Solid Ionics—Solid Electrolyte Cells

Takehiko Takahashi* and Osamu Yamamoto

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Furo-Cho, Chikusa-Ku, Nagoya, Japan

ABSTRACT

The characteristics of the solid electrolyte cells $Ag/RbAg_4I_5/Te$ and $Ag/RbAg_4I_5/Se$ have been studied. The open-circuit voltages of these solid electrolyte cells were 0.217V and 0.265V, respectively, at 20°C. These cells could discharge in the temperature range of −75° to 150°C. Only a small polarization was observed at relatively high current density discharge. Diffusion coefficients of Ag in these systems were also evaluated from the time-dependent behavior of the cell voltage as a function of current density.

Although the various types of solid electrolyte cells have been investigated by many authors (1-3), most of them were able to discharge only in the microampere range at room temperature, the reason being the poor conductivity of the electrolyte used. Recently, as higher ionic conductivity solid electrolytes have been found (4-8), a high performance solid electrolyte cell operating in a milliampere range at ambient temperature has been developed.

Previous investigations on solid electrolyte have dealt almost exclusively with the simple compounds like silver halides, the highest conductivity of which was between 10^{-6} and 10^{-5} ohm^{-1} cm^{-1} at room temperature. In recent years, in order to find high ionic conductivity solids, the solid state reaction products of binary and ternary systems have been studied by Takahashi, Bradley and Owens, and Ag_3SI (4), $Ag_2Hg_{0.25}S_{0.5}I_{1.5}$ (5), $Ag_4HgSe_2I_2$ (6), and $RbAg_4I_5$ (7, 8) have been found to have high ionic conductivities at room temperature (Table I).

Accordingly by using these high ionic conductivity solids as electrolytes, it is possible to make an excellent solid electrolyte cell by combining it with a suitable electrode. As silver ions are charge carriers in these compounds, silver is always used for the anode. The cathode material of solid electrolyte cells should have the properties of: (*i*) showing as positive a potential as possible, (*ii*) ease of forming thin film, (*iii*) a low discharge polarization, and (*iv*) discharge product functioning as a silver ion conductor. Requirements *i* and *ii* are necessary for attaining compactness and high voltage of the cell, while requirements *iii* and *iv* are for obtaining a high current density. Takahashi *et al.* (9) reported a solid electrolyte cell, $Ag/Ag_3SI/I_2$, and Argue *et al.* (10) the cell $Ag/RbAg_4I_5/RbI_3$, with cell voltages of 0.67 and 0.66V, respectively, and these cells can discharge at relatively high current density. The ionic conductivity of solids such as Ag_3SI and $RbAg_4I_5$ is relatively unstable in iodine atmosphere, especially at high temperature, and iodine vapor is so highly corrosive for metals, that the cell must be gastight. In this paper a solid electrolyte cell is described in which the vapor pressure of the cathode material is very low over a wide temperature range and the high voltage is maintained during discharge even at a high current density. Results of our search for substances which satisfy the above stated requirements have indicated tellurium and selenium to be excellent. Tellurium is a solid having a very low vapor pressure and high electrical conductivity (2.6 ohm^{-1} cm^{-1} at 20°C) at room temperature and a melting point of 450°C. Furthermore, tellurium is capable of forming a thin film easily by vacuum evaporation. The melting point of selenium is 217°C and the vapor pressure at room temperature is low enough. The electrical conductivity of selenium, 10^{-5} ohm^{-1} cm^{-1} at room temperature, is substantially less than that of tellurium. Selenium can also form a thin film readily by vacuum evaporation. In this paper, the performances of the cell $Ag/RbAg_4I_5/Te$ or Se are described.

Experimental

Preparation of the solid electrolyte, $RbAg_4I_5$.—The solid electrolyte, $RbAg_4I_5$, was prepared according to the method described by Owens and Argue (8). Weighing of 0.8 mole fraction of silver iodide and 0.2 mole fraction of rubidium iodide was followed by mixing and grinding. The mixture was sealed in a glass tube under vacuum, and it was heated at 500°C for 2 hr. Then after being cooled abruptly, it was maintained at 160°C for 15 hr thereby to synthesize $RbAg_4I_5$. The x-ray diffraction pattern of the resulting $RbAg_4I_5$ showed a cubic structure, lattice parameter being 11.0Å at 25°C, the value of which was identical with those in the literature (11, 12). The electrical conductivity measured at 1000 Hz was 1.7×10^{-1} ohm^{-1} cm^{-1} at 25°C. $RbAg_4I_5$ melted incongruently at 235°C.

Table I. Conductivity of ionic conductors at 25°C

Substance	Conductivity at 25°C, ohm^{-1} cm^{-1}
Ag_3SI	1×10^{-2}
$Ag_4HgSe_2I_2$	2×10^{-2}
$Ag_2Hg_{0.25}S_{0.5}I_{1.5}$	7×10^{-2}
$RbAg_4I_5$	2.4×10^{-1}

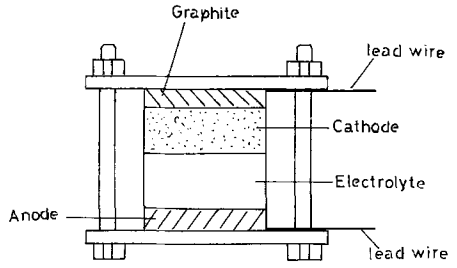

Fig. 1. Schematic diagram of the solid electrolyte cell

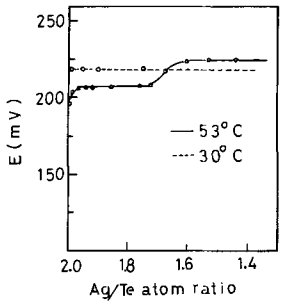

Fig. 2. EMF of the cell $Ag/RbAg_4I_5/Ag\text{-}Te$ vs. ratio of Ag/Te at 30° and 53°C.

Cell structure.—In this experiment, the electrolyte, $RbAg_4I_5$, was placed between the anode which consisted of a tablet of a mixture of silver powder and $RbAg_4I_5$ and the cathode. The cell assembly is shown in Fig. 1. A mixture of 0.6g $RbAg_4I_5$ and 0.3g 200 mesh passed silver powder and 1.2g $RbAg_4I_5$ were stacked in laminar arrangement and pressed into a tablet of 1.2 cm diameter to form anode and electrolyte, respectively. As the cathode material, the mixtures of Te and Ag_2Te (2g:1g), Se and Ag_2Se (1g:2g), Te, Ag_2Te, graphite and $RbAg_4I_5$ (0.3g: 0.1g:0.1g:0.7g) or Se, Ag_2Se, graphite, and $RbAg_4I_5$ (0.3g:0.1g:0.1g:0.7g) were used in the form of tablets pressed at 5 tons/cm^2. The cell was sealed in a vessel together with a silica gel.

Results and Discussion

Open circuit voltage.—The measured open-circuit voltages of the cells

$$Ag/RbAg_4I_5/Te - Ag_2Te \quad (I)$$

$$Ag/RbAg_4I_5/Se - Ag_2Se \quad (II)$$

at different temperatures are shown in Table II. In the silver-tellurium system, in addition to the compound Ag_2Te, an intermediate phase $Ag_{1.66-x}$ Te ($x = 0.03 \sim 0.045$) has been suggested to exist at room temperature by Kracek *et al.* (13).

The cell reaction of cell (I), therefore, may be considered to be either the formation of Ag_2Te or $Ag_{1.66-x}Te$ as represented by the following chemical equation

$$2Ag + Te = Ag_2Te \quad [1]$$

or

$$(1.66 - x)Ag + Te = Ag_{1.66-x}Te \quad [2]$$

In order to clarify the above consideration, the emf of the cell

$$Ag/RbAg_4I_5/Ag\text{-}Te \quad (III)$$

has been determined as a function of the Ag/Te ratio at 30° and 53°C, and the results are shown in Fig. 2 to indicate that, at room temperature, although Ag_2Te is the only compound that exists in the Ag_2Te-Te system, at 53°C, in addition to Ag_2Te, an intermediate phase $Ag_{1.66-x}Te$ is recognized where x is about $0.03 \sim 0.05$, the cell emf of which is 0.207V.

Kiukkola and Wagner (14) calculated the standard molar free energy of formation of α-Ag_2Te, (a high-temperature modification of Ag_2Te) from the measured emf of the cell, $Ag/AgI/Ag_2Te$-Te to be -11.4 kcal/mole at 250°C. This value corresponds to a cell voltage of 248 mV. Further, the emf of the cell, $Ag/AgNO_3$/Ag-Te has been determined at room temperature by Puschin (15) to be about 200 mV. However, no accurate

Table II. Open-circuit voltage of the cell $Ag|RbAg_4I_5|Te$ and $Ag|RbAg_4I_5|Se$

Temp, °C	$Ag\|RbAg_4I_5\|Te$ Cell OCV (V)	$Ag\|RbAg_4I_5\|Se$ Cell OCV (V)
20	0.217	0.265
60	0.219	0.268
100	0.223	0.271

standard molar free energy of formation of β-Ag_2Te (a lower temperature modification of Ag_2Te) has been reported. From the temperature dependence of the standard free energy of formation of β-Ag_2Te calculated by the emf of the cell (I), it follows that

$$2Ag(s) + Te(s) = Ag_2Te(s)$$
$$\Delta F° = -8.47 - 0.0048\,T \text{ kcal}$$
$$\Delta H° = -8.47 \text{ kcal}, \quad \Delta S° = 4.8 \text{ eu} \quad [3]$$

The standard molar entropy of Ag_2Te at 298°K is obtained as

$$S°_{Ag_2Te} = \Delta S° + 2S°_{Ag} + S°_{Te}$$
$$= 4.8 + 2 \times 10.206 + 11.88 = 36.09 \text{ eu} \quad [4]$$

The reaction of cell (II) may be considered to be the formation of Ag_2Se represented by Eq. [5]

$$2Ag + Se = Ag_2Se \quad [5]$$

Kiukkola and Wagner (14) measured the emf of the cell $Ag/AgI/Se\text{-}Ag_2Se$ at high temperature. Using thermodynamic data of α-Ag_2Se and the enthalpy and entropy changes of Ag,Se and Ag_2Se between 298° and 500°K, they calculated that $\Delta F° = -11.94$ kcal, $\Delta H° = -11.38$ kcal, and $\Delta S° = 5.24$ eu at 298°K. Thermodynamic data calculated from our experimental results are as follows

$$2Ag(s) + Se(s) = Ag_2Se(s)$$
$$\Delta F° = -11.18 - 0.00345\,T \text{ kcal}$$
$$\Delta H° = -11.18 \text{ kcal}$$
$$\Delta S° = 3.45 \text{ eu}$$

and the standard molar entropy of Ag_2Se at 298°K is obtained as

$$S°_{Ag_2Se} = \Delta S° + 2S°_{Ag} + S°_{Se}$$
$$= 3.45 + 2 \times 10.206 + 10.0 = 33.86 \text{ eu} \quad [6]$$

Anodic polarization of $Ag/RbAg_4I_5/Ag$.—The solid electrolyte $RbAg_4I_5$ has an ionic conductivity high enough to produce only a very small ohmic potential drop at current densities of the order of milliampere per square centimeter. However, large polarization at the boundary between the electrode and the electrolyte would make the solid electrolyte cell so constructed not usable.

The anodic polarization of the cell, $Ag/RbAg_4I_5/Ag$, was measured using a silver plate reference electrode put in the electrolyte at the cathode side of the cell. It is shown in Fig. 3. As the measurements were carried out with a current interrupter, the measured overvoltage is free from resistance polarization. A plot of logarithm of current density *vs.* overvoltage gives a straight line with slope of about 22 mV at lower current densities. However, above 10 mA/cm^2 at 25°C and 1 mA/cm^2 at 0°C, the overvoltage rapidly increases with current density and tends to increase gradually with time.

Cathode polarization of the cells, $Ag/RbAg_4I_5/Te\text{-}Ag_2Te$ *and* $Ag/RbAg_4I_5/Se\text{-}Ag_2Se$.—The discharge reactions of the above cells are Eq. [1] for the tellurium cathode and Eq. [5] for the selenium cathode, respec-

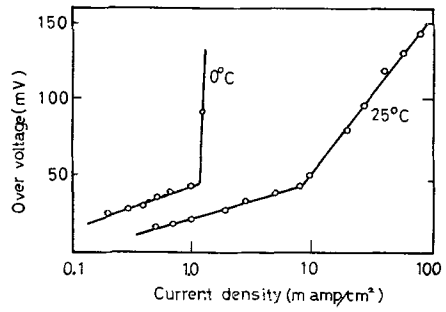

Fig. 3. Anodic polarization of the cell Ag/RbAg$_4$I$_5$/Ag

tively. Accordingly, the reaction product Ag_2Te or Ag_2Se is deposited on the boundary between the electrolyte and the cathode. Therefore, in order to maintain the continuous discharge, silver must move through the reaction product layer, and the transport of silver in Ag_2Te and Ag_2Se may be the rate-determining step of the discharge reaction at higher current drain.

The time dependence of the voltages of the cells, Ag/RbAg$_4$I$_5$/Te-Ag_2Te and Ag/RbAg$_4$I$_5$/Se-Ag_2Se, was measured; results at 25°C are shown in Fig. 4 at various current densities. These curves indicate that the cell voltage decreases linearly with discharge time and the slope increases with current density. Polarization voltages at various temperatures are shown in Fig. 5. These relations also give the straight lines at each temperature and the slope is found to decrease with increasing temperature.

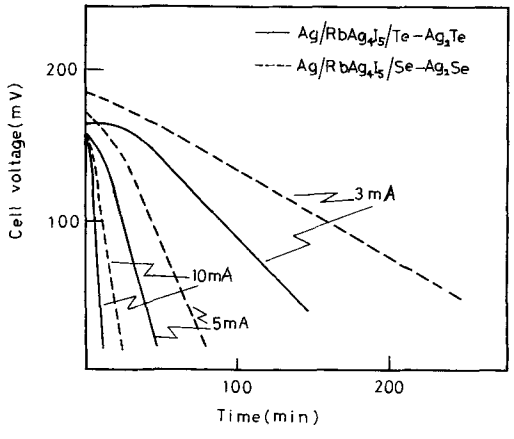

Fig. 4. Voltage *vs.* time of the cells Ag/RbAg$_4$I$_5$/Te-Ag_2Te and Ag/RbAg$_4$I$_5$/Se-Ag_2Se at 25°C.

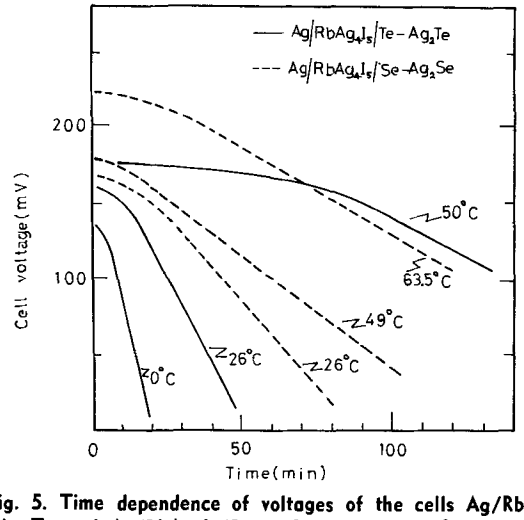

Fig. 5. Time dependence of voltages of the cells Ag/RbAg$_4$I$_5$/Te-Ag_2Te and Ag/RbAg$_4$I$_5$/Se-Ag_2Se at 5 mA/cm^2 constant current discharge.

These curves can be divided into three parts. The initial part corresponds to the rapid decrease of the cell voltage within 1 sec, the second part to the non-linear decrease of it for several minutes, and the third part to the linear decrease of the cell voltage. The analysis of the linear part of the curve has been carried out as follows, considering that the transport of silver in reaction product is the rate-determining step of the discharge reaction.

In order to maintain continuous discharge, silver must move through the reaction product layer. The current density I is given by

$$I = -\frac{eN\mathbf{F}^2}{RT} D_{Ag} \frac{\delta \mu_{Ag}}{\delta x} \qquad [7]$$

where D_{Ag} is the diffusion coefficient of silver in Ag_2Te or Ag_2Se, μ_{Ag} the chemical potential of silver, N the amount of silver/cm^2 in Ag_2Te or Ag_2Se, and x the distance from the electrolyte side of Ag_2Te or Ag_2Se. Integrating Eq. [7] with respect to x, we obtain

$$lI = -\frac{eN\mathbf{F}^2}{RT} D_{Ag} [\mu_{Ag}(x = l) - \mu_{Ag}(x = 0)] = \frac{eN\mathbf{F}}{RT} D_{Ag} \Delta E \qquad [8]$$

where l is the thickness of Ag_2Te or Ag_2Se layer, and ΔE the potential difference in Ag_2Te or Ag_2Se. In the discharge process, if the cell reaction product grows uniformly on the cathode surface obeying Faraday's law

$$l = \frac{mIt}{2\rho \mathbf{F}} \qquad [9]$$

where ρ is the specific gravity of Ag_2Te or Ag_2Se (8.32 for Ag_2Te and 8.0 for Ag_2Se, respectively), m the molecular weight of Ag_2Te or Ag_2Se, and t the discharge time. Inserting Eq. [9] into Eq. [8] and rearranging, one obtains

$$\Delta E = \frac{m}{2\rho \mathbf{F}} \times I^2 t \Big/ \frac{eN\mathbf{F}}{RT} D_{Ag} \qquad [10]$$

and

$$\frac{d\Delta E}{dt} = \frac{m}{2\rho \mathbf{F}} \times I^2 \Big/ \frac{eN\mathbf{F}}{RT} D_{Ag}$$

Thus a plot of $d\Delta E/dt$ *vs.* I^2 should give a straight line with a slope of 3.93 x 10^{-12} (T/D_{Ag}) (V·cm^4/sec·A^2) for the tellurium cathode and 3.13 x 10^{-12} (T/D_{Ag}) (V·cm^4/sec·A^2) for the selenium cathode, respectively. This has been confirmed for tellurium at room temperature as shown in Fig. 6. The results substantiate the above concept (Fig. 6). The diffusion coefficients of silver in Ag_2Te and Ag_2Se calculated from the experimental $d\Delta E/dt$ values using Eq. [10] with appropriate value of the slope of Fig. 6 at various temperatures (−15° ~ 120°C) are plotted in Fig. 7 *vs.* the reciprocal of the absolute temperature. The current density in the range of 2-10 mA/cm^2 was used to determine the diffusion coefficient. For

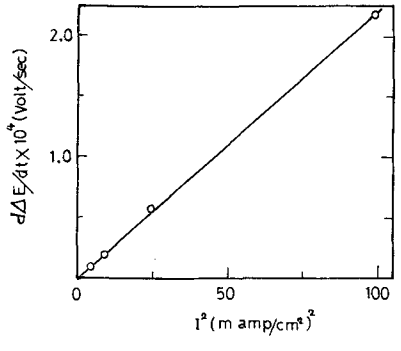

Fig. 6. $d\Delta E/dt$ *vs.* I^2 of the cell Ag/RbAg$_4$I$_5$/Te-Ag_2Te at 26°C

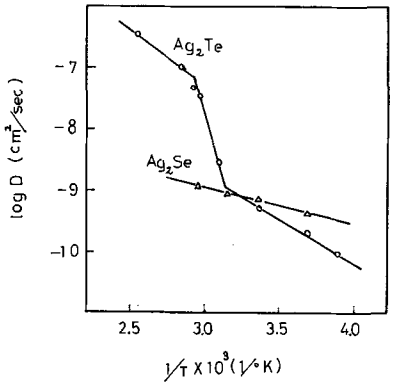

Fig. 7. Temperature dependence of diffusion coefficient of Ag in Ag_2Te and Ag_2Se.

β-Ag_2Se a good straight line is shown, but for β-Ag_2Te, a jump of the diffusion coefficient is indicated at near 50°C. This jump can be attributed to the intermediate compound $Ag_{1.66-x}Te$, described earlier in the paper. It exists above 50°C in the Ag-Te system. Silver will have a higher diffusion coefficient in $Ag_{1.66-x}Te$ than in Ag_2Te.

Characteristics of the cells $Ag/RbAg_4I_5/RbAg_4I_5$-Te *and* $Ag/RbAg_4I_5/RbAg_4I_5$-Se.—According to the measurement of the cathodic polarization, it was found that the potential drop in the cell reaction product Ag_2Te or Ag_2Se became a dominant factor for the cell voltage in long time current drain. For practical use, the mixture of tellurium and the electrolyte $RbAg_4I_5$, and selenium and the electrolyte $RbAg_4I_5$ should be used as the cathode in order to enlarge the surface area on which the charge transfer reactions would take place.

A mixture of 0.7g $RbAg_4I_5$, 0.5g tellurium, 0.1g Ag_2Te, and 0.1g graphite was pressed into a tablet 1.2 cm in diameter to form the cathode. The cell so constructed had an internal resistance of 1 ohm at room temperature. Typical discharge curves are shown in Fig. 8 together with the case of the selenium base cathode.

The cell with the tellurium-base cathode was somewhat rechargeable. In Fig. 9, typical charge and discharge curves are shown. The cell voltage increases rapidly to about 600 mV at overcharge. With charge-discharge cycling, the cell performance deteriorated, for example, in ten cycles, the cell capacity was reduced to about two-thirds of the initial value.

One advantage of this type of solid electrolyte cell is to have the wide range of operating temperature, theoretically, up to 235°C, the melting point of the electrolyte $RbAg_4I_5$. If AgI is used in place of the

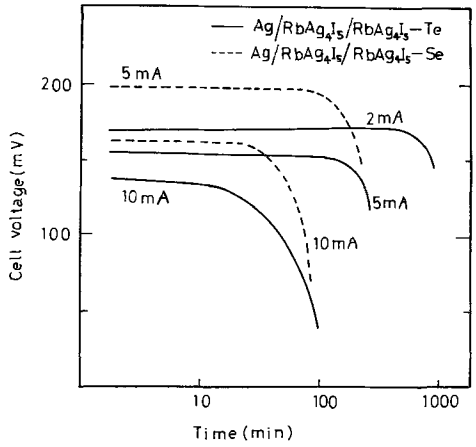

Fig. 8. Time dependence of voltage of the cells $Ag/RbAg_4I_5/RbAg_4I_5$-Te and $Ag/RbAg_4I_5/RbAg_4I_5$-Se.

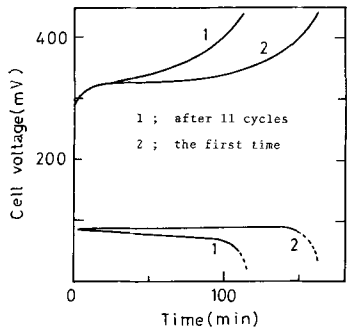

Fig. 9. Charge and discharge curves of the cell $Ag/RbAg_4I_5/RbAg_4I_5$-Te at a current density of 10 mA/cm² at 25°C.

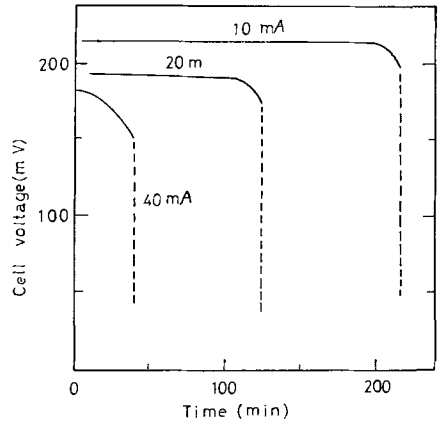

Fig. 10. Time dependence of voltage of the cell $Ag/RbAg_4I_5/RbAg_4I_5$-Te at 150°C.

electrolyte $RbAg_4I_5$, the cell can be operated up to 350°C at which the eutectic mixture of tellurium and Ag_2Te melts. However, this type of cell cannot be discharged at high current density below 147°C, because at this temperature silver iodide transforms from high ionic conductivity α-modification to low ionic conductivity β-modification. For example, the discharge curves at 150°C are shown in Fig. 10. At high temperature, there is no appreciable polarization even at a current density of 10 mA/cm². On the other hand, at −75°C, when it is discharged with a current density of 0.1 mA/cm², the cell voltage becomes 90 mV.

Conclusion

Although the solid electrolyte cells, $Ag/RbAg_4I_5/Te$, and $Ag/RbAg_4I_5/Se$ exhibit a lower open-circuit voltage than a cell in which halogen is used as the cathode material, the cell of this type is capable of discharging with a current density of several milliamperes per square centimeter even at room temperature. Tellurium and selenium can be used as cathode materials up to 350° and 217°C (their respective melting points) and fully gastight cells can be readily fabricated.

When tellurium is used as cathode, the thin film cathode can be formed in a simple manner by vacuum evaporation, so that the entire cell can be made extremely thin.

Sulfur or oxygen cannot be used conveniently as the cathode material instead of tellurium or selenium, since Ag diffusion through the cell reaction product, Ag_2S or Ag_2O, is very low at room temperature. As a result, characteristics of the cell are greatly inferior to that of tellurium or selenium at room temperature.

The Products of the Anodic Oxidation of an Iron Electrode in Alkaline Solution

H. Graham Silver and Elfriede Lekas

Bayside Research Center of General Telephone & Electronics Laboratories, Inc., Bayside, New York

ABSTRACT

X-ray diffraction patterns have been recorded of the surface of an activated iron electrode during anodic oxidation in 30% KOH. At the end of the first plateau (−0.8V relative to a Hg/HgO reference electrode), only α-Fe and $Fe(OH)_2$ are detected. At the end of the second plateau (0.0V), α-Fe and δ-FeO(OH) are detected on the first discharge. On subsequent discharges, a gradual conversion to α-Fe and Fe_3O_4 is observed. In 30% KOH saturated with LiOH, α-Fe and Fe_3O_4 are detected at the end of the second plateau on the first and subsequent cycles.

The anodic discharge of a fully charged iron electrode in alkaline solutions (*e.g.*, 5*N* KOH) occurs at two discrete voltage levels. The first at −0.85V *vs.* Hg/HgO corresponds to the conversion of metallic iron to $Fe(OH)_2$ (1, 2). However, the nature of the products formed during the second anodic process at −0.65V is contradictory, various workers regarding this process as the conversion of metallic iron to $Fe(OH)_3$ (3) or the oxidation of $Fe(OH)_2$ to Fe_2O_3 (2) or $Fe(OH)_3$ (4, 5).

In more recent studies of the products of the anodic oxidation of an iron electrode in alkaline solution, x-ray diffraction patterns of the iron electrode surface have been recorded during discharge by *in situ* techniques (6, 7). Well-defined diffraction peaks for $Fe(OH)_2$ during anodic discharge at −0.8V *vs.* Hg/HgO along the first plateau are reported. However, once again, the nature of the products of the second anodic process is still unclear. One group of workers reports that the major oxidized phase generated at the end of the second plateau (about −0.3V) is Fe_3O_4 (6). Another group presents strong evidence for the formation of δ-FeO(OH), and not Fe_3O_4, on the lower plateau (7).

As a result of these contradictory observations, a careful re-examination of the chemical compounds generated on the surface of an iron electrode during anodic oxidation in alkaline solution, has been undertaken using x-ray diffraction techniques.

Experimental

A carbonyl iron electrode 2 x 2 x 0.025 in. and weight ~5g was cut from a carbonyl iron plaque obtained from Sylvania Electronic Components, Emporium, Pennsylvania. After the four corners of the electrode had been trimmed in order to enable it to fit into a Teflon ring of diameter 2.25 in., it was activated[1] and charged at 0.5A for 3 hr in 30% KOH electrolyte using a nickel counter electrode. The iron electrode was then slipped into the Teflon ring, which was attached in the vertical position to the rotatable wheel of a modification of a specially designed sample holder (8, 9). The lower half of the electrode was immersed in 30% KOH, and, as the wheel rotated at ¼ rev sec^{-1}, a thin film of electrolyte at room temperature was constantly maintained over the upper surface of the electrode, which was exposed to air.

An x-ray beam produced by a Siemens Kristalloflex 4 constant potential generator, utilizing Cu radiation at 35 kV and 18 mA, was directed at this exposed upper surface and the intensity of the reflected radiation measured, after it had passed through a LiF monochromator, into a Geiger counter detector. Excellent peak to background diffraction patterns were thus obtained. A 4° prescatter slit and 1° receiving slit were used in the monochromator and an angular range of 10°-75° (2θ) was recorded using goniometer scan speeds of ¼° and 1° min^{-1}. The resulting x-ray diffraction pattern was then compared with the x-ray patterns listed in the ASTM powder diffraction data file (10).

The electrode was removed from the Teflon ring, again charged at 0.5A for 3 hr in 30% KOH and then discharged to the end of (*a*) the first plateau (−0.8V *vs.* Hg/HgO reference) and (*b*) the second plateau (0V *vs.* Hg/HgO reference) at a discharge current of 0.2A, at which points x-ray diffraction patterns were again recorded, as described previously. The iron electrode was then repeatedly charged and discharged to the end of the second plateau, x-ray diffraction patterns being recorded after each cycle for the completely discharged state. The whole procedure was repeated using, as the cycling electrolyte, 30% KOH saturated with LiOH and the results of the two series of runs compared.

For the rotating iron electrode technique here described, there is the possibility that atmospheric oxy-

[1] Ten minutes in 1*N* H_2SO_4, rinse > 3 min in cold, running, distilled water, then 1 hr in 100 ml of a solution of 32g S dissolved in 1 liter 30% KOH with occasional agitation.

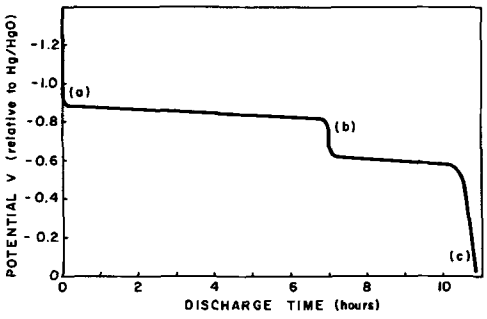

Fig. 1. Discharge curve for an iron electrode vs. a Hg/HgO reference electrode in 30% KOH.

gen could react with that section of the wetted iron surface exposed to the air, to form a surface oxide. However, previous observations (7) indicated that this does not occur, as was fully borne out in the present work. For example, no changes were observed in the products of the anodic oxidation of an iron electrode discharged to the end of the first plateau (−0.8V *vs.* Hg/HgO reference) even after leaving the electrode rotating, but constantly covered with the thin film of electrolyte, for over 24 hr. However, care was taken not to remove an iron electrode unnecessarily, at any point during its charge/discharge cycle, from the alkaline electrolyte and leave it exposed to the atmosphere, except for the few seconds when transfer from the cycling apparatus to the x-ray sample holder was affected.

Moreover, although fresh electrolyte was used each day for all the experimental procedures described, it was found that the use of 30% KOH, which had been left exposed to the atmosphere for over a week and had absorbed considerable CO_2, did not produce results at variance with those to be reported. The presence of dissolved carbonate in the alkaline electrolyte apparently did not affect the products of the anodic oxidation of the iron electrode.

Results and Discussion

A typical discharge curve of the potential of the iron electrode discharged at 0.2A (measured against a Hg/HgO reference electrode) in 30% KOH, is shown in Fig. 1. X-ray diffraction patterns were recorded at points a, b, and c, as well as of the uncharged electrode. The lines are broad in some cases possibly due to small crystallite size. From an analysis of these x-ray diffraction patterns, a definitive identification of the compounds generated on the electrode at these points, was made and is shown in Table I. The experimental results are shown in Table II together with the ASTM standard lines for α-Fe, $Fe(OH)_2$, δ-FeO(OH), and Fe_3O_4 for comparison.

The uncharged electrode, whether activated or unactivated, gave an x-ray diffraction pattern which corresponded to that of α-Fe as listed in the ASTM file. Moreover, no reflections due to a sulfide of iron were detected on the surface of the uncycled freshly activated iron electrode, even though the latter had turned black.

The freshly charged iron electrode (point a) always produced an x-ray diffraction pattern characteristic of α-Fe. Occasionally, after cycling the electrode back and forth over the first plateau, very weak lines were observed in the charged state, which were attributed

to traces of $Fe(OH)_2$. At the end of the first plateau (point b), only the diffraction patterns due to $Fe(OH)_2$ and α-Fe were observed, as shown in Fig. 2.

Ample evidence was accumulated with this and other electrodes prepared, activated and cycled in the same manner, that, on the first discharge of the iron electrode to the end of the second plateau (point c), δ-FeO(OH) was always formed (7). However, on subsequent cycles, a gradual conversion to Fe_3O_4 was observed to occur, the x-ray diffraction patterns of both compounds being detected simultaneously. Finally, after 9 or 10 cycles, only the diffraction pattern of Fe_3O_4 was observed (6). The series of changes is shown in Fig. 3.

Moreover, if an electrode, which had been discharged once to the end of the second plateau (point c), was then stored in a covered container of 30% KOH for several days, there was an aging process, which apparently converted the δ-FeO(OH) to Fe_3O_4. The aging process, which is a chemical reaction taking between 5 and 6 days for completion, involves a partial reduction of the ferric ion to ferrous ion and may be expressed as follows

$$Fe^\circ + 8FeO(OH) = 3Fe_3O_4 + 4H_2O$$

On electrochemically reducing the δ-FeO(OH) during the charging process, Fe_3O_4 is stated to be the first reduction product formed on the way through $Fe(OH)_2$

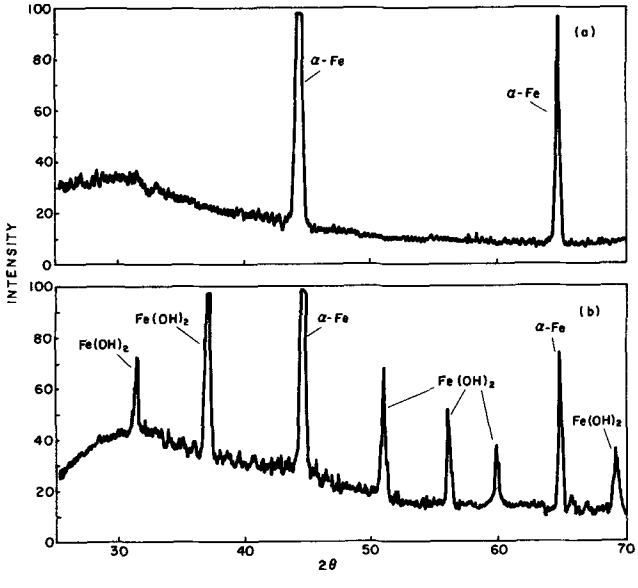

Fig. 2. X-ray diffraction patterns of activated iron electrode: (a) fully charged electrode (point a on discharge curve in Fig. 1); (b) electrode discharged to end of first plateau (point b on discharge curve in Fig. 1).

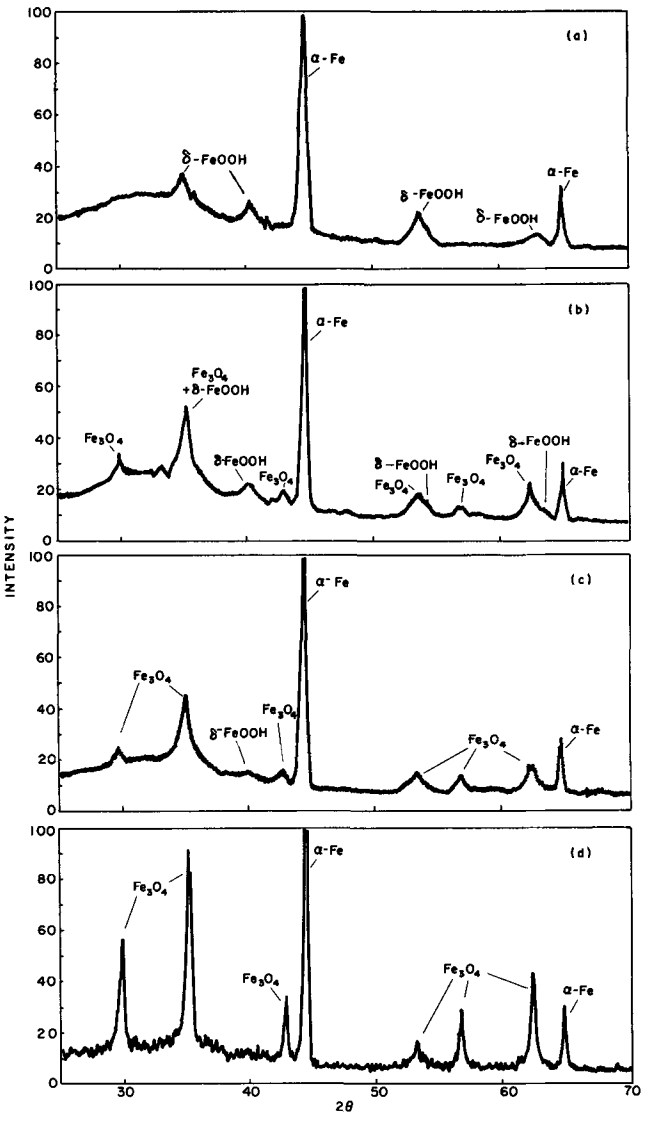

Fig. 3. X-ray diffraction patterns of activated iron electrode: (a) electrode discharged to end of second plateau (point c on discharge curve in Fig. 1), once; (b) electrode discharged to end of second plateau, four times; (c) electrode discharged to end of second plateau, five times; (d) electrode discharged to end of second plateau, ten times.

to metallic α-Fe (11). If all the Fe_3O_4 is not completely reduced during the charging process, then, on subsequent discharge, there is a possibility that, owing to the increasing presence of crystallites of Fe_3O_4, the $Fe(OH)_2$ will gradually cease to oxidize completely to the +3 state, *i.e.*, to δ-FeO(OH). The oxidation process will halt when two out of three Fe^{2+} ions have been converted to the Fe^{3+} ion, *i.e.*, to Fe_3O_4.

On discharging an electrode at 0.5A from the end of the 1st plateau to the end of the 2nd plateau, *i.e.*, a higher rate discharge, an incomplete oxidation of the carbonyl iron occurred, since mainly α-Fe and $Fe(OH)_2$, but only a trace of Fe_3O_4 or δ-FeO(OH), were detected. Discharges at rates greater than 0.25A always gave incomplete oxidation of the carbonyl iron particles and were never used if a definitive identification of the compounds generated on the 2nd plateau was important. However, in this case, the incompletely oxidized electrode was stored in a covered container of 30% KOH for about a month and periodically re-examined by x-ray diffraction to observe whether changes in the line intensities or in the chemical composition of the surface had occurred. No significant changes were noted, although there was a slight decrease in the α-Fe line intensity and a corresponding increase in the $Fe(OH)_2$ line intensity. This observation is not unexpected since the reaction of Fe with water or OH^- ion in solution to form $Fe(OH)_2$ is thermodynamically possible (12). Thus, it would appear that $Fe(OH)_2$ is quite stable in alkaline solution and does not oxidize readily, since no special precautions were taken to exclude oxygen from the solution and container. This is in complete contrast to laboratory-prepared $Fe(OH)_2$ which, after both washing free of alkali and drying in a nitrogen atmosphere, oxidizes immediately on contact with air, to form a brown product, presumably $Fe_2O_3 \cdot nH_2O$ (13). Moreover, although the domain of stability of $Fe(OH)_2$ is completely included in that of Fe_3O_4 and, in the massive state, it is stated that $Fe(OH)_2$ decomposes spontaneously to a mixture of magnetite and iron (14):

$$4Fe(OH)_2 = Fe_3O_4 + Fe + 4H_2O$$

this does not appear to have occurred in this case.

An iron electrode which had been discharged once to the end of the second plateau (α-Fe and δ-FeO(OH)) and stored in a covered container of 30% KOH for a month, was re-examined by x-ray diffraction and found to have converted, as expected, to α-Fe and Fe_3O_4. The electrode was charged at 0.5A for 9 hr and then discharged at 0.2A to the end of the second plateau. Although the normal discharge time for such an electrode is usually between 12 and 14 hr, the potential of this electrode fell to zero after only 2¼ hr. After two further chargings of 3 hr at 0.5A, the discharge time fell to (a) 1½ hr and (b) ½ hr, and presumably would have fallen to zero after further cycles. An x-ray diffraction pattern of the completely discharged electrode surface was then taken, and only α-Fe was detected with possible traces of Fe_3O_4. Presumably, this inability to build up oxide/hydroxide compounds of iron is the reason for the low capacity and may be caused by a very thin, but electrically, poorly conductive, layer of γ-Fe_2O_3 having formed on the iron particles composing the electrode surface (15-17). The oxides Fe_3O_4 and γ-Fe_2O_3 are known to be structurally closely related (18-20).

From an analysis of the x-ray diffraction patterns obtained with the activated iron electrode cycled in 30% KOH saturated with LiOH, the compounds generated on the electrode at several points along the discharge half-cycle, were identified and are shown in Table III.

Contrary to what was observed for the iron electrode cycled in 30% KOH, Fe_3O_4 was formed on this electrode on the first and subsequent discharges to the end of the second plateau. Even after a 4½ hr overdischarge given to the electrode on reaching 0V *vs.* the Hg/HgO reference electrode, α-Fe and Fe_3O_4 were the only compounds detected. No changes were observed in the x-ray diffraction patterns of the fully discharged electrode surface, after storing the electrode in a covered container of the KOH/LiOH mixed electrolyte for about 20 days. Moreover, no lithium compounds were detected on any of the iron electrodes cycled in the KOH/LiOH electrolyte (21, 22).

Conclusion

An x-ray diffraction study of the surface of an activated iron electrode discharged in 30% KOH to different points along the discharge half-cycle has identified the following phases: charged electrode, α-Fe; end of 1st plateau, α-Fe and $Fe(OH)_2$; end of 2nd plateau (discharged), α-Fe, δ-FeO(OH), or Fe_3O_4. On the first

Table III. Compounds generated on the electrode

Phase	α-Fe	α-Fe $Fe(OH)_2$	α-Fe Fe_3O_4

discharge of the iron electrode to the end of the second plateau, δ-FeO(OH) was always formed. However, on subsequent cycles, a gradual conversion to Fe_3O_4 was observed. The same conversion was observed on aging a once-discharged electrode in the alkaline electrolyte for several days. For an electrode cycled in 30% KOH saturated with LiOH, the following phases were identified: charged electrode, α-Fe; end of 1st plateau, α-Fe and $Fe(OH)_2$; end of 2nd plateau (discharged), α-Fe, Fe_3O_4 (always).

Formation of New Phases during Anodic Dissolution of Zn-Rich Cu-Zn Alloys

Howard W. Pickering

Edgar C. Bain Laboratory for Fundamental Research, United States Steel Corporation, Research Center, Monroeville, Pennsylvania

ABSTRACT

Preferential anodic dissolution of Zn from brass is examined from the point of view of the volume diffusion mechanism. Results from x-ray investigations of partially dissolved γ-brass (Cu 65 a/o (atomic per cent) Zn) and ε-brass [Cu 86 a/o Zn] specimens show the appearance of new, more Cu-rich, intermediate and terminal phases. Gradients in chemical composition also result within individual phases and are always in the direction of copper enrichment. These results indicate that preferential anodic dissolution of Zn from Cu-Zn alloy occurs to a significant extent via interdiffusion of the constituent metals in the alloy. Volume diffusion at 23°C may be operative via excess mono- and divacancies, with divacancy diffusion prevailing at high total vacancy concentrations. A few data are presented on the preferential vaporization of Zn from Cu-Zn alloy.

In previous papers (1, 2) it was concluded from x-ray and electron diffraction investigations that preferential dissolution of Cu from Cu-Au alloy occurs via solid state diffusion of Cu and Au in the alloy. Detection of volume diffusion by diffraction methods generally requires optimum sensitivity, and this may explain why other investigators (3-5) using electron diffraction and photographic film methods have not observed similar effects. This is particularly true in transmission electron diffraction experiments (5) since one necessarily examines a very early stage of dissolution when volume diffusion cannot be very pronounced. At such a stage surface diffusion may play a significant role although this can hardly continue during a longer span of attack.

The present paper, as a continuation of the earlier work, investigates the role of volume diffusion in the preferential dissolution of Zn from Cu-Zn alloy by x-ray diffraction. The analogous process of the preferential vaporization of Zn from the same alloys is also investigated. Preliminary results indicate that the formation of new phases does occur during preferential dissolution of Zn from Cu-Zn alloys (6), as does also the much earlier x-ray data (1934) of Stillwell and Turnipseed (7). Other data of Forty and Humble (8) are in agreement with the occurrence of volume diffusion during dezincification of α-brass.

X-ray investigations are easy to make on partially dissolved Cu-Zn specimens, and the interpretation, although requiring much effort due to the many lines of the Cu-Zn phases, is straightforward. Two features of interest may occur in the diffraction patterns of partially dissolved specimens. Both are indicative of a gradient in the chemical composition of the alloy and as such both are evidence that solid state diffusion

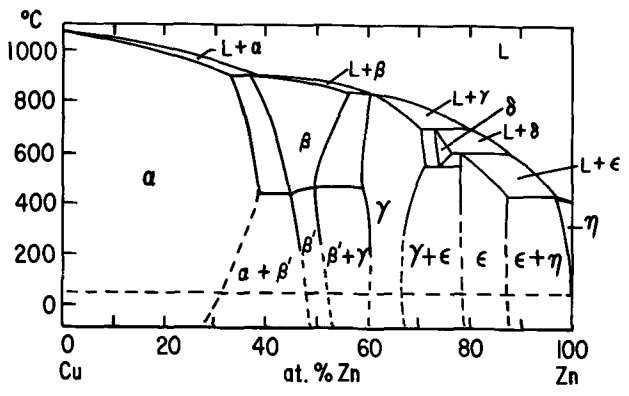

Fig. 1. Phase diagram of the Cu-Zn alloy system

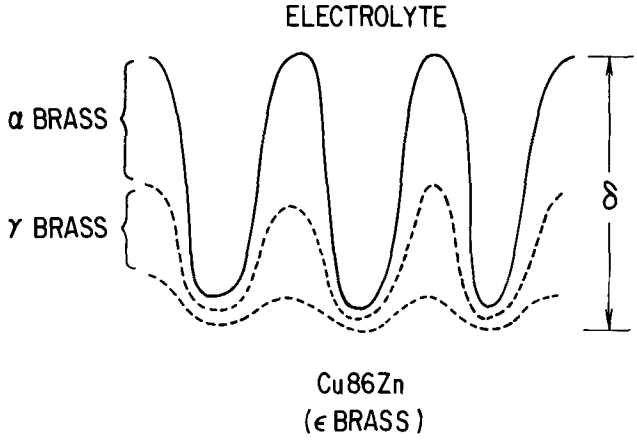

Fig. 2. Diffusion layers after early primary pore formation. With increasing time of dissolution the thickness, δ, over which compositional differences exist becomes increasingly larger than the average diffusion distance ($\lesssim$ one-half the pore wall thickness).

occurs during anodic dissolution of the alloy (see Discussion section).

The first and most clearly recognizable feature is the appearance in the diffraction pattern of new peaks due to the formation of new phases. New phases may form at certain compositions within the gradient if they have a lower free energy than the starting phase. The probable phases at room temperature of the Cu-Zn alloy system are alpha (α), ordered beta (β'), gamma (γ), epsilon (ϵ), and eta (η) phases as shown in Fig. 1.[1] Thus, the preferential dissolution of Zn from ϵ-brass ($\sim$ 76 to 86 a/o Zn) may lead to the formation of γ-, β'-, and α-phases within regions of Zn-depleted alloy. New peaks corresponding to γ-, β'-, and α-phase may then appear in the diffraction pattern. Similarly, preferential dissolution of Zn from γ-brass may result in formation of α- and β'-phases. New peaks due to α and β' would then be observed in the diffraction patterns.

The second feature is a change of the average position of the peaks of a particular phase in the direction of Cu enrichment. This may happen if the lattice parameter within a single phase region varies with composition. This is the method of analysis which was used successfully in the aforementioned x-ray investigations of anodically dissolved Cu-Au alloys.

Since the depth of x-ray penetration is very much greater than the actual solid state diffusion distance, extensive surface roughening is required before sufficient diffracted intensity is obtained from regions of interdiffusion (1); the thickness of the resulting porous layer, δ, approximates the depth of the region of interdiffusion. Very extensive surface roughening has been demonstrated for preferential dissolution of Cu from Cu-Au alloy by polarization capacity measurements (10, 11), and the formation of porous layers have often been reported, especially for Cu-Zn and Cu-Au alloys (12). Surface roughening and the formation of new phases during dissolution of ϵ-brass may occur as illustrated in Fig. 2 if α and γ are the stable, more Cu-rich phases at room temperature.

Analogous to the situation at elevated temperatures (13-17) there may develop in the interdiffusion regions large internal stresses due to local variations in lattice parameter; plastic deformation and recrystallization may then occur in the presence of high excess concentrations of vacancies. Also, porosity at a fine scale may develop giving effectively a fine particle size. Although these developments will affect the diffraction of x-rays, they will not be easily recognizable while there occurs simultaneously the formation of new phases and large changes in composition (lattice parameter) which produce gross changes in the diffracted intensity. Conversely, their presence will not seriously interfere with the identification of new phases or of large changes in lattice parameter of an existing phase.

[1] The β' phase may be unstable at room temperature, in accord with the results of Shinoda and Amado (9) who indicate a eutectoid decomposition into α and γ at about 255°C.

Experimental Procedure

In order to test for the occurrence of Cu and Zn interdiffusion during preferential dissolution of Zn from Cu-Zn alloys, x-ray investigations were carried out on samples of ϵ- and γ-brass anodically dissolved at 23°C. Single-phase alloys of γ- and ϵ-brass were prepared. The alloys were induction melted under helium in a zirconia crucible from starting metals of 99.999% Cu and 99.999% Zn. The compositions of the alloys were determined by chemical analysis to be Cu 65 a/o Zn (Cu 65 Zn) and Cu 86 a/o Zn (Cu 86 Zn). The Cu 65 Zn and Cu 86 Zn ingots were homogenized in small evacuated silica capsules for 2 weeks at 700°C and for 5 weeks at 380°C, respectively. These homogenization treatments produced fully single-phase ϵ- and γ-brass with an average grain diameter of 1-2 mm, as determined by metallographic examination of mechanically polished and etched samples. Visual examination of the silica capsules after the homogenization treatment indicated negligible loss of Zn.

Disk-shaped specimens about 0.1 cm thick were cut from the 1.25 cm (diameter) ingots using a cut-off wheel on the ϵ-brass ingot and a spark cutter on the more brittle γ-brass ingot. Some of the ϵ-brass specimens were annealed in a small evacuated silica capsule at 380°C for 2 hr, and given a light polish with 4/0 emery, but for others only coarser mechanical polishing was done in order to remove cold-worked or Zn-depleted material at the surface. Both procedures gave essentially the same results in the x-ray investigations. The γ-brass specimens were mechanically polished, 320 emery followed with 4/0 emery, to remove Zn-depleted material at the surface resulting from the spark cutting operation.

Nickel-filtered Cu or vanadium-filtered Cr radiation was used to examine the partially dissolved specimens (2). To reduce atmospheric absorption of the soft Cr radiation, the Cr target, specimen and scintillation counter were enclosed in a helium-filled bag. Calibration of the diffractometer stage was made against a gold standard. The arrangement permitted an accuracy of about $\pm 0.01°$ which was better than required. Since the x-rays "reflect" from rather than pass through the specimen, information is obtained on changes in composition which occur in a volume of alloy next to the surface; some variation in the volume of material sampled may occur if the depth of penetration of the x-rays is appreciably influenced by the degree of porosity.

A closed Pyrex cell containing a Pt wire counter-electrode was used to dissolve the specimen at a controlled current density in the range, 1-5 mA/cm^2. Prepurified helium was passed through the cell in order to remove oxygen. A mercury-mercurous sulfate elec-

trode connected to the cell via a Luggin capillary was used to measure the potential of the specimen during dissolution. The potentials are all reported relative to the standard hydrogen electrode (SHE). Electrical contact to the specimen was made with a Teflon-coated Cu rod which has one end slotted and fitted with a tightening screw. The small contact area between the sample and rod was sealed from the environment with lacquer. Contact between the specimen and the electrolyte completed the circuit, so that current flowed during the entire time the specimen was in contact with the electrolyte. At the end of each dissolution period the specimen was withdrawn from the electrolyte, rinsed in water and methanol, and dried prior to x-ray examination. Periodic metallographic examination was performed to observe the formation of porous layers.

Data were obtained with several electrolytes: 1*N* H_2SO_4 and the buffered solutions (pH ~ 5): 1*N* Na_2SO_4-0.05*N* $NaC_2H_3O_2$-0.05*N* $HC_2H_3O_2$, 1*N* $ZnSO_4$-0.05*N* $NaC_2H_3O_2$-0.05*N* $HC_2H_3O_2$, 1*N* $ZnCl_2$-0.05*N* $NaC_2H_3O_2$-0.05*N* $HC_2H_3O_2$ and 0.1*N* $HC_2H_3O_2$-0.1*N* $NaC_2H_3C_2$.

Anodic Dissolution Investigations

X-ray results for ϵ-brass.—The x-ray patterns obtained from specimens of ϵ-brass prior to dissolution show only peaks due to ϵ-brass. After anodic dissolution in all of the electrolytes, new peaks belonging to γ-phase appear in the diffraction patterns. Identification of γ-phase is positive in view of the many peaks of γ which appear in the region $35 < 2\theta < 150°$, and the fact that no superposition due to other Cu-Zn phases occurs in the case of several of these peaks. Table I lists the intensities observed for the various diffracting planes of γ-phase using the patterns obtained after dissolution of ϵ-brass. These data are compiled from x-ray patterns where diffraction due to other phases of Cu-Zn and especially oxides and hydroxides were weak.

Figure 3 shows a segment of three patterns out of 40 obtained at intermittent stages of dissolution at 5 mA/cm² of a single-phase ϵ-brass specimen in the buffered 1*N* Na_2SO_4 electrolyte. The single electrode potential, *E*, of the ϵ-brass specimen was −0.5V. The top pattern, taken prior to dissolution, shows only peaks due to the starting ϵ-phase. After about 20 to 30

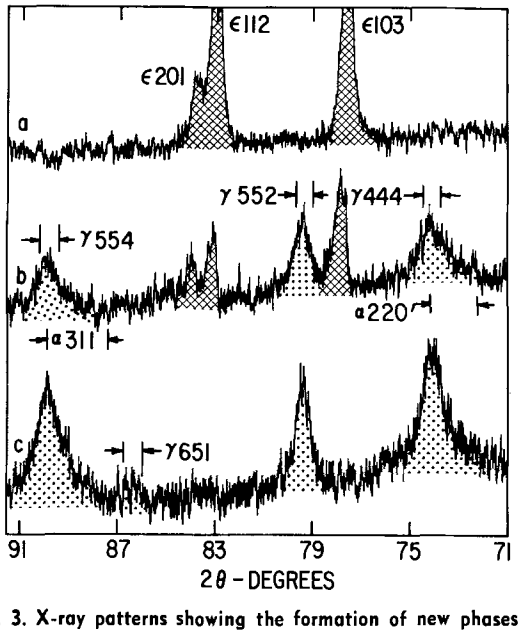

Fig. 3. X-ray patterns showing the formation of new phases during dissolution of ϵ-brass at 5 mA/cm² in buffered 1*N* Na_2SO_4 of pH ~ 5. Cu radiation. The dotted and cross-hatched peaks belong to the newly forming γ- and disappearing ϵ-phases, respectively: (a) prior to dissolution; (b) after dissolution for 67 min (20 C/cm²); and (c) after dissolution for 370 min (110 C/cm²).

Table I. Observed intensities of γ-phase peaks after anodic dissolution of ϵ-brass (5 mA/cm² in 1*N* Na_2SO_4-0.05*N* $HC_2H_3O_2$-0.05*N* $NaC_2H_3O_2$), after vaporization of ϵ-brass (420°C and 5 x 10^{-5} mm Hg) and of a powder sample from Westgren and Phragmen (18). Superscripts indicate γ lines for which other phases may contribute to the total intensity. W, weak; VW, very weak; M, medium; S, strong; VS, very strong; abs, absent.

* α-brass has a line within the 2θ range of this γ-brass line.
‡ β′-brass has a line within the 2θ range of this γ-brass line.
× ZnO has a line within the 2θ range of this γ-brass line.

min at 5 mA/cm² (6 to 9 C/cm²), new peaks due to γ-phase are first detected. The new peaks grow and those due to the starting ϵ-phase diminish in intensity as dissolution continues. The middle pattern taken at an intermediate stage of dissolution shows three of the new γ-peaks (filled with dots), γ554, γ552, and γ444. At a much later time of dissolution shown in the bottom pattern, γ is still the predominant phase, although some α-phase also is indicated as is discussed next.

In the middle pattern the γ554 and γ444 peaks are asymmetrical with increased diffracted intensity on the right side. Both of these regions of increased intensity correspond to 2θ positions of α-phase, *viz.*, α311 and α220. The left and right boundaries of the α311 and α220 2θ regions shown in Fig. 3 correspond to pure Cu and Cu 30 a/o Zn, respectively. It can be seen that symmetric peaks are normal for γ-phase by examining the γ552 peak for which diffraction from neighboring γ640 ($77.3 < 2\theta < 78.0°$) and γ642 ($80.8 < 2\theta < 81.5°$) is negligible and for which no superposition by other phases occurs.

An alternative explanation of the asymmetry is that part or all of the increased intensity of the γ554 and γ444 peaks is due to weakly diffracting γ800 and γ631 at $2\theta \cong 88.5°$ and $2\theta \cong 72.5°$, respectively. This is not supported though by the results at later times of dis-

solution where the diffracted intensity causing the asymmetry is decreased whereas γ-peaks generally are stronger, as seen for example in the bottom pattern of Fig. 3. On the other hand these data are in accord with a shift of the average compositions of α-phase and γ-phase material with time of dissolution toward their Cu-rich boundaries, where both phases have nearly identical 2θ positions, 74.3° for γ444 and α220 and 90.1° for γ554 and α311.

A single-phase ϵ-brass specimen also was dissolved potentiostatically at −455 mV (SHE) and intermittently examined with x-rays. The x-ray results were the same as already described for the amperostatic case (Fig. 3).

Detailed examination of the x-ray patterns shows also that the average position of the peaks of the starting ϵ-phase shifts in the direction of Cu-enrichment of the alloy. This result is observed at relatively early periods of dissolution before the peaks of new phases show. A typical result is shown in Fig. 4 for the {110} line of ϵ-phase. For the largest amount of dissolution used in this series (pattern c of Fig. 4) the average position of the ϵ-peak is at $2\theta \cong 112.1°$ and diffracted intensity extends to $2\theta \cong 113.0°$, compared to the starting average position, $2\theta \cong 111.8°$ (pattern a). A shift to higher 2θ values corresponds to Cu-enrichment of the affected material. An emerging gamma peak, γ541, is just recognizable in pattern c at $2\theta \cong 113.2°$.

All peaks which appeared in the diffraction patterns between $16 < 2\theta < 150°$ were attributable to ϵ-, γ-, or α-brass, except after prolonged dissolution (> 7 hr at 5 mA/cm² or 120 C/cm²) in the buffered electrolytes of pH ≅ 5 when extra, weak peaks due to ZnO appeared.

The presence or absence of ordered β'-brass could not be resolved due to superposition of other Cu-Zn peaks (mainly γ-phase) and the limited amount of data. A detailed comparison of γ-peak intensities as a function of dissolution time would be helpful in this regard, as would also data at longer times when the diffracted intensity from γ-phase has decreased.

X-ray results for γ-brass.—X-ray results for γ-brass show features similar to those in Fig. 3 and 4 for ϵ-brass. After anodic dissolution broad diffracted intensity occurs at the 2θ regions of α-phase accompanied by a decrease in intensity of the γ-peaks. The average position of the new α peaks shifts with increasing amounts of dissolution from a 2θ value corresponding to α brass of high Zn content to a value corresponding to essentially pure Cu. Also shifts in composition within the starting γ-phase are observed at the early stages of dissolution and are in the direction of Cu-enrichment (as in Fig. 4 for the ϵ-brass sample).

X-ray results for two-phase ($\epsilon + \eta$) brass.—X-ray results were also obtained for a two-phase alloy consisting of a small amount of the terminal Zn-rich η-brass in a matrix of ϵ-brass. This is the "as-melted" rather than the homogenized condition of the Cu 86 a/o Zn alloy. X-ray patterns taken after early stages of dissolution in the buffered chloride solution show the η-peaks to fall off rapidly compared to the ϵ-peaks with increasing amounts of dissolution. Then new peaks due to γ-phase are detected (> 6 C/cm² passed), and the x-ray patterns thereafter are similar to those obtained from completely single-phase ϵ-brass specimens as already discussed (Fig. 3 and 4).

Auxiliary investigations.—Cross-sectional metallographic examination of partially dissolved ϵ- and γ-brass specimens (Fig. 5) shows that a poorly reflecting layer forms not unlike the porous layers (1, 2) found in partially dissolved Cu-Au alloys. The layers formed in Cu-Zn specimens apparently also are porous. This was indicated by metallographic examination, by the tendency of the layers to flake and crumble, and by seepage of liquid out of the layer.

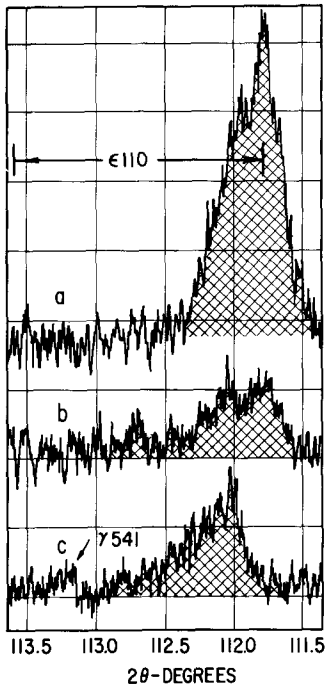

Fig. 4. X-ray diffraction patterns of dissolved ϵ-brass illustrating increased diffracted intensity at the more Cu-rich compositions within the single-phase region of ϵ. Cr. radiation. (a) After 6.7 min at 5 mA/cm² (2 C/cm²) in the buffered Na_2SO_4 solution of pH 5; (b) after 16.7 min (5 C/cm²); (c) after 50.0 min (15 C/cm²).

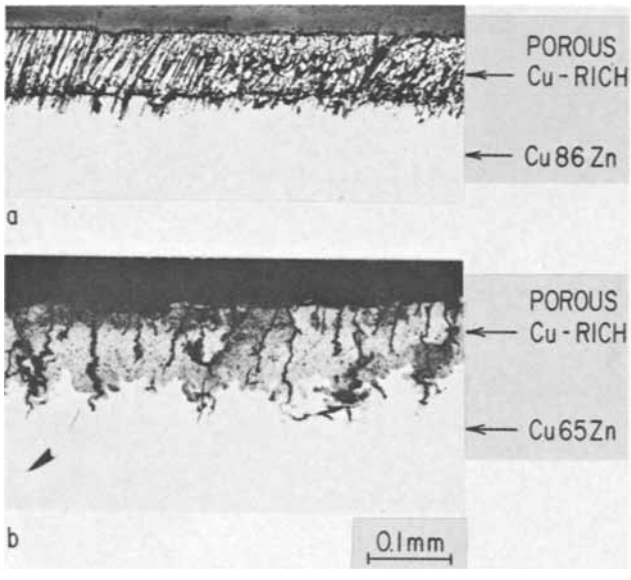

Fig. 5. Cross sections of anodically dissolved ϵ-brass and γ-brass specimens illustrating the porous, Cu-rich layer which forms during preferential dissolution of Zn. Unetched. (a) ϵ-brass after 103 C/cm² passed and (b) γ-brass after 140 C/cm² passed.

The number of moles of Zn dissolved per unit area is $it/2\mathbf{F}$ where i is the current density based on the geometrical surface area, t is the time, and $\mathbf{F}$ is the Faraday constant. The Zn content of a porous layer of depth δ per unit area is $\delta N^{o}_{Zn}/V_m$, where N^{o}_{Zn} is the mole fraction of Zn in the bulk alloy and V_m is the molar volume. If it is assumed that all of the Zn is removed to a depth of δ one has

$$\delta = \frac{it}{2\mathbf{F}} \frac{V_m}{N^{o}_{Zn}}$$

For $V_m \cong 8$ cm³/mole[19] and $it = 103$ and 140 C/cm² for the ϵ- and γ-samples in Fig. 5, one obtains calcu-

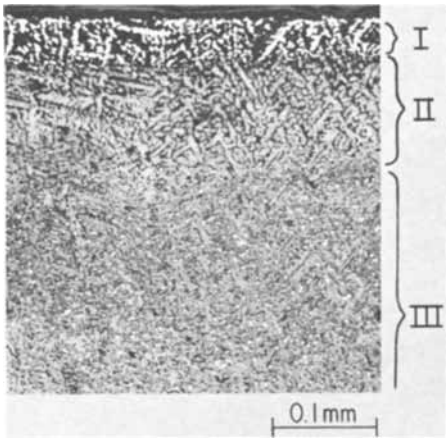

Fig. 6. Cross section of a two-phase sample consisting of $\epsilon + \gamma$-phases after dissolution at 1 mA/cm^2 in 0.1*N* $HC_2H_3O_2$-0.1*N* $NaH_2C_3O_2$ for 15 hr (54 C/cm^2). Layer I, both phases dissolved to an appreciable extent; layer II, only η-phase dissolved; layer III, undissolved two-phase alloy.

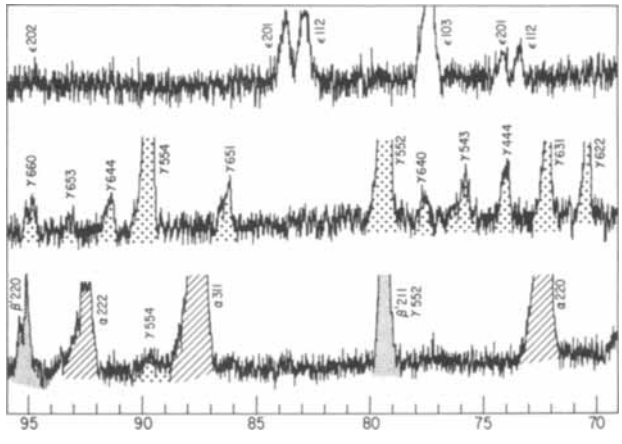

Fig. 7. X-ray diffraction patterns of ϵ-brass after vaporization at 420°C and 5 x 10^{-5} mm Hg. Cu radiation. The peaks with dots, more dense random dots, and cross-hatching belong to the newly forming γ-, β'-, and α-phases, respectively. (a) Prior to vaporization; (b) after ½ hr vaporization; (c) after 10 hr vaporization.

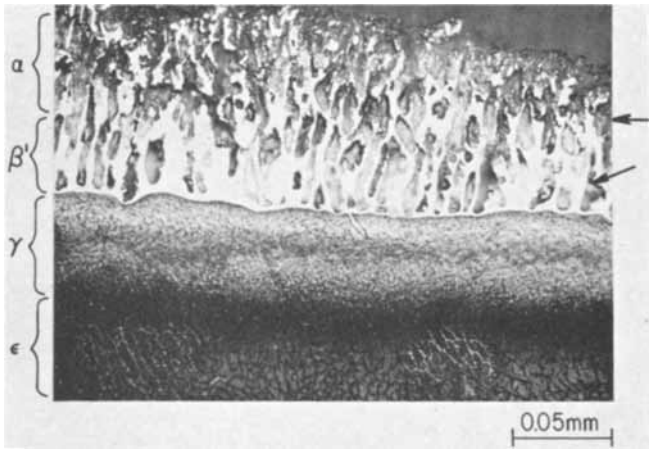

Fig. 8. Cross section of the ϵ-brass specimen used to obtain the diffraction data in Fig. 10. Arrows point to pores. Etched with 5% Nitol followed with saturated picral acid.

lated values of $\delta = 0.05$ and 0.09 mm, respectively. These values are, respectively, about one-half and about equal to the depth measured on the micrographs, and indicate that for ϵ-brass only about one-half and that for γ-brass nearly all of the original Zn within the depth δ has been dissolved. This is in agreement with the x-ray data after large amounts of dissolution which show the porous region of ϵ-brass to consist of γ (and possibly β') and α-brass, and of γ-brass to consist of Cu-rich α-phase.

Metallographic examination of the as-melted two-phase ($\epsilon + \eta$) specimens after dissolution shows that the dispersed η-phase dissolves faster than the matrix ϵ-phase, and to such an extent that η-phase situated beneath the surface also is attacked, probably via interconnection with η-phase originally at the surface. This is seen in the cross section of Fig. 6 which was taken at an advanced stage of dissolution of one of the specimens, and shows a layer (I) of porous alloy at the surface, another layer (II) consisting of undissolved ϵ-phase and holes where η had existed, and furthest in from the surface the as yet completely undissolved two-phase alloy.

Chemical analysis of the electrolyte (*a*) after dissolution of ϵ-brass showed no trace of Cu for current densities in the range of 1 to 5 mA/cm^2, and (*b*) after dissolution of γ-brass showed only a small amount of Cu for even the highest current densities of 5 mA/cm^2. Hence strong preferential dissolution of Zn occurs for both alloys during dissolution at the aforementioned current densities in accord with the x-ray and metallographic data and with the polarization curves for the individual components presented elsewhere (20).

Elevated Temperature Vaporization of Cu-Zn

Similar experiments involving preferential vaporization of Zn from single-phase Cu 86 Zn (ϵ-brass) and Cu 65 Zn (γ-brass) were carried out at 420°C and 5 x 10^{-5} mm Hg. The x-ray results of these experiments are in basic agreement with the voluminous literature on the vaporization of Zn from Cu-Zn alloys. The α-, β'-, and γ-phases are stable at 420°C, as Elam (21) and others have shown. This is illustrated in a sequence of patterns obtained at different stages of vaporization of ϵ-brass in Fig. 7.

Figure 8 shows in cross section that there are four roughly parallel layers next to the surface. These are the α-, β'-, γ-, and ϵ-phases,[2] proceeding inward from the surface according to metallographic and electron microprobe examinations. The α- and β'-layers, although not distinguishable in this micrograph, were distinguishable in the microscope by their color difference. The α- and β'-layers are filled with pores, whereas pore formation is not observed within the γ- and ϵ-layers. The porosity appears in large part to be due to surface roughening.

Figure 9 shows in cross section an originally single phase γ-brass specimen after vaporization at 420°C and 5 x 10^{-5} mm Hg. The γ-β' interface is shown, and the β'-α interface could readily be seen under the microscope. In the α-layer immediately adjacent to the surface, severe porosity has resulted, and in the β'-layer relatively few, very large voids have formed, many of which do not appear connected to the surface. Under the microscope it was seen that α-phase had formed at the surface of all of the porous structure which appeared to be connected to the external surface, in accord with vaporization of Zn from these surfaces; on the other hand α-phase was not observed to have formed at the surface of the large voids within the β'-layer.

Discussion

Volume diffusion during anodic dissolution.—Anodic dissolution which occurs via the interdiffusion of the components in the alloy is consistent with and appears to be the only satisfactory explanation of, the formation of new alloy phases during preferential dissolution of Zn from brass. Neither the often-mentioned ionization-redeposition nor the surface diffusion mechanism appears capable of producing new alloy

[2] This micrograph does not give the proper ratio of the phase widths due to edge effects. γ is relatively thicker than shown.

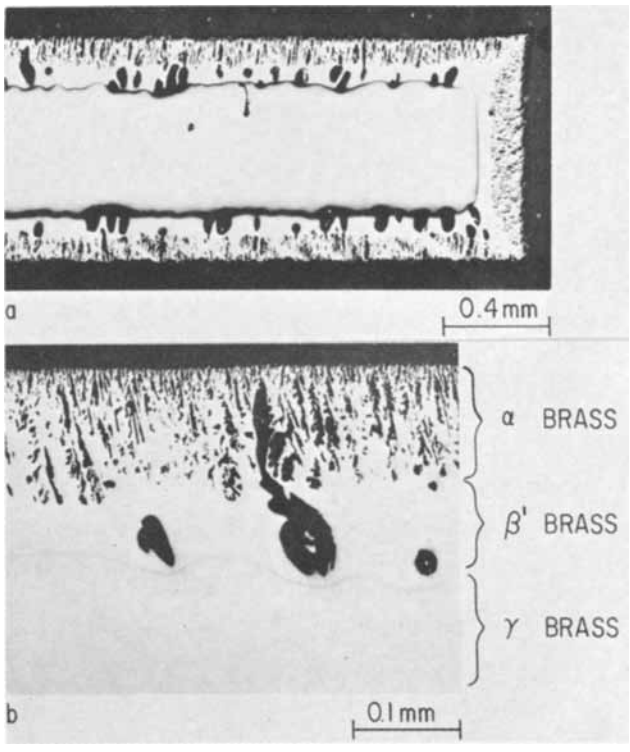

Fig. 9. Cross section of a γ-brass specimen after vaporization at 420°C and 5 x 10^{-5} mm Hg. Etched electrolytically in dilute sulfuric acid.

containing appreciable amounts of the less noble metal. Wagner (22) has calculated the gradients of the potential and of the various ionic species within a pit for anodic dissolution of Cu-Au alloy at the bottom of the pit. From these results he was able to establish that redeposition of Au is thermodynamically impossible on the side walls of the pit, in the absence of "coupling" of the anodic reactions. Rather, he found that there is the tendency for Au to dissolve at the side walls when Au dissolution occurs at the bottom of the pit. There is also the tendency for Cu to dissolve at the side walls irrespective of the presence or absence of the coupling process. Hence, thermodynamic considerations appear to rule out the formation of Cu-Au alloy on the side walls of porous structure by a cathodic deposition process, while anodic dissolution of the alloy occurs at the advancing front of the porous structure. Even without calculations this may be understood when one considers that the potential in the electrolyte for anodic polarization increases with increasing distance into the pit. The same holds for anodically dissolving Cu-Zn alloys.

The accumulation of alloy deposits by migration of adatoms over the surface requires a significant concentration of adatoms of the less noble metal. On polarizing a pure metal anodically, one has to expect a decrease in the number of adatoms in comparison to the state of equilibrium. This is the reverse of the situation for cathodic polarization, which is discussed especially by Bockris and Damjanovic (23). The concentration of adatoms of the less noble metal of a binary alloy, therefore, may be expected to be low at the advancing front of the porous structure where most of the anodic dissolution occurs, and furthermore to be even lower along the side walls in accord with the sign of the potential gradient in the electrolyte. Hence it seems highly unlikely in this case, too, that deposits may form which contain appreciable amounts of the less noble metal by a process involving surface migration of adatoms of the less noble metal.

Volume diffusion at room temperature requires the presence of excess divacancies which may be created

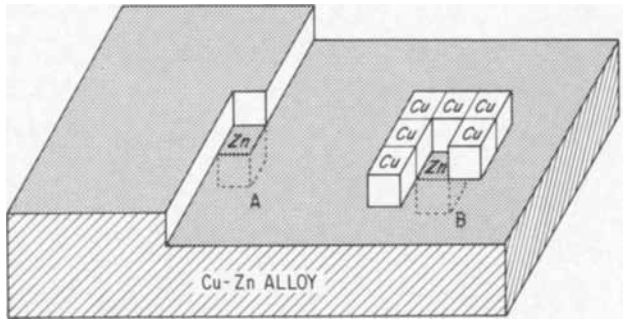

Fig. 10. Variations on the model of vacancy formation offered by Pickering and Wagner (1).

at the surface by a high driving force for dissolution (1). A model for divacancy formation at the surface has been presented which involves ionization from terrace sites of atoms of the less noble metal. It has been questioned whether the operating overvoltages are sufficient to dissolve atoms directly from terrace sites (24). Direct ionization from a terrace site, however, may not be necessary. Sketch A of Fig. 10 shows a Zn atom in a position directly beneath a kink. Dissolution of this Zn atom may occur in the normal kink-ledge-terrace sequence by moving into the neighboring kink position. Schwoebel (25) has considered vacancy formation by a similar rearrangement at a kink. Variation B involves adatoms of the more noble metal (Cu) which may be only momentarily in the positions shown.[3] The designated Zn atom in the layer beneath the adatoms may move up into the "pocket" of the adatoms, thereby creating a vacancy in the underlying atom layer. Divacancies may form similarly, or by the joining of monovacancies which may have a higher mobility in the surface layer(s) than in the bulk alloy.

Using activation energies reported by Ramstetter *et al.* (26) for movement of mono- and divacancies in Cu, it was shown in an earlier work (1) that diffusion of divacancies in Cu is reasonably rapid at room temperature. Monovacancies on the other hand were calculated to be virtually immobile. There is some disagreement in the literature on the activation energy for migration of monovacancies, but even using the lowest value, $E_{\square}^{m} = 0.9$ eV of Simmons and Balluffi (27) one finds that monovacancies are not particularly mobile in copper at 25°C. With $E_{\square}^{m} = 0.9$ eV the diffusivity of monovacancies, $D_{\square}$, in pure copper at 25°C equals 0.9 x 10^{-16} cm²/sec, and for $t = 1000$ s the root-mean-square displacement is only ~40°A. It is a more significant point, however, that at high total concentrations of vacancies the concentration of divacancies exceeds that of monovacancies. Hence, even if monovacancies were highly mobile, interdiffusion still may occur predominantly via the divacancies.

Although data on the mobility of vacancies in Cu-Zn alloys are not available, the greater intrinsic diffusivity of Zn in α brass (the Kirkendall effect) indicates that vacancy migration is faster in α brass than in pure Cu. Also the elevated temperature interdiffusion of Cu and Zn is known to increase with increasing addition of Zn to Cu throughout the α and γ composition range, e.g., as in ref. (13) and (28-30). Hence it seems reasonable to conclude that excess divacancies as well as possibly monovacancies greatly enhance the interdiffusion of Cu and Zn during preferential dissolution of Zn from Cu-Zn alloys at room temperature.

The x-ray results for the two-phase (ε + η) alloy show that the more Zn-rich phase, η, dissolves faster.

[3] The concentration of adatoms of the more noble metal may be quite high if the more noble metal does not dissolve at the potential which prevails during dissolution of the less noble metal

This is in agreement with other data which show that the higher the zinc content of the alloy the lower is the required potential to sustain a given rate of Zn dissolution, (20, 31-33) and with the often-made observation that in two-phase $\alpha + \beta'$ alloys, the more Zn-rich β' phase dissolves faster (34).

The results of investigations on the (preferential) vaporization of Zn from ϵ- and γ-brass were qualitatively the same as for anodic dissolution at room temperature with the exception that for the latter peaks due to β' were not resolved. Also metallographic examination shows severe porosity (Fig. 8, 9) which appears to be the result of both surface roughening and internal void formation. The conclusion that certain voids have formed internally is substantiated by the observation that α-phase does not form at the surfaces of these voids; *i.e.*, if the voids, instead, were connected to the external surface, vaporization accompanied by formation of α-phase would occur from their surfaces as at all external surfaces.

Internal void formation has often been observed as, for example, in the work of Balluffi and co-workers (14, 15) and others (35, 36) during vaporization of Zn from α-brass and during other processes involving interdiffusion of Cu and Zn at higher temperatures ($\gtrsim$700°C). Internal void formation has generally been understood (37-39) as due to the accumulation of excess vacancies, with local supersaturation of vacancies being the result of unequal diffusivities of the component metals (Kirkendall effect).

The occurrence of surface roughening during preferential dissolution or vaporization is in agreement with theoretical considerations by Wagner (40) and by Harrison and Wagner (41). They found that if diffusion (within the alloy) of the reacting species to the surface is rate controlling, there is the tendency for surface roughening to occur, and they and others have shown experimentally the occurrence of surface roughening when this condition is met.

Equilibrium phases.—During the formation of the new phases at room temperature the concentration of vacancies must greatly exceed the equilibrium value in view of the need for a very large vacancy population if appreciable diffusion is to occur in the first place (1). Hence there is the question as to what extent the new phase formed during anodic dissolution are characteristic of the corresponding, equilibrium, room-temperature phases. In the elevated-temperature vaporization of Zn the new phases which form are for all practical purposes identical, or very soon become so, to the equilibrium phases. This can readily be checked since the equilibrium structure can be obtained in annealing experiments. Contrary to the situation at elevated temperatures, an independent determination of the equilibrium phases at room temperature by chemical diffusion is not, practically speaking, possible. Indeed it is for this reason that phase diagrams at room temperature are not available for most alloys.

A change in γ-phase in the 250°-320°C range is indicated in the data of Köster (42) and others (43, 44), although the nature of the change is not clear. More recently Melikhov *et al.* (45) have reported that a change in lattice parameter and crystal structure of γ-phase occurs ~275°C. The data in the present paper do not confirm this.

Concluding Remarks

The most definitive and important result of this investigation is the demonstration of the occurrence of new phases during preferential dissolution of Zn from Zn-rich Cu-Zn alloys. This in turn means that interdiffusion of Cu and Zn in the alloy occurs as an integral part of the mechanism of preferential dissolution of Zn from brass.

Evolving out of these investigations is the interesting possibility that preferential dissolution in conjunction with x-ray diffraction analysis may be used as a tool for determining and roughly mapping out the stable phases of alloy systems at room temperature.

Acknowledgment

The author is especially grateful to Dr. Carl Wagner of the Max Planck Institute für Physikalische Chemie, and Drs. J. C. M. Li, R. A. Oriani, L. S. Darken, and S. S. Brenner and Mr. L. Zwell for valuable discussions and helpful comments. He also wants to acknowledge the skillful assistance of Mr. P. J. Byrne in the anodic dissolution, vaporization, and x-ray phases of the investigation, and of Mr. R. M. Lytle in the metallographic work. All except Professor Wagner are staff members of the E. C. Bain Laboratory for Fundamental Research of the United States Steel Corporation.

Manuscript submitted April 4, 1969; revised manuscript received Aug. 29, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

Characterization of Corrosion Layers on Aluminum by Shifts in the Aluminum and Oxygen X-Ray Emission Bands

P. D. Gigl, G. A. Savanick, and E. W. White

Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania

ABSTRACT

An x-ray emission technique is outlined for the characterization of thin layers of aluminum oxides, aluminum oxyhydroxides, and aluminum hydroxides on aluminum. Shifts in the Al Kβ and O Kα x-ray emission lines of standard compounds are presented and are then used to characterize thin corrosion layers on aluminum.

Characterization of aluminum oxides, aluminum oxyhydroxides, and aluminum hydroxides can present serious problems when they are poorly crystallized and especially when they occur as thin layers on metal substrates. This study was undertaken to establish the feasibility of using shifts in the aluminum K-emission band (Al Kβ) and the oxygen K-emission band (O Kα) to determine the chemistry and short-range structure of various corrosion products on aluminum and its alloys. It has been well established that K-emission bands of the second and third period elements undergo significant changes among various compounds, but consistent rules governing such changes have not been established (1, 2). A major purpose of this investigation is to develop methods for identifying thin Al-O-OH layers on aluminum.

In the case of anhydrous aluminum oxides and alumino silicates it has been shown that Al Kβ shifts depend on the number of oxygens coordinating the Al^{3+} and also on the mean Al-O distance in a given structure (3). More recently a study was undertaken on some of the compounds in the Al-O-OH system using the Al Kβ line but the results were not very definitive (4). The principal result of that study was to establish for the first time the characteristic difference in the Al Kβ from α-Al_2O_3 *vs.* γ-Al_2O_3.

The oxygen K-emission band has been studied in considerable detail by at least three investigators, but their results have not led to a quantitative interpretation of the shifts (5-7). The most recent of these studies indicated that bond character may be the most common factor contributing to changes in the O Kα (7).

Experimental

A set of reference standards for the common Al-O-OH compounds was commercially obtained or synthesized and carefully characterized to confirm their structure and composition. These compounds included: α- and γ-Al_2O_3, boehmite [AlO(OH)], diaspore [AlO(OH)], gibbsite [$Al(OH)_3$], and bayerite [$Al(OH)_3$]. These standards were studied in the form of thin (2-5μ thick layers) deposited from dilute suspension in carbon tetrachloride onto polished surfaces of ¼ in. diameter spectrographic grade carbon rods.

An ARL model EMX electron microprobe operated at 20 keV and 1.5-3.7 x 10^{-8}A specimen current was used to excite and analyze the x-ray spectra. An electron beam diameter of about 100 μm was used in order to minimize specimen damage. A 4-in. radius curved crystal spectrometer, which displays wavelength directly for an ammonium dihydrogen phosphate (ADP) crystal, was used with a thin formvar window flow proportional counter.

