A study has been made of room-temperature implantations of large doses of P, As, and Sb into Si substrates, followed by annealing in the temperature range 550°-600°C and of implantations of these species into Si substrates maintained at 600°C. Neutron activation combined with anodic oxidation and HF stripping techniques was used to determine the profiles of the implanted ions. Electrical evaluation of the implanted layers by Hall effect and sheet resistivity measurements in conjunction with anodic oxidation and HF stripping techniques yielded profiles of the net electrically active species. The profiles obtained for 600°C implantations are markedly orientation dependent since the crystalline nature of the Si lattice is maintained during the implantation. Most of the P, As, or Sb ions implanted at room temperature are electrically active after annealing at 550°-600°C, and the carrier mobility observed in the implanted layer approaches that observed in comparably doped bulk Si. Only a small fraction of the ions implanted at 600°C are electrically active and uncompensated, and the carrier mobility in these layers reflects the increased scattering due to charged compensating defects.

In the process of ion implantation doping of silicon at room temperature, the overlapping of disordered regions produced by the energetic heavy ions eventually results in the formation of a completely amorphous region extending to the surface of the silicon substrate, provided the implanted dose is sufficiently large (1). The recrystallization of such amorphous regions occurs in the temperature range 500°-600°C and results in epitaxial regrowth onto the underlying undamaged Si substrate (1,2). If the substrate is maintained at a high enough temperature (*e.g.*, greater than 400°C for dose rates normally employed in ion implantation) during the implantation process, enough radiation damage is annealed during the course of the implantation to preclude the formation of a completely amorphous region (3). In a previous publication, the presence of a completely amorphous region was demonstrated to be advantageous in achieving a large fraction of the implanted species electrically active and uncompensated (P, As, and Sb in Si) at a low annealing temperature (*e.g.*, 600°C) (4). The purpose of the present paper is to expand these initial investigations. The profiles (total and net electrically active) for P, As, and Sb implanted into Si have been investigated for (*a*) room-temperature implantations followed by a 550°-600°C post implantation anneal and (*b*) implantations into Si substrates maintained at 600°C. The total doses employed were sufficiently large to produce a visible amorphous region for the room-temperature implantations.

Experimental

The group V ions were implanted into Si samples using a Cockcroft-Walton accelerator capable of operation to 300 kV. The ions P and As were obtained from gaseous species (PF_5, AsH_3) in an oscillating electron source of our design (5). An Ar plasma was used to heat solid Sb in a quartz crucible suspended inside the same source, thereby obtaining a sufficient vapor pressure of Sb. The ion beam was focussed, mass analyzed magnetically, and scanned uniformly over the sample (4 cm^2). In the case of Sb, Sb^{123} was employed since this isotope, upon neutron activation, yields Sb^{124} which has a 60.9-day half life. The Si substrates were <100> wafers cut from Czochralski-grown crystals, which were boron doped and 1 ohm-cm resistivity. The substrates were lapped and chemically polished. It was possible to heat the samples as high as 700°C during implantations. The total dose was obtained by integrating the current from the samples (room-temperature implantations) or from a beam profile monitor (high-temperature implantations). The currents were measured with a Faraday cup. Dose rates were typically 1-5 $\mu A\ cm^{-2}$. For this study, accurate target alignment (*i.e.*, within 0.1°) was not available since the beam sweep was over approximately ±1°.

After implantation, the wafers to be used for obtaining the total profile of the implanted species were subjected to a thermal neutron flux $10^{13}\ cm^{-2}\ sec^{-1}$ for a few days to produce P^{32}, As^{76}, or Sb^{124} depending on the implanted species. After sufficient time for the Si^{31} (half life 2.5 hr) to decay, the wafers were sectioned by anodizing and dissolving the anodic oxide in dilute HF. A radiochemical assay by liquid scintillation counting was performed on the resultant solutions to determine the specific activity of each section; precautions were taken to insure against the loss of any radioactive material and to avoid cross contamination. The system was calibrated by including a standard wafer of known impurity concentration with each group of activated wafers. Half-life determinations and γ-ray spectral analyses were used for positive identification of the isotopes.

The electrical evaluation of ion-implanted layers utilizing Hall effect and sheet resistivity measurements on van der Pauw configurations in conjunction with anodic oxidation and HF stripping techniques has been described fully by Mayer, Marsh, Shifrin, and Baron

[1] Present address: SEMI, 1910 W. Cheryl Drive, Phoenix, Arizona.

(6). In the following experiments, the electrical profiling operation was performed in one sample holder (Fig. 1). This design allows etching, anodic oxide formation, and electrical measurements to be performed *in situ*, with electrical contacts being applied only once. To facilitate good electrical contact to the implanted regions, diffused contact pads (As doped) were utilized. Clover-leaf van der Pauw configurations (Fig. 2) were obtained by etching techniques employing a 3:2:1 mixture of nitric acid, acetic acid, and hydrofluoric acid. Contact to the diffused contact pads was achieved by evaporated Al. A fifth large-area Al contact was evaporated onto the rear of the wafer (for use in evaluating the effectiveness of the electrical isolation provided by the p-n junction formed by the implanted species in the B-doped Si substrates). The contacts were sintered at 450°C for 5 min. Electrical contact was made by fastening Pt wires to the Al pads by means of conducting Ag paste.

The anodic oxide growth (and consequent Si removal) was accomplished *in situ* by the insertion of a Pt cathode into the sample holder (Fig. 1) and the use of the Hall contacts and the rear contact to complete the circuit. The electrolyte used was a 0.001*N* solution of potassium nitrate in N-methylacetamide to which was added 3% water. The film growth was terminated automatically by presetting the limiting voltage on a constant current power supply. Typical oxide film thicknesses ranged from 430 to 1000Å (corresponding to 200-460Å of Si removed).

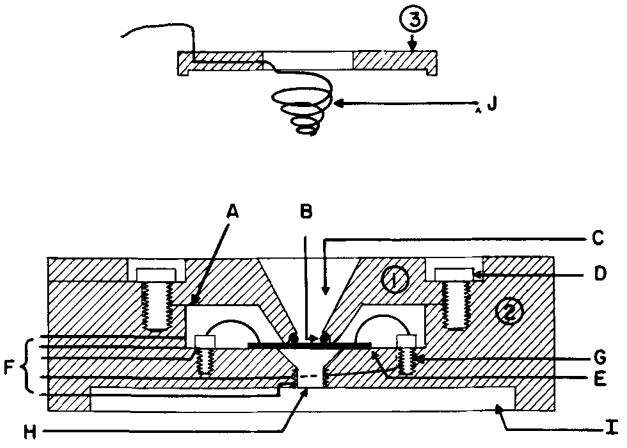

Fig. 1. The sample holder used for stripping and measurements consists of three parts. The holder consists of two Teflon parts, 1 and 2, which fit together well enough to provide a seal at A to protect the contact areas from anodizing and etching solutions. An "o" ring provides a seal at B between the Si wafer, E, and the upper section, 1, thus defining a reservoir, C, for containing anodizing and etching solutions. The upper and lower sections, 1 and 2, are held together by nylon screws, D. Electrical contacts terminate in a Jones plug, F, which has five connections, four to the van der Pauw sample and one to the back of the Si substrate. Contact to the van der Pauw sample is provided by Pt wires attached to the Al pads (Fig. 2) and soldered to the posts, G. Contact to the back of the sample is provided by Ag paste between Al on the wafer and the contact, H. A groove, I, in the lower section fits over one pole face of the magnet, allowing reproducible alignment of the sample. The section 3 constructed from Teflon and with a Pt cathode, J, provides a reproducible cell geometry for the anodic oxidation.

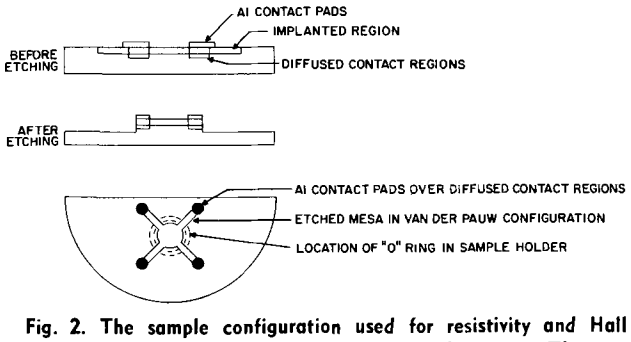

Fig. 2. The sample configuration used for resistivity and Hall measurements is a modified van der Pauw configuration. The test sample is produced by etching a mesa, relying on the junction to provide electrical isolation from the substrate. The portion of the sample which is stripped is inside the area delineated by the "o" ring.

Electrical measurements were made by conventional d-c potentiometric techniques. The van der Pauw configuration is ideally suited to stripping techniques in that a viton "o" ring seal may be inserted between the contact pads and the central region (Fig. 2). The contacts are unaffected by the etching and oxide growth to be performed on the central region and therefore need be applied only once. The magnetic field used for the Hall measurements was 7.5 kilogauss. At the beginning of a stripping run, typical currents, provided by a constant current power supply, were 10^{-4} A and were reduced as the sample resistance increased to minimize the voltage drop across the sample contacts but yet maintain sufficient sensitivity in the Hall measurement.

At the conclusion of a stripping experiment, one has a set of sheet Hall coefficients and sheet resistivities corresponding to a number of successive removals of a known quantity of Si. These data can be reduced to a profile of the concentration and mobility of carriers as a function of the depth from the surface. The details of this data reduction are fully explained in Ref. (6).

The samples which were used for electrical evaluation were implanted under identical conditions to those used to obtain the total profile of implanted atoms with neutron activation analysis and stripping techniques. The use of two separate samples was dictated by the fact that, during the process of neutron activation, massive damage to the sample is incurred which would also influence the annealing characteristics of electrical properties of the implanted ions.

Experimental Results and Discussion

Profiles of implanted species.—Typical profiles obtained by neutron activation and stripping techniques are presented for P (Fig. 3), As (Fig. 4), and Sb (Fig. 5) implanted into <100> silicon wafers. For the P implantations (Fig. 3), the energy of the ions was 280 keV and the dose was 9 x 10^{15} cm^{-2} (room-temperature implantation) and 3 x 10^{15} cm^{-2} (600°C implantation). The room-temperature implantation exhibits a somewhat smaller most probable range, R_p, than the 600°C implantation (0.38 and 0.42μ, respectively). The significant difference in the profile obtained at 600°C relative to the profile obtained at room temperature is the markedly more asymmetric and broader distribution of ions which penetrate more deeply into the Si substrate than the most probable range. For As implantations (Fig. 4), similar results were obtained [R_p = 0.19μ (room temperature) and 0.24μ (600°C)]. The implantation parameters for these As implantations were: 280 keV, total dose = 4 x 10^{15} cm^{-2} (room temperature) and 3 x 10^{15} cm^{-2} (600°C). The solid curve in Fig. 4 was obtained for a <100> silicon substrate misoriented by 7° during the 600°C implantation of 3 x 10^{15} As cm^{-2} (the data points are omitted for clarity).

During the room-temperature implantations, most of the implanted ions impinge on amorphous Si, since the total dose in all cases was more than sufficient to produce a completely amorphous region extending to the substrate surface. Crystalline effects such as channeling were thus not important for most of the ions implanted at room temperature, since channeling is markedly reduced when sufficient lattice disorder is present (7, 8). During 600°C implantations, much of the damage is continuously annealed (3), and crystalline effects, such as channeling, were important

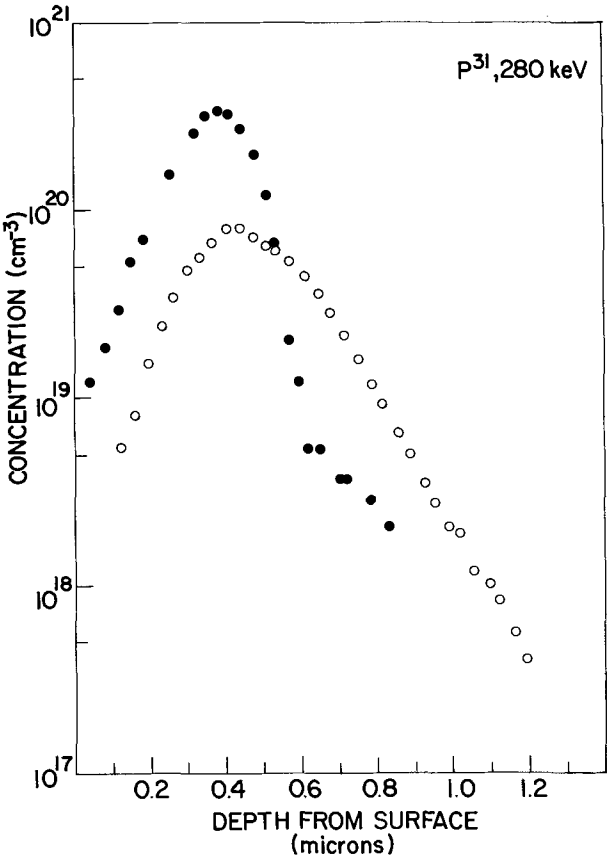

Fig. 3. Implantation profiles of P^+, 280 keV, into <100> Si. Open circles, ○, represent 500°C implant (3 x 10^{15} cm^{-2}), and closed circles, ●, represent room-temperature implant (9 x 10^{15} cm^{-2}).

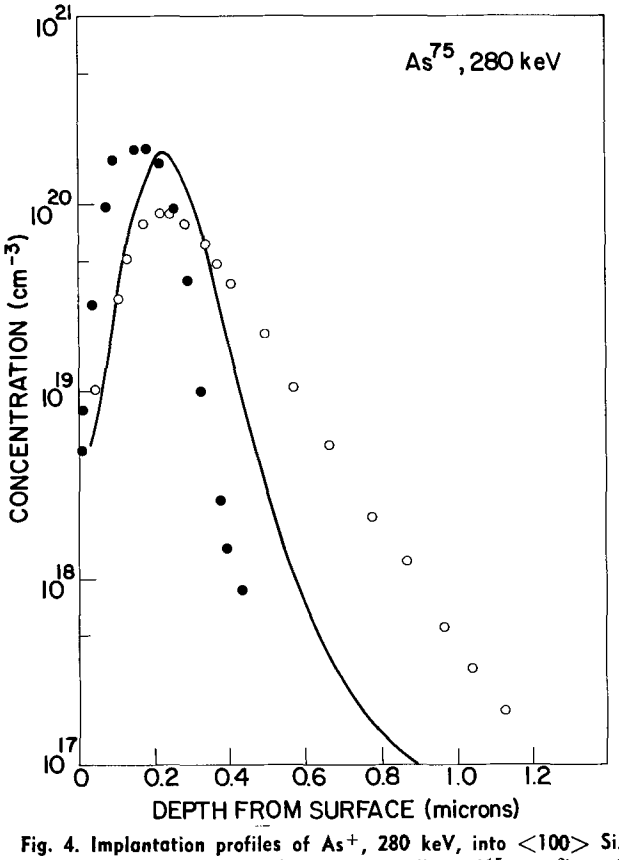

Fig. 4. Implantation profiles of As^+, 280 keV, into <100> Si. Open circles, ○, represent 600°C implant (3 x 10^{15} cm^{-2}), and closed circles, ●, represent room-temperature implant (4 x 10^{15} cm^{-2}), and the solid line represents 600°C implant (3 x 10^{15} cm^{-2}) in which the <100> wafer was misoriented by 7 deg.

during the entire implantation. The asymmetry in the 600°C implantations is thus due to crystalline effects (channeling) and the orientation of the substrate is important, as evidenced in the marked difference in profiles obtained at 600°C for the <100> silicon substrate and the <100> silicon substrate misoriented by 7°. Although not shown in Fig. 4, a nearly identical profile to that obtained for the <100> silicon substrate was observed for 280 keV As (3 x 10^{15} cm^{-2}) implanted into a <111> silicon wafer at 600°C (no misorientation).

Figure 5 depicts the profile obtained from a room-temperature Sb^{123} implantation (120 keV, 1 x 10^{15} cm^{-2}) into <100> Si. The deeply penetrating tail is undoubtedly due to channeling effects present during the initial stages of the implantation when the amount of lattice disorder is not sufficient to prevent such effects, as has been experimentally verified for As implantations at room temperature (7).

Profile of net electrically active species.—A comparison of the profile of total P atoms (280 keV, 8 x 10^{15} cm^{-2}) with the net electrically active carriers is presented in Fig. 6. The implantations were conducted at room temperature into <100> Si substrates. The electrically active profile was obtained after a series of 30 min isochronal anneals from 500° to 800°C. After the 550°C isochronal anneal, the sheet resistivity of this implantation was 14 ohms/sq with a corresponding carrier concentration of 6.4 x 10^{15} cm^{-2}. After the 800°C annealing step, the sheet resistivity was 12 ohms/sq with a corresponding 6.1 x 10^{15} carriers cm^{-2}. Most of the implantation is thus electrically active after only a 550°C, 30 min anneal.[2] From Fig. 6, it is apparent that essentially all of the P atoms implanted are electrically active after an 800°C anneal, except perhaps in the tail region beyond 0.6μ. The carrier mobility of this sample as a function of carrier concentration is presented in Fig. 7, which indicates that the mobility in the implanted layer is comparable to what would be observed for bulk Si of comparable doping levels [after Irvin (9)].

Quite a different situation is observed for P implantations conducted at 600°C (Fig. 8). The implantation parameters were 300 keV, 1.5 x 10^{16} P cm^{-2}, 600°C, Si substrate <100> orientation. The carrier concentration is markedly lower than the concentration of implanted P atoms. In addition, the mobility of the carriers in this sample is markedly lower than that predicted for bulk Si of comparable carrier concentrations, perhaps indicating increased scattering by charged compensating defects responsible for the lack of complete electrical activity of the implanted P atoms (Fig. 7).

Analogous results were also obtained for As and Sb implantations; namely, room-temperature implantations followed by a 600°C anneal produced material in which most of the implanted species are electrically active with a mobility characteristic of bulk Si of comparable doping levels, while 600°C implantations yielded layers in which most of the implanted atoms are not electrically active and uncompensated and the mobility observed is markedly lower than expected for uncompensated bulk Si of comparable carrier concentrations, indicative of appreciable scattering by defect centers.

The profiles resulting from annealing room-temperature implantations of As (280 keV, 4 x 10^{15} cm^{-2},

[2] The carrier concentration referred to here is an effective carrier concentration cm^{-2} determined from the sheet Hall coefficient of the entire implanted layer by the simple relationship $[n^*_s = 1/(R_H e)]$, where n^*_s is the effective number of carriers cm^{-2}, R_H is the measured sheet Hall coefficient, and e is the electronic charge. The number of carriers cm^{-2} determined from this measurement is always lower than the true number cm^{-2} obtained by integrating over the observed carrier distribution. This occurs because the sheet Hall coefficient is a weighted average which favors carriers of higher mobility [see Ref. (6) for a good discussion of this point]. The decrease in resistivity and the decrease in effective carriers cm^{-2} upon annealing to 800°C is due primarily to the fact that the tail of the distribution becomes electrically active only at the higher annealing temperature. This point is discussed more fully in connection with Fig. 9 of the text.

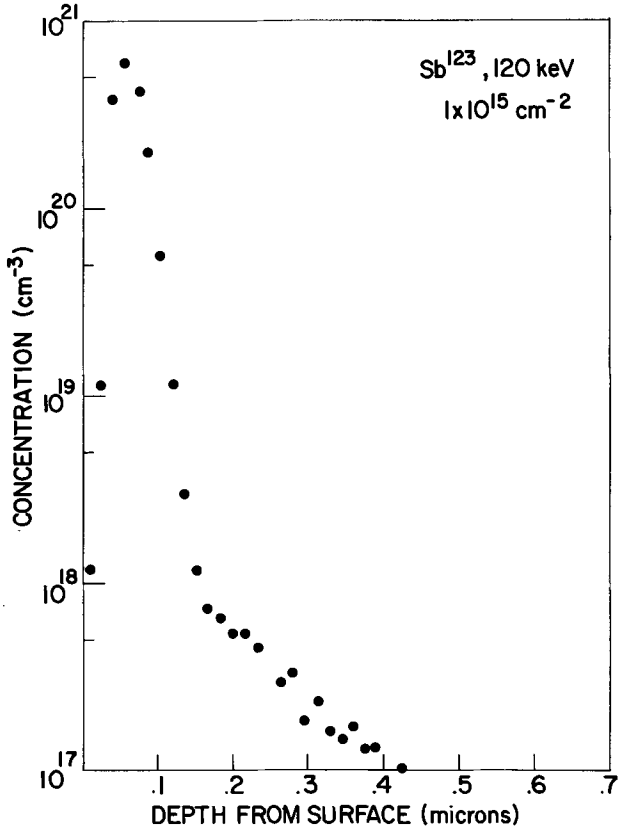

Fig. 5. Implantation profile of Sb^+, 120 keV, into <100> Si. The total implanted dose was 1 x 10^{15} cm^{-2}.

<100> Si) for 30 min at either 550° or 800°C are shown in Fig. 9. The observed carrier concentration beyond 0.36μ in the sample annealed at 500°C exhibits a marked fall-off relative to that in the sample annealed at 800°C. This phenomenon is due to only a small fraction of the implanted As atoms being electrically active and uncompensated in this tail region in the sample annealed at 550°C rather than to a diffusion of As atoms occurring in the sample annealed at 800°C. In a previous study, it was determined that no noticeable diffusion of implanted As atoms occurred at temperatures below 850°C (7). An attractive explanation of this phenomenon is that the amorphous Si layer did not extend as deep as 0.36μ and thus a temperature much higher than 550°C would be required to achieve a large fraction of the implanted ions in the tail as electrically active and uncompensated. This is consistent with the previously published annealing characteristics of P and As implantations at doses below the critical dose required to produce an amorphous Si layer (4).

Summary

As in our previous study (7), for sufficiently high doses of P, As, or Sb ions, the profiles obtained by room-temperature implantations are relatively insensitive to crystalline orientation. "Tailing," due to channeling in the initial stages of the implantation (7), is more pronounced for P than for As or Sb (*i.e.*, for equal doses, a larger fraction of the implanted ions is partially channeled for P than for As or Sb) as expected, since more damage per ion produced by the heavier As or Sb would curtail channeling at an earlier stage. In this paper, we have demonstrated that, for 600°C implantations, crystalline effects remain important during the entire implantation and that the orientation of the substrate is important in determining the final profile.

Implantations conducted into Si substrates maintained at 600°C result in only a fraction of the implanted ions electrically active and uncompensated. The carrier mobility in such implanted layers reflects

increased scattering from charged defects yielding mobilities markedly lower than that expected from uncompensated bulk Si of comparable carrier concentrations. In contrast to this behavior, high-dose implantations of P, As, or Sb into Si substrates at room temperature followed by a 550°-600°C anneal yield the majority of the implanted carriers electrically active

and uncompensated with carrier mobilities approaching that expected for bulk Si of comparable doping levels. Temperatures markedly higher than 550°C are required to render the atoms in the tail of the distribution of room temperature implantations of P, As, or Sb electrically active and uncompensated, presumably due to the fact that these atoms lie outside the amorphous Si surface layer.[3]

[3] Note added in proof: This comment applies only to that portion of the tail of the distribution which lies outside the amorphous Si layer but within a layer which, although crystalline, is heavily damaged. Ions still deeper within the crystal (e.g., channeled ions) in a region of lower damage density may require lower annealing temperatures.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

Contact Resistance in Diffused Resistors

I. F. Chang

IBM Burlington, Components Division, Essex Junction, Vermont

ABSTRACT

The metal-silicon interface resistance is an important factor in the total resistance value of a diffused resistor. A contact correction term has to be considered for the design of resistors on an integrated circuit chip. This correction term is explored both experimentally and theoretically. Experimental results of contact correction are obtained for aluminum, sputtered molybdenum, and pyrolytic molybdenum to silicon contacts of various dimensions. Theoretically, a modified transmission line (MTL) model is introduced to describe the contacts of the diffused resistors. This model is based on the considerations of the geometry and the fabrication processes of the diffused resistor and its contacts. Model calculations compare very well with experimental findings. Thus, the equations derived from the MTL model can be used as design formulas to estimate a realistic value of the contact correction term for any given contact size and fabrication process, provided the process parameters are determined experimentally. In addition, the lower limit of the contact correction term is also obtained based on geometrical considerations only.

The design of monolithic integrated circuits requires a set of simple and correct device formulas as a design guide. For a diffused resistor, one usually uses the simple formula (1) for the resistance, R

$$R = \rho_s \frac{L}{W} \quad [1]$$

where L and W are the resistor length and width. The sheet resistance, ρ_s, is defined (2) as

$$\rho_s = \frac{\rho}{X_j} = \frac{1}{q\mu N X_j} \text{ (for uniform doping profile)} \quad [2]$$

or

$$\rho_s = \frac{1}{q\bar{\mu}\int_0^{X_j} N(x)\,dX} \text{ (for graded doping profile)} \quad [3]$$

where ρ is the resistivity and X_j is the junction depth of the diffusion. $N(x)$ is the doping profile and q and $\bar{\mu}$ are, respectively, the charge and average mobility of the majority carriers. When formula [1] is used in practice, it is often found to be yielding incorrect resistance values for actual diffused resistors. This discrepancy exists because the contacts to the resistor are contributing some resistance to the over-all resistor value. This extra resistance is particularly important in the design of low value resistors and resistors with tracking requirements. Therefore, one must add a contact correction term to Eq. [1] as

$$R = \rho_s \frac{L}{W} + 2R_{cc} \quad [4]$$

in order to achieve a correct design. R_{cc} is defined as the contact correction term per single contact. It is the intention of this work to analytically determine the added term, R_{cc}, such that Eq. [4] can be used as a design formula.

In general, the contact correction term may consist of several parts which may be caused by various different or combined mechanisms. For instance, the current crowding phenomenon due to the geometry of the resistor contacts can contribute to the R_{cc} term. This effect has been studied by Kennedy and Murley (3) using a two-dimensional model. The electric field distribution in the resistor is numerically determined. The current crowding in the vicinity of the ohmic contacts is clearly shown in their graphical presentation. Their model assumes a perfect metal-semiconductor interface which is never the case. In reality, one may have a metal semiconductor alloy at the contact region which may or may not be ohmic. The nonohmic type contacts fall outside the range of our concern here. The ohmic type, depending on the metallurgical processes, of course, contributes some resistance to R_{cc}.

A few measurements (4-6) of metal-silicon contacts have been performed in the past. However, these studies were made on large contacts and did not consider the chemical and metallurgical processes involved in the integrated circuit technology necessary for fabricating the diffused resistors. In particular, there is evidence (7) indicating that sometimes conductive or nonconductive films may exist at the metal-semiconductor interface. These films could be either by-products of some chemical masking processes or left-overs of imperfect cleaning and etching processes. They may also contribute to the contact correction term.

The above-mentioned possible contributions to R_{cc} can occur simultaneously and cannot be separately determined by experimental measurements. However, the contact correction term as a whole may be analytically obtained. This work intends to show that an analytic formula can be used to calculate the contact correction term as a whole for all sizes of contacts provided two process parameters are experimentally determined. This is necessary since R_{cc} is definitely a function of fabrication processes.

The measurements and the results of various metallurgical contacts of various sizes are described. Experimental data of contacts from aluminum, sputtered molybdenum, and pyrolytic molybdenum to silicon have been statistically compiled. An analytic model simulating a metal contact of a diffused resistor is introduced. Model calculations are compared with experimental results. A formula for the contact correction term is obtained. Furthermore, based on geometrical considerations only, a formula for contact correction can be derived to serve in the lower limit cases of R_{cc} for any given size of contacts. Conclusions are made.

Measurements

In order to study the contact correction term with respect to geometry and dimensions, resistors with various contact sizes and shapes were designed on a chip. Figure 1 shows a typical resistor pattern. All dimensions, W, a, d are nominal wafer dimensions. The side diffusion effect and contact over etch effect has been accounted for in the design. Two metal pads were connected to each contact so that one could be used as a voltage terminal and one as a current terminal. Thus, any contact resistance introduced by mea-

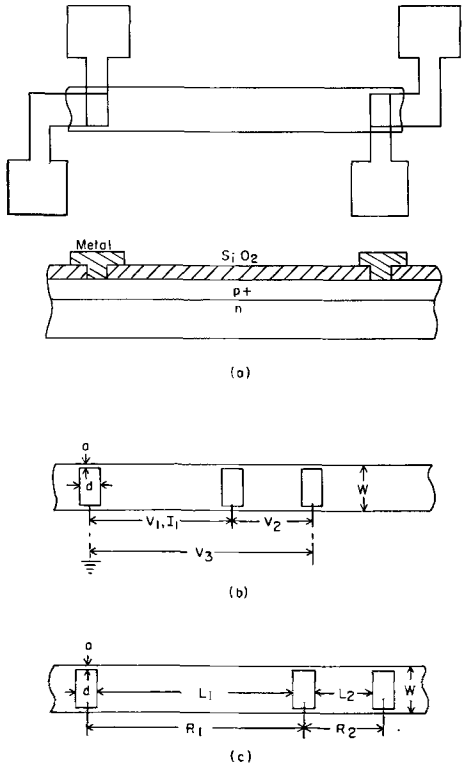

Fig. 1. Resistor test pattern for measurement of contact correction.

suring probes are excluded from the measurements. All the measurements were performed on the COSMIC programmed tester using an IBM 1130 computer. By program instruction, two probes can be chosen to be current terminals which supply constant current at 1 or 10 mA levels. The remaining probes sequentially measure the potentials on different contacts with respect to the grounded current terminal. The program is repeated when the test probes step on to the next chip. The series of measurements, according to the information they provide, can be classified as follows:

1. The measurement of resistor value with respect to the current direction into the contact: The current is applied to two contacts through any pair of pads as shown in Fig. 1(a). The potential between two pads is recorded accordingly. Resistor values derived from these measurements, however, do not show significant differences.

2. The measurement of R_c (defined below): The current is applied between two adjacent contacts on a long diffused resistor. Voltages on one contact and its neighboring contact [shown in Fig. 1(b)] are recorded. Thus R_c is defined as

$$R_c = \frac{V_2}{I_1} = \frac{V_1 - V_3}{I_1} \qquad [5]$$

3. The measurement of the contact correction term and sheet resistance of the diffused resistor: Fig. 1(c) shows the scheme for measuring two resistors with identical contacts. From measured resistor value R_1 and R_2 we obtain the sheet resistance and the contact correction term of the diffused resistor

$$\rho_s = \frac{W(R_1 - R_2)}{L_1 - L_2} \qquad [6]$$

$$R_{cc} = \frac{R_2L_1 - R_1L_2}{2(L_1 - L_2)} \qquad [7]$$

The above measurements were performed on a large number of chips. Different wafers were made with aluminum, sputtered molybdenum, and pyrolytic molybdenum contacts. In all cases, the metal deposition is made immediately after a conventional light hydrofluoric acid etch. In the case of molybdenum contacts, a thin layer of platinum silicide is formed at the interface in order to make good ohmic contact with molybdenum. The results of ρ_s, R_{cc}, and R_c obtained from the chips on these wafers have a fairly tight distribution. The mean values, peak values, and ranges of these measured results are shown in Table I. The sheet resistances obtained are essentially within a few per cent deviation from the mean values. Thus, only the mean values are shown in the table. The experimentally determined contact correction term is plotted as a function of contact width and length in the next section when comparison is made with the MTL model calculations. It can be seen from the table that the molybdenum contacts, in general, have higher contact correction values than the aluminum contacts.

Modified Transmission Line (MTL) Model

As mentioned before, the contact correction term not only depends on the geometry of the contact but also depends on the chemical and metallurgical processes involved in making the diffused resistor and its contacts. Therefore, one can only take an analytic approach to arrive at a useful formula. The formula should be such that an integrated circuit designer could use it to calculate contact corrections for various

sizes of contacts and resistors. Any process parameter involved in the formula should be experimentally measured for any given fabrication process.

Recently Berger (8) has proposed a transmission line (TL) model to describe the contact problem. However, when it is applied to the cases discussed here, one finds that the TL model calculations do not agree with the experimental results presented in the section on Measurements. Nevertheless, if certain modifications are made, a correct and useful formula for contact correction can be derived. The modifications are based on fabrication process considerations. We introduce these modifications along with a brief description of the TL model below.

The TL model assumes a parameter, σ_c, conductivity per unit area, to describe the contact sheet resistance. The series resistance beneath the contacts is described by the same sheet resistance, ρ_s, of the diffused resistor. This is not always a valid assumption, since in most cases the contact region is a metal-semiconductor alloy which will definitely have different resistivity. Furthermore, the contact width is assumed to be the same as the diffused resistor in the TL treatment. This approximation will lead to errors when the contact width is much smaller than the resistor width. However, considering the two assumptions above, an equivalent circuit can be drawn for the contact. Figure 2(a) shows the equivalent circuit in which R' and G' are defined as follows

$$R' = \frac{\rho_s}{W} \qquad [8]$$

$$G' = \sigma_c W \qquad [9]$$

The transmission line equation for this equivalent circuit can be written in terms of the load voltage and the load current. For open end termination, one obtains

$$V = E_R \cosh(\gamma y) \qquad [10]$$

$$I = \frac{E_R}{Z_o} \sinh(\gamma y) \qquad [11]$$

where

$$Z_o = \left(\frac{R'}{G'}\right)^{1/2} = \frac{1}{W}\left(\frac{\rho_s}{\sigma_c}\right)^{1/2}$$

$$\gamma = (R'G')^{1/2} = (\rho_s \sigma_c)^{1/2}$$

and E_R and I_R are the voltage and the current, respectively, at the load end. From Eq. [10] and [11] one can derive the following

$$R_{cc} = \left.\frac{V}{I}\right|_{y=d} = \frac{Z_o}{\tanh(\gamma d)} = \frac{1}{W}\frac{(\rho_s)^{1/2}(\sigma_c)^{-1/2}}{\tanh[(\rho_s\sigma_c)^{1/2}d]} \qquad [12]$$

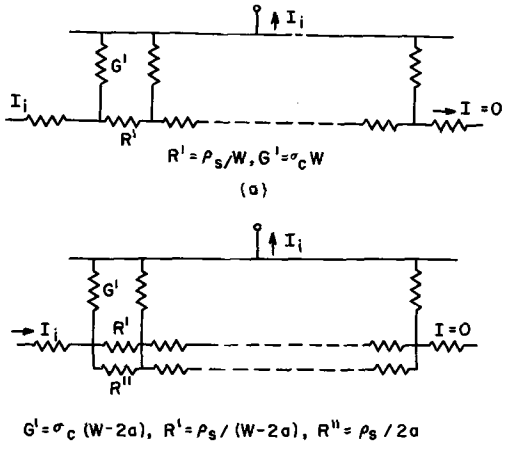

Fig. 2(a). Equivalent circuit for TL model. (b). Equivalent circuit for MTL model.

$$R_c = \left.\frac{E_R}{I}\right|_{y=d} = \frac{Z_o}{\sinh(\gamma d)} = \frac{1}{W}\frac{(\rho_s)^{1/2}(\sigma_c)^{-1/2}}{\sinh[(\rho_s\sigma_c)^{1/2}d]} \qquad [13]$$

Equation [12] gives the input impedance which is equivalent to the contact correction term R_{cc}, and Eq. [13] is the transfer impedance identified as R_c. From Eq. [12] and [13] one obtains the parameter

$$\sigma_c = \frac{1}{\rho_s}\left[\frac{1}{d}\cosh^{-1}\frac{R_{cc}}{R_c}\right]^2 \qquad [14]$$

which can be determined by the experimental measurement.

If the TL model were correctly predicting the contact correction term, then σ_c determined from Eq. [14] should be a constant regardless of contact size. However, this is not the case. The reason is that R_{cc}/R_c varies with the contact width W. This can be illustrated in another fashion. For example, we measured

$$\rho_s = 161 \text{ ohms/sq}$$
$$R_{cc} = 17 \text{ ohms}, R_c = 10 \text{ ohms}$$
$$W = 1 \text{ mil}, d = 0.5 \text{ mil}$$

for a typical sample of pyrolytic molybdenum contacts. The calculated σ_c of Eq. [14] is 0.0317 ohm/mil^2. However, when substituting this value into Eq. [12] and [13], one obtains values of R_{cc} and R_c, 87.9 and 51.43, which are far above the values we measured.

In view of the fabrication processes used for making the contacts, the above result is expected. When certain fabrication processes are used, they are likely to produce metal-semiconductor alloy at the contacts. This alloy may consist of the semiconductor material and the same metal used for the contact, or a different kind of metal. For example, in the case of our molybdenum test wafers platinum is used to form platinum silicide between the molybdenum and silicon at the contacts. Therefore, the assumption made in the TL model should be modified.

A new parameter

$$\rho_s' = \frac{\rho'}{X_j} \neq \rho_s$$

is introduced here to represent the series resistance at the contacts. A further modification should be made, that is to take into account the fact that the contact width is usually designed to be smaller than the resistor width. An exact treatment of this case would be too complicated. However, one could approximate this case by employing a parallel resistor scheme shown in the modified equivalent circuit, Fig. 2(b). Therefore, the contact correction term is

$$R_{cc} = \frac{\left[\left(\frac{\rho_s'}{W-2a} /\!/ \frac{\rho_s}{2a}\right)/\sigma_c(W-2a)\right]^{1/2}}{\tanh\left\{\left[\left(\frac{\rho_s'}{W-2a} /\!/ \frac{\rho_s}{2a}\right)\sigma_c(W-2a)\right]^{1/2} d\right\}} \qquad [15]$$

and

$$R_c = \frac{\left[\left(\frac{\rho_s'}{W-2a} /\!/ \frac{\rho_s}{2a}\right)/\sigma_c(W-2a)\right]^{1/2}}{\sinh\left\{\left[\left(\frac{\rho_s'}{W-2a} /\!/ \frac{\rho_s}{2a}\right)\sigma_c(W-2a)\right]^{1/2} d\right\}}$$

$$R_{cc}/R_c = \cosh\left\{\left[\left(\frac{\rho_s'}{W-2a} /\!/ \frac{\rho_s}{2a}\right)\sigma_c(W-2a)\right]^{1/2} d\right\} \qquad [16]$$

where $A /\!/ B = \dfrac{AB}{A+B}$.

At this point, we can directly compare the experimental data with the results of the MTL model, specifically, Eq. [15] and [16]. From Table I, R_c and R_{cc} of

Table II. Calculated ρ_s' and σ_c of metallurgical contact

Wafer	Al	Sputtered Mo	Pyrolytic Mo	
ρ_s	94	148	159	ohm/sq
ρ_s'	33.75	44	39.8	ohm/sq
σ_c	0.2178	0.202	0.1784	ohm/mil

the widest contacts are used to determine ρ_s' and σ_c by Eq. [15] and [16]. Table II shows the calculated ρ_s' and σ_c of all three different metallurgical contacts. The sheet resistance, ρ_s, of different wafers is also included in the table. Since the model predicts the contact correction term for all contact sizes once the process parameters ρ_s' and σ_c are determined, we could calculate R_c and R_{cc} as functions of contact width, which is equal to $W - 2a$, and the contact length, d. The results of aluminum, sputtered molybdenum, and pyrolytic molybdenum coated wafers are plotted in Fig. 3, 4, and 5, respectively. The contact correction, R_{cc}, and R_c are plotted as functions of the contact width with the contact length as a parameter. The experimental data are included in these figures for comparison. The agreement is very good. One notes that all three figures show the effect of the contact width on the contact correction, that is, the smaller the width the higher the contact correction. Furthermore, the measured and calculated results of aluminum contacts with $d = 0.3$ mil and $d = 0.5$ mil are given in Fig. 3 which indicates that R_{cc} is higher for smaller d. In the case of molybdenum contacts, three

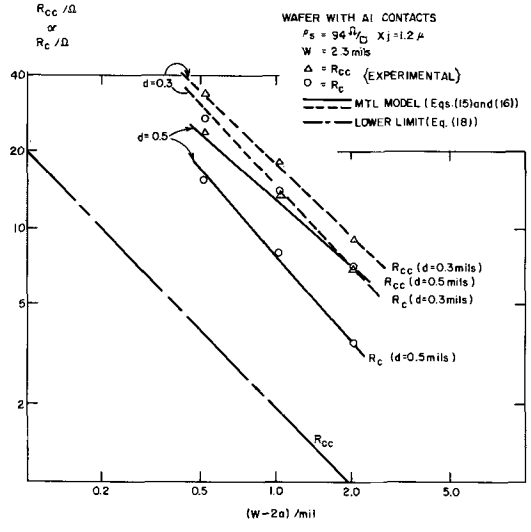

Fig. 3. Contact correction for aluminum contacts

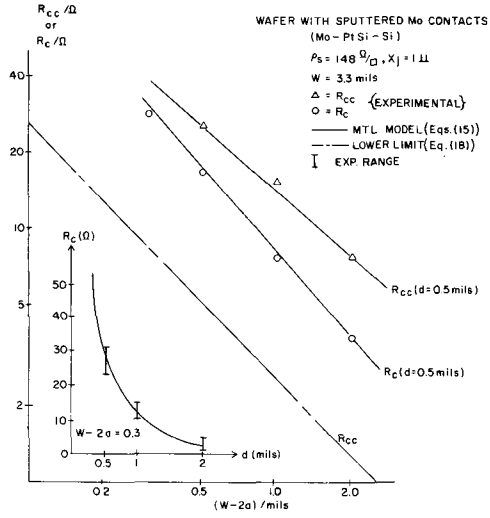

Fig. 4. Contact correction for sputtered molybdenum contacts

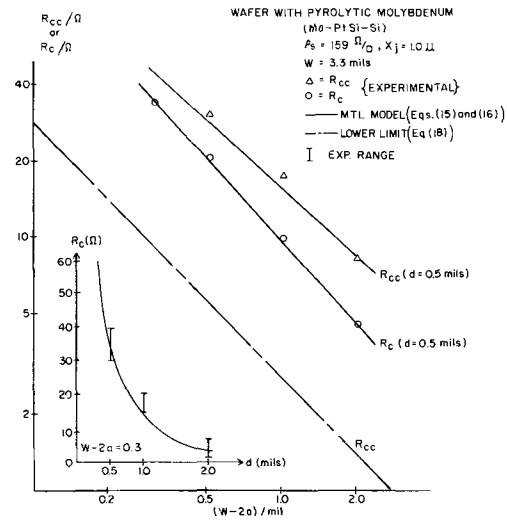

Fig. 5. Contact correction for pyrolytic molybdenum contacts

contacts with identical widths but different lengths were measured. Calculations made as a function of contact length, d, are compared with the data. This is shown in the left hand corners of Fig. 4 and 5. The data fall on the curves of the formulated hyperbolic functions.

Since the calculations agree very well with the measured results, we conclude that these curves shown in Fig. 3, 4, and 5 for different metal contacts can be used to estimate the contact correction term for any given size of contact. In other words, Eq. [15] and [16] can be used as design formulas for the contact correction of diffused resistors. For example, if the sputtered molybdenum contacts of size $W = 0.8$ mil and $d = 0.5$ mil were to be used, one would obtain the contact correction term to be 17 ohms by Fig. 4.

It is interesting to know whether one can obtain a lower limit for the contact correction by considering only the geometry of the contact and the resistor. If this limit could be obtained in an analytical form, it will be a useful formula in addition to Eq. [15] and [16]. Let us consider a simple case which assumes that the contact holes have the same width as the resistor. A perfect, intimate metal-semiconductor contact is also assumed. With these considerations, we see only the geometrical effect on contact correction, R_{cc}. We can now represent this resistor by a two dimensional mathematical model originally due to Hall (9, 10) and recently evaluated in detail for thin film resistors by Ting (11). The model assumes that the metal surfaces are at constant potential and so does the center cross section of the diffused resistors since $L >> X_j$. Then the resistance, R_{AC}, can be calculated by making use of the Schwartz-Christoffel transformations (12, 4). One obtains

$$R_{AB} = 2R_{AC} = 2\left[\rho_s \frac{L}{2W} + \frac{2}{\pi}\frac{\rho_s X_j}{W} \ln\left(\frac{2}{1 - e^{-\pi d/x_j}}\right)\right] \quad [17]$$

where ρ_s and X_j are defined as in Eq. [2]. In normal practice, the contact length, d, is at least one order of magnitude higher than X_j. Therefore, the exponential term in Eq. [17] can be neglected. Comparing Eq. [4] and [17] we obtain

$$R_{cc} = 0.441 \frac{\rho_s X_j}{W} \quad [18]$$

This result is arrived at entirely from geometrical considerations. It is applicable only when the metal-semiconductor contact resistance is negligible. Therefore, Eq. [18] serves as a lower limit formulation of R_{cc}. Together with Eq. [15] and [16] they serve as design formulas. In Table I, Fig. 3, 4, and 5, the lower limit data derived from Eq. [18], are also shown for comparison.

Conclusions

A useful formula for the contact correction term is derived from the MTL model. Model calculations compare very well with experimental data of various metal-silicon contacts. Equations [15] and [16] of this analytic model are recommended to be design formulas for diffused resistors. Furthermore, a lower limit for the contact correction term can be established by considering the geometry of the diffused resistor only. This lower limit together with the MTL results can sufficiently serve as guide lines in the design work of diffused resistors on an integrated circuit chip.

Interface Properties of Si-(SiO_2)-Al_2O_3 Structures

M. T. Duffy* and A. G. Revesz[1]

RCA Laboratories, Princeton, New Jersey

ABSTRACT

Aluminum oxide films have been deposited on silicon substrates at 420°C by thermal decomposition of aluminum-isopropoxide. An electrical evaluation of the interface properties of Si-Al_2O_3 and Si-SiO_2-Al_2O_3 structures has been made. MOS capacitance measurements have shown the important role of a postdeposition heat treatment in O_2 in eliminating room-temperature hysteresis and reducing the scatter in flat-band voltage values of Si-Al_2O_3 structures. This treatment has an overriding effect on the influence of deposition conditions on interface properties. The density of interface states varies from 10^{10} to 10^{11} cm^{-2} $(eV)^{-1}$, and the flat-band voltage (for ~1000Å oxide) is about +2V. The flat-band voltage gradually shifts to more positive values under large negative bias (field ~10^6 V/cm) at 250°C. There is a strong tendency toward localized conduction in these films and there are indications that conduction is controlled by the interface(s) rather than by the bulk material. This problem was alleviated by growing a thin SiO_2 film (~200Å) on Si prior to deposition. The interface properties of Si-SiO_2-Al_2O_3 structures depend on the Si orientation. For (100) orientation, the density of interface states is about 10^{10} cm^{-2} $(eV)^{-1}$ and the flat-band voltage is zero. The radiation resistance of deposited Al_2O_3 is better than that of SiO_2 and comparable to that of Al_2O_3 films prepared by plasma anodization. Irradiation by 1 MeV electrons under +10V bias introduces a density of positive oxide charge of a few times 10^{12} e/cm^2.

Silicon dioxide films are widely used for passivation of silicon device surfaces. The technological importance of these devices led to extended research activity which yielded a reasonably good understanding of the properties of the oxide film and the oxide-silicon interface (1). However, some problems remain unsolved. These include a somewhat high radiation sensitivity and the inability to obtain positive flat-band voltage values relative to silicon. In addition, the relatively low value of the dielectric constant of SiO_2 makes the use of an insulator with higher dielectric constant desirable.

Recently, Al_2O_3 films have drawn the attention of several workers (2-8). A comparison of the bulk properties of Al_2O_3 and SiO_2 (*see* Table I) shows Al_2O_3 superior in some respects, including higher dielectric constant and greater density. Other advantages are the lower radiation sensitivity and greater impermeability to impurity diffusion. The ability to deposit films at temperatures as low as 400°C is also desirable.

The purpose of this work was to explore the potential of Al_2O_3 in MOS devices. Hence, we were mainly concerned with interface properties. MOS measurements have been performed on Si-Al_2O_3 and Si-SiO_2-Al_2O_3 structures and their stability and radiation resistance examined.

Experimental

Thin film deposition.—Thin dielectric films of aluminum oxide have been deposited on silicon substrates by the pyrolysis of Al-isopropoxide in the presence of oxygen (2). The alkoxide vapors were transported to the rf-heated substrates by bubbling helium through the molten alkoxide at 125°C. This gas was subsequently mixed with nitrogen and oxygen. The deposition temperature was usually 420°C, but in some cases depositions have been performed at various tempera-

Table I. Comparison of Al_2O_3 and SiO_2

tures from 350° to 925°C. The experimental arrangement of the rf system was the same as that reported by Duffy *et al.* (9).

Both p- and n-type silicon substrates of (111) and (100) orientation were used. The resistivity was usually 10 ohm-cm, but some degenerate substrates were also used for dielectric investigations. The wafers were cleaned by standard chemical means prior to deposition and had a residual SiO_2 film of about 30Å. Because of conduction problems associated with Si-Al_2O_3 structures, Al_2O_3 films were also deposited on Si-SiO_2 samples prepared by thermally oxidizing silicon in dry O_2 at 1100°C. The oxide thickness was usually 200Å. The oxidation was followed by 15 min He annealing at 1100°C prior to deposition of Al_2O_3; these processes were performed *in situ*. Postdeposition heat treatments in He, N_2, H_2, and O_2 have also been investigated. For electrical evaluation, MOS contacts were provided by vacuum deposition of aluminum.

Measurements.—Thickness and refractive index values were determined by ellipsometry at the mercury wavelength 5461Å in the case of Al_2O_3 films up to 1400Å. In the case of SiO_2-Al_2O_3 structures, the SiO_2 film thickness was separately determined after etching off the Al_2O_3 film in phosphoric acid. Film structure was determined by reflection electron diffraction and the morphology by optical microscopy. Some films were analyzed by mass spectrometry using an ultrapure gold electrode for sparking.

The frequency dependence of the dielectric constant and loss tangent was determined in the range 10^2 to 10^5 Hz on a capacitance bridge. These measurements were performed on films deposited on degenerate silicon or on Si-Al_2O_3 structures which showed strong accumulation at zero bias.

Interface properties were studied by the MOS capacitance and conductance methods (1). Most capacitance-voltage (C-V) measurements were made at 1 MHz using an automatic recording apparatus (10). Many specimens were also examined by an MOS impedance method in the frequency range 3 x 10^2 to 10^5 Hz using phase-sensitive detection (11). MOS measurements also gave information on the apparent resistivity (as an order of magnitude) of films with appreciable d-c conduction. Computer analysis of the C-V curves gave the surface charge density as a function of energy within the Si forbidden band. From this information the charge density at flat-band condition, Q_{FB} (charges/cm^2), and the interface state density, Q_{SS} (/cm^2 · eV), were determined. The interface state density was also determined from the MOS conductance (G-V) measurements assuming a uniform distribution (energy-wise) of these states in the Si forbidden band (12).

The stability of the charge distribution was measured by applying positive and negative voltages for varying times to the gate electrodes of samples kept in He atmosphere at 250°C. Differences between C-V measurements, made both before and after the bias-temperature (BT) tests, indicated the resulting charge redistribution.

Radiation resistance measurements were made by irradiating MOS units, while under applied gate bias, with 1-MeV electrons. The fluence level corresponding to each bombardment was 10^{14} e/cm^2 and a bombardment was made at each of the gate voltages 0, −2, −5, −10, +2, +5, +8, and +10V successively. MOS capacitance measurements were performed after each bombardment and the density of induced charge determined.

Results

Bulk properties.—Aluminum oxide films ranging in thickness up to 8000Å have been obtained. The deposition rate was usually about 100 Å/min at 420°C but in some cases deposition was performed at a slower rate (17 Å/min). The etch rate was about 90 Å/min in 85% H_3PO_4 at 40°C. The refractive index varied from 1.60 to 1.68. Films deposited at temperatures up to 700°C were noncrystalline, and remained noncrystalline even after O_2 treatment for 30 min at 700°C. By contrast, films deposited at 925°C and also those heated in O_2 at 800°C were polycrystalline. Films were uniform and did not show any discernible structure when examined by optical microscopy. An order of magnitude estimate of the impurity-to-aluminum ratio (atomic) was obtained by mass spectrometry. The ratio for Zn, Cu, and Cr was 10^{-3}; for S, 10^{-2}; and for C, 10^{-2} to 10^{-1}.[2]

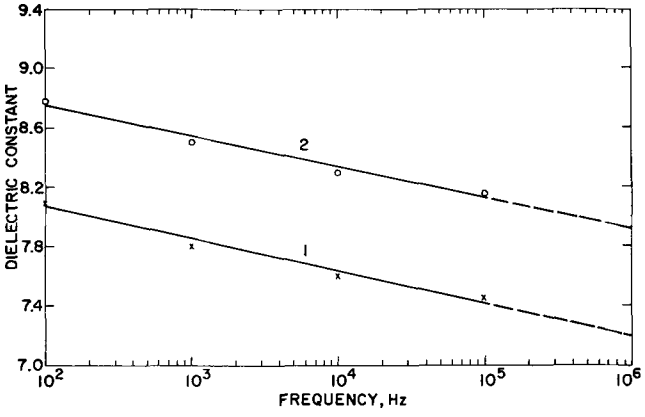

Fig. 1. Frequency dependence of dielectric constant of Al_2O_3. Curve 1, as deposited; curve 2, oxygen treated.

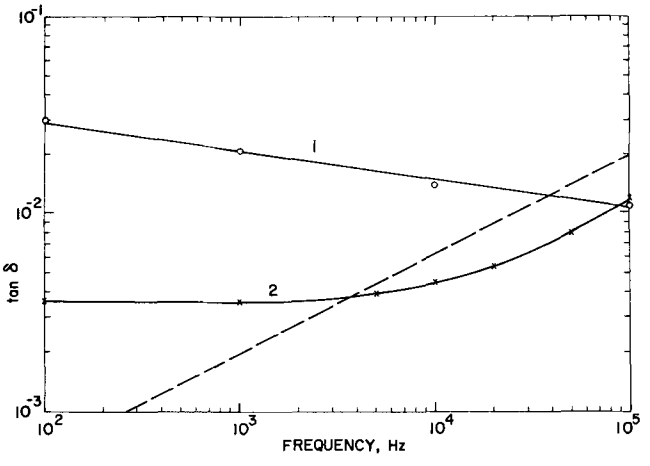

Fig. 2. Loss tangent vs. frequency. Curve 1, as deposited on degenerate silicon; curve 2, deposited on ~ 10 ohm-cm silicon and heat treated in O_2. The upward trend of curve 2 results from the resistance of the substrate; the broken curve approximates the expected effect.

The dielectric constant and loss tangent are frequency dependent; typical curves are presented in Fig. 1 and 2. The curve labeled 1 in both figures represent data obtained on an untreated film which was deposited on degenerate silicon, while the curves labeled 2 represent the data from measurements on a sample which received an *in situ* postdeposition O_2 treatment at 700°C. The substrate in this latter case was ~ 10 ohm-cm silicon; the series resistance of this substrate accounts for the upward trend in curve 2, Fig. 2. The broken curve approximates the expected effect. The results of Fig. 1 and 2 indicate that the O_2 treatment increases the dielectric constant and decreases the apparent value of the loss tangent.

[2] These results were originally obtained as impurity-to-silicon ratios. Since the depth of the crater produced by sparking is much larger (~5μ) than the oxide thickness (~1000Å), large errors may be introduced in conversion to the above form. However, the experimental value of the Al/Si ratio corresponds to 6 × 10^{22} Al atoms/cm^3 in the oxide which approximates the calculated value 4.3 × 10^{22} (taking the density as 3.7 g/cm^3). The O/Al ratio was about unity, in good order of magnitude agreement with the theoretical value 1.5. Also the Al/Si ratio for a blank Si specimen was three orders of magnitude lower than that of the Si-Al_2O_3 specimen. From these considerations, the order of magnitude values of impurity content are probably correct.

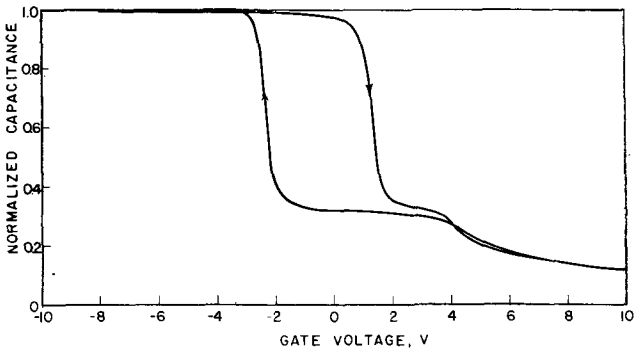

Fig. 3. Typical MOS capacitance curve for 1000Å Al_2O_3 film

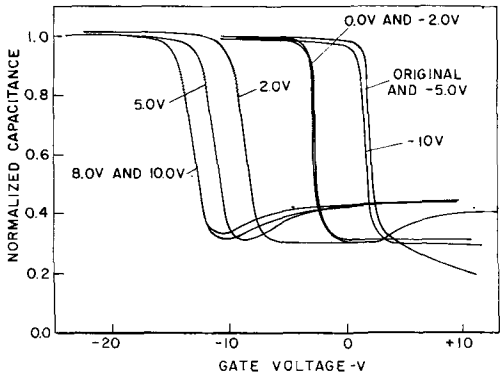

Fig. 4. Effect of electron irradiation on MOS capacitance of 1400Å Al_2O_3 film. The parameter is the gate bias during irradiation.

Interface properties.—The C-V behavior of as-deposited Si-Al_2O_3 structures shows large scatter in flat-band voltage values and large room-temperature hysteresis. A typical example is shown in Fig. 3. The extent of the hysteresis depends on the deposition temperature and rate of deposition. Higher deposition temperatures and slower deposition rates favor reduced hysteresis and less scatter in flat-band voltage values. The nature of the hysteresis is such that negative and positive gate biasing results in a shift of the flat-band voltage toward more positive and negative values, respectively. Postdeposition heat treatments in He, N_2, and H_2 were unsuccessful in modifying the C-V behavior. However, a heat treatment in O_2 at 700°C eliminated the room-temperature hysteresis and reduced the flat-band voltage scatter. This treatment had an overriding effect on the influence of the deposition conditions on interface properties.

After oxygen treatment, the charge density at flat-band condition varied from -5×10^{11} e/cm^2 to -1.5×10^{12} e/cm^2 [3] (corresponding to +1.4 to 3.6V flat-band voltages for 1000Å oxide film) as determined from C-V measurements at 1 MHz. The density of interface states, determined from G-V measurements, varied from 10^{10} to 10^{11} states/$cm^2 \cdot$ eV.

Bias-temperature (BT) tests on O_2-treated specimens revealed that the charge distribution in the Si-Al_2O_3 structures is unstable. The principal effect is a shift in the flat-band voltage to more positive values under negative bias. The extent of this shift is typically about 4.5V for 1000Å oxide after the application of −5V gate bias for 5 min at 250°C. The application of −10V usually led to excessive conduction. Positive biasing did not cause a shift to more negative values, and in some cases actually caused a shift toward more positive voltages.

A typical set of C-V curves obtained after successive irradiation of a 1400Å film (under varying bias) with 1-MeV electrons as previously described is presented in Fig. 4. Bombardment under +10V bias led to a shift (normalized to 1000Å oxide thickness) of −9.8V. This corresponds to an induced charge of 4.6×10^{12} e/cm^2 at flat-band condition. The smallest shift observed for +10V bias was −6.4V, corresponding to an induced charge of 2.7×10^{12} e/cm^2. No significant effect results from irradiation under negative bias. The density of interface states was found to increase slightly during bombardment; a typical value is 2×10^{11} to 7×10^{11} states/$cm^2 \cdot$ eV. In the case of Al_2O_3 samples which were not treated in oxygen, the induced oxide charge was unstable. The negative shift in flat-band voltage resulting from irradiation decreased after the irradiation was stopped.

Conduction.—Most MOS capacitors showed very varied d-c conduction behavior. Conduction was usually observed during C-V measurements as a decrease in the set bias when gate contact was made. This decrease in applied bias is due to d-c current flow through the capacitor. This conduction is localized in the sense that a given sample had conducting and nonconducting capacitors. It has not been possible to correlate this behavior with process parameters including postdeposition oxygen treatment, nor with morphological defects. However, it has been found that conduction developed or became greatly enhanced during BT tests, even when samples were heated in helium at 250°C without bias; *e.g.*, a sample which initially showed no apparent conduction (estimated $\rho > 10^{12}$ ohm-cm), had an apparent resistivity of about 10^8 ohm-cm after heating in He at 250°C for 10 min. The largest change was observed for a polycrystalline specimen which had been deposited at 925°C. No noticeable conduction occurred before the BT test, but after applying −5V at 250°C for 5 min in He the apparent resistivity changed to less than 10^4 ohm-cm. In general, the development of conduction was accompanied by the occurrence of the Schottky depletion layer capacitance (13) as observed in the C-V measurements (*see* Fig. 3) on both O_2-treated and untreated specimens, while nonconducting samples did not exhibit the Schottky depletion layer capacitance. Some samples developed this depletion capacitance during electron bombardment, but this effect and the induced charge were unstable and reverted at a diminishing rate to the original state after irradiation. During the relaxation process, the Schottky capacitance disappeared (*see* Fig. 5).

Si-SiO_2-Al_2O_3 *structures.*—The problem of conduction associated with Al_2O_3 films was alleviated by growing a SiO_2 film (~200Å) before deposition of Al_2O_3 (1000-1300Å). The double insulator structures did not show any hysteresis effects, even when no post-deposition O_2 treatment was applied. In contrast to the case of Si-Al_2O_3 structures, both the flat-band voltage and the density of interface states characteristic of the double insulator structures depend on the Si crystallographic orientation. Typically, for (111) orientation the flat-band voltage is about −2.5V (corresponding to about 7×10^{11} e/cm^2 charge density) for a combination of 1000Å Al_2O_3 and 200Å SiO_2 films, and

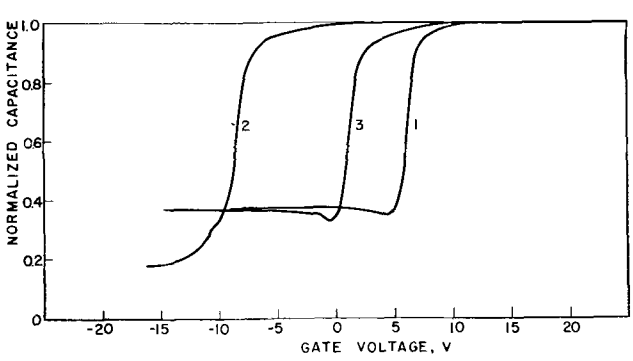

Fig. 5. Unstable charge distribution resulting from electron irradiation. Curve 1, C-V behavior before bombardment; curve 2, after bombardment at −5V gate bias; curve 3, final state after termination of relaxation process at room temperature.

[3] *e* Represents the absolute value of the electronic charge.

the interface state density varies from 4 x 10^{10} to 2 x 10^{11} states/cm^2 · eV. For (100) orientation the flat-band voltage is approximately zero, and the interface state density varies from 1 x 10^{10} to 4 x 10^{10} states/cm^2 · eV. Similar results were obtained on both n- and p-type substrates.

Bias-temperature tests revealed that the charge distribution in the double insulator structure is also unstable. This is demonstrated in Fig. 6 where the flat-band voltage is plotted as a function of time for which the bias was applied. The principal effect is caused by negative biasing. In the range from −5 to −13V, the change in flat-band voltage is approximately proportional to the change in bias. The effect of a given negative bias saturates with time even when the sequence of applying negative bias is interrupted by the application of positive bias (*see* part B of Fig. 6). Unlike Si-Al_2O_3 structures, the composite films consistently showed a shift in the flat-band voltage under positive bias during the BT test. The extent of this shift is time dependent and varies from 1 to 4.5V. The magnitude of the bias apparently has no influence on this shift. The effect of positive bias was independent of whether the BT test started with negative or positive bias.

A different instability behavior was observed for Si-SiO_2-Al_2O_3 structures which were not treated in O_2 after deposition of Al_2O_3 (*see* Fig. 7). Before the BT test, the specimen had an appreciable d-c conduction and the C-V curve showed the development of the Schottky capacitance. After applying +5V for 5 min at 250°C, both the d-c conduction and the Schottky capacitance disappeared, and the flat-band voltage shifted to a more negative value. Application of −5V bias shifted the flat-band voltage to a more positive value; the extent of the shift is comparable to that shown in Fig. 6. It also led to the reappearance of the Schottky capacitance and d-c conduction. The C-V curve is now distorted and reveals a hysteresis which is in the opposite sense to that observed for Si-Al_2O_3 structures.

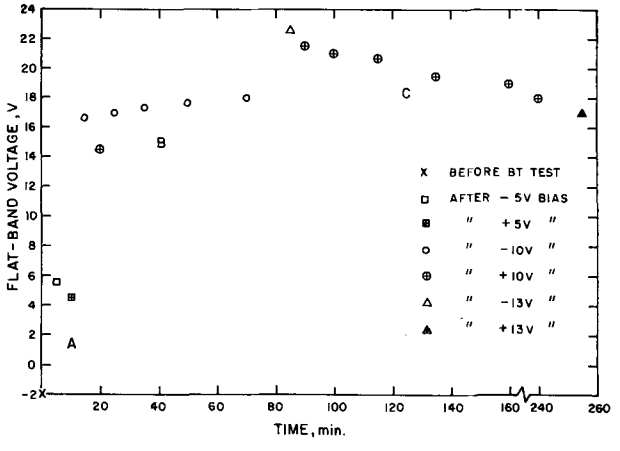

Fig. 6. Flat-band voltage as a function of time for which gate bias was applied during bias-temperature tests on a Si-SiO_2-Al_2O_3 composite structure corresponding to 200Å SiO_2 and 1000Å Al_2O_3.

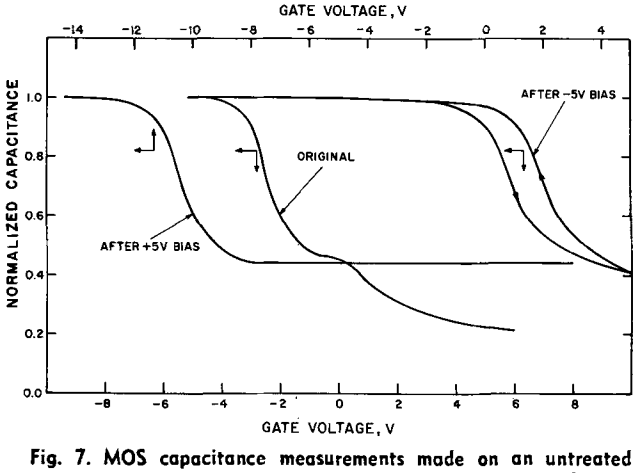

Fig. 7. MOS capacitance measurements made on an untreated Si-SiO_2-Al_2O_3 specimen during bias-temperature tests (200Å SiO_2 and 1100Å Al_2O_3).

Although the conduction problem was largely alleviated by growing a thin SiO_2 film before the deposition of Al_2O_3, the double insulator structures still showed localized conduction to a greater extent than thermally grown SiO_2.

Electron bombardment of the double insulator structures caused negative shifts in the flat-band voltage under positive bias and positive shifts under negative bias. The scatter in the results was quite large. Nevertheless, even the largest shift at +10V bias (about −20V) was less than that observed for dry oxygen-grown SiO_2 of comparable thickness (about −50V). Aluminum oxide films alone show better radiation resistance than the SiO_2-Al_2O_3 structures. The bias dependence of the radiation induced charge did not show the asymptotic behavior characteristic of SiO_2 or Al_2O_3 films alone. Also, the charge distribution was generally unstable even at room temperature. The radiation behavior of the Si-SiO_2-Al_2O_3 interface system requires more study.

Discussion

Bulk properties.—No systematic study of the effect of deposition parameters on bulk properties has been undertaken in this investigation. This has been treated in detail by Aboaf (2). Our measured values of refractive index are higher than those reported in Ref. (2), but are still lower than the refractive index of γ-Al_2O_3 (1.7) or α-Al_2O_3 (1.765). These differences may represent differences in density or mole refraction. The frequency dependence of the dielectric constant is typical of a noncrystalline dielectric (14). Oxygen-treatment at 700°C (Fig. 2) decreases the apparent value of tan δ; this value, 3.5 x 10^{-3} at 10^3 Hz, is comparable to that reported (2) for Al_2O_3 deposited in the absence of O_2 and is lower than the value 7.5 x 10^{-3} given for O_2-deposited films. The tan δ values represented by curve 1, Fig. 2, are larger than expected on the basis of Ref. (14). This may be due to d-c conduction through the film of the untreated sample.

The crystallization behavior of these films upon annealing exhibits a similar trend to that reported by Aboaf (2) but differs significantly from that reported by Nishimatsu *et al.* (7) who report crystallization at 500°C. It appears from Ref. (7) that the deposition of alumina films was performed in the absence of oxygen, while in the present work oxygen has been used. Matsushita and Koga (4) have shown that pyrolytic alumina films deposited in the absence of oxygen and at high deposition rates can have an Al_2O_3 content as low as 80%, the remaining film possibly consisting of polymer impurity, while those films deposited at low deposition rates in the presence of oxygen contain as high as 100% Al_2O_3. They also report significant differences in insulating properties of the two types of films. The above differences in crystallization behavior may be due to differences in impurity content of the respective films, and it is expected that significant differences in interface properties will also occur. That this is so can be seen from a review of the results reported here and in Ref. (7).

Interface properties.—The charge instability effects, including hysteresis, displayed by Si-Al_2O_3 structures show the same trend as reported for Si-SiO_2(grown)-SiO_2(deposited) structures (15) but differ from those of the Si-Si_3N_4 system (16).

The diminished hysteresis obtained at higher deposition temperatures and lower deposition rates suggests that this effect is associated with incomplete oxidation of the Al-alkoxide, possibly the presence of H^+ or

OH^- ions in the oxide. The effectiveness of a post-deposition O_2 treatment in eliminating the hysteresis may result from the deactivation of these species upon further oxidation.

Another possibility is that the O_2 treatment modifies the defect structure of the Si-Al_2O_3 interface. Such a process could be a modification of the defect structure of the residual SiO_2 (~ 30Å) on the silicon surface. A "densification" of this oxide prior to deposition of Si_3N_4 was reported (17) to have a large influence on the charge transfer behavior of the Si-Si_3N_4 interface. However, the hysteresis associated with Si-Al_2O_3 structures is in the opposite sense to that expected for such a transfer mechanism at the Si-Al_2O_3 interface. The observed hysteresis is similar to that resulting from charge transfer at the gate electrode or ionic polarization of the oxide resulting from ions present or produced by field ionization of defects in the Al_2O_3 film. However, the presence of a 200Å thick SiO_2 film between the Si and Al_2O_3 eliminates the hysteresis. It is unlikely that these mechanisms could be greatly influenced by the presence of a 200Å SiO_2 film except insofar as that the field in the latter is about twice as high as in the Al_2O_3 film. Thus, it has not been possible to explain the observed hysteresis in terms of charge transfer at the gate electrode. We cannot, at present, propose a satisfactory model for the hysteresis effects in Si-Al_2O_3 structures.

In agreement with previous reports (4-7), the Al_2O_3 film (including the Si-Al_2O_3 interface) is associated with negatively ionized acceptor states. By contrast, Al_2O_3 films produced by plasma anodization of aluminum have an associated positive charge (3). However, after a hydrogen heat treatment, the charge in the plasma-grown oxide becomes negative. A typical final value is -8×10^{10} e/cm^2. This behavior has been attributed to electron and hole capture during anodization and subsequent emptying of traps by thermal excitation. The fact that the negative charge density is higher for deposited than for plasma-grown oxide suggests that trapped holes in the latter partially compensate the negative charge due to trapped electrons. No appreciable hole injection can occur during chemical deposition because of the absence of a high electric field across the oxide. Consequently, the apparent negative charge density is larger.

Because of the frequent development of excessive conduction during the BT tests, no detailed study of the charge instability was made. The observations indicate, however, that the instability may be due to a redistribution of positive or negative ions which were originally in the vicinity of the Si-oxide or oxide-gate interface, respectively. As in the case of Si-SiO_2 structures (1), such a process could result in a voltage asymmetric instability, but in the opposite sense. Another possibility is that under negative bias electrons are injected from the gate electrode into the oxide, leading to positive space charge in the silicon. This process seems plausible in view of the general tendency toward electron trapping in Al_2O_3. The occasionally observed positive shifts under positive bias are similar, but again in the opposite sense, to the slow trapping instability associated with imperfect Si-SiO_2 interface structures (1). This can be attributed to the injection of electrons from silicon in Al_2O_3 and trapping near the interface.

Si-Al_2O_3 structures are more resistant to high energy electron radiation than MOS devices using SiO_2 as insulator. Bombardment of 1000Å of Al_2O_3 under +10V gate bias produces a flat-band voltage shift of −9.8V (4.6×10^{12} e/cm^2 induced charge) which compares with ~ −50V for SiO_2 (18) (1.3×10^{13} e/cm^2 induced charge). Since the dielectric constant of Al_2O_3 is about twice as large as that of SiO_2, an identical change in the surface charge, as due to irradiation, gives rise to only half the shift in the flat-band voltage.

It can be seen from Fig. 4 that, like SiO_2 and plasma-grown Al_2O_3 (3), the effect of positive bias under irradiation saturates. The behavior under negative bias is, however, different from the other cases. In the case of SiO_2, irradiation under negative bias also results in an increase in the positive oxide charge (though to a lesser extent than under positive bias). Irradiation of plasma-grown Al_2O_3 under negative bias leads to an increase of the negative oxide charge. This has been attributed to electron trapping in the Al_2O_3 film (3). The difference in behavior between chemically deposited and plasma-grown Al_2O_3 can again be explained by the presence of trapped holes in the latter.

The results of irradiation experiments demonstrate that the defect structure of Al_2O_3 is different from that of SiO_2. The predominant feature of the latter is an abundance of hole traps which capture the radiation-produced holes. This results in a net positive charge in the oxide (18). Recent investigations of radiation effects in SiO_2 and Al_2O_3 films, using the thermoluminescence glow curve technique, showed that polycrystalline Al_2O_3 has a large density of traps (probably both hole and electron traps) which hardly increases with irradiation, whereas the pre-irradiation trap density in SiO_2 is low but increases substantially during irradiation (19). Because of the presence of electron traps in Al_2O_3, the net trapped positive charge is much less than in SiO_2. Another contributing effect could be the recombination of radiation-generated electrons and holes before significant trapping takes place. From our observations, it is evident that Al_2O_3 has a greater tendency toward conduction than SiO_2. On the other hand, samples showing no observable d-c conduction were not more sensitive to radiation than those showing some conduction. However, there are indications that conduction is controlled by the interface(s) so that appreciable movement of electrons and/or holes might occur in the oxide without giving rise to d-c conduction. The instability of the induced charge in samples which did not receive an O_2 treatment possibly resulted from such recombination, and demonstrates again the effect of this treatment in changing the defect structure of the oxide.

Conduction.—Most conducting samples exhibit the Schottky depletion capacitance during C-V measurements. This indicates that the minority carriers (electrons for p-type material) cannot accumulate in the silicon space-charge region but are injected into the oxide and drift to the positively biased gate electrode. Similar behavior has also been observed in Si-SiO_2 structures where the SiO_2 film was prepared by anodic oxidation of silicon. This oxide film shows localized conduction to a greater extent than thermally grown SiO_2 (1). This behavior differs from that observed for Si-SiO_2 structures having a large density of interface states (20), since holding the gate under positive bias did not lead to accumulation of minority carriers in the space-charge region and, thus, to the disappearance of the Schottky capacitance. Rather the behavior is similar to that reported for semiconductor-electrolyte systems where injection of electrons from a p-type semiconductor into the electrolyte occurs when the latter is under negative bias (21).

The simultaneous development of conduction and Schottky capacitance in BT-stressed samples suggests that conduction is controlled by the interface(s). Processes (*e.g.*, heat treatment, irradiation) which affect interface properties have a large influence on the observed conduction. The nature of the interface(s) apparently changes from blocking to injecting and in many cases electron and/or hole injection at the Si-Al_2O_3 interface controls the conduction. That Al_2O_3 films have a greater tendency toward conduction than SiO_2 films has also been observed by Matsushita and Koga, especially for pure Al_2O_3 (4). It would be premature to speculate on the exact mechanism of conduction, but it is unlikely that it is a bulk-controlled Frenkel-Poole mechanism as proposed for silicon nitride (16).

Si-SiO_2-Al_2O_3 *structures.*—The fact that, in contrast to Si-Al_2O_3 structures, the surface state density of the Si-SiO_2-Al_2O_3 structures is orientation dependent corroborates the argument that this dependence is related to the mechanism by which the SiO_2 film grows on silicon (1). When the insulator is deposited instead of grown no orientation dependence can be observed.

The charge instability associated with these structures under negative gate bias is probably due to injection of electrons from the gate into the Al_2O_3 and/or to field ionization of defects in Al_2O_3. In the latter mechanism, positive ions and electrons are generated by the field and the electrons repelled to the Al_2O_3-SiO_2 interface which they cannot penetrate. Such a mechanism has been proposed to explain the instability behavior of Si-SiO_2(grown)-SiO_2(deposited) structures (15). The instability under positive bias is probably due to Na^+ ions since no attempt was made to provide a sodium-free environment during the growth of the SiO_2 film. It is unlikely that it is caused by injection or trapping since the instability effect is independent of the magnitude of the positive bias and the extent of flat-band voltage shift during previous negative biasing (*see* Fig. 6).

The stability behavior of Si-SiO_2-Al_2O_3 structures, which did not receive a postdeposition O_2 treatment, requires more study. This behavior (Fig. 7) again demonstrates that d-c conduction is controlled by the interface(s), which, in turn, can be modified by the BT tests.

Summary and Conclusions

1. Thermal decomposition of Al-isopropoxide at ~ 420°C results in noncrystalline Al_2O_3 films whose refractive index varies from 1.60 to 1.68. The dielectric constant at 100 kHz is about 7.5, and the tan δ is about 0.01. The MOS capacitance curves show large scatter and room-temperature hysteresis.

2. Postdeposition heat treatment in oxygen at 700°C reduces this scatter and eliminates the hysteresis. This treatment overrides the effects on interface properties of the deposition conditions. A typical value of the flat-band voltage (for 1000Å thick film) is +2.0V. The density of interface states varies from 10^{10} to 10^{11} states/cm^2 · eV. Localized conduction occurs frequently in these films; there are indications that it is controlled by the interface(s).

3. Bombardment with 1 MeV electrons (fluence = ~ 10^{14} e/cm^2) under positive bias results in a relatively small shift in the flat-band voltage; the smallest value observed was −6.4V under +10V bias (equivalent to 2.7 x 10^{12} e/cm^2 surface charge). Bombardment under negative bias has practically no effect.

4. The conduction observed in Si-Al_2O_3 structures was greatly reduced by growing ~200Å thick SiO_2 film on silicon prior to the Al_2O_3 deposition. Typical flat-band voltages for ~1200Å total insulator thickness are −2.5V and zero volt for (111) and (100) orientations, respectively. The corresponding interface state densities are 4 x 10^{10} − 2 x 10^{11} e/cm^2 · eV and 1 x 10^{10} − 4 x 10^{10} e/cm^2 · eV.

5. Under large negative bias (corresponding to about 10^6 V/cm field) at 250°C, the flat-band voltage shifts to more positive values. At a given bias, a stable situation can be achieved within roughly 20 min. Positive bias shifts the flat band to more negative values but only by about 1V.

6. The results reported here differ significantly from those of Nishimatsu *et al.* (7). This is particularly marked in the crystallization behavior of the respective alumina films and the charge instability phenomena, including hysteresis, associated with Si-Al_2O_3 and Si-SiO_2-Al_2O_3 structures. These differences may be due to differences in impurity content of the films resulting from differing preparation conditions (*e.g.*, presence or absence of oxygen during deposition).

The results reported here have been obtained without using special clean technology. The radiation resistance of the Si-Al_2O_3 structures, the positive values of the flat-band voltage, the lack of significant instability effects of prestressed samples, and the value of dielectric constant make Al_2O_3 attractive from the viewpoint of device fabrication. However, the problem of localized conduction must be brought under control.

Oxygen Diffusion in Monoclinic Zirconia

D. J. Poulton and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

Oxygen-18 enriched oxygen and carbon dioxide-carbon monoxide atmospheres have been used in the determination of the oxygen self-diffusion coefficient in monoclinic zirconia at 990°C. Oxygen exchange measurements were made on zirconia spheres in the average size ranges of 90 and 126μ. The diffusion coefficient was found to be independent of both oxygen partial pressure over the range 1-10^{-19} atm and sphere size. The value of the diffusion constant has been used with previously determined electrical conductivity data to verify postulates of a defect model involving oxygen ion vacancies for monoclinic zirconia.

The nature of the defect structure and the transport properties of oxygen in monoclinic zirconia have been the subjects of several recent investigations (1, 2). For example, Vest, Tallan, and Tripp (3) measured the electrical conductivity of zirconia at 990°C as a function of oxygen pressure from 1 to 10^{-23} atm and found an electronic semiconductor, with the transition from n-type to p-type conductivity occurring at approximately 10^{-16} atm. Their results have been further discussed by Kröger (1) who advanced a Schottky-type model involving both isolated oxygen vacancies and zirconium vacancies singly associated with oxygen vacancies, and also by Douglass and Wagner (2) who proposed an anti-Frenkel type model involving oxygen vacancies and interstitials. It is predicted by both of these models that oxygen ionic conductivity may be considered to be predominant at moderately low oxygen pressures, between the extremes of n- and p-type electronic conductivity.

Recently, Madeyski and Smeltzer (4, 5) have applied the gas-solid oxygen-18 exchange technique to determine the oxygen self-diffusion coefficient in monoclinic zirconia prepared as annealed spheres at temperatures in the range 800°-1000°C and at oxygen pressures close to atmospheric. In this paper, these results have been extended at 990°C to oxygen partial pressures as low as 10^{-19} atm, by the use of oxygen-18 enriched CO-CO_2 atmospheres.

Experimental

In Fig. 1, a schematic drawing of the gas preparation train and the reaction apparatus is given. The oxygen exchange apparatus is identical to that previously described (5).

The preparation of microspheres of near-stoichiometric ZrO_2 in the size ranges 75-105μ and 105-147μ by oxidation of 99.92 w/o (weight per cent) zirconium sheet (4), and of oxygen gas containing about 1.3 a/o (atomic per cent) ^{18}O has already been described (5). Carbon dioxide containing about 0.9 a/o ^{18}O was prepared by equilibrating normal carbon dioxide with oxygen-18 enriched water in the five-liter flask shown on the diagram, followed by removal of the water by trap-to-trap distillation between dry ice-acetone and liquid nitrogen traps. Carbon monoxide containing about 0.9 a/o ^{18}O was prepared by exposing either the oxygen or the CO_2 prepared as above to an excess of activated charcoal for approximately 24 hr at 1000°C, followed by transfer through three liquid nitrogen traps to a 5-liter storage flask with the aid of a Toepler pump. The equality of the oxygen-18 enrichment in the carbon monoxide and carbon dioxide was carefully checked by mass spectrometric analysis and adjusted to better than 0.2 relative per cent difference.

Microspheres of stoichiometric zirconia were first annealed for 24 hr in the reaction chamber containing a CO-CO_2 atmosphere of normal isotopic composition and desired oxygen partial pressure. Oxygen partial pressures were calculated from the free energies of formation of carbon monoxide and carbon dioxide as tabulated by Rossini *et al.* (6). In a few experiments, pure oxygen was used at pressures of approximately 0.5 atm. At the conclusion of the anneal, the normal gases were pumped out and an oxygen-18 enriched CO-CO_2 atmosphere of identical oxygen partial pressure was admitted. The progress of the exchange reaction was then followed by taking approximately ten samples of the gas atmosphere over a total time period of generally about 30 hr.

Oxygen self-diffusion coefficients D^* were obtained from the mass spectrometric analyses of the gas samples with the aid of the error function equation developed by Carmen and Haul (7)

$$\frac{Q - Q_1}{Q_2 - Q_1} = \frac{\gamma_1}{\gamma_1 + \gamma_2} \operatorname{eerfc} \frac{3\gamma_1}{\lambda}\sqrt{\tau} + \frac{\gamma_2}{\gamma_1 + \gamma_2} \operatorname{eerfc} \frac{-3\gamma_2}{\lambda}\sqrt{\tau} \quad [1]$$

where

$$\gamma_1 = \frac{1}{2}\left[\sqrt{1 + \frac{4\lambda}{3}} + 1\right], \gamma_2 = \gamma_1 - 1, \quad \tau = D^*t/a^2 \quad [2]$$

In this equation, Q, Q_1, and Q_2 represent the atom fraction of oxygen-18 in the atmosphere at time t, in the oxide at zero time (taken as the natural abundance 0.00204), and in the atmosphere at zero time, respectively; a is the sphere radius and λ is the ratio of the total mass of oxygen in the gas atmosphere to that in the solid oxide. These calculations were performed with the aid of a computer.

Results and Discussion

Plots of the results, $\sqrt{\tau}$ *vs.* $\sqrt{t}$, are illustrated in Fig. 2-4. For clarity, successive plots have been dis-

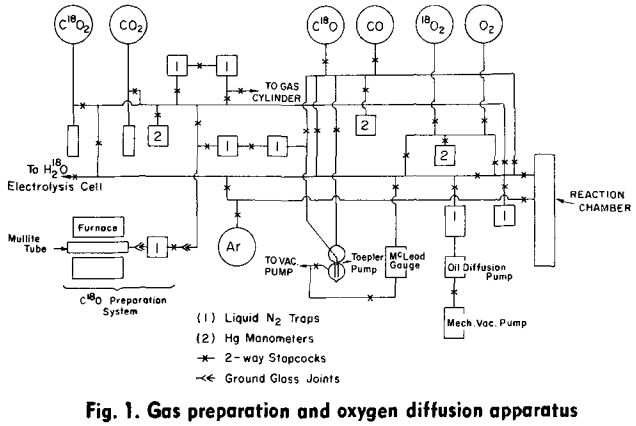

Fig. 1. Gas preparation and oxygen diffusion apparatus

* Electrochemical Society Active Member.

placed by $\sqrt{\tau} = 0.03$ in Fig. 2-3 and $\sqrt{\tau} = 0.04$ in Fig. 4. Since they are linear and extrapolate to the origin, oxygen diffusion in the spheres would appear to determine the exchange kinetics. In Fig. 5, the values of the self-diffusion coefficient D^* have been plotted against the oxygen partial pressure over the range 10^{-19}-1 atm. Least squares analysis of these results demonstrated that the oxygen self-diffusion coefficient was independent of both oxygen partial pressure and sphere size, and to have the value

$$D^* = (1.9 \pm 0.3) \times 10^{-12} \text{ cm}^2 \text{ sec}^{-1} \quad [3]$$

This result agrees favorably with the value $D^* = 1.98 \times 10^{-12}$ cm^2 sec^{-1} calculated for $P_{O_2} \sim 0.5$ atm from the Arrhenius equation presented earlier (5).

The partial electrical conductivity due to oxygen ions may be related to the oxygen self-diffusion coefficient

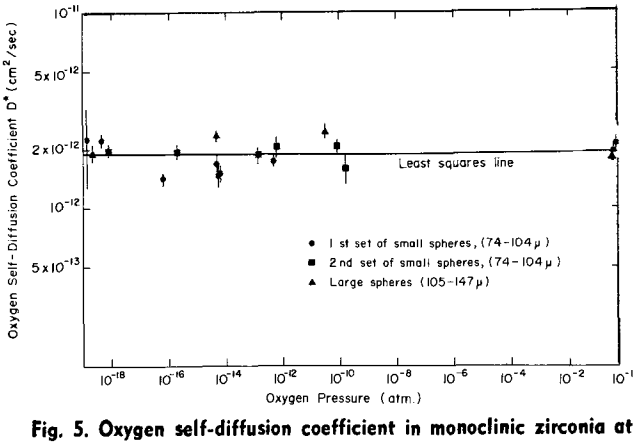

Fig. 5. Oxygen self-diffusion coefficient in monoclinic zirconia at 990°C.

by means of the Nernst-Einstein relationship to a first approximation by the following expression

$$\kappa_{ion} = \frac{4F^2D^*}{V_mRT} = 3.2 \times 10^{-7} \text{ ohm}^{-1} \text{ cm}^{-1} \text{ at } 990°\text{C} \quad [4]$$

where V_m, the molar volume of oxide, is equal to 21.15 cm^3 mole^{-1}. In Fig. 6, the ionic conductivity at 990°C is compared with the total electrical conductivity, as determined by Vest *et al.* (3). As illustrated by the pressure dependency of the conductivity, n-type conductance is predominant at $P_{O_2} \leq 10^{-18}$ atm and p-type conductance is predominant at $P_{O_2} \geq 10^{-10}$ atm. It is also to be seen that the ionic conductance, which is independent of oxygen pressure over the range 10^{-19}-1 atm, lies within the range typical of both the intrinsic and n-type electrical conductivity.

If it is assumed that the minimum value of the total electrical conductivity is associated with oxygen ion migration, the excess electrical conductivity illustrated in Fig. 6 at 10^{-17} atm for the polycrystalline hot-pressed zirconia may be explained as being due to short-circuit anionic conductivity. This behavior associated with structure would appear to be most probable since the total weight per cent of zirconia in the compacts and spheres is of the same order of magnitude, 99.82 *vs.* 99.92 w/o. In previous investigations on the oxygen diffusional properties of the microspheres and polycrystalline oxide (5, 8), it has been shown that

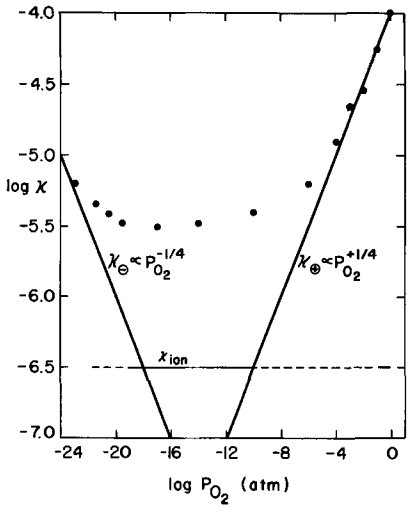

Fig. 6. Ionic and electronic conductivity of monoclinic zirconia at 990°.

the diffusion rate was much larger in the latter structure and of values typical for short-circuit diffusion in the temperature range 750°-950°C. Accordingly, the apparent electrical conductivity κ_{app} is written in terms of the lattice conductivity κ_L and boundary conductivity κ_B as follows

$$\kappa_{app} = \kappa_L (1 - f) + \kappa_B f \quad [5]$$

where f is the fraction of oxygen ion sites at line defects such as dislocations and crystal boundaries. The values of f may be estimated from the ionic conductivity calculated here together with an estimate of κ_B derived from the results of oxygen diffusion measurements in polycrystalline zirconia slabs performed earlier (8). If one estimates that $f = 0.1$ in the polycrystalline slabs, D_B at 990°C is found to be approximately 3×10^{-8} cm²/sec, from which one obtains $\kappa_B = 5 \times 10^{-3}$ ohm^{-1} cm^{-1}. Substituting these values into Eq. [5] and solving for f, one obtains $f = 5 \times 10^{-4}$. This represents somewhat defective material with 0.05% of the oxygen lattice sites located at crystal boundaries or line defects such as dislocations.

Two defect models involving oxygen ion vacancies have been proposed for monoclinic zirconia from which theoretical predictions may be made on the variation of the electronic and ionic conductivities as a function of oxygen pressure. Kröger (1) has proposed a Schottky-type model involving zirconium vacancies singly associated with oxygen vacancies, as follows

$$\text{nil} \rightleftarrows (\square_{Zr}\square_O)'' + \square_O{\cdot\cdot} \quad K_1 = C_A C_{\square} \quad [6]$$

where C_A denotes the concentration of associated vacancies. On the other hand, Douglass and Wagner (2) have proposed anti-Frenkel disorder, similar to that found for calcium fluoride by Ure (9)

$$\text{nil} \rightleftarrows \square_O{\cdot\cdot} + O_i'' \quad K_1' = C_{\square} C_i \quad [7]$$

Equations for the production of electrons and electron holes, and for the incorporation of oxygen from the gas phase, which are common to both models, may be written as follows

$$\text{nil} \rightleftarrows e' + h{\cdot} \quad K_2 = C_\theta C_\oplus \quad [8]$$

$$\frac{1}{2} O_2 + \square_O{\cdot\cdot} + 2e' \rightleftarrows O_L \quad K_3 = \frac{1}{C_{\square} C_\theta^2 P_{O_2}^{1/2}} \quad [9]$$

where O_L represents a lattice oxygen ion. From these equations, together with the appropriate approximation for the electroneutrality condition, equations for the oxygen pressure dependence of the various defects may be written.

Under conditions in which the zirconia exists with nearly ideal stoichiometric composition, the electroneutrality condition may be expressed by

$$C_{\square} = C_i = K_1'^{1/2} \quad \text{or} \quad C_{\square} = C_A = K_1^{1/2} \quad [10]$$

and it follows from Eq. [6] to [9]

$$C_\theta = K_3^{-1/2} K_1^{-1/4} P_{O_2}^{-1/4} \quad [11]$$

and

$$C_\oplus = K_2 K_3^{1/2} K_1^{1/4} P_{O_2}^{1/4} \quad [12]$$

At very low oxygen pressures, where an excess of oxygen vacancies exists in oxygen-deficit zirconia, the electroneutrality condition may be expressed by

$$2C_{\square} = C_\theta \quad [13]$$

and from [9] it follows that

$$2C_{\square} = C_\theta = \left(\frac{2}{K_3}\right)^{1/3} P_{O_2}^{-1/6} \quad [14]$$

At very high oxygen pressures, in oxygen-rich zirconia, the electroneutrality relationship may be expressed in terms of either oxygen interstitials or zirconium vacancies associated with oxygen vacancies, as follows

$$2C_i = C_\oplus \quad \text{or} \quad 2C_A = C_\oplus \quad [15]$$

Using Eq. [6]-[9], it may be seen that

$$2C_i = C_\oplus = (2K_1' K_2^2 K_3)^{1/3} P_{O_2}^{1/6} \quad [16]$$

or

$$2C_A = C_\oplus = (2K_1 K_2^2 K_3)^{1/3} P_{O_2}^{1/6} \quad [17]$$

depending on whichever model is selected. It is therefore seen that the two models are mathematically equivalent, with O_i'' in the anti-Frenkel model corresponding directly to $(\square_{Zr}\square_O)''$ in the Schottky model, provided that, in the Schottky model, further association of a second oxygen vacancy or dissociation of the complex is neglected.

The ionic and electronic conductivity of zirconia may now be explained by reference to these models. Figure 6 shows that the ionic conductivity is independent of oxygen pressure over the range $1\text{-}10^{-19}$ atm. Apparently, the solid behaves as an intrinsic semiconductor in which the total oxygen defect concentration involving oxygen vacancies and interstitials is fixed by the value of the constant, K_1 or K_1', being much greater than the value of the constant K_2. That the value observed for the ionic conductivity refers to both formation and movement of oxygen vacancies has been shown by the fact that the activation energy for oxygen diffusion in spheres at 0.5 atm pressure, 56 kcal (5), is approximately twice that observed for oxygen diffusion in plates of columnar zirconia of identical composition (8). Hence, the electroneutrality relation would not appear to be markedly influenced by impurities present in the oxide specimens and accordingly may be defined by Eq. [10], within the experimentally accessible pressure range. Consequently the concentrations of electrons and holes would be given by Eq. [11] and [12], respectively.

The partial electronic conductivity, κ_e, may be expressed by

$$\kappa_e = \kappa_\theta + \kappa_\oplus = \mathbf{F}(\mu_\theta C_\theta + \mu_\oplus C_\oplus)/V_m \quad [18]$$

where $\mathbf{F}$ is the Faraday constant, V_m the molar volume, and μ_θ and $\mu_\oplus$ the mobilities of electrons and positive holes. Substituting Eq. [11] and [12] into [18], it is found that

$$\kappa_e = \frac{\mathbf{F}}{V_m} [\mu_\theta K_3^{-1/2} K_1^{-1/4}) P_{O_2}^{-1/4} + (\mu_\oplus K_2 K_3^{1/2} K_1^{1/4}) P_{O_2}^{+1/4}] \quad [19]$$

The electronic conductivity has been shown in Fig. 6 where it is seen that a $P_{O_2}^{+1/4}$ relationship is consistent

with Vest *et al.*'s results at $P_{O_2} = 1\text{-}10^{-4}$ atm. The low pressure data does not extend to a sufficiently low pressure to verify the $P_{O_2}^{-1/4}$ relationship.

The partial ionic conductivity, κ_{ion}, in terms of the mobilities for the point defects is given by

$$\kappa_{ion} = 2\mathbf{F}\,(\mu_{\square} C_{\square} + \mu_A C_A)\,/V_m \qquad [20]$$

or

$$\kappa_{ion} = 2\mathbf{F}\,(\mu_{\square} C_{\square} + \mu_i C_i)\,/V_m \qquad [20a]$$

depending on which defect model is selected. If the Schottky disorder type were present, the zirconium vacancies present in the associates would be expected to contribute somewhat to μ_A, resulting in a zirconium self-diffusion coefficient within a few orders of magnitude of the oxygen self-diffusion coefficient. However, if the anti-Frenkel defect model were present, the cationic lattice would be nearly perfect compared to the anionic lattice and the zirconium self-diffusion coefficient would be several orders of magnitude lower than the oxygen self-diffusion coefficient. Unfortunately, data on zirconium self-diffusion in pure zirconia is lacking. Extrapolation of data on zirconium self-diffusion in calcia-stabilized zirconia at 1700°-2200°C (10) to 990°C, would indicate D^*_{Zr}/D^*_O to be approximately 10^{-6}, apparently favoring the anti-Frenkel model as the predominant defect structure for monoclinic zirconia. However, in stabilized zirconia, the concentration of zirconium vacancies or oxygen interstitials (dependent on which model is chosen) is expected to be lower than the value for pure zirconia by an amount dependent on the equilibrium constant for association of oxygen vacancies with calcium ions in stabilized zirconia (1). Thus the value of D^*_{Zr} in pure zirconia can be expected to be higher, and it is therefore concluded that a decision on which defect model is important for either oxide must await the experimental determination of values for D^*_{Zr} in pure zirconia.

Conclusions

The oxygen self-diffusion coefficient in monoclinic zirconia microspheres at 990°C was determined to be $D^* = 1.9 \times 10^{-12}$ cm^2 sec^{-1}. This value is independent of both sphere size in the range 90-126μ and oxygen pressure in the range $1\text{-}10^{-19}$ atm. A comparison of the partial electrical conductivity due to oxygen ions as calculated from the Nernst-Einstein relationship to the total conductivity of hot-pressed compacts indicates monoclinic zirconia to be an n-type electronic conductor at $P_{O_2} \leq 10^{-18}$ atm and a p-type electronic conductor at $P_{O_2} \geq 10^{-10}$ atm, with predominant oxygen ionic transport at intermediate pressures. The excess electrical conductivity exhibited by the polycrystalline compact at intermediate pressures is believed to be due to short-circuit anionic conductivity, with an estimate of approximately 0.05% of the oxygen ions situated at line defects. Although data for zirconium diffusion in stabilized zirconia would appear to support the anti-Frenkel model as the predominant defect model for pure zirconia, it is impossible to draw a conclusion until a value for the zirconium self-diffusion coefficient in pure zirconia has been measured.

Technical Notes

Luminescent Properties of Eu^{2+} and $Eu^{2+} + Mn^{2+}$ Activated $BaMg_2Si_2O_7$

Thomas L. Barry*

Sylvania Lighting Center, Sylvania Electric Products Incorporated, Danvers, Massachusetts

Recently, a great deal of work has been done on divalent europium activation of silicate phases (1-9), largely devoted to three ternary systems:

1. CaO — MgO — SiO_2
2. SrO — MgO — SiO_2
3. BaO — MgO — SiO_2

and their respective bounding binary systems. In particular, joins and isothermal sections between phases with analogous formulas were considered; examples of this being the 3-1-2 and 2-1-2 (RO-MgO-SiO_2) compounds in the ternary isothermal sections (common in all three systems) and the 2-1 compounds in the bounding alkaline earth oxide-silica binary joins. Such selections are easily understandable due to the wide variety of substitution possible in such compositional regions and the accompanying changes in the excitation and emission spectra which may be studied.

* Electrochemical Society Active Member.

Key words: phosphors alk earth silicates, luminescence alk earth silicates, subsolidus phase relations, europium (2+) activation, emission spectra, excitation spectra, energy transfer Eu(2+) to Mn(2+), sensitizer and activator dependencies.

The subsolidus phase relationships in the BaO-MgO-SiO_2 system were initially studied by Klasens, Hoekstra, and Cox (10) and recently redone by Argyle (11), the latter reporting three new compounds ($3BaO \cdot 5SiO_2$; $5BaO \cdot 8SiO_2$; $BaO \cdot MgO \cdot 3SiO_2$). The features of the two diagrams which are pertinent to this luminescence study, however, are identical.

Figure 1, taken from the work of Argyle (11), gives the subsolidus relationships. Five ternary compounds exist in the system luminescence being studied in the 3-1-2 and 2-1-2 compounds (1, 5, 7). A compound with the 1-2-2 stoichiometry occurs only in this system. It does not form in the other two ternary systems mentioned. This compound melts congruently at 1600°C and provides the matrix on which the luminescence studies of this paper have been conducted.

Other features of Fig. 1 which are referred to later are the observations that (*A*) the 1-2-2 compound lies on a binary join between $BaMgSiO_4$ (1-1-1) and $MgSiO_3$ (1-1), and also between $BaSi_2O_5$ (1-2) and MgO; (*B*) the compounds $BaSiO_3$ (1-1) and Mg_2SiO_4 (2-1), and BaO plus $MgSiO_3$ (1-1) possess such stoichiometries that when mixed in the proper proportions and completely reacted yield the 1-2-2 compound.

Experimental

Of the starting materials, the barium carbonate, silicic acid, and manganese carbonate were luminescent-grade chemicals, the barium chloride hexahydrate and ammonium chloride were commercially available reagent grade chemicals; the basic magnesium carbonate was a Mallinckrodt analytical reagent containing less than 0.005% sulfate as an impurity; and the europium oxide was 99.9% purity. Assays were run on those materials where it was necessary to compensate for sorbed water. Appropriate proportions of the raw materials were dry blended in a Spex Mixer/Mill for 15 min to obtain starting mixtures. The blended mixtures were fired in a wet forming-gas atmosphere (80% nitrogen-20% hydrogen passed through water at temperatures around 50°C) at temperatures between 950° and 1250°C and times of from 1 to 4 hr. The particular combination employed depended on the flux combination and/or concentration. Lower temperatures and longer times were used when a concurrent double flux of NH_4Cl and $BaCl_2$ was used (*e.g.*, 4 hr at 1000°C) and higher temperature and shorter time when just a relatively small amount of NH_4Cl was employed (*e.g.*, 1 hr at 1200°C). After firing, the samples were cooled to near room temperature in the reducing atmosphere. Chemical analysis of phosphors prepared as described showed no chloride retained in the finished phosphor. This established chloride as a flux, influencing the luminescence of the phosphor produced and the course of the reaction yet not being incorporated in the matrix.

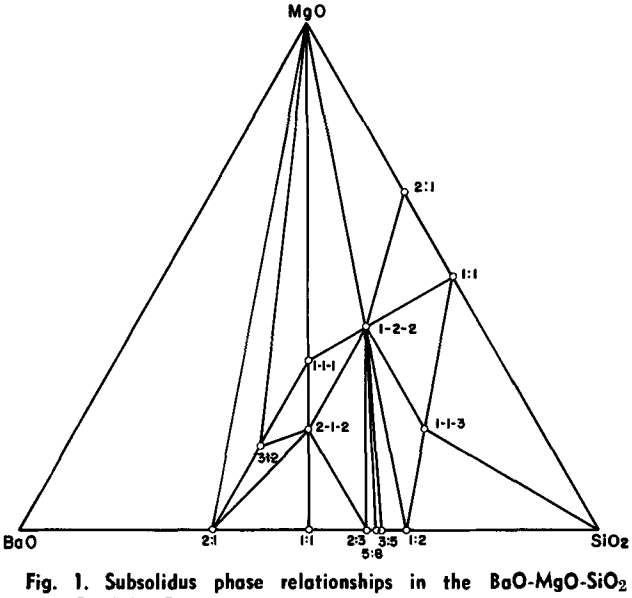

Fig. 1. Subsolidus phase relationships in the BaO-MgO-SiO_2 system. [Ref. (11)].

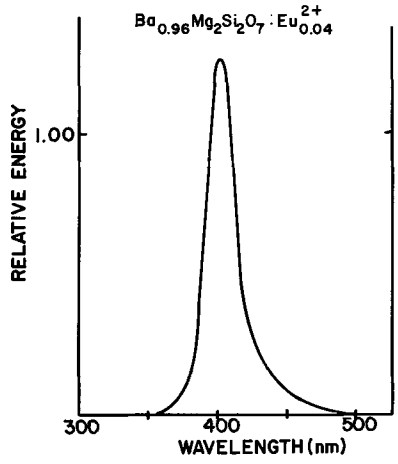

Fig. 2. Spectral energy distribution curve for $Ba_{0.96}Mg_2Si_2O_7:Eu^{2+}_{0.04}$ (2537Å excitation).

A Norelco diffractometer with filtered CuKα-radiation was used in phase identification for virtually every run on every sample. Excitation spectra were obtained with a modified Hitachi Perkin-Elmer fluorescence spectrophotometer, Model MPF-2A, which has been corrected for the output from the source. The emission spectra and peak height measurements were determined using equipment and techniques previously described by Eby (12). The luminescence intensities given in Fig. 2, 3, 4, 6, and 7 were obtained *vs.* $Zn_2SiO_4:Mn^{2+}$ (Relative Energy = 1.00) as a standard and are thus directly comparable.

Results and Discussion

Luminescent properties of $BaMg_2Si_2O_7:Eu^{2+}_{0.04}$.—When the 1-2-2 compound is prepared under equilibrium conditions (flux methods described in experimental section) and activated by divalent europium, a phosphor whose SED curve (254 nm excitation) is given in Fig. 2 is obtained. This phosphor responds to both long- and short-wavelength u.v. as well as to cathode-ray excitation giving an emission band peaking at 400 nm and a width at half height of 25 nm.

The peak wavelength of this phosphor is considerably less (~35 nm) than those obtained from compounds or crystalline solutions with a 3-1-2 stoichiometry (1, 5). These phases had previously yielded the shortest peak wavelengths of the alkaline earth silicates reported to date. Additionally, the luminescence intensity of this compound (1-2-2) at its peak wavelength is greater than the vast majority of the 3-1-2 phases at their particular peak wavelengths.

Luminescent properties of nonequilibrium preparations.—When equilibrium is not attained in synthesizing this phosphor (when no fluxing action is employed), an SED curve such as that given in Fig. 3 may be characteristic of the assemblage obtained. Three peaks are evident in the composite SED curve. Data from x-ray diffraction and u.v. microscope studies previously reported on by Bouchard (13) have been used to explain such a distribution. Employing these methods, the formation and identification of a reaction intermediate have been established. The intermediate phase,[1] $BaMgSiO_4:Eu^{2+}$, in many instances is difficult to detect in spectral energy data due to overlapping peaks, and in x-ray patterns due to the small amount present. This phase is immediately obvious when viewed under the u.v. microscope since its peak (440

[1] A 1-1-1 reaction intermediate was also observed in the synthesis of ternary compounds in the CaO-MgO-SiO_2 system by Drs. A. L. Smith and A. D. Power, of Radio Corporation of America, especially when the larger alkaline earth oxide to silica ratio in the blend was 1:2, as is the ratio in the present work.

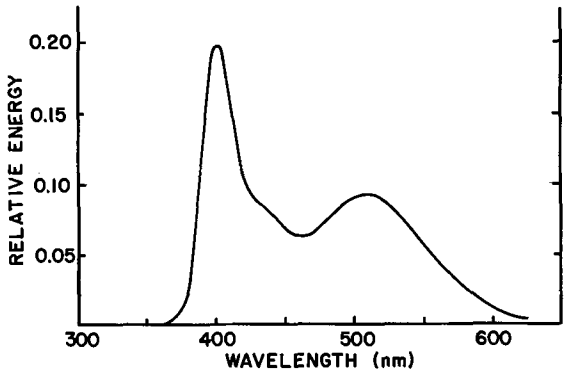

Fig. 3. Spectral energy distribution curve for a nonequilibrium assemblage (no flux employed in synthesis).

nm) is displaced approximately 40 nm from that of the violet peak of the major phase. In addition to the presence of this intermediate which may be detected as a shoulder in the emission peak in the violet region, a second, broader peak appears in the green region of the spectrum.

This is a much grosser effect than the one just described. This green emission was at first thought to be due to an additional secondary phase. Microscopic examination utilizing ultraviolet radiation showed the emission bands to be due to individual crystallites, rather than multiple emission from crystallites composed of intergrown phases. Thus crystallites giving rise to the individual emission bands could be separated. X-ray diffraction data taken on separated fractions showed only the (1-2-2) phase to be present, and the same degree of crystallinity, whether dominated by either green or violet emission. Thus these two emission bands are due to divalent europium in two different positions in the same lattice. The violet emission is attributed to the substitution of Eu^{2+} in Ba^{2+} sites. The green emission, which results from a metastable condition and can be removed by prolonged heating is possibly due to substitution of Eu^{2+} for Mg^{2+}, or more likely the incorporation of Eu^{2+} in structural holes in the lattice (as in feldspars).

An attempt was made to take advantage of the fact that $BaMgSiO_4:Eu^{2+}$ is formed as an intermediate when the constituent oxides are reacted. This compound and enstatite ($MgSiO_3$) were synthesized and reacted to form $BaMg_2Si_2O_7:Eu^{2+}$ according to the following reaction

$$BaMgSiO_4: Eu^{2+} + MgSiO_3 \rightarrow BaMg_2Si_2O_7:Eu^{2+}$$

Note that in Fig. 1 the product (the finished phosphor) lies on a binary join between these reactants.

Although a well-reacted product could be obtained at somewhat lower temperatures (100°-150°C) than required to react the constituent oxides (x-ray evaluation), the luminescence of these samples was considerably less (~50-60%) than that of the samples prepared from the oxide raw materials. An additional reaction, represented by another binary join in Fig. 1, between $BaSi_2O_5$ and MgO was also explored.

$$BaSi_2O_5:Eu^{2+} + 2MgO \rightarrow BaMg_2Si_2O_7:Eu^{2+}$$

Better results were anticipated here as syntheses involving silicate and oxide materials are generally considered to be more reactive than syntheses when the reactants are both silicates. However, the output of the phosphor prepared in this manner was only 25-30% of that prepared from the constituent oxides.

The two other schemes investigated involved reacting two silicates or an oxide and a silicate

$$BaSiO_3:Eu^{2+} + Mg_2SiO_4 \rightarrow BaMg_2Si_2O_7:Eu^{2+}$$
$$BaO:Eu^{2+} + 2MgSiO_3 \rightarrow BaMg_2Si_2O_7:Eu^{2+}$$

with the correct stoichiometries to yield the desired product. These proved to be even less successful.

Incorporation of other alkaline earth ions.—Since no (1-2-2) compound exists in either the CaO or SrO analogs of the $BaO-MgO-SiO_2$ system, varying compositions between compounds with analogous formulas is not a possibility. Attempted Ca^{2+} or Sr^{2+} substitution for Ba^{2+} in this matrix resulted in a decrease in the luminescence intensity in both instances. With Sr^{2+}, the drop is gradual up to the 0.20 atom fraction Sr^{2+} formulation, followed by a quite drastic decrease in the luminescence intensity for formulations containing greater Sr^{2+} concentrations. At the same time, an emission band from a secondary phase emerges at (460-470 nm) attributable to $Sr_2MgSi_2O_7:Eu^{2+}$. The appearance of this compound is easily rationalized, as no 1-2-2 compound forms in the $SrO-MgO-SiO_2$ system. The composition which corresponds to this stoichiometry falls in a three-phase field. The compound $Sr_2MgSi_2O_7$ is the only one efficiently activated by divalent europium. The other two phases are forsterite (Mg_2SiO_4) and enstatite ($MgSiO_3$) which are not efficiently activated by Eu^{2+} for exciting radiation between 180 and 320 nm.

When the incorporation of Ca^{2+} is attempted, the luminescence intensity again drops with increasing Ca^{2+} concentration, in this case in almost a continuous manner. The SED curves of these samples show the appearance of a new emission band at 445 nm due to the diopside ($CaMgSi_2O_6:Eu^{2+}$) secondary phase formed. Beyond 0.30 atom fraction calcium, the intensity of the 445 nm band also drops and a third band at 535 nm due to the formation of akermanite ($Ca_2MgSi_2O_7:Eu^{2+}$) results.

These observations again may be explained due to the nonexistence of a compound with the 1-2-2 stoichiometry in the $CaO-MgO-SiO_2$ system. Again formulating to this stoichiometry leads to a composition falling in a three-phase field where diopside ($CaMgSi_2O_6$), forsterite (Mg_2SiO_4), and akermanite ($Ca_2MgSi_2O_7$) are in equilibrium. The changes in the relative amounts of the phases, which can be efficiently activated by divalent europium, can thus be observed in the SED curves run on these samples. These data are intended only to show in a qualitative manner the detrimental effect on the luminescence intensity of attempted Ca^{2+} or Sr^{2+} substitution for Ba^{2+} in this matrix under the specific conditions of synthesis employed (4 hr at 1200°C).

Double activation with Eu^{2+} *and* Mn^{2+}.—The SED curve of the phosphor which results when both europium and manganese are incorporated as activators is given in Fig. 4. The emission from Eu^{2+} remains at 400 nm, and a new band appears at 690 nm due to emission from Mn^{2+}. The SED curve in Fig. 4 is for

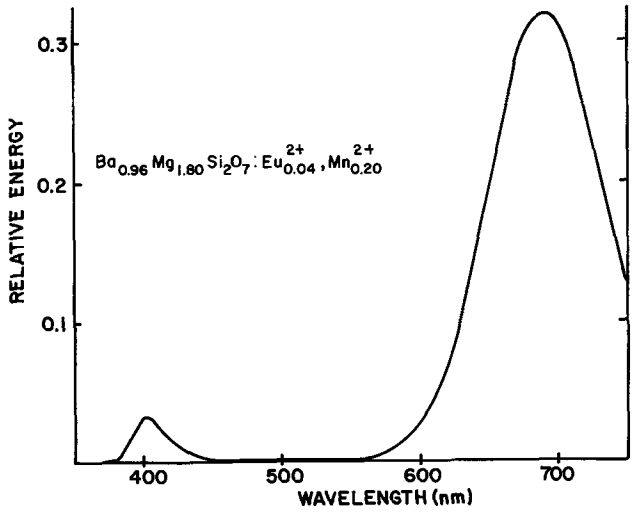

Fig. 4. Spectral energy distribution curve for the europium, manganese doubly activated phosphor, $Ba_{0.96}Mg_{1.80}Si_2O_7:Eu^{2+}{}_{0.04}$, $Mn^{2+}{}_{0.20}$.

the phosphor when the formulation allows for Eu^{2+} substitution for Ba^{2+} and Mn^{2+} substitution for Mg^{2+}. More detail of the effect on luminescence intensity of the substitution schemes which allow for the incorporation of the activator ions is given in a subsequent section of this paper.

Figure 5 presents the excitation spectra for emission peaked at 400 nm, in samples with Eu activator only, or 690 nm in those having Eu + Mn or Mn alone. Identity of the excitation spectra for the first two shows there is $Eu^{+2} \rightarrow Mn^{+2}$ energy transfer, while the third curve shows that direct excitation of Mn (sensitivity was increased 10 to 100 times over that used for the others to obtain this curve) is weak.

Effect of Mn^{2+} and Eu^{2+} concentrations on luminescence intensity.—The effect of varying the manganese concentration, as the Eu^{2+} is held constant, on the two emission bands is shown in Fig. 6. Data are given for two postulated substitution schemes.

(*A*) $Ba_{1-x-y}Mg_2Si_2O_7:Eu_x^{2+}, Mn_y^{2+}$

(*B*) $Ba_{1-x}Mg_{2-y}Si_2O_7:Eu_x^{2+}, Mn_y^{2+}$

In the series run covering both substitution schemes, x was held constant at 0.04, and y was varied from 0.10 to 0.50 in steps of 0.10. In the first scheme (*A*), maximum red emission at 690 nm, due to emission

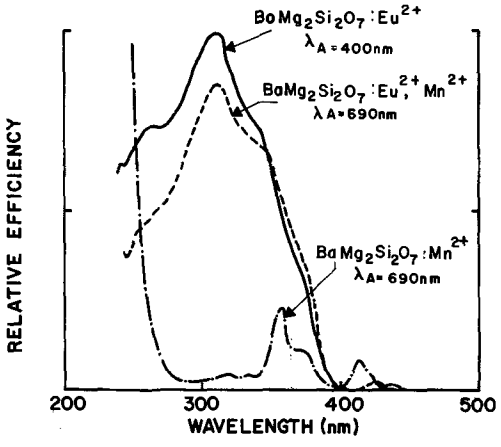

Fig. 5. Excitation spectra of $BaMg_2Si_2O_7:Eu^{2+}$, $BaMg_2Si_2O_7:Mn^{2+}$, and of the doubly activated phosphor $BaMg_2Si_2O_7:Eu^{2+}, Mn^{2+}$.

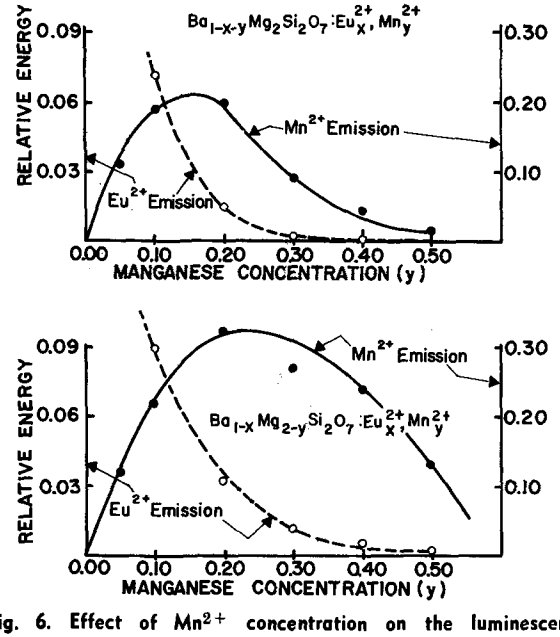

Fig. 6. Effect of Mn^{2+} concentration on the luminescence intensity according to two postulated substitution schemes, $Ba_{0.96-y}Mg_2Si_2O_7:Eu^{2+}{}_{0.04}, Mn^{2+}{}_y$, and $Ba_{0.96}Mg_{2-y}Si_2O_7:Eu^{2+}{}_{0.04}, Mn^{2+}{}_y$.

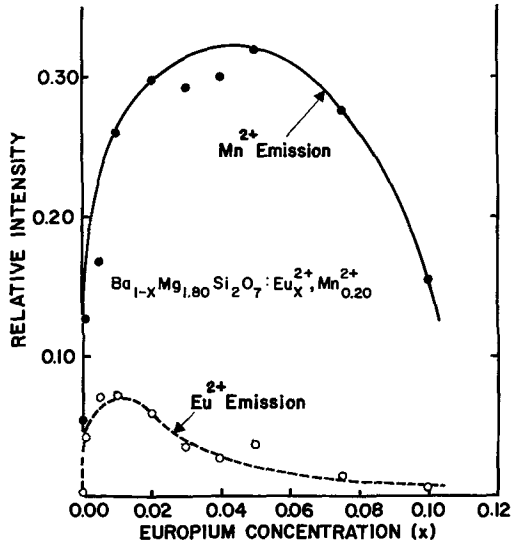

Fig. 7. Effect of Eu^{2+} sensitizer concentration, at optimum Mn^{2+} activator concentration, on the luminescence intensity of the phosphor $Ba_{1-x}Mg_{1.80}Si_2O_7:Eu^{2+}{}_x, Mn^{2+}{}_{0.20}$.

from manganese, occurs at $y = 0.10$-0.20 and falls off drastically at $y = 0.30$, probably due to concentration quenching. When a value of $y = 0.50$ is reached in this scheme, the typical emission bands as in Fig. 4 are extremely weak and some line emission from Eu^{3+} now appears. For the same substitutions made according to scheme (*B*), maximum red emission occurs for $y = 0.20$ and is 50% greater than the maximum achieved in scheme (*A*).

Even at $y = 0.50$ in scheme (*B*), substantial emission due to Mn^{2+} is realized. These results show that maximum red emission from manganese is realized in scheme (*B*) and intimate that manganese substitutes for magnesium rather than barium in this pyrosilicate phase. This scheme is more in line with simple crystal chemical considerations, such as ionic size and phase relations in magnesium silicate–manganese silicate systems.

The effect of varying that Eu^{2+} concentration when the Mn^{2+} is held at the optimum value is shown in Fig. 7. Initially, there is a rise in both europium and manganese emission. The initial rise in europium emission is due to improved u.v. absorption by the phosphor as the europium concentration is increased. The initial rises are followed by a decrease in europium and a further increase in manganese emission as the energy transfer process becomes more efficient. Finally, a decrease in both emissions as europium self-quenching sets in and less energy is available for transfer to manganese.

Acknowledgments

The author gratefully acknowledges the encouragement and valuable discussions during this investigation with Dr. K. H. Butler and Dr. M. J. B. Thomas. Appreciation is likewise extended to Mr. A. Rudis for the synthesis and spectral measurements on the samples and to Miss M. Skeadas for the x-ray diffraction data.

Effect of Water Vapor on the Combustion of Flash-Heated Beryllium Droplets[1]

Jack L. Prentice

Michelson Laboratories, Naval Weapons Center, China Lake, California

Corrosion and corrosion processes are of exceptional importance to both science and technology. In particular, oxide transport in the Be-BeO-H_2O system through corrosion processes is of importance in the fields of ceramics, nuclear reactor technology, and propellant combustion. The reaction

$$BeO_{(solid)} + H_2O_{(gas)} \rightleftharpoons Be(OH)_{2(gas)}; \quad \Delta H°_{298} = +42 \text{ kcal/mole} \quad [1]$$

is reported to be the principal process and is probably the one of importance here although there is as yet no spectroscopic identification of the gaseous species $Be(OH)_2$. The process has both advantages and disadvantages, depending on where it is encountered. In ceramics and nuclear reactor technology, oxide transport through corrosion processes results in damaged or destroyed apparatus (with possible dire consequences). In some industrial applications, the process is either employed to grow large BeO single crystals or to produce high-purity BeO of very fine crystallite size ($\sim 1\mu$). In propellant combustion, the mechanism of combustion of the beryllium metal additive can be changed by the presence of significant amounts of water vapor.

To this author's knowledge, no previous demonstration of oxide transport from burning beryllium droplets has been reported. Such a phenomenon is described in this communication.

When submillimeter diameter Be particles were burned at atmospheric pressure in air, carbon dioxide, or a mixture of 20% oxygen in argon, long, well-formed hexagonal whiskers of BeO were formed on the droplet surface during the intermediate phases of burning (1, 2). Continued oxidation accompanied by rising droplet temperature resulted in total encapsulation of the droplet by molten beryllia. Repetition of such experiments with the gases saturated with water vapor at room temperature results in the prevention of oxide accumulation on the droplet surface, and neither whisker formation nor encapsulation occurs.

In our combustion experiments, each Be particle, nominally 500μ in diameter, was prepared and ignited by exposing a small square of Be foil to the thermal pulse from a high-intensity xenon flash discharge lamp. In this technique, developed by Nelson (3), a metal foil, 1.6 mm on a side and 12.7μ thick, was permitted to fall freely through a glass reaction vessel in which an appropriate oxidizer was provided and whose top was surrounded by a helical quartz flash lamp. As the particle passed through the lamp area, the lamp was fired electrically and the foil ignited, forming a sphere. Individual burning particles were quenched on Pyrex plates at various distances from the flash lamp and withdrawn for study with a scanning electron microscope (SEM). By judicious sampling, a complete picture of the evolution of the burning particle geometry may be reconstructed.

Figure 1 is a composite of SEM photomicrographs sketching the evolution of particle geometry for Be burning in a dry oxygen-argon mixture. The figure shows random growth of ill-formed BeO on a spongy, unmolten Be substrate, growth of hexagonal whiskers of BeO on a molten droplet of Be (mp = 1556°K), and finally encapsulation of the Be droplet by molten BeO

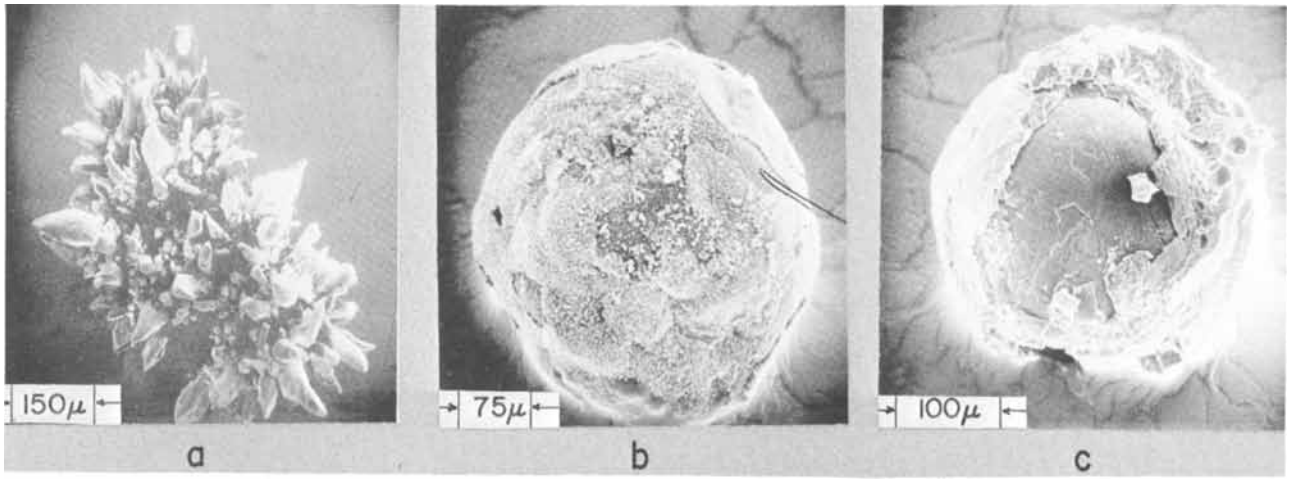

Fig. 1. SEM micrographs sketching the evolution of particle geometry for flash-ignited beryllium foil burning in a mixture of 20% oxygen-argon at 705 ±5 Torr. Particles quenched at (a) 20, (b) 30, and (c) 40 cm from the lamp.

(mp = 2820°K). Shortly after encapsulation, radiative heat loss from the extensive beryllia surface lowers the temperature enough to freeze the oxide, vapor phase combustion is terminated, and particle temperature decays to ambient. These specimens were quenched at 20, 30, and 40 cm from the lamp and represent burning times (*i.e.*, time from ignition to quench) of about 250-500 msec. Figure 1(c) shows a specimen in which the heavy surface oxide has fractured on cooling.

Optimum beryllium combustion proceeds by a vapor phase mechanism. The ambient temperature must therefore be kept high enough to keep the encapsulat-

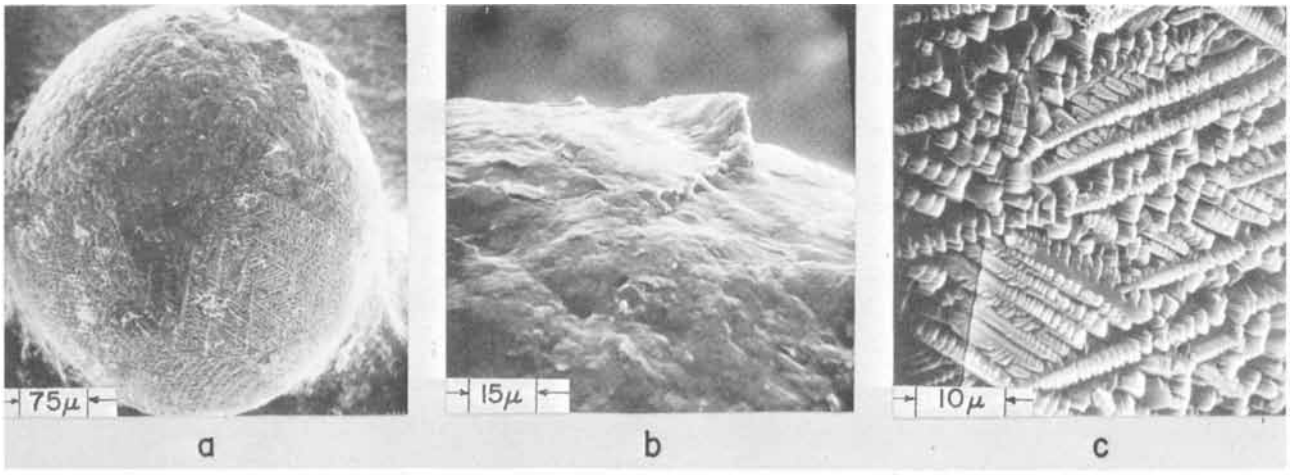

Fig. 2. SEM micrographs of flash-ignited beryllium particle quenched while burning in 1 atm of 20% oxygen-argon saturated with water vapor at 28°C. Note clean surface burning.

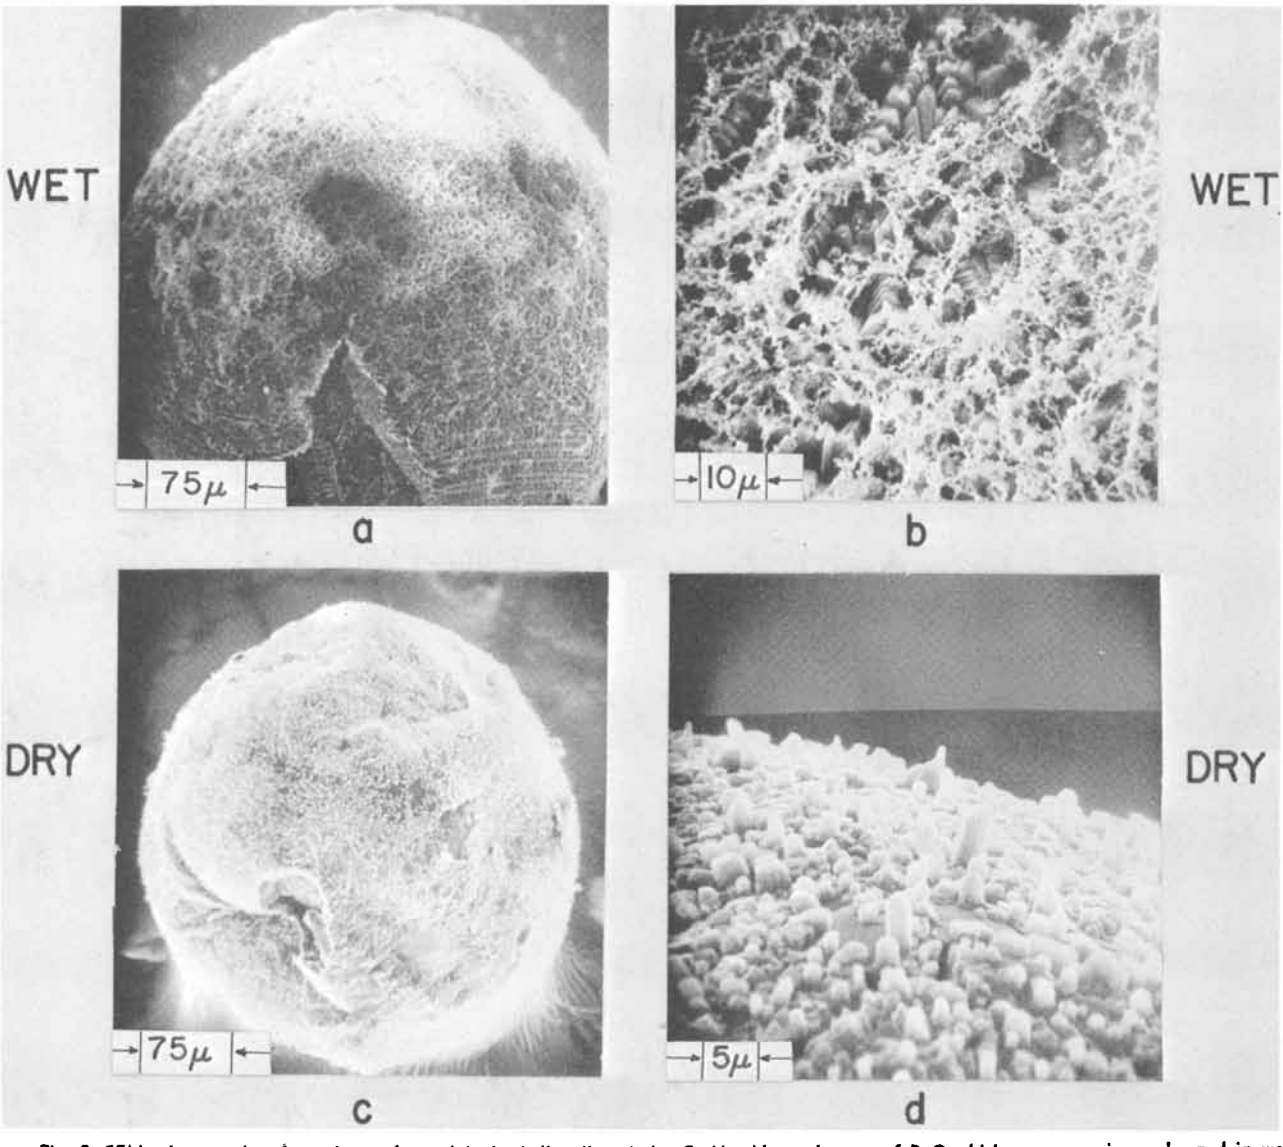

Fig. 3. SEM micrographs of specimens burned in both "wet" and dry O_2/Ar. Note absence of BeO whiskers on specimens burned in wet gas (a, b). Both specimens (a, c) quenched 30 cm from flash lamp.

ing oxide molten or the vapor phase combustion will be stifled and the droplet combustion will be forced to proceed *via* the much slower process of oxidizer diffusion through the oxide crust and subsequent surface reaction. Gulbransen and Andrew (4) have shown that the vapor pressure of beryllium may be reduced by as much as 100-fold by an oxide coating 0.4μ thick at 1200°K. Thus, oxide skins or films on burning beryllium particles similar to that in Fig. 1c, which may be as much as 50μ thick, must surely exert a retarding effect on combustion efficiency.

Figure 2 is a composite of SEM photomicrographs showing the effect of burning a beryllium particle in an oxygen-argon mixture saturated with water vapor. No trace of hexagonal whisker formation exists on specimens burned in the presence of water. When examined by low-power ($\sim$60X) optical microscopy, such specimens appear as shiny, bright metallic-looking spheres as contrasted with the opaque, milky-white oxide encapsulated specimens in Fig. 1. Figure 3 contrasts beryllium droplets quenched while burning in "wet" and dry oxygen-argon.

Douglas (5) has reviewed the high-temperature thermodynamics of the BeO-H_2O system and has postulated that higher gaseous hydrates of beryllium oxide may be important at high temperature. For example, he suggests that the trimer $(BeO)_3 \cdot H_2O$ is prevalent above about 1850°K. The analysis indicates that the JANAF thermodynamic data may be in error and that at temperatures above 2500°K there would be more BeO in the gas phase than indicated by the JANAF tables which assume $BeO \cdot H_2O$ to be the gaseous species. Douglas' analysis indicates that at 2000°K the partial pressure of $(BeO)_3 \cdot H_2O$ would be only about 10% of that of $BeO \cdot H_2O$, but at 3000°K the partial pressure of $(BeO)_3 \cdot H_2O$ would be 100 times that of the monomer $Be(OH)_2$.

The experiments reported here appear to lend support to the conclusions of Douglas. The specimen in Fig. 2 shows that no BeO has accumulated on the droplet surface indicating that BeO is being destroyed or removed at least as fast as it is being formed. The JANAF data indicate that this should occur only at temperatures $\geq$ 4500°K, and yet the physical condition of the quenched particles shown in the figures leads to the conclusion that the droplet temperature was somewhere between 1600° and 2800°K (between melting points of metal and oxide). Lack of oxide accumulation on the droplet as shown in Fig. 2 is difficult to reconcile with the reaction in Eq. [1] where only one BeO molecule is transpired by each water molecule. In view of the observed rate of oxide removal and the probable droplet temperature, it would appear that higher gaseous hydrates than the monomer are involved in the oxide transport processes during combustion of beryllium droplets in wet gases.

In reporting on a study of beryllium particle combustion in a flat-flame burner, Maček and Semple (6) report that addition of $\sim$ 1% water to their flame gases resulted in an increase of burning time of about 30%. The presence of water also resulted in lower droplet temperatures and narrower particle tracks than when burning in dry gases. Maček and Semple suggest that, despite the significant change in burning rate, only a slightly modified vapor phase diffusion model is adequate to describe the combustion. They leave open the cause of the flame zone contraction but suggest that it may be due to reduced vapor pressure of beryllium caused by an exceptionally heavy preignition deposit of oxide in the presence of water which persists during combustion. The quenched beryllium particles shown in Fig. 2 and 3 demonstrate that such is not the case. [For a more extensive discussion of this matter, *see* Ref. (7).]

Narrower particle tracks (relative to dry gases) and lower color temperatures are characteristic of flash-ignited beryllium droplets burning in wet gases. The reaction in Eq. [1] is endothermic by 42 kcal/mole and thus it or a similar reaction of the form

$$nBeO_{(c)} + H_2O_{(g)} \rightleftharpoons (BeO)_n \cdot H_2O_{(g)} \qquad [2]$$

should be a significant energy sink during droplet combustion in the presence of water vapor. Thus the oxide transport process is seen to have an effect on the flame temperature, flame radius, droplet geometry, burning rate, and burning mechanism.

Epitaxial Growth of $GaAs_xP_{1-x}$ from the Liquid Phase

K. K. Shih*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York

$GaAs_xP_{1-x}$ is a useful material because it emits visible light efficiently from p-n junctions (1). $GaAs_xP_{1-x}$ has been prepared in various ways such as by vapor transport in both closed-tube (2) and open-tube (3, 4) systems, and by horizontal Bridgman (5) and solution growth (6) methods. For a number of materials, the liquid phase epitaxial method of growth has produced grown-in p-n junctions of superior quality; for example, as evidenced by the improved luminescent properties in the case of GaAs (7), GaP (8), and $Ga_xAl_{1-x}As$ (9). In the present work, the liquid phase epitaxial method has been employed to grow single crystals in p-n junctions of $GaAs_xP_{1-x}$ on GaP single-crystal substrates. The growth parameters and some luminescent properties of the junctions are described.

The vertical growth method described by Rupprecht *et al.* (9) was employed. This method permits the

* Electrochemical Society Active Member.

formation of both sides of a p-n junction in a single cooling cycle. An alumina crucible charged with Ga, GaAs, and GaP was contained in a vertical quartz tube. For n-type growths, the donor dopant, Te, was added; the acceptor, Zn, was added for p-type growths. The epitaxial layers were deposited mostly on B($\bar{1}\bar{1}\bar{1}$) oriented GaP substrates supported on a graphite holder. GaP single-crystal substrates were grown by the solution growth method (10) and zone-bomb method (11). GaAs substrates have been tried but they dissolved in the melt which contains Ga, GaAs, and GaP during the growth process. High-purity forming gas was passed through the system prior to and during the overgrowth cycle. The layers deposited during cooling from 955° to 860°C.

The composition of the deposited layers was adjusted by varying the proportions of GaAs and GaP added to the melt. In order to form built-in p-n junctions, the first layer, an n-type layer about 2 mils thick, was deposited on an n-type substrate with carrier concentration about 10^{17} cm^{-3} by cooling from 955° to 900°C. Then the melt was counterdoped, with sufficient acceptor dopant to overcompensate the previous dopant, and cooling was continued to 860°C to produce a p-layer about 2 mils thick, then the substrate with deposit was lifted from the melt. It was found that the best results were obtained when the melt which contained Ga and different amounts of dissolved GaAs was "saturated" with GaP, depending on the desired composition, with none or a slight excess floating on the melt. It is recognized that this is not a true equilibrium since the melts are not stable in the presence of either of these pure components. This situation is generally encountered in liquid epitaxy experiments and pseudo-equilibrium appears to be achieved when the remaining undissolved solid becomes coated with a layer of the mixed compound, thus preventing further dissolution.

In order to establish the conditions for this pseudo-equilibrium, the take-up of GaP by melts containing various amounts of dissolved GaAs was measured. The experiment was similar to that reported by Hall (12) and the amount dissolved was determined by weight loss. The results at 945° and 955°C are shown in Fig. 1.

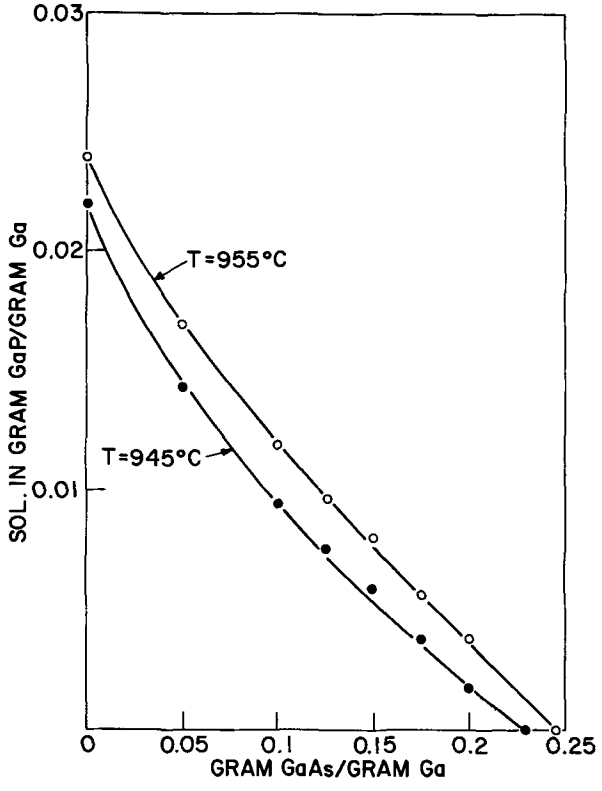

Fig. 1. Solubility of GaP in Ga-GaAs melt at 945° and 955°C

The information in Fig. 1 is helpful for determining the amount of GaAs and GaP which should be used in order to grow good GaAs$_x$P$_{1-x}$ p-n junctions.

The deposits had smooth surfaces when grown on either side of the (111) oriented GaP substrates, but material grown on the B($\bar{1}\bar{1}\bar{1}$) surface looks a little better. A terraced or sometimes coarse granular surface resulted if the substrate was off more than 1° from the (111) orientation. Microscopic examination of delineated p-n junctions revealed them to be quite planar, as shown in Fig. 2. By inspecting the color change of the crystal, it seems that the content of GaAs in the ternary alloy increased gradually along the direction of growth.

For the fabrication of electroluminescent diodes, the substrate side of the wafer was thinned to reduce series resistance, then Au-Sn and In-Zn alloy dots were applied to the n and p sides, respectively, of a small cleaved section in an atmosphere of flowing forming gas. The emission spectra were measured with a Bausch-Lomb monochromator. The quantum efficiency was measured with an integrating sphere type of apparatus, using Si photodiodes as detectors.

The electrical and optical properties of a large number of diodes were studied. No GaP-Ga(As, P) heterojunction was observed. The current-voltage characteristics of all diodes had the same general characteristics. The current varied as a function of voltage according to the equation $I = I_0\ (eV/\beta\ kT)$. In the linear region from $I = 10^{-4}$ mA to 5 mA at 300°K, $\beta = 2$ indicating that recombination is in the space-charge region (13).

The diodes emit light from the visible to the infrared range of the spectrum, with the peak energy depending on the composition of the melt from which the epitaxial layers were grown. For example, when 2g GaAs and 0.21g GaP were added to a 20g Ga melt, the resulting diodes emitted light with a peak at about 6800Å with about 70 meV width at 300°K as shown in Fig. 3.

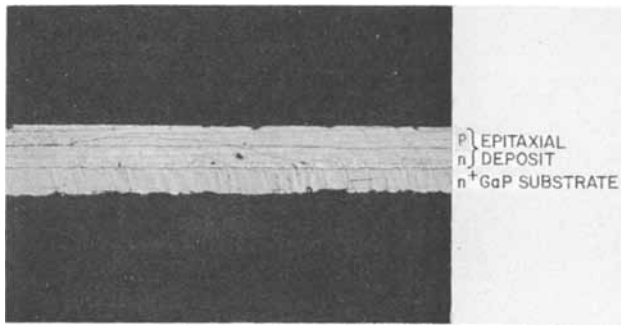

Fig. 2. Typical cross section of a GaAs$_x$P$_{1-x}$ p-n junction structure grown in GaP substrate cleaved and chemically stained to reveal the individual regions.

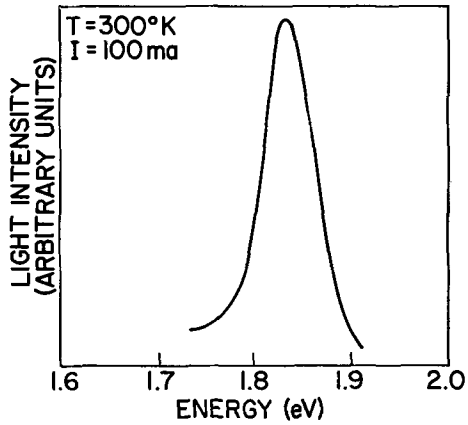

Fig. 3. Spectral distribution of the electroluminescence in GaAs$_x$P$_{1-x}$ diodes.

Because of the narrow width of this emission, it is identified as a band-to-band transition. An external quantum efficiency of about 5 x 10^{-4} at 6800Å at room temperature was measured. This increased by more than a factor of 10 at 77°K. The efficiency may improve by optimizing the doping profile.

Brief Communications

Oxidation Studies on Iron Using the Mössbauer Effect

D. A. Channing and M. J. Graham[1]

Central Electricity Generating Board, Berkeley Nuclear Laboratories, Berkeley, Gloucestershire, United Kingdom

This communication indicates the potential of Mössbauer spectroscopy for quantitative study of high-temperature oxidation processes on iron. In particular, we describe experiments concerning the formation at 500°C of the duplex scale Fe_3O_4 and α-Fe_2O_3.

Johnson-Matthey iron foils of purity 99.9 + % and thickness 9.5 μm were used. Oxidation was performed in one atmosphere of high purity oxygen (B.O.C. grade X). Mössbauer absorption measurements were made on the starting foils and after specified oxidation periods. The spectrometer, a "constant acceleration" instrument, employed a Co^{57}/Pd single-line source and a NaI (Tl) scintillation detector. All spectra were determined with both source and absorber at room temperature using a fixed counting arrangement. Background radiation was essentially unchanged between measurements and $\simeq$ 20% of the recorded counts.

By reference to standard spectra of Fe^{57} in Fe_3O_4 and α-Fe_2O_3, the presence of the two oxides in the scale is immediately established from the measured spectrum. The relative quantities of the oxides, and of unused metal, are obtained from the respective intensities of absorption. Taking n_i as the areal density of Fe^{57} (atoms · mm^{-2}) in the i^{th} component, we may write (1)

$$n_i = kA_i/f_i$$

where A_i is the corresponding total absorption area corrected (upwards) for "saturation effects," f_i is the recoil-free fraction, and k is a constant. The f_i factors are not expected to differ greatly, and our experiments confirm this. Saturation corrections range up to $\simeq$ 15% and may be estimated from tables (2). Thus, roughly, the relative number of resonant atoms in the three components is simply the ratio of observed absorption intensities.

Measurements are presented in Fig. 1-3. Included are the line positions, indexed 1, 2, 3, ..., of the individual components. The spectra for iron and α-Fe_2O_3 are single Zeeman patterns of six lines [ref. (3) and (4, 5), respectively]. For Fe_3O_4, the spectrum comprises two superposed Zeeman patterns which are incompletely resolved (6-8). The first has lines at 1, 3, 5, 7, 9, and 10, the second at 2, 4, 6, 8, 9, and 10.

Figure 1 shows the simultaneous growth of the two phases. The spectra are for a foil oxidized for successive periods up to a total of $\simeq$ 31 hr, by which time most of the metal is consumed. The course of oxidation is best followed by lines α-Fe_2O_3 1, Fe_3O_4 1 and 2, and Fe 1. At all stages, Fe_3O_4 is the major oxide. With continued oxidation, the source of metal is exhausted and the flow of iron to the reaction zone stops. The oxidation of Fe_3O_4 to α-Fe_2O_3 can then be directly investigated and results are displayed in Fig. 2. No metal is detected at $\simeq$ 77 hr, and at $\simeq$ 395 hr the conversion to α-Fe_2O_3 is almost complete. Analogously, if the oxygen supply is cut off once a scale has formed, the reduction by iron of α-Fe_2O_3 to Fe_3O_4 can be directly studied. Thus, in Fig. 3, spectrum (a) was obtained for a foil oxidized 18 hr, and spectrum (b) after a subsequent 1 hr vacuum anneal ($< 10^{-5}$ Torr). Referring to lines α-Fe_2O_3 1 or 6, a marked decrease in α-Fe_2O_3 is clearly evident after the anneal.

Spectral areas are determined as follows. First, we assume that the relative line intensities within each Zeeman pattern remain unaltered throughout the ex-

[1] Present address: Division of Chemistry, National Research Council, Ottawa, Ont., Canada.

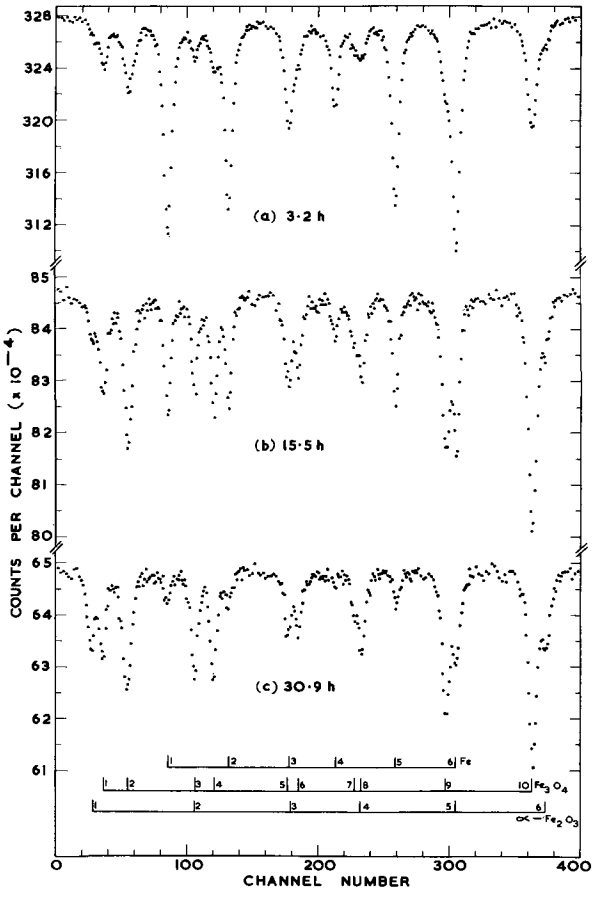

Fig. 1. Mössbauer spectra of a 9.5 μm iron foil heated in 1 atm of oxygen at 500°C for the times specified. Background radiation is not subtracted.

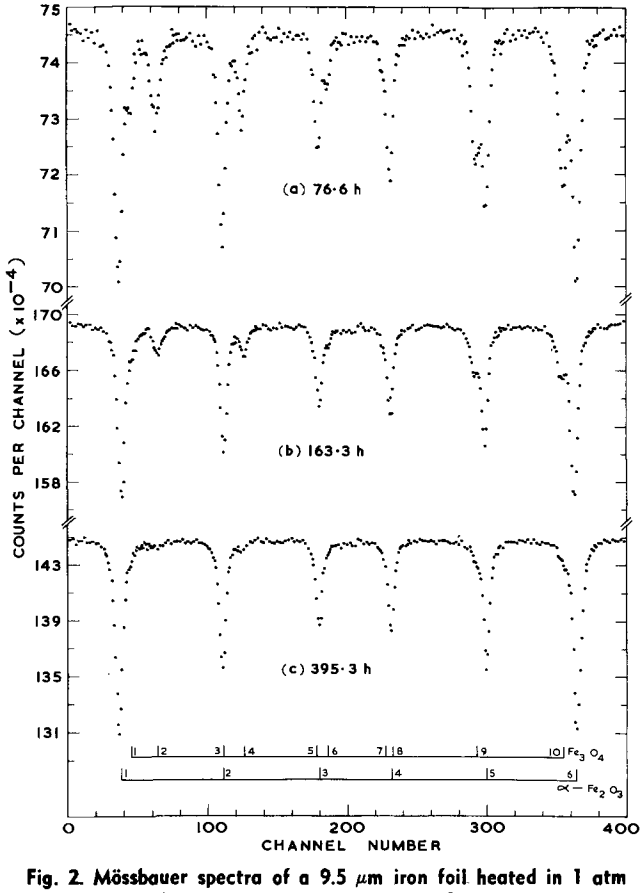

Fig. 2. Mössbauer spectra of a 9.5 μm iron foil heated in 1 atm of oxygen at 500°C for the times specified. (Continued oxidation of the foil used in Fig. 1.) Background radiation is not subtracted.

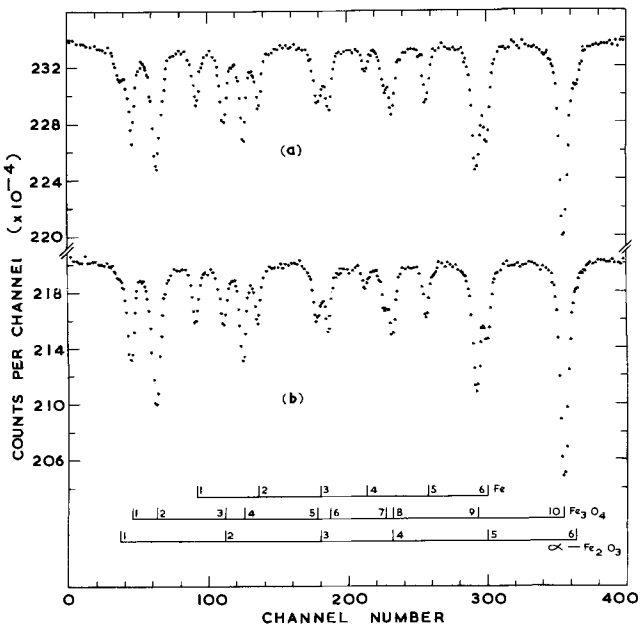

Fig. 3. Mössbauer spectra (a) for a 9.5 μm iron foil heated in 1 atm of oxygen at 500°C for 18 hr, and (b) after a subsequent 1 hr vacuum anneal (also at 500°C). Background radiation is not subtracted.

periments. This appears to be a reasonable assumption. [Significant variations are expected only if major changes in magnetization occur (3). Saturation effects will introduce some variation, but this is small and would not easily be detected.] Having established these ratios, the total absorption areas are then derived by analyzing only the outer most intense lines, specifically Fe 1, Fe_3O_4 10, and α-Fe_2O_3 1 or 6. The ratios adopted (2.7 : 2.2 : 1.0 : 1.0 : 2.2 : 2.7 for iron, 2.7 : 1.5 : 1.0 : 1.0 : 1.5 : 2.7 for both Fe_3O_4 and α-Fe_2O_3) are based upon detailed analysis of the two initial metal spectra, spectrum (c) of Fig. 2 which shows virtually only α-Fe_2O_3, and spectrum (b) of Fig. 3 showing predominantly Fe_3O_4 but also metal. These same four spectra are also used for checking the variation of f_i factors. Thus, noting that the total number of Fe^{57} atoms in a given foil is constant, equations of the type

$$\Sigma_i (A_i/f_i) = A_o/f_{Fe}$$

are solved, where A_o is the corrected starting metal absorption. We find $f_{Fe} : f_{Fe_3O_4} : f_{\alpha\text{-}Fe_2O_3} = 1 : 1.15$ ($\pm$0.15) : 1.20 ($\pm$0.12). Visual curve fitting is employed throughout the analysis, and the absorption of a line is taken as depth times half-width.

More detailed experiments on growing iron oxide films, at temperatures 400°-550°C, are in progress. Our main aim is to provide data for the diffusion of iron ions through Fe_3O_4 and of oxygen ions through α-Fe_2O_3. In preliminary experiments at 700°C, three phase scales of FeO, Fe_3O_4, and α-Fe_2O_3 have been observed and analyzed.

Anodic Oxidation of InSb in Nonaqueous Electrolytes

L. C. Brennan*[1] and N. J. Gri[2]

Avco Laboratories, Cincinnati, Ohio

The anodic oxidation of InSb in aqueous electrolytes has been extensively investigated by Dewald (1). This system was chosen by Dewald because InSb has the zinc blende structure which does not have a center of inversion and thus anodization rates on (111A) and (111B) faces are different. During work carried out at Avco Laboratories, it was found that, at current densities greater than 1 mA/cm^2, anodic oxidation was limited to a film thickness of ~1200Å when the anodization was carried out in an aqueous electrolyte. If anodization was continued to higher voltages, the anodic film began to break down and a black oxidation product was formed. In an attempt to grow thicker films at higher current densities, the anodic oxidation of InSb in nonaqueous or largely nonaqueous electrolytes has been investigated. This report constitutes the initial results of this investigation.

Some of the solutions investigated were: (*a*) n-methylacetamide/KOH, (*b*) tetra-hydro-furfuryl alcohol/KOH, and (*c*) ethylene glycol/sodium tetraborate/H_2O (90% ethylene glycol, 5% $Na_2B_4O_7$. $10H_2O$, 5% H_2O).

The InSb used was supplied by Cominco American Incorporated and was n-type, tellurium doped with a carrier concentration of 1 x 10^{15} at 77°K.

The slices were approximately 1 in. in diameter by 25 mils thick cut parallel to the (111) plane. The B surface was lapped and the A surface was polished to a smooth surface using 3/10μ alumina. Just prior to anodization, the wafers were etched in a 10% solution of HNO_3 in lactic acid for 5 min.

It was found that for all the electrolytes studied, at current densities greater than 1 mA/cm^2, anodization could be carried out to much greater thicknesses than is the case for aqueous electrolytes. For example, at current densities of 1.5 mA/cm^2, it was found that breakdown of the anodized layer occurred at ~1200Å, whereas, for the same current density, breakdown of the anodized layer did not occur up to 5000Å when the films were formed in a solution of sodium pentaborate in ethylene glycol (Soln. C). A possible explanation of the fact that anodization can be carried out to greater thicknesses in nonaqueous electrolytes could be that in nonaqueous electrolytes an outer porous film is formed on an inner compact layer as is the case for the anodization of aluminum. To check this possibility, the nature of the surface was examined using surface replica electron microscopy. The surface replicas were prepared by the colloidal stripping method. Several areas of the sample had a surface structure consisting of a high density of hillocks. However, at the magnifications used (16, 500, X) no evidence of porosity was obtained. No patterns were obtained when this material was examined by electron diffraction indicating that the material is amorphous.

Electrical measurements were taken on the anodized InSb surface using the metal-oxide-semiconductor (MOS) method (2). MOS test units were made by evaporating chromium over the oxide and alloying indium to the back for an ohmic contact. Some of the evaporated surface electrodes were kept less than 100Å thick to allow testing for light-induced surface potential shifts which have been observed (3-5) in thin anodic oxides formed in aqueous electrolytes.

The capacitance-voltage characteristics were obtained at 77°K using a capacitance bridge operating at 1 MHz. A positive interface charge Q_{ss} was observed on all samples. Measured values of Q_{ss}/q were 1-8 x 10^{11} cm^{-2}, showing similarity to those reported by Chang and Howard (6) for thin anodic oxides formed in aqueous electrolytes.

A significant difference has been observed in that light-induced surface potential shifts did not occur in the thick oxides formed in nonaqueous electrolytes. This observation was made in all cases where the MOS samples were strongly illuminated with zero, positive, or negative voltages applied to the surface electrode, in contrast to reported (3-5) surface potential shifts under the same conditions for thin oxides. These results indicate that photon absorption and charge buildup occur within the oxide and not at the semiconductor interface.

Passivation Phenomena and Potentiostatic Corrosion in Molten Alkali Metal Carbonates

H. J. Davis* and D. R. Kinnibrugh

Research Laboratories, Ferranti-Packard Limited, Toronto, Ontario, Canada

ABSTRACT

Potentiostatic corrosion rates of certain metals and alloys in molten carbonates at 680°C have been studied under both partially and fully immersed conditions using a variety of gas atmospheres above the melt. Measurements were made within the range 0.00 to −1.00V *vs.* Au/(O_2 − CO_2) 1:2 reference electrode. Of particular interest was the resistance to corrosion of ferroaluminum-type alloys. These materials have been successfully tested in working molten carbonate fuel cells under conditions where contact between the corrosive electrolyte and a supporting member is unavoidable.

The purpose of this investigation was to determine the suitability of certain metals for structural parts of molten carbonate fuel cell assemblies. In the past, the only materials exhibiting sufficient long-term resistance to the melt have been those based on high-temperature sintered oxides, namely alumina and magnesia. However, these materials are fragile and show poor resistance to thermal shock. From the mechanical point of view, metals would offer many advantages. Up to the present time, most metals have exhibited high corrosion rates when exposed to molten carbonates. Janz and co-workers (1-3) have investigated certain materials for corrosion resistance including the noble metals and some of their alloys and, in addition, nickel, 304 and 347 stainless steels, and silver. The noble metals exhibit a varying amount of resistance to the melt, but are not suitable from the cost point of view. Nickel and, to a lesser extent, 304 and 347 stainless steels are corroded by molten alkali metal carbonates, but some degree of passivation was observed in our measurements. The degree of protection afforded, however, has proved to be insufficient to warrant their use for structural components of molten carbonate fuel cells. Nevertheless, the fact that passivation was observed led us to suspect that other materials were well worth investigating in this respect, especially as certain metal oxides (*e.g.*, alumina) are very resistant to molten carbonates. For this reason, we included some commercial ferroaluminum alloys in our study.

Experimental

The standard technique for obtaining potentiostatic corrosion current densities for metals was adopted. The potentiostat used was a Wenking Model 6622 TRH, and the potential scan was generated by a Wenking motor potentiometer, MP 0.64. The current was recorded by monitoring the voltage drop across a standard resistor by means of either an X-Y recorder (Mosely Model No. 7000 A), or a digital voltmeter. Some details of the electrochemical cell used for these studies are shown in Fig. 1. The reference electrode was of the type described by Borucka (4). The counterelectrode consisted of gold foil spot-welded to gold wire. The crucible containing the melt, the gas pipes, and the various parts of the reference electrode were all of high-purity sintered alumina. The gas atmosphere over the melt could be controlled. The reference electrode was fed continuously with a gas mixture consisting of 67 m/o carbon dioxide and 33 m/o oxygen. The reference electrode assembly was connected to the bulk of the electrolyte by an electrolyte film on the concen-

Key words: molten carbonate fuel cells, corrosion.

tric alumina separating crucible, C. This was done to avoid the possibility of contamination of the electrolyte in the reference electrode compartment by corrosion products from the test sample. The cell assembly was so arranged that only gold, recrystallized pure alumina, and the test sample were in contact with the melt. This consisted of a binary eutectic mixture of analytical-grade sodium and lithium carbonates. The test sample took various forms which ranged from 0.06 in. diameter wire to strip cut from rolled sheet. The area of immersion of the samples was of the order of 1 cm^2. The samples were cleaned with abrasive paper no finer than 400 grit. No attempt was made to obtain a high degree of finish on the test samples, as the main object was to establish their suitability for structural components of molten carbonate fuel cells.

Table I shows the composition of certain of the metals investigated. These alloys are based on either iron or nickel, with their high-temperature oxidation controlled by formation of chromium or aluminum oxides. The samples were first investigated while completely submerged in the melt. The material under test was spot-welded to 0.01 in. diameter gold wire and the sample was completely immersed such that the meniscus was in contact with the gold wire. In this case, the atmosphere above the melt was continuously swept with a mixture of dry air containing 1% carbon dioxide.

Further measurements were made with corrosion samples only partially submerged in the melt. Under these conditions, the observed currents were strongly dependent on the nature of the gas atmosphere above the melt and reproducible measurements were obtained for oxidizing, neutral, and reducing atmospheres.

Results and Discussion

Measurements with fully submerged samples.—Some of the results obtained under these conditions are seen in Fig. 2. The scan rate was approximately 60 mV/hr. This is a realistic compromise since the traverse should actually be carried out infinitely slowly. The curves were quite reproducible and for the resistant alloys were unaffected by the position on the potential scale from which the scan was started, provided that a short period (typically ¼ hr) was allowed for equilibration. The curves were also unaffected by the direction of scan. The apparent high degree of reversibility at these scan rates can be attributed to the fact that the number of coulombs associated with the formation of a protective oxide film becomes small compared with the product of the background current and time. At high sweep rates (10-150 V/hr), hysteresis was expected and observed. Departure from ideality was considered to be small for sweep rates of 60 mV/hr. The scale of Fig. 2 was chosen to show a direct comparison with the passivation phenomena observed for 347 stainless steel. Nickel is included as a guide to the extent of corrosion which can be observed. It is apparent that certain of the alloys exhibit superior corrosion resistance when compared with either 347 stainless steel or nickel. The exact nature of the surface species restricting corrosion of the samples was not determined, although for the Kanthal and Hoskins alloys it is quite probable that this is an alumina film or reaction products of alumina with the melt, *e.g.*, lithium aluminate.

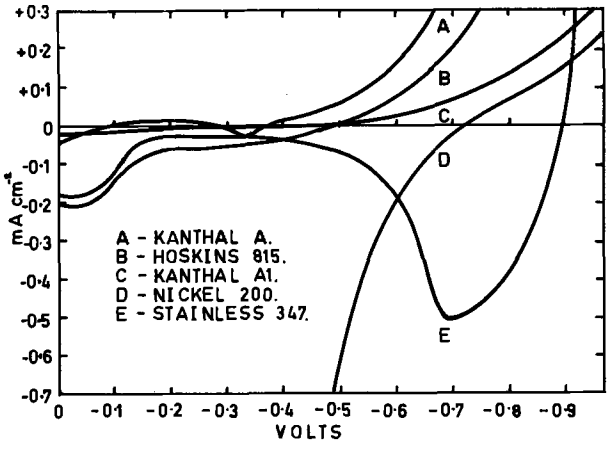

Fig. 2. Potentiostatic polarization curves for fully submerged samples, binary sodium, lithium carbonate eutectic, 680°C.

The open-circuit potential of fully submerged Kanthal A-1 in a binary sodium and lithium carbonate eutectic at 680°C with respect to the gold/oxygen plus carbon dioxide (1:2) reference electrode was also investigated. The voltage between the sample and the reference electrode fell quite rapidly initially and continued to decrease for approximately 6 hr at which time a final potential of approximately —71 mV for the Kanthal A-1 was obtained. This is close to the meniscus potential which might be expected for the gold supporting wire with the particular gas atmosphere present above the melt and suggests complete passivation of the Kanthal. The sample remained mirror-bright after 40 hr of exposure.

In Fig. 3, the alloy Kanthal A is shown. A number of 0.01 in. diameter wires were embedded in a paste mixture of molten carbonate and an inert filler, and heated at 700°C for more than 1000 hr. The wires were not connected to an external circuit, no polarization being applied. This represents a practical utilization of corrosion resistant metals in molten carbonate fuel cells in that the wires were used to reinforce the paste electrolyte and improve its resistance to mechanical and thermal shock prior to melting. It is apparent that the depth of corrosion is hardly significant and, in fact, this wire could not be distinguished from a sample which had not been exposed to the melt.

Based on the assumption that the corrosion rate of totally immersed samples is directly measured by the current density observed, the data in Table II were obtained. The rate of attack was predicted by assuming

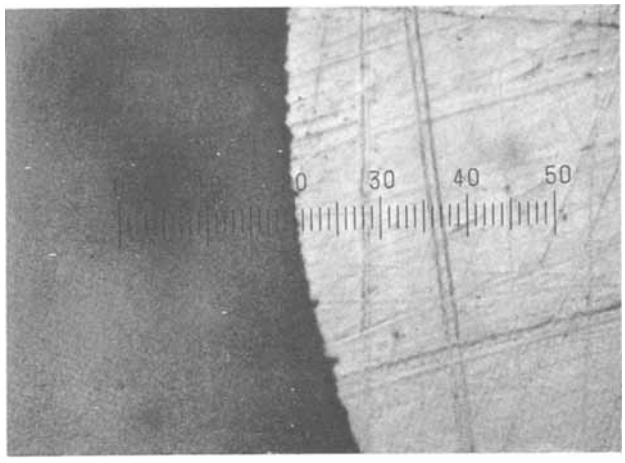

Fig. 3. Cross section of 0.010 in. diameter Kanthal A wire after 1000 hr in 53% lithium aluminate plus ternary sodium, lithium, potassium carbonate eutectic paste at 700°C (1 div = 2×10^{-5} in.).

that the observed current was entirely due to the conversion of iron to the ferrous state. The corrosion rates at two potentials representing approximately the working potentials of the anode and the cathode are given. It is seen that Kanthal A and A1 and some of the other alloys are superior to 347 stainless steel. For samples with low corrosion currents (*e.g.*, Kanthal), the current due to corrosion of the alloy becomes comparable to the current due to the gas reaction.

$$2e + CO_2 + \tfrac{1}{2} O_2 \rightleftharpoons CO_3^{2-}$$

occurring at the meniscus of the 0.01 in. diameter gold supporting wire and actual corrosion rates cannot be estimated with any degree of accuracy. It seems probable, however, that fully submerged Kanthals can have an even lower corrosion rate than those indicated in Table II, since samples which had been exposed under open-circuit conditions at the rest potential remained untarnished for long periods.

Measurements with partially submerged samples.— The highly satisfactory results obtained with certain alloys in the completely submerged condition led to the investigation of their performance in situations more closely akin to those found in some structural components of molten carbonate fuel cells. Under these conditions, they could be in contact both with electrolyte and gaseous phases. The potentiostatic corrosion curves were therefore obtained for samples which were only partially submerged, the unsubmerged portions being exposed to various gas atmospheres. The atmospheres used were either oxidizing (*e.g.*, oxygen/carbon dioxide mixtures), inert (either nitrogen or helium), or reducing (carbon dioxide, nitrogen, hydrogen mixtures), and always contained at least 1% carbon dioxide to limit decomposition of the melt. The total pressure of the gas atmosphere was maintained fractionally greater than the atmospheric pressure.

Table II. Estimated corrosion rates (mm/yr) for fully submerged materials at the electrode working potentials. (Binary sodium, lithium carbonate eutectic, 680°C.)

Metal/alloy	− 850 M. V.	− 100 M. V.
Kanthal A	0	0.02
Kanthal A1	0	0.16
Hoskins 815	0	0.60
347 Stainless	2.2	1.30
Nikrothal 80	0	3.6
310 Stainless	1.5	4.2
321 Stainless	6.9	7.6
Duranickel 301	0	8.0
Nickel 200	0	29.4
Iron	105.0	525.0

The results were plotted in two ways, either by considering the same metal in differing atmospheres or different metals in one atmosphere. The currents for these measurements on partially submerged samples were plotted as a function of the meniscus length on the specimens (*e.g.*, μA cm^{-1}). This was done largely as a consequence of the observation that samples tended to show far greater corrosion currents in the meniscus or electrolyte film regions than in the fully submerged regions. Even this is an approximation, since the submerged part of the electrode will be carrying a small portion of the current.

Figure 4 shows the corrosion currents for alloys in a partially immersed condition, with a 50/50 mole ratio oxygen/carbon dioxide atmosphere. It will be noted that the alloys which previously showed resistance, namely the Kanthal A series and the Hoskins alloys, again show a high degree of resistance to the melt, and exhibit low corrosion currents compared with 347 stainless steel. Hoskins 875 is very similar in composition to Kanthal A1, as is Hoskins 815 to Kanthal A. It is apparent that the oxidizing atmosphere in this case does nothing to destroy any protective film which is likely to be formed on the samples.

In Fig. 5, the oxidizing atmosphere has been replaced by an inert one, namely nitrogen. Helium was investigated and gave results very nearly identical to those for nitrogen. The currents per unit meniscus length are somewhat higher and the positions of zero current have been moved to more negative potentials.

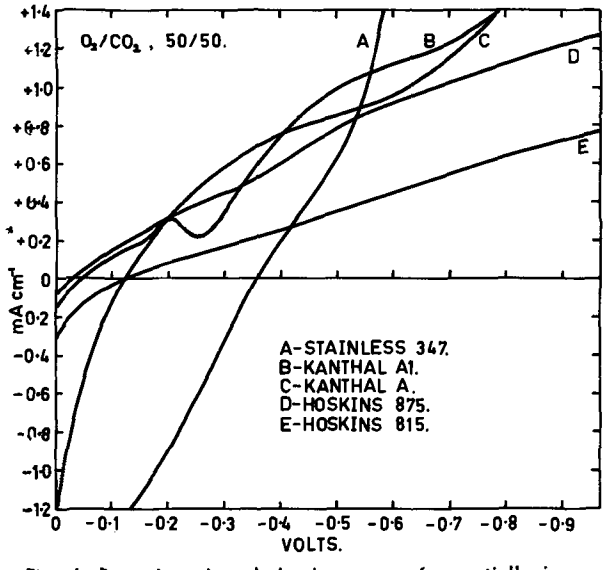

Fig. 4. Potentiostatic polarization curves for partially immersed samples, binary sodium, lithium carbonate eutectic, 680°C.

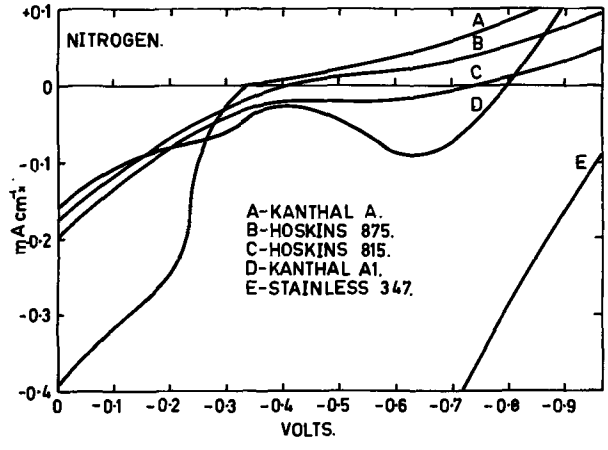

Fig. 5. Potentiostatic polarization curves for partially immersed samples, binary sodium, lithium carbonate eutectic, 680°C.

It is reasonable to assume that the currents at potentials more negative than −0.3V are largely due to formation of oxides and that only a small part of the current is due to the carbon dioxide/oxygen evolution reaction (*see* Fig. 8 and 9). Unfortunately, it is not possible from this experiment to determine the current efficiency of either of these reactions. It will be noted, however, that the position of 347 stainless steel under the same conditions is much inferior. Figure 6 shows the effect of a reducing atmosphere. In this case, all the alloys exhibit net anodic currents for most of the potential range investigated. One of the few conclusions that can be drawn is that appreciable anodic currents can be obtained from all the samples under reducing atmospheric conditions, and any insulating, protective film must therefore be destroyed by the presence of hydrogen at all the potentials of interest. It is not possible to determine what the corrosion rates would be in the potential range −700 to −1000 mV, where the anode is normally operated, since the electrode reaction

$$CO_3^{=} + H_2 \rightarrow CO_2 + H_2O + 2e^-$$

does not necessarily involve corrosion of the metal. However, the formation of steam at 680°C greatly increases the probability of direct chemical corrosion of the metal.

Comparison of the curves obtained for partially immersed samples with a reducing atmosphere, with those obtained for the completely submerged samples attached to 0.01 in. diameter gold wire leads shows that, in both cases, two competing reactions govern the observed corrosion potentials. These are: (*a*) the reactions involving the gas phase, principally in the meniscus region, and (*b*) the normal corrosion reactions occurring where the submerged surface contacts the electrolyte. When the gas phase reaction is limited to that occurring at the meniscus region on 0.01 in. diameter gold supporting wire (*i.e.*, total immersion of the sample), the corrosion reaction might be expected to predominate except in cases where passivation of the sample is almost complete.

For partially submerged samples, however, the gas phase reaction can be enhanced and its current capacity increased by the much greater meniscus length involved. Since in terms of current-carrying capability the electrode process involving the gas phase might now be expected to be much greater than that attributed to the immersed corrosion reactions, the potential moves toward that of the gas reaction

$$CO_3^{=} \rightleftharpoons CO_2 + \tfrac{1}{2}\,O_2 + 2e$$

which is also occurring at the reference electrode. This explains why certain materials, *e.g.*, 347 stainless steel in CO_2/O_2, appear more noble at their rest or corrosion potentials (partially immersed, zero external current) than they do when fully immersed in the melt, despite the fact that in the partially immersed mode they could be corroding by internal currents due to the difference in potential between the meniscus and immersed zones. Under these conditions, therefore, a more "noble" corrosion potential cannot necessarily be interpreted as a decrease in corrosion rate.

In the case of alloys which are protected from high-temperature oxidation by chromic oxide (Fig. 7), behavior, as might be expected (Table I), is somewhat similar to 347 stainless steel, the main difference for Hastelloy N being that the bulk of the material is now nickel. The material appears to corrode in an oxygen/carbon dioxide/nitrogen atmosphere and is comparable to stainless steels in this respect.

Measurements with the nickel-based alloys containing chromium indicated a tendency toward higher corrosion rates with decreasing chromium content. Nickel-based alloys containing aluminum (*e.g.*, Duranickel 301, Inconel 702) did not show the same degree of resistance as the iron-based alloys.

Figure 8 shows the effect of oxidizing and reducing atmospheres on partially submerged gold. The gold in this case appears to be acting as a reversible gas electrode and the potential shift corresponds closely to that which would be expected from the gas composition at the sample compared with the reference electrode. The curve for the atmosphere containing hydrogen is something of a measure of gold's ability to act as a hydrogen electrode, since the high currents for curve B can be attributed to the reaction

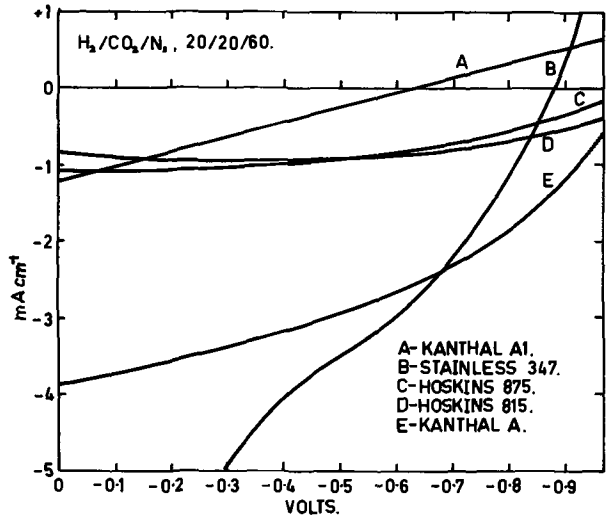

Fig. 6. Potentiostatic polarization curves for partially immersed samples, binary sodium, lithium carbonate eutectic, 680°C.

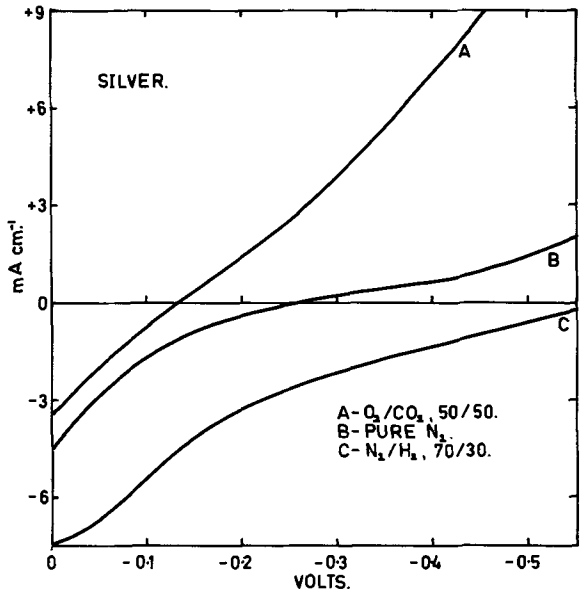

Fig. 9. Potentiostatic polarization curves for partially immersed silver wire (0.04 in. diameter; 0.75 in. immersed), binary sodium, lithium carbonate eutectic, 680°C.

$$H_2 + CO_3^{=} \rightarrow H_2O + CO_2 + 2e$$

The currents for silver (Fig. 9) are higher than might be expected, especially for the nitrogen atmosphere, where anodic currents are in excess of the predicted rate for carbon dioxide-oxygen evolution. The high value was subsequently found to be largely due to the formation of silver dendrites around the melt-atmosphere interface, which enormously increased the surface area of the silver at the three-phase boundary. Similar effects have been observed by Broers (5).

An experiment was carried out to determine the long-term resistance of Kanthal A1 to exposure to air, cathode gases, and other gases in the environment of a working molten carbonate fuel cell. Two disks of the metal were used as anode and cathode supporting members in the cell. The disks were both in contact with the electrolyte and with either anode or cathode and their respective fuel and oxidant gases. Creepage of electrolyte over both the inner and outer surfaces of the disks occurred immediately, but inspection after 1200 hr of operation indicated that the cathode disk was substantially unchanged. Corrosion of the anode disk was appreciable, but nevertheless far superior to any other non-noble metal or alloy so far used under these conditions.

In summary, corrosion of ferroaluminum alloys occurs most rapidly with a molten carbonate film in the presence of a reducing atmosphere, and is very much reduced in the presence of oxygen. The most favorable case appears to be the totally immersed open-circuit condition, where corrosion rates seem likely to be lower than for some noble metals, e.g. platinum.

Manuscript submitted April 24, 1969; revised manuscript received ca. Dec. 11, 1969. This was Paper 352 presented at the Montreal Meeting, Oct. 6-11, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

Preparation and Properties of Sputtered Hafnium and Anodic HfO_2 Films

M. T. Thomas[1]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Hafnium films sputtered at high voltages (4 kV) had a density of 98% of the bulk, specific resistivities as low as 50 μohm-cm and TCR as high as 1580 ppm/°C. Films with a density of 50% of that of the bulk, a specific resistivity of 815 μohm-cm, and TCR of 800 ppm/°C were obtained at the lower sputtering voltages (1.5 kV). High- and low-density films had Hall coefficients of -2×10^{-5} cm³/coulomb and $+12 \times 10^{-5}$ cm³/coulomb, respectively. All the sputtered films had the same hexagonal close-packed structure as the bulk material, although the high- and low-density films had different preferred orientation. The oxide density, anodization constant, and dielectric constant for hafnium oxide were found to be 7.9 g/cm³, 20 Å/V, and 18, respectively. The anodized hafnium oxide had a monoclinic polycrystalline structure with some preferred orientation, $(11\bar{1})$ or (001) plus $(10\bar{2})$. Test capacitors with anodic oxides formed to 100V at 1 mA/cm² had capacitance density values of 0.085 μf/cm², dissipation factors below 0.01 at 1 kHz, and a frequency dependence of capacitance of ±1% in the range of 0.1-100 kHz relative to the 1 kHz value. Temperature coefficient of capacitance values varied from 300 to 600 ppm/°C.

Sputtered and reactively sputtered tantalum films have been investigated in considerable detail with respect to their electrical, structural, and anodization properties. A reliable thin film passive component technology, suitable for integrated circuits, has been developed as an outgrowth of these studies (1). Recent studies on diode sputtered hafnium films showed that capacitors formed from these films by anodic oxidation had interesting properties (2-5).

The purpose of this paper is to present some experimental data on the electrical, structural, and anodization properties of hafnium films. In particular, the

[1] Present address: Washington State University, Department of Physics, Pullman, Washington.

density, resistivity, temperature coefficient of resistance, and the Hall coefficient of these films were studied for different sputtering voltages and sputtering current densities. The structure of these films was determined using reflection x-ray and electron microscope techniques.

The anodization characteristics in various electrolytes using both the constant current and constant voltage methods for anodization were also investigated. Hafnium-anodic hafnium dioxide-gold structures were used to measure the capacitance, temperature coefficient of capacitance, and frequency dependence of capacitance. From all of these measurements, it was possible to determine the hafnium dioxide density, anodization constant, and dielectric constant of anodic hafnium dioxide.

Experimental Procedure

The sputtering experiments were conducted in a CVC 18 in. metal bell jar system which was capable of reaching an ultimate pressure in the low 10^{-6} Torr range. This system consisted of a 15 CFM mechanical fore pump backing a 6 in. diffusion pump (untrapped pumping speed of 1520 liters/sec for air) which was isolated from the experimental chamber by a liquid nitrogen cold trap and a gate valve. The dynamic argon flow d-c sputtering technique was used for all experiments. The substrates could be heated to approximately 400°C and were covered by a shutter so the cathode could be cleaned by presputtering. A thermocouple imbedded in the substrate heater was used to monitor the temperature during all stages of the deposition procedure. Figure 1 shows the geometrical arrangement of the sputtering chamber. The cathode to substrate distance was fixed at 7.62 cm. As can be seen, both sides of the cathode were used to sputter hafnium films simultaneously. Before any films were deposited, the cathode was cleaned of any etching residues by a 3 hr presputter (6).

The cathode consisted of a square hafnium sheet 14.92 cm on a side and 0.145 cm thick, and was supplied by Wah Chang Corporation, Albany, Oregon. The chemical analysis supplied by the manufacturer indicated that the cathode contained 2.15% zirconium with the following other impurities (in ppm): C—90, O-180, Nb—<100, Fe—265, and Ta—<200. All the other impurities were less than 40 ppm. A number of hafnium-coated sapphire slides were analyzed using x-ray fluorescence to detect some of these impurities in the films themselves. No niobium or tantalum peaks were seen above the background signal, but iron and zirconium were detected on all samples tested. By comparing the x-ray fluorescence data obtained from the sputtered material to those taken on a bulk sample, it was found that the concentration of zirconium in the films (for both the 4 and 1 kV sputtered films) was the same as that of the bulk cathode. For zirconium in a hafnium matrix, therefore, there is approximately a one to one transferal of these low-concentration alloying atoms during the sputtering process. The presence of zirconium and iron in the films could be an important factor influencing the behavior of these hafnium films based on the results of metal alloying for thin-film tantalum oxide capacitors (7).

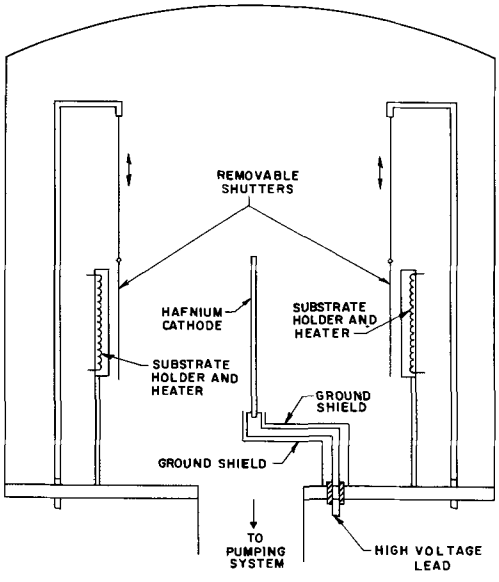

Fig. 1. Schematic of the sputtering chamber

Film Properties as a Function of Sputtering Parameters

The specific resistivity, temperature coefficient of resistance, the Hall coefficient, and the density of the hafnium films were studied as a function of sputtering voltage, sputtering current density, time of presputter, film thickness, and substrate temperature. Most of the films were deposited on 1 x 3 in. Corning alumino-borosilicate glass slides, although the thickness calibrations and the density measurements were performed on films deposited onto 1 in. square sapphire slides. In addition, the structure and topology of the films were examined with x-ray, reflection electron diffraction, electron-transmission, and replica techniques. For the electron transmission studies, very thin hafnium layers were sputtered onto mica, SiO films, and a carbon-coated molybdenum screen.

Hafnium films with electrical properties closest to that of the bulk were obtained with a sputtering voltage of 4000V and a sputtering current density of 0.112 mA/cm^2. These films had a shiny metallic appearance and ranged from 5000 to 6000Å thick (1 hr sputtering time, corresponding to a deposition rate of 80-100 Å/min). The specific resistivity of these films varied from 50 to 68 μohm-cm depending on the substrate temperature and ambient pressure of the system as compared to the bulk value of 35 μohm-cm. The lowest specific resistivities were obtained with the substrate at 400°C and the lowest background gas pressures in the chamber. As might be expected, there was no change in the electrical characteristics of the films resulting from a deposition of a few minutes to a few hours, nor were any changes seen upon varying the presputtering time from 15 min to 2 hr. For most experiments, a presputtering time of 30 min was chosen to insure that the system had reached dynamic equilibrium.

Figure 2 gives the deposition rate for hafnium in μg/(min-cm^2) and the density of the sputtered films in g/cm^3 as a function of sputtering voltage. A constant current density of 0.112 mA/cm^2 and a substrate temperature of 400°C were used for all of these measurements. Because of the large change of film density between the sputtering voltages of 2 and 3 kV, the

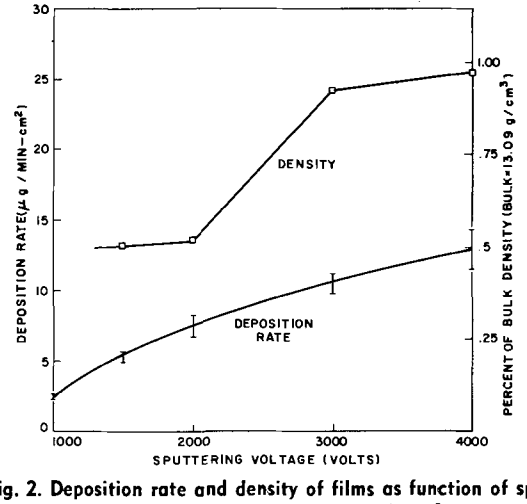

Fig. 2. Deposition rate and density of films as function of sputtering voltage (sputtering current density 0.112 mA/cm^2).

deposition rate is given in terms of the mass per unit area per unit time rather than in angstroms per unit time as is usually done. At 4 kV the density of the films was 12.8 g/cm^3 or about 97.7% of the bulk density, while at 1.5 kV the density dropped to 6.6 g/cm^3 or about one half that of the bulk density. Accompanying this change in density was a change in specific resistivity from about 53 μohm-cm at 4 kV to about 815 μohm-cm at 1.5 kV as shown in Fig. 3. It should be noted that similar changes in the film density and resistivity as a function of sputtering voltage have been reported previously with tantalum (8, 9). However, in contrast to low-density tantalum films, the resistivity of low-density hafnium films did not drift as a function of time after exposure to the atmosphere. This probably means there is not the same large uptake of oxygen by the hafnium films as there is by the tantalum films (8). Figure 3 shows the resistivity at room temperature and the TCR measured between room temperature and liquid nitrogen temperature as a function of the sputtering voltage. Qualitatively, the TCR varies in a manner that would be expected from the resistivity curve; *i.e.*, the TCR decreases when the resistivity increases, although the decrease is not as large as expected on the basis of an impurity scattering mechanism. The 4 kV films had a TCR of about 1580 ppm/°C, while those sputtered at 1 kV had a TCR of about 800 ppm/°C (the bulk TCR value is 4.4 x 10^3 ppm/°C at 20°C).

The low-density hafnium films were quite different in appearance from the high-density films. The former were black, nonmetallic looking, and quite transparent. Light could be seen through even the thickest films (approximately 10,000Å thick, sputtering time: 2 hr). The low-density films have a very porous quality as can be seen in Fig. 4(*a*) which is an electron micrograph taken of a carbon replica of 5000Å film sputtered at 1.5 kV on alumino-borosilicate glass. The films consist of many voids and interconnected islands. It is this very open structure with the many grain boundaries, comparable to low-density tantalum, that contributes to the high specific resistivity observed with these films. For comparison, Fig. 4(*b*) shows a carbon replica of a film sputtered at 4 kV and, as can be seen, these films are much more continuous and uniform. The appearance of the hafnium films is the same when viewed with transmission electron microscopy. For example, Fig. 5(*a*) and 5(*b*) show micrographs of films approximately 400Å thick deposited on SiO films at a voltage of 1.5 and 4 kV, respectively. The appearance of the films was independent of the substrates used for the electron microscope studies. Both the electron diffraction and x-ray diffraction studies show that both the high- and low-density films had the close-packed hexagonal structure which is the normal bulk material structure. The films deposited at 4 kV showed both (10.0) and (00.2) planes

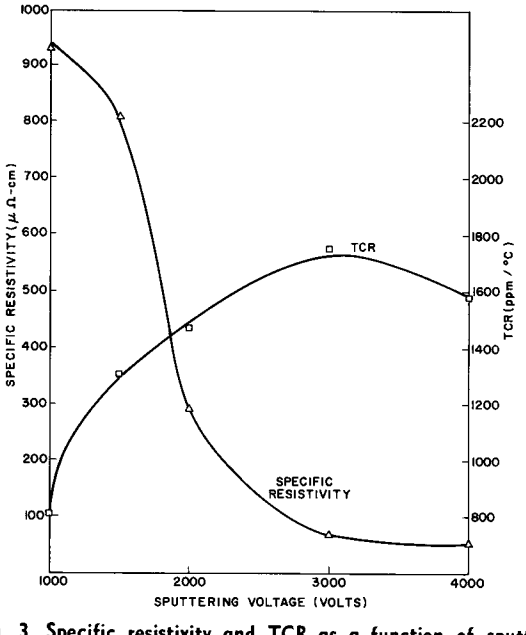

Fig. 3. Specific resistivity and TCR as a function of sputtering voltage (sputtering current density 0.112 mA/cm^2).

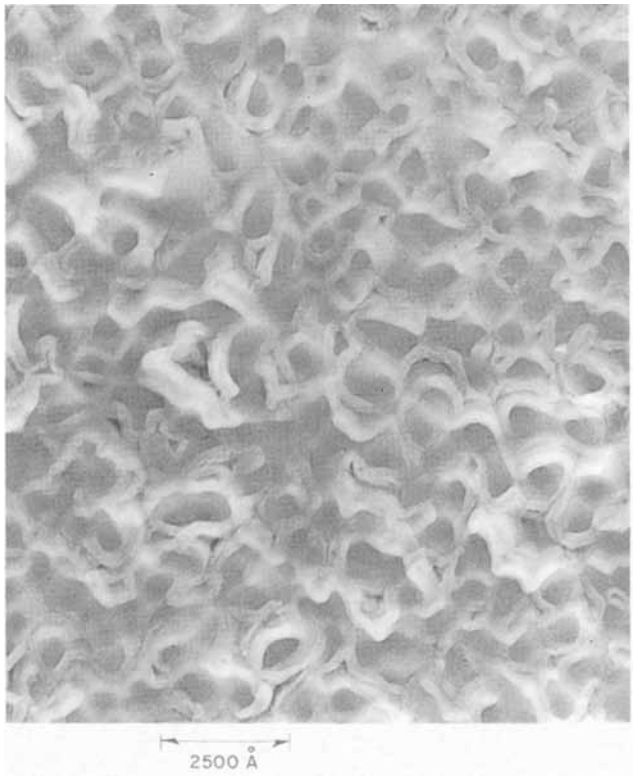

Fig. 4(*a*). Electron micrograph from a carbon replica of a low-density hafnium film, 5000Å thick deposited on a 7059 glass.

Fig. 4(*b*). Electron micrograph taken from a carbon replica of high-density hafnium film, 5000Å thick deposited on 7059 glass.

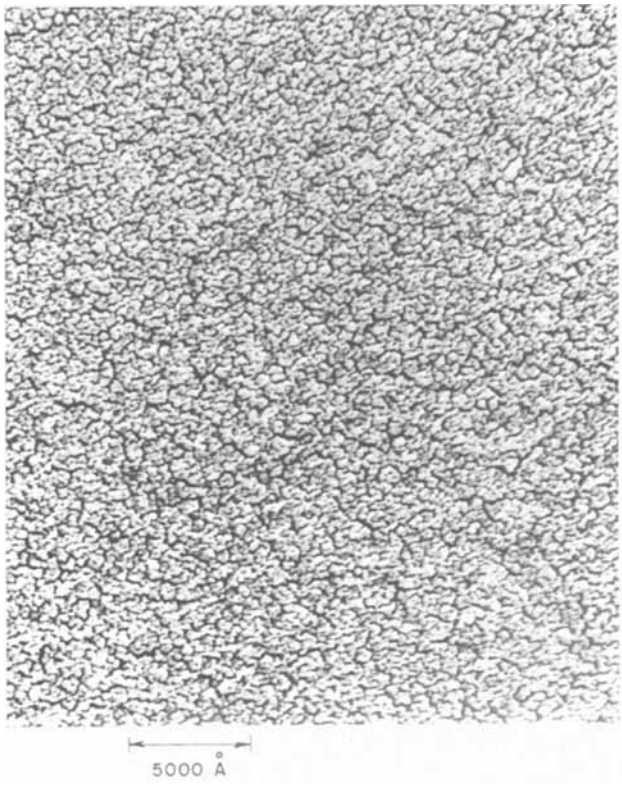

Fig. 5(a). Transmission electron micrograph of low-density hafnium film about 400Å thick deposited on SiO.

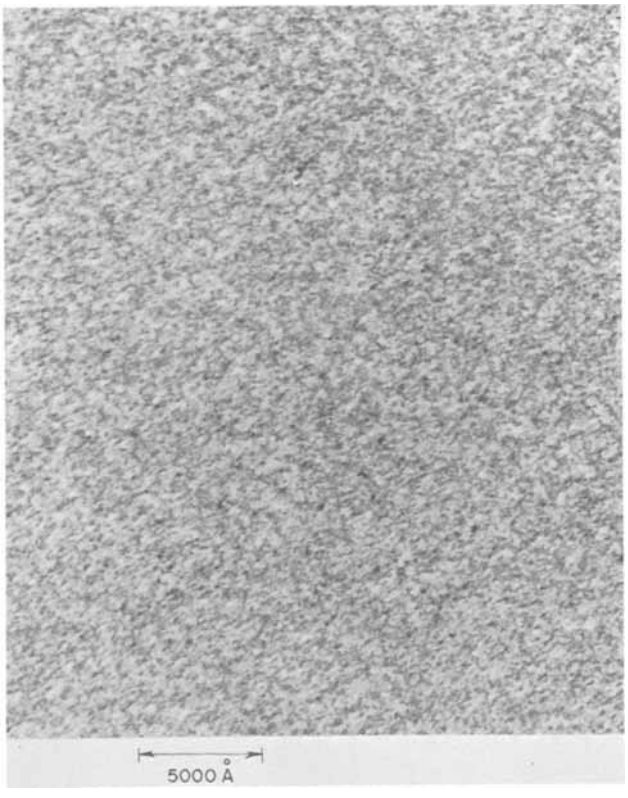

Fig. 5(b). Transmission electron micrograph of a high-density hafnium film about 400Å thick deposited on SiO.

preferentially parallel to the substrate surface, while the films deposited at 1.5 kV had the (10.0) planes about 40° to the substrate surface with no preferred orientation parallel to the substrate surface. At the higher current densities for the films deposited at 4 kV there appeared to be more (00.2) preferred orientation, and at times some (10.1) orientation was observed. Some preferred orientation was seen for films sputtered on cold as well as hot substrates. The crystallite size of both the high- and low-density films was about a few hundred angstroms.

Figures 6 and 7 show the variations of the deposition rate, density, resistivity, and TCR of films sputtered at 4.0 kV, but at various current densities. As would be expected, the deposition rate increases linearly with current density except for the higher currents where backscattering at pressures of the order of 40 x 10^{-3} Torr causes the deposition rate to drop off from the expected rate. There is no appreciable change in the density and only a slight increase in the specific resistivity of the films over the range of current densities investigated—from 0.112 to 0.672 mA/cm^2. The TCR, however, varies more than would be expected from the small change in resistivity, which means that Matthiessen's rule (10) does not apply. White and Woods (11) have reported a departure from Matthiessen's rule for bulk hafnium samples with varying amounts of zirconium. For divalent or multivalent metals which must be described by a two-band model, Matthiessen's rule is not necessarily expected to hold (12). Such materials may have complicated Fermi surfaces which could overlap more than one Brillouin zone and one might have to take into account interband scattering. This situation can vary as a function of crystal orientation for anisotropic materials (hafnium has a hexagonal close-packed structure). The resistivities of these materials are sensitive to changes in the amount and type of impurities present as well as on the orientation in the sample. Generally it is assumed that Matthiessen's rule may be applied to each band separately but not to the total conductivity. As is seen below, one may have to assume two types of carriers for hafnium. Although there was not a large

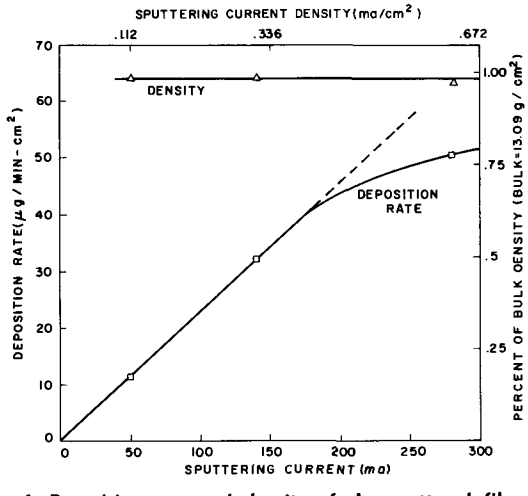

Fig. 6. Deposition rate and density of the sputtered films as a function of sputtering current (sputtering voltage 4000V).

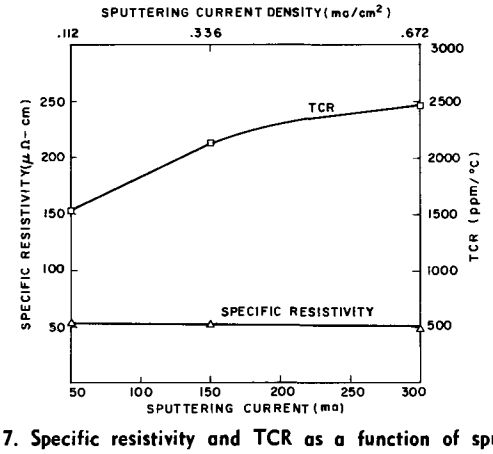

Fig. 7. Specific resistivity and TCR as a function of sputtering current (sputtering voltage 4000V).

change in resistivity with sputtering current, one would expect an additional impurity content in the films sputtered at the lower deposition rates. Also, as mentioned above, there was some effect in the preferred orientation of the film with increasing current density. The films seemed more strongly oriented as the current density increased, which, coupled with a variation in the impurity concentration, might contribute to the changes in TCR seen in Fig. 7.

Figure 8 shows the variation of the Hall coefficient, R, of the hafnium films as the sputtering voltage was varied with a constant sputtering current density of 0.112 mA/cm^2, and Fig. 9 shows the variation in the Hall coefficient for 4 kV sputtering voltage as the current density was varied. As can be seen, the Hall coefficient varied from -2×10^{-5} to $+12 \times 10^{-5}$ cm^3/coulomb as the voltage varied from 4 to 1 kV. Such a change in sign was an unexpected result and indicates that one must assume two types of carriers in hafnium; *i.e.*, both electrons and holes must be present. Vol'Kenshteyn and Galoshina (13) have reported a value of $+4.3 \times 10^{-5}$ cm^3/coulomb at room temperature with hafnium sample of 99.4% purity, the major impurity being 0.5% zirconium. However, they reported a change in sign of the Hall coefficient at 56°K, and at liquid helium temperature R had a value of about -2×10^{-5} cm^3/coulomb. To explain this variation of the Hall coefficient with temperature, Vol'Kenshteyn and Galoshina assumed a two-band model where the effective masses, mobilities, and carrier type differed in each band. In a tabulation of electrical properties of hafnium, Martin and Pizzolato (14) reported a value of the Hall coefficient of -0.16×10^{-5} cm^3/coulomb at room temperature, but unfortunately no information as to the purity of the sample was given. An unambiguous value for the bulk value of the Hall coefficient for hafnium has not been found in the literature.

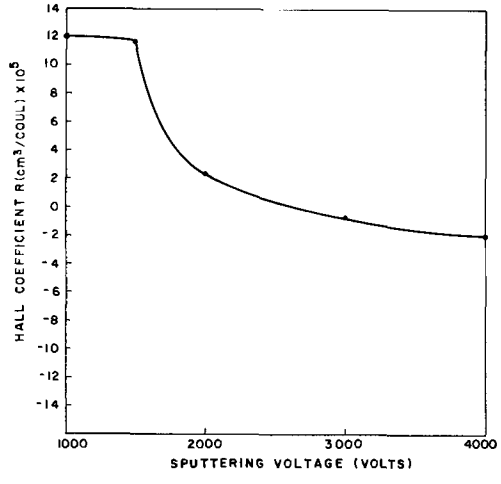

Fig. 8. Hall coefficient of sputtered films as a function of sputtering voltage (sputtering current density 0.112 mA/cm^2).

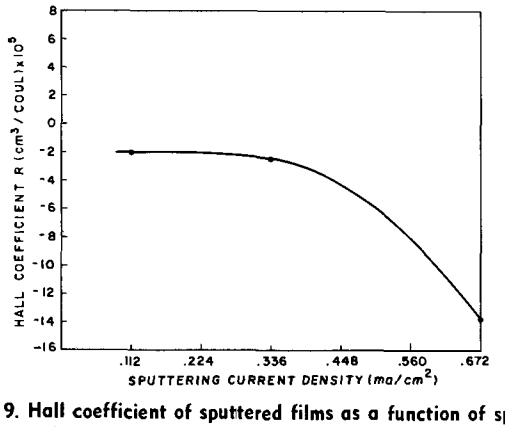

Fig. 9. Hall coefficient of sputtered films as a function of sputtering current density (sputtering voltage 4000V).

The fact that the low-density films have a high resistivity due to their porous and granular structure does not explain the variation in the Hall coefficient. Koppe and Ryan (15) have shown by a theoretical argument that voids and holes in a material do not effect the Hall voltage. Roesch and Willens (16) have reported that the Hall coefficient of titanium has different values and sign depending on the orientation of the sample in the magnetic field. In particular, they reported values of $R_{\parallel} = +4.2 \times 10^{-5}$ cm^3/coulomb and $R_{\perp} = -7.7 \times 10^{-5}$ cm^3/coulomb, where $R_{\parallel}$ and $R_{\perp}$ are the Hall coefficients when the magnetic field is parallel to and perpendicular to the c axis, respectively. For anisotropic media, the Hall coefficient must be considered a tensor quantity rather than a scalar quantity. As was stated above, the low-density films have a preferred orientation different from that of the high-density films which could explain both the change in sign and magnitude of the results measured on the hafnium films. Figure 9 shows the variation of the Hall coefficient with sputtering current density. Again, as was stated above, the greater the current density the more oriented the films became, which could explain the change in the magnitude of the Hall coefficient. Also, there may be more incorporation of impurities at the smaller current densities which might also contribute to the variation seen here. Before any definitive statements can be made concerning the mechanisms responsible for the changes in the Hall coefficient in the sputtered hafnium films, further studies must be performed, including perhaps measurements on pure bulk single crystals.

Anodization Characteristics of Sputtered Hafnium Films

The anodization characteristics of both the 4 kV, 0.112 mA/cm^2 and the 1.5 kV, 0.112 mA/cm^2 sputtered hafnium films were investigated using 0.01% citric acid in water, or equal volumes of aqueous solution of oxalic acid and ethylene glycol, or 1% potassium hydroxide in water as electrolyte. All anodizations were done at room temperature. Of course, the surface temperature of the film may increase slightly during the constant current method of anodization and may rise considerably during the constant voltage method of anodization. High-density hafnium films (4 kV sputtering voltage) anodized in a manner similar to high-density tantalum films, but, in contrast to low-density tantalum films (8), the low-density hafnium films anodized completely at very low forming voltages. Figure 10 shows typical voltage and current *vs.* time plots of anodizations of high-density hafnium films using the constant current technique. Curves A and B correspond to a current density of 1 mA/cm^2, while

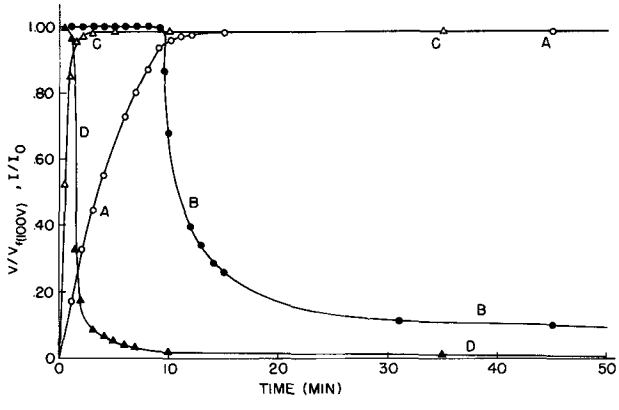

Fig. 10. Anodization characteristics of hafnium sputtered films in saturated aqueous solution of oxalic acid and ethylene glycol (anodized to 100V). Curves A and B, V/V_f and I/I_o, respectively, for 1 mA/cm^2 current density anodization. Curves C and D, V/V_f and I/I_o, respectively, for 5 mA/cm^2 current density anodization.

curves C and D correspond to a current density of 5 mA/cm². In both cases, the forming voltage was 100V. As can be seen, the current dropped to 10% of the starting current I_0 for the 1 mA/cm² anodization, but it dropped to about 1% of the starting current I_0 for the 5 mA/cm² anodizations, implying the oxide may be more dense for the higher current density anodizations. It was observed that there was more gas evolution (oxygen) as the anodizing current density was increased and also at the higher forming voltages. Gas evolution was associated with pinholes that were observed in the oxide. There were only minor differences in the anodization characteristics using the above-mentioned electrolytes. The constant voltage technique of anodization was also tried using the oxalic acid-ethylene glycol solution. The films anodized very rapidly using this method and, at least with the films used, the oxide growth was accompanied by a considerable amount of bubbling on the film surface, *i.e.* gas evolution.

The low-density, 1.5 kV films could not be anodized above 10V which means that all of the metal had been consumed at 10V and therefore no further oxide could be grown at the high voltages. This can be seen in Fig. 11 which shows the voltage *vs.* time curves during anodization of these films at different voltages. Curve A shows an attempt to anodize a film to 130V. Curves B and C show attempts to anodize two different portions of the same slide to 20 and 10V, respectively. In all of these cases, the resulting film was completely transparent. There was, however, a very slight darkish tinge on the film anodized to 10V. Even for the thickest films sputtered at 1.5 kV, approximately 10,000Å, an anodization of 10V produced a clear, transparent film. Such behavior is not too difficult to understand if it is realized that these are highly porous metal films. From the electron micrographs of these films [*see* Fig. 4(*a*) and 5(*a*)], it is seen that these films are composed of many voids and empty spaces. This means that the hafnium metal which forms the boundaries of the voids is of such a size as to be completely anodized at about 10V. Using an anodization constant of 20 Å/V determined below and assuming that twice as much area of the film is exposed to the anodization solution, the film structure should be composed of islands about 400Å in size. This estimate agrees with the size of the crystallites obtained from the structural studies. These anodization characteristics are quite different than those found for low-density tantalum. Low-density tantalum exhibits an induction period during anodization where the voids are filled with oxide followed by the normal anodization characteristics of high-density tantalum films (8). The interpretation of this is that, after the voids in the tantalum film are filled, there is still sufficient metal remaining to produce the typical anodization characteristics.

X-ray investigations show that for both the 4 and 1.5 kV films the oxide formed is monoclinic HfO_2 and that the oxide has a polycrystalline structure rather than being completely amorphous. The crystallite size of the oxide formed on the 4 kV films was approximately the same as those in the film, while for the 1.5 kV films the crystallite size of the oxide was smaller (less than 100Å) than those in the film. There was a slight $(11\bar{1})$ orientation on the oxide from the 4 kV films, and on the oxide from the 1.5 kV films there was a slight (001) and $(10\bar{2})$ orientation. This is not too surprising since the metallic hafnium films had a different preferred orientation. In addition, there appeared an extra diffraction line at the position of the strongest line of the high-temperature HfO_2 tetragonal phase (1965°C).

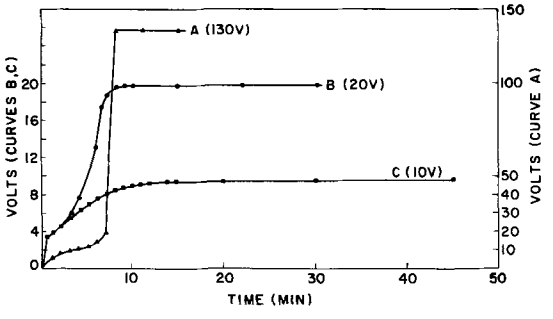

Fig. 11. Anodization characteristics of low-density sputtered hafnium films.

Density, Anodization Constant, Dielectric Constant of HfO_2

Estimates of the density, anodization constant, and dielectric constant for the oxide grown on the sputtered films were obtained from measurements of the mass change during anodization and oxide thickness (17). For these evaluations, the normal stoichiometry of the hafnium oxide was assumed which may not be true, especially at the oxide-hafnium interface. Also, for these calculations the measured value of the 4 kV sputtered film density was used rather than the bulk density of hafnium. The average density of hafnium oxide was found to be 7.9 g/cm³ which is about 19% lower than the bulk value.

Using the calculated value of the oxide film density, the constant current anodization constant was 20 Å/V. For constant voltage anodization, however, the anodization constant was 45 Å/V. In this case, the bulk oxide density was used in the calculation since preliminary data indicate that the oxide formed by constant voltage anodization is higher than that formed by constant current anodization. The scatter in the data includes the bulk value. Qualitatively, the reason for this difference in the anodization constant between two methods of anodization can be explained by noting that for constant voltage anodization the initial stages of oxide growth are accompanied by a large current surge which could develop localized heating on the surface of the film, increasing the temperature and thus enhancing film growth. Huber reported an anodization constant of 65 Å/V for constant voltage anodization (2).

The dielectric constant can be determined from the anodization constant and measured values of capacitance density. The area of each capacitor was 0.105 cm² and both gold and nichrome gold counterelectrodes were used. Table I gives some typical values of the capacitance density and dissipation factors for the three electrolytes used and for various anodization parameters. It should be noted that the capacitance density is a function of the electrolyte, current density during formation, and the technique of formation (constant current or constant voltage).

If the low value of hafnium oxide density is assumed, the dielectric constant is calculated to be 18. However, if the bulk oxide density is assumed, the anodization constant becomes 26.6 Å/V and the dielectric constant has a value of 24 which agrees quite well with the values reported in the literature. For example, Goldstein and Leonhard (18) have reported a value of 24.5 for the dielectric constant of reactively sputtered hafnium dioxide, and Gerstenberg (19) in a recent tabulation of dielectric constants of various thin-film dielectrics formed by anodic oxidation and reactive sputtering listed a value of 25. Huber has reported (2) a dielectric constant of 45 for hafnium oxide formed by constant voltage anodization, and capacitance densities for oxide formed to 130V of about 6.2×10^4 $\mu\mu$f/cm². These capacitance densities agree with those measured during this investigation; *see* Table I. For comparison, the dielectric constant for anodic tantalum oxide formed on sputtered tantalum thin films often reported (18, 19) is 25, and the capacitance density of tantalum oxide formed to 130V is about 10×10^4 $\mu\mu$f/cm². It should be noted that the value of the dielectric con-

stant of Ta_2O_5 formed on bulk tantalum or tantalum foil measured by Young (20) is 27.6.

Frequency and Temperature Dependence of Capacitance

The capacitance and dissipation factor of the test capacitors as a function of frequency in the range from 0.1 to 100 kHz were studied. Only a $\pm 1\%$ variation in $c/c_{1\ kHz}$ was found in this range and there was very little difference in the frequency dependence for the oxides formed in the oxalic acid-ethylene glycol, KOH, and citric acid solutions. This capacitance *vs.* frequency variation agrees very well with that reported by Huber (2). Low values of the dissipation factor, ≤ 0.01 at 1 kHz were measured for all the electrolytes and the normal variation of tan δ with frequency was observed.

The initial attempts to measure TCC indicated that for either gold or nichrome-gold counterelectrodes the capacitance varied in an erratic and nonreproducible fashion as a function of temperature. The gold counterelectrodes seemed to have the wider variations. Only after placing the capacitors in a chamber and evacuating to a few microns did the capacitance as a function of temperature cycle in a reproducible manner and then only after one complete temperature cycle. This behavior was basically the same whether any of the three electrolytes were used or whether constant current or constant voltage anodization was used to form the dielectric. The TCC values varied from about 300 to about 600 ppm/°C, with the lowest values measured with the capacitors formed at constant voltage. It is interesting to note that a change in capacitance of about half that measured by increasing the temperature to 100°C was obtained upon placing the capacitors in a vacuum of a few microns. One possible explanation for this behavior and the erratic capacitance changes is that the capacitors are very sensitive to humidity. This would be expected if the oxide were porous which seems the case for the oxide formed with the anodization conditions used (the anodic oxide density was found to be about 20% lower than that of the bulk oxide). The larger variation observed with the gold counterelectrode could have been caused by adhesion problems. The values of TCC reported here are larger by a factor of 2 to 4 than those reported previously (2, 3), even for those formation conditions that closely approximated those studies.

Conclusions

As is the case with many materials and in particular tantalum, the electrical and structural properties of hafnium are a function of the sputtering parameters. No phase of hafnium equivalent to the β-phase (21) in tantalum was observed but a low-density film was obtained at the low sputtering voltages. In contrast, sputtered niobium (22) exhibits neither a low-density structure nor a β-phase. These low-density films have a large specific resistivity and a large positive Hall coefficient in contrast to the films sputtered at the higher voltages. All of the films sputtered had a hexagonal close-packed structure which was the same as the bulk but with preferred orientations that were dependent on the sputtering conditions. These different preferred orientations may be the cause of the change in sign and magnitude of the Hall coefficient for the different films.

The hafnium films sputtered at 4 kV anodized in a manner similar to tantalum, although the final anodization current did not decrease by the same percentage as that with tantalum. One implication of this might be that there is a larger variation in the stoichiometry of the oxide than with tantalum or the film may have a greater number of defects. This, coupled with the fact that the density of the high-density hafnium films is smaller than the bulk value, could explain the relatively low value of the density of the HfO_2 films. Klerer (17) reported the density of the tantalum oxide formed on the sputtered films smaller than that of the bulk oxide. The anodization constant for hafnium was found to be about 20 Å/V which is somewhat higher than that of tantalum, 16 Å/V. Also, the value of the dielectric constant was determined and found to be 18 using the low value of the oxide density.

One of the problems encountered during anodization, which is not unique with hafnium, was gas evolution during oxide growth and pinholes in the final oxide. Pinholes affect capacitor yields and performance. The capacitance densities, capacitance as a function of frequency, and the leakage current agree reasonably well with those reported previously (2, 3). However, the values of TCC measured were higher by a factor of 2 to 4. In addition, it was found that the capacitors are quite sensitive to the environment, probably humidity, and only after placing the capacitors in an evacuated oven were reproducible capacitance *vs.* temperature data obtained.

One of the interesting facts discovered about the anodic oxide was that it was not amorphous but polycrystalline monoclinic with some preferred orientation. Also, x-ray studies showed a diffraction ring belonging to either the high-temperature tetragonal oxide or the bcc hafnium oxide postulated by Passerini (23).

Acknowledgments

The extensive aid of Mrs. M. H. Read is appreciated for her contributions to the x-ray analysis of these films, as well as helpful discussions with N. Schwartz.

Electrodeposition of Thin Magnetic Permalloy Films

H. V. Venkatasetty*

Honeywell Corporate Research Center, Hopkins, Minnesota

ABSTRACT

A citrate-complexed nickel-iron electrolyte which has a long useful plating life from the point of view concerning the magnetic properties of the plated films and a better plating efficiency compared to the conventional baths has been used to plate thin magnetic films of 80:20 nickel-iron from about 150 to about 8000Å. The magnetic properties, like the coercive force (H_c) and the anisotropy field (H_k), were determined at a known thickness as a function of current density, pH, temperature, and the concentration of citrate ion and the plating conditions optimized. The ferromagnetic domain patterns observed by the Bitter technique as a function of thickness show the same behavior as those observed in evaporated films. Internal stress measurements made as a function of thickness, current density, and temperature show that both the current density and the temperature have significant effect on stress. Photomicrographs of deposits obtained at a wide range of current density show the differences in the structure of the deposits.

Within the last ten years, the study of electrolytic preparation and properties of thin ferromagnetic films of permalloy and permalloy type material useful as memory elements for computers (1-6) has received great attention by research workers. Electrodeposition has the unique advantage in that controlled quantities of elements like P, As, S, *etc.*, can be introduced into the deposit to produce films of varying magnetic properties (2, 5-7). By manipulating the plating parameters, like the current density and the temperature of the bath, the roughness of the surface topography of the substrate material can be varied and, by subsequent plating of ferromagnetic material on such a surface, a wide range of specific desirable magnetic properties can be produced (8). The disadvantage of electroplating lies in the difficulty in controlling the impurity content of the bath, the adsorption of ions on the cathode, and the codeposition of hydrogen. In the conventional permalloy bath where either ferrous sulfate or ferrous formate is used, ferrous ions undergo anodic oxidation to ferric ions during plating. Ferric hydroxide and other hydrolysis products like $Fe(OH)^{++}$ and $Fe(OH)_2^+$ are incorporated into the deposit and affect the magnetic properties of plated permalloy (9).

With a view to preventing the adsorption and inclusion of the ferric compounds in the deposit causing a deleterious effect on the magnetic properties of the permalloy on prolonged plating, citrate ion was added to the solution and the conditions to plate permalloy were optimized. It has been found that permalloy films of good magnetic properties can be obtained from the citrate bath even when used over a long period of time ($\sim$ 25 hr), whereas similar studies with the sulfate bath show that the films exhibit poor magnetic properties after a few hours of use ($\sim$ 10 hr) and a new bath should be used (9). It is also found that the unstirred sulfate bath is very sensitive to small changes in the operating parameters like the current density, pH, and the temperature of the bath, whereas the citrate bath is much less sensitive to the above operating parameters making it easier to reproduce the films with good magnetic properties (9). This paper describes a method for preparing 80:20 nickel-iron films of varying thickness and the effect of plating parameters like the pH, temperature, citrate ion concentration, ferrous sulfate concentration on the magnetic properties of the films. Ferromagnetic domain patterns are observed as a function of film thickness. Stress measurements made with and without saccharin in the bath are also described.

Experimental Procedure

The method of preparation of the bath, though similar to the Ni-Fe-Mo bath prepared by Freitag and Mathias (5), is different from the composition of the

* Electrochemical Society Active Member.
Key words: electrodeposition, permalloy, memory element, thin film, coercive force, anisotropy field.

present bath and the bath is operated at a different pH and current density. The typical plating solution is made with reagent-grade chemicals by dissolving in distilled water about 112g of $NiSO_4 \cdot 6H_2O$, 5g of $FeSO_4 \cdot 7H_2O$, 75g of citric acid and/or sodium citrate, 1.5g of K_2SO_4, 0.0-0.4g of sodium lauryl sulfate, and 1.0g of saccharin, and diluting the solution to 1 liter. The pH is adjusted to 4.8 by sodium hydroxide or citric acid. The plating cell is a liter flask with a flat surface fitted with a Lucite cover that can hold the electrodes rigidly and can be positioned accurately. A platinum sheet was used as anode. Glass slides with chromium and gold evaporated on them were used as substrates and the films were deposited from a nonagitated bath using a sequence of current pulses of varying amplitude (7.5 mA/cm²-18 mA/cm²) with 3 sec on period and 3 sec off period from a constant current source to minimize the concentration gradients across the thickness of the deposit. The bath can be operated from 25° to 45°C, and the films were made at 25°C and 30°C. A coil wound around the bath generates a uniform vertical magnetic field of about 100 Oe.

The coercive force (H_c) and the anisotropy field (H_k) of the films were measured in a 1000 cycle hysteresis loop tracer using the standard procedure (10). The standard spectrophotometric method was used to estimate iron in the deposit (11) at 522 mμ using a Beckman Du spectrophotometer. The iron was precipitated twice and complexed with dipyridyl. The amount of iron in the deposit was calculated with a calibration curve made using 99.8% A.R. grade iron wire. These determinations are accurate to ±2% or better. The thicknesses of the films were estimated from the total weight of the alloy deposited in a given area and these measurements are accurate to ±10%.

The well-known Bitter technique using a Zeiss metallographic microscope was used to observe the domain walls (12, 13). The photomicrographs of the deposits made at different current densities were also obtained using a Zeiss metallographic microscope. The internal stress in the deposits was measured using a Brenner and Senderoff spiral contractometer (14). The copper spiral was coated with gold (~3000Å) and a smooth deposit of copper (~3000Å) using a proprietary copper bath and the procedure recommended by Brenner and Senderoff was used. The measurements are accurate to ±10%.

Results and Discussion

Permalloy films (2000-8000Å) deposited at 7.5 and 10 mA/cm² as a function of pH at 25° and 30°C show that at pH less than 4.5 the deposits are rough looking and give distorted B-H loops (Fig. 1). The deposits plated at pH 4.6-5.2 are shiny and have good magnetic properties and square hysteresis loops in the easy direction (Fig. 1). The deposits plated at pH more than 5.2 are rough looking with high values of H_c and H_k (Fig. 2) with distorted B-H loops. The variation of pH can cause a large variation in nickel content of the alloy deposited from the citrate bath. It has been shown that above pH of 6 the deposit consists mainly of nickel due to the preferential complexing of iron by the citrate ion (15). Apparently, the relative affinity of citrate ion for complexing iron and nickel must vary with pH. The Freitag and Mathias bath seems to be highly sensitive to pH change and it was operated at pH 5.2 (5) which is the limiting end of the pH range applicable to the present bath (Fig. 2). They prepared Ni-Fe-Mo films (600-800Å) which were highly magnetostrictive, whereas the present studies relate to nonmagnetostrictive films covering a wide range of thickness (500-8000Å) since nonmagnetostrictive forms of permalloy comprise the bulk of the magnetic film material used for magnetic storage and switching purpose.

The films of thickness 2000 and 3000Å deposited at different temperatures from 25° to 55°C show that the

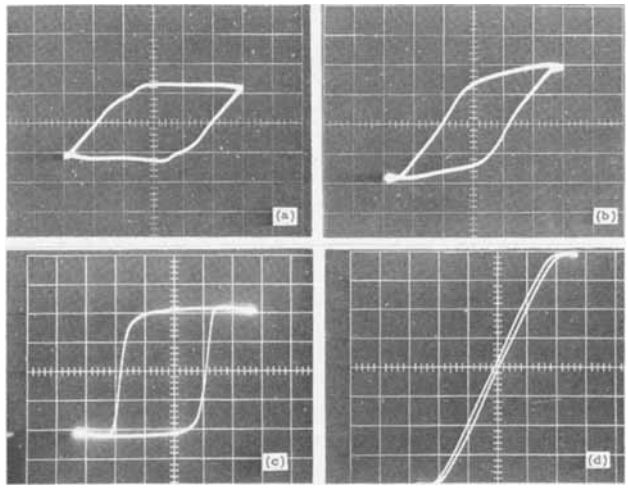

Fig. 1. B-H loops of easy and hard axis of 3000Å Ni-Fe films plated at different pH: (a) easy axis loop at pH 3.7, (b) hard axis loop at pH 3.7, (c) easy axis loop at pH 4.8, (d) hard axis loop at pH 4.8.

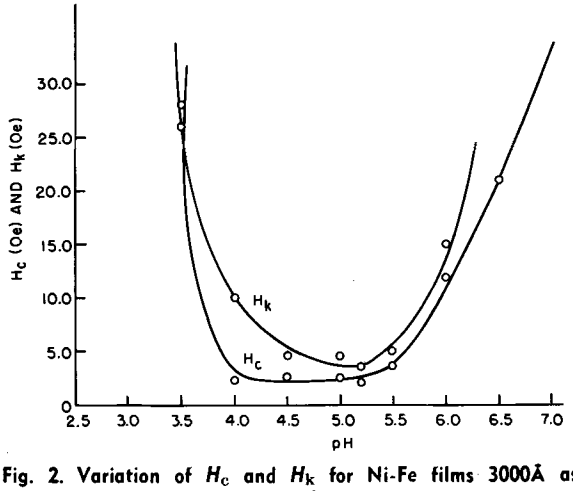

Fig. 2. Variation of H_c and H_k for Ni-Fe films 3000Å as a function of bath pH; C.D. 10 mA/cm² at 30°C.

deposits have good magnetic properties up to 45°C, above which the deposits become rough looking with distorted B-H loops with high values of H_c and H_k (Fig. 3). The magnetic properties of the deposits (~3000Å), H_c and H_k, were studied as a function of the citrate ion concentration. It is found that both H_c and H_k values remain almost constant up to citrate ion concentration of 125 g/liter, above which the H_c and H_k increase (Fig. 4) and the B-H loops are distorted. The effect of citrate ion on the composition of nickel-iron deposit has been described (16). It has been found that the iron content of the alloy increases with increase in the citrate ion concentration in the bath, and the deposits from a bath with very much citrate ion were found to contain organic inclusions (16).

