Experimental

The apparatus used to perform these experiments was a single slice vertical reactor using r.f. heating of a quartz coated graphite susceptor (Fig. 1). The gas manifold was constructed entirely of stainless steel, and the reaction tube was quartz. A rotary shaft was provided for substrate rotation; and contained vacuum seals to enable leak checking with a vacuum pump and pressure gauge. The substrate temperature was measured by a Huggins Infrascope infrared pyrometer placed vertically above the substrate. All temperatures are quoted for a constant emissivity correction of 0.65.

The silicon wafers used in these experiments, except for I.R. studies, were 2 ohm cm phosphorus doped <111> oriented and optically polished to ~250μ thickness. The I.R. wafers were 50 ohm cm <111> oriented phosphorus doped and both sides optically polished to ~1000μ. Slices were degreased and then cleaned in 50% HF and boiled in nitric acid with intermediate and final washes in 18 Mohm deionized water. The slices were dried in a stream of dry nitrogen and pretreated in the reactor at 1200°C for 5 min in hydrogen to remove any residual oxide. After adjustment to the desired substrate temperature the carbon dioxide and silane were admitted. The carbon dioxide used was Coleman grade (99.99% min. purity), the hydrogen was Matheson ultrapure grade (99.999% min. purity), and the argon was Matheson high purity (99.995% min. purity).

Oxide thickness was determined in two ways; for growth rate studies the thickness was measured by comparison with a color chart, but for etch rate determinations the thickness was measured with a Hilger and Watts interferometer.

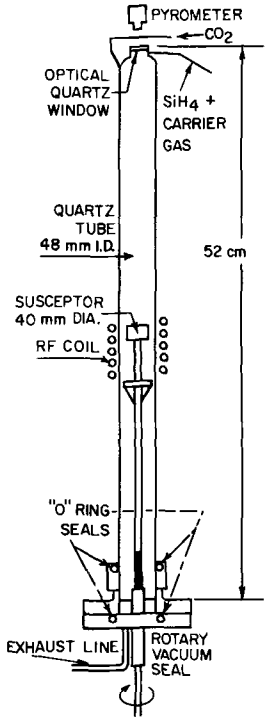

Fig. 1. Single slice vertical reactor

* Electrochemical Society Active Member.

Surface charge measurements were made by depositing aluminum by electron beam evaporation and etching 400μ diameter dots. The electron beam damage was annealed out at 560°C for 5 min in nitrogen. Plots of capacitance *vs.* voltage were then made on an automated C-V plotter.

Results

It is important to emphasize that the results, in particular those of growth rates, will be reproducible only in a reactor of similar geometry and heating method (Fig. 1).

Growth rates.—Growth rates were studied as a function of substrate temperature, percentage silane, percentage carbon dioxide, and total flow rate. Figure 2 shows the deposition rate as a function of percentage silane for a range of substrate temperatures from 700° to 1100°C. In this case, the carbon dioxide:silane ratio was 100:1 and the balance gas was hydrogen. Growth rates vary from 15 to 4000 Å/min over the range explored. It can be seen that the growth rate is less temperature sensitive between 900° and 1100°C than between 700° and 900°C. Figure 3 is a similar graph of deposition rate *vs.* percentage silane except for using argon as balance gas, instead of hydrogen. The salient difference is the significantly higher growth rate at 700°C. At 0.18% silane, is 800 Å/min for the argon case and 100 Å/min for the hydrogen.

From the two families of growth rate curves, plots of deposition rate *vs.* $1/T$ were derived, but no meaningful activation energy could be calculated from the plots that were linear only over a small temperature range. The reason for this nonlinearity was upstream decomposition, which became more pronounced at high substrate temperatures. The susceptor mass and geometry were found to affect the amount of upstream decomposition; and in this work it should be noted that the susceptor was quartz-enclosed graphite.

The effect of carbon dioxide concentration on growth rate was studied at a fixed silane concentration of 0.037% and substrate temperature of 900°C. Figure 4 shows that the growth rate curve, although having a decreasing slope, does not saturate even at a carbon dioxide:silane ratio of 250:1.

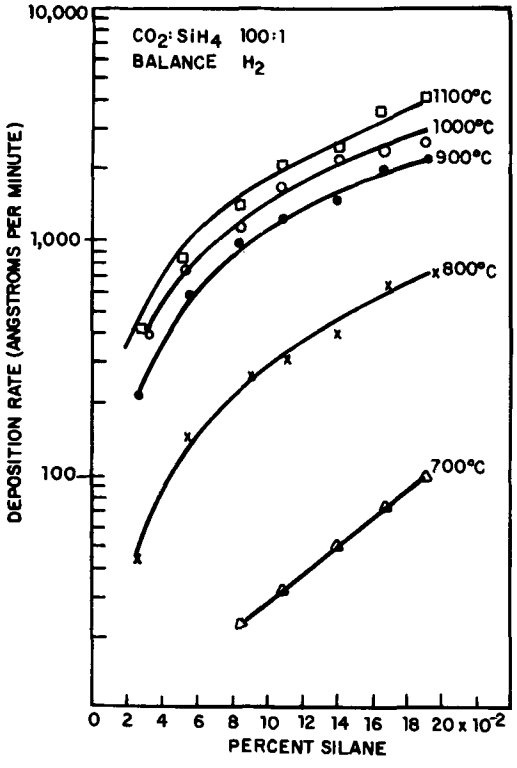

Fig. 2. Deposition rate of SiO_2 *vs.* SiH_4 concentration at different temperatures with H_2 as carrier.

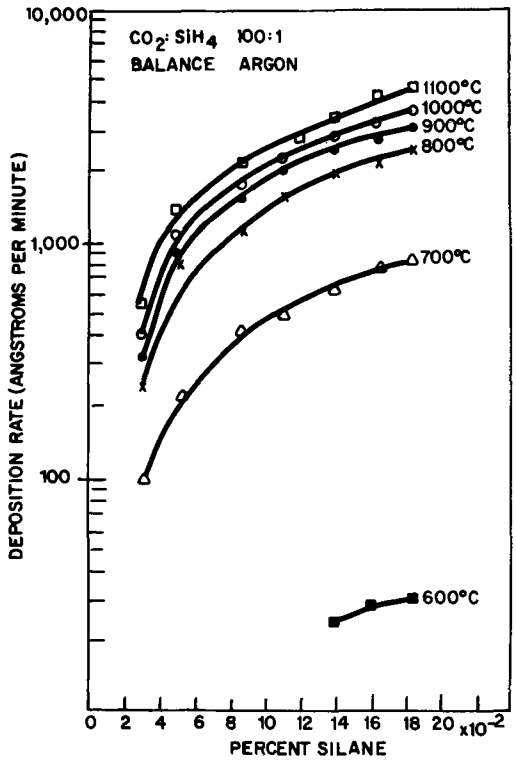

Fig. 3. Deposition rate of SiO_2 *vs.* SiH_4 concentration at different temperatures with argon as carrier.

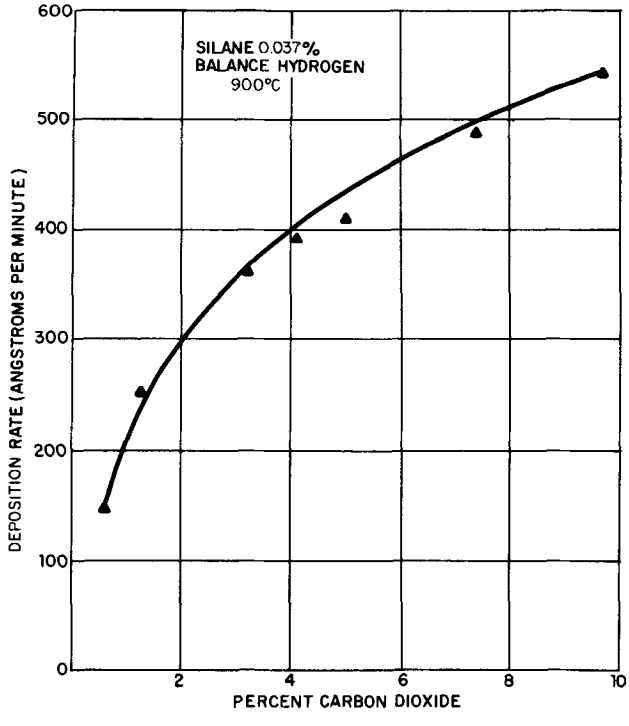

Fig. 4. Deposition rate of SiO_2 *vs.* CO_2 concentration

Growth rates were studied as a function of total flowrate (Fig. 5) at a fixed carbon dioxide:silane ratio (100:1) and the balance gas was hydrogen. All three gases were proportionately increased for each determination of growth rate at a constant substrate temperature of 900°C. The reaction is seen to be transport controlled up to approximately 1.4 l/min and thereafter the growth rate is substantially constant.

Infrared.—Figures 6 and 7 show the extremities of the conditions in this study. There was no obvious difference in the IR spectra for samples deposited using the two different carrier gases. There was, how-

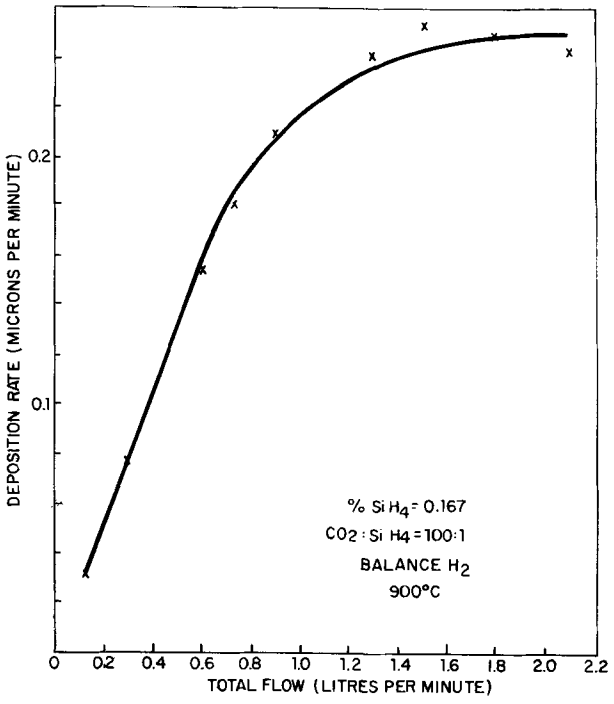

Fig. 5. Deposition rate of SiO_2 vs. total flow rate.

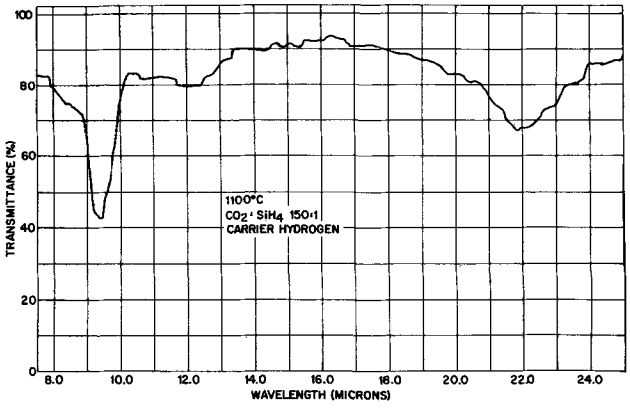

Fig. 6. IR spectra of SiO_2 deposited at high temperature and high CO_2:SiH_4 ratio.

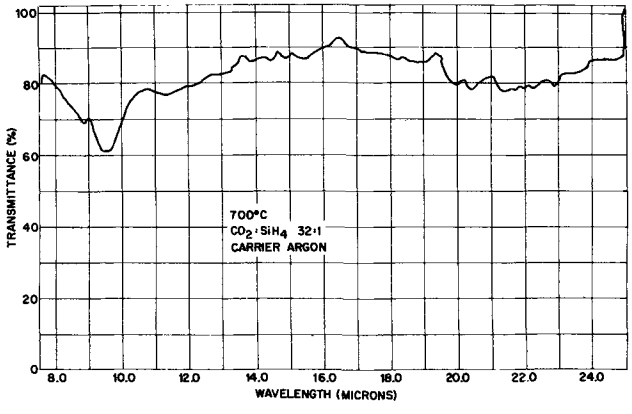

Fig. 7. IR spectra of SiO_2 deposited at low temperature and low CO_2:SiH_4 ratio, showing a shoulder at 8.8 μ.

ever, a dependency on substrate temperature and carbon dioxide/silane ratio. The 9.3μ absorption was more intense at high substrate temperatures and high carbon dioxide/silane ratios. In general these films were comparable to thermally grown oxides, whereas, at low substrate temperatures and low carbon dioxide/silane ratios (Fig. 7) a low intensity 9.5μ peak is observed which has a definite shoulder at 8.8μ. These films are probably silicon rich as is discussed later.

Etch rates.—Controlled etch rate studies were only performed on the oxides produced with hydrogen as carrier gas. Etch rates were not measured on layers deposited in argon as these left a thin brown film on etching. Rates were determined using a P etch solution (20°C) in which dry thermally grown oxides etch at 2 Å/sec (10). The highest etch rate was observed on films grown at 900°C, and this was 6.5 Å/sec. The etch rate fell to 4.5 Å/sec at 1100°C and 4.0 Å/sec at 700°C.

Interface charge properties.—Silicon dioxide was deposited at substrate temperatures between 700° and 1100°C at a carbon dioxide:silane ratio of 100:1 using both carrier gases. The oxides grown in hydrogen showed surface charges typically between 1 and 3 x 10^{11} charges/cm^2. These oxides were very stable under bake bias. An increase of $\sim$1 x 10^{11} in the surface charge for an applied field of 2 x 10^6 V/cm for 30 min at 250°C was a normal result. These surface charge and stability measurements were made over a period of several months and the stability and charge were found to be repeatable. Low-temperature (77°K) C-V plots did not show any fast states around inversion.

The oxides grown in argon behaved differently. The oxide quality depended markedly on deposition temperatures. The C-V curves of the 700°C oxide showed room temperature hysteresis. The curves were very similar to those of silicon nitride, *i.e.*, the amount of hysteresis depended on the applied voltage. At deposition temperatures of 1000°C however, this room temperature hysteresis disappeared and low charge oxides were formed.

Discussion

Steinmaier and Bloem (4), Tung and Caffrey (11), and others, using the $SiCl_4$-CO_2-H_2 reaction have proposed that their reaction proceeded in two steps.

$$H_2 + CO_2 \rightleftharpoons H_2O + CO \quad [1]$$

$$SiCl_4 + 2H_2O \rightarrow SiO_2 + 4HCl \quad [2]$$

The silicon dioxide is therefore formed by the hydrolysis of the halide. These authors recognized that intermediate steps must exist.

Similarly, in the SiH_4-CO_2-H_2 system it is possible for two reactions to coexist, that is the water gas reaction and the direct oxidation of SiH_4 by CO_2 as shown below.

$$SiH_4 + 4CO_2 \rightarrow SiO_2 + 4CO + 2H_2O$$

$$\Delta F + -116 \text{ kcals/mole at } 1200°K \text{ (12)}$$

The water formed by this reaction may hydrolize further SiH_4.

That the reaction does not proceed solely by the water gas reaction was verified by the substitution of argon for hydrogen. In fact the growth rate in argon was considerably greater; for instance, at 800°C the growth rate in argon was approximately four times that in hydrogen. It is thought the different growth rates result from the different thermodynamic properties of the gases, and thus there is less upstream decomposition in the case of argon.

Film properties are certainly modified when using argon, in particular at low temperature the films were much softer and, as mentioned before, a residue not etchable in HF was found at the interface. The loss factor of SiO_2 formed in argon at 700°C was 0.015, but for a film grown in argon at 1000°C the loss factor was 0.005.

These facts together with the infrared data indicate that these low-temperature films deposited in argon contain free silicon. The effect of free silicon on the dielectric loss in silicon nitride has previously been reported. (13)

Conclusions

The silane-carbon dioxide reaction has been characterized for a specific deposition system. The resultant film properties were found to be dependent on the balance gas in that argon gave films that were mechanically soft and nonadherent at low substrate temperatures. On the other hand, the use of hydrogen as balance gas produced films of superior mechanical and electrical properties.

The MOS capacitance-voltage measurements showed that the oxide would make an excellent passivating film for a gate dielectric because of its stable and low interface charge. The charge densites ($\sim$1-3 x 10^{11}/cm on <1-1-1> silicon) were the same as those normally quoted for thermally oxidized films, and it is expected that even lower values would result from using <1-0-0> oriented surfaces.

Deposited silicon dioxide offers a distinct advantage over thermally grown oxide in that the time and temperature of growth can be minimized. For example, at 900°C deposition rates ranging from 200 to >2000 Å/min can be achieved; whereas a dry or wet thermal oxidation would require approximately 8 hr and 20 min, respectively, to grow 1000Å of silicon dioxide.

The chemical compatibility of this reaction with the silane-ammonia reaction offers the capability of depositing sequential layers of silicon nitride and oxide (or *vice versa*) for a variety of semiconductor applications.

Acknowledgment

The authors are indebted to P. Stauffer who prepared the samples and to D. Pitzer who helped with the electrical measurements. The authors also wish to thank Dr. R. M. Warner, Jr. for his many helpful comments.

Technical Notes

Effect of Ce^{+3}, Pr^{+3}, and Tb^{+3} on the Brightness of YVO_4:Eu under Cathode-Ray Excitation

E. J. Mehalchick, F. F. Mikus,* and J. E. Mathers*

Sylvania Electric Products Inc., Chemical and Metallurgical Division, Towanda, Pennsylvania

The behavior of YVO_4:Eu when excited by uv was studied extensively (1, 2) and its utility as a red emitting color TV phosphor is well known (3). The effect of Tb^{+3} in alkaline metal rare earth tungstates and in Y_2O_3 was reported by Van Uitert (4) and by Ropp (5). Thompson has reported the effect of Ce^{+3}, Pr^{+3}, and Tb^{+3} in his patent (6). The effect of Ce^{+3} is reported by Kano and Otomo (7). The present work shows the effect of Tb^{+3}, Pr^{+3}, and Ce^{+3} on the brightness of YVO_4:Eu under cathode-ray excitation. Small additions of Tb^{+3} and Pr^{+3} cause significant increases in luminescence while small amounts of Ce^{+3} decrease it.

Experimental

Yttrium oxide of extremely high purity was used in all phosphor preparations. Results of quantitative analysis of the rare earth are shown in Table I. Stock solutions of Ce^{+3}, Pr^{+3}, and Tb^{+3} containing 6.435 x 10^{-4} g Ln/cc of solution were prepared by dissolving a known quantity of the corresponding oxide in nitric acid and diluting to volume. The required volume of solution containing the desired ion was added to a nitrate solution of yttrium and europium from which the rare earths were coprecipitated as oxalates. Am-

monium metavanadate was added to the dried oxalate and the mixture was fired at 950°C for 2 hr to produce the YVO_4:Eu (Ln) phosphor. The concentration of Tb^{+3} and Pr^{+3} were varied from 2.5 x 10^{-4} g/g Y_2O_3 to 5 x 10^{-5} g/g Y_2O_3 at Eu concentrations of 1, 3, and 5 m/o (mole per cent). The resultant phosphors, settled on glass slides, were excited with 12 kV electrons at a beam current of 6 μA. The intensity of the emission was measured with a Weston foot lambert meter.

Results and Discussions

Enhancement of the light output of YVO_4:Eu in the red region of the spectra by Tb^{+3} and Pr^{+3} are shown in Fig. 1 and 2, respectively. In Thompson's patent (6) he claims that 200 ppm Tb^{+3} give brilliant luminescence, a vague term since europium activated vanadates are generally brilliant. Our data point out that optimum luminescent efficiency is achieved when 50-75 ppm of Tb^{+3} or Pr^{+3} are added to the yttrium vanadate matrix. We have further evidence to show that the amounts of rare earth dopants he claims produce brilliant luminescence would result in a very inefficient phosphor. This effect increases rapidly from 0 to about 75 μg of Tb^{+3} and Pr^{+3} with gradual tapering off as more of each is added. These lanthanides behave uniquely in YVO_4:Eu in that no emission characteristic of these ions was observed under cathode-ray or uv excitation. A comparison of the excitation spectra of YVO_4:Eu with that of YVO_4:Eu,Tb (Fig. 3) indicates that an additional quenching is obtained with small amounts of these elements. The spectral energy distribution of YVO_4:Eu (0.01), YVO_4:Eu (0.01) Tb^{+3}, and Y_2O_3:Eu (0.01) Pr^{+3} are shown in Fig. 4. The emission of YVO_4:Eu (0.01) in the 430-480 nm and in the 530 and 580 nm range is quenched with both Tb^{+3} and Pr^{+3} under CR excitation. This is also manifested in the shift in the chromaticity coordinates to the more saturated red region. The low value of the x coordinate for the YVO_4:Eu suggests a significant contribution to the color from the lower wavelength emissions.

Addition of the 5 x 10^{-5}g Ce^{+3}/g Y_2O_3 to 5 x 10^{-4}g Ce^{+3}/g of Y_2O_3 decreases the brightness of YVO_4:Eu significantly as shown in Fig. 5. Thompson, in his patent (6), claims that he obtains brilliant luminescence with 100 ppm Ce^{+3}. We disagree very strongly as is shown in Fig. 5. At 100 ppm Ce^{+3} and 3 m/o Eu the luminescent efficiency of YVO_4:Eu would be 20% less as compared to material containing no Ce^{+3}. This statement is borne out further by work completed by Kano and Otomo. They show a significant drop in the cathodoluminescence efficiency when small amounts of Ce^{+3} are present in the phosphor. It was reported earlier that high purity Y_2O_3 is important in the preparation of efficient YVO_4:Eu phosphors. This is again demonstrated in Fig. 6 which shows the washing out

of the beneficial enhancement effect from Tb^{+3} and Pr^{+3}.

In conclusion, it can be said that: 1, with very pure Y_2O_3 as raw material, the brightness of YVO_4:Eu phosphor is increased by additions of Pr^{+3} and Tb^{+3}; 2, Ce^{+3} decreases the brightness of YVO_4:Eu; 3, emissions of Tb^{+3} and Pr^{+3} in the YVO_4:Eu system are not observed under either CR or uv excitation; and 4, addition of Pr^{+3} and Tb^{+3} increase the saturation of a red emission of the YVO_4:Eu at all europium levels tested.

Acknowledgments

The authors wish to express their thanks to D. T. Palumbo and S. Z. Toma for their helpful discussions. They wish also to thank M. Dyer and W. Persun for the phosphor measurements.

Self-Activated Luminescence of β-Ga_2O_3

William C. Herbert,[1] Henry B. Minnier, and Jesse J. Brown, Jr.[2,] *

Sylvania Electric Products, Incorporated, Chemical and Metallurgical Division, Towanda, Pennsylvania

Gallium sesquioxide, Ga_2O_3, is known to exist in at least two stable crystalline modifications. The stable, low-temperature (α) form has the α-corundum crystal structure in which the oxygen ions approximate a hexagonal close-packed array and all of the Ga^{3+} ions are in octahedral coordination. Foster and Stumpf (1) prepared α-Ga_2O_3 by heating gallium monohydrate in air at about 400°C. Above approximately 600°C, α-Ga_2O_3 transforms to β-Ga_2O_3, the high-temperature polymorph. Since β-Ga_2O_3 is extremely persistent even below the $\alpha \rightleftarrows \beta$ transition temperature, it is the polymorph normally encountered in commercial gallia. Sheka *et al.* (2) discuss three other crystalline modifications of Ga_2O_3, *i.e.* γ, δ, ϵ, with each appearing to have an Al_2O_3 analog. The crystal structure of β-Ga_2O_3 has been investigated by Geller (3) and is monoclinic with $a_o = 12.23$, $b_o = 3.04$, $c_o = 5.80$Å, and $\beta_o = 103.7°$. Four molecules are contained in each unit cell, and the most probable space group is C 2/m. The structure is similar to that of θ-Al_2O_3 and is characterized by two nonequivalent cation sites, one tetrahedrally and one octahedrally coordinated by oxygen.