An ADP crystal (2d = 10.64Å) was scanned at 0.01 Å/min to diffract the first order Al Kβ line. A clinochlore crystal (2d = 28.39Å) was scanned at 0.0267 Å/min to diffract the oxygen Kα line. The resolution of the ADP is approximately 1000 ($\lambda/\Delta\lambda$) at 8Å and the clinochlore crystal (8) has a resolution of about 500 at 25Å. The Al Kβ peak count rates were in the range of 10-50 counts/sec while the O Kα peak count rates varied from 20 to 50 counts/sec. The peak positions were measured at two-thirds height and could be reproduced within ±0.0026Å for Al Kβ and ±0.0027Å for O Kα. This relatively poor precision in individual measurements of peak positions results from a random error in bringing the specimen to the proper position on the spectrometer circle. By taking the average of eight to ten separate scans, confidence in the mean value approaches ±0.0008Å in each case.

It is imperative to work at quite low specimen currents and large elecrton beam diameters, otherwise the action of the electron beam can induce decomposition of the hydrated films in the time required to record the spectrum. Fortunately, in the microprobe one can monitor the specimen current as an indication of specimen decomposition. A slight decrease in specimen current is a sensitive indication of dehydration. A range of ±0.1 x 10^{-8}A was taken as a safe specimen current variation for a single peak scan.

Results

Typical spectra recorded in this study are reproduced in Fig. 1 and 2. Data on changes in peak position and line widths are shown in Table I. The values are recorded as changes in peak position as measured at 2/3 height and referenced to the peak of α-Al_2O_3.

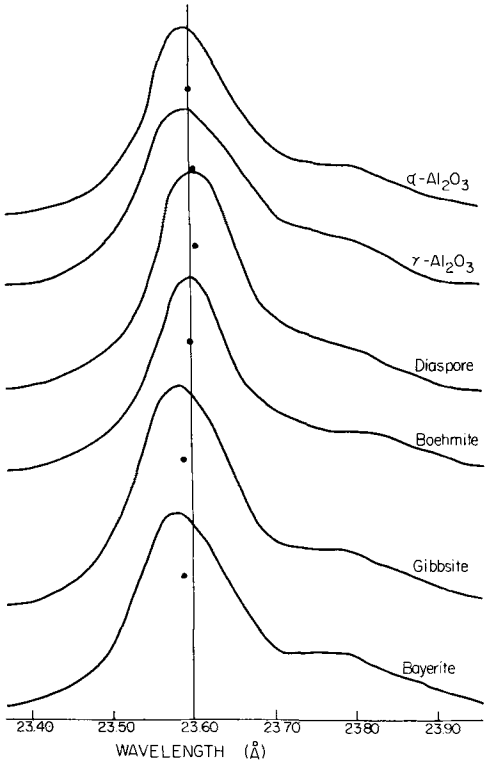

Fig. 1. O Kα emission spectra of the aluminum hydroxides, oxyhydroxides, and oxides given in Table I. Note the wide band widths of γ-Al_2O_3, gibbsite, and bayerite. The 2/3 height peak positions are indicated by the dots in the diagram.

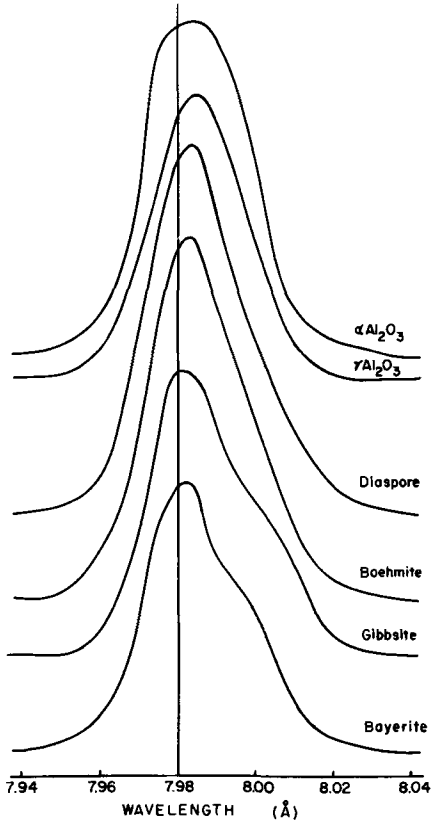

Fig. 2. Al Kβ emission spectra of the same materials shown in Fig. 1. Note the long wavelength shoulder of gibbsite and bayerite.

Figure 1 is a compilation of the O Kα emission bands from the standards. Each band consists of a well-defined main peak with a tail on the longer wavelength side. The γ-alumina and diaspore, corundum and boehmite, gibbsite and bayerite form comparable pairs at similar wavelengths. With corundum as the reference, the O Kα peaks from γ-alumina and diaspore occur at longer wavelengths while gibbsite and bayerite are at shorter wavelengths. The association of greater widths of the O Kα peaks from the $Al(OH)_3$ compounds together with their occurrence at shorter wavelengths is a distinctive feature. γ-alumina also exhibits a broad band, but it falls at significantly longer wavelength than the peaks from $Al(OH)_3$ compounds.

Table I. O Kα and Al Kβ wavelength shifts of the hydroxides, oxyhydroxides, and oxides of aluminum. The wavelength of the band from corundum was used as the reference position.

Standard	Formula	ΔOK (Å × 10⁴)	OKα width 2/3 ht (Å × 10⁴)	ΔAlKβ (Å × 10⁴)	AlKβ width 2/3 ht (Å × 10⁴)
Corundum	α-Al_2O_3	0	91	0	27
γ-Alumina	γ-Al_2O_3	45	107	1	23
Diaspore	AlO(OH)	67	86	−11	21
Boehmite	AlO(OH)	−16	86	−7	25
Gibbsite	$Al(OH)_3$	−99	104	−14	20
Bayerite	$Al(OH)_3$	−120	104	−23	20

Figure 2 is a compilation of the Al Kβ emission bands from the powder standards. The separation of 2/3 peak position is not very pronounced. Another difficulty is the low intensity of the Al Kβ emission. Consequently, a clear-cut distinction cannot be made by position alone. The shape of the curves can be used to distinguish the $Al(OH)_3$ compounds from the lower hydrates by means of the peak shoulder on the long wavelength side of the emission band.

Application to corrosion problems.—Wafers cut from an aluminum ingot were oxidized in hydrothermal cold seal pressure vessels under the conditions shown in Table II. The O Kα and the Al Kβ emission bands were recorded without disturbing or removing the oxide layer. The results are given in Table II and indicate that a complex oxide layer is formed.

In the case of the O Kα peaks there is a definite change of wavelength toward that obtained from the aluminum trihydroxides as the oxidation time is increased. The presence of bayerite [$Al(OH)_3$] was confirmed on sample C by x-ray diffraction, but no crystalline products could be detected on the other samples with thinner oxide layers.

The use of the Al Kβ peak shift is somewhat complicated by the presence of the aluminum substrate. The electron beam voltage must be drastically reduced for the thin oxide coatings in order to limit the Al Kβ emission to just the oxide film. Using this limitation, one can estimate the oxide layer thickness by assuming an electron beam range relation of $R(mg/cm^2) = 0.572\ E^{1.67}$ with E in MeV (9) and a linear loss of maximum electron beam energy (E) with depth in the oxidation layer that is assumed to have a density of 2.5. The maximum electron beam energy is taken as the largest beam potential which does not produce aluminum x-radiation from the aluminum substrate. Sample A, the thinnest oxide layer, was calculated to be about 0.5 μm. Because of the substrate interference and the lower intensity of x-ray emission, the Al Kβ band is not as useful as the O Kα band.

Summary

Shifts in the x-ray emission band positions and shapes from aluminum and especially oxygen for the hydroxides, oxyhydroxides, and oxides of aluminum have been shown to be large enough to be used to differentiate among the six compounds dealt with in this study. Unknown reaction products can be identified through the application of the data contained in Table I and Fig. 1 and 2, provided that the unknown is a single phase of one of the compounds.

In the case of complex corrosion layers consisting of more than one compound, there is a problem of

superposition of emission bands from the various compounds; consequently the layers cannot be positively identified by this method. On the other hand, chemical changes in oxidation layer as thickness increases can be observed quite easily, and trends in the dominating chemistry and short-range structures are indicated by the band positions and shapes. This method can also be extended to study changes in chemistry with depth in stratified oxidation layers. By incrementing the electron beam voltage over a range from about 3 to 40 keV, the maximum depth of x-ray emission will be incremented over a range of about 0.1 to 15 μm. Thus the x-ray emission bands recorded at various keV settings will contain the sum of x-ray emission from all layer components to that depth.

The oxygen band is not as well resolved as reported recently by Chun and Handel (7). However, it is advantageous to use the electron microprobe to study peak shifts because they can be recorded quickly (15 min per scan) on a linear intensity scale. Only a very small sample is required and the method is nondestructive. The ability to study very small areas (5-100 μm in diameter) on a sample surface makes this aspect of microprobe analysis particularly useful in the study of layers of nonuniform thickness. It will also be of considerable value in studies of how layers vary from grain to grain on chemically and structurally complex alloy systems.

The main advantages of this technique is that one can study types of surface layers *in situ* under conditions of relatively high spatial resolution with respect to area and depth. This work stresses the use of the oxygen K-emission band which is essentially free of interference from the metallic substrates. By using the newly introduced clinochlore analyzing crystal one can detect oxide layers as thin as about 25Å (10). In comparison, Auger electron spectroscopy will undoubtedly emerge as a complementary tool, but it is not yet clear as to what its relative importance will be eventually. Certainly the problem of sample decomposition is common to both techniques. Resolution in most Auger spectrometers is such that one could not measure the chemical shift as sensitively as reported here. Finally, by using x-ray instrumentation with a broad electron beam (up to ½ in. diameter), the thickness sensitivity could be improved to detect oxide layers as thin as about 2Å (one atomic layer) which is comparable to that in Auger spectrometry.

As we increase our knowledge of how a material's chemistry and structure influence the wavelength and shape of the x-ray emission bands this method should became more useful as a general method for characterization of surface layers on materials.

Effect of Nickel in Cr-Ni Stainless Steels on the Critical Potential for Stress Corrosion Cracking

H. H. Lee† and H. H. Uhlig*

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Increasing amounts of alloyed Ni in 20% Cr stainless steels improve resistance to stress corrosion cracking in part by shifting to more noble values the critical potentials below which failures are not observed. When the critical potential for any alloy becomes more noble than the corresponding corrosion potential (>26% Ni) the alloys are resistant to $MgCl_2$ at 130°C for >200 hr. Nevertheless, rapid failure of such alloys up to 35% Ni, and probably including 45% as well, can be induced by anodic polarization to a potential which is noble to the corresponding critical value.

Gradual drift of corrosion potentials to more noble values, eventually exceeding the critical potentials, is the likely cause of stress corrosion cracking in practice of <45% Ni stainless steels. Above 45% Ni, structural factors at the surface of plastically deforming alloys become dominant, and failures do not occur regardless of the prevailing potential. Pure nickel is anodic to the 20% Cr-Ni stainless steels and can be used as sacrificial anode to protect them cathodically against stress corrosion cracking. The over-all data support the mechanism of failure based on stress sorption cracking.

The critical potential for stress corrosion cracking (scc) of 18-8 stainless steel in boiling $MgCl_2$ above which failure occurs, but not below, has been reported by Hines and Hoar (1), Barnartt and van Rooyen (2), Smialowski and Rychik (3), and by Uhlig and Cook (4); and similarly in boiling $CaCl_2$ by Brennert (5). Most of the reported values are consistent with the value -0.15 ± 0.01V (SHE) despite variations of chloride concentration, temperature, and applied stress, plus the use of several commercial sources of 18-8 stainless steels in the tests. Uhlig and Cook (4) showed in addition that the critical potential [-0.145V (SHE)] for Type 304 cold-rolled 18-8 stainless steel in $MgCl_2$ boiling at 130°C is shifted by tens of millivolts in the noble direction by salt additions which act as inhibitors of scc, *e.g.*, sodium acetate or sodium nitrate. When the concentration of added salt was sufficient to shift the critical potential to a value more noble than the corrosion potential, cracking did not take place within the maximum test period (200 hr), whereas in the absence of added salts the cracking time was 1 hr or less. Minimum inhibiting concentrations approximated 1% sodium acetate or 2.5% sodium nitrate based on the weight of the $MgCl_2$ solution.

The effect of alloyed Ni to increase resistance of austenitic stainless steels to scc, and to confer essential immunity in amounts greater than 45 w/o (weight per cent) is well known both through laboratory tests and practical service exposures (6, 7). The beneficial effect of nickel has been attributed to higher stacking fault energy (8) leading to tangled rather than coplanar arrays of dislocations when the alloy is plastically deformed, thereby making crack propagation more difficult (9). However, coplanar arrays of dislocations, although seemingly necessary, are not a sufficient condition for scc, as was shown by examination of many different kinds of alloys. Other unknown factors apparently enter the mechanism in addition to dislocation arrangement (9-11).

The results on inhibiting salts cited above suggested that the effect of alloyed Ni may be to shift the critical potential for cracking to more noble values rather than to alter the metallurgical structure of the alloy, or that perhaps both factors are relevant. The present work was undertaken to explore this possibility.

Experimental

A series of stainless steels containing variable Ni was prepared in the laboratory from deoxidized-decarburized electrolytic iron, carbonyl nickel (courtesy International Nickel Company), and high-purity chromium obtained from the Electrometallurgical Company. Two exceptions were the high- and low-nitrogen 20% Ni alloys which were supplied by courtesy of the Naval Research Laboratory and prepared from electrolytic Fe and Cr, and carbonyl Ni. The former alloys were melted in vacuum, the furnace then filled with 1 atm purified N_2 and the melting continued for about 5 to 10 min. The latter step was essential because it had been shown earlier that austenitic pure stainless steels are relatively resistant to scc unless they contain a minimum amount of interstitial nitrogen (12-14). Casting was accomplished by drawing the melt from the N_2 atmosphere into 7 mm diameter Vycor tubing and quenching in water. The ingots were homogenized for 24 hr at 1050°C in argon and then water quenched. They were cold rolled to 0.04 in. (0.016 cm) equivalent to about 80% reduction in thickness. Chemical analyses are given in Table I. The lower N content of the 18.9% Cr, 20.0% Ni alloy was intentional. The lower N content of the 49.4 and 57.8% Ni alloys, on the other hand, compared to other alloys of the series

was probably a result of diminished solubility of N in stainless steels of increasing Ni content (15). The solubility of N in pure Ni at 1600°C for example is about 0.001%.

Specimens were sheared to 1-3/4 x 3/16 x 0.04 in. (4.5 x 0.5 x 0.1 cm) and tested in the cold-rolled state with the rolling direction parallel to the long dimension. Cold-rolled specimens were chosen because of their shorter cracking times compared to times required for annealed specimens (13). Specimens were abraded to No. 0 emery paper, degreased in benzene, and pickled in 25 v/o (volume per cent) H_2SO_4, 25 v/o HCl at 90°C for 5 min followed by a pickle in 15 v/o HNO_3, 5 v/o HF at the same temperature and time. Specimens were immediately bent beyond the elastic limit to a span of 1-5/8 in. (4.1 cm), transferred by means of a metal gauge to insulated holders of the test apparatus, adjusted to a final span of 1-7/16 in. (3.7 cm) and held in this position by a compressed spring. The spring insured that tests in $MgCl_2$ boiling at 130°C were carried out under conditions of essentially constant flow stress. Failure time was recorded by an electric clock. Other details of the test have been described previously (13).

Controlled potential tests made use of the Heathkit or Wenking potentiostats. The 250 ml test cell (Fig. 1) was equipped with two opposing side arms separated by glass frits, each containing auxiliary electrodes of platinized titanium, and a center arm also separated by a glass frit in which a Luggin capillary was connected to a saturated calomel electrode at room temperature. Solutions in the side arm were of $MgCl_2$ of slightly lower concentration than the boiling solution inside the cell. Preliminary tests established that the geometry of the cell and the high conductivity of the electrolyte made any corrections for IR drop unnecessary. A Ni wire 0.025 in. (0.065 cm) diameter was spot welded to one end of the stressed specimen and completely encased in small diameter Teflon tubing in order to reduce any current reaching the wire. Because of accumulating electrolysis products, controlled potential runs were not carried out beyond 100 hr in comparison with simple immersion tests which were run to a maximum of 200 hr.

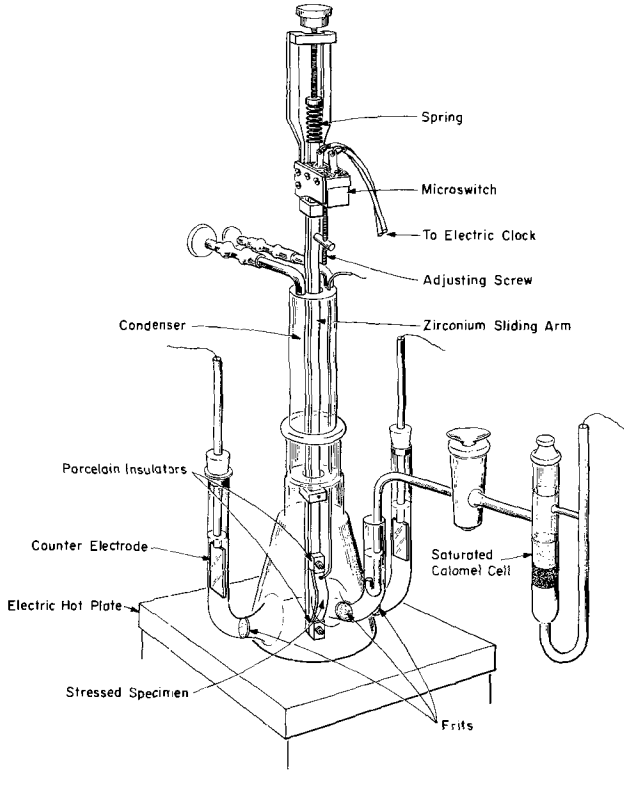

Fig. 1. Test cell for measuring critical potentials of stainless steels in boiling $MgCl_2$ solution.

Corrosion potentials were measured for the unstressed alloys partly immersed for at least 20 hr in the boiling $MgCl_2$ solution at 130°C avoiding immersion of the spot-welded junction to the connecting Ni wire. Barnartt and van Rooyen (2) showed previously that stress does not appreciably affect the potential behavior of stainless steels in $MgCl_2$ solution. All potentials are reported on the standard hydrogen scale, omitting corrections for liquid junction and thermal gradients.

Results

Figure 2 shows that failure time of the alloys in $MgCl_2$ at 130°C increases with Ni content. At and above 30.8% Ni, the alloys were not susceptible to scc within the maximum time of test (200 hr). The 19.5% Ni alloy shown in Fig. 2 is that containing 0.13% N. The similar alloy containing only 0.036% N did not fail within 200 hr, confirming previous results on the detrimental effect of interstitial nitrogen (12-14).

Anodic polarization of the otherwise resistant 30.8% and 34.8% Ni alloys induced total failure by cracking within a few hours. Pitting accompanied cracking at the most noble applied potentials. However, alloys containing 49.4% Ni or more (or the 20% Ni low-N alloy) could not similarly be made to fail when anodically polarized 10 or 20 mV more noble than the corrosion potentials. Prolonged anodic polarization or polarization to still more noble potentials served only to induce random pitting without cracking.

The relation of time to failure at various constant applied potentials for all susceptible alloys is shown in Fig. 3 and 4 together with corrosion potentials at the

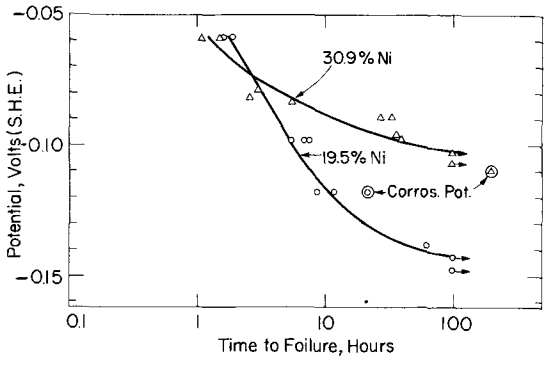

Fig. 4. Effect of applied potential on stress corrosion cracking of 20% Cr stainless steels in $MgCl_2$ at 130°C.

end of 24 hr. A critical potential below which the alloy did not fail within the maximum time of test (100 hr) is clearly defined for the 9.4% Ni alloy at −0.15 to −0.16V which is in reasonable agreement with corresponding potentials reported previously for commercial 18-8. For higher Ni alloys, the critical potentials lie at less negative (more noble) values. The precise value for each alloy at 100 hr is defined to within better than ±5 mV, and it is likely that such values also apply to longer times. The one apparent exception is the 19.5% Ni alloy for which the slope of potential *vs.* failure time is still appreciable at 100 hr. The critical potential for this alloy, corresponding to long failure times, may lie therefore somewhat below −0.14V.

A plot of critical and corrosion potentials (Fig. 5) shows that a crossover occurs at about 26% Ni. Although critical potentials for scc were not observed for alloys above 34.8% Ni, the corrosion potentials of high Ni alloys tend toward increasingly noble values. Surprisingly, the value for pure Ni drops to −0.18V which is consistently more active than the corrosion or critical potentials of any of the alloys. Barnartt and van Rooyen (2) previously observed that Ni, although initially active, may become noble to 18-8 after long exposure times, but their observations apply to $MgCl_2$ boiling at 146°C. At 130°C, a reversal of potential was never observed. The active value for Ni accounts for the observation of Cook (16) that even a small length of exposed Ni wire coupled to 18-8 specimens immersed in the $MgCl_2$ test solution serves to cathodically protect 18-8 against scc. In other words, Ni acts as a sacrificial anode. The coupled Ni wire, however, did not affect time to failure under conditions of controlled potential. The 49.4% Ni or 57.8% Ni alloys, for example, did not crack when anodically polarized using either Ni wire or a wire of the sample composition

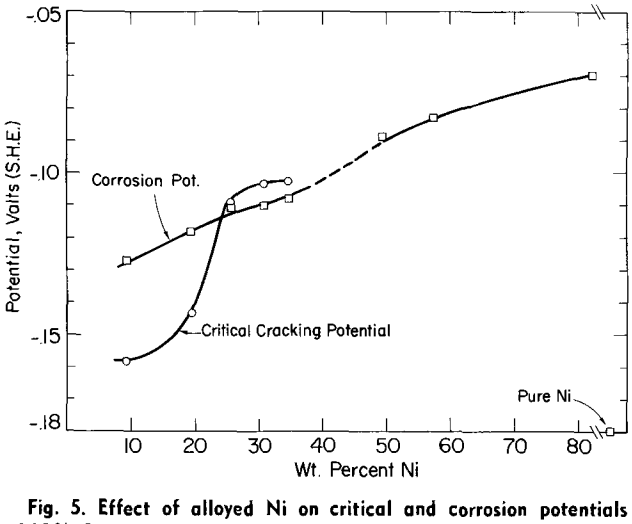

Fig. 5. Effect of alloyed Ni on critical and corrosion potentials of 20% Cr stainless steels in $MgCl_2$ at 130°C.

as the test specimen. Furthermore the measured critical potential for commercial 18-8 was the same using either Ni or 18-8 wires (16). Neumann and Griess (17) reported earlier that Ni-plated austenitic stainless steels, even when the coating was discontinuous, prevented scc in a solution containing dissolved oxygen and 50 ppm chloride at 300°C. Nickel in this instance presumably also polarized the stainless steel below its critical potential.

Discussion

The present results lend further support to the view that susceptibility to scc can occur only if the corrosion potential is noble to the critical potential. Alloyed Ni shifts the critical potential in the noble direction; when the corrosion potential is exceeded, cracking no longer occurs. This is the same relation reported for 18-8 by Uhlig and Cook (4) when inhibiting concentrations of sodium acetate or nitrate are added to $MgCl_2$ solution, the critical potential being shifted by the added salts to values which are noble to the corrosion potential. In other words, alloyed Ni up to 34.8% (and perhaps up to at least 45%) increases resistance of stainless steels to scc in part by a mechanism which parallels that of inhibiting salt solutions.

At least two factors may account for the crossover composition (Fig. 5) coming at about 26% rather than at 45% Ni corresponding to observed immunity in less pure or in commercial alloys. The first is that the present pure alloys contain only nitrogen as a sensitizing impurity. Commercial alloys, by way of comparison, contain many additional impurities which can accelerate cracking, a number of which were listed by Lang (18). The second factor is the relatively short exposure times used of necessity in the present tests. Copson (7) for example, ran tests up to 30 days. Furthermore, our results, as well as those of others (1, 2, 19), show that the corrosion potential tends in time to drift toward more noble values; hence it is probable that the corrosion potentials for alloys containing 30.8% and 34.8% Ni eventually become noble to their critical potentials, at which time but not before, failure takes place. Absence of an observed critical potential for alloys containing 49.4% or more Ni (probably >45% Ni) suggests that such alloys are immune to scc for structural reasons related for example to unfavorable dislocation arrays, low N solubility and similar factors.

Drift of Corrosion Potential and Pitting

Why does the corrosion potential drift toward more noble values? It is not considered likely that the passive film normally associated with stainless steels is accountable despite recurring mention of this possibility in the literature. There are several reasons for reaching this conclusion: (*i*) Potentiostatic polarization curves in $MgCl_2$ solutions at the test temperatures show no evidence of a passive region (2-4). Furthermore, (*ii*) addition of HCl to the $MgCl_2$ test solution which should break down or dissolve passive films shifts the corrosion potential in the noble direction opposite to the direction accompanying any supposed loss of passivity (2). In accord with the noble shift, scc of 18-8 stainless steel occurs in shorter times compared to the nonacidified $MgCl_2$ solution (20). (*iii*) Pre-exposure of unstressed 18-8 to $MgCl_2$ test solution at 154°C is found to affect subsequent scc behavior of the stressed alloy. This occurs not because a surface film is disrupted, as Hoar and Hines suggested (19), but instead because of a metallurgical change in the alloy induced at 154°C (21). The same subsequent shorter failure times are observed whether the specimens are heated at 154°C in the boiling $MgCl_2$ solution or in air. (*iv*) Finally, the corrosion potential of 18-8 in $MgCl_2$ at 130°C is active to the hydrogen electrode potential in the same solution indicating that the alloy is in the active state (4).

The trend of potential, therefore, may be caused by (*i*) changing composition of $MgCl_2$ solution, *e.g.*, changing *p*H, or accumulation of metal ions; (*ii*) changing

composition of the alloy surface, *e.g.*, preferential dissolution of specific alloy components or redeposition of cations like Ni^{++}; (*iii*) formation of a hydrated oxide film acting as a diffusion barrier [similar to a film of $Fe(OH)_2$ on iron exposed to water, or $PbSO_4$ on Pb exposed to H_2SO_4]. The first possibility was eliminated by changing the $MgCl_2$ solution after 24 hr and noting that the potentials of several alloys were unchanged in the new solution after a few minutes exposure. The second possibility is more difficult to assess, especially since relevant composition changes may concern only monolayer quantities. Certainly preferential dissolution of stainless steel components in an acid pickling solution is not observed. Furthermore, if Ni^{++} were to redeposit, the potential would drift in the active, not in the noble direction, since the corrosion potential of Ni in $MgCl_2$ at 130°C is decidedly active to that of any of the present stainless steels. A surface alloy change is possible, therefore, but not probable. Finally, the third possibility appears to be the most plausible because a surface film showing weak interference colors becomes visible after several hundred hours' exposure to $MgCl_2$ at 130°C (at 154°C the film is black). Chemical analysis of the resultant $MgCl_2$ solution for heavy metals compared to weight loss of the immersed stainless steel specimens suggests that the film after 190 hr exposure grows to a thickness of about 4500Å. The analysis indicates furthermore that the film probably consists mostly of $Fe(OH)_3$, perhaps partially hydrated, which might be expected on the basis that $Ni(OH)_2$ is more soluble than $Fe(OH)_3$ or $Cr(OH)_3$. Detailed data are given in Table II.

Although a more complete quantitative analysis of the film and its structure require further detailed investigation, there is no doubt that the film exists, that it is relatively thick, and that as it forms it appreciably reduces the uniform corrosion rate of stainless steels in $MgCl_2$ solution (20). It is the reduction in corrosion rate that likely accounts for the shift of corrosion potential in the noble direction. The responsible film is obviously not the usual passive film on stainless steels both because the film is very much thicker than the passive film, and because there is no evidence of a Flade potential.

The presence of a surface reaction product film explains why anodic polarization may induce corrosion pitting, particularly at noble potentials. The alloy dissolution rate is expected to be higher at local sites of the metal surface where the reaction product film is thinner or absent, hence corrosion tends to be localized. Pitting usually begins only after a certain induction period presumably because of the time necessary to establish an adequate surface film.

For the highest Ni alloys, it was observed that a linear succession of pits often tended to localize in the areas of maximum tensile stress and that failure therefore could be interpreted as occurring perhaps by pitting rather than by cracking. It is probable, however, because nucleation of pits is usually random, that in such instances cracks form first, and that the resultant crevices become favored sites for accelerated localized attack because of exposed film-free metal. A linear succession of pits, therefore, was interpreted as evidence of prior failure by scc.

Mechanism of scc

Several mechanisms of scc have been proposed, the many details of which lie outside the scope of the present paper. Discussion will be limited to the electrochemical theory dependent on anodic dissolution of metal atoms at the tip of a crack, and to the theory of stress sorption cracking dependent on dissociation of strained metal atom bonds at the crack tip weakened by adsorption of damaging ions (22). On the basis of the electrochemical mechanism, it is not certain why alloyed Ni should shift the critical potential for scc in the noble direction. It can be assumed, for example, as in typical instances of cathodic protection, that the critical potential is related to the open-circuit anode potential. Hines and Hoar made this assumption (1). Then the anode potential can be assumed to move in the more noble direction the higher the Ni composition for reasons similar to those applying to observed shift of the corrosion potential. But the fact that the corrosion potentials for 30.8% and 34.8% Ni stainless steels are *active* to their respective critical potentials casts doubt on this possibility, as well as on any model of scc based on a galvanic cell the anode of which is situated at the tip of a growing crack. The corrosion potential of a galvanic cell must always be noble to the open-circuit anode potential; the inverse can never occur. Assuming that only partial cathodic polarization toward the open-circuit anode potential suffices to prevent scc is not of any help to the electrochemical model because such polarization always shifts the potential in a direction active, not noble, to the corrosion potential.

Bearing on this matter are observations that anodic polarization curves for 18-8 in $MgCl_2$ at 130°C show no evidence of increased polarization (corresponding to decreased corrosion) in the presence of sodium acetate which inhibits scc (4). Furthermore, anodic polarization curves in $MgCl_2$ at 130°C as obtained presently for the 20% Ni low-N alloy which resists scc are identical to the corresponding curves for the 19.5% Ni high-N alloy which is susceptible to scc.

On the basis that the mechanism of stress sorption cracking applies instead, Ni shifts the critical potential in the noble direction because Ni has less affinity for Cl^- than does either Cr or Fe. For example, the standard free energies of formation of $NiCl_2$, $FeCl_2$, and $CrCl_2$ at 25°C are −65.1, −72.2, and −85.2 kcal, respectively (23). Hence, if these values are used as a qualitative measure of Cl^- affinities, a more positive applied potential is required the higher the Ni content, as is observed, to affect adequate adsorption of Cl^- on defect sites of plastically deforming alloy accompanying reduction of the cohesive strength of surface metal bonds. On this view, electrochemical factors may affect the corrosion potential which in turn determines whether adsorption of Cl^- is favorable or unfavorable for crack initiation and growth, but the mechanism is not one of dissolution of metal atoms at the tip of the crack. It is one of physical parting of metal atoms instead for which adsorbed components of the environment play a major role, analogous to the role of specific metal atoms as cause of liquid metal embrittlement, *e.g.*, cracking of stressed brass by liquid Hg. The critical potential is interpreted accordingly as that value above which Cl^- ions adsorb on appropriate defect sites of plastically deforming stainless steel, and below which Cl^- ions desorb.

In addition to factors of the environment leading to adsorption, it is also obviously necessary for scc that the surface defect structure of the metal must be favorable for adsorption. For example, the 20% Ni low-N alloy is found not to crack despite anodic polarization to relatively noble values, contrary to the 19.5% Ni high-N alloy which fails whether polarized or not. Further evidence comes from the lack of failure of alloys containing 49.4% or more Ni despite anodic polarization.

The above considerations therefore lead to the conclusion that necessary and sufficient conditions for scc are (*i*) a potential favorable to adsorption of damaging components of the environment on appropriate defect sites of the metal surface, (*ii*) both a metallurgical

Magnetic Properties of Electrodeposited Nickel-Iron-Phosphorus Thin Films

Koichi Mukasa, Masayoshi Sato, and Masao Maeda

Department of Electronics, Faculty of Engineering, Hokkaido University, Sapporo, Japan

ABSTRACT

The effect of hypophosphite ions in the plating bath on the uniaxial magnetic anisotropy in nickel-iron thin films electrodeposited on uniaxially scratched substrates was investigated. It was observed that the presence of hypophosphite ion in the plating bath results in a decrease of the uniaxial magnetic anisotropy. This decrease of the uniaxial magnetic anisotropy was found to be due to the decrease of the saturation magnetization of the films electrodeposited from the plating bath containing hypophosphite ions. Three possibilities for the effect of the phosphorus on the saturation magnetization are considered.

Nickel-iron thin films which were electrodeposited in an applied magnetic field may prove useful as computer memory and logic elements. Recently, the electrodeposited thin films have been investigated by many authors because of the simplicity of their preparation. It is known that the nature of the substrate surface affects the magnetic properties of thin films. For example, the magnetic properties of electrodeposited films are known to be a very sensitive function of the scratches of the substrate surface (1).

Many workers have shown that one can achieve uniaxial magnetic anisotropy in deposited permalloys by depositing on a surface scratched predominantly in one direction (2-5). And, in a previous paper (6), it was reported that this uniaxial anisotropy constant K_u is described as

$$K_u = \frac{1}{2} \cdot (N_t - N_p) \cdot I_s^2 + \frac{3}{2} \cdot 2\sigma \sin^2\theta \qquad [1]$$

where N_t and N_p are the demagnetizing factor of the film in the direction perpendicular and parallel to the scratches, respectively, σ is the tensile stress in the film, and λ is the saturation magnetostrictive constant.

It is known that the presence of hypophosphite ions in the plating bath results in phosphorus in the deposits (7, 8). This is true also in the case of electroless deposition (9). Mechanical properties (8, 9), metallurgical structure (10-12), and magnetic properties (13-15) of Ni-P and Ni-Fe-P films have been investigated in detail. And it was observed for films electrodeposited on a smooth surface that the coercive force and anisotropy field of Ni-Fe-P films are small compared with that of Ni-Fe films (7). In this work the effects of sodium hypophosphite ($NaH_2PO_2 \cdot H_2O$) in the plating bath on the uniaxial magnetic anisotropy in nickel-iron thin films electrodeposited on uniaxially scratched substrates were investigated. That is, the uniaxial magnetic anisotropy studied in this work is not the anisotropy induced in the film by depositing in the presence of magnetic field, but the anisotropy achieved in the film by depositing on a surface scratched predominantly in one direction.

Experimental Procedures

Films used in this work were electrodeposited at room temperature. The chemical compositions of the electrolyte were $NiSO_4 \cdot 6H_2O$ (140 g/liter), $FeSO_4 \cdot$

$7H_2O$ (20 g/liter), H_3BO_3 (15 g/liter), NH_4Cl (16 g/liter), and $NaH_2PO_2 \cdot H_2O$ (0 ~ 5 g/liter). A rolled nickel plate was used as the anode. The current density of deposition was 25 mA/cm². Films used for the measurement of magnetic torque curves and of saturation magnetization were electrodeposited on scratched copper substrate. The diameter and the thickness of films used for the measurement of the torque curves were 1 cm and 500Å. The diameter of films used for the measurement of the saturation magnetization was 0.5 cm and the five films of 5000Å in thickness were measured in a group. The saturation magnetization of both films electrodeposited from the bath containing 0 and 5 g/liter hypophosphite concentration did not vary much with thickness for thickness less than 5000Å. And, especially for films electrodeposited from the bath with hypophosphite, it was observed that the variation of the saturation magnetization was small. Thus the films of 5000Å in thickness were used for the measurement of the saturation magnetization because of the convenience of the facilities in the Sucksmith's balance measurement. Films used for the measurement of the film thickness and for the observation of the electron micrography were electrodeposited on the substrate which was made from ordinary microscope cover glass which had been coated with vacuum evaporated layers of chromium and copper.

The torque curves were measured by means of a torque magnetometer in a uniform magnetic field of 13 kOe at room temperature. The saturation magnetization was measured by Sucksmith's ring balance in a nonuniform magnetic field of about 10 kOe. The film thickness was measured by multibeam interferometry. For the observation of electron diffraction and transmission electron micrography, the copper layer attached to the deposits having thickness of 250Å was dissolved in a solution of sodium cyanide (20 g/liter). The electron beam which was accelerated by 130 kV was perpendicular to the surface of the films. The content of phosphorus in the films was measured by the use of the x-ray microanalyzer and colorimetric method.

Results and Discussion

Thickness of films.—In order to examine the effects of phosphorus on the film thickness, the thicknesses of the films electrodeposited from the bath with and without the hypophosphite were measured as a function of the plating time, and the results are shown in Fig. 1. It is seen in Fig. 1 that the measured thicknesses of the films increase with increasing plating time for the plating time less than 30 sec when the films are electrodeposited from the plating bath without hypophosphite, but the measured thickness of the films is thicker than the thickness which is calculated from the weight of the film and the density data (16) by about 25%. Thus it is considered that the thin films electrodeposited from the plating bath without hypophosphite include voids, as was discussed in a previous report (6).

In the case of the films electrodeposited from the plating bath with hypophosphite, it was known that the films contain phosphorus (5). The measured thickness of the films with phosphorus is equal to the thickness of the films without phosphorus as seen in Fig. 1, so that the sodium hypophosphite content in the bath (0 ~ 5 g/liter) seems to have no influence on the thickness of the films. If it is assumed that the density of Ni-Fe-P alloys is equal to the density of Ni-Fe alloys, the thicknesses of films both with and without phosphorus were the same when it was calculated from the weight of the films. Accordingly, it is also considered that the films containing phosphorus will include voids, as well as in the case of the deposits without phosphorus.

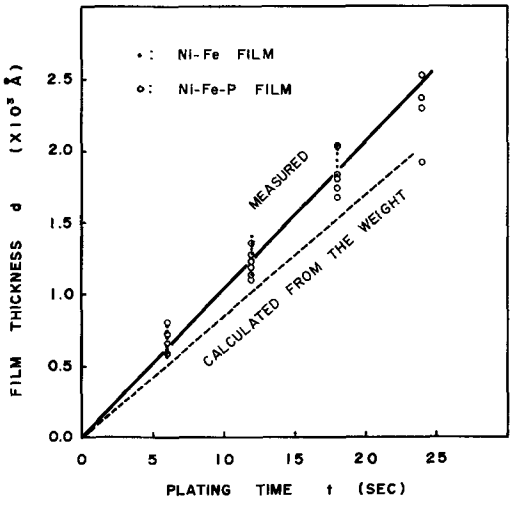

Fig. 1. Thickness of films, *d*, plotted as a function of plating time, *t*, for Ni-Fe and Ni-Fe-P thin films {$NaH_2PO_2 \cdot H_2O$ (5 g/liter) in plating bath}.

Figure 2 shows the two interference patterns by multibeam interferometry for the films electrodeposited from the plating bath containing hypophosphite; one is for the film electrodeposited with stirring the plating bath during the deposition and the other is for the film electrodeposited without stirring. It is seen in Fig. 2(a) that, for the film electrodeposited

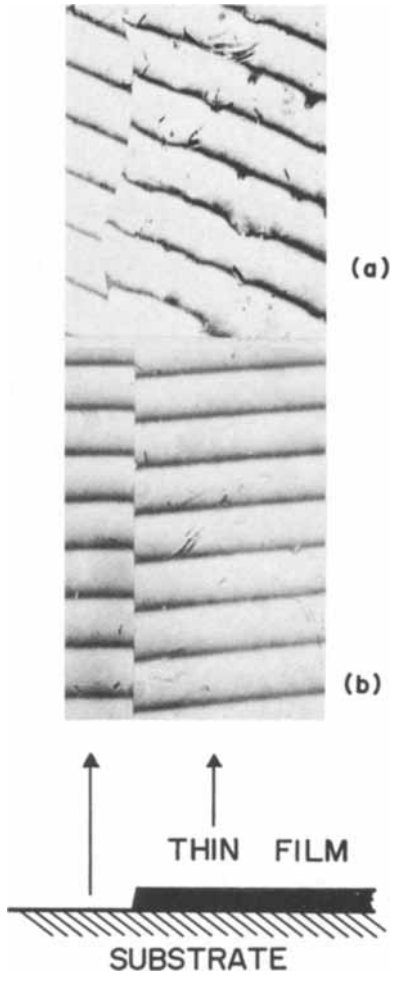

Fig. 2. Interference patterns by multibeam interferometry for the films electrodeposited from the plating bath containing hypophosphite: (a) for films electrodeposited without stirring the plating bath, (b) with stirring. The thickness of the films is about 1500Å.

without stirring during the deposition, the fringes of the interference pattern are spaced irregularly; that is, the surface roughness of the films is observed, but the roughness vanishes when the plating bath is stirred during the electrodeposition as seen in Fig. 2(b). Accordingly, it may be said that the surface roughness of the films containing phosphorus is due to hydrogen bubble formation.

Uniaxial magnetic anisotropy of Ni-Fe-P films.—Figure 3 shows the measured effective uniaxial magnetic anisotropy constant, K_u^* (17), as a function of the concentration of the hypophosphite in the plating bath from 0 to 5 g/liter. The measured K_u^* was calculated from the torque maximum divided by an apparent volume of the films. The measured K_u^* in Fig. 3 decreases with increasing hypophosphite concentration. For example, the values of the measured K_u^* are about 1.3×10^5 erg/cc and 4.0×10^4 erg/cc for the film without hypophosphite and for the film more than 2 g/liter hypophosphite concentration, respectively.

Since the composition of films used in this work is about 75Ni-25Fe, it is considered that the measured K_u^* is due to shape contribution alone as magnetostriction contribution will be small for this composition (6). The effective uniaxial magnetic anisotropy constant, K_u^*, which is a function of the volume of the nonmagnetic inclusions, of thin films electrodeposited on a surface scratched predominantly in one direction is described as

$$K_u^* = \frac{v}{v^*} \cdot K_u = \frac{v}{v^*} \frac{1}{2} (N_t - N_p) I_s^2 = \frac{1}{2} (N_t - N_p) \cdot \frac{v^*}{v} \cdot I_s^{*2} \quad [2]$$

where v^* and v are the volume of magnetic films with and without the nonmagnetic inclusions, respectively. As was stated in a previous section, the value of v^*/v was constant for both Ni-Fe and Ni-Fe-P films. In an attempt to explain the behavior of the measured K_u^* in Fig. 3, the effective saturation magnetization, I_s^*, was measured as a function of hypophosphite concentration and is shown in Fig. 4. It is seen in Fig. 4 that the effective saturation magnetization, I_s^*, decreases with increasingly hypophosphite concentration and becomes constant for films with more than 2 g/liter hypophosphite. It may be understood qualitatively from the decrease of I_s^* in Fig. 4 and Eq. [2] that the value of K_u^* decreases with increasing hypophosphite.

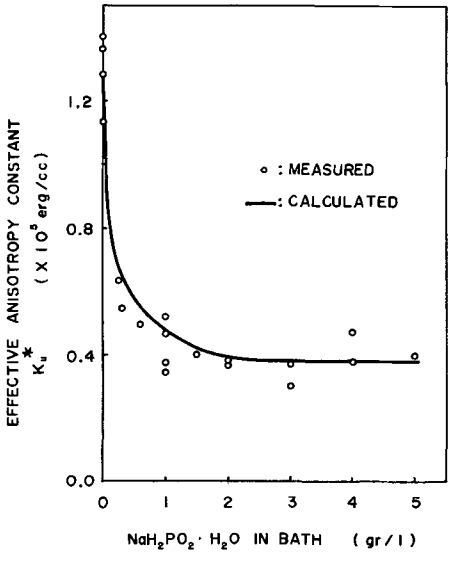

Fig. 3. Effective uniaxial magnetic anisotropy constant, K_u^*, plotted as a function of the concentration of the hypophosphite in the plating bath, together with the solid curve calculated from Eq. [2].

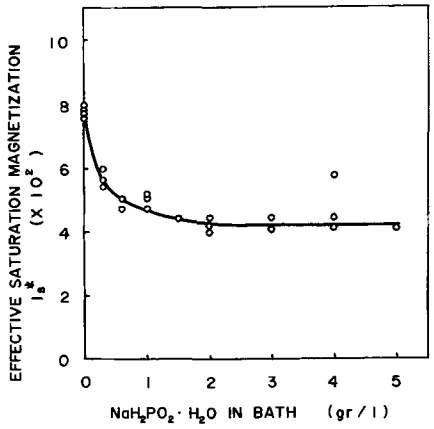

Fig. 4. Effective saturation magnetization, I_s^*, plotted as a function of the concentration of the hypophosphite in the plating bath.

Next, we shall calculate the value of K_u^* as a function of hypophosphite concentration from Eq. [2] using the measured values of I_s^* in Fig. 4. The values of $(N_t - N_p)$ are determined from the measured values of K_u^* and I_s^* for films without phosphorus. Assuming the constant value of $(N_t - N_p)$ calculated above remains unchanged in the cases of the deposits containing phosphorus, the calculated K_u^* is shown in Fig. 3 by the solid curve. It is seen in Fig. 3 that the measured K_u^* is in good agreement with the calculated K_u^*. Accordingly, it is concluded that the decrease of the effective uniaxial magnetic anisotropy constant in Ni-Fe-P films is due to the decrease of the effective saturation magnetization of the films with phosphorus. Thus, the variation of the measured K_u^* in Fig. 3 is well interpreted in terms of the variation of the effective saturation magnetization, I_s^*, in Fig. 4. And the assumption that the value of $(N_t - N_p)$ is constant may be valid since the surface roughness, which affects the value of $(N_t - N_p)$, of films electrodeposited on scratched substrate surfaces probably does not vary with the concentration of the hypophosphite ions in the plating bath.

Effects of the phosphorus on the saturation magnetization.—As was seen in Fig. 4, the effective saturation magnetization, I_s^*, decreases with increasing hypophosphite concentration in the bath. On the other hand, no change in thickness and in weight with hypophosphite concentration was observed as was stated in the first section. Thus it becomes evident that the saturation magnetization, I_s, varies with hypophosphite concentration. It has been observed that the composition of films electrodeposited without hypophosphite in the bath was about 75Ni-25Fe, that iron concentration in the film increases with increasing hypophosphite concentration, and that the Fe-Ni ratio and the phosphorus concentration are constant for films electrodeposited with more than 2 g/liter hypophosphite concentration. Thus it will be considered that the decrease of the saturation magnetization does not depend on the increase of the Fe-Ni ratio but on the increase of phosphorus content in the film. And it is considered that the saturation magnetization becomes constant as shown in Fig. 4 because of the phosphorus content becoming constant for films electrodeposited with more than 2 g/liter hypophosphite concentration. Thus the result that the uniaxial magnetic anisotropy becomes constant as shown in Fig. 3 may be due to the result that the saturation magnetization becomes constant as shown in Fig. 4.

We discuss why the saturation magnetization, I_s, decreases with increasing hypophosphite concentration. The electron transmission micrographs and electron

transmission diffraction patterns of the film are shown in Fig. 5(a) and (b); (a) is for the films without phosphorus and (b) is for the films with phosphorus. It is seen in Fig. 5 that the diffraction pattern for the films without phosphorus can be indexed as a face-centered-cubic structure. It is also seen in Fig. 5 that, with increasing hypophosphite concentration, the diffraction line of the films becomes broader. Therefore, as effects of the phosphorus on I_s* of the electrodeposited Ni-Fe films, three possibilities can be considered.

1. In Fig. 5(b), it is observed that the diffraction rings for the films with phosphorus become broader. Goldenstein *et al.* (10) obtained a similar result concerning the diffraction pattern of chemically deposited Ni-P films, and concluded that Ni-P deposits are amorphous liquidlike structures. It may then be assumed from the diffraction pattern shown in Fig. 5(b) that the electrodeposited Ni-Fe-P films used in this work are partially amorphous or that the lattice of the films is distorted. Then the decrease of saturation magnetization may be explained.

2. In Fig. 5(b), it is observed that the diffraction rings become broader, but a few reflections in the diffraction patterns are distinguishable. Graham *et al.* (9) obtained a similar result concerning the diffraction pattern of chemically deposited Ni-P films and concluded that Ni-P deposits were polycrystalline and that phosphorus dissolves in crystalline nickel-iron. Therefore, on the basis of his viewpoint, it may be said that according to the band theory proposed by Stoner the magnetic moment decreases.

3. In Fig. 5(b), it is observed that the diffraction rings become broader, and it is seen from the micrographs that the grain, if what is seen in the micrographs is grain, becomes smaller. Graham *et al.* (9) obtained a similar result concerning the electron diffraction and the micrography of chemically deposited Ni-P films, and concluded that this result was due to the effect of fine grain size. Therefore, following his conclusion, it may be said that the decrease of saturation magnetization is due to superparamagnetism, which was discussed for isolated small single-domain particles and closely packed ferromagnetic films with different strengths of interaction (18).

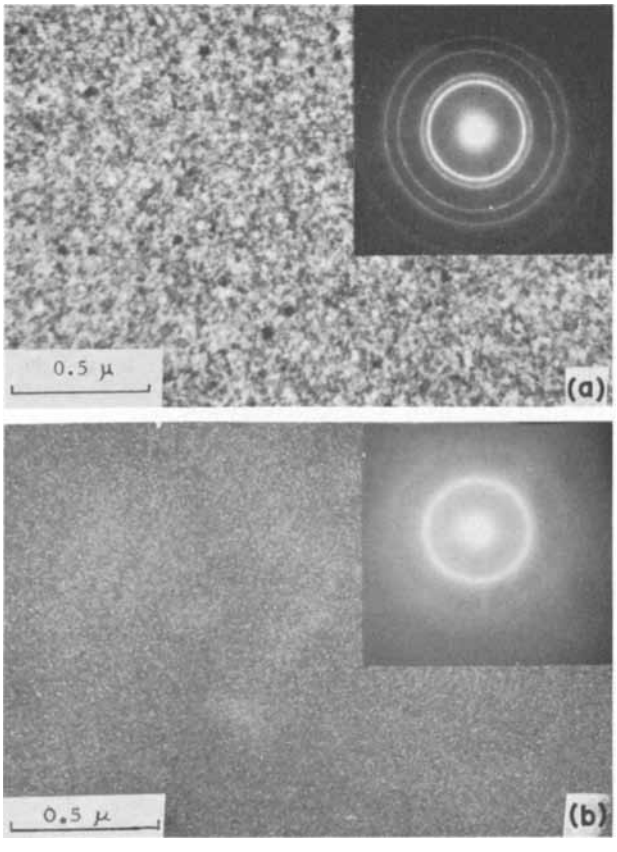

Fig. 5. Electron transmission micrographs and electron transmission diffraction patterns of the films without phosphorus (a) and with phosphorus (b).

Summary

1. It was observed that the presence of hypophosphite ions in the plating bath results in a decrease of the effective uniaxial magnetic anisotropy in nickel-iron thin films electrodeposited on unidirectionally scratched substrates.

2. It was also observed that the presence of hypophosphite ions results in a decrease of saturation magnetization of films.

3. The decrease of the effective uniaxial magnetic anisotropy was found to be due to the decrease of the saturation magnetization of films electrodeposited from the plating bath containing hypophosphite ions.

4. As effects of the phosphorus on the saturation magnetization of nickel-iron thin films, three possibilities are considered.

Acknowledgments

The authors would like to thank Professor T. Takeyama for his advice, Mr. G. Tomita for his cooperation in taking the electron micrographs, Professor M. Nagayama and Dr. S. Kawamura for their advice on the colorimetric method and for supplying the microbalance, and Dr. H. Fujiwara for his advice on multibeam interferometry.

Polarographic Studies of Bivalent Germanium in Perchloric and Hydrochloric Acids

Kuan Pan and Y. Chang Fu

Department of Chemistry and Chemistry Research Center, National Taiwan University, Taipei, Taiwan, China

ABSTRACT

Polarographic behavior of the Ge(II) ion was studied in mixtures of $HClO_4$ and HCl at various H_3O^+ ion concentrations and ionic strengths at 5° intervals from 20° to 35°C. The cathode reduction of Ge(II) at a dropping mercury electrode was found to be $Ge^{++} + 2e = Ge^0$ for $[H^+] > 2M$ in mixed solutions of $HClO_4$ and $NaClO_4$. In the presence of Cl^- ion at 25°C, the reduction of Ge(II) was found to be a two-electron reversible reaction. The formation of $GeCl_3^-$ and $GeOCl_2^=$ was presumed from the polarographic data. The cathode reduction is expressed by $GeCl_3^- + 2e = Ge^0 + 3Cl^-$ ($[H^+] > 5.0M$) and $GeOCl_2^= + 2H^+ + 2e = Ge^0 + 2Cl^- + H_2O$ ($[H^+] < 1.0M$).

The existence of complex anion GeX_3^- in halogen acid solutions was reported by Tchakirian (1) and Karantassis *et al.* (2) and confirmed by the observation of Raman spectra by Tchakirian and his collaborators (3, 4). By reducing Ge(IV) to the Ge(II) state with hypophosphite in hydrochloric acid solution, a cathode wave due to the reduction, Ge(II) + 2e = Ge, was found by Alimarin and Ivanov-Emin (5), while an anodic wave due to the oxidation, Ge(II) = Ge(IV) + 2e, was observed by Cozzi and Vivarelli (6). The polarographic behavior of Ge(II) in hypophosphorous acid and hydrochloric acid was subsequently reinvestigated by Everest (7). In any of the aforementioned investigations, however, no evidence has been given for the existence of the single Ge^{++} ion in aqueous solution.

In order to observe the polarographic behavior of Ge(II) ion in acid solutions, therefore, the present investigators (8) have prepared Ge(II)-perchlorate which, though unstable, may be expected to give a reduction wave of Ge^{++} or $Ge(H_2O)_6^{++}$ ion in perchloric acid solution at a dropping mercury electrode. The purpose of the present investigation is, therefore: first, to make a polarographic study of Ge(II) ion in perchloric acid and in a mixture of hydrochloric and perchloric acids without the presence of hypophosphite; and, second, to find the ligand number of chloride of the Ge(II)-chloride complex ion and its reduction mechanism at a dropping mercury electrode.

Experimental

All chemicals used, except germanium dioxide (Alfa Inorganic Inc. Chemicals, 99.999% purity), were of Baker Analyzed Reagent grade. A mixture of Ge(II)-chloride and hypophosphite was prepared by reducing Ge(IV) to Ge(II) with sodium hypophosphite in hydrochloric acid, according to Everest (7).

Germanium(II)-hydroxide (9, 10) was prepared by neutralizing the mixture of Ge(II)-chloride and hypophosphite with dilute ammonia solution. The brownish yellow precipitate was washed repeatedly with deaerated water in a current of deoxygenated nitrogen until the ammonium, chloride, and hypophosphite ions were free from the wash liquid as determined by the qualitative tests.

Solutions of Ge(II)-perchlorate in perchloric acid and Ge(II)-chloride in hydrochloric acid were prepared by dissolving Ge(II)-hydroxide in the corresponding acid. Another solution of Ge(II)-chloride was prepared by dissolving the solid germanium dichloride, obtained from the reaction of germanium tetrachloride with germanium (11) in hydrochloric acid for comparison. The content of bivalent germanium was determined, after addition of the Ge(II) solution to a greater amount of ceric sulfate solution, by potentiometric titration with a standard solution of ferrous sulfate.

Polarograms were taken with a Yanagimoto Type PB-105 pen-recording polarograph using a H-type cell and a saturated calomel electrode. In order to prevent the electrolyte solution from evaporating during passage of nitrogen gas, a gas-washing bottle containing the corresponding acid or the mixed acids of the same concentration was inserted between washing bottles for gas purification and the polarographic cell in the thermostat at 25° ± 0.1°C. A 0.001% gelatin solution was used as the maximum suppressor.

Results and Discussion

Polarographic behavior of Ge(II)-perchlorate.—A well-defined cathode wave was observed in polarograms of Ge(II) in the mixtures of perchloric acid and sodium perchlorate at various hydronium ion concentrations and ionic strengths at 25°C (Table I), and in those at constant hydronium ion concentration and various ionic strengths at 5° intervals from 20° to 35°C (Table II). Above $[H_3O^+] = 2.0M$, the value of $E_{1/2}$ of the cathode wave is practically independent of hydronium ion concentration at constant ionic strength, which shifts to a more positive value with increasing ionic strength, as shown in Table I. At

1.000	−0.420	−0.425	−0.415	−0.410

Table III. The values of $-E_{1/2}$ for Ge (II) in the mixtures of $HClO_4$, $NaClO_4$, and NaCl at 25°C ($[H^+] = 1.0M$)

$\sqrt{I}$ \ [Cl⁻]	0.25	0.50	0.75	1.00	1.25	1.75
2.225	0.335	0.350	0.355	—	0.375	0.390
2.000	0.345	0.355	0.370	—	0.390	0.395
1.733	0.350	0.370	0.375	—	0.395	0.400
1.414	0.360	0.375	0.390	—	0.400	0.405
1.000	0.370	0.385	0.400	0.405	—	—

constant hydronium ion concentration, $[H_3O^+] = 1.0M$; however, the value of $E_{1/2}$ shifts to a more negative value with decreasing ionic strength, as shown in Table II.

Though plots of $\log i/(i_d - i)$ *vs.* $E_{d.e.}$ give a slope of 0.03, we could not make sure that the reaction $Ge^{++} + 2e = Ge$ in $HClO_4$ is reversible since the value of $(E_{3/4} - E_{1/4})$ changes from 0.04 to 0.08, and the Ge(II) ion is so unstable in $HClO_4$ that the diffusion current decreases as time progresses. The positive shift in $E_{1/2}$ with increasing ionic strength at constant hydronium ion concentration may be attributable to the decrease in activity, while the positive shift in $E_{1/2}$ with decreasing hydronium ion concentration at constant ionic strength may be attributable to the possible change in aquo struction of the electroactive species, say from $Ge(H_2O)_6^{++}$ to $Ge(OH)_n(H_2O)_{6-n}^{2-n}$.

Polarographic behavior of Ge(II) in the mixtures of chloride and perchlorate ions.—The bivalent germanium has been found to be more stable toward hydrolysis and oxidation in hydrochloric acid than in perchloric acid. The values of $E_{1/2}$ obtained from the cathode wave of Ge(II) in the mixtures of HCl, NaCl, and $NaClO_4$ at various chloride ion concentrations and ionic strengths at constant hydronium ion concentration, $[H^+] = 1.0M$, are indicated in Table III. By plotting $E_{1/2}$ *vs.* $\sqrt{I}$ at various chloride ion concentrations at 25°C, a series of straight lines was obtained as shown in Fig. 1. The slope of these linear plots changes from 0.027 to 0.036 as the chloride ion concentration changes from 0.25 to 1.75M; *viz.*, $0.0591/n = 0.027$, 0.029, 0.032, 0.033, and 0.036 with $[Cl^-] = 0.25$, 0.50, 0.75, 1.25, and 1.75M, respectively. The fact that plots of $\log i/(i_d - i)$ *vs.* $E_{d.e.}$ for Ge(II) in the mixtures of HCl and $NaClO_4$ at various chloride ion concentrations and ionic strengths give $n = 2$, and the value of $(E_{3/4} - E_{1/4})$ changes in the range of $0.03 \sim 0.04$, indicates the cathode reduction to be a reversible two-electron process.

In the mixtures of hydrochloric acid and sodium chloride at constant ionic strength and chloride ion concentrations, $I = [Cl^-] = 5.0$, 4.0, and 3.0M, the half-wave potential is independent of hydronium ion concentration when $[H^+]$ is higher than 1.5M, as shown in Table IV. In the mixtures of hydrochloric acid and ammonium chloride, as well as ammonium hydroxide and ammonium chloride at constant ionic strength, $I = 0.48$; however, the half-wave potential in volts *vs.* SCE varies with pH of the solution at 25°C. The values of $E_{1/2}$ are given as functions of pH as follows

$$E_{1/2} = -0.362\text{-}0.059\,pH \quad (pH\ 1 \sim 2)$$

and

$$E_{1/2} = -0.165\text{-}0.055\,pH \quad (pH\ 7.6 \sim 9)$$

Table IV. Dependence of half-wave potential on hydronium ion concentration at 25°C

		$I = 5.0$, $[Cl^-] = 5.0M$			
$[H^+]$	0.53	1.07	1.60	2.13	2.67
$-E_{1/2}$	0.425	0.445	0.455	0.455	0.455
		$I = 4.0$, $[Cl^-] = 4.0M$			
$[H^+]$	0.53	1.06	1.58	2.11	2.64
$-E_{1/2}$	0.420	0.445	0.450	0.450	0.450
		$I = 3.0$, $[Cl^-] = 3.0M$			
$[H^+]$	0.50	1.00	1.50	2.00	2.50
$-E_{1/2}$	0.420	0.440	0.450	0.450	0.450

Dependence of $E_{1/2}$ on Cl^- ion concentration in mixtures of HCl, NaCl, and $NaClO_4$ at constant H_3O^+ ion concentration and various ionic strengths is shown in Fig. 2. The data are summarized in Table III. Dependence of $E_{1/2}$ on Cl^- ion concentration at constant ionic strength, $I = 5.0$, and various H_3O^+ ion concentrations is shown in Fig. 3. The slope of these linear plots changes from 0.09 to 0.06 as H_3O^+ ion concentration decreases from 5.0 to 1.0M. Dependence of $E_{1/2}$ on

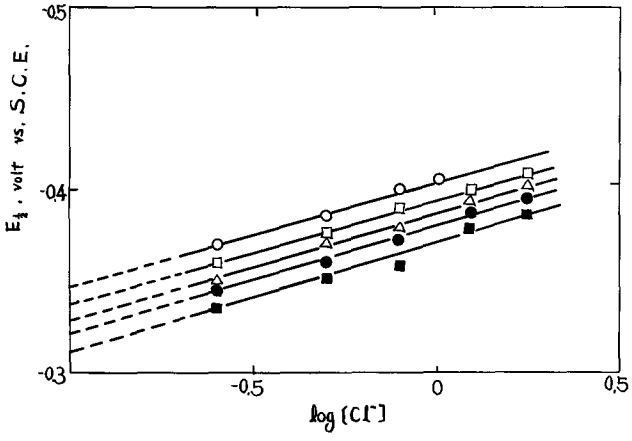

Fig. 2. Dependence of $E_{1/2}$ on Cl^- ion concentration in mixtures of HCl, NaCl, and $NaClO_4$ at $[H^+] = 1.0M$ (25°C): $I = 1.0$, ○; 2.0, □; 3.0, △; 4.0, ●; 5.0, ■.

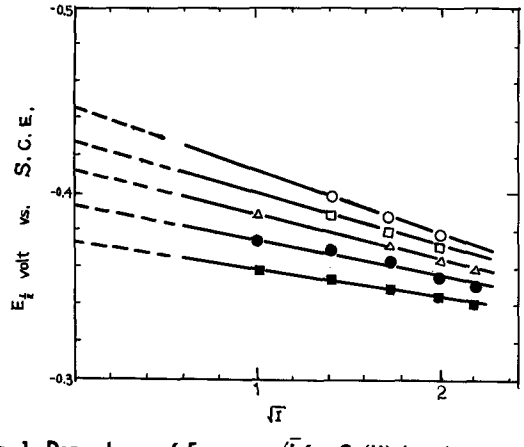

Fig. 1. Dependence of $E_{1/2}$ on $\sqrt{I}$ for Ge(II) in mixtures of Cl^- and ClO_4^- ions at $[H^+] = 1.0M$ at 25°C: $[Cl^-] = 0.25$, ■; 0.50, ●; 0.75, △; 1.25, □; and 1.75M, ○.

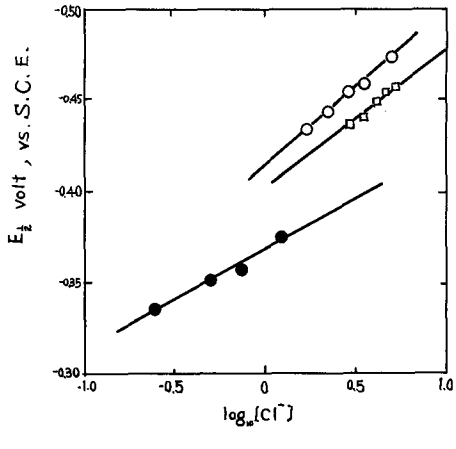

Fig. 3. Dependence of $E_{1/2}$ on Cl^- ion concentration in mixtures of HCl, NaCl, and $NaClO_4$ at $I = 5.0$ (25°C): $[H^+] = 1.0$, ●; 3.0, □; 5.0, ○.

H_3O^+ ion concentration at constant Cl^- ion concentration and ionic strength is shown in Table IV.

Assuming Ge(II) to be cationic in property in acid solution, it can be expected to form complex $Ge(H_2O)_xCl_p^{2-p}$ or be abbreviated as $GeCl_p^{2-p}$. Since the cathode reduction of Ge(II) has been assigned to be a two-electron reversible reaction at a dropping mercury electrode, the half-wave potential may be expressed in the following form

$$E_{1/2} = e + \frac{0.0591}{n} \log \frac{K_c f_c k_a}{f_a k_c f^p_{Cl^-}} - p \frac{0.0591}{n} \log [Cl^-] \quad [1]$$

Taking the second term of the right-hand side of Eq. [1] as a constant at constant H_3O^+ ion concentration and ionic strength, the slope of the linear plots of $E_{1/2}$ *vs.* log $[Cl^-]$ is given by

$$\Delta E_{1/2}/\Delta \log [Cl^-] = -p(0.0591/n) \quad [2]$$

From the experimental results obtained above, therefore, the ligand number of chloride is given by $p = 3$ for $[H^+] > 5.0M$ and $p = 2$ for $[H^+] < 1.0M$.

In the mixtures of hydrochloric acid and perchlorate at $[H^+] = 1.0M$, the values of i_d/C are 4.71, 4.60, and 5.89 and those of the diffusion constant, $i_d/C\ m^{2/3}\ t^{1/6}$, are 3.49, 3.39, and 4.41 at ionic strengths, $I = 5.0$, 3.0, and 1.0, respectively. Though the diffusion current and half-wave potential of Ge(II) have been shown to change with the concentrations of Ge(II) and H_3O^+ ion as well as the ionic strength, at constant hydronium ion concentration the value of i_d/C decreases with increase in ionic strength. At constant hydronium ion concentration and ionic strength, however, the diffusion current is proportional to the concentration of Ge(II). The fact that the chloride ligand number is 3 for $[H^+] > 5.0M$, and 2 for $[H^+] < 1.0M$, and that the half-wave potential is independent of H_3O^+ ion concentration for $[H^+] > 1.5M$ and the linear plot of $E_{1/2}$ *vs.* pH gives a slope of 0.059 for pH < 1.0 at 25°C, appears to support the mechanism of the cathode reduction at the dropping mercury electrode

$$GeCl_3^- + 2e = Ge^o + 3Cl^- \quad ([H^+] > 5.0M)$$

and

$$GeOCl_2^{--} + 2H^+ + 2e = Ge^o + 2Cl^- + H_2O \quad ([H^+] < 1.0M)$$

Electrical Conductivities of Molten Aluminum Chloride-Potassium Chloride Mixtures

C. R. Boston,[1] L. F. Grantham, and S. J. Yosim

Atomics International Division of North American Rockwell Corporation, Canoga Park, California

ABSTRACT

The electrical conductivities of aluminum chloride-potassium chloride mixtures were measured over the composition range 15-80 m/o (mole per cent) $AlCl_3$ and at temperatures of 180°-1080°C. A minimum at 33 m/o $AlCl_3$ and a maximum at 50 m/o were observed in the equivalent conductivity as a function of composition. The system was considered as consisting of the two binary systems, KCl-$KAlCl_4$ and $KAlCl_4$-Al_2Cl_6, since the compound $KAlCl_4$ is extremely stable in the liquid. The compound $KAlCl_4$ had a maximum specific conductance with temperature near 1000°C. The negative deviations of conductivity isotherms for the KCl-$KAlCl_4$ system are apparently due to large differences in anion polarizabilities, whereas the positive deviations for the $KAlCl_4$-Al_2Cl_6 system are attributed to basic changes in melt structure.

Aluminum halide-alkali halide mixtures are of interest as solvents because of their low melting points and their great range of acidic properties as the composition is varied. Previous conductivity measurements (1-8) on these systems have been limited for the most part to compositions between 50 and 80 m/o AlX_3, since below 50 m/o the liquidus curve rises very rapidly, and above 80 m/o a two-liquid phase region usually occurs. Also, most measurements have been made below 300°C because of the high vapor pressures characteristic of these mixtures. This work extends the composition range to 15 m/o $AlCl_3$ and the temperature range to over 1000°C. No attempt was made to determine conductivities above 80 m/o since independent, visual measurements showed that this system does not exhibit normal consolute behavior.

Experimental

Aluminum chloride was prepared from high-purity aluminum metal and HCl (9). Anhydrous KCl was

[1] Present address: Metals and Ceramics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830.

prepared from reagent-grade material by a method similar to that used by Boston and Smith (10) for the purification of LiCl-KCl eutectic. The $AlCl_3$-KCl mixtures were prepared by weighing the components into conductivity cells in a dry box purged with high-purity argon.

The type of conductivity cell used was a modification (11) of that described by Grantham and Yosim (12). This cell was designed to permit accurate conductivity measurements of molten salt systems at high temperatures and pressures and was especially well suited to the study of aluminum chloride-containing systems over a wide temperature and composition range. The tungsten electrode material used in these cells was found to be inert to $AlCl_3$-KCl mixtures even at temperatures of 1000°C.

The procedure for measuring electrical conductivities has been described (12) previously. Conductivities were found to be frequency insensitive in the range 1-5 kHz. To prevent cell rupture an external pressure was applied to the conductivity cell for only one composition—70 m/o $AlCl_3$. The technique (13) for applying external pressure to the cell consisted of enclosing it in a pressurized Hastelloy N container and applying pressures slightly greater than the internal vapor pressure of the salt.

Results

The specific conductivities, K, are plotted against temperature in Fig. 1. Equivalent conductivities, Λ, were calculated using the density data of Morrey and Carter (14) for the mixtures. The conductivity and density data of Van Artsdalen and Yaffe (15) were used for pure KCl. Specific conductivity was plotted against composition at various temperatures in Fig. 2, and a similar plot of equivalent conductance is shown in Fig. 3. For convenience, compositions were calculated on the basis of KCl and monomeric $AlCl_3$, even though liquid aluminum chloride exists as Al_2Cl_6

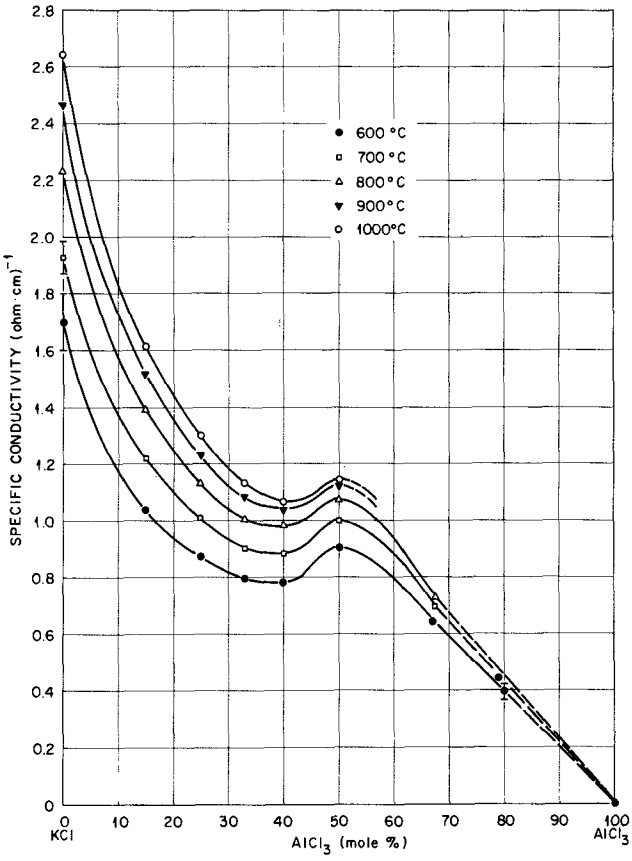

Fig. 2. Specific conductivity vs. composition for various temperatures.

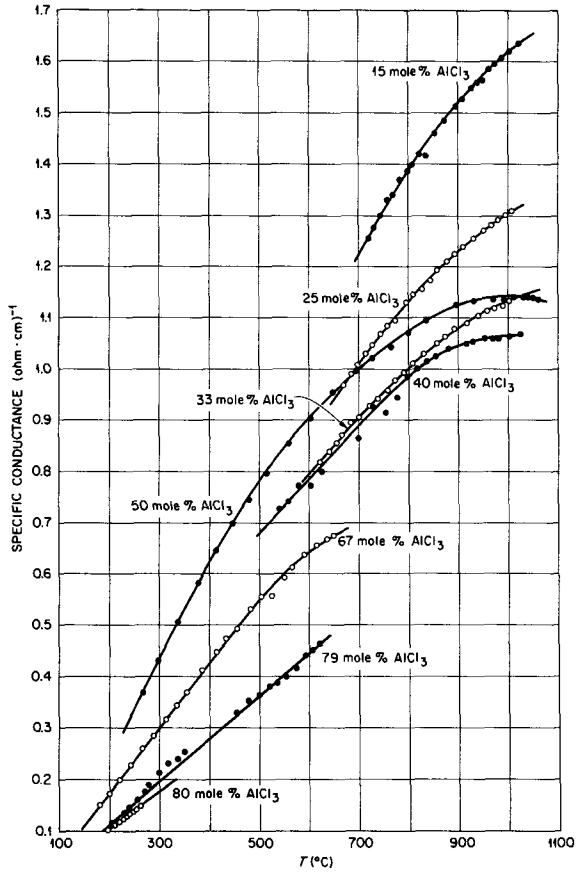

Fig. 1. Specific conductance vs. temperature for various compositions.

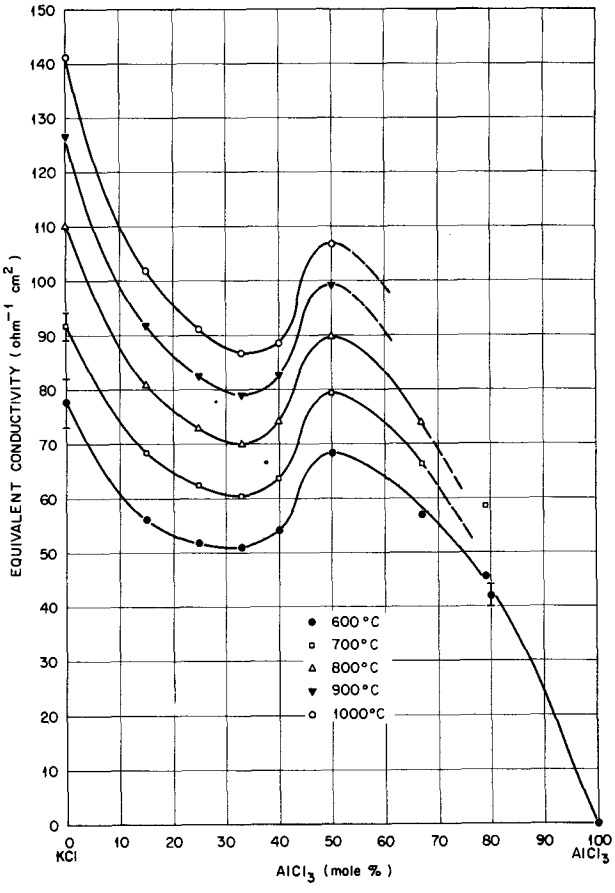

Fig. 3. Equivalent conductivity vs. composition for various temperatures.

dimers (16). For the complete system, the general shapes of the conductivity isotherms are essentially unchanged by use of the dimeric formula. However, in later discussions when the aluminum chloride-rich region is considered as a separate system, the dimeric nature of aluminum chloride is emphasized by use of the formula Al_2Cl_6.

From these plots one can see that the deviations from additivity were quite large. The deviations were negative on the KCl-rich side and positive on the $AlCl_3$-rich side and were relatively insensitive to temperature. The larger deviations (60-80%) occurred at compositions near 50-70 m/o $AlCl_3$.

Values of K from smoothed curves of K *vs.* T were used in constructing Fig. 2 and 3. It is interesting to note that, if the low-temperature linear portions of the K *vs.* T plots were extrapolated to obtain conductivities at higher temperatures, this raised the conductivity isotherms near 50 m/o $AlCl_3$ thus making the deviations from additivity even larger in this region.

The conductivity *vs.* temperature curves in Fig. 1 have the same general shape as those often observed (11) for pure compounds. The conductivities at first increase linearly with temperature but gradually the slopes decrease, resulting in a conductivity maximum. For the $AlCl_3$-KCl mixtures, the temperature of maximum conductivity, T_{max}, was usually above the temperature-pressure limits of the apparatus, an exception being the 50 m/o mixture, corresponding to the compound $KAlCl_4$, where T_{max} was about 1000°C.

Discussion

Many studies have been made of conductivity changes with composition in binary molten-salt mixtures. Deviations from additivity have usually been interpreted as evidence for changes in the degree of ionic association in the melt or of actual compound formation. Delimars'kii (17) suggests that in a qualitative way deviations from additivity can be correlated with phase diagrams in that such deviations tend to increase in both number (positive and negative) and magnitude as the phase diagram becomes more complex, *i.e.* with progression from solid solutions to eutectics and finally to congruently melting compounds. The more stable the compounds in the liquid phase, the greater the deviations from additivity.

The phase diagram (18, 19) for $AlCl_3$-KCl shows eutectics at 49.0 m/o $AlCl_3$, 250°C, and at 67 m/o $AlCl_3$, 128°C. A two-liquid region extends from 82 to 99 m/o $AlCl_3$. A congruently melting compound, $KAlCl_4$, melts at 256°C and is quite stable in the liquid phase. Grothe (20) reports a vapor pressure at this composition of 22 mm Hg at 700°C, and extrapolation of his data indicates that the vapor pressure is still less than 1 atm at 1000°C. Several Raman studies (21-23) of the liquid indicate the presence of tetrahedral tetrachloroaluminate ions even though there is some disagreement about details in the spectra. Dewing (24) has shown that the corresponding sodium compound, $NaAlCl_4$, even exists in the vapor phase. Thus, the phase diagram for $AlCl_3$-KCl is fairly complex with at least one very stable compound so that one might expect large deviations from additivity for conductivity isotherms.

Potassium chloride-rich mixtures.—Since the 1:1 compound is so stable, it may be more reasonable to consider the KCl-$AlCl_3$ system as consisting of the two separate systems, KCl-$KAlCl_4$ and $KAlCl_4$-Al_2Cl_6. When this is done, the equivalent conductivities for the KCl-$KAlCl_4$ system show negative deviations from simple additivity over the entire composition range. The maximum deviation at 600°C was 28% and occurred near 50 m/o $KAlCl_4$. The equivalent conductance of $KAlCl_4$ at 600°C was 136 ohm^{-1} cm^2.

Negative deviations of this magnitude have been observed even for relatively simple systems such as LiCl-KCl which shows a 26% deviation (15) from additivity at 800°C. The explanation offered by Van Artsdalen and Yaffe (15) for such negative deviations was in terms of a contracted or expanded chloride semilattice as one substitutes Li^+ or K^+, respectively. The over-all conductivity being determined largely by cation mobility might be expected to decrease as the chloride semilattice contracts and increase as it expands. However, this explanation would predict positive deviations at high LiCl compositions where the chloride semilattice is expanded by K^+ additions, but they actually found negative deviations. Furthermore, this interpretation would predict positive deviations instead of the negative deviations observed in this study at low $AlCl_4^-$ composition where the chloride semilattice is again expanded by addition of the large $AlCl_4^-$ ions. These authors also measured equivalent conductivities for the KCl-KI system, which bears some resemblance to the KCl-$KAlCl_4$ system (common cation and different anions). Again, negative deviations were observed over the entire composition range. Markov and Shumina (25) have shown that negative deviations are actually to be expected for noninteracting mixtures and have derived the equation, $\lambda_{mix} = x_1^2\lambda_1 + x_2^2\lambda_2 + 2x_1x_2\lambda_1$, to predict the equivalent conductivity of such mixtures. The x's are mole fractions, and λ's are equivalent conductivities. The derivation assumes random mixing and an over-all rate of transposition of ions in the melt which is determined by the lesser conducting constituent. However, the deviations observed for KCl-$KAlCl_4$ were approximately twice those predicted. The maximum deviation from both simple additivity (−28%) and the theoretical (Markov-Shumina) curve (−17%) occurred near 50 m/o $KAlCl_4$.

The negative deviations observed by Van Artsdalen and Yaffe for the KCl-KI system, mentioned above, were also greater (−4%) than those predicted by the Markov-Shumina equation, and it has been suggested (17) that this is due to the difference in polarizabilities of the chloride and iodide ions. Following this line of reasoning, the much larger deviations observed here for the KCl-$KAlCl_4$ system would indicate an even greater difference in polarizabilities of the Cl^- and $AlCl_4^-$ ions. Thus, polarizabilities would appear to fall in the order, $I^- > Cl^- >> AlCl_4^-$.

The only previous conductivity measurements on KCl-rich mixtures of KCl and aluminum chloride are those of Grothe (6). The compositions measured were 43, 35, and 7 m/o KCl-$KAlCl_4$. This was sufficient to show that strong negative deviations and, in fact, a minimum in conductance occurred with change in composition. However, the composition range was insufficient to locate either the minimum or the point of maximum deviation. Although our conductivities are in fairly good agreement with those of Grothe, we disagree with his interpretation. He suggests that the replacement of poorly conducting, dimeric K_2Cl_2 by the more highly conducting $KAlCl_4$ would explain the increase in conductivity between 43 and 7 m/o KCl. Since independent evidence for K_2Cl_2 is lacking, we feel that the suggestion of such specific entities to explain these results is unnecessary. Certainly, one might argue for varying degrees of association in the melt as implied when discussing relative anion polarizabilities, but the suggestion of dimer formation does not appear justified.

We feel that the large negative deviations observed in the KCl-$KAlCl_4$ system are best explained in general terms in the following way. Pure molten-salt conductivities appear to be largely a function of cation mobility with the size of the anion being much less important than its polarizability. In this system it appears that cation mobility is considerably greater in the pure $AlCl_4^-$ semilattice than in the pure Cl^- semilattice—the equivalent conductivity of $KAlCl_4$ being almost twice that of KCl. This is not too surprising, since one would expect the $AlCl_4^-$ ion to be

less polarizable than the chloride ion, thus giving less resistance to cation migration. In the mixed anion semilattice the cations have a lower mobility as reflected by the Markov-Shumina equation (*i.e.*, negative deviations), and may be even lower than in either pure anion semilattice alone (*i.e.*, minima, as observed here) when anion polarizabilities differ greatly. Thus, the large negative deviations observed for KCl-$KAlCl_4$ represent an extreme case of conductivity behavior observed previously in such systems as KCl-KI.

Aluminum chloride-rich mixtures.—Equivalent conductivity (and, to a lesser degree, specific conductivity) isotherms show positive deviations on the aluminum chloride-rich side of the KCl-$AlCl_3$ composition diagram shown in Fig. 3. When a similar plot is made for $KAlCl_4$-Al_2Cl_6, the deviations are even more apparent with a maximum positive deviation from additivity of about 50% occurring near the 50 m/o composition. This is apparently due to the drastic change in the nature of molecular Al_2Cl_6 when it reacts with $AlCl_4^-$ to form such species as $Al_2Cl_7^-$. In this way aluminum chloride changes from a nonconducting (26) entity to an ionic species contributing to the over-all conduction of the mixtures. Evidence for $Al_2X_7^-$ ions in these melts is indirect and consists of phase diagrams (19, 27) and vapor pressure measurements (24, 28).