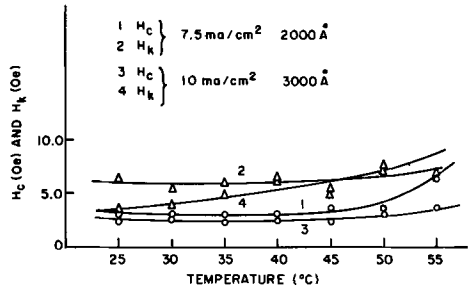

Fig. 3. Variation of H_c and H_k with temperature of the bath

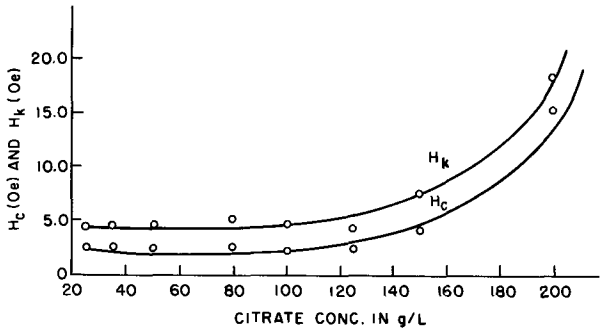

Fig. 4. Variation of H_c and H_k with citrate concentration for Ni-Fe films, 3000Å plated at pH = 4.8.

The chemical analysis of the films with zero magnetostrictive properties showed that the film composition corresponds to 80% nickel and 20% iron by weight. The deposits plated at 25° and 30°C with 7.5 and 10 mA/cm² were very slightly iron-rich below ~ 1000Å, and from 1000Å to 1μ they were all zero magnetostrictive with good magnetic properties (Fig. 5). Experiments done with near zero or zero magnetostrictive films (~ 600-8000Å) to determine the effect of film thickness on H_c and H_k show that, while H_c is very much thickness dependent with a value of 4.2 Oe at ~ 600Å and 1.0 Oe at 8000Å, H_k is less dependent on thickness with a value of 5.2 Oe at ~ 600Å and leveling off at 4.0 Oe from 1000 to 8000Å in good agreement with the results of Wolf for films made from the sulfate-chloride bath (1) (Fig. 6).

Films (~ 3000Å) were deposited from the baths containing varying amounts of ferrous ion concentration at constant nickel ion concentration, and H_c and H_k were measured. At 2.5g of $FeSO_4 \cdot 7H_2O$/liter, the film has high H_c of 15.0 Oe and drops to about 1.2 Oe at 3.75g of $FeSO_4 \cdot 7H_2O$/liter, remains about the same at 5.0g of $FeSO_4 \cdot 7H_2O$/liter, above which it increases steadily to 1.8 Oe at 10.0g of $FeSO_4 \cdot 7H_2O$/liter. At 2.5g of $FeSO_4 \cdot 7H_2O$/liter, the film has H_k of 17.0 Oe, drops to 4.0 Oe at 3.75g $FeSO_4 \cdot 7H_2O$/liter, and remains at 4.0 Oe up to 5.0g of $FeSO_4 \cdot 7H_2O$/liter, above which it increases rapidly with increase of ferrous sulfate in the bath, reaching a value of 9.5 Oe at 10.0g $FeSO_4 \cdot 7H_2O$/liter (Fig. 7). These results are in excellent agreement with those of Wolf (1) and point out the well-known composition dependence of H_k with a minimum value in the zero magnetostrictive range.

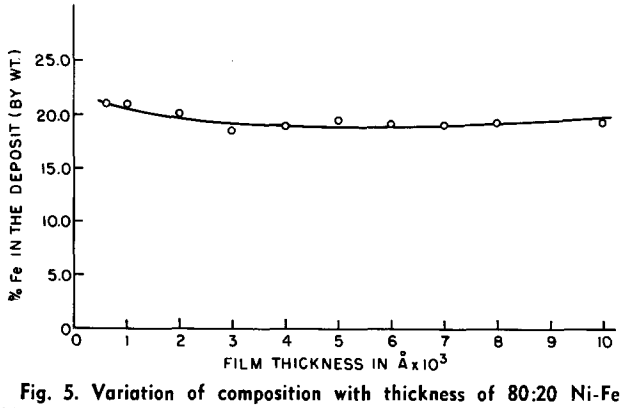

Fig. 5. Variation of composition with thickness of 80:20 Ni-Fe films plated at 25° and 30°C.

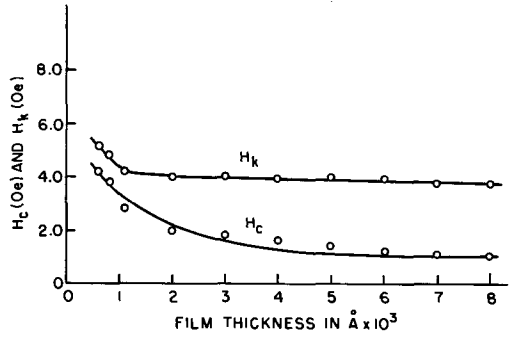

Fig. 6. Variation of H_c and H_k with film thickness for 80:20 Ni-Fe films.

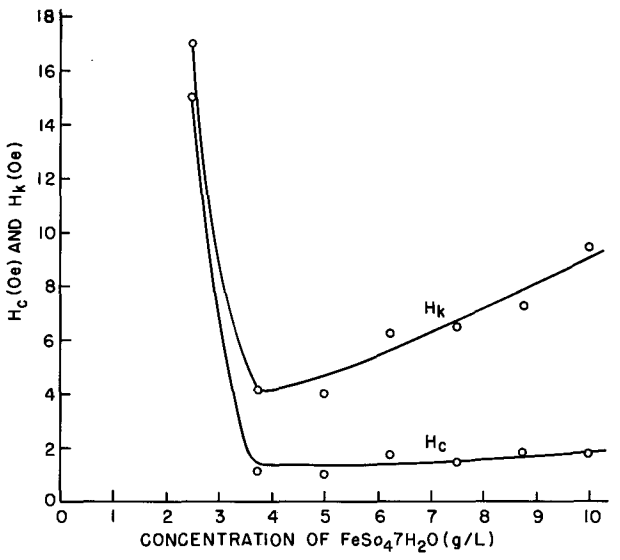

Fig. 7. Variation of H_c and H_k with ferrous sulfate concentration in the bath at constant nickel sulfate concentration for Ni-Fe films, 3000Å.

Experiments run to determine the plating efficiency of the bath at various current densities (7.5-18.0 mA/cm²) at 30°C show that the plating efficiency is about 85% compared to about 60% for conventional sulfate baths. The lower plating efficiency of the sulfate bath can be explained in terms of lower operating pH ~ 2.6 where a significant amount of hydrogen is liberated.

The internal stress developed in an electrodeposited material is possibly caused by the mismatch and disorder in the arrangement of the atoms in the lattice during the growth process. Some of the factors that influence the stress are the substrate roughness, impurities in the bath, temperature, pH, and current density. Stress measurements made as a function of current density and film thickness show that stress is tensile in nature and is very much dependent on plating current density. At each current density, the initial stress is high and levels off with increasing thickness which indicates that the film substrate interface has a great effect on stress. Stress measurements made at 6.5 mA/cm² as a function of temperature show that stress decreases from a value of about 9.7 x 10^9 dynes/cm² at 25°C to about 5.0 x 10^9 dynes/cm² at 47°C. It is found that, on adding weighed quantities of saccharin to the bath, the stress of 6.0 x 10^9 dynes/cm² measured at 5 mA/cm² with no saccharin gradually decreases with increase of saccharin to a constant value of 1.9 x 10^9 dynes/cm² at saccharin concentrations of 1 g/liter and above (Fig. 8). Stress values measured in this work compare favorably with those of Maeda and Mukasa for permalloy (17).

Though it is well known that the domain wall properties are important to the study of ferromagnetic films and their applications, very little work is reported on the domain wall studies of electrodeposited films. Bitter pattern observations were made on demagnetized nickel-iron films as a function of film thickness from ~ 150 to 2800Å. It is apparent from these observations that, as the film thickness increases, the influence of the stray fields on domain wall configuration changes. As predicted from theory, Néel walls are observed at ~ 150 and ~ 250Å films [Fig. 9(*a*), (*b*)], whereas at ~ 600Å cross-tie walls appear [Fig. 9(*c*)], and in thick films ~ 2800Å Bloch walls are observed [Fig.

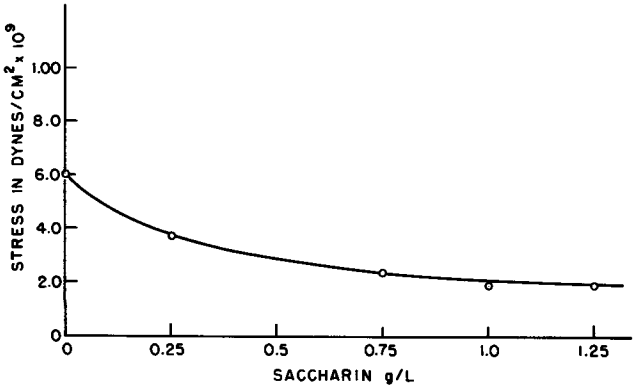

Fig. 8. Effect of saccharin on the residual stress of electrodeposited Ni-Fe films ~ 7000Å.

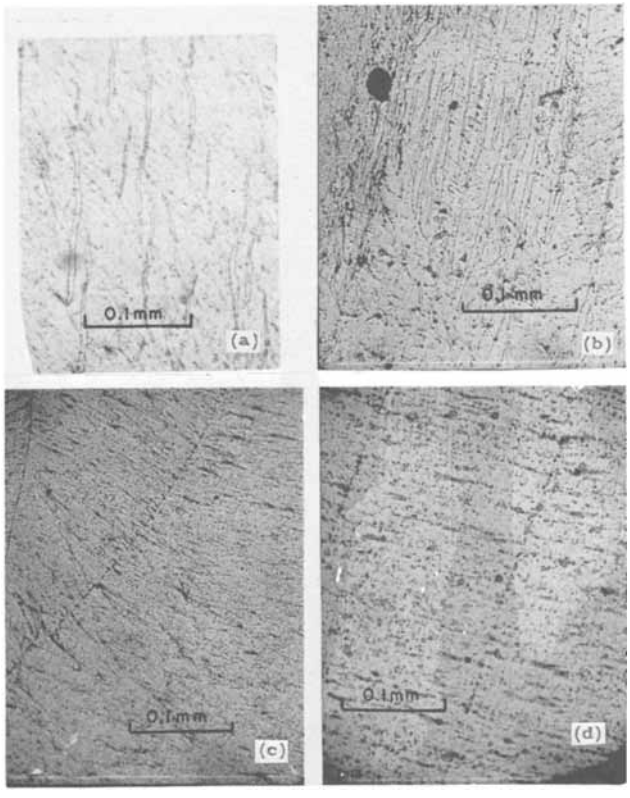

Fig. 9. Bitter patterns of the domain walls in Ni-Fe films as a function of film thickness: (a) Néel walls ~ 150Å Ni-Fe film, easy axis approximately vertical; (b) Néel walls ~ 250Å Ni-Fe film, easy axis approximately vertical; (c) cross-tie walls ~ 600Å Ni-Fe film, easy axis approximately vertical; (d) Bloch walls ~ 2800Å Ni-Fe film, easy axis approximately vertical.

9(*d*)]. The localized field due to the free magnetic pole lying inside the thin ferromagnetic film will be directed parallel to the surface in the case of Néel walls. The colloidal particles of the Bitter solution are used for easy flux closure, thus giving rise to very intense deposits of colloids. In Bloch walls, these localized strong fields lie perpendicular to the surface and hence have a weaker force on the colloidal particles giving rise to poorly defined lines. Cross-tie walls represent a transition from Bloch to Néel walls, wherein the cross-ties serve to decrease the magnetostatic energy (18, 19). Kainuma and Tsuya (20), who studied the domain patterns of electrodeposited Ni-Fe films, could not observe these patterns below 300 magnification, whereas the present observations could be made at magnifications of 60 and above. Maeda and Nukasa (21), who made domain pattern studies of electrodeposited Ni-rich and Fe-rich samples of Ni-Fe films from 400 to

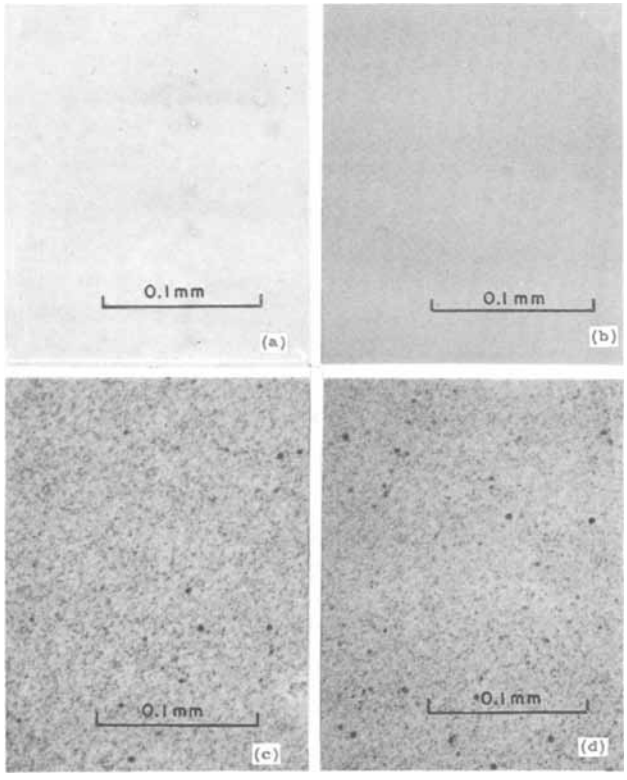

Fig. 10. Photomicrographs of the surface of Ni-Fe films deposited at different current densities: (a) 1 mA/cm², (b) 5 mA/cm² (c) 20 mA/cm², and (*d*) 25 mA/cm².

7000Å, observed cross-tie walls for 450-1300Å and Bloch walls at 7000Å.

The photomicrographs of 80:20 NiFe films plated at different current densities show that the films are smooth and shiny [Fig. 10(*a*), (b)] with low values of H_c, H_k, and easy axis dispersion (α_{90}) and square loop in the easy direction at 1 and 5 mA/cm², whereas at 20 and 25 mA/cm² the deposits become rough [Fig. 10(*c*), (*d*)] with high values of H_c and H_k and easy axis dispersion (22).

Conclusion

It has been shown that, using the citrate bath, 80:20 nickel-iron films of varying thickness with magnetic properties comparable to films made by vacuum deposition can be produced. The bath has a higher plating efficiency and longer useful life and the process has a high degree of reproducibility as compared to the sulfate bath.

Vapor Phase Etching of GaAs in the H_2-H_2O Flow System

Chinyueh Lin, Lin Chow, and Kenneth J. Miller*

Department of Chemistry, Northeast Louisiana State College, Monroe, Louisiana

ABSTRACT

The GaAs-H_2O-H_2 etch reaction has been studied as a function of flow rate, temperature, and GaAs surface area. Experimental and calculated equilibrium constants for the reaction have been compared. The formation of Ga_2O_3(s) is considered. The variation of sample surface texture with gas composition is examined.

An understanding of the chemical equilibrium of a reaction is essential for its useful application. In this study, the chemical equilibrium of the GaAs-H_2-H_2O reaction has been studied particularly as this reaction may be applied to the controlled *in situ* etching of samples prior to epitaxial deposition of thin films by chemical transport. Such *in situ* etching may be useful for purity control of substrate surfaces. Since this reaction also takes place at the "source" when H_2O vapor transport is used in epitaxial deposition under a temperature gradient, it is also important to understand its equilibrium to control epitaxial deposition. Various experimental methods have been used in prior studies of this etch reaction (1, 2); in the present study, a horizontal reactor suitable for processing relatively large area samples has been used and the effect of temperature, flow rate, and GaAs surface area on the reaction equilibrium and of gas composition on etched surfaces has been studied.

Experimental

Single-crystal ($\bar{1}\bar{1}\bar{1}$) oriented GaAs sample wafers obtained from the Monsanto Chemical Company were lapped and polished in 1800 grit alumina and with Linde B, and chemically polished in bromine-methanol solution according to the method of Sullivan *et al.* (3). Hydrogen was pre-purified grade obtained from Matheson Company and was further purified by passing through a Pd-Ag diffusion tube purifier. Hydrogen was bubbled through DI water held in a Pyrex saturator immersed in an ice-water bath. For all etching, the H_2O/H_2 mole ratio was $\cong 6 \times 10^{-3}$. Figure 1 shows a schematic drawing of the furnace and furnace temperature profile. A 28 mm ID X 24 in. long quartz reaction tube was used. The furnace temperature profile was constant within $\pm 1°$ over about 5 in. The GaAs sample was placed on a flat quartz sample holder held in the center of the reaction tube by a quartz tube with a test tube end fused to the bottom of the flat sample holder directly below it so that the sample temperature could be measured with a thermocouple. The experimental details of similar flow reactors have been described by Moest (4) and by Lawley (5).

Results

Figure 2 shows an Arrhenius plot of the data for the etch reaction giving an experimental activation energy of approximately 44 kcal/mole in the 900°-1050°C temperature range for a H_2O-H_2 flow rate of 300 cm^3/min and a H_2O-H_2 gas flow velocity of 50 cm/min. The latter flow rate etched samples at a rate convenient for useful etching, between 0.1-2 μ/min. The sample area used to determine this plot was approximately 3 cm^2, large enough to minimize nonuniform edge etching. It was not possible to distinguish different etch rates between the ($\bar{1}\bar{1}\bar{1}$) and (100) surfaces.

Figure 3 shows a plot of GaAs sample weight loss at 1000°C as a function of H_2O-H_2 flow rate for sample areas > 10 cm^2. A weight loss of approximately 23 X 10^{-4} g/min was obtained at a flow rate of 300 cm^3/min for sample areas > 10 cm^2. However, a weight loss of approximately 5.56 X 10^{-4} g/min was obtained for the 3 cm^2 area normalized to 1 cm^2, as used to obtain Fig. 2. This decrease in weight loss with decrease in surface area at constant flow rate and temperature indicates

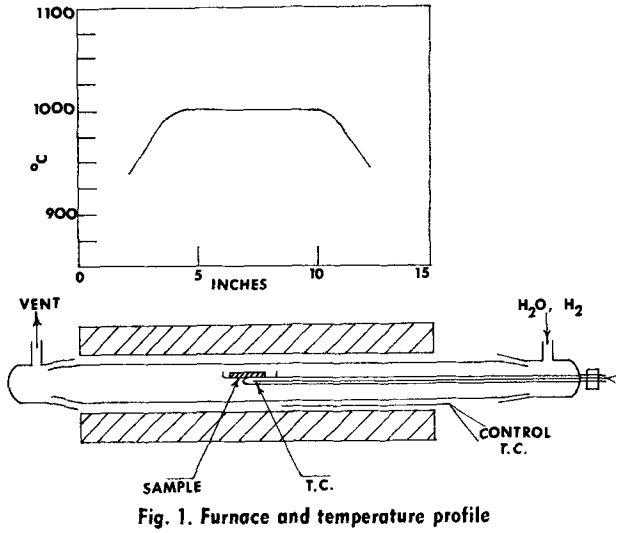

Fig. 1. Furnace and temperature profile

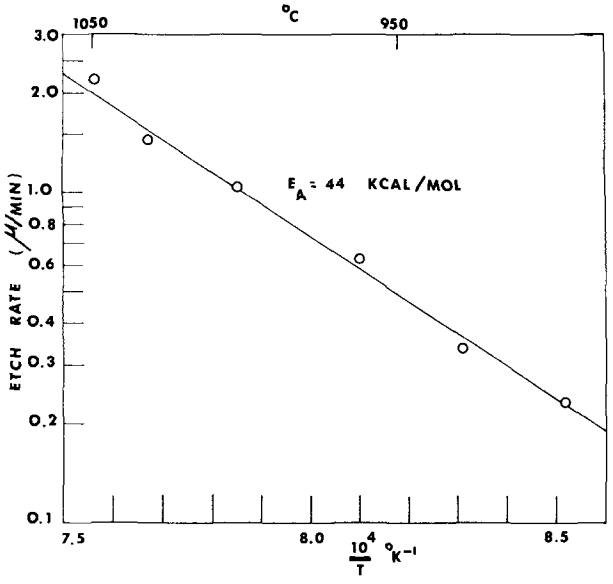

Fig. 2. GaAs etch rate as a function of temperature at H_2O/H_2 mole ratio 6×10^{-3} and H_2O-H_2 flow rate 300 cm³/min.

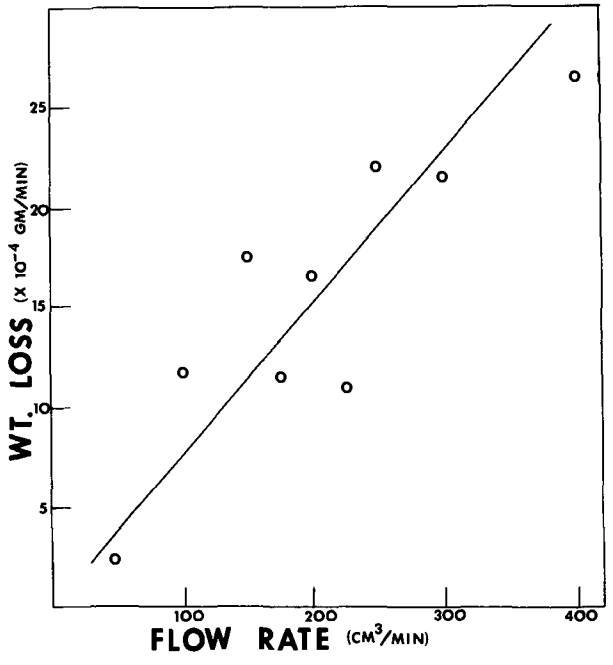

Fig. 3. GaAs weight-loss at 1000°C as a function of H_2O-H_2 flow rate for sample area > 10 cm².

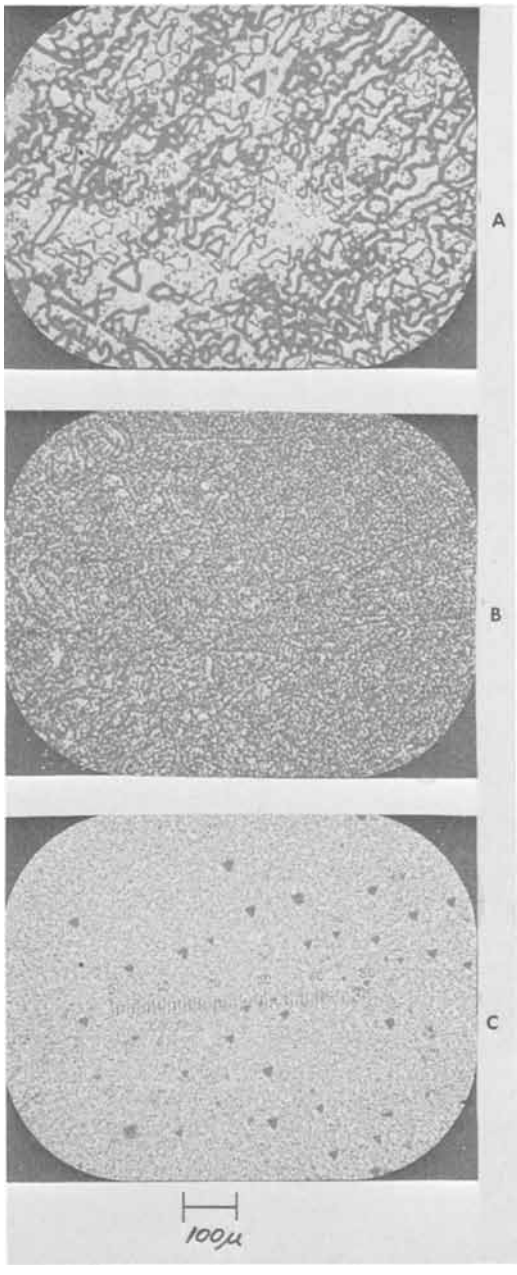

Fig. 4. GaAs ($\bar{1}\bar{1}\bar{1}$) face following etching at 1000°C: A—600 cm³/min, 5 min; B—100 cm³/min plus 300 cm³/min N_2 by-pass, 5 min; C—50 cm³/min plus 400 cm³/min N_2 by-pass, 15 min.

incomplete reactivity of the reactants. The dependence of reaction rate on surface area is not unexpected and is usual for the relatively fast flow rates used when reactions are applied in practice. Figure 3 indicates that the etch rate reaction under the experimental conditions used to obtain the data in Fig. 2 is closer to a steady-state equilibrium than a true thermodynamic equilibrium. If it is assumed that, for sample surface area > 10 cm² the reaction of reactant gases is complete at a flow rate of 300 cm³/min, then sample weight loss under these conditions should be independent of surface area and represent a close to true thermodynamic equilibrium.

Figure 4 shows photomicrographs of the ($\bar{1}\bar{1}\bar{1}$) GaAs face following etching at 1000°C. When the H_2O-H_2 gas composition is diluted with nitrogen, it can be seen that the GaAs surface is smoother and more uniform. The effect of nitrogen on etching is believed to be primarily due to H_2O-H_2 dilution rather than to chemical reaction since etching is taking place at about the decomposition temperature of gallium nitride (6). When (100) surfaces were etched, it was found that they yielded a smoother etched surface as compared to ($\bar{1}\bar{1}\bar{1}$) surfaces etched under the same conditions.

Discussion

The over-all idealized etch reaction, limited by temperature and partial pressures of H_2 and H_2O, can be written

$$GaAs(s) + \tfrac{1}{2}H_2O(g) \rightleftarrows \tfrac{1}{2}Ga_2O(g) + \tfrac{1}{2}H_2(g) + \tfrac{1}{2}As_2(g) \quad [1]$$

where the pressure of As_4 has previously (2) been shown to be less than 10% of the total arsenic pressure above approximately 900°C. An equation showing the variation of the equilibrium constant for [1] with temperature in the 1000°-1400°K range has been obtained using recently evaluated free energy functions for GaAs(s) from Lichter and Sommelet (7), free energy functions for $Ga_2O(g)$ from Cochran and Foster (8) and heats of formation using the data of Arthur (9), and Thurmond and Frosch's (10) value for $\Delta H°_{f298}$ of

$Ga_2O(g)$, as well as data from JANAF Thermochemical Tables (11) and Stull and Sinke (12)

$$\log K_p = \frac{-13.15 \times 10^3}{T} + 8.21 \qquad [1a]$$

At 1000°C, K_p calculated for reaction [1] using [1a] is 7.6×10^{-3} as compared with the value for K_p obtained from the experimental data in Fig. 2 of 2×10^{-3}. The latter experimental value for K_p varies from K_p calculated by about one order of magnitude; however, it should be noted that the thermal data uncertainty of ± 1.5 kcal causes an uncertainty of approximately one order of magnitude in calculated K_p values. The K_p obtained from the experimental data of Fig. 3 where sample area is > 10 cm^2 and flow rate is 300 cm^3/min is 0.9×10^{-2}, comparing more closely with the K_p calculated, than the value obtained at 3 cm^2 sample area, indicating that closer to true thermodynamic equilibrium has been achieved in this case. The method used for the determination of experimental K_p values has previously been described (2). Figure 5 shows smooth semilog plots of K_p for the etch reaction [1] as a function of temperature as calculated from [1a] and as obtained experimentally from the kinetic data of Fig. 2. For comparison, Fig. 5 shows the two experimental values in this temperature range from the work of Michelitsch *et al.* (2). In the latter study, gas velocity was considerably greater than that used in this present study.

The range of partial pressures of H_2O and H_2 in reaction [1] is limited by the formation of $Ga_2O_3(s)$. The reaction for $Ga_2O_3(s)$ formation when p_{H_2O} is relatively high or p_{H_2} relatively low, based on experimental observations, is proposed as

$$\tfrac{1}{2}Ga_2O(g) + H_2O(g) \rightleftarrows \tfrac{1}{2}Ga_2O_3(s) + H_2(g) \qquad [2]$$

An equation showing the variation of K_p for [2] with

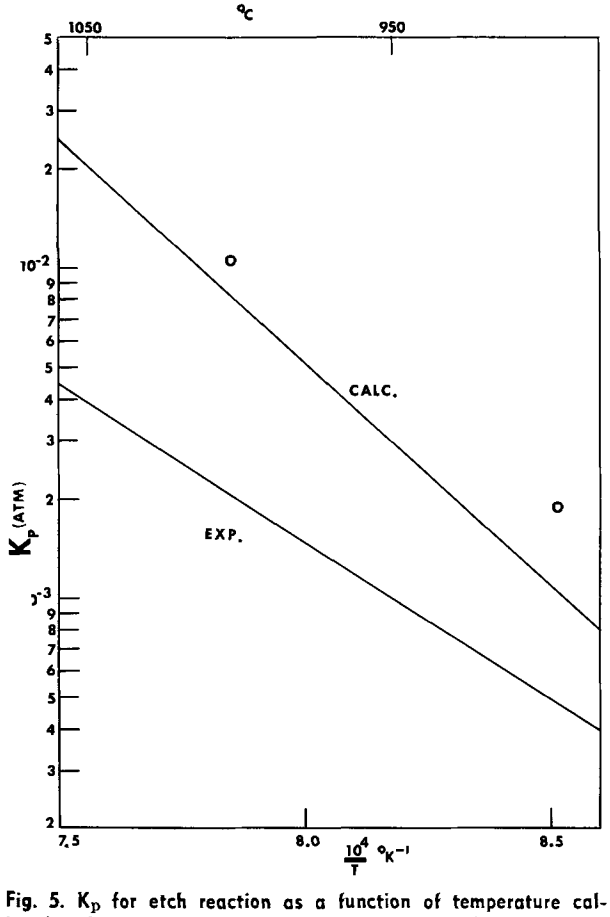

Fig. 5. K_p for etch reaction as a function of temperature calculated and experimentally determined compared with experimental values of Michelitsch et *al.* (o).

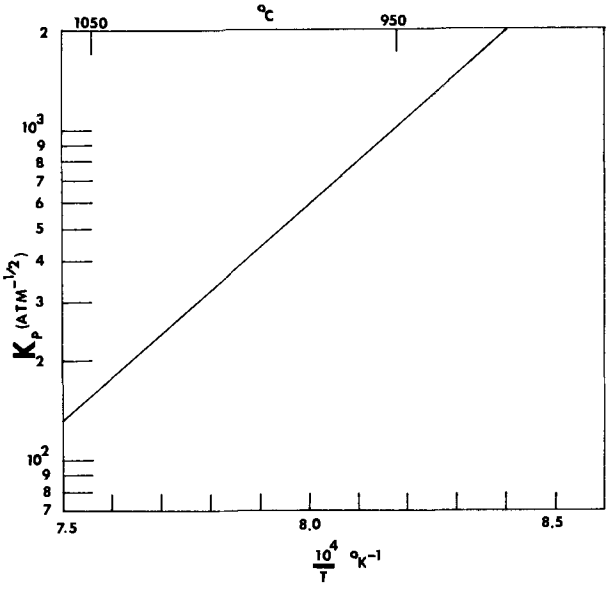

Fig. 6. Calculated K_p for the reaction $\tfrac{1}{2}Ga_2O(g) + H_2O(g) \rightleftarrows \tfrac{1}{2}Ga_2O_3(s) + H_2(g)$.

temperature in the 1000°-1400°K range has been obtained as follows

$$\log K_p = \frac{13.5 \times 10^3}{T} - 8.02 \qquad [2a]$$

Figure 6 shows a smooth semilog plot of K_p calculated from [2a] as a function of temperature, indicating that reaction [2] can affect the etch reaction significantly unless the partial pressure of H_2O is small compared to that of hydrogen. Equation [2a] has been obtained using free energy functions given by Cochran and Foster (8) for $Ga_2O(g)$ and $Ga_2O_3(s)$, $\Delta H°_{f298}$ for $Ga_2O_3(s)$ of −261 kcal/mole (13) and $\Delta H°_{f298}$ for $Ga_2O(g)$ of −21.5 kcal/mole (10).

Compatibility of Battery Materials with Fuel Cell Catalysts

C. H. Weeks

CSIRO, Division of Mineral Chemistry, Port Melbourne, Victoria, Australia

Materials for constructing low-temperature fuel cell batteries must be carefully selected not only to resist attack by corrosive electrolytes, but also to avoid poisoning of catalysts. Very few systematic studies of fuel cell catalyst poisoning have been published. Witherspoon and Adams (1) studied a Rh-Pd hydrogen anode catalyst and found that cupric and ferrous ions in solution and a surfactant (Triton x 100) caused some loss of activity, while sulfide ion caused severe poisoning. Terry (2) reports that short life of hydrogen-air cells was attributable to poisoning from sulfur in molded rubber cell frames. Cathro (3) has found that platinum-based formaldehyde anodes fail rapidly in the presence of copper and silver ions in acid solution. Workers at Esso Research and Engineering (4) found that copper poisoned methanol anodes, but that aluminum had no effect.

Active catalysts for the oxidation of both methanol and formaldehyde have been developed in this laboratory (5, 6) and tested successfully for long periods in small-scale fuel cells. Early versions of larger cells and batteries were less successful, showing poor performance and short life, and it was evident that anode catalysts were becoming poisoned by impurities in solution. The experiments described below were undertaken to determine the undesirable impurities and their sources and to investigate possible substitutes.

Experimental

Each test was performed using a covered 2 liter glass pot cell. Five holes in the cover contained leads to the working and counterelectrodes, a probe leading out to a mercury/mercurous sulfate reference electrode, a glass-sheathed immersion heater, and a glass thermistor pocket. Anode catalyst (approx 150 mg of Pt-Re-Sn) was electrodeposited onto a gold-plated expanded tantalum or niobium disk of 13 cm^2 nominal area to form the working electrode. The counterelectrode was platinum gauze, and was surrounded by a glass tube to prevent evolved hydrogen reaching the working electrode. The solution was maintained at 60°C and agitated by the use of a magnetic stirrer unit. The working electrode was supplied with a current of 0.5A (38 mA/cm^2) from an external source. The fuel used was formaldehyde (0.3 ± 0.15M) dissolved in 2M sulfuric acid electrolyte. A few experiments were also performed with methanol (approx 1.0M) as fuel. Results were generally similar to those with formaldehyde.

The procedure for each test was to run the electrode for 50 or more hours to allow it to reach a steady potential, then to introduce a sample of the material to the pot. Where possible, size and physical form of the samples were selected to correspond with the maximum exposure likely in a practical battery. Working electrode potential was recorded daily, and any poisoning effect was detected by the resulting rise in potential. Corrections for *IR* drop were determined by a simple interruption technique.

Results and Discussion

One electrode was tested for several hundred hours in a solution free of impurities, using reagent-grade formaldehyde. The potential remained steady at 0.21 ± 0.02V *vs.* SHE throughout this time. The fuel supply was then changed to commercial 40% formaldehyde which contained some 8 ppm of iron. No evidence of poisoning was observed, and the electrode has now maintained the same potential for over 9000 hr.

The metals aluminum, zinc, and iron were tested as possible poisons. These are often present in liquid fuels stored in steel or aluminum containers and in contact with rubber seals or hoses. Aluminum was introduced to the test pot as chips of commercial metal which slowly dissolved, while the other metals were added as reagent-grade sulfates. In each case, the concentration was approximately 2 g/liter, but no poisoning was detected over periods exceeding 100 hr. This result for iron is in contrast to the poisoning detected by Witherspoon and Adams (1) using alkaline electrolyte and hydrogen anodes.

Further tests were made with 28g of unfilled polypropylene sheet and with 26g of plasticized PVC tube immersed in the solution. Slight poisoning (*see* Fig. 1) was apparent with PVC, perhaps from the plasticizer which was leached out by the acid formaldehyde solution.

Tests with rubbers and components of rubber compounds proved the most informative. As shown in Fig. 2, sulfur cured butyl rubber (used for seals in early battery tests) caused rapid and severe poisoning. Leaching the rubber samples for 4 weeks in a mixture of hot 2M sulfuric acid and ethanol retarded but did not eliminate this poisoning. Three other nonsulfur cured rubbers were tested—a peroxide cured ethylene-

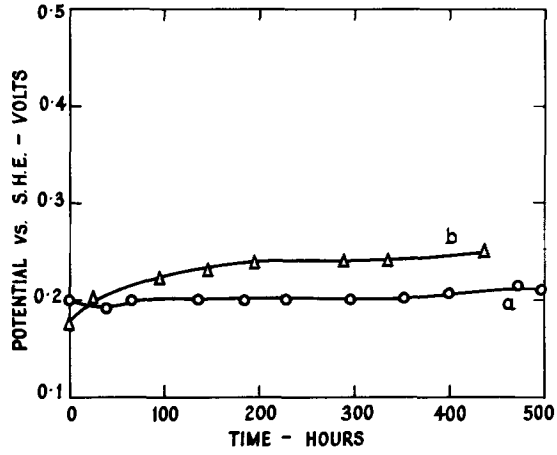

Fig. 1. Effect of plastics on formaldehyde electrodes: (a) 28g polypropylene (Shell KM 61) in cell; (b) 26g plasticized PVC tube (assorted pieces) in cell.

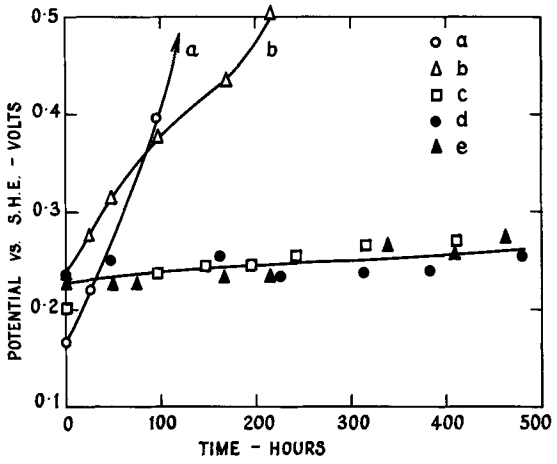

Fig. 2. Effect of rubbers on formaldehyde electrodes: (a) 20g sulfur cured butyl rubber in cell; (b) same as (a), but rubber preleached for 4 weeks in acid-ethanol solution; (c) 14g peroxide cured ethylene-propylene-diene terpolymer in cell; (d) 7g resin cured butyl rubber in cell; (e) 7g Permalux cured chlor-butyl rubber in cell.

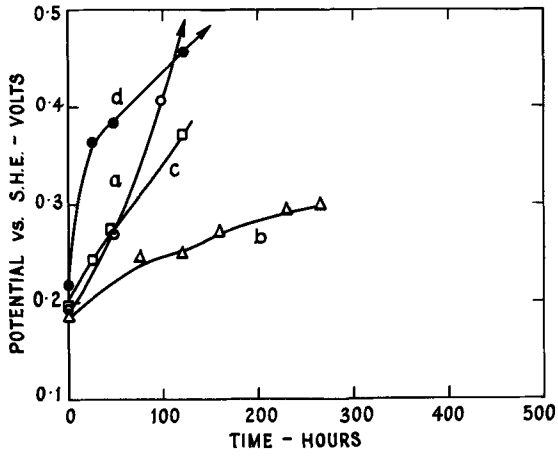

Fig. 3. Effect of rubber formulation components on formaldehyde electrodes: (a) 0.20g commercial sulfur in cell; (b) 0.10g mercaptobenzothiazole in cell; (c) 0.10g tetramethyl thiuram disulfide in cell; (d) 0.10g sodium diethyl dithiocarbamate in cell.

propylene-diene terpolymer, a resin cured butyl rubber, and a Permalux cured chlor-butyl rubber. (Permalux is a diorthotolyl guanidine salt of dicatechol borate.) The resulting potential changes (Fig. 2) were small or negligible. Slow poisoning was observed with some samples of ethylene-propylene-diene rubber, probably a result of contamination with traces of sulfur during manufacture.

Various components of these rubber compounds were then tested individually. Zinc oxide (*see* zinc test above), sample carbon blacks, a process oil, Permalux curing agent, and Santoflex I.P. anti-ozonant (N isopropyl N′ phenyl paraphenylene diamine) were found to cause no significant poisoning. Several sulfur-containing organic compounds, and also a sample of commercial sulfur, caused rapid poisoning (*see* Fig. 3). Evidently the hot acid-formaldehyde solution attacks these compounds, releasing sulfide ion or some other soluble sulfur species equally effective as a catalyst poison. These and similar compounds are widely used in rubber formulations as curing agents, accelerators, and anti-oxidants. Except where the sulfur is present in an oxidized form such as sulfate or polystyrenesulfonic acid, all sulfur-containing organic compounds need to be considered as possible catalyst poisons.

Conclusions

The catalysts used in this study are not affected by substantial concentrations of iron, zinc, and aluminum in solution.

Any sulfur-containing component should be completely eliminated from rubber formulations used for molding fuel cell frames or seals. Sulfur-free formulations are available which show reasonable acid resistance and life and eliminate the risk of catalyst poisoning. Unfilled polypropylene has proved a satisfactory material for construction, unlikely to affect electrode catalysts.

The Electrodeposition of Metals in Porous Glass

Francis P. Fehlner[1]

Research and Development Laboratories, Corning Glass Works, Corning, New York

Porous glass impregnated with a soft superconductor such as lead behaves like a hard superconductor having a high critical magnetic field (1). Schmidt and Charles (2) made such a material by hydrostatically injecting molten metal into the fine capillary labyrinth of porous glass. The metal was dispersed in the glass as filaments or adjoining spheres having a diameter of less than 100Å. In the present work, an electrochemical method has been used to impregnate Corning Code 7930 porous glass with both lead and silver.

[1] Present address: Signetics Corporation, Sunnyvale, California.

Experimental

Glass preparation proved to be the most critical step in the experimental procedure. Samples of 3/16-in. porous glass sheet (pore size: 40-60Å) 1½ in. square were cleaned by boiling in 5% H_2O_2 or baking in air at 500°C. Indium film electrodes, 1 in. square, were evaporated onto one side of the glass and a lead wire was attached to the electrode with indium solder. The edges of the glass and the electroded side were completely covered with paraffin. This was done so that the plating solution could only approach the indium electrode by

passing through the glass. The final step in preparing a sample for electrolysis was humidification of the glass so that it would not crack when it was introduced into the plating solution.

The unsymmetrical a-c electrolysis apparatus is outlined in Fig. 1. A negative d-c bias on the indium electrode is combined with a 60-Hz, half-wave rectified a-c signal to produce an unsymmetrical a-c signal. The waveform produced by this signal is shown in Fig. 2. The positive portion of the voltage waveform applied to the lead or silver electrode brings about plating in the pores of the glass. Conversely, the negative portion causes deplating. The plating/deplating ratio can be adjusted by changing the relative a-c and d-c components of the unsymmetrical a-c signal.

During the lead deposition in porous glass, the unsymmetrical a-c signal was applied for upward of 3 hr. A d-c level of 1V at 30 mA was employed but, because of the d-c blocking resistor located next to the a-c source (Fig. 1), an a-c level of 30 V_{RMS} was required to obtain 7 mA. These numbers are given to show the magnitudes involved, and are to be considered neither exact nor ideal, since some interference occurred between the a-c and d-c portions of the circuit shown in Fig. 1.

The lead-plating solution (3) consisted of the following compounds dissolved in distilled water: $Pb(OH)_2 \cdot 2PbCO_3$, 0.150g ml^{-1}; HF (50%), 0.240g ml^{-1}; and H_3BO_3, 0.105g ml^{-1}. The resulting solution was stirred at room temperature in a Teflon beaker. The counterelectrode was technical-grade sheet lead.

In the case of silver, a solution of 0.133g $AgNO_3$ ml^{-1} of distilled water was used, along with a sheet-silver counterelectrode.

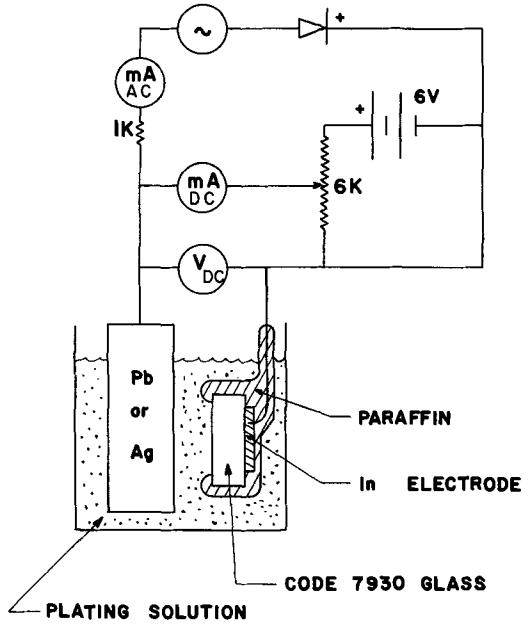

Fig. 1. Diagram of the circuit used for unsymmetrical a-c electrolysis.

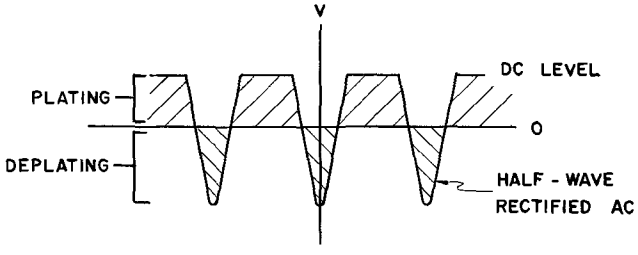

Fig. 2. Waveform of the unsymmetrical a-c voltage across the plating bath. The voltage level refers to the lead or silver electrode. Plating and deplating occur in the pores of the Code 7930 glass.

Results

Deposition of metal in the pores of Code 7930 glass did not begin immediately when a prepared sample was introduced into the plating solution and the unsymmetrical a-c voltage was applied. Instead, there was a lag of approximately 20 min during which the electrolyte diffused from the front of the glass, through the pores, to the indium electrode. After this induction period, a black deposit could be seen to grow over the indium and into the glass. This was the beginning of metal deposition in the pore structure.

Under the influence of a d-c potential alone, portions of the metal deposit grew faster than the rest of the deposit. These "leading dendrites" quickly reached the surface of the glass, preventing further deposition of metal in the pores. The unsymmetrical a-c electrolysis corrected this problem by deplating metal fastest at the points of highest potential gradient, *i.e.* at the "leading dendrites." During the subsequent plating pulse, metal was deposited uniformly over the whole growth front. In this manner, the "leading dendrites" were destroyed and the metal growth front advanced steadily through the sample.

The density of lead electrodeposited in Code 7930 porous glass was not as high as was theoretically possible. After 3 hr, only 10% of the pore volume had been uniformly filled with lead. It should be possible to improve both the rate of deposition and the per cent of pore filling by adjusting the process variables such as temperature and plating/deplating ratio.

Unsymmetrical a-c electrolysis has also been used to deposit filamentary silver in porous glass. Sample preparation and plating conditions similar to those used for lead gave good results. In fact, the silver samples appeared to be of better quality than the lead specimens.

Optical microscopy showed that the metal deposited in porous glass formed a dendritic structure which continuously branched into shorter and shorter limbs.

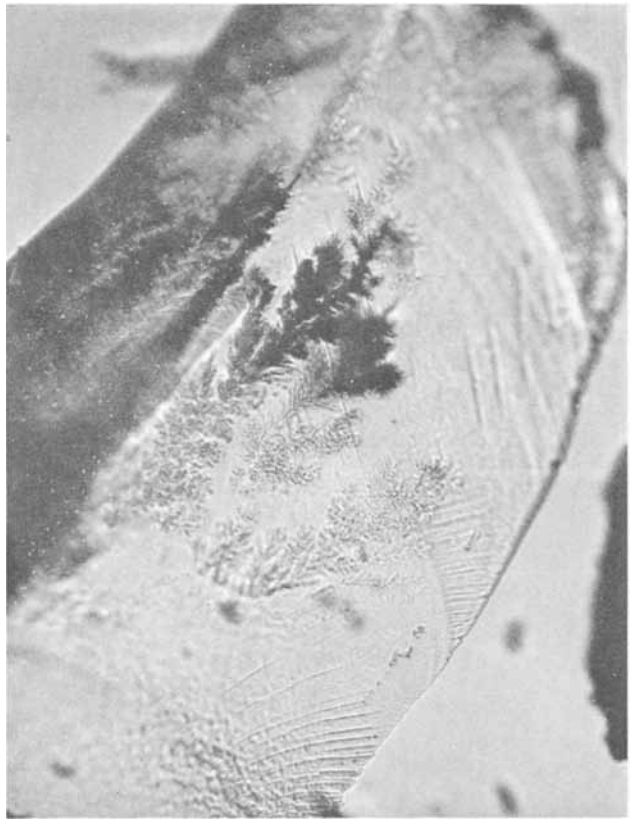

Fig. 3. Photomicrograph of lead electrodeposited in Code 7930 porous glass. Transmitted light; 200X.

An optical micrograph of chips from a lead-impregnated sample is shown in Fig. 3. The diameter of the smallest branches could not be resolved optically, although the dendritic structure, both in the direction of growth and in cross section, was readily visible. Electron microscopy of a silver deposit showed that the diameter of the metal filaments was less than 100Å. This compares well with the pore size of approximately 50Å.

Conclusions

Unsymmetrical a-c electrolysis is a useful method for impregnating the pores of Corning Code 7930 glass with metals. In the case of lead and silver, glass preparation is the most critical step in the procedure. However, it will be necessary to experiment further with the plating parameters, if a denser deposit is desired.

A Simple Procedure for Mounting Sodium-Tungsten Bronze Electrodes

R. S. Alwitt* and A. K. Vijh*,[1]

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

Recently, Mannan (1) has reported a rather elaborate method for mounting sodium-tungsten bronze electrodes in a glass-Teflon assembly. Here, a much simpler procedure, which is a minor variation of our previous suggestion for preparing metallic electrodes (2), is described.

A Na_xWO_3 crystal, C in Fig. 1(*a*), is chiseled with a diamond wheel and/or a diagonal cutter (or a suitable substitute) to give it the form of a crude cone. This chiseled end is deposited in the slightly funneled, flame-polished end of a "Trubore" (or any other) glass tubing, G [Fig. 1(*a*)]. After C is placed in G, this end of the glass tubing, G, is surrounded by a suitable length [Fig. 1(*b*)] of a special, heat-shrinkable, two-layered Teflon tubing available commercially (*e.g.*, "Flotite" manufactured by Pope Scientific Incorporated, Menominee Falls, Wisconsin). The Teflon tubing is then heated by means of a heat gun to $\geqslant$ 330°C *first* at glass-Teflon boundary (shown by 1) and then, after cooling, at the Teflon-glass-bronze boundary (as shown by 2). A compact and satisfactory seal of Teflon thus connects the bronze to the "Trubore" glass tubing. The electrical contact may then be made by means of a copper wire and a mercury drop (or some suitable substitute, *e.g.* Ga-In alloy). The electrode surface may be made smooth by polishing gently on an abrasive wheel with subsequent cleaning by a variety of solvents. A typical electrode thus obtained is shown schematically in Fig. 2.

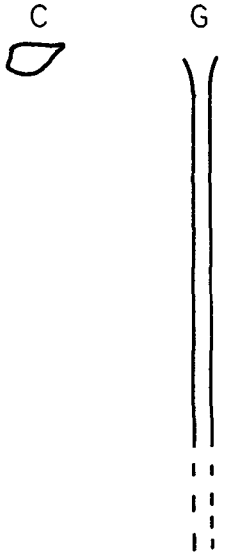

Fig. 1(*a*). A sodium tungsten bronze piece chiseled into a rough cone, C, and a "Trubore" glass tubing, G, with its end slightly funneled and flame polished.

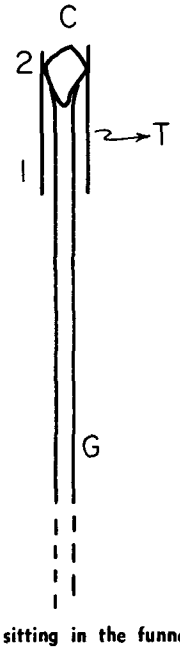

Fig. 1(*b*). Cone, C, sitting in the funneled end of glass tubing, G. The C-G boundary is surrounded by a piece of "Flotite" tubing, T. Heat must be applied first around the region marked 1 and then at 2.

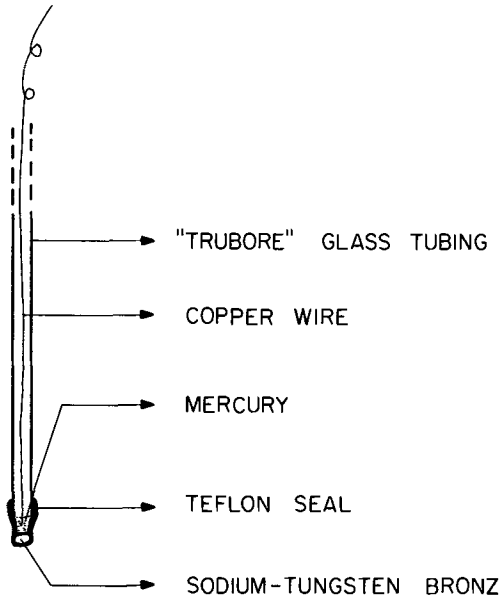

Fig. 2. A schematic representation of a sodium-tungsten bronze electrode mounted in a glass-Teflon assembly.

It may be added that, with slight obvious modifications, the described procedure may be used for mounting *any* metallic (2) or nonmetallic electrode material provided that it can withstand temperatures up to *ca.* 400°C [for substances with somewhat lower melting points, *see* Ref. (2)]. This procedure would thus be expected to be also suitable for preparing electrodes from germanium, silicon, graphite, carbides, borides, and a variety of other materials.

Acknowledgment

Thanks are due to Mr. J. McHardy of the Electrochemistry Laboratory, University of Pennsylvania, for providing sodium-tungsten bronze crystals.

Manuscript received Aug. 1, 1969.

Erratum

In the paper "Studies on Chlorate Cell Process, V. Theory and Practice of a Modified Technology for Electrolytic Chlorate Production" by M. M. Jaksić, A. R. Despić, I. M. Csonka, and B. Z. Nikolić which was published on pp. 1316-1322 of the September 1969 issue of the JOURNAL, Vol. 116, No. 9, several errors appeared in Appendixes I and II (pp. 1320-1322). The corrected Appendixes follow.

APPENDIX I

One can arrive at Eq. [5] both in the given and an extended form, which takes into account all kinds of losses in the electrolytic production of chlorate for a closed-loop system, by considering the material balance of available chlorine with respect to the cell at quasi steady-state condition, which is defined by [*cf.* (4)]

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right) = 0 \qquad [15]$$

The partial contributions of individual components of production, consumption, and loss of available chlorine during the process would be as follows:

(*a*) Anodic generation of available chlorine, which is converted to chlorate by two possible parallel paths (Eq. [2] and [3])

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{G1} = \frac{t_1 \cdot I}{2\mathbf{F}} \qquad [16]$$

where t_1 is the fraction of current used for generation of chlorine by anodic oxidation of chloride

$$2Cl^- \rightarrow Cl_2 + 2e \qquad [17]$$

with subsequent hydrolysis

$$Cl_2 + 2H_2O \rightleftharpoons HClO + H_3O^+ + Cl^- \qquad [18]$$

and *conversion* (Eq [2]), or further *anodic oxidation* (Eq. [3]) to chlorate.

(*b*) Anodic generation of available chlorine, which is subsequently lost in the electrolytic production process by cathodic reduction

$$ClO^- + H_2O + 2e \rightarrow Cl^- + 2OH^- \qquad [19]$$

is described as

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{G2} = \frac{t_2 \cdot I}{2\mathbf{F}} \qquad [20]$$

where t_2 is the fraction of the current used for generation of that part of available chlorine.

(*c*) Anodic generation of available chlorine, which is subsequently lost by evaporation in the hydrogen stream

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{G3} = \frac{t_3 \cdot I}{2\mathbf{F}} \qquad [21]$$

where t_3 is the fraction of the current used for unhydrolyzed chlorine.

(*d*) Further anodic oxidation of available chlorine to chlorate (Eq. [3]).

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{OX} = -\frac{t_4 \cdot I}{\mathbf{F}} \qquad [22]$$

where t_4 is the fraction of the current for the anodic chlorate formation.

(*e*) Available chlorine consumption by cathodic reduction

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{RED} = -\frac{t_2 \cdot I}{2\mathbf{F}} \qquad [23]$$

which corresponds to Eq. [20].

(*f*) Current losses by chlorine evaporation in the hydrogen stream

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{E} = -\frac{t_3 \cdot I}{2\mathbf{F}} \qquad [24]$$

(*g*) Conversion of available chlorine to chlorate (Eq. [2]) inside the cell (18, 19), which operates as back-mix flow reactor

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{CH} = -3f_c^2 \cdot k_{r,c} \cdot V_c \cdot [HClO]_c^2 \cdot [ClO^-]_c \qquad [25]$$

(*h*) The difference in quantities of available chlorine leaving the cell and entering the cell from the holding volume in the considered time interval (which is equal to the conversion of available chlorine to chlorate inside the holding volume)

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{H} = -q(C_{sc} - C_{sh}) \qquad [26]$$

The material balance (Eq. [15]) thus is given by the following relation

$$\frac{t_1 \cdot I}{2\mathbf{F}} + \frac{t_2 \cdot I}{2\mathbf{F}} + \frac{t_3 \cdot I}{2\mathbf{F}} - \frac{t_4 \cdot I}{\mathbf{F}} - \frac{t_2 \cdot I}{2\mathbf{F}} - \frac{t_3 \cdot I}{2\mathbf{F}} - 3f_c^2 \cdot k_{r,c} \cdot V_c \cdot [\mathrm{HClO}]_c^2 \cdot [\mathrm{ClO}^-]_c - q(C_{sc} - C_{sh}) = 0 \quad [27]$$

Individual fractions of the anodic current are, in that case, connected by the relation

$$t_1 + t_2 + t_3 + t_4 = 1 \quad [28]$$

By combining Eq. [27] and [28], one obtains the explicit expression for the current efficiency on chlorate

$$t_1 = \frac{2}{3} + \frac{2f_c^2 \cdot k_{r,c} \cdot V_c \cdot \mathbf{F}}{I} \cdot [\mathrm{HClO}]_c^2 \cdot [\mathrm{ClO}^-]_c + \frac{2}{3}\mathbf{F}\left(\frac{q}{I}\right) \cdot (C_{sc} - C_{sh}) - \frac{2}{3}(t_2 + t_3) \quad [29]$$

in which further transformations of the second and third terms are possible, as given in the main part of the paper. By dividing all terms of Eq. [27] by three, one can relate the generation and consumption of available chlorine with chlorate production, which means that t_1 also defines the current efficiency in the process of electrolytic chlorate production.

The current losses due to the catalytic decomposition of available chlorine and chlorate, or the anodic oxidation to perchlorate, are practically avoided under normal conditions of production, and thus need not be taken into consideration in the presented analysis.

The fraction of the current loss due to cathodic reduction is given as a ratio of the difference between the theoretical amount of hydrogen (V_o) and that actually produced amount (V_1), to the theoretically given amount (V_o) for a certain duration of electrolysis, namely

$$t_2 = \frac{V_o - V_1}{V_o} \quad [30]$$

The fraction of the current loss due to chlorine evaporation can also be determined by gas analysis as the ratio of percentage fractions of chlorine (Q) and hydrogen (H)

$$t_3 = \frac{Q}{H} \quad [31]$$

under the conditions of negligible cathodic reduction of available chlorine. If it is not negligible, this relation gives the ratio of evaporated chlorine to the theoretical amount of hydrogen developed for the same time interval.

In the presence of dichromate ions, with sufficiently high current densities and in a suitably defined pH region, both kinds of loss tend to zero, and Eq. [29] reduces to Eq. [5].

APPENDIX II

The equation for calculating the current efficiency from the gas analysis, which takes into account all kinds of losses, listed in Appendix I, can be derived using Faradaic stoichiometry, *i.e.* coulometric balance.

Consider the passage of N faradays through the cell during a definite time interval under quasi steady-state conditions of electrolytic chlorate production. This should be distributed as follows:

(*a*) Let x be the fraction of the charge, N, at the anode which is used to oxidize those chloride ions (Eq. [17]), which on discharge give molecular chlorine subsequently lost by evaporation (unhydrolyzed chlorine). Then $x \cdot \mathbf{F}$ produce $x/2$ moles of evaporated chlorine at the anode, and $x/2$ moles of hydrogen at the cathode.

(*b*) Let y be the fraction used to oxidize chloride ions which produce available chlorine to replace that which is consumed by chemical conversion to chlorate (Eq. [2]). Then $y \cdot \mathbf{F}$ produce $y/2$ moles of available chlorine at the anode and $y/2$ moles of hydrogen at the cathode.

(c) Let z be the fraction used to oxidize further the available chlorine into chlorate (Eq. [3]). Then $z/4$ moles of oxygen are produced at the anode and $z/2$ moles of hydrogen at the cathode.

d) Let w be the fraction which produces hypochlorite ions to replace those reduced at the cathode (Eq. [19]). Then $w \cdot \mathbf{F}$ produce $w/2$ moles of available chlorine at the anode and reduce the same amount at the cathode.

All the fractions must sum up to give the total amount of charge as

$$x + y + z + w = N \quad [32]$$

The fraction of oxygen (S) in the gas mixture should then be

$$S = \frac{\mathrm{O_2}}{\mathrm{H_2} + \mathrm{O_2} + \mathrm{Cl_2}} = \frac{\frac{z}{4}}{\left(\frac{x}{2} + \frac{y}{2} + \frac{z}{2} + \frac{z}{4} + \frac{x}{2}\right)} \quad [33]$$

while the content of unhydrolyzed (evaporated) chlorine (Q), obtained by gas analysis, is given by the equation

$$Q = \frac{\mathrm{Cl_2}}{\mathrm{H_2} + \mathrm{O_2} + \mathrm{Cl_2}} = \frac{\frac{x}{2}}{\left(\frac{x}{2} + \frac{y}{2} + \frac{z}{2} + \frac{z}{4} + \frac{x}{2}\right)} \quad [34]$$

The current fraction lost by cathodic hypochlorite reduction ($P = t_2$) is expressed by the following relation

$$P = \frac{\frac{w}{2}}{\left(\frac{x}{2} + \frac{y}{2} + \frac{z}{2} + \frac{w}{2}\right)} \quad [35]$$

The current efficiency of chlorate formation (t_1), which has to be equal to the theoretical amount of electricity required for the yield divided by the actual amount used, is then given, expressed as a fraction of unity, by

$$t_1 = \frac{\frac{y}{2}}{\left(\frac{x}{2} + \frac{y}{2} + \frac{z}{2} + \frac{w}{2}\right)} \quad [36]$$

Equations [33-36] represent a system of four homogenous linear equations, which can be solved for t_1 by eliminating the unknown quantities x, y, z, and w

$$t_1 = \frac{(1 - 2Q - 3S)(1 - P)}{1 - Q - S} \quad [37]$$

The partial fractions of oxygen (S) and chlorine (Q) are determined by the gas analysis, while the determination of the current fraction losses by hypochlorite reduction at the cathode ($P = t_2$) is discussed in Appendix I. Carbon dioxide is added to the oxygen content in the present calculations.

Unsteady-State Phenomena on Oxygen Cathodes of Hydrogen-Oxygen Fuel Cells

Joseph O. DeVet,[1] Ronald G. Barile, and Lyle F. Albright

School of Chemical Engineering, Purdue University, Lafayette, Indiana

ABSTRACT

The phenomenon of oxygen transfer to the surface of a platinum cathode has been clarified for a hydrogen-oxygen fuel cell. The cathode which was partially submerged in acid electrolyte was investigated at various steady-state conditions, for various methods of raising and lowering, and at several start-up conditions. Large currents are generated in the cathodic area close to the meniscus because transfer of oxygen is relatively easy there. Larger currents can be obtained by lowering or in some cases by raising a cathode which is partially immersed in the acid electrolyte.

Convincing evidence has been presented recently that the most important reaction zone on the anode of a hydrogen-oxygen fuel cell is the thin portion of the meniscus and the adjacent thin film of electrolyte (1-6). The diffusion path of the hydrogen from the gas phase to the electrode surface is short in this zone, and concentration polarization is reduced (3, 4, 7-9).

Vertical movements of the anode of a hydrogen-oxygen cell partially immersed in acid electrolyte were found by Will (3) to produce significant transient effects. Currents were initially depressed when a platinized anode was raised, but they were increased when it was lowered. Ennis (6) found, however, for a sand-blasted platinum anode that the currents were larger than steady-state with both raising and lowering. Davitt and Albright (5) resolved this apparent anomaly by demonstrating that the character of the surface roughness is important relative to these transient currents. They also reported large initial surges of current with quick anode lowering and increased currents with gradual constant-speed lowering. The average current was found to depend on the rate of anode movements, applied potential, and surface condition.

In the present investigation, unsteady-state current responses during cathode motion were studied. The objectives were to provide detailed data for motion of the oxygen cathode in acid electrolyte similar to those presented by Davitt asd Albright (11) for the anode and to examine further the constant-speed lowering phenomena. Steady-state, stationary-cathode data are compared with the unsteady-state currents. Current changes during lowering are proposed to be similar to the transient currents at cell start-up. Results of cathode raising are explained in terms of changes in the meniscus region.

Experimental

The cell was constructed mainly of borosilicate glass (Pyrex) and consisted of a large cathode chamber separated from the smaller (450 ml) anode chamber by a porous glass disk. The electrolyte was 1*N* sulfuric acid prepared from reagent grade acid and distilled water. A bubbler, which was immersed in the electrolyte 4 in., was shielded by a glass cylinder with an open end immersed 5 in. Oxygen was bubbled through the electrolyte at the rate of about 800 cc/hr and then flowed to the cathode chamber. A glass stirrer was used to agitate the electrolyte and assure its homogeneity. The temperature of the electrolyte was maintained at 30° ± 0.3°C, and the cathode chamber was operated at atmospheric pressure.

The three cathodes used were prepared from platinum foil 0.0125 cm thick and 3 cm wide by 8 cm high. The top of each cathode was spot-welded to a 12 cm length of platinum wire which was connected by copper wire to the external circuit. The first cathode (S) was unaltered foil with a mirror-like surface. It produced low currents which did not achieve steady-state but which decayed over long periods of time. Similar difficulties with smooth platinum has been reported by others (4). Because a reliable steady-state reference could not be developed for this cathode, only limited experimentation was tried with it. The other two cathodes were platinized using 10% chloroplatinic acid and a current density of 10 mA/cm^2. Platinizing for 120 sec produced a "moderately platinized" cathode (henceforth called cathode M) and for 240 sec yielded a "heavily platinized" cathode (cathode H). Roughness factors (BET surface/geometric surface) for the three cathodes were calculated to be 1, 75, and 150 for the smooth, moderately platinized, and heavily platinized cathodes, respectively. These calculations are based on the measured capacitances at the rest potential and the specific capacitance (capacitance/BET surface area) reported earlier (10, 11).

The anode (often partially submerged in the electrolyte) consisted of two rectangular strips of platinum foil totaling 48 cm^2 geometric surface area, which was platinized for 5 min at a current density of 20 mA/cm^2. Hydrogen was continuously supplied to the anode chamber at approximately 800 cc/hr.

Potentials were referred to a Leeds and Northrup saturated calomel electrode (SCE) which has a poten-

[1] Present address: Humble Oil and Refining Company, Baytown, Texas.

tial relative to the normal hydrogen electrode (NHE) of 0.242V at 30.0°C (12). A potentiostat similar to the one described by Schwarz and Shain (13) was used to control the cathode potential. Current measurements were reported continuously on a Sargent Model SR recorder.

A glass tube through which the electrical lead from the cathode was passed was used as a support for the cathode. It was often connected to a motor-driven elevator for adjusting the vertical height of the cathode at various constant rates. Alternatively, the position could be hand adjusted by 2 to 4 cm in less than 1 sec. The currents as reported here for stationary positions of the cathode are the steady-state values obtained after about 20-40 min. For runs at a constant rate of raising, the fully submerged cathode was first allowed to reach a steady-state current before raising was started.

Prior to each run the electrode was cleaned by immersion for 0.5 hr in a solution of 20% reagent grade nitric acid at the boiling point. After a thorough rinse in distilled water the cathode was introduced into the cell, and the cell was allowed to equilibrate 4-12 hr before the start of the run. Experiments with stationary cathodes resulted in currents which were reproducible to within ±3%, while those with moving cathodes were reproducible to within ±5%.

Results

Stationary cathodes.—The current phenomena for the moderately platinized and the heavily platinized cathodes were investigated at cell start-up. In each case, the cathode was immersed in the electrolyte and then allowed to equilibrate in the system for at least 3 hr at open-circuit. The circuit was then closed, and a given potential was applied. Figure 1 indicates resulting current responses reported as mA/cm² for both cathode M (moderately platinized cathode) and cathode H (heavily platinized cathode).

A high initial current was obtained in all cases at start-up, but the current decayed rapidly toward the steady-state value in the first few minutes. Higher initial currents were obtained at 0.158V as compared to 0.558V. The difference in the results for the two cathodes at 0.158V was small. If the cell was shut down (*i.e.*, the circuit was opened) and then restarted within less than 3 hr, the initial current was less than that shown in Fig. 1. Hence equilibration of the cathode with the surroundings is an important consideration.

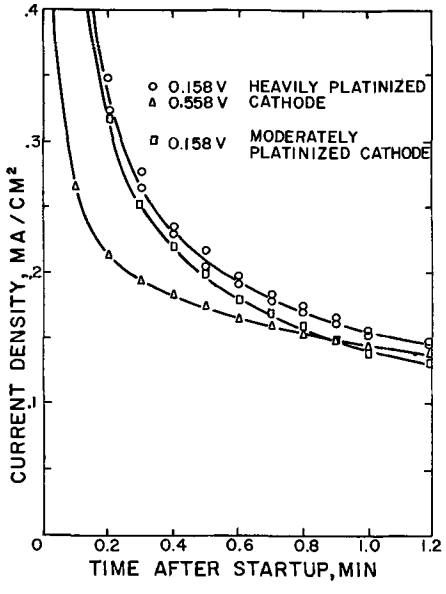

Fig. 1. Current as a function of time after cell start-up for heavily platinized cathode (cathode H) and for moderatively platinized cathode (cathode M).

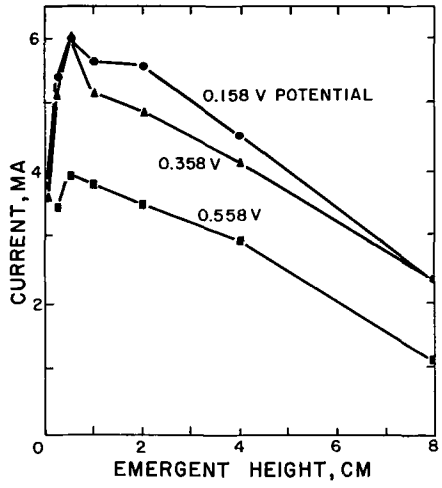

Fig. 2. Current as a function of emergent height for cathode H at three applied potentials.

Steady-state currents were obtained after about 20-40 min, and these currents were investigated as a function of the length of the cathode extending above the surface of the electrolyte, called here the emergent height, h. Figure 2 shows the results for cathode H at heights between fully submerged, $h \leq 0$, and just touching the electrolyte (but with a complete meniscus), $h = 8$ cm. The results for cathode M were essentially identical.

The meniscus contributed the increase in the steady-state current between $h = 0$ and approximately $h = 0.5$ cm (at which height the meniscus was fully developed), or the total current at $h = 8$. In most cases, these two current values were identical within experimental accuracy. The completely submerged cathode of course contributed the current at $h = 0$. The currents at 0.158 and 0.358V were quite similar and significantly higher than those at 0.558V. At about $h = 0.5$ cm, the meniscus produced for cathodes M and H approximately 40% of the total current at 0.158 and 0.358V, and about 30% at 0.558V. The meniscus for the smooth cathode (cathode S) however produced less than 5% of the current for that cathode. At 0.158V, the meniscus for cathodes M and H contributed about 0.38 mA/cm of meniscus length which is in excellent agreement with 0.40 mA/cm found by Maget and Roethlein (4) at 0.156V.

Comparisons of the currents obtained from similarly polarized cathodes and anodes are of interest. Table I gives one such comparison. The results of cathode H at 0.158V and of the anode at 0.55V as used by Davitt and Albright (5) were used to prepare this table. These voltages represent polarizations (deviations from open circuit) for the similarly activated electrodes of about 0.6 and 0.8V, respectively. The current density of the completely submerged cathode was about 60% greater than that of the submerged anode. The meniscus current of the anode was, however, about 4.7 times greater than that of the cathode. Comparisons of the meniscus

Table I. Comparison of currents generated at cathode and anode

	Cathode, (this work)	Anode (5)
Potential SCE	0.158V	0.55V
Polarization	0.6V	0.8V
Dimensions	3 cm × 8 cm	2.5 cm × 8 cm
Geometrical surface area, cm²	48	40
Current when completely submerged, mA	3.8	2.0
Current when completely submerged, mA/cm²	0.08	0.05
Meniscus current, mA	2.2	9.0
Current per linear length of meniscus, mA/cm	0.37	1.8
Estimated current density in meniscus area (0.25 cm meniscus height assumed)	1.5	7.2

currents for an anode (3) and of a cathode (4) at lower polarizations gave a similar result. Current densities in the meniscus region are greater by a factor of about 20 and 150 as compared to the densities in the submerged portions of the cathode and anode, respectively, if it is assumed that the effective height of the meniscus in each case is 0.25 cm.

Rapid height changes of cathodes.—Current-time response was investigated for a rapid change in height (within 1 sec or less) from $h = 2$ to $h = 6$ cm, or vice versa. Lowering cathode H caused the currents at potentials of 0.158 and 0.558V to first surge rapidly above 14 mA and then to decay in a few seconds to within 3 mA of the new steady-state currents at $h = 2$ cm (see Fig. 3). The current-time response when the cathode was quickly lowered from a position completely withdrawn from the electrolyte to a given emergent height h was found to be identical within experimental accuracy to the response for the start-up of the stationary cathode at the same height.

Raising cathode H rapidly caused an initial current depression then a 5-10 mA surge and finally a decay to the steady-state current at $h = 6$ cm, as shown in Fig. 4. The current surges and the time of decay were considerably greater at 0.158V than at 0.558V. The current responses for both rapid raising and lowering were found to be quite similar for cathodes H and M.

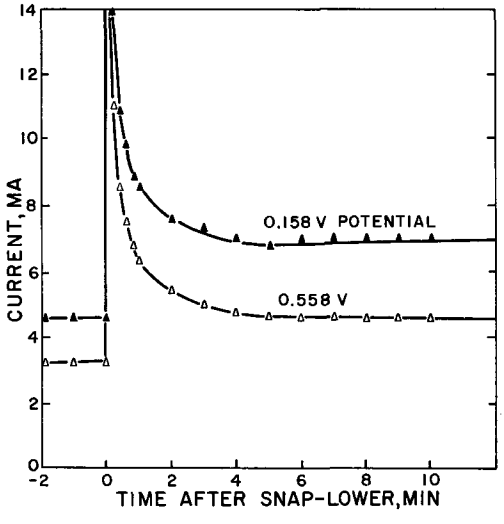

Fig. 3. Current as a function of time after rapid lowering of cathode H.

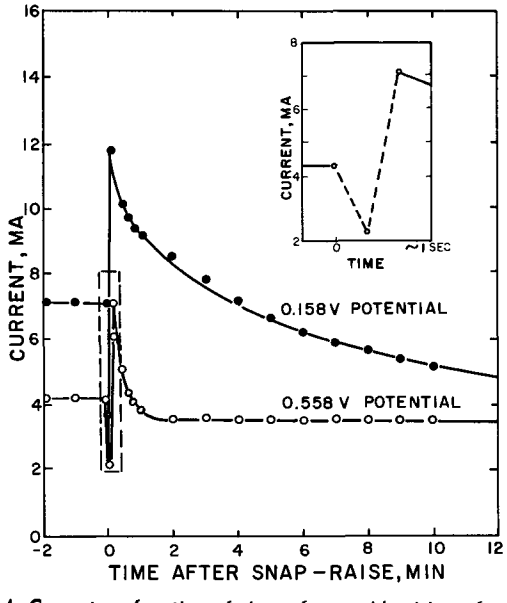

Fig. 4. Current as function of time after rapid raising of cathode H. The insert indicates the current response immediately after raising the cathode at 0.558V.

Constant-speed movement of cathode.—Constant-rate raising or lowering experiments with cathodes M and H were begun with the cathode either completely submerged at steady-state current or completely exposed to an oxygen atmosphere, respectively. Figures 5 and 6 show results for cathode H at 0.558 and 0.158V, respectively. In these figures, the current was plotted *vs.* the emergent height for various rates of lowering and raising. Larger increases of current were obtained especially at 0.158V, as the rate of lowering increased. The currents for the stationary cathode (*i.e.*, zero rate of lowering) are also shown and designated as steady-state currents. About a seven-fold increase was obtained when the rate of lowering was 18.5 cm/min as compared to the currents for the stationary cathodes.

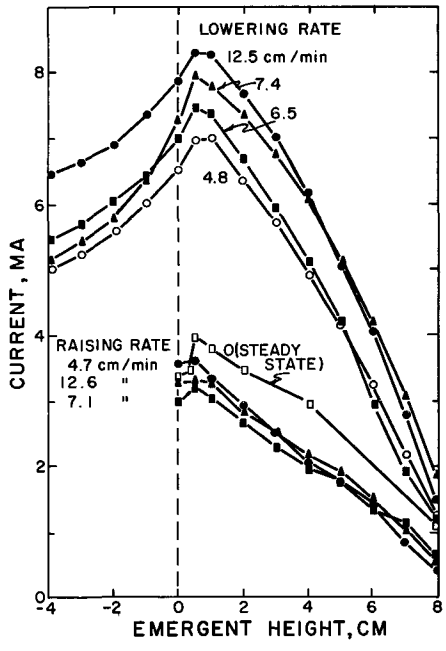

Fig. 5. Current as a function of emergent height during constant-speed motion of cathode H at 0.558V.

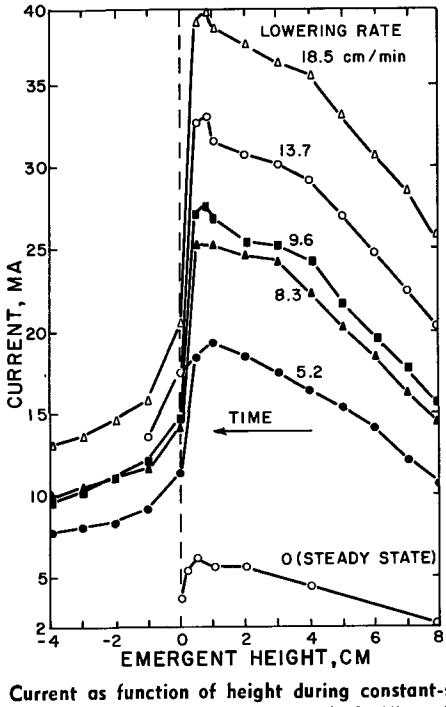

Fig. 6. Current as function of height during constant-speed lowering of the heavily platinized cathode (cathode H) at 0.158V potential.

These higher currents continued even when the cathode was completely submerged in the electrolyte, that is for $h < 0$ cm.

Raising cathode H at rates of 4.7-12.6 cm/min caused the current to decrease slightly as compared to the steady-state values of current when the potential was 0.558V, as also shown in Fig. 5. Larger currents were obtained however at 0.158V when the cathode was raised at constant rates. In general, this trend was proportional to the rate of raising as the rate was increased to about 8 cm/min. About a 2-fold increase of current was obtained at this rate as compared to the currents for the stationary cathode. No significant change in current was noted however between raising rates of 8.0 and 18.4 cm/min.

The average current obtained during either the raising or the lowering of the cathode at constant speed was calculated by averaging the current-emergent height data from 0 to 8 cm. Such an averaging technique is useful in quantitatively comparing how the rate of lowering or raising the cathode affects the current density. Results for raising and lowering at both 0.158 and 0.558V with cathodes H and M are shown in Fig. 7. Cathode H produced slightly higher currents, but the types of electrode surface had relatively less effect as compared to the applied potential and the direction of motion.

Discussion of Results

The general phenomena and current responses noted in the present investigation for various cathodes were quite similar in character to those noted earlier for anodes (5). As had also been found in the anode study, the current generation is controlled to a considerable extent by physical effects rather than by electrochemical ones. Controlling factors for the cathode include transfer of the oxygen to the electrode and the character of both the meniscus and adjoining film.

The results of Fig. 2 indicate that steady-state currents for partially submerged cathodes were diffusion controlled, especially in the range of 0.158-0.358V. In this range, they increased slightly with decreasing potential. Activation control is thought, however, to be limiting at 0.558V and above, at which potentials considerably lower currents are obtained. These conclusions and the general character of the current-height curves are in good agreement with Maget and Roethlein (4).

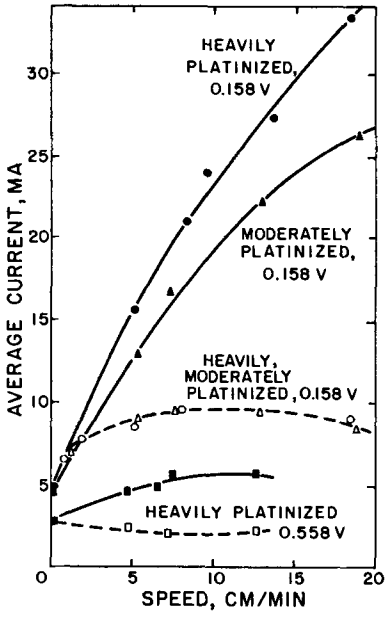

Fig. 7. Average current as a function of speed during constant-speed motion of cathodes (solid lines indicate lowering experiments and dotted lines indicate raising experiments).

Current on fully submerged electrode.—When a gas diffuses through a liquid as is occurring at both the cathode and the anode, the molar flux (N) for such a transfer is expressed by Fick's law (12). For a dilute system, the molar flux through a given thickness of liquid to a flat electrode is proportional to the product of the diffusivity coefficient (D) of the gas and the concentration gradient (ΔC)/L of the gas dissolved in the liquid

$$N_{gas} = D_{gas\text{-}liquid}\, \Delta C/L$$

ΔC is equal to the concentration in the main body of the electrolyte minus the concentration at the electrode surface and L is the diffusion layer thickness. For diffusion-limited conditions such as frequently occur in the case of the submerged cathode or anode (5), the reactant concentration at the surface is essentially zero. The dissolved concentration in the bulk of the electrolyte in this work is almost equal to the saturated concentration since efforts were made to keep the electrolyte saturated.

Using available values for the diffusivity coefficients and for the equilibrium concentrations of the two gases in water (14), the diffusion layers for the cathode and anode were calculated to be in the range 1000-2000 μ thick. For the conditions compared in Table I, the diffusion layer for the cathode was the thicker of the two. These calculations indicate that the ratio of the current densities generated on the submerged portions of a cathode and anode are at least in relatively good agreement with theory if diffusion is the rate-limiting step.

Meniscus current.—Currents generated in the region of the menisci of both the cathode and anode are diffusion controlled (rather than limited) at high polarizations, *e.g.*, 0.158V for the cathode or 0.56V for the anode. The controlling step is slow diffusion but current is nevertheless dependent on potential because the molar driving force, $C_{bulk} - C_{adsorbed}$, varies as $C_{adsorbed}$ varies with potential (3,15). Although the driving force is larger in the fully submerged region where $C_{adsorbed} = 0$, the diffusion length is smaller in the upper portions of the meniscus where the liquid thickness is 50μ or less. Significantly increased current densities are generated in these portions of the meniscus (4).

Raising cathodes.—Rapid raising of cathodes acted to disrupt and extend the stationary meniscus and film which were relatively oxygen-rich as compared to the diffusion layer surrounding the submerged portion of the cathode. The following events likely occur after the cathode is moved:

(*i*) The original meniscus is stretched and thinned. The newly formed meniscus has a lower concentration of oxygen than the original.
(*ii*) Motion of the electrode causes disturbance of the diffusion layer surrounding the cathode, forced convection currents are induced in the electrolyte, and the oxygen transfer rate increases.
(*iii*) Electrolyte clinging to the withdrawn portion of the cathode absorbs oxygen as it drains into the meniscus increasing available oxygen for reaction.
(*iv*) Eventually a stable meniscus is reformed and steady-state concentrations develop resulting in a steady-state current.

These meniscus effects, which likely occur more or less in a chronological order, suggest a rationale for the observed current phenomena after a quick raise of the cathode. Step (*i*) is the reason for the initial drop of current. Sudden meniscus stretching causes a condition similar to a thin film above a stationary meniscus where it has been shown that concentration and ohmic polarization both limit current (4). Steps (*ii*) and (*iii*) are responsible for the higher currents

noted, as shown in Fig. 4, before steady-state conditions are established.

Whether the currents obtained during constant-speed raising are greater or less than the steady-state current depends on the applied potential. Since the slopes of constant-speed raising curves are about equal to the steady-state slopes (see Fig. 5), meniscus changes are presumably responsible for the major deviations from steady-state currents. All the meniscus effects postulated for quick raising should apply to constant-speed raising, but they would occur simultaneously. Meniscus stretching and lower meniscus oxygen concentration would reduce current, whereas forced convection to the submerged electrode and electrolyte draining would counteract this tendency. The over-all effect is a slight decrease in current during steady raising at 0.558V and a moderate increase at 0.15V (not shown) compared to steady state. Note that a slow activation step at 0.558V more than cancels convection and draining during steady raising, but for quick raising the larger molar convection flux apparently increases oxygen concentration at the submerged electrode surface to an extent that the slow reaction is accelerated.

Lowering cathodes.—The large current surges with rapid lowering of the cathode are thought to be caused by at least one of the following two factors:

1. The lower end of the cathode moves into fresh electrolyte in which the concentration of the oxygen is high.

2. The portion of the electrode initially above the electrolyte surface carries some absorbed oxygen (and oxygen dissolved in the electrolyte film) into the electrolyte where it quickly reacts. The exact condition of the oxygen is not known. Some of it may be present as a chemisorbed state and some as a platinum oxide (16). This latter phenomenon is designated as the start-up effect.

It is of interest to note that the relationship between current and time is essentially identical for both quick lowering of the cathode into the electrolyte and for start-up of the cathode after open circuit. The same effects which cause the current surges with quick lowering of the cathode are apparently responsible for the current behavior with constant-speed lowering. A differential area on the cathode surface experiences a surge in current density when it first contacts the electrolyte. The current generated at this area then decays (as at cell start-up, see Fig. 1) as the cathode moves into the electrolyte. The bottom edge of the cathode however continuously encounters fresh electrolyte and its current density will therefore be maintained at a relatively high level.

A simplified model is proposed for a cathode which is lowered at a constant rate into electrolyte. The start-up effect for this model is arbitrarily assumed to apply only to the upper half of the submerged portion of the cathode. The fresh electrolyte effect is assumed to apply to only the lower half of the cathode. Calculations were performed for cathode H at 0.158V. Current densities on the upper half of the submerged portion of cathode H were calculated using the start-up data for this cathode. An arbitrary function for the fresh electrolyte effect was devised so that the predicted value at $h = 4$ cm and 8.3 cm/min fit the actual current data. The function was actually the measured start-up current for time ≥ 0.2 min with the initial current surge replaced by a smoothed curve extrapolated to 0.86 mA/cm^2 at time $= 0$. This same function was used in subsequent calculations for other rates of lowering. Calculated curves for 5.2, 8.3, and 18.5 cm/min are presented in Fig. 8.

The model rather accurately predicts the results for low-speed lowering, but it is less accurate at higher rates. It is inaccurate up to about 20% for 13.7 cm/min and up to 25% for 18.5 cm/min. When the model was modified, however, to include the start-up effect over

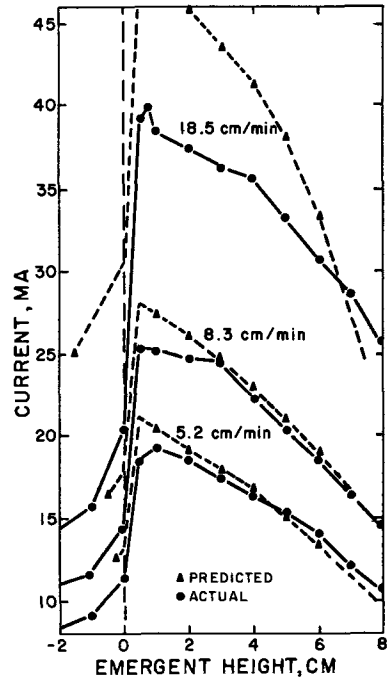

Fig. 8. Predicted model for average current as function of emergent height during constant-speed lowering of cathode H at 0.158V (dotted lines indicate predicted values and solid lines indicate experimental values).

the entire cathode, the model accurately represented the results at 18.5 cm/min. It seems logical that the start-up effect would be more important and the fresh electrolyte effect less important for higher rates of lowering of the cathode. In such cases, the oxygen at or near the cathode would be less depleted between $h = 8$ and $h = 1$ cm, and the relative contribution of oxygen convection from the bulk electrolyte would be reduced.

Figure 9 illustrates qualitatively the proposed manner in which the current density varies with the submerged distance during cathode lowering. These curves are based in part on the model just described. Since the model is accurate at low speeds, the proposed low-speed current density profile is similar to the profiles assumed for the model, *i.e.*, there is a significant fresh electrolyte effect at the lower end of the cathode. The predictions of the model were too high at higher

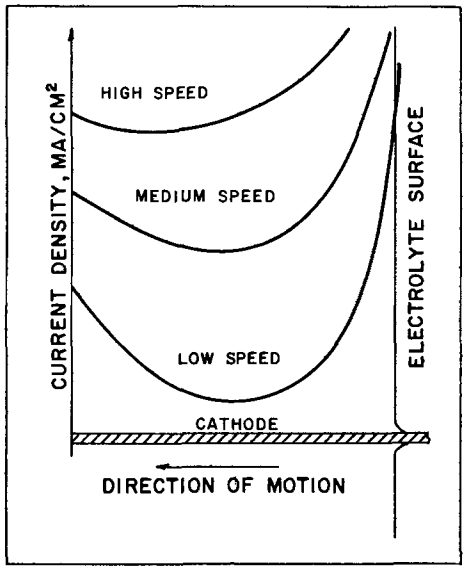

Fig. 9. Proposed family of current density profiles for a cathode being lowered.

speeds, and the error was probably caused by overestimating the importance of the fresh electrolyte effect. The proposed current density profile for high-speed lowering includes less allowance for this effect than does the model.

Conclusions

Transfer of oxygen is controlling in the reactions which occur on the surface of a highly polarized cathode that is partially immersed in a dilute acid electrolyte. Large currents are generated in the cathodic area close to the meniscus because transfer of oxygen is relatively easy there. Larger currents can be obtained by lowering or in some cases by raising a cathode which is partially immersed in the acid electrolyte.

The Hydrated Nickel Hydroxide Electrode Potential Sweep Experiments

D. M. Mac Arthur*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The mechanism of the hydrated nickel hydroxide electrode, used in the nickel cadmium battery, is a matter of considerable controversy. Potential sweep experiments were performed on film nickel hydroxide electrodes in an effort to determine the oxidation-reduction mechanism. The existence of more than one reduced structure was confirmed and the structure known as α-nickel hydroxide was studied in detail. A model based on a reversible charge transfer step with a rate-controlling diffusion process was used to analyze the data. The results were in good agreement with the model. The over-all reaction for α-nickel hydroxide was found to be

$$2[3Ni(OH)_2 \cdot 2H_2O] + 6\,OH^- + 3/2KOH \rightleftarrows 2[3NiOOH \cdot 7/2H_2O \cdot 3/4KOH] + 3H_2O + 6e^-$$

The rate-controlling process, which was assumed to be proton diffusion, was found to have a diffusion coefficient of approximately 2×10^{-9} cm^2 sec^{-1}. Evidence for the formation of a poorly conducting layer during discharge of the electrode was found and capacity loss was attributed to this.

The commercial success of the nickel cadmium battery has aroused considerable interest in the nickel electrode used in this battery. Many studies (1-4) have been reported in which the structure and the electrochemical mechanism have been the subject of investigation. No real progress was made in understanding this electrode until recently when several (5-7) investigations achieved some success in understanding the structural modifications of the electrode. Although the structure is now partly understood, the electrochemical mechanism of this electrode is still not clear.

It is well established that the reduced form is $Ni(OH)_2$[1] and the oxidized form is generally believed to be NiO(OH). Both these structures have been shown (6) to exist in two modifications called α and β for the reduced structure and correspondingly γ and β for the oxidized structure. The reduced α form has further been shown to have the formula $3Ni(OH)_2 \cdot 2H_2O$. These structures and their modifications are probably hydrated to a greater or lesser extent. It was also shown that α nickel hydroxide is formed by electrochemical precipitation from $Ni(NO_3)_2$ solutions as used in preparing the electrodes for this study. It was further found that α nickel hydroxide is unstable on standing on open circuit or cycling. Lukovtsev (8) has presented a theoretical argument for a redox mechanism in which proton diffusion through the lattice is one of the reaction steps. Lukovtsev and Slaiden (9) have reported experimental results intended to measure the rate of diffusion of protons in the electrode but their

[1] $Ni(OH)_2$ is used here as an abbreviated symbol for the nickel hydroxide electrode which exists in a variety of hydrated forms.

results were only qualitative. Sagoyan (10) used isotopic tracers to show that during the redox reaction, protons are exchanged with the solution while there is very little oxygen exchange.

Feitknecht (11) and coauthors measured the diffusion coefficient of protons in the nickel hydroxide lattice by measuring the rate of exchange of radioactive hydrogen with water vapor. They found that at temperatures above 100°C the enthalpy of diffusion was about 23 kcal deg^{-1} $mole^{-1}$ and D_0 in the expression $D = D_0 \exp(-\Delta H/RT)$ was about 2×10^{-7} cm^2 sec^{-1}, although the latter value could be wrong by several orders of magnitude since the data showed considerable scatter.

Experimental

Electrolysis cell.—A sketch of the cell is shown in Fig. 1. A four-necked flask constructed of alkali resistant Corning No. 7280 glass was used to hold the solution. The working electrode was a disk of high purity Inco 270 Ni which was machined to give a surface area of 1 cm^2. The sides and back of the disk as well as the supporting wire were insulated with heat shrinkable polyethylene tubing. The sides of the disk itself were coated with a thin film of alkali resistant resin glue before the shrinkable tubing was applied since this resulted in a very close fit of the tubing onto the disk. Nonetheless, it was found that in the more concentrated KOH solutions, electrolyte was beginning to work its way between the tubing and the disk after about one week in the solution, and a new electrode would have to be prepared.

The reference electrode was a Hg/HgO electrode in a solution of the same concentration as that in the electrolysis cell. It was connected to a Luggin capillary through a Pyrex glass tube. The counterelectrode was a coiled Pt wire. N_2 was continuously bubbled through the solution from a glass fritted disk.

The screen electrode shown in the diagram was a nickel hydroxide sintered electrode about 1 $in.^2$. It was used for experiments not included in this report but had the additional feature of exposing a large surface area to adsorbable impurities and thus probably helping to keep the working electrode cleaner than would otherwise occur.

Solutions.—Baker analyzed reagent grade KOH was used to prepare solutions in distilled water. Ordinary precautions were taken to minimize carbonate formation. The solution used for precipitating $Ni(OH)_2$ films was 0.5M reagent $Ni(NO_3)_2$ and fresh solution was used in the preparation of each electrode.

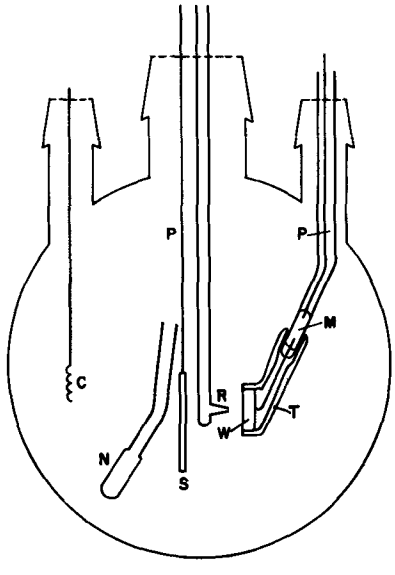

Fig. 1. Electrolysis cell. M, mercury contact; N, nitrogen diffuser; P, platinum wire; R, Luggin capillary; S, screen electrode; T, shrinkable polyethylene tubing; W, working electrode; C, counterelectrode.

Equipment.—A Wenking Model 61RS potentiostat and motor potentiometer were used in the potential control circuit. An X-Y recorder was used to measure current as a function of potential. The X axis was calibrated with a precision voltage calibrator and the Y axis with a precision milliammeter. The X-Y recorder was fitted with microswitches which reversed the direction of the potential scan at any preset voltage. This made it possible to automatically run many scans on an electrode.

Preparation of electrode.—The surface of the disk was polished with several grades of emery paper, the last being 4/0, before washing with 10% HCl and distilled water. It was then immersed in 0.5M $Ni(NO_3)_2$ solution and made cathodic. The counterelectrode was a sheet of Inco 270 nickel. The current distribution was essentially uniform over the cathode surface. After deposition the electrode was washed in running tap water and running distilled water and then immersed in the KOH solution. Scanning was started about 1 min later. All experiments were done at room temperature (25°C).

Currents and deposition times used in the preparation of the electrodes are given in Table I.

Results and Discussion

Aging characteristics.—In preliminary work it appeared that the potential at which the oxidation peak occurred varied with the history of the electrode. The shift in potential was about 50 mV moving to higher potentials as the electrode was cycled or was allowed to stand in KOH. Because the magnitude of the potential shift was similar to that found by Bode (6) and because it occurred while the electrode was immersed in KOH, we assume that this shift in potential corresponds to the conversion of α nickel hydroxide to β nickel hydroxide as described by Bode. It was found that the rate of this conversion was accelerated in more concentrated KOH and while potentiostated in the reduced state. The conversion is illustrated in a series of consecutive scans of an electrode in Fig. 2. The rate of conversion shown here was unusually rapid and was a result of the electrode being potentiostated at reducing potentials for a longer time than that used for the scans in the later work.

According to Bode (6) α-nickel hydroxide is oxidized to the γ structure. The work of Bode and coworkers has not established that γ may be reduced to α. From the results presented here, evidently it is possible to cycle between the α and γ structures, although only for a limited time.

Potential scans at various KOH *concentrations.*—From the preceding work it was found that it was possible to work with the α structure for a reasonable period of time. It was not possible, however, to do the same with the β structure because there always was evidence of at least some α present. As a result, potential scans in KOH of various concentrations were taken only of the α structure in an attempt to obtain the dependence of the reversible potential on the KOH concentration.

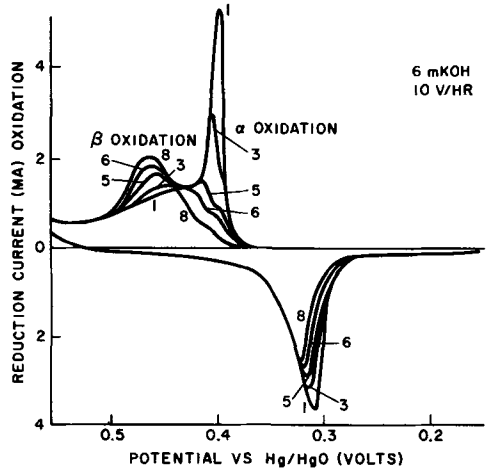

Fig. 2. Consecutive scans of a film electrode. Numbers refer to order of potential scans.

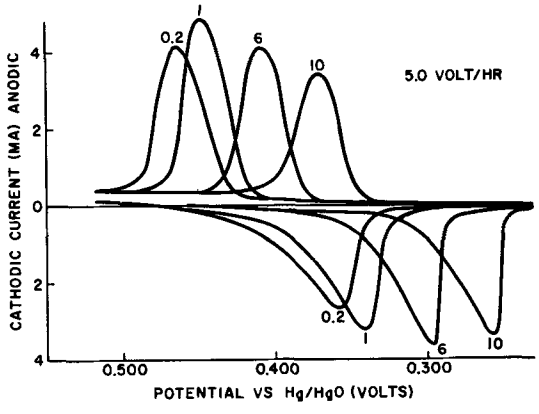

Fig. 3. Potential scans in various KOH solutions. Numbers are molalities.

The well-known hysteresis of the charge-discharge curves for the nickel electrode has suggested that the reaction is irreversible. Examination of the potential scans, however, reveals a potential range where both oxidation and reduction may occur. It was therefore decided to take the reversible potential as that potential at which the oxidation and reduction currents are equal.[2] This reversible potential was found to be influenced to a small extent by the scanning speed but for slow and moderate speeds was essentially independent of the scan rate (see Fig. 4).

Several electrodes were used at each KOH concentration and the reversible potentials of the different electrodes were averaged. Potential scans at the various concentrations are shown in Fig. 3. Since the Hg/HgO reference electrode has the same dependence on hydroxyl ion activity as the nickel electrode, the changes in potential were associated with dependence on KOH and water activities. The reversible potentials found in the different solutions are given in Table II. These potentials are for the reaction

$$HgO + 2[Red] + mKOH \rightarrow Hg + 2[Ox] + nH_2O$$

where [Red] and [Ox] are the reduced and oxidized forms of the $Ni(OH)_2$ electrode and m and n are constants for the reaction. The potential of the reaction may be written as

$$E_r = E_o - 0.0591 \log \frac{[a_{KOH}]^m}{[a_{H_2O}]^n}$$

at 25°C. Substituting the values for E_r and using

[2] The justification for this choice rests on the observation that the reverse current during a scan in either direction was negligible. This phenomenon probably is related to the structural changes taking place in the lattice.

Table II. Reversible potentials in different solutions

KOH (molality)	E_r vs. Hg/HgO (volts)
0.200	0.435
1.00	0.414
6.00	0.382
8.00	0.367
10.0	0.360
12.0	0.348

values given by Akerlof and Bender (12) for a_{KOH} ($= \gamma^{\pm 2} m^2$) and a_{H_2O}, a least squares fit gives

$$E_o = 0.411 \pm 0.003V$$

$$m = 0.494$$

$$n = 0.0012$$

The above chemical reaction may be separated into two half reactions

$$HgO + H_2O + 2e^- \rightarrow Hg + 2OH^-$$

$$2[Red] + mKOH + 2OH^- \rightarrow 2[Ox] + (n+1)H_2O + 2e^-$$

Taking the probable value for n as zero we find the $Ni(OH)_2$ half reaction to be

$$2[3Ni(OH)_2 \cdot 2H_2O]^{3} + 6OH^- + 3/2KOH \rightleftarrows 2[3NiOOH \cdot 7/2H_2O \cdot 3/4KOH] + 3H_2O + 6e$$

Bode (6) has given the formula $[NiO(OH)]_8O_3(OH)K_2$ for the oxidized γ structure. In the present work the same mole ratio of potassium to nickel has been found (1:4) but there is some difference in the water content. This agreement between two different techniques (Bode's formula was based on x-ray analysis) is encouraging. Equations derived by other workers for what was probably $\beta Ni(OH)_2$ are

$$2Ni(OH)_2 \cdot 1.28H_2O + 0.14KOH + 2OH^- \rightleftarrows 2NiOOH \cdot 0.14KOH + 4.56H_2O + 2e^-$$

[Bourgault and Conway (13)]

$$2Ni(OH)_2 \cdot 2H_2O + 2OH^- \rightleftarrows 2NiOOH \cdot H_2O + 4H_2O + 2e^-$$

[Zedner (2)]

$$2Ni(OH)_2 + 2OH^- \rightleftarrows 2NiOOH \cdot 0.2H_2O + 1.8H_2O + 2e^-$$

[Forster (14)]

$$2Ni(OH)_2 + 2OH^- + 0.067KOH \rightleftarrows 2NiOOH \cdot 0.067KOH \cdot 1.16H_2O + 0.84H_2O + 2e^-$$

[Kornfeil (15)]

It may be seen that our dependence on H_2O and KOH is greater than any of these. This is not surprising since our results were obtained for α nickel hydroxide which has a more open structure.

Potential scans at different rates.—Several attempts (9-11) have been made to measure the rate of diffusion of protons in the nickel hydroxide lattice. Only one was successful in obtaining quantitative data and this (11) for temperatures greater than 100°C. There appears to be little data available for proton diffusion coefficients in hydrated lattices at room temperature. A very wide range extending from 10^{-5} cm^2 sec^{-1} for solutions to about 10^{-18} cm^2 sec^{-1} for self-diffusion in solids would appear to encompass reasonable values for the proton diffusion coefficient. With such

[3] We use Bode's formula for $\alpha Ni(OH)_2$.

a wide range of possible values to choose from it appeared that some relatively unsophisticated experiments should be done in order to obtain an estimate of the diffusion coefficient in the hydrated nickel hydroxide lattice.

The model that we use to describe the nickel electrode reaction is a simplified one. It ignores some features that other authors have used, particularly that of phase changes in the solid. Electron transfer through the nickel hydroxide lattice is believed to occur rapidly in comparison to proton transfer (thus the redox reaction $Ni^{II} \leftrightarrows Ni^{III}$ may be regarded as reversible). Protons are released adjacent to the nickel ion sites when Ni^{II} is oxidized to Ni^{III} and a proton vacancy is created when Ni^{III} is reduced to Ni^{II}. During oxidation the proton diffuses to the electrolyte interface where it reacts with OH^- to form a water molecule in the electrolyte. During reduction protons diffuse from the interface into the lattice to fill up the proton vacancy. The rate of the reaction is believed to be controlled by the rate of proton transfer. This reaction meets the following conditions: (*i*) the electrode process is rapid compared with the rate of diffusion, and (*ii*) the reaction product is soluble either in the solution or in the material of the electrode. Randles (16) has solved the semi-infinite diffusion problem for these conditions and obtained the current-voltage relationship for a potential scan. Delahay (17) has shown that the solution may be written in the form

$$i_p = 2.7 \times 10^5 n^{3/2} A D^{1/2} C^\circ V^{1/2}$$

where i_p (A cm^{-2}) is the peak current during a potential scan at 25°C as a function of scan rate V in V sec^{-1}. Accordingly a plot of the peak current against (scan rate)$^{1/2}$ will be a straight line with slope proportional to the area of the electrode (A, cm^2), the square root of the diffusion coefficient (D, cm^2 sec^{-1}) and the initial concentration (C°) which here is taken as the number of nickel sites per unit volume expressed as moles/cm^3. This is simply the density of the nickel hydroxide film divided by the molecular weight. For this calculation the molecular weight used was that of $\alpha Ni(OH)_2 \cdot 2/3H_2O$ and the density was taken as 2.5 g/cm^3, the value found by x-ray measurements (6). Potential scans for a single electrode in 1M KOH at various rates are shown in Fig. 4, and a plot of i_p *vs.* (scan rate)$^{1/2}$ for electrodes of various thickness is given in Fig. 5. The plot shows a linear relationship indicating a diffusion-limited reaction; however, the change in slope as the thickness of the film varied was unexpected. The explanation of this result was sought in the relationship between the thickness of the film, the duration of the experiment, and the diffusion coefficient for the reaction. (It may be noted that it was not possible to increase the thickness of the film beyond that used here since thicker films generally were less adherent.)

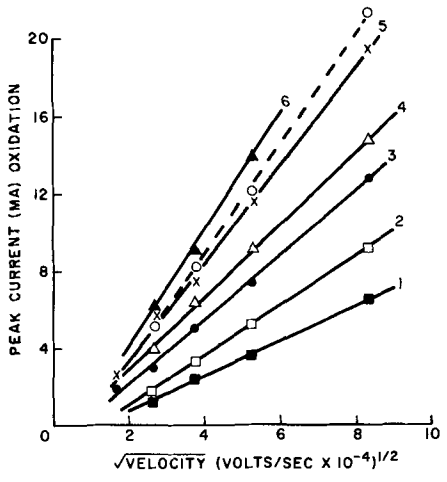

Fig. 5. Oxidation peak height vs. (sweep rate)$^{1/2}$. Numbers refer to films of increasing thickness (0.17, 0.31, 0.51, 0.93, 1.3, 1.8μ). The dashed line was obtained after correction for thicknesss.

An estimate may be made of the maximum diffusion coefficient which would still allow use of the semi-infinite diffusion equation. The depth of the diffusion layer may be estimated as $\sqrt{2Dt}$ where D is the diffusion coefficient and t is the time from the start of the diffusion process. This depth must be less than the film thickness if the semi-infinite diffusion equation is to be applicable or, expressed mathematically

$$d \geq \sqrt{2Dt}$$

where d is the film thickness in centimeters. The time required for the potential to scan through the oxidation peak was about 360 sec. The maximum D allowed, therefore, is about 0.5×10^{-10} cm^2 sec^{-1} for the thickest films (1.8×10^{-4} cm, estimated from the electrode capacity). As will be shown below, D apparently exceeds this value, therefore, it is not surprising that the slope of the lines in Fig. 5 varied with the thickness of the film. In an effort to obtain an approximate value for the diffusion coefficient, an attempt was made to extrapolate from the data to an infinitely thick film.

A plot of the peak current at various scan rates as a function of the electrode capacity (proportional to film thickness) is shown in Fig. 6. These curves were fitted with an empirical equation of the form $i_p = i_{p_\infty}(1 - \exp - 7Q)$ where Q is the capacity of the film and i_{p_∞} is the peak height for an infinitely thick film. The form of this equation was chosen because it approaches a limiting value as the thickness of the film increases. The coefficient of 7 was found to give

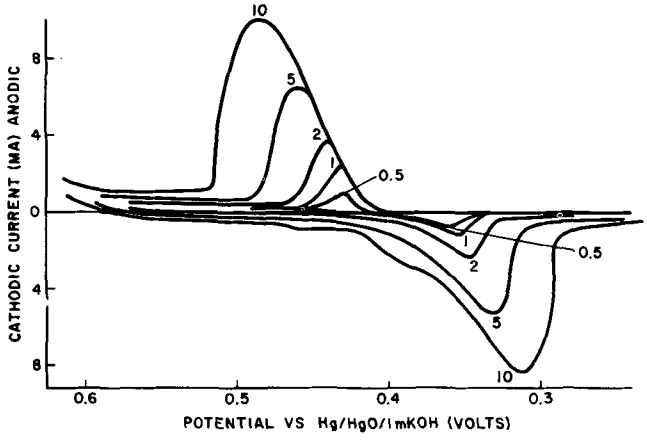

Fig. 4. Potential scan at various sweep rates. Numbers are volts/hour.

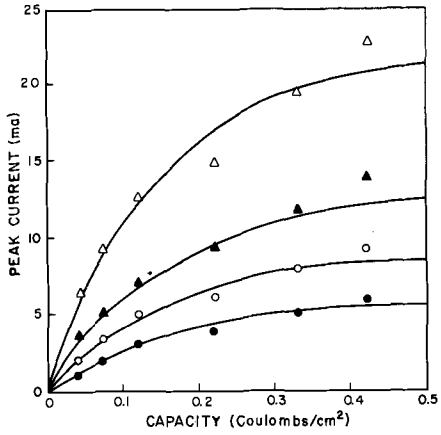

Fig. 6. Oxidation peak current as a function of calculated film thickness. Symbols refer to various scan rates.

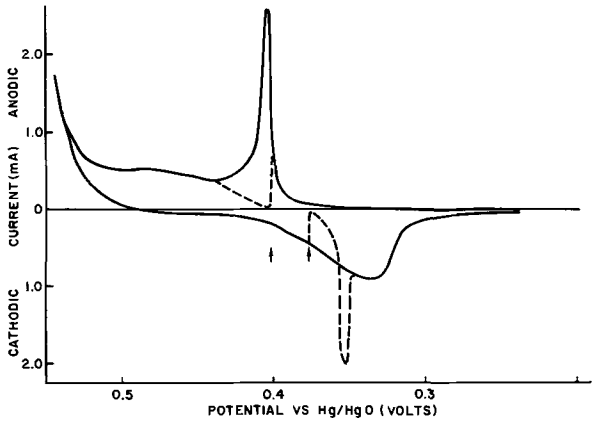

Fig. 7. Interrupted scans. Dashed lines show curves following a pause (arrow) in the scan in 6.0M KOH.

the best fit for the various rates of scan. As may be seen these curves pass below the experimental points for the thickest films. We attribute this to a complicating reaction that occurs with these thicker films. As the film thickness increases, the potential at which the peak current appears is shifted to more anodic potentials where the proposed competing reaction (8)

$$OH^- + NiO_2 \rightarrow NiO(OH) + O_{ads} + e^- \quad [4]$$

begins to take on greater importance. Thus the current is abnormally high for the thicker films.

The values for i_{p_∞} were obtained for each scan rate. These values of i_{p_∞} for which diffusion is presumed to be the only mechanism for introducing protons into the surface layer, are shown in Fig. 5. A dashed line has been drawn through them. From the slope of this line, the diffusion coefficient was found to be 1.9×10^{-9} cm^2 sec^{-1}. It was found that the slope of the line was independent of the electrolyte concentration as indeed it should be for the proposed mechanism. Because of the uncertainties contained in the curve fitting procedure, this value may be considered only an order of magnitude estimate. It is, however, the first quantitative estimate of the diffusion coefficient. This value is about four orders of magnitude smaller than the corresponding value for ions in solution. It suggests that the diffusion occurs in a solid.

Intermittent scans.—The model that has been used for these calculations is that of a reversible charge transfer step with a diffusion limiting process. Although the species involved have not been unambiguously established, we believe the charge transfer step occurs at the nickel ion sites in the lattice. During charging a proton is released at the site and diffuses to the surface. During discharge the proton moves from the surface to the nickel site. The slow step in this reaction is believed to be the proton diffusion process. However, the assumption of a reversible charge step requires further investigation in view of the fact that the open-circuit potential varies depending on whether the electrode has been undergoing oxidation or reduction (18).

This apparent irreversibility was investigated by the use of an intermittent scan technique (Fig. 7). In this procedure the potential scan was stopped at various potentials in the oxidation and reduction regions during successive scans (arrows on Fig. 7). The potential was held constant until the current had fallen to zero. The scan was then continued. In the oxidation region it was noted that the electrode had become almost fully charged during the pause and when the scan was continued there was no unusual increase in current. In the reduction region, however, the electrode did not become completely discharged during the pause and on continuing the scan there was a sharp current peak that occurred at a potential roughly 20 mV more cathodic. This behavior was observed throughout the potential range where reduction occurs.

These results suggest that a poorly conducting film forms during reduction. The film resistance apparently increases when the electrode is held at constant potential and prevents further reduction of the electrode. In order to achieve film breakdown, a potential several tens of millivolts more cathodic is required, at which time a surge of current is noted. There are several compounds which could form this layer; NiO at the substrate interface, Ni_3O_4 or unhydrated $Ni(OH)_2$ at the electrolyte interface. The most likely compound is Ni_3O_4 on the basis of the potentials involved. The standard potential for the nickel hydroxide electrode was found to be 0.411V vs. Hg/HgO. On the hydrogen scale in basic solution this potential is 0.499V. Reduction of $Ni_2O_3 \cdot H_2O$ (which may also be written as $NiO(OH)$) to Ni_3O_4 occurs at a potential of 0.477V as given by Pourbaix (19). Thus the Ni_3O_4 electrode might be expected to have a potential about 20 mV more negative and the apparent irreversibility of the nickel hydroxide electrode reaction possibly is caused by the formation of Ni_3O_4 during reduction.

[4] The surface may be oxidized to the Ni^{IV} state, if not the reaction might be $OH^- + NiO(OH) \rightarrow Ni(OH)_2 + O_{ads} + e^-$.

Effect of Electron Donor and Acceptor Elements on Passivity of Copper-Nickel Alloys

F. Mansfeld*,[1] and H. H. Uhlig*

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

The electron configuration theory of passivity is further evaluated through data obtained for two additional nontransition elements, *i.e.*, Ge and Ga (electron donors) added to Cu-Ni alloys. These studies follow previous investigations on effects of alloyed Zn and Al. Data are also presented for Cu-Ni alloys containing transition metal components, *i.e.*, Fe and Co, which act as electron acceptors. Potentiostatic polarization curves and potential decay-time data in 1*N* H_2SO_4 are employed as an index of passivity, or of its absence. The results show that a critical alloy composition exists for each alloy series at which and for higher electron donor percentages, passivity is no longer observed. The critical composition is interpreted as that at which surface *d* electron vacancies of Ni are just filled by valence electrons from donor elements. Hence, Cu, Ge, Al, and Zn are found to donate 1, 4, 3, and 2 electrons per atom, respectively. Ga donates more nearly 2 electrons per atom, perhaps in accord with the tendency of Ga to form lower valent as well as trivalent compounds. Fe and Co act in accord with their expected behavior as electron acceptors, favoring passivity rather than eliminating it as in the case of electron donors. The present quantitative data lend additional support to the theory and to the concept of a passive film on Cu-Ni alloys made up largely of chemisorbed oxygen, the formation of which is favored by surface *d* electron vacancies. When such vacancies are filled by valence electrons of alloyed component atoms, passive properties are no longer observed presumably because oxygen is no longer chemisorbed.

A previous investigation (1) on passivity of Cu-Ni alloys showed that a critical Ni composition exists above which potentiostatic polarization curves exhibit a typical passive current density qualitatively similar to that shown by nickel, and below which the passive current density disappears and the alloys behave like copper. The critical composition, interpreted in accord with the electron configuration theory of passivity (2), is that at which one electron per Cu atom just fills the available surface *d* electron vacancies of Ni (1.6/atom).[2] When, for example, Zn is alloyed with Cu-Ni (3), the critical composition shifts to a lower Cu/Ni ratio consistent quantitatively with donation of two electrons per Zn atom; similarly when Al is alloyed (4) the contribution is three electrons per Al atom. These facts persuaded us to survey other possible alloy additions, *e.g.*, Ga and Ge which are predicted to contribute 3 and 4 electrons per atom respectively. In addition, the question arose: What would be the effect on the critical composition of Cu-Ni alloys of an added transition element which supplies electron vacancies? According to theory it should shift the critical composition in the opposite direction, that is toward a higher Cu/Ni ratio. Hence, alloys containing Fe and Co, the *d* electron vacancies of which per atom are known from magnetic saturation moment data, were included in the present program.

Experimental

The choice of possible alloying components was limited to those having reasonable solid solubility in Cu-Ni alloys. The passivity of many single phase alloys can be satisfactorily interpreted based on electron sharing, but that of multiphase alloys is more complex. Single phase alloys were presently assured by adding only small concentrations of the components previously named. The maximum amount in each case was estimated from the binary phase diagrams and was later checked by metallographic examination of the swaged and annealed ingots.

Alloys were prepared by induction melting in vacuum using dense pure alumina crucibles. After the alloys were melted, the furnace was filled with purified argon to 1 atm, and the melt was drawn into 7 or 9 mm Vycor tubes, then water quenched. Subsequent additions to the melt were made as required, followed by periodic casting. The ingots were then homogenized in argon in a quartz tube at 850°-950°C for 24 hr, swaged to a smaller diameter, annealed in argon at 850°-950°C for 1 hr, and air cooled while remaining in argon within the quartz tube. They were swaged to the final diameter rod (0.35-0.45 cm) and then annealed and cooled as before.

Alloys were prepared from high-purity Cu (99.999%) and from carbonyl nickel, the latter being supplied by courtesy of the International Nickel Company. Germanium was of semiconductor grade. Gallium of 99.99% purity was weighed in glass bulbs, cooled by solid CO_2, and added to the melt as frozen pellets. Iron was electrolytic grade further decarburized, and cobalt (99.9%) was obtained through courtesy of the Cobalt Information Center at Battelle Memorial Institute. Chemical analyses of the final alloys are listed in Table I.

Electrodes were machined in the form of cylinders approximating 1.5 cm long and 0.3 cm diameter. They were mounted in a special glass holder using a Teflon gasket as described previously (3). After mounting, the electrodes were degreased in hot benzene and then briefly pickled in dilute HCl and H_2SO_4 at 90°C. Subsequent anodic polarization in 1*N* H_2SO_4 before each run assured removal of the cold-worked surface.

Potentiostatic anodic polarization curves were obtained in 1*N* H_2SO_4 deaerated with nitrogen. Either a

[2] It is also possible to show that *d* vacancies of Ni may be filled by donor electrons from Cu independent of surface effects. In this case the assumption is made that mutual coupling of *d* electrons of metal atoms, having a maximum number of vacancies in the gaseous state, is linearly related to concentration of such atoms in the alloy, resulting in the observation that the solid metal contains fewer uncoupled *d* electrons or *d* vacancies the higher its concentration in the alloy. For example, there are 2 *d* vacancies per atom for gaseous Ni but only 0.6 *d* vacancy per atom for solid Ni. On this basis, it is calculated that the *d* band of Ni is filled by electrons from Cu at and below 41 a/o (atom per cent) Ni in conformity with measurements of magnetic susceptibility. H. H. Uhlig, to be published.

continuous sweep rate of ±20 mV/min was employed, or a stepwise procedure was used instead for which the potential was kept at a fixed value until the current was relatively constant for at least 2 min. Potential steps were 20 mV in the active and passive regions and 40 mV in the transpassive region. In general, the alloy composition at which the passive current density, i(pass.) converged with the critical current density i(crit.) (polarization in noble-to-active direction), corresponded to disappearance of passivity as presently defined. It occurred at the same composition whichever polarization procedure was followed. Two or more runs were made for each alloy composition.

Measurements were extended into the region of secondary passivity, noble to the region of primary passivity, where either the current density decreased again, or oscillations of current (unstable secondary passivity) and O_2 evolution occurred. The current density was noted just before it decreased or before oscillations occurred, and again at the minimum value beyond which oscillations, if they were observed, diminished and finally ceased. It was assumed that observed oscillations of current accompanied the formation and breakdown of passivity within the secondary region, the minimum current, therefore, corresponding to the passive state. In accord with this assumption, oscillations were not observed for any of the alloys which proved to be nonpassive in the primary region.

Potential decay curves were obtained in 1N H_2SO_4, supplementing polarization data as a measure of passive properties. The alloy was first polarized into the region of secondary passivity (2V) remaining there for 5 min. The polarizing current was then shut off and the potentials recorded corresponding to points of inflection in the potential-time curve using a Keithley No. 602 electrometer as amplifier. The latter insured minimum polarization of the alloy electrode during decay, serving both to improve detection of small discontinuities of slope corresponding to Flade potentials, and the accurate determination of such potentials. Typical potential-time curves are given in ref. (4) and (5).

All measurements were carried out in a constant temperature room maintained at 25° ± 0.5°C.

Results

It was felt advisable to first establish in further detail the potentiostatic polarization characteristics of the binary Cu-Ni alloys in the region of critical composition. Curves for i(crit.) and i(pass.) based on 10 alloys are shown in Fig. 1. Good agreement was found with similar data reported previously by Osterwald and Uhlig (1). Characteristics of secondary passivity and decay potentials for the same alloys were reported earlier (5). Although values of i(crit.) and i(pass.) were readily established for the alloys exhibiting passivity, values of current density analogous to i(crit.) for the nonpassive alloys at which a rapid

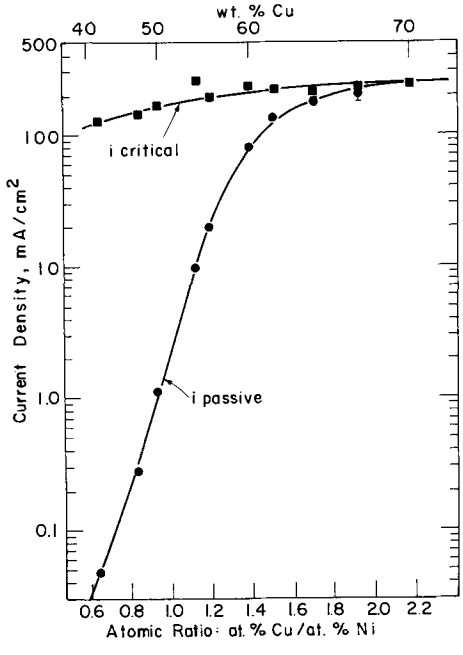

Fig. 1. Critical and passive current densities for copper-nickel alloys obtained from potentiostatic polarization curves (noble → active) in 1N H_2SO_4, 20 mV/min, 25°C.

change of slope occurred beyond the linear Tafel region, were less easily estimated [see, for example, the polarization curve for Cu in Fig. 2, ref. (4)]. The procedure used for the nonpassive alloys and for similar alloys to be described later was to take the value of current density corresponding to the intersection of two straight lines representing polarization data on either side of the region of maximum curvature. The same procedure was used for estimating values of potential corresponding to discontinuities in slope of potential decay curves. The potentials obtained in this manner were less arbitrary than those chosen at some point of maximum change of slope, especially in cases where the change of slope was not marked.

Because of the asymptotic approach of i(pass.) to i(crit.), the critical composition for the Cu-Ni alloy series cannot be determined precisely. It may be taken at the composition corresponding to an atomic ratio of 1.92 or at the higher atomic ratio of 2.16 (Fig. 1). For data obtained in the active-to-noble direction (not shown), typical overshoot in the polarization curves makes it necessary to take the critical composition as that value beyond which a constant difference between i(crit.) and i(pass.) is observed. The same atomic ratio approximating 1.9-2.2 is obtained either way.

Polarization curves corresponding to the region of secondary passivity (5) locate the critical composition at an approximate atomic ratio of 1.7-1.9. Because of the nature of the measurements in this region, these values are considered less reliable than those obtained in the region of primary passivity.

Data for potential decay (5) show that Flade potentials become more noble as the critical alloy composition is approached. The values reported previously for binary Cu-Ni alloys and presently for Cu-Ni alloys with addition elements are more noble than the values reported previously for the 45% Ni-Cu-Al alloys (4). This difference occurs partly because the method of intersecting lines presently used to estimate the potentials leads to somewhat more noble values; the trend, however, is not altered. The particular method employed for estimation does not affect absolute values corresponding to secondary passivity because the change of slope is relatively abrupt. But for Flade potentials of Cu-Ni alloys for which the change of slope is gradual, the method used for estimation becomes more important. The change of slope is so small for Ni compared to that for iron, for example, that Flade (6) originally reported nickel to show no "umschlagspunkt" (Flade potential) at all.

Gallium series.—Curves for i(pass.) and i(crit.) are shown in Fig. 2 with convergence at an atomic ratio of 1.89. Shapes of the curves, in particular a minimum in i(pass.), are similar to those reported earlier for Al additions (4). Convergence occurred at the same ratio whether the data were obtained proceeding from the noble-to-active or active-to-noble directions. Analogous curves for secondary passivity are shown in Fig. 3 showing parallel convergence at an atomic ratio of 1.89 and a similar minimum in the lower current density at an atomic ratio of 1.7.

Decay potentials related to both secondary passivity and to primary passivity (Flade potentials) are shown in Fig. 4. No discontinuities of slope were observed for alloys of atomic ratio greater than that of the critical composition in either the primary or secondary regions, at 0° or 25°C. Instead the potentials decayed smoothly to active values approximating the corrosion potential. This behavior is consistent with the previous conclusion that such alloys are not passive, that is they show no evidence of a decreasing current density or i(pass.) on shift to more noble potentials in typical potentiostatic polarization curves.

Decay potentials for secondary passivity of the Cu-Ni-Ga alloys were not observed at 25°C for alloys of atomic ratio less than 1.53 even though polarization curves indicate passive behavior. The probable reason

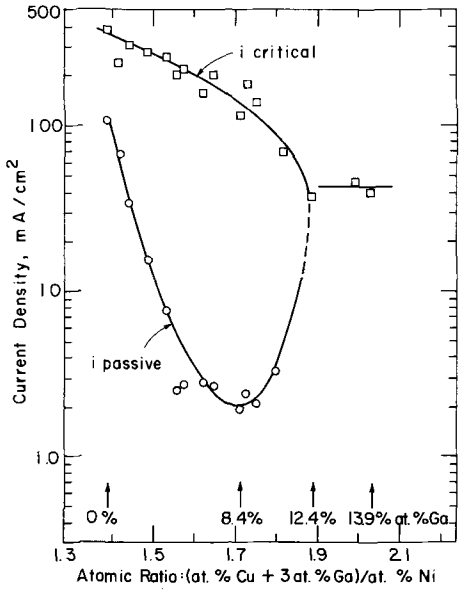

Fig. 2. Critical and passive current densities for copper-nickel-gallium alloys obtained from potentiostatic polarization curves (noble → active) in 1*N* H_2SO_4, stepwise scanning, 25°C.

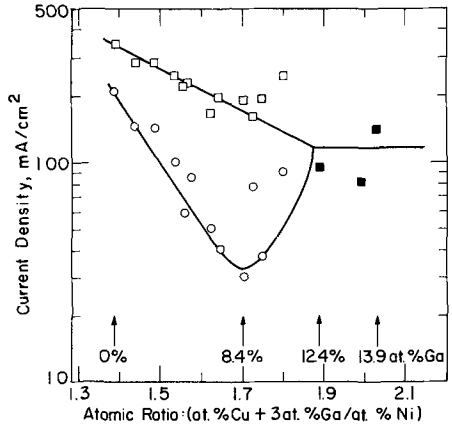

Fig. 3. Upper and lower current densities for secondary passivity of copper-nickel-gallium alloys obtained from potentiostatic polarzation curves (active → noble) in 1*N* H_2SO_4, stepwise scanning, 25°C.

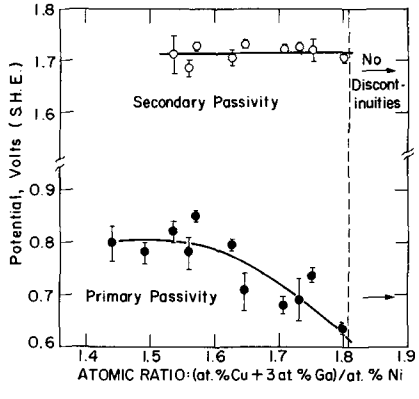

Fig. 4. Potentials corresponding to discontinuities in slope of potential decay-time curves for copper-nickel-gallium alloys in 1*N* H_2SO_4, 25°C. (Each point is average of 4 runs.)

is that the relevant current densities become so high that soluble corrosion products accumulating at the alloy surface rapidly destroy the passive film after the polarizing current is shut off. For the same reason, Flade potentials were not observed below a ratio of 1.44. Decay potentials of Fig. 4 corresponding to secondary passivity are independent of atomic ratio or

gallium content, but the Flade potentials tend toward more active values at higher atomic ratios.

Germanium series.—Curves for i(pass.) and i(crit.) are given in Fig. 5. These show that stepwise polarization measurements lead to higher values of i(crit.) than are observed with continuous polarization measurements, but values for i(pass.) are the same, and the convergence of the two current densities occurs at the same atomic ratio of 1.7. Small additions of Ge decrease values of i(pass.), but only slightly, and larger additions have the opposite effect. A minimum occurs at about 2 a/o (atomic per cent) Ge corresponding to an atomic ratio of 1.5. Values of i(crit.) decrease as the critical alloy composition is approached similar to the behavior of other alloy series of relatively constant Ni content. The trend is opposite in Cu-Ni alloys for which Ni content decreases as the critical composition is approached.

Secondary passivity was observed in the potential region >1.6V for alloys of atomic ratio less than 1.7, but the differences in current density characteristic of secondary passivity were smaller than for the Cu-Ni alloys and less reproducible. For this reason they were not plotted.

Decay potentials corresponding to both the secondary and primary regions of passivity are shown in Fig. 6. Measurements were taken at 1°C because passivity is more stable at low than at room temperature making it possible to discern small discontinuities in potential-time curves similar to those depicted in curves of Fig. 6, ref. (4). The potentials corresponding to secondary passivity lie between 1.7 and 1.8V showing a slight trend toward more active values as the critical composition is approached. The Flade potentials show an even steeper negative slope. Consistent with polarization data, no discontinuities in either the secondary or primary regions were observed at or above an atomic ratio of 1.7 which corresponds to the critical composition shown in Fig. 5, and above which a passive current density is not observed.

Iron and cobalt series.—These series of alloys were made up with variable Cu and Ni contents but approximately constant in Fe (2.5 a/o) or cobalt (2.3 a/o). The shapes of curves for i(pass.) and i(crit.) are similar to those for Cu-Ni (Fig. 7 and 8). Fe and Co, as well as Ni, are transition metals, hence the atomic ratio: a/o Cu/[a/o Ni + a/o (Co or Fe)] groups these addition elements with Ni rather than with Cu with which the nontransition elements are grouped. The critical compositions for convergence of i(pass.) and i(crit.) lie at higher atomic ratios compared to Ga or Ge additions, confirming that alloyed Fe and Co act like Ni.

Convergence of current densities for the Fe series, according to Fig. 7, occurs at an atomic ratio greater than 2.1. The extrapolated ratio is about 2.2, and the corresponding calculated critical composition is given in Table I. Secondary passivity data (Fig. 9) confirm that the critical composition for the Fe series lies above the atomic ratio 2.1. For the Co series the critical composition occurs at or above a ratio 2.14 with some possible justification for choosing 2.39 instead. Secondary passivity data (Fig. 10) lend weight to a critical composition at an atomic ratio 2.1.

Although a systematic study was not carried out at this time, preliminary potential decay-time curves for the two series at 25°C showed two discontinuities for the alloys of lowest atomic ratio, but either one or no discontinuity for alloys approaching the critical composition. As mentioned before, it is probable that high current densities characteristic of the critical composition served to destroy passive films before potential decay measurements could be carried out. As with the other alloy series, discontinuities were more pronounced at lower temperatures where passivity decayed less rapidly.

Discussion

It is apparent that as the critical composition is approached, decreasing i(crit.) is usually accompanied by decreasing Flade potential ϕ_F (Al, Ga, Ge series). On the other hand, when i(crit.) increases, ϕ_F also increases (Ni-Cu series), or when the change of i(crit.) is small, change in ϕ_F is small (Zn series). This interdependence can be explained by the relation presented previously (7): $\phi_F - \phi_{corros.}$ = activation polarization + concentration polarization. Since the corrosion potential $\phi_{corros.}$ is observed to be about the same for all the alloys (0.2V), $\phi_F - \phi_{corros.}$ increases as ϕ_F becomes more noble. Furthermore, since the Tafel slope for anodic dissolution of all the alloys in the active region was observed to be about 30 mV, the current density i(crit.) required to polarize to ϕ_F is obviously greater the more noble the value of ϕ_F. Similarly, if ϕ_F becomes more active with alloy composition, corresponding values of i(crit.) show a decreasing trend.

Since the intersection of i(pass.) with i(crit.) at the critical composition occurs at a current density of about 100 mA/cm² or higher, this value corresponds to the removal of about 170 atom layers per second. Limited diffusion in the metal lattice at room temperature accompanied by continuous rapid removal of surface atoms make it likely that surface composition does not differ essentially from the over-all alloy composition.

It will be noted that the absolute values of i(pass.) lead to a less satisfactory correlation with alloy composition than does the present correlation based on both convergence of i(pass.) with i(crit.) and on potential-decay curves. The probable reason is that values of i(pass.), which are proportional to prevailing corrosion rates in the passive state, are subject both to variables of alloy composition additional to those entering formation of the passive film, as well as on prevailing potentials of the metal exposed to the electrolyte. On the other hand, the criteria of passivity used in the present paper merely indicate whether or not a passive film is present without relation to absolute reaction rates. Similarly, current oscillations as presently employed to indicate the presence of a secondary passive film may vary widely depending on the alloy, its environment and the relevant applied potential.

In accord with the discussion presented in earlier papers, the critical composition is interpreted as the specific atom ratio below which surface d electron vacancies exist and above which such vacancies are filled. Nickel on which oxygen of the passive film is adsorbed was assumed to supply 1.6 vacancies per atom (0.6 per Ni atom plus 1 vacancy resulting from electron transfer to adsorbed O). Copper, on the other hand, was assumed to donate 1 electron per atom accounting for a predicted filled d band at 62 a/o Cu or at an atomic ratio Cu/Ni of 1.6. The observed convergence of i(pass.) and i(crit.) according to data of Fig. 1 comes very close to this atomic ratio but is more precisely located at a higher ratio of 1.9 or 2.2.

By similar reasoning, it was shown in accord with prediction that alloyed Zn supplies 2 electrons per atom, the atomic ratio

$$(\text{a/o Cu} + 2\ \text{a/o Zn})/\text{a/o Ni}$$

for convergence of i(pass.) with i(crit.) occurring at 1.65 compared to the theoretical 1.60. Similarly, for alloyed Al, supplying 3 electrons per atom, the corresponding atomic ratio (a/o Cu + 3 a/o Al)/a/o Ni was observed at 1.68. Following the same principles, the critical atomic ratios, all of which are expected at 1.6 for nontransition components, are presently observed at values of 1.9 for Ga and 1.7 for Ge. For the alloyed transition metal Fe, the critical atomic ratio a/o Cu/(a/o Ni + a/o Fe) should also be observed at 1.6 provided that Fe behaves as does Ni, or at some higher value if the number of d electron vacancies per Fe atom is greater than for Ni. The same situation applies to alloyed Co. Data of Table I show that the critical atomic ratios are 2.2 and 2.14, respectively, hence Fe and Co probably contribute more d vacancies per atom than does Ni. Magnetic saturation moment data confirm that d electron vacancies per Fe atom are 2.2 and for Co they are 1.7 (8). At the surface, because of adsorbed oxygen, they are assumed to increase by 1 (2), and hence they become 3.2 and 2.7, respectively. Data of Fig. 1, 7, and 8 show that the differences between i(pass.) and i(crit.) at an atomic ratio of 1.6 are 70 mA/cm² for Cu-Ni, 90 mA/cm² for Cu-Ni-Co, and 180 mA/cm² for Cu-Ni-Fe alloys. Hence at the same atomic ratio, Fe is more effective than Co which

in turn is more effective than Ni, in imparting passivity to Cu-Ni alloys.

At the critical composition the number of vacancies equals the number of donor electrons, therefore the following general relation is expected to hold

$$\text{a/o Cu} + n(\text{a/o Y}) = 1.6(\text{a/o Ni})$$

where n is the number of electrons donated per atom of alloyed element Y. Similarly: a/o Cu = 1.6(a/o Ni) + v(a/o Z) where v is the number of vacancies per transition metal atom Z. It is possible therefore to plot a/o Cu − 1.6(a/o Ni) against n(a/o Y) having negative unit slope for alloyed nontransition elements or electron donors, and similarly against v(a/o Z) with positive unit slope for alloyed transition metals or electron acceptors. Doing so for the critical compositions given in Table I produces a straight line passing above the origin with a slope of 1.35 as shown in Fig. 11. For Ge, n = 4; for Al, n = 3; for Ga, n = 3 (or 2); and for Zn, n = 2. For Fe and Co, v = 3.2 and 2.7, respectively. The Ga point is relatively accurately placed by polarization data both in the primary and the secondary regions. If Ga were to contribute 2 instead of 3 electrons per atom, the point then lies close to the line representing other elements. Consideration, therefore, should be given to this possibility, especially since the chemical properties of Ga have established that it tends to form lower valent compounds much more readily, for example, than does Al (9).

The slope of the line is obviously high; it can be reduced to unity and at the same time pass through the origin in accord with predictions of the equations given heretofore by assuming that Cu donates less than one electron per atom (*e.g.*, 0.7-0.8) and that Ni has fewer vacancies per atom (*e.g.* 1.4-1.5). Justification for modifying the number of donor electrons or *d* vacancies per atom, and also the conditions under which such modifications may be expected to apply, lie outside the scope of the present discussion and are more properly the subject of a future communication. The fact that the points of Fig. 11 lie close to a straight line on either side of the Cu value without additional assumptions, is in itself significant.

Conclusions

The first conclusion derived from the accumulated data, therefore is that several nontransition elements added to the Ni-Cu alloy system apparently donate all or the major part of their valence electrons to the *d* electron vacancies of Ni, and that when such vacancies are filled, passivity is no longer observed. Transition metal additions, to the contrary, favor conditions for passivity by acting as electron acceptors, supplementing the number of *d* vacancies of Ni. These relations support the electron configuration theory of passivity beyond any of the evidence previously available.

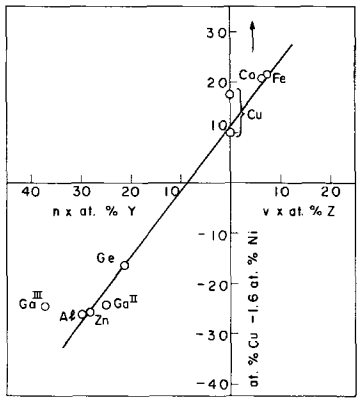

Fig. 11. Plot of excess electrons donated by Cu over surface *d* electron vacancies of Ni at the critical composition of Ni-Cu alloys, vs. electrons per atom donated by nontransition element Y or vacancies per atom supplied by transition metal Z. Assumption: 1.6 vacancy/Ni atom; 1 electron donated/Cu atom.

The second conclusion is that the presently reported relations between *d* band vacancies and observed passivity provide strong support for an adsorbed structure of the passive film having monolayer to multilayer dimensions in accord with the adsorption theory of passivity (10-13). Metals containing *d* band vacancies (transition metals) are well-known to favor chemisorption of oxygen, for example, more so than metals with filled *d* bands (nontransition metals). Passivity in Ni-Cu alloys accordingly is observed only when surface *d* electron vacancies are present; when such vacancies become filled by electrons from alloyed components, the required chemisorption of oxygen making up the passive film does not occur.

The simple band theory, therefore, successfully describes conditions leading to passivity or activity in the present alloys. Similar success has been achieved in explaining magnetic susceptibility (14). Some doubt has been expressed that such a model can adequately explain properties of Ni-Cu alloys such as electrical resistance, electronic specific heat, or thermo-electric properties (15, 16) indicating that refinements of theory are needed. These refinements can be expected as further data become available and as theoretical concepts of alloy structure mature. It is obvious in any event that the property of passivity, which is important not only to Ni-Cu alloys but also to several transition metal alloys, *e.g.*, Cr-Fe (stainless steels), must be included in any extension of present theories of the metallic state to more general explanations of alloy properties.

Oxide Growth on Copper and Alpha-Brasses in Aqueous Ammonia

J. A. S. Green* and H. D. Mengelberg[1]

ABSTRACT

An ellipsometric study of the kinetics of oxide growth for pure copper and a series of alpha-brasses immersed in tarnishing ammoniacal environments has established that the growth of the oxide, shown to be cuprous oxide, obeys a linear law in each case, and that the rate of growth increases significantly with (*a*) increasing zinc content of the solid, (*b*) increasing temperature, and (c) the application of anodic potentials. On the basis of these results it is suggested that the oxide is porous and that oxide growth involves the dissolution of metal ions at the base of the pore (anodic reaction) and their deposition at the oxide surface (cathodic reaction), electrons flowing through the oxide film. The influence of zinc content on the oxide-growth rate is attributed to its effect on the dissolution kinetics.

The intergranular stress-corrosion cracking (SCC) of alpha-brass in aqueous ammonia, commonly referred to as season cracking, occurs in those ammoniacal environments which cause tarnishing (1, 2), and it has been suggested that the tarnish plays an important role in the cracking process (3, 4). Electron diffraction (3), x-ray (5), and electron microprobe (6) studies have shown that the tarnish formed on Cu-30 Zn consists mainly of an epitaxed layer of cuprous oxide, Cu_2O, which is severely depleted in zinc with respect to the alloy. The mechanism of tarnishing, however, has not been established. In this respect several investigators (4, 7) have suggested that the tarnish is fully dense and protective, and that the growth process involves the solid-state diffusion of cuprous ions across the film. Conversely, other workers (3, 6, 8) have suggested that it is porous. Tromans and Nutting (8) based their suggestion on the observation of pores at both grain and twin boundaries in replicas of tarnish formed on Cu-30 Zn by exposure to moist ammonia vapor. Forty and Humble (6) supported their conclusion by the fact that when glass tubes containing tarnishing solutions were sealed with thin brass foils, leaks eventually developed even though the foils apparently remained coherent. Electron microscope studies by the latter workers also showed the tarnish to consist of an aggregate of small platelets of crystallites, about 500Å in diameter and about 100Å thick.

The present ellipsometric studies were undertaken to provide quantitative data on the kinetics of the growth process and thereby to clarify the mechanism of tarnish growth. In addition to the kinetic measurements of oxide growth, electron-diffraction studies were carried out to determine the composition of the tarnish for a wide range of alpha-brasses.

Experimental

The studies were carried out on 99.999% pure copper; on brasses, prepared from base metals of similar purity, containing, 5, 10, and 20 w/o (weight per cent) zinc; and on 30 w/o zinc alloy of 99.97% purity. Disks of each material, 1.9 cm in diameter and 0.05 cm in thickness, were cut from annealed sheet and silver-soldered onto a copper base plate. The base plate was firmly attached to a glass specimen holder by a polytetrafluoroethylene seal. The surface of the specimen was prepared by mechanical polishing using ¼ μm diamond abrasive on a napped cloth, followed by electropolishing in a 60/40 orthophosphoric acid/water solution. Finally, before use, the surface was rinsed in distilled water, methanol, and spectro-grade acetone, and then dried in a blast of oxygen. This procedure produced surfaces which gave rise to reproducible results.

The tarnishing ammoniacal solution was prepared by dissolving 8g of electrolytic copper dust in 1 liter of oxygen-saturated 15*N* aqueous ammonia. This solution was the same as that used for previous stress-corrosion studies (2, 9). The refractive index of this solution was 1.3535 at 25°C; small changes of the refractive index of this aqueous solution as a function of temperature were neglected (10).

Electron-diffraction studies were carried out to establish the composition of the tarnish formed on pure copper and all the α-brasses. Metal foils were prepared by electropolishing in orthophosphoric acid/water solution. Diffraction patterns were then obtained both before and after immersing the foil in the tarnishing environment.

The ellipsometric technique and its application to the measurement of the thickness of films formed during corrosion and oxidation has been described in detail elsewhere (11-16). Essentially the technique depends on the fact that the state of polarization of elliptically polarized light incident on a surface is changed on reflection. The change in ellipticity is measured in terms of two parameters, tan ψ and Δ, where tan ψ represents the relative amplitude ratio and Δ, the relative phase retardation of an equivalent set of electric field vectors parallel and normal to the plane of incidence. In addition to the film thickness d, the change in ellipticity on reflection is dependent on several factors such as the optical properties of the media involved, the angle of incidence ϕ, the wavelength of light λ. In terms of these factors, the change in ellipticity may be expressed as

$$(\tan \psi)\, e^{i\Delta} = f(\hat{n}_1, \hat{n}_2, \hat{n}_3, \phi, d, \lambda) \qquad [1]$$

where $\hat{n}$ is the refractive index. For an absorbing medium the latter is a complex quantity which may be expressed as

$$\hat{n} = n(1 - ik) \qquad [2]$$

where n is the real part of the refractive index, k the extinction coefficient (both for a given wavelength),

and i is $\sqrt{-1}$. The suffixes 1, 2 and 3 refer to the environment, the film, and the substrate respectively. Accordingly, for a metal/environment system in which $\hat{n}_1$, $\hat{n}_3$, ϕ and λ are known it is possible to compute values of tan ψ and Δ for films of various thicknesses and optical constants, *i.e.*, n_2 and k_2 values. In this study the computations were carried out using a program developed by McCrackin (17). The thickness of the film then may be determined by selecting the optical constants which provide the closest agreement between the computed data and the experimental results.

In general, the ellipsometer arrangement used in this study was similar to that described by Kruger (13), although some minor modifications were introduced. For instance, due to light absorption, the blue ammoniacal solution required the use of blue light. Thus a monochromater was employed to isolate a blue line ($\lambda = 4358$Å) of the mercury arc. Also to permit rapid filling of the cell (volume $\approx$ 100 cm^3) by a gravity-feed system a large diameter (1.25 cm) inlet tube was connected to the cell. Two platinum electrodes were located in the cell so that when the specimen was completely immersed, the environment completed the circuit between the electrodes and indicated the start of the test on a recorder. The ellipsometer cell was constructed so that the optical axis of the cell windows intersected the plane of the specimen surface giving an angle of 70° with the normal to the surface. Each window of the cell consisted of two optical flats, separated by an evacuated space, in order to avoid condensation of moisture on the outer window at lower test temperatures. To obtain the lower temperatures, the cell was wrapped with cooling coils and insulated with polystyrene foam so that the temperature could be maintained, within ±3°C of the required value, in the range −35° to +25°C. Methanol, precooled in a methanol/dry ice mixture, was used as coolant.

In the ellipsometric technique it is generally necessary to measure the optical parameters of the bare metal surface and usually in solution environments this is accomplished by cathodically protecting the specimen. In this instance, however, this procedure was not possible since cathodic deposition of copper occurred. Thus an alternative procedure was adopted in which the polished specimen was inserted into the cell and the ellipsometric values of the electropolished surface were measured in air. The optical parameters of the "bare" metal surface were then calculated from this data. The "bare" surface was probably covered with an oxide film as a result of washing with water (18) and might also be coated with a thin phosphate film from the electropolishing process (19). However, the ellipsometric parameters as measured *in situ* were found to be virtually unchanged when the electropolished specimen was cathodically polarized in a solution of phosphoric acid (in which there was no dissolved copper) indicating that the electropolished surface was covered by a film which was much thinner than the film thickness to be determined in the ammonia solution.

After the parameters of the initial surface condition had been established, the ammoniacal solution was introduced to the cell and subsequent changes in ellipsometer values were monitored by manual operation of the instrument. For the Cu-30 Zn alloy oxide growth was too rapid to be followed in this manner. In this case the ellipsometer was preset to certain values of Δ and ψ, corresponding to a particular film thickness. It should be noted that in most film-covered systems the Δ values are cyclic and any particular Δ value is repeated at certain intervals which are a function of film thickness (11). The time intervals required for the oxide to attain these preset values are then measured. To do this the photodetector output is recorded, a minimum of light intensity being observed each time the actual parameters of the film approximated the preset values. The interval between successive minima corresponds to an increment of thickness which may be computed. To provide a useful estimate of the increment of thickness the actual ψ value need not be exactly equivalent to the preset values (in most of the experiments in this study ψ is cyclic but the exact values are not repeated, see Fig. 2). It should be emphasized that this method gives only a rough estimate of the rate of film growth, but it was used because no other technique was available to measure the very rapid oxide growth of the Cu-30 Zn alloy.

The rate of oxide growth was measured for pure copper and the α-brasses as a function of temperature, and for the Cu-30 Zn alloy also as a function of applied anodic potential.

Results

The ellipsometric results are presented in polar-coordinate diagrams in which Δ and ψ are the angular coordinate and radial coordinates, respectively. The changes in ellipsometer values, measured as a function of time for pure copper at two temperatures, are shown in Fig. 1. Similar measurements for the series of brasses investigated are illustrated in Fig. 2. Figure 1 shows that, at ambient temperature, the ellipsometer values move in an anticlockwise direction and almost describe a closed loop, while at 10°C the sense of rotation changes to a clockwise direction after one loop.

The fact that the ellipsometer values describe a loop is significant in terms of the thickness of the surface film. For a nonabsorbing film on an absorbing substrate, the film thickness corresponding to a change of 360° in Δ is that thickness which shifts the phase of the incident radiation by an amount equal to its period (11) as shown in Fig. 3a. This thickness, d, is given by

$$d = \frac{\lambda}{2 \cdot n_2 \cdot \sin \phi} \qquad [3]$$

For absorbing films ($k_2 \neq 0$) approximately the same situation exists. It may be seen from the computed

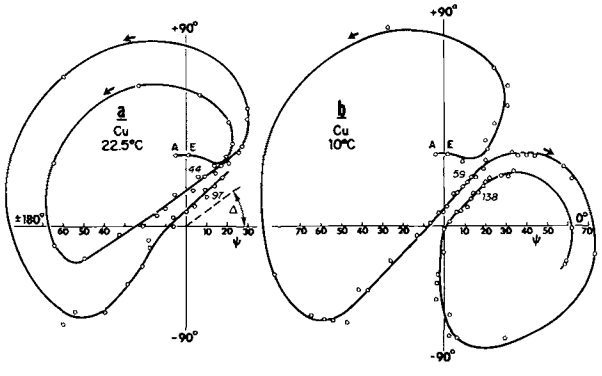

Fig. 1. Experimentally determined ellipsometric curves of Δ and ψ plotted on polar coordinates for the growth of cuprous oxide on copper at (a) 22.5°C and (b) 10°C. In each diagram point A indicates the parameters of the "film-free" surface in air and point E represents the initial surface in the ammoniacal environment. The numbers beside each curve indicate the elapsed time, in minutes, from the moment of immersion.

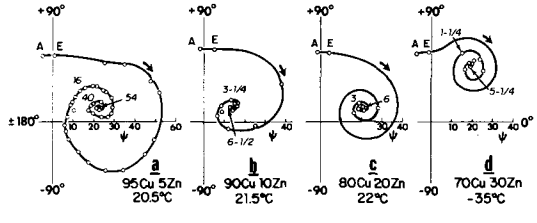

Fig. 2. Experimentally determined ellipsometric curves of Δ and ψ plotted on polar coordinates for the growth of cuprous oxide on a range of brasses. Points A and E and the numbers beside each curve have the same significance as in Fig. 1.

curves shown in Fig. 3 that each 360° rotation about the center of the spiral corresponds to the same increment in film thickness. The electron-diffraction studies showed that for pure copper and all the α-brasses the tarnish film was composed of cuprous oxide Cu_2O. Thus, in this particular case ($\lambda = 4358$Å) if the refractive index, n_2, of Cu_2O is taken as 2.75 (14), then the value of d is approximately 900Å. However changes in the optical constants, *i.e.*, n_2 and k_2 values of the film may alter this estimate of thickness, although in this respect only changes in n_2 will be significant. The observed changes in the direction of rotation of the curves in Fig. 1 and 2 suggest that the optical constants are not the same in every case. Thus it is necessary to determine whether and to what extent these constants change as a function of the experimental variables before making any estimate of film thickness.

To examine whether the changes in the shape of the curves shown in Fig. 1 and 2 are due to changes in n_2 and/or k_2, a series of curves were computed assuming various n_2 and k_2 values for the film. The computations were made using the parameters for the electropolished surface,[2] *i.e.* point A in Fig. 1 and 2, and n_2 and k_2 of the film were assumed to vary between 2.3-3.2 and 0.0-1.0, respectively. Figures 3 and 4 represent a selection of these computed curves. Figure 3 illustrates curves computed assuming constant n_2 (2.75) and varying k_2 (0.0-0.2), while Fig. 4 illustrates curves for constant k_2 (0.2) and varying n_2 (2.5-2.9). These figures show that the changes of shape in the experimental curves of Fig. 1 and 2 are not due to changes in n_2 (Fig. 4) but may be accounted for solely on the basis of small changes in k_2 (Fig. 3) which would not appreciably affect the estimate of film thickness. Figures 3 and 4 also show that the completion of one ellipsometer loop[3] is equivalent to an oxide thickness of 900Å. In fact, the figures show that even if the refractive index, n_2, varied within the range 2.5-2.9, a considerably greater variation than that reported for Cu_2O films grown under different conditions (14), the computed thickness would be in error by only 10%. Using the time to complete one ellipsometer loop as an increment of given thickness it was possible to examine the influence of zinc content, temperature, and applied potential on the kinetics of oxide growth by simply measuring the time required to complete successive loops under the various conditions. These results are presented below.

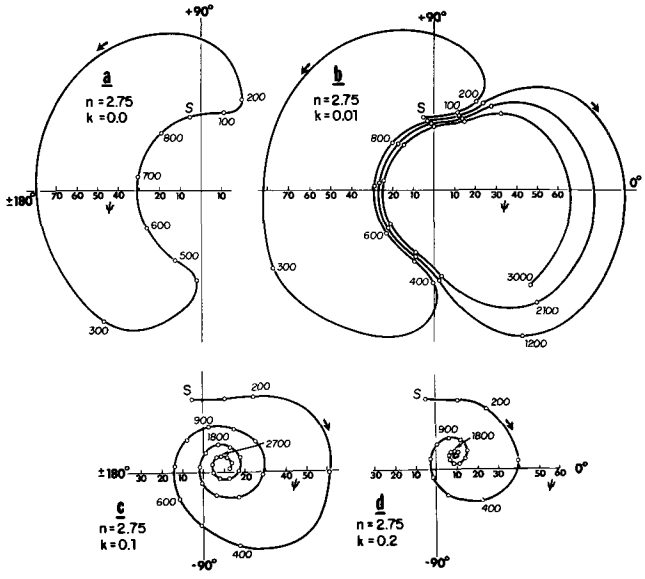

Fig. 3. Computed ellipsometric curves of Δ and ψ plotted on polar coordinates for the growth of cuprous oxide on copper assuming for the oxide constant n (2.75) and varying k (0.0-0.2). In each diagram point S indicates zero film thickness and the numbers beside each curve indicate values of film thickness in angstroms.

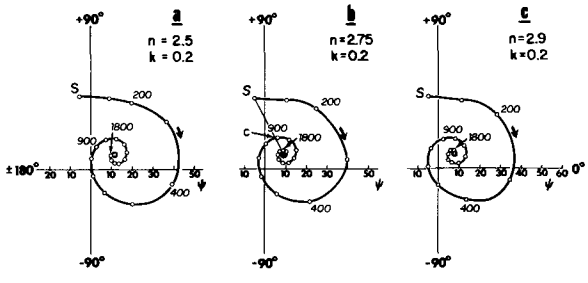

Fig. 4. Computed ellipsometric curves of Δ and ψ plotted on polar coordinates for the growth of cuprous oxide on copper assuming for the oxide varying n (2.5-2.9) and constant k (0.2). Point S indicates zero film thickness and the numbers beside each curve indicate values of film thickness in angstroms.

Influence of zinc content.—Figure 2 and Table I indicate the influence of zinc content on the oxide growth kinetics. Figure 2 shows that curvature of the ellipsometric spiral increases for increasing zinc content of the substrate, and a comparison of this figure with the computed curves of Fig. 3 suggests that the extinction coefficient, k_2, of the oxide increases for increasing zinc content of the brass. Table I shows that the time required to grow an oxide of given thickness decreases with increasing zinc content of the substrate, *i.e.*, the oxidation rate is more rapid the higher the zinc content of the brass. In fact, in the case of Cu-30 Zn the process was found to be so rapid that it could only be followed manually at −35°C. However, by using the technique described earlier in which the ellipsometer was preset to certain values, it was estimated that an oxide of ~ 900Å thickness was formed in ~ 1-2 sec at room temperature.

A further result apparent from Table I is that, for the range of oxide thicknesses studied (0-2700Å), the oxidation process follows a linear law, *i.e.*, the time required for the oxide to grow the second 900Å increment is almost the same as for the first increment. This result, which appears to be valid both over the temperature range investigated (−25°-+25°C) and under conditions of applied potential, is well illustrated in the case of Cu-5 Zn at −20°C, see Table II. In this instance if it is assumed that a 900Å oxide is formed in 37.5 min, then the time required to form

[2] The complex refractive index of the copper substrate was calculated to be 1.5 (1-2.39i). This value is in the range of values reported in Winterbottom's survey (11). It should be pointed out that this value was not substantially changed for the alloys and was therefore also used in all calculations. Changes of the refractive index of the substrate over the temperature range investigated were calculated to be small and were therefore neglected (20).

[3] For a spiral-shaped curve a loop is said to be complete when a line drawn from the beginning to the center of the spiral cuts the spiral itself, *i.e.*, at point C in Fig. 4b.

successive increments of oxide may be calculated assuming both linear and parabolic growth laws. Table II shows that the experimental observations approximate to the values computed assuming the linear law.

Effect of temperature.—For pure copper and the alloys the rate of oxide growth was found to increase with temperature, Table I. The variation in the time required to form an oxide of given thickness as a function of temperature was used to estimate the activation energy of the process. For pure copper a plot of the time to form a 900Å film *vs.* the reciprocal temperature gave an activation energy of 84.44 kjoules/mole (20.2 kcals/mole) for the reaction. For the alloys, however, no estimate of the activation energy was possible as the dependence was not linear over the limited range of temperatures examined.

Effect of anodic potential.—The application of a potentiostatically controlled anodic potential was found to increase the oxidation rate of Cu-5 Zn at 22°C. In fact, the results in Table III suggest that the logarithm of the time to grow a 900Å film follows a linear relationship as a function of applied potential. If it is assumed that the oxide thickness is equivalent to the quantity of material dissolved,[4] then this suggests that a Tafel relationship is operative, *i.e.*, that the logarithm of the current is proportional to the applied potential. Generally a Tafel relationship is obeyed when anodic dissolution under activation control occurs. During these measurements it was also noted that the applied current required to sustain a given potential was virtually constant during film growth, indicating that the oxide formed is not protective.

Discussion

The present results provide considerable insight into the mechanism of oxide growth. The observation of linear kinetics over the thickness range 0-2700Å indicates that diffusion across the film is not rate-controlling. Thus, these results would appear to eliminate an earlier suggestion that the process is controlled by the solid-state diffusion of cuprous ions across the film (4, 7). Furthermore, such a model cannot be reconciled with the rates of film growth observed in the present studies, *viz.*, from $\sim 10^{-8}$ cm/sec for Cu to $\sim 10^{-5}$ cm/sec for Cu-30 Zn. Taking the diffusion coefficient of cuprous ions in cuprous oxide at ambient temperature to be $\sim 10^{-26}$ cm^2/sec (21) and assuming a concentration gradient across a 1 μm film to be $\sim 10^{-3}$ mole/cm^3, then it may be shown that solid-state diffusion of copper ions would give rise to a rate of oxide growth of only $\sim 2.4 \times 10^{-24}$ cm/sec.

The linear growth process and the observation during anodic polarization that the oxide is not protective both support the suggestion (6, 8, 22) that the oxide is porous and that the environment has access to the metal via pores. Thus it is suggested that oxide growth involves dissolution of metal ions at the base of the pore (anodic reaction) and their deposition at the oxide surface (cathodic reaction) electrons flowing through the oxide film. Such a process is also consistent with the earlier observations that the oxide is severely depleted with respect to zinc (6). Moreover, this model can account for the observed growth kinetics. Thus, taking the diffusion coefficient of copper ions in solution at ambient temperatures to be $\sim 10^{-5}$ cm^2/sec (23) and again assuming the concentration gradient of copper ions across a film of 1 μm thickness to be 10^{-3} mole/cm^3, then it may be shown that diffusion in solution would give rise to oxide-growth rates of $\sim 2.4 \times 10^{-3}$ cm/sec.

While in the present work oxide growth is linear over the thickness range 0-2700Å, previous workers (24) have reported that a limiting thickness is eventually reached. It was shown for Cu-30 Zn immersed in Mattsson's solution (1) of pH $\sim$ 7.2, that a limiting thickness of 5 μm was attained, at which point it was suggested that the rate of growth was equal to the rate of dissolution of the oxide. In terms of the present observations it is possible that, for film thicknesses considerably in excess of 2700Å, diffusion through pores would be rate-controlling. Alternatively, oxide growth could be limited either by an increase in the copper ion concentration at the base of the pore which would in itself restrict the dissolution kinetics (25) or by electron transport through the film.

The magnitude of the activation energy of the oxide-growth process for copper, ~20 kcal/mole, and the fact that the process appears to obey a Tafel relationship suggests that the rate-controlling step is anodic dissolution at the base of the pore. Accepting this, then the strong influence of zinc content on the oxide-growth rate of the metal can be attributed to the influence of zinc on the kinetics of anodic dissolution which, in turn, may be attributed to the high thermodynamic activity for dissolution of zinc. It is reasonable to suggest that the dissolution of a copper atom from the surface occurs via some type of active site, such as a kink site or ledge, and that the rate of dissolution of copper atoms is related to the number of such active sites. If zinc atoms, because of their high thermodynamic activity for dissolution, may be dissolved directly from the plane surface producing monotomic pits, then this would lead to the creation of a large number of additional active sites from which dissolution of copper atoms would be facilitated.

While the present results provide a general outline of the mechanism of oxide growth, several details remain to be established. In particular, the specific role (24) of the cupric complex, $Cu(NH_3)_4^{2+}$, in the tarnishing process is not understood. It has been suggested (5) that the reduction of these complexes provides an efficient cathodic reaction but the precise role of this reaction is not clear. Also, it is not understood why the base of the pore remains free of oxide. It is well established that oxide formation is critically dependent on the chemical composition of the environment, particularly on pH (1, 2). However, the way in which the reactions at the base of the pore maintain oxide-free conditions requires further attention. Finally, it would appear that season-cracking might be curtailed by controlling the anodic dissolution reaction at the base of the pores; for example, by the addition of minor alloying elements which might poison the active sites at which dissolution occurs.

A Simple Crevice Corrosion Theory

D. A. Vermilyea* and C. S. Tedmon, Jr.*

Research and Development Center, General Electric Company, Schenectady, New York

ABSTRACT

A simple theory for the concentration and potential variation in a crevice is compared with experimental results from a model crevice. A consequence of the theory, confirmed by experiments, is that a small potential difference in a crevice can cause a large concentration change and a corresponding large increase in corrosion current at a given applied potential. The theory gives a simple way to estimate concentrations in crevices in real corrosion situations.

We wish to present a very simple approximate theory for the concentration changes which accompany current flow to an electrode confined in a crevice. The treatment is especially applicable to corrosion along a grain boundary when the sides of the crevice are entirely inert, but with simple modifications it could be used to predict concentration changes in a pit. Following the derivation of equations, experiments using a model crevice are discussed in the light of the theory. This theory differs from the more complicated analyses of concentration changes in crevices by Beck and Grens (1) and by Posey (2) principally in the fact that the sides of the crevice are completely inert.

Theoretical

Consider a crevice of depth l having a thickness w and an arbitrary dimension perpendicular to w and l. The current is assumed to flow only in a direction parallel to the depth, and to be carried by only one ion, for instance, an ion of the metal being dissolved. In each volume element perpendicular to l of thickness dx we have

$$d\phi = I\,dR = \frac{I\rho dx}{A} \qquad [1]$$

in which ϕ is the electrical potential, I is the current flowing in the crevice, R is the resistance of the solution in the crevice, ρ is the resistivity of the solution, and A is the cross-sectional area of the crevice. For dilute solutions the resistivity is given by

$$\rho = \frac{1}{z\mathbf{F}\mu C} \qquad [2]$$

in which z is the valence of the ion which carries the current, $\mathbf{F}$ is Faraday's constant, μ is the ion mobility, and C is the ion concentration. If each volume element is electrically neutral, a very good approximation in most situations of interest (3), then the concentration of the current-carrying ion must be equal to that of the anion (assumed to have equal charge). The concentration of the anion is given by

$$C = C_0 \exp ze\phi/kT \qquad [3]$$

in which C_0 is the concentration of the anion in the bulk of the solution. Introducing the value for C from Eq. [3] and the Einstein relationship $\mu = zDe/kT$ with D the diffusion coefficient, e the electronic charge, k Boltzmann's constant, and T the temperature into Eq. [2] and [1] gives

* Electrochemical Society Active Member.

$$C_o \exp ze\phi/kT \, d\phi = \frac{J \, dx \, kT}{z^2 \, \mathbf{F}eD} \quad [4]$$

in which J is the current density. A solution of Eq. [4] is

$$C = \frac{Jx}{z\mathbf{F}D} + \text{const.} \quad [5]$$

Since $C = C_o$ at $J = 0$ we have from Eq. [5]

$$C - C_o = \frac{Jx}{z\mathbf{F}D} \quad [6]$$

The potential at any point in the crevice can be found by integrating Eq. [4] and noting that $\phi = 0$ at $x = 0$, which gives

$$\phi = \frac{kT}{ze} \ln\left(1 + \frac{Jx}{z\mathbf{F}DC_o}\right) \quad [7]$$

$$= \frac{kT}{ze} \ln\left(1 + \frac{\Delta C}{C_o}\right) \quad [8]$$

where ΔC is the concentration change at the position in question.

Equations [6] and [8], the fundamental equations resulting from the theory, are limited to very dilute solutions in which the ion mobility is not a function of concentration. To a first approximation, however, the equations are useful to concentrations of about molar.

There are two modifications which make the basic equations more useful. The first is to consider the concentration change in the solution just outside the crevice. The same general method for that region, which has approximately cylindrical geometry, leads to the equation

$$\Delta C = \frac{Jw \ln r_2/r}{\pi z\mathbf{F}D} \quad [9]$$

in which r_2 is the radius at which the bulk concentration is reached and r is equal to $w/2$. Equation [8] is valid for the potential in this region, with $\phi = 0$ corresponding to the point where the bulk concentration is reached.

The second modification is useful for total applied potentials large enough so that the concentration reaches a value in excess of molar within the crevice, and the resistivity is no longer represented adequately by Eq. [2]. A crude approximation is to consider that Eq. [6] and [8] are valid to a distance x_1 at which the concentration reaches some value such as molar, and that deeper in the crevice the resistivity of the solution is constant. The value of x_1 is found from Eq. [6] to be

$$x_1 = \frac{z\mathbf{F}D \, \Delta C_{max}}{J} \quad [10]$$

in which ΔC_{max} is the difference in concentration between 1 M/l and the concentration at the mouth of the crevice. The equation for the total potential in the crevice is then

$$\Phi = J \cdot \rho_{max} (1 - x_1) + \frac{kT}{ze} \ln\left(1 + \frac{\Delta C_{max}}{C_o}\right) \quad [11]$$

in which ρ_{max} is the constant resistivity reached deep within the crevice.

Experimental

Sample preparation.—Two types of samples were attempted. First, attempts were made to prepare samples by clamping thin iron foil between optically flat quartz plates; this approach was unsuccessful because electrolyte always penetrated between the foil and the quartz.

The second type of sample, which was more successful, was prepared in the following manner. Optical flats were prepared on pieces of Lucalox,[1] which is a sintered form of Al_2O_3 having theoretical density. The Lucalox pieces were about 2.5 cm² by 0.25 cm thick. A strip 0.1 cm thick was masked off along one edge of the optical flat surface of each piece, and iron was vaporized onto the surface to a thickness of 8000Å. The two pieces were then sintered together at 900°C for 1 hr in hydrogen. A load of about 25 lb was placed on the pieces to promote good contact and sintering. Following the sintering treatment, gold was vaporized onto the end of the sandwich for an electrical contact to the iron. A schematic illustration of the completed sample is shown in Fig. 1. During subsequent experiments, the sides of the sample were coated with stopcock grease to prevent access of the electrolyte to the iron except in the crevice.

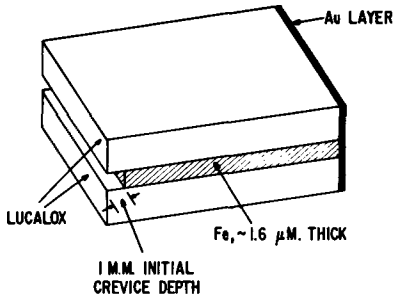

Fig. 1. Schematic of the model crevice

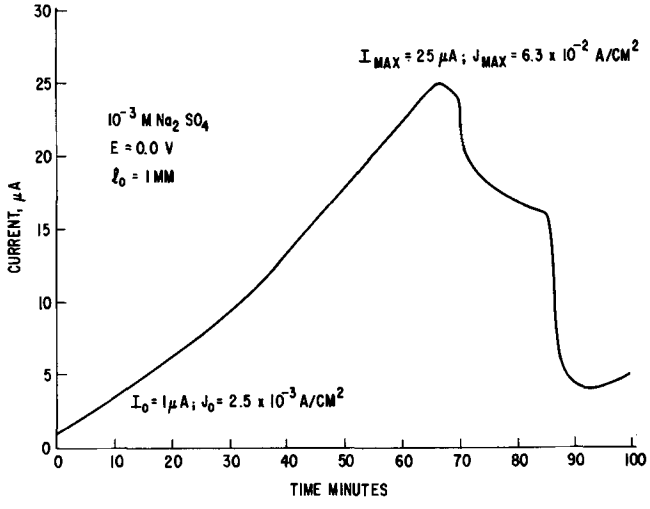

Fig. 2. Results of experiment using 10^{-3}M Na_2SO_4 at 25°C

Potentiostatic anodic polarization experiments.—Polarization experiments were carried out in 10^{-3} M Na_2SO_4 and 10^{-3} M H_2SO_4, using a Wenking Model 66-TA-10 potentiostat. A saturated calomel reference electrode (SCE) was employed with a salt-bridge, Luggin-probe, and Pt counterelectrode. All runs were carried out at room temperature (25°C) in air saturated solutions. Current was measured as a function of time at constant potential. Samples were equilibrated overnight under open-circuit conditions prior to a run.

Results

Figure 2 is a plot of current *vs.* time at an applied potential of 0.0V SCE in 10^{-3} M Na_2SO_4. The experimentally measured initial current was 1 μA, corresponding to an initial current density of 2.5 x 10^{-3} A/cm². The initial current may be calculated from the electrolyte resistivity, the initial crevice depth, the area of the crevice. and the open-circuit potential. In this experiment, the electrolyte resistivity was 5000 ohm-cm and the open-circuit potential was −0.50V. For these conditions, the initial resistance of the elec-

[1] Tradename.

trolyte within the crevice is calculated to be 1.25 x 10^6 ohms and the initial current should have been 0.4 μA.

There are two reasons why the calculated and experimental initial currents may not be in exact agreement. First, some dissolution of the iron may occur while the sample is being equilibrated under open circuit conditions, leading to a decrease of the electrolyte resistance and therefore an increase in the initial current. Second, it is difficult to measure the current during the first few seconds of the run while the applied potential is being adjusted to the desired level. Consequently the calculated value given above may be considered to be in reasonable agreement with the experimental value.

The current was observed to increase steadily for about 1 hr, reaching a maximum value of 25 μA, which corresponds to a current density of about 6.3 x 10^{-2} A/cm^2. The slow increase of current is a consequence of the gradual concentration of the solution in the crevice as the current flow continues. At that point the current was observed to decrease in an irregular manner to a value of 4-5 μA.

From Eq. [3], [8], [9], and [11] the values of concentration and potential at various points in the system were calculated with the following assumptions. The contribution of Na^+ was neglected, since current flow removes it from the crevice; this neglect introduces a small error in the results for the space outside the crevice. The contribution of OH^- was also neglected, since it is present in the bulk solution at a very low concentration. It was assumed that the bulk concentration was reached at $r_2 = 10^{-2}$ cm because of natural convection. With these assumptions, using $z = 2$, $\mathbf{F} \cdot D = 1$, the observed current density (0.063 A/cm^2), $w = 1.6 \cdot 10^{-4}$ cm, $r = 0.8 \cdot 10^{-4}$ cm, and $\rho_{max} = 5$ ohm-cm, the results shown in Table I were obtained.

The theory predicts that the concentration at the bottom of the crevice is greater than 1 M/l and that the potential at that point is −0.105V SCE. For comparison, potentiostatic experiments using 1M Na_2SO_4 solutions and pure iron specimens of various kinds showed that the current density reached values of about 0.15 A/cm^2 at a potential of −0.4V SCE, and then fell to 0.05 A/cm^2 at a potential of −0.2V SCE and remained at that value to +0.25V SCE. These results are in excellent agreement with those from the crevice corrosion experiment. The decrease in current at long times in Fig. 2 may be the result of partial passivation by precipitation of $Fe(OH)_2$ in the crevice.

In order to minimize $Fe(OH)_2$ precipitation further experiments were made using 10^{-3} M H_2SO_4, with the result shown in Fig. 3. In these experiments 2 hr were allowed for the initial equilibration, and the open circuit potential was again −0.5V SCE. In each run the current was still increasing when the run was terminated, but evidently a steady-state was approached. One problem encountered in these experiments is that the crevice depth increases during the run. After each run, the crevice depth was measured optically (the Lucalox is translucent), and the increase in crevice depth was always consistent with the coulometrically integrated current-time curves. Figure 4 presents a photograph of a typical sample after a series of runs in the 10^{-3} M H_2SO_4. It is evident that iron dissolution was relatively uniform along the crevice.

In the experiments of Fig. 3 a potential of −0.2V SCE was used. Calculations like those performed above but using $J = 1.1 \cdot 10^{-1}$ A/cm^2 gave the results shown in Table II.

Numerous experiments using M H_2SO_4 are reported in the literature, and all agree that a current density of about 0.1 A/cm^2 would be expected at a potential of about −0.34V SCE in good agreement with the observed value. It is interesting that an iron wire in the same 10^{-3} M H_2SO_4 solution at −0.2V SCE gave a current density of only 2 x 10^{-3} A/cm^2, an impressive demonstration of the effectiveness of the crevice in increasing the corrosion rate. As with the experiments in Na_2SO_4, the initial current of about 5 μA in Fig. 3 is higher than the calculated value of 1 μA. In the longer crevice (Fig. 3, run 2) the currents are lower as expected.

Summary

The simple theory for the concentration and potential variation in a crevice makes predictions which are in reasonable accord with experimental results. A consequence of the theory, confirmed by experiments, is that a small potential difference in a crevice can cause a large concentration change and a corresponding large increase in corrosion current at a given applied potential. The theory gives a simple way to estimate concentrations in crevices in real corrosion situations.

Acknowledgment

A conversation with Dr. C. P. Bean was very instrumental in developing the model presented in this paper.

Transport Numbers and the Structure of Porous Anodic Films on Aluminum

A. Dekker and A. Middelhoek

N. V. Philips' Gloeilampenfabrieken, Development Laboratory, Zwolle, The Netherlands

ABSTRACT

Experiments are described in which aluminum samples, covered with a porous oxide layer by anodization in oxalic acid, are subsequently re-anodized in boric acid ("forming"). The experimental techniques employed combine standard voltage and current measurements with gravimetric and optical methods for film thickness determination and measurements of the rate of film dissolution. The results show that for a given anodizing electrolyte the porosity depends only on the anodizing voltage and that it decreases with increasing voltage. The growth of the porous films is determined solely by the formation of oxide at the oxide/metal interface. This can be used to define a transport number for the positive ions during anodization, which was found to be $t_+ = 0.33$. During forming in boric acid of a sample already covered with a porous oxide layer some of the oxide is formed in the pores and some at the metal/oxide interface. For this process a transport number $t_+ = 0.24$ was obtained. The average pore diameter, cell diameter, and barrier layer thickness vary linearly with the anodizing voltage, the cell wall thickness being somewhat thinner than the barrier layer.

It is well known that aluminum may be covered with an oxide layer by anodic oxidation. The structure of these anodic films depends markedly on the electrolyte used, particularly on the degree to which it acts as a solvent for the oxide. In a solution containing oxalic acid or other acids which attack the oxide, a porous layer is obtained, whereas in boric acid solution a compact uniform layer is formed. The difference between these two extreme cases is clearly demonstrated by the shape of the voltage *vs.* time curves obtained during growth of the layers at constant anode current density. In oxalic acid the voltage first rises to a relatively low maximum (5-100V), then decreases slightly and approaches a constant value (*e.g.*, Fig. 1). However in boric acid the voltage increases linearly with time, at least until the "sparking voltage" (usually several hundred volts) has been reached. A general review of the subject is given by Young (1).

It is also possible to re-anodize an aluminum sample in boric acid which has been anodized previously in oxalic acid. In fact Dekker and Van Geel (2) used this as a technique to obtain information about the structure of the porous layer laid down initially. According to these authors the pores of the porous layer are filled during the re-anodization process and from the voltage *vs.* time curve obtained at constant current density during this process they deduced a value for the porosity of the original film. This technique has received little further attention in the literature. The interpretation of Dekker and Van Geel has been rejected in the literature (3), but in our opinion without any factual justification. Recently, however, Dunn (4) essentially confirms the pore-filling process.

The present paper deals with experimental results obtained by anodization of aluminum in oxalic acid and subsequent re-anodization in boric acid. In the following the re-anodization in boric acid shall be referred to as "forming;" the term "anodizing" is reserved for the production of a porous layer in oxalic acid. The present study extends that of Dekker and Van Geel by combining the standard current and voltage measurements with optical and gravimetric methods for film thickness determinations and measurements of the rate of film dissolution. The data obtained permit the determination of the porosity of the films produced by anodization, the transport numbers associated with anodization and subsequent forming, and the diameter and density of the pores in porous films.

Key words: anodic oxidation, transport numbers, porosity of aluminum oxide films, Tolansky thickness measurements.

Experimental Evidence for the Pore-Filling Process

In this section we discuss some simple experiments which confirm and extend the results obtained earlier by Dekker and Van Geel. They provide conclusive evidence for the pore-filling mechanism and lead to a model which is used for the interpretation of the results described in the sections that follow. We first describe briefly the procedures and equipment used in these experiments.

Samples

The samples were punched from aluminum foil of 100μ thickness and a purity of 99.98% (impurities in ppm: Cu 26, Si 51, Fe 24, Mg 6). They consisted of a circular area of 50 mm diameter and were provided with a contact strip; it turned out that a constriction in the stem just above the circular area prevented the electrolyte from creeping up. The total anodizable area was 39.0 cm^2. The samples were cleaned by subjecting them to the following sequence of procedures: (*a*) immersion in NaOH (20 g/liter) at 20°C for 9 min; (*b*) rinsing in deionized water at 20°C for 2 min; (*c*) immersion in 48% sulfuric acid at 90°C for 3 min; (*d*) rinsing in deionized water at 20°C for 2 min; (*e*) immersion in a mixture of 950 ml deionized water, 50 ml H_3PO_4 (85%) and 20g CrO_3 at 85°C for 2 min; (*f*) rinsing in deionized water at 20°C for 2 min; (*g*) rins-

ing in alcohol at 20°C for 5 min; and (*h*) drying in a furnace at 50°C for 30 min.

Anodizing

The anodization process was carried out in an oxalic acid solution (80 g/liter) at a constant current, supplied by a constant current generator (maximum variation 1% from 0 to 500V) in a thermostat held constant within 0.1°C. The current generator could be regulated between 100 and 500 mA for voltages between 0 and 1000V. An aluminum plate served as cathode. During the process the voltage (V) across the cell was recorded as a function of time (t) on a Philips line recorder (Type PR 2210 U/21). After anodizing (or forming) the samples were cleaned twice in alcohol at 20°C, the first time for 10 min and the second time for 20 min; alcohol was used rather than water to prevent hydration of the oxide and because of the good solubility of oxalic acid in alcohol. Afterward, the samples were dried in air at 50°C. Since further heating of the samples in air at 450°C for 30 min did not produce a detectable change in weight, the drying procedure was considered satisfactory.

Forming

Forming of a single sample was carried out at a constant current density of 0.38 mA/cm² at 25° ± 0.5°C in an electrolyte prepared as follows. A solution consisting of 27.9g glycol, 24.9g boric acid, and 12.4g ammonia (13*N*) was heated at 140°C until its specific resistivity was about 5000 ohm-cm at 25°C, and diluted with alcohol to give a forming electrolyte with a specific resistivity of approximately 1300 ohm-cm at 25°C.

Results and Discussion

First of all a number of experiments analogous to those performed by Dekker and Van Geel were carried out, *i.e.*, the voltage V was measured as a function of time t during forming with constant current in boric acid of samples that had been anodized previously. Since these results confirmed those of Dekker and Van Geel it may suffice to give one illustrative example. Two samples have been anodized with different current densities J_a and J_b (Fig. 1). The corresponding curves for subsequent forming at equal current densities (Fig. 2) show different initial slopes; the steepest slope is found for the specimen that has been anodized with the highest current density. The first stage in both cases corresponds to the pore-filling

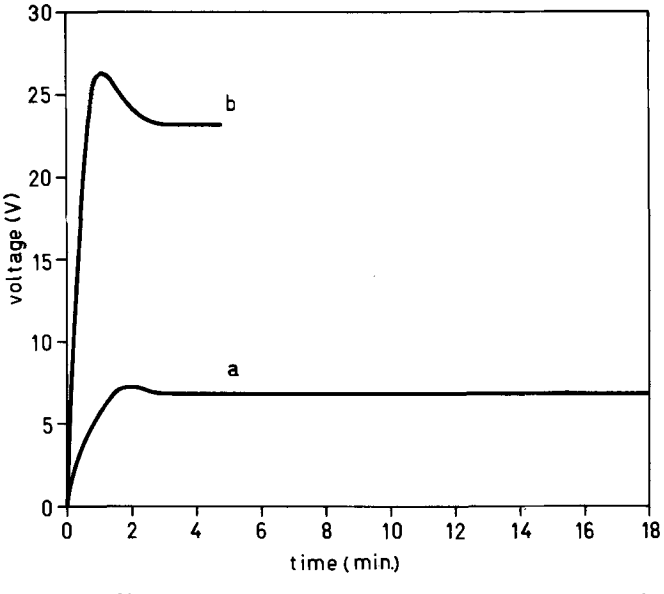

Fig. 1. Voltage vs. time during anodizing in 80 g/l oxalic acid at 20°C. Curve (a) corresponds to an over-all current density J_a = 0.63 mA/cm² for 18 min; curve (b) corresponds to J_b = 2.54 mA/cm² for 4.5 min.

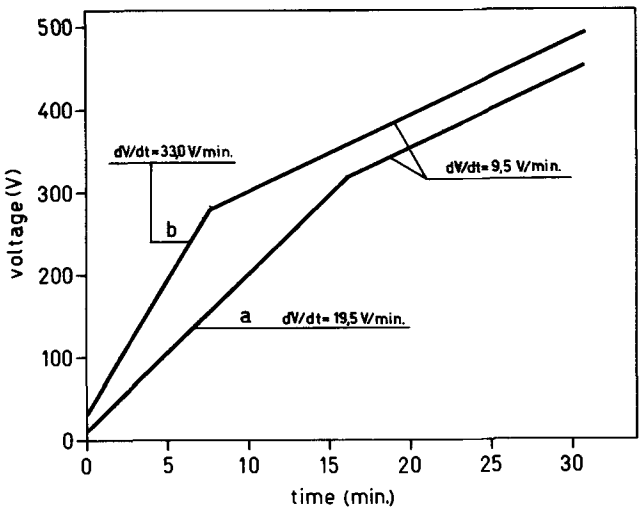

Fig. 2. Voltage vs. time during forming with 0.38 mA/cm² at 25°C after anodizing; curves (a) and (b) refer to the anodizing current densities J_a and J_b of Fig. 1.

mechanism proposed by Dekker and Van Geel. The final slopes are equal to that found for a virgin specimen formed with the same current density. Hence the point where the two straight parts of the V-t curve meet (the "knee-voltage") corresponds to the situation where the pores have been filled completely. Since dV/dt is constant during the pore-filling stage it makes sense to introduce a porosity α_a of the anodized layer defined by the total cross-section of the pores per unit area of the sample. It follows from Fig. 2 that the porosity increases with decreasing anodizing current density. If all the oxide during forming were produced at the pore-base/electrolyte interface, α_a would simply be given by the ratio of the final and initial slopes. However a part of the oxide, as will be shown later, is produced during forming at the metal/oxide interface. This complicates the determination of α_a. The nonzero value of V for $t = 0$ (Fig. 2) results from the presence of a compact barrier layer in the porous films adjacent to the metal; this barrier is built up during the anodizing of the sample (Fig. 1).

A second type of experiment was performed with two samples of which one was anodized for 12 min in oxalic acid with a current density J_a and subsequently for 3 min with another current density J_b, and the other sample was similarly anodized with the same current densities but in reverse order (Fig. 3). The V-t curves recorded during forming (Fig. 4) now consist of three linear stages with slopes that are equal to those encountered in the first type of experiment within the limits of accuracy. From the order in which these slopes occur, one may conclude that the porous layer grows at the metal/oxide interface, *i.e.*, the "old" oxide will be found at the top of the layer.

The anodizing conditions during the second stage may be chosen in such a way that the corresponding porosity α_a approaches unity so that the layer produced during the first stage no longer adheres to the metal. In a typical experiment of this kind a sample was first anodized with a current density of 5.1 mA/cm² during 45 min at 20°C and thereafter with a current density of 0.13 mA/cm² at 40°C. With great care it was possible to obtain in this manner an oxide membrane of about 8 μm thick. This was found to be permeable to a colored liquid (a solution of picric acid in dimethylformamide), which supports the conclusion that such layers are porous. It is interesting to note that w[illegible] heated for 2 hr at 640°C, its weight decreased by only 1.4%, implying that the degree of hydration of the membrane is very low [see also Bernard and Randall (5)]. Subsequent boiling in deionized water for 3 min

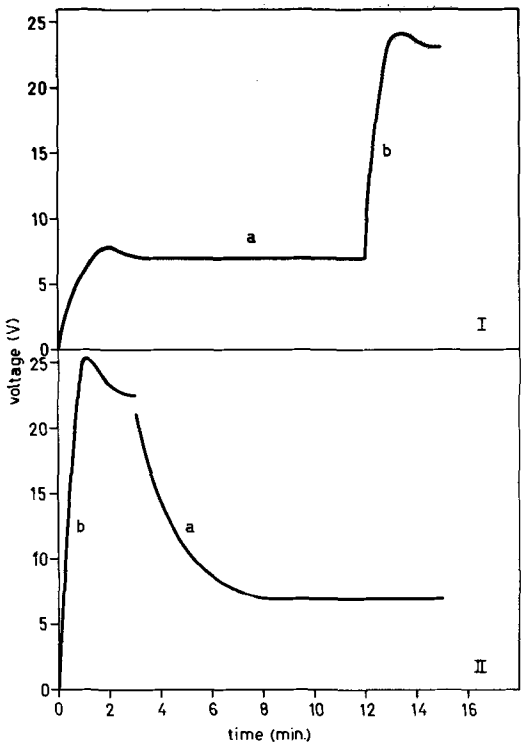

Fig. 3. Voltage *vs.* time during anodizing in 80 g/l oxalic acid at 20°C. I refers to an anodizing current density $J_a = 0.63$ mA/cm^2 applied for 12 min and, subsequently, $J_b = 2.54$ mA/cm^2 for 3 min. II corresponds to the reverse sequence.

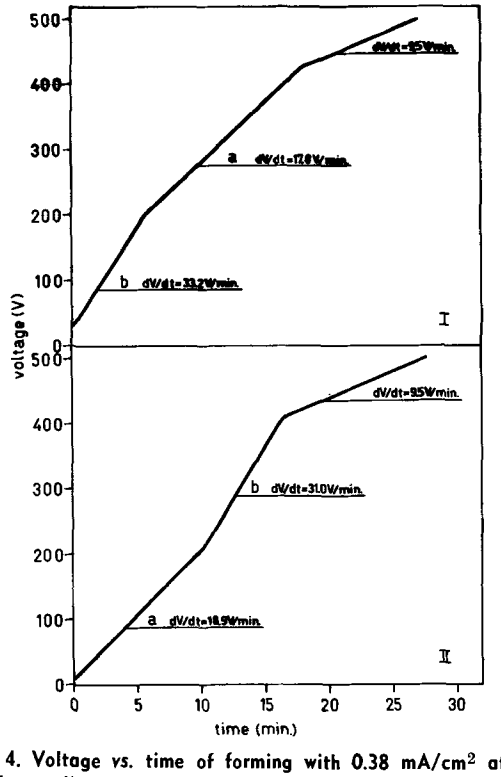

Fig. 4. Voltage *vs.* time of forming with 0.38 mA/cm^2 at 25°C after the anodizing procedures I and II of Fig. 3.

increased the weight by 11.6%; this water could be removed easily by heating. One may thus conclude that the anodized layers are porous and contain originally relatively little water, in contrast to the opinion of Murphy and Michelson (6).

Similar information as referred to above concerning the structure of porous layers can be obtained by current rather than voltage measurements during forming. Such measurements have been carried out in particular with a "duo-circuit" in which two samples are formed in parallel in boric acid with a constant total current; one of the samples a virgin aluminum specimen and the other anodized previously in oxalic acid. For this system we then measured the current drawn by the virgin specimen, $I_f(t)$, the current drawn by the anodized specimen, $I_{a,f}(t)$, and the voltage $V(t)$ across the cell during the forming process. Typical results are shown in Fig. 5. We can distinguish three stages: During the first of forming stage (from $t = 0$ to $t = t_a$) only the virgin sample draws current. For $t = t_a$ the field across the barrier layer of the anodized sample becomes large enough to allow ionic transport and the second stage is reached in which $I_{a,f}$ and I_f remain essentially constant with $I_{a,f} < I_f$. This is consistent with the interpretation that during the second stage the pore-filling mechanism is operative. Near $t = t_b$ the pores are practically filled and the field becomes large enough for the onset of ionic transport through the whole area of the anodized plate; this leads to the final stage in which the samples share the total current equally. The time t_b was found to be proportional to the period of anodization, in agreement with the pore-filling mechanism. The overshoot in the $I_{a,f}(t)$-curve (Fig. 5) near A is a transient effect which is of no further interest to us here. The dip near B in this curve indicates the presence of a constriction in the pores, presumably related to their initiation because the oxide at the top of the layer is produced during the initial stages of the anodization process. For higher anodizing temperatures and/or lower anodizing current densities the constriction is not observed and may even be transformed into an enlargement as a result of the aggressive action of the electrolyte.

Even for thick porous layers, for which the "knee-voltage" of the Dekker-Van Geel technique cannot be determined, the duo-circuit method can be used con-

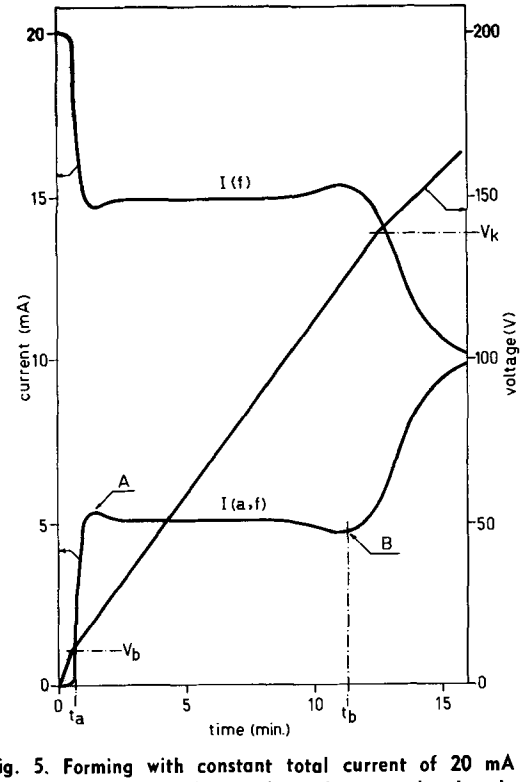

Fig. 5. Forming with constant total current of 20 mA in the "duo-circuit" of a virgin sample and a sample that had been anodized in 80 g/l oxalic acid with 1 mA/cm^2 for 6 min at 15°C. $I_f(t)$ and $I_{a,f}(t)$ represent the currents drawn by the virgin and anodized sample, respectively. The common voltage V is also shown as a function of time, V_k refers to the "knee-voltage" and V_b to the voltage across the barrier layer $t = t_a$.

veniently because it incorporates directly a virgin reference anode.

Model of the Pore-Filling Process

The results described above as well as those reported earlier by Dekker and Van Geel show that during forming in boric acid of a sample covered with a porous oxide layer at least some of the new oxide is formed in the pores. It is evident that this requires transport of positive ions under influence of the electric field from the metal/oxide interface to the pore-base/electrolyte interface. On the other hand, the results do not exclude the possibility that some of the new oxide is formed at the metal/oxide interface as a result of the motion of negative ions. In the next section we shall see that this is actually what happens. The assumption of transport of positive as well as negative ions leads to a schematic model as given in Fig. 6 as a basis for the discussion of the process of forming in boric acid of a sample already covered with a porous layer. Let A_t be the total area of the anodized portion and let A_p represent the total cross section of the pores. The porosity α_a of the porous layer may then be defined as

$$\alpha_a = A_p/A_t \qquad [1]$$

Let $I_{a,f}$ be the current employed during forming and suppose that the pores are only partly filled. The weight of new oxide produced per unit time is then

$$\left(\frac{dw}{dt}\right)_{a,f} = e_{a,f}\,\eta_{a,f}\,I_{a,f} \qquad [2]$$

where $e_{a,f}$ is the electrochemical equivalent of the new oxide and $\eta_{a,f}$ the current efficiency of the process. We may then define a transport number t_+ for the positive ions by

$$t_+ = \frac{\text{weight of new oxide formed in the pores/unit time}}{\text{total weight of new oxide formed/unit time}} \qquad [3a]$$

For simplicity we assume that the density of the oxide formed in the pores, $\rho_{a,f}$ is the same as that formed at the metal/oxide interface.

Using Fig. 6 and Eq. [2], Eq. [3a] becomes

$$t_+ = \rho_{a,f}\,A_p\,(dh_+/dt)/(e\eta)_{a,f}\,I_{a,f} \qquad [3b]$$

Similarly

$$(1 - t_+) = \rho_{a,f}\,A_t\,(dh_-/dt)/(e\eta)_{a,f}\,I_{a,f} \qquad [3c]$$

Solving [3b] and [3c] for the sum $(dh_+/dt + dh_-/dt)$ or $(dh/dt)_{a,f}$, and replacing A_p/A_t by α_a from [1], gives

$$(dh/dt)_{a,f} = \left(\frac{e\eta}{\rho}\right)_{a,f}\frac{I_{a,f}}{A_t}\left[\frac{t_+}{\alpha_a} + (1 - t_+)\right] \qquad [4]$$

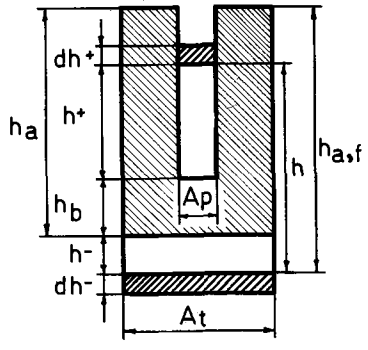

Fig. 6. Schematic picture of forming of an anodized sample in the pore-filling stage. A_p represents the total cross section of all pores in a sample of total area A_t. h_+ and h_- represent the oxide formed in the pores and at the metal side, respectively. h_b represents the thickness of the barrier layer.

For a virgin aluminum sample formed with a current I_f the rate of change of thickness would be given by

$$\left(\frac{dh}{dt}\right)_f = \left(\frac{e\eta}{\rho}\right)_f\frac{I_f}{A_t} \qquad [5]$$

In order to discuss the kind of experiments described above it is convenient to transform from thicknesses to rates of change of voltage across the samples. Thus, let E_f and $E_{a,f}$ represent the effective electric field strengths during forming of the virgin and anodized samples, respectively. Multiplying [4] by $E_{a,f}$ and [5] by E_f, gives the rates of change of voltage, *i.e.*, Eq. [6] and [7].

$$\left(\frac{dV}{dt}\right)_{a,f} = \gamma_{a,f}\frac{I_{a,f}}{A_t}\left[\frac{t_+}{\alpha_a} + (1 - t_+)\right] \qquad [6]$$

$$\left(\frac{dV}{dt}\right)_f = \gamma_f\frac{I_f}{A_t} \qquad [7]$$

where

$$\gamma_{a,f} = \left(\frac{e\eta E}{\rho}\right)_{a,f} \text{ and } \gamma_f = \left(\frac{e\eta E}{\rho}\right)_f \qquad [8]$$

The basic Eq. [6] and [7] can be used to discuss experimental results such as shown in Fig. 2 and Fig. 4 as well as those shown in Fig. 5. For example, the condition required during the second stage of the duo-circuit experiment of Fig. 5 reads

$$\left(\frac{dV}{dt}\right)_{a,f} = \left(\frac{dV}{dt}\right)_f \qquad [9]$$

from which we find for the ratio of the two constant currents

$$\beta \equiv \frac{I_{a,f}}{I_f} = \frac{\gamma}{(t_+/\alpha_a) + (1 - t_+)} \text{ with } \gamma \equiv \gamma_f/\gamma_{a,f} \qquad [10]$$

Solving for t_+ we may write this relation in the following convenient form

$$t_+ = \left(\frac{\alpha_a}{1 - \alpha_a}\right)\left(\frac{\gamma - \beta}{\beta}\right) \qquad [11]$$

From its definition it is clear that γ must be approximately equal to unity, small deviations may arise, for example, from a slight difference between E_f and $E_{a,f}$. In fact, from a rather intricate analysis of experimental results, which we shall not give here, we found $\gamma = 0.98$.

From Eq. [6] and [7] we can also derive an expression for the ratio of the final and initial slopes of a V-t curve during forming of a single anodized plate, such as given in Fig. 2. The final slope must then be identified with $(dV/dt)_f$ and the initial one with $(dV/dt)_{a,f}$. The condition for this type of experiment is expressed by

$$I_{a,f} = I_f \qquad [12]$$

and we find for the "voltage ratio" from [6] and [7]

$$\frac{(dV/dt)_f}{(dV/dt)_{a,f}} = \frac{\gamma}{(t_+/\alpha_a) + (1 - t_+)} = \beta \qquad [13]$$

For the anodizing conditions pertaining to Fig. 5 we actually found a voltage-ratio of 0.33, which is nearly equal to the experimental current-ratio of 0.34, as required by [13]. According to [11] the transport number t_+ can be obtained from experimental values of α_a and β, assuming γ is known or taken equal to unity as a reasonable approximation. We therefore discuss next the determination of α_a.

Determination of the Porosity

The porosity of a porous layer produced by anodization with a current density of 1 mA/cm^2 in 80 g/liter acid at 15°C was determined by gravimetric and optical thickness measurements. The principle of this determination may be explained with reference

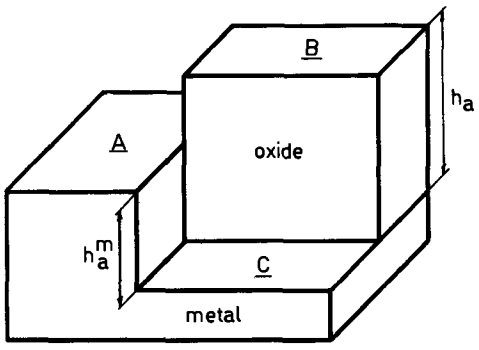

Fig. 7. Schematic view of a partly anodized sample from which part of the oxide has been removed, illustrating the principle of the thickness measurements according to Tolansky.

to Fig. 7 where h_a represents the thickness of the anodized layer and h_a^m the thickness of the metal layer consumed for the anodization. Let W_a and W_a^m represent the corresponding weights per unit over-all area; ρ_a is the density of the oxide (excluding the pores) and ρ_m the density of the metal. Making use of the definition [1] of the porosity α_a we may write

$$dW_a = \rho_a (1 - \alpha_a)\, dh_a \qquad [14]$$

or

$$\alpha_a = 1 - \frac{1}{\rho_a}\frac{dw_a}{dh_a} = 1 - \frac{\rho_m}{\rho_a}\frac{dW_a/dW_a^m}{dh_a/dh_a^m} \qquad [15]$$

The porosity was obtained by measuring the quantities appearing in the last expression.

The densities ρ_a and ρ_m were measured by weighing the anodized samples in air as well as in distilled glycol with a density of 1.1108 g/cm^3 at 20°C and a temperature coefficient of −0.58 mg/cm^3 °C in the region between 15° and 30°C. By repeating this procedure after removal of the oxide in chromic-phosphoric acid the required densities could be found. The results obtained from at least three determinations were

$$\rho_a = 2.96 \pm 0.03 \text{ and } \rho_m = 2.698 \pm 0.003 \text{ g/cm}^3 \qquad [16]$$

The weights W_a and W_a^m were obtained by weighing the samples before anodizing, after anodizing, and after removal of the anodized layer in chromic-phosphoric acid. The results are plotted for a series of experiments in Fig. 8, and we conclude that the so-called "coating ratio"

$$dW_a/dW_a^m = 1.16 \qquad [17]$$

The thickness measurements were carried out by the Tolansky method (7) employing a Leitz Metallux Microscope provided with a sodium light source. Since this method requires very flat surfaces, evaporated aluminum layers on glass were used. For this purpose Corning 7059 glass sheets were cleaned by ultrasonic agitation in isopropylalcohol for 10 min. Afterward they were rinsed in hot isopropylalcohol in a Soxleth apparatus. The substrate was then heated in vacuum for 1 hr at about 350°C to remove adsorbed water in order to obtain good adherence. The aluminum was deposited at about 150°C substrate temperature from a tungsten spiral to a thickness of about 1μ. After anodizing the oxide was removed from one half of the anodized surface in chromic-phosphoric acid. Finally, the whole surface was covered with a thin layer of evaporated aluminum to obtain sufficient reflection. The interference lines were photographed in regions where differences in height occurred. From the shift of the interference lines at a particular step the step height could be determined with an error of a few per cent. The results obtained for various periods of anodization were plotted in the form of a graph of h_a as a function of h_a^m (Fig. 9).

$$dh_a/dh_a^m = 1.21 \qquad [18]$$

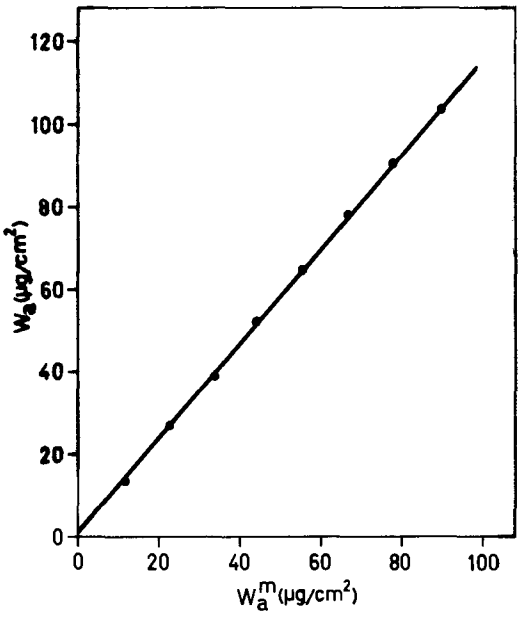

Fig. 8. Weight of anodic oxide (W_a) as a function of the weight of aluminum consumed (W_a^m) for anodization with a current density of 1 mA/cm^2 in 80 g/l oxalic acid at 15°C. The points refer to anodization periods of 2, 4, 6, 8, 10, 12, 14, and 16 min.

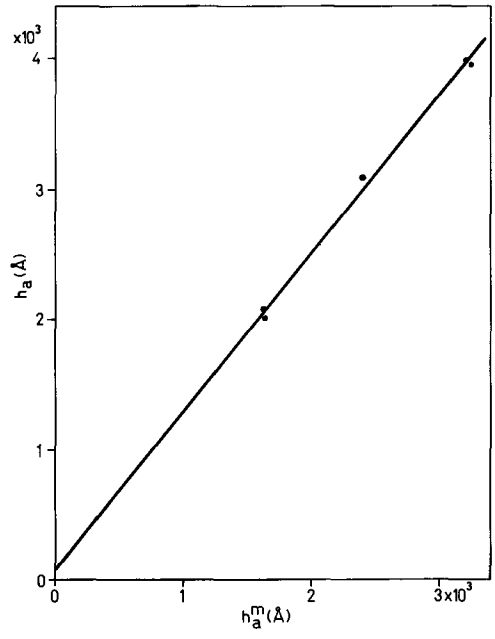

Fig. 9. Height of the oxide film (h_a) as a function of the height of the metal layer consumed (h_a^m), determined by the Tolansky technique for evaporated samples anodized in 80 g/l oxalic acid at 15°C. The points refer to anodization periods of 8, 12, and 16 min.

We may remark that the values found for h_a^m were in good agreement with those calculated from the current density and the period of anodization, assuming a current efficiency $\eta_a = 1$. From the last four formulas we thus obtain for the porosity of the anodized layer, under the experimental conditions used, $\alpha_a = 0.13$.

The porosity can also be obtained from the formula

$$\alpha_a = \frac{h_a - W_a/\rho_a}{h_a - h_b} \qquad [19]$$

which follows immediately from Fig. 6. Using a barrier layer thickness $h_b = 150$Å (as determined in the next section) and the values of h_a and W_a corresponding to an anodizing time of 18 min in Fig. 8 and 9, we

find $\alpha_a = 0.11$. In what follows we shall use

$$\alpha_a = 0.12 \quad [20]$$

The Transport Numbers

From the above information one can calculate the transport number t_+ of the positive ions during forming in boric acid of a sample previously covered with a porous layer. In fact, substituting into expression [11] the value $\beta = 0.34$ (obtained from Fig. 5), $\alpha_a = 0.12$, and $\gamma = 0.98$ one finds $t_+ = 0.26$. A check on this value was obtained as follows. Equation [3] can be changed from weight to volume terms assuming for simplicity that the density of the oxide formed in the pores equals the density of the oxide formed at the metal/oxide interface. Thus from Fig. 6

$$t_+ = \frac{\alpha_a h_+}{\alpha_a h_+ + h_-} \text{ where } \begin{matrix} h_+ = h_a - h_b - (h_{a,f} - h) \\ h_- = h_{a,f} - h_a \end{matrix} \quad [21]$$

For a sample anodized for 16 min with a current density of 1 mA/cm² at 15°C and formed subsequently in boric acid to 395V, the Tolansky technique yielded $h_a = 3930$Å and $h_{a,f} = 5320$Å. The quantities h_b and h were determined by charging the sample before and after forming with a small current density (5 μA/cm²) so that further growth was prevented and a constant voltage was reached. Under these circumstances 1V corresponds to 13.4Å and from the measured voltages we found $h_b = 150$Å and $h = 4870$Å. Substitution into [21] then yields $t_+ = 0.22$. We thus find an average value

$$(t_+)_{\text{forming}} = 0.24 \quad [22]$$

Consequently, the largest fraction of the current during forming of an anodized layer is carried by negative ions, at least under the experimental conditions used.

In recent years several values for the transport number have been reported based on techniques employing some kind of "marker." For example, Davies *et al.* (8) introduced Xe as a marker and reported in one series of experiments with an electrolyte consisting of a solution of borax in glycol and water $t_+ = 0.58$. In another series using an aqueous citrate solution they reported values varying between 0.33 and 0.72. More recently Randall (9) found $t_+ = 0.27$ by employing P^{32} as a marker. The reliability of these results will strongly depend on the absence of interaction of these marker atoms with the environment. It would seem that our method is more direct and, consequently, more reliable than methods using markers.

We shall now discuss the transport number of the positive ions during the anodization process in oxalic acid, *i.e.*, during the formation of the porous layer itself. In this connection it is important to realize that in the stationary period of growth with constant anode current the voltage across the sample remains constant (Fig. 1), *i.e.*, that the distance between the metal/oxide interface and the pore-base/electrolyte interface remains constant. From this we conclude that during anodization the rate of dissolution of oxide at the pore-base/electrolyte interface must just cancel the rate of growth of the barrier layer between the pore-base and metal. Assuming again transport of positive and negative ions, the amount of oxide that dissolves at the pore-base consists of two portions: (*i*) the amount of oxide that would be produced in the pores by that part of the current that is carried by positive ions; and (*ii*) a fraction α_a of the oxide produced at the metal/oxide interface due to transport of negative ions. Consequently, only the fraction $(1 - t_+)(1 - \alpha_a)$ of the anodizing current is effective in producing oxide. Since this newly formed oxide is distributed over a fraction $(1 - \alpha_a)$ of the total area of the sample, the over-all thickness of the anodic oxide layer (h_a in Fig. 7) is determined directly by the transport number $t_- = (1 - t_+)$ of the negative ions. Employing the nomenclature introduced in earlier sections we may thus write for the stationary state during anodization with a current density J

$$\frac{dh_a}{dt} = (1 - t_+)\frac{e_a}{\rho_a}\eta_a J \quad [23]$$

Expressing the current density in terms of the amount of metal consumed during anodization

$$\eta_a J = \frac{\rho_m}{e_m}\frac{dh_a{}^m}{dt} \quad [24]$$

this leads to the relation

$$1 - t_+ = \left(\frac{e_m}{e_a}\right)\left(\frac{\rho_a}{\rho_m}\right)\frac{dh_a}{dh_a{}^m} \quad [25]$$

According to [18] $dh_a/dh_a{}^m = 1.21$ and from [16] we obtain $\rho_a/\rho_m = 1.10$. If we assume that the oxide is pure Al_2O_3 the ratio of the electrochemical equivalent $e_a/e_m = 1.89$ and we find $(1 - t_+) = 0.70$ or $(t_+)_{\text{anodizing}} = 0.30$. However, a titration with $KMnO_4$ showed that the anodized layer contained 3.85% oxalate. This incorporation of foreign material in the oxide would change the effective ratio of the electrochemical equivalents to $e_a/e_m = 1.97$, leading to $(t_+)_{\text{anodizing}} = 0.33$.

In any case, there is some difference between the transport numbers obtained for the anodizing and forming process, indicating some dependence of t_+ on the electrolyte used. Employing the duo-circuit we also found that for given anodizing conditions the current ratio β and the knee voltage V_k (see Fig. 5) depend somewhat on the forming electrolyte used.

Pore Diameter and Pore Density

In this section the structure of porous oxide layers on aluminum is studied in more detail by employing measurements of the porosity α_a as a function of the anodizing voltage V_a and additional information obtained by measurements of the rate of dissolution of the films.

Consider a porous film containing N pores per unit area. With each pore one can associate a "cell" with a diameter D defined by the relation

$$\tfrac{1}{4}\pi N D^2 \equiv 1 \quad [27]$$

Per unit area the total pore area is equal to the porosity α_a and we can define a pore diameter p such that

$$\tfrac{1}{4}\pi N p^2 \equiv \alpha_a \quad [28]$$

In terms of these definitions we have

$$\alpha_a = p^2/D^2 \quad [29]$$

The Dependence of p and D on V_a

An extensive series of measurements of α_a covering a temperature range between 3° and 45°C, a current density range between 0.1 and 20 mA/cm², and a voltage range between 3 and 50V showed that for a given anodizing electrolyte α_a depends only on V_a. For this purpose α_a was determined by substituting into expression [11] or [13] the observed ratio β and taking $t_+ = 0.24$ in accordance with [22]. The results for oxalic acid (80 g/l) and sulfuric acid (63.5 g/l) are shown in Fig. 10. According to [29] these results imply that p/D is also a function of V_a only.

Now, from a study of the geometrical properties of porous anodic films on aluminum, Keller, Hunter, and Robinson (10) arrived at a model in which p, D, and the anodizing voltage V_a satisfy the relation

$$D = 2AV_a + p \quad [30]$$

where A is a constant. Assuming this relation to be correct it is easy to show in combination with [29] that one should have

$$\frac{p}{A} = \frac{2\sqrt{\alpha_a}}{1 - \sqrt{\alpha_a}}V_a \text{ and } \frac{D}{A} = \frac{2}{1 - \sqrt{\alpha_a}}V_a \quad [31]$$

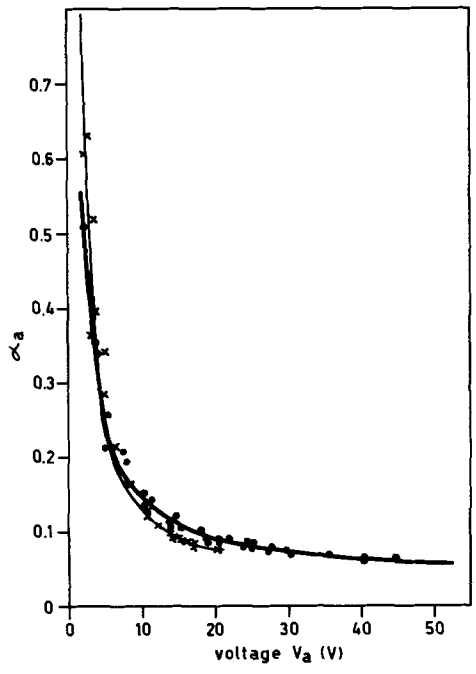

Fig. 10. Porosity α_a as a function of anodizing voltage V_a. The points refer to 80 g/l oxalic acid and the crosses to 63.5 g/l sulfuric acid.

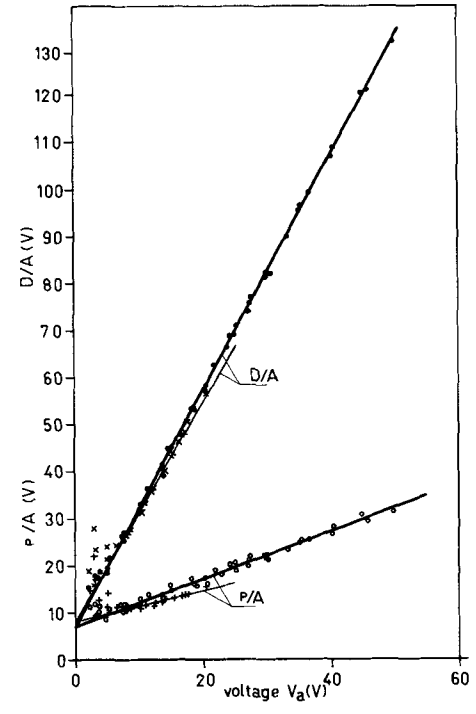

Fig. 11. Quantities p/A and D/A as a function of anodizing voltage. The points and open circles refer to oxalic acid, the crosses and plus signs refer to sulfuric acid.

From a knowledge of α_a as a function of V_a one can thus calculate p/A and D/A as a function of V_a. The results shown in Fig. 11 show that formula [30] indeed applies if both D and p are considered to be linear functions of V_a. The latter result evidently contradicts the conclusion of Keller, Hunter, and Robinson that p is independent of V_a.

Determination of the Pore Diameter and Pore Density

Additional information concerning p and D was obtained by dissolving an anodized layer at constant temperature (25°C) in chromic-phosphoric acid and measuring the reduction in weight as a function of time. Similar experiments have been carried out by Nagayama and Tamura (11). In these experiments it is assumed that there is a constant rate of dissolution $v = -dh/dt$ where h represents the thickness of any part of the oxide surface exposed to the etching solution. A typical result for the change in weight of an anodized sample as a function of the etching time is shown in Fig. 12. There is evidently a rather well-defined time t_R required to dissolve the anodized layer completely. The quantity A introduced in expression [30] pertaining to the Keller-Hunter-Robinson model is clearly related to t_R as follows

$$S \equiv \tfrac{1}{2}(D - p) = vt_R = AV_a \qquad [32]$$

where S represents the cell wall thickness. Once v and t_R are known, A can be obtained and from it p and D can be determined from [31].

The rate of dissolution v was determined as follows: A sample covered with a porous oxide layer was formed in boric acid together with a virgin specimen in the duo-circuit until the knee voltage V_k was reached (see Fig. 5). The pores are then just filled and the thickness of this layer was determined by charging the sample with a small current density (5 μA/cm^2) and measuring the final constant voltage V_m across the sample. Since 1V corresponds to 13.4Å this is an effective method for determining the thickness of the layer. Typical results for the measured voltage V_m as a function of the etching time in chromic-phosphoric acid at 25°C for such layers are presented in Fig. 13 for various anodizing current densities. Since the amount of forming oxide in the pores is relatively small ($\approx$10%), it is assumed that the rates of dissolution so determined are characteristic for the porous layers. Experimental values of v are given in Table I; they depend somewhat on the anodizing current density. From v and t_R we found A = 9.0 Å/V. Values of p and D calculated from [32] and [31] are also given in Table I, together with the current ratio β from which α_a was calculated from [11] assuming t_+ = 0.24. Finally, Table I gives the values of the barrier layer thickness, h_b, which amounts to 10.6Å/V. Note that this is somewhat larger than A, *i.e.*, the barrier layer is somewhat thicker than the cell wall S.

It is of interest to point out that the explicit form of the time-dependence of W_a during etching can also be used to determine p and D. Assuming that the dissolution occurs with the same rate v at the top of the layer, inside the pores and at the base layer we can set up an expression for $W_a(t)$ as follows. With reference to Fig. 6 we may write during etching

$$h_a(t) = h_a(0) - vt \text{ and } p(t) = p(0) + 2vt \qquad [33]$$

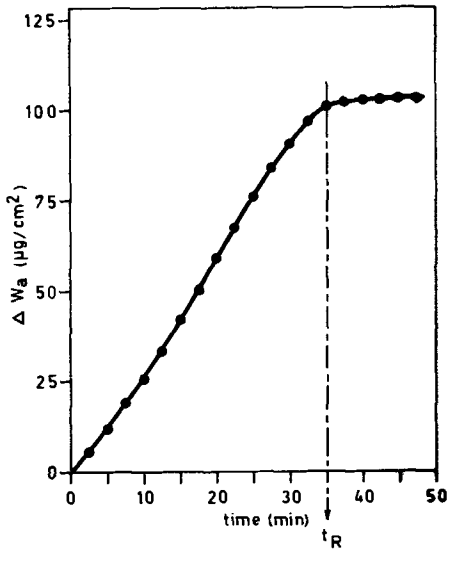

Fig. 12. Change in weight as a function of etching time for a sample anodized with a current density of 1 mA/cm^2 during 16 min.

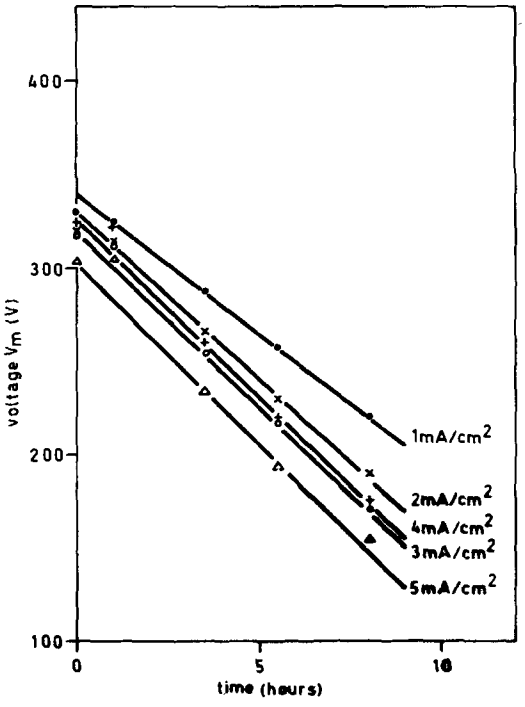

Fig. 13. Measured voltage V_m as a function of dissolution time for sample anodized with various current densities.

where $p(t)$ represents the pore diameter. Let h_p represent the pore depth, *i.e.*, the distance between the top of the oxide layer and the pore base. The weight of the oxide layer per unit area at $t = 0$ is then

$$W_a(0) = \rho_a[h_a(0) - \tfrac{1}{4}N\pi h_p p^2(t)] \quad [34]$$

and after a period t of etching

$$W_a(t) = \rho_a[h_a(0) - vt] - \tfrac{1}{4}\pi N h_p \rho_a[p(0) + 2vt]^2 \quad [35]$$

Note that h_p is constant. Consequently

$$\frac{\Delta W_a}{t} \equiv \frac{W_a(0) - W_a(t)}{t} = \rho_a v[1 + N\pi h_p p(0)] + \rho_a N\pi h_p v^2 t \equiv C + Bt \quad [36]$$

An experimental example of this relationship is shown in Fig. 14 for a sample anodized with a current density of 5 mA/cm². In this case $B = 1.10 \times 10^{-2}$ μg/cm² min² and $C = 0.77$ μg/cm² min. In terms of B and C the original diameter $p(0)$ and the density of pores N are given by

$$p(0) = \left(\frac{C - v\rho_a}{B}\right)v \text{ and } N = \frac{4}{\pi D^2} = \frac{B}{\pi\rho_a h_p v^2} \quad [37]$$

When we calculate $p(0)$ and D by substituting the experimental values for the various quantities into [37] we find, with $h_p = 3260$Å, $p(0) = 282$Å and $D = 930$Å, in good agreement with the corresponding values in Table I for an anodizing current density of 5 mA/cm².

Conclusions

The results obtained above lead to the following conclusions.

(a) Anodic films obtained in oxalic acid are indeed porous in the sense that the pores can be filled by subsequent forming in an electrolyte that does not dissolve the oxide, such as boric acid. The porosity decreases with increasing anodizing current density.

(b) During forming in boric acid of a sample already covered with a porous layer some of the oxide forms at the pore-base/electrolyte interface and some at the metal/oxide interface. This behavior can be used to define a transport number t_+ for the positive ions; under the experimental conditions used it was found that $t_+ = 0.24$. This invalidates the quantitative interpretation of Dekker and Van Geel (2) because these authors tacitly assumed $t_+ = 1$.

(c) The growth of a porous anodic film is determined solely by the formation of oxide at the oxide/metal interface. This can also be used to define a transport number for the anodization process, which was found to be $t_+ = 0.33$.

(d) The average pore diameter, cell diameter, and barrier layer thickness of a porous film vary linearly with the anodizing voltage, the cell wall thickness being somewhat less than the barrier layer thickness. This requires some modification of the Keller-Hunter-Robinson model (10) in which pore diameter is considered independent of the anodizing voltage.

Table I

J (mA/cm²)	V_a (V)	v (Å/min)	β	α_a	p (Å)	D (Å)	h_p (Å)

Anodic Oxidation of Hydrocarbons

T. N. Hartley

Blackburn College of Technology and Design, Blackburn, England

and D. Price

Chemistry Department, University of Salford, Salford, Lancashire, England

ABSTRACT

The anodic oxidation of ethylene in 1.5M sulfuric acid at 80°C has been shown to occur at a gold-coated platinum electrode with a Tafel slope of 0.083V. The effect of variation of the weight of electrodeposited gold and also of temperature were studied. The products were carbon dioxide, acetone, acetaldehyde, and propionaldehyde, the Faradaic efficiency of conversion to carbon dioxide being 20% at 0.79V (*vs.* NHE). The addition of surface active agents to the electrolyte tended to increase the overpotential for ethylene oxidation at platinum and gold electrodes. The effect was particularly pronounced in the case of cetyl pyridinium bromide, probably because of preferential adsorption of bromide ions on the electrodes. Partial anodic oxidation of acetylene in 1.5M sulfuric acid was observed at the gold electrode at 80°C. Much less oxidation was observed for methane and ethane.

In recent years there has been much fundamental research into electro-organic oxidation, particularly with reference to fuel cells. Because of the large numbers of parameters involved (*e.g.*, electrode type, nature of electrolyte, fuel gas, temperature, etc.) much more investigation is required before a comparative picture of the electro-oxidation of hydrocarbons over a reasonably wide range of parameters can be obtained. This work is a study of the anodic oxidation of some simple hydrocarbons.

Experimental

All experiments were carried out in a thermostated Pyrex H-cell, of conventional design, which contained 1.5M sulfuric acid as electrolyte. The anode and cathode compartments were separated by means of a sintered glass disk which prevented diffusion of gases or products between compartments. Connection between the anode and the reference electrode was via a Luggin capillary (1). The reference electrode was mercury-mercurous sulfate in contact with the same 1.5M sulfuric acid electrolyte which was used in the cell. This eliminated any liquid junction potential. The reference electrode was standardized at 20°C against a hydrogen electrode with 1.5M sulfuric acid as electrolyte. The platinum and gold anodes were prepared as electrodeposits, the method of plating being chosen to give a powdery deposit of high surface area (2). Before each run the electrodes were electrically pulsed to remove adsorbed oxygen and organic impurities. Frequent "blank" experiments were used to test for electrode poisoning. When this had become significant, the electrode was stripped and replated.

A 6V lead-acid accumulator was used as a d-c current source, the actual current through the cell being controlled by means of a simple galvanostat. For each run, the anode and cathode compartments were first purged with nitrogen to remove any dissolved oxygen or carbon dioxide. The nitrogen supply to the catholyte was maintained, while that to the anolyte was replaced by hydrocarbon gas bubbled through at about 6-8 cc/min. The rest potential was observed for some 30 min after the hydrocarbon had been admitted. The desired current was then set and the anode potential recorded when a stable potential (potential change less than 10 mV/hr) had been reached. All potentials are expressed *vs.* the normal hydrogen electrode at 20°C.

The Faradaic efficiency for the oxidation of ethylene to carbon dioxide was determined by a titrimetric procedure (3).

The effect of the surface active agents on the anodic oxidation of ethylene was investigated by adding them as a 0.1% w/v solution in the 1.5M sulfuric acid in the anode compartment. The cathode and reference compartments contained 1.5M sulfuric acid only. Blank runs with no surfactant added were carried out before every addition of surfactant to check that the electrodes retained their original activity throughout the experiments.

Reagents.—The methane, ethane, and ethylene were Matheson C.P. grade and the acetylene and nitrogen commercial "oxygen-free" grade. The water used had been previously de-ionized. Sulfuric acid and hydrochloric acid were "Analar" grade and the chlorauric acid was laboratory reagent grade. Mercurous sulfate was anodically generated from mercury and sulfuric acid by the flowing anode method (4). The surface active agents used were anionic-Teepol-610 (Shell Chemicals)—mixture of sodium secondary alkyl sulfates, cationic-cetyl pyridinium bromide (laboratory reagent grade), and nonionic-Nonidet P40 (Shell Chemicals)—an octyl phenol/ethylene oxide condensate.