High-purity (99.9+% pure), commercial Ga_2O_3 normally contains the beta phase and is nonluminescent.

Experimental Procedure

Raw material purity.—99.999+% pure gallium oxide as received from two vendors was analyzed semiquantitatively by spectrographic methods for trace impurities. The results shown in Table I indicate the relatively high purity of starting materials. The only impurities present in both lots that are normally associated with impurity activation are Cu and Mo. (Ca, Mg, and Pb are possible acceptors and could also contribute to luminescence.) Neither of these starting materials showed significant luminescence as received. Elements sought but not detected (detection limits vary depending on elements, but, in all cases, detection limits are less than 10 ppm): As, B, Ba, Be, Bi, Cd, Co, Ce, Fe, Ge, Mn, Ni, P, Sb, Si, Sn, Sr, Ta, Th, Ti, W, Zn, and V.

Sample preparation.—Compositions were heat treated in alumina or fused silica crucibles in electric resistance furnaces. Some reaction with the fused silica crucibles was encountered and, therefore, the outer ¼ in. of exposed sample was routinely discarded before any measurements were made. Noble metal containers were unsatisfactory because of apparent amalgamation between the crucible metal and gallium.

Measurements.—Routine phase identification was achieved using a Norelco x-ray diffractometer which employed nickel-filtered CuKα radiation and operated at 40 kV and 15 ma.

All photoluminescent excitation and emission spectra and peak height measurements were obtained at room temperatures using a Perkin-Elmer spectrofluorimeter as previously described (4). Reflectance spectra were also measured using this instrument. Cathodoluminescent spectra were obtained using a demountable cathode ray tube operating at 12 kV anode potential and 6 μA beam current over a standard scan TV raster of 1-in.^{2} area. Brightnesses under these conditions were measured with an eye-corrected Weston foot-lambert meter.

Experimental Results

Commercial grades of Ga_2O_3 are normally nonluminescent, although in some cases an extremely weak emission can be detected. Upon heat treatment at high temperatures, *e.g.* above 1250°C, a bright blue luminescence develops. This emission is characterized by the spectrum shown in Fig. 1 and the optical data listed in Table II. Under 253.7 nm excitation, unactivated β-Ga_2O_3 has a peak emission at 456.0 nm and a ½ I_{max} band width of 130 nm. This corresponds to a shorter wavelength of emission and a more narrow band width than that of $MgWO_4$ (NBS 1027) which emits at 501.0 nm and has a band width of 150 nm. Luminescent β-Ga_2O_3, properly prepared, has a more intense peak emission than $MgWO_4$, and, consequently, the integrated area of the emission spectrum of β-Ga_2O_3 is slightly larger than that of $MgWO_4$.

Under cathode ray excitation, β-Ga_2O_3 is about 19% as bright as ZnS:Ag, the conventional blue-emitting, color-television phosphor.

The intensity of the photoluminescence varies considerably depending on the temperature and duration of heat treatment. In addition, the luminescence appears to be very sensitive to low level impurities, including those present in the furnace atmosphere and the fused silica container. It is not possible to describe a given procedure for the preparation of this phosphor, since each lot of Ga_2O_3 appears to behave somewhat differently. Phosphor preparations under mildly reducing conditions, generated by adding a few per cent NH_4Cl and firing in covered crucibles, markedly enhance the luminescence brightness. This modification does not change the other emission characteristics.

Substitutions of Si^{4+} and Zn^{2+} for Ga^{3+} were found to increase the peak emission wavelengths to approximately 510 nm. These substitutions, which can be represented by the formula $(Ga_{0.99}^{3+},Si_{0.005}^{4+},Zn_{0.005}^{2+})_2O_3$

Table II. Comparison of photoluminescence and cathodoluminescence of self-activated β-Ga_2O_3 with standard phosphors

Photoluminescence (λex = 253.7 nm)	β-Ga_2O_3	$MgWO_4$ (NBS 1027)
Peak wavelength (nm)	456.0	501.0
Peak intensity (%)	144	100
Band width at ½ I_{max} (nm)	130	150
Relative areas of emission peak (%)	106	100

x	0.184	0.234
y	0.207	0.320

Cathodoluminescence	β-Ga_2O_3	ZnS:Ag (P-21 Blue)
Brightness (ft-L)	6.2	33.5
Chromaticity coordinates		
x	0.176	0.149
y	0.166	0.043

indicate that the luminescence is sensitive to some chemical additions even when they are present in low concentrations.

The photoluminescence excitation spectrum for luminescent β-Ga_2O_3 obtained in the present study (Fig. 2) is in basic agreement with the optical absorption data of Tippins (4).

Discussion of Results

In view of the high purity and especially the low concentration of potential activator ions present in the Ga_2O_3 raw material, it is unlikely that the observed luminescence arises from absorption of energy by impurity activator ions. The broad, apparently structureless, absorption and emission spectra of luminescent β-Ga_2O_3 substantiate this viewpoint. This does not eliminate the possibility of these ions acting as coactivators or sensitizers.

The most likely explanation of the absorption mechanism has been discussed by Tippins (4) in which he semiquantitatively relates the experimental optical absorption of β-Ga_2O_3 to a $Ga^{3+} + O^{=} \rightarrow Ga^{2+} + O^{-}$ type process. The excitation spectrum for luminescent β-Ga_2O_3 shown in Fig. 2 is in close agreement with the optical absorption spectra measured by Tippins.

Although this appears to be a plausible explanation of the absorption (excitation) mechanism in β-Ga_2O_3, it does not explain why luminescence is observed only when the oxide has been subjected to high-temperature heat treatments. Evidently, energy absorbed by β-Ga_2O_3 is transferred quite freely through the lattice until it is eventually dissipated as heat. Luminescence does not develop until something, either vacancies or impurity ions, is introduced in sufficient concentration into the lattice to disrupt the continuity and serve as energy traps and, subsequently, emission centers. High-temperature heat treatments, therefore, are necessary to form vacancies.

Only recently, Lorenz, Woods, and Gambino (5) have shown by Hall coefficient and resistivity measurements that β-Ga_2O_3 can be an insulator or semiconductor depending on the conditions of preparation. In oxidizing atmospheres, the material exhibits insulating properties, but mild reduction introduces semiconducting characteristics. Semiconduction was attributed to the presence of anion vacancies. Optical absorption spectra obtained from the semiconducting β-Ga_2O_3 is in good agreement with the results of Tippins (4) and those of the present study.

Summary

The preparation of luminescent β-Ga_2O_3 can be achieved by simply heat treating the oxide at high temperatures in a nonoxidizing atmosphere. The resultant broad band emission peaks at 456 nm. As is typical for this type of luminescence, the emission wavelength can be varied somewhat by introducing impurity levels in the normally forbidden band gap.

Brief Communication

A Chemical Polish for $Sn_xPb_{1-x}Te$

J. Edward Coker

Autonetics Division of North American Rockwell Corporation, Anaheim, California

Single-crystal wafers of $Sn_xPb_{1-x}Te$ for $0 \leq x \leq 1$ have been polished down to a thickness of 3-4 mils. The resulting surface is specular, providing enough material has been removed to remove damage due to cutting or mechanical polishing.

To date, no one has reported a good polish for $Sn_xPb_{1-x}Te$. In an attempt to polish $Sn_xPb_{1-x}Te$, several chemical polish-etches were tried; among those tried was a lead telluride polish consisting of 40 cc saturated $K_2Cr_2O_7$ solution and 9 cc concentrated HNO_3 (1). A tin telluride polish that was used was prepared by dissolving 0.35g I_2 in 40 ml ethanol to which was added 10 ml distilled H_2O and 4.0 ml 49% HF (2). Also tried was $PbSe_{1-x}Te_x$ polish which was made by dissolving 0.5g disodium ethylenediamine tetraacetate in 25 ml distilled H_2O, then adding 50 ml 30% H_2O_2 and 25 ml glacial acetic acid (3). All of these display one or more undesirable properties. The polishes for PbTe and $PbSe_{1-x}Te_x$ leave stains on the surface; the tin telluride polish produces orange peel surfaces if careful control is not maintained.

The problem in polishing compounds of tin and lead lies in the fact that very few compounds of tin are soluble in aqueous solutions. To obtain the desired solubility, it is necessary to oxidize tin to the Sn(IV) state and lead to the Pb(II) state. This can be accomplished with the use of bromine in an acidic solution. A polish-etch has been found which is particularly good for polishing surfaces and/or etching patterns in $Sn_xPb_{1-x}Te$ substrates. The polish-etch contains 6 parts by volume bromine and 100 parts 48% hydrobromic acid which is used at room temperature. The crystals of $Sn_xPb_{1-x}Te$, when immersed in the polish-etch, will form a dark stain which is easily removed by agitating the liquid. The polish lends itself readily to tumbling techniques or the use of a magnetic stirrer. Quenching of the etch is accomplished by successive dilution with either methanol or deionized water. For thinning or etching patterns, wafers can be mounted on glass slides and, while stirring the liquid, etched to the desired thickness with a smooth reflective surface. Investigation indicates the polish-etch works well with a range of from 2 to 12 parts bromine.

The range of etch rates was found to be from 20 to 25 μ/min at 2%, to 80-85 μ/min at 12% concentrations of bromine.

A single sample of $Cd_{0.15}Hg_{0.85}Te$, a related infrared material, was polished with a 2% concentration of bromine in hydrobromic acid. The sample was a saw-cut wafer which had a very rough surface. After removal of the damage introduced by the saw ($\sim$15-20μ), the surface was both smooth and reflective.

Contribution of Spacer Paper to the Frequency and Temperature Characteristics of Electrolytic Capacitors

Robert S. Alwitt*

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

Electrolyte-impregnated capacitor paper has dielectric properties typical of a colloidal dispersion. The parallel capacitance of the paper is substantially enhanced by contact with aluminum oxide. The capacitance loss exhibited by aluminum electrolytic capacitors at low temperatures and/or high frequencies is accounted for by the combined effects of the etch structure of the foil electrodes and the dielectric properties of the impregnated paper.

Foil-type electrolytic capacitors exhibit a capacitance decrease at low temperatures and/or high frequencies that cannot be accounted for by a simple discrete capacitance for the oxide dielectric. Some performance curves for capacitors designed to illustrate this behavior are shown in Fig. 1. This effect has been ascribed to a capacitance of the electrolyte-impregnated spacer paper (1, 2) and to a decrease in the effective area of etched foil electrodes because of a "tuning out" of the interior of the etch structure (2, 3). It has recently been suggested that pores in the anodic oxide may contribute to the capacitance loss (3). Each of these factors is now considered briefly.

Assigning a fixed capacitance to the impregnated spacer paper helps reproduce the impedance *vs.* frequency characteristic of a capacitor (1, 3), but it does not account for all of the capacitance decrease at higher frequencies (3).

The treatment of the electrical properties of a porous capacitor electrode as a distributed network of capacitance and resistance was first presented in a quantitative fashion by Vergnolle (4). The capacitance due to the oxide dielectric was distributed along the pore walls, while the electrolyte resistance was distributed along the pore interior. A detailed consideration of the electrical properties of rough and porous electrodes has been presented by deLevie (5). The mathematical analysis of the electrical properties of etched foil electrodes presented by Broadbent (3) is essentially correct, but his experimental results did not show that characteristically different results were obtained with etched foil compared with plain foil. This was probably the result of not separating out the effect of the impregnated spacer paper that was measured in series with the foils.

Young (6) has shown that pores and microfissures in a dielectric film can be detected by the frequency dependence of the series resistance. If such discontinuities are present, there is a deviation from a linear R *vs.* $1/f$ relationship due to high series resistance at low frequencies. Broadbent (3) found a linear R *vs.* $1/f$ relationship, so it is unlikely that the capacitance loss he ascribes to pores or cracks can be accounted for in that fashion. Moreover, the effect of fissures would be least at those conditions which produce the largest capacitance loss, *i.e.* high frequency and low temperature.

Thus, the low-temperature and high-frequency characteristics of foil-type electrolytic capacitors have not yet been satisfactorily explained. This is due primarily to incorrect interpretations of the dielectric properties of the electrolyte/spacer system. The main purpose of this paper is to describe some electrical properties of impregnated spacer paper. Consideration of these properties, in conjunction with the known characteristics of the oxide dielectric and etch structure, permits a complete operational description of the low-temperature and high-frequency behavior of aluminum electrolytic capacitors.

Properties of Impregnated Spacer Paper

General.—More than 30 years ago, Fricke and Curtis (7) observed that an aqueous suspension of cellulose exhibited a very broad low-frequency dielectric dispersion. The apparent dielectric constant of the suspension was as much as several orders of magnitude greater than that of water and had a strong frequency dependence. Other colloidal systems showed the same effect. This property arises from the motion of ions, under the influence of an external electric field, along the surface of the solid particles. Schwarz (8) showed that the net ionic current tangential to the solid surface would be out of phase with the impressed field so as to give rise to a surface capacitance. He showed that the apparent dielectric constant arising from this effect could account very well for the experimental results.

It might be expected that the cellulose fibers in paper sheet would still retain many colloidal properties. Indeed, we have reported recently that paper sheet exhibits the same kind of dielectric dispersion as cellulose suspensions (9). It was found that the dielectric constant of electrolyte-impregnated spacer paper varied over the range 10^2 to 10^7 and depended on frequency, temperature, and solute concentration (9).

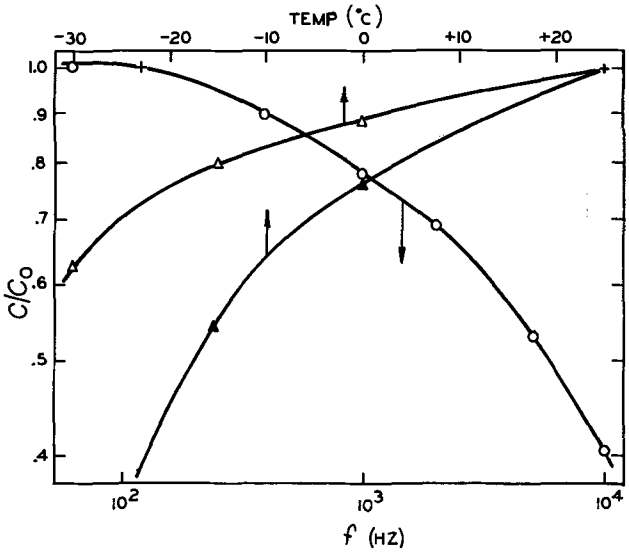

Fig. 1. Capacitance of 5V aluminum electrolytic capacitors made with Benares paper and an 800 ohm-cm glycol electrolyte: (○) = frequency dependence at 25°C; (△) = temperature dependence at 120 Hz; (▲) = temperature dependence at 1000 Hz; (+) = C_0 reference points.

* Electrochemical Society Active Member.

The temperature and solute concentration determine electrolyte resistivity with a particular solvent. The resistance R_p of any one paper type is proportional to electrolyte resistivity (10). The paper capacitance C_p is proportional to the dielectric constant, where C_p is in parallel with R_p. It has now been found that, when the data presented in Ref. (9) are plotted as C_p *vs.* fR_p, all the results with the same paper type fall within a narrow band, independent of the particular temperature or concentration. It should be noted that this is an empirical correlation. No theoretical grounds for the correlation would be expected since C_p is an interfacial property, while R_p is presumably determined by ionic conduction in electrolyte outside the range of surface effects.

The correlations obtained for a 1-mil thick Benares paper and a 2.4-mil Manila paper in electrolytes of sodium salicylate in ethylene glycol are shown by the line marked (a) in Fig. 2. The data were obtained at solute concentrations from 0.015 to 0.5M, temperatures from −24° to +80°C, and frequencies from 60 to 10^4 Hz. Both papers had about the same capacitance over much of the range of fR_p. Paper properties, experimental procedures, and further discussion of these data have been presented elsewhere (9, 10).

Behavior in a capacitor.—The effect of the dielectric properties of the impregnated spacer on the capacitance of an electrolytic capacitor is illustrated in Fig. 3. The fractional capacitance of a 4V smooth aluminum anode is shown as a function of frequency and electrolyte resistivity. Measurements were made at 25°C at frequencies up to 10,000 Hz and in glycol electrolytes with resistivities up to 10,000 ohm-cm. The reference capacitance C_o was about 1 mfd/cm², obtained at 60 Hz in a 12 ohm-cm aqueous electrolyte with no spacer present. Measurements with paper were made using a sandwich consisting of a central aluminum foil anode separated from two platinized electrodes by electrolyte-impregnated spacers (single sheets). The paper had been soaked overnight in electrolyte at 25°C. Care was taken to exclude air from the sandwich. Measurements without paper were made using the apparatus described by Bernard (11), with the aluminum electrode maintained at a separation of about 2 mils from a platinized electrode. The decrease in C/C_o in the absence of a spacer was probably due to residual surface roughness and possibly slight misalignment of the electrodes.

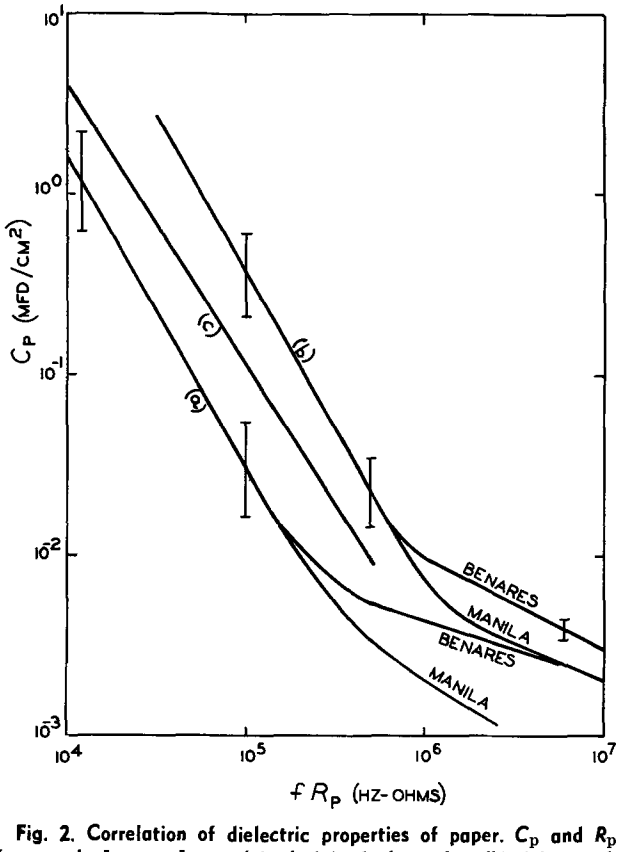

Fig. 2. Correlation of dielectric properties of paper. C_p and R_p for sample 1 cm x 1 cm; (a) platinized electrodes, (b) 4V smooth Al electrode, (c) etched Al electrodes. Vertical lines show range of data. See text for other details.

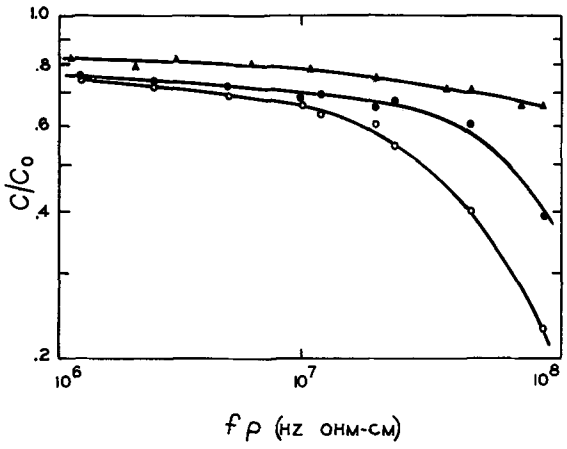

Fig. 3. Dependence of capacitance on frequency and electrolyte resistivity. Smooth, 4V Al at 25°C. (△) = no paper, (●) = Manila paper, (○) = Benares paper.

The capacitance and resistance of the paper in these sandwiches were calculated from the total series C and RC measured on a conventional bridge and the independently measured C and RC of the anodized aluminum foil. The procedure was the same as that used for measurements made between platinized electrodes (9) but with the oxide dielectric substituted for the external capacitor. This calculation treats the total capacitance and resistance as consisting of the oxide C_{ox} and R_{ox} in series with the parallel combination of paper C_p and R_p. Values of C_p and R_p were determined from the data in Fig. 3, and from data obtained over the same ranges of frequency and resistivity but at temperatures down to −24°C.

At any particular condition, the value of R_p was the same as found previously when using platinized electrodes. However, C_p was about an order of magnitude greater with the aluminum electrode. The correlation for these data obtained with a smooth, 4V Al anode is shown in Fig. 2 as line (b).[1]

Measurements of C and RC of some low-voltage miniature aluminum electrolytics were analyzed in a similar fashion and the correlation line for the paper properties is shown in Fig. 2 as line (c). These capacitors were made with etched foils and both Benares and Manila papers. Several electrolytes were used, including glycol/sodium salicylate and glycol/borate electrolytes. The correlation line is intermediate to those obtained with platinized electrodes and with a smooth Al electrode.

The fact that these lines are parallel indicates that the substitution of an oxidized Al electrode for a platinized electrode produced an increase in the magnitude of the dielectric constant of impregnated paper, rather than the introduction of a new dielectric phenomenon. This was made more evident by an examination of the dependency of paper dielectric constant on temperature, solute concentration, and frequency. In each case, the functional dependence was the same for both electrode materials.

Heavy metal cations are known to have a large effect on the surface properties of fibrous materials, including paper pulp (12). It was thought that even slight dissolution of aluminum or aluminum oxide might

[1] To estimate C_p for any particular condition in Fig. 3, one can calculate fR_p from $f\rho$ by using Eq. [4] in Ref. (10), treating R_p as frequency-independent. For the conditions of this study, this gives $R_p = 0.040\rho$ for Benares paper and $R_p = 0.025\rho$ for Manila paper for an area of 1 cm².

have imparted unsuspected properties to the paper, resulting in an increased capacitance. However, the addition of as much as 10^{-2} $Al(NO_3)_3$ to a glycol/sodium salicylate electrolyte did not shift the correlation line for Benares paper measured between platinized electrodes. Thus, dissolved aluminum seemed an unlikely source for the enhanced capacitance.

Contact with aluminum electrodes produced no permanent change in paper as evidenced from the fact that impregnated paper that had been in contact with aluminum for an extended time had the same capacitance, measured between platinized electrodes, as freshly prepared paper.

The following experiment established that it was the paper/Al_2O_3 interface, and not the presence of the aluminum electrode, that produced the enhanced dielectric constant for the impregnated paper. The capacitance of a smooth Al foil anodized to 3V was measured *vs.* platinized electrodes in a 10^4 ohm-cm glycol electrolyte at 25°C under the following conditions:

(*a*) Electrode separation about 25 mils; no paper present.

(*b*) Same electrode separation; one layer of Benares paper pressed against platinized electrodes but not touching Al.

(c) Electrode separation reduced so that paper is in intimate contact with both platinized and Al electrodes.