The aluminum chloride-potassium chloride system bears some resemblance to both the $MgCl_2$-KCl (29) and the $ZnCl_2$-KCl (30) systems. All three cases involve the breakdown of associated structures as KCl is added. Neutral Al_2Cl_6 dimers in the liquid are broken to form ionic species as described above, while the network structure of liquid $ZnCl_2$ also breaks down to form smaller ionic units. The structure of liquid $MgCl_2$ is less certain, but one would expect the relative degrees of association to be in the order $AlCl_3$ (dimers) >>> $ZnCl_2$ (network) >> $MgCl_2$ > KCl. As might be expected, similarities in conductivity isotherms are observed for these three systems. Negative deviations are found in the KCl-rich region, while positive deviations appear on the other (acidic) side of the composition diagram. The deviations are less pronounced for the $MgCl_2$-KCl and $ZnCl_2$-KCl mixtures than for aluminum chloride-potassium chloride mixtures in keeping with the above order of degrees of association.

In summary then, the KCl-rich mixtures (*i.e.*, KCl-$KAlCl_4$ system) appear to be of the simple "noninteracting" type with the large negative deviations being mainly due to the large difference in anion polarizabilities. The aluminum chloride-rich mixtures (*i.e.*, $KAlCl_4$-Al_2Cl_6 system), on the other hand, show large positive deviations presumably due to a basic change in melt structure on mixing. Thus, the aluminum chloride-potassium chloride system may be thought of as an extreme example of behavior which has been observed to a lesser extent for systems such as KCl-KI and KCl-$ZnCl_2$.

The Mechanism of Hydrogen Evolution at a Stainless Steel Electrode in Basic Solution

R. N. O'Brien and P. Seto[1]

Department of Chemistry, University of Victoria, Victoria, British Columbia, Canada

ABSTRACT

The mechanism of the hydrogen evolution reaction at the stainless steel Type 304 (18.20% Cr, 18.20% Ni, austenitic) was investigated in the presence of plain NaOH solutions and with various ions added. It is concluded that the mechanism is

$$H_2O + M + e \underset{}{\overset{\text{(slow)}}{\rightleftharpoons}} M\text{-}H; \quad 2M\text{-}H \overset{\text{(fast)}}{\rightarrow} H_2$$

Tafel parameters are given.

While the hydrogen evolution reaction has been most frequently studied at the platinum (1), the dropping mercury (2), the iron (3-5), the silver (6, 7), and the nickel (8-11) electrodes, it has yet to be studied at the commercial austenitic stainless steel (s.s.) Type 304 metal in strong sodium hydroxide solution. The electrolytic evolution of hydrogen at the s.s. 304 alloy in the alkaline media was undertaken because of the possibility of industrial application. The elemental composition of commercial austenitic s.s. 304 is listed as 18-20% Cr, 18-20% Ni, 2% Mn, 1% Si, 0.08% max C, 0.045% P, 0.03% S, and the rest Fe (12). The structure of the metal alloy is therefore very complex and, hence, its surface. Furthermore, a passivating film of unknown structure and nature exists on the surface on exposure to air or oxidizing media (13). The thickness of the ultrathin film ranged from 30 to 60Å (14). It is this thin film that gives a shiny luster characteristic to the alloy surface. It is speculated that the passive film disappears either under hydrogen evolution conditions (13, 15), or pickled with HCl (13), or pickled with Br_2|MeOH mixture (14).

Theory

In neutral or alkaline solutions, four mechanisms for the electrolytic hydrogen evolution at the solid metal electrodes are regarded as possible. The mechanisms can be represented by:

$$(A)\quad H_2O + M + e \underset{\underline{1}}{\overset{\text{(slow)}}{\rightleftharpoons}} M\text{-}H; \quad 2M\text{-}H \overset{\text{(fast)}}{\underset{\underline{2}}{\rightarrow}} H_2 \qquad b = 120\ \text{mV}$$

$$(B)\quad H_2O + M + e \overset{\text{(fast)}}{\rightleftharpoons} M\text{-}H; \quad 2M\text{-}H \overset{\text{(slow)}}{\rightarrow} H_2 \qquad b = 30\ \text{mV}$$

$$(C)\quad H_2O + M + e \overset{\text{(slow)}}{\rightleftharpoons} M\text{-}H;$$
$$H_2O + M\text{-}H + e \overset{\text{(fast)}}{\underset{\underline{3}}{\rightarrow}} H_2 + OH^- \qquad b = 120\ \text{mV}$$

$$(D)\quad H_2O + M + e \overset{\text{(fast)}}{\rightleftharpoons} M\text{-}H;$$
$$H_2O + M\text{-}H + e \overset{\text{(slow)}}{\rightarrow} H_2 + OH^- \qquad b = 40\ \text{mV}$$

where M represents a metal site on which a water molecule can be discharged to form an adsorbed intermediate M-H and each step is rated fast or slow relative to the other in the mechanism. Several criteria, such as the Tafel slopes, the stoichiometric number, and the concentration of M-H, are available for distinguishing the above mechanisms (1, 10, 16, 19, 22). An experimental criterion such as the maximum current density as the mechanism changes from one mechanism to another, sometimes called the limiting current density, is also available (1).

[1] Present address: Chemistry Department, University of Western Ontario, London, Ontario, Canada.

Experimental

Electrodes and procedures.—Commercial austenitic stainless steel Type 304 rods supplied by Atlas Steel Company were employed as test electrodes. Electrodes of surface areas of 0.23 and 0.44 cm^2 were prepared as described previously (17). Similar electrolytic cells and experimental procedures were also employed.

Polarizing circuit.—An electronic current interrupter technique similar to that described by Hoey and Cohen (18) was used to isolate the ohmic and activation overpotentials. As shown in Fig. 1(a), the test electrode was polarized *via* the counterelectrode by a constant current source. As usual this constant current source was composed of a high-capacity 90V dry cell battery and a variable high-resistance box. A pulse generator and a vacuum diode were inserted between the current source and the electrolytic cell to interrupt the polarizing current. Negative current pulses ($T_r < 22$ nsec) were drawn from the General Radio Pulse Generator Type No. 1217-B which was powered by its analogous GR Power Supply Type No. 1201-B. The pulse repetition frequency (PRF) and the pulse duration employed were 100 Hz and 100 μsec, respectively. Current interruption was obtained by adjusting the amplitude of the negative pulses to a slightly larger value than the current supplied by the battery source. The 6AL5 vacuum diode did not conduct during the time of each negative pulse. As a result, for each 10-msec period, the current flowed in the circuit for 9.9 msec and the electrolysis current was interrupted for 0.1 msec (100 μsec). The polarizing current was measured with a Simpson's microammeter while any noise in the circuit was filtered by the 10-μf electrolytic capacitor.

The switching on and off of the polarizing current resulted in a build up and decay of the electrode potential which was monitored by a Tektronix Type

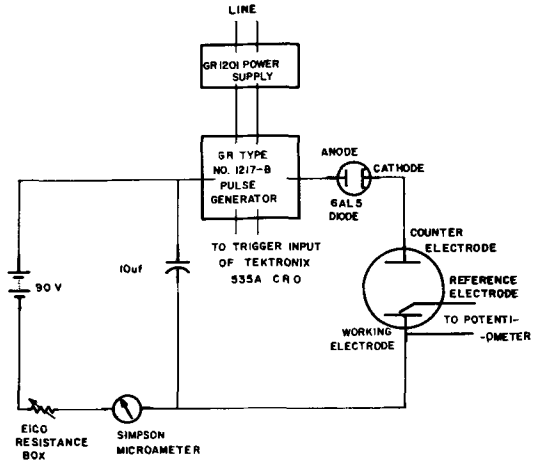

Fig. 1(a). Stainless steel electrode polarizing circuit.

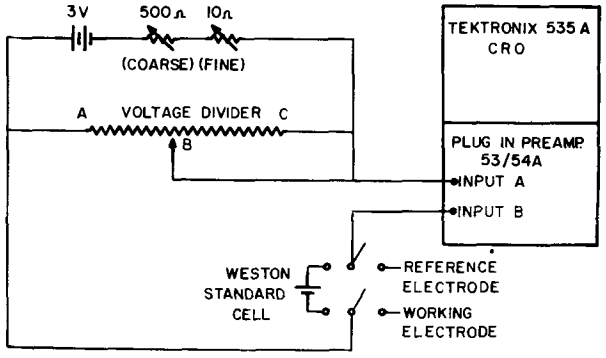

Fig. 1(b). Switching and monitoring circuit.

535 A C.R.O. as shown in Fig. 1(b). By synchronizing the interruption rate with the time base of the C.R.O., a stationary trace was obtained on the C.R.O. screen. The inputs were amplified with a Tektronix Type D preamplifier. It should be noted that the C.R.O. acted as the galvanometer in the usual potentiometer circuit; hence, the electrode potentials were monitored simultaneously.

Results and Discussion

A typical Tafellian plot of decreasing-increasing-decreasing current density runs is shown in Fig. 2. The combination of the lower Tafel slope and of the lower overpotential indicated that the initial electrode surface was less contaminated by absorbed impurities during the first decreasing run. Generally, the electrode potential went up after prolonged electrolysis. For this reason, the average initial down runs are reported.

The cathodic electrode potential-log apparent current density relationships for 0.10, 1.0, 3.0, 5.0, and 10M NaOH solutions are shown in Fig. 3. With the exception of the 5M NaOH solution, a general trend of decreasing overpotential with decreasing NaOH concentration can be observed. The Tafel plots converged at current densities higher than 10 mA/cm^2. Below 10 mA/cm^2 the lines diverged to their respective reversible potential given by the Nernst equation. Tafel parameters calculated from the Tafel equation

$$\eta = \epsilon - \epsilon_r = a - b \log i_c \qquad [1]$$

are summarized in Table I.

It can be seen that the b values decreased with increasing NaOH concentration which may be caused by the same trend in the transfer coefficient. Symmetrical potential energy surfaces were obtained for the 3.0M NaOH ($\alpha = 0.50$). The Tafel slopes 134-105 mV are compatible with mechanisms *A*, *C*, and *D* (1, 10, 20, 23). Mechanism *D* can be ruled out because the electrode surface must be highly covered with atomic hydrogen for the mechanism to be operative. It is unlikely that the stainless steel surface would be covered with a monolayer of H atoms because of the low exchange current density (Table I). In fact the activity of s.s. 304 metal is intermediate between Fe (3) and Ni (9) as compared in Table II. From current-time transient measurements, it was found that a monolayer of adsorbed atomic hydrogen was not reached in the present range of current densities studied.

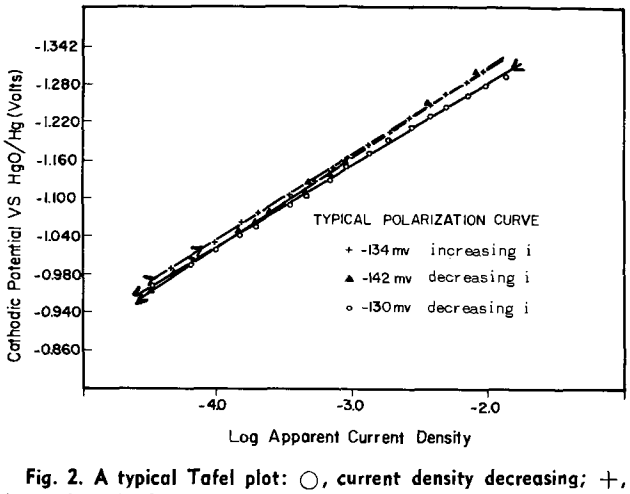

Fig. 2. A typical Tafel plot: ○, current density decreasing; +, increasing; ▲, decreasing.

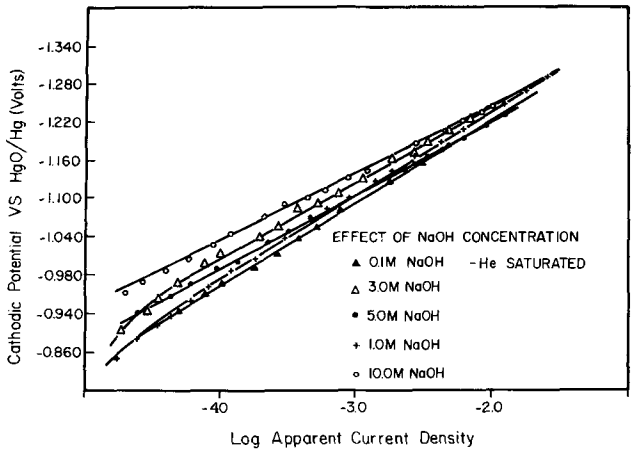

Fig. 3. Effect of electrolyte concentration

Addition of NaF, NaCl, NaI, $BaCl_2$, and $LaCl_3$ did not significantly affect the rate of hydrogen evolution. The anions F^-, Cl^-, and I^- were probably repelled from the highly negatively charged metal surface. The multivalent cations should remain beyond the reaction plane since their hydration numbers should be quite high.

As shown in Fig. 4, iodate ion was very electroactive at the stainless steel surface in alkaline media. The IO_3^- ion was probably reduced according to the equation

$$IO_3^- + 3\,H_2O + 6e = I^- + 6OH^- \qquad [2]$$

It is obvious that the iodate ions were competing with H_2O molecules to be reduced since, at higher IO_3^- concentrations, the discharge of water molecules was shifted to higher electrode potentials.

Uhlig (13) and Popat and Hackerman (15) speculated that the shiny passive film, which is characteristic of Cr-Fe, Cr-Ni, and Cr-Ni-Fe alloys, would dissolve under cathodic hydrogen evolution conditions. This concept should be true in acid solutions. The Pourbaix diagram of a chromium-water system (21)

showed that $Cr(OH)_2$ or CrO_2^- could exist at the potential and at the *p*H ranges covered in this work. Similar potential-*p*H diagrams do not show the existence of any nickel or iron hydroxides/oxides under the same conditions. After the three runs as shown in Fig. 2 (over a period of 3 hr) visual examination of the stainless steel metal surface showed that the characteristic shiny luster remained. Addition of ammonia decreased the hydrogen overvoltage significantly as shown in Fig. 5. The reagent ammonia may have dissolved some chromium hydroxides and/or oxides (20), resulting in a modification of the *M-H* interaction energy. Since the alloy comprised about 70% Fe, it would be expected that the color of the oxide-free and carbon-impregnated (0.08% max) alloy would be black. After prolonged electrolysis at 12.5 mA/cm² for a 44-hr period or at 4 A/cm² for 2½ hr, the electrode surface became black, the characteristic color of carbon steel. The black material could be scraped off gently and a new shiny surface appeared. When the black material was not scraped off, a shiny surface reappeared on dipping into nitric or chromic acid. This suggested that an oxide is present throughout on the s.s. alloy lattice. The electrolytic evolution of hydrogen at an oxide surface has been studied by Makrides (11) and has been discussed by Frumkin (23) and Makrides (9, 11).

A maximum current density for one mechanism of about 4.5 A/cm² was obtained in 1.0M NaOH solution as shown in Fig. 6. It is unlikely that the observed curvature is due to solution concentration polarization as the stirring rate was increased considerably and no effect noted. An electrode of surface area of 0.02 cm² was used to obtain the curve so that solution heating effect was avoided. The phenomenon of the

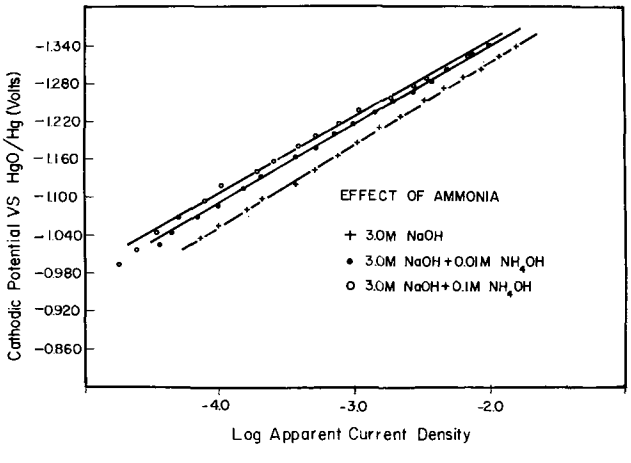

Fig. 5. Effect of ammonia concentration

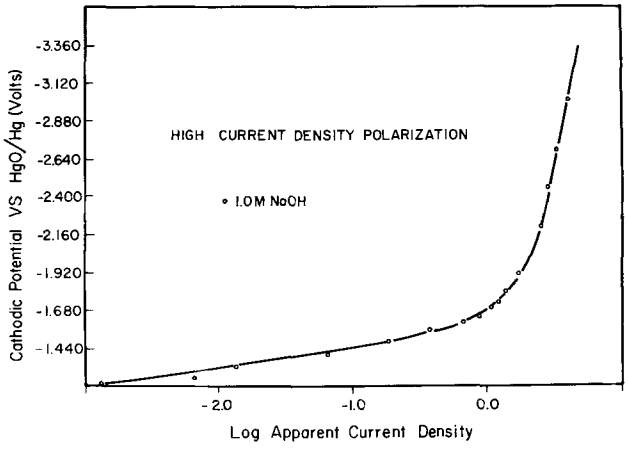

Fig. 6. Limiting current density in 1.0M NaOH

infinite Tafel slope has been interpreted as the maximum rate at which atomic hydrogen combination can occur (1, 10). At this stage the electrode surface is believed to be saturated with atomic hydrogen (monolayer) and mechanism *D* provided an alternative or parallel path to mechanism *A*.

Mechanisms and Kinetics of H_2 Dissociation and Open-Circuit Accumulation of H Atoms during the Formation of the Equilibrium H_2/H^+ Electrode on Platinum

Murray Rosen[*,1] **and Sigmund Schuldiner**[*]

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C.

ABSTRACT

The rate at which dissolved H_2 dissociates and accumulates on a clean, H- and O-free Pt electrode as the reversible H_2/H^+ electrode is formed has been studied under dissociation, diffusion, and mixed control. The kinetics of the open-circuit hydrogen accumulation reaction (h.a.r.) in H_2-saturated (1 atm) 1M H_2SO_4 were determined by a galvanostatic double-pulse method in which the first pulse strips the surface, and the second pulse measures the amount of H accumulated in a given time. Under dissociation control, the accumulation of the first 70% of the equilibrium concentration of H obeys a second-order kinetic relation in which the maximum rate at zero time is 4.46 mA/cm^2. As the h.a.r. proceeds, the initial reaching of zero volt cannot be equated with equilibrium of the H_2/H^+ reaction. A slower rearrangement of adsorbed and dermasorbed H atoms occurs before thermodynamic equilibrium is reached. The hydrogen oxidation limiting current density of 2 mA/cm^2 (0.05-0.7V, vigorous H_2 stirring) is shown to be the geometric average of $i_{diss,max}$ (4.46 mA/cm^2) and $i_{diff,max}$ (geom) (7.25 mA/cm^2). This mixed control indicates that diffusion causes the effective H_2 partial pressure at the electrode surface to be reduced from 1 to 0.45 atm. Only a small fraction of the total number of Pt atoms which are associated with H atoms at equilibrium are active dissociation sites. Non-faradaic charging corrections were found to be complex and involved adsorption/desorption processes as well as double-layer charging.

The object of this study is to determine the kinetics of H_2 dissociation and the instantaneous rate of accumulation of H atoms which associate with a clean Pt electrode; or, in terms of Pt atoms, the instantaneous rate of disappearance of available Pt atoms which can associate with H atoms. A known, Pt electrode/solution interface is electrochemically prepared by applying a galvanostatic pulse of predetermined amplitude and length. The amount of accumulated H atoms or the corresponding loss of available Pt atoms is obtained from the amount of H atoms oxidized on a second pulse that is applied a known time after the first pulse. The solution is either vigorously stirred with H_2 or is a quiescent H_2-saturated solution, both at $P_{H_2} = 1$ atm.

The experimental procedure for applying two identical galvanostatic pulses separated in time by a preset counter has been previously described (1, 2). In the present study, pulses of two different coulombic contents (current density x time) are used so that for the initial pulse either one of two final polarization potentials are reached. In one case, the amplitude and length of the first pulse of a set are fixed so that the electrode is polarized to 1.76V thereby oxidizing all the H associated with the electrode and forming just one monolayer of Pt-O_{ad} on the surface (1, 2). In the second case, the amplitude and length of the first pulse of a set is fixed so that the electrode is polarized to 0.8V thereby oxidizing essentially all the Pt-associated H but not forming any Pt-O_{ad}. Consequently, the loss of available Pt atoms or gain of H atoms is studied: (*a*) when the process occurs on a clean, H- and O-free Pt electrode immediately after the electrode is stripped of a monolayer of Pt-O_{ad} and (*b*) when the process occurs on a clean, H- and O-free Pt electrode immediately after the electrode is stripped of atomic H. In the first case, the Pt-O_{ad} + H_2 reaction occurs first, depleting the interface region of H_2 both by reaction and dilution.

Hence, for the first case, the dissociation of H_2 that follows the removal of Pt-O_{ad} begins under conditions in which the concentration of H_2 at the interface is different from the concentration in the bulk of the solution. On the other hand, in the second case, the dissociation of H_2 takes place at a solution interface free of an H_2 diffusion layer. Consequently, a method for determining the rate at which the H_2/H^+ equilibrium is established at clean, H- and O-free Pt under H_2 diffusion-controlled and H_2 dissociation-controlled conditions is provided.

The pulse length for case (*b*) was not set to polarize the Pt electrode to 0.88V, the potential at which Pt-O_{ad} has been observed to first form (3), because the end of the H oxidation and the beginning of the Pt-O_{ad} region is not sharply defined. The limit of 0.8V was chosen so that Pt-O_{ad} formation would be insignificant. It also is evident that at 0.8V the residue of H atoms is negligibly small.

To facilitate reporting and discussing the results for the H atom accumulation reaction (h.a.r.), four experimental cases based on the initial pulse polarization limits [cases (*a*) and (*b*)] and the stirring conditions are defined in terms of the symbols used in the graphical representation of the data. Cases ▲ and △ represent initial pulse polarization to 1.76V in rapidly stirred and quiescent solutions, respectively. Cases ● and ○ represent initial pulse polarization to 0.8V in rapidly stirred and quiescent solutions, respectively.

Experimental

The closed system of glass pipe construction, the helium and hydrogen purification, and the Pt electrode and miniature glass reference electrodes have been previously described (3, 4). The general procedures

* Electrochemical Society Active Member.

for solution preparation, electrochemical cell, and solution cleaning and pre-electrolysis techniques have been reported in the same references. Ultrapure sulfuric acid (E. Merck A. G., Darmstadt) was used. The Pt bead working electrodes were 0.668 and 0.332 true cm^2 in the two systems used. These true areas were determined from the linear oxygen atom adsorption region of anodic charging curves taken in clean, H_2-saturated 1M H_2SO_4 solution (3). All current densities in this paper are in true areas, so defined, unless otherwise noted. For cleanliness criteria *see* Ref. (2, 5). All results were obtained at 25° ± 1°C. All potentials are reported with reference to the normal hydrogen electrode (NHE).

Galvanostatic anodic pulses (1-2 A/cm^2) were provided by an Electro Pulse Model 3450C or Model 3450D pulse generator. A Tektronix Type 547 oscilloscope with Type 1A1 or 1A5 plug-in was used to display the data which was then recorded on film. The solution *IR* drop was largely removed from the display when using the 1A1 unit by subtracting the appropriately attenuated rectangular pulse at the generator output from the signal across the cell. The 1A5 unit is equipped with a Comparison Voltage Circuit which by use of a panel dial can be equated to the solution *IR* drop. A Hewlett-Packard 5214L Electronic Preset Counter provided accurately spaced triggering pulses to the pulse generators. The time intervals (10^{-3} to 100 sec) between the two pulses were known to within 10^{-3} sec. For time intervals greater than 100 sec, the second pulse was triggered manually with the time interval being known to about 0.1 sec.

For cases ● and ○, the preset time (time between initiation of the first and second pulses) can be considered to be "real" time, *t*, because the open-circuit decay immediately following the first pulse is extremely rapid, allowing H atoms to be observed on the second pulse well within 5 msec. In addition, the time correction due to the length of the first pulse is insignificant compared to the open-circuit time for h.a.r.

Since in cases ▲ and △, the Pt-O_{ad} + H_2 reaction has to occur before H_2 begins dissociating and accumulating on the surface at a detectable rate, the time, τ_o, for the Pt-O_{ad} reaction to be completed has to be determined and then subtracted from the preset time read on the counter to obtain "real" time, *t*, for h.a.r.

Experimentally, two different systems consisting of cleaning trains, gas-tight cells, and Pt electrode beads were used in case ▲, and τ_o's are 0.46 sec (0.668 cm^2) and 0.25 sec (0.332 cm^2). The 0.668 cm^2 electrode was used for case △ (τ_o = 0.545 sec) and cases ● and ○. When the solution was stirred, the H_2 flow rate into the cell was from 500 to 700 ml/min. The time interval waited between each set of double pulses was at least 7 min.

Results

H.A.R.—The amount of hydrogen dissociated and accumulated following a time, *t*, is considered equal to the amount of H oxidized by the second pulse. Any H atom contribution by H^+ reduction would be negligible because of anodic double-layer discharge and positive potential during open-circuit decay. The term q_H ($\mu C/cm^2$) represents the total H associated with the electrode. Two examples (Fig. 1) of first (traces 1, 2) and second (traces 1′, 2′) pulses of case ● are typical illustrations of a set for any polarization and stirring condition. As the time allowed for open-circuit decay is increased from 0.045 sec (traces 1, 1′) to 0.047 sec (traces 2, 2′), the amount of q_H observed on the second pulses (traces 2′ *vs.* 1′) has increased while at the same time the potential reached as the second pulse is applied is less noble (0.15 *vs.* 0.16V). From such oscilloscope traces, q_H can be plotted as a function of time. Figure 2 shows a q_H *vs.* log *t* plot to permit display of the total time.

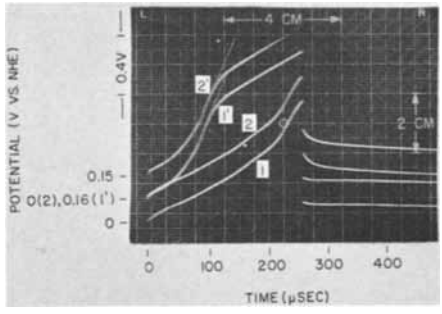

Fig. 1. Two typical sets of anodic charging curves for the double-pulse method. Case ● (see Symbols). Time interval between first (1) and second pulse (1′) is 0.045 sec. Time interval between first (2) and second pulse (2′) is 0.047 sec. Open-circuit potential on first pulses (1, 2) is 0.000V. Open-circuit potential on second pulses (1′, 2′) is 0.16 and 0.15V, respectively.

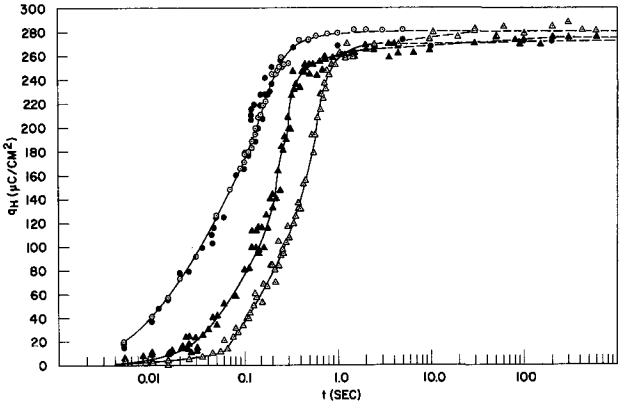

Fig. 2. Dependence of q_H on *t* for various cases. See Symbols

Double-layer correction.—In order to be able to calculate q_H from the raw data (Fig. 3), which includes double-layer discharging, the value of the charge required to polarize the double layer, q_{dl}, over the same potential limits must be determined. The value of q_{dl} can be determined by integrating the area under a C_{dl} *vs.* *E* curve, where C_{dl} represents the double-layer capacitance at a potential, *E*. The limits for the integration are set by the instantaneous potential, *E*, that the system decays to after the first pulse (Fig. 4) and by the end of the hydrogen region of the second pulse (0.8 or 0.88V). The value of C_{dl} can be calculated from the slope of an *E* *vs.* *t* oscilloscope trace taken by

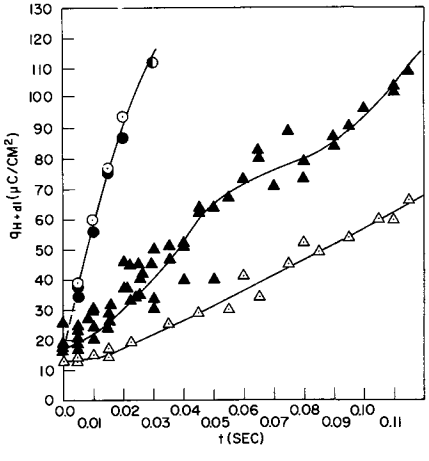

Fig. 3. Total amount of charge, q_{H+dl}, required to oxidize H atoms accumulated after first pulse and to charge double-layer capacitance after times, *t*, for various cases. See Symbols.

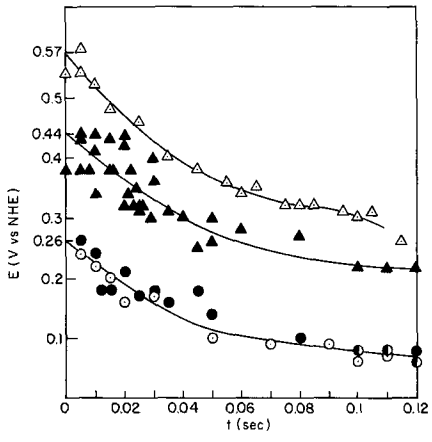

Fig. 4. *E vs. t* during h.a.r. for various cases. See Symbols

either a long constant current charging pulse (5 μsec) or a short pulse ($\sim$ 100 nsec).

The C_{dl} as a function of E has been determined using 5 μsec pulses by Schuldiner and Roe (3), and an average value of 40 μF/cm^2 between 0.2 and 0.8V was determined. However, recent measurements at the same laboratory (6) using $\sim$ 100 nsec pulses gave a significantly different C_{dl} *vs.* potential relation with an average value of 19 μF/cm^2. Quite obviously, the earlier higher value for capacitance reflects significant contributions from faradaic and other processes, *e.g.* hydrogen oxidation at lower potentials and probably adsorption-desorption processes especially at the higher potentials. However, to use the shorter pulse corrections for the entire potential range would include such adsorption-desorption contributions in q_H at higher values of E. The correction used becomes increasingly more important as the initial potential at the start of the second pulse becomes less noble.

The transitional potential above which corrections are based on the longer pulses is taken to be 0.34V because this is the beginning potential for charging curves taken in He-saturated solutions (3). Below this potential of 0.34V, corrections are based on measurements taken with the 100 nsec pulses so that the total charge due to H oxidation can be more accurately measured. Above 0.34V, corrections based on the longer pulses are used so that the unknown probable adsorption-desorption processes can be subtracted out.

The reliability of this complex correction procedure can be demonstrated by comparing the q_{dl} determined by the above procedure to the value of q_{dl} determined by extrapolating the q_{H+dl} *vs. t* plot (Fig. 3) to zero time. The values determined from Fig. 3 for q_{dl} at $t = 0$ are 17, 17, and 12 μC/cm^2 for overlapping cases ● and ○, and for cases ▲ and △, respectively. The values determined by the double-layer correction procedure used are 18.5, 16, and 11 μC/cm^2, respectively. The potential at zero time for each experiment can be found by extrapolating to zero time the *E vs. t* plot (Fig. 4).

Equilibrium establishment.—The dissociation of H_2 and accumulation of H atoms continues until the system reaches equilibrium. During this time, the potential first decays rapidly and then levels off as the system reaches equilibrium. The relative rates for potential decay for all four cases are compared in Fig. 5. An example of the time required for a system to reach equilibrium is shown in Fig. 6 for case ●. Here three sets of double pulses were taken at pulse-interval time, t, equal to 0.2, 2.0, and 200 sec. In order to be sure that the system was initially at the H_2/H^+ equilibrium, each set of double-pulse measurements was spaced at least 7 min apart.

Discussion

H.A.R.—Figure 2 shows that the net rate of H atom accumulation is the greatest when first pulse polarization is limited to 0.8V (cases ● and ○) so that Pt-O_{ad} does not form. The h.a.r. for these cases is largely independent of stirring conditions (a small stirring effect is indicated in Fig. 5—compare traces 1 and 2—which show a significant stirring effect below 0.1V) indicating that a major diffusion component to the reaction control for case ● does not exist. Also, H_2 dissociation and accumulation of H atoms proceeds rapidly after the first pulse is terminated.

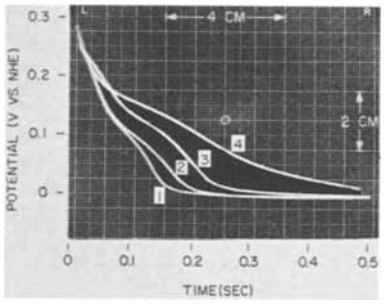

Fig. 5. Oscilloscope traces for potential *vs.* time relation of h.a.r. for Case ●, trace 1; Case ○, trace 2; Case ▲, trace 3; Case △, trace 4. See Symbols.

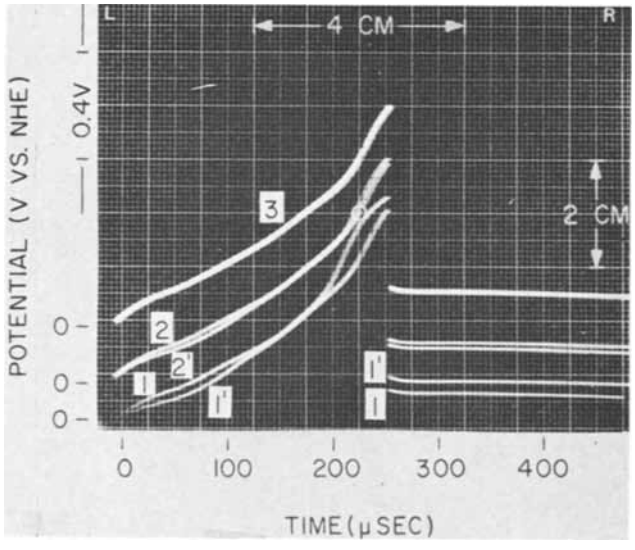

Fig. 6. Effect of *t* on the amount of accumulated H and polarization behavior. Case ●. Pulse interval time between 1 and 1′ is 0.2 sec; between 2 and 2′ is 2.0 sec; between 3 and 3′ (3 and 3′ overlap) is 200 sec.

On the other hand, cases ▲ and △ show a diffusion dependency and a period where the initial build-up of H atoms increases relatively slowly. The diffusion dependency arises from the preceding Pt-O_{ad} + H_2 reaction which depletes the solution at the electrode interface of molecular hydrogen, simultaneously generates water, and establishes a diffusion gradient that is only partially decreased by stirring (case ▲). As to be expected, the diffusion dependency is greater for the quiescent solution (case △) than it is for case ▲. The scatter of points for each case is random. The results of cases ▲ and △ indicate that diffusion gradients continue to exist until the equilibrium H_2/H^+ exchange is established. The initially slow h.a.r. is attributed to removal of the last traces of Pt-O_{ad} and to an initial lag in diffusion of H_2 to the surface.

The rounding off to the limiting q_H plateau in Fig. 2 represents the approach of system equilibrium as the concentration of accumulated H atoms reaches its limiting value, q_{H_∞}. As illustrated in Fig. 2, equilibrium is not reached in the same manner for all cases. In case ○, the plateau is formed soon after the round-

ing off occurs, whereas in case △ there is an additional rise following the rounding off before equilibrium values of q_H are observed. As will be shown later, the reproducibility of the measured equilibrium concentration of hydrogen, q_{H_x}, is poor. This variation is attributed to the presence of gaseous H_2 which contacts the electrode surface and can contribute to the measured q_H.

As can be seen in Fig. 2, the plateau value of q_{H_x} for quiescent solutions is slightly higher than those values for the stirred solutions. This difference also is attributed to effects of gaseous H_2. Stirring may reduce the actual electrode coverage with H_2 gas.

Equilibrium establishment.—The criteria used to determine when a system reached equilibrium are based on the matching of the first and second charging and decay curves (Fig. 6). Since the first charging curve is from the equilibrium H_2/H^+ reaction, a match by the second pulse gives the time required to reach equilibrium at open circuit. The matching of the potential decay, shown in Fig. 6 as parallel lines on the right side of the picture, is a very sensitive indication of the maximum polarization of the first and second pulses. An interesting point is seen at the $t = 0.2$ and 2.0 sec curves of Fig. 6 (curves 1, 1′, 2, 2′). In all these cases, E is zero, but the overlapping of the charging curves does not begin until about 0.3V. Moreover, prior to the overlapping there is a potential region for which the charging curves of the second pulse dip below those charging curves of the first pulses indicating that less polarization is required to oxidize the same number of H atoms in this potential range. This difference is attributed to the transient distribution of weakly and strongly adsorbed and dermasorbed H atoms which are not in the equilibrium distribution for curves 1′ and 2′. Thus, even though the active, weakly bonded H atoms which establish the equilibrium potential are present at virtually their equilibrium concentration, the equilibrium distribution of all the H atoms associated with Pt is not established in these cases. The relative rates at which equilibrium is established for the four cases are seen in the curves of Fig. 2. However, it must be kept in mind that both an E of zero volt and a q_{H_x} accumulation of H atoms are required for true equilibrium since distributions of $q_H < q_{H_x}$ can give zero volt.

Diffusion gradient.—The effect of a substantial gradient produced by the preceding Pt-O_{ad} removal reaction has already been mentioned as the primary reason for the dissimilar results of cases ▲ and △ as compared with the results of cases ● and ○. By plotting q_H *vs.* t for case ▲ and △ (Fig. 7), it can be determined whether or not a constant diffusion gradient is established. The required linear relationship is found only for the curve of case △ above 0.2 sec. This relationship requires that the concentration of H_2 at the surface remains very small and constant. Hence, the h.a.r. is under nearly complete diffusion control and occurs at a constant rate of 3.1 x 10^{-4} A/cm² as given by the slope between 0.2 and 0.7 sec (80 and 240 μC/cm²). When the solution is stirred, case ▲, a definite linear region is not observed, indicating that the h.a.r. is most likely under mixed diffusion and dissociation control.

The initial plateau for case △ (0-0.06 sec) most likely represents the interaction of H_2 with the last traces of atomic O which reduces the net value of q_H. From 0.06 to about 0.16 sec a transition to the linear diffusion-controlled h.a.r. occurs.

E vs. q_H.—In order to compare the transient concentration of accumulated H atoms to those obtained under steady-state conditions, a plot of E *vs.* q_H was prepared (Fig. 8). The data in this curve are the average values for five different methods of determinations of E *vs.* q_H. These are: (*a*), (*b*) the transient ●, ○ cases; (*c*) previously reported (3) steady-state data for which the potential was controlled by the partial pressure of stirred H_2 and $H_2 + O_2$ mixtures, and (*d*), (*e*) unreported steady-state potentiostatic relations between q_H and E in both H_2 and helium-stirred solutions determined at this laboratory. All q_H values have been corrected for double-layer capacitance by the method indicated under the heading *Double-layer correction* in the Results section of this paper. Since the values obtained by these five different methods are the same within the experimental precision, they are all lumped together in Fig. 8 (average values are ○ points), where the spread of all the data is shown by the hatched lines. The E *vs.* q_H relationships for cases ▲ and △ do not fit the Fig. 8 data and are plotted separately in Fig. 9 (the dotted line represents the curve in Fig. 8).

As can be seen in Fig. 8, E *vs.* q_H follows an almost linear relation after the initial rapid decay. Most important is the fact that the transient (cases ● and ○) data are essentially the same as the steady-state, open-circuit, and potentiostatic data indicating that either parameter q_H or E can be used to define the system.

On the other hand, comparing Fig. 8 and 9, the curves indicate that for the same quantity of H atoms, q_H, less potential decay has been achieved in cases ▲ and △. These differences may be explained by considering the effect of H_2 diffusion. Since the diffusion gradient created by the Pt-O_{ad} removal reaction is limiting the supply of H_2 to the surface, the partial pressure of H_2 at the surface ($P_{H_2,S}$) is less than it is in the bulk. Hence, since q_H and $P_{H_2,S}$ determine the measured potential, it is more positive for the cases ▲ and △.

Diffusional effects also account for the E *vs.* q_H relation for case △ from 140 μC/cm² and above (Fig. 9). The diffusion dependency causes a time lag during which H associated with the electrode may migrate to other lattice sites on the surface or is dermasorbed.

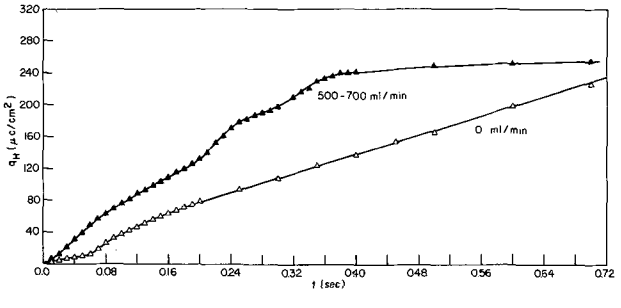

Fig. 7. q_H *vs.* t for cases ▲ and △. H_2-stirring rate for ▲ was 500-700 ml/min, and for △ was 0 ml/min.

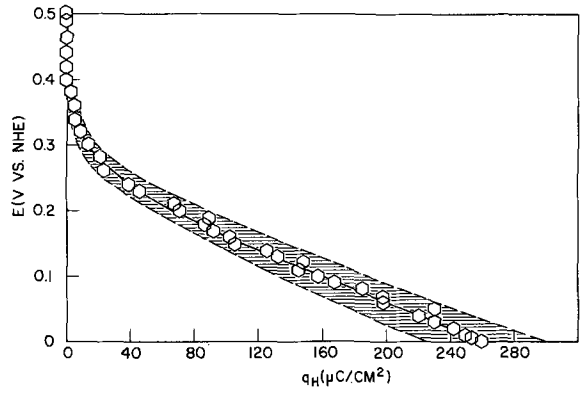

Fig. 8. E *vs.* q_H. Summary of all cases primarily not under diffusion control. See Symbols for definition of ○. Hatched lines show spread of data.

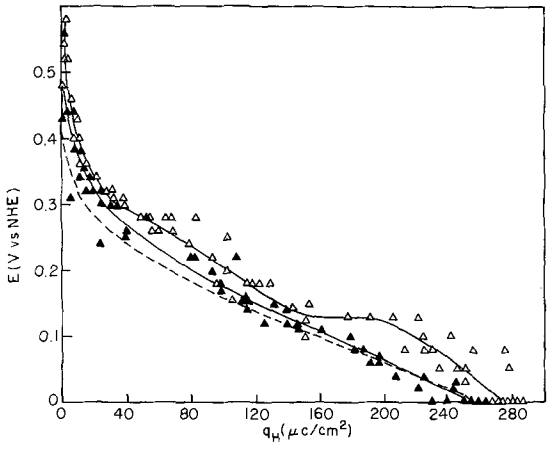

Fig. 9. E vs. q_H for cases ▲ and △ which are primarily under diffusion control. Broken line is data for ○ (Fig. 7). See Symbols.

Such behavior suggests that, in terms of time and/or potential, not all H atom-Pt associations are equivalent and that given sufficient time rearrangements can occur. In the other cases, where diffusion dependency is less or does not exist, rearrangements have less effect on the E *vs.* q_H relations.

If rearrangement of H atoms does occur, then sometime before equilibrium is reached the rearrangement effects should cause the dE/dq_H to decrease at a faster rate. Note that this does occur between 200 and 280 $\mu C/cm^2$ (△, Fig. 9). Any possibility that enough time was not allowed for equilibrium to be reached is rejected in light of Fig. 2 which shows cases ○ and △ coming to equilibrium at the same q_H.

Hydrogen regions.—Previous (3) charging curve data taken from the H_2/H^+ equilibrium potential of zero volt have shown that H ionization can be considered to occur in six potential regions. In the present study, these regions are investigated using many more samples to obtain much greater detail and, consequently, the limiting potential of each region is more precisely determined.

For each charging curve at time t for cases ● and △, q_H for each region is plotted as a function of log t (Fig. 10) to show the rate at which the various H regions (HR) accumulate H atoms both in the presence and absence of an H_2 diffusion layer. The assumption made in constructing these curves is that regions, *i.e.* HR_1, HR_2, *etc.*, exist and are being filled. The potential decay to a particular potential (E) is related to these regions. This assumption, however, should not be taken so that only higher potential regions are being first filled since extremely small amounts of H atoms may exist in the lower potential regions simultaneously. In short, a few atoms may accumulate in HR_1 and HR_2, but not enough to significantly affect E. This requirement is necessitated by the opinion that HR represents different forms and degrees of association between H atoms and Pt. It should be emphasized that the value of an HR accumulation plot lies in demonstrating, on a relative basis only, that different regions acquire H atoms at different times and at different rates.

Examining the results of case ● (Fig. 10), the following points can be established. When the h.a.r. begins, H atoms simultaneously fill the $HR_{6,5,4}$ regions (but note that none of them are filled to their equilibrium levels or fill at the same rate). When the lower potential regions ($HR_{1,2}$) begin filling, the processes are rapid and reach a definite maximum and finally level off at a lower q_H.

In case △, when the h.a.r. begins, only the HR_6 and HR_5 regions accumulate H atoms, and other than the fact that longer times are required, the patterns of filling $HR_{6,5,4}$ are about the same as for case ●. However, in case △, $HR_{3,2,1}$ do show differences from case ●. To be noted are the higher peaks for $HR_{1,2}$ and the rapid filling of HR_3 after an initial lag. These differences in association with observations in the potential decay curves (Fig. 5) may explain the E *vs.* q_H behavior of case △ in terms of the rearrangement of H atoms in the several regions.

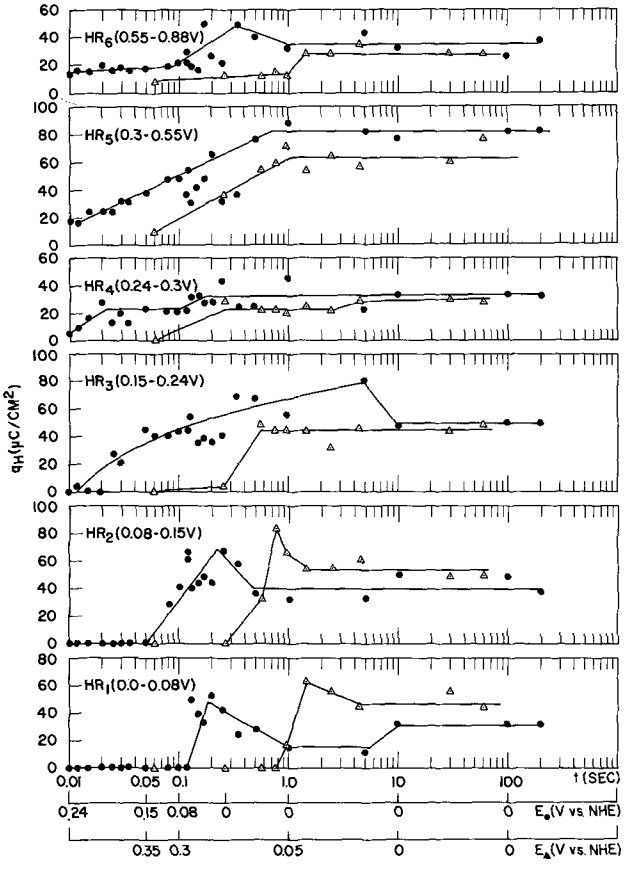

Fig. 10. Relationships between q_H vs. t (and E) for each of the six hydrogen oxidation regions, HR_{1-6} for cases ● and △. See Symbols.

Upon examining Fig. 5, one notes that the last break in the E *vs.* t curve as the equilibrium potential is approached corresponds for case ● (curve 1, 0.15 sec) to the maximum of HR_1 (0.15 sec, Fig. 10), whereas for case △ (curve 4, Fig. 5, 0.3 sec) the last break corresponds to the beginning of HR_2 (0.3 sec, Fig. 10). Timewise, for case △, it can be seen that at 0.3 sec HR_3 also begins to fill. The HR_3 of case ●, however, does not reach its maximum value until about 5 sec or its equilibrium value until 10 sec, either of which is after HR_1 has peaked. The opposite behavior is true in case △. The significance of this extended period of time in case ● has been brought out already by case ● reaching equilibrium (Fig. 6, t = 2 sec) where, even though HR_4 is filled and HR_3 is not, the potential decays to zero volt. Consequently, it is concluded that, because of the time lag produced by the diffusion layer, a rearrangement process occurs which allows HR_3 to be filled. The equilibrium values for each region must be the same for cases ● and △, and the differences seen in Fig. 10 must be due to the effects of adsorbed H_2 gas and experimental error.

The question as to which regions determine the open-circuit potential at time t is difficult to answer. One may conclude that all regions could influence the potential in a partitioning manner, *i.e.* at any E; all regions will contain some H atoms that influence the potential to some, but not equal, degrees. However, the reason why the E *vs.* q_H relation should be virtually linear is not apparent.

Mechanisms and Kinetics

H.A.R. kinetics.—The rate at which the H_2/H^+ equilibrium is established on Pt can be measured in terms of the disappearance of available Pt sites or in terms of the accumulation of H atoms. The net h.a.r. may be written as

$$H_2 + 2Pt \underset{k_2}{\overset{k_1}{\rightleftharpoons}} 2Pt\text{-}H \qquad [1]$$

The following kinetic relationship can be written for the rate of the h.a.r., $d[Pt\text{-}H]/dt$

$$\frac{d[Pt\text{-}H]}{dt} = 2k_1 [H_2] [Pt]^2 - 2k_2 [Pt\text{-}H]^2 \qquad [2]$$

$$\tfrac{1}{2}\frac{d[Pt]}{dt} = \frac{d[H_2]}{dt} = -\tfrac{1}{2}\frac{d[Pt\text{-}H]}{dt} \qquad [3]$$

Assuming that the reverse reaction is negligible and that $2k_1 [H_2]$ is a constant, rate Eq. [2] converted to electrical units becomes

$$\frac{d(Pt\text{-}H)}{dt} = k'_1 (Pt)^2 \qquad [4]$$

where $d(Pt\text{-}H)/dt$ is in $\mu A/cm^2$, (Pt-H) and (Pt) are in $\mu C/cm^2$, and k'_1 is in $cm^2/\mu C$ sec.

Since (Pt-H) + (Pt) = q_{H_∞}, Eq. [4] can be written in terms of (Pt-H), *i.e.*

$$\frac{d(Pt\text{-}H)}{dt} = k'_1 [q_{H_\infty} - (Pt\text{-}H)]^2 \qquad [5]$$

Integrating Eq. [5], and since at $t = 0$ the integration constant is $1/q_{H_\infty}$, the h.a.r. rate equation can be written as

$$\frac{1}{q_{H_\infty} - (Pt\text{-}H)} = k'_1 t + 1/q_{H_\infty} \qquad [6]$$

where (Pt-H) is q_H at time t. Equation [6] was tested for cases ▲ and △ (Fig. 11) and cases ● and ○ (Fig. 12). For cases ▲ and △ where a diffusion gradient is present, the kinetic plots (Fig. 11) are curved during the accumulation of the first 180 and 140 $\mu C/cm^2$, respectively.

For case ● (Fig. 12), a straight line whose slope of 0.059 $cm^2/\mu C$ sec, equal to k_1', is observed from the extrapolated zero time to 0.11 sec. Case ○ follows the same straight line up to 0.07 sec, but then deviates. This is due to the stirring effect noted in Fig. 5 at potentials below 0.1V. At longer times, the ● points do not fall on the straight line indicating that the assumed kinetic model for the h.a.r. may break down. Due to the scatter, the reproducibility of measurement of q_H is poor. Nevertheless, during the linear portion about 64% (180/280) of q_{H_∞} has been accumulated. It

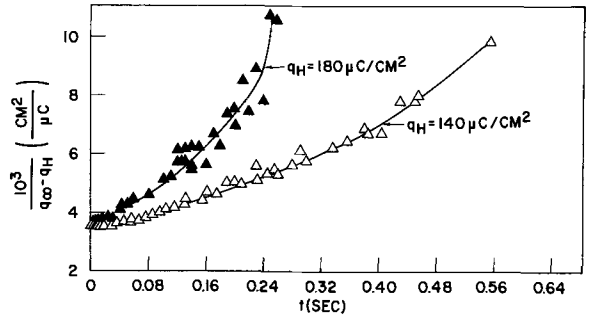

Fig. 11. Plot showing that cases ▲ and △ do not fit kinetic model (Eq. [6]). See Symbols.

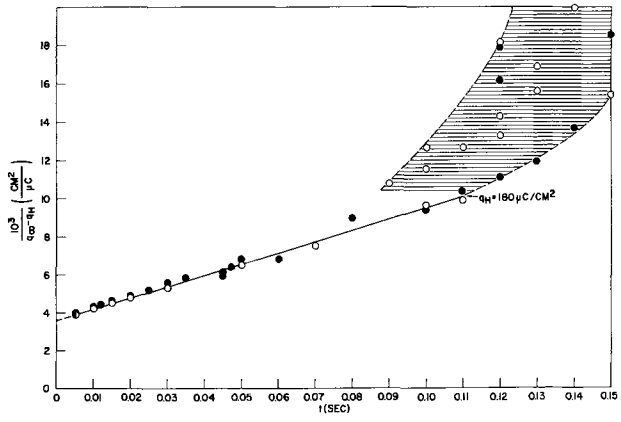

Fig. 12. Fit of data for cases ● and ○ to kinetic model (Eq. [6]). See Symbols.

is interesting to note that 0.11 sec corresponds to the time when HR_1 begins to accumulate H atoms.

To further test the validity of the kinetic model, the instantaneous rates of case ● calculated from Eq. [4] were plotted and gave the curve shown in Fig. 13. The instantaneous rate from the "chain rule" calculation of Breiter (7)

$$\frac{d(Pt\text{-}H)}{dt} = \frac{d(Pt\text{-}H)}{dE} \times \frac{dE}{dt} \qquad [7]$$

were determined also and are shown as "■" points in Fig. 13. Equation [7] does not depend on a specific kinetic model. The value of $d(Pt\text{-}H)/dE$ was obtained from Fig. 8, and the value of dE/dt was obtained from a potential decay curve (Fig. 5). The curve in Fig. 13 was determined by differencing q_H changes in each msec of time during decay and then obtaining an average △(Pt-H) value over each 10 msec interval.

The agreement between the "■" points and the curve in Fig. 13 is reasonably good down to a potential of 0.10V. The disagreement between "■" points at small values of t reflects the difficulty in reading small changes on a potential decay curve under conditions where rates of decay are very fast. The scatter of "■" points below 0.10V most likely reflect the error in determining q_H as equilibrium is reached (*see* Fig.

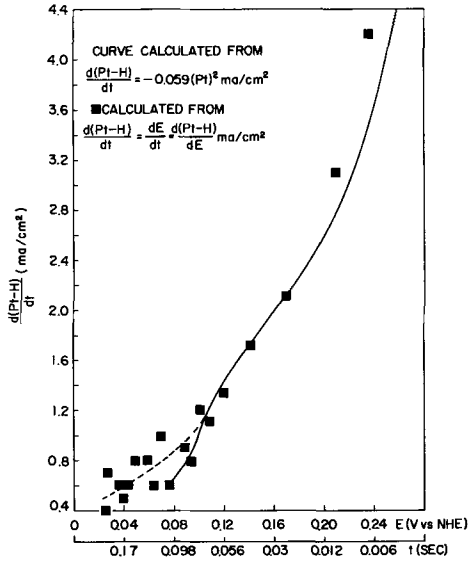

Fig. 13. Comparison of dependence of rates of h.a.r. on E and t for cases ● and ○ calculated from kinetic model and from instantaneous rate by "chain rule" calculation. Broken line is average of ■ points on graph. See Symbols.

12). The fact that the solid line curve deviates significantly from the average of the "■" points, as indicated by the broken line in Fig. 13, implies that the h.a.r. kinetic model does break down above 0.11 sec (*see* Fig. 12).

Hydrogen regions.—The h.a.r. kinetic model fits down to 0.10V for cases ● and ○. The maximum rate at which the h.a.r. can proceed on an H- and O-free Pt electrode in the absence of a diffusion gradient for H_2 occurs at $t = 0$. Calculating this rate using Eq. [4] at the estimated $t = 0$ value gives 4.46 mA/cm². As t increases, the number of available Pt atoms for H atom association decreases, and the net rate at which additional H atoms are accumulated rapidly decreases and would, of course, be zero at equilibrium. In other words, the rate at which the H_2/H^+ equilibrium is reached on an initially H- and O-free Pt electrode can be described by Eq. [4] and is primarily dependent on the rate at which H atoms accumulate in $HR_{6,5,4,3}$. Once H atoms begin to accumulate in $HR_{2,1}$, the kinetic model expressed by Eq. [4] no longer holds.

The departure from the kinetic model of Eq. [4] cannot be explained by the reverse reaction in Eq. [1] becoming significant. Correcting the kinetic model for an H atom combination reaction only would lower the calculated net rate, whereas the correct kinetic model must increase the rate (Fig. 13).

Maximum H_2 diffusion current.—Schuldiner (8) found that from about 0.05 to 0.7V a limiting current density, i_L, of 2 mA/cm² (true area) is obtained for H_2 oxidation in vigorously stirred (>1000 ml H_2/min) solution of 1M H_2SO_4, $P_{H_2} = 1$ atm. The often argued question as to whether i_L is diffusion or dissociation controlled can be examined in view of the present results.

Our results have shown that, in the absence of a diffusion layer, the maximum rate at which H_2 dissociates and H atoms accumulate on a clean, H- and O-free Pt electrode (0.26V, $t = 0$) is 4.46 mA/cm² (Fig. 13). Since the exchange current density for H atom oxidation/reduction is about 0.4 A/cm² (6), the rate of H atom oxidation at potentials in excess of 0.05V would be greater and would increase with increasingly positive potentials. Therefore, the maximum rate at which H_2 could be oxidized on an H- and O-free Pt electrode in the absence of a diffusion layer would be 4.46 mA/cm² and would be dissociation controlled. Hence, a comparison of the i_L value of 2 mA/cm² under steady-state polarization with the H_2 dissociation rate of 4.46 mA/cm² leads to the conclusion that i_L must be under partial diffusion control.

The contribution of the diffusion current density (geom. area) to i_L can be calculated. The oxidation of H under steady-state potentiostatic conditions can be limited by either $H_2 \xrightarrow{I} H_{2,s} \xrightarrow{II} 2H$ or a combination of diffusion (I) and dissociation (II). The terms H_2, $H_{2,s}$, and H refer to hydrogen in the bulk solution, surface, and associated with the electrode as H atoms, respectively. Under steady-state conditions, the rate of H_2 oxidation is not dependent on the h.a.r. since at any potential the steady-state concentration of (Pt-H) has been reached and, if the potential is positive enough (>0.3V), (Pt-H) is effectively zero. It is diffusion and/or dissociation of H_2 which then becomes rate determining.

The basis of calculating the contribution of the diffusion current density to i_L is writing separate equations for the dissociation current density, i_{diss}, and for the diffusion current density, i_{diff} (true area for the present argument). Since under steady-state, potentiostatic conditions at the limiting current density, dissociation and diffusion must occur at the same rate, so that

$$i_L = i_{diss,\,L} = i_{diff,\,L}$$

From these equations a relationship for i_L in terms of $i_{diff,\,max}$ (geom. area) and $i_{diss,\,max}$ can be derived. The latter terms represent the maximum rate at which H_2 would be oxidized by either total diffusion or total dissociation control.

The diffusion current density (true area), i_{diff}, is given here as being ½ the Nernst diffusion equation (9) because we have found that our Pt bead electrodes have roughness factors of about 2; thus, i_{diff} (geom.) $\approx 2\, i_{diff}$

$$i_{diff} = \frac{DF(C_b - C_s)}{2 \times 10^3\,\delta} = \frac{(1 - C_s/C_b)}{2}\left(\frac{DFC_b}{\delta \times 10^3}\right) \quad [8]$$

[$i_{diff,\,max}$ (geom.) is given by the last parenthesized term on the right.] Here D is the diffusion coefficient, F is the faraday, C_b is the concentration of H_2 in the bulk of the solution in equiv./L, C_s is the concentration at the surface, and δ is the "effective thickness" of the diffusion layer.

Converting to H_2 partial pressures, C_b and C_s are equal to $1.33 \times 10^{-3}\, P_{H_2,b}$ and $1.33 \times 10^{-3}\, P_{H_2,s}$, respectively (Eq. [5], Ref. 9). Since $P_{H_2,b} = 1$ atm

$$i_{diff} = \frac{i_{diff,\,max}\ (\text{geom.})}{2}(1 - P_{H_2,s}) \quad [9]$$

Equations for the dissociation/combination step, assuming a Langmuir isotherm are

$$i_{diss} = k_{diss}\,(1 - \theta)^2 P_{H_2,s}$$

and

$$i_{comb} = k_{comb}\,\theta^2$$

At equilibrium

$$i_{diss} = i_{comb} = i_o = k_{diss}\,(1 - \theta_o)^2$$

where θ is the fraction of available Pt dissociation sites covered with H atoms, θ_o is the value of this fraction at equilibrium, and i_o is the exchange current density for the dissociation reaction. The net i_{diss} when the back reaction is negligible is

$$i_{diss} = i_o\left(\frac{1 - \theta}{1 - \theta_o}\right)^2 P_{H_2,s} \quad [10]$$

The maximum current under dissociation control is when $P_{H_2,s} = 1$ atm and $\theta = 0$.
Hence

$$i_{diss} = i_{diss,\,max}\,(1 - \theta)^2 P_{H_2,s} \quad [11]$$

For the limiting current density, $i_{diss} \to i_L \leftarrow i_{diff}$, and $\theta = 0$; hence, Eq. [9]

$$i_{diff,\,L} = i_L = \frac{i_{diff,\,max}\ (\text{geom.})}{2}(1 - P_{H_2,s,L}) \quad [9a]$$

and Eq. [11] becomes

$$i_{diss,\,L} = i_L = i_{diss,\,max}\,P_{H_2,s,L} \quad [11a][2]$$

Solving Eq. [9a] or [11a] for $P_{H_2,s,L}$ and then substituting for $P_{H_2,s,L}$ in the other equation, the geometric averaging of $i_{diff,\,max}$ and $i_{diss,\,max}$ for i_L is obtained, *i.e.*

$$i_L = \frac{(i_{diss,\,max}) \times (i_{diff,\,max}(\text{geom.}))}{(2\, i_{diss,\,max}) + (i_{diff,\,max}(\text{geom.}))} \quad [12]$$

or

$$\frac{1}{i_L} = \frac{2}{i_{diff,\,max}\ (\text{geom})} + \frac{1}{i_{diss,\,max}} \quad [13]$$

Therefore, since i_L is known (2×10^{-3} A/cm²) and since $i_{diss,\,max}$ is $i_{h.a.r.,\,max}$ (4.46×10^{-3} A/cm²), $i_{diff,\,max}$ (geom.) is found to be 7.25×10^{-3} A/cm². Equation [13] is similar to the one derived by Castellan (10).

Schuldiner (8) has shown that for 0.05 to 0.7V, i_L is independent of potential. This behavior necessitates

[2] Thus, $P_{H_2,s,L} = \dfrac{2\ \text{mA/cm}^2}{4.46\ \text{mA/cm}^2} = 0.45$ atm, which is the effective partial pressure of H_2 at the electrode surface at i_L.

the conclusion that the majority of the H atoms associated with the electrode above 0.05V are not adsorbed on Pt atoms that are required for H_2 dissociation. The total number of Pt atoms which are associated with H atoms at equilibrium is considered to be equivalent to 260 ± 40 μC/cm^2 (not one monolayer = 210 μC/cm^2). However, only a small portion of that total number of Pt atoms are actually involved in H_2 dissociation, and it is this small number of Pt atoms that are "covered" when $\theta = 1$. Otherwise, on the basis of the total number of Pt atom association with H atoms, 260 μC/cm^2, the fraction of Pt atoms associated with H atoms would go from 0.81 at 0.05V to 0.62 and 0.42 at 0.10 and 0.15V, respectively (*see* Fig. 8), while at the same time i_L remains constant. However, by defining θ as the fraction of available Pt dissociation sites covered with H atoms, θ must be approximately zero above 0.05V under conditions of the i_L described by Schuldiner (8). In the definition used for θ, the relationship between Pt sites available for H_2 dissociation and actual number of Pt atoms is not necessarily on a basis of one atom to one site; *e.g.*, a site may involve junction of two atoms.

It is not definite whether the effective coverage of available Pt dissociation sites with H atoms, the potential near and at equilibrium, and the relation with HR_1 and possibly HR_2 are all related, but our results indicate that they probably are related. As is shown in Fig. 10, above 0.05V (*e.g.*, 0.15 sec) the number of H atoms in HR_1 is about zero, and the number of H atoms in HR_2 is only about 50 μC/cm^2. If θ is to be equated with $HR_{1,2}$, then it must follow that, under steady-state conditions above 0.05V, H_2 molecules are dissociated and are oxidized at Pt sites which are equivalent to $HR_{1,2}$, but whose H content is virtually zero.

Diffusion-layer thickness.—The "effective thickness" of the diffusion layer, δ, can be calculated for case △ (quiescent solution) and for the potentiostatic steady-state oxidation of hydrogen (stirring rate > 1000 ml/min). In the latter case, δ is 8.6 x 10^{-4} cm as calculated from Eq. [8]

$$i_{diff,\,max}(geom.) = 7.25 \times 10^{-3}\ A/cm^2 = \frac{DFC_b}{\delta \times 10^3}$$

where D is 4.87 x 10^{-5} cm^2/sec (11). For case △, δ can also be calculated from the right-hand side of Eq. [8] since the latter is equal to the slope of q_H *vs.* t (Fig. 7, 0.2-0.7 sec). Since C_s would be small, δ is 1 x 10^{-2} cm, and $i_{diff,\,max}$(geom.) is 0.62 mA/cm^2 under these conditions.

A comparative calculation of δ for case △ can be made by first calculating the depth, d, of hydrogen depletion caused by reducing a monolayer of Pt-O_{ad} (420 μC/cm^2 of Pt-O_{ad}). The depth is given by

$$d\ cm = \frac{\text{mole } H_2/cm^2\ (geom.)}{\text{mole } H_2/cc\ solution} \qquad [14]$$

where the numerator is

$$\frac{420 \times 10^{-6} C}{cm^2} \times \frac{equiv.}{9.65 \times 10^4 C} \times \frac{mole}{2\ equiv.} \times 2 = \frac{4.35 \times 10^{-9}\ \text{mole } H_2}{cm^2\ (geom.)} \qquad [14a]$$

and the denominator is

$$\frac{\text{mole } H_2}{22{,}400\ cc\ H_2} \times \frac{0.0149\ cc\ H_2}{cc\ solution} = \frac{6.65 \times 10^{-7}\ \text{mole } H_2}{cc\ solution} \qquad [14b]$$

Equation [14a] is multiplied by 2 because d must be calculated on a geometric area basis, and 1 cm^2 true area is about 0.5 cm^2 geometric area. The H_2 solubility in 1M H_2SO_4 term in Eq. [14b] is taken from Ref. (12). Hence, d is 6.5 x 10^{-3} cm. To complete the comparative calculation, it is necessary to make $\delta = 2d$ because diffusion Eq. [8] assumes a linear H_2 diffusion gradient which means that the diffusion layer will be only one half depleted of H_2 in 6.5 x 10^{-3} cm. Thus, δ calculated this way is 1.3 x 10^{-2} cm and is comparable to the δ value (1.0 x 10^{-2}) determined from Fig. 7.

Conclusions

1. The open-circuit hydrogen accumulation reaction (h.a.r.) under dissociation control obeys the following second-order kinetic relation

$$i_{h.a.r.} = i_{diss} = dq_H/dt = 0.059(275\text{-}q_H)^2 \qquad 0 \leq q_H < 180\ \mu C/cm^2$$

The $i_{diss,\,max} = 4.46 \times 10^{-3}$ A/cm^2 $\qquad q_H \sim 0\ \mu C/cm^2$

2. The open-circuit h.a.r. under diffusion control was measured in a quiescent solution where i_{diff} (geom.) ≡ 6.2 x 10^{-4} A/cm^2. The "effective thickness" of the diffusion layer in quiescent solution is 1.0 x 10^{-2} cm.

3. Only a small number of the total number of Pt atoms which are associated with H atoms at equilibrium (260 ± 40 μC/cm^2) are involved in the available Pt dissociation sites.

4. Under potentiostatic steady-state hydrogen oxidation (0.05-0.7V, vigorous H_2 stirring), the limiting current density (2 x 10^{-3} A/cm^2) was shown to be under mixed dissociation and diffusion control. The $i_{diss,\,max}$ = 4.46 x 10^{-3} A/cm^2 and the $i_{diff,\,max}$ (geom.) = 7.25 x 10^{-3} A/cm^2 show that, even though the H_2 oxidation is primarily dissociation controlled, diffusion does cause the effective hydrogen partial pressure at the electrode surface to be reduced from an applied pressure of 1 to 0.45 atm. The "effective thickness" of this diffusion layer is 8.6 x 10^{-4} cm.

5. The h.a.r. under dissociation control reaches zero volt in about 0.3 sec, but at least 100 sec are required to reach the equilibrium Pt-associated H atom concentration.

6. The h.a.r. under diffusion control reaches zero volt in about 10 sec, but also requires at least 100 sec to reach the equilibrium Pt-associated H atom concentration.

7. Items 4 and 5 show that a slow rearrangement of adsorbed and dermasorbed H atoms are required before the Pt-H_2/H^+ electrode reaches thermodynamic equilibrium.

8. Nonfaradaic charging corrections were found to be complex and involved adsorption/desorption processes as well as double-layer charging.

Current Distributions on Plane, Parallel Electrodes in Channel Flow

W. R. Parrish and John Newman

Inorganic Materials Research Division, Lawrence Radiation Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California

ABSTRACT

Current distributions on two plane, parallel electrodes embedded in the walls of a flow channel have been calculated for separation distance between electrodes to electrode length ratios of 0.5, 1, and 10. Secondary current distributions were calculated using the linear and Tafel polarization laws. Using the Tafel polarization law, current distributions were calculated at various fractions of the limiting current. In all cases considered, the electrodes are nearly independent of one another if the height to length ratio is ten or more.

Many industrial electrochemical processes use channel flow between two plane, parallel electrodes as shown in Fig. 1. The limiting current distribution for this flow geometry is well known (1). A procedure for determining current distribution below the limiting current has been outlined previously (1). The method uses the concept of having concentration variations restricted to a thin diffusion layer very near each electrode surface (2), allowing the bulk region and the diffusion layers to be treated separately. The same concept has been applied previously to the rotating disk electrode (3, 4) and to the single plane electrode (5).

In the treatment of the problem, the following assumptions are made:

1. The electrodes are embedded in infinite, parallel, plane, insulating walls.

2. Fully developed, laminar flow exists, and the velocity profile can be considered linear inside the diffusion layer. Thus, the diffusion layer thickness should be small compared with the distance between

Key words: electrochemical mass transfer, electrode kinetics, current distribution.

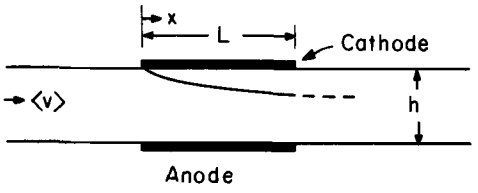

Fig. 1. Plane electrodes in the walls of a flow channel

the walls. In such diffusion layers it is appropriate to neglect diffusion in the direction parallel to the electrode.

3. Dilute solution theory with constant physical properties is applicable.

4. The transport equations used here apply to either single salt deposition or ions reacting in an excess of supporting electrolyte. The effect of ionic migration for intermediate cases is not considered.

Mathematical Formulation of Problem

The general approach to the problem is outlined in ref. (1) through (5). The potential in the bulk region satisfies Laplace's equation

$$\frac{\partial^2\Phi}{\partial x^2} + \frac{\partial^2\Phi}{\partial y^2} = 0 \qquad [1]$$

where Φ is the potential measured by a reference electrode of the same type as the working electrode. The appropriate boundary conditions are

$$\partial\Phi/\partial y = 0 \text{ at } y = 0 \text{ and } y = h \text{ for } x < 0 \text{ and } x > L \qquad [2]$$

$$\partial\Phi/\partial y = -\,i/\kappa_\infty \text{ at } y = 0 \text{ and } y = h \text{ for } 0 < x < L \qquad [3]$$

Equation [2] applies to the insulating surfaces bounding the electrodes, and Eq. [3] relates the normal potential gradient to the electrode current density i, where κ_∞ is the solution conductivity in the bulk region. The current is taken to be positive on the anode and negative on the cathode.

The solution (1) to Eq. [1] with the boundary conditions is

$$\Phi(x,y) = \Phi^* - \frac{1}{2\pi\kappa_\infty} \times \left\{ \int_0^L i_{\text{cath}}(x') \ln[\sinh^2(\pi(x-x')/2h) + \sin^2(\pi(y-h)/2h)]\,dx' + \int_0^L i_{\text{anode}}(x') \ln[\sinh^2(\pi(x-x')/2h) + \sin^2(\pi y/2h)]\,dx' \right\} \qquad [4]$$

where the anode is at $y = 0$ and the cathode is at $y = h$. The potential very near the cathode surface is then

$$\Phi^o{}_{\text{cath}}(x) = \Phi^* - \frac{1}{2\pi\kappa_\infty} \times \left\{ \int_0^L [i_{\text{cath}}(x') \ln \sinh^2(\pi(x-x')/2h) + i_{\text{anode}}(x') \ln \cosh^2(\pi(x-x')/2h)]\,dx' \right\} \qquad [5]$$

The expression for the anodic potential is the same as above except that the subscripts are reversed. These potentials represent the potentials of the bulk region extrapolated to the electrode surface as if the actual current prevails but there is no concentration variation near the electrodes. The integration constant, Φ^*, is determined by the requirement that the total currents for the two electrodes must be equal in magnitude, *i.e.*

$$\int_0^L [i_{\text{cath}}(x') + i_{\text{anode}}(x')]\,dx' = 0 \qquad [6]$$

To obtain a relationship between the current and concentration on each electrode, an equation has been derived from the limiting current expression

$$i_{\text{lim}}(x) = -\frac{n\mathbf{F}D}{(1-t)} \frac{c_\infty}{\Gamma(4/3)} \left(\frac{2<v>}{3hDx}\right)^{1/3} \qquad [7]$$

Application of Duhamel's theorem (6) yields an equation which is applicable to either electrode (1)

$$i(x) = \frac{n\mathbf{F}D}{(1-t)\Gamma(4/3)} \left(\frac{2<v>}{3hD}\right)^{1/3} \times \int_0^x \frac{dc_o(x')}{dx'} \frac{dx'}{(x-x')^{1/3}} \qquad [8]$$

For many electrode reactions, the current density and surface overpotential, η_s, can be related by

$$i(x) = i_o(c_o/c_\infty)^\gamma \times \{\exp[\alpha Z\mathbf{F}\eta_s/RT] - \exp[-\beta Z\mathbf{F}\eta_s/RT]\} \qquad [9]$$

where α and β are characteristic parameters of the electrode reaction, and i_o is the exchange current density at the bulk concentration. The exchange current density is assumed to be proportional to the surface concentration, c_o, raised to the power γ. The surface overpotential on each electrode is related to the electrode potential, V, by

$$\eta_s = V - \Phi^o - \eta_c \qquad [10]$$

The concentration overpotential, η_c, is taken to be (2)

$$\eta_c = -(RT/Z\mathbf{F})[\ln(c_\infty/c_o) - t(1 - c_o/c_\infty)] \qquad [11]$$

where

$$Z = -z_+z_-/(z_+ - z_-) \text{ for a single salt} \qquad [12]$$

$$Z = -n \text{ with supporting electrolyte} \qquad [13]$$

The transference number, t, is zero if there is an excess of supporting electrolyte. The number Z was inserted into Eq. [9] in order to make more simple the dimensionless parameters which describe the system. For a solution of a single salt, the effect of the variation of conductivity across the diffusion layer is included in Eq. [11], and in this case the derivation was restricted to a metal deposition reaction. The kinetic parameters are αZ and βZ, not α and β alone.

Numerical Calculations

To calculate current and concentration distributions on the two electrodes, two sets of five equations must be solved simultaneously; these are Eq. [5], [8], [9], [10], and

$$i_{\text{avg}} = \frac{1}{L} \left| \int_0^L i(x)\,dx \right| \qquad [14]$$

i_{avg} is a specified average current density applying to both electrodes (Eq. [14] replaces Eq. [6]). For a given distribution of total overpotential, $\eta_c + \eta_s$, Eq. [8] was solved in conjunction with Eq. [9] and [10] using the method of Acrivos and Chambré (7). Simpson's method was used to evaluate Eq. [14]. Gaussian quadrature integration, using 96 points (8), was used to calculate the total overpotential in Eq. [5]. To get intermediate values of the integrand required for the Gaussian integration, Lagrange's interpolation formula was used. Simpson's method had been used for evaluating Eq. [5], but was found to be less accurate and efficient than the Gaussian method. The singularity at $x' = x$ in Eq. [5] was eliminated by adding and subtracting $i(x)$ as suggested by Kantorovich and Krylov (9).

The answers were considered satisfactory if they did not change by more than 1% when the number of evenly spaced intervals was increased by 20. The required number of intervals varied between 100 and 180, depending on the uniformity of the current and concentration distributions.

The following doubly reiterative procedure was used:

1. As a first guess, the total overpotential was assumed constant over the entire electrode. The overpotentials were calculated from Eq. [9] using $i(x) = i_{avg}$ and $c_o = c_\infty$.
2. For a given overpotential distribution, the current and concentration distributions were calculated from Eq. [8], [9], [10], and [11].
3. The average current was then calculated and compared with i_{avg}. If the two values differed by more than 0.001%, the overpotential distribution was changed uniformly by adding a constant to each value. The new overpotentials were then put back into step 2. The constant was found by assuming that the overpotential at $x = 0$ was proportional to the calculated average current density or its logarithm for the cathode or the anode, respectively.
4. Using the current distributions that satisfy Eq. [14], new values of the overpotentials were calculated from Eq. [5] and [10]. If the old and new values differed by more than 0.1%, the two values were averaged (usually with unequal weights because of stability problems) and put back into step 2.

This numerical procedure works well for the range of current distributions considered in this paper. Three to eight iterations were required to obtain convergence in the inner loop, and the convergence rate depended on how near the overpotential distributions were to the "correct" values. Up to 70 iterations were required in the outer loop. The required number of outer iterations increased with increasing nonuniformity of the current and concentration distributions.

Results

Eight parameters are required to define completely each problem, h/L, the transference number, t, α, β, and γ which are characteristic of the electrode reaction (although it is not necessary, the same kinetic parameters are assumed to apply to both electrodes), and three dimensionless quantities which are analogous to those defined for the flat plate (5) and the rotating disk (3) electrodes

$$J = ZFLi_o/RT\kappa_\infty \qquad [15]$$

$$N = \frac{nZF^2Dc_\infty}{(1-t)RT\kappa_\infty}\left(\frac{6<v>L^2}{hD}\right)^{1/3} \qquad [16]$$

$$\delta = |i_{avg}|\, ZFL/RT\kappa_\infty \qquad [17]$$

where J, N, and δ represent the dimensionless exchange, average limiting, and average current densities. The average limiting current corresponds to $\delta = 0.807N$, obtained by substituting Eq. [7] and [14] into [17].

The two extreme cases are the primary and limiting current distributions which are shown in Fig. 2 for several values of h/L. The primary current distribution occurs when the electrode is reversible and there are no concentration effects ($N = \infty$, $J = \infty$). The primary current distribution (1) is

$$i/i_{avg} = \frac{\epsilon \cosh \epsilon/K(\tanh^2 \epsilon)}{\sqrt{\sinh^2 \epsilon - \sinh^2 (2x-L)\epsilon/L}} \qquad [18]$$

where $\epsilon = \pi L/2h$ and $K(m)$ is the complete elliptic integral of the first kind.

The limiting current occurs when the current distribution is limited by the mass transfer rate through the diffusion layer and is given by

$$i/i_{avg} = (2/3)(x/L)^{-1/3} \qquad [19]$$

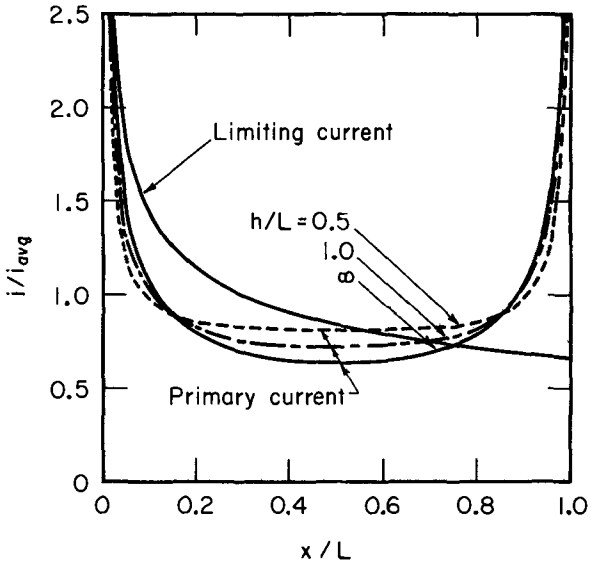

Fig. 2. Primary and limiting current distributions on channel electrodes.

Secondary current distributions occur when there is a surface overpotential but no mass transfer effects ($N = \infty$). If the current density is small ($\delta << J$), the polarization law [9] can be linearized to give

$$i = (\alpha + \beta)(ZF/RT)i_o\eta_s \qquad [20]$$

Using the coefficient in Eq. [20] [which, after multiplication by L/κ_∞, becomes $(\alpha + \beta)J$] as a parameter, Wagner (10) calculated secondary current distributions for the two cases of $h/L = \infty$ and $h/L << 1$. Linear secondary current distributions are shown in Fig. 3 for $(\alpha + \beta)J$ equal to 8π (this corresponds to Wagner's parameter $a/k_c = 4\pi$) and several values of h/L. To give an indication of current uniformity, the ratio of the maximum to minimum current density has been plotted in Fig. 4 as a function of $(\alpha + \beta)J$ and h/L.

If the average current is much greater than the exchange current ($\delta >> J$), Tafel polarization will ap-

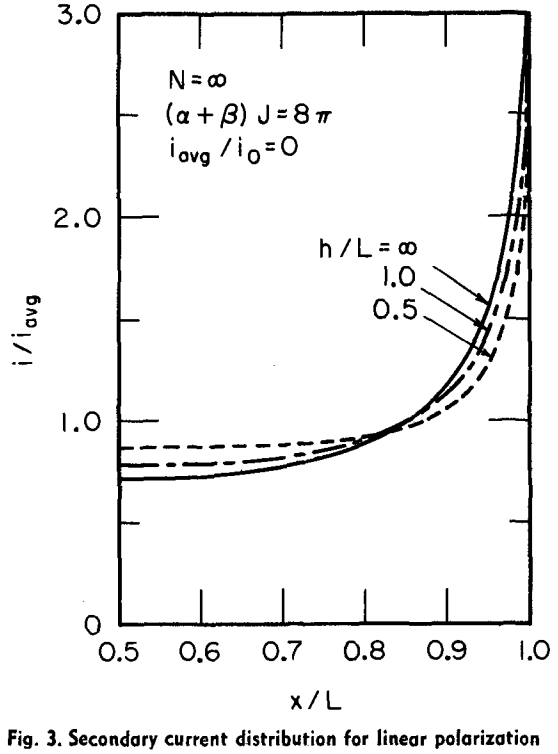

Fig. 3. Secondary current distribution for linear polarization

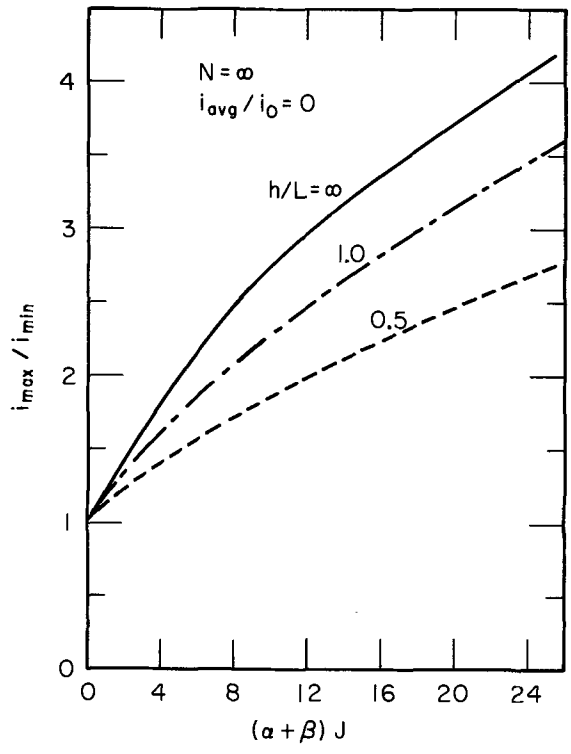

Fig. 4. Ratio of maximum to minimum current for linear polarization as a function of the parameter $(\alpha + \beta)J$.