Results

Anodic oxidation of ethylene at gold electrode.—Figure 1 shows the polarization curve obtained for the oxidation of ethylene in 1.5M sulfuric acid at 80°C at anodes plated with varying quantities of gold. A linear relationship is observed in the approximate region +0.75 to +0.95V. Except in the case of the electrode with the heaviest gold deposit, anode potentials stabilized almost instantaneously in the Tafel region and were independent of changes in ethylene flow rate. Below +0.75V the potentials were slow to stabilize and were very nonlinear. This was attributed to charging of the double layer. The slope of the Tafel region is

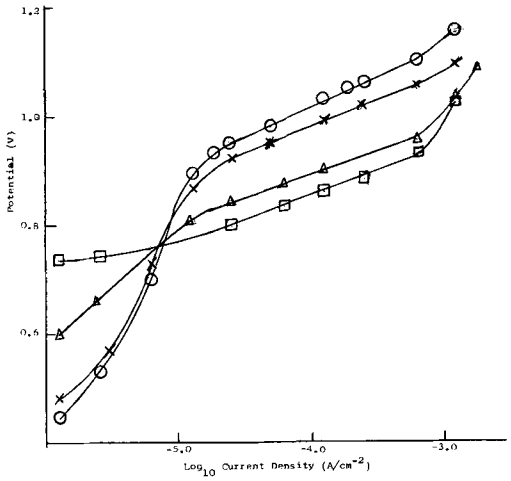

Fig. 1. Current-potential curves for anodic oxidation of ethylene in 1.5M sulfuric acid at 80°C, variation with weight of deposited gold. ○ 0.4375 mg Au cm^{-2}; X 1.5625 mg Au cm^{-2}; △ 4.0375 mg Au cm^{-2}; □ 7.325 mg Au cm^{-2}.

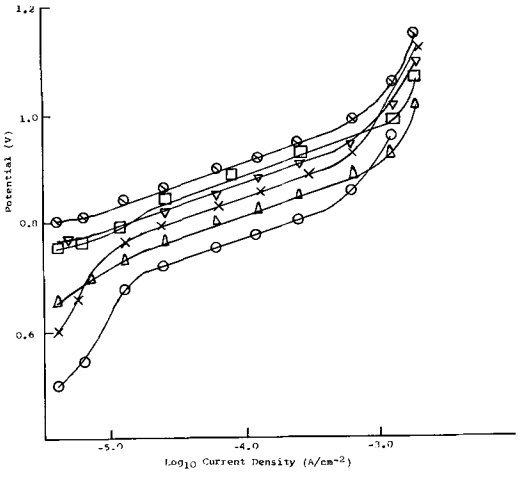

Fig. 3. Current-potential curves for anodic oxidation of ethylene in 1.5M sulfuric acid, effect of temperature. ○ 90°C; △ 70°C; X 60°C; ▽ 50°C; □ 40°C; ⊘ 26°.

0.085V, which corresponds closely to (2.303 RT)/F, at all electrodes except that with the lowest weight of gold, at which it is 0.110V. Figure 2 shows the variation of rest potential with gold coverage.

Polarization curves for ethylene oxidation at the gold electrode at temperatures between 26° and 90°C are shown in Fig. 3. The slope and length of the Tafel lines are independent of temperature within the range investigated, but the Tafel line is displaced toward higher potentials as the temperature is decreased. Calculation of an apparent activation energy for the ethylene oxidation from this data gave a value of 13 kcal $mole^{-1}$. This value will include heats of adsorption of products and reactants as well as the true activation energy which refers to reactants at the electrode surface.

Gas chromatographic analysis, using a hydrogen flame detector, of the anolyte after oxidation of ethylene at the gold anode indicated the presence of propionaldehyde, acetone, and acetaldehyde, the latter two in approximately equal trace amounts. Carbon dioxide was the only product conclusively detected in the effluent gases from the anode compartment. The Faradaic efficiency for the oxidation of ethylene to carbon dioxide at the gold anode was determined as 20%. Figure 4 shows the effect of the presence of three

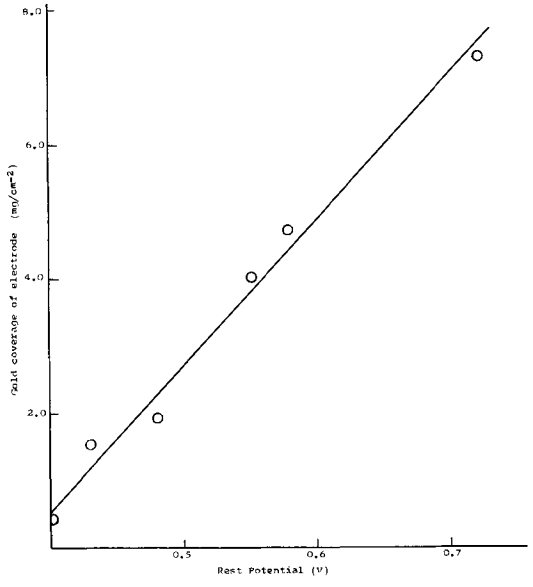

Fig. 2. Variation, with gold coverage, of the rest potential in the presence of ethylene in 1.5M sulfuric acid at 80°C.

different surface active agents on the polarization curves obtained for the anodic oxidation of ethylene at gold and platinum electrodes.

Anodic oxidation of methane, ethane, and acetylene at gold electrode.—Current-potential curves obtained with these gases in 1.5M sulfuric acid with the gold electrode are shown in Fig. 5. The curves for the two saturated hydrocarbons indicate that some oxidation occurred insofar as a short Tafel region can be seen in the 10^{-5} A cm^{-2} region. The acetylene plot shows a Tafel region from 1.25 x 10^{-4} A cm^{-2} to 7.5 x 10^{-3} A cm^{-2}, the slope of the line being 166 mV which corresponds closely to 2(2.303 *RT*)/**F**. Potentials in this region exhibited a slow, continuous oscillation within ±4 mV of the mean value. On completion of the experiment, the anolyte had acquired a golden-yellow color and had an aldehydic odor.

Discussion

The results shown in Fig. 1 confirm that ethylene can be anodically oxidized at gold electrodes. Kuhn *et al.* (5) proposed the following mechanism for this reaction

$$C_2H_4 \rightleftharpoons C_2H_4\ (ads) \qquad [1]$$

$$H_2O \rightleftharpoons OH\ (ads) + H^+ + e \qquad [2]$$

$$C_2H_4\ (ads) + OH\ (ads) \rightarrow -CH_2-O-CH_3\ (ads) \qquad [3]$$

$$-CH_2-OCH_3\ (ads) \xrightarrow{\text{Desorption}} CH_3-C(=O)-H$$

$$-CH_2-OCH_3\ (ads) \xrightarrow{\text{Oxidation}} -CH-CH_2\cdot + H_2O \rightarrow CO_2 \qquad [4]$$

where reaction [3] is rate determining. The results described in this work are consistent with this mechanism. The Tafel slope of 85 mV is associated with a chemical reaction following first charge transfer or following any later charge transfer in which the reactant is at full coverage (6). Substitution of nitrogen for ethylene at the gold anode produced an immediate rapid rise in potential in the Tafel region, whereas at the platinum electrode little change occurred until 10 min after the gas substitution. This supports the view that the rate-determining step at the gold anode involves the species C_2H_4 (ads) [3], while at the platinum anode the slow step is the preceding water discharge reaction [2]. The observed production of aldehydes from the anodic oxidation of ethylene on gold is probably due to the desorption of intermediates from the gold surface, reaction [4]. This reaction should be more rapid at the gold electrode than at a platinum electrode because the strength of a partially covalent bond be-

Fig. 4. tween metal and organic species is about 20 kcal lower for gold than platinum (7).

Passivation of the gold electrode is shown by the continuous increase in potential at higher current densities. This is probably due to retardation of the ethylene oxidation process due to geometric and catalytic retardation effects of oxide formation.

The slopes of the Tafel plots shown in Fig. 1 show that the oxidation of ethylene is little affected by the platinum substrate on which the gold electrode is plated. The displacement of the Tafel line to more positive potentials as the gold coverage decreases (Fig. 2) can be attributed to roughness factor variations. Comparison of the current densities at a single potential indicates that the roughness factor for the high gold weight electrode was approximately fifty times greater than that for the low gold weight electrode. Figure 1 indicates a limiting current density of approximately 10^{-3} A cm^{-2} at which the ethylene oxidation reaction becomes diffusion-controlled. A similar

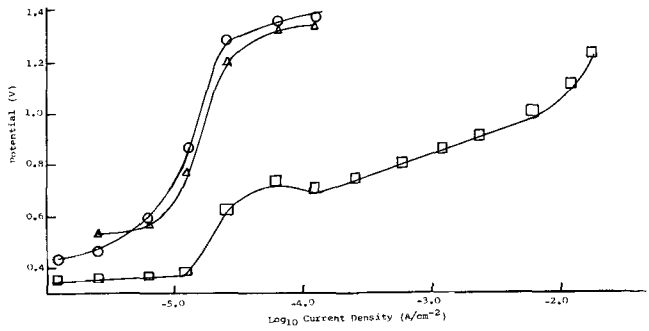

Fig. 5. Current-potential curves for anodic oxidation at gold electrode of various hydrocarbons in 1.5M sulfuric acid at 80°C. □ acetylene; ○ methane; △ ethane.

region has been observed at platinum electrodes (3). A Fick's law calculation indicates that the value lies between 2.6 x 10^{-3} and 0.5 x 10^{-3} A cm^{-2} which is in good agreement with our experimental value. Thus, diffusion control in the limiting current region is due to slowness of transport of sufficient ethylene from the solution to the electrode surface.

Figure 3 shows that the effect of variation of temperature (26° → 90°C) on ethylene oxidation at the gold electrode was merely to displace the linear Tafel regions to higher or lower potentials. The length and slope of the Tafel region was unaffected, showing that anodic oxidation of ethylene on gold can be carried out in the region of ambient temperatures. The value of 13 kcal $mole^{-1}$ obtained for the apparent activation energy for ethylene oxidation at the gold anode is lower than the value of 20 kcal $mole^{-1}$ calculated by Bockris (3) for the oxidation at the platinum electrode. It should be remembered that complete oxidation to carbon dioxide occurs at the platinum electrode whereas, at the gold electrode, oxidation is incomplete. The relationship between this apparent activation energy and the true activation energy at the electrode surface, could well be quite different for the gold than for the platinum electrode because of the greater number, complexity, and variation of absorbed species occurring at the gold surface.

For complete conversion of ethylene to carbon dioxide 12 electrons per molecule are transferred, whereas if only aldehydic compounds are produced the number is 2. In our experiments, using the gold electrode, 20% of the ethylene was oxidized to carbon dioxide. Hence the average number of electrons transferred per molecule of ethylene electro-oxidized was approximately four. The efficiency of the gold electrode as a current-producing device is, therefore, in the region of 30%. Since gold has a similar capital cost to platinum, it would appear that gold is not a practical possibility as an ethylene fuel cell anode, in spite of the reaction having a lower Tafel slope and activation energy compared to the values at the platinum electrode. The temperature effect is of value, however, if the products of the partial oxidation of ethylene are required.

The detection of propionaldehyde, acetaldehyde, and acetone in the electrolyte after anodic oxidation of ethylene is in agreement with a reaction sequence in which the final stage is a branched reaction involving desorption of intermediates to form aldehydes. That partially oxidized products other than acetaldehyde were obtained indicates that the desorption branch of Eq. [4] is an oversimplification. In addition to desorption to produce acetaldehyde, the postulated intermediate —CH_2—O—CH_3 (ads) may undergo further reaction at the gold surface, possibly with adsorbed ethylene, to produce other intermediates containing more carbon atoms.

It is likely that the effects observed when various surfactants were present in the electrolyte, Fig. 4, were due to adsorption of various species at the surface of the electrodes resulting in changes in the effective electrode potentials. Bromide ions are known to be

strongly adsorbed at platinum electrodes (8-10). Vasil'ev and Bogotskii (9) state that the introduction of Cl^-, Br^-, or I^- ions in $10^{-2}N$ concentration will completely inhibit the electrolytic oxidation of an organic substance, an effect which they ascribe to microblocking of the electrode surface. It has also been shown (9) that various organic molecules (aldehydes, carboxylic acids, and high molecular weight alcohols) are adsorbed at a platinum electrode and have an inhibiting effect on the electro-oxidation of ethanol and formic acid.

The polarization curves obtained in the presence of cetyl pyridinium bromide are probably due to the electrostatic attraction between the electrode and bromide ion leading to preferential adsorption of the Br^- ion rather than ethylene. The steeper polarization curve obtained at the platinum electrode indicates that Br^- ion is more strongly absorbed at the platinum than the gold electrodes under the conditions of our experiments.

With the exception of the non-ionic surfactant at the gold electrode, the effect of the anionic and non-ionic compounds is to displace the Tafel lines to more anodic potentials, but without a change in slope. It would appear that the mechanism of ethylene oxidation is not changed by the presence of these agents, but that the number of active sites is reduced probably by blocking due to preferential adsorption of the surfactant molecules.

Figure 5 shows that acetylene is much more strongly oxidized than methane and ethane at the gold anode at 80°C in 1.5M sulfuric acid. The presence of aldehydes in the anolyte indicates that the oxidation is incomplete. The rapid stabilization of potential at low current density observed for acetylene is consistent with the observations of Bianchi (11). Bianchi attributed rest potentials on platinum in the presence of ethane, ethylene, and acetylene to be due to firmly adsorbed acetylene and carbon radicals formed by successive hydrogenation and dehydrogenation of the hydrocarbon. Potentials anodic to the rest potential but less positive than the commencement of the Tafel region were considered due to dehydrogenated carbon radicals whose rate of formation is most rapid in the case of acetylene.

A change in the nature of the species adsorbed at the electrode, in the presence of acetylene, is indicated by the onset of the second region, 1.25×10^{-5} to 1.25×10^{-4} A cm^{-2}, in Fig. 5. The observed Tafel slope of $2(2.303\ RT)/F$ for the acetylene oxidation indicates that the reaction mechanism is different to that for ethylene oxidation (Tafel slope $2.303\ RT/F$). The Tafel slope for the acetylene oxidation suggests that the rate-determining step is a charge transfer reaction. However, Bockris *et al.* (12) state that if the total coverage is linearly dependent on potential, a chemical reaction involving adsorption of one radical as rate-determining step would also give the observed Tafel slope. More experimental data is required to determine the reaction mechanism for the anodic oxidation of acetylene at the gold electrode.

Acknowledgments

We wish to thank the Blackburn College of Technology for research facilities, and Mr. J. G. Sunderland for performing some of the gas-chromatographic analyses.

Photoelectrochemical Processes on Silver-Silver Oxide Electrodes

R. Memming, F. Möllers, and G. Neumann

Philips Zentrallaboratorium GmbH, Laboratorium Hamburg, Germany

ABSTRACT

Oxidation and reduction processes of silver-silver oxide electrodes were studied, especially the influence of light excitation on these processes. The experimental results have shown that light absorption by silver (I) oxide leads to an anodic oxidation to silver (II) oxide. The electrochemical reduction of silver (II) oxide formed during illumination is considerably inhibited. A possible mechanism explaining the photoelectrochemical processes and the inhibition is discussed.

The electrochemical behavior of silver-silver oxide electrodes has been extensively studied during the last two decades because of great interest in its application in high energy batteries. It is well-known that silver is oxidized in two steps (1) using alkaline solutions. It is generally assumed that silver (I) oxide is formed in the first step and silver (II) oxide in a second step. There is still uncertainty about the existence of oxides in which silver apparently has an oxidation state greater than two.

Several authors have found also that the illumination influences the electrochemical properties of a silver electrode. Blocher and Garrett (2) observed a shift of the rest potential during illumination and suggested

that oxide layers are involved in this process. Principally an illumination could lead either to a photodecomposition of the silver (I) oxide followed by a re-oxidation of the silver nuclei or to a further oxidation into silver (II) oxide. Göhr and Breitenstein (3) performed measurements with electrodes produced by evaporating silver on gold substrates. They concluded from their results that photodecomposition is always the primary step. In order to obtain more information about the photochemical reactions we performed corresponding electrochemical investigations with different kinds of silver electrodes.

Experimental

Different types of silver electrodes were used in our experiments: silver sheets, single crystals, and silver film produced by vacuum evaporation or electrolytic deposition. In the latter case (film) a nickel substrate covered with a gold film was used. The silver sheet and single crystals were etched in HNO_3 solution before each measurement.

The experiments were performed in 1*N* KOH saturated with silver (I) oxide. The current-potential curves were measured using a Wenking potentiostat, the electrode potential determined *vs.* a Hg/HgO electrode in 1*N* KOH.

For measuring photocurrents a tungsten lamp (100W) was used as a light source. The full intensity of this lamp was necessary in those cases where products formed during illumination had to be analyzed. In other cases, *e.g.*, measuring the potential dependence or the spectral distribution of the photocurrent itself, considerable changes of the surface layers on the electrode during illumination had to be avoided. Then the intensity was reduced by several orders of magnitude using graded filters, the light was chopped (60 cycles) and the corresponding photocurrent amplified (lock-in amplifier) and displayed on a recorder. In order to distinguish between photocurrents measured at high and low intensities, the latter one (a-c method) will be called "differential photocurrent."

Results and Discussion

As already mentioned in the introduction it is a well-known fact that silver electrodes are readily oxidized during anodic polarization. Sweeping across the corresponding potential range with constant speed two main current peaks could be generally observed (Fig. 1a). As it was proved by several authors (4-6) the first current peak is due to the oxidation of silver to silver (I) oxide ($Ag \rightarrow Ag_2O$) and the second peak to the formation of silver (II) oxide ($Ag_2O \rightarrow AgO$). The corresponding reduction peaks occur during the potential sweep in the cathode direction. The electrode reactions are given by

$$2Ag + 2\,OH^- \rightleftharpoons Ag_2O + H_2O + 2e^- \quad [1]$$

$$Ag_2O + 2\,OH^- \rightleftharpoons 2AgO + H_2O + 2e^- \quad [2]$$

The oxidation from Ag_2O to AgO occurs at a rather high overvoltage (redox potential at +0.47V). Dirkse and co-workers (7) discussed the origin of this overvoltage. Since it is not important for our investigations it will not be used in our paper.

On the other hand the shape of the current-potential curves depend very much on the pretreatment of the electrode. This is especially observed for the first oxidation step $Ag \rightarrow Ag_2O$. In Fig. 1a a typical current-potential behavior is presented (as measured with a silver sheet) after several oxidation-reduction cycles, *i.e.*, after 5 or 6 cycles the shape of such a curve is not changed any more. In the first cycle of a freshly prepared electrode, however, no distinct Ag/Ag_2O peak is visible, only a very weak current peak extending over a much larger potential range was observed. Experiments with other types of electrodes, *e.g.*, Ag single crystals or evaporated films, have shown that different types of electrodes show a different behavior only during the first potential sweeps.

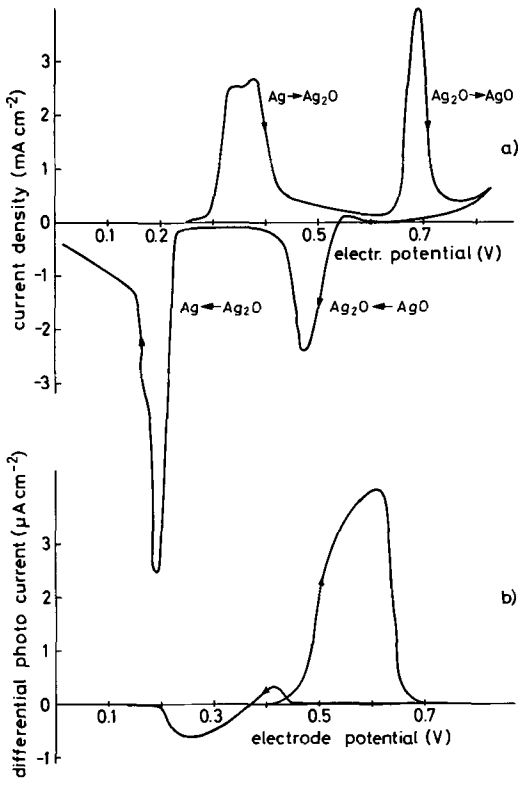

Fig. 1. (a) Interfacial current vs. electrode potential (measured against Hg/HgO in 1*N* KOH) for a silver sheet in 1*N* KOH. Sweeping speed: 50 mV/min. (b) Differential photocurrent vs. electrode potential (measured simultaneously with the curve in (a). [Differential photocurrent is measured during illumination with chopped light of low intensity, *i.e.*, dark current is eliminated.]

As already reported by Göhr (3) the anodic current is increased by illuminating the electrode provided that Ag_2O is present on the electrode surface. We also observed a fast current increase as soon as the light is switched on and a slow decrease within about 10 min as demonstrated in Fig. 2. This result indicates that the Ag_2O film is changed during the illumination. In order to obtain more information on the origin of this photoprocess, we measured the potential dependence of the photocurrent as shown in Fig. 1b, using a differential method as described in the previous section. In this case the light intensity was kept low so that the composition of the Ag_2O layer remained unchanged and

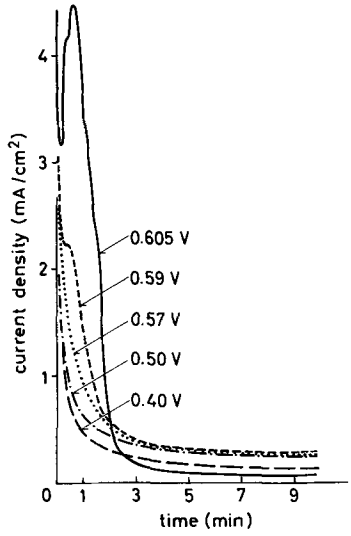

Fig. 2. Interfacial current vs. time during illumination of an Ag/Ag_2O electrode at different electrode potentials. (Electrolyte: 1*N* KOH.)

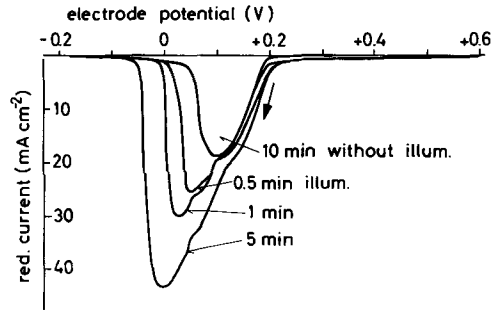

Fig. 3. Reduction (dark) current vs. electrode potential after anodic formation of an Ag_2O layer on the silver (sheet) electrode followed by illumination at $U_E = +0.55V$. The electrode was kept at this potential always for 10 min. In the latter part of this period the electrode was illuminated for a certain time interval as indicated. (Electrolyte: 1*N* KOH.) Sweeping speed: 20 mV/sec.

consequently the differential photocurrent remained constant over a long period of time. This small differential photocurrent was measured independently from the dark current (Fig. 1a).

Comparing Fig. 1a and 1b it is quite obvious that the anodic differential photocurrent sets in as soon as a Ag_2O layer is formed on the electrode, as was reported by Göhr (3). During the potential sweep in the cathodic direction a photocurrent was observed also as soon as the higher oxide (AgO) was reduced to Ag_2O. In this case, however, photocurrents of different signs were found. This result implies that the origin of the photocurrent cannot be explained only by an increase of the electron conductivity within the bulk of Ag_2O.[1] This problem will be discussed later.

As mentioned above, the anodic current increases considerably within a certain potential range during strong illumination and decreases within several minutes (Fig. 2). The main question is what kind of product is formed by light excitation. Göhr (3) explained this process by assuming a decomposition of Ag_2O into silver and oxygen followed by an electrochemical reoxidation of silver nuclei to Ag_2O if the electrode potential is more cathodic than the redox potential[2] of Ag/AgO (= 0.37V on our scale), whereas above this potential the silver nuclei are re-oxidized directly to AgO. In the first case (below 0.37V), however, the decrease of the photocurrent is difficult to understand. This difficulty does not occur if only AgO is formed within the whole potential range. Then the formation of AgO during illumination must not necessarily proceed via photodecomposition. It is also possible that holes are generated within the Ag_2O by light excitation which leads directly to a further oxidation from Ag_2O to AgO.

The existence of AgO after illumination should be very easy to prove since the reduction of AgO to Ag_2O appears as a typical current peak near 0.5V when sweeping toward cathodic potentials (see Fig. 1). We performed corresponding experiments and the results are plotted in Fig. 3. These reduction curves were obtained after having illuminated the electrode at +0.55V for different time intervals. For the illumination we selected an electrode potential (+0.55V) at which the formation of an Ag_2O film is completed and no AgO is formed in the dark. For comparison we also plotted a curve measured after having kept the electrode at the same electrode potential in the dark. Contrary to the assumption that Ag_2O is oxidized to AgO during illumination, the typical current peak AgO → Ag_2O around +0.5V (see Fig. 1a) is not visible in Fig. 3. On the other hand a new current peak around $U_E = 0$ is built up in a potential range where Ag_2O is reduced to Ag. Although the AgO → Ag_2O peak is not visible it may be concluded that the product formed during illumination is at least partly reducible. In order to get information about the origin of this product we checked the charge balance in the oxidation-reduction cycle and studied the composition of the oxide layer using x-ray analysis.

[1] According to Le Blanc and Sachse (8) the conductivity of Ag_2O is of the order of 10^{-8} ohm^{-1} cm^{-1}.

[2] This is a theoretical value determined from the redox potentials Ag/Ag_2O and Ag_2O/AgO.

Composition of Oxide Layers

For measurements of the x-ray diffraction pattern the electrode was separated from the electrolyte following polarization at a certain electrode potential. The validity of this method was tested by studying the diffraction pattern after polarizing the electrode without illumination. In this case we found, as expected, typical signals of an Ag_2O structure after having polarized the electrode around +0.5V, whereas the AgO structure occurred after polarizations above 0.7V. The latter one disappeared again as soon as the AgO was reduced at 0.25V (see Fig. 1a). This is in agreement with the results obtained from the electrochemical oxidation-reduction cycle.

The same AgO pattern was also found after illuminating an Ag_2O film in the potential range 0.30-0.50V, where no AgO was formed in the dark.

According to these results the anodic photocurrent observed during illumination of the Ag_2O layer is only due to the formation of AgO. Obviously this AgO cannot be reduced around 0.5V (see Fig. 3) but only in a more cathodic potential range where normally, *i.e.*, without previous illumination, the reduction of the Ag_2O to Ag occurs.

Charge Balance

The charges consumed during the anodic and cathodic processes were determined as follows (see also Fig. 4): an Ag_2O layer was formed during a potential sweep from −0.2 to +0.5V (sweeping speed 0.1 V/min). Within this potential and time interval the growth of the Ag_2O layer was completed. The charge $Q_{0.1}$ [3] consumed in this process was determined from the corresponding current-time curve. Then the electrode was polarized at a certain potential (between +0.4 and 0.6V) and illuminated (strong light intensity) for 10 min until the photocurrent dropped to a very low level. In this time interval the photocurrent was also recorded and the corresponding charge, Q_L, could be determined. Immediately afterward the illumination was turned off and the electrode was reduced by sweeping back toward cathodic potentials. From the current-time relation we obtained the charge ($Q_{2.1}$) necessary for the reduction of AgO to Ag_2O and the sum of charges necessary for the reduction of Ag_2O to Ag and of the species produced during illumination ($Q_{1.0} + \Delta Q$). The experimental conditions, *i.e.*, the time dependence of light intensity, potential, and current, are shown schematically in Fig. 4.

The charges obtained by this method are plotted in Fig. 5 against the electrode potential U_L at which the electrode was illuminated. As shown in Fig. 5 the sum of all charges consumed during the anodic process ($\Sigma Q_{anod.}$) are within a few per cent identical with those found in the cathodic process ($\Sigma Q_{cath.}$). Since the anodic charges were always slightly larger than the cathodic values we assume that a few per cent of the anodic charge were used for the evolution of oxygen. It should be emphasized that the same amount of charge is lost performing those experiments without any illumination. From this follows

$$\underbrace{[Q_{0.1} + Q_L]}_{\Sigma Q_{anod.}} \approx \underbrace{[Q_{2.1} + (Q_{1.0} + \Delta Q)]}_{\Sigma Q_{cath.}}$$

This result demonstrates clearly that the oxidation products remain on the electrode. In Fig. 5 we also plotted the charges Q_L and $Q_{2.1}$ which were determined separated as outlined above. The additional

[3] The index represents the oxidation state of silver, *i.e.*

$Q_{0.1}$: Ag → Ag_2O $Q_{1.0}$: Ag_2O → Ag
$Q_{1.2}$: Ag_2O → AgO $Q_{2.1}$: AgO → Ag_2O
Q_L = charge consumed during illumination.

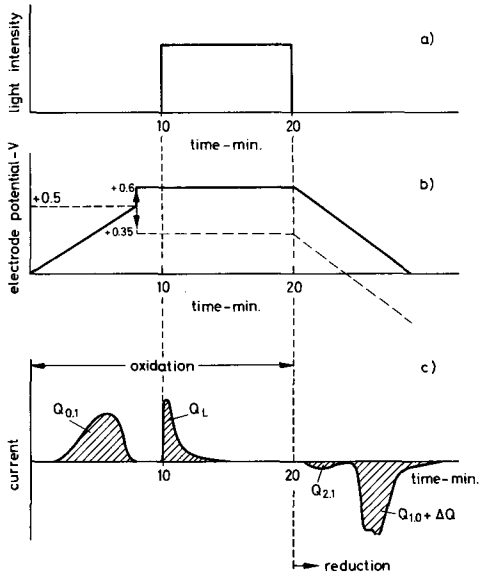

Fig. 4. Schematic presentation for the time dependence of light intensity, electrode potential, and current, applied for determining charges given in Fig. 5 and 6. (For definition of different Q's see footnote 3.)

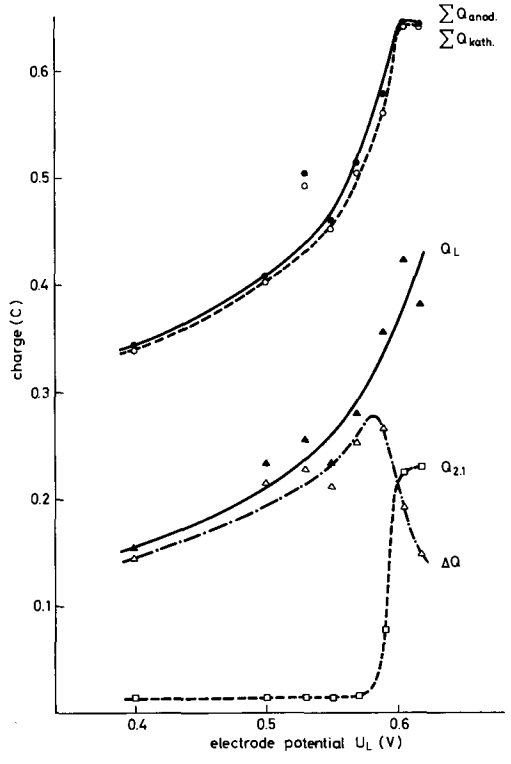

Fig. 5. Charges consumed in different processes *vs.* electrode potential for a silver sheet in 1*N* KOH.

charge ΔQ found in the reduction process after illumination can be calculated according to Fig. 4c using the equation

$$\Delta Q = (Q_{1.0} + \Delta Q) - Q_{0.1}$$

and is plotted in Fig. 5. According to this figure the additional charge ΔQ found during the reduction period after illumination below $U_L = 0.57V$ is practically identical with the charge Q_L consumed during the illumination. Our x-ray measurements show qualitatively that AgO is formed by illuminating an Ag_2O layer at anodic polarization. From this result and from the fact that the anodic charge Q_L consumed during illumination is regained completely during the reduction period ($\Delta Q \approx Q_L$), it has to be concluded that the anodic photocurrent is only due to the oxidation of Ag_2O to AgO. Consequently, photodecomposition has to be excluded. Since no reduction of AgO was found in the potential range (around +0.50V) where it is usually observed after strong anodic oxidation in the dark, the reduction of the AgO formed by light excitation is obviously inhibited. A model for this inhibition will be given in the next section.

On the other hand when illuminating the electrode above $U_L > 0.57V$, the mechanism changes. Now AgO produced above 0.57V is reduced in the potential range where it is also found without illumination, since $Q_{2.1}$ increases (see Fig. 5) whereas ΔQ decreases. The charge Q_L consumed during illumination also rises rapidly. This increase, however, is not equivalent to an increase of the photocurrent itself. This is indicated by the fact that in this case the current did not decay immediately after the light was switched off (after about 20 sec). This also is shown by Fig. 2 (solid line) where a second current peak appears after about 1 min of illumination. Obviously, the oxidation proceeds in this potential range even in the dark after having formed few AgO nuclei during illumination. This illumination potential U_L at which $Q_{2.1}$ increases, could be shifted toward lower values by increasing the light intensity or using thinner Ag_2O layers.

We studied the charge balance with different types of electrodes, silver sheets, single crystals, and evaporated films. In all cases we obtained similar results, *i.e.*

$$\Sigma Q_{anod.} = \Sigma Q_{cath.} \text{ and } \Delta Q \approx Q_L$$

Göhr (3) did not obtain the same result. He observed that $\Sigma Q_{cath.}$ is considerably smaller than $\Sigma Q_{anod.}$. During the reduction period these authors only found a certain percentage of the charge Q_L consumed during illumination. The percentage varies from 0 to 50%. Actually Göhr's model is based on this result: the charges lost in this process Göhr interpreted to be due to the formation of oxygen during photodecomposition.

The question arises, of course, why our results differ from those obtained by Göhr. In connection with this problem it has to be mentioned that Göhr only determined the charge balance with silver layers after many oxidation-reduction cycles. Since we first thought that the pretreatment may be important for the mechanism, we studied several types of electrodes. As mentioned above we found $\Sigma Q_{anod.} = \Sigma Q_{cath.}$ in all cases. Only for rather poor films formed by depositing a thin layer electrolytically is the percentage of charges lost during an oxidation-reduction cycle somewhat larger. In this case, however, the absolute value of Q_L was also much lower than for good electrodes as shown in Fig. 6. We therefore think that the mechanism is identical for all types of electrodes.

Mechanism of Photo-oxidation and Reduction

Measurements of the charge balance have shown that the oxidation products formed in the dark and during illumination are completely reducible. Moreover, it could be concluded from x-ray diffraction measurements that AgO is produced during illumi-

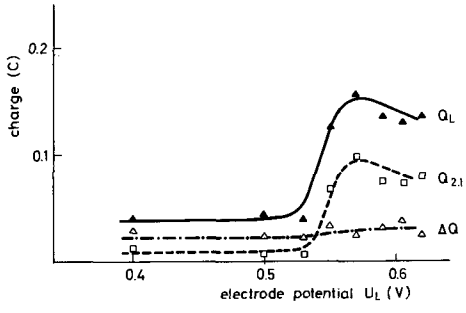

Fig. 6. The same experiment as in Fig. 5 with a thin silver film electrode (0.4μ) deposited on a gold substrate at high evaporation rate in a poor vacuum.

nation. According to our results discussed above the question arises, however, why the reduction of AgO is inhibited if it is produced by illuminating the Ag_2O layer. In order to solve this problem the reaction mechanism itself has to be discussed in more detail.

As reported above, an Ag_2O film is efficiently grown on an Ag electrode above 0.27V. The thickness of this oxide layer depends very much on the pretreatment of the electrode surface. After several oxidation-reduction cycles it reaches about several hundred Angstroms. Basically the film growth is controlled by the ionic conductivity in the oxide itself. The ion transport can proceed by interstitials, lattice vacancies, or pores. Since rather thick oxide layers are formed and since the anodic current decreases rapidly as soon as a certain thickness is obtained, mainly pores must be involved in the transport process.

A further oxidation to AgO occurs at the Ag_2O/electrolyte interface. It is not possible that AgO is formed on the silver itself for thermodynamic reasons. Consequently the oxidation to AgO sets in as soon as the potential at the Ag_2O surface passes a certain value so that some crystal nuclei of AgO are formed. Since the highest electrical field is maintained at surface areas where the original Ag_2O layer is rather thin, the oxidation will mainly proceed within those pores.

As it was proved in the previous sections the electrochemical oxidation from Ag_2O to AgO occurs at lower anodic potentials (see Fig. 1b) when the electrode is illuminated. Since visible light is absorbed by the Ag_2O layer electron-hole pairs are created in Ag_2O by light excitation so that more charge carriers are available for a further electrode process. This phenomenon is very well-known from studies with semiconductor electrodes (9, 10). In general it is observed with this kind of electrodes that, without light excitation, charge transfer processes are practically blocked if minority carriers are involved. Provided that an anodic process proceeds, *e.g.*, via the valence band and not sufficient holes are available at the surface (n-type semiconductor) then the over-all reaction rate is enhanced by formation of holes (minority carriers) during illumination. According to this model we have to assume that in Ag_2O, holes created by light excitation are consumed for further oxidation. This process, however, is only possible in that region of Ag_2O where light is absorbed, *i.e.*, the thickness of an AgO layer depends mainly on the penetration depth of light in the Ag_2O region. In this case deep pores extending further than the penetration depth of light have not much influence on this process. According to its spectral distribution (Fig. 7) the photocurrent is observed below a wavelength of 1.3μ and reaches a maximum at about 0.7μ. Rough absorption measurements have shown that the light absorption in Ag_2O also sets in at about 1.3μ. Since the absorption edge for the higher oxide AgO is even shifted toward the infrared region, AgO also absorbs light around 0.7μ, *i.e.*, AgO formed on the Ag_2O surface screens off the Ag_2O with respect to light excitation.

As we have shown pores extending further into the nonilluminated region of Ag_2O do not affect essentially the oxidation process induced by light. Consequently, we have a discrete layer structure consisting of Ag/Ag_2O/AgO/electrolyte as shown schematically in Fig. 8. This scheme leads also to an interpretation of the inhibition of the cathodic reduction of AgO: since the silver electrode is separated from the AgO by an Ag_2O layer of rather low conductivity the reduction current in a potential region between 0.25-0.5V is relatively small. Obviously, the reduction of AgO can only proceed with a higher rate when the Ag_2O layer is made sufficiently thin by reducing part of it. This model explains the result that, after illumination, the reduction of AgO occurs mainly at more negative potentials, *i.e.*, in this case in the same potential range where the lower oxide Ag_2O is reduced. It should be mentioned again that, in contradiction to the behavior of AgO after illumination, AgO is formed in the dark

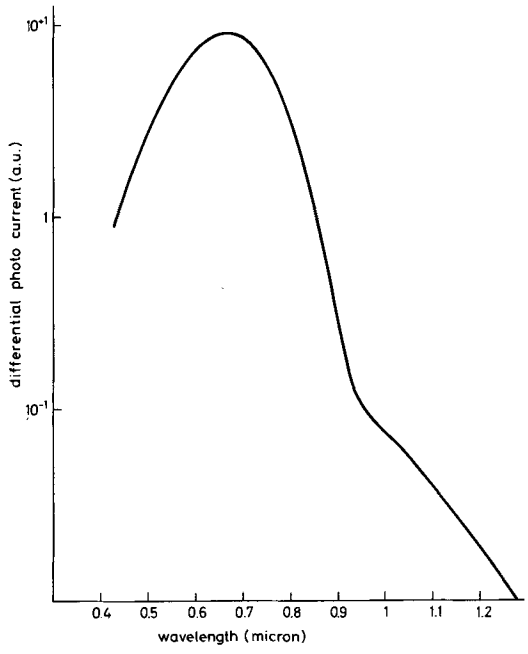

Fig. 7. Spectral distribution of differential photocurrent after formation of an Ag_2O layer on a silver (sheet) electrode. (Electrolyte: 1*N* KOH.)

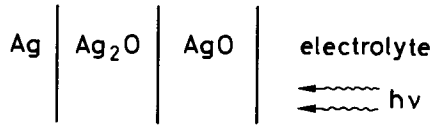

Fig. 8. Schematic structure of a silver-electrolyte interface during and after illumination.

only in those areas (pores) where the Ag_2O layer is rather thin. In this case it is not necessary to reduce some of the Ag_2O prior to the reduction of AgO.

We tried to test this model as follows:

A thin layer (about 0.1μ) of silver was evaporated on a glass plate covered with a conducting transparent SnO_2 layer (see Fig. 9b). Then most of the silver was oxidized electrochemically into Ag_2O. By using such an electrode arrangement with a transparent electrode it is possible to illuminate the Ag_2O from two different directions, through the electrolyte (case I) or through the glass plate (case II). In the first case we would not expect any results different from those ob-

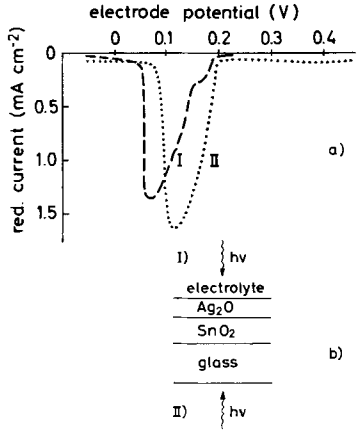

Fig. 9. Reduction current *vs.* electrode potential after anodic formation of an Ag_2O layer on a SnO_2 substrate. These curves were obtained after having illuminated the electrode from two different directions as indicated in the lower part of this figure. (Electrolyte: 1*N* KOH).

tained with solid Ag electrodes. After illumination we observed no reduction of AgO around 0.5V, but only at more cathodic potentials. Following illumination of the Ag_2O from the reverse side (through the glass plate), the reduction of the AgO formed during illumination occurs at more anodic potentials than in the first case, as shown in Fig. 9a. These two experiments differ from each other in so far as the absorption of light within the Ag_2O occurs near the electrolyte if the oxide is illuminated through the electrolyte (case I), whereas the light is absorbed in an oxide region near the SnO_2 layer if the oxide is illuminated through the glass plate (case II). In the latter case AgO is formed in an area adjacent to the silver layer on the SnO_2 surface, *i.e.*, AgO produced in this way is not separated from the Ag by a thick low conducting Ag_2O layer. It should be mentioned, however, that oxidation in this region can only occur if OH^- ions are also available, which may be provided via pores, *i.e.*, the photo-oxidation does occur near the Ag surface but probably only at pores. This argument may also explain the fact that reduction of AgO in case II is still shifted toward cathodic potentials with respect to the reduction following the formation of AgO in the dark.

Potential Dependence of Photocurrent

As mentioned before, an anodic photocurrent was always observed as soon as a thin Ag_2O layer was formed (see Fig. 1). Figure 1b shows the differential photocurrent during growth and reduction of the oxide layers, *i.e.*, Fig. 1b does not really give a defined potential dependence of the differential photocurrent because no equilibrium was achieved. For measuring the potential dependence itself we prepared the Ag_2O layer at first by polarizing the silver electrode at +0.55V for about 10 min. Within this time interval the dark current decreased to a very low value. After having completed the Ag_2O layer in this way we obtained within a certain range a linear dependence between differential photocurrent and electrode potential as shown by curve (a) in Fig. 10. It should be mentioned again that in this experiment also the light intensity was kept so low that further oxidation was negligible. The values of curve (a) were independent of the sweeping direction, *i.e.*, they are stationary values within the potential range 0.22 . . . 0.55V.

According to this result the anodic photo-oxidation, represented by the differential photocurrent in curve (a) in Fig. 10, sets in not only at lower potentials than without illumination but also below the redox potential of Ag_2O/AgO (0.47V). Similar potential shifts were always found with typical semiconductor electrodes (9, 10) and could be explained by the fact that no equilibrium between electrons and holes exists during light excitation. Such a deviation from equilibrium is, of course, relatively large for low conducting materials or if the equilibrium concentration of one type of charge carriers (electrons or holes) is small. Since also in Ag_2O electrons and holes are produced by illumination, at least the density of holes is increased considerably above its equilibrium value in this process.

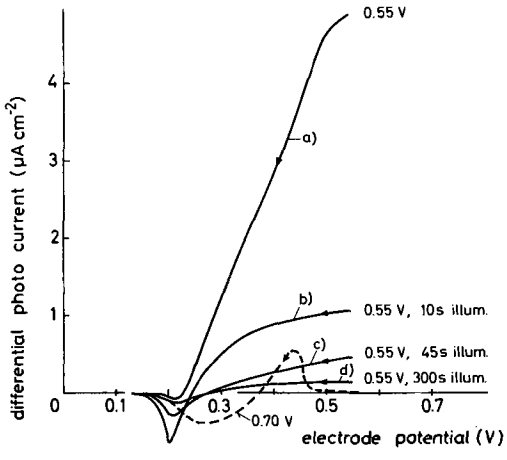

Fig. 10. Differential photocurrent vs. electrode potential after anodic formation of Ag_2O on a silver electrode. (Electrolyte: 1N KOH). (a) Without previous illumination. (b)-(d) After strong illumination at +0.55V. Dotted line: replotted from Fig. 1b.

In further experiments the Ag_2O layer was illuminated with a rather strong light intensity for a certain period of time. As discussed previously, a certain portion of the Ag_2O is transformed into AgO at the Ag_2O/electrolyte interface. Since AgO absorbs visible light, the anodic photocurrents are smaller now as shown by curves (b), (c), and (d) in Fig. 10. In contradiction to the first case [curve (a)], however, a cathodic photocurrent occurs around 0.2V, especially in curve (b). This effect disappears after a long preillumination. This result leads to the conclusion that the reduction process ($AgO \rightarrow Ag_2O$) may be enhanced by light excitation. All differential photocurrents (anodic and cathodic) disappear, however, as soon as the AgO layer filters away too much light.

In the same way the differential photocurrents measured during a complete oxidation-reduction cycle can be interpreted (Fig. 1b). For comparison the photocurrent obtained within the reduction period in Fig. 1b is replotted in Fig. 10 (dotted line).

Conclusion

The experimental results presented in this paper have definitely shown that light absorption by an Ag_2O layer leads directly to anodic oxidation to AgO. It is postulated that holes present in the dark only in negligible concentrations are involved in the oxidation process. Since the over-all reaction rate is controlled by the number of holes at the surface it is considerably enhanced by light excitation. According to our studies with different types of electrodes, the photodecomposition of Ag_2O into silver and oxygen postulated by Göhr (3) has to be excluded.

Moreover, we observed that the reduction of AgO formed during light excitation is inhibited. This result could be interpreted by the fact that this AgO layer was separated from the silver substrate by a rather thick Ag_2O layer of low conductivity. The thickness of the AgO layer is limited by the penetration depth of the exciting light. The inhibition depends slightly on the type of electrode. In the case of very thin porous evaporated silver films the inhibition is somewhat weaker than for silver sheet electrodes.

Acknowledgments

The authors are indebted to Dr. C. W. Berghout, Philips Research Laboratories, Eindhoven, for providing silver single crystals. Thanks are also due to Dr. K. H. Beckmann and Dr. G. Schwandt for stimulating discussions and to Mr. H. Tolle for performing the measurements.

Manuscript submitted Sept. 8, 1969; revised manuscript received ca. Dec. 12, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

An Unusual 6-Aminopurine Polarographic Wave

Borivoj Janik and Philip J. Elving*

University of Michigan, Ann Arbor, Michigan

ABSTRACT

In addition to a normal four-electron d-c polarographic reduction wave, some 6-amino- and 6-alkylaminopurines, including the biologically important adenine nucleotides, yield a more negative wave of anomalous behavior. The latter wave, which has some of the characteristics of a maximum of the second kind, is primarily due to an enhanced supply of purine as a result of onset of streaming of the solution over the electrode surface; the wave may also involve reduction of the 1,6 C=N bond in the pyrimidine ring which is regenerated by deamination of the initial reduction product. The second d-c polarographic wave of isoguanine is due to catalytic hydrogen evolution. Catalytic hydrogen evolution is a participant in the single voltammetric reduction wave obtained on the HMDE with some derivatives, *e.g.*, adenine and AMP, due to accumulation of reduction product at the electrode surface.

Some 6-amino-substituted purines (1), as well as adenine (6-aminopurine) nucleosides and nucleotides (2) produce at the dropping mercury electrode (DME) under certain conditions, in addition to a normal diffusion-controlled four-electron (4*e*) d-c polarographic reduction wave, a second more negative wave, which can be considered to be unusual or abnormal in the sense that its behavior and current-controlling factors do not follow any common pattern. The few references to such a wave in the literature are mostly in connection with adenine, which is the only 6-substituted purine whose polarographic reduction mechanism and analytical utilization (3-6) have been extensively studied. A postwave, which was eliminated by 0.002% Triton X-100, was observed in adenine solution in *p*H 2-4 chloride and McIlvaine buffers (5, 7). A second wave seen on the background discharge in acidic adenine (8, 9) and adenine 1-N-oxide (10) solutions was ascribed to catalytic hydrogen ion reduction. Whenever the abnormal wave was observed, it was treated as a complicating factor due to its unusual behavior, ill-definition, and interference with the normal wave.

Because of both the intrinsic interest in the odd behavior of the abnormal wave and the necessity of being able to isolate it from and minimize its effect on the normal faradaic wave pattern of the 6-aminopurines, which are among the most important naturally occurring purines as in DNA and RNA, the mechanism of the abnormal wave process was investigated.

Experimental

The chemicals, buffer solutions, apparatus, and procedures were the same as those previously described (1, 2) with the following additions.

Controlled-potential electrolysis was carried out in a three-compartment H-cell, whose main compartment contained a bunch of twelve dropping mercury electrodes as a working cathode, an indicator DME and a 1.0 m*M* adenine solution in *p*H 3.0 McIlvaine buffer. One of the other compartments, which was separated from the main compartment by a Sial No. 4 glass frit, contained a counterplatinum anode in the background solution; the other contained a reference saturated calomel electrode. Nitrogen was bubbled through the main and counterelectrode compartments during electrolysis. A Laboratorni Pristroje LP 60 polarograph and a EZ 2 recorder were used for manual control of potential and for recording of polarographic curves during the course of electrolysis.

Current-time curves were recorded on a Akademie-werkstätten-Berlin GWP 563 polarograph at a chart speed of 10 mm/sec for serial drops from a capillary, whose end was tilted to an angle of 45° (11).

Voltammograms and cyclic voltammograms at the HMDE (hanging mercury dropping electrode) were recorded at polarization rates of 1 to 2 and 100 mV/sec, respectively.

The DME was observed by a laboratory microscope with a 30-fold magnification. Powdered active charcoal was added to the solution examined in an amount just sufficient to indicate streaming of the solution. Accumulation of small bubbles at the capillary orifice indicated hydrogen evolution.

Unless otherwise indicated, measurements were made on 0.5 *M* ionic strength solutions at 25°C.

Abnormal Wave Characteristics

The abnormal wave is generally difficult to define due to its merging with the normal wave and/or background discharge.

Effect of depolarizer nature and concentration.—The abnormal wave has only been observed with purine derivatives having amino or substituted amino groups in the 6-position, *e.g.*, 6-amino- (adenine), 6-methylamino-, 6-hexylamino-, and 6-benzylaminopurines, adenosine-5′-phosphate (AMP), deoxyadenosine-5′-phosphate (dAMP), adenosine-5′-diphosphate (ADP), and adenosine-5′-triphosphate (ATP). 6-Phenylamino- and 6-dimethylaminopurines, adenosine, and deoxyadenosine produce only the normal wave; however, the limiting portion of the latter is often steeply inclined, indicating the presence of an additional faradaic process. Isoguanine (2-hydroxy-6-aminopurine) yields a second more negative wave, whose behavior, as subsequently discussed, differs markedly from that of the abnormal wave. Purine and its 6-methyl- and 6-methoxy- derivatives exhibit no wave in addition to the one or two waves which represent the 4*e* reduction of the 1,6 N=C and 2,3 C=N bonds of the purine ring.

Below 0.1 to 0.2 m*M* depolarizer concentration, the abnormal wave is small and ill-defined, and is usually

* Electrochemical Society Active Member.

seen as an additional contribution on the normal wave limiting portion. With increasing concentration, the abnormal wave height increases relatively more than that of the normal wave; the ratio in pH 3.1 McIlvaine buffer is 1.0, 1.4, and 1.8 in 0.25, 0.50, and 1.00 m*M* adenine, respectively.

Effect of pH, buffer concentration and composition, and ionic strength.—Since the abnormal wave gradually merges with background discharge as the pH decreases or increases, a relatively well-defined limiting portion is usually obtained only between *ca.* pH 2 and 4 to 5 (Fig. 1). The wave exists in a narrower pH region at lower concentrations for some derivatives, *e.g.*, 0.25 m*M* benzylaminopurine exhibits the abnormal wave only in pH 2 chloride buffer.

The half-wave potential, $E_{1/2}$, of the abnormal wave shifts negatively with increasing pH at a rate similar to that of the normal wave for the compound involved (1, 2). Variation of i_l with pH depends on the depolarizer concentration, *e.g.*, i_l increases with increasing pH in 0.50 m*M* solutions and remains practically constant in 0.125 m*M* solutions (Fig. 1). The second isoguanine wave sharply decreases with increasing pH and disappears at *ca.* pH 5; at pH 1, it is about eight times as high as the normal wave.

Formation of the abnormal wave is more favorable in McIlvaine than in acetate buffers, *e.g.*, the wave has been observed in pH 3.9 McIlvaine buffer but not in acetate buffer of the same pH.

In pH 3-4 McIlvaine buffer of 0.1*M* ionic strength, the abnormal wave either is not formed, *e.g.*, below *ca.* 0.5 m*M* adenine, or appears as a nonmeasurable current superposed on the normal wave limiting portion, *e.g.*, adenine and AMP above *ca.* 0.5 and 0.2 m*M*, respectively. With increasing buffer concentration or ionic strength, *e.g.*, on addition of KCl, the abnormal wave gradually increases to a limiting value at ionic strength *ca.* 1; formation of the abnormal wave is less evident with AMP when background concentration is brought up just by adding KCl.

Variation of limiting current with mercury column height.—The variability of plots of i_l *vs.* h, *e.g.*, linear or curved with slopes varying from slightly positive to more or less negative inclination to the h axis, is at least partially due to the ill-definition of the abnormal wave and to the marked change of its shape with h with resulting uncertainty in estimation of i_l. Depending on pH, the abnormal wave more or less merges with background discharge at low h. As h increases, the limiting portion becomes better defined due to a positive shift of the wave, while the background discharge potential does not change. At the same time, the normal wave shifts negatively so that it gradually merges with the abnormal wave; a similar effect occurs when the drop-time is gradually shortened by hitting the capillary.

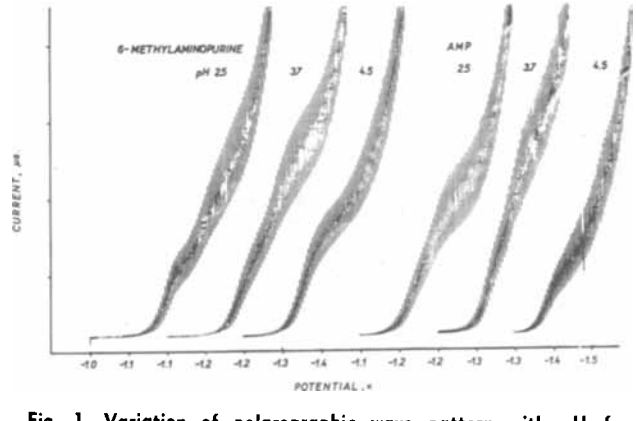

Fig. 1. Variation of polarographic wave pattern with pH for 0.125 mM 6-methylaminopurine and 0.50 mM AMP in McIlvaine buffer (0.5M ionic strength) at 25°C. Current axis: 2.0 μA/division for 6-methylaminopurine and 10 μA/division for AMP.

Effect of temperature.—The temperature coefficient of the abnormal wave in pH 3.0 McIlvaine buffer varies from 4.5 to 9.0% for adenine, 6-methylaminopurine, and AMP, compared to 1.1-2.2% for the normal wave. The abnormal wave is too small at 10°-15° to be measured meaningfully, *e.g.*, in adenine and AMP at 0.5*M* ionic strength, and completely disappears at lower temperatures (Fig. 2), *e.g.*, no indication of it can be seen at 1.5° and 0.1*M* ionic strength.

Effect of surface-active substances.—The abnormal wave given by up to 0.5 m*M* adenine (Fig. 3) and 6-benzylaminopurine is completely eliminated by only 0.0006% Triton X-100. The same is true for other derivatives below *ca.* 0.2 m*M*. At higher depolarizer concentrations, 0.0006% Triton suppresses the abnormal wave by 20-60%, 0.001-0.002% Triton almost completely eliminates it but at the same time decreases the normal wave by 10-20%, and higher Triton concentrations distort the wave shapes. In general, Triton is more effective at higher pH and lower depolarizer concentration, and in such situations where only an additional current is superimposed on the normal wave limiting portion, where the normal and abnormal waves are relatively well separated and where the latter wave merges with the background discharge.

Other surface-active substances are also effective, *e.g.*, less than 0.002% agar completely eliminates the abnormal wave of 0.5 m*M* adenine in pH 3.0 McIlvaine buffer.

Current-time curves.—At potentials on the rising part of the abnormal wave, the parabolic character of the i-t curves on a single drop is gradually distorted as the potential becomes more negative; the distortion, which is pronounced on the limiting portion of the wave, is abrupt with adenine and 6-methylaminopurine and less apparent with AMP.

Microscopic observation of mercury electrodes.—Streaming of the solution past the DME surface is observable at potentials starting at the foot of the abnormal wave, *e.g.*, for adenine, 6-methylaminopurine

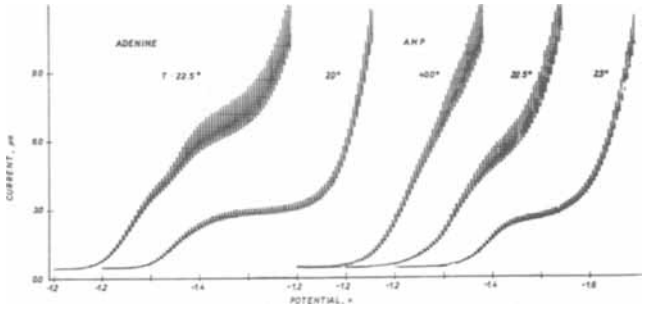

Fig. 2. Effect of temperature on polarographic wave pattern for 0.5 mM adenine and 0.50 mM AMP in pH 3.2 McIlvaine buffer (0.5M ionic strength) at 25°C.

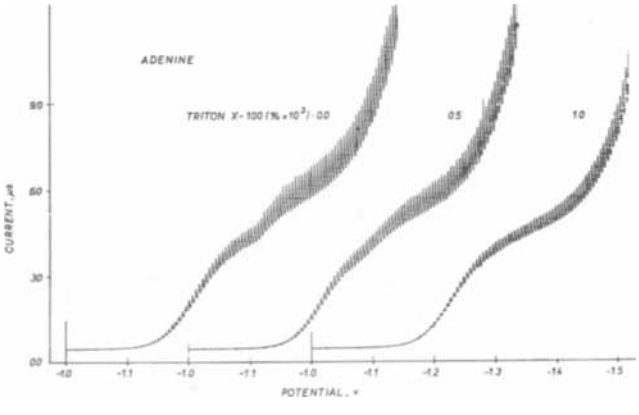

Fig. 3. Effect of Triton X-100 concentration on polarographic wave pattern for 0.25 mM adenine in pH 3.0 McIlvaine buffer (0.5M ionic strength) at 25°C.

and AMP solutions, or, where the abnormal wave is absent, *e.g.*, with adenosine, at the foot of the background discharge. No or only negligible streaming occurs at potentials on the normal and second isoguanine waves. The direction of the streaming is from the bulk solution to the bottom of the DME, over the mercury surface to the top of the drop and from there back to the bulk solution. The streaming is more intense as the potential becomes more negative and diminishes with decreasing h. Addition of 0.002% Triton to 0.5 m*M* adenine at pH 3.0 eliminates the abnormal wave, while the intensity of the streaming is only lowered by a third.

On the hanging mercury drop electrode, HMDE, where only the normal wave appears, streaming does not occur in 0.5 m*M* adenine even at constant potentials on the background discharge.

Hydrogen evolution is not observed at the DME until the background discharge is reached even in saturated, *i.e., ca.* 6 m*M*, solutions of adenine and AMP at pH 2-5, while it occurs on the HMDE at constant potentials at the foot of the normal wave.

Behavior on the HMDE.—Adenine, 6-methylaminopurine, and AMP produce at pH 2.5-4 only a single cathodic wave on single-sweep voltammograms and a single cathodic peak on cyclic voltammograms. $E_{1/2}$ of the wave and E_p of the peak are up to 30 and 100 mV, respectively, more negative than $E_{1/2}$ of the normal DME wave under similar conditions; the difference becomes smaller with decreasing pH. The voltammetric wave is ill-defined due to merging with background discharge; on the second and subsequent runs at the same drop in unstirred solution, $E_{1/2}$ shifts more negatively and the background discharge more positively so that the wave finally disappears. Cyclic voltammograms of isoguanine in pH 2.5 McIlvaine buffer exhibit two peaks, whose E_p are *ca.* 100 mV more negative than $E_{1/2}$ of the corresponding DME waves.

Electrolysis of adenine.—The ratio of the adenine normal and abnormal heights during controlled potential electrolysis at pH 3 at a potential on the crest of the normal wave approximately equals that found for corresponding concentrations in fresh solution. $E_{1/2}$ of the normal wave and, even more so, of the abnormal wave shift more negatively during electrolysis with the abnormal wave consequently merging with background discharge; the potential of the latter may shift up to 30 mV more positively during electrolysis.

Nature of the Electrode Process

The experimental data concerning the nature and origin of the abnormal wave are equivocal in the sense that several possible processes are more or less both supported and refuted. Consequently, decision has to be made on the basis of the relative merits of the evidence and the implications that can be drawn from it.

The possibilities of the abnormal wave being a diffusion-controlled wave or an adsorption postwave involving the oxidized form of the depolarizer are eliminated by the concentration, h, and temperature dependences, and by the i-t curves [*cf.* ref. (12)]; the wave height is several times higher than would be expected for an adsorption wave (12, 13) and the depolarizers are strongly adsorbed only at potentials about 0.7V more positive than those of the reduction (1, 2).

Maximum of the second kind.—Streaming of the solutions as well as the direction of such streaming at the DME at potentials on the abnormal wave strongly indicate that the latter is a maximum of the second kind (13, 14). Corroborative evidence is afforded by the following: (*a*) the wave decreases in height and finally disappears with decreasing ionic strength and buffer concentration, (*b*) the wave height shows a high temperature coefficient, (*c*) surfactants suppress the wave, and (*d*) streaming diminishes on lowering h and does not occur at the HMDE. Two aspects of the behavior of the wave indicate that it may not involve a common maximum of the second kind: (*a*) streaming can continue, only moderately diminished, when the wave is completely suppressed by Triton addition, and (*b*) i_l is not proportional to h. The latter is not too decisive an argument since it is difficult to measure i_l precisely.

Catalytic hydrogen evolution.—Although some features of the abnormal wave support participation of a catalytic hydrogen evolution (15), *e.g.*, location near or on the background discharge, effect of surfactants, increase of wave height with increasing buffer concentration, and shift to more negative potential with increasing pH, the bulk of the evidence is not consistent with an appreciable contribution from a catalytic hydrogen process (13, 15), *e.g.*, the wave shifts to more negative potential with increasing depolarizer concentration and its height increases with increasing pH or is, at least, pH-independent and varies from a fraction to twice that of the normal (4*e*) wave. A catalytic hydrogen wave involving the purine species as participant would normally be expected to decrease with increasing pH and to have a height which is many times that of a corresponding diffusion controlled wave (13, 15), *e.g.*, in pH 3 buffer containing 1 m*M* purine, it would be expected to be several times the height of the 4*e* purine wave; actually, it is only 1.8 times that height. Furthermore, even though the normal adenine wave, due to its behavior, was postulated to contain a catalytic hydrogen component (3), hydrogen evolution was not observed on the DME at potentials more positive than that of the background discharge.

The oxidized and reduced forms of most purine derivatives, as well as the degradation products of the latter, shift the background discharge to more positive potential, *e.g.*, the shift, whose magnitude increases with pH and depolarizer concentration (2, 3), occurs even at pH where the purine derivative is not reduced (1, 2, 3) and in solutions where adenine has been completely electrolyzed (3). The shift, which has been ascribed to catalytic evolution of hydrogen (3), could interfere with the abnormal wave. However, hydrogen evolution seems to be negligible in the abnormal wave at the DME; its presence at the foot of the normal wave at the HMDE is most probably due to accumulation of reduction product at the electrode surface which promotes the catalytic reduction of hydrogen ion and makes the reduction of purine more difficult (13).

The second isoguanine wave, which markedly differs from the abnormal wave, *e.g.*, in having a counterpart on cyclic voltammograms at the HMDE and in exhibiting no streaming at the DME, is probably a catalytic hydrogen wave, as indicated by its being several times higher than the normal wave, decreasing sharply with increasing pH, and being proportional to h.

Deamination reaction.—As previously mentioned, the abnormal wave has been observed only with purines having an amino or substituted amino group in the 6-position. Exhaustive electroreduction of 6-aminopurine (adenine) at a mercury pool electrode is a 6*e* process, involving reduction of the 1,6 and 2,3 double bonds, deamination at the 6-position and reduction of the regenerated 1,6 double bond (3). Since deamination is slower than the electrochemical steps (3, 16), it does not proceed appreciably under polarographic conditions at potentials less negative than the crest of the normal adenine reduction wave (3). However, deamination may be promoted by the electrostatic attraction of the protonated reduction site to the electrode and, consequently, could occur at the more negative potentials, where the abnormal wave is observed. Current resulting from reduction of the regenerated 1,6 C=N bond may thus be involved at the abnormal wave. Moreover, deamination as well as subsequent hydrolysis of the reduction product may result in local concentration and charge gradients and, consequently, in surface tension differences, which, in turn, may

promote streaming of the solution over the DME surface.

Conclusions

The results of exhaustive electrolysis of adenine indicate either that the abnormal wave is associated only with the oxidized form of adenine or that the reduced adenine decomposes sufficiently rapidly that it does not accumulate and, consequently, does not contribute appreciably to the abnormal wave process; degradation products of reduced adenine evidently also do not contribute to the abnormal wave current.

The supply of depolarizer for the abnormal wave process is, therefore, essentially due to an increased transport of the oxidized form of the purine to the DME as a result of streaming at the potentials where the abnormal wave is seen. Simultaneous creation of a depolarizer via a chemical reaction involving restoration of the reducible 1,6 double bond through deamination, may also be a contributing factor in the abnormal wave current.

Although data for the normal purine reduction wave obtained in the presence and absence of the abnormal wave are essentially identical, the proximity of the two waves makes data for the normal wave obtained in absence of the abnormal wave more accurate. Consequently, it is recommended that in future electrochemical studies of 6-aminopurines and their derivatives the complicating presence of the abnormal wave be avoided by the use of low ionic strength solutions and low temperature; an ionic strength of 0.1*M* and temperature below 5°C are recommended.

Alternatively, if it is desired to use solutions of 0.5*M* ionic strength at 25° or the equivalent, the concentration of the electroactive species should not exceed 0.1 m*M*. Thus, in a study (17) of oligonucleotides the abnormal wave was not clearly indicated with ApA, $(Ap)_3A$, and $(Ap)_5A$ and with dinucleotides containing the adenine moiety, apparently due to the low concentrations employed (*ca.* 0.05 m*M*) and to a marked positive shift of background discharge, especially with ApG and GpA.

ABSTRACT

The rotating ring-disk electrode (RRDE) was used to study the oxidation of Br^- at platinum electrodes in 1.0*M* H_2SO_4 supporting electrolyte. In addition to the electrochemical oxidation of Br^- to Br_2 by a convective-diffusion controlled reaction, a small amount of HOBr was produced by oxidation of adsorbed Br^- with concurrent oxidation of the platinum electrode surface. Bromide does not adsorb at an anodized platinum surface, whereas adsorption is very rapid at a reduced platinum surface. The equilibrium surface coverage by Br^- corresponds to a monolayer for bulk concentrations of KBr greater than $4.5 \times 10^{-3}M$.

The purpose of this research was to study the formation of positive oxidation states of bromine at a platinum electrode in 1.0*M* H_2SO_4. No study of such a process is to be found in the literature even though the oxidation of iodine to higher oxidation states at a platinum electrode has been discussed by many authors. A review of this literature is given by Beran and Bruckenstein (1).

Many investigators have studied the Br_2/Br^- couple at platinum electrodes with the primary ob-

* Electrochemical Society Active Member.

jective of determining the electrode mechanism (2-5). The standard reduction potential for the reaction

$$Br_2 + 2e = 2Br^- \quad [1]$$

is +0.841V (*vs.* SCE) (6).

The two most likely higher oxidation states which might be produced in 1.0*M* H_2SO_4 at a platinum electrode appear to be HOBr and BrO_3^- whose standard reduction potentials are (6)

$$HOBr + H^+ + e \rightleftharpoons 1/2\,Br_2 + H_2O, \quad E^\circ = 1.34V \text{ (SCE)} \quad [2]$$

$$HOBr + H^+ + 2e \rightleftharpoons Br^- + H_2O, \quad E^\circ = 1.09V \text{ (SCE)} \quad [3]$$

$$BrO_3^- + 6H^+ + 5e \rightleftharpoons 1/2\,Br_2 + 3H_2O, \quad E^\circ = 1.27V \text{ (SCE)} \quad [4]$$

$$BrO_3^- + 6H^+ + 6e \rightleftharpoons Br^- + 3H_2O, \quad E^\circ = 1.20V \text{ (SCE)} \quad [5]$$

Our experimental results indicate that a limited amount of HOBr can be produced by oxidation of adsorbed bromide at a platinum electrode in 1.0*M* H_2SO_4 via a surface controlled process and that no detectable amounts of BrO_3^- are produced.

Experimental

Instrumentation.—The ring-disk electrode used in this research was constructed by Pine Instruments of Grove City, Pennsylvania. The electrode dimensions are given in Table I of ref. (7) where the electrode is designated as electrode B. For this electrode $\alpha = 0.089$, $\beta^{2/3} = 0.151$, and $N = 0.090$, the area of the disk is 0.470 cm^2.

The four electrode potentiostat was constructed according to a design given previously (8) using an Analog Device 303 Operational Amplifier as the reference potential follower, F-1 in Fig. 1 of ref. (8), and Analog Devices 108 Operational Amplifiers in the remainder of the circuit. Current potential (*I-E*) curves were recorded using an EAI, X-Y-Y', 1130 Variplotter.

Most experimental work was performed at 25° ± 1°C, although the determination of the diffusion coefficient of Br^- in 1.0*M* H_2SO_4 was made at 25.0° ± 0.2°C. Except for instances when bromide was present in the supporting electrolyte, air was removed from the solution with Air Products', high purity (99.999%) nitrogen which was presaturated with H_2O, and a nitrogen atmosphere was maintained above the solution.

The counterelectrode was a platinum wire coil placed in a fritted glass compartment containing 1.0*M* H_2SO_4. The reference electrode was a Beckman, Fiber-Junction, SCE in electrical contact with the solution through a Luggin capillary, containing a saturated KNO_3 solution. The tip of the Luggin capillary was placed about 2 mm from the surface of the rotating electrode, normal to the Teflon between the ring and disk electrodes. All potentials were measured and are reported in volts *vs.* the SCE.

Chemicals.—All chemicals used were Mallinkrodt Analytical Reagent grade. Solutions were prepared using triply distilled water, with the second distillation being from alkaline permanganate solution.

A stock solution of HOBr (approximately 0.2*M*) was prepared according to a procedure similar to those described in ref. (9-11). An excess of Br_2 was added to a mixture of approximately 0.01*M* HNO_3 and silver acetate. The hydrolysis reaction of Br_2 produces Br^- and HOBr, and the reaction is made complete by the precipitation of Br^- as AgBr. The precipitate was separated by filtering and the excess Br_2 removed by bubbling with nitrogen. The presence of HNO_3 aided coagulation and separation of the AgBr precipitate. The HOBr was used approximately 2 hr after preparation.

Notation.—The subscripts d and r to symbols for current, *I*, and potential, *E*, represent the corresponding quantities at the disk and ring electrodes, respectively. The subscript *l*, used with symbols I_d and I_r, signifies that the designated quantity corresponds to the convective-diffusion limited value. The superscripts *a* and c used only with the symbol E_d define the extreme anodic (+) and cathodic (−) disk electrode potentials used in obtaining the particular *I-E* curve. Cathodic current is considered as a positive and anodic current as a negative quantity. All electrical currents are given in microamperes.

Results and Discussion

I_d-E_d curves of Br^-.— Figure 1 shows I_d-E_d curves obtained in a 1.0*M* H_2SO_4-3.3 × 10^{-4}*M* KBr solution. E_d was scanned between $E_d^c = -0.20$V and the E_d^a-value specified until no change in the I_d-E_d curve was observed with continued potential scans. For [KBr] > 1 × 10^{-4}*M*, no change in the *I-E* curve was observed after the second cyclic potential scan. E_d^a was varied from 1.00 to 1.40V by 0.10V increments and a final curve was obtained for $E_d^a = 1.60$V. Three anodic waves were obtained with apparent $E_{1/2}$ values of 0.90V, 1.06V, and 1.24V. These waves are designated A, B, and C, respectively, for discussion purposes. The observed $E_{1/2}$ for wave A of 0.90V is in agreement with data presented in ref. (4) and (12) for the oxidation of Br^- to Br_2 in a similar solution and we conclude that wave A is due to the oxidation of Br^- to Br_2. The small reduction peak, *D*, obtained on the cathodic scan, $E_{peak} = 0.9$V, disappears at faster rotation speeds and/or slower E_d scan rates, and we conclude it is caused by reduction of Br_2 present in the convective-diffusion layer adjacent to the electrode.

The reduction peak E, $E_{peak} = 0.5$V, is also observed in the absence of Br^- (12, 13) and is caused by the electrochemical reduction of the oxidized platinum electrode surface. In Br^--free 1.0*M* H_2SO_4, electrode oxidation occurs if $E_d^a > 0.65$V (12, 13). Figure 1 shows that peak E is obtained in this solution only if $E_d^a > 1.0$V. Hence, electrode oxidation does not occur until the electrode surface concentration of Br^- is zero, *i.e.*, until I_d equals the convective limiting current for Br^- oxidation to Br_2, $I_{d,l}$ ($Br^- \rightarrow Br_2$). As E_d^a increases beyond 1.0V, the height of peak E at 0.5V increases, thus electrochemical oxidation of the platinum disk

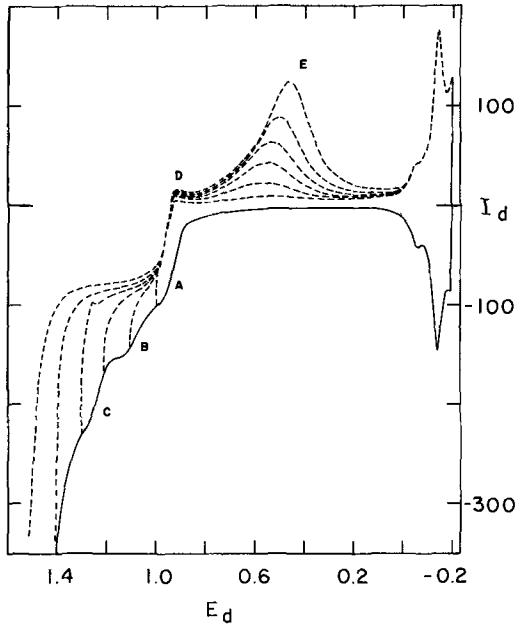

Fig. 1. I_d-E_d *vs.* E_d^a; 1.0*M* H_2SO_4-3.3 x 10^{-4}*M* KBr, 400 rpm, E_d scan rate = 6.0 V min^{-1}, ——— anodic E_d scan, - - - - cathodic E_d scan.

electrode surface occurs concurrently with the processes associated with waves B and C. The inhibition of platinum oxidation by halide ions in acidic media is attributed to halide adsorption at the electrode surface (12, 14).

The shape of the I_d-E_d curves in the potential region $E_d < 0.1$V has been discussed and the cathodic and anodic processes are identified as the formation and dissolution of molecular hydrogen, respectively (12).

I_d-E_d curves were also obtained while holding the electrode stationary, Fig. 2, in 1.0M H_2SO_4-1.0 $\times$ $10^{-3}M$ KBr. The appearance of a reduction peak, F, at 1.15V on the cathodic E_d scan indicates that wave C involves the production of a soluble electroactive species other than Br_2, possibly a higher oxidation state of bromine such as HOBr or BrO_3^-. There is no evidence that wave B corresponds to any reaction other than oxidation of the electrode surface.

I_d-E_d curves were obtained at 400 rpm in the solution used for Fig. 1 as a function of E_d scan rates from 2-10V min^{-1}. These curves showed that, after correcting for double layer charging current, wave A was independent of E_d-scan rate, while the heights of waves B and C increased in approximately a linear manner with increasing E_d scan rate. These results suggest that waves B and C correspond to surface controlled reactions since the magnitude of convective-diffusion limiting currents are independent of E_d scan rate.

I_d-E_d curves were obtained at 400 rpm in a solution identical to that for Fig. 1 for $E_d{}^a = 1.60$V and varying $E_d{}^c$ from -0.20 to $+0.80$V. Differences in the I-E curves in the region of $E_d > 0.80$V obtained for $-0.20\text{V} < E_d{}^c < 0.40\text{V}$ were negligible. For $E_d{}^c > 0.60$V, however, the height of waves B and C decreased. Waves B and C disappeared for $E_d{}^c \geq 0.80$V. Note that for $E_d{}^c \geq 0.80$V, platinum oxide formed at the electrode surface for $E_d > 1.0$V is not reduced during the cathodic portion of the potential cycle. The magnitude of wave A at 1.0V was not affected by variation of $E_d{}^c$. On the basis of these results and the observation in Fig. 1 that $I_d = I_{d,l}$ ($Br^- \rightarrow Br_2$) during the cathodic E_d scan for $1.0 < E_d < 1.4$V, we conclude that the disk electrode reaction resulting in the production of peak F of Fig. 2 is controlled by surface changes at the disk electrode which occur simultaneously with the electrode surface oxidation.

Diffusion coefficient for Br^- *in 1.0M* H_2SO_4.—Values of $I_{d,l}$ ($Br^- \rightarrow Br_2$), wave A, were measured as a function of [KBr] (2, 3, 4, and 5 $\times$ $10^{-4}M$) and rotation speed (400-10,000 rpm) for an E_d scan rate of 0.5V min^{-1}. At this slow scan rate the heights of waves B and C were negligible in comparison to that of wave A. Plots of $I_{d,l}$ *vs.* $\omega^{1/2}$ measured at $E_d = 1.15$V were linear with zero intercepts over the entire range of concentrations. The diffusion coefficient of Br^-, D_{Br^-}, was calculated from each slope using the Levich equation for convective diffusion limited currents (15). The average of 16 slope measurements yielded $D_{Br^-} = (1.58 \pm 0.06) \times 10^{-5}$ cm^2 sec^{-1}.

Ring-disk studies in KBr solutions.—I_r-E_d curves were recorded simultaneously with I_d-E_d curves in 1.0M H_2SO_4-3.3 $\times$ $10^{-4}M$ KBr solution, in the manner described previously (7, 8), for $E_d{}^a = 1.60$V and $E_d{}^c = -0.20$V. E_r was varied from 0.00 to 1.30V by 0.10V increments. I_r-E_d curves for three values of E_r are shown in Fig. 3.

The I_r-E_d curves obtained for $0.20\text{V} \geq E_r \leq 0.70$V were identical, those for $E_r = 0.80$V and 0.90V were identical as were the curves for $1.10\text{V} \leq E_r \leq 1.30$V. I_r-E_d curves obtained for E_r in the vicinity of the $E_{1/2}$ for the reaction described in Eq. [1] varied qualitatively in the expected manner for a slightly irreversible process (16). The I_r-E_d curve obtained for $E_r = 0.10$V and 0.00V were identical to that for $E_r = 0.40$V except that the ring current increased sharply for $E_d > 1.4$V due to the ring electrode reduction of oxygen produced at the disk electrode. The ring current observed at $E_d = 1.10$V for $E_r = 0.40$V results from the reduction of the Br_2 produced at the disk electrode to Br^- (wave A). The experimental collection efficiency at $E_d = 1.1$V calculated from Fig. 3 and the I_d-E_d curve obtained simultaneously, $N_{exp} = -I_r/I_d$, is 0.090 in satisfactory agreement with the theoretical collection efficiency for this electrode.

In Fig. 3, peak P corresponds to a soluble, electrochemically reducible species which was detected at the ring electrode, for $E_r = 0.40$V and 0.80V, coincident with the appearance of wave C at the disk electrode. When the cathodic E_d-scan was reversed at $E_d{}^c = 0.80$V, peak P was not obtained and $I_r = -NI_{d,l}$ ($Br^- \rightarrow Br_2$) for $E_d > 1.0$V on both the anodic and cathodic E_d scans in agreement with results discussed above for wave C at the disk electrode.

For $E_r = 1.20$V, the ring current observed at $E_d < 0.9$V is equal to $\beta^{2/3}$ times $I_{d,l}$ ($Br^- \rightarrow Br_2$) in the absence of complicating reactions at the disk electrode, *e.g.*, Br^- adsorption (16). For $E_d = 1.1$V and $E_r = 1.2$V, $I_r = (\beta^{2/3} - N)$ times $I_{d,l}$ ($Br^- \rightarrow Br_2$) (16).

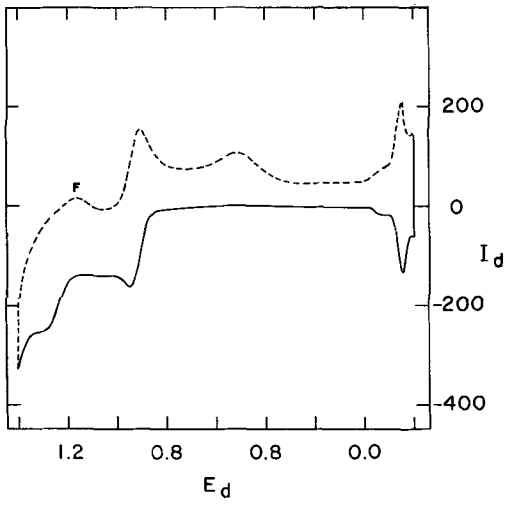

Fig. 2. I_d-E_d; 1.0M H_2SO_4-1.0 x 10^{-3}M KBr, 0 rpm, E_d scan rate = 6.0 V min^{-1}, ——— anodic E_d scan, - - - - cathodic E_d scan.

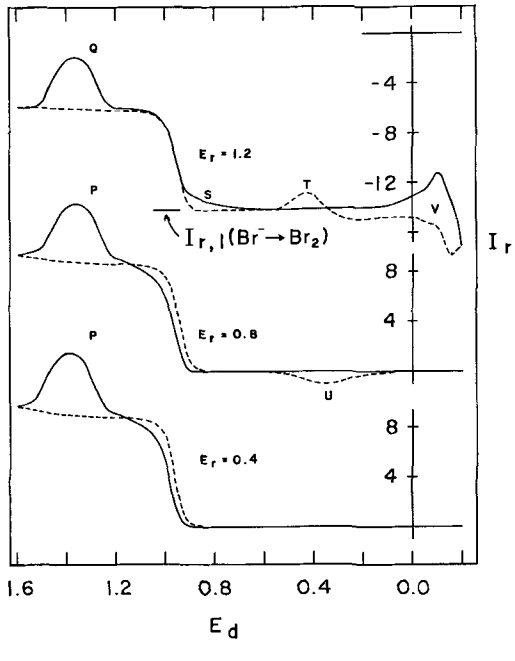

Fig. 3. I_r-E_d *vs.* E_r; 1.0M H_2SO_4-3.3 x 10^{-4}M KBr, 400 rpm, E_d scan rate = 6.0 V min^{-1}, ——— anodic E_d scan, - - - - cathodic E_d scan.

An additional current decrease, peak Q, occurs in this experiment for 1.2V < E_d < 1.5V on the anodic E_d scan (region of wave C). This peak wave was not obtained if $E_d^c \geq 0.80$V.

Figure 2 shows that the electroactive species generated at the disk electrode during wave C is reduced for E_d < 1.2V. Since as stated above, the I_r-E_d curves obtained for E_r = 1.10V and 1.30V are identical, the supposed positive oxidation state of bromine produced at the disk electrode during wave C does not reach the ring electrode during this experiment and undergoes a homogeneous decomposition in the electrode diffusion layer. A reaction sequence which is consistent with the data discussed above pertaining to wave C is

(disk electrode, surface controlled)

$$H_2O + Br^- \rightleftharpoons HOBr + H^+ + 2e \quad [6]$$

and/or

$$H_2O + 1/2Br_2 \rightleftharpoons HOBr + H^+ + e \quad [7]$$

(solution, diffusion layer)

$$HOBr + Br^- + H^+ \rightleftharpoons Br_2 + H_2O \quad [8]$$

(ring electrode)

$$Br_2 + 2e \rightleftharpoons 2Br^- \ (E_r < 0.9V) \quad [9]$$

$$Br^- \rightleftharpoons Br_2 + 2e \ (E_r > 0.9V) \quad [10]$$

The equilibrium constant for reaction [8] has been calculated to be 1.7 × 10^8 (17). Thus, in 1.0*M* H_2SO_4, this reaction lies far to the right at equilibrium. The proposed reaction sequence is consistent with the experimental results shown in Fig. 3 provided reaction [8] is very fast. Eigen and Kustin calculated the rate constant for the hydrolysis of Br_2, the reverse of reaction [8], as 110 sec^{-1} (18). We calculate the rate constant for the forward direction of reaction [8] to be 1.9 × 10^{10} M^{-2} sec^{-1}, fast on the time scale of this experiment.

The above reaction sequence is also in agreement with the results shown in Fig. 2. For E_d > 1.0V, the surface concentration of Br^- is zero and any HOBr present at the electrode surface cannot undergo reaction according to reaction [8] and will subsequently be reduced to Br_2 during the cathodic E_d scan at E_d < 1.2V.

We have excluded the possibility that BrO_3^- is formed as a product of wave C because: (*i*) BrO_3^- does not react rapidly with Br^- in 1.0*M* H_2SO_4 acid to form Br_2, (19), and (*ii*) BrO_3^- is not electrochemically reduced in 1.0*M* H_2SO_4 at potentials more positive than 0.2V in the presence of Br^- or Br_2.

I_d-E_d curves of HOBr *in 1.0M* H_2SO_4.—I_d-E_d curves were obtained for a solution of 1.0*M* H_2SO_4-9 × 10^{-4}*M* HOBr, Fig. 4. These curves show the expected two-step reduction wave corresponding to the one electron reductions of hypobromite to bromine and that of bromine to bromide. HOBr is reduced for E_d < 1.2V, a result which is consistent with our proposal that the product of wave C is HOBr.

I-E curves of Br_2 *in 1.0M* H_2SO_4.—Figure 5 shows a I_d-E_d curve obtained at the stationary disk electrode in 1.0*M* H_2SO_4-2 × 10^{-4}*M* Br_2. The curve shown is the "reproducible" curve observed after five cyclic E_d scans. Again three waves are formed in the anodic region of E_d > 0.8V corresponding to the oxidation of Br^- (produced during the previous cathodic scan) to Br_2, the initiation of platinum surface oxidation and production of HOBr. On the cathodic portion of the E_d scan, peaks are observed for HOBr reduction (E_{peak} = 1.15V), Br_2 reduction (E_{peak} = 0.95V), surface oxide reduction (E_{peak} = 0.50V), and oxygen reduction (E_{peak} = 0.2V). Reversing the potential scan at E_d^c = 0.80V produced a subsequent I_d-E_d curve showing no production or reduction of HOBr, consistent with results considered above.

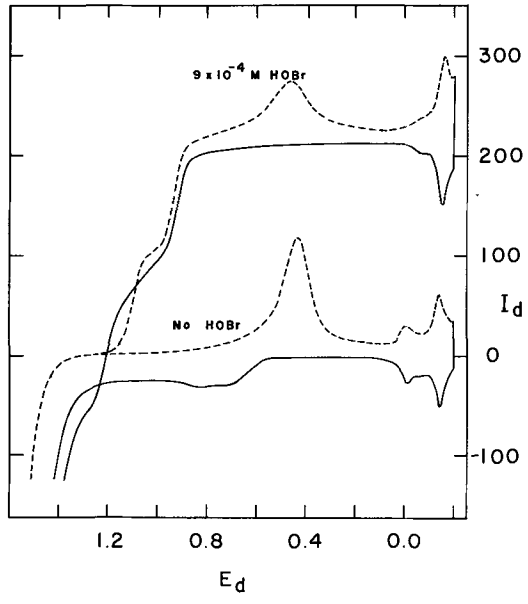

Fig. 4. I_d-E_d; 1.0M H_2SO_4-0M, 9 x 10^{-4}M HOBr, 400 rpm, E_d scan rate = 3.0 V min^{-1}, ——— anodic E_d scan, - - - - cathodic E_d scan.

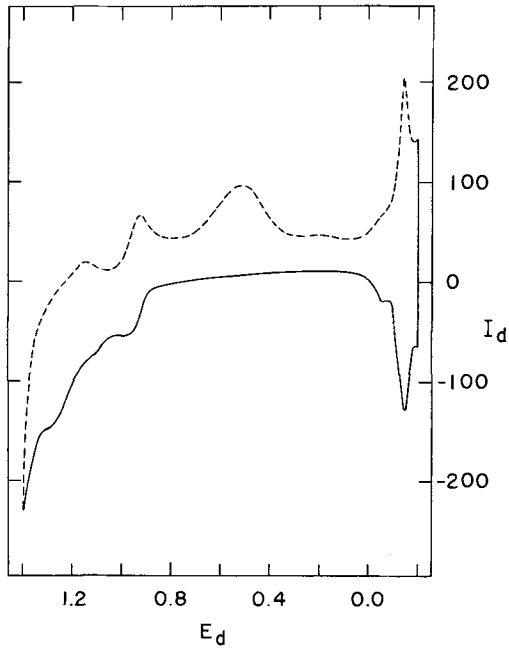

Fig. 5. I_d-E_d; 1.0M H_2SO_4-2 x 10^{-4}M Br_2, 0 rpm, E_d scan rate = 6.0 V min^{-1}, ——— anodic E_d scan, - - - - cathodic E_d scan.

I_r-E_d curves were obtained at 400 rpm in 1.0*M* H_2SO_4-1 × 10^{-4}*M* Br_2 for E_d^a = 1.60V and E_d^c = −0.20V varying E_r from 0.20 to 1.40V by 0.10V increments. I_r-E_d curves for four values of E_r are shown in Fig. 6. The curves recorded for 0.30V ≤ E_r ≤ 0.50V were identical to each other as were those for 0.60V ≤ E_r ≤ 0.80V, those for E_r = 1.0 and 1.1V, and those for E_r > 1.2V. The curve found with E_r = 0.20V showed the reduction of oxygen produced at the disk for E_d > 1.4V.

Note that no ring current peak is observed in the E_d region of wave C for E_r = 1.20V. The absence of peak R is in accord with the proposed reaction sequence, since the bulk concentration of Br^- is zero in this solution. HOBr produced at the disk electrode does not undergo rapid homogeneous reaction in the solution adjacent to the disk electrode, in the absence of Br^-, and will be transported by convective-diffu-

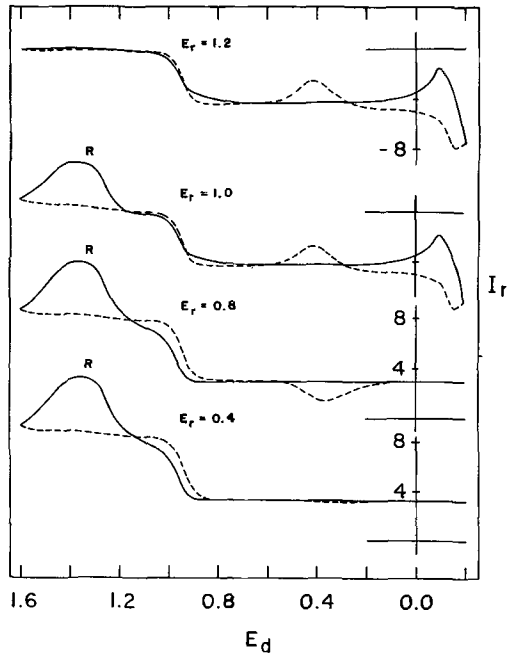

Fig. 6. I_r-E_d vs. E_r; 1.0M H_2SO_4-1 x 10^{-4}M Br_2, 400 rpm E_d scan rate = 6.0 V min^{-1}, ——— anodic E_d scan, - - - - cathodic E_d scan.

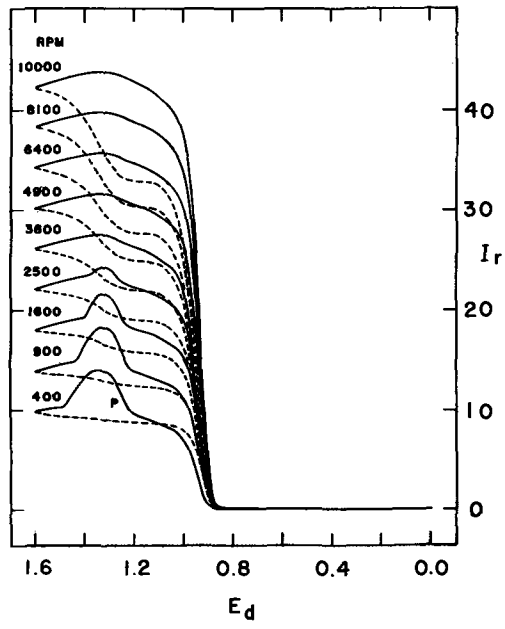

Fig. 7. I_r-E_d vs. rpm; 1.0M H_2SO_4-3.3 x 10^{-4}M KBr, E_d scan rate = 6.0 V min^{-1}, ——— anodic E_d scan, - - - - cathodic E_d scan.

sion to the ring electrode where it will be reduced as peak R.

On the basis of the reaction sequence proposed in the above discussion, it would seem that peak R for the collection of the HOBr at E_r = 0.8V should be twice as great as observed at E_r = 1.0V. The conclusion would follow since at E_r = 1.0V, HOBr is reduced to Br_2 at the ring while for E_r = 0.8V it is reduced to Br^-. Comparison of the areas for peak R obtained at the same time as wave C shows the area at E_r = 0.8V is only about 30% greater than that at E_r = 1.0V. This discrepancy probably arises because Br^- is formed at the ring electrode at E_r = 0.8V and some of the HOBr from the disk reacts with this Br^- to produce Br_2 in the solution adjacent to the ring electrode. The fraction of this Br_2 ultimately collected at the ring electrode will be less than unity, hence the total ring current will be less than that predicted by the disk current and the theoretical collection efficiency.

Effects of variation of electrode rotation speed.—Figure 7 shows I_r-E_d curves obtained in 1.0M H_2SO_4-3.3 x 10^{-4}M KBr for 400 ≤ rpm ≤ 10,000. The ring electrode peak current, P, corresponding to wave C decreases in area with increasing rotation speed. Also the difference between the limiting ring electrode collection current at E_d = 1.1V for the anodic and cathodic E_d scans increases with higher rotation speed. The decrease in the area of peak P and other qualitative changes observed with increased rotation speed were produced at 400 rpm when small (10^{-6}M) increments of Na_2SO_3 were added to the solution. Evidence has been presented previously that the presence of sulfite impurity in sulfuric acid will affect *I-E* curves obtained from Pt electrodes in such solutions (13). Reference (13) also states that the sulfite level slowly increases in a bottle of concentrated sulfuric acid opened repeatedly to the room atmosphere. In this study also, the affects of increased rotation speed, as shown in Fig. 7, were most severe when the electrolyte was prepared from bottles of "old" concentrated sulfuric acid.

Adsorption of Br^-.—Evidence has been given that wave C results in the production of a small amount of HOBr at the disk electrode via a surface controlled reaction that occurs simultaneously with disk electrode surface oxidation. Two possible mechanisms for this reaction are apparent, (*i*) the further oxidation of a portion of the Br_2 produced by the convective-diffusion limited oxidation of Br^- involving a process catalyzed by platinum oxidation, and (*ii*) the oxidation of adsorbed Br^- or Br_2. If the production of HOBr is the result of a surface catalyzed process at active electrode sites, one would expect to see a large effect of E_d scan rate variation on the quantity of HOBr produced during wave C as estimated from the I_r-E_d curves. This prediction follows since oxidation of the platinum surface prevents HOBr formation. Hence, for decreasing scan rates the surface would remain in a "catalytically active" state for a longer time and the amount of HOBr found would be expected to increase. This prediction does not agree with the experimental observation that the amount of HOBr produced is independent of scan rate from 2 to 10 V min^{-1}.

Studies using electrochemical and radiochemical techniques (12, 20-25) have shown that Br^- is strongly adsorbed at platinum surfaces in acidic media. Reference (24) reports that in 1N H_2SO_4 the desorption of Br^- at anodic potentials does not proceed until E > 1.3V (SCE) which is consistent with the observed initial production of HOBr on the anodic E_d scan (Fig. 1, 3, 5). This reference also reports finding bromate in the solution after the desorption process was carried out at E = 2.0V (NHE). HOBr is known to decompose slowly to produce BrO_3^- and Br_2 (10).

The hypothesis that the HOBr stems from the oxidation of adsorbed Br^- can be tested using the ring-disk electrode. For exceedingly large concentrations of KBr the quantity of HOBr produced will be limited by the maximum disk electrode surface coverage by adsorbed Br^-. Simultaneous I_d-E_d and I_r-E_d curves for E_r = 0.60V were obtained at 400 rpm for 2.5 x 10^{-4}M ≤ [KBr] ≤ 6.0 x 10^{-3}M. The area under peak P, Q_p, corresponding to the extra Br_2 collected due to the production of HOBr at the disk electrode and its subsequent reaction according to Eq. [8], increased with increasing [KBr] in the manner shown in Fig. 8. For [KBr] < 1.5 x 10^{-3}M the points lie approximately on a straight line having nearly a zero intercept. For [KBr] > 4.5 x 10^{-3}M, Q_p reached a limiting value of about 27.5 μcoul. Although the convective-diffusion equation has not been solved for this case,

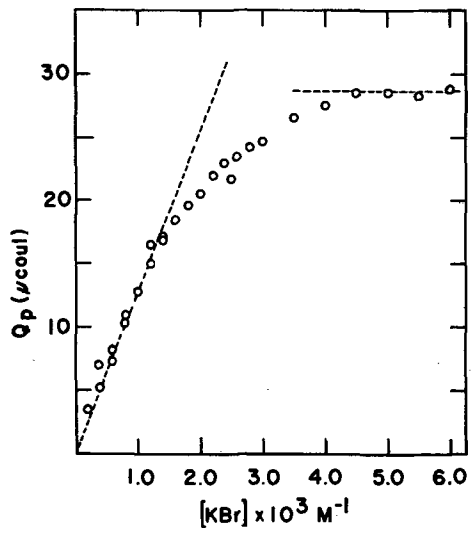

Fig. 8. Q_p vs. KBr; 1.0M H_2SO_4, 400 rpm, E_d scan rate = 6.0 V min^{-1}.

if it is assumed that one molecule of Br_2 is produced in the diffusion layer for each HOBr produced at the disk electrode, and that the fraction of this Br_2 collected at the ring electrode is nearly N_{theory}, the limiting surface coverage of adsorbed Br^- responsible for wave C, Γ, can be calculated as in Eq. [11]. In Eq. [11], n, the number of equivalents per mole for the reduction of Br_2, equals 2.

$$\Gamma = \frac{Q_p}{n(\text{disk area})\, F\, N_{theory}} = \frac{(27.5 \times 10^{-6})}{2(0.470)\,(9.65 \times 10^4)\,(9.0 \times 10^{-2})} \quad [11]$$

$$= 3.4 \times 10^{-9} \text{ g-ions cm}^{-2}$$

Using 1.5×10^{15} atoms cm^{-2} for the atomic packing density for platinum as calculated from the density (26), the surface coverage for an equivalent monolayer is 2.5×10^{-9} g-ions cm^{-2}. Radiotracer studies indicate a surface coverage of 1.3×10^{-9} g-ions cm^{-2} for a $1N$ H_2SO_4-$10^{-3}N$ NaBr solution (24). From Fig. 8, $\Gamma = 1.6 \times 10^{-9}$ g-ions cm^{-2} for $1 \times 10^{-3}M$ KBr. In view of the assumptions made regarding the relation of Q_p to the quantity of HOBr produced at the disk electrode and the inevitable differences in the surface roughness of our electrode and that used in ref. (24), the close agreement between our work and the radiotracer studies may be fortuitous. We conclude, however, that the results given in Fig. 8 are consistent with a mechanism whereby HOBr is produced during wave C at the disk electrode by oxidation of adsorbed Br^-. Furthermore, we conclude that Fig. 8 shows that the limiting value of Q_p corresponds to complete disk electrode surface coverage by adsorbed Br^- for [KBr] $> 4.5 \times 10^{-3}M$.

Examination of the I_d-E_d curves obtained for the various concentrations of KBr in the above experiment revealed that the magnitude of waves B and E remained nearly constant for increasing KBr concentration. Hence, wave B does not correspond to an oxidation of adsorbed Br^- to either the atomic state or a positive oxidation state and we conclude that wave B results only in the oxidation of the platinum electrode surface. Furthermore, the extent of surface oxidation corresponding to wave B is unaffected by the surface coverage with adsorbed Br^-. I_r-E_d curves were obtained, as shown in Fig. 3, for $E_r = 0.80$V. Stopping the anodic E_d scan at 1.10V for times to 30 sec did not result in a significant decrease in the amount of HOBr produced on commencing the anodic E_d scan. Thus, platinum oxide formed at the disk electrode with wave B does not result in a decrease of the disk electrode surface coverage by adsorbed Br^-.

A mechanism for the surface controlled production of HOBr which is consistent with the experimental results discussed above is given in Eq. [12]-[16].

(Oxide-free platinum surface)

$$Pt + Br^- \rightarrow Pt(Br^-_{ads}) \quad [12]$$

$(1.0V < E_d < 1.2V)$

$$Pt(Br^-_{ads}) + H_2O \rightarrow PtO(Br^-_{ads}) + 2H^+ + 2e \quad [13]$$

$$Pt + H_2O \rightarrow PtO + 2H^+ + 2e \quad [14]$$

$(E_d > 1.2V)$

$$PtO(Br^-_{ads}) + H_2O \rightarrow PtO + HOBr + H^+ + 2e \quad [15]$$

$$PtO + H_2O \rightarrow PtO_2 + 2H^+ + 2e \quad [16]$$

The I_r-E_d curve shown in Fig. 3 for $E_r = 1.20$V in the region $E_d < 0.8$V shows effects of Br^- adsorption at the disk electrode. Deviation of I_r from the convective-diffusion limiting value in this E_d region, $I_{r,l}$ ($Br^- \rightarrow Br_2$), will occur due to adsorption and desorption of Br^- at the disk electrode surface. Adsorption of Br^- will result in $I_r > I_{r,l}$ ($Br^- \rightarrow Br_2$) and desorption will result in $I_r < I_{r,l}$ ($Br^- \rightarrow Br_2$). Note that the anodic ring currents are negative quantities. The value of $I_{r,l}$ ($Br^- \rightarrow Br_2$) shown in Fig. 3 was obtained by stopping the E_d scan at $E_d + 0.6$V and letting I_r come to a steady-state value. Areas of deviation from $I_{r,l}$ ($Br^- \rightarrow Br_2$) in Fig. 3 are labelled S, T, U, and V. The interpretation of these waves must also be consistent with the following observations:

1. The reduction of the platinum oxide formed at the disk electrode for $E_d > 1.0$V occurs in the designated E_d region.
2. A small amount of soluble electroactive platinum(II) has been found to be a product of this disk reduction reaction [13] and this platinum(II) species may form bromide complexes (27).
3. The amount of platinum dissolution increases with increased halide concentration (28).
4. Adsorption of bromide at an oxide covered platinum surface is very slow but occurs rapidly following the reduction of the oxide (29).
5. Adsorption of atomic and/or molecular hydrogen competes with bromide adsorption for $E_d < 0.1$V (12).

The I_r-E_d curve for $E_r = 1.2$V in Fig. 3 shows that the adsorption of Br^- at the disk electrode during the cathodic E_d scan for $E_d < 0.9$V is negligible until reduction of the platinum oxide at the disk electrode occurs, $E_d = 0.6$V. The rapid adsorption of Br^- at the reduced disk electrode produces wave T at the ring electrode. This observation is consistent with statement 4 above. I_r-E_d curves were obtained for $E_r = 1.20$V, $E_d{}^c = -0.20$V and $1.0\text{V} \leq E_d{}^a \leq 1.60$V. Wave T was obtained only for $E_d{}^a > 1.2$, region of wave C, even though oxidation of the platinum electrode surface occurs for $1.0\text{V} < E_d < 1.2$V, Fig. 1. This observation is consistent with the hypothesis that HOBr is produced by oxidation of adsorbed Br^- since for $E_d{}^a < 1.2$V no HOBr is produced and no adsorbed Br^- is removed from the disk electrode.

Figure 3 also shows that for $E_r = 0.8$V an anodic peak wave, U, is obtained during the cathodic E_d scan. This, we conclude, is the result of oxidation of a soluble platinum(II) and/or platinum(II) bromide complex species formed at the disk electrode. Comparison of the peak potentials for waves T and U shows that Br^- adsorption occurs prior to the production of the soluble platinum(II) species. These observations are also consistent with the I_r-E_d curves obtained in Br_2 solution and shown in Fig. 6.

For E_d in the "hydrogen region," region V in Fig. 3, Br^- is desorbed on the anodic E_d scan as a result of

the preferential adsorption of atomic and/or molecular hydrogen. On the succeeding anodic E_d scan, the adsorbed hydrogen is ionized and Br^- is again adsorbed. A similar discussion may be given for the observations shown in Fig. 6.

Because of the relatively slow E_d scan rates used in obtaining the I-E curves in Fig. 3 and 5, it is difficult to accurately integrate the I_r *vs.* time in order to attempt a correlation with Q_p. Potential step techniques at a RRDE are useful for the study of adsorption processes (30). Figure 9 shows I_r-t curves obtained in 1.0M H_2SO_4 containing KBr, for E_r = 1.2V, as a result of a E_d step from −0.2 to 0.8V. Figure 9a shows the results for 1.1 × $10^{-3}M$ KBr. Integrating the difference between I_r and $I_{r,l}$ ($Br^- \rightarrow Br_2$) *vs.* time shows that the decrease in Br^- flux to the ring electrode as a result of the E_d step is 7.75 μcoul, *i.e.*, the disk surface coverage by Br^- is 1.9 × 10^{-9} g-ions cm^{-2}. For the same solution, I_r-E_d curves were obtained in a manner identical to that for Fig. 3. The area under wave P, Q_p, was measured to be 13.2 μcoul indicating a disk surface coverage calculated by Eq. [11] of 1.6 × 10^{-9} g-ions cm^{-2}. In view of the lack of theoretical support for a calculation of surface coverage from Q_p, as discussed earlier, we conclude that the results of Fig. 9a shows that sufficient Br^- is adsorbed on the disk electrode surface to account for the production of HOBr during wave C by oxidation of adsorbed Br^-.

Figure 9b shows that for 1.1 × $10^{-4}M$ KBr, the rate of Br^- adsorption at the disk electrode is controlled by the rate of convective-diffusion of Br^- from the bulk solution to the disk electrode surface (30). This was also the case for [KBr] < 1.1 × $10^{-4}M$. This suggested that if the proposed mechanism is correct, variation of the length of time E_d is in a potential region where Br^- adsorption can occur will cause a variation in the amount of HOBr produced during wave C. This would hold provided the disk surface coverage by adsorbed Br^- does not reach the equilibrium value, *i.e.*, very low bulk concentrations of Br^-. Figure 10 shows I_r-E_d curves obtained in the usual manner for E_d^a = 1.6V, E_d^c = 0.0V, and E_r = 0.6V with the exception that the E_d scan was stopped at 0.8V during the anodic scan and held for 0 sec ≤ t ≤ 30 sec before completing the potential cycle. For [KBr] = 0.6 × $10^{-5}M$, Q_p increased in approximately a linear manner with time for t < 25 sec. For t ≥ 25 sec, the disk surface coverage of Br^- reached its equilibrium value for that concentration of KBr. For [KBr] = 1.1 × $10^{-5}M$, equilibrium surface coverage was achieved from t ≥ 10 sec and for [KBr] = 3.3 × $10^{-5}M$, equilibrium coverage was achieved for all t > 0 sec, *i.e.*, within the time required for the normal E_d cycling. These results are in agreement with the proposed mechanism.

Since Br^- adsorption at the platinum disk electrode does not occur until the oxidized surface layer is reduced and since the E_d for the production of HOBr (wave C) is approximately equal to the $E°$ for reaction [3], no conclusion can be drawn from the above data as to whether the oxidation of adsorbed Br^- is catalyzed by oxidation of the platinum electrode surface. The pH dependence of waves A, B, and C is presently being studied in the attempt to answer this question.

A Transient Impedance Technique for the Study of Electrode Kinetics

Application to Potentiostatic Methods

Arthur A. Pilla

ESB Incorporated Research Center, Yardley, Pennsylvania

ABSTRACT

A generalized approach to the study of the dynamic behavior of electrochemical systems is presented in terms of the transient impedance technique. It is shown that interpretation of the time domain electrode response to an arbitrary perturbation by conversion of both functions to the frequency domain allows maximum usage of experimental information with minimum ambiguity. Both real and imaginary axis Laplace transformation are used to generate $Z(\sigma)$ and $Z(j\omega)$, respectively. The theoretical and experimental usefulness of both functions is considered in detail and it is shown that a very wide frequency range extending to 10^8 rad/sec may be studied. The basis for the use of aperiodic equivalent circuits to represent active or passive electrodes is considered and sample circuits, rigorously derived, are presented. The equivalent circuit approach is thus generalized and it is shown how their use may constitute shorthand notation for the rigorous solution of the differential equations used to describe a particular electrode model. Application of the transient impedance method to potentiostatic techniques is presented with emphasis on the manner in which this approach allows instrumental errors and artifacts to be markedly reduced, particularly at high frequencies.

The use of time as a variable to study the behavior of electrochemical systems is well-known (1-3). Techniques employing this variable usually involve perturbing the system with supposedly known functions of voltage (4-8), current (9-14), or charge (15-20); *e.g.*, steps or pulses, and observing the corresponding response. The relation of this response to the kinetic processes occurring during the perturbation (or during the relaxation from it) requires data analysis which involves the creation of a physically significant model and subsequent derivation of working equations which may be employed to obtain parameters that describe the mechanism and kinetics of the system under study.

Working equations have been obtained from the original differential equations describing the particular model chosen either by their analytic solution (4, 6, 7, 10-12, 14-18, 20) for certain simple cases or their numerical solution (21-24) for more complex cases. Certain limitations are present in both approaches since the analysis is usually performed in the time domain. One of the major problems in time domain analysis lies in the difficulty with which the total amount of information which is contained in the response function can be obtained (25). Thus, in the cyclic voltammetry technique, one of the most useful diagnostic criteria is the variation of peak current with voltage sweep speed (21). However, while this relation has certainly allowed much information to be gained for certain electrode reaction mechanisms, all of the available information from the total response curve has not been used simply because it is not available in a conveniently usable format. This can result in some ambiguity for complex reactions.

Another problem lies in the fact that the closed form working equations which have been obtained for, *e.g.*, the potential step method, are not readily usable in complete form because of their complexity. Certain approximations are often required for their use, such as measurement at times short (or long) enough so that simple time functions (*e.g.*, $\sqrt{t}$ or $1/\sqrt{t}$) may be obtained. These approximations normally do not allow all of the information content in the response function to be employed. In addition, they place restrictions on data acquisition and often result in some ambiguity in the interpretation of results (26-28). Thus, the time range over which simple functional behavior can be observed may be at such short times that errors in the measurement apparatus (*e.g.*, nonlinearity) can falsify the results. Further, this time interval may be so small that its exact detection could be highly subject to error.

In addition to the above considerations, it has become increasingly apparent that many electrode reactions are more complex with respect to heterogene-

ous reaction steps than had previously been suspected (29-34). Thus, in addition to charge transfer, surface processes such as adsorption may take place. It is, therefore, of increasing importance to obtain information relative to the structure and components of the electrode-electrolyte interphase region (35-36). This means essentially that an attempt should be made to evaluate the double layer capacitance, surface excess and electrode charge in the presence of a faradaic reaction. If the reaction contains heterogeneous steps more complex than charge transfer then the possibility that these may be very rapid, and perhaps also inseparable from the double layer charging process (37-40), places certain severe requirements on both the mode of measurement and data analysis. For example, in these cases, it is no longer acceptable to extrapolate over large time (or frequency) ranges in which measurements were not made to evaluate parameters such as the double layer capacitance (41, 42). This is especially true if measurements were made only over fairly restricted time (or frequency) intervals. It is thus necessary to obtain meaningful data over as wide a time range as possible including the shortest experimentally accessible times.

It is the purpose of this study to present an approach to the interpretation of the pulse response of electrochemical systems such that the concept of pulse impedance may be introduced. It will be shown that this approach generates, for most systems of interest, algebraic equations which are much less ambiguous to interpret than classical time domain expressions, thus eliminating the above-mentioned difficulties to a large extent. In addition, instrumental problems, especially for short time or high frequency measurements, are eliminated.

Theoretical

Time to frequency domain conversion.—Impedance of an electrochemical system can be defined validly only in an appropriate frequency domain (43), because of its vector or phasor properties. Therefore, in order to obtain an impedance function from time domain behavior, it is necessary to convert both the perturbation and response from time functions into frequency functions. This is accomplished normally through the use of a transformation technique which operates on the time variable. One of the most useful techniques which may be employed for this is the Laplace transformation (44). Using this, a time function, $f(t)$, may be transformed to a complex frequency function, $F(s)$, according to

$$F(s) = \int_0^\infty f(t) \exp(-st)\, dt \qquad [1]$$

where s is the Laplace transform variable. The quantity s is a complex number given by $s = \sigma + j\omega$, in which σ is the real and $j\omega$ the imaginary part. The complete function $F(s)$ is thus described by a complex plane in which all absolute values of both σ and $j\omega$ may be employed provided the integral in [1] converges. This plane is known as the complex frequency plane. Examination of the properties of the function $F(s)$ indicates that it is possible to perform the integration along either or both the real and imaginary axes of the complex frequency plane under certain conditions. Thus, considering the real axis ($s = \sigma$), Eq. [1] may be written

$$F(\sigma) = \int_0^\infty f(t) \exp(-\sigma t)\, dt \qquad [2]$$

It is clear that this integral exists when $\sigma > 0$ for any time function which converges when multiplied by $\exp(-\sigma t)$. This includes essentially all time functions of interest in electrode kinetic studies. When [2] is carried out, this will be termed real axis transformation. This type of transformation was first suggested for electrochemical applications by Wijen (45), who considered the current response to a potential step for a diffusion coupled charge transfer reaction. The scope of his approach was, however, somewhat limited in nature since the aspect of impedance was not considered and thus such problems as more complex reactions, double layer charging, or the use of an imperfect potential step (*e.g.*, with finite rise) were not taken into account. Real axis transformation has since been considered by other workers (46, 47), however, essentially their approach has been simply to express some classical faradaic impedance expressions in terms of the complex frequency variables. No attempt was made to generalize the technique in terms of transformation along both axes or to illustrate the enormous advantages in the actual measurement of impedance [see, however, ref. (48)].

In order to see how real axis transformation is actually carried out on an experimental curve, consider Fig. 1. Here the time function is a typical current response to a potential step having finite rise time. The current function, $i(t)$, is multiplied by the exponential function $\exp(-\sigma t)$ shown on Fig. 1. The area under the resulting curve is then equal to the integral defined in [2]. This operation is performed using the total time function (*i.e.*, from $t = 0$) for as many σ values as desired. The resulting quantity, $I(\sigma)$, then expresses the current as a function of the frequency variable σ in radians per second.

If the same operation defined in [2] is performed on the voltage driving function, $V(t)$, the corresponding frequency function $V(\sigma)$ is obtained. Knowledge of both $V(\sigma)$ and $I(\sigma)$ allows the real axis pulse impedance of the system, $Z(\sigma)$, to be defined as

$$Z(\sigma) = V(\sigma)/I(\sigma) \qquad [3]$$

The quantity $Z(\sigma)$ is a real function and as such is the simplest of the impedance functions. To illustrate this, consider an RC series circuit. The real axis impedance of this circuit is given by

$$Z(\sigma) = R + \frac{1}{C\sigma} \qquad [4]$$

This relation may be utilized in the same manner as a normal algebraic equation containing real variables. Thus, the quantities R and C may be obtained simply by plotting $Z(\sigma)$ as a function of $1/\sigma$ as normally would be done for an equation of this type.

In addition to real axis transformation, conversion into the frequency domain by imaginary axis transformation ($s = j\omega$) may be performed. In this case, [1] may be written

$$F(j\omega) = \int_0^\infty f(t) \exp(-j\omega t)\, dt \qquad [5]$$

Equation [5] is the well-known single-sided Fourier transform (49). Inspection of [5] indicates that this integral will converge only for certain time functions. Thus, functions of the type $\exp(-at)$ and $\operatorname{erf}(\sqrt{bt})$ or $\operatorname{erfc}(\sqrt{bt})$ allow [5] to converge when multiplied by $\exp(-j\omega t)$.

Most electrochemical systems respond, in part, according to functions of the type indicated above. How-

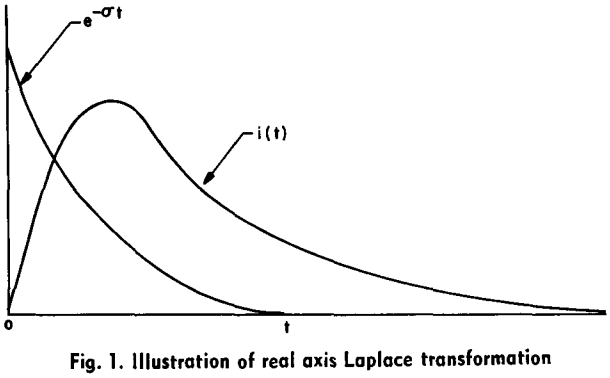

Fig. 1. Illustration of real axis Laplace transformation

ever, the complete time function may contain additive constant terms and it is clear that the integral in [5] will not converge. Use may be made, however, of the fact that imaginary axis transformation actually describes the system behavior in the same manner as if the perturbation were a steady-state sinusoidal function (50). In this case, it is permissible to carry out the complete transformation as described in [1] on the constant portion of $f(t)$ and make the substitution $s = j\omega$ to obtain the result which could have been obtained if [5] could have been employed. If the above is performed, it is now clear that the imaginary axis transformation for a constant A is $A/j\omega$. Therefore, if $f(t) = A + \exp(-at)$, then the complete imaginary axis transformation is obtained by using [5] for $\exp(-at)$ and making the above substitution for A. The complete transformation is then

$$F(j\omega) = \frac{A}{j\omega} + \frac{1}{a + j\omega} \qquad [6]$$

Use of the above procedure enables the pulse behavior of essentially every electrochemical system to be expressed in terms of imaginary axis Laplace transformation.

In order to see how imaginary axis transformation is actually carried out on an experimental curve, it is convenient to rewrite Eq. [5] as

$$F(j\omega) = \int_0^\infty f(t) \cos \omega t \, dt - j \int_0^\infty f(t) \sin \omega t \, dt \qquad [7]$$

in which the complex function $F(j\omega)$ is expressed in terms of its real and imaginary parts. It can be seen that in both cases multiplication of the original time function by a trigonometric function is involved. This is illustrated in Fig. 2. Here, the time function is again the current response, $i(t)$, to a potential step input. This is multiplied from $t = 0$ to the time at which $i \simeq 0$ by a sine (or cosine) function of given frequency, ω. The area under the resulting curve is, as in real axis transformation, equal to the integral defined in [5]. This operation is performed, for both the real and imaginary parts of $F(j\omega)$, for as many ω values as desired. The resulting complex function $I(j\omega)$ is then the total current expressed in terms of the real frequency, ω.

A similar series of operations may be performed on the voltage driving function (in the case of, *e.g.*, the potential step method) to obtain the corresponding complex voltage frequency function, $V(j\omega)$. Knowledge of both $V(j\omega)$ and $I(j\omega)$ allows, similar to the previous case, the imaginary axis pulse impedance of the system, $Z(j\omega)$, to be defined as

$$Z(j\omega) = V(j\omega)/I(j\omega) \qquad [8]$$

In this case, $Z(j\omega)$ is a complex function having both real, $\mathrm{Re}(Z(\omega))$, and imaginary, $\mathrm{Im}(Z(\omega))$, parts and the corresponding phase angle, $\theta(\omega)$. This function is mathematically identical in form to that employed in classical a-c techniques (51-58), where sinusoidal steady-state conditions prevail. It is to be remembered, however, that $Z(\omega)$ in this study is always considered as obtained under nonsinusoidal conditions (*i.e.*, from conversion of both the input and response time domain functions).

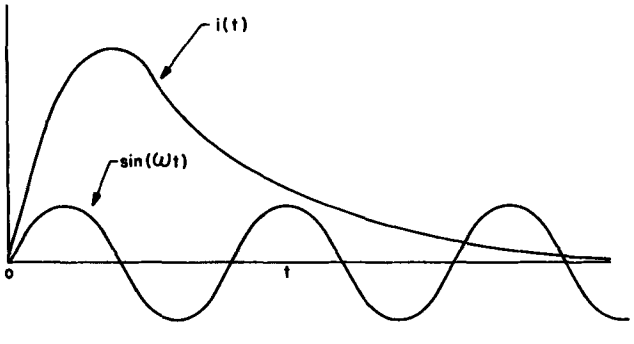

Fig. 2. Illustration of imaginary axis Laplace transformation

Use of $Z(j\omega)$ for the RC series circuit considered for the previous case results in the following complex function

$$Z(j\omega) = R - \frac{j}{C\omega} \qquad [9]$$

In contrast to the simple impedance function obtained above for this case Eq. [4], analysis of Eq. [9] to obtain the quantities R and C requires, as is well-known (57), the use of a complex plane. Among the various approaches using this type of analysis, it is preferable to consider separately, the functional relationships which describe $\mathrm{Re}(Z(\omega))$, $\mathrm{Im}(Z(\omega))$, and $\theta(\omega)$ since this is, in fact, the most sensitive test of whether a given model is valid or not. In terms of Eq. [9], a plot of $\mathrm{Re}(Z(\omega))$ and $\mathrm{Im}(Z(\omega))$ *vs.* $1/\omega$ should result in a horizontal line for the former, the value of which is equal to R, and a straight line for the latter, the slope of which allows C to be obtained. The use of $\theta(\omega)$ is not necessary in this simple case.

It is to be emphasized that obtaining both $Z(\sigma)$ and $Z(j\omega)$ involves operating upon the appropriate time domain functions from $t = 0$ (*e.g.*, along the rise of a potential step). Thus, it is possible to obtain both impedance functions at frequencies as high as 10^8 rad/sec provided the system can be perturbed to such an extent that an observable response is obtained at nanosecond times. In the case of real axis transformation, the use of large σ values heavily weights the short time behavior of $f(t)$ since $\exp(-\sigma t)$ is a very rapidly decaying function in this case. As σ becomes smaller, short time data contributes relatively less to the total integral. Correspondingly, for imaginary axis transformation, large ω values emphasize the short time system response. This is so since the major contribution to the product $f(t) \sin \omega t$ for large ω occurs only in those time intervals during which the value of $f(t)$ changes significantly over one frequency cycle. This means that only small time constants will be observable for relatively large values of ω. Note that, although obtaining $Z(j\omega)$ from pulse measurements results in data identical to that of classical a-c techniques, the requirement that the system actually be perturbed by a sine wave function has been relaxed. In fact, the restriction that the perturbing function be exactly known for either $Z(\sigma)$ or $Z(j\omega)$ is no longer applicable. This is highly significant with respect to experimental measurement especially at high frequencies since the input perturbation and response may be arbitrary functions, even a highly distorted sine wave. In addition, as long as the nonlinearities in the measurement system are the same for both voltage and current functions, the calculation of $Z(\sigma)$ and $Z(j\omega)$ allows their elimination. This will be treated further below.

It can be seen that the use of both real and imaginary axis Laplace transformation on the single time domain response of an electrochemical system and the single time domain driving function, either being of arbitrary form, allows a considerable amount of information to be obtained concerning the impedance of the system. The use of both $Z(\sigma)$ and $Z(j\omega)$ permits four basic functions to be described, the specific functional relationships of which can be used to provide less ambiguity in the elucidation of relatively complex systems.

Aperiodic equivalent circuit interpretation.—The pulse impedance method lends itself quite readily to the description of an electrochemical system by an electrical equivalent circuit containing frequency independent elements (aperiodic equivalent circuit). The use of equivalent circuits as electrical analogs for some electrode reactions is, of course, well-known (51, 52, 54, 58). However, the circuits employed usually con-

tain frequency dependent elements. Little work has been reported concerning the use of aperiodic equivalent circuits. The notable exception is the work of Barker (15) who quite ingeniously, although somewhat empirically, developed aperiodic circuits which describe a variety of electrochemical systems. The use of Laplace transformation to derive the current and voltage frequency behavior of various electrochemical reaction steps allows a great deal of flexibility insofar as the development of a complete model for the particular electrode impedance is concerned. The pulse response of an electrochemical system can then be measured experimentally and $Z(\sigma)$ and $Z(j\omega)$ evaluated with a minimum of *a priori* assumptions necessary concerning the actual mechanism present. Diagnostic criteria, consisting essentially in the determination of the number of time constants and their placement in the appropriate equivalent circuit (topology requirement) can then be employed.

To illustrate this approach, the construction of an aperiodic equivalent circuit will be performed for an electrode at which an adsorption coupled charge transfer faradaic process occurs. It will be assumed at the onset that *a priori* separation may be made of double layer charging current from faradaic current. Thus, the electrode reaction may be considered as a leak across the double layer capacitor, C_d. The general equivalent circuit for this concept is shown in Fig. 3 wherein R_e and Z_F represent the solution resistance and faradaic impedance, respectively. The impedance of this circuit may be written in terms of s, as

$$Z(s) = R_e + \frac{1}{1/Z_F(s) + C_d s} \qquad [10]$$

In general, the complexity of $Z_F(s)$ depends directly on the complexity of the electrode process. It can be shown (59) that one additional time constant must be added to Eq. [10] for every series reaction step, with the exception of charge transfer. Thus, as $Z_F(s)$ becomes more complex, it is increasingly necessary to render experimental conditions such that the time constant representing double layer charging, $R_e C_d$, be independently observable so that it may be appropriately eliminated from the total electrode impedance. This may be performed if a high enough frequency range can be chosen such that the condition $1/Z_F(s) << C_d s$ may be obtained. In this case, Eq. [10] is written

$$Z_F(s) = \frac{1}{C_d s} + R_e \qquad [11]$$

which, in terms of σ and $j\omega$, is given by Eq. [4] and [9], respectively. The general diagnostic criteria for double layer behavior (if separable from the faradaic process) is then, for real axis transformation linearity of $Z(\sigma)$ *vs.* $1/\sigma$, and for imaginary axis transformation linearity in $1/\omega$ for $\mathrm{Im}(Z(\omega))$ and constancy in ω for $\mathrm{Re}(Z(\omega))$. If at least an order of magnitude in frequency range may be obtained for all of these functional relationships, then it may be considered with reasonable assurance that double layer behavior is being observed. This then allows the elimination of one time constant from the general impedance expression (Eq. [10]) unmasking the faradaic impedance for further analysis.

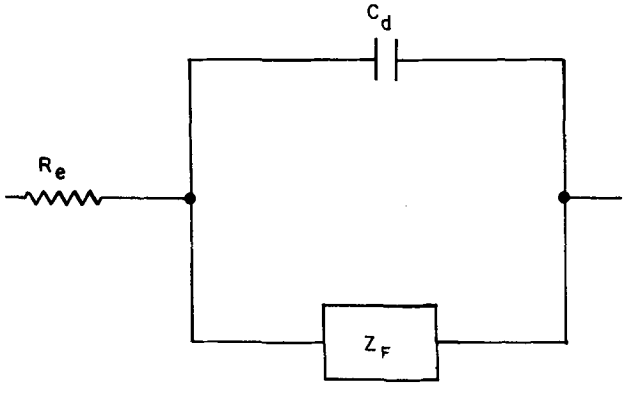

Fig. 3. General aperiodic equivalent circuit for a microelectrode having uniform potential distribution and at which double layer and faradaic processes may be separated.

In order to derive $Z_F(s)$ for a series adsorption coupled charge transfer process the impedance of each of these reaction steps can first be obtained and then appropriately added. The charge transfer impedance may be derived in a straightforward fashion from, *e.g.*, the commonly employed rate equation (60), written in terms of s, as

$$I(s) = I_o \int_o^\infty \exp\left[-\frac{\alpha n\mathbf{F}}{RT} [E(t) - st] \right] - I_o \int_o^\infty \exp\left[\frac{1-\alpha n\mathbf{F}}{RT} [E(t) - st] \right] \qquad [12]$$

where $I(s)$ is the current due to charge transfer; $E(t)$ the overvoltage driving this process; I_o the exchange current density; α the transfer coefficient; the other quantities have their usual significance. This equation, while describing a potential dependent resistor, may be used under certain linear conditions (*i.e.*, low level perturbation) to obtain a simple resistor, R_t. Thus, as $E(t) \to 0$, [12] may be written

$$\frac{E(s)}{I(s)} = \frac{1}{I_o} \frac{RT}{n\mathbf{F}} = R_t^{eq} \qquad [13]$$

which is simply the well-known (61) charge transfer resistance under equilibrium conditions. As $E(t)$ becomes relatively large (*e.g.*, the cathodic Tafel region) and when $\Delta E(t) \to 0$, representing a small perturbation from steady-state conditions, Eq. [12] becomes

$$\frac{\Delta E(s)}{\Delta I(s)} = \frac{1}{I_o} \frac{RT}{\alpha n\mathbf{F}} \frac{1}{\exp(\alpha n\mathbf{F}E/RT)} = R_t \qquad [14]$$

which also represents a pure resistor provided that the exponential term remains essentially constant during the perturbation, which is the case if it is of low level. Note that R_t given by Eq. [14] is of lower value than R_t^{eq}, as expected. The above is an illustration of the procedure of linearizing about a steady-state condition which can be applied to the majority of electrochemical reaction steps, allowing potential dependence to be examined in a relatively convenient fashion.

To develop an equivalent circuit for the adsorption process, standard reaction rate consideration may be employed with no *a priori* assumptions concerning the actual kinetics of adsorption (62, 63). Thus, the net adsorption rate, v, can be expressed as

$$v = k\, C_i^a(s) - k^1\, C_i(o,s) \qquad [15]$$

where $C_i^a(s)$ and $C_i(o,s)$ are the complex frequency concentration functions of the adsorbed species, i, and of the same species in solution at the electrode-electrolyte interphase region, respectively, and k and k^1 are adsorption and desorption rate constants, respectively. These quantities may be arbitrary complex functions of C_i^a, C_i, and the number and nature of available adsorption sites. The actual form of k and k^1 depends on the type of adsorption kinetics involved (Langmuir, Frumkin, etc.).

If equilibrium or steady-state conditions are defined as

$$v_o = k\, C_i^a(o) = k^1\, C_i(o,o) \qquad [16]$$

where v_o is the exchange adsorption rate and the concentrations are those before the application of the perturbation ($t = 0$), then the following may be written

$$v = v_o \left[\frac{C_i^a(s)}{C_i^a} - \frac{C_i(o,s)}{C_i} \right] \qquad [17]$$

This relation describes the adsorption process in terms of a departure from equilibrium or steady-state conditions. The first ratio on the r.h.s. of Eq. [17] relates to the change in concentration of the adsorbed species and the second takes into account mass transport of this species in the electrolyte. If mass transport is negligible (as assumed in this simple model) then $C_i(o,s)/C_i = 1$ and Eq. [17] is correspondingly simplified.

The impedance function for adsorption require knowledge of both the current due to adsorption and its potential dependence. The former is given by

$$I_a(s) = n\mathbf{F}\,[v + s\,C_i^a(s)] \qquad [18]$$

which simply states that the frequency dependence of the total adsorption current is the sum of that due to the net adsorption rate, v, and that due to the change in concentration of adsorbed species, $s\,C_i^a(s)$, as a result of the perturbation. The frequency dependence of the voltage function may be obtained from the linearized Nernst equation

$$E_a(s) = \frac{RT}{n\mathbf{F}}\,\Delta C_i^a(s) \qquad [19]$$

where $\Delta C_i^a(s) = (C_i^a(s) - C_i^a)/C_i^a$, representing the relative concentration change of adsorbed species. Using Eq. [18] and [19], the impedance expression for adsorption is then

$$Z_a(s) = \frac{RT}{n^2\mathbf{F}^2}\left[\frac{C_i^a}{s + v_o/C_i^a}\right] \qquad [20]$$

Inspection of Eq. [20] reveals that it is identical to the complex impedance function for an R_a-C_a parallel circuit where R_a and C_a are the equivalent adsorption resistance and capacitance, respectively. Identification of Eq. [20] with the expression for the actual equivalent circuit allows physical significance to be given to the circuit elements. Thus

$$C_a = \frac{n^2\mathbf{F}^2}{RT}\,C_i^a \qquad [21]$$

which states, as is to be expected, that C_a is a measure of the concentration of adsorbed species (analogous to the storage of charge in a capacitor). R_a is given by

$$R_a = \frac{RT}{n^2\mathbf{F}^2}\,\frac{1}{v_o} \qquad [22]$$

indicating that it contains adsorption and desorption rate constants. In general, R_a is relatively large for slow or irreversible adsorption becoming relatively smaller as adsorption rate increases.

In order to construct a complete aperiodic equivalent circuit representing the complex impedance of the electrochemical system described above, it is merely necessary to substitute for Z_F in Fig. 3 the subcircuits derived for both charge transfer and adsorption placed in series. This is shown in Fig. 4. Analysis of both impedance functions for the presence of this circuit is relatively straightforward, particularly when the double layer time constant is able to be isolated. This will be shown below.

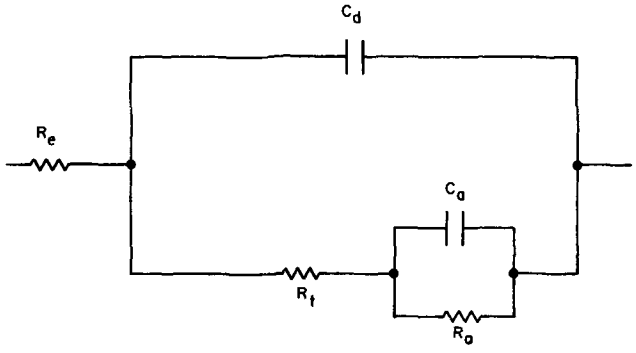

Fig. 4. Aperiodic equivalent circuit for an electrode exhibiting double layer behavior and adsorption coupled charge transfer.

As a specific illustration of the advantage of frequency domain over time domain analysis, a linear diffusion coupled charge transfer process for which the electrolysis conditions are the application of a constant current pulse will be considered. The total current, I_T, is the sum of the faradaic current, I_F, and the double layer charging current, I_C. This condition, which has been generally employed for current step and other relaxation studies (1), implicity assumes that *a priori* separation exists for the double layer and faradaic processes. The total current is then, in terms of s

$$I_T(s) = I_F(s) + I_C(s) \qquad [23]$$

Using the classical definition of capacity charging current, I_C is given by

$$I_C(s) = E(s)\,C_d s \qquad [24]$$

where $E(s)$ is the voltage developed across the double layer. The faradaic current is given by

$$I_F(s) = E(s)/Z_F(s) \qquad [25]$$

The faradaic impedance, $Z_F(s)$, can be constructed by considering that the charge transfer resistance is in series with the diffusion impedance as the model for this process assumes. Thus, $I_F(s)$ is given by, using the linearized rate equation

$$I_F(s) = I_o\left[\frac{C_O(o,s)}{C_O} - \frac{C_R(o,s)}{C_R} - \frac{n\mathbf{F}}{RT}E(s)\right] \qquad [26]$$

in which I_o is the exchange current density for charge transfer; C_O and C_R, the bulk concentrations of the oxidized and reduced species, respectively; $C_O(o,s)$ and $C_R(o,s)$ represent the complex frequency dependence of these concentrations at the electrode surface; and the other symbols have their usual meaning. Inspection of Eq. [26] shows that, in reality, the diffusion impedance, composed of terms due to C_O and C_R, and contained in the concentration ratios, is in series with the charge transfer resistance contained in the last term within the brackets on the r.h.s. of Eq. [26]. (See Eq. [13] for $R_t^{eq.}$)

A specific expression for the concentration ratios in Eq. [26] may be obtained by solving Fick's second law, written in terms of s, for planar diffusion with appropriate boundary conditions for semi-infinite character. The solution is of the form

$$\frac{C_i(o,s)}{C_i} = \frac{I_F(s)}{n\mathbf{F}C\sqrt{D_i}\sqrt{s}} + \frac{1}{s} \qquad [27]$$

in which D_i is the diffusion coefficient of the diffusing species, i. There are as many equations of this type as there are diffusing species. Substitution of Eq. [27] written for C_O and C_R in Eq. [26] gives

$$I_F(s) = \frac{E(s)}{B/\sqrt{s} + RT/n\mathbf{F}\,I_o} \qquad [28]$$

where

$$B = \frac{RT}{n^2\mathbf{F}^2}\left[\frac{1}{C_O\sqrt{D_O}} + \frac{1}{C_R\sqrt{D_R}}\right] \qquad [29]$$

Use of Eq. [24] and [28] allows an expression for $E(t)$ in the time domain to be obtained provided that the form of the current input is known. A true current step would allow $I_T(s)$, Eq. [23], to be written as I_O/s. For this, the simplest of input perturbations, the complete time domain relation for $E(t)$ is given by Eq. [11]

$$E(t) = \frac{I_o}{C_d(a-b)}\left\{\frac{a}{b^2}\left[\exp(b^2t)\,\mathrm{erfc}\,(bt^{1/2}) + \frac{2b\sqrt{t}}{\sqrt{\pi}} - 1\right] - \frac{b}{a^2}\left[\exp(a^2t)\,\mathrm{erfc}\,(at^{1/2}) + \frac{2a\sqrt{t}}{\sqrt{\pi}} - 1\right]\right\} \qquad [30]$$

where

$$\frac{a}{b} = \frac{nFI_oB}{2RT} \pm \left[\frac{n^2F^2I_o^2B^2}{4R^2T^2} - \frac{nF}{RT}\frac{I_o}{C_d} \right]^{1/2} \quad [31]$$

in which B is given by Eq. [20]. As can be seen by Eq. [30], analysis of this system in the time domain involves the manipulation of a relatively complex equation. One approach extensively employed is simplification which requires that measurements be made at short times. This, as stated earlier, allows a more usable $\sqrt{t}$ function to be employed. However, in the case of, *e.g.*, relatively rapid charge transfer kinetics, such short times may be required that the finite rise of the current function can cause considerable error. When this occurs, $I_T(s)$ can no longer be given by I_0/s, but assumes a more complex form thereby adding at least another time constant to a new and even more complex time domain function for $E(t)$. The separation of appropriate kinetic parameters then becomes exceedingly difficult.

The above-mentioned problems are avoided when complex frequency domain analysis is carried out for this system. In this case, the impedance function as given in Eq. [10] may be employed. This normally allows sufficiently high frequencies to be obtained that the double layer time constant may be isolated according to Eq. [11], thus unmasking the faradaic impedance for further analysis. Inspection of Eq. [28] shows that it can be used to obtain $Z_F(s)$. Thus

$$Z_F(s) = \frac{E(s)}{I_F(s)} = \frac{B}{\sqrt{s}} + \frac{nF}{RT}\frac{1}{I_o} \quad [32]$$

in which B is again given by Eq. [29]. The last term on the r.h.s. of Eq. [32] is, as stated earlier, the charge transfer resistance R_t^{eq} (see Eq. [13]). The term $B/\sqrt{s}$, which represents the diffusion impedance, $Z_D(s)$, is identical in form to the imepdance, $Z_L(s)$, of an R_LC_L semi-infinite transmission line. Thus

$$Z_L(s) = \frac{R_L}{C_L}\frac{1}{\sqrt{s}} \quad [33]$$

in which R_L and C_L are the uniformly distributed resistance and capacitance per (arbitrary) unit length of line. The electrochemical equivalence of R_L and C_L can be obtained using the relation $Z_D(s) = Z_L(s)$ and the original partial differential equations describing both diffusion (Fick's second law) and the transmission line. The latter results in $D_i = 1/R_LC_L$. In this manner, R is given by

$$R_L = \frac{RT}{n^2F^2}\frac{1}{C_iD_i} \quad [34]$$

and C_L by

$$C_L = \frac{n^2F^2}{RT}C_i \quad [35]$$

The above discussion indicates that the aperiodic equivalent circuit for planar diffusion is a semi-infinite transmission line. The complete equivalent circuit for this system can thus be constructed as shown in Fig. 5, where the charge transfer impedance, R_t, is in series with the diffusion impedance, Z_D.

Comparison of Eq. [32] with [30] clearly shows that the former is much simpler in form. In addition, exact knowledge of the function for the current input is not required. All of the necessary kinetic constants are readily obtainable from Eq. [32] with no approximations. In the case of real axis transformation, the diagnostic plot is $Z_F(\sigma)$ *vs.* $1/\sqrt{\sigma}$, the intercept of which gives R_t^{eq}, while the slope contains D. Imaginary axis transformation gives the well-known results for $\mathrm{Re}(F(j\omega))$ and $\mathrm{Im}(F(j\omega))$ both of which are linear in $1/\sqrt{\omega}$, having identical slopes containing D_i. The intercept of $\mathrm{Re}(F(j\omega))$ again allows R_t^{eq} to be obtained.

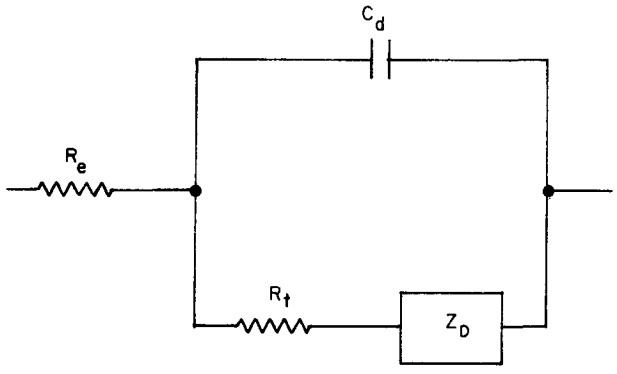

Fig. 5. Aperiodic equivalent circuit for an electrode exhibiting diffusion coupled charge transfer.

The above examples are presented as illustrations of the relative ease with which even a complex electrochemical system may be analyzed using equivalent circuits which may be coupled, if desired, with the pulse impedance approach. The use of aperiodic equivalent circuits allows the representation of the linearized rate expressions for each reaction step by simple frequency independent circuit elements. Once the subcircuits have been established for all of the heterogeneous and homogeneous reaction steps generally encountered in electrochemical reactions, it is relatively simple to construct a complete circuit for specific faradaic processes. To do this, the subcircuits are placed in any series or parallel combination which it is thought adequately represents the electrode reaction under study. In addition, the possibility of obtaining linear behavior at any steady-state condition allows the potential dependence of appropriate circuit elements to be determined, thus facilitating the elucidation of electrode mechanism and kinetics. This approach will be presented in generalized form elsewhere.

It is to be noted that expressing electrode behavior in terms of equivalent circuits does not constitute an empirical approach. The circuits are merely shorthand notation for the rigorous solutions to the several simultaneous differential and partial differential equations needed to describe a particular electrochemical model.

Application to potentiostatic techniques.—The transient impedance approach readily lends itself to potential control methods which offer certain experimental advantages especially with respect to high frequency studies. To illustrate this, the dynamic behavior of a general single amplifier potentiostat will be discussed. Special emphasis is given to the method of elimination of potentiostat parameters thereby allowing only electrochemical quantities to be examined.

The general circuit for single amplifier potential control of an electrode having an arbitrary impedance is given in Fig. 6 wherein the representation of all

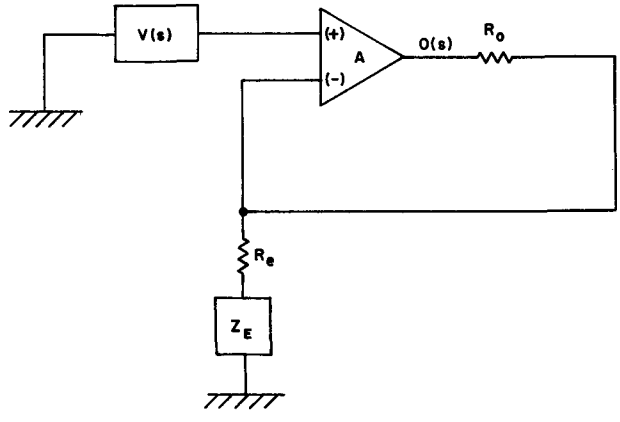

Fig. 6. Block diagram of general potentiostat circuit

functions is made in terms of the Laplace transformation. Here, the output voltage $O(s)$, of the potentiostat, A, is applied to the electrochemical cell, R_e, Z_E, through R_o, which represents the output impedance of A, the counterelectrode impedance, and a current measuring resistor, if present. The driving perturbation, $V(s)$, appears across the electrochemical cell as $E(s)$.

To describe the behavior of the potentiostat-electrolytic cell mentioned above in a quantitative manner, it is sufficient to consider the transfer function of the complete system. This function is defined as the ratio of the transform of the output voltage, $O(s)$, to that of the input voltage, $V(s)$. This ratio is given by

$$\frac{O(s)}{V(s)} = \frac{G(s)}{1 + G(s)\,H(s)} \qquad [36]$$

where $G(s)$ is the open loop gain function of the potentiostat and $H(s)$ is the function representing the fraction of the output voltage which is fed back to the input of the potentiostat. The potentiostat gain function determines, to a large extent, the fidelity with which it can reproduce the driving function, $V(s)$, across its control points as $E(s)$. This is especially important when it is desired to make measurements at short times. Thus, for maximum perturbation and response signal amplitude at, *e.g.*, nanosecond times, the potentiostat should be able to respond to a step function such that meaningful measurements may be obtained at these times. Optimum gain functions for high speed applications have been discussed elsewhere (64). Briefly, however, the ideal potentiostat would be characterized by $G(s) = K$, where K is the open loop d-c gain (usually greater than 1000). Unfortunately, all potentiostats presently available have a finite rise time and, as such, cannot be described by the simple function given above. In order to adequately describe a finite rise potentiostat, a first order gain function of the type

$$G(s) = \frac{K}{s\tau + 1} \qquad [37]$$

must be employed. Equation [37] clearly indicates, if τ is known, the time or frequency at which the potentiostat itself will have sufficient gain for observable response. To illustrate the generality of the potentiostatic transient impedance approach, no *a priori* assumptions will be made concerning the actual form of $G(s)$. It is to be borne in mind, however, that $G(s)$ must allow a signal of sufficient amplitude to be observed at the shortest times compatible with the highest frequencies desired to be obtained by real or imaginary axis transformation.

The function $H(s)$ is simply the ratio of the output voltage appearing across the potentiostat control points to the total output voltage. Thus, for the system described in Fig. 6, $H(s)$ is given by

$$H(s) = \frac{R_e + Z_E(s)}{R_o + R_e + Z_E(s)} \qquad [38]$$

The transfer function is then obtained using [36] and [38]

$$\frac{O(s)}{V(s)} = \frac{[R_o + R_e + Z_E(s)]G(s)}{R_o + R_e + Z_E(s) + [R_e + Z_E(s)]G(s)} \qquad [39]$$

This relation may be employed to derive all of the functions needed to develop an expression for the transient impedance of an electrochemical system when a potentiostat is employed. Note that no *a priori* assumptions have been made concerning the electrode impedance, $Z_E(s)$. Thus, the nature of the electrode impedance has neither been considered nor will it affect the results.

To obtain an impedance expression $Z(s)$ usable for the evaluation of electrochemical parameters knowledge of $E(s)$ and the total output current, $i(s)$, is necessary. $E(s)$ is given by

$$E(s) = O(s) - i(s)R_o \qquad [40]$$

from which, using [39]

$$\frac{E(s)}{V(s)} = \frac{[R_e + Z_E(s)]G(s)}{[R_e + Z_E(s)][G(s) + 1] + R_o} \qquad [41]$$

Examination of Eq. [41] indicates that it is, in reality, an expression for the ideality ratio of the potentiostat. Thus, a perfect potentiostat would have $E(s)/V(s) = 1$. Departure from unity is caused by both $G(s)$ and R_o. Reduction of R_o by, *e.g.*, proper cell design and elimination of current measuring resistors in the negative feedback loop effectively reduces potentiostat rise time. In addition, the smallest value of τ (see Eq. [37]), also reduces potentiostat rise time.

The total output current is given by

$$i(s) = \frac{O(s)}{R_o + R_e + Z_E(s)} \qquad [42]$$

from which, using [39]

$$\frac{i(s)}{V(s)} = \frac{G(s)}{[R_e + Z_E(s)][G(s) + 1] + R_o} \qquad [43]$$

Division of Eq. [41] by Eq. [43] allows the impedance expression to be obtained. The result is

$$Z(s) = E(s)/i(s) = R_e + Z_E(s) \qquad [44]$$

Inspection of Eq. [44] indicates that both $G(s)$ and R_o have been eliminated and that $Z(s)$ is a function only of what appears across the potentiostat control points (*i.e.*, between reference and working electrodes). In this way, the potentiostat characteristics and the impedance of the counterelectrode, current sampling resistors, and wire inductance in the negative feedback loop are not included in the final measurement. The only inductance which may remain is that of the working electrode lead which, in practice, may be reduced to a negligible amount.

It has thus been shown that knowledge of the function $Z(s)$, as defined in Eq. [44], allows the characteristics of the electrochemical system to be isolated from the most troublesome instrumental artifacts when a potentiostat is employed. $Z(s)$ is obtained from both the real and imaginary axis transformation of the voltage appearing across the potentiostat control points, $E(t)$, and the potentiostat output current, $i(t)$. As indicated in the theoretical discussion, both $E(t)$ and $i(t)$ may be obtained at times as close to zero as experimentally feasible. The shortest time at which meaningful results can be obtained is determined, to a large extent by the speed of the potentiostat, *i.e.*, $G(s)$.

Experimental and Results

In order to illustrate and test the transient impedance technique, the general potentiostat circuit shown in Fig. 6 was employed. The specific form of Z_E was initially chosen to be a real electric circuit consisting of a capacitor representing the double layer, C_d, in series with the electrolyte resistance, R_e, as shown in Fig. 7. The potentiostat, A, (Fig. 6), is the ultrafast rise Tacussel Model PIT-20-2A provided with external phase compensation to correctly match the potentiostat with Z_E for fast, smooth and easily measurable response. The step voltage source, $V(s)$, (Fig. 6), is the Monsanto 300A pulse generator which can be correctly mated to the input of the potentiostat through the use of its variable rise and fall times. All voltage

Fig. 7. Equivalent circuit representing double layer behavior only

and current time functions were measured on a Tektronix 556 oscilloscope equipped with two 1A5 preamplifiers. Active probes were used exclusively since the signal is detected at the probe tip at relatively high impedance allowing faithful signal reproduction at rise times as short as 3 nanosec, effectively eliminating the influence of cable length. For those cases in which current could be measured outside the negative feedback loop, two Tektronix P6045 FET probes were employed. When the current measuring resistor was placed inside the negative feedback loop [thus constituting part of R_o, (Fig. 6)], two Tektronix P6046 differential probes were employed. In each case, identical type probes were utilized so that correct signal matching could be maintained. Identical probes could be matched to better than ±5% by appropriate peaking of the high frequency circuits within the respective probe amplifiers to obtain as closely identical pulse shapes from the same signal source as possible. In this way, nonlinearities which may be present in signal measurements are nearly identical for both current and voltage and cancel out of the resulting impedance expression.

Initial experiments were carried out using $R_e = 5$ ohms and $C_d = 0.15$ microfarads. Note that measurements performed on electrical analogs at the times and frequencies attainable in this work require suitable high frequency components. For this reason, only metal film resistors and glass capacitors were used throughout this study. The photograph shown in Fig. 8 illustrates the oscilloscopic recording of current and voltage time traces at 50 nanosec per major horizontal division for the circuit given above. It can be seen from Fig. 8 that an initial voltage or current point at 10 nanosec is readily accessible. As will be seen below, this is sufficient, along with adequate point spacing, to enable frequencies as high as 10^8 rad/sec to be examined.

Both real and imaginary axis transformations were performed by carrying out the mathematical operations in Eq. [2] and [7] numerically using a digital computer (Burroughs 5500 or EAI 640). Complete details of the digital computer calculations will be published elsewhere. Briefly, however, the calculations proceed in the following fashion. Data points in digital form accurately representing the complete experimental time curve are introduced at the beginning of the program and a data check is made to detect errors in transcription, *e.g.*, time voltage or current increment errors. Note here that all data is recorded with a point spacing which corresponds to a maximum of a 10% change in successive points. In practice, when using an oscilloscope, several time overlapping pictures must be obtained to accomplish this. Work is presently underway in this laboratory to directly record data in digital fashion. This will be performed using very fast sample and hold modules to record appropriate spaced initial time points coupled with the single cycle data input mode available on most small computers (such as EAI 640) enabling a data point to be obtained each memory cycle (usually 1 to 1.5 μsec).

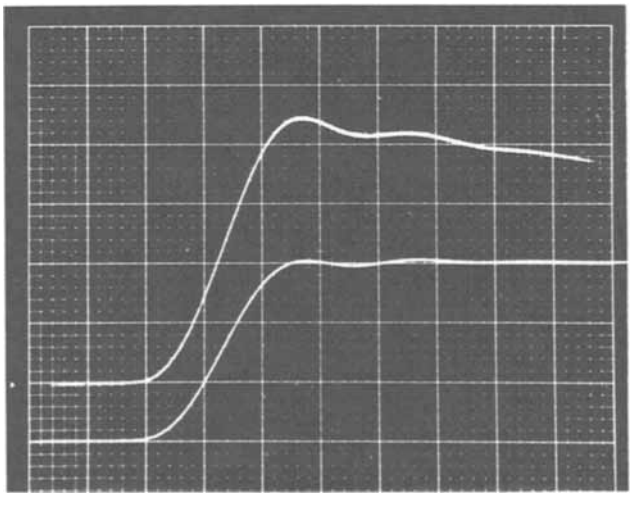

Fig. 8. Actual oscilloscope trace at 50 nanosec per major horizontal division. Lower curve is voltage and upper curve current.

Once the data has been checked, the calculations then proceed, according to the following algorithm in the case of real axis transformation

$$F(\sigma) = \sum_i \left[\frac{[f(t_i+1)e^{-\sigma t_{i+1}} - f(t_i)e^{-\sigma t_i}][t_{i+1} - t_i]}{\ln [f(t_i+1)e^{\sigma t_{i+1}}/f(t_i)e^{\sigma t_i}]} \right] + \frac{f(t_\infty)}{\sigma} \quad [45]$$

where t_i and t_{i+1} represent successive time points; and t_∞ is the time at which the signal achieves steady state, if present. Inspection of Eq. [45] indicates that this integration is carried out by assuming exponential behavior between any two successive data points. The numerical summation is performed for every value of σ desired for all voltage and current points whereupon $Z(\sigma)$ may be evaluated according to Eq. [3].

In the case of imaginary axis transformation, the real and imaginary parts of the time function are evaluated on the basis of Eq. [7]. The alogorithms employed again assume exponential behavior between any two successive data points and are given by, for the real part

$$\mathrm{Re}[F(j\omega)] = \sum_i \frac{1}{a^2+\omega^2} \begin{bmatrix} f(t_{i+1})[a\cos\omega t_{i+1} + \omega \sin \omega t_{i+1}] \\ -f(t_i) \quad [a\cos\omega t_i + \omega \sin \omega t_i] \end{bmatrix} \quad [46]$$

and for the imaginary part

$$\mathrm{Im}[F(j\omega)] = \sum_i \left\{ \frac{1}{a^2+\omega^2} \begin{bmatrix} f(t_{i+1})[a\sin\omega t_{i+1} - \omega \cos \omega t_{i+1}] \\ -f(t_i) \quad [a\sin\omega t_i - \omega \cos \omega t_i] \end{bmatrix} \right\} - \frac{f(t_\infty)}{\omega} \quad [47]$$

where

$$a = \frac{\ln [f(t_{i+1})/f(t_i)]}{t_{(i+1)} - t_i} \quad [48]$$

The summations given in Eq. [46] and [47] are performed for all desired ω values for all voltage and current points from which $Z(j\omega)$ is evaluated by the appropriate division of $V(j\omega)$ and $I(j\omega)$.

It was found that an exponential approximation describing the function between two successive data points was the best possible for both transformations provided that these points are correctly spaced. That this is so can be seen from the fact that, for an electrochemical system which can be described by an aperiodic equivalent circuit, only a single time constant will be predominant over a sufficiently small time interval and a single exponential will, therefore, prevail. Note that the exponential approximation is also valid for diffusion coupled systems exhibiting error function behavior since over relatively small time intervals, this function also behaves exponentially to a very good approximation. An obvious ambiguity in this approach exists for those cases in which two (or more) time constants are essentially identical. In this case, the system will behave as though only one time constant were present over the time interval considered and separation will indeed be difficult. One possible solution to this problem is to vary the initial conditions of the experiment with respect to, *e.g.*, potential and/or concentration, which, in most cases, alters the lumped time constants to widely differing degrees.

One of the major problems in numerical real and imaginary axis transformations as performed in this

study is truncation error which may arise, *e.g.*, in the subtraction of two large numbers. It is therefore important to arrange the steps of the computer program in a sequence designed to minimize this possibility. It is also necessary to have a sufficient number of correctly spaced data points (following the 10% signal variation noted above) over the time region which contribute most heavily to a particular value of σ or ω. If this condition is not met, severe truncation error will also result.

The numerical procedure outlined above was applied to both current and voltage time curves, with initial points being taken at 10 nanosec, obtained for the Re-C_d series circuit mentioned above (Fig. 7). Both $Z(\sigma)$ and $Z(j\omega)$ were then obtained. As indicated by Eq. [4], a plot of $Z(\sigma)$ *vs.* $1/\sigma$ should result in a straight line for this circuit, the slope of which contains C_d while the intercept gives R_e. This plot is shown in Fig. 9 for the highest frequency range attainable in this work (10^8 to 10^6 rad/sec). It can be seen that even at the highest frequency, the results are meaningful and adequately describe the system behavior in terms of Eq. [4]. Maximum error occurs at frequencies above 5 x 10^7 rad/sec and for this system, ranged from ±1% at 5 x 10^7 rad/sec to ±5% at 10^8 rad/sec.

The evaluation of $Z(j\omega)$ for this case allows the examination of its real and imaginary parts as a function of $1/\omega$, according to Eq. [9]. A plot of both of these quantities is shown in Fig. 10 for the frequency range 10^8 to 10^6 rad/sec. It can be seen that expected behavior is observed and, as indicated earlier, provides a rather powerful crosscheck allowing decreased ambiguity in the elucidation of double layer behavior. Maximum error occurs in the frequency interval from 10^7 to 10^8 rad/sec ranging from ±3 to 10%.

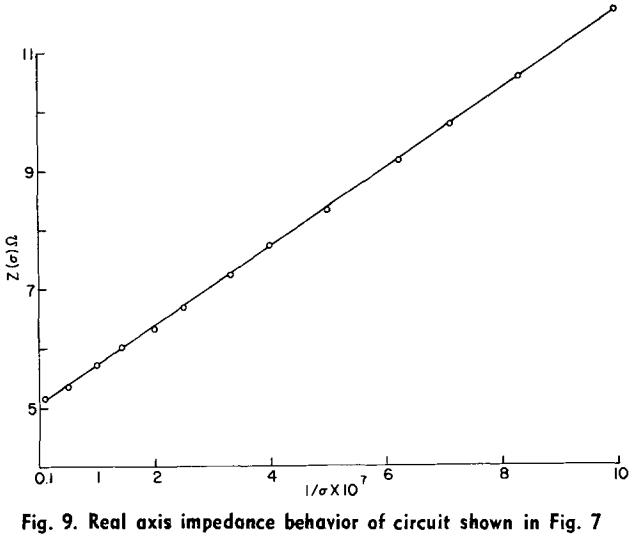

Fig. 9. Real axis impedance behavior of circuit shown in Fig. 7

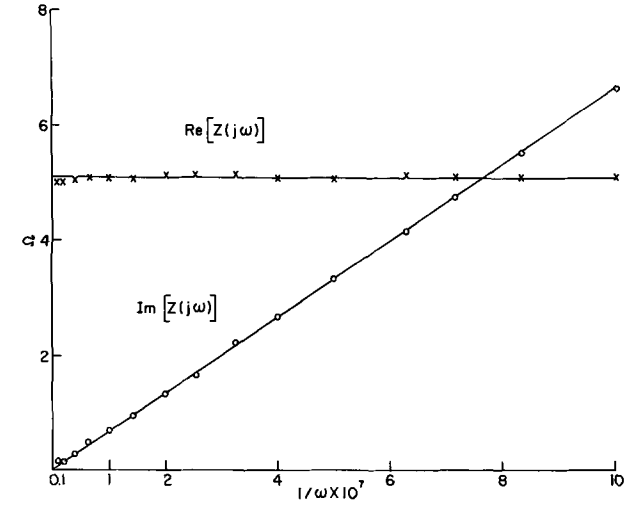

Fig. 10. Imaginary axis impedance behavior of circuit shown in Fig. 7.

In order to more fully test the transformation technique, the equivalent circuit shown in Fig. 4 was examined. This circuit represents, as indicated earlier, an electrode exhibiting double layer behavior along with charge transfer and adsorption, *i.e.*, a system with two time constants The circuit components chosen were R_e = 5 ohms, C_d = 0.15 μF, R_t = 50 ohms, C_a = 1.5 μF, and R_a = 10 kohms. The value of R_a was chosen to be relatively large in order to represent irreversible adsorption for which R_a can then essentially be neglected. An example of this is the hydrogen-platinum system at potentials anodic to the RHE which has recently been studied in this laboratory with the aid of the transient impedance method (65).

The total impedance of this system, in terms of its equivalent circuit (Fig. 4) is given by, neglecting R_a

$$Z(s) = R_e + \frac{R_tC_as + 1}{R_tC_aC_ds^2 + (C_d + C_a)s} \qquad [49]$$

which becomes, at sufficiently high frequencies

$$Z(s) = R_e + \frac{1}{C_ds} \qquad [50]$$

thus illustrating that, for this case, there is a frequency range over which only double layer behavior will be observed (see Eq. [10]). At sufficiently low frequencies, Eq. [49] becomes

$$Z(s) = R_e + \frac{R_tC_a}{C_d + C_a} + \frac{1}{(C_d + C_a)s} \qquad [51]$$

Examination of Eq. [50] and [51] indicates that there are two frequency ranges over which both $Z(\sigma)$ and $Z(j\omega)$ exhibit inverse frequency behavior.

In order to illustrate this, $Z(\sigma)$ was evaluated numerically and diagnostic plots of $Z(\sigma)$ *vs.* $1/\sigma$ are shown in Fig. 11, 12, and 13. Over-all behavior is shown in Fig 11 in the frequency range 10^6 to 10^4 rad/sec which covers the crossover region between only double layer behavior and combined double layer and faradaic behavior. It can already be seen that there is some indication that the system may be diagnosed according to Eq. [50] and [51], however, linearity in $1/\sigma$ is too short in either region to be unambiguous. Figure 12, therefore, shows the high frequency behavior of this system over the range 10^8 to 10^6 rad/sec. The plot is linear over nearly this complete frequency range and allows the evaluation of R_e and C_d which were within ±5% of their known values. Figure 13 shows the low frequency behavior of

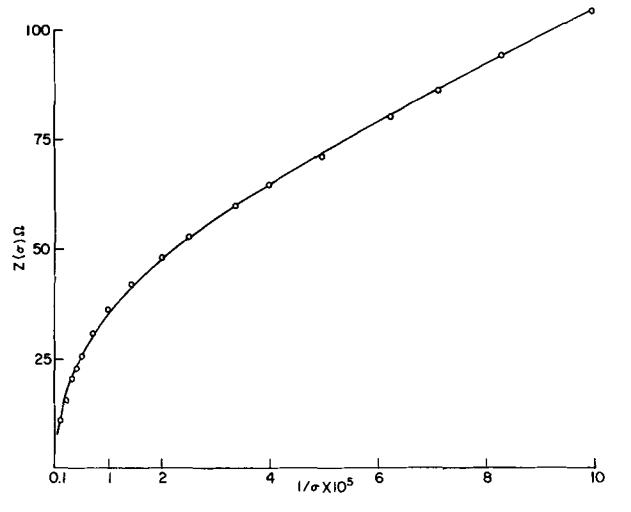

Fig. 11. Over-all real axis impedance behavior of circuit shown in Fig. 4.

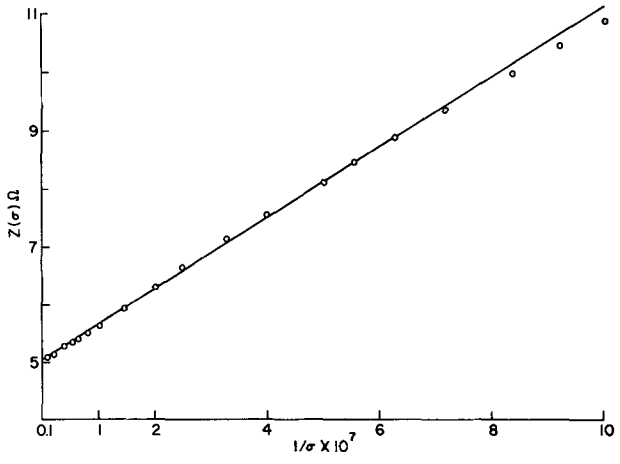

Fig. 12. High frequency real axis impedance behavior of circuit shown in Fig. 4.

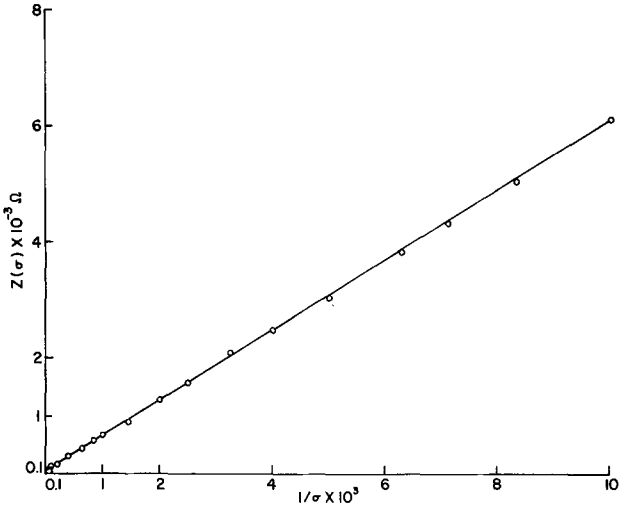

Fig. 13. Low frequency real axis impedance behavior of circuit shown in Fig. 4.

this circuit from 10^4 to 10^2 rad/sec. As can be seen, this plot is again linear in $1/\sigma$ over this frequency range. The values of R_t and C_a calculated from this behavior were within $\pm 5\%$ of their known value. Essentially similar results were obtained for $Z(j\omega)$.

It is to be noted that the time constants of this example were chosen so that double layer behavior can be observed only if relatively high frequencies can be obtained. An electrochemical system exhibiting this behavior is the platinum-hydrogen case (13, 65, 66). Linearity of $Z(\sigma)$ *vs.* $1/\sigma$ in the relatively low frequency range begins at approximately 10^5 rad/sec, normally a high frequency for most impedance studies. Since this plot is a good diagnostic for double layer behavior, it might be assumed that this system did not exhibit adsorption properties, if relatively higher frequencies were not examined. This then illustrates the importance of making frequency studies over as wide a frequency range as possible, especially if adsorption is suspected.

Conclusions

The transient impedance technique presented in this work represents an approach to the study of electrode kinetics which allows the system to be examined using relatively simple algebraic equations with a marked reduction in instrumental errors and artifacts over a relatively wide frequency range. The analysis indicates that meaningful results may be obtained at frequencies as high as 10^8 rad/sec because of the inherent elimination of nearly all instrumental nonlinearities normally encountered at these frequencies. The complete impedance function is generated from time domain data through the use of real and imaginary axis Laplace transformation carried out numerically with the aid of a digital computer. Knowledge of both $Z(\sigma)$ and $Z(j\omega)$ allows considerable cross checking of results once diagnostic plots representing specific types of electrode behavior are available. These criteria may be obtained by the solution of equations describing a particular model in terms of impedance. In this way, both double layer and faradaic behavior (in the presence of each other) may be expressed as relatively simple frequency domain functions as compared with the corresponding time domain functions which, for complex systems, become intractable if, in fact, they can be obtained in closed form at all. In addition, use of the time domain does not allow the inherent simple reduction of instrumental errors. Once the electrode impedance functions have been rigorously derived, they can be identified with aperiodic electrical equivalent circuits for convenience. Thus, circuit elements representing the double layer and faradaic steps such as diffusion, adsorption, charge transfer, etc., can be independently derived and combined in a total equivalent circuit following the particular electrode model chosen. In addition, the variation of these subcircuits with potential can be easily derived if impedance is obtained using small perturbations from steady-state potentials as well as at the equilibrium potential allowing further elucidation of the system under study. It is to be emphasized that the impedance of an electrochemical system must be studied over as wide a frequency range as possible to obtain minimum ambiguity in the interpretation of results. This is especially important when it is desired to evaluate the double layer in the presence of a faradaic reaction, particularly when adsorption or other surface processes may be present.

Acknowledgments

The author sincerely thanks Dr. R. B. Roe and Mr. R. Abramson for their considerable help in establishing the computer programs. Much of this work was performed while the author was at the U.S. Army Electronics Command Research Laboratories, Ft. Monmouth.

Manuscript submitted Oct. 14, 1969; revised manuscript received ca. Dec. 22, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

The Absence of a Detectable Potential-Dependence of the Transfer Coefficient in the Cr^{+3}/Cr^{+2} Reaction

Fred C. Anson,* Nancy Rathjen, and Robert D. Frisbee

Gates and Crellin Laboratories of Chemistry, California Institute of Technology, Pasadena, California

ABSTRACT

The rate of reduction of Cr^{+3} at mercury electrodes has been measured polarographically in an extensive series of electrolytes to search for the potential dependence of the transfer coefficient recently reported (2) for this reaction. No clear evidence of such a potential dependence was found and it is concluded that unavoidable propagation of experimental errors coupled with uncertainties in Frumkin double-layer corrections prevent detection of the predicted potential dependence.

The first systematic study specifically intended to test the prediction of Marcus (1) that the transfer coefficient, α, should show a potential-dependence was described recently by Parsons and Passeron (2). On the basis of their polarographic measurements of the Cr^{+3}/Cr^{+2} electrode reaction they concluded "that there is clear evidence for the existence of the variation of the transfer coefficient with overpotential, and the magnitude of this effect is in agreement with the theoretical prediction within experimental error." This paper has been widely cited because it appeared to offer a very satisfactory confirmation of an important aspect of the Marcus theory.

With the intention of examining the effect of the composition of the supporting electrolyte on the poten-

* Electrochemical Society Active Member.

tial-dependence of α, we undertook a series of polarographic experiments with the Cr^{+2}/Cr^{+3} reaction to extend the work of Parsons and Passeron which was confined to a single concentration ($\mu = 0.5$) of a single electrolyte ($NaClO_4$). We began by attempting to duplicate the results of Parsons and Passeron but were not able to do so. A large number of additional experiments was performed in a search for the source of this discrepancy and some of the results of these experiments are reported here. Our conclusion is that in none of the cases studied is a clear potential dependence of α evident. The unavoidable propagation of experimental errors during the usual conversion of polarographic i/i_d values to rates, and of rates at various potentials to transfer coefficients, results in such large uncertainties that any potential dependence of α is hidden by the theoretical and experimental errors.

Experimental

A water-jacketed polarographic H-cell was employed with a mercury pool serving as the auxiliary electrode. The reference electrode compartment contained supporting electrolyte and the reference electrode was a commercially available saturated calomel electrode in which the KCl electrolyte was replaced with NaCl to prevent the precipitation of $KClO_4$ in the fiber junction. Such dilute solutions of Cr(III) were employed (0.1-0.5 mM) that ohmic drops in the cell were always negligible. The DME (dropping mercury electrode) had a natural drop time of 5.5 sec at −800 mV; drops were not mechanically dislodged.

Solutions were scrupulously deoxygenated by means of a nitrogen stream that passed through copper turnings at 450°C, and a V^{+2} washing tower. Reagent grade salts were used without further purification. The sodium perchlorate solution was prepared from $HClO_4$ and NaOH. The Cr^{+3} solutions were prepared by weighing out crystals of $Cr(ClO_4)_3$ prepared by the reduction of an acidic solution of CrO_3 with H_2O_2, heating to destroy excess peroxide, and concentrating the solution by evaporation until crystals formed. Treatment of supporting electrolytes with prepurified charcoal produced no changes in subsequent polarograms.

Current-potential curves were obtained manually by adjusting the potential of the DME with a solid state operational amplifier-based polarograph and recording the resulting current for several drops with a high precision undamped pen and ink recorder. The potential was then changed by 10 mV and the process repeated. The maximum currents at the end of drop life were used in analyzing the polarograms by means of the Oldham-Parry formula (3) for approximating the Koutecky function (4).

Data analysis.—The polarographic currents recorded at the end of drop life were corrected for the residual current and the ratio, i/i_d, of the current at each potential to the diffusion current was calculated.

In a number of the supporting electrolytes studied the polarographic wave was shifted to the vicinity of the standard potential of the Cr^{+2}/Cr^{+3} couple so that it became quasi-reversible. In such cases, the observed i/i_d ratio was corrected for the back reaction, *i.e.*, Cr^{+2} oxidation, according to Eq. [1]

$$\left(\frac{i}{i_d}\right)_{corr} = \left(\frac{i}{i_d}\right)_{obs}\left[1 + \left(\frac{D_{Cr^{+3}}}{D_{Cr^{+2}}}\right)^{1/2} \exp\left[f(E - E^0)\right]\right] \quad [1]$$

where $(i/i_d)_{corr}$ is the corrected value of the ratio, $(i/i_d)_{obs}$ the experimentally observed ratio, $D_{Cr^{+3}}$ and $D_{Cr^{+2}}$ are the diffusion coefficients of Cr^{+3} and Cr^{+2}, E is the electrode potential, E^0 is the standard potential of the Cr^{+3}/Cr^{+2} couple (−0.65V *vs.* SCE), and $f = F/RT$. When Frumkin double-layer corrections were being applied ($E - \phi_2$) was substituted for E in Eq. [1], where ϕ_2 is the potential at the outer Helmholtz plane. According to the data of Cornelissen (5) $D_{Cr^{+3}} = 5.6 \times 10^{-6}$ cm^2 sec^{-1}, $D_{Cr^{+2}} = 7.9 \times 10^{-6}$ cm^2 sec^{-1}, and $(D_{Cr^{+3}}/D_{Cr^{+2}})^{1/2} = 0.84$. The resulting values of $(i/i_d)_{corr}$ were then substituted into the formula of Oldham and Parry (3) to obtain values of the rate of the electrode reaction at each potential.

The sets of data relating logarithm of rate to potential were used to prepare Tafel plots by fitting with a standard least squares computer program to Eq. [2]

$$\ln \lambda = a_0 + a_1 (E - E^0) \quad [2]$$

where λ is proportional to the rate of the reaction at electrode potential E and $a_1 = -\alpha F/RT$. The apparent value of the transfer coefficient, α, was calculated from the resulting value of a_1.

To test for a potential dependence in α the same data were also fitted by least squares to Eq. [3]

$$\ln \lambda = a_0 + a_1 (E - E^0) + a_2 (E - E^0)^2 \quad [3]$$

The resulting value of a_2 expresses the potential dependence of the transfer coefficient. Equations [2] and [3] differ slightly from the corresponding equations employed by Parsons and Passeron (2) to evaluate the same parameters. They used the overvoltage, η, *i.e.*, the difference between the electrode potential and its equilibrium value in the Cr^{+2}-Cr^{+3} mixtures employed, rather than $(E - E^0)$, the difference between the electrode potential and the standard potential for the couple. According to the Marcus theory (1) $(E - E^0)$, not η, is the independent variable that should be used. However, the error introduced by the use of η instead of $(E - E^0)$ was probably not too large since the Cr^{+2}-Cr^{+3} mixtures employed by Parsons and Passeron covered only a small range of equilibrium potentials which were all fairly close to E^0 (6).

Maxima.—The Cr^{+3} reduction wave tended to develop a pronounced maximum when lower concentrations of supporting electrolyte were employed. This problem could be partially circumvented by employing low concentrations of Cr^{+3} (0.1-0.5 mM) but the maxima appeared in all electrolytes if the ionic strength was decreased sufficiently. This difficulty imposed the lower limit on the supporting electrolyte concentrations that could be employed.

Less severe problems with maxima were also encountered at ionic strengths of 0.5-1M if the Cr^{+3} concentration exceeded about 1.5 mM. Not infrequently the pen and ink recording of the individual current-time curves gave no clear indication of the presence of erratic behavior attributable to maxima, but the collection of current-potential points became harder to reproduce from run to run. Under these circumstances the individual current-time curves were not completely identical from drop to drop when they were inspected in detail by means of an oscilloscope. We concluded that concentrations of Cr^{+3} above 1 mM were to be avoided to prevent errors arising from incipient maxima. Similar behavior has also been reported by Cornelissen (5).

Parsons and Passeron (2) do not specify the concentrations of Cr^{+2} and Cr^{+3} they employed but if values as large as 2-5 mM were used (7), it seems quite likely that their data could have been affected by the presence of inconspicuous maxima.

pH effects.—Parsons and Passeron adjusted the pH of their solutions to 3.4 with $HClO_4$ but employed no buffering agent. A pH value as high as 3.4 seems somewhat dangerous because of the extent of hydrolysis of Cr^{+3} that would result [the hydrolysis constant for Cr^{+3} is $K = 10^{-4}$ M (8)]. An especially worrying point is the question of the pH prevailing at the electrode surface during the reduction of Cr(III). At a pH of 3.4 and a total Cr(III) concentration of 2 mM the concentration of $CrOH^{+2}$ and H^+ are equal. The hydroxide ion liberated by reduction of $CrOH^{+2}$ (Cr^{+2} is unhydrolyzed at pH 3.4) will cause the pH at the electrode surface to become greater than 3.4 and the nature and

charge of the Cr(III) species being reduced will change. To test these suspicions a series of polarograms were recorded for 0.5 mM Cr(III) in a 0.5*F* $NaClO_4$ supporting electrolyte having *p*H values from 2.0 to 4.0. The result was that the polarograms for *p*H values of 2.0, 2.5, and 3.0 were essentially identical. At *p*H 3.5 the individual current-time curves were becoming less reproducible from drop to drop and at *p*H 4.0 the current-time curves displayed very erratic behavior. The erratic current-time behavior becomes more severe as the Cr(III) concentration is raised so that data obtained by Parsons and Passeron (2) at *p*H 3.4 with Cr(III) concentrations of 2 mM and higher would very likely have suffered from the same difficulties. To avoid this source of error in the present experiments we adjusted all solutions to *p*H 2.0 with perchloric acid and used Cr(III) concentrations of 0.5 mM or less.

Corrections for the double layer.—Frumkin double-layer corrections were applied to some of the data by application of Eq. [4] and [5] as is explained in the section on Results and Discussion. For perchlorate electrolytes the values of ϕ_2 required for the Frumkin correction were obtained by interpolation from the data of Payne (9) for the corresponding concentration of perchloric acid or from the data of Wroblowa *et al.* (10) for sodium perchlorate. For iodide electrolytes, the data of Grahame (11) and Breiter, Kleinerman, and Delahay (12) were used, and for bromide electrolytes, the data of Lawrence, Parsons, and Payne (13). The specific adsorption of chloride is so slight at the potentials where Cr^{+3} is reduced (14) that the data for sodium fluoride were employed with the potassium chloride electrolyte.

For the lanthanum chloride electrolytes the Joshi-Parsons equation (15) was used to calculate values of ϕ_2 as a function of q^m, the charge on the electrode, assuming the absence of specific adsorption. Next, Russell's tables (16) were used to evaluate the electrode potential, *E*, which would give the same values of q^m in sodium fluoride solutions having concentrations equal to the ionic strength of the lanthanum chloride solution. The values of ϕ_2' corresponding to these values of *E'* were then used to calculate the electrode potentials corresponding to the initially calculated values of ϕ_2 for the lanthanum chloride solution. That is, at constant q^m, $E = E' - (\phi_2 - \phi_2')$, where *E* is the electrode potential and ϕ_2 the potential at the outer Helmholtz plane, in a lanthanum chloride solution and *E'* and ϕ_2' are the corresponding quantities in a sodium fluoride solution of the same ionic strength.

Results and Discussion

Polarograms for 0.5 mM Cr^{+3} in 0.5M $NaClO_4$-0.01M $HClO_4$ were obtained for comparison with the data of Parsons and Passeron (2). Contrary to the behavior they reported, we observed rather straight Tafel plots before Frumkin double-layer corrections were applied, and when the data were forcibly fit to a quadratic relation, Eq. [3], by a standard least square computer program the "goodness of fit," as measured by the *F*-level (17), decreased markedly, and the coefficient, a_2, of the term in $(E - E^0)^2$ had the opposite sign from that reported in ref. (2). Figure 1 shows a typical Tafel plot and compares it with the plot that is predicted by the coefficients given by Parsons and Passeron (2). The same discrepancy was also obtained in a variety of other supporting electrolytes. As is shown in Table I, which summarizes the data obtained, only in lithium perchlorate electrolytes did the coefficient a_2 in Eq. [3] become less than zero. And even in this case, the *F*-levels resulting from the quadratic fit were so low that it is of doubtful significance.

Polarograms resembling more closely those that Parsons and Passeron apparently obtained did result when the *p*H was raised to 3.5, or if the Cr(III) was obtained from older stock solutions which contained substantial amounts of Cr(III)-polymers as indicated by the ratio of their absorptions at 260 and 230 nm (18).

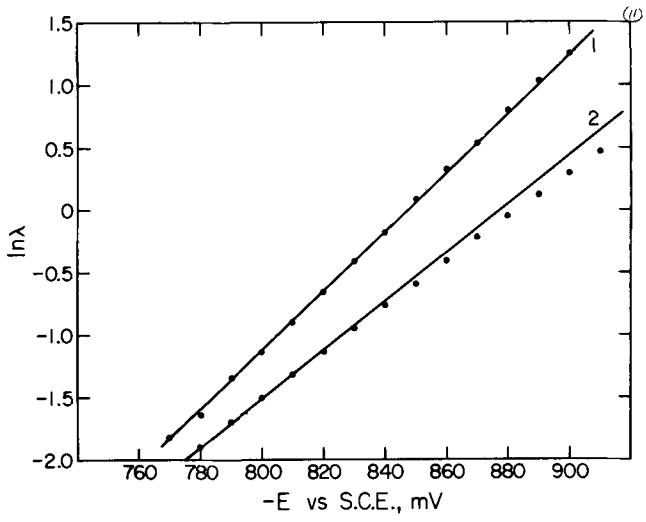

Fig. 1. Tafel plots for reduction of Cr^{+3} in 0.5M $NaClO_4$. Curve 1, Data from the present work; curve 2, data calculated from the parameters given in (2).

It seems likely, therefore, that the solutions used by Parsons and Passeron contained hydrolyzed Cr(III) species which produced Tafel plots unrepresentative of the behavior of monomeric Cr^{+3} ion.

The theoretical prediction that the transfer coefficient should show a potential dependence (1) remains, however, and it was of interest to see if any such dependence could be found in the data obtained with solutions containing only monomeric, Cr^{+3} ions. To do so requires that Frumkin double-layer corrections be applied to the data because the uncorrected data show an apparent potential-dependence of α which has the opposite sign from that predicted by the Marcus theory (1). This behavior does not necessarily throw doubt on the theory because the expected double-layer effects act in the opposite direction to that predicted for the potential dependence of α, *i.e.*, the apparent transfer coefficient before the double-layer correction is applied increases as the potential becomes more negative.

The data were, therefore, re-examined by fitting them via least squares to the equations

$$\ln \lambda + ZF\phi_2 = b_0 + b_1 (E - E^0 - \phi_2) \qquad [4]$$

and

$$\ln \lambda + ZF\phi_2 = b_0 + b_1 (E - E^0 - \phi_2) + b_2(E - E^0 - \phi_2)^2 \qquad [5]$$

where *Z* is the average charge of the Cr(III) in the bulk of the solution, account being taken of any ion pairing between Cr^{+3} and the anions of the supporting electrolyte, ϕ_2 is the potential at the outer Helmholtz plane, and λ, *E*, and E^0 have the same significance as in Eq. [2]. The coefficients b_0, b_1, and b_2 were evaluated by means of least-squares fit of the data to Eq. [4] or [5]. The results of this procedure are also shown in Table I. In all cases, applying the double-layer corrections produced decreases in *F*-levels and increases in the standard errors of the coefficients resulting from the linear least-squares fit. For the quadratic fit the double-layer corrections produced no clear trend in standard errors or *F*-levels (Table I) but in every case the sign of the coefficient of the term in E^2 remained positive. Thus, within the limits set by the uncertainties in the double-layer corrections, the data show no evidence of a potential dependence in the transfer coefficient. We do not regard these results as demonstrating the absence of any potential dependence in α. Rather what has become clear is that much more precise rate measurements, as well as more accurate Frumkin double-layer corrections, will be required before a judgment can be reached.

The last point can be emphasized by examining the errors inherent in any polarographic evaluation of the

rate of irreversible electrode reactions: The standard procedure involves measurements of instantaneous or average currents at small potential intervals on the rising portion of the wave. These current measurements, normalized by division by the diffusion current, are then usually converted to a parameter proportional to the rate constant of the reaction by means of the tabulated conversion tables of Koutecky (4). Recently, Oldham and Parry (3) devised a simple algebraic formula which comes very close to matching the Koutecky tabulation and has the advantage of being a continuous function. Using the Oldham-Parry formula, the equation relating the rate of a one-electron, irreversible cathodic electrode reaction to the experimentally determined ratio of i/i_d becomes

$$\lambda = K\left(\frac{0.4X(3-X)}{1-X}\right)\exp\left[-\alpha f(E-E^0)\right] \quad [6]$$

where λ is proportional to the rate of the electrode reaction, $X = i/i_d$, K represents a combination of experimental constants, $f = F/RT$, E is the electrode potential, and E^0 the standard potential of the redox couple. The transfer coefficient, α, is assumed to be independent of potential. If the only experimental error in the polarographic measurements is assumed to reside in the evaluation of the current, then it can be shown that the error in $\ln\lambda$ resulting from an error, ΔX, in X is given by

$$\Delta \ln\lambda = \left(\frac{1}{X} - \frac{1}{3-X} + \frac{1}{1-X}\right)\Delta X \quad [7]$$

The values of X are confined to the interval from zero to unity and measurements typically cover the range 0.1-0.9. Within this range the first factor on the r.h.s. of [7] varies from a maximum of 10.8 (at $X = 0.1$) to a minimum of 3.6 (at $X = 0.5$). Thus, if current measurements are made with a precision of, say, 1%, and potential measurements are free of error, the values of $\ln\lambda$ are established with a precision of only *ca.* 4-10%.

This uncertainty is increased further when the values of $\ln\lambda$ are used to evaluate the coefficient of $(E - E^0)^2$ in Eq. [3]

$$a_2 = \frac{\ln\lambda - a_0 - a_1(E-E^0)}{(E-E^0)^2} \quad [8]$$

If the maximum value of $(E - E^0)$ attained in the experiment is 0.25V, as in the experiments of Parsons and Passeron (2), a 5% uncertainty in $\ln\lambda$ results in a minimum uncertainty of *ca.* 80% in the value of a_2. When double-layer corrections are introduced (by using Eq. [5] to evaluate the coefficient b_2) the resulting uncertainties in b_2 are even larger. Thus, the limits of error reported by Parsons and Passeron for their values of b_2, *i.e.*, *ca.* ±30%, seem unduly optimistic. When the combined uncertainties arising from the limited precision of polarographic rate measurements and simple Frumkin double-layer corrections are considered it is difficult to see how any polarographically measured reaction rate at values of $(E - E^0)$ less than about 1V could be expected to give reliable estimates of the value of b_2 in Eq. [5]. The same general limitation would apply to the recent proposal of Mohilner (19) that experimental searches for potential-dependent transfer coefficients might be more fruitful with intrinsically faster reactions than Cr^{+3}/Cr^{+2} because the absolute value of b_2 would be larger. To do so would require rate measurements much more precise than are achievable polarographically because the attainable values of $(E - E^0)$ would necessarily be smaller due to present experimental limits on the fastest rates which can be measured. The uncertainty introduced into the values of b_2 because of the small size of the $(E - E^0)^2$ term can be overcome in principle (19), but only by achieving a precision in the measurement of the electrode reaction rate considerably better than any that has been attained up to now.

As pointed out by Parsons and Passeron (2), an independent estimate of the magnitude of the potential dependence of the transfer coefficient predicted by the Marcus theory can be obtained from Eq. [9] and [10] (1)

$$k_s \cong 10^4 \exp\left[\frac{-\Delta G^{0\ddagger}}{RT}\right] \quad [9]$$

$$-2\frac{RT}{F}b_2 = \frac{F}{8\Delta G^{0\ddagger}} \quad [10]$$

where k_s and $\Delta G^{0\ddagger}$ are, respectively, the rate constant and free energy of activation of the reaction at E^0. After double layer corrections are applied, most of the values for k_s in Table II are close to $10^{-6.1}$. This value and Eq. [9] give a value of about 14 kcal for $\Delta G^{0\ddagger}$ which leads to a predicted value of $-0.20\ V^{-1}$ for the coefficient $2\ RT/F\ b_2$. Coefficients having much larger absolute values than this resulted when most of the present data were forcibly fit to a quadratic equation but the coefficients had the wrong sign and the standard errors increased greatly (Table I). The fact that data which fit a normal linear Tafel plot very closely can, nevertheless, produce quadratic coefficients which equal or exceed those predicted by the Marcus theory, further emphasizes the need for increased precision in data employed to test this aspect of the theory.

Comments on the data summarized in Table I.—A few features of the data in Table I deserve special comment. The double-layer data of Wroblowa *et al.* (10) and Payne (9) give discrepant values of ϕ_2 but very similar values of $\partial\phi_2/\partial E$. This accounts for the fact that very similar values of α result from the linear fit after double-layer correction using either set of ϕ_2 *vs.* E data.

On the basis of the corrected rate data in Table II, however, there seems some basis for preferring the data of Payne (9) to that of Wroblowa *et al.* (10).

For KBr, the value of α resulting from the linear fit is greater after the Frumkin correction is applied, while the contrary is true with the other electrolytes. This difference results from the fact that $\partial\phi_2/\partial E$ in 1M bromide is negative instead of positive, as in the other electrolytes.

Adequate double-layer data were available to apply the Frumkin correction in the case of 0.5M KI (11, 12). However, the Cr^{+3}-reduction is greatly catalyzed by iodide adsorption as is indicated by the smaller values of $E - E^0$ at which the wave occurs. In fact, some non-Frumkin type of catalysis appears to be involved because the observed cathodic currents occur at potentials where net anodic currents are calculated to flow if the usual Frumkin correction and back-reaction correction are applied.

The two $LaCl_3$ supporting electrolytes were used to assess the importance of matching the size and charge of the supporting electrolyte ions to those of the reactant ion, as advocated by Asada *et al.* (20). Extremely linear Tafel plots were obtained both before and after the Frumkin correction but comparable behavior was also obtained with $NaClO_4$ and $LiClO_4$ electrolytes after the Frumkin correction was applied. A clearer test is posed if the values of the standard rate constant for the electrode reaction calculated from the Frumkin correction are compared. This comparison is shown in Table II from which it appears that the standard Frumkin correction leads to a reasonably constant value of the rate constant in all of the electrolytes examined except for KCl. In particular, the $LaCl_3$ electrolytes do not yield values which differ significantly from those for $NaClO_4$ or KBr. Thus, the restrictions on suitable supporting electrolytes suggested by Asada *et al.* (20) for accurate application of the Frumkin correction do not appear to apply to the Cr^{+3}/Cr^{+2} reaction. This observation, coupled with the recent discovery (21, 22) that the apparent failure of simple diffuse layer theory in mixed electrolytes, as reported by Joshi and Parsons (15), resulted from an error in the data analysis, suggests that the effective planes of closest approach for ions of differing size and charge may not be as incongruent as has been imagined (23).

Electrochemical Reduction of Chromate in the Presence of Nickel Chloride in Molten Lithium Chloride-Potassium Chloride Eutectic

Branko Popov[1] and H. A. Laitinen*

Department of Chemistry and Chemical Engineering, University of Illinois, Urbana, Illinois

ABSTRACT

Chronopotentiometry of chromate in the presence of $NiCl_2$ in molten LiCl-KCl eutectic reveals a diffusion controlled, three electron reduction step. In the presence of excess $NiCl_2$, chromate is reduced at -0.35V *vs.* Pt(II)/Pt reference electrode and the electroactive species responsible for the chronopotentiometric wave is estimated to have a diffusion coefficient of $1.06 \cdot 10^{-5}$ cm^2 sec^{-1} at 450°C. The stoichiometry of the reduction product depends mainly on the temperature at which the deposit is formed. At 500°C the deposit approaches the composition $LiNi_2CrO_4$. X-ray powder diffraction shows the deposit to be a single compound with a face centered cubic lattice. The length of the unit cell edge is estimated to be 4.14Å. At 1400°C a weight loss of the deposit is observed. X-ray powder diffraction shows the presence of two phases, which are identified as NiO and $NiCr_2O_4$. The weight loss is attributed to volatization of Li_2O.

Laitinen and Propp (1) have shown that the electrochemical reduction product of K_2CrO_4 in LiCl-KCl eutectic containing dissolved $MgCl_2$ is a single unstoichiometric compound of formula $Li_xMg_yCrO_4$, where $x + 2y = 5$. The values of x and y depended on the conditions of the electrolysis, namely current density, temperature, and the molar ratio of Mg(II) to Cr(VI) dissolved in the melt. Typical values of x ranged between 0.3 and 0.5.

Hanck (2) observed that the reduction of chromate in the presence of Zn(II) was shifted from -1.0V *vs.* Pt(II)/Pt reference to -0.5V. Analysis of the deposit indicated the composition to be $LiZn_2CrO_4$. The stoichiometry of the compound was not affected by the electrolysis conditions.

The present investigation was undertaken to determine whether the reduction of K_2CrO_4 is affected by the presence of $NiCl_2$ and to establish the composition of the reduction product. Spectrophotometric measurements failed to indicate any interaction between Ni(II) and chromate in the melt (3). Ni(II) is known to exist as stable chlorocomplexes (4) in chloride melts, and it was of interest to determine whether any chloride is contained in the deposit. Also the reduction potential of Ni(II) lies about 0.2V below that of chromate in the absence of divalent ions and it was of interest to determine whether the deposition of metallic nickel could be avoided.

Experimental

Apparatus.—A Hevi-Duty MK 3012-S vertical split tube furnace (Hevi-Duty Electric Company, Watertown, Wisconsin) was utilized in this work. The temperature sensing element was a chromel alumel thermocouple (Onega Engineering, Inc., Springdale, Connecticut). All experiments were made at 450°C except as noted.

A Sargent Model IV coulometric current source was used for the electrolytic preparation of the electrode deposits. The constant current source for the chronopotentiometric studies has been described previously (1).

A Tektronix 503 oscilloscope served to record chronopotentiograms and to monitor the potential of the working electrode continuously during the preparation of the electrode deposits. The Pyrex cell and envelope have been described previously (5).

Electrodes.—The Pt indicator electrode used in this study has been previously described (6). The electrode had a geometric area of 0.5 cm^2 and was constructed so the glass metal seal was always kept above the level of the melt. The Pt(II)/Pt reference electrode was constructed as described by Ferguson (8).

The platinum gauze electrodes used to prepare samples of the film, as well as the carbon electrode which served as the counterelectrode in all electrochemical investigations in the melt, were constructed as described by Propp (1).

Chemicals.—All chemicals used in this study were reagent grade. Potassium chromate (J. T. Baker Chemical Company, Phillipsburg, New Jersey) was vacuum dried at 150°C before use. Anhydrous $NiCl_2$ was prepared by heating the hexahydrate (J. T. Baker Chemical Company) in vacuum to 180°C over a three day period. Analysis indicated it to be 99.3% pure.

The LiCl-KCl eutectic was obtained from Anderson Physics Laboratories, Inc., Champaign, Illinois. The method of purification has been described (7).

Solid chemicals were added to the melt by means of a small glass spoon. A blanket of argon was kept over the melt at all times to exclude oxygen and water vapor. The purification train used in purifying the argon has been described (8).

Experimental techniques.—Samples of the electrode deposit resulting from the reduction of chromate in the presence of $NiCl_2$ were obtained by constant current electrolysis using platinum gauze electrodes. The gauze electrodes were cleaned in boiling $HClO_4$, rinsed with distilled water, dried at 120°C for 16 hr, and weighed before their insertion into the molten salt solution. After electrolysis the gauze electrodes were

washed with deionized water, dried at 120°C, and reweighed. The electrode deposits were dissolved in boiling 72% perchloric acid. The nickel content of the deposit was determined by an EDTA titration using a murexide indicator. The method chosen for the chromium determination is a modification of that of Meier, Myers, and Swift (9). The procedure used has been previously described (1). Lithium was quantitatively determined by flame photometry.

Results and Discussion

Chronopotentiometry of K_2CrO_4-$NiCl_2$-LiCl-KCl *systems.*—The effect of Ni(II) on the reduction of chromate was demonstrated by successively increasing the concentration of Ni(II) at constant chromate concentration. Figure 1 shows that at a Ni(II) concentration of 7.29 · $10^{-3}M$, two transitions were obtained: one at 0.35V *vs.* Pt(II)/Pt reference and the other at −1.0V. Additional increases in the nickel concentration caused the wave at −0.35V to grow larger. At a sufficiently high Ni(II)/Cr(VI) concentration ratio (2.1), the wave at −1.0V disappeared but a new wave appeared at approximately −0.85V which corresponds to the reduction of Ni(II). Further increase in the Ni(II) concentration had no influence on the first reduction step. This can be seen from the fact that identical transition times were obtained for 1.56 x $10^{-2}M$ K_2CrO_4 solution containing 3.28 x $10^{-2}M$ $NiCl_2$ and for one containing 5.6 x $10^{-2}M$ $NiCl_2$.

According to the Sand equation the product of $I\tau^{1/2}$ is independent of I for a semi-infinite linear diffusion controlled process. The dependence of $I\ \tau^{1/2}$ on I is demonstrated in Table I for the reduction of K_2CrO_4

in the range of 7.8 x $10^{-3}M$ to 2.75 x $10^{-2}M$. The results indicate that the reduction of chromate in the presence of Ni(II) is diffusion controlled over the time interval investigated. Using $n = 3$ from the controlled current coulometry, a value of 4.19 ± 0.010 · 10^2 A $sec^{1/2}$ cm^3 mol^{-1} for the transition time constant and 0.5 cm^2 for the area of the electrode, we calculate $D = 1.06 \pm 0.06 \cdot 10^{-5}$ cm^2 sec^{-1} for the chromate reduction in the presence of Ni(II) at 450°C. From the slope in Fig. 2 (plot of $I \cdot \tau^{1/2}$ *vs.* C) the same value for the diffusion coefficient was obtained.

In order to establish the chemical composition of the electrode deposit, samples of the deposit, which had been prepared by constant current electrolysis over a wide range of preparative conditions were analyzed. To guard against the deposition of metallic nickel, the potential of the working electrode never was allowed to become more cathodic than −0.35 *vs.* Pt(II)/Pt. The influence of temperature, current density, and molar ratio of Ni(II) to Cr(VI) on the deposit composition was studied.

While holding the current density and the Ni(II) to Cr(VI) ratio constant, a series of deposits was prepared at 400°, 450°, and 500°C. The results of chemical analyses of these deposits are shown in Table II. From this table one can see that Li(I) content increases and the Ni(II) content correspondingly decreases as the temperature of the molten salt bath is increased. Table II also shows that the sum of the weight percentages of the three oxides, NiO, Li_2O, and Cr_2O_3 is very close to 100%, indicating that the chromium in the deposit is in the +3 oxidation state, and that no chloride or potassium ion is present. The absence of chloride in the deposit requires that the nickel chlorocomplex dissociate before the Ni(II) is incorporated into the deposit. That such a dissociation occurs rapidly enough to prevent inclusion of chloride in the deposit is remarkable. From Table II it is also obvious that in spite of the fact that the reduction potential of Ni(II) lies about 0.2V below that of chromate in the absence of divalent metal ions, no evi-

Table II. Composition of electrode deposit as function of temperature

$C_{K_2CrO_4} = 0.052M$			$C_{NiCl_2} = 0.198M$		
Temperature (°C)	Wt % Li_2O	Wt % NiO	Wt % Cr_2O_3	Total %	Formula
400	3.75	66.8	31.90	102.0	$Li_{0.60}Ni_{2.10}CrO_{3.91}$
450	4.09	64.5	30.60	99.2	$Li_{0.68}Ni_{2.12}CrO_{3.96}$
500	5.10	64.0	31.90	101.0	$Li_{0.88}Ni_{2.03}CrO_{3.96}$

dence to the deposition of metallic nickel was obtained. The empirical formula which best describes the deposit composition is $Li_xNi_yCrO_4$. As was observed by Propp (1) in his study of the $MgCl_2$-K_2CrO_4 system, $x + 2y = 5$ indicating that no oxide is lost during the electrolysis. At high temperature the deposit approaches the composition $LiNi_2CrO_4$.

Table III indicates that there is only a small change in the composition of the electrode deposit on changing the molar ratio of Ni(II) to Cr(VI). There is a slight decrease in Li(I) content and an accompanying increase in Ni(II) content as the molar ratio of Ni(II) to Cr(VI) is increased. The effect of current density on the composition of the electrode deposit on holding the temperature and the molar ratio of Ni(II) to Cr(VI) constant was observed and is indicated in Table IV. Current density in the range 1-10 mA/cm^2 does not appear to be a significant factor in determining the chemical composition of the electrode deposit.

X-ray powder diffraction studies.—Table V indicates that the deposit is a single compound with a face centered cubic lattice. The length of the unit cell edge is estimated to be 4.14Å.

Thermal stability of electrode deposit.—A sample of deposit, while still on the platinum gauze electrode, was heated in air and in an argon atmosphere to 1000°C for a period of 48 hr. Weight losses were only 0.5% in argon and 0.04% in air. Chemical analyses on the heated samples were in agreement with the previous analyses of unheated samples The heated samples contained 3.87% Li_2O, 66.7% NiO, and 37.50% Cr_2O_3 corresponding to the empirical formula $Li_{0.60}Ni_{2.11}CrO_{3.91}$. The x-ray powder pattern of the deposit appeared to change slightly after heating to temperatures above 950°C. The original face centered cubic lines appeared to shift to give larger "d" spacings and diffuse lines were observed at 4.788 and 2.494Å.

A powdered sample of the deposit was heated to 1430°C in an air atmosphere. The x-ray diffraction pattern of the heated sample is shown in Table VI.

The pattern shows the presence of two phases; a diamond cubic phase with a unit cell edge of 8.305Å and a face centered cubic phase with a unit cell edge of 4.169Å. The face centered cubic phase corresponds reasonably well to NiO (a = 4.176Å) and the diamond cubic phase to $NiCr_2O_4$ (a = 8.32Å). No lines were observed which could be assigned to the unheated nickel compound or to pure Li_2O.

Chemical analyses of the electrode deposit heated to 1400°C are in agreement with x-ray data. The deposit contained 67.01% NiO, 32.3% Cr_2O_3, and no Li_2O, which corresponds to the empirical formula $Ni_{2.11}CrO_{3.61}$.

The empirical formula of an unheated sample was found to be $Li_{0.7}Ni_{2.10}CrO_4$. If the Li_2O is lost during heating, the remainder of the compound must have the empirical formula $Ni_{2.10}CrO_{3.6}$ which is in agreement with chemical analyses of the heated sample.

The Electrochemical Reduction of Meta-Dinitrobenzene in Dimethylsulfoxide

John S. Dunning† and Douglas N. Bennion*

School of Engineering and Applied Science, University of California, Los Angeles, California

ABSTRACT

The electrochemical reduction of meta-dinitrobenzene (m-DNB) in solutions of dimethylsulfoxide was studied on platinum electrodes. The rotating disk electrode and the potential step technique were used. The diffusion coefficient of m-DNB in the electrolyte solution was found to be 6.15 x 10^{-6} cm^2/sec. The kinematic viscosity of the test solutions was also determined. The electrochemical reduction in the absence of a proton donor takes place in two steps which correspond to the formation and reduction of the m-DNB radical anion. When a proton donor is added, homogeneous reaction takes place with the radical anion in the solution near the electrode resulting in an effective increase in the number of electrons transferred to four. This corresponds to the reduction to m-nitrophenylhydroxylamine.

The electrochemical reduction of organic compounds in various media has been investigated by numerous workers. In the absence of proton donors, Hoijtink *et al.* (1) found that the chief steps in the reduction of hydrocarbons could be described as follows

$$R + e^- \rightleftharpoons R^- \qquad [I]$$

$$R^- + e^- \rightarrow R^= \qquad [II]$$

The first reaction is the formation of a radical anion by a reversible one electron transfer. The second reaction is the reduction of the radical anion. Reaction [II] occurs at more negative potentials than reaction [I], giving rise to two wave behavior on a dropping mercury electrode polarogram.

The product of reaction [I] may also diffuse into the bulk of the solution and react with a hydrogen ion to form RH which then may dimerize or disproportionate. This would serve to reduce the observed number of electrons below 2.0 for the second wave because all R^- produced by reaction [I] would not be available for reaction [II]. $R^=$ will also diffuse into solution to react eventually with hydrogen ions to form RH_2. In addition, $R^=$ may undergo reaction in the solvent to produce a species which is electroactive at more positive potentials than those of reaction [II]. Such behavior would increase the effective number of electrons transferred in the second step. Observation of exactly two electrons for the second step is rather unlikely as a result of these competing reaction sequences.

If a proton donor is present in the solution, the nature of the reduction process becomes quite complicated and many types of behavior can be displayed. Given and Peover (2), on investigation of the reduction of aromatic hydrocarbons and carbonyl compounds in dimethylformamide, found that five different types or classes of behavior resulted from the addition of phenol and benzoic acid. The major difference between classes is whether the protonation occurs with the R, R^-, or $R^=$ species and the potential at which further reduction takes place.

Kolthoff and Reddy (3) have reported that the reduction of benzoquinone and quinhydrone in 0.1M tetraethylammonium perchlorate (TEAP) solutions in dimethylsulfoxide (DMSO) gave two waves. The first corresponds to a one electron reversible step, while the second wave corresponds to an irreversible addition of, effectively, less than one electron. This is just reactions [I] and [II]. On addition of hydrochloric acid, the second wave shifted to more positive potentials. They suggest that the $R^=$ radical anion is protonated, shifting the second reduction to a more positive potential.

Kemula and Sioda (4) have reported the polarographic behavior of two nitrocompounds in dimethylformamide (DMF). They found that the addition of benzoic acid to a nitrosobenzene solution with $NaNO_3$ as a supporting electrolyte caused the appearance of a new wave at potentials less negative than the first wave. This can be explained as protonation of the reactant, R, which can then react at a more positive potential than R. The addition of benzoic acid to nitrobenzene solution caused an increase in the height of the first wave to the height of the second wave observed in the absence of benzoic acid. The conclusions of Kemula and Sioda were that the reduction of the aromatic nitro-group was a four electron reaction in the presence of a proton donor, and the first step in absence of the proton donor represented the one electron formation of the free radical anion.

In a later study, Kemula and Sioda (5) reported the visible spectrum of the nitrobenzene free radical anion. Geske and Maki (6) have used ESR spectroscopy to observe the electrochemical generation of nitrobenzene free radicals.

Cadle, Tice, and Chambers (7) have studied the reduction of several aromatic nitrocompounds as a function of the proton donor in solutions of acetonitrile, DMSO, propylene carbonate, and DMF. They found that certain proton donors (trichloroacetic acid, o-phthalic acid, and others) caused new waves to appear at potentials more positive than the wave for the formation of the radical anion. Proton donors such as benzoic acid, phenol, hydroquinone, and water at low concentrations did not produce the behavior. It was also found that the reduction of p-chloronitrobenzene in o-phthalic acid solutions of acetonitrile resulted in an effective transfer of three to four electrons. It was also found that four moles of acid were used per mole of p-chloronitrobenzene. This suggests the formation of chlorophenyl-hydroxylamine, which was found by subsequent analysis of the reaction products. P, p dichloro-azoxybenzene was also found, indicating that there are at least two paths through which the reduction can proceed. It is interesting to note that the complete reduction to the aniline, involving six electrons and six hydrogen ions, was not observed. Apparently, in these particular systems, the phenylhydroxylamine is resistant to further reduction and only four electrons are transferred for each nitro-group.

The purpose of the present study was to determine the number of electrons transferred in the reduction, on a platinum electrode, of meta-dinitrobenzene (m-DNB) in DMSO in the presence and absence of a proton donor, ammonium perchlorate. Two independent electrochemical methods were used for the deter-

* Electrochemical Society Active Member.
† Electrochemical Society Student Member.

minations. These were the rotating disk technique and the potential step technique.

In order to use the techniques proposed, determinations of the diffusion coefficient of m-DNB and the kinematic viscosity of the test solutions had to be made.

The potential step technique, involving the solution of the semi-infinite spherical diffusion equation, has been described by Delahay (8). The equation for the time-dependent limiting current is

$$i = n\mathbf{F}AD^{1/2}\ C^{o}\frac{1}{\pi^{1/2}t^{1/2}} + n\mathbf{F}ADC^{o}\frac{1}{r_0} \qquad [1]$$

where n = number of electrons transferred/mole of active species, $\mathbf{F}$ = Faraday's constant, A = area of electrode, D = diffusion coefficient of the active species, C^o = bulk concentration of the active species, t = time from the start of electrolysis, and r_0 = the radius of the spherical electrode.

By measuring the current-time relationship after imposition of a potential step, the number of electrons transferred can be calculated.

The rotating disk technique has been described by Levich (9) and Riddiford (10). Newman (11) has shown that the limiting current on the rotating disk can be given by

$$i_{lim} = \frac{0.554\ n\mathbf{F}D^{2/3}\ \nu^{-1/6}\ \omega^{1/2}\ C^{o}A}{0.8934(1 + 0.298\ Sc^{-1/3} + 0.14514\ Sc^{-3/4})} \qquad [2]$$

where n, $\mathbf{F}$, D, C^o, and A have the same meanings as for the potential step case and ν = kinematic viscosity of the test solution, ω = rotation speed of the disk, and Sc = Schmidt number for the system.

By measuring the limiting current as a function of rotation speed, the number of electrons transferred can be calculated from Eq. [2].

Experimental

Diffusion coefficient.—The diaphragm cell method of Stokes (12) was used to determine the diffusion coefficient of m-DNB in the electrolyte solutions of 0.1M TEAP in DMSO. The glass cell (13) was a vertical tube separated into two compartments by a sintered glass diaphragm and fitted with glass encased magnetic stirring bars for each compartment. The diaphragm was 10 mm in diameter and 3 mm thick with a pore size of 10 to 15μ. During experimental runs, a water bath maintained the temperature at 25.0° ± 0.1°C. Calibration was done with 0.1*N* KCl in water in the lower compartment and redistilled water in the upper compartment. Analysis of the calibrating solutions was done by precipitating the chloride ion as AgCl and weighing. The durations of the calibration runs varied from 175 to 7180 min. The average cell constant was $\beta = 6.19\ cm^{-2}$ with an average deviation of 9.2%.

Two runs were made to determine the unknown diffusion coefficient. The runs were 5840 and 8225 min in length and measured the diffusion coefficient in the concentration range between infinite dilution and 0.05M m-DNB in DMSO. Concentrations of m-DNB were determined by comparing absorbance at 420 mμ with that of known standard solutions. A Beckman Model DU spectrophotometer with slit width set at 0.22 mm was used for this purpose.

Kinematic viscosity.—The kinematic viscosity of m-DNB solutions in 0.1M TEAP-DMSO was measured as a function of concentration. A Cannon Ubbelohde Semi-Micro viscometer was used. It was calibrated to have a constant of 0.003910 centistokes/sec. Measurements were done in a constant temperature oil bath at 24.2°C.

Potential step.—The potential step cell (13) was a glass cylinder containing 190 ml of solution and sealed from the atmosphere. The working electrode was a sphere with an area of $8.55 \times 10^{-2}\ cm^2$ formed by melting the tip of a piece of platinum wire in an oxygen-gas flame. The electrode was sealed into a thin Pyrex glass tube for insertion into the cell. The counterelectrode (also used as a reference) was a cylinder of platinum screen which surrounded the working electrode at a distance of about 1.5 cm. The potential was set between the working and counterelectrodes with an Anotrol Model 4100 Research Potential Controller. Current was measured as a function of time from the application of the potential step by a Tektronix 545-A oscilloscope fitted with a Polaroid camera. The oscilloscope measured the voltage drop across a General Radio precision decade resistor. Potentials of −1.8 and −2.3V were applied to the working electrode to investigate the two waves in the reduction of m-DNB. Preliminary, slow potential sweeps indicated that these potentials are well into the limiting current region for the respective reactions. This was confirmed by adjusting the potential ±0.1V without any observed change in results. Total observed times of electrolysis were less than 2.0 sec from the application of the potential step. The supporting electrolyte was 0.1M TEAP in all cases.

Rotating disk.—The rotating disk electrode equipment (13) consisted of a variable speed motor which drove a rotating shaft by means of pulleys. The motor, bearings, and electrode mountings were constructed so that vibration was minimized. The working electrode was a cross section of platinum wire 0.258 cm in diameter which was force fitted through a Teflon shaft of 3 cm diameter. The surface of the electrode was carefully machined to eliminate wobble and the face was polished to a mirror surface on No. 00 emery paper.

The platinum working electrode was cleaned with a saturated solution of ferrous sulfate in sulfuric acid. It was washed with distilled water and rinsed with the test solution before each run. Between experimental runs, the electrode was carefully repolished with a soft tissue. The cell was washed and dried whenever a fresh solution was being used.

The current through the cell was controlled by a Heathkit Model IP-32 regulated power supply which supplied power through a Clarostat power resistor decade box in series with the cell. A Keithly Model 610B electrometer was used to measure the potential and a Simpson Model 262 volt-ohm-milliammeter measured the current.

The potential was measured *vs.* a saturated Ag/$AgClO_4$, DMSO reference electrode (13) or in some cases *vs.* the counterelectrode. Since the platinum counterelectrode's area was 3000 times the area of the working electrode it was effectively at a fixed potential and performed the same as the Ag/$AgClO_4$ electrode.

Current potential curves were generated for speeds between 200 and 1200 rpm and for concentrations of m-DNB from 0.01 to 0.04M. In all cases the supporting electrolyte was 0.1M tetraethylammonium perchlorate.

The effects of water content on the results of the rotating disk experiments were examined. Distilled DMSO with water content below 100 ppm, as determined by Karl Fischer titration, was used in a sealed cell under a dry nitrogen atmosphere. The m-DNB was recrystallized three times from methanol and the melting point was determined to be 89°C, which is in good agreement with the literature values. The tetraethylammonium perchlorate and ammonium perchlorate used were dried in a vacuum oven for 24 hr at 80°-100°C.

It was found that increasing the water content of the DMSO up to 0.2% did not change the results of the experiments. This is illustrated by Fig. 8 and 9 in which the m-DNB concentration of 0.02*M* represents the data found using a nitrogen blanketed closed cell and the other points represent the results obtained with the reaction vessel open to the atmosphere. These tests were done at ambient (22°-24°C) temperatures.

In addition to the above study, the effect of adding NH_4^+ as ammonium perchlorate was investigated. For these measurements, a 0.02*M* m-DNB solution was used at a rotation speed of 300 rpm. Limiting currents were

recorded as a function of the concentration of the ammonium ion.

Results

Diffusion coefficient.—The results of the two experiments to determine the diffusion coefficient of m-DNB in the solution of 0.1*M* TEAP-DMSO are summarized in Table I.

A simple analysis of the above data indicates some discrepancies for run No. 1. The volumes of the two compartments were determined by filling with water and weighing. They were 25.6 cm^3 for the bottom compartment and 25.7 cm^3 for the top compartment. Using these volumes, it is possible to calculate any one of the four concentrations in Table I from the other three. This can be done by means of the following molar balance

$$C^f_t V_t - C^i_t V_t = C^i_b V_b - C^f_b V_b \qquad [3]$$

The results of the first experimental run do not satisfy Eq. [3]. Because of this discrepancy the second run was undertaken. Run No. 2 gave much better agreement with Eq. [3] and yielded a diffusion coefficient of 6.49 x 10^{-6} cm^2/sec. The value of C^f (top) seems to be in error in run No. 1. This value was discounted and a "corrected" final dilute concentration of 0.0018M was calculated from Eq. [3]. The resulting diffusion coefficient was 5.81 x 10^{-6} cm^2/sec. The mean value of the two runs, used to analyze the electrochemical experiments, was D = 6.15 x 10^{-6} cm^2/sec ±10%. This leads to a discrepancy of ±4% in the value of $D^{2/3}$ used in the rotating disk experiments for determining the number of electrons.

Stokes (12) has reported that accuracies of better than 1% can be obtained with the diaphragm cell technique. In this study deviations of up to 10% were found among the various calibration runs and in the final determination of the unknown diffusion coefficient. It is believed that the main cause of this error was the blockage of some of the pores in the diaphragm by air bubbles. Although the solutions were deaerated by evacuation with an aspirator water pump, some bubble formation was noted as the solution was sucked through the diaphragm to start the experiment. The compartments were refilled before the runs were started, but there is a possibility that some air was still trapped in the diaphragm. This would cause the cell "constant" to be different for different experimental runs, possibly enough to account for the observed discrepancies.

Kinematic viscosity.—The efflux times for flow from the viscometer test section were recorded at each concentration of m-DNB. The results of these measurements are summarized in Table II for various concentrations of m-DNB in 0.1M TEAP-DMSO solutions.

Potential step.—The application of a potential step caused a soluble red product to appear at the platinum sphere electrode. The product was slightly less dense than the 0.1M TEAP-DMSO solution, *i.e.*, it streamed to the surface of the cell. If no m-DNB was present in the cell, the red substance did not appear.

Figures 1 and 2 are plots of the observed current *vs.* the inverse of the square root of the time from the application of the potential step. Figure 1 data result from the application of −1.8V *vs.* the counterelectrode and corresponds to the first step in the reduction of m-DNB. Figure 2 data represent the second step in the reduction due to a −2.7V potential step. It is clear that, for times between 0.2 and 2.0 sec, the plots are linear and pass through the origin for each concentration investigated. Figure 3 shows the dependence of the slopes of Fig. 1 and 2 on the bulk concentration of m-DNB. This is in agreement with Eq. [1] and in-

dicates that the desired diffusion controlled process has been attained under the conditions of these experiments. From Eq. [1], the slopes of the lines in Fig. 3, and the diffusion experiment results, the number of electrons transferred in the first and second steps were calculated to be 0.95 ± 0.1 and 1.71 ± 0.1, respectively.

Rotating disk electrode.—Passage of current through the rotating disk produced a red product identical to that observed in the potential step experiments. Figure 4 shows the dependence of the voltage on current for the galvanostatic reduction of 0.02M m-DNB in the 0.1M TEAP-DMSO solution. The voltage was measured *vs.* the $Ag/AgClO_4$ reference electrode. Two steps in the reduction are clearly visible and are marked by limiting currents at 27 and 46 μA, respectively.

Figure 5 shows the voltage-current curves for four rotation speeds in 0.0381M m-DNB. The potentials in this case are measured *vs.* the platinum counterelectrode. The voltage drop due to solution resistance has not been subtracted from the data. It can be seen that the limiting currents for the two waves increase with rotation speed. The dependence of the limiting currents for the first and second waves on the square root of rotation speed is shown in Fig. 6 and 7. The effect of different concentrations of m-DNB is shown in Fig. 8 and 9. The linear nature of Fig. 6 through 9 is consistent with Eq. [2]. From the data and Eq. [2] the effective numbers of electrons were calculated to be 1.01 ± 0.1 for the first wave and 1.76 ± 0.1 for the second wave.

When ammonium perchlorate was added to the solution, the characteristic red color of the first step product began to fade. At higher ammonium perchlorate concentrations the red color was not observed at all. The reduction of the ammonium ion appeared to interfere with the second wave of the m-DNB reduction. (This is apparently hydrogen evolution, although cur-

rents were too small to create hydrogen bubble evolution.) Because of the interference, the effect of NH_4^+ addition on the first wave only was considered in this study.

The addition of the NH_4^+ ion to the test solutions had a marked effect on the limiting currents observed. The quantity R_d is defined as the ratio of the concentration of the ammonium perchlorate to the concentration of m-DNB in solution. In these experiments the m-DNB concentration was held constant at 0.02M while the NH_4^+ ion concentration was increased by adding ammonium perchlorate. The rotation speed was held constant at 300 rpm. Figure 10 shows the effect of increasing R_d on the reduction of m-DNB. As R_d is increased, the limiting current also increases. Figure 11 shows the effect of increasing R_d on the limiting current of the first wave. At values of R_d below approximately three, the limiting current is proportional to R_d. Above this value, the limiting current is insensitive to R_d.

Discussion

The results of both the potential step and rotating disk experiments are summarized in Table III. They indicate that the reduction of m-DNB in 0.1M TEAP-DMSO solutions occurs in two steps. The first step results from a single electron transfer. This suggests the formation of the m-DNB radical anion. The second step adds an effective 0.75 electrons to the radical anion produced by the first step.

Kemula and Sioda (4) found for nitrobenzene that the second wave height of the reduction in DMF was less than proportional to the concentration of nitrobenzene at concentrations greater than 3.5 x 10^{-4}M. In all probability, considering the general reaction scheme

Table III. Number of electrons transferred in the absence of proton donors for m-DNB reduction in DMSO

Rotating disk	1.01 ± 0.1	1.76 ± 0.1
Potential step	0.95 ± 0.1	1.71 ± 0.1

of Hoijtink (14), the second wave involves the reduction of the radical anion to the di-negative state. The fact that less than one electron is involved is not surprising. The radical anion may be destroyed by side reactions in solution which prevent it from reacting electrochemically. On the other hand, a reaction mechanism recently proposed by Grieg and Rogers (17) in the reduction of trifluoromethyl substituted nitrobenzene suggests that an electroactive nitroso compound may be formed by the action of the solvent (or of residual water) on the dianion. This would increase the effective number of electrons transferred. It is proposed that a mixture of these effects occurs here, with the destruction of the radical anion being dominant.

The effect of the addition of ammonium perchlorate on the reduction of m-DNB appears to correspond to the behavior reported by Given and Peover (2) as class C. This involves the protonation of the radical anion formed by the first electron transfer. The first reduction step in the absence of a proton donor produced a red product. This corresponds to the formation of the m-DNB radical anion, or perhaps a product of the decomposition of the radical anion after formation. If the radical anion disappears by reaction in solution on addition of proton donors, one would expect the color to disappear also. The observed loss of red color on addition of ammonium ions is considered evidence that a reaction, such as protonation, occurs.

A detailed mechanism corresponding to class C behavior of Given and Peover was proposed by Koopmann and Gerischer (15) for the reduction of nitrobenzene in weakly alkaline aqueous solutions. By extension of their mechanism to the present case, the reduction of m-DNB may take place as follows:

I. A single electron step at the electrode which takes place four times

$$4\,\phi\begin{matrix}NO_2\\NO_2\end{matrix} + 4e^- = 4\left(\cdot\phi\begin{matrix}NO_2^-\\NO_2\end{matrix}\right)$$

II. A reaction in solution with the ammonium ion

$$4\left(\cdot\phi\begin{matrix}NO_2^-\\NO_2\end{matrix}\right) + 3NH_4^+ \xrightarrow{k} \phi\begin{matrix}NHOH\\NO_2\end{matrix} + 3\phi\begin{matrix}NO_2\\NO_2\end{matrix} + 3NH_3 + OH^-$$

The over-all reaction is

III. $$\phi\begin{matrix}NO_2\\NO_2\end{matrix} + 3NH_4^+ + 4e^- = \phi\begin{matrix}NHOH\\NO_2\end{matrix} + 3NH_3 + OH^-$$

Reaction III predicts that the stoichiometric ratio of NH_4^+ ions to m-DNB in the solution is 3 to 1. Experimentally, this is confirmed by Fig. 11 which shows the current increasing with NH_4^+ concentration to the point where the 3 to 1 ratio is reached. At this point the ammonium ion concentration no longer limits the current and the current becomes independent of the NH_4^+ concentration.

Equation [2], which was used to predict the number of electrons transferred as a function of the limiting current, was derived for the case in which no chemical reactions were taking place in solution. Reaction II represents just such a reaction and, consequently, Eq. [2] must be modified to account for this. In order to do this, the convective diffusion equations for the species of interest must be solved. If C_1 represents m-DNB concentration and C_2 the radical anion concentration, these equations become

$$\frac{dC_1}{dt} = 0 = D\frac{d^2C_1}{dx^2} - v_x\frac{dC_1}{dx} + \frac{3}{4}kC_2$$

$$\frac{dC_2}{dt} = 0 = D\frac{d^2C_2}{dx^2} - v_x\frac{dC_2}{dx} - kC_2$$

where v_x is the hydrodynamic velocity in the x direction (*i.e.*, perpendicular to the electrode). The boundary conditions are

at $x = 0$, the electrode surface

$$C_1 = 0 \qquad \text{(limiting current condition)}$$

and

$$\frac{dC_1}{dx} = -\frac{dC_2}{dx} \qquad \text{(assuming equal diffusion coefficients)}$$

at $x = \infty$

$$C_1 = C^0 \qquad \text{(bulk concentration of m-DNB)}$$
$$C_2 = 0$$

In addition, the flux of the active species at the electrode surface must be compatible with the observed value of limiting current. This final condition enables the calculation of the rate constant k for reaction II, assuming this is an irreversible reaction. The above equations were solved numerically using an IBM 360/75 computer using the technique of Newman (16). A parabolic form of the velocity profile at the rotating disk surface given by Levich as

$$v_x = -0.51\,\omega^{3/2}\,\nu^{-1/2}\,x^2$$

was used along with the measured values of ν, D, ω, and the limiting current. A rate constant of $k = 336$ sec^{-1} with concentrations expressed in units of moles/cm^3 was found to give good agreement with the observed limiting currents. Almost identical results were obtained (13) using a simpler stagnant diffusion layer model with the layer thickness, δ, calculated from Levich's (9) equation for the mass transfer boundary layer thickness at a rotating disk. It is possible, therefore, to obtain a wave height corresponding to only 3.46 electrons instead of 4 by consideration of the kinetics of a regenerative reaction producing electro-active m-DNB within the diffusion layer. This explanation is also consistent with the observed ratio of 3 proton donors for each m-DNB molecule.

Alternate explanations can be arrived at by proposing competing, parallel reaction sequences. For example, the presence of azoxybenzene as a product in the reduction of nitro compounds have been reported (7, 17, 18). This reaction sequence consumes only three electrons per mole of nitro compound. If this reaction occurs in parallel with a 4 electron sequence, an over-all or effective 3.46 electron reaction results if 54% of the M-DNB reacts through the 3 electron sequence. For our case, this possibility does not clearly explain the observed proton to m-DNB ratio. However, the data thus far cannot definitely establish one mechanism or the other.

Chambers and Adams (19) have suggested a mechanism in which the OH^- ion product further reacts with the dinitrobenzene compound to form a phenol. If all of the OH^- ions reacted in this manner at the electrode, it would have the effect of reducing the over-all electrons transferred to 2 per nitro group reacting. Our data precludes this. If the reaction occurred only partly and in the diffusion layer, its effect is to change slightly the interpretation of the reaction rate constant, k. Since the OH^- concentration will be very small, it seems unlikely that this contribution is large, however.