The decrease in over-all series capacitance with increasing frequency is shown in Fig. 4 for these three cases. The large decrease in equivalent series capacitance for case (c) shows that C_p, the effective parallel capacitance of the paper, was much greater than in case (*b*). The necessity for paper-oxide contact to produce very high C_p is supported by the results with etched foil (Fig. 2). With roughened foil, the actual contact area between foil and paper was reduced, resulting in a smaller C_p than with smooth Al foil.

Evidence that the high capacitance is localized near the oxide/paper interface is that, upon substituting three sheets of Benares paper for a single sheet in a sandwich made with a smooth 4V Al foil, no change in the measured capacitance occurred. A decrease of almost 25% would have been predicted at the particular conditions used if the dielectric properties had been uniformly distributed.

It has been shown elsewhere (9) that the dielectric constant of impregnated paper sheet is dependent on temperature, frequency, fiber dimensions, bulk electrolyte properties, and surface charge density. It would seem that only surface charge density (σ_0) could be affected by proximity to an electrode surface. To a first approximation, $\Delta\epsilon' \propto \sigma_0^3$ (9), so a relatively small change in σ_0 could produce a large change in dielectric constant.

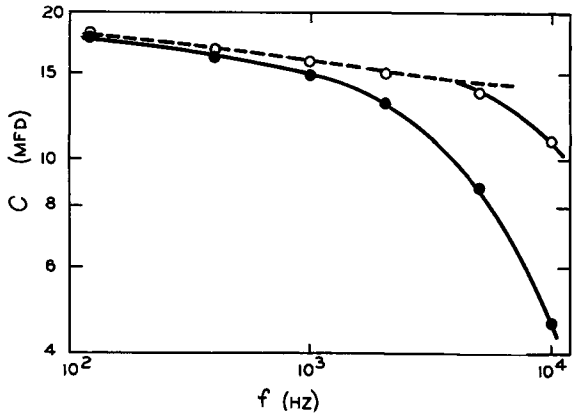

Fig. 4. Effect of paper/oxide interface on capacitance decrease. Dashed line represents results with no paper, (○) = Benares paper not in contact with oxide, (●) = Benares paper in contact with oxide.

Although paper in contact with anodized Al acts as if it had acquired an increased surface charge density, it is not apparent how this process could take place. Furthermore, it has been shown (9) that contact with platinized electrodes imparts no special properties, as evidenced by the fact that $\Delta\epsilon'$ was found to be the same for three sheets as for one sheet of paper. Thus, any explanation of the effect of an Al electrode must account for the difference between a metal and an oxide contact.

Etch Structure

The theory of porous electrodes (5) predicts that the effective capacitance of an oxide-covered electrode depends on the parameter $f\rho C_0$. At a critical value of $f\rho C_0$, the impedance of the furthest regions of the pores becomes sufficiently high, relative to the impedance of the surface regions, that the current and potential lines in the surrounding electrolyte no longer penetrate the full length of the pore. As $f\rho C_0$ increases above this value, the effective surface area, and hence C/C_0, becomes proportional to $(f\rho C_0)^{-1/2}$. The critical value depends on the ratio of pore diameter to length and increases as this ratio becomes larger.

During the course of our investigation of paper properties, it was found that paper impregnated with electrolytes using a mixed solvent of 1:1 water:glycol had no effect on the capacitance of foil sandwiches over a wide range of frequencies and electrolyte resistivities. This provided a convenient tool for studying the effect of etch structure on capacitance. Recent results in this area presented by Broadbent (3) did not exclude the capacitive contribution of the spacer paper.

Sandwiches were made as described under "Behavior in a capacitor," but using an anodized, etched aluminum foil as the central electrode and electrolytes made with the mixed solvent. Measurements were made over a frequency range of 60-1000 Hz at temperatures from —40° to 25°C and with electrolytes with resistivities at room temperature of 2 x 10^3 and 10^4 ohm-cm.

Four different etched aluminum foils were examined; two foils with a fine etch structure used for low-voltage applications, a foil with a coarser structure used for high voltages, and a cathode foil. These were anodized to several voltages up to 30V.

As expected, for each foil the value of C/C_0 was dependent on oxide thickness, temperature, *etc.*, only insofar as it affected the value of $f\rho C_0$. Surprisingly, there was not much difference among the several types of foils. All of the results could be described reasonably well by the single line shown in Fig. 5. The vertical bars describe the total range for the four foils. The points represent results obtained with one of the low-voltage foils. The slope of the line at high values of $f\rho C_0$ is —0.46, close to the theoretical value of —0.50. The gradual approach to this slope, rather than a sharp transition, is due to the presence of a distribution of pore sizes each with their own cut-off point.

The ordinate in Fig. 5 represents the effective surface area of the electrode. The oxide series resistance is inversely proportional to area and so will be inversely proportional to C/C_0.

Discussion

Equivalent circuit.—Based on the considerations in the preceding sections, one can arrive at the equivalent circuit shown in Fig. 6. The anode capacitance and resistance and cathode capacitance are shown as being distributed with the electrolyte resistance in the pores. The electrolyte/spacer system should also be represented by distributed parameters but this cannot be done in a simple fashion. Instead, C_p is depicted as a lumped parameter dependent on frequency and electrolyte resistivity.

If the capacitor section is sufficiently large, the resistance and inductance of the foil electrodes may be-

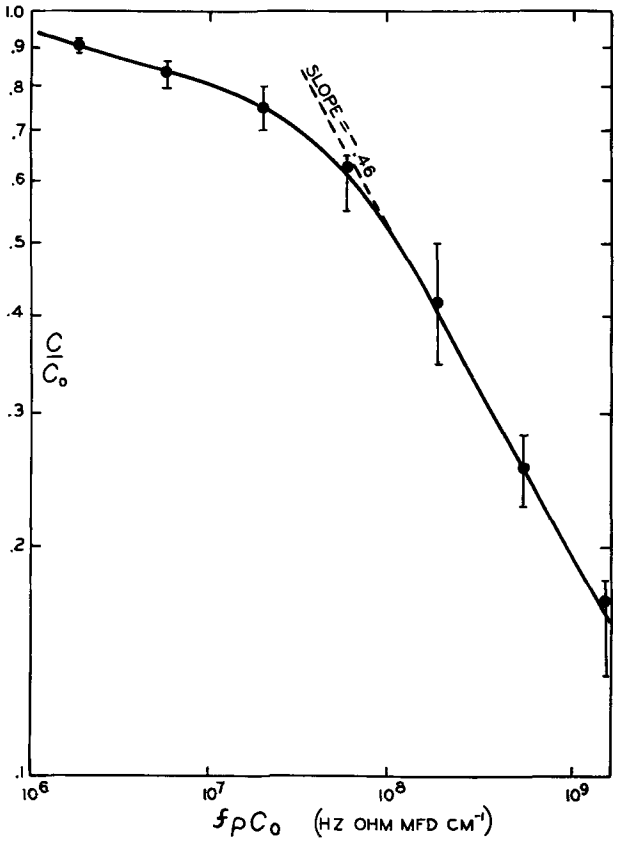

Fig. 5. Capacitance decrease of etched Al foil. Vertical lines show total range for four foils, points are results with a low-voltage foil.

come important. Peekema and Beesley (13) have recently presented an analysis of this situation. In such a case, the circuit in Fig. 6 would represent a unit element of the capacitor to be distributed over the foil resistance and inductance.

An important point of this work, and one emphasized by Peekema and Beesley (13), is that an accurate representation of an electrolytic capacitor requires that all major parameters be treated as distributed rather than lumped. Under certain conditions, some of the parameters can be approximated by discrete capacitance or resistance, but probably only lead and contact resistances can truly be considered as lumped parameters.

Predicting capacitor performance.—In principle, it should be possible to predict the capacitance and resistance of an electrolytic capacitor as a function of frequency and temperature from measurements of the foil, paper, and electrolyte properties by use of the circuit in Fig. 6. The effective capacitance and resistance of the foil-electrolyte system can be found in a straightforward manner. The paper/electrolyte properties in a capacitor are more difficult to assess. The resistance of impregnated paper will depend on the degree of constraint within the capacitor section

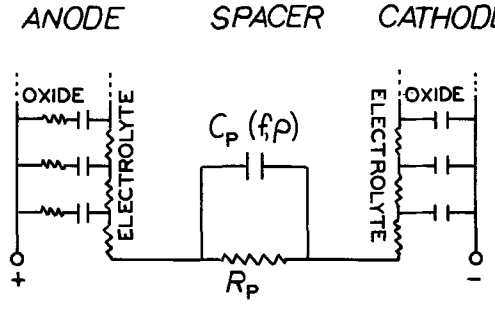

Fig. 6. Equivalent circuit for electrolytic capacitor

and the time-temperature history after impregnation (10). Since the value of C_p used for the calculation will be determined by the value of R_p chosen for use in Fig. 2, any error in selecting R_p is compounded. Our experience has been that with a low-resistance paper, such as Manila, the etched foil properties are dominant and a reasonable estimate of R_p is sufficient to provide good agreement between observed and predicted values of capacitance over a wide range of frequencies and temperatures. With a more resistive paper, such as Benares, the paper properties determine the capacitance loss at the lowest temperatures and/or highest frequencies and, unless an accurate value of R_p is used, there could be a substantial difference between observed and calculated values. Of course, even without an accurate value of R_p, this approach could be used to predict the relative effects of design changes or use of new materials.

An interesting aspect of the localization of the high C_p near the oxide/paper interface is that, when calculating the effect of paper for a capacitor using multilayers of paper, C_p is that corresponding to R_p for a single layer, even though the effective R_p in the capacitor will be that for all the layers.

The correlation between C_p and R_p shown in Fig. 2 can be used with systems other than those discussed here. Results with paper equilibrated with electrolyte at 85°C, as well as at 25°C, fell on line (b). An extensive study with smooth aluminum anodes showed that data obtained with uncalendered Kraft paper fell on line (b), as did results obtained with other electrolyte systems, *e.g.* using dimethylformamide as solvent. Presumably, line (c) would have this same generality though this was not studied in detail.

Conclusions

1. Electrolyte-impregnated capacitor paper exhibits dielectric properties typical of a colloidal dispersion. It can be inferred that the effective capacitance of the paper is increased by contact with aluminum oxide.
2. A correlation between C_p and fR_p exists for several paper/electrolyte systems.
3. The effective capacitance of etched Al foil is essentially that predicted by the theory of porous electrodes.
4. The effect of low temperature and high frequency on the capacitance of electrolytic capacitors can be accounted for by the combined properties of the etched foil and impregnated spacer paper.

Electrodeposition of Molybdenum Coatings

Frank X. McCawley,* Charlie Wyche, and David Schlain*

College Park Metallurgy Research Center, Bureau of Mines, United States Department of the Interior, College Park, Maryland

ABSTRACT

The electrodeposition of coatings of molybdenum from a sodium and lithium metaborate-molybdate-molybdenum oxide fused salt system was investigated. Coatings up to 16 mils thick were deposited on Inconel, Carpenter 20 stainless steel, nickel, copper, and graphite at current densities of 3.1-6.2A dm^{-2} (0.2-0.4A $in.^{-2}$) and 900°C under an argon atmosphere. The composition of the electrolyte is critical; deposits are obtained only when the electrolyte contains between 1.0 and 3.3% molybdenum.

Interest in molybdenum has increased rapidly with the advent of the missile and space industries (1). However, the production methods, such as compact powder sintering and arc casting, are expensive and useful forms of molybdenum metal are difficult to fabricate. The Bureau of Mines undertook this investigation to develop methods for applying coherent coatings of molybdenum on several substrates in order to take advantage of the properties of the molybdenum and to bypass expensive fabrication techniques.

Earlier investigators claimed deposits of molybdenum alloys from aqueous solutions (2, 3) and deposits of molybdenum metal from fused salt systems (4-7). Senderoff and Brenner (8) attempted to repeat some of these experiments and concluded that molybdenum had not been electrodeposited from aqueous, organic, or molten salt systems by the methods described. In 1954, Senderoff and co-workers developed a method for making coherent, dense molybdenum deposits up to 0.02 in. thick from a LiCl-KCl-K_3MoCl_6 fused salt electrolyte (8-11). Later, McCawley (12) and Cummings *et al.* (13) prepared coarse dendritic crystals of high-purity molybdenum by electrodeposition from fused salt mixtures made up with one or more alkali metal or alkaline earth chlorides and molybdenum pentachloride or potassium hexachloromolybdate, respectively. At about the same time, Heinen and Zadra (14, 15) described the electrowinning of high-purity molybdenum from sodium phosphate-borate-halide fused salt baths containing MoO_3. In 1964, Mellors and Senderoff (16-18) described a method for electroforming dense, coherent deposits of molybdenum from molten fluoride baths.

Starting with a 37.5% NaCl-37.5% KCl-25% K_3MoCl_6 fused salt electrolyte, the Bureau of Mines was able to obtain thick coatings. For example, adherent, dense coatings of molybdenum of up to 16 mils in thickness were made from this electrolyte at 900°C on graphite and stainless steel substrates. Cathode current efficiencies were from 80 to 99% for coatings made at current densities (C.D.) up to 9.3A dm^{-2}. However, corrosive vapors diffused through the protective graphite liner, attacked the structural parts of the cell, and contaminated the electrolyte.

The chemical similarity of molybdenum and tungsten and the success in preparing coatings of tungsten from the metaborate electrolyte by Davis and Gentry (19) and the improvement by McCawley *et al.* (20) suggested the use of a similar plating electrolyte for molybdenum. Therefore, this investigation deals mainly with the $NaLiB_2O_4$-$NaLiMoO_4$-MoO_3 fused salt system.

Experimental Equipment and Procedures

A special furnace which allowed visual observation of the cell during the high-temperature electrodeposition process was used in this investigation. The furnace is described in detail in a paper on electroplating thick tungsten coatings (20). However, a short description of the apparatus is given below and an isometric diagram of the apparatus is shown in Fig. 1.

Equipment.—The container used for plating consisted of a 4-in.-diam by 5-in.-high platinum crucible. The cell had one molybdenum anode and a cathode of nickel, Inconel, Carpenter 20 stainless steel, graphite, or copper. The two electrodes usually had the same dimensions, about 1 in. wide, 3-6 in. long, and 0.031-0.125 in. thick. They were spaced 1⅛ in. apart and were generally immersed in the electrolyte to a depth of 1-3 in., giving submerged areas of about 2-6 $in.^2$. The electrodes were attached to Inconel[1] extension rods. The cathode was connected to a d-c power supply by means of a constant low-voltage drop rotating assembly (21) which utilized mercury metal as the electrical contact. A thermocouple encased in ¼-in. OD Inconel tube covered with a 5-mil coating of platinum or molybdenum was used to measure the temperature and activate the temperature-controlling mechanism.

The cell was enclosed in a Pyrex furnace tube, the ends of which were sealed with wax into grooves on the brass end plate. These end plates were water-cooled by means of copper coils silver-soldered to the outside edges. The top end plate had an opening which was sealed with an "O" ring and an aluminum lid. The anode extension rod and the cell thermocouple passed through gastight seals in this lid. A 7-in.-high by 2-in.-diam aluminum interchange chamber was attached to the furnace lid. The cathode extension rod passed up through the interchange chamber lid. A gate valve separated the interchange chamber from the main furnace chamber and deposits were removed and fresh cathodes were introduced without allowing the cell or its contents to come in contact with the outside atmosphere. The bottom end plate was solid except for two gastight fittings. One was the argon gas inlet and the other supported a second thermocouple. The cell was heated by means of a high-voltage, 10-kw, 450-kHz rf induction generator. Cell temperature was maintained within ±5°C.

A resistance furnace was used to fuse and dry the electrolyte salts in a controlled atmosphere. A vacuum oven was used for predrying the salts. A stainless steel dry box was used for crushing, weighing, and mixing the salts under an Ar or N_2 atmosphere.

Bend tests were made using an adjustable bend fixture (Fig. 2) which allowed the specimen to bend as a beam in a three-point loading. This test method is similar to the method used for testing refractory metal sheet (22). The fixture rolls were adjustable to 1.0, 1.25, and 1.75 in. and the radii of the wedge tips were 0.05 in., 0.10 in., and a sharp knife edge. The wedge and rolls were attached to a compression tester and were closed at a controlled rate.

Hardness was determined on a Tukon microhardness tester.

Preparation of electrolyte.—The electrolyte was made up of sodium and lithium metaborates ($NaBO_2$ and $LiBO_2$), sodium and lithium molybdates (Na_2MoO_4 and Li_2MoO_4), and molybdenum oxide (MoO_3). The salts were obtained from commercial sources and were of the highest quality available. The $NaBO_2$, which was received with 4 molecules of H_2O, and the $LiBO_2$, which contained only a small amount of H_2O, were predried at 200°C in a vacuum oven at a pressure of < 0.2 mm Hg and then fused at 980° and 900°C, respectively. The Na_2MoO_4 and Li_2MoO_4 were fused and the MoO_3 was dried at 600°C. The salts were always fused under an argon atmosphere and in platinum dishes. Spectrographic analyses of the dried salts are shown in Table I.

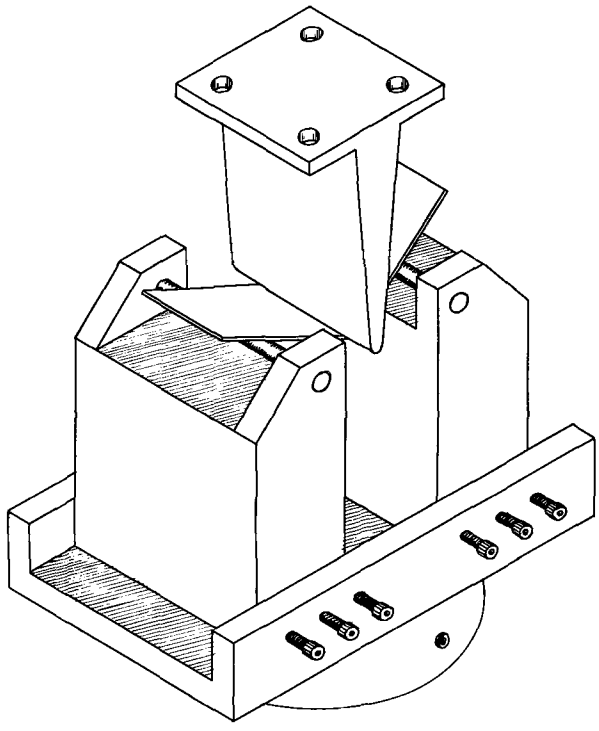

Fig. 2. Adjustable bend vise and wedge assembly, showing three-point loading of a bend specimen.

The fused salts were crushed in the dry box under a dry atmosphere of N_2 or Ar. Proper proportions of the salts were transferred to a bottle; the bottle was tightly sealed, removed from the dry box and tumbled for several hours. The mixture was then transferred to the cell.

Preparation of electrodes.—Anodes were made of cold-rolled molybdenum sheet and had a purity of 99+%. Prior to weighing, they were washed in warm, soapy water, hand rubbed with pumice, rinsed with distilled water, washed with alcohol, and air-dried. The nickel, stainless steel, and Inconel cathodes were wet ground on 80 and 120 grit belts prior to the washing treatment above. Copper and graphite cathode surfaces were hand ground with 3/0 emery paper prior to the washing treatment. Graphite electrodes were oven-dried to remove any water from the internal pores.

Electrolysis.—The dry weight of electrolyte used in the experiments was about 500-1400g. Electrolysis must be performed under an inert atmosphere and the electrolyte must be free of H_2O. Therefore, the replacing of air with argon in the furnace chamber was started immediately after placing the crucible and mixed proportions of electrolyte in the chamber and securing the chamber lid. Argon continuously flowed through the furnace chamber throughout the heating, the electrolysis, and the cooling periods at a rate of 150 cc min^{-1} and at a pressure of about 1½ in. of H_2SO_4. The electrodes were immersed in the molten electrolyte with a small applied potential to eliminate any corrosion of the cathode and contamination of the bath.

The cathode was rotated at 250 rpm during electrolysis to agitate the bath and eliminate stratification of the electrolyte. Cell current and voltage were continuously measured and recorded throughout the experiment. Cell voltages were measured outside the

cell chamber and included the voltage drops through the connections, the extension rods, and the mercury rotating assembly. The resistance of these was measured at approximately 0.049 ohms and was considered negligible. The quantity of electricity was determined by a copper coulometer.

"Conditioning" of the electrolyte was required for new batches and for electrolytes which had become contaminated with air or water vapor. A "conditioning" run consisted of an electrolysis at a high current density with molybdenum electrodes.

After electrolyses, the electrodes and deposits were washed in warm distilled water for several hours. Loose material was removed at this time. Then the electrodes and deposits were washed in distilled water, rinsed in alcohol, and air-dried. The loose material was collected and treated in the same manner as the adherent deposit. Loose material was usually weighed separately.

Evaluation of the deposits.—Anode and cathode current efficiencies were based on changes in the weights of the electrodes and the weight of copper deposited in the copper coulometer. The thickness of the deposit was calculated from the weight of the adherent deposit and the area of the plate, using the value of 10.2g cc^{-1} for the density of molybdenum.

Samples for metallurgical and microhardness examinations were cut from the "as-plated" deposits and from deposits which had been subjected to the controlled bend tests. The samples were cut from edges of the deposits and from the central areas of the deposit surfaces. The samples were mounted in Lucite in a manner suitable for studies of the substrate and coating cross sections. They were polished to a mirror finish and some were etched with a 3% $K_3Fe(CN)_6$-0.5% NaOH solution. Hardness measurements were made on the mounted samples at points adjacent to the substrate, adjacent to the surface of the coating, and halfway between these two points. In the samples which were bent, the hardness measurements were made on both the tensile-stressed and the compressive-stressed coatings. The hardness indentations were made parallel to the substrate and perpendicular to the columnar structure of the coatings. The average of several indentations was calculated for each microhardness number.

Electron probe analyses were made on samples cut from the corners of the Mo coatings by the X-ray Section of the College Park Metallurgy Research Center. The concentration profiles were made along a path perpendicular to the sample surface. The probe spot was at least 2μ in diameter. Semiquantitative spectrochemical analyses were made on crystals of nonadherent metal scraped from the surfaces of the deposits.

Experimental Results and Discussion

Deposits made under optimum conditions.—During this investigation, the optimum cell conditions for electroplating molybdenum coatings were determined. The optimum initial electrolyte contained, on a dry weight basis, 55.5% $NaBO_2$, 41.9% $LiBO_2$, 1.0% Na_2MoO_4, 0.9% Li_2MoO_4, and 0.7% MoO_3. Hereafter in this paper, this composition of electrolyte is called the standard electrolyte. The optimum cathode C.D. was 3.1-6.2A dm^{-2} (0.2-0.4A $in.^{-2}$) and the cathode was rotated. The optimum bath operating temperature was 900°C and the cell was operated under a dry inert atmosphere.

Coherent, adherent coatings of molybdenum were deposited on nickel, Inconel (Fig. 3), Carpenter 20 stainless steel, copper, graphite, and molybdenum sheet. A smooth, uniform coating of molybdenum was deposited on a stainless steel pipe, tees, elbows, and plugs (Fig. 4). Cathode deposit current efficiencies were above 95%. The apparent anode current effi-

ciencies based on total anode weight losses were almost always above 100%. Deposits were up to 13 mils in thickness. A summary of results of typical deposits is given in Table II.

Microscopic examination showed that the coatings were composed of closely packed crystals. X-ray diffraction patterns identified the crystals as cubic with predominantly cubic (100) and dodecahedron (110) faces on the surface of the sample. Metallographic studies showed the crystals have an elongated columnar structure (Fig. 5).