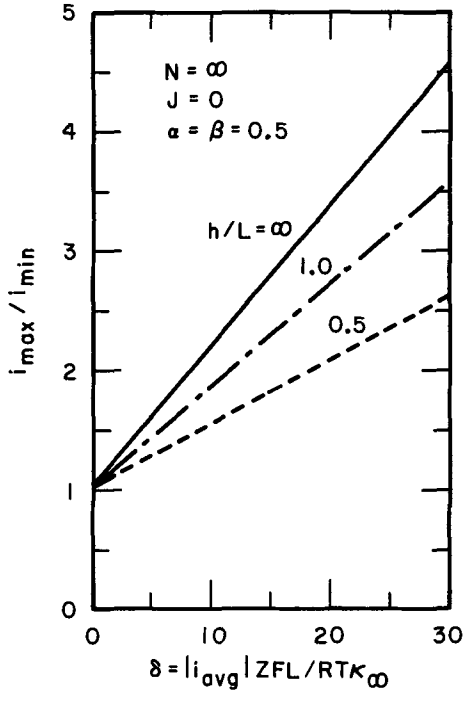

Fig. 6. Ratio of maximum to minimum current for Tafel polarization with no mass transfer effects as a function of the dimensionless average current.

ply. Equation [9] can then be written as

$$\eta_s = -(RT/ZF\beta)[\ln|i| - \ln i_o] \qquad [21]$$

for the cathode. (For the anode, α replaces β and the minus sign is omitted.) Poddubnyi, Rudenko, and Formin (11) have calculated secondary current distributions for Tafel polarization and $h/L = \infty$. Figures 5 and 6 show current distributions and current uniformity curves for Tafel kinetics.

As can be seen in Fig. 3 through 6, the current distributions become increasingly more sensitive to h/L as the ratio decreases. For all the cases considered, the current distributions for $h/L = 10$ were very close to the distributions for $h/L = \infty$.

Because mass transfer effects are important at higher current densities, we used Tafel polarization in calculating current distributions involving concentration effects. Figure 7 shows the current distribution on the cathode at various fractions of the limiting current and for three values of h/L. The current distribution on the anode is shown in Fig. 8 for a current which is 95% of the limiting current. Near the front of each electrode, the current drops rapidly, behaving like a secondary current distribution. However, on the cathode, mass transfer effects become more important with

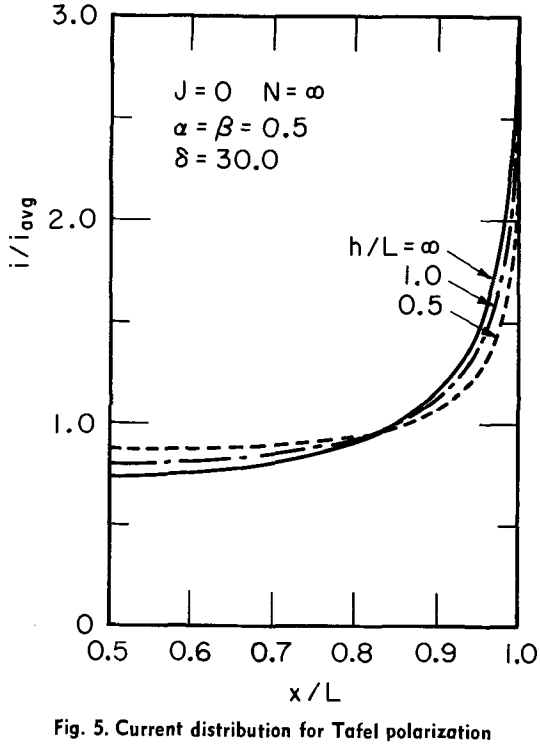

Fig. 5. Current distribution for Tafel polarization

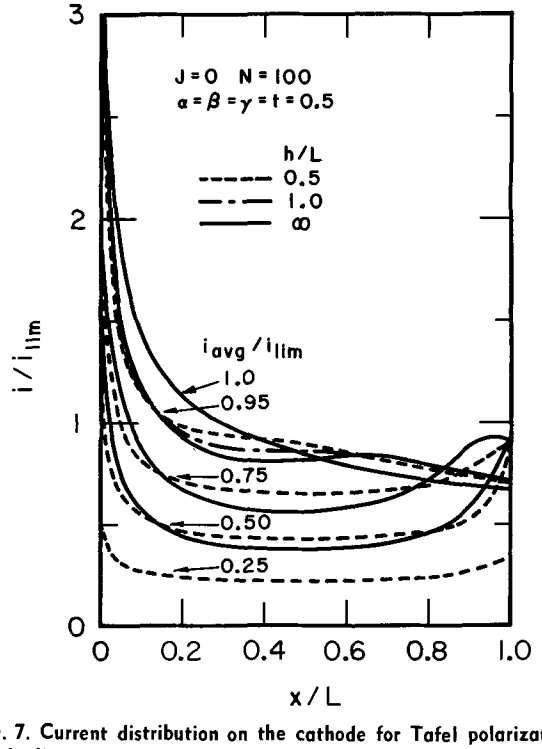

Fig. 7. Current distribution on the cathode for Tafel polarization near the limiting current.

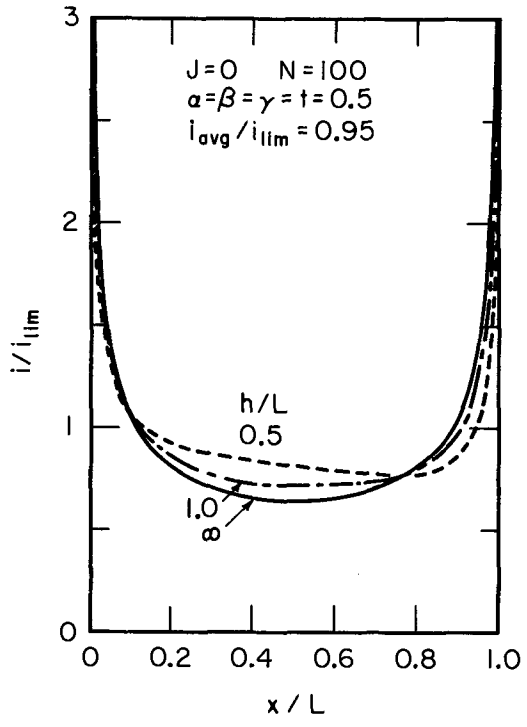

Fig. 8. Current distribution on the anode for Tafel polarization with the current at 95% of the cathodic limiting current.

increasing x/L. As the concentration profiles for the cathode show in Fig. 9, the cathodic current cannot continue to behave like a secondary current because the reactant concentration has been lowered inside the diffusion layer. But concentration effects are relatively unimportant on the anode, and the anodic current continues to resemble a secondary current distribution. The interaction between the two electrodes through Laplace's equation is very apparent for the case of $h/L = 0.5$.

The above considerations explain the maxima in the cathodic current densities. These arise from a compromise between the secondary and limiting distributions of current. The depletion of the diffusion layer eventually begins to be felt, although the local value of the limiting current density can be exceeded [compare with the disk (3)].

For the cathode, at higher current densities, the concentration drops rapidly at the front of the electrode and, as x/L increases, the concentration increases slightly before decreasing again for h/L equal to 1.0 or more. This behavior is caused by the rapid depletion of reactant at the beginning when the current density is very high. However, after the current has dropped, the concentration has a chance to increase by diffusion into the diffusion layer. Then, when the current increases, the concentration starts decreasing again. A similar but opposite behavior occurs on the anode as is shown in Fig. 10.

Although not shown, current and concentration distributions were calculated for N equal to 5 and 20, for comparable fractions of the limiting current and h/L as discussed above. At the lower values of N, the differences between the current distributions at h/L of 0.5 and infinity were less than 5 and 12% on cathode and anode at $x/L = 0.5$. Thus, for these lower values of N, some idea of the cathodic current distribution can be obtained from ref. (5). This result is in harmony with the observation that large values of the conductivity and hence small values of N and δ mean that the electrodes behave independently since they were coupled only through the ohmic potential drop. For an infinite value of the conductivity, the problem is similar to one of mass transfer and nonelectrochemical catalysis (1, 12).

Conclusions

A general approach, applied previously to flat plate and rotating disk electrodes, has been used to calculate current distributions on two plane, parallel electrodes embedded in the walls of a flow channel. The method of solution takes into account mass transfer effects as well as electrode kinetics and ohmic drop in the bulk region. The same approach should be applicable to other flow geometries if the velocity gradient is known at the electrode surface and if the potential distribution in the bulk region can be obtained from Laplace's equation.

Based on the above results, the two electrodes can be treated separately if h/L is ten or more. This is also a fairly good approximation for h/L down to 0.5 if the current density (or $(\alpha + \beta)J$ in the case of linear polarization) is relatively small. This assumption greatly reduces the numerical work required to calculate current and concentration distributions on electrodes in flow channels.

Emf of Isothermal and Nonisothermal Formation Cells of Molten Silver Halides

C. R. Metz*,[1] and R. L. Seifert*

Department of Chemistry, Indiana University, Bloomington, Indiana

ABSTRACT

Studies of isothermal formation cells by the electronic commutator method gave the following equations for $E°$ of formation of silver halides.

AgCl (478°-731°C): $E° = 0.9081 - 0.280 \times 10^{-3} (t - 455) + 0.110 \times 10^{-6} (t - 455)^2$

AgBr (447°-743°C): $E° = 0.7997 - 0.288 \times 10^{-3} (t - 432) + 0.097 \times 10^{-6} (t - 432)^2$

AgI (558°-730°C): $E° = 0.5720 - 0.227 \times 10^{-3} (t - 558) + 0.220 \times 10^{-6} (t - 558)^2$

The $E°$'s and derived formation constants $\Delta G°$, $\Delta H°$, $\Delta S°$, and $\Delta C°_p$ are compared with values obtained by others from calorimetric data and by use of reversible formation cells. Nonisothermal data reveal that large errors in reversible cell measurements will result from small temperature changes produced at the cathode by adding halogen from outside the cell. Combination of the iso- and nonisothermal data gives the following values, in mV/deg, for the thermoelectric power of molten silver halide thermocells.

AgCl (500°-700°C): $\theta_{Ag} = -0.378 \quad \theta_{Cl_2} = -0.725 + 2.4 \times 10^{-4} (t - 500)$

AgBr (500°-700°C): $\theta_{Ag} = -0.417 \quad \theta_{Br_2} = -0.776 + 3.5 \times 10^{-4} (t - 500)$

AgI (600°-700°C): $\theta_{Ag} = -0.432 \quad \theta_{I_2} = -0.859$

These values agree with direct determinations within the present rather large error limits. However, consistencies in the observed variations suggest that in formation cells the concentration gradients of solutes resulting from solution of silver and halogen at the electrodes may produce a significantly greater potential drop in the thermal gradient of a nonisothermal formation cell than in the corresponding thermocell, having a smaller gradient of only one solute.

The important thermodynamic quantities, $\Delta G°$, $\Delta H°$, $\Delta S°$, and $\Delta C°_p$ for the formation of a binary molten electrolyte, can be evaluated most readily from measurements over a range of temperature of $E°$ for its formation cell, *i.e.* a reversible voltaic cell in which the cell reaction is the formation of the electrolyte from its constituent elements. Such measurements have been made for a number of molten chlorides, bromides, and iodides with the cell $C|M|MX_n(liq)|X_2,C$, where X_2 is the halogen Cl_2, Br_2, or I_2, and M is the metal of the halide MX_n. However, when cells have been used in which the halogen has been introduced at the carbon cathode from an external source, different investigators have in many cases obtained widely varying results with the same halide. Apparently this is due primarily to thermal gradients within the cells and/or to depolarization when the halogen is introduced too slowly or does not contact the entire surface of the electrode or, as in some cases, when its flow has been interrupted during emf measurements. The pulsed electrolysis, or electronic commutator, technique for determining the reversible $E°$ of such cells has been shown to be reliable in studies with silver chloride (1) and lead chloride (2). In each case, however, a temperature existed above which it was not possible to produce cells free of depolarization, 910°C for AgCl and 640°C for $PbCl_2$ (extended to 865°C with chlorine atmosphere above the melt). Below these temperatures the cells met the requirements of reproducible emf, absence of hysteresis effects, and adherence to the Nernst equation with changing pressure. The reproducibility of emf values indicated a precision of measurement greater than that achieved in most earlier studies by the conventional reversible cell method.

In the commutator method, square-wave current pulses are passed between inert graphite electrodes in the molten halide to form the constituents of a reversible cell. Pulsing cycles have ranged from 0.04 to 1.0 sec, with current pulse lengths of 0.008-0.25 sec. Cell emf is determined as a function of time between pulses. If satisfactorily functioning electrodes are formed, there is rapid decay of overpotential, followed by a slow, essentially linear emf decay resulting from diffusion of one or both reactants from the electrode(s). The linear, diffusion-controlled portion of the emf decay curve is extrapolated to current-off time to obtain the reversible cell emf for the reactant activities at that time. Pulse current and/or pulse time are increased until a constant value is obtained for this extrapolated emf of the cell at 760 Torr. This is $E°$ for the cell if mutual solubilities of cell constituents are very low. If mutual solubilities of the elements and the salt are significant, proper corrections must be made by use of the Nernst equation. Observation of the shape of the emf decay curve and its change, if any, with time and with increasing pulsing current reveals whether the electrodes are functioning satisfactorily, whether maximum activities at 1 atm have been obtained, and whether convection currents that produce fluctuating electrode temperature are present in the cell. The cell signal, therefore, gives more information about the state and functioning of the cell than is available to one employing the conventional reversible cell method. Because no gas bubbles through the melt from an external source, it is easier to maintain a uniform cell temperature. A more detailed discussion of the technique has been given by Warner (3).

In this investigation isothermal measurements were made with silver bromide and silver iodide to deter-

Key words: formation cell, nonisothermal cell, fused salt, silver halides.

[1] Present address: Department of Chemistry, Indiana University-Purdue University at Indianapolis, Indianapolis, Indiana.

mine whether suitable bromine and iodine electrodes can also be achieved by this technique. Measurements with silver chloride were repeated because the improved equipment and techniques permit greater precision and accuracy than could be achieved in the earlier investigation (1). The emf of these three halide formation cells was also measured under nonisothermal conditions to determine the magnitude of error arising from relatively small temperature differences between the cell electrodes and, by combination with the isothermal data, to derive emf values of silver and halogen thermocells for the three silver halides.

Experimental

Reagents.—Reagent grade silver chloride (Fisher Scientific Company) was used. The silver bromide (Goldsmith Brothers) had stated purity of 99.9% and the AgI was certified by the supplier (Fisher Scientific Company) to have silver content of 45.95%. No additional purification was attempted. After overnight evacuation of each cell, the halide was melted under vacuum. Dry, oxygen-free nitrogen was then introduced and permitted to flow slowly through the upper part of the cell container. A bubbler, with adjustable head of Halo-carbon polychlorotrifluoroethylene oil, was used to maintain a nitrogen pressure of 760 Torr in the cell.

Electrodes.—Each electrode consisted of a short length of spectroscopic graphite rod (Ultra Carbon Corporation, lot 1001-5, 3/32 in. diam) the pointed end of which had been thermally pretreated as described by Warner (2, 3). The graphite was sealed in a 4-mm ID fused quartz tube by evacuating the tube and, by heating, collapsing the quartz onto the graphite from 1 cm above the pointed end of the electrode for a length of 1-2 cm, which covered the junction of a platinum wire lead with the graphite. The quartz tube below the seal provided a hood about the electrode.

This construction of the electrodes resulted in the following cell after silver, Ag, and halogen, X_2, were liberated at the graphite electrodes by electrolysis pulses

$$(-)\ \mathrm{Cu|Pt|C|Ag|AgX(liq)|X_2,C|Pt|Cu}\ (+) \quad [A]$$

The cell diagram [A] is written to include all interfaces up to the measuring circuit. The copper-platinum junctions were at room temperature and the platinum-graphite junctions were at the electrode temperatures.

Temperature measurement.—Cell temperatures were determined with Pt-$Pt_{90}Rh_{10}$ thermocouples, calibrated against a Leeds and Northrup Reference Thermocouple (certified maximum error of ±0.75°C below 1100°C). Each thermocouple was protected from electrolysis products by a close-fitting fused-quartz sheath containing a small amount of the molten salt as heat transfer medium. A differential thermocouple, with junctions 2.5 cm apart in a fused-quartz sheath, was used to detect thermal gradients in the melt.

Electronic commutator and associated circuitry.—The circuit used was similar to that employed by Warner (3), but was modified to provide total on- and off-time cycles as large as 1.1 sec and to reduce instability and noise in the observed signal. Circuit details are given elsewhere (4). During the period of diffusion-controlled emf decay, the cell emf was balanced against a L&N type K-3 potentiometer and the difference signal, amplified by a Philbrick Type P2 d-c amplifier, was displayed on a Tektronix Type 585A CRO with Type D plug-in unit and was readily compared with a trace for grounded input. The horizontal sweep was internally triggered at any desired time following the current-off pulse from the commutator. Cell emf at any desired time during a single trace could be determined with a precision of about ±0.03 mV. However, due to small convection currents within the cell or other transient effects, successive traces wandered randomly from an average, or midpoint, value by ±0.1 mV under the best conditions at the lower temperatures to as much as ±1.0 mV at the highest temperatures. A midpoint trace was used to determine the cell emf.

Isothermal cell.—The melt was held in a 50-cc Triangle RR Morganite alumina crucible, contained in a 5.7-cm OD x 61-cm closed-end Coors alumina tube. This outer tube fitted into a 6.3-cm ID x 24-cm well in a 12.5-cm OD x 28-cm Hastelloy X heat ballast inside a 12.8-cm ID x 31-cm crucible furnace. The alumina tube was closed at the top by an aluminum plate making a gastight O-ring seal with a water-cooled aluminum ring sealed to the tube by quartz cement. A 4.5-cm diam x 1.8-cm graphite cover was placed on the 50-cc crucible to function as a heat shield, to reduce convection currents immediately above the cell, and to reduce loss of salt by evaporation. Its effectiveness was limited by the four holes passing through it to admit the electrodes, thermocouple, and differential thermocouple. Further details are given elsewhere (4).

Electrodes and thermocouples were inserted after the halide had been melted under vacuum and positive pressure of purified nitrogen had been established. The electrodes and the thermocouple for measurement of cell temperature were placed at the same level in the melt. Pressure inside the cell was adjusted to 760 Torr and current was pulsed through the cell until a steady value was obtained for the cell emf extrapolated to current-off time. About 15 min were usually required. Pulsing current or the ratio of on- to off-time was increased until the extrapolated emf became constant with further increase in current. The vapor pressures of the silver halides (5, 6) and the solubility of silver in silver chloride and silver bromide (7, 8) are negligible in the temperature ranges of these measurements. In the absence of quantitative data concerning the solubility of silver in silver iodide and of each halogen in the corresponding silver halide, it has been assumed that these solubilities are negligible, and that the observed maximum extrapolated emf values at 1 atm are $E°$ values. For this assumption to introduce an error of 0.1 mV in the reported values of $E°$, a solubility would have to exceed 0.2 m/o (mole per cent); for an error of 0.5 mV, 0.8 m/o. After a prolonged period of measurements, depolarization of cell emf occasionally became apparent. This resulted from growth of a silver dendrite to a point near the halogen electrode and was eliminated by rotation of the silver electrode or insertion of new electrodes.

The electrolyte temperature at the level of the electrodes was maintained constant within ±0.1°C during measurements near 450°C and ±0.5°C near 750°C. The maximum vertical temperature gradient was 1.9°C/cm, observed during a measurement at 650°C. For each set of data, $E°$ determinations were made both while ascending and descending the temperature range. Maximum temperature for measurement was determined by the point at which it was impossible to attain constant extrapolated emf by increase in pulsing current. Reproducibility was determined by making successive runs for each halide with different samples of the halide and by using more than one electrode pair in six of the eight runs. The electrodes differed in the size and location of the opening in the hood and in the area of exposed graphite surface.

Nonisothermal cell.—The nonisothermal data were obtained with a U-shaped fused-quartz cell having 15-mm ID x 36-cm vertical arms and a horizontal tube, 4 mm ID x 13.5 cm. A graphite electrode and thermocouple were inserted in each cell arm so that the thermocouple junction was at the same height and approximately at the same distance from the cell wall

as the electrode. The cell was heated in an H furnace, permitting independent temperature control of the two electrode compartments. Each vertical arm of the cell was enclosed for a height of 19 cm inside the furnace by a heavy-wall Inconel tube to aid in maintaining a uniform temperature. The temperature of one electrode was held at a constant reference value while that of the other electrode was set at various values within ±50°C of the reference temperature. Cell emf was determined as described for the isothermal cells, except that the cell was open to the atmosphere. Emf corrections to 760 Torr were calculated. Corrections were also made for the thermoelectric emf introduced by the platinum-graphite junctions at the electrodes and for small changes in the reference electrode temperature during a series of measurements.

Results

Isothermal cells.—Typical data are given in Table I for the cell C|Ag|AgCl(liq)|Cl_2,C. A total of 56 determinations of $E°$ were made for silver chloride in the temperature range 478.4°-731.3°C, 54 for silver bromide (447.0°-742.9°C), and 44 for silver iodide (558.1°-730.4°C). For each halide the regression coefficients were evaluated for the best representation of the data by linear through fifth-order polynomials in temperature, using the method given by Bennett and Franklin (9). Computations by a CDC 3600 computer gave the regression coefficients with error estimate, the standard deviation of the experimental data for each order equation, and an analysis of variance to determine the proper order of equation to employ. Although higher order equations were valid for some individual runs, for the combined data for each halide analysis of variance indicated that quadratic equations should be used to express $E°$ as a function of temperature. Constants a, b, and c for the resulting quadratic equations, with their estimated errors based on a 99% probability limit, are given in Table II, and are to be used in the equation

$$E°\,(\text{volt}) = a - bW + cW^2 \qquad [1]$$

W is 0.001 $(t - t_{m.p.})$ where t is the cell temperature in °C, and $t_{m.p.}$ is the arbitrarily accepted melting point of the halide (Table II). The standard deviations of the experimental points from these equations for AgCl, AgBr, and AgI were ±0.7, ±0.8, and ±0.8 mV, respectively. Values of $E°$ calculated by these equations within the experimental temperature ranges have possible errors, based on a 99% probability limit, of ±0.42, ±0.54, and ±0.57 mV, respectively. The experimental points are shown on the difference plots given in Fig. 1, 2, and 3. In each figure the dark curve corresponds to Eq. [1] and Table II. The light curves represent results of electrochemical measure-

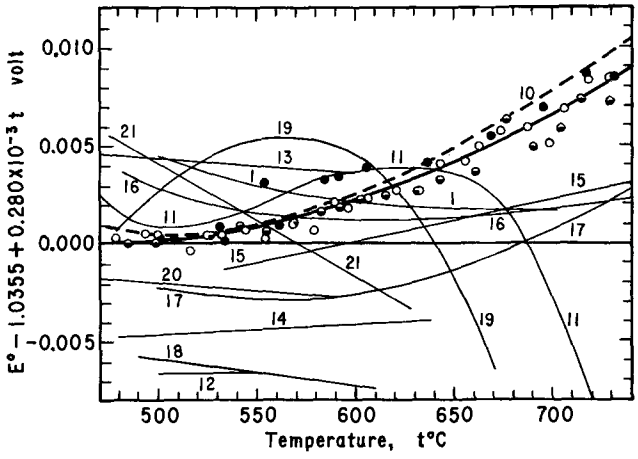

Fig. 1. $E° - (a - bW)$ for the cell C|Ag|AgCl(liq)|Cl_2,C for three independent runs, indicated by ○, ◒, ●. Dark curve is based on constants in Table II used in Eq. [1]. Dashed curve is based on thermochemical data (10). Light curves represent electrochemical measurements by investigators who are identified by the curve numbers, which correspond to entries under References.

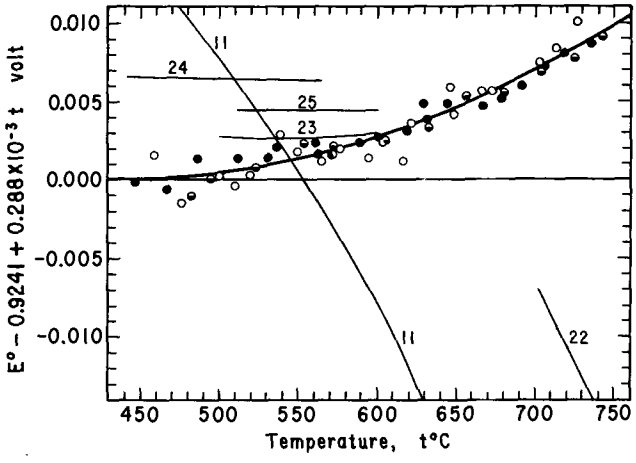

Fig. 2. $E° - (a - bW)$ for the cell C|Ag|AgBr(liq)|Br_2,C for three independent runs, indicated by ○, ◒, and ●. Dark curve is based on constants in Table II used in Eq. [1]. Numbered curves represent measurements by other investigators, (11, 22-25).

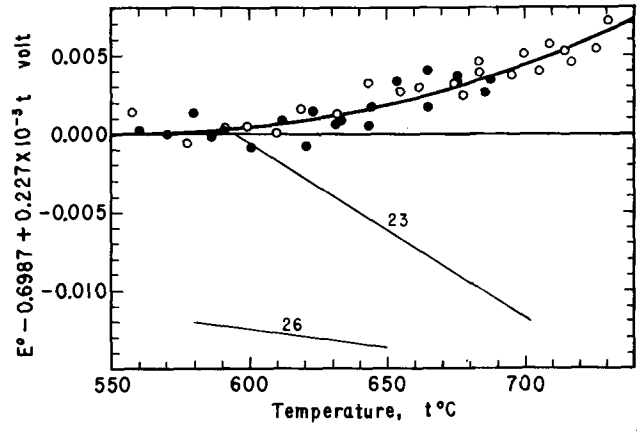

Fig. 3. $E° - (a - bW)$ for the cell C|Ag|AgI(liq)|I_2,C for two independent runs, indicated by ○ and ●. Dark curve is based on constants in Table II used in Eq. [1]. Numbered lines represent measurements by other investigators, (23) and (26).

ments by other investigators who are identified by the numbers of the curves, which correspond to entries under References. Some of these investigators present their results only as a linear equation. This linearity is preserved in these figures by plotting all results relative to the line defined by the first two terms in Eq. [1], *i.e.* by plotting differences of $E°$ from $a - bW$ where a, b, and W are given in Table II for each halide.

In Fig. 1 the dashed curve corresponds to $E°$'s calculated by Hamer, Malmberg, and Rubin (10) from thermochemical data. A five-term equation of the form they used in their calculations was used to interpolate between the values they give for $E°$ at 500°, 600°, 800°, 1000°, and 1500°C. The dashed curve lies within the 99% probability limit for the dark curve from 491° to 626°C. The data for curve 1 were obtained by the electronic commutator polarization method during its early development. Temperature measurement and control were not as accurate as for the present measurements. Data for curves 11 and 12 were obtained by the polarization method in which the halide was electrolyzed for a considerable time and the emf of the resulting cell was measured as rapidly as possible thereafter. The remaining curves are based on data obtained by the conventional reversible cell method. The data for curves 1, 11, and 13-18 were free from or had been corrected for the thermoelectric emf resulting from the temperature gradient in dissimilar leads to the cell electrodes. The authors of (12), (19), (20), and (21) do not state whether this correction was made for the silver and graphite leads in their cells. If it was not made, the corresponding curves in Fig. 1 may be low by as much as 1.0 mV at 450°C to 2.1 mV at 750°C, depending on the temperature at the connection of the electrode materials with the measuring circuit. Curves 11 and 19 show clearly the effect of depolarization at high temperatures resulting from rapid diffusion of chlorine from the cathode. Similar drop in emf was observed in this investigation at temperatures above the ranges for which data are reported. Some or all of the variation between curves in Fig. 1, 2, and 3 not resulting from depolarization may result from temperature gradients within the cells. Halogen introduced from outside the conventional reversible cell must be preheated to exactly the cell temperature. As shown by the measurements with nonisothermal cells in this investigation, cooling of the chlorine electrode by only 7°C produces the same vertical displacement (5 mV) of a point at 600°C in Fig. 1 as an error of 20°C in measurement of the temperature of an isothermal cell.

In Fig. 2 and 3, curves 11, 22, and 23 were obtained by the polarization method. [Czepinski's results (11) for AgI are not shown in Fig. 3 because they lie below −0.030V on the scale plotted, and Weber's (22) results for AgCl are not shown in Fig. 1 because they lie above 0.027V.] Graphite electrodes were used for curves 11 and 22. Silver and graphite electrodes were used for curves 23 but it was not stated whether correction was made for the thermoelectric emf present. Curves 24-26 are based on properly corrected reversible formation cell data. The values of $E°$ calculated from thermochemical data by Hamer, Malmberg, and Rubin (27) differ from the dark curves, calculated by Eq. [1] and Table II, by 0.45, 0.44, −0.07, −0.05, and −0.85 mV for AgBr at 450°, 500°, 550°, 600°, and 800°C, respectively, and by 0.15 and −1.95 mV for AgI at 600° and 800°C. Except for the values at 800°C, which is above our experimental temperature range (Table II), these differences are all within the 99% probability error limits of the equations given by Eq. [1] and Table II. However, disagreement is greater with other compilations based on thermochemical measurements.

Equations for $\Delta G°$, $\Delta S°$, $\Delta H°$, and $\Delta C°_p$ of formation of each liquid silver halide from silver and the corresponding halogen can be derived from Eq. [1]. Values of constants d, e, f, g, h, and i are given in Table II for use in the following equations (gibbs = cal/deg).

$$\Delta G° \text{ (kcal/mole)} = -d + eW - fW^2 \quad [2]$$

$$\Delta S° \text{ (gibbs/mole)} = -e + gW \quad [3]$$

$$\Delta H° \text{ (kcal/mole)} = -h + iW + fW^2 \quad [4]$$

$$\Delta C°_p \text{ (gibbs/mole)} = i + gW \quad [5]$$

Values calculated by these equations are given in Table III for each halide at its reference temperature (for which $W = 0$) and at multiples of 100° up to 1000°K. To one significant figure, the 99% probability error limits computed from the error terms in Table II are the same for the AgCl and AgBr results, being ±0.02 kcal/mole for $\Delta G°_f$, ±0.3 gibbs/mole for $\Delta S°_f$, and ±0.3 kcal/mole for $\Delta H°_f$. For AgI the corresponding terms are ±0.01 kcal/mole, ±0.6 gibbs/mole, and ±0.6 kcal/mole, respectively. For $(\Delta C°_p)_f$ the 99% probability error limits are best stated as percentages of the values given for $(\Delta C°_p)_f$ in Table III, being ±44.5% for AgCl, ±45.1% for AgBr, and ±67.9% for AgI (which are also the percentage errors of f in Table II).

Table III also includes the corresponding thermodynamic formation constants calculated by the equations of Wicks and Block (28) for AgCl and AgBr and values estimated by them for AgI at 1000°K. Their equations are based on a survey of thermodynamic literature published through 1959. For AgCl the values of $\Delta S°_f$, $\Delta H°_f$, and $(\Delta C°_p)_f$ agree well within the 99% probability error limits of Eq. [3-5]. However, the differences for $\Delta G°_f$ are three times the calculated 99% probability error limit. Except for the $(\Delta C°_p)_f$ values, where the error limits are large for the electrochemically determined values, agreement is poor for AgBr, as is the agreement between the values calculated by Eq.[2-4] for AgI at 1000°K and those estimated by Wicks and Block (28). For AgBr their values of $\Delta G°_f$ and $\Delta H°_f$ are less negative by as much as 4.44 and 3.46 kcal/mole, respectively; and for AgI at 1000°K their estimated values of $\Delta G°_f$ and $\Delta H°_f$ are more negative by 6.50 and 8.57 kcal/mole, respectively. These

Table III. Comparison of thermodynamic formation constants calculated by Eq. [2-5] and Table II with values calculated by equations derived by Wicks and Block (28)

(Values in parentheses are for temperatures beyond the range given for the equations. Values in brackets are estimates by Wicks and Block.)

Halide	Temp, °K	$\Delta G°_f$ (kcal/mole)		$\Delta S°_f$ (gibbs/mole)		$\Delta H°_f$ (kcal/mole)		$(\Delta C°_p)_f$ (gibbs/mole)

	800	−17.83	−13.60	−6.22	−7.19	−22.81	−19.35	3.6	3.63
	900	−17.23	−12.90	−5.77	−6.77	−22.43	−19.00	4.1	3.43
	1000	−16.68	(−12.24)	−5.32	(−6.42)	−22.00	(−18.66)	4.5	(3.23)
AgI	831	−13.19		−5.24		−17.55		8.4	
	900	−12.87		−4.52		−16.94		9.1	
	1000	−12.45	[−18.95]	−3.53	[−5.60]	−15.98	[−24.55]	10.1	

differences for $\Delta G°_f$ are considerably greater percentage-wise than those between the $E°$ data for AgBr and AgI and the $E°$ values calculated from thermochemical data by Hamer, Malmberg, and Rubin (27). Since both sets of authors utilized essentially the same compilations of thermochemical data, their results differ because of differences in the selection of the data they considered most reliable and in the techniques used to interpolate and extrapolate from the available data.

Wicks and Block (28) utilize as $\Delta H°_{298}$ for AgCl, AgBr, and AgI the values −30.36, −20.06, and −22.3 kcal/mole, respectively, attributing them to their Ref. (112) [Rossini *et al.*, "Selected Values of Chemical Thermodynamic Properties," NBS Circ. 500, (1952)]. The corresponding values actually given in NBS Circ. 500 are −30.362, −23.78, and −14.91 kcal/mole. The value −22.3 kcal/mole used for AgI by Wicks and Block is given in their Ref. (11). The source of their value −20.06 kcal/mole for AgBr is not apparent. Values given in the references referred to in the compilations utilized by Wicks and Block range from −22.7 to −23.81 kcal/mole. If the NBS Circ. 500 value of −23.78 kcal/mole had been used by Wicks and Block for $\Delta H°_{298}$ of AgBr, their values for $\Delta G°_f$ at 705°, 800°, 900°, and 1000°K would be −18.02, −17.32, −16.62, and −15.96 kcal/mole, which are less negative than our values by 0.42, 0.51, 0.61, and 0.72 kcal/mole; and their values for $\Delta H°_f$ at 705°, 800°, 900°, and 1000°K would be −23.42, −23.07, −22.72, and −22.38 kcal/mole, which are more negative than our values by 0.29, 0.26, 0.29, and 0.38 kcal/mole. When the equation for $\Delta G°_f$ of AgBr given by Wicks and Block (28) is used to calculate $E°$ values in the temperature range of Fig. 2, the corresponding difference values, calculated as for Fig. 2, vary from −0.180V at 450°C to −0.184V at 750°C, lying far below all the electrochemical data shown in Fig. 2. The value estimated by Wicks and Block (28) for $\Delta G°_f$ of AgI at 727°C corresponds to an $E°$ value that would lie at 0.188V on the ordinate scale of Fig. 3. Since these values lie so far from the electrochemical determinations, it follows that, at least for AgBr and AgI, the selection and utilization of thermochemical data by Hamer, Malmberg, and Rubin (27) provide more reliable values of $E°$ and the thermodynamic formation constants than that by Wicks and Block (28).

Nonisothermal formation cells.—The complete diagram for the nonisothermal silver halide formation cells, including all interfaces up to the measuring circuit, is as follows

$$(-)\ \underbrace{\mathrm{Cu}\mid\mathrm{Pt}\mid\mathrm{C}}_{t_{room}}\mid\underbrace{\mathrm{Ag}\mid\mathrm{AgX}}_{t_{Ag}}\mid\underbrace{(\mathrm{liq})\mid\mathrm{X_2,C}}_{t_{X_2}}\mid\underbrace{\mathrm{Pt}\mid\mathrm{Cu}}_{t_{room}}\ (+) \qquad [B]$$

where t_{room} is room temperature and t_{Ag} and t_{X_2} represent the temperatures of the silver and halogen electrode chambers, respectively. To correct for the Pt-graphite thermoelectric emf present in the circuit, a determination was made of the thermoelectric power, $\theta_{Pt\text{-}C}$, of a Pt-C-Pt thermocouple constructed with a graphite rod of the type used to make the cell electrodes. Based on emf measurements with one junction held at 0°C and the other at temperatures in the range t =25°-1100°C and the convention that the emf of the thermocouple is the potential of the platinum lead from the hot junction relative to that from the cold junction, the thermoelectric power was found to be

$$\theta_{Pt\text{-}C}(\mathrm{mV/deg}) = -3.3 \times 10^{-3} - 19.2 \times 10^{-6}\, t \qquad [6]$$

The correction $\theta_{Pt\text{-}C}(t_{X_2} - t_{Ag})$, where $\theta_{Pt\text{-}C}$ is taken at $t = (t_{Ag} + t_{X_2})/2$, was subtracted from the observed emfs of the nonisothermal cell [B] to obtain E', the emf that would have been observed if the temperature change from electrode temperatures to room temperature had occurred in graphite leads, as in schematic cell [C]

$$(-)\ \underbrace{\mathrm{Cu}\mid\mathrm{C}}_{t_{room}}\mid\underbrace{\mathrm{Ag}\mid\mathrm{AgX}}_{t_{Ag}}\mid\underbrace{(\mathrm{liq})\mid\mathrm{X_2,C}}_{t_{X_2}}\mid\underbrace{\mathrm{C}\mid\mathrm{Cu}}_{t_{room}}\ (+) \qquad [C]$$

The resulting values of E' for cell [C] are plotted in Fig. 4. Each series of measurements, in which one electrode was held at constant temperature, t_{ref}, and the other at variable t, may be represented by the linear equation

$$E'(\mathrm{volt}) = \alpha + \beta \times 10^{-4}\,(t - t_{ref}) \qquad [7]$$

Table IV gives the values of α and β for each series of measurements, as calculated by the method of least squares, and also gives the standard deviations of the data from the corresponding lines in Fig. 4. With each value of t_{ref} in Table IV is given its standard deviation during the series of measurements. The error

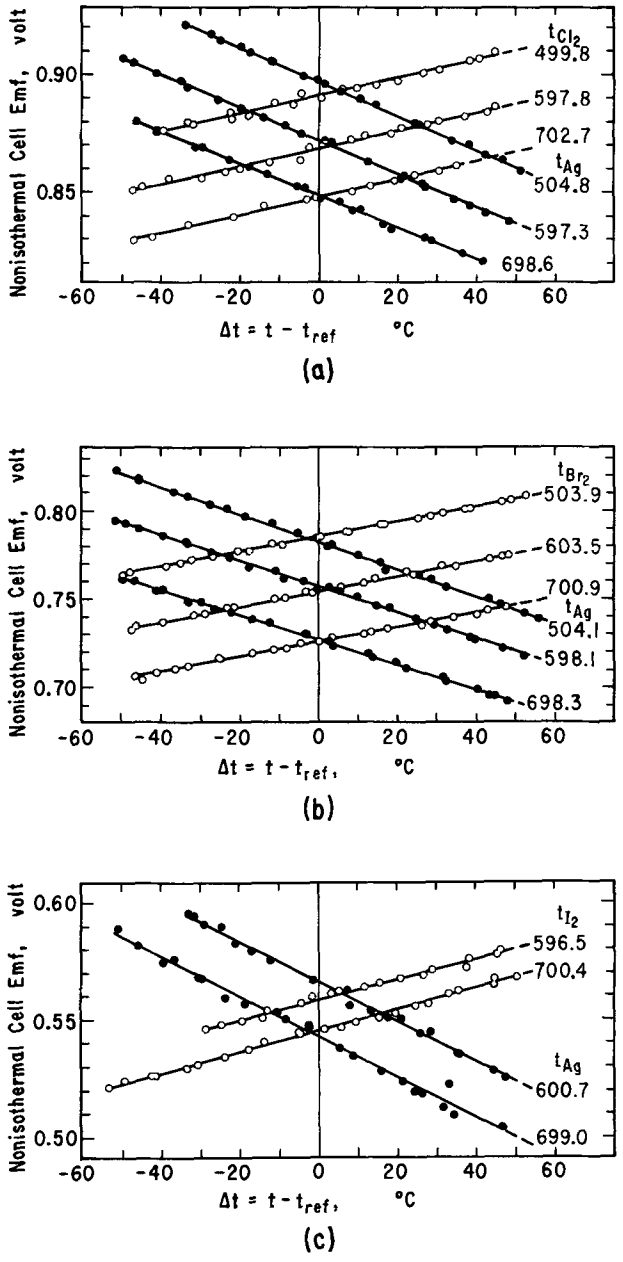

Fig. 4. Emf, E', of the nonisothermal formation cells [C] as a function of the temperature difference between the electrodes. ○ for constant $t_{X_2} = t_{ref}$ and variable $t_{Ag} = t$. ● for constant $t_{Ag} = t_{ref}$ and variable $t_{X_2} = t$. For each line t_{ref} is given at the right. (a) Silver chloride cell, X = Cl. (b) Silver bromide cell, X = Br. (c) Silver iodide cell, X = I.

Table IV. Constants for Eq. [7] to represent the nonisothermal cell data and their standard deviations

Halide	Reference electrode	t_{ref} (°C)	$E°_{ref}$ (volt)	α	β	Standard deviation (mV)

term for β is the estimate of confidence based on a 99% probability limit.

Values of $E°_{ref}$ in Table IV were calculated by Eq. [1] and Table II for the isothermal cell [A] at t_{ref}. The random variation (up to 5.6 mV) between $E°_{ref}$ and α no doubt results primarily from failure to eliminate temperature gradients within the electrode chambers of the nonisothermal cells. Small temperature differences must have existed between electrode and thermocouple in one or both chambers. Since the electrode and thermocouple placements were not changed during the series of measurements for each reference temperature, any error from this source was fairly constant for the reference electrode and, although somewhat variable in magnitude, always in the same direction for the other electrode. This would shift each average line in Fig. 4 to left or right, with little influence on the slope, which is the characteristic utilized in the following discussion.

The data in Table IV, for the nonisothermal formation cells, can be combined with data in Table II, for the isothermal formation cells, to obtain emf's for the silver halide thermocells. This provides a means of checking the self-consistency of all the electrochemical data involved, and in this case provides information regarding the iodine-silver iodide thermocell which has apparently not yet been studied.

As seen from the following cell diagrams, the sum of the interphase potential differences in a silver halide thermocell with halogen electrodes at temperatures t_{ref} and t (suppose, for the time being, that t is the temperature of the hotter electrode)

$$\underbrace{\mathrm{C,X_2|AgX}}_{t_{ref}}\underbrace{\mathrm{|X_2,C}}_{t} \quad (E_{th,X_2}) \qquad [D]$$

equals the sum of the interphase potential differences in the series combination

$$\underbrace{\mathrm{C,X_2|AgX|Ag|C}}_{t_{ref}} - \underbrace{\mathrm{C|Ag|AgX}}_{t_{ref}}\underbrace{\mathrm{|X_2,C}}_{t}$$

$$(E = -E°_{ref} + E'_{Ag}) \qquad [E]$$

where $E°_{ref}$ is the emf of the isothermal formation cell [A] at t_{ref}, and E'_{Ag} is the emf of nonisothermal formation cell [C] with the silver electrode held at the constant reference temperature. Similarly, the sum of interphase potential differences in

$$\underbrace{\mathrm{C|Ag|AgX|X_2,C}}_{t_{ref}} - \underbrace{\mathrm{C,X_2|Ag}}_{t_{ref}}\underbrace{\mathrm{X|Ag|C}}_{t}$$

$$(E = E°_{ref} - E'_{X_2}) \qquad [F]$$

where E'_{X_2} is the emf of cell [C] with the halogen electrode held at the constant reference temperature, equals the sum for the thermocell

$$\underbrace{\mathrm{C|Ag|Ag}}_{t_{ref}}\underbrace{\mathrm{X|Ag|C}}_{t} \quad (E_{th,C|Ag}) \qquad [G]$$

If the liquid AgX phases were pure, the potential drop induced by the temperature gradient between electrodes in the thermocells would equal that in the corresponding nonisothermal formation cells. However, the molten silver halide in the formation cells contains a concentration gradient of dissolved halogen (presumably present primarily as X_3^-) and of dissolved silver (probably present primarily as Ag_2^+ or $Ag_n^{(n-1)+}$). The halide in the thermocell with halogen electrodes then contains a small concentration gradient of X_3^-, resulting from the small difference in solubility of X_2 at t and t_{ref}; whereas, in the corresponding portions of halide melt in the two formation cells, the concentration gradients of X_3^- are much greater and there is also an opposing gradient of Ag_2^+ at very low concentrations. For each solute the concentration gradient in one formation cell opposes that in the other cell. Therefore any accompanying potential gradients are opposed, but their net contribution to potential drop will equal that resulting from the smaller concentration gradient in the thermocell only if the potential drop accompanying concentration change is dependent only on the concentrations of the solute at the electrodes and if the contribution to potential drop resulting from temperature gradient is independent of solute concentration. The corresponding situation, with X_3^- and Ag_2^+ interchanged, exists in the thermocell with Ag electrodes and the corresponding combination of formation cells. If the net effect of the potential gradients resulting from the concentration gradients is negligible in every case, or if it is essentially the same for a combination of formation cells as for the corresponding thermocell, then the observed emf of each thermocell, [D] or [G], should equal that of the corresponding combination of formation cells, [E] or [F].

To deal with the contingency where $t < t_{ref}$, *i.e.*, where the variable temperature electrode in the thermocell is cooler than the constant reference temperature electrode and Δt (Fig. 4) is negative, the following algebraic conventions must be introduced.

By convention, the emf of a thermocell, E_{th}, like that of a thermocouple, is the potential of the lead from the hotter electrode relative to that of the lead from the cooler electrode. The emf of the silver halide formation cells [A], [B], and [C] is the potential of the lead from the halogen electrode relative to that of the lead from the silver electrode. It is then necessary to use $\pm$ in Eq. [8], [9], and [10], according as $\Delta t = \pm$, so that

$$E_{th,X_2} = \pm E\,[D] = \pm (E'_{Ag} - E°_{ref}), \text{ for } \Delta t = \pm \qquad [8]$$

$$E_{th,C|Ag} = \pm E\,[G] = \pm (E°_{ref} - E'_{X_2}), \text{ for } \Delta t = \pm \qquad [9]$$

In past studies of thermocells with silver electrodes, silver leads have connected the electrodes with the measuring circuit or correction has been made for the thermoelectric emf introduced by use of different leads. Since the values of E' plotted in Fig. 4 and calculated by Eq. [7] are for graphite leads, cell [C], it is necessary to correct Eq. [9] for the graphite-silver thermoelectric emf, E_{C-Ag}, to obtain values comparable with reported emf's for thermocells with silver electrodes and leads

$$\underbrace{\mathrm{Ag|AgX}}_{t_{ref}}\underbrace{\mathrm{|Ag}}_{t} \quad (E_{th,Ag}) \qquad [H]$$

This gives

$$E_{th,Ag} = \pm (E°_{ref} - E'_{X_2}) - E_{C-Ag}, \text{ for } \Delta t = \pm \qquad [10]$$

where E_{C-Ag} is the potential of the carbon lead from the hot junction of a C-Ag-C thermocouple relative

to that of the carbon from the cold junction. E_{C-Ag} and $E_{th,Ag}$ are both negative quantities.

Combination of published Ag-Pt thermoelectric data (29) with Pt-C data for the graphite used in this investigation, Eq. [6], gave

$$E_{C-Ag}(mV) = -(2.31 \times 10^{-3} + 3.99 \times 10^{-6}\,\Delta t + 7.98 \times 10^{-6} t_{ref})\Delta t \quad [11]$$

The maximum value of $-E_{C-Ag}$ was only 0.407 mV.

Thermocell data are expressed as thermoelectric power, $\theta = (\partial E_{th}/\partial t)_{t_{ref}}$. Therefore, from Eq. [7], [8], [10], and [11]

$$\theta_{X_2}(mV/deg) = (\partial E_{th,X_2}/\partial t)_{t_{ref}} = 0.1\,\beta_{Ag} \quad [12]$$

where β_{Ag} is the value of β in Table IV for Ag reference electrode, and

$$\theta_{Ag}(mV/deg) = (\partial E_{th,Ag}/\partial t)_{t_{ref}} = -0.1\,\beta_{X_2} + 2.31 \times 10^{-3} + 7.98 \times 10^{-6} t_{ref} \quad [13]$$

where β_{X_2} is β in Table IV for halogen reference electrode. Values thus obtained from the formation cell data are compared in Table V with thermocell data. The average of β for different reference temperatures in Table IV has been used to calculate θ_{X_2} and θ_{Ag} except where variation with temperature is consistent and exceeds the probable experimental error.

For θ_{Ag} the seven literature values with AgCl thermocells cover a range of 0.205 mV/deg or 43% of the midrange value; the three with AgBr thermocells, a range of 0.064 mV/deg or 13%; and the three with AgI, 0.12 mV/deg or 26%. If the early thermocell values by Reinhold (20) are disregarded, the ranges become 0.045, 0.010, and 0.015 mV/deg, respectively. The four literature values of θ_{Cl_2} cover a range of 0.040 mV/deg or 6%. There is only one literature value for θ_{Br_2}, by Reinhold (20), and none for θ_{I_2}.

Values of θ_{Ag} calculated by Eq. [13] from formation cell data (Table IV) are less in absolute value than the averages of the experimental thermocell values by 0.047, 0.054, and 0.030 mV/deg or 11, 11, and 6% for the AgCl, AgBr, and AgI cells, respectively. If the values by Reinhold (20) are disregarded the differences are, respectively, 0.021, 0.034, and 0.066 mV/deg or 5, 8, and 13% less in absolute value. The corresponding 99% probability error limits given by Eq. [12] and Table IV for the calculated θ_{Ag} values are ±.03, ±0.02, and ±0.03 mV/deg for AgCl, AgBr, and AgI, respectively. The value of θ_{Cl_2} for 600°C from Eq. [12] and Table IV is 0.031 mV/deg or 5% greater in absolute value than the average of the thermocell values and that of θ_{Br_2} at the melting point of AgBr is 0.185 mV/deg or 30% greater in absolute value than the single value by Reinhold (20). The 99% probability error limits for the calculated values are ±0.02 mV/deg for θ_{Cl_2} and θ_{Br_2} and ±0.06 mV/deg for θ_{I_2}. Possible errors in the thermocell data may in some cases be of comparable magnitude, although most of the values are reported to three figures.

Table V. Thermoelectric power of silver halide thermocells

Thermocell	θ (mV/deg)	Temperature range (°C)	Reference
Ag|AgCl|Ag	−0.378	500-700	Eq. [13]
	−0.400	470-570	(18)
	−0.58	465-550	(20)
	−0.395	455-650	(30)
	−0.420	490-590	(31)
	−0.375	500-900	(32)
	$-0.404 + 6.47 \times 10^{-5}(t - 500)$	500-630	(33)
	$-0.402 + 1.6 \times 10^{-5}(t - 500)$	640-825	(34)
Cl_2|AgCl|Cl_2	$-0.725 + 2.4 \times 10^{-4}(t - 500)$	500-700	Eq. [12]
	−0.695	500-645	(18)
	−0.664	500-900	(32)
	−0.655	500-900	(35)
	−0.667	480-680	(36)
Ag|AgBr|Ag	−0.417	500-700	Eq. [13]
	−0.51	425-500	(20)
	−0.456	450-550	(31)
	$-0.446 + 5.5 \times 10^{-5}(t - 500)$	450-600	(37)
Br_2|AgBr|Br_2	$-0.776 + 3.5 \times 10^{-4}(t - 500)$	500-700	Eq. [12]
	−0.61	425-465	(20)
Ag|AgI|Ag	−0.432	600-700	Eq. [13]
	−0.39	560-600	(20)
	−0.505	540-625	(31)
	−0.490	560-650	(38)
I_2|AgI|I_2	−0.859	600-700	Eq. [12]

The differences between the experimental thermoelectric power values of the silver halide thermocells and the corresponding values calculated by Eq. [12] and [13] are therefore of the same order of magnitude as the sum of the possible errors. There is some consistency among the differences in that, for all three halides, the calculated value of each θ_{Ag} is less negative than the corresponding average thermocell value and, for each of the two halides for which thermocell values are available, the calculated value of θ_{X_2} is more negative than the thermocell value. However, this may be fortuitous or result from an undetected systematic error. Therefore, within present experimental errors Eq. [12] and [13] and the assumptions involved may be considered to be valid, at least for cells in which the solubilities of the reactants at the electrodes are low. To detect effects of concentration and thermal gradients in such cells will require greatly improved accuracy of measurement.

To obtain quantitative data related to the influence of simultaneous thermal and concentration gradients on the potential drop in a molten salt, it may be more profitable to use only formation cells, isothermal and nonisothermal, because the concentration gradients are greater in such cells than in thermocells. The sum of interphase potential differences in the combination

$$\underbrace{C|Ag|AgX}_{(a),\,t}\,\underbrace{|X_2,C - C,X_2|AgX|Ag|C - C|Ag|}_{(b),\,t_{ref}}\,\underbrace{AgX|X_2,C}_{(c),\,t}$$

equals that in an isothermal formation cell (d), C|Ag|AgX|X_2,C, at temperature t. The effect on potential drop in AgX resulting from thermal gradient in cell (a) cancels that in cell (c) unless each is influenced by the concentration gradients of Ag_2^+ and X_3^-, each of which is opposed to the thermal gradient in one cell but not in the other, so that they will not have compensating effects unless the effect of concentration gradient of Ag_2^+ equals that of X_3^- in each cell. From left to right, the concentration increase of X_3^- in cell (a) is essentially the same as its decrease in (b); the increase of Ag_2^+ in (b) is essentially the same as its decrease in (c). The remaining concentration changes of Ag_2^+ in (a) and X_3^- in (c) are essentially the same as in cell (d). Therefore the net influence of concentration gradient on potential drop in the AgX of cell (d) should equal that in the cell combination (a) + (b) + (c) unless the latter is influenced by the thermal gradients in (a) and (c). If there is no such influence, then

$$E^\circ_t = E'_{X_2} - E^\circ_{t_{ref}} + E'_{Ag} \quad [14]$$

From Eq. [7], where the constant α equals E° at t_{ref}

$$dE^\circ/dt\ (mV/deg) = 0.1(\beta_{Ag} + \beta_{X_2}) \quad [15]$$

By Eq. [1] and [15] and Tables II and IV, with β values averaged as for Table V, dE°/dt is always less negative than $0.1(\beta_{Ag} + \beta_{X_2})$. For AgCl cells at 500°, 600°, and 700°C the differences are 0.070 ± 0.05, 0.068 ± 0.05, and 0.066 ± 0.05 mV/deg, respectively; for AgBr at the same temperatures, 0.077 ± 0.04, 0.061 ± 0.04, and 0.046 ± 0.04 mV/deg; and for AgI at 600° and 700°C, 0.210 ± 0.09 and 0.254 ± 0.09 mV/deg. These calculated differences range from two to four times those obtained when comparing thermocells with isothermal plus nonisothermal formation cells and the 99% probability error limits are a smaller fraction of the differences. As might be expected, the differences for AgBr are closer to those for AgCl than to those for AgI.

In every case the calculated difference is in the direction such that, if there is an interaction between

thermal gradient and concentration gradients in non-isothermal formation cells, its net effect is to increase the potential of the high-temperature electrode relative to that of the cooler electrode if the gradients of temperature and Ag_2^+ concentration are in the same direction and to decrease its relative potential if the gradients of temperature and X_3^- concentration are in the same direction. Although the possible existence of systematic errors, unrecognized and therefore uncorrected, precludes firm quantitative conclusions, the results suggest that the net effect in silver halide cells may be of the order of hundredths of a millivolt per degree and therefore capable of evaluation with increased accuracy of measurement of cell potentials and electrode temperatures.

Electrode Studies in Nonaqueous Electrolytes

I. The Lithium Electrode in $LiClO_4$-Propylene Carbonate Solutions

Stuart G. Meibuhr

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

The electrochemical properties of the smooth lithium electrode in $LiClO_4$-propylene carbonate solutions were studied at temperatures up to 70°C by galvanostatic methods. For the range of current densities, temperatures, and $LiClO_4$ concentrations studied, the anodic and cathodic polarization data were symmetrical through zero current density. Values for the exchange current density, i_o, were calculated at each experimental condition; at 28°C and 1M $LiClO_4$, i_o was 0.95 ± 0.05 mA/cm². The ΔH^*_o value was 8.5 ± 0.3 kcal/mole, and α had a temperature independent value of about 0.67. The electrochemical reaction order was 1 for concentrations up to 1M in Li^+ ion.

The extensive interest in organic electrolyte batteries (1-3) has produced a recent increase in the number of investigations of electrochemical phenomena in solutions of organic solvents. However, only a limited amount of work has been devoted to the study of the electrode kinetics at solid electrodes.

Rao has examined the electrode reactions at the cathodes of copper (4) and lead (5) in a 1M $LiAlCl_4$-propylene carbonate (PC) solution, whereas Burrows and Jasinski (6) studied the lithium anode in 1M $LiClO_4$-PC at 28°C. From the slope of their current-polarization data, a value for the exchange

current density (i_o) is calculated to be 0.0275 mA/cm^2. Scarr (7), however, reported a value for i_o of about 0.6 mA/cm^2 at 23°C in a $LiClO_4$-PC solution. Zotov and Khlystova (8) found that the process of lithium deposition from LiCl-dimethylformamide solutions was crystallization limited.

The purpose of this work was to study the electrochemical properties of the smooth lithium electrode in $LiClO_4$-PC solutions at temperatures up to 70°C. Two series of experiments were performed. The lithium reference electrode in $LiClO_4$-PC solutions was evaluated by investigating the open-circuit potential of a Li/Li^+ concentration cell at ambient temperature; and the Li/Li^+ electrode kinetics were studied by analyzing the data obtained by anodically and cathodically polarizing Li electrodes in $LiClO_4$-PC solutions.

Experimental

Materials.—The propylene carbonate solvent, obtained from Jefferson Chemical Company, was vacuum distilled at 3-4 mm of mercury using a 90-cm long column packed with glass rings. The first 30% of the pot charge that distilled was discarded. The next 60% was collected and used in these experiments. The distilled PC had a water content of <35 ppm; the analysis was performed by the Karl Fischer method in an apparatus exposed to the air; consequently, the actual amount of water was probably considerably below the 35-ppm level. Gas chromatographic analysis of distilled PC showed only one impurity peak. A typical chromatogram (using the thermal conductivity detector) is given in Fig. 1. The post-PC peak was identified as ethylene carbonate, and its concentration was calculated at about 0.5% (9). Only one other impurity could be detected; about 20 ppm of 1, 2 propanediol was present in the distillate.

The $LiClO_4$ was of the highest purity available; it was (*a*) dried at 150° in a vacuum oven for at least 16 hr, (*b*) cooled in vacuum, and (*c*) transferred promptly to a dry box.

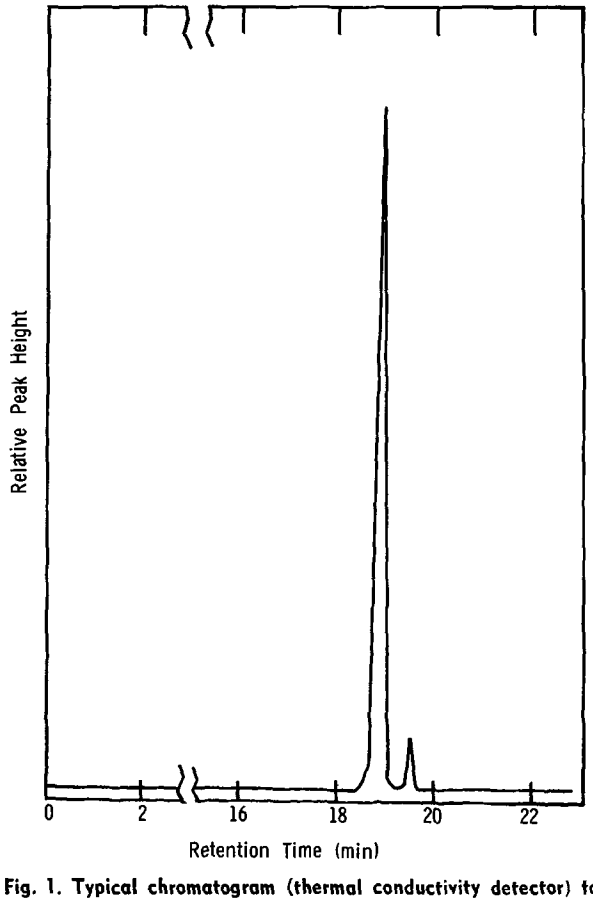

Fig. 1. Typical chromatogram (thermal conductivity detector) for distilled PC.

Solutions of concentrations ≧ 1M were made by weighing in a dry box sufficient solute to add to 100 ml of PC. The less concentrated solutions were prepared by diluting the concentrated solutions with PC. All solutions were stored over solid lithium which could act as a getter for water (6). These solutions also showed a water content <35 ppm. The solutions were stored in ungreased, ground glass stoppered bottles in the water, O_2, and N_2 free atmosphere of the dry box [manufactured by Vacuum Atmospheres Corporation, (VAC)].

Lithium electrodes (0.08 cm^2 in area) were prepared in the VAC dry box by sealing a bright lithium wire (metal impurities = 0.01% obtained from Alfa Inorganics Company), approximately 40 mm long, in epoxy resin. A small alligator clip, which was attached to one end of the wire for making electrical contacts, was partially sealed in the epoxy also. When hard, one end of the potted wire was ground to expose the bright lithium surface with an area equal to the cross-sectional area of the wire. Three such electrodes served as the test, counter, and reference electrodes.

Equipment.—The potential measurements of the Li/Li^+ concentration cells were performed in a glass U-tube with the arms (ID = 8 mm) separated with a fritted glass disk.

The galvanostatic measurements were performed in a glass cell mounted over a hot plate shown schematically in Fig. 2. The three epoxy-sealed lithium electrodes and a thermometer were inserted in inlet ports in the glass cell cover, and the solution was stirred with argon bubbling through a glass frit in the cell. The solution temperature could be maintained within ± 0.5°C. The argon gas that was bubbled through the solution contained 6% H_2 because the presence of H_2 was necessary to regenerate the copper turnings in the O_2-removal furnace. It was found that the presence of H_2 did not affect the measurements.

Because of the relatively low specific conductivity [approximately 10^{-2} ohm^{-1} cm^{-1} for 1M $LiClO_4$ at 25°C (10, 11)] of these solutions, it was necessary to measure the resistance between the working and reference electrodes (12) before each experiment. This solution resistance was determined from the oscilloscope trace of a single current pulse. The electrical circuit mounted outside the dry box was similar to one described previously (13) except that a variable resistor was in series with the single cell lead-acid battery; with this resistor, the current flowing through the circuit could be varied. With the oscilloscope operating at 20 μsec/cm, the *iR* loss was determined at 6-8 different currents. The largest current that was pulsed was always larger than the maximum current used during a polarization run. For a given set of conditions, repeat determinations of R gave values within

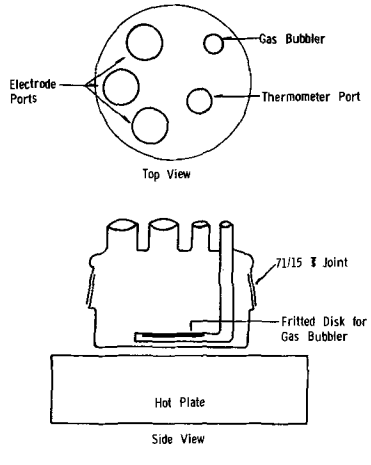

Fig. 2. Polarization cell

10% of one another. These values of R were used to obtain iR-free polarization curves. The current was determined from the iR drop across a 1000-ohm precision resistor.

Experimental method.—All electrochemical measurements and associated materials handling were performed in the VAC dry box.

The potential of the concentration cell

$$\underset{c_1}{\text{Li/LiClO}_4\text{-PC//LiClO}_4\text{-PC/Li}}\ \ \underset{c_2}{}$$

was measured for values of $c_1 = 0.5$ or 1.0M and $c_2 = 0.1$ to 1.0M. Included in the measured emf was an unknown junction potential which was estimated using the Henderson equation (14)

$$E_j = RT/F \frac{\lambda^o_+ - \lambda^o_-}{\lambda^o_+ + \lambda^o_-} \ln \frac{c_1}{c_2} \qquad [1]$$

where λ^o_+ and λ^o_- are the limiting ionic mobilities of Li^+ and ClO_4^-, respectively. The values of λ^o_+ for Li^+ have been determined in dimethylsulfoxide as 11.4 (15), in dimethyl formamide as 25 (16), and in formamide as 8.5 (16). Applying Walden's rule, the value for λ^o_+ in PC becomes 8.7. The value for λ^o_- can be calculated from

$$\Lambda_o = \lambda^o_+ + \lambda^o_-$$

The value for Λ_o has been determined to be 30.4 (11); hence, λ^o_- is 21.7.

The polarization studies were made in the following manner. Sixty milliliters of solution were added to the cell, and the electrodes were placed in position. The solution was bubbled with argon presaturated with PC. The potential between the working and reference electrodes was monitored with a Keithley electrometer. When this potential came to a steady value <0.5 mV, the voltage leads were connected to the oscilloscope and Polaroid prints were made of the traces obtained by applying a single pulse to the working electrode at 6-8 different values. The iR correction could then be calculated for each current for which the polarization was measured. When equilibrium was again regained (as indicated above), the anodic polarization run was made for increasing values of the current. In some experiments a cathodic run was made when the system returned to equilibrium. Before a duplicate anodic run was made, the test electrode was removed from solution, dried, and repolished to expose a fresh lithium surface. It was necessary to redetermine the resistance between the working and reference electrodes after each repolishing step.

The exchange current densities were calculated from the equation

$$i_o = iRT/\eta_{iR-free}F \qquad [2]$$

where $\eta_{iR-free} = E_{exptl} - E_{oc} - iR$.

Results and Discussion

Concentration cell studies.—Table I shows the measured emf values for the cell together with the calculated E_j values and the corrected emf values. The data show a 68 ± 1 mV change/decade of Li^+ ion concentration. Considering the assumptions that were made in calculating the E_j values, the potential responded to the varying Li^+ ion concentration in reasonable accordance with the Nernst equation. Thus, a solid lithium electrode immersed in solutions of Li^+ ion from 0.1 to 1M behaved satisfactorily for a reference electrode, in agreement with results (6) obtained by measuring (*a*) the stability of potential with time and (*b*) the recovery of the electrode after micropolarization.

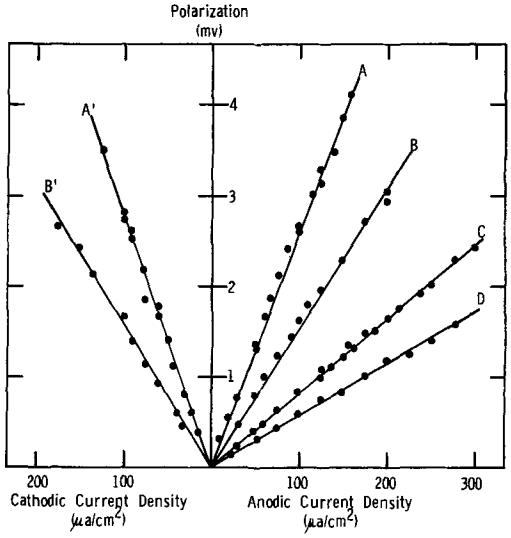

Fig. 3. Current density-iR free polarization data for a 1M $LiClO_4$ solution. Curves A, A', 29°C; B, B', 43°C; C, 58°C; D, 67.5°C.

Polarization studies.—Figure 3 shows typical anodic and cathodic iR-free polarization data; these were taken at 28° in a solution of 1M $LiClO_4$. Under all experimental conditions, the current density-polarization plots were linear; the slope of the cathodic portion agreed with the slope of the anodic branch within 4%. Duplicate anodic polarization runs produced slopes which were within 10% of one another. The i_o variations with temperature and Li^+ ion concentration are summarized in Table II.

The anodic and cathodic i_o values for a 1M $LiClO_4$ solution at 28° were 0.95 ± 0.05 mA/cm² determined in five separate experiments over a period of months. This value is about 35 times greater than the value calculated from data of Burrows and Jasinski (6). An extrapolation of the log i_o − $1/T$ data to lower temperatures (Fig. 4, curve C) for the 1M solution yielded an i_o value at 23° of 0.7 mA/cm². This value agreed with the 0.65 value reported by Scarr also at 23° (7). One explanation for the large discrepancy between the i_o value calculated from Burrows and Jasinski (6) on the one hand and the values given by Scarr (7) and the present work on the other hand is that in the former case the polarization values may have included the solution iR loss. If this occurred, the calculated i_o values would be too low, the magnitude depending on the exact value for the included iR drop. If a resistance value of about 235 ohms is

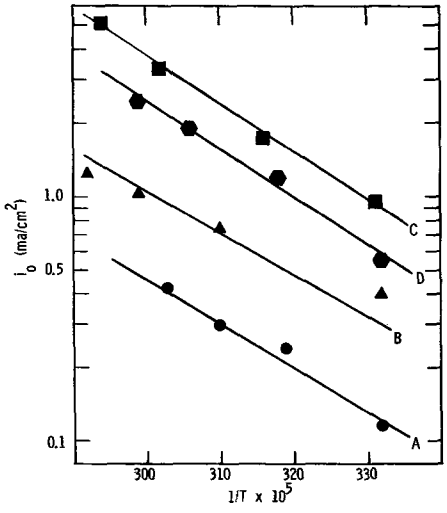

Fig. 4. Plot of the i_o values against $1/T$. Curve A, 0.1M; B, 0.5M; C, 1.0M; D, 2.0M $LiClO_4$.

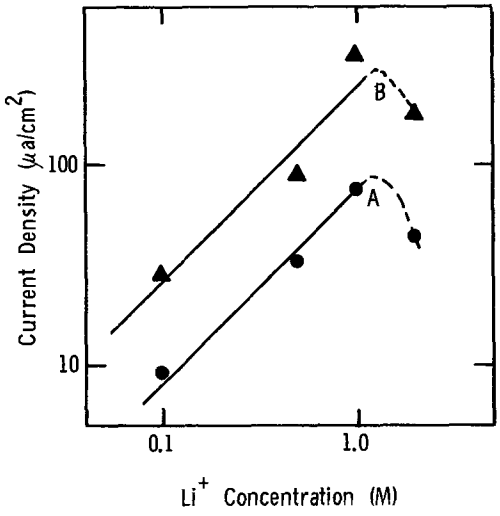

Fig. 6. Determination of the reaction order for solutions containing only $LiClO_4$. Curve A, 28°C; B, 70°C.

assumed (and this value is reasonable for a 1M $LiClO_4$ solution having the electrodes spaced approximately 1 cm apart), the calculated value for i_o then agrees with the value determined in this work.

From the results of the temperature effect on the polarization, the enthalpy of activation at zero polarization (ΔH_o^*) was calculated using the equation

$$\frac{\partial \ln i_o}{\partial (1/T)} = \frac{\Delta H^*_o}{R} \qquad [3]$$

The values of i_o were calculated from the slopes of the polarization plots using Eq. [2]. Plots of the log i_o against $1/T$ are given in Fig. 4. The lines were drawn parallel to give the best fit for all the points in that figure. The value obtained for ΔH^*_o was 8.5 ± 0.3 kcal/mole. This value is of the order of magnitude expected for metal dissolution and deposition.

The transfer coefficient, α, was calculated indirectly from the slope of the plot $\partial \log i_o / \partial \log C_{Li^+}$ (17). The data in Fig. 5 (curve A) yield a value for α of about 2/3; this value remained constant with increasing temperature.

The electrochemical reaction order can be obtained by plotting the log i, at constant overvoltage, against the log of the apparent concentration of a given species (18). In Fig. 6 is shown the current density dependence on the Li^+ ion concentration in solution. Curve A represents data at 28°C whereas curve B denotes data at 70°C. Several important items of note include: the linear plots are parallel; their slope equals 1; and at concentrations above 1M there is a marked change in the reaction order. The change may be associated with the causes for the decrease in conductivity (10, 11) at $LiClO_4$ concentrations greater than 1M. Also, in these concentrated solutions ion association may occur. The current density value associated with the 2M solution (see Fig. 6) corresponds to a Li^+ ion concentration of about 0.6M in the linear region. This concentration is about 1/3 the amount of Li^+ ion added to the solution. More polarization data at Li^+ ion concentrations greater than 1M and the Li^+ ion activity coefficients are needed before an unambiguous explanation for the apparent change in reaction order can be presented.

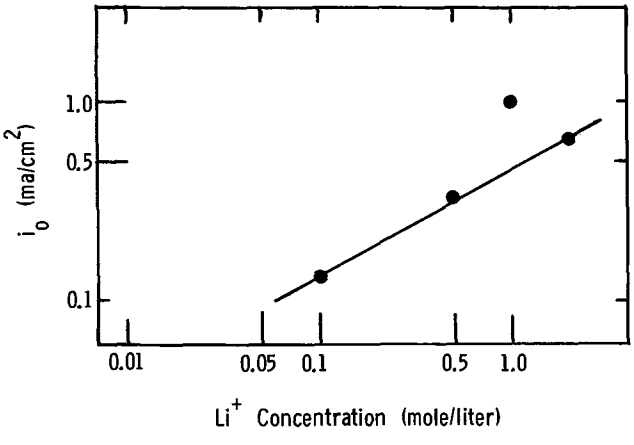

Fig. 5. Determination of the $(1-\alpha)$ value. Temperature, 28°

It may be concluded from these studies that the data for the dissolution and deposition of lithium from solutions containing only $LiClO_4$ are consistent with the charge transfer rate-determining step

$$Li \rightleftharpoons Li^+ + e$$

Electrode Oxidation of Hydrazine and Related Compounds in Liquid Ammonia Electrolytes

M. H. Miles*, [1] **and P. M. Kellett**

Naval Weapons Center, Corona Laboratories, Corona, California

ABSTRACT

Potential sweep investigations of the electrochemical oxidation of hydrazine on platinum in liquid ammonia electrolytes yield current-potential curves which depend markedly on the nature of the electrolyte anion present. These anion effects are interpreted in terms of the principle of soft and hard acids and bases and specific adsorption at the electrode. In general, the "harder" the electrolyte anion, the better is the performance of the hydrazine anode. Low-temperature studies show that hydrazine can be electrochemically oxidized in liquid ammonia at −60°C, demonstrating the high reactivity of this fuel. The oxidation of hydrazine on platinum appears to be a diffusion-controlled, highly irreversible reaction. Hydrazine is also electrochemically oxidizable in liquid ammonia on Ir, Rh, Re, Pd, V, Mo, Au, and on nitrocarbides and nitrides of transition metals. Of various substituted hydrazine compounds tested, only hydroxylamine compared with hydrazine in reactivity.

Fuel cells using hydrazine are emerging from the laboratory (1, 2); this development is a result of fundamental research on the electrochemical oxidation of this reactive fuel (3-6). Except for a few results in several organic electrolytes and hydrogen fluoride electrolytes (7), this research has been limited to aqueous solutions. Contrary to earlier work by Hammer (8), we have established that hydrazine can be electrochemically oxidized in liquid ammonia electrolytes (9). The high electrochemical activity of hydrazine and its infinite solubility in liquid ammonia make hydrazine attractive for use as a soluble fuel in low-temperature fuel cells with liquid ammonia electrolytes. Furthermore, the use of hydrazine as a fuel appears to be thermodynamically more favorable in liquid ammonia than in aqueous electrolytes, because of the abnormal stability in liquid ammonia of the hydrogen ions produced in the electrochemical oxidation of hydrazine (10).

Experimental

The chemicals used include Baker reagent hydrazine sulfate and Matheson hydrazine hydrate (99-100%). Hydrazine sulfate is convenient to handle and undergoes ammonolysis (11)

$$N_2H_4 \cdot H_2SO_4 + 2NH_3 \rightarrow N_2H_4 + (NH_4)_2SO_4$$

to produce anhydrous hydrazine and insoluble ammonium sulfate. The electrolyte solutions were prepared from anhydrous ammonia (Matheson Company, 99.99%) and vacuum-dried, reagent-grade salts.

Inorganic salt solutions of liquid ammonia were prepared in a special flask which permits vacuum drying of the salt and formation of the solution without exposure to air. Various salts, such as NH_4SCN, NH_4I, $LiNO_3$, $LiClO_4$, NaSCN, and NaI form ammonia solutions where the vapor pressure of NH_3 at ambient temperature is below 1 atm (9, 12). Unless stated otherwise, these solutions having a salt concentration of about 5-10M were used. These liquid ammonia solutions were taken into a drybox and poured into a vacuum-tight, controlled-atmosphere electrochemical cell fitted with screw cap thermometer adapters with O-rings (Scientific Glass Apparatus) which seal the electrodes. A smaller, three-compartment cell equipped with the screw cap thermometer adapters was used for the low-temperature studies; anhydrous ammonia was condensed directly into the cell thermostatted at −60°C. A special pressurized cell (13) was used for investigations where the vapor pressure of ammonia exceeds 1 atm. The reference electrode used for all measurements was $Pb/Pb(NO_3)_2$ (saturated) with a single glass microcrack separating the reference electrode and solution. Further details of the electrochemical measurements are given elsewhere (9).

For low-temperature investigations, slush baths of dry ice in organic solvents conveniently cover the liquid range of ammonia and provide temperature control of ±1°C (14). A dry ice slush bath of a mixture of o-xylene and m-xylene was used for studies at −60°C while 3-heptanone was used for the −35°C bath.

Results and Discussion

Electrocatalysts for hydrazine oxidation.—Various nitrocarbides, nitrides, carbides, and borides of transition metals and alloys prepared by the Bureau of Mines, Pittsburgh Coal Research Center under NASA contract No. 12,300, were tested as catalysts for the electrochemical oxidation of hydrazine in acid liquid ammonia solutions. In general, the nitrogen-containing compounds, such as the nitrocarbides and nitrides, showed more promise as catalysts than the other

* Electrochemical Society Active Member.

Key words: adsorption, ammonia, anions, electrocatalysts, fuel, hydrazine, hydroxylamine, oxidation, platinum, temperature.

compounds. However, it appears that none of these compounds show catalytic activity comparable to that for platinum.

Various transition metals were also tested as catalysts for the electrochemical oxidation of hydrazine in liquid ammonia electrolytes. The metals iridium, rhodium, rhenium, and palladium showed catalytic activity comparable to that for platinum. Hydrazine oxidation was also observed on vanadium, molybdenum, and gold. Tantalum, titanium, aluminum, wolfram, zirconium, chromium, and gallium were all found to be inactive for hydrazine oxidation. Hydrazine was also tested on cobalt, copper, iron, indium, lead, mercury, and tin, but oxidation of the metal itself obscured the results.

Tests of other related compounds on platinum.—Several substituted hydrazine compounds were tested for electrochemical oxidation on Pt in liquid ammonia electrolytes including phenylhydrazine, 1,2-diphenylhydrazine, 1,2-dimethylhydrazine dihydrochloride, 2,4-dinitrophenylhydrazine, carbohydrazide, and hydroxylamine hydrochloride. All showed evidence for oxidation on Pt; however, only hydroxylamine showed reactivity comparable to that for hydrazine.

Constant current and potential scan methods were used in testing these various compounds. Figure 1 gives the results for constant current oxidation of $N_2H_4 \cdot H_2SO_4$ and $NH_2OH \cdot HCl$ on Pt in stirred NH_3-$LiNO_3$ solutions. Similar results were obtained in NH_4NO_3 and NH_4SCN ammonia electrolytes; *i.e.*, almost 4 electrons/molecule for hydrazine oxidation and about 2 electrons/molecule for the oxidation of hydroxylamine. This suggests that the net oxidation reactions for these compounds in ammonia electrolytes are

$$N_2H_4 \rightarrow N_2 + 4H^+ + 4e^-$$
$$NH_2OH \rightarrow \tfrac{1}{2}N_2O + \tfrac{1}{2}H_2O + 2H^+ + 2e^-$$

Nitrous oxide is also believed to be a major product in the electrochemical oxidation of hydroxylamine in dimethylsulfoxide (15).

The constant current oxidation of the other compounds did not give the sharp inflections observed for hydrazine and hydroxylamine (Fig. 1); hence, the electron yield per molecule was indeterminate for the oxidations of these other compounds.

Anion effects.—Potential scan investigations of hydrazine oxidation on platinum in various concentrated salt-ammonia solutions show that the results depend markedly on the nature of the electrolyte anion. Figures 2, 3, and 4 give the results in NH_3-NH_4SCN, NH_3-NH_4I, and NH_3-NH_4NO_3, respectively. Oxidation of the iodide ion (Fig. 3) tends to obscure part of the hydrazine oxidation peak. Figure 4 shows the interesting build-up when time is allowed between potential sweeps of a second hydrazine oxidation peak at about +0.2V in the nitrate solutions, as well as a peak build-up at about −0.2V due to hydrogen oxidation. This build-up with time of a second hydrazine oxidation peak was also observed in NH_3-NH_4ClO_4 solution at 0°C, but in NH_3-NH_4SCN and NH_3-NH_4I no such effect was observed. The rest potential (V_R) was −0.15V in the nitrate solution and +0.15V in the thiocyanate solution; however, V_R in NH_3-NH_4SCN gradually shifted over a period of several days to the −0.15V value. Results in neutral ammonia solutions (NH_3-NaSCN, NH_3-NaI, and NH_3-$LiNO_3$) were very similar to those in the acid solution containing the same anion.

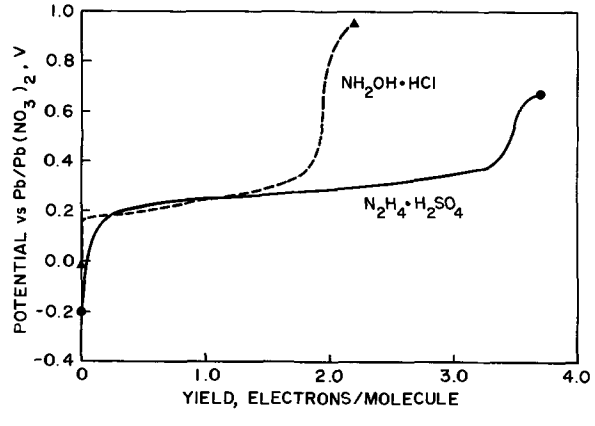

Fig. 1. Constant current oxidation of $N_2H_4 \cdot H_2SO_4$ and $NH_2OH \cdot HCl$ in stirred NH_3-$LiNO_3$ solutions using platinum electrode of about 50 cm² geometrical area. I = 1.00 mA; T = 20°C.

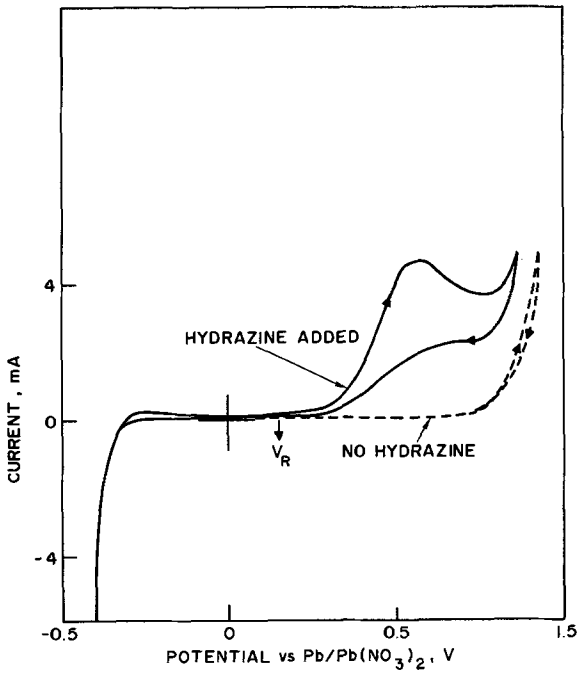

Fig. 2. Cyclic voltammogram for 0.02M $N_2H_4 \cdot H_2SO_4$ in NH_3-NH_4SCN at 20°C using platinum wire electrode with geometrical area = 0.3 cm². v = 250 mV/sec.