Rotating Ring-Disk Study of the Silver Electrode in Alkaline Solution

B. Miller*

Bell Telephone Laboratories, Inc., Murray Hill, New Jersey

ABSTRACT

Rotating ring-disk electrodes have been used for observing the soluble products on charge and discharge of potential or current controlled silver disks in 1.0-10.1M KOH and 1.0M NaOH. Limits on the solubility of higher valent silver species corresponding to AgO formation and the oxygen evolution region are given. The relative surface concentration of Ag(I) for all disk conditions has been measured and related to existing solubility data, the polarization characteristics of silver, and the reaction mechanisms.

The current-potential characteristics of silver electrodes in alkaline solution and the solubility of the oxide phases have been extensively investigated, particularly since both these aspects are critical in determining the service of secondary cells incorporating a silver positive. The purpose of the present work is to seek a direct correlation of polarization and solubility behavior by simultaneous measurement of the parameters of a charge-discharge cycle and the concomitant distribution of species between the electrode and the contacting solution phase. This may be accomplished by application of the rotating ring-disk technique (1-3) which permits quantitative assessment of the electrode/solution mass balance through use of the detecting surface (ring) concurrent with recording of the current-potential-time behavior of the silver test electrode (disk).

In the present case, potentiostatically controlled rings allow distinguishing silver (I) from higher states formed in the soluble phase by the disk reaction. With a known system collection efficiency, as defined by the ring-disk geometry (4), the fraction of disk anodic current going into film formation at any time (or cumulatively) may be obtained (5). Where complications due to multiple oxidation states exist, as in regions of transition from one oxide phase to another, the split-ring disk approach (5-7), which adds a second equivalent detecting surface to treat the increased number of variables, is of value. In such cases, with the appropriate separation of redox potentials that exists for the different silver oxides, the concentrations of soluble silver (I) and higher valent silver species, as well as the amount of film, can be obtained. Identification of oxidation state by split-ring limiting current ratios independent of actual collection efficiencies is feasible, as previously shown for the related copper system in alkaline solution (5).

* Electrochemical Society Active Member.

Studies on the solubility of bulk Ag_2O and AgO are of relevance both to the elucidation of the electrode mechanisms and to the understanding of the practical cell which is affected by transport of soluble silver species to the (zinc) negative and their subsequent reduction. With the ring-disk electrode it becomes readily practical to examine the solubility as a function of the state of the silver electrode with possible implications, therefore, for specifying optimal operating conditions with respect to this factor in a battery. Earlier data on the solubility of Ag_2O (8, 9) were extended by Amlie and Ruetschi (10) through the KOH concentrations of interest in the operating cell and indicate a maximum at about 6*N* KOH. Data of Pleskov and Kabanov (11), obtained by a rotating disk method, and of Kovba and Balashova (12), taken through radioactive tracer techniques, both show a gradual levelling of Ag_2O solubility with increasing hydroxide concentration but no intermediate maximum.

The composition of the soluble silver (I) species was suggested as AgO^- or its equivalent, $Ag(OH)_2^-$, by the earlier workers (8, 9) from the linearity of the solubility of Ag_2O with $[OH^-]$ at lower hydroxide concentrations. A later proposal that the chief form is $[Ag_3O(OH)_2]^-$ (11) was challenged by Sillén *et al.* (13) who found evidence only for mononuclear complexes in up to 11.5M KOH, further concluding that $Ag(OH)_2^-$ is predominate to at least 5M KOH, above which other species such as $Ag(OH)_3^{-2}$ may perhaps occur, though there was no positive evidence for them.

The situation for AgO has been confused by the experimental fact that the apparent solubilities of AgO and Ag_2O in terms of total silver in solution nearly coincide (14). Amlie and Ruetschi (10) and Pleskov (15) have shown by polarographic techniques that higher valent silver species are essentially absent, less than 10^{-6}M concentration (10), in electrolyte equilibrated with AgO. The expectation (16, 17) of a higher

solubility for AgO than Ag_2O because of the higher oxidation state (a more acidic oxide) does not necessarily follow because of the now accumulated evidence [see ref. (18) for review] that solid AgO is a Ag(I)-Ag(III) compound. Reaction sequences (17) based on the assumption that AgO is really soluble but disappears rapidly have had little experimental basis. The ring-disk method, which makes it feasible to determine higher valent silver and/or its monovalent decomposition products in the solution phase contacting an AgO disk, offers a ready test of such schemes.

Experimental

The rotating ring and split-ring disk mechanical (19) and electronic (7) systems, as employed in this laboratory, have been described elsewhere. The electrodes involved in the present study were fashioned as split-ring disks according to the procedure previously outlined (7). Shorting of the split-rings gives the equivalent of a conventional ring-disk and was the configuration normally used in this work. Where ring current measurements for different potentials were accumulated in pairs by use of the split-ring, this will not be differentiated from the shorted, conventional manner unless specific use is made of the ratio of the currents. Silver disks with either graphite or gold split-rings were employed; the dimensions were disk radius 0.238 cm, inner ring radius 0.262 cm, and outer ring radius 0.321 cm (disk area 0.178 cm^2). The insulating gaps forming the split-ring reduced the calculated collection efficiency (4) by 1-2% (0.1 mm gap), yielding a theoretical ring-current/disk-current ratio for an equal number of electrons transferred at ring and disk of about 0.16_5 per half-ring. Surface polishing of the electrodes was completed on Linde A (0.3μ) alumina.

KOH solutions were prepared directly from the reagent grade for 1.0-10.1M and determined by titration. The cell was modified from an earlier design (6) to an all-glass version with an auxiliary electrode compartment separated by a fritted disk. A saturated calomel electrode (SCE) was used as reference, terminating a capillary-tip bridge to which it was sealed with a standard taper joint, effectively preventing chloride contamination within the experimental time scale (6). Nitrogen was passed continuously into the solution. Experiments were carried out at 23°C.

The previously described operational amplifier circuitry (7) permits galvanostatic or potentiostatic control of the silver disk under conditions of constant, stepped, or linearly time swept values of either controlled variable, while fixed potentials on the half rings are maintained. The latter were normally held at potentials corresponding to limiting currents for reduction of all silver species to silver metal or of only higher valent silver species to silver (I), as determined from experimental disk current-potential cycles.

Displays were fed from the operational amplifier circuitry into a Honeywell 580 XYY' recorder. For the study of solubility through ring currents, when a steady-state flux of disk material was achieved, the outputs from the amplifiers measuring current were occasionally directly read from a Hewlett-Packard 3430A digital voltmeter.

Results and Discussion

Potential sweep experiments.—The controlled potential cycling of a freshly polished silver disk electrode from a totally reduced condition to oxygen evolution on AgO and immediately back is shown in Fig. 1, with the anodic and cathodic sweeps separated for clarity. The right-hand points of the separated traces actually coincide in time. Accompanying the disk traces are simultaneously measured limiting ring-currents for two potentials; −0.2V for the reduction of all soluble silver species to metal and +0.2V for the reduction of higher valent species to Ag(I). It is to be noted that the ring-current scale is 200 times more sensitive than that of the disk, reflecting the disk film-

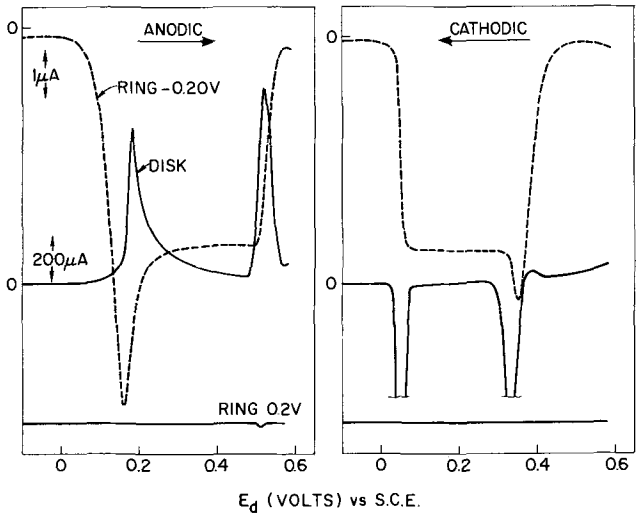

Fig. 1. 5 mV/sec potential sweep at 1000 rpm of freshly polished silver disk with graphite split ring in 1N KOH. Anodic scan (left) followed immediately by cathodic scan (right) with ring monitoring at −0.20 and +0.20V *vs.* SCE. Ring current scales both 1 μA per indicated length, disk current 200 μA per same unit. Anodic currents (ring or disk) increase upward, cathodic downward.

ing processes that limit transport to the ring. This can be further seen in the fact that disk current-potential curves for stationary disks are not distinguishable from those on rotated electrodes. In the disk behavior may be seen the successive formation of Ag_2O and AgO and the corresponding two-step reduction of the oxides. This result for a freshly polished surface is essentially repeated on cycling, except that the first anodic peak ($Ag \rightarrow Ag_2O$) at the disk and the resultant cathodic ring current (−0.2V) may be broadened or, more usually, show a second peak or more complex structure superimposed on the major transition. This effect, which typically develops after the polished surface has been electrochemically oxidized and reduced once, is shown along with additional effects due to higher hydroxide concentrations in the superimposed (as recorded) anodic and cathodic sweeps in 6.24M KOH of Fig. 2.

The cathodic ring current for reduction of all species to silver metal becomes constant independent of potential after the initial single or structured peak of disk current on anodization (Fig. 1 and 2) and remains so until the disk reaction reaches the $Ag_2O \rightarrow AgO$ stage. If the scan is stopped in the peak region, the ring-current decays to this constant, potential invariant, value. During the $Ag_2O \rightarrow AgO$ disk transition this ring current for total reduction declines to a minimum associated with the minimum disk current (conversion to AgO surface). If the anodic scan were continued, the cathodic ring current at potentials in the −0.15 and −0.20V region would increase because of oxygen evolution at the disk and its interfering reduction at the ring. The ring current at the AgO disk minimum current increases with hydroxide concentration and with the accompanying shift of oxygen evolution closer to the point of AgO formation; but at no hydroxide concentration up to the 10.1M limit studied does the ring current at the AgO minimum become equal to that from an Ag_2O electrode. In the concentrated hydroxide solutions the current at the ring, when set at potentials for reduction to the metal as negative as the −0.20V *vs.* SCE of Fig. 1, shows a sharp peak at the end of the disk potential independent plateau before the decline to the AgO minimum. If the ring potential is moved 50-100 mV more positive, still giving a limiting current for Ag(I) → Ag(O), this peak is drastically reduced, indicating that it is due to oxygen being generated before efficient nucleation of AgO in concentrated base and not to higher valent silver or its decomposition products. The potential region involved

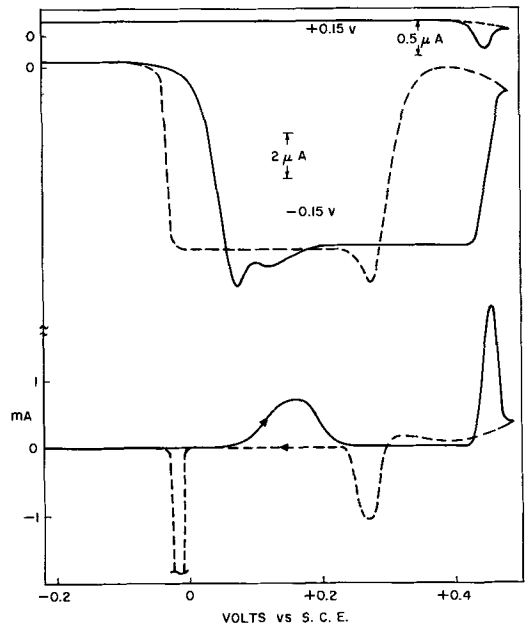

Fig. 2. Superimposed potential sweeps (anodic, solid line, followed by cathodic, dashed line) of previously cycled electrode. Scan rate 5 mV/sec at 1000 rpm in 6.24*N* KOH. Ring current (upper traces) sensitivities at +0.15 and −0.15V are 0.5 and 2 μA per indicated markers, respectively. Left axis shows disk current (lowest trace).

at the ring corresponds to much less than four electron reduction of oxygen, being just on the rising current portion of the reduction curve of the latter, much below the limiting current values.

In Fig. 1 and 2, the rings held positive of Ag(I) reduction but negative of AgO reduction show only residual current until the $Ag_2O \rightarrow AgO$ transformation. Corresponding to this latter process is a ring current peak that increases with hydroxide concentration from only about 1/50 of the value of the ring cathodic plateau current in 1M hydroxide for a Ag_2O covered disk (Fig. 1) up to approximately ¼ of the plateau current in 10.1M KOH. From the relative heights, about 1:30, of the same two ring currents in the intermediate 6.24M electrolyte in Fig. 2, the formation of higher valent soluble species increases appreciably in concentrated base. However, these reduction current peaks for higher valent species are maximum values detected during a transient process. On the completed AgO surface beyond the peak, the current is substantially less.

On the cathodic sweep, the disk current first rises slightly in the anodic direction (Fig. 1 or 2) before the well-defined peak for AgO reduction. The anodic current apparently represents a net corrosion reaction to Ag(I) occurring below the potential of AgO formation whose self-discharge also contributes to a Ag(I) flux. This conclusion with respect to the product is substantiated by the fact that the cathodic ring current at −0.20 or −0.15V begins to increase during this anodic region at the disk, followed by a maximum as the AgO disk reduction proceeds and the net disk current is cathodic. Thereafter a value independent of disk potential is reached exactly equal to that found in the anodic sweep for the Ag_2O region. As the second disk reduction step strips the electrode to metal, the ring current returns to the residual value. The final reduction at the disk is always extremely narrow with no structure, in spite of the varying shape of the $Ag \rightarrow Ag_2O$ step on a polished or cycle-produced surface. During the disk sweeps both conversions, $Ag \rightarrow Ag_2O$ and $AgO \rightarrow Ag_2O$, result in transient supersaturation peaks for Ag(I) at the ring, followed by identical equilibrium levels of ring current from Ag_2O coated disks. Further substantiation of this interpretation will be shown later.

The ring held positive of Ag(I) reduction detects essentially nothing on the disk cathodic sweep (upper trace of Fig. 2 especially). Only in very high hydroxide concentrations, like 10.1M, is there a distinguishable ring current level before AgO reduction, yet only about ¼ the peak found in the anodic sweep which, as noted, was itself only about ¼ of the $Ag(I) \rightarrow Ag(O)$ ring plateau current. Considering equal numbers of electrons transferred in the corresponding ring reactions ($II \rightarrow I$ and $I \rightarrow O$), this suggests even in 10.1M KOH the solubility of AgO is only about 1/16 of that of Ag_2O.

Thus, for the entire range of KOH concentration studied, the $Ag_2O \rightarrow AgO$ step produces a surface from which a much lower level of soluble species is apparently found, as evidenced by the drop of the ring currents for reduction to metal and the low currents produced for reduction to +1. The fact that both these currents are low with respect to the plateau ring current from Ag_2O demonstrates that a solubility mechanism for AgO of a high dissolution rate followed by a very fast, in-transit decomposition of higher valent species to Ag(I) cannot be operative. This is simply ruled out by the more negative ring-potential result, where Ag(I), generated in a post-electrode reaction, would also be counted. The absence of any such appreciable current in Fig. 1 and 2, which are representative of all the solutions examined, shows this mechanism to be a minimal factor. One possible argument for an actual high AgO solubility in spite of these facts would be that the rate of dissolution of AgO is very slow and responsible for the low ring currents. Contradicting this thesis is the low degree of supersaturation seen in the ring current trace at −0.15 or −0.20V for the initiation of the AgO transition at the disk. For an appreciable solubility, *i.e.*, a moderate K_{sp}, to obtain with an assumed small dissolution rate K_{diss}, the precipitation rate, K_{ppt}, would necessarily be correspondingly small since $K_{sp} = K_{diss}/K_{ppt}$. This argument thus predicts a distinct supersaturation for AgO formation in contradiction to experiment.

The ring-disk evidence in the AgO solubility question corresponds well to the conclusions of Amlie and Ruetschi (10) and Pleskov and Kabanov (11) that a bulk AgO saturated solution contains micromolar or less levels of a higher oxidation state. It further proves for the electrolytically formed surface that this is certainly not the result of fast solution decomposition nor very probably the result of slow equilibrium. Since the half-life necessary for a higher oxidation state decomposing in transit from disk to ring not to be detected is of the order of milliseconds, the technique used here is more likely to find detectable concentrations than conventional microelectrode inspection of an equilibrated solution of KOH and solid AgO. The measured levels of ring currents for the AgO surface may be converted to disk surface concentrations of higher valent silver by using an approximate estimate at 1000 rpm rotation speed of a disk current density equivalent of about 0.5 mA/cm²/mM soluble silver from the Levich equation parameters (29). On this basis the detected transient peaks correspond to a few micromolar higher valent silver at 1M KOH [compare 180 micromolar Ag_2O solubility (10)]. In 10.1M KOH, from the ring current at +0.15V on formed AgO surfaces, the disk surface concentration of higher valent silver (calculated as +2) is in the range of 25 μM, or better than one order of magnitude down from the Ag_2O equilibrium silver data (10) of 440 μM.

A more severe test of the conclusion from the disk potential sweeps that the current from a continuous Ag_2O surface is disk-potential independent comes from the results of potential steps within this region as shown in Fig. 3. In this experiment the disk and ring are allowed to equilibrate, with the ring held at −0.20V (unchanged throughout) and the disk at +0.25V (Ag_2O surface). The disk is stepped 100 mV positive until nearly equilibrated, then back, with a second cycle of this kind also shown. The ring response

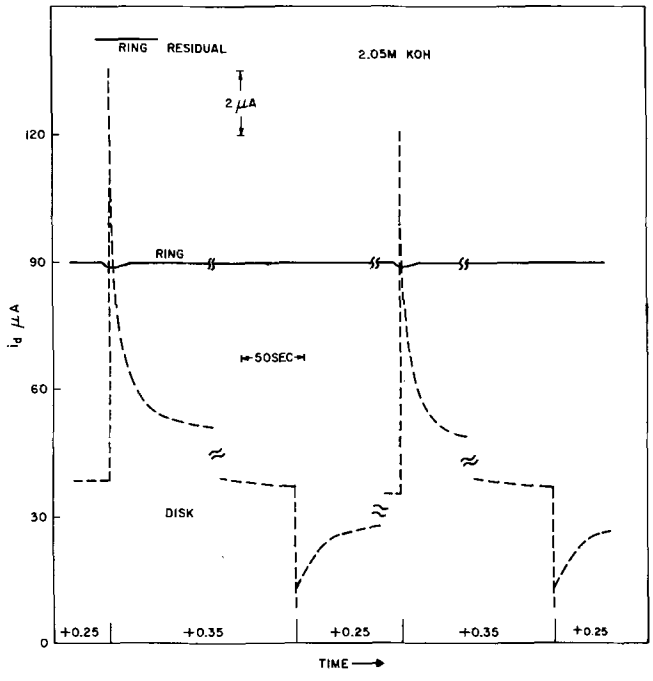

Fig. 3. Potential steps at silver disk between +0.25 and +0.35V vs. SCE with ring current monitored at a constant −0.20V. Steps occur at bars on time axis; disk current left axis. 2.05M KOH, graphite ring, 1000 rpm. 2 μA ring and 50 sec time markers are indicated.

is essentially zero, while the disk traces indicate sharp pulses corresponding to step direction and a very slow recovery to what is eventually a steady-state, potential-independent value. The results indicate that the ring current under the experimental conditions is a function only of the solubility of the oxide film on the disk. The effect at the disk is a thickening (positive step) or thinning (negative step) of the Ag_2O film with a slow attainment of the current level corresponding to the steady-state replacement of the dissolving film. The steady-state values of the ring-current disk-current ratio are in satisfactory agreement with the 0.33 calculated collection efficiency of the shorted half-rings, with uncertainty lying mostly in the slight slow drift of the disk current around an equilibrium value. This is probably due, from the appearance of Fig. 3, to a very small, long-term variation in the control potential.

The above conclusions may be compared to those of Oshe and Kabanov (20, 21) for similar experiments on zinc electrodes in hydroxide solutions. For a zinc disk, the limiting current for zinc ion reduction at the ring for anodic disk currents resulting from small positive potential steps at potentials somewhat positive of initial passivation is that given by the geometric collection efficiency. At quite positive potentials with respect to the open circuited zinc couple, the ring current has only a small sensitivity to disk change, nearing that of the silver case. The behavior exhibited by the Ag_2O-filmed electrode is apparently approached by zinc oxides under the latter conditions, but at less positive potentials, the thinner solid phase acts either partly or entirely as a potential dependent barrier to dissolution of underlying zinc. The insulating silver oxide phase represents a classically simple chemical-dissolution-limited passivity, and this aspect will be quantitatively examined later.

Although solid AgO contains nonequivalent silver atoms and is formulated as the Ag(I) Ag(III) mixed oxide, it is also well-established (22) that AgO yields divalent silver on dissolution in mineral acids. This behavior has been rationalized (23) by the equilibrium (24) $Ag(III)\ O^+ + Ag(I)^+ + 2H^+ \rightleftarrows 2\ Ag(II)^{+2} + H_2O$. It is therefore of interest to examine the number of electrons transferred in the oxidation of Ag(I) ion to AgO. Immediate coulometric distinction between the schemes

$$2\ [Ag(I) \rightarrow Ag(II) + e] \qquad [1a]$$

$$2\ Ag(II) \xrightarrow{OH^-} Ag^{I}\ (OAg^{III}O) \qquad [1b]$$

and

$$Ag(I) \rightarrow Ag(III) + 2e \qquad [2a]$$

$$Ag(I) + Ag(III) \xrightarrow{OH^-} Ag^{I}\ (OAg^{III}O) \qquad [2b]$$

cannot be made since the ratio of Ag(I) reacted to electrons transferred is the same in both if [2b] is very rapid and quantitative. The first scheme implies that the origin of Ag(III) is coupled with the formation of AgO; effectively a solid state disproportionation yields the more stable, mixed valent silver oxide rather than a true $Ag^{II}O$. The second path suggests that only half the Ag(I) is oxidized and precipitates an equivalent amount of Ag(I). No mechanistic detail other than distinguishing whether the nonequivalence of the silver atoms originates in the electron transfer process (scheme [2]) or not (scheme [1]) is to be implied. For example, the process of Ag(I) oxidation by adsorbed OH· radicals (from $OH^- \rightarrow OH\cdot_{ads} + e$) as $Ag(I) + OH\cdot \rightarrow AgO + H^+$ (25) is coulometrically a scheme [1] process in its implications for the behavior of all +1 silver ions reaching the surface at appropriate potentials.

Experimentally, the oxidation of soluble Ag(I) produced at the disk was examined by using the split-ring version of the potential sweeps already described, with one half-ring held at −0.20V and the other at potentials positive of the AgO disk peak. The reducing half-ring has the known one electron reaction $Ag(I) \rightarrow Ag(O)$ and the simultaneous current at the second half-ring for the oxidation of an equal Ag(I) flux can thus be compared. Graphite half-rings operated independently at −0.20V give Ag_2O plateau currents (as in Fig. 1 and 2) within 1% of each other. However, with either a gold or graphite split ring at potentials up to considerable oxygen evolution, no anodic current was found during a disk sweep except for an increasing anodic residual (oxygen, surface oxides) current, while the −0.20V half-ring was showing the expected curve. If the half-ring connections were then reversed, though, so that the silver plated half-ring from the −0.20V operation instead of clean gold or graphite was made about +0.50V *vs.* SCE, an anodic trace, reduced by a constant factor from being an anodic mirror image of the −0.20V cathodic currents, was found during the disk anodic sweep.

The above result implies that oxidation of $Ag(OH)_2^-$ occurs readily only on a previously AgO nucleated surface. Since ring deposition is not radially uniform and the constant factor mentioned was variable between runs, the experiment was repeated with an all-silver split-ring disk electrode produced by plating the graphite split-rings from a cyanide bath formulated from reagent purity materials. The result achieved is shown in Fig. 4, with an anodic half-ring potential of +0.51V. The two half-ring traces above residual currents are effectively reflections of each other, but the measured anodic/cathodic plateau ratio obtained is 0.93. The anodic current is measured above a residual of height comparable to the Ag_2O solubility current, and further positive shifts of potential beyond about +0.52V to be sure of reaching a limiting-current condition are restricted by the stability of the background.

The best interpretation of the results is that the actual ratio of electrons is unity and the direct electrode oxidation product of all the Ag(I) is Ag(II) which is subsequently incorporated into the AgO solid. This result is independent of rotation speed variation. While the 50% $Ag(I) \rightarrow Ag(III) + 2e$ conversion scheme [2] cannot be ruled out, it is rather difficult to visualize a limiting current process with quantitative precipitation of AgO from equal surface concentrations of oxi-

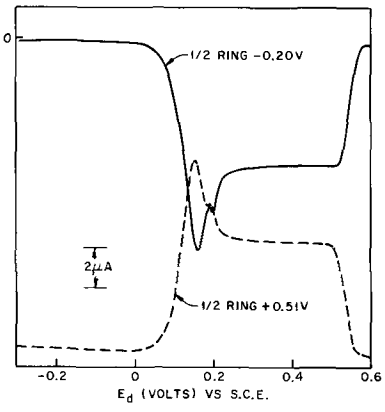

Fig. 4. Half-ring currents during silver disk anodic potential sweep (10 mV/sec at 4000 rpm). Silver-plated graphite half-rings held at −0.20 and +0.51V *vs.* SCE, with the same current sensitivity in 1*N* NaOH. The zero current level of the positive half-ring is below the area of the figure (see text).

dized Ag(I) (Ag(III)) and precipitant Ag(I). This would be necessary for the ring current to be equivalent to one electron per Ag(I) in the flux generated at the disk. In acid solutions, the oxidation of Ag(I) has also been identified as a one electron reaction using the ring-disk electrode technique (26) under conditions where all silver species are soluble. Interpretation of these latter data as a direct Ag(I) → Ag(III) electron transfer process is even more unlikely than in the alkaline case because the complex clathrate solids (18) are not involved and an extremely stable I-III solution complex would have to be invoked.

Constant current and linear current sweep experiments.—Galvanostatic charge and discharge conditions have been applied in most silver electrode studies. Earlier work on the potential-time or coulomb behavior has been reviewed by Dirkse (27). In the present study these aspects can be discussed in terms of the ring-current indications of the concentrations of soluble species, with the results of the previous section's potential sweeps also in mind. A representative potential-time plot for a disk, here anodized in 6.24M KOH at 1.87 mA/cm², is shown in Fig. 5, together with the ring current for reduction back to metal (−0.20V). The current was reversed to cathodic at the disk just as the potential began to rise sharply to oxygen evolution. The cathodic part of the cycle is carried through here beyond the disk potential shift from the "AgO" level to the "Ag_2O" level, as is familiar in the operation of the silver positive. The ring current trace at +0.15 or 0.2V, shown in the potential sweeps, is not included here simply because almost no soluble higher valent

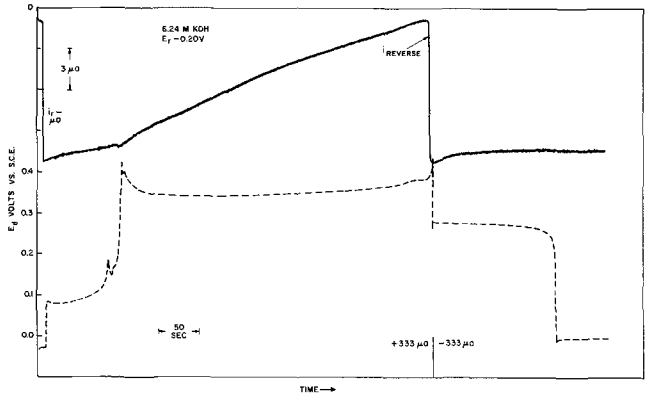

Fig. 5. Lower trace: potential (E_d) *vs.* time trace of disk anodized at 1.87 mA/cm² with current reversal at indicated point. 1000 rpm in 6.24M KOH, 50 sec time marker indicated. Upper trace: ring current at −0.20V, residual zero at upper left. 3 μA marker near left axis indicates sensitivity.

material is detected. For example, the ring current at 0.15V found in the AgO region on charge in 1M hydroxide is indistinguishable from that in the Ag_2O region within the <0.02 μA noise level of the trace.

The disk potential traces, on initiation of anodic current, show typically a small overshoot of potential and a shallow minimum at about the middle of the Ag_2O transition when the electrode is well stripped of oxide before starting. Otherwise, the overshoot and minimum are absent. At the end of the Ag_2O step the potential shows the characteristic large overshoot to nucleation of the AgO phase. A small, premature potential rise is shown on the trace in Fig. 5 before the major AgO shift. This feature was sometimes absent and varied from run to run but with no corresponding variation in the ring current trace, which is shown exactly as recorded. The AgO potential plateau was longer than the Ag_2O step for every concentration of hydroxide and current level studied, a well-known characteristic of these conversions and independent of the rotation of the disk. After the current was reversed at the point of potential rise to oxygen evolution, the equally characteristic shorter discharge plateau at the AgO potential is seen. The rest of the discharge (not shown) extends normally to a 90% or more recovery of the coulombs of charge.

The ring current for reduction to silver shows an initial peak on disk anodization. With higher current densities, the peak has a much more accentuated maximum and a more rapid following decay than that shown in Fig. 5. The ring current declines to a value at the point of the AgO transition that is equal to the plateau ring current in a potential sweep with the same KOH concentration and rotation speed. The galvanostatic experiment indicates an Ag(I) concentration in excess of Ag_2O solubility, presumably because of supersaturation in pores. This continues up to the point of complete coverage of the surface with Ag_2O (equilibrium solubility indicated by the ring current), and this is identified with the initiation of AgO formation. The ring current declines after the potential shift to the AgO level in an almost coulombically linear manner to a minimum nearly equal to the residual value at the point of the potential jump to oxygen evolution. The ring-current decline is actually a little faster than the coulomb equivalent, and this is accentuated as the hydroxide concentration is lowered. The current is due throughout the AgO step to Ag_2O remaining on the surface. This is confirmed by the absence of any current level greater than the minimum shown for a −0.20V ring for a ring held at a more positive potential detecting only higher oxidation states. The actual current at any stage presumably corresponds to the fractional surface coverage by the lower oxide.

In contrast to the Ag_2O → AgO surface conversion, the reverse disk process produces a (Ag(I)) supersaturation peak at the ring and forms an Ag_2O covered film from the beginning of the cathodic current application. Also of interest is the ring behavior in the transition to the Ag_2O level during which the disk potential falls sharply more than 0.25V; the current is completely unaltered by this change. The ring current remains at a constant level until some small nonuniformity of the over-all formation and stripping leads to a drop in ring-measured Ag(I) before the final potential fall (not shown in Fig. 5). Even in this region, the ring current recovers to the previous constant value on open circuiting the disk until discharge is very nearly complete.

The ring trace in the conversion of Ag_2O → AgO shows that for practical battery purposes the amount of soluble silver is minimized by maintaining the positive at full charge. The current reversal shows the discharging cell produces Ag_2O solubility levels immediately. Disk electrodes open circuited at the point of oxygen evolution show gradual increases of ring current to that of the Ag_2O solubility level by self-discharge and further corrosion of underlying silver to +1 as the passive film thins. A net anodic current

must therefore be passed to retain the AgO surface and a minimum soluble material state. Ag(I) ions already in solution will also be slowly deposited as AgO under these conditions.

Supersaturation levels of $Ag(OH)_2^-$ have been shown in both potentiodynamic and galvanostatic formation of Ag_2O on silver and AgO. A further clear demonstration of this process may be obtained from linear current scan studies. If a critical surface concentration of $Ag(OH)_2^-$ must be reached to initiate the nucleation of a solid phase, then −0.2V ring current disk current plots up to that point should be linear with slopes corresponding to the collection efficiency. The experimental results with the disk potential also monitored are shown in Fig. 6. A linear region with a slope in good agreement with the calculated value (0.315 and 0.33, respectively) is obtained. At i_r of about 11 μA, the ring current ceases to increase linearly with disk current and subsequently goes through a maximum, declining (off the disk current scale of the plot) to the equilibrium solubility value (12 μA) just before AgO formation is reached. Allowing for concentration of KOH changes, the monitored disk potential in Fig. 6 shows an Ag/Ag_2O potential corresponding to the initial stage of reaction in the potential sweeps of Fig. 1 and 2. The detectable supersaturation levels in linear current or potential sweeps or constant current anodization vary with the particular conditions, but a factor of nearly two times the solubility is about as high as has been observed. Other systems, $Cu/Cu(OH)_2$ (5) or $Pb/PbSO_4$ (26) for example, exhibit ring-measured relative supersaturations more than an order of magnitude higher than Ag/Ag_2O. The same recovery of totally dissolved Ag(I) on current scans to the point of critical supersaturation has been shown for the reaction AgO → Ag_2O when the i_r/i_d slopes are taken at disk potentials negative enough of the open circuit value that self-discharge processes do not contribute appreciably to the ring current.

Charge capacity-rotation speed and current levels.— When a film forms at a disk in the ring-disk system, the disk coulombic capacity (quantity of film) and the ring currents measuring the instantaneous flux of soluble species during the filming process have a different sensitivity to some of the experimental variables. It would be predicted, for example, that ring currents observed on discharge (Fig. 5) depend systematically on rotation speed (*vide infra*) but that the anodized film layer thickness (coulombic capacity) would be little dependent on stirring in a system of low film solubility. These factors are examined in a series of cycles with fixed rotation speed and varied disk current (Fig. 7) and fixed current and varied rotation speed (Fig. 8).

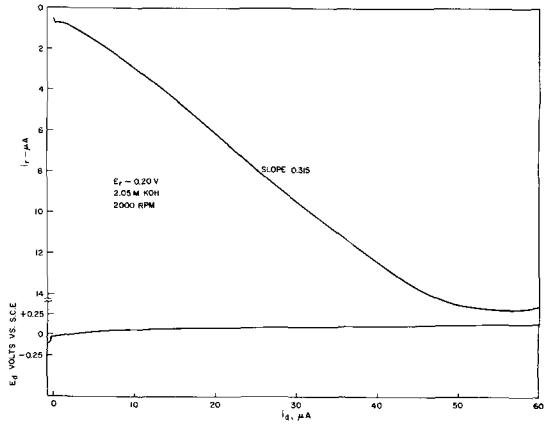

Fig. 6. Lower trace: disk potential *vs.* disk current during 0.1 μA/sec linear current sweep at 2000 rpm in 2.05M KOH. Upper trace: ring current at −0.20V during i_d scan with $\frac{\Delta i_r}{\Delta i_d}$ slope at 0.315 in linear region.

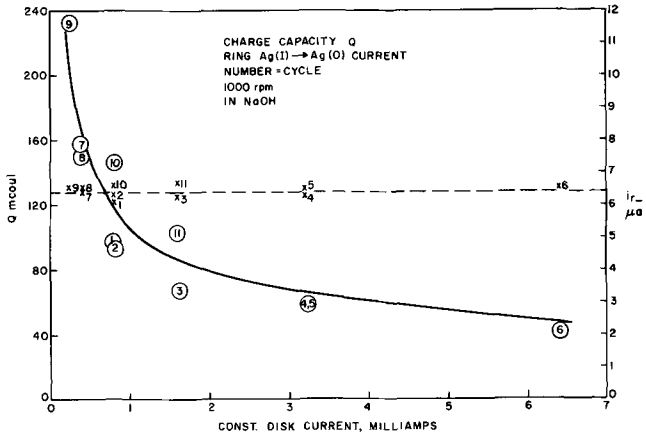

Fig. 7. Solid line: charge capacity, Q, plotted *vs.* constant disk current for cycles of silver disk in 1*N* NaOH at 1000 rpm. Number in points indicates the cycle. Dashed line: ring current, i_r−, at −0.20V for Ag_2O surface (see text) with cycle number indicated.

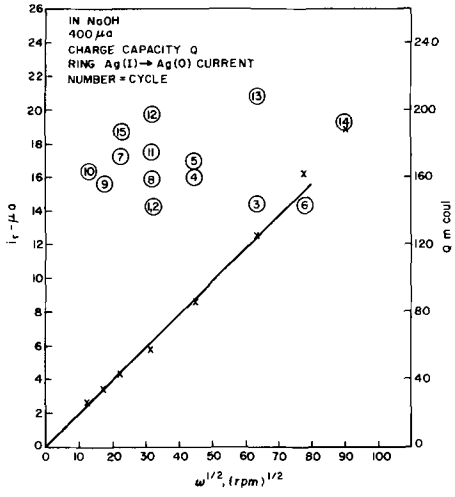

Fig. 8. Circled points are charge capacity, Q, plotted *vs.* $\omega^{1/2}$ for constant 400 μA cycles in 1*N* NaOH, cycles as numbered. Solid line is ring current, i_r−, at −0.20V for Ag_2O surface (see text), with all points at given ω averaged.

The charge capacity, *Q*, is taken as the number of millicoulombs passed in going from silver to the point of the potential excursion to oxygen evolution. Any other measure of capacity would give equivalent trends for the present purposes. For each point a complete cycle is run with current reversed as in Fig. 5. The ring currents for Ag(I) → Ag(O) are taken from the discharge, although the value at the point of the Ag_2O → AgO transition on charge is equivalent. The declining slope of ring current for short oxidation times (down to 6 sec) is so steep at that point, however, that experimentally the stable value on discharge is more reproducible and certain of measure. In both Fig. 7 and 8, the numbers on the points represent the number of the cycle. It is clear from Fig. 7 that the ring current is independent of the current density at the disk for a constant rotation speed. On the other hand, the coulombic capacity is decreased by more than a factor of five for a current density increase from 1.4 to 36 mA/cm², the extremes of measurement. Additionally, the capacity increases slowly in the course of cycling and roughening.

In Fig. 8 it is seen that at constant disk current the charge capacity is essentially independent of rotation speed but tends to increase with cycling. The ring current is a linear function of the square root of the rotation speed and is constant within experimental error for each series of cycles at the given speed. The same results would obtain for any other fixed current density. The essential independence of capacity and rotation speed is a reflection of this small amount of

solubilized material relative to the total coulombs of charge, seen also in the fact that the disk potential-time-current behavior is nearly the same at all speeds. Also, the larger proportion of charge is delivered at the AgO level, and this stage produces ring currents less than the Ag_2O values in Fig. 7 and 8.

Solubility and diffusion coefficients from ring measurements.—The above evidence has amply indicated that the ring current from a Ag_2O-surfaced disk is determined by the solubility of that phase. Placing this on a quantitative basis requires combining a simple model for the dissolution rate with the Levich transport parameters for the system. The dissolution rate of ionic crystals is ideally dependent only on the transport of solute ions by diffusion through a layer of thickness δ (28), assuming that the solution remains saturated at the surface. This is well-supported by both the time-constancy of the ring current and its independence of disk potential. The equivalent disk current for dissolution into a silver-free KOH electrolyte is given by

$$i_d = \frac{n \mathbf{F} A C_s D}{\delta}$$

where n, $\mathbf{F}$, and A are the number of electrons transferred per silver atom (=1), the Faraday, and the disk area, respectively. C_s is the equilibrium solubility of Ag_2O in terms of silver ion, D is the diffusion coefficient of the dissolving silver species (presumed to be $Ag(OH)_2^-$), and δ is the thickness of the diffusion layer. For the rotating disk, Levich (29) found $\delta = K D^{1/3} \nu^{1/6} \omega^{-1/2}$, with K a constant, $\nu^{1/6}$ the kinematic viscosity, and ω the rotation speed. Substitution gives the Levich equation

$$i_d = K_n \mathbf{F} A C_s D^{2/3} \nu^{-1/6} \omega^{1/2}$$

in its usual form except that it is expressed for boundary conditions of $C_{Ag(OH)_2^-} = C_s$ at $x = 0$ (the electrode surface) and $C_{Ag(OH)_2^-} = 0$ at $x = \infty$ instead of the more usual, reverse situation of deposition at the disk from a saturated solution of Ag_2O.

Since $i_{r-} = N i_d$, where i_{r-} is the limiting ring current for the Ag(I) → Ag(O) reaction and N is the geometric collection efficiency, the relation between the two measured parameters i_{r-} and $\omega^{1/2}$ may be expressed as

$$\frac{i_{r-}}{\omega^{1/2}} = (K_n \mathbf{F} A N) D^{2/3} \nu^{-1/6} C_s$$

The data shown already in Fig. 8 have verified the square root relationship. Extension of measurements to cover the range of KOH concentrations from 1.00 to 10.1M is shown in Fig. 9. For these measurements, the disk was potentiostatically held in the Ag_2O region

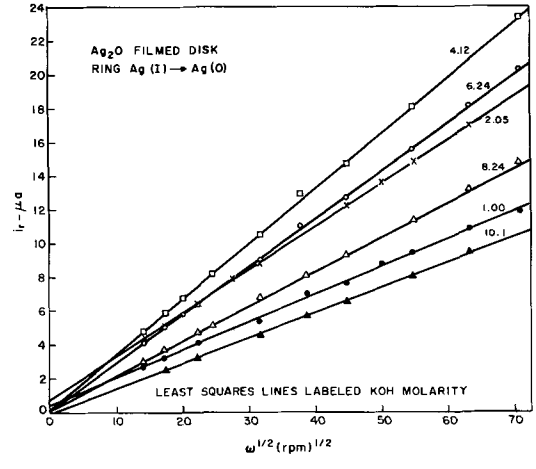

Fig. 9. Plot of ring current, i_{r-}, for the Ag(I) → Ag(O) ring reaction from a potentiostatically held, Ag_2O-filmed disk *vs.* $\omega^{1/2}$. KOH molarity labeled on corresponding line.

and the ring current read for various rotation speeds at −0.20V. The lines are drawn with slopes and intercepts obtained from a least squares treatment and are of higher precision than those obtainable by the techniques outlined for Fig. 8 which involves many cycles of the electrodes. Equivalent data have also been obtained by anodizing the silver disk to an Ag_2O film and then measuring the ring current with the disk at open circuit, replacing the Ag_2O as required. Of particular interest in Fig. 9 is the maximum in the slope as a function of the KOH concentration, 4.12M yielding the highest value of $i_{r-}/\omega^{1/2}$. This maximum is suggestive of the solubility data of Amlie and Ruetschi (10), but the product $D^{2/3} \nu^{-1/6}$, which also determines the slope, changes considerably from 1 → 10M KOH and must be accounted for prior to conclusions regarding the shape of C_s *vs.* KOH concentration.

Two equivalent approaches were utilized. In the first, constancy of the $D\eta$ product (η = viscosity) was assumed for the KOH concentration range involved and a corrected $i_{r-}/\omega^{1/2}$ *vs.* KOH molarity curve was compared to the solubility curve (10). In the second, the solubility data of Amlie and Ruetschi were taken and the $D\eta$ and D values calculated, checking the constancy of the former and comparing the latter to the available data of Pleskov and Kabanov (11). The conclusion of Sillén *et al.* (13) that $Ag(OH)_2^-$ is the only species for which there is evidence supports testing the $D\eta$ assumption.

With $D\eta$ first taken as constant, the Levich product $D^{2/3} \nu^{-1/6}$ is proportional to $\eta^{-2/3} (d/\eta)^{1/6} = \eta^{-5/6} d^{1/6}$, the density, d, being obtainable from Akerlof and Bender (30). Viscosities were interpolated from the data of Klochka and Gadneva (31) and McIntyre (32). Table I gives the values of $\eta^{-5/6} d^{1/6}$ normalized to 1.00 at 1.00M KOH.

The solubility data of Amlie and Ruetschi are plotted in the upper dashed curve in Fig. 10 with the right-hand axis giving the silver concentrations. The left-hand axis has been plotted with the solubility in 1.00M KOH normalized to unity. The lower dashed line represents the solubility data normalized by multiplication by the factors of Table I and thus represents a predicted curve for the normalized experimental $i_{r-}/\omega^{1/2}$ slopes of Fig. 9. The experimental values from Fig. 9 will yield the solid line in Fig. 10, which is in satisfactory agreement with the predicted. The value denoted by the square datum is from the slope of a $i_d/N\omega^{1/2}$ plot for a 6.24M KOH solution equilibrated overnight with solid Ag_2O, where i_d is the cathodic limiting current for the reduction of Ag(I) at the silver disk. The small deviation of the point from the two lines is in the direction of incomplete saturation. The agreement of the predicted and measured curves, if not a fortuitous product of the assumptions, suggests that the maximum of Ag_2O solubility (10) at around 6M KOH is correct rather than the monotonic variation found by other workers (11, 12).

With the Amlie and Ruetschi solubility data and literature values of ν substituted in the expression for ring current, the diffusion coefficients and $D\eta$ product were calculated and are plotted in Fig. 11 along with the existing four D determinations of Pleskov and Kabanov (11). The present data give D's ranging from 8.6 x 10^{-6} cm²/sec (1M) to 2.3 x 10^{-6} cm²/sec (10.1M). The Schmidt number ν/D varies from about 1,100 to 11,000 over this range. Applying the nearly exact

numerical solution of Newman (33) instead of the Levich equation, the D value range would be 9.0 to 2.3 x 10^{-6} cm^2/sec. Either set of values is in appreciable disagreement with Pleskov and Kabanov only at their lowest concentration point. The Pleskov and Kabanov values were obtained for cathodic disk currents in determinatively prepared Ag_2O solutions and the Levich equation. Their solubility determinations, which do not show a maximum, were made by multiplying the ratio of disk current for a saturated solution to that from the known solutions by the known concentration.

The $D\eta$ product is constant within experimental error at 8.4 x 10^{-8} g cm/sec^2. From rotating disk reduction studies in the 2-8M KOH concentration range Davis, Horvath, and Tobias (34) found 13 x 10^{-8} g cm/sec^2 for oxygen. The present data are best consistent with an interpretation of the solubility of Ag_2O passing through a maximum and the soluble species being $Ag(OH_2)^-$ (or some other single formula) in major proportion throughout the KOH range studied.

Examination for Ag(III).—The formation of a relatively soluble Ag(III) species by high current density (70 mA/cm^2) anodization of a silver sheet has been reported recently by Cohen and Atkinson (35). The solubility of this ion, identified by the authors as $Ag(OH)_4^-$, was found to be 2-5 times greater than that of $Ag(OH)_2^-$ in the 1-10M KOH studied in the present work. All controlled potential sweep and constant current curves described to this point were carried only to the region of the minimum of disk current in AgO formation or to the corresponding point of transition to oxygen evolution. For these experiments, when carried further in the anodic direction, a small transient peak at the ring is obtained for the reduction of an almost immediately insoluble product at the disk, the potentials for reduction being kept positive of these responsive to oxygen. The described behavior is similar to that noted for copper in hydroxide solutions which was interpreted as due to transient Cu(III) formation and generation of oxygen on the higher oxide (5). Such a transient oxide conversion is also suggested from resistivity measurements (36).

The current density of the Cohen and Atkinson experiment yields profuse oxygen generation. At a ring-disk electrode, in spite of rotation, bubbles collect and have the effect of lowering the ring current to some fraction of its normal, collection efficiency value. This is readily seen by switching back to an Ag_2O surface and observing the change in the well-defined Ag(I) → Ag(O) ring current level. Thus, quantitative measurements with appreciable oxygen generation currents flowing (visible bubbles) are not feasible without a correction for the effect. The cell used, however, is also equipped with an L-shaped glass tube with medicine dropper bulb which directs a jet of electrolyte across the plane of the spinning disk, removing bubbles. Recovery of the ring response is noted and a reasonable estimate of the unperturbed current can be made.

In experiments under both potential sweep and constant current control, with ring potentials corresponding to reduction to a metallic silver surface, no further appreciable silver species is detectable even at 70 mA/cm^2 and with allowance for the above bubble effects. For example, in 4.12M KOH, when the anodic current at the disk was increased in stages to 80 mA/cm^2, the ring current at 0.00V *vs.* SCE increased to no more than 1 μA higher than that at the minimum in the AgO surface conversion. At 1000 rpm, an Ag_2O disk surface produces limiting current at the ring of 10 μA, though the 0.00V potential yields about 2.5 μA. The solubility curve of Cohen and Atkinson (35) suggests that more than 50 μA should have been measured in the 80 mA/cm^2 experiment, considering that the ring potential is such as to yield > 2 and < 3 electrons, according to their work. Uncompensated resistance effects between reference and working electrodes are in a direction to shift the ring potential more negative with increasing anodic current and thereby to be further certain of not missing any Ag(III) species.

From the ring-disk electrode experiments it must be concluded that there is no appreciable solubility of an Ag(III) species from a strongly oxidized silver disk. Other citations of Ag_2O_3 (37, 38) emphasize its difficulty of formation and instability, and the present experiments are suggestive only of a further incorporation of oxygen into the surface with possibly a small amount of Ag(III) being formed at the point of free oxygen evolution. The experimental discrepancy with the Cohen and Atkinson paper remains currently unresolved.

Summary

From the perspective of ring-current measurements, the anodic-cathodic cycling of a silver electrode may be described as the following. On either controlled-potential sweep or constant-current anodization of silver, Ag_2O is formed through a dissolution-precipitation process involving a supersaturation approaching a detectable maximum of two times the solubility. Actual capacity losses by dissolution and not recoverable on cycling depend on current levels, sweep rates, hydroxide concentrations, and convective diffusion or other transport, but the mechanism will follow for all kinds of silver electrodes. At constant disk current, the ring current does not reach an equilibrium level until the disk Ag_2O → AgO transition. This implies that the film does not become uniform until that point, with the excess solubility coming from unblocked (pore) silver surface, as was also concluded from resistance studies

(36). The thickness of the film at the $Ag_2O \rightarrow AgO$ transition is primarily dependent on current density. In the potential sweep or step formation of the Ag_2O film, the initially higher currents at the ring drop to the equilibrium solubility level of the formed surface. Film thickness depends on potential, reaching the value at which transport across it is equal to the dissolution rate. Shifts in potential, once the film is formed, alter only the thickness of the film, not the dissolution rate. Quantitative studies of the relation of ring current to growth processes, nucleation, and surface coverage remain to be done.

The formation of AgO, seen particularly clearly in the constant current studies, occurs through the volume of the anodized layer with the nuclei on the surface completely converged at the point of the potential rise to oxygen evolution. The surface coverage by AgO increases faster than the coulombs passed, more so at lower KOH concentrations. On reduction, the surface is almost immediately covered with Ag_2O with a supersaturation indicating an initial dissolution-precipitation mechanism. On increasing the thickness of the resistive Ag_2O layer to some value at which the conversion rate of AgO cannot be maintained, the potential shifts to the level at which elementary silver can be formed. The corresponding drop in resistance (36), however, is not accompanied by any surface change; the ring current does not respond indicating the maintenance of a Ag_2O surface until the end of discharge.

The solubility curve for Ag_2O obtained on the basis of the Levich equation, ring currents and a constant Walden product assumption support a maximum in the solubility as a function of KOH concentration. The solubility of AgO is less than that of Ag_2O throughout the hydroxide range of 1-10.1M KOH. The only evidence for a higher oxidation state in solution even at current densities to 70 mA/cm^2 is the transient formations of an additional reducible species which gives a decaying pulse of current at the ring at the initiation of oxygen evolution, as also suggested in resistance studies (36). Higher levels of Ag(III) generation (35), other than the transient presumably due to Ag_2O_3 are not supported by ring evidence.

Study of the Behavior of Ethylene Carbonate as a Nonaqueous Battery Solvent

Gianfranco Pistoia, Mario De Rossi, and Bruno Scrosati*

Istituto Elettrotecnico, Università di Roma, Rome, Italy

In recent years propylene carbonate (PC) has been the solvent most used in the efforts to realize high energy nonaqueous batteries (1). Prototypes of batteries using this solvent have been already constructed (2, 3).

Ethylene carbonate (EC) has some favorable physical properties with respect to PC, such as higher dielectric constant and lower viscosity (see Table I), which have encouraged a detailed study on the possibility of its use in a nonaqueous system. In this paper preliminary results of this study are reported.

The main factor which may have so far limited the investigations on EC as a useful solvent in nonaqueous cells could be its solid state at room temperature. Nevertheless this could represent a remarkable benefit in realizing a thermal battery in which eventual self discharge processes would be greatly reduced. Furthermore, due to the high molal lowering of freezing point of EC (5.5°C), it is also possible to have liquid solutions at room temperature by choosing suitable electrolytes.

Since there is a lack of data about the properties of EC solutions of the salts generally used in organic solvent batteries, such as KPF_6, KCNS, $LiClO_4$ and so on, it seemed useful to acquire all the necessary basic information before examining the behavior of a cell using an electrolytic EC solution.

Purification of the solvent.—EC, reagent grade, was distilled twice on CaO under vacuum at 75°C to avoid decomposition. The analysis of the purified solvent was made by gas chromatography on a Cromosorb W column packed with Carbowax 1500 (8%) at 120°C, using flame ionization detection and helium as a carrier gas. The major impurities were ethylene glycol (10 ppm) and a not yet identified organic substance having a boiling point close to that of ethylene glycol (70 ppm). Other organic impurities were less than 5 ppm.

The water content was estimated to be about 15 ppm by the Karl Fischer method using a radiometer apparatus. The specific conductivity was determined to be $7 \cdot 10^{-7}$ ohm^{-1} cm^{-1} at 40°C and the freezing point 36.2°C, in agreement with the data reported by Seward and Vieira (4).

Preparation of the solutions.—The salts, all reagent grade, were dried under vacuum. The manipulation of the products and the preparation of the solutions were done in a dry box under argon atmosphere.

* Electrochemical Society Active Member.

Table II. Solubilities (g/100g solution) of selected salts at various temperatures in EC

Temperature, °C	KPF_6	KCNS	$LiClO_4$	$(CH_3)_4NBr$	KBF_4	LiCl
25	17.0	27.1	26.1			
30	17.6	27.4	26.3			
35	18.3	27.7	26.6			
40	18.8	28.0	26.9	0.09	0.04	0.83

Solubility.—The salts generally used in PC and similar solvents as electrolytes for battery purposes were: KCNS, $(CH_3)_4NBr$, LiCl, KPF_6, KBF_4, and $LiClO_4$.

The solubility of KCNS at various temperatures and of $(CH_3)_4NBr$ and LiCl at 40°C was determined volumetrically using a method previously described (5).

The solubility of KPF_6 and $LiClO_4$ at various temperatures and of KBF_4 at 40°C, was determined by an evaporation technique. Known amounts of supernatants from saturated solution were slowly dried in an oven and the residual salt weighed until constancy was reached.

Both the volumetric and the evaporation techniques have been tested dissolving known amounts of salts in EC. The accuracy was of the order of 1-2%. The solubility values are reported in Table II.

Specific conductivity.—The specific conductivity of most soluble salts in EC, among those investigated, was measured at 25.00° ± 0.02°C by a Tinsley bridge, Type 4896.

Concentrated solutions of each salt in EC were progressively diluted to measure conductivity at various concentrations.

The specific conductivities of the electrolytic solutions in EC are greater than those of the corresponding solutions in PC, as shown in Table III. The values are of the order of $1 \cdot 10^{-2}$ ohm^{-1} cm^{-1} in spite of the high value of the dielectric constant and the relatively low value of the viscosity of the solvent. As it has already been emphasized in the case of solutions of alkali halides in formamide and its derivatives (5-7), the presence in nonaqueous solutions, even at high dielectric constant, of nonconducting species (pairwise

and higher than pairwise association) causes conductivity values, at high concentrations, much lower than those obtainable in aqueous solutions. This remains one of the problems in the use of organic electrolytes in batteries.

Lowering of the freezing point.—The molal lowering of the freezing point of EC has been determined by using urea solutions. The average value of two different sets of measurements is 5.5°C. This high value justifies the possibility of having liquid solutions of KCNS or KPF_6 or $LiClO_4$ in EC at room temperature.

Compatibility of electrode and solvent.—It is very important to determine the behavior of the solvent with respect to high reactive electrodes such as magnesium and lithium.

A Mg electrode (1.4g) was dipped at 25°C in a solution 0.85M $LiClO_4$ in EC (5g). After 24 hr the concentration of Mg^{2+} ions in solution was polarographically detected to be 100 ppm.

A lithium foil was dipped for 7 days in a similar $LiClO_4$-EC solution and neither gas evolution nor physical changes of the metal surface were observed.

In conclusion the solvent does not seem to significantly attack magnesium or lithium.

Half cell potentials.—Lithium electrode.—As pointed out by Elliott and co-workers (8), the behavior of metallic electrodes in organic solutions is greatly influenced by the electrolyte used in connection with both the open circuit and under load potential.

In this work lithium potentials have been measured in EC solutions of KPF_6, KCNS, and $LiClO_4$, respectively, using a platinum foil as counterelectrode and a silver foil as reference electrode.

Silver was used as a reference electrode instead of Ag/AgCl because of the possible deterioration of the latter in PC solutions (9) and because a poised silver reference electrode has been reported elsewhere (10, 11). In the present investigation the stability of the silver electrode was ±0.03 mV during repeated polarization experiments. This stability was sufficient for the purpose of this work. For greater reproducibility in other work involving lithium electrodes and electrolytes containing lithium ions, a lithium reference electrode may be preferred (12).

The concentration of the solutions used for the polarization runs were those corresponding to the maximum conductivity, *i.e.*, KCNS 1.3M, KPF_6 1.0M, $LiClO_4$ 0.85M. Lithium rod, 99.9% pure, was reduced in a dry box under argon atmosphere in foils of 2 cm^2 of surface for each side.

Figure 1 shows polarization (reported as the difference between the OCV and the voltage at the indicated current density) *vs.* current density, for the lithium electrode in the three solutions. Lithium shows the best behavior in the $LiClO_4$ solution. In comparison the behavior of the same electrode in a solution 1M $LiClO_4$ in PC is also shown,

Figure 2 shows polarization-time curves at constant current density (10 mA/cm^2) for the lithium electrode in the three solutions. These curves were obtained after the polarization runs and show good stability of the lithium electrode.

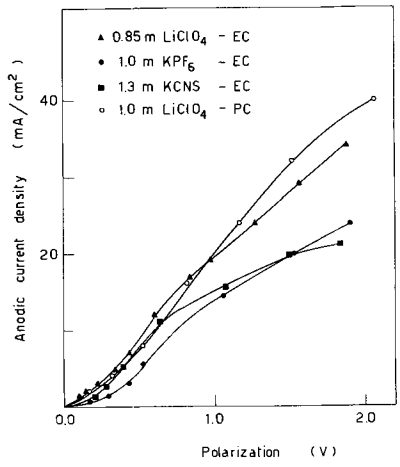

Fig. 1. Polarization of lithium anodes in various electrolytic EC solutions at room temperature and after a 3 min hold on the indicated current density. The PC solution polarization curve is taken from Elliott and co-workers (9).

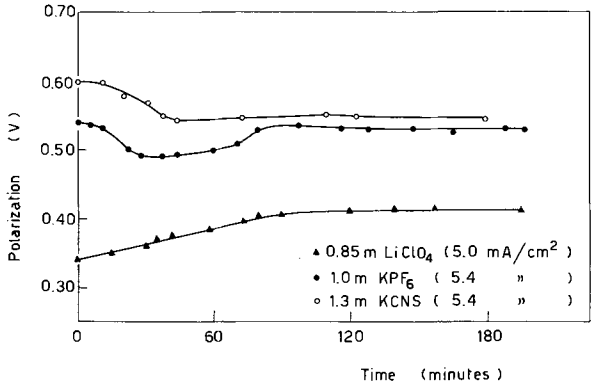

Fig. 2. Polarization-time behavior of lithium anodes at 10 mA/cm^2 in various electrolytic EC solutions at room temperature.

CuF_2 *electrode.*—The CuF_2 electrode has been chosen for preliminary investigations in EC electrolytic solutions, since it is the cathode most widely used in primary organic batteries (13). The solubility of CuF_2, polarographically determined to be 0.009 mol/kg solv. at 25°C in a solution 0.85M $LiClO_4$ in EC, is of the same order of magnitude as that found in $LiClO_4$-PC solutions (13).

The electrode has been prepared with a technique similar to that described by Boden and co-workers (14). A powder made of CuF (85%), graphite (10%) and polyethylene (5%) was dissolved in hot toluene and the paste obtained was spread on a copper net. After drying in an oven at a temperature of 45°-55°C, the electrode was heated for 10 min at 90°C and then compacted at a pressure of 2500 kg/cm^2 for 3 min.

The initial OCV of the CuF_2 electrode *vs.* an Ag reference electrode in a solution 0.85M $LiClO_4$ in EC is 0.35-0.40V. The polarization curve of CuF_2 in the same solution is shown in Fig. 3. The behavior of the electrode under forced discharge is not very satisfactory since, even at low current densities (*i.e.*, current densities greater than 0.6 mA/cm^2), it acquires negative potentials *vs.* Ag. At the end of the polarization run, the OCV of the electrode did not recover and stabilized on values of the order of ±0.03V *vs.* Ag. Similar behavior has been found in $LiClO_4$-PC solutions (9).

Battery test.—As a final test for the utilization of EC electrolytic solutions in the development of nonaqueous battery in this program, the following cell was considered

$$Li/LiClO_4/CuF_2, Cu \quad [1]$$

EC

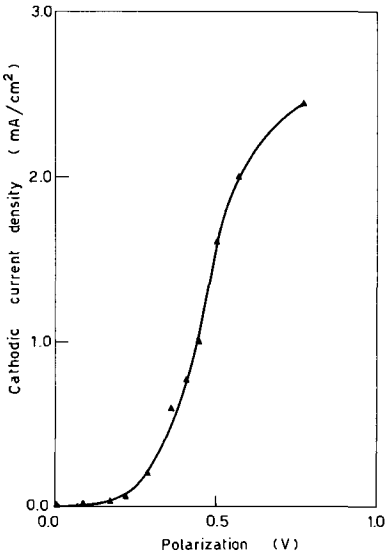

Fig. 3. Polarization curve of the CuF_2 electrode in 0.85M $LiClO_4$-EC at room temperature.

The structure of the cell was essentially a CuF_2 cathode between two lithium anodes and the construction details are reported in Table IV. The OCV is 3.4V at room temperature.

Figure 4 shows typical discharge curves of cell [1] at room temperature and at various current densities. The capacity of cell [1] is limited by the utilization coefficient of the CuF_2 electrode which is on the average 10% (1.5V endpoint), comparable with that found by Jasinski for a similar electrode in $LiClO_4$-PC solutions (15).

Attempts to recharge cell [1] were made. The cell was charged at 4-5 mA/cm² and at a voltage of 3.85-3.90V and submitted to few charge-discharge cycles without showing appreciable changes in its performances. Since the successful use of CuF_2 in secondary battery has not yet been accomplished (13), the rechargeability shown by cell [1] could tentatively be explained by the occurrence of the anodic reaction

$$Cu + 2ClO_4^- \longrightarrow Cu(ClO_4)_2 + 2e$$

We have tried to prove this mechanism by charging and discharging the cell

$$Li/LiClO_4/Cu, C \qquad [2]$$
$$EC$$

at the same condition as cell [1].

After charging, cell [2] showed the same OCV obtained with cell [1] but very short times of discharge. Furthermore, the OCV of the charged cell [2] continuously dropped with time.

Another possible explanation of the apparent rechargeability shown by cell [1] could be a certain

Table IV. Characteristics of cell [1]

Anode: lithium foil 99.9% (4.3 cm² each side).
Cathode: CuF_2 85%, graphite 10%, polyethylene 5% (4.3 cm² each side).
Cell a: 0.86 total grams on a copper net support.
Cell b. 0.68 total grams on a copper net support.
Separator: fiber glass 0.3 mm thick.
Electrolyte $LiClO_4$ 9% (0.85M) in EC.

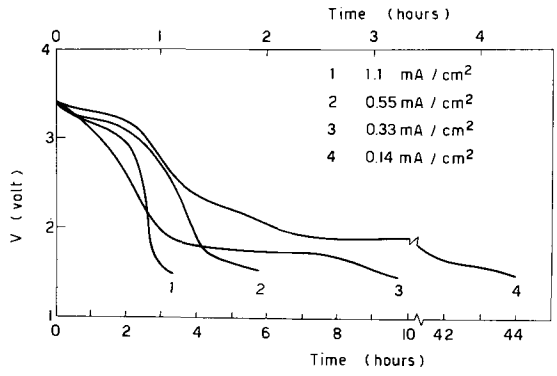

Fig. 4. Typical discharge curves of cell [1] at various current densities and at room temperature. Curves 1 and 2 refer to upper scale and to cell a, curves 3 and 4 refer to lower scale and to cell b (see Table IV).

reactivation of the cathode which could allow the utilization of undischarged CuF_2.

Conclusions

The above reported evidence indicates that EC is a useful solvent for nonaqueous battery development investigations.

Performance of cell [1] could be appreciably improved by using a different separator, by optimizing the preparation of the cathode used or by changing to a more effective positive electrode. This is, however, outside the scope of the present research and will be the object of future work.

Determination of Optical Constants and Growth Rates of Anodic Alumina by Ellipsometry

R. M. Goldstein, R. J. Lederich, and F. W. Leonhard[1]

McDonnell Research Laboratories, McDonnell Douglas Corporation, St. Louis, Missouri

An ellipsometric study of alumina anodic films formed in aqueous ammonium pentaborate (0.125M) and ammonium pentaborate-ethylene glycol (34% weight of salt) electrolytes has been made.

Briefly, the experimental procedure consisted of mechanically polishing aluminum disks of 99.99% purity and 7.90 cm^2 in area and then electropolishing them at 0°C in an electrolyte composed of 100 ml distilled water, 200 ml nitric acid, 300 ml of 85% phosphoric acid, and 400 ml glacial acetic acid. The aluminum disks (the backside masked) are anodized in a cell consisting of a platinum foil cathode, the disk as anode (separation of 7 cm), another electrode in common with the anode to measure potential drop across the electrolyte and the aqueous ammonium pentaborate (AAP) or ammonium pentaborate-ethylene glycol (AP-EG) solution as electrolyte which is stirred and heated or cooled to 50° or 5°C by a constant temperature bath (Blue M). A constant current density of 0.3 mA/cm^2 is used in all the anodization, and the anodization voltage is monitored on a high impedance (1 Mohm) recorder. An ellipsometer (Gaertner L119) is used, and measurements are made at 6328Å at an angle of 70°. The detector is a photomultiplier (EMI 9502B) coupled to a lock-in amplifier (Ithaco 353) and chopper. The disks are measured for their zero point (*i.e.*, clean substrate) after electropolishing, and the oxide thickness is measured immediately after anodization.

The method used in determining optical constants and thickness values for the anodic alumina film is a standard [for example, ref. (1)] and involves obtaining a best fit of the experimental ellipsometric parameters ψ and Δ to those calculated by the computer program of McCrackin and Colson (2). The parameters ψ and Δ are defined by $\tan \psi = (R_p/R_s) \cdot (E_s/E_p)$ and $\Delta = (\beta_p - \beta_s)_{\text{reflected}} - (\beta_p - \beta_s)_{\text{incident}}$ where E_s and E_p are the amplitudes of the incident beam, R_s and R_p are the amplitudes of the reflected beam, β_s and β_p are phase angles, and where the subscripts s and p refer to the resolution of the light into two components; p is light with the electric vector in the plane of incidence, and s is light with the electric vector perpendicular to the plane of incidence. Figure 1 shows this fit for the oxide films formed in AAP electrolyte at 5°C and gives the optical constants as $n = 1.65 \pm 0.02$, $k = 0.0$. Similarly, Fig. 2 shows that the optical constants for the anodic oxide films formed in the AP-EG solution at 5° and 50°C are $n = 1.67 \pm 0.02$, $k = 0.0$. These values are in good agreement with Barrett (3) who obtained values of $n = 1.66$, $k = 0.0$ for aluminum anodized in 3% ammonium tartrate electrolyte. The oxide thickness values obtained by use of Fig. 1 and 2 have been plotted as a function of forming voltage in Fig. 3. The forming voltage is defined here as the applied voltage corrected for electrolyte drop and the reversible potential for oxide formation. We find that at a current density of 0.3 mA/cm^2 the growth rate for the AAP (5°C) is 12.2 Å/V, while for the AP-EG the growth rate is 11.5 Å/V at 5°C and 13.3 Å/V at 50°C. Previous studies (4, 5) with these electrolytes have indicated growth rates comparable to the results reported here.

Chronopotentiometric Measurements of Chemical Reaction Rates

III. On the Finite Difference Approach to the ECE Mechanism

Henry N. Blount[1] and Harvey B. Herman*,[2]

Department of Chemistry, The University of Georgia, Athens, Georgia

Current reversal chronopotentiometry has been applied to kinetic studies of the ECE mechanism (1, 2). This reaction scheme may be represented by

$$A + n_1e^- \rightarrow B \qquad |E_{A/B}| \qquad [1]$$

$$B \xrightarrow{k} C \qquad [2]$$

$$C + n_2e^- \rightarrow D \qquad |E_{C/D}| < |E_{A/B}| \qquad [3]$$

during the forward electrolysis, and by

$$B - n_3e^- \rightarrow E \qquad |E_{E/B}| \qquad [4]$$

$$C + n_2e^- \rightarrow D \qquad |E_{C/D}| < |E_{E/B}| \qquad [5]$$

during the reverse electrolysis. In the case where $n_1 = n_3$ and A = E (*e.g.*, the *p*-nitrosophenol system), the Laplace transform solution of the partial differential equations describing the electrochemical system is exact (1). However, in the case where $n_1 \neq n_3$ and A $\neq$ E (*e.g.*, the *p*-nitrophenol system), the published solution is approximate [see Appendix, ref. (1)].

The technique of finite difference calculations has been shown to be valuable in the solving of the partial differential equations describing electrochemical behavior (3-7), and in particular those related to the ECE mechanism.

It is the purpose of this work to apply the finite difference approach to the heretofore approximate current reversal chronopotentiometric treatment of the ECE mechanism. Moreover, the effect of an oxidation-reduction equilibrium between the E/B and C/D couples (Eq. [4] and [5]) as proposed by Feldberg *et al.* (4, 6) is considered from two different points of view.

Experimental

Current reversal chronopotentiometric data were obtained in the manner already described (2). Measurements were made at 25.0°C in 20 v/o (volume per cent) aqueous ethanol maintained at a pH of 4.92 by an equimolar acetic acid/sodium acetate buffer system, $C_{HA} = 1.0M$, with total ionic strength adjusted to one molar with potassium nitrate. The *p*-nitrophenol (PNO_2P) was obtained as the indicator from Eastman Organic Chemicals and was used as received. Current reversal chronopotentiometric data were corrected for spherical diffusion and adsorption effects by the perturbation treatment of Deron and Laitinen (8).

Finite difference calculations were performed with an IBM System 360/65 computer. A central difference boundary condition was employed and is fully described elsewhere (9).

Results and Discussion

ECE mechanism.—Current reversal chronopotentiometric working curves for the ECE mechanism were determined for the case where $n_1 \neq n_2 = n_3$ (*i.e.*, the PNO_2P case) using both the approximate Laplace transform (L.T.) solution and the exact finite difference (F.D.) solution. These working curves shown in Fig. 1 coalesce at very large and very small values of kt_f. They are, however, significantly different in the region $-1 < \log (kt_f) < +1$ which is the region of paramount interest. The validity of the finite difference treatment was demonstrated by the fact that this approach gave rise to the same result that was obtained through the use of the exact Laplace transform solution in the case where $n_1 = n_2 = n_3$, the *p*-nitrosophenol (PNP) case.

Values of the rate constant for the dehydration of *p*-hydroxyphenyl-hydroxylamine, the product of the first reduction step in the electrolysis of PNO_2P (1),

were determined from current reversal chronopotentiometric data. Kinetic results obtained at various levels of PNO_2P concentration using the "exact" working curve are shown in Table I. Also, the data of Herman and Bard [ref. (1), Table IV-B] were re-evaluated using this exact working curve. The results of this re-evaluation are summarized in Table II. The values of the rate constant obtained both in the present work and through the proper treatment of the Herman-Bard data are in good agreement with other workers' measurements of this parameter (2, 10) determined under the same experimental conditions. The results shown in Table II clearly demonstrate the difference between the approximate and exact solutions of the partial differential equations describing the system. As was the case in the earlier work (1), it is not possible to assess the accuracy of the experimentally determined kinetic parameter without prior knowledge of this quantity.

Nuances of the ECE mechanism.—Hawley and Feldberg (4) have considered the effects of "nuances" of the ECE mechanism (*i.e.*, perturbations by the E/B-C/D redox equilibrium) on the measured rated constant for the intervening chemical reaction. These workers have shown that the chronoamperometric working curves are severely altered by such nuances (4). The effects of such perturbations on current reversal chronopotentiometric working curves were yet to be determined.

In order to qualitatively see the effects of this redox nuance, the simpler PNP system where $n_1 = n_3$ and A = E will be used as a model. Consider, in addition to Eq. [1-5], the following

$$A + D \underset{k_b}{\overset{k_f}{\rightleftharpoons}} B + C \qquad [6]$$

where k_f/k_b may also be represented by the equilibrium constant, K, since

$$\frac{k_f}{k_b} = \frac{[B]\,[C]}{[A]\,[D]} = K \qquad [7]$$

Heretofore, current reversal chronopotentiometric treatments of the ECE mechanism (1, 2) have not taken into account the possibility of the reaction given by Eq. [6] and have thereby forced the value of the equilibrium constant given by Eq. [7] to be $K = 0/0$ (4). Since Eq. [3] indicates that the reduction of C occurs more easily than that of A, the observed chronopotentiometric behavior may be represented by Fig. 2(a).

In the case where the nuance reaction given by Eq. [6] is occurring and the value of the equilibrium constant is very small ($K << 1$), the qualitative picture shown in Fig. 2(a) is again valid since this situation corresponds to $|E_{C/D}| << |E_{A/B}|$.

At the other extreme is the situation where $|E_{C/D}| >> |E_{A/B}|$ which corresponds to a very large

Table II. Comparison of current reversal chronopotentiometric kinetic data obtained using Laplace transformation (1) and finite difference ECE working curves

Data of Herman and Bard (1) for 1.8 m*M* PNO_2P, T = 24.8°C in 20 v/o aqueous ethanol, pH = 4.9, HMDE area = 3.6 × 10^{-2} cm². See ref. (1), Table IV-B.

		2	B→A, D→C

value of the nuance equilibrium constant. The chronopotentiometric behavior of this case may be qualitatively represented by Fig. 2(b).

The intermediate case where $|E_{A/B}| \approx |E_{C/D}|$ is the most difficult to treat experimentally. The chronopotentiometric behavior representing this situation is shown in Fig. 2(c).

A major problem which arises in the current reversal chronopotentiometric treatment of a nuance-perturbed ECE system is that of adopting a consistent convention of defining "forward" and "reverse" transition times which will be valid for all values of the equilibrium constant. In the cases where $K << 1$ and $K >> 1$, this consideration is relatively straightforward. However, when $K \approx 1$, a transition corresponding to a single entity is imperceptible. One may choose to treat the total forward and total reverse times given by regions 1 and 2, respectively, in Fig. 2(c).[3] Experimentally, this method is most straightforward. Alternatively, one could adopt the convention of defining transition time as that for the $A \rightleftarrows B$ process and then either (*i*) use pretransition current reversal such that the forward electrolysis time is less than that required for the $A \rightarrow B$ process, or (*ii*) follow the surface concentration of A and B with a spectral technique such as internal reflection spectrometry (11, 12).

There are two possible approaches to the formulation of the equations describing the ECE system in the case of redox nuances. The first involves the use of various values of the equilibrium constant, K, as was done by Feldberg *et al.*, in the chronoamperometric treatment of the problem (4, 6). In the finite difference representation of this approach, diffusion of all species is allowed to take place for one time unit, then equilibrium is forced to be maintained through imposition of the conditions specified by K in Eq. [7]. Following application of the "central difference" boundary condition (9), the entire process is repeated for subsequent units of time. In this approach, the calculations must be handled differently in each of several cases, namely where $K < 1$, $K = 1$, and $K > 1$.

A second approach involves the use of the individual rate constants k_f and k_b as defined in Eq. [7] rather than the equilibrium constant, K. From Eq. [1-3] and [7], one may write the following diffusion equations with appropriate kinetic perturbations

$$\frac{\partial C_A}{\partial t} = D\frac{\partial^2 C_A}{\partial x^2} - k_f[A][D] + k_b[B][C] \quad [8]$$

$$\frac{\partial C_B}{\partial t} = D\frac{\partial^2 C_B}{\partial x^2} - k[B] + k_f[A][D] - k_b[B][C] \quad [9]$$

$$\frac{\partial C_C}{\partial t} = D\frac{\partial^2 C_C}{\partial x^2} + k[B] + k_f[A][D] - k_b[B][C] \quad [10]$$

$$\frac{\partial C_D}{\partial t} = D\frac{\partial^2 C_D}{\partial x^2} - k_f[A][D] + k_b[B][C] \quad [11]$$

The above equations completely describe the diffusion and homogeneous chemical reactions involving all species present in solution. Hence in a given time unit, the finite difference program need only treat diffusion with appropriate kinetic complications as described by Eq. [8-11] and boundary conditions. This singular treatment is valid for all values of the equilibrium constant, K, as defined by Eq. [7]. If the magnitudes of k_f and k_b are chosen such that the products of these rate constants times their corresponding concentration terms are large compared to the product $k[B]$, then the effect of maintaining the redox equilibrium in solution is realized. Moreover, if the chemical system under consideration involves a nonequilibrium redox perturbation, then this fact is easily represented through appropriate choice of k_f and k_b.

The validity of this latter "kinetic" approach has been established through the chronoamperometric treatment of the ECE nuance and comparison of these results with those obtained by Hawley and Feldberg (4) who used the "equilibrium" approach to the problem. The results of the two treatments are indistinguishable over the entire range of K or k_f/k_b when the kinetic approach is applied under conditions where equilibrium is maintained.

The equilibrium nuance approach has been applied to the current reversal chronopotentiometric treatment of the ECE mechanism. Participation in the reaction scheme by the A/B-C/D redox nuance has a marked effect on the current reversal chronopotentiometric working curves both in the case where the total forward and total reverse times are considered (Fig. 3) and in the case where the current is reversed when the surface concentration of A approaches zero. In the latter case, the reverse transition time is taken when the surface concentration of B approaches zero (Fig. 4).

In the limit of very small values of the equilibrium constant, the behavior is that of an ECC scheme, those reactions being

$$(E) \quad A + n_1e^- \rightarrow B \quad [12]$$

$$(C) \quad B \xrightarrow{k} C \quad [13]$$

$$(C) \quad A + D \overset{K}{\rightleftarrows} B + C \quad [14]$$

where $K << 1$. In the limit of very large values of the equilibrium constant, the system exhibits apparent EC behavior, namely

$$(E) \quad A + n_1e^- \rightarrow B \quad [15]$$

$$(C) \quad B \xrightarrow{K} C \quad [16]$$

$$(NR) \quad A + D \overset{K}{\rightleftarrows} B + C \quad [17]$$

where $K >> 1$ and NR indicates no appreciable reaction of B and C. These limits were correctly suggested by Hawley and Feldberg (4), although the chronopotentiometric approach was not treated in that work.

It is possible to formulate the exact expression for the boundary conditions in both limiting cases because the surface concentration of C is zero in the ECC

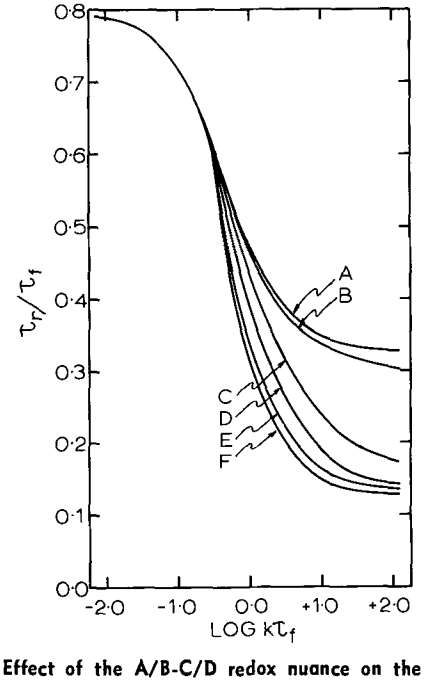

Fig. 3. Effect of the A/B-C/D redox nuance on the current reversal chronopotentiometric working curve for the PNP system where the total forward and total reverse times are considered. These results are for $i_f = 2i_r$ at a plane electrode. The equilibrium constant is defined in Eq. [7]. A: $K \leq 10^{-5}$. B: $K = 10^{-3}$. C: $K = 10^{-1}$. D: $K = 9 \times 10^{-1}$. E: $K = 10^{1}$. F: $K \geq 10^{3}$.

[3] The authors acknowledge the helpful criticism of a reviewer who suggested this particular appproach.

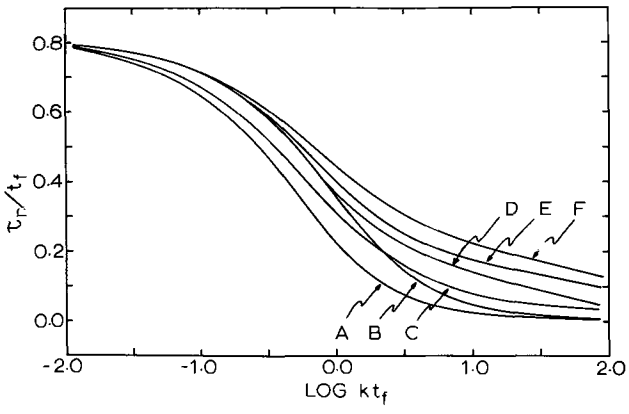

Fig. 4. Effect of the A/B-C/D redox nuance on the current reversal chronopotentiometric working curve for the PNP system where the current is reversed when the surface concentration of A approaches zero and the reverse transition time is taken when the surface concentration of B approaches zero (both 0.1% of initial concentration of A). These results are for $i_f = 2i_r$ at a plane electrode. The equilibrium constant is defined in Eq. [7]. A: ECC working curve as well as all $K \leq 10^{-5}$. B: EC working curve as well as all $K \geq 10^{3}$. C: $K = 10^{-3}$. D: $K = 10^{1}$. E: $K = 9 \times 10^{-1}$. F: $K = 10^{-1}$.

scheme and the flux of C is zero in the EC scheme. An iterative procedure was necessary to calculate the surface concentration and flux of C for intermediate values of K. Convergence was found to be very rapid.

The boundary value problem involved in the kinetic nuance approach is indeed complex. This boundary condition could conceivably be applied in two ways: through the use of heterogeneous rate expressions or through the use of equilibrium arguments at the electrode surface and the iterative procedure described above. Neither approach was attempted in this work.

Other workers have evaluated nuance participation effects on current reversal chronopotentiometric working curves in the limiting case of $K = 0$, and their results (13) are in agreement with those of this study. Although some chemical systems show nuance participation in their ECE behavior (6), it is apparent from electrochemical results (1, 14), curve B in Fig. 4, and the Laplace transform ECE working curve (1) that such participation is imperceptible in the case of the PNP system.

Ohmic Potential Measured by Interrupter Techniques

John Newman

Inorganic Materials Research Division, Lawrence Radiation Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California

Interruption of the current is used frequently to assess the magnitude of the ohmic potential drop which is included in the measurement of electrode potentials during the passage of current. The value so measured corresponds to the primary current distribution in the electrode system being studied.

When the current is interrupted, the double-layer capacity is left charged at the value prevailing locally. This double-layer capacity may then be discharged by means of a faradaic reaction. The time constant for this decay of charge may be approximated by

$$\tau_1 = RTC/\mathbf{F}i_0 \qquad [1]$$

For an exchange current density i_0 of 1 mA/cm^2 and a double-layer capacity, C, of 20 μF/cm^2, this equation yields $\tau_1 = 0.51$ msec at 25°C. The electrode potential may subsequently shift by decay of the concentration overpotential.

Immediately after the current is interrupted, the current density is not necessarily zero everywhere. If the double layer was nonuniformly charged, current will flow through the solution from one part of the double layer to another in an attempt to make the state of charge uniform. A characteristic time for this process is

$$\tau_2 = r_0 C/\kappa \qquad [2]$$

where r_0 is a length characteristic of the electrode. The value $\tau_2 = 0.5$ msec is obtained for $r_0 = 0.25$ cm, $C = 20$ μF/cm^2, and a solution conductivity of 0.01 mho/cm. For an ideally polarizable electrode, this process will take precedence over decay by a faradaic reaction and in at least one case obscured observation of double-layer relaxation at such an electrode (1, 2).

Let us ignore for the moment the concentration overpotential. A nonuniformly charged double layer is associated with a nonuniform ohmic potential drop during the passage of current. In such a case, what ohmic potential drop is measured by an interrupter technique? It must be some average value which does not prevail everywhere on the electrode. Since, on interruption, the double-layer capacity remains charged, the potential just outside the double layer (relative to the reference electrode) changes by a uniform amount over the entire surface of the electrode. Hence, independent of the current-density distribution prevailing before interruption, the current density changes by amounts which

correspond to a primary distribution, and the observed ohmic drop measured by the interruption corresponds to this distribution. (Here the thickness of the double layer is taken to be small compared to the size of the electrode, a condition which is unlikely to be violated. This allows the double layer to be treated as part of the boundary, being characterized locally by its surface charge density and faradaic current density.)

A rotating disk electrode can be used to illustrate this general conclusion. The current and potential distributions have been worked out under steady conditions (3), and the frequency dispersion in capacity measurements has recently been treated (4) for a disk electrode embedded in a large insulating plane. The potential Φ_0 just outside the double layer can be represented by a series in Legendre polynomials

$$\frac{ZF}{RT}\Phi_0 = \sum_{n=0}^{\infty} B_n P_{2n}(\eta) \qquad [3]$$

where $\eta = \sqrt{1 - (r/r_0)^2}$. (To be consistent with ref. (3), the coefficient ZF/RT has been introduced; it will cancel out shortly.) By means of the orthogonal property of the Legendre polynomials, the coefficients B_n can be expressed as

$$B_n = (4n + 1)\frac{ZF}{RT}\int_0^1 \Phi_0(\eta)P_{2n}(\eta)\,d\eta \qquad [4]$$

In particular, the first coefficient B_0 can be related to the total current flowing to the disk

$$B_0 = \frac{ZF}{RT}\int_0^1 \Phi_0(\eta)\,d\eta = \frac{ZF}{RT}\,\frac{I}{4r_0\kappa} \qquad [5]$$

Let quantities after interruption be denoted by primes. Then, since the double-layer charge does not change instantaneously on interruption

$$\Phi_0' = \Phi_0 - \Delta\Phi$$

where $\Delta\Phi$ is constant over the disk and represents the ohmic drop measured by the interrupter technique. The value of B_0' must be zero since the total current is now zero. Hence

$$B_0' = 0 = \frac{ZF}{RT}\int_0^1 (\Phi_0 - \Delta\Phi)\,d\eta = \frac{ZF}{RT}\left(\frac{I}{4r_0\kappa} - \Delta\Phi\right) \qquad [6]$$

Thus $\Delta\Phi = I/4r_0\kappa$. The change in potential and the resistance $\Delta\Phi/I$ measured by the interrupter technique correspond to the primary current distribution (5). Suitable allowance can be made for the position of the reference electrode probe (5), and the conclusion also remains valid for other electrode geometries. (Except for B_0, the other B_n's will not change at the instant of interruption, that is, $B_n' = B_n$ for $n = 1, 2, \ldots$.)

It may be noted that the current distribution will approximate the primary distribution when the concentration and surface overpotentials are small compared to the ohmic drop. In this case, the interrupter may yield the desired value of the ohmic drop. On the other hand, when the current distribution is more nearly uniform, the ohmic drop will not be large compared to the overpotential, and the interrupter may still yield results of satisfactory accuracy.

Of course, the value measured by current interruption will correspond to the ohmic potential drop to some point on the electrode surface. On the basis of Fig. 1 of ref. (3), one can estimate that this point will be about 80% of the way from the center to edge of the disk. At this point the current density will be approximately equal to the average current density, and errors associated with the nonuniform current density and potential distributions at the disk will largely cancel if one associates the average current density with the ohmic drop measured by the interrupter technique.

The concentration overpotential will complicate the picture slightly. With an excess of supporting electrolyte, conductivity variations probably make a negligible contribution to the ohmic drop. For discharge of an ion from a binary electrolyte, this contribution is larger but can be estimated separately. The observed ohmic drop would not correspond exactly to the primary resistance in this case.

McIntyre and Peck (6) recently perfected a short-time interrupter for use under potentiostatic conditions. For a rotating disk electrode, the ohmic resistance was observed to be independent of current. This should be expected in view of the analysis presented here. It would be desirable to compare their value with one estimated from the disk radius and the solution conductivity, with due allowance for the placement of the reference electrode and the size of the insulating disk in which the electrode was embedded.

Brief Communications

Cuprous Halide and Cuprous Sulfide as Electrolytes in Galvanic Cells

R. Routie, P. Taxil, and J. Mahenc

Institut du Génie Chimique et Laboratoire d'Electrochimie, Faculté des Sciences de Toulouse, Toulouse, France

Among the different types of solid electrolyte galvanic cells, Foley (1) has recently considered several cases of solid electrolytes using Ag^+, Cl^-, Na^+, and H^+ transport.

The purpose of this communication is to give an account of the use of cuprous halide and cuprous sulfide in the galvanic cell (at 400°C)

$$Cu\text{-}CuI\text{-}Cu_2S\text{-}S(liq)\text{-}Pt$$

the arrangement of which is the same as in Lehovec and Broder's cell (2) with AgI and Ag_2S as solid electrolytes at about 200°C.

Favorable conditions for a solid-component battery able to produce a high current density result from the particular lattice structure of cuprous halide and cuprous sulfide. Wagner (3) has defined the various types of conductivity occurring in such solid materials. The current, in cuprous sulfide, is carried by Cu^+ ions as well by electronic holes: the electronic conductivity is assumed to depend on the deviations of ideal stoichiometry and is calculated as a function of the ratio copper/sulfur (4). The conductivity in CuI is exclusively due to Cu^+ ions, the transport number of Cu being very close to unity. However, cuprous halide is essentially an ionic conductor (about 1 $ohm^{-1} \cdot cm^{-1}$), between 380° and 450°C, when submitted to a polarizing potential of less than 0.3V: at higher potentials a p-type conduction appears in addition to the ionic conduction (5). In CuI and Cu_2S, high conductivity is a consequence of the lattice structure: the anions (I^- or $S^=$) are bound to fixed lattice positions [large size and extremely low diffusivity (6)] whereas, according to x-ray investigations (7), the cations (Cu^+) are virtually distributed at random among a larger number of nearly equivalent lattice sites.

In the cell under consideration, CuI is inserted to avoid electronic conductance. It is in fact a genuine electrolyte.

Cuprous sulfide was prepared at about 450°C by reaction of copper with sulfur vapor in a glass tube filled with argon. The product was then compressed to obtain cylindrical pellets 12 mm in diameter and 6 mm thick.

Pellets of 99.99% pure copper and cuprous halide (3 mm thick) were used to assemble the cell in a Pyrex glass vessel (Fig. 1). Sufficient electrical contacts, between the different solids, were secured by applying a slight pressure by means of a compressed steel spring. The choice of the thickness of the different solid phases was made in order to avoid crushing the cell.

All the experiments were conducted in an atmosphere of purified argon in an electrical furnace at 400°C.

To obtain current density *vs.* voltage curves, a current of appropriate intensity was drawn from the cell by inserting a platinum load between the cuprous halide and cuprous sulfide pellets (Fig. 1).

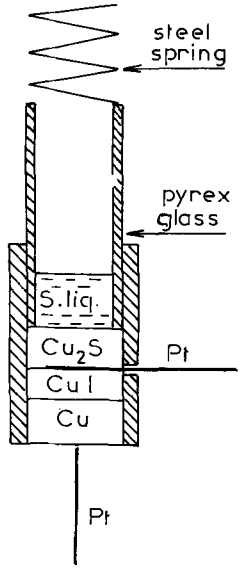

Fig. 1. Experimental cell Cu-CuI-Cu_2S-S(liq)-Pt

Results

In the absence of an external connection, the open circuit voltage of the cell Cu-CuI-Cu_2S-S(liq)-Pt is 0.450V at 400°C. At this potential (higher than 0.3V) a transfer of electrons and copper ions occurs internally, within the cuprous halide, by means of partial electronic conduction. Furthermore, the cuprous sulfide in equilibrium with liquid sulfur (or sulfur vapor) has, at 400°C, a relatively important electronic conductivity. The life of the battery under open circuit conditions (shelf life) is therefore determined by the progress of the cell reaction (formation of Cu_2S) and by the weights of copper and sulfur present in the cell. The shelf life of this cell, at operating temperature, is however considerable (several days) and the internal current is always very small compared to the external current.

The electrical performance of the cell is reported in terms of current density *vs.* voltage curves for operation at constant current, and is shown in Fig. 2.

Within a few seconds after the circuit is switched off, the voltage drops swiftly as a result of internal resistance, polarization and interface resistance occurring in this cell.

During roughly the first 50 min, the voltage decreases parabolically as a function of time; the voltage is given by

$$U = A - B\sqrt{t}$$

$$\text{with} \begin{cases} A = 450 - 1.08I \\ B = 8.10^{-2}I \end{cases}$$

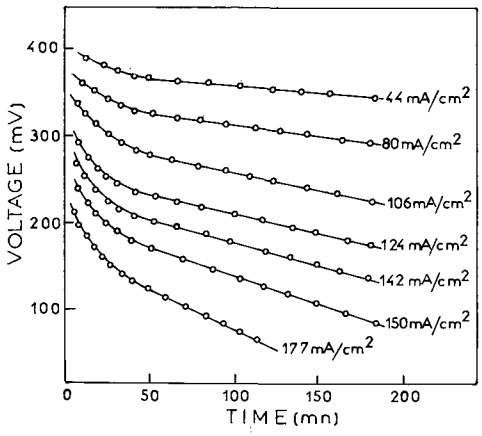

Fig. 2. Current density vs. voltage curves

U and A are expressed in mV; t in min; I in mA/cm^2; and B in mV/min$^{1/2}$.

After this transition state, the voltage decreases as a linear function of the time

$$U = C - Dt$$

$$\text{with} \begin{cases} C = 450 - 1.58I \\ D = 4.10^{-3}I \end{cases}$$

C is expressed in mV and D in mV/min.

The decrease of the voltage appears to be related to the increase in thickness of the product of the cell reaction, *i.e.*, cuprous sulfide. The existence of two different steps for the electrochemical sulfurization of copper (parabolic step and linear step) also conforms with the observations of Mrowec (8) on the copper tarnishing reaction in a sulfur atmosphere, when the product of the reaction is sufficiently thick. The parabolic sulfurization time is also about 50 min. The copper diffusion, within cuprous sulfide, results from a concentration gradient: cuprous sulfide not being an ideal stoichiometric crystal. The diffusion constant is 3.10^{-5} cm^2/sec according to Mrowec and 10^{-5} cm^2/sec according to Wehefritz (9).

Electrogenerative Chlorination

Stanley H. Langer* and Sergei Yurchak

Chemical Engineering Department, University of Wisconsin, Madison, Wisconsin

To-date, few direct organic electrogenerative (1) processes have been reported or investigated to any appreciable extent; systems involving migrating anions other than hydroxyl ions would be of particular interest. (We define electrogenerative processes as those in which two or more materials react at electrodes in a manner such that favorable thermodynamic factors drive the reaction, a useful product is produced, and by-product electricity is generated.) We report here the electrogenerative chlorination process in which chlorine and olefin are reacted with the assistance of catalytic electrodes and suitable electrolyte under favorable conditions to give dichloroalkanes and chlorohydrin in varying amounts with accompanying generation of electrical current. Chlorine is reduced at the cathode to chloride ions which are transported through the electrolyte to the anode, where they combine with ethylene to form reaction products and electrons which are conducted through an external circuit to the cathode for reaction with more chlorine. The chlorine gas and unsaturated hydrocarbon are introduced into cathode and anode chambers which are separated by the electrolyte barrier phase bounded by suitable gas permeable electrodes. Both electrodes operate at a positive potential relative to the standard hydrogen electrode under favorable thermodynamic influence. Chlorination rate and potential of the over-all cell can be varied and adjusted with the external resistive circuit (1).

Observed cell reactions, based on product analysis, may be represented generally as

$$\text{Cathode:} \quad Cl_2 + 2e \rightarrow 2Cl^- \qquad [1]$$

$$Cl^-(\text{cathode}) \rightarrow Cl^-(\text{anode}) \qquad [2]$$

* Electrochemical Society Active Member.

$$\text{Anode:} \quad RCH{=}CHR' + 2Cl^- \rightarrow \underset{\displaystyle Cl}{\overset{\displaystyle |}{RCH}}\!\!-\!\!\underset{\displaystyle Cl}{\overset{\displaystyle |}{CHR'}} + 2e \qquad [3]$$

or

$$RCH{=}CHR' + 2Cl^- + H_2O \rightarrow \underset{\displaystyle Cl}{\overset{\displaystyle |}{RCH}}\!\!-\!\!\underset{\displaystyle OH}{\overset{\displaystyle |}{CHR'}} + HCl + 2e \qquad [4]$$

For ethylene, electrogenerative chlorination requires no external power source and differs further from conventional electrochemical chlorination with aqueous electrolyte [reviews in ref. (2) and (3)] in that no significant amount of ethylene glycol is formed in the electrolyte (4, 5).

The free electrolyte phase of our study was generally acidic. In most cases, 2M aqueous potassium chloride was employed but 2M NaCl—1M $HClO_4$ electrolyte did not significantly alter cell performance. The molded gas permeable, electrolyte impermeable LAA-1 platinum black-polytetrafluoroethylene electrodes which confined the electrolyte were of a commercial type[1] and have been described in the literature (6). They were supported on 50-mesh tantalum screen. Carbon-polytetrafluoroethylene electrodes were unsupported. Exposed electrode area was 5.1 cm^2. Cell construction was similar to that of Landi *et al.* (6) except that only Teflon and Viton contacted the hydrocarbon and its reaction product. Electrolyte was static. Design of our gas handling system enabled the chlorination cell to be operated with gas flow or as a closed static system with gas circulation by a Teflon-

[c] Liquid 1,2-dichloroethane, E° = 0.69 for gaseous dichloroethane.

glass pump. Current generated by the cell was coulometrically equivalent to the chlorine consumed.[2] Typical operating data for several hydrocarbon gases under flow conditions are shown in Table I.

Open circuit potentials are surprisingly close to calculated values, based on free energies of formation, for operable cells despite the fact that these cells generally are not considered to be reversible. The absence of carbon catalytic activity for the reaction of interest at the anode is reflected in a low open circuit potential and operating current. However, carbon electrodes are operable as the cathode. The low open circuit potential for cyclopropane could reflect the weak adsorption of that material (7, 8), especially in the presence of specifically adsorbed chloride ion (9, 10). This cell would appear to be essentially a chlorine concentration cell since no chlorinated product was found. However, with electrogenerative hydrogenation, cyclopropane more nearly resembles olefins with respect to open circuit potentials and current production (1). In the chlorination process, it would seem that our catalyst does not position reactants on the surface in a manner resembling the transition state so that the thermodynamic driving force is brought to bear on the reaction.

At 22°C, the measured potential of the Cl_2/Cl^- electrode in 2M KCl is +1.11V *vs.* the saturated calomel electrode in the current density range 0 to 13 mA/cm² (close to the standard potential of +1.36V for the chlorine electrode); therefore, the bulk of the polarization occurs at the anode. Liquid junction potentials and other corrections would be expected to be small under these conditions.

Since chlorination occurs at potentials significantly lower than the reversible potential for the oxidation of chloride ions, it would appear that the organic molecule participates in the electron transfer reaction. Quantitative determination by gas chromatography of the yield of 1,2-dichloroethane relative to the amount of ethylene reacted as a function of anode potential showed a strong dependence (in a flow system) that has not been previously reported. At an anode potential of +1.05V, a 90% yield was observed while at 1.24V this had diminished to 40%.

Gas chromatographic analysis of the electrolytes by conversion of the aqueous solutions to trimethylsilyl ethers and hexamethyldisiloxane with hexamethyldisilazane (11, 12) and a trace of HCl showed the presence of only 1, 2-chlorohydrin compounds, no glycols being detected. It would seem then that reaction is initiated with formation of $C_2H_4Cl_{adsorbed}$ which can react further by alternate routes.

One would hope that by suitable combination of catalyst, electrolyte, and potential it might be possible to increase control of the product of reaction of olefins and chlorine under electrogenerative conditions. With this in mind, we are investigating these reactions further.

[2] We found it necessary to correct the chlorine gas volume changes at the cathode for small constant losses through the cell gasketing. Only trace quantities of 1,2-dichloroethane were observed on open-circuit at the anode, well below that expected on the basis of chlorine losses.

High Activity Silver Electrodeposited from Silver Chloride

Y. J. van der Meulen[1] and F. A. Kröger*

Department of Materials Science, University of Southern California, Los Angeles, California

In the course of experiments on the electronic conductivity of silver chloride (1), the emf of the cell C, Cl_2 (1 atm) |AgCl|Ag was measured. The chlorine electrode consisted of high purity carbon in a 1 atm chlorine ambient. The silver electrode consisted either of pure Ag-foil (4*N*) or of silver deposited by slow electrolysis of the silver chloride crystal at 390°C with a field $\leq$ 150 mV/cm at current densities $\leq$ 5 mA cm^{-2}. Cells with the former type of electrode gave an emf reproducible within 1 mV and independent of time, its value corresponding reasonably closely to the tabulated value of the free enthalpy of the reaction $\frac{1}{2}Cl_2 + Ag \rightarrow AgCl$ (Fig. 1).[2] In the cells with the electrodeposited

* Electrochemical Society Active Member.
[1] On leave of absence from Utrecht State University, Utrecht, The Netherlands.

[2] A slightly larger value, E (392°C) = 951 mV, $dE/dt = 5.8 \times 10^{-4}$ V/°C, was reported by Reinhold (2).

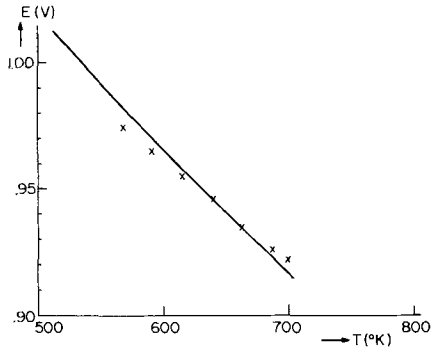

Fig. 1. EMF = $f(T)$ as measured for the cell C, Cl_2 (1 atm) |AgCl|Ag (foil) (individual points) compared with values calculated from thermodynamic data (drawn line).

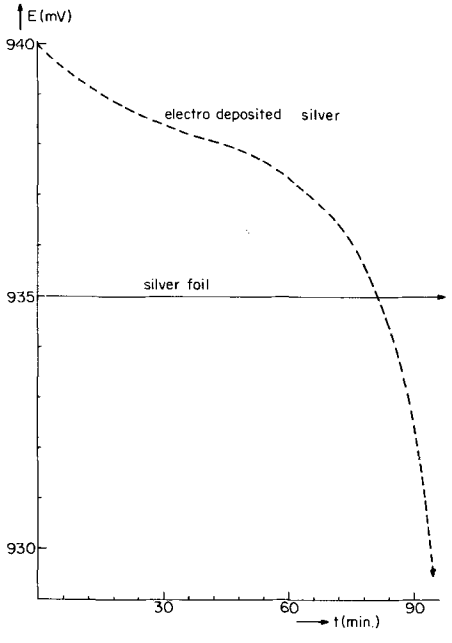

Fig. 2. EMF = $f(t)$ at 390°C for silver foil and electrodeposited silver in the cell C, Cl_2 (1 atm) |AgCl|Ag. The deposition took place on platinum at approximately 2 x 10^{-3} A cm^{-2}. Total amount deposited was approximately 0.20 mg Ag.

silver electrodes, however, the emf measured immediately after termination of the electrolysis changed with time and was initially higher than when silver foil was used (Fig. 2). The result was the same for electrodeposition of silver by electrolysis of ultra pure AgCl containing (5 to 10) x 10^{-6} divalent impurities, mainly Cd, and of AgCl doped with 3 x 10^{-5} Cd. The more slowly the electrolysis was carried out, the more closely the emf approached the value found with the foil. If it is accepted that the emf measured with the foil electrode represents the standard equilibrium value corresponding to the reaction between silver at $a_{Ag} = 1$ and $P_{Cl_2} = 1$ atm, the excess emf with electrodeposited silver could be due to one of the following effects: (*i*) effect due to preferential plating out of less noble impurities, (*ii*) polarization of the AgCl, (*iii*) formation of Cl_2 at $P_{Cl_2} > (P_{Cl_2})_{\text{established}}$, and (*iv*) formation of Ag with activity > 1.

Possibility (*i*) is unlikely, in the first place because of the purity of the AgCl used, in the second place because impurities giving a higher emf would need a higher voltage to be deposited, and therefore preferential deposition is not to be expected.

Possibility (*ii*) is unlikely because of the small overvoltage used in the electrolysis. An internal silver activity > 1 is only to be expected as long as Ag has not nucleated. In such a situation internal excess activities corresponding to 1 mV were observed for the plating of silver from Ag_2S at 400°C (3); this overvoltage dropped to zero with a relaxation time of ≈1 min when nucleation took place.

Possibility (*iii*) may possibly occur for $(P_{Cl_2})_{\text{established}} < 1$ atm if inert gas is present, but is unlikely for $(P_{Cl_2})_{\text{established}} = 1$ atm. The observed overvoltage would correspond to a chlorine pressure $P_{Cl_2} = \exp(\Delta E/kT)$ which for ΔE = 7-8 mV as measured for silver and chlorine discharged at 390°C on carbon, leads to P_{Cl_2} = 1.18-1.23 atm. Since chlorine is evolved at the AgCl-carbon interface, its escape involves diffusion along the interface or through the carbon; and therefore a certain overpressure may be built up during the electrolysis. It is doubtful, however, that this overpressure may be as high as 0.18-0.23 atm under the conditions of the experiment, and it is certainly unlikely that this overpressure would remain over a period of 1 hr, particularly since chlorine is continuously consumed by the chlorination of silver (see below). This then leaves only possibility (*iv*) open as an explanation for the excess emf, the effect being due to the high activity of the deposited silver. Now $a_{Ag} = \exp(\Delta E/kT)$, and for silver deposited on carbon at 390°C where ΔE = 7-8 mV, a_{Ag} = 1.18-1.23.

Silver deposited on platinum[3] gave values of ΔE up to 4 mV, corresponding to a silver activity a_{Ag} = 1.11. Thus the silver is more nearly normal. The emf, however, decreased initially more rapidly than with the Ag/C electrode. This effect is attributed to the diffusion of Ag into the platinum during electrolysis and out of the platinum during the emf measurements (4). Measurements of this kind provide us with a sensitive tool to study the properties of electrodeposited metals as a function of deposition conditions.

ΔG, and thus also ΔE, is related to the dimensions of the surface structure, points or rims. For spherical particles this relation is $\Delta G = 3\gamma V/r$ where γ is the surface energy, V the molar volume, and r the radius. With $\gamma \approx$ 2.5-4 x 10^{-4} cal cm^{-2}, and V = 10 cm^3, ΔE = 5 mV corresponds to $r \approx 0.1\mu$ which is not unacceptable.

The decrease of the emf with time and the final drop after 90 min is due to the consumption of silver of the electrode by reaction with chlorine at the other side. This occurs even when no measurements are made, its rate being limited by ambipolar diffusion of $Ag_i^{\cdot}$ or V'_{Ag} and electrons or holes through the AgCl. In this process the contact between the silver and the crystal is lost. That this is actually the mechanism is shown by the fact that application of a pressure on the electrode, temporarily re-establishes the contact Ag-AgCl and therewith the emf. The gradual lowering of the emf with time in the initial period is due to the preferential consumption of the silver with the highest activity.

Low Temperature Oxidation (24° to 200°C) and Krypton Adsorption Studies on Polycrystalline and Single Crystal Iron Surfaces

M. J. Graham, S. I. Ali,[1] and M. Cohen*

Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada

ABSTRACT

Rates of oxidation of polycrystalline, (110), and (112) surfaces of iron have been measured at 24°, 100°, and 200°C by a manometric method using an initial oxygen pressure of about 1.3 x 10^{-2} Torr. At the lower temperatures the relative rates of oxidation are found to be polycrystalline, (110), and (112) in decreasing order. At 200°C the different single crystal surfaces oxidize at essentially the same rate. Logarithmic rate laws are obeyed reasonably well for oxidations up to 200°C, at which point the oxidation rate, after a time, obeys a parabolic law. Using this parabolic rate constant for the oxidation of polycrystalline iron at 200°C, together with previous microbalance data for the low pressure oxidation of iron at 350° and 400°C (1), an activation energy of 32 kcal. $mole^{-1}$ is found for the formation of magnetite on iron. Surface areas of polycrystalline and (112) surfaces have been measured before and after oxidation using the BET method, employing krypton adsorption at 77°K. It is found that the number of surface sites for the adsorption of krypton is dependent on the nature of the adsorbent surface.

Recent work in this laboratory has considered the oxidation of iron in low oxygen pressures at 350° and 400°C (1) and 450°-500°C (2). The microbalance used in this work was inadequate for kinetic measurements at low temperatures and in order to extend the study of magnetite formation to 200°C and below a manometric system was designed. The apparatus could also be used for surface area measurements. This paper reports the kinetics of magnetite formation between room temperature and 200°C, correlating the 200°C results with the microbalance work (1), and also discusses the effect of an oxide film on monolayer krypton adsorption.

Experimental

Material and surface preparation.—Ferrovac E iron, analyzed to contain the following impurity concentrations (in ppm); Mn, 1; Si, 10; Ni, 10; Al, 10; Cu, 10; Co, 5; Cr, 5; C, 70; N, 20; O, 200 was used. Single crystals of known orientations were produced from this 0.02 cm thick material by strain annealing.

Polycrystalline iron coupons, 4-5 cm x 1 cm were degreased, abraded with 600 grit silicon carbide, and electropolished for 1 min in a 95% glacial acetic acid-5% perchloric acid (70%) solution (3). The specimens were then annealed in vacuum at 700°C for 2 hr and re-electropolished for a further minute. The single crystals were also electropolished before use.

Oxidation apparatus.—The oxidation apparatus is shown schematically in Fig. 1. A Pirani gauge was used to follow the kinetics of oxidation by measuring the change in oxygen pressure with time (at constant volume). With the exception of glass pressure gauges and specimen chamber the apparatus was all metal. Hoke diaphragm seal valves (denoted by S in Fig. 1) were silver soldered directly into stainless steel couplings and Varian flanges, minimizing the apparatus volume by eliminating interconnecting tubing. After an overnight bake at 200°C, pressures better than 10^{-7} Torr were measured by the ion pump.

The walls of the Pirani and reference tubes were maintained at constant temperature by immersing the tubes in an ice-water bath. The Pirani was calibrated against a Decker Model 306 Differential Pressure Gauge which had a sensitivity of 0.187 V $Torr^{-1}$ found by previous calibration against a McLeod gauge. The response of the Pirani gauge was found to be linear up to an oxygen pressure approaching 4 x 10^{-2} Torr, with a calibration of 1.61V $Torr^{-1}$ for oxygen. An oxy-

[1] Former Post-doctorate Research Fellow.

gen uptake causing the Pirani balance to change by 1 mV was equivalent to a mean thickness of $\frac{3.72}{SA}$ Å Fe_3O_4, where SA is the specimen surface area.

The working volume of the system, *i.e.*, volume enclosed by valves S_2 and S_4, was found to be 50.0 ml and the volume enclosed by S_2, S_3, and S_4 equal to 24.0 ml. The small doser between S_1 and S_2 contained an approximate volume of 3.6 ml.

The specimen chamber was rectangular in shape with internal dimensions of 7.0 x 1.3 x 0.2 cm. The chamber was joined to a Kovar seal which was argon-arc welded into a Varian flange.

Oxidation procedure.—After the system had cooled following an overnight bake and when the pressure was about 1 x 10^{-7} Torr, the specimen air-formed oxide film was reduced with hydrogen at about 4 Torr pressure for 1 hr at 570°C. In order to maintain a H_2O:H_2 ratio as low as possible, the system was evacuated and refilled with fresh hydrogen four times during the hour.

After the hydrogen was removed, the specimen was cooled by lowering the furnace, then reheated under continuous pumping, and maintained at the oxidation temperature for half an hour before admitting oxygen. The temperature gradient of the oxidation furnace over the length of the specimen was ±2° at 200°C.

In all experiments the initial oxygen pressure used was about 1.3 x 10^{-2} Torr. The change in pressure, read on a 50 mV recorder range, measured the uptake of oxygen by the specimen as the oxidation progressed. When the oxygen pressure had fallen by about 40% another dose was added to re-establish the initial pressure.

Surface area measurements.—Surface areas of both hydrogen-reduced and oxidized specimens were measured in an all glass system which was similar in design to the apparatus described above.

After the specimen had cooled to room temperature and the system was thoroughly evacuated, the specimen chamber was immersed in a liquid nitrogen bath to a fixed level, which was maintained constant throughout the experiment. The temperature was allowed to stabilize for 15 min before krypton was admitted and the equilibrium pressure read after a steady state had been reached. Four or five equilibrium measurements taken in a relative pressure range of 0.01-0.1 were sufficient for determining the area. From the equilibrium pressures and initial dose sizes, the volume of krypton adsorbed by the specimen may be found after applying a dead space correction obtained by measurement in the absence of a specimen. The values of the equilibrium pressure were corrected for the thermal transpiration effect using the expression of Bennett and Tompkins (4).

The number of krypton adatoms in a monolayer, N_m, was calculated from the standard BET equation. Knowing N_m and a value of the cross-sectional area of krypton, the surface area may be determined.

Electron diffraction.—Reflection electron diffraction observations were carried out at 50 kV to identify the oxide phases present. After oxidation, the specimens were cooled rapidly to room temperature in the oxidizing atmosphere and transferred to the diffraction apparatus. Following oxidations at 200°C and below, only Fe_3O_4[2] was observed; epitaxial relationships agreed with those reported in the literature, *e.g.*, ref. (5). Specimens oxidized at 260°-400°C for krypton adsorption studies showed α-Fe_2O_3 as well.

Results

Kinetic data.—The early stages of oxidation of polycrystalline iron at a series of temperatures from 24°-200°C are shown in Fig. 2. (Oxide thicknesses are calculated by assuming a roughness factor of 1.) It is observed that the oxidation proceeds in two stages:

[2] A cubic oxide comprising probably both Fe_3O_4 and γ-Fe_2O_3.

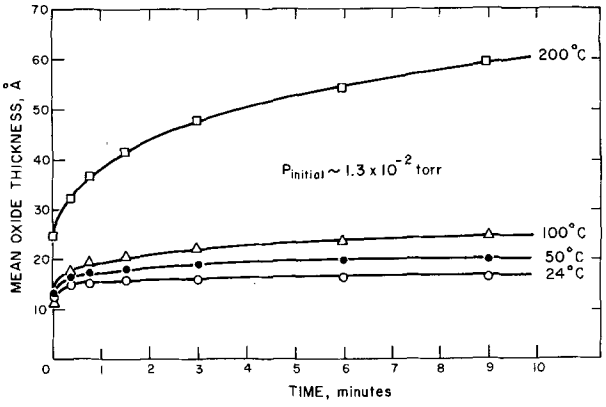

Fig. 2. Early stages of low temperature oxidation of polycrystalline iron.

(*a*) an initial instantaneous oxidation, followed by (*b*) a sharp transition to a period of much lower oxidation rate. The oxide thickness at the turnover of the kinetic curves is dependent on the temperature and also on metal substrate orientation as is seen from Fig. 3, 4, and 5 where the rates of oxidation of polycrystalline, (110), and (112) surfaces of iron at 24°, 100°, and 200°C are shown.

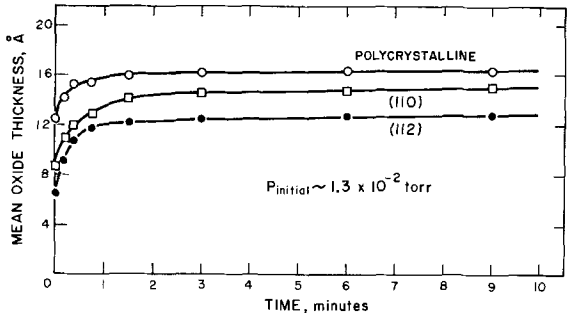

Fig. 3. Oxidation of polycrystalline, (110), and (112) iron surfaces at 24°C.

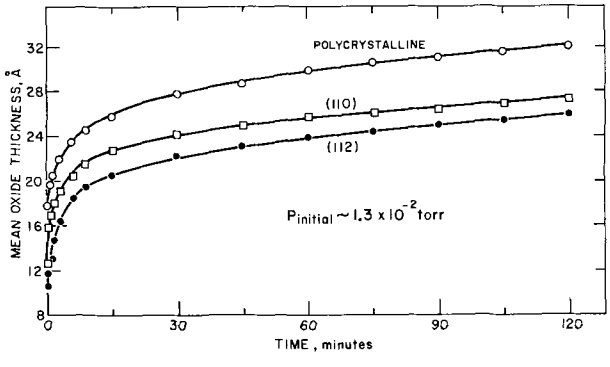

Fig. 4. Oxidation of polycrystalline, (110), and (112) iron surfaces at 100°C.

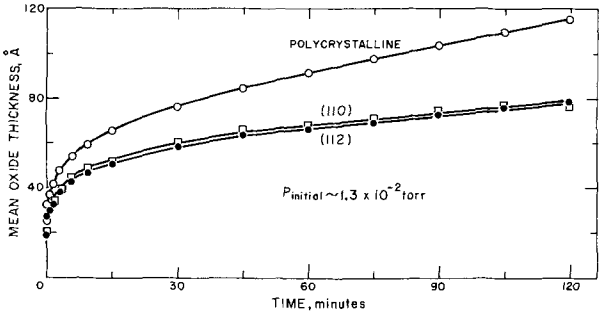

Fig. 5. Oxidation of polycrystalline, (110), and (112) iron surfaces at 200°C.

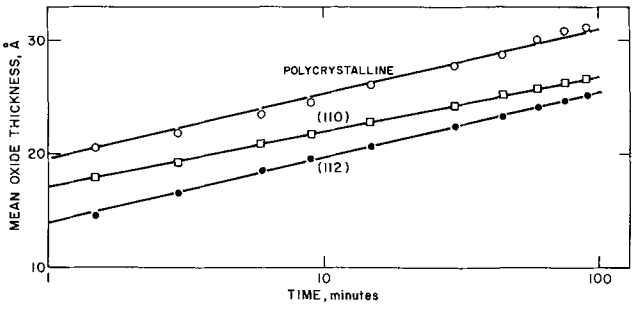

Fig. 6. Logarithmic plot of data from oxidation of polycrystalline, (110), and (112) iron surfaces at 100°C.

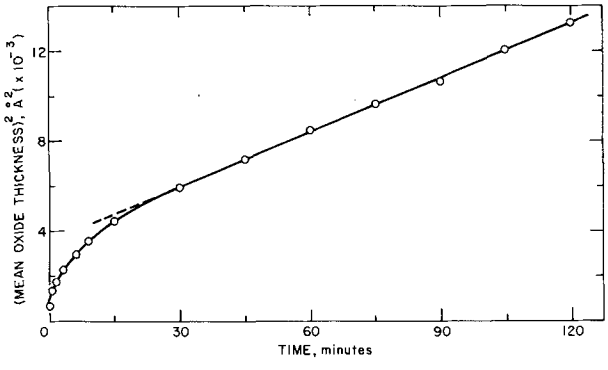

Fig. 7. Parabolic plot of data from oxidation of polycrystalline iron at 200°C.

Oxidations at 24° and 100°C followed a logarithmic rate law of the form $x = A \ln t + B$ (x = film thickness, t = time) reasonably well and the logarithmic plot for the oxidation of various surfaces of iron at 100°C is shown in Fig. 6. At 200°C, the results for the first 20 min of oxidation fit a logarithmic plot after which time the data is best represented by a parabolic plot, as shown in Fig. 7 for polycrystalline iron.

Surface area measurements.—In the BET equation a value of 3.0 Torr was used for the vapor pressure of krypton at 77°K. Having evaluated the monolayer coverage, from the slope of the BET plot, a value for the cross-sectional area of krypton is required in order to determine the surface area. It is becoming increasingly more certain that physically adsorbed atoms are held on surface sites and not adsorbed in a close-packed array, and so the cross-sectional area of, *e.g.*, krypton will be determined by the site density of the particular adsorbent used. Cross-sectional areas, σ, for krypton adsorbed on iron, derived by Brennan and Graham from coverages based on site adsorption (6) are as follows:

Polycrystalline: $\sigma(\text{Kr}) = 17.9\text{Å}^2$
(112) plane : $\sigma(\text{Kr}) = 20.0\text{Å}^2$
(100) plane : $\sigma(\text{Kr}) = 16.4\text{Å}^2$
(110) plane : $\sigma(\text{Kr}) = 17.4\text{Å}^2$

the polycrystalline value of 17.9Å² being the mean value of the cross-sectional area of krypton on the three major low index planes listed above. The appropriate σ values have been used to calculate the surface areas of hydrogen reduced specimens given in Table I. [The above values compare with a commonly used one of $\sigma(\text{Kr}) = 19.5\text{Å}^2$ (7).]

Table I. Surface areas of polycrystalline and (112) iron specimens

Surface orientation	BET surface area (cm²)	Geometric area (cm²)	Roughness factor
Polycrystalline	15.6	12.6	1.2
(112)	15.0	11.2	1.3

Each area measurement was repeated 3 or 4 times and the values were reproducible to an accuracy of ~8-10%. (The reduction in monolayer capacity for krypton of a surface after oxidation will be considered in the discussion.)

Discussion

Kinetics.—It has been found, using a variety of experimental techniques, that the room temperature oxidation of iron involves an initial rapid chemisorption process followed by a slow approach to a mean film thickness of around 10-30Å (8-12), the value depending on surface pretreatment, oxygen pressure, time of exposure, etc. The present result of a thickness of 17±0.5Å after 10 min of oxidation of polycrystalline iron is in keeping with previous findings. Oxide thicknesses after oxidation for 2 hr at 100° and 200°C, viz., 30±2Å and 120±8Å (mean of two separate experiments) are in good agreement with those reported by Gulbransen (8) and Winterbottom (9).

The relative rates of oxidation at 24° and 100°C are found to be polycrystalline, (110) and (112) in decreasing order (Fig. 3 and 4). At 200°C the polycrystalline material again oxidizes at a faster rate than either the (110) or (112) face, but now both single crystals oxidize at essentially the same rate (Fig. 5). The anisotropy of oxidation is probably related to a varying oxide grain size or subgrain size with metal orientation. The smaller the oxide grain size, the higher the oxidation rate because of the presence of more leakage paths for easy diffusion. At higher temperatures where α-Fe_2O_3 is observed, the rate of oxidation will also depend on the rate of nucleation of α-Fe_2O_3 to form a continuous layer (1, 13, 14).

The present oxidation results at 24° and 100°C (and for the first 20 min of oxidation at 200°C) appeared to fit a direct logarithmic plot better than an inverse logarithmic plot, although after about 60 min, the experimental points, particularly for room temperature oxidation, did begin to deviate from a direct logarithmic plot and fitted equally well an inverse logarithmic dependency. As the data do not permit unequivocal rate law interpretation, it is not considered useful to speculate on the particular mechanism of this thin film oxidation (15-18).

The rate constant for the parabolic region of the oxidation at 200°C (from Fig. 7) is compared in Table II with parabolic rate constants determined in a previous study (1) for the initial oxidation of polycrystalline Ferrovac E iron at 350° and 400°C at about the same pressure of 10^{-2} Torr. It should be emphasized that the rate constants refer to the formation of magnetite alone; from electron diffraction studies no α-Fe_2O_3 was detected during these parabolic periods.

An Arrhenius plot of the parabolic rate constants given in Table II is shown in Fig. 8. Here it is observed that the present data at 200°C correlates well with the previous microbalance work, and the resulting activation energy for the formation of magnetite on iron in the temperature range 200°-400°C is found to be 32 kcal. mole^{-1}. This is higher than the approximate value reported previously using data obtained at only 350° and 400°C (1).

Reduction in surface sites following oxidation.—Krypton adsorption measurements on clean metal (prior oxide hydrogen reduced) and oxide covered polycrystalline and (112) iron surfaces show that following oxidation, the number of krypton atoms ad-

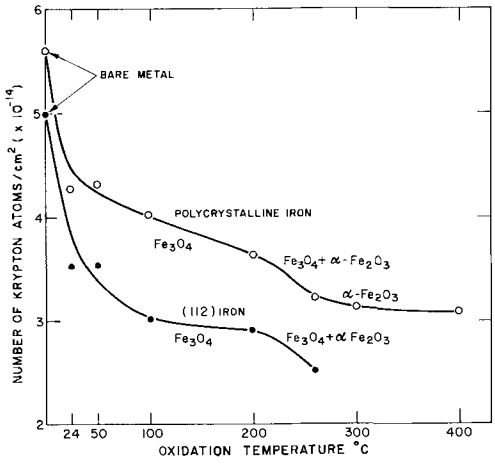

Fig. 9. Reduction in site density for the adsorption of krypton on oxide films formed at various temperatures.

sorbed in a monolayer is reduced. Workers using evaporated metal films find the monolayer capacity of a surface is nearly always lowered by the presence of a chemisorbed layer. The most probable explanation is that following oxidation or chemisorption, the number of surface sites for krypton adsorption has been reduced.

This reduction in site density on oxide films formed at various temperatures is shown in Fig. 9. The reference point for the number of krypton atoms adsorbed per square centimeter (using the "real" surface area) of bare metal is $1/\sigma$, the values of the cross-sectional area of krypton used were those given earlier. In Fig. 9 it is observed that the number of krypton atoms required to complete a monolayer not only changes from a bare metal to an oxidized surface but also depends on the particular oxide formed; αFe_2O_3 appears to provide fewer surface sites than Fe_3O_4. The cross-sectional area of an adsorbate is probably controlled by the site density of the adsorbent and thus would be expected to change as the nature of the adsorbent surface is changed.

Etch Patterns on Zone-Refined Fe

M. E. Straumanis* and C. D. Kim

Graduate Center for Materials Research and Department of Metallurgical Engineering of the University of Missouri-Rolla, Rolla, Missouri

ABSTRACT

Upon dissolution of zone-refined Fe in strong acids, mainly three kinds of corrosion patterns were observed in the crystallites of the sections. Regardless of the acids, the {110} plane always appeared on the three patterns in the form of smooth and even steps, ledges, or facets. The {112}, {122}, and {123} planes were also developed but to a much lesser degree. The {100} and {111} planes were not observed because grains of the respective orientation were missing on the sections. Attempts were made to explain the formation of the planes by taking into consideration the reticular density of the planes and the frequency of their appearance. The theoretical relative corrosion rates of the separate crystallographic planes were estimated. The trend obtained agreed with the observed rates.

Zone-refined iron is attacked only slightly even by strong acids. As a result, in contrast to a previous investigation where a fine crystalline Fe was used (1), characteristic etch patterns appeared on the polycrystalline sample, each grain showing an array of steps, ledges, and facets. The surface was also highly resistive to atmospheric corrosion.

Etch patterns on single Fe crystals (2, 3), kinetics of dissolution of Fe whiskers (4), potentials (5), and anodic dissolution rates of separate crystal planes (6) were investigated previously. However, no reports on angular measurements between the ledges produced on single crystallites of an iron sample by the action of strong acids could be found. The aim of this study was, therefore, to determine the indices of the faces developed on separate grains during corrosion of zone-refined Fe in several acids and to compare the results with those of other investigators who worked, *e.g.*, with single crystal spheres and plates (2,3,6).

The luster of the etched samples originates not only from the strongly reflecting ledges on each grain, but also from other, usually weaker reflecting step systems. If these systems are within the same crystallographic zone, the angles between them can be measured with an optical goniometer. As the wide and shiny steps (see *e.g.*, Fig. 4) are easily indexed (see below), the indices of the other faces of the same zone can be determined from the angles optically measured, the bright steps serving as reference planes.

Samples and Technique

High-purity zone-refined Fe was obtained from Battelle Memorial Institute. The main impurities in ppm were: Ni, 20; Al, 15; Ca, 10; Si, 10; C, 9; P, 9; Cu 7; and other elements in still smaller amounts. The Fe rods were sliced into pieces of about 5 mm thick, and each slice was ground and polished. The specimens, 1-5 cm^2 in surface area, were deeply etched using as solutions concentrated HCl, 1.5*N* HNO_3, 2*N* H_2SO_4, aqua regia (25%), and concentrated HF (48%). Two hours produced an etch pattern in concentrated HCl, whereas several days were required to obtain the same pattern in 2*N* H_2SO_4. Etching in each solvent was continued until the grain boundaries were clearly resolved.

As the Fe rods consisted mainly of large crystallites (2-5 mm in diameter), their orientation could be determined from Laue back-reflection patterns (Fe radiation, sample-to-film distance, 3 cm). The strong reflections were read with the aid of the respective Greninger (-Bond) chart, plotted into Wulff's stereonet and the indices found in the usual way (7, 8).

To determine the indices of the brightest, most reflective planes developed by etching (Fig. 4) on each grain of the sample, the latter was mounted on the head of an optical goniometer and so adjusted that the reflective steps of the grain became perpendicular to the goniometer vertical circle axis, which, in turn, was parallel to the x-ray beam.

With the goniometer head and the adjusted sample now in the Laue camera, the indices of the surface of the parallel steps could easily be found. Minor optical reflections, *e.g.*, the sides of the steps with larger area, were determined in the same way. This procedure of investigating grain after grain was continued on several sections of the polished and etched Fe samples.

Results

Figure 1, representing a unit triangle of a standard (001) stereographic projection, shows a random orientation distribution of the grains.

The etch patterns on each grain were similar to each other although various etchants were used. However, only concentrated HCl produced very clean surfaces with a shining metallic luster. Samples treated with H_2SO_4 and HF were covered with a layer of whitish-gray salts, and those etched with HNO_3 and aqua regia partly exhibited a brown oxide film. Nevertheless, the surface structure of all the grains on the sections was generally similar.

Three major corrosion patterns could be distinguished: (*i*) a set of grooves running nearly parallel across the grains (Fig. 2); (*ii*) triangles or pyramids (Fig. 3); and (*iii*) irregular but shiny ledges running roughly parallel to each other (Fig. 4). Evidently the formation of these etch patterns depended on the degree of inclination of some crystallographic planes within the grains to the surface of the sample.

All of the Laue patterns obtained from the larger area facets of different grains, etched with various

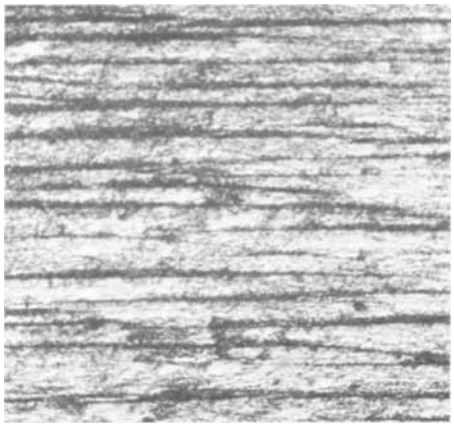

Fig. 2. Crystallite of zone-refined Fe. Etchant: conc. HCl, 12 hr. 150X.

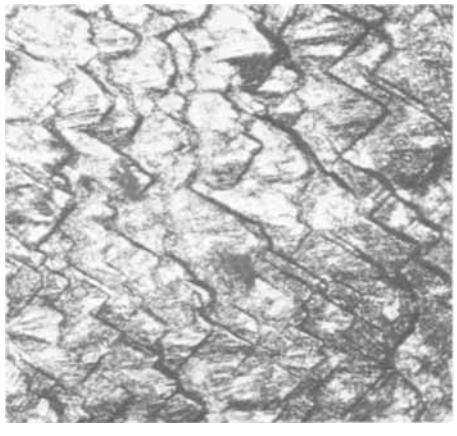

Fig 3. Ditto. Triangles and set of parallel short dark lines on another grain. 150X.

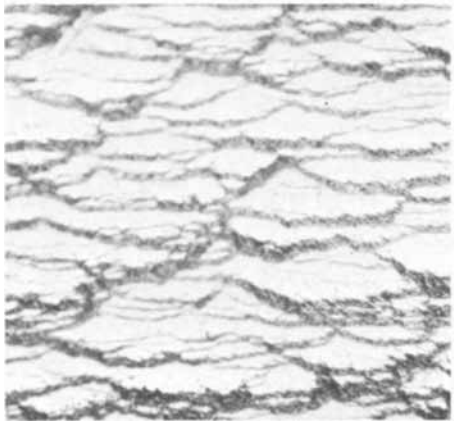

Fig. 4. Ditto. Irregular ledges roughly parallel to each other. 320X.

acids, were indexed. The orientation of these facets is shown by their projections (Fig. 5).

In HF the grains were covered with a layer of corrosion products too thick for goniometric examination. No attempts were made to study these specimens.

Figure 5 clearly shows that the indices of the larger reflecting areas were (in HCl): 6 close to (011), 4 to ($\bar{1}22$), and one to ($\bar{1}23$). In aqua regia: 6 close to (011), 1 to ($\bar{1}22$). In H_2SO_4: 5 close to (011), and in HNO_3: 5 close to (011) and 2 to ($\bar{1}22$). The planes mentioned are not in the ideal positions of (011), ($\bar{1}22$), and ($\bar{1}23$) because the planes formed due to corrosion are never smooth and large enough to produce sharp signals from each crystallite in the goniometer during the setting procedure.

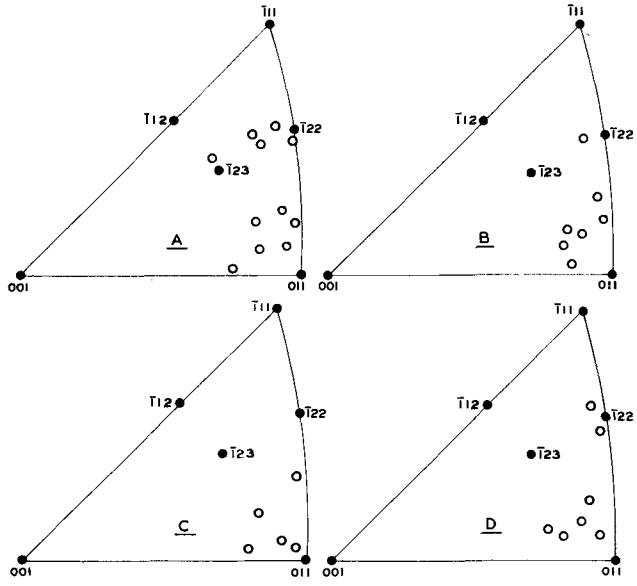

Fig. 5. Orientations of the best defined facets on the grains of Fe samples etched with various acids: A, conc. HCl (10 grains); B, 25% aqua regia (7 grains); C, 2*N* H_2SO_4 (5 grains); D, 1.5*N* HNO_3 (7 grains); full circles, ideal planes; open circles, planes determined.

In addition, there were a series of other weaker optical reflections, the respective planes inaccessible to the x-ray technique. The optical goniometer was a useful tool here.

The angles between the reflections on crystallites showing the etch pattern, Fig. 2, were measured normal to the striations. Surprisingly enough, no new planes were found (Fig. 6).

To obtain as many reflections as possible on grains with etch pattern, Fig. 3, the vertical circle (carrying the sample) was also rotated: at each 5° interval the corroded surface of a certain grain was scanned by turning the horizontal circle. However, the reflecting planes were all the same, but in addition there were weak reflections from {112} and {123}.

Etch pattern 3 (Fig. 4) was investigated in the same way. Very strong reflections from the {011} planes and weak ones from {122} were obtained.

Generally, only the {110} plane appeared as a main facet on the corrosion patterns of zone-refined Fe; the other planes were much smaller in extent and dissolved faster in the acids used.

Discussion

Since the Fe used for the etching experiments was very pure, no significant local corrosion ensued. The corrosion patterns observed are, therefore, a consequence of the reaction of the acids with the body centered structure of crystalline Fe. Such a possibility is deduced from the very slow attack of carbonyl Fe by acids (1) and by the recent facts that the four acids in agreement with Buck and Leidheiser (2, 3), produced in essence the same corrosion patterns (see Fig. 2, 3, and 4) and the planes

$$\{110\},\ \{112\},\ \{122\},\ \text{and}\ \{123\} \qquad [1]$$

This corrosion form of Fe can be compared with that calculated for a body centered crystal (in equilibrium with its vapor) by Kossel and Stranski (9-12)

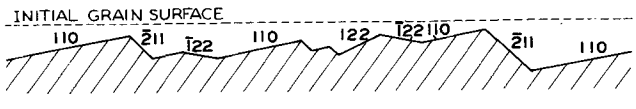

Fig. 6. Planes measured on a crystallite of Fig. 2 with striations within the vertical axis of the horizontal circle of the optical goniometer. Section perpendicular to the striations.

{110}, {100}, {112}, and {111} [2]

whereby the appearance of other planes is not excluded.

The explanation as to why in series [1] the {100} and {111} planes are missing is that none of the grains on the sections were close to these orientations (Fig. 1). On the other hand the (110)-planes are not mentioned, *e.g.*, by Buck and Leidheiser. Thus, there are considerable differences between the theoretical equilibrium form [2] and the corrosion form obtained with Armco Fe or L-steel (2, 3), but there are minor ones between [2] and [1].

However, series [2] can also be obtained, if one assumes that the most stable planes in a homopolar crystal are those with the highest reticular density. The sequence of planes with decreasing relative density, *s*, is then

(110), (100), (112), (111), (123), (122) [3]

s, as listed in Table I, was obtained from both purely geometrical considerations and by calculation from

$$s \sim 1/(h^2 + k^2 + l^2)^{1/2} \quad [4]$$

where *h*, *k*, and *l* are the x-ray indices of a body-centered structure (13).

Thus, the experimental corrosion form [1], would agree with the theoretical form [2] or [3] if the (001) and (111) planes had been in the section areas of the Fe samples.

A further question is which of the planes of form [3] would appear as dots and which would produce larger areas during attack by strong acids? Only estimates can be made, and for this purpose the frequency of appearance of various planes (multiplicity factor, *m*, in x-ray analysis) has to be considered. Assume that the (001)-plane of some crystallites is inclined to the surface of the sample and an etchant is applied. The latter will remove the atoms from the surface and penetrate into the depth of the respective crystallite. But on its way, before reaching the next sound $(00\bar{1})$-plane it will meet one of the high reticular density (101)-planes which occur more frequently ($m = 12$, see Table I) than the (100)-planes with $m = 6$.

The corrosive process, therefore, will be blocked by such planes and penetrate laterally and parallel to them to produce a stairlike structure across the *grains* with (110) as main broad faces and with {112}, {221}, and others as narrow lateral ones (see, *e.g.*, Fig. 4 and 6). Even the {hkl} planes, such as {123} will appear. However, if a (001)-plane is parallel to the sample surface, it may remain during corrosion. The same pertains to the (111)-plane, which is corroded, according to Buck and Leidheiser (2, 3), faster than (001), evidently because of the lower reticular density (Table I).

The relative velocity of corrosion, *V*, of various crystallographic planes can also be estimated, assuming that the rate is proportional to the multiplicity, *m*, of the respective dissolving planes and inversely proportional to the reticular density *s*. This operation will also reduce the corrosion rates of the various planes to the same surface area

$$V = km/s \quad [5]$$

Thus a plane will dissolve faster, the more equivalent directions available to the etchant: the corrosion process on a (001)-plane spreads in 5 directions (or 6, if undermining occurs); on a {110}-plane—in 6 to 12 directions and on {123} or generally {hkl}—in at least 24 directions (up to 48 during undermining), etc. The latter face will, therefore, produce a much higher corrosion rate than (100). This statement is confirmed by the results of Buck and Leidheiser (3). No extensive faces will be developed, only small dots, because of the various inclinations of the {123} planes to the sample surface. A development of larger {123} reflecting planes thus becomes impossible: due to the increased rate of dissolution, corrosion resistive planes, *e.g.*, (101) will be reached soon and steps will develop as already described.

The theoretical maximum *m/s* values are summarized in Table I, the next column showing the relative rates. In the last column rate ratios, as obtained with Fe whiskers by Shemenski *et al.* (4), are given for comparison. Although objections can be raised against this method of calculating rate ratios, the trend does agree with the experimental data obtained by several authors for various kinds of Fe in different solvents (2, 3, 4, 6). Calculated rate ratios for the {hhl} and {hkl} planes are too high because the highest *m* values were taken. Furthermore, ion diffusion rates would limit the velocity of corrosion. On the other hand oxidizers, such as $K_2S_2O_8$ would increase the low rates. The presence of impurities in appreciable amounts would distort the over-all picture. Taking these factors into consideration, the agreement between the theoretical and experimental rate ratios for various crystallographic planes should be regarded as very satisfactory, explaining why the corrosion rate depends on the crystallographic direction, at least for pure Fe.

Films of Oil Oxidation Products on Copper

G. W. Poling*[1]

Research and Technical Department, Texaco, Inc., Beacon, New York

ABSTRACT

Films formed on metallic copper catalyzing the low temperature oxidation of pure hydrocarbon liquids and insulating oils were analyzed using reflectance infrared spectroscopy. Onset of rapid air oxidation of n-decane, p-cymene, mineral oil, and a low aromatic content transformer oil at 90°-100°C coincided with the appearance and rapid growth of copper oxalate films on the copper. Cuprous oxide and copper carboxylate species appeared earlier on the copper surfaces but these were not related directly to the autoxidation process. Addition of oxalic acid impurity to mineral oil both increased its power factor and reacted with the copper to form copper oxalate films. Oxalic acid appeared to be an important product in the oxidative deterioration of paraffinic hydrocarbons and insulating oils. Rapid air oxidation of decalin produced copper nitrate reaction products on the copper surfaces. No oxalate was detected. Addition of 1-H benzotriazole to an insulating oil effectively inhibited corrosion of the copper by forming a film of copper benzotriazolate on the copper. Such films retarded the catalytic action of the copper in oxidation of the oil.

Exposure to metallic copper catalyzes the low temperature, liquid-phase oxidation of many oils. For example, transformer oils, exposed to air in the presence of copper and other metals suffer accelerated oxidation. Formation of species such as peroxides, aldehydes, and organic acids causes corrosive attack of the windings and other exposed metals and leads to earlier breakdown of the dielectric. Accelerated tests of the oxidation stabilities of these oils often make use of the catalytic action of copper. One convenient test employs periodic measurement of the d-c conductivity (converted to power factor) of an oil at 95°C exposed to air and copper for several days (1).

In the absence of so-called copper "passivating" additives the oxidation of the oil is usually governed by the copper in solution (2-4). If corrosion of the metallic copper source is inhibited sufficiently, the surface reactions or heterogeneous mechanisms can become rate controlling. Krieger (5) found that dissolution of Cu_2O films normally present on metallic copper, provided the main source of the soluble copper. Freshly reduced copper surfaces did not exert a catalytic action. Adding copper corrosion inhibitors (called "passivators" in insulating oil usage) to the oil could also make the heterogeneous reactions controlling (6). Some inhibitors served a dual function in also chelating the soluble copper to act as "metal deactivators" (4, 6).

Previous studies of the role of copper during the oxidation of oils have focused attention mainly on the changes in composition of the oil phase. Melchiore and Mills (4) found a correlation between increasing power factors and increasing carbonyl contents of degrading transformer oils. Power factor measurements (see Experimental section) provided sensitive tests of the extent of oxidation of their oils. These and other authors have also reported that varnish-like deposits covered the surfaces of the metallic copper catalysts after prolonged oxidation of the oils. To our knowledge, no prior attempts have been made to analyze these thin reaction product films. Knowledge of their composition and structure should aid in understanding the mechanism of the catalytic action of the copper and how to prevent it.

This paper reports infrared multiple reflectance spectroscopic studies of reaction products formed on copper mirrors used as oil oxidation catalysts. Supplemental tests on the oil phase included: power factor measurements, hydroperoxide (ROOH) titrations, and gas chromatographic analysis for other oxidation products. Oxidation tests were conducted usually at 90°-100°C by bubbling air or oxygen for several hundred hours through oil containing the copper mirror catalysts. Periodically, the mirrors were removed from the hydrocarbon, washed in n-pentane, air dryed, and their reflectance spectra recorded. Results are reported for the oxidation of n-decane, decalin, p-cymene, white mineral oil, and several commercial transformer oils. Reflection spectra from the copper mirrors often changed dramatically during the course of an oxidation test. Initial reaction product films usually consisted of thin films (< 100Å) of copper soaps $(RCOO^-)^2Cu^{++}$ on top of thin Cu_2O films. No significant increases in power factor occurred during the appearance and growth of these products. Onset of rapid oxidation of n-decane, p-cymene, and mineral oil was paralleled by formation and rapid growth of copper oxalate (CuC_2O_4) films on the copper. The copper oxalate films often attained thicknesses in excess of 400Å after prolonged oxidation. No copper oxalate was detected from the oxidation of the naphthene decalin. Instead, after several hundred hours of oxidation, formation of copper nitrate ($Cu(NO_3)_2$) films paralleled a sharp increase in power factor.

Addition of benzotriazole ($C_6H_4N_3H$), an effective copper corrosion inhibitor, to the oil produced protective films on the copper and prolonged the low power factor life of an insulating oil.

Experimental

Recording spectra of films.—Spectra of thin films formed on the copper-mirror "catalysts" were recorded from 230 to 4000 cm^{-1} on a Beckman IR-12 spectrophotometer using multiple reflectance accessory optics. Details of this accessory have been provided in a previous paper (7). These optics provided seven reflections at 73° increase from two planar sample mirrors (76 x 38 x 3 mm and 51 x 38 x 3 mm). Use of these multiple reflections increased sensitivity to record absorption of the infrared by thin semitransparent films on the mirror surfaces. A wire-grid polarizer was installed in the monochromator section of the spectrophotometer. This was oriented to transmit the component of light parallel to the plane of incidence of the light at the sample mirrors to further enhance sensitivity (7). Similar optics with "clean" copper mirrors were installed in the reference beam of the IR-12 double beam spectrophotometer. This maintained optical balance and enabled spectra of films on the sample mirrors to be recorded differentially.

Absorption band intensities in the reflectance spectra were measured in terms of ΔR, the fractional change in reflectivity at a band maximum, *i.e.*, $\Delta R = (R_o - R)/R_o$

* Electrochemical Society Active Member.
[1] Present address: Department of Mineral Engineering, University of British Columbia, Vancouver, British Columbia, Canada.

where R_0 = reflectivity in absence of a film; R = reflectivity at band maximum. ΔR values as low as *ca.* 0.0005 could be measured reproducibly. Film thicknesses were calculated using the formula (8)

$$d_A \simeq \frac{(6.38 \times 10^5 N_1^3)}{\nu K_1} \Delta R$$

(for 73° incidence angle of the parallel component) where N_1 = refractive index of the film material; K_1 = absorption constant of the film = $\alpha\lambda/4\pi$; where α = absorption coefficient in cm^{-1} and λ = wavelength of light in cm; ν = band position in cm^{-1}.

Values of K_1 were determined from reference transmission spectra of analogous compounds. Refractive indices were taken from the literature (9). Both represent approximations of the appropriate K_1 and N_1 values for the thin films on copper. Previous similar studies (10,11) in which film thicknesses were checked interferometrically have indicated that errors in the infrared spectroscopic values should be less than 10%. Spectra of films as thin as one monomolecular layer could be recorded using this technique.

Materials and procedures.—Copper mirrors were prepared by electropolishing plates milled from OFHC copper (99.95% Cu) in a 1:1 mixture of H_3PO_4:H_2O as electrolyte (12,13). The freshly polished plates were washed in distilled water, 10% H_3PO_4, boiling distilled water, and finally methanol to ensure that no phosphate was retained on the mirror surfaces (14, 15). Since these mirrors contacted air they were covered rapidly by Cu_2O films 10-20Å thick (12).

The n-decane was Philips Research grade; p-cymene (p-isopropyl toluene) was Eastman White Label; decalin (decahydronaphthalene) was a mixture of cis and trans forms; and the mineral oil was Squibb-Nujol which was composed of 38.4% naphthenic carbon and 61.6% paraffinic carbon with a molecular weight of *ca.* 450. Three different commercial transformer oils were tested. The aromatic, naphthenic, and paraffinic carbon contents of these three oils were respectively: A, 12.5, 42.7, and 44.8%; B, 15.1, 35.5, and 49.4%; and C, 1.9, 50.8, and 47.3% Transformer oil C was reported to also contain about 0.3% of a phenolic-type oxidation inhibitor.

Oil oxidation tests were conducted with the copper mirrors fully immersed in 100-200 ml of the oil at 90°-100°C contained in a tubular glass flask *ca.* 4.5 cm diameter by 20 cm long. Each flask had a 40 mm viton-A o-ring joint at the top to provide access for the mirrors. A gas bubbler tube extended to the bottom of the flask. When testing volatile hydrocarbons, a water-cooled reflux condenser was fitted to the top closure of each flask.

The copper mirrors were removed periodically from the oil, rinsed in n-pentane, air dried, and their IR reflectance spectra recorded. At the same time the power factor of the oil was measured at 95°C using ASTM procedure D-924. Power factor (P.F.) is related to the resistivity (R) of the oil by the equation P.F. = $1/\sqrt{(2\pi f\ CR)^2 + 1}$ where f = frequency, Hz, and C is capacitance. Hydroperoxide contents were determined by $S_2O_3^=$ titrations (16). Tests were continued for several days until high levels of power factor (*i.e.*, P.F. > 5%) were attained.

Results and Discussion

Oxidation of mineral oil.—Argon, CO_2 and air purging.—Figure 1 shows four reflection spectra taken from a sequence of 13 that were recorded during 1884 hr of oxidation of Nujol oil at 90°C. In this test the oil was purged first with argon gas for 141 hr, second with CO_2 for 890 hr, and third with air for 853 hr. The spectra shown in Fig. 1 were selected to illustrate the dramatic changes that occurred in the composition of the reaction product films on the copper mirrors. These spectra were replotted from spectra recorded on a 0-1.0 absorbance mode so that band intensities can be compared directly. In early stages of film growth,

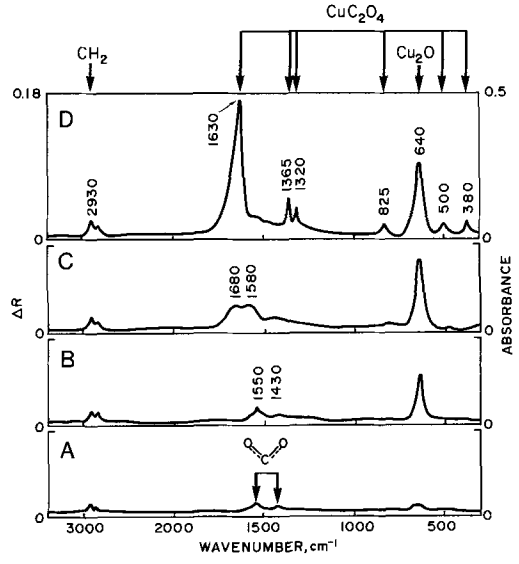

Fig. 1. Reflection spectra from copper exposed to mineral oil at 90°C. A, After 302 hr (141 hr with argon purging +161 hr CO_2); B, 1031 hr (+729 hr CO_2); C, 1225 hr (+194 hr air); D, 1884 hr (+659 hr air).

spectra were also recorded in an expanded per cent transmission mode (up to 25x). This resulted in greater sensitivity to characterize these thin films than is indicated by Fig. 1A, for example. Background reflectance spectra of freshly electropolished copper mirrors were flat and featureless from 4000 to 230 cm^{-1}. Absence of an infrared band characteristic of the air-formed Cu_2O films was due to the fact that spectra were recorded differentially. Nearly identical sets of copper mirrors were present initially in both sample and reference beams. Assignments of the characteristic bands are shown at the top of Fig. 1. These assignments are based on reference to transmission spectra of pure copper compounds (17-20) and on other independent analyses described later.

Figure 2 shows how the intensities (ΔR's) of some of the characteristic IR bands and the power factor of the Nujol changed during the 1884-hr exposure. During the initial 141-hr argon purged exposure, thin films consisting of the equivalent of about one monolayer of a copper carboxylate (R — C  Cu) formed on the Cu (see spectrum A of Fig. 1). During the subsequent 890-hr CO_2-purged exposure, the copper carboxylate films grew to a thickness of ~200Å (Fig. 1B). This was accompanied by growth of relatively thick (~800Å) Cu_2O films on the copper as evidenced by the 640 cm^{-1} Cu_2O band in spectrum B of Fig. 1 (10). One possible

explanation for the growth of thick Cu_2O films might be the disproportionation of a CO_2 corrosion product such as $Cu(HCO_3)_2$, *i.e.*, $Cu(HCO_3)_2 \rightarrow Cu_2O - Cu + H_2O + 2CO_2$. Copper bicarbonate is formed readily in the presence of small amounts of water and oxygen (22). Neither air nor oxygen purging of the hydrocarbons resulted in formation of such thick Cu_2O films on the copper. The power factor of the Nujol remained low (<0.5%) throughout the initial 1031 hr of exposure.

On changing to an air purge, after 1031-hr exposure, the Cu soap films thickened and a new C=O band appeared at 1680 cm^{-1} (see spectrum C of Fig. 1). After about 700 hr of air purge the power factor increased rapidly. This deterioration was paralled by the formation and rapid growth of copper oxalate (CuC_2O_4) on the copper mirrors (see Fig. 2). At the end of the 1884 hr of exposure, the mirror surface had a varnish-like appearance. The copper oxalate was identified by: (*i*) appearance of new, highly characteristic infrared bands at 1630, 1365, 1320, 825, ~500, 380, and 285 cm^{-1}. These corresponded closely to reference transmission spectra of bulk copper oxalate (18-20); (*ii*) reflection electron diffraction patterns from the copper mirrors; (*iii*) solvation in water ≃ 3 mg/100 cc at 25°C but insolubility in most organic solvents; (*iv*) spot test analyses for oxalate in aqueous extracts of the films. The copper oxalate films were calculated to be about 220Å thick at the end of the 1884-hr exposure (see spectrum D of Fig. 1). Figure 2 indicates that the copper oxalate was the only surface species that was related directly to the autoxidation of the Nujol.

Oxygen purging.—A test similar to that described above but using an oxygen purge produced similar results. When the oil began to oxidize appreciably, as indicated by increased power factor and hydroperoxide contents, copper oxalate again appeared and grew on the copper mirrors. Results are summarized in Table I. One notable difference between these and the above results was that with oxygen purging the Cu_2O films did not thicken appreciably during the 1161 hr of exposure. Figure 2 indicates that in the previous test, most of the Cu_2O film growth occurred during the CO_2 purging period.

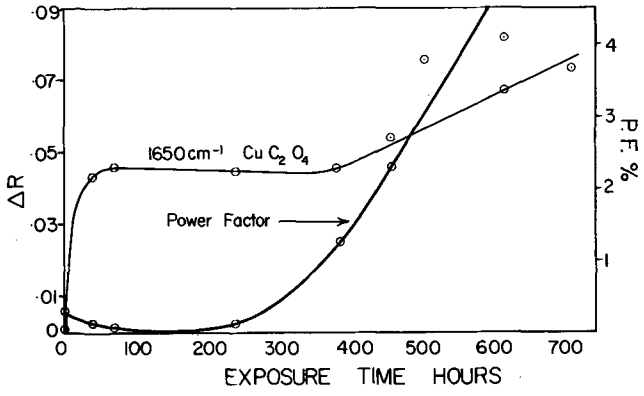

Fig. 3. Effect of adding 0.01 w/o oxalic acid to mineral oil

With oxalic acid addition.—The copper oxalate films described previously were believed derived from an oxalic acid oxidation product in the oil. A test was therefore conducted on Nujol containing 0.01 w/o (weight per cent) of oxalic acid to test the effects of this impurity on both power factor and film composition. Results are shown in Fig. 3. This small addition of oxalic acid increased the 95°C power factor from 0.05 for pure unoxidized Nujol to 0.28. After about 70 hr of oxidation at 90°C using air purging, the power factor had returned to 0.07, which was close to its original value. Part of the oxalic acid impurity had been converted to copper oxalate films approximately 55Å thick on the copper mirrors. These oxalate films did not then grow thicker until the Nujol began to oxidize appreciably after about 300 hr.

The 55Å thick copper oxalate films covering the 108.5 cm^2 area of the copper mirrors accounted for only a fraction of the 0.01 w/o oxalic acid addition. Other reactions involving the reducing property or decomposition of oxalic acid probably also contributed to the consumption of the acid impurity as such during the 70 hr of exposure. The above test did show, however, that both the power factor and film composition were sensitive to the oxalic acid impurity.

Oxidation of n-decane.—The copper catalyzed oxidation of n-decane was studied to compare the behavior of a pure, normal paraffin with the above results on Nujol, a mixture of naphthenic and paraffinic hydrocarbons. In this test, the copper mirrors were exposed to air-saturated n-decane at *ca.* 95°C for a total time of 2516 hr. Reflection spectra were recorded from the copper mirrors at 14 different stages in this exposure. Results of some of these and other analyses are summarized in Table II. Power factors were recorded with the decane at 25°C rather than the standard 95°C to minimize the fire hazard. This made the power factor relatively insensitive to the onset of severe oxidation (21).

Spectra A and B of Fig. 4 illustrate the dramatic changes that occurred in the films on the copper mirrors from 1990 to 2516 hr exposure, respectively. Spec-

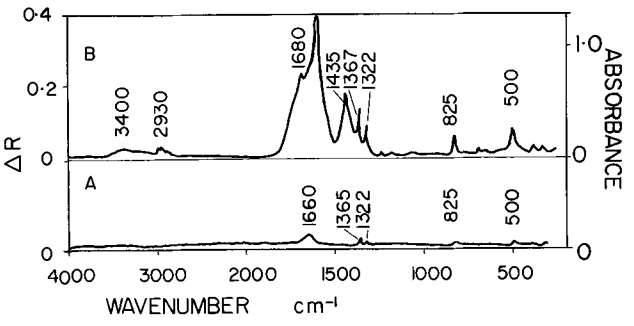

Fig. 4. Reflection spectra from copper exposed to air-saturated n-decane at 95°C for: A, 1990 hr; B, 2516 hr.

tra recorded from ca. 600 to 1990 hr exposure were all similar to spectrum A of Fig. 4. These identified the main constituent of the thin reaction product films as copper oxalate. In spite of this appearance of oxalate, oxidation of the decane appeared to progress slowly up to the last 60-70 hr of this test. While the decane was still clear and colorless at 2450-hr exposure, at the end of 2516 hr it had a blue-green hue and sludge was visible at the bottom of the flask. In addition, the copper oxalate had thickened rapidly to about 500Å during this last exposure period. This result was based on the intensities of the copper oxalate bands at 1650, 1365, 1322, 825, and 500 cm^{-1} in spectrum B of Fig. 4. Although this spectrum identified the majority of the film as copper oxalate, additional bands at 3400, 2960, 2930, 2860, 1680, and 1435 cm^{-1} were attributed to the presence of ketone and ester products as well. Decomposition of hydroperoxide probably provided these products. Table II indicates that the hydroperoxide content of the decane fell appreciably during this last exposure period. Results in Table II and Fig. 4 show that rapid growth in thickness of the copper oxalate film coincide with the onset of rapid or autocatalytic oxidation of the decane.

Oxidation of decalin.—Decalin (decahydronaphthalene) was selected for study to analyze films formed on copper by the oxidation of a naphthenic hydrocarbon. The copper mirrors were exposed for a total of 346 hr to air-saturated decalin at 90°C. Results are summarized in Table III. Reflection spectra from the copper mirrors recorded after A, 20 hr; B, 226 hr; and C, 346 hr are shown in Fig. 5. These spectra illustrate the pronounced changes that occurred in the composition of the reaction product films during this test. Thin films of Cu soap that formed during the first few days of exposure exhibited spectra similar to Fig. 5A. Additional bands that appeared in spectra of the 114 and 226-hr films were assigned tentatively to amide or covalent nitrate complexes (Fig. 5B).

The hydroperoxide content and power factor of the decalin increased slowly and almost linearly for 226 hr of exposure. Both then exhibited a sharp increase in the last 120 hr of exposure and a relatively thick film of copper nitrate appeared on the copper. Bands at 1435, 1335, 1045, and 815 in spectrum C of Fig. 5 were attributed to the copper nitrate (17, 18). Treatment of the filmed mirrors in solvents such as $CHCl_3$ and CH_3CN had no effect on these IR absorption bands

Table III. Copper-catalyzed 90°C air oxidation of decalin

Exposure, hr	Power factor at 95°C	Hydroperoxide, m/o	IR spectra of film: Composition	IR spectra of film: Approximate thickness, Å

but water extracted the species responsible for them. Chemical analysis of the aqueous extract confirmed the presence of copper nitrate. No oxalate was detected in these films. This is in contrast to results of the previous tests. The only source for the nitrate found in this test appeared to be fixation of nitrogen from the air purge. Further study is necessary to explain this unexpected result.

Oxidation of p-cymene (p-isopropyl toluene).—Air-saturated p-cymene ($p\text{-}CH_3C_6H_4CH(CH_3)_2$) was oxidized for a total of 334 hr at 90°C. After 330 hr, severe oxidation of the aromatic hydrocarbon began and was accompanied by growth of copper oxalate films (~100Å thick) on the exposed copper mirrors. In addition to copper oxalate, the reaction product films exhibited weak aliphatic C-H bands. No aromatic C-H bands were detected in the films. During this test the hydroperoxide content increased from 0.3 to 2.0 m/o (mole per cent) and the power factor attained a final high value of 8.3%.

Oxidation of commercial insulating oils.—Transformer oils A and B were of similar composition in terms of their aromatic, napthenic, and paraffinic carbon contents. In 90°C, air-saturated oxidation tests of these oils, the initial thin product films formed on the copper-catalyst mirrors consisted primarily of copper carboxylates. After rapid oxidation had occurred, films exhibiting spectra similar to that shown in Fig. 6A had formed on the copper mirrors. This spectrum was recorded after 158-hr exposure of copper mirrors to transformer oil-A. By this time the power factor had risen from an initial value of ca. 0.1% to a high value of ca. 5%. The main bands in spectrum A are believed due to copper bicarbonate present at a film thickness of several hundred angstroms. Although no reference spectrum of copper bicarbonate was found in the literature, the similarity of Fig. 6A to spectra of other bicarbonates gives some credance to this interpretation. This product was insoluble in several organic solvents but dissolved readily in water to leave

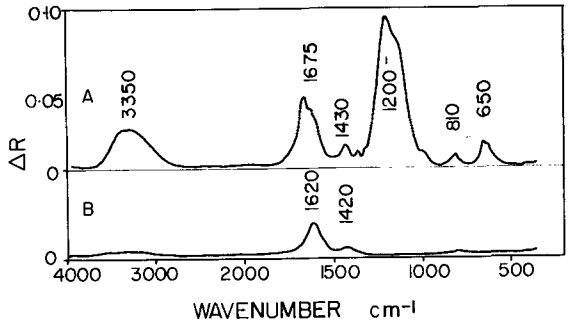

Fig. 6. Reflection spectra from copper exposed to air-saturated transformer oil-A at 90°C for: A, 158 hr; B, after extraction of film in H_2O.

the underlying copper soap films exhibiting spectrum B of Fig. 6. No copper oxalate was detected in these films.

Blending of 0.01 w/o of an effective copper corrosion inhibitor, benzotriazole ($C_6H_5N_3$), into these transformer oils resulted in major improvements in their oxidation stabilities. For example, inhibited transformer oil-A exhibited a power factor of about 1% after 140 hr exposure instead of 5-7% which was typical without this additive. Reflectance spectra from the copper mirrors showed that the benzotriazole had reacted with the copper "catalyst" to form highly protective films of copper benzotriazolate (11). These spectra indicated that the protective films formed quickly. They attained a thickness of *ca.* 90Å after 1-hr and 200Å after *ca.* 140-hr exposure.

Oxidation tests on the low aromatic content transformer oil-C differed significantly. This oil resisted severe oxidation, with air-purging at 95°C, for over 1000 hr. During this period the usual thin films of copper carboxylate were formed on the copper mirrors. After 1200 hr, the oil was oxidized severely and copper oxalate made up a major proportion of the relatively thick films formed on the copper.

Conclusions

Onset of severe air oxidation of several hydrocarbons was accompanied by the formation of highly characteristic reaction product films on the surface of exposed metallic copper catalysts. Infrared multiple reflection spectra provided a sensitive means for analyzing both the composition and thickness of these films.

Paraffinic hydrocarbons generated copper oxalate films on copper when they began to autoxidize appreciably. These copper oxalate films appear to result from reaction of the copper (+ Cu_2O) surfaces with oxalic acid oxidation products generated in the liquid phase. In addition, the power factor of an insulating oil was found to be sensitive to the presence of small amounts of oxalic acid impurity. For example, addition of 0.01 w/o oxalic acid to mineral oil increased its 95°C power factor by approximately 5 times (*i.e.*, from 0.05 to 0.28%). Data in the literature indicated that other expected oxidation products such as monocarboxylic acids exert much smaller effects (21). In addition, the lower the molecular weight of these acids the larger their effect on the power factor. These results suggest that generation of oxalic acid plays an important role in the oxidative deterioration of insulating oils of low aromatic content. This infrared spectroscopic study provides what appears to be the first evidence for the production of such species during such low temperature (< 100°C) oxidations. The concentrating action of scavenging oxalic acid from the liquid phase by the copper mirrors probably contributed significantly to our detection of oxalic acid derivatives.

Evidence on the mechanism of the formation of oxalic acid is still lacking. Reaction of CO_2 gas with an oxidation product like formic acid appears to be ruled out by the observation that oxalate films were formed using pure oxygen purging conditions.

Reactively Sputtered Silicon Oxynitride as a Dielectric Material for Metal-Insulator-Metal Capacitors

R. I. Frank[1] and W. L. Moberg

Sperry Rand Research Center, Sudbury, Massachusetts

ABSTRACT

Silicon oxynitride was formed by rf reactive sputtering of silicon in mixtures of N_2 + N_2O. The dependence of dielectric constant, etch rate, breakdown strength, and IR transmittance on the N_2O concentration in the plasma was determined. Five to ten per cent N_2O gave an average breakdown strength of 1.1 x 10^7 V/cm for metal-insulator-metal capacitors having molybdenum electrodes. The other capacitor parameters were also measured. An explanation of the high breakdown strengths in these capacitors is suggested.

The properties of rf reactively sputtered silicon nitride and silicon oxynitride have been studied as part of a program to investigate new dielectric materials for use in passive components in integrated circuits, particularly for metal-insulator-metal (MIM) capacitors. Silicon nitride was investigated because of its compatibility with integrated circuits and because its higher dielectric constant and higher dielectric strength promised a greater capacitance per unit area than sputtered silicon dioxide (1). Sputtering was used

[1] Raytheon Company, Equipment Division, 528 Boston Post Road, Sudbury, Massachusetts.

because it is a low-temperature process which permits deposition over existing metallization, such as bottom capacitor electrodes and interconnection patterns. The reactive sputtering approach was chosen because of the high-purity silicon source material available and the possibility of varying the composition of the deposited film by controlling the composition of the reactant gas. Finally, rf sputtering was selected because of the superior film properties that had been obtained in comparison with d-c sputtering (2).

Since the low etch rate of pure silicon nitride (3) makes it a difficult material to process in integrated circuit work by direct etching (4), an investigation was undertaken to determine whether the addition of an oxygen-bearing species to the reactant gas would form a silicon oxynitride which would have properties intermediate between those of pure oxide and nitride. This would result in the desired increase in etch rate and in a less desirable, but unavoidable, decrease in dielectric constant compared to pure nitride. It was, in fact, found that the etch rate in 7:1 buffered HF could be increased from 20 Å/min for pure silicon nitride to 200 Å/min with a decrease in dielectric constant of no more than 20%. Thus, a reasonably fast etch rate was achieved, while a substantial advantage in dielectric constant over pure silicon dioxide was still retained. At the same time, a substantial increase over pure silicon nitride in both breakdown strength and yield of capacitors was obtained, greatly increasing the usefulness of this material in integrated circuit applications.

Experimental

Equipment and procedure.—The sputtering system was a CVC AST 100 Plasma Vac Unit with AST 200 rf dielectric sputtering accessory. This system uses an auxiliary filament as a source of electrons to sustain the discharge at low pressures and an external magnet to confine the plasma. A vertical geometry was used for the target and substrate, with the silicon target supported by a rod extending from the rf feedthrough and screwed into an aluminum disk bonded to the back of the silicon. Sputtering of aluminum from this disk was prevented by clamping a silicon backup plate against the rear of the target. This plate had a hollowed-out recess to fit over the aluminum disk, as shown in Fig. 1. The target was a 3-in. diameter by ⅛-in. thick high-purity polycrystalline silicon disk. A 5-in. diameter Pyrex tube enclosed the target and the electron beam traveling upward from the auxiliary filament. It also served to confine the discharge and the deposition of sputtered materials. A rotating substrate holder was placed just outside this tube at a distance of 2½ in. from the target. This holder was a circular plate that held six 1-in. diameter silicon wafers by means of spring-loaded clips. An electrically isolated shield with a hole opposite each wafer was used over the front of the substrate holder to prevent deposition onto adjacent wafers during sputtering. By depositing onto a single wafer and then rotating the next wafer into position, a number of sputtering conditions could be investigated in a single pumpdown.

The substrate plate was electrically isolated and could be biased to a particular voltage during sputtering. It had a heater and thermocouple, with the leads brought out through a slip-ring arrangement. A schematic of the fixturing is shown in Fig. 2, and details of the substrate assembly are shown in Fig. 3 and 4.

The vacuum system had an oil diffusion pump with a liquid nitrogen cold trap. A pressure of 2×10^{-7} Torr was reached before the sputtering gas was admitted. The vacuum-tight gas inlet system was stainless steel and Pyrex. The gas manifold is seen in Fig. 5 along with an over-all view of the vacuum system. For sputtering, nitrous oxide (N_2O) was first admitted and the pressure was set by the ion gauge, since the flow rate was usually too small to register on a flow meter. Ni-

trogen was then admitted to give a total pressure of 3μ. Ion gauge readings were checked periodically during a run. The nitrogen was analyzed research-grade gas containing less than 1 ppm of impurities. The oxynitride was formed by the addition of nitrous oxide rather than oxygen to the sputtering gas. This permitted the use of larger quantities of the additive gas, and made the mixing of the reactant gases easier to control. For instance, sputtering in a mixture of 5% oxygen and 95% nitrogen was found to be sufficient to shift the IR absorption maximum of the silicon oxynitride from the 12μ location obtained with 100% N_2, to 9.3μ, which is characteristic of pure SiO_2. Over 20% of N_2O in N_2 was necessary to cause the same IR shift. The N_2O was mass spectrometer analyzed and found to contain 20 ppm argon as the only detectable impurity. The flow rate used was 15 standard cc/min, which was chosen to be as large as possible without causing excessive forepressure, in order to reduce the effect of outgassing from the fixturing and chamber walls during sputtering.

Measurement procedures.—This section describes the measurements made and the methods used for measuring.

Thickness.—Since this is a basic measurement required in the determination of etch rate, dielectric constant, and breakdown strength, its accuracy is of the utmost importance. In order to determine thickness, a portion of a silicon wafer with a sputtered dielectric layer was coated with black wax, and the wafer was immersed in buffered HF until the sputtered deposit was completely removed from the unwaxed portion. The height of the step resulting from this procedure was then equal to the thickness of the sputtered deposit. After removal of the wax and after coating the wafer with silver, the step height was determined by the Tolansky method of multiple beam interferometry, which gives the film thickness to within $\pm$ 50 to 100Å. A typical film thickness was 1500Å.

Etch rate.—The etch rate of the dielectric film is perhaps the most sensitive method of detecting slight changes in film structure or composition. Etch rate was determined by measuring the time required to etch completely through the dielectric layer to the bare silicon underneath, as detected by the sudden change in wettability which occurs when the bare silicon surface is exposed. An etchant of 7:1 buffered HF was used for all measurements. This etchant was prepared by dissolving 1 lb of NH_4F in 680 cc of water, and then adding 100 cc of this solution to 15 cc of water.

Infrared transmission spectrum.—IR transmission measurements give an absorption spectrum associated with film composition and structure. In the case of silicon nitride a single broad band is obtained at $\approx$ 12.0μ, while for SiO_2 a sharp band at 9.3μ is obtained. Intermediate compositions give bands between these two values. IR measurements were done routinely on all samples using a Perkin-Elmer dual-beam IR spectrophotometer. Bare silicon was used in the reference beam, and nitride coated silicon was used for the sample.

Dielectric constant—This quantity is determined from the capacitance, electrode area, and nitride thickness using the usual formula (5) $K = TC/\epsilon_0 A$, where K = delectric constant, T = thickness, C = capacitance, A = electrode area, and $\epsilon_0 = 8.85 \times 10^{-12}$ F/m. The capacitance was determined on a Wayne-Kerr or Boonton bridge, which together covered the frequency range from 100 Hz to 1 MHz. The electrode area was measured by photographing the electrode with a calibrated scale, and the thickness was determined as described above.

Breakdown strength.—This measurement was made with the wafer on a movable stage which allowed a set of probes to be brought into contact with each capacitor in succession. To determine breakdown, the I-V trace on a Tektronix 575 curve tracer was observed. The voltage was gradually increased from zero until either the current trace went suddenly off scale, indicating the device had broken down, or until the current through the capacitor (typical area 175 square mils) reached 0.05 mA. At this current level, the I-V trace was so steep that the voltage remained nearly constant to complete breakdown. A typical I-V trace from this measurement is shown in Fig. 6.

I-V measurements.—I-V measurements were made using a Cary vibrating reed electrometer for currents between 10^{-14} and 10^{-9}A and a Hewlett-Packard 425 A microvoltammeter for currents between 10^{-9} and 10^{-4} A.

Types of structures used for dielectric measurements.—Bare 1 ohm-cm n-type silicon wafers were used as substrates for determining physical properties such as etch rate, thickness, and infrared absorption spectra of the oxynitride films. For electrical measurements and capacitor studies the substrates were first coated with a sputtered or pyrolytic oxynitride layer, and were then metallized in a vacuum system. For general electrical measurements, the oxynitride was deposited over this continuous metal film, which served as a common bottom electrode. The top electrodes were 15 mil diameter metal dots formed by etching a second evaporated layer. A schematic of this structure is shown in Fig. 7. In addition, capacitors suitable for mounting on headers were made by etching individual electrodes in the bottom metal layer, followed by oxynitride deposition and top electrode deposition. It was then necessary to etch windows through the dielectric in order to make contact to the bottom electrodes. The capacitors mounted on headers could be used for high frequency measurements and the determination of the temperature coefficient of

capacitance. A schematic of this structure is shown in Fig. 8.

Results and Discussion

Electrode materials.—The properties of Al, Mo, Ni, Cr, Au, and Pt were investigated for use as both top and bottom electrode materials. The best results were obtained with Mo, with Al and Cr second best. In addition, silicon was tested as a bottom electrode material by depositing the oxynitride directly onto bare silicon substrates. Poor adherence of metal to dielectric and low breakdown strength were encountered with Au, Pt, and Ni. Molybdenum for both top and bottom electrodes gave breakdown strengths higher by about a factor of 1.5 over Al-Al or Mo-Al structures. The breakdown strength of Mo-Si MIS capacitors biased so that the voltage drop across the dielectric was the same as that of Mo-Mo structures. Molybdenum as a top electrode gave about 10% greater capacitance, and hence a higher effective dielectric constant than other materials used as top electrodes. This was found to be independent of the bottom electrode material. In addition, Mo is hard, durable, and highly adherent to silicon oxynitride, and its bulk resistivity is only twice that of Al. The Mo was deposited by electron beam evaporation.

Contacts.—A contact material was necessary in capacitors that were to be mounted on headers, since gold wires could not be attached directly to Mo. In addition, the Mo was not electrically continuous at the point where the top electrode crossed over the bottom electrode, so that the contact material had to be extended onto this crossover as shown in Fig. 8. Gold was used for the contact material, but, since it did not adhere well to Mo during processing, a nichrome interlayer was used to provide adherence. This gold-nichrome layer was adherent and provided electrical continuity at the crossover.

Effect of substrate preparation.—The effect of substrate preparation on breakdown strength was very pronounced. This seemed to be a joint effect of both smoothness and cleanliness. In the case of MIM capacitors with Mo bottom electrodes, a much higher breakdown strength was obtained with the common bottom electrode structure than with the structure having individual bottom electrodes. Since the only difference in the fabrication method between the two structures was in the photoresist work done to form the individual bottom electrodes, contamination from this step must have been responsible for the difference in breakdown strength. It was found that the breakdown strength of the individual electrode structure could be increased by either reverse sputtering of the bottom electrodes after photoresist processing or by the deposition of the bottom electrodes through a metal mask, thus avoiding all photoresist work on the bottom electrodes.

Substrate smoothness as defined by the absence of any points of light in dark field illumination also had a strong effect on breakdown. Even devices with a common bottom electrode would show a poorer yield when prepared on poor substrate material. Best results were obtained on substrates which had been etched in HCl gas at 1200°C. These substrates had the best appearance under dark field illumination, considerably better than those cleaned by even the most elaborate wet chemical procedures.

Dielectric properties as a function of N_2O concentration in the sputtering gas.—Measurements of the electrical and physical properties of the sputtered silicon oxynitride films were carried out as described before over a range of N_2O concentrations in nitrogen varying from 0 to 20%. In addition, silicon dioxide was sputtered in a plasma consisting of 50% O_2 in argon in order to obtain a comparison with the N_2O data. Each type of measurement was carried out on 5-10 wafers sputtered under the same conditions, and the results were then averaged. Electrical measurements were made on 50-100 capacitors randomly distributed over each wafer.

The results of these measurements are shown in Table I. The first column, for etch rate, shows a value of 20 Å/min for "pure" silicon nitride, which is in general agreement with that obtained by other workers (6). This value is not as low as the value of 10 Å/min obtained in this laboratory for pyrolytically grown silicon nitride, indicating that the sputtered nitride has a "looser" structure than the pyrolytic nitride. The etch rate values increase monotonically with increasing per cent of N_2O until a value of 1300 Å/min is reached for the 50% O_2 addition, which is somewhat higher than that obtained for thermally grown silicon dioxide.

The second column shows that the IR absorption maximum also changes monotonically from the value for pure silicon nitride to the value for pure silicon dioxide. The location of the IR absorption maximum for sputtered silicon nitride agrees with that for pyrolytic nitride, which indicates the greater sensitivity of etch rate in comparison with IR measurements for detecting slight changes in film structure. Figure 9 shows a series of IR absorption curves for various N_2O concentrations. The next column, for breakdown field, will be discussed separately and in more detail in the following sections.

Measurements for dielectric constant are shown in column four and in Fig. 10. These measurements were

made with molybdenum for both top and bottom electrodes. As mentioned above, the use of molybdenum as a top electrode material gives a higher capacitance and therefore a higher effective dielectric constant than other materials, which accounts for the rather high dielectric constant of 9.1 for pure silicon nitride. The last value in the column, 3.9, agrees closely with that for thermally grown silicon dioxide.

The last column gives the usual figure of merit for capacitors, which is based on the product of dielectric constant and dielectric strength. It is proportional to the maximum capacitance per unit area obtainable with a given dielectric material. The maximum in the figure of merit which occurs for 3% N_2O addition is due to the high dielectric strength at this point. Normally the dielectric having the largest figure of merit would be the most desirable choice for thin film capacitors. However, the effect of capacitor yield is not fully taken into account in the figure of merit, and since yield is of the utmost importance in integrated circuit applications, the better choice is actually the oxynitride made with 5% N_2O addition, as discussed below.

Breakdown strength and yield of capacitors.—While most properties change monotonically with increasing N_2O concentration, the dielectric strength and breakdown strength distribution or capacitor yield, are exceptions and have a maximum in the range of 5-10% N_2O. Here yield is defined as the percentage of dots breaking down within a given range of the most probable breakdown, as determined from a breakdown distribution plot. Figure 11 shows a set of such plots for N_2O concentrations of between 0 and 20% of the reactant gas. The data were obtained from devices having a Mo common bottom electrode and 15 mil diameter Mo dots for top electrodes. To construct these curves the

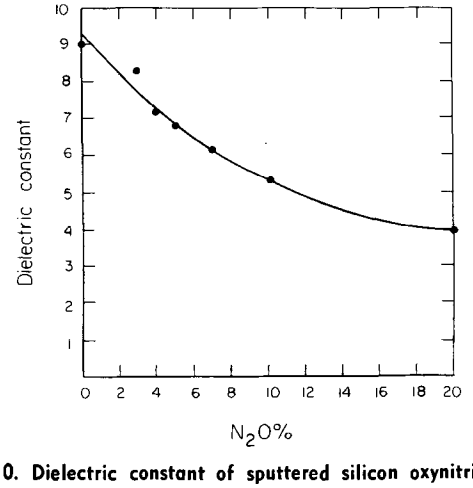

Fig. 10. Dielectric constant of sputtered silicon oxynitride as a function of per cent of N_2O in the sputtering gas.

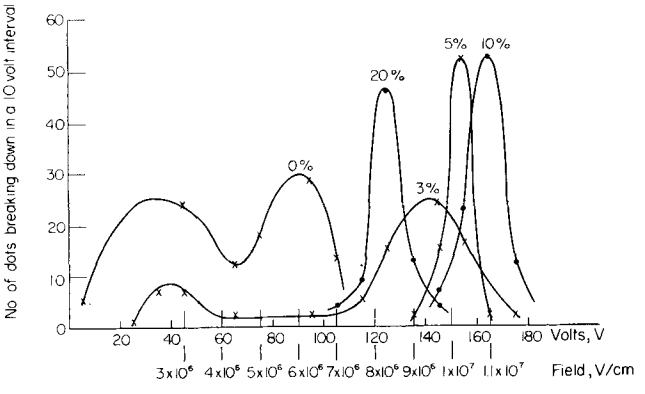

Fig. 11. Effect of N_2O additions on the breakdown voltage distribution curves for MIM capacitors. (Dielectric thickness 1500Å, Mo top and bottom electrodes.)

number of dots breaking down in a particular 10V range is plotted *vs.* the midpoint of that range, and a smooth curve is then drawn through these points. Each curve is based on a sample of 50-100 dots taken at random over the wafer. The curves show the striking effect of the different N_2O additions. The curves for the 0% N_2O addition show a characteristic double-peak structure, which probably indicates the presence of two distinct breakdown mechanisms. The lower peak occurs at a field of $\approx 3 \times 10^6$ V/cm, and the upper peak at $\approx 6 \times 10^6$ V/cm. At 3% N_2O addition the lower peak has decreased substantially in height, while the upper peak has shifted to much higher fields of $\approx 9 \times 10^6$ V/cm. For 5 and 10% N_2O additions, the lower peak has vanished[2] and the upper peak is narrow and is shifted to still higher fields. For N_2O additions in excess of 15% the single-peaked distribution curves remain, but become somewhat broader, and the breakdown field at the peak decreases to about 9×10^6 V/cm. The curve for 20% N_2O illustrates this behavior. A sharply peaked distribution curve means a high capacitor yield will be obtained. For use as capacitors in integrated circuits, the lowest N_2O percentage giving both a high yield and dielectric constant, *i.e.* N_2O additions of 4-5%, are most desirable.

Other dielectric measurements.—High-frequency measurements of capacitance and loss tangent were made on devices with individual molybdenum top and bottom electrodes, which had a dielectric sputtered in the presence of 5% N_2O added to the nitrogen. These capacitors were mounted on TO-5 headers. The loss tangent of these devices was 0.003 at 1 kHz, 0.0015 at 10 kHz, and 0.01 at 1 MHz. These low frequency losses are quite small compared to other thin film capacitors, and the increase at 1 MHz was due to losses in the electrodes (7). The dielectric constant changed by only 3% in going from 100 Hz to 1 MHz. The temperature coefficient of capacitance is + 150 ppm/°C between 25° and 125°C at 1 and 10 kHz. Thus, the measurements show these devices to have highly desirable properties as thin film capacitors.

I-V measurements on MIS samples with 5% N_2O addition showed ohmic conduction to fields of $\approx 1 \times 10^6$ V/cm, followed by a relationship of the form $I \propto \exp(\text{const } V^{1/2})$ all the way to breakdown. Typical currents through a 15 mil diameter dot were 10^{-12} A at a field of 1×10^6 V/cm and 200 μA at 1.2×10^7 V/cm. There was only a slight polarity dependence, which with the observed I-V relationship probably indicates a bulk limited Poole-Frenkel conduction mechanism (8).

Observations on breakdown processes in silicon oxynitride.—Molybdenum top electrodes of devices with high breakdown voltage were observed through a microscope. As the applied field was gradually increased to about 5×10^6 V/cm, tiny sparks appeared at

[2] Sometimes a few capacitors break down at low voltages, but they are a very small fraction of those which have higher voltage breakdowns.

random across the surface. During this time, momentary current spikes were superimposed on the I-V trace of the device. If the voltage remained at this value, the sparking gradually decreased and stopped. When the sparking ceased, so did the current spikes. At this point, the initially smooth electrode surface exhibited tiny pits. The observed sparking therefore represented localized breakdown which burned away the molybdenum at faults in the dielectric. The striking result, however, was the fact that after the sparks had disappeared, the field could be increased typically to a value of 10^7 V/cm until the whole molybdenum electrode disintegrated at once. In contrast, other electrodes, such as gold and platinum, exhibited a general breakdown at the lower fields that resulted only in the onset of sparking with molybdenum electrodes.

As Table I indicates, the high ultimate breakdown voltage was observed only with molybdenum, and then only with silicon nitride containing a particular range of N_2O concentrations. This suggests that there exists a fortunate combination of molybdenum and silicon oxynitride that results in the rapid consumption of molybdenum when heated. This reaction of the molybdenum is so rapid that the localized electrical breakdown process is terminated before it can affect the surrounding dielectric. This termination must be due to removal of the field over the dielectric at the localized regions where the molybdenum electrode is burned away. The high breakdown strength of Mo-silicon oxynitride capacitors thus results from the self-healing action of this particular electrode-dielectric combination. For other electrode material-silicon oxynitride combinations, the electrode is apparently not consumed rapidly enough to prevent lateral (probably thermal) propagation of the breakdown process leading to premature distruction of the capacitor.

Summary

The rf reactive sputtering of Si in 5% N_2O + 95% N_2 mixtures yields a silicon oxynitride with many desirable properties for use in integrated circuit applications. Principally, these are high breakdown strength, high yield, a dielectric constant of 6.8, and an etch rate of $\approx$ 200 Å/min. Due to the increased breakdown and dielectric constant, the maximum capacitance per unit area is about 2.5 times that of sputtered silicon dioxide. In relation to pure silicon nitride (0% N_2O) the most striking features are the increased etch rate, increased breakdown strength, and high yield as shown by the sharply peaked breakdown distribution curve.

Mechanism of Heterogeneous Deposition of Thin Film Rutile

R. N. Ghoshtagore

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

The kinetics of rutile (TiO_2) thin film deposition on silicon from the reaction $TiCl_4 + O_2 \rightarrow TiO_2 + Cl_2$ has been studied over a range of temperature (673°-1320°K), titanium tetrachloride partial pressure (2.9×10^{-2} to 9.28×10^{-1} Torr), and oxygen partial presure (2.5×10^{-1} to 760 Torr) in a horizontal flow system with a rf-heated susceptor. Between 673° and 1120°K the reaction has been found to proceed by a Rideal-Eley mechanism with the surface reaction rate constant (k_s) following the relationship $k_s = 4.9 \times 10^3 \exp(-0.775 \pm 0.044\ eV/kT)$, over a range of partial pressures and flow rates. Homogeneous reaction becomes appreciable above 1120°K.

The vast influence of solid surfaces on reaction kinetics has been the subject of catalysis for more than a century. But a detailed understanding of the molecular mechanism of such interactions requires a knowledge of chemical reaction equilibria and kinetics, vapor pressures of all the participating species, fluid dynamics of the system, and the adsorption and desorption characteristics (including surface diffusion) of all the chemical entities. So few of these quantities are known for most systems that a complete theoretical and/or experimental analysis of most chemical vapor deposition reactions becomes almost impossible. However, several guidelines are available in this direction.

Chemical vapor deposition under large supersaturations or chemical driving force, is controlled by growth, producing a fine-grained, roughly random deposit (1), with growth rates tending to approach a maximum as fixed by the slowest (rate determining) process. Under low supersaturations (fixed by vapor-

phase mass transport) nucleation can become rate-controlling, preferred-orientation deposits can form (epitaxy or oriented growth), and growth rates can be less than the maximum.

Titanium dioxide thin films are currently the subject of many investigations (2-5) since their potentially high dielectric constants would be of value in numerous applications. Since very little is known about the kinetics and mechanism of chemical vapor deposition of TiO_2 film (6, 7) from the system $TiCl_4 + O_2 \rightarrow TiO_2 + Cl_2$, this paper reports some measurements designed to elucidate such information. The polycrystalline films prepared have the rutile structure (8). Detailed examination of the structural and electrical properties of these films has been made, and the results will be communicated in future publications.

Experimental Technique

The experiments utilize the chemical reaction between titanium tetrachloride and oxygen on a heated substrate in a conventional horizontal quartz tube "silicon epitaxial" reactor at atmospheric pressure (9). Purified titanium tetrachloride (prepared by multiple distillation of 99.995% pure material) in thermostat-held quartz bottles is used as a titanium source bubbler through which a carrier gas of ultrapure argon or ultrapure oxygen (Matheson) is passed at a controlled rate. This gas (saturated with $TiCl_4$ vapor) is then mixed with additional ultrapure oxygen and/or argon through a set of calibrated flowmeters, liquid traps, and filters and the mixture reacted on a quartz encapsulated high purity graphite susceptor heated by rf induction. The over-all reaction can be described by

$$TiCl_4(g) + O_2(g) \rightleftharpoons TiO_2(\text{rutile})(s) + 2Cl_2(g) \quad [1]$$

Free energy changes (ΔF) for this reaction, calculated from known thermochemical data (10), are −33.0, −30.3, −27.7, and −25.2 kcal/mole at 700°, 900°, 1100°, and 1300°K, respectively.

Single crystal silicon wafers (15-20 mils thick) of (111), (100), and (110) orientations, obtained from Texas Instruments, were lapped, polished in Linde B, and then chemically etched in 15:5:3 HNO_3:HAc:HF to a mirror finish by the supplier. Substrates for TiO_2 deposition were prepared by scribing 5 mm squares out of these wafers. The substrates were then degreased by boiling in trichloroethylene and acetone and chemically polished in 15:5:3 HNO_3:HAc:HF to remove about 5-10μ of surface layer. The substrates were then blown dry in dry nitrogen, mounted on the susceptor, and baked for 20-30 min in ultrapure hydrogen at 900°-1000°C to remove any residual oxide film (11).

The reactor atmosphere is then flushed with ultrapure argon and the substrate temperature is adjusted, the temperature being monitored with an optical pyrometer [corrected for absorption by the quartz tube wall, reactor atmosphere, and substrate emissivity (12)] and/or an infrared radiation pyrometer. Titanium tetrachloride vapor in the carrier gas is then passed into the reactor (after prolonged purging to vent), argon flow is discontinued and mainline ultrapure oxygen is introduced at a predetermined flow rate. The deposits and substrates are then pushed off the susceptor at regular time intervals with a quartz push rod and the deposition rate is determined from an average of 16-18 samples run for 8-9 different time periods. Film thicknesses were determined by reference to an ellipsometrically calibrated color chart. The temperature of titanium tetrachloride was maintained at 25° ± 0.5°C and that of the substrates to ±5°C.

Results

The kinetics of the polycrystalline rutile film growth reported in this section was independent of substrate orientation [(100), (110), or (111)], resistivity level (0.01-30 ohm cm), and resistivity type (8) (arsenic and phosphorus-doped n-type or boron-doped p-type). So, no mention of these factors will be necessary in the following.

Flow rate relationships.—Dependence of rutile thin film growth rates on the total gas flow rate is shown in Fig. 1(a) and 1(b). The slope of the mass transfer controlled region (where the growth rate is a function of the flow rate) approximates the theoretical value (13) of 1/2 at all p_{TiCl_4} and at temperatures at or below 1100°K. Deposition rates could not be determined at very low flow rates because of nonuniformity of deposition (apparently controlled by nucleation). Apparent slope of > 1/2 at 1205° and 1320°K will be discussed in a later section. At all temperatures and p_{TiCl_4} (p_{O_2} = 1 atm) the surface reaction rate (as measured from the growth rate) attain a constant value at high flow rates. Boundary layer theory predicts that under such circumstances the gas-phase mass-transfer coefficient is much higher than the surface-reaction rate constant and the reaction kinetics is controlled by an activated process (adsorption, desorption, or surface reaction). Figure 2 shows a plot of the maximum p_{TiCl_4} that can be used to attain an activated process control of the heterogeneous reaction as a function of total flow rate at constant p_{O_2} of 1 atm. At any temperature under 1100°K they can be described by the relationship

$$V = C/p_{TiCl_4} \quad [2]$$

where V is the minimum flow rate and C is a tempera-

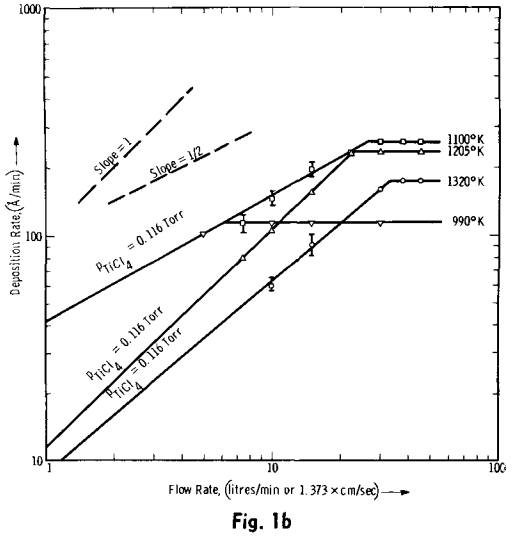

Fig. 1b

Fig. 1. Flow rate dependence of rutile deposition rate on silicon in 54 mm ID horizontal quartz tube epitaxial reactor at different substrate temperatures and titanium tetrachloride partial pressures, and a fixed oxygen partial pressure of 1 atm (susceptor dimensions: 43 x 13 x 150 mm).

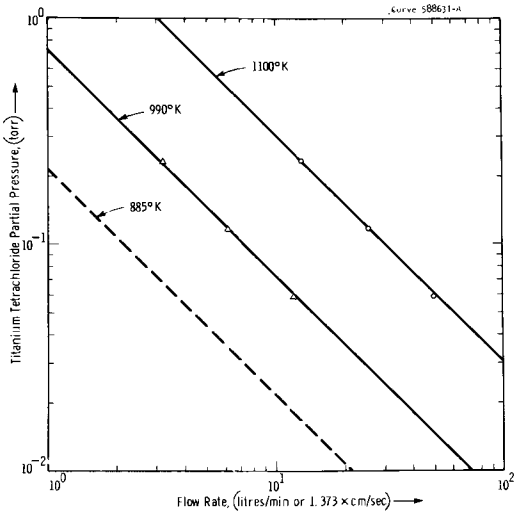

Fig. 2. Maximum titanium tetrachloride partial pressure for activated rutile deposition on silicon as a function of average gas flow rate at different temperatures (oxygen partial pressure ≅ 1 atm).

ture-dependent constant. No attempt was made to obtain such a relationship at higher temperatures because as can be seen from Fig. 1(b) they do not follow such a simple model.

Reactant partial pressure relationships.—Deposition rates of the rutile thin film as a function of p_{TiCl_4} is shown in Fig. 3 at different substrate temperatures and at a fixed p_{O_2} of 1 atm. At each of these temperatures the total flow rate was maintained such that the deposition rate was independent of the flow rate (*cf.* Fig. 1 and 2) at each p_{TiCl_4} used. As is evident from Fig. 3 the surface reaction is of first order with respect to titanium tetrachloride at or under 1100°K. But at 1205° and 1320°K the apparent reaction order is more than one and is a function of temperature.

The surface reaction rates (as measured from deposition rates) as a function of p_{O_2} at different but constant p_{TiCl_4} is shown in Fig. 4 at two temperatures where the reaction is of first order with respect to titanium tetrachloride. The reaction is of one-half order at low oxygen partial pressures, but becomes zero order above a minimum p_{O_2} whose value increases with increasing p_{TiCl_4} as shown in Fig. 5. All these data were obtained at or above a total flow rate extrapolated from Fig. 2 using ultrapure argon as diluent. Since the data of Fig. 1 were obtained for p_{O_2} = 1 atm, their validity at low p_{O_2} was verified and found to hold. As can be seen from Fig. 5, within the

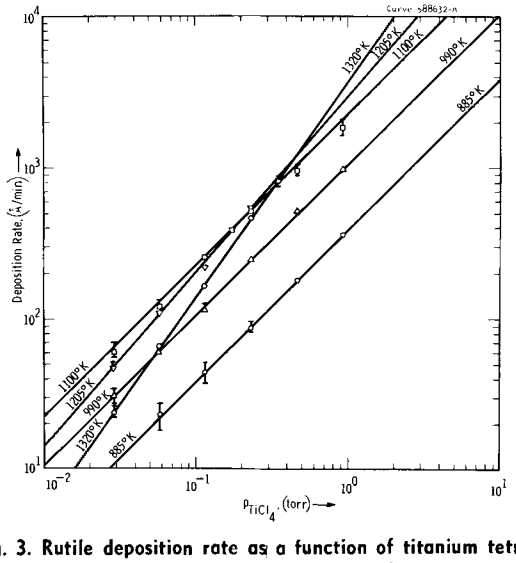

Fig. 3. Rutile deposition rate as a function of titanium tetrachloride partial pressure at different temperatures (oxygen partial pressure ≅ 1 atm).

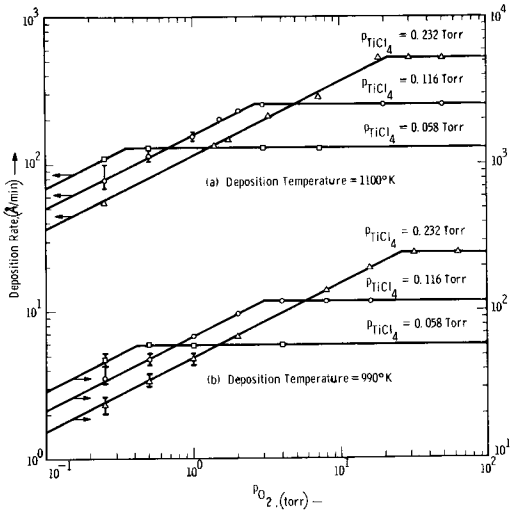

Fig. 4. Oxygen partial pressure dependence of rutile deposition rate at different titanium tetrachloride partial pressures.

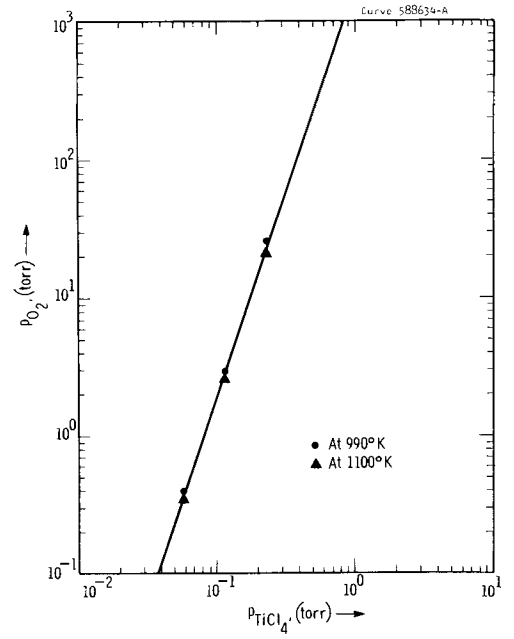

Fig. 5. Minimum oxygen partial pressure required for zero order (with respect to oxygen) activated rutile deposition at different titanium tetrachloride partial pressures.

range of experimental accuracy, the minimum p_{O_2} required for oxygen pressure independent deposition rate at any p_{TiCl_4} is independent of temperature (below 1100°K). This can be described by the equation

$$p_{O_2} = 1.8 \times 10^3 \, (p_{TiCl_4})^3 \qquad [3]$$

where the partial pressures are expressed in millimeter Hg. It can be noted from Fig. 5 that the maximum p_{TiCl_4} for 1 atm of total pressure is of the order of 7.6×10^{-1} Torr. This explains why the data of Fig. 3 could not be determined at higher p_{TiCl_4}.

Temperature coefficient of the heterogeneous reaction.—Deposition rates are plotted as a function of inverse absolute substrate temperature in Fig. 6. These data represent the rates of the rate-determining activated process because the volume flow was maintained at or above the value where the growth rate is independent of flow rate. At 850° ± 5°C the film growth rate attained a maximum at each of the p_{TiCl_4} values used. Surface deposition rates in units of molecules $TiO_2/cm^2/sec$ shown in the left ordinate of Fig. 6 was calculated from the determined deposition rate and theoretical density of 4.26 for rutile. The surface reac-

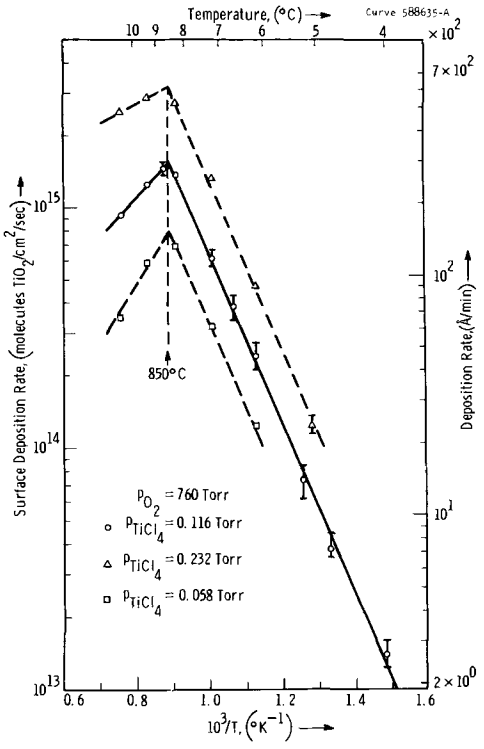

Fig. 6. Temperature dependence of rutile deposition rate at 1 atm of oxygen partial pressure and different titanium tetrachloride partial pressures.

tion rate constants were calculated from the data of Fig. 6 using the relationship

$$G = \frac{C_G}{N} k_s \qquad [4]$$

where G is the growth rate in cm/sec, C_G is the titanium tetrachloride gas phase concentration in molecules/cm³, N is the number of TiO_2 molecules per unit volume of the film, and k_s is the surface reaction rate constant (cm/sec). These data for k_s are shown in Fig. 7 as a function of absolute substrate temperature and below 850° ± 5°C can be represented by the equation

$$k_s = 4.9 \times 10^3 \exp(-0.775 \pm 0.044\ \text{eV}/kT)\ \text{cm/sec} \qquad [5]$$

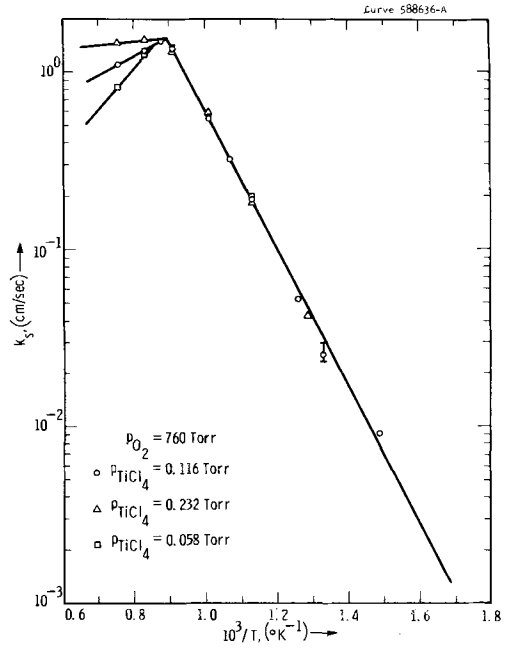

Fig. 7. Arrhenius plot of the surface reaction rate constant

This activation energy of 0.775 ± 0.044 eV/molecule agrees with that for the velocity of reaction (0.796 eV) determined by Antipov *et al.* (6). The reasons for the invalidity of Eq. [5] above 850°C will be discussed later.

Reaction efficiency.—Fractional efficiency (E) of this heterogeneous reaction at any temperature and p_{TiCl_4} (p_{O_2} = 1 atm) can be calculated from the equation

$$E = \frac{G}{C_G V} \qquad [6]$$

where G is the film deposition rate in moles TiO_2/cm²/sec, C_G is the gas phase $TiCl_4$ concentration in moles/cm³, and V is the average calculated (from reactor cross-section) gas velocity in cm/sec. These data are shown in Fig. 8. Below 850°C all these lines (at different p_{TiCl_4}) have a slope of 0.65 eV. At any temperature below 850°C the efficiency increases proportionally with p_{TiCl_4} at fixed p_{O_2} of 1 atm. This explains why these data are not comparable with those of Antipov *et al.* (6) and Shchegrov (7), neither of whom published p_{TiCl_4} data of their experiments. The fact that the efficiency of the heterogeneous reaction decreases with increasing temperature at any p_{TiCl_4} is consistent with the fact that the equilibrium constant of the reaction represented by Eq. [1] [calculated from the available thermochemical data (10)] also decreases with increasing temperature.

Discussion

Reaction behavior below 850°C.—It is generally accepted that a gaseous reaction involving two species on a solid surface involves the following steps: (*i*) diffusion of reactants to the surface, (*ii*) adsorption of one or both of the reactants on the surface, (*iii*) surface reaction preceded by surface diffusion and formation of activated complex, (*iv*) desorption of gaseous products with or without some surface migration, and (*v*) diffusion of products away from the surface. The following reasons will let one exclude steps (*i*) and (*v*) as the rate-controlling mechanism in this system:

(*1*) Steps (*i*) and (*v*) are not activated processes whereas the rate studied was that for an activated process. To be certain that the studied rate was that of an activated process the value of the average boundary layer thickness was calculated from a completely mass-transfer controlled model and found to be very much higher than that calculated from fluid dynamic

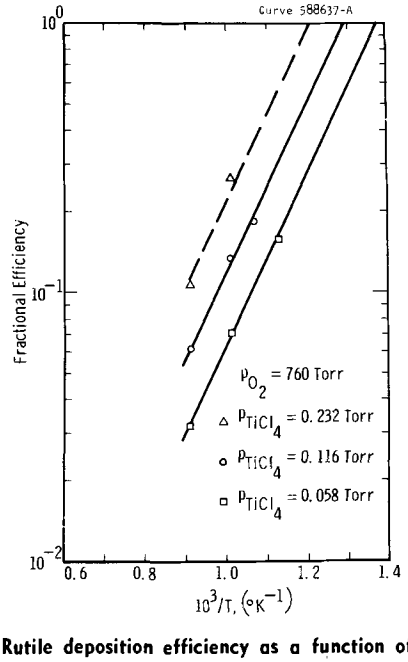

Fig. 8. Rutile deposition efficiency as a function of temperature at different titanium tetrachloride partial pressures.

relationships. Moreover, the determined deposition rate was found to vary exponentially with inverse absolute temperature and not with 1.5-2.0 power of temperature.

(*II*) The value of activation energy of surface reaction rate constant (Eq. [5]) is too high to be that of diffusion in the gas phase.

Surface diffusion and desorption of the gaseous product chlorine (step *iv*) also appears to be very unlikely as a rate-limiting step because:

(*a*) chlorine is not known to be strongly adsorbed on either silicon or rutile;

(*b*) at any temperature the calculated p_{Cl_2} (from thermodynamic K_p, the stoichiometric Eq. [1] and the condition that $p_{O_2} + p_{TiCl_4} + p_{Cl_2} = 1$ atm) is 3 to 4 orders of magnitude higher than that in the immediate vicinity of the surface (calculated from the efficiency of reaction and gas phase p_{TiCl_4}) and so the concentration of chlorine is almost negligible;

(*c*) chlorine introduced into the reactor with the reactants (at about the same concentration as $TiCl_4$) had no detectable effect on the deposition rate.

Now, of the two remaining possible rate-controlling steps [steps (*ii*) and (*iii*)] there are two broad possibilities:

(*a*) Langmuir-Hinshelwood Mechanism. In this mechanism the reaction occurs between both the species adsorbed on adjacent sites with considerable competition for the adsorption sites.

(*b*) Rideal-Eley Mechanism. Here the reaction occurs between an adsorbed species and a gaseous species without any competition for the adsorption sites.

The major distinguishing feature of these two mechanisms is that in the former the rate (R) will pass through a maximum as the partial pressure of either reactant is varied, whereas in the latter the rate will reach a limiting value when the partial pressure of one of the reactants is varied (which is the one that is adsorbed). It has been shown before that

$$R \propto (p_{O_2})^{1/2} (p_{TiCl_4}) \quad [7]$$

at low p_{O_2} and all p_{TiCl_4}, whereas

$$R \propto p_{TiCl_4} \quad [8]$$

at high p_{O_2} (depending on p_{TiCl_4}) and all p_{TiCl_4}. Since the surface reaction rate is proportional to adsorption it is clear that Rideal-Eley mechanism is operating with atomic oxygen as the chemisorbed species and molecular $TiCl_4$ colliding on the surface from the gas phase. The fact that at any temperature p_{O_2} required to saturate the surface and follow Eq. [8] increases more than proportionally with p_{TiCl_4} can be explained by considering the unknown equilibrium: O_2(gas) → O(chemisorbed).

For a closer examination of other possible intermediate species that may be involved in the reaction and the nature of the surface reaction the following facts are noted:

(*i*) $TiCl_4$ is only a dimer in the liquid (14) and so can be expected to be virtually unassociated in the gas phase at high temperatures.

(*ii*) Available thermodynamic data (10) indicate the equilibrium concentrations of TiCl, $TiCl_2$, and $TiCl_3$ above 400°C to be 7-10 orders of magnitude less than that of $TiCl_4$.

(*iii*) $TiOCl_2$ is not an intermediate product in this reaction (7). This was reverified during this study using a very sensitive technique due to Fowles *et al.* (15) and found to hold.

(*iv*) The deposition rates reported here were at high supersaturations and growth-controlled region, and the deposition rate and preferred deposit orientations were substrate orientation independent.

(*v*) ESR studies show the presence of both charged and uncharged adsorbed oxygen atoms on TiO_2 (16-18).

(*vi*) No silicon oxide could be detected at the film-substrate interface (IR spectroscopy).

Combining this information with the Rideal-Eley mechanism a detailed atomic mechanism can be pictured. After the supersaturation-controlled initial nucleation on silicon, atomic oxygen (charged or uncharged, dissociation after adsorption or adsorption of dissociated molecules) is chemisorbed on titanium sites only. During the collision process of gaseous $TiCl_4$ molecules with these chemisorbed oxygen atoms titanium-oxygen linkage must be formed for tetrahedrally bonded titanium of $TiCl_4$ to be incorporated in octahedral configuration in bulk rutile. These configurational changes of $TiCl_4$ in catalyzing organic reactions have been discussed in the literature (19). Subsequent reaction of such bonded $TiCl_4$ with the surface oxygen atom in the adjacent site produces rutile (which can chemisorb more atomic oxygen) and removes chlorine atoms (ultimately as molecules). However, there does not seem to be any clear reason for producing rutile form of TiO_2 exclusively by this system in contrast to other known systems producing anatase (2). From this atomic mechanism it appears that the surface reaction is the rate-controlling step in this heterogeneous reaction (at high p_{O_2}).

Reaction behavior above 850°C.—In discussing the reaction behavior above 850°C it should first be pointed out that the recorded rate at these temperatures were also of some activated process or processes. The major abnormalities of the reaction at these temperatures are listed below.

(*i*) In the mass transfer control range (Fig. 1) the slope of the apparent reaction rate as a function of flow rate is more than one-half, *i.e.*, less apparent deposition rate than would be predicted by vapor phase mass transport.

(*ii*) At fixed p_{O_2} (= 1 atm) and temperature more than proportional amount of TiO_2 is deposited with increasing p_{TiCl_4} (Fig. 3).

(*iii*) At fixed p_{O_2} (= 1 atm) the drop in the apparent surface reaction rate as a function of $1/T$ is slower the higher the p_{TiCl_4} (Fig. 6 and 7).

It is clear now that a process which decreases the effective p_{TiCl_4} is involved. The probabilities are (*a*) sudden change in chemisorption rate of atomic oxygen, (*b*) depletion of p_{TiCl_4} by reaction on the reactor tube wall, and (*c*) depletion of p_{TiCl_4} by homogeneous reaction. Since such sharp change (as shown in Fig. 6) in the adsorption of a gas on a solid surface is not known for any system and hardly any TiO_2 deposit is found on the reactor tube wall above 850°C, the first two possibilities appear improbable. Moreover, since the homogeneous reaction at any temperature and high p_{O_2} (zero order range) will consume a fixed fraction of $TiCl_4$, the more is the input p_{TiCl_4} the more is the unreacted p_{TiCl_4} available for surface reaction. Thus homogeneous reaction becomes quite appreciable and can account for all the anomalous behavior of the reaction above 850°C, including the disparity of the behavior of Arrhenius plots of Antipov *et al.* (6) and those reported in this study (Fig. 6 and 7). Since Antipov *et al.* (6) designed their experiments to determine the total reaction rate of Eq. [1], they could not distinguish the fraction of the reaction that proceeded by adsorption on the solid (TiO_2) surface.

Conclusions

The heterogeneous reaction of titanium tetrachloride and oxygen on silicon surface proceeds by Rideal-Eley mechanism. Atomic oxygen is chemisorbed on the titanium sites of the initial rutile nuclei and molecular $TiCl_4$ reacts with this oxygen from the gas phase. This explains why the reaction is first order with respect to $TiCl_4$ and one-half order with respect to oxygen up to 850°C. No intermediate chemical species like TiCl, $TiCl_2$, $TiCl_3$, and $TiOCl_2$ seem to be involved. Above 850°C the Arrhenius relationship does not hold because of the appreciable consumption of titanium tetrachloride by the homogeneous gas phase reaction. Because of very low chemisorption rate of atomic

oxygen on rutile at high temperatures a larger amount of oxygen is required (for maximum possible rate at any temperature) than indicated by the stoichiometric equation.

The Solidus Boundary in the GaP-InP Pseudobinary System

L. M. Foster* and J. E. Scardefield

IBM Research Division, Yorktown Heights, New York

ABSTRACT

The solidus boundary in the GaP-InP system was determined by a technique which uses the electron microprobe to analyze the solid phase of compositions equilibrated in the solid-liquid phase field. The boundary shows the substantial positive deviation from ideal behavior found in a number of other analogous III-V systems. Vegard's law for the relation between lattice parameter and composition holds for this system.

$Ga_xIn_{1-x}P$ is one of the systems that is currently being investigated for p-n junction electroluminescence. Hilsum (1) pointed out the possibility of achieving direct band-to-band transitions up to about 2 eV in energy in compositions of this material that contained substantial amounts of InP. Lorenz *et al.* (2) showed experimentally that direct gap character actually is preserved up to about $x = 0.8$, where band-to-band transitions up to about 2.2 eV at room temperature should be possible.

GaP-InP forms a series of solid solutions over the entire composition range, and a T-x diagram similar in general character to those of GaSb-InSb, InSb-AlSb, GaSb-AlSb, InAs-GaAs, InSb-InAs, and InP-InAs is expected (3). It is desirable to know the details of the T-x diagram in order to explore the possibility of single crystal growth from the melt.

Panish (4) has determined the liquidus in the GaP-InP pseudobinary system. The melting points of the end products, InP and GaP, are known from the literature. In the present study the solidus over the entire range of mixed crystals was determined to complete the diagram.

Experimental

Previously, the solidus boundaries of similar systems were generally determined in one of two ways (3). In the first method, finely ground mechanical mixtures or rapidly quenched two-phase ingots are annealed at progressively higher temperatures until complete homogenization is achieved, as evidenced by an x-ray pattern showing only a single phase, then the melting point of the mixed crystal is measured. This method was first employed by Stohr and Klemm (5) to establish that miscibility existed over the complete range of compositions in the Ge-Si system.

In the second method, an intimately mixed, two-phase charge is equilibrated at a temperature that is above the solidus but below the liquidus, then it is rapidly quenched. The composition of the solid phase is then found by determining its lattice parameter and comparing this with the values of the lattice parameter obtained as a function of composition for single-phase alloys that are prepared separately by the first method (or by assuming that Vegard's law holds without experimental verification). This method was employed by Woolley and Lees (6) to determine pseudobinary diagrams with InSb as one component, and has been discussed in detail by Woolley and Smith (7).

We have employed a modification of this technique to determine the solidus in the GaP-InP system. In our case, the quenched, two-phase mixture that had been equilibrated above the solidus was analyzed with the electron microprobe. This provided a direct de-

* Electrochemical Society Active Member.

termination of the composition of the solid phase and circumvented the additional step of preparing homogenized samples for x-ray analysis.

The sample was in the form of a pellet pressed from a finely ground GaP-InP powder mixture with the aid of a fugitive binder. After outgassing to remove the binder, the pellet was sealed in a quartz capsule with a minimum of free space so that the phosphorus loss during dissociation of the sample on melting would not significantly change the composition of the charge. At temperatures below 1200°C the capsule had sufficient strength to contain the phosphorus pressure arising from decomposition of the charge. For higher temperatures, the capsule was backed by a graphite container. For very high temperatures it is desirable to contain the pellet in a separate alumina container to prevent contact with the quartz. This is essential for the study of the reactive systems, InAs-AlAs and InP-AlP, for which the same assembly is being used (8). The assembly is shown in Fig. 1.

The composition of the starting mix for a particular temperature was chosen to be approximately along the straight line connecting the melting points of the two terminal compounds. This assured very roughly equal amounts of liquid and solid at equilibrium.

The charge was held at the chosen temperature for one week. The initial experiments showed that equilibrium had been achieved in that time. No survey was made to determine whether a shorter time would have been adequate. After the holding period, the capsule was removed rapidly from the furnace. It was established that the equilibrated solid could be readily distinguished from the quenched liquid when this procedure was followed and that a more rapid quench was not necessary.

The sintered pellet was sectioned approximately through the center and lapped with 3μ grit. For the electron microprobe analysis, an 0.8μ beam was moved across the lapped surface in 10μ steps. Pure GaP and InP standards were included, and the usual corrections for absorption and atomic number were made. Ga, In, and P counts were taken. Ga and In were considered to offer the greatest precision and over-all compositions based on one agreed to within ± 5% with those based on the other.

Results and Discussion

The success of this technique depends entirely on whether equilibrium is indeed achieved, and, if so, whether the equilibrium solid can be clearly distinguished from the nonequilibrium quenched liquid. The micrographs in Fig. 2 of three representative samples show that the liquid and solid can be clearly distinguished. The top sample was the more typical and shows a mosaic structure with large grains of the solid separated by the fine-particle quenched liquid. The center sample shows an unusual case where much of the solid is found in one large grain situated near one edge of the pellet, possibly as a result of a very slight temperature gradient. For the bottom sample, the initial composition was inadvertently very near the

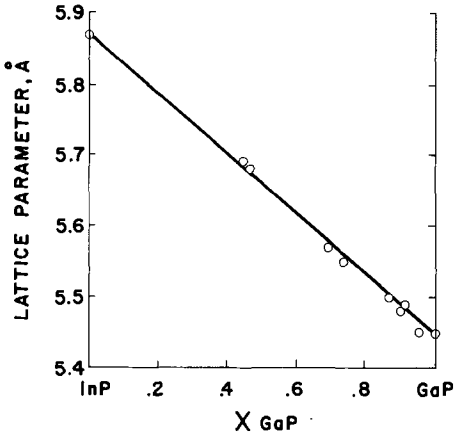

Fig. 5. Lattice parameter vs. composition for GaP-InP system

solidus boundary so only a small amount of liquid remained between the solid grains.

Criteria for equilibrium are that the phase richest in GaP must be the equilibrium solid, and the individual grains of this phase must be of constant composition across their entire breadth. That these criteria were met is evident from Fig. 3, which shows the microprobe data for part of the two top samples of Fig. 2. The top trace shows an excursion across four prominent arms of the structure and the indium-rich quenched liquid in between. The bottom trace shows an approach along an indium-rich valley and arrival at the large equilibrated grain where the composition remained constant within the precision of the method for its entire width of about 1000μ (100 data points). A sufficient excursion was made across each of the eight samples of the series to ensure that a number of plateaus were included in the data, and that no regions more rich in GaP than the plateaus existed.

The data are shown in Fig. 4. The InP melting point of 1070°C was taken from Koster and Ulrich (9). This agreed within ± 2 degrees with the recent determination by Panish and Arthur (10). The melting point for GaP of 1465°C was taken from Richman (11). The liquidus curve shown by the dashed line was determined by Panish (4) and is included in Fig. 4 to complete the diagram.

The dependence of the lattice parameter on composition was determined on the same series of samples by making powder x-ray patterns from the finely ground pellets. A typical pattern consisted of discrete reflections corresponding to the smallest parameter (highest GaP content) phase, followed at larger angle by broad bands of close-spaced reflections from the nonhomogeneous, In-rich, quenched liquid. The results are shown in Fig. 5. It is seen that Vegard's law is followed within the precision of the x-ray data on these samples, which were not ideally suited to x-ray work because of the large amount of second phase present.

Acknowledgment

The authors are indebted to Messrs. J. D. Kuptsis and J. Angilello for the electron microprobe and x-ray analyses, respectively; and to Mr. R. J. Chicotka for supplying the InP.

Insulating Films on Ni-Fe-Mo Alloy Powders by Fluorination

J. H. Swisher, F. Schrey, P. K. Gallagher, and E. O. Fuchs

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

A new method has been developed to produce insulating films on Ni-Fe-Mo alloy (permalloy) powders by fluorination. The method consists of passing argon-fluorine gas mixtures through a fluidized bed of the powder at 350°C. Magnetic permeability and electrical resistivity data are given for bars pressed from the powders. Film thicknesses of 0.6μ or greater are required to obtain pinhole-free films on the powders; however, high resistivities are obtained with thinner films by subsequently oxidizing portions of the particle surfaces exposed by the pinholes. With an improvement in the stress-relief annealing procedure, this method would be competitive with the presently used $Mg(OH)_2$-Na_2SiO_3 coating process for inductance coils.

Magnetic alloy powders which have been coated with an insulating film and pressed into toroids are used commercially in inductance coils. For one widely used coil, an 81% Ni, 17% Fe, and 2% Mo alloy powder (2 Mo permalloy) is coated with a magnesium hydroxide-sodium silicate insulating film. The powder is first produced from cast ingots using a grain-boundary embrittlement technique. Sulfur is added to the liquid alloy, and a grain-boundary sulfide network forms during hot rolling which causes the grains to break apart. The insulation is applied as an aqueous slurry and dried by baking. Talc and zinc stearate are added to the slurry to facilitate pressing the powders into cores. The processing procedures are described in greater detail by Harendza-Harinxma (1). Improvements in coating technology are needed for miniaturization of the coils, higher permeability, better process control, and lower cost.

Flaschen and Garn (2) used fluorination as a means of forming insulating coatings on aluminum and copper. Resistivities of the order of 10^{14} ohm-cm were obtained for AlF_3 and CuF_2 films; however, the films were hygroscopic and tended to oxidize at 500°C (AlF_3) and 250°C (CuF_2).

Nickel and its alloys are used as container materials for handling fluorinating agents because nonhygroscopic, protective NiF_2 films are formed when nickel is exposed to fluorine. Cannon *et al.* (3) review previous studies on the fluorination of nickel and copper alloys and also present additional data on the passivation reactions. The literature on the fluorination of nickel alloys led us to believe that adherent, insulating films could be formed on molybdenum permalloy powder by direct reaction in a fluidized bed reactor. In pursuing this idea, films of several thicknesses were formed by varying the fluorination time and temperature and the fluorine partial pressure. Resistivity and permeability measurements on pressed bars were used to characterize the properties of the materials.

Experimental

The permalloy powder was taken from a commercial lot of material produced by the Western Electric Company, Chicago. These powders are screened to pass a 120 mesh sieve (125μ screen opening). The average particle size is about 40μ. A sample of powder insulated with a $Mg(OH)_2$-Na_2SiO_3 coating was obtained from the same supplier. This sample served primarily as a comparison standard for the fluorinated materials.

Figure 1 shows a schematic diagram of the reactor used for fluorinating the powders. The dimensions of the inside of the reaction chamber were 4 cm diameter by 4 cm high. Nickel was used in all parts of the reactor exposed to fluorine. Argon-fluorine gas mixtures were passed through a preheating coil, then through a porous nickel frit with a 75μ pore diameter. The reactor was contained in a vertical resistance furnace. A thermocouple in the furnace was used to control the furnace temperature, and another thermocouple inserted through the cover plate in the reactor was used to monitor the temperature of the sample The temperatures used for fluorination were in the range from 200° to 450°C. Most of the treatments were done at 350°C, with reaction times ranging from 15 min to 8 hr.

The usual procedure was to add 100g of powder to the reactor with nitrogen flowing through the system. A gas flow rate of 1 liter/min was used. This flow rate was sufficient to maintain movement in the bed of particles; however, the density of the particles was too great to fluidize the bed in the usual sense. For most of the work, mixtures of 10% F_2 in Ar were prepared by metering the individual gases. Undiluted fluorine and premixed cylinders of 1 and 5% F_2 in Ar were used in a few experiments. The fluorine was 99% pure. The sum of the impurity concentrations of HF and CO_2 was 0.4%, the sum of the N_2 and O_2 concentrations was 0.5%, and CF_4 was present at the ppm level. The only purification step used was passage of the fluorine through an NaF trap to remove HF.

Commercially, the insulated powders are pressed into toroids of various sizes at a pressure of 200,000

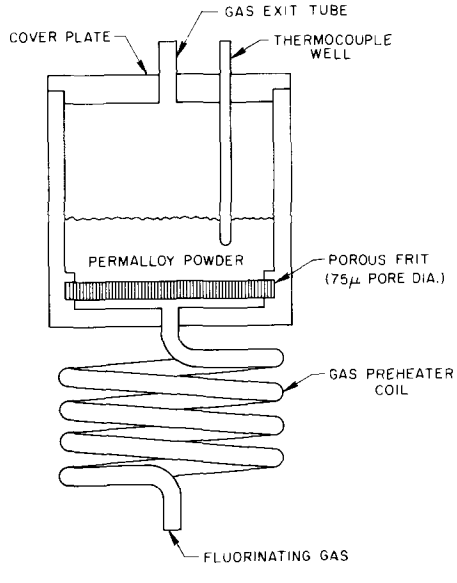

Fig. 1. Fluidized bed reactor

psi. The pressed cores are stress relieved in a forming gas atmosphere at 625°C. The magnetic permeability of the annealed cores is determined from an a-c inductance measurement. The quality of the insulation is determined by winding the cores with copper wire and measuring the eddy current losses in the material.

Facilities were not readily available to obtain the same data on the fluorinated samples, so the following method was devised to determine the quality of the experimental materials. Rectangular bars, 0.25 x 0.25 x 4.3 cm, were pressed from the powder at 100,000 psi. The permeability was determined from a d-c measurement, using a balanced solenoid and a Lowell Electronics DC Hysteresigraph. The electrical resistivity of the pressed bars was measured with an ohmmeter when the resistivity was sufficiently low. For higher resistivity values, a 500V d-c bridge was used.

Stress-relief annealing of the bars insulated by fluorination proved to be an important step in the processing. Heating the bars in a reducing or an inert gas atmosphere to 625°C resulted in loss of fluorine from the samples by reduction or vaporization. Annealing in air at 625°C resulted in partial conversion of the fluoride to oxide. While breakdown of the insulation did not occur during air annealing, the permeability of the material could not be increased, which was the purpose of the annealing step. The most satisfactory procedure proved to be encapsulation of the bars under vacuum in quartz tubing with a small amount of CuF_2 added to the capsules. The capsules were then annealed at 625°C for 2 hr. The commercial analogue of encapsulation would be bell jar annealing.

The fluorine content of the treated powders was determined by measuring the weight loss of samples after hydrogen reduction of the fluoride film. The method consisted of passing hydrogen over the specimens in a controlled-atmosphere tube furnace for 2 hr at 650°C. Under these conditions, the fluoride is readily reduced by hydrogen to form HF, which is continuously swept from the furnace. No additional weight loss was observed when the specimens were held for longer times. The fluorine content obtained for one sample was cross-checked with a magnetic moment measurement using a pendulum magnetometer and also with a wet chemical analysis. The magnetic moment measurement yielded a fluorine content about 10% greater than by the weight loss method, and the wet chemical analysis gave a fluorine content about 15% greater. The weight loss method was adopted because it was considered sufficiently accurate for the present purpose, and it was the most convenient to use.