Electrolyte composition.—The borate (BO_2^-) and molybdenum (Mo) contents of the electrolyte must be maintained within definite concentration ranges to obtain satisfactory electrodeposition of molybdenum (23). The concentration ranges can be defined in terms of a BO_2^-:Mo weight ratio and a molybdenum weight percentage. To obtain smooth, adherent, coherent metallic molybdenum coatings, the electrolyte must contain from 1.0 to 3.3% Mo and have a BO_2^-:Mo ratio of 75:1 to 21:1. The initial mixture of the standard or optimum electrolyte contained 1.4% Mo and had a BO_2^-:Mo ratio of 52:1. The BO_2^-:Mo ratio and the molybdenum content of an electrolyte changed slightly with each electrodeposition test owing to the difference between the anode and cathode current efficiencies. One standard electrolyte was still operable after 220 hr of electrodeposition time covering 15 months. If necessary, electrolyte composition can be adjusted by small additions of the proper components.

Deposits made from electrolytes which contained less than 1% Mo and had BO_2^-:Mo ratios of approximately 80:1 were partially in the form of nonadherent powders. When electrolytes contained less than 0.7% Mo and had BO_2^-:Mo ratios of approximately 100:1, only nonadherent powders were obtained; however, the cathode current efficiencies were above 90%. When the initial electrolyte contained only the borate salts, enough molybdenum accumulated in the electrolyte after several hours as a result of anode solution to enable deposition of a nonadherent powder at a low current efficiency.

Deposits made from an electrolyte which contained somewhat more than 3.3% Mo were chiefly in the form of smooth, adherent, and coherent coatings. These were partially covered with dark, flat, hexagon-shaped nonmetallic crystals. Cathode current efficiencies were low. When electrolytes contained 6% Mo and had a BO_2^-:Mo ratio of 9:1, the deposits were entirely nonmetallic crystals. Furthermore, even without a flow of current, these crystals formed in a fused salt mixture which contained 23% Mo and had a BO_2^-:Mo ratio of 18:1. Later, upon the application of d-c current, these crystals were deposited on the cathodes. Chemical analyses of several samples of these crystals showed that they contained 67-69% Mo, 2.5-3.7% Li, and 0.7-0.3% Na; the balance is assumed to be oxygen. X-ray diffraction patterns of the crystals did not correspond to any known compounds.

Cell operation.—Two-hour deposits of molybdenum were made at 900°C on Inconel cathodes at current densities of 3.1 to 12.5A dm^{-2} (0.2-0.8A in.$^{-2}$). The data are summarized in Table III. At C.D. up to 7.7A dm^{-2}, the deposits were smooth; however, the deposits made at C.D. of 9.3A dm^{-2} were rough and had heavy edges (Fig. 6).

* Current density, 6.2A in.$^{-2}$; Inconel cathodes rotated at 250 rpm.

Three deposits were made to a thickness of 5.6 mils at C.D. of 12.5, 6.2, and 3.1A dm^{-2} for 2, 4, and 8 hr, respectively (Table III). These experiments indicated low-C.D., long-time deposits are smoother and more coherent than high-C.D., short-time deposits of equal thickness.

Two-hour deposits were made on Inconel cathodes at a C.D. of 6.2A dm^{-2} and at electrolyte temperature of 750°-950°C. The results are summarized in Table IV. Cell voltage decreased as the temperature increased. Coatings made at 875°-925°C were bright, adherent, and consolidated. Deposits made at 850°C were partially in the form of dark, hexagonal, flat, nonmetallic crystals which covered a smooth consolidated plate. At 750° and 800°C, the major portion of the deposits was dark flakes. The composition of these crystals was the same as those described in a previous section. Attempts to make deposits at 950°C were abandoned because of excess volatilization of the bath.

Platinum crucibles used in the molybdenum investigation showed no corrosion or deterioration as a result of contact with the bath. Graphite crucibles were found to be unsuitable. The repeated cooling and heating of the electrolyte caused small particles of graphite to break off and float on the surface of the electrolyte. Agitation of the electrolyte with these particles in suspension produced rough, dark deposits. An Inconel crucible, with a weld seam corroded at the weld, caused contamination of the electrolytes and was unsatisfactory for molybdenum deposition.

Examination of deposits on several substrate materials.—One- and 2-hr deposits of molybdenum were made at 900°C on graphite, Inconel, Carpenter 20 stainless steel, and nickel cathodes at current densities of 3.1, 6.2, and 9.3A dm^{-2}. All deposits had cathode current efficiencies of over 95%. The deposits on metal substrates were bright, smooth, consolidated coatings, but those on a graphite substrate were pitted and easily chipped.

Coatings 0.7-4.2 mils in thickness deposited on the Inconel, Carpenter 20 stainless steel, and nickel substrates were bent to angles of approximately 90° on the adjustable bend apparatus. The fixture rolls were spaced 1.0, 1.25, and 1.75 in. for the stainless steel, nickel, and Inconel substrates, respectively. The bend tests did not cause the coatings to separate from the metal substrates; however, examination of the outside surface area of a bent specimen showed small parallel cracks running from edge to edge. Microscopic and metallographic examinations of samples cut from these areas showed the coatings were cracked along the crystal boundaries perpendicular to the substrate on the tensile side (outside) of the bend (Fig. 7), while no such cracking occurred on the compressive side (inside) of the bend. Regardless of the substrate material, the thickness of the deposits, or the specifications of the test, all specimens showed the same types and degrees of failure.

Electron probe analyses were made on cross sections cut from molybdenum coatings deposited on Inconel, Carpenter 20 stainless steel, and nickel substrates. Lα radiation was used for the analysis of molybdenum and Kα radiation was used for the analyses of Fe, Ni, and Cr. Figure 8 is a reproduction of the electron probe chart obtained from the analysis of a molybdenum coating on a nickel substrate. The dip in the nickel line begins as the circular probe beam spot, which is a minimum of 2μ, approaches the molybdenum coating and the line reaches zero when the spot falls completely on the coating. The molybdenum line goes from zero to maximum intensity at the same time. This change in the relative intensities

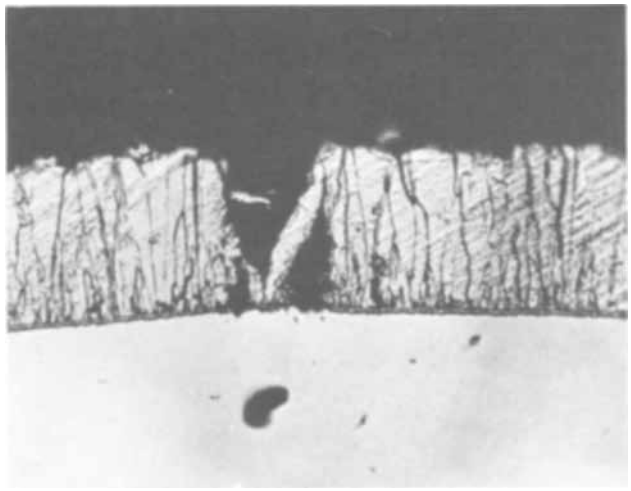

Fig. 7. Molybdenum deposit on nickel substrate, showing crack in molybdenum. Cathode and deposit bent 92° with knife edge between a horizontal distance of 1.25 in.; rate of wedge travel, 1 in. min^{-1}. Sample etched with 5 g/liter NaOH, 30 g/liter $K_3Fe(CN)_6$ (original mag., 500X).

in an area of 5-8μ is not evidence of interdiffusion between the molybdenum coating and the nickel substrate. The electron probe analyses of coatings on Inconel and stainless steel substrates gave similar results.

Average microhardnesses for the molybdenum coatings deposited on nickel, Inconel, and Carpenter 20 stainless steel substrates were 250-270 KHN_{100}. The hardness of the molybdenum anode material was 280 KHN_{100}. Spectrochemical analysis did not indicate any noticeable refinement of the molybdenum metal.

Conclusions

Smooth, adherent, consolidated coatings of molybdenum can be electrodeposited from a $NaLiB_2O_4$-$NaLiMoO_4$-MoO_3 fused salt bath. The composition range of the electrolyte was determined and was found to be critical. The optimum conditions of cathode current density and electrolyte temperatures were determined. The process is a true electrodeposition process and not a diffusion process.

Electron Resists for Microcircuit and Mask Production

M. Hatzakis

International Business Machines Corporation, Thomas J. Watson Research Center, Yorktown Heights, New York

ABSTRACT

The properties of poly-(methyl methacrylate), a new electron resist developed at IBM Research, are presented in comparison to commercial photoresists under electron beam exposure. It is shown that methacrylate resist, with suitable processing, presents a means for submicron device fabrication with reasonable speed. Transistors with one- and half-micron emitter stripe widths have been fabricated using this resist as a medium for diffusion masking with SiO_2. Also, a method for producing high-resolution, defect-free masks through methacrylate resist is presented.

The advantages of using electron beam systems rather than light optical systems for the exposure of photoresist layers for microcircuit fabrication are the resolution, power density, and deflection capabilities of electron beams. It is possible to build a practical electron beam system that produces a 10^{-8}A, 2000Å diameter electron beam that can be deflected over a 50- x 50-mil field. This would require a beam deflection over 6250 spot diameters in two dimensions, and a beam convergence angle of approximately 8 x 10^{-3} radians, with the assumption that the aberration contribution is less than 10% of the final spot diameter over the field. The above figures represent only an estimate and are obtained through the uniform field aberration expression, assuming a 1-cm long deflecting field (1). The beam current of 10^{-8}A can be realized by using a LaB_6 electron gun with a brightness of 2 x 10^5 A/cm^2-steradian which is within the range of the long-life cathode reported by Broers (2). Such a system, together with a suitable electron resist, is capable of fabricating submicron geometry devices with extremely high packing densities. Also, it has been shown theoretically and experimentally (3) that a decrease in the size of the transistor active area, and particularly the emitter width, results in an increase in transistor switching speed. Since practical optical

systems are ultimately limited in resolution by the wavelength of light, electron beams present the only known means for fabricating submicron structures.

Electron Resist Evaluation

Initially, the resolution of several commercially available photoresists was evaluated under electron beam exposure. The resists tested included KTFR,[1] KOR,[1] KPR,[1] and KMER,[1] all of which have been investigated already for electron beam exposure sensitivity by Thornley and Sun (4) who reported that a charge density of approximately 10^{-5} coulombs/cm^2 at 10-20 kV was required in each case for correct exposure. In order to evaluate edge resolution, lines 2μ wide were exposed with the beam on resist-coated silicon wafers. After exposure, the resists were developed and the substrates broken in a direction perpendicular to the direction of the lines. The cross sections were then observed in a scanning electron microscope with 200Å resolution. These investigations revealed sloping profiles on either side of the lines extending as far as 2μ beyond the edges of the lines. Figure 1 shows a scanning electron micrograph of the cross section of a 2-μ wide line (as indicated by the arrows) with the sloping edge clearly visible. In this typical test, a 5000Å layer of KTFR was exposed with a 1000Å, 12-kV beam which was wobbled to 2μ with a fast scan, while a slow scan swept the beam in the direction of the line. KOR, KPR, and KMER exhibited similar edge effects. The sloping edge profiles (most probably caused by a combination of beam scattering in the resists and substrates as well as the exposure characteristics of the negative photoresists) make these resists unsuitable for high-resolution work (line width 1μ or less).

Shipley resist AZ-1350,[2] was tested next and was found to develop correctly only in a narrow range of exposure around 5×10^{-5} coulombs/cm^2 $\pm$ 50% at 14 kV. For this reason, and also because Shipley resist cannot be used in basic etch baths, it was considered unsuitable for the reliable microcircuit fabrication system.

Poly-(methyl methacrylate) resist, developed at the IBM Watson Research Center through controlled polymerization of the monomer (5) was tested and found to exhibit most of the properties desirable for high-resolution, electron beam exposure. Poly-(methyl methacrylate), henceforth abbreviated to methacrylate, is a positive electron resist, insensitive to light, and only slightly less electron sensitive than commercial photoresists. The exposure characteristics of a 3000Å thick resist layer are shown in Fig. 2 at 7.5, 10, and 14 kV. It can be seen that the exposure latitude of this resist extends over an order of magnitude in charge density from 5×10^{-5} to 5×10^{-4} coulombs/cm^2. Beyond this charge density, cross-linking dominates so that overexposed resist cannot be removed easily.

Resist exposure within the charge density shown above results in random scission of the molecule chains which effectively reduces the average molecular weight of the polymer. Development is based on the change in solubility in the exposed areas due to the molecular weight reduction, and it is accomplished by soaking in a mixture of two liquids, one of which is a solvent and one of which is a nonsolvent of the original polymer. During electron beam exposure of the resist film, a small fraction of the polymer is decomposed into volatile products due to the random scission of the macromolecules, but this was found to reduce the original resist thickness by less than 10% after exposure at 5×10^{-4} coulombs/cm^2.

The methacrylate resist used in all the experiments described below was prepared by dissolving the polymer in methyl ethyl ketone in various concentrations. When spin coated at 5000 rpm on oxidized silicon wafers, 7% polymer concentration produced a dried resist thickness of 3000Å. For a 5000Å resist thickness, a 10% polymer concentration was required.

All resist-coated samples were baked at 170°C for at least 15 min before exposure and were subsequently exposed in a vacuum of approximately 5×10^{-6} Torr. All samples were developed immediately after exposure by soaking in a 3:1 solution of isopropyl alcohol and methyl isobutyl ketone for 1 min followed by a 30-sec spray with the same solution.

In order to study resolution, lines were exposed with an electron beam on silicon wafers coated with this resist. Figure 3 shows a resist pattern with lines 1μ wide separated by 0.5μ. This pattern was generated by a 1000Å diameter electron beam under the control of an optical scanner (6). The scanner (*see* Fig. 4) consists of a 5-in., high-resolution C.R.T., which generates a 1000 line raster that is projected through a lens onto a 8.5- x 11-in. mask. Light transmitted through the clear areas of the mask falls on a photomultiplier, and the resulting electrical signal is used to modulate the beam. Exposure time for the optical scanner system was set at 10 sec as a compromise between electron beam performance and exposure speed.

Chemical etching experiments indicated that 2000Å resist layers can withstand basic or acidic etch baths for as long as 10 min. To study etch characteristics in buffered HF baths, silicon wafers oxidized with 3000Å of SiO_2 were coated with methacrylate resist, baked for 30 min at 170°C to improve resist adhesion and to complete solvent evaporation, exposed to a line pattern by the beam, and developed. Subsequently,

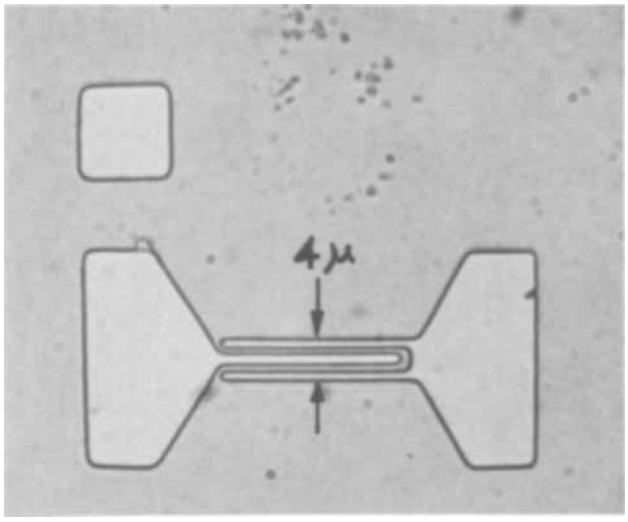

Fig. 3. Electron beam exposed and developed pattern on methacrylate resist.

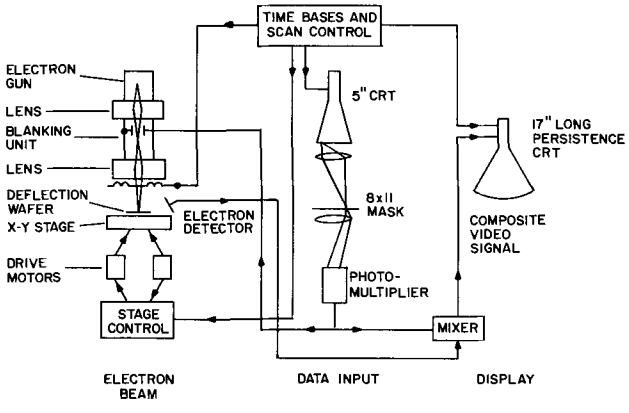

Fig. 4. Schematic of the electron beam machining system

the wafers were etched in buffered HF without agitation until all of the SiO_2 was removed in the lines. It was found with this technique that considerable widening of the lines was taking place during etching. It was also found that the widening effect could be reduced or eliminated if the wafers were baked after resist development and before chemical etching. To study this effect in more detail, a wafer with resist lines was broken in a direction perpendicular to the direction of the lines and three sections of the same line structure were observed in the scanning microscope after processing (*see* Fig. 5). Sample "A" shows the cross section of two 0.5-μ wide lines and one 0.2-μ (2000Å) wide line, exposed and developed in 0.5-μ thick resist layer without postbaking. Of particular interest is the slight undercut in the edges of the two 0.5-μ wide lines. Samples "B" and "C" indicate the effects of postbaking on the edge structure of the lines. If samples "B" or "C" are used in etching the underlying SiO_2, it is clear that the resultant lines would be even narrower than the original lines in sample "A." This phenomenon presents the possibility of adjusting the line width in the etched pattern even after resist development. The resolution of the resist seems to be limited only by the undercut effect which, in a 0.5-μ resist layer exposed at 12 kV, is 2-5°. This means that the bottom of a 0.5-μ deep line in resist is recessed by at most 500Å from the top edge of the line. For thinner resist layers, the effect is considerably reduced. An example of the resolution obtained in SiO_2 etched in HF is presented in Fig. 6. (The fine structure on the edges of the cut is an artifact due to mechanical vibration of the specimen in the scanning microscope.) It is believed that an optimized

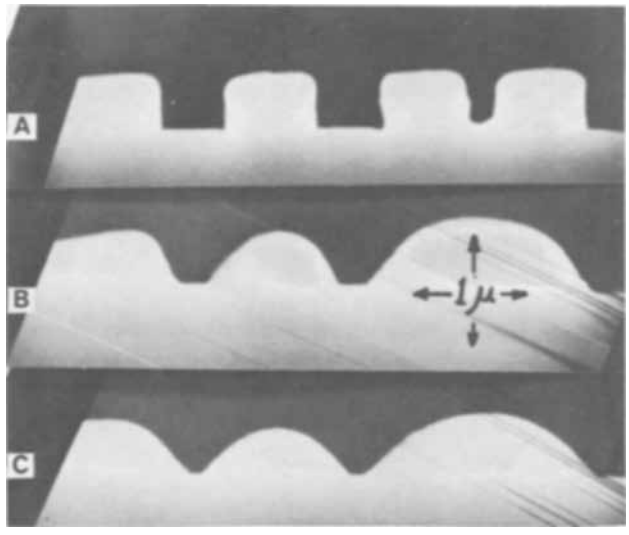

Fig. 5. Cross section of resist lines on SiO_2: A—before baking; B—after baking at 135°C, 5 min; C—after baking at 135°C, 10 min.

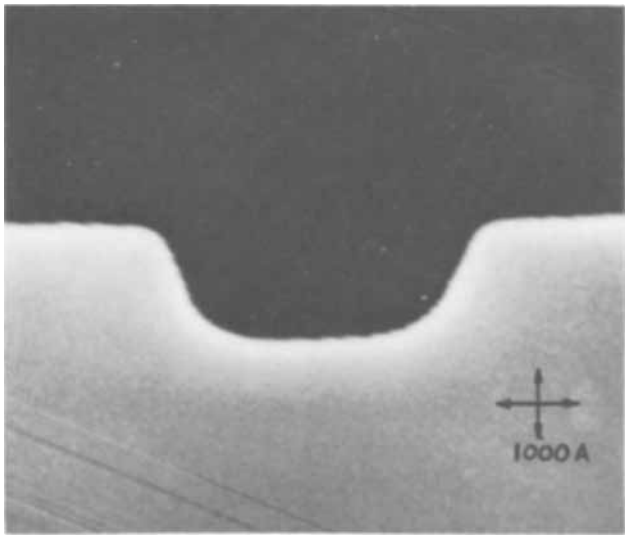

Fig. 6. Profile of a 3000Å wide and 1500Å deep cut in SiO_2 etched in HF through methacrylate resist.

combination of reduction in resist thickness and postbaking can produce even higher resolutions.

Metallization

As can be seen from the above results, methacrylate resist is an excellent medium for submicron diffusion masking with SiO_2. However, metallization presents an additional problem in microcircuit and device fabrication, particularly in the contact area of the base and emitter of submicron transistors. It is well known that aluminum (the most commonly used contact metal) structures produced by chemical etching exhibit edge irregularities of the order of 1μ due mainly to nonuniformity in the evaporated aluminum which causes nonuniform etching rates. These irregularities impose a limitation on the minimum aluminum line width that can be reliably etched that is well over 1μ.

A new method of metallization has been developed through the use of the undercut effect in the methacrylate resist described above. Figure 7 illustrates this method in which the metal is evaporated onto the wafer after the application and exposure of the resist. Note that the undercut in the resist structure results in a discontinuity between metal in the slot and metal on top of the resist, as long as the metal thickness is kept below the resist thickness. This discontinuity allows solvent to penetrate to the unexposed resist

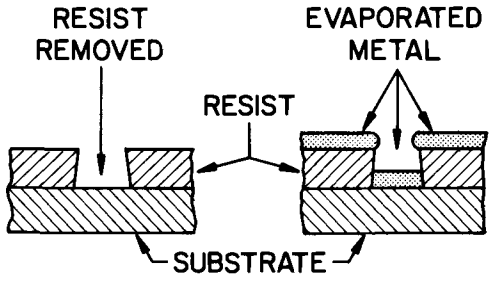

Fig. 7. Metallization through a methacrylate resist mask

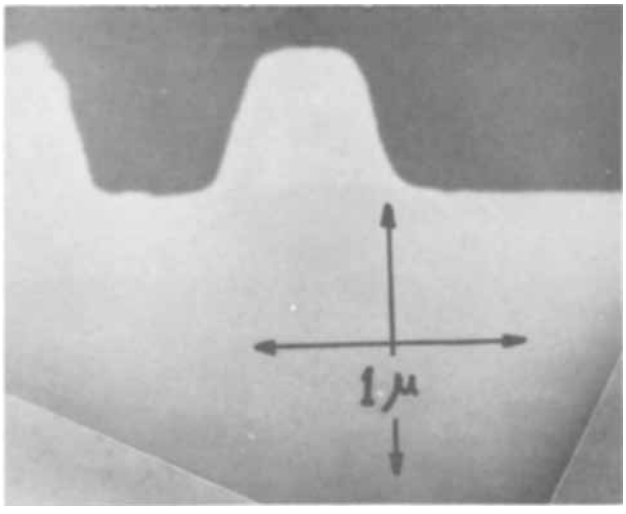

Fig. 8. Cross section of aluminum lines evaporated through a methacrylate resist mask.

layer and remove the resist together with the metal over it. This stripping is accomplished in hot trichloroethylene with moderate agitation. Figure 8 is a scanning electron micrograph of a cross-section of aluminum lines fabricated in this manner. The center line is 0.5μ high and 3000A wide at the top. The excessive tapering of the sides was caused by the resist being overdeveloped before the aluminum evaporation, and by too short a distance between the evaporating source and the sample due to the limited size of the evaporator.