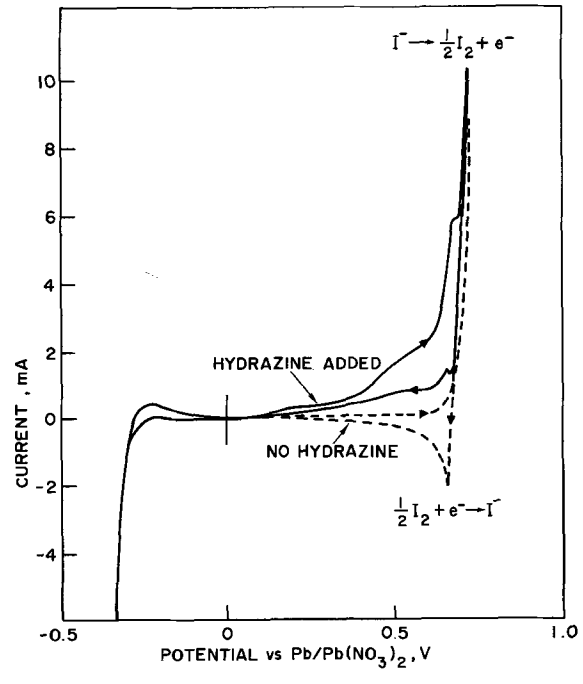

Fig. 3. Cyclic voltammogram for 0.02M $N_2H_4 \cdot H_2SO_4$ in NH_3-NH_4I at 20°C using platinum wire electrode with geometrical area = 0.3 cm². v = 250 mV/sec.

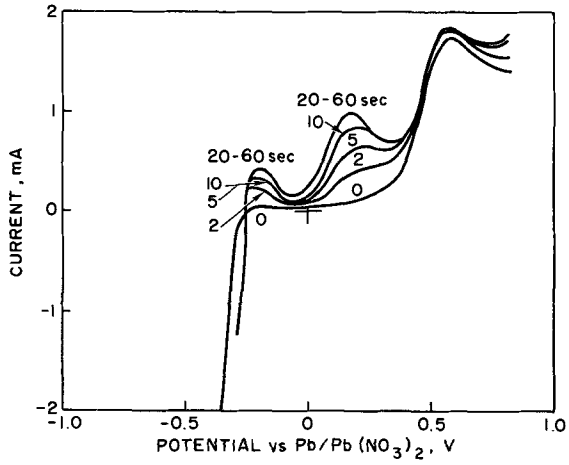

Fig. 4. Effect of allowing time between potential sweeps on current potential curves for 0.02M $N_2H_4 \cdot H_2SO_4$ in NH_3-NH_4NO_3 at 20°C using platinum disk electrode with geometrical area = 0.2 cm^2. Electrode potentiostatted at −0.35V between sweeps. v = 250 mV/sec.

Investigations were also conducted at about 25°C in 1M salt-ammonia solutions in the pressurized electrochemical cell fixture. The results were practically identical to those obtained at atmospheric pressure in the concentrated salt-ammonia solutions containing the same anion. For example, Fig. 5 shows cyclic voltammograms for hydrazine oxidation in 1M $LiNO_3$-ammonia solution at about 25°C in the pressurized cell giving the usual two oxidation peaks observed in nitrate solutions. No reduction of the oxidized species was ever observed (*see* Fig. 2, 3, and 5), indicating that the hydrazine oxidation is highly irreversible.

Low-temperature studies of hydrazine oxidation at −60°C and −35°C were made in 1M NH_4Cl, 1M NH_4Br, and 1M NH_4I ammonia solutions in order to evaluate the relative effect of these halogen anions on the reaction. Results are given in Fig. 6 and 7. Note that, in the NH_4Cl solution, hydrazine oxidation at −60°C is observed near the potential of the Pb reference. The oxidation current obtained is dependent on the anion present, increasing in the order $I^- < Br^- < Cl^-$. At −35°C, the oxidation current in the bromide solution approaches that for the chloride solution as the potential increases. Similar hydrazine

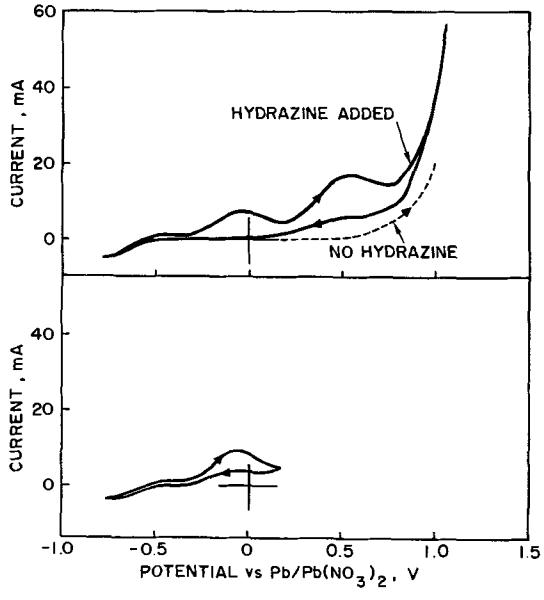

Fig. 5. Cyclic voltammograms for 0.02M $N_2H_4 \cdot H_2SO_4$ in NH_3-1M $LiNO_3$ in pressurized cell at about 25°C using platinum disk electrode with geometrical area = 1 cm^2. v = 250 mV/sec. In the bottom voltammogram the anodic sweep range is reduced.

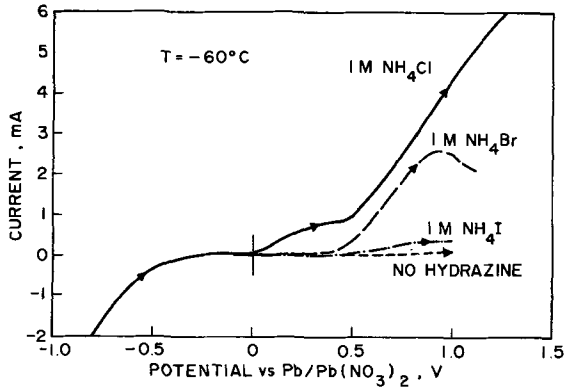

Fig. 6. Current potential curves for 0.2M $N_2H_4 \cdot H_2O$ in 1M NH_4Cl, 1M NH_4Br, 1M NH_4I ammonia solutions at −60°C using platinum wire electrode with geometrical area = 0.2 cm^2. v = 250 mV/sec.

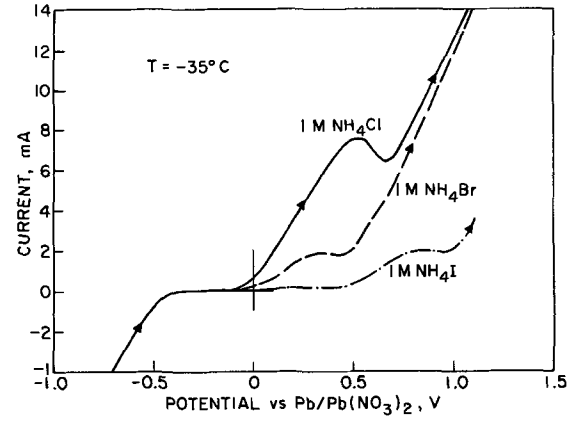

Fig. 7. Current potential curves for 0.2M $N_2H_4 \cdot H_2O$ in 1M NH_4Cl, 1M NH_4Br, and 1M NH_4I ammonia solutions at −35°C using platinum wire electrode with geometrical area = 0.2 cm^2. v = 250 mV/sec.

investigations in 1M NH_4NO_3 solution at −60°C yield an oxidation current intermediate between that in the chloride and iodide solutions; however, the build-up when time is allowed between potential sweeps of a second hydrazine oxidation peak does not occur readily at these low temperatures.

Discussion of anion effects.—The observed anion effects can be interpreted in terms of the principle of soft and hard acids and bases (SHAB) and specific adsorption at the platinum electrode. The SHAB principle states that hard acids prefer to bond to hard bases and soft acids prefer to bond to soft bases (16). Bulk metals, such as platinum, have the properties of soft acids (16, 17); hence, soft bases will tend to bond to platinum, blocking the active sites on the metal. Barclay (18) has shown that the classification of anions in terms of softness can be related to the potential at the point of zero charge (E_{pzc}) which shifts cathodically with increasing specific anion adsorption. Table I shows the relationship between E_{pzc} for mercury and Pearson's classification of the anion in terms of the SHAB principle.

The SHAB principle predicts that the order of anion specific adsorption will not vary greatly with the solvent, which is the case experimentally as anions appear to be specifically adsorbed in the same general order in most solvents (19, 20). Since both NH_3 and H_2O are classified as hard bases (21), the order and extent of anion specific adsorption should be similar in these two solvents.

The SHAB principle also predicts that the order of anion specific adsorption will not vary with the electrode metal used. Experimentally it is found that, as

Table I. Relationship between potential of zero charge (E_{pzc}) for mercury in aqueous solutions and softness of anions

Anion	E_{pzc} (*v vs.* NHE)	Pearson's classification of anion
$S^=$	−0.638	Soft
I^-	−0.451	Soft
SCN^-	−0.347	Soft
Br^-	−0.293	Borderline
NO_3^-	−0.236	Hard
ClO_4^-	−0.228	Hard
Cl^-	−0.219	Hard
$SO_4^=$	−0.196	Hard
OH^-	−0.196	Hard
F^-	−0.195	Hard

Salt concentrations were 0.1M except for $S^=$ (0.5M) [*see* Ref. (18)].

for mercury, halide adsorption decreases in the order $I^- > Br^- > Cl^-$ on platinum (22), gallium (23), and cadmium (24). However, the potential regions where anion adsorption is significant will depend on the electrode metal used, since the point of zero charge depends markedly on the nature of the metal (25-30). Barclay (18) considers the electrode at the point of zero charge to be soft. Anodically increasing the potential from the point of zero charge results in increased anion adsorption; however, the electrode becomes increasingly harder (as an acid) as the potential increases, and it is feasible that soft anions could be desorbed and hard anions or bases adsorbed at extreme positive polarization.

Hydrazine and ammonia are clasisfied as hard bases (21), while I^- and SCN^- are soft bases (Table I), which should interact strongly with platinum (soft acid) and block the active surface. In the SCN^- and I^- solutions, only in the extreme anodic potential region are these soft anions desorbed sufficiently to allow hydrazine access to the surface (Fig. 2 and 3), while, in the NO_3^- (hard base) solution, hydrazine competes for access to the surface at lower potentials (Fig. 4 and 5). Because of the much higher concentration of NO_3^- than N_2H_4, time is required for hydrazine to reach a steady-state concentration on the electrode surface (Fig. 4). Results at −60° and −35°C show that hydrazine can be electrochemically oxidized at lower potentials and give higher currents in Cl^- solution than in I^- solution, while Br^- solutions are intermediate (Fig. 6 and 7), indicating that, in accord with the SHAB principle, the softer anions more effectively block the platinum surface. The passivity produced with the soft anions is probably caused by the saturation of the free valencies of the electrode surface by the chemisorbed anions (31).

Peak current and peak potential analysis.—The effect of the potential sweep rate (v) and reactant concentration (C) on the peak current (I_p) and peak potential (E_p) is useful in extracting information from potential scan experiments. For a diffusion-controlled process with linear diffusion, we have the following three general cases (32):

1. *Reversible, soluble reactants and products*
   $I_p \propto v^{1/2}C$, $E_p \neq f(v,C)$
2. *Reversible, insoluble product*
   $I_p \propto v^{1/2}C$, $E_p \neq f(v)$, $E_p = f(C)$
3. *Highly irreversible*
   $I_p \propto v^{1/2}C$, $E_p = f(v)$, $E_p \neq f(C)$

For an adsorption or desorption controlled process, we have the following two general cases (33):

1. *Reversible (quasi-equilibrium)*
   $I_p \propto v$, $I_p \neq f(C)$, $E_p \neq f(v,C)$
2. *Highly irreversible*
   $I_p \propto v$, $I_p \neq f(C)$, $E_p = f(v)$, $E_p \neq f(C)$

The current-potential curves for hydrazine oxidation in NH_3-NH_4SCN as a function of v are given in Fig. 8, and Fig. 9 shows the results in NH_3-NH_4NO_3 solution. Potentiostating the electrode at −0.35V for

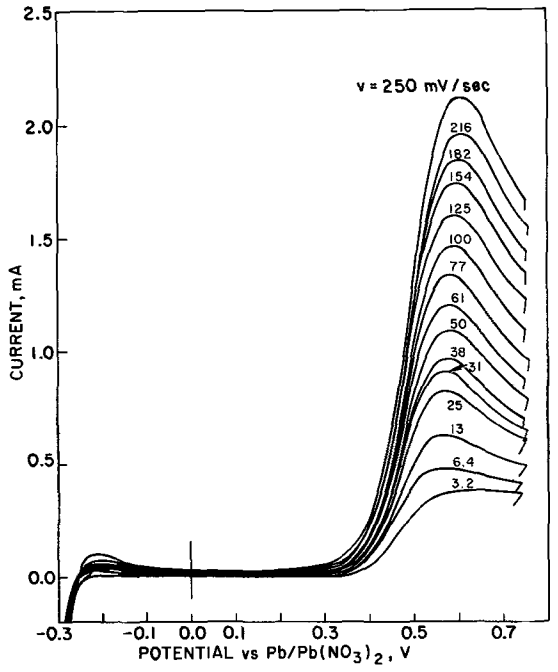

Fig. 8. Effect of sweep rate on current potential curves for 0.02M $N_2H_4 \cdot H_2SO_4$ in NH_3-NH_4SCN at 20°C using platinum disk electrode with geometrical area = 0.2 cm². Electrode potentiostatted for 30 sec at −0.35V between sweeps.

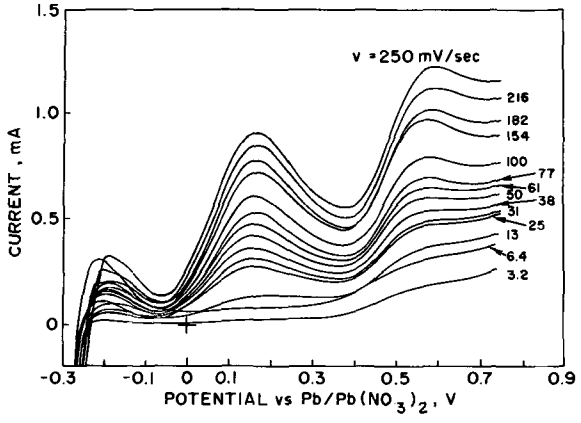

Fig. 9. Effect of sweep rate on current potential curves for 0.015M $N_2H_4 \cdot H_2SO_4$ in NH_3-NH_4NO_3 at 20°C using platinum disk electrode with geometrical area = 0.2 cm². Electrode potentiostatted for 30 sec at −0.35V between sweeps.

30 sec prior to the potential sweep establishes a steady-state condition for the hydrazine oxidation (*see* Fig. 4). Note that the nitrate solution gives a much higher hydrogen oxidation peak near −0.2V than the thiocyanate solution, again illustrating the anion effect described above.

Experimentally, I_p is found to be proportional to $v^{1/2}$ and C for hydrazine oxidation in the NH_4SCN and NH_4NO_3 ammonia solutions (Fig. 10, 11, and 12). This indicates that, where active sites on the metal are available, diffusion of hydrazine to those sites is the rate-determining step rather than adsorption, desorption, or kinetic steps.

The peak potential, E_p, becomes more anodic with increasing v for hydrazine oxidation in liquid ammonia electrolytes, but the shift is rather small; E_p also becomes more anodic with increasing hydrazine concentration. (The rest potential also shifts from −0.18V with 0.001M hydrazine to −0.13V with 0.01M hydrazine.) The behavior of E_p does not clearly fit any of the general cases mentioned above; however, the evolution of nitrogen in the hydrazine oxi-

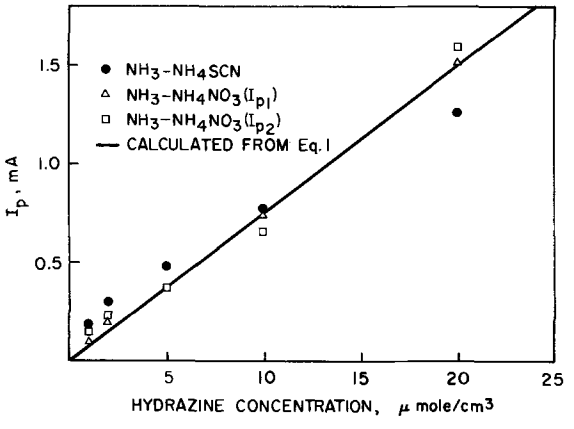

Fig. 12. Relationship of peak current to hydrazine sulfate concentration in NH_3-NH_4 SCN and NH_3-NH_4NO_3 at 20°C using platinum disk electrode with geometrical area = 0.2 cm^2. v = 125 mV/sec.

dation is a highly irreversible process. Experimental evidence for the irreversibility of hydrazine oxidation is shown by the absence of any corresponding reduction peaks.

For a diffusion-controlled, highly irreversible process (32)

$$I_p = 3.04 \times 10^5 n (\alpha n_a)^{1/2} A D^{1/2} C v^{1/2} \quad [1]$$

at 20°C. Comparing the shape of the current-potential curves for hydrazine oxidation in liquid ammonia electrolytes (Fig. 8, and 9) with standard curves given by Delahay (32), we can determine graphically that $\alpha n_a = 0.5 \pm 0.1$ for all observed peaks. Using $n = 4$ for hydrazine oxidation (Fig. 1), the diffusion coefficient for hydrazine can be calculated from Eq. [1], yielding $D_{N_2H_4} = 1 \times 10^{-6}$ cm^2 sec^{-1} in both the NH_3-NH_4SCN electrolyte and the NH_3-NH_4NO_3 electrolyte at 20°C. Viscosity determinations gave 3.2 centipoise for the NH_3-NH_4SCN solution and 4.4 centipoise for the NH_3-NH_4NO_3 solution, both measured at 20.0°C. The expected variation in diffusion coefficients due to this difference in viscosity is small compared with experimental errors. Using $n = 4$, $\alpha n_a = 0.5$, and $D_{N_2H_4} = 1.5 \times 10^{-6}$ cm^2 sec^{-1} in Eq. [1] gives reasonable agreement with experiment for the effect of hydrazine concentration on I_p up to 0.02M hydrazine concentrations (Fig. 12, solid line is calculated from Eq. [1]). Higher concentrations tend to give peak currents smaller than calculated.

Summary

The main results of this study are:

1. Hydrazine can be electrochemically oxidized in liquid ammonia elecrolytes on Pt, Ir, Rh, Re, Pd, V, Mo, and Au. Nitrocarbides and nitrides of transition metals also show activity for hydrazine oxidation.

2. Substituted hydrazine compounds can also be electrochemically oxidized in liquid ammonia electrolytes on Pt, but hydroxylamine was the only compound tested which compared with hydrazine in reactivity. Oxidation of hydroxylamine in liquid ammonia electrolytes yields about 2 electrons/molecule.

3. Current-potential curves obtained for the electrochemical oxidation of hydrazine on Pt in liquid ammonia electrolytes depend markedly on the nature of the electrolyte anion present. These anion effects can be interpreted in terms of the principle of soft and hard acids and bases and specific adsorption at the platinum electrode. The "harder" the electrolyte anion, the better will be the performance of the hydrazine anode.

4. Low-temperature studies show that hydrazine can be electrochemically oxidized at −60°C. The limitation of the reaction at this low temperature by anion adsorption rather than by slow kinetics demonstrates the high reactivity of hydrazine.

5. The electrochemical oxidation of hydrazine on Pt in liquid ammonia electrolytes appears to be a diffusion-controlled, highly irreversible reaction.

Acknowledgments

The authors wish to thank Dr. S. J. Szpak and Dr. W. S. Harris for helpful discussions, and Dr. R. E. Panzer for the use of his pressurized electrochemical cell.

The Electrocrystallization of Zinc Dendrites in High-Purity, and Inhibitor Doped, Alkaline Zincate Solutions

John W. Diggle*,[1] and A. Damjanovic

The Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

The influence of electrolyte purity on the initiation times and propagation rates of zinc dendrites grown in alkaline zincate solution is examined. No significant difference was found to exist between the results obtained in the present high-purity systems and those reported previously for the unpurified system. It is proposed that this is due to the fact that the zinc deposition potential is so far removed from the pzc of zinc that the electrode coverage with impurities present in unpurified solutions is far below that known to affect both morphology and kinetics. Evidence supporting this view was obtained in the case of benzene-doped zincate solutions, where 10^{-4} mole liter^{-1} benzene did not affect the growth of dendrites. Lead and organic cation-doped zincate solutions were found to be effective in retarding dendrite initiation, the degree of retardation depending on their concentration.

In a previous paper (1) a mechanism for the dendritic electrocrystallization of zinc was proposed in which the role of impurities was not considered. The crystallization was performed under conditions where rigorous purification of solutions was not made, and the purpose of the present paper is to ascertain whether, and to what extent, the presence of impurities may have influenced previous results and thus have affected subsequent theoretical analysis.

It is known that the presence of impurities influences greatly both the type of morphology obtained in metal electrodeposition and also the kinetic parameters (2-5). For example, the presence of 10^{-8} mole liter^{-1} of n-decylamine was found (3) to be effective in preventing a full development of pyramids on the (100) face of copper single crystals; and 10^{-7} mole liter^{-1} completely prevented their formation. These observations are particularly pertinent to the present investigation, since the initiation of zinc dendrites was proposed (1) to be due to a pyramidal type of growth under linear diffusion control. The adsorption of certain impurity molecules at specific sites would then be expected to prevent the initiation of dendrites. The extent of electrode coverage required to inhibit completely the formation of dendrites can be estimated by considering that there are, for instance, 10^8 screw dislocations/cm^2 from which a pyramidal growth and hence a dendrite may arise (1); therefore at least 10^8 molecules/cm^2 are required to prevent development of pyramids. This is equivalent to a coverage of about 10^{-6} (assuming one molecule of impurity per atom in the metal surface). However, in the case of n-decylamine adsorption on Cu, it was found (3) that an estimated coverage $>10^{-4}$ was required to promote truncation of pyramids. Under conditions where $\theta < 10^{-4}$, *i.e.*, at very low decylamine concentrations ($< 10^{-8}$ mole liter^{-1}) and at potentials far from pzc of Cu, no effect on morphology was noted.

The presence of impurities has been proposed by Price, Vermilyea, and Webb (6) to be important in the growth of metal whiskers, in which a critical current density, required to sustain growth, is dependent on the third root of the impurity concentration in the

Key words: zinc, dendrites, electrocrystallization, electrodeposition, inhibition.

solution. However, a discrepancy in the derivation of the exact critical current density-impurity concentration negates this third root dependence; nevertheless, some dependence of the growth rate on impurity concentration can be expected if the impurity molecule is adsorbed and buried by the advancing metal-electrolyte interface.

In conclusion, a survey of the literature on the influence of impurities in metal deposition suggests that some dependence on both the initiation and propagation of dendrites is to be expected, provided that the impurity molecule is adsorbed.

Experimental

Solution preparation.—The system chosen for the investigation of the effect of solution purity was 10% potassium hydroxide-0.1M zincate solution, $\eta = -100$ mV, and room temperature (~27°C).

Rigorous purification of potassium hydroxide solution was carried out as follows: Approximately 100 ml of saturated potassium hydroxide solution in conductivity water was treated with 5 ml 1% H_2O_2 in order to oxidize any oxidizable impurities present, the excess hydrogen peroxide being decomposed by heating the solution for 1 hr at 70°-80°C.[2] This treated solution was then transferred to an all-glass pre-electrolysis cell, and sufficient redistilled conductivity water was added to it to reduce the KOH concentration to 10%. All operations, from the moment of adding the concentrated KOH to the pre-electrolysis cell, are carried out in a closed, all-glass system.

The solution was then pre-electrolyzed in a three-electrode system composed of two gold gauze electrodes (area 50 cm^2 each) and a palladium subsidiary electrode in a compartment isolated from the main pre-electrolysis system by a fine frit (Fig. 1). One gold electrode was held manually at the zero charge potential (+1.1V HE, as measured against the palladium electrode) in order to adsorb any neutral organic molecules. The second gold electrode was held at +1.6V HE. The palladium electrode was chosen as the counter-electrode so that hydrogen atoms, instead of evolving as H_2, would be absorbed and therefore minimize the contamination of the purified potassium hydroxide. The pre-electrolysis was performed in a N_2 atmosphere [the N_2 being purified according to Mattson and Bockris (7)]. In order to purge the system of any evolved O_2 and to destroy any H_2O_2 which could be produced[3] at the gold electrode held at +1.1V HE, N_2 was continually bubbled through the electrolyte maintained at 70°-80°C.

Following 24 hr pre-electrolysis, a portion of the purified KOH solution was transferred to a usual three-compartment cell (9) and, after saturation with O_2, the O_2 evolution reaction on platinum was carried out. The current density at which the electrode begins to depolarize is taken as a measure of the purity of the solution (9, 10). The O_2 evolution test was repeated for different times of pre-electrolysis, as well as upon the "impure" KOH solution prepared as outlined in previous work (1).

The preparation of zincate solution was carried out by adding a suitable quantity of the purified KOH solution to a half saturated zinc amalgam (~1% Zn/Hg), and dissolving the required amount of zinc. The preparation of the zinc amalgam, the subsequent transfer of KOH, and the zinc dissolution process were all carried out in a closed all-glass system.

The final zincate concentration was then determined by EDTA titration in buffered pH 10 media (11); the zincate concentration was adjusted to 0.10M by additional short periods of zinc dissolution. This solution was then transferred, through a closed system, to the test cell (1).

[2] The influence of dissolved silicates has been found to be negligible in the present work (see section on possible influence of dissolved silicates introduced during purification).

[3] H_2O_2 formation at the +1.1V gold electrode is possible due to the partial reduction of oxygen produced at the +1.6V gold electrode (8).

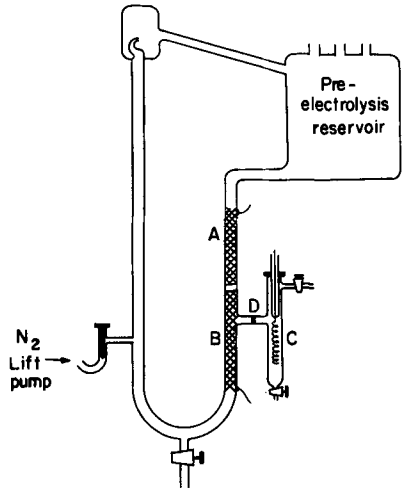

Fig. 1. Circulatory pre-electrolysis system comprising of a gold electrode controlled at the pzc (A), a gold electrode controlled at a high anode potential (B), and a subsidiary palladium electrode (C) separated from the main system by a fine frit (D).

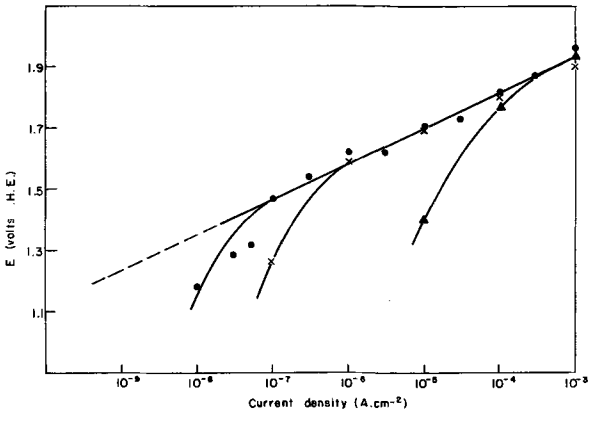

Fig. 2. Electrode potential E (volts HE) *vs.* current density for the evolution of oxygen on platinum as a function of 10% potassium hydroxide solution purity. ▲, No pre-electrolysis; ×, 24 hr pre-electrolysis; and ●, 72 hr pre-electrolysis.

Electrode preparation and procedure.—Electrode preparation and all procedures involved in total current-time and dendrite length-time measurements were identical to those outlined previously (1).

Results

Criteria for potassium hydroxide solution purity.—Figure 2 shows the plots of log i *vs.* E (HE) for the oxygen evolution on Pt for three states of purity. The Tafel slope is 0.118V, in agreement[4] with previous work in 1N KOH. Extrapolation of the linear E-log i plots to the reversible oxygen potential produces $i_o = 10^{-9}$ A-cm^{-2}, as compared (9) to 10^{-8} A-cm^{-2} obtained from the high current density region in 1*N* KOH.

Total current-time phenomenon.—The total current density for zinc deposition (based on geometric area) *vs.* time of deposition is shown in Fig. 3 for various degrees of solution purification. No significant effect of purification was observed. The initiation time for rapid current increase due to dendrite appearance, τ_i, is seen to be the same regardless of purification.

The influence of benzene, lead (added as Pb_3O_4), and tetraethyl ammonium bromide doped zincate solution (10^{-4} mole liter^{-1} dopant) are shown in Fig. 4. Benzene is seen to have no effect, tetraethyl ammonium bromide has some effect on the initiation time,[5] and

[4] It was noted that no break was found in the Tafel slope at low overpotentials, as was previously reported (9).

[5] The initiation time elongation has been shown not to occur in 10^{-4}M KBr doped zincate solutions. Thus the effect is due to $(C_2H_5)_4N^+$.

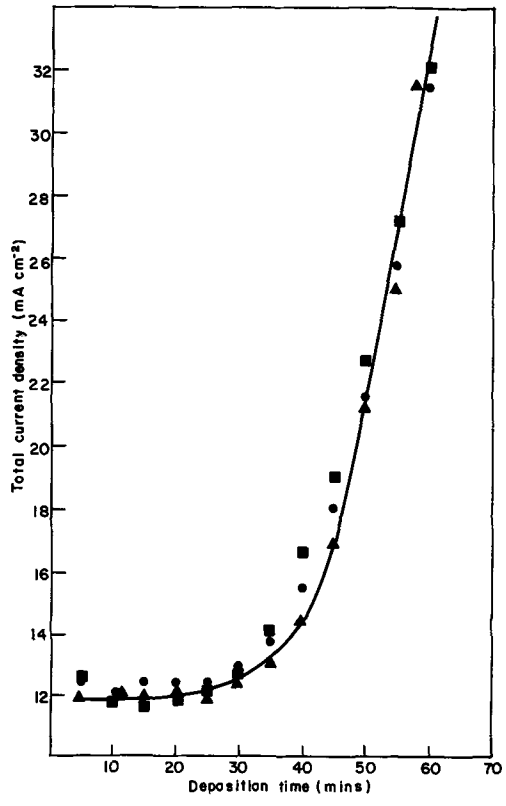

Fig. 3. Total current density vs. deposition time as a function of zincate solution purity for the conditions: 10% KOH + 0.1M zincate, $\eta = -100$ mV, and $T = 27°C$. ●, Impure system; ▲, 10^{-6} purity (24 hr pre-electrolysis); and ■, $<10^{-7}$ purity (72 hr pre-electrolysis).

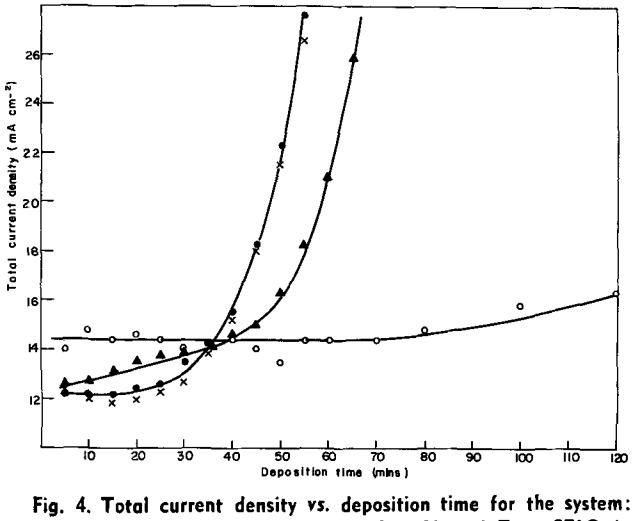

Fig. 4. Total current density vs. deposition time for the system: 10% KOH + 0.1M zincate, $\eta = -100$ mV, and $T = 27°C$, in the presence of 10^{-4}M benzene (×), lead (○), and tetraethyl ammonium bromide (▲). The blank impure system is represented by (●).

lead completely suppresses dendrites. The influence of lead on zinc morphology has also been shown earlier by Kudryavtsev (12).

Dendrite length-time behavior.—The dendrite length, y, *vs.* time of deposition as a function of solution purity, is shown in Fig. 5. Table I summarizes these results in terms of the dendrite tip current density, i_{tip}. The influence of purification is again seen to be negligible, both in terms of growth rate and initiation time, τ_d.[6]

[6] The notation used here is that of a previous paper (1). τ_i is the initiation time as determined by the time of rapid current increase (Fig. 3), whereas τ_d is that initiation time obtained by extrapolating the dendrite length-time of deposition line to zero dendrite length (Fig. 5).

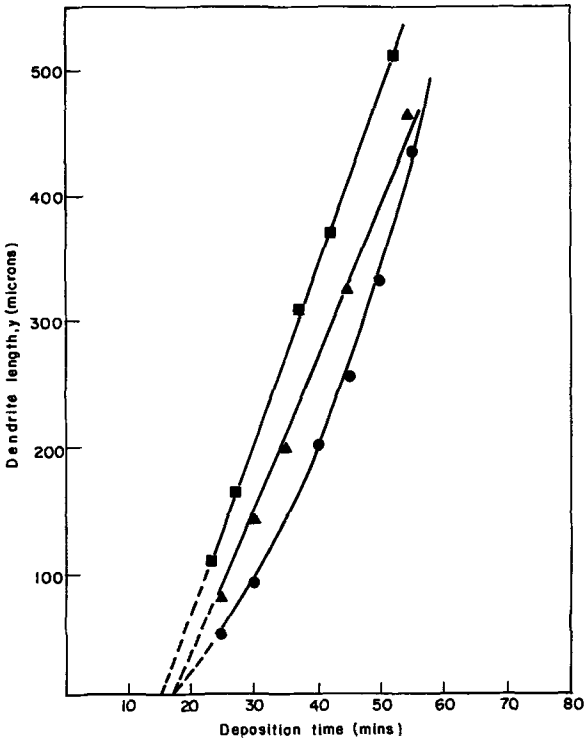

Fig. 5. Dendrite length, y, vs. deposition time as a function of zincate solution purity. Conditions and symbols identical to those in Fig. 3. Extrapolation of growth line to y = 0 produces initiation time, τ_d.

Possible influence of dissolved silicates introduced during purification.—The addition of 10^{-2}M silicate to an unpurified 0.1M zincate solution was found to be ineffective in terms of both the initiation time and the propagation rate, *i.e.*, a propagation rate of 14 μmin^{-1} was observed for the silicate doped zincate system for $\eta = -100$ mV and $T = 25°C$, compared to 15 μmin^{-1} reported previously (1) for the identical unpurified zincate system.

Discussion

Those impurities which were present within the "impure" system investigated earlier (1) clearly do not influence the results obtained, either in terms of the initiation time or the growth rate. This, then, leads to the question, "What type of impurity is present in the impure system, and why does it not influence the results?"

Since some impurities were clearly present in the impure system (Fig. 2), comparison with any impurity theory (6) (Table I) will be invalid if it can be shown that the impurities are not adsorbed and therefore are ineffective in reducing the dendrite growth rate. However, if the impurities are adsorbed, then a comparison of the present results with the Price, Vermilyea, and Webb theory (6) would indicate that the impurity theory is invalid in the present experiments.

Figure 4 shows that the influence of 10^{-4}M benzene, lead, and tetraethyl ammonium bromide on the total

Table I. Comparison of experimental dendrite tip current densities, i_{tip}, as a function of impurity level with that calculated from Price, Vermilyea, and Webb (6) theory on whisker growth

Impurity level, c_i (moles/liter)	i_{tip} experimental (A-cm²)	i_{tip} calculated*
10^{-4}	0.37 ± 0.02	4.6×10^{-2} K
10^{-6}	0.38 ± 0.02	10^{-2} K
2×10^{-7}	0.42 ± 0.02	5.9×10^{-3} K

* $i_{tip} = \left(\frac{K_2}{K_1}\right)^{2/3}\left(\frac{1}{\tau_{tip}}\right)^{1/3} c_i^{1/3} = K c_i^{1/3}$.

current density-time phenomenon. Benzene has no influence, $(C_2H_5)_4NBr$ increases the initiation period, τ_i, but does not prevent dendrites, whereas 10^{-4}M Pb completely suppresses dendritic growth. Further experiments have shown that 10^{-6}M Pb is ineffective in suppressing dendrites when $\eta = -100$ mV.

It may be concluded, therefore, that the impurity present in previous work was either:

(*A*) A neutral organic molecule whose adsorption is completely inhibited because the experimental zinc deposition potential (−1.5V NHE) is nearly IV negative to the zero charge potential (−0.65V NHE) (13) for zinc. From the work of Heiland, Gileadi, and Bockris (14), and the theoretical analysis of Bockris, Gileadi, and Müller (15) on the adsorption of benzene on Pt in pH = 11 solutions, the surface coverage drops sharply to near zero when the potential is 0.4V away from the zero charge potential. Furthermore, from the work of Damjanovic, Paunovic, and Bockris (3, 4) the coverage of n-decylamine was estimated as 10^{-5} at a potential 0.25V from the zero charge potential of Cu. Thus, it is easily seen that the coverage of zinc by benzene, at −0.85V from zero charge potential, can be $<10^{-6}$, and probably a great deal lower; or

(*B*) Metallic cations whose concentration was less than or equal to 10^{-6}M.

The ineffectiveness of positively charged organic cations in preventing dendrites (at least up to 10^{-4}M) may be related to the fact that, although they are positively charged, as the potential in the electric double layer goes increasingly negative, it is observed (16, 17) that such large cations can be desorbed. It is also reported (16) that this negative potential, required for desorption, becomes increasingly negative as the concentration of the organic cation increases.

Conclusions

1. Impurities present in previously reported work (1) have been shown to be ineffective in producing changes in dendrite initiation and propagation. The presence of organic molecules has been suggested which, due to the fact that the zinc deposition potential is far from zero charge potential, are not adsorbed to an extent sufficient to influence either morphology or kinetics. This was demonstrated in the case of benzene-doped electrolytes. Thus, in the absence of adsorbed impurities, any comparison with the Price, Vermilyea, and Webb theory (6) will be invalid.

2. The presence of lead has been shown to be effective in retarding dendritic growth; 10^{-4}M renders complete inhibition, whereas 10^{-6}M is ineffective (both with reference to $\eta = -100$ mV).

3. The presence of tetraethyl ammonium bromide (10^{-4}M) was shown to be effective in increasing the initiation time, but ineffective, at least at this concentration, in preventing dendrites.

4. The results in the section on dissolved silicates and the negligible difference found between unpurified and highly purified systems, indicates that silicates are ineffective as inhibitors for dendrites under the present conditions.

Electrical Polarization Experiments on Silver Chloride

Y. J. van der Meulen[1] and F. A. Kröger

Department of Materials Science, University of Southern California, Los Angeles, California

ABSTRACT

The electronic conductivity in AgCl equilibrated with either chlorine or silver was measured at temperatures between 100° and 425°C. The measurements were carried out for crystals containing various amounts of divalent cationic impurities. A clear distinction could be made between a native Frenkel disorder controlled region and an impurity controlled conductivity region. The emf of the cell $Cl_2|AgCl|Ag$ was found to agree with the value calculated from tabulated thermodynamic data. Combination of our results with published data for the band gap and the chlorine induced absorption in AgCl shows that the latter stems from self-trapped rather than from free holes.

In silver chloride as in a number of other halides in a neutral atmosphere ionic conductivity strongly prevails at temperatures ranging from room temperature up to the melting point (455°C) (1, 2). The electronic component of the current is small and normally goes unnoticed. Previous investigators arrived at values for the electronic (hole) conductivity from the tarnishing rate of silver by chlorine (T = 300°-400°C) (1) and from the increase of the current through the crystal on changing from a nitrogen to a chlorine ambient (T = 50°-200°C) (3). Both methods are feasible over a limited temperature range only; moreover no distinction can be made between conduction by electrons and by holes.

As was first suggested by Hebb (4) and Wagner (5) the ionic part of the current can be blocked by the use of a material, that does not contain the constituents of the crystal, for one of the electrodes. The other one may contain the constituents and is preferably chosen to do so in order to fix the electrochemical potentials of the crystal at that side of the cell. Thus, for silver chloride, one can use a carbon anode and a silver cathode, or a carbon cathode and a carbon/chlorine anode. Comparable experiments have been published in detail for silver bromide (6, 7). For silver chloride only a few results were reported previously (6). These did not conform to existing theory and were highly irreproducible.

It was the purpose of the present investigation to determine the electronic conductivity of silver chloride as a function of temperature using both silver and chlorine as the chemically active electrode. Both undoped and Cd-doped crystals were used.

Theory

The equations governing the one-dimensional, electronic current flow through an ionic crystal with one reversible and one inert electronically conducting electrode have been derived before (5, 8, 9). Thus for the cell

$$+ \text{C}, \text{Cl}_2\ (1\ \text{atm})\ |\text{AgCl}|\text{C}, \text{N}_2 - \qquad \text{(I)}$$

we have

$$i_{tot} = i_h + i_e = \frac{RT}{LF}\left\{ \sigma_h(\text{I})\ (1 - e^{-EF/RT}) + \sigma_e(\text{I})\ (e^{EF/RT} - 1) \right\} \qquad [1]$$

And for the cell

$$- \text{Ag}|\text{AgCl}|\text{C}, \text{N}_2 + \qquad \text{(II)}$$

we find

$$i_{tot} = i_e + i_h = \frac{RT}{LF}\left\{ \sigma_e(\text{II})\ (1 - e^{-EF/RT}) + \sigma_h(\text{II})\ (e^{EF/RT} - 1) \right\} \qquad [2]$$

[1] On leave of absence from Utrecht State University, Utrecht, The Netherlands.

Here L is the cell constant, defined as the ratio of the thickness of the crystal and the effective electrode contact area (dimension: cm^{-1}); E is the applied voltage; $\sigma_e(\text{I})$ and $\sigma_h(\text{I})$ are the specific electron and hole conductivities in AgCl equilibrated with Cl_2 (1 atm.), $\sigma_e(\text{II})$ and $\sigma_h(\text{II})$ are the corresponding conductivities for the equilibrium with Ag ($a_{Ag} = 1.0$). These conductivities depend on the composition of the crystal and are different for pure and doped crystals. The other symbols have their usual meaning.

Equations [1] and [2] are valid under the condition that the ionic current is completely suppressed. However, a residual ionic contribution to the current may arise from chlorine evolution at the blocking electrode and is to be expected for conditions under which the steady-state chlorine pressure at this electrode is relatively high.

The chlorine evolved may be absorbed by the carbon and diffuses away or is flushed away. For cell I this condition exists at lower applied voltages where the equilibrium chlorine pressure at the blocking electrode is described by $p_{Cl_2} = e^{-2EF/RT}$. For cell II, the equilibrium chlorine pressure at the inert electrode is described by $p_{Cl_2} = e^{-2(E_d - E)\,F/RT}$. Here E_d is the decomposition voltage, *i.e.*, the voltage for which $p_{Cl_2} = 1$ atm. Thus, in this case the chlorine evolution becomes important at higher applied voltages. The theoretical hole and electron currents together with the deviations to be expected from the unavoidable chlorine evolution are schematically depicted in Fig. 1a and b for T = 246°C. Although a total current has been indicated as well, it should be stressed that the relative size of the components is unknown in advance and will vary from one case to another.

From the figures it can be seen that i_e can best be determined from measurements on cell II at low applied voltage. Thus we find σ_e (II). The determination

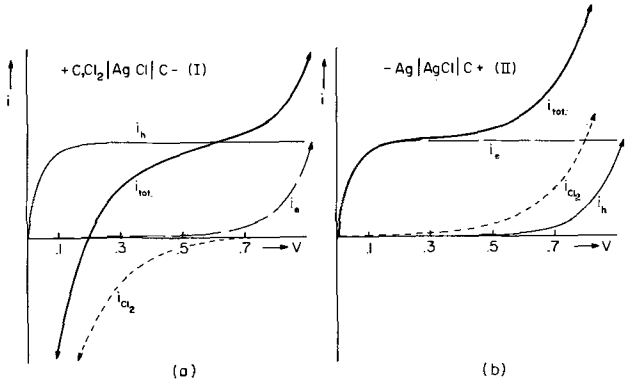

Fig. 1. Partial and total currents (schematic) at T = 246°C for cell I (a) and cell II (b). The relative size of the three current components is arbitrary.

of the σ_h (I) can best be done in cell I at higher applied voltage, as we expect only a small electron contribution in this configuration.

σ_h (I) and σ_h (II) are related through the free energy of formation of AgCl, as can be seen by considering the relevant defect equilibria

$$Ag_{Ag}^x + V_i^x \rightleftarrows V'_{Ag} + Ag^{\cdot}_i ; H'_F \quad [3]$$

$$V^x_{Ag} \rightleftarrows V'_{Ag} + h^{\cdot} ; H_A \quad [4]$$

$$\tfrac{1}{2}(Cl_2)_g \rightleftarrows Cl_{Cl}^x + V_{Ag}^x ; H_{Cl2V} \quad [5]$$

In pure and weakly doped crystals the defects formed by Frenkel disorder [3] are the dominant species. Thus, indicating concentrations by square brackets

$$[V'_{Ag}] \approx [Ag^{\cdot}_i] \quad [6]$$

and

$$[V'_{Ag}] \approx K'_F{}^{1/2} \quad [7]$$

From [4]

$$K_A = \frac{[V'_{Ag}]\,[h^{\cdot}]}{[V^x_{Ag}]} = \frac{K'_F{}^{1/2}\,[h^{\cdot}]}{[V^x_{Ag}]} \quad [8]$$

From [5]

$$K_{Cl2V} = \frac{[V^x_{Ag}]\,[Cl^x_{Cl}]}{p_{Cl_2}{}^{1/2}} = \frac{[V^x_{Ag}]}{p_{Cl_2}{}^{1/2}} \quad [9]$$

Thus [8] + [9] gives

$$[h^{\cdot}] = \frac{K_A K_{Cl2V}}{K'_F{}^{1/2}}\, p_{Cl_2}{}^{1/2} = \frac{K_{Cl2Vh}}{K'_F{}^{1/2}}\, p_{Cl_2}{}^{1/2} \quad [10]$$

We may write $\sigma_h(I) = [h\cdot(I)]qv_h$, $\sigma_h(II) = [h\cdot(II)]qv_h$, in which q is the electronic unit charge, v_h is the hole mobility and $[h\cdot(I)]$ and $[h\cdot(II)]$ are the hole concentrations in AgCl in equilibrium with Cl_2 and Ag, respectively. Then

$$\sigma_h(I)/\sigma_h(II) = p_{Cl_2}{}^{1/2}(I)/p_{Cl_2}{}^{1/2}(II) = 1/p_{Cl_2}{}^{1/2}(II) \quad [11]$$

Now in cell II

$$a_{Ag}(II) \cdot p_{Cl_2}{}^{1/2}(II) = p_{Cl_2}{}^{1/2}(II) = K_T = e^{-\Delta G/RT} \quad [12]$$

ΔG being the standard free enthalpy of formation in AgCl.

Thus finally

$$\sigma_h(I) = \sigma_h(II)\, e^{\Delta G/RT} \quad [13a]$$

For the electrons we find correspondingly

$$\sigma_e(I) = \sigma_e(II)\, e^{-\Delta G/RT} \quad [13b]$$

The last formulas enable us to correlate data found in measurements on one cell with data found for the other cell arrangement.

In doped samples, or in samples containing residual contamination, the impurities dominate the defect equilibria at lower temperatures and Eq. [6] and [10] do not apply anymore. For Cd we have

$$[Cd^{\cdot}_{Ag}] \approx [V'_{Ag}] \quad [14]$$

and using [8] and [9] we find in this extrinsic region

$$[h^{\cdot}] = \frac{K_A K_{Cl2V}}{[Cd^{\cdot}_{Ag}]}\, p_{Cl_2}{}^{1/2} = \frac{K_{Cl2Vh}}{[Cd^{\cdot}_{Ag}]}\, p_{Cl_2}{}^{1/2} \quad [15]$$

Thus it can be seen that Eq. [11] through [13b] remain valid in this region.

The various equilibria for the intrinsic Frenkel disorder controlled region are summarized in Table IV. The numerical data for the thermodynamic parameters result from our experiments as will be discussed in a later section.

Experimental

General set-up and procedures.—Measurements were carried out both on a nominally undoped and on Cd-doped AgCl crystals. The doped crystals were grown from a melt containing 1 x 10^{18} and 1.8 x 10^{20} atoms Cd/cm^3, respectively. At room temperature second phase segregation occurred in the heavily doped crystal. Complete redissolution took place, however, on reheating to the lowest measuring temperature.

Disk-shaped samples were cut from the boules with a jeweler's saw. The surfaces were polished on various grades of polishing paper and successively etched in HNO_3 and NH_4OH. Samples were rinsed with deionized water and with acetone, and dried on filter paper. The thickness of the samples thus obtained varied from 0.5 to 2.5 mm.

Subsequently the samples were mounted in a Pyrex polarization cell (Fig. 2). This cell was designed to allow both sides of the crystal to be kept in a different ambient. The crystal was sandwiched between two tubes, c, that pressed against the outer edge. Tension was provided by a stretched rubber collar, g. Current contacts to the crystal were made by hollow carbon electrodes, b. For some of the experiments one of these electrodes was covered with evaporated silver or silver foil. The electrodes were centrally mounted on Pyrex glass tubes, m, that could be adjusted separately. In order to avoid complications resulting from the attack of chlorine on platinum, the sections of the main outgoing leads subjected to elevated temperature were made of carbon yarn. The danger of attack by chlorine also prevented the use of a Pt blocking electrode, which otherwise might have been preferable.

Both the preparation and the mounting of the sample were done under red light. The cell was shielded from light during the measurements. Nitrogen and chlorine were used as ambients. The nitrogen was passed over a catalyst (ICI 29-1) to remove traces of oxygen. Both gases were dried with Union Carbide molecular sieves. To insure gas purity glass tubing was used throughout.

The measuring cell was contained in a furnace, the temperature control and stability of which were better than 0.5°C. After assembling, the cell was thoroughly flushed with nitrogen. It as then heated to 390°C and

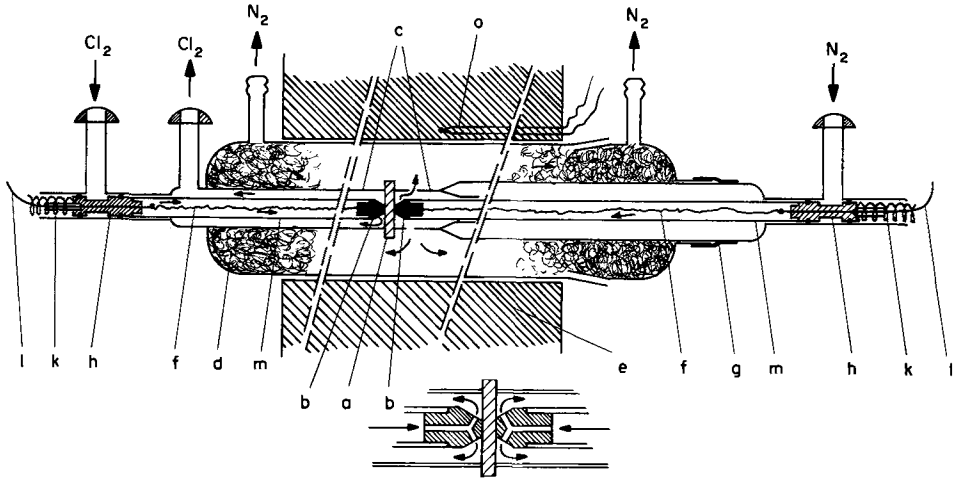

Fig. 2. Polarization cell (detail; electrode configuration): a, crystal; b, carbon electrodes; c, glass tubes; d, glass wool insulation; e, furnace; f, carbon electrode leads; g, rubber collar; h, Teflon end pieces; k, coiled springs; l, outgoing platinum leads; m, electrode mounting tubes; o, thermocouple. The direction of the gas flow is indicated by arrows.

the tubes, c, were pressed on the crystal. Due to the plasticity of AgCl at that temperature this resulted in a gastight seal. The cell was then cooled to 200°C and the carbon electrodes were pushed against the crystal. The nitrogen at the left-hand side was replaced by chlorine, and a polarizing voltage of 400 mV was applied to the crystal (Cl_2-side positive). Following Raleigh the electrode contact was optimized by heating the cell until surface melting set in. This was indicated by an abrupt rise in the cell current. The cell was then cooled down again, and the electrode springs were released. The i-V characteristics were measured for a number of temperatures for the configurations I and II.

The latter arrangement was effected by first replacing the chlorine by nitrogen and then increasing the cell voltage for a short time above the decomposition limit. For some slices of crystal, measurements were only carried out in the second configuration, and the silver electrode consisted of evaporated silver or silver foil. During all experiments a gas stream of 5-20 cm^3/min was maintained through both electrode compartments. The d-c electrical circuit is schematically shown in Fig. 3a.

The sample and electrode geometry were of rather ill-defined dimensions. To determine the cell constant of each sample, the a-c resistivity (at 5-50 kc) was measured as a function of temperature. These measurements when combined with literature data for the specific resistivity as a function of doping concentration and temperature (10), not only yielded the cell constant but also the concentration of electrically active foreign constituents (Cd). The a-c bridge circuit is schematically shown in Fig. 3b. The measurements were usually carried out after the polarization experiments had been finished. Results with and without silver plating the electrodes were somewhat different. At the highest temperatures, the relatively high resistivity of the carbon yarn had to be taken into account.

Inspection of the sample and the contacts after completion of the measurements showed that as a rule the electrodes adhered firmly to the crystal. Samples had not darkened visibly even after runs of a month's length, the surface was very smooth, probably as a result of local melting.

Current fluctuations and their prevention.—Measurements on the cell I configuration went off smoothly, and only minor problems were encountered. Measurements on the cell II configuration, however, presented a different picture. The current in this case was very unstable showing sharp positive peaks. Moreover the time required to establish a new equilibrium value of the current after a charge of the applied voltage was much longer than for cell I. Various attempts were made to correct these problems. They included the use of silver foil as a cathode instead of electrolytically deposited silver, and the use of a mixed carbon-silver electrode, consisting of a carbon electrode that had only partially been covered with evaporated silver in a dotted pattern. These modifications were not successful; moreover they made it impossible to carry out successively measurements on the same sample for both configurations. The

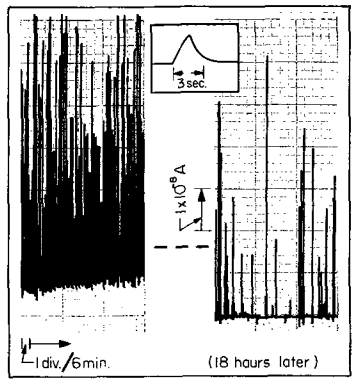

Fig. 4. Current fluctuations registered for a cell Ag|AgCl|C before and after an 18-hr long annealing period. In all cases the annealing finally eliminated virtually all excursions. Cell voltage = 500 mV, T = 300°C. Inset: The form of a single current fluctuation registered at a higher magnification of the time base.

best results were obtained at temperatures above 350°C, after annealing the crystals at the highest operating temperature and voltage for an extended period. This treatment directly followed the electrodeposition of silver on one of the electrodes and eliminated the sharp current fluctuations almost completely (Fig. 4).

We are inclined to believe that the breaks are bursts of ionic conduction released when a trapped dislocation breaks loose from a pinning point. Annealing may be assumed to result in the removal of the most loosely trapped dislocations from the space charge region near the blocking electrode, "loosely" being defined with respect to the applied field. An alternative explanation could be that the contact between crystal and electrode is not perfect. Thus there exist unpolarized regions at the surface of the crystal. On establishing contact with one of these spots a burst of ionic current could arise from the polarization of that region.

Experimental Results

Cells of type I.—I-V characteristics were measured on AgCl samples mounted between a chlorine (1 atm) anode and a carbon cathode at temperatures ranging from 98° to 426°C. Care was taken not to exceed the decomposition voltage at a given temperature. The curves all show a well-defined saturation of the hole current (Fig. 5a and b). At lower applied voltages the effect of chlorine evolution at the blocking electrode can be seen clearly. Use of platinum foil as an electrode material could have sealed off the crystal better, but was precluded by the formation of platinum chlorides at the temperatures and chlorine pressures involved.

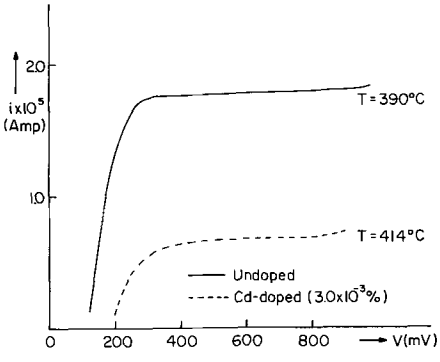

Fig. 5a. I-V characteristics for undoped and lightly Cd-doped AgCl crystals in cell configuration I. A second rise in the current at the highest applied voltages is barely perceptible. The difference in the saturation current is mainly due to a difference in cell constant.

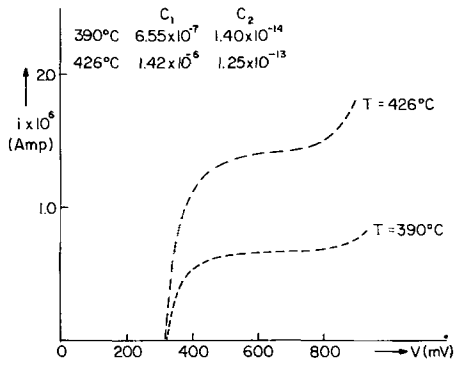

Fig. 5b. I-V characteristics for the heavily doped AgCl crystal. The exponential contribution at higher applied voltage is much more pronounced than in the previous case (Fig. 5a). The hole conduction has become smaller. The values obtained for C_1 and C_2 (Eq. [16]) have also been indicated.

In the case of the undoped and lightly doped material only at $T > 390°C$ some evidence was found of a contribution by electrons to the current at the highest applied voltages ($E > 850$ mV). Nowhere did this contribution exceed 4% of the total current.

In the case of the heavily doped crystal the saturation of the hole current is evident again, but now a rise in the current at higher applied voltage indicates a contribution by electrons as well. The high-voltage part of the curves found in the last case can be represented by

$$i_{tot.} = i_h + i_e = C_1(1 - e^{-EF/RT}) + C_2(e^{EF/RT} - 1) \quad [16]$$

The best values for C_1 and C_2 have been indicated in Fig. 5. By entering now the measured values of $i_{sat}(T)$ and the cell constant L in Eq. [1], $\sigma_h(I)$ is found as a function of temperature. The result for undoped material is plotted in Fig. 6. The change is slope at 210°C is related to the transition from the extrinsic, Cd-dominated range at lower temperature to the Frenkel disorder controlled, intrinsic region at higher temperature. It can be seen that the transition for the lightly doped crystal takes place at a higher temperature (255°C). The heavily doped crystal remains extrinsic up to the highest temperature (426°C).

The discrepancy in the intrinsic, high-temperature region between the curves as found for the undoped and the lightly doped crystals gives some idea of the accuracy with which L can be determined: The two curves should almost coincide. Also entered in the same figure are the results found by Wagner from the rate constant of bromination (1) and by Luckey from the excess conductivity (3).

The a-c conductivity of the crystals examined relative to the conductivity of very pure AgCl (10, 11) is shown in Fig. 7. The curves of the undoped and lightly doped crystals have been adjusted to fit the $\sigma/\sigma_0 = 1$ level at higher temperature, *i.e.*, in the intrinsic region. Comparison of these curves with literature data concerning doped crystals indicates a divalent impurity mole fraction of $5 \times 10^{-6} - 10^{-5}$ in the undoped material and a Cd^{++} mole fraction of 3.0×10^{-5} ($=7 \times 10^{17}$ at. Cd/cm³) in the lightly doped material. For the heavily doped crystal spectrochemical analysis indicated a Cd^{++} hole fraction of 1.82×10^{-2} ($=4.2 \times 10^{20}$ at. Cd/cm³). Both values are close to the Cd concentration of respectively 1×10^{18} and 1.8×10^{20} cm^{-3} in the melt.

Cells of type II.—The best reproducible measurements on cells of type II were obtained while working with the lightly doped crystal. Doping is unimportant in this case because all measurements were carried out at relatively high temperature well outside the extrinsic region. Up to an applied voltage $E = 600$ mV the graphs are well described by Eq. [2].

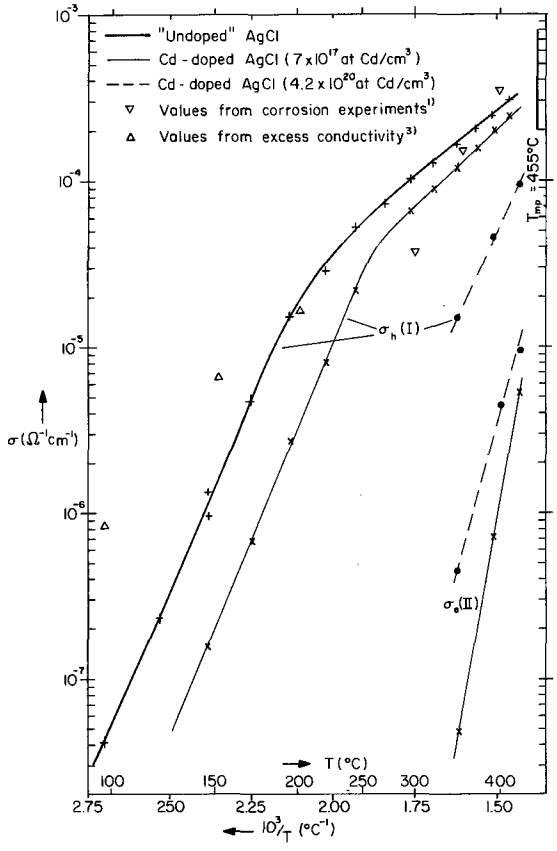

Fig. 6. Conductivity vs. temperature for AgCl containing various amounts of divalent cationic impurities. Both the hole conductivity $\sigma_h(I)$ and the electron conductivity $\sigma_e(II)$ are shown. The influence of the impurity concentration on the transition temperature is obvious. Values for the electronic conductivity by Wagner and Luckey have also been entered in the graph.

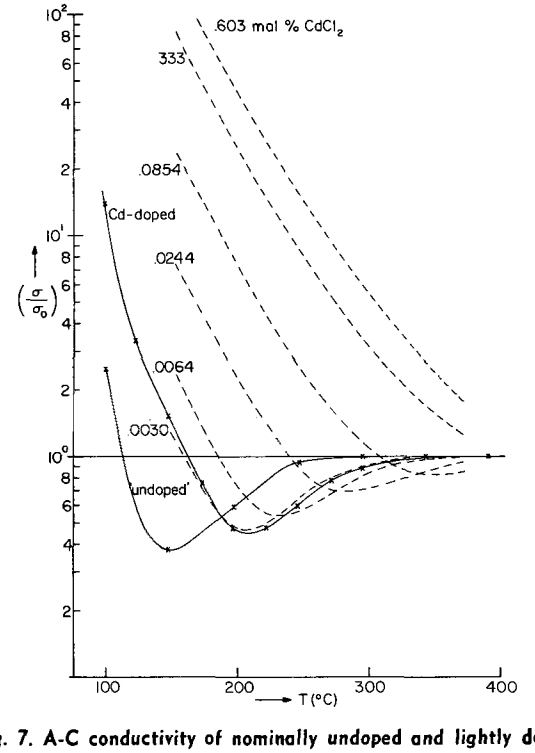

Fig. 7. A-C conductivity of nominally undoped and lightly doped AgCl relative to the conductivity of pure AgCl as a function of temperature. Dashed curves were taken from ref. (10).

The resulting values for $\sigma_e(II)$ and $\sigma_h(II)$ are given in the first columns of Table I. The third column gives values of $\sigma_h(I)$ determined from cells I. The fifth

426	9.3×10^{-6}	3.71×10^{-9}	9.4×10^{-5}	$10^{6.60}$	2.4×10^{-11}	2.23×10^{-16}

column contains values for $\sigma_h(II)_{expected}$ calculated from $\sigma_h(I)$ using Eq. [13a]. It is seen that $\sigma_h(II) \approx 10 \times \sigma_h(II)_{exp}$. This indicates that either $\sigma_h(II)$, $\sigma_h(I)$, or ΔG must be in error.

Electromotive force measurements between 295° and 426°C on a cell Ag|AgCl|C,Cl_2 gave values that are within 1% of the ones calculated from $E = -\Delta G/F$ using tabulated values (12, 13) in the calculation of ΔG. On the other hand $\sigma_h(I)$ seems to be beyond doubt. Thus $\sigma_h(II)_{exp}$ must be correct. This leaves only $\sigma_h(II)$ as possibly erroneous. It seems most likely that this is due to the fact that most of the extra current interpreted as $\sigma_h(II)$ is actually an ionic current due to decompositon of the crystal as a result of chlorine evolution at the anode (cf. Fig. 1b). The fact that it is possible to describe this contribution to the total current by an exponential function may be accidental.

The last column of Table I shows the product $\sigma_e(II)\sigma_h(II)_{exp}$. This product equals $K_i q^2 \mu_e \mu_h$ and should not depend on whether the sample under consideration is pure or doped, or is in the extrinsic or intrinsic conductivity range.

Measurements on the heavily doped crystal could not be fitted satisfactorily by Eq. [2]. Thus in this case we used

$$i_{tot} = C_1(1 - e^{-EF/RT}) + C_2(e^{EF/RT} - 1) + C_3E \quad [17]$$

The third term is equivalent to an ohmic contribution to the total current. This could be caused by leakage along the surface of the crystal. The numerical value of the constant C_3 varied from 10^{-8} at 343°C to 1.5×10^{-7} at 426°C. Omission of the third term did not result in a pronounced change in C_1 or C_2, but simply made the curve fitting far worse. Values found for $\sigma_e(II)$ and $\sigma_h(II)$ for this crystal have been entered in Table II. Here again the expected value of $\sigma_h(II)$ has been calculated and tabulated. The discrepancy between the observed and expected values of $\sigma_h(II)$ is in this case even higher than in the previous case where electronic conduction in the intrinsic ionic range was examined. Instead of showing a decrease as expected for $\sigma_h(II)$ in the presence of high [Cd], the value of $\sigma_h(II)$ has actually increased. The product $\sigma_e(II)\sigma_e(I)_{exp}$ has again been entered in the last column of Table II. Both sets of electron conductivity data have been plotted in Fig. 6. Figure 8 shows the values of $\sigma_e(II)\,\sigma_h(II)_{exp}$ from Tables I and II. These values were determined on crystals that are intrinsic and extrinsic in ionic defects. It is seen that the two sets of data agree satisfactorily and can be described by the equation

$$\sigma_e\sigma_h = 2.70 \times 10^{10} \times 10^{-1.81 \times 10^4 \times T^{-1}} \text{ (ohm cm)}^{-2} \quad [18]$$

This agreement can be considered as an over-all check on the reliability of the results.

Discussion

The conductivity data found from our experiments may be combined with published data of the free hole concentration to yield the hole mobility as a function of temperature. Moser (14) and Ulrici, Koswig, and Stasiw (15) measured the chlorine induced absorption in AgCl. They found a maximum absorption around 800 mμ and a half width of approximately 1.60 eV. At a given temperature the absorption is proportional to the square root of the chlorine pressure and inversely proportional to the concentration of divalent cations in the crystal. These findings prove that the absorption is due to a positive species, almost certainly holes; it cannot be caused by holes trapped at silver vacancies as suggested earlier (16), for this species is effectively neutral (V^x_{Ag}). An estimate of the number of absorbing centers N′ per cm^3 may be obtained using the Smakula equation. It seems best in our case to use a modified expression derived without considering the Lorentz local field (17).

$$N' f_{ab} = 1.43 \times 10^{16} \times n_o \times K(E)_{max} \Delta E \text{ cm}^{-3} \quad [19]$$

Here n_o is the index of refraction, K_{max} the maximum absorption constant in cm^{-1}, and ΔE the half width in eV; f_{ab}, the oscillator strength, can be considered as an adjustable parameter. The reported measurements (14, 15) give an identical result (Table III) for N'_h as a function of T

$$N'_h f_{ab} = 8.0 \times 10 \times T^{5.34} \text{ cm}^{-3} \quad [20]$$

If the absorption is attributed to free holes, μ'_h may be obtained from

$$\mu'_h\,(T) = \frac{\sigma_h(I)}{N'_h(T)\,q} \text{ cm}^2 \text{ V}^{-1} \text{ sec}^{-1} \quad [21]$$

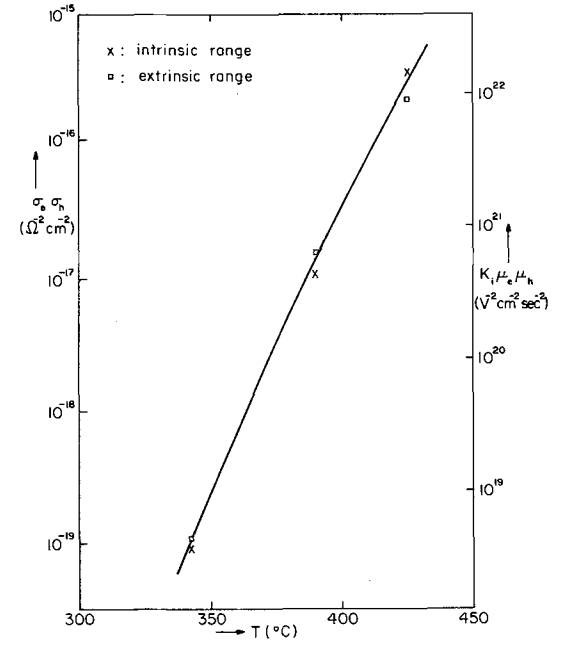

Fig. 8. The product $\sigma_e(II)\,\sigma_h(II)_{exp}$ (left-hand scale) and $K_i\mu_e\mu_h$ (right-hand scale) as a function of temperature for lightly doped (intrinsic conductivity range) and heavily doped (extrinsic conductivity range) silver chloride.

Table III. Values of $\mu'/f_{ab} = f(T)$, using $N'_h f_{ab}$ calculated from literature (14, 15) with the modified Smakula equation, and σ_h from our experiments. Also shown are $K_i \exp(E_{ex}/kT)$ calculated from optical data (19) using Eq. [25] and [26], and $K_i \mu_e \mu_h$ calculated from the experimental results using Eq. [28]

T, °C	$\frac{10^3}{T}$, °K^{-1}	$N'_h f_{ab}$, cm^{-3}	σ_h, ohm^{-1} cm^{-1}	μ'_h/f_{ab}, cm^2 V^{-1} sec^{-1}	$K_i e^{E_{ex}/kT}$, cm^{-6}	$K_i \mu_e \mu_h$, cm^{-2} V^{-2} sec^{-2}
441	1.40	—	—	—	2.7×10^{21}	—
393	1.50	9.5×10^{16}	2.60×10^{-4}	1.69×10^{-2}	4.2×10^{19}	7.4×10^{20}
352	1.60	6.9	1.80	1.60	7.3×10^{17}	1.15×10^{19}
315	1.70	5.1	1.25	1.52	1.15×10^{16}	—
282	1.80	3.7	8.6×10^{-5}	1.45	1.74×10^{14}	—
253	1.90	2.7	6.0	1.38	3.0×10^{12}	—

Values of σ_h (I) in the intrinsic region (Fig. 6) can be expressed as

$$\sigma_h\ (I) = 6.37 \times 10^{-2} \times e^{-3.67 \times 10^3 \times T^{-1}}\ \text{ohm}^{-1}\,\text{cm}^{-1} \quad [22]$$

or, expanding the exponential as a power of T

$$\sigma_h\ (I) = 9.16 \times 10^{-22} \times T^{6.18}\ \text{ohm}^{-1}\,\text{cm}^{-1} \quad [23]$$

Combination of [21] and [23] gives

$$\mu'(T)/f_{ab} = 7.16 \times 10^{-3} \times T^{0.84}\ \text{cm}^2\,\text{V}^{-1}\,\text{sec}^{-1} \quad [24]$$

Values at various temperatures are given in Table III. Since f_{ab} should be a number close to unity it is seen that μ'_h is rather low and nearly temperature independent.

Another line of approach can be taken by calculating K_i from

$$K_i = N_e N_h = g_c g_v\, 4 \left(\frac{2\pi kT}{h^2}\right)^3 \left(\frac{m_e^*\, m_h^*}{m_e^2}\right)^{3/2} e^{-E_g/kT}\ \text{cm}^{-6} \quad [25]$$

Here E_g is the width of the forbidden gap; g_c and g_v are the statistical weights of the conduction and valence band: $g_c = 1$, $g_v = 12$ (18). We use $m_e^* = 0.3\ m_e$ and, tentatively, $m_h^* = m_e$. Brown's optical data (19) for $T > 300$°K can be represented by

$$E_g - E_{ex} = 3.39 - (1.02 \times 10^{-3})\,T\ \text{eV} \quad [26]$$

E_{ex}, the exciton dissociation energy, is unknown but will be retained in the expression for K_i obtained from [25] and [26]

$$K_i e^{E_{ex}/kT} \approx 3.00 \times 10^{46} \times 10^{-1.79 \times 10^4 \times T^{-1}}\ \text{cm}^{-6} \quad [27]$$

Values calculated from (27) are also given in Table III. Combining [18] with

$$\sigma_e(I)\ \sigma_h(I) = N_e\, N_h\, q^2\, \mu_e\, \mu_h = K_i\, q^2\, \mu_e\, \mu_h \quad [28]$$

we get

$$K_i\, \mu_e\, \mu_h = \frac{\sigma_e \sigma_h}{q^2} = 1.05 \times 10^{48} \times 10^{-1.81 \times 10^4 \times T^{-1}}\ (\text{cm V sec})^{-2} \quad [29]$$

Values for $\sigma_e \sigma_h$ were taken from Fig. 8. The result is given in Table III. By dividing $K_i\, \mu_e \mu_h$, which results completely from our experiments, by $K_i e^{-E_{ex}/kT}$, which was calculated from optical data, we arrive at

$$\mu_e \mu_h\, e^{-E_{ex}/kT} = 35 \times 10^{-2 \times 10^2 \times T^{-1}}\ \text{cm}^4\,\text{V}^{-2}\,\text{sec}^{-2} \quad [30]$$

or

$$\mu_e \mu_h \approx 35 \times e^{(E_{ex} - 0.04)/kT}\ \text{cm}^4\,\text{V}^{-2}\,\text{sec}^{-2} \quad [31]$$

The Hall mobility of electrons in AgCl has been measured by several authors up to 400°K (20-22). The high-temperature results can be expressed as

$$\mu_e = 2.54 \times 10^5 \times T^{-3/2} \approx 3.45 \times \exp\,(0.083/kT)\ \text{cm}^2\,\text{V}^{-1}\,\text{sec}^{-1} \quad [32]$$

The latter part of the equation is an approximation holding in the range 600°-700°K. Combination of [31] and [32] gives

$$\mu_h = 10 \times \exp\,(E_{ex} - 0.123)/kT\ \text{cm}^2\,\text{V}^{-1}\,\text{sec}^{-1} \quad [33]$$

Comparison with the value of μ'_h/f_{ab} derived from [21], reveals a considerable discrepancy. The ratio between μ_h and μ'_h can be written

$$\mu_h/\mu'_h \approx 2.65 \times 10^2 \times f_{ab}^{-1} \times \exp\,(E_{ex} - 0.076)/kT \quad [34]$$

This ratio varies from 61.5 to 74.5 between 600° and 700°K for $E_{ex} = 0$ and $f_{ab} = 1$ and it becomes larger with increasing E_{ex} and decreasing f_{ab}.

A possible explanation for the deviation of μ_h/μ'_h from unity may be that the optical absorption as found by Moser and Ulrici, *et al.* does not originate from free hole absorption but has to be assigned to self-trapped holes at an energy level E_T slightly above the valence band. Indications of the occurrence of self trapping have been found previously in electron spin resonance experiments at low temperature (23). The use of N'_h stemming from the optical absorption to calculate the hole mobility is then not justified: $N'_h = (N_h)_{\text{self trapped}}$.

The expected ratio between free and self-trapped holes is

$$\frac{(N_h)_{s.t.}}{N_h} = \frac{N_T e^{\Delta E/kT}}{N_V} = \frac{2 \times 2.3 \times 10^{22} \times e^{\Delta E/kT}}{g_v \times 2\left(\frac{2\pi mkT}{h^2}\right)^{3/2}} = 10.7 \times \exp\,(\Delta E + 0.083)/kT \quad [35]$$

N_T = trap density = 2 x number of atoms per cm^3 on one sublattice, N_V = density of states in the valence band, $\Delta E = E_T - E_V$, E_V being the energy of the edge of the valence band. This ratio must equal the ratio between the two mobilities (34):

$$\frac{(N_h)_{s.t.}}{N_h} = \frac{N'_h}{N_h} = \frac{\mu_h}{\mu'_h} \quad [36]$$

From [34], [35] and [36] we finally find

$$\Delta E = E_{ex} + (3.21 - \ln f_{ab})\ kT - 0.16\ \text{eV} \quad [37]$$

The calculation restricts the validity of [37] primarily to the 600°-700°K range. If, instead of using the modified equation, we had used the original version of Smakula's equation, which includes the Lorentz field, the result would have been, again for $T = 600$°-700°K,

$$\Delta E = E_{ex} + (1.75 - \ln f_{ab})\ kT - 0.16\ \text{eV} \quad [38]$$

With reasonable values of E_{ex} (0.10 eV $< E_{ex} <$ 0.20 eV), Eq. [37] and [38] lead to values for ΔE between 0.04 and 0.22 eV at $T = 650$°K and $f_{ab} = 1$. A lower oscillator strength tends to shift these values slightly upwards: for $f_{ab} \approx 1/2$ we find ΔE between 0.08 and 0.26 eV, values that are quite acceptable.

Thus it seems that the discrepancy between the mobility values can be explained by the fact that the chlorine-induced extra absorption in AgCl originates from self-trapped rather than free holes. This situation contrasts with the one found in AgBr, where the analysis did not point to self-trapped holes (24).

In the alkali and ammonium halides the valence band is mainly due to Cl^- ions and a self-trapped hole can be considered to be a Cl_2^- molecule ion, as

Table IV. Reactions involving structure elements of AgCl and AgBr and the parameters of their reaction constant $K = K_0 \exp(-H/kT)$, with $K^0 = \exp(\Delta s/k)$

Reaction	K	AgCl		AgBr	
		H, eV	ΔS, cal. °K^{-1}·mole^{-1}	H, eV	ΔS, cal. °K^{-1}·mole^{-1}
$\frac{1}{2}X_2(g) \rightleftarrows X_X^x + V'_{Ag} + h^\cdot$	K_{X_2Vh}	0.91	−22.2	0.84	−8.9
$Ag(s) + V_i^x \rightleftarrows Ag_i^\cdot + e'$	K_{Ag}	2.64	26.0	2.28	25.9
$Ag_i^\cdot + V'_{Ag} \rightleftarrows Ag_{Ag}^x + V_i^x$	K'^{-1}_F	−1.14	−8.32	−1.06	−13.5
$AgX(s) \rightleftarrows Ag(s) + \frac{1}{2}X_2(g)$	K_{AgX}^{-1}	1.29	12.38	1.13	+12.2
$0 \rightleftarrows e' + h^\cdot$	K_I			3.19	15.7
	K_i (opt.)	3.70	7.9	2.97 + E_{ex}	17.9

has been confirmed by various means (25, 26). In AgCl the valence band is mainly due to Ag^+ ions and a self-trapped hole center should consist of Ag^{2+} + 6 neighboring Cl^- atoms. Further evidence, that the optical absorption in chlorinated crystals may well originate from self-trapped holes, stems from observations on AgCl: Cu^{2+} (27). After selective illumination of the crystals at liquid helium temperature an absorption band speculatively assigned to a $(CuCl_6)^{4-}$ complex was found which was very similar to the one produced by chemically injected holes (14).

The trapping energy according to [37] and [38] is in our case somewhat temperature dependent. It must be remembered that approximations included in [36] and [37] restrict these expressions to the range 600°-700°K. Furthermore, a linear temperature dependence of the band gap may not be quite correct, and a possible temperature dependence of the exciton energy has been neglected. Thus it is the absolute value of ΔE rather than its temperature dependence that seems most important.

As mentioned earlier, the various equilibria for the intrinsic region have been summarized in Table IV together with the results for both AgCl and AgBr. For AgCl we put $f_{ab} = 1.0$, $E_{ex} = 0.15$ eV, $p_{Cl_2} = 1$ atm and the number of molecules $N = 2.33 \times 10^{22}$ cm^{-3}.

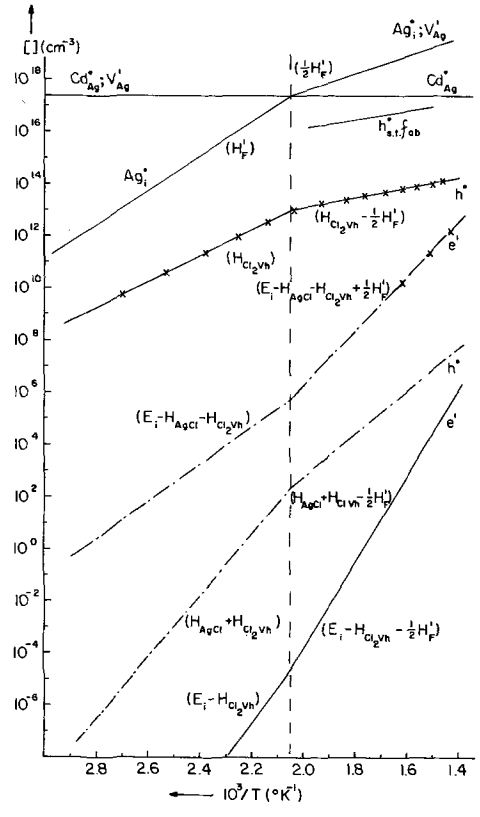

Fig. 9. Concentrations of the imperfections in AgCl + 10 ppm Cd as a function of temperature. Solid lines, AgCl in equilibrium with Cl_2 (1 atm); broken lines, Ag-Cl in equilibrium with Ag ($a_{Ag} = 1.0$). The slopes of the various lines are given in brackets.

The data taken on the undoped sample have been used. The value of K_{AgCl} was calculated at $T = 500$°K. The value found for K'_F agrees well with the low-temperature value reported by Müller (2). For AgBr we modified the results from an earlier publication (16). K'_F was taken from ref. (24), the value of K_{AgBr} was also calculated for $T = 500$°K, and the hole mobility was taken to be $\mu_h = 8 \times 10^6 \times T^{-2.69}$ cm^2 V^{-1} sec^{-1} (29) rather than $\mu_h = 1.5 \times 10^{14} \times T^{-5.5}$ cm^2 V^{-1} sec^{-1} (7). It can be seen that for AgBr the result for K_i agrees very well with the result of optical measurements and that the differences between AgCl and AgBr are quite acceptable.

Figure 9, finally, shows the concentrations of ionic and electronic defects in AgCl + 10 ppm Cd equilibrated with, respectively, 1 atm Cl_2 and Ag(s). Note the bends in the concentration of holes and electrons at the temperature where the ionic defects change from being impurity controlled to Frenkel disorder controlled. In the plotting of the data the same values of the various parameters have been used as before.

Acknowledgment

Thanks are due to Dr. F. Moser, Eastman Kodak Research Laboratories, Rochester, New York for putting at the authors' disposal the undoped and lightly doped AgCl crystals. This work was supported by the Directorate of Chemical Sciences, Air Force Office of Scientific Research under Contract AF-AFOSR-68-1405.

Manuscript received Aug. 13, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

Technical Notes

Influence of Porosity of Thin Gold Layers Used as the Substrate for Electrodeposited Permalloy

F. E. Luborsky

General Electric Research and Development Center, Schenectady, New York

The substrate requirements for the vacuum deposition of NiFe films suitable for static memory operation are well documented (1, 2) and reasonably well understood. Of particular interest is the recent study (3) of various metallic underlayers; the observed effects on the Permalloy properties were attributed to the microstructure and morphology of the underlayers. Similar requirements and effects are expected in the case of the substrate used for electrodeposition of NiFe. In many cases, these substrates use a thin gold film over a copper base (4, 5). The gold film has two characteristics needed to produce Permalloy films with the required magnetic characteristics: a very fine grain size and an electrode potential (4) close to that of Permalloy in the electrolyte in use.