Results

A metallographic study of the permalloy powders insulated both by fluorination and with the standard 0.3μ $Mg(OH)_2$-Na_2SiO_3 coating was made by Bennett (4). Two scanning electron micrographs obtained from this study are reproduced in Fig. 2. Figure 2(a) was obtained from a purposely mixed sample of uninsulated and oxide-insulated powders. At the beam potential of 2 kV, the insulated particle appears much darker than the uninsulated particles. The dark spots on the surfaces of the uninsulated particles are presumed to be sulfide and/or oxide inclusions which were present at grain boundaries in the original ingots. It is this second phase material at grain boundaries that causes the ingots to disintegrate into fragments during the final stage of rolling.

Figure 2(b) was obtained from a powder sample treated in an Ar plus 10% F_2 mixture at 350°C for 2 hr. There appeared to be fluoride crystal growth swirls on the particles, meaning that the fluoride films are not uniform in thickness; however, there was complete coverage of the metal surfaces, at least under these fluorinating conditions.

The results of an initial series of experiments are listed in Table I. The gas composition was Ar plus 10% F_2 and the reaction time was 2 hr. Direct comparisons should not be made between the permeability values given in Table I and values obtained on commercially processed powder cores. Differences in the magnetic test methods, powder compaction pressures, and other processing procedures lead to large differences in the permeability values obtained. A comparison was made on the oxide-coated material using the two processing and test methods. The permeability was about four times higher by the a-c inductance test on cores pressed at 200,000 psi than by our d-c method on bars pressed at 100,000 psi. When the same comparison was made on fluoride-coated material, the difference was about a factor of three.

The film thicknesses in Table I were computed by considering the particles to have a uniform diameter of

40μ. The fluoride film was assumed to be (Ni, Fe)F_2 and to have a density of 4.4 g/cm^3. (NiF_2 has a density of 4.6 g/cm^3, and FeF_2 has a density of 4.1 g/cm^3.) By dissolving the fluoride film from the surfaces of one powder sample in boiling water and chemically analyzing for Ni, Fe, and Mo, the ratio of Ni to Fe in the fluoride was found to be 3.12 (weight basis). The corresponding ratio for the starting alloy was 4.77, so some enrichment of iron in the fluoride phase occurred. No molybdenum was detected in the fluoride, which is understandable in view of the high vapor pressure of MoF_6.

Examination of the data in Table I leads to the conclusion that the rate of fluorination is strongly temperature dependent. The rate was fast, but still controllable at 350°C. At higher temperatures, the exothermic nature of the reaction led to temperature excursions in the sample of more than 200°C. At 350°C there was an initial increase of about 30°C during the first few minutes of exposure, then the temperature in the bed decreased slowly and approached the temperature of the furnace. In all subsequent experiments, the furnace temperature was maintained at 350°C.

Data are plotted in Fig. 3 which show the computed film thickness as a function of the square root of reaction time. The rate during the first hour is essentially parabolic and is presumed to be controlled by diffusion through an adherent film. At longer times, a gradual acceleration occurs which is attributed to a loss of adherency of the film. Although the diffusing species in NiF_2 is known to be the fluoride ion (5), interdiffusion of metal and fluoride ions may occur in (Ni, Fe)F_2 films. The observation that the Ni to Fe ratio in the fluoride differs from the ratio in the underlying metal is an indication that interdiffusion may be occurring.

Figure 3 shows data relating the permeability of pressed bars, both before and after annealing in quartz capsules, to the computed film thickness. Corresponding values are plotted for material insulated with a $Mg(OH)_2$-Na_2SiO_3 coating. The film thickness in the oxide-coated material is taken to be 0.32μ (6). The limiting permeability obtainable in the pressed bars is 39.7, which is the value obtained when uninsulated powder is pressed and annealed. In Fig. 4, the permeabilty of the fluorinated specimens can be seen to decrease in a regular manner with increasing film thickness.

The theoretical permeability of pressed powder cores is given by the following equation (6).

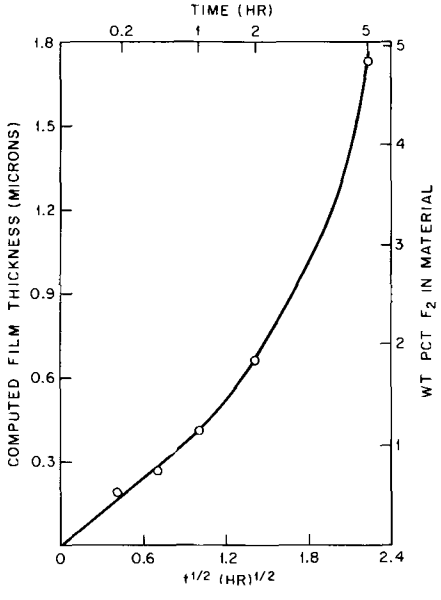

Fig. 3. Film thickness vs. time plot for fluorination of permalloy powder in Ar + 10% F_2 at 350°C.

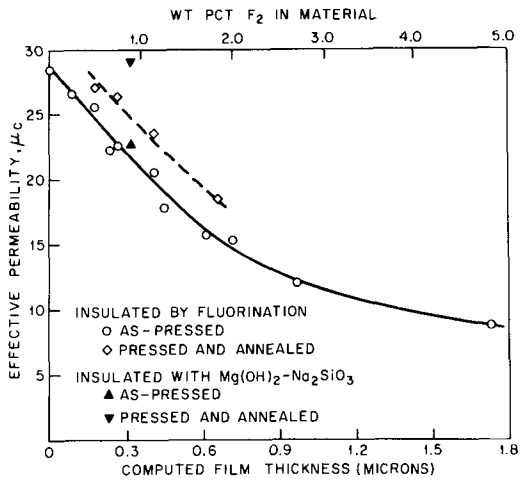

Fig. 4. Permeability of pressed bars of insulated permalloy powder as a function of film thickness.

$$\mu_c = \frac{\mu}{\tau(\mu - 1) + 1} \qquad [1]$$

where μ_c is the effective permeability of the core, μ is the permeability of the magnetic particles, and τ is the ratio of the length of the flux path through the "air gaps" to the total length of the magnetic circuit. Here "air gap" includes both the insulating film and voids in the pressed material. Higher permeabilities can be achieved by decreasing the air gap and by annealing the compacts to increase the permeability of the particles. Greater compaction pressures and thinner insulating films both decrease the air gap and increase the effective permeability.

Notice in Fig. 4 that while the as-pressed permeability of the oxide- and fluoride-coated materials are nearly the same for the same film thickness, the oxide-coated material is somewhat better after annealing. The reasons for this difference are not obvious. One possibility is that the fluoride film thickens during annealing, due to oxygen or fluorine pickup within the capsule.

In Fig. 5, data are plotted which show the variation of the electrical resistivity of pressed bars with film thickness. In the range of film thicknesses from 0 to 0.6μ, the logarithm of the resistivity increases approximately linearly with film thickness. While this behavior can be rationalized qualitatively in terms of

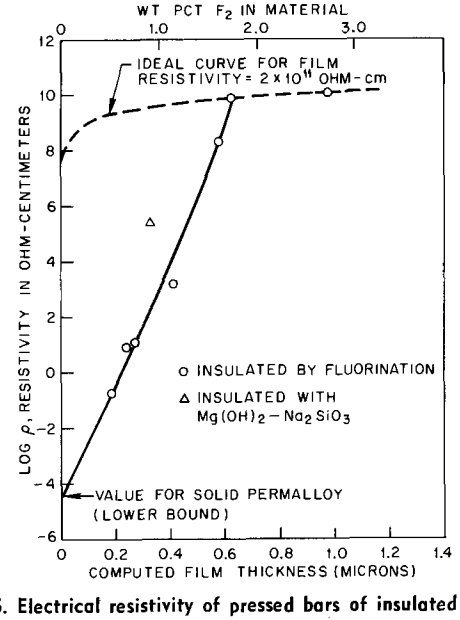

Fig. 5. Electrical resistivity of pressed bars of insulated permalloy powder as a function of film thickness.

variations in charge-carrier concentrations across the film, the results of other experiments demonstrated that pinholes and other defects to a large degree limited the resistivities obtained in the thinner films. When thin fluoride films were formed on permalloy strip specimens and gold spots evaporated onto the fluoride films, electrical continuity between the gold spots and the underlying metal was observed. It was also found that the resistivity of pressed bars in which the fluoride film thickness was 0.2-0.4μ could be increased by about three orders of magnitude by air baking the bars at 400°C for 5 hr. Thus, by oxidizing the base metal under the pinholes in the film, resistivity values were obtained which were about the same as for the $Mg(OH)_2$-Na_2SiO_3 insulated material with the same film thickness. There was no measurable change in the permeability of the materials after this heat treatment.

Referring again to Fig. 5, when the film thickness increased from 0.6 to 1.0μ, the resistivity increased by a much smaller amount, indicating that conduction through pinholes was no longer important. An approximate calculation based on these data yielded a fluoride film resistivity of 2 x 10^{11} ohm-cm. The estimated uncertainty in this value is half an order of magnitude. For films thicker than 1μ, the resistivity decreased somewhat, due presumably to the loss of adherence of the thicker films to the metal particles. This effect was also mentioned in connection with the results shown in Fig. 3. Using a value of 2 x 10^{11} ohm-cm for the fluoride resistivity, the ideal curve in Fig. 5 was computed for pinhole-free insulation on the powders.

Discussion

Fluorination as a means of insulating permalloy powder offers some advantages over the presently used process of forming a complex oxide film by applying an aqueous slurry to the particles and removing the water from the slurry by heating. A fluorination process is simpler, more direct, and should in principle lead to lower costs and better process control. Fluorinated powders can also be pressed into dense and strong toroids without the use of pressing aids. There are some limitations, however, which must be overcome before a fluorination process can be considered better than the presently used commercial process. Among these limitations are defects present in the films of the desired thickness and the difficulty of annealing the parts after pressing.

The advantages of forming defect-free fluoride films on the powders are apparent if we examine the ideal resistivity curve in Fig. 5. A 0.1μ defect-free film should result in a resistivity of 10^9 ohm-cm in the pressed material, which is about four orders of magnitude higher than in the presently used 0.3μ oxide insulation. With this reduction in film thickness from 0.3 to 0.1μ, the permeability would be increased by a factor of three from Eq. [1], if the "air gap" were reduced by the same factor.

The safety hazard in fluorination processes, particularly when fluorine gas is used, is another factor of importance. While undiluted fluorine reacts vigorously and sometimes explosively with nearly all substances the same reactions often occur at controllable rates when fluorine is diluted with an inert gas. In our experiments at 350°C, the fluorination of permalloy powder could not be controlled when undiluted fluorine was used. With 10% F_2 in Ar, the fluorination reaction was easily controlled as long as the 350°C operating temperature was not exceeded. By diluting further to 5% F_2 in Ar, no noticeable change in the reaction rate was evident. (Some of the points in Fig. 4 and 5 were obtained using 5% F_2 in Ar.) When 1% F_2 in Ar was used, the reaction rate was still appreciable, although slower by approximately a factor of two. Based on these data, dilution of the fluorine by a factor of approximately one to one-hundred is recommended for large-scale processing because of safety considerations.

Fluorination of permalloy powder can be achieved without using fluorine gas. A weaker fluorinating agent such as NH_4F can also be used. A few experiments were performed to demonstrate that fluoride films are formed when permalloy is exposed to NH_4F. Solid NH_4F and permalloy powder samples were placed in adjacent boats in the hot zone of a horizontal tube furnace at 350°C. The vapor pressure of NH_4F is appreciable at this temperature. Helium was passed over the NH_4F, then over the permalloy sample. Insulating fluoride films were formed on the permalloy samples in this way, although a more elaborate technique was needed to coat the particles uniformly. A better technique might have been to insulate the particles in a two-stage fluidized bed reactor, the first stage to introduce NH_4F into a carrier gas and the second stage to react NH_4F in the gas with the permalloy sample. In both the NH_4F and the direct fluorination experiments, an alternative method would have been to drop the powder through a furnace chamber with the fluorinating gas flowing upward through the chamber.

Thus far the discussion has been limited to materials for powder cores. Permalloy is also used in tape-wound cores, high quality transformer laminations, and as the soft magnetic component in twistor wire. There is no reason why fluorination could not be used to form insulating films required for these applications. Here a fluorination process might be more attractive than for powder cores because annealing could be done before insulating the material.

Summary

Molybdenum permalloy powders were successfully insulated by direct reaction with argon-fluorine gas mixtures. Permeability and electrical resistivity data were obtained on bars pressed from powders insulated under various fluorinating conditions. The magnetic and electrical properties were comparable to but not better than properties obtained commercially with an oxide-coating process. The potential advantages of a fluorination process are simplicity, better control over properties, and possibly lower cost. The disadvantages are handling problems associated with fluorinating agents and the difficulty of annealing without breakdown of the insulation.

Acknowledgments

Single Crystal Growth of Titanium Carbide by Chemical Vapor Deposition

Takehiko Takahashi,* Kohzoh Sugiyama, and Hideaki Itoh

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

ABSTRACT

Various forms of titanium carbide crystals were deposited on graphite substrates from the vapor phase consisting of hydrogen, titanium tetrachloride, and a hydrocarbon in the temperature range of 1200°-1350°C. The correlations between the crystal morphology and the growth conditions (temperature, gas flow-rates, concentrations, impurities, etc.) were investigated. The decomposition of the hydrocarbon was found to play an important role on the growth process. By x-ray diffraction, it was concluded that the growth direction of these crystals was mainly <111> although sometimes kinked toward <1$\bar{1}$1>. The growth mechanism of the single crystal was further studied by observation of the etching figures of the cross section which showed hexagonal growth layers. Finally the tensile strength of needle or pillar crystals was measured and a linear relation (on log-log scale only) was confirmed between the diameter and the strength.

Titanium carbide, one of the typical interstitial compounds having a high melting point of 3250°C and Vicker's hardness of 3200 kg/mm^2, has been well-known as a super-hard and refractory material. Boule single crystals of titanium carbide have been prepared by the Arc-Verneuil process and many studies have been made on its crystal structure and physical properties (1-4). Few papers, however, have been published on the preparation of needle or whisker forms of the single crystal from vapor phase, except a brief report by Hertl (5) who obtained fibrous titanium carbide from TiO_2 and colloidal carbon in a chlorine atmosphere.

The purpose of this investigation was to deposit needle, whisker, pillar, or polyhedron single crystals at least several millimeters long and to investigate the growth reaction, crystal morphology, and growth mechanism. In discussing the crystal growth process, the theory on whisker growth of Wagner *et al.* (6) was instructive as well as the experimental study on silicon carbide (7) and boron carbide whiskers (8). The extrapolated values of the tensile strength may be compared with published values of other whisker materials.

Experimental

The schematic diagram of the experimental apparatus is illustrated in Fig. 1. Titanium carbide single crystal was prepared according to the reaction: $TiCl_4 + C_xH_y + H_2 \rightarrow TiC + HCl + C_mN_n$, where C_xH_y was propane in this experiment. The reaction was performed in a horizontal quartz tube, the inside diameter of which was about 35 mm. A cylindrical graphite tube (50 mm in length, 30-32 and 10-23 mm in outside and inside diameters, respectively) was placed at the center of the tube, and served as the substrate for deposition of titanium carbide. The tube was heated by induction. Titanium tetrachloride (bp 136.5°C) was introduced into the hydrogen stream by means of a bubbling-type saturator, maintained at 90°C. The gas flow rates of dried hydrogen and propane were measured with a flow meter. After precleaning the reaction tube with hydrogen, the flow of mixed gases of titanium tetrachloride, hydrogen, and propane was initiated. It was necessary to keep the gas mixture at 90°-100°C by cooling water at the inlet which was 20-50 mm in front of the surface of the graphite substrate to prevent the propane from decomposing excessively due to radiation from the heated graphite. The substrate temperature was measured through the glass window W_1 with a photopyrometer and the growth process was observed through the other glass window W_2. Impurities such as Au, Pd, H_2PtCl_6, HgCl, $MnCl_2$, $Mn(NO_3)$, $AgNO_3$, Na_2SO_4, etc., were incorporated into the graphite and the impurity effect on the crystal growth was investigated.

The morphology of each single crystal was observed through the microscope. The deposits were identified by x-ray diffractometer and the growth directions were determined by the Laue method. The cross section of needle and pillar crystals was etched in hot concentrated nitric acid for 5 min, after abrading the surface.

The fracture strength along the crystal axis was measured by the buoyancy method, whereby the crystal was fixed at both ends on copper supports, one of which was connected to a buoy via thin tungsten wire and was loaded continuously in tension by draining the water which sustained the buoy.

Results

Growth conditions.—The conditions for single crystal growth were investigated as a function of temperature, gas flow rate, and the shape of the graphite substrate in the reaction tube. The temperature dependence was noteworthy; when the temperature of the substrate was below 1200°C, a thin film of titanium carbide (9) was coated on the surface, and when above 1400°C, polycrystals were deposited rapidly. In this experiment, the single crystal growth was studied in detail in the temperature range of 1200°-1400°C. Figure 2 shows the influence of temperature and the propane gas flow rate on the crystal growth, when the hydrogen gas flow rate was 4.0-8.0 cc/sec (linear velocity 27.5-55.0 cm/sec in the graphite tube). It should be noted from Fig. 2 that a suitable temperature range for single crystal growth is from 1240°-1280°C. Using a

* Electrochemical Society Active Member.

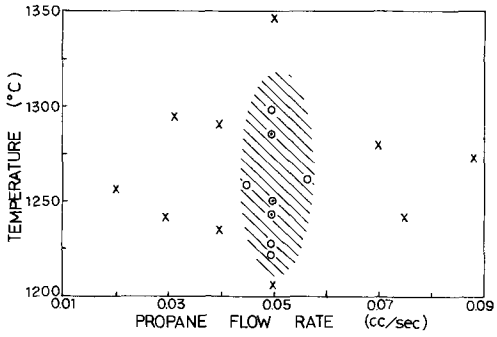

Fig. 2. Influence of temperature and propane gas flow rate on crystal growth.

propane gas flow rate of 0.05 cc/sec [0.8 m/o (mole per cent)] is essential. The influence of hydrogen gas flow rate and temperature on the crystal morphology is shown in Fig. 3 at a fixed propane gas flow rate of 0.05 cc/sec. Needle or whisker crystals were found to deposit at a relatively high flow rate of about 7.7 cc/sec (53.1 cm/sec), while pillar crystals were deposited at a lower flow rate of 6.2 cc/sec (43.8 cm/sec), and polyhedron crystals at a higher temperature range of 1250°-1300°C. These experimental data were obtained when the inside diameter of substrate was 10 mm. As the inside diameter decreased a number of needle crystals 6-7 mm long were deposited, but it was difficult to obtain reproducible data.

Crystal morphology.—Figures 4 and 5 show the needle crystals observed from two different directions. They occur in radiating clusters, apparently from a single nucleus. The initial growth rate is from 5 to 7 mm/hr, but the rate decreases abruptly in 60-80 min. This seems to show that the growth region of needles is limited to the thin gas film over the graphite surface, because some long needles kink toward the appropriate atmosphere at the tip. Whiskers from 2 to 12μ in diameter were observed together with fine needles at a higher linear flow rate of hydrogen gas (Fig. 6 and 7). A few pillar single crystals, shown in Fig. 8, grow in different directions from a single nucleus just like the needle crystals. These are from 30 to 50μ in diameter and from 1 to 5 mm in length, but the growth rate is lower than that of needles. One pillar crystal is magnified in Fig. 9, where the side plane of the hexagonal prism and the tip of the truncated pyramid are observed. Each side has a smooth plane and a metal gloss, except for a special case described later. Polyhedron crystals grown for several hours in a high temperature range, have a different sort of mor-

phology, for example, hexahedron or octahedron. Figure 10 shows the polyhedron crystals, whose tips are octagonal pyramids, and they grow large enough to become adjacent to each other.

Growth direction.—After the identification with the titanium carbide ASTM card, the growth direction was determined by the Laue method. X-ray beam from a molybdenum target was radiated on a needle or pillar crystal mounted vertically on the goniometer head. Figure 11 (a and b) are Laue photographs taken

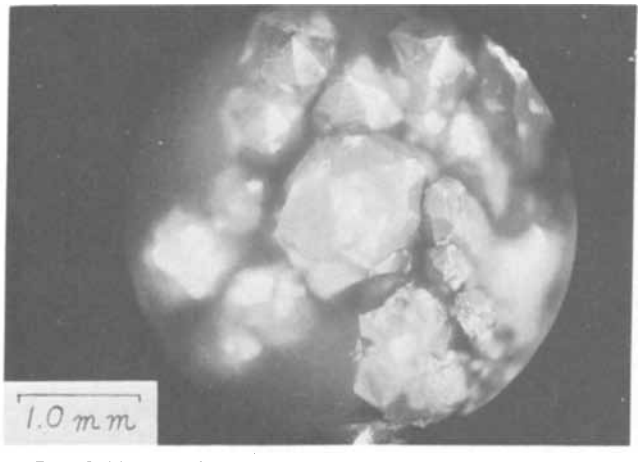

Fig. 10. Micrograph of polyhedron crystals (temperature, 1320°C)

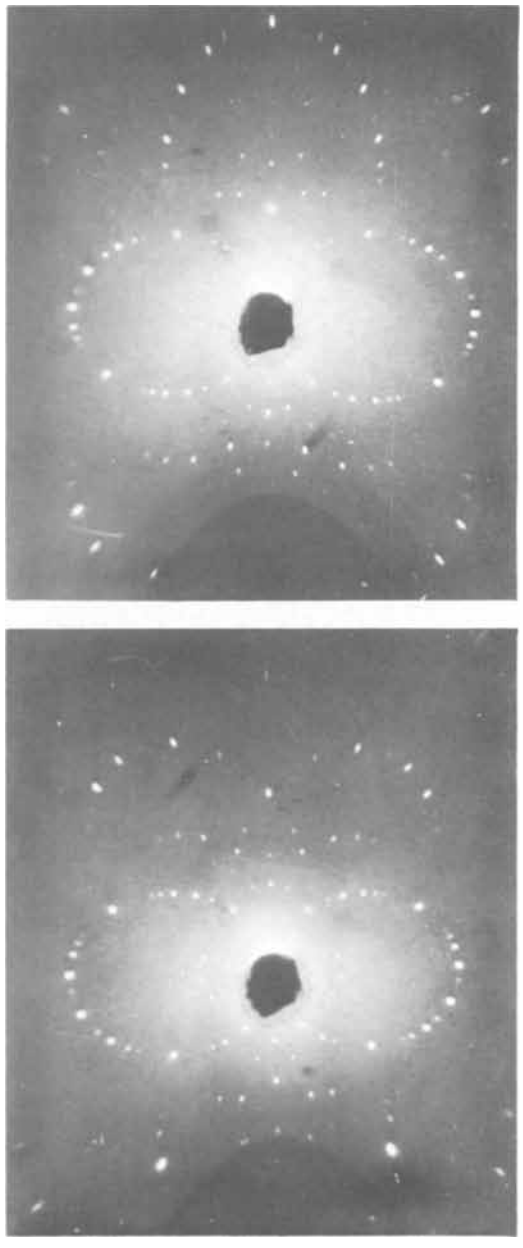

Fig. 11. Laue photographs (target, molybdenum; exposure, 40 kV, 15 mA, 90 min; crystal-to-film distance, 16 mm). (a) Laue spots with a mirror symmetry, radiated from a given direction, (b) Laue spots from a rotated direction by 60° around the axis.

from a given position (a), and from the rotated position by 60° (b). It is suggested from the two mirror symmetries in the figures that <111> is the growth direction, since titanium carbide has a NaCl type crystal structure. Therefore, each side of the hexagonal prism observed in Fig. 9 is apparently (110). Figure 12 shows the kinking of needle crystals described above, and the measured angle of the kinked tip to the original direction <111> is about 108°, so that the kinking direction is assigned the same form $<1\bar{1}1>$.

Etching figure and growth steps.—Etching of the cross section in hot concentrated nitric acid reveals the growth layers shown in Fig. 13 and 14. Figure 13 shows the etching figure of a needle crystal, where the nearly circular growth layers are observed. On the other hand, there are regular hexagonal growth layers in Fig. 14, which show the etching figure of a pillar crystal. Each side of the hexagon is found to correspond to the (110) plane indexed previously. At the center of the cross section, there is a circular projected part about 10μ in both figures, which is difficult to etch.

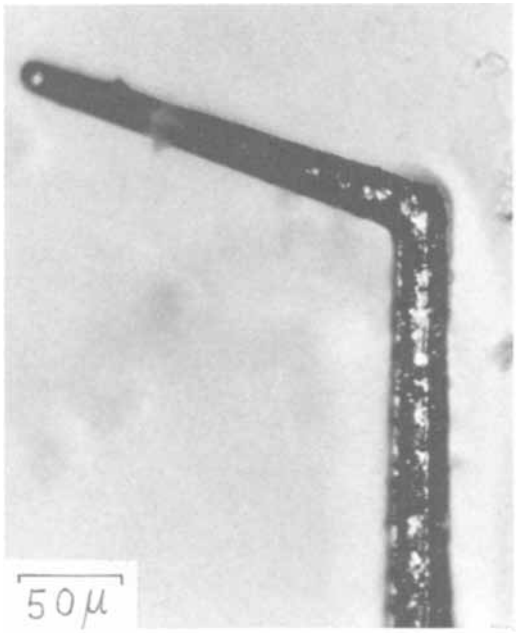

Fig. 12. Micrograph of a kinked needle crystal

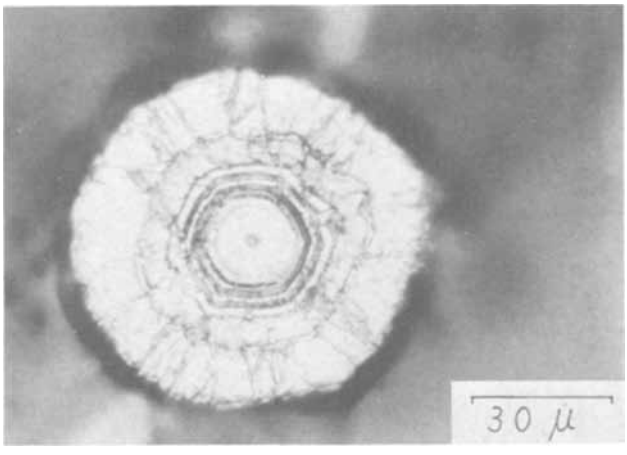

Fig. 13. Etching figure on the cross section of a needle crystal

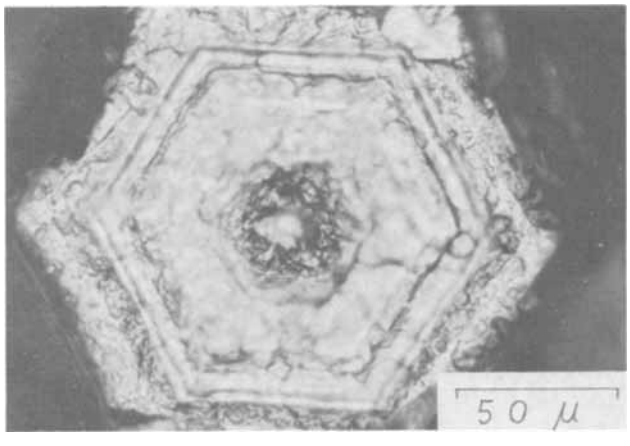

Fig. 14. Etching figure on the cross section of a pillar crystal

Continuous large growth steps were observed on the side of a pillar crystal (Fig. 15 and 16 magnified) and each step has a secondary step at the edge. Figure 17 shows a few irregular and larger growth steps for a crystal grown at the higher temperature range.

Impurity effect.—Though it was difficult to get an exact quantitative knowledge about the impurity effect, we could establish the difference of deposition rate by incorporating a few kinds of impurities into various parts of the graphite substrate. For example, manganese nitrate shows a positive effect on the crystal growth, as shown in Fig. 18. It was found similarly that Au, Pt, Pd, Ag, etc., represented positive effects, while Cu, Fe, Co, Zn, etc., showed negative effects.

Tensile strength.—The fracture strength *vs.* the diameter of needle or pillar crystals is plotted on logarithmic scales in Fig. 19. A linear relation can be seen from Fig. 19. The extrapolated value to 5μ is about 1000 kg/mm^2. The tensile strength of titanium carbide whiskers, therefore, is estimated to exceed that of iron (250 kg/mm^2), sapphire (350 kg/mm^2), and alumina (560 kg/mm^2) for the same diameter (10).

Discussion

Vapor phase reaction and crystal morphology.—The fact that the propane gas flow rate of 0.05 cc/sec (0.8 m/o) and cooling of gas mixture at 90°-100°C were essential for growth of a single crystal, means the decomposition reaction of hydrocarbon play an important part in the formation of titanium carbide single crystals. This suggestion seems to be supported by the study of Pearce (11) who discussed the reaction mechanism and concluded the initial formation of pyrocarbon is important rather than the reduction of the halide to elemental titanium. An appropriate temperature distribution and gas diffusion process in the reaction tube should be employed to provide pyrocarbon on the surface of the graphite substrate. In addition, a constant supersaturation at the growth tip should be maintained to obtain a given crystal morphology as described by Gatti (8). When the inside diameter of the cylinder is large, for example, it is difficult to introduce the proper quantity of pyrocarbon while keeping the temperature of the atmosphere constant. Consequently the reproducibility decreases. However, with small inside diameters, the linear flow rate of hydrogen gas is higher, making it easier to grow a fine whisker, as shown in Fig. 3.

Growth mechanism.—Observations of the etching figures (Fig. 13 and 14) suggest differences in the growth mechanism between the center and the circumference. It is convenient to describe two steps; one is the whisker growth and the other is the side growth of the needle or whisker crystals. Through microscopic observations, however, small globules could not be found at the tip of the whisker or needle crystals. Also impurities were not always essential for whisker growth as indicated before. So it is not acceptable to explain whisker growth by V.L.S. mechanism (12). More detailed investigations on the microstructure and the impurity effect should be made to learn the mechanism of whisker growth.

The growth layers in Fig. 13 and 14 suggest the variations of chemical composition. The growth steps in Fig. 15 and 16 show that the lateral growth rate increases when bunched growth steps pass through any side. Therefore we conclude the pillar crystals grow by the movement of steps on the side simultaneously with the tip growth, while in the case of the needle crystals, the side growth is a little slower than the tip growth.

Conclusion

Single crystals of titanium carbide were grown from the vapor phase in the temperature range of 1200°-1350°C. It was found that the gas flow rate or the shape and the impurities of the substrate greatly affected the crystal morphology. Above all, the contribution of propane gas flow rate was so remarkable that the decomposition of propane gas was considered to define strictly the growth range of single crystals.

Polyhedron crystals were deposited in the high temperature range, and have smooth and glossy planes on the crystal surface. Pillar crystals grew gradually as hexagonal prisms, while needle crystals grew rapidly from a growth nucleus. Whisker crystals about 3μ in diameter were observed among them. The growth direction of needle or pillar crystals was found to be <111> by the Laue method and the kinking direction was $<\bar{1}11>$.

Etched hexagonal growth layers, the large growth steps, and impurity effects suggested that the tip growth of whiskers was followed by the movement of growth steps on the side.

From the linear relation between the strength and the diameter, the tensile strength of 1000 kg/mm^2 was estimated at 5μ in diameter. Titanium carbide whiskers, are worthy of note, as a material having superior high tensile strength, as well as the other mechanical properties.

Structure and Electrical Properties of $FeO-P_2O_5$ Glasses

D. L. Kinser

Vanderbilt University, Nashville, Tennessee

ABSTRACT

Dielectric loss measurements, d-c conductivity, and transmission electron microscopic observations were made on thermally treated $55FeO-45P_2O$ (mole fraction) glasses. The results of this study indicate that this glass is partially devitrified after low temperature treatments. This dispersed crystalline phase gives rise to Maxwell-Wagner-Sillars heterogeneous dielectric dispersions similar to those previously attributed to electron hopping resonance in these glasses.

The electrical properties of $FeO-P_2O_5$ glasses have been investigated by Hansen (1). He has reported the d-c conductivity behavior of a $55FeO-45P_2O_5$ glass with varying $Fe^{3+}/Fe^{3+} + Fe^{2+}$ ratio, with a minimum at equal concentrations. Hansen *et al.* (2) have also reported a dielectric dispersion in three iron phosphate glasses with different $Fe^{3+}/Fe^{3+} + Fe^{2+}$ ratios. These dielectric relaxation peaks were tentatively attributed to resonance of the hopping electrons between ferrous and ferric sites. His x-ray and transmission electron microscope investigations of these glasses revealed no evidence of crystalline phases or liquid-liquid separation after annealing at 500°C.

Previous work by the present author (3) in sodium phosphate-vanadium pentoxide glasses has shown the appearance of dielectric losses with thermal treatments that cause small amounts of crystallization. Marked changes in the d-c conductivity due to thermal treatment were also reported in vanadium glasses by Hamblen *et al.* (4).

The present paper presents results of dielectric measurements on a $55FeO-45P_2O_5$ glass with different thermal treatments. A dielectric loss peak in the audio frequency range has been shown to appear concurrently with the formation of crystals that were observed by transmission electron microscopy. The dielectric loss, d-c conductivity, and transmission electron microscopy were correlated using heterogeneous dielectric models.

Experimental Procedure

Glasses examined in this study were prepared from reagent grade Fe_2O_3 and P_2O_5, melted 1 hr at 1300°C in platinum exposed to air in an electric furnace. The glass was poured in a steel mold that yielded samples approximately 17 mm diameter and 5 mm thick. All samples were annealed 1 hr at 300°C and air-cooled.

Samples used for electrical measurements were thermally treated, then polished to approximately 3 mm final thickness. After polishing, gold electrodes were vapor deposited in a guard-ring configuration. Alternating current electrical measurements were conducted in a specially designed environmental chamber that allowed atmosphere and temperature control during measurements.

Alternating current electrical measurements were accomplished using conventional audio and radio frequency transformer ratio-arm bridges. Direct current measurements were conducted in a guarded configuration using a conventional electrometer with an applied field of approximately 2 V/mm.

Samples for transmission electron microscopy were prepared from glass buttons, cast, and thermally treated as above. The samples were mechanically cut to approximately 0.3 mm thick and 3 mm in diameter. The outer annulus of approximately 1 mm width was then masked with a lacquer stop and the sample was placed in a boiling solution of equal parts HCl and H_2O. The sample was left in this solution until a "dimple" developed, then etching was stopped, and the outer masking ring was removed with acetone. The dimpled sample was then placed in the same solution and held by the outer ring with tweezers. As the first hole developed within the dimple, the sample was removed and washed in distilled H_2O. The samples were then placed in a Philips EM-300 electron microscope and examined by conventional techniques. No conducting layer was necessary to prevent charging as is required in silicate glasses. This is apparently the result of the electronic conductivity and lack of polarization in these glasses.

Each of the thermally treated glasses was also examined in a Debye-Scherrer x-ray diffraction camera.

Results

Electrical.—The d-c resistivity-inverse temperature dependence of each of the thermally treated glasses is shown in Fig. 1. The resistivity shows a subtle decrease with the 1-hr thermal treatments up to 500°C. Comparison of the d-c conductivity after annealing at 500°C with Hansen's data indicates that the $Fe^{3+}/Fe^{3+} + Fe^{2+}$ ion ratio is 0.12. Thermal treatments of 1 hr at temperatures of 600°, 700°, and 800°C cause pronounced increases in resistivity. Results of the dielectric measurements are given in Fig. 2, 3, 4, and 5 in the form

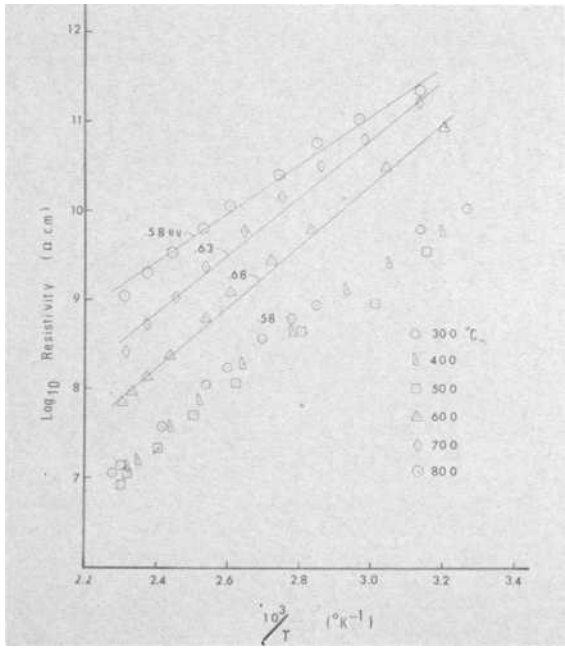

Fig. 1. D-C resistivity as a function of inverse temperature after noted thermal treatments of 1 hr duration.

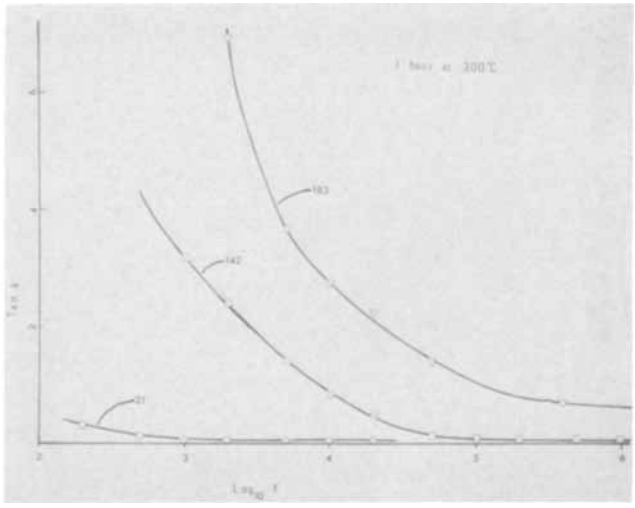

Fig. 2. Loss tangent as a function of $\log_{10}$ of frequency for $55FeO-45P_2O_5$ glass thermally treated 1 hr at 300°C. Measurement temperatures noted on curves in °C.

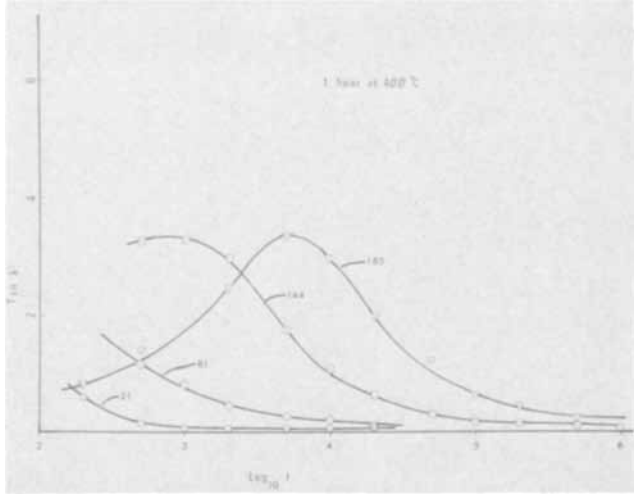

Fig. 3. Loss tangent as a function of $\log_{10}$ of frequency for $55FeO-45P_2O_5$ glass thermally treated 1 hr at 400°C. Measurement temperatures noted on curves in °C.

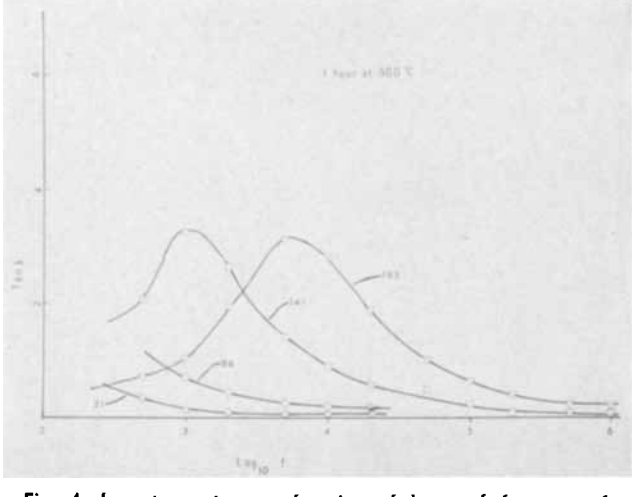

Fig. 4. Loss tangent as a function of $\log_{10}$ of frequency for $55FeO-45P_2O_5$ glass thermally treated 1 hr at 500°C. Measurement temperatures noted on curves in °C.

of tan δ_{Total} as a function of frequency. The d-c contributions were not subtracted because the resistivity is so large as to make this unnecessary. Samples treated for 1 hr at 300°C (Fig. 2) show that no resolved loss peak appears in the frequency range 10^2 to 10^6 Hz. After a 1-hr treatment at 400°C (Fig. 3), a broad loss peak appears. A similar, but somewhat sharper, loss peak also appears in the sample treated 1 hr at 500°C (Fig. 4). A 1-hr thermal treatment at 600°C (Fig. 5) yields a sample free of loss peaks in the 10^2-10^6 Hz frequency range. Thermal treatment for 1 hr at 700°C gives loss behavior indistinguishable from Fig. 5.

Microscopy.—Optical microscopy of samples thermally treated in the same manner as the electrical samples shows crystals approximately 0.1 mm diameter in the 700°C samples and approximately 100μ in diameter in the 600°C samples, but no crystals in the samples treated at lower temperatures.

Transmission electron microscopy of the samples thermally treated 1 hr at 500°C (Fig. 6) shows a fine dispersion of crystals of elongate morphology, 20,000-50,000Å in length and volume fraction probably less than 1%. Electron micrographs of the samples thermally treated 1 hr at 400°C show (Fig. 7) a still finer dispersion of elongated crystals, 5,000-10,000Å in length and volume fraction indistinguishable from the 500°C sample. Transmission electron micrography of the sample thermally treated 1 hr at 300°C shows no resolvable crystals (probably <50Å) and no evidence of liquid-liquid separation. The glass-glass phase separation could be present, but undetected, because the separated amorphous phases would have nearly equivalent electron scattering behavior.

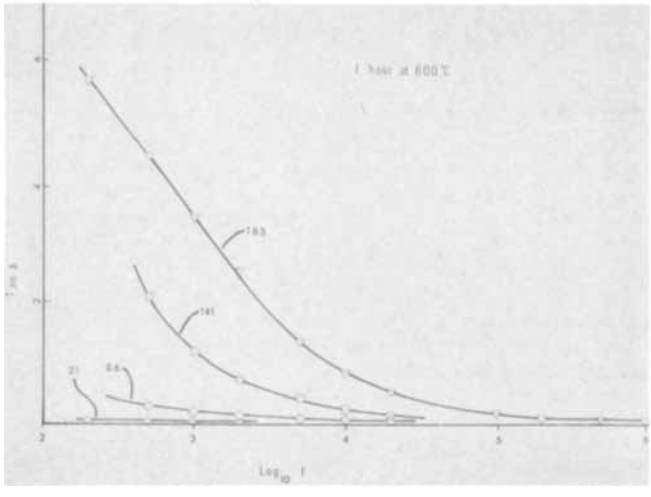

Fig. 5. Loss tangent as a function of $\log_{10}$ of frequency for $55FeO-45P_2O_5$ glass thermally treated 1 hr at 600°C. Measurement temperatures noted on curves in °C.

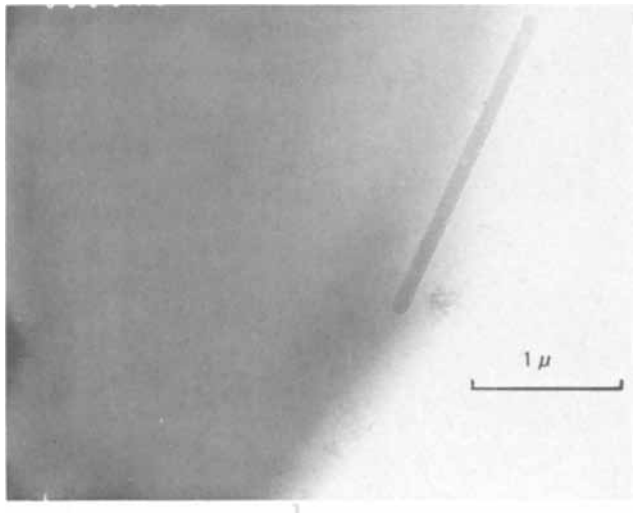

Fig. 6. Transmission electron micrograph of $55FeO-45P_2O_5$ glass after thermal treatment of 1 hr at 500°C.

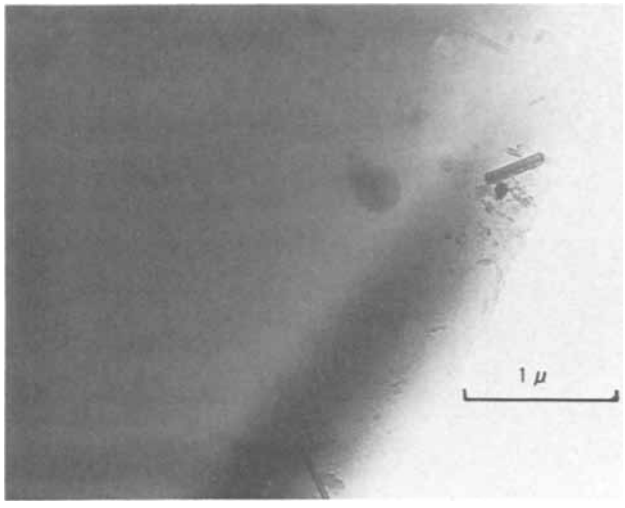

Fig. 7. Transmission electron micrograph of $55FeO-45P_2O_5$ glass after thermal treatment of 1 hr at 400°C.

The Debye-Scherrer technique shows crystals after 1 hr at 600° and 700°C. These crystals have been tentatively identified as $Fe_3(PO_4)_2$, although several lines are shifted as if solution of either FeO or P_2O_5 were present in the crystal.

Discussion

The resistivity decrease with thermal treatment temperature up to 500°C indicates that the matrix of the material is becoming a better conductor. There are two possible explanations of this observation. The first is that the increasing annealing temperature is decreasing the volume of the material and the ferrous-ferric ions are coming closer together. As the material is an electronic conductor, this approach would increase the conductivity. The second, and more probable, explanation is that the crystals observed after low temperature treatment are preferentially formed from ferrous ions, leaving the matrix relatively richer in ferric ion, thus increasing the conductivity according to Hansen's (1) observations.

After the higher temperature treatment, however, the opposite effect occurs, in that the dispersed crystals preferentially incorporate ferric ions, leaving the matrix depleted in ferric ions. The dispersed conducting phases do not contribute to the d-c conductivity because they are not contiguous; hence, no high conductivity path exists. The activation energies noted in Fig. 1 do not change appreciably with thermal treatment and compare favorably with previous results. The small deviation from linearity is also in agreement with previous results.

The Maxwell-Wagner-Sillars (5-7) heterogeneous dielectric analysis indicates that a highly conducting dispersed phase gives rise to dielectric dispersion. Conditions which give rise to this type of loss appear to be present in these materials after 400° and 500°C thermal treatments. The microscopic results indicate that the glass after a 300°C thermal treatment is homogeneous and no dielectric dispersion is observed in glasses so treated. After thermal treatments at either 400° or 500°C, a finely dispersed crystalline phase is observed in these glasses. As these crystals appear, a dielectric dispersion also appears in these crystal-glass materials. It seems that the crystalline phase is more conductive than the matrix phase, although no independent conductivity data for the crystals are available. Thermal treatments at higher temperatures (600°C and above) yield a very few large crystals which, because of their number, do not lead to observable losses.

In summary, it can be said that the dielectric loss behavior of the glasses examined in this work is consistent with partial devitrification during thermal treatments which have been previously used as annealing treatments. This result is confirmed by transmission electron microscopy, dielectric loss behavior, and d-c resistivity data.

It also appears likely that the dielectric relaxation behavior observed by Hansen in glasses of $Fe^{3+}/Fe^{3+} + Fe^{2+}$ ratios of 0.793, 0.465, and 0.147 can be attributed to similar preferential segregation in a crystalline phase.

Conclusions

1. Dielectric losses observed in $55FeO-45P_2O_5$ glasses can be attributed to Maxwell-Wagner-Sillars heterogeneous loss mechanisms, rather than the electron hopping resonance between Fe^{3+}-Fe^{2+} ion sites previously proposed.

2. The assumption of preferential segregation of a particular oxidation state of transition metal ion is necessary to explain the pronounced d-c conductivity changes observed in this glass. It is probable that similar behavior in other semiconducting transition metal oxide glasses results from similar segregation.

Dielectric Properties of Crystalline Gamma-Al_2O_3 Formed on Dilute Al-Cu Alloys

A. J. Brock

Metals Research Laboratories, Olin Corporation, New Haven, Connecticut

At temperatures of 425°C and above pure aluminum oxidizes to form films consisting of both amorphous and crystalline γ-Al_2O_3 (1). The outer amorphous component grows by outward diffusion of aluminum ions whereas the crystalline phase grows as a series of expanding cylinders at the amorphous oxide-metal interface by the inward migration of oxygen ions through the amorphous film. The parabolic rate constant for amorphous oxide formation has a high-temperature sensitivity, 54 kcal/mol, and is independent of the presence of underlying crystals of oxide. The crystalline oxide appears to offer little or no resistance to the egress of aluminum ions.

Saunders and Pryor (2) determined an activation energy of 19.1 kcal/mol for the parabolic growth of γ-Al_2O_3 on copper-3% Al-2% Si in the temperature range 450°-740°C. These γ-Al_2O_3 films were crystalline at higher temperatures and had excellent protective properties. The pre-exponential constant, A, in the Arrhenius equation for the formation of amorphous γ-Al_2O_3 on pure aluminum below 525°C was around 2×10^8 times greater than for the formation of the structurally similar films of alumina on the copper alloy. Since the A value was considered by the authors to represent the number of cation diffusion paths in the oxide, they concluded that copper ions occupied vacant cation sites in the defect cation lattice of γ-Al_2O_3, hence decreasing the rate of outward diffusion of aluminum ions. Since the number of copper ions retained in the oxide increased with increasing temperature, reduced temperature sensitivity together with low growth rate resulted.

To throw further light on this phenomenon the dielectric characteristics of crystalline γ-Al_2O_3 formed on high-purity aluminum and on an aluminum-0.1% Cu alloy were determined. The composition of the metals is shown below.

The aluminum-0.1% Cu alloy was solution treated at 500°C for 8 hr in high vacuum and quenched in still water.

Specimens were etched for 15 min in 0.5N NaOH solution at 25°C, rinsed, immersed for 1 sec in 50% HNO_3 at 85°C, rinsed in distilled water and methanol, and stored in a desiccator for 24 hr. The specimens were oxidized in 76 Torr oxygen for 72 hr at 500°C. Such a procedure results in an oxide containing both crystalline and amorphous γ-Al_2O_3 with crystalline oxide coverage being essentially complete. This is evident from the transmission electron micrographs of the oxides stripped from the metals (Fig. 1).

Gravimetric experiments (Fig. 2) permit calculation of the total weight and, hence, the total thickness of

Table I. Composition of aluminum and aluminum-0.1% Cu alloy

Nominal composition	Cu	Fe	Si
Al	<0.0005	0.0027	0.0005
Al-0.1% Cu	0.095	0.0018	0.0005

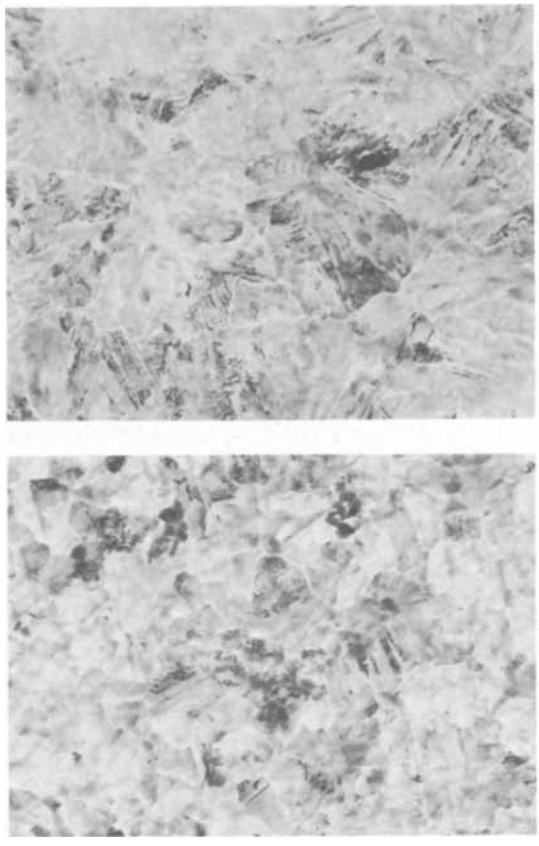

Fig. 1. Transmission electron micrographs of oxide films formed on (a) (top) Aluminum, and (b) (bottom) aluminum-0.1% copper alloy after oxidation for 72 hr at 500°C in 76 Torr oxygen. 16,000X.

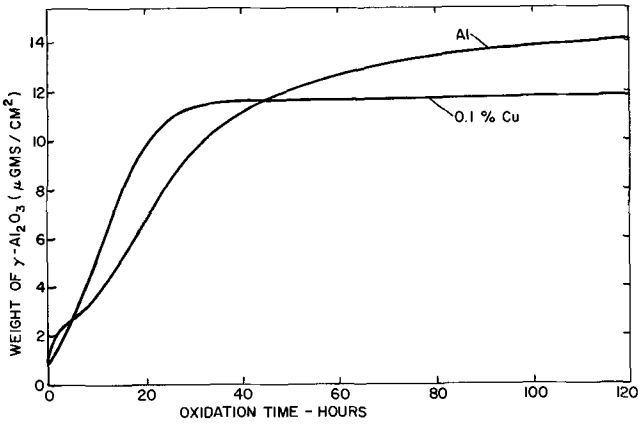

Fig. 2. Relationship between weight of γ-Al_2O_3 formed on aluminum and aluminum-0.1% copper alloy to time of oxidation in 76 Torr dry oxygen at 500°C.

oxide formed on pure aluminum after 72 hr at 500°C. Previous work on pure aluminum (1) showed that the crystalline layer was 217Å thick. Subtraction of this from the total thickness of oxide results in the thickness of amorphous oxide which was 128Å. When such a duplex film is thinned to a maximum degree in sodium chromate solution (3) the equivalent series capacitance increases to a steady value. This value, together with the equivalent series capacitance of the unthinned oxide, permits calculation of the thickness of amorphous oxide dissolved (the solution will not dissolve crystalline oxide) and hence the thickness of amorphous oxide when thinning has been completed. Results for pure aluminum are contained in Table II.

The thickness of crystalline oxide formed on Al-0.1% Cu alloy was measured directly by shadowing the inner suface of a stripped oxide film and yielded a value of 130Å. Gravimetric experiments (Fig. 2) permit calculation of the amorphous film thickness after oxidation for 72 hr at 500°C which was 151Å. Similar thinning experiments established the thickness of the amorphous oxide present on Al-0.1% Cu alloy after thinning in chromate solution to be 23Å (Table II).

The equivalent parallel resistance and equivalent series capacitance measurements made at 1 kHz on duplex films that had been fully thinned in chromate solution, with corrections being made for the residual amorphous film which remained (Table II), permits calculation of the resistivities (resistance/thickness) and apparent dielectric constants of the γ-Al_2O_3 formed on aluminum and Al-0.1% Cu alloy. These results are shown in Table III.

The dielectric properties of the crystalline γ-Al_2O_3 formed on the Al-0.1% Cu alloy are virtually identical to those of amorphous γ-Al_2O_3 whereas the crystalline oxide formed on pure Al is an extremely poor and lossy dielectric. It seems unlikely that these results can be explained in terms of the faults present in the crystals since the crystals formed on Al and Al-0.1% Cu alloy are visually faulted to the same degree (Fig. 1). Accordingly, the high apparent dielectric constant of the crystalline alumina formed on pure aluminum most likely results from the relatively large numbers of defects (vacant cation sites) in the cation lattice (2-2/3 per unit cell at stoichiometry). Such an effect has previously been observed by Gray (4) on introducing large numbers of defects into bulk rutile, and by Pryor (5) on introducing fluoride ions into amorphous γ-Al_2O_3. Since these cation vacancies will be preferred sites for aluminum ion diffusion the greater their number the lower will be the ionic resistance.

Table II. Initial thickness, thickness removed and final thickness of amorphous γ-Al_2O_3 formed on Al and Al-0.1% Cu alloy

Alloy	Initial thickness, A	Thickness removed, A	Final thickness, A
Al	128	113	15
Al-0.1% Cu	151	128	23

Table III. Thickness and dielectric properties of crystalline γ-Al_2O_3 formed on aluminum and aluminum-0.1% Cu alloy

Alloy	Capacitance at 1kHz, μF/cm^2	Thickness, A	Apparent dielectric constant	Resistivity at 1kHz, ohm-cm
Al	4.54	217	117	4.6×10^7
Al-0.1% Cu	0.554	130	9.2	3.5×10^9

Copper ions entering the crystalline oxide will have a strong tendency to associate with these vacant sites particularly since both Cu_2O and CuO form spinels with γ-Al_2O_3 (6, 7). Consequently, the preferred paths for cation migration will be decreased in number thereby explaining the increased resistance of the crystalline oxide formed on Al-0.1% Cu alloy. This result is in complete agreement with the recent work of Saunders and Pryor (2). Furthermore, since the number of cation vacancies is decreased by doping with copper ions a more normal dielectric constant is to be expected.

Resistance measurements at 1 kHz are generally taken to reflect the presence of both electronic and ionic defects in γ-Al_2O_3. Accordingly, in the present experiments and at relatively large film thicknesses, the loss measurements at 1 kHz appear more sensitive to changes in ionic conductivity than electronic conductivity since the latter must have increased due to the presence of electrons in the oxide required to preserve electrical neutrality.

Further evidence that the ionic resistance of the crystalline oxide is increased by addition of copper ions is seen from the rates of oxidation of the two metals at 500°C presented in Fig. 2. After oxidation for about 60 hr, where crystalline coverage is substantially complete, the slope of the weight gain-time curve for oxide formation on Al-0.1% Cu alloy is considerably less than that for oxide formation on high-purity aluminum. Since these slopes represent the rate of amorphous oxide formation on both alloys, when crystalline coverage is complete, the low rate on the Al-0.1% Cu alloy is due to the crystalline oxide affording additional substantial resistance to the egress of aluminum ions because its dielectric properties are similar to those of the amorphous oxide. This is in distinction to pure aluminum where the crystals of γ-Al_2O_3 are so lossy as to present no significant barrier to the passage of aluminum ions.

Variation of the Optical Energy Gap with Composition in MnSe-CdSe Solid Solutions

Heribert Wiedemeier and A. Gary Sigai[1]

Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York

Increasing attention has been directed toward the investigation of alloy semiconductors, particularly with respect to the variation in energy gap with composition in pseudo-binary solid solutions. Studies of such alloys of II-VI, IV-VI, and III-V compounds show that the change in energy gap with composition is essentially linear in some cases [*e.g.*, ZnS_xSe_{1-x} (1), $PbSe_xTe_{1-x}$ (2), $Zn_xCd_{1-x}S$ (3)] and sublinear in others [*e.g.*, $Ga_xIn_{1-x}Sb$ (4)]; in some cases there is even a minimum in energy gap [*e.g.*, $ZnSe_xTe_{1-x}$ (1)].

The compounds MnSe and CdSe have the NaCl (cubic) and wurtzite (hexagonal) structure, respectively. The temperature-composition phase diagram of the pseudo-binary $Mn_xCd_{1-x}Se$ system (5, 6) includes a cubic one-phase region between 0 and 10 m/o (mole per cent) CdSe and a hexagonal one-phase region between 50 and 100 m/o CdSe, separated by a two-phase region. The present work deals with transmittance measurements on single crystals and reflectance measurements on powders of solid solutions in the MnSe-CdSe system to determine the variation in energy gap with composition. Measurements have been performed on samples in both the cubic and hexagonal one-phase regions.

Experimental

Preparation of materials.—The compounds MnSe and CdSe were synthesized from high-purity elements by vapor transport reactions (7) with iodine as the transporting agent. Powdered mixtures of various mole ratios of the pure compounds were thoroughly mixed, pressed into pellets at a pressure of 13.5 Kbar, and sealed under a vacuum of 10^{-6} Torr or less in outgassed quartz ampules. The CdSe-rich mixtures were annealed for several one-week periods at 500°C, the MnSe-rich mixtures for similar periods at 1100°C. To insure homogeneity of the solid solutions, the samples were powdered and repressed after each annealing period until the lattice parameters remained constant. Single crystals of MnSe (8) and of CdSe were prepared by vapor transport reaction; single crystals of two hexagonal solid solutions were grown by sublimation of annealed powder samples in evacuated quartz ampules at 960°C in a temperature gradient of less than 10°C. Crystals of several millimeter edge length were obtained in the form of platelets and columns. The as-grown faces of the MnSe crystals were (111) planes, and those of the CdSe and solid solution crystals were (0001) planes, as determined by the Laue back-reflection technique.

Analysis.—Quantitative chemical analysis of the pure compounds by EDTA titration (9) revealed that both materials were stoichiometric within the limits of experimental error (Cd (exp.) = 58.60%, Cd (calc.) = 58.74%; Mn (exp.) = 40.96%, Mn (calc.) = 41.03%). On the basis of radioactive tracer studies by Schäfer and Odenbach (10), the amount of iodine incorporated into the transported material is estimated to be less than 10^{-2} m/o. Emission spectrographic analysis of the compounds gave the following metal impurities in ppm by weight: Si(6-60), Cs(30-300), Mg(3-30), Fe(3-30), Al(15-150), Ca(10-100), Cu(6-60). Debye-Scherrer x-ray diffraction studies were carried out using a 114.59 mm camera and Ni-filtered CuKα-radiation to determine lattice parameters for the pure compounds and solid solutions. The final composition of the solid solutions as confirmed by lattice parameters agreed with the nominal weights of MnSe and CdSe used within the limits of experimental error. The linear dependence of lattice parameter on composition was established previously (6) and yielded the equations $a_o = 5.462 + 0.202 \cdot N$ (for the MnSe-rich cubic phase) and $a_o = 4.173 + 0.124 \cdot N$, $c_o = 6.822 + 0.193 \cdot N$ (for the CdSe-rich hexagonal phase), where N is the mole fraction of CdSe.

Reflectance measurements.—In the absence of single crystal platelets sufficiently large for transmittance measurements over the entire range of solid solution, the diffuse reflectance of microcrystalline powders was used to provide a relative measure of the absorption. This method has been fully described by Fochs (11). The intensity of the diffusely reflected light from the powdered sample on a 3.5 cm diameter disk was measured with a Beckman DU Spectrophotometer. Magnesium carbonate was used as a reference. Diffuse reflectance spectra for several $Mn_xCd_{1-x}Se$ solid solutions are shown in Fig. 1, where the per cent diffuse reflectance is plotted against wavelength. The curves possess a region of relatively constant reflectivity at the shorter wavelength end since the particles are completely absorbing. With increasing wavelength the absorption coefficient decreases, leading to multiple reflections and refractions in the powder and to a net increase in the diffuse reflectivity. When the absorption coefficient is very low, the reflectivity may approach unity. The energy gap was calculated from the wavelength at the intersection of the straight-line extrapolations above and below the short-wavelength knee of the curve. Fochs (11) and Godik and Ormont (12) have shown that this method of evaluation yields

Key words: linear variation, optical energy gap, MnSe-CdSe solid solutions, transmittance and reflectance measurements.

an accuracy of 1-2% and does not depend critically on the particle size of the powder.

Transmittance measurements.—Measurements of the transmittance (I/I_0) were made on single crystal platelets of CdSe, two hexagonal solid solutions and MnSe, all grown from the vapor phase. A Cary recording spectrophotometer Model 14R was used. The incident light was perpendicular to the faces of the crystal platelets, and the degree of inherent polarization of the instrument was between 15 and 30% (13) in the wavelength range of interest. The energy gap was determined from the wavelength given by the intersection of the extrapolated linear portion of the steeply descending transmittance curve with the wavelength axis. The uncertainty in the wavelength intercepts is estimated to be less than ±10 nm.

Results and Discussion

The compositions, lattice parameters, colors, and energy gaps of the investigated materials are summarized in Table I. The variation of the energy gap with composition for the one-phase regions of the MnSe-CdSe system is shown in Fig. 2. It is seen that there is a linear dependence of the energy gap on composition in the CdSe-rich hexagonal one-phase region up to the phase boundary at 50 m/o CdSe. The relationship can be expressed by the equation

$$E_G = 2.78 - 1.08 \cdot N \qquad [1]$$

where N is the mole fraction of CdSe and E_G is given in eV. CdSe is known to have a direct band transition (14); the linear variation of the band gap could indicate (15) that the solid solutions might also have direct gaps.

The value of the energy gap for pure CdSe obtained from reflectance measurements (1.70 eV) is identical with values obtained from transmittance measurements on three CdSe (0001)-platelets of different thickness (1.70 eV, with light partially polarized perpendicular to the c-axis). These results are in reasonable agreement with the value found by Keller and Pettit (16) (1.72 eV, with light polarized perpendicular to the c-axis). The slight disparity is probably due to different experimental conditions.

Qualitative thermoelectric measurements on CdSe platelets indicate n-type conductivity in agreement with previous observations (17). This is usually explained by the selenium deficiency of CdSe, since the entire homogeneity range of CdSe apparently lies on the Cd-rich side of the stoichiometric composition (17). Thermoelectric measurements on solid solution single crystals with 50 and 60 m/o CdSe, respectively, also indicated n-type conductivity.

Reflectance measurements on polycrystalline powders of pure MnSe and solid solution samples containing 10 m/o CdSe yielded energy gap values of 2.00 and 1.94 eV, respectively. Preliminary investigation of transmittance measurements on single crystal platelets of MnSe indicated an extrapolated absorption edge at 680 nm (1.8 eV). An energy gap value for MnSe of 2.5 eV was reported by Lawson and Nielsen (18) with no indication of the experimental technique used. Makovetskii and Sirota (19) obtained a value of 0.7 eV from measurements of the electrical conductivity as a function of temperature on sintered polycrystalline powders of MnSe. Since the MnSe spectrum is complicated by transitions within the d-levels of manganese, similar to the situation found for MnS (20, 21), a detailed analysis of the low temperature spectrum of MnSe will be necessary in order to determine unambiguously the fundamental absorption edge. For this reason the data reported for MnSe can be regarded as only preliminary.

Table I. Lattice parameters, colors, and room temperature energy gaps for MnSe, CdSe, and their solid solutions

Bulk composition, m/o CdSe	Lattice constant (Å)* a_0	c_0	Color	λ_{edge}, nm	Energy gap,† eV
0	5.462		Brown-Black	620	2.00
10	5.483		Brown-Black	640	1.94
50	4.236	6.919	Orange-Red	555	2.23
60	4.247	6.938	Crimson-Red	585	2.12
70	4.261	6.958	Red-Violet	605	2.05
80	4.272	6.973	Black	645	1.92
90	4.285	6.997	Black	695	1.78
100	4.298	7.016	Black	730	1.70

* The error limits for a_0 are ±0.001Å in the cubic phase (0 and 10 m/o CdSe), and ±0.001 and ±0.003Å for a_0 and c_0, respectively, in the wurtzite phase.

† From reflectance measurements; the uncertainty in the energy gap is estimated not to be greater than 1-2%.

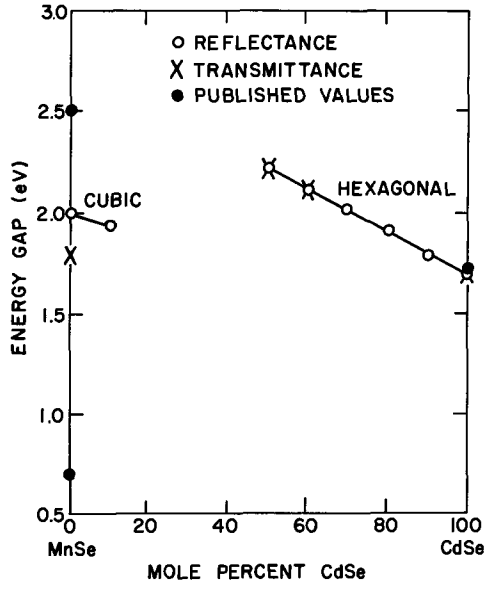

Fig. 2. Energy gap as a function of composition in the cubic and hexagonal one-phase regions of the MnSe-CdSe system.

Preparation of Thin Silicon Crystals by Electrochemical Thinning of Epitaxially Grown Structures

H. J. A. van Dijk and J. de Jonge

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven-Netherlands

The availability of large area, thin silicon crystals on insulating substrates would increase the possibilities of design and fabrication of semiconductor devices. Silicon on sapphire may be one approach to this subject. Another way to obtain single crystals thinner than 20μ with areas larger than 1 cm^2 consists of controlled thinning of lapped wafers by mechanical or chemical means. Mechanical thinning is not an easy way. Machines used for this work are mechanically complicated because of the need of precise thickness and plane-parallelism control. Equally thinning of wafers by chemical etching requires a good control of the etching conditions to realize a preset and uniform thickness over larger areas. The preparation of thin silicon crystals by selective electrochemical etching of suitable epitaxial structures is described in this paper. The system is designed to be self-controlling; the etching process stops automatically at a preset thickness without the need of highly controlled etching conditions. Crystals with thicknesses of 0.5-20μ and as large as 10 cm^2 can be made easily in routine operations.

The anodic dissolution of silicon has been studied by numerous workers (1). We investigated the anodic dissolution rate of plate-shaped silicon single crystals in some detail, using a 5% solution of hydrofluoric acid in water as an electrolyte. In Fig. 1, schematically, the current density of the silicon anodes is plotted *vs.* the applied potential. Since the current density is related to the dissolution rate of silicon, it can be seen that p-type and heavily doped n-type material can be dissolved, whereas n-type silicon does not dissolve at sufficiently low voltages. It should therefore be possible to separate n$^+$- or p-type regions from n-regions by electrochemical dissolution. This principle was evaluated to obtain high quality thin crystals starting from suitable epitaxially grown structures.

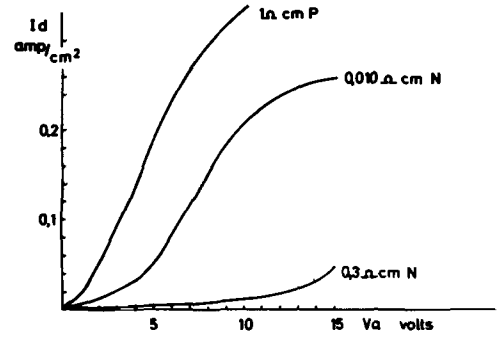

Fig. 1. Current density *vs.* applied potential of silicon anodes in 5% HF.

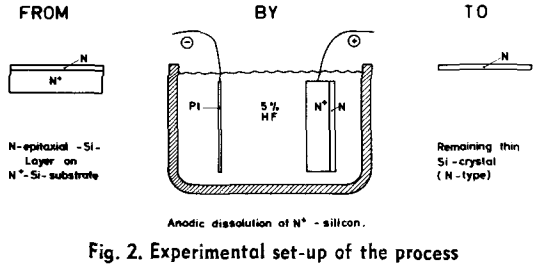

Fig. 2. Experimental set-up of the process

Experimental Technique

The experimental set up is shown schematically in Fig. 2. On a heavily doped n-type substrate with a specific resistance of less than 0.015 ohm-cm an n-type layer is grown epitaxially with a specific resistance higher than 0.3 ohm-cm. The epitaxial wafer is mounted face down on a glass plate with beeswax. The anode contact is made by pressing a platinum strip on the n$^+$-side of the wafer close to its edge. The wafer is immersed completely in the electrolyte and the n$^+$ substrate is dissolved anodically using a current density of about 150 mA/cm^2. The dissolution process stops at those areas where the n-epitaxial layer becomes exposed to the electrolyte. A thin, plate-shaped crystal is left.

In order to prevent the formation of isolated n$^+$-islands (residues of substrate material) on the remaining n-layer, the substrate is bevelled prior to etching in such a way that it is somewhat thinner at the area remote from the anode contact. This bevelling operation is not a critical process step and can be done by hand lapping. To prevent any etching of the epitaxial layer as soon as it is exposed to the electrolyte some precautions must be taken. Mechanical damage of the epilayer, the presence of hole-injecting structures as well as excessive heating and exposure to light should be avoided. Hence the electrolyte is kept at room temperature, and the etching is performed in total darkness.

Often, after electrochemical etching, the newly exposed crystal surface has a dull appearance due to a thin deposit ($<0.1\mu$) of unknown composition. A treatment with a slow-working etch (*e.g.*, a solution containing HF, acetic acid and some $KMnO_4$) results in a smooth and shiny surface. It may be clear that thickness variations of the thin crystals prepared by this technique only depend on the thickness control during the epitaxial growth.

The preparation of thin, p-type crystals is possible by this technique starting from n$^+$np-structures. After mounting on a glass plate with wax (with the p-type zone adjacent to the glass) the n$^+$ substrate is dissolved anodically. The n-type intermediate layer acts as the etching-stop. This n-type layer, which can be very thin, can be etched away chemically. A con-

venient way to prepare thin p-type crystals is to start with an epitaxially grown p-type layer with a specific resistivity higher than 0.5 ohm-cm on a n^+-substrate. The substrate is dissolved anodically, leaving a thin p-type crystal with a very thin n-type layer adjacent to the former substrate side.

Also thin n-type silicon crystals with a thin n^+-base (total thickness, *e.g.*, 10μ) can be prepared with this technique starting with multilayer epitaxial structures of suitable geometry and doping levels. Both n^+ (substrate) nn^+n and n^+ (substrate) pn^+n-structures can be used. After the substrate has been dissolved electrochemically the n- or p-type layer can be etched away chemically leaving the overlying thin crystal with n^+n-structure. The chemical etching is not a critical process and can be carried out in the conventional way.

The selective electrochemical etching process outlined above may contribute to silicon device and circuit technology in various ways. One possibility is first to carry out all necessary diffusions, metallizations etc. on the epitaxial silicon wafers followed by the removal of the substrate by electrochemical etching. MOS transistors and other devices with "vertical" junctions have been prepared. The preparation of targets for silicon-vidicon-TV pick-up tubes is possible with this technique. Thin membranes of single crystalline silicon showed excellent properties for the preparation of pressure sensitive devices for medical and other purposes.

The Effect of Gas Concentrations in the Diffusion of Silicon from a Phosphine Source

James S. Kesperis

U. S. Army Electronics Command, Electronic Components Laboratory, Integrated Electronics Division, Fort Monmouth, New Jersey

The use of the gas phosphine (PH_3) as a diffusion source for silicon was originally presented by Donovan and Smith (1). These workers pointed out that adjustment of the diluted phosphine concentration in a nitrogen carrier gas containing very low O_2 concentrations offered a means of creating a local P_2O_5 diffusion source in a predictable manner. There has been, however, no discussion in the literature of those process and control factors whch determine the utility of the process as a practical and applicable technology. In the present paper, the experimental results on the effect of O_2 and PH_3 concentrations on sheet resistance (r_p), phosphosilicate glass growth, and process control are presented in a range pertinent to the fabrication of npn-bipolar based integrated circuits, and more specifically to the fabrication of emitter and other high conductivity areas of such circuits.

Experimental

In all cases, diffusion depositions were carried out in a Thermco furnace with a 20-in. thermal zone flat to ±1°C. Depositions were made with the silicon mounted horizontally on the diffusion boat. The phosphine source is commercially prepared as a 1% diluted mixture in argon. An analysis by infrared spectroscopy provides the specific concentration. The phosphine was injected through a quartz vane which terminated in the 55 mm diffusion tube at a point corresponding to a temperature of 625°C. Brooks Instrument Corporation flow meters, with calibrated graduations for argon, were used to monitor the phosphine flow rate in relation to the source tank analysis. Directly calibrated N_2 and O_2 flow meters of similar type were used. The meters were kept in a cabinet at a temperature of 80° ± 2°F. It was assumed that the flow meters exhausted into an open tube diffusion reactor (atmospheric pressure). N_2 and O_2 were injected at the rear of the tube. Half of the total N_2 flow was coinjected with the PH_3 through the vane. One-inch diameter wafers were used, the orientation was (111), and the resistivity was p-type, 1 ohm-cm ±10%. The same total flow rate, 1700 cc/min was used in all cases. With the exception of the data on the dependence of sheet resistance on temperature, all depositions were made for 20 min. A deposition was initiated by inserting the wafers in a nitrogen flow. After a stabilization period of 1 min, the proper amount of oxygen is introduced for a period of 1 min. The phosphine is then turned on for the deposition period. O_2 and N_2 are allowed to flow for an additional minute after the PH_3 is turned off. The O_2 is turned off and the wafers are left in a nitrogen flow for an additional minute before pull-out.

It should be noted that in practice, diffusion runs are made in tubes which are maintained in a "doped" condition. All runs in this study were made only after the tube had received a minimum of 1 hr predoping during the day of the run under conditions of 1500 ppm PH_3 and 35% O_2. Observations on the behavior of the tube itself as an absorber or emitter of P_2O_5 have been described (2). For the flow concentrations and dynamics in the present study, tube predoping was found to have a negligible effect in the sheet resistance range of interest, and successive emitter fabrication runs showed indistinguishable spreads in r_p between wafers within a run and on a run-to-run basis. The fact that the tube itself acts as a source means that a phosphorous-containing oxide is formed on the silicon surface during the 2-min interval in the furnace prior to the introduction of the phosphine source so that an immediate diffusion source exists for the silicon.

Effect of O_2 and PH_3 Concentrations

In Fig. 1, r_p is plotted against the PH_3 concentration for oxygen concentrations ranging from 1.5 to 70.6%

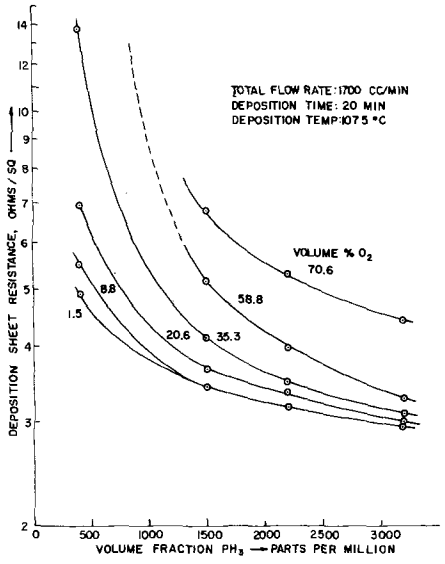

Fig. 1. Variation of r_p with volume fraction PH_3

by volume. Each point represents an averaging of eight independent runs made under the indicated conditions. All curves, with the possible exception of the one with 70.6% O_2, converge with increasing PH_3 concentration. The rate of change of sheet resistance decreases as the PH_3 concentration increases. Process saturation, however, when defined as zero change in r_p with change in PH_3 concentration, is not reached even at 3200 ppm PH_3.

A change in oxygen concentration, from 1.5 to 8.8% produces no significant r_p change for 1500 ppm PH_3 or more. Above 8.8% O_2 the change in r_p with per cent O_2 change increases with increasing oxygen. The effect of increasing O_2 concentration, important from a process control viewpoint, is to produce increasingly rapid r_p changes as the phosphine concentration decreases, the effect being maximum at high oxygen concentrations and at low phosphine concentrations.

In Fig. 2, the same r_p data are plotted in terms of equal volume fraction ratios (cc PH_3/cc O_2) against r_p with cc PH_3 as the parameter. Here it can be seen that equal volume concentrations do not produce equal sheet resistances. The r_p values depend on the PH_3 flow rate, and the curves shift upward and to the left

Table I. Sheet resistance control
(values in ohms/square, ± extreme variation)

	ppm PH_3			
% O_2	420	1500	2200	3200
1.5	4.94 ± 1.9%	3.45 ± 0.8%	3.17 ± 0.7%	2.95 ± 0.5%
8.8	5.51 ± 3.7%	3.45 ± 1.0%	3.20 ± 1.1%	2.95 ± 1.0%
20.6	6.97 ± 3.2%	3.66 ± 1.9%	3.37 ± 1.8%	2.99 ± 0.7%
35.3	10.70 ± 3.2%	4.15 ± 2.0%	3.51 ± 1.7%	3.10 ± 1.8%
58.8	—	5.19 ± 5.3%	3.97 ± 4.0%	3.28 ± 2.2%
70.6	—	6.78 ± 5.0%	5.33 ± 4.6%	4.44 ± 2.8%

with closer spacing as PH_3 saturation of r_p is approached. Furthermore, it is obvious that r_p decreases as the concentration of both reactants (O_2 and PH_3) is increased.

Process Reproducibility

The reproducibility of the process increases generally as r_p goes toward saturation with respect to either PH_3 or O_2 concentration. In Table I, the average sheet resistance of eight runs for each point is listed together with the variation of the measured extremes about their mean in per cent. It can be seen that for ppm PH_3 = 1500 and % O_2 = 35.3, the maximum variation is ±2%. The process is uncontrollable with 58.8 and 70.6% O_2 at 420 ppm PH_3 for the indicated conditions of time, temperature, and total flow rate.

Phosphosilicate Glass

The formation of a phosphosilicate oxide (glass) during the deposition process appears to be essential for controllable diffusion with this process. Attempts to utilize the thermal cracking of PH_3 in a nonoxidizing atmosphere

$$2\,PH_3 \xrightarrow[440°C]{\Delta} 3H_2 + 2P \qquad [1]$$

for diffusion temperatures of 1000°-1100°C gave erratic results while causing damage to the silicon surface. No controllable conversion to n-type resulted in the reducing atmosphere, although localized conversion was observed. Frequently, random pitting resulted, suggesting enhanced reactions at surface defect sites. At all times heavy deposits of phosphorus were observed at both the back and exit ends of the reaction tube. In the presence of oxygen, the general dependence of glass thickness on O_2 and PH_3 concentration can be seen in Fig. 3. In this figure, the indicated points were determined by interference techniques to establish the order and by very careful matching and

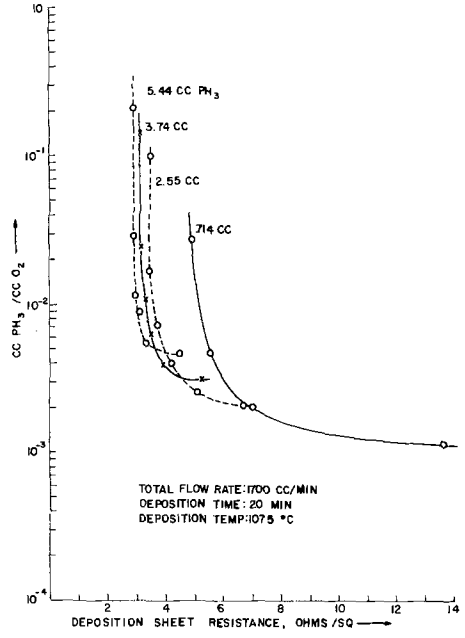

Fig. 2. Variation of r_p with the volume ratio PH_3/O_2

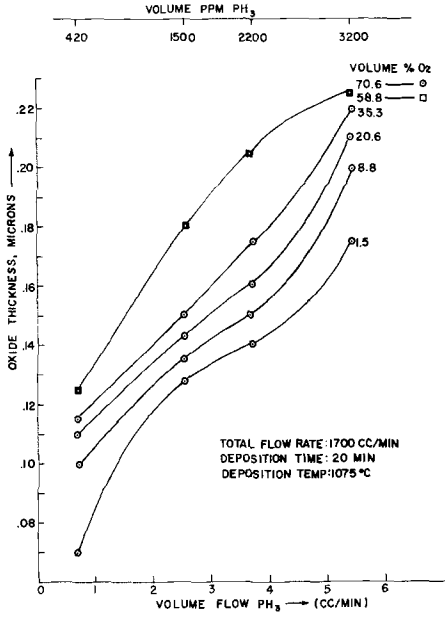

Fig. 3. Dependence of oxide thickness on volume fraction PH_3

interpolation-approximation between established interference colors using actual calibrated oxidized silicon samples. (In addition, this approximation involves an undetermined error in absolute oxide thickness because of differences in the indices of refraction of the doped oxides and that of pure SiO_2.) The thickness can be seen to increase with both PH_3 and oxygen concentrations. Changes from 58.8 to 70.6% O_2 produced no detectable color change for any given PH_3 concentration, and the convexity (above 1500 ppm PH_3) of this curve is in contradistinction to the others in the figure, suggesting that the glass growth rate mechanism differs at high oxygen concentrations. Assuming the correctness of the curve shapes in Fig. 4, there is no simple quantitative relationship between growth rate and either O_2 or PH_3 concentrations. There are several possible reactions involved in the deposition process which can determine both phosphorus source availability and glass growth rate.

For low oxygen concentrations, Donovan and Smith have postulated reactions [1], [2], and [3].

$$4P + 5\,O_2 \rightarrow 2P_2O_5 \qquad [2]$$

$$2P_2O_5 + 5Si \rightarrow 5SiO_2 + 4P \qquad [3]$$

The last [3] reaction involves the localized reduction of a P_2O_5 source by the silicon, with the growth of a SiO_2-P_x glass phase from which diffusion takes place. In the present study, water was consistently observed at the exit port of the diffusion tube, with the amount condensed heaviest at 3200 ppm PH_3. This suggests that for the dynamic tube conditions the P_2O_5 source is maintained by

$$2PH_3 + 3\,O_2 \rightarrow P_2O_5 + 3H_2O \qquad [4]$$

In the presence of excess O_2 or H_2O from [4], an increased oxidation rate of silicon would limit the direct reduction of P_2O_5 by the silicon as postulated by [3]. However, for any fixed O_2 concentration, an increase in PH_3 produces a thicker oxide and a lower sheet resistance (Fig. 1 and 3) suggesting the incorporation of more available phosphorus in the growing glass which acts as the diffusion source. On the other hand, with constant PH_3, increases in O_2 concentration generally yield an increased glass thickness with an increase in sheet resistance throughout most of the experimental range, suggesting for this range source limitation in which diffusion determines the phosphorus availability to the silicon.

Temperature Dependence of r_p

An expression for r_p as a function of average mobility (μ), surface concentration (N_s) deposition time (t_p), and an exponential thermal dependence of the diffusion constant D_o is given by the following for constant source conditions

$$r_p = (\sqrt{\pi}/2\; q\mu \sqrt{D_o t_p})\,(1/N_s)\; e^{E/2KT} \qquad [5]$$

If N_s and μ show small variations over the temperature range, then a semilog plot of the data should result as shown in Fig. 4. The above dependency has been observed for various deposition systems, for example $POCl_3$, BBr_3 (2), and P_2O_5-CaO (3) among others. Phosphine depositions made for 1 hr in this study showed reasonable agreement with respect to sheet resistance and activation energy with the P_2O_5-CaO closed box depositions of Mackintosh (3) in the same temperature range.

The points on curve 4 were made under conditions of 35% O_2 and 1500 ppm PH_3 for 1 hr in the temperature range of 975°-1100°C. Three independent runs were made at each temperature and averaged. No point group showed a maximum spread of greater than 2%. It was found impossible to construct such a curve at 70.6% O_2 because of poor control at temperatures below 1075°C with 1500 ppm PH_3. One hour r_p values of 2.08 ohms/sq with 1.5% O_2 and 1500 ppm at 1075°C, and 4.20 ohms/sq with 8.8% O_2 and 1500 ppm at 1000°C have been reproducibly obtained, suggesting that lines of approximately the same slope lying below the 35% O_2 curve can be readily obtained for lower oxygen concentrations. Extrapolation, however, to lower temperatures for any fixed condition should not be made; and the relationship should be established empirically for desired conditions of time, concentrations, and total flow rate, first to establish the reproducibility and second to determine inflection points to increased slope, which limited experiments in this study have shown to occur at temperatures below 1000°C.

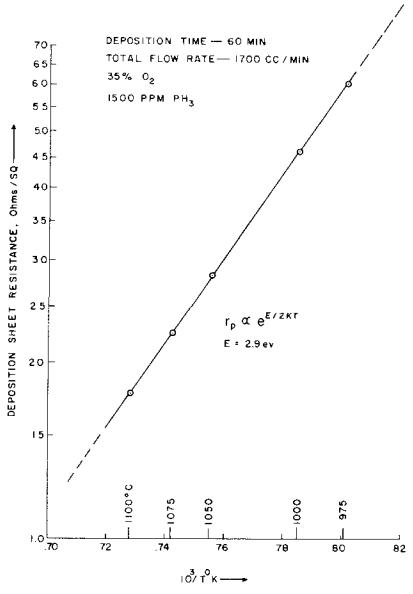

Fig. 4. Thermal dependence of r_p

Discussion

The phosphine process, with its requirement for an oxidizing atmosphere and its dependence on the transport of a P_2O_5 source to the silicon surface for diffusion of phosphorus, is similar to the well-known solid P_2O_5 and liquid $POCl_3$ source processes. The formation of water is unique with the PH_3-O_2 system, but bears no parallel to the deleterious effect of moisture on the control of sheet resistance with the P_2O_5 source, since with this system the P_2O_5 species is locally and controllably created within the diffusion tube in the vapor state.

The control of the process is excellent, particularly in the sheet resistance range of interest in this study, and maximum control is obtained when the process is performed at near saturation conditions of r_p. For 20-min deposition times, the use of the 35% O_2, 1500 ppm PH_3 process has yielded a 4.19 ohms/sq ± 2.5% (2-sigma) variation in 140 test wafers used to monitor emitter deposition runs during IC and bipolar fabrication. From Table I, it can be inferred that this control would be even tighter for the more saturated conditions of lower O_2 and higher PH_3 concentrations.

The uniformity and predictability of oxide color is excellent and surpasses that observed for equivalent $POCl_3$ and P_2O_5 depositions. Visual perfection and lack of microscopic defects is invariably obtained with occasional nonuniformity observed only where the oxide thickness was less than 1250Å (values for 420 ppm PH_3). This oxide thickness increases with the PH_3 flow rate (and the volume concentration) for any fixed experimental oxygen volume concentration. The thickness also increases with oxygen concentration for fixed PH_3 concentrations up to ≈ 60% O_2. In terms of volume ratios, the oxide thickness increases with (cc PH_3/cc O_2) for constant oxygen concentration and decreases for constant PH_3 concentration for oxygen concentrations less than 60%.

It can be seen that for a given time and temperature, this process uniquely permits selection from a wide range of controllable emitter sheet resistances and

oxide thicknesses by variation of the phosphine or oxygen concentrations. This permits two degrees of freedom over the variation of temperature conventionally used with other sources. Operational simplicity is a further advantage; the desired rates are set by flow meter, the process can be readily automated, and there is no source preparation or reservoir maintenance involved. The process is completely compatible with the fabrication of silicon integrated circuits. The fact of water formation and the possibility of PH_3-Ar commercial source contamination adversely affecting the electronic quality of the device or the final SiO_2 layer has been examined through the fabrication of high-gain bipolars. These devices, using phosphine-deposited emitters with areas as high as 3 square mils and with the deposition oxide retained, have exhibited gains of 1,000 with VCB = 0 at a collector current of 1 μA. The collector currents were exponential with qV_{BE}/KT from at least 100 pA to a few milliamperes, while the base currents varied with exp qV_{BE}/nKT with $n = 1.2$ at a V_{BE} corresponding to a collector current of 1 μA. Conventional wet/dry oxidation techniques were used for the original thermal oxide.

Brief Communication

Oxygen X-Ray Emission Band Shifts Applied to the Characterization of Transition Metal Oxide Surface Layers

H. B. Krause,[1] G. A. Savanick, and E. W. White

Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania

In the course of a research program on metallic corrosion an investigation was undertaken to determine the feasibility of employing shifts in the oxygen x-ray emission band to characterize structurally and chemically the thin, often amorphous, oxide layers that form when a metal corrodes. The first results of this research were reported by Gigl, Savanick, and White (1), who observed shifts in the aluminum x-ray emission band (Al Kβ) and the oxygen x-ray emission band (O Kα) and used these shifts to characterize thin corrosion layers on aluminum.

This note demonstrates that shifts in the O Kα band can be used to characterize oxide films on transition metals. Prior to experimentation on thin films it was necessary to investigate the oxygen x-ray band shifts with chemical variations of the emitter, using bulk samples of known composition.

Three series of transition metal oxides (Ti, Mn, and Fe) were included in this study. The oxide standards were in powder form and were prepared by drying from suspension onto polished carbon rods (¼ in. diameter) after being ground under alcohol.

The oxygen x-ray emission bands were recorded with an Applied Research Laboratories electron probe microanalyzer model EMX, equipped with a flow proportional counter. A clinochlore crystal (2d=28.39A) was used to disperse the oxygen x-ray emission bands. Baun and White (2) have described clinochlore and demonstrated that it is particularly well suited for the x-ray spectrometry of oxygen.

An accelerating voltage of 20 keV was selected and the sample current was adjusted to 0.1 μA resulting in peak O Kα count rates of 100-350 cps. A large (100μ) electron beam diameter was used to minimize beam damage in the specimen. The peaks were scanned at approximately 0.03 Å/min. Scans were repeated in triplicate from three areas of each sample. Peak positions were measured by extrapolating the line of midchords to the peak intensity. All wavelength measurements were made with respect to the O Kα from quartz (α-SiO_2). This quartz peak was arbitrarily assigned a wavelength of 23.60Å.

The data presented (Fig. 1 and 2) demonstrate that the magnitude of the shifts in the oxygen x-ray emission bands is a continuous function of the metal to oxygen ratio of the emitter. A plot of the position of the peaks for a series of manganese oxides of different chemical compositions is presented in Fig. 1, along with similar data for a titanium oxide series. Figure 2 shows the O Kα wavelength shifts with changing oxidization state of the cations in a series of iron oxides. In all these three series the peaks shift toward shorter wavelength with increasing oxidation.

These plots demonstrate that the cation valence of these transition metal oxides can be determined from measurements of the O Kα wavelength. These data for the titanium oxides corroborate the findings of Fischer and Baun (3) who published a figure showing a progressive shift in the intensity maximum of the oxygen band in the series TiO-Ti_2O_3-TiO_2. The oxygen band shift technique was applied to a thin (0.5μ) oxide layer prepared by heating a polycrystalline iron bar

at 290°C under a pressure of 20,000 psi for 16 hr. The oxide existed as a blue surface layer and was positively identified as Fe_3O_4 by x-ray diffraction. Figure 2 shows that the wavelength of the O Kα band emitted from the blue oxide is essentially the same as that measured from Fe_3O_4 and is significantly different from the wavelengths of FeO and Fe_2O_3. Thus, thin iron oxide films can be identified with reference to oxygen shift data.

Oxide films thicker than 100Å can be investigated by this technique free of interference from the metallic substrate. The oxide films need not be crystalline or of uniform thickness.

Acknowledgment

Financial support for this work was provided by the Office of Naval Research under contract number NR-032-502. The authors would like to thank P. D. Gigl who provided the iron oxide surface layer.

Manuscript received Nov. 24, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

Lithium/Silver Chloride Button Cells

Glenn M. Cook

Research & Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

The operating parameters for a laboratory model Li/AgCl button cell are presented. The cell voltage is given as a function of current density over a temperature range from −55° to +125°C. Cathode utilization is 90% at 0.46 mA/cm² at room temperature. Cell life for these rudimentary cells is estimated for several temperatures. These studies indicate that the Li/AgCl cell has properties which differ considerably from those of existing commercial systems and which permit it to satisfy new power requirements.

Over the past several years, many workers have directed their efforts toward the development of various nonaqueous battery systems (1). It is the purpose of this paper to examine the temperature dependence of the shelf life and operating characteristics of cells based on the system, $Li/LiAlCl_4$, PC/AgCl, Ag [PC = propylene carbonate (2)].

The nonaqueous Li/AgCl cell has certain advantages and certain disadvantages. The advantages are:

1. The high cell voltage allows the use of fewer cells in a battery.
2. The operating temperature range is very wide.
3. The low temperature performance is good.

The disadvantages are:

1. The cells must be fabricated under an inert atmosphere and the solvent carefully distilled (3, 4).
2. The high electrolyte resistance restricts the usage of these cells to low rate applications.
3. The present shelf life is low, roughly equivalent to that of Leclanché cells.

Results

The three-piece polypropylene cell case used for these studies is illustrated in Fig. 1. The internal dimensions are 15 mm in diameter by 13 mm high. The cells were fabricated in a controlled-atmosphere dry box containing less than 1 ppm water or oxygen in the vapor phase. The cathode compartment is filled with about 1g of a silver chloride-acetylene black mix. The anode consists of 1/3g of lithium metal, which makes the cells cathode limited. About 4 cc of a $LiAlCl_4$-PC electrolyte, saturated with LiCl, was used. The over-all cell weight was 10g and the open-circuit voltage was 2.84V.

Some precautions were taken with the preparation of the electrolyte. These included the use of freshly distilled PC with a water content of about 40 ppm, the slow dissolution of $LiAlCl_4$ to prevent overheating, and electrolyte storage in the presence of lithium. All of the necessary manipulations were carried out in a dry box. This electrolyte was found to have a $[Cl^-]$ activity which permits the formation of $AgCl_2^-$ to a concentration of 10^{-4} molar. This was determined by using procedures similar to those of Butler (4). Some cell anodes were found to have very small quantities of silver on them. The presence of silver is not unexpected, and the small quantities observed validate the low concentration of $AgCl_2^-$ calculated above.

Cell polarization.—The term cell polarization, as used here, is the sum of all factors causing a reduction in cell voltage from the open-circuit potential. For convenience, the figures give the cell voltage rather than the polarization. This is done in order to provide a measure of cell output which is needed to determine its suitability for a particular use.

The first important cell polarization effect is its increase with increasing current density and decreasing temperature. The data shown in Fig. 2, which gives the cell voltage *vs.* current density as a function

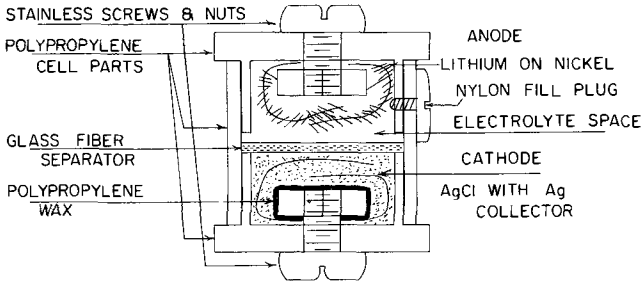

Fig. 1. Construction detail of Li/AgCl button cells

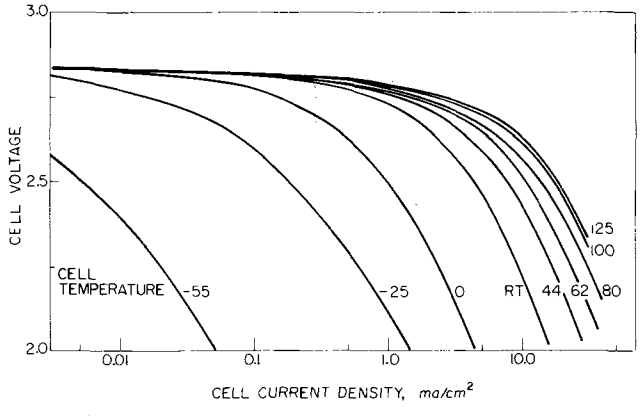

Fig. 2. Cell voltage *vs.* current density of fresh cells at various temperatures, °C.

of cell temperature, were obtained as the average for two fresh cells at each temperature. The smooth curves were obtained by drawing them through the average of all data points. Three current densities per decade were selected and the current held constant for 1 min prior to recording the cell voltage. The current was then stepped to the next value. Data were obtained for both increasing and decreasing currents. No data were obtained beyond 30 mA/cm^2 or below a cell voltage of 2V.

Two hours were allowed for the cells to reach thermal equilibrium prior to testing. Identical results were obtained when the cells were retested after an additional stand of 2 hr at temperature.

The curves for the lower temperatures are somewhat distorted as compared to those obtained at higher temperatures. The internal resistance of the Li/AgCl cells is higher than that of existing systems because of the use of the low-conductivity, nonaqueous electrolyte. As a result, heating effects are of greater importance.

The variation of cell current with inverse temperature at constant cell voltage yields some information regarding the source of cell polarization. Figure 3 is such a representation for a voltage drop of 10% from OCV. Similar plots can be made for other amounts of cell polarization from the data in Fig. 2. If such plots are made, it is found that the cell polarization arises from *IR* losses, concentration effects, and chemical polarization. The first two of these factors are expected to vary with temperature in the same manner as the electrolyte conductivity. At high temperatures the rate of reaction, cell current, is roughly proportional to electrolyte conductivity with only a small polarization attributable to chemical polarization. At lower temperatures, there appears to be an increase in chemical polarization as determined by the methods of Gorbachev (5). No specific values were determined since the cells were not identical, but only similar to one another.

The other important cell polarization effect is its increase with the increase in the extent or depth of discharge. All systems show a decreasing cell voltage as the discharge continues (6). The more constant the cell voltage throughout the discharge, the higher is the "quality" of the system as a power source. Figure 4 compares the Li/AgCl cell voltage-time characteristics with those of three important commercial systems (6-8). All of the characteristics are for cells of similar structure, the button or cylindrical dry cell configuration. The 100 hr rate was chosen since the cell polarization of the Li/AgCl cell is quite good at the 100 hr rate. It would be expected to be even better at a lower rate.

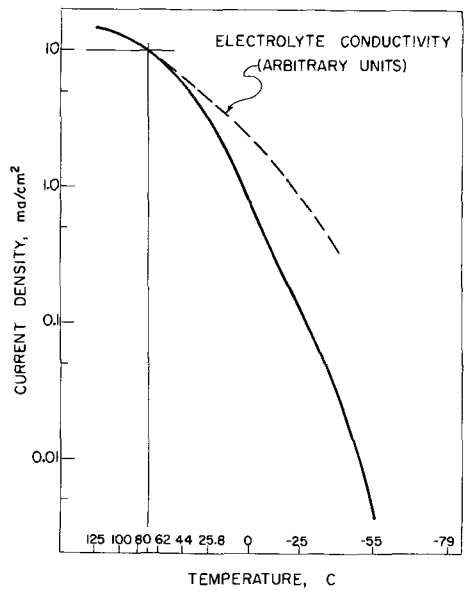

Fig. 3. Comparison of electrolyte conductance with current density as a function of temperature. The current is obtained at a 10% drop in cell voltage from OCV.

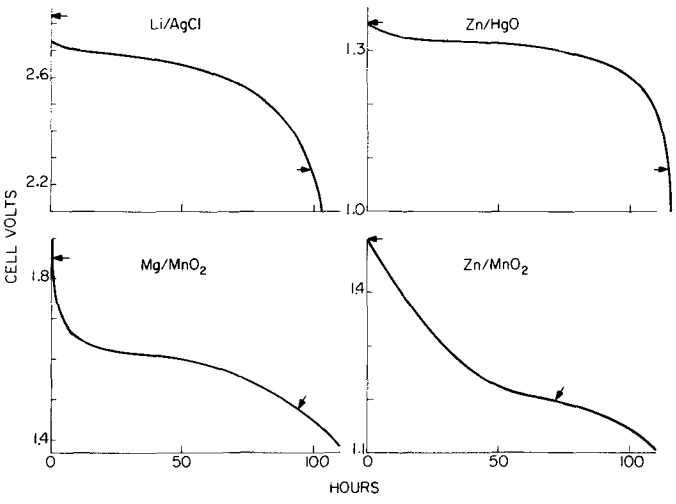

Fig. 4. A comparison of the cell voltage of four systems discharged at comparable rates. Arrows indicate OCV and 0.8 OCV.

Cell capacity.—The theoretical cell capacity is the number of ampere-hour equivalents corresponding to the amount of active material used in the limiting electrode. For this study, the working or true cell capacity is defined as the value of i x t obtained at a voltage greater than 80% of the initial closed-circuit voltage. Therefore, the true capacity is a function of the current density and the temperature of operation. This dependence is not easily described. However, experimental results of commercial mercury and Leclanché cells have successfully been illustrated as approximately linear on log-log plots of discharge time *vs.* current density (8). Figure 5 treats the data for Li/AgCl cells in this manner over a wide temperature range. The measured capacities achieved from 10 to 90% of that theoretically obtainable from the cathode. The discharge times corresponding to 25, 50, and 100% of theoretical capacity are indicated for convenience. Figure 6 compares the Zn/HgO cell with the Li/AgCl cell at 0°C. The mercury cell has a stronger dependence on current density. Figure 7 illustrates the variation in the current density to produce 100% capacity as a function of temperature. The performance of the mercury cell falls rapidly with a decrease in temperature. The current density in the silver cell is low but decreases only very slowly with a decrease in temperature. As a result, the Li/AgCl cell outperforms the mercury cell at temperatures lower than —5°C at all current densities.

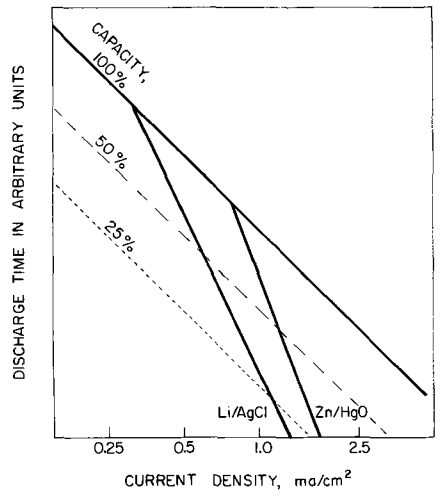

Fig. 6. Comparison of the current density dependence of cell capacity for the Zn/HgO and Li/AgCl button cells at 0°C.

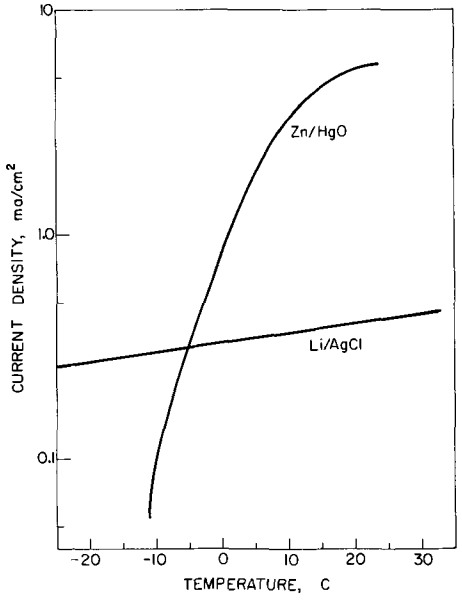

Fig. 7. Maximum current density possible for achieving 100% capacity as a function of temperature.

Cell life.—The shelf life of a battery is an important parameter. However, in new cell systems it is impractical to depend on such long-term tests to provide direction for a development program. Accelerated testing is the only way in which data can be obtained rapidly enough to be of use.

The shelf life data of commercial systems have been presented as linear plots with the logarithm of the life *vs.* the reciprocal absolute temperature (9). In other words, the degradation process behaves as though it is activation controlled. In this way, it is possible to estimate the room-temperature life from high-temperature data. It is not the purpose of this work to prove the validity of this procedure. One of the uncertainties in this procedure is that the degradation mechanism may be a function of temperature, so that the slope of the curve does not remain constant. For this reason, it is preferable to obtain data as near to the use temperature as possible.

These extrapolative procedures often do not yield results rapidly enough. Further acceleration of the testing and lower-temperature data can be obtained from the time variation of the rate of discharge at a given cell voltage. Since flat parallel electrodes are used, the capacity as well as the rate of discharge can be arbitrarily assumed to be proportional to the area or quantity of available active material. Under this assumption, a plot of log i_o/i_t *vs.* time should be linear for a first order reaction (where i_o is the initial current and i_t is the current at time, t). Under the experimental conditions of this study, this assumption seems to hold true as illustrated in Fig. 8. The actual cell discharge capacity was checked in several cases and found to be in substantial agreement with this concept. In this way, it is possible to extrapolate data to obtain a life to some predetermined capacity remaining in the cell, such as 10% of the original working capacity. Data obtained in this manner are given in Fig. 9. The end of cell life is at 10% of the original capacity.

The actual cell capacity was measured for a group of cells stored at 62°C. Cells were periodically removed from storage, then discharged at room temperature. Cells stored for a short time gave a very *long* extrapolated life. As the storage time became longer, the rate of degradation increased as indicated by both i_t and actual cell capacity. It may be possible that poor construction techniques lead to seal problems which result in a short life through electrolyte loss.

The extrapolation to room temperature is not obvious. For lack of a better method, the slope of the lines given in Fig. 9 is the same as that obtained by other workers for the degradation of aqueous batteries. These results indicate a room-temperature life of 1.3-4.0 yr with a possible maximum as large as 7.8 yr. The

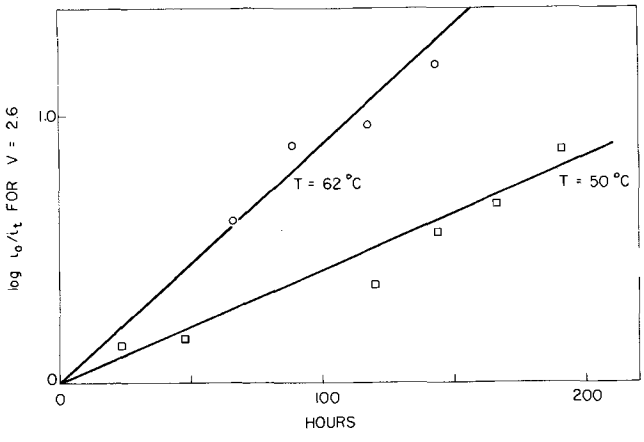

Fig. 8. Cell degradation data, for cells at two temperatures.

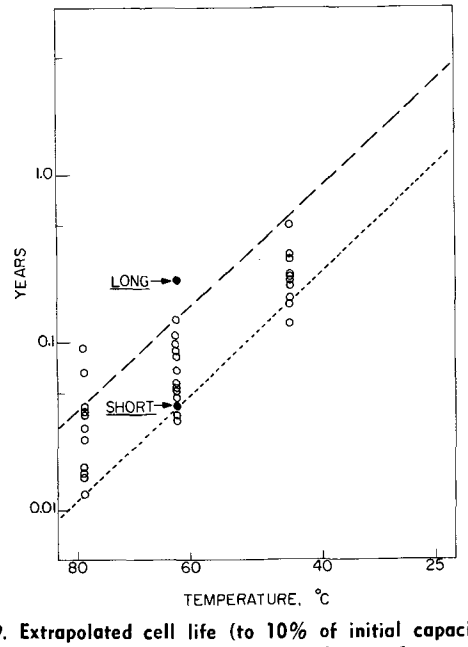

Fig. 9. Extrapolated cell life (to 10% of initial capacity) as a function of storage temperature. Solid circles are for a cell which initially degraded very slowly to yield *long* then rapidly to yield the over-all value labeled *short*.

last figure is estimated from the *long* life extrapolated from 62°C.

The life of these crude laboratory cells is actually quite good and approximately equivalent to the life of standard Leclanché cells.

Discussion

The operating parameters of most cell systems are given in terms of expected usage. With a new system, this is not quite possible since a use is not established. The testing that has been done and is reported here gives an indication of possible uses. These are limited, to some degree, by the fact that the results presented in the preceding paragraphs are for a single rudimentary button cell design. The size and capacity of this cell is roughly that of the PX-14 2.7V mercury battery.

The operating characteristics of these cells are different from any existing cell systems and thus have different possible applications. These Li/AgCl button cells are expected to be useful in low rate (C/100) applications where a wide operating temperature range and good voltage regulation is required. At low temperatures and rates, the discharge characteristics are competitive with Zn/HgO button cells. In addition, the higher cell voltage permits the fabrication of smaller, high-reliability multicell batteries. To estimate the possibility for using the Li/AgCl system as a power source, these properties can be compared with the required properties. Basically, the Li/AgCl cell is not a replacement for all applications of any existing battery. It has certain operating characteristics that present batteries lack. It is a new system which can fill some old, as well as some new, requirements.

Chemical Vapor Deposition of Silicate Glasses for Use with Silicon Devices

I. Deposition Techniques

Werner Kern* and Richard C. Heim[1]

David Sarnoff Research Center, RCA Corporation, Princeton, New Jersey

ABSTRACT

Compositions synthesized include borosilicates, phosphosilicates, aluminosilicates, aluminoborosilicates, and some zinc glasses. The compositions containing aluminum or zinc were prepared by simultaneous oxidation of the hydrides and trimethyl aluminum or diethyl zinc vapor. The deposition temperatures were in the 300°-500°C range. The effects of system variables on the deposition rate and composition of borosilicate films obtained from silane, diborane, and oxygen were examined in detail. Variables investigated included carrier gas and hydride flow rates, silane/diborane and oxygen/hydride ratios, deposition time and temperature, and reactor geometry.

The need to protect semiconductor devices from humid or corrosive environment is well recognized in the manufacturing of transistors and integrated circuits. Conventionally, a passivating layer of thermally grown silicon dioxide has been used to stabilize devices, but its molecular network structure is not sufficiently impervious to contaminants, and the thermal expansion mismatch with the substrate limits the layer thickness. The devices must therefore be sealed in hermetic enclosures. A more desirable packaging technology is based on the sealing of semiconductor device wafers with an impervious dielectric layer so that hermetic enclosures are no longer required. Chemical vapor deposition of silicate glasses is an attractive approach toward this objective. Glass films of suitable composition and high purity can be deposited at relatively low substrate temperatures, the film thickness can be readily controlled, and the films conform to the surface contours of a substrate.

Both organic and inorganic source materials can serve for the chemical vapor synthesis of silicate glasses. Eversteijn (1) deposited aluminosilicate films from tetraethyl siloxane and tri-isobutyl aluminum in oxygen at 400°C. Mayer, Kern, and Goldsmith (2) utilized simultaneous pyrolytic oxidation of tetraethyl siloxane and trimethyl borate or trimethyl phosphate to form borosilicate or phosphosilicate films at 730°C. The synthesis of lead silicate and lead borosilicate glasses with excellent passivating properties was achieved by incorporating tetraethyl lead in the vapor mixture, followed by a thermal densification treatment of the films. Low deposition rates, toxicity, and other shortcomings of the organic systems led us to investigate low-temperature hydride reactions based

* Electrochemical Society Active Member.
[1] Present address: Kasper Instruments, Incorporated, Santa Clara, California.

on the silane oxidation system originally described by Goldsmith and Kern (3). The incorporation of diborane or phosphine leads to borosilicate or phosphosilicate films, respectively. Ternary glass compositions were synthesized by simultaneous gas phase oxidation of silane, diborane, and either trimethyl aluminum leading to aluminoborosilicates, or diethyl zinc leading to zinc borosilicates. The binary borosilicates synthesized from the hydrides and oxygen were found particularly well suited for glassing of silicon devices; this system will therefore be discussed in some detail. The properties of these various glasses will be described in Part II (4) of this paper.

Experimental

Reactants and carrier gases.—Semiconductor-grade silane, diborane, and phosphine, in concentrations of 4-8 vol % in argon (The Matheson Company, Inc.) were used as starting materials. Mass spectrographic gas analysis served to establish the exact gas compositions; the results are shown in Table I. Trimethyl aluminum and diethyl zinc (Ethyl Corporation) of commercial purity were used for preparing the glasses containing aluminum or zinc. The purity of the oxygen was 99.9% and that of nitrogen was 99.998%. The nitrogen and oxygen were passed through a submicron range final filter before entering the flow meters.

Gas distributing system.—A schematic of the gas handling system is shown in Fig. 1. For clarity, the nitrogen-flush for each of the hydride lines has been omitted. The system is operated nominally at atmospheric pressure, but provision is made for pumping out gas lines initially, and for flushing them with nitrogen prior to start-up. A small volume of liquid metal alkyl is drawn from the storage cylinder into a constant temperature bubbler, *e.g.* 25°C, through which nitrogen is passed to carry alkyl vapor to the reaction chamber. Final mixing of the gases is accomplished by turbulence and convection in the deposition chamber.

Deposition apparatus.—The deposition apparatus consists essentially of a heated gear assembly which rotates the substrates in planetary fashion. A commercial high-temperature hotplate with thermostatic control is used to attain substrate temperatures up to 500°C. An opening between the glass chamber and the hotplate surface serves as exhaust. The apparatus is capable of reproducibly depositing uniform films simultaneously on three semiconductor substrate wafers of up to 1.5 in. diameter. A complete description of the equipment has been published previously (5).

General deposition procedure.—The deposition processes were optimized for obtaining various glass compositions, but the general procedure can be summarized as follows. The substrate wafers placed on the cold pedestals are introduced in the preheated, nitrogen-purged chamber. Thermal equilibration of the rotating wafers is attained within 5 min. Diluted silane is introduced first, followed by the oxygen 20 sec later. This sequence of introduction of the substrates and the gases is designed to minimize oxidation of the metal in the case of metallized device wafers. For synthesizing borosilicates, diborane is introduced next. If the diborane were introduced before sufficient oxygen was present in the deposition chamber, oxygen-deficient films could form. The introduction of phosphine or of metal alkyls is less critical with respect to the oxygen excess. For synthesizing ternary compositions, the alkyls are added to the gas stream subsequent to the introduction of the hydrides. Layer structures can be made homogeneous, graded, or abrupt by suitable adjustment of the appropriate gas stream(s). The deposition is terminated by reversing the gas flow sequence.

Fixed test conditions for parameter studies.—The evaluation was based on the deposition rate, the thickness uniformity, several dielectric properties, and the chemical composition of 1μ thick films deposited on silicon.

The fixed conditions for the borosilicate system were as follows: 1—mechanically polished silicon wafers (111-oriented, 10 ohm-cm p-type, 0.015 in. thick) were used as substrates; 2—the temperature at the wafer surface was held at 450° ± 3°C; 3—a hydride mixture corresponding to 22.5 m/o (mole per cent) B_2H_6 and 77.5 m/o SiH_4 was metered, yielding a borosilicate composition of approximately 17 m/o B_2O_3. 4—the oxygen/hydride volume ratio was 40:1; 5—the nitrogen/hydride volume ratio, 530:1; 6—the exit opening of the reaction chamber was 1 mm; 7—the reactive gas flowrates were chosen to yield intermediate deposition rates in the range of 1400-1800 Å min^{-1} and were kept constant within each experiment; 8—the deposition was started and terminated by briefly lifting the reaction chamber during the start of the gas introduction and before shutting off the gases. This procedure avoids formation of the initial and final thin silicon dioxide layers that would complicate the film analysis.

Rate of film deposition.—Film deposition does not begin immediately upon introduction of the reactive gases but it is delayed for a period that depends on the deposition conditions and the substrate surface. Timing of the deposition was therefore started at the precise moment a tan interference-colored deposit appeared on the surfaces of the substrate wafers. For films having a refractive index close to 1.5, this color represents a thickness of approximately 500Å, which was taken into account in the calculation of deposition

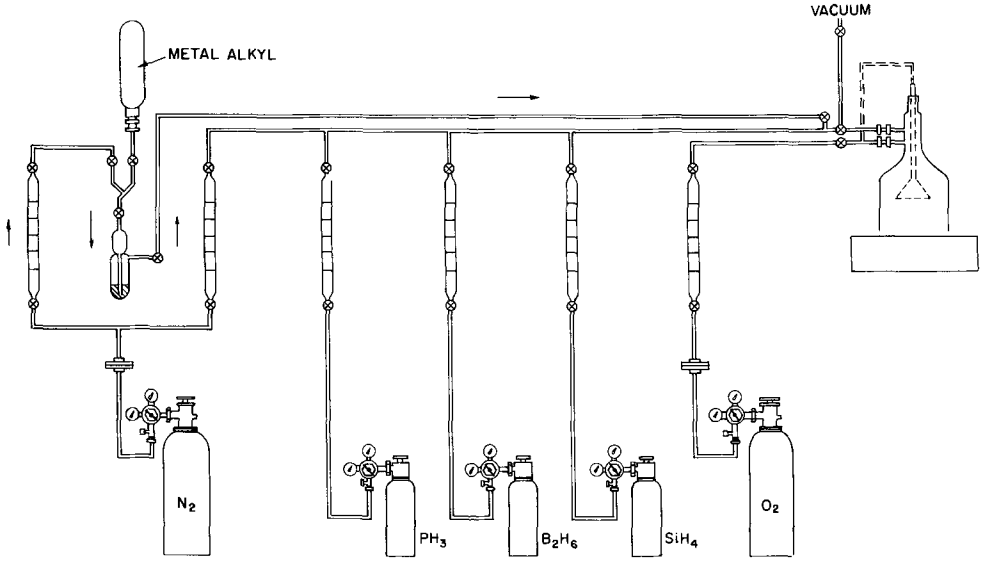

Fig. 1. Schematic of gas regulating and distributing system for chemical vapor glassing.

rates. The exact thickness and composition of the films were determined by methods described in the second paper of this series (4).

Chemical Vapor Deposition of Borosilicate Glasses

Deposition Rate and Borosilicate Composition as a Function of System Variables

Hydride flow rates.—Within certain limits of hydride and nitrogen inputs, the glass deposition rate is directly proportional to the silane-diborane gas flow rates. The linear range of the deposition rate extends up to a flow rate of 11 cm^3 undiluted hydride per minute, where a film deposition rate of 3200 Å min^{-1} is obtained. The reaction yield of vitreous borosilicate glass product on the sample and metal surfaces within the deposition chamber averages about 20%. The remainder forms a powdery deposit on the walls of the reactor or passes out with the exhaust gases. It will be shown later that the yield of vitreous product can be substantially increased by operating at different temperatures and flow rates. If the hydride flow rates are increased beyond 11 cm^3 min^{-1}, the deposition rates under the present conditions tend to level off, but the glass properties and film uniformity are not affected appreciably. For example, doubling the gas flow to 22 cm^3 min^{-1} yields a deposition rate of 3640 Å min^{-1}, an increase of barely 20%.

Nitrogen flow rate.—The main purpose of the nitrogen is to dilute the reactive gases to a safe concentration. The oxidation of the hydride is so vigorous that even at a concentration of only 1.6% silane-diborane in nitrogen the reaction proceeds with a bluish flame when mixed with excess oxygen (32:1). Dilution to 1.2% or below allows the reaction to take place without flame. The concentration in the present test series was 0.17%. As seen from Fig. 2, insufficient dilution of the hydride mixture with nitrogen depresses the rate of deposition. The rates begin to level off at nitrogen flow rates of about 2000 cm^3 min^{-1}; some additional increase is attained by extending the nitrogen flow rate beyond the maximum in Fig. 2 to 4000 cm^3 min^{-1}. Still higher flows impede the deposition rate and lead to nonuniform films.

Silane-to-diborane ratio.—The ratio of silane/diborane is the primary factor that determines the chemical composition of the resulting glass films, provided a large stoichiometric excess of oxygen is present. Figure 3 presents a correlation of the hydride composition with the resulting film composition at the substrate temperature of 450°C. The dashed line indicates the relationship expected on a stoichiometric basis. The boron content in the glass was determined by dissolving the films in hydrofluoric acid and reacting the BF_4^- complex with N-methylthionine (6). The colored complex was extracted and measured spectrophotometrically (7, 8). The precision of each coordinate point in Fig. 3 is defined by the X-Y spread drawn.

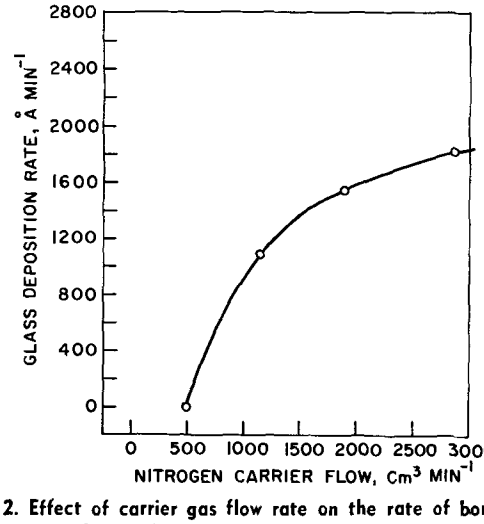

Fig. 2. Effect of carrier gas flow rate on the rate of borosilicate film deposition for the diborane-silane system.

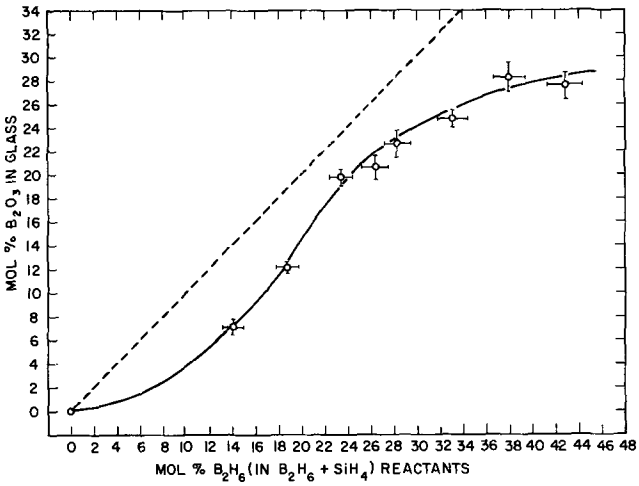

Fig. 3. Glass composition as a function of the hydride composition from which the borosilicates were synthesized at 450°C.

Oxygen-to-hydride ratio.—Based on the stoichiometric reactions of the hydrides with oxygen to form the oxides and water as products, the stoichiometric ratio of oxygen to hydride required for our silane plus diborane mixture is 2.25. In practice, a much larger ratio is required to prevent the formation of the oxygen-deficient films. The composition of such films has not been determined with certainty, but they are poorly insulating and are insoluble in hydrofluoric acid, have a high refractive index, and show no infrared absorption bands in the B-O, B-O-Si, or Si-O regions of 2.5-15μ. Figure 4 indicates that constancy in deposition rate and film composition is attained at ratios beyond 20, a 9-fold stoichiometric excess. It should be pointed out that this graph was obtained for the particular system conditions stated. (For example, borosilicates were obtained at oxygen ratios close to stoichiometry at 400°C under different gas flow and reaction chamber conditions, but the B_2O_3 content in these films was abnormally high.)

Deposition time.—The increase of glass film thickness with deposition time was tested up to a thickness of 42μ (deposition period of 4½ hr) and found to be linear. The deposit on the wall of the reactor was allowed to accumulate during this test and had no measurable effect on the glass composition.

Substrate temperature.—The effect of temperature on the rate of film deposition is presented graphically

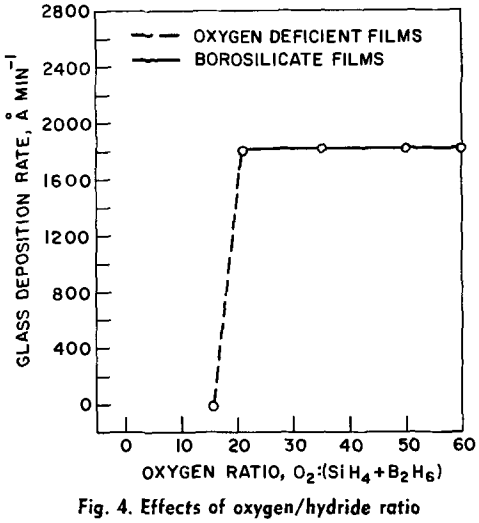

Fig. 4. Effects of oxygen/hydride ratio

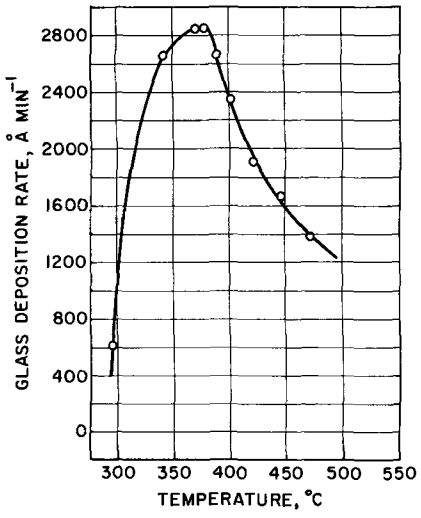

Fig. 5. Film deposition rate vs. substrate temperature

in Fig. 5. A plot (not shown here) of the log deposition rate *vs.* the reciprocal, absolute temperature reveals that the curve is a composite of two straight lines. Borosilicate films begin to deposit at a substrate temperature of about 280°C. The rate of deposition increases steeply with increasing temperature, levels off at about 370°, and drops steeply as the temperature is increased above 375° because of homogeneous gas phase nucleation. The rate of deposition on the walls of the reactor is thereby increased, competing with the formation of glassy borosilicate films on the substrate surface.

The deposition temperature also affects the film composition (Fig. 6). Up to 375°C, the boron oxide content in the glass increases rapidly; above this temperature, the change with increasing temperature is much smaller. Raising the temperature from 400° to 425° increases the boron oxide content about 4%. The temperature of 450° is least sensitive, and would be a desirable one from the standpoint of glass composition control. However, the rates attainable at the lower temperatures are so much greater that a compromise of 400° is usually employed.

The specifically marked data points in Fig. 6 were obtained by using a premixed diborane-silane-argon

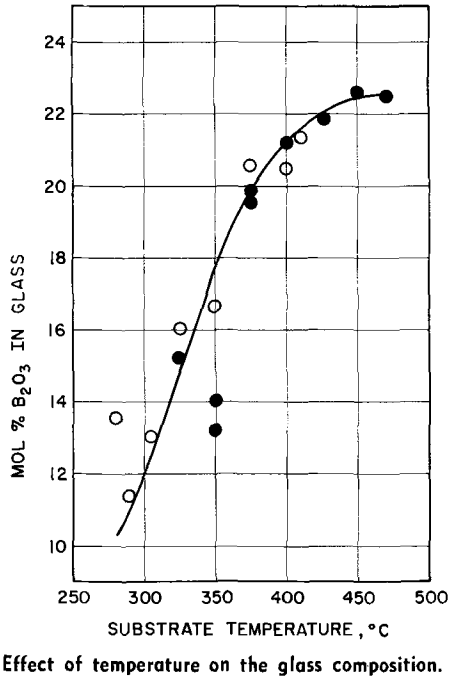

Fig. 6. Effect of temperature on the glass composition. The solid data points were obtained from a premixed diborane-silane mixture.

* "Silicon" concentration in gas = SiH_4 concentration.
** "Boron" concentration in gas = twice B_2H_6 concentration.
The mass spectrographic analyses were carried out by Gollob Analytical Service, Inc. (Gases A-D) and by the Matheson Company, Inc. (Gases E-H). All concentrations are expressed as vol %. The gas samples were scanned by mass spectrographic analysis from mass 2 through mass 100 and no other constituents were detected. The detection threshold for most constituents is 0.001% or better. "d" means by difference.

gas source to guarantee uniformity in the hydride ratio. The mixture contained a slightly higher diborane concentration than used normally, yielding a glass composition with 22.5 m/o B_2O_3 at 450°C; this composition was matched by the separate source mixture.

Deposit on reactor wall.—Three types of oxide product are formed: 1—a glassy borosilicate film on the heated substrate and the metal hotplate surfaces; 2— a white powdery deposit on the inside glass walls of the reactor and the glass support ring; and 3—colloidal oxide particles in the reaction exhaust gases. To increase the yield of glassy product and to avoid contamination of the glass films, the formation of powdery product should be minimized. The build-up of wall deposit was measured both by the time required for the chamber to become translucent by visual observation, and by weighing the wall deposit in the reactor.

Table II lists the effects of three critical system variables on the deposition rate on the walls: 1—temperature of substrate; 2—temperature of reactor wall; and 3—flow rate of carrier gas. The data are presented in terms of stoichiometric yield of glassy substrate deposit and of deposit on the reactor wall. An estimate of the time for the reaction chamber to become translucent is also listed. The theoretical 100% value was calculated from the following chemical reactions, the hydride flow rates used, and a glass density of 2.1 g cm^{-3}:

$$SiH_{4(g)} + 2\,O_{2(g)} \rightarrow SiO_{2(s)} + 2H_2O_{(g)}$$

and

$$B_2H_{6(g)} + 3\,O_{2(g)} \rightarrow B_2O_{3(s)} + 3H_2O_{(g)}$$

It was assumed that the reaction proceeded to completion and that the entire exposed surface area of the heated sample stage was uniformly glass coated with the film thickness measured on the silicon wafers. The data in Table II indicate that lowering the temperature increases the yield of the glassy deposit and decreases the powdery deposit on the reactor wall. If the reactor walls are purposely heated, nearly all of the product deposits on the walls as a glassy layer. Water cooling the wall slightly increases the product yield on the substrate while slightly decreasing that on the wall. The best combination is a lowered substrate temperature and an increased flow rate of carrier gas without deliberately modifying the temperature of the reactor walls. The major portion of product now deposits as uniform glass coating on the substrate surface.

Reactor geometry.—The geometry of the reactor influences the flow patterns in the gas stream. Several different reaction chambers were tested in addition to the standard bell-shaped reactor.[2] These include chambers with modified neck curvature, cylindrical shapes, bottle and deflected designs, and reactors with provisions for either water cooling or heating of the vessel walls. The effects of these variations are minor. However, the nonrestrictive concentric gas exit design of the present chambers was found superior to tubular or slotted openings with respect to deposit uniformity and deposition rate. The spacing between the reaction chamber and the hot stage affects the rate of film deposition to some extent. The rate decreases 7%/mm increase of the opening.

Nature of substrate.—The nature of the substrate surface has a marked effect on the induction period for film growth. The differences can be measured by simultaneously depositing a thin (*e.g.*, 2000Å) glass film on differently treated substrates and comparing the film thicknesses on the samples. For example, an HF-etched polished silicon surface has a short induction time, whereas thermally grown silica or silicon nitride layers have longer times.

Preferred combination of deposition conditions.—Based on the results of this study, a favorable combination of conditions was formulated for the deposition of borosilicate films for our apparatus. A substrate temperature of 400°C and a hydride mixture yielding a glass having 17 ± 1 m/o B_2O_3 were chosen. The hydride mixture satisfying this condition corresponds to 24 m/o B_2H_6 and 76 m/o SiH_4. An oxygen/hydride volume ratio of 25:1 was chosen, and a nitrogen/hydride volume ratio of approximately 400:1. The gas flow rates were adjusted to yield deposition rates in the range of 2000-3000 Å min^{-1}.

Stability of Silane and Diborane Sources

Separate hydride sources.—The stability during storage of diluted silane and diluted diborane was evaluated so that reproducible glass compositions could be prepared. As seen from Table I, variable fractions of higher hydrides of boron and silicon were detected in each of these mixtures, necessitating proper corrections of the gas concentrations by assuming complete oxidation of the higher hydrides. The composition of borosilicate films deposited after various periods of storage but otherwise identical conditions from stoichiometrically equivalent mixtures of these gases has shown that silane and diborane, both in argon at concentrations up to 8 vol %, are reasonably stable at room temperature over a period of at least 10 months (Table III).

Silane plus diborane mixtures.—Premixed gas sources consisting of silane, diborane, and argon would simplify the control of the gas flow rates and assure a uniform composition. Stability studies conducted in our laboratory in connection with doped oxides deposited from silane plus diborane mixtures have shown variable degrees of instability, generally

on the order of 5% decrease in the diborane content per month (9). In the present investigation, glass films were deposited from a mixture containing 6 vol % SiH_4 and 1.3 vol % B_2H_6 in argon (Precision Gas Company) over a period of 6 months. The mixture had high concentration of disilane (600 ppm as compared to normally 30 ppm) and a slightly increased amount of higher boranes. The glass composition deposited initially and after 3 months showed a boron decrease of 7%. After 5 months of gas storage, it had decreased by an average of 11%, and after 6 months, by 13%. The magnitude of these decreases should not adversely affect the glass composition if the mixture is used within a period of a few months. There is no question that argon-diluted diborane mixed with silane is less stable than without silane, which may cause diborane to polymerize to higher boranes that have a low vapor pressure. These would remain in the cylinder causing the gas to decrease in boron content as polymerization continues. Trace impurities may have an inhibiting or catalyzing effect on this reaction; consequently, it is recommended that the highest gas purity available be used and the concentrations of higher silanes and boranes be held to a minimum.

Chemical Vapor Deposition of Other Silicate Glasses

Several other binary and ternary silicate compositions were synthesized from the hydrides with and without metal alkyls. The effects of important deposition parameters on the film composition are summarized below.

Phosphosilicates and Phosphoborosilicates

Films of phosphosilicates were deposited from nitrogen-diluted silane, phosphine, and oxygen, analogous to the borosilicates from silane and diborane. Incorporating diborane in the gas mixture yielded phosphoborosilicate with a composition similar to that expected from the separately deposited binary glasses.

Phosphosilicate films deposited at 400°C from a mixture containing 0.93 vol % PH_3 and 9.08 vol % SiH_4 in argon, at an oxygen/hydride ratio of 12:1, contained 4.7 m/o (10 w/o) P_2O_5. The composition corresponds very closely to the 4.6 m/o expected from the chemical equation based on oxide and water formation. At concentrations up to 5 m/o P_2O_5, the reaction at 400°C proceeds stoichiometrically, but at higher phosphine ratios the phosphorus oxide content in the glass does not increase proportionately. The composition of glasses in the range of 5-10 m/o P_2O_5 is not affected markedly by changes in deposition temperatures of 325°-475°C and oxygen/hydride ratios of 4-24. For example, films prepared at 325° and an oxygen/hydride ratio of 4:1, and films deposited at 475°, ratio of 24:1, had a chemical composition agreeing within 10%. It can generalized that the phosphine-silane system is affected by deposition parameters to a lesser extent than the diborane-silane system. Furthermore, the chemical stability of phosphine on storage is much better than that of diborane; phosphine diluted with argon, or mixtures of phosphine-silane-argon, were found to be stable over periods of at least 1 yr (9).

Aluminosilicates and Aluminoborosilicates

Films of aluminum oxide were obtained from trimethyl aluminum vapor and oxygen at various temperatures (10). Incorporating nitrogen-diluted trimethyl aluminum vapor in the mixture of silane and oxygen, or of silane-diborane-oxygen, yielded aluminosilicates or aluminoborosilicates, respectively. Reaction conditions similar to those employed for binary borosilicate formation were used.

Trimethyl aluminum was selected from aluminum alkyl compounds because of the large aluminum-to-organic ratio, its relatively high vapor pressure which allows liquid alkyl source to be used at room temperature, and the high reactivity of the compound permitting relatively low deposition temperatures. The nitrogen carrying the alkyl vapor should be introduced in the diborane-silane-nitrogen stream just before it enters the reaction chamber to prevent possible condensation of aluminum borohydride in the gas lines. Controlled oxidation of the alkyl-hydride mixture was carried out by introducing oxygen in the reaction chamber as for the binary borosilicate depositions at substrate temperatures of 450° or 475°C. A large stoichiometric excess of oxygen and a relatively high temperature promote complete oxidation of the organic constituents to carbon dioxide and water with the formation of aluminum oxide according to the over-all reaction

$$Al_2(CH_3)_{6(g)} + 24\,O_{2(g)} \rightarrow Al_2O_{3(s)} + 6CO_{2(g)} + 9H_2O_{(g)}$$

Zinc Silicates and Zinc Borosilicates

Vitreous films of zinc oxide, zinc silicates, and zinc borosilicates were prepared analogously to the alumino-glasses. Diethyl zinc vapor was introduced to the system with nitrogen carrier gas from a liquid source bubbler. Zinc oxide films were deposited from diethyl zinc vapor and oxygen at 275°C. The soft film deposits could be hardened by a heat treatment in air at 600°C. Zinc silicates were deposited on silicon substrates at 450°C from diethyl zinc, silane, and a large excess of oxygen with nitrogen as diluent gas. Zinc borosilicates were prepared by adding diborane to the gas stream. These films were deposited at a rate of 800 Å min^{-1}.

Conclusions

The reaction of hydrides, or mixtures of hydrides and metal alkyl vapors, with oxygen at 275°-475°C in a special rotary reactor, has been optimized for the deposition of glass films. Reactants were silane, diborane, phosphine, trimethyl aluminum, diethyl zinc, and oxygen. Nitrogen and argon were the carrier gases. Glass compositions synthesized include borosilicates, phosphosilicates, aluminosilicates, zinc silicates, aluminoborosilicates, and zinc borosilicates.

The deposition parameters for binary borosilicates synthesized from silane, diborane, and oxygen have been discussed in detail. Conclusions of particular importance are: 1—To prevent spontaneous ignition, nitrogen should be added to the reaction mixture to dilute the hydride concentration to 1% or less. 2—The molar boron/silicon ratio in the deposited films is lower than that in the reactant gas. 3—The oxygen/hydride ratio should be at least 20:1 to assure complete oxidation of the hydrides. 4—Starting at 280°C, the deposition rate of borosilicate films increases steeply as the substrate temperature is increased to 375°. The rate declines with a further temperature increase because of the formation of powdery deposits

on the reactor walls. 5—The deposition temperature also affects the composition of the glass films, the boron content in the glass decreasing with decreasing temperatures, especially below 400°C. 6—Borosilicate glasses with a high silica content that are difficult to prepare homogeneously by conventional ceramic techniques (because of their high viscosity and liquidus temperature) can be readily prepared.

For phosphosilicate films containing up to 5 m/o P_2O_5, the deposition from silane, phosphine, and oxygen at 400°C proceeds stoichiometrically, but at higher concentrations the yield of phosphorus oxide diminishes.

The simultaneous gas phase oxidation at 450°-475°C of trimethyl aluminum or diethyl zinc vapor with the silane or silane-diborane yielded aluminosilicate, zinc silicate, aluminoborosilicate, or zinc borosilicate compositions.

A thermal densification is required to approach bulk glass properties. The effects of this treatment are discussed in Part II (4) of this series, together with an evaluation of chemical, dielectric, thermal, and optical properties of the films.

Acknowledgments

We thank especially George F. Stockdale, Larry K. Baker, and Eugene R. Skaw, for independently testing and verifying the chemical vapor glassing technology described in this paper, and James A. Amick for critically reviewing the results and the manuscript. We are also indebted to Bernard L. Goydish for the chemical analyses of glass compositions.

Chemical Vapor Deposition of Silicate Glasses for Use with Silicon Devices

II. Film Properties

Werner Kern* and Richard C. Heim[1]

David Sarnoff Research Center, RCA Corporation, Princeton, New Jersey

ABSTRACT

Chemical, dielectric, thermal, and optical properties of glass films synthesized by chemical vapor reactions from the hydrides are discussed. The binary borosilicate glasses deposited at low temperature from silane, diborane, and oxygen require a thermal densification to approach bulk glass properties. The rate of densification in the temperature range of 770°-800°C is very rapid but water vapor has an accelerating influence, allowing densification at reasonable rates at temperatures as low as 450°C. The thermal expansion match with silicon was sufficiently close to allow the crack-free coating of wafers with 12μ of glass. Borosilicate films of 5μ thickness on silicon withstood severe thermal shock, temperature cycling, moisture penetration, and corrosion resistance tests. Densified borosilicate of typical compositions had a dielectric constant of 3.8-4.1 and a dissipation factor at 10^3 Hz of 0.10-0.15. The d-c dielectric field strength sustained by MIS capacitors made from 1μ thick densified films measured before and after a 1-yr exposure to room air, was 6 to 8 x 10^6 V cm^{-1}. The properties of vapor-deposited phosphosilicate glasses and of glasses containing the oxides of aluminum and zinc are briefly described.

This paper is concerned with the properties of glass films deposited by chemical vapor reaction from hydrides and oxygen by the methods presented in Part I of this series (1). Particular emphasis is placed on binary borosilicate glass compositions synthesized from silane, diborane, and oxygen at 400°-450°C. This type of glass is well suited for glassing silicon device wafers.

Experimental

Film thickness.—Approximate thicknesses of less than 1μ were estimated from the interference color of the films on polished silicon, using the known colors for SiO_2 (2) and taking into account changes of the refractive index of the various glasses. Precision measurements of films up to 2μ were made by multiple-beam interferometry (3) of samples in which a step in the glass was etched followed by overcoating with an opaque metal film (4); the accuracy was typically ±100Å. Much thicker layers were cross-sectioned and measured directly under a Leitz microscope using a calibrated filar eye piece.

Film composition.—Except for the borosilicate glasses, the chemical composition of the films was determined by standard microchemical techniques (1).

* Electrochemical Society Active Member.
[1] Present address: Kasper Instruments, Santa Clara, California.

Routine composition measurements of the borosilicate films were carried out by infrared absorbance. The analysis is based on the ratio of the net intensities of two characteristic main absorption bands, one for B-O and one for Si-O. The absorbance ratios of a series of primary standards of deposited borosilicate films were correlated with the compositions obtained by chemical analysis to establish a calibration curve. Details of the method were presented elsewhere (5).

Film etch rate and density.—The determination of the etch rate was carried out by a technique previously described (6). The measurements were made at 25.0° ± 0.1°C with etchants including hydrofluoric acid of various concentrations, ammonium fluoride buffered HF (454g NH_4F, 654 cm^3 H_2O dist., 163 cm^3 HF 49%), and P-etch (7).

The film density was calculated from thickness, weight, and surface area measurements using 5-10μ thick glass films deposited on 1.25 in. diameter polished silicon wafers. A microbalance (Mettler Type M-5) was used for the weight determinations.

Index of refraction and infrared absorption.—The refractive indices of 1μ thick films were determined interferometrically by reflection spectrophotometry (8) in the visible wavelength region using a double-beam grating spectrophotometer (Beckman Model DB-6).

Infrared measurements were used not only for determining the film composition but also for comparing spectral shifts caused by structural and chemical changes during densification and corrosion tests. Polished high-resistivity silicon wafers of constant and high infrared transmission were used as substrates. Half of each wafer was stripped of its coating and placed in the reference beam of the spectrophotometer (Perkin-Elmer Model 137 B) to cancel possible substrate effects.

Dielectric properties.—One-micron thick glass films were deposited on low-resistivity polished silicon wafers. Circular top electrodes of 0.014 in. diameter aluminum were vacuum-evaporated on these films to form parallel plate capacitors. Capacitance and dissipation factor measurements were made with a capacitance bridge (General Radio Company Model 716-C) at 10^3 Hz. Measurements were made on at least six capacitors per sample to obtain reliable average values.

The d-c dielectric strength of the films was measured by connecting the capacitors so that the silicon was at positive potential to obtain the true dielectric strength of the glass (9). The tests were carried out at 15% relative humidity and 21°C. The voltage was raised in increments to a current of 1 na leakage. The results reported are the arithmetic means of the breakdown field values sustained by 10 different capacitors on the same wafer.

Glass densification treatments.—Densification of the films was conducted in a quartz tube furnace. The ambient gases consisted of high-purity nitrogen or argon, or room air. Water vapor generated from deionized and distilled water in a quartz vessel was used for low-temperature densification.

Properties of Vapor-Deposited Borosilicate Glasses

Film etch rates.—The isothermal etch rate of borosilicates is a characteristic function of the boron oxide content of the glass and the etchant composition. The etch rate in aqueous hydrofluoric acid increases with increasing boron oxide content of the glass as shown in Fig. 1. Etch rates for the same samples after thermal densification are also shown for comparison. The boron content of the hydride mixture can be correlated with the boron content of the glass by means of Fig. 3 presented in Part I of this paper (1). A semilog plot of etch rates as a function of the boric oxide in the glass obtained by this (nonlinear) relation is shown in Fig. 2 for the concentration range 0-30 m/o, (mole per cent) B_2O_3.

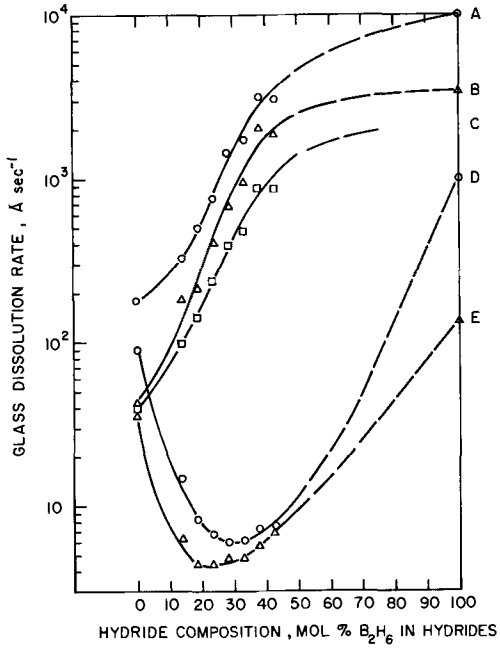

Fig. 1. Etch rate of borosilicate films as functions of the hydride composition from which they were deposited, densification conditions, and etchant. A—Approximate etch rates for films as deposited at 450°C, dilute HF etchant (1 vol 49% HF: 2 vol H_2O). B—Densified 5 min 770°C, Ar; HF etchant (1 vol 49% HF: 2 vol H_2O). C—Densified 5 min 770°C, air; HF etchant (1 vol 49% HF: 2 vol H_2O). D—As-deposited at 450°C, HF-buffer etchant. E—Densified 5 min 770°C, Ar; HF-buffer etchant.

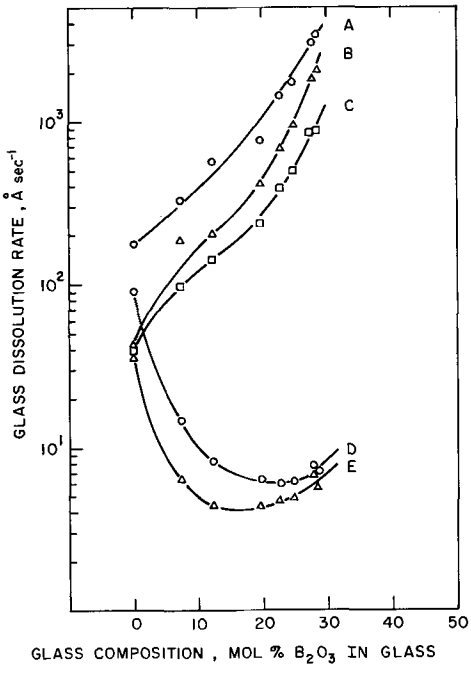

Fig. 2. Etch rate of borosilicate films as functions of glass composition, densification conditions, and etchant. A—Approximate etch rate for films as deposited at 450°C, dilute HF etchant (1 vol 49% HF: 2 vol H_2O). B—Densified 5 min 770°C, Ar; HF etchant (1 vol 49% HF: 2 vol H_2O). C—Densified 5 min 770°C, air; HF etchant (1 vol 49% HF: 2 vol H_2O). D—As-deposited at 450°C, HF-buffer etchant. E—Densified 5 min at 770°C, Ar; HF-buffer etchant.

Different HF-water compositions lead to different etch rates, but the slopes of the curves are similar. P-etch (7), a composition of diluted HF containing some HNO_3, also yields similar slopes. Thermal densification lowers the film etch rates without greatly altering the slope of the curves. The rates of the densified films are similar to those obtained with borosilicate

bulk glasses of comparable composition. The etch rate of a borosilicate glass can therefore serve as a rapid test for estimating its boron content.

The etch rate in buffered HF decreases as the boron oxide content is increased, apparently because of a lowered reactivity of this etchant toward Si-O-B bonds. The increase in etch rate beyond the 20-23 m/o B_2O_3 composition appears to be caused by free B_2O_3. Vapor synthesized borosilicate compositions containing more than approximately 25 m/o B_2O_3 tend to devitrify and may be soluble in boiling water before and after densification at 800°C.

Corrosion resistance.—Thermally densified borosilicate film deposits of standard composition, or compositions containing a lower concentration of boron oxide, were found by infrared analysis to be stable, insoluble, and corrosion resistant even under the following conditions: 1—exposure to cold concentrated HCl, concentrated H_2SO_4; 2—chromic/sulfuric acid at 125°C; 3—sulfuric acid/hydrogen peroxide at 125°C; and 4—boiling deionized and distilled water for 1 hr. The last treatment is a particularly severe stability test for glass films (10). The borosilicates withstood all treatments without change except for a small amount of reversible OH-uptake during the boiling water treatment. Microscopic examination of borosilicate layers containing up to 19 m/o B_2O_3 that had been exposed for 144 hr to 95% relative humidity at 95°C showed no signs of devitrification or other defect formation in both the undensified and the densified states.

Film density.—A 5μ thick borosilicate film deposited at 400°C contained 18 m/o B_2O_3 and had a density of 2.25 g cm^{-3}. Densification in argon at 800°C for 20 min proceeded without detectable loss in weight, while the layer thickness decreased by several per cent. Since there was no loss in weight, the changes observed represent a molecular compaction or densification effect. As expected, the density decreases as the boron oxide content of the glass increases. A sample of a 7μ thick borosilicate film deposited at 375°C contained 20 m/o B_2O_3 and lost no weight on densification at 800°C. The density of this film after heat treatment was 2.24 g cm^{-3}. The density values agree with those for bulk borosilicate glasses of comparable composition.

Resistance to moisture penetration.—The moisture resistance of glass layers was tested by exposing "uncanned" glassed transistors to high humidity at elevated temperature and monitoring critical electrical parameters. Silicon planar npn transistors with a primary passivating layer of thermal SiO_2 and metallized with vapor deposited tungsten (11) were used as test vehicles. The device wafers were coated with 5μ of the borosilicate glass, followed by densification at 770°C, photoresisting, and chemical etching to expose the bonding pads and grid lines for scribing. The device pellets were mounted by conventional techniques on headers, and wire bonded (11). Each transistor was protected mechanically with a topless metal can. Two types of tests were conducted to check for moisture resistance: 1—Exposure to 95% relative humidity at 70°C for periods up to 150 hr followed by 30 min drying in room air. The moisture-sensitive collector-base leakage current (I_{CBO} at −10V d.c., in the low nanoamp range) was monitored. 2—Operating life stress tests at 95% relative humidity and 70°C for 680 hr at periodically increasing power levels. The parameter monitored was V_{BE}, the forward bias potential of the emitter junction required to maintain the rated power dissipation. This test was carried out at high temperature (heat from ambient and heat generated at the collector junction) under reverse bias and at high humidity. The electrical stability observed demonstrated clearly that no moisture had penetrated through the films under these test conditions.

Thermal and structural strength properties.—An important requirement for achieving high-quality glass-to-substrate seals is the absence of stresses that would lead to cracks or other defects. A glass composition with an average coefficient of thermal expansion close to that of the substrate should yield a stress-free system. Actually, a slightly lower coefficient for the glass is preferable to force it under compressive stress, thereby increasing its mechanical strength considerably. In addition to stresses associated with mismatches in thermal expansion, stresses are introduced during the process of film deposition. The total stresses of the various glass compositions were compared empirically observing the maximum layer thickness that could be built up on polished silicon wafers without forming microcracks. The films were deposited at 450°C at rates of 650-1000 Å min^{-1} and analyzed chemically as described earlier. The results presented in Table I indicate that the thermal expansion and contraction match of the glass/silicon system improve with increasing boric oxide content, as expected. The standard composition containing 17 m/o B_2O_3 yielded crack-free layers of approximately 12μ. Compositions much richer in B_2O_3 permit the build-up of substantially thicker layers, but the stability of these boron-rich glasses is poor.

The maximum thickness of crack-free glass obtainable is influenced by the surface area of the substrate. Layers of standard borosilicate were deposited on silicon wafer sections of approximately 1 cm^2. Layers as thick as 54μ were found free of cracks before and after densification at 800°C.

The softening temperatures were measured semiquantitatively by determining the temperature at which two pieces of a glass-coated silicon wafer would fuse under pressures on the order of a few hundred pounds per square inch. The softening temperature was in the range of 800°-850°C for borosilicates of standard composition. It should be noted that a few hundred Angstroms of a SiO_2 layer over the glass are sufficient to prevent fusion.

Thermal shock tests were conducted as follows: Silicon wafers coated with a 5μ layer of glass were cycled from a dry ice-acetone slurry at −65°C to boiling water and back, allowing equilibration periods of 30 sec. Similar tests were also run using liquid nitrogen (−196°C) and boiling water. Microscopic examination at 1000-fold magnification showed that no cracks or other defects formed during these stress tests. When glassed silicon wafers were deliberately fractured, the glass did not separate from the silicon even though silicon fragments tore out of the silicon substrate.

Effects of film densification.—As a general rule, the properties of dielectric films deposited at low temperature can be significantly improved by a heat treatment which densifies the film structure and relieves lattice stresses introduced during deposition. The rate of densification is dependent on both temperature and ambient. Pliskin and Lehman (7) found water vapor to be particularly effective for densifying silicon dioxide films deposited from organo-oxysilanes. Effects of thermal densification of silicon dioxide films from silane (12, 13) and of a variety of glass films synthesized from organic reactants (14) were discussed

Table I. Maximum thicknesses of coherent borosilicate films on silicon wafers as a function of glass composition

previously. The silicate glasses described in the present paper can be densified similarly.

The etch rate data presented in Fig. 1 and 2 are for films as deposited at 450°C and also after densification at 770°C for 5 min in pure argon or in nondried room air. No data for buffered etch were taken for the borosilicate samples densified in air, but the etch rate value for SiO_2 previously reported (12) was 21% lower than for the same sample densified in argon, indicating a generally increased effectiveness of air. The major decrease of the film etch rates at temperatures from 770° to 800°C takes place within the first 5 min of heat treatment. Further decreases proceed at a slow logarithmic rate which is accelerated by water vapor in the ambient as reported in a separate paper (5). This accelerating effect is much more pronounced at lower temperatures. For example, nearly complete densification of a standard borosilicate composition can be achieved in steam at 450°C in about 5 hr, whereas dry ambients would require extremely long periods at this temperature (5). Densification conditions compatible with a particular device structure and metallization can therefore be chosen. The accumulative effects of progressive densification of the films are also manifested in changes of the infrared absorption bands and in the dielectric properties, as shown below.

Infrared absorption.—The infrared spectrum of a typical borosilicate film before and after densification at 800°C is presented in Fig. 3 and compared with the spectrum of a silicon dioxide film deposited from silane. The dominant absorbance maximum between the wavelengths of 9.2 and 9.4μ in each curve, and the smaller peak of 12.4μ, are caused by the Si-O stretching vibration. The peak at 10.85μ in the borosilicate spectra indicates the Si-O-B stretching vibration, and that at 7.4μ, the B-O stretching. The ratio of the absorbance maxima for the 7μ B-O peak and the 9μ Si-O peak was found to be related to the glass composition and was utilized for quantitative analysis. The minor peak at 2.7μ is caused by O-H stretching and disappears during the densification. Other effects of densification for both types of films are an increase in the absorbance intensity of the Si-O major peak and its shift toward shorter wavelengths, similar to SiO_2 films deposited from other source materials (7). It is significant that the absorbance intensity of the B-O peak remains constant, indicating that no loss of B_2O_3 occurs during the heat treatment of the glass films.

Index of refraction.—Films prepared under a variety of deposition conditions were tested before and after densification. Similar to other film properties, the refractive index was relatively independent of deposition conditions for a given glass composition. Typical borosilicate films measured in the 5000-6000Å wavelength region before and after densification, had a refractive index of 1.42-1.43. The refractive index increased toward the shorter wavelength region, the behavior normally observed for glasses.

Dielectric properties.—Dielectric properties of 1μ thick borosilicate films deposited under various conditions were evaluated before and after heat treatment at 800°C in air. The vapor compositions were adjusted to yield glasses containing between 17 and 19 m/o B_2O_3, regardless of the deposition conditions. The results presented in Table II indicate that the dielectric properties are not influenced greatly by these variations.

The dielectric constant for densified films was similar to that of a pure borosilicate bulk glass consisting of 22.1 m/o B_2O_3 and 77.9 m/o SiO_2, which has a value of 4.05 for the frequency range 10^2 to 3 x 10^9 at 25°C (15). The same borosilicate bulk glass has a dissipation factor of 0.086 (most commercial borosilicate glasses containing minor additional components have much higher values) (15). Some loss tangent measurements were also made in the rf range; vapor-deposited and densified borosilicate films of standard composition had a dissipation factor of approximately 1.3% when tested at 2 x 10^9 Hz at 23°C (16). The d-c electrical field strength sustained by MIS capacitors made from various as-deposited 1μ thick films ranged from 6 to 10 x 10^6 V cm^{-1} but decreased substantially on sample storage in room air over a period of 1 yr, whereas capacitors made from the densified films remained perfectly stable. The dielectric breakdown potential measured at a leakage current at 1 na ranged from 650 to 800V (normalized to 10,000Å film thickness), corresponding to 6.5-8.0 x 10^6 V cm^{-1}. The films deposited at 400° and 450°C showed distinct improvements in dielectric strength compared to those formed at 375°C.

The instability in dielectric strength noted above is explained as follows. Undensified borosilicates lose boric oxide on storage. The residual film has, therefore, a lower density which causes a decrease in the

dielectric strength. The loss of B_2O_3 is slow, but can be detected over a period of time by infrared analysis.

Phosphosilicates

The effects on the film composition of variations in the silane/phosphine/oxygen ratio at deposition temperatures from 325° to 475°C were described in Part I (1) of this series. A summary of dielectric properties, etch rates, and infrared absorbance of two typical phosphosilicate films as-deposited at 475°C and after densification at 770°C in argon is presented in Table III.

The most remarkable differences between the phosphosilicates and all other silicates tested are: 1—the absence of marked changes of the dielectric constant on densification, 2—the long-term stability in dielectric strength of both densified and undensified films, and 3—the much smaller decrease of the etch rate after densification. In the more selective P-etch, etch rate changes are more pronounced than in buffered-HF, and the etch rate increases sharply with increasing P_2O_5 content.

Infrared spectra of a phosphosilicate film before and after densification are presented in Fig. 4. The Si-O band in the 9μ region is much broader than that observed for SiO_2 (Fig. 3) and shifts on densification toward shorter wavelength to a greater extent, probably because of a phosphorus-induced increase in polymerization of SiO_4 tetrahedra (17, 18). A second pronounced change on densification (particularly for films deposited at 325°C) is the large increase of absorbance of the P-O band in contrast to the B-O band in borosilicates.

Eleven-micron thick phosphosilicate layers containing 4.65 m/o P_2O_5 and deposited at 400°C on silicon substrates were weighed before and after heat treatment at 800°C in argon. As for borosilicates, no weight loss was detectable on densification. The surface of the glass at this thickness was nodular but the thermal expansion matched silicon sufficiently well to prevent cracking of the films when deposited on wafers. Phosphosilicate compositions containing 13 m/o P_2O_5 were deposited in 25μ thick layers without cracking. Thinner layers of 5μ had a grainy microstructure and exhibited a grayish appearance, whereas films less than 1μ thick were similar to deposited oxide films in appearance.

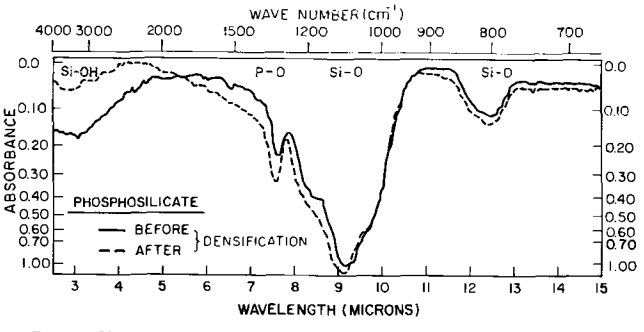

Fig. 4. *IR* absorption spectra of a vapor-deposited phosphosilicate film as-deposited at 475°C and after densification at 770°C in argon for 20 min.

The chemical stability of phosphosilicate films toward moisture at elevated temperature is generally poor because of their inherent hygroscopic nature. For device glassing, phosphosilicates should therefore be used only in conjunction with a more stable outer layer.

Aluminosilicate and Aluminoborosilicates

Aluminosilicate films deposited from silane, trimethyl aluminum, and oxygen at 475°C (1) contained up to 11 m/o Al_2O_3. Properties of a typical aluminosilicate film are shown in Table III. The infrared absorption spectrum was similar to that of SiO_2 films deposited was 8 x 10^6 V cm^{-1} and remained stable over weak absorption maximum noticeable in undensified films in the region of 10.8-11μ.

The incorporation of trimethyl aluminum in the silane-diborane-oxygen reaction mixture did not markedly affect the borosilicate composition. Films deposited at 450°C at a rate of 600 Å min^{-1} consisted typically of 1.5 m/o Al_2O_3, 18 m/o B_2O_3, and 80.5 m/o SiO_2. Layers of 12μ thickness were deposited on silicon without cracking. Properties of a film with a higher alumina content and deposited at 475°C are included in Table III. The dielectric properties, etch rates, and infrared absorption characteristics of these films as-deposited and after densification in argon were very similar to those of binary borosilicates of the same boron content. Microscopic examination of undensified and densified films of aluminosilicates and aluminoborosilicates that had been exposed to 95% relative humidity at 95°C for 144 hr showed no devitrification or other changes. Life tests with transistors as described for borosilicates but employing 5μ of densified aluminoborosilicate withstood moisture penetration tests (680 hr exposure to 95% relative humidity at 70°C).

Zinc Silicates and Zinc Borosilicates

These films were deposited from the appropriate hydride(s), diethyl zinc vapor, and oxygen (1). The

etch rate of zinc silicate films in buffered HF solution was similar to that of silane-deposited SiO_2 films. Crack-free films of 2μ thickness were deposited; crack formation set in at 4μ. Infrared absorption spectra were similar to those for deposited SiO_2 except for the presence of an absorption peak at 10.8μ, which is probably due to Si-OH bending similar to that observed in evaporated SiO_2 films (7). Layers of 1μ thickness withstood dielectric breakdown potentials of greater than 400V.

Crack-free zinc borosilicate films of 4μ thickness were obtained on silicon wafers; line cracks began to set in at 9μ. Etch rates and infrared band positions were very similar to those for binary borosilicates of comparable boron content. As for zinc silicates, the dielectric breakdown potential of 1μ thick film was in excess of 400V.

Conclusions

Important properties of borosilicate films prepared by chemical vapor reaction of silane and diborane with oxygen have been evaluated. The thermal expansion and contraction match with silicon of compositions of typically 17 m/o B_2O_3 are sufficiently good to allow the crack-free build-up of several-micron thick glass layers suitable for glassing of silicon devices. A thermal densification treatment is essential to produce stable films of optimum properties; water vapor accelerates the rate of densification significantly, particularly at low temperatures. The dielectric properties of borosilicate films deposited under a variety of conditions were found to be relatively independent of deposition parameters. For densified films of glasses containing 17-19 m/o B_2O_3, the dielectric values are as follows: dielectric constant, 3.8-4.1; dissipation factor, 0.10-0.15; d-c dielectric breakdown field strength sustained, 6-8 x 10^6 V cm^{-1}. The electrical stability on life testing of borosilicate glassed planar transistors indicates that the glass layer was effective in preventing moisture penetration. Several-micron thick densified borosilicate films are smooth, uniform, transparent, free of cracks or crazing, resist moisture penetration, and are well suited for silicon device glassing.

The ratios of absorbance of the B-O and the Si-O infrared absorption maxima are related to the glass composition and have been utilized for quantitative film composition analysis. The etch rate of borosilicates in specific etchants is a characteristic function of the boron oxide content and can be utilized to check the approximate glass composition. In aqueous HF solutions or in P-etch, the etch rate increases exponentially with increasing boron oxide. In buffered HF, it decreases steeply to a minimum and then increases rapidly with increasing boron oxide concentration due to free B_2O_3. Densification of the films at temperatures from 450° to 800°C lowers the etch rates markedly, indicating an increase of the apparent film density. Densification of borosilicates at 800°C proceeds without weight loss and leads to densities comparable to borosilicate bulk glasses.

The dielectric constant of phosphosilicate films chemically vapor deposited from silane, phosphine, and oxygen did not change on densification, in contrast to all other vapor-synthesized silicate films. The sustained dielectric breakdown field of films as deposited was 8 x 10^6 V cm^{-1} and remained stable over 3 yr of storage in air at room temperature. Phosphosilicates require a protective top layer because of their hygroscopic nature. The properties of silicate glasses containing the oxides of aluminum or zinc showed no distinct advantages over the simpler binary borosilicates.

Technical Note

The Development of a Primary Nonaqueous Lithium/Mercuric Fluoride Cell

S. Lerner and H. N. Seiger*

Electrochemical Research Laboratory, Gulton Industries, Incorporated, Metuchen, New Jersey

The purpose of this program was to investigate the lithium/mercuric fluoride system. This communication describes our efforts to make the HgF_2/Hg electrode dischargeable to a signficant extent in a nonaqueous electrolyte. The theoretical watthours/in.^{3} (59) and watthours/lb (343) for the Li/HgF_2 system compare favorably to those of the Ag/Zn system (61 whr/in.^{3} and 195 whr/lb). In addition, the theoretical open-circuit voltage of 3.4V is more than twice that of Ag/Zn (1.60V).

Because of the dearth of information about such systems, the approach chosen was based on previous experience with the lithium/nickel fluoride nonaqueous system (1).

Preparation of Electrodes

Mercuric fluoride was purchased commercially from Alfa Inorganics, Incorporated. Each shipment of HgF_2 was analyzed for purity by x-ray diffraction. Lithium metal was purchased as a dispersion in mineral oil from Foote Mineral, Incorporated.

The mercuric fluoride electrodes were prepared by pasting a mixture of HgF_2, UCET acetylene black, silver powder, and Microthene on an expanded Monel screen. The UCET is present as a conductive diluent, as the HgF_2 is not conductive. The silver is present to prevent electrode poisoning by amalgamating with the mercury formed as a discharge product. The Microthene is a microporous polyethylene used as a binder. After pasting, the electrodes were heated to 110°C to allow the binder to flow.

The lithium anodes were prepared by pasting lithium in a mineral oil dispersion onto an expanded nickel screen. The pasted screen was pressed in an inert atmosphere to produce a uniform electrode. Prior to constructing a cell, the dispersion oil was removed by leaching in hexane.

The electrolyte chosen after investigations of a number of possible solvent-solute pairs was propylene carbonate-phenyl trimethyl ammonium hexafluorophosphate.

Cell Testing

Cells were constructed using lithium anodes, cathodes of composition 54% HgF_2, 18% Ag, 18% UCET,

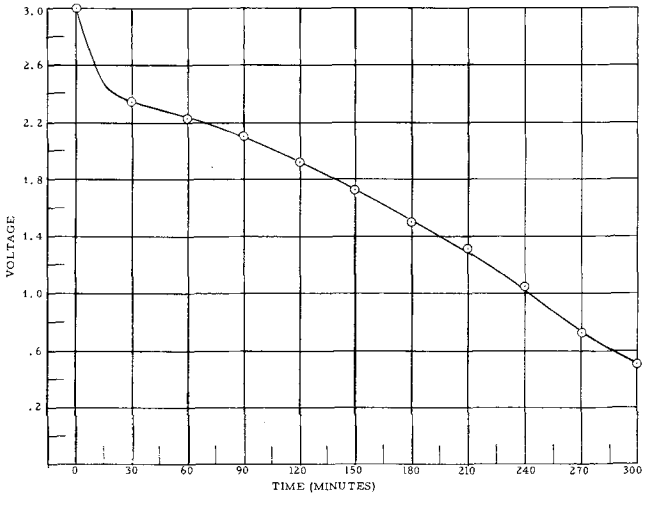

Fig. 2. C/6 discharge curve—HgF_2/Li cell—electrolyte PC/$PTMAPF_6$—54% HgF_2/18% Ag/18% C/10% binder (10 mA = 2 mA/cm^2).

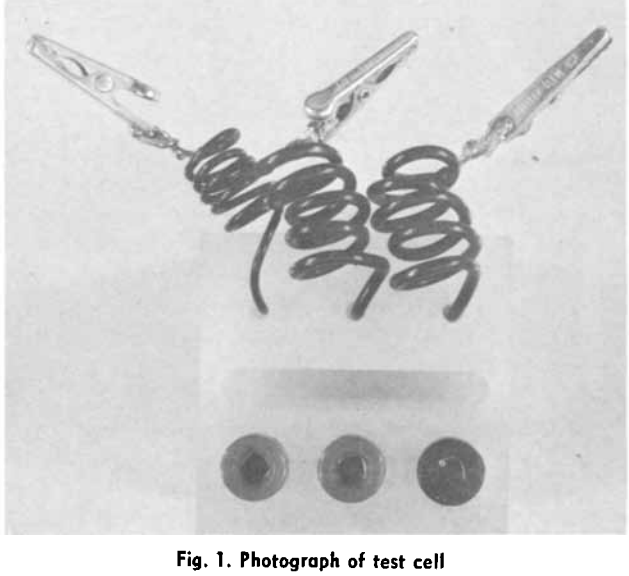

Fig. 1. Photograph of test cell

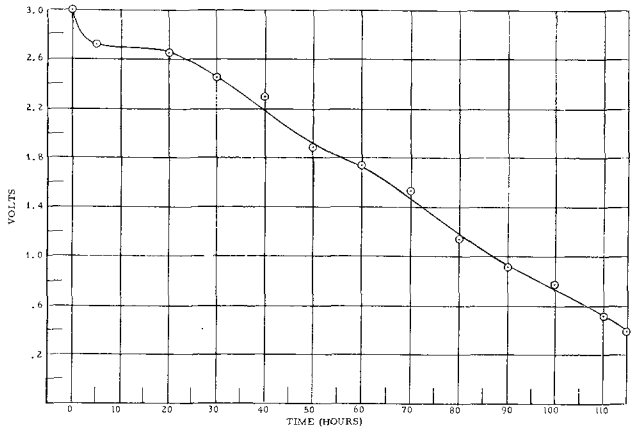

Fig. 3. C/150 discharge curve—HgF_2/Li cell—electrolyte PC/$PTMAPF_6$—54% HgF_2/18% Ag/18% C/10% binder (0.4 mA = 0.08 mA/cm^2).

* Electrochemical Society Active Member.
Key words: primary batteries, nonaqueous cells, lithium, mercuric fluoride, lithium/mercuric fluoride system.

and 10% Microthene binder, and an electrolyte consisting of a saturated solution of phenyl trimethyl ammonium hexafluorophosphate in propylene carbonate. The test cell block is shown in Fig. 1. The electrodes are placed in the slot and connections are made to the positive, negative, and reference electrodes. The jacks allow connection to an external recorder. Typical discharges of cells of this type are shown in Fig. 2 and 3. Figure 2 is a C/6 discharge (10 mA or 2 mA/cm^2) in which the cell delivered 41% of its theoretical capacity at an average voltage of 1.66V. Figure 3 is a discharge at the 150 hr rate (0.4 mA or 0.08 mA/cm^2) in which the cell delivered 39% of its theoretical capacity. The average cell voltage for the entire discharge was 1.6V.

Later analysis showed the material to be about 50% HgF_2 and 50% HgO. Based on the HgF_2 content, discharge showed about 80% utilization of theoretical capacity. Qualitatively, self-discharge occurs to a significant extent over a 2-week period.

Conclusions

The goal of this program was to prepare a mercuric fluoride electrode, dischargeable in a nonaqueous medium.

The work described in this communication indicates that a HgF_2 primary electrode can be prepared which yields a ramped shape voltage characteristic averaging 1.6V at discharge rates of C/6 or lower, and is about 80% efficient based on a two-electron change after correcting for the HgF_2 content. It has also been found that the electrode polarization is, to a large measure, electrolyte dependent. Also, the addition of silver to the electrode markedly increases the voltage level on discharge. We believe this is due to amalgamation of the Hg as it forms, more so than to an increase of conductivity.

Manuscript submitted Aug. 7, 1969; revised manuscript received Dec. 18, 1969.

A. Electrical Energy

1. U. S. Generation.—In 1968, the electrical utility industry of the United States scored records in production, generating capability, construction expenditures, sales, and revenues. Production by the industry was 1326 billion kwhr; the increase of 114 billion kwhr over 1967 represented an increase of 9.4%. Further large gains are anticipated for 1969 (1).

The total United States electrical power system capacity at the end of 1968 was 293,366 Mw, of which the major portion, 226,293 Mw or 77.1%, was obtained from fossil fuel. Contributing factors to the large proportion of fossil fuel plants are reductions in the cost for transporting coal, and construction of mine-mouth plants (2).

Hydroelectric power continued as the second most important, but declining, source of the total U.S. power supply. Conventional hydroelectric plants account for 51,161 Mw or 17.6% of the total capability. This amounts to only 26% of the estimated resources available. Yet the lack of suitable-size hydro installations handicaps future growth of water power. Opposing this trend is the advent of "pumped-storage" stations. For the first time, pumped-storage statistics have been separated from conventional hydroelectric production figures. While the number of conventional hydro plants continues to dwindle each year, the development of sites for the pumped-storage capacity is growing (3).

2. Nuclear Power.—Nuclear energy did not make the operational gains in 1968 that were expected. Just 380 Mw were added according to the data from the Federal Power Commission. As a result, the total of 2817 Mw nuclear-fueled generation in commercial operation amounts to only 1% of the total electrical power system capability. This is the same relative position as a year ago.

Industry, however, is planning increasing reliance on nuclear generation. It is expected that nearly 35% of future expansion installations will be of this variety. Orders for delivery through 1974 approximated 60-65,000 Mw of nuclear-fueled capacity. Reportedly over 70 units are involved, of 500-1100 Mw size. Only 10% of this capacity is expected to produce by the end of 1970 (3).

The total additions to U.S. power generation are listed:

Generation additions in megawatts

Prime mover	Added 1968	Planned for: 1969	1970	1971	1972	Total additions planned
Hydro	2,493	1,757	1,723	1,461	3,915	8,856
Pumped storage	818	400	—	1,020	9,730	11,150
Fossil steam	15,839	18,941	16,952	20,698	38,967	95,588
Nuclear steam	805	2,885	6,873	8,065	44,444	62,267
Internal combustion	345	267	60	47	522	896
Gas turbine	2,495	4,107	2,261	256	666	7,290
Total	22,795	28,357	27,869	31,547	98,244	186,017

3. D-C Power Transmission.—Utility networks added 18,452 circuit miles of 23 kV and over, high-voltage power lines in fiscal 1968. This was an increase of 19% over 1967.

Construction continued on the intertie system linking the Pacific Northwest and the Southwest. Two legs are 500 kV a-c lines, already in operation. A third leg will be an 825 mile, 800 kV, d-c line from the Dalles Substation on the Columbia River to the Sylmar substation in Los Angeles. The fourth line, also 800 kV d.c., extends from Dalles to Hoover Dam. Both d-c lines are capable of delivering 1350 Mw and will reach completion in 1969 and 1972, respectively. When complete, the entire system can transfer 4 million kw of power in either direction (3).

B. Chlorine-Caustic Soda

1. Production.—The production of chlorine increased last year to a new record of 8,460,000 tons in the United States, according to the preliminary figures of The Chlorine Institute, Inc (4). This is an increase of about 10.7% over the 1967 production of chlorine gas. In Canada, gas production also reached a new high of 775,500 tons, up about 10.4% over the preceding year. Average annual growth rate during the period 1959-1968 in the U.S. has been 7¾%.

During 1968, the U.S. daily chlorine capacity jumped 1852 tons, or about 8%. During the same period, Canadian capacity grew by 197 tons, or about 8.6%. The increased U.S. and Canadian capacity in 1968 stemmed from four new and seven expanded chlor-alkali plants, somewhat fewer than for the previous year, and despite three plant shutdowns.

Despite the availability of additional production facilities, U.S. manufacturers in 1968 operated at average monthly rates of 96.4% of capacity, while Canadian manufacturers operated at 89.7%.

At the end of the year, caustic soda was in tight supply. Although the growth rate for caustic is not projected to be as great as that for chlorine, it is

[1] This report is sponsored by the Industrial Electrolytic Division of The Electrochemical Society. Formerly it was known as the "Chlor-Alkali Report," but since 1963 it has been expanded to include other electrolytic industries although it remains primarily a summary of production and developments in the chlor-alkali industry.

The material presented herein has been gathered from many sources, as noted in the References, and does not necessarily represent the opinions of the authors.

* Electrochemical Society Active Member.

anticipated that any future oversupply of caustic soda will be solved by shifting the markets between soda ash and caustic soda. Caustic soda has already replaced soda ash in aluminum potlines, and it may accomplish a similar replacement in the glass industry (5).

2. Expansions.—The Chlorine Institute estimates that, by the end of 1969, projects now under way will increase current U.S. daily capacity of 25,090 tons by more than 2700 tons. Combined U.S. and Canadian annual capacity should reach 10,667,000 tons by the year's end.

Recent changes and announced plans for capacity changes are shown below (6, 7):

Company & location	Type of cell	Capacity, tons/day	Completion date
(a) Shutdown			
Monsanto, Sauget, Mo.	Hooker Diaphragm		Jan. 1969
Monsanto, Anniston, Ala.	DeNora Mercury		May 1969
(b) Production Started			
Alcoa, Point Comfort, Texas	DeNora Mercury	230	April 1968
Allied Chemical Corp., Baton Rouge, La.	Hooker S-4 Diaphragm	500	4th Quarter 1968
Allied Chemical Corp., Syracuse, N. Y.	Hooker S-4 Diaphragm	150	4th Quarter 1968
Dow Chemical of Canada Ltd., Fort Saskatchewan, Alberta	Dow Diaphragm	300	4th Quarter 1968
Hooker Chemical Corp., Taft, La.	Hooker S-4 Diaphragm	140	?
Olin Mathieson Chemical Corp., Charleston, Tenn.	Olin E-812 Mercury	300	Mid-1968
Olin Mathieson Chemical Corp., Saltville, Va.	Olin E-812 Mercury	?	1st Quarter
Reactive Metals, Inc., Ashtabula, Ohio	Downs	50% exp.	Portion mid-1968
Vulcan Materials Co., Newark, N. J.	Hooker Diaphragm	100% exp.	2nd Quarter 1968
(c) Building or Planned			
American Magnesium, Snyder, Texas	Magnesium Cells		Portion 1969 Bal. over 1970
Canso Chemicals Ltd., Abercrombie, Nova Scotia	ICI Mercury		1st Quarter 1970
Consolidated Chemicals, Jamaica		500	1970
Dow Chemical Co., Pittsburgh, Calif.	Dow Mercury	450	Mid-1970
Dryden Chemicals Ltd., Brandon, Manitoba	Dryden Diaphragm	60	2nd Quarter 1969
GAF Corp., Linden, N. J.	BASF-Krebs Mercury	250	3rd Quarter 1969
Interprovincial Cooperative Ltd., Saskatoon, Saskatchewan	Kureha HD-4 Mercury	70 exp.	1st Quarter 1969
Kaiser Aluminum & Chemical Corp., Gramercy, La.	Hooker S3B Diaphragm	300 exp.	May 1969
National Lead, Magnesium Div., Salt Lake City, Utah (Near Grantsville)	Magnesium Cells	360	1971
PPG Industries, Lake Charles, La.	DeNora Mercury	600	1st Quarter 1969
PPG Industries, Puerto Rico	DeNora Mercury	500	1971
Stauffer Chemical Corp., St. Gabriel, La.	Uhde Mercury	500	1st Quarter 1970
Velsicol, Memphis, Tenn.	Hooker S-4 Diaphragm		2nd Quarter 1969
Wyandotte Chemicals Corp., Geismar, La.	Hooker S-4B Diaphragm	350	April 1969

The greatest single end-use for chlorine is as a bleaching agent by pulp and paper mills, accounting for about 17% of all chlorine consumption, and the rate of growth of this usage is about as fast as the average of all the other uses.

The major growth market for chlorine is in the production of vinyl chloride. It was estimated that more than 10% of the 1968 chlorine production was used for vinyl chloride production as compared to less than 9% in 1964, and the share going into monomer production will increase even more, since PVC output rose 15% in 1968 and is still moving up (8).

3. New Developments.—a. Pricing. In the last quarter of 1968, a price hike of $4/ton of chlorine was announced, which brought the price of chlorine in bulk tank-car quantities to $73-$74/ton (8).

b. Mercury. The chlor-alkali industry continued to be the largest user of mercury, with significant increases this year in pharmaceutical and mildew-proofing paint applications. Use of mercury in catalysts dropped.

Mine production of 25,600 flasks was up 8% over 1967, and secondary production increased 35%. In addition, the General Services Administration contributed to the supply by continuing to release surplus mercury at the average rate of 1700 flasks/month. In the first nine months of the year this amounted to 15,175 flasks, but the stock was expected to be exhausted in early 1969. Ninety per cent of the domestic production was realized from California and Nevada, with the remainder from Alaska, Arizona, Idaho, Oregon, Texas, and Washington. Primary production was valued at $13.9 million.

Imports of mercury decreased 12%, though world output remained about constant. Turkey began expanding its production, and Cominco's Pinchi Lake mine in British Columbia commenced production slated to reach 20,000 flasks/yr.

The estimated average U.S. price was $542/flask in 1968, compared with $489 for 1967 and $342 for the 1962-1966 five-year period (9).

Diamond Shamrock began production of mercury in Texas in a plant having an initial capacity of 2000 flasks/yr. This company is also involved in development work in Alaska where, with Hydrametals Corp., it is evaluating a high-grade cinnabar deposit (10).

C. Other Alkalis and Electrolytic Processes

1. Caustic Potash.—Preliminary production figures for caustic potash show an increase of about 8% to almost 178,000 tons in 1968 (11). The price for flake and liquid remained steady during 1968 (12).

Canadian natural potash production continued to rise, and, for the companies with production facilities in both New Mexico and Saskatchewan, there is strong commercial justification for increasing output at the latter at the expense of New Mexico (13).

2. Soda Ash.—Natural and synthetic sodium carbonate (soda ash) production was 2.0 (14) and 4.42 million (15) tons, respectively, in 1968. The bulk of the U.S. natural production came from the Green River formation in Wyoming, with smaller amounts from dry lake beds in California.

While the quantity of natural soda ash rose about 16% over the 1967 figure, the value of this production increased only 12%. Year-end bulk price was $1.55-$1.60/cwt; bagged price was $2.05-$2.15 in hundred-pound paper bags.

According to *British Chemical Engineering*, disproportionately rising chlorine consumption and the attendant caustic excess has spurred design of an improved "electrolyser" by Czech researchers. The outmoded Hargreaves/Bird unit (introduction of carbon dioxide on the cathode side of a diaphragm cell to convert hydroxide to soda) has been modified to a vertical cell with a deposited diaphragm, and graphite anodes. The hydroxyl ions are mostly converted to carbonate ions and this catholyte processed to the final product by a second-stage carbonation in towers. An 80% conversion with a current efficiency of 93-95% is reported (16).

3. Sodium Chlorate.—United States production of sodium chlorate in 1968 was 166,925 tons. This is about an 11% increase over the 1967 figure, larger than the 8% growth rate previously predicted (17). This growth rate is expected to continue with the Penn-Olin completed expansion to 31,000 tons/yr, and the Hooker and the American Potash expansions planned for early 1970 which will add 34,000 tons/yr to industry capacity (18).

The price of drummed chlorate gradually increased to $190/ton by the end of 1968 (19).

4. Sodium.—The projected production of sodium metal, based on the first nine months of 1968, shows a drop of about 5%: 156,000 tons for 1968 compared to 163,000 tons in 1967. Actual figures through September list 116,819 tons produced. Brick price continued most

of the year (20) at $0.225/lb, but ended the year (19) selling for $0.24/lb; fused prices, in the 18,000-lb lots were $0.225/lb at year's end.

The largest use of sodium is by far (over 80%) for the lead alkyl business; tetra-ethyl-lead and tetra-methyl-lead. Of the several possible new markets for sodium, the brightest appears to be NACON (Simplex Wire & Cable and Union Carbide Corp.) Corp.'s metallic sodium polyethylene-clad electrical cable (21). A number are on test in low-voltage applications, and the next target is high-voltage cable. Other possibilities include liquid sodium as a coolant in nuclear power stations, and as a reducing agent in the manufacture of titanium sponge.

5. Aluminum.—Production of primary aluminum in the United States in 1968 continued at near capacity for most of the year but dropped slightly to 3.25 million short tons, partly because of a midyear strike at the two leading producers (22).

Apparent consumption of aluminum in 1968 increased slightly to about 4.1 million tons. The slight decrease in primary aluminum production was offset by an increase in imports, in purchases from surplus Government stocks, and a decrease in producers' stocks. Secondary aluminum production capacity increases at existing installations were made by addition of new potlines at:

Anaconda Aluminum Co., Columbia Falls, Mont.
Consolidated Aluminum Corp., New Johnsonville, Tenn.
Intalco Aluminum Corp., Bellingham, Wash.
Kaiser Aluminum & Chemical Corp., Tacoma, Wash.
Reynolds Metals Co., Longview, Wash.

New plants are being built by:

Eastalco Aluminum Co., Frederick Co., Md.
Gulf Coast Aluminum Corp., Lake Charles, La.
National Southwire Aluminum Co., Hawesville, Ky.
Northwest Aluminum Co., Inc., Warrenton, Ore.
Revere Copper & Brass Co., Scottsdale, Ala.

The total Canadian production in 1968 was approximately 994,500 tons. It is expected that the production will increase about 10% in 1969 (23, 24).

6. Magnesium.—Apparent consumption of magnesium in 1968 was estimated at 103,000 tons. A midyear shortage caused a severe stock depletion coupled with an increase in net exports. Only 3600 tons of magnesium were imported in the January to September period *vs.* exports of 14,000 tons. In October, however, legislation enacted permitting the General Services Administration to offer 55,000 short tons of magnesium from the national stockpile yielded only acceptable bids for 2600 tons. Thus it would appear the midyear shortage had been alleviated (25).

Domestic production of primary magnesium in 1968 was 97,000 short tons, or about the same as 1967. Secondary magnesium recovery, too, was similar to 1967, totaling 13,000 tons this year.

Dow Chemical Co. plants at both Freeport and Velasco, Texas, operated at capacity, producing magnesium from seawater; Alabama Metallurgical Corp. continued production from dolomite at Selma, Ala.; and Titanium Metals Corp. of America at Henderson, Nev., manufactured magnesium for titanium production. As reported last year, American Magnesium Corp. began construction of a 30,000-tons/yr plant at Snyder, Texas. By mid-1969, 10,000 tons of annual capacity should be operable. This facility will use magnesium chloride obtained from underground brines (26).

Northwest Magnesite Co. permanently shut down their operation of magnesite production at Chewelah, Wash. It was reported that FMC planned to discontinue operation of its magnesium oxide plant at Newark, Calif., if no buyer was found by the end of the year. Regarding the Magnesium Project (of National Lead Co., Magnesium Division) at Great Salt Lake, plans are moving forward to operate a 45,000-tons/yr electrolysis plant for magnesium metal (and 81,000 tons/yr of *liquid chlorine*). A major step for MP cost considerations was realized when the Utah Public Service Commission ordered Utah Power and Light Co. to begin negotiations which would supply the project with 3.1 mil power on an uninterruptable basis. Pilot operations at Henderson have produced about 20 tons of magnesium metal for development purposes (27).

Increasing use of the BOF in the steel industry has reduced the per unit requirements for magnesium refractories. Accordingly, continuing the trend started in 1966, production and demand of refractories fell again in 1968.

Dominion Magnesium, Ltd., the only primary magnesium producer in Canada, shipped almost 22,200,000 lb in 1968 as compared to 19,550,000 lb in 1967. The demand is expected to continue strong in 1969 (28).

7. Manganese.—A reduction in import duties for manganese ferroalloys and metal was experienced in 1968, together with continuing soft ore prices. Domestic production of manganese ore, ore concentrate, and nodules—containing 35% or more manganese continued to be insignificant compared to consumption, while both domestic consumption and imports showed little change from those of the preceding year. Australia's new Groote Eylandt deposits became a major supplier of manganese ore for both local consumption and export (29).

Domestic ore consumption was expected to be approximately 2.4 million tons, which is roughly the same as that for each of the two previous years. Foote Mineral Co.'s large new electrolytic manganese metal plant went on stream in May 1968 at New Johnsonville, Tenn.

American Metal Market quotations for manganese ore containing 46-48% manganese dropped 1¢ early in February to $0.59-$0.63 nominal, per long ton unit, c.i.f. eastern seaboard and Gulf ports. Manganese ore prices in all markets remained poor from the standpoint of suppliers. Effective October 21, the price of standard electrolytic manganese metal was cut to $0.266/lb from $0.2985. Reductions were made in other grades of electrolytic metal.

8. Beryllium.—For the fourth consecutive year, the consumption of beryllium in the U.S. increased. General imports of beryl during the January to September period of this year totaled 3486 tons, valued at $2,323,639 at foreign ports. Domestically, Colorado and South Dakota produced small quantities of hand-sorted beryl, but production data are confidential. The Brush Beryllium Co., and Kawecki Berylco Industries (Beryllium Corp. and Kawecki Chemical Co. merger) processed hand-sorted beryl, and electrorefined beryllium was made by Beryllium Metals and Chemical Corp.

Government inventories at midyear showed 28,244 tons of beryl, containing 11% BeO; 7387 tons of Beryllium copper-master alloy; and 229 tons beryllium metal. The General Services Administration sold 16,857 short ton units (stu) of beryllium oxide in September at $50.16-$53.27/stu. The same quality was offered for sale by the GSA at the end of 1968 (30).

In June, Albert Hayward (Assistant Director of Defense Engineering and Research) stated that, in order to guarantee a supply of beryllium metal for defense, the Government may consider subsidizing research in beryllium production or possibly even direct aid to producers. A Government report on sources and fabricating capability, supposedly due in October, was to determine Government action (31).

9. Chromium.—The United States continued to rely exclusively on imports for its chromite requirements. For the first nine months, the metallurgical industry consumed 634,000 short tons of chromite in producing 287,026 tons of chromium alloys, while the refractory and chemical industries consumed 249,000 and 150,000 tons, respectively (32).

Industrial inventory of chromite on September 30 was 26% lower than at the beginning of the year as the

three consuming industries reported significant decreases in stocks.

General Services Administration under a long-range disposal program placed on order for future delivery 99,031 short dry tons of metallurgical chromite. This brought the total for the program to 678,920 tons. During the first 11 months of the year, industry took delivery of 131,220 tons. In October and again in November, an additional 183,680 tons of metallurgical grade chromite were offered for sale on a competitive bid basis. All bids were rejected for both offerings. The material is now available for sale on a negotiated basis.

In November, GSA offered for sale on a competitive bid basis approximately 22,000 tons of chemical-grade chromite. (No acceptable bids were received.) Industry has shown no interest in purchasing this material over the past three years.

Price of metallurgical-grade chromite continued to increase owing to United Nations economic sanctions against Southern Rhodesia, one of the principal suppliers of domestic requirements prior to 1967. The price of Russian (54-56% Cr_2O_3, 4-1 chromium to iron ratio) chromite per long ton was quoted at \$30.50—\$33.00 in 1967, \$36.50—\$40.00 in 1968, and \$45.50—\$49.20 for 1969 delivery. The price of Turkish ore followed a similar pattern.

10. Titanium.—Titanium sponge (refined ore) metal consumption dropped appreciably from 20,000 tons in 1967 to less than 15,000 tons this year. Sponge production decreased 25%, due partly to a strike at Reactive Metals Inc. (owned by U.S. Steel Corp. and National Distillers & Chemical Corp.), Ashtabula, Ohio, plant, and partly resulting from decreased demand. Through September, general imports (including some scrap) decreased about one third. There were no sales of titanium sponge metal from the Government stockpile during 1968. At the end of the year, 99.3% purity titanium sponge metal sold for \$1.32/lb; Japanese sponge metal was quoted at \$1.25/lb.

The slump in the use of titanium is almost wholly due to cutbacks in aerospace programs, which take about 90% of the total U.S. output (33). Principally, these were reductions in federal spending caused by tighter budgets and the stretch-out of the supersonic transport (SST) program (34). In an effort to bolster the sagging market, Titanium Metals Corp. of America (owned by Allegheny Ludlum Steel Corp. and National Lead Co.) cut its prices on sheet, strip, and plate by about 20-30% in August (35). It is hoped the price reductions will make the strong-but-light and anticorrosive qualities of titanium more attractive to construction and chemical industries. Commercially pure sheet and strip (in 4000-lb lots, F.O.B. customer plant) dropped to \$3.45/lb; alloy, \$6.00-\$9.90; plate HR, commercially pure, \$3.00; alloy, \$3.25-\$4.85.

Domestic production and imports of ilmenite both rose significantly. Consumption of ilmenite, chiefly used for making titanium pigment, remained nearly constant. December prices for domestic ilmenite of 60% TiO_2 content ranged from \$30-\$35/short ton; imported ilmenite of 54% TiO_2 content \$20-\$21/long ton or \$1-\$3/long ton less than in December 1967.

Due to cessation of production in July by M&T Chemicals, sole U. S. producer, domestic output of rutile was less than a third of what it was in 1967. Rutile imports were also lower. Demand for rutile, used in making pigment and metal, increased again this year, but not so much as in the last few years. In December 1968 imported rutile of 96% TiO_2 content was \$121-\$125/short ton, or \$2-\$4/ton more than last year (36).

11. Lithium, Cesium, and Rubidium.—The production of lithium minerals and lithium carbonate derived from natural sources was higher in both quantity and value than the previous year.

The processors of lithium raw materials to lithium primary products were Foote Mineral Co. at Sunbright, Va., and Silver Peak, Nev.; American Potash & Chemical Corp., at Trona, Calif.; and Lithium Corp. of America, Inc., at Bessemer City, N.C. Production data were not available for publication (37).

Some quoted prices for lithium products are: lithium metal—100-lb lots, delivered, \$8.00/lb; lithium carbonate—drums, car lots, ton lots, delivered, \$0.445/lb; and lithium chloride, anhydrous, car lots, ton lots, delivered, \$0.85-\$0.87/lb. (19).

Production and prices of cesium and rubidium in 1968 were about the same as in 1967 (38).

12. Copper. The industry-wide copper strike, which began July 15, 1967, continued through the first quarter of 1968 and resulted in a reduction of mine copper output again for the year of 1968. The 1968 total was 1,199,000 tons, a reduction of 16% from the 1,429,000 ton high established in 1966; the monthly output, however, based on the last nine months of 1968 was 123,000 tons which exceeded the 119,000 tons per month figure for 1966 (39).

Smelter production from domestic and foreign primary materials was listed, respectively, at 890,000 and 220,000 tons for the first ten months in 1968, compared to 1,127,570 and 298,250 tons in 1966. The consumption of refined copper also declined for the second straight year, to 1,860,000 tons; this represents a decrease of 4% from 1967 to 21% from 1966. Imports of refined copper and blister copper were up, estimated at 400,000 and 300,000 tons, respectively, over the 1967 values of 330,000 and 269,000 tons. Exports of refined copper were 280,000 tons, or about the same as 1966, after a drop of 159,000 tons in 1967.

Stocks of refined copper rose at primary refineries, totaling 48,000 tons; inventories and unrefined copper also rose slightly to 272,000 tons by the end of 1968.

In April, major copper producers raised the price to \$0.42/lb (from \$0.38). Copper scrap, at a U.S. high of \$0.48/lb in February, fell with the resumption of production to \$0.30/lb in May and leveled out at \$0.33/lb as the year progressed. The London Metal Exchange, similarly, quoted wire bar at a high of \$0.90 which declined to \$0.58 by December.

13. Nickel.—Great activity in the exploration for, and development of, nickel deposits throughout the world, coupled with virtually universal production increases, featured the industry in 1968. Supplies remained tight, however, despite the fact that no marked gain in domestic consumption was registered. The producer price remained unchanged amid rumors of an increase in the offing and differing opinion as to its probable timing (40).

Domestic production of primary nickel from domestic ore was 13,050 short tons, contained in ferronickel. In addition to this production, there was expected to be approximately 1000 tons as a by-product of copper refining and 25,000 tons from secondary sources.

Consumption in the United States at approximately 170,000 tons, as estimated from nine months' data, was at approximately the same level as that of the preceding year—still down from the high of 1966.

The producer price for cathodes remained at \$0.94/lb, F.O.B. shipping point, while ferronickel remained at \$0.915/lb, same basis. *Metals Week* quotations for merchants' or dealers' cathodes had dropped by December to \$1.55-\$1.65/lb, delivered, from \$1.95-\$2.05 at the start of the year.

Imports were expected to approximate 150,000 tons of contained nickel with exports at the previous year's level of approximately 32,000 tons gross weight.

World production of nickel increased approximately 553,000 tons with higher production credited for each of the important producing countries. Exploration and development were vigorously pursued around the world.

In Canada, The International Nickel Co. of Canada Ltd. announced that construction was to start immediately on an \$85-million refinery at Copper Cliff, Ontario. Also in Canada, Falconbridge Nickel Mines Ltd. brought two new mines into production, and

Sherritt Gordon Mines Ltd. was constructing a $2-million pilot plant for testing lateritic ores from the Philippines and elsewhere.

Both Falconbridge and International Nickel proceeded with plans designed to lead to eventual production from lateritic deposits in the Dominican Republic and Guatemala, respectively.

Plans for underdeveloped lateritic deposits of the Philippines, Indonesia, New Caledonia, and elsewhere advanced as did development of the Australian sulfide deposits.

14. Zinc.—The increased smelter output and the continued high imports consumed in 1968 were responsible for a substantial recovery in the domestic zinc industry. Despite work loss at some locations due to strikes, smelter production this year rose 6% to 1,070,000 tons, nearly equaling the all-time 1966 high of 1,108,000 tons. The production of pigments, compounds, and galvanizing by direct use of concentrates increased about 9% to 124,000 tons of contained zinc. Projected general imports of zinc will reach all-time highs, approximately equaling the 1943 ore value of 539,000 tons and the slab figure of 278,000 tons attained in 1966.

Despite the 1968 surge, U.S. mine production of zinc dropped for the third straight year; the 526,000-ton yield was the smallest since 1963. Fifty-three per cent of the total came from Tennessee, New York, Idaho, and Colorado, in ranking order.

Prime Western grade zinc on the East St. Louis market held steady for the year at $0.135/lb. The London Metal Exchange price varied a few tenths of a cent during the year, and was $0.119 in October (41).

D. Developments of Interest

1. Vanadium Refining.—The Bureau of Mines Metallurgy Research Laboratory has developed an electrolytic cell process for refining vanadium to 99.99% purity for breeder reactor use. The process uses a molten salt electrolyte containing vanadium chloride. The anode is a cylindrical double basket containing 99.5% pure vanadium briquettes, and the current passed through the cells deposits the high-purity metal on a central cathode of molybdenum (42).

2. Dimensionally Stable Anode (DSA).—A development of major interest to the $500-million/yr chlorine/caustic soda industry came this year with the announcement by Diamond Shamrock Corp. (Cleveland, Ohio) and Oronzio De Nora Impianti Elettrochimicici (Milan, Italy) of a dimensionally stable anode (DSA). The anode is made domestically by Diamond's subsidiary, Electrode Corp. (formerly Permelec Corp.) which holds exclusive rights to produce, lease, and service the new anode in the U.S. and Canada and Mexico. De Nora is making the DSA in Italy. Monsanto, long the agent marketing de Nora cells in North America, will continue on this role.

The DSA is basically an expanded titanium sheet having a thin coating of a mixture of several conductive metallic oxides. The new anode is said to stay on stream twice as long as the conventional graphite anode. At this time, servicing is required which consists of recoating the titanium substrate with the unidentified metallic oxides formulation. Although the coating remains company-confidential, ruthenium oxide is thought to be one of the components (43).

The advantage attributed to a dimensionally stable anode would be the constant anode-cathode gap. It is reported that cells using the DSA operate at 0.8V less than graphite. Such a condition reduces power losses, and power is the largest single operation expense.

A cell containing these electrodes is reported to operate at 50% higher current density, increase cell productive capacity by 50%, reduce electrical power requirements by 10-20%, and require less mercury initially. It is also expected to operate with less mercury loss per ton of chlorine produced (44).

3. Great Salt Lake.—The Utah Land Board, three years ago, determined to grant nonexclusive rights to extract the dissolved salts contained in Great Salt Lake. In the intervening period, two projects have grown to major significance: (*a*) Lithium Corp.-Salzdetfurth A.G.'s "Great Salt Lake Minerals and Chemicals Corp." and (*b*) National Lead Co.-Magnesium Division's "Magnesium Project." Neither complex will be fully operable before 1970 (27).

The Great Salt Lake Minerals and Chemical Corp. is facing a total expenditure exceeding $30 million for a solar evaporation (completion spring 1968) and lithium and salts recovery complex. The "Magnesium Project" outlay, in the order of $50 million over the next two years it is reported, will encompass an electrolysis plant, a gypsum plant, and other unspecified salts recovery plants.

Recovery of salts other than sodium chloride is complicated by the unique composition (relatively high SO_4 content) and strength of Great Salt Lake brine. Sea water runs about 3.5% dissolved salt; G.S.L. analyses 27%: typically 70% NaCl, 14% $MgCl_2$, 12% Na_2SO_4 and 4% KCl plus important small concentrations of bromine (100 ppm) and lithium (40 ppm). The Lake covers 1000 square miles and is reported to be the biggest source of low-cost K_2SO_4 in the world, in addition to the boon to chemical production of magnesium, lithium, and the other salts.

Manuscript received July 22, 1969. This report was presented at the Industrial Electrolytic Division Luncheon at the New York Meeting, May 4-9, 1969.

Any discussion of this report will appear in a Discussion Section to be published in the December 1970 JOURNAL.

Techniques for Melt-Growth of Luminescent Semiconductor Crystals under Pressure[1]

A. G. Fischer*

RCA Laboratories, Princeton, New Jersey

ABSTRACT

Wide-bandgap III-V and II-VI binary semiconductor crystals can be grown from the melt by a variety of methods, all requiring pressure. The necessary apparatus, from the simple to the sophisticated, has been investigated. Methods using resistance or rf heating, unsupported or supported ampoules of several materials, without or with high-pressure autoclave, under inert or active gas pressure, and the required control systems, are described. A broad description of the liquid encapsulation method is given, and construction details are contained in the figures. Special attention is given to the growth of gallium phosphide crystals and to the preparation of the starting material from the elements.

Compounds like ZnS [mp 1830°C (1)], ZnSe [mp 1515°C (2)], CdS [mp 1475°C (1)], ZnTe [mp 1300°C (3)], and GaP [mp 1470°C (4)] decompose into their volatile components far below their melting points so that crystals can be grown from the melt only under pressure. Since large crystals can be grown from the melt faster and hence more inexpensively than by other methods, the need for initially costly pressure equipment is no longer a major deterrent.

As usual in many fields, the long period of dormancy in which only a few devoted enthusiasts do the exploratory work, without much response, is over for crystal growth from the melt under pressure. Recently it became the focus of attention. This was caused by the coincidence of an industrial need for GaP crystals for electroluminescent diodes, triggered by the achievement of high efficiency in the visible, and the achievement of large GaP single crystals made by pulling through a boric oxide blanket under pressure.

Many of the results described here are scattered in government contract and conference reports so that a review of this increasingly important field is now timely. The results of other workers in this field are included. Most of the methods described below have actually been tested by us, so that their advantages and disadvantages can be related with authority.

The paper is organized by describing the techniques in sequence of increasing complexity and refinement, which coincides frequently with the chronological order of their conception. Since materials synthesis is closely intermeshed with crystal growth, the synthesis methods are not described separately, but within the proper context. We treat Bridgman and Czochralski methods under high inert gas pressure and under cation or anion vapor pressure, the necessary equipment, control systems as they become necessary, and material synthesis from the elements. Since it is of prime importance now, we describe in detail crystal growth using liquid encapsulation, published by Metz, Miller and Mazelsky (5) in 1962, applied to GaP first by Bass and Oliver (6) at SERL, and amplified by our own results (7).

The paper contains, besides numerous new scientific results, practical experiences and technological innovations, especially in the figures. The paper is confined to *techniques and methods;* properties of the prepared crystals have been and will be described elsewhere.

Resistance Heater Methods

Bridgman growth under high inert gas pressure.— Tiede and Schleede (8) found that ZnS and CdS could be melted by retarding the decomposition with high nitrogen pressure. We found this method to work only for II-VI compounds, where cation and anion are similar in volatility. With III-V compounds, the metal has hardly any vapor pressure and thus is retained in the crucible, whereas the anion escapes. GaN and InN decompose even under 200 atm of N_2 pressure. Due to the stability of the N_2-molecule, nitrogen behaves like an inert gas in this case.

To repulse the emanating vapors effectively, the pressure of the inert atmosphere should be as high as possible; more than 100 atm are usually applied for ZnS and CdS. The atmosphere at the melt surface should be still, not turbulent, which precludes crystal pulling because of strong thermal drafts at the open meniscus of the melt. The crucible should be covered by a lid.

After examining other possible constructions (1, 9), we found that the most advantageous graphite tube furnace, suitable for 2200°C max and 200 atm, is the one shown in Fig. 1 (10, 11). In this furnace, a straight, high-density carbon tube, which can be tapered in its wall thickness along its length at will to influence the thermal gradient, is clamped and contacted at one end by a packing of compressed graphite granules to allow for thermal expansion and contraction. The autoclave lid is one electrode, the bottom vessel the other. Since only 12V max are needed, the pressure gasket seal also acts as an electrical insulator. For

Key words: crystal growth, semiconductor crystals, liquid encapsulation.

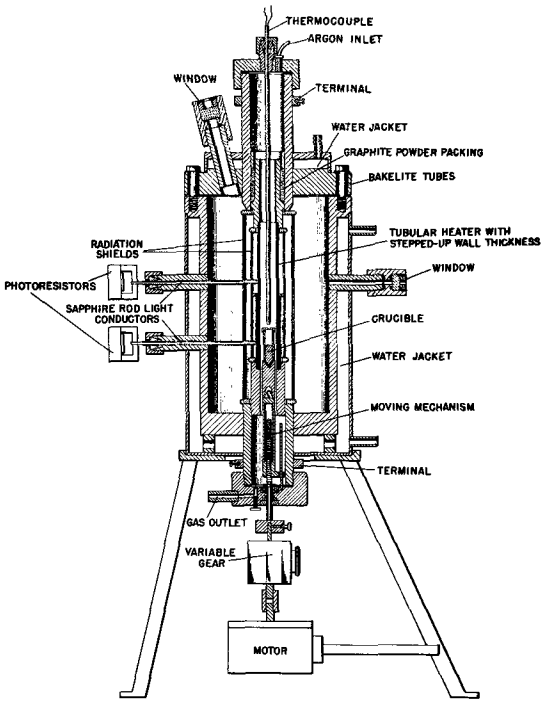

Fig. 1. Carbon-tube furnace (12V, 2000A) for up to 2200°C, 250 atm. The carbon tube with stepped-up wall thickness and radiation shields is held by granular carbon packings at the ends.

reasons of purity, use of carbon or molybdenum cylinders as radiation baffles is preferable to granular ceramic insulation (12). Other graphite furnaces using delicate double-wall graphite tubes or double helixes, with contacts at the same side, are not as rugged and flexible in use.

Corrosive vapors from the melt attack thermocouples; smoke and thermal schlieren in the compressed, dense gas make the use of optical pyrometers inaccurate. Therefore, the temperature is sensed best with a sapphire rod light conductor (10), as shown in Fig. 1. Stabilization of the input power against line voltage fluctuations[2] is advantageous in all crystal growth equipment described. For this particular furnace, temperature control was *via* saturable reactor and step-down transformer, using a proportional controller. To allow accurate control by the sluggish big saturable reactor, load inertia had to be increased by using a thick-walled, cylindrical graphite radiation baffle, not shown in the figure. (To prevent oscillations, a control system must be able to respond faster than the process to be controlled.) A simple electromechanical melting-point detector (12) was found to be very useful.

Crystals of all wide-gap II-VI compounds are now being grown successfully by this method at many places.

The capillary-tipped ampoule method for ZnTe.— ZnTe has a relatively low melting temperature and decomposition pressure, but the starting material usually contains a slight, hard-to-remove excess of tellurium. The ZnTe therefore develops a higher pressure when it is sealed into a quartz ampoule than its true stoichiometric decomposition pressure, which is 1.9 atm.[3] This leads to thermoplastic expansion of the ampoule.

[2] Automatic voltage regulator, General Radio Company, Concord, Massachusetts.

[3] This value is higher than the published value of 0.6 atm obtained by extrapolation from measurements at lower temperature. We determined it by lowering the pressure over a liquid-encapsulated melt (*see* later in this article) until the melt started fuming violently. The corresponding values for ZnSe (2.2 atm), and for CdS (3.2 atm), also differ from published values. ZnS could not be measured by this method due to rapid volatilization of the encapsulant at 1830°C.

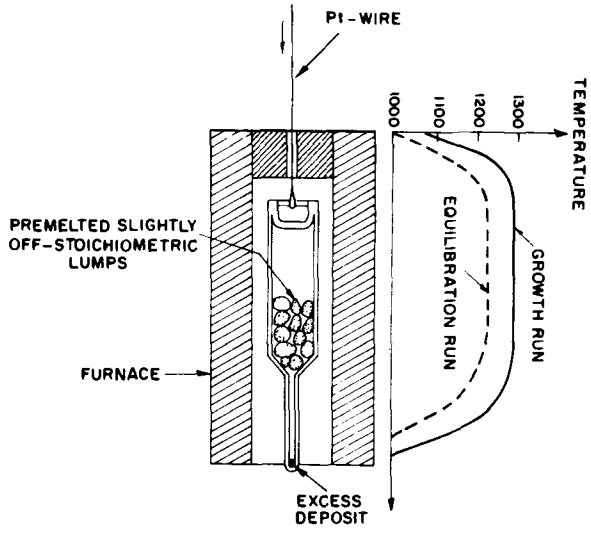

Fig. 2. Melting of ZnTe in unsupported quartz ampoules with capillary cold trap to remove excess components.

It was found that ZnTe crystals can be grown from the melt in unsupported quartz ampoules if the ampoules have a capillary extension which protrudes from the furnace into the cold, where it is closed (13). This cold capillary traps the excess volatile component and then seals itself (Fig. 2). This simple method is applicable to other similar compounds.

The "soft ampoule" method.—In order to control the stoichiometric composition of the growing crystal, one has to apply excess cation or anion pressure. This requires a gas-tight container which is inert at temperatures of about 1500°C, where compounds such as GaP, ZnSe or CdS melt.

A quartz or borosilicate (Vycor) ampoule, even when thermoplastic at the melting point of the compound, serves as a gastight inert vessel. By letting the internal decomposition pressure drive it against a tight-fitting graphite enclosure which counteracts the mechanical forces (14) (*see* Fig. 3), many atmospheres of pressure can be sustained. This method works for ZnSe and CdS, and has been used recently in modified form for GaP (15).

It was found earlier (14) that, during the initial heating of a compound to the melting point, the internal pressure could be high while the ampoule is still brittle, leading to ampoule failure. This can be prevented by heating the ampoule very fast, so that it reaches its softening temperature while the charge is still relatively cool, and therefore, does not exert its full decomposition pressure. This method is simple but limits the time of growth runs to a few hours due to gradual divitrification of the quartz, unless alkali contamination is carefully avoided (26).

Preparing II-VI compounds from the elements.— The II-VI compound materials can be purchased as chemically prepared fluffy powders.[4] Particle size can be enlarged by firing in hydrogen. But if one melts such densified powders, the volume of the final ingot is still only about 1/5 of the original powder, leaving too much unused crucible space.

As compared to the customary laborious synthesis of polycrystalline chunks from the elements by vapor reaction in sealed ampoules, the following method is much simpler and yields compact slugs which can be made exactly to fit the crucible that is later used for single-crystal growth.

The spectroscopically pure elements are reacted in a small "bomb" (Fig. 4) which is pressurized with full

[4] For instance from General Electric Company, 1099 Ivanhoe Rd., Cleveland 10, Ohio.

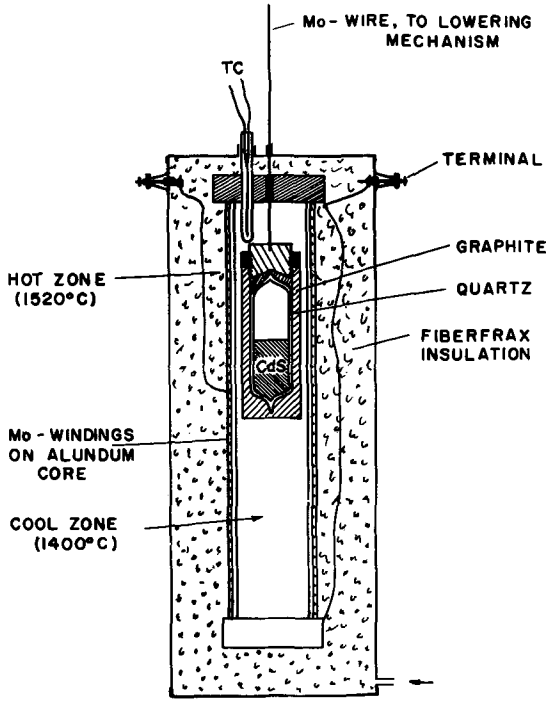

Fig. 3. Growth of CdS by "soft ampoule" method also applicable for ZnSe and GaP.

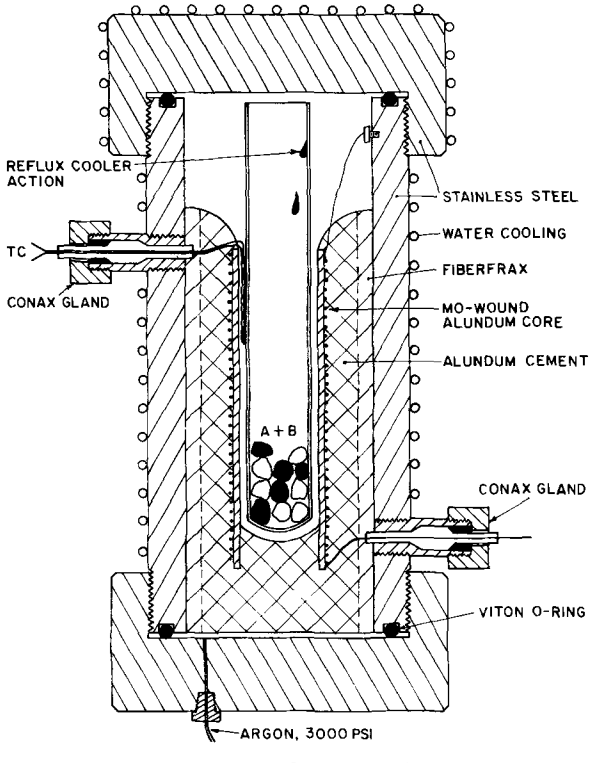

Fig. 4. Bomb for synthesis of polycrystalline II-VI ingots from the elements.

tank pressure of argon (250 atm) (11). When the Mo-wound heater is slowly warmed to the melting point of the compound, the pressure rises to about 400 atm by thermal expansion of the gas. The mixed pieces of the elements, even if they should react strongly exothermically, cannot create a shock wave, due to the inert atmosphere slowing down the rate of the reaction. The upper end of the quartz tube reaches out of the furnace into the colder part of the bomb, acting as a trap and "reflux" cooler. Since some anion vapor is usually lost, one adds more than needed at the beginning.

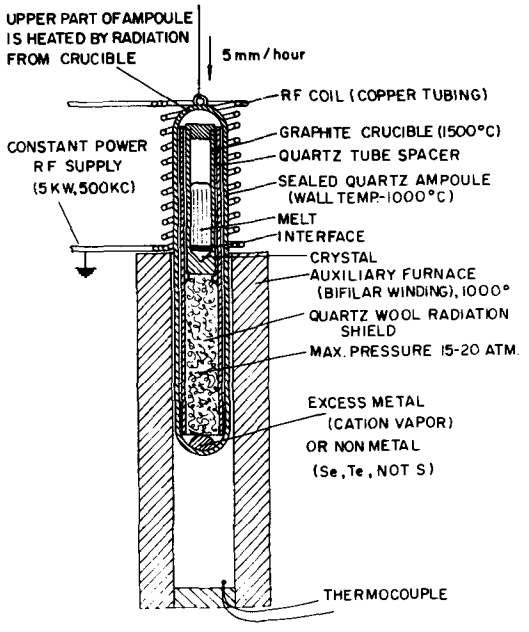

Fig. 5. RF Bridgman growth under controlled atmosphere in unsupported quartz ampoule.

All II-VI compounds can be synthesized quite easily in this way, including ZnS. For the III-V compounds, especially the phosphides, better methods are described later.

Induction Heater Methods

Vertical and horizontal Bridgman method in unsupported quartz ampoules.—Induction heating can be more advantageous than resistance heating because it allows one to heat a graphite crucible to a very high temperature *inside* a quartz ampoule, whereas the ampoule itself can be kept below its weakening temperature. Standard-wall quartz tubes of 1-in. OD can stand 30 atm of pressure up to 1000°C. However, safety shields should be used for protection of the operator.

In the arrangement shown in Fig. 5, the lower, cooler part of the ampoule extends into a wire-wound heater which is bifilarly wound (two parallel helixes connected at one end, with both terminals at the other end) as are all wire-wound resistance heaters located near rf coils, to prevent rf coupling. It contains the excess cation or anion material which provides the required vapor pressure. The upper, hotter part receives an experimentally adjusted amount of radiative heat from the graphite susceptor inside (13). The temperature of this part can be roughly checked with "Tempilstik" thermocrayons.[5]

To melt-grow ZnS and CdS, a sulfur atmosphere cannot be used with porous carbon susceptors because of CS_2 formation which leads to explosions (10, 16). Vitreous carbon is more inert, but the growth runs still must be short. Much better results are obtained by melting II-VI compounds under their metal vapors. In this way, ZnS, CdS, and ZnSe can be prepared highly n-type and with high mobility (10) (especially with additional aluminum doping) in a one-step process, in contrast to other methods which require after-firing of the crystal submerged in a cation metal melt.

This method can also be used for horizontal zone melting (16). For example, silver impurities have been effectively swept to one end of a ZnSe ingot, rendering it weakly p-type (17).

Vertical Bridgman growth in pressure-relieved ampoules.—To remove the explosion hazard of quartz ampoules, the decomposition pressure inside the ampoule, which reaches a dangerous magnitude in the preparation of GaP (35 atm), can be balanced by external gas pressure in a steel autoclave.

[5] Tempilstik Corporation, New York, N. Y.

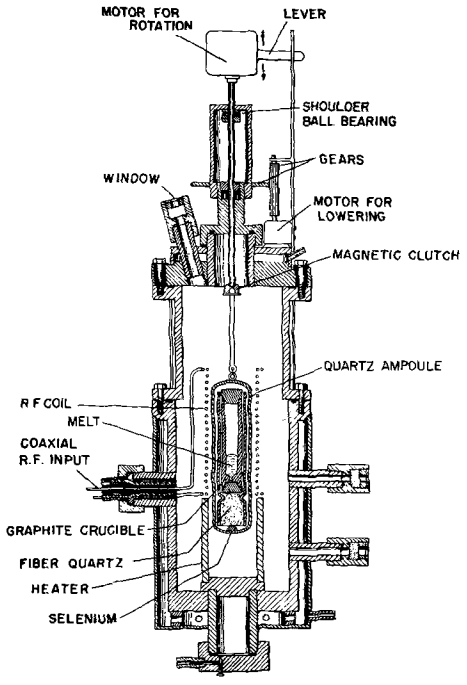

Fig. 6. RF Bridgman growth of ZnSe in pressure-compensated sealed ampoule in steel autoclave. Note the coaxial rf input.

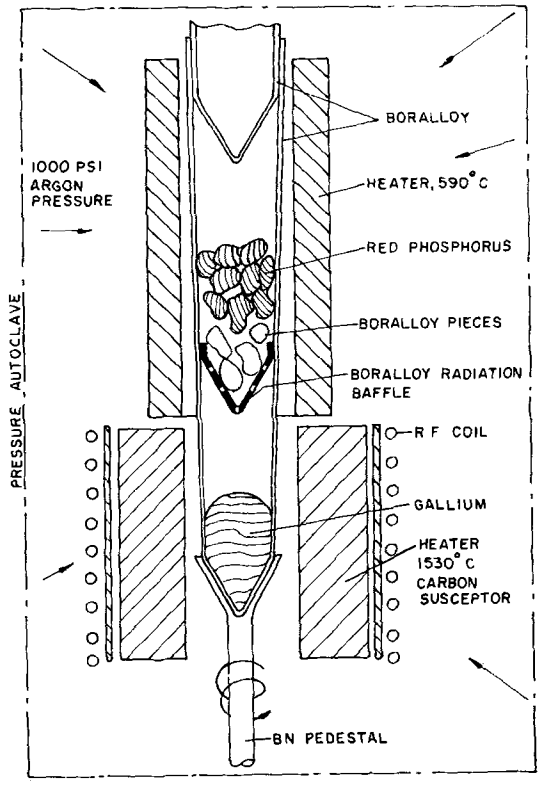

Fig. 7. GaP synthesis and crystal growth in a demountable pyrolytic BN ampoule.

An rf work coil placed inside a thick-walled steel vessel does not lead to significant power losses if 2-3 in. of clearance is maintained. The water-cooled rf leads should be brought through the steel walls coaxially if magnetic steel walls and/or frequencies above 1 megacycle are used. For nonmagnetic (stainless steel) walls, which are preferable for cleanliness, and for frequencies of 500 kilocycles or lower, simple straight parallel feedthroughs with Teflon bushings[6] are sufficient.

This vertical Bridgman method (Fig. 6) has been successfully used for ZnSe crystal growth (10, 17, 18) and is applicable to GaP growth under P pressure.

In order to simplify this method and do away with ampoule pumping and sealing, a demountable, reusable ampoule with a ground joint can be used (17). The internal atmosphere communicates with the external pressurized gas (which, for this reason, must be of ultrahigh purity) through a capillary which is heated to prevent clogging. The crystal grows, in the case of ZnSe for example, in an argon-selenium atmosphere. This method has the additional advantage that the added argon pressure prevents bubbling of the solidifying melt caused by exudation of the excess anion concentration of the melt at the interface, which is frequently observed in pure anion atmospheres. The disadvantage is, of course, that some anion vapor escapes through the capillary and contaminates the autoclave; this can be minimized by trapping it on a nearby cold surface.

For melt-growth of GaP we found early (10) that boron nitride containers are desirable since BN does not react with GaP (19). "Boralloy" pyrolytic BN crucibles[7] are ideal since they are very pure and can be reused almost indefinitely because the GaP does not stick to the walls. For II-VI compounds, vitreous carbon[8] makes an excellent container material.

This growth method, in conjunction with Boralloy containers, has yielded the most economical method for GaP synthesis and crystal growth (*see* Fig. 7). Pure gallium and red phosphorus[9] are placed in a long conical Boralloy crucible, separated by a perforated radiation baffle, as shown. The crucible is closed by a loosely fitting Boralloy lid, made intentionally nonfitting by a piece of red phosphorus which volatilizes subsequently. The whole system is pumped, filled, and pressurized with argon to 75 atm. The gallium is heated to 1500°C and the phosphorus to 590°C, corresponding to 40 atm of phosphorus pressure. The red phosphorus is quite stable and decomposes only very gradually to attain its thermal equilibrium pressure.

After the GaP has formed, the Boralloy crucible is slowly cooled, or lowered into a cooler zone, for Bridgman-type crystallization. The thin and flexible Boralloy container does not exert mechanical strain on the crystal by differential thermal expansion. After this, the system is shut off and depressurized. The GaP crystal falls right out of the inverted Boralloy crucible. This is a one-step operation which can be fully automated, with no contamination by silicon (which occurs by contact with quartz) or carbon (if a carbon rf susceptor in a phosphorus atmosphere is used), and all parts can be reused indefinitely.

In all of these methods, the necessary rf power setting for reaching the melting point must be determined in a preliminary "dry" run where a thermocouple is inserted into the crucible. Tungsten-rhenium thermocouples[10] are most suitable, even though they drift somewhat due to contamination. This effect is much stronger in platinum-rhodium thermocouples which are very sensitive to phosphorus.

During the actual run, one usually relies on the constancy of the generator output which is sensed *via* rf pickup coil and "thermocross" tube[11] (Fig. 8), or grid-dip meter. An additive combination of thermocouple temperature signal and rf pickup signal proved to give even better constancy (20) (better than ± 1°C). Very small loads (thimble-sized crucibles) require fast-responding control systems using thyristors or thyratrons in the rf power supply (20), whereas larger (about pound-sized) loads can be conveniently controlled with customary, sluggish saturable reactor systems in the line power supply. For medium-sized loads, such as for a crucible of 200g weight, it is bet-

ter to use small fast-responding presaturated saturable reactors in the pulsed d.c. of the high-voltage line to the rf tubes,[12] presently still more reliable than SCR's, rather than a bulky reactor in the line voltage supply. Temperature control systems employing fast smooth all-electronic signal transfer[13] are inexpensive and preferable to jerky electromechanical systems.