Transistor Fabrication

Planar silicon transistors have been fabricated, with methacrylate resist for base and emitter diffusion masking through HF-etched SiO_2 and aluminum contact metallization, using the process described above (section on Metallization). Figure 9 is a scanning electron micrograph of a typical transistor at a viewing angle of 45°. The base area for this device is 10 x 15μ, the emitter stripe width is 0.8μ, and the metallization stripe width is 1μ. The transistor is one of 32 transistors made on a silicon epitaxial wafer. All of these transistors show very similar characteristics, a beta of 25, and a cutoff frequency (f_T) of 2.2 GHz. This is much lower than the expected value of 10 GHz and is attributed to the lack of an appropriate diffusion process for these dimensions.

Figure 10 is a similar micrograph of a 0.5-μ (metallization stripe width) dummy transistor which contains all the steps required except diffusions.

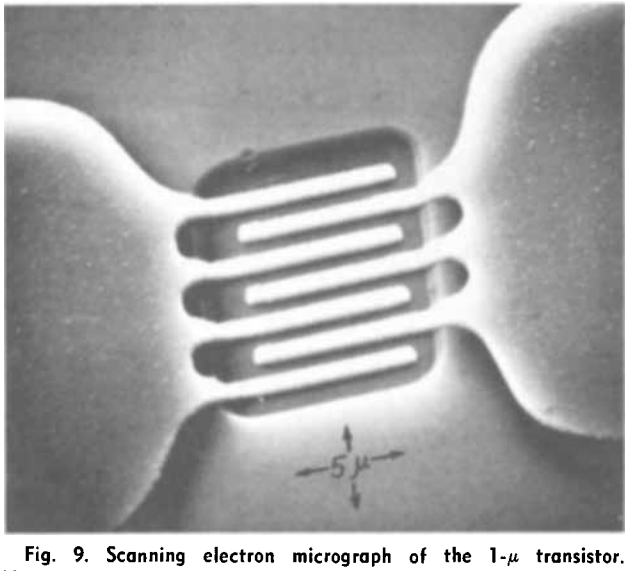

Fig. 9. Scanning electron micrograph of the 1-μ transistor. Viewing angle: 45°.

Mask Fabrication

The metallization process described above can be applied in a slightly modified manner to instances of mask fabrication where more durable masks are re-

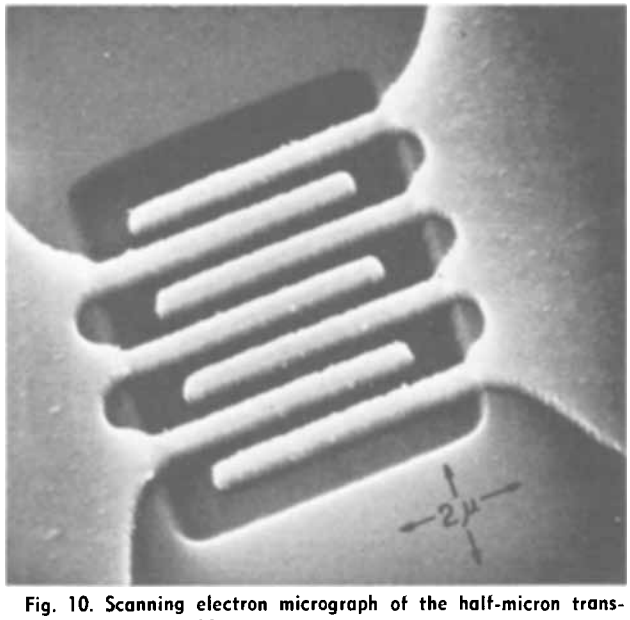

Fig. 10. Scanning electron micrograph of the half-micron transistor. Viewing angle: 30°.

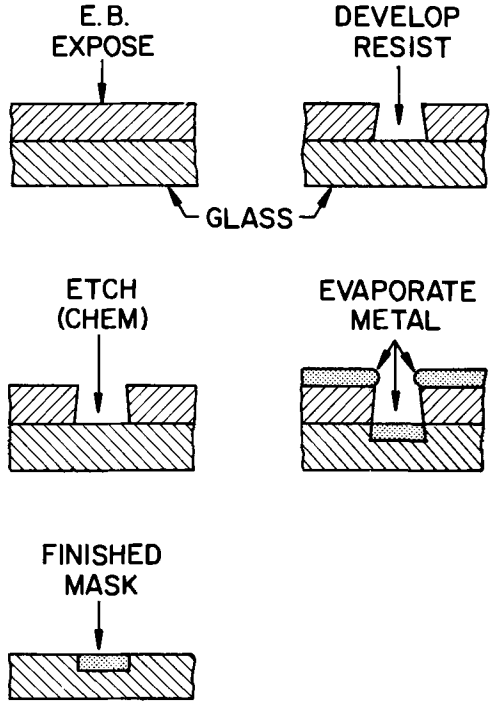

Fig. 11. Mask fabrication steps

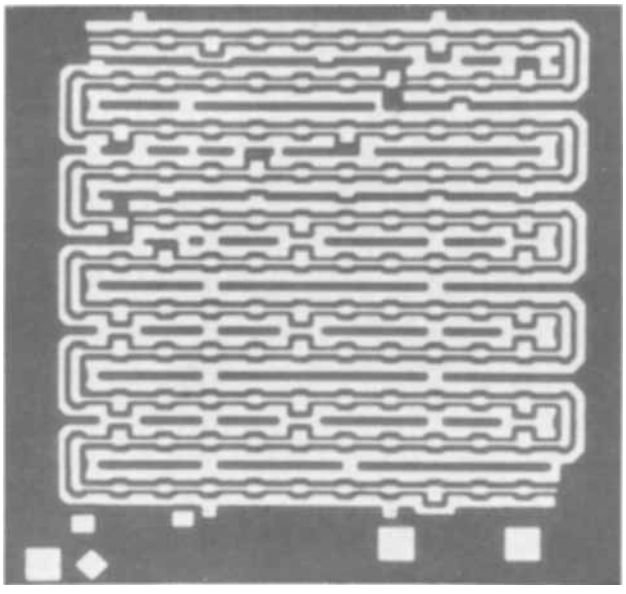

Fig. 12. Reflected light photo of a 10- x 10-mil mask made by evaporation of Al through a methacrylate resist.

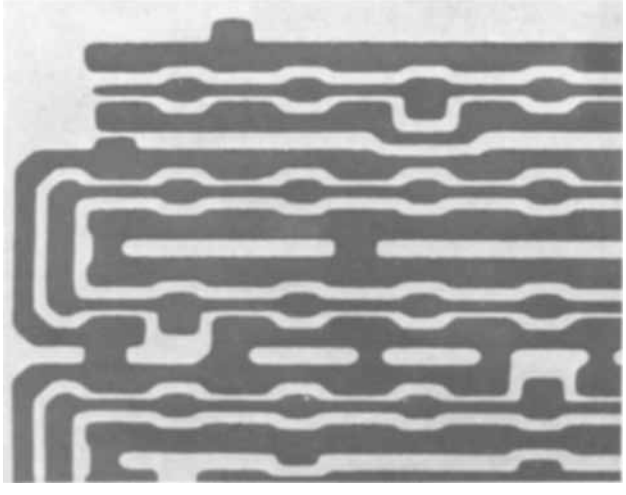

Fig. 13. Transmitted light photo of part of the mask shown in Fig. 12. Minimum line width: 1μ.

quired, free of defects, and with high edge resolution. One solution to the mask problem is the chromium-on-glass mask. Unfortunately, chromium mask fabrication is hampered by two conflicting requirements: the metal layer must be kept very thin in order to obtain good edge resolution, and kept thick in order to avoid pinhole formation. The process presented here eliminates the conflict and makes it possible to produce masks with metal thicknesses as high as 0.5μ (5000Å) while maintaining excellent edge definition. The metal can be on the surface of the glass substrate or it can be completely, or partially, buried in the glass. The fabrication steps are outlined in Fig. 11. One other advantage of this method is that the mask can be made from any opaque material that can be evaporated or plated, so long as the substrate temperature does not exceed 100°C during deposition.

Figure 12 is a reflected light photograph of a 4000Å thick aluminum mask partially buried in a fused quartz substrate. Minimum width of the metal lines is 1μ. Figure 13 is a transmitted light photograph of a section of this mask where, again, the minimum line width is 1μ. This mask was also made from a 8.5- x 11-in. transparency using the optical scanner shown in Fig. 4.

Conclusions

A process has been presented which allows the fabrication of microcircuits and devices with a resolution exceeding that of any previous practical process. Devices have been fabricated with almost 100% yield on several silicon wafers. In addition, a method for fabricating high-resolution, defect-free masks has been outlined. The process presents possibilities for high packing density and high speed integrated circuit fabrication if used with a high-performance electron beam system and pattern generator.

A Contribution to the Theory of Electrolytic Chlorate Formation

T. R. Beck*

Boeing Scientific Research Laboratories, Seattle, Washington

ABSTRACT

Analysis of literature data indicates that anodic discharge of hypochlorite in relatively concentrated salt solutions approximately fits the Ibl-Venczel correlation for mass transport at gas evolving electrodes. In this correlation, the mass transfer coefficient varies as the one-half power of the gas evolution rate. Equations are derived for a model system employing a separate electrolyzer and reactor with circulating flow between them, considering the Foerster mechanism for homogeneous formation of chlorate in solution and the mass transport limited anodic discharge. Efficiency of chlorate formation is related to appropriate dimensionless groups containing the important system parameters. It is proposed that the model provides a basis for economic optimization of an electrolyzer-reactor flow system.

The production of sodium chlorate by electrolysis of relatively concentrated neutral sodium chloride solutions is an old and well-known commercial process (1). Although Foerster and co-workers (2) formulated the cell reactions that to date have not been superseded, the process is still not completely quantitatively understood. Foerster showed that chlorine produced at the anode by discharge of chloride is hydrolyzed to hypochlorite which in turn is converted to chlorate in the bulk solution by auto-oxidation. He also showed that hypochlorite is anodically discharged to form chlorate and oxygen. The latter process leads to a current efficiency of 66.7% for chlorate formation compared to 100% for the solution reaction. The rate constant for the solution reaction was determined by Foerster (2) and by Knibbs and Palfreeman (3). Although Foerster apparently recognized that hypochlorite discharge is mass transport controlled, he did not treat it quantitatively.

The first attempt at quantitative treatment of the mass transport of hypochlorite to the anode was made by de Valera (4). He made an analysis of cell data in which he assumed a constant diffusion layer thickness of 0.05 cm at the anode, which gave an approximate fit to the data. Hammar and Wranglen (5) conducted experiments which showed that hypochlorite discharge at both the anode and cathode (without chromate addition) is mass transport limited. They recognized that gas evolution at the cathode affected the diffusion layer thickness and, at the suggestion of Ibl (6), applied the correlation of Ibl and Venczel (7, 8) which is described later.

Ibl and Landolt (9) have done experiments and analysis for a flowing electrolyte system with well-defined hydrodynamic conditions using dilute sodium chloride solution. They found that in dilute sodium chloride solution, chlorine hydrolysis occurred within the diffusion layer and that a model involving coupling of mass transfer with a first-order chemical reaction for the hydrolysis proceeding in the diffusion layer adequately described their data.

The present paper deals with a treatment of mass transport of hypochlorite to the anode for the concentrations and conditions of commercial electrolysis and with an analysis of a system consisting of a separate cell and reactor. This work was first presented in 1961 (10) and is now modified in accordance with new data available in the intervening period. The whole analysis presented here is based on data available in the literature. Although the analysis is limited to the chlorate system, it is believed that the concepts involved could be applied to other electrochemical systems in which there are simultaneous reactions in solution and mass transport limited electrode reactions.

The reason for considering the system with separate electrolyzer and reactor is that process economics dictates a high current efficiency for chlorate formation and a low cell voltage. The two requirements are contradictory unless the electrolyzer and reactor are separated. A relatively large reactor volume is required to promote the formation of chlorate by the higher-efficiency solution reaction, whereas a minimum anode-cathode spacing is required in the cell to minimize cell voltage. In practice, these requirements are now met by suspending a battery of bipolar graphite electrodes in a large tank and using convection developed by the cell gases to circulate the electrolyte or to use a separate cell and reactor with circulating pump.

A review of cell reactions, kinetics of the solution reaction, and mass transport at the anode is presented as background for the model for separate electrolyzer and reactor.

Reactions

The chlorate cell reactions and stoichiometry proposed by Foerster (2) are used as a basis for the model:

Anode reactions

1. $6Cl^- \rightarrow 3Cl_{2(aq)} + 6e$
2. $6ClO^- + 3H_2O \rightarrow 2ClO_3^- + 4Cl^- + 6H^+ + 3/2\,O_2 + 6e$

Solution reactions

3. $3Cl_{2(aq)} + 3H_2O \rightarrow 3HClO + 3Cl^- + 3H^+$
4. $HClO \rightleftarrows ClO^- + H^+$
5. $ClO^- + 2HClO \rightarrow ClO_3^- + 2Cl^- + 2H^+$

Cathode reaction

6. $6H^+ + 6e \rightarrow 3H_2$

The first anode reaction is discharge of chloride ion to form dissolved chlorine near the reversible potential for this reaction. The dissolved chlorine hydrolyzes in solution to form hypochlorous acid. Ionization of hypochlorous acid gives hypochlorite ion in equilibrium with the acid. Reaction of hypochlorite ion and hypochlorous acid gives chlorate ion in solution. This sequence would give 100% current efficiency for chlorate formation.

Discharge of hypochlorite anodically gives chlorate and oxygen. The potential for hypochlorite discharge is well below the anode potential (2). In slightly alkaline solutions, reactions 1 and 2 predominate and the current efficiency for chlorate formation approaches 66.7%. In neutral or slightly acid solutions with a large cell volume, reactions 1, 3, 4, and 5 predominate and

the current efficiency approaches 100%. There is a limit to the beneficial effect of increasing acidity, however, because gaseous chlorine is liberated.

With chromate inhibitor, cathodic reduction of hypochlorite and chlorate can be minimized and hydrogen is essentially the only cathode product.

Chemical Reaction Rate

Foerster (2) and Knibbs and Palfreeman (3) present reaction rate data for the purely chemical conversion of hypochlorite to chlorate. The rate of change of concentration of hypochlorite ion is first order in respect to ClO^- and is second order in respect to hypochlorous acid concentration, so the reaction rate can be expressed by:

$$\frac{d(C_{ClO-})}{dt} = -k(C_{ClO-})(C_{HClO})^2 \qquad [1]$$

The temperature dependence of the apparent rate constant, k, from 30° to 80°C was determined by Knibbs and Palfreeman (3).

The exact mechanism may be different than that implied by these expressions, as shown by Lister (11), but the expressions provide a suitable description for the present analysis.

Mass Transport of Hypochlorite

The correlation of mass transfer coefficient for hypochlorite discharge *vs.* the anodic gas evolution rate calculated from Foerster's data (2) was first presented in 1961 (10). The correlation was compared to data of Ibl and Venczel (7) developed at about the same time for reduction of Fe^{+3} at a hydrogen evolving platinum electrode. Calculations based on the recent data of Hammar and Wranglen (5) are now added to the correlation. Experimental conditions used by the three sets of investigators are summarized in Table I and the correlation is plotted in Fig. 1.

Ibl and Venczel (7, 8) showed that the mass transfer coefficient is relatively large at a gas evolving electrode compared to usual values for free convection and that it varies as approximately the one-half power of the gas evolution rate. The relatively large value compared to values for natural convection (without gas evolution) is because bulk solution displaces the gas bubbles at the electrode surface as they are released. This in effect short-circuits the diffusion layer. Ibl and Venczel derived an equation for this simple displacement model which gave an exponent of one half and a coefficient in

$$K_L = Bv^{1/2} \qquad [2]$$

that was close to their experimental value.

Mass transfer coefficients for hypochlorite discharge and gas evolution rate at the anode were calculated from the Foerster (2) and the Hammar and Wranglen (5) data using the equations[1]

$$K_L = \frac{i_a \epsilon_2}{C n_a \mathbf{F}} \qquad [3]$$

$$v_a = \frac{i_a R T \epsilon_2}{P n_a' \mathbf{F}} \qquad [4]$$

where ϵ_2 is the current efficiency for reaction 2 (oxidation loss of Hammar and Wranglen), $n_a = 1$ for reaction 2 (one electron per hypochlorite) and $n_a' = 4$ for oxygen. The Foerster data and calculated values of K_L and v are given in Table II. The following equations were used for the cathodic reduction data of Hammar and Wranglen:

$$K_L = \frac{i_K \epsilon_K}{C n_K \mathbf{F}} \qquad [5]$$

[1] Applies when transference is negligible as for the hypochlorite ion considered in this paper because of the excess of supporting electrolyte, NaCl.

$$v_K = \frac{i_K(1-\epsilon_K)RT}{Pn_{K'}\mathbf{F}} \quad [6]$$

where ϵ_K is their reduction loss, $n_K = 2$ for $ClO^- + H_2O + 2e \rightarrow Cl^- + 2OH^-$ and $n_{K'} = 2$ for hydrogen evolution.

Observations and tentative conclusions drawn from Fig. 1 are as follows:

1. The mass transfer coefficients calculated from the Foerster anodic oxidation data and the Hammar and Wranglen reduction data appear to fit the one-half power law (Eq. [2]).

2. The Foerster value of K_L when extrapolated to 25°C and the Hammar and Wranglen values of K_L for oxidation of hypochlorite fell above the Ibl and Venczel data, whereas the Hammar and Wranglen values of K_L for reduction fell below the Ibl and Venczel data. The differences are considerably larger than what might be expected for differences in diffusivities of the ions in the respective solutions based on the ratios of mobilities of Fe^{+3} and halide containing ions at infinite dilution[2] and the correction for viscosity of the H_2SO_4 and NaCl solutions.[3] Some other factors are apparently involved. It is possible that the high values of K_L for oxidation of hypochlorite are due to formation of hypochlorite within the diffusion layer by reaction 3 as found by Ibl and Landolt (9) for dilute NaCl solutions.

3. Stirring increases the value of K_L as indicated by the Foerster data at 12°C, where K_L was increased by more than a factor of two with a bent glass stirrer rotated at 1750 rpm inside the concentric gauze electrodes. It is suggested that the mass transfer coefficients resulting from gas bubble disengagement and from the convective diffusion layer are additive as these processes are essentially in parallel (14):

$$K_L = K_G + K_C \quad [7]$$

The flow conditions in the electrolyzer could therefore play an important but secondary role in determining the value of K_L.

Model of Electrolyzer-Reactor System

A schematic of the electrolyzer-reactor system is given in Fig. 2. The basic assumptions used in the model are listed in Table III. Equations describing the Foerster system of reactions are combined with material balances for the steady-state electrolyses system shown in Fig. 2.

Electrolyzer:

Hypochlorite formed by reactions 1 and 3 $= \dfrac{\epsilon_1 I}{2\mathbf{F}}$

Hypochlorite discharged by reaction 2 $= K_L A C_e$ [4]

Hypochlorite reacted by reaction 5 assuming Foerster kinetics $= k(C_{ClO^-})_e\,(C_{HClO})_e^2\,V_e = kf_eV_eC_e^3$ [5]

[2] From "Handbuch der Physik" (12), the ratio of equivalent conductivities at infinite dilution of Cl^- to $Fe^{+3} = 1.12$ and of ClO_4^- to $Fe^{+3} = 0.995$. The ratio of mobilities of ClO- and HClO to Fe^{+3} might also be expected to be near unity.

[3] From "International Critical Tables" (13), the ratio of viscosities of 2.5M NaCl to 1M H_2SO_4 at 25°C is 1.07. The ratio of diffusivities would be approximately the reciprocal, again near unity.

[4] It is assumed that both ClO- and HClO diffuse to anode because, even if only ClO- were discharged, reaction 4 should be fast enough to convert HClO to ClO- at the electrode surface. Hammar and Wranglen (5) show that efficiency for discharge of hypochlorite is independent of pH from pH 6 to 10, in support of this assumption.

[5] Combining $C = C_{ClO^-} + C_{HClO}$ with $\dfrac{(C_{ClO^-})\,(C_{H^+})}{(C_{HClO})} = K_i$

gives $C_{HClO} = \left[\dfrac{C}{1+\dfrac{K_i}{C_{H^+}}}\right]$ and $C_{ClO^-} = C\left[1-\dfrac{1}{1+\dfrac{K_i}{C_{H^+}}}\right]$

$\therefore (C_{ClO^-})\,(C_{HClO})^2 = C^3 f$, where $f =$

$$\left[\frac{1}{1+\frac{K_i}{C_{H^+}}}\right]^2 \left[1-\frac{1}{1+\frac{K_i}{C_{H^+}}}\right]$$

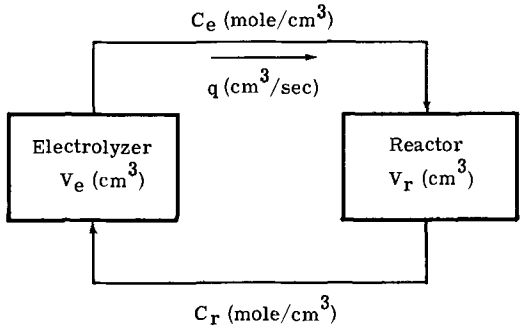

Fig. 2. Schematic of chlorate cell system with separate reactor

Hypochlorite in entering stream $= qC_r$

Hypochlorite in leaving stream $= qC_e$

Material balance gives:

$$qC_r + \frac{\epsilon_1 I}{2\mathbf{F}} = K_L A C_e + kf_eV_eC_e^3 + qC_e \quad [8]$$

Similarly for reactor, material balance gives:

$$qC_e = kf_rV_rC_r^3 + qC_r \quad [9]$$

Equation [3] rewritten:

$$I\epsilon_2 = K_L A C_e \mathbf{F}$$

A Faradaic balance gives:

$$\epsilon_1 + \epsilon_2 = 1 \quad [10]$$

Eliminating C_e, C_r, and ϵ_1 gives:

$$N_r\left[\frac{3/2\,\epsilon_2}{N_q} + \epsilon_2 + \frac{N_e}{N_q}\epsilon_2^3 - \frac{1}{2N_q}\right]^3 + 3/2\,\epsilon_2 + N_e\epsilon_2^3 - 1/2 = 0 \quad [11]$$

where:

$$N_e = \frac{kf_eV_eI^2}{K_L^3 A^3 \mathbf{F}^2}$$

(dimensionless electrolyzer number) [12]

$$N_r = \frac{kf_rV_rI^2}{K_L^3 A^3 \mathbf{F}^2}$$

(dimensionless reactor number) [13]

and

$$N_q = \frac{q}{K_L A}$$

(dimensionless circulation rate number) [14]

The electrolyzer and reactor numbers are essentially the ratios of the rate of the solution reaction in the electrolyzer and reactor, respectively, to the anodic discharge rate. The circulation rate number expresses the ratio of the rate that hypochlorite is carried out of the electrolyzer to the rate that it is anodically discharged.