In this note, we will show some interesting fluctuations in the magnetic properties and composition of the Permalloy as the thickness of the gold underlayer is increased. The minimum thickness of gold required to achieve good magnetic properties will be shown to correspond to the completion of a change in the character of the cathode potential *vs.* time for the deposition of NiFe at constant current. The change in these cathode potentials, as the gold thickness increases, is most likely due to the "covering" of the copper by the gold.

Samples were prepared, as previously described (5, 6), on 0.010 in. thick copper substrates plated with about 5-10μ of copper, varying thicknesses of gold, and finally 600Å of Permalloy. All samples were annealed in an easy axis field of 1000 Oe before the magnetic measurements (5, 6). The gold films were deposited from a proprietary (7) electrolyte, Orosene 999, at room temperature, at a pH of 4.5, and at a current density of 12 mA/cm^2. The grain size of the gold films were all in the range of 90-130Å, as determined from x-ray line broadening for films from 500 to 5000Å thick. Line widths were not corrected for any stress contribution, and thus these grain sizes may be somewhat larger. There was no evidence for any crystal orientation in any of the films. The average surface roughness (center line average) of the substrates after depositing the copper was 250Å as averaged over 0.025 cm intervals. This roughness did not change on depositing gold up to thicknesses of 10,000Å.

The electrolytes used for the Permalloy deposition contained nickel and iron sulfates, boric acid, and thiourea as previously described (5). They were operated under conditions to obtain the zero magnetostrictive composition, 81.5% Ni, when deposited on gold (4-6, 8). The magnetic properties resulting from depositing a 600Å thick Permalloy film, using the above conditions, onto copper substrates with increasing thicknesses of a gold film are shown in Fig. 1. For thicknesses of gold on the substrate of more than about 300Å, the properties are independent of gold thickness; namely the coercive force along the easy axis, H_c, the coercive force along the hard axis $H_{c,\perp}$, the anisotropy field H_k, and the anisotropy dispersion α_q. Below about 300Å of gold H_c, $H_{c,\perp}$, H_k', and α_q increase sharply. These changes in properties may be due to a combination of many factors that are changing as the gold film becomes very thin, *e.g.*, the Permalloy composition may change, its crystallite size may change, the strain between the substrate and the Permalloy film may change, and the roughness may change.

The change in composition with gold thickness was determined by three independent measurements: x-ray fluorescence, saturation magnetization M_s, and magnetostriction. The results obtained from each of these, shown in Fig. 2, all agree with one another. Compositions were obtained from x-ray fluorescence through the use of alloy film standards normalized

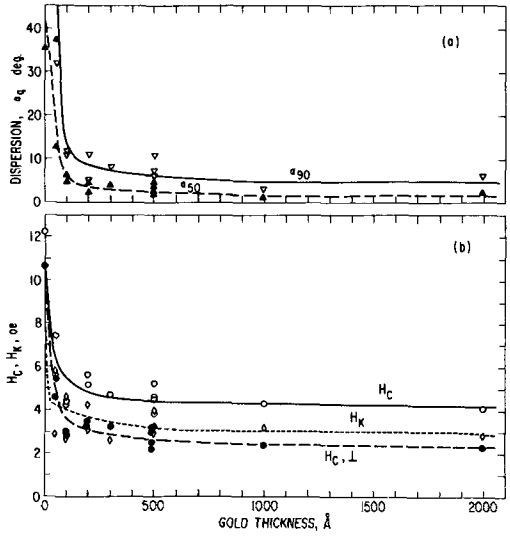

Fig. 1. Magnetic properties of Permalloy films 600Å thick, all deposited under the same conditions, but onto substrates with increasing thicknesses of gold deposited over 5μ of electrodeposited copper. NiFe deposited at 28°C, pH = 2.5, 4.3 mA/cm^2, 160 mg/l of thiourea, 19% Fe^{++} to Fe^{++} + Ni^{++}. Measurements made after an easy axis magnetic anneal of 4 hr at 150°C.

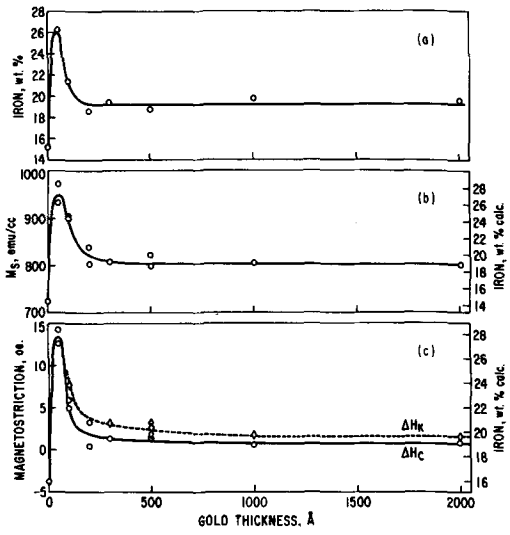

Fig. 2. Average film composition from (a) x-ray fluorescence, (b) saturation magnetization and (c) magnetostriction for films reported in Fig. 1.

to 81.5% Ni for a zero magnetostrictive film. The x-ray fluorescence also showed that all the films were the same thickness to within ± 1%. Compositions were obtained from the M_s measurement using a value of 17.5 (emu/cm³)/w/o Ni for M_s *vs.* composition through the 81.5% Ni point, as obtained from published (9) data. Compositions were calculated from the magnetostriction measurements using the value (6) of 1.46 Oe change in H_k/w/o Ni for the 0.06% strain used in this work. The change in the average Permalloy composition for substrates with very thin Au layers must be due to the change in substrate potential with increasing gold thickness. It appears from these measurements that about 200-300Å of gold are required to remove the influence of the copper.

The cathode potential measured during the deposition of the Permalloy on substrates with different Au thicknesses are shown in Fig. 3. Although the time response of the recorder was only ~ 0.2 sec (equivalent to the deposition of about 10-15Å of NiFe) the initial potentials, plotted in Fig. 4, still vary in a consistent manner with the thickness of the gold film. The open circuit or equilibrium potentials of a copper electrode, shown in Fig. 4, show the same trend with increasing thicknesses of gold. The results of Fig. 3 and 4 also indicate that about 300Å of gold are required to completely remove the influence of the copper substrate.

In a previous paper (5) it was shown that the deposited copper substrates had a grain size of 350-500Å and that NiFe deposited on this copper, from the same electrolyte as used in this work, had the same 350-500Å grain size, while deposition on gold films with a

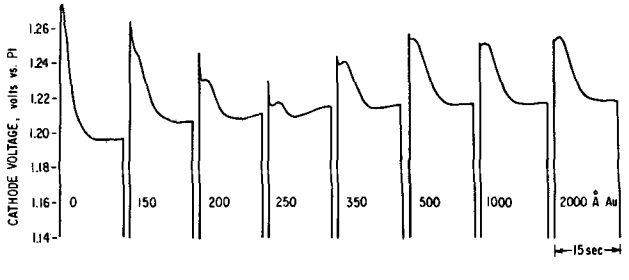

Fig. 3. Potential *vs.* time for deposition of 600Å of NiFe onto substrates with increasing thicknesses of gold. NiFe deposited at 38°C, pH = 2.50, 13.1 mA/cm², 320 mg/l thiourea, 17.75% Fe^{++} to Fe^{++} + Ni^{++}.

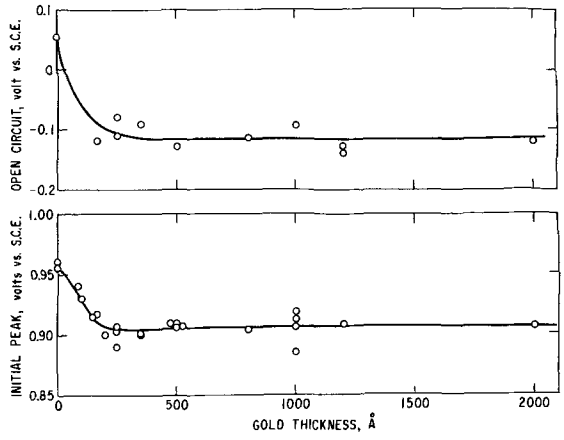

Fig. 4. Initial cathode potential and the open circuit cathode potential as a function of gold thickness for samples prepared as in Fig. 3.

100Å grain size produced NiFe with a 100Å grain size. Thus, it appears that the NiFe deposits epitaxially on both the copper and the gold. In the range of gold film thicknesses where the gold film is discontinuous or has large regions of copper exposed, it is expected that the NiFe film will have regions both with the fine grain size and the coarser grain size. The dispersion α_q will then decrease as the fraction of the film with the larger grain size decreases since α_q is proportional to grain size (1). Since these films are magnetostrictive, the dispersion will also be affected by the difference in strain between the NiFe and Au and between NiFe and Cu.

We conclude that the poor magnetic properties of Permalloy deposited on films of gold less than about 250Å thick results from the influence of the copper substrate. This influence appears as a change in the electrode potential which affects the Permalloy composition; a change in the local grain size of the substrate which affects the local grain size of the Permalloy; and a change probably in the local stress in the Permalloy film. Each of these changes is known to increase H_c, H_k, and α_q. Gold films thicker than about 250Å appear to eliminate the effect of the copper and can be used as substrates to prepare nonmagnetostrictive films with H_c = 4 Oe, H_k = 3 Oe, and $\alpha_{50} < 1°$ for films 600Å thick.

Acknowledgment

The contributions of B. J. Drummond in carrying out the experimental work is greatly appreciated. Helpful discussions with R. Girard of CNRS, Grenoble, are acknowledged.

Properties of a Leached K^+-Selective Glass Electrode

I. Altug and M. L. Hair

Research & Development Laboratories, Corning Glass Works, Corning, New York

The origin of the electrochemical potential which arises when a glass membrane is inserted between solutions of different concentrations has been investigated for many years. This potential is the basis of the glass electrode, giving a standard technique for measuring *p*H. Interest recently has centered on the selectivity of various glasses toward monovalent and divalent cations. Eisenman (1) obtained a correlation between the electrochemical selectivity and ratio of alkali metal to alumina in the glass. Thus, glasses with a high Na/Al ratio are preferentially sensitive to K^+ over Na^+, whereas if Na/Al is less than 3, the glasses are preferentially sensitive to Na^+ over K^+.

Recently we showed that porous glass (with a controlled pore diameter, dry, of approximately 40Å) behaves as an ionic membrane and its properties are adequately accounted for by the Theorell-Meyer-Sievers theory (2). This theory applies to monovalent cations and assumes no selectivity between the various ions. The porous glass membrane, however, has a considerable selectivity. Thus, in its normal, porous state, K_{CaK}^{pot} is approximately 15, whereas K_{NaK}^{pot} is about 1.8. However, when the porous glass was sintered, the membrane potential increased, the calcium selectivity decreased and, just prior to complete sintering, the selectivity of K^+ over Na^+ increased (3). A maximum value of $K_{NaK}^{pot} = 10$ was eventually obtained. This value corresponds to the highest selectivity observed with normal K^+-selective glass electrodes, yet the glass composition (96% SiO_2, 3% B_2O_3, 1% Na_2O) bears no relationship to the compositional ratios projected by Eisenman.

As it is known what happens when a porous glass is gradually sintered so as to become essentially nonporous, it seemed of interest to leach a conventional potassium-selective glass electrode and measure the change in its electrochemical properties. An NAS_{27-4} glass membrane (59% SiO_2, 27% Na_2O, 4% Al_2O_3), which had originally been tested as a potassium electrode, was kept in aqueous solution for 17 months prior to the determination of its ion selectivity. The membrane potentials were measured using the techniques described previously, (3) and the selectivities of K^+ and Na^+ relative to Ca^{2+} were measured.

Freshly prepared K^+-selective glasses do not exhibit appreciable ion selectivity unless they have been stored in aqueous solution for a considerable time to produce a hydrated layer on the surface of the glass. This membrane was no exception, and a six-week immersion in $NaHCO_3$ solution was required to produce the maximum K_{NaK}^{pot} value of 10. At this point, there was negligible response to Ca^{2+}. However, after aging for 17 months, it was found that the divalent response had increased, while the selectivity of K^+ relative to Na^+ had decreased from 10 to 5.6. On further leaching, the glass rapidly became completely porous and eventually fell apart.

On immersing any glass in aqueous solution, at least two processes occur. One is an ion exchange in which the alkali metal ions in the glass are replaced by protons. The second is a dissolution of either one phase or the whole of the glass network. It is probably the first process that gives rise to the hydrated layer necessary for K^+ selectivity. If the leaching process that occurs with the NAS_{27-4} glass can be considered to be the reverse of the sintering of a porous glass (both affecting the hydration state of the medium), then it is possible that these apparently different types of glass would have similar electrochemical properties. The selectivity constants obtained for the leached NAS_{27-4} membrane

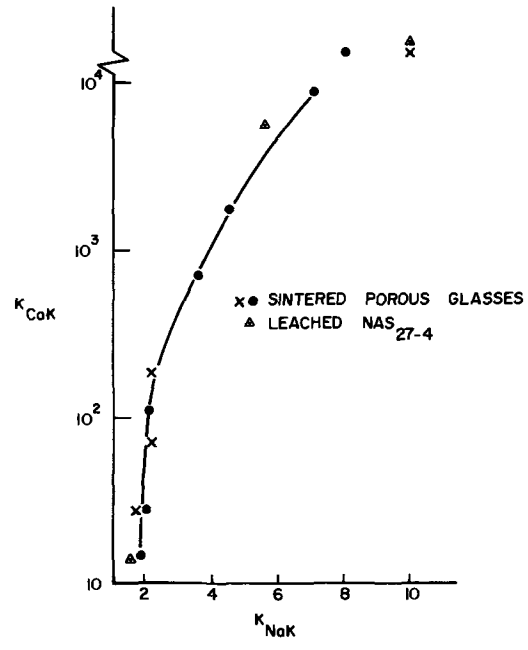

Fig. 1. Selective behavior of sintered porous glasses compared with NAS_{27-4}.

are plotted in Fig. 1 with the data previously reported for sintered porous glasses. The properties of the partially leached aluminosilicate glass are almost identical with those obtained for a partially sintered porous glass. Complete leaching of the NAS_{27-4} membrane formed a completely porous, fragile membrane whose electrochemical properties were similar to those of a porous glass.

The ion selectivity of the sintered porous glasses was explained on the basis of very small "pores" of the order of 2-3Å in the resultant membrane. The leaching of a sodium aluminosilicate glass, particularly if it shows very fine phase separation or clustering of the alkali metal ions, can also give rise to small "pores" within the glass. The leached layer then approximates a molecular sieve, rather than a silica gel. This analogy has been previously suggested by Garfinkel (4) on the basis of diffusion measurements on both "wet" and "dry" samples of NAS_{27-4}. Furthermore, the leaching of both alkali silicate and alkali aluminosilicate (5) glasses is known to give rise to materials with molecular sieve properties and pore sizes in the range of 2-7Å. The present results indicate the formation of such a hydrated layer on the surface of K^+-selective glass electrodes.

A High-Speed Switch for Isolation of the Reference Electrode Circuit to Hold-Off IR Changes during Current Interruption or Pulsing

David R. Flinn,[1]* Murray Rosen,[1]* and Sigmund Schuldiner*

Electrochemistry Branch, Chemistry Division

and James D. Fahey

Electronics Division, Naval Research Laboratory, Washington, D. C.

Determination of electrochemical parameters by current interruption or by pulse polarization is difficult in dilute solution because of high solution resistance. The sensitivity of the oscilloscope or other recording device is limited due to overdriving and the resultant saturation of the electronic amplifiers by the solution IR component which is much larger than the electrode polarization component. Besides the loss in sensitivity many microseconds or even milliseconds may be required before the correct potential may be recorded.

By the use of a field-effect transistor (FET), it is possible to construct a simple device through which the potential response of a reference electrode may be recorded over any desired time interval. The potential response measured between the reference and working electrodes may be "held-off" until the applied current is completely shut off.

The field-effect transistor acts as a simple toggle switch or relay contact. In the open or off state, it has an impedance in the order of 10^{12} ohm. In the conduction or on state, it has an impedance of approximately 15 or 20 ohm. The minimum time from off to on or on to off states can be as fast as 1.5 to 2 nsec (1, 2). The actual transition time depends on the rise and fall time of the gating pulse used.

By using the FET in conjunction with a high input impedance operational amplifier, the reference electrode sees no apparent change in impedance from the off to the on state of the FET and, therefore, there is no differential change in loading of the reference electrode. Thus a much higher input impedance is provided than normally available from an oscilloscope probe. Also, with the use of a wide bandwidth operational amplifier, there should be no significant loss in oscilloscope bandwidth capabilities. This FET switch should prove capable of replacing mercury relays in many applications, without the difficulties inherent in such mechanical devices (3).

For current interruption measurements an applicable switching circuit is shown in Fig. 1a. The FET (2N4859) is biased to the nonconducting state by the −15V from the power supply. Any signal which will raise the gate control signal input to a potential of approximately −1V will render the source (S)-to-drain (D) of the FET fully conducting, with a negligible resistance as compared to the high input impedance operational amplifier. The gate must not be driven positive, however, as this potential will be transferred to the drain point. Input signals as large as 50V may be "held-off" by this FET in its nonconducting state.

In most applications, a potential step from some point in the cell polarization or measurement circuitry (*e.g.*, pulse generator) will be available for the FET gating control. In many cases the gate potential of the recording oscilloscope may be used as the gate control signal.

In our application (Fig. 1) the FET drain was fed into a Model 1011 Philbrick/Nexus operational amplifier. The high impedance (10^{11} ohm) and low input capacitance (4 pF) of this amplifier prevents loading of the FET. Although an amplifier gain of 2 is shown here, any reasonable value may be used.

The 1N914 diode between the amplifier (plus) input and ground serves to provide a current path for the small amplifier bias current (<30 pA). For the circuit of Fig. 1a, the direction of this diode is unimportant for small signal applications. Where signals greater than the breakdown value of the diode are to be examined, the direction of the diode may be reversed. With the diode in the circuit the effective input impedance is approximately 5 x 10^9 ohm.

For pulse polarization applications, the FET switch may be used in the reverse sense to that shown in Fig. 1a. In Fig. 1b the gate connections are made so that the FET is normally conducting. The FET may be rendered nonconducting for any desired time period by a gate control potential of −4V or greater.

The effective switching time for the circuit of Fig. 1a is illustrated in Fig. 2-4. In Fig. 2, a small d-c potential applied to the FET source is gated through the FET after about 1μsec. The true switching time is much faster than the 0.7 μsec shown here, but is masked by ringing. The upper curve of Fig. 3 illustrates a typical galvanostatic high current density anodic pulse polarization of a platinum electrode in H_2-saturated, 1M H_2SO_4 solution. For the lower curve of Fig. 3, the FET has been gated into the conducting mode after about 3 msec, thereby holding-off the potential response to the reference electrode for that period of time.

In Fig. 4, curve (a) shows the potential-time response to a 2 μsec constant current pulse applied to the same electrode used for Fig. 3, with the FET switch conducting throughout the entire response shown. Curve (b) of Fig. 4 was made at ten times greater sensitivity, with the FET gated on only after pulse

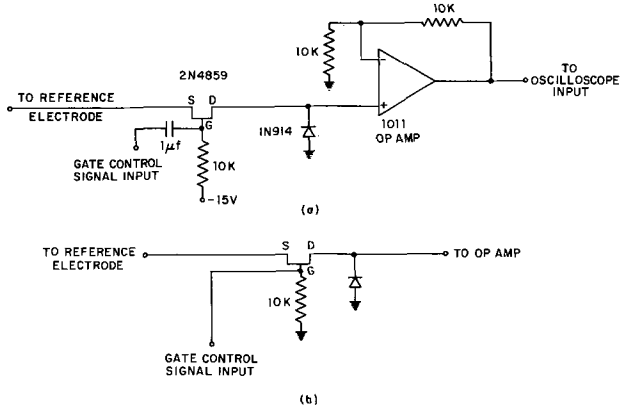

Fig. 1(a). Switching circuit with FET in normally nonconducting mode. A signal of 12-14V through the gate control signal input will render the FET conducting; Fig. 1(b) FET in normally conducting mode. A gate control input signal more negative than −4V will render the FET nonconducting.

cut-off. This illustrates that the solution IR component can be virtually eliminated and the electrode polarization response can be measured at high precision.

No photograph is shown for the response of the circuit of Fig. 1b to a 2 μsec constant current pulse applied under the same conditions to the same electrode used in Fig. 3 and 4 because the result is essentially identical with that observed in Fig. 4. The line visible at the lower left in Fig. 4 represents the ground potential which in this case is the potential of the working and reference electrodes. Under other experimental conditions or with some other reference electrodes the

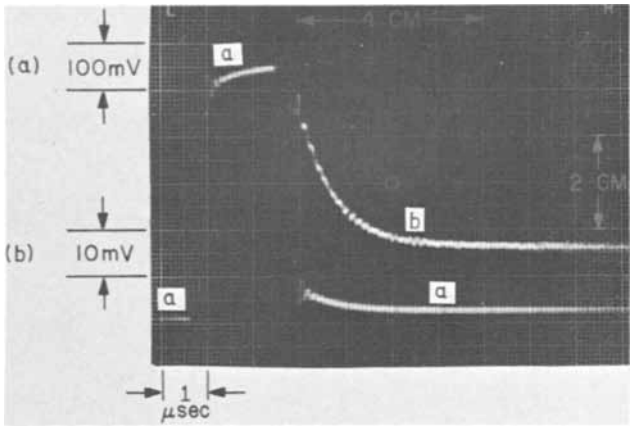

Fig. 4. Potential response to 2 μsec galvanostatic anodic pulse for same electrode used in Fig. 3. (a) FET conducting throughout; vertical sensitivity of 0.1 V/div; (b) FET conducting only after pulse cut-off; vertical sensitivity of 10 mV/div.

potential of the reference electrode will be different from that of the grounded working electrode.

The advantage of the circuit of Fig. 1b over the one of Fig. 1a is that the cell potential is recorded both prior to and after a pulse polarization perturbation. The potential at the + input of the operational amplifier, while the FET is biased off during the pulse period, depends to some extent on the risetime of the signal used to render the FET nonconducting. A transient voltage spike may appear which is caused by the very small amount of charge required to bias the FET, which in turn can charge the small capacitance (4 pF) of the amplifier. With proper adjustment of the FET gating signal risetime, this transient may be entirely eliminated. The circuit of Fig. 1a also may be used for pulse polarization studies, but an independent measurement of the initial cell potential must be made, either by shorting across the FET or by gating the FET on without polarizing the cell.

The 2N4859 used here is an n-channel FET. For holding off large negative going signals a p-channel FET would offer an advantage in that a lower gating potential could be used than for an n-channel FET. Also, the positive gate bias which is required may be more convenient in some applications.

Brief Communications

Auger Electron Analysis of Electropolished High-Purity Aluminum

C. G. Dunn* and L. A. Harris

Research and Development Center, General Electric Company, Schenectady, New York

The topography of electropolished aluminum has been studied extensively (1-12), but the composition of the surface reaction film has received little attention. It is generally believed to be an amorphous oxide of aluminum formed either in the electrolyte or subsequently on exposure to water or air. Holló (8) obtained a porous oxide film on aluminum electropolished in phosphoric acid/n-butyl alcohol. Halfawy (12) concluded from electron diffraction data that the surface of aluminum electropolished in perchloric acid/acetic anhydride was initially free of oxide. Morize and Lacombe (13) reached the same conclusion from solution potential measurements. On the other hand Beck *et al.* (14) stated that electropolishing in typical baths produced an aluminum surface containing perchlorate ions which prevented the subsequent formation of high resistivity anodic oxide films. Similarly, using aluminum specimens initially electropolished in a perchloric acid electrolyte, one of the authors (CGD) observed surface reactions (to be described elsewhere) that indicated impurity contamination by the electropolish. These observations in fact led to the present study by Auger electron emission (15) of atom species present on electropolished aluminum.

* Electrochemical Society Active Member.

The Auger analyses were made on electropolished aluminum sheet of 99.999% purity and on similar specimens chemically treated to remove residual films or reaction products. Electropolishing involved raising the voltage beyond the first current maximum to a point within the polishing region (16, 6) (about 15V) and holding the voltage constant for 3 min or more in a 1:4 (by volume) solution of perchloric acid (71%) in absolute ethanol maintained between 5° and 10°C. After thorough rinses in alcohol and in distilled water, samples were dried in a stream of clean nitrogen.

Auger analyses of electropolished samples revealed the presence of O, C, S, Cl, and N (top curve of Fig. 1). Treatments after electropolishing such as 10 min in 30% NaOH at room temperature, or 5 to 10 min in 10% HNO_3 at 90°C, had the following effects on surface concentrations: a slight reduction in oxygen and carbon, a significant decrease in sulfur, a decrease in chlorine to nondetectable levels, and no significant change in nitrogen (middle and bottom curves of Fig. 1). Treatments in an oxide stripping bath (35 ml of 85% phosphoric acid and 20g of chromic acid per liter) (17) at 90°C appeared to remove most of the chlorine in 1 min and perhaps all of it in 10 min. Reactions in this oxide stripping bath, as Fig. 2 shows, resulted in surface films containing appreciable

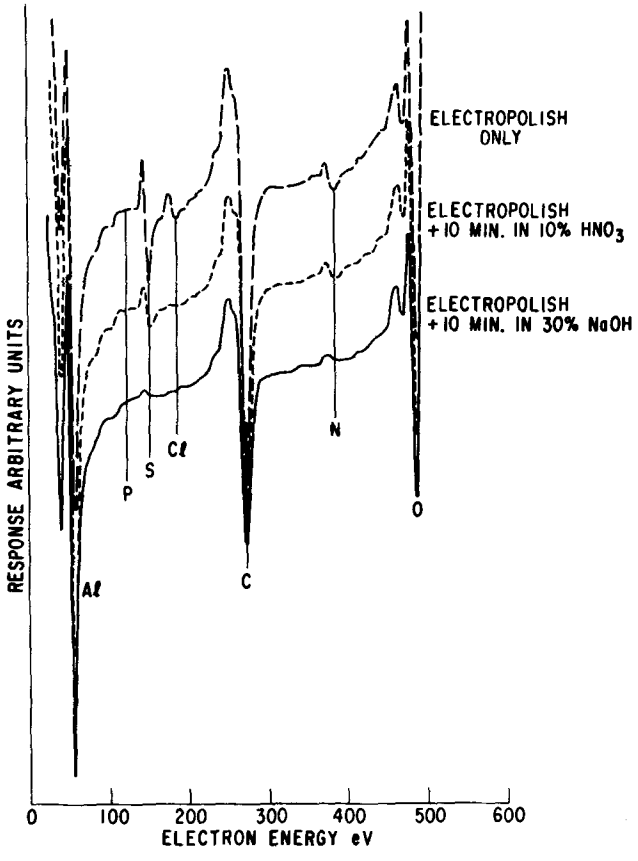

Fig. 1. Auger spectra of electropolished aluminum before and after chemical treatments.

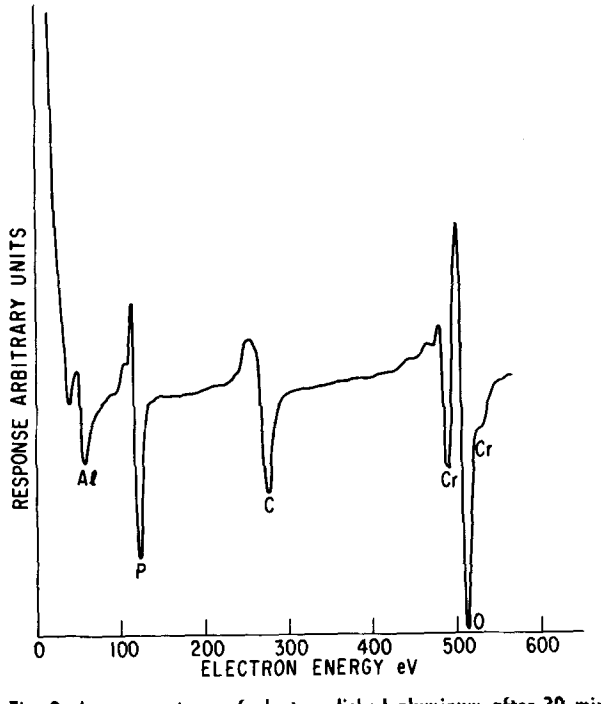

Fig. 2. Auger spectrum of electropolished aluminum after 30 min in a phosphoric acid/chromic acid bath at 90°C and a thorough wash in water.

amounts of phosphorus and chromium. The latter result confirms other published work, particularly the tracer studies of Lewis and Plumb (18) on radioactive phosphorus and chromium initially added as phosphates and chromates in their phosphoric acid/chromic acid bath.

Since the composition of the electropolishing bath consisted mainly of C, H, O, and Cl, and since the Auger analysis revealed the presence of C, O, and Cl on electropolished aluminum samples, we conclude that elements in the polishing bath, particularly chlorine and carbon can enter in a surface reaction product and contaminate the aluminum. The oxygen contamination could originate from the water in the washing treatment, from exposure to air (12, 13), or from the electrolyte. The source of the nitrogen and sulfur contamination was not determined.

Theoretical Electromotive Forces of Metal-Halogen Cells

Some Recalculations Based on Recent Data

Reuben E. Wood* and Walter J. Hamer*

National Bureau of Standards, Washington, D. C.

Since the publication of the calculations of Hamer, Malmberg, and Rubin on the theoretical electromotive forces of cells containing a single solid or molten chloride (1), fluoride (2), bromide (2), or iodide (2), new data have become available, and tabulations of thermodynamic properties, particularly those of Stull *et al.* (3), have been published. We have used these newer data to recalculate emfs for the cases covered by the JANAF tabulations (3). We shall not here attempt to evaluate the reliability of data leading to the differing results, but shall only indicate the cases in which substantial discrepancies exist between the older and newer values.

Both the tabulations of Hamer, Malmberg, and Rubin (H) and those in the JANAF publications (J) give values (emfs in the H tables, ΔG°'s in the J tables) at 25°C (298.15°K). At higher temperatures the H tables give values at rounded Celsius temperatures, the J tables at rounded Kelvin temperatures. As a representative high temperature, 1100°K was chosen. This required only a short extrapolation of the H values from 800°C.

Table I compares, for cases in which a difference of 100 millivolts or more in the standard emfs of formation (2.3 kcal [1] per equivalent difference in ΔG°), the emfs given by H and those we have calculated from the ΔG's given by J. It can be pointed out that for those cases in which the higher temperature comparison can be made, most of the discrepancies are of the same order of magnitude and in the same direction at both temperatures. This suggests strongly that the usual

Kinetics of the Phosphidation of Copper

Shiro Ueda, Yoshinori Sasaki, Mikio Matsuura, and Shuichi Nishimura

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoicho, Chiba, Japan

ABSTRACT

A study on the kinetics of the phosphidation of copper sheets exposed to phosphorus vapor was undertaken at temperatures of 400°-650°C and at phosphorus partial pressures between 0.8 and 110 Torr. The phosphidation rate increased with rising temperature and with increasing partial pressure of the phosphorus vapor. When the phosphide layer reached a certain thickness, a transition from a linear rate to a parabolic or a cubic one took place. The relation between the phosphorus vapor pressure, P, (0.8-110 Torr) and the linear rate constant, K_l, (3.3-200 x 10^{-5} g/cm^2-min) found in the initial stage gave $K_l \propto P^{0.83}$ at 500°C. In general, the phosphides obtained have been composed of Cu_3P or the mixture of Cu_3P and CuP_2. The CuP_2-formation at temperatures above 600°C seldom has been observed from the x-ray patterns of the phosphides.

Preparations and structures of copper phosphides have been extensively investigated by many authors (1). However, no investigation involving the rate of phosphidation of copper has been made except by Edwards and Murphy (2).

The present study was undertaken to provide further information concerning the kinetics of the attack of phosphorus vapor on copper sheets at elevated temperatures.

Experimental

Materials.—Copper sheet.—Commercial copper sheets of high purity (more than 99.95%), about 15 mm wide, 30 mm long, and 0.3 mm thick, were employed in this work. They were polished through 3-0 emery paper. After degreasing with trichloroethylene or toluene in a soxhlet-type apparatus, they were treated with a mixture of 50 parts of nitric acid and 1 part of hydrofluoric acid to remove surface oxides, after which they were washed with alcohol and acetone. They were transferred in a desiccator filled with argon dried over phosphorus pentoxide.

Red phosphorus.—Commercial red phosphorus (amorphous) was treated with a boiling 8% solution of sodium hydroxide for about 3 hr to remove any yellow phosphorus, then with dilute hydrochloric acid and with a dilute solution of potassium cyanite to remove trace amounts of metals or their compounds contained in the red phosphorus. After washing with distilled water, the refined red phosphorus was preserved in a desiccator which was filled with argon dried over phosphorus pentoxide.

Apparatus and Procedure

It is necessary to carry out phosphidation of metals in the absence of air to avoid formation of metal oxides, metal nitrides, or various oxides of phosphorus. In this study, an apparatus depicted in Fig. 1 was used to evade these problems.

A copper sheet was suspended from a quartz helix (sensitivity 0.1 mm/mg) hanging from a glass hook inside the top of a quartz reactor. The extension of the quartz helix caused by the weight increase of the specimen was measured using a cathetometer with a precision of 0.01 mm.

A quartz cell filled with the refined red phosphorus was placed at the bottom of the reactor. The temperatures of the specimen and of the red phosphorus were controlled independently with two automatic regulators. The rate of sublimation of red phosphorus was controlled by adjustment of the temperature of the lower electrofurnace. Since the gaseous P_4 molecule scarcely dissociates into P_2 molecule at temperatures below 800°C, the phosphorus vapor can be regarded as consisting of P_4 molecules over the temperature range from 400° to 650°C employed in this work.

An argon carrier gas was dried by passing through phosphorus pentoxide and deoxygenated by passing through heated active copper, and then introduced into the bottom of the reactor from the heated side tube at a flow rate of 100 ml/min and at 1 atm. The extension of the quartz helix was in practice unaffected by the flow of the carrier gas. Partial pressures of phosphorus vapor were calculated from the rate of sublimation to P_4 vapor and the flow rate of this carrier gas.

Results and Discussion

Plots of the weight gain per unit area against the elapsed time are shown in Fig. 2(a) and (b), which

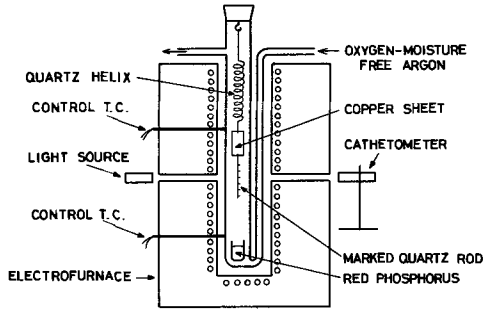

Fig. 1. Schematic diagram of the reaction apparatus

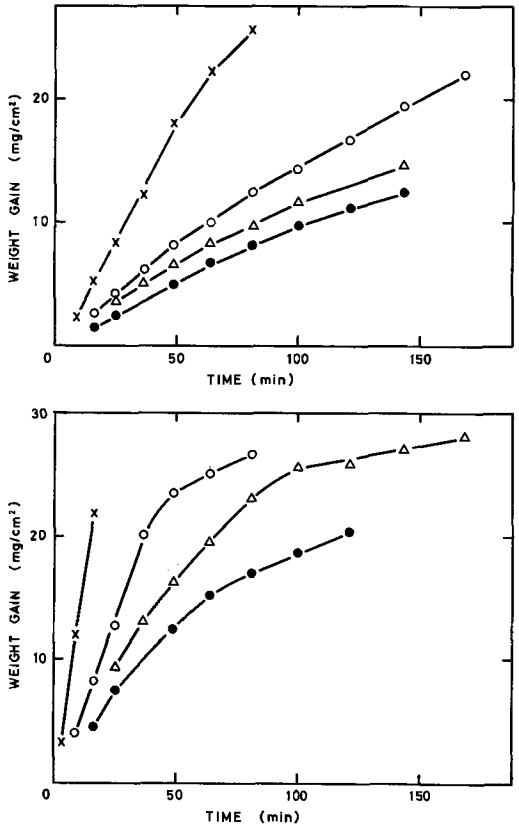

Fig. 2. Phosphidation of copper between 400° and 650°C at phosphorus partial pressures of (a) (top) 3.7 and (b) (bottom) 13.2 Torr: × 650°; ○ 600°; △ 500°; ● 400°C.

represent the results of the phosphidation of copper sheets at phosphorus partial pressures of 3.7 and 13.2 Torr, respectively. It is obvious from Fig. 2 that the weight of the copper sheet increased with rising temperature, and that phosphidation appears to follow approximately a linear rate law in the early stage.

Figure 3 represents the results of the influence of partial pressures of phosphorus vapor between 0.8 and 110 Torr at 500°C. By varying the partial pressure of phosphorus vapor the phosphidation rate of copper can be altered considerably. It will be seen that at the pressures below 6.7 Torr the phosphidation proceeded nearly according to a linear rate law while at pressures above 13.2 Torr, up to 110 Torr, it approximately followed a parabolic or a cubic rate law in the advanced stage. The log-log plots of the data for the

pressure of 3.7 Torr at 650°C and for the pressure of 13.2 Torr at 600°C show transition from linear to parabolic or cubic behavior after a certain thickness is reached. The linear kinetics in the early stages may indicate phase boundary control.

The rate constant, K, can be obtained by extrapolating log t to zero. However, only approximate values of the slope were evaluated from Fig. 3, inasmuch as the extrapolation cannot be applied for any curve. Since all the phosphidations approximately followed a linear rate law in the early stage, the linear rate constants, K_1, were obtained from each slope in Fig. 2 and from the slopes on the weight gains *vs.* time plots of the data given in Fig. 3. These values are summarized in Table I.

Needlelike crystals of phosphide formed at 650° and 600°C under pressures of 3.7 and 13.2 Torr, at 500°C under pressures ranging from 2.5 to 110 Torr, and at 400°C under a pressure of 13.2 Torr, but not at 500°C under a pressure of 0.8 Torr and at 400°C under a pressure of 3.7 Torr. As most of the phosphidations proceeded with the formation of numerous mounds and needles, the reaction appears not necessarily to follow the parabolic rate law which is based on the assumption of a plane parallel scaling film. As illustrated in Fig. 3, the phosphidation behaved according to mixtures of linear, parabolic, and cubic rate laws.

X-ray powder diffraction patterns of the typical phosphides obtained in this work are illustrated in Fig. 4, in which those of Cu_3P and CuP_2 were quoted from the ASTM card (4) and from the result given by Oloffson (3), respectively. The phosphide layer appears to consist almost entirely of Cu_3P at the lower partial pressures of phosphorus vapor, while at 500°C and the partial pressures between 6.7 and 110 Torr the formation of CuP_2 was also observed.

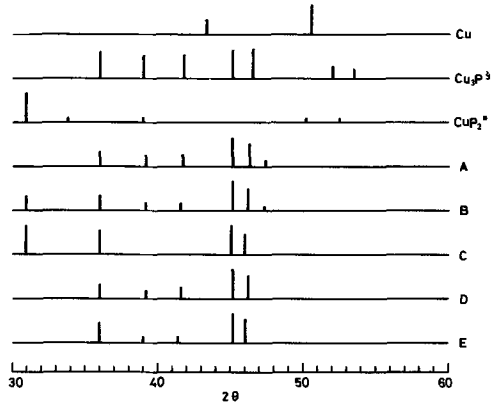

Fig. 4. Sketched line diagrams from the x-ray patterns of the obtained phosphides, (θ, diffraction angle). A, 13.2 Torr, 600°; B, 13.2 Torr, 500°; C, 13.2 Torr, 400°; D, 3.7 Torr, 500°; E, 3.7 Torr, 400°C.

§ ASTM card (4), * Oloffson (3).

It is interesting that no product other than Cu_3P was formed at 600° and 650°C. It is known that CuP_2 decomposes to form Cu_3P in the temperature range from 600° to 800°C with an evolution of P_4 vapor. The partial pressure, P_{Torr}, of phosphorus vapor composed of P_4 molecules is given for this decomposition as a function of the absolute temperature, T, as follows

$$\log P_{Torr} = -11{,}370/T + 13.827$$

According to this equation, the partial phosphorus pressures of a mixture of CuP_2 and Cu_3P, for example, at 600° and 500°C, are $10^{1.3}$ and $10^{-0.9}$ Torr, respectively. The reason why the formation of CuP_2 at 600° and 650°C has been seldom observed is revealed from this readily decomposable property of CuP_2.

The phase diagram of the copper-phosphorus system has been determined up to 15% copper. According to this diagram, the solubility of phosphorus in metallic copper is about 1.6% at 650°C and about 1.5% at 600°C. A semilogarithmic plot of K_1 for 3.7 and 13.2 Torr against the reciprocal of the temperature is shown in Fig. 5. The appearance of a quite high increase in value of K_1 at 650°C is presumed to be attributable to a predominance of phosphorus dissolution process in metallic copper.

A graph showing the dependence of the linear rate constant on the partial pressure of phosphorus vapor at 500°C is given in Fig. 6. The dependence interestingly gives a straight line, whose slope corresponds to 0.83, in spite of the approximate value of K_1. It may be interpreted in terms of a phosphorus chemisorption equilibrium followed by a rate-determining step governed by nucleation and growth of the phosphide nuclei.

It seems reasonable to conclude that in the initial stage the chemisorption of phosphorus at the phosphide-phosphorus interface is responsible for the phosphidation rate. It may be suggested that the appearance of a parabolic rate in the advanced stage is a result of the rate-determining diffusion of phosphorus or copper ion through the phosphide layer.

The present difficulties in the explanation of the phosphidation mechanism result from the complicated structure of the copper phosphide scaling layer and lack of information concerning the phosphorus chemisorption and the diffusion of phosphorus and copper ion.

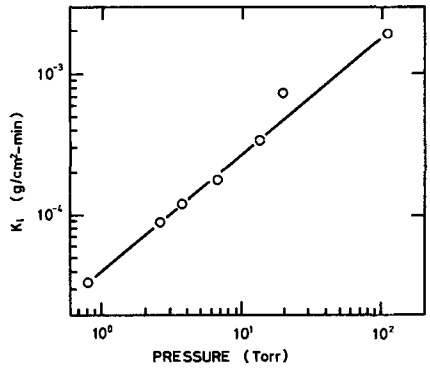

Fig. 6. Phosphorus vapor pressure dependence for linear rate of the phosphidation of copper at 500°C.

Summary and Conclusions

A study on the kinetics of the elevated temperature phosphidation of copper sheets was undertaken. The weight increase of the copper sheets exposed to phosphorus vapor (P_4 molecule) in an argon carrier gas was determined by measuring the extension of the quartz helix suspending the sample copper sheet.

The phosphidation rate increased with increasing temperature from 400° to 650°C and also with increasing phosphorus partial pressures from 3.7 to 13.2 Torr.

The relation between the phosphorus vapor pressure, P, (0.8-110 Torr) and the linear rate constant, K_1, (3.3-200 x 10^{-5} g/cm²-min) found in the initial stage gave $K_1 \propto P^{0.83}$ at 500°C.

In general the phosphidation proceeded nearly according to a linear rate law in the early stage, while it approximately followed a parabolic or a cubic rate law in the advanced stage. The transitions appeared to take place when the phosphide layer reached a certain thickness.

The phosphides obtained have been composed of Cu_3P or the mixture of Cu_3P and CuP_2. The formation of CuP_2 at temperatures above 600°C seldom has been observed from the x-ray patterns.

From the experimental results the rate-determining step seems to change from an adsorption to a diffusion step with the increasing thickness of the phosphide layer. The growth of numerous phosphide mounds and needles complicates the phosphidation mechanism.

Fluorescence Properties of Alkaline Earth Oxyanions Activated by Divalent Ytterbium

The Bayside Research Center of General Telephone and Electronics Laboratories Inc., Bayside, New York

ABSTRACT

The luminescence of Yb^{2+} in alkaline earth phosphates and vanadates is reported. Particular attention has been given to those compositions possessing apatite and spodiosite structures. Emissions from Yb^{2+} are broad and sensitive to host composition. Single and double emission bands are observed which exhibit a variety of temperature dependent relationships. The decay of the Yb^{2+} fluorescence, under cathode-ray excitation, is short.

Spectroscopic studies of rare earth ions have concentrated largely on the interpretation of the inner shell 4f-4f transitions of the rare earth ions. There are generally a large number of 4f-4f emissions in the fluorescence spectrum of a rare earth ion, and they are relatively sharp and easily resolved at liquid nitrogen or helium temperatures. Consequently changes in the emission features brought about by the environment of the rare earth ions are useful in arriving at a quantitative description of the crystal field. However, this is not true for the 4f-5d emission spectra of rare earth ions. Due to the strong interaction of the 5d orbitals with the crystal field, there are a few very broad 4f-5d emission bands. As a result, the 4f-5d fluorescence spectra are not easily interpreted and do not readily lend themselves to basic investigations of the quantum process. Nonetheless, there have been some attempts to do so. For example, Blasse and Bril (1) have described the absorption bands of Ce^{3+}-activated phosphors in terms of the crystal field splitting of the 5d(^{2}D) state. Wood and Kaiser (2) have described the absorptions of Sm^{2+} in the alkaline earth fluorides. The latter investigations used a strong-field formulism to describe the 5d levels and a weak field formulation to describe the 4f levels of Sm^{2+}. An approximate energy level diagram was constructed by combining the 5d and 4f levels. Blasse *et al.* (3) have used the same approach to describe the energy level scheme of Eu^{2+}-activated silicates.

The rare earth ions which most commonly exhibit 4f-5d fluorescence spectra are Ce^{3+}, Eu^{2+}, and Yb^{2+}. There have been relatively few investigations of the spectroscopic properties of Yb^{2+}, even though this ion can have only 4f-5d transitions, since its ground state is $4f^{14}$. Butement (4) has investigated the absorption and emission properties of Yb^{2+} in $SrCl_2$, $BaCl_2$, and of $YbCl_2$ in aqueous media. Kaplyanskii and Feofilov (5) and Feofilov (6) have reported on the emission and absorption spectrum of Yb^{2+} in CaF_2. Bryant (7) has observed and interpreted the free ion emission spectrum of Yb^{2+}. Probably the most complete analysis of a Yb^{2+} absorption spectrum was given by Piper, Brown, and McClure (8), who carried out a complete quantum calculation of Yb^{2+} in $SrCl_2$, taking into consideration the electrostatic interaction, spin orbit coupling, and crystal field.

This paper reports the results of investigations of the emission and excitation spectra of Yb^{2+} in the Ba, Sr, and Ca chlorophosphates with apatite structure, $M_5(PO_4)_3Cl$, the Ca chlorophosphate and chlorovanadate with spodiosite structure, M_2PO_4Cl, and Sr orthophosphate. Some of these matrices have previously been reported as effective hosts for Eu^{2+}, and the Eu^{2+} emission was reported to be sensitive to host composition (9). The Yb^{2+} emission features in these hosts were also found to vary and the results are described herein.

* Electrochemical Society Active Member.

Experimental

The alkaline earth halophosphates and halovanadates were formed in the following manner. The halophosphates were formed by firing appropriate mixtures of Yb_2O_3, $MHPO_4$ (M = Ca, Sr, Ba) and the corresponding halide MCl_2 in hydrogen (9). Similarly, the calcium halovanadate was prepared by firing the appropriate mixture of Yb_2O_3, V_2O_5, $CaCO_3$, and $CaCl_2$ in air, as described by Banks *et al.* (10). The halide is added in excess for fluxing purposes. Reaction temperatures used for synthesis ranged from 800° to 1300°C. The temperature ranges for formation of the spodiosite and apatite structures were 800°-1050°C and 1100°-1300°C, respectively. After the reaction was complete (> 1 hr), the melt was air quenched to room temperature and the excess MCl_2 leached out with hot H_2O washings.

The alkaline earth orthophosphates, unlike the halophosphates, did not require preparation under hydrogen atmosphere for efficient luminescence response under CR excitation. Appropriate mixtures of Yb_2O_3, $MHPO_4$, and MCO_3 can be reacted in either air, nitrogen, or hydrogen. An alternative mixture consisting of only $MHPO_4$ + Yb_2O_3 does, however, require a hydrogen atmosphere to yield an efficient phosphor. Either procedure requires that the starting materials be fired at temperatures above 1200°C for periods of at least 2 hr; the samples are then air quenched to room temperature.

Activator concentration used in either the halo- or orthophosphates can be between 0.0025 and 0.10 gram-atom per gram-atom of host cation.

The excitation and emission spectra were recorded with a Hitachi MPF-2A fluorescence spectrophotometer and corrected for instrumental response by a computer program. The correction curve for the emission spectra was obtained with the use of a NBS standard lamp. The correction curve for the excitation spectra was generated with the use of sodium salicilate and rhodamine B as standards. The relative excitation spectra are expressed in quanta as a function of wavelength.

The temperature measurements were taken under x-ray excitation using a Mo tube. The phosphor was deposited on a copper plate which was then fitted into the slot of a metal block dewar. The temperature was measured with the use of a copper-constantan thermocouple which was in contact with the copper plate while the spectra were recorded. A ¼ meter Jarrell-Ash monochromator and photomultiplier tube with a S-10 response were used to record the spectra. Since the centers of the emission bands shift with temperature, the spectra were corrected for photomultiplier and monochromator discrimination. The areas under the curves recorded at the various temperatures were then compared. The temperature dependencies under uv excitation were found to correspond to those observed under x-ray excitation. The three emission

bands in Ca apatite are exceptionally temperature dependent and decay rapidly on heating above liquid nitrogen temperature. Because of the difficulty in recording the change in intensity over the narrow temperature range at which emission occurs, only visual observations were made and therefore not included in Fig. 9.

The decay times were measured by pulsing the grid of a demountable CR tube. The emitted radiation was detected by a 1P21 photomultiplier tube which drove a Tektronix 535 oscilloscope. The trace on the oscilloscope was photographed, and the time to decay to 10% of initial brightness was measured from the photographs.

Results

The emission bands of the Yb^{2+}-activated phosphors were found to vary considerably with host. Their room and liquid nitrogen temperature emission and excitation spectra, along with the room-temperature reflectance spectra, are shown in Fig. 1-8. Table I gives peak wavelengths of the emission and excitation bands at room and liquid-nitrogen temperature, emission color, and the peak of the reflectance bands at room temperature.

Except for the calcium phosphate apatite, all the Yb^{2+}-activated phosphors have moderate response under CR excitation. The exponential decay times to 10% of the initial brightness of the phosphors under CR excitation are also listed in Table I.

The temperature dependence of the emission intensities of the Yb^{2+}-activated phosphors varied considerably from host to host (Fig. 9). For example, the Ca phosphate apatite shows no emission at room temperature while the emission from the Sr orthophosphate phosphor is still evident at 300°C. Even in those hosts where two or three emission bands are present, these bands exhibit a marked difference in their temperature dependence. Thus, at liquid nitrogen temperature the Sr apatite shows a bluish-white emission due to two bands centered at 450 and 620 nm, while at room temperature this phosphor exhibits a yellow emission which results from the quenching of the 450 nm emission.

It was also noted that under high energy photon excitation, *i.e.* x-ray radiation from a Mo target, the emissions correspond to those observed under uv excitation in all cases except that for the calcium apatite phosphor. In this case, the emission observed under uv excitation at 435 nm is not observed under x-ray excitation.

Discussion

In the free ion calculation of the energy levels of Yb^{2+}, Bryant (7) has shown that for the first excited state levels ($4f^{13}5d^1$) the Jj coupling scheme is the most appropriate, since Yb^{2+} has strong spin-orbit coupling constants (J_f = 2950.2 cm^{-1}, J_d = 1211 cm^{-1}). In this scheme the $4f^{13}$ core is coupled as in Yb^{3+} to form $^2F_{7/2}$ and $^2F_{5/2}$ states (J_1). The spin and orbital angular momentum of the 5d electron is coupled to form $d_{3/2}$, $d_{1/2}$ orbitals (j). The angular momenta J_1 and j are coupled to form states with a total angular momentum J. However, the electrostatic interactions between the $4f^{13}$ and $5d^1$ electrons cannot be neglected, as shown by the relatively large (≈8000 cm^{-1}) (7) splitting of the $[^2F_{7/2}]d_{3/2}$, $[^2F_{7/2}]d_{5/2}$, $[^2F_{5/2}]d_{3/2}$, and $[^2F_{5/2}]d_{5/2}$ levels (Fig. 10). Figure 10 shows the $4f^{13}5d^1$ free ion energy level scheme. All the electric dipole transitions from the $^1S_0$ ground state to these levels, except those where $J = 1$, are not allowed due to the $\Delta J = 0, \pm 1$ (not $0 \leftrightarrow 0$) selection rule. Of these, the $J = 1$ level of the $[^2F_{5/2}]d_{5/2}$ state is predominantly ^1P in character, and therefore the transition to the ground state is spin allowed; the $J = 1$ levels of the $[^2F_{7/2}]d_{5/2}$ and $[^2F_{5/2}]d_{3/2}$ states are predominantly ^3D and ^3P in character (7), and therefore the transition to the ground state is not allowed because of the $\Delta S = 0$ selection rule. Piper *et al.* (8) have investigated the effect of a cubic crystal field on the free ion levels of Yb^{2+}. They obtained good agreement with the absorption spectrum of Yb^{2+} in $SrCl_2$ by calculating the mixing of the un-allowed states with the ^1P state in cubic symmetry and taking a Dq value of 800 cm^{-1} for the crystal field strength. Only those levels which had T_{1u} symmetry in a cubic

field were considered, since this is the symmetry of the ^1P state in a cubic field. In this treatment, no reasonable approximations were possible, since the electrostatic interactions, the spin-orbit coupling, and the crystal field for Yb^{2+} were of the same magnitude.

The electrostatic and spin-orbit coupling interactions tend to make the transitions from the lower levels of the $4f^{13}5d^1$ to the ground state not allowable. The effect of the crystal field is to make the transitions partially allowable. Therefore the decay times for the Yb^{2+} transitions should be longer than is observed for Ce^{3+} ($\approx 10^{-7}$ sec) and Eu^{2+} ($\approx 10^{-6}$ sec), where the crystal field effects are dominant (3). However, they should be shorter than the decay times of the 4f-4f transitions in the rare earth ions ($\approx 10^{-3}$ sec), where the effects of the crystal field are minimal. Indeed, decay times of the Yb^{2+} emissions in the hosts described in this paper under CR excitation are of the order of 10-60 x 10^{-6} sec to 10% I_0 (Table I).

The Ca, Sr, Ba apatites and the Ca spodiosite lattices have two low symmetry metal ion sites, C_3, C_s and C_2, C_s point symmetries, respectively. Contrary to the case in $SrCl_2$, where the high symmetry of the crystal field allows only a select few number of states to mix with the ^1P state, in the spodiosite and apatite metal ion sites all the $[^2F_{7/2}]d_{3/2}$ and $[^2F_{7/2}]d_{5/2}$ states can mix with the ^1P state. Furthermore, the crystal field can totally remove the degeneracy of the J states, so that there can be a total of 80 individual levels. The $[^2F_{5/2}]d_{3/2}$ and $[^2F_{5/2}]d_{5/2}$ states are not considered because they are too far above the ground state to be observed. Since the Yb^{2+} ion in these hosts exhibits only four main absorption and excitation bands in the 400-280 nm region, we are probably not observing the splitting of the individual J states within the $[^2F_{7/2}]d_{3/2}$ and lower lying $[^2F_{7/2}]d_{5/2}$ states, at least not at liquid nitrogen temperatures. The effect of the crystal field is probably to broaden the J states.

The excitation spectra for the Yb^{2+} emissions show relatively sharp and well-defined bands, *e.g.*, Fig. 1B, 4. This is in contrast to the excitation spectra of other activators whose emissions also involve $4f^n5d^1 \rightarrow 4f^{n+1}$ transitions, *e.g.*, Ce^{3+} and Eu^{2+}, but whose excitation spectra are relatively broad and without fine structure (3, 9). In the absence of appropriate theoretical calculations, these differences can be explained qualitatively in the following way: In the case of Ce^{3+}, whose lowest excited configuration is $4f^05d^1$, the energy level scheme can be explained on the basis of the splitting of the pure 5d orbital by the crystal field (1). The excited state levels are therefore expected to interact strongly with the crystal field leading to broad excitation bands. On the other hand, the Yb^{2+} and Eu^{2+} excited states are $4f^{13}5d^1$ and $4f^65d^1$, respectively, and therefore contain a large degree of f orbital character. As a result the crystal field does not broaden these levels to the same extent that the pure d-character excited states of Ce^{3+} are broadened. However, in the case of Eu^{2+}, the observed broadening can be attributed instead to the greater complexity of its electronic structure in comparison to that of Yb^{2+}. The $4f^6$ core in Eu^{2+} has a ^7F Russell-Saunders state, which will couple with the d electron to produce the lowest lying $4f^65d^1$ levels. The total multiplet splitting of the ^7F state is observed to be approximately 5000 cm^{-1} in Eu^{3+}. Indeed, Freiser *et al.* (11) have observed the structure of the lowest lying uv absorption band of EuF_2 at 20°K and have attributed the seven observable bands to the individual J components of the ^7F state. At room temperature thermal broadening will result in the observation of one broad band. Finally, Yb^{2+} is unique in the sense that the $4f^{13}$ core produces only a $^2F_{7/2}$ and a $^2F_{5/2}$ level, which are well separated by a strong spin-orbit coupling parameter. Consequently, this leads to a relatively well-defined excitation spectrum.

Ca *chlorophosphate and vanadate spodiosite systems.*—The emission spectra of Yb^{2+}-activated Ca chlorophosphates and vanadates with spodiosite structure at liquid nitrogen and room temperature are shown in Fig. 1A, 2A. The fluorescence spectrum of the phosphate spodiosite at liquid nitrogen temperature exhibits two bands centered at 455 nm and 505 nm. As evident in Fig. 1B, the excitation spectrum at liquid nitrogen temperature for each band is distinct and relatively sharp ($\lambda_{1/2} \approx 20$ nm).

The Ca chlorovanadate of spodiosite structure exhibits only one broad band emission at liquid nitrogen temperature (Fig 2a), which is centered at 460 nm. The broad band excitation spectrum is similar to the reflectance spectrum of the unactivated vanadate (Fig. 2b) and is undoubtedly due to absorption into the vanadate host which is followed by transfer to the Yb^{2+} ion. If we assume that the Yb^{2+} is distributed between the two available lattice sites, then the single emission band may be either a composite of the fluorescence of ions on both sites or representative of luminescence from one site only. The complex nature of the fluorescence intensity *vs.* temperature curve of the vanadate compound (Fig. 9b) supports the argument that there are two overlapping emissions present. The temperature relationship appears to approximate a composite of that observed for the two emissions in the Ca phosphate spodiosite (Fig. 9c, d).

Ba, Sr, *and* Ca *chlorophosphates with apatite structure.*—At liquid nitrogen temperatures the emission spectra of Yb^{2+} in the Ba, Sr, and Ca apatites consist of one, two, and three bands as shown in Fig. 3, 5, and 6. The presence of three fluorescence bands in the Ca apatite, which has two available sites for the activator, implies that at least two of the bands are a result of transitions of the Yb^{2+} in the same site. The blue emissions centered at 455 and 435 nm in the Sr and Ca apatites show relatively small Stokes shifts of approximately 3700 and 1700 cm^{-1}. The lowest lying excited states for these emissions are at 390 and 405 nm. This small Stokes shift is probably also responsible for the relative sharpness of these emissions ($\lambda_{1/2} \approx$ 500-600 cm^{-1}). In contrast the emission centered at 620 nm in Ca apatite has a Stokes shift of approximately 11,000 cm^{-1} and an emission halfwidth of approximately 3000 cm^{-1}.

Among the apatites, the Yb^{2+} emission intensity in the Ca compound is the one most influenced by temperature, while the Yb^{2+} emission intensity in the Ba compound is the least affected (Fig. 9). This trend among isostructural hosts is also found to be true for the Eu^{2+} emission intensities in the silicates (3). The smaller size of the sites in the Ca compound allows for a stronger vibronic interaction of the activator excited state and the host and a higher probability of a nonradiative transition.

In the phosphors where there is more than one emission band, the emissions with the smaller Stokes

shifts have a lower quenching temperature. For example, as can be seen in Fig. 9f and g, in Sr apatite the 450 nm emission is thermally quenched at a much lower temperature than the 610 nm emission. This is unusual, since Blasse *et al.* (3) have shown that in Eu^{2+}-activated silicates the emissions that have the larger Stokes shifts usually have a much lower quenching temperature, due to a higher probability of crossover between the ground state and excited state of the activator ion.

Sr *orthophosphate system.*—The $Sr_3(PO_4)_2$ lattice also provides two divalent metal ion sites which have slightly higher symmetries (D_{3d},C_{3v}) than those in the apatite and spodiosite structures. The emission of Yb^{2+} in $Sr_3(PO_4)_2$ shows only one main absorption band at room and liquid nitrogen temperatures. In this compound the emission intensity *vs.* temperature curve (Fig. 9a) is not complex, and therefore there probably is emission from predominantly only one site.

Acknowledgments

The authors are grateful to J. Ragusin for his assistance in the experimental work. Helpful discussions with C. S. Wiggins, S. Natansohn, and R. Amster are acknowledged. The use of a computer program to apply the correction functions to the recorded spectra was supplied by O. J. Sovers. The C.R. decay measurements were recorded by V. D. Meyer.

The Deposition and Physical Properties of Aluminosilicate Films

S. K. Tung[1] and R. E. Caffrey

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania

ABSTRACT

A CO_2-H_2-$AlCl_3$-$SiCl_4$ process used to deposit various compositions of aluminosilicate films on a silicon substrate held at various temperatures is described. The film deposition rate with a total vapor (0.42 Al_2Cl_6 + 0.58 $SiCl_4$) concentration of 0.12 v/o (volume per cent) in the gas phase is 2500 Å/min at 1100°C and 150 Å/min at 880°C with an activation energy of 42.5 kcal/mol. in this temperature range. The deposition rate is increased as the Al_2Cl_6 concentration is increased. The chemical composition of the films was determined by x-ray fluorescence. The films were smooth to the eye but grainy at 12,000 times. A compositional relationship between indices of refraction of Al_2O_3 (1.76) and SiO_2 (1.46) was found. The dielectric strength of the films (6×10^6 — 1.7×10^7 V/cm) was found to be similar to SiO_2 (5-6 $\times 10^6$ V/cm) or higher.

Sodium diffusion data for aluminosilicate films and silica films are presented. For a given film depth sodium concentration in an aluminosilicate film is less than the concentration in a silica film. CV measurement of an MIS capacitor gave a typical surface charge (Q_{ss}) of 1-2 $\times 10^{11}$/cm^2. Films of less than 50% Al_2O_3 were etchable in concentrated hydrofluoric acid or in buffered hydrofluoric acid. Films of greater than 50% Al_2O_3 were somewhat resistant to hydrofluoric acid but were etched in hot (180°C) phosphoric acid with a rate about 100 Å/min.

The beam-lead-sealed-junction (BLSJ) technology has been developed in order to eliminate the need for vacuum sealed packages in high reliability semiconductor devices and circuits. For application to bipolar devices BLSJ structures utilize the Lepselter metallurgy and silicon nitride (1). To apply this same technology to insulated gate field effect transistors the dielectric film used must have a stable and a low surface charge density in order to achieve and maintain a low threshold voltage. In addition the film must provide resistance to sodium penetration in order to achieve long-term stability. Although silicon nitride (Si_3N_4) films have been shown to be good barriers to alkali ions (2) they normally exhibit a comparatively high surface charge density which yields a higher than desired threshold voltage (> 2V). Several techniques, *i.e.*, *in situ* cleaning and *in situ* oxide deposition, were used in an effort to improve the properties of the Si_3N_4 films (3). However, the characteristic surface charge density of such films was too high for the required devices. Thus another insulator film was sought. This search has led to alumina, an insulator which, when placed over a thin film of SiO_2 satisfies the requirements.

The deposition of metal (Si, Al, Ti) oxide on silicon by the reaction of the respective metal halide compound

[1] Present address: IBM Components Division, Essex Junction, Vermont.

with a hydrogen-carbon dioxide mixture had been studied previously by Tung and Caffrey (4). A film composed of a mixture of aluminum oxide and silicon dioxide had also been cursorily studied. This paper discusses more recent work on deposited aluminosilicate film using the H_2-$SiCl_4$-$AlCl_3$ system and discusses process parameters, physical properties, and the composition of the films.

Experimental

The system employed for deposition was a vertical, single wafer system developed for deposition of epitaxial silicon and silicon dioxide (4). To deposit an aluminosilicate film, sources of both aluminum and silicon were required, and $AlCl_3$ and $SiCl_4$ were used. Because $AlCl_3$ is a solid, and has a low-vapor pressure at room temperature, it was necessary to vaporize $AlCl_3$ at an appropriate elevated temperature in the region of 95°-115°C. Aluminum chloride exists as a dimer (Al_2Cl_6) in the gaseous state (5). The dimer was kept in the gaseous state, diluted with hydrogen (H_2), and delivered to the reaction zone close to the silicon substrates unreacted and still in the gaseous state. This was accomplished by placing the aluminum chloride source in a specially designed saturator within an oven and wrapping the gas line downstream of the oven with heating tape to heat the gas line 30°-50°C hotter than the oven temperature. Al_2Cl_6 and $SiCl_4$ vapors in H_2 were carefully monitored by means of flowmeters and were admitted to the reaction chamber simultaneously. The compositions of the Al_2Cl_6 and $SiCl_4$ vapor mixtures were calculated from the respective source temperatures and the corresponding flow rates. Figure 1 shows a schematic drawing of the system used for aluminosilicate film deposition.

The aluminosilicate films were usually deposited on 50 ohm-cm, p-type silicon slices. Occasionally 10 ohm-cm, n-type silicon slices or slices of other resistivities were used for deposition studies. In general the oxide deposition was independent of the silicon substrate resistivity.

A typical aluminosilicate deposition was performed in the following manner. The silicon substrate was etched with a 2% (by volume) hydrogen chloride (HCl) gas in H_2 at 1275°C for 10 min. This operation removed approximately 12μ of silicon and gave a clean, strain-free surface. After gas etching the oxide deposition was done either (*a*) by lowering the slice temperature from 1275°C to the deposition temperature ($\leq$ 950°C) and admitting the reactant gases or (*b*) by lowering the temperature from 1275°C to approximately 800°C, admitting the reactant gases and raising the slice temperature to the deposition temperature ($\geq$ 950°C). The latter procedure was designed to deposit a film without any etching occurring at the oxide-free silicon interface. Such a phenomenon has been occasionally observed at the SiO_2-Si interface when SiO_2 was deposited at high temperatures ($\geq$ 1200°C). The deposition procedure chosen depended on the deposition temperature used because etching of the interface was not observed in aluminosilicate deposition at $\leq$ 1000°C.

The rate of deposition of an aluminosilicate film deposited from a gaseous mixture of 42% Al_2Cl_6 and 58% $SiCl_4$ was studied as a function of temperature. The deposition procedure was that outlined in method (*a*) above. The gas mixture had a total vapor ($SiCl_4$ + Al_2Cl_6) concentration of 0.12 v/o. The carbon dioxide (CO_2) concentration was about 1%.

Results and Discussion

Factors affecting the rate of oxide deposition.—A plot of logarithm of the deposition rate *vs.* $1/T$ where T is absolute temperature resulted in a straight line and is shown in Fig. 2. The activation energy derived from the slope is 42.5 kcal/mol. As a comparison the activation energy for SiO_2 deposition from the CO_2-H_2-$SiCl_4$ process was 51.6 kcal/mol (4) and the activation energy for Al_2O_3 deposition from the CO_2-H_2-$AlCl_3$ process was 30.3 kcal/mol.

Figure 3 is a plot of the deposition rate at 1100°C *vs.* the percentage of Al_2Cl_6 vapor concentration in an Al_2Cl_6-$SiCl_4$ vapor mixture, which constituted 0.1% of the total gas input to the reactor. The deposition procedure was that outlined previously in method (*a*). This figure indicates a tendency for the deposition rate to increase as the percentage of Al_2Cl_6 vapor concentration is increased; however, the deposition rates of the SiO_2-rich aluminosilicate compositions were higher

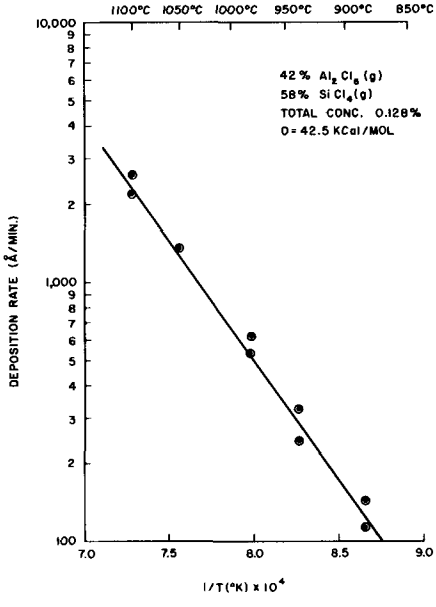

Fig. 2. Deposition rate vs. 1/substrate temperature

than the expected values. If a simple hydrolysis reaction were the deposition mechanism, one would have expected a simple addition of the percentages of the individual oxide rates (Fig. 3, broken line) for the aluminosilicate deposition rates; thus, a simple hydrolysis reaction is not sufficient to account for the deposition rate of aluminosilicate films. The break in the two regions is not explained except to note that the electron diffraction patterns of the films changed near the break. That is, the film structure was polycrystalline with an associated amorphous background on the low side of the Al_2Cl_6 concentration and was polycrystalline with preferred orientation on the high side of the Al_2Cl_6 concentration. These results will be discussed more extensively in a later paper.

The deposition rate was averaged in several trial runs at various gas compositions by depositing slices for various times and measuring the thickness with an uv-visible spectrophotometer (6). The measured thickness was corrected by a factor deduced from the composite index of refraction according to the vapor composition. The measured film thickness should be corrected by a factor derived from the actual film composition. However, the correction factor is not a very sensitive function of the refractive index, and thus the thickness is not in great error. The error in the real thickness is estimated to be no greater than 4 per cent. The spectrophotometric method used to make the thickness measurements was discussed in reference (6) and was calibrated by multiple-beam interferometry.

Chemical composition of aluminosilicate films.—An x-ray fluorescent technique was used to determine the compositions of aluminosilicate films deposited on tantalum substrates. Tantalum was employed because of its limited fluorescence contribution to the measurement of the film; hence all the counting can be attributed to the film only. Figure 4 shows the resultant data showing the composition of Al_2Cl_6 in the vapor *vs.* measured Al_2O_3 in the film.

If similar over-all reaction rates for the hydrolysis of Al_2Cl_6 and $SiCl_4$ are assumed, the solid aluminosilicate film should have the same composition as the respective vapor constituents. This relationship is shown as a broken line in Fig. 4. Experimentally the actual alumina (Al_2O_3) composition in the film was slightly higher than that of Al_2Cl_6 in the vapor state. This deviation is thought due to a rate difference between the hydrolysis reaction of aluminum chloride (Al_2Cl_6) and that of silicon tetrachloride ($SiCl_4$), *i.e.*, Al_2O_3 deposited faster than SiO_2 (see Fig. 3).

Film structure and composition.—The film structure was determined by electron diffraction. When the aluminum chloride concentration (Al_2Cl_6) was 15% or less the films were found to be amorphous. As the Al_2Cl_6 concentration is increased, the film becomes more crystalline. However, the crystalline film structure is complex and is composed of andalusite, sillimanite, κ- and α-alumina depending on the vapor concentration and the deposition temperature. These structures will be discussed in detail in another paper.

Some properties of aluminosilicate films.—Surface characteristics.—The aluminosilicate films usually were transparent and smooth to the eye; however, the film surface (at 12,000 × magnification) was somewhat grainy when compared with a deposited SiO_2 film surface. Figures 5a and 5b show electron micrographs of surface replicas of aluminosilicate and SiO_2 films, respectively.

Index of refraction.—The indices of refraction of the films were measured with an ellipsometer. Figure 6 shows a plot of index of refraction versus oxide composition. The oxide composition was the vapor composition corrected according to Fig. 4. The deviation of the points from a straight line relationship in Fig. 6 probably represents a small error resulting from the use of empirical corrections of the calculated gas compositions.

Dielectric strength.—The dielectric strengths of the films measured with a ROYCO anodicator are given in Table I. It can be noted that the value for pure alumina was found to be about the same as that for SiO_2 (4). For a mixed oxide film of approximately 50% Al_2O_3 the values were somewhat higher.

Sodium diffusion and surface charge density.—Aluminosilicate films deposited at 900°C with a composition of approximately 50% Al_2O_3 and 50% SiO_2 were investigated for their response in sodium diffusion and also for evaluation of surface charge density. The sodium diffusion experiment was done by a radioactive tracer technique (7). $Na^{22}Cl$ and $Na^{23}Cl$ were evaporated onto the film and heated at 600°C in forming gas for 22 hr. The film was then etched, and the Na^{22} activity was counted. Figure 7 shows a plot of total sodium concentration *vs.* film depth. The result indicates that when 750Å of the film was removed the sodium concentration in the film dropped from 7×10^{19} at./cm^3 to 1.2×10^{17} at./cm^3. As a comparison, sodium diffusion data on a steam grown silica film under similar heat-treatment conditions is also shown in Fig. 7. It can be noted that the concentration of Na^{22} in the SiO_2 film for a given film depth was an order of magnitude or more higher than the concentration in an aluminosilicate film.

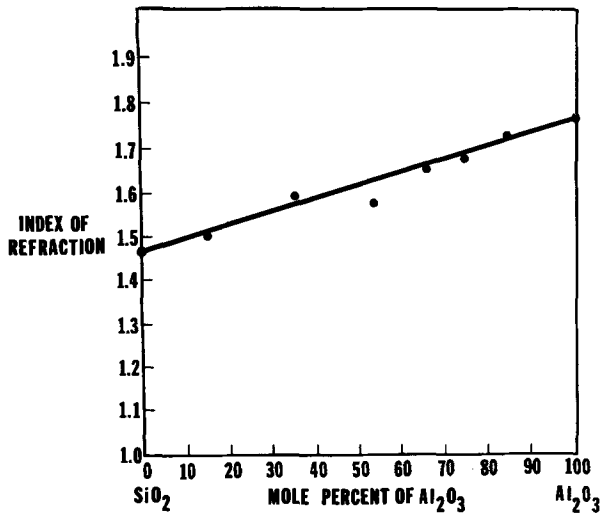

Fig. 6. Index of refraction vs. aluminosilicate film composition

The total surface charge density was evaluated by means of a C-V measurement of a metal-insulator-semiconductor (MIS) capacitor. Typically 1-2x10^{11}/cm^2 was observed.

Etching.—Aluminosilicate films deposited at 1100°C with a composition of 50% Al_2O_3 or higher showed resistance to hydrofluoric acid (48%). Films with less than 50% of Al_2O_3 could be etched in concentrated HF or in ammonium fluoride buffered HF acid. However, etch figures such as those shown in Fig. 8 were developed after etching in buffered HF. These effects were thought due to the precipitation of etching products during the etching. No etch figures were observed when films were etched in concentrated HF. Tillotson (8) observed similar etching figures and attributed them to etching solutions. He stated: "The form of the etch figures is independent of the chemical composition of the glass, and is determined by the composition of the etching solution; *i.e.*, buffered HF." Hot phosphoric acid was found capable of etching the films not etched in HF. A typical rate for hot (180°C) H_3PO_4 of films with greater than 50% Al_2O_3 was about 100 Å/min.

Summary

A CO_2-H_2-$AlCl_3$-$SiCl_4$ process has been described for depositing aluminosilicate films of various compositions on silicon substrates held at various temperatures. The activation energy for the deposition process was found to be 42.5 kcal/mol from about 850° to 1100°C. The deposition rate increased as the aluminum chloride vapor concentration increased.

The chemical composition of the films as measured by an x-ray fluorescence technique gave higher values than the respective vapor constituents. The error of this measurement is estimated to be less than 5%.

Table I. Film dielectric strength as measured with an anodicator*

Film composition calculated from vapor composition		Dielectric strength
Al_2O_3 (%)	SiO_2 (%)	(V/cm)
100	—	5.95 × 10^6
100	—	6.95 × 10^6
81.9	18.1	7.20 × 10^6

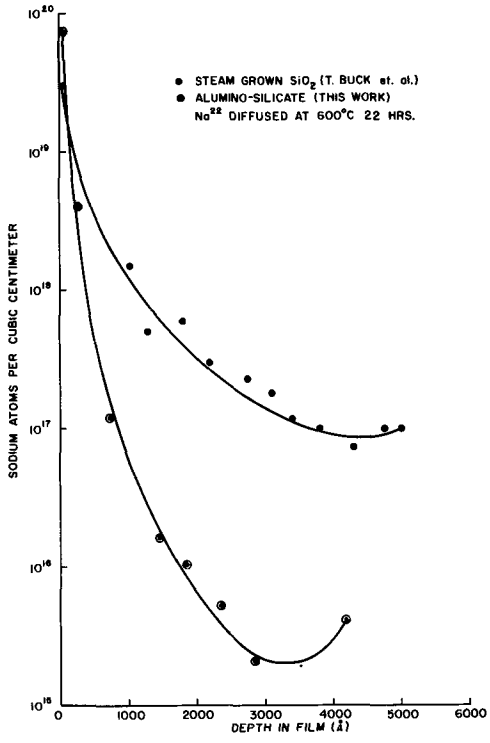

Fig. 7. Sodium profile in aluminosilicate film

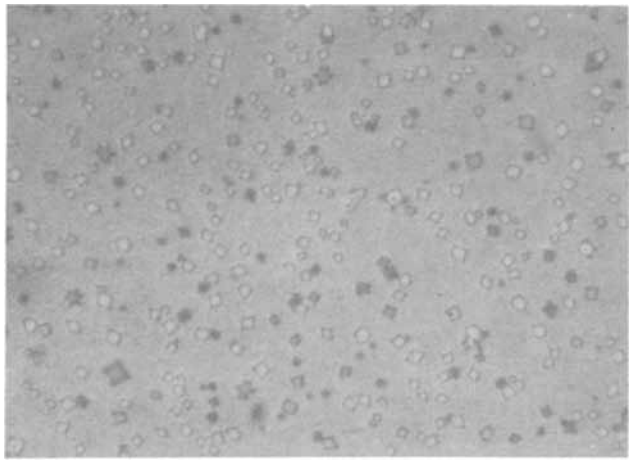

Fig. 8. Etch figure of aluminosilicate film in buffered hydrofluoric acid. Magnification 450X.

Aluminosilicate film surfaces appeared smooth to the eye, but were grainy at a magnification of 12,000×. The index of refraction of the films seemed to bear a simple relationship to indices of Al_2O_3 and SiO_2. The dielectric strengths of the films were the same or somewhat higher than that of SiO_2. Sodium diffusion data of aluminosilicate film and data of silica film were compared. For a given film depth the sodium concentration in aluminosilicate films was significantly lower than the concentration in similarly treated silica films. Measurement of a typical MIS capacitor gave a surface charge density of 1-2x10^{11}/cm^2. Films of less than 50% Al_2O_3 can be etched in concentrated hydrofluoric acid or in buffered hydrofluoric acid. Films of greater than 50% Al_2O_3 showed resistance to HF, but can be etched in hot (180°C) phosphoric acid with a rate about 100 Å/min.

Growth and Properties of Thin Germanium Films

D. J. Dumin

RCA Laboratories, Princeton, New Jersey

ABSTRACT

Germanium films have been grown via the pyrolysis of GeH_4-H_2 mixtures on thin films of silicon grown on spinel and sapphire. The thin layer of silicon (≈1000Å) was used to produce improved crystal structure in the germanium layer. In addition, the silicon undercoating provided improved adhesion of the germanium to the substrate, particularly at germanium growth temperatures above 700°C. The electrical properties of the films are described in terms of substrate orientation, silicon and germanium growth temperatures, and doping density. Both p- and n-type films 2 μm thick have been grown reproducibly with mobilities in excess of 1200 cm^2/V sec at carrier concentrations in the $10^{16}/cm^3$-$10^{17}/cm^3$ range. These films were sufficiently perfect to allow observation of the indirect-direct transition in the conduction band at 0.8 ev in the optical absorption data.

Epitaxial growth of semiconducting films on insulating substrates has been reported for such material combinations as silicon-on-sapphire (1), silicon-on-spinel (2), germanium-on-sapphire (3), germanium-on-spinel (4), germanium-on-calcium floride (5), and gallium arsenide-on-sapphire (6). Various techniques for transporting the semiconductor have been reported with vacuum deposition, chemical vapor transport, hydride decomposition, and reduction from the halide being used. With respect to germanium films on insulating substrates, relatively high carrier mobilities have been reported in films thicker than 10 μm. In particular, 20-40 μm thick films deposited by chemical vapor transport on sapphire have had mobilities of 1500 and 560 cm^2/V sec at carrier concentrations of $3 \cdot 10^{16}/cm^3$ and $9 \cdot 10^{18}/cm^3$ in p- and n-type films, respectively (3). Polycrystalline germanium films vacuum deposited on sapphire (7) and glass (8) have had mobilities as high as 1455 and 270 cm^2/V sec, respectively, for film thicknesses of the order of 8-17 μm.

The mobility of germanium-on-insulator films is known to drop as the film thickness is reduced; however, mobilities as high as 800 cm^2/V sec have been reported on 2 μm thick p-type films vacuum deposited on calcium fluoride (5). We have been studying the electrical characteristics of germanium films less than 10 μm thick grown on sapphire and spinel substrates via the decomposition of germane-hydrogen mixtures. The mobilities reported for germanium films grown on spinel in the hydride system have been relatively low, and the electrical characteristics of these films appear to be dominated by crystalline imperfections (4).

It has been shown that defects in both heteroepitaxial silicon (9) and germanium (10) are partially self-annihilating as the films grow thicker. Recently, evidence has been presented indicating that the defects can behave electrically as relatively deep donors and acceptors in silicon-on-sapphire films (11) and as shallow acceptors in germanium-on-sapphire or spinel films (12). Thus, any improvement in the crystal structure of the initial germanium layer grown near the germanium-substrate interface would be expected to lead to an improvement in the properties of the films as reflected in both a higher mobility and a lower defect and shallow acceptor concentration. In the case of germanium-on-spinel films grown via decomposition of GeH_4, it was observed that, as the growth temperature increased, the mobility rose and the acceptor concentration dropped (4). However, at growth temperatures in excess of 700°C, the films tended to agglomerate, and, while good single crystals of germanium could be grown on the spinel at growth temperatures in excess of 700°C, the films were often either discontinuous or highly nonuniform in thickness. It proved impossible to grow 1-2 μm thick germanium films on sapphire or spinel at growth temperatures above 700°C because of the tendency of the germanium to agglomerate. Also, films grown on the spinel in the hydride system often were so poorly bonded to the substrate that they could be removed easily from the substrate by scratching.

In order to attempt to grow thin germanium films at higher growth temperatures and to provide a good nucleating layer, it was decided to try using a very thin (≈ 1000Å) layer of silicon grown on the sapphire or spinel at a high temperature prior to growth of the germanium layers. This paper describes the results of experiments conducted using a thin layer of silicon as the undercoat for the germanium. The improvement in the quality of the germanium layer will be shown to be reflected electrically in both lower acceptor concentration and higher Hall mobilities than have previously been obtained using the hydride system. The improvement in the film quality was also reflected optically in a sharp indirect-direct transition in the absorption data. A somewhat analogous scheme has recently been successfully used for the growth of GaAs on Ge-on-sapphire (13).

Experimental Techniques

The experimental techniques used to grow the films are similar to those previously described for growing heteroepitaxial silicon (14) and germanium (4), and only the salient features will be discussed here. The films were grown via decomposition of GeH_4 or SiH_4 in

hydrogen in a vertical reaction chamber utilizing RF heating of a silicon susceptor and water cooling of the reactor walls. The doping of the films was controlled by adding dilute mixtures of B_2H_6, or AsH_3 in H_2 to the gas stream during growth. The film thickness was monitored during growth and controlled to the nearest 0.05 μm by using infrared interference techniques (15).