Czochralski-type pulling under pressure.—Gremmelmeier-type pulling (21) under pressure in sealed quartz ampoules, with force transfer by rotating magnets, requires rather accurate bucking of the internal decomposition pressure by external autoclave pressure to prevent explosions or inplosions (10). The slow attainment of the equilibrium phosphorus vapor pressure over red phosphorus necessitates a differential manometer (10), but this adds further complication. There are other additional reasons which make this method unduly difficult. In addition to the auxiliary heaters to maintain the vapor pressure, one needs additional heaters to keep the viewing windows unfogged, since visibility is mandatory for crystal pulling. Furthermore, for pulling II-VI compounds, atmospheres consisting of the group VI vapors cannot be used because S, Se, and Te vapors are opaque (10). If one attempts to grow under cation vapor pressure, the required temperatures to reach the proper vapor pressures are above 700°C, where the magnets become very weak. Instead of the Gremmelmeier-type, one must use demountable ampoules with precision-sealed rotating quartz shafts (Fig. 9) (10), with elaborate baffle shields to prevent sticking by formation of deposits. Such systems have been built, and much effort was spent to pull GaP crystals under phosphorus pressure using a magnetic pulling apparatus (25), with only partial success, due to these complications. However, in the perspective of this paper, the method illustrated in Fig. 9 is presently the only one which would permit *pulling* of II-VI crystals, for which no suitable encapsulants (*see* later) are available as yet.

Crystal Growth Using Liquid Encapsulation (L.E.)

Czochralski pulling.—Crystal pulling using an oriented seed is undoubtedly the best crystal growth method. By placing a liquid blanket of molten boric oxide on top of the semiconductor melt and applying inert gas pressure exceeding the decomposition pressure, melt decomposition and escape of vapors can be prevented in an elegant and simple way, making auxiliary heaters and ampoule enclosures unnecessary (5, 6, 22). Now crystal pulling under pressure through the vitreous viscous blanket is possible. At 1500°C, the B_2O_3 evaporates only very slowly, so that crystal growth runs extending over many hours are possible. The loss of phosphorus is very slight. The boric oxide glass blanket is also beneficial in reducing the temperature loss of the melt surface, and by dampening oscillations of the melt meniscus caused by external vibrations.

[12] McDowell Electronics Company, Metuchen, New Jersey.
[13] Electronic Control Systems, Inc., Fairmont, West Virginia.

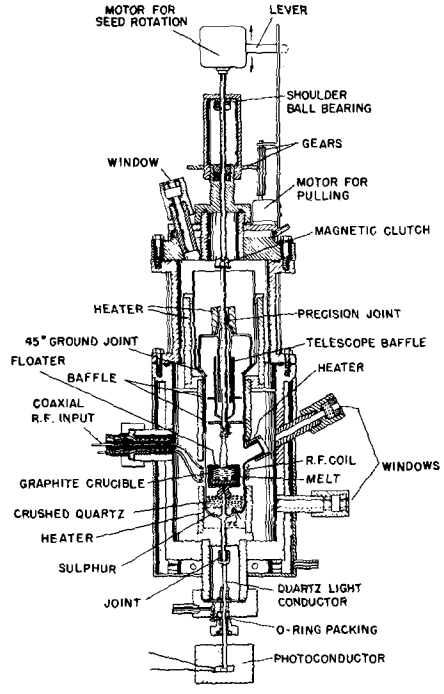

Fig. 9. Pressure puller using close-fitting rotating shaft

Temperature control at the beginning of the run is very critical. If the melting temperature is exceeded too far, the melt starts fuming and becomes metal-rich. This inevitably leads to polycrystallinity. To reduce this risk, the inert gas pressure should be as high as possible. We use 75 atm for GaP.

At present, boric oxide* seems to be the only practical encapsulant. It must be vacuum-dried for 24 hr at 1200°C (6). To be suitable, an encapsulant must wet the crucible, otherwise vapors will escape through the annular slot at the crucible wall (7, 10). Proposed molten salts such as BaF_2 (22) do not wet carbon or BN; they wet quartz, but heavily attack it. Also, these molten salts are "pervious" blankets for II-VI compounds because they are solvents for the melt (7, 10). Since they are not vitreous, they drip off the seed near the interface and hence do not protect the pulled crystal. In thick layers such molten salts may be usable for Bridgman growth, provided they do not contaminate or dope the melt with their constituents.

The boron contamination of III-V melts from B_2O_3 is below the ppm range. However, II-VI melts pick up about 300 ppm of boron (7). ZnSe can be pulled (7), but II-VI pulling is much harder than III-V crystal pulling due to the miscibility of molten B_2O_3 with the II-VI melt. New encapsulants may have to be found for satisfactory II-VI pulling.

Our equipment for L. E. pulling is shown in Fig. 10 and 11.[14] The system can be run in a normal laboratory, with direct personal control and viewing, as opposed to commercial systems which require remote-control, closed-circuit television viewing, and special, explosion-protected buildings.

It is important to start with a GaP polycrystalline ingot which fills the crucible solidly, for the following reason: If one starts with a crucible filled with irregularly shaped chunks, too much boric oxide is needed to fill the crevices and to cover the tops of the highest chunks to prevent the escape of phosphorus. When the GaP finally melts, the resultant B_2O_3 layer is too thick for easy pulling, since visibility through this layer gradually deteriorates due to emerging excess gallium

[14] Built at a total cost of $12,000, including the controls shown in Fig. 8 and the rf generator (only 8 kw are needed with proper impedance matching).

* Ultrapure B_2O_3, United Minerals & Chemical Co., New York, N. Y.

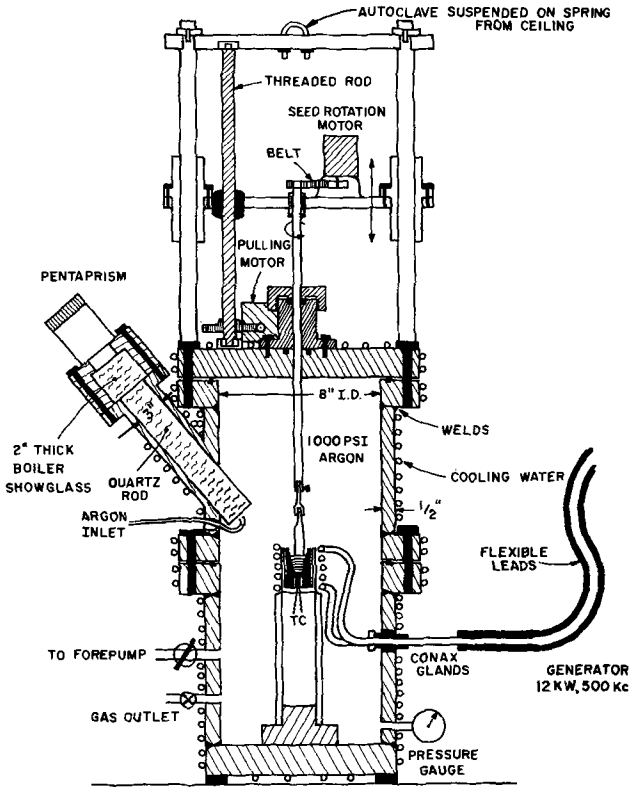

Fig. 10. Apparatus for liquid encapsulation-pulling under 1000 psi (75 atm) pressure, with direct viewing. The quartz rod eliminates most of the optical turbulence and is self-defogging. Vibrations have been minimized by rubber-mounting the motors and by hoisting the autoclave on a spring.

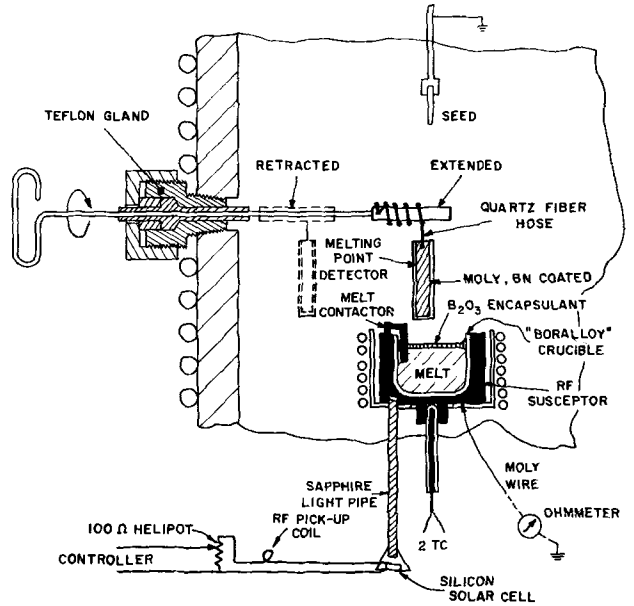

Fig. 11. Crucible arrangement and accessories for liquid encapsulation pulling. Note retractable melting point detector and electro-optic temperature sensor combined with rf power signal pickup for control. Temperature is measured by W-Re thermocouples. Contact between seed and melt is monitored by an ohmmeter.

which forms gallium subborate dispersed in the B_2O_3. One can then see the pulled part of the crystal only minutes later, when it emerges from the encapsulant layer. In general, the layer should not be thicker than 3/8 in. We therefore found it advantageous to synthesize a solid ingot in the same type of crucible from which the crystal is pulled later on. Demountable reusable equipment capable of producing sound, stoichiometric GaP ingots of 80g weight is shown in Fig. 12.

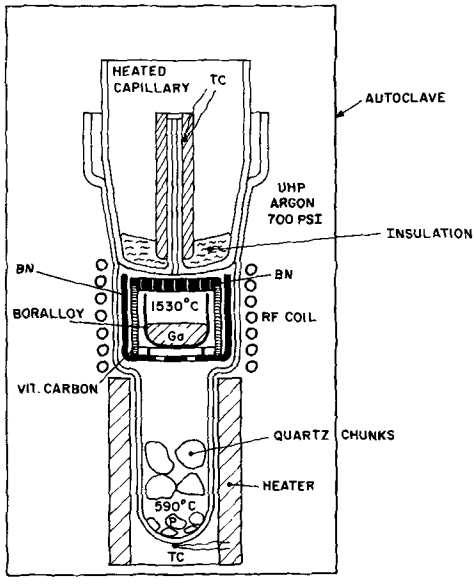

Fig. 12. Demountable setup for synthesis of GaP ingots

The temperature control problem presents here a new difficulty. One must take great care to prevent the runaway effect, which is much more serious here than in normal crystal pulling, due to the high temperature, and due to the limitation of visibility through the B_2O_3 layer. If one wants the crystal to become thicker, the increasing crystal size draws more heat from the melt, thereby cooling it, so that in the extreme case the whole melt solidifies. On the other hand, if one wants the crystal to become thinner, for instance for forming a neck at the beginning of growth to eliminate twins, the thinner crystal draws less heat from the melt; if the power input remains constant, the melt temperature increases, until the crystal is interrupted.

Maximum use of the "reset" function of the 3-action controller makes melt temperature more independent of heat demand. This is preferable to simply keeping input power constant. Instead of a thermocouple, a sapphire rod light conductor (10) which pipes the visible heat radiation into a silicon solar cell is very sensitive for controlling, due to the T^4 dependence of radiation intensity. One can combine this signal with a signal from the rf output power pickup sensor (Fig. 11), in varying proportions.

Liquid encapsulation Bridgman growth.—The previously described L. E. pulling method, though a great advance over previous methods, requires highly skilled manpower and does not yield a good crystal every time. L. E. Bridgman growth, although it usually does not yield oriented crystals, is more economical since it can be fully automated. Compared to the method described before (see under Vertical Bridgman growth in pressure-relieved ampoules), however, it does not permit synthesis and growth in one run, and the GaP crystal cannot be so easily removed from the Boralloy crucible since the B_2O_3 pulls off a thin BN skin each time.

Liquid encapsulation zone leveling.—The growth of mixed arsenide-phosphide or sulfo-selenide crystals (which are of interest for electroluminescence) from the melt by horizontal zone leveling was formerly impossible because one could not provide the correct pressurized anion vapor atmosphere mixture. This difficulty can now be overcome easily by covering a long horizontal boat containing the alloy with B_2O_3, applying inert gas pressure, and zoning in an autoclave (7).

Liquid encapsulation floating zone growth.—Frosch and Derick (23) have already reported crucible-free floating zone growth of GaP. By embedding the initially polycrystalline GaP rod in a B_2O_3-melt, one can use the buoyancy to grow a thicker crystal than with-

out the liquid encapsulation. Despite this, it is clear that this interesting method (24) poses no advantages at present.

Summary and Conclusion

Melt-growth of crystals under pressure from decomposable materials has come of age, especially for the important wide-gap III-V and II-VI materials. A synopsis of available methods reveals that, for obtaining GaP single crystals, liquid encapsulation (L.E.) pulling is the most elegant method. However, a new unified synthesis and Bridgman growth method in Boralloy containers may be more economical. L.E. pulling of II-VI crystals is more difficult and must probably await a more suitable encapsulant than B_2O_3 before its widespread application. For II-VI materials, the various Bridgman methods using component vapor or inert gas pressure for the suppression of decomposition can be employed.

For all of these methods, the requisite technologies and most suitable methods have been investigated, evaluated, and described.

Acknowledgments

I wish to thank the numerous colleagues who contributed to this program, and the referees who helped to improve this manuscript, especially C. J. Nuese.

Manuscript submitted Aug. 12, 1969; revised manuscript received Nov. 3, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

Reports on ECS Summer Assistance Awards and Weston Fellowship Award for 1969

During the summer of 1969, the following graduate students received $800 each, representing three Summer Assistance Awards of The Electrochemical Society.

Larry R. Faulkner, Harvard University, Cambridge, Mass., was awarded the Edward Weston Fellowship.

Lucien Papouchado, The University of Kansas, Lawrence, Kan., was designated recipient of the Colin Garfield Fink Fellowship.

Kathryn R. Bullock, Northwestern University, Evanston, Ill., received the ECS Summer Fellowship Award.

The Summer Assistance Award is made "without regard to sex, citizenship, race, location, or financial need to a fellow or teaching assistant pursuing work between the degree of B.S. and Ph.D. on a subject in a field of interest to The Electrochemical Society." It is intended to cover a period during which the recipient has no financial support for the continuance of his work.

The Edward Weston Summer Fellowship Report

A summary of Mr. Faulkner's report is given below.

Magnetic Field Effects on Some Fluid-Solution Processes Involving Anthracene Triplets and Their Relevance to the Mechanism of Electrogenerated Chemiluminescence

Over the past few years, a fairly substantial research effort has been directed toward a greater understanding of a novel group of chemiluminescent electron-transfer reactions (1-4). As an example, a typical reaction of this type might involve the homogeneous one-electron oxidation of the rubrene radical anion in some nonaqueous solvent such as N,N-dimethylformamide. When one carries out this reaction, one often observes the emission of light having the same spectral distribution as the fluorescence of rubrene. Moreover, one observes the same emission if one reduces the radical cation of rubrene in a homogeneous reaction using some suitable reductant (5). Several studies have shown that this kind of chemiluminescent electron-transfer reaction is common among aromatic hydrocarbons and their derivatives and also among several heterocycles (2, 6-8). Since the reactants are most easily generated and studied electrochemically, this phenomenon has become known as "electrogenerated chemiluminescence" (ECL).

The investigations which have been carried out thus far with these organic systems strongly suggest that excited molecular electronic states are populated directly in the redox step. That is, the results indicate that excited states are actually intermediates in these redox reactions. Since electron-transfer reactions are fundamental to all of chemistry, the discovery that excited states participate in the transfer in some cases raises questions of substance to many different fields, such as the study of quenching mechanisms of excited states and the study of electron-transfer in biological systems. Thus it is not surprising that investigators working in this area have sought to understand the more intimate details of this reaction and its mechanism.

Highlights for Los Angeles Meeting

The Electrochemical Society Lecture

Dr. Leo Brewer, Professor of Chemistry and Head of the Inorganic Materials Research Division of the Lawrence Radiation Laboratory at the University of California in Berkeley, has been selected to deliver the ECS Lecture, choosing as his topic "Electrons —The Universal Glue." It will be presented at the Plenary Session of the 137th ECS National Meeting in Los Angeles, California, on Monday, May 11th, at 9:00 A.M.

Dr. Brewer attended California Institute of Technology and received his B.S. in 1940. He attended the University of California, Berkeley and received his Ph.D. in 1943. He then became a Research Associate, Manhattan District Project, University of California, Berkeley. In 1946 he was appointed assistant professor, University of California, in 1950 associate professor, and in 1955 he became professor of chemistry. Since 1961 he is also Head of the Inorganic Materials Research Division of the Lawrence Radiation Laboratory. He became a member of the Natural Academy of Sciences in 1959. A frequent invited speaker at national and international meetings such as the International Congress of Pure and Applied Chemistry, Paris, 1957, he has delivered honorary lectures at universities throughout the country.

Dr. Brewer is an inorganic physical chemist of international stature who, by introducing the discipline of modern high-temperature chemistry over 15 years ago and most recently formulating an alloy theory for the transition metals, has advanced the understanding of the behavior of materials in areas most in need of improvement. He has systematically attacked important chemical problems at high and very high temperatures by experimental and theoretical means. His approach includes an unusual array of techniques from the arsenal of modern chemistry, physics, and metallurgy, combined with a great imagination and a keen judgment of critical factors.

Dr. Brewer is keenly interested in communicating the most advanced scientific results to his students and those concerned with the application of this knowledge to practical problems. Very interested in the education of our youth, he has been actively engaged in the reform of high school science curricula in California.

Some of the national awards received are: Guggenheim Fellow, Oxford, 1950-1951; Leo Hendrick Baekeland Medal, ACS, 1953; E. O. Lawrence Memorial Award of the AES, 1961.

Dr. Leo Brewer

Banquet Speaker

Dr. William H. Pickering, Director of the Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California will be the guest speaker at the Annual Banquet of the 137th ECS National Meeting in Los Angeles on Tuesday, May 12th at 6:30 P.M. His topic will be "Exploring the Solar System."

For over a decade since the launching of the Soviet earth satellite Sputnik in late 1957, Dr. Pickering has been devising, developing, and supervising significant space and satellite programs for military and civilian agencies of the United States Government. Under his direction, the U. S. lunar and planetary missions, RANGER, MARINER, and SURVEYOR were planned, developed, and carried out at JPL.

In December 1962 the MARINER II spacecraft successfully completed a fly-by mission of the planet Venus, culminating a 109-day journey of over 180.2 million miles. This date marks the birth of the interplanetary age, indicating the first time that man penetrated the depths of space to the vicinity of another planet and obtained first-hand information. In July 1964, the spectacular flight of RANGER VII radioed to earth 4,316 high-resolution pictures of the lunar surface of the moon which proved to be 2,000 times better than those produced by the best earth-based telescopes. Again, in February and March of 1965, RANGERS VIII and IX successfully photographed still other selected areas of the moon.

In July 1965 after a 228-day journey of over 325 million miles, the first close-up pictures of another planet (Mars) were obtained by the MARINER IV spacecraft.

In June 1966 the SURVEYOR I spacecraft, built under the technical direction of JPL, landed gently on the surface of the moon after a near-perfect 63-1/2 hour flight. Over a period of 42 days, SURVEYOR received and acted upon approximately 120,000 commands from the earth and returned over 11,000 pictures of which the first 144 were relayed "live" through commercial television and Early Bird satellite to the nation and to Europe.

Dr. Pickering was born in Wellington, New Zealand. He attended Canterbury College, University of New Zealand, before leaving for the United States to continue his studies at the California Institute of Technology. He received his B.S. degree in Electrical Engineering in 1932, his M.S. in 1933, and his Ph.D. in Physics in 1936. He then joined the Caltech faculty as an instructor in electrical engineering and was appointed, successively, assistant professor, associate professor, and in 1946 professor in electrical engineering. In 1954 he was appointed Director of the Jet Propulsion Laboratory.

Dr. Pickering is a member of the National Academy of Sciences and a Charter Member of the National Academy of Engineering. He is past president of the International Astronautical Federation; an Honorary Fellow and Past President of the American Institute of Aeronautics and Astronautics; a Fellow of the Institute of Electrical and Electronic Engineers; the American Academy of Arts and Sciences; and the American Association for the Advancement of Science. He is a member of the International Astronautics Academy; the American Association of University Professors; the American Geophysical Union; and the Royal Society of New Zealand. He is an Honorary Fellow of the British

Dr. William H. Pickering

sense. Since I was doing a lot of translating in other languages for the boys here, I thought I'd better get the Russian, too."

Dr. Frary, the man of science, found no conflict between religion and science. He considered religion the single most important factor in a man's life, saying: "A man is hired for his character and ability, and religion builds character."

Today, technicians at Alcoa Research Laboratories have the opportunity to start or continue their education with tuition loans from the Francis C. Frary Educational Fund. He established the fund with the $1000 he was awarded with the Acheson Medal of The Electrochemical Society.

About retirement, Dr. Frary said: "My main argument for retirement is that when a man gets to a certain age he should move along and let some of the young man have their shot."

Until they moved to the nearby Presbyterian Home, a grandfather clock, in the family since 1788, stood on the stair landing in the Frary home. Dr. Frary's study was an alcove with an antique desk and a wall of French windows looking out on his apple trees.

Said his wife Alice: "The trees got exactly five sprays a year and a spring pruning—and every pruning wound got a dab of aluminum paint. He loved to travel and work with his hands. He even built a fallout shelter downstairs. He never had enough time to read. And he had a passion for fruit. But, above all, work was his gospel."

NEWS ITEM

Mathers Lectureship Established at Indiana University

A lectureship in chemistry, honoring Dr. Frank C. Mathers, professor of chemistry at Indiana University, has been set up through an anonymous donation from a former student of Dr. Mathers. Recognizing Dr. Mathers' productivity as a research chemist, the lectureship was established to present discussions of their research by noted chemists. The first holder of the lectureship is John S. Griffin, professor of chemistry at Indiana University, who will give a series of four lectures during the 1970 spring semester.

Dr. Mathers has continued to work regularly in his Indiana University research laboratory since his retirement 20 years ago. when he had served on the faculty 47 years. Many of his former students have advanced to top-level positions in industry and as educators.

His principal research interest has been in electrochemistry, especially electroplating. He is credited with many improvements in technique in this field. During World War I, he discovered a workable method of preparing fluorine gas. Fluorine produced by his method was used at Oak Ridge National Laboratory in the processing of uranium for atomic reactors.

Born on a Monroe County farm in 1881, Dr. Mathers received his A.B. and his M.A. degrees at Indiana University, and his Ph.D. from Cornell University. He returned to Indiana University as an assistant professor, advancing to associate professor in 1913 and professor in 1923. He was interim chairman of the Department of Chemistry in 1946-1947.

Dr. Mathers was President of The Electrochemical Society in 1940-1941 and has published many articles in the JOURNAL. In 1959 he became an honorary member.

Notice to Members

April 1 is Cut-Off Date

Your attention is called to Article III, Section 9 of the Society Constitution which states: "Any member delinquent in dues after April 1 of each year shall no longer receive the Society's publications, and will not be allowed to vote in any Society election until such dues are paid. All members in arrears for one year after the first of April shall lose their membership status and can be reinstated only by action of the Board of Directors." Members who have not sent in 1970 payments were mailed a second notice in March and are urged to make payment promptly in order to avoid delay in receipt of the JOURNAL.

POSITIONS AVAILABLE

Please address replies to the box number shown, c/o The Electrochemical Society, Inc., 30 East 42 St., New York, N.Y. 10017.

Solid State Chemist Physicist or Metallurgist sought to take part in government sponsored project in major east coast university. Required is interest in theoretical and calculatory work diffusion in solids. Reply Box B-52.

Applications invited for Research Team in Electrochemistry to be built up on Campus East Coast University. Good background in modern electrode kinetics, practical knowledge in electronic instrumentation is advantage. Hiring at **Technician B.S.** and **Ph.D. level group leader** intended. Apply Box B-53.

Book Reviewers Needed

The Electrochemical Soceity needs competent individuals to review books for the Journal.

Any Society member who wishes to volunteer his services should send his name, address, and field of competence to the attention of the Book Review Editor, Dr. Julius Klerer, c/o The Electrochemical Society, 30 East 42 Street, New York, N. Y. 10017.

Polarization Characteristics of a Cupric Chloride Cathode in a Lewis Acid Organic Electrolyte

M. Eisenberg,* R. E. Kuppinger, and K. M. Wong

Electrochimica Corporation, Menlo Park, California

ABSTRACT

The polarization characteristics of copper-cupric chloride electrodes in Lewis acid-type organic electrolytes, using propylene carbonate as an aprotic solvent, were studied. Two experimental techniques were used: a multireference polarization cell (MRP) and a rotating disk electrode (RDE). For the latter, a range of rotational velocities from 25 to 2000 rpm was covered. Following elimination or accounting for concentration polarization, the remaining polarization is considered to be attributable not only to charge transfer steps, but also to chemical steps such as a slow dissolution of the cupric chloride crystal in this electrode of the second kind. Apparent exchange current density values in the range of 3-6 x 10^{-5} A/cm^2 have been determined for the reduction of $CuCl_2$ to copper.

The interest in high energy battery systems employing organic nonaqueous electrolyte with aprotic solvents has focused attention on metal halides as cathode materials (1). Little is known about the polarization behavior of electrodes of this type in Lewis acid-type electrolytes in cyclic ester solvents such as propylene carbonate. The purpose of this study was to develop and adopt two techniques for a steady-state determination of the polarization characteristics of metal halide electrodes in nonaqueous media, and as an initial study to determine the cathodic polarization of a copper-cupric chloride electrode in LiCl-$AlCl_3$-propylene carbonate electrolyte.

Apparatus and Experimental Procedure

Cathodic polarization of copper-cupric chloride electrodes has been determined by the use of two galvanostatic methods in which the steady-state polarization is achieved at successively increased levels of current density. One of the methods is based on the employment of a cell with a precise, uniform geometry and equipped with a multiplicity of sidewall reference electrodes (MRP cell); the other is based on the use of the rotating disk electrode in a closed system cell specifically developed for work with nonaqueous electrolytes.

Multireference polarization cell (MRP cell).—The MRP cell was designed as a symmetrical cell of cylindrical uniform cross section in which the working electrode (under investigation) is located centrally between two auxiliary electrodes, completing the basic cell. A schematic presentation of this cell is shown in Fig. 1. Figure 2 shows an exploded view of the cell components. The uniform cylindrical geometry of the cell, the mounting of the electrodes to the accurately machined polypropylene sections of the cell, and the

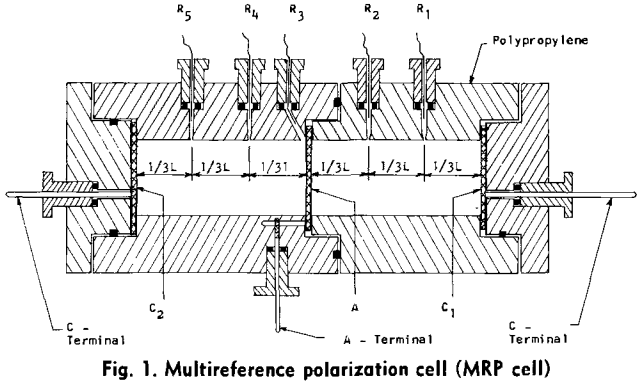

Fig. 1. Multireference polarization cell (MRP cell)

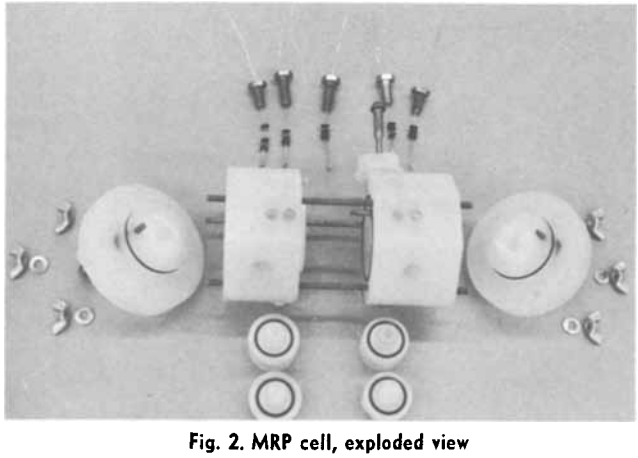

Fig. 2. MRP cell, exploded view

* Electrochemical Society Active Member.

equidistant position of the electrode under study between the two auxiliary electrodes provides a uniform primary current distribution at the surface of the electrode.

Several silver-silver chloride reference electrodes are located at precise distances, on both sides, from the plane of the electrode under study. The capillary leading to each reference electrode compartment is built into the side wall of the polypropylene cell without any protrusions or indentations; thus, the primary current distribution remains undisturbed, and there are no shielding effects commonly involved in kinetic work where protruding glass capillaries are used. The location of the capillary openings for references R_1, R_2, R_4, and R_5 (see Fig. 1) is such as to divide each half-cell compartment exactly into 1/3 lengths. Thus a measurement of the emf while current is passing through the cell between references R_1 and R_2, or R_4 and R_5 provides a direct value for the iR-drop involved for the distance 1/3 L.

There are several different ways in which the MRP cell can be employed for galvanostatic polarization studies. As can be seen in Fig. 1, it is possible to omit an electrode in position, *A*, place the working electrode under study, *e.g.*, in position C_2, place a suitable counterelectrode in position C_1, thus spacing current from one end of the cell to the other end. Through the use of reference electrodes R_5, R_4, and R_3 obtaining and carrying out measurements between the working electrode, C_2 and reference R_5, as well as between the other references, the extrapolative method may be used to correct for the iR drop included in the measurement between C_2 and R_5, since the same iR drop is involved in the distance C_2-R_5 as in the distance R_5-R_4.

It is also possible to employ the cell by placing the electrode under investigation in the center and employ the two end electrodes as counterelectrodes. In this case, a balanced polarizing circuit is employed to assure that the same amount of current flows to both sides of the electrode under investigation. This is illustrated in Fig. 3. It should be noted that in this case, by the use of reference electrode R_3, which is connected by means of a 45° capillary directly to the face of the working electrode (or a similar reference electrode R_6 on the other side), it is possible to reduce the iR drop involved in the measurement to a very small value, depending on how small and properly machined the capillary is. At the same time, if the diagonal capillary R_3 is small, it indeed comes very close to the surface of electrode A.

The polarization of the central electrode, A can be determined by employing all references, R_3, R_4, and R_5. It should be noted that the potential difference between R_3 and R_4 includes not only the iR drop, but also the effects of any concentration changes at the surface of the working electrode. Thus, the measurement employing reference, R_3, offers the means for assessing reasonably closely the effects of concentration polarization. Consequently, another way to express activation polarization is offered by the relation

$$\Delta E_{act} = (AR_4)_{net} - \Delta(R_5R_4)_{net} - [\Delta(R_4R_3) - \Delta(R_5R_4)] \quad [1]$$

where the last term in the square bracket represents the major portion of concentration polarization component, ΔE_{conc} (depending on the accuracy of the R_3 location). In the experimental studies reported here, the method expressed by Eq. [1] was employed. Lithium electrodes were used as counter-working electrodes to avoid any gas or undesirable by-product generation which would disturb the experiment.

The silver-silver chloride reference electrodes were constructed of silver wires, 0.020 in. diameter, terminating with a small loop. The wires were carefully cleaned to remove any surface oxides and coated with silver chloride by dipping in a melt of AgCl. The reference electrodes were equilibrated by immersion in the electrolyte prior to insertion into the reference electrode compartments of the MRP cell. The cell was assembled and filled with electrolyte in an argon drybox. It was then removed from the drybox and used in the normal laboratory environment. A Keithley Model 621 electrometer and a Hewlett-Packard Model 405CR digital voltmeter were used for the emf measurements. During the run a current was set and emf measurements performed until steady state was achieved. Subsequently, a larger current density level was set. During the run, reference to reference emf measurements were taken at several current values.

Rotating disk electrode.—In order to work with nonaqueous electrolyte systems under exclusion of air and moisture, a special housing was constructed for the rotating disk electrode using polypropylene materials which are inert to the cyclic esters, and a gastight construction with "O" rings for the top and bottom plates of the cell. The cell has a large ID (6.35 cm) to accommodate a variety of rotating disk diameters. A schematic diagram of the cross section of the cell is shown in Fig. 4. The diagram illustrates the relative positions of the rotating disk electrode (RDE) and of the Luggin capillary leading to an Ag/AgCl reference electrode. The distance of the tip of the capillary, which is in the same plane as the RDE from the

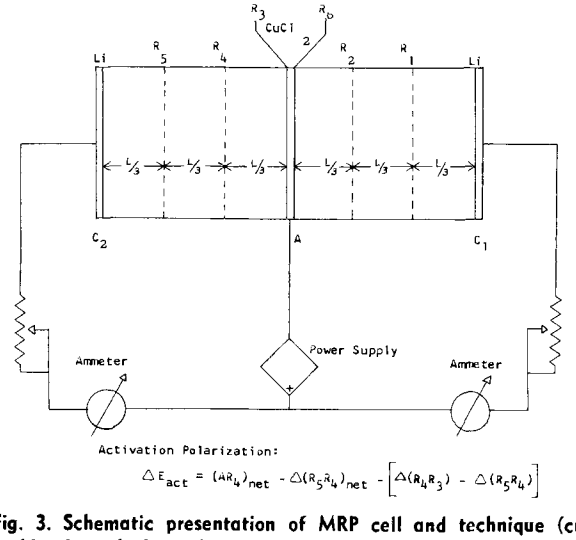

Fig. 3. Schematic presentation of MRP cell and technique (cupric chloride cathode in the center).

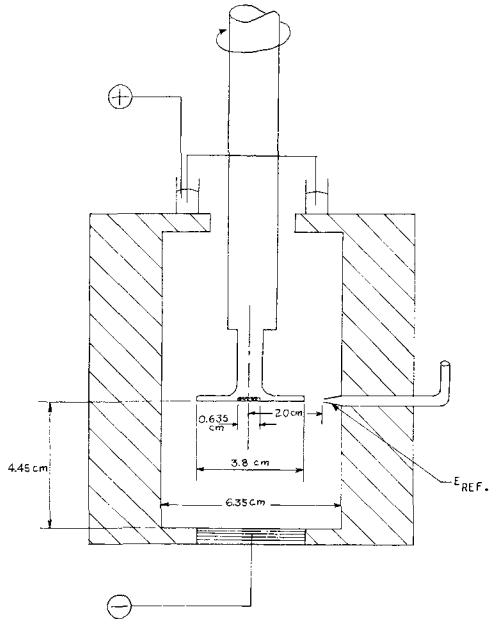

Fig. 4. Schematic diagram of RDE electrode

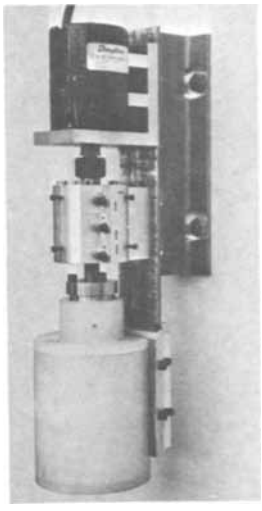

Fig. 5. Rotating disk electrode, assembled

access of the latter, is an important parameter since it affects the iR drop through the solution included in the steady-state measurement. Figure 5 shows the assembled cell in operation in the normal laboratory environment following its assembly inside an argon drybox. A mercury well is employed on top of the cell to provide both electrical contact to the RDE and a seal from the air atmosphere. The emf measurements between the RDE and the Ag/AgCl reference electrode (prepared similarly to those for the MRP cell) were made with a Keithley Model 621 electrometer and with a Hewlett-Packard Model 405CR d-c digital voltmeter. The RDE cell is constructed in such a way that the distance between the center of the active area of the RDE and the tip of the Luggin capillary can be adjusted over a range of values. For these experiments this radial distance was set at 0.635 cm, and the radius of the active area of the electrode was $R_0 = 0.318$ cm. Thus, the surface area of the RDE was 3.16 cm^2.

The elimination of the iR drop between the working electrode and the Luggin capillary tip of the reference electrode is an important matter for consideration, especially due to the relatively lower conductivity of the electrolyte employed. Under favorable experimental circumstances, it is possible to obtain the value of the resistance involved by experimental means, such as the use of an interruptor and an analysis of the emf decay trace obtained on an interruption of the current. Efforts to employ an interruptor consisting of a mercury wetted Reed relay activated by an oscilloscope (Tektronix 535) sweep pulse were not successful in obtaining the iR drop at a fixed current load, because of the surface resistance of the copper chloride layer on the electroformed electrode. Different values were obtained depending on the thickness of the electroformed layer. For this reason, the method of calculation of the iR drop in the cell developed by Newman and Hsueh (2) was employed, using an experimentally determined value of the specific conductivity of the electrolyte, K. When the Luggin capillaries are located in the plane of the RDE, their relation can be expressed as

$$R = \frac{\tan^{-1}\lambda_o}{2\pi r_o K} = \frac{0.523}{K} = 102.0 \qquad [2]$$

where

$$\lambda_o = \sqrt{\frac{r}{r_o} - 1} \text{ at } z = 0$$

and the values applicable to this study are:

K = specific conductivity (5.13×10^{-3} mhos/cm^2)
r_o = radius of disk electrode (0.318 cm)
r = radial distance to Luggin capillary of reference electrode (0.635 cm)

Using the resistance value $R = 102$ ohms, the iR drops were calculated for each level of current density employed during the polarization run and subtracted to obtain net total polarization values.

The experimental procedure consisted of fixing a given rotational speed, obtaining the open-circuit emf difference between the copper-copper chloride RDE, and the Ag/AgCl reference electrode. Subsequently, a given current density was applied, held constant until steady state was achieved, and the emf determined at each level. Three levels of rotational velocity were employed throughout this study: 25, 300, and 2000 rpm. The rotational speed was determined by using a magnetic pickup, sensing the passage of a small magnet attached to the rotating shaft. The speed of the electrode, driven by a d-c series motor (1/5 hp), was controlled by a d-c regulated power supply (Power Designs Inc. Model 5015-S).

Electrolyte and electrode preparation.—The electrolyte was prepared from propylene carbonate (Jefferson Chemical Company), twice vacuum distilled at 50 mm of mercury and a temperature of 150°C. Anhydrous aluminum chloride (Matheson, Coleman and Bell) was dissolved in it to yield a molality of 0.8*M*. Lithium chloride (J. T. Baker), additionally dried in a vacuum oven overnight at 150°C, was added to yield a molality of 0.7*M*. At the LiCl:$AlCl_3$ ratio of 0.7:0.8, the solution is essentially saturated in respect to LiCl. The solution was stored in a glass stoppered Erlenmeyer inside an argon drybox. The physical properties of this electrolyte were determined by conventional methods to be as follows

Specific conductivity: 25°C
$K = 5.13 \times 10^{-3}$ mhos/cm (± 0.1)
Viscosity: $\mu = 4.05$ Hz
Density: $d = 1.243$ g/cc
Kinematic viscosity: $\nu = 3.25 \times 10^{-2}$ cm^2/sec

As far as the copper-cupric chloride cathode is concerned, it was deemed necessary to employ a simple, essentially nonporous electrode in which only the species copper and cupric chloride would be present. Initial efforts to paste a suspension of anhydrous cupric chloride in acetone onto a copper foil were unsuccessful, since poor adhesion resulted after drying of the electrode. It was consequently decided to prepare the electrode by anodic electroforming of a surface layer of $CuCl_2$ in an organic electrolyte essentially of the same nature as the electrolyte in which the electrode is to be studied. This approach was found successful and the final procedure adopted consisted of cleaning a copper foil (0.015 in. thick) to remove oxides, rinsing with acetone and subsequently with propylene carbonate, and then electroforming by making the foil anodic in a 1.5*M* $AlCl_3$ solution in propylene carbonate, using platinum electrodes and applying a current density of 0.5 mA/cm^2 for time periods of 24-48 hr. These electrodes, in the form of a circular disk of the proper diameter, could then be inserted into the MRP cell in such a way that an active surface area of 4 cm^2 presented itself to the electrolyte inside the MRP cell.

For the RDE studies, the electrode was prepared by subjecting the exposed and cleaned end of the solid copper electrode-rotor to the same electroforming treatment. Care was taken to provide a sufficient amount of electroformed cupric chloride to cover the consumption occurring during the cathodic polarization runs and provide for a safe margin.

While the electroformed cathodes represent the basic approach taken in this study, it was of some interest to investigate the comparative behavior of a porous pressed electrode. These could only be studied in the MRP cell, since a reliable attachment of a pressed layer to the rotor electrode of the RDE cell could not be achieved. The pressed electrode for the MRP cell was prepared to provide an equimolar ratio of Cu-metal and $CuCl_2$. This corresponded to a weight per cent ratio of 67% $CuCl_2$ and 32% Cu, to which 1% (by weight) of a polyethylene binder was added. The copper was added as a metal powder (No. MD 151). The $CuCl_2$ (J. T. Baker) was dehydrated by treatment

with thionyl chloride and vacuum oven removal (at 150°C) of SO_2 and HCl by-products. Electrodes 0.035 in. thick were produced by pressing this mixture onto a 24-mesh copper screen. The resulting volume porosity was 26%.

The counterelectrodes employed in both the MRP and the RDE cells were lithium pressed to a nickel foil.

Results

MRP cell studies.—A sample calculation for the activation polarization, ΔE_{act}, using Eq. [1] is given in Table I. As discussed previously, to the extent that R_3 is small and accurately located, the bracketed expression given in column 5 of Table I represents all or a major portion of the concentration polarization. This polarization remains small at lower current densities and reaches 14.4% (0.15V out of a total of 1.049V) at an apparent current density of 3 mA/cm². A comparison of column 3 (which expresses the iR-drop involved in the polarization measurement of column 2) and of columns 5 and 6 serves to give an appreciation of the importance of iR corrections and concentration polarization corrections for the accuracy of a Tafel plot. With an appreciation of these limitations, Eq. [1] appears to offer a reasonable approach to a determination of net electrode polarization.

The results for electroformed copper-copper chloride cathodes are shown in Fig. 6 in the form of a Tafel plot. Four runs are presented, each with a fresh electrode; two for the cathode positioned in the center of the cell, and two for the cathode positioned at one end. The polarization, expressed in the form of activation polarization, was calculated from Eq. [1], or an equivalent form of it. The curve in Fig. 6 was drawn through the points for the cathode position in the center of the cell, since these results were somewhat more reproducible. It may be noted, however, that for the other two runs the polarization values are only slightly higher. It should be noted from the data that a straight Tafel line would only apply over a limited range of current density values (approximately up to 1 mA/cm²).

The results for the pressed (26% porous) electrodes are given in Fig. 7 which shows independent runs; two

for the cathode position in the center, and two for the end of the cell. Here, again, the runs with the electrode in the center are more reproducible and, consequently, the line was drawn through these data. However, in general, the results are in agreement for both electrode positions in the cell. A comparison of the results obtained for the two types of cathodes is shown in Fig. 8. The relatively close agreement of the results was at first considered surprising, since a lower polarization for the same apparent current density was expected for the pressed electrode. The results indicate that the porosity of the pressed electrode, produced in this case at a pressure of 6 tons/in.², must have been of the same order of magnitude as the natural porosity of the $CuCl_2$ layer on the surface of the anodically formed electrode. In the current density range of 0.1-0.5 mA/cm², Tafel slopes in the range $b = 0.18$ to $b = 0.23$ appeared to be applicable. However, deviation from linearity for current density of 1 mA/cm² or above, was significant. It should be remembered that the polarization values as plotted in Fig. 8 are already those obtained after subtraction of the concentration polarization component represented by the bracketed expression of Eq. [1]. As can be seen from the sample data shown in Table II, this concentration polarization (columns 2a and 2b) is subtracted from the total polarization (columns 1a and 1b) before the activation polarization, ΔE_{act} (columns 3a and 3b) is plotted in the figure. It should be noted that the concentration polarization values (columns 2a and 2b) for the two types of electrodes do not agree too well for a given current density. However, this may be due to the drift of the reference electrode potential which often occurred during a run. Such references

had to be replaced from time to time. The difference may also, however, be due to the different natures of the electrode and its effect on the surface concentration of the chloride ion (see discussion in next section).

RDE cell studies.—The polarization values obtained in the RDE cell after the iR correction formally still contain a mass transfer or concentration polarization component. There is no direct way for its assessment, the way this could be done in the MRP cell. However, it can be readily estimated that for an electrode process which is productive, rather than consumptive (*i.e.*, in which a concentration build-up occurs at the interface; in this case, a build-up of Cl^- ions or $AlCl_4^-$ ions), concentration polarization is usually negligibly small. Furthermore, it should be noted that in the RDE cell the diffusional mass transport is practically of a radial nature (considering the small size of the electrode compared to the shape of the electrolyte volume in the cell). Thus, a more uniform steady state is produced in the RDE cell than in the case of the stationary electrodes in the MRP cell.

Figure 9 shows the total polarization (iR free) obtained for two runs at 25 rpm. Unlike the MRP cell, the data here are in agreement with the Tafel line over a wider range of current densities. Both curves in Fig. 9 give a slope of $b = 0.18$, although somewhat different a values have resulted. The results at 300 rpm (Fig. 10) are, again, not completely reproducible, but they fall within a fairly narrow range of slopes of $b = 0.18$-0.23. The same can be said about the results obtained at 2000 rpm (Fig. 11) where, however, one run yielded significantly higher values of the constant, a. It may be interesting to know that by comparing the results of Fig. 9, 10, and 11, increased rotational velocity did not diminish the total polarization. This, indirectly, verifies the previously discussed estimate of negligible concentration polarization in the MRP cell results.

Discussion

It is interesting to compare the RDE cell results with those of the MRP cell. It can be seen in Fig. 8 for the straight lines with slopes $b = 0.18$ and $b = 0.23$

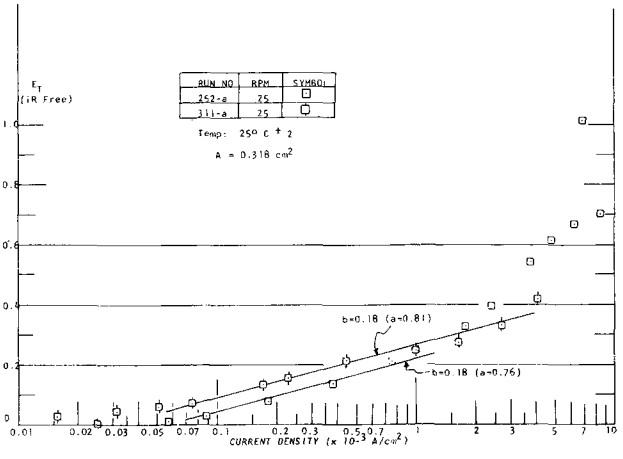

Fig. 9. Total polarization of $Cu/CuCl_2$ electroformed cathode in the RDE at 25 rpm.

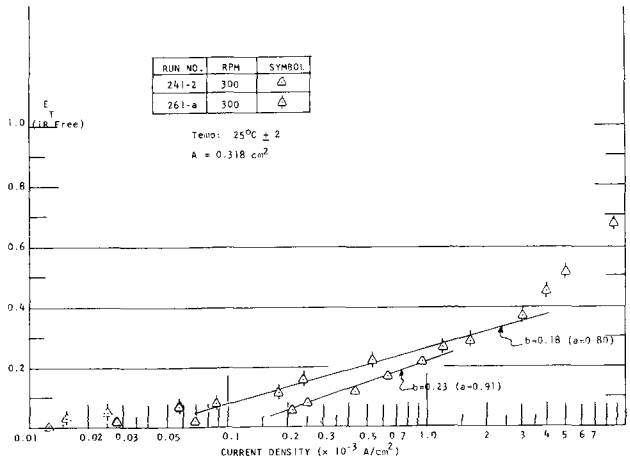

Fig. 10. Total polarization of $Cu/CuCl_2$ electroformed cathode in the RDE at 300 rpm.

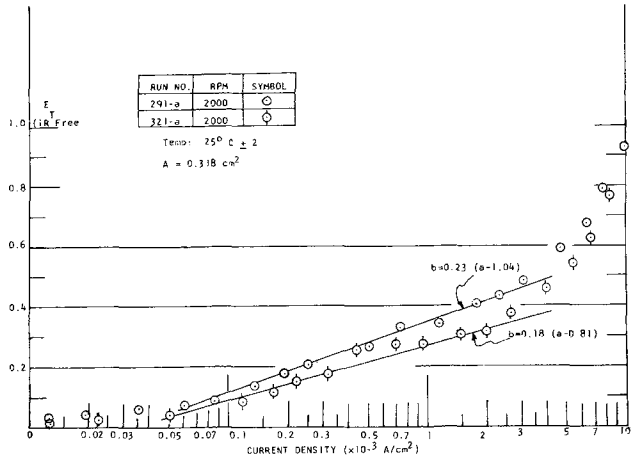

Fig. 11. Total polarizaton of $Cu/CuCl_2$ electroformed cathode in the RDE at 2000 rpm.

(and with a range of a-values bracketing the results of the RDE cell) that fair agreement is obtained in the lower ranges of current density, but serious deviation of linearity is indicated for the MRP cell above 0.5 mA/cm², while linearity is preserved for the RDE cell data up to 4 or 5 mA/cm². This indicates that possibly ohmic effects resulting in a resistance type polarization are important for the stationary cathode in the MRP cell, and that these effects can become very significant. For instance, at 3 mA/cm², Fig. 10 indicates a polarization of the order of 0.35V for the RDE cell. The corresponding value for the MRP cell is 0.84V (see Fig. 8). In light of the fact that the MRP cell method already subtracts the bulk solution concentration polarization, this large typical difference can only be attributed to ohmic effects on the surface of the cathode itself, as may result from a possible crystallization of lithium chloride as the discharge of $CuCl_2$ (and consequently, local build-up of chloride ions) proceeds in the electrolyte layer immediately adjacent to the cathode and already saturated in respect to LiCl. Another possibility is that the larger polarization is not due to an ohmic effect, but to a "reaction polarization" associated with an increased resistance to the dissolution of $CuCl_2$ which may be a chemical step preceding the charge transfer step in the over-all kinetics (see discussion further). In any event, the MRP cell should not be employed for appreciable current densities and in runs with prolonged duration. On the other hand, the RDE cell, with a small electrode area compared to a large volume of electrolyte and with a uniform and high rate of mass transfer, is conducive to obtaining overvoltage data free of resistance polarization components associated

with partial or total surface coverage by lithium chloride, or any other species which may be involved in the mechanism.

The over-all reaction in the discharge of the cupric chloride electrode can obviously be stated as

$$CuCl_{2(s)} + 2e^- \rightarrow Cu^0_{(s)} + 2Cl^- \qquad [3]$$

This is an electrode of the second kind, the kinetic treatment of which is complex, since the over-all process involves not only charge transfer, but also several chemical reactions. Not only is a solid phase $CuCl_2$ involved, but also the possibility of complex ion formations which the cupric or cuprous state of the copper may enter into with Cl^- ions or with Lewis-acid ions, $AlCl_4^-$. A theoretical treatment of electrodes of this general type involves, according to Jaenicke (4, 5) and Vetter (6), the reaction velocity of the chemical step, namely, the dissolution of the ionic crystal immediately at the phase boundary with the metal conductor (here, $CuCl_2$) prior to the charge transfer step in the following scheme

$$\begin{aligned} &1.\ Cu^{++}(\text{crystal}) + 4Cl^- \rightleftharpoons [CuCl_4]^{-2}{}_{\text{soln.}} \\ &2.\ [CuCl_4]^{-2}{}_{\text{soln.}} \rightleftharpoons Cu^0 + 4Cl^- + 2e^- \end{aligned} \qquad [4]$$

In reactions of this type the rate-determining step is usually the first one. This has, of course, not yet been established specifically for the reaction investigated here. As far as step 2 is concerned, it may in reality consist of two sequential steps, namely, a reduction, first, of Cu^{++} to the cuprous state, and then to the metallic state. The possibility of further interactions between the Cu^{++} state and Cu^0 state may also need consideration.

In this first study an elucidation of the detailed mechanism was not undertaken. From a realization of the complexity of the kinetics, the limited theoretical significance of an over-all exchange current density, i_o, and of the transfer coefficient, α, is appreciated. These values should be regarded as apparent values. On the other hand, from the point of view of an assessment of over-all reversibility of the processes involved, their calculations appear to be of interest. The values as obtained from the individual methods and under specific conditions are given in Table III.

The effective or apparent exchange current density, i_o, would appear to be predominantly of the order 6×10^{-5} A/cm^2 for the results of the MRP cell, and predominantly of the order of 3×10^{-5} A/cm^2 for the RDE cell. A statement of these effective values amounts to a statement that the electrochemical reduction of $CuCl_2$ in the organic electrolyte under study does not proceed very reversibly and that the predominant mode of polarization one can expect would be activation polarization, by which we mean all modes of polarization other than that attributable to mass transfer resistance in the electrolyte. Obviously, when the geometric relationship in the cell, the quantity of available electrolyte, and a limited rate of mass transfer of the chloride ion away from the surface of the $Cu/CuCl_2$ cathode, combined with an appreciable build-up of surface crystallization of lithium chloride (or of other possible compounds in the particular electrolyte, *e.g.*, $LiAlCl_4$), an appreciable component of resistance polarization or of "reaction polarization" associated with inhibition of step 1 may result, as was clearly demonstrated by the results of the MRP cell, compared to those of the RDE cell. In the discharge of a galvanic cell, where the limitations of mass transfer may be even more severe than they were in the MRP cell, the importance of this phenomenon must be fully appreciated.

Table III. Values from individual methods, under specific conditions

	Slope b	a	App. trans coefficient, α	App. exchange curr. density, i_o, A/cm^2
MRP cell	0.18	0.77	0.164	5.3×10^{-5}
	0.23	0.96	0.128	6.75×10^{-5}

Charge Acceptance of the Cadmium-Cadmium Hydroxide Electrode at Low Temperatures

Y. Okinaka* and C. M. Whitehurst

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Premature hydrogen evolution occurs when a discharged cadmium hydroxide electrode is brought to a low temperature and charged at a moderate rate. It was found that, in addition to various other known factors, the discharge rate and the temperature during discharge just prior to the temperature lowering greatly affect the charge acceptance in the first low temperature charge. Light and electron microscopic examination and BET surface area measurement showed that the cadmium hydroxide crystals formed at lower discharge rates and at higher temperatures are larger in size and more difficult to reduce. The results are interpreted on the basis of the mechanism involving a soluble intermediate species in both the charging and the discharging reactions. X-ray and electron diffraction analyses of the cadmium hydroxide crystals formed on discharge in 6.9*N* KOH at temperatures below $-18°C$ showed the presence of γ-$Cd(OH)_2$ in addition to the ordinary β-$Cd(OH)_2$. Electrodes containing γ-$Cd(OH)_2$ have a greater low-temperature charge acceptability than those containing β-$Cd(OH)_2$ alone.

When a sealed nickel-cadmium battery is brought to a low temperature in the discharged state and charged, hydrogen gas may evolve from the negative electrode before the positive electrode is fully charged (1). Since the rate of hydrogen recombination in the cell is practically negligible, it accumulates on repeating the low-temperature charge and eventually leads to a high internal pressure and a failure due to explosion. This is one of the serious limitations in the applicability of sealed nickel-cadmium batteries.

Gottlieb (2) made an extensive investigation of various factors affecting the charge acceptance of the negative cadmium hydroxide electrode and found that the charge acceptance decreases with increasing charge rate, decreasing temperature during the charge, and increasing temperature during the preceding charge-discharge cycles. He interpreted these results on the assumption that larger and/or more perfect cadmium hydroxide crystals are formed on discharge at higher temperatures and they are difficult to reduce on charge at lower temperatures and at higher rates. Popat and Rubin (3) reported experimental results similar in some respects to Gottlieb's, but they proposed an entirely different interpretation. It was postulated by them and Rubin (4) that "active" and "inactive" forms of cadmium hydroxide are formed during discharge, and they are reduced at different potentials on charge.

The main purpose of this communication is to present experimental evidence supporting Gottlieb's assumption and showing that there is a close correlation between the low-temperature charge acceptance and the size of the cadmium hydroxide crystals. Experimental results are also presented showing that, in addition to the three factors studied by Gottlieb, the discharge rate and the temperature during the discharge immediately preceding the low-temperature charge have a profound effect on the size of cadmium hydroxide crystals formed and, consequently, on the charge acceptance in the first low temperature charge. An incidental finding made during the course of this investigation was that γ-$Cd(OH)_2$, the monoclinic modification, is formed preferentially on discharge at lower temperatures rather than β-$Cd(OH)_2$, the ordinary hexagonal modification.

* Electrochemical Society Active Member.

Key words: cadmium, cadmium hydroxide, battery, nickel-cadmium battery.

Experimental Methods

All experiments were performed in flooded cells with 6.9M KOH. The cadmium hydroxide impregnated sintered nickel plate electrodes had a theoretical capacity ranging from 543 to 575 mA·hr. Their dimensions were approximately $5.6 \times 2.5 \times 0.076$ cm. The electrodes were prepared by a vacuum impregnation method consisting of impregnation in 4M $Cd(NO_3)_2$, reduction in hot 25% KOH, washing, and drying in nitrogen. This sequence was repeated five times. The electrodes were then subjected to eleven forming charge-discharge cycles at various currents. After final full discharge they were washed, dried, and stored under nitrogen atmosphere. The test cell contained one cadmium electrode, two nickel sheet counterelectrodes, and a 6.9M KOH salt bridge connecting the cell to a Hg/HgO (6.9M KOH) reference electrode. In each experiment, the cadmium electrode was first "conditioned" by repeating the following cycle three times: charge at 200 mA with approximately 50% overcharge and then a full discharge to -0.5V against the reference electrode at the same current. Finally the electrode was charged fully at 200 mA before it was subjected to a study of various experimental variables. This conditioning was carried out at room temperature.

Optical photomicrographs were taken with polarized light with a Unitron Metallograph BNX-11 using a xenon illuminator. Electron photomicrographs were obtained on specimens prepared by transferring cadmium hydroxide crystals from the electrode surface to a collodion film. X-ray diffraction data were obtained by using CuK_α radiation. Electron diffraction analysis was made by Ladd Research Industries, Inc., Burlington, Vermont, on carbon replicas prepared from collodion film specimens. BET surface area measurements were made by Numec Instruments and Controls Corporation, Monroeville, Pennsylvania, using an Orr surface-area pore-volume analyzer. Krypton was used as the adsorbate. The samples were degassed at 50°C for 24 hr.

Results and Discussion

To illustrate the problem, a potential-time curve obtained on charge and discharge at $-18°C$ is compared in Fig. 1 with the curve obtained at 25°C before the temperature lowering. Both curves were obtained at a constant current of 200 mA. It is seen that the

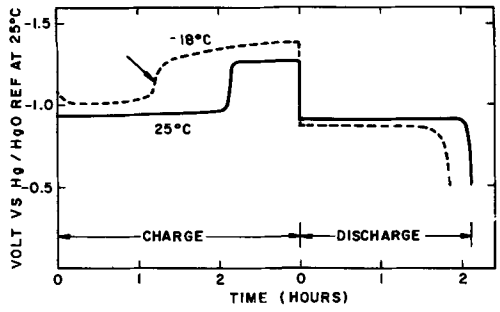

Fig. 1. Charge-discharge curves of cadmium hydroxide electrode at 25° and at —18°C after discharge at 25°C.

rise in potential at —18°C toward the hydrogen evolution range occurs after only about 60% of the 25°C discharge capacity is returned to the electrode. The arrow sign indicates where the gas bubble formation begins to become visible. The term "charge acceptance" is defined here as the ratio of the charge that the electrode accepted before this point to the charge capacity found in the discharge prior to the lowering of temperature. It is true that the charging reaction at the low temperature continues after the potential has reached the hydrogen evolution region, as is evidenced by the fact that the capacity found on the subsequent discharge was considerable greater than the charge that the electrode accepted before the onset of hydrogen evolution. However, it is the charge acceptance defined above that is important in sealed nickel-cadmium batteries because no hydrogen gas can be permitted to accumulate. Two distinct plateaus on potential-time curves, which were reported by Popat and Rubin (3) and Rubin (4) and attributed by them to the reduction of "active" and "inactive" cadmium hydroxides, were not observed under our experimental conditions.

In the previous study, Gottlieb (2) mentioned that the charge acceptance at low temperatures is not affected by the current used for the preceding cycles at a higher temperature. We found the contrary to be true, *i.e.*, the low-temperature charge acceptance is greatly affected by the magnitude of the current used for the discharge prior to the charge. Results are shown in Fig. 2. The experiments were carried out in the following manner. After the conditioning cycles described in the preceding section, the cell was placed in a bath maintained at a desired temperature and, after temperature equilibration, discharged fully to —0.5V at a specific rate. The test electrode was then removed from the cell, and a small portion of it was cut off for microscopic and other examination purposes, while the remainder of the electrode was immediately placed back into the cell. The cell was then transferred into a —18°C bath and, after a 2-hr open-circuit stand, charged at the C/2 rate. The charging current was adjusted on the basis of the capacity found in the preceding discharge appropriate correction having been made for that portion of the electrode which had been cut off. The reproducibility of the charge acceptance measurement was found to be about ±4% for the discharge rates of C/2 and C/20 at room temperature. This is indicated by the vertical lines on the two points in Fig. 2.

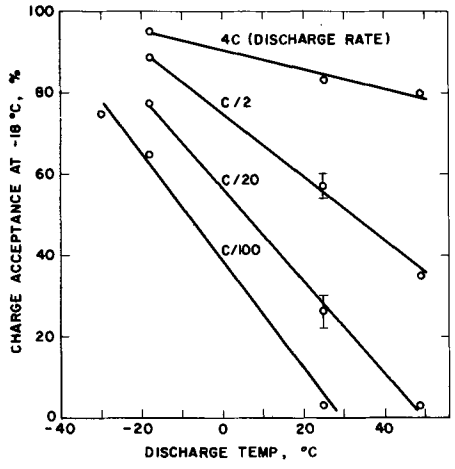

Fig. 2. Charge acceptance of cadmium hydroxide electrodes at —18°C at C/2 after discharging at various rates and temperatures. Small vertical lines indicate the reproducibility of measurement.

Figure 2 shows that the low-temperature charge acceptance is higher after the electrode is discharged at higher rates and at lower temperatures. The charge acceptance values were found to be independent of the extent of loading of the electrode with the active material in the range between 75 mA·hr/plate and 896 mA·hr/plate. On the other hand, it is striking that the charge acceptance varies from almost 0 to 100% depending on the conditions during discharge. It is of interest to note in Fig. 2 that the charge acceptance found when the electrode was first discharged at —30°C and then charged after raising the temperature to —18°C was greater than the value found when both discharge and charge were carried out at the same temperature of —18°C.

These results can be accounted for qualitatively on the basis of the mechanism involving a soluble intermediate species in both the discharging and the charging reactions. In the potential range of interest, these reactions may be represented by the following simple equations (5, 6)

Discharge:

$$Cd + 3\,OH^- \rightarrow Cd(OH)_3^- + 2e^- \quad [1]$$

$$Cd(OH)_3^- \rightarrow Cd(OH)_2 + OH^- \quad [2]$$

Charge:

$$Cd(OH)_2 + OH^- \rightarrow Cd(OH)_3^- \quad [3]$$

$$Cd(OH)_3^- + 2e^- \rightarrow Cd + 3\,OH^- \quad [4]$$

There is some evidence indicating that anodically produced cadmium hydroxide crystals can also be reduced directly without going through the soluble intermediate (6). It will be shown in this paper that all experimental results described here can be accounted for without depending on a direct reduction mechanism. The dissolution-precipitation mechanism for the discharge reaction [1] and [2] predicts the size of $Cd(OH)_2$ crystals to be larger when they are formed at lower discharge rates. The reasoning is as follows. At lower discharge rates the rate of formation of the soluble complex $Cd(OH)_3^-$ is slower, and this should cause the precipitation reaction [2] to proceed more slowly from a more dilute, and hence less supersaturated solution. As a general rule, it is known that particles of crystalline precipitates formed from more dilute solutions are larger in size (7). The dissolution-precipitation mechanism also predicts that larger $Cd(OH)_2$ crystals should form on discharge at higher temperatures, because the degree of supersaturation of the electrolyte with the soluble complex $Cd(OH)_3^-$ should be less at higher temperatures owing to an increased solubility. This predicted relation between the crystal size and the discharge conditions has been substantiated experimentally, as will be described in the subsequent section. From considerations of surface area effects in conjunction with the solution-reduction mechanism [3] and [4], it can easily be understood why large $Cd(OH)_2$ crystals yield a poor charge acceptance. This mechanism also predicts that for a given electrode with $Cd(OH)_2$ crystals of a given size, the charge acceptance should decrease with increasing charging current and with decreasing charging temperature. These relations have been found experimentally by Gottlieb (2).

Size and shape of $Cd(OH)_2$ *crystals.*—A large number of electron and optical photomicrographs were taken in order to establish the effect of discharge rate

and temperature on the size of cadmium hydroxide crystals. Some examples of transmission electron photomicrographs of actual crystals (dark areas) are reproduced in Fig. 3. Although the crystal size in each plate varies over a wide range, it is clearly seen that the crystals formed at C/20 are much larger on the average than those formed at C/2. It is also seen that the crystals formed at higher temperatures are larger. The crystals produced at C/100 were so large that they were very clearly observable under the light microscope (see Fig. 4).

In both photomicrographs it is seen that the electrodes discharged at −18° and at −30°C contained long, needle-shaped crystals, while the crystals in the electrodes discharged at higher temperatures were all hexagonal and flat. X-ray and electron diffraction analyses showed conclusively that the needlelike crystals are γ-$Cd(OH)_2$, the monoclinic modification (8), while the normal hexagonal ones are β-$Cd(OH)_2$. Typical x-ray diffraction intensity diagrams are shown in Fig. 5. It is seen that no lines corresponding to γ-$Cd(OH)_2$ appeared in the pattern obtained with the electrode discharged at 25°C, while the electrodes discharged at −18° and at −30°C showed many distinct lines corresponding to γ-$Cd(OH)_2$. It is also apparent that more γ-$Cd(OH)_2$ formed at −30° than at −18°C. This is clearly seen also from the light photomicrographs shown in Fig. 4. γ-$Cd(OH)_2$ was identified in all electrodes discharged at −18°C regardless of the rate of discharge (4C to C/100).

Recently, Breiter and Vedder (9) reported that γ-$Cd(OH)_2$ was identified on solid polycrystalline cadmium electrodes oxidized in 1M and 5M KOH at room temperature. In 6.9M KOH and with sintered-plate type electrodes, we found no γ-$Cd(OH)_2$ at room temperature and also at 49°C at all discharge rates studied. In 1M KOH, however, a large number of γ-$Cd(OH)_2$ crystals were formed even at room temperature. As already reported by Breiter and Vedder, γ-$Cd(OH)_2$ is unstable and slowly converted to β-$Cd(OH)_2$ on open-circuit stand in contact with KOH. The conversion is, however, quite slow at room temperature. For example, the appearance of the electrode surface discharged at C/100 at −30°C (Fig. 4, top) did not change appreciably after 10 days' open-circuit stand at room temperature. At 49°C, however, the conversion was considerably accelerated, and no γ-$Cd(OH)_2$ remained only after 3 days' open-circuit stand.

BET surface area.—The information obtained by the microscopic observation pertains only to the surface of the electrode, and there is no assurance that the same relation between crystal size and charge accept-

ance holds for the crystals within the pores of the electrode. Measurement of the total surface area by the BET method should provide a means of comparing the size of crystals within the electrodes. With some samples brown coloration apparently due to the oxidation of undischarged cadmium occurred under the degassing conditions used (50°C, 24 hr). The data for such samples were discarded. In Fig. 6 the charge acceptance at −18°C is plotted against the BET surface area for only those samples which showed no discoloration. The surface area is expressed per gram of the electrode and not of the cadmium hydroxide crystals, since the contribution of cadmium metal particles left undischarged to the total surface area did not vary very much from electrode to electrode. The discharge capacity of all of the electrodes for which the BET measurement was made ranged approximately from 75 to 90% of the theoretical capacity. Thus, the trend shown in Fig. 6 is believed to be attributable to cadmium hydroxide crystals.

It is seen that at constant temperatures (25° and −18°C) the surface area and the charge acceptance were both smaller for electrodes discharged at lower rates. Also, the surface area of the electrode discharged at C/20 at 49° was less than that of the electrode discharged at 25°C at the same rate. The observed effect of discharge rate and temperature on the surface area parallels that on the crystal size, and undoubtedly the general conclusion drawn from the microscopic observation holds also for the crystals within the electrode.

It is significant to note in Fig. 6 that the electrodes discharged at −18° and −30°C had a considerably smaller surface area than those discharged at 25°C and yet exhibited a good charge acceptability. It appears that γ-$Cd(OH)_2$ is more readily chargeable than β-$Cd(OH)_2$ for the same surface area. Breiter and Vedder's experiments with a solid cadmium electrode also indicated that γ-$Cd(OH)_2$ is more easily reduced than β (9). In practical sealed cells, however, there seems to be no way of utilizing the favorable characteristics of γ-$Cd(OH)_2$ because of its instability at higher temperatures. With an electrode containing both β- and γ-phases, it was found that γ-$Cd(OH)_2$ crystals were all converted into the β-form after only a few 50% depth charge-discharge cycles at room temperature. It has been suggested that the active and inactive cadmium hydroxides postulated by Rubin (4) might correspond to the γ- and β-forms. With electrodes containing both γ- and β-$Cd(OH)_2$, however, we failed to observe such two separate potential plateaus as reported by Rubin.

As already described by Gottlieb (2), the greatly reduced charge acceptance is observed only in the first charge after temperature lowering. If the electrode is continuously cycled at the low temperature, the charge acceptance in the second and subsequent charge cycles becomes almost normal. This can be expected from the crystal size effect, because the $Cd(OH)_2$ crystals formed on the second and subsequent cycles should be small since these cycles are carried out at the low temperature. The formation of γ-$Cd(OH)_2$ may also be responsible for the increased charge acceptance.

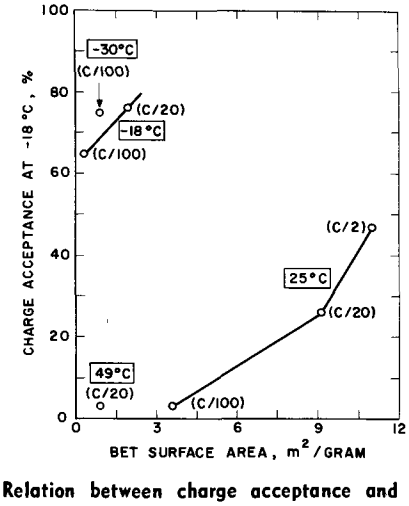

Fig. 6. Relation between charge acceptance and BET surface area. Temperatures and rates shown refer to discharge conditions.

Effect of partial cycles.—All experimental results discussed in the previous sections were obtained with electrodes discharged completely following a full charge. In sealed nickel-cadmium cells, the cadmium hydroxide electrode is not cycled in this fashion but only partially cycled, because the cells are constructed with a large excess capacity in the negative electrode. Effects of such partial cycles on the low-temperature charge acceptance were studied to simulate more closely the conditions encountered by sealed cells. Results are tabulated in Table I. In these experiments, electrodes previously charged completely at the C/2 rate were first discharged at C/20 (exp. 1 to 4) or C/2 (exp. 5 to 8), charged at C/2 until 50% of the discharge capacity was returned, and then fully discharged at various rates. This partial cycle was given at room temperature and only once except for exp. 2, in which 9 partial cycles were given. After the final full discharge, the cells were left on open circuit in a bath maintained at −18°C for 2 hr and charged at the C/2 rate.

The results of exp. 1 to 4 show that under these conditions, the charge acceptance is determined by the rate used for the initial discharge prior to the partial cycle (C/20) rather than the discharge rate used in the partial cycle. These results can be explained in the following manner. Suppose that the size of the $Cd(OH)_2$ crystals formed after the initial C/20 discharge was distributed according to a certain distribution law, for example, the normal law. On partial charge, the size of each crystal must have decreased regardless of the extent of the charge and the "tightness" (the magnitude of the standard deviation) of the distribution, whereas the total number of crystals may or may not have decreased depending on these two factors. Under the present experimental conditions, the total number of crystals appears to have remained essentially unchanged before and after the partial charge, and the $Cd(OH)_2$ crystals of reduced size which existed at the end of the partial charge appear to have grown back to the initial size on completion of the final discharge. This explains the fact that the charge acceptance observed after the partial cycle was nearly the same as that found after the full, straight C/20 discharge. The observed independence of the charge acceptance on the discharge rate used in the partial cycle probably indicates that no new nuclei were formed during the final discharge.

The same explanation applies also to exp. 5 and 6, in which the initial discharge was carried out at C/2. When the final discharge rate used in the partial cycle was very low as compared to the rate used for the initial discharge (exp. 7 and 8), the charge acceptance was considerably lower than that observed after

Table I. Effect of partial cycle (50%) at room temperature on charge acceptance at −18°C (Charge acceptance measured at C/2 rate)

Exp. No.	Rate used for full discharge prior to partial cycle	Partial cycle: Charge rate	Partial cycle: Discharge rate	Charge acceptance found, %: After partial cycle	Charge acceptance found, %: Without partial cycle
1	C/20	C/2	C/2	25	26
2	C/20	C/2	C/2 (9 cycles)	20	
3	C/20	C/2	C/26	33	
4	C/20	C/2	C/50	22	
5	C/2	C/2	C/2	51	57
6	C/2	C/2	C/25	53	
7	C/2	C/2	C/46	37	
8	C/2	C/2	C/100	3	

a straight, full discharge at C/2. This result appears to indicate that the very low rate discharge caused the small crystals initially formed at C/2 to either agglomerate or grow into large crystals.

All results listed in Table I were obtained after 50% depth partial cycles. If the depth of partial cycle is increased sufficiently when the initial discharge rate is low and the final discharge rate is high (*e.g.*, in exp. 1), a better charge acceptance is expected because of the possibility of forming small new nuclei during the final high rate discharge. Experimentally, this was found to occur, but the effect was relatively small until the depth of partial cycle was increased to about 90%. For example, the charge acceptance measured after an 87% partial cycle (C/20 full initial discharge, 87% charge at C/2, and full discharge at C/2) was found to be 36% as compared to 25% after a half depth cycle and 57% after a full depth cycle.

Practical significance of crystal size effect.—Practical significance of various experimental results described here can be summarized as follows:

1. The low-temperature charge acceptance of the negative electrode in sealed cells containing a large excess negative capacity is determined by the size of the excess cadmium hydroxide crystals, and no significant improvement in charge acceptance can be expected by high rate cycles. Consequently, sealed cells should be constructed using negative electrodes with small cadmium hydroxide crystals. Fast rate, low-temperature forming cycles should help produce small crystals.
2. Even if the negative electrode initially contains small crystals, they grow large on open-circuit stand by recrystallization. Since the rate of recrystallization is slower at lower temperatures, cells should be stored at a low temperature if they are not to be used for an extended period of time.
3. Cells in the charged state should not be left on open circuit for a long time, because the charged positive electrode self-discharges slowly to give off oxygen, and the latter discharges the negative electrode at a slow rate, which leads to the formation of large $Cd(OH)_2$ crystals.
4. Extremely low rate discharge should be avoided. This produces large $Cd(OH)_2$ crystals and possibly agglomerates of small crystals.
5. If conditions permit, temperature should be lowered when the cell is in the fully charged state rather than in the discharged state, so that the first operation at the low temperature becomes a discharge and not a charge.

Conclusion

There is little doubt that the size and the structure of $Cd(OH)_2$ crystals play an important role in determining the low-temperature charge acceptance of cadmium hydroxide electrodes. A number of experimental results can be accounted for in terms of these effects in conjunction with the reaction mechanism involving a soluble intermediate species in both the charging and the discharging reactions. However, it cannot be stated that the crystal size and structure effect explains all results. For example, we observed that the charge acceptance decreases to some extent with increasing number of charge-discharge cycles given to the electrode prior to the low temperature charge. This may be due to a redistribution of the active material within the electrode which is known to occur as a result of use (10). More complete understanding of the phenomenon would require a further investigation.

The Effect of Lead Ions on the Dissolution and Deposition Characteristics of a Zinc Single Crystal in 6*N* KOH

F. Mansfeld*[1] and S. Gilman*

National Aeronautics and Space Administration, Electronics Research Center, Cambridge, Massachusetts

ABSTRACT

Dissolution of the basal plane of single crystal zinc and deposition of zinc on the same material in alkaline solutions in the presence of 10^{-4}M lead ion, has been studied using *in situ* microscopy and the scanning electron microscope (SEM). It was found that in the presence of lead ions, most of the surface was protected against dissolution when polarized as much as 100 mV positive to the rest potential. Dissolution occurs initially in the form of a limited number of hexagonal etch pits that grow in size and number with time. The pits appear to correspond to sites of macroscopic crystalline imperfection.

In the absence of Pb ions, deposition of Zn on the basal plane of a zinc crystal tends toward epitaxial growth at low overpotentials. In the presence of Pb ions, at both high and low overpotentials, Zn deposition tends to initiate mainly at the few sites not protected by the microscopically smooth Pb film. At high overpotentials, growth tends to be cylindrical and microcrystalline, rather than dendritic. It is shown that, under the present conditions, no increase in the cathodic current is to be expected with increase of time.

The alkaline zinc electrode is encountered in several commercial and proposed aqueous battery devices. Its attractiveness as a uniquely high-energy anode material (for aqueous systems) is diminished by such concomitant problems as poor quality of the electrodeposit (secondary battery application) and corrosion of zinc. The use of additives incorporated into the anode, or dissolved in solution, has been proposed over the years and evaluated empirically. Most of the research effort in this area has been concentrated at industrial laboratories.

The use of Pb and Sn ion additions to the electrolyte as suggested earlier by Kudryavtsev is quoted in (1). The use of Pb ions was again investigated by Oxley and Fleischmann (2) who found that the deposit adherency on polycrystalline Zn increased when lead acetate was added at an optimum concentration of 0.5 g/l to a solution of 43% KOH, 1.13M in zinc ions. The reason for the influence of lead on deposit adherency was unclear.

Recently Bockris *et al.* (3) claimed that "the presence of 10^{-4} molar lead completely suppresses dendrites." This conclusion was reached, however, only from the change of the total current density with time without microscopical observation of the actual deposit.

At this laboratory an investigation of the effect of additives, especially lead, on dissolution and deposition characteristics of single crystal zinc has been carried out using the light microscope in a way similar to Powers' experiments (4, 5) and the scanning electron microscope as demonstrated by Naybour (6, 7). Powers studied deposition of zinc on the basal plane of a single crystal of zinc and on polycrystalline material (4) and, with Breiter (5), dissolution and passivation of the basal plane. Naybour investigated the effect of substrate orientation on growth (6) as well as the effect of electrolyte flow on the morphology of zinc deposits (7). Both optical methods have not been used previously in investigations of the effects of additives.

The effect of metal cations, anions and neutral molecules on the hydrogen evolution rate of polycrystalline zinc in 6*N* KOH and rate of hydrogen evolution of Zn-Pb and Zn-Al alloys will be reported in a separate paper. (12).

Experimental

The zinc electrodes were obtained by cleavage from single crystal rods grown from 99.9995% pure zinc. The crystal was cooled to liquid nitrogen temperature and then cleaved and rewarmed in a drybox under argon. The cell used for microscopic observation under polarization was similar to that used by Powers (4), with the only significant modification being to the window of the optical coverglass. The coverglass was fused to the Pyrex sleeve thereby avoiding the use of adhesives which dissolve more or less rapidly in KOH. The reference electrode was a zinc rod (99.95%), the counterelectrode was gold foil. The zinc electrode potential was controlled by a Tacussell potentiostat and monitored by a Keithley electrometer. The current was recorded on a Moseley strip-chart recorder. The microscope was by Reichert, Austria, used mainly with Nomarski interference contrast.

The solution of 6*N* KOH + 20 g/l ZnO was made up from reagent grade KOH and bidistilled water using a quartz still and ZnO, "pure" (99.9%). Lead was added in the form of the acetate salt in a concentration of 1 x 10^{-4}M. Previous experiments with addition of 10^{-4}M acetic acid had shown that the acetate ion has no effect on deposition characteristics.

Results

Anodic dissolution.—In the investigation of the effect of lead on anodic dissolution of the basal plane of zinc, a constant potential of +75 or +100 mV *vs.* zinc in the same solution was applied after the specimen had been in contact with the solution for 5 min. In the absence of lead the surface changes in the same way as on cathodic deposition (4), the difference of course being dissolution of the surface. This indicates that dissolution and deposition occur at the same sites, probably screw dislocations. After about 60 sec one observes pits in the form of hexagonal pyramids (Fig. 1). These hexagonal pits cannot be observed with dark field methods and are consequently not visible in the paper of Powers and Breiter (5), (Fig. 2). Addition of 10^{-4}M lead to the electrolyte does not result in a perceptible coating of lead on the zinc surface (*c.f.*,

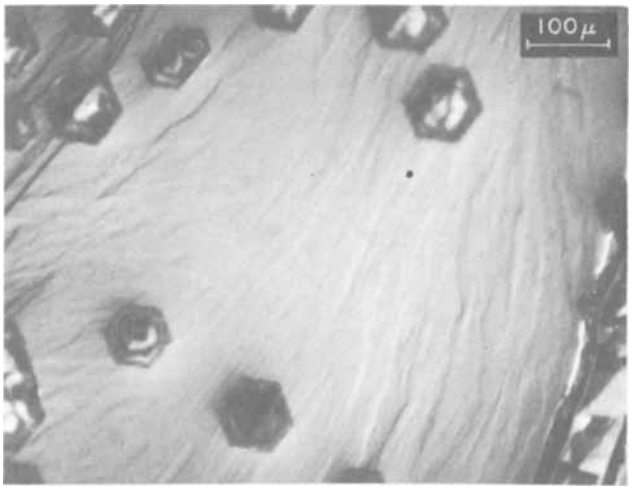

Fig. 2. Anodic dissolution of zinc, (0001) plane at +100 mV in 6*N* KOH + 20 g/l ZnO + 10^{-4}M PbAc after 240 sec. NIC, 110X.

Fig. 2), but does have a profound effect on the anodic dissolution characteristics. After applying the anodic potential hexagonal pits are observed which grow in size and number (Fig. 2). They are very numerous at more macroscopic defects of the crystal such as cracks introduced by cleavage (see right corner of Fig. 2). This difference in dissolution is also reflected in the different change of current with time (Fig. 3). With no additions, the current rises sharply and then decays; with additions, it increases slowly with the number

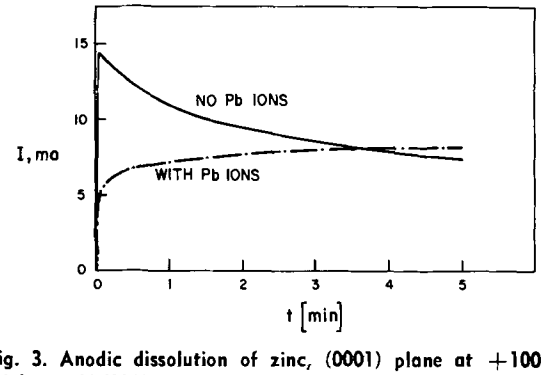

Fig. 3. Anodic dissolution of zinc, (0001) plane at +100 mV. Solid line, 6*N* KOH + 20 g/l ZnO; dashed line, 6*N* KOH + 20 g/l ZnO + 10^{-4}M PbAc. Geometric area of electrode = 0.178 cm^2.

and size of pits. Observation with the scanning electron microscope (SEM) shows that the pits are shallow, have a flat bottom and stepped sides (Fig. 4). The sides of all pits are parallel to [11$\bar{2}$0]. These pits occur probably on sites with macroscopic damage or irregularities of the crystal as can be seen from Fig. 5. The crystal was left at the open-circuit potential for 2 hr. A number of hexagonal pits were observed; they were

concentrated at cracks in the surface like the one in Fig. 5b. These macroscopic defects serve as anodes, where zinc dissolves, while Pb (and hydrogen) plate out on the cathodes.

Cathodic deposition.—Cathodic deposition on the basal plane of zinc was carried out from a solution of 6*N* KOH + 20 g/l ZnO with or without additions of 10^{-4}M lead acetate at potentials of —100 or —200 mV *vs.* zinc in the same solution. The results without additions of lead were the same as already shown by Powers (4): at —100 mV the deposit was in the form of pyramids, the number of which declines with time as the more active pyramids cover the less active ones. No classical dendrites were observed at this potential even after 1 hr of plating, although a number of small protrusions were observed.[2] At —200 mV the number of growth centers was much larger and after a short time dendrites with side branches occurred. If the potential is held at —100 mV for about 30 min and then changed to —200 mV, a large number of new growth centers appear on the sides of the previously formed pyramids. After some time dendrites are observed. If the potential is brought back to —100 mV after 1 or 2 min at —200 mV, the growth centers formed at —200 mV disappear while the pyramids continue to grow.

The effect of lead additions is shown in Fig. 6 for deposition at —100 mV. It can be seen from Fig. 6a that two different types of deposit are obtained: little bumps or hills consisting of many little crystallites and flat areas consisting of a very large number of pipes growing perpendicular to the surface. Figure 6b shows both types at a higher magnification.

Figure 7 shows the deposit at —200 mV from the same solution. The deposit is completely different from that obtained in the absence of lead (classical dendrites), it reminds one of corals. The deposit consists of a very large number of crystallites, the structure of the protrusions and of the flat areas of the surface seem to be the same. Figure 7c is a magnification of one of the flat areas. The depression corresponds to blockage of deposition by a hydrogen bubble. In order to obtain additional information about the effect of lead additions, an experiment was conducted with

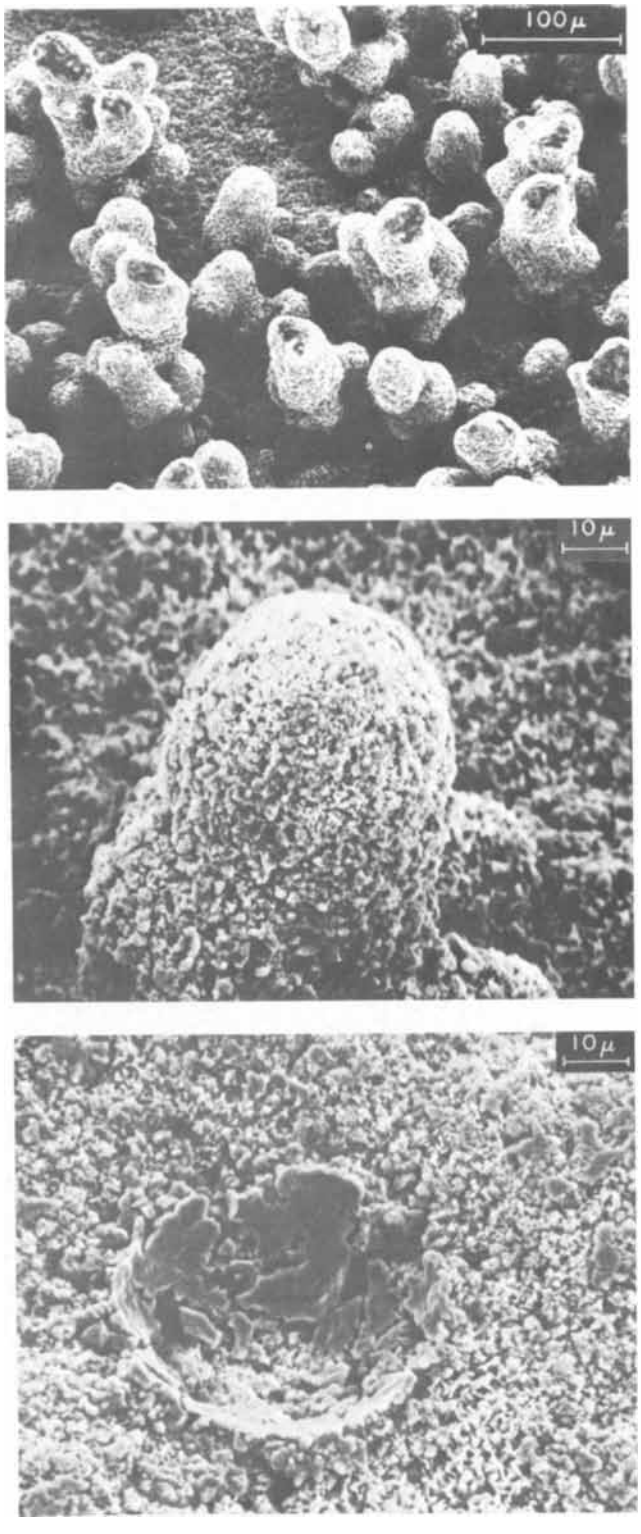

Fig. 7. Deposit at —200 mV from 6*N* KOH + 20 g/l ZnO + 10^{-4}M PbAc after 3600 sec, SEM, 45°. (a) (top) 180X; (b) (center) and (c) (bottom) 800X.

[2] The nature of these protrusions has been studied in more detail in (13).

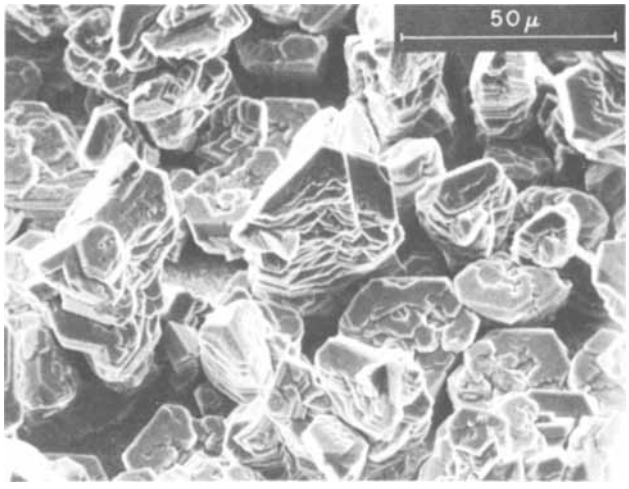

Fig. 8. Deposit at −100 mV: 60 sec in 6*N* KOH + 20 g/l ZnO + 10^{-4}M PbAc, followed by 3600 sec in 6*N* KOH + 20 g/l ZnO, SEM, 45°. 560X.

deposition at −100 mV for 1 min in a solution containing 10^{-4}M of lead, followed by additional deposition in lead-free solution. Figure 8 shows the deposit obtained at −100 mV after 1 hr of plating in the latter solution. The deposit is different from that obtained with addition of lead ions; it is similar to the protrusions observed in lead-free solutions after longer plating times (13). The protrusions are clearly crystalline with layer growth parallel to the surface but also with planes having an angle to the main crystallographic axis (center of Fig. 8).

Experiments where deposition at −100 mV in 6*N* KOH and 20 g/l ZnO was followed by deposition in the same solution with addition of lead ions produced deposits very similar to the ones shown in Fig. 6. The flat areas of the surface are again covered with pipe-shaped growths of varying length (Fig. 9). Deposition at −200 mV produced deposits similar to the ones shown in Fig. 7.

Discussion

Our results clearly show that the addition of lead ions to a solution of KOH containing zincate strongly affects anodic dissolution of the basal plane of a zinc single crystal and deposition of zinc on the same specimen. Without an externally applied potential, a microscopically smooth lead coating is deposited on the zinc surface while zinc dissolves on the anodic sites, which are thought to be major defects of the crystal (Fig. 4). If an anodic potential is applied, the crystal only dissolves at these latter sites, the other sites, which are active during dissolution in lead-free solutions (Fig. 1), are blocked and protected by lead. The pits observed after dissolution for 5 min are all rather shallow and all seem to have the same width. They are oriented with their edges parallel to $[11\bar{2}0]$ which implies that $(11\bar{2}0)$ dissolves faster than $(10\bar{1}0)$ and this in turn faster than (0001), in parallel with increasing packing density. Ashton and Hepworth (8) came to the same conclusion by measuring anodic polarization curves on the (0001), $(10\bar{1}0)$, and $(11\bar{2}0)$ plane of zinc in 0.5 NaOH.

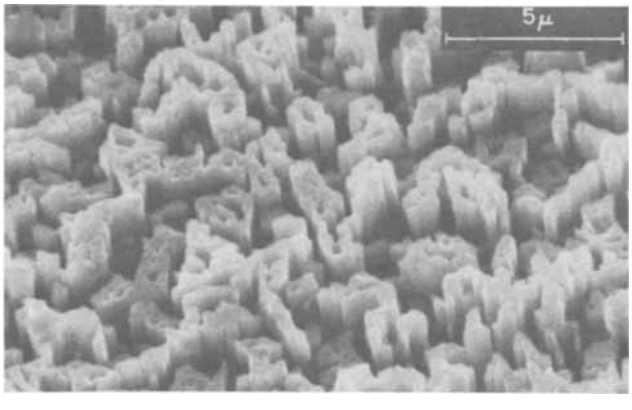

Fig. 9. Deposit at −100 mV: 150 sec in 6*N* KOH + 20 g/l ZnO followed by 1200 sec in 6*N* KOH + 20 g/l ZnO + 10^{-4}M PbAc, SEM, 45°. 4600X.

The results of deposition in lead-free solutions suggest that at the less negative potential (−100 mV) and lower deposition currents, the zinc particles diffuse on the surface to growth sites leading to pyramid growth. At more negative potentials (−200 mV) and higher deposition currents, the rate of arrival of zincate ions is higher than the rate of diffusion to growth sites, the zinc adatoms "inhibiting" their own diffusion. This results in dendritic growth. The results obtained by switching the potential from −100 to −200 mV (new nuclei, dendritic growth) and switching from −100 to −200 mV and after a short time back to −100 mV (disappearance of nuclei formed at −200 mV) support this scheme.

From our observations of the anodic dissolution of zinc in the presence of lead it follows that most of the sites for dissolution are blocked by lead. If it can be assumed that the sites for deposition and dissolution are the same, namely screw dislocations (9), then one would expect that growth on these sites is also blocked by lead. In addition it is possible that the presence of lead changes deposition characteristics from the crystallographic form of dendrites (according to Naybour (7) both tip and side branches of a dendrite grow in the $[11\bar{2}0]$ direction, the main stem and the side branches being monocrystalline) to protrusions which are no longer monocrystalline but consist of a large number of small crystals. In fact, the results of Fig. 6 and 7 show that parts of the surface are inactive for growth; the areas of larger growth consist of a large number of very small crystallites. The results of Fig. 8 show indeed that lead blocks parts of the surface, subsequent growth in lead-free solution exhibits crystalline growth again, the deposit growing mainly in the vertical direction, while large areas remain active. The nature of the sites for growth under these conditions is not known, but it seems possible that the same physical defects (or impurity centers) that act as anodes on dissolution in the presence of lead act as growth sites in deposition. Vaughan and Pick (10) assumed that copper nucleation sites were impurity centers, physical defects acting as preferred sites for impurity segregation. Although Naybour (6) showed that the number of surface defects on a zinc crystal was less than the number of growth sites, conditions are different in the present case where more surface defects are produced through local action currents. Figure 7 also shows that no classical dendrites are obtained when lead is present in the solution most likely due to incorporation of lead. There seems to be no major difference in the structure of the deposit at −100 and −200 mV in solution containing lead (Fig. 6b and 7b), the little bumps growing to larger protrusions with time under diffusion control. The nature of the pipe-like structure in Fig. 6 and Fig. 9 is not known at the present.

The conclusion of Bockris *et al.* (3) that lead addition suppresses dendrites is correct only in so far as the protrusion is not a monocrystal anymore but consists of many small crystallites. The lack of a parabolic increase of current with time as observed in (3) might be due to a lack of dependency of the diffusion current upon a radius of curvature of the substrate (11) in the case of lead additions, growth probably being linear-diffusion controlled for the type of protrusions shown in Fig. 7. A parabolic or exponential increase of current with time as observed by Bockris and co-workers (3, 11) seems questionable, however, since it was not observed by Powers (4) and in the present work in solutions free of lead ions. It could

result from the special preparation of the electrodes in (11) which consist of zinc electrodeposited on small Pt spheres and which are quite different from the much larger (0.495 cm^2) single crystal plane used in (4) and the present work. It should be remembered also that the parabolic increase of current with time in the treatment of Bockris *et al.* (11) results from the assumption that dendrite initiation is continuous, but from Naybour's (6) work it seems that dendrite initiation is instantaneous.

The small increase of current with time while dendrites grow in lead-free solutions observed in (4) and the present work results most likely only from an increase in total area as the dendrites penetrate the diffusion layer. In the presence of lead the current does not change appreciably after about 60 sec of deposition at −200 mV. The protrusions produced in this experiment have a cylindrical shape and grow perpendicular to the base contrary to real dendrites. From Table I which gives some average parameters of those protrusions it can be seen that the largest protrusions have reached a length comparable to the thickness of the diffusion layer, which is calculated to be 0.03 to 0.003 cm by using a limiting c.d. of 35 mA/cm^2 and a value of the diffusion coefficient of 2×10^{-5} to 2×10^{-6} cm^2 sec^{-1} (2). It follows that no substantial increase in area and therefore in current is expected as protrusions grow.

Conclusion

The presence of small amounts of lead ions in an alkaline solution markedly changes the anodic dissolution behavior of the basal plane of zinc by blocking most of the active sites for dissolution. Its presence also changes deposition characteristics from monocrystalline dendrites to protrusions consisting of many small crystals while large parts of the surface are inactive for deposition. It is concluded that, in the presence of lead, dissolution and deposition occurs at more macroscopic physical defects of the crystal.

It is possible that other metal ions which have a reversible potential sufficiently more noble than zinc act in a similar way. It is not entirely clear at the present how the above results apply to secondary batteries. The change in deposit morphology is certainly beneficial since no sharp dendrites result which would penetrate separators. It remains to determine what happens to the lead additions through cycling of a battery. The beneficial effect of lead ions in the electrolyte or lead alloyed in small amounts to zinc on hydrogen evolution will be reported in a separate paper (12).

Direct Current-Voltage Characteristics of Calcia Stabilized Zirconia with Porous Platinum Electrodes

Hiroaki Yanagida,[1] R. J. Brook,[2] and F. A. Kröger*

University of Southern California, Los Angeles, California

ABSTRACT

The direct current-voltage characteristics of symmetrical cells Pt, O_2(I), $|Zr_{0.85}Ca_{0.15}O_{1.85}|$Pt, O_2(II), with pO_2(I) = pO_2(II), were measured at 560°C under oxygen pressures from 1 to 10^{-20} atm. The characteristics were nonohmic, the deviation from ohmic law being mainly due to the potential drop at the cathode interface between the solid electrolyte and the gas ambient. The characteristics consist of two parts. The first is characterized by a marked oxygen pressure dependence and is observed at voltages lower than approximately 2V (weak polarization). In this range, the rate-determining process is the diffusion of oxygen atoms (resulting from dissociation of O_2 or H_2O) through the platinum of the Pt paste electrode. The second part of the characteristic is almost independent of the oxygen pressure and is observed at voltages higher than approximately 2V (strong polarization). Here the rate-determining step is the process in which neutral oxygen atoms, adsorbed at the cathode surface of the electrolyte, combine with effectively neutral oxygen vacancies V_O^x, (oxygen ion vacancies which have trapped two electrons) to form a normal O^{2-} lattice ion (O_O^x). This process utilizes the part of the electrolyte surface not in contact with the platinum, but close to points where the platinum makes contact, and involves migration of electrons from the platinum over the surface of the electrolyte.

Stabilized zirconia with the composition $Zr_{0.85}Ca_{0.15}O_{1.85}$ crystallizes in the CaF_2 structure (1, 2) and contains 7.5% extrinsic vacant oxygen sites (2, 3). The electrical conduction at high temperature in air or oxygen is ionic in nature and is due to the migration of oxygen ions by a vacancy mechanism (2-4). The vacancies involved are oxygen ion vacancies with an effective charge +2, $V_O^{\cdot\cdot}$ (5). At lower oxygen pressures, however, electronic conduction sets in (2, 5, 6). An ionic transference number t_i is defined by

$$t_i = \sigma_i/(\sigma_i + \sigma_e) \qquad [1]$$

where σ_i is the ionic and σ_e the electronic conductivity. The value of the oxygen pressure at which this transference number is 0.5 is a function of temperature (2, 6) and varies from sample to sample (4). Typical values of $(pO_2)_{0.5}$ for stabilized zirconia of the composition given above are 10^{-42} atm at 560°C, 10^{-32} atm at 800°C, 10^{-26} atm at 940°C (2). A galvanic cell with platinum electrodes and stabilized zirconia as a solid electrolyte operated with different oxygen pressures at the two sides, gives an open circuit emf E_{open} given by (2, 7)

$$E_{open} \equiv E_{II} - E_I = \frac{1}{4F}\int_I^{II} t_i(\mu O_2)\, d\,\mu O_2 = \frac{RT}{4F}\int_I^{II} t_i\,(pO_2)\, d \ln pO_2 \qquad [2]$$

where $\mu O_2 = RT \ln pO_2$. The cell can be used as a fuel cell or a solid-state battery (8) and also as an oxygen pressure monitor (7).

The emf arises as a consequence of the simultaneous migration of ionic and electronic defects. In the stationary state, the total electrical current carried by these defects at open-circuit voltage must be zero, and therefore the electronic current j_e and the ionic current j_i must be equal and opposite

$$J = j_e + j_i = 0 \text{ or } j_e = -j_i \neq 0 \text{ at } V = E_{open} \qquad [3]$$

The ionic current is stopped by the application of a voltage E_{stop} (9, 10) given by

$$E_{stop} = \frac{1}{4F}[\mu O_2(II) - \mu O_2(I)] \qquad [4]$$

Since $t_i \leq 1$ comparison of [2] and [4] shows that

$$E_{stop} \geqq E_{open} \qquad [5]$$

Application of a voltage higher than E_{stop} causes oxygen ions to move through the electrolyte from the lower oxygen pressure side toward the higher pressure side, and thus oxygen gas is pumped from the side of lower oxygen pressure to the side of high oxygen pressure (11-13). The oxygen pump not only pumps O_2, but can also decompose H_2O (11) and CO_2 (13). If ionic currents flow, and as seen above this is true in all cases unless $V = E_{stop}$, the chemical potential of oxygen in the electrolyte at the cathode surface (where oxygen is taken up) is lower than that of its gas ambient, and the chemical potential of oxygen in the electrolyte at the anode surface (where oxygen gas is evolved) is higher than that of its gas ambient. These potential drops, if appreciable, must be expected to reduce the accuracy of oxygen pressure monitor cells and the efficiency of fuel cells or oxygen pump cells. Their presence is indicated by the nonohmic character of the current-voltage characteristics; such nonohmic effects have been observed with several ionic conductors (12-15). It is the purpose of the present study to investigate the current-voltage characteristics of calcia stabilized zirconia in order to gain insight into the processes taking place at the electrodes. In this study, mainly symmetrical cells with pO_2(I) = pO_2(II) and $J = 0$ at $E_{stop} = 0 = E_{open}$ have been used. This was done to avoid possible complications arising from the ionic current inside the electrolyte in asymmetrical cells at $J = 0$ [see (3)]. Asymmetrical cells were only used to separate the effects of anodic and cathodic potential drops. The oxygen pressure of the gas ambient under which the measurements were made was between 10^{-20} and 1 atm.

Experimental Procedures

Sample preparation.—Zirconium dioxide was made by slow calcination of zirconium tetra-acetyl-acetate (supplied by Matheson Coleman and Bell Company) at 800°C in air. Major impurities present in the acetate were [in weight per cent (w/o)]: 0.15 SiO_2, 0.005 Fe_2O_3, 0.003 Al_2O_3, 0.003 MgO, 0.003 TiO_2, 0.004 (Na_2O + K_2O). The ignition loss was 71.23 w/o. Calcium carbonate supplied by Mallinckrodt was used as a source of calcia. For this, the maximum limits of major impurities, given in weight per cent, are: 0.10 Na, 0.10 Sr, 0.02 Mg, 0.01 K, 0.005 Ba. Zirconium dioxide and calcium carbonate powders were weighed to give the composition (0.15 CaO + 0.85 ZrO_2), mixed in an agate mortar for 2 hr, and pressed to pellets. The pellets were heated in dry Argon gas at 1900°C for 2 hr in an induction furnace with a graphite crucible. The pellets as fired showed a brown color. The color disappeared on heat-treatment in air at 800°C. X-ray analysis showed the diffraction pattern of the fluorite structure only. The pellets in their final state were 1 mm thick and 10 mm in diameter.

Experimental set-up.—The specimen, whose characteristic was to be studied, was kept in a stabilized zirconia tube through which a carrier gas (5 ml/sec) containing various amounts of oxygen was circulated. The experimental set-up is shown schematically in Fig. 1. Nitrogen gas was used as the carrier gas and was found to contain $\approx 10^{-4}$ oxygen as an impurity. In addition water vapor was present. The oxygen content was varied by passing the gas through an oxygen pump cell consisting of stabilized zirconia as a solid electrolyte with platinum paste electrodes (11-13). The oxygen pressure was reduced by applying to the pump cell, operated at 670°C, a voltage higher than E_{stop} corresponding to the two oxygen pressures, $pO_2(I) \approx 10^{-4}$ atm (N_2) and $pO_2(II) \approx 0.2$ atm (air). The oxygen pressure was increased by applying a voltage smaller than E_{stop}. To reduce the amount of water vapor in the gas ambient around the test specimen, a liquid nitrogen cold trap was used with the trap usually at position A. Some measurements were carried out without the trap to find the effects of water vapor.

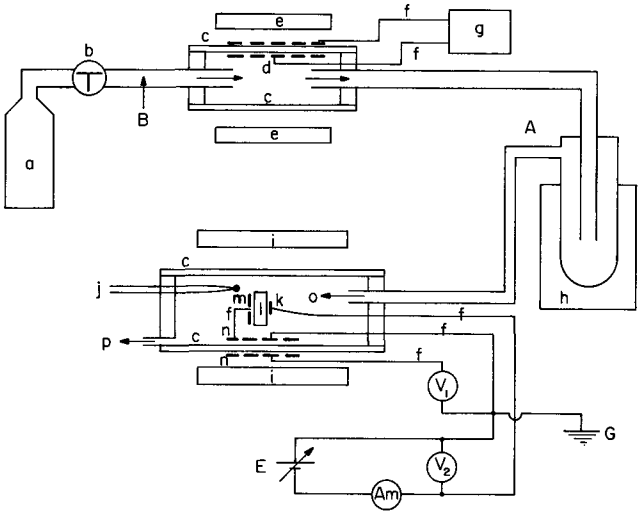

Fig. 1. Experimental set-up. a, inert gas bottle; b, cock and flow meter; c, stabilized zirconia tube; d, platinum paste electrodes for oxygen pump; e, oxygen pump furnace; f, platinum leads; g, d-c power supply for oxygen pump; h, liquid nitrogen cold trap; i, furnace for *I-V* characteristic measurements; j, thermocouple; k, platinum paste cathode; l, test specimen; m, platinum paste anode; n, platinum paste electrodes for oxygen pressure monitoring; o, gas input; p, gas outlet; V_1, volt meter for oxygen pressure monitoring (Cary 31); V_2, volt meter for *I-V* characteristic measurements (Cary 31); Am, d-c power supply and voltage regulator; G, ground; A, position of the liquid nitrogen trap used in most of the experiment; B, alternative position of the cold trap.

Some measurements were also done with the trap at position B rather than at A. The oxygen pressure around the specimen was monitored by a zirconia cell using the wall of a commercial Zircoa B grade stabilized zirconia tube with the composition $(ZrO_2)_{0.90}(CaO)_{0.10}$ as the electrolyte.

The test specimen was provided with platinum paste electrodes at the two sides. The platinum paste was prepared using a submicron platinum powder and an organic suspending medium. At one side the paste covered much of the surface specimen (5-20 mm^2); at the other side the electrode had an area of ≤ 1 mm^2. Contact to the electrodes was made by spring loaded platinum wires (0.01 in. diameter) which were dipped in platinum paste prior to their application to the electrodes.

The specimen with electrodes and contacts in place was heated to 800°C for about ½ hr in order to remove the organic material and to sinter partially the platinum powder. The microscopic configuration of the contact is shown schematically in Fig. 2. The platinum has a spongelike structure with interconnected gas channels. It makes direct contact with the zirconia over part of the surface, leaving a gas-zirconia contact over the remaining surface area. Lines where the triple contact platinum-zirconia-gas occurs are indicated by T. Usually only half of the characteristic will be reported, *viz.*, that half for which the small area electrode is the cathode.

The voltage differences between the electrodes of the oxygen pressure monitor cell and between those of the test specimen (pellet) were measured with a vibrating reed electrometer (Cary 31, Applied Physics Corporation). The current through the specimen was measured with the aid of a Keithley 610B multipurpose electrometer. The voltage applied over the specimen was changed with a voltage divider, Dekavider DV-412 (Electro-Measurements, Inc.). A Burgess 5156 (Clevite Corporation) dry battery was used as a direct current source. Most of the measurements were carried out at 560°C, a temperature chosen to be high enough to keep the resistance at a reasonable level, but low enough to reduce F center migration from the cathode into the electrolyte which complicates the analysis.

In one instance, measurements were made on an asymmetric cell, *i.e.*, where $pO_2(I) = 10^{-20}$ atm and $pO_2(II) = 0.2$ atm. For this experiment, the sample was cemented to the end of a zirconia tube and placed in a furnace containing an air atmosphere. The interior of the tube was filled with flowing nitrogen which had been purified to $pO_2 = 10^{-20}$ atm by the zirconia pump, this value being measured by the open-circuit emf of the sample itself. Paste electrodes and platinum wire contact probes were used for this experiment in the same way as described above for the symmetric cells, except in that both electrodes were of the same area ~ 1 mm^2.

Minimum oxygen pressures around the test specimen.—The lowest oxygen pressure monitored near the test specimen was 10^{-20} atm at 560°C. This is well above the values (16) monitored within the oxygen pump cell itself (11). The pressure increase is due to

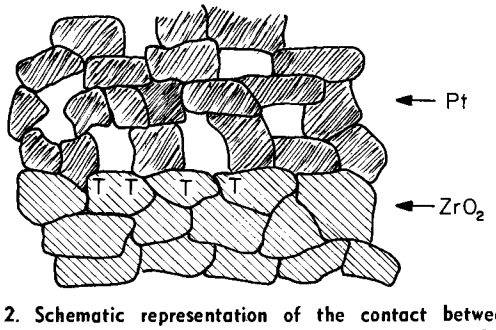

Fig. 2. Schematic representation of the contact between the electrolyte and a sintered Pt contact made by sintering Pt paste at 800°C.

leakage through the wall or release of oxygen from the wall of the glass tube connecting the pump to the measuring vessel. An alternative experimental arrangement with the cold trap at the position B in Fig. 1 gave pressures in the measuring cell well above those found with the trap in the usual position A. The difference is due to the buffering action of hydrogen (11). If water vapor present in the tank nitrogen is still present when the gas enters the pump cell (*i.e.*, the set-up with the trap at A), the water is decomposed with the formation of an equivalent amount of hydrogen. Drying the gas at A then removes most of the residual water and leads to a certain value of the water-hydrogen pressure ratio $(pH_2O/pH_2)_A$. On the other hand, with the cold trap in position B, the water is largely removed before the gas enters the cell, and therefore the amount of H_2 that can be formed is largely reduced. This leads to a higher value of the water-hydrogen pressure ratio $(pH_2O/pH_2)_B$. If no leakage would occur, each would give rise to an oxygen pressure given by the ratio

$$pO_2^{1/2} = K_{H_2O} pH_2O/pH_2 \qquad [6]$$

with $(pO_2)_A < (pO_2)_B$. Moreover, leakage of oxygen occurs and this will have a much stronger effect if the H_2 pressure is low (case of position B) than if it is high (case of position A). As a result, the value of pO_2 finally measured in the monitor cell is again smaller in case A than in case B.

Experimental Results and Discussions

Hysteresis.—If at a given oxygen pressure the current is measured as a function of applied voltage, first increasing the voltage from zero to 6V at a rate of 1 v/min, and then decreasing it to zero at the same rate, hysteresis is observed. Figure 3 shows the result for a measurement with the cell in air. Both the decrease of current wtih time (4, 9, 17) and the increase of current with time (9, 11) were previously reported. The hysteresis, however, has not been satisfactorily explained (9). The present authors believe that the increase is due to the injection of F centers into the electrolyte from the cathode at voltages ≧2V, and that the decrease is due to the time required for the completion of polarization or, if it is after a considerable number of F centers have been formed, the time required for these centers to disappear. The most reproducible curves were obtained with measurements taken during the decrease of the applied voltage from 6 to 0V at a rate of 1 V/min (the solid curve in Fig. 3) after the voltage had been increased from 0 to 6V beforehand at the same rate and held at 6V for half a minute. The times involved are supposed to be long enough to build up space charges characteristic of polarization, but are still short enough to keep F centers, formed at the cathode at high voltages, from drifting into the electrolyte to an appreciable extent. From here on, only the characteristics obtained according to this schedule will be discussed.

Oxygen pressure dependence of the direct-current vs. voltage characteristics.—Some examples of current-voltage characteristics measured at various oxygen pressures are shown in Fig. 4. It is seen that variation of the oxygen pressure affects the characteristic in different ways. At $V > 2V$ the current slightly decreases with increasing oxygen pressure in the range $10^{-14.5}$ to $10^{-4.3}$ atm and hardly changes with the oxygen pressure in the range $pO_2 > 10^{-4.3}$ atm. This behavior is more easily seen from a plot of the slope of the *I-V* characteristic, *i.e*, the dynamic conductance $(\partial I/\partial V)$, as a function of applied voltage. The inverse of this derivative, $(\partial V/\partial I)$, is of the dimension of a resistance and is called dynamic resistance. Figure 5 shows the relation between $(\partial V/\partial I)$ and applied voltage for various oxygen pressures. The effect of oxygen pressure upon the dynamic resistance is strongest where applied voltage is zero, and weakest at voltages higher than 2V. This behavior suggests that the characteristic is determined by two different mechanisms, the effect of one being dominant at $V < 2V$, the other being dominant at voltages >2V.

A difference in mechanism is also indicated by a difference in the effect of the presence of water vapor (Fig. 6). The effect of a variation in pH_2O is seen only at low O_2 pressures where oxygen atoms are present mainly as water molecules, and at $V < 2V$; at higher voltages there is practically no effect.

Finally the time dependence in the high and low voltage regions is different: the current at high voltages increases with time probably as a result of the occurrence of electronic conduction, increasing when F centers formed at the cathode drift into the electrolyte. That at low voltages tends to decrease.

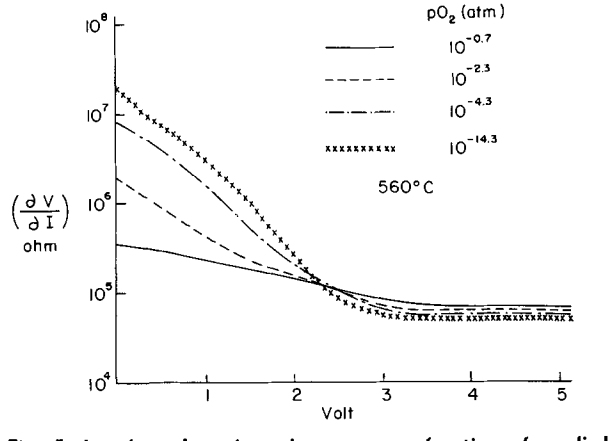

Fig. 5. Interface dynamic resistance as a function of applied voltage and oxygen pressure.

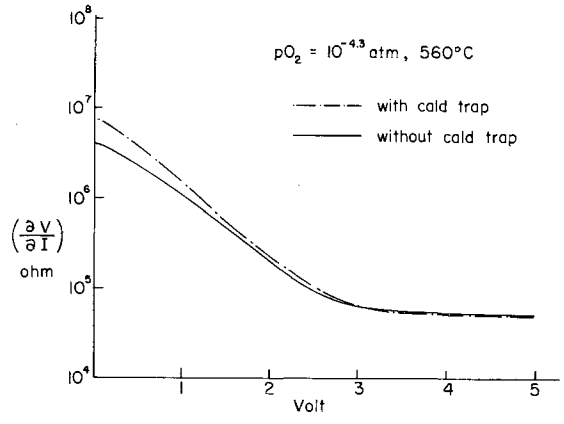

Fig. 6. Effect of water vapor on the dynamic resistance as a function of voltage.

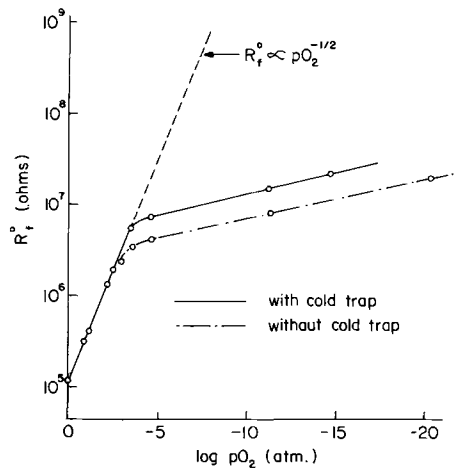

Fig. 7. R_f^0 as a function of oxygen pressure ($R_b = 5 \times 10^5$ ohm)

Low voltage section of the characteristic.—Dynamic resistance at zero volts.—Since the test specimen was operated with the same oxygen pressures at the two sides, E_{stop} as given by [4] is zero. Since no ionic current occurs when the applied voltage is E_{stop}, no potential drop can be present at the electrolyte-gas ambient interfaces. Furthermore, since the applied voltage is zero in this case, there is no oxygen chemical potential drop across the electrolyte.

The equivalent circuit consists of three resistances in series: one, R_c represents the resistance between the electrolyte and its gas ambient at the cathode side, the second, R_b, the bulk resistance of the electrolyte, and the third, R_a, the resistance between the ambient and the solid electrolyte at the anode side interface. The relation

$$\left(\frac{\partial V}{\partial I}\right)_{V=0} = R_b^0 + R_c^0 + R_a^0 \qquad [7]$$

holds, where the superscript 0 indicates that the applied voltage is zero. Or, introducing the total interface resistance R_f, defined by

$$R_f^0 = R_c^0 + R_a^0 \qquad [8]$$

and noting that R_b is ohmic so that $R_b^0 \equiv R_b$, [7] can be written

$$\left(\frac{\partial V}{\partial I}\right)_{V=0} = R_b + R_f^0 \qquad [9]$$

The resistance across the electrolyte is practically independent of oxygen pressure since the concentration of anion vacancies responsible for ionic conduction is fixed and determined by the calcium oxide content; also the electronic contribution to the conductivity across the electrolyte is hardly measurable in the oxygen pressure range 1 to 10^{-20} atm covered in this study, so that $t_i \approx 1$. Hence, the change in the dynamic resistance $(\partial V/\partial I)_{V=0}$ with pO_2 must be mainly due to a change in the interface resistance R_f^0. Equation [9] tells us that if a constant ($=R_b$) is subtracted from the observed dynamic resistances, the residue should be the R_f^0, which is a function pO_2. Trial and error shows that a plot of log R_f^0 *vs.* log pO_2 is linear for the oxygen pressure range from 10^{-4} atm up to 1 atm if $R_b = 5 \times 10^5$ ohms; the line has a slope of $-\frac{1}{2}$, indicating that $R_f^0 \propto pO_2^{-1/2}$ (Fig. 7). The value of R_b found in this manner should be compared with reported values for the resistivity of stabilized zirconia. According to Kingery *et al.* (3), $\rho(560°C) \approx 2.9 \times 10^4$ ohm cm. For a sample thickness, t, of ≈ 1 mm, a gross cathode contact area, S_g, of ≈ 1 mm^2, an anode area of 5 mm^2, and thus for an effective cross section of the conduction path of $S_{eff} = (5 - 1)/\ln 5 = 2.5$ mm^2, the calculated value of the bulk resistance $\left(\rho \frac{t}{S_{eff}}\right)$ is 1.16×10^5 ohms. The fact that the characteristic leads to a slightly larger value may be due to the fact that the actual contact area for the low voltage mechanism, S_L, is less than S_g. For $S_L/S_g = 1/4.3$, the two resistance values agree. This phenomenon, described here in terms of S_L and S_g has been discussed elsewhere (19) in terms of a "constriction resistance."

The plot of log R_f^0 *vs.* log pO_2 shown in Fig. 7 has a sharp change in slope near $pO_2 = 10^{-4}$ atm, indicating that R_f^0 is only weakly dependent on the oxygen pressure for $pO_2 < 10^{-4}$ atm. This sharp change in behavior requires a distinction between R_f^0 for high and for low oxygen pressure, *i.e.*, between $R_{f,h}^0$ and $R_{f,l}^0$. Comparison of the results of experiments with and without the liquid nitrogen cold trap (*i.e.*, with gas of the same oxygen pressure but containing different amounts of water vapor) shows that $R_{f,l}^0$ is variable, but $R_{f,h}^0$ is not affected. This indicates that $R_{f,h}^0$ involves oxygen atoms deriving from O_2 molecules, but that $R_{f,l}^0$ involves oxygen atoms deriving from buffer molecules, *e.g.*, H_2O or CO_2 (in the present case probably the former). It indicates also that we are dealing with a different rate-limiting process. We shall deal with the oxygen process and with the water process below.

The relative importance of the two terms, R_c^0 and R_a^0, may be shown by noting that a change in the gross anode surface area from 5 to 20 mm^2 did not give any alteration of the observed characteristics whereas changing the cathode area did alter the behavior. This indicates that R_f^0 is determined mainly by R_c^0: it is mainly the cathodic processes that determine the current-voltage characteristics. Consequently

$$R_f^0 \approx R_c^0 \qquad [10]$$

and

$$R_c^0 >> R_a^0 \qquad [11]$$

The same feature is indicated by a comparison of the *I-V* characteristic of an asymmetrical cell, for which $pO_2(I) = 10^{-20.0}$ atm and $pO_2(II) = 0.2$ atm, with the *I-V* characteristics of symmetrical cells operated at these two pressures. As shown in Fig. 8, the section of the asymmetrical characteristic for $V > E_{open}$ (curve 1a) where the electrode at the low pO_2 side is the cathode, is almost identical with the symmetrical characteristic for $pO_2 = 10^{-20.0}$ atm (curve 2) if the latter is shifted by E_{open} (curve 2). Similarly the section of the asymmetric characteristic for $V < E_{open}$ (curve 1b) where the electrode at the high pO_2 side is the cathode, is almost identical with the characteristic of the symmetrical cell having $pO_2 = 0.2$ atm (curve 3) similarly shifted (curve 3'). Thus the gas present at the cathode (negative relative to E_{open}) determines the shape of the characteristic.

If the cathode process determines R_f^0, the pressure dependence of R_f^0 mainly arises from the pressure dependence of R_c^0. Since $R = C^{-1}$, where C is the conductance, the pO_2^{-n} dependence of R_c^0 corresponds to the following relation for the conductance C_c^0 at the cathode side interface

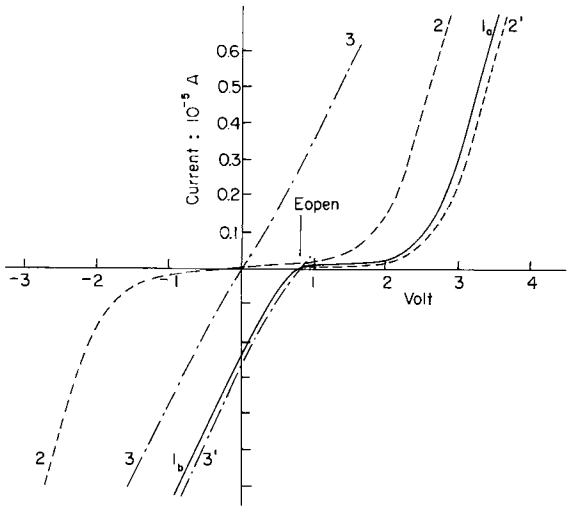

Fig. 8. Comparison of the *I-V* characteristic of an asymmetrical cell with those of symmetrical cells. 1_a, asymmetrical characteristic for $V \geqq E_o$ (E_o = 810 mV, at 560°C, $pO_2(I) = 10^{-20.0}$ atm and $pO_2(II) = 10^{-0.7}$ atm); 1_b, asymmetrical characteristic for $V \leqq E_o$; 2, symmetrical characteristic for $pO_2 = 10^{-20.0}$ atm; 2', 2 shifted to the right by 810 mV; 3, symmetrical characteristic for $pO_2 = 10^{-0.7}$ atm; 3', 3 shifted to the right by 810 mV.

$$C_c^0 = \frac{1}{R_c^0} \propto pO_2^n \qquad [12]$$

where $n = \frac{1}{2}$ at high oxygen pressures and $n \approx 0$ at low oxygen pressures. The conductance is given by

$$C_c^0 = \left(\frac{\partial I}{\partial V}\right)_{V=0} \qquad [13]$$

The current I is given by the number of O^{2-} ions formed per second from $O_2(g)$ or $H_2O(g)$ at the cathode and transferred to the solid electrolyte (15). This may happen in various ways, each involving a number of steps, one of which is the rate-determining one.

Determination of the rate-limiting step: $pO_2 >> pH_2O$.—At relatively high oxygen pressures, when $pO_2 >> pH_2O$, the over-all cathode process consists of the dissociation and ionization of oxygen and its incorporation into the zirconia

$$\tfrac{1}{2}\,O_2(g) + 2e^-(Pt) \rightarrow O^=(ZrO_2) \qquad [14]$$

It has been argued (13) that since species in three phases are involved in this process, it has to occur at a triple contact where these three phases meet (Fig. 2,T). It should be understood, however, that this triple contact is one-dimensional and cannot carry any current. Although the actual process will occur more or less close to T, it must take place across a two-dimensional surface, *e.g.*, an area either at the Pt side or at the zirconia side (or at both sides) of T. In the first case the process must involve diffusion of an oxygen species through or over the platinum; in the latter case it must involve electron diffusion from the Pt at T over the free zirconia surface. It is proposed that the first mechanism is responsible for the low-voltage behavior and that the second mechanism accounts for the high-voltage behavior. We shall now proceed with a discussion of the former. The following steps, indicated schematically in Fig. 12 are supposed to be involved.

$$\tfrac{1}{2}\,O_2(g) \rightleftarrows \tfrac{1}{2}\,O_2(Pt/g) \qquad [15]$$

$$\tfrac{1}{2}\,O_2(Pt/g) \rightleftarrows O(Pt/g) \qquad [16]$$

$$O(Pt/g) \rightarrow O(Pt/ZrO_2) \qquad [17]$$

$$O(Pt/ZrO_2) + V_O{}^{\cdot\cdot} \rightleftarrows O_O{}^x + 2h^{\cdot} \qquad [18]$$

$$2e^-(Pt) + 2h^{\cdot} \rightleftarrows 0 \qquad [19]$$

Here $O_2(Pt/g)$ are oxygen molecules adsorbed at the interfaces between the platinum crystals and the gas phase either at the outer surface of the paste electrode or inside the platinum sponge; $e^-(Pt)$ are electrons of the platinum, with energies corresponding to its Fermi surface; $O(Pt/g)$ are oxygen atoms in the platinum at the platinum-gas interface (the formation of charged forms of oxygen in the platinum, *e.g.*, O^- or $O^=$, is not energetically favored), $O(Pt/ZrO_2)$ are oxygen atoms in the platinum near the Pt, ZrO_2 interface, $V_O{}^{\cdot\cdot}$ are the oxygen ion vacancies present in the zirconia at a concentration given by that of calcia (2, 3), $O_O{}^x$ is the structure element symbol for a normal $O^=$ ion in the zirconia, and $h^{\cdot}$ are electron holes formed in the ZrO_2 surface by solution of the oxygen atoms from the platinum.

Each of the steps in the reaction sequence must be considered as a possible rate-limiting step. To treat them in turn, reaction [15] represents access of the oxygen gas to the platinum surface and could be the rate-limiting step if diffusion of oxygen molecules through a boundary layer were slow. The oxygen flux would then be

$$J_O = \frac{2D'}{\eta}\,[pO_2(g) - pO_2(Pt/g)] \qquad [20a]$$

where η is the boundary layer thickness and D' the diffusion coefficient for oxygen in the boundary layer.

By an analysis similar to that used in the next section, it can be shown that this leads to an equation for the interface resistance of the form

$$R_f{}^0 = \frac{RT}{4\mathbf{F}B'}\,pO_2{}^{-1}(g) \qquad [20b]$$

where **F** is the Faraday and B' is a constant (cf. Eq. [35]). The resistance thus varies linearly with $pO_2{}^{-1}(g)$ whereas the experimental observations (Fig. 7) vary with $pO_2{}^{-\frac{1}{2}}(g)$. Thus [15], which has been recognized in the literature (19) as a possibly important rate-limiting process (gas phase polarization), is not the rate-controlling step in any of the present experiments.

In a similar manner, reaction [16] can be eliminated as a rate-limiting step since it also shows a conductance proportional to $pO_2(g)$. Of all the reactions, only [17] and [18] have the required $pO_2{}^{\frac{1}{2}}$ dependence through the equilibrium of [16] combined with [17]. Of these two, [18] has no voltage dependence since the activity of $V_O{}^{\cdot\cdot}$ may be considered constant as determined by the calcium concentration. If the current capable of being given by [18] is greater than $I_b = V/R_b$ given by the ohmic bulk resistance, R_b, and this must be expected to occur close to the origin of the *I-V* curve where I_b is small, the over-all current must be limited by R_b and be independent of pO_2. On the other hand, if the current given by [18] is the smaller one so that [18] becomes the rate-limiting step it leads to a voltage independent current $I_m \propto pO_2{}^{\frac{1}{2}}$. The resulting *I-V* characteristic near the origin would be as shown in Fig. 9. The experimental results in the present work show, however, that in the area where the dynamic resistance is proportional to $pO_2{}^{-\frac{1}{2}}$, the current near $V = 0$ is dependent on both $pO_2{}^{\frac{1}{2}}$ and V. Therefore [18] cannot be rate limiting, and [17] is indicated as the rate-determining step.

Low voltage I-V characteristic for $pO_2 >> pH_2O$.—The fact that [17] is the rate-determining step leads to an expression for $(\partial V/\partial I)_{V=0}$ which may be compared with the data. As mentioned earlier, in any situation in which ionic current flows, *i.e.*, where $V \neq E_{stop}$, the chemical potential of oxygen at the cathode surface of the electrolyte is lower than that of its gas ambient. For $pO_2(I) = pO_2(II)$ as holds for the cells investigated in the present study, and in accordance with the experimental results which indicate that the cathode resistance $R_c >> R_a$ the anodic resistance, the variation of the chemical potential of oxygen through

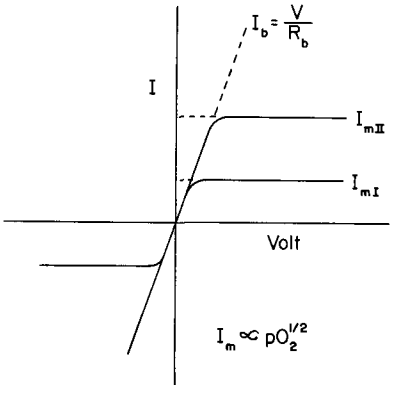

Fig. 9. Schematic diagram for the case where the process [18] would be the rate-determining step. It would be expected that $(\partial V/\partial I)_{V=0} = R_b$ near the origin; $I_m \propto pO_2^{1/2}$.

the cells can be shown schematically as in Fig. 10. As shown, the drop in μO_2 at the cathode is much larger than the increase in μO_2 at the anode: $\mu O_2(g) - \mu O_2(c) >> \mu O_2(a) - \mu O_2(g)$

$$\Delta\mu O_2 = \mu O_2(a) - \mu O_2(c) \approx \mu O_2(g) - \mu O_2(c)$$

The induced potential difference $\Delta\mu O_2$ over the electrolyte represents an emf

$$E_{a-c} \approx E_{g-c} = \frac{\Delta\mu O_2}{4F} \qquad [21]$$

which is almost of the magnitude and sign to stop the migration of ions under the influence of the outer field. The ionic conduction processes may be represented by the equivalent circuit (Fig. 11). The limitation of electronic conduction may be represented by a resistance, R_e, parallel to the others which represent the resistance to ionic conduction. In this equivalent circuit, the polarization emf (21) works over the resistance $R_f \approx R_c$. Since there is practically no electronic conduction under the conditions of the experiments, $R_e \approx \infty$. A small ionic current is kept going if the applied voltage is larger than the polarization voltage (21)

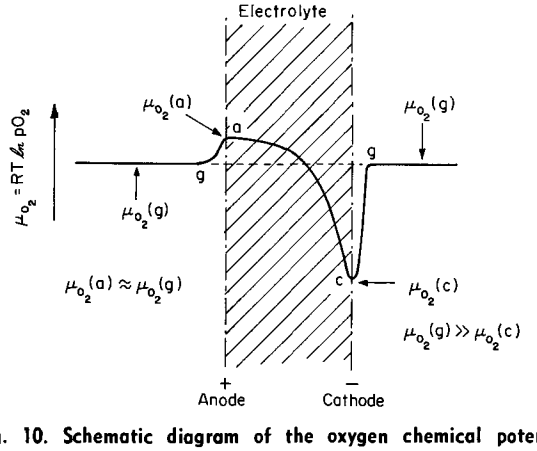

Fig. 10. Schematic diagram of the oxygen chemical potential across the circuit (electrode-electrolyte) if ionic current flows.

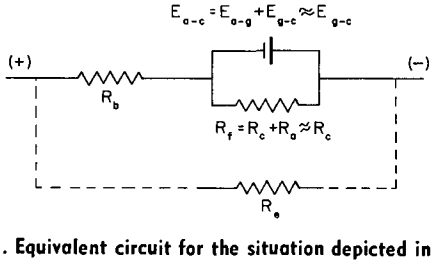

Fig. 11. Equivalent circuit for the situation depicted in Fig. 10

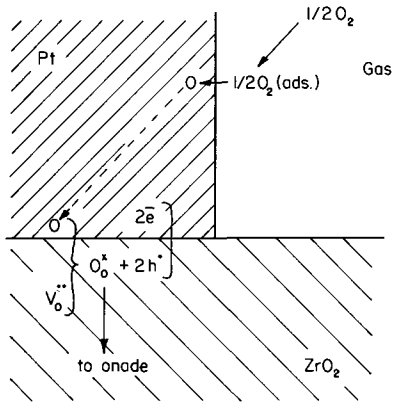

Fig. 12. Reaction steps in the low-voltage mechanism. The dotted line indicates the rate-controlling step.

$$V = I \cdot R_b + E_{a-c} \qquad [22]$$

$$E_{a-c} = \frac{RT}{4F} \ln \frac{pO_2(a)}{pO_2(c)} = \frac{RT}{4F} \ln \frac{pO_2(g)}{pO_2(c)} \qquad [23]$$

If [17] is the rate-determining step, the rate is given by a diffusion flux equation

$$J_O = D \frac{\partial}{\partial x} [O(Pt)] \qquad [24]$$

where D is the diffusion constant of O atoms for diffusion through the platinum from the Pt/gas surface to the Pt/ZrO_2 interface along any of the paths pp', qq', rr', tt' in Fig. 13; it may include diffusion along the Pt/ZrO_2 interface (path Ts in Fig. 13) but not diffusion along the Pt/gas interface (p → q → r → t → T), since the latter would be effected faster by a diffusion of O_2 molecules through the gas phase. (This is true in particular in pure oxygen where concentration gradients cannot occur, and since there is no indication of a change in mechanism on going from pure oxygen to inert gas-O_2 mixtures, the same appears to hold for operation in these mixtures also. Gas diffusion of O_2, if rate determining, would also give a rate $\propto pO_2$.)

The maximum contact area for the proposed process is the total area S of the Pt/ZrO_2 interfaces (wT in Fig. 13). As we saw in the section on Dynamic resistance at zero voltage, the contact area for the low voltage mechanism $S_L \approx (1/4.3)S_g$. The total ZrO_2 surface becomes accessible only if the ZrO_2 becomes sufficiently conductive at its surface to transport electrons from the platinum over the ZrO_2 surface.

Assuming a linear gradient, [24] can be changed to

$$J_O = \frac{D}{\partial}\{[O(Pt/g)] - [O(Pt/ZrO_2)]\} \qquad [25]$$

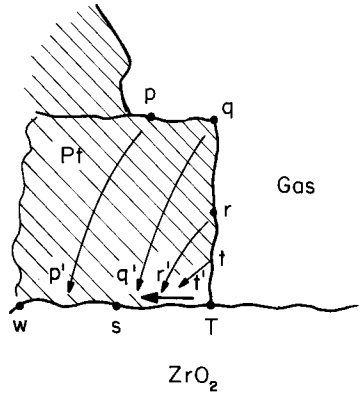

Fig. 13. Various diffusion paths for O in Pt

Here ∂ is the effective length of the diffusion path, *i.e.*, in Fig. 13, the appropriate average of the lengths of paths pp' to tt'.

The equilibrium for [15] and [16] leads to

$$[O(Pt/g)] = K_1 pO_2^{1/2}(g) \quad [26]$$

and one can also write (Fig. 10)

$$[O(Pt/ZrO_2)] = K_1 pO_2^{1/2}(Pt/ZrO_2) \equiv K_1 pO_2^{1/2}(c) \quad [27]$$

Consequently

$$J_O = \frac{D}{\partial} K_1 \{pO_2^{1/2}(g) - pO_2^{1/2}(c)\} \quad [28]$$

At the interface Pt/ZrO_2, O atoms are transformed into $O^=$ ions by reaction [18]. Therefore the particle current [28] ultimately represents an equivalent electrical current through the ZrO_2 of

$$I_h = 2\mathbf{F}S_L J_O \quad [29]$$

Here S_L is the effective area of the Pt/ZrO_2 interface, **F** is the Faraday, and the subscripts h and L are used to indicate respectively relatively high O_2 pressure ($pO_2 >> pH_2O$) and a low voltage. Combining [29] with [22], [23], and [28], we find

$$V = I_h R_b + \frac{RT}{4\mathbf{F}} \ln pO_2(g)/pO_2(c) \quad [30]$$

and

$$I_h = 2\mathbf{F}S_L \frac{D}{\partial} K_1 \{pO_2^{1/2}(g) - pO_2^{1/2}(c)\} = B\{pO_2^{1/2}(g) - pO_2^{1/2}(c)\} \quad [31]$$

where

$$B = 2\mathbf{F}S_L(D/\partial)K_1 \quad [32]$$

Eliminating $pO_2(c)$ from [30] and [31] we get

$$V = I_h R_b + \frac{RT}{4\mathbf{F}} [\ln pO_2(g) - 2 \ln \{pO_2^{1/2}(g) - I_h/B\}] \quad [33]$$

and, by differentiation

$$\frac{\partial V}{\partial I} = R_b + \frac{RT}{2\mathbf{F}B} \{pO_2^{1/2}(g) - I_h/B\}^{-1} \quad [34]$$

or, for zero voltage where $I_h = 0$

$$\left(\frac{\partial V}{\partial I}\right)_{V=0} = R_b + \frac{RT}{2\mathbf{F}B} pO_2^{-1/2}(g) \quad [35]$$

This is just the form observed for R_f^0 at $pO_2 > 10^{-4}$ atm (Fig. 7). The current by this mechanism cannot exceed a limiting value given by [31] with $pO_2(c) = 0$, *i.e.*

$$(I_h)_{lim} = BpO_2^{1/2}(g) \quad [36]$$

This limiting value is approached when $V \to \infty$; $\partial V/\partial I$ as given by [34] approaches ∞, or $\partial I/\partial V$ approaches zero. In the present experiments the saturation level is not reached, a different mechanism with a larger current taking over at large voltages. This new mechanism is discussed below.

Low-voltage characteristic for $pO_2 << pH_2O$.—At lower oxygen pressures and in an incompletely dried gas where $pO_2 < pH_2O$, oxygen atoms are present mainly in the form of water molecules, and the O atoms in the platinum will be mainly formed from these. The successive steps of the entire cathodic process are then

$$H_2O(g) \to H_2O(g/Pt) \quad [37]$$

$$H_2O(g/Pt) \rightleftarrows H_2O(Pt/g) \quad [38]$$

$$H_2O(Pt/g) \rightleftarrows O(Pt/g) + H_2\uparrow \quad [39]$$

followed by [17]-[19]. The fact that the voltage dependence of the current is similar to that in the O_2 governed case and different from the dependence shown in Fig. 9 suggests that we are again dealing with a diffusion controlled process. If it is assumed that [17] is again the rate-limiting step, then the concentration of O(Pt/g) depends on the activity of H_2O and H_2 through [38] and [39] and the current may be represented by

$$I_l = 2\mathbf{F}S_L \frac{D}{\partial} K_2 \left[\frac{pH_2O}{pH_2}(g) - \frac{pH_2O}{pH_2}(c)\right] \quad [40]$$

K_2 being the equilibrium constant of [38] and [39] combined. But since $pH_2O/pH_2 = K_{H_2O}pO_2^{1/2}$, this would make I_l again $\propto pO_2^{1/2}$, whereas a much weaker dependence was observed (see Fig. 7). Thus [17] cannot be the rate-limiting step. The observed behavior is found if diffusion across a boundary layer in the gas phase, *i.e.*, [37], is the rate-limiting process. This leads to a current

$$I_l = 2\mathbf{F}K_3 \{pH_2O(g) - pH_2O(g/Pt)\} \quad [41]$$

dependent on pH_2O in the gas and pH_2O at the gas-Pt surface, the latter depending on the applied field in a manner similar to that found for $O(Pt/ZrO_2)$ in the oxygen governed case.

The weak pO_2 dependence seen in Fig. 7 is at least qualitatively explained by the way in which pH_2O is linked to pO_2, in that a lowering of pO_2 results from the decomposition of H_2O with the formation of H_2. Thus a decrease of pO_2 is tied to a decrease of pH_2O and increase of pH_2. But whereas pO_2 is determined by pH_2O/pH_2, the rate of [37] depends on pH_2O alone, and the latter may vary only slightly while the former varies considerably. However, a quantitative fit on the basis of this model with $(K_{H_2O})_{560°C} = 7.6 \times 10^{12}$ atm$^{1/2}$ is not obtained, and further experiments with well-defined buffer mixtures are required to clarify the mechanism operating in this range.

High-voltage section of the characteristic.—At voltages above 2V a new mechanism becomes operative. It might be assumed that the change in mechanism is due to a change from ionic conduction, dominant at low voltages, to electronic conduction at high voltages. This, however, cannot be the case. The electronic conductivity σ_e and the concentration of free electrons [e'] in calcia stabilized zirconia vary with the oxygen pressure as (2, 6)

$$\sigma_e \propto [e'] \propto pO_2^{-1/4} \quad [42]$$

whereas the high-voltage conductivity $(\partial I/\partial V)_H$ is practically independent of pO_2. Thus apparently the current remains largely ionic. This conclusion is also supported by the fact that the dynamic resistance, $(\partial V/\partial I)_H$, shown in Fig. 5 and 6, has a value of 5-8 x 10^4 ohms which is close to the value 1.16 x 10^5 ohms calculated on the basis of the published ionic conductivity (3) and the dimensions of the cell, assuming the cathode electrode to be active over its whole surface. The following mechanism is proposed.

As shown in Fig. 10, the chemical potential of oxygen at the cathode surface of the ZrO_2 (point c) is lower than that of the gas ambient. This is the result of the slow process at the interface and represents polarization. Although a certain amount of polarization takes place at all voltages, its extent increases with applied voltage. Increasing the strength of polarization results in a lowering of μO_2 at point c. Since the concentration of electronic defects is related to pO_2 by [42], types of oxygen vacancies different from the ones present under normal conditions can be formed

$$V_O^{\cdot\cdot} + e^- \rightleftarrows V_O^{\cdot} \quad [43]$$

$$V_O^{\cdot} + e^- \rightleftarrows V_O^{x} \quad [44]$$

where $V_O^{\cdot}$ and V_O^{x} are oxygen ion vacancies with one and two trapped electrons respectively. Once V_O^{x} vacancies are present, it is possible for the oxygen adsorbed at the surface of the ZrO_2 to enter the lattice directly by the reaction

$$O(ZrO_2/g) + V_O^x \rightarrow O_O^x \quad [45]$$

The O_O^x can then pass to the anode.

This model relies on having V_O^x close to the ZrO_2-gas interface. Since the polarization occurs at the platinum cathode, the V_O^x occurs initially at that point and diffuses away with longer times of polarization as shown in Fig. 14. As a result of the sideways diffusion of the F-centers (V_O^x), path a in Fig. 14, the free ZrO_2 surface next to the platinum becomes electronically conductive and becomes available to the adsorbed oxygen for the reaction of Eq. [45].

The spreading of an area with increased, probably electronic, conductivity has been observed by Kleitz (13). Also, inspection of samples used in the present work revealed F-centers (a purple coloration) over the entire contact area if the samples were subjected to voltages >6V. The high voltage characteristic is time dependent, with current increasing with time; this is predicted by the model (*i*) because F-centers diffuse into the zirconia away from the interface (path b in Fig. 14) causing some electronic conduction in the bulk (this is the effect that was minimized in the design of the experiments; section on Experimental set-up), and (*ii*) because the sideways diffusion increases the surface area that can take part in the O transport of Eq. [45] (the distance vT in Fig. 14 increases with time). In the present experiments the maximum sideways diffusion path length is of the order of the radius of the platinum particles, *i.e.*, small relative to the thickness of the sample. Therefore, a state is very quickly reached where the entire free surface is active. From then on the only time dependence is due to process (*i*).

Once the entire free surface area is available for reaction [45], the sequence of processes involved in the incorporation of oxygen is (Fig. 15)

$$\tfrac{1}{2}O_2(g) \rightleftarrows \tfrac{1}{2}O_2(ZrO_2/g) \quad [46a]$$

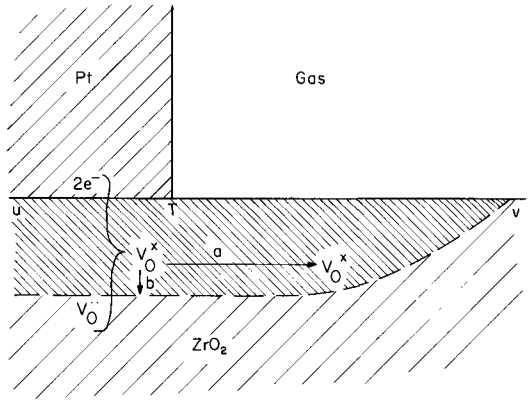

Fig. 14. Diffusion of F-centers away from the platinum electrode region into the zirconia.

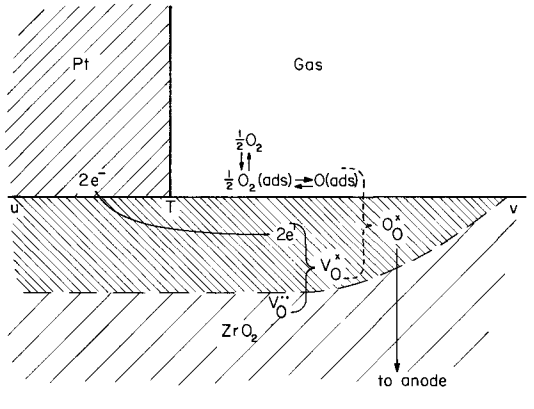

Fig. 15. Reaction steps for the high-voltage mechanism. The dashed lines indicate the rate-controlling step.

$$\tfrac{1}{2}O_2(ZrO_2/g) \rightarrow O(ZrO_2/g) \quad [46b]$$

$$2e^-(Pt) \rightarrow 2e'(ZrO_2) \quad [47a]$$

$$2e'(ZrO_2) + V_O^{\cdot\cdot} \rightarrow V_O^x \quad [47b]$$

together with reaction [45]. The rate-controlling step in this sequence can be determined in much the same way as for the low voltage case. Experimentally, the high voltage characteristic is voltage dependent but not oxygen pressure dependent. Since [46a] and [46b] and [47a] are oxygen pressure dependent, and [47b] is voltage independent, the indication is that [45] is the rate-controlling step.

The oxygen pressure independence of reaction [45] may be shown as follows. The number of neutral oxygen atoms adsorbed on the zirconia surface is

$$O(ads)_H = K_4 S_H p{O_2}^{1/2}(g) \quad [48]$$

where K_4 is the equilibrium constant of [46a] and [46b] combined, and S_H is the effective surface area for the mechanism. The concentration of V_O^x vacancies is given by [43], [44], with equilibrium constants K_5, K_6, and [42]

$$[V_O^x(c)] = K_5 K_6 [V_O^{\cdot\cdot}] p{O_2}^{-1/2}(c) \quad [49]$$

The current generated by the high voltage mechanism with [45] as the rate-limiting step is equivalent to the number of O_O^x lattice ions formed per second

$$I_H = 2F\frac{dO_O^x}{dt} = 2F A S_H [V_O^x] O(ads) \quad [50]$$

where A is the rate constant for reaction [45]. Using [48] and [49]

$$I_H = C\,[pO_2(g)/pO_2(c)]^{1/2} \quad [51]$$

with $C = 2F A K_4 K_5 K_6 S_H [V_O^{\cdot\cdot}]$. Or using [23]

$$I_H = C \exp\frac{2F}{RT} E_{a-c} \quad [52]$$

From [22] and [52]

$$V = I_H R_b + \frac{RT}{2F} \ln (I_H/C) \quad [53]$$

and

$$\frac{\partial V}{\partial I_H} = R_b + \frac{RT}{2F} I_H^{-1} \quad [54]$$

These expressions do not contain pO_2 and thus give the required independence from oxygen pressure. They also represent a voltage dependent current as required. The dynamic resistance [54] approaches R_b with increasing current, *i.e.*, at large voltages, as is observed (Fig. 5 and 6).

Since the bulk resistivity of the electrolyte, ρ_b, is independent of voltage, the bulk resistance applicable to the low voltage mechanism is

$$R_{b,L} = \rho_b \frac{y}{S_L}$$

and the bulk resistance applicable to the high voltage mechanism is

$$R_{b,H} = \rho_b \frac{y}{S_H}$$

where y is the sample thickness, and S_L, S_H are the active contact areas appropriate to the two mechanisms. From above, $R_{b,L} = 5 \times 10^5$ ohms, and from Fig. 5 and 6, $R_{b,H} \approx 2 \times 10^5$ ohms. Thus, as an approximate figure

$$\frac{S_H}{S_L} \approx 2.5$$

or in other words, the platinum crystals physically cover about 30% of the zirconia surface "covered" by the paste.

Transition from the low- to the high-voltage mechanism.—Although we have spoken about low-voltage and a high-voltage mechanism with a transition at $\approx$ 2V, in reality both mechanisms occur at all voltages: only the ratio in which they contribute varies. The total ionic current is the sum of the current generated by the two mechanisms, *i.e.*, that from the low voltage mechanism, I_L, and that from the high voltage mechanism, I_H. Then

$$I = I_L + I_H \qquad [55]$$

I_L in turn involves two types of oxygen atom source, one at high oxygen pressures, I_h, and one at low oxygen pressures, I_l. These are given by [31] and [41]. Then

$$I_L = I_h + I_l \qquad [56]$$

Consequences of the proposed models.—The models proposed here have been developed on the basis of experiments on moderately sintered Pt-paste contacts. They are sufficiently general, however, to be applied to other types of contacts and contact configurations, *e.g.*, Pt, Au, and Ag point contacts as used by Kleitz (13), evaporated or sputtered Pt contacts as used by Heyne (9) and Karapachev *et al.* (18). The oxygen dominated low-voltage regime was found to depend on diffusion of O through the platinum and was characterized by a diffusion coefficient D and an effective thickness ∂. As shown in [32]-[34], the resistance is greater than the bulk electrolyte resistance and is proportional to ∂ as long as ∂ is not too small; a decrease of ∂ will decrease the resistance until a constant resistance R_b is reached. For large ∂, the resistance is quasi-ohmic but polarization occurs; for small ∂, the resistance is truly ohmic, and no polarization occurs. The conclusions only hold if other rate-limiting steps are avoided.

Absence of polarization with thin sputtered Pt cathodes and the occurrence of polarization with thicker Pt layers was actually observed by Heyne (9). An increase of the current, attributable to a decrease of the effective diffusion path, was observed by Karapachev *et al.* (18) in experiments in which they made scratches in evaporated Pt layers, thus creating 3-phase boundaries with small effective ∂. In terms of Fig. 13, the unscratched layer corresponds to $\partial \approx$ pp', while the scratched one reduces ∂ to the average of pp'-tt'. An almost ohmic characteristic was also found by Yuan *et al.* (11) who used a thinly spread paste cathode in pumping experiments.

An investigation of the electrode characteristics in the O_2 dominated low-voltage range should show a material dependence through the solubility of O and its diffusion constant. This may account for the differences observed between Pt, Au, and Ag point contacts (13). The high-voltage mechanism was based on the utilization of free ZrO_2 surface. Therefore, a cathode geometry which reduces the free surface area (*e.g.*, evaporated or sputtered platinum) should suppress the current based on this mechanism and may make an increase in current due to electronic conduction (characterized by a $pO_2^{-1/4}$ dependence) observable.

A transition from a low- to a high-voltage mechanism has been observed by others, *e.g.*, Kleitz (13) and Guillou *et al.* (15). These authors used point contacts and therefore must have observed ionic effects of the type discussed here. Experiments with porous cathodes as employed in the present investigation but with zirconia doped with donors (5) should show a high-voltage mechanism as discussed in the present paper, but setting in at a lower voltage. The discussion given so far applies to densely sintered zirconia. With porous zirconia other models become possible in which oxygen may reach the Pt/ZrO_2 interface by diffusion as O_2 through the pores in the zirconia. This as the rate limiting step would lead to a current $\propto pO_2$.

Determination of transference numbers by polarization techniques.—It is interesting to consider in the light of the results presented in this paper, the use of polarization experiments to determine the extent of electronic conduction in stabilized zirconia. In the technique of Vest and Tallan (4), the time dependence of the voltage needed to drive a constant current across the sample is measured, and the electronic transport number obtained from the relation

$$t_e = \frac{E(0)}{E(\infty)} \qquad [57]$$

where $E(0)$ is the voltage at time = 0, and $E(\infty)$ is that at time = ∞. This relation is as pointed out, valid only when the electrodes are blocking to the passage of oxygen. With the electrodes used in the present paper, blocking behavior was not observed, and values of t_e deduced from the time effects would not be correct; that Vest and Tallan were able to observe isolated electronic conduction may well be due to their use of "fluxed" platinum paste electrodes, *i.e.*, electrodes with a glass additive used to improve adhesion. The presence of the glass would seem to improve the blocking effect of the electrode, presumably by sealing gas permeation channels and thus increasing ∂ in Eq. [25]; at any rate the different behavior with at first sight similar (both Pt) electrodes, emphasizes the need to consider the details of electrode structure when interpreting observations of electrical behavior in largely ionic conductors.

Summary

The direct current-voltage characteristics of cells Pt, O_2/(Zr, Ca) O_2/Pt, O_2 with the same oxygen pressures at both sides were measured at 560°C under oxygen pressures ranging from 1 to 10^{-20} atm. The characteristics were markedly nonohmic and showed two distinct regions. One, at voltages <2V shows an oxygen pressure dependence, the conductance varying as $pO_2^{1/2}$ as long as O_2 is the major O-containing species; a weaker pO_2 dependence is found if H_2O is the main O-containing species. The rate-determining step for the O_2 case is the diffusion of O atoms through the platinum of the electrode. The high-voltage region shows practically no pO_2 dependence. Here the rate-limiting step is the combination of O atoms adsorbed at the ZrO_2 gas interface with V_O^x formed as a result of polarization.

The importance of the electrode material and the electrode geometry is stressed.

Electrodeless Electrolysis

Abner Brenner* and John L. Sligh, Jr.*

National Bureau of Standards, Washington, D. C.

ABSTRACT

Solid ionic conductors and fused salts were electrolyzed without contact of solid electrical leads. The current was carried to the materials to be electrolyzed either by means of electrons emitted by a hot filament or by a glow discharge. The materials were made the separating wall between the anode and cathode compartments of an apparatus constructed of glass or fused silica. Electrolysis of glass produced a white opaque material which did not seem to differ chemically from the original glass. Dendrites of several metals were obtained in the glow discharge electrolysis of fused salts. The results of the latter process resembled conventional electrolysis with metal electrodes and was not similar to the glow discharge electrolysis of aqueous electrolytes.

In electrodeposition or electrolysis as ordinarily practiced, the electrodes are metals or graphite, and the products of electrolysis form at the interface between the electrode and the electrolyte. Most of the data of electrolysis have been obtained with the use of such electrodes, and their characteristics have entered into the theories. Thus, the cathode provides a pathway by means of which electrons can flow to the electrolyte-cathode interface. However, the electric current is conducted by other kinds of systems, such as the electron beam and rarified gases; and the question arises as to whether electrochemical reaction will occur with such systems in contact with an electrolyte.

The purpose of this investigation was to call attention to prior work that showed that electrolysis could be accomplished without the use of conventional electrodes and to explore further the variety of unconventional ways in which electrolysis could be accomplished.

Electrolysis in the absence of the conventional electrode-electrolyte interface will in this paper be called, for brevity, "electrodeless electrolysis," although it is recognized that the electron beam, rarified gas, or other conducting phase in contact with the electrolyte is performing the function of the conventional electrode.

The subject of electrodeless electrolysis has not previously been unified in the literature as a single topic or branch of electrochemistry. For that reason the introductory part of this paper has been amplified beyond the customary scope of an introduction, so as to present a survey of the field. We define electrodeless electrolysis as the occurrence of an electrochemical reaction, such as those resulting in deposition of metal or evolution of gas, at locations in the system which are remote from the metallic conductors which bring the current to the system. Electrodeless electrolysis has been observed in a variety of experiments, and the nature and, hence, the explanation of the phenomena, are not necessarily the same for all. Probably the first example of electrodeless electrolysis was that reported by Grotthuss (1) in 1819 who passed a current through a crack in a glass vessel which was wet on both sides by a silver nitrate solution. Silver separated out in the vicinity of the crack. The phenomena was studied in detail by Braun (2) in 1891 who gave it the name electrostenolysis. Metal deposition or evidence of a chemical reaction also was observed by a number of electrochemists at an organic membrane, such as a pig bladder or at an inorganic membrane, such as copper ferrocyanide, on the passage of current through systems consisting of a membrane separating solutions of heavy metal salts:

Anode/salt solution//membrane//salt solution/cathode

Electrostenolysis differed from deposition at membranes in that the former required 20V or more, whereas the latter process occurred with the low voltages used in ordinary electrodeposition. The subject of the electrolytic processes at membranes has been capably reviewed and discussed by Söllner (3) and, thus, there is no need for further treatment here.

Electrodeless electrolysis of an entirely different kind occurred with the glow discharge above an aqueous solution. The phenomenon was first reported by Gubkin in 1887 (4). In an evacuated vessel containing an electrolyte (and water vapor) he passed a current between an electrode suspended in the vapor and an electrode situated beneath the surface of the electrolyte. A potential of several hundred volts was required. This phenomena was studied in some detail by several workers some 50 or 60 years later [(5), no attempt is made here to give a complete bibliography of glow discharge electrolysis].

Glow discharge electrolysis is very different from conventional electrolysis. Either reduction (for example, of permanganate ion) or oxidation (for example, of ferrous ion) can occur and the yield may be several times greater than that expected from Faraday's law. Furthermore, in some experiments it makes little difference whether the anode or cathode is placed in the electrolyte (5b) (the other electrode being in the space above the electrolyte) or whether direct or alternating current is used. The separation of metal was reported in two instances (5a, 5c), but this seems to be a rare occurrence and the observations are open to question. One explanation of the glow discharge electrolysis is that water vapor is decomposed in the

* Electrochemical Society Active Member.

Key words: electrolysis, electrodeless electrolysis, glow discharge, electrolysis of fused salts, electrolysis of glass, electron beam electrolysis.

discharge into free radicals which then react with the dissolved salt.

Although the term "glow discharge electrolysis" has been used almost invariably in the literature as the name of the phenomena described in the preceding paragraph, it is unlikely that the phenomena involve the mechanism of conventional electrolysis. Hence, the use of the word "electrolysis" in connection with the action of the glow discharge of aqueous solutions is a little unfortunate.

Couch and Brenner (6a) observed a green corona above a copper solution and a blue corona above an indium solution with the glow discharge. Sastry (6b) observed similarly colored corona with some other salt solutions but not with fused salts. He concluded that the presence of water was necessary and that the decomposition of water vapor into free radicals in the cathode fall was involved in the mechanism.

A very different type of electrodeless electrolysis was described by Burt in 1925 (7a, 7b) and by Selenyi (7c) in 1927. They placed an ordinary (evacuated type) light bulb in a bath of fused sodium nitrate in which a wire was placed and served as anode. The filament of the lamp was made incandescent by passage of an a-c current. Then a d-c potential was placed between the wire serving as anode in the sodium nitrate and the filament, which was made negative. Current passed through the glass bulb and pure sodium collected on the upper cool walls of the interior of the bulb. The yield was exactly in accordance with Faraday's law. The explanation of the phenomena was that sodium ions migrated through the bulb from the sodium nitrate and were discharged on the inner surface of the bulb by the stream of electrons from the hot filament.

We have extended electron beam electrolysis to materials other than glass; this work is described in a subsequent section. The fused salt bath, which presumably served as a source of sodium ions, we found not to be an essential part of the experiment, as electrolysis could be performed with the bulb immersed in distilled water instead of fused sodium nitrate or with the electrical contact established through copper, plated on the outside of the bulb. Thus, the glass was actually electrolyzed to yield sodium.

The systems described in the previous examples of electrodeless electrolysis all possessed a sharp discontinuity between an electrolyte and another phase, for example, between a membrane and an electrolyte or between a gaseous phase and an electrolyte. Milicka (8) described an unusual example of electrodeless electrolysis in which both phases were aqueous. In a U-tube a concentrated solution of potassium iodide was placed and above it, in one limb, distilled water was placed. Current was passed through the liquids in the U-tube, and iodine was observed to separate out at the interface between the two liquids. Substitution of copper sulfate for the iodide resulted in the deposition of copper or copper hydroxide at the interface. Milicka stated that these experiments were well known to the earlier electrochemists, but gave no reference.

Since nothing in the current theories of electrolysis would lead one to expect electrolysis to occur at the boundary of two aqueous liquids, we attempted to verify the report. In our experiment the amount of iodine was very slight, and it was necessary to introduce starch into the liquids to make its presence visible. A blue color did occur on passing a current of 50 mA at about 1000V through the column. It appeared to form chiefly next to the wall of the glass tube. It is likely that the phenomenon is not as simple as it seems, and the presence of the glass wall may be essential to the electrolysis.

The most recent example of electrodeless electrolysis was described by Palit (9) in 1968. He observed that gas collected in a salt bridge which was used to connect a vessel of catholyte to a vessel of anolyte. The gas began to appear after about 6 hr of electrolysis, and the composition of the gas ranged from 60% to 90% oxygen. The formation of the gas was attributed to the production of charged water molecules which migrated away from the electrodes and reacted with either hydroxyl or hydrogen ions.

Our experiments on electrodeless electrolysis which are described below deal mainly with the electrolysis of solid materials and fused salts. Aqueous solutions were not involved. The phase contacting the material to be electrolyzed was a partial vacuum ranging from about 1.0 to 10^{-5} Torr/(133 to 0.00133 N/m^2). It will be noted that in some of these experiments materials have been electrolyzed almost in free space, as the only electrical contact with the specimen was an electron beam and/or a gas at low pressure.

Electron Beam Electrolysis

Apparatus and procedure.—A schematic diagram of the apparatus is shown in Fig. 1. It is taken from U.S. Patent 3,366,562 in which it is fully described. The apparatus consisted of a glass envelope, 10 and 12, which was provided with a large port, 17, for evacuation by an oil diffusion pump, 18, and with vacuum-tight seals, 20, 21, and 28, for introducing the electrical leads, 26 and 30. The tungsten filament, 25, was heated by alternating current and could carry up to 17A. The specimen to be electrolyzed took a number of forms, but for some of the work it was a solid, cast around the end of the anode lead and was placed in the top of the holder shaped like a long stem funnel. The latter was made from fused silica or mullite. The stem of the holder protruded through a vacuum-tight seal to the outside and served both as a conduit for the positive lead and to prevent short circuiting of the latter by the electron beam. The voltage for electrolysis was applied between the tungsten filament, 25, and the positive lead, 30. The pressure in the vessel was about 10^{-5} Torr.

The solid materials which were electrolyzed had to be heated to attain a conductivity sufficient for electrolysis. For example, glass required about 400°C and selected ceramics still higher temperatures. In some experiments the tungsten filament was placed only a centimeter or two distant from the electrolyte, and the heat from the filament was sufficient to raise the temperature of the electrolyte to a point that it became conducting. However, this was not adequate for

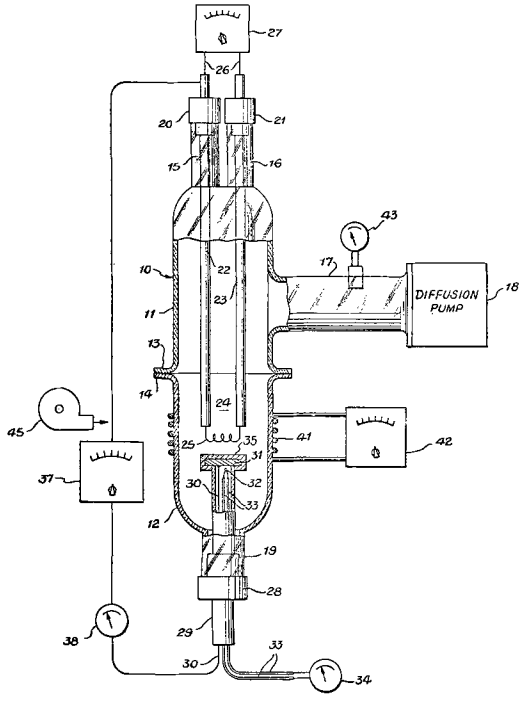

Fig. 1. Diagram of apparatus for electron beam electrolysis. Figure taken from U.S. Pat. No. 3,366,562. The numbers refer to the description in the patent.

some materials, and it was necessary to use a noninductively wound resistance heater which was placed inside of the glass envelope around the solid electrolyte. Heating by induction with a metal susceptor placed around the electrolyte was not successful, as the magnetic field of the induction coil apparently dispersed the stream of electrons and no current could be made to pass through the system.

In a typical experiment the apparatus was pumped down to 10^{-5} Torr and as a check on the system the high voltage, 1000-1500V d.c., was applied between filament and the positive lead with the resistance heater off. The absence of current flow was evidence that there was no electrical leakage. The heating element was next energized to make the solid conductive. As the latter became hot, current began to flow. Usually the current was held below 50 mA as a higher current (and a higher voltage) occasionally caused perforation of the specimen, in which case all the current flowed through the pore and electrolysis ceased.

The main difficulty with electron beam electrolysis was establishing a good electrical connection between the anode lead and the solid electrolyte. A solid metallic connection was unsatisfactory. A number of methods were evaluated using glass as a representative solid electrolyte. In the electrolysis of glass it was well known before 1900 that solid contacts were unsatisfactory, but that molten salts or sodium amalgam could be used. Markin (10) showed that the difficulty with solid electrodes was that the contact that it made with a solid electrolyte occurred only at isolated points and resulted in a very high local current density. This caused either arcing through or the formation of dendrites, which soon extended through the solid and shorted the electrodes.

In Burts' light bulb experiment the anode lead to the glass was a fused salt. However, this is not generally applicable, because so few materials are readily obtainable in the form of a bulb. We, therefore, gave up the attempts to find a suitable solid positive contact and turned to conduction through a rarified gas to establish the electrical contact with the electrolyte. This subject is treated in a later section of this paper.

Materials for electrolysis.—Preparation of a solid electrolyte in a shape suitable for electrodeless electrolysis, whether by electron beam or by the glow discharge method, was a difficulty that we did not completely overcome. In these methods of electrolysis high voltages had to be used because even the heated solid materials were not very conductive. Consequently, the slightest pore which traversed a solid electrolyte allowed the circuit to be completed without passage of current through the electrolyte. Solid electrolytes made by fusing a salt and allowing it to solidify all seemed to have cracks. Very slow cooling, particularly in a metal container made of foil, helped to eliminate some of the stresses arising from contraction on cooling. However, to obtain a sound disk of a salt, it seemed that cutting a slice from a single crystal was the only solution. The solid materials which could be obtained readily for electrolysis, therefore, were silver chloride, which is plastic at room temperature, glass, ceramic materials commercially available in the form of plates or impervious tubes closed at one end, and single crystals.

Results of experiments with electron beam electrolysis.—In our apparatus the "light bulb" experiment of Burt was easily carried out as follows. A glass test tube filled with an easily fusible salt mixture was placed near the tungsten filament. The open end of the tube extended through a vacuum-tight seal to the outside. The positive lead was inside of the test tube. Under these circumstances the outside wall of the glass tube was exposed to the electron beam and readily electrolyzed. The sodium could not be collected because it was spread as a mist or film over the extensive inner surface of the chamber. However, the film was dissolved in water and titrated. The alkalinity corresponded to over 90% of the amount of sodium predicted by Faraday's law.

A similar experiment with a mullite tube resulted in the formation of a dark layer on the outside of the tube, but the nature of the transformation was not investigated.

In other experiments the arrangement shown in Fig. 1 was used, which involved direct contact of the materials with the positive metallic lead. Copper and nickel dendrites were obtained from their chlorides which had been melted with potassium chloride and cooled. Silver dendrites were obtained from solid silver chloride. The deposition occurred on the surface facing the heated filament, and dendrites extended into the body of the solid. Here is a clear instance of an electron beam acting as a cathode exactly as would be expected of a metal or any other electronically conducting cathode, *i.e.*, the dendrites formed at the cathode-electrolyte interface and grew into the electrolyte.

In one experiment solid sodium tetraborate was electrolyzed, but the heat of the filament and the IR drop caused the salt to melt, and consequently the experiment was actually electrolysis of the fused salt. At the conclusion of the experiment a lump of transparent boric oxide was found on top of the melt; the sodium liberated by the electrolysis had volatilized. Materials which normally did not electrolyze, also did not undergo electrolysis with the electron beam. For example, molybdenum disulfide, which is an electronic conductor, did not undergo any observable change in the electron beam experiment.

Glow Discharge Electrolysis of Solid Electrolytes

Development of process, apparatus, and procedure.—The difficulty of obtaining a satisfactory electrical contact of the positive lead to the solid electrolyte in electron beam electrolysis led to the investigation of glow discharge electrolysis. The first experiment was a hybrid type of electrolysis—a modification of the one with a glass tube described earlier. In that experiment the outside surface of the tube was exposed to the electron beam for electrolysis; the inside contained a molten salt for making a good electrical connection to the positive lead wire. In the modified experiment with glow discharge the fused salt was not used. Instead, the interior of the tube was evacuated to a low pressure at which a good glow discharge occurred. The path of the current thus went from the positive lead through the rarified gas to the inside wall of the glass tube, and finally through the wall to the electron beam. Satisfactory operation of the glow discharge as a positive lead to the solid electrolyte suggested using the glow discharge also on the outside wall of the glass tube to carry the current instead of the electron beam. Thus, in essence, a body would be electrolyzed without any palpable contact with metallic electrical connections.

The first experiment in which the glow discharge was used to make electrical contact to both sides of a glass wall was performed with simple equipment. A 96% silica glass[1] tube about 5 cm in diameter and 75 cm in length served as one electrode chamber. At one end of the tube was a connection to a vacuum pump and a graphite electrode which passed through a vacuum-tight seal. The other electrode chamber was simply a long glass test tube about 2.5 cm in diameter which extended into the larger tube through a vacuum-tight seal. This smaller tube likewise was provided with a graphite electrode and a vacuum connection. The central part of the apparatus was heated by a tube furnace to 400°-500°C. On placing a potential of about 1400V across the two graphite electrodes (both vessels being evacuated to between 0.1 and 1.0 Torr) a glow discharge occurred and a current of about 40 mA flowed. The path of the current was from one graphite electrode, through the rarified gas,

[1] Vycor, Registered TM, Corning Glass Works.

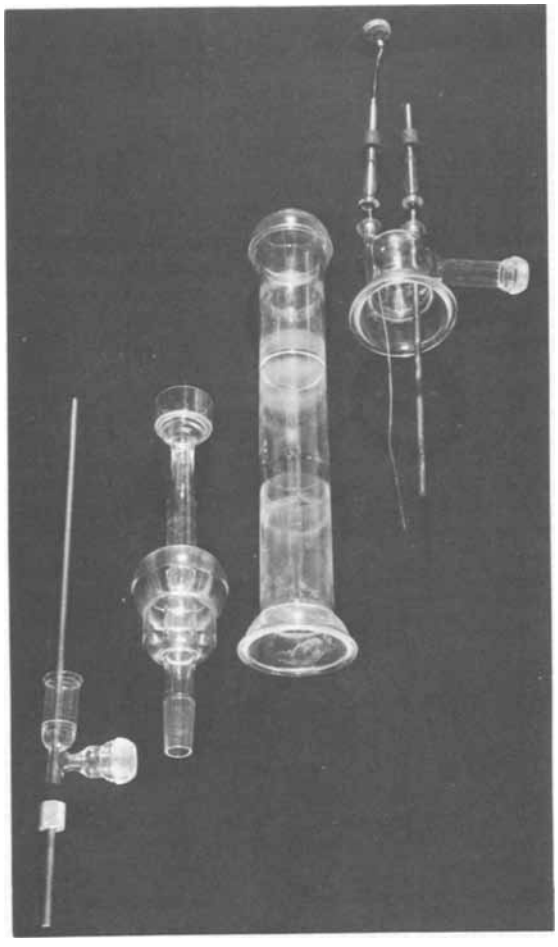

Fig. 2. Disassembled apparatus for glow discharge electrolysis

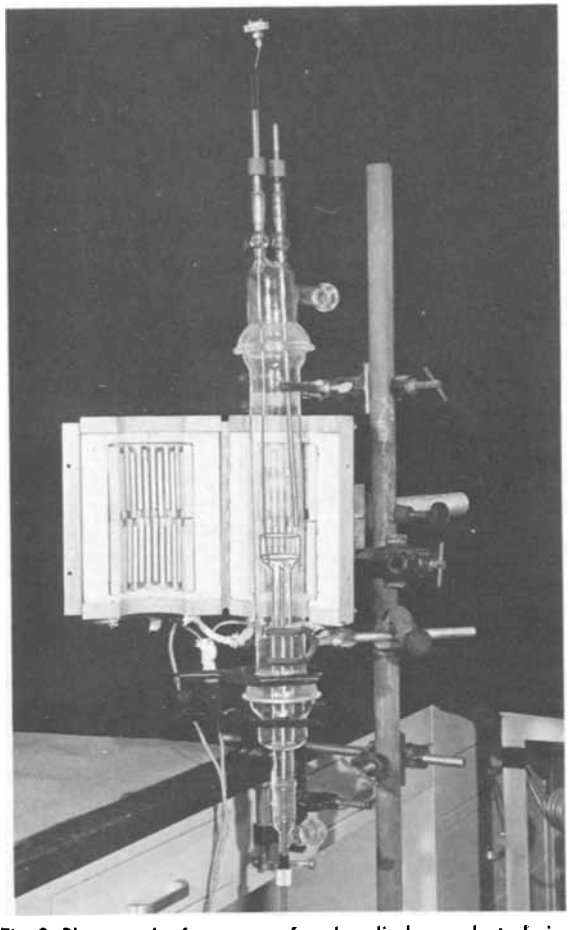

Fig. 3. Photograph of apparatus for glow discharge electrolysis

through the glass wall and through rarified gas on the other side to the other graphite electrode. The appearance of the glass after electrolysis was similar to that of the tube electrolyzed by the hybrid glow discharge-electron beam procedure described in the preceding paragraph.

The next step in the development of the apparatus was to provide for the electrolysis of solid materials in the form of a slab or disk because, as already mentioned, we had difficulty in obtaining materials in the form of a thin-walled tube (1-3 mm thick). The apparatus which was designed is shown disassembled in Fig. 2 and assembled in Fig. 3. It was essentially a modification of the electron beam apparatus with the filament and the positive lead replaced by a graphite rod.

The main envelope was again a silica glass tube about 6 cm in diameter with spherical joints at each end. The glass fixture which was attached to the upper end of the envelope carried a side tube for attachment to an ordinary vacuum pump (a high vacuum was not necessary) and two tubulations which were provided with vacuum-tight seals. One tubulation carried a graphite rod (6 mm in diameter) which served as an electrode and the other carried a sheathed thermocouple, about 1.5 mm in diameter. The glass fixture attached to the lower end of the envelope also was provided with a side tube for connection to a vacuum pump and a vacuum-tight seal for a graphite electrode.

The part of the apparatus which needs further elaboration is the funnel shaped part which projected upward to about the middle of the main chamber. It is shown schematically in Fig. 4. It was made of fused silica, and it was integral with the lower fixture, just described. It may be noted that, by closing the mouth of the funnel with a disk, the apparatus became divided into two chambers, the large outer

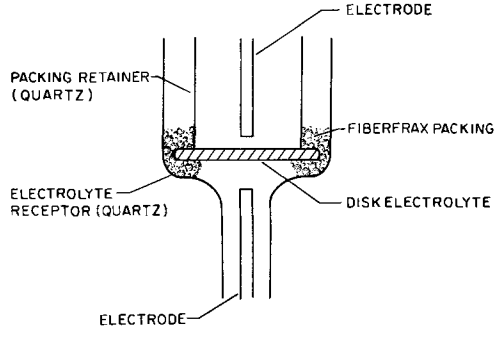

Fig. 4. Diagram of funnel shaped holder of electrolyte in glow discharge electrolysis.

chamber and the smaller chamber consisting of the fused silica funnel.

As with electron beam electrolysis, one of the most significant problems was to prevent short circuiting by flow of current between the edges of the disk and the mouth of the funnel. The key to the solution of the problem was the observation that the glow discharge would not penetrate through a tortuous path, even though it was porous enough for gas to flow through. For example, powdered magnesium oxide (which is a good insulator even at elevated temperatures) packed in a tube so as to make a compact about 1 cm thick prevented the glow discharge. A fibrous mineral material[2] was also satisfactory and easier to use. To prevent leakage around the disk of solid electrolyte, which was inserted into the mouth of the funnel, the fibrous mineral was packed underneath the outer perimeter of the disk and around its sides so as to fill the space between the disk and the funnel wall. To still further increase the length of the tortuous path, a fused silica cylinder was placed on the sur-

[2] Fiberfrax, Registered TM, Carborundum Company.

face of the disk and fibrous mineral packed around it, as shown in the diagram, Fig. 4. This arrangement prevented current from leaking, even up to an applied potential of 6000V.

The packing was useful also for preventing electrical leakage between the electrodes via the tubing connected to the vacuum pump. The vacuum connections at the top and bottom of the apparatus were connected to a T-joint which led to the vacuum pump. In some instances the discharge took the path of going from one side tube, through the rubber tubing and the T-connection to the other side tube, thus, effectively short-circuiting the flow of current through the disk. This short-circuiting was prevented by packing fibrous material lightly in the tubing between the T-joint and the apparatus. The glow discharge was thereby discouraged from traversing this path.

In the first experiments the residual air sustained the glow discharge. Replacement of the residual air by argon (at low pressure) was found necessary in the electrolysis of silver chloride, because otherwise the silver formed was oxidized to silver oxide. In most experiments, therefore, argon was introduced through a tube which ended in the vicinity of the disk. The flow of gas was controlled simply by manipulating a screw clamp on the rubber tubing and observing the bubbling of the gas as it flowed through oil in a U-tube. Argon gave a glow discharge over a wider range of pressure than air, namely, between 0.05 and 8 Torr at a voltage between 1000 and 3000.

In comparison with electron beam electrolysis, the glow discharge experiments were much easier to perform because (*i*) a higher pressure was satisfactory (as much as 1.0 Torr could be used as compared to less than 10^{-4} Torr for the electron beam process), (*ii*) contamination from a filament was eliminated (in the electron beam procedure some tungsten evaporated from the filament); (*iii*) short circuiting between the cathode and anode chambers was minimized.

Usually an electrolysis current of about 25 mA was desired. This required from 1000 to 3000V. Heating of the specimen was necessary to obtain sufficient conductivity for passage of current, and the tube furnace used is shown in Fig. 3. It permitted a temperature of about 800°C to be obtained, but this temperature was inadequate for obtaining conductivity of some ceramics.

The source of voltage in the glow discharge experiments was a commercial instrument which delivered a maximum of 30 kV at 35 mA. During the glow discharge experiments, particularly those in which a gas flowed through the system, regulation of the pressure was necessary. This was accomplished by a commercial electronic instrument which had a thermocouple type of pressure gauge as a sensing device. The instrument automatically turned the vacuum pump on and off so as to keep the pressure between two prescribed limits, for example, between 0.1 and 0.2 Torr.

Results of experiments with solid electrolytes.— Silver chloride was the electrolyte which we used for exploring the variables of operation and the modifications of equipment. Silver chloride is easily melted, gives a sound ingot on solidification, and is plastic, so that it does not develop pores and cracks. In electrolysis, the side facing the negative lead became covered with silver. On long electrolysis (an hour or more) silver dendrites eventually grew through the disk and shorted out the flow of current through the silver chloride. Silver iodide electrolyzed similarly to silver chloride. In a quantitative experiment, we found that the silver chloride disk lost weight about equal to the amount of chlorine that should have been liberated on the basis of Faraday's law. No silver was observed on the anode side unless the experiment was run long enough for the dendrites formed on the cathode side to penetrate completely through the electrolyte. This further demonstrates that the process which occurred was truly an electrolysis between plasma electrodes and not a thermal decomposition. We believe this to be the first reported example of an electrolysis between two gas plasma electrodes.

The most interesting results were obtained with the electrolysis of glass. In an electrolysis performed (as described earlier) with a fused salt bath serving as the anode connection, the glass did not change its appearance, even though sodium was liberated.

In the electrolysis of glass with the glow discharge (or with the glow discharge on one side and the electron beam on the other, as in an earlier section) the side of the glass facing the cathode became dull and developed some blisters, while the side toward the anode developed an opaque white layer which readily flaked off, as shown in Fig. 5. The chemistry of the change was not elucidated, as the opaque material gave an x-ray pattern similar to that of the original glass and the content of silica in the materials seemed to be almost the same as that in the original glass. The dramatic change in the appearance of the glass on electrolysis warrants further investigation.

Thin disks of some titanates, such as barium titanate which were initially light yellow in color became brown or black on electrolysis, the discoloration occurring throughout the thickness of the disk. The disk also became electrically conductive. A similar phenomenon resulted on heating a disk of the titanate to 700°C in an atmosphere of hydrogen.

Several other materials in the form of disks sawed from a single crystal were electrolyzed and, although they changed in appearance, no clear evidence was obtained of the nature of the chemical change. It is thought that in some of these instances, the conductivity of the material was too low at the temperature of the experiment, and that the flow of current may have been through pores or cracks which developed as a result of thermal shock. A single crystal disk of sodium chloride became opaque on the side facing the cathode and a thin white film deposited on the surface of the containing vessel. The film gave an alkaline reaction and probably was derived from vaporized sodium. Similar results were obtained with a disk of potassium bromide. Calcium fluoride did not allow enough current to pass, even at 750°C, to permit an adequate amount of electrolysis for qualitative examination.

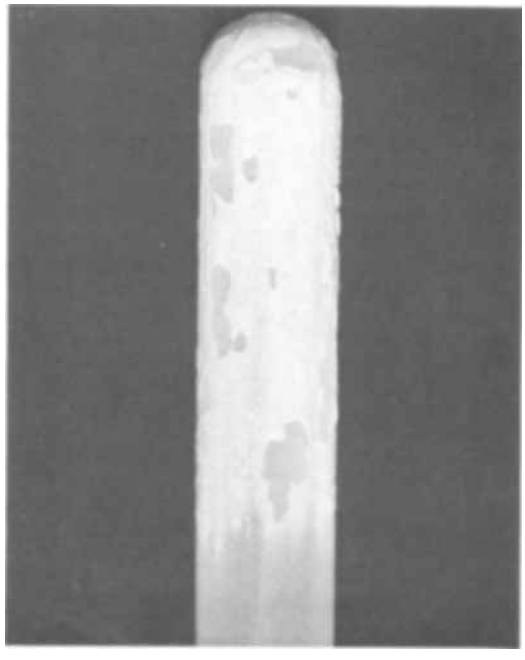

Fig. 5. Glass test tube electrolyzed by the glow discharge method.

Glow Discharge Electrolysis of Fused Salts

Background.—It was pointed out in the introduction and survey that the glow discharge electrolysis of aqueous solutions differed from conventional electrolysis with metal electrodes in that the products were not those usually obtained (metals were seldom reported as having been deposited) and the yields were several times greater than those expected on the basis of Faraday's law. This kind of electrolysis involves complexities in the vapor phase. By contrast the glow discharge electrolysis of fused salts is simpler, resembling conventional electrolysis in products formed and their yields. The fact that the current is conducted to the molten electrolyte by a gas at low pressure instead of metal conductors appears to make no difference in the results, except that reaction or alloying of the product with a metallic electrode can be avoided.

Of the various types of electrodeless electrolysis which have been described, the glow discharge electrolysis of fused salts was the process most easily performed and seems to be the one most likely to have any practicable use.

Apparatus.—The most obvious kind of apparatus to use for the glow discharge electrolysis of fused salts is a U-tube, such as shown in Fig. 6. The tube was made of glass or fused silica. The fused salt, B, was contained in the bend of the U-tube and was separated into two portions by the porous diaphragm, D. The U-tube was constructed with a considerably reduced diameter at the bend, which was occupied by the fused salt (diameter at the bend about 2 mm), so as to restrict the amount of melt electrolyzed to about 1 or 2 ml. This was necessary because the amount of metal formed in electrolysis was small (amounting to 10-50 mg in a typical experiment) and, consequently, was very difficult to recover from a large mass of fused salt. After each experiment, the U-tube was sawed through at the diaphragm in order to separate the cathode and anode compartment and make possible the working up of the salt for the products of electrolysis.

Most of the experiments in fused salt electrolysis were done with the simple apparatus shown in Fig. 7. Since in all of the experiments the main interest was in the metal deposit, the cathode chamber, A, was made small, and it was immersed in a larger amount of fused salt, B. The chamber A was introduced empty into the test tube C at the beginning of an experiment. On lowering the chamber into the melt, the latter entered through the porous disk D. The purpose of the disk was to filter the fused melt which was to be electrolyzed and to prevent loss of products which formed

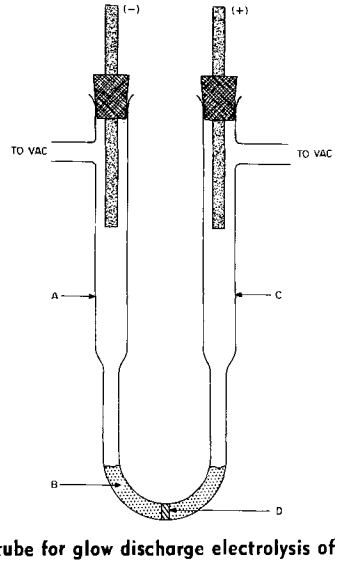

Fig. 6. U-tube for glow discharge electrolysis of fused salts

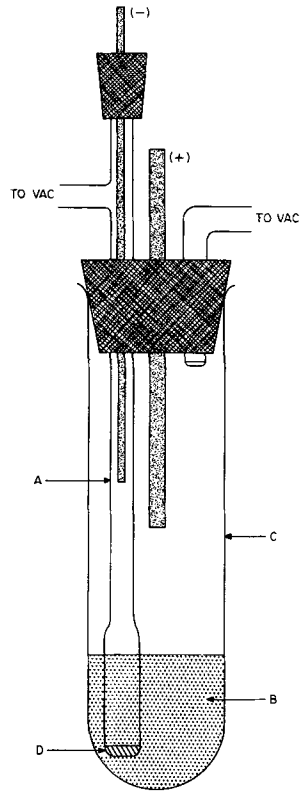

Fig. 7. Apparatus with a test tube envelope for the glow discharge electrolysis of fused salts.

in A during electrolysis. At the conclusion of the electrolysis, the chamber A was removed and the molten salt allowed to drain out. The chamber was then sawed through a short distance above the frit so as to expedite the collection of the product.

In all of the experiments the degree of vacuum was the same as that used for the glow discharge electrolysis of solid electrolytes. Care had to be taken in evacuating the vessel to prevent an inequality in pressure from forcing the melt completely from one chamber into the other.

In these experiments the phenomena in the anode chamber were not investigated and were not of concern, particularly since the diaphragm prevented any products from the anode compartment from entering the cathode compartment. Therefore, in most experiments a metallic anode was used is the anode chamber instead of a glow discharge. However, in at least one experiment, the electrolysis of molten silver chloride, the glow discharge was used in both chambers to demonstrate that solid electrodes were not essential.

Results of experiments with fused salts.—The glow discharge electrolysis of fused cupric chloride in potassium chloride yielded no deposit, probably because the electrolysis resulted only in a reduction of cupric ion to cuprous. The electrolysis of molten cuprous chloride at first also yielded no deposit. However, it was surmised that the presence of a small concentration of cupric ion was responsible for this failure. The molten cuprous chloride (in potassium chloride melt) was then treated with copper powder in the anode compartment prior to the electrolysis and then forced through the porous diaphragm in the cathode compartment. A yield of copper dendrites was obtained in the cathode compartment on electrolysis.

Silver chloride was electrolyzed in the U-tube without difficulty. After electrolysis, the solidified melt was obtained in the form of a rod after breaking away the glass tubing. On compressing the plastic chloride into a thin, transparent sheet, silver dendrites were readily visible, as shown in Fig. 8. The yield was roughly in accord with Faraday's law.

Tin dendrites were obtained from stannous chloride, cobalt dendrites from cobalt chloride, and nickel dendrites from nickel chloride. These products were separated from the solidified melts by dissolving the latter with water.

In the electrolysis of magnesium chloride, small, shining crystals collected in the tube above the level of the melt, thus indicating that the metal had been liberated at the surface of the melt as a vapor and had then subsequently condensed on the cooler portion of the apparatus.

Conclusion

This investigation of electrodeless electrolysis is only of an exploratory nature. The glow discharge electrolysis of ceramics and solid materials warrants further investigation. We suggest that the apparatus be designed to permit the ceramic electrolyte to be heated to much higher temperatures than we used, in order to promote a higher conductivity. If vessels could be constructed of a transparent, high melting material like yttrium oxide (mp 2410°C), the work would be greatly facilitated. Further work is in order to explain the curious change produced in glass on electrolysis.

The high voltages required for electron beam or glow discharge electrolysis militates against their use for any but a highly specialized application. The residual electrical conduction imparted to ceramics by the glow discharge electrolysis might be of some practicable use. The glow discharge electrolysis of fused salts might be of advantage in a situation in which the contamination of the deposit by a metallic cathode could not be permitted.

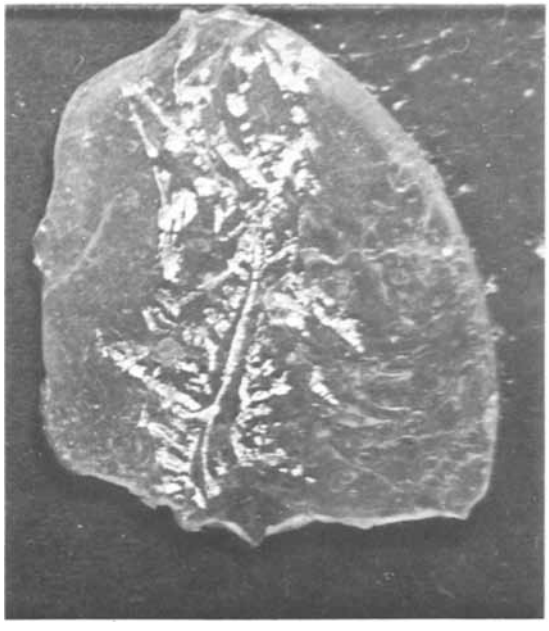

Fig. 8. Dendrites of silver in silver chloride which had been electrolyzed in the fused state.

The main interest in these exploratory experiments in electrodeless electrolysis, however, is in calling for a broader understanding of electrochemical phenomena by calling attention to the wide variety of situations in which chemical changes can be produced by the electric current.

To generalize as to the common denominator underlying all these curious examples of electrolysis, it seems that the presence of a metallic conductor is not it. Rather it seems that the essential factors are (assuming the presence of at least one ionic conductor) that the two materials in contact be different phases (gas, liquid, solid) and /or differ greatly in electrical conductivity.

ABSTRACT

The phenomenon of macro- and microcurrent distribution in plating systems is studied. At high current densities where mass transport of the reacting species is rate controlling, the plating process will yield relatively uniform macro- but nonuniform microcurrent distribution. At low current densities where depletion of the reacting species is negligible, relatively uniform micro- but nonuniform macrocurrent distribution will be observed. The effect of surface roughness and current density on the microcurrent distribution of gold plated from a citrate bath is studied experimentally. The microcurrent distribution is found to improve considerably by reducing the surface roughness and by performing the deposition process at a lower current density. Due to the low gold content of most gold baths, practical gold plating is performed under conditions where mass transport limitations of the reacting species are significant.

The electrodeposition of gold is becoming increasingly important due to its wide applications in electronics equipment. The purpose in plating a thin layer of gold over certain parts of a substrate surface is to protect the parts from corrosion, reduce the electrical contact resistance, or provide a conducting path between devices. More uniform deposition both on a macro- and microscale and deposits with lower porosity and better mechanical properties are the goals pursued by the modern plating industry.

In this paper, the current distribution of a gold plating system is considered. The theoretical aspects of macro- and microcurrent distributions concerning systems involving only one electrochemical reaction are first examined. The conclusions from these considerations can be applied to many practical plating systems. Experimental observations on the microcurrent distribution of gold plated from a citrate gold bath are then reported.

Phenomenological Description of Macro- and Microcurrent Distribution

A typical linear dimension for a microprofile on a surface is in the order of 50μ whereas the linear dimension for a macroprofile is about 1000μ or larger. Transition between micro- and macrodimensions occurs between these limits. These definitions are somewhat arbitrary. The dimension of micro- *vs.* macroprofiles suggested here falls in the range used by most electroplaters. A rigorous definition can be established from the concept of the diffusion layer thickness. This will be treated in a later section.

Many investigators have found that a fundamental difference of current distribution occurs on macro- and microprofiles. For instance, Meyer (1) and Gardam (2) found that, in acid copper bath, uniform plating into the pores of the basis metal occurred although the macrocurrent distribution was poor. In a cyanide copper bath, the filling of microgrooves was poor whereas the macrocurrent distribution was relatively uniform. Reinhard (3), Foulke and Kardos (4), and Kardos (5) all found that the microcurrent distribution for all baths became less uniform with increasing current density. It is well known to electroplaters that (6), as a common rule, in the absence of a leveling agent, a bath having relatively uniform macrocurrent distribution generally has nonuniform microcurrent distribution and *vice versa*.

Fundamental Transport Processes in Plating Systems

A general theory of current distribution on electrodes is based on a consideration of the phenomenological theory of transport processes in electrochemical systems. The fundamental transport equations in dilute solutions have been discussed in detail by Levich (7) and more recently by Newman (8). Application of these equations has followed two main courses. At low current densities where change of concentration near the electrode-solution interface can be neglected, the transport equations reduce to the Laplace equation (9)

$$\nabla^2\phi = 0 \qquad [1]$$

and the current density is given by

$$\vec{i} = -\kappa\nabla\phi \qquad [2]$$

where ϕ is the potential in the solution, $\vec{i}$ is the current density vector, and κ is the electrical conductivity of the solution. An extensive review of the solution of the Laplace equation for electrochemical systems has been completed by Fleck (10). At high current densities and when electrical migration is neglected, the mass transport of the reacting species becomes rate controlling and the transport equations reduce to the convective diffusion equation (9)

$$\frac{\partial c_i}{\partial t} + \vec{v}\cdot\nabla c_i = \nabla\cdot(D_i\nabla c_i) \qquad [3]$$

and

$$\vec{i} = -z_i\mathbf{F}D_i\nabla c_i \qquad [4]$$

where c_i, D_i, z_i are the concentration, differential diffusion coefficient, and valency of species i, $\vec{v}$ is the fluid velocity, and **F** is the Faraday constant. Methods of solving the convective diffusion equation have been treated in detail by Levich (7).

These two limiting cases play an important role in electroplating. The application to the phenomenon of macro- and microcurrent distribution is given below.

Application to the Phenomenon of Macro- and Microcurrent Distribution

An important parameter used in systems where mass transport is slow is the Nernst diffusion layer thickness δ_N. For a single electrode reaction, it is defined by

$$i = -z_i\mathbf{F}D_i\left(\frac{\partial c_i}{\partial y}\right)_{\text{at electrode}} \equiv z_i\mathbf{F}D_i\frac{c_{iB} - c_{iI}}{\delta_N} \qquad [5]$$

where y is a distance coordinate normal to the electrode surface, c_{iB} and c_{iI} are the concentration of the reacting species i in the bulk and at the interface, respectively. δ_N is a function of Reynolds number and Schmidt number in forced convection systems and a

Key words: electrodeposition, current distribution, gold.

function of Grashof number and Schmidt number in free convection systems (11). Typical values of δ_N in gently stirred solutions range from 50 to 100μ (12). δ_N can be used conveniently to establish an operational definition of macro- and microprofiles (4, 5, 14). When the linear dimension of a surface profile is in the same range or slightly smaller than δ_N, the profile is considered to be microscopic. When the linear dimension is at least one order of magnitude larger than δ_N, the profile becomes macroscopic. Since δ_N depends on both the flow condition and physical properties of the system, the dimension of macro- and microprofiles varies accordingly. The local variation of δ_N determines the characteristics of local mass transport. For instance, a faster transport results from a thinner diffusion layer. Consequently, from the standpoint of mass transport, microprofiles are "rough" whereas macroprofiles are "smooth." On the other hand, when mass transport of the reacting species is not rate controlling, ohmic drop in the solution and electrode overpotential at the interface are the important parameters to consider. Let us now examine the two cases.

Ohmic drop and electrode overpotential controlling.—This is the case where low current density is applied. The concentration gradient of the reacting species at the interface is negligible. On a macroprofile, the effect of ohmic drop in the solution is predominant in determining the current distribution. Primary current distribution results when electrode overpotential is negligible. The current distribution depends only on geometrical factors concerning the electrochemical cell and electrode arrangements. On a microprofile, the effect of ohmic drop in the solution is outweighed by the electrode overpotential at the interface. The microcurrent distribution is governed by the secondary current distribution. A linear electrode overpotential-current density relation exists when the electrode overpotential is small

$$i = \frac{i_0 n\mathbf{F}}{RT}\eta \qquad [6]$$

where i_0 is the exchange current density for the reaction, n is the number of electrons transferred for the reaction, η is the electrode overpotential, R is the gas constant, and T is the absolute temperature. The current distribution depends on the same geometrical factors as to the primary current distribution and, in addition, to the dimensionless parameter (9, 13) $(L/\kappa)(di/d\eta)$ where L is a characteristic length of the microprofile. For large cathodic overpotentials, the electrode overpotential-current density relation is given by the Tafel equation

$$\eta = -\frac{RT}{(1-\alpha)n\mathbf{F}}[\ln(-i) - \ln i_0] \qquad [7]$$

where α is the transfer coefficient. The current distribution now depends on the parameter (9, 13) $|i_{avg}|(1-\alpha)n\mathbf{F}L/RT\kappa$, where i_{avg} is the average current density. It has been confirmed in numerous cases (14, 15) that, at low current densities, the secondary current distribution on a microprofile is uniform due to the high overpotential of the deposition reactions and the high conductivity of most plating baths. This is the reason for the statement (6) "a bath of poor macrocurrent distribution has good microcurrent distribution."

Mass transport controlling.—At high current densities when mass transport of the reacting species becomes rate controlling, the Nernst diffusion layer thickness is the most important parameter to consider. A relatively uniform distribution of current is seen on the macroprofile due to the uniform thickness of the Nernst diffusion layer over the profile whereas the local variation of the diffusion layer thickness over the microprofile is responsible for the poor microcurrent distribution. Of course, current distribution can be highly nonuniform at electrode edges. For instance, the theoretical current density is infinite at the leading edge of a flat plate in the direction of electrolyte flow (16). Therefore, the above statement is only valid at regions where both the momentum and the diffusion boundary layers are fully developed.

For most plating baths, the metal ion concentration is so high that the two limiting cases can readily be distinguished and consequently lead to the interesting observation of macro- and microcurrent distribution. However, the gold content in a gold plating bath is usually so low (approximately 10-20 g/l) that under most operating conditions, the process is influenced by both electrode potential, ohmic drop and mass transport. To study the applicability of the above theoretical considerations, experimental investigation on the microcurrent distribution of a gold plating system was carried out.

Experimental

Electrolyte.—The Ehrhardt acid citrate bath (17) which contained 21.3 g/l potassium gold cyanide and 50 g/l ammonium citrate (dibasic) was chosen for these experiments. At 60°C, the *p*H of the bath was 5 and the conductivity of the bath was 0.063 ohm^{-1} cm^{-1} measured by a conductivity bridge which supplied 1000 Hz bridge current.

Electrodes.—Two types of cathodes were used to study the effect of the dimension and geometry of surface inhomogeneities. Electroformed nickel with a wavy surface of amplitude approximately 25μ and polished planar OFHC copper plates were chosen to study the microcurrent distribution. The surface area for both electrodes was 1 cm^2. Three identical V-shaped grooves, 2.5 mm apart, were cut into the copper plates. The angles of the grooves were 30°, 60°, and 90°, and the groove depths were approximately 50, 125, and 250μ. The anode was a platinum coil.

Experimental procedures.—Prior to plating, both the nickel and the copper electrodes were cleaned and degreased using acetone and trichloroethylene, respectively. The copper electrodes were then bright-dipped for approximately 10 sec in a solution containing 250 ml H_2SO_4, 125 ml HNO_3, 4 ml HCl, and 250 ml water. Both electrodes were then rinsed with distilled water. The plating cell was cylindrical in shape with a volume of 200 ml. For each plating, 150 ml of the citrate gold solution was used. Oxygen-free nitrogen was bubbled through the solution for 30 min prior to electrolysis, and a nitrogen atmosphere was maintained above the solution during electrolysis. No stirring was applied. The plating was performed at 60°C. The applied cathodic current density was 2, 4, and 6 mA/cm^2. The limiting current density for gold deposition in this experiment was found to be 6.3 mA/cm^2. The Tafel slope for the system was measured under galvanostatic condition using a rotating disk electrode at a constant rotational speed of 1730 rpm. The value was found to be 130 mV at 60°C. Depending on the depths of these grooves and the current density used, the duration of electrolysis was varied between 1 to 6 hr for optimum observation. To protect the gold surface for sectioning, approximately 12μ of Watts nickel was plated over the gold coating.

These electrodes were then mounted in epoxy, sectioned, polished, and etched in an equivolume mixture of acetic acid, nitric acid, and phosphoric acid. The microcurrent distribution of the citrate gold was determined by microscopic examination.

Results

Typical results from photomicrographs are shown in Fig. 1 to Fig. 5. They can be summarized as follows:

1. The microcurrent distribution is relatively uniform on the electroformed nickel electrode.

2. On the copper electrode, the microcurrent distribution becomes less uniform at increasing cathodic current densities and sharpening V-angles.

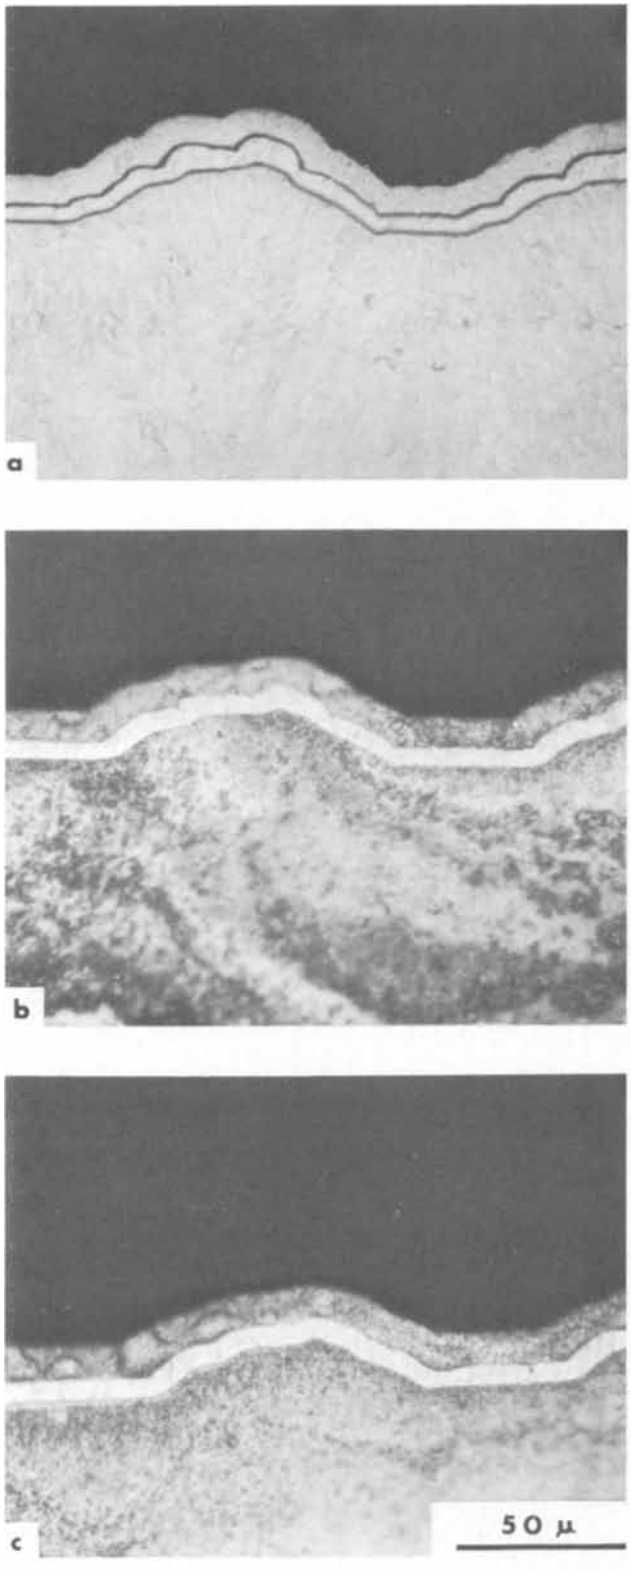

Fig. 1. Photomicrographs of gold deposits on nickel substrates with wavy surfaces: (a) 2 mA/cm^2; (b) 4 mA/cm^2; (c) 6 mA/cm^2.

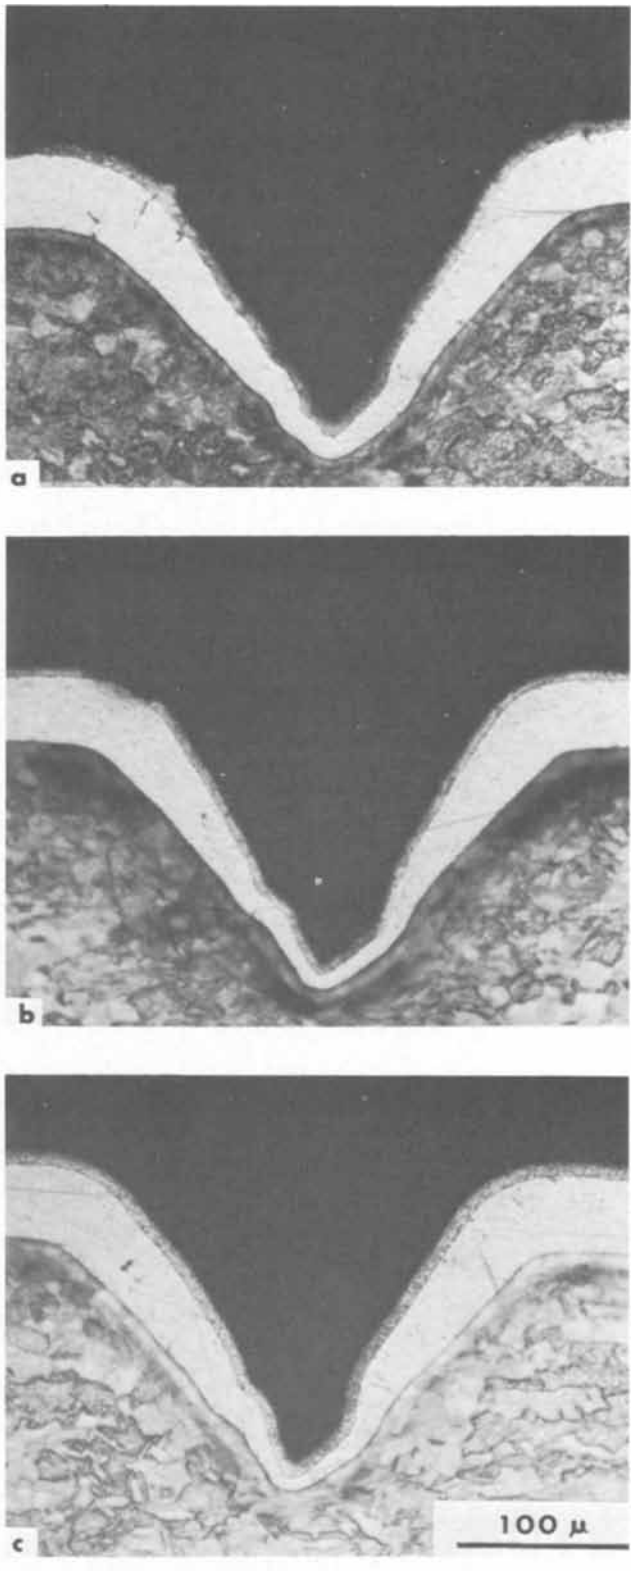

Fig. 2. Photomicrographs of gold deposits on copper substrates with triangular grooves: (a) 2 mA/cm^2; (b) 4 mA/cm^2; (c) 6 mA/cm^2.

3. On the copper electrode, the microcurrent distribution becomes less uniform at increasing groove depth.

Quantitative information on the microcurrent distribution of citrate gold plating are plotted in Fig. 6 to Fig. 8. The current distribution is represented by a gold plating thickness ratio h_1/h_2 where h_1 is the average deposit thickness on a planar surface and h_2 is the thickness at the bottom of a triangular groove. Geometrical factors used in these figures are the groove depth d and groove angle θ, and the operating variable chosen here is the current density.

Discussion

It has been concluded that the secondary current distribution depends heavily on the dimensions and geometry of the surface profile that is being plated. It is, therefore, not surprising to find that, on electro-

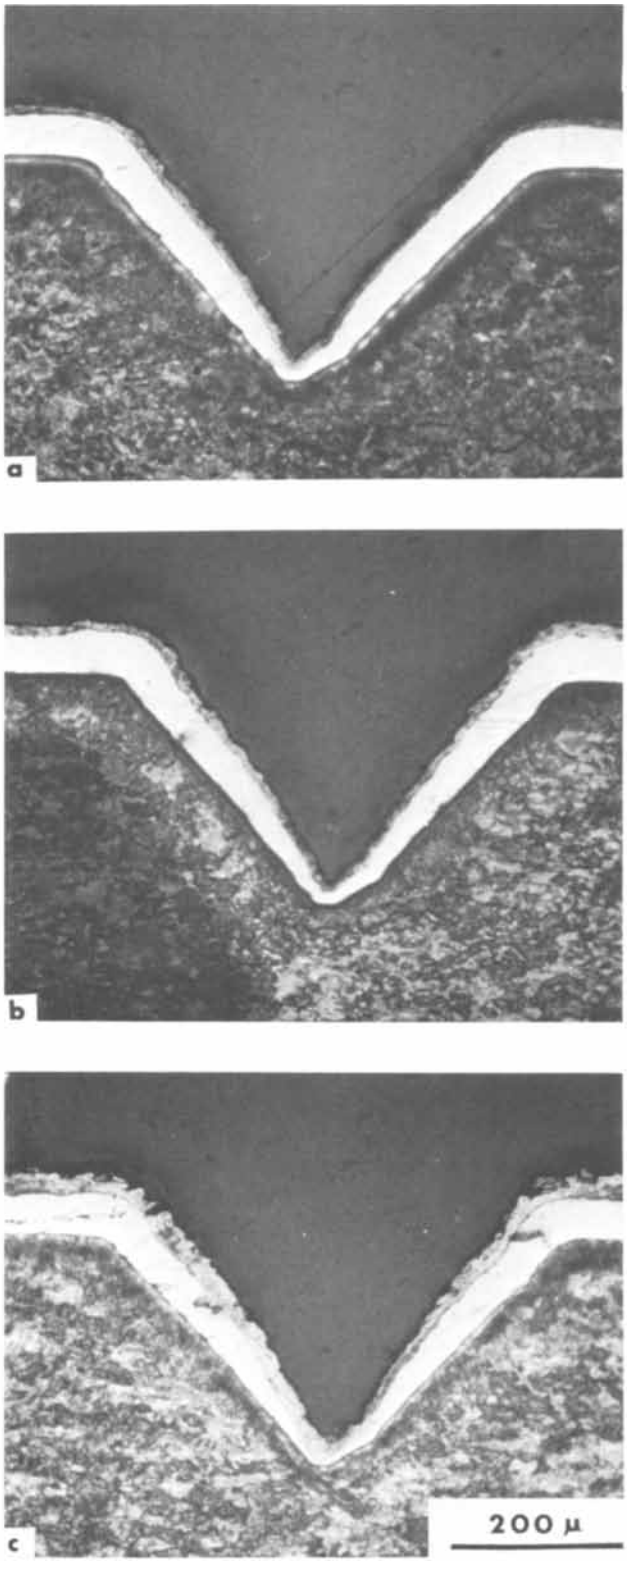

Fig. 3. Photomicrographs of gold deposits on copper substrates with triangular grooves: (a) 2 mA/cm^2; (b) 4 mA/cm^2; (c) 6 mA/cm^2.

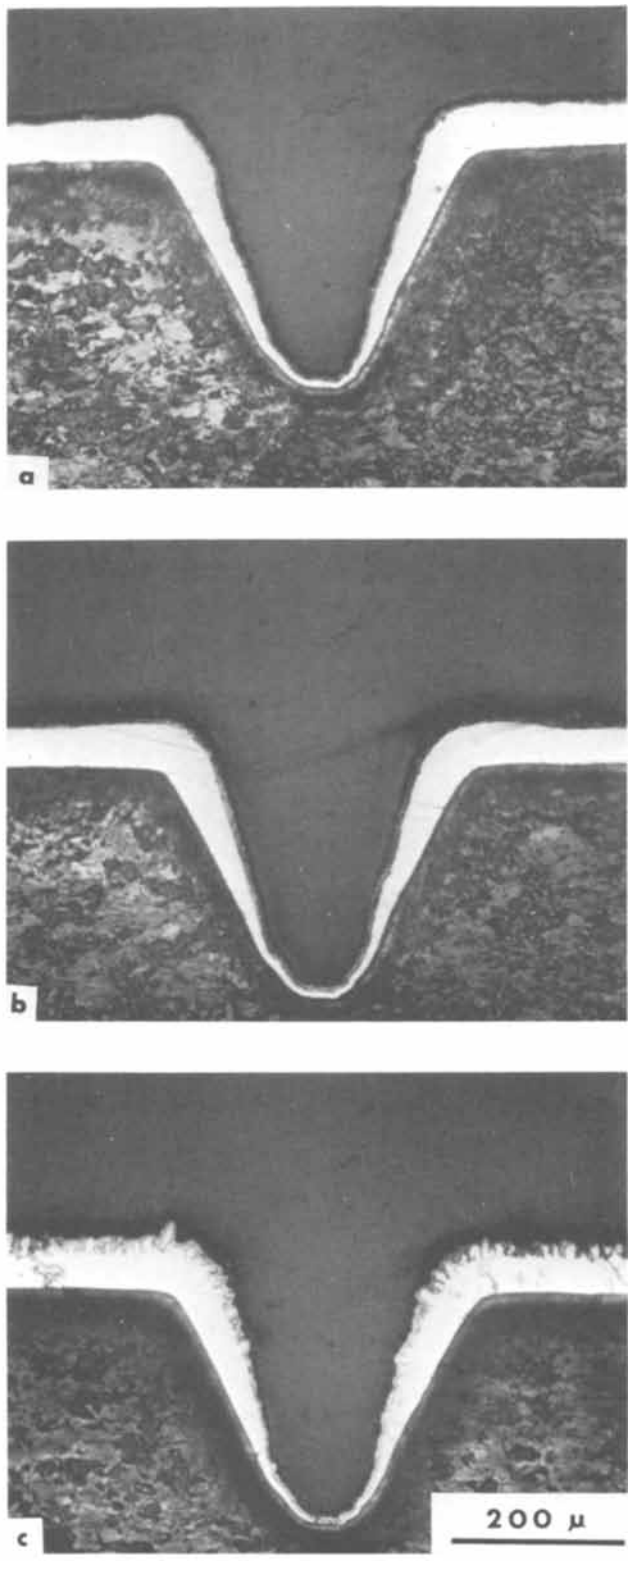

Fig. 4. Photomicrographs of gold deposits on copper substrates with triangular grooves: (a) 2 mA/cm^2; (b) 4 mA/cm^2; (c) 6 mA/cm^2.

formed nickel surface which is relatively smooth, the microcurrent distribution is rather uniform.

At increasing cathodic current densities, the process becomes increasingly mass transport limited and consequently, the microcurrent distribution becomes less uniform. At the limiting current density, gassing is observed at the electrode. The deposit becomes incoherent and frequently rough or powdery.

Wagner (18) has calculated theoretically the secondary current distribution on a triangular wave surface when the counterelectrode is far removed from the working electrode. The geometrical parameter is shown to be 1/2 (cos $\theta/2$/sin $\theta/2$) where θ is the angle between the two adjacent sides of the triangle. For linear polarization,

$$\frac{i_p - i_r}{i_{avg}} = \frac{L}{\kappa}\frac{di}{d\eta}\frac{1}{2}\frac{\cos\theta/2}{\sin\theta/2} \qquad [8]$$

whereas for Tafel polarization

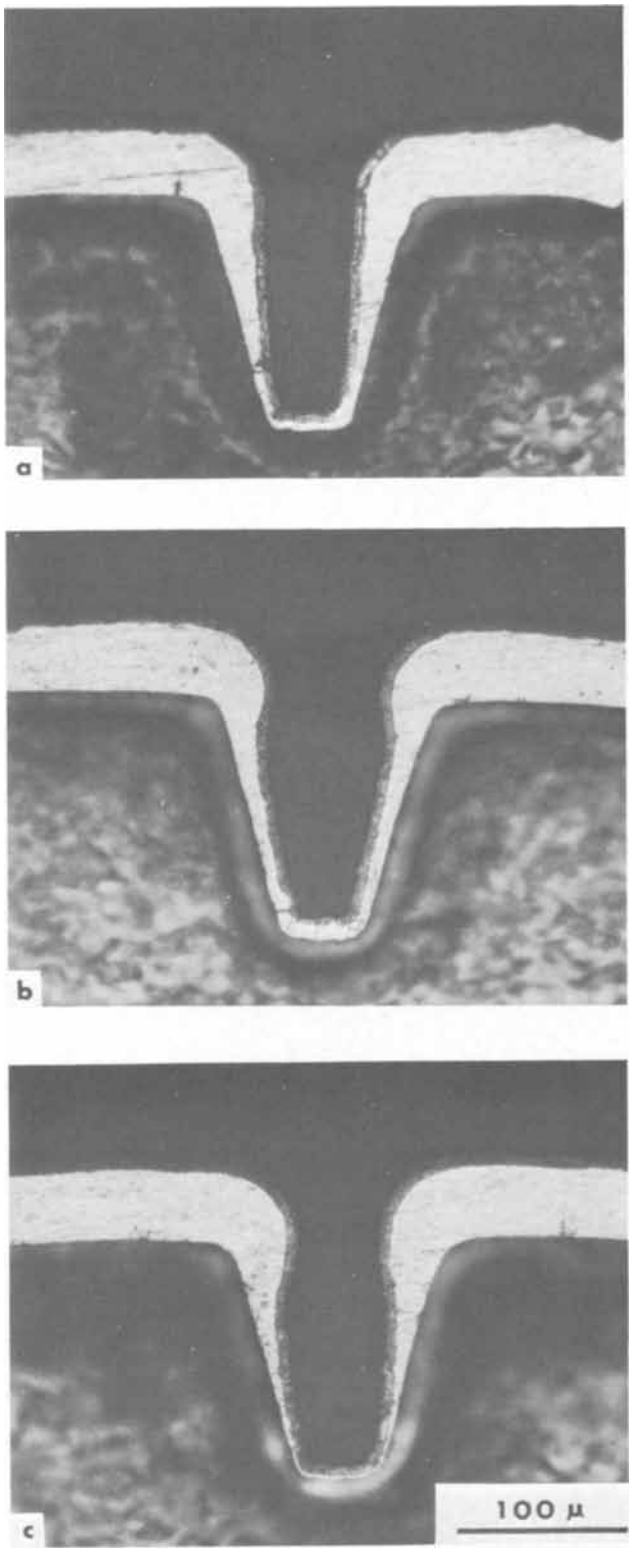

Fig. 5. Photomicrographs of gold deposits on copper substrates with triangular grooves: (a) 2 mA/cm^2; (b) 4 mA/cm^2; (c) 6 mA/cm^2.

$$\ln \frac{i_p}{i_r} = \frac{|i_{avg}| L(1-\alpha)n\mathbf{F}}{\kappa RT} \frac{1}{2} \frac{\cos \theta/2}{\sin \theta/2} \qquad [9]$$

where i_p is the current density at the peak, i_r is the current density at the recess, and L is the distance between two adjacent peaks. Varying θ from 90° to 30°, the geometrical parameter increases by approximately a factor of ten. Therefore, the microcurrent distribution is very sensitive to the value of this angle. This conclusion is also amply demonstrated in the present investigation as shown in Fig. 6-8.

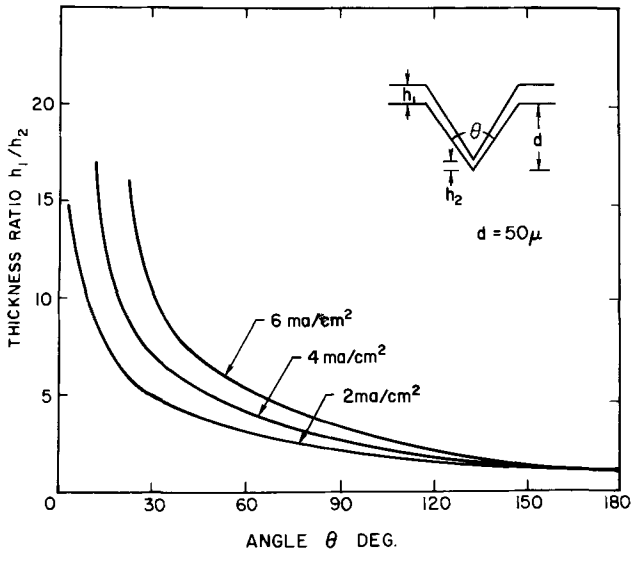

Fig. 6. Microcurrent distribution of gold deposits on copper substrates.

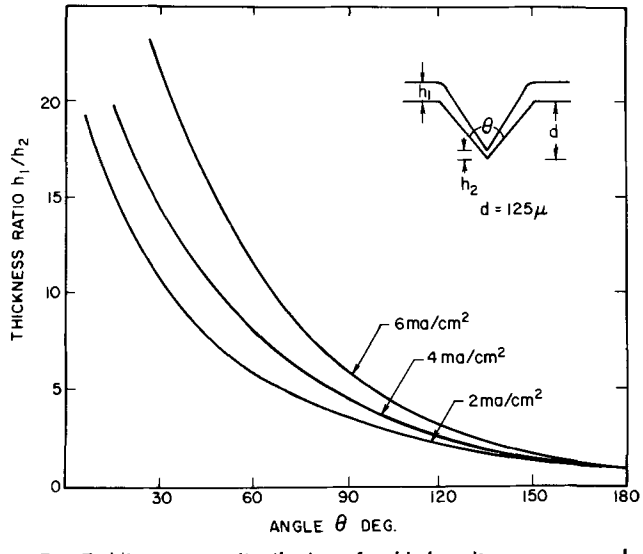

Fig. 7. Microcurrent distribution of gold deposits on copper substrates.

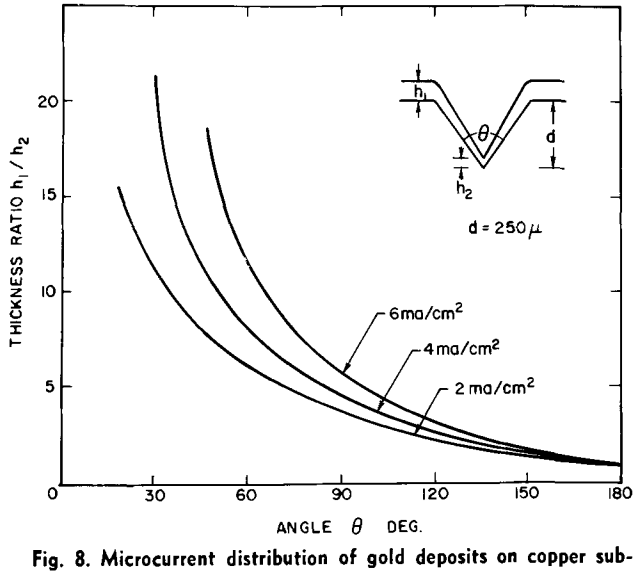

Fig. 8. Microcurrent distribution of gold deposits on copper substrates.

Considering the effect of groove depth from these figures, a significant increase in the thickness ratio is seen when groove depth is increased from 50 to 125μ but less change is found from 125 to 250μ. This can be explained by a consideration of the mass transfer aspect. Using the limiting current density of 6.3 mA/cm^2 and assuming the diffusion coefficient of gold ion as 9 x 10^{-6} cm^2/sec, δ_N is calculated from Eq. [5] to be 100μ. The difference between the diffusion path is, therefore, greater when d is changed from 50 to 125μ than from 125 to 250μ. Ignoring the effect of electrical migration, the interfacial concentration of gold ion is 10 g/l at a cathodic current density of 2 mA/cm^2 and 5.7 g/l at 4 mA/cm^2. Comparing these values to the bulk concentration of gold (15 g/l), it is seen that even at 2 mA/cm^2, the effect of mass transport is appreciable. It is therefore concluded that for most gold baths, due to the low gold content, the plating process is performed under conditions where mass transport limitations cannot be ignored.

Conclusions

Theoretical aspects of macro- and microcurrent distribution are presented. Two operating regimes for plating systems are established. At low current densities where concentration gradients near the electrode-solution interface can be neglected, a plating bath with no leveling agents will have relatively uniform microcurrent distribution but nonuniform macrocurrent distribution. At high current densities where mass transport of the reacting species is rate controlling, the plating bath will have nonuniform microcurrent distribution but relatively uniform macrocurrent distribution.

Quantitative information on the microcurrent distribution of a citrate gold plating system have been obtained. Effect of surface roughness as well as operating conditions such as metal concentration and current density on the current distribution has been established. It is also confirmed that most gold plating systems are operated under conditions where the effect of mass transport of the reacting species cannot be neglected.

In order to improve the microcurrent distribution, reduction of surface roughness and application of low current densities are both essential. An alternative approach will be either to search for suitable leveling agents or to raise the gold content of the bath thereby reducing the mass transfer controlling effect on microcurrent distribution.

Electroless Deposition of Certain Metal Oxides

I. Alpha-PbO_2

W. Mindt*[1]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Electroless deposition of α-PbO_2 films by oxidation of lead(II) acetate with peroxydisulfate is described. Investigations into the mechanism of this reaction show it to be a mixed electrolytic process with the two partial reactions $Pb^{++} + 2H_2O \rightarrow \alpha\text{-}PbO_2 + 4H^+ + 2e^-$ and $S_2O_8^= + 2e^- \rightarrow 2SO_4^=$. The variation of mixed potential and growth rate with the *p*H of the electrolyte is studied and interpreted in terms of the *p*H dependence of both partial reactions. A mechanism of the reduction of $S_2O_8^=$ at PbO_2 is proposed.

The anodic oxidation of some metal ions in aqueous solutions leads under certain conditions to the deposition of an oxide at the anode, according to the electrode reaction

$$mMe^{z+} + nH_2O \rightarrow Me_mO_n + 2nH^+ + (2n - mz)e^- \quad [1]$$

(in acid solutions). Some well-known examples are the systems Pb^{++}/PbO_2, Mn^{++}/MnO_2, $Ni^{++}/$"NiO_2", Tl^+/Tl_2O_3 and Ag^+/AgO. If the oxidation of the metal ion is carried out as a controlled heterogeneous reaction by a suitable oxidizing agent instead of an external electrical current, the deposition of the metal oxide can be called "electroless" in analogy to the corresponding process known for metals.[2] In general, the conditions under which electroless deposition of metal oxides is possible are equivalent to those for metals: The oxidizing agent must have, of course, a higher redox potential than the equilibrium potential of reaction [1], and its reduction at the metal oxide must be kinetically possible. The reduced species should be soluble in the electrolyte and should not interfere with the anodic process, *e.g.*, due to adsorption at the metal oxide. Nucleation of the metal oxide in the solution should be prevented since this results in an uncontrolled precipitation. Finally, since oxidation and reduction steps occur at different locations, charge transport within the metal oxide must be possible, *i.e.*, the metal oxide has to be an electrical conductor.