Equation [11] is plotted in Fig. 3 in the form of ϵ_1 *vs.* $(N_e + N_r)$ with N_q as a parameter. The family of

Table III. Assumptions used in model

1. The system consists of a separate electrolyzer and reactor with circulating loop of electrolyte as shown in Fig. 2.
2. The Foerster reactions 1 to 6 describe the stoichiometry. No cathodic reduction of hypochlorite occurs with suitable addition of chromate. No OH^- or water is discharged at the anode to form oxygen.
3. The pH is high enough to avoid appreciable loss of chlorine or HClO.
4. Reaction 5 is kinetically limited in the bulk solution and can be described by the Foerster kinetics.
5. Reaction 2 is mass transport limited at anode in respect to diffusion of both ClO- and HClO. Electrolytic migration is not important at the high salt concentration.
6. Perfect mixing occurs within the electrolyzer and the reactor.

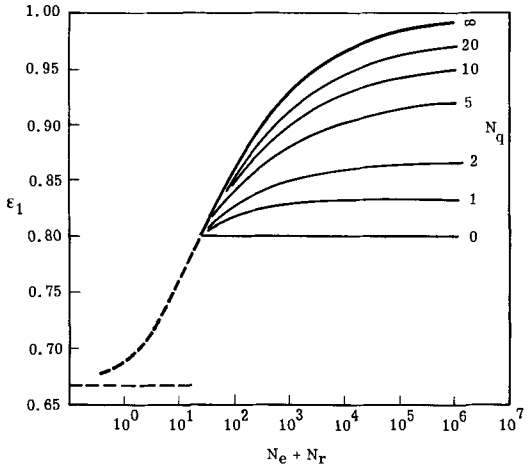

Fig. 3. Plot of current efficiency vs. $(N_e + N_r)$ with N_q as parameter (for $N_e = 25$).

curves for a particular value of $N_e = 25$ is one of many similar families for various values of N_e. It can be seen that a large reactor volume is effective only for a relatively large value of N_q. When $N_q = 0$, the efficiency is limited by the electrolyzer only. When $N_q \rightarrow \infty$ (perfect mixing between electrolyzer and reactor), Eq. [11] reduces to a form similar to that of de Valera (4). However, the form is slightly different because he assumed that only ClO^- ions discharge whereas HClO is also assumed to discharge by reaction 2 in the present model. The diffusion layer thickness of 0.05 cm used by de Valera, combined with a diffusivity of approximately 10^{-5} cm²/sec for hypochlorite, gives a value of $K_L = 2 \times 10^{-4}$ cm/sec which is on the low side of the data exhibited in Fig. 1. The data of Hammar and Wranglen for anodic discharge of hypochlorite give values of K_L nearly an order of magnitude larger, thus emphasizing the need to determine the value of the mass transfer coefficient under the conditions of electrolysis.

Figure 3 clearly indicates the need for economic optimization of a chlorate cell system. For example, high Faradaic efficiency is obtained by providing a larger reactor and a high circulation rate. Within the limits of the assumptions, the model equations provide a means for making economic balances. In making the balance between efficiency and circulation rate, it may also be necessary to consider the second-order effect of flow on K_L at high flow rates as well as the capital and operating costs of pumps.

A limitation of the present analysis is that it was based solely on laboratory cell data. Even a simple laboratory cell, though, may be subject to the limitations due to flow if the electrodes do not bound the whole cell volume and there is less than complete mixing. The derivation was also based on complete mixing within the electrolyzer and reactor and, under certain conditions, plug flow could occur in actual equipment giving somewhat different numerical values. A test of the model with pilot-plant data for a circulating system with separate electrolyzer and reactor will be presented in another paper (15).

Conclusions

1. Examination of literature data on electrolytic formation of chlorate in relatively concentrated salt solutions indicates that anodic discharge of hypochlorite is mass transport limited and that the mass transfer coefficient is determined largely by the gas evolution rate, *i.e.*

$$K_L = Bv^{1/2}$$

2. Equations have been derived relating current efficiency to dimensionless numbers containing the important system parameters for an electrolyzer reactor system for chlorate production.

Acknowledgments

Grateful acknowledgment is given to Dr. Norbert Ibl for his helpful comments relating to the mass transport phenomena and to Mr. Joseph C. Schumacher of American Potash and Chemical Corporation for permission to present the original version of this work.

Multicell Assemblies for Studying Ion-Selective Electrodes at High Pressures

M. Whitfield

CSIRO, Division of Fisheries and Oceanography, Cronulla, N.S.W., Australia

ABSTRACT

Two compact assemblies are described that enable simultaneous measurements to be made on two or three galvanic cells at pressures up to 3 kilobars. One unit, with pressure transmitted by a Teflon piston, is designed for use with Mouquin-Garman (flat membrane) glass electrodes. The second, which uses a mercury trap for pressure equilibration, can be adapted to take a range of ion-selective electrodes. The cells are gastight so that systems sensitive to oxidation or to the partial pressure of dissolved gases can be studied. Mercury or silver-based reference electrodes are used. Examples are given which illustrate the versatility of the system and its application to studies of junction-free cells with a variety of ion-selective electrodes.

Since Distèche first used *p*H-sensitive glass membranes at high pressure (1), the technique has been applied to a variety of problems (2-7) but little effort has been made to refine the method or apply it to a wider range of ion-selective electrodes. The principle of Distèche's method (1) was to use a light, nonconducting fluid (*e.g.*, silicone oil) to equilibrate the pressure on either side of the glass membrane and to act as an insulating layer between the internal and external reference electrodes. The sample solution was held in an open beaker. It is difficult to prevent contamination of the solution in this kind of cell. Even trace quantities of grease or dust can cause erratic behavior, especially in the silver/silver chloride reference electrodes (1, 8). Further problems arise when the cell reaction is sensitive to oxidation or to the presence of carbon dioxide (1).

These problems can be minimized by enclosing the electrode system in a syringe vessel within the pressure vessel itself. This approach has been adopted by Culberson *et al.* (4, 5) who used rubber bungs to transmit the pressure to the solution. Their technique is restricted to robust bulb-type electrodes. Recent investigations (9) indicate that this form of electrode is inferior to the more delicate flat-membrane types in its performance at high pressure. In addition, it is difficult to expel all the air from the kind of cell they describe.

These earlier investigations (1-5) were directed toward problems of oceanographic importance. For these studies, accurate data are needed over a moderate temperature and pressure range (—5° to +30°C, 1 to 1000 bars). When mounted in a thick-walled pressure vessel, the cell may take up to 1 hr to re-equilibrate after a pressure or temperature change. At low temperatures, the situation is aggravated by the slow response of the membrane electrode (10, 11). When the solutions are complex, a large body of experimental data must be gathered before a significant thermodynamic analysis can be made. In consequence, there is considerable advantage in designing high-pressure electrode systems so that several solutions can be investigated simultaneously.

Apparatus

The high-pressure electrode system is suspended from the lead plug of the pressure vessel so that the whole assembly can be removed as a unit. The electrical leads are made from magnesia-insulated triaxial cable and sealed into the lead plug by a modified Bridgman seal so that they can be readily removed and replaced (12). The present assembly can accommodate four such leads.

Key words: electrodes, pressure.

A temperature-comparator bridge gives a time-shared trace on a potentiometric recorder that compares the temperature sensed by thermistors placed inside and outside the pressure vessel. This can be used to reduce by 20-30% the time required for equilibration after a temperature or pressure step (13). The cell potentials are measured by using a precision potentiometer (Leeds and Northrup Type K-4) to back off the input signal to an electrometer (Keithley Model 610BR) which acts as an amplifier and a null detector. All connections are made with noise-free coaxial cable. The output signal from the electrometer is fed to the potentiometric recorder. The pressure is also recorded by a microtorque potentiometer mounted on one of the Bourdon tube pressure gauges. The simultaneous recording of temperature, pressure, and cell potential on a single chart provides a sensitive indication of the attainment of a steady state within the pressure vessel (*see* Fig. 5). The input signals to the recorder could also be used in conjunction with a process programmer to automate the measuring procedure.

Low pH Cells

The Mouquin-Garman (M-G) glass electrode (G, Fig. 1) acts as a combined beaker and sensor and has several advantages that make it particularly suitable for high-pressure work (9, 14). Only Corning 015 glass is at present available in sufficient quantity to make these electrodes. Their use is, in consequence, restricted to low *p*H work or to studies of anion or cation activity using colloidon or protamine coated membranes (15). The low *p*H cell has been designed to accommodate these electrodes.

The pressure is transmitted to the tube containing the electrodes by a gastight stopper (A, Fig. 1). A bleed hole that can be closed by a screw (E) allows gas bubbles to be expelled when the cell is filled. The lead tube (B) is made of precision-bore Pyrex tube (25 mm ID) with four platinum wires sealed into its walls at 90° intervals *via* carefully annealed Housekeeper seals (16). Araldite adhesive placed at the platinum/glass junction on the outside of the test tube prevents the seals from cracking even at high pressures and low temperatures (3 kilobars, —5°C). The external leads are insulated with PVC sleeving and soldered to Teflon insulated sockets (12) set in an annular collar (D).

The lead tube is connected to the electrode holder (C) by a ground-glass joint. Two M-G glass electrodes are held side by side in the holder by a Teflon former (F). The platinum leads are welded to the silver wires which are used as the metal base for the silver/silver chloride reference electrodes (H). These were prepared *in situ* by series electrolysis.

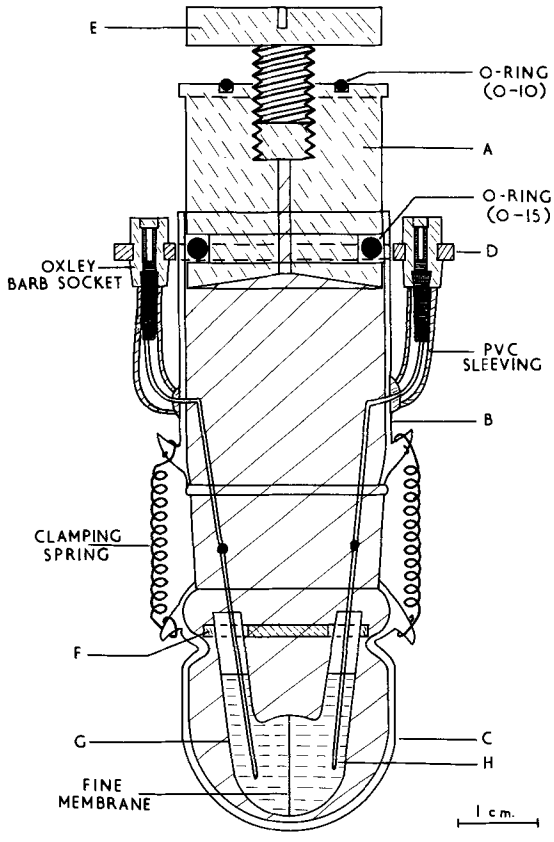

Fig. 1. Low pH cell: A—gastight piston (Teflon), B—lead tube (Pyrex), C—electrode holder (Pyrex), D—fiberglas collar, E—bleed screw (Teflon), F—Teflon former, G—glass electrode (Mouquin-Garman), H—silver/silver chloride electrode. The second glass electrode is stacked alongside the one shown. After the electrodes have been placed in position, the whole cell is filled with n-heptane.

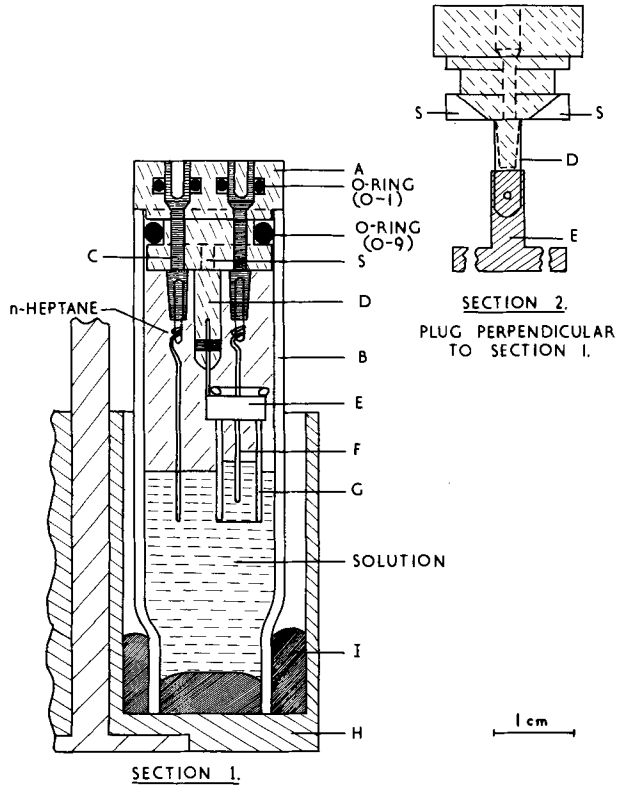

Fig. 2. General-purpose cell: A—Teflon plug, B—cell body (Pyrex), C—platinum contact, D—Teflon rod, E—platinum stirrup, F—silver/silver chloride electrode, G—glass electrode, H—holder, I—mercury trap, S—slots in piston. Redistilled silicone oil (MS 200/5 cs) may be used instead of n-heptane in the insulating layer.

n-Heptane is chosen as the pressure-transmitting fluid because it maintains a low viscosity at high pressures and low temperatures. It has a smaller compressibility than the light silicone oils previously used (1) and this reduces the temperature changes accompanying adiabatic compression. n-Heptane is a good electrical insulator and is available commercially in a pure form. In addition, it is volatile and is readily cleaned off the cell components at the end of the experiment.

General Purpose Cell

This cell consists of an open-ended glass tube sealed at the top by a Teflon cap and at the base by a mercury trap which acts as a pressure-equalizing piston (Fig. 2). The electrode assembly is suspended from the cap which also carries the electrical leads.

The cell body (B, Fig. 2) is formed by a length of precision-bore Pyrex tubing (15 mm ID). The lower end of the tube is restricted slightly to insure a good mercury seal in the space available. Extra insulated leads can be fed through the mercury pool without disturbing the effectiveness of the seal. The mercury can also be used as the metal base for an external reference electrode. In this case, the inside of the tube is given a hydrophobic coating of Teflon (17) or a silicone compound (18). If the mercury seal does not perform any auxiliary function, the base of the tube can be constricted to leave only a pinhole (0.25 mm diam) for pressure equilibration. The cells can then be interchanged without disturbing the contents.

The platinum lead pins (C) are machined to give a force fit in the holes in the Teflon piston. Silicone rubber O-rings were introduced to insure a good seal under all conditions. Pistons made in this way had a leakage rate of only 10 μl/hr under full vacuum.

The silver/silver chloride reference electrodes were prepared by an electrolytic method on a 1-mm diameter platinum or silver base. They were prepared and stored according to the recommendations of Brown and MacInnes (19).

A platinum foil holder (E) for the glass electrode is secured to a Teflon rod (D) which protrudes from the lower surface of the cap. The electrode stem is 3 cm long and the upper centimeter is insulated by a tight-fitting collar of heat shrinkable Teflon. Slots (S) are machined in the base of the piston to allow air bubbles to be expelled from the cell in the final stages of filling.

The mercury reservoir (E, Fig. 3) is machined from a single block of Perspex or Teflon in the form of a beaker divided into three equal segments. The three mercury pools are electrically isolated and are not connected to earth. A locating collar holds the glass tubes vertically in the reservoir during assembly. The cells are clamped lightly against the base of the reservoir by a securing plate (D). This plate is slotted to match a key (F, Fig. 3) which is screwed into the plug carrying the electrical leads into the pressure vessel. The key fits into a recessed slot machined on the underside of the securing plate. This quick release mechanism enables the cell assembly to be exchanged for a new unit in only a few minutes.

So far, three types of cell have been investigated using this assembly. In the first (Fig. 2), silver/silver chloride electrodes are used for reference and a flat-membrane glass electrode is employed. A wide range of glasses can be used to form a membrane of this type on a soda-glass stem. For example NAS 27-4 and LAS 25-10 glasses (20) as well as membranes blown from commercial high pH glass bulbs can be used. In all cases, stable and reliable glass electrodes result. The fineness of the membrane enables good seals to be made between apparently incompatible glasses (21).

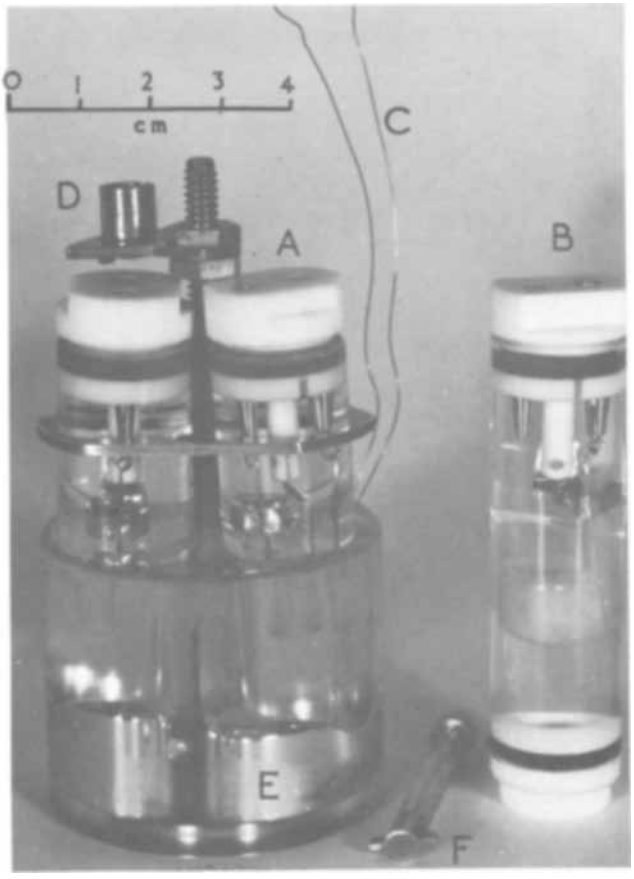

Fig. 3. Cell assembly: A—glass electrode cell (Fig. 2), B—calomel/liquid ion-exchange cell (Fig. 4), C—Thermistor leads, D—securing plate, E—mercury reservoir, F—key.

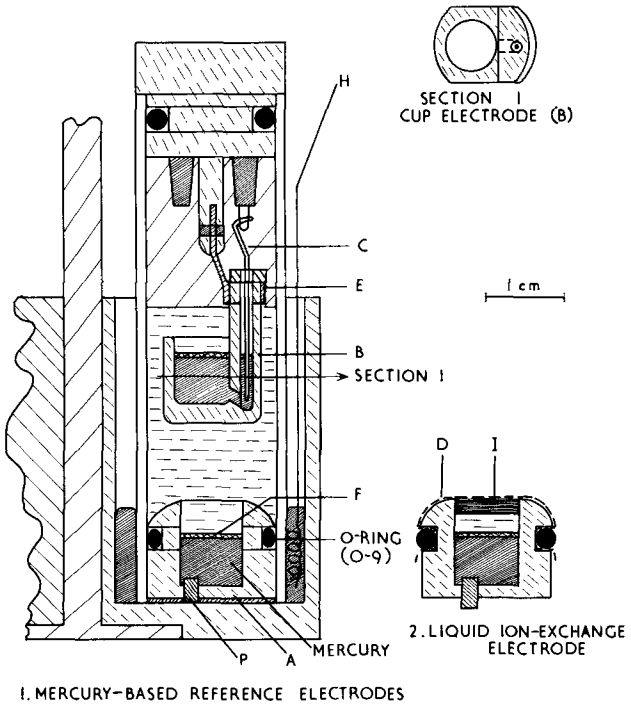

Fig. 4. Calomel/liquid ion-exchange cell (details of cap omitted). 1. Mercury-based: A—combined electrode/piston (FEP polymer), B—cup electrode (FEP polymer), C—contact wire, E—platinum stirrup (see Fig. 2), F—calomel layer, P—platinum, H—contact to mercury reservoir. 2. Liquid ion-exchange: D—sheet of dialysis membrane, I—ion-exchange oil (other components as in 4—1).

The second assembly (Fig. 4—1) was used to investigate the properties of mercury-based reference electrodes at high pressures. Here the pressure is equalized by a piston (A) sealed to the cell walls by an O-ring. The piston is machined in the form of a cup from FEP fluorocarbon polymer (22). This material is as inert as Teflon but it has the added advantage that it can be heat treated and so irregularities introduced by the machining process can be smoothed out. It is translucent to transparent, depending on its thermal history, and it provides a hydrophobic surface that is essential for the proper functioning of mercury-based electrodes (18). A platinum pin (P, Fig. 4) in the base of the cup connects the electrode base to the mercury reservoir which acts as the external lead.

A calomel electrode is prepared by filling the cup to a depth of 6 mm with purified mercury and by adding a relatively thick skin of calomel (F, Fig. 4) according to the instructions of Covington *et al.* (23). A layer of the appropriate halide solution is then added. Other metal/insoluble salt electrodes with mercury or amalgam bases can be prepared in this way. The second electrode in the cell (B, Fig. 4—1 is prepared in a similar way in an FEP holder that is suspended from the platinum stirrup in the cell cap. The completed assembly is shown on the right hand side of Fig. 3.

A third cell (Fig. 4—2) employs a liquid ion-exchange electrode for pressure equilibration. Several distinct problems arise in the preparation of these electrodes (24, 25). A layer of light ion-exchange oil must be held between a reference and an unknown solution. The interfaces between this oil and both solutions must be stable and reproducible. In addition, an equal pressure must be applied to both solutions to maintain the hydrostatic stability of the system. This problem is made more difficult by the high solubility of the ion-exchange oil in organic hydraulic fluids. In the assembly illustrated (Fig. 4—2), a calomel electrode acts as an internal reference. Electrical contact is maintained by a platinum pin (P). The electrode is then filled to a depth of 5 mm with the internal reference solution and a 2-mm layer of ion-exchange oil (I) is floated on top of this. The upper surface of the oil is then trapped by a permeable or semipermeable barrier to complete the electrode. This barrier can consist of a No. 3 grade porous glass plug treated with silicone water-repellent or, more simply, a sheet of cellulose dialysis tubing (D) which is fixed in place by the O-ring that seals the electrode to the wall of the cell. When a porous glass plug is used, a 0.25-mm hole is drilled in the base of the FEP body to improve pressure equilibration across the ion-exchange surface.

Results

The versatility of the system is best illustrated by showing examples of problems that can be investigated using the various cell configurations. In the first example (Fig. 5), the triple cell assembly was used to compare the behavior of silver/silver chloride and calomel reference electrodes. Two symmetrical calomel cells (I and II, Fig. 5) and a symmetrical silver/silver chloride cell (III, Fig. 5) were prepared. The electrodes were immersed in a 0.1M solution of hydrochloric acid. A miniature thermistor was introduced into cell III. Figure 5 illustrates the response of this arrangement to a pressure step of 290 bars at 20°C. The emf of cell I as well as the temperature and pressure profiles were recorded directly on the strip chart. The emf's of cells II and III were measured at regular intervals and are plotted on the same time and potential scales as cell I. This figure illustrates well the amount of data that can be recorded from a single experiment with the multicell system.

Both sets of calomel electrodes show relatively high bias potentials that decay exponentially after the pressure step. Experiments involving calomel reference electrodes therefore require much slower rates of pressure application and release than those employing silver/silver chloride electrodes.