The substrates were $(1\bar{1}02)$ oriented sapphire wafers or (111) and (100) oriented spinel wafers approximately 300 μm thick. Both materials were mechanically polished to a scratch free surface and were subjected to a 1200°-1400°C heating in H_2 prior to growth to restore a single crystal surface to the wafer. The silicon undercoat was grown at various temperatures between 1000° and 1200°C at an average growth rate of 5 μm/min, and unless stated otherwise, was about 1000Å thick. The temperature was then lowered to the germanium growth temperature, and the germanium was grown at temperatures between 500° and 900°C at a growth rate of 2 μm/min. In order to maintain the germanium growth rate of 2 μm/min, it was necessary to increase the GeH_4 flow rates as the substrate temperature was lowered below 700°C. When no dopant was added to the GeH_4 supply, the GeH_4-H_2 mixture used to grow the films produced 2-3 ohm-cm p-type germanium when grown on 40 ohm-cm n-type Ge or 25 ohm-cm p-type germanium, which indicates that this GeH_4 supply was contaminated with acceptors to levels of the order of low-10^{15}/cm^3. The undesired doping due to impurities in the gas supplies was small when compared to the doping levels considered in the experiments performed on the germanium films.

The Hall mobility and resistivity of these films were measured using six terminal etched Hall bars and the carrier concentration derived from the Hall data under the assumption that the ratio of drift to Hall mobility was unity. The deformation of several of the films was measured on a cross section microscope using a previously described technique (16). The films were isotropically deformed and under a compressive stress of about 10^9 dynes/cm^2 which is slightly less than the stress measured in silicon-on-sapphire films (16). The optical absorption coefficient in the energy range from 0.5 to 1.2 ev was determined by measuring the optical density of several films on a Cary Model 14 CMR spectrophotometer.

The Hall mobility and resistivity of several 0.1 μm thick layers of silicon-on-sapphire and spinel were measured to determine what effects the silicon undercoating would have on the measured electrical properties of the germanium films. In general, the Hall mobilities of the silicon undercoatings were 60-120 cm^2/V sec and the carrier concentrations were of the order of 10^{15}-10^{16}/cm^3. Thus the shunting effects of the thin silicon layer could be neglected when interpreting the measurements made on the thicker, higher mobility germanium films.

A schematic sketch of the structure of a typical film grown on sapphire is shown in Fig. 1. The thickness of the interdiffused silicon-germanium region was estimated at less than 500Å by using a diffusion constant of Si in Ge of 10^{-14} cm^2/sec at 850°C (17). The possible effects of this interdiffused alloy region and of the aluminum autodoping on the electrical characteristics of the films will be considered below in some detail.

Experimental Results

Germanium growth temperature.—The temperature at which the germanium was grown strongly influenced the electrical characteristics of the films. At very low growth temperatures and very high growth temperatures, the Hall mobilities were low, and, as in the case of silicon-on-sapphire (14) or spinel (18), there was a growth temperature at which the highest mobility was obtained.

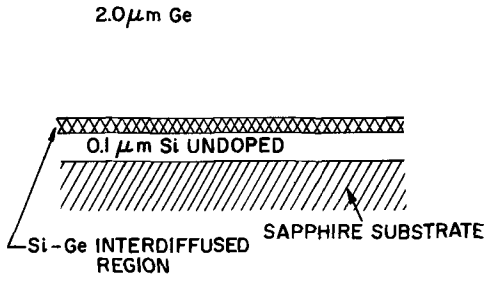

Fig. 1. Schematic sketch of a germanium film grown on a thin layer of silicon-on-sapphire.

Measured values of Hall mobility and carrier concentration are shown in Fig. 2 and Fig. 3, respectively, for 2 μm thick p-type Ge films grown on 0.1 μm of silicon on $(1\bar{1}02)$ sapphire. The silicon undercoat was grown at 1125°C. No intentional doping was added to the gas stream during growth of these films. The films were single crystal (100) oriented as determined from spot patterns on Laue back reflection photographs. These films are compared with some previously reported 2 μm thick germanium films grown directly on sapphire and spinel. Since it proved to be impossible to grow continuous 2 μm thick germanium films on the insulator at growth temperatures above 700°C without the benefit of the thin silicon undercoating, the comparison with films grown directly on the insulators has only been made for growth temperatures below 700°C.

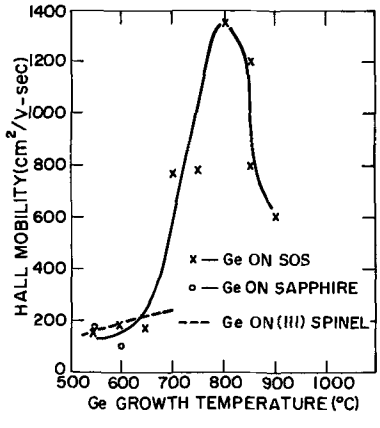

Fig. 2. Measured values of Hall mobility of 2 μm undoped germanium films as a function of germanium growth temperature. Films were p-type.

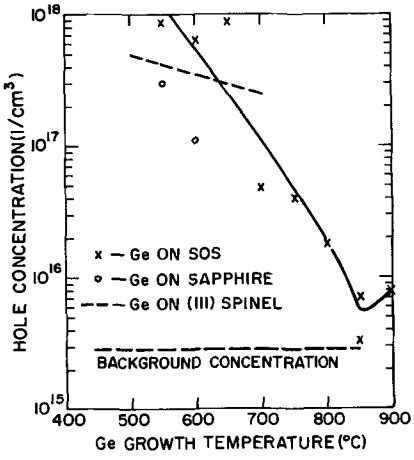

Fig. 3. Carrier concentration vs. germanium growth temperature for p-type films grown with no intentional added dopant.

As seen in Fig. 2, the highest mobility films were obtained at growth temperatures in the vicinity of 800°-850°C where Hall mobilities in excess of 1000 cm^2/V sec were obtained. The mobility fell off at both higher and lower growth temperatures. The resistivity of all of the films rose as the growth temperature increased and films of the order of 1-2 ohm-cm were obtained at growth temperatures of 850°-900°C. The lowest carrier concentrations were obtained at growth temperatures of 850°-900°C. The data of Fig. 2 and Fig. 3 show that the optimum germanium growth temperature was around 800°-900°C where both high mobilities and low acceptor concentrations were obtained when the thin silicon undercoating was present.

No doping was purposely added to these films and yet the hole concentration measured in Fig. 3 was, in general, dropping as the growth temperature increased. Similar effects of lowered carrier concentrations as a function of increasing growth temperatures have been reported in Ge-on-spinel (4) and Ge-on CaF_2 (5) and has been attributed to the action of defects acting as acceptors (5). The possibility that impurities could be doping the films should be considered, however. The fact that the carrier concentration dropped as the growth temperature increased would argue against an autodoping process based on either aluminum originating from the back of the wafer or from the silicon undercoating.

The thickness of the silicon undercoating had relatively little effect on the measured electrical characteristics of the films, provided, of course, that the thickness of the silicon was small compared to the germanium thickness. The silicon undercoating was varied in thickness from 0.04 to 0.3 μm and the mobility and carrier concentration of 2 μm thick germanium films grown on these undercoatings did not appear to significantly vary. Several of the undoped p-type germanium films were annealed at 850°C in H_2 for 1 hr to 4 hr immediately after growth, and no significant changes in the electrical characteristics of these films were found when compared with unannealed films.

Silicon growth temperature and substrate orientation.—The temperature at which the silicon undercoat was grown and the substrate orientation played an interrelated role in determining the electrical properties of the germanium layers. In order to demonstrate the relationship between silicon growth temperature and substrate orientation on the properties of the germanium films, a series of germanium films were grown on silicon undercoatings grown at different temperatures on three orientations of substrates. The substrate orientations and growth temperatures chosen for this experiment are shown in Fig. 4, where published curves of Hall mobility *vs.* growth temperature for 2 μm thick silicon-on-sapphire and silicon-on-spinel films are plotted (19). Silicon films 0.1 μm thick were grown at the six orientation-temperature points shown in Fig. 4. On top of these thin undercoatings, 2 μm thick films of undoped germanium were grown. The electrical characteristics of these films are described in Table I. All of the films were p-type, and

Table I. Properties of germanium films grown on 0.1 μm layers of silicon grown at different temperatures and on different substrate orientations. Germanium films were grown with no impurities intentionally added during growth and all of the films were p-type.

Substrate	Silicon growth temp, °C	Hall mobility, cm^2/V sec	Resistivity, ohm-cm	Carrier concentration, l/cm^3
$(1\bar{1}02)$ Sapphire	1050	1040	1.2	$5.5 \cdot 10^{15}$
$(1\bar{1}02)$ Sapphire	1125	1200	1.5	$3.5 \cdot 10^{15}$
$(1\bar{1}02)$ Sapphire	1200	360	0.3	$6 \cdot 10^{16}$
(100) Spinel	1200	730	0.7	$1.3 \cdot 10^{16}$
(111) Spinel	1125	250	0.16	$1.4 \cdot 10^{17}$
(111) Spinel	1200	870	0.8	$9 \cdot 10^{15}$

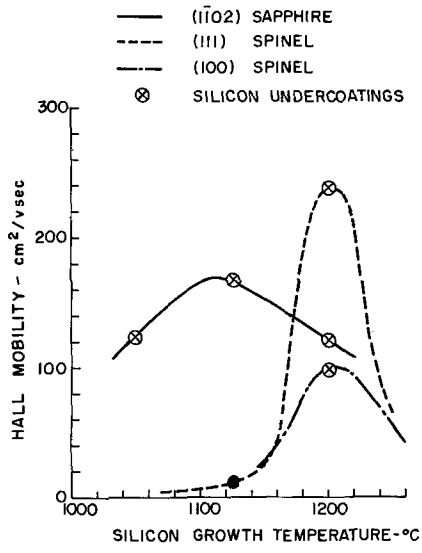

Fig. 4. Hall mobility of 2 μm thick silicon-on-sapphire and silicon-on-spinel films as a function of orientation and growth temperature. Points marked were chosen for growth of the silicon undercoatings. Curves taken from ref. (14) and (18).

the carrier concentration and Hall mobility were reasonably well correlated with the mobility of the thicker silicon films grown on the insulators.

For example, of the three films grown on silicon-on-$(1\bar{1}02)$ sapphire, the highest Hall mobility and the lowest carrier concentration were measured on the film grown on silicon grown at 1125°C. This temperature is relatively close to the maximum in the mobility *vs.* growth temperature curve for thicker silicon-on-$(1\bar{1}02)$ sapphire. The film grown on the silicon grown at 1050°C had a higher carrier concentration than the film grown on the silicon grown at 1125°C, which would argue against a doping mechanism based on autodoping of the films by aluminum. These same general comments apply to the three films grown on silicon-on-spinel where the highest mobility and lowest carrier concentration were measured in the film grown on the silicon grown on (111) spinel at 1200°C.

Variation in mobility with doping density.—The variation in the Hall mobility of boron and arsenic doped films was measured as a function of carrier concentration in the range between $10^{15}/cm^3$ to $10^{19}/cm^3$. The dopant was added to the gas stream as B_2H_6 or AsH_3 during growth. The Hall mobilities of the p-type films are compared with mobilities reported for bulk germanium (20) in Fig. 5. The films were grown on silicon grown on $(1\bar{1}02)$ sapphire at temperatures between 1050° and 1100°C. At higher carrier concentrations the mobility of both the films and bulk germanium dropped due to ionized impurity scattering. At the lower concentrations, the mobility rose and was

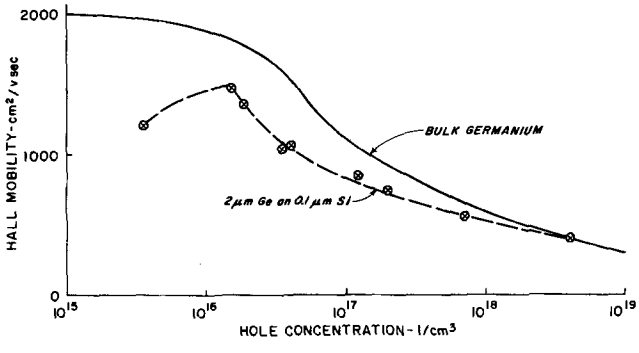

Fig. 5. Hall mobility of p-type germanium films as a function of carrier concentration.

about 60% of bulk values for films with carrier concentrations of the order of 10^{16}-10^{17}/cm^3. The dominant scattering mechanism in these films, as determined from Hall data taken as a function of temperature, was phonon scattering and is described in detail in another paper (12). The film doped $3.5 \cdot 10^{15}$/cm^3 was an undoped germanium layer and would be typical of the undoped films in which defects, acting as acceptors, dominated the electrical properties. In films grown such that the defect density was higher and defect scattering more important, the measured values of Hall mobility were considerably lower than those in Fig. 6. For example, the undoped film grown with carrier concentration of $6 \cdot 10^{16}$/cm^3 described in Table I had a mobility of 360 cm^2/V sec, while the boron doped films grown with similar carrier concentrations, but presumably lower defect densities, had mobilities of the order of 1000 cm^2/V sec.

An attempt was made to grow boron doped films, with a constant boron concentration, on silicon-on-sapphire undercoatings grown at various growth temperatures. The measured values of Hall mobilities of 2 μm thick germanium films on silicon-on-(1$\bar{1}$02) sapphire, doped 10^{16}/cm^3 $\pm$ 30% as a function of growth temperature of the silicon undercoating are shown in Fig. 6. The range in the doping density of the films represents the degree of reproducibility of the present growth system at what is presently considered low doping levels. Although the Hall mobility of these films varied with the silicon growth temperature, the relatively low values often obtained with undoped films were not obtained. In fact, the highest p-type mobilities have consistently been obtained on films containing a small amount of boron doping.

When describing the measurements made on the n-type films as a function of doping density, two effects must be kept in mind. One is that the measured values of electron density represented the difference between the donor (As) density and the defect-caused acceptor density. The n-type films were thus compensated to varying degrees, and, at doping levels comparable to the defect density, low values of mobility may be measured. The second effect concerns the variation of defect density with film thickness. The defects acted as acceptors, and the defect density increased as the film thickness decreased (5, 12). Thus, the portion of the germanium near the silicon interface contained both a higher defect density and a higher acceptor density. This effect, of course, was present in the p-type films. In the n-type films this compensation-thickness variation implied that the films were highly nonuniform in electrical properties as a function of thickness, and the measured values of

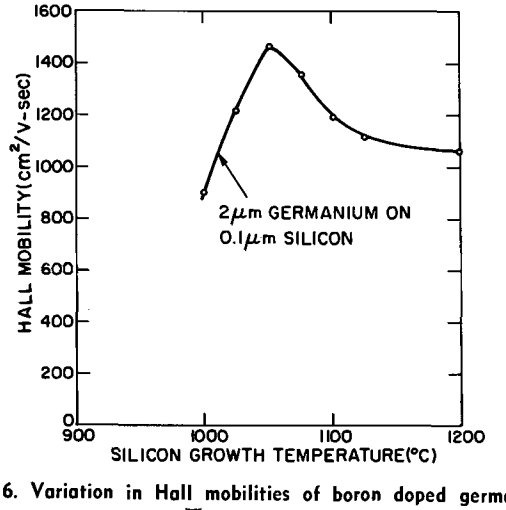

Fig. 6. Variation in Hall mobilities of boron doped germanium films grown on silicon-on-(1$\bar{1}$02) sapphire. Mobilities were measured on films grown on silicon grown at different temperatures.

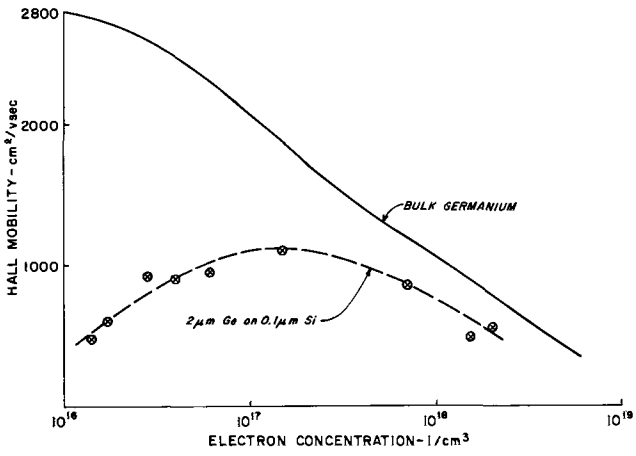

Fig. 7. Hall mobility of n-type germanium films as a function of carrier concentration.

Hall mobility *vs.* carrier concentration shown in Fig. 7 should be taken as indicating an average over the film thickness. The mobility of the outermost layer was higher than the material near the silicon-germanium interface, and on the most lightly doped wafers the germanium near the silicon-germanium interface was over-compensated with defect-acceptors and was p-type (12).

From the variation in Hall mobility with electron concentration as plotted in Fig. 7, it is seen that at high electron concentrations, the mobility paralleled the bulk values (21) where mobilities of 60% bulk mobility have been observed. As the carrier concentration was reduced to the low 10^{17}/cm^3 range, the defect-acceptor compensation became important and dominated the Hall data to concentrations of the order of 10^{16}/cm^3. No 2 μm n-type films have been grown with carrier concentrations lower than 10^{16}/cm^3, which represents the present limits due to the defect-acceptor density.

Absorption coefficient measurements.—The absorption coefficient of several 2 μm thick germanium films was measured in the energy range from 0.5 to 1.2 ev. Two films grown on thin silicon layers with mobilities in excess of 1000 cm^2/V sec and one film grown directly on sapphire with a mobility of 200 cm^2/V sec were used. All three films had smooth surfaces with no large surface structure visible. The absorption coefficient *vs.* energy is plotted in Fig. 8 for these three films. The two films grown on silicon had both lower

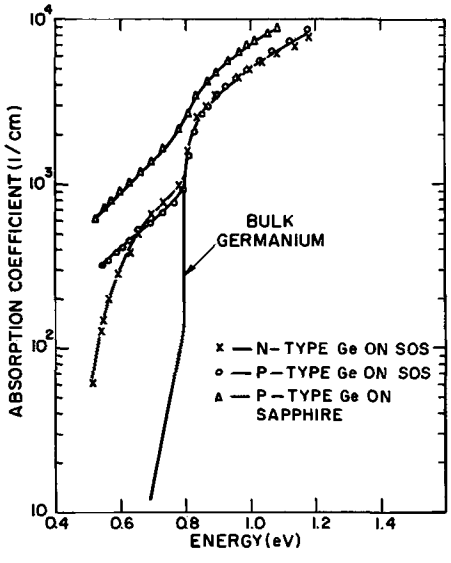

Fig. 8. Absorption coefficient of germanium films with and without the silicon undercoating.

values of absorption coefficient and showed a sharp increase in absorption coefficient at 0.8 ev. The film grown directly on the sapphire had higher values of absorption and only a small increase in absorption coefficient at 0.8 ev. In bulk Ge the increase in absorption coefficient at 0.8 ev has been attributed to excitation of the direct transition to a minimum in the conduction band at $\kappa = [000]$ (22). The absorption coefficients measured on the germanium films grown on silicon-on-sapphire were considerably lower than values reported for germanium directly deposited on sapphire (23). It should be noted that both the thinness of the silicon undercoating and the larger band gap of silicon effectively eliminated the silicon from interfering with these optical measurements.

Discussion and Conclusions

The usefulness of using a thin silicon undercoating to bond germanium films to an insulator has been demonstrated by comparing the electrical and optical properties of these films with films grown directly on the insulator. The silicon undercoating appears to act as a bonding agent to firmly attach the germanium to the sapphire. Even though the silicon undercoating was far from crystallographically perfect, it was sufficiently well structured to allow the high mobility germanium films to be grown using the hydride system.

The effects of the growth parameters on the electrical characteristics of the film were summarized by measuring the film properties grown on various orientations of sapphire and spinel and by varying both the germanium and silicon growth temperatures. The electrical properties of the germanium films depended heavily on the silicon film quality, and it appears as if the highest mobility germanium films were grown on the silicon grown near the optimum growth temperature for that particular substrate and substrate orientation. This makes both (111) spinel and $(1\bar{1}02)$ sapphire attractive for use as a substrate provided the differences in the silicon mobility-growth temperature curves for these two materials are known.

The maximum in the Hall mobility-germanium growth temperature curve shown in Fig. 2 did not occur at the same growth temperature as the minimum in the hole concentration-growth temperature curve shown in Fig. 3. The highest mobility p-type films grown with either no added impurities or with boron added to the films occurred at carrier concentrations of about $1\text{-}2 \cdot 10^{16}/cm^3$. If the defect-acceptor had an activation energy of about 0.15 ev, the Fermi level would lie below this energy in the films doped $2 \cdot 10^{16}/cm^3$, and the acceptor would be neutral, while in the films doped $3 \cdot 10^{15}/cm^3$, the Fermi level would lie above the acceptor energy, and the defect-acceptor would be ionized (24). The larger scattering center associated with the charged center would be expected to result in lower mobilities. While this agreement is highly speculative it would explain the apparent discrepancy in the data shown in Fig. 2 and 3. The assignment of an activation energy for the defect acceptor of 0.15 ev is in reasonable agreement with the multiple shallow levels found in bulk germanium (25).

The effects of the silicon undercoat on the measurement of the electrical properties of the germanium has been neglected even though these silicon layers were doped in the 10^{15}-$10^{16}/cm^3$ range and had mobilities as high as 60-100 cm^2/V sec. Over the range of doping densities and mobilities being considered here, the effects of this silicon underlayer on the measured electrical characteristics of the germanium were certainly negligible. The thin silicon layer was shunted by a thicker layer of germanium which had a higher mobility than the silicon. There was some interdiffusion of the silicon and germanium but this interdiffused region was only of the order of 0.06 μm. The doping density of several silicon undercoatings was measured after the germanium films had been removed and no significant changes in thickness or doping density could be observed when these layers were compared with some test films of thin silicon. Thus, it would also appear that the aluminum present in the thin silicon undercoating was not appreciably doping the germanium film, which would agree with calculations based on the known diffusion constant of Al in Si[26] and Ge[27] at 800°-900°C.

The Hall mobility-carrier concentration data presented in Fig. 7 show the effect of the defect-acceptor on compensating the lightly doped n-type germanium films. The compensation became more significant as the carrier concentration dropped and it was impossible to grow 2 μm thick n-type films with carrier concentrations below $10^{16}/cm^3$. If the defect-acceptor concentration can be used as a measure of the film quality, then the p-type, undoped films reported here have both lower acceptor concentration and higher mobility than have been reported on other similar thickness germanium films. The mobilities and carrier concentrations measured on the n-type films also attest to the relatively high quality of these films grown on the thin silicon undercoating.

The compatibility of the silane-germane system has been used to grow silicon-germanium alloys with composition that could be varied from 30 to 100% Si. These alloys were 1-2 μm thick films, were single crystal, and had measured values of Hall mobilities of the order of 100-150 cm^2/V sec.

In passing, it should be noted that oxygen in the reactor, either in form of a leak or in the form of an oxide on the silicon underlayer, led to agglomeration of the germanium films. The problems associated with growing germanium in the presence of minute traces of oxygen have been discussed recently (28).

Some Recent Developments in Fused Glass Films on Semiconductor Devices

M. Dumesnil* and R. Hewitt

Fairchild Semiconductor Research and Development Laboratory, Palo Alto, California

ABSTRACT

An investigation of methods developed to fabricate and deposit glass films in the near-colloidal state and with a sodium content of less than 10 ppm is described. A brief review of the characteristics and charge effects in high lead glass films is given. Several examples of lead glasses and their application as films on aluminum metallized silicon devices for scratch protection, corrosion resistance, and in mesa isolated structures are presented.

The deposition of dielectric films on metallized silicon devices and microcircuits is primarily directed at the formation of a secondary dielectric layer for crossover or two-layer metal interconnection, mechanical protection of the metal conductor lines, and device stability in nonhermetic packaging. Since aluminum is commonly used as the conductor metal, this puts an upper limit on the secondary dielectric application temperature (577°C Al-Si eutectic). Three low-temperature dielectric deposition techniques are available: glass sedimentation, rf sputtering, and vapor deposition. In contrast to the last two methods, which can produce the equivalent of high-temperature softening point glasses on relatively low-temperature substrates, glass sedimentation requires glass materials of low-temperature softening point. Sedimentation has the advantage of rapid film formation, greater thickness (1.5-6μ or more), simple deposition equipment, and the capability of bonding face-to-face diffused, metallized silicon wafers in the construction of mesa isolated devices.

The recent development of a convenient method of sodium analysis at low levels by flame spectrophotometry has simplified the analysis and control of sodium in materials associated with the processing of semiconductor devices. It has also made possible the evolution of techniques for the processing of substantially low sodium glass. Very good agreement is obtained between sodium content and the drift indicated by MOS C-V analysis.

After a brief review of the physical characteristics and charge effects of lead glasses applicable by sedimentation and low temperature fusion, this paper describes an investigation of methods to fabricate glass in the colloidal state at a sodium level less than 10 ppm. Several examples of lead glass films and their application for silicon device metal scratch protection, corrosion resistance, and in mesa isolated structures are presented.

General Properties of Lead Glass Films

Physical properties.—Sedimented glass is the earliest type of secondary insulating films applied on transistors and diodes. The application of sedimented glass films on silicon devices was first reported by Perri *et al.* (1961) (1), Langdon *et al.* (2), Davis *et al.* (3), and Kerr (4). Pliskin and Conrad (5) showed the importance of the solvent system used in the deposition technique. The first major commercial application of this method is on the silicon diodes and transistors incorporated in IBM's system 360.

In comparison with alternative dielectric deposition methods which utilize either vacuum or a gas phase, sedimentation involves a finely subdivided solid (a glass) set in position by its ability to flow under application of heat. After lowering its viscosity to a point where the solid powder is converted into a continuous transparent film, the layer returns on cooling from its soft state to the brittle, hard characteristic of glass. Glass films of excellent clarity and uniformity can be obtained by sedimentation. The technique involves placing a wafer at the bottom of a centrifuge cup and filling the cup with a measured amount of glass suspension. Centrifugation for a few minutes at about 2000g deposits the glass on the wafer as a fairly adherent layer. A drying and firing step transforms the layer to a glossy, clear film. The two decisive factors resulting in smooth, defect-free films are the glass particle size and the properties of the organic solvents. The smaller the glass particle size, the better. A combination of solvents with widely different dielectric constants but similar viscosity and drying rate is necessary to obtain consistently uniform glass layers (5). The technique is incorporated in the process outline shown in Fig. 1. Glass-coated planar devices are masked and etched to expose the metal contacts. Devices scheduled to be mounted face down are then covered with a metal mask through which a 1-2 mil thick aluminum layer is deposited to form the required metal pads for inverted bonding.

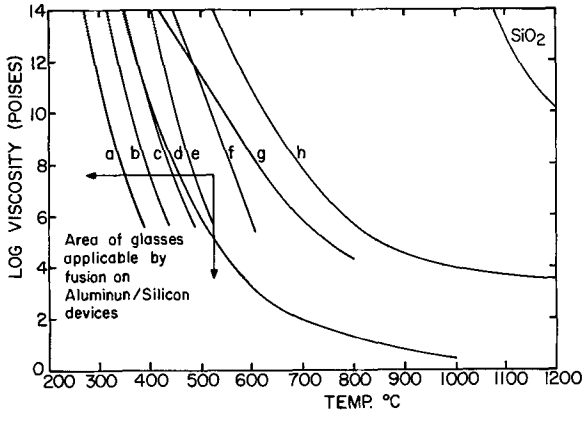

Fig. 3. Relationship between temperature and viscosity of lead glasses, ref. (7) and (8).

The application of a glass film on an oxidized silicon wafer without undesirable cracks in the glass which would impair the effectiveness of the glass film as a hermetic seal requires the selection of a glass with a thermal expansion closely matching silicon to minimize strain. The presence of a layer of SiO_2 between the glass and silicon improves the situation since a graded seal is formed at the silica-glass interface by the solution of the glass into silica to a depth averaging 400-800Å, depending on the time and temperature of fusion. Therefore, the thinner the glass film, the greater the permissible mismatch in thermal expansion. It is possible to apply glass films with a thermal expansion as high as 100 x 10^{-7} 1/°C if the thickness of the glass remains no higher than 1.5μ. Tests with low expansion but high melting glasses demonstrate that mechanically stable 5-15μ thick films can be applied on silicon with glasses having an expansion α no greater than 45 x 10^{-7} 1/°C.

Interest in lead glasses stems from the well-known low gas permeability (Fig. 2) and low alkali diffusivity through high lead glasses which are attributable not only to the large size of the lead cation, but also to the ability of lead to polarize the surrounding oxygen ions and become part of the network. Although lead is not a glass former, PbO and SiO_2 become compatible at high temperature. Both Si^{4+} and Pb^{2+} ions can form stable symmetrical polyhedra due to the polarizability of the Pb^{2+} and O^{2-} ions with silicon to form the normal regular SiO_4 tetrahedron, each oxygen ion being linked to three Pb^{2+} ions and one Si^{4+} ion. This structural picture shows good agreement with the electron diffraction patterns of high lead silicate glasses. The lack of visible absorption of lead glasses suggests that the PbO_6 groups become fairly regular octahedra on cooling the melt. Glasses in the lead corner of the lead borosilicate system possess a uniquely combined balance of low softening temperature, high electrical resistivity, low power factor, and fair moisture resistance. Figure 3 compares the temperature dependence of the viscosity η, and Table I compares the corresponding α, of some typical high lead glasses with two commercial glasses and with fused silica. The significant difference in high lead glasses is the very steep slope of $\Delta\eta/\Delta T$, advantageous in reaching rapidly the working range necessary to obtain a smooth film from the compacted glass powder. It is worthwhile to note that for application on aluminum metallized devices, the glass viscosity curve must intersect the enclosed area in the lower left-hand corner of Fig. 3.

The parent ternary phase diagram, shown in Fig. 4, is useful in determining the liquid temperature which corresponds to the minimum glass smelting temperature as a function of composition. This diagram, however, representing by definition a system in thermodynamic equilibrium, does not tell us whether a glass will be formed by cooling a binary or ternary melt and what properties the glass will assume. If a glass is formed, its softening point will roughly follow the trend of the liquidus-solidus points shown in the diagram. The information the phase diagram will predict exactly is the constitution of the crystalline phases

appearing in the glass on partial or complete devitrification, *i.e.*, recrystallization.

The $PbO-B_2O_3-SiO_2$ ternary contains a most extensive glass forming region. A plot of the softening points as a function of composition produces the envelope shown in Fig. 5. Glasses with a softening point lower than 560°C are limited to the high lead and high boron corners. The excessive water solubility of the high boron oxide glasses rules them out of consideration. The thermal expansion coefficient α of the glasses in the lead borosilicate system is plotted in Fig. 6 and 7. Starting from the binary lead oxide-silica tie line, both α and η decrease initially on addition of boron oxide, but beyond a certain amount of boron α increases (6,7). The lowest points in the valley represent the region of maximum proportion of boron with four oxygen instead of three as nearest neighbors. The presence of up to 10% by weight alumina in lead glasses decreases

α without unduly increasing the softening point or decreasing the viscosity/temperature slope (8,9). Further lowering of α is achievable by the partial replacement of lead oxide by zinc oxide. The properties of four typical lead glasses of increasing compositional complexity are listed in Table II.

The average strain produced in silicon by lead glass films with different linear thermal expansions was derived from the measured radius of curvature of silicon strips parallel to [112] covered with a layer of thermal oxide and a fused glass layer on one side only. As expected, a compressive stress in silicon was found as evidenced by the negative radius in the six samples in Table III. These compressive stresses in silicon can be compared with the 2950 kg/cm² tensile stress caused by the thermal oxide layer on silicon. Although the maximum thickness of glass which can be formed on oxidized silicon without cracks is inversely proportional to the glass thermal expansion, the induced stress in silicon is not. This seeming contradiction may be resolved by considering the relative amount of thermal oxide dissolved by each glass (Fig. 8) (10).

Space-charge polarization in lead glass films.—The capacitance-voltage analysis of metal-insulator-semiconductor (MIS) capacitors is a sensitive detection method to study charge transport and polarization effects in insulators. Three types of effects are distinguishable: drift of mobile cations within the dielectric, dipole-type polarization, and charge transfer between the dielectric and the silicon electrode. The in-

sulator layer may be either a single or multilayer dielectric.

Kerr (11) first reported the use of the MIS method to study polarization in several glasses in the lead-aluminoborosilicate and zinc-aluminoborosilicate systems deposited on bare silicon by sedimentation and fusion. The initial surface charge levels were quite low ($N_{FB} < 2.7 \times 10^{11}/cm^2$), indicating that this technique of applying glass causes a very low density of surface states or charge density in the insulator. For each glass ΔV_{FB} was approximately symmetric under positive and negative bias with no tendency for ΔV_{FB} to saturate. All the glasses had 10^{19} sodium at./cm³ or more; that is, greater than 100 ppm Na. Snow and Dumesnil (12) provided a quantitative theoretical model for the case of a double-layer dielectric and an experimental application to a sedimented glass layer containing 75% PbO, 12% SiO_2, 10% B_2O_3, and 3% TiO_2 by weight (glass A) on thermally oxidized silicon. Ion migration in deposited glass films can be studied more easily and more quantitatively by this method. As expected, it was found that the C-V characteristic shifted in the positive direction after application of a negative gate bias and vice versa. The amount of the shift ΔV increased with the length of time the bias was applied, but eventually approached a saturation value ΔV_{sat}. The rate at which ΔV approached its saturation value was used to obtain the ionic mobility or the diffusion coefficient. The results obtained for the 75% lead glass were compared with direct diffusion data for lead ions in a glass of similar composition (75% PbO-25% SiO_2). The excellent agreement indicated that lead is the mobile ion.

The time dependence of the long-term drift under positive bias which is shown in Fig. 9 does correlate with sodium content, and the following mechanism was proposed. After applying a positive bias, the lead ions in the glass migrate rapidly toward the glass-SiO_2 interface until the field in the glass is reduced to zero. The lead ions appear to be immobile in the SiO_2 and hence, if there were no alkali ions present, the drift would saturate as in the negative bias case. The situation we actually have, however, is a uniform concentration of Na^+ ions in the field-free glass layer and zero concentration of Na^+ ions in the high-field SiO_2 layer. Ions in the glass near the oxide interface will tend to diffuse in the concentration gradient. On reaching the glass-oxide interface, they will enter the high-field region and will be swept across the oxide by the field to

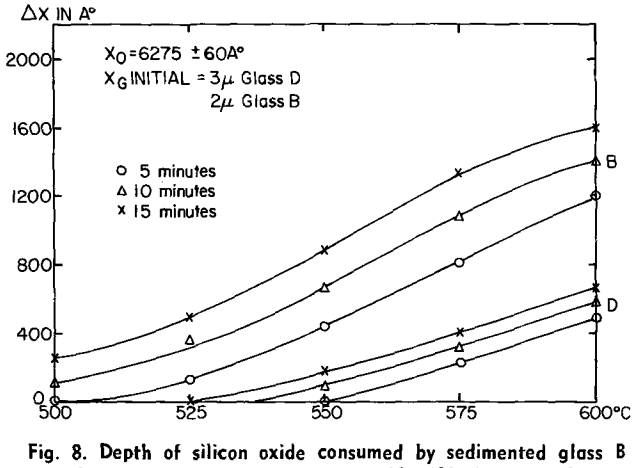

Fig. 8. Depth of silicon oxide consumed by sedimented glass B and D films in the temperature range 500°-600°C for 5, 10, and 15 min.

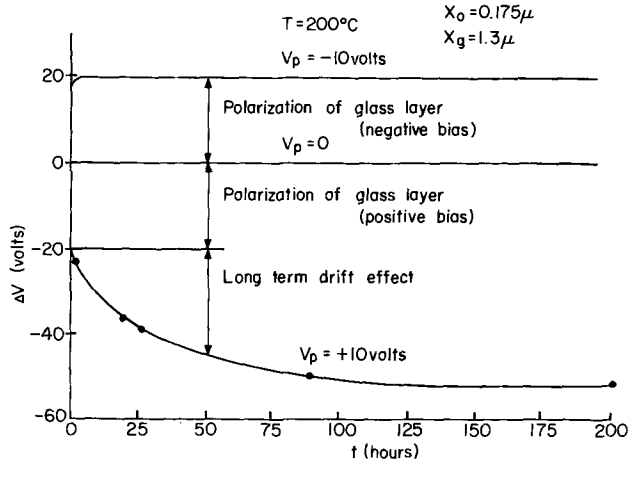

Fig. 9. Shift of the C-V characteristic with time under positive, negative, and zero bias at 200°C. Note that there is a rapid initial polarization which is symmetrical under positive and negative bias, but only under positive bias is there an additional long-term drift effect.

appear at the oxide-silicon interface. The situation is identical to the boundary-layer model developed in (13), and the solution for the excess charge induced in the silicon by the ions accumulated at the oxide-silicon interface is

$$Q_s'(t) = 2qN_0(Dt/\pi)^{1/2}$$

for $t << 4x_g^2/\pi^2D$. The data in Fig. 9 show approximately this square root of time dependence. The data can be replotted as Q_s' *vs.* $t^{1/2}$ and the slope of such a plot used to calculate D from the above equation. N_0 is the initial sodium concentration in the glass and was 3×10^{18} cm^{-3} for this sample. In this manner one obtains for the diffusion coefficient of sodium in the glass at 200°C a value of about 10^{-19} cm^2/sec at this temperature. Aside from this remarkably low diffusion coefficient, all aspects of the above model are in agreement with the experiments described earlier, including the fact that after a unit has been drifted under positive bias for many hours, it can be recovered and drifted again in only a few minutes. This shows that the slow step in the original drift was gettting the ions out of the glass, and that field transport in the SiO_2 layer is very fast, in agreement with previous work (13).

Sodium analysis and control.—Space-charge polarization studies add considerably to our understanding of the instability problems associated with early sedimented glass films. The diffusion coefficient of sodium being very low in high lead glass, this type of insulator should be an efficient barrier to external sodium. The internal sodium level in the glass layer must be, however, drastically reduced if long-term stability in silicon devices is to be achieved. A refined flame spectrophotometric method has been used to analyze and control the sodium content in glass at each processing step. The method has been described elsewhere (14). It utilizes a modified Beckman Model DU spectrophotometer, the instrument being carefully tuned to the sodium emission line with a sodium standard. The method is relatively inexpensive and simple to use, with a detection limit in water of 0.05 ppb sodium. Table IV lists the typical sodium content of commercial metal oxides used in glass preparation. The wide variations in alkali content of commercial chemicals require a careful choice of sources and an analysis of each new lot. Sodium analyses of a series of the same glass smelted in platinum indicated no increase in sodium at a level averaging 12-15 ppm. A comparison of these analyses with the expected calculated sodium content is shown in Table V. Glass comminution was investigated next. A substantial sodium level increase occurs during mechanical size reduction of glass by ball milling. Sodium contamination increases linearly with milling time, so an alternative comminution method was adapted for the production of high-purity glass powder. The resulting dry powder is ultrasonically mixed with an organic solvent and centrifuged at 1000g to precipitate all particles larger than 1μ. The supernatant liquid is calibrated in terms of height of suspension per micron of glass thickness. Analysis of this glass powder shows no measurable increase in sodium above the initial content of the metal oxides acting as glass components. To obtain some measure of possible alkali impurity contributed by this technique, two borate glasses were prepared and ground into a 1μ powder. Table VI demonstrates the effectiveness of the process at the 4 and 6 ppm sodium level.

Table IV. Sodium content of commercial metal oxides

Materials	Sodium content, ppm
Lead oxide PbO	None detected
Zinc oxide ZnO	<1
Aluminum oxide Al_2O_3	23
Anhydrous boron oxide B_2O_3	280
Boric acid H_3BO_4	20
Silicon dioxide SiO_2	18
Titanium dioxide TiO_2	300
Bismuth oxide Bi_2O_3	34
Niobium pentoxide Nb_2O_5	15
Antimony oxide Sb_2O_3	21
Vanadium pentoxide V_2O_5	48
Zinc fluoride ZnF_2	4

Table V. Sodium content of lead glass A

	Calculated Na content, ppm
75% by weight PbO	0
12% by weight SiO_2	18 ppm × 0.12 = 2.2
10% by weight B_2O_3	20 ppm × 0.10 = 2.0
3% by weight TiO_2	300 ppm × 0.03 = 9.0
	Total 13.2

Applications in Semiconductor Device Technology

Effects on device characteristics.—The space-charge polarization effect present in high lead content glass films limits their application to device areas not affected by this polarization or where the glass is above the metallization layer. To date over two million device hours, including operating life, high-temperature reverse bias, and 300°C storage, have been accumulated with type A, B, and D glassed small-geometry npn and pnp bipolar transistors in hermetic metal cans. The sodium content in these glasses was maintained at a value of less than 45 ppm. These lifetest studies extending to 4000 hr detected no surface parameter drift nor any unusual failure mode. The leakage current remained below 20 na at 50V base-collector reverse biased junction. However, an appreciable decrease in h_{FE} during the initial glassing operation is observable with sensitive low current h_{FE} devices. This h_{FE} drop was prevented by the addition of a thin silicon nitride layer at the oxide-glass interface. All glass-coated bipolar devices in which the sodium content of the glass layer was greater than 100 ppm invariably experienced a one to three order of magnitude increase in leakage current within a few hours of thermal stress.

Device scratch protection.—A 2μ layer of glasses type B, C, and D over the surface of a microcircuit is effective in eliminating practically all scratches and shorts in a dense aluminum intraconnection arising from the normal handling of a processed wafer during electrical sorting, scribing, dicing, optical inspection, and final packaging steps.

To measure the mechanical strength provided by sedimented glass films over etched aluminum films, localized mobile pressure was applied by means of a wedge-shaped diamond stylus moving at the rate of 1 in./min. The tip area being equal to 0.15 mm^2, a 10g stylus pressure is equal to a force of 7 kg/cm^2. The stylus pressure was increased by increments of 5g from 5 to 20g. Densely metallized silicon wafers were utilized, the aluminum thickness on the devices being equal to 1.4μ. The effect of the stylus was observed in two areas: between the metal lines to measure the indentation depth produced by the diamond point in the dielectric surface, and over the metal pattern. It was noted that an increasing pressure will eventually induce cracks localized at the aluminum edges followed, with further pressure, by collapse of the dielectric and entrainment of the metal over some distance.

The failure point was taken as the pressure required to smear aluminum metal from one line to the next in a dense pattern without concern for dielectric crack

Table VI. Analysis of two low sodium processed glasses

Sample	Sodium content, ppm

Sedimented glass C	2	15-20
Sedimented glass D	3.5	>20

Note: 10g stylus pressure = 7 kg/cm².

formation. The mechanical strength required in a dielectric film to provide a notable yield improvement in manufacturing is of the order of 15g. A comparison between sedimented glass films and other dielectric films deposited at a temperature lower than 550°C is shown in Table VII. This table indicates that sufficient scratch resistance of a 1.4μ aluminum pattern is in general provided by dielectric films which can be formed 1.5μ thick or more.

Corrosion protection.—For effective surface protection of semiconductor devices, the glass film should have long-term stability to ambient attack, particularly moisture. The water stability and the effect of moisture on various glass films can in general be compared by physical examination, weight loss, thickness difference, and infrared spectroscopy. Weight loss and film thickness measurements are generally inadequate, except for highly stable glasses, since glass dissolution can be offset by water absorption. The relative compositional changes of some of the glass components can be determined with infrared spectroscopy by the sharpness and shifts of band positions. The presence of water and silanol groups can be detected by this method (15).

Surface attack of a lead glass film is easily detected visually by the appearance of pitting or colored fringes, accompanied by loss of gloss. A lead glass can be affected by a decrease in film thickness or by preferential leaching of the glass components to form a porous structure. Of the two modes of attack, preferential leaching is the most undesirable. In thicker films, it often increases the tensile stress in the glass to the point of initiating fracture lines. Boron is the element most susceptible to be selectively removed in a high lead glass. To prevent this effect the boron concentration in the glass formulation can be reduced or the network tightened by the addition of titania. TiO_2 even in small concentrations is quite effective in increasing the water and acid resistance of lead glasses, its specificity being related to its small size (0.64Å) and high coordination number (12).

Prolonged moisture exposure at elevated temperature was simulated by accelerated high-pressure steam treatment in a gold-plated pressure vessel. Exposure to 16 psi steam is equivalent to eight times the exposure at 95°/95% relative humidity. Practically all the high lead glasses are severely pitted when exposed to steam. The addition of a few per cent titania to the lead glasses maintains a bright, shiny surface on the glass even after exposure to 16 psi steam for 400 hr.

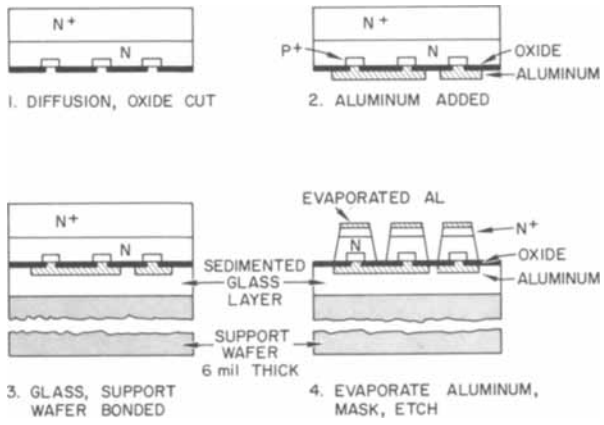

Fig. 10. Step-by-step processing of mesa isolated diode array

A second series of high-pressure steam treatments included the addition of cured epoxy resin powder to simulate the condition encountered by epoxy encapsulated devices exposed to moisture. Increased stress occurs when cured epoxy is added to the samples in a high pressure vessel. The comparative stability of various low-temperature dielectric films to high pressure steam is seen in Table VIII. Although titania-containing sedimented glass films withstand a long-term exposure to high pressure steam, only glass D resisted the presence of epoxy. Glass-coated devices packaged in epoxy resin survive a 72-hr high-pressure steam treatment, whereas non-surface-protected devices will fail within a few hours under similar conditions.

Sedimented glass in mesa isolated structures.—Mesa isolated integrated planar devices are fabricated commercially by sealing face down a diffused, metallized wafer with glass type D on a backing silicon wafer. The back of the active wafer is thinned to approximately 20μ and an isolation pattern etched in the silicon. On exposure of the bottom side of the original top thermal oxide the individual devices are in fact isolated, being connected only by the first metal pattern on the other side of the thermal oxide and now buried in the glass layer. At this point the metal pads are exposed by photoetching. Since the glass sealing step is performed at a temperature lower than 560°C standard, optimized pnp or npn devices are utilized. Similarly, the technique is applicable to the construction of diode arrays (Fig. 10), described elsewhere (16), and the combination of pnp's and npn's in one single structure (17). In the latter case, the metal pads of the substrate devices are exposed by photoetching together with the bottom side of the top pads (Fig. 11 and 12). A major advantage of mesa isolation when compared with p-n junction and most dielectric isolation processes is simplicity of design fabrication, fewer steps, and better electrical performance.

Conclusions

By suitable refinements glass comminution can be used to reproducibly fabricate glass in the near-colloidal state with a sodium content of less than 10 ppm. The lower sodium contamination limit provided by this method has not been determined but appears to be appreciably less than 1 ppm. The major source of contamination now arises from the commercially pur-

chased metal oxides utilized in the synthesis of the lead glasses.

It was found that silicon planar bipolar devices remain electrically stable when covered with a fused lead glass film containing no more than 50 ppm sodium. The application of this type of film must be limited because of polarization and drift effects to device areas not affected by strong electrical fields.

Lead glass films are applicable for corrosion resistance and aluminum scratch protection and as a bonding layer in mesa isolated structures.

Acknowledgment

The authors wish to acknowledge the preliminary development on mesa isolation carried out by J. Schroeder and R. Rusert. B. Yurash and R. Ceynowa conducted the flame analyses reported in this paper and R. Erkson prepared most of the samples. The authors also wish to thank H. Sello, G. Moore, B. Deal, and E. Snow for their helpful advice and encouragement during the course of this work.

Flux Growth of Cubic CuCl Crystal Using a Small Thermal Gradient

Sidney G. Parker* and Jack E. Pinnell

Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

Cubic CuCl crystals can be used to modulate light by application of an electric field. Because it is difficult to grow large, strain-free crystals from the melt, crystals have been grown by vapor transport and from molten salt or flux solutions. We have grown single crystals up to 25 x 15 x 7 mm from flux solutions with a small thermal gradient between the crystal growth region and the charge. Crystals were grown from KCl, $SrCl_2$, and $PbCl_2$ fluxes. Use of a KCl flux leads to cellular growth and bubble inclusions caused by constitutional supercooling and decomposition of CuCl. Similar inclusions and growth behavior were not noted for the other fluxes. The electro-optical properties of the CuCl crystals differed as a function of the growth media. The CuCl crystals also differ in their properties from those grown from the same fluxes using the Bridgeman technique with a larger thermal gradient. Good crystal growth is more likely to be obtained with a small thermal gradient, but poor mixing caused by lack of strong convection currents may influence growth.

Cubic CuCl is a material whose refractive index can be changed by application of an electric field. Therefore, CuCl has been used for modulation of light in the 0.5-10 μm range (1). Because the percentage of modulation depends on crystal length transversed by the light, large crystals are desired.

It is difficult to grow large, strain-free, cubic CuCl crystals from the melt because the material freezes with a hexagonal structure at 420°C and transforms to a cubic structure at 407°C. Vapor transport (2), flux growth (3, 4), and aqueous solution in gel (5) have been used to grow crystals below the transition temperature. CuCl forms eutectics (6) with numerous halides which can be used for flux growth. The Bridgeman technique has been applied to flux growth of CuCl, but we chose to use a small thermal gradient technique we had used successfully for the flux growth of cubic ZnS crystals (7).

Experimental

Figure 1 is a diagram of the crystal growth apparatus. Because the loaded growth tubes were pushed into the furnace at the desired operating temperature, these tubes were made of quartz to reduce thermal shock.

Reagent grade CuCl was further purified for these experiments by dissolving it in concentrated HCl solution and precipitating by dilution with H_2O. This was followed by a sublimation step that gave CuCl of the purity listed in Table I. The flux halides, KCl, RbCl, $SrCl_2$, $PbCl_2$, and $BaCl_2$, were reagent grade and were not further purified.

Phase diagrams were constructed from differential thermal analysis data for some of the systems which were not discussed in the literature. These diagrams, shown in Fig. 2, were necessary to establish the operating conditions for possible crystal growth. For crystal growth, 2-8 m/o (mole per cent) of flux was dissolved in the CuCl by heating to about 400°C, then the mixture was quickly quenched and placed in the growth tube to serve as the charge at the cooler end containing the heat sink. Additional CuCl was placed at the higher temperature end of the growth tube to serve as the main source of CuCl for crystal growth. The system was outgassed at 150°C and 10^{-3} Torr for 1 hr, then cooled to 25°C before it was sealed off at 10^{-5} Torr. The tubes were then pushed into furnaces which were at the desired operating temperature and had the proper thermal gradient between the crystal growth and charge regions. Growth continued for 2-4 weeks, after which the furnace was shut off and the tubes were cooled to 25°C over a 3-hr period.

Results and Discussion

Most work was done with KCl or $SrCl_2$ fluxes because they have wide temperature and compositional ranges from which CuCl crystals can be obtained. Because of a peritectic with about 4 m/o $BaCl_2$, the system $BaCl_2$-CuCl was not studied for CuCl crystal growth. RbCl and $PbCl_2$ were also investigated as fluxes.

A few unsuccessful attempts were made to grow on a CuCl seed crystal, but the seeds dissolved before growth conditions were established. Thus, crystal growth was limited to self-nucleation, which began in the coolest regions at the heat sink. The conditions for crystal growth are listed in Table II. A wide range of conditions was used for each flux, but the ones listed in Table II appeared to give the largest crystals. Generally, concentrations of flux greater than those listed have led to inclusions of flux in the CuCl crystals. Temperature gradients of up to 30°C were used, but caused the growth of many small crystals.

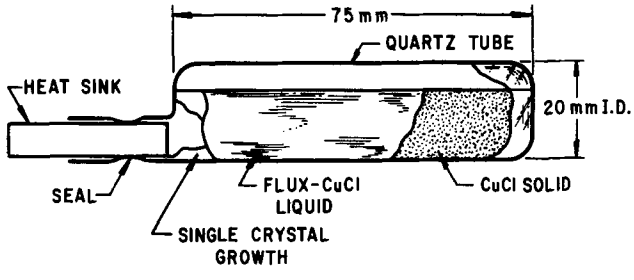

Fig. 1. Apparatus for flux growth of cubic CuCl

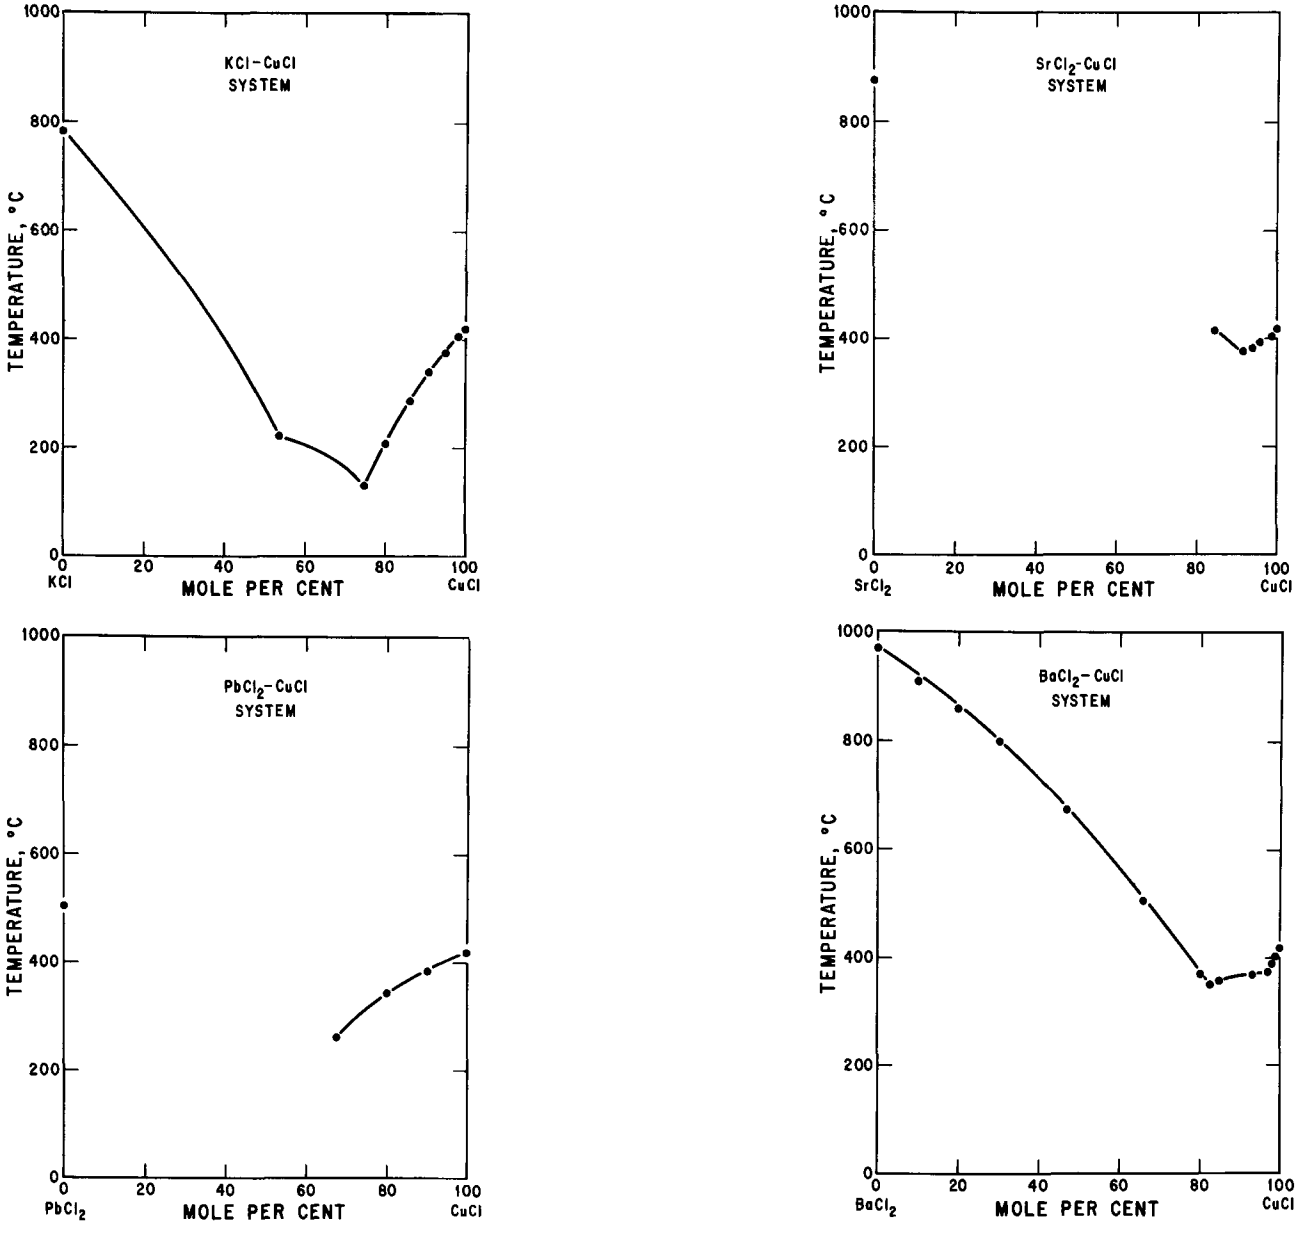

Fig. 2. Phase diagrams for (a) (top left) KCl-CuCl; (b) (top right) $SrCl_2$-CuCl; (c) (bottom left) $PbCl_2$-CuCl; (d) (bottom right) $BaCl_2$-CuCl.

CuCl crystals up to 25 x 15 x 7 mm in size were grown from all the fluxes except RbCl, which gave smaller crystals. The concentration of impurities in typical crystals grown from different fluxes is given in Table III. Crystals grown from KCl are rather pure, while those grown from $PbCl_2$ and $SrCl_2$ contain much flux. There seems to be little correlation between the amount of flux in the crystals and the resistivity. The amount of flux occluded in the crystals increased with decreasing operating temperatures.

As shown in Table IV, crystals grown from KCl usually had much greater optical transmission than those from the other fluxes. The inclusion of flux during growth from $SrCl_2$ or $PbCl_2$ probably contributed

to the reduced transmission, but there was no direct correlation between transmission and impurity level. That the transmission of crystals from $SrCl_2$ and $PbCl_2$ is less than that of crystals grown from KCl is in disagreement with the results reported by Soga *et al.* (3) for crystals grown from these same fluxes by a Bridgeman technique. The differences in the occlusions or defects which give the crystals their opaque character may be caused by the different thermal gradients used in the two methods. In our experiments thermal gradients of 2°-7°C/in. were used, while crystals have been grown by the Bridgeman technique with a gradient of 20°-50°C/in. Small gradients should aid in obtaining a better crystal growth (7, 8), but this may be negated by constitutional supercooling and poor mixing which are likely to occur with small thermal gradients. Constitutional supercooling (9) would lead to cellular growth and entrainment of solvent at the grain boundaries. Large thermal gradients would cause greater mixing and tend to minimize supercooling effects. Use of a large thermal gradient of 15°-30°C/in. in our system led to polycrystalline growth probably because of simultaneous formation of many nucleation centers. Evidence of cellular growth in some growth runs is illustrated in Fig. 3 which shows a cross section of a CuCl crystal grown from flux with a small gradient. X-ray back reflection confirmed that the material was polycrystalline.

The purity of the CuCl affected not only the resistivity but also the optical transmission of CuCl crystals, particularly those grown from KCl. CuCl which was purified by sublimation contained traces of $CuCl_2$ but material produced by reprecipitation from HCl solution and then sublimed was relatively free of $CuCl_2$ and other impurities. Yet crystals grown from the purer CuCl were more opaque, as noted in Table IV. Figure 4 shows that CuCl crystals grown in KCl flux from the purer CuCl contained bubbles, which in many cases were arranged in a periodic manner. Because as-received CuCl did not give crystals containing voids, it was thought that these voids were somehow related to the equilibrium between CuCl and $CuCl_2$. When 1-5 m/o $CuCl_2$ was added to the reprecipitated and sublimed CuCl, the number of voids

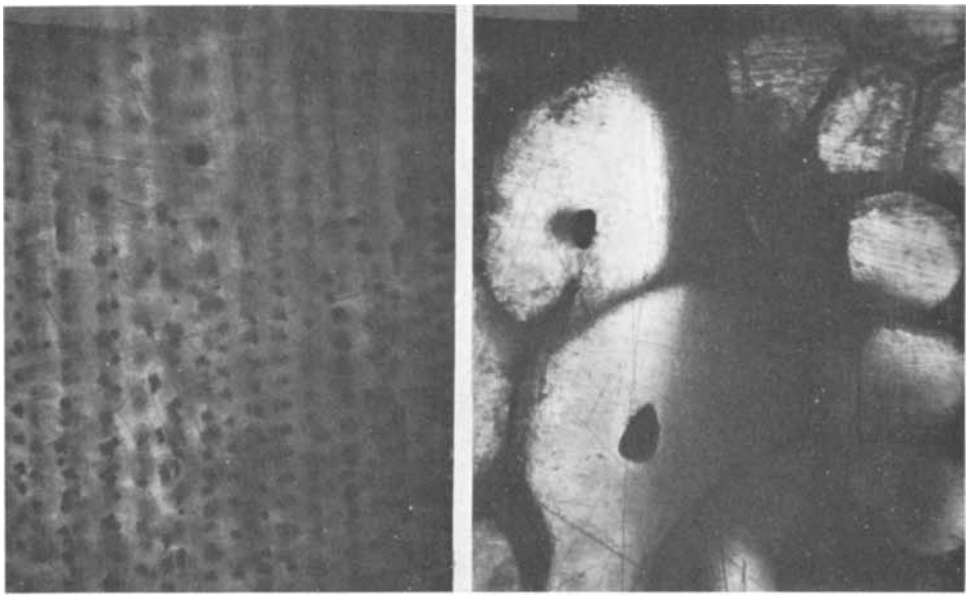

Fig. 3. CuCl crystals grown from KCl flux and showing evidence of cellular growth: (a) (left) parallel to growth direction; magnification 160X approximately; (b) (right) normal to growth direction; magnification 32X approximately.

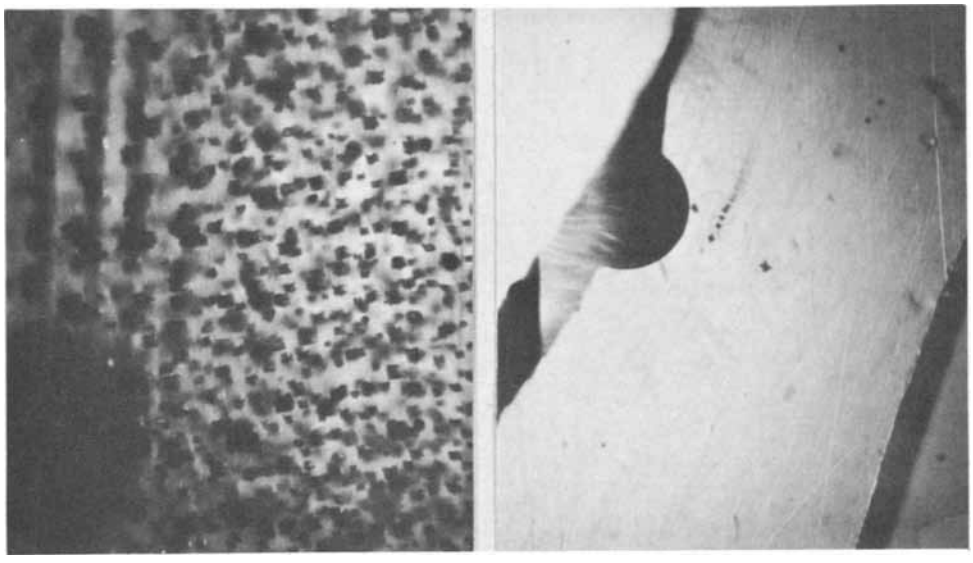

Fig. 4. CuCl crystals grown from KCl flux: (a) (left) high-purity CuCl; (b) (right) high-purity CuCl with $CuCl_2$ added. Magnification 160X approximately.

was greatly reduced. A comparison of CuCl crystals grown from high purity CuCl and crystals from a CuCl-$CuCl_2$ mixture is given in Fig. 3.

Only a few randomly distributed voids were formed with the other fluxes. Some CuCl crystals were grown from a flux composed of 2 m/o each of KCl and $SrCl_2$. These crystals were semitransparent and did not contain voids, but did have 10-50 ppm of Sr.

In the limited number of experiments made with RbCl, bubble formation was much less than in the experiments with KCl. The reduced bubble formation is reflected in the increased optical transmission for crystals grown from RbCl, although the amount of RbCl in the crystals is large. The resistivities for crystals from KCl and RbCl were about the same. Transmission of crystals from RbCl was about the same as or greater than that of crystals from $SrCl_2$ or $PbCl_2$; this is contrary to results obtained with the Bridgeman technique.

Optical rotation was measured by first crossing the direction of the polarizers, then determining the number of degrees of rotation necessary to return to the original light intensity while applying an electric field. The electrodes were on the (111) planes; the light was at right angles to the electrodes, thus giving a transverse mode. The electric breakdown of the CuCl crystals was usually much lower than that of crystals grown by other techniques (3). Thus, the number of impurities as well as their state of incorporation in the CuCl crystals seem to greatly influence the electro-optical properties.

Summary

Rather large cubic CuCl crystals were grown from several alkali or alkaline halides by using a small thermal gradient of 5°-12°C between the feed region and the crystal growth region.

The properties of the crystals grown by this technique are different from those of crystals grown by a Bridgeman technique, in which a large thermal gradient exists between the growing crystal and the melt. Some evidence of constitutional supercooling was found with the small thermal gradient.

Crystals grown in KCl flux from high-purity CuCl contained bubbles which were related to the breakdown of CuCl to give $CuCl_2$.

ABSTRACT

The early stages of the oxidation-decarburization kinetics have been investigated for austenitic iron alloys of carbon contents 0.23-1.07 w/o exposed to carbon dioxide-carbon monoxide atmospheres at the temperature of 950°C. Complex reaction behavior was observed for these alloys in the range 10-100 v/o carbon dioxide. The initial selective oxidation of carbon from sheet specimens exhibited linear kinetics. During late stage scale growth of wustite crystals, decarburization occurred by gaseous transport of carbon oxides through pores in the oxide. An oxidation-decarburization model based on surface controlled reaction steps accounted most adequately for decarburization and wustite formation before onset of control by diffusion processes.

Oxidation of a metal-carbon alloy is an unusual process since the metal oxides are generally solids and the carbon oxides are gaseous (1-7). The character of the reaction is therefore strongly circumscribed by the location of the carbon-oxygen reaction. Webb *et al.* (1) have recognized two possible reaction sequences: (*a*) rapid decarburization occurs by gas penetration through cracks in the scale, and (*b*) decarburization occurs without scale rupture due to carbon diffusion in both the metal and scale leading to the occurrence of the oxygen reaction at the oxide/gas interface. Engell and Peters (2) and Engell and Bohnenkamp (3, 4) have examined these propositions for alloys containing 0.1-0.8 w/o carbon on exposure in various atmospheres over the temperature range 750°-1050°C. They noted that decarburization occurred without scale rupture. While the alloys oxidized parabolically in air, this dependence could not be attributed to sequence (*b*) since carbon solubility in wustite was found to be so low that its diffusion through the scale had to be discounted as a significant reaction step. Furthermore, when specimens were exposed to carbon dioxide atmospheres, the wustite scale grew by the linear kinetics usually associated with a phase boundary reaction. Since decarburization involved both carbon diffusion in the metal and carbon transport through the scale, these authors concluded that formation of pores in the scale permitted effusion of gaseous carbon oxides. Although Langer and Trenkler (5) have suggested that both carbon and iron may diffuse sufficiently rapidly through the scale to react with the gaseous reactants at the oxide/gas surface, the results recently obtained by Manenc *et al.* (6) and Boggs and Kachik (7) for carbon gradients in the alloy have demonstrated that a compact scale essentially acts as a barrier to carbon diffusion.

It would therefore appear that decarburization of an iron-carbon alloy during oxidation involves depletion of carbon by its diffusion in the metal and by effusion through pores in the oxide scale as gaseous carbon oxides. This investigation was undertaken using metallographic and gravimetric techniques to clarify the reaction mechanism in the early stages of oxidation for alloys containing 0.23-1.07 w/o carbon exposed to carbon dioxide-carbon monoxide atmospheres at a temperature sufficient for stabilization of austenite and wustite.

Experimental

Specimens were prepared from disks 0.25 in. thick cut from 1 in. diameter homogenized alloy bars of carbon contents in the range 0.23-1.07 w/o. Analyses are recorded in Table I. In the case of the 0.23 w/o carbon alloy, disks were directly cold rolled to sheets 0.07 cm thick. Sheets of the higher carbon alloys, however, could be obtained only after soaking at 1000°C in argon and hot rolling. Rectangular plate specimens, 1 x 1.5 cm, were cut from the sheets and polished, finishing with 1μ diamond abrasive.

Flowing carbon dioxide-carbon monoxide atmospheres at 1 atm pressure were utilized for oxidation tests. Carbon dioxide, 99.95 v/o pure, was dried by passage through columns containing magnesium perchlorate, reduced copper oxide, and activated alumina. The carbon monoxide, minimum purity of 99.6 v/o, was further purified by passage through columns containing magnesium perchlorate and ascarite. The gases were metered with capillary flowmeters, mixed in a Pyrex bulb packed with glass wool, and directed through Pyrex tubes to an inlet at the bottom of the oxidation tube. To prevent thermal segregation of the gases, the flow rate was maintained at 0.6 cm/sec.

The vertically mounted mullite reaction tube contained a calibrated 5 mil Nispan-C wire spring which was raised or lowered by a winch to position the specimen in the furnace. Weight changes of an oxidizing specimen were recorded by following the spring extension with a cathetometer. In a typical experiment, the apparatus was evacuated to 10^{-4} Torr and the furnace adjusted within $\pm$ 2°C of the test temperature. The oxidation cell was then returned to atmospheric pressure by the introduction of nitrogen followed by the reaction gas in desired proportion, and the reaction tube was purged for 1 hr. A specimen carrying the normal room temperature oxide film was then lowered into the furnace and the weight changes were recorded. On completion of the test, the specimen was raised to the portion of the tube at room temperature and cooled in the flowing gas. A specimen was mounted in epoxy resin for metallographic examination.

Results

All results were obtained from specimens exposed at the temperature of 950°C. Typical weight-change curves for exposures up to 500 min are illustrated in Fig. 1 and

2. Under reducing atmospheric conditions with respect to wustite (< 30 v/o CO_2), the negative slopes of the decarburization curves become smaller with increasing exposure time. For atmospheres containing greater than 30 v/o carbon dioxide, the slopes of the curves initially exhibited negative values due to weight losses, but ultimately became positive due to wustite formation.

Since the reaction curves were approximately linear during the initial and final stages of exposure, the initial and final linear reaction rate constants were extracted and recorded for the three alloys in Table II. Results for the 1.07 w/o carbon alloy are notable in that the initial rate revealed the most extreme negative

value in pure carbon dioxide, a smaller extreme near 30 v/o carbon dioxide, and the least extreme value near 80 v/o carbon dioxide.

To ascertain the carbon loss during simultaneous oxidation of iron and carbon, several specimens were quenched after different intervals and analyzed for residual carbon. The equilibrium carbon concentration in the iron is essentially zero for atmospheres containing greater than 60 v/o carbon dioxide, and it is 0.05 w/o carbon for the atmosphere of 30 v/o carbon dioxide. Results from the above experiments for the 1.07 w/o carbon alloy are shown in Fig. 3 in comparison to the over-all reaction kinetics. Decarburization was essentially complete for the specimen exposed 2 hr in a 30 v/o carbon dioxide atmosphere when lateral growth of wustite was insufficient to interfere with surface decarburization. In the pure carbon dioxide atmosphere, lateral growth of wustite and onset of linear scale growth tends to stifle decarburization, and the carbon content of the alloy approached its equilibrium value more slowly.

The surfaces of specimens exhibited thermal etching at grain boundaries when decarburized under reducing conditions for wustite formation. Metallographic examination of the metal after oxidation under conditions for wustite formation gave results in accord with the observations of Engell and Bohnenkamp (3, 4). As illustrated in Fig. 4, the structure shows typical carbon diffusion profiles, the amount of pearlite being proportional to the carbon content.

In the metal oxidation regions, wustite grows laterally from nuclei distributed randomly over the metal

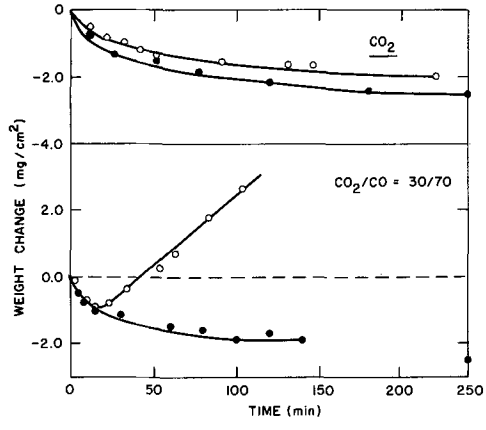

Fig. 3. Curves for oxidation-decarburization kinetics (○) and carbon loss (●) for an Fe-1.07 w/o C alloy in CO_2-CO atmospheres. (The weight loss for carbon for complete decarburization by each atmosphere is shown on the right-hand ordinate).

surface. These nuclei, which expand vertically more than laterally, coalesce until only a scale consisting of oxide crystals is visible. The scale exhibits good adherence to the metal, and the oxide crystals are characterized by very rugged surfaces consisting of macroscopic ledges. Impingement of these surfaces presumably leads to formation of pores in the scale.

These considerations may be discussed by referring to tests on the 1.07 w/o carbon alloy since wustite growth was similar for the three alloys studied. As illustrated in the micrographs of Fig. 5 obtained from specimens exposed in a 60 v/o carbon dioxide atmosphere, the wustite nuclei have grown after 5 min to considerable thickness over a large fraction of the metal surface. Oxide coverage was only slightly more extensive after 10 min. Coalesced areas then appear, and developing porosity may be associated with the crystal boundaries. There is microscopic evidence for porosity in the scales on specimens exposed up to about 30 min, Fig. 6. Metallographic cross sections illustrated that both surfaces of a scale were irregular and that the impingement of crystals is associated with small regions of iron protruding into the oxide. The observations showed that the wustite weight increased with increasing pressure of carbon dioxide. For example, coverage of the surfaces in pure carbon dioxide was essentially complete after 30 min.

Discussion

Several possibilities involving diffusion and surface control processes must be examined in order to elucidate the decarburization kinetics for the cases of nonscaling and scaling of the base-metal iron. It is therefore essential to consider carbon diffusion in the metal substrate and the nature of the scale with regard to transfer of carbon oxides.

The decarburization range.—The simplest possibility is that decarburization is controlled by the rate of carbon diffusion in the metal when the oxidizing potential is insufficient for wustite formation. This is obtained simply from the desorption conditions for a plane sheet (8, 9). The result of a sample calculation is shown in Fig. 7 corresponding to a 1.07 w/o carbon alloy exposed to a 10 v/o CO_2 atmosphere. The calculation is based on published results for carbon concentrations and diffusion coefficients (10, 11) and involves the assumption that the surface carbon concentration is the equilibrium value for the atmosphere used. Since the observed decarburization rate in the early stages of the reaction is much smaller than the calculated value,

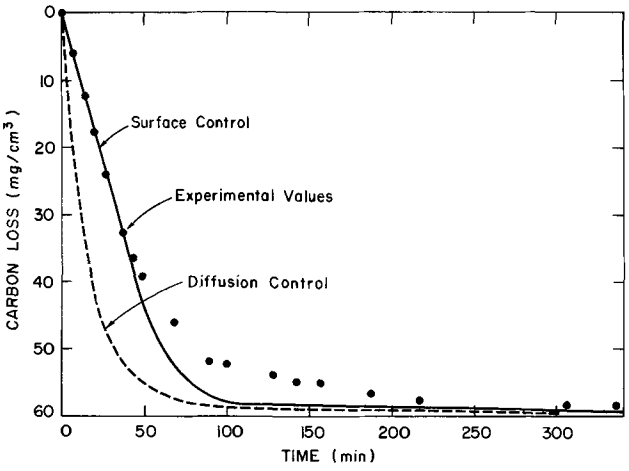

Fig. 7. Comparison of curves calculated for surface and diffusion controlled decarburization to experimental results for an Fe-1.07 w/o C alloy exposed in a 10/90 CO_2-CO atmosphere. The diffusion control curve was that calculated from equations for a finite plate [8], [9]; the surface control curve was calculated from Eq. [3] in integrated form and the experimental value of k_1.

decarburization must be inhibited initially by chemical reaction at the metal surface.

We therefore consider the transfer of oxygen from a carbon dioxide atmosphere to react with carbon at the surface of iron. Two parallel reaction chains have been considered by Doehlemann (12). In the first chain

$$CO_2 = O^*_{ads} + CO \qquad \text{(slow)} \qquad [1]$$

$$O^*_{ads} + C = CO \qquad \text{(fast)} \qquad [2]$$

O^*_{ads} refers to oxygen absorbed on sites where it reacts with carbon. That is, the reaction rate is not dependent on the surface diffusion of oxygen to an active site to react with carbon. Doehlemann applied the theory of chemical kinetics to this sequence of reactions with the assumption that the dissociation of carbon dioxide is the rate-determining step to obtain the following expression for the reaction rate

$$R_1 = k_1 \, p_{CO_2} \left(1 - \frac{C_e}{C}\right) \qquad [3]$$

where k_1 is the rate constant for dissociation of CO_2, and where C and C_e are the carbon concentrations after a given exposure period and the equilibrium value, respectively, for a specified carbon dioxide-carbon monoxide atmosphere.

In atmospheres of higher oxidizing potential, the decarburization kinetics may assume a parallel dependence upon the dissociation step for carbon dioxide and a surface diffusion step of adsorbed oxygen to an active site for reaction with carbon. Doehlemann (12) has also considered this chain of reactions

$$CO_2 = O_{ads} + CO \qquad \text{(fast)} \qquad [4]$$

$$O_{ads} = O^*_{ads} \qquad \text{(slow)} \qquad [5]$$

$$O^*_{ads} + C = CO \qquad \text{(fast)} \qquad [6]$$

where O_{ads} refers to inactive adsorbed oxygen. It was assumed that the adsorbed oxygen is in local equilibrium with the atmosphere and the occupied random surface sites, the controlling reaction [5] being a short surface diffusion step in which O_{ads} migrates to active sites to form O^*_{ads}. The reaction rate may then be written as

$$R_2 = k_5 \frac{p_{CO_2}}{p_{CO}} \left(1 - \frac{C_e}{C}\right) \qquad [7]$$

where k_5 is the rate constant for surface diffusion. Consequently, the net initial decarburization rate may be expressed as

$$R_{dec} = R_1 + R_2 = (k_1 p_{CO_2} + k_5 \, p_{CO_2}/p_{CO})(1 - C_e/C) \qquad [8]$$

It is conceivable that k_5 has a value relative to k_1 such that the second term in Eq. [8] is insignificant in the pure decarburization range at $p_{CO_2} < 0.3$ atm but becomes significant at higher pressures approaching 1 atm. Doehlemann (12) found for the decarburization of alloys fabricated from electrolytic iron that the ratio $k_1/k_5 \simeq 20$ at 920°C whereas Grabke (13) recently demonstrated that the decarburization rate of alloy foil containing high-purity iron was dependent only on $k_1 p_{CO_2}$ at temperatures in the range 800°-1000°C in atmospheres up to those sufficiently oxidizing for wustite formation. As shown by the plots in Fig. 8, it would appear that the initial decarburization rate for the alloys of this work, which is directly dependent upon the partial pressure of carbon dioxide, is correctly described by Eq. [3]. It will be shown, however, that this consideration is only valid for pure decarburization at low pressures of carbon dioxide; the term $k_5 p_{CO_2}/p_{CO}$ becoming significant in the oxidation-decarburization range.

The oxidation-decarburization range.—It is essential to consider both concurrent decarburization and wustite formation in the atmospheres of sufficient oxidizing potential for stability of wustite. Since randomly distributed oxide nuclei would be present on the surface after partial reduction of the air formed room temperature film at the reaction temperature, adsorbed oxygen would react with iron at these nuclei boundaries. Lateral growth of oxide would then be determined by complicated processes for oxygen adsorption and surface diffusion. By analogy with the rate processes for decarburization, two limiting oxidation cases may be considered. In the first reaction chain, carbon dioxide dissociating at active sites adjacent to the oxide nuclei would determine the reaction rate. The second reaction chain would involve a rate-determining surface diffusion step for adsorbed oxygen from the randomly distributed sites to these active oxidation sites.

The first oxidation chain may be represented by

$$CO_2 = O^{**}_{ads} + CO \qquad \text{(slow)} \qquad [9]$$

$$O^{**}_{ads} + Fe = FeO \qquad \text{(fast)} \qquad [10]$$

where the dissociation of carbon dioxide at the active

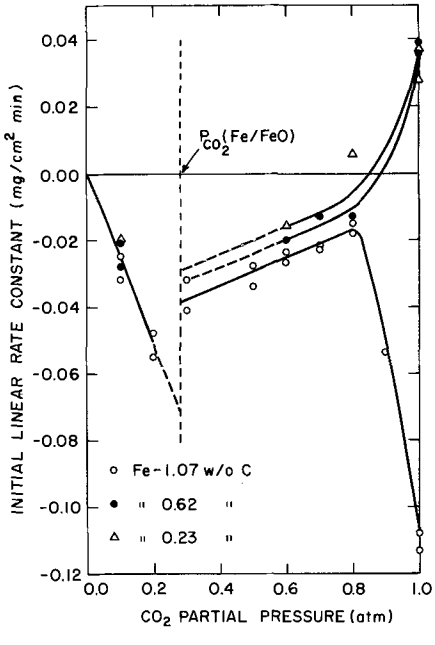

Fig. 8. Initial oxidation-decarburization linear rate constants as a function of CO_2 partial pressures. Symbols (○), (●), and (△) are for the 1.07, 0.62, and 0.23 w/o carbon alloys respectively.

sites is the rate-determining step. The surface coverage of adsorbed oxygen then corresponds to the value for equilibration of iron with wustite. A detailed balance of the reactions with this restriction gives for the initial oxidation rate

$$R_3 = k_9 P_{CO_2} (1 - K P_{CO}/P_{CO_2}) \quad [11]$$

where the constant K represents the gas pressure ratio for equilibration of wustite with iron and k_9 is the rate constant for dissociation of carbon dioxide at the active oxidation sites.

The reaction chain for oxygen surface diffusion as the rate determining step is

$$CO_2 = O_{ads} + CO \quad \text{(fast)} \quad [4]$$

$$O_{ads} = O^{**}_{ads} \quad \text{(slow)} \quad [12]$$

$$O^{**}_{ads} + Fe = FeO \quad \text{(fast)} \quad [10]$$

If the species given in [4] and [10] are regarded as being at equilibrium concentrations for the atmospheric oxidizing potential and the iron-wustite reaction, the resulting expression for the oxidation rate is of the form

$$R_4 = k_{12}k_4 P_{CO_2}/P_{CO} \left(1 - \frac{k'_{12}}{k_{12}K_4K_{10}} P_{CO}/P_{CO_2}\right) \quad [13]$$

where K_4 and K_{10} are the equilibrium constants for reactions [4] and [10], and k_{12} and k'_{12} are the forward and backward rate constants for the surface diffusion steps. Accordingly, a concentration gradient of adsorbed oxygen would then exist from the iron surface to the Fe/FeO boundary for surface diffusion of oxygen.

Thus, the initial rate for lateral growth of wustite on the surface may be expressed as

$$R_{oxid} = R_3 + R_4 = k_9 P_{CO_2} (1 - K\ P_{CO}/P_{CO_2}) + k_{12}K_4 P_{CO_2}/P_{CO} \left(1 - \frac{k'_{12}P_{CO}}{k_{12}K_4K_{10}P_{CO_2}}\right) \quad [14]$$

The net initial reaction rate in the oxidation-decarburization range is therefore the summation, $R_{dec} + R_{oxid}$, given by Eq. [8] and [14]. They are comprised of two leading terms, one being directly proportional to the partial pressure and dissociation rate of carbon dioxide and the other to the P_{CO_2}/P_{CO} ratio and the rate constants describing the oxygen surface diffusion to the active decarburization and oxidation sites.