In the present work some systems are investigated in which these conditions are fulfilled. In the first part, deposition of α-PbO_2 is described. Films of this oxide are of interest for use as counterelectrodes in solid valve metal oxide capacitors, since they have a considerably higher conductivity than MnO_2 films which are used so far, and capacitors with PbO_2 coatings show similar self-healing properties (2, 3).

The oxidizing agent used in our experiments is peroxydisulfate (persulfate). The studied over-all reaction is

$$Pb^{++} + 2H_2O + S_2O_8^= \rightarrow \alpha\text{-}PbO_2 + 4H^+ + 2SO_4^= \quad [2]$$

This reaction was described earlier by Rüetschi and Cahan (4). The authors obtained α-PbO_2 as precipitate from solution by a homogeneous reaction. Occasionally, the formation of PbO_2 films at the walls of the glass beakers in which the reaction was carried out was observed (5); however, this effect was not further studied. In the experiments described here, reaction [2] was carried out heterogeneously on PbO_2 substrates under conditions where no precipitation of PbO_2 in the solution occurred.

It is of some practical interest to be able to deposit adherent α-PbO_2 films on insulating substrates. In electroless metal deposition, this is usually accomplished by treating the substrate surface in such a way that it acts as catalyzer during the deposition of an initial metal layer. We did not investigate an equivalent procedure of surface activation. As an alternative method, an initial PbO_2 layer of a few hundred angstroms was precipitated from solution by catalyzing reaction [2] with Ag^+, as will be described in the experimental part. Further growth of PbO_2 was carried out by electroless deposition. α-PbO_2 films obtained in this way showed good adherence up to a thickness of 1μ on various substrates, such as glass, quartz, ceramics, or Ta_2O_5.

Experimental

All experiments were carried out in a supporting electrolyte of M $NH_4C_2H_3O_2$ which was prepared from 30% NH_4OH and glacial acetic acid (both Baker "electronic grade"). Lead acetate was added to this solution in the form of PbO (Fisher "certified") and an equivalent amount of acetic acid. In most experiments, a concentration of lead acetate of 50 mM was used. $S_2O_8^=$ was added from a freshly prepared aqueous solution of ammonium persulfate (Fisher "certified") which was brought to the *p*H of the studied solution by addition of NH_4OH.

The PbO_2 electrodes used for the current/potential measurements were prepared by anodic deposition of a *ca.* 0.5μ thick layer on a 0.25 cm^2 Pt electrode. The deposition was carried out immediately before each measurement in the same electrolyte, applying a current density of 0.5 mA/cm^2. Weight measurements of the deposited PbO_2 were carried out on electrodes of larger surface area to achieve a higher accuracy. For this purpose, 3 x 1 in. glass slides were used, on which an initial layer of 500Å PbO_2 was precipitated in the following way: Glass slides were exposed in a vertical position to a solution prepared by mixing 100 ml of 50 mM lead acetate dissolved in M $NH_4C_2H_3O_2$ with 100 ml of 2M $(NH_4)_2S_2O_8$, both brought to a *p*H of 6. To this solution, $AgNO_3$ was added as catalyst in a concentration of 5 x 10^{-5}M. After an induction time of about 15 min, the solution turned slowly brown, and after 45 to 90 min, a continuous film of 500Å PbO_2 was precipitated on the glass slides. After washing with distilled water and drying at room temperature, the slides were used for the weight and open-circuit potential measurements. Results of these measurements should be, of course, independent of the way in which the initial PbO_2 layer was obtained. This was confirmed by experiments carried out on 20 cm^2 Pt elec-

* Electrochemical Society Active Member.

[2] Electroless deposition of a metal oxide is known so far only in the case of MnO_2. Films of this oxide are deposited by reduction of MnO_4^- (1). It is, however, doubtful if the term "electroless" can be applied to this process, since it is precipitation from solution rather than a controlled heterogeneous reaction.

trodes, on which PbO_2 was electrodeposited, as well as by using glass substrates on which PbO_2 was deposited by hydrolysis of lead tetraacetate as described by Robinson (2).

The potential/current measurements were carried out potentiostatically, using a 1*N* calomel reference electrode (NCE) and a Pt counterelectrode. Stationary conditions were achieved after a few minutes at low current densities (< 10 $\mu A/cm^2$) and after several seconds at higher current densities. The electrolyte was stirred. All experiments were carried out at 25°C.

Results

In Fig. 1, stationary current/potential curves are shown which demonstrate that the nature of the deposition is a mixed electrolytic process. Curve 1 was obtained in a solution of 50 mM lead acetate in M $NH_4C_2H_3O_2$ at *p*H 8.5. In this solution, where the lead ions are solubilized by complexing with acetate, the anodic reaction is

$$Pb^{++} + 2H_2O \rightarrow \alpha PbO_2 + 4H^+ + 2e^- \qquad [3]$$

with cathodic currents, PbO_2 is reduced to a lower oxide. Curve 2 was obtained after addition of 50 mM ammonium persulfate to the above solution. The net current results from the superposition of reaction [3] and the reduction of $S_2O_8^=$

$$S_2O_8^= + 2e^- \rightarrow 2SO_4^= \qquad [4]$$

By subtraction of curve 1 from curve 2, the partial current voltage curve of reaction [4] is obtained (curve 3). At open circuit, deposition of PbO_2 occurs at the mixed potential U_m with the partial current density i_d. Independent determinations of i_d by weight measurements of the deposited PbO_2 give the same result. This can be seen in Fig. 2 which shows i_d and U_m as a function of *p*H. The electrolyte was again 50 mM lead acetate and 50 mM ammonium persulfate in M ammonium acetate. The *p*H was varied between 5 and 10 by addition of $HC_2H_3O_2$ or NH_4OH, respectively. i_d was determined from the stationary anodic current at the potential U_m in the absence of $S_2O_8^=$ as described before as well as by weight measurements. The results of both methods were reproducible with deviations not larger than 10%. A current density of 1 mA/cm^2 corresponds to a deposition rate of 760 Å/min. The deposition current increases with *p*H, following the relationship

$$\log i_d = \text{const} + 0.81\, pH \qquad [5]$$

U_m was determined on PbO_2 films deposited on Pt and on glass substrates. With increasing *p*H, U_m shifts in negative direction by (59 ± 5) mV per *p*H unit.

The observed *p*H dependence of i_d and U_m results from influences of both anodic and cathodic reactions.

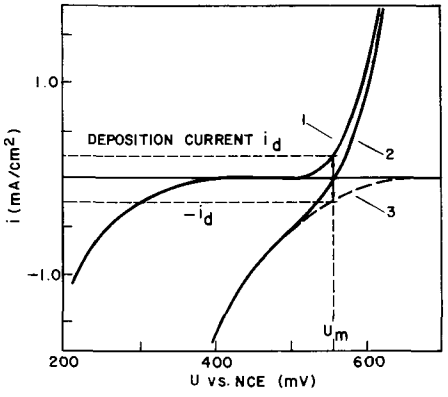

Fig. 1. Stationary current/potential curves at PbO_2 electrode. Curve 1, anodic partial reaction [3], measured in a solution of 50 mM lead acetate in 1M ammonium acetate at *p*H 8.5; curve 2, over-all reaction [3] + [4], measured after addition of 50 mM ammonium persulfate; curve 3, cathodic partial reaction [4], calculated by subtraction of curve 1 from curve 2.

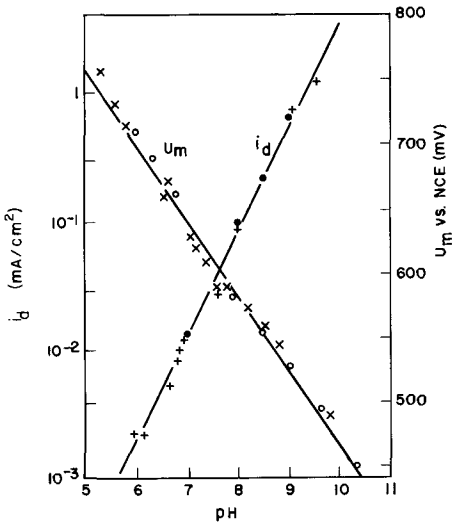

Fig. 2. Deposition current i_d and mixed potential U_m as function of *p*H. Electrolyte: 50 mM lead acetate + 50 mM ammonium persulfate in 1M ammonium acetate. ●, i_d from current at U_m in absence of $S_2O_8^=$; +, i_d from weight measurements; o, U_m at PbO_2 deposited on platinum; x, U_m at PbO_2 deposited on glass (1 mA/cm^2 corresponds to 760 Å/min).

This becomes evident from Fig. 3 in which the partial current/potential curves of the two reactions are plotted at different *p*H values. The anodic curves were determined in a solution of 50 mM lead acetate in M ammonium acetate. The *p*H was varied as before. The reduction of $S_2O_8^=$ could not be studied in a similar way in a solution containing $(NH_4)_2S_2O_8$ only. Under this condition, the PbO_2 electrode turned slowly into a passivated state, and the current measurements were irreproducible. It is assumed that this is the effect of adsorption of the reaction product, $SO_4^=$. Apparently, the PbO_2 surface which is freshly formed during the deposition shows a different behavior with regard to the kinetics of the $S_2O_8^=$ reduction. The partial current/potential curves of the $S_2O_8^=$ reduction near U_m were determined from the difference between the currents of the Pb^{++} oxidation and the over-all reaction [2] as described for Fig. 1. The intersections between anodic and cathodic curves at the same *p*H represent open-circuit conditions (zero net current), *i.e.*, give the values of i_d and U_m. The dotted line is obtained from the experimental data of i_d and U_m in Fig. 2. The log i/U curves of the Pb^{++} oxidation approach at higher current densities and low *p*H a Tafel slope of 118 mV which is expected for this reaction if the trans-

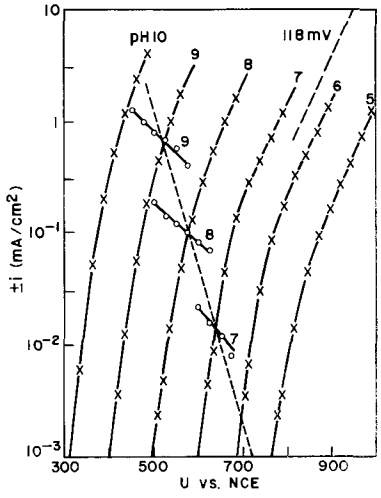

Fig. 3. Partial current/potential curves at various *p*H. x, anodic reaction [2]; o, cathodic reaction [4]; dotted line, i_d *vs.* U_m from data in Fig. 2.

fer coefficient α is 0.5. In the region studied here (dotted line), the slopes are generally smaller. The Tafel slopes of the reduction of $S_2O_8^=$ vary between 210 and 270 mV, corresponding to transfer coefficients between 0.28 and 0.22. The low transfer coefficient is typical for this reaction, *e.g.*, a value of $\alpha = 0.32$ was obtained by Müller (6) in alkaline solutions at Pt electrodes.

In Fig. 4, the partial cathodic current is plotted as a function of the $S_2O_8^=$ concentration at constant electrode potentials. This experiment was carried out again in a solution of 50 mM lead acetate in 1M $NH_4C_2H_3O_2$, to which $(NH_4)_2S_2O_8$ was added from a 2M aqueous solution. The pH was kept constant at 8.50. At low concentrations, the current is proportional to the square root of the persulfate concentration indicating a reaction order of 0.5 for the $S_2O_8^=$ ion. The deviation from linearity at higher concentrations is probably the effect of the presence of $SO_4^=$ ions which seem to inhibit the reaction. This assumption is supported by the fact that an addition of 0.1M $(NH_4)_2SO_4$ to the solution results in a decrease of the current to nearly zero.

Properties of the PbO_2 *films.*—The electron diffraction pattern of the PbO_2 films deposited on glass substrates showed only lines of the α-modification. There was no evidence for the presence of lower lead oxides. In some cases, the crystallites had a slight orientation with the (100)-plane parallel to the substrate as is observed also on electrodeposited α-PbO_2 (7). The crystallite size of a 5000Å thick film deposited at pH 8 is about 2000Å as determined by electron microscopy.

The electrical properties are, in general, similar to those of electrodeposited α-PbO_2 (8). Hall effect measurements showed that the carrier density is about 10^{21} cm^{-3} and is nearly independent of the pH at which the films were deposited. There is, however, an effect on the resistivity with increasing pH, *e.g.*, a 5000Å thick film deposited at pH 7 had a resistivity of 2×10^{-3} ohm cm, whereas at pH 10 a resistivity of 3×10^{-2} ohm cm was obtained.

Discussion

The result that the deposition occurs at the rate expected from the stationary current potential relations indicates that the deposition is a pure electrochemical process, *i.e.*, that no "chemical" deposition due to a reaction without charge exchange at the interface is involved. The deposition rate is controlled by the potential U_m which is a function of the composition of the electrolyte.

The variation of U_m with pH was found to be linear in the studied pH region with a slope of −59 mV/pH. An interpretation of this result is difficult since it arises from a complex pH dependence of the current potential relations of both partial reactions, as was seen in Fig. 3. In the following, the origins of the pH dependence of the two reactions are discussed.

The drift of the anodic current potential curves with pH is mainly the effect of the variation of the equilibrium potential of the anodic reaction. The equilibrium potential of reaction [3] is

$$U_o = 1.450 - 0.0296 \log (Pb^{++}) - 0.1183\, pH \quad [6]$$

Measurements of the open-circuit potential of a PbO_2 electrode in a solution of 50 mM lead acetate in 1M ammonium acetate are shown in Fig. 5 (dotted line). The variation with pH is linear and has a slope of −90 mV/pH instead of −118 mV/pH which would be expected for reaction [3]. Better agreement with this result would be given by the reaction

$$Pb(OH)^+ + H_2O \rightleftharpoons PbO_2 + 3H^+ + 2e^- \quad [7]$$

with

$$U_o = 1.270 - 0.0296 \log [Pb(OH)^+] - 0.0887\, pH \quad [8]$$

It is, however, not certain what composition the lead acetate complex has in this solution. The assumption that a complex of the type $Pb(OH)(C_2H_3O_2)_n^{(n-1)-}$ exists is not unreasonable, since $Pb(OH)^+$, respectively $Pb_4(OH)_4^{4+}$, is the hydrolyzed form stable in this pH region in perchlorate medium according to Olin (12). It should be mentioned that the absolute values of the open-circuit potentials in Fig. 5 cannot be compared with the calculated equilibrium potentials, since no liquid junction potentials and activity coefficients have been taken into account. The fact that the deviation is as high as 150 mV indicates that the activity coefficient of lead(II) in this solution is very low.

Besides the pH dependence of the equilibrium potential, there is also an effect of the pH on the rate of the anodic reaction, as can be seen in Fig. 3. At higher pH, the current potential curves are steeper. It is unlikely that this is an effect of an increase of the exchange current of reaction [3], since the influence of the reverse current should be negligible at overpotentials more than about 120 mV. It may be suggested that the mechanism of the reaction changes at higher pH, possibly due to the formation of $Pb(OH)_2$ or a complex of this with acetate.

The result that the cathodic curves are pH dependent is at first surprising, since $S_2O_8^=$ as well as the reaction product $SO_4^=$ are almost completely dissociated in the studied pH region. The mechanism of the $S_2O_8^=$ reduction on platinum electrodes in alkaline solution, as proposed by Müller (6)

$$S_2O_8^= \rightleftharpoons (2SO_4^{-\cdot})_{ads} \quad [9]$$

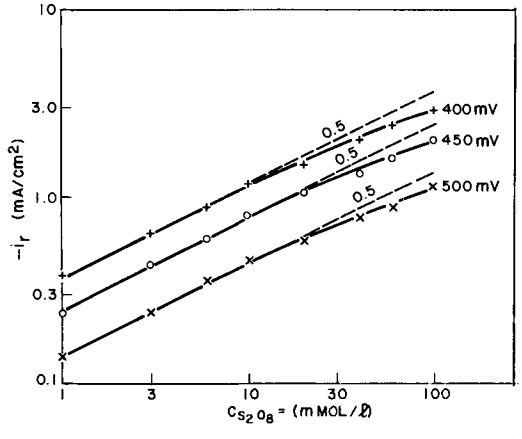

Fig. 4. Partial current of $S_2O_8^=$ reduction at PbO_2 *vs.* concentration of $S_2O_8^=$. Electrolyte: 50 mM lead acetate + x mM ammonium persulfate in 1M ammonium acetate, pH 8.50.

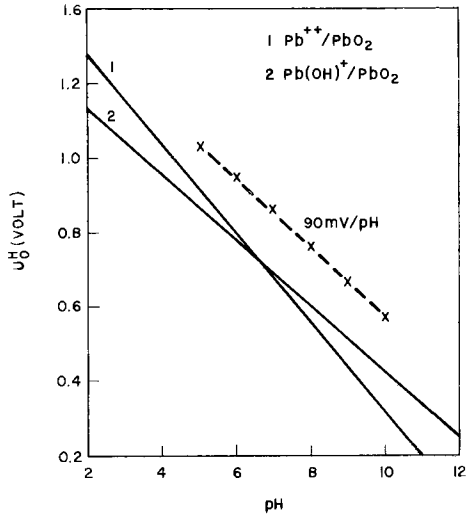

Fig. 5. Equilibrium potentials calculated from thermodynamic data (9) *vs.* pH. x, open-circuit potentials of PbO_2 electrodes measured in a solution of 50 mM lead acetate in 1M ammonium acetate.

$$2(SO_4^-)_{ads} + 2e^- \rightarrow 2SO_4^= \quad [10]$$

does also not explain the pH dependence found here. It has been proposed by several authors (10) that the sulfate radical is converted to the OH· radical, according to

$$SO_4^- + H_2O \rightleftharpoons OH\cdot + SO_4^= + H^+ \quad [11a]$$

or

$$SO_4^- + OH^- \rightleftharpoons OH\cdot + SO_4^= \quad [11b]$$

Recent investigations on the photolysis of persulfate ions (11) showed that between pH 8.5 and 10.8 the stability of the SO_4^- radical decreases rapidly, indicating the existence of a pH dependent equilibrium like Eq. [11]. Although the path of the conversion of SO_4^- into OH· is not yet clarified, the following mechanism of the reduction of $S_2O_8^=$ at PbO_2 can be proposed

$$S_2O_8^= \rightleftharpoons 2SO_4^-{}_{ads} \quad [9]$$

$$2SO_4^-{}_{ads} + 2\,OH^- \rightleftharpoons 2\,OH\cdot_{ads} + 2SO_4^= \quad [11]$$

$$2\,OH\cdot_{ads} + 2e^- \rightarrow 2\,OH^- \quad [12]$$

The steady-state conditions for $SO_4^-{}_{ads}$ and $OH\cdot_{ads}$ are

$$\frac{d[SO_4^-]}{dt} = 2k_9\,[S_2O_8^=] - k_9'\,[SO_4^-]^2 - k_{11}\,[SO_4^-][OH^-] + k_{11}'\,[SO_4^=][OH\cdot] = 0 \quad [13]$$

$$\frac{d[OH\cdot]}{dt} = k_{11}\,[SO_4^-][OH^-] - k_{11}'\,[SO_4^=][OH\cdot] - k_{12}\,[OH\cdot] = 0 \quad [14]$$

and

$$i = \mathbf{F}\,k_{12}\,[OH\cdot] \quad [15]$$

Assuming that the equilibrium of reaction [11] is on the left side in the studied pH region, $k_{11}'/k_{11} >> 1$, and that $k_{12} << k_{11}'$, the following relation is obtained for the current at a constant potential

$$i = -\mathbf{F}\frac{k_{11}\,k_{12}}{k_{11}'}\sqrt{2\frac{k_9}{k_9'}}\frac{[OH^-][S_2O_8^=]^{1/2}}{[SO_4^=]} \quad [16]$$

This result is in agreement with the reaction order of 0.5 found for the $S_2O_8^=$ ion at low concentrations (Fig. 4). Furthermore, it gives an explanation for the pH dependence of reaction [4], although the experimental data in Fig. 3 are not sufficient to determine if the reaction order of OH^- is actually one. Finally, Eq. [16] shows that an increase of the sulfate ion concentration will decrease the current. This was also observed in the experiments; however, a passivation of the PbO_2 surface by formation of lead(II) sulfate may have a similar effect.

Acknowledgments

The author would like to thank U. B. Thomas and P. C. Milner for their interest in this work and many helpful discussions. He is also indebted to H. C. Montgomery for the provision of facilities for the Hall effect measurements and to G. W. Kammlott for carrying out the electron diffraction and electron microscopic studies.

Electrochemical Behavior of Selenium and Tellurium in Fused LiCl-KCl Eutectic

F. G. Bodewig and James A. Plambeck***

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada

ABSTRACT

Liquid selenium has been reduced coulometrically in fused LiCl-KCl eutectic at 400°C. Nernstian behavior is observed for the cell C,Se(1)/$Se^=$, LiCl-KCl//Pt^{++},LiCl-KCl/Pt. The standard potentials of the selenium/selenide couple at 450°C with respect to the appropriate standard platinum reference electrode are −1.141, −1.172, and −1.252V on the molar, molal, and mole fraction scales, respectively. Voltammetric studies showed an anodic wave at +0.05V ascribed to $2Se + 2Cl^- \rightarrow Se_2Cl_2(g) + 2e^-$ and a cathodic wave at −1.07V ascribed to $Se + 2e^- \rightarrow Se^=$. For tellurium an anodic wave at −0.15V is ascribed to Te → Te(II) + $2e^-$ and a cathodic one at −1.40V to the plating of lithium into tellurium; the formation of free telluride does not appear to occur. The standard potential for the couple Te(II)/Te is estimated at −0.1V.

A recent publication from this laboratory (1) reported the electrochemical behavior of sulfide in the fused LiCl-KCl eutectic. The present paper extends this study to selenium and tellurium.

The literature on selenium and tellurium in fused salt media is scanty. Verdieck and Yntema (2) measured the deposition potential of tellurium from solutions of tellurium dioxide in fused $AlCl_3$-NaCl-KCl at 218°C. The solid electrolyte cells Ag(s)/AgI(s)/Ag in Te or Se have been investigated by Kiukkola and

** Electrochemical Society Active Member.
* Electrochemical Society Student Member.

Wagner (3). Foster and Liu (4) employed the cell $Li_3Bi(s)$, Li in Bi(l)/LiCl-LiF/Li in Te(l), Li_2Te to obtain the free energy of formation of Li_2Te by emf measurements, and a similar cell has been used in the Bi-Te system by Liu and Angus (5). Selenium and tellurium have been used as cathode materials in secondary cells with fused salt electrolytes at Argonne National Laboratory (6, 7).

Experimental

Apparatus.—Potentials were measured with a digital voltmeter (Model 3440A, Hewlett-Packard). Coulometric generations employed a Model IV Coulometric Current Source (E. H. Sargent and Company). An Anotrol Model 4100 Potential Controller was used for voltammetric investigations.

A Lindberg Hevi-Duty Model 54381A furnace with a Model 59344 temperature controller was employed. Temperatures were measured with a chromel-alumel thermocouple calibrated at the melting point of zinc.

The electrolytic cell was essentially the same as described previously (8).

Solvent.—The preparation of the LiCl-KCl eutectic solvent (59.5 m/o LiCl, mp 352°C) has been described previously (1).

Chemicals.—Reagent grade LiCl (Fisher Scientific Company) and KCl (Fisher Scientific Company or Shawinigan Chemicals) were used. Selenium (99.99%) was obtained in ¼ x 2 in. rods from A. D. Mackay, Inc. Tellurium (99.999%) was obtained from Atomergic Chemetals Company. Graphite electrodes were Special Spectroscopic Electrodes ⅛ in. in diameter (National Carbon Company). Argon was dried by passage through a magnesium perchlorate column and two traps cooled by a dry ice-acetone bath.

Electrodes.—A reference electrode based on the Pt(II)/Pt couple (about 0.03M) was generated coulometrically for each experiment by anodization of a coil of platinum wire.

The selenium electrode consisted of a small Pyrex cup (7 mm diameter, 5 mm long) containing pieces of selenium. Contact with the selenium (liquid at operating temperature) was made with a graphite rod attached to Nichrome leads well above the melt level. The Pyrex cup rested on the bottom of the isolation compartment and was totally immersed in the melt.

The tellurium electrodes were made by melting lumps of tellurium in a 4 mm Pyrex tube under argon. A tungsten wire was inserted into the liquid tellurium which was then allowed to solidify. The electrode was removed by carefully breaking the glass.

A graphite rod in an isolation compartment was used as the counterelectrode.

Procedure.—The crucible containing the frozen eutectic, isolation compartments, and electrodes was placed inside the outer glass jacket of the electrolytic cell which could be connected to a vacuum pump. Transfers of frozen eutectic to the crucible were made inside a dry box under nitrogen. The outer jacket was closed to the atmosphere by means of a Pyrex cap connected to it with a 75 mm O-ring joint. On this cap were blown five 14/20 ground-glass joints which were used to insert a thermocouple, an argon inlet tube, and the electrodes. The isolation compartments were made of 10 mm Pyrex sealing tubes with 10-20μ frits (D porosity; Ace Glass Inc.) The temperature of the cell was slowly raised to 370°C under vacuum in order to dry the glass equipment and electrodes before fusion of the eutectic. After fusion of the eutectic, argon was introduced and bubbled through the melt during all experiments. The compartments were allowed to fill with eutectic during a period of 8-10 hr. The selenium or tellurium was added as a final step. Ionic species were generated by anodization or cathodization of the selenium or tellurium. The cells were operated at 400° ± 2°C to minimize loss of volatile materials from the melt, which was still the most serious problem encountered in the investigation.

Electrode potentials were measured against the platinum reference electrode and corrected to the Pt(II), 1.0 *M*/Pt standard molar platinum electrode (SMPE) of Laitinen and Liu (9); they are reported in conformance with the IUPAC "Stockholm" sign convention. The thermoelectric potential of the graphite and leads was measured as +10 mV with respect to platinum. It was essentially invariant with temperature from 400° to 450°. The potentials were corrected for this effect. They were then converted from 400° to 450°C using the experimentally determined potential-temperature relationships (see below) and the actual temperature of each potential measurement. The amount of solvent in each isolation compartment was determined by a potentiometric chloride titration; when necessary, selenide was removed by acidification (in a hood). The concentrations of $Se^=$ and Pt^{++} were determined from the coulombs passed and solvent volume (9). The least-square calculations were done on the University of Alberta IBM/360 computer, and copies of the programs used are available in the thesis of one of the authors (F.G.B.).

The voltammetric procedure was as described previously (1).

Results

Voltammetric results.—The voltammetric curves obtained for selenium and tellurium are shown in Fig. 1, denoted respectively by triangles and circles. In the absence of selenium and tellurium, the only electrochemical phenomena observed are anodic chlorine evolution (+0.3V) and cathodic lithium deposition (>−2.1V) as in previous work (1, 9).

The cathodic branch observed with selenium is ascribed to $Se(l) + 2e^- \rightarrow Se^=$. A red-brown color was observed leaving the electrode until the entire compartment contents were colored when cathodic current was passed. Extrapolation of the linear part of the curve to zero current gave −1.07 ± 0.02V for the "decomposition" potential, in good agreement with the potentiometric results given below. The anodic wave is ascribed to $2Se(l) + 2Cl^- \rightarrow Se_2Cl_2(g) + 2e^-$, analogous to the reaction $2S(l) + 2Cl^- \rightarrow S_2Cl_2(g) + 2e^-$ observed previously (1). The "decomposition" potential was +0.05 ± 0.02V. Colorless gas bubbles were observed forming on the electrode at this potential and leaving the melt. No attempt was made to trap the gas since Se_2Cl_2 is reported as unstable at considerably lower temperatures than those employed here. Stable potentials could not be obtained, as is expected when the species produced electrochemically volatilizes from the melt.

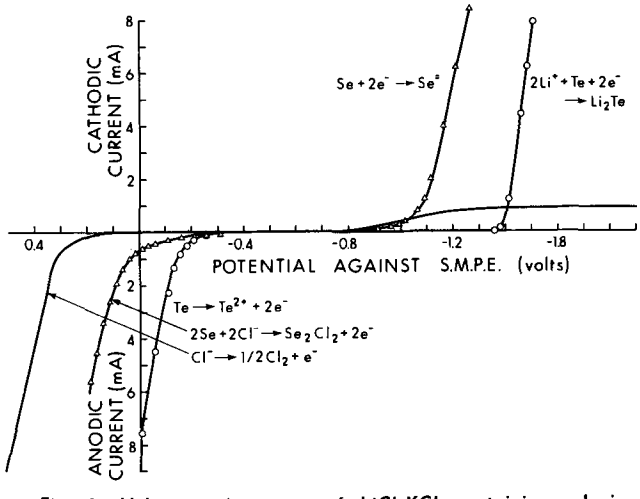

Fig. 1. Voltammetric curves of LiCl-KCl containing selenium (triangles) or tellurium (circles). Temperature 400°C, reference potential SMPE. Area of selenium pool approximately 0.4 cm^2, of tellurium rod 1.1 cm^2. Voltammetric curve of pure melt on graphite electrode is line without symbols.

Voltammetric curves were also taken with selenium electrodes in compartments in which selenide had been generated. Two typical curves are shown in Fig. 2. Identical straight lines were always obtained regardless of the direction of voltage change as long as precautions were taken to prevent significant changes in the ion concentration between measurements. These precautions included stirring and, when necessary, oxidation or reduction such that the zero current potential remained within 3 mV of its original value. The slope of these lines was approximately 15 ohms and represents the cell resistance. These curves show the $Se/Se^{=}$ couple to be reversible in this solvent system.

The cathodic branch observed with tellurium (Fig. 1) is ascribed to the formation of stable lithium-tellurium intermetallic compounds whose limiting composition is Li_2Te (4); the reaction written as $Te(s) + 2Li^+ + 2e^- \rightarrow Li_2Te(s)$ is probably an oversimplification. The potential characteristic of this reaction was -1.40 ± 0.02V. Liquid alloys were observed to form on the tellurium rod on cathodization beyond this potential. Such alloy formation on cathodization has been observed in previous studies of the Li-Te system (4, 10). The anodic wave is ascribed to $Te \rightarrow Te(II) + 2e^-$. An orange-brown color was observed leaving the electrode upon anodization. The "decomposition" potential for this reaction was -0.15 ± 0.03V, in good agreement with the potentiometric measurements given below.

Potentiometry of selenium.—Three complete experiments, each involving multiple cells, were carried out with new compartments, electrodes, and eutectic charge used in each. A total of 52 data points were taken at 400° ± 2°C. For each point, the emf became constant, within 0.5 mV, 30-90 min after completion of coulometric reduction of selenium and stirring. The potential was thereafter constant, within 1 mV, over several hours.

The effect of temperature on the emf was determined in several experiments over the temperature range 380°-420°C, with both increasing and decreasing temperature. The measured potential was, for a fixed selenide concentration, linearly dependent on temperature. A plot of $\Delta E/\Delta T$ against the logarithm of the molar concentration (as moles $Se^{=}$/liter of eutectic at 450°C) was linear (Fig. 3). Least square analysis of this plot gives $\Delta E/\Delta T = +0.123 \log [Se^{=}] - 0.510$ mV/°C, with a relative standard error of 6% in the slope and 1.5% in the intercept, for the temperature dependence of the cell (−)C, Se(l)/$Se^{=}$, LiCl-KCl// Pt(II), LiCl-KCl/Pt (+). This equation is identical to that obtained for the analogous sulfide cell (1) within experimental error. It was used to extrapolate all measured potentials to 450°C. This temperature is accepted as standard for potential measurements in this fused salt system [(11), and references cited therein].

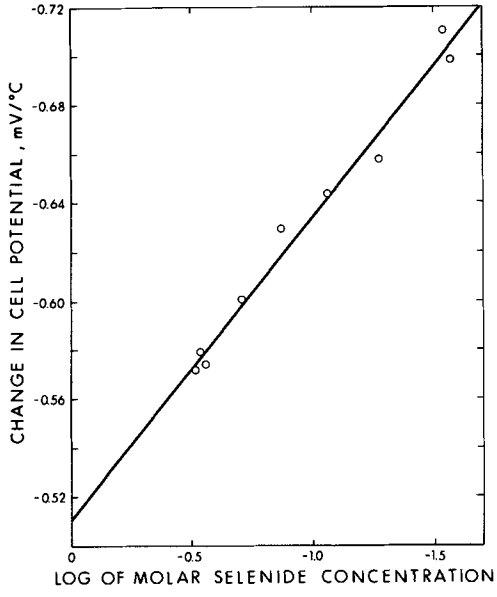

Fig. 3. Temperature dependence of potential as a function of selenide ion concentration. Line is that given by least-squares analysis. Temperature range 380°-420°C.

These extrapolated potentials gave linear Nernst plots over the concentration range 0.015-0.35M selenide. A typical plot of potentials against the logarithm of selenide concentration (Fig. 4) shows that Henry's law is obeyed over the concentration range studied. A summary of all runs is given in Table I; the original data are available in the thesis of F.G.B. Least square analysis of all points gave a standard potential of -1.141V for the Se(l)/$Se^{=}$ couple (molarity scale) at 450°C, with a standard error of 0.002V. This corresponds to values of -1.172 and -1.252V, with the same standard error, on the molality and mole fraction scales, respectively (11), all potentials being with respect to the appropriate standard platinum electrode. The slope of the Nernst plot was -0.0660 V/log unit with a standard error of 0.0014, corresponding to 2.17 ± 0.05 electrons taking part in the reaction. This is in agreement with the theoretical value of 2 expected for $Se + 2e^- \rightarrow Se^{=}$.

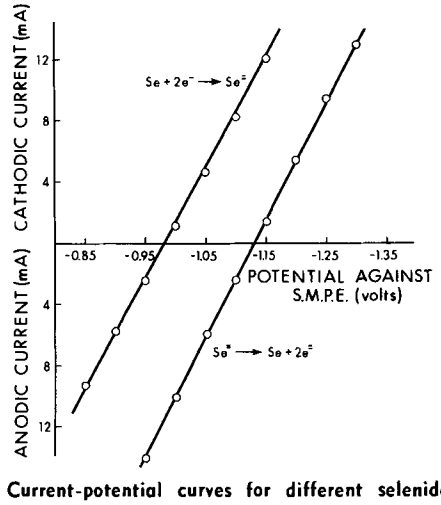

Fig. 2. Current-potential curves for different selenide concentrations in the same compartment. Reference potential SMPE, temperature 400°C.

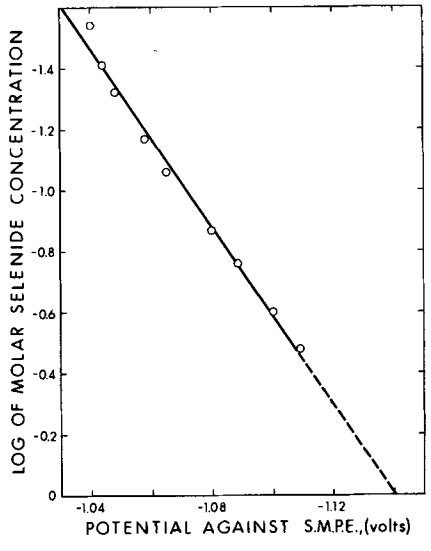

Fig. 4. Electromotive force of selenide electrode (vs. SMPE) as a function of selenide concentration in a typical run, showing obedience to Henry's law. Temperature (extrapolated) 450°C.

Table I. Standard emf determinations for the $Se/Se^{=}$ couple*

* Values corrected to 450°C and SMPE; each entry is a separate compartment, the first being run 1, the next two being run 2, and the remainder being run 3.

Stable potentials could not be obtained on anodization of selenium electrodes, for the reasons discussed above.

Potentiometry of tellurium.—Attempts were made to measure the standard potential of the $Te(s)/Te^{=}$ couple. These attempts were unsuccessful because the solubility of "Li_2Te" in the LiCl-KCl eutectic in the presence of excess tellurium is very low; even an attempt to produce $2 \times 10^{-3}M$ $Te^{=}$ resulted in the formation of liquid on the surface of the tellurium electrode. The potentials obtained in this manner were quite stable. They correspond, after correction for reference electrode, to those observed by Foster and Liu (4) for very tellurium-rich alloys of lithium and tellurium in a similar system, and therefore cannot be considered as true tellurium/telluride electrode potentials.

Anodization of tellurium produced an orange-brown solution. Long needles of tellurium were observed extending from the electrode. The potentials measured were unstable, however, and drifted in the negative direction continuously after anodization was completed. At the same time, the color of the solution slowly disappeared. A yellow powder sometimes condensed in the cooler top of the isolation compartment. This behavior would be expected if a volatile species such as $TeCl_2$ (bp 327°C) escaped from solution at 400°. The experiment was repeated at 375°, but the species formed still volatilized from solution.

Attempts to produce meaningful Nernst plots from the potential data for this system were unsuccessful. The slope varied between 0.067 and 0.134 V/log unit. Since 0.033 V/log unit would be expected for a four-electron process, the ionic species produced should be Te(II) rather than Te(IV). From these plots and the voltammetric curves the standard potential (molarity scale) of the Te(II)/Te(s) couple is estimated as -0.10 ± 0.03V, placing it between Rh(III)/Rh and Ir(III)/Ir couples in this medium (11). Attempts to further oxidize the Te(II) species at a graphite electrode were unsuccessful.

Discussion

The potential between selenium and lithium electrodes, using literature data for lithium (11) and the result of the present study for selenium, is 2.2V at 450°C. This is in good agreement with the open-circuit potentials of 2.3-2.4V obtained from the Li/Se secondary cell between 350° and 400°C (7) and implies that at nearly full charge the selenium electrode potential of that cell may well be determined by soluble $Se^{=}$ in the electrolyte rather than electrode composition. The free energy of the reaction $2Se(l) + Cl_2 \rightarrow Se_2Cl_2(g)$ can be estimated as −11 kcal/mole from the voltammetric curves. No literature data could be found with which to compare this value; it seems reasonable, however, as it is similar to that for the formation of gaseous S_2Cl_2 (1).

The Li/Te secondary cell is reported (4, 6) to have an open-circuit voltage of 1.7-1.8V which is in agreement with the value of 1.9V obtained from the voltammetric curves of the present study.

There is a significant point raised in the present work related to lithium-chalcogen cells. Clearly, a soluble selenide species determines the potential of the selenium electrode under the conditions of the present study. Such a species, whether $Se^{=}$ or Li_2Se, can be expected to be present in Li/Se cells (6) and to diffuse to the lithium electrode if cell construction so permits. This will lead to reduced cell efficiency and eventual cell failure. The problem appears less significant in the Li/Te system due to lower solubility of the species produced.

Kinetics of the Hydrogen Evolution Reaction on Titanium

N. T. Thomas* and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California

ABSTRACT

The kinetics of the hydrogen evolution reaction on titanium in sulfuric acid solutions between pH 0.25 to 2.25 have been investigated. The Tafel slope of the HER was 150 mV at all pH values, and the electrochemical reaction order was 0.6 with respect to the hydrogen ions. The corrosion potential varied negligibly with pH; $(\partial \log i_{corr}/\partial \text{ pH}) = -0.57$; $(\partial \log i_o/\partial \text{ pH}) = -0.23$. If it is assumed that a thin incipient oxide film covers the surface of active titanium, a mechanism for the HER based on Temkin adsorption behavior, electrochemical desorption as the rate-determining electrode reaction step, and the dual barrier model is consistent with the experimental results.

There have been a number of investigations of the hydrogen evolution reaction (HER) on titanium in aqueous solutions. However, a mechanistic study of the HER on titanium has not been reported thus far.

Hackerman and Hall (1) reported an HER Tafel relationship of $\eta' = 1.30 + 0.154 \log i$, volts, for titanium in sodium chloride solutions. Straumanis *et al.* (2) and Andreeva (3) obtained HER Tafel slopes of 175 and 160 mV for titanium in 0.5*N* and 40% H_2SO_4, respectively. Kolotyrkin and Petrov (4) observed the Tafel behavior of $\eta' = 0.82 + 0.135 \log i$, volts, and a first order dependence on the concentration of hydrogen ions for the HER on titanium in sulfuric acid solutions. Petrenko (5) and Artemova (6) obtained Tafel relationships of $\eta' = 0.97 + 0.119 \log i$ and $\eta' = 0.97 + 0.135 \log i$, volts, for titanium in 2*N* H_2SO_4, respectively.

This work is an investigation of the kinetics and mechanism of the HER on titanium in sulfuric acid solutions of pH ranging from 0.25 to 2.25 at room temperature. Experimental details have been given elsewhere (7).

Results

Figure 1 shows the results of the cathodic polarization of titanium in sulfuric acid solutions. The HER Tafel slope was 150 mV for all pH values. It should be observed that deviations from the Tafel behavior occurred at about −1.0V *vs.* SCE for all pH values. At more active potentials, the current density was greater than the value obtained by extrapolating the Tafel line. This behavior suggests the possible commencement of a second reduction process.

As shown in Table I, the corrosion potential did not vary significantly with the pH. The corrosion current at each pH was determined by extrapolating the Tafel line to the corrosion potential. These values and the exchange current densities are also given in Table I.

Figure 2 is a cross plot of the data in Fig. 1. The log i *vs.* pH lines at constant potential ψ, in the Tafel region, are all parallel with slope

$$\left(\frac{\partial \log i}{\partial \text{pH}}\right)_{\psi} = -0.60 \qquad [1]$$

Similarly, the ψ *vs.* pH lines at constant current i, in the Tafel region, are all parallel as shown in Fig. 3. The slopes were

$$\left(\frac{\partial \psi}{\partial \text{pH}}\right)_{i} = -90 \text{ mV} \qquad [2]$$

Figure 4 gives the dependence of the corrosion current on the pH of the solution and shows that

$$\frac{\partial \log i_{corr}}{\partial \text{pH}} = -0.57 \qquad [3]$$

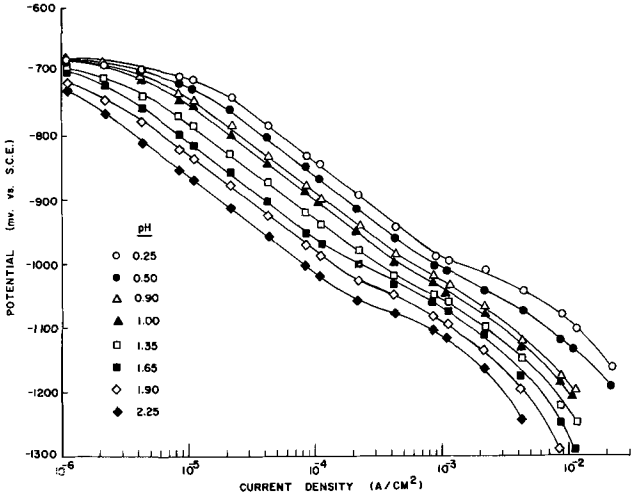

Fig. 1. Cathodic polarization curves of titanium in H_2SO_4

The dependence of the exchange current of the HER on the pH is given in Fig. 5 and shows that

$$\frac{\partial \log i_o}{\partial \text{pH}} = -0.23 \qquad [4]$$

Values of the Tafel slopes and the exchange current densities for the HER obtained in this investigation are comparable to the values reported by other investigators (1, 2, 4-6). The corrosion rates are in reasonable agreement with the values reported by Millaway (8).

In the Tafel region, the rate of the HER can be expressed as

$$i = k a_{H^+}{}^n \exp\left(\frac{-\alpha F \psi}{RT}\right) \qquad [5]$$

where k is the rate constant, a_{H^+} is the activity of the hydrogen ions, α is the over-all transfer coefficient, and n is the electrochemical reaction order with respect to the hydrogen ions. The over-all transfer coefficient, $\alpha = 0.4$, is determined from the cathodic Tafel slope of 150 mV. The slope of the curves in Fig. 2

Table I. Cathodic parameters of titanium in H_2SO_4

pH	Active corrosion potential, mV *vs.* SCE	Tafel slope, mV	Corrosion current, μA/cm²	Exchange current, μA/cm² × 10³	$R_p \times 10^{-3}$, ohm-cm²
0.25	−680 ± 10	150	9.0 ± 0.7	15.4 ± 1.2	4.0 ± 0.5
0.50	−675	150	6.0	13.5	5.7
0.90	−670	150	3.4	11.5	8.0
1.00	−665	150	2.9	10.5	11.0
1.35	−678	150	2.0	8.8	14.0
1.65	−675	150	1.4	7.5	23.0
1.90	−680	150	1.0	6.5	34.0
2.25	−685	150	0.6	5.5	51.0

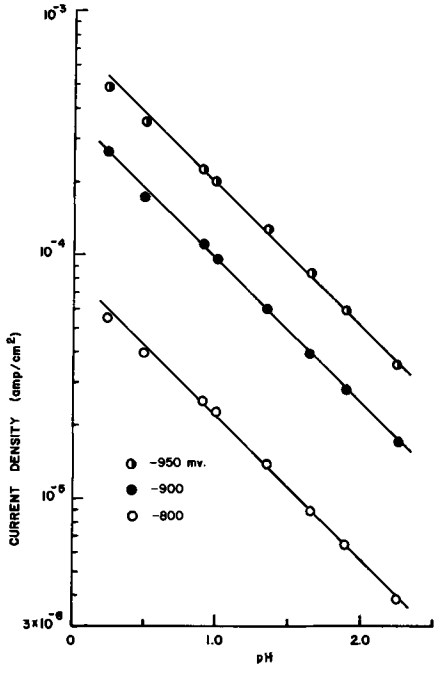

Fig. 2. Plot of logarithm of current density *vs.* pH in the Tafel region of the HER.

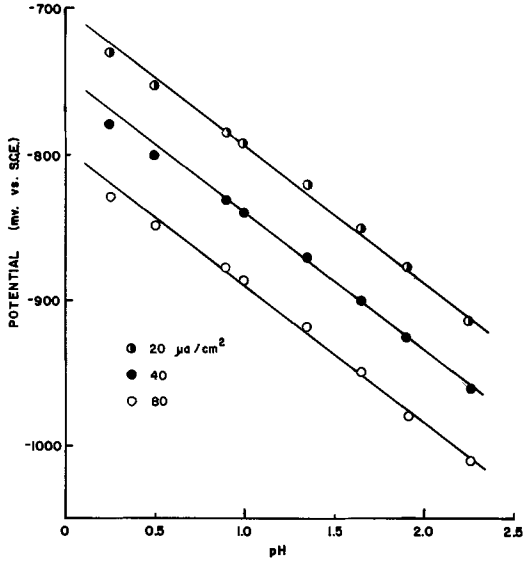

Fig. 3. Plot of potential *vs.* pH in the Tafel region of the HER

gives the reaction order

$$n = -\left(\frac{\partial \log i}{\partial pH}\right)_{\psi} = 0.60 \qquad [6]$$

Equation [5] shows that $(\partial\psi/\partial pH)_i = -2.303\ RT/\mathbf{F}$ $n/\alpha = -90$ mV which agrees with the experimental value of Eq [2]. The equation for the exchange current density can be obtained from Eq. [5]

$$i_o = k a_{H^+}{}^n \exp\left(\frac{-\alpha \mathbf{F}\psi_o}{RT}\right) \qquad [7]$$

It follows from Eq. [7] and the Nernst equation, $\psi_o = -2.303\ RT/\mathbf{F} \log a_{H+}$ that $i_o = k a_{H^+}{}^{n-\alpha}$. Thus

$$\frac{\partial \log i_o}{\partial pH} = -0.20 \qquad [8]$$

which is in good agreement with Eq. [4]. The equation for the corrosion current can also be obtained from Eq. [5]

$$i_{corr} = k a_{H^+}{}^n \exp\left(\frac{-\alpha \mathbf{F}\psi_{corr}}{RT}\right) \qquad [9]$$

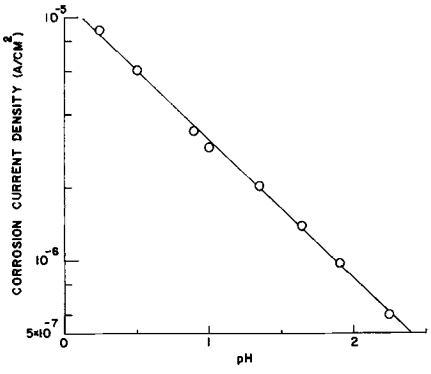

Fig. 4. Dependence of corrosion current on pH

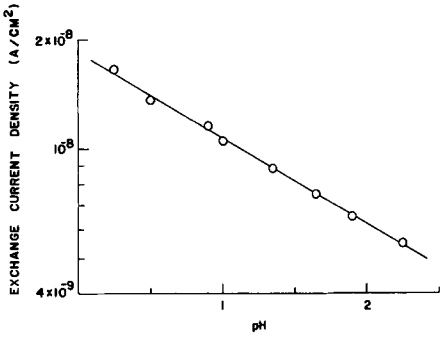

Fig. 5. Dependence of the HER exchange current on pH

From Eq. [9], the pH dependence of the corrosion current can be determined

$$\frac{\partial \log i_{corr}}{\partial pH} = -n + \frac{\alpha \mathbf{F}}{2.3RT}\left(\frac{\partial \psi_{corr}}{\partial pH}\right) \qquad [10]$$

Since it has been shown that $\partial\psi_{corr}/\partial pH \approx 0$

$$\frac{\partial \log i_{corr}}{\partial pH} \approx -n = -0.60 \qquad [11]$$

and this value agrees well with Eq. [3].

Since a single anodic process and a single cathodic process can describe the corrosion of titanium in sulfuric acid, the polarization current can be expressed as

$$i = i_{corr}\left[\exp\left(\frac{\alpha_a \mathbf{F}\eta}{RT}\right) - \exp\left(\frac{-\alpha_c \mathbf{F}\eta}{RT}\right)\right] \qquad [12]$$

where α_a and α_c are the over-all transfer coefficients of the anodic and cathodic processes, respectively, and $\eta = \psi - \psi_{corr}$. From Eq. [12] the relation between the polarization resistance, R_p, and the corrosion rate, i_{corr}, can be determined (9)

$$R_p = \left(\frac{\partial \eta}{\partial i}\right)_{\eta \to 0} = \frac{RT}{i_{corr}(\alpha_a + \alpha_c)\mathbf{F}} \qquad [13]$$

Figure 6 shows a linear plot of $(\psi - \psi_{corr})$ *vs.* the applied current for titanium in sulfuric acid of various pH values. The slope of each curve is the polarization resistance which is given in Table I. A plot of log R_p *vs.* log i_{corr} is shown in Fig. 7. It is seen that a slope of -1 correlated the data well. The polarization resistance-corrosion current values were comparable to those values obtained for a number of different metals as shown in Fig. 5 of ref. (10).

The $R_p - i_{corr}$ data and $\alpha_c = 0.40$ indicates that $\alpha_a = 0.44$. Thus, an anodic Tafel slope of 136 mV for titanium electrodissolution can be estimated.

Equation [5] can be expressed as

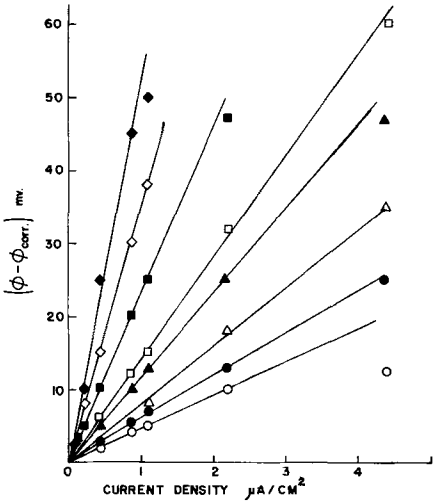

Fig. 6. Linear plot of (ψ—ψ_{corr}) vs. current density. Same symbols as in Fig. 1.

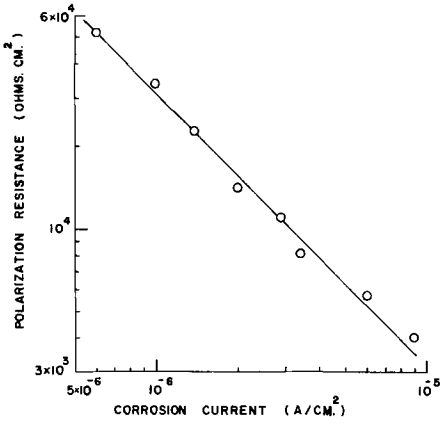

Fig. 7. Log. polarization resistance (ohm cm^2) vs. log corrosion current (A/cm^{-2}).

$$i_{corr} = k a_{H^+}{}^n \exp\left(\frac{-\alpha_c \mathbf{F} \psi_{corr}}{RT}\right) \quad [14]$$

Equations [13] and [14] can be used to express the pH dependence of the polarization resistance as shown in Eq. [15]

$$\frac{\partial \log R_p}{\partial pH} = n + \frac{\alpha_c \mathbf{F}}{2.303\, RT}\left(\frac{\partial \psi_{corr}}{\partial pH}\right) \quad [15]$$

Since it has been shown that $\partial\psi_{corr}/\partial pH \approx 0$

$$\frac{\partial \log R_p}{\partial pH} \approx n = 0.60 \quad [16]$$

Figure 8 shows a plot of log R_p vs. pH. The slope of the straight line which best fits the experimental points is 0.57 and agrees well with Eq. [16]. The slope of Fig. 8 is also consistent with the results given in Eq. [3]. The above analysis has shown that the experimental results of this investigation are self-consistent.

The rate of the HER on titanium in sulfuric acid between pH 0.25 to 2.25 can be expressed by the equation

$$i = k a_{H^+}{}^{0.6} \exp\left(\frac{-0.40 \mathbf{F} \psi}{RT}\right) \quad [17]$$

Figure 9 shows the results of the measurements of the differential capacitance of titanium in pH 0.25 solutions as a function of potential. At potentials more negative than the active corrosion potential, the capacitance decreased with decrease in potential. A minimum capacitance value is attained at approximately

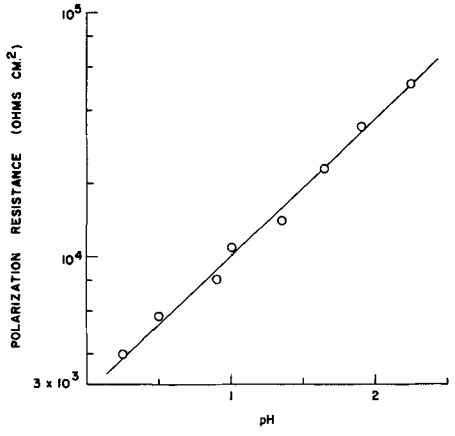

Fig. 8. Dependence of the polarization resistance on pH

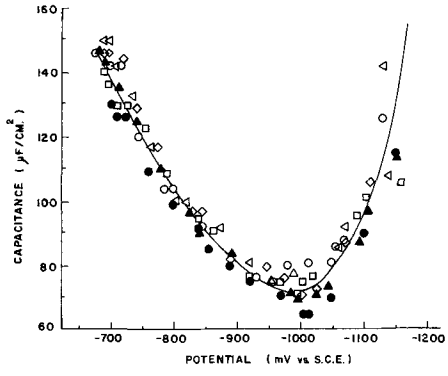

Fig. 9. Differential capacitance of titanium in 1N H_2SO_4 as a function of potential.

−1.0V. The capacitance increased again with further decrease in potential.

Discussion

The reaction steps in the HER which are generally considered are Eq. [18], [19], and [20]:

$$H^+ + e^- \rightarrow H_{ads} \quad [18]$$

and

$$H^+ + H_{ads} + e^- \rightarrow H_2 \quad [19]$$

or

$$H_{ads} + H_{ads} \rightarrow H_2 \quad [20]$$

A detailed account of the mechanisms of the HER on metals, assuming the applicability of the Langmuir isotherm for the adsorption of hydrogen atoms, is given by Bockris (11). Parsons (12), Thomas (13), and Conway and Salomon (14) have considered the kinetics of the HER using the Temkin isotherm for the adsorbed hydrogen atoms.

The experiments of Tomashov *et al.* (15) show that a mixed oxide film of TiO_2 and Ti_2O_3 is present on the surface of passive titanium. The thermodynamic data of these oxides indicate their possible presence even on active titanium in the Tafel region of the HER

$$Ti + 2H_2O = TiO_2 + 4H^+ + 4e^-; \quad \psi^o = -1.100\text{V } vs.\text{ SCE} \quad [21]$$

and

$$2Ti + 3H_2O = Ti_2O_3 + 6H^+ + 6e^-; \quad \psi^o = -1.405\text{V } vs.\text{ SCE} \quad [22]$$

The presence of other titanium oxides are also possible in the HER Tafel region, and it is surmised that in this region a thin oxide film is always present on the surface of titanium.

Meyer (16) has utilized a dual barrier model to develop electrode kinetic equations for metals covered with thin oxide films. Meyer (16, 17) and Posey *et al.* (18) interpreted the kinetics of reduction reactions on

zirconium and passive steel, respectively, in terms of the dual barrier model. MacDonald and Conway (19) used this model to analyze the kinetics of the oxygen evolution reaction on gold. The electrode reaction rates for this model are dependent on the potential across the oxide film, ψ_f, and across the double layer in the electrolyte, ψ_d. Thus

$$\psi = \psi_f + \psi_d \quad [23]$$

The rate of electron transport through the thin oxide film can be described by Eq. [24]

$$i = k_f \exp\left(\frac{-\alpha_f \mathbf{F}\psi_f}{RT}\right) \quad [24]$$

where α_f is the transfer coefficient for the electromigration of electrons in the film and k_f is the film rate constant. It is assumed that the charge transfer across the film and the electrolyte double layer are both rate determining. Analysis has shown that experimental data is consistent with the electrochemical desorption step, Eq. [19], as the rate-determining step for the HER and with Temkin behavior for adsorbed hydrogen atoms. For this case

$$i = k' a_{H^+}^{(1+\beta)} \exp\left(-\frac{2\beta \mathbf{F}\psi_d}{RT}\right) \quad [25]$$

Equations [24] and [25] lead to Eq. [26]

$$i = k'' a_{H^+}^{\frac{(1+\beta)\alpha_f}{2\beta+\alpha_f}} \exp\left[-\frac{2\beta\alpha_f \mathbf{F}\psi}{(2\beta+\alpha_f)RT}\right] \quad [26]$$

Expressions for the reaction order and the HER Tafel slope can be determined from Eq. [26]

$$n = \frac{(1+\beta)\alpha_f}{2\beta+\alpha_f} \quad [27]$$

$$\frac{\partial\psi}{\partial \log i} = -2.303\frac{RT}{\mathbf{F}}\frac{(2\beta+\alpha_f)}{2\beta\alpha_f} \quad [28]$$

By substituting the experimental values, $n = 0.60$ and $\partial\psi/\partial \log i = 150$ mV, one obtains $\alpha_f = 0.67$ and $\beta = 0.5$. These derived values indicate that a mechanism consistent with the experimental results of the HER on titanium in sulfuric acid can be based on Temkin adsorption, electrochemical desorption as the rate-determining electrode reaction step, and the dual barrier model.

Bockris and Srinivasan (20) present a plot of log i_o of the HER *vs.* the work function of metals. This plot shows that the metals fall into three groups, those with high hydrogen overpotentials, medium hydrogen overpotentials, and low hydrogen overpotentials. The rate-determining step for the HER on these three groups of metals was ascribed to be ion discharge, electrochemical desorption, and recombination, respectively. This correlation shows that titanium is included in the medium hydrogen overpotential group, that is, the electrochemical desorption step is the rate-determining step which is in accord with the analysis of the experimental results of this work. In the present study, the values of log i_o for the HER on titanium in H_2SO_4 were between -7.8 to -8.3 for solutions of *p*H between 0.25 and 2.25 which is in good agreement with the data used in the correlation reported by Bockris and Srinivasan (20).

It was observed in the polarization of titanium in sulfuric acid that, at approximately -1.0V, deviations from Tafel behavior commenced with an anomalous increase in the cathodic current. A possible explanation of this phenomenon is the complete reduction of the incipient oxide film at this potential and the subsequent hydrogen ion discharge on oxide-free titanium. This interpretation seems to be in accord with the results of Beck (21) who reported that the rate of the HER on an oxide-free titanium surface in 12M HCl was greater than on an oxide-covered surface.

A second feasible explanation of the nonlinearity in the ψ-log i curve is the possible titanium hydride formation from the hydrated oxides Ti_2O_3 and TiO_2, at about -1.0V, as indicated by calculations based on thermodynamic data obtained from Pourbaix (22, 23)

$$Ti_2O_3 + 10H^+ + 10e^- = 2TiH_2 + 3H_2O; \quad \psi^o = -1.027\text{V } vs.\text{ SCE} \quad [29]$$

$$TiO_2 + 6H^+ + 6e^- = TiH_2 + 2H_2O; \quad \psi^o = -0.910\text{V } vs.\text{ SCE} \quad [30]$$

It should be noted that Pourbaix's calculations (22) were based on the standard free energy of formation of titanium hydride reported by Baymakov and Lebedev (24), ΔG_f^o (TiH_2) = 10.00 kcal/mole. On the other hand, thermodynamic data reported by Stalinski and Bieganski (25) indicate a value, ΔG_f^o (TiH_2) = -20.6 kcal/mole. Based on the latter value, the standard potentials of TiH_2 formation from Ti_2O_3 and TiO_2 are as follows

$$Ti_2O_3/TiH_2;\ \psi^o = -0.764\text{V } vs.\text{ SCE} \quad [31]$$

$$TiO_2/TiH_2;\ \psi^o = -0.692\text{V } vs.\text{ SCE} \quad [32]$$

It is also seen that, at approximately -1.0V, a minimum in the differential capacitance of titanium in 1*N* H_2SO_4 occurred as shown in Fig. 9. The potential of zero charge of titanium, -942 mV *vs.* SCE, was calculated from the work function by Petrenko (5). At present, no significance is attached to this apparent agreement between the potential of the capacitance minimum and the calculated potential of zero charge.

Specular Reflection Studies of Gold Electrodes *in situ*

T. Takamura, K. Takamura, W. Nippe, and E. Yeager*

Department of Chemistry, Case Western Reserve University, Cleveland, Ohio

ABSTRACT

Multiple specular reflection has been used to examine the gold electrode in acid and alkaline solutions. Reflectivity-potential and linear sweep voltammetry curves have been recorded simultaneously. The wavelength dependence indicates that reflectivity changes with potential arise principally because of the interaction of the d-c electric field at the interface with the internal photoelectric effect in gold corresponding to a 5d → 6s band transition. The results demonstrate that multiple specular reflection techniques are particularly well suited to *in situ* studies of the specific adsorption of ions, the formation of mono- and polylayer oxides, and the Faraday adsorption of ions such as lead and cadmium to form monolayers of these metals on gold.

Substantial interest has been expressed by electrochemists recently in the use of optical techniques for the examination *in situ* of electrode-solution interfaces. Ellipsometry and reflectance measurements have received the principal attention.

The purpose of this publication is to demonstrate how a simple multiple specular reflection technique can be used to obtain interesting information concerning adsorption phenomena, oxide formation, and the electronic properties of metal electrode surfaces. McIntyre (1) also has called attention to the suitability of specular reflection methods for *in situ* studies of adsorption and the formation of various layers. Holden and Ullman (2) have used specular reflectance to study anodic film formation interferometrically. Walter (3, 4) has used a grazing-angle specular reflection technique for *in situ* examination of electrode surfaces.

Gold electrodes were chosen for study not only because of their importance to electrochemistry but also because of the marked wavelength dependence of reflectance in the visible portion of the spectrum. An internal photoelectric effect (5-7) involving a 5d → 6s band transition ($L_{32} \rightarrow L_2$) leads to an edge in the optical reflectivity at approximately 2.3 eV or 5500Å. This transition should be sensitive to the interaction of surface orbitals with adsorbed species and the electric field at the interface. The plasmon excitation in gold is at ~8 eV, far in the vacuum ultraviolet.

Apparatus and Experimental Procedure

The measurement cell (Fig. 1) consisted of two flat gold electrodes mounted parallel with a 2-mm separation and backed by glass plates. These electrodes were connected in parallel and a third gold electrode (E in Fig. 1) was used as the counterelectrode in a compartment separated from the main compartment by a fritted glass disk. The potential of the parallel working electrodes was measured relative to a saturated calomel electrode in a separate vessel connected by a Luggin capillary whose tip was placed near the center of the parallel gold working electrodes but outside of the optical path. This arrangement is satisfactory provided the current density on the working electrodes is sufficiently small for no appreciable ohmic drop to occur in the electrolyte between them. Such was true for all of the work reported here with the exception of the cathodic peak associated with oxide reduction.

This cell was not gas tight and hence should be considered a preliminary model. Air-saturated solutions were used rather than having the solutions contaminated with some unknown amount of O_2 from the air. The electrolyte solutions were prepared from

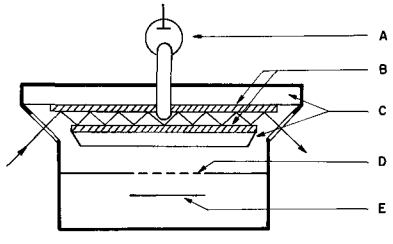

Fig. 1. Schematic diagram of specular reflection electrochemical cell. A, reference electrode (SCE): B, gold plates (working electrode).

* Electrochemical Society Active Member.

high-purity reagent grade chemicals and triply distilled water. The $HClO_4$ and H_2SO_4 solutions were pre-electrolyzed with gold electrodes. The NaOH solutions were not pre-electrolyzed and hence were contaminated with iron and other species.

The flat gold plates used as working electrodes were 99.99% pure, 0.5 mm thick, 25 mm high, and about 40 mm in length. They were polished on a flat glass plate with 5μ alumina grinding powder followed by 0.3μ chromic oxide grinding powder. After final polishing, the plates were cleaned with acetone, hot sodium hydroxide-ethanol mixture, and pure concentrated nitric acid, and finally rinsed with triply distilled water.

A monochromatic beam from a Beckmann DU spectrophotometer with a tungsten source was passed through the optically flat cell windows (Fig. 1) into the electrolyte and externally reflected approximately 20 times between the working electrodes at an angle of incidence near 50°. The reflected light was detected by a photomultiplier (RCA 1P28) and the signal then amplified with a chopper amplifier (Beckmann Model 5800) and fed to an X-Y plotter (Mosley Model 7000A) on which was also displayed the potential of the parallel gold electrodes *vs.* the reference electrode. The linearity of the photomultiplier-amplifier system with respect to optical intensity was checked by comparison with the detection-readout system ordinarily used with the Beckmann DU spectrophotometer. No polarizer was used in the optical system, but after a few specular reflections from the gold the light became plane polarized perpendicular to the plane of incidence.

Linear sweep cyclic voltammetry curves were recorded simultaneously on a second X-Y plotter in the usual manner with a Wenking potentiostat and Hewlett-Packard function generator (Model 3300A) at voltage sweep rates normally between 33 and 100 mV/sec. All potentials in this paper are relative to the saturated calomel reference electrode. The temperature was 22°-23°C.

Results

A typical reflectivity-potential curve at 5400Å and corresponding linear sweep voltammetry curve are given in Fig. 2 for a 0.2*M* $HClO_4$ solution. Small variations occur in the reflectivity and reflectivity dependence on potential from sample to sample, depending on the quality of the surface finish, but the shapes of the curves are invariant. Specific adsorption effects should be relatively small in this solution. The reflectivity-potential curve consists of two regions: linear characterized by slight hysteresis; and nonlinear corresponding to formation of an oxide layer and characterized by large hysteresis. Formation of stable gold oxide begins at about +1.1V on the anodic sweep branch (8-12) and at the same potential the reflectivity begins to decrease rapidly. The over-all decrease in Fig. 2 amounts to about 1% per single reflection. During the reverse potential sweep the reflectivity remains constant until the oxide layer starts to be reduced at about 1.0V. The large peak in the cathodic sweep in the voltammetry curve at 0.98V is attributed to the reduction of the oxide. Similar reflectivity-potential curves were obtained at all wavelengths (4800-8000Å) in both $HClO_4$ and H_2SO_4 solutions, although at wavelengths longer than 6000Å the plots showed some curvature in the region from 0 to 1.0V.

In Fig. 3 are superimposed the curves for the potential dependence of charge and reflectivity changes associated with formation and reduction of the oxide layer in 0.2*M* $HClO_4$. The charge-potential curve was obtained by integrating the voltammetry curve of Fig. 2. The reflectivity changes plotted in this figure correspond to the difference between the observed relative reflectivity in Fig. 2 and the value obtained by a linear extrapolation of the reflectivity change-potential curve recorded while scanning anodically in the potential range 0-1.0V. The two curves, including the hysteresis effects, correlate fairly well providing further evidence of the formation of the oxide layer and the attending reflectivity changes. At more anodic potentials in Fig. 3, the oxide layer is certainly more than a monolayer. Curves similar to those given in Fig. 3 have been obtained in 0.5*M* NaOH. Both the reflectivity and charge curves in Fig. 3 may be somewhat distorted by IR drop within the solution and nonuniform current distribution on the electrode surfaces.

The reflectivity change-potential curve in Fig. 3 resembles corresponding plots of the relative amplitude and phase retardation *vs.* potential obtained by Sirohi and Genshaw (12) from ellipsometric measurements on gold at 5500 and 6328Å in acid solutions at potential steps of 0.1V.

The relationship between the change in reflectivity and the extent of oxidation of the surface has been further examined by recording simultaneously the change in reflectivity and the charge passed as a function of time when the potential is stepped from a value just below that at which oxide starts to form (0.96V) to a value sufficient to form a multilayer oxide (*e.g.*, 1.20V). The plots of the change in reflectivity *vs.* charge associated with formation of oxide indicate two linear regions (Fig. 4) with the change in slope occurring at ~500 μcoul/cm^2, which probably corresponds to the completion of monolayer coverage.

The reflectivity-potential and voltammetry curves for an alkaline solution are shown in Fig. 5. The presence of oxygen in the solution contributed waves associated with the O_2-HO_2^- couple in the anodic and cathodic sweeps at potentials in the range 0 to −0.20V. The hysteresis in this potential range is probably caused by this couple. In contrast to the results in acid solution at wavelengths shorter than 6000Å, the non-oxide portion of the reflectivity-potential curve in NaOH solution is no longer characterized by a single linear region but rather appears to consist of two approximately linear portions intersecting at about −0.40V for the sweep in either the anodic or cathodic direction. This potential value corresponds to the point

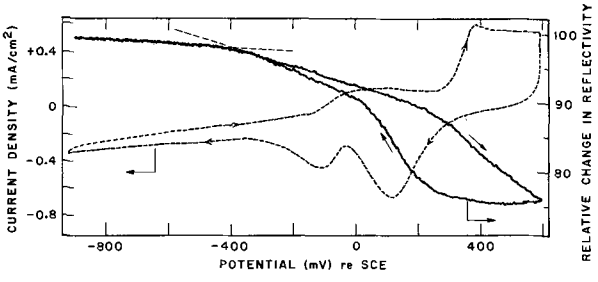

Fig. 5. Relative change in reflectivity-potential (—) and current-potential (- -) curves of gold in 0.5M NaOH at 22°C. Potential sweep rate, 104 mV/sec; wavelength, 5400Å; exposed electrode area, 23 cm^2; incident angle, 50°; number of reflections, 18.

of zero charge (pzc) reported by Eyring and co-workers (13) for gold in NaOH solutions. According to these workers, the pzc for gold in the 0.2*M* $HClO_4$ solutions used for the measurements in Fig. 2 is approximately −0.05V which is more cathodic than the voltage regions scanned in this figure.

To obtain further information on the relation of the reflectivity to the pzc, iodide ions were added to 0.5*M* NaOH solution (Fig. 6). The specific adsorption of I^- shifts the pzc to more negative values. The potential (E_A) of the intersection of the two linear portions of the reflectivity-potential curves is likewise shifted. A plot of E_A *vs.* log C_{I^-} is given in Fig. 6. Linearity is expected on the basis of the Esin-Markov effect (14). Three points in the semilog plot in Fig. 6 fall on a straight line with a slope of −0.060V/decade.

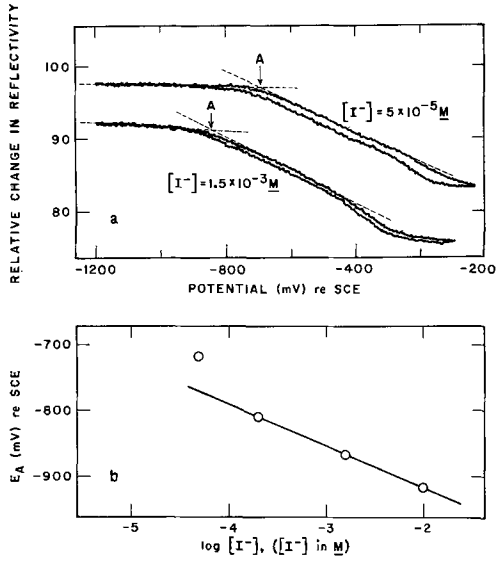

Fig. 6. Effect of iodide ions on the reflectivity-potential curves of gold: (a) in 0.5M NaOH and the shift of the potential of intersection of the two linear regions (E_A) with iodide concentration (b). Wavelength, 5600Å; other conditions same as in Fig. 5.

Some of the small hysteresis observed in Fig. 6 may be associated with the slow adsorption-desorption of I^-.

The sensitivity of the reflectivity curves to the pzc and specific ionic adsorption cannot be readily explained on the basis of the dependence of the reflectivity on the refractive index of the ionic double layer. The calculations of Stedman (15) and Prostak and Hansen (16) have shown that such effects should be too small to cause changes in the reflectivity of the magnitude observed in the present work.

The adsorption of ions on the electrode surface, however, can produce changes in the charge on the metal surface and the penetration of the electric field into the surface of the metal. These in turn would lead to changes in the carrier concentration in the surface of the metal as well as to changes in the photon energies required for the 5d → 6s band transition. Both of the effects would produce a change in the complex refractive index and hence the reflectivity of the interface.

The wavelength dependence of the reflectivity at various potentials provides further insight into the mechanism by which reflectivity changes with change in electrode potential. The wavelength dependence of the reflectivity, however, could not be recorded directly at given electrode potentials because the intensity of the light reaching the photomultiplier changes far too rapidly with wavelength after the large number of reflections involved in the present system. Consequently the wavelength dependence of the slopes of the reflectivity-potential curves has been examined instead. In Fig. 7 are plotted the relative rates of change of the reflectivity with respect to potential expressed in per cent $[(100/R)\ (dR/dE)]$ evaluated at 0.27V and +0.70V at 0.2*M* $HClO_4$. The slopes are the same at these two potentials for $\lambda \leq 5500$Å since the reflectivity-potential plot is linear in this region. Also plotted in this figure is the change in reflectivity associated with the formation of the oxide at a potential of +1.20V (taken as the distance X-Y in Fig. 2). The maxima in all three curves occur at 5500Å where the reflectivity of gold changes rapidly due to the 5d → 6s band transition (see insert drawing in Fig. 7). This implies that the maximum in these curves is caused by the rapid change in reflectivity of the gold. Feinleib (17), using an a-c modulation technique obtained a peak at the same wavelength in his electrochemical reflectance studies of gold. The slopes plotted in Fig. 7 correspond to the a-c signal obtained by Feinleib, who used a modulation potential of 2V which probably encompassed the linear region of Fig. 2, the oxide region, and perhaps the H_2 evolution region. Thus the quantitative significance of his results is in doubt.

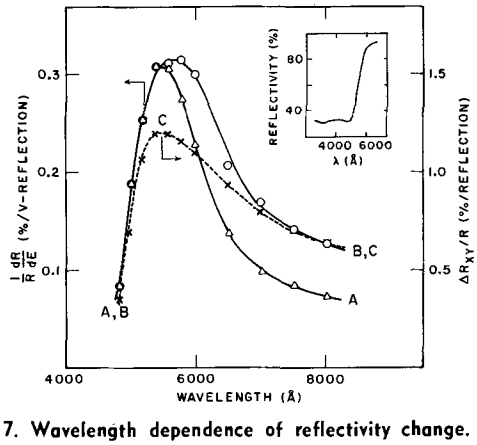

Fig. 7. Wavelength dependence of reflectivity change. Curve A, $(1/R)\ (dR/dE)$ at $E = +0.27$V re SCE. Curve B, $(1/R)\ (dR/dE)$ at $E = +0.78$V re SCE. Curve C, relative reflectivity change (X-Y in Fig. 2) for oxide formation. Conditions same as for Fig. 2. Insert figure, reflectivity of gold in air (17).

The relative slope *vs.* wavelength plot for +0.27V in Fig. 7 indicates that the effects of potential become relatively small at wavelengths remote from the maximum. Even when these relative slopes are converted to absolute values by multiplying by the absolute reflectivity, the absolute slope for +0.27V still passes through a pronounced maximum at 5500Å. This means that the principal effect of changing the electrode potential on the reflectivity-wavelength curve at potentials from 0 to ~+0.4V is to translate the curve along the wavelength scale with the change in reflectivity negligible at wavelengths shorter than the threshold for the 5d → 6s band transition. The direction of the shift along the wavelength scale indicates that the photon energies required for the transition become lower with increasing anodic potential. Such a decrease in the minimum photon energy required for this transition is in accord with the idea that the transition is from the top of the 5d band to the Fermi level and that the top of the 5d level bends upward (higher energy) at the surface, while the Fermi level is relatively invariant.

Prostak and Hansen (16) calculated the change in reflectivity for the gold-electrolyte (1*M* KCl) interface assuming a 0.5Å thick surface layer in the metal phase in which the optical constants have been modified by an amount equivalent to a photon energy of 0.1 eV due to penetration of the electric field into the metal. By applying Maxwell's equations to a three-layer structure, these authors obtain a change in reflectivity (100 $\Delta R/R$) at normal incidence of 0.07% at 5500Å, compared with a value of $(1/R)dR/dE = 0.3\%/$ V per reflection observed at this wavelength in the present work at an angle of incidence of 50° for an applied potential +0.27V. The four-fold discrepancy is not surprising since the comparison is valid only if the penetration depth is 0.5Å and 10% of the change in applied potential occurs within this layer, aside from the difference in angle of incidence. The calculated change in reflectivity should be larger for a deeper penetration and for a larger electric field within the metal. Therefore, the experimental values appear reasonable in terms of a model involving the penetration of the field into the metal to a depth of the order of 1Å.

The shift in the slope of the linear portion of the reflectivity-potential curve associated with passing through the pzc can be explained on the basis of a change in the fraction of the applied electric field which penetrates into the metal surface. Such a change in the distribution of the potential at the interface is certainly to be expected when the ions predominating in the plane of closest approach to the electrode surface are changed from anions to cations and the solvent dipoles at the interface probably reorient.

The maximum in the curve in Fig. 7 corresponding to the reflectivity change for the oxide can be interpreted in terms of a shift in the threshold frequency of the 5d → 6s band transition resulting from the interaction of the oxide ions with the surface orbitals of the metal. An alternate view of the same phenomenon is that the local field produced by the oxide ions penetrates into the metal phase thus shifting the threshold frequency of the 5d → 6s transition. The decrease in reflectivity caused by the oxide, however, persists at longer wavelengths (see Fig. 7) and hence the reflectivity is decreased by some other mechanism at longer wavelengths. One possibility is a change in carrier concentration and mobility in the surface layers of the metal due to the local field of the oxide ions.

Various workers (12, 18-20) have proposed that the chemisorption of an oxygen species; *i.e.*, AuO or AuOH, occurs on gold at potentials more cathodic than those of oxide layer formation. Sirohi and Genshaw (12) have explained the changes in phase retardation and amplitude in their ellipsometric studies of gold at relatively cathodic potentials in terms of the chemisorption of an oxygen species, which modifies the optical constants of the metal phase. Without some kind of relatively slow adsorption-desorption process, these authors find it difficult to explain the observed time dependence.

Unfortunately the present results do not provide strong evidence for or against such chemisorption at potentials cathodic to the oxide region although it may cause the curvature noted in the reflectivity-potential curves in the potential range +0.3 to 1.0V at $\lambda > 6000$Å. Why this curvature is not evident at shorter wavelengths remains to be explained.

The Faradaic adsorption of lead and cadmium on the gold electrodes has been examined using the present apparatus. Lead or cadmium ions strongly adsorb on gold at far more positive potentials than the standard electrode potentials of these ions (21, 22). Reflectivity-potential and current-potential curves for gold in 0.2*M* $HClO_4$ containing 5 x 10^{-4} *M* Pb^{2+} are shown in Fig. 8. The Faradaic adsorption and desorption peaks for Pb occur at +0.10V in the voltammetry curve. The surface concentration of adsorbed Pb estimated from the area under the voltammetry peaks corresponds to 400 μcoul/cm^2, providing further evidence for monolayer formation. The reflectivity-potential curve shows a marked change on adsorption or desorption of the lead atoms and is quite wavelength-dependent (Fig. 9). At shorter wavelengths, *e.g.*, 5000Å, the reflectivity increases on the formation of the Pb monolayer, whereas at longer wavelengths, *e.g.*, 7500Å, the reflectivity decreases. A similar situation has been found with cadmium (Fig. 9).

The wavelength dependence of the change in reflectivity attending the formation of lead and cadmium monolayers remains to be explained but is not sur-

prising since a monolayer of foreign metal atoms on the gold surface has specific electronic and hence optical properties. This wavelength dependence should provide an important tool in studying the electronic properties of such monolayers.

The work reported here is preliminary. It has demonstrated, however, that specular reflection techniques can be used to: (*i*) establish the point of zero charge for solid metal electrodes, (*ii*) follow adsorption and desorption, and (*iii*) obtain information concerning the surface electronic properties of metal electrodes and the penetration of the electric field into the metal phase.

Galvanostatic Overpotential Transients and Electrocrystallization Processes on Copper Single Crystals in Solutions of Cupric Perchlorate

L. H. Jenkins*

Solid State Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

Overpotential transients have been measured on copper single crystal surfaces oriented (100), (110), (111), and (321) undergoing galvanostatic dissolution or deposition in acidic solutions of $Cu(ClO_4)_2$. In the current density range 1-400 $\mu A/cm^2$ it is shown that maximum values observed in overvoltage-time relationships respond to analytical treatment. For the (100) and (110) the anodic and cathodic overpotential maxima *vs.* current density relationships were symmetric about the equilibrium point, but not for the (111) and (321). From plots of certain functions of overvoltage maxima *vs.* current density, orientation sensitive quantities similar to exchange current densities could be calculated. At the low and intermediate current densities it was established that a "deposition anomaly" was observed on all orientations. Deposited material did not seem to occupy crystal lattice positions, and moreover, affected subsequent anodic overpotential-time relationships in a manner related to the extent of the deposition. *In situ* photomicrography and goniometric observations were used to determine the orientations and rates of facet development on the various surfaces when subjected to long term deposition or dissolution, and these results are discussed in terms of the relative ease of movement of monatomic steps over the various orientations. A model is proposed of a sequence of events on the surface and in the diffusion layer which provides a self-consistent explanation of all the experimental data.

The behavior of copper serving as electrodes in acidic solutions of cupric perchlorate have previously been studied by Piontelli, Poli, and Serravalle (1) and by Bockris and Enyo (2). Among other things, both studies attempted to relate kinetic parameters of the systems to structural characteristics of various electrode surfaces. Also, Shanefield and Lighty (3) have observed the changes in growth forms on copper (100) surfaces produced by electrodeposition from cupric perchlorate solutions containing various impurities.

The report of Piontelli *et al.* concerned data for copper single crystal surfaces oriented (100), (110), and (111) in which the "quasi-steady" overvoltages observed under galvanostatic conditions at current

* Electrochemical Society Active Member.

densities of ~ 1-10 mA/cm^2 were orientation dependent. Anodic and cathodic data were not symmetric about the equilibrium point for any one orientation, nor were the relative differences between orientations the same for anodic and cathodic processes. Employing spherical electrodes ~ 0.1 cm in diameter, Bockris and Enyo determined kinetic parameters for surfaces prepared by melting in helium or by electrodeposition. In ~ 0.1M $Cu(ClO_4)_2$ at current densities $\gtrsim$ 10 mA/cm^2 the data indicated charge transfer to be the rate-controlling step, but it was suggested that at lower current densities surface diffusion was the slow process. Certain differences observed between the two types of electrodes were thought to arise from differences in dislocation densities.

Data such as these indicate that perhaps the determination of pertinent kinetic parameters at current densities lower than those studied previously would, when augmented by observations of changes in surface structure resulting from long-term dissolution or deposition, yield information regarding the effects of structure on the reactivity of a metal surface. Obviously there are many other relevant reports in the literature concerning the behavior of copper electrodes in solutions of copper ions. As a matter of fact, data regarding systems of copper sulfate far exceed that related to perchlorates. However, the work previously cited regarding the latter provides an adequate basis to discuss the research reported here, and similar work in sulfate systems which is currently being prepared for publication will provide opportunity later for discussion of other systems.

Materials.—Preferentially oriented cylindrical copper single crystal slugs approximately 25 mm diameter x 100 mm were grown in this laboratory by seeding 99.999+% metal from the melt in graphite crucibles. From such crystals coin-shaped specimens ~ 7 x 25 mm were cut with an acid string saw, and the flat surface chemically polished on a soft cloth polishing wheel using an aqueous solution containing $CuCl_2$, HCl, and H_3PO_4. Finally, the crystals were electropolished in a copper-containing phosphoric acid bath, rinsed in dilute phosphoric acid, and washed in distilled water. [Details of these procedures have been published previously (4, 5).] The manipulations introduced no new dislocations into the crystals, and the average dislocation density in as-grown material was ~ 5 x 10^4-10^6 cm^{-2}. The large surfaces prepared in this manner were not absolutely flat, but rather contained a few gentle undulations such that the average orientation was within ± 0.1° of that desired.

Solutions of $Cu(ClO_4)_2$ were prepared from doubly recrystallized material and stored in rack reservoirs in the manner previously described (6). All solutions used in this study were 0.20M in $Cu(ClO_4)_2$ with pH adjusted to ~ 1 by addition of $HClO_4$. When introduced into the Teflon cells they were free of dissolved oxygen, under an atmosphere of hydrogen, and in equilibrium with polycrystalline metallic copper. Ultrapure grade (99.999+%) tank hydrogen was passed through a platinum catalytic purification system and then through magnesium perchlorate drying towers before using.

Experimental methods.—Two types of reaction cells were used. One type, illustrated in Fig. 1, was used to obtain galvanostatic current-potential data. The apparatus consisted of a large brass support plate with a flat surface and an O-ring groove. On this was mounted a pipe flange-type reaction flask cover with fine ground face and standard taper outer joints. A shallow dish of Teflon sat within this enclosure. Four ports with thin, beveled lips in the bottom of the Teflon dish provided for isolation of the crystal orientation of interest. The copper specimens were pressed against the lips of the port and held in place by gentle pressure from the mounting screws in the manner shown. The diameter of the ports was such that 2 cm^2 geometric

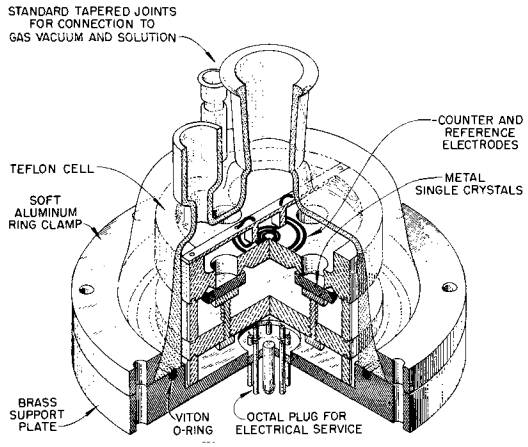

Fig. 1. Cell for isolating single orientations and determining current-overpotential characteristics.

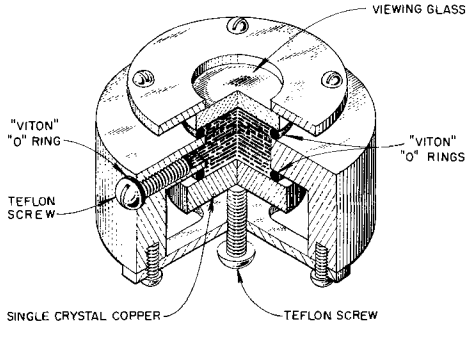
area of each crystal surface was exposed to the solution. Infrequently, crystals of different orientation were mounted in each of the four available ports. Usually only three orientations were used in order to obtain duplicate data for one of them. Polycrystalline copper wires suspended from a cross member over the dish served as counter and reference electrodes. Electrical access was provided through a vacuum tight octal plug welded in the brass support plate. After the crystals were mounted and appropriate electrical connections made, the flask cover was placed over the dish and secured to the plate by a ring clamp. The entire apparatus was then attached to the solution flask and hydrogen and vacuum lines on a mounting rack. Usually a glass electrode inserted through the small standard taper port served as an auxiliary reference electrode. After repeated evacuation and flushing with hydrogen over a period of at least two days, solution was admitted to the system. Appropriate stopcocks were then closed, the entire system detached from the rack, and placed in an air bath maintained at 23.00° ± 0.02°C and which was surrounded by a Faraday cage. Potential measurements were made with either vibrating reed electrometers or a Philbrick P-2 operational amplifier, and data were recorded either on a strip chart recorder or by photography of oscilloscope traces, respectively.

The second type of reaction cell is shown in Fig. 2. The main body of the cell was machined from 99.99+% copper. After the viewing glass was attached, an electropolished crystal was mounted and pressed against the lower Viton O-ring. (Since all O-rings contacted the solution, they previously had been soaked for many hours in hot solutions of the same composition as the test solution.) Solution was introduced to the system through the small side port in the main body of the



Electrolytic Cell for Microscopic Observation.

Fig. 2. Cell permitting microscopic observation and time-lapse photomicrography of surfaces. Main cell body of 4/9s copper serves as counterelectrode.

cell with the aid of a pipette drawn to a needle tip capillary. Obviously, it was impossible to maintain an inert atmosphere within the cell while filling the system. Because of this, the solutions used in the 2-ml capacity cells were not free of dissolved oxygen, nor certainly were they initially at equilibrium with copper metal. As in the previous cell, 2 cm^2 geometric surface area of the crystal was exposed to the solution. The cell was filled to the top of the port such that insertion of the closure screw with O-ring seal caused overflow and prevented entrapment of air within the system. After filling and sealing, the cell was set aside for a period of at least two weeks so that equilibrium could be established. The cell was then placed on a microscope stage, and using the body of the cell as a counterelectrode, changes in single crystal surface structures due to dissolution or deposition process concomitant with the passage of current through the system were observed and recorded by time lapse photomicrography. A few systems were closed with a Teflon screw which contained a polycrystalline copper wire sealed through its length to serve as a reference electrode, but usually no attempts were made to measure potentials within these cells. All the data discussed here were obtained under galvanostatic conditions. The current source was a dry cell pack, and current flow was regulated by fixed in-line resistors with resistance values very large compared with those of the various cells.

In all cases when the reaction cells were opened, crystals were examined and photographed under the microscope. Orientations of surface facets were determined with a two-circle reflection goniometer. In instances in which deposition had been to an extent great enough to make the observations valid, Laue back reflection x-ray techniques were used to establish the orientation of the deposited metal.

Experimental Results

Changes in surface structure.—Using the copper body cells, observations were made on surfaces oriented (100), (110), (111), and (321). Data were taken at constant currents of 4, 40, and 400 $\mu A/cm^2$ original surface area for all orientations during both dissolution and deposition, and a few observations were made at other current densities also. Under any given combination of experimental conditions the changes observed in a surface structure were reproducible. Data always were obtained from duplicate systems, and in many cases from triplicate, so that the results discussed below derive from more than 60 different crystals. In all cases tested, deposits were single-crystalline and oriented like the substrate.

(100).—Under all experimental conditions dissolution of the (100) was completely uniform and regular, and resulted in the formation of square pits. Figure 3 shows that rapid removal produced a more regular and well-defined pit than removal of a like amount of material at a lower rate. At lower current densities sides of pits were less well defined and apparently relatively more material was removed by motion of steps over the original surface than at higher current densities. Nevertheless, in general, such differences were of degree rather than kind.

By comparison, deposition on the (100), although accompanied by the formation of four-sided pyramids, did not occur in as regular and uniform a manner. At higher current densities pyramids of a uniform size developed, but at current densities $\lesssim$ 100 $\mu A/cm^2$ (although initial deposition and growth occurred uniformly) some pyramids soon began to develop at a much greater rate than others. A few of these larger pyramids, appearing dark to the viewer, had sides $\sim$ 22° from the (100), but they were outnumbered approximately 10:1 by the lighter appearing large kind with sides $\sim$ 8° from the original surface. The number of large pyramids, both light and dark, comprised less than 1% of the total number on the surface. However, initial deposition occurred uniformly, and the formation of large pyramids seemed apparently a random fluctuation. As a first approximation, growth rates of topographic features were linear in time. Deposition growth forms occurred in an even less uniform manner at 4 $\mu A/cm^2$. Again, although nucleation of small pyramids apparently occurred over the entire surface, random large growths began to develop. At this low current density much of the material seems to have been deposited by step motion over the original surface, similar to the case for dissolution, for the volume of material contained in the pyramids was calculated to be only $\sim$ 20% of the total deposited.

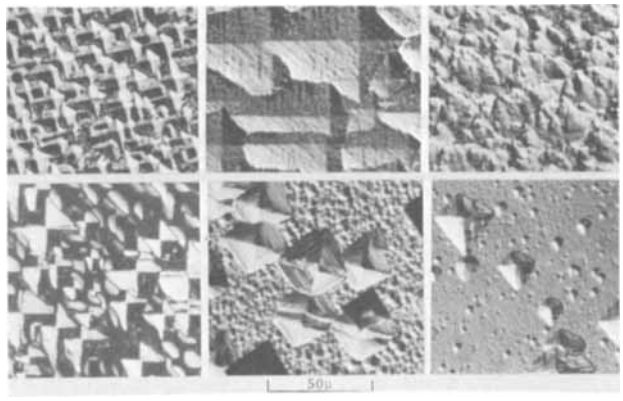


Fig. 3. Structures developed on (100) due to long-term galvanostatic processes. Upper photographs represent features developed by anodic process after removal of the equivalent of $\sim$ 4.5 coulombs cm^{-2} at current densities (left to right) of 4000, 40, and 4 $\mu A\ cm^{-2}$, respectively. Lower photographs after deposition equivalent to $\sim$ 1.0 coulombs cm^{-2} at (left to right) 400, 40, and 4 $\mu A\ cm^{-2}$.

Facets formed by both pyramids and pits always were oriented along <100> zones, and no facets on any other zones were ever obtained under the stated conditions. As in the case previously reported (7) pit bottoms always were within $\sim$ 5° of the original (100), but as indicated above, deposition-formed facets exhibited more varied orientations.

(110).—Structures developed on the (110) were very similar under all conditions. Reaction always occurred in a uniform manner and invariably resulted in the formation of a well-defined series of sharp-topped ridges separated by equally sharp-bottomed valleys, as illustrated in Fig. 4. Ridge sides were never formed other than along the <100> zone, and faceting was more or less continuous along this zone out to $\sim$ 40° from the (110).

(111).—The (111) also seemed to react in a completely uniform manner. Either dissolution or deposition apparently occurred by the removal of material at submicroscopic steps on the surface. In early stages, these

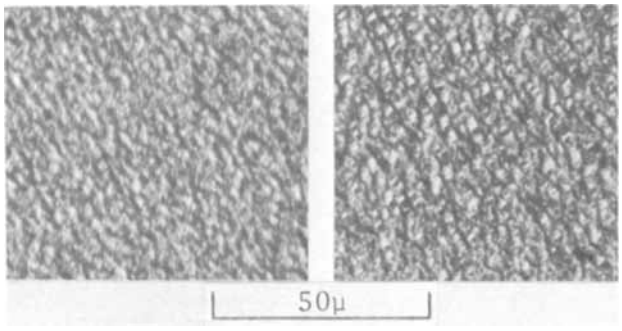

Fig. 4. Typical structures developed on the (110), left, and (321) right. Former shown after dissolution of $\sim$1.5 coulombs cm^{-2} at 4 $\mu A\ cm^{-2}$, and the latter after equivalent deposition at 400 $\mu A\ cm^{-2}$.

steps interacted to form small ledges of such great density that the entire surface appeared roughened. As the process continued, small ledges interacted to form large ledges separated by apparently flat (111) surfaces, such that the surface appeared as smooth over local areas as at initiation of reaction. Figure 5 is a series of photomicrographs, some taken *in situ* of the same area, which illustrates this process. The large ledges formed in all cases were, of course, highly faceted.

(321).—This surface also seemed to react in a uniform manner with no appreciable difference in the facets produced by dissolution or deposition. A great deal of (111) faceting was always observed (see Fig. 4), and this was accompanied by the development of companion facets along the two <100> zones, such that nonsymmetrical, triangular shaped pits or pyramids were formed. At high current densities facets developed along these zones approached within 4° of the (100). At lower current densities faceting along the <100> zones tended to be further removed from the (100) and nearer the (210).

Potential vs. time data.—Data obtained in the Teflon cells at all current densities (1-400 μA/cm^2), both anodic and cathodic, and on all four orientations studied revealed that potential *vs.* time curves of working electrodes exhibited maxima generally of the shape observed by Roiter *et al.* (8) on zinc single crystals in solutions of zinc sulfate. However, one important difference must be noted: The times to formation of the maxima reported here are much too long (generally by an order of magnitude) to be associated with charging of the double layer. True steady-state overpotentials could not be established on any of the crystals, in that, following establishment of a maximum value, if the current passed long enough, the measured overpotential gradually decreased. Ultimately microscopic changes in surface structure could be observed without a true steady state being established, although pseudo-steady states frequently were observed shortly after maxima were established. Figure 6 illustrates typical potential-time curves of overvoltages for the orientations studied. The excellent reproducibility of the values of the potential maxima, as well as times to formation, for successive anodic pulses is clearly indicated. Cathodic overpotential-time relationships were equally reproducible. As shown, excellent agreement between the absolute values of anodic and cathodic maxima were obtained, although at current densities $\lesssim$ 100 μA/cm^2 slightly longer times were often required to establish the latter. Note also at the lower current density shown the post-maximum overvoltage-time relationship is quite different in the anodic and cathodic cases. At higher current densities times to formation of maxima were approximately equal for both processes, but again over-all overvoltage-time relationships were not precisely similar.

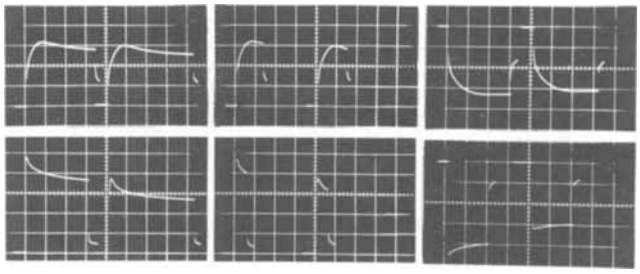

Fig. 6. Oscilloscope traces of "normal" overpotential-time relationships. Top row all at 30 μA/cm^2, 5 mV/div vertical scale, 2 sec/div horizontal scale, from left to right: anodic (110), (321); anodic (110), (321); cathodic (110), (321). Bottom row all at 150 μA/cm^2, 10 mV/div vertical scale, 1 sec/div horizontal scale, from left to right: anodic (100), (111); anodic (100), (111); cathodic (100), (111).

The most interesting feature of the deposition process was its effect upon a subsequent anodic pulse. Overvoltage-time relationships were altered drastically for an anodic process which had been preceded by a cathodic pulse. [Similar phenomena have been observed on other single crystalline material (9).] This is illustrated in Fig. 7 which, when compared with Fig. 6, shows that such anodic maxima can take much longer to become established than under postanodic conditions. Also, the absolute values of these overpotential maxima are greatly reduced at higher current densities, and in all cases the entire overvoltage-time relationship is altered. Interestingly enough, only very slight differences were observed between postanodic and postcathodic overpotential-time relationships during deposition, and the value of a cathodic overpotential maximum rarely showed noticeable effects of previous electrode processes. Due to excessively long decay times following cathodic current interruption, an exhaustive study of postdeposition cathodic overpotential-time relationships was not undertaken. These observations will be of considerable significance in later discussions concerning interpretation of all the data.

The extent of this postdeposition anomaly was dependent on the current density, deposition time, orientation of the surface to some extent, and the time lapse

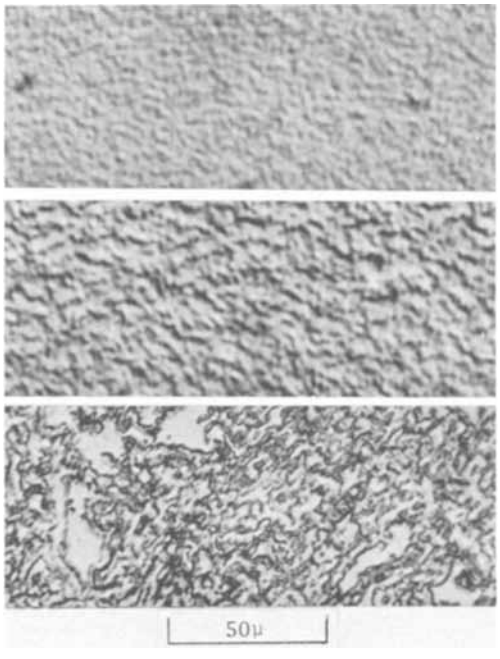

Fig. 5. A (111) surface undergoing dissolution at 400 μA/cm^{-2}. Top and middle are *in situ* views of the same area after 6- and 15-min reaction, respectively. Lack of definition is due to the difficulty of lighting and focusing through the cell and solution. Bottom illustrates a view of the same crystal after removal from the cell following 1 hr of reaction.

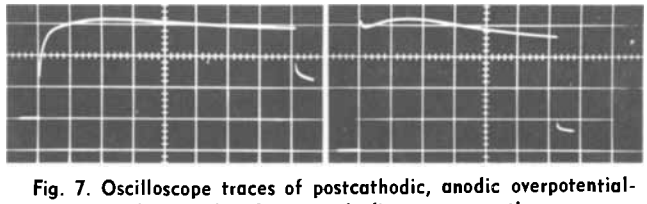

Fig. 7. Oscilloscope traces of postcathodic, anodic overpotential-time relationships ½ hr after a cathodic process at the same current density. Left: (110) at 30 μA/cm^2, 5 mV/div vertical scale, 2 sec/div horizontal scale. Right: (100) at 150 μA/cm^2, 10 mV/div vertical scale, 1 sec/div horizontal scale. Compare with extreme left trace, top and bottom, respectively, of Fig. 6.

between deposition and subsequent dissolution. The effect was more pronounced at low current densities, < 25 $\mu A/cm^2$, than at high, > 150 $\mu A/cm^2$. Consequently, effects of deposition time were also more pronounced at lower current densities. In general, low current density deposition, as indicated in Fig. 8, increased the time to formation of the succeeding anodic maximum by an amount proportional to the extent of deposition. At current densities > 200 $\mu A/cm^2$ even slight deposition effects were not detectable after periods more than one hour. At extremely low current densities, < 5 $\mu A/cm^2$, the effect could be observed for periods of many hours.

Other ambiguous potential-time relationships were observed. Whether the electrode supported an anodic or cathodic process at higher current densities, about 10 min were required to re-establish equilibrium potential after the flow of current was interrupted. However, at low current densities recovery time was much longer. For example, a current of 300 $\mu A/cm^2$ flowing for 1 sec typically would establish an overvoltage maximum near 50 mV in $\sim$ 0.03 sec, and would regain rest potential within 10 min following current interruption. After 60 sec at 5 $\mu A/cm^2$ (equal charge passed) a maximum typically would not have yet been established, the observed overvoltage would not have exceeded $\sim$ 10 mV, and still it could require hours for the rest potential to become re-established. Therefore, it appears that the rate of potential decay was not directly related to the absolute value of the observed overvoltage, nor, in a simple manner, to the quantity of current flowing. In general, recovery time following a cathodic process would exceed that following an exactly similar anodic pulse.

Current potential data.—At this point it is important that it be understood that, unless otherwise indicated, the overpotentials quoted in the presentations which follow are always values of the postanodic maxima. That is to say, every cathodic pulse applied in systems in which current-potential characteristics were being determined was followed by an anodic pulse of equivalent magnitude and duration. This latter pulse was disregarded, and equilibrium allowed to become established in the system. Only then was the next electrode process of interest initiated and data recorded.

Figure 9 illustrates the current-potential relationships obtained on the various surface orientations in this study. The following experimental observations are shown by the figure: (*i*) The curves for (100) and (110) are symmetrical about zero current and overpotential. (*ii*) While it is not obvious from this figure,

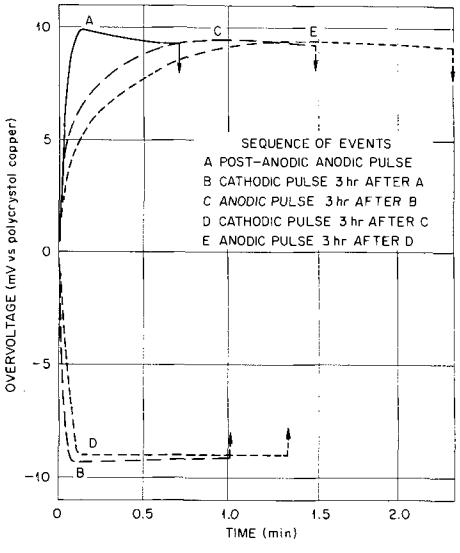

Fig. 8. Effects of deposition on overvoltage-time relationships on the copper (321) orientation at 15 $\mu A/cm^2$.

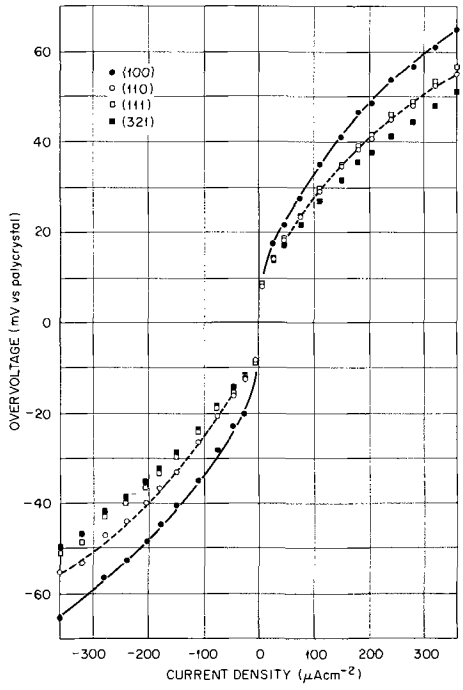

Fig. 9. Overvoltage maxima for variously oriented copper single crystals as a function of current density in solutions of 0.2M $Cu(ClO_4)_2$ and $HClO_4$ (pH $\sim$ 1) at 23°C.

the (321) data are not exactly symmetric about zero. (*iii*) The (111) data are obviously asymmetric in that at any given current density the absolute value of the cathodic maximum is smaller than that of its anodic counterpart. (*iv*) At any current density the absolute value of the overvoltage associated with the process was a function of crystal orientation, increasing in the order (321) $<$ (110) $<$ (100). The (111) obviously cannot be included in this generalization because of the asymmetric character of the data. (*v*) Since the step densities on the (100), (110), and (111) must be approximately equal and much smaller than that of the (321), measured overvoltage maxima are independent of the surface step density.

Discussion

Surface structure.—The classic model of electrocrystallization processes assumes that, after crossing the double layer and undergoing stepwise discharge, atoms ultimately are incorporated into the crystal lattice at kink sites on steps. Whether this is accomplished by diffusion of adatoms over the surface to steps or by direct action at step and/or kink sites, deposition or dissolution ultimately may be described as occurring by the "motion of steps" over the crystal surface, and use of the phrase here does not imply a choice as to the mechanistic detail. Sources of steps are crystal edges, dislocations, new steps nucleated during the processes, and departures from close-packed arrangements due to crystal orientation. It is difficult to assess the exact number of steps arising from dislocations, but if it is assumed that all dislocations have a screw component and that an equal distribution of dislocations of equal and opposite sign exists, the maximum number of steps generated by dislocations should be of the order of the square root of the dislocation density. On the other hand, a misorientation of only $\sim$ 0.1° from a close-packed arrangement will produce $\sim$ 10^5 steps cm^{-1}. It is readily seen that, since the surfaces used in this study could not be prepared with orientations better than $\pm$ 0.1°, the density of orientation related steps was approximately two orders of magnitude greater than that produced by the maximum dislocation density, $\sim$ 10^6 cm^{-2}. Furthermore, although apparently it is not generally recognized, the major

source of steps on a large number of noncleaved metal surfaces employed in studying electrocrystallization phenomena is just such slight misorientations. One other fact is most helpful in discussing the structures developed on the surfaces reported here: Young and Hulett (10) have demonstrated that steps on a copper (111) surface arising from misorientations of $\sim 0.1°$ can sustain a current density as great as 10 mA/cm^2 over long periods of time without nucleation of new steps becoming necessary. This is a current density two orders of magnitude greater than the highest employed in these studies.

It could be assumed that facets developed on (321) surfaces are the end products of complex step interactions and reflect more of the nature of such interactions than of the model substrate supporting the steps. On the other hand the interaction on the (111) of steps to form ledges, which in time aggregated to form larger ledges separated by apparently flat (111), does indicate something of the nature of that orientation. First it is clear that bunched steps constitute a reasonably stable array. Their rapid rates of formation suggest material is as easily added or removed on this surface from such an array as from the initial configuration. Ledges formed are large enough to be considered discreet areas of orientation other than (111), which in turn suggests that step motion over the (111) occurs with some difficulty. At lower current densities on the (100) observations clearly indicated a large portion of the process had to be sustained by step motion since all material was not accountable by pit or pyramid formation. However, as kinetic demands increased, it appears step motion was insufficient to support the reaction, and facets over which steps could move with greater facility were formed. The absolute failure ever to develop facets within $\sim 5°$ of the (100) would indicate that step motion over this orientation is most difficult of any orientation studied. The same type of argument can be used to explain formation of a ridge-valley structure on the (110). In summary, it is proposed that facet development on close-packed orientations is a consequence of the relative difficulty with which steps move over such surfaces. However, facets of close-packed arrangements can be developed as a result of step motion on surfaces with large step densities, such as (321), since the latter contain components of the former within their structure. As a consequence of this argument it must be concluded that, once facets are developed on a surface, little reaction occurs on the areas covered by low index facets, and the surface is in a true sense no longer acting in a uniform manner.

The fact that regardless of initial orientation a large proportion of the total facets formed were oriented along <100> zones suggest that steps move along the <100> zone with relative ease. The low angle facets developed on (100) indicate that the degree of faceting is related to the rate of the surface process in that only those facets necessary to support the reaction are formed. This proposal is substantiated by the observation that at high current densities facets on the (321) formed orientations near the (100), while those formed at lower current densities were further removed from the (100) along the two <100> zones.

Finally, it should be stated there was no evidence that the defect structure of the copper crystals played a significant role in crystal growth or dissolution. Even the pits and pyramids on the (100) could not be related to the crystal defect density.

Overpotential-time data.—Before discussing the overpotential-time data, it is helpful to consider the entire system in the manner employed by Bertocci (11). Although he treated steady-state conditions, the concepts should be applicable to transient processes. Three reactions must be considered: a redox reaction

$$Cu^+ \rightleftarrows Cu^{++} + e \qquad \text{(i)}$$

the reaction between adatoms and cuprous ions

$$A \rightleftarrows Cu^+ + e \qquad \text{(ii)}$$

and the exchange of adatoms with the metal lattice

$$M \rightleftarrows A \qquad \text{(iii)}$$

Bertocci, in treating the general case, assumed the concentration of adatoms always to be the equilibrium value so considerations here are a bit less specific. At any rate, however, it can be shown that the equilibrium potential can be expressed as

$$E_{eq} = E^{o}_{Cu^+/Cu^{2+}} + \frac{RT}{F} \ln \frac{(a_{Cu^{2+}})_{eq}}{(a_{Cu^+})_{eq}} = E^{o}_{A/Cu^+} + \frac{RT}{F} \ln \frac{(a_{Cu^+})_{eq}}{(a_A)_{eq}} \qquad [1]$$

and that when activities of the various species at the interface depart from equilibrium values, the potential of the electrode may be expressed as a sum of the reversible potential of the pertinent reaction and the overvoltage for that reaction

$$E = E_{Cu^+/Cu^{2+},\,rev} + \eta_i = E_{A/Cu^+,\,rev} + \eta_{ii} \qquad [2]$$

Using the notation that $E_i \equiv E_{Cu^+/Cu^{2+},\,rev}$, etc., it follows that

$$E_i - E_{eq} = \frac{RT}{F} \ln \frac{(a_{Cu^{2+}}) \times (a_{Cu^+})_{eq}}{(a_{Cu^{2+}})_{eq} \times (a_{Cu^+})} \qquad [3]$$

$$E_{ii} - E_{eq} = \frac{RT}{F} \ln \frac{(a_{Cu^+}) \times (a_A)_{eq}}{(a_{Cu^+})_{eq} \times (a_A)} \qquad [4]$$

Since electrocrystallization processes must be associated with reaction (iii), the electrocrystallization overvoltage, will be noted as η_{iii}. It has been defined by Vetter (12) as

$$\eta_{iii} \equiv \frac{RT}{F} \ln \frac{(a_A)_{eq}}{(a_A)} \qquad [5]$$

Note that this expression for η_{iii} is contained in Eq. [4] so that also

$$E_{ii} - E_{eq} = \frac{RT}{F} \ln \frac{(a_{Cu^+})}{(a_{Cu^+})_{eq}} + \eta_{iii} \qquad [6]$$

Still following the method of Bertocci it can be shown from Eq. [2], [3], [4], and [5] that, since

$$E - E_{eq} \equiv \eta \qquad [7]$$

$$\eta = \frac{RT}{F} \ln \frac{(a_{Cu^{2+}}) \times (a_{Cu^+})_{eq}}{(a_{Cu^{2+}})_{eq} \times (a_{Cu^+})} + \eta_i = \frac{RT}{F} \ln \frac{(a_{Cu^+}) \times (a_A)_{eq}}{(a_{Cu^+})_{eq} \times (a_A)} + \eta_{ii} \qquad [8]$$

and that

$$2\eta = \frac{RT}{F} \ln \frac{(a_{Cu^{2+}}) \times (a_A)_{eq}}{(a_{Cu^{2+}})_{eq} \times (a_A)} + \eta_i + \eta_{ii} = \frac{RT}{F} \ln \frac{(a_{Cu^{2+}})}{(a_{Cu^{2+}})_{eq}} + \eta_i + \eta_{ii} + \eta_{iii} \qquad [9]$$

Among others, Bertocci considered the special case in which $2\eta = \eta_i$. He pointed out such circumstances required that $(a_{Cu^{2+}}) = (a_{Cu^{2+}})_{eq}$ and that reaction (ii) occur completely reversibly (that is $\eta_{ii} = 0$). These requirements also were those necessary for Bockris and Enyo to interpret their data obtained under conditions of charge transfer control. However, Eq. [8] indicated such circumstances also require that $(a_A) = (a_A)_{eq}$, a limitation which would seem obtainable only if, under the stated conditions, adatoms are indistinguishable from those occupying lattice sites, and therefore, that the adatom concentration equal the number

of surface lattice sites. This relationship will be explored more fully in discussions which follow.

Bertocci's model can be used to explore situations in which charge transfer is not the rate-controlling process, and it is necessary that this be done, for Bockris and Enyo also clearly demonstrated that the redox reaction could not be rate limiting under the experimental conditions reported here. It could be thought, for example, that premaxima overvoltage transients resulted solely from the occurrence of the redox reaction within the diffusion layer without a net flux of material across the interface prior to the establishment of maxima. Since the equilibrium constant for the reaction, $Cu^{o} + Cu^{++} \leftrightarrows 2Cu^{+}$, is approximately 10^{-6} (13), it can readily be demonstrated there were sufficient cuprous ions within the diffusion layer to support the necessary current. This mechanism dictates that, during the time of the premaximum transients, reactions (ii) and (iii) do not occur. From the data of others it is only reasonable to assume that also $(a_{Cu^{2+}}) = (a_{Cu^{2+}})_{eq}$. However, a consequence of the mechanism is that concentrations of cuprous ions in the diffusion layer are smaller than at equilibrium for anodic processes and larger for cathodic. The second portion of Eq. [8] reveals that such circumstances require either that anodic processes exhibit negative overpotentials or $\eta_{ii} \neq 0$. Since either choice is unacceptable the proposed mechanism must be considered most implausible. Moreover, it does not aid in understanding the deposition anomaly. However, as is indicated below, this situation related to cuprous ion activities within the diffusion layer is permissible if surface adion concentrations depart from the equilibrium value.

All the time dependent characteristics of overpotentials reported here cannot be explained on the basis of the classic model of adatom diffusion over the surface to steps where they eventually can be incorporated into the crystal lattice. The data are easier understood if it is assumed that surface diffusion coefficients are much smaller than those for similar processes in solutions. Also, it is necessary to make one alteration in the assumptions generally made regarding the classic model: It will not be assumed that exchange of adatoms at steps occurs more rapidly than other surface processes, but rather that the action is hindered in some manner, and a barrier to exchange exists.

The formation of maxima, the dependence of the rate of decay of overpotential on the current density prior to opening the circuit and on the total charge passed, as well as the inverse relationship between current density and total charge passed at overpotential maxima formation suggest the following interpretation of the data. On closing a circuit at a higher current density the initial current was carried largely without reaction at steps. As the surface concentration of adatoms changed rapidly from the equilibrium value, other necessary events occurred such that the conditions required for steps to act as sources or sinks for adatoms were established. Thereafter, reaction began to occur at steps, and continued reaction produced gradual changes in surface adion concentrations toward the equilibrium value in efforts to establish desired steady-state concentrations. However, under the given experimental conditions, the net flux of adatoms at steps was such that the theoretical steady-state surface adion concentration was slow in being established since most of the adatom flux at steps served largely to support the net reaction rather than to change the average surface concentration of the species. (As will be seen later, it is also proposed that voltage-time relationships are influenced by events occurring at the metal-solution interface.) Obviously such a mechanism assumes the occurrence of time-dependent phenomena. Consequently, if it is assumed that at higher current densities overvoltage maxima were formed before significant reaction occurred at steps, premaxima current flow can be expressed in terms of adion activities

$$(a_A)_{eq} - (a_A)_t = kit/\mathbf{F} \qquad [10]$$

where (a_A) = activity of surface adions at equilibrium or time, t, as designated,

i = current density,
k = fraction of the total current carried by adion reaction,
$\mathbf{F}$ = the Faraday.

By combining Eq. [5] and [10] one obtains the expression

$$\exp(-z\mathbf{F}\eta_{iii}/RT) + kit/\mathbf{F}(a_A)_{eq} = 1 \qquad [11]$$

Consequently, the shape of premaxima portions of overvoltage-time curves at higher current densities should reflect the indicated relationship between overvoltage and time. For the few conditions tested, this was found to be the case, but effects of orientation, current density, polarity, etc., were such that additional studies of these phenomena are being conducted. Shapes of postmaxima portions of overvoltage-time curves should be a complex function of, among other things, the rate of change of surface adion concentration toward equilibrium values, events in the diffusion layer, and changes in surface structures produced by the process under observation. The absolute values of maxima resulting from such a reaction mechanism could, as experimentally observed, be independent of the surface step density, although postmaxima overvoltage-time relationships should not necessarily be.

The failure to establish a true steady-state potential at higher current densities over reasonable times suggests the time required for such an event is of the order of that for significant alterations in initial surface structure. Data shown in Fig. 10 clearly indicate that "normal," postanodic maxima were established before the equivalent of a monolayer of copper had reacted. The high current density data suggest that the equilibrium concentration of adatoms is at least two orders of magnitude less than the total number of lattice sites, if as previously suggested, the initial current flow was largely supported without reaction at steps.

Such a mechanism also accounts satisfactorily for the more rapid establishment of equilibrium conditions following termination of high current density pulses as compared with low decay rates of overpotential

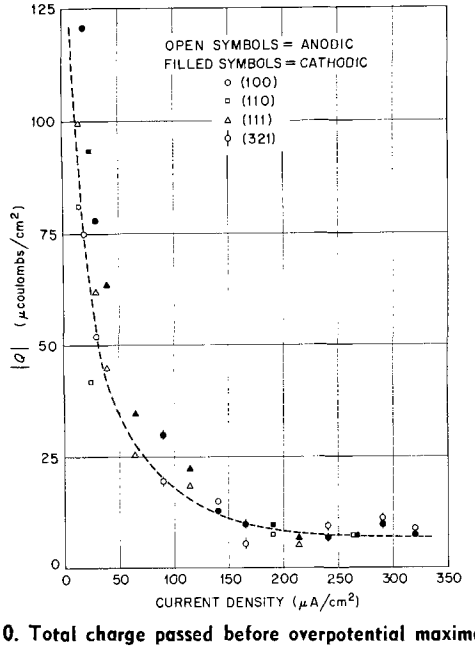

Fig. 10. Total charge passed before overpotential maxima formed on different orientations as a function of current density.

after low current density processes. On interruption of large currents, the potential for a short time, although rapidly decaying, was still sufficient to exceed the barrier to exchange at steps such that they still could act as sources or sinks for adatoms. During this time the total number of adatoms approached the equilibrium value, and additional time was required only for the proper equilibrium distribution to become established.

Anodic pulses at low current densities apparently followed the same general pattern. However, the data in Fig. 9 and 10 suggest that at current densities $\lesssim 25$ $\mu A/cm^2$ "normal" anodic maxima were formed by a current flow supported extensively by reaction at steps. Otherwise, the surface adatom concentration would have been so depleted that much higher overpotentials should have been observed. Also, since early, premaxima stages of current flow were accompanied by a slow monotonic increase in overpotential at low current densities, it would appear that at least a portion of the barrier to reaction at steps was indeed due to the occurrence of some sort of time dependent phenomena. The extremely slow rate of decay to equilibrium potential following interruption of a low current density pulse suggests that related processes at steps also were dependent on the overpotential. On interruption of small anodic currents, overpotentials during decay apparently were of such a relatively small magnitude that the barrier to reaction at steps was not exceeded sufficiently to produce adatoms at a rate necessary to satisfy rapidly the equilibrium requirements. Therefore, rates of potential decay during open circuit following low current density anodic processes were slower because they reflected the rate of production of adatoms at steps rather than, as at higher current densities, attainment of an equilibrium distribution by an adequate adion concentration. It will be seen that cathodic processes at low current densities can be understood on the basis of the same general model, although slight, but significant, alterations must be made.

Since Piontelli (14), as well as others, questions the validity of overpotential maxima and generally attributes their existence to the presence of impurities, perhaps some comments on the systems reported here would be useful. Admittedly neither the data of others obtained at higher current densities nor present theories of electrocrystallization phenomena are too helpful in assessing these results. It seems highly unlikely they can be dismissed as an impurity effect because it is difficult to propose a model of surface processes involving impurities which accounts satisfactorily for all the experimental results reported here.

At this point it is informative to discuss in some detail a part of the data reported by Bockris and Enyo (2). Although they were concerned primarily with the determination of kinetic parameters for copper electrodes exposed to various acidic solutions of different copper salts under conditions such that charge transfer was the slow process, only that portion of the data gathered when such conditions were not met ($i \lesssim 10$ mA/cm^2) is considered here. As much as is possible reference is made only to data concerned with cupric perchlorate systems. However, unless specifically excluded by the authors, it is assumed their general remarks drawn from all the data apply equally to perchlorate solutions. Using spherical copper electrodes they obtained different current-overpotential relationships for electrodes prepared by melting in helium and others of similar origin which were subjected to electrodeposition before use. In general, electrodes of the latter type acted in a much more consistent and understandable manner. For example, cathodic Tafel behavior was obtained for the latter, but not the former type, and values of anodic overpotentials gathered from the two kinds of electrodes did not agree completely. It was proposed that such behavior resulted from the different surface properties of the electrodes. They suggested that electrodes melted in helium contained an oxide film which, on exposure to acidic solutions, dissolved to expose a "new (clean) copper surface" on which the exchange current density would be expected to be greater than on a surface formed by electrodeposition. Further, they assumed a dislocation density of $\sim 10^9$ cm^2 for the former type and that of the latter to be greater, and concluded, therefore, that because electrodes melted in helium had this lower density of growth sites a surface process (diffusion) could become rate determining. It was also concluded that, at the lower current densities studied, surface diffusion was the rate-controlling step on both types of surfaces, which also helped explain the observation that rise times of overpotentials were greater than expected and differed for the two types of electrodes, as well as in anodic and cathodic cases for a single type.

The surface processes suggested by Bockris and Enyo are not unreasonable, but more credible alternatives do exist. From considerations of elementary geometry it can be shown that surfaces of spherical copper electrodes must have an average step density of $\sim 10^7$ cm^{-1} due solely to the intersection of crystallographic planes by the circumference of the sphere. Since, as previously discussed, the number of steps generated by dislocations intersecting a surface surely cannot exceed the square root of the dislocation density, defect related steps on the electrodes of Bockris and Enyo most probably did not number more than $\sim 10^5$ cm^{-1}. Therefore, growth sites produced by electrode geometry far outnumbered those associated with line defects in both types of electrodes, and it appears highly improbable that surface diffusion processes were affected to any significant extent by dislocations present in either type of electrode. Since average step densities on the two electrodes must have been approximately equal, it is much more reasonable to assume that differences measured on the two surfaces were not related to the average number of steps, but rather to the arrangement and distribution of this number of steps due to the different methods of surface preparation. This suggestion is compatible with the changes they observed on "new (clean)" helium-melted surfaces as more data was gathered on them. Presumably the net reaction on such electrodes in time would produce a surface similar to that resulting from electrodeposition, which, because of the method of preparation (15), surely must have consisted of ledges, facets, etc., formed by the bunching of steps.

It is not the primary purpose of this discussion to argue whether the interpretation presented here for the data of Bockris and Enyo is preferable to that of the authors, but rather to demonstrate that data gathered by others under entirely different conditions than those described in this report can reasonably be interpreted in a manner to lend support to the argument that a surface can yield vastly different current-potential and potential-time characteristics depending upon the arrangement of steps on that surface. The surfaces reported in this study upon which current-potential data were gathered contained steps distributed, as previously indicated, in a more or less continuous manner. The reactions performed on these surfaces were conducted at such low rates that the initial step distribution was changed very little during the course of the measurements, and it is certain these data are representative of structures quite different from those of Piontelli *et al.* and Bockris and Enyo. Therefore, it is not surprising that apparently little correlation can be made between any of these experimental results.

Before attempting an analytical treatment of observed overpotential maxima, it would be informative to discuss the data illustrated in Fig. 9 in more gen-

eral terms. It is conceivable that current-potential data for (100), (110), and (111) alone could support an argument that the differences observed on different orientations were related to the relative ease of direct reaction at steps on these orientations. However, the similarity of cathodic data for (321) and (111) preclude the possibility of direct discharge at steps on these orientations, since under such conditions the magnitude of the overvoltages should be proportional to the orientation related step densities which are $\sim 10^7$ and 10^5/cm, respectively. Moreover, the nearly perfect symmetry of the anodic and cathodic branches of the (321) data indicates that the mechanism also is not operable during dissolution from the (321). Then because of their relationships to the (321) and to each other [relative differences between (100) and (110) are greater than between (110) and (321)] and because of their perfect symmetry in anodic and cathodic branches, the (100) and (110) also appear unlikely to react by such a mechanism.

In considering the possibility of nucleation phenomena occurring, it is helpful again to compare cathodic data for the (321) and (111) with their structures. While the idealized (111) is a familiar structure, the ball model of a fcc (321) is perhaps not so well known. The model shows that 40% of the atoms on this surface are located along continuously kinked steps, and on the average, of course, a step occurs every 2½ atom rows. The only "nucleus" capable of existence on the model surface would be a long chain of single atoms at the half position between steps. Placement in any other lattice position would constitute direct growth at steps. Although a real crystal surface most surely does not have that of the idealized model, the arrangement must be such that $\sim$ 40% of the atoms, on the average, represent a kink stepped arrangement. Otherwise, the real surface area of the (321) would have to increase due to formation of preferred orientations, an occurrence which has previously been shown not to happen (5). Therefore, regardless of the real structure of the (321), the similarity of its cathodic current-potential maxima to those of the (111) argue against nucleation as a major event on these surfaces. It would seem then that data concerning the current-potential maxima relationships do not offer any objections to the modified model of surface processes previously proposed.

It does appear strange, however, that overpotential-current relationships should show such a pronounced orientation effect but apparently be free from any influence of step density. This is especially true in view of the relationship between current and step densities derived from the theoreies of electrocrystallization overvoltage. Several authors have considered surfaces from which material is added or removed by step motion, and they have arrived at expressions which relate step density to the average current density and overpotential. Bertocci *et al.* (16) have discussed these models and have shown that it is possible that a proportionality between step and current densities could be observed for misorientations an order of magnitude greater than those of surfaces used in these studies. However, all such models assume that adatom exchange at steps is unhindered. Because of this and also because effects obviously related to crystal orientation were observed, it is unreasonable to conclude that overvoltage characteristics reported here are unrelated to electrocrystallization phenomena. This argument is strengthened further by treating the data for (100) and (110) as indicated in Fig. 11. That similar results are not obtained by treating (321) and (111) data in this manner is demonstrated in Fig. 12. The assumption of indicated values for certain parameters leads to a slight misfit for (321) and a gross misfit for (111) data. Figure 13 shows that a better fit for the (111) is obtained if the value of α is assumed to be 0.46 for this orientation. The slight misfit observed for (321) data suggests an

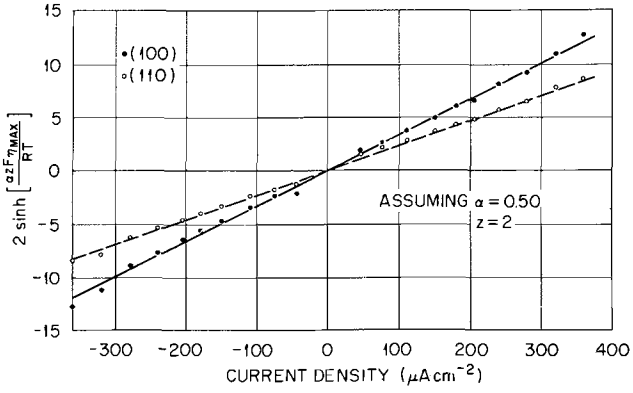

Fig. 11. Relationships between overpotential maxima and current densities on the (100) and (110) at 23°C in 0.2M $Cu(ClO_4)_2$ + $HClO_4$ (pH ~ 1).

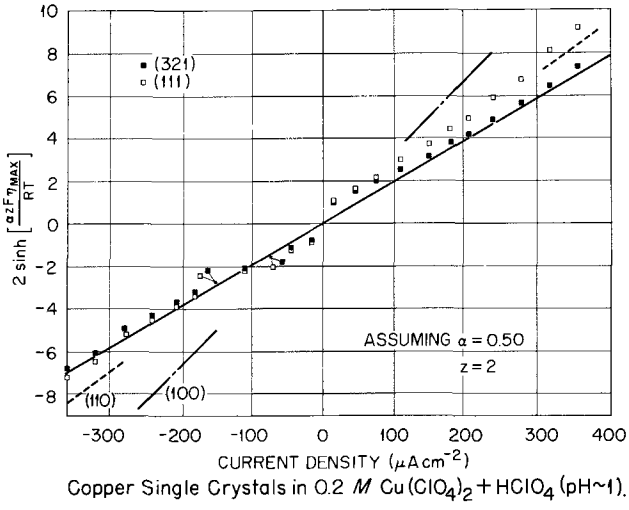

Fig. 12. Relationships between overpotential maxima and current densities on the (111) and (321) if same parameters assumed which permit proper fitting of (100) and (110) data.

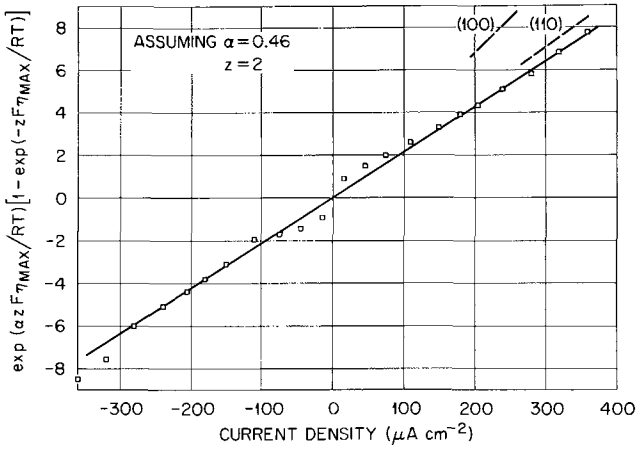

Fig. 13. Relationships between overpotential maxima and current densities on the (111) at 23°C in 0.2M $Cu(ClO_4)_2$ + $HClO_4$ (pH ~ 1) at indicated values assumed for α and Z.

α value of $\sim$ 0.49 for this surface, and further calculations are judged to be not worthwhile. From such plots it is readily seen that the relationship between values of overpotential maxima and the current flowing in the system can be described by the expression

$$i = K\left\{\exp\left[\frac{\alpha z\mathbf{F}\eta_*}{RT}\right] - \exp\left[\frac{-(1-\alpha)z\mathbf{F}\eta_*}{RT}\right]\right\} \quad [12]$$

where η_* = value of overpotential maximum
α = an orientation sensitive transfer coefficient having the values (100) and (110) = 0.50; (321) = 0.49; (111) = 0.46.
z = a factor relating the electrocrystallization overvoltage to the measured overvoltage.
K = a pre-exponential function having the dimensions of current density. The orientation dependent values measured from the slopes of the lines in Fig. 11, 12, and 13 are: (100) = 30; (110) = 40; (111) = 45; (321) = 50 $\mu A/cm^2$
i = current density.

The remaining terms have the significance previously indicated.

Previously it has been postulated that premaxima currents were accompanied by changes in surface adatom concentrations without concomitant action at steps. This is, of course, in agreement with the requirements that surface adatom concentrations be less than the equilibrium value during anodic processes when $\eta_{iii} \neq 0$. A cursory examination of Eq. [9] reveals that data of others regarding $(a_{Cu^{2+}})$ and η_{ii} define conditions such that $2\eta = \eta_i + \eta_{iii}$. The preceding analytical treatment of current-overpotential maxima data requires that $\eta_{iii} = 2\eta$. Therefore, it is necessary to determine conditions under which η_i can approach zero, and to decide if those conditions can be established. Again referring to Eq. [8] and considering the anodic case, it is obvious that η_i can approach the limiting zero value only under the circumstances previously discussed when $(a_{Cu^+})_{eq} > (a_{Cu^+})$. This, in turn, is permissible in the specific case considered when $(a_A)_{eq} > (a_A)$. Therefore, it appears the analytical treatment is reasonable in terms of a model reaction sequence which requires that $(a_{Cu^{2+}}) = (a_{Cu^{2+}})_{eq}$, $\eta_{ii} = 0$, $\eta_i \rightarrow 0$, and that reaction (i) occur within the diffusion layer at a rate greater than reaction (iii) occurs on the surface during the time of the transient. Apparently voltage time characteristics resulted from complicated interactions due to these latter two reactions, and in view of such processes even the twin maxima often observed during postcathodic anodic transients illustrated in Fig. 7 seem reasonable and comprehensible.

At current densities higher than those reported here it would appear that $\eta_i >> 0$ and $\eta_{iii} < 2\eta$. Eventually at still higher current densities the conditions become established whereby, as reported by others, $\eta_{iii} = 0$ and $\eta_i = 2\eta$. It is interesting to note that the data of Piontelli *et al.* were obtained in just this transitional range of current densities where it is suggested that the relationship between η_i and η changes with current density.

Figures 11 to 13 indicate that overpotential values obtained at current densities $\lesssim$ 100 $\mu A/cm^{-2}$ do not agree with the proposed mechanism and treatment as well as those obtained at higher current densities. However, this effect is consistent with the assumption that maxima occurring under the former conditions were not established before significant reaction had occurred at steps. The significance of the pre-exponential constants determined for each orientation depends on the validity of the suggested model of events on the surface and in the diffusion layer. If the proposals advanced to explain the experimental observations are correct, and if the adatom concentrations at equilibrium are about equal on all orientations, then K values could closely approximate the values of the exchange current density of adatoms and ions in solution. It is interesting to compare them with the value of 20 $\mu A\ cm^{-2}$ obtained by Roiter *et al.* (8) on single crystalline zinc in zinc sulfate solutions. Anodic and cathodic maxima were symmetric about the equilibrium point in the zinc system, and it was determined that observed values of maxima depended upon the nature of the preceding electrode process. Unfortunately, no reference is made to the orientation(s?) of zinc crystals used in the study so analogies regarding orientations cannot be drawn. Obviously K values are lower by factors of $\sim$ 200 than the exchange current densities determined by Bockris and Enyo under conditions of charge transfer control. However, as previously noted, such experimental conditions require that adatoms and metal atoms be indistinguishable, a condition not demanded of the systems reported here. This suggests the possibility that excessive removal rates so alter copper surfaces that measurements determined thereon are concerned with surfaces of marked physical differences, in the sense of geometric arrangements, adsorbed species, identity of nearest neighbors, etc., from those on which removal rates are low enough that a surface process may be rate controlling.

Anomalous deposition effects.—The previous treatment accounts in a self-consistent manner for most of the experimental phenomena mentioned earlier, but it still must be shown that the proposed model accommodates equally well the observed effects of deposition on a succeeding dissolution process. If material is incorporated into the metal lattice at steps, it must become identified with, and indistinguishable from, the rest of the crystal. Therefore, no "deposition effect" should be observed following such a process. By the same token, if nucleation occurred and the deposit formed over the old substrate, only the new steps bounding deposits should serve as possible sources of different effects since material bounded by the steps should be identical with the substrate. However, data shown in Fig. 9 indicate that the deposition process was independent of step density in the range $\sim 10^5$-10^7 cm^{-1} since almost identical cathodic branches of current-overpotential data were obtained for the (321) and (111). Therefore, it is difficult to believe that nucleation phenomena could account for the observed deposition anomaly. A reasonable alternative is suggested by the shapes of anodic overpotential-time curves of the type illustrated in Fig. 8. If, as proposed, the shape of low current density "normal" anodic overpotential-time curves reflect both reaction at steps as well as depletion of surface adatoms, then the relationships between cathodic and subsequent postcathodic, anodic curves indicate that material deposited at low and intermediate current densities had more the characteristics of adatoms than of the crystalline substrate. (Although it is not to be assumed that the process is completely independent of the substrate.) Moreover, these characteristics were retained over long periods of time. Therefore, it is suggested that much of the material deposited at low current densities over relatively short periods of time did not occupy half-crystal positions, and in this sense could not be distinguished from adatoms. Since, as indicated in Fig. 8, the anomaly could be observed for the total deposit equivalent to much more than a monolayer of material, such deposits probably have extremely open structures with high vacancy concentrations. This is equivalent to proposing that under these conditions crystal growth occurred more or less by direct addition of atoms at random sites, with little subsequent surface diffusion. While conceptually the idea lacks a certain appeal, it appears that, following a low current density cathodic process, the observed smaller values of anodic maxima and increases in times to establishment can be explained on the basis of an increased concentration of adatom-like material under conditions of "pseudo-equilibrium."

A further indication of the differences in dissolution and deposition processes at low and intermediate current densities is seen by comparing the post-maxima shapes of overpotential-time curves of Fig. 6. Such dif-

ferences were more difficult to detect at current densities in excess of ~ 200 $\mu A/cm^2$, and with the exception of the (111) and possibly the (100), at higher current densities overpotential-time relationships were almost precisely similar for anodic and cathodic processes at the same current density on any one orientation.

A somewhat more quantitative discussion of the deposition anomaly is possible. The data in Fig. 10 show clearly that "normal" maxima for both anodic and cathodic processes at the indicated current densities were established on all orientations well before the equivalent of a monolayer of copper had reacted. But as indicated in Fig. 8 the deposition effect was not restricted to the charge passed in establishing a maximum, but rather to the total amount of material deposited. The highest current density at which it was established that ensuing anodic maxima formed only when the total previous deposit had been removed was 160 $\mu A/cm^2$. Six hours following depositions lasting 1 min at this current density, dissolution produced anodic maxima only after one minute at the same current density. ("Normal" anodic maxima under such conditions were established in ~ 0.1 sec on all orientations and had larger absolute values than observed in postcathodic instances.) These depositions corresponded approximately to the equivalent of 15 atom layers. At lower current densities the largest deposit which was precisely duplicated in a succeeding anodic overvoltage-time to maximum curve corresponded to ~ 50 atom layers. Neither of the examples cited here were established as limiting cases, nor indeed were any of the limiting conditions precisely defined. However, it was observed that at current densities $\gtrsim$ 200 $\mu A/cm^2$ the effect diminished as the current density increased, and a relationship between the total amount of deposit and the amount removed at the time of anodic maximum formation could not be established at higher current densities.

A most intriguing aspect of the overpotential data is that the (321) and (111) have nearly identical cathodic but quite different anodic branches. Previously it has been pointed out that, as illustrated in Fig. 6, on any orientation postmaxima anodic and cathodic overpotential-time relationships are not always identical for any one reaction rate, even at the highest current densities studied. This indicates that immediately after the maximum change in adion concentration had been established, subsequent surface events were not precisely equivalent for dissolution and deposition. The suggested model of reaction seems suitable for anodic processes, but further discussion is required in the cathodic case. The relative step densities on the (321) and (111) suggest that the lack of symmetry in the (111) overpotential data resulted from lower values for cathodic processes rather than excessively high values for the anodic. If so, it was not diffusion over the surface which limited the maximum cathodic overpotential developed on the (111), otherwise the (321) surfaces would not have produced data identical to that obtained for the (111). At higher current densities it is possible that unusual growth processes might have occurred on the (111). It could be that diffusion was such a relatively slow process that growth was accomplished on the flat surface areas rather than by diffusion to step sites. However, there is insufficient evidence to suggest nucleation processes occurred, and furthermore, by analogy to observations on all orientations at low current densities, it seems preferable to think of growth on the (111) as being accomplished by rather ill-defined methods which produced atom layers with a very high vacancy content.

A more plausible reason for the asymmetric behavior of the (111) and (321) could be a consequence of the fact that the (111) is the close packed plane in copper. In face-centered cubic systems such as copper the close packed planes are stacked in the sequence ABCABC-AB . . ., etc., but it is not at all certain that adatoms on a (111) area are restricted to sites representing proper crystal sequential orders. So while there are two types of geometrically similar sites available to adatoms on this surface, in terms of permanent occupancy of such sites one of them is crystallographically improper. Growth occurring in such unsuitable arrays, rather than by movement of crystallographically correct steps over the surface, could have been responsible for the asymmetric behavior observed. The slight asymmetric property of the (321) data emphasizes the fact that a tremendously high step density was incapable of causing complete obliteration of this effect, and that perhaps it is indeed an intrinsic property of the close-packed arrangement. Therefore, it is not at all certain that the "deposition anomaly" observed on all orientations at lower current densities did not also occur undetected on all orientations at higher current densities. It is possible that diffusion over any orientation was relatively so difficult that initial growth at all the current densities reported here occurred in such a way that structures with very high vacancy content always were formed.

Manuscript submitted Jan. 27, 1969; revised manuscript received *ca.* Dec. 24, 1969. The data reported here were presented in part as Paper 110 at the Washington Meeting, Oct. 11-15, 1964, and in part as Paper 72 at the Philadelphia Meeting, Oct. 9-14, 1966. The research on this paper was sponsored by the USAEC under contract with Union Carbide Corporation.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

Oxygen Reduction on Active Platinum in 85% Orthophosphoric Acid

A. J. Appleby*

Institute of Gas Technology, Chicago, Illinois

ABSTRACT

The oxygen reduction reaction on platinum that has been anodized, followed by reduction at 500 mV, has been studied in 85% orthophosphoric acid over a wide temperature range. This anodized platinum surface is more active for oxygen reduction than annealed reduced platinum in the 850-950 mV potential range and has a higher Tafel slope (1.79 $RT/\mathbf{F}$ at 25°C, compared to 1.04 $RT/\mathbf{F}$ for the annealed surface). Activation energy at the reversible potential is 14.9 ± 1.5 kcal. It is suggested that the rate-determining step on this surface is

$$S + O_2 + H^+ + e^- \rightarrow SO_2H$$

under conditions in which the adsorption of the product is close to Langmuirian. Hydrogen peroxide is *not* appreciably involved in the reduction mechanism. These results are interpreted in terms of the surface structure of the electrode after oxide reduction.

It is well-known that platinum that has been freshly anodized behaves as a more effective catalytic surface for a wide range of electrochemical processes. This effect has been explained by Kolthoff and Nightingale (1) and by Davis (2) as being due to facilitated electron transfer from the oxidized platinum surface by an oxygen-bridge mechanism. Other workers, on the other hand, have argued that a chemical mechanism is responsible in which reagents react directly with the oxidized surface, which is unstable under reducing conditions (3, 4).

Anson (5) considered that platinum that has been oxidized then reduced by a redox system is covered by a thin, platinized layer, and behaves as a specially active surface. This argument is supported by the observation that marked roughening of the surface occurs under a-c conditions (6). However, Gilman (7) has shown that only a small increase in area is produced by one polarization cycle, and this is true only if reduction of the oxidized surface is rapid. An alternative explanation was advanced by Feldberg, Enke, and Bricker (8) who attributed the enhanced activity of oxidized and reduced platinum to an adsorbed layer of PtOH.

In general, no special increase in activity other than that which may be attributed to impurity adsorption (9, 10) is observed by pulsing platinum to 1.6V (11). Under these conditions, approximately one monolayer of adsorbed oxygen on the platinum surface is involved (12). At higher potentials, more than one monolayer of oxide may form (13-15).

In this paper, the reduction of oxygen in 85% orthophosphoric acid is studied on reduced platinum that has been previously anodized at high potentials. Kinetics and mechanism on this active surface are compared with those occurring on a reduced, annealed platinum surface (10).

Results are interpreted in terms of surface modification due to partial reduction of the oxide layer, with the formation of a strained lattice containing dissolved oxygen and with a high density of surface defects (16).

Experimental

The all-silica cell in which the experiments were carried out has been described in a previous publication (17). The working electrode consisted either of one of a number of 1-cm² platinum foils suspended from wires, or of the disk of a rotating ring-disk electrode. Electrodes (zone-refined grade, nominal 99.999% purity) were degreased and washed in concentrated HCl, conductivity water, and the electrolyte itself before use. The reference electrode was a dual bubbling hydrogen system equipped with a Luggin capillary. Hydrogen for the reference electrode and oxygen or oxygen-nitrogen mixtures (reproducibly mixed to the required P_{O_2} by capillary flowmeters) were led to the cell via presaturators. All measurements throughout this work were carried out by conventional galvanostatic methods, although with the ring-disk electrode a potentiostat was used. The latter electrode was used to study the formation of hydrogen peroxide intermediates in the reaction and to obtain polarization data over a longer activation-controlled range.

The electrolyte was purified by treatment with hydrogen peroxide in a manner previously described (17). All potentials throughout this paper are expressed relative to the bubbling hydrogen electrode in the same solution (HRE potentials).

Electrode pretreatment.—Electrodes were anodized at a potential of 2V HRE for 2 min and were then allowed to reduce galvanostatically at a current density of 20 μA/cm² until the potential reached 500 mV. Following this treatment the cathodic galvanostatic current was switched off and the electrode was allowed to attain its equilibrium rest potential.

Rest potentials.—Rest potentials of the electrodes were approximately 990-1010 mV. The values were not significantly temperature dependent; initial experiments, carried out by adding small quantities of analytical grade 85% orthophosphoric acid to the pure electrolyte, established that small traces of impurities resulted in lowered values.

Tafel plots were obtained as soon as the electrode had reached an open-circuit potential whose value had changed by less than 5 mV in the previous 2 min. It was noted, however, that the potentials of electrodes left on open circuit slowly rose over a period of hours to a maximum of 1020-1030 mV.

Tafel plots.—Galvanostatic Tafel plots were made using a conventional battery-operated, high impedance circuit allowing sufficient time (up to 5 min at low current density, 1-2 min at higher current density) for equilibrium to be reached at each point. Steady-state readings were taken when the potential changed by less than 2 mV in the previous interval of 1 min. Plots were obtained in this way at 25.1°, 52.1°, 76.1°, 95.9°, 116.0°, and 136.1°C (Fig. 1). In general, they could be traced forward and backward with very little hysteresis.

Each potential-log current plot shows a gently sloping region extending from the rest potential, followed

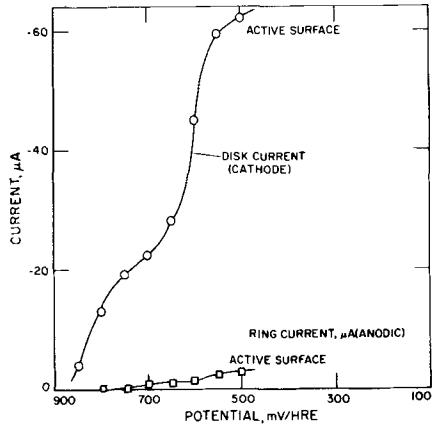

Fig. 3. Ring-disk electrode data, 4840 rpm at 76.1°C

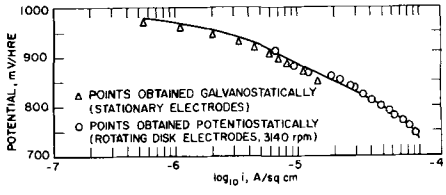

Fig. 4. Tafel plot at 76.1°C on active platinum: stationary and rotating disk electrode data.

by a Tafel region starting at about 925 mV. The Tafel slopes and $1/\alpha$ values at each temperature studied are given in Table I. In addition, Table I contains exchange current values obtained by extrapolating the Tafel line to the calculated reversible potential at each temperature (assuming $P_{O_2} = 1$ and $P_{H_2} = 1\text{-}p$ atm, where p is the water vapor pressure above phosphoric acid).

In each case the experimentally obtained exchange current has been corrected to 1 atm oxygen partial pressure assuming a first order mechanism (see below).

Order of reaction for oxygen.—A series of Tafel plots was made at different oxygen partial pressures. At the lower partial pressures it was necessary to wait for some time to elapse before the first point was taken to allow oxygen evolved during electrode pretreatment by anodizing to disperse before reproducible results could be obtained. Tafel plots at four oxygen partial pressures on active platinum electrodes at 52.1°C have been previously published (18). A log-log plot of polarization data in the Tafel range of these plots is shown in Fig. 2, which indicates that the chemical reaction order for oxygen reduction is unity.

Hydrogen peroxide.—A rotating ring-disk electrode was used to determine the percentage of hydrogen peroxide produced, either as the end product of a parallel mechanism or as an intermediate in the overall process of oxygen reduction to water. In these experiments the disk electrode was prepared by anodizing followed by reduction in the same way as the platinum foil working electrodes referred to previously. The lightly platinized ring of the electrode was maintained at a constant potential of 1.3V HRE; at this potential hydrogen peroxide oxidation is diffusion controlled. Experiments were carried out at 76.1° and 116.0°C in 85% orthophosphoric acid purified by hydrogen peroxide treatment. Disk current and the corresponding anodic ring current were determined at various cathodic potentials applied to the disk by means of a potentiostatic circuit. A typical reduction wave for oxygen at 76.0°C is shown on Fig. 3, for a rotational velocity of 4840 rpm. Unlike the corresponding case on oxide-free annealed platinum (10), little effect of impurity adsorption on oxygen reduction kinetics in the double layer region was noted.[1] At 76.1°C, small quantities of hydrogen peroxide were detected at the electrode ring. The collection factor of the electrode used was 35%; on this basis hydrogen peroxide accounted for less than 10% of the total reaction product or detectable intermediate. At the same temperature on annealed oxide-free platinum, hydrogen peroxide accounted for a greater proportion, approximately 16% of the total product or intermediate. At 116°C, no hydrogen peroxide could be detected at the ring when the disk was in the "active" state.

The ring disk electrode at 3140 rpm was used to confirm the Tafel slope at 76.1°C over a greater range than was possible in the electrolyte stirred by gas bubbling. At this rotation speed, the linear Tafel range at the electrode was increased by approximately a further decade. Figure 4 shows that there is good agreement between the Tafel slope for platinum foil electrodes under stirring by gas bubbling and a rotating disk electrode at a high rate of hydrodynamic stirring.

Activation energy.—Figure 5 shows an Arrhenius plot of the extrapolated i_0 values (corrected for oxygen partial pressure). Activation energy at the reversible potential on this basis is about 14.9 ± 1.5 kcal (10), and the value on active platinum is close to that observed on oxidized platinum (13.1 kcal) (17).

The higher temperature i_0 values lie somewhat off the line; this is probably due to the uncertainty in measuring the Tafel slope (assumed to be about 125 mV/decade) at the higher temperatures.

Table I. Kinetic data for oxygen reduction on active platinum in 85% orthophosphoric acid

Temp, °C	i_0, A/cm² (atm O_2)	Tafel slope, mV/decade	$1/\alpha$
25.1	2.7×10^{-10}	106	1.79
52.1	3.4×10^{-9}	119	1.85
76.1	1.5×10^{-8}	120	1.76
95.9	4.0×10^{-8}	124	1.69
116.0	1.2×10^{-7}	125	1.62
136.1	2.8×10^{-7}	125	1.52

[1] This deactivation is attributed by Bockris *et al.* (19) to $H_2PO_4^-$ ion adsorption.

Discussion

Nature of the active platinum surface.—Platinum which has been anodized at high potential has on its surface a phase oxide film at least two monolayers thick (13-15). In addition, the outer layers of the platinum lattice appear to contain "dermasorbed" oxygen, that is, oxygen dissolved in the first two or three atomic layers of the platinum. Evidence for the existence of the latter type of dissolved oxygen has been given by Schuldiner and Warner (20), and is implicit in the observation that the anodic charge in galvanostatic transients is always greater than the cathodic charge in the platinum oxidation reduction cycle. The evidence for this has been reviewed by Vetter (21) and Hoare (22). This observation has been explained by Gilman (23) in terms of an impurity oxidation reaction contributing to the anodic current, by Laitinen and Enke (14) in terms of oxygen evolution in the anodic cycle, and by Vetter and Berndt (24) in terms of a cathodic mechanism involving a 2-electron reduction of the oxide film so that hydrogen peroxide was the end product rather than water. The latter reaction is unlikely, in view of the ring-disk electrode data of Frumkin *et al.* (25), which indicated that no detectable hydrogen peroxide was produced during oxide-film reduction on platinum. Equally, the first two explanations are unlikely as the same phenomenon is observed under conditions of high purity (additionally oxidation of many species is strongly inhibited on oxidized platinum) (26) and oxygen evolution is not normally apparent at low potentials, at which this effect is still observed.

Feldberg *et al.* (8) offer an explanation for this phenomenon in terms of a partial reduction of the platinum oxide film [which consists of PtO (27) if the potential of the electrode is not greater than about 1.8V] to PtOH, on the assumption that the reduction of this compound is highly irreversible. This is difficult to accept on kinetic grounds, and it is hard to see how an oxide film some monolayers thick can be exactly half reduced to a PtOH film with the same thickness.

A previous publication (10) has described the kinetics of oxygen reduction on a platinum surface prepared by electrochemical reduction to remove any residue oxide followed by anodic and cathodic pulsing (at a maximum anodic potential of 1.2-1.5V) to produce a surface free of adsorbed capillary-active impurities. If PtOH is the end product of the reduction of the PtO produced in the anodic pulse, it would be expected that the electrode surface would be covered with a monolayer of this material. The surface produced by this treatment is, however, kinetically similar to platinum pretreated by hydrogen reduction at 500°C. The latter surface is unlikely to carry any oxidized platinum; in addition, it is hard to see how radicals such as O_2H or O can be adsorbed on a surface bearing a monolayer of a similar species (OH) and still obey a Temkin-type adsorption isotherm, in which the heat of adsorption of species of similar electronegativity (for example, OH, O, O_2H) falls off as the total coverage increases (28). This isotherm accurately applies only at intermediate coverages ($0.2 < \theta < 0.8$); at $\theta \rightarrow 0$ or 1, adsorption is Langmuirian. Hence, with a coverage of —OH close to unity, the adsorption isotherm for O or O_2H would be expected to be also Langmuirian.

It seems reasonable to assume that the charge imbalance in anodic and cathodic galvanostatic transients is caused by diffusion of oxide ions into the first few monolayers of the platinum lattice (20) where they become inaccessible for reduction. Because of the high energy of the platinum lattice containing interstitial oxygen, it is energetically difficult for the oxygen to diffuse out through the reduced outer one or two monolayers of platinum. The latter are envisaged to be, therefore, situated on top of a disordered highly strained lattice of Pt-O alloy, so that the surface after oxide reduction is a high-energy, randomly oriented platinum layer containing numerous vacancies and lattice defects.

It is interesting to note that the "active" surface is not produced by pulsing to 1.5V, where only one monolayer of reducible oxide is involved (12). It is necessary to strongly oxidize the surface by anodizing at high potential, followed by reduction at about 600-700 mV to remove the superficial reducible oxide layer. The disordered surface containing dissolved oxygen thus produced is not particularly stable, but is more stable than would be expected for a very lightly platinized surface, of the type suggested by Anson (5).

As Feldberg *et al.* (8) have shown, the active surface degrades very slowly above 700 mV, but is reduced relatively quickly to give a normal annealed platinum surface at 300 mV. It seems likely that the nitric-acid-treated platinum surface reported by Hoare (29) is a similar high-energy surface containing dissolved oxide ions.

Mechanism of Reaction on the Active Surface

The principal kinetic characteristics of the active surface are: (*i*) first order reduction of oxygen, and (*ii*) Tafel slopes of 1.79 *RT*/**F** to 1.54 *RT*/**F**, depending on temperature. In addition, the surface is more active than annealed, oxide-free platinum, less affected by impurities, and produces less hydrogen peroxide.

On normal (annealed) platinum the Tafel slope is *RT*/**F**, and oxygen reduction is first order. It has been shown that this is consistent with the rate-determining step (10, 11)

$$SO_2 + H^+ + e^- \rightarrow SO_2H$$

in which it is assumed that the adsorption of SO_2H follows the Temkin isotherm. This is justified on the following grounds. The rate equation for the above reaction is

$$i = \theta' k\mathbf{F} \exp(-\beta\mathbf{F}V/RT - \beta r\theta/RT)$$

where β is a symmetry factor, θ' is the coverage of molecular oxygen, θ is the total coverage of similar oxygenated compounds (—O, —OH, and —O_2H) on the electrode surface, r is the change in heat of absorption for unit change in θ, and k is the specific rate constant. **F**, *R*, and *T* have their usual meanings. Only the adsorption of the product of the reaction follows the Temkin isotherm; the observation that oxygen reduction is first order implies that $pO_2 \propto \theta'$; that is, a

Langmuir isotherm (at low coverage) operates for the reactant (10).

Assuming that the oxidation products of water (—O and —OH) are in equilibrium on the electrode, and their adsorption obeys a Frumkin isotherm (Temkin approximation in the coverage range $0.2 < \theta < 0.8$) then it can be shown in this interval of θ (30)

$$\partial V/\partial\theta = \frac{r}{\mathbf{F}}$$

and $\mathbf{F}V = r\,\theta$ (29)

Hence

$$i \propto pO_2 \exp(-\mathbf{F}V/RT)$$

Damjanovic and Brusic (11) have also shown that this treatment is consistent with their observed pH dependence.

In principle, the oxygen electrode on oxide-free platinum behaves like a normal charge transfer process with a Tafel slope $2RT/\mathbf{F}$, which is progressively poisoned (*i.e.*, the rate constant decreases) by the increasing surface coverage of the oxidation products of water with increasing potential. The reduction reaction on the active surface apparently involves the same rate-determining step taking place under conditions of increased heat of adsorption of the reaction intermediate ($—O_2H$),[2] thus accounting for the increased rates, and where this effective poisoning (fall in rate constant due to change in heat of adsorption with coverage) is less apparent. We must postulate that the adsorption isotherm of O_2H is more nearly Langmuirian on the "active" surface.

If we consider a surface with a high proportion of lattice defects, it is probable that the range of energy distributions at individual defects is not too wide. On this basis, with only a small number of sites that are active at any time, approximately Langmuir conditions of adsorption at relatively low coverage are possible. The effect of $O^=$ within the lattice must not be discounted. If the Temkin isotherm on the annealed surface is caused by an induced heterogeneity effect, due to dipole interaction at the surface, then the effect of lattice oxygen may be to reduce these interactions and allow a more Langmuirian isotherm to operate.

The activation energy on the reduced annealed surface was previously determined to be approximately 22.9 kcal at the reversible potential (10). This figure contains a heat of adsorption term due to fall in bond-strength of reaction intermediates as —O coverage on the electrode rises with potential. For this reason, it is more legitimate to compare activation energies for the two surfaces at a potential where coverage by adsorbed —O is low, rather than at the reversible potential. On this basis, the difference in activation energy at about 800 mV ($\eta \sim -400$ mV) is (22.9-14.9) $-$ $(\alpha_1 - \alpha_2)\,\eta\mathbf{F}$ kcal, where α_1 and α_2 are the mean transfer coefficients on each surface. With $\alpha_1 \sim 1.0$ and $\alpha_2 \sim 0.59$, this difference amounts to approximately 2.5 kcal. If one assumes that the total increase in surface energy is equivalent to about one surface defect for every ten surface atoms, then it is possible to account for most of the activation energy decrease on this basis. If a platinum atom at a defect has extra energy available for bonding equal to 4 available Pt-Pt bonds, then the excess energy of each site (compared with normal platinum) is about 4 $Ls/6$ where Ls is the latent heat of sublimation of platinum. On the basis of Pauling's equation (31) for the strengths of polar bonds, the increase in bond strength of the reaction intermediate at each site will be approximately

$$\frac{1}{2}\,\frac{4Ls}{6} \sim 40 \text{ kcal/mole}$$

The net increase in bond strength over the whole surface will thus be about 4 kcal. If one assumes that the change in activation energy will be given by $\beta \times 4$ kcal where β is a symmetry factor, a change of 2 kcal might be expected, with $\beta = 1/2$.

It is also likely that the electronic work function at a defect site is not canceling, *i.e.*, it appears in the over-all rate equation. This possibility has been discussed by Damjanovic, Setty, and Bockris (32). Hence, if the electronic work function is lower at defects, an additional reduction in the activation energy may be expected.

[2] This also explains the lower proportion of H_2O_2 detected in comparison with that at the annealed oxide-free surface (10).

Conclusion

The "active" surface of platinum is kinetically different from a normal annealed platinum surface prepared by reduction. This may be attributed to the effect of dermasorbed oxygen (20) within the first few layers of the lattice, and to a high degree of surface disorder. Since the structure of the surface is not stable, eventual rearrangement and recrystallization take place with the production of a platinum surface with normal properties. The method of activation by anodizing and reducing is consequently not a promising method for long-time improvement in the electrocatalytic properties of the substrate.

Technical Notes

Zinc-dichromate High Power Primary Cell

Gianfranco Pistoia and Bruno Scrosati*

Istituto Elettrotecnico, Universitá di Roma, Rome, Italy

It is known that the electrochemical cells so far developed, at high discharge current drains, *i.e.*, current densities greater than 0.15 A/cm^2, generally have the characteristic of showing an appreciable voltage drop at the electrodes. This makes it impossible to obtain high specific power values, *i.e.*, power densities greater than 0.25 W/cm^2, with such systems.

The characteristics necessary in an electrochemical system for the development of a high power cell, *i.e.*, a cell capable of tolerating high discharge rates, are in essence: (*a*) high values of open circuit potential (OCV), (*b*) very low internal resistance to ensure that IR drops through the cell are almost negligible, and (*c*) very low electrode polarizations even at high discharge rates.

None of the high power cells based on metallic anodes and halogens as cathodes, such as Mg/Cl_2 (1), Zn/Cl_2 (2), and Mg/Br_2 (3) has all these characteristics. In these systems, in order to dissolve the halogens, it is necessary to use electrolytes containing halide salts, such as NaCl and NaBr (1), $CaCl_2$ and $ZnCl_2$ (2), and $MgBr_2$ (3), which do not possess high specific conductivities. This results in an appreciable voltage drop under discharge and, consequently in the impossibility of obtaining high power values. Furthermore, the necessity of a continuous supply to the positive electrode of the gaseous or liquid halogen from a separate container creates enormous problems as far as both materials and techniques are concerned. Finally the high cost and the use of substances which are dangerously toxic makes this type of cell limited in its application.

It would seem more practical to use, as a cathode, a couple in which the oxidized form is present on the electrode support, as in the Zn/KIO_3 (4) and Zn/AgO (5) systems, or, alternatively, in solution. The latter has some advantage over the former, since it does not require preformation of the cathode, as it is sufficient to provide an inert electrode, such as graphite, at whose surface the oxidized species may be reduced.

One of the cells which works with a liquid depolarizer is the zinc-dichromate cell. This cell is an old concept and could in principle be discharged at high current drains (6). On the other hand the cell, in its old construction, presents serious disadvantages, such as electrode polarizations and very short shelf life, which have so far prevented its use for high power purposes. These disadvantages can be overcome by recirculating the electrolyte through the electrodes, choosing the best electrolyte concentration and working temperature and by careful design of the cell. Using a similar technique, Crowley *et al.* were able to realize a high rate performance cell based on a Mg/CrO_3 system having a recirculating acidic electrolyte (7).

In this work the characteristics and the performance of an improved zinc-dichromate cell are reported.

Experimental

Choice of electrolyte.—Before arriving at the system Zn/$Na_2Cr_2O_7$ in acidic solution, several other possible cathodic couples for the development of high power cells, were taken into consideration. Among these were

$S_2O_8^{2-}/SO_4^{2-}$	$E° = 2.01$V
Co^{3+}/Co^{+2}	$E° = 1.81$V
MnO_4^-/Mn^{2+}	$E° = 1.69$V
Ce^{4+}/Ce^{3+}	$E° = 1.61$V

The respective voltage under load of cells using each of these systems coupled with a zinc anode and in sulfuric solution was, at best, about 1V for current densities of the order of 0.05 A/cm^2.

More encouraging results were obtained with systems utilizing the $Cr_2O_7^{2-}/Cr^{3+}$ couple and therefore attention was focused on this cathodic material. The characteristics of the zinc-dichromate system were thoroughly studied, particularly as far as the composition of the electrolyte and its recirculation procedure through the electrodes were concerned.

It is known that the formal potential of the $Cr_2O_7^{2-}/Cr^{3+}$ couple varies widely with the nature and the concentration of the acid (8). In HCl and $HClO_4$ solutions, especially when dilute, the formal potential is considerably lower than in H_2SO_4 solutions. It was noted that progressively increasing the H_2SO_4 concentration up to 4.5M [32 w/o (weight per cent)] the OCV of the zinc-dichromate system correspondingly increases to a value very close to the 2.12V expected from the formal potentials of the two electrodes.

Also the dichromate concentration plays an important role especially as far as the oxidation reaction rate is concerned (9). It is known that in acidic solution the following equilibria are present

$$HCrO_4^- \rightleftharpoons H^+ + CrO_4^{2-}$$

$$2HCrO_4^- \rightleftharpoons H_2O + Cr_2O_7^{2-}$$

It appears that the most active ion in the oxidation process is $Cr_2O_7^{2-}$ which predominates at high concentrations (8). It follows that the use of concentrated dichromate solutions is necessary in order to obtain the high reaction rates that are essential to realize an electrochemical system able to work at high current drains.

* Electrochemical Society Active Member.

Several tests were performed with the system Zn/$K_2Cr_2O_7$ using a 32 w/o H_2SO_4 aqueous solution and with a $K_2Cr_2O_7$ concentration increasing from 3 to 10g for 100g of sulfuric solution. The cell performance improvement was consistent with the concentration increase. Potassium dichromate, however, is not very soluble and it was not possible to reach a concentration higher than 10 w/o of the salt in the sulfuric solution. Since sodium dichromate has greater solubility, the Zn/$Na_2Cr_2O_7$ system was examined, with the dichromate concentration increasing from 10 to 20 w/o. Since concentrations higher than 15 w/o did not improve the cell performance significantly, the solution H_2SO_4 32 w/o and $Na_2Cr_2O_7$ 15 w/o in water, was chosen as the optimum electrolyte solution.

Cell structure.—A possible cell structure is shown in Fig. 1. This cell essentially consists of a circular amalgamated zinc plate forming the anode which faces the cathode, a circular graphite plate. The surface of each electrode is 50 cm^2 and the distance between them 0.2 cm.

The electrodes are kept at the desired distance by an inert support on which are located both the inlet and the outlet for the recirculating electrolyte. The system is sealed by the external casing and by gasket rings. The cell performance improves with the temperature increase of the solution. In order to avoid an external heat source, an initial working temperature has been chosen that could be obtained simply by mixing the $Na_2Cr_2O_7$ aqueous solution with the sulfuric acid before the activation of the cell. For this purpose the sulfuric acid and the dichromate solutions are kept in two separate containers (Fig. 2). By this procedure it is possible to obtain a temperature of 75°C and an electrolytic conductivity of 0.97 $ohm^{-1} \cdot cm^{-1}$ compared with 0.66 at 20°C.

At the moment of the cell activation, known amounts of the two solutions are released and mixed together

Average working temperature; 60°C; OCV: 2.10-2.12V; electrode surface: 50 cm^2; electrode separation 0.2 cm.

Current density ($A/cm^2 \cdot 100$)	Average voltage at electrodes (V)	Power ($W/cm^2 \cdot 100$)	Time of discharge (min)
1.6	1.88	3.0	50
8.0	1.83	14.6	25
13.6	1.76	23.9	10
20.0	1.64	32.8	10
30.0	1.59	47.7	8
40.0	1.54	61.6	5
44.0	1.41	62.0	4
48.0	1.22	58.5	4
50.0	1.00	50.0	3

in a third container situated below. By means of a pump, the electrolyte is then continuously recycled between the electrodes. The electrolyte inlets are designed so as to ensure a uniform distribution of the liquid on the plates. At the end of the cell operation the exhausted electrolyte is eliminated from the mixing container by an outlet at the bottom of the container itself. In this way the contact between electrodes and solution is restricted solely to the period when the cell is operative. Consequently, self discharge processes are minimized. A value in the upper part of the container eliminates the possibility of any pressure build-up.

The electrolyte recirculation is extremely convenient for this type of cell, because allowing a continuous renewal of the liquid layer in contact with the electrode surfaces avoids accumulation of reaction products in the vicinity of the electrodes.

Results

The performance of the cell is reported in Table I, from which it can be seen that the values of the voltage under load remain sufficiently high even at high discharge current densities. This is due both to the very low value of the internal resistance, calculated as 0.004 ohm at the working temperature, and to the rapid renewal of the electrolytic solution. The first characteristic makes the IR drop almost negligible and the second avoids serious concentration polarization effects.

Figures 3 and 4 show the performance of this cell compared with those based on the most common system so far developed for operation at high current density rates. It can be seen that the cell is able to furnish current and power density values twice as great as those of the Mg/Br_2 cell (3) which to date has been considered the best of the high power cells operating for the periods of time shown in Table I. For instance with the zinc-dichromate cell it is possible to obtain

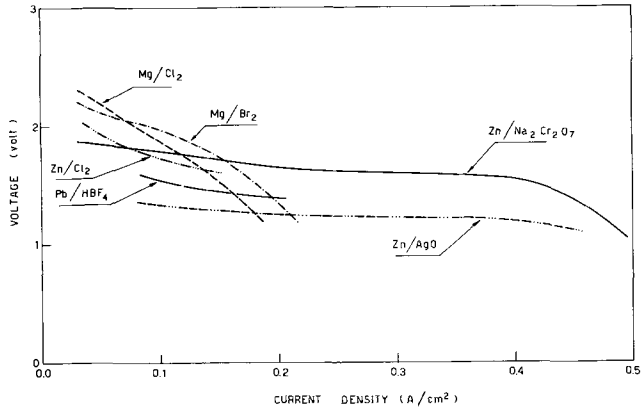

Fig. 3. Voltage-current density for the zinc/dichromate and other batteries at high drain rates. Data related to Zn/AgO and Pb/HBF_4 systems were obtained in pulse condition (10). For data related to Mg/Cl_2, Zn/Cl_2, and Mg/Br_2 see ref. (1), (2), (3), respectively.

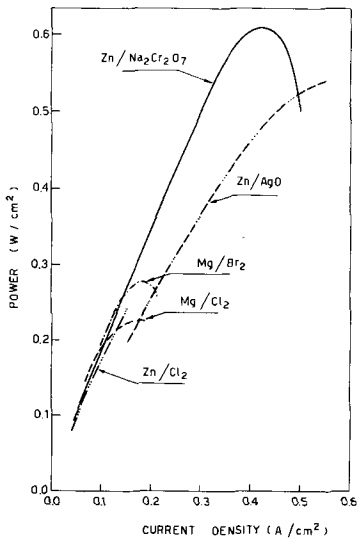

Fig. 4. Power-current density curve for the zinc-dichromate and other batteries at high drain rates. Data related to the Zn/AgO are obtained in pulse condition (10). For data related to Mg/Cl_2, Zn/Cl_2, and Mg/Br_2 see ref. (1), (2), (3), respectively.

a maximum power density value of about 0.62 W/cm² at 0.44 A/cm², while the Mg/Br_2 cell gives a maximum value of 0.28 W/cm² at 0.19 A/cm².

No attempt has yet been made on optimizing the volume and the weight of the cell and therefore no W/g or W/cm³ values are here reported.

The low cost of manufacture, the safety, and the simplicity of use represent other important advantages of the zinc-dichromate cell over the metal-halogens type.

Electrode Overvoltages in Molten Fluorides
The Corrosion of Zirconium Electrodes in Molten KHF_2

S. Pizzini*,[1], G. Sternheim

Euratom CCR, Materials Department, Petten, North Holland

In the previous papers (1, 2) dealing with the evolution of hydrogen at bright Pt electrodes as well as in a paper of this series (3) dealing with the corrosion of aluminum electrodes in KHF_2 melts, it was shown that in anhydrous melts or in melts where the water contamination is lower than about 0.1% by weight, the limiting current for the cathodic evolution of hydrogen and accordingly, the corrosion current of aluminum, is negligibly small. Indeed, it has been felt that the cathodic deposition of the refractory metals from KHF_2 melts should be feasible if the solubility of the fluorides of the refractory metals in KHF_2 melts is sufficiently high or if the diffusion coefficient of the cations is high enough at the relatively low working temperatures. In order to obtain preliminary information on this subject, zirconium was chosen as a test material and corrosion as well as polarization experiments on zirconium electrodes were carried out.

A flanged copper cell with Viton gaskets [a slightly modified version of the graphite cells described in ref. (2)] was used. As before, Teflon was used as a container for the melt and a graphite ring as the auxiliary electrode. KHF_2, twice-crystallized in water-10% ethanol mixtures and dried under vacuum, was used.

Pure anhydrous nitrogen gas was used as cover gas to minimize the contamination of the melt. Electrodes of known geometrical dimensions (about 1 cm²) were mechanically polished, rinsed with ethanol, and then used for corrosion or polarization measurements. The electrodes used for corrosion experiments were quickly extracted from the melt and cleaned in ethanol in an ultrasonic bath. Overvoltage measurements were carried out by the galvanostatic method, as previously described (1-3). As reference electrode, an iso-electrodic zirconium or a hydrogen electrode was used. The voltage of a cell constituted by a hydrogen electrode and a zirconium electrode is about −500 mV. The solubility of ZrF_4 (added to the melt after being previously dried under vacuum) is of the order of 2×10^{-3} moles/liter at 250°C.

Figure 1 shows the ϵ *vs.* current density plot for the cathodic polarization of zirconium electrodes. From this figure one recognizes the presence of a limiting current at about 1×10^{-2} A/cm² and of small plateau at about −1700 mV.

Inspection of the electrode, after polarizing it at about −2000 mV, revealed the presence of a film of potassium metal. When anodically polarized, the electrode eventually passivates. In Fig. 2 the results of different corrosion experiments (at different cathodic polarizing currents) are reported. The experimental value of $i°_K$, the corrosion current under conditions of spontaneous corrosion, equals 3.96×10^{-2} A/cm² (average of 20 experiments). The corresponding mean square deviation is quite large (1.22×10^{-2} A/cm²), thus indicating poorly reproducible surface conditions.

* Electrochemical Society Active Member.
[1] Present address: Istituto di Elettrochimica e Metallurgia dell' Università, via G. Venezian 21, Milano, Italy.

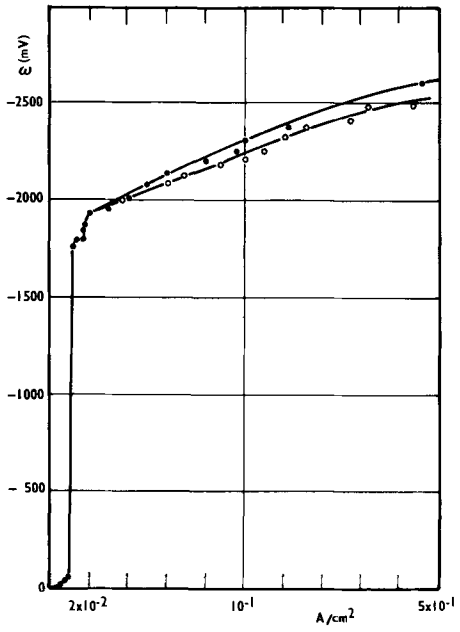

Fig. 1. ϵ *vs.* current density plot for the cathodic polarization of zirconium electrodes in KHF_2 melts. Temperature, 250°C, zirconium reference electrode.

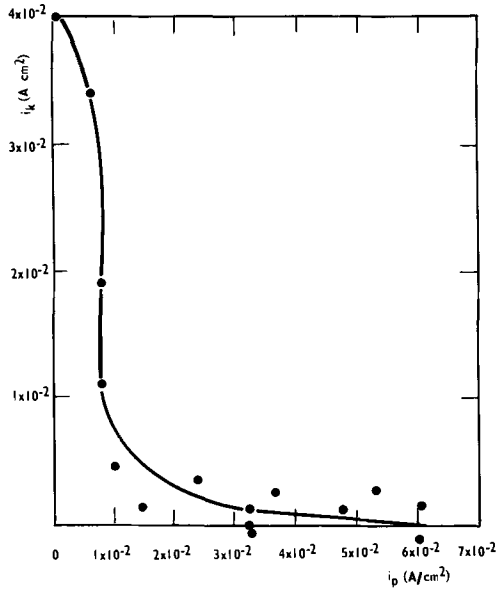

Fig. 2. Weight changes *vs.* polarization current plots for the cathodic polarization of zirconium electrodes in KHF_4 melts. Temperature, 250°C. Weight changes are expressed in terms of corrosion current.

Figures 1 and 2 show that the corrosion rate is greatly reduced and eventually suppressed at voltages between −1700 and −2500 mV. It appears, however, that when the corrosion rate is zeroed, a discharge of potassium takes place. (The negligibly small weight increase observed at the highest cathodic polarization could, however, indicate simultaneous discharge of Zr and K). The zirconium deposition rate is, however, insignificant for any technological application. As this behavior is similar to that of aluminum in the same melt (3), discussion of these present experimental results could be carried out by analogy with the aluminum case, when considering zirconium as a corrosion electrode.

Figure 3 is a picture of the possible reactions which occur at such a corrosion electrode, when the cathodic reactions are supposed to be, according to our previous papers (1, 2), the reactions

$$(\alpha)\ HF + e \rightarrow \tfrac{1}{2}H_2 + F^-$$

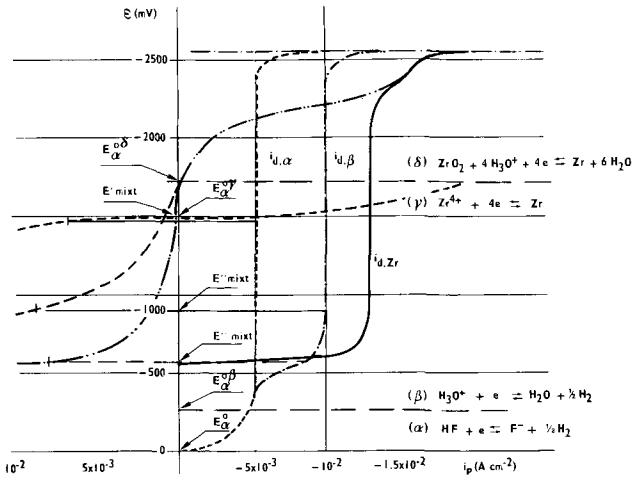

Fig. 3. Schematic diagram of the partial anodic and cathodic reactions at a zirconium electrode in steady state corrosion conditions.

and

$$(\beta)\ H_3O^+ + e \rightarrow \tfrac{1}{2}H_2 + H_2O$$

both of which are diffusion limited. In the case of (β) reaction it has been demonstrated that the limiting current is a function of the water content (1). The overvoltage *vs.* the current density (c.d.) curves for (α) and (β) reactions, reported in Fig. 3 correspond to that measured at Pt electrodes in KHF_2 melts containing water; although the overvoltage for the H_2 discharge could be very different at the Zr electrode, the value of the limiting current must be the same in melts of the same composition.

In the same figure, a guess is also made for the shape of the overvoltage *vs.* c.d. for the possible anodic reactions

$$(\gamma)\ Zr \rightleftharpoons Zr^{4+} + 4e$$

and [see also ref. (4) for the same reaction in aqueous solutions]

$$(\delta)\ Zr + 6H_2O \rightleftharpoons ZrO_2 + 4H_3O^+ + 4e$$

Reaction (γ), whose standard potential (indicated in Fig. 3 as $E_\alpha^{\circ\gamma}$) has been calculated (5) from the free energy of the reaction

$$Zr + 4HF = ZrF_4 + 2H_2 \quad \Delta G^{250°C} = -151.9 \text{ kcal/mole} \quad [1]$$

for a melt saturated in KF as well as in ZrF_4,[2] should account for the free corrosion of zirconium, when the partial cathodic reaction is reaction (α)

$$(\alpha)\ HF + e \rightarrow \tfrac{1}{2}H_2 + F^-$$

Reaction (δ), whose standard potential (indicated in Fig. 3 as $E_\alpha^{\circ\delta}$) has been calculated from the free energy value of the reaction

$$Zr + 2H_2O = ZrO_2 + 2H_2 \quad \Delta G^{250°C} = -132.2 \text{ kcal/mole} \quad [2]$$

is the usual expression for the half cell reaction of an oxide electrode (6).

In Fig. 3 the ϵ *vs.* i_P curves for reactions (γ) and (δ) have been drawn (as dotted and dashed lines) in a manner that supposes the absence of effects of overvoltages for reaction (γ)[3] and a strong hindering (due to the presence of a ZrO_2 layer, possibly nonstoichiometric) of reaction (δ).

Although reaction [1] is apparently thermodynamically favored, reaction [2] should occur as soon as

[2] The possible formation of zirconium hydride has not been accounted for, inasmuch as this effect may be considered as a slight reduction of the thermodynamic activity of zirconium metal.

[3] This condition, based on the assumption that zirconium is a "normal metal" with an exchange current of the order of 10^{-2} A/cm², is, however, unessential for the treatment which follows.

the accumulation of metal cations and water near to the electrode leads to supersaturation and consequent precipitation of the sparingly soluble ZrO_2.

In the same figure different possible values of the mixed potential of the corrosion electrode have been indicated, which only depend on the shape of the anodic overvoltage curve for reactions (γ) and (δ). Reactions (α) and (β) in fact occur under conditions of diffusion-limited current. If it is supposed that reaction (γ) occurs, coupled with reaction (β), then the value of the mixed potential E'_{mixt} closely corresponds to the E_α^γ value and the corrosion current i°_K can be calculated from the known value of $i_{d,\beta}$ as (3)

$$i^\circ_K = i_{d,\beta}$$

Figure 3, where the curves of Fig. 1 (solid lines) are replotted by recognizing that the inflection at −1750 mV corresponds to the zirconium deposition plateau and that the plateau at −2000 mV corresponds to potassium deposition, shows, however, that the potential which the electrode takes under current-less conditions (*i.e.*, E'''_{mixt}) is definitely more anodic than that corresponding to the E'_{mixt} value. Moreover, the corrosion current takes a value

$$i^\circ_K = 3\, i_{d,\beta} = 3\, i_{d,Zr}$$

(where $i_{d,Zr}$ is the cathodic limiting current measured at the Zr electrode, see Fig. 1) if we consider that the average content of water of a KHF_2 bath after the treatments used for the present experiments corresponds to a limiting current for the (β) reaction of about 1.3 x 10^{-2} A/cm² (1, 2).

From the ϵ *vs.* current density curves for the anodic polarization of a zirconium electrode reported in Fig. 3, it appears that the present experimental behavior is well accounted for, if one assumes that the electrode works according to reactions (δ) and (β), *i.e.*, as a covering layer electrode.

When considering a stationary film thickness of the order of 100Å or less [as results from the extrapolation of the data of ref. (4) to a formation voltage corresponding to the overvoltage of the partial anodic reaction (δ)] and ambipolar migration in the semiconducting[4] layer, more insight into the corrosion mechanism could be gained by using the phase-scheme of Fig. 4 for a Zr, ZrO_2 electrode. Here the electrode is represented as a "Korrosion Deckschicht Elektrode" according to Lange (9) and it is supposed that the rate-determining step for the corrosion reaction is the diffusion of H_3O^+ across the diffusion layer. Mobility of Zr^{4+} and O^{--} in the ZrO_2 film does not imply that we assume the migration of ions as a volume process via lattice defects; faults, dislocations, and grain boundaries are alternative paths (10, 11).

From Fig. 4 it is apparent that reactions (γ) and (β), subdivided in the elementary reaction steps and written as

$$(\pi + Zr^{4+} - \text{transf.} + \theta)\underset{I}{Zr^{4+}} \rightarrow \underset{II}{Zr^{4+}}$$

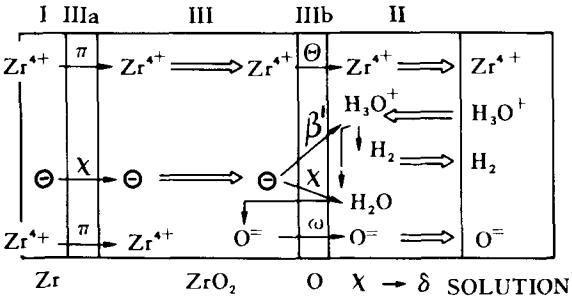

Fig. 4. Phase scheme of a "Korrosion Deckschicht Elektrode." The metal phase is indicated with I, the oxide phase with III, and the solution phase with II. δ indicates the thickness of the diffusion layer. Other Greek symbols indicate, as in the previous paper (3), reactions taking place at the interfaces IIIa and IIIb.

and

$$(\chi + e\text{-transf.} + \beta')\ \underset{II}{H_3O^+} + \underset{I}{e} \rightarrow \underset{II}{H_2O} + \underset{II}{\tfrac{1}{2}H_2}$$

(where Zr^{4+} — transf. and *e*-transf. indicate the mass and charge transfer processes across the ZrO_2 phase) occur simultaneously at a rate which equals the limiting current of β reaction.

If the coupling of reactions (γ) and (β) were the unique process responsible for the corrosion reaction, then the corrosion current i°_K should equal the value of the limiting current $i_{d,\beta}$. This is not apparently the case, because of the side reaction with H_2O, which is a product of reaction (β) and reacts with Zr according to the partial reactions

$$(\chi + e\text{-transf.} + \chi')\ \underset{II}{H_2O} + \underset{I}{2e} \rightarrow \underset{III}{O^=} + \underset{II}{H_2}$$

and

$$(\pi)\ \underset{I}{Zr^{4+}} \rightarrow \underset{III}{Zr^{4+}}$$

and occur as well with a maximum rate which equals the $i_{d,\beta}$ value. In steady state conditions we have therefore

$$i^\circ_K = i_{d,\beta} + 2\, i_{d,\beta}$$

which is a figure very close to the experimental value. This result confirms the proposed model and suggests as a reasonable explanation for the observed codeposition of Zr and K, the permanence (see Fig. 3) of a ZrO_2 layer [with the overvoltage associated with the polarization of the electrode according to reaction (δ)] at voltages higher than the discharge potential of Zr according to reaction (γ).

Nomenclature

E^j_α	Potential of an electrode j, *vs.* a hydrogen electrode whose reaction is α
ϵ	Electrical potential difference measured at the terminals of the tensiometric cell
i_P	Polarizing current A/cm²
i_d	Diffusion limiting current
i°_K	Corrosion current, A/cm², when external current is zero
i_K	Corrosion current, A/cm²
$_I Me^{z+} = {}_I Me - Z_I e$	

Subscripts I, II, III indicate the metal, solution, and oxide phases, respectively.

APPENDIX

In this paper the symbols for the electrode reactions have been written according to our previous papers (1-3) and the nomenclature used is a slightly modified version of the Lange and Göhr symbolism (6).

The arbitrary zero of the potential scale of Fig. 3 is the potential of the reaction (α) for hydrogen at 1 atm and HF at 39.8 mm Hg, which is the equilibrium pressure of a melt of KHF_2 at 250°C saturated with KF.

The potential of reaction (β) is calculated according to ref. (1) by taking into account the free energy of the reaction

$$H_2O + HF \rightleftarrows H_3O^+ + F^-$$

($\Delta G \simeq 9000$ cal/mole at 250°C) and corresponds, for H_2O at 1 atm and HF at the equilibrium partial pressure, to −263 mV.

Acknowledgments

The authors are greatly indebted to Dr. J. H. Westbrook for his valuable suggestions.

On the Electrical Analog Circuit for the Study of Metal Solution Interfaces by the Square Wave Technique for Capacitance Measurements

R. G. Barradas*

Department of Chemistry, Carleton University, Ottawa, Ontario, Canada

and E. M. L. Valeriote*

Department of Physical Chemistry, University of Bristol, Bristol, England

In an earlier paper (1) we evaluated the technique for capacitance measurements published by McMullen and Hackerman (2) and reported that capacity *vs.* potential (*C. vs. E*) curves change in using different values of R_s [see ref. (1)]. At that time the maximum possible values of R_s were used and we argued that there was some empiricism in assuming the electrical analog of the metal-solution interface. In a subsequent communication (3) we suggested an experimental improvement in the electrode assembly to minimize the problems due to R_s. However, on further reconsideration, the following electrical analysis is now offered by way of an appendix as a more plausible explanation of some of the anomalies observed. Referring to McMullen and Hackerman's analysis and nomenclature of time-potential curves it is not necessary to assume that $R_p = \infty$ (see Fig. 1). It is to be noted that R_p should, in principle, be more rigorously represented by the complex faradaic impedance (Z_f). The representation of a faradaic process by a simple resistor (R_p) is somewhat restrictive with respect to *a priori* separation of this process from double layer charging. The exact form of Z_f depends on the model for the faradaic process. In the limiting case, when Z_f approaches infinity, the same conclusions will be reached. Hence, one could alternately replace R_p by Z_f throughout this paper, and subsequently R by Z (see Eq. [13]), where $Z = (R_s + R_c)Z_f/R_s + R_c + Z_f$, but this appears to be a less desirable choice because it would involve mixing complex quantities with purely real or imaginary ones. However, this simple treatment is limited to near ideally polarizable electrodes, where negligible faradaic processes occur, such as the hanging mercury drop electrode (3) for which the assumption that Z_f approaches infinity renders the model depicted in Fig. 1 to be valid.

If $R_c = 0$ as stated in case I [ref. (2)]

$$E_c = \frac{R_p E_i}{R_p + R_s}\left[1 - \left(\frac{\exp[-R_p + R_s]\,t}{R_p R_s C^1}\right)\right] \quad [1]$$

If the period of the square wave $\tau << \dfrac{R_p R_s C^1}{(R_p + R_s)}$ the exponential term in Eq. [1] can be linearized to give $E_c = E_i t/R_s C^1$. Following McMullen and Hackerman's analysis [case III in ref. (2)] when $R_c = 0$ one obtains

$$E_x = iR_c + E_i t/R_s C^1 \quad [2]$$

as a correct equation for E_x (the observed signal) for each half-cycle obtained on the oscilloscope. The slope of the observed linear oscilloscope trace is then given by

$$dE_x/dt = R_c\ di/dt + E_i/R_s C^1 \quad [3]$$

The first term on the right hand side of Eq. [3] is not independent of the parameters in the second term and may not be negligible in comparison. The negligence of $R_c\ di/dt$ is therefore questionable.

To investigate this point more rigorously, the circuit analysis should be carried out with the initial condition that R_c could take any value (except infinity). Assuming that R_p and R_s are finite, application of Kirchoff's laws yields the following equations

$$E_i = iR_s + E_x \quad [4]$$

$$E_x = E_c + iR_c \quad [5]$$

$$E_c = i_p\ R_p \quad [6]$$

$$dE_c/dt = i_c/C^1 \quad [7]$$

$$i = i_p + i_c \quad [8]$$

Solving Eq. [4] and [5] gives

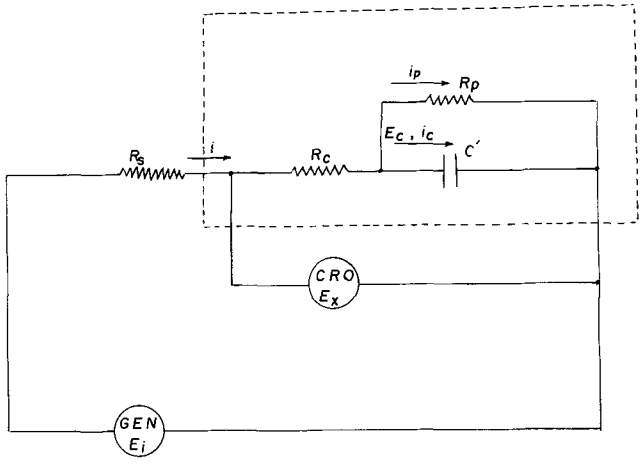

Fig. 1. Electrical analog circuit with the addition of GEN (generator) and CRO (oscilloscope) symbols.

* Electrochemical Society Active Member.

$$E_x = E_c\left(\frac{R_s}{R_s + R_c}\right) + E_i\left(\frac{R_c}{R_s + R_c}\right) \quad [9]$$

and

$$E_i = (R_s + R_c)i + E_c \quad [10]$$

From Eq. [6] and [8]

$$E_c = R_p(i - i_c) \quad [11]$$

Combination of the differentials of [10] and [11], and recalling that E_i is constant during each half cycle

$$dE_i = 0 = (R_p + R_s + R_c)di - R_p\, di_c \quad [12]$$

Integrating the right hand side of Eq. [12] using the boundary condition that at $t = 0$, $E_c = 0$; it follows from Eq. [4] and [5] that $(E_i)_{t=0} = i/(R_s + R_c)$. Setting

$$\underline{R} = (R_s + R_c)\, R_p/R_s + R_c + R_p \quad [13]$$

yields:

$$i_c = \frac{R_s + R_c}{\underline{R}}\left[i - \frac{E_i}{R_s + R_c} \right] \quad \text{and}$$

$$\frac{di_c}{dt} = \frac{R_s + R_c}{\underline{R}} \cdot \frac{di}{dt} \quad [14]$$

Combining Eq. [7] with [14] and the differential of [10] then results in

$$\frac{di_c}{i_c} = \frac{-dt}{\underline{R}C^1} \quad [15]$$

Integration of [15] from $i_c = E_i/(R_s + R_c)$ to i_c and $t = 0$ to $t = t$, and taking the exponentials of the resulting expression, one obtains

$$i_c = \frac{E_i}{R_s + R_c} \exp(-t/\underline{R}C^1) \quad [16]$$

Substitution of [16] into Eq. [7], and integrating, on substitution into Eq. [9] leads to

$$E_x = \frac{E_i}{R_s + R_c}\left\{ \frac{R_s\underline{R}}{R_sR_c}\left[1 - \exp\left(-t/\underline{R}C^1\right)\right] + R_c \right\} \quad [17]$$

t is always $\leq \tau/2$ during a half cycle, hence at large enough frequencies so that $t \leq \tau/2 << RC^1$ the exponential in [17] can be linearized to give

$$E_x = \frac{E_iR_c}{R_s + R_c} + \frac{E_iR_s}{(R_s + R_c)^2} \cdot \frac{t}{C^1} \quad [18]$$

the condition under which linearization can be made equivalent to $\tau/2 << C^1(R_s + R_c)$, since $\underline{R} \to R_s + R_c$ as $R_p \to \infty$. This condition is realized to a good approximation as long as no faradaic process occurs. It is to be noted from Eq. [18] that as long as the wave is linear, the form of E_x is independent of the value of R_p. The slope of the output wave is given by

$$\frac{dE_x}{dt} = \frac{E_i}{C^1} \cdot \frac{R_x}{(R_s + R_c)^2} \quad [19]$$

or

$$C = \frac{C^1}{A} = \frac{E_iR_s}{A(R_s + R_c)^2} \cdot \frac{1}{(dE_x/dt)} \quad [20]$$

where A is the electrode area and C is the differential capacity. If $R_c << R_s$ then

$$C = \frac{E_i}{AR_s(dE_x/dt)} \quad [21]$$

Equation [21] is not dissimilar in essence from the one ultimately arrived at by McMullen and Hackerman (2). However, when R_c becomes significant compared to R_s, Eq. [21] will give values of C which are greater than those obtained from the more accurate Eq. [20] because $R_s/(R_s + R_c)^2$ is $< 1/R_s$ for $R_c > 0$. This analysis goes a long way toward explaining the anomalous dependence of capacities on R_s reported in ref. (1). Examination of Fig. 2, 3, and 4 in ref. (1) suggests that a potential shift is also occurring. An assumption that R_c changes as a function of potential alone could not explain the difference between cathodic and anodic branches for small values of R_s. In all likelihood, it is more probable that for small values of R_s it is reasonable to consider that there is some undesirable faradaic reaction occurring in the case of the large Hg pool electrode (5 cm^2), but the faradaic process should be minimal if not insignificant with the use of a hanging Hg electrode [ref. (1)]. R_c may well vary as a function of potential if it is not to be regarded as purely the electrolyte resistance. In any case, it is possible to incorporate the nonelectrolyte component of R_c into a term such as Z_f if R_p is replaced by it; thereby making R_c the electrolyte resistance only (6). The anomalies for large R_s values (implying constant current conditions) appears in all probability to be solely due to departure from constant current conditions at given potential if a faradaic process was occurring, in which case the simple model shown in Fig. 1 would be invalid unless the form of Z_f and its coupling with the charging impedance were considered as mentioned earlier. The present model is not intended, as stated previously, to cover such a case and the technique is not meant to be used under such conditions. Considering the availability of many other more accurate methods for determining capacitance data from slopes of oscilloscope traces [see *e.g.*, ref. (4) and (5)] the technique as published by McMullen and Hackerman (2) does not appear to warrant further complicated theoretical considerations. McMullen and Hackerman's objective was meant for a specialized application, namely to obtain electrode surface area measurements where no faradaic processes occur. The technique could indeed be useful under either constant current or constant voltage conditions.

A Simple Cell and Reference Electrode for Voltammetry in Alkaline Melts

E. Banks,* C. W. Fleischmann,*,[1] and L. Meites[2]

Department of Chemistry, Polytechnic Institute of Brooklyn, Brooklyn, New York

Various techniques are used to provide conductance between two or more otherwise isolated compartments of an electrolytic cell. For molten salt studies, isolation of the compartments is usually accomplished by fritted glass, porous silica disks, or asbestos plugs. Examples are given in recent reviews (1-4). These materials, however, are severely attacked by alkaline melts. For use in such melts, particularly those of the alkali tungstates, a simple, inexpensive, and easily constructed two-compartment cell was designed. This cell employed commercial laboratory porcelain as a nonporous conductive separator between the working and reference half-cell compartments.

Sodium glasses have been employed as conductive separators in molten salts (5, 6), but the use of glass limits work to below 500°C. Labrie and Lamb (7), however, developed a reference electrode employing the Ag/Ag(I) couple in which a sodium-containing porcelain separator was used in melts up to 900°C. These workers also demonstrated the feasibility of commercial porcelain as a separator.

Reference half-cells reversible to oxygen have been employed in oxide-containing melts (1-4), but because they are inconvenient, they have not been recommended (3) for use in fused-salt voltammetry. A large Pt electrode is frequently employed as a reference for voltammetry in melts (1-4), but since it had not been demonstrated that such an electrode is well poised in tungstate melts, a metal, metal ion couple was preferred. The Ag/Ag(I) couple has been used as a reference in a number of melts (1-4), and Ag/Ag_2WO_4 was found to be a successful half-cell for use as a reference with the present cell design.

The Ag_2WO_4 used in these studies was prepared by precipitation from aqueous solutions. A filterable precipitate was obtained by mixing together *0.1-0.2F* solutions of reagent-grade $AgNO_3$ and Na_2WO_4 and allowing the precipitate to digest, overnight, in the dark. The precipitate was washed several times with water, then acetone, and dried in air.

The cell is illustrated in Fig. 1. A 5-ml Coors porcelain crucible served both as the container for the Ag/Ag_2WO_4 reference half-cell and as the conductive septum. This crucible was placed in a 10-ml porcelain tray along with the study melt. For improved conductance, the area of the crucible in contact with the melt was increased by placing the crucible on a loose platform of alumina tubes or rods. The resistance between the reference and working electrodes was determined for each cell by means of an a-c bridge so that the recorded voltammograms could be corrected for the potential drop across the porcelain.

Reproducibility of the potential of a Ag/Ag_2WO_4 half-cell was determined to be ±10 mV from the potentials of nine cells of the composition

$$Ag/Ag_2WO_4//Na_2WO_4//Ag_2WO_4/Ag$$

Potentials were measured at 750°C with the cells under argon. A second measurement on some cells was made after 3 hr to establish the extent of the potential drift with time. Table I records the potential of cells prepared as follows: Cells 1 through 4, constructed from freshly synthesized Ag_2WO_4 and previously unused Ag-wire electrodes; Cells 5 and 6, one half-cell was prepared from Ag_2WO_4 recovered from a previous reference compartment; and in cells 8 and 9, new and previously used silver wires were opposed. In cell 7, one porcelain crucible was of more recent manufacture than the other (8).

Ag/Ag_2WO_4 half-cells are polarized only about 5 mV at 100 mA/cm² (750°C) as shown by an extrapolation of the current-voltage data in Fig. 2 to that current density. This figure gives the total polarization of the anodic and cathodic reactions at two silver wire electrodes immersed in silver tungstate. The polarization at each electrode may be taken to be 2-3 mV at 100 mA/cm² assuming that the anodic and cathodic contributions to the total polarization are equal. This assumption is supported by voltammograms obtained at silver microelectrodes in Ag_2WO_4 which did show equivalent anodic and cathodic polarizations.

Since most voltammetric studies employ a small study electrode (*e.g.*, a 1-mm diameter Pt bead), the current density at the reference would be of the order of 1 mA/cm². Such a current density would give rise to negligible polarization as may be read from Fig. 2.

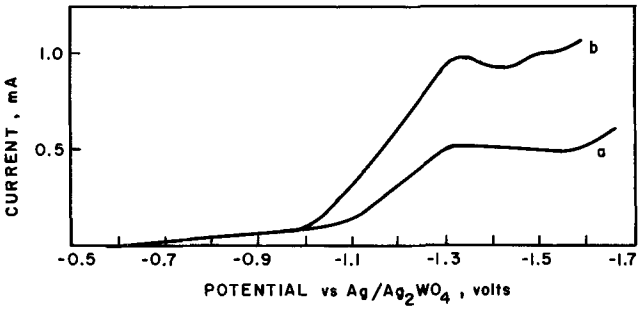

Fig. 3. Voltammograms for Pt bead (0.03 cm^2 area) in Na_2WO_4 containing: (a) 0.2 m/o Cd(II), (b) 0.4 m/o Cd(II), 750°C. Sweep rate, —250 mV/min.

The cell shown in Fig. 1 was employed to study the reduction of WO_3 and simple cations from alkali tungstate melts. As an illustration, Fig. 3 presents voltammograms obtained for the reduction of 0.2 and 0.4 m/o (mole per cent) Cd(II) from Na_2WO_4, 750°, at a Pt bead (0.03 cm^2 area).

This cell design was also employed for synthesis. For electrosynthesis at constant current when it is not desired to monitor the potential of the study electrode, any suitable couple may be employed on the other side of the porcelain membrane. As an example, tungsten bronzes were electrodeposited from polytungstate melts and a suitable anodic reaction on the other side of the porcelain was the electro-oxidation of alkali tungstate at Pt.

Factors Affecting the Growth of Porous Anodic Oxide Films on Zirconium

B. Cox*

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

ABSTRACT

Although anodization of zirconium and its alloys generally results in the formation of barrier-type films, porous anodic oxide films can be produced in some electrolytes and by some preparation techniques. A survey of common electrolytes reveals that those containing nitrate, chromate, dichromate, and phosphate ions commonly lead to porous anodic films. An electron microscope study of the films produced in these electrolytes, and others giving barrier-type films, has shown that no single explanation fits all instances of porous film formation. While incorporation of the electrolyte anion in the oxide may be the primary factor influencing the formation of porous oxide films, it appears to operate primarily by affecting the local transport of oxygen ions through the films. This effect may be achieved by influencing the crystallization of the oxide during growth so that in some instances local oxidation and cracking occur at grain boundaries, while in other instances it leads to the general development of a porous structure.

Zirconium and Zircaloy-2 readily form barrier-type anodic oxide films in a wide range of electrolytes (1-4), including gaseous plasmas (5). A few instances of the formation of thick porous anodic films have been reported, generally associated with anodization at high voltages in solutions containing the nitrate ion (1, 6). We have found that porous films can be formed even at low voltages and have used such films in testing a porosimeter designed to measure pore sizes in zirconia films *in situ* (7, 8).

It was found that the capacitance, and especially the resistance, of even the barrier-type oxide films was much less than would be predicted from optical measurements of the oxide thickness and previous measurements of the resistivity of zirconia films using dry metallic contacts (9, 10). This effect was most pronounced for Zircaloy-2, an alloy containing small second phase particles, but was also present with the batch of crystal-bar zirconium used in our experiments.

It appeared that there might be a whole spectrum of degrees of porosity from electrolyte to electrolyte, and we set out to study this possibility and to correlate the effect with observable variations in the ionic transport process through the oxide film.

Experimental

Paddle shaped specimens, with 2 x 2 cm blades, were cut from one sheet of crystal-bar zirconium (Be) and one of Zircaloy-2 (Bh). Analyses of these batches of material are listed in Table I. The specimens were chemically polished in mixed nitric/hydrofluoric acids, washed in water and alcohol, and weighed prior to and after anodization.

Anodization was carried out either by the stepwise constant voltage technique, holding for different predetermined times in the range 0.5-100 min at each voltage step or by the constant current technique with applied currents between 1.0 and 5.0 mA/cm^2 and a predetermined final voltage. The electrolytes used were "normal" solutions of the following in water: H_2SO_4, Na_2SO_4, HNO_3, NH_4NO_3, KNO_3, KNO_2, KOH, NH_4OH, $K_3Fe(CN)_6$, $K_2Cr_2O_7$, $KCrO_4$, tartaric, lactic, formic, oxalic, acetic, and citric acids; saturated solutions of potassium persulfate, ammonium borate, and boric acid; 2% ammonium borate in ethylene glycol; 0.5M NH_4NO_3 in ethylene glycol; 85% phosphoric acid; a

Key words: zirconium alloys, oxidation, anodization, oxide films, morphology, electron microscopy.

1:2:3 mixture of water, oxalic acid, and ethylene glycol, and a complex solution recommended by workers at Oak Ridge National Laboratory (4).

At the final anodization voltage and time the d-c source was disconnected and the leakage rates of the films determined by plotting the voltage decay on a high speed recorder. The anodic oxide surface was examined by optical microscopy, replica electron microscopy, and scanning electron microscopy. The metal-oxide interface was examined with the scanning electron microscope. The electrical properties of the films were determined with a GR1680A automatic impedance bridge during immersion in a molar ammonium nitrate solution; capacitative and resistive components (based on a parallel equivalent circuit) were followed as a function of immersion time. Measurements were also made using mercury and Viking alloy LS232 liquid metal contacts (8), and in a mercury porosimeter designed to measure pore sizes in insulating oxide films (7).

The "optical thickness" of the oxide films was determined by comparing the interference colors of the oxide on individual metal grains with a calibration strip prepared using the data of Wilkins (11) and checked with a spectrophotometer. The refractive index of the films was assumed to be insensitive to the forming electrolyte. The insensitivity of the refractive index to the forming electrolyte was demonstrated by Wilkins (3) for a limited range of electrolytes, and has been generally assumed to hold for all electrolytes by other investigators (4, 12). The "capacitative thickness" was determined from the capacitative component of the a-c impedance of the specimen, assuming the oxide to be effectively a parallel sided slab of dielectric. Average current efficiencies were determined from the optical thickness and the time taken to reach the final voltage. Instantaneous current efficiencies were calculated from the slope of the voltage/time plot on the assumption that the formation rate (Å/V) was constant throughout the period of film growth.

Results

Electrical measurements.—Selected measurements of optical thickness and impedance of the oxide films are presented in Table II to demonstrate the variations in the behavior observed in the various electrolytes. Further details may be obtained from the author. The oxide formation rates (based on the optical thickness of the oxide) for those electrolytes where sufficient specimens were anodized to give a meaningful average are quoted in Table III in comparison with other published values for which the formation method is known. Porous oxides could be detected electrically either by following the change in capacitance of a specimen with time after immersion in an aqueous electrolyte (Fig. 1) or by comparing the apparent thickness indicated by liquid metal and aqueous electrolytic contacts [see Ref. (8), Fig. 19]. The much greater degree of porosity of the films formed in NH_4NO_3 than in H_2SO_4 could be readily seen from the separation of the curves of apparent thickness measured in an aqueous electrolyte and in mercury. The capacitative thickness of apparently nonporous films is plotted against their optical thickness in Fig 2.

The degree of porosity of the other anodic films was also estimated from a comparison of the apparent oxide thickness measured with mercury, LS232, and an aqueous electrolyte as contacts (Table II). A consistently higher apparent thickness in the liquid metals

is indicative of the total oxide thickness, while the final apparent thickness in ammonium nitrate measures the barrier thickness. The sizes of the flaws present in some films have been determined using a mercury porosimeter (Fig. 3) and the results can be correlated with the observed defects seen by electron microscopy [see Ref. (7) for details].

During forming at constant current the characteristic plateau (13) in the voltage-time curve was often observed. The duration of this plateau varied enormously with the electrolyte being used and in any given electrolyte was always longer for Zircaloy-2 specimens than for zirconium specimens. During the plateau localized oxygen evolution could be observed at a number of sites. Anodization was attempted initially at ~1 mA/cm² for all specimens; in some instances the current had to be increased as much as a factor of five before the plateau could be passed. The current was returned to 1 mA/cm² once film growth resumed. Typical examples of the shapes of the constant current curves for Zircaloy-2 are shown in Fig. 4, and for zirconium in Fig. 5. The voltage decay curves were obtained for zirconium and Zircaloy-2 specimens after formation at constant current. Examples are shown in Fig. 6. The decay currents of specimens formed at constant voltage in different electrolytes were also measured [see Ref. (8), Fig. 24].

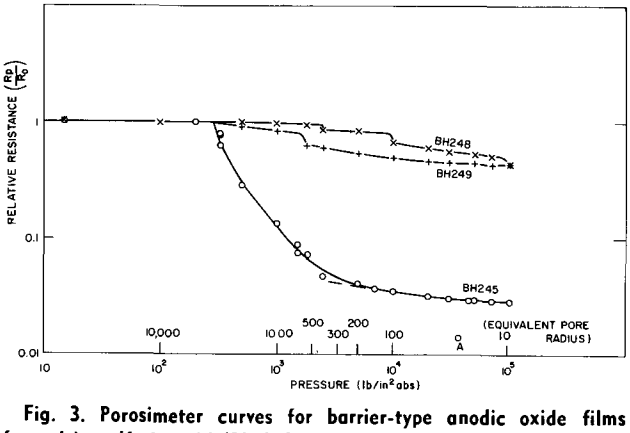

Fig. 3. Porosimeter curves for barrier-type anodic oxide films formed in sulfuric acid (Bh 248, Bh 249) and a porous anodic film formed in ammonium nitrate (Bh 245).

Visual observations.—Observation of the specimens in the optical microscope showed that (for most electrolytes) the interference colors were uniform over the zirconium matrix. Large intermetallic particles were clearly different in interference color from the surrounding matrix, but in most instances were too small for the film thickness on the intermetallics to be determined in the optical microscope, or even to estimate whether it was greater or less than the surrounding oxide thickness. Electrolytes giving porous oxide films commonly yield irregular interference colors, and some other electrolytes reproducibly gave local variations in oxide thickness.

Examination of the specimens with the electron microscope and scanning electron microscope showed that most anodic films, especially on Zircaloy-2, contained a number of flaws, even when they would be classified as good barrier-type oxide films from an examination of the electrical measurements. These flaws fell into a few characteristic types (illustrated by Fig. 7-9) which appeared commonly in a number of solutions and in the case of cracking at grain boundaries became more prominent with increasing oxide thickness.

However, the phenomena which were studied in most detail were those leading to more severe breakdown of the oxide and to generally porous oxide films. These can be divided into three different types of failure.

1. Formation of thicker oxide along grain boundaries and around intermetallic particles leading to cracking along grain boundaries and ultimately to spalling of the oxide (see Fig. 10-12).
2. Local formation of patches of thicker rough oxide eventually leading to spalling (Fig. 13 and 14).
3. Formation of generally porous oxide films which continue to grow considerably in thickness when held at the forming voltage (Fig. 15-17).

Transmission electron microscopy of stripped oxide films from selected specimens formed in sulfate, hydroxide, tartrate, and nitrate electrolytes showed unique features associated with the films formed in nitrate. In bright and dark field illumination the

crystallite size was clearly smaller in the nitrate films compared with films formed in the other three electrolytes (Fig. 18). In addition to being larger the crystallites were also less distorted in the barrier-type films. In the nitrate films the thickness varied in an irregular fashion not evident in the other oxides, and small thin patches, which might be the early stage of pore development, could be seen (Fig. 19). The diffraction patterns, from basal planes of the zirconium matrix, showed that the nitrate film was also unique in being essentially all monoclinic ZrO_2, whereas the other films had large percentages of cubic ZrO_2 ($\geq$75%) and only traces of the monoclinic phase (Fig. 20). There were differences between the barrier-type films in the randomness of the distribution of the cubic oxide crystallites. In some instances, especially tartaric acid, the crystallites were almost random, giving rise to complete rings (Fig. 21), whereas in the other barrier-type oxides the crystallites were highly oriented.

22), whereas the interfaces of barrier-type films were generally smooth except in the vicinity of second phase particles.

Discussion

Identification of porous oxide films from electrical measurements.—A study of the impedance measurements (*e.g.*, Table II) shows that porous oxide films result for specimens formed in solutions containing the nitrate ion (NH_4NO_3, HNO_3, KNO_3) and phosphoric acid. The mode of formation has some influence on the results, however. Zircaloy-2 specimens formed at constant voltage or constant current showed little difference in the relative thickness indicated by liquid metal and aqueous contacts (*c.f.*, specimens Bh 225, 328, and 329), whereas for crystal-bar zirconium, films formed at constant current showed less evidence of porosity than those formed at constant voltage. This conclusion from the impedance measurements was confirmed by electron microscopy. The oxide surface on the zirconium specimen was found to be uneven, but not obviously porous. This conclusion might have been different had the specimen been held at the final voltage for some time after forming at constant current, if the increase in porosity found for Zircaloy-2 specimens held at constant voltage for increasing lengths of time is indicative of general behavior (Fig. 15-17).

Oxide films formed on Zircaloy-2 in chromate and dichromate solutions showed extensive areas of breakdown. There was correspondingly less evidence for breakdown on a zirconium specimen formed in potassium chromate solution at constant current, than for a comparable Zircaloy-2 specimen both from impedance measurements and electron microscopy.

Films formed in most other electrolytes showed relatively small differences between apparent thickness measurements in liquid metals and aqueous electrolytes. Of the former the measurements in LS232 are the more reliable because of its better ability to wet zirconia (8). Of those showing major differences between the impedance with aqueous and liquid metal contacts (a factor of two or more differences in apparent thickness in NH_4NO_3 and LS232) porosity, or other major flaws, were confirmed by electron microscopy and porosimetry only for films formed in phosphoric and sulfuric acids. Differences less than a factor of two can probably be explained on the basis of a

number of small flaws associated with the intermetallic particles.

Banter (4) has demonstrated for zirconium that in many electrolytes the anion is incorporated into the anodic film. However, with the exception of the organic acids, the other electrolytes for which he demonstrated this phenomenon were ones which we have found to yield porous or cracked oxide films. Thus, it

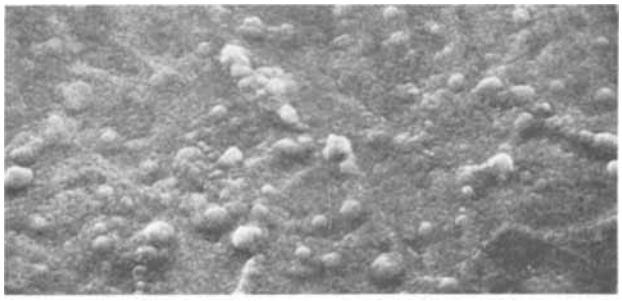

Fig. 22. Oxide metal interface of thick porous anodic oxide film formed in ammonium nitrate (Bh 247, 97 V).

is possible that anions from the electrolyte adsorbed in the porous structure rather than incorporated into the oxide lattice led to many of his observations. Nevertheless, it seems likely that anions from most if not all electrolytes are incorporated into nonporous anodic oxides (12, 15), but at levels generally below the level of detection of the methods employed by Banter.

That the incorporation of anions does not lead to any major change in the physical properties of the oxide formed is shown by the small spread of the impedance/thickness data for relatively defect free oxides in Fig. 2. The phosphate films for which Banter observed the outer layers dissolving faster than the inner ones were likely also to have been porous (Fig. 17) and the dissolution may have been due to this porosity rather than to the incorporation of a larger fraction of phosphate ions into the oxide lattice in the outer regions of the film. Absorbed phosphate would almost certainly have been more highly concentrated within the porous layer than within the inner "barrier-type" film, thus leading to the possible misinterpretation of the observations.

Current decay curves and leakage currents.—The formation of porous anodic films could also be detected in the current decay curves for specimens formed at constant voltage. An essentially constant (but fluctuating) current was observed for specimens forming porous films. Cracking and breakdown of the film can be distinguished from this process as they usually lead to discontinuous increases in the forming current. The rate of decay of the current during forming does not seem to be indicative of the quality of the final film as determined from a-c impedance measurements. Presumably the size of this current (which is probably mainly electronic at long decay times) measures the effectiveness with which the intermetallic particles are anodized, although no correlation could be found with the apparent thickness of the oxide on the intermetallic particles in those instances where this could be estimated.

Unusually high decay currents were observed for films formed in KOH. This current represents mainly oxygen evolution at intermetallic sites and might be thought to be due to lack of film formation on these intermetallics. However, electrical measurements on these films did not show them to be of significantly lower resistance than other films which did not yield such high leakage currents. The high decay currents in KOH also explain the apparent difference between our values for the formation rate in KOH (Table III) and those quoted by Wilkins (3, 11). Our specimens were held at each voltage step for a constant time whereas Wilkins' were held until a predetermined leakage current (0.2 mA/cm^2) was reached. Our data suggest that this would represent a long time at each voltage step and would be expected to yield a higher formation rate in Å/V. The good agreement when equivalent formation methods are compared is shown by the results in sulfuric acid. Wilkins' technique is equivalent to a decay time of about 1 min at each voltage, and therefore the formation rates are very close for the two equivalent conditions.

During formation at constant current, breakdown of the type observed in chromate and dichromate reveals itself as a failure of the voltage to continue to rise (Fig. 5). This feature is not observed with specimens forming porous films in nitrate or phosphate solution. These, and other, films show the normal arrest in the anodic growth curve (1, 16) at about 5V, at the current densities used here.

The height and length of this arrest varied from 3.7-6.3V and from a few seconds effectively to infinity depending on the electrolyte. In any given electrolyte the height was also a function of the current density. Extrapolation of our curves of "plateau" height *vs.* current density to the current densities of Adams *et al.* (16) gives good agreement with their data. Observation of local oxygen evolution during this plateau together with other data suggests that the plateau is caused by the presence of second phase particles in the zirconium matrix. The plateau is commonly very small or absent for unalloyed zirconium except at very low current densities, or for roughly abraded surfaces (16) where embedded abrasive particles may substitute for the intermetallic particles in Zircaloy-2.

The variation from electrolyte to electrolyte in the length of the plateau, and the current density needed to exceed it, is presumably a measure of the ability of each electrolyte to form a nonconducting film on the intermetallic particles. In Zircaloy-2 these are either Zr-Fe-Ni or Zr-Fe-Cr phases and the critical step may be the formation of an oxide film other than ZrO_2 on these particles. The big variation in the length of the plateau for different organic acids is surprising in this context since little difference would be expected in the ability of lactic, tartaric, and citric acids (for instance) to oxidize the intermetallic particles.

For unalloyed zirconium a clear distinction was found in leakage rate for porous and nonporous oxide films (Fig. 6). This distinction was not apparent with anodic films formed on Zircaloy-2, showing that in the latter instance the properties of the oxide formed on the intermetallic particles were more important in determining the leakage rate of the oxide than the porosity of the oxide formed on the majority of the surface. That this conclusion is reasonable may be judged from the fact that the porous oxide films all apparently have a barrier-layer at the oxide-metal interface, as judged from impedance measurements during immersion (Fig. 1). The intermetallic particles are large enough to short-circuit the whole oxide if the oxide over them is very thin, cracked, or more conducting (electronically) than that on the matrix. Further confirmation of this explanation may be provided by the apparent correlation between the leakage rate (estimated from the residual voltage after 10 sec) and the average current efficiency for formation (indicated by the time to reach 25V) for most of the specimens where no change in current density was needed to exceed the plateau (Table IV). Since most of the time taken to reach 25V was required to overcome the effect of the intermetallic particles the second of the above quantities probably measures the efficiency with which these particles are oxidized in a particular electrolyte.

Electron microscope studies.—Unlike anodic oxide films on many other valve metals, those formed on zirconium and its alloys are essentially microcrystalline (17) and bear a striking resemblance in the transmission electron microscope to thin thermal oxide films formed at ~300°C (18). Although marker studies using rare gas atoms indicated that the moving species during anodization is oxygen (19); the oxides used by Davies *et al.* were formed in nitrate solution and were therefore probably porous. Thus, electrolyte could have migrated past the markers via the pores. Further studies by Whitton using charged marker ions and oxides formed in borate solution have confirmed that the migrating species is oxygen but that migration is not through the bulk of the lattice

(15). Thus, since the latter films were probably nonporous, it appears that in anodic films, as in thermal films (20), the oxygen transport process is via the boundaries between the oxide crystallites (or any residual amorphous material between the crystallites) rather than through the bulk of the oxide lattice.

The various processes by which irregular or porous oxide films are formed in different electrolytes are thought to be related to the effect of incorporated electrolyte ions on the crystallization or recrystallization of the oxide film. Thus, transmission microscopy has shown that crystallite size and degree of orientation are affected by the electrolyte used. These effects are most readily seen in the enhanced oxidation and ultimate cracking (perhaps) due to local stresses observed at grain boundaries in sulfuric acid, and to a lesser extent in potassium nitrite. The effect of such cracks on dielectric loss in films formed in sulfuric acid has already been reported by Young (21). Disorder at grain boundaries might be expected to lead to variations in the density of easy diffusion paths and locally enhanced oxidation via local modifications in the field strength in the oxide. That this phenomenon is infrequent during anodic oxidation presumably indicates a normally greater degree of order at crystallite boundaries in anodic films than is present in thermal oxide films so that locally enhanced anodic oxidation at grain boundaries is the exception rather than the rule. The observation that barrier-type films are predominantly cubic ZrO_2, would be expected to lead to less lattice disorder in crystallite boundaries than in thermal oxide films which are predominantly monoclinic.

The electron microscope study of films formed in nitrate, phosphate, and dichromate solutions shows that the porosity originates in the growth of films having relatively rough outer and inner interfaces, and apparently associated with a high percentage of monoclinic ZrO_2 in the film. In nitrate and phosphate solutions these rough films cover virtually the whole surface, and eventually develop a network of pores. Thicker films do not form along residual scratches in the metal, which can often be seen in the optical microscope because the interference color film over them is of normal thickness (8). Presumably the distorted nature of the underlying metal prevents the formation of the thicker films at these points, although the precise reason for this is not clear. Perhaps the cold work in the surface causes the formation of cubic oxide at these sites, and this inhibits the development of roughness and porosity.

It is concluded therefore that electrolytes, which lead to the formation of porous oxides, modify the crystallization of the oxide thus permitting the development of a thick and ultimately porous oxide. The cell structure (such as it is) in the thick films formed in nitrate solutions seems to develop from a pattern of crystallization which occurs in the first few seconds of formation (Fig. 19). The manner in which the pore structure develops from this has not been elucidated. Penetration of the electrolyte into the pores and the development of a columnar crystallite structure would permit this growth process to continue. In chromate and dichromate solutions the course followed seems to be basically the same, but becomes irregular on a small scale. This leads to small local patches of thicker oxide which eventually crack and spall, presumably due to the more severe local stresses in these films than in the nitrate or phosphate films.

Previous studies of the crystal structure of anodic oxide films on zirconium by x-ray and glancing angle electron diffraction (22-25) have been unable to agree on the relative proportions of cubic, monoclinic, and amorphous oxide in the film formed in different electrolytes. Previous studies of anodic films by transmission electron microscopy have stopped short of attempted interpretations of the diffraction patterns (17).

The basic processes relating the changes in oxide morphology to the effect of the incorporated ions and changes in the crystallization process require a detailed study of the films by transmission electron microscopy. This is currently in progress but is beyond the scope of the present work.

Conclusion

A survey of the anodization of zirconium alloys in a number of electrolytes has shown that (using a forming method involving long holds at constant voltage) porous anodic films can be formed in solutions containing nitrate, chromate, dichromate, and phosphate ions. Flaws formed at intermetallic particles and by cracking of the oxide along grain boundaries are also prevalent being worst in sulfuric acid of the electrolytes tested here, but being found to a greater or lesser extent in most of the electrolytes yielding barrier-type films.

In the electrolytes yielding porous films the precise mechanism of their formation is apparently different for each electrolyte, however the underlying mechanism is believed to be associated with the incorporation of anions into the oxide and their effect on the crystallization of the oxide during anodization.

Acknowledgments

The author is indebted to R. A. Ploc for the transmission electron microscopy quoted here. This forms part of a broader study of the structure of anodic oxide films on zirconium alloys which is still in progress. The photo-emission electron microscopy was kindly performed by Balzer's Ltd. (see Fig. 12).

Manuscript submitted Oct. 7, 1969; revised manuscript received *ca.* Jan. 26, 1970. This was Paper 30 presented at the New York Meeting of the Society, May 4-9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

Reactions Caused by Additive Coloration of Tl^+- and Pb^{+2}-Doped KCl

L. Ben-Dor, A. Glasner, and A. Zudkevitz

Department of Inorganic and Analytical Chemistry, The Hebrew University, Jerusalem, Israel

ABSTRACT

Additive coloration of KCl doped with Tl^+ may reduce the substitute $-Tl^+$ ions to Tl^0 neutral centers or to negative "Tl^-" complex centers. In the case of Pb^{+2}-doped KCl, an intermediate Pb^+ and a Pb^0 netural center are formed.

Tl^+-Doped Alkali Halides

The spectra of Tl^+-doped alkali halides is well understood (1-1c) and is thought to be directly connected with electron excitations confined to the impurity ion. Additive coloration performed by heating the crystal in vacuum or low nitrogen pressure, in alkali metal vapor as well as radiative coloration, performed by x-rays or γ-rays, of the doped alkali halides have been studied (2-4), but attention was paid mainly to the effect of the impurity on F-center formation.

In the case of KBr, Tamai (5) observed the formation of two distinct bands on additive coloration by potassium vapor: a Tl neutral center (TNC) peaking at 4.1 eV (310 nm) and a Tl complex center (TCC) peaking at 3.1 eV (400 nm). The nomenclature adopted had been used earlier (2). The TNC is supposed to be a Tl^+ ion associated with one F center, and the TCC a Tl^+ ion associated with two F centers.

The formation of Tl^0 as well as Tl^{+2} in KCl as a result of low-temperature γ-irradiation was studied (6). Coloration by irradiation causes both reducing and oxidizing processes. The elucidation of the resulting absorption spectra is complicated because of the simultaneous formation of a variety of V, F, and impurity centers. Also, the species thus formed are highly excited and labile, disappearing on warming above liquid nitrogen temperature. In contrast, additive coloration forms only reduced centers, which are stable to heat- and bleaching-treatments in general. It seemed advisable to carry out a further investigation to check the new "reduced-only" color centers formed and possibly confirm the existence of a negatively charged TCC center in other alkali halides besides KBr.