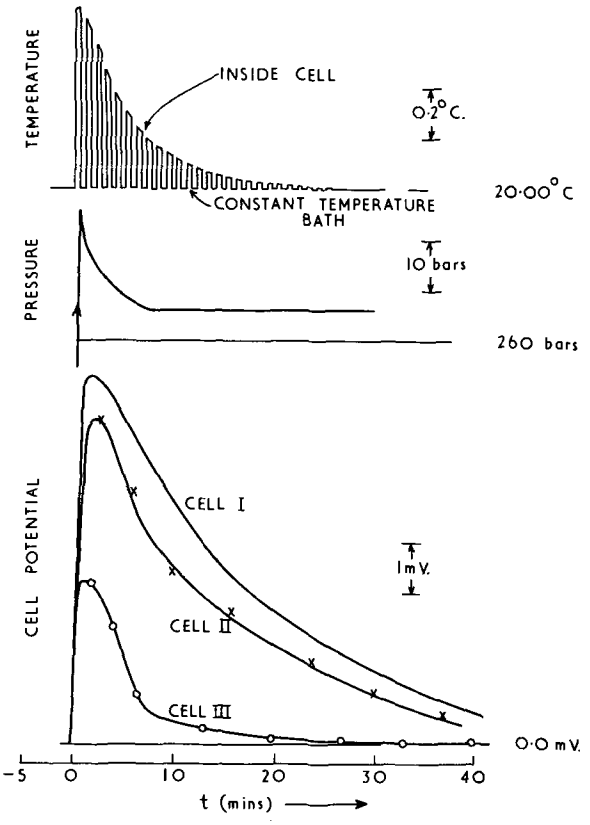

Fig. 5. Response of symmetrical cells to a sudden pressure step. Cells I and II, calomel electrodes (Fig. 4—1); Cell III silver/silver chloride electrode (Fig. 2).

Both assemblies (Fig. 1 and 2) have been used to compare the properties of a range of glass electrodes with different membrane geometries (9). The cells were symmetrical with 0.1M hydrochloric acid on either side of the membrane. In Fig. 6, the asymmetry potentials of three different types of electrodes measured in a single experiment are plotted as a function of pressure. The simple bulb type shows considerable hysteresis that is not exhibited by the other two electrodes. Data for a Mouquin-Garman electrode from a separate experiment using the low *p*H cell are included to illustrate the stable performance of these electrodes.

The reproducibility of three identical cells mounted together is shown in Fig. 7. In this instance, flat-membrane electrodes, prepared by reworking commercial high *p*H bulbs, were mounted in a general-purpose cell (Fig. 2). The internal solution was a potassium chloride/hydrochloric acid buffer and the external solution a carbonate/bicarbonate buffer. The general agreement between the three cells was good (within ± 0.05 mV). The hysteresis exhibited by cell III was traced to the poor performance of the silver/silver chloride electrodes employed. This underlines the need for caution in preparing and handling these electrodes which form the least reliable link in the electrochemical chain. The relationship between cell response and applied pressure deviates from a straight line at pressures above about 1 kilobar. This is in concordance with the data of Distèche (1-3) who worked below 1 kilobar.

The final example (Fig. 8) is taken from work on electrodes sensitive to cations other than hydrogen ions. The electrodes were prepared with a 0.1M filling solution of the appropriate halide. Flat-membrane glass electrodes made from NAS 27-4 glass (20) were used in the sodium chloride cells and liquid ion-exchange electrodes in the calcium chloride cells. A commercial liquid ion-exchange resin (26) was employed. Three electrodes of a given type were mounted

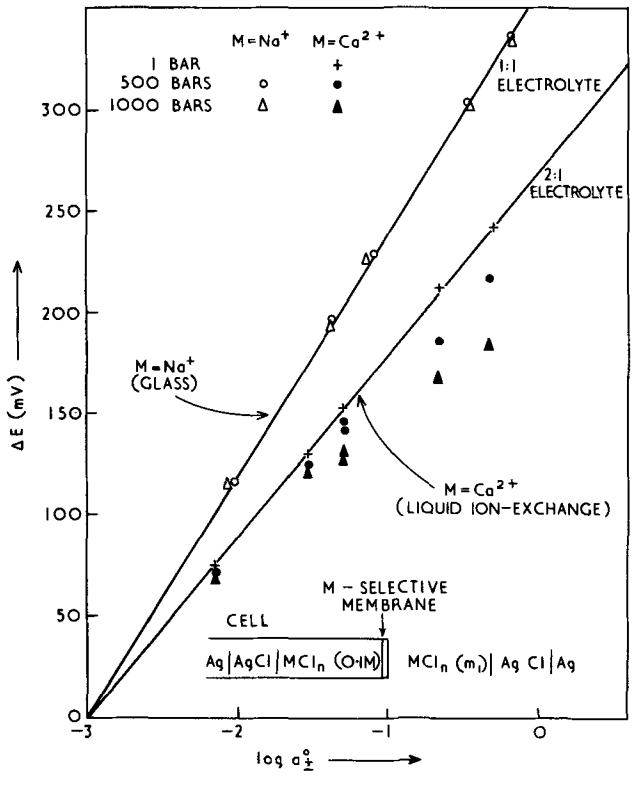

Fig. 8. Response of cation-selective electrodes as a function of pressure at 25°C. Solid lines indicate theoretical slope.

together in the pressure vessel with a different external solution in each. At least one cell in the assembly had a 0.001M external solution. In plotting the data, the potential of this cell was set arbitrarily at zero. The potentials of the other cells were then plotted relative to this point. If a different cell is used each time as the arbitrary reference point, then the composite curve obtained represents a fair picture of the performance of that particular electrode type. Errors caused by asymmetry potentials, irregularities in the individual electrodes, and effects caused by pressure cycling are effectively averaged out. The curves shown in Fig. 8 are composites of three experimental runs on three separate cells.

Pressures up to 1 kilobar have only a small effect on the activity coefficients of simple electrolyte solutions (1, 27). In consequence, a plot of log $a_{\pm}^{\circ}$ (mean ion activity coefficient of electrolyte at 25°C and 1 bar) *vs.* the cell potential relative to the value in the reference solution (ΔE) should give a straight line with the appropriate Nernst slope if the electrodes are behaving ideally. The slope would be 120 mV for each tenfold change in activity for a 1:1 electrolyte and 90 mV for a 2:1 electrolyte if the cell is composed of electrodes selective to both the anion and the cation of the electrolyte.

The sodium chloride cell (Fig. 8) behaves well up to 1 kilobar in agreement with previous work on pH-selective glass electrodes. The liquid ion-exchange cells, although performing well at atmospheric pressure, show poor response at high pressure. A number of interface types have been tried, all with similar results. Further work is being carried out on this problem; in particular, a solid ion-exchange electrode with a high selectivity to divalent ions (28) is being studied.

Technical Notes

Properties of Some Selected Europium-Activated Red Phosphors

S. S. Trond,* J. S. Martin, J. P. Stanavage, and A. L. Smith*

Radio Corporation of America, Electronic Components, Lancaster, Pennsylvania

Since the advent of rare earth phosphors, numerous red-emitting, europium-activated materials have been synthesized. For various reasons, the extensive use of these materials has been limited to the yttrium based phosphors listed in Table I.

The materials used in the study described in this paper were the oxide, vanadate, and oxysulfide phosphors of yttrium, gadolinium, and lanthanum. The investigation was made to determine the comparative stability of various europium-activated, red-emitting phosphors under conditions which would show the relative merit of these materials as the red component of color-television picture tubes. The stability of these phosphors during heat treatment, acid washing, and milling was studied. It is pertinent that any commercial phosphor have high stability during heat treatment in the presence of organics to achieve a kinescope product of high quality with respect to light output. Stability during acid washing may be required to facilitate reclamation which is necessary for economical utilization. Reclamation, as referred to in this paper, is the recovery of usable phosphor and not the recovery of rare earth raw materials which must be reworked into new virgin phosphor.

Phosphors Evaluated

All of the phosphors in Table II were prepared from luminescence-grade rare earth oxides by conventional phosphor preparatory techniques. The yttrium vanadate and yttrium oxysulfide phosphor samples were standard RCA phosphor products; the remaining samples were experimental. All efficiency readings are given relative to the RCA yttrium vanadate standard. Although the experimental phosphors may not be optimum with respect to efficiency and color, any discrepancy is slight.

The cathodoluminescent efficiencies of the phosphor powders were measured with a RCA-built spectroradiometer as described by Hardy (1). The spectroradiometer was equipped with an eye-corrected Weston Photronic Cell No. 856RR, whose output was measured with a sensitive, low-impedance galvanometer. The color coordinates were calculated from precise spectral emission data recorded by a General Electric spectroradiometer. All of the phosphors had good efficiencies and reasonable emission colors, except the lanthanum oxide and lanthanum vanadate phosphors. Although these two lanthanum phosphors were quite inefficient and had a desaturated red emission color, they were included in the study. The comparative data of YVO_4:Eu and YVO_4:Eu,Bi agree with Datta's (2) findings that the incorporation of bismuth enhances the brightness and is coupled with an emission color shift. Datta suggested that under cathode-ray excitation, the increased brightness is due to a Bi^{+3} emission (also leading to the color shift) and that there is little effect on the Eu^{+3} emission intensity. The relative brightness, with respect to emission color, of the yttrium oxysulfide and gadolinum oxysulfide phosphors agree with the data reported by Haynes and Brown (3); however, the lanthanum oxysulfide reported in Table II is superior to the respective phosphor discussed by the above authors. Bril (4) and his associates also found that the lanthanum oxide phosphor was significantly less efficient than the oxide phosphors of yttrium or gadolinium.

The median particle size by weight is also listed in Table II. These measurements were made with a Coulter Counter; again, no effort was made to optimize the size of the experimental samples.

All of the phosphors produced sharp, crystalline, and characteristic x-ray patterns. It was carefully noted that all vanadate and oxysulfide samples were free of their respective oxides.

Milling Stability

The stability of the phosphors during milling was determined by use of small samples milled in water in a half-pint mill. Table III shows the per cent efficiency lost by each phosphor as a result of milling in water for 1 and 2 hr.

Within each phosphor type, the lanthanum samples suffered the greatest degradation during milling. The modified yttrium vanadate (YVO_4:Eu,Bi), the gadolinium vanadate, and the yttrium oxide phosphors showed remarkable stability under the test conditions. All of the milled samples retained sharp characteristic x-ray patterns. The milled vanadate and oxysulfide samples remained free of their respective oxides.

* Electrochemical Society Active Member.

The significance of the milling test is to illustrate the effect of attempts to reduce particle size manually, if such reduction were necessary. Obviously, only a few of the materials could withstand such treatment. In most cases, however, the phosphor can be synthesized to the desired particle size and milling is not necessary. It should be noted that milling in the presence of PVA during slurry preparation is an entirely different situation, as is discussed later.

Acid Stability

From an economic standpoint, it is mandatory that any commercial rare earth phosphor must be salvaged either as a usable phosphor or for its rare earth raw materials values. As was pointed out earlier, this paper deals with the reclaim of salvage as usable phosphor because this is felt to be the most economical approach. The use of this salvaged phosphor must yield a finished color picture tube of quality comparable to that of the product fabricated from its virgin phosphor. The salvage recovery procedure requires acid treatment to assure the required quality. Acid treatment is necessary either to control the chromium level in the salvaged phosphor or to remove blue and/or green sulfide phosphor contamination from the salvaged phosphor.

This investigation has shown that, with respect to acid stability, the ten phosphors in question fall into two distinct classes:

I. Phosphors which are quite soluble in mild acid solutions at room temperature. These phosphors suffer in luminous efficiency as a result of acid digestion.

II. Phosphors which have very limited solubilities in mild acid solutions at elevated temperatures and/or very limited solubilities in strong acid solutions at room temperature. These phosphors do not suffer in luminous efficiency as a result of acid digestion.

Table IV lists the effects of digestion on the phosphors of Class I with 5 and 10% nitric acid solutions and with a 10% hydrochloric acid solution. Each sample of virgin phosphor was digested for 30 min at room temperature. The table lists the per cent weight loss of each digestion, as well as the efficiency of the recovered sample relative to its untreated virgin sample.

All three lanthanum-based phosphors are in Class I, as well as the oxide phosphors of yttrium and gadolinium. The latter two phosphors suffered gross losses in luminous energy when exposed to the acid solutions. The table shows the high weight losses of the three most efficient phosphors of this class (Y_2O_3, Gd_2O_3, and La_2O_2S). It should be emphasized that the acid conditions specified do not dissolve blue or green sulfide contaminants; therefore, these phosphors cannot be separated from such contamination by this technique.

The conventional technique for removal of blue and/or green sulfide contaminants from the yttrium vanadate phosphor is to digest the salvaged phosphor in 5-10% nitric acid solution at temperatures of 50°-70°C. The most severe condition (10% HNO_3/70°C) was chosen to evaluate the acid stability of the Class II phosphors. Under this condition, sulfide contamination is dissolved rapidly and completely. Because this condition may not represent optimum acid concentration and temperature, the relative weight losses should be examined rather than the absolute values.

Table IV. Dilute acid digestions of Class I phosphors at 25°C

	Conditions of Digestion					
	5% HNO_3/0.5 hr		10% HNO_3/0.5 hr		5% HCl/0.5 hr	
Phosphor	% Wt loss	% Eff	% Wt loss	% Eff	% Wt loss	% Eff
Y_2O_3:Eu	18.0	61.5	16.4	38.0	18.1	30.3
Gd_2O_3:Eu	98.4	51.8	100		100	
$LaVO_4$:Eu	7.8	83.4	12.2	83.0	—	
La_2O_2S:Eu	76.8	88.5	88.8	57.1	90.8	57.0
La_2O_3:Eu	100		100		—	

Table V. 10% Nitric acid digestions of Class II phosphors at 70°C

	0.5-Hr digestion		1-Hr digestion	
Phosphor	% Wt loss	% Efficiency	% Wt loss	% Efficiency
YVO_4:Eu	4.6	101	7.6	101
YVO_4:Eu,Bi	3.8	105	5.4	104
$GdVO_4$:Eu	18.6	105	38.4	108
Y_2O_2S:Eu	8.1	101	15.6	103
Gd_2O_2S:Eu	13.6	106	25.8	105

Table V lists the per cent weight losses and efficiencies of the recovered samples. The efficiency readings are given relative to the efficiency of each untreated virgin sample. This acid treatment had no detrimental effect on any of the samples with respect to luminous efficiency. The gadolinium vanadate and gadolinium oxysulfide phosphors proved to be much more soluble than the yttrium vanadate and yttrium oxysulfide phosphors. The yttrium oxysulfide phosphor, on the other hand, was significantly more soluble than either of the yttrium vanadate phosphors. The modified yttrium vanadate phosphor was slightly more stable than the bismuth-free yttrium vanadate.

Further investigations revealed that blue and/or green sulfide phosphor contaminants can be removed as efficiently and as rapidly at room temperature by increasing the nitric acid concentration to values greater than 20%. For this study, the Class II phosphors were digested in 25% nitric acid solutions at room temperature.

Table VI lists the results of this test. Again, the acid digestion was nondetrimental to the luminous efficiency in all cases. Under this condition, there was much less deviation in stability within the Class II phosphors. The yttrium oxysulfide phosphor displayed remarkable stability at high nitric acid concentrations at room temperature. Even the gadolinium vanadate and gadolinium oxysulfide phosphors could be treated under this condition if the digestion time was carefully monitored.

Under the same concentration and temperature conditions, hydrochloric acid is as effective as nitric acid in the complete and rapid dissolution of blue and/or green sulfide phosphor contaminants. Yttrium vanadate (nonmodified) and yttrium oxysulfide phosphors were evaluated at room temperature and 70°C with hydrochloric acid. Table VII lists the results. Again, the luminous efficiencies of the Class II phosphors were not affected by acid digestion. At room temperature with 25% solutions, the results were essentially the same as in the nitric acid study. However, at 70°C, the yttrium oxysulfide was much more stable in 10% hydrochloric acid than it was in 10% nitric acid.

For all ten of the rare earth phosphors tested in this study, there was essentially no change in emission color or x-ray pattern as a result of acid treatment.

Table VI. 25% Nitric acid digestions of Class II phosphors at 25°C

	1-Hr digestion		2-Hr digestion	
Phosphor	% Wt loss	% Efficiency	% Wt loss	% Efficiency

YVO_4:Eu,Bi	2.6	101	4.2	103
$GdVO_4$:Eu	4.8	104	7.6	106
Y_2O_2S:Eu	2.0	101	1.8	103
Gd_2O_2S:Eu	4.2	105	4.0	107

Table VII. HCl digestions of YVO_4:Eu and Y_2O_2S:Eu

	10%/70°C				25%/25°C	
	0.5 Hr		1 Hr		1 Hr	
Phosphor	% Wt loss	% Eff	% Wt loss	% Eff	% Wt loss	% Eff
YVO_4:Eu	2.8	101	3.9	100	1.5	102
Y_2O_2S:Eu	3.2	103	6.8	103	1.8	102

This acid stability study has determined that the phosphors of Class I cannot be recovered by a salvage procedure which requires the removal of sulfide phosphor contaminants by acid treatment; the phosphors of Class II can be recovered readily and efficiently by such a procedure. If the salvaged phosphors have not been contaminated with sulfide phosphors, the residual chromium content can be controlled by treatment with a 3% nitric acid solution. Again, the Class I phosphors are not stable to such a recovery technique.

Heat Treatment Stability

During the fabrication of picture tubes, the phosphor is heat treated in the presence of polyvinyl alcohol (PVA). Some salvage recovery procedures also require baking at temperatures that will remove all traces of PVA. Both situations require temperatures of approximately 450°C.

To study the effect of baking in the presence of PVA on the efficiency of each of these phosphors, pilot slurries were prepared with each phosphor. The slurries were of standard RCA red phosphor formulation, but were unsensitized. The slurry preparation included a milling step in the presence of PVA. The slurries were held with agitation for 25 hr, and then the phosphor from each was salvaged by thoroughly washing in a centrifuge. After drying, the salvaged phosphors were baked at 450°C for 2 hr in air.

Table VIII lists the powder efficiencies of the reclaimed phosphors. The yttrium- and gadolinium-based phosphors proved to be quite stable under these test conditions, while the lanthanum-based phosphors showed severe luminous efficiency losses.

The recovery of these phosphors from sensitized slurries was also investigated. Slurries were again prepared; however, after the milling step, the appropriate amount of ammonium dichromate was added (as in the standard RCA formulation). As with the unsensitized slurries, these sensitized slurries were held with agitation for 24 hr, and then the phosphor from each was salvaged by thorough washing in a centrifuge. The salvaged phosphors were then dried and were measured under simulated tube conditions. Because the spectroradiometer used to measure all previous samples was not capable of the voltages needed for this test (~25 kV), 2- x 2-in. glass slides were water settled with each phosphor to be tested. A control slide of each virgin sample was also prepared as a reference. The slides were then baked at 450°C for 2 hr in air. The slides were measured on a demountable test set. Each salvaged phosphor was measured relative to its control; Table IX shows the results.

The values obtained can actually be regarded as hypothetical conversion factors for each phosphor with regard to the luminous energy retained through tube processing. Of course, the test was modfied with regard to the tube-processing procedures and run under fairly optimum conditions. Still, the results can be reviewed relative to each other with regard to salvageability and luminous energy retention during tube processing.

The vanadate and oxysulfide phosphors of yttrium and gadolinium have remarkable luminous conversion factors. In practice at RCA, tubes prepared with virgin rare earth red phosphor (either yttrium vanadate or yttrium oxysulfide) are indistinguishable from tubes prepared with the respective reclaimed salvage. Both of these phosphors exhibited high conversion factors in this test.

The oxide phosphors of both yttrium and gadolinium have lower luminous conversion factors. The lanthanum phosphors all have low luminous conversion factors. The dichromate was readily adsorbed by the three oxide phosphors and caused a discoloration of these phosphors even after centrifuge washing. This result did not occur with any of the other phosphors.

This conversion factor is extremely important because it allows the rapid rating of materials relative to one another with respect to luminous energy available in a fabricated picture tube. For example, the La_2O_2S phosphor used in this study was 130% of the YVO_4 phosphor; however, when the luminous conversion factor is applied, the red field of the YVO_4 picture tube is actually about 108% of the red field of the La_2O_2S kinescope.

It is believed that the reclaimed salvage of any phosphor which has a low luminous conversion factor will not provide picture tubes comparable to those prepared with its virgin phosphor.

Summary

When some form of acid treatment is required for the recovery of rare earth salvage as a usable phosphor, the phosphors of Class I are immediately eliminated as desirable red components. The remaining phosphors, the vanadates and oxysulfides of yttrium and gadolinium (Class II), have comparable stability to acid treatment under selected process conditions. From an economic standpoint, the gadolinium-based phosphors become impractical because of Gd_2O_3 raw material cost. Although this cost may be alleviated in the future, these phosphors offer no advantages over their yttrium counterparts. As a result, the yttrium-based phosphors of Class II are the most practical red components for color-television picture tubes at the present time.

It is possible that a technique for the recovery of Class I phosphors as usable phosphors, which does not require acid treatment, could be devised. The lower conversion factors exhibited by these Class I phosphors make continual reclaim and reuse questionable.

The reclaim of salvage of any rare earth phosphor is mandatory to justify its use. If a given rare earth phosphor, which cannot be reclaimed as a usable material, is found to possess certain desirable characteristics, its use should not be discouraged on this factor alone. Any rare earth phosphor salvage can be reclaimed by recovering the rare earth raw materials by standard chemical means and synthesizing into new virgin phosphor. From an economic standpoint, such a reclaim procedure is more expensive than the direct recovery of salvage as usable material. A phosphor which cannot be directly reclaimed must have unusual merit in order to justify the added cost of complete reprocessing.

Acknowledgments

The authors express their thanks to W. G. Rudy and his associates for their determination of the cathodo-

luminescent and spectral data within this paper. Graditude is also extended to M. M. Fornoff and R. H. Woods for their x-ray determinations.

The light microscope has long been used to reveal the surface morphology of aluminum foil etched for electrolytic capacitors (1), but its effectiveness has been partly limited by insufficient depth of focus at high magnifications. The electron microscope with its greater depth of focus and higher resolution has been used to reveal considerable detail in configurations like those produced by tunnel corrosion in a 2S aluminum alloy (2) and tunnel electroetching in aluminum foil of 99.8% purity (3), but the anodic oxide replica samples for this technique have to be relatively transparent to electrons.

The scanning electron microscope (SEM), on the other hand, has neither of these limitations. It has a depth of focus generally 50-100 times that of the optical microscope and samples may be thick and opaque to electrons. Nonconducting samples, however, require the addition of a thin conducting layer such as vapor-deposited carbon or gold. In fact, gold-coated anodic oxide replicas are found to be excellent SEM samples for studying the morphology of etched aluminum. Illustrations have been reported for lightly etched foil (4, 5). The present communication gives a brief description of the preparation of SEM samples for studying both lightly and heavily etched foil.

Lightly etched foil and final oxide replicas were obtained in the following way. A specimen of annealed 99.99% Al foil was given an oxide-removing treatment in a NaOH bath, a 5-sec electroetch at 10 A/in.^{2} in a hot NaCl electrolyte, and a thorough wash in distilled water. An anodic film of about 600Å thickness was then formed in an aqueous solution of ammonium pentaborate. Small sheared pieces were placed in a bromine-methanol solution to dissolve the aluminum matrix and thus free the oxide replicas. Each replica was mounted with the oxide-metal interface up. Vapor deposition of about 500Å of gold in the normal direction completed the preparation of the SEM samples.

Figure 1 shows a region within a single grain of the annealed aluminum where the oxide replica takes a "jungle-gym" configuration. This morphology arises from tunnel etching along <100> directions (6).

Figure 2 shows a region involving three grains of aluminum in a specimen etched 10 sec at 1 A/in.^{2}. The jungle-gym structures, of course, join together at grain boundaries; the details of this and other features are best seen using stereo SEM micrographs.

When tunnel etching extends beyond the midsection of the foil thickness, the final oxide replicas from both surfaces tend to be joined together. They generally can

be separated, however, and the interior view obtained. Alternatively, one may fracture the joined pair to obtain a cross-section view. A simpler procedure for obtaining a three-dimensional, cross-section (or any other section) view is to prepare the ordinary metallographic section and to finish with an electropolish that removes the aluminum to the desired depth, leaving the oxide replica in relief. Application of a gold coating completes the preparation of the sample.

Manuscript received March 25, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Electromotive Force Investigation of the Bismuth-Tellurium System

Chung-Chiun Liu[1] and John C. Angus

Chemical Engineering Science Division, Case Western Reserve University, Cleveland, Ohio

ABSTRACT

The bismuth-tellurium alloy system was investigated by electromotive force measurements, coulometric titrations, x-ray diffraction, and differential thermal analyses. The thermodynamic properties of the system have been obtained from the electromotive force measurements. The partial molar free energy, enthalpy, and entropy have been measured as a function of alloy composition at 655°, 700°, and 766°K. The integral thermodynamic properties were computed from the experimental data. The heat of formation of the compound Bi_2Te_3 is estimated at -46 ± 10 kcal/g mole at 766°K. The phase equilibrium diagram was established from experimental data. The results confirm that a very narrow single γ-phase region exists near the compound Bi_2Te_3.

Significant research and development effort has been devoted to thermoelectric materials in recent years. A bismuth-tellurium alloy in the form of Bi_2Te_3, when properly doped, has been found to be one of the most promising thermoelectric materials, especially in the thermoelectric refrigeration applications. However, the thermodynamic properties of the bismuth-tellurium system are only partially known and of questionable accuracy. Also, the exact form of the phase equilibrium diagram of the bismuth-tellurium system is still obscure, and notable discrepancies exist among reported phase diagrams. This paper is a report on the investigation of the bismuth-tellurium system by electromotive force measurements, coulometric titrations, x-ray diffraction, and differential thermal analyses. The first part of this paper covers the thermodynamic properties of the bismuth-tellurium compounds obtained from the emf measurements; the second part discusses the construction of the phase diagram of the system from the results of emf measurements and coulometric titrations.

The reversible galvanic cell used was

$$\text{Bi}(l) \mid \text{BiCl}_3 \text{ in LiCl} + \text{KCl} \mid \text{Bi-Te}$$

The bismuth ions in the melt are trivalent Bi^{3+} throughout our experimental region. This can be shown from the data on the bismuth-gold system by Kleppa (1). Furthermore, the results of our coulometric titrations independently confirm the valence of the bismuth ions in the melt.

When the emf measurements are carried out over a significantly large composition and temperature range, this method gives us, in principle, the data required for an evaluation of the: activity, partial molar free energy, entropy and enthalpy of the constituents. Also integral thermodynamic properties can be calculated from these partial molar quantities.

The basic relationships used to relate the cell potential to the thermodynamic properties are

$$\bar{\mu}_{Bi} - \mu_{Bi}^{\circ} = RT \ln a_{Bi} \qquad [1]$$

$$\bar{\mu}_{Bi} - \mu_{Bi}^{\circ} = -ZFE \qquad [2]$$

In Eq. [1], a_{Bi} refers to the activity of the bismuth in the Bi-Te alloy; the activity of pure bismuth is taken as unity.

Thermodynamic Properties

Experimental Procedure

Preliminary studies indicated that bismuth chloride is highly volatile. Therefore, a closed, isothermal cell was used. Within the cell, the equilibrium between the bismuth existing in different phases could be reached at any desired temperature under isothermal conditions provided a sufficient quantity of the bismuth chloride was present in the molten electrolyte.

The experimental cell used was made of Pyrex glass and is shown in Fig. 1. The cell had an over-all length of 22 cm and an outside diameter of 2.54 cm. Each electrode compartment was approximately 2 cm in length and 0.8 cm in diameter. The leads for the electrodes were made of 0.025 cm diameter platinum wire (99.99+% pure). After fabrication of the cell, the electrodes were prepared, one of pure bismuth, and the second, an alloy of bismuth-tellurium. About 1.5-2.1g of metals for each electrode were used. High-purity (99.999+%) bismuth and tellurium, each in powder form of particle size 20-325 mesh, were used. The correct amount of metal was carefully weighed and packed into the electrode compartments.

The electrodes were then reduced in order to remove any trace of bismuth and tellurium oxide and to have ideal conditions for the melting and forming of the electrodes. A mixture of 90% nitrogen and 10% hydrogen was employed as the reducing gas. The temperature during reduction was gradually increased and was kept at the melting point of the alloy for 3 to 4 hr after the melting temperature was reached in order to obtain complete reduction. The cell was then cooled under the stream of the reducing gas and the electrodes solidified. The diameter of the upper section of the cell was narrowed from 2.54 to 0.6 cm (see the dotted line in Fig. 1). This procedure later aided in making a vacuum seal.

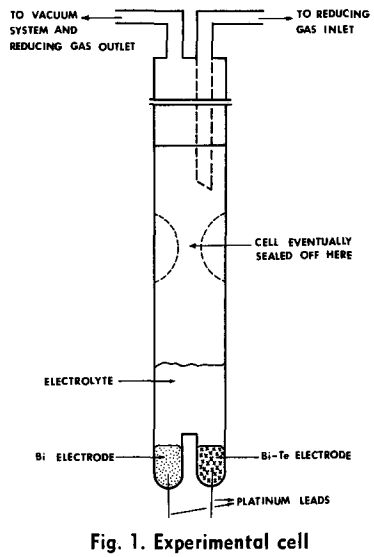

Fig. 1. Experimental cell

[1] Present address: Chemical and Petroleum Engineering Department, University of Pittsburgh, Pittsburgh, Pennsylvania 15200.

Key words: bismuth-tellurium system, thermodynamic properties, phase diagram.

During the preparation of the electrode, a small amount of the tellurium could vaporize. A careful collection of the vaporized tellurium in the upper part of the experimental cell indicated that the loss of the tellurium under the most unfavorable condition, *i.e.*, prolonged annealing at high temperature, was approximately 0.2 m/o (mole per cent) of the tellurium used. Therefore a maximum correction of —0.2 m/o tellurium must be made in the "weighed-in" alloy composition.

A mixture of $BiCl_3$ and LiCl + KCl eutectic was used as electrolyte. The LiCl + KCl eutectic was purified according to the method of Laitinen, Ferguson, and Osteryoung (2). The bismuth chloride used was reagent grade and was dehydrated under vacuum before use.

Approximately 8g of LiCl + KCl eutectic and 1.5g of $BiCl_3$ were used as the electrolyte in each cell. All the material transference was performed inside a high-purity nitrogen-filled dry box in which oxygen was less than 2 ppm and moisture 0.5 ppm. The cell was then sealed under vacuum.

The experimental cell was placed vertically in a 7.62 cm ID split furnace. Glass wool was used as packing material around the cell to assure a firm vertical position. The leads of the cell were connected to a potentiometer. The temperature of the cell was measured with a chromel-alumel thermocouple which was attached to the bottom of the cell.

The temperature of the furnace was gradually brought up to 766°K, the highest desired temperature in this study, in a period of 2 hr. The emf became constant once thermal equilibrium was attained. The emf measurements were recorded every 10-30 min for a period of 12-24 hr. The experimental data show that the fluctuation of these measurements during this period was less than 1 mV. The operating temperature was lowered to 700° and then 655°K. At each temperature the system was held for a period of 12-24 hr, and the emf measurements mentioned above were repeated. Subsequently, the operating temperature was raised again to 766°K in order to observe any hysteresis effect.

Results and Discussion

A summary of the experimental data is presented in Table I. The emf was taken as positive if the bismuth-tellurium alloy electrode was positive. At each temperature, the emf increased as the tellurium composition in the alloy increased. The emf increased as the operating temperature decreased for each alloy having a tellurium composition of 34.9 m/o or more. For alloys which had a tellurium composition less than 34.9 m/o, the emf decreased slightly as the operating temperature decreased.

As mentioned before, the emf for each alloy composition at each temperature was recorded every 10-30 min for a period of 12-24 hr, and the emf's reported in Table I are average values of those recorded during that 12-24 hr period. In each cell, at a fixed temperature, the initial emf and that at the end of the 12-24 hr period were very close. The difference was generally 2% or less of the reading. In each run, the temperature was cycled between 766° and 655°K at least once. In some runs, the temperature was cycled three times. The emf's were always within 2% of those previously recorded, indicating no appreciable hysteresis effect for any alloy composition at any temperature. The reversibility and stability of this galvanic cell with fused salt electrolyte were exceptionally good, as was the reproducibility of the emf measurements. But at lower temperatures, the impedance of the cell increased, which made the emf measurement more difficult and affected the precision of these measurements.

The activity of the bismuth in the alloy was calculated from the emf measurements. The relation between the activity of the bismuth in the alloy and the composition of the alloy at 766°K is shown in Fig. 2. As expected, the activity of the bismuth in the alloy inclines more toward the ideal solution value as the bismuth atom fraction approaches unity. The activity of the bismuth deviates from Raoult's law considerably when the bismuth content is less than 49.9 m/o.

The activity of the tellurium in the alloy at 766°K was obtained by graphical integration of the Gibbs-Duhem relation

$$\ln a_{Te} = -\int_0^{x_{Bi}} \frac{x_{Bi}}{1 - x_{Bi}} \left(\frac{\partial \ln a_{Bi}}{\partial x_{Bi}} \right) dx_{Bi} \quad [3]$$

The equation above can be integrated by parts, thus

$$\ln a_{Te} = \int_0^{x_{Bi}} \frac{\ln a_{Bi}}{(1 - x_{Bi})^2} dx_{Bi} - \frac{x_{Bi}}{1 - x_{Bi}} \ln a_{Bi} \quad [4]$$

The activity of the tellurium in the alloy at 766°K is also plotted as a function of the alloy composition in Fig. 2. There are two comments which should be made concerning the accuracy of the computed values of a_{Te}.

1. Considerable uncertainty was introduced during the integration of the Gibbs-Duhem relation in Eq. [4], since the measurements of the emf's were not available for alloys having a very high or low bismuth composition. Therefore, at best only fair accuracy in evaluating the activity of the tellurium should be expected.

2. At high tellurium composition, the computed activity of the tellurium has a positive deviation from Raoult's law whereas at low tellurium composition a negative deviation. Similar behavior has been observed in the activity of the aluminum in the silver-aluminum system at 1273°K (3, 4). A physical meaning of this positive and negative deviation from Raoult's law for a component is not readily apparent.

The partial molar free energy, *i.e.*, the chemical potential, of the bismuth in the alloy at 766°K can be

calculated directly from the experimental measurements. The partial molar free energy of the tellurium was calculated from the activity of the tellurium obtained above. Both the partial molar free energy of the bismuth and the tellurium in the alloy at 766°K, using pure bismuth and pure tellurium, respectively, as the reference states, are presented in Table II. For a binary system, the relative integral molar free energy is defined as

$$G^m = x_{Bi}(\bar{\mu}_{Bi} - \mu_{Bi}^{\circ}) + x_{Te}(\bar{\mu}_{Te} - \mu_{Te}^{\circ}) \quad [5]$$

The relative integral molar free energy of the bismuth-tellurium alloy at 766°K was computed and is plotted as a function of the alloy composition in Fig. 3.

The relative partial molar entropy of the bismuth in the alloy can be calculated using the equation

$$\bar{S}_{Bi} - S_{Bi}^{\circ} = ZF\left(\frac{\partial E}{\partial T}\right)_P \quad [6]$$

The temperature coefficient of the emf in our case was estimated only by measurements between 700° and 766°K. The relative partial molar entropy of the tellurium in the alloy may be obtained by a graphical integration of the Gibbs-Duhem relation in the form of

$$\Delta\bar{S}_{Te} = \int_{x_{Bi}=0}^{x_{Bi}} \left(\frac{x_{Bi}}{x_{Te}}\right) d\Delta\bar{S}_{Bi} \quad [7]$$

The limit of the integration is so chosen that the relative partial molar entropy of the pure tellurium is zero. This choice of limit simplifies the calculation and has been adopted by Lewis and Randall (5), Kleppa (6), and Wagner (7). Both the relative partial molar entropy of the bismuth and the tellurium in the alloy are presented in Table III. The relative integral molar entropy of the bismuth-tellurium alloy at 766°K is plotted as a function of the alloy composition in Fig. 4. The uncertainty in the integration mentioned earlier is, of course, reflected in both $\bar{S}_{Te}$ and S^m. In addition, the slope dE/dT, is somewhat uncertain because of the limited number of points at different temperatures. The estimated value of S^m at the compound, Bi_2Te_3, is −7.8 ± 2.3 cal/g at. °K. The relative integral molar entropy of the bismuth-tellurium alloy, therefore, is negative. There are binary metallic systems which also possess a negative molar entropy such as gold-cadmium, sodium-lead, and iron-silicon, etc. (8). Radcliffe (9) and his co-workers have found that the relative integral molar entropy of iron-aluminum alloy has a negative value. Radcliffe qualitatively associated this negative value with changes in the configurational, magnetic, vibration, and conduction-electron energies of the alloy. In the bismuth-tellurium system, we consider that similar effects may account for the negative value. However, a quantitative discussion of each contribution to the relative integral molar entropy is not possible.

The relative partial molar enthalpy of the bismuth was computed from

$$\bar{H}_{Bi} - H_{Bi}^{\circ} = (\bar{\mu}_{Bi} - \mu_{Bi}^{\circ}) + T(\bar{S}_{Bi} - S_{Bi}^{\circ}) \quad [8]$$

The relative partial molar enthalpy of the tellurium was obtained by a graphical integration of the Gibbs-Duhem relation in a calculation analogous to that of the relative partial molar entropy. Both the relative partial molar enthalpy of the bismuth and the tellurium at 766°K are presented in Table IV. The relative integral molar enthalpy at 766°K is plotted as a function of the alloy composition in Fig. 5. The relative integral molar enthalpy of an alloy corresponding to Bi_2Te_3 is −46 ± 10 kcal/g mole Bi_2Te_3 at 766°K. Using the heat of formation and heat capacity data of Bi_2Te_3 compiled by Kubaschewski and his co-workers (8), we computed the relative integral molar enthalpy of Bi_2Te_3 and obtained a value of −30.06 kcal/g mole at 766°K. This value is significantly smaller than our experimental result. The deviation may be caused by uncertainties in the Gibbs-Duhem integrations and the determination of dE/dT.

* Value obtained from $\Delta\bar{G}_{Bi} = \Delta\bar{H}_{Bi} - T\Delta\bar{S}_{Bi}$ and rounded to three significant figures.

The thermodynamic data obtained above permit a qualitative understanding of the characteristics of the alloy. For instance, the relative integral molar enthalpy of the alloy gives an estimate of the bonding energies. The relation between the relative integral molar enthalpy and the bonding energies formulated by Herzfeld and Heitler (10), Guggenheim (11), Bethe (12), and Wagner (7) is adopted here

$$H_{Bi\text{-}Te}^{m} = J_{Bi\text{-}Te}[U_{Bi\text{-}Te} - \tfrac{1}{2}(U_{Bi\text{-}Bi} + U_{Te\text{-}Te})] \quad [9]$$

where J designates the number of Bi-Te atom pairs and U the corresponding energy for the individual combination of atom pairs referred to the gaseous state.

In this study, the values of $H_{Bi\text{-}Te}^{m}$ obtained from the experimental results are negative throughout the composition range of $x_{Bi} = 0 - 1.0$. These negative values of $H_{Bi\text{-}Te}^{m}$ indicate that the bonding energy of the pair atoms Bi-Te, $U_{Bi\text{-}Te}$, is greater than the average bonding energy of pair atoms Bi-Bi and Te-Te. This conclusion agrees with the bismuth telluride structure proposed by Drabble and Goodman (13). They suggest that the bonding length between Te atoms (3.57Å) in adjacent layers is greater than that between the bismuth and the tellurium atoms (3.12-3.22Å) in the layer. The large spacing between the Te layers suggests that the layers are held together by weak van der Waals forces between the Te atoms, whereas the bonding between the Bi-Te atoms is predominately covalent.

Also relevant to the constitution of alloys are (*i*) the different electronic states, and (*ii*) the electronic contributions to the thermodynamic properties. From the relation of the electronegativities and the changes in the electron/atom ratio that take place in the alloying process. Wagner (6) has shown, in the silver-tellurium system, how the difference in the electronic states contributes to the thermal properties of the alloys. We have adopted his basic approach and assumed (*A*) that in the bismuth-tellurium system, as in the silver-tellurium system, elemental bismuth releases electrons to form cations and tellurium species take up electrons to form anions, and (*B*) that the valence of the bismuth ions equals +3 throughout the composition range.

The alloys may be characterized at any of the following three states:

1. The mole ratio between Bi and Te is greater than 2:3 ($n_{Bi}/n_{Te} > 2/3$). Thus, there is an excess of bismuth, and the predominant constituents are Bi^{3+} and composite anions with more than two negative charges per atom of tellurium.
2. The mole ratio between Bi and Te is equal to 2:3 ($n_{Bi}/n_{Te} = 2/3$). This is the case of an ideal stoichiometric composition, and the only constituents are Bi^{3+} and Te^{2-}.
3. The mole ratio between Bi and Te is less than 2:3 ($n_{Bi}/n_{Te} < 2/3$). There is an excess of tellurium, and the predominant constituents are Bi^{3+} and composite anions with less than two negative charges per atom of tellurium.

Therefore, two cases may be distinguished in the relative partial molar enthalpy of bismuth.

1. When the bismuth is transferred from its pure state (Bi^{3+}, e^{-}) to an alloy rich in bismuth, a rearrangement of the quasi-free electrons will not occur because there are only Te^{2-} ions saturated with electrons. The corresponding relative partial molar enthalpy of the bismuth will be relatively small.
2. When the bismuth is transferred from its pure state to an alloy rich in tellurium, the electrons introduced will be taken up by the tellurium, since there are tellurium anions with less than two negative charges per atom of tellurium, these will tend to become saturated Te^{2-} ions. The relative partial molar enthalpy will therefore be strongly negative, corresponding to the electron affinity of the unsaturated tellurium anions.

The experimental results of the relative partial molar enthalpy of the bismuth in our study show a behavior exactly as predicted above. $\Delta\bar{H}_{Bi}$ has a slightly positive value of +182 cal/g-mole with a tellurium content of 17.83 m/o, but becomes negative and attains a value of −23500 cal/g-mole with a tellurium content of 89.10 m/o in the alloy. The relation between $\Delta\bar{H}_{Bi}$ and composition of the alloy is shown in Fig. 6. This suggests that the states of the bismuth-tellurium alloys discussed above are reasonable.

Phase Diagram

The phase equilibrium diagram of the bismuth-tellurium system has been studied by different investigators. However, the exact form of the phase equilibrium diagram of this system is still obscure. Hansen (14) summarized earlier work by others and pre-

sented a phase diagram, but the solidus curves were not given. Phase diagrams of the bismuth-tellurium system have been proposed independently by Brown and Lewis (15), Abrikasov and Bankina (16), and Glatz (17). There is remarkable disagreement among these reported phase diagrams, particularly in the region around the compound Bi_2Te_3 (60 m/o Te). Both Brown and Lewis and Hansen report the "compound" Bi_2Te_3 can exist as a single phase over a wide composition range while Abrikasov and Bankina and Glatz report a very narrow range of stability for Bi_2Te_3. These apparent discrepancies indicate that a more detailed investigation of the bismuth-tellurium system is required in order to clarify the phase diagram.

Electromotive force measurements, coulometric titrations, x-ray diffraction, and differential thermal analyses were employed in this study. The experimental procedure and results of each method are discussed below.

Electromotive Force Measurements

The application of emf measurements in determining phase diagrams has been discussed by Chipman (4) and Wagner (7), and the detailed experimental procedure for emf measurements on the bismuth-tellurium system has been described in the previous section. An important advantage of studying phase transitions by this technique is that it permits a horizontal examination of the phase diagram rather than a vertical one. In other words, the emf measurements detect the phase boundaries on a horizontal, constant temperature segment of the phase diagram. Thus, at each specific temperature, a plot of the cell potential as a function of the alloy composition will indicate the phase boundaries. A plot of the potential at 766°K (Fig. 7) shows three regions on the curve with a slope of zero, indicating these three regions are two-phase regions. One region appears between the tellurium composition of 34.8 ± 0.1 and 45.9 ± 0.1 m/o; another, between 58.5 ± 0.1 and 60.5 ± 0.1 m/o; and the third between 61.9 ± 0.1 and 88.9 ± 0.1 m/o. One can compare the discrepancies between previous published phase diagrams and the results of our study. Hansen proposed that there are two two-phase regions existing at 766°K: one, between 35 and 52 m/o tellurium; another, between 61.5 and 83 m/o tellurium. Brown and Lewis suggested that these two-phase regions at 766°K exist between 34 and 56.5 m/o and 61.5 and 83 m/o tellurium. Glatz proposed that, at 766°K, there are three two-phase regions; the first one from an undefined lower boundary up to 46.5 m/o tellurium, the second one between 57.5 and 59.7 m/o, and the third one from approximately 60 m/o tellurium up to an undefined upper boundary. Abrikasov and Bankina gave the boundaries of these two-phase regions at 766°K as 34.0 to 49.0 m/o, 54.7 to 60.2 m/o, and 61.0 to 84 m/o tellurium, respectively.

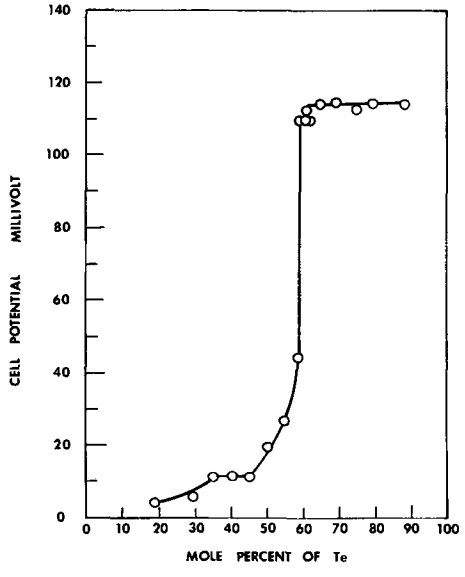

Fig. 7. Cell potential vs. composition at 766°K

Qualitatively, our results agree with those of Glatz and of Abrikasov and Bankina extremely well. This is particularly noticeable in the region near 60 m/o tellurium, namely, near the compound Bi_2Te_3, where our results and those of Glatz and of Abrikasov and Bankina show a narrow single phase region rather than the wide range represented by Hansen and Brown and Lewis. Quantitatively, we find the single β-phase region to exist between the boundaries of 45.9 — 58.5 ± 0.1 m/o tellurium at 766°K. Glatz defines the boundaries as 46.5 — 57.5 m/o at the temperature, and Abrikasov and Bankina, as 49.0 — 54.7 m/o tellurium. Our experimental result confirms quantitatively the boundaries of the β-phase at 766°K postulated by Glatz.

The emf's of each experimental cell were measured at 700° and 655°K as well as 766°K. The relation between the emf and the composition at the two lower temperatures can also be shown analogously to that shown in Fig. 7 for 766°K. However, the impedance of the galvanic cell increased considerably at the lower temperatures and affected the precision of the measurements. Therefore, one cannot rely absolutely on the precision of data obtained at the lower temperatures, particularly at 655°K. Consequently, low-temperature measurements must be complemented with supplementary techniques.