Pb^{+2}-Doped Alkali Halides

The absorption of Pb^{+2}-doped alkali halides, unlike the Tl^+-doped salts, is attributed solely to charge transfer transitions (7). The existence of Pb^{+2}-cation vacancy complexes has been reported by many investigators (8-10). In studies of X-irradiated NaCl doped with Pb^{2+}, a gray coloration caused by Pb^0 (11) and an "atomary" lead center (12), peaking at 254 nm, were reported. Low-temperature colorability of doped KCl was also studied (13, 14), but no attention was given to uv impurity bands formed thereby. In this work, the reduced species formed on additive coloration are more closely defined.

Experimental Section

All chemicals used, KCl, TlCl, $PbCl_2$, were J. T. Baker Analyzed Reagents. Single crystals were grown by the Stockbarger method, and additive coloration was performed both in Pyrex (550°C) and in nickel (700°C) (16) containers at a pressure of ~50 Torr nitrogen. The optical absorption was recorded on a Perkin-Elmer Model 137 uv spectrophotometer, working in the double beam mode. A special holder with 1 mm slit was used in the sample beam of the spectrophotometer, so that a 1-2 mm thick crystal plate, cleaved from the center of the colored single crystal (13 mm on the edge), could be moved in front of the beam. In this manner the spectrum of a desired region of the crystal plate could be recorded at various distances from the exposed surface. The spectra were taken at room temperature.

Results and Discussion

A KCl crystal containing 0.01-0.05 m/o (mole per cent) Tl^+ did not show F absorption on coloration as

the high impurity concentration acted as an efficient trap for electrons. Crystals containing less than 0.001 m/o Tl^+ were easily colored and showed a distinct band peaking at 290 nm, besides the well-defined F band (Fig. 1). The additively colored crystal plates cleaved from the center of the colored cube exhibited three distinct areas [cf. ref. (2)]: an outer bluish F-zone about 2.5 mm wide, a brown-yellow zone containing the reduced center (290 nm), and an innermost colorless zone containing the unreacted Tl^+ ions. The same crystals, when colored for longer periods (2 hr instead of 1 hr) and/or at higher nitrogen pressure (100 Torr instead of 50 Torr), or in the presence of thallium chloride powder added to the coloring vessel, showed another previously unobserved band peaking at 345 nm (Fig. 2). It was found that the center responsible for this latter band is formed mainly in the outer zone, overlapping the F zone, of the crystal. On the other hand, the center responsible for the 290 nm band is found in the inner square of the crystal plate, 4.5-5 mm deep inside the face exposed to the coloring alkali metal vapor. The 247 nm A band of the Tl^+ ions survives in the interior colorless square (Fig. 3). Following former nomenclature, we wish to identify the 290 nm band as being due to TNC and the 345 nm as a TCC, reasoning that the doubly reduced TCC is formed only under drastic reducing conditions in the outer zone, where the concentration of electrons is highest. Comparing the centers observed in KBr by Tamai (5) with those found by us:

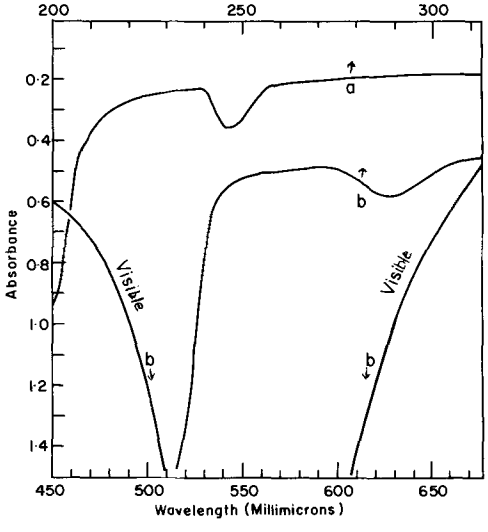

Fig. 1. Absorption spectra of Tl^+ doped KCl: (a) before coloration, (b) after additive coloration (1 hr, 700°C, 50 Torr nitrogen).

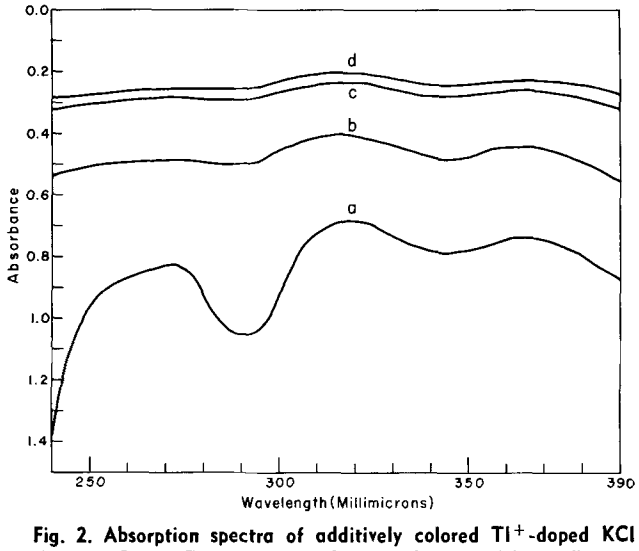

Fig. 2. Absorption spectra of additively colored Tl^+-doped KCl (2 hr, 550°C, 100 Torr nitrogen). Spectra shown in (a) to (d) were taken in progressively inner parts of the crystal.

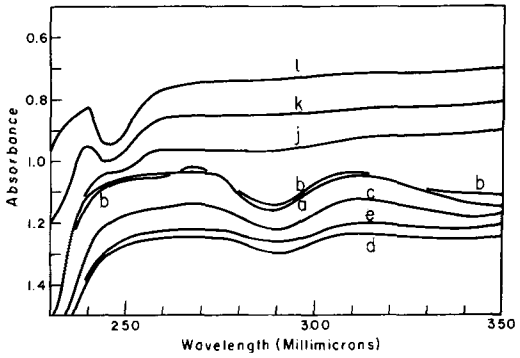

Fig. 3. Absorption spectra of additively colored Tl^+-doped KCl (conditions of coloration as in Fig. 2). Spectra shown in (a) to (d) were taken at ½ mm distances from the exposed face. Spectra (e)-(i) were omitted for clarity; (j)-(l) show spectra to 6 mm from the face.

	TNC, eV	TCC, eV
KCl	~4.3	3.6
KBr	4.0	3.1

one observes a shift in the same direction and similar magnitude when changing the matrix from KBr to KCl.

Delbecq *et al.* (6) identified a Tl^0 center in low-temperature γ-irradiated KCl, showing a weak band at ~300 nm, as well as a comparatively stronger band peaking at 380 nm, and three other extremely weak bands peaking in the visible and near IR regions. All these bands are attributed to Tl^0 centers on the basis of an analogy with the well-established Ag^0 center (17). The authors point out (7) that the 380 nm absorption is associated with a transition from the $^2P_{1/2}$ ground state to a $^2S_{1/2}$ resonant level in the conduction band. This latter excited level may be unstable at high temperatures. On the other hand, the 290 nm band prominent in our spectra may be due to a transition in the Tl^0 center from the ground state completely up to the conduction band. Thus, in the additively colored crystals only a single absorption band in the uv, arising from the Tl^0 center, was observed.

The 345 nm band produced only under more drastic conditions of coloration is attributed to a negative thallium complex, *i.e.*, a substitute Tl^0 atom associated with an F center. The Tl^0 center first produced carries an effective negative charge making its association with an anion vacancy highly probable. Under the drastic coloring conditions this associate could then capture a second electron to produce the negative complex center.

KCl single crystals containing 0.025-0.05% Pb^{+2}, as grown, showed besides the characteristic 273 nm Pb^{+2} band an absorption band at 325 nm (Fig. 4). This 325 nm band was also observed in concentrated KCl solutions containing ~100 ppm Pb^{+2} ions. Crystals absorbing in this region invariably had a yellow coloration, reminiscent of the yellow-brown coloration appearing in Tl^+ as well as in Zn^{+2}, Cd^{+2}, or Hg^{+2} doped (15) KCl crystals when additively colored. In all these cases the characteristic absorption band causing the yellow-brown coloration was attributed to the formation of neutral atomic species. Hence we suggest that, in the case of lead-doped crystals, dispersed neutral species appear to be formed by reduction in the melt, or by a photochemical decomposition, during crystal growth

$$PbCl_2 \rightarrow Pb^0 + Cl_2$$

Hence the 325 nm band is attributed to an atomary Pb^0-center. On the other hand, the gray coloration ob-

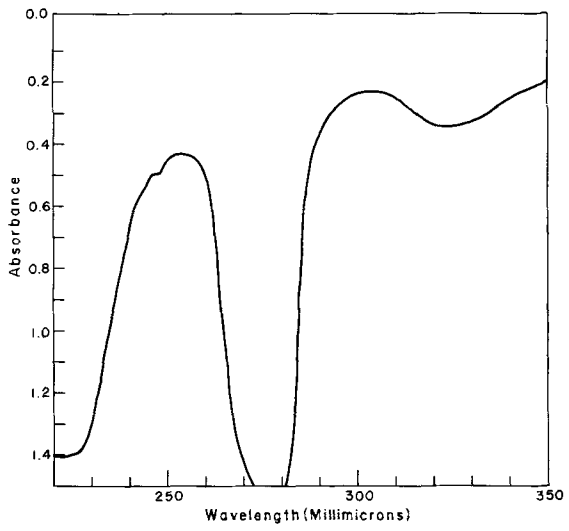

Fig. 4. Absorption spectra of Pb^{+2}-doped KCl after growth (the kink at ~250 nm should be disregarded).

served by Schulman *et al.* (11) in NaCl is indicative of colloidal lead aggregates.

On additive coloration of the Pb^{+2}-doped KCl, a further band, not well resolved, situated at ~254 nm, was obtained (Fig. 5). Since this band is different from the one described above, 325 nm, attributed to Pb^{o}, and since the crystal had neither a yellow nor a gray coloration, it must be due to another intermediary reduced species, viz., Pb^{+} center.

The Pb^{2+}-doped crystals were further studied by irradiative coloration at r.t., and it was found that with very low doping concentration (0.002 m/o Pb^{+2}), F centers are formed, but the presence of any other band is hardly discernable, although the characteristic Pb^{+2} band at 273 nm diminishes in intensity. Optical bleaching by direct sunlight renders the crystals colorless, and on further heat-treatment for 2 hr in a closed ampoule at ~200°C, the previously observed 254 nm band is formed. We claim, in accordance with Schulman *et al.* (11), that irradiation causes the formation of Pb^{o} centers (in low concentration not discernable in the spectrum) as well as immobile oxidizing species such as holes. During heat-treatment the Pb^{o} centers are partly reoxidized, causing the appearance of the band at 254 nm. This center, formed both by a reduction (additive coloration) and by an oxidizing process, could only be a Pb^{+} center.

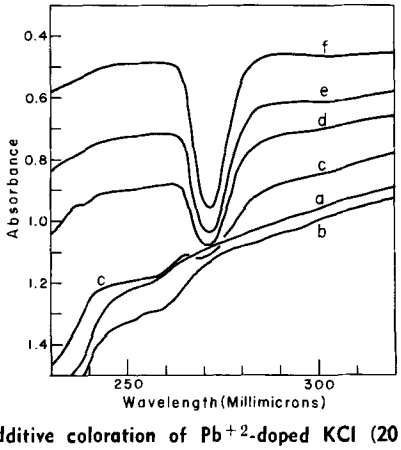

Fig. 5. Additive coloration of Pb^{+2}-doped KCl (20 hr, 550°C, 100 Torr nitrogen). Spectra shown in (a) to (f) were taken in progressively inner parts of the crystal. Note weak 254 nm band in outer parts, its disappearance toward the interior with the simultaneous appearance of the Pb^{+2} band (273 nm).

In summary, both Tl^{+} and Pb^{+2} substituted in KCl crystals act as electron traps; therefore crystals containing high concentrations of these ions do not color, *i.e.*, no F centers are formed either on irradiation or treatment with alkali metal vapor. In each case a maximum of two electrons per impurity ion may be trapped, but the impurity ions prefer to be reduced to the neutral atomary state.

In moderately doped KCl crystals the following centers were observed and may be identified as follows:

Tl^{o} (290 nm), Tl^{o}-F center complex	(345 nm)
Pb^{+} (254 nm), Pb^{o}	(325 nm)

The position of the bands is indicated in parentheses. Our results in the case of Tl^{+}-doped KCl are similar to those of Tamai (5) with KBr, but the models attributed to the respective centers are different, as shown above.

The apparent discrepancy between low-temperature irradiative coloration (6) and the results obtained on additive coloration of Tl^{+}-doped KCl is explained.

Of all the cation impurities studied, to date, only thallium was found to form a complex center formed from an association of Tl^{o} (neutral) with an F center. In the case of Pb^{2+}-doped KCl, the reduced species formed are most probably Pb^{+} and Pb^{o} centers. The 254 nm band is thus identified as a monovalent Pb^{+} center, rather than an "atomary" center as had been casually suggested (12) in the case of NaCl crystals.

Manuscript received Oct. 20, 1969; revised manuscript received *ca.* Jan. 15, 1970. This paper is based on the M.Sc. Thesis of one of the authors (A.Z.) (1965).

Physical and Electrical Investigations on Silicon Epitaxial Layers on Sapphire Substrates

J. Mercier

Section Physique des Couches Minces,
Laboratoire d'Electrostatique et de Physique du Métal, Grenoble-Gare, France

ABSTRACT

X-ray microdiffraction and special IR spectrometry techniques are used to explain the peculiarities of electrical properties of silicon thin films on sapphire substrates. Taking into account an autodoping effect due to the transfer of aluminum from the substrate into the layer, an optimum epitaxial temperature is observed. The results are interpreted in terms of misoriented regions, which are related to the presence of various Si-O bonds, the nature and the amount of which are dependent on the epitaxial temperature. It is concluded that chemical interactions between the substrate and the layer are more effective than crystallographic effects in determining the particular electrical properties of these silicon layers.

The need for physical methods is especially strong in the field of heteroepitaxy studies. This need does not arise from the number of the preparation steps, but from the intricate nature of the physical parameters involved in the process. The electrical characteristics, so useful with respect to the applications of these layers, give no physical insight. Furthermore they often involve long, sometimes destructive steps before measurements.

For these reasons, x-ray diffraction methods and IR spectrometry techniques complement the conventional electrical methods, in order to characterize thin silicon films grown by pyrolysis of silane, in hydrogen, on single crystal sapphire.

The aim of this study is an attempt to answer the following question: what are the relative contributions of fundamental factors and of incidental ones, inherent to the fact that the film properties are different from those of bulk material? The discrimination between these factors lies in the ability to improve the incidental ones, while the fundamental ones can only be optimized.

Experimental Conditions

Following Matare's general analysis presented in his excellent review paper (1), we can state some fundamental factors, optimizing in principle the experimental conditions:

1. High crystalline quality, Al_2O_3 ingots are used: they are Czochralski grown, and various tests confirm this quality (etching techniques, Borrmann effect).

2. The orientation $(01\bar{1}2)$ of the substrates gives two related advantages: (*a*) a nonpreferential *in situ* etching with H_2 at high temperature (1300°C), and (*b*) a quasi-systematic epitaxy of Si (100) as determined by x-ray and electron diffraction methods.

3. The substrate, 500 μm, and film, 5 μm, thick are chosen to minimize the strain of the layers.

4. Stresses are also avoided by a slow cooling rate after epitaxy ($\sim$ 100°/min).

5. The residual contamination level is low. With quite identical process conditions, silicon homoepitaxy is performed in the range 1000°-1200°C (2). Layers 5 μm thick are grown with N-type conductivity: when on 5-10 ohm cm P-type substrates, the layers resistivities are >100 ohm cm, and when on 0.01 ohm cm Sb doped substrates, the impurity concentration is less than 10^{14} cm^{-3}, at 1150°C.

6. The flow conditions (H_2 as a carrier gas, silane prediluted in H_2) have been determined to get low supersaturations required for epitaxy. The mean growth rate is 0.1 μm/min at 1100°C.

Electrical Results

The mean value results are shown in Fig. 1. Two processes have been used: process A, in which a chemical treatment of the substrate by hot phosphoric acid prior to insertion in the reactor is employed; and process B, without this chemical treatment. In any case, no intentional doping is performed.

From Fig. 1a, it follows that P-type doping occurs in the higher range of temperature, whatever the process, but N-type layers are grown at low temperatures, with the A process only.

Figure 1b gives the variation of Hall mobility with the epitaxial temperature. In the experimental range, a maximum value occurs at some optimum temperature (say T_0 = 1100°C). But if the sensitivity is far less in the A process than in the B process, the maximum value in the former case is slightly less than in the latter one.

Figure 1c gives another picture of this last result. If, instead of absolute values, a quality factor, F expressed as follows

$$F = \frac{\text{Hall mobility (film)}}{\text{Hall mobility (bulk for the same type and conc.)}}$$

is used, the difference between both processes disappears. We note that F increases with T_{epi} and reaches 50-60% at T_0.

Using a MOS structure, the majority carrier concentration (N_S) and the minority carrier lifetime (τ_S) near the free surface of the film (3, 4) has been measured.

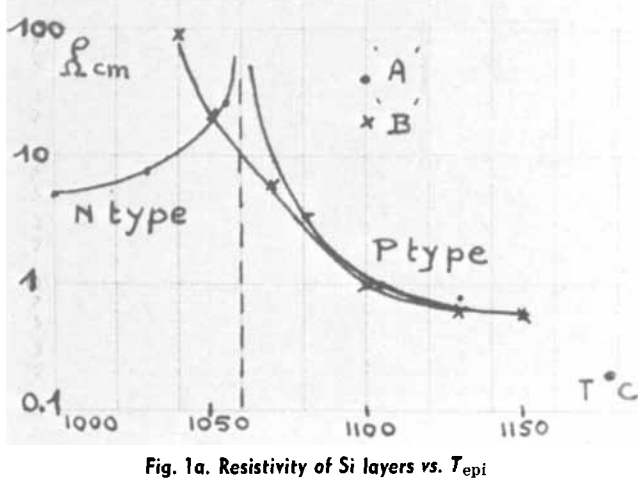

Fig. 1a. Resistivity of Si layers vs. T_{epi}

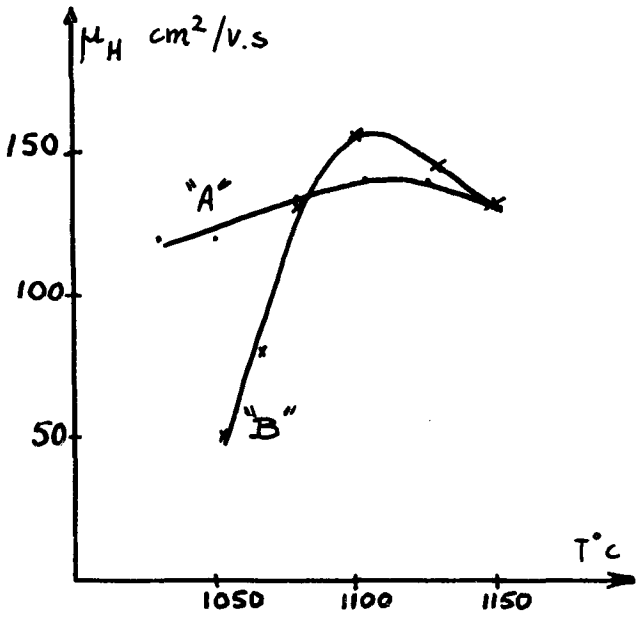

Fig. 1b. Hall mobility vs. T_{epi}

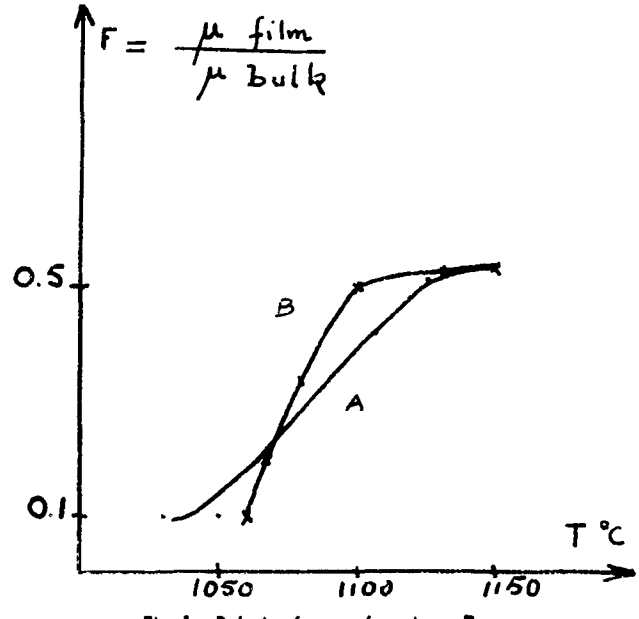

Fig. 1c. Relative factor of merit vs. T_{epi}

The variation of τ_s and its apparently high maximum value, when compared to other results (5) have been noted. The results are given in Table I.

Furthermore, some N-type layers were subjected to short time moderately high temperature, H_2 atmosphere treatments. For example, a 10 ohm cm N-type layer after 5 min at 1100°C turns to 150 ohm cm P-type. This change could not be explained in terms of usual dopant's diffusion. That it occurs only with H_2 atmosphere seems to indicate interfacial electrical states similar to those reported in ref. (6).

Table I. Electrical characteristics of Si layers

T_{epi}	Type	ρ, ohm cm	N_S, cm^{-3}	τ_S(ns)	Nature of oxide
1030	N	7.6	3.3×10^{15}	90	Pyrolitic
1055	N	23.8	1.1	7	Pyrolitic
1080	P	3.5	8.0	4	Anodic
1105	P	1	7.0	45	Anodic
1150	P	0.55	1.1×10^{16}	3	Anodic

Discussion

Some of these results can be now interpreted.

1. It has been ascertained by (7, 8) that Al from the substrate gives rise to P-type autodoping. The exact mechanism involved has not been clearly demonstrated. But from the variation of the layer resistivities, it seems reasonable to suppose that the N-type contamination is due to phosphorous residues after etching. This contamination has thus no other reason, but is inherent with the difficulties involved in the chemical surface preparation of the substrates. This result is to be compared with more subtle interfacial contamination effects (9). As a consequence, P-type layers grown at high temperature in the A process conditions are certainly electrically compensated. This explains the slightly lower maximum value of μ_f for the A process than for the B process (Fig. 1b).

2. The observed reduction of mobility (expressed by F) being independent of the type and doping level, it is plausible to explain in terms of structure defect the limitations at low temperature. This assumption must be checked by specific methods (discussed later). On the other hand, the decrease of mobility values in the higher temperature range can be attributed to impurity defects, the level of which increases with temperature.

X-ray Surface Topography

In the analysis of structural defect limitations, the first step to be considered is the state of preparation of the substrate surface. Reflection techniques as schematically described in Fig. 2 are used (10). Plate and sample under study are simultaneously moved to explore the whole surface, the resolution is fairly good (10μ).

Figure 3 shows a well polished substrate, and Fig. 4a presents a poorly polished one. An optical examination would have given in either case a very flat appearance. Then the same last wafer, after subjection to an H_2 treatment at 1300°C is seen in Fig. 4b. The efficiency of this treatment is demonstrated by the removal of

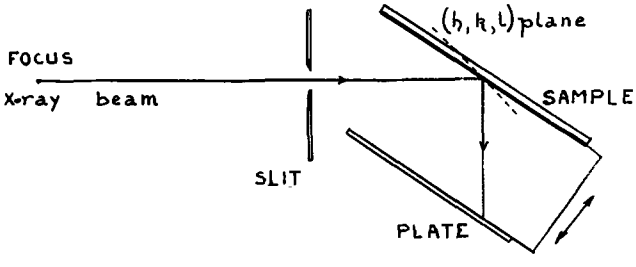

Fig. 2. X-ray surface topography arrangement

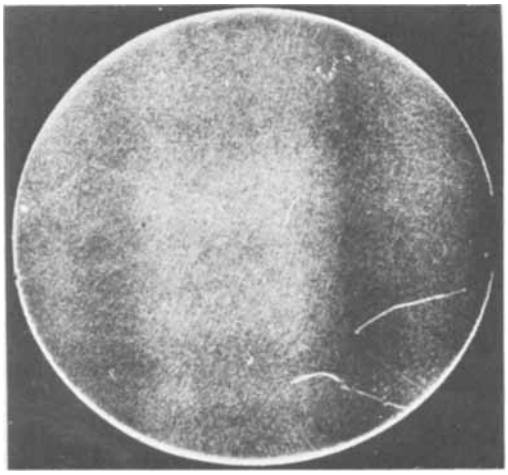

Fig. 3. X-ray surface topography of a well polished Al_2O_3 substrate.

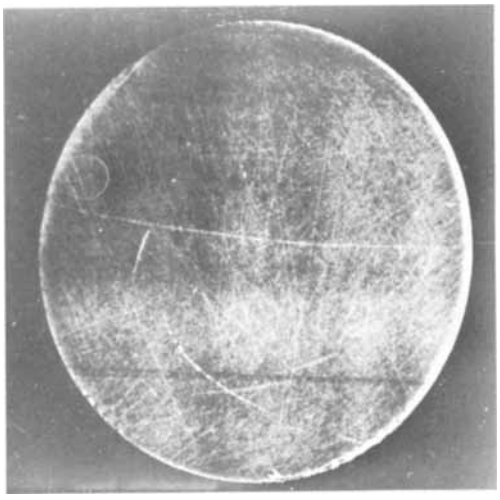

Fig. 4a. X-ray surface topography of a poorly polished Al_2O_3 substrate before H_2 treatment.

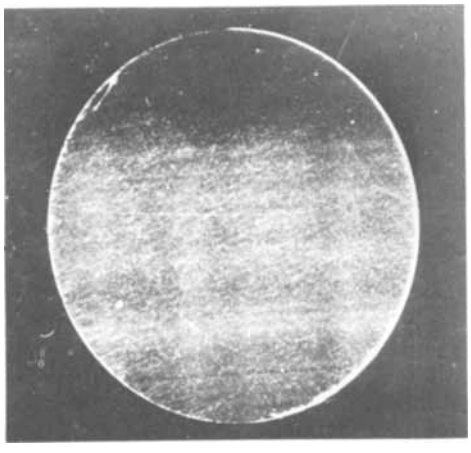

Fig. 4b. X-ray surface topography of a poorly polished Al_2O_3 substrate after H_2 treatment.

fine scratches and the smoothing of dislocation lines. Some preferential etching is indicated by the [100] direction as seen in Fig. 5, which is a G x 10 part of that substrate. This direction has been spotted with the [$0\bar{2}1$] reference direction. This last one is the intersection of the (3.2.4) reflecting plane with the (01.2) plane.

From these results, one may say that, in spite of difficulties, mechanical and gaseous polishing give good surfaces for epitaxy.

After growing a silicon layer, it is possible, with a proper choice of film thickness to investigate during the same experiment the free surface of the silicon film and the silicon-substrate interface (obviously with different reflecting planes: for Si (440) is convenient). Generally no structure is seen. But Fig. 6a (silicon surface) and Fig. 6b (interface) are special cases: the structures' replica is apparent (see the right corner

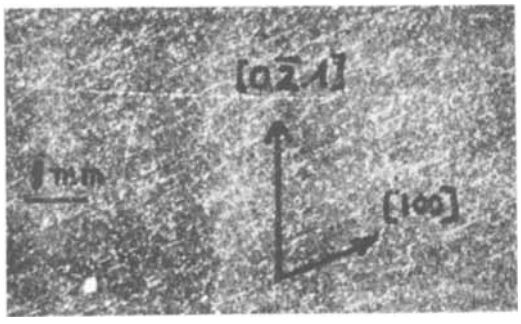

Fig. 5. Part (G x 10) of that wafer

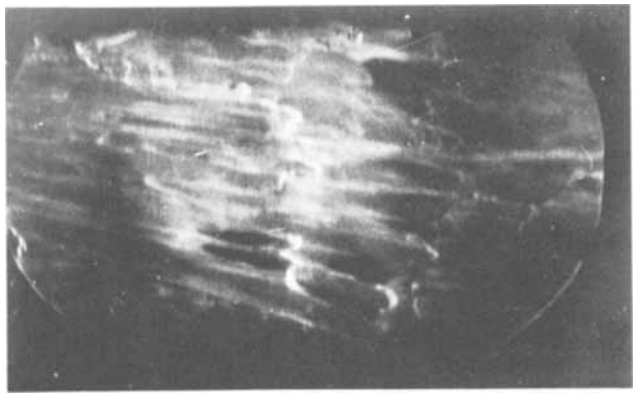

Fig. 6a. X-ray surface topography of the silicon film free surface

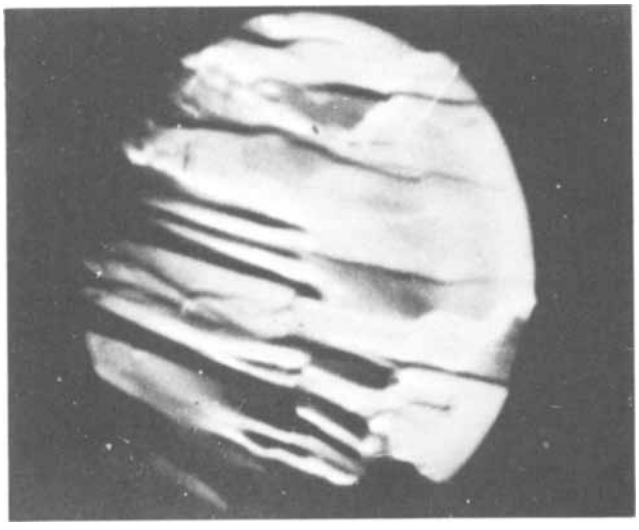

Fig. 6b. X-ray surface topography of the Si-Al_2O_3 interface

down). As these structures are visible only if a rapid cooling rate after epitaxy takes place, it may be concluded that the contrast is due to thermal stresses both in the silicon film and in the substrate.

Assessment of Crystalline Quality of Films

The x-ray diffraction method is a powerful technique for this aim, its interesting features are: (*i*) nondestructive, (*ii*) analysis of net planes in the film and not only of the surface structure, and (*iii*), semiquantitative: the diffracted intensities are comparative estimates of this quality.

Table II shows relative intensities of the Cu $K\alpha_1$ radiation, diffracted on various planes for six layers (D 1 to 6), deposited at different temperatures.

The (400) plane-reflection corresponds to the predominant (100) orientation of Si films. Regardless of the position of the x-ray spot (2 x 5 mm^2) on the surface, and whatever the sample under study, this intensity is constant and is the strongest one. It will be taken as a reference, with a value of 10^6 in arbitrary unit.

The (200) plane-reflection does not normally satisfy the Bragg condition, unless some planes are missing.

Table II. Relative intensities of x-ray diffracted beam

T_{epi}, °C →	1030	1055	1080	1105	1125	1150
Plane:						
(400)	10^6	10^6	10^6	10^6	10^6	10^6
(200)	1.6×10^3	10^4	1.2×10^5	<40*	1.4×10^4	400
(220)	2×10^3	200	<40	<40	2.8×10^3	200

* 40 is the (relative) detection limit.

This means that stacking faults are present in the layers and the given figures are indicative of their density. It must be noticed that the reported values are maximum ones, for the intensity varies from place to place.

The (220) plane-reflection, which has been reported by others (11) is due to an epitaxial defect orientation (110). Its intensity is uniform for a given film.

The stressed layers as shown in Fig. 6 were (110) mono-oriented.

In conclusion, the comparison of figures in Table II, gives an optimum temperature from both the point of view of stacking fault and of misorientation densities. This temperature is the same one as for mobility values.

Substrate Layer Chemical Interactions

That chemical interaction occurs at the initial stages of the heteroepitaxial process is ascertained with a simple experiment: the selective removal of the epitaxial layer leaves a disturbed Al_2O_3 surface (12) which is not observed solely due to an H_2 heat treatment.

It has generally been assumed that heteroepitaxy occurs in this specific case, by the way of a substitution for Al atoms by Si atoms (13). A reducing action of Si itself seems to have been demonstrated (14-16) in vacuum deposition. However, these authors agree that a very low supersaturation gives this etching effect, and this condition is not generally met in normal deposition conditions. In fact, this would not allow the reversible reaction

$$2Si + Al_2O_3 \rightleftarrows 2SiO + Al_2O$$

to take place but, the following reactions

$$Si + Al_2O_3 \rightleftarrows SiO_2 + Al_2O$$

$$SiO_2 + H_2 \rightleftarrows SiO + H_2O$$

involving less silicon but also the presence of H_2 would be favored due to the extremely dry atmosphere of the experimental conditions.

In any case, however, two consequences of this reactivity are expected: (*i*) the association between the epitaxial condition and the presence of Al in the layer, and (*ii*) the introduction of various Si-O bonds at the film-substrate interface, and probably in the layer itself, due to the high solubility of oxygen in silicon.

Infrared Spectroscopy

In order to check these two points, we have conducted experiments in infrared spectroscopy.

Infrared interferences in the range 1.5-7μ are used for layer thickness measurement. But absorption lines, characteristic of specific chemical bonds are well known. For Si-O bonds they lie in the 700-1400 cm^{-1} range, and for Si-Al the optically excited line is 560 cm^{-1} (0.067 eV) (see the special references at the end of this article).

The use of IR spectrometry however gives rise to two main difficulties with respect to: (*i*) selectivity to avoid interfering effects of the substrate, and (*ii*) sensitivity due to the small amount of Si, containing a low impurity concentration (from a chemical point of view).

The attenuated total reflection method in an arrangement first proposed by Harrick (17) using multiple reflections, has been devised for this purpose. The principle is given in Fig 7. A monochromatic light of the proper wavelength hits a prism in optical contact with the sample. With a suitable refractive index of this prism, a total reflection condition is obtained, and light transfers some part of its energy to a certain depth inside the absorbing medium (Si) (18).

Experimental difficulties, with the optical contact, the low transmittance (<20%), the need for a compensating circuit in the reference beam, add to the theoretical difficulties in the interpretation of the results.

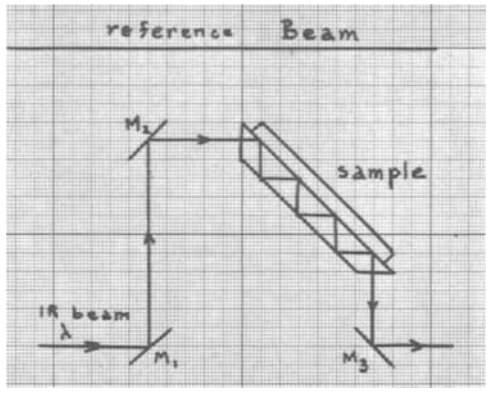

Fig. 7. Attenuated total reflection arrangement

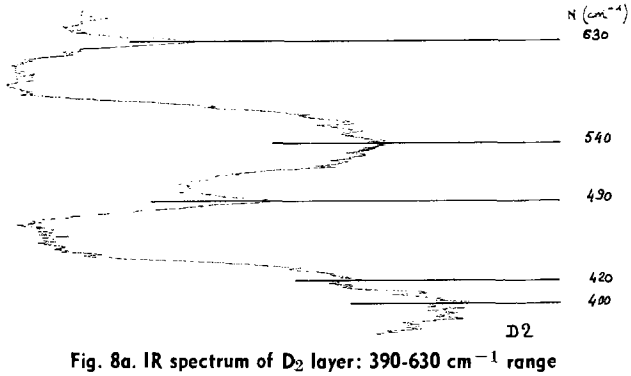

Fig. 8a. IR spectrum of D_2 layer: 390-630 cm^{-1} range

For example, difficulties inherent to the method are: (*a*) shift toward long wavelengths, (*b*) attenuation of short λ bands, and (*c*) reduction of spectrum contrast.

For the moment, only qualitative results are given in Table III. Some spectra are given for the D_2 and D_1 layers (Fig. 8 and 9) and an Al_2O_3 substrate (Fig. 10).

Discussion

1. The Si-Al bond is detected in all epitaxial layers, whatever the epi temperature process and therefore electrical type of the layer.

2. Various Si-O bonds are found, the nature and the amount of which depend on the epi temperature. No apparent continuous transition between amorphous poly- and monocrystalline forms is found when increasing T_{epi}. But for the same optimum T as before,

(*a*) the number of absorption lines is minimum, and (*b*) no amorphous SiO and SiO_2 quartz bonds are present in this layer.

Quartz as a separate phase might have its own orientation, quite independently of the substrate and as a result misorientation effects could be ascribed to its presence.

To resolve an objection against the preceding discussion, we have performed the same experiment on N/N^+ homoepitaxial silicon layers without finding any evidence of Si-O and Si-Al bonding. This removes the possible influence of impurities in silane itself.

Conclusion

Even in our optimized conditions, imperfections are always present in heteroepitaxial Si layers. The optimum range of epitaxial temperatures, around 1100°C, has been found for the majority carrier mobility and has been correlated to crystalline quality from x-ray diffraction methods. IR spectrometry has pointed out the outstanding influence of chemical bonds in explaining most of the layer properties. This conclusion does not mean that crystallographic defects are not of great importance, but it seems that their effects are essentially indirect, due to interaction between dislocations and impurities for example.

Acknowledgments

This work is partly supported by the French Délégation Générale à la Recherche Scientifique and by the French Centre National de la Recherche Scientifique. The author thanks these Administrations for permission to publish. I am grateful to Professor L. Neel for allowing this work and to Dr. B. K. Chakraverty for valuable discussions. It is a pleasure to thank Dr. G. Blet and his group of the L.R.B.G. of Thomson-Houston for his contribution to physical measurements. Without his help, I would not have so rapidly demonstrated the possibilities of infrared techniques in such studies. I also thank Mr. Jund of the C.S.F. laboratory for performing special electrical measurements.

The Role of Damage in the Annealing Characteristics of Ion Implanted Si

Billy L. Crowder

IBM T. J. Watson Research Center, Yorktown Heights, New York

ABSTRACT

Carrier concentration profiles are presented for Si which has been implanted with a low (3 x 10^{13} cm^{-2}), intermediate (3 x 10^{14} cm^{-2}) or high (8 x 10^{15} cm^{-2}) dose of 280 keV P^{31} ions at room temperature and subjected to a 30 min post implantation anneal in the temperature range 550°-850°C. The annealing behavior of these samples is correlated with the amount of damage produced by the room temperature implantation. If a continuous amorphous region is present, ions within this region become electrically active and uncompensated during the epitaxial recrystallization of the layer between 550° and 600°C. These results are generalized to provide a model for the annealing characteristics observed for room temperature and elevated temperature ion implanted Si layers.

Ion implantation doping of silicon at or near room temperature has been shown to produce gross structural defects consisting of amorphous (or highly disordered) regions along the path of the ion (1). Theoretical estimates of the spatial distribution of damage in "amorphous" Si have indicated that the average projected range of the ions is somewhat larger than the average damage depth and that the straggling in these quantities are comparable (2, 3). Recent experimental observations confirm these estimates for implantations of P, As, B, and Si into Si (4). Annealing is required to remove such gross lattice damage and to achieve the desired electrical activity of the implanted dopant. Previous investigations of the dose dependence of the annealing characteristics of Si doped with P or As by room temperature ion implantation have indicated a minimum in the number of carriers per implanted ion as a function of the number of implanted ions in the temperature range 500°-700°C (5, 6). The purpose of this investigation is to demonstrate that this minimum is due to three factors: (*i*) the damage distribution lies closer to the surface than the implanted ion distribution (4), (*ii*) the compensating centers remaining after the annealing of the damage clusters are thermally stable up to temperatures characteristic of diffusion processes in Si (4), and (*iii*) a continuous amorphous layer, if present, recrystallizes epitaxially onto the underlying substrate at 500°-600°C (1).

Experimental

Implantation was accomplished with a Cockcroft-Walton accelerator capable of operation to 300 kV. The P ions were obtained from gaseous PF_5. The ion beam was focused, mass analyzed magnetically, and electrostatically scanned uniformly over a 4 cm^2 area. The total dose was obtained by integrating the current from the samples. Dose rates were typically 1 μamp cm^{-2}. Accurate target alignment was not available since the beam sweep was over approximately $\pm$ 1°.

The Si substrates were <100> wafers cut from Czochralski-grown crystals, which were boron-doped and 1 ohm-cm resistivity. The substrates were lapped and chemically polished. Contact areas were diffused with As prior to implantation to facilitate good electrical contact to the implanted region.

The electrical evaluation of ion implanted layers was accomplished by Hall effect and sheet resistivity measurements on van der Pauw configurations in conjunction with removal of Si layers by anodic oxidation and HF stripping. This technique has been fully described by Mayer *et al* (7). The details of our experiments have been covered in a previous publication and will not be repeated here (8)

Experimental Results

Table I summarizes the electrical properties observed for Si implanted with 280 keV P^{31} ions at a low, inter-

mediate, and high dose and subjected to annealing for 30 min at the temperature given in column 2. In column 4, the effective number of carriers cm^{-2} as determined from the sheet Hall coefficient of the implanted layer is presented. This number is less than the true number of carriers cm^{-2} (presented in column 5 and obtained from stripping experiments) due to the fact that it represents a weighted average which favors higher mobility carriers (7). The utilization of the implanted P ions (*i.e.*, the ratio of carriers observed to P implanted), presented in Table II, exhibits the minimum observed by previous authors (5, 6).

The depth distribution of carriers for Si implanted with P^{31} and annealed at various temperatures for 30 min are given in Fig. 1 (3×10^{13} P cm^{-2}), Fig. 2 (3×10^{14} cm^{-2}), and Fig. 3 (8×10^{15} cm^{-2}). In Fig. 3, the total P atom profile [obtained by neutron activation analysis as described in ref. (9)] is also shown. The carrier concentration after an 850°C anneal (not shown in the figure) corresponds closely to this total P profile [see ref. (8)]. It should be emphasized that no appreciable differences were observed between the total P profile obtained by neutron activation analysis for samples which were not annealed and samples which were annealed at 850°C for 30 min; *i.e.*, no appreciable diffusion occurs as a result of the annealing step (9). The low dose implant (Fig. 1) exhibits a large "tail" which is due to partially channeled P ions. As the damage produced during the course of the implantation is increased, channeling of P ions is eventually curtailed (10). Channeled P ions contribute less to the profile for the intermediate dose (3×10^{14} cm^{-2}, Fig. 2) than to that for the low dose. For the high dose implant, ions which have partially channeled represent only a small fraction of the implanted dose (Fig. 3).

The Hall mobility observed in Si implanted with 3×10^{14} cm^{-2} 280 keV P ions (see Fig. 2 for profiles) are presented in Fig. 4 as a function of the observed carrier concentration. After a high temperature anneal (850°C), the mobility of the implanted layer is comparable to that observed for bulk Si, as previously observed for well annealed ion implanted layers by Baron *et al.* (11). At lower annealing temperatures, where most of the implanted P ions are not electrically active and uncompensated, the observed mobility is lower for layers within approximately 0.5μ of the surface, presumably because of the presence of charged compensating species. Similar behavior was observed for the Hall mobility in the low dose implants (3×10^{13} cm^{-2}) in that the mobility after a 550°C anneal was lower than that observed in uncompensated bulk Si, for layers within 0.5μ of the surface.

The surface of the substrate implanted with 8×10^{15} P ions cm^{-2} exhibited the "milky" appearance characteristic of amorphous Si. The depth of this amorphous region was determined to be 0.5μ by interference fringes observed in the optical absorption spectrum of a similarly implanted wafer (12). The surface still exhibited the milky appearance after annealing at 550°C for 30 min, but the depth of the amorphous layer was only 0.1μ. This observation is consistent with the epitaxial regrowth onto the crystalline substrate previously reported (1). Annealing for 30 min at 600°C

Table II. Utilization factor for Si implanted with 280 keV P^{31}

Dose (cm^{-2})	Utilization factor[a] 550°C	600°C	700°C	850°C
3×10^{13}	0.13	0.8	~1[b]	1
3×10^{14}	0.02	0.2	0.7	0.9
8×10^{15}	~1[b]	1.0	~1[b]	0.9

[a] The utilization factor (defined as the total number of carriers observed to the number of P ions implanted) is given as a function of the temperature at which the sample was annealed for 30 min.
[b] These values are obtained from the effective number of carriers cm^{-2} (rather than the total number of carriers cm^{-2}), estimating the profile correction from the data given at temperatures for which wafers were stripped and profiled.

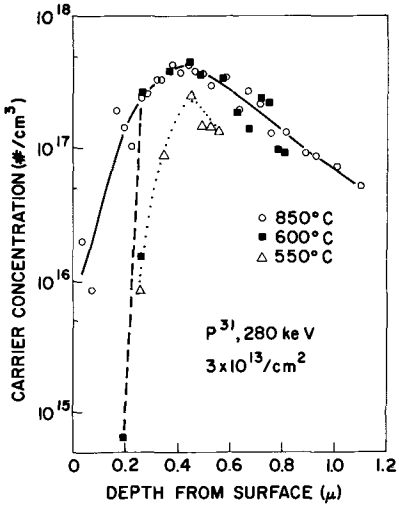

Fig. 1. Carrier concentration profile of <100> Si implanted with 3×10^{13} cm^{-2} 280 keV P^{31}. Samples were annealed for 30 min at 550°C (open triangles), 600°C (closed squares), or 850°C (open circles).

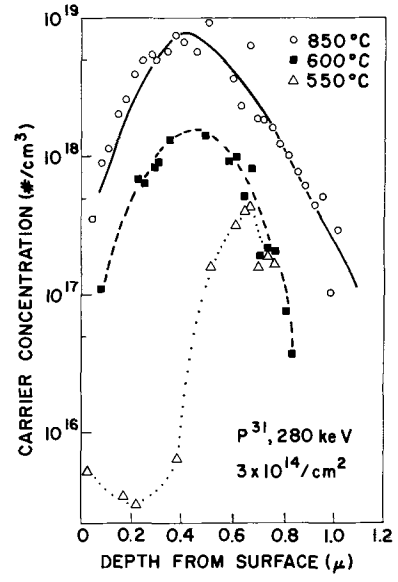

Fig. 2. Carrier concentration profile of <100> Si implanted with 3×10^{14} cm^{-2} 280 keV P^{31}. Samples were annealed for 30 min at 550°C (triangles), 600°C (squares), or 850°C (circles).

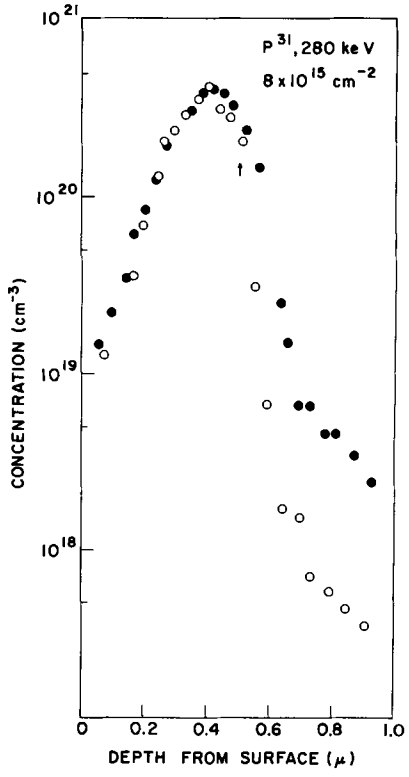

Fig. 3. Concentration profile of <100> Si implanted with 8 x 10^{15} cm^{-2} 280 keV P^{31}. Closed circles represent total P concentration as determined by neutron activation analysis. Open circles represent carrier concentration observed after a 30 min anneal at 600°C. Arrow marks depth of continuous amorphous region present after implantation and before annealing.

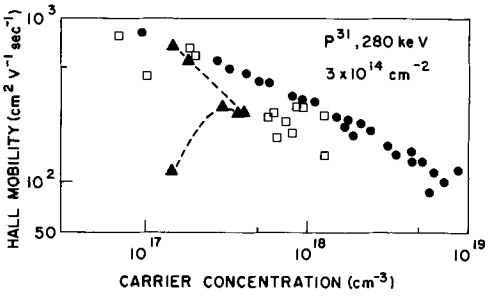

Fig. 4. Hall mobility of Si ion-implanted layers as a function of observed carrier concentration of the layer. Carrier concentration profiles of these samples are given in Fig. 3. Samples were annealed for 30 min at 550°C (triangles), 600°C (open squares), or 850°C (circles).

was sufficient to eliminate this milky appearance. These results may explain the higher annealing temperatures reported for P-implanted layers by Davies, who employed a four point probe (*i.e.*, contacting only the high resistance surface layer) to measure resistivity (13).

Discussion of Results

In a study of the electrical properties of Si implanted with 400 keV P ions, Gibson *et al.* observed essentially complete annealing at temperatures as low as 550°C for low dose (1 x 10^{13} cm^{-2}) and high dose (1 x 10^{15} cm^{-2}) implantations in a random direction (14). These authors did not report on intermediate doses, but the results of the previous section indicate that for such doses only a fraction of the implanted P ions are electrically active and uncompensated after a 550°C anneal for 30 min, in spite of the fact that the gross lattice damage produced by low dose implants anneals below 400°C (15).

Experimental investigations on the spatial distribution of damage in Si produced by P ions in the energy range 70-280 keV show that the ratio of the average damage depth (*i.e.*, the depth from the surface at which the peak in the damage distribution profile occurs) to the average projected range of the P ions (R_p) is between 0.6 and 0.7 [ref. (4)]. For 280 keV P implantations considered here, the maximum damage density occurs at 0.24-0.28μ. Since the damage increases with increasing ion dose, the amount of damage in the spatial region in which most of the P ions lie is much greater for a dose of 3 x 10^{14} cm^{-2} than for 3 x 10^{13} cm^{-2}. These factors are clearly reflected in both the profile of carrier concentration after a 550°C anneal in Fig. 1 and 2 and the low mobilities observed for carriers in this region of highest damage density. An analogous situation is observed for implantations conducted at temperatures above 400°C, where gross lattice damage anneals during implantation. Thermally stable defects remain after the annealing of isolated damage clusters, whether annealing occurs during or after implantation. The density of these defects in the vicinity of the ion distribution is higher for higher doses. Higher temperatures, at which diffusion processes can eliminate such compensating centers, are required to achieve a large fraction of the implanted ions electrically active and uncompensated.

In the case of a high dose which produces a continuous amorphous region, the annealing behavior is markedly different. After a 600°C anneal, the carrier concentration profile corresponds closely to the implanted P ion profile (Fig. 3) to a depth of 0.5μ and the Hall mobility is that expected for bulk Si of comparable doping. Beyond this point, the carrier concentration is markedly lower than the P concentration. Since most of the implanted P ions lie within 0.5μ of the surface, a 600°C anneal results in nearly complete utilization of the implanted P (Table I). The process of epitaxial regrowth of the amorphous region onto the underlying crystalline Si substrate provides a mechanism for the incorporation of most of the P atoms substitutionally and the elimination of any compensating defect centers. Annealing at 550°C also results in nearly complete utilization of the implanted P, even though the surface is still amorphous. As shown earlier, the depth of the amorphous region after a 550°C anneal is only 0.1 to 0.13μ so that most of the P ions lie within recrystallized Si. The diffused contact areas serve to make good electrical contact to this "buried" conducting region.

Similar results are obtained for high dose As implantations, as presented in Fig. 5. The depth of the continuous amorphous region was determined to be 0.35 to 0.36μ [stripping and visual observation; interference fringes (12)] as shown by the arrow. Arsenic ions which are within 0.35μ of the surface (*i.e.*, within the amorphous region) become electrically active and uncompensated after a 550°C anneal for 30 min.

In the high dose P and As implantations, the distribution of ions which lie just beyond the boundary of the amorphous layer produced by room temperature implantation are located in a region of relatively high damage density, thus requiring temperatures characteristic of diffusion processes in Si in order to become uncompensated and electrically active.

Summary

The fact that the damage distribution lies closer to the surface than the ion distribution giving rise to the damage has been shown to have interesting consequences in the low temperature annealing behavior of room temperature implantations of P into Si. These results can be generalized as follows:

1. At a sufficiently low dose, the damage density is so low in the region where the bulk of the ion distribution lies that a large fraction of the implanted species

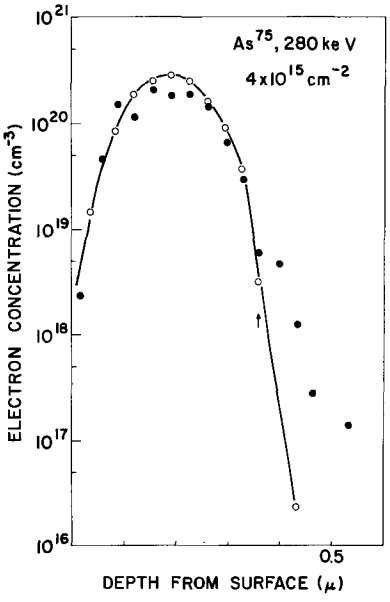

Fig. 5. Carrier concentration profile of <100> Si implanted with As^{75}, 280 keV, 4 x 10^{15} cm^{-2}. Samples were annealed for 30 min at 550°C (open circles) or 800°C (closed circles). Arrow marks depth of continuous amorphous Si region present after implantation and before annealing.

are electrically active and uncompensated after a low temperature anneal, as observed, *e.g.*, for P implants by Gibson *et al.* (14) and for low dose B implants by Seidel and MacRae (16).

2. As the dose is increased, the amount of damage in the region occupied by the ion distribution increases. A fraction of the damage centers which remain after the gross lattice damage has annealed are thermally stable to temperatures characteristic of those at which diffusion processes can occur (4). When this fraction of compensating defects is comparable to or exceeds the ion concentration, high temperatures are required to achieve a high degree of electrical activity in the implanted layer. These observations apply for the situation where annealing is accomplished during implantation as well as low temperature implantations followed by a post implantation anneal. Such behavior has been noted for B, P, and As implantations by a number of authors [see, *e.g.*, ref. (9) and (16)].

3. If the dose is sufficiently high and the temperature sufficiently low to allow the formation of a continuous amorphous region overlapping the ion distribution, the epitaxial regrowth of this amorphous region "sweeps out" the compensating defects and the ions within this regrown region are electrically active and uncompensated. At a given temperature, light ions require a higher dose to produce this amorphous layer than heavy ions, as shown, *e.g.*, for room temperature implantations of P or As (6). For a given ion, lower doses are required at lower temperatures, as demonstrated for B implantations into Si by Davies (13). The required dose may approach a limiting value at sufficiently low temperatures.

Ionic Instabilities in Pyrolytically Deposited SiO_2 Films

P. M. Dunbar[1] and J. R. Hauser

North Carolina State University, Raleigh, North Carolina

ABSTRACT

Forms of ionic instability in pyrolytic SiO_2 layers are investigated through movements of the flat band voltage. The films were in the thickness range of 1000Å, deposited at 725°C, and annealed at 800°C in a steam atmosphere. As deposited, the films exhibited the presence of both positive and negative charge. This charge was also found to be highly mobile. The annealed films exhibited only positive ionic charge but high flat band voltages with instability present only after long term bias.

The process of pyrolytic deposition has become quite widely used in semiconductor device fabrication. Basically, the process concerns the deposition of thin insulator films such as SiO_2 for both diffusion and electrical insulation. Some of the initial work with this process was performed by Jordan (1) in his attempt to apply the process as a suitable method for diffusion masking on germanium. Klerer (2, 3) expanded on Jordan's work and studied the chemical

[1] Present address: Howard University, Washington, D. C. 20001.

reactions involved in a pyrolytic deposition. Other evaluations showed densified pyrolytic films to be quite comparable to thermally grown SiO_2. However, ionic instability usually occurred in the films. These instabilities have been noted briefly (4), and this present work expands on this problem.

Experimental Techniques and Results

The apparatus used in this work was similar to that used by Jordan (1). A diagram of the complete system is shown in Fig. 1. This system allows the three basic operations of purging, deposition, and annealing in a steam atmosphere. The nitrogen purge takes place prior to any deposition and while the furnace is heating or cooling. When the slice obtained proper temperature, the deposition was initiated by introducing nitrogen into the bubbler which contains liquid tetraethyoxysilane. The tetraethyoxysilane was standard reagent grade material. This flow rate and the purge rate can be controlled by flowmeters 1 and 2. The bubbler was held at 32°C in order to regulate the absorption rate of the tetraethyoxysilane into the nitrogen carrier. This allowed an improvement in repeatability by excluding room temperature as a process parameter. The substrates used were n-type silicon slices. The resistivity was in the 10 ohm-cm range, and the crystal orientation was [100]. The slices were approximately 3 cm in length by 1.5 cm in width.

The substrates were stored in methyl alcohol prior to deposition, and placed wet into a 200°C furnace at the outset of a run. The system was then purged with a nitrogen flow rate of 1.0 l/min for about 15 min. When proper temperature was reached, deposition was begun by diverting 0.5 l/min of nitrogen through the tetraethyoxysilane while allowing 0.5 l/min of nitrogen to flow freely into the furnace, giving a total deposition flow rate of 1.0 l/min. This combination yielded the best results, because a higher or lower rate through the bubbler detracted from the uniformity of the films. At the end of the desired deposition time, the bubbler flow was cut off and the purge flow of 1.0 l/min was returned. After allowing 2 min for the system to clear of tetraethyoxysilane vapors, the power to the furnace was shut off. The slice was then removed after the temperature dropped to 300°C. Deposition temperatures were in the 700°C range with deposition rates of 60 to 160 Å/min. This range of deposition rates had no detectable effect on the stability results.

The resulting films were clear in appearance and the thicknesses, estimated from the film color, were in the 1000Å range. Although the films suffered from a thickness nonuniformity in the range of 20%, the region over which metal was evaporated had no more than a 5% variation. The annealed films were processed identically except that a 15 min steam treatment at 800°C was included.

To fabricate the capacitors, 17 mil diameter dots were evaporated onto the slice. Both gold and aluminum were used, but the metal thickness was 4000Å throughout. Electrical contact was made to these devices with a probing technique.

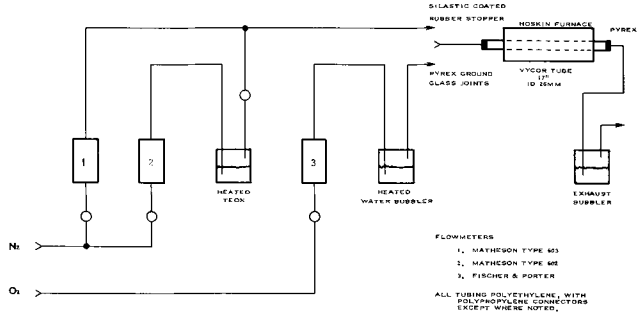

Fig. 1. Apparatus for pyrolytic deposition of thin insulating films

Evaluation

Studies of these devices showed the steam annealed films to be quite similar to thermal oxides with respect to dielectric strength and structural qualities such as pinhole characteristics. Although the unannealed devices had both high leakage currents and pinhole counts, the breakdown strength of all the devices were in the 10^7 V/cm range. The relative permeativity values were quite scattered, but generally were 20% higher than in thermal oxides.

It is known that pyrolytic oxides obtained from tetraethyoxysilane can contain considerable concentrations of impurities which can dope the silicon either p- or n-type. No doping effect on the silicon was noted for the temperatures and times used in the present work. The possible presence of a p-type layer was checked by etching the oxide from several wafers after testing and checking for the conductivity type which remained n-type. Similar deposits on p-type wafers of about 10 ohm·cm resistivity have also failed to show the presence of a thin n-type layer due to diffusion from the pyrolytic oxide during the temperatures and time employed in this work.

The apparatus used to determine the capacitance *vs.* voltage characteristics involved a standard capacitance bridge outfitted so that the voltage could be automatically swept across the device. A block diagram of this system is shown in Fig. 2. A 50 msec ramp voltage from the oscilloscope was used to sweep the device voltage. The ramp was 50V in height but the beginning and end points could be adjusted by means of the series bias. The scope could be triggered externally or allowed to free run, depending on the mode of sweep voltage desired. Comparisons of the curve shifts were made by photographs of the scope face.

The initial curves were obtained by single sweeps of the ramp voltage across the device. After the initial curve was obtained, the ramp voltage was allowed to free run across the device for several thousand cycles to detect any rapid movements of the curve. The bridge was then disconnected, and a 9V d-c bias was connected across the device for a 4-hr period with the metal positive. At the end of this time, the battery was disconnected and the bridge reconnected, and another "initial" curve was obtained. As before, the ramp was then set on free run to detect any rapid changes. This was then repeated for the opposite polarity for the 4-hr bias.

The need to bias the ramp voltage resulted from the need to sweep the device voltage in a bipolar method. This bias, however, resulted in a d-c component of voltage placed across the device whenever a sweep was made. Although this d-c component had no detectable effect in the single sweep mode, the effect was quite appreciable during the free run time. The voltages applied to the devices during the free running mode are shown in Fig. 3. Typical initial curves for both types of devices are shown in Fig. 4 and 5. The flat band voltage for this oxide thickness and substrate doping occurred when C/C_{max} was in the order of 0.7. These curves depict the movements somewhat typical of unstable oxides. Note however, that the unannealed films exhibited positive flat band voltages after negative stress. This indicates the presence of a fairly large negative charge density in the layer.

Note also, that after annealing in a steam atmosphere the effect of this negative charge could also explain the low flat band voltage of the unannealed films

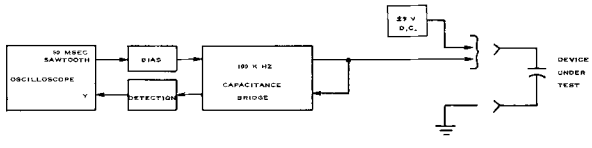

Fig. 2. Capacitance *vs.* voltage apparatus

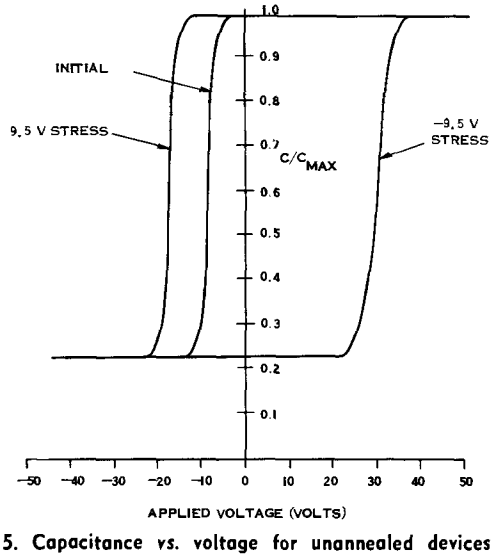

Fig. 5. Capacitance vs. voltage for unannealed devices before and after stress.

as compared to the annealed films, since the negative charge would counteract any positive charge present in the layer, thus lowering the flat band voltage. Since the annealing seems to eradicate these charge centers, the counteracting effect would not be present in the annealed films, allowing the now free positive charge to raise the flat band voltage. The positive charge and its related high flat band voltage could, of course, have been caused by a contamination entering at some point in the process; however, the apparent nulling of the negative charge by annealing suggests that this negative charge is inherent in the unannealed pyrolytically deposited SiO_2 films.

Another major difference between the annealed and unannealed devices was exhibited when the sweep voltage was set to free run in order to detect any rapid movements. The unannealed devices, as shown in Fig. 6 and 7, exhibited a very rapid flat band movement, indicative of a highly mobile charge species. Two factors indicate that the mobile charge causing this is the negative charge. Primarily, this type of rapid hysteresis was not present after annealing. This, when coupled to the indication that the negative charge was eliminated by annealing points to this charge as the cause of the rapid shifts.

A close examination of the rapid instability also indicates that negative charges can explain the rapid shifts in flat band voltage. Note that after positive stress, the positive charge would be near the SiO_2-Si interface, having a more pronounced effect in V_{FB} than the negative charges which are at the SiO_2-metal interface. The d-c component of the free running sweep, then would move the negative charges to the SiO_2-Si interface but the positive charges would remain comparatively unmoved, thus counteracting the negative charge movement, slowing down any hysteresis effects. The case of negative stress points this out in somewhat more dramatic fashion. After stress, the positive charge is now at the metal-SiO_2 interface,

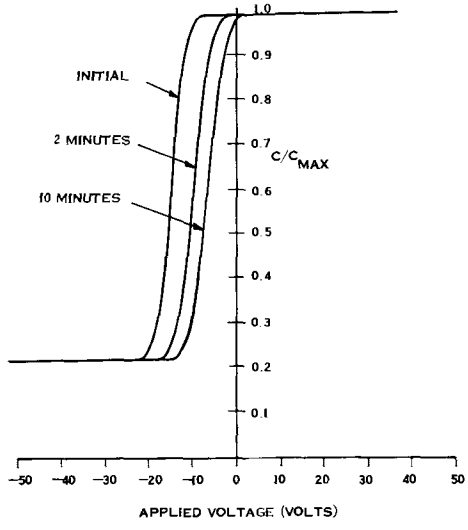

Fig. 6. Capacitance vs. voltage showing rapid charge movement after positive stress in unannealed devices.

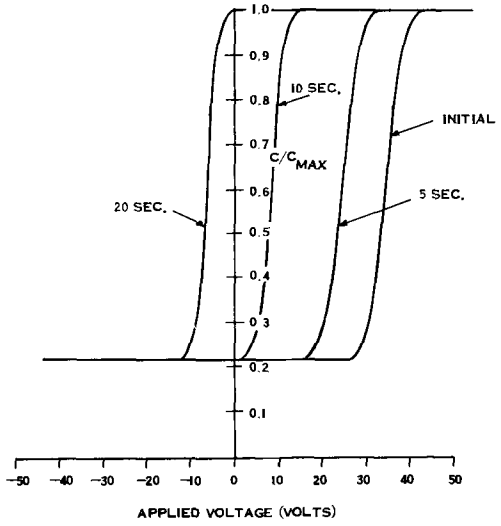

Fig. 7. Capacitance vs. voltage showing rapid charge movement after negative stress in unannealed devices.

where it has little effect on V_{FB}, and the negative charge, now at the SiO_2-Si interface, is the controlling factor. So, when the free run component occurs, this negative charge now moves rapidly to the metal-SiO_2 interface, lowering the V_{FB} just as rapidly, causing the rapid movement as seen in Fig. 7.

These results, however, were somewhat scattered. Although the characteristics shown in Fig. 6 and 7 were quite typical, the speed of the movements varied widely, indicating a somewhat unpredictable mobility of the negative charge. Another factor of note is that these rapid changes did not occur until after the devices were put under a long term bias.

Summary and Conclusions

Stability studies showed the films to be unstable with high flat band voltage as compared to good thermally grown oxides. Both the annealed and unannealed films exhibited the effects of charge movement indicative of positive ionic charge in the oxide layer. The unannealed devices indicated the presence of both positive and negative charge in the oxide layer.

The presence of the negative total charge in the oxide differs from that of thermal oxides where positive ionic charges are observed. The origin of the negative charge can only be speculated on at this point. Ionic instabilities in SiO_2 have been studied in considerable detail (5, 6). The rapid movement of the negative charges in the present study would require, however, a much larger mobility than has previously been reported for ions. Hofstein (7) has reported on a hydrogen ion trapping instability in SiO_2 which gives times more consistent with the rapid shifts observed in this work. The hydrogen ion, however, is a positive charge whereas the present observations indicate a rapid movement of negative charges. The negative charges may in fact be just electronic motion within the pyrolytic SiO_2 layer. A thin higher quality thermal oxide at the silicon interface could prevent the electrons from flowing out of the pyrolytic oxide into the silicon, resulting in their accumulation at the pyrolytic-thermal oxide interface.

The improvement in the C-V shifts following annealing in a stream atmosphere appear to be due largely to the elimination of the rapid negative charge movements within the oxide. The steam annealing process can have two effects on the insulating layer. Previous work (2-4) has indicated this process results in a densification of the pyrolytic oxide films. Also, there is likely some increase in the thickness of the thermal oxide between the silicon and the pyrolytic oxide. Both of these processes may contribute to the improved electrical properties following annealing.

Water Contamination in Thermal Oxide on Silicon

G. L. Holmberg,[1] A. B. Kuper,[2] and F. D. Miraldi

School of Engineering, Case Western Reserve University, Cleveland, Ohio

ABSTRACT

Wet-grown, baked 5400Å films were controllably hydrated in tritiated-water vapor under conditions approximating device operation (50°-250°C, 0.25-8 hr, 25-400 Torr water vapor pressure). Fast penetration and fast outdiffusion suggest a micropore diffusion mechanism. This conclusion is supported by a low diffusion activation energy (0.3 eV) and exponential profiles in the bulk oxide. Strong surface peaking of the hydrogen tracer in both indiffusion and outdiffusion is attributed to surface energy lowering (Gibbs effect). "Water" under these conditions gave negligible MOS ΔQ_{ox} or ΔQ_{is} even with a hydrogen concentration of 5×10^{18} cm^{-3} at the silicon. Sodium contamination gave an order higher water entry rate. Water, likewise, increased sodium entry rate and charge production by the sodium.

Water has long been considered a serious contaminant in oxide-passivated silicon planar devices. Since it is not possible to eliminate it in device manufacture or, except by hermetic sealing, in device use, it is desirable to study its effects under likely contamination conditions.

In previous studies (1, 2), fused silica was hydrated at high temperatures (600°-1200°C) to measure the diffusion coefficient and the activation energy for water diffusion in silica. The same studies indicated that water interacted with bridging oxygens to form silanol (Si-OH) groups on entering the silica.

Oxides on silicon have been grown in tritiated steam at 1000°C (3, 4). The diffusion coefficient (3, 4) and activation energy (3) determined from bakeout were comparable to those determined for water diffusion in fused silica, but bakeout data were not taken below 500°C. Only one study (5) has produced a hydrogen profile associated with water contamination; the sample was contaminated by boiling in tritiated water.

Electrical effects of water contamination in thermal oxide on silicon have been studied. Water has been shown (6) to promote channel conduction on p-type surfaces. Water under certain conditions is believed (5, 7) to act as a positively charged species, probably due to formation of H^+ ions. Water also acts to annihilate interface states (8-10) and is known to increase dielectric loss in bulk silica (11). Water introduced during oxidation appears to have no charge associated with it as evidenced by the fact that the hydrogen in

[2] On leave 1969-1970 to Electrical Engineering, Technion, Haifa, Israel.

tritiated-steam grown oxides (3, 4) did not redistribute under bias-temperature stress.

Since data were not available on the diffusion of water in silica below 600°C, we had to extrapolate fused-silica data to the lower temperatures of interest in our work. The validity of the extrapolation from 600°C is questionable; in addition, significant differences exist between the oxide and bulk silica. The oxide is very thin and therefore may be dominated by surface effects. It is under large compressive stress, contains concentration gradients of silicon and oxygen, and has a different thermal history than the fused silica; in particular, the oxide film is formed below its softening point. Evidence recently summarized (12) also suggests a micropore structure in the oxide.

A number of experiments have demonstrated the interaction of water with sodium in silica. Increased sodium transport in the presence of water (13) and increased wet oxidation rates in the presence of sodium (12) have been shown. Sodium is thought to release hydrogen (5) in the oxide. Glass corrosion studies indicate (14) that water can release sodium in silica.

In our study, oxides were hydrated in tritiated-water vapor under controlled conditions approximating device operating conditions. Sets of hydrogen profiles were developed with time, temperature, and water vapor pressure as parameters. Outdiffusion and other experiments further characterized the hydration. Models are presented for the hydration process. MOS measurements of charge and interface-state density were made to assess the electrical effects of the water.

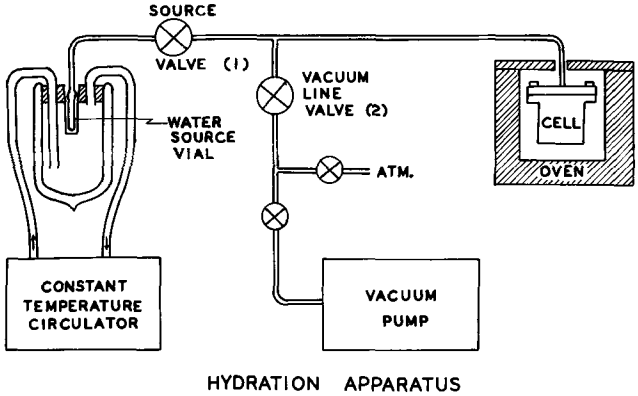
Radioactive sodium and water were diffused together in some samples; profiles and MOS electrical effects were measured to determine interactions between the two diffusants.

Experimental

Samples were 1 or 10 ohm-cm, n-type, {111}-oriented silicon. They were wet-oxygen oxidized in a quartz-tube furnace at 1200°C to a thickness of 5400Å, then baked for 30 min at 1000°C in dry nitrogen.

Hydrations were carried out in the apparatus shown in Fig. 1. The sample cell was a solid aluminum cylinder into the top of which several slots had been milled; the remainder of the apparatus was stainless steel, sealed to the cell by a Viton O-ring. Oxidized wafers were dropped into the slots and held in good thermal contact with the aluminum by means of Teflon strips at their edges. The source vial contained 0.5 cc of tritiated water with specific activity of approximately 250 mc/g. The tubing and valves were wrapped with heating tape and kept well above the temperature of the source vial to prevent water condensation anywhere except in the source vial.

The tritiated-water source vial was valved off while loading the samples. The source vial was then cooled with liquid nitrogen, the source valve opened, and the apparatus evacuated with a mechanical forepump. After evacuation, the source valve was closed, the cell and samples brought to temperature in a thermostated oven, and the source vial thermostated at a temperature corresponding to the desired water vapor pressure.



HYDRATION APPARATUS

Fig. 1. Apparatus for tritiated-water hydrations

When source and samples were at the proper temperature, the vacuum line valve was closed, the source valve opened, and timing started. At the end of the desired hydration time, these operations were reversed to recondense the water into the source vial and to remove the samples.

An experiment was done to test pressure equilibration. With a glass plate in place of the sample cell, it was found that water immediately condensed onto the glass on opening the source valve. A calculation confirmed that pressure in the apparatus should equilibrate within a second after opening the source valve. Thus we felt it unnecessary to have a manometer in the system, and pressures are based on source vial temperature.

The apparatus allowed close control of hydration conditions. Accuracy and precision of temperature were within 1°C, pressure was within 1%, and time was accurate within a few seconds. Also, the cell allowed several samples to be loaded simultaneously and exposed to identical hydration conditions.

Samples were etched in dilute HF and the etchants were liquid-scintillation counted. Since the efficiency of liquid scintillation counting is degraded by large amounts of aqueous material in the solution, an apparatus was built to minimize etchant volume. The apparatus allowed etching with 0.5 cc of acid and rinsing in 1 cc of water with good reproducibility.

Samples were washed in water before sectioning to exchange off adsorbed tritiated water from the surface and thus to avoid contaminating the first section with adsorbed activity. Samples were also washed between sections to avoid cross-contamination between adjacent sections.

The etchant was neutralized with calcium hydroxide, then solubilized with a xylene-PBD mixture by means of Beckman Biosolve BS-3 solubilizer. Counting was done in a Picker Ansitron II liquid scintillation counter. Counting efficiency was approximately 25% and background about 25 counts per minute. Sufficiently long counts were taken to keep one-sigma counting errors below 5%.

Counting efficiency was determined by counting a standard along with the etchants. The standard had the same chemical composition as the unknowns, and its activity was known to ±3%. Accuracy of relative concentrations (for profile shapes or for comparisons of profiles) was equal to the 5% counting error. However, uncertainty in the specific activity of the tritiated water in the source vial limited accuracy of absolute hydrogen concentrations to about 20%.

Sodium-water interactions were studied with a $Na^{22}Cl$ tracer. Samples were either baked or else equilibrated with a wet ambient (nitrogen, 95°C dew point) at 800°C. They were next contaminated by dipping them into a methanol solution of the tracer and air drying them. The samples were then sandwiched between two bare silicon wafers to minimize sodium evaporation during the diffusion and were diffused in a tube furnace. The dry (baked) oxides were diffused in a dry nitrogen ambient and the wet oxides in a wet (95°C dew point) nitrogen ambient.

The sodium-contaminated samples were sectioned in dilute HF. The etchant was gamma scintillation counted with a 4 x 4 in. NaI(Tl) crystal and a multichannel analyzer. A counting standard (±3%) was again used.

Some samples were diffused both with $Na^{22}Cl$ and with tritiated water. These samples were etched like other hydrated samples and liquid scintillation counted. Two analysis channels were set up on the liquid scintillation counter to count the two isotopes in the presence of each other. Counting efficiencies and the interferences of the isotopes on each other were determined from counting standards. Sodium concentrations were also checked by gamma scintillation counting.

Aluminum dots were evaporated onto some of the samples, and 1-MHz C-V curves were run. Room temperature flatband voltage was used to measure fixed charge in the oxide. Interface state density was measured by the Gray-Brown (15) technique of determining the shift in flatband voltage between room temperature and liquid nitrogen temperature.

Hydration Results

A typical hydration profile is shown in Fig. 2. The profile is made up of three regions: at the air interface is a sharp spike of hydrogen; in the bulk oxide the profile is rather flat; at the silicon interface there is a slight peak with a dip just before the peak. The spike at the air interface is present in all profiles, the peak and dip at the silicon only in some profiles. This profile and others to be presented are simply drawn through the data points and represent no theoretical fit.

Figure 3 shows the time development of the hydration profile at constant temperature and pressure (hydration time was the time during which tritiated water vapor was actually in contact with the samples). The spike at the air interface is present in all profiles. In the bulk oxide the profile is roughly exponential (*i.e.*, linear on the semilog plot). The effect of increasing hydration time is to fill and flatten the profile in the bulk oxide. Concentration in the oxide near the air interface increases with increasing hydration time, but penetration of the spike remains roughly constant.

For 15-min hydrations, not shown in the figure, the hydration profile is nonreproducible and shows anomalous peaking near the silicon. Even for the profiles shown, however, the penetration is much faster than expected. A diffusion coefficient estimated from the profiles in Fig. 3 is 10^{-13} cm²/sec, more than an order larger than estimated by extrapolating fused silica hydration data (1) from 600°C.

The effect of hydration temperature at constant time and pressure is shown in Fig. 4. The effect of increasing hydration temperature is similar to the effect of increasing hydration time. The profile fills and flattens in the bulk, and the surface spike rises in amplitude at constant penetration.

The anomalous peaking in the 50° and 100°C profiles is similar to that at short times. It appears that there is some defect in the oxide which interacts with

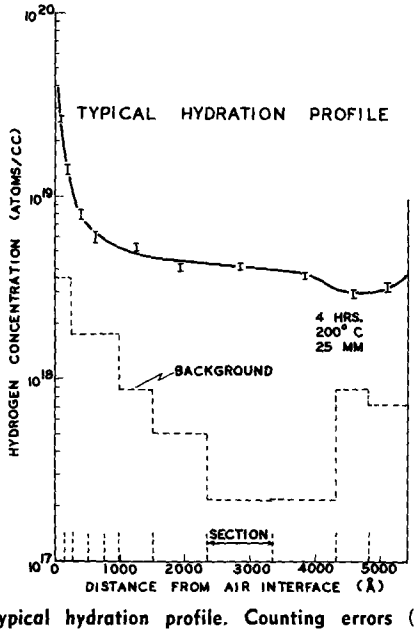


Fig. 2. Typical hydration profile. Counting errors ($\pm 1\sigma$) are shown by error bars. Concentration equivalent of counting background is represented by dashed curve and sectioning by vertical dashed lines. Reproducibility on individual data points was about ±10% from sample to sample.

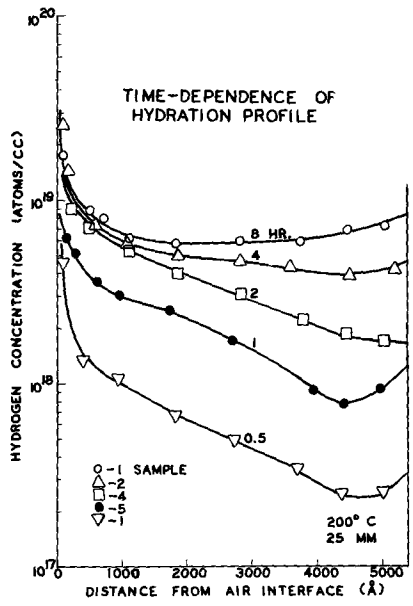

Fig. 3. Time development of hydration profile at constant temperature and pressure. Profiles are in reasonable agreement with Hofstein's (5) profile for a dry oxide. Data are averages of one or more samples, as indicated.

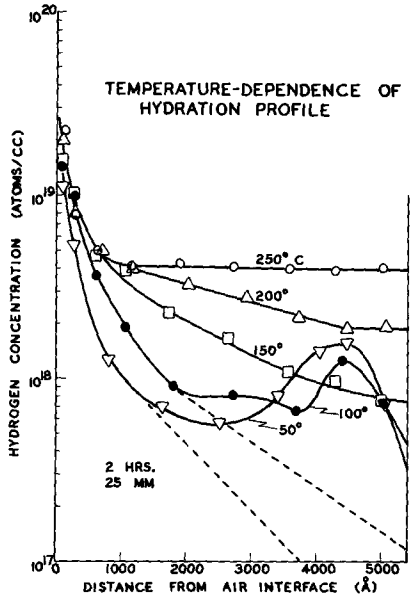

Fig. 4. Effect of temperature on hydration profile at constant time and pressure. Anomalous peaking at low temperature is similar to that seen for short times. Activation energy for diffusion was about 0.3 eV.

the "water" and then saturates. At higher temperatures (or longer times) the hydrogen profile levels itself out.

For error-function profiles, either the total hydrogen in the oxide (N) or the intercept (x) of the profile with a given concentration level should have the same temperature dependence as $D^{1/2}$ (D is the diffusion coefficient). Although the profiles are not actually error functions, Arrhenius plots were made for N and x (from Fig. 4) and the slope used to approximate the energy dependence of $D^{1/2}$. The former method estimated an activation energy of 0.25 eV for D (0.13 eV for $D^{1/2}$), and the latter gave 0.3 eV.

An activation energy of 0.3 eV is less than half of the activation energies found for fused silica hydration (1, 2), steam oxidation (16), or wet-oxygen oxidation (17) of silicon, or for outdiffusion of water from steam-grown oxides (3). The low activation energy suggests that hydration rates could be appreciable at room temperature.

The effect of hydration pressure is shown in Fig. 5. Increase in pressure shifts the hydration profile uniformly to higher concentrations. Concentration of hydrogen in the oxide varies as the square root of hydration pressure, as expected from fused silica hydration data (1, 2), which indicates the breakup of the water molecule into two independently diffusing fragments on entering the oxide. The square root pressure dependence throughout the oxide implies that little of the hydrogen tracer exists as water molecules in the oxide.

Several experiments were done to characterize the hydrogen surface spike. As shown in Fig. 3-5, the amplitude of the spike increased with time, temperature, and pressure with no significant increase in penetration. It was considered possible that the surface region of the oxide was different from the remainder of the oxide, possibly due to local stress-relief.

In order to test this hypothesis, 1000Å of oxide was etched from the surface. The etched oxide and an unetched oxide were then hydrated together for 4 hr. The surface spike was still present in the oxide which had been etched before hydration. The same result was obtained in the same experiment with a 1-hr hydration.

It was also considered possible that the spike was an experimental artifact. As mentioned previously, the sample surface was thoroughly washed before the first section was taken in order that adsorbed surface activity not be contained in the first section, thus making its concentration incorrectly high. Also, samples were soaked overnight in concentrated HCl and washed overnight in running water with no noticeable effect on the spike. Thus, the spike was apparently actually present in the oxide surface region.

An outdiffusion experiment was done to characterize further both the surface spike and the bulk diffusion mechanism. Three samples were hydrated simultaneously. One was etched immediately as a control (profile A in Fig. 6) and showed good agreement with other samples hydrated previously under the same conditions.

A second sample was vacuum-baked after hydration. After baking, it had the profile shown as profile B in Fig. 6. Note that roughly half of the hydrogen outdiffused in 4 hr at 200°C. Extrapolation of bake-out data for tritiated-steam grown oxides (3) would give a negligible outdiffusion rate at 200°C. This suggests that water diffused at 200°C is incorporated differently into the oxide than it is incorporated during a steam oxidation.

The first 1250Å of the third sample was sectioned (profile C in Fig. 6). This profile agreed well with the profile in the surface region of the control. We assume

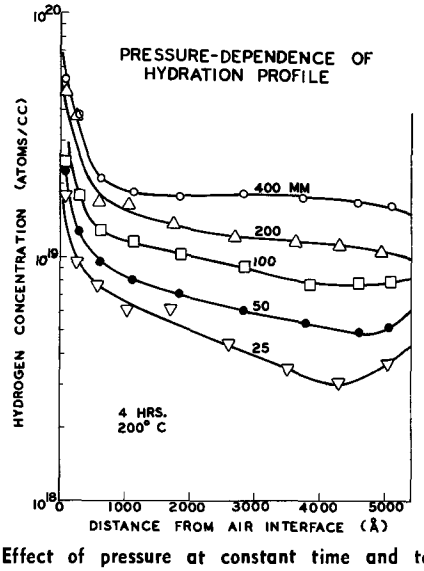

Fig. 5. Effect of pressure at constant time and temperature. Concentration varied as square root of pressure.

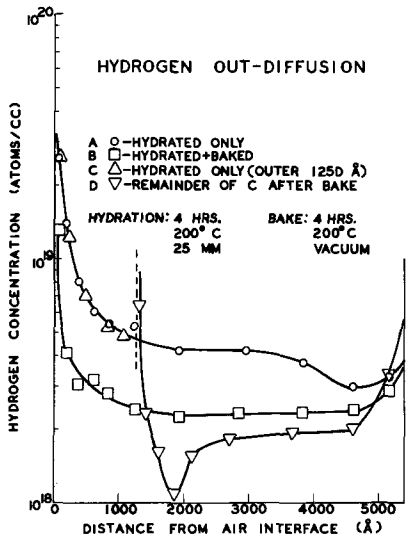

Fig. 6. Outdiffusion behavior of hydrated oxides

that the remainder of the profile in this sample was similar to that in the control. After vacuum baking, the partially etched sample had the profile shown as profile D in Fig. 6. Again the outdiffusion rate is large. Of greater significance, however, is the fact that the surface spike reformed in the outdiffusion. In fact, the dip in the profile just beyond the spike suggests that hydrogen was preferentially segregated from this region into the surface region.

It should perhaps be emphasized that these results were obtained on single samples, and reproducibility was therefore not checked. Similar results have, however, been obtained (18) for a similar outdiffusion experiment with sodium in an oxide film.

There were essentially no MOS electrical effects from hydrations at 200°C or below, even though hydrogen concentrations as high as 5×10^{18} cm^{-3} were measured at the silicon. Room-temperature flatband voltage showed a positive shift of about 1V (4×10^{10} electrons cm^{-2}), attributed to annealing. No measurable change in interface state density was observed. Annihilation of states was complete for hydrations at 800°C, however, suggesting that temperature is important to the annihilation.

Interpretation of Results

To interpret the hydration data two models are considered, one for bulk oxide profiles, one for the surface spike.

In bulk oxide, hydration is characterized by fast in- and outdiffusion, exponential profiles, low activation energy, and anomalous peaking for "gentle" hydrations (as in Fig. 4, 50° and 100°C). It is possible that extrapolation from high temperature data underestimates the diffusion coefficient. This would explain "fast" penetration. However, it would not explain the anomalous peaking, nor the fact that the profile does not have the expected error-function shape.

A model in which the oxide is assumed to contain a network of micropores could explain the observations. A "network of micropores" as used here does not mean actual pinholes through the oxide. Rather it means an interconnected network of small (probably a few atom diameters) disturbed regions which have a somewhat higher diffusivity than the bulk oxide. Such a model for oxide structure has been previously suggested (12).

We considered diffusion in such a micropored structure to be analogous to grain boundary diffusion and applied Fisher's (19) diffusion model to the hydration data. In Fisher's treatment, the diffusant is considered to penetrate very quickly along the high diffusivity path and then to side-diffuse. The model predicts exponential profiles, as observed, and appears consistent with the fast diffusion, low activation energy, and even the anomalous peaking which was observed.

Such a high diffusivity path would, of course, show up most strongly at low temperatures where bulk diffusion is slow. At high temperatures, such as in steam oxidations, bulk diffusion would be expected to dominate, as has been observed (3, 4, 17).

Several explanations were considered for the surface spike. We first thought that the spike represented a second, slower-diffusing hydrogen species. However, the shape of the spike and the change in amplitude with no penetration change were not consistent with this interpretation.

Surface rate limitation would give the observed behavior of the spike for indiffusions. However, it could not explain reformation of the spike from a flat profile in outdiffusion.

The remaining possibility was enhanced solubility in the surface region, either electrically or chemically caused. Electrical binding was rejected since no evidence was found of charge associated with the "water."

In keeping with the micropore model, it was considered possible that the surface region had a higher pore density and therefore retained more water than the bulk oxide. However, to explain the experiments in which the oxide surface was etched before in- and outdiffusion, it would be necessary to assume that the heavily pored region reformed in hours at 200°C.

The model which we favor has recently been described in papers on near-surface effects in metal-metal diffusions (20, 21) and is referred to as the Gibbs effect. In a diffusion system such as water-silica, where the reaction between the diffusant and the host matrix is exothermic, segregation of the diffusant near the surface of the host matrix leads to lowering of surface free energy. Thus, water segregates near the surface of the oxide simply because this lowers the energy of the system. The penetration of the spike in our profiles (a few hundred angstroms) is in good agreement with the penetration in the profiles shown in ref. (21).

With this model it would be expected that surface concentration would rise with bulk concentration, as observed. The constant penetration and the shape of the spike are reasonable. The reformation of the spike in outdiffusion would be expected.

Sodium-Water Interactions

Sodium chloride was diffused wet and dry as previously described, and sodium distributions and their electrical effects were measured. Although the diffusion length was orders greater than the oxide thickness (11) for dry diffusions at 600°C, profiles were steeply falling and diffusion time (1 to 60 min) had little effect on the profile. It appeared that the sodium was being preferentially segregated in the surface region of the oxide. This segregation could possibly be explained again by the Gibbs effect (20, 21). An alternative explanation, given by Fowkes and Burgess (18), is a surface layer of negative oxide ions which attract the sodium ions and bind them near the surface.

In wet diffusions the profile showed a definite development with time, *i.e.*, a filling and flattening with increasing time. Furthermore, profiles for wet diffusions peaked at the silicon, which has been associated with image charge in the silicon (22). Profiles for 1 hr wet and dry diffusions are shown in Fig. 7. In addition to the other differences noted between wet and dry diffusions, the water had the effect of significantly increasing the quantity of sodium transported. Such an effect has been previously noted (13).

Electrically, a definite sodium-water interaction is also seen. Charge production in the silicon is shown in Fig. 8 as a function of diffusion time. In dry diffusions at 600°C charge buildup was slow as expected from the sodium profiles. At 800°C charge buildup also behaved as expected [the decrease for long diffusion times has been attributed to anion compensation (23)].

Charge buildup in the wet diffusions, however, was very rapid. This is expected from the larger amount of sodium transported in the wet diffusions. However,

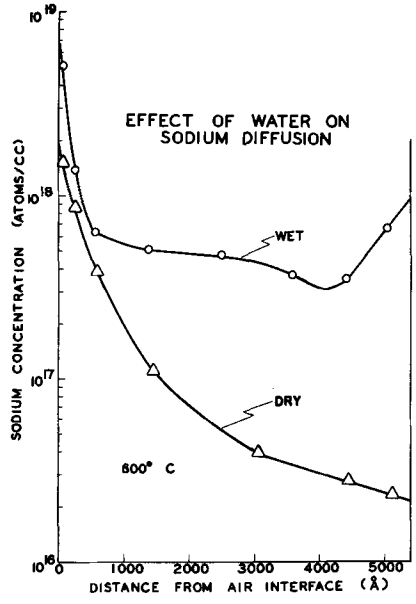

Fig. 7. Comparison of sodium profiles for 1-hr wet and dry diffusions of $Na^{22}Cl$ at 600°C.

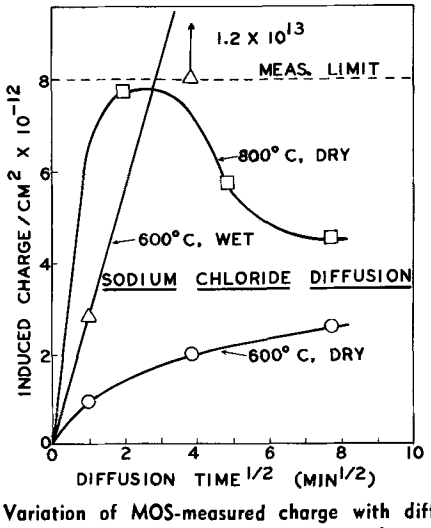

Fig. 8. Variation of MOS-measured charge with diffusion time for NaCl. Wet diffusions at 800°C gave charge beyond measurement limit for all diffusion times.

the larger sodium transport alone does not appear sufficient to explain the magnitude of charge production. The same amount of sodium can easily be transported in a dry diffusion (by increasing diffusion temperature, for example) as was transported in these wet diffusions without producing as large a charge (22). This implies that water enhances the charge production of sodium. The mechanism of such enhancement has not been ascertained.

It was noted in the wet diffusions that the sample coverplates were oxidized several times faster where they were in contact with the contaminated samples than they were on areas remote from the contamination (the covers were larger than the samples). Since the water in the wet nitrogen ambient was necessarily the oxidant, this observation implied that sodium also enhanced the transport of water into the oxide. Such sodium-enhanced oxidation has been previously observed (12) and could possibly be explained by Charles' (14) proposed mechanism for the sodium-enhanced corrosion of silica.

The hypothesis that sodium enhanced the water transport was directly checked in a 200°C hydration. Sodium-contaminated and uncontaminated samples were hydrated together and sectioned. The profiles are shown in Fig. 9. The sodium level in the contaminated

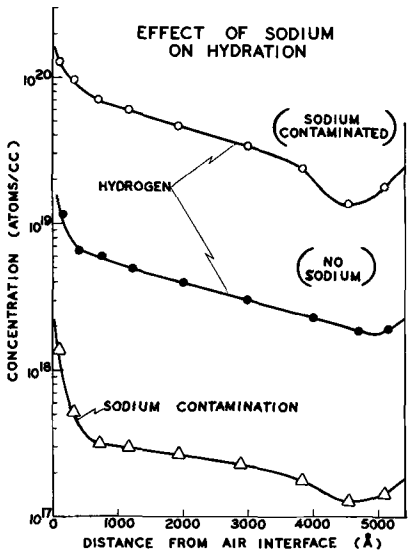

Fig. 9. Effect of sodium contamination on hydration at 200°C. Lowest profile represents sodium contamination in contaminated samples. Other profiles are hydration profiles in uncontaminated and contaminated samples, respectively.

oxides was rather low, a few times normal residual levels. However, this small amount of sodium was sufficient to increase "water" transport by roughly an order of magnitude as shown by the hydrogen profiles for contaminated and for uncontaminated oxides.

Electrically, however, water still appeared to have no effect at 200°C, even in a sodium-contaminated oxide. Room-temperature flatband voltage and interface state density were measured on samples after sodium diffusion. Hydration of these samples had no measurable effect on interface state density and gave the same slight positive shift of room-temperature flatband voltage as noted in hydration of clean oxides.

Summary

1. At "device" temperatures (200°C) hydration of a thermal oxide appears to occur via micropores; this may help to elucidate the structure of the oxide.

2. The diffusing species is not known, but water molecules separate into two independently diffusing fragments on entering the oxide.

3. Peaking of hydrogen in the surface region of the oxide is characteristic of the water-silica system and is explained by the Gibbs effect (surface energy lowering).

4. Water enhances sodium transport and positive charge production at moderate temperatures (600°-800°C).

5. Sodium enhances water transport at "device" temperatures (200°C).

6. At the device temperatures of interest in this study, diffused water has negligible effect on silicon surface potential or on interface-state density.

Epitaxial GaAs Kinetic Studies: {001} Orientation

Don W. Shaw*

Texas Instruments, Incorporated, Dallas, Texas

ABSTRACT

Gallium arsenide deposition rate studies were conducted with an open tube, chloride transport system which permitted independent control of the reactant input partial pressures. A recording microbalance was adapted to the deposition apparatus so that the epitaxial growth rates could be continuously measured during the actual deposition process. At low temperatures and high reactant partial pressures the process appears to be kinetically controlled. The rate then becomes inversely proportional to the gallium monochloride partial pressure and may indicate the presence of a competitive adsorption process. At high temperatures and low partial pressures the rates may be described in terms of a "quasi-equilibrium" model where a fraction of the incoming gas stream equilibrates with the condensed phase.

Studies of the influence of substrate temperature on GaAs epitaxial growth rates in the $Ga/HCl/As/H_2$ system have indicated that at low temperatures the process operates under kinetic control (1). Under such conditions the growth rate is independent of the total gas flow rate but is strongly dependent on the crystallographic orientation of the substrate. In addition the rate increases rapidly with increasing substrate temperature contrary to the behavior predicted from thermodynamic considerations. The epitaxial growth rates as well as the electrical characteristics of the deposits are also known to be significantly influenced by the composition of the vapor from which the layers are grown (2, 3). These facts indicate the utility of a detailed investigation of the influence of the gas phase composition on the kinetics of GaAs epitaxial growth.

Kinetic studies in gas flow systems are often limited by lack of precision of the rate data. Usually the studies are conducted by deposition for a fixed time period with subsequent measurement of the layer thickness. Although this approach is straightforward, it is time consuming and relatively imprecise. Implicit in its use is the assumption that the deposition rate is constant over the time interval used for deposition of the layer. An effort was made in the present investigation to eliminate these problems by use of an apparatus which permitted continuous measurement of the epitaxial growth rate as the layer was being deposited. This consisted of a recording microbalance adapted to the epitaxial deposition system. By suspension of the substrate crystal from one arm of the microbalance, the weight of the crystal was continuously measured. The details of this approach are described in the following section.

Experimental

Under proper conditions the growth of GaAs from a $GaCl/As_4/HCl/H_2$ ambient is a surface catalyzed process (1). This is a critical requirement to the study of epitaxial growth kinetics since it permits growth on the substrate only. Extraneous growth on the tube walls or the substrate holder would greatly complicate the results due to depletion of the gas stream of reactants. Obviously, if the epitaxial growth rate is to be obtained by continuous gravimetric measurements of the crystal, extraneous growth on the specimen hangdown and support must be eliminated. The GaAs system to be described meets these requirements, particularly if a small excess of HCl is added to the reactant gas phase (1).

The experimental apparatus is illustrated in Fig. 1. It consists principally of two parts: a microbalance, from one arm of which the specimen is suspended, and the fused silica reactor assembly. The microbalance is a Cahn RG Electrobalance (Cahn Instrument Company, Paramount, California) which uses the null balance principle. As the specimen weight changes, the deflection of the beam from its equilibrium point is detected. Attached to this beam is a coil positioned in a magnetic field. As the beam is deflected, a current is applied to the coil which restores the beam to the equilibrium position. From the measured current the specimen weight is obtained. Ideally, the balance is sensitive to 0.1 μg with a maximum capacity of 1g. As the specimen weight changes, it does not move vertically within the reaction apparatus. Consequently the length of the flat profile region of the furnace is minimized. The temperature variation over the length of the substrate crystal was found to be $< 2°C$. Both the weight and growth or etch rates are continuously measured. The latter data are obtained by electronically differentiating the balance output with time using a Cahn Mark II Time Derivative Computer. Usually the rate was displayed on one channel of a dual pen recorder, while the variable under study (temperature, partial pressure, etc.) was displaced simultaneously on the other channel. The noise level for both the rate and the weight outputs was minimized by electronic filtering.

The materials employed in construction of the balance mechanism are not inert to the corrosive gases used in deposition. Consequently, it was necessary to protect the balance by use of a hydrogen counterflow. This flow entered the center arm of the balance chamber, passed over the balance mechanism, and then flowed downward. The protective hydrogen flow rate

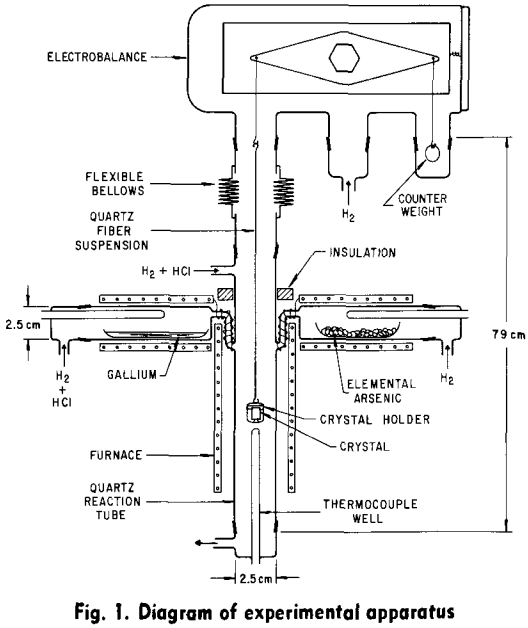

Fig. 1. Diagram of experimental apparatus

* Electrochemical Society Active Member.

amounted to one half of the total flow rate passing over the specimen. Coupling of the balance chamber to the actual epitaxial apparatus was achieved with a flexible Teflon bellows attached to the standard taper joints with heat shrinkable tubing. Initially a fused silica tube was used in the coupling, but mating of fused silica tapers between the balance chamber, deposition apparatus, and the coupling tube required very precise axial alignment. The use of a flexible Teflon bellows eliminated this problem.

Specimen removal and replacement was accomplished by movement of the balance chamber while the deposition apparatus was held in a fixed position. In this case the balance chamber was mounted on a rack and pinion device which permitted vertical movement. In addition, the balance chamber and mount could be translated in the horizontal direction. In order to change samples, the balance was moved upward, thus detaching it from the coupling tube. The hangdown fibers were unhooked at the opening and the balance then shifted horizontally. Finally, the lower hangdown fiber was extracted together with the specimen. The reverse procedure was followed in loading a new specimen.

Gaseous gallium monochloride and arsenic were the reactants. As mentioned earlier, some hydrogen chloride was added to retard nucleation and growth of extraneous material on the specimen hangdown or the tube walls. Gallium monochloride is formed by reaction of HCl with liquid gallium at 925°C. Earlier experiments (1) showed that the reaction goes essentially to completion at temperatures as low as 900°C. Thus the gallium monochloride input partial pressure was calculated from the total flow rate, the H_2-HCl flow rate over the gallium source, and the HCl partial pressure in the latter flow. Experimentally the gallium monochloride partial pressure was varied by changing the HCl partial pressure in the gas stream passing over the gallium source. This HCl partial pressure as well as that entering the tube as free HCl were continuously monitored with thermistor type thermal conductivity cells. Pure H_2 flowed through the reference sides of these cells. The arsenic input was obtained by passing hydrogen over elemental arsenic. The arsenic partial pressure was empirically determined from independent measurements of arsenic weight loss as a function of temperature. The same carrier gas flow rate over the arsenic source was used for all experiments, and the arsenic partial pressure was varied by changing the arsenic source temperature. All temperatures were monitored with thermocouples inside fused silica tubes. The thermocouple measuring the substrate temperature extended to just below the suspended substrate. Furnace profiles permitted determination of the actual substrate temperature from the thermocouple reading. Kanthal wound resistance furnaces were used throughout. Since gallium monochloride is unstable at low temperatures, it was necessary to prevent the gas temperature from falling below the substrate temperature between the gallium source and the substrate. Failure to do so would result in premature disproportionation of GaCl. This was prevented by heating the GaCl inlet tube with resistance wire wound as shown in Fig. 1.

The flow rates measured at room temperature were as follows:

Protective H_2 flow through balance chamber	300 ml/min
H_2-HCl flow over Ga source	100 ml/min
H_2-HCl flow—free HCl input	100 ml/min
H_2 flow over arsenic source	100 ml/min

Since the GaAs epitaxial growth rate is often dependent on the substrate orientation, under the experimental conditions it was necessary to expose essentially only one surface orientation to growth. For the {001} orientation used in this study this was achieved by using very thin specimens polished on both sides. Typical substrate dimensions were 1 × 1 × 0.02 cm. The slices were cleaved into squares, which exposed very smooth {110} sides. This resulted in 96% of the geometrical surface area being the {001} orientation while the remainder was {110} [which is typically a slower growing orientation (4)]. The samples were supported in a sample basket constructed of fused silica fibers. This was suspended from the balance by a fused silica hangdown fiber 125 μm in diameter. Usually, the sensitivity of the apparatus was determined by the noise level, which resulted from mechanical vibrations, thermal effects, or the aerodynamic drag (5) exerted on the specimen and the hangdown by the flowing gas. The latter is very significant, although not so severe as to prevent successful results. A change in the total flow rate results in an immediate change in the zero position of the balance. However, if the flow is held constant the drag is constant and the new zero position remains stable. For epitaxial kinetic studies a precise determination of the actual weight is unnecessary. Only the rate of change is important; thus zero shifts due to the gas flow effects are of little significance since they do not result in long term drifts. Under typical experimental conditions a change in rate of 0.005 mg/min may be detected. For a 2 cm^2 GaAs specimen, this corresponds to a change in rate of 0.275 μm/hr, which exceeds the sensitivity of the usual rate determination methods in open flow systems.

The rate-partial pressure experiments were conducted in such a manner as to gain simultaneously information concerning the sensitivity of the growth rate to temperature and reactant partial pressure. This was accomplished by very slowly cooling the substrate at a fixed gas phase composition. The deposition rate, as determined from the balance output, was plotted on one axis of an x-y recorder, while the output of the substrate thermocouple was measured on the other. This, in effect, yielded a rate-temperature plot for a given gas composition. The partial pressure of one of the reactants would then be changed and the experiment repeated. This would be continued until the rate-temperature curves were obtained for a range of reactant partial pressures. Isothermal sections from these curves yielded the rate-partial pressure curves for any desired temperature in the experimental range studied. Usually the previous deposit was removed by *in situ* etching between cycles so that each cycle represented growth on a similar surface. Since the weight gain during a temperature cycle represented the deposit thickness, the amount necessary for removal by etching between cycles was always known. After etching, at the beginning of each new cycle, an isothermal, steady-state growth rate was established before cooling to minimize effects of variations in the initial growth rates due to the freshly vapor etched surface.

Results

Figure 2, which was constructed from x-y plots of rate *vs.* thermocouple reading, summarizes the influence of deposition temperature on the {001} growth rate. Several curves are illustrated, each representing a different arsenic partial pressure. Constant values of the GaCl and HCl partial pressures were maintained for all runs. In general shape, the curves agree with the preliminary results reported in ref. (1), which were obtained by a set of fixed time depositions at various temperatures. Previous evidence (1) identifies the low-temperature regions, where the rate increases with increasing temperature, as kinetically or surface limited regions. Here the rate is limited principally by a relatively slow surface step which might be an adsorption or desorption process or an actual surface reaction. At higher temperatures each curve passes through a maximum, beyond which the rate begins to decrease with further increases in temperature. Figure 2 shows that the actual value of the temperature, T_{max}, where the maximum rate is observed, is a function of the arsenic partial pressure.

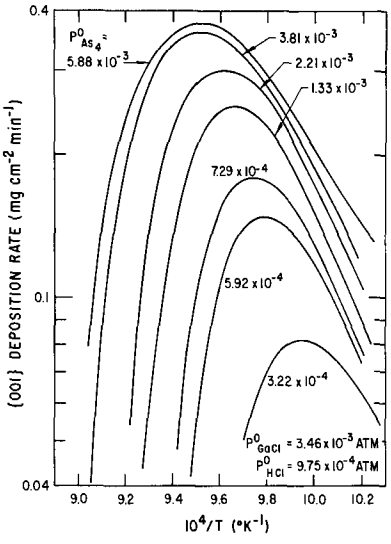

Fig. 2. Growth rate as a function of reciprocal temperature at several arsenic input partial pressures in atmospheres.

A similar set of rate *vs.* $1/T$ curves at various gallium monochloride partial pressures is given in Fig. 3. For these experiments the arsenic and hydrogen chloride partial pressures were held constant. Again the same basic curve shape is observed. As in Fig. 2, the value of T_{max} is a function of the gas phase composition. Apparent activation energies measured in the kinetic regions exhibit good agreement among the various runs and yield an average value of 48.7 ± 3.5 kcal/mole. No dependence of the activation energy on gas phase composition was evident.

If the deposition temperature is continually reduced, a point is ultimately reached at which the growth rate actually passes through a minimum. Additional temperature reductions result in an apparently increasing growth rate. Termination of the experiment after the temperature had been reduced below the minimum and examination of the crystal and its support revealed that extraneous GaAs deposits were beginning to form on the fused silica crystal support and hangdown fiber. Thus the apparent increase in growth rate was the result of the increased surface area and weight which accompanied the nucleation of these extraneous deposits. As the substrate temperature is lowered in the kinetic region, the growth rate decreases, even though the gas phase supersaturation is increasing, due to a reduction in the rate of some activated surface process. This will continue until the supersaturation exceeds the critical value necessary for nucleation on fused silica; then an apparent rate increase would be observed with our technique for rate measurement. The earlier stages of this effect are apparent in Fig. 3 for the curves corresponding to the three highest gallium monochloride partial pressures. Although this particular experiment was not extended so far as to produce an actual minimum in rate, a decrease in slope of the curves is evident at very low temperatures. The decrease occurs at higher temperatures as the gallium monochloride partial pressure is increased since the critical value of gas phase supersaturation is reached at higher temperatures.

Figure 4 illustrates the influence of the arsenic initial partial pressure on the deposition rate at several selected temperatures. At low temperatures the plots are nearly linear (on a log-log scale) with relatively small slopes. At intermediate temperatures the low partial pressure region exhibits an increased slope. This slope becomes characteristic of the entire curve at high temperatures. These plots are actually isothermal sections from Fig. 2. Comparison of Fig. 2 and 4 reveals that the regions where the rate is most sensitive to arsenic partial pressure variations, *i.e.*, at low arsenic partial pressures and high temperatures, correspond to regions of Fig. 2 where the growth rate decreases with increasing temperature. This illustrates the value of obtaining the rate-partial pressure data at several temperatures. Certainly, erroneous conclusions would be obtained if rate-partial pressure variations were interpreted in terms of a kinetic model when at low partial pressures the rate is no longer kinetically limited. For example, only the high partial pressure points of the 754° curve in Fig. 4 actually correspond to the kinetically limited region.

Interesting results are obtained when the growth rate is plotted as a function of the gallium monochloride partial pressure. This is shown in Fig. 5 where the curves for several deposition temperatures are given. It is apparent that, at least at the lower temperatures, the rate passes through a maximum with increasing gallium monochloride partial pressure. As in the preceding case, it is important to identify those portions of these curves which correspond to the kinetically limited region. Again this may be ascertained by comparison with Fig. 3. Although there might be a small region of the ascending portions of the curves in Fig. 4 which represent kinetic control, only the descending regions beyond the maximum definitely correspond to the activated regions in Fig. 3. Although not shown in Fig. 5, the growth rates actually

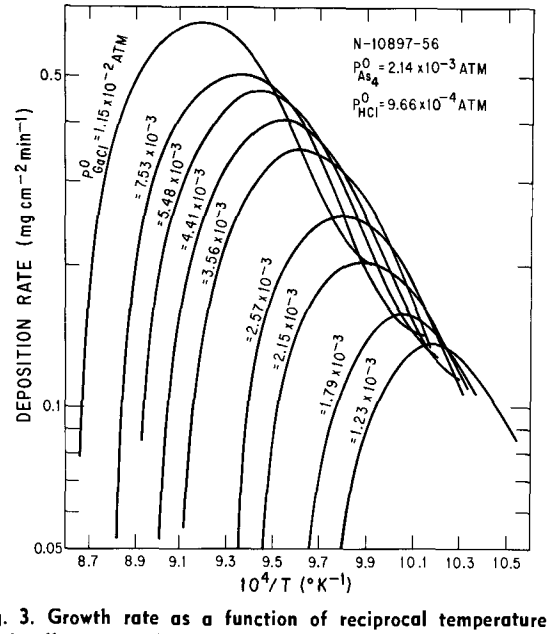

Fig. 3. Growth rate as a function of reciprocal temperature at several gallium monochloride input partial pressures in atmospheres.

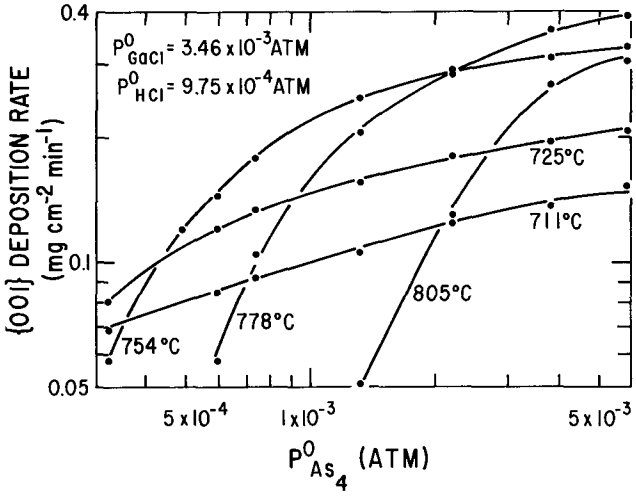

Fig. 4. Growth rate as a function of arsenic input partial pressure for several substrate temperatures.

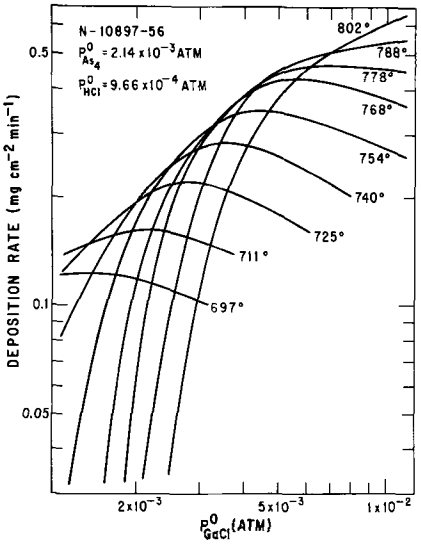

Fig. 5. Growth rate as a function of gallium monochloride input partial pressure for several substrate temperatures.

pass through a minimum at high partial pressures considerably in excess of the value for the rate maximum. This is due to two-dimensional nucleation on the fused silica hangdown fiber which results in extraneous growth as previously mentioned. Since this is independent of the single crystal epitaxial growth, such data will be excluded from the discussion. The results shown in Fig. 4 and 5 correspond only to conditions where growth is confined to the substrate crystal.

In general the results may be summarized in terms of two unique growth regions. The first region, which corresponds to low partial pressures and high temperatures, is characterized by rates which decrease with increasing temperature and increase when the partial pressure of one reactant is increased while holding the other constant. In the second region, the rate increases with increasing temperature and with increasing arsenic partial pressure, but actually decreases when the other reactant, gallium monochloride, is increased.

Discussion

As previously stated, the low-temperature region where the rate increases with increasing temperature is believed to represent a region where the process operates under kinetic control. This interpretation is supported by the following evidence: (*i*) The deposition rate exhibits a strong orientation dependence (4). (*ii*) An exponential temperature dependence is observed which is contrary to that predicted from equilibrium considerations (1). (*iii*) The rate is independent of the total gas flow rate (1). Having now established the influence of reactant partial pressures on the growth rate in this kinetically controlled region, it is of interest to examine the possibilities of extracting information concerning the nature of the slow surface process. The process might be adsorption of either reactant species, some surface reaction between adsorbed species, or desorption of the products.

The inverse dependence of the rate on the gallium monochloride partial pressure may indicate a competitive adsorption process whereby GaCl competes with arsenic for adsorption sites. Consider, for example, that As_4 is in gas phase equilibrium with As_2 which in turn is adsorbed dissociatively on the {001} surface. If GaCl should compete for these sites, perhaps by attraction of the Cl portion of the molecule to the surface, the amount of surface available for arsenic adsorption would be reduced. By assuming a Langmuir type adsorption process, the fraction of the surface covered by arsenic atoms could be expressed by the following equation

$$\theta_{As} = \frac{\beta_{As_2}{}^{1/2} P_{As_2}{}^{1/2}}{(1 + \beta_{As_2}{}^{1/2} P_{As_2}{}^{1/2} + \beta_{GaCl} P_{GaCl})} \quad [1]$$

where β_{As_2} and β_{GaCl} represent the Langmuir adsorption coefficients for the subscripted species. If the rate-limiting process involves a reaction of adsorbed arsenic atoms, then the rate may significantly begin to decrease with increasing gallium monochloride partial pressures when

$$\beta_{GaCl} P_{GaCl} > 1 + \beta_{As_2}{}^{1/2} P_{As_2}{}^{1/2} \quad [2]$$

Actually, several different rate-limiting surface processes may be imagined which involve adsorbed arsenic atoms. General rate expressions were derived for many of these processes in an attempt to describe the actual growth mechanism in the kinetic region. However, the resulting equations all involve several undetermined constants. Although many of the rate expressions appear to agree with the experimental results, the undetermined constants precluded identification of which if any of the mechanisms was the most valid. Consequently, one cannot determine the true nature of the rate-limiting process in the region of kinetic control. However, a competitive adsorption process between arsenic and gallium monochloride for the arsenic adsorption sites can qualitatively account for the experimental observations.

The high temperature-low partial pressure regions where the rate exhibits a negative temperature dependence could be due to an activated etching process which becomes significant at higher temperatures. However, this is unlikely since earlier results (1) indicated that the orientation dependence diminishes markedly in this region. Another possibility is that, at high temperatures or low partial pressures, the entire gas stream approaches equilibrium with the condensed phase. In order to investigate this possibility, equilibrium calculations were carried out for conditions which corresponded to our experiments. In these calculations, the composition of a mixture was determined which represented the minimum free energy of the system subject to the mass balance constraints. Thermodynamic values employed in the calculations were taken from Day's (6) compilation. However, comparison of the experimental rates described earlier with the calculated values revealed a large discrepancy. Yet when the two results were plotted, the curve shapes were very similar, particularly in the regions of high temperatures and low reactant partial pressures.

Sedgwick (7) described a method for treating silicon epitaxial deposition in which a "quasi-equilibrium" is assumed. In this case, only a fraction of the incoming gas stream equilibrates with the condensed phase, while the remainder passes by unreacted. Silvestri (8) has successfully applied this approach to germanium deposition from $GeCl_4$ and H_2. Actually the quasi-equilibrium approach is very similar to models which assume diffusion control, where all diffusing species have the same diffusion coefficients and the rate is determined by the difference between the bulk stream partial pressure of a given species and its equilibrium value at the crystal surface.

According to Sedgwick, the deposition rate for a process operating in the quasi-equilibrium mode may be expressed as

$$D = J \cdot \alpha \cdot \beta \quad [3]$$

where J is the flux of the species being deposited, α is a theoretical efficiency factor which represents the fraction of the flux which would be deposited if complete equilibrium were achieved between the entire gas stream and the substrate, and β is the fraction of the incoming gas stream which actually equilibrates with the condensed substrate. For the case where the entire gas stream equilibrates with the condensed phase, β is unity. However, for the quasi-equilibrium case, β is less than unity and is a highly geometry dependent factor.

Calculations of the factor $J \cdot \alpha$ were made for portions of the data shown in Fig. 2 through 5. The factor β was then estimated by assuming that the quasi-equilibrium approach was valid at 740°C and the lowest gallium monochloride partial pressure (1.23×10^{-3} atm) shown in Fig. 5. A value of $\beta = 0.093$ was obtained. This value was assumed to remain constant for all the experimental conditions described since the same geometry and linear gas stream velocity were used throughout the study. It should be noted that β should be only weakly dependent on temperature. Using the above mentioned value of β, theoretical curves for the dependence of the deposition rate on the arsenic and gallium monochloride initial partial pressures were determined. These curves, together with points representing the experimental results, are shown in Fig. 6 and 7. The same value of β was used in construction of the curves for both figures.

Very poor agreement between the theoretical and experimental values is obtained at low temperatures, but, as the deposition temperature is increased, the agreement becomes better. Very good agreement is obtained at 768°C at the lower partial pressure values. Comparison of Fig. 6 and 7 with Fig. 2 and 4 reveals that deviations between the experimental and calculated values become significant when the data falls in the activated regions or where the process begins to operate under kinetic control. However, in the high temperature-low partial pressure regions good agreement is apparent, indicating that the quasi-equilibrium model is applicable in the region. The value of $\beta = 0.093$ for the GaAs system may be compared with a value of 0.3 obtained for Ge deposition (8) and the range of values from 0.03 to 0.30 for Si deposition (7).

In summary, with the present system, GaAs can be deposited epitaxially under two unique regimes depending on the temperature and reactant partial pressures. At low temperatures and high reactant partial pressures the GaAs deposition rate is limited by some surface process. The rate is then inversely dependent on the gallium monochloride partial pressure and may indicate a competitive adsorption process between gallium monochloride and arsenic. With lower partial pressures and high deposition temperatures, the rate behavior agrees well with a quasi-equilibrium model.

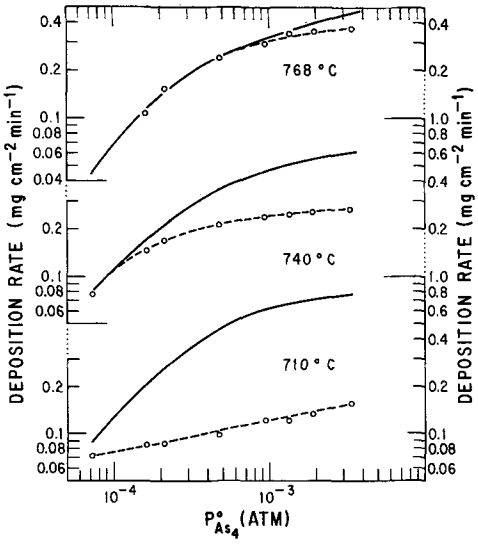

Fig. 6. Theoretical curves of rate as a function of arsenic input partial pressure. Open circles represent experimental data. Ordinate scales on each side of the figure correspond to 710°, 740°, and 768° in ascending order.

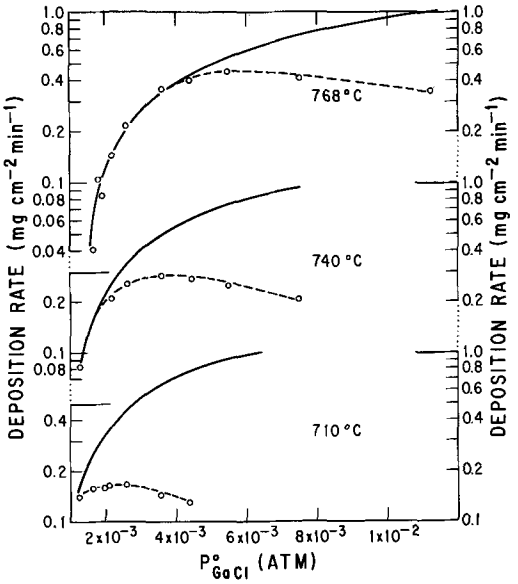

Fig. 7. Theoretical curves of rate as a function of gallium monochloride input partial pressure. Open circles represent experimental data. Ordinate scales on each side of the figure correspond to 710°, 740°, and 768° in ascending order.

These two types of deposition should be accompanied by differences in surface morphologies and electrical characteristics. For example, Silvestri (8) has observed that smooth surfaces are obtained when Ge is deposited under conditions corresponding to the quasi-equilibrium case, while structured surfaces predominate when surface limitations are significant. Differences in the electrical characteristics may also be observed since growth in the high temperature region occurs under conditions which more closely approach equilibrium than in the low temperature kinetically controlled region. Such differences will be the subject of future studies.

Acknowledgments

Appreciation is expressed to Miss Carolyn Banks for her assistance with the experimental work. In addition, the author wishes to thank Drs. L. G. Bailey and B. G. Secrest for their interest and several stimulating discussions.

The Theory of Anomalous Diffusion in Solids Near Diffusant Saturation Concentrations: Example–Phosphorus in Silicon

P. E. Bakeman, Jr.

Rensselaer Research Corporation, Troy, New York

and J. M. Borrego

Electrophysics Division, Rensselaer Polytechnic Institute, Troy, New York

ABSTRACT

This paper presents a diffusion theory for the diffusion of impurities which exhibit solid solubility saturation. The theory is based on a simple assumption for impurity atom interaction which yields a self-consistent result for the diffusion constant and chemical potential of the impurity. The theory predicts the diffusion constant of the diffusing species to be: $D' = D(C_{max} + C)/(C_{max} - C)$, where D is the low level diffusion constant, C is the impurity concentration, and C_{max} is the saturation impurity concentration. The theory is compared with available experimental data on the diffusion of phosphorus in silicon. The theory and experiment are in excellent agreement.

It is the purpose of this paper to advance a theory of diffusion which is capable of explaining the anomalous diffusion behavior observed in the diffusion of impurities which exhibit solid solubility saturation, such as phosphorus diffusing in silicon. The assumption is made that atoms of the diffusing species do interact with each other during diffusion as opposed to the assumption that they move independently, which is implicit in deriving Fick's first law. The rationale for the atomic interaction assumption is presented and the assumed interaction is expressed both phenomenologically and as a term in the chemical potential equation.

A recent communication (1) evaluates the effect of ambipolar or field aided diffusion of impurities in silicon and concludes that this effect is insufficient to cause experimentally observed diffusion anomalies. In fact, it can be shown that ambipolar diffusion effects can account for a maximum increase in D, the impurity diffusion constant, by a factor of 2 in semiconductors if Maxwell-Boltzmann statistics are used (2). In the degenerate case, Shockley (3) has evaluated the ambipolar diffusion effect using Fermi statistics and derived the relation

$$\frac{D^*}{D} = 1 + \left(\frac{\pi}{6}\right)^{1/3}\left(\frac{N_d}{N_c}\right)^{2/3} \qquad [1]$$

This correction still cannot explain the experimentally observed diffusion phenomena.

Theory

Let us derive a one dimensional expression for the impurity atom flux density as a function of concentration and concentration gradient. In the classical derivation, which yields Fick's first law, the following assumptions are made (4).

1. The impurity atoms move in discrete jumps (length = α) with a jump frequency Γ (jumps/sec) which is a function of neither concentration nor concentration gradient.
2. Each impurity atom moves at random independent of other diffusing impurity atoms.

The second assumption indicates that there is an equal probability of an impurity atom, at plane x, jumping in the $+x$ and $-x$ directions on any given jump. Thus, the probability, $P(+,x)$, that it jumps in the $+x$ direction is 1/2 and, similarly, the probability, $P(-,x)$, that it jumps in the $-x$ direction is 1/2. By definition

$$P(+,x) + P(-,x) = 1 \qquad [2]$$

These assumptions yield the result that (4)

$$D = 1/2\ \Gamma\alpha^2 \qquad [3]$$

Let us change assumption 2 to account for impurity atom interaction as follows:

2'. Each impurity atom moves at random to available sites within the host material. Also assume that the total concentration of impurity cannot exceed C_{max}.

The effect of the new assumption is to change the values of $P(+,x)$ and $P(-,x)$ so that they are no longer equal, but their sum is still unity.

The probabilities $P(+,x)$ and $P(-,x)$ are mathematically determined by counting the density of empty sites in planes $x + \alpha$ and $x - \alpha$. Since we have assumed that the impurity atom will diffuse into any empty site with equal probability

$$\frac{P(+,x)}{P(-,x)} = \frac{N_{max} - N(x+\alpha)}{N_{max} - N(x-\alpha)} \qquad [4]$$

where N_{max} = maximum density of impurity in an atomic plane; $N(x)$ = density of impurity atoms in atomic plane at x (number/cm^2); and α = spacing of atomic planes.

Combining Eq. [2] and [4] yields the values of $P(+,x)$ and $P(-,x)$

$$P(+,x) = \frac{N_{max} - N(x+\alpha)}{[N_{max} - N(x+\alpha)] + [N_{max} - N(x-\alpha)]} \qquad [5a]$$

$$P(-,x) = \frac{N_{max} - N(x-\alpha)}{[N_{max} - N(x+\alpha)] + [N_{max} - N(x-\alpha)]} \qquad [5b]$$

Referring to Fig. 1, we calculate the atom flux density $J(x)$ across plane x. The net flux equals the number of impurity atoms flowing from plane $x - \alpha/2$ to plane $x + \alpha/2$ minus those moving from $x + \alpha/2$ to $x - \alpha/2$

$$J = N\left(x - \frac{\alpha}{2}\right) P\left(+, x - \frac{\alpha}{2}\right)\Gamma - N\left(x + \frac{\alpha}{2}\right) P\left(-, x + \frac{\alpha}{2}\right)\Gamma \qquad [6]$$

where Γ = impurity jump frequency.

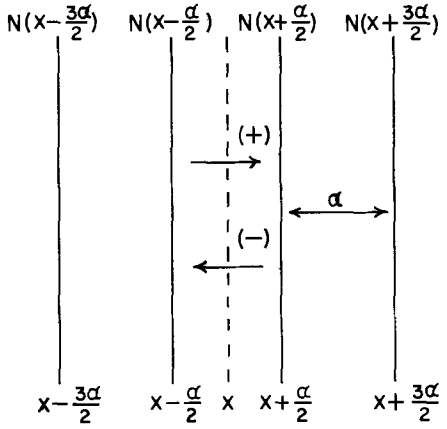

Fig. 1. Atomic flux density across plane x

By transforming the value of x in Eq. [5a] and [5b], we find

$$P\left(+, x-\frac{\alpha}{2}\right) = \frac{N_{max} - N\left(x+\frac{\alpha}{2}\right)}{\left[N_{max} - N\left(x+\frac{\alpha}{2}\right)\right] + \left[N_{max} - N\left(x-\frac{3\alpha}{2}\right)\right]} \quad [7a]$$

$$P\left(-, x+\frac{\alpha}{2}\right) = \frac{N_{max} - N\left(x-\frac{\alpha}{2}\right)}{\left[N_{max} - N\left(x-\frac{\alpha}{2}\right)\right] + \left[N_{max} - N\left(x+\frac{3\alpha}{2}\right)\right]} \quad [7b]$$

The relationship between area concentration, $N(x)$, and volume concentration, $C(x)$ is

$$N(x) = C(x)\,\alpha \quad [8]$$

Combining Eq. [6] through [8] yields

$$J = -1/2\,\Gamma\alpha^2 \frac{dC(x)}{dx} \frac{C_{max}^2 - C(x)^2 + \left(\frac{\alpha}{2}\frac{dC(x)}{dx}\right)^2}{[C_{max} - C(x)]^2 - \left(\frac{\alpha}{2}\frac{dC(x)}{dx}\right)^2} \quad [9]$$

but

$$\frac{\alpha}{2}\frac{dC(x)}{dx} << C_{max} - C(x) \quad [10]$$

therefore

$$J = -\tfrac{1}{2}\Gamma\alpha^2 \frac{dC(x)}{dx}\frac{C_{max} + C(x)}{C_{max} - C(x)} \quad [11]$$

Thus, from Eq. [3] and [11], the effective diffusion constant D', is a function of concentration and equals

$$D' = D\frac{C_{max} + C(x)}{C_{max} - C(x)} \quad [12]$$

where, D = the impurity diffusion constant at low impurity concentrations. Equation [12] shows that the diffusion constant, D', of an impurity in a material is a function of the actual concentration of the impurity relative to its saturation concentration. At low concentrations [$C(x) << C_{max}$] the impurity diffusion constant equals D and is independent of concentration; at high impurity levels Eq. [12] must be used to calculate D' as a function of concentration.

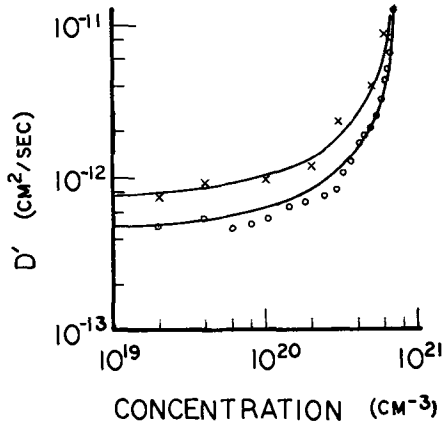

Fig. 2. Diffusion constant, D', of phosphorus in silicon as a function of phosphorus concentration. Data points are experimental measurement of two samples diffused at 1050°C for 30 min each, from Tannenbaum (5). Curves are as calculated from Eq. [12] using $D = 7.4 \times 10^{-13}$ cm²/sec and $C_{max} = 7.4 \times 10^{20}$ cm^{-3} (upper) and $D = 4.8 \times 10^{-13}$ cm²/sec and $C_{max} = 7.7 \times 10^{20}$ cm^{-3} (lower).

It should be noted that Eq. [12] can be derived using the random-walk approach to diffusion theory (7) and the directional jump probabilities presented in Eq. [5a] and [5b].

Discussion

Figure 2 is a graph of effective diffusion constant *vs.* impurity concentration for the diffusion of phosphorus in silicon. The data points were obtained by Tannenbaum (5) from experimental radioactive tracer data of two diffusion runs under identical conditions. The upper and lower curves are calculated from the theory presented herein using values for D of 7.4 and 4.8 x 10^{-13} cm²/sec and for C_{max} of 7.4 and 7.7 x 10^{20} atom/cm³, respectively. It can be seen that the theory and experiment show remarkable agreement. Similar experimental verification can be shown using recent experimental data by Vick and Whittle (6) for the diffusion of boron in silicon.

The chemical potential for an impurity in a solid with the assumption of no impurity atom interaction is

$$\phi = +kT \ln C(x) + \text{constant} \quad [13]$$

It can be shown from Eq. [12] that the chemical potential in the system based on assumption 2′ is

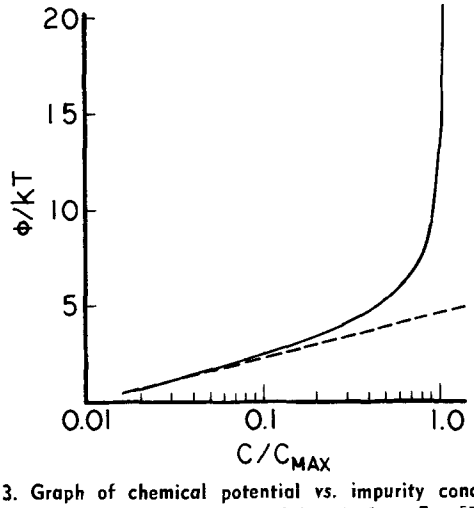

Fig. 3. Graph of chemical potential *vs.* impurity concentration for the two diffusion theories. Dotted line is from Eq. [13]. Solid line, corrected for impurity atom interaction, is from Eq. [14].

$$\phi = +kT \ln \frac{C(x)}{\left[1 - \frac{C(x)}{C_{max}}\right]^2} + \text{constant} \quad [14]$$

These equations are plotted in Fig. 3. The abrupt rise in ϕ' at $C = C_{max}$ is precisely what is required of an impurity for it to exhibit a maximum solid solubility at a concentraton C_{max}.

Acknowledgment

The authors wish to thank Dr. H. B. Huntington for his assistance in reviewing the manuscript.

Manuscript submitted Aug. 29, 1969; revised manuscript received ca. Jan. 5, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

New Data on Basic Lead Sulfates

H. W. Billhardt[1]

Mineralogisches Institut der Universität (TH), Karlsruhe, Germany

ABSTRACT

High-temperature x-ray and DTA investigations of the lead oxide-lead sulfate system confirmed the phase relations established by Esdayle and Lander. In order to elucidate discrepancies in the literature and to insure positive identification of the three basic lead sulfates $PbO \cdot PbSO_4$, β-$2PbO \cdot PbSO_4$, and $4PbO \cdot PbSO_4$, single crystals were prepared and investigated by several x-ray techniques. Indexed x-ray powder data, cell parameters, and also IR-absorption spectra are presented. A high-temperature x-ray pattern is given for α-$2PbO \cdot PbSO_4$.

During the investigation of lead silicate sulfate glasses and their crystallization products, the well-known system PbO-SO_3 (1-6) was re-investigated. Discrepancies were found between the x-ray data given in previous papers and those obtained from our own measurements. In order to insure positive identification of all basic lead sulfates, single crystals were prepared and investigated by means of several x-ray techniques. IR-absorption spectra were also recorded.

Pure PbO and $PbSO_4$ were used for the preparation of the basic lead sulfates. The oxides in stoichiometric relation were fused in Pt crucibles, taking into account the loss caused by evaporation. To protect the Pt crucible from reaction with Pb a small amount of NH_4NO_3 was added to the sample in order to get an oxidizing atmosphere [Merker and Wondratschek (7)] and then the batch was heated very slowly. A serious attack of the crucibles by Pb-rich melts was never observed. After each preparation the Pt crucibles were cleaned by a soda-borax melt. The loss of Pt was always less than 1 mg.

In the lead oxide-lead sulfate system, the monobasic, the α- and β-dibasic and the tetrabasic lead sulfate are the only phases which are observed. The phase diagram established by Esdaile (3) and Lander (4) has been confirmed (Fig. 1). It stands in strict contradiction to the newly published paper of Margulis and Kopylov (6). Our repeated DTA-analyses and high-temperature x-ray measurements under different heating and cooling rates, revealed that the diagram given by Margulis and Kopylov is based on systems not in equilibrium and on cooling-curves with retarded crystallization effects and should, therefore, be rejected.

Monobasic Lead Sulfate

Monobasic lead sulfate obtained by slow cooling of a $PbO \cdot PbSO_4$ melt in Pt crucibles was found to be identical with the mineral lanarkite. The crystallographic space group is C2/m and the monoclinic cell parameters tabulated in Table I are in close agreement with the data of lanarkite described by Richmond and Wolfe (8) and Binnie (9). The cell parameters presented in this paper are the result of refinement of the x-ray powder data in Table II (AEG-Guinier camera, $CuK\alpha_1$-radiation, intensities photometrically measured) with the help of a least-squares computer procedure.

Dibasic Lead Sulfate

Dibasic lead sulfate exists in two modifications (3, 10). High-temperature x-ray investigations (Nonius-Guinier camera) revealed that this compound is unstable below about 640°C and decomposes at this temperature to mono- and tetrabasic lead sulfate. This decomposition takes place very slowly. Even at cooling rates of 10°C/hr, α-$2PbO \cdot PbSO_4$ is stable down to 450°C and then it forms metastable β-$2PbO \cdot PbSO_4$.

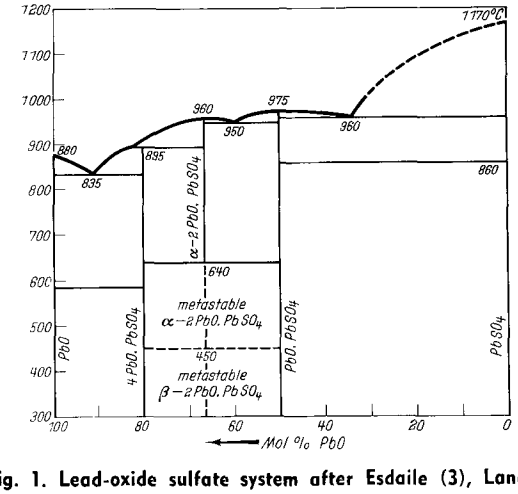

Fig. 1. Lead-oxide sulfate system after Esdaile (3), Lander (4), and the author's measurements.

This low-temperature modification has the monoclinic space group $P2_1/m$ or $P2_1$, in agreement with Boivin, Thomas, and Tridot (10), but we could not confirm all the cell parameters given by these authors (a = 7.814Å, b = 5.803Å, c = 8.035Å, β = 102.64°, ρ_{calc} = 6.98 g/cm³, ρ_{exp} = 7.08 g/cm³). Our repeated density measurements and x-ray single-crystal investigations led to the following cell parameters: a = 8.06 ± 0.02Å, b = 5.79 ± 0.02Å, c = 7.17_5 ± 0.02Å, and β = 103°C ± 0.02°.

The calculated density is 7.63 g/cm³, assuming two formula weights per unit cell. This density is close to our experimentally determined density of 7.6 ± 0.05 g/cm³. The β-$2PbO \cdot PbSO_4$ single crystals are twinned about a twofold [101] rotation axis or a $(10\bar{1})$ twin plane. The angle between a_1^* of the one cell and c_2^* of the other cell is about 8.4 ± 0.3°.

DTA-heating curves and high-temperature x-ray measurements reveal that the metastable β low-temperature modification exists up to about 450°C and then decomposes to mono- and tetrabasic lead sulfate. At or above 640°C, $2PbO \cdot PbSO_4$ recrystallizes from the two basic lead sulfates, but now in the α-form. It is remarkable that the inflection point at 640°C is not strictly

reversible at normal cooling rates and may be easily overlooked.

The transformation of α-$2PbO \cdot PbSO_4$ (which is metastable below 640°C) to the β-form occurs even during quenching at 450°C. The high-temperature x-ray data of α-$2PbO \cdot PbSO_4$, recorded in Table III, are similar to those of β-$2PbO \cdot PbSO_4$. In order to index these data, further high-temperature single-crystal investigations are necessary and are planned.

Tetrabasic Lead Sulfate

Zimkina and Shchemelev (11) gave for tetrabasic lead sulfate the following rhombic, pseudotetragonal crystal data: a = 11.5Å, b = 11.7Å, and c = 7.3Å, obtained from electron diffraction patterns. Pinsker and Farmakovskaya (12) determined the hexagonal cell parameters a = 8.98Å and c = 24.8Å. The material had been obtained by deposition from an aqueous suspension by dusting it through a silk screen. The data of Pinsker and Farmakovskaya (12) are similar to those of a basic lead carbonate $2PbCO_3 \cdot Pb(OH)_2$ described by Cowley (13).

In the course of our investigation, it was possible to synthesize the incongruently melting compound $4PbO \cdot PbSO_4$ in large single crystals out of a ternary silicate sulfate melt having the over-all composition 60 m/o (mol per cent) PbO, 15 m/o $PbSO_4$, and 25 m/o $PbSiO_3$. Oscillation, Weissenberg, and precession photographs revealed that the data of Zimkina and Shchemelev (11) are only approximate. The new cell dimensions are: Probable space group: $P2_1/a$ and a = 11.443 ± 0.02Å, b = 11.666 ± 0.02Å, c = 7.316 ± 0.02Å, and β = 90.82 ± 0.2°. The calculated density is 8.13_5 g/cm^3, assuming the number of formula weights per unit cell, Z = 4. The experimental density is 8.1 ± 0.1 g/cm^3. With these cell parameters, the powder diffraction pattern in Table V could be indexed completely. We have never observed the hexagonal modification of $4PbO \cdot PbSO_4$ described by Pinsker *et al.* (12), nor any other basic lead sulfate with hexagonal cell parameters.

The $4PbO \cdot PbSO_4$ data in Table V has, like the other basic lead sulfates in Tables II and IV, many more d-values than the (unindexed) ASTM-cards 6-0275, 308, 382, 388; 2-1276 and 12-775. Furthermore, the differing intensities reveal that possibly the ASTM-cards are based on samples which were not free of texture.

The IR-absorption data of all basic lead sulfates are collected in Table VI. They are compared with those of $PbSO_4$, anglesite, and those of the free SO_4^{2-} anion (14). The typical SO_4^{2-} absorption bands appear in all basic lead sulfates, but they show relatively large splitting (*e.g.*, $\nu 4$) which indicates that the SO_4^{2-} ion in the basic lead sulfates has lower site-symmetry than in lead sulfate.

Acknowledgments

The author expresses his thanks to Professor Dr. H. Wondratschek for his interest and support of this work. He is grateful to Dr. G. Weitz and Dr. W. E. Klee (Mineralogisches Institut der Universität Karlsruhe) for many helpful discussions.

ABSTRACT

Molybdenum and tungsten films formed by the pyrolytic decomposition of the respective carbonyls were investigated to determine their usefulness as conductors in microcircuit devices. The relations between deposition variables (such as pressure of carbonyls, pressure of the carrier gas, rate of gas flow, and substrate temperature) and deposition parameters (such as rate of film growth) or film properties (such as resistivity) were studied. The effects of carrier gas substitution on molybdenum film resistivity were determined. At a carbonyl pressure of 0.001 Torr, a hydrogen pressure of 0.01 Torr, a gas flow of 12 std cc/min, and a substrate temperature of 500°C, molybdenum films were deposited with a resistivity close to that of bulk (5.6 μohm cm), at a rate of 3.7 Å/sec. In molybdenum films deposited at lower substrate temperatures the resistivity increased, presumably because of increased carbon within the films. The resistivity of tungsten film is always greater than the resistivity of Mo films deposited under equivalent conditions. The lowest resistivity achieved in a tungsten film was approximately twice the value for bulk tungsten (5.5 μohm cm). The structures of both molybdenum and tungsten films deposited under conditions that favored the formation of films with the lowest resistivities were examined by x-ray diffraction as well as replica electron microscope techniques. Measured lattice parameters, when corrected for independently determined stress, were approximately equal to the parameters reported for pure molybdenum and tungsten. In all tungsten films studied, tensile stresses were found, but in molybdenum films the stresses were tensile for substrate temperatures greater than 500°C and compressive for lower temperatures.

Molybdenum and tungsten are potentially interesting materials for semiconductor device applications because of their relative inertness, high-temperature stability, satisfactory electrical resistivity, low thermal expansion coefficients, and good etching properties. Since damage to the semiconductor surface should be minimal during deposition of metal interconnections, chemical vapor deposition is preferable to sputtering or electron-bombardment evaporation. Of several ways to vapor-deposit molybdenum and tungsten, the most attractive are hydrogen reduction of metal halides and thermal decomposition of carbonyls. The latter process has the advantage of a starting material that is a fairly inert, volatile solid, which allows a relatively simple system design. It does, however, require operation at reduced pressure, in contrast to halide reductions (1-6), which usually proceed at atmospheric pressure.

In the pioneering study of molybdenum and tungsten carbonyl decomposition by Lander and Germer (7, 8) the main emphasis was placed on the mechanical properties of thick coatings used to protect bearing surfaces against wear. Electrical properties were not considered and deposition rates were not systematically studied. A general article on carbonyl metallurgy by Carlton and Goldberger (9) considers thermodynamics and kinetics. Carlton and Oxley (10) have determined the kinetics of iron carbonyl decomposition. Matyuskenko *et al.* (11) have investigated the morphology of molybdenum and tungsten films deposited via carbonyl decomposition. More recently, Cuomo (12) has described preliminary work on molybdenum and tungsten films formed from their respective carbonyls.

In the present work, the carbonyl decomposition process was characterized with regard to deposition rate and to properties (resistivity, stress, orientation, grain size) of the films produced. The effects were investigated of varying the parameters (temperature, pressure, and rate of gas flow) and of modifying the chemistry of the system. A specific aim of some of these experiments was to reduce carbon in molybdenum films.

Apparatus and Method

All films were deposited as follows in an apparatus shown schematically in Fig. 1. The apparatus consisted of a diffusion-pumped vacuum system 1 connected to a vertical reactor tube 2. A cylindrical molybdenum susceptor 3, supported and rotated from below, was heated inductively through use of a coil mounted outside the tube. The substrate, generally an oxidized silicon wafer, was placed on the susceptor and was perpendicular to the direction of the incoming gas. The gas (hydrogen or other carrier gas at reduced pressure, containing a known partial pressure of metal carbonyl) entered through the top of the tube. The carbonyl pressure was established by regulating the temperature of solid carbonyl in a reser-

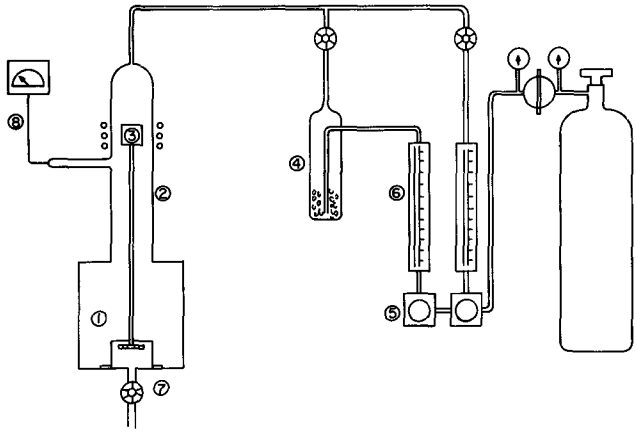

Fig. 1. Schematic drawing of apparatus used for film deposition

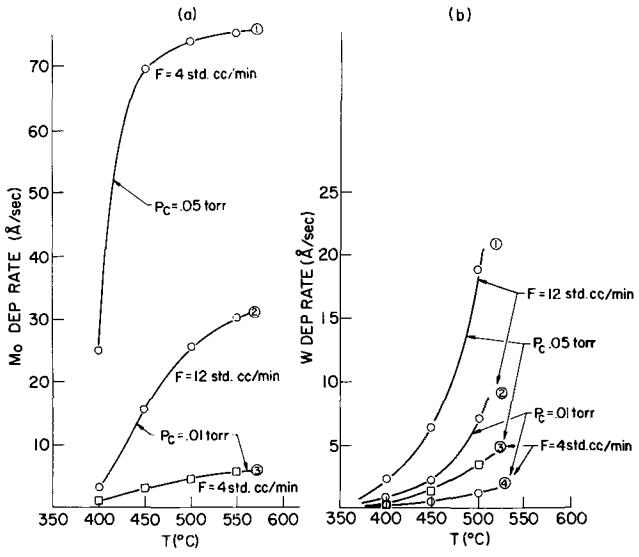

Fig. 2. Rate of metal deposition vs. deposition temperature. a. P_H = 0.07 Torr; b. P_H = 0.23 Torr.

voir 4 through which the carrier gas passed. This reservoir (shown in the diagram as a single chamber) consisted of a superheated carbonyl source followed by an equilibrating chamber maintained at the desired temperature. The rate of flow was regulated by a needle valve 5 and calibrated flow meter 6. Pressure in the tube was determined by setting the vacuum valve 7 and was read by a calibrated Pirani gauge 8.

The temperature of the molybdenum susceptor was read from a thermocouple rigidly fastened to it. The substrate was thermally coupled to the susceptor by a layer of liquid gallium which maintained susceptor and substrate at essentially identical temperatures. To prevent reaction between the gallium and the molybdenum susceptor, the upper surface of the susceptor was coated with reactively sputtered silicon nitride. The hydrogen and argon (Matheson research grade, 99.995% pure, with nitrogen the main impurity) were used without further purification. The molybdenum carbonyl (99.5% purity)[1] was found by emission spectroscopy to contain less than 0.01% metallic contaminants.

Typically, film deposition would begin with evacuating the reactor tube to a pressure of 2 x 10^{-5} Torr. Carrier gas was then admitted through a by-pass at low flow rate and pressure, while the substrate temperature was raised to the desired point. The carrier gas was then allowed to flow through the carbonyl powder and into the reactor at the desired flow rate, while the vacuum valve was used to adjust reactor pressure. After the desired deposition time, gas flow and heat were turned off, and the substrate was cooled to room temperature, while carrier gas flow was maintained. The most important process parameters that could be varied independently were substrate temperature, carbonyl partial pressure, carrier gas pressure, and carrier gas flow rate. Each significantly affected the rate of deposition, but deposition temperature appeared to affect the resistivity of the films formed most significantly.

Thickness measurements were made with a Talysurf instrument and/or a Tolanski interferometer. Film resistivities were derived from resistance measurements obtained from a linear four-point probe and a Keithley 503 milliohmeter. A qualitative evaluation of film adhesion was obtained by means of the so-called "Scotch-tape test."

Results and Discussion

Process rate studies.—Figure 2a and b show the effect of substrate temperature on deposition rates of Mo and W, respectively, for several typical sets of operating parameters. Although the conditions for the two metals were not fully equivalent, it may be noted that deposition rates for Mo were higher than those for W. As the deposition temperature is increased, the deposition rate tends to rise sharply at first but then levels off at high temperatures. However, the leveling off effect shown by the Mo rate curve at higher temperatures is not exhibited by the W curves. Additional results have shown that for deposition temperatures lower than 400°C, the rates of growth of Mo films appear to increase slightly with decreasing temperatures. A maximum in deposition rate is reached at about 300°C. Since this unexpected increase in deposition rate occurs under conditions where molybdenum carbide rather than molybdenum films are obtained, it is likely due precisely to the formation of molybdenum carbide. At temperatures below 300°C the rate of deposition falls rapidly to zero.

The effect of carbonyl partial pressure P_c on deposition rate is shown in Fig. 3a and b for Mo and W, respectively, for various conditions of temperature and flow. In all cases approximate linearity is observed in the initial portions of the curves, generally followed by a leveled-off portion. The importance of carrier gas flow rate F, at constant P_c and total pressure, in determining the rate of Mo and W deposition is clearly shown in Fig. 4a and b, for low and high levels of temperature and carbonyl pressure.

[1] Purchased from Gallard-Schlesinger Chemical Manufacturing Corporation, Carle Place, New York.

In vapor decomposition processes such as those considered here, two mechanisms are generally expected to play a rate-controlling role: (*i*) the chemical decomposition of the carbonyl, and (*ii*) gaseous diffusion of carbonyl vapor to the deposition surface. Also, in this latter diffusion mechanism one should include the diffusion of by-products, in this case CO, away from the same surface.

The individual processes should each exhibit a different temperature dependence. Thus, as the temperature is raised, the rate of the chemical decomposition will increase as exp $(-Q/kT)$ (where Q is the activation energy), while the rate of a gaseous diffusion will vary only as the $\sqrt{T}$ (13). Hence, while the carbonyl decomposition might be the rate-limiting step at some lower temperature range (here, apparently 200°-400°C), the diffusion steps would limit the rate at higher temperatures.

It should also be noted that an experimental limitation can be caused by the carbonyl depletion of the gas at high deposition rates. A quick calculation indicates that under the deposition conditions used here, such a depletion effect contributes to the leveling-off in the deposition rates recorded in curves 1 and 2 of Fig. 2a.

The shape of the curves (deposition rate *vs.* carbonyl pressure) in Fig. 3 suggests that gaseous diffusion of carbonyl molecules to the substrate surface is rate-limiting. The rate of such diffusion should be linear with carbonyl concentration until the concentration becomes high enough that diffusion is no longer the slowest process. At higher carbonyl pressure the over-all rate should be much less affected by pressure, and the curves should level off.

The effect of flow rates on the rate of deposition is shown in Fig. 4. The curves do not extrapolate to a deposition rate of 0 at 0 flow rate. This undoubtedly reflects the diffusion of carbonyl vapor from the source to the reactor. The approximate proportionality observed between deposition rate and pressure (at equal temperature) at the lowest flow rates substantiates this point. The more than linearly increasing variation of deposition rate at high flow rate in curves 3 and 4 of Fig. 4a remains unexplained.

From the temperature dependence as shown in Fig. 2, one may attempt to calculate an over-all activation energy for the reactions. The form of these curves indicates that, in the case of Mo, carbonyl decomposition is rate-limiting only at the lower temperature ranges. Figure 5 shows an Arrhenius-type plot of the rate/temperature data for a typical set of conditions (0.05 Torr of Mo $(CO)_6$ flowing at 0.9 std. cc/min). For Mo $(CO)_6$ an activation energy of 23 kcal/mole was found, while the corresponding value for W $(CO)_6$ was 18 kcal/mole. These figures are roughly in the same range as the value of 14 kcal/mole reported (14) for the decomposition of nickel carbonyl, Ni $(CO)_4$.

Lander and Germer (7) found that Mo deposition on an iron surface stops totally when the temperature is lowered to 160°C. In the course of this study, a similar behavior was found to occur at temperatures which varied with choice of substrate surfaces. In each case, the expected exponential decay of deposition rate with temperature was interrupted by a sudden cutoff of deposition. In order to initiate deposition at temperatures in the range immediately above the cutoff, it was found necessary to raise the system pressure to several Torr for a few seconds. Once deposition began, pressure could be lowered to the desired level (usually about 0.01 Torr) and deposition continued. Minimum Mo deposition temperatures were established for oxidized silicon surfaces, as well as for various polymer surfaces. On SiO_2, Mo deposition cuts off between 180° and 170°C. On oxidized silicon wafers coated with AZ1350, a photosensitive varnish used in semiconductor technology,[2] deposition does not occur below 210°C. Although not all deposition parameters were studied for all cases, it was found that the cutoff temperature for SiO_2 surfaces was not significantly dependent upon carbonyl pressure or flow rate.

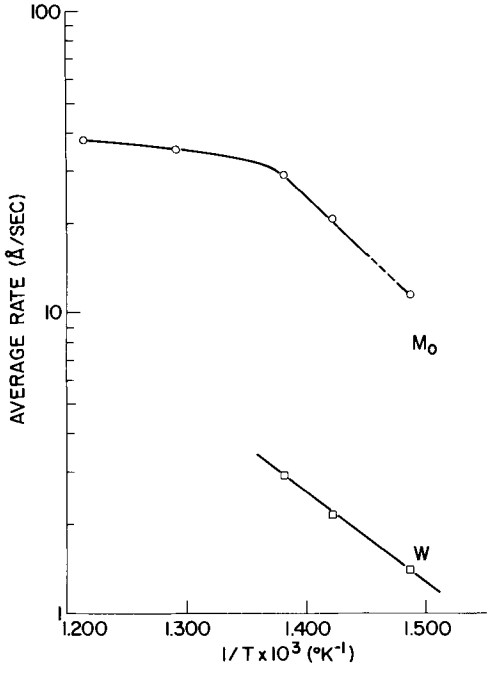

Fig. 5. Log (rate) vs. 1/T

Film properties.—Adherence.—Adherence of films to a substrate is a function of two types of opposing forces. One arises from the bonding between film and substrate and the other from the state of stress of the film. If the stresses in the film are effectively independent of film thickness, adhesion will decrease with increasing film thickness because of the increased shearing force at the film-substrate interface. On the other hand, the increase in film adhesion usually observed with increasing temperature of deposition may be attributed to the formation of chemical bonds between substrate and film material. In general, films formed above 500°C were perfectly adherent. Molybdenum films with thicknesses of 13,000Å or less deposited at 450°C were satisfactory according to the "Scotch-tape test." The Mo films deposited at lower temperatures were unsatisfactory. The same finding is essentially true for tungsten films of the same thickness.

To obtain adherent films in the lower temperature ranges so that other film properties might be evaluated, several potentially useful methods were developed. The addition during the first minute of deposition of a partial pressure (1-2 Torr) of an oxidizing gas (O_2 or H_2O) greatly improved adhesion to SiO_2 surfaces and allowed deposition temperatures as low as 325°C. Similarly low temperatures were made practical by first depositing at a very low rate (0.1-1.0 Å/sec) up to a thickness of several hundred angstroms. Deposition at normal rates following this step yielded adherent films at substrate temperatures as low as 325°C. Adherence of films depends strongly on the nature of the substrate surface. Ultrathin coatings (*e.g.*, 100Å) of AZ1350, or other photosensitive varnishes, on the oxidized silicon wafers allowed deposition of adherent Mo films at all substrate temperatures down to the 210°C cutoff temperature. Aside from the effects of such coatings, no relationship between film adhesion and substrate preparation procedures could be established.

Electrical resistivity.—The resistivity of metal films is of paramount importance for most microelectronic applications. The most probable cause for high resistivities in the films produced by carbonyl decomposition is the incorporation of carbon into the metal struc-

Table I. Resistivity and carbon content for various deposition conditions

Carrier gas	Deposition Temperature, °C	Rate, Å/sec	P_{H_2O}, mm	Resistivity, μohm cm	Carbon content, ppm
H_2	430	5	0	28	4400
H_2	480	5	0	10.1	2800
CO_2	480	5	0	9.5	1600
H_2	480	5	0.0003	8.8	1100
H_2	430	5	0.0003	9.0	1100
Ar	480	5	0	9.0	1000
H_2	500	5	0.0003	6.2	700
H_2	530	5	0	5.8	700
H_2	480	0.8	0	5.8	<260

ture either as interstitial atoms or in the form of a finely divided carbide. Such a cause/effect relationship is strongly suggested by the data in Table I. Here, the average carbon content, obtained by chemical analysis (oxidation followed by micro-gas-analysis), is listed with average resistivity for various deposition conditions, including the presence of water vapor in the plating gas. A good correlation between carbon content and resistivity is evident.

Figure 6a and b show the effect of deposition temperature on resistivity for films of Mo and W formed via carbonyl decomposition. It may be noted that resistivity of films deposited in the high range of substrate temperature is essentially invariant with temperature. For any given pressure and flow conditions, however, there will be some substrate temperature below which the resistivities of deposited films are found to increase. In fact, a decrease of 50°C in substrate temperature in this range can cause the resistivity of the resultant film to be 10-100 times as high as that of films formed at higher temperatures. Indications are that resistivity may level off again for still lower deposition temperatures. However, diffraction studies indicate that a carbide phase is deposited at such temperatures.

The dramatic effect of deposition temperature on resistivity of the deposited films shown in Fig. 6 can be explained, at least qualitatively, in terms of the thermodynamics of the CO/CO_2 equilibrium. When thermodynamic equilibrium is assumed, the ratio of carbon to metal deposited in the films can be derived from a consideration of the following reactions

$$M(CO)_6 = M + 6\,CO \qquad [1]$$

$$C + CO_2 = 2\,CO \qquad [2]$$

Clearly, the number of moles of deposited carbon will be equal to the number of moles of CO_2. From the knowledge of the equilibrium constant K for Eq. [2] one may then calculate the ratio of moles of deposited carbon to moles of deposited metal. This is expressed by the relation

$$\frac{n_m}{n_c} = \frac{K}{6} \cdot \frac{1}{P_{CO}} + \frac{1}{3} \qquad [3]$$

where n_m and n_c are the numbers of moles of deposited metal and carbon, respectively. Calculated values of the ratio n_c/n_m, together with values of K (15) as a function of T are listed in Table II. At least in the lower concentration range, n_c/n_m should be linear with resistivity. The values of CO pressure used were obtained by assuming a carbonyl pressure of 0.0076 mm (a typical pressure here) and using the derived relationship

$$P_{CO} = \frac{K}{4}\left(-1 \pm \sqrt{1 + 48\ P_c/K}\right) \qquad [4]$$

It is apparent that an increasingly sharp rise in the ratio n_c/n_m is to be expected as the deposition temperature is lowered. In practice, as is seen in Fig. 6, this effect reaches noticeable proportions below 450°C in molybdenum and generally below about 500° for tungsten.

Table II. Calculated deposition of carbon in films as function of temperature
(For $P_c = 7.6 \times 10^{-3}$ mm $= 10^{-5}$ atm)

Temperature, °C	Equilibrium constant, $K = p_{CO}^2/P_{CO_2}$	P_{CO}, atm	n_m/n_c	n_c/n_m, $\times 10^6$
800	10.0	6.23×10^{-5}	9.95×10^5	1
750	2.98	5.96×10^{-5}	2.96×10^6	3
700	1.01	6.06×10^{-5}	1.02×10^7	10
650	0.347	6.07×10^{-5}	3.52×10^4	28
600	0.079	5.99×10^{-5}	7.90×10^3	127
550	0.019	5.98×10^{-5}	1890.0	552
500	3.7×10^{-3}	6.01×10^{-5}	369.0	2,710
450	5.6×10^{-4}	5.07×10^{-5}	47.6	21,000
400	9.2×10^{-5}	3.45×10^{-5}	5.60	179,000

Although no correlation between resistivity and any one deposition parameter other than deposition temperature was established, the resistivity of molybdenum films was found to change with deposition rate, as illustrated in Fig. 7. These films were deposited on substrates at 400°C and had relatively high resistivities. Results obtained with films deposited at 500°C might be expected to show a similar relationship between resistivity and rate. However, because the resistivities of such films were so close to bulk value, they were almost indistinguishable. The more sensitive parameter of resistivity ratio ($\rho_{\text{room temperature}}/\rho_{\text{liquid } N_2}$) was used in an attempt to discover a relation-

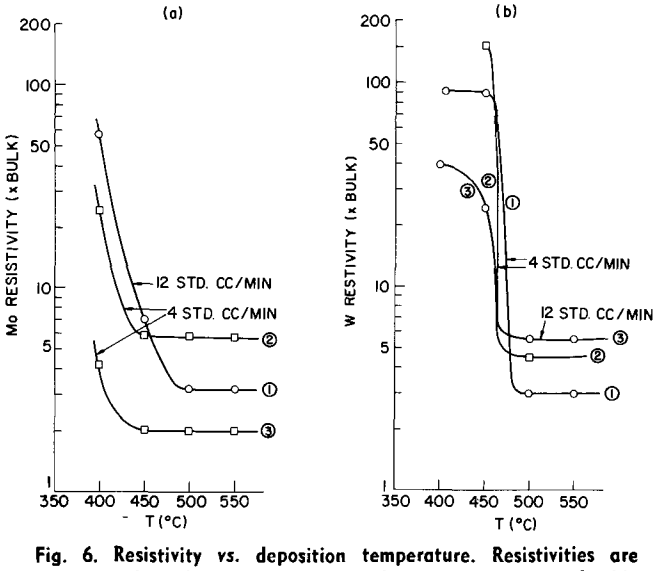

Fig. 6. Resistivity vs. deposition temperature. Resistivities are given as number of times bulk value, taken as 5.7 μohm cm for Mo and 5.5 μohm cm for W. a. $P_H = 0.074$ Torr; b. $P_H = 0.23$ Torr.

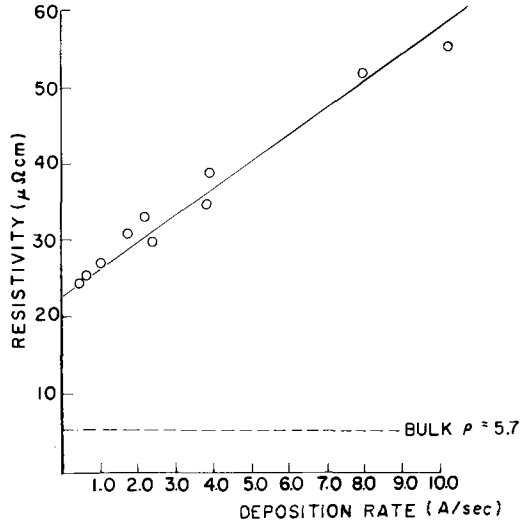

Fig. 7. Resistivity vs. deposition rate

ship between the resistivity and rate of growth of films deposited at 500°C, but no clear-cut relation was found. The dependence of resistivity on deposition rate, observed in films deposited at 400°C, is possibly explained by the physical incorporation of adsorbed carbon-containing molecules (CO and CO_2) into the growing film. If the rate of deposition is high enough that an adsorbed biproduct molecule is covered before it can move away, the molecule will become an impurity in the film. Lower rates of deposition might allow a greater portion of biproduct molecules to escape before entrapment and thus yield films with lower resistivity.

An investigation aimed at determining the optimum deposition parameters for molybdenum films deposited at the lowest possible substrate temperature, but still displaying a resistivity of approximately 6 μohm cm (close to that of pure bulk molybdenum), yielded the following results: substrate temperature 500°C, carbonyl pressure 0.001 Torr, hydrogen pressure 0.01 Torr, rate of gas flow 12 std. cc/min, rate of film growth 3.7 Å/sec. Attempts to obtain films with as low resistivities, but deposited at lower substrate temperatures, were all unsuccessful.

Some alloys of Mo and W were formed by simultaneous decomposition of the two carbonyls in appropriate molar ratios. Alloys prepared from such mixtures containing 0, 2, 5, 10, and 50% W had resistivities of 6.9, 7.3, 7.7, 8.6, and 14.7 μohm cm. Experience with chromium impurities in certain batches of molybdenum carbonyl in this work indicated that Cr exerts a deleterious influence on the resistivity of Mo films. This effect, which appears quite large, may be partly due to the formation of chromium carbide.

Structure, orientation, and stress.—Films deposited at different substrate temperatures were examined by the usual replica electron microscopy technique and by x-ray diffraction. In some instances, the stresses in the films were determined by the "wafer bending technique," (16) in which stresses are evaluated from the optically determined bow imparted to the underlying silicon substrate.

Measurements made on an XRD-5 diffractometer with a Cu target yielded information about structure, preferred orientation, and particle size; and through lattice parameter (17) determination (with an accuracy of ± 0.0015Å) gave values for the homogeneous film stresses. Strains measured from lattice parameter measurements were correlated with stresses determined by optical means, according to the formula

$$\epsilon_z = \frac{2\nu}{E}\sigma_x \qquad [5]$$

where ϵ_z is the strain normal to the surface of the film, ν is the Poisson ratio, E the modulus of elasticity, and σ_x is the homogeneous film stress in the direction parallel to the film surface. The values (18) of ν and E are 0.32 and 3.2 x 10^{12} dynes/cm^2, respectively, for pure molybdenum.

For tungsten $E = 3.5 \times 10^{12}$ dynes/cm^2, and $\nu = 0.27$, from the listed values (19) of E and G, the modulus of rigidity. The diffraction line broadening was partitioned into two parts, respectively proportional to $1/\cos\theta$ and $\tan\theta$, which yielded values of particle size and heterogeneous film stresses. A few samples were also examined by electron diffraction.

Molybdenum films used for structural studies were deposited under conditions that produced films with the lowest value of film resistivity obtained. The carbonyl pressure was 0.0015 Torr, hydrogen pressure 0.01 Torr, and rate of gas flow 12 std. cc/min; only the substrate temperature was varied for the different film depositions.

The residual stresses measured by optical means at room temperature were tensile for films deposited at high substrate temperatures (1.5 to 2 x 10^9 dynes/cm^2, 580°C) and compressive, with quite high values, for films deposited at lower substrate temperatures. Compressive stress values of 2 x 10^9 dynes/cm^2, 1.3 x 10^{10} dynes/cm^2, and as high as 2.3 x 10^{10} dynes/cm^2 were determined for films deposited at substrate temperatures of 530°, 480°, and 430°C, respectively.

Figure 8 shows the surface topography of a film deposited at 580°C, as shown by the microscope. X-ray diffraction indicates that such a film has a very strong (100) orientation. The lattice parameter measured on a similar film was found to be 3.1456Å, and 3.1468Å after correction for a film stress of 2 x 10^9 dynes/cm^2. (The listed lattice parameter (20) is 3.1466Å for pure molybdenum.) The particle size, from x-ray measurements, was $\sim$ 2500Å in a direction normal to the film surface. If one assumes that Fig. 8 gives a good indication of the grain size in a direction parallel to the film surface, it would appear that the grain structure is approximately equiaxed. Values of heterogeneous stresses, approximately ± 3.5 x 10^9 dynes/cm^2, appear quite high.

Figure 9 is an electron micrograph of a replica taken from a 5000Å thick film of molybdenum deposited at a substrate temperature of 530°C. This film showed a mixed (100)-(211) orientation, with the (211) part predominant. The combination of orientations, as well as an apparently smaller grain size, probably accounts for the more complex surface aspect displayed in Fig. 9 as compared with Fig. 8. The high lattice-parameter value, measured as 3.1490Å (corresponding to 3.1475Å after correction for a stress of 2.3 x 10^9 dynes/cm^2) corroborates indications that the film is in a state of compressive stress. Diffraction-determined grain size and heterogeneous stress values are about equal to those reported above for a film deposited at 580°C. Film orientations do not correspond to those observed by Lander and Germer (7) who reported mostly (111) orientations.

Films deposited at a substrate temperature of 480° and 430°C displayed nondistinctive surface structures on examination by electron microscopy.

When films deposited at a substrate temperature of 480°C were studied by x-ray diffraction, strong (211) and (111) peaks were obtained, while (200) peaks were either absent or extremely weak. The lattice parameter of one such film was 3.1562Å, or 3.1480Å after correction for a compressive stress of 1.3 x 10^{10} dynes/cm^2. The diffraction peaks were quite wide. If

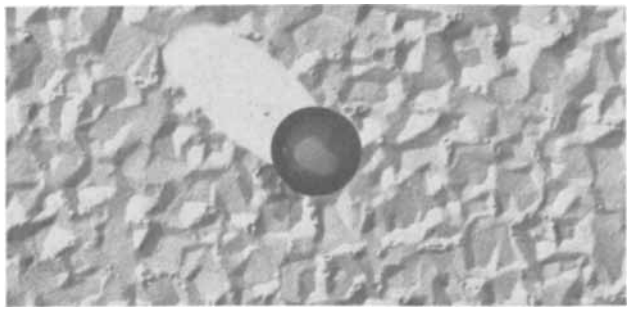

Fig. 8. Electron micrograph of a molybdenum film, 9000Å thick, deposited at a substrate temperature of 580°C. The latex ball has a diameter of 5000Å (as on the other photographs).

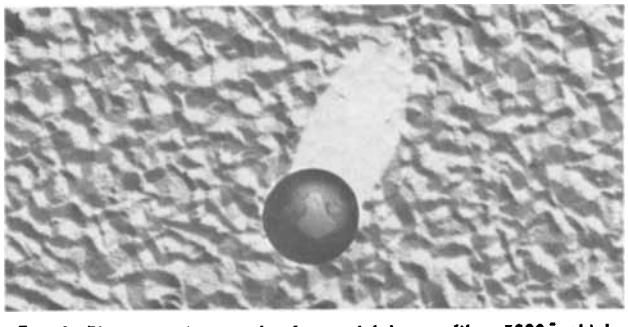

Fig. 9. Electron micrograph of a molybdenum film, 5000Å thick, deposited at a substrate temperature of 530°C.

one assumes, as was found in films deposited at higher temperatures, that the line broadening can be partitioned equally between grain size and heterogeneous stress effects, the grain size would be of the order of 600Å and the heterogeneous stress approximately $\pm 5.5 \times 10^9$ dynes/cm^2.

Several films were deposited at a substrate temperature of 430°C. Unfortunately, because of poor adhesion and other difficulties, these had to be used independently for optical stress measurements and for x-ray studies. A compressive stress with a magnitude of 2.3×10^{10} dynes/cm^2 was observed in one of these films. This apparently corresponds to a lattice parameter of 3.1622Å determined in a similar film with a (100) orientation, which would give a value of 3.1477Å after correction for stress. However, most films deposited under similar conditions appeared to have a random orientation and a lattice parameter of 3.1510Å. This latter value would fit quite well with a stress value of 3.6×10^9 dynes/cm^2 which was also measured in a film deposited at 430°C under identical conditions. It was not possible to determine the cause of the two orientations and of the relation between film stress and film orientation. In all of these films, regardless of substrate temperature during deposition, the lattice parameters (after correction for stress), agree within the accuracy of these measurements with the lattice parameter of pure molybdenum. Impurities, therefore, do not contribute significantly to the lattice parameter of the films.

When the substrate temperature during deposition is below 400°C, molybdenum carbide films rather than molybdenum metal films are obtained. The transition between deposition temperatures that correspond to molybdenum films and those that correspond to molybdenum carbide films occurs rather sharply at about 400°C. Only in films deposited at this temperature were diffraction lines characteristic of molybdenum and molybdenum carbide obtained simultaneously. Films deposited at 415°C appeared to be essentially "pure" molybdenum and films deposited at 370°C "pure" carbide. This value of the transition temperature appears in rough agreement with the one that can be extrapolated from the work of Lander and Germer. In spite of rather strong preferred orientations in carbide films, enough diffraction peaks were obtained to establish that the carbide phase is the cubic form reported by the same authors.

Molybdenum carbide films deposited at substrate temperatures of 375°C or below had very strong (100) orientations, although in films deposited at 300°C this orientation was somewhat less pronounced. Figure 10 is an electron micrograph of a replica taken from a 5000Å film deposited at 345°C. The apparent grain size is commensurate with a value of 1200Å determined in a similar film by x-ray diffraction. In general, carbide films had remarkably sharp diffraction lines, indicating that grain size did not decrease much below 1000Å and that heterogeneity either of stress or composition was limited. The lattice parameter, which seems to increase with decreasing temperature of deposition, may be influenced by lack of carbon stoichiometry. Values of 4.136, 4.146, and 4.160Å were found for films deposited at 370°, 350°, and 300°C, respectively.

For purposes of structural examination, tungsten films were deposited at a carbonyl pressure of 0.002 mm, at a hydrogen pressure of 0.01 mm, at a flow rate of 12 std. cc/min, and at substrate temperatures of 450°, 400°, 350°, and 300°C. X-ray diffraction examination of the films showed that all of them were "pure" tungsten, without detectable carbide lines. These results were confirmed by electron diffraction for the films deposited at 450°, 400°, and 300°C. Thus, as previously observed by Lander and Germer, the tendency to form carbides is much less in tungsten films than in molybdenum films. The film deposited at 450°C had a (100) orientation, while the others were randomly oriented. For both tungsten and molybdenum films, higher temperatures of deposition favor (100) orientations. However, for equal temperatures of deposition, tungsten films show tensile stress, whereas molybdenum films show compressive stresses. From two tungsten films deposited at 400°C, the value of the tensile stress was found to be $4.6 \pm 1 \times 10^9$ dynes/cm^2. In a film deposited at 450°C the lattice parameter was 3.1616Å, which, when compared with a lattice parameter of 3.1650Å for pure tungsten (21), corresponds to a tensile stress of 5.3×10^9 dynes/cm^2. Diffraction line broadening showed the film had heterogeneous stresses of $\pm 4 \times 10^9$ dynes/cm^2 and a particle size of 1200Å. Comparison of this value with the apparent grain size of the same film in Fig. 11 indicates that the structure might be slightly columnar.

The stress level in the tungsten films is approximately twice the 2.6×10^9 dynes/cm^2 value that would be expected on the basis of differential contraction between tungsten and silicon, for films deposited at about 400°C. It appears, therefore, that the films are deposited with intrinsic tensile stresses. The molybdenum films, however, display compressive stresses, which probably are due to carbide precipitation.

Effects of gaseous additions and substitutions.—Since low resistivity is desired for conducting films in microelectronic devices, different techniques were used to try to decrease the resistivity of molybdenum films. Generally speaking, the aim was to improve the resistivity by decreasing the carbon incorporated in the films during deposition.

Addition of water vapor and hydrogen sulfide to carrier gas.—The removal of carbon from metals, according to the reaction

$$H_2O + C = H_2 + CO \qquad [6]$$

is well established. However, excessive concentrations of H_2O in a system could lead to oxidation of the host material, according to a reaction such as

$$Mo + 3\,H_2O = MoO_3 + 3H_2 \qquad [7]$$

which would be expected to deleteriously affect the resistivity. Hence, with increasing water vapor, the resistivity passes through a minimum. In fact, the oxidation of Mo by mixtures of H_2 and H_2O is thermodynamically favored up to 800°C for the minimum

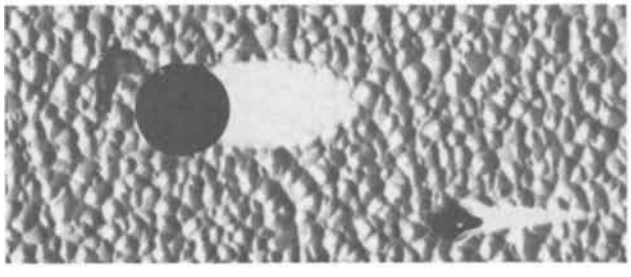

Fig. 10. Electron micrograph of a molybdenum carbide film, 5500Å thick, deposited at a substrate temperature of 345°C.

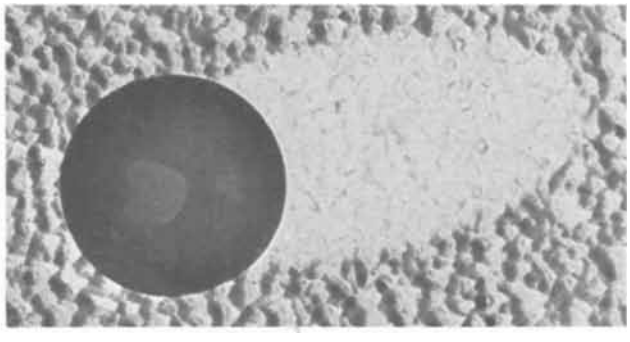

Fig. 11. Electron micrograph of a tungsten film, 3000Å thick, deposited at a substrate temperature of 450°C.

H_2O/H_2 ratio (0.01) used in this work. Calculations indicate that an H_2O/H_2 ratio at 2×10^{-6} is just oxidizing at 400°C. These calculations were based on the data of Glassner (22) for MoO_3 ($\Delta F = -157$ kcal/mol at 300°K and -115 kcal/mol at 800°K) and for MoO_2 ($\Delta F = -116$ kcal/mol at 300°K and -89 kcal/mol at 800°K) and on the method described in Darken and Gurry (23). [The substantial disagreement between this value and the 0.062 mentioned by Lander and Germer (7) probably is due to their use of unreliable data for the free energies of formation of the two molybdenum oxides.] Results of experiments on adding water vapor to the hydrogen carrier gas are shown in Fig. 12. Although resistivity improved substantially at low deposition temperatures, where resistivity values generally are high, very little improvement occurred in films deposited at 500°C, which had a resistivity close to that of bulk molybdenum even when deposited without added water vapor. To determine whether reaction [6] plays a significant role in the resistivity of films deposited in the presence of water vapor, several films deposited at a substrate temperature of 480°C (with water vapor pressure of 0.001-0.002 Torr) were subsequently annealed in hydrogen at 600°C. This treatment had no effect on the resistivity of the films. It is possible that the negative result is due to the difficulty in reaching equilibrium at this comparatively low temperature for molybdenum.

Removal of carbon by H_2S could be envisaged according to the following reaction

$$2H_2S + C = 2H_2 + CS_2 \qquad [8]$$

Although such a reaction is not thermodynamically favored, under equilibrium conditions, decreases in the carbon content of molybdenum films deposited in the presence of H_2S were reported by Lander and Germer (7).

Results obtained here indicate that although the addition of H_2S produces a substantial decrease in resistivity at a deposition temperature of 350°C, no advantage is gained for deposition at 500°C. In fact, it has been observed that even extremely small concentrations of H_2S cause the resistivity to rise for films deposited at this temperature.

Substitution of argon or carbon dioxide for hydrogen. —The water-carbon reaction of Eq. [6] suggests another means for reducing the carbon content in these films. When hydrogen is used as a carrier gas, it tends to drive this reaction to the left, causing carbon to form by the reduction of the CO biproduct from the carbonyl decomposition. Hence, substitution of an inert gas such as Ar might be expected to reduce carbon content. Figure 13 compares the electrical resistivity of films made with H_2 with that of films made with Ar carrier gases at various temperatures.

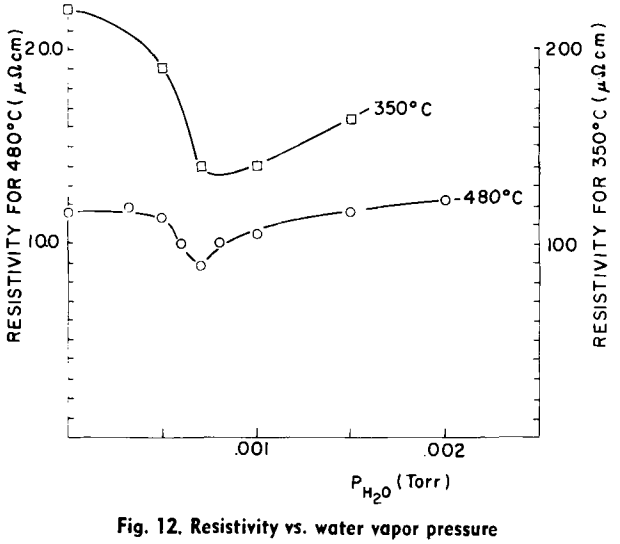

Fig. 12. Resistivity vs. water vapor pressure

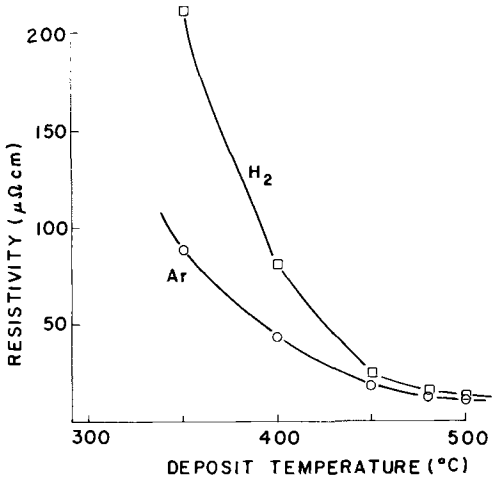

Fig. 13. Resistivity vs. deposition temperature for two carrier gases.

Although at low deposition temperatures the carrier gas substitution has a definite advantage, improvement falls off rapidly with increasing temperature. Carbon analysis of films deposited at 480°C shows no substantial differences in carbon content when the carrier gas is changed.

The disproportionation of carbon monoxide, shown in Eq. [2] to be a likely source of carbon in the films, theoretically should be reversed by an increase in concentration of CO_2. As in the case of water, however, too much CO_2 can constitute an oxidizing atmosphere and react with the depositing metal M, according to the reaction

$$M + 3\,CO_2 = MO_3 + 3\,CO \qquad [9]$$

It was to be expected then that pure CO_2 carrier gas would lead to large resistivities. A mixture of CO_2 and H_2 might minimize both oxide and carbon impurities. Figure 14 shows resistivity as a function of mole fraction of H_2 in the carrier gas for films deposited at 400°C. A minimum is evident in the region of 30 m/o (mole per cent) H_2.

Conclusions

Molybdenum films with a resistivity approaching the bulk value can be deposited from decomposition of molybdenum carbonyl at temperatures of 500°C, or above, and at growth rates of 3-4 Å/sec. At lower deposition temperatures films with bulk resistivity cannot be obtained, presumably because of carbon incorporation within the films, as evidenced by the correlation between film resistivity and carbon content.

In molybdenum films the stress changes from a tensile value of 1.5-2 x 10^9 dynes/cm^2 for films deposited at 580°C to a compressive value of 2.3 x 10^{10} dynes/cm^2 for films deposited at 430°C. In tungsten films deposited in a similar range of temperatures,

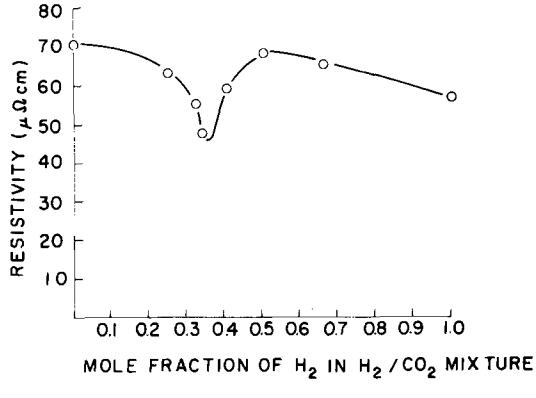

Fig. 14. Resistivity vs. mole fraction of H_2 in H_2/CO_2 mixtures

only tensile stresses were observed, with a value of 4.6 x 10^9 dynes/cm^2 for a film deposited at 400°C. This difference between tungsten and molybdenum films is probably related to the formation of a carbide phase, which was found to form much more readily in molybdenum than in tungsten.

Attempts to produce films with low resistivity by making chemical deposition conditions more oxidizing were most successful at deposition temperatures of about 400°C. However, the improvements obtained were not sufficient to reduce resistivity to values approaching bulk value. Additions of water vapor, hydrogen sulfide, carbon dioxide, and argon to hydrogen, and various combinations of these were not effective in the temperature range of 450°-500°C, where the unmodified carbonyl decomposition in hydrogen gives films with resistivities of 1.5-2 times bulk value. Thus it must be concluded that production of molybdenum films with bulk resistivity by carbonyl decomposition at substrate temperatures below 500°C is unlikely.

Acknowledgments

The authors are pleased to acknowledge the help of Mr. W. C. Metzger who accomplished most of the experimental work involved in depositing the films and in making the stress determinations. Mr. C. Aliotta made the replicas and obtained the electron micrographs. Comments by T. Sedgwick were extremely helpful.

The Ga-GaP-GaAs Ternary Phase Diagram

G. A. Antypas

Varian Associates, Palo Alto, California

ABSTRACT

The ternary phase diagram of Ga-GaP-GaAs has been calculated using Darken's quadratic formalism for a ternary liquid in equilibrium with a regular solid solution. Liquidus isotherms have been calculated from 900° to 1450°C in 50°C increments. GaP distribution curves have also been calculated for 0.95, 0.9, 0.8, 0.7, 0.6, 0.5, 0.4, 0.3, and 0.1 mole fraction of GaP. The calculated ternary and pseudobinary phase diagrams are in excellent agreement with available experimental data.

Since it was demonstrated that the GaP-GaAs system forms continuous solid solutions (1) the system has attracted great attention, primarily because a portion of the system has a bandgap corresponding to the visible region of the spectrum. Initially, the GaAs-GaP crystals were prepared by vapor transport techniques, using AsH_3 and PH_3 as the source materials (2). It has been demonstrated, however, that III-V compounds grown from solution have a lower native defect density (3) and in general have more efficient radiative recombination properties. Thus an understanding of the thermodynamic properties of both the liquid and solid solutions is necessary for establishing optimum growth conditions. The model to be presented has already been applied to the In-Ga-As and Ga-As-Sb (4) systems where it gave excellent agreement with available experimental data. It can also be applied to all III-V ternary solids forming continuous solid solutions.

Phase Equilibria of III-V Ternary Compounds

Ternary-phase diagrams of III-V compounds have been calculated using the quasi-chemical equilibrium treatment (5) and the regular solution treatment (6). In computing the conditions for equilibrium between a ternary liquid solution A, B, C (Ga, P, As) and a pseudobinary solid solution AB-AC (GaP-GaAs), Stringfellow and Greene (5) derived the following equations

$$\ln \gamma_{AB}x = \ln 4N_AN_B + \ln (\gamma_A\gamma_B/\gamma_A^{STC}\gamma_B^{STC}) + \Delta S^F_{AB}(T^F_{AB} - T)/RT$$
$$\ln \gamma_{AC}(1-x) = \ln 4N_AN_C + \ln (\gamma_A\gamma_C/\gamma_A^{STC}\gamma_C^{STC}) + \Delta S^F_{AC}(T^F_{AC} - T)/RT \quad [1]$$

where γ_{AB} and γ_{AC} are the activity coefficients of AB and AC in the solid solution, x is the mole fraction of AB, N_i and γ_i (i = A, B, C,) are the atom fraction and

activity coefficient of i in the liquid solution, respectively, γ_i^{STC} is the activity coefficient of N_i at the stoichiometric composition, ΔS^F_{AB} is the entropy of fusion of AB, T^F_{AB} is the temperature of fusion of AB, R is the universal gas constant, and T is the temperature in °K.

Under the restriction

$$N_A + N_B + N_C = 1 \qquad [2]$$

Eq. [1] can be solved numerically on a computer to yield two sets of curves, one describing the liquidus isotherms and the other describing the solidus isoconcentration curves of the system.

In previous investigations the activity coefficients were determined by the quasi-chemical equilibrium (5) approach and by considering the ternary liquid as a strictly regular solution (6). In the present communication, however, the determination of the activity coefficient in the liquid phase is based on Darken's quadratic representation, which for a binary liquid is

$$\ln \gamma_A = \alpha_{AB} N_B^2$$
$$\ln (\gamma_B/\gamma^0_B) = \alpha_{AB}(-2N_B + N_B^2) \qquad [3]$$

where A is the solvent and B is the solute, γ^0_B is the activity coefficient of B at infinite dilution, and α_{AB} is the interaction parameter of the system. Equation [2] reduces to that describing a regular solution if $\ln \gamma^0_B = \alpha_{AB}$. This formalism has been satisfactorily applied by Darken (7) and Turkdogan and Darken (8) to a number of liquid metallic solutions for concentration of up to 60%. This formalism is consistent with the Gibbs-Duhem equation and satisfies Raoult's and Henry's laws as the limiting cases. The quadratic formalism was also extended by Darken (9) to ternary systems, which results in activity coefficients given by

$$\begin{aligned}
\ln\gamma_A &= \alpha_{AB}N_B^2 + \alpha_{AC}N_C^2 + (\alpha_{AB} + \alpha_{AC} - \alpha_{BC})N_BN_C \\
\ln(\gamma_B/\gamma^0_B) &= -2\alpha_{AB}N_B + (\alpha_{BC} - \alpha_{AB} - \alpha_{AC})N_C \\
&\quad + \alpha_{AB}N_B^2 + \alpha_{AC}N_C^2 + (\alpha_{AB} + \alpha_{AC} - \alpha_{BC})N_BN_C \\
\ln(\gamma_C/\gamma^0_C) &= -2\alpha_{AC}N_C + (\alpha_{BC} - \alpha_{AB} - \alpha_{AC})N_B \\
&\quad + \alpha_{AB}N_B^2 + \alpha_{AC}N_C^2 + (\alpha_{AB} + \alpha_{AC} - \alpha_{BC})N_BN_C
\end{aligned} \qquad [4]$$

where component A is the solvent and components B and C are the solutes, γ^0_C is the activity coefficient of component C at infinite dilution, and α_{i-j} are the interaction energies of the various binary systems. The above formalism is also consistent with the Gibbs-Duhem equation, and furthermore it reduces to the binary quadratic formalism as one of the solutes in the ternary approaches infinite dilution.

The solid solution in equilibrium with the ternary liquid was assumed to be regular, *i.e.*, $\Delta F^{xs} = \alpha_{AB\text{-}AC}x(1 - x)$, where $\alpha_{AB\text{-}AC}$ is the interaction energy and x is the mole fraction of one of the components in the solid. The activity coefficients are thus given by

$$\ln \gamma_{AB} = \alpha_{AB\text{-}AC}(1 - x)^2$$
$$\ln \gamma_{AC} = \alpha_{AB\text{-}AC}x^2 \qquad [5]$$

Substituting Eq. [4] and [5] in Eq. [1] the ternary phase diagram can be calculated numerically to yield the liquidus and solid distribution curves.

Calculation of the Ga-GaP-GaAs Phase Diagram

The parameters necessary in calculating the ternary phase diagram are the temperatures T^F and entropies ΔS^F of fusion of the III-V compounds and the interaction parameters α_{AB}, α_{AC}, α_{BC}, and $\alpha_{AB\text{-}AC}$. T^F and ΔS^F for GaP and GaAs can be obtained directly from the literature and are shown in Table I. Vieland (10) has used regular solution theory to calculate the liquidus of III-V compounds. The interaction parameter obtained from such a treatment is

$$\alpha = \frac{\Delta S^F (T - T^F)\,[1 + R/\Delta S^F \ln 1/4x(1 - x)]}{2(x - 0.5)^2} \qquad [6]$$

Table I. List of thermodynamic parameters used in calculating the Ga-GaP-GaAs phase diagram

	GaP	GaAs	As-P	GaP-GaAs
α (cal/mole)	7900-7.00 T (11)	−3.7 T (12)	2000	1000
ΔS^F (eu)	15 (11)	16.64 (12)	—	—
T^F (°C)	1470	1238	—	—

where x is the column V element in solution. For a regular solution α should be independent of temperature and composition. Thurmond (11), however, demonstrated that for GaAs and GaP α is a linear function of temperature given by

$$\alpha_{GaAs} = 9960 - 11.15\ T$$
$$\alpha_{GaP} = 7900 - 7.00\ T \qquad [7]$$

When the interaction parameter α is divided by RT so that it will be thermodynamically consistent with Darken's formulation it takes the form of

$$\omega = \frac{\mathcal{L}}{RT} - \frac{\mathcal{S}}{R} \qquad [8]$$

which is of the form derived by Turkdogan and Darken (8), where $\mathcal{L}$ and $\mathcal{S}$ have the units of enthalpy and entropy, respectively.

In calculating α_{GaAs}, Thurmond assumed a ΔS^F_{GaAs} value of 14.0 eu. Arthur (12) pointed out that when a recently measured value for ΔS^F_{GaAs} of 16.64 eu is used, then

$$\alpha_{GaAs} = 5160 - 9.16\ T$$

Arthur has also calculated the activity coefficient of As from As vapor pressure measurements, and using a regular solution treatment found that the interaction parameter is accurately given by

$$\alpha_{GaAs} = -3.7\ T$$

The interaction parameter of the As-P system was calculated to be 2000 cal/mole by fitting the liquidus curve to a regular solution model and comparing it to available experimental data (13). Similarly, the interaction parameter of the GaP-GaAs system was determined by fitting the solidus to recently published data of the GaP-GaAs pseudobinary (14). Calculations performed by Moon (15) on GaP-GaAs were in good agreement for $\alpha_{GaP\text{-}GaAs} = 1000$ cal/mole.

Figure 1 represents the calculated ternary phase diagram. Solid lines represent the liquidus isotherms from 900° to 1450°C by 50°C increments, while dotted lines represent GaP isoconcentration curves at 0.95, 0.9, 0.8,

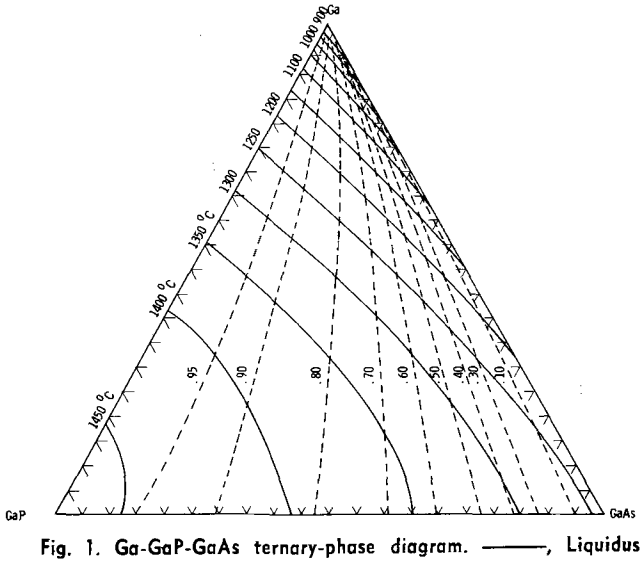

Fig. 1. Ga-GaP-GaAs ternary-phase diagram. ———, Liquidus isotherms, - - - - -, GaP isoconcentrations curves.

0.7, 0.6, 0.5, 0.4, 0.3, and 0.1 mole fraction of GaP. The pseudobinary obtained from Fig. 1 is shown on Fig. 2 along with available experimental data (14). Figures 3, 4, and 5 compare the experimental results reported by Thurmond for the GaAs and GaP compounds, and by Panish (16) for the Ga-GaP-GaAs solution growth and solution epitaxy results. Figure 3 is a portion of Fig. 1, plotted in cartesian coordinates, showing the

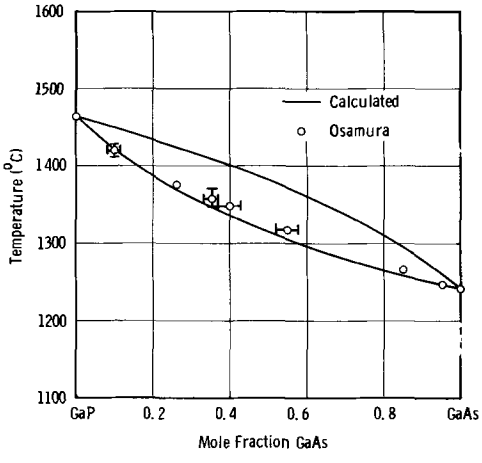

Fig. 2. GaP-GaAs pseudobinary-phase diagram

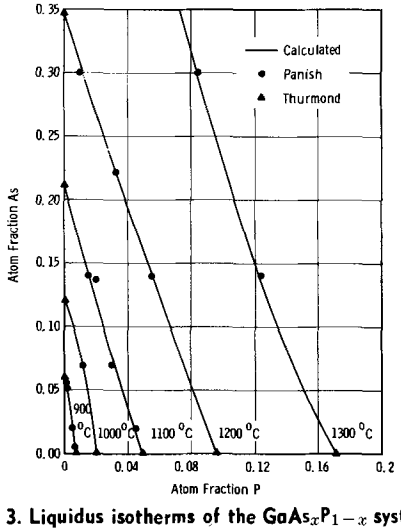

Fig. 3. Liquidus isotherms of the $GaAs_xP_{1-x}$ system

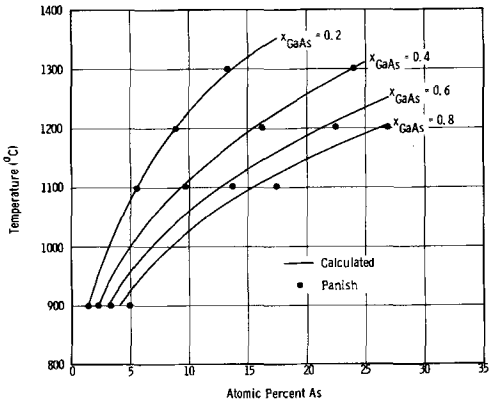

Fig. 5. GaAs isoconcentration curves plotted as a function of temperature and As concentration in the melt.

equilibrium solubility of P as a function of the As concentration in the melt for 900°, 1000°, 1100°, 1200°, and 1300°C isotherms. Excellent agreement is obtained between calculated and experimental results. Figure 4 also shows a portion of the ternary-phase diagram in greater detail, on which the solubility of P is plotted as a function of temperature at isoarsenic concentrations. Figure 5 represents the distribution of GaAs in equilibrium with the ternary melt as a function of the As present in the liquid solution. The distribution coefficient is defined by

$$D = \frac{\gamma_{GaP}}{\gamma_{GaAs}} \frac{x_{GaAs}/x_{As}}{x_{GaP}/x_P}$$

where γ_{GaAs}, x_{GaAs}, and x_{As} are the activity coefficient of GaAs in the solid solution, the GaAs mole fraction, and the atom fraction of As in the liquid solution, respectively. For the 1100°C isotherm, D varied between 0.13 for $x_P = 0.045$ and 0.27 for $x_P = 0.002$.

Conclusions

It has been shown that ternary phase diagrams of III-V compounds calculated by Darken's phenomenological quadratic formalism are in excellent agreement with available experimental data. The parameters used in calculating the Ga-GaP-GaAs phase diagram were either directly obtained from the literature, or were obtained by fitting the model to available experimental data. Although this model is derived to describe the solution in the vicinity of the major component (in solution epitaxy and solution growth of GaP_xAs_{1-x} in the vicinity of the Ga corner of the ternary diagram), the agreement between the calculated and experimental results of the pseudobinary phase diagram indicate that the quadratic formalism accurately describes the ternary phase diagram of Ga-GaP-GaAs for concentration of up to 50%.

Properties of Aluminum Oxide Obtained by Hydrolysis of $AlCl_3$

T. Tsujide, S. Nakanuma,* and Y. Ikushima

IC Division, Nippon Electric Company, Tokyo, Japan

ABSTRACT

A study has been made of aluminum oxide films prepared by the hydrolysis of mixtures of $AlCl_3$, H_2, and CO_2. Positive shifts of the flat band voltage of the MAS structure occur independently of the polarity and type of the applied bias when this is higher than a critical voltage. This phenomenon can be explained by electron injection and trapping. The trapped electrons have a long lifetime, but are excited by radiation such as x-rays and electron beam without introduction of damage.

One of the most important processes in the fabrication of semiconductor devices is the passivation of the semiconductor surface. For this purpose, various dielectric films have been examined, among which the most studied has been thermally grown silicon dioxide, because of its ease of preparation. Unfortunately, it exhibits instabilities such as shifts in device characteristics due to the migration of impurities, especially Na ions through the oxide at elevated temperatures under bias conditions (1) and degradation of device characteristics under irradiation environments (2); more demanding requirements have therefore led to the need for insulating films superior to this oxide.

It is a reflection of such requirements that recently silicon nitride and aluminum oxide have been receiving a great deal of attention. These materials were found to have properties superior to silicon dioxide films, in that the ion migration effect has been shown to be sufficiently negligible that they may be used as a barrier for contamination (3, 4), making it possible to fabricate capless devices. In addition, they have a high radiation resistance (5, 6). However, silicon nitride has some disadvantages of high surface charge density and crack generation during subsequent heat-treatment. On the other hand, it has been reported that aluminum oxide makes the silicon surface more p-type due to the negative charge (7, 8). This is pertinent to the fabrication of insulated gate field effect transistors with low threshold voltage as well as n-channel enhancement mode devices. Moreover, there are several applications of the aluminum oxide such as a diffusion mask, passivating film for bipolar type devices, and other new structures.

There are various methods for formation of aluminum oxide: pyrolysis of organic compounds such as $Al(C_3H_7O)_3$ (3, 9) and $Al(C_2H_5O)_3$ (10), anodization of aluminum in oxygen plasma (11), reactive evaporation (12), and reactive sputtering (13, 14). The films obtained by the above methods are structureless, *i.e.*, amorphous, but some of these aluminum oxide films have instabilities under thermal stress which are found to be reduced by post annealing at temperatures as low as 400°C. On the other hand, deposition of polycrystalline aluminum oxide films on silicon by the hydrolysis of $AlCl_3$ at about 800°C was reported by Nigh (15) and Doo and Tsang (16). The properties of such polycrystalline films, namely refractive index, etch rate, infrared absorption, and dielectric constant, have been studied by us as a function of deposition conditions, and the MAS (metal-aluminum oxide-silicon) structures have been used to evaluate the electrical properties of the Si-Al_2O_3 interface. All of these results are discussed here.

* Electrochemical Society Active Member.

Experimental

The system used for the deposition of aluminum oxide films on silicon wafers was similar to that reported by Nigh (15) in which H_2O vapor, formed by the reaction of CO_2 with hydrogen, hydrolyzes $AlCl_3$ vapor. All deposition runs were carried out using the following conditions: the flow rates of CO_2, hydrogen saturated with $AlCl_3$ vapor and make-up hydrogen were 326 cc/min, 2 l/min, and 20 l/min, respectively, and the temperature of the silicon wafers was measured by means of an optical pyrometer and was kept at 850°C. The deposition rate of aluminum oxide was approximately 70 Å/min. The silicon wafers with (100) orientation and resistivities of $3 \sim 5$ ohm-cm, either p-type or n-type, were mechanically-chemically polished and carefully cleaned. The cleaning procedure involved rinses in trichlorethylene and acetone using ultrasonic agitation immediately prior to the deposition.

The refractive index and the thickness of the aluminum oxide films were measured by ellipsometry. The etch rate was determined by measuring thickness after each successive etching.

For the evaluation of the electrical properties of the aluminum oxide films and the Si-Al_2O_3 interface, the MAS structure was constructed by the deposition of aluminum oxide on silicon, followed by the evaporation of aluminum electrodes of 1 mm diameter and mounting on TO-5 headers. The C-V characteristics of the MAS structure were measured at 1 MHz. From the area of the electrode, the thickness of the film, and the capacitance of the MAS structure under accumulation conditions the dielectric constant was obtained. The I-V characteristics of the aluminum oxide were also measured by the same MAS structure using a Keithley electrometer in order to analyze the conduction mechanism in the aluminum oxide.

Results

Ellipsometric measurements on the aluminum oxide yielded values for the relative permittivity of $7.6 \sim 7.8$. These are consistent with 7.6 for the film obtained by anodization in oxygen plasma (11), but are less than

those of 8.9 ~ 9.3 (15) and 11 (17) for the films formed by the hydrolysis of $AlCl_3$.

The dielectric strength measured using the MAS structure was found to depend on the polarity of the applied voltage. When positive voltage was applied to the Al electrode, dielectric breakdown occurred at fields of $6 \sim 7 \times 10^6$ and $8 \sim 9 \times 10^6$ V/cm at room and liquid nitrogen temperature, respectively, while for negative polarity it occurred with time dependence, *i.e.*, when a somewhat lower field than $1.1 \sim 1.2 \times 10^7$ V/cm was applied for a few minutes, a thermal current fluctuation of nA order was observed and finally the film underwent breakdown. Similar phenomena have been observed for steam-grown silicon dioxide films, though the polarity dependence was opposite (18).

Figure 1 shows the capacitance-voltage characteristics of an Al_2O_3 film of 1200Å in thickness on n-type silicon substrate at three different temperatures, −196°, 25°, and 250°C. It should be noted that this unit has a nearly zero flat band voltage at room temperature in coincidence with the ideal MIS diode characteristic; the C-V curve shifts in the positive voltage direction at liquid nitrogen temperature and in the negative direction at 250°C. The MAS structure with p-type silicon, however, showed the opposite shifts to that with n-type silicon, indicating that fast surface states exist in the energy gap of silicon. These shifts can be explained by the existence of acceptor- and donor-type surface states near the band edge of the conduction and valence bands, respectively, as reported by Gray and Brown (19) for the thermal grown oxide film. With decreasing temperature down to liquid nitrogen temperature the acceptor-type states above the room temperature Fermi level are filled with electrons so as to make the surface of the silicon more p-type. The amount of scatter in the flat band voltages at room temperature is in the range $0 \sim 0.5$V for n-type silicon and $0.4 \sim 3.0$V for p-type. These positive flat band voltages imply that negative charges of $10^9 \sim 10^{11}$ electron charges/cm^2 exist either at the Si-Al_2O_3 interface or within the Al_2O_3 film. The origin of the negative charge has been explained in terms of the existence of negative ions in the Al_2O_3 film (10), but the negative charge reported here is believed to be due to electrons, as will be discussed later.

The MAS structure exhibited an interesting behavior in that the C-V curves shifted in the positive direction after application of voltages higher than a critical voltage, below which the C-V curves are very stable and reproducible. This positive shift occurred independently of the polarity and type of the bias, such as +d.c., −d.c., a.c., and pulse. Figures 2(a) and 2(b) show the effects of positive and negative bias, respectively, applied to the metal electrode on the C-V

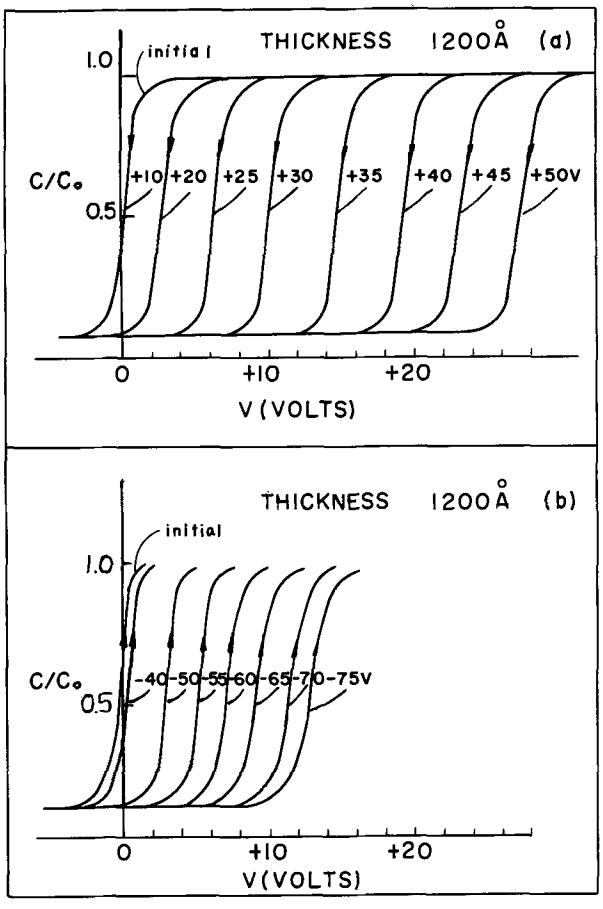

Fig. 2. Capacitance-voltage characteristics after application of various voltages to the Al electrode at room temperature for 1 min: (a) the effect of positive bias; (b) the effect of negative bias.

characteristics of the MAS structure with an Al_2O_3 film of 1200Å in thickness. These curves were taken after application of the bias indicated in the figures at room temperature for 1 min. Figure 3 shows the voltage shifts *vs.* the applied bias, where the critical voltages for the negative and positive bias were +15 and −40V, respectively. With positive bias, voltage shifts continue to increase linearly with applied bias until dielectric breakdown occurs, while with negative voltage linear positive shifts above the negative critical voltage followed by a decrease of the positive shifts are observed. This decrease is always accompanied by increasing current through the aluminum oxide film, which will be discussed later. Such positive shifts were also observed at liquid nitrogen temperature as shown

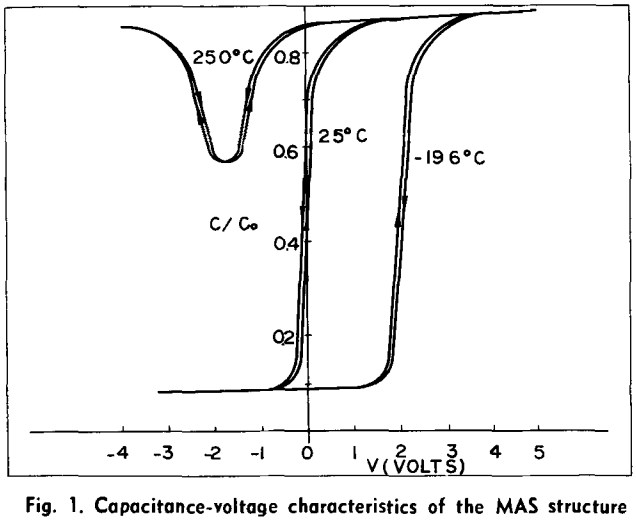

Fig. 1. Capacitance-voltage characteristics of the MAS structure at −196°, 25°, and 256°C, 3 ohm-cm n-type silicon substrate.

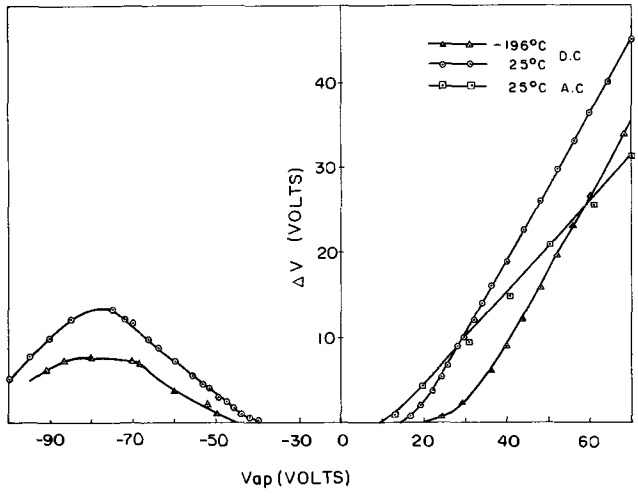

Fig. 3. Relationship between positive shift ΔV and applied voltage (d.c. and a.c., 50 Hz) at room and liquid nitrogen temperature. A-C bias shows peak value; initial flat band voltage is +0.2V.

in Fig. 3, but the lower the temperature, the higher are the critical voltages.

Figure 4 shows the change in the positive shifts when the negative bias is applied to the MAS structure after the positive shifts caused by the positive bias, and when positive bias is applied after the positive shifts by the negative bias. This means that the shifted voltages are kept constant to the same values when the voltage is reversed.

The time dependence of the positive shifts in the C-V characteristics of a typical sample with a 1200Å aluminum oxide film at room temperature for bias values of +40 and −60V is shown in Fig. 5. Although there seems to be a broad distribution of time constant, saturation was observed about 100 min after the application of the bias in both cases. The decay of the shift was studied as a function of film thickness, temperature, and polarity of the applied bias and the results are shown in Fig. 6 and 7. Figure 6 shows a typical decay curve of the positive shift at room temperature, where the shift was caused by application of +100V for 1 min to the MAS structure with a 2400Å aluminum oxide film. An initial decrease of the shift is followed by a very slow decay, where it takes 10^{14} hr to decay by a half of the shift. Figure 7 shows decay curves of the MAS structure with a 1200Å aluminum oxide film at several temperatures, the shifts of which were caused by the application of positive bias as well as negative bias, where samples having nearly the same values of the shift were used. Apparently the decays consist of two parts; 1, a rapid decay for the first several minutes especially for the samples with the shift caused by a positive bias, which compares with the initial rapid increase of the shift shown in Fig. 5 and has considerably large temperature and polarity dependencies; 2, a subsequent slow decay which is in proportion to the logarithm of time, the temperature dependence of which is less sensitive than that of the rapid decay and the slope of which is larger for the positive bias than the negative bias.

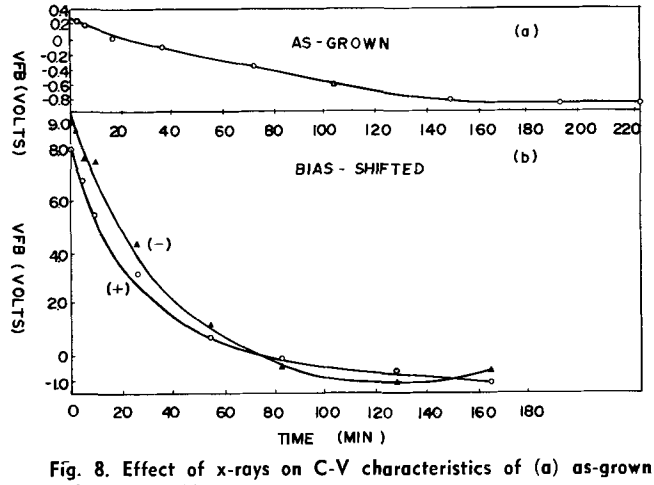

Fig. 8. Effect of x-rays on C-V characteristics of (a) as-grown and (b) shifted MAS structure.

and the shifted one, respectively, where x-rays from a copper target tube operated at 25 kV and 2 mA were irradiated through the aluminum electrode at a distance of 5 cm. No difference of the decay constants for the shift by positive bias and by negative bias was observed. Logarithm of flat-band voltage *vs.* radiation time gave a straight line, indicating exponential decay. The shapes of the C-V curves before and after irradiation were unchanged and an MAS structure which had been returned to the initial state by irradiation with x-rays or an electron beam showed the same positive shift on application of bias greater than the critical voltage as it did in the first place.

In addition to the large positive shifts for the MAS structure, a very slight C-V hysteresis of the order of 0.05V was observed, as shown in Fig. 1, which at room temperature occurred in the same direction of shift as that due to ion migration or polarization, but in the opposite direction at liquid nitrogen temperature. This was also observed on the positive shifted C-V curve with the same order of the hysteresis, that is, this is independent of the positive shift.

A time dependence of the I-V characteristics of the MAS structure was observed. When the applied voltage exceeds the critical voltage above which the positive shift of the C-V curve occurs, the current through the aluminum oxide film decreases gradually for 15 min or longer, then reaches a steady state. An additional I-V measurement of this MAS structure gave lower currents than the previous ones regardless of the polarity. Below the critical voltage, neither a time dependence nor a polarity dependence of the I-V characteristic was observed with ohmic currents in the picoampere range.

Figure 9 shows a typical I-V characteristic of the MAS structure with a 1400Å aluminum oxide film for positive and negative bias, where each point indicates the current measured 20 min after application of the bias. At higher voltages than the critical voltage, the current increases exponentially with the square root of the applied voltage over several decades of current.

The temperature dependence of the current through aluminum oxide films is shown in Fig. 10 and 11.

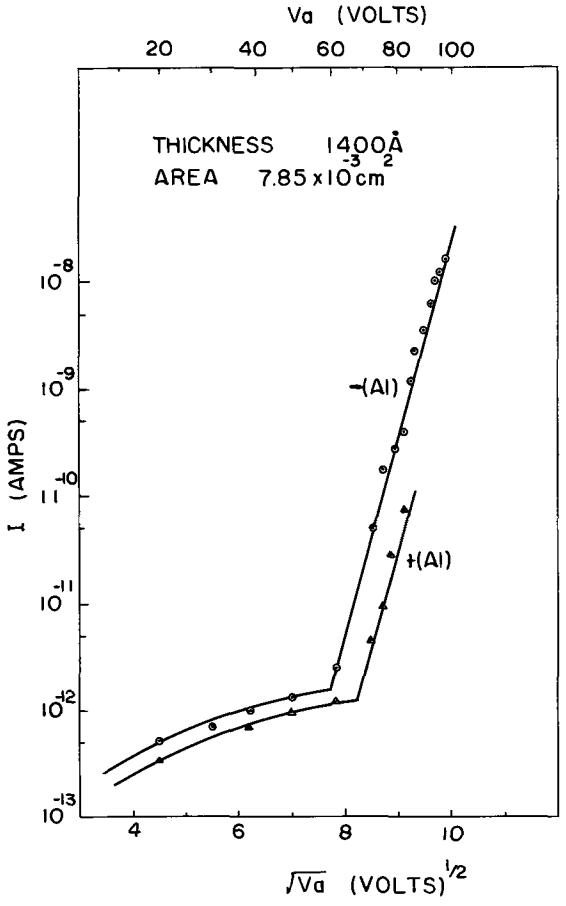

Fig. 9. Current *vs.* square root of applied voltage for both polarities at room temperature for MAS structure with 1400Å aluminum oxide film and electrode area of 7.85×10^{-3} cm^2. Positive bias is applied after measurement of I-V characteristic with negative bias.

Discussion

Positive shifts by bias voltages have been reported in MIS structures with insulators such as phosphosilicate glass (20), silicon nitride (21, 22), and reactively sputtered aluminum oxide (12) by several workers. Those of the phosphosilicate glass, the silicon nitride, and the aluminum oxide have been explained in terms of polarization of the glass, injection of electrons, and mobile negative ions, respectively. The aluminum oxide in this work shows a different type of positive shift, that is, the positive shifts occur independently of the type and polarity of the applied bias such as +d.c., −d.c., a.c., and pulse, and are observed in the same direction even at liquid nitrogen temperature. This means that these shifts are neither due to ionic transport nor to ionic polarization, but to electronic phenomena. Therefore, the positive shifts of the aluminum oxide are based on a different origin than those for the reactively sputtered aluminum oxide because ionic migration is quite improbable at liquid nitrogen temperature. These shifts can be explained by electron trapping in the aluminum oxide as follows: when a positive bias is applied to the MAS structure, electrons are injected from the semiconductor into the aluminum oxide by tunneling (23) and some of them are trapped in trapping states. This injection needs some energy which results in the critical field as reported in silicon nitride by Deal *et al.* (22). However, when a negative bias is applied, electrons are injected from the metal to the aluminum oxide to cause the positive shifts. Similar explanations have been proposed for sputtered silicon nitride, although the

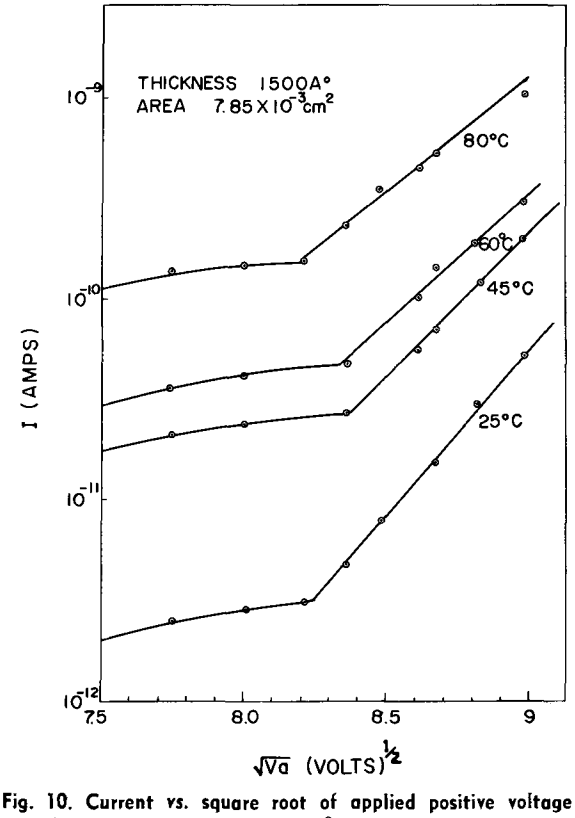

Fig. 10. Current *vs.* square root of applied positive voltage at four different temperatures with 1500Å aluminum oxide.

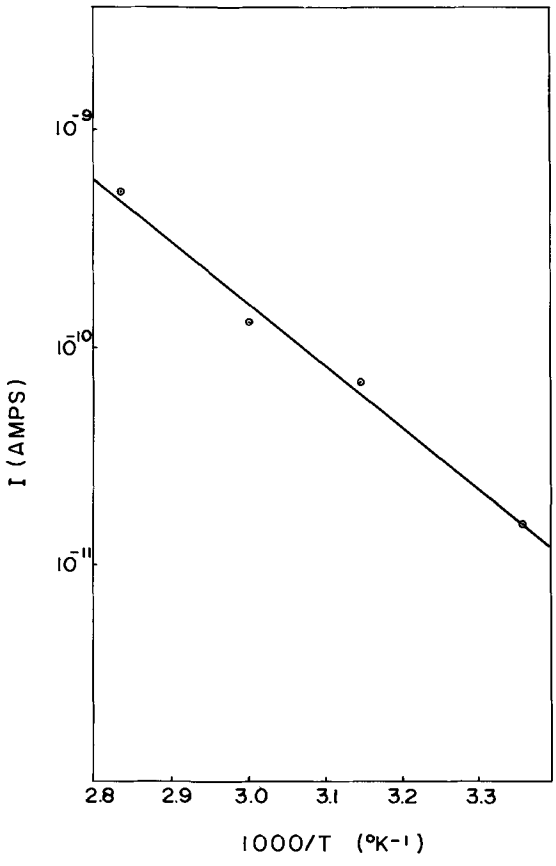

Fig. 11. Current vs. $1/T$ at voltage of + 75V in Fig. 10

carriers injected were holes rather than electrons (24). As the electron trapping near Si-Al_2O_3 interface is efficient, it takes more energy to trap electrons at negative than at positive bias. This model for the positive shifts is supported (*i*) by the fact that the positive shifts by negative bias decay more slowly and have smaller initial decay than those by positive bias as shown in Fig. 7, that is, the trapped electrons near the interface are more easily released than those away from the interface; and (*ii*) by the fact that the trapped electrons by negative bias as well as by positive bias can be excited by radiation such as x-rays and electron beam without introduction of damage. Although several radiation effects have been reported and explained by radiation damage in MIS structures (25), with the excitation of trapped electrons the drift due to the built-in field in the aluminum oxide is responsible for the exponential decay of the positive shifts by x-rays, as shown in Fig. 9.

The decrease of the positive shifts by higher negative bias as shown in Fig. 3 is always accompanied by an exponential increase of the current through the aluminum oxide, so that this is due to the release of trapped electrons by the rapid increase in current. A similar decrease was reported for a MOS structure with three different SiO_2 films (26).

The aluminum oxide film used in this work did not show any distinguishable change in its electrical properties when it was heated below the deposition temperature. Further, under bias temperature stress of the MAS structure, no appreciable change was observed in its flat band voltage below a critical voltage at the temperature of the bias temperature stress.

The critical voltage for the positive shifts is temperature dependent. As shown in Fig. 3, the critical voltages increase with decreasing temperature with negative bias as well as with positive bias because of the increase of the barrier height for injection.

The initial decay of the positive shifts with a strong temperature dependence as shown in Fig. 7 is also explained by the barrier height lowering at elevated temperature. The decay of the positive shifts depends on the distribution of trapped electrons, so the application of higher negative voltage after positive shift by a positive bias produces a redistribution of trapped electrons, that is, the trapped electrons near the interface are easily released to the semiconductor. Therefore, positive shifts thus obtained are more stable than those by the positive bias alone. Similar redistribution occurs when positive shifted MAS structures are exposed to x-rays and electron beams.

On the other hand, the time dependence of I-V characteristics previously mentioned can be interpreted by the change of space charge distribution due to electron injection. This is closely related to the time dependence of the C-V characteristics. This means that the electric field in the aluminum oxide has a spatial distribution due to the electron injection, particularly, near the Si-Al_2O_3 interface. This is one of the reasons why we describe the positive shifts as a function of applied voltage rather than electric field.

The I-V characteristics obtained in this work are very similar to those reported by Sze for silicon nitride (27) due to hopping of thermally excited electrons from one isolated state to another at lower voltages. Assuming the rapid increase in current as internal Schottky or Poole-Frenkel current, a static dielectric constant of 3.4 is obtained which is in approximate agreement with the square of the refractive index of 1.78. Furthermore, from the slope of ln I *vs.* $1/T$, an activation energy of 1.3 eV is obtained which is to be compared with 1.3 and 1.5 eV for Si_3N_4 obtained for the $SiCl_4$-NH_3 system and the SiH_4-NH_3-H_2 system (28), respectively.

The MNOS structure has been extensively investigated for memory devices (29). This MAS structure also has been utilized for the fabrication of a read-only memory (30) consisting of MAS FET's, which can be written by electron injection from the semiconductor as well as from the metal. The amount of current through the Al_2O_3 film is 2 orders smaller than that through Si_3N_4 films and, as can be seen from Fig. 8, both the positive-shifted MAS structure and the as-grown one are very stable between ±20V which corresponds to an electric field of 2×10^6 V/cm.

Conclusions

The properties of aluminum oxide films prepared by the hydrolysis of $AlCl_3$ have been evaluated by using a MAS structure. The positive shifts of the flat band voltages of the MAS structure occur independently of the polarity and type of the applied bias when this is higher than a critical voltage, under which the MAS structure has stable C-V characteristics. These positive shifts can be explained by electron injection and trapping in the aluminum oxide. The trapped electrons persist for a long time before discharge. However, they can be excited by radiation such as x-rays and electron beams without damage to the MAS structure and, as they drift and discharge, the positive shift decays exponentially. These aluminum oxide films are suited for the insulator in nonvolatile field-effect memory devices.