These considerations may be demonstrated by examining the plots of the net initial reaction rates *vs.* gas consumption for the three alloys investigated, Fig. 8. A sharp break in the reaction rate curve at the partial pressure of carbon dioxide for wustite formation is due to retention of partial coverage of oxide resulting from partial reduction of the air-formed film. This oxide would act as nuclei for subsequent growth of wustite. In the intermediate pressure range, $0.3 < P_{CO_2} < 0.8$, reactions [1] and [9], as described by Eq. [3] and [11], involving dissociation of carbon dioxide must be rate limiting since the net reaction rate involving both decarburization and oxidation are directly dependent on carbon dioxide pressure. It is to be noted that the effective contribution of the decarburization reaction was larger for an alloy of higher carbon concentration which would be associated with the larger number of active carbon surface sites for dissociation of the reactant gas. Contributions to reaction control associated with the P_{CO_2}/P_{CO} ratio, Eq. [7] and [13], appear to become effective at carbon dioxide pressures exceeding 0.8 atm. Apparently the surface coverage of adsorbed oxygen became sufficient in atmospheres of high oxidation potential for reactions [5] and [12] to enter into competition for oxygen by diffusion to one of the other of the active decarburization and oxidation sites. The oxidation rate was dominant for the alloys containing 0.23 and 0.62 w/o carbon. On the other hand, decarburization wins out over oxidation in the case of the 1.07 w/o carbon alloy where oxygen diffused preferentially by shorter diffusion paths to the decarburization sites.

Model for the oxidation-decarburization reaction kinetics.—A model based on the growth of a wustite scale from oxide nuclei randomly distributed on the alloy surface may be advanced to generate the shape of the reaction curves. The nuclei, as illustrated in Fig. 9, are regarded for simplicity as spherical caps which grow laterally and vertically, their lateral growth reducing decarburization in proportion to the areal coverage of the alloy surface. The rate constants k_o and k_d may then be defined to describe the vertical growth of wustite and the decarburization process, respectively. A large number of nuclei covering a fraction of the surface corresponding to A_o is assumed to be present at the commencement of the reaction due to partial reduction of the air formed oxide film on exposure of the specimen at the reaction temperature. This coverage at time, t, is defined by the relationship

$$A(t) = 1 - (1 - A_o) \exp(-at) \quad [15]$$

where a is the rate constant for lateral growth of wustite in order that the oxide coverage of the surface will vary from $A(0) = A_o$ at $t = 0$ to $A(\infty) = 1$ for complete coverage at very long times.

Since the weight change of a specimen may be expressed as

$$\Delta W = \Delta W_o + \Delta W_d \quad [16]$$

where ΔW_o is the oxidation weight gain and ΔW_d is the decarburization weight loss, the instantaneous rates given by means of Eq. [15] and [16] are

$$\frac{d\ \Delta W_o}{dt} = k_o A = k_o [1 - (1 - A_o) \exp(-at)] \quad [17]$$

$$\frac{d\ \Delta W_d}{dt} = -k_d (1 - A) = -k_d (1 - A_o) \exp(-at) \quad [18]$$

Upon integration of Eq. [17] and [18] followed by substitution into [16]

$$\Delta W = k_o \left[t - \frac{1 - A_o}{a} (1 - \exp - at) \right] - k_d \left[\frac{1 - A_o}{a} (1 - \exp - at) \right] \quad [19]$$

It may be shown that Eq. [19] describes the shape of the reaction curves by examining several limiting approximations. The initial weight change of a specimen found to occur by a linear rate relationship would be given by

$$\Delta W(0) = [-k_d + (k_d + k_o) A_o] t \quad [20]$$

When the alloy surface is covered completely by a wustite scale at long exposure intervals, the linear relationship would be

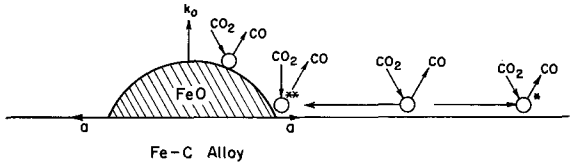

Fig. 9. Oxidation-decarburization model for a large number of oxide nuclei distributed randomly on the alloy surface. The nuclei are spherical caps covering a fractional area A_o at the commencement of the reaction. The rate constant, a, defines the lateral growth rate of wustite, k_o is the rate constant for vertical wustite growth, O* and O** represent oxygen adsorbed at active decarburization and oxidation sites.

$$\Delta W(\infty) = k_o t \qquad [21]$$

neglecting any decarburization due to effusion of gaseous carbon oxides at wustite crystallite boundaries. Equation [19] may also be solved for the time corresponding to the minimum observed in the reaction curves where oxidation and decarburization occur at equal rates. This relationship is

$$t_m = \frac{1}{a} \ln k_o/(k_o + k_d)(1 - A_o) \qquad [22]$$

We see therefore that the reaction curves illustrated in Fig. 1 and 2 have a shape described by Eq. [19]. One further qualitative point of agreement of the model with the reaction kinetics may be noted by examining the terms in Eq. [22]. Since the rate constant, a, for lateral growth of wustite is the leading term and corresponds to R_{oxid}, Eq. [14], it would be expected to show a dependence on both the partial pressure of carbon dioxide and the pressure ratio P_{CO_2}/P_{CO}. Moreover, this constant determines the location of the minimum of the curve, the larger is its value, the shorter is t_m, and they should be inversely proportional. We have plotted $1/t_m$ *vs.* P_{CO_2} in Fig. 10 obtained from the reaction curves for the 1.07 w/o C alloy, and the predicted tendency is clearly shown. At low partial pressures of carbon dioxide, 0.3 to 0.8 atm, the magnitude of the rate constant is proportional to pressure since the dissociation step of carbon dioxide at active oxidation sites is most important. Its magnitude then becomes dependent on the P_{CO_2}/P_{CO} ratio for atmospheres at high partial pressures of carbon dioxide since the active oxidation sites at wustite nuclei boundaries enter into competition with active decarburization sites for adsorbed oxygen supplied by surface diffusion.

It is clear that this simple model reproduces the qualitative character of all features of the reaction. However, it does not take account of long time decarburization by gaseous transport at oxide crystallite boundaries in the scale and the known change of the oxidation to parabolic kinetics at very long times. The linear behavior implies that the surface control reaction is much slower than the diffusion of iron through the scale to the reaction front at its external surface. According to earlier work on the linear kinetics for wustite formation on pure iron (14, 15), the oxidation rate constant k_o, Eq. [21], would be expected to show a proportional dependence on the partial pressure of carbon dioxide greater than that for equilibration of wustite with iron. Values of the linear reaction rate constants obtained for the three alloys at long exposures are plotted in Fig. 11, and it is to be seen that

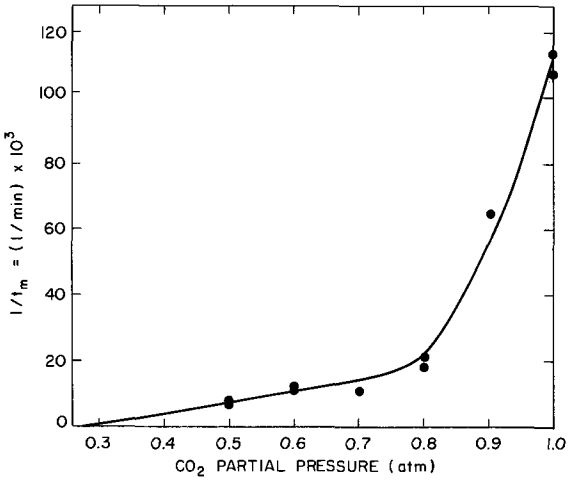

Fig. 10. Variation of time for kinetic minima with partial pressure of carbon dioxide for concurrent oxidation of iron and carbon for 1.07 w/o C alloy.

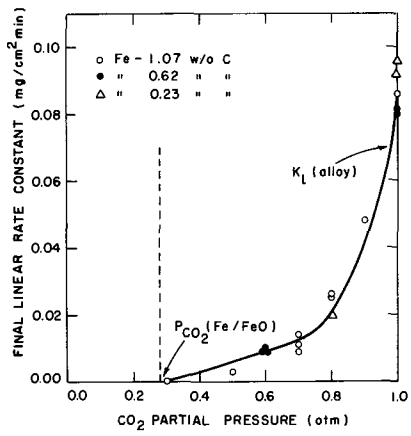

Fig. 11. Final oxidation-decarburization linear rate constants as a function of CO_2 partial pressure.

they do show this proportional dependence up to a carbon dioxide partial pressure of 0.8 atm and a larger dependence at higher pressures. Apparently wustite formation is enhanced and decarburization decreased at these latter pressures. Since the scales on the alloys are porous, a larger area for wustite formation at external and internal surfaces would lead to less effective porosity and decreased decarburization. These properties would lead to the higher observed rates for wustite formation but the complex processes involved, however, are not amenable to simple analysis.

Summary

An investigation has been carried out on the oxidation-decarburization kinetics and the morphological development of the wustite scale on iron alloys containing 0.23-1.07 w/o carbon exposed to carbon dioxide-carbon monoxide atmospheres at a temperature sufficiently high for stabilization of the metal as austenite. Under reducing atmospheric conditions with respect to wustite formation, the decarburization rate increased with increasing pressure of carbon dioxide, but decreased with increasing exposure time due to onset of carbon diffusion in the metal substrate. Growth of wustite stifled decarburization in proportion to the areal coverage by oxide. In the late stage of the reaction decarburization occurred only by gaseous effusion of carbon oxides through pores in the scale. The magnitudes of the initial linear oxidation-decarburization rate constants were examined as a function of carbon dioxide partial pressure. These constants showed a direct dependence at low pressure while at high pressure they were dependent on both the partial pressure of carbon dioxide and the P_{CO_2}/P_{CO} ratio. An explanation was advanced for this behavior by considering both oxidation and decarburization to be controlled by a chain of surface reactions where either dissociation of carbon dioxide at active oxidation and decarburization sites or surface diffusion of adsorbed oxygen to these active sites acted as rate determining steps. Finally, an oxidation-decarburization model based on stifling of the decarburization reaction by lateral growth of wustite was advanced to generate the general features of the reaction curves.

Decarburization of an Iron 0.8 w/o Carbon Alloy in the Presence of a Wustite Scale

A. S. Reeves[1] and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

The decarburization kinetics have been investigated for an austenitic Fe-0.81 w/o C alloy in the presence of a wustite scale exposed to a carbon dioxide atmosphere or vacuum at 950°C. During the stage of linear reaction kinetics in carbon dioxide, iron oxidation was approximately tenfold more rapid than carbon oxidation. The latter reaction occurred predominately with carbon dioxide rather than by reduction of wustite. The primary rate-controlling steps in decarburization were reaction steps at the alloy surface with a small resistance possibly occurring to the passage of carbon oxides by pores in the scale. The maximum area affected by porosity in a scale was 2-3%. Under vacuum decarburization conditions, the effectiveness of the pores in the wustite scale as a means of transport for carbon oxides was dependent on its thickness and the concentration of carbon at the metal/oxide interface.

An oxidation-decarburization model based on surface controlled reaction steps has been shown previously by Billings *et al.* (1) to account most adequately for the initial rates of decarburization and wustite formation on austenitic iron-carbon alloys on their exposure in carbon dioxide-carbon monoxide atmospheres. The initial selective oxidation of carbon from sheet specimens exhibited linear kinetics, and decarburization occurred by gaseous transport of carbon oxides through pores in the oxide during the late stage growth of wustite crystals. The purpose of this investigation was to obtain additional information for interpretation of the decarburization reaction at relatively long exposure intervals. The reaction kinetics consisting of simultaneous oxidation of iron and carbon were allowed to occur until a layer of wustite formed on the metal surface. Decarburization was then allowed to proceed without wustite formation.

Experimental

The methods for preparing the Fe-0.81 w/o C alloy and the method for carrying out the reaction tests at 950°C in flowing carbon dioxide at 1 atm pressure were identical to those methods previously reported (1). Rectangular plate specimens of the alloy, 0.7 x 0.5 x 0.3 cm, were polished finishing with 1μ diamond paste. During oxidation-decarburization of a specimen, the flow rate of the carbon dioxide gas was maintained at 0.6 cm/sec. Vacuum decarburization of a specimen *in situ* was carried out at a residual pressure of 10^{-5} Torr.

Specimens were mounted in epoxy resin for metallographic examination. Both cross sections and tapered sections through the oxide layer at angles less than 5° from the surface plane were used. Where etching of the metal surface was employed, the etchant was 2% nital.

Carbon analyses of oxidized specimens were carried out by the Orsat method. An entire specimen was combusted after removal of the wustite layer by pickling in dilute hydrochloric acid at room temperature until visual examination showed complete removal of oxide. It was established that the loss of metal by this pickling procedure was negligible.

Results

When a specimen is exposed to carbon dioxide at 950°C, the observed change in weight is the result of both wustite growth and carbon loss. The reaction curves and the carbon analyses of specimens reacted under various conditions will be shown, as well as photomicrographs illustrating structural features of the metal and oxide scale.

Reaction kinetics.—Typical reaction curves for the Fe-0.81 w/o C alloy in carbon dioxide are shown in Fig. 1. The initial slope of a curve was positive giving way to a region of constant slope and finally a region of decreasing slope as the reaction tended to become partially governed by diffusion processes. In the previous research (1), the initial slope in the reaction curve was found to be positive for Fe-0.6 w/o C and negative for Fe-1.07 w/o C. The value from the present work is intermediate between these values. The linear reaction rate constant calculated from the data in Fig. 1 is 0.093 ± 0.012 mg/cm^2 min.

An abrupt change from weight increase to weight decrease was usually observed immediately after

[1] Present address: Defence Research Establishment Atlantic, Dartmouth, Nova Scotia.

* Electrochemical Society Active Member.

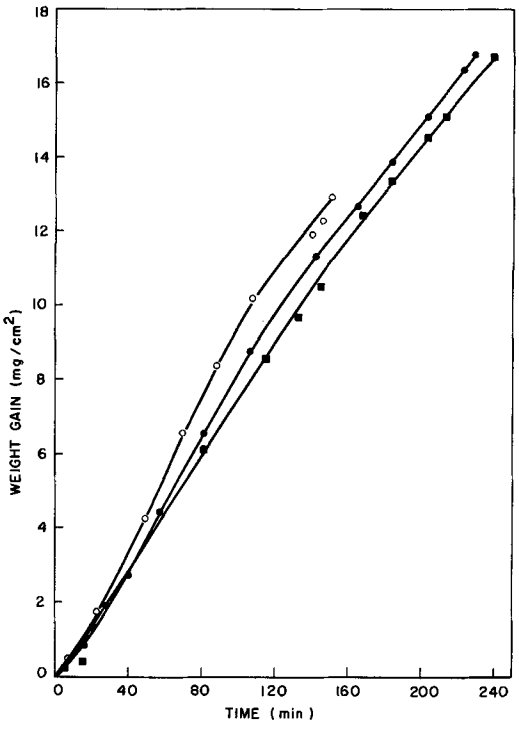

Fig. 1. Reaction kinetics of Fe-0.81 w/o C alloy in carbon dioxide at 1 atm. pressure at 950°C.

shutting off the carbon dioxide supply and allowing a scaled specimen to react under vacuum. The results are shown in Fig. 2. The loss of carbon from a specimen became continuously slower with increasing exposure time. Moreover, the rate of carbon loss decreased as the oxide thickness increased. With very thick oxide scales, approximately 100μ thick, decarburization was not observed during the time of the experiments.

Carbon analyses.—Specimens were oxidized in carbon dioxide for different intervals and then analyzed for residual carbon. The upper graph in Fig. 3 shows the carbon loss during the oxidation-decarburization period. Carbon loss occurred after an initial period of more rapid rate over an extended period by a constant rate equal to 6.0 x 10^{-3} mg/cm^2 min. Microscopic examination of the wustite scales illustrated that the onset of the linear rate behavior corresponded approximately to coverage of the metal surface with wustite.

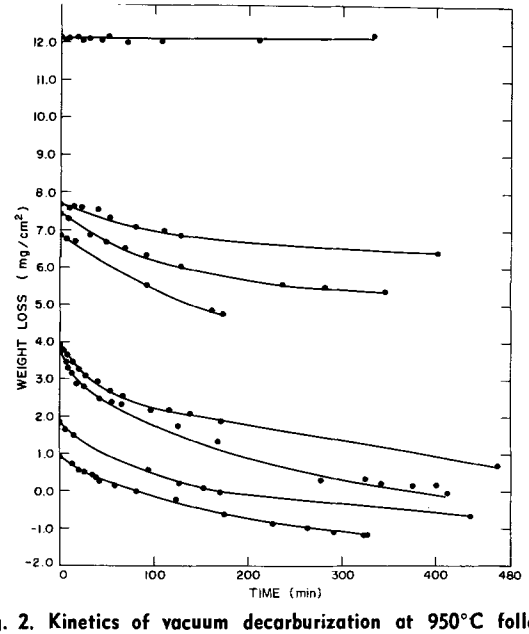

Fig. 2. Kinetics of vacuum decarburization at 950°C following immediately after oxidation in carbon dioxide.

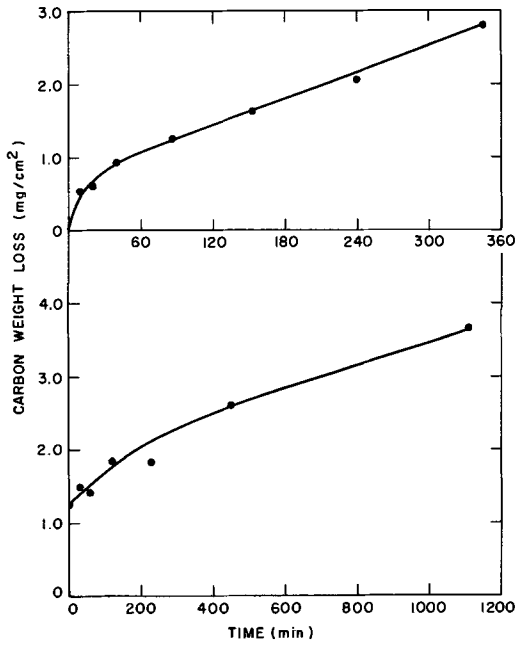

Fig. 3. Carbon loss from a specimen during oxidation in carbon dioxide (upper graph) and during vacuum decarburization after exposure to carbon dioxide for 90 min (lower graph).

In another series of experiments, the reaction time in carbon dioxide was kept constant at 90 min. Specimens were then decarburized under vacuum and analyzed for residual carbon. These results are given in the lower graph of Fig. 3. Carbon loss by oxide reduction at approximately 1.7 x 10^{-3} mg/cm^2 min occurred more slowly than during reaction of a specimen in carbon dioxide.

Metallography.—When a specimen was exposed to carbon dioxide, the surface became covered with wustite crystallites within a period of 30-40 min. The growth of the crystallites was very irregular, the general trend being toward larger size crystallites as the oxide layer thickened. The oxide was generally very adherent to the metal as shown in Fig. 4. Sometimes, however, reaction of carbon with wustite occurred at the metal interface with the result that voids were formed, and iron precipitated at the interface, as shown in Fig. 5. It appeared that blistering of the scale occurred at these regions. Figure 6 taken from a tapered section of a specimen suggests this possibility. The micrograph of the metal shows

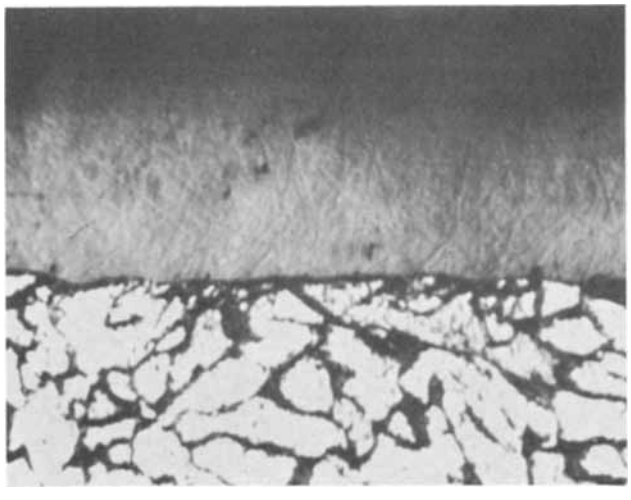

Fig. 4. Metal/oxide interface after oxidation of the specimen in carbon dioxide (Magnification 200X).

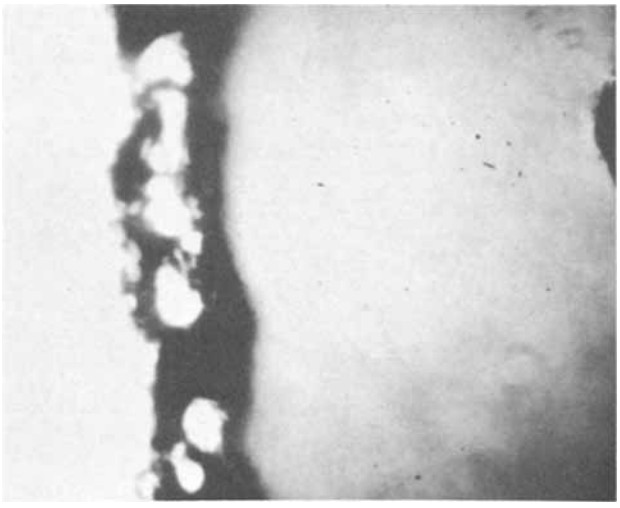

Fig. 5. Void formation and iron precipitation at metal/oxide interface after oxidation in carbon dioxide (Magnification 380X).

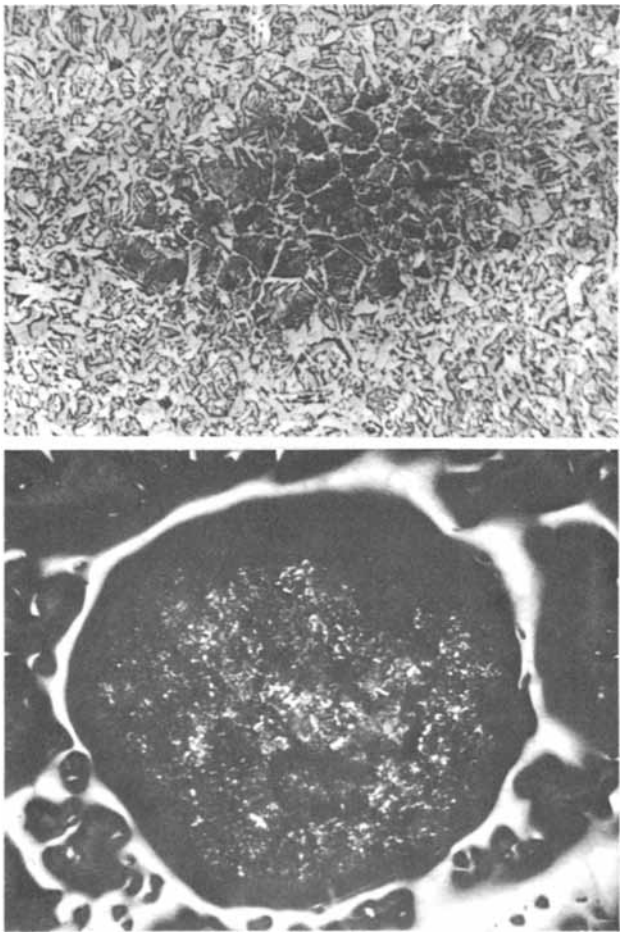

Fig. 6. Taper sections of a specimen after oxidation in carbon dioxide. Upper micrograph, metal surface showing nonuniform carbon content, dark area is of larger pearlite content due to higher carbon content (magnification 100X); lower micrograph, blistering of oxide, the central area of the blister is the underlying metal.

an area of high carbon content surrounded by an area of extensive decarburization. In the other micrograph showing the presence of wustite, the scale appears to be ruptured and the dark etching of the underlying metal suggests that this may be a high-carbon area.

Void formation and iron precipitation at the metal/oxide interface became a general feature when an oxidized specimen was allowed to decarburize under vacuum. As shown in Fig. 7, this interface became

Fig. 7. Void formation and iron precipitation at metal/oxide interface after vacuum decarburization of oxidized specimen for 3 hr at 950°C (magnification 400X).

extremely uneven as wustite was reduced, and voids were formed at the interface. In this photomicrograph, the void volume (39%) is of the same order of magnitude as the difference in the volume of the metal and oxide (43%). This appeared to be a common feature of the decarburization reaction by wustite reduction. An additional effect apparently caused by the presence of pores in the scale through which carbon monoxide escaped could be seen by taper-section metallography. As shown in Fig. 8, spires of metal, which extended into the wustite scale, developed at the surfaces of pores during reduction of wustite by carbon monoxide. In the case of a thin scale, wustite could be completely reduced in some places exposing areas of reduced metal. Cross sections of these regions, as illustrated in Fig. 9, also showed the presence of the iron spires formed by the reduction of wustite at the walls of pores.

Discussion

The observations are consistent with the proposition that decarburization is controlled largely by the reaction steps at the alloy surface with pores in the wustite scale possibly offering a small resistance to the transfer of gaseous carbon oxides. These pores

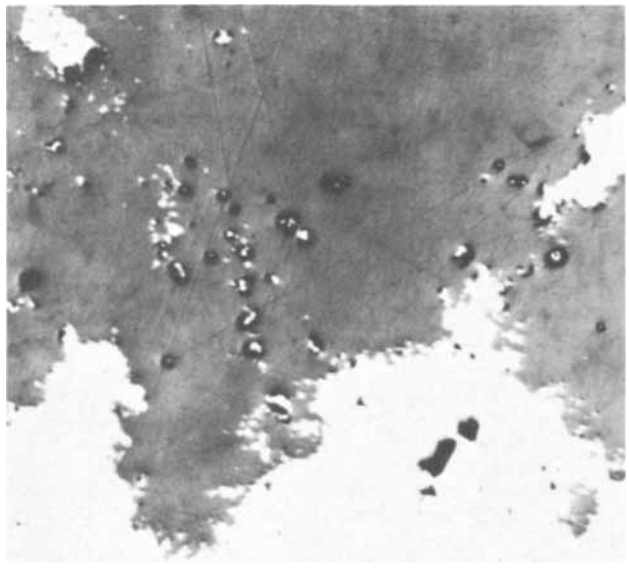

Fig. 8. Taper section of metal and oxide scale after vacuum decarburization of specimen (magnification 170X). Iron precipitation extends into wustite scale at pores.

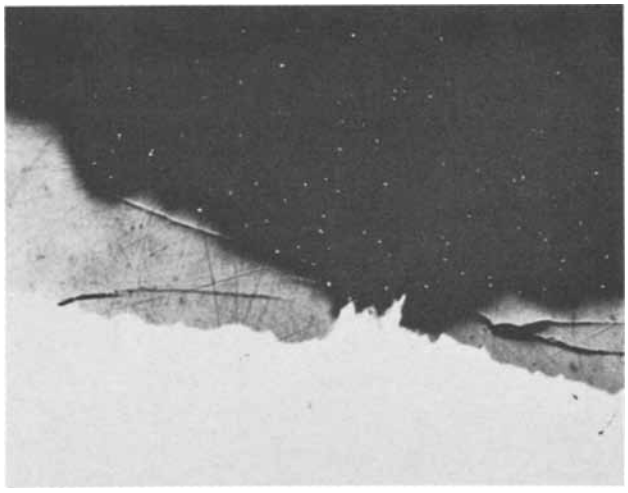

Fig. 9. Cross section of oxidized specimen after vacuum decarburization showing iron spires associated with oxide porosity (magnification 170X).

remain effective for gas transport under conditions which would appear to be a complex function of the original carbon content in the alloy, the exposure atmosphere, and the amount of wustite formation.

Decarburization was relatively rapid and wustite formation relatively slow during the initial stages of the reaction. Nevertheless, the reaction kinetics for both processes became approximately constant after 30 min. The linear weight gain corresponding to both oxidation and decarburization was 0.093 mg/cm^2 min (Fig. 1) while the decarburization rate was 0.006 mg/cm^2 min (Fig. 3). This latter rate is equal to an oxygen consumption of 0.008 mg/cm^2 min assuming that the reaction product is carbon monoxide. Thus, iron oxidation occurred approximately tenfold more rapidly than carbon oxidation in the steady-state condition for the Fe-0.81 w/o C alloy exposed in a carbon dioxide atmosphere.

It was found in the previous investigation that iron and carbon both enter into competition for adsorbed oxygen resulting from the dissociation of carbon dioxide during the early stages of the reaction (1). Since lateral growth of wustite blocks active decarburization sites and stifles this reaction, the area of metal exposed to the atmosphere approaches a small value, the atmosphere finally contacting the alloy through pores where wustite crystallites impinge on one another. An estimate may be made of this area affected by porosity during the steady-state oxidation-decarburization condition. In the absence of wustite formation, a carbon loss of 0.21 mg/cm^2 min would be expected using data from Fig. 8 and Eq. [3] of ref. (1). The actual loss, 0.006 mg/cm^2 min, is much lower. Assuming that this decrease is caused by the areal coverage of wustite stifling decarburization, the above rate shows that 2-3% of the surface area is affected by porosity. This is a maximum estimate since any influence of the P_{CO_2}/p_{CO} ratio in the expression for the decarburization rate, Eq. [8] of ref. (1), was neglected. Also, account could not be given to any possible resistance arising from geometry of pores to gas access to the metal surface.

The rate-controlling steps in decarburization would appear to be associated with the reaction at the alloy surface and transport of gaseous carbon oxides through the scale. If the surface reaction was completely rate controlling, the pores in the scale need only be large enough to permit free passage of carbon oxides to and from the metal surface. On the other hand, a constant resistance to gas flow would be required if transport of the carbon oxides through a thickening scale became rate determining. To account for this behavior in the case of the decarburization reaction of these alloys exposed in air, Sachs (2) has suggested that a resistance to gas flow cannot be due to friction along the walls which would increase with scale thickness. He suggests therefore that the resistance is caused by a single narrow restriction in each pore which remains open as long as sufficient carbon monoxide is evolved. It would appear, however, that the decarburization rate observed under the exposure condition employed in this investigation is largely controlled by the surface reaction steps. Even when the surface was covered with a thick scale, the relatively rapid passage of carbon dioxide through the pores was sufficient to maintain the surface decarburization reaction involving adsorbed oxygen at least threefold more rapid than under the condition of oxygen supply from wustite during its reduction (Fig. 3). Also, the decarburization rate was not independent of wustite scale thickness and decreased with time when this reaction proceeded by direct reduction of wustite in vacuum (Fig. 2). These characteristics suggest that the rates of the surface reactions coupled with the supply of carbon to the reaction sites are the most significant factors for determining the kinetics under scaling and nonscaling conditions.

The pores in the scale remained effective for the transfer of carbon oxides up to the longest exposure interval in the carbon dioxide atmosphere. Under vacuum decarburization conditions, however, the rate of carbon loss was a function of the amount of wustite formed and the residual carbon in the alloy. To obtain additional information on this relationship, the instantaneous rates for vacuum decarburization were obtained by taking limiting tangents to the plots in Fig. 2. These rates are plotted *vs.* the scale thickness in Fig. 10. Decarburization became negligible when the scale thickness exceeded 100μ and the residual carbon content of the alloy was less than 0.5 w/o. It would appear therefore that the reaction of carbon with wustite may reach a state of equilibrium in the absence of a reactive atmosphere. Engell (3) calculated an equilibrium pressure of 16 atm for the carbon monoxide gas arising from the reaction of carbon in a 0.5 w/o C alloy with wustite at 950°C. This value, which is accurate probably to a factor of not greater than five by present limitations of thermodynamic data (4, 5), would represent the maximum pressure to be found in a closed pore of the wustite scale at the metal interface since the carbon concentration is the average concentration of an oxidized specimen. Peters and Engell (5, 6) also measured the adherence of wustite to iron and iron-carbon alloys by determining the force required to separate the scale from the metal and obtained values ranging from 100 atm for pure iron to 30 atm for Fe-0.6 w/o C. This latter value lies in the range of the calculated equilibrium

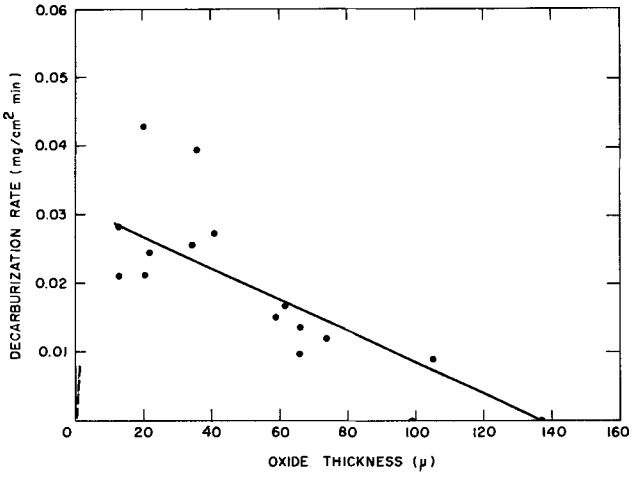

Fig. 10. Dependence of the initial vacuum decarburization rates on wustite scale thickness of the Fe-0.81 w/o C alloy immediately after oxidation in carbon dioxide at 950°C.

pressure of carbon monoxide, which suggests, as was found, that the wustite may become protective to decarburization at carbon contents below a critical value in the absence of a reactive atmosphere.

This investigation dealing with the reaction kinetics and observations on the structural features of the alloy and scales has substantiated the consideration that the reaction of carbon dioxide and wustite with carbon from an iron alloy occurs predominantly at the metal/oxide interface (1, 5-7). Carbon monoxide only reduced wustite at walls of pores to form a metal decoration as spires extending into the scale (Fig. 8). During vacuum decarburization, the small voids which appear at the metal/oxide interface could be accounted for by the difference in volume between wustite reduced and iron formed. These phenomena associated with the surface decarburization reaction and passage of carbon oxides through a porous wustite scale were most common. One other feature, blistering of the scale from the alloy did occur. Apparently growth and coalescence of wustite crystallites occasionally annihilated porosity in a scale at small localized areas, carbon build-up subsequently occurred and sufficient pressure of carbon monoxide was generated from the reaction of carbon with wustite for blistering of scale (Fig. 6). This type of reaction, nevertheless, was only of minor significance.

Summary

An investigation has been carried out on the oxidation and decarburization kinetics of a Fe-0.71 w/o C alloy at 950°C. Iron oxidation occurred approximately tenfold more rapidly than carbon oxidation under the steady-state reaction condition in the carbon dioxide atmosphere. The rate-controlling steps for decarburization were associated with the reaction at the alloy surface and possibly with a small constant resistance to passage of gaseous carbon oxides by pores in the wustite scale. A comparison of decarburization rates in the absence and presence of wustite indicated that the area of the surface affected by porosity was a maximum of 2-3%. Also, it was possible to show that these pores in the scale remained effective for gas transport at scale thicknesses less than 100μ and residual carbon contents in the alloy greater than 0.5 w/o under the conditions of vacuum decarburization. A small degree of scale blistering from the alloy surface was found to occur by the generation of a high pressure of carbon monoxide from the reaction of carbon with wustite at areas where growth and coalescence of the oxide crystallites annihilated scale porosity.

The Sublimation Pressure and Sublimation Coefficient of (100) Oriented Lead Telluride Single Crystals

Edward E. Hansen and Zuhair A. Munir

Department of Materials Science, School of Engineering, San Jose State College, San Jose, California

ABSTRACT

The sublimation pressure of (100) oriented single crystals of lead telluride was measured by the torsion-Langmuir method over the temperature range of 871°-993°K. The resulting expression for the free-surface sublimation pressure is $\log P(\text{atm}) = -(1.085 \pm 0.049)\ 10^4/T + (6.716 \pm 0.536)$ where T is the absolute temperature and the quoted errors are the standard deviations. Equilibrium sublimation pressures, as determined by the torsion-effusion technique in the temperature range of 919°-1042°K, were found to obey the expression: $\log P(\text{atm}) = -(1.109 \pm 0.026)\ 10^4/T + (7.119 \pm 0.261)$. Calculations of the third-law enthalpies for free-surface and equilibrium sublimations gave the values 54.95 ± 0.37 and 54.34 ± 0.13 kcal/mole, respectively.

Because of their properties as semiconductors, the chalcogenides of lead have been the object of considerable interest in recent years (1-3). A common method of preparation of thin films of these compounds employs a vapor deposition technique. In order to interpret the properties of the deposited films and to select suitable conditions for deposition, it is necessary to know the vapor pressure and the sublimation mechanism of these semiconductors.

Pashinkin and Novoselova (4) determined the sublimation rates from porous samples of lead telluride employing the Knudsen and Langmuir-like methods. Combining the results of these methods they concluded that the sublimation coefficient of lead telluride was essentially one. More recently, Brebrick and Strauss (5), employing an optical absorption method, determined the partial optical densities of vapors in equilibrium with solid lead telluride. They then used

the results of ref. (4) to calculate partial pressures of $Te_2(g)$ and PbTe(g) over PbTe(s).

Since vapor pressure values measured over free porous surfaces represent only upper limits, a total understanding of the sublimation mechanism of lead telluride is not complete without knowledge of the sublimation rates from single crystal samples. Furthermore, it would seem highly desirable to determine the equilibrium vapor pressure of this compound using the weight-loss-independent torsion method.

Experimental

The torsion-effusion and torsion-Langmuir methods have been adequately described in recent publications (6, 7). Detailed description of the apparatus used in this investigation has been given elsewhere (8).

Cylindrical cells made from National Carbon ZT101 Grade graphite were used in the torsion-effusion study. Previous experience with identical cells proved the absence of leakage around the friction-fitted lids (8). Graphite blocks with diagonally situated sample wells were used in the torsion-Langmuir portion of this study. Geometric descriptions of all cells used in this work as well as the appropriate Freeman-Searcy force correction factors (9) appear in Table I.

Temperatures were measured by means of a calibrated Pt-Pt/10% Rh thermocouple inserted inside a dummy cell which is situated about 1 cm below the torsion cell in the center portion of a tungsten heating element. Calibration of this thermocouple was accomplished by measuring the freezing points of aluminum, silver, and copper samples placed inside the dummy cell. As an additional check on the validity of results obtained in this apparatus the vapor pressures of tin, zinc, and silver were redetermined in the range from 10^{-6} to 10^{-3} atm. These measurements gave third-law $\Delta H°_{298}$ values of 72.4 ± 0.1, 31.6 ± 0.2, and 68.49 ± 0.05 kcal/mole, respectively. Hultgren *et al.* (10) list $\Delta H°_{298}$ values of 72.2, 31.2, and 68.10 for the above-mentioned elements, respectively.

Lead telluride samples were obtained as cylindrically shaped ingots with approximate diameters of 1.5 cm. These ingots, which had been prepared from "99.9999% pure" elements by the Bridgeman technique, were examined by x-ray methods. The resulting Laue patterns showed them to be single crystals with the easy cleavage (100) planes perpendicular to the cylinder major axis (lead telluride has the NaCl structure). Furthermore, Debye-Scherrer powder patterns indicated the presence of the lead telluride phase only.

Wafer samples (about 1 mm thick) to be used in the torsion-Langmuir experiments were obtained by means of a spark cutter. Laue photographs showed that the orientation of the faces of the wafers was within 2° of the (100) planes of the crystal. Powder samples used in the torsion-effusion experiments were filed from the ingots using a tungsten carbide file.

The congruency of sublimation of powder and single crystal samples of lead telluride was established from x-ray evidence. Samples which had been heated in vacuum, at temperatures and for time periods corresponding to about 30% weight loss, showed no discernible change in the x-ray patterns. The only observable change was a darkening of color of the heated powders at or near their surface. Crystallographic examinations of heated wafers showed no change in their orientation even after they had suffered up to about 80% weight loss by vacuum heating.

* This quantity is the orifice area in torsion-effusion cells and is the surface area of the sample in the torsion-Langmuir runs.

Results

Figure 1 shows the results of the vapor pressure measurements of both the torsion-effusion and torsion-Langmuir studies of lead telluride.

Using three cells, torsion-effusion sublimation pressures were measured between 919° and 1079°K. Calculations of the mean free path to orifice diameter ratios, λ/d, showed a systematic increase in the pressure results as this ratio fell significantly below one. Thus only vapor pressure values whose λ/d ratios were greater than one were included in all subsequent calculations. Based on the following reaction

$$PbTe(s) = PbTe(g) \qquad [1]$$

the least-square fit of the torsion-effusion data in the temperature range of 919°-1042°K was found to be

$$\log P(\text{atm}) = -(1.109 \pm 0.026)\ 10^4/T + (7.119 \pm 0.261) \qquad [2]$$

where P is the pressure, T is the absolute temperature, and the quoted errors are the standard deviations. Based on Eq. [1] and [2] second-law heat and entropy changes at 980°K were calculated to be 50.7 kcal/mole and 32.6 eu, respectively. Using reported Cp values (11, 12) the corresponding thermodynamic quantities at 298°K, $\Delta H°_{298}$ and $\Delta S°_{298}$, were found to be 54.9 ± 1.2 kcal/mole and 39.1 ± 1.2 eu. In order to determine third-law $\Delta H°_{298}$, free-energy functions were calculated from reported heat capacity data for PbTe(g) (11) and PbTe(s) (12). These calculations whose results appear in Table II gave an average value of $\Delta H°_{298}$ of 54.34 ± 0.13 kcal/mole.

Figure 1 also shows the results of the torsion-Langmuir studies of the sublimation from (100) oriented crystals of lead telluride. Employing a least-square fit for these data the expression for the sublimation pressure over the temperature range of 871° to 993°K was found to be

$$\log P(\text{atm}) = -(1.085 \pm 0.049)\ 10^4/T + (6.716 \pm 0.536) \qquad [3]$$

where T is in degrees Kelvin and the stated errors are the standard deviations. Second-law calculations of the heat and entropy of sublimation gave $\Delta H°_{932}$ =

49.6 kcal/mole and $\Delta S°_{932} = 30.7$ eu, respectively. Using the cited heat capacity data the corresponding values at 298°K were calculated to be 53.4 ± 2.3 kcal/mole and 36.9 ± 2.4 eu. Free-energy functions, calculated from Cp data referred to above, were used to calculate third-law heat of free-surface sublimation. Results of these calculations are shown in Table III. From this table an average value of $\Delta H°_{298}$ was found to be 54.95 ± 0.37 kcal/mole.

Discussion

The congruency of sublimation of lead telluride established in this work by x-ray methods is in agreement with observations made by others (4, 13). Porter (13), using mass spectrometric techniques, studied the composition of vapors effusing from graphite Knudsen cells containing solid lead telluride. His observations showed PbTe(g) to be the most significant gaseous species over PbTe(s). From optical absorption measurements, Brebrick and Strauss (5) concluded that PbTe(g) constitute about 98% of the sublimate from lead telluride.

The existence of equilibrium conditions inside the torsion-effusion cells was demonstrated by the observation that measured pressures showed no dependency on orifice size (14). The only deviation from equilibrium conditions came from data points for which the λ/d ratio was less than one. These points which correspond to nonmolecular flow conditions (15) were not included in the thermodynamic calculations.

Effects of volume diffusion through the walls of the torsion cell, and of surface diffusion around the orifice were examined. The former effect contributes no net torque to the cell and hence is of little significance in any study employing the torsion method. In accordance with theoretical considerations (16) a check was made on the magnitude of the surface diffusion effect. Results of such analyses proved the insignificance of any loss of material by means of surface diffusion around the orifice.

Because of the relatively small thickness (~1 mm) of the lead telluride samples used in the torsion-Langmuir experiments, and in view of the manner in which they were positioned and held on the graphite cells (approximately three fourths of their surface was in contact with graphite), it is unlikely that the phenomenon of evaporation-cooling (17) can create a significant temperature gradient across the samples and thus lead to erroneously low free-surface sublimation pressures. The negative deviation of the reported pressures at the high temperature end of the torsion-Langmuir studies may be suspected of being caused by evaporation-cooling. However, on examination of the remainder of the data, it becomes difficult not to attribute this deviation to the experimental scatter in the reported pressure results.

Torsion-Langmuir studies on (100) oriented crystals gave sublimation pressures somewhat lower than the equilibrium values in the corresponding temperature range. Based on this pressure difference, calculations of the sublimation coefficient, α, at 1000°K gave a value of about 0.7. In spite of the uncertainties in the data used in the calculation of this coefficient, justification for the reported value of α is based on the theoretical treatment given by Hirth and Pound (18). According to this treatment sublimation coefficients of low-index crystalline planes are expected to have a theoretical value of considerably less than one, even for such nondissociative sublimation processes as that of Eq. [1]. Measured sublimation rates from oriented single crystals of silver have in effect demonstrated this (19).

Technical Notes

Multiple Activation of YVO_4

S. Faria* and D. T. Palumbo

Sylvania Electric Products Inc., Chemical and Metallurgical Division, Towanda, Pennsylvania

The YVO_4 matrix serves as an efficient host for many rare earth (1) and nonrare earth (2) activators. Most works treat the singly activated systems or the combination of a rare earth and non-rare-earth activator (3, 4) or at most two rare earths in combination (5), except in the case of Brixner and Abramson (6) where emissions due to low concentrations of rare earth impurity were observed. In this note we discuss the spectra of YVO_4 multiply activated with combinations of Dy, Er, Sm, Eu, Bi, or In. Our aim was to prepare a single component phosphor having the same chromaticity as Illuminant A.

Experimental

The phosphors were prepared using conventional procedures as described in previous papers (2a, 5). The uncorrected emission spectra were recorded with a Perkin-Elmer Hitachi MPF-2A spectrophotometer. The phosphors were tested in 40W low-pressure fluorescent lamps for light output and color rendering index (7).

* Electrochemical Society Active Member.

Experimental Results

YVO_4:Dy,Er,Sm,Eu.—Because of its strong emission at low concentrations, Dy was selected as the primary activator. Various concentrations of the other rare earth elements (Er,Sm,Eu) were then added to YVO_4:Dy(0.003). The amounts required to approximate the Illuminant A energy distribution were usually less than the optimum concentration needed for the singly activated YVO_4. For example, the optimum Eu content was between 3 and 5 m/o (mole per cent) in YVO_4, while in YVO_4:Dy(0.003), 0.3-0.5 m/o Eu was sufficient to initiate quenching of the Dy emission. The emission spectrum of YVO_4:Dy(0.003) is shown in Fig. 1. Other rare earths are known to emit their major characteristic emission lines in the spectral area not occupied by the Dy multiplets. Rare

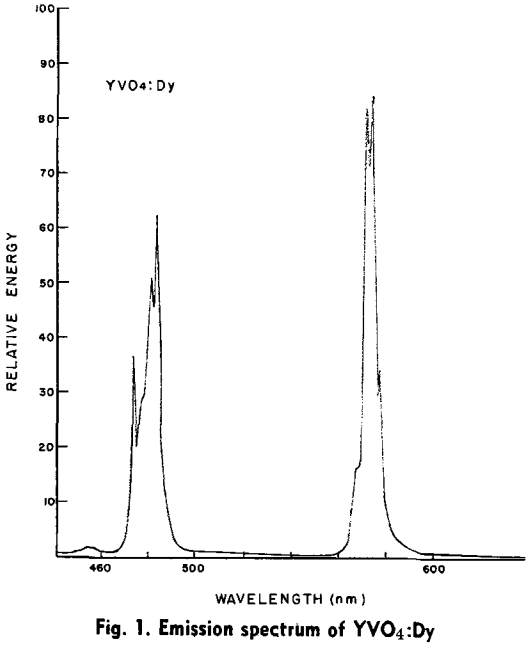

Fig. 1. Emission spectrum of YVO_4:Dy

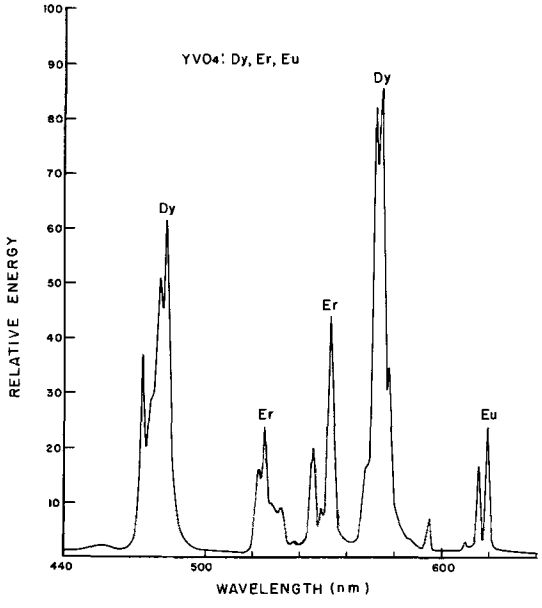

Fig. 2. Emission spectrum of YVO_4:Dy, Er, Eu

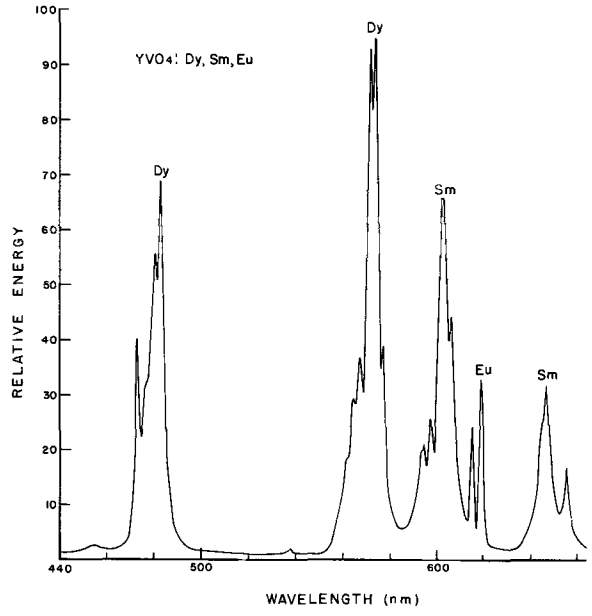

Fig. 3. Emission spectrum of YVO_4:Dy, Sm, Eu

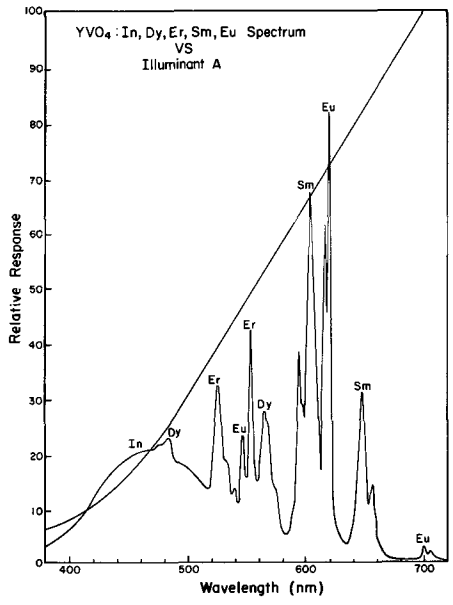

Fig. 5. Emission spectrum of YVO_4:In, Dy, Er, Sm, Eu

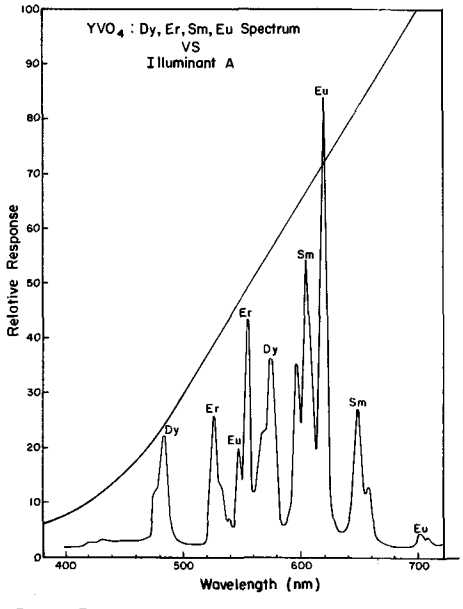

Fig. 4. Emission spectrum of YVO_4:Dy, Er, Sm, Eu

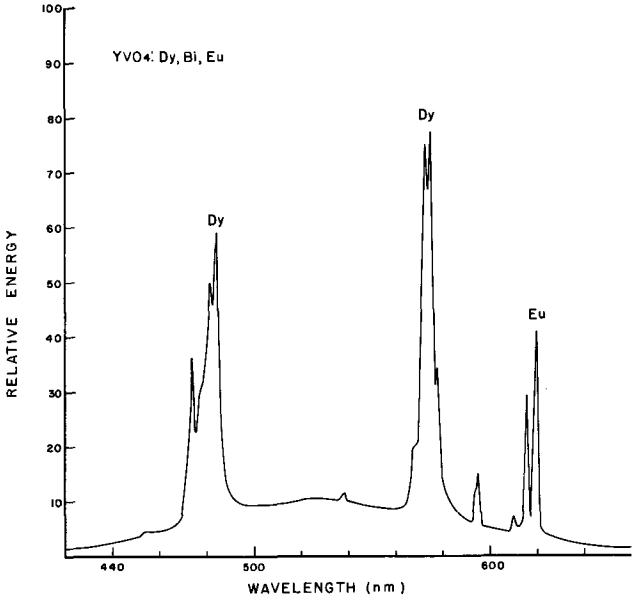

Fig. 6. Emission spectrum of YVO_4: Dy, Bi, Eu

earth elements known to emit between the two Dy multiplets are Tb at 543nm, Er at about 550nm, and Ho at about 545nm. Of these three, Er was the only one to show strong intensities in the presence of Dy and small traces of Eu. Figure 2 shows the emission spectrum of YVO_4:Dy(0.003), Er(0.007), and Eu (0.0003). Erbium lines are shown to be very strong at 525, 545, and about 555 nm. In the long-wavelength spectral region, *i.e.*, beyond the 575 nm Dy lines, Sm and Eu are the most intense rare earth emitters.

Samarium was incorporated together with Dy and Eu. Figure 3 shows Sm lines appearing at about 600 and around 645 nm. In this spectrum the concentration of Sm was 0.008 while Dy was kept at 0.003 and Eu at 0.0003. The addition of Er to YVO_4:Dy,Eu,Sm fills the gap in the emission spectrum between the Dy multiplets. Figure 4 shows the emission spectrum of all these rare earths, Dy, Er, Sm, and Eu. Figure 4 gives the spectrum of YVO_4:Dy,Er,Sm,Eu compared to Illuminant A (tungsten lamp at 2848°K) which is shown as the superimposed line. The composition of the phosphor represented in Fig. 4 is YVO_4:Dy(0.0007), Er(0.008), Sm(0.005) and Eu(0.0025). Note that the Dy lines are still very strong even in the presence of more than ten times as much Er, seven times as much Sm, and three times as much Eu. This phosphor composition, however, lacks some blue and red emission compared to the Illuminant A distribution.

YVO_4:In,Dy,Er,Sm,Eu.—The blue emission of YVO_4:Dy,Er,Sm,Eu was enhanced by incorporating In, a non-rare-earth element. By adjusting the proportions of each rare earth and by using about 2 m/o In, a chromaticity closer to Illuminant A was obtained. The color coordinates of the YVO_4:In(0.02), Dy (0.0007), Er(0.008), Sm(0.005), Eu(0.0025) phosphor shown in Fig. 5 were $x = 0.429$ and $y = 0.393$ with 254 nm excitation, compared to $x = 0.448$ and $y = 0.408$ for Illuminant A.

YVO_4:Dy,Bi,Eu.—The addition of Bi to YVO_4:Dy,Eu introduced the typical broad emission band of YVO_4:Bi (3, 4) with a peak at about 550 nm. Dy, Eu, and Bi were incorporated in YVO_4 yielding a phosphor with the following composition, YVO_4:Dy(0.003), Bi(0.002), Eu(0.002). The emission spectrum is shown in Fig. 6. By slightly increasing the Dy content to 0.004 in this phosphor, we obtain color characteristics close to

Illuminant A. The x color coordinate was 0.438 and the y was 0.403, measured in 40W fluorescent lamps with an output of about 2500 lumens and a color rendering index of 50.

Summary

YVO_4 can simultaneously accommodate a multiplicity of rare earth and non-rare-earth activators, each emitting its characteristic spectral lines or bands. Although the color of Illuminant A can be obtained with reasonable light output, the gaps in the spectral energy distribution, as a consequence of the use of line emitters, give poor color rendition.

Epitaxially Grown Graded Heterojunctions of (Zn, Cd)S

W. J. Biter and R. B. Lauer[1]

University of Delaware, Newark, Delaware

In this communication we wish to report the epitaxial growth of CdS crystals on ZnS single crystal substrates. Due to the elevated temperatures at which these heterojunctions are grown there exists a transition region between the pure ZnS and the pure CdS. The transition region which has its origin in interdiffusion is a region of spatially dependent energy gap (1). The heterojunctions at 80°K show blue photoluminescence on the ZnS side and green photoluminescence on the CdS side. The majority of the work done on epitaxy in the II-VI compounds has been limited to the deposition of thin films of one II-VI onto another II-VI, either by chemical transport, vacuum evaporation, or flow method (2).

The technique used to grow the heterojunctions was basically the self-sealing method of Piper and Polich (3), except that an orientated ZnS single crystal was placed in the tip of the growth tube as shown in Fig. 1. [The ZnS crystal was grown in this laboratory and had impurities on the order of 10 ppm (4). The CdS powder was Semi-Elements and 99.999% pure.] The ZnS single crystal was orientated so that its c-axis was parallel to the axis of the growth tube. The ZnS single crystal was chemically etched in HCl prior to use. The optimum conditions for the successful epitaxial growth of CdS onto the ZnS were: (*a*) charge temperature of 1120°C; (*b*) an initial temperature difference of 20°C between the charge and the face of the ZnS; (*c*) a drive rate of 1.3 cm/day; and (*d*) a temperature gradient of 20°C/cm in the growth zone. The ambient used was 100 mm of Hg of HCl and 660 mm of Hg of H_2S. These crystal growth parameters represent optimum values. The HCl is added for doping; however, it probably increases the transport process as well. The duration of the growth run was 24 hr giving CdS regions of about 1 cm thick. The CdS crystal was composed of a number of large single crystals.

Back reflection Laue photographs showed that the c-axis of the epitaxially deposited CdS crystal was parallel to the c-axis of the ZnS substrates. Preliminary microscopic observations indicated that the transition region was between 50 and 100 μm thick. By means of electron microprobe analysis the exact spatial extent as well as the ratio of Zn to Cd in the transition region could be determined. Electron microprobe data for a typical heterojunction are shown in Fig. 2. Since a concentration gradient exists in the

[1] Present address: Itek Corporation, Lexington, Massachusetts.

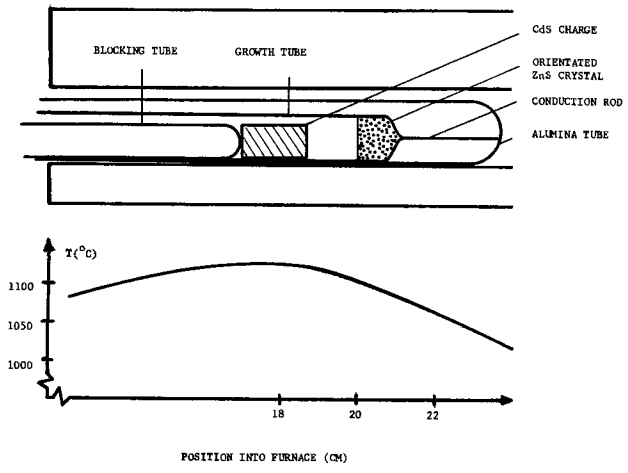

Fig. 1. Furnace and temperature profile for the growth of epitaxial heterojunctions of (Zn, Cd)S.

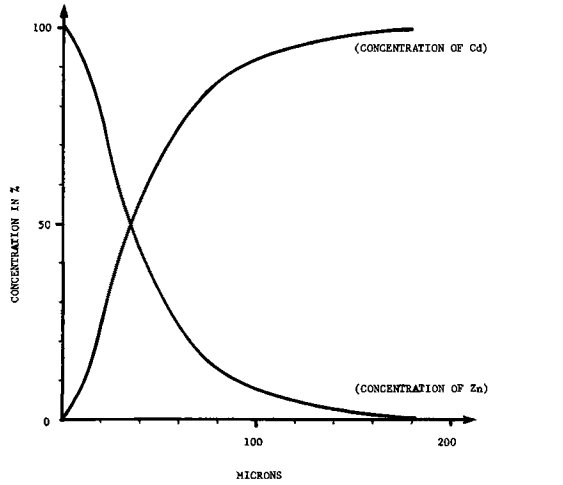

Fig. 2. Concentration of Zn and Cd as a function of position in (Zn, Cd)S graded heterojunctions.

system, it is necessary to consider the transition region as a region of spatially dependent energy gap (5).

Owing to the complex nature of the interdiffusion process it is impossible to relate the diffusion to a specific type of diffusion, or to calculate an exact diffusion constant. This technique of epitaxial crystal growth does serve as a method for obtaining graded heterojunctions of II-VI compound systems, and should be readily applicable to such systems as CdS on ZnTe or CdSe on ZnS. Although it is impossible to generalize on the nature of the interdiffusion process, an order of magnitude diffusion constant characterizing the diffusion process can be obtained from the electron microprobe data by taking the two end points and assuming that the diffusion follows the relation $C(x,t) = C'$ erfc $(x^2/4Dt)^{1/2}$. The value of D obtained for 1100°C is 10^{-11}cm^2/sec. This value most likely represents a weighted average value for the combined diffusion of Zn into CdS and Cd into ZnS.

SEM Observation of Self-Healing Breakdown in Thermally Grown SiO_2 Films

P. Wang* and N. Van Buren

General Telephone and Electronics Laboratories, Inc., Woburn, Massachusetts

and P. Edraos

Rome Air Development Center, Griffiss AFB, New York

During a study of switching in thin dielectric films, we observed, through a low-power microscope in a darkened room, faint bluish light emission generally along the periphery of the top electrode when a gradually increasing negative potential was applied. A typical test vehicle was a thin silicon dioxide film (between 0.06 and 0.1 μm thick) grown by thermal oxidation at 1050°-1100°C in a clean environment on a p-type silicon substrate of 0.002-0.008 ohm-cm resistivity. An evaporated gold film was used to provide backside contact, and the top electrodes were formed by electron beam evaporation of thin aluminum (of approximately 0.1 μm thickness) to form dots through a metal mask. The light emission was generally concurrent with an increase in leakage current observable on a Tektronix 575 curve tracer, beginning at well below bulk breakdown field strength. At a potential near, or slightly exceeding, bulk breakdown the device switched from a high resistance state, typically greater than 10^7 ohms, to a high conductance state of typical resistance of less than 100 ohms for a 0.020 in. diameter Al dot. By means of an appropriate current pulse, the device could be switched back to the high resistance state. The transition time for the switching effect is submicrosecond. The switching cycle might be repeated for tens or even hundreds of times with little visually detectable change in the appearance of the device structure until it failed. Its failure was usually accompanied by a white flash and a partially damaged top electrode. This was true for either devices on a slice or devices mounted on a transistor base with aluminum wire bonded contacts.

It is known (1, 2) that in an actual dielectric thin film structure there are weak spots in the dielectric material which must be cleared out by self-healing breakdowns before the true bulk electrical breakdown can be seen. For thin dielectric films and thin aluminum top electrodes, as in our case, the breakdown may be dominated by either structural defects or field distortion, which may be due to surface roughness or to the irregular edge of the electrode which is shaped by evaporation with a mask. Electrical breakdown in dielectric material may be due to an electronic avalanche caused by the stripping and acceleration of electrons by the applied field. In our devices, breakdown usually occurred at voltages between 60 and 100V. Sometimes, we observed a series of bluish light spots before the device was turned on. Since scanning electron microscopy has been of value in the study of semiconductor device failure, we decided to examine our devices in a JEOLCO model JSM scanning electron microscope by both secondary electron mode and beam-induced-current mode. Phase-contrast microscopy was also used to examine the test devices (before and after SEM study) for minute structural changes.

Selected open devices were examined on the JEOL scanning electron microscope with step increase in the applied bias to the aluminum top electrode. Each voltage step was held for several minutes, and Polaroid photographs were taken of the CRT displays. For instance, in device DS-0035-1B-6, the following figures show the beam-induced-current mode image of devices under varying bias. Figures 1a and 1b are at bias voltages less than 45V. The luminous effect at the periphery is explained as due to the enhanced conduction near the electrode edge at which a fringing electric field can accelerate injected beam-electrons toward the positive return. However, when a continuous bias of −50V was applied, we began to see microplasmas in the device areas, as shown in Fig. 1c to 1e. These three pictures show a sequence of self-healing breakdowns and a growing number of locations where beam-induced current gradually ceased to flow. We propose that these breakdowns in the area of the mask-evaporated aluminum electrode occurred at thinly covered spots on the dielectric film, and that those at the edge occurred where the deposited aluminum film was thinner, feathering out to the edge. In

* Electrochemical Society Active Member.

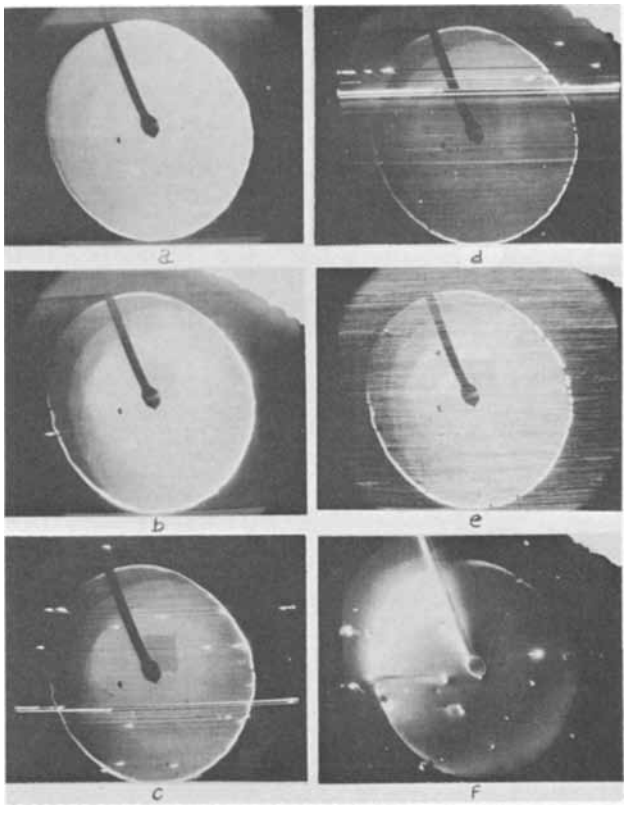

Fig. 1 SEM photographs of Al/SiO_2/p^+ Si thin film device: a, BIC Mode —20V; b, BIC Mode —45V; c, BIC Mode —50V, frame No. 1; d, BIC Mode —50V, frame No. 2; e, BIC Mode —50V, frame No. 3; f, SE Mode (voltage contrast) —50V. Magnification 90X.

such locations, the electrons of the scanning beam could most readily penetrate the negatively biased electrode, thus entering a strong accelerating field toward the positive electrode. Such electron current, at high field, then avalanched causing discharge of the device capacitance through the small breakdown region, generating enough heat to evaporate and/or fuse the thin film, resulting in disconnection from the bias. Thereafter, only thicker aluminum nearby remained biased, and being relatively impenetrable, the scanning beam had much less opportunity to be injected into the field. As seen in Fig. 1e, only the edge was bright at the fringing field, and the weak spots inside the dielectric film were essentially eliminated by the single-hole-propagated self-healing breakdown mechanism. Physical damage to the electrode may be seen in the voltage contrast, secondary electron mode photograph shown in Fig. 1f. A picture (inverted) taken later by means of a Reichert metallograph with phase-contrast attachment (Fig. 2) further illustrates the physical damage introduced during SEM examination. There is a one-to-one correspondence between the light spots and the burned areas.

Additional support to the proposed model was obtained by capacitance measurement of test devices on a General Radio conductance-capacitance bridge. Device capacitance was measured initially and after each of several pulsed switching cycles. Each cycle resulted in a small decrease in capacitance, due to localized

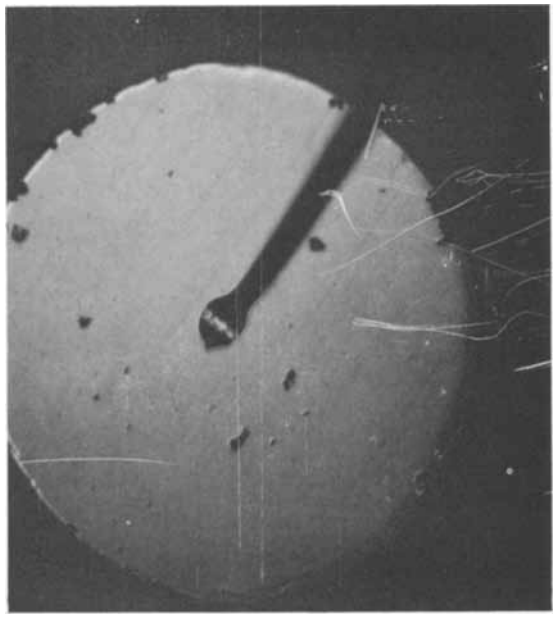

Fig. 2. Phase-contrast micrograph of same device after SEM examination, Magnification 125X.

erosion of aluminum near a conduction path, amounting to a few per cent or tenths per cent. Ultimately, the device under test would remain in a conductive state, or its capacitance would decrease substantially (say, to 10%) due to gross upper electrode destruction.

This phenomenon was observed in aluminum oxide, silicon nitride and silicon nitride-on-silicon dioxide films, and in silicon oxide films with sputtered molybdenum top electrodes. In these film devices, switching appears to occur at fields slightly above bulk breakdown and to proceed by a destructive mechanism. Although these devices may function for a large number of cycles, we cannot predict their life expectancy. We have attempted to modify the structure of the dielectric films by means of x-ray (40 kV) and high energy neutron (3 and 14 MeV) irradiation and by introduction of impurities during device fabrication with the hope that different modes of switching in these films would result. However, no significant difference in their switching behavior was observed.

Acknowledgment

The authors wish to acknowledge the valuable discussion on the subject of dielectric breakdown in silicon oxide thin films with Professor N. Klein of the Faculty of Electrical Engineering, Israel Institute of Technology. The scanning electron micrographs were taken by Mr. Joshua Varon of GT and E Laboratories, Bayside Research Center.

Brief Communication

Residual Impurities in High-Purity Epitaxial GaAs

C. M. Wolfe,* G. E. Stillman, and E. B. Owens

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts

Vapor and liquid epitaxial growth techniques have been notably successful in obtaining low concentrations of electrically active impurities in GaAs, and the total ionized impurity densities in the higher purity samples have been analyzed in some detail (1). By using a vapor growth method we have obtained epitaxial layers with total ionized impurity densities as low as 6.9 x 10^{13} cm^{-3} ($\mu_{77°K}$ = 210,000 cm^2/V-sec) (2). However, little is known about the residual total impurity content of these high-purity epitaxial layers, and the residual electrically active impurities have not been identified. Here we report the results of mass spectrographic analyses with detection limits down to 1 x $10^{15}cm^{-3}$ for samples of epitaxial GaAs with total ionized impurity concentrations as low as 7.6 x 10^{13} cm^{-3} ($\mu_{77°K}$ = 200,000 cm^2/V-sec).

The epitaxial samples analyzed here were grown on Cr-doped semi-insulating substrates with the $AsCl_3$-Ga-H_2 vapor flow system. Electrical measurements and mass spectrographic analyses were performed on either the same sample or samples grown during the same run. The Cr-doped substrates and the Sn ohmic contacts for the electrical measurements together with the regrown region below the contacts were removed before the mass spectrographic analyses.

The electrical measurements were performed in the van der Pauw configuration on symmetrically-shaped samples at a magnetic field of 5 kG. The shallow donor concentration (N_D) and the total acceptor concentration (N_A) were determined to within an estimated 10% by analyzing the temperature dependence of the Hall constant with the usual single donor statistics and/or by using the Brooks-Herring equation for ionized impurity scattering to analyze the Hall mobility at a temperature where other scattering mechanisms are minimal (3). When both analyses could be performed on the same sample, the results were in excellent agreement.

The results of these analyses for five epitaxial samples with total ionized impurity concentrations ($N_D + N_A$) from 2.6 x 10^{15} to 7.6 x $10^{13}cm^{-3}$ together with the measured mobilities at 300° and 77°K are shown in Table I. The properties of an undoped horizontal Bridgman grown crystal (sample No. 1) are shown for comparison. It is clear from these data that the epitaxial samples have a considerably lower electrically active impurity content than the melt grown sample. The sample thicknesses (last column in Table I) were generally large enough to obtain detection limits in the low $10^{15}cm^{-3}$ range for the mass spectrographic analyses.

The mass spectrographic analyses were performed with a double focusing mass spectrograph of the Mattauch-Herzog geometry (4) using a rf spark discharge as the ion source and a photographic plate as the detector. Pieces of the sample were used as self electrodes in the spark system. Only the singly charged ion lines were used in the quantitative evaluation. The lines were measured with a densitometer-analog computer system that corrected for the photoplate response and integrated the corrected intensity values as each line was scanned. Background corrections were made by subtracting the values obtained by integrating the spectral background immediately adjacent to each line for the same time interval required to scan that line. The photoplate was calibrated by the Churchill two-line method (5).

Table I. Results of electrical analyses

Sample No.	$\mu_{300°K}$, cm^2/V-sec	$\mu_{77°K}$, cm^2/V-sec	N_D, cm^{-3}	N_A, cm^{-3}	Thickness, μm
1	4400	6700	4.3 x 10^{16}	2.7 x 10^{16}	355
2	7700	53,000	1.8 x 10^{15}	8.0 x 10^{14}	135
3	8100	120,000	2.5 x 10^{14}	1.6 x 10^{14}	400
4	7500	155,000	1.0 x 10^{14}	9.0 x 10^{13}	295
5	8000	185,000	6.6 x 10^{13}	4.8 x 10^{13}	175
6	8200	200,000	4.6 x 10^{13}	3.0 x 10^{13}	150

It was assumed that the system was equally sensitive for all elements except that correction was made for the known mass effect on photoplate sensitivity (6). This assumption is necessitated by the lack of appropriate standards and can lead to errors as large as a factor of three in the absolute value of the concentrations reported. However, since it seems probable that the behavior of any one impurity would be the same in the ionization of all GaAs samples, it is estimated that the relative values for any one element in the several samples would be correct to within some 25%.

The results of these analyses for elements which have been reported to be donors in GaAs (O, Si, Sn, Te, Pb) and for elements reported to be acceptors (C, Fe, Cu, Zn, Cd) (7), together with the results of the electrical measurements for N_D and N_A from Table I, are shown in Table II. The nominal detection limit (NDL) for each sample is given in the last column. Other impurities which were detected in some samples at levels generally below $10^{16}cm^{-3}$ were N, Al, K, Ca, V, Sr, and Ta. It is interesting to note that no large difference in total impurity content is observed between the melt grown sample (sample No. 1) and the epitaxial samples or between the epitaxial samples with the highest and lowest electrically active impurity concentrations. This is in contrast to the three orders of magnitude difference in electrically active impurity content in these samples. The dominant impurities in all the samples are oxygen (2 x 10^{17} —1 x $10^{18}cm^{-3}$) and carbon (4 x 10^{17} —3 x $10^{18}cm^{-3}$). The total concentrations of possible donors and acceptors are greatly in excess of the electrically active donors and acceptors.

Obviously, with these high total impurity levels it is difficult to assign responsibility for the observed electrical activity to any particular impurity. Oxygen is generally believed to be a deep donor so that it would probably not be observed in the temperature range (4.2°-300°K) of the electrical measurements. The hydrogenic nature of the residual electrically active donors (8) strongly suggests a simple substitutional impurity and any of the remaining possible donors could be electrically active in a simple substitutional site. Silicon is observed in the melt grown

Sample No.	N_A	C	Fe	Cu, cm^{-3}	Zn	Cd	NDL
1	2.7×10^{16}	4×10^{17}	—	—	—	4×10^{16}	1×10^{15}
2	8.0×10^{14}	3×10^{18}	4×10^{15}	7×10^{15}	4×10^{16}	2×10^{16}	7×10^{15}
3	1.6×10^{14}	8×10^{17}	—	—	—	—	2×10^{15}
4	9.0×10^{13}	8×10^{17}	—	—	—	—	1×10^{15}
5	4.8×10^{13}	1×10^{18}	—	—	—	—	2×10^{15}
6	3.0×10^{13}	5×10^{17}	—	—	—	—	2×10^{15}

sample and in the epitaxial sample with the lowest detection limit in the analysis, while large amounts of Te are detected in most of the epitaxial samples.

The electrical analyses should detect all electrically active acceptors. Carbon is observed in all the samples, and all the other possible acceptors are found in large quantities in the lowest purity epitaxial sample. Although these acceptors were not found in the other epitaxial samples, it should be noted that the nominal detection limits are much higher than the concentrations of electrically active acceptors.

The high total impurity contents found in high-purity epitaxial GaAs are similar to those observed in high-purity silicon ($N_D + N_A \sim 10^{13}cm^{-3}$) where large quantities of oxygen ($10^{15} - 10^{18}cm^{-3}$), carbon ($10^{15} - 10^{20}cm^{-3}$), and aluminum ($10^{15} - 10^{17}cm^{-3}$) have been detected by various analytical techniques (9). The large Al content in silicon is believed to be rendered electrically inactive by the formation of compounds with oxygen. Considering the high levels of possible donors and acceptors and the high levels of oxygen observed in epitaxial GaAs, it is conceivable that similar effects also occur in GaAs.

We conclude that the high density of apparently electrically inactive impurities in high-purity epitaxial GaAs suggests the possibility of complicated impurity interactions in the solid and makes the identification of the residual electrically active impurities a formidable problem.

A New Fast-Charging Power Source

P. Bro* and N. Marincic*

P. R. Mallory & Company, Incorporated, Laboratory for Physical Science, Burlington, Massachusetts

ABSTRACT

A new rechargeable system has been developed comprising the cell: $Cd/ZnCl_2$, $CdCl_2$, $NaClO_4/AgCl/Ag$. Practical cells have been made which can be charged at rates between 30° and 90°C *via* a dual charging process involving the primary deposition of zinc and its subsequent replacement by cadmium from solution. The open-circuit voltage of the cells is 0.75V, and they can be discharged at either high or low rates with low overvoltages. No gas evolution occurs at the high rates of charge, and sealed cells have been operated through ten cycles with discharge efficiencies above 95%. The high rate capability is associated with a low specific capacity and a low energy density.

A new type of rechargeable cell has been developed which is capable of being charged with impunity at rates as high as 90°C. The cells give low charge recoveries when charged at low rates, and they are restricted in use to fast-charging regimes only, where they operate with high coulombic efficiencies. No such restrictions apply to the discharge of the cells; they may be discharged at either high or low rates. The purpose of this report is to describe the work which led to the development of the cells and to describe their mode of operation and their essential operating characteristics.

The search for a fast-charging, aqueous, electrochemical system led us to examine the intrinsic charging rate capability of a large number of anodes and cathodes in a variety of electrolytes. Our objective was to find a set of matching electrodes that could be charged to useful specific capacities at the 100°C rate without any gas being produced at the electrodes during the high rate of charge. It became apparent that anodes formed by deposition from concentrated solutions of an anode salt had much higher specific rate capabilities than anodes formed *via* solid-solid transformation processes such as the charging of cadmium anodes from cadmium oxide or hydroxide in an alkaline electrolyte. The same general principle applied to the cathodes, except that in this case the dissolved species would be the anion of the cathode active material. In addition, other limitations had to be considered, such as the solubility of the active material and the possible occurrence of passivation.

The only cathode found to be satisfactory was the Ag/AgCl electrode, and its high rate charging characteristics have been reported already (1). The most promising fast-charging anode was the Zn/Zn^{+2} electrode, and its mass transfer limiting rate characteristics have been reported (2). The experimental data available in the literature (3) on the $Zn/ZnCl_2/AgCl/Ag$ cell indicated that it had a high self-discharge rate. We found that the self-discharge rate could be reduced to a tolerable value by decreasing the zinc chloride concentration of the electrolyte, and we proceeded to develop practical $Zn/ZnCl_2/AgCl/Ag$ cells. However, gas accumulated in the cells on long-term active stand due to the corrosion of the zinc in the acidic electrolyte, and the gas bubbles caused current inhomogeneities which led to the formation of dendrites and cell shorts during subsequent high rate charges. Because of the gassing, the $Zn/ZnCl_2/AgCl/Ag$ cells could not be considered for any practical applications.

Attention was then focused on the $Cd/CdCl_2/AgCl/Ag$ system as the second choice for the development of a fast-charging cell. The low half-cell voltage of the cadmium electrode, its relatively high hydrogen overvoltage (4), and its charging rate characteristics (5) suggested that practical cells would be feasible. $Cd/CdCl_2/AgCl/Ag$ cells were constructed and operated at charging rates between 10° and 100°C with apparently satisfactory results. However, the discharge efficiency of the cells varied between about 60 and 90%. Extensive studies indicated that cadmium chloride induced a structural transformation of the glassy film of silver chloride on the cathode which changed to a powdery form and lost contact with the substrate. The rate of the silver chloride transformation process could be reduced to a tolerable level by decreasing the cadmium chloride concentration to 0.1M $CdCl_2$ or less, but such an electrolyte could not support the high charging rates sought for the rechargeable system. We were thus confronted with the dilemma that the high-rate $Zn/ZnCl_2/AgCl/Ag$ system could not be used because of gassing on long-term stand and the high-rate $Cd/CdCl_2/AgCl/Ag$ system could not be used in the high-rate charging mode.

The dilemma was resolved by developing a dual charging process consisting of the following sequence:

1. *Electrical charging*:

$$ZnCl_2 + 2e^- \rightarrow Zn + 2Cl^-$$
$$2Ag + 2Cl^- \rightarrow 2AgCl + 2e^-$$

2. *Electrochemical exchange*:

$$Zn + CdCl_2 \rightarrow Cd + ZnCl_2$$

This scheme depended on the selection of an electrolyte with a sufficiently high zinc chloride concentration to give the required electrical charging rate and an

* Electrochemical Society Active Member.

amount of cadmium chloride in solution such that the cadmium chloride concentration would be less than 0.1M $CdCl_2$ at the end of the exchange reaction. It was found to be successful in eliminating both the long-term gassing associated with the zinc anode and the deterioration of the silver chloride cathode caused by high concentrations of cadmium chloride. Although the exchange reaction proceeded more slowly than did the electrical charging process, it did not prevent the immediate use of the cell. In fact, on immediate use the zinc anode participated in the discharge and a greater cell voltage was realized than with pure cadmium alone.

Cell Design and Experimental Procedures

The characteristics of the Ag/AgCl electrode (1) indicated that charge densities of about 2 mAh/cm^2 could be obtained on flat cathodes at current densities up to 300 ma/cm^2, and the characteristics of the Zn/Zn^{+2} electrode (2) showed that charge densities of 2 mAh/cm^2 could be obtained on flat anodes at current densities below 360 mA/cm^2 in a 2.0M $ZnCl_2$ electrolyte. Therefore, it should be possible to operate parallel-plate type cell structures with anodes and cathodes of equal areas. Flat circular cells were constructed with an interelectrode spacing of 0.4 cm, and they were operated under a variety of conditions. All the cells failed after a few cycles, and the dominant cause of failure was the shorting of the cells due to zinc dendrites. Attempts were made to eliminate the shorting problem by using flat cells with anode areas twice those of the cathodes and by using peripheral current baffles tapering from a large diameter on the anode side to a small diameter on the cathode side. It was found that the shortness of the current path was inadequate to spread the current over the entire anode, and the cells failed after a few cycles again due to dendrite formation.

The cell structures were changed, therefore, to a concentric arrangement with a central silver rod as a cathode substrate and a peripheral cadmium cylinder as an anode substrate. The design is shown schematically in Fig. 1 and a photograph of the cell and its components is shown in Fig. 2. The cylindrical cell worked satisfactorily. Two features of the design appeared to be of some importance: the shape of the end baffles and the absorber structure. The former was shaped to reduce the deleterious edge effects observed during the charging of the anode, and the absorber decreased the intensity of the convective flows of the electrolyte during charging which otherwise caused a nonuniform current density on the electrodes and a subsequent premature failure. The cells were filled in a vacuum chamber using a degassed electrolyte to avoid the entrapment of air bubbles in the cells.

The electrolyte contained 2.0 moles/liter of zinc chloride (AR), 1.5 moles/liter of sodium perchlorate

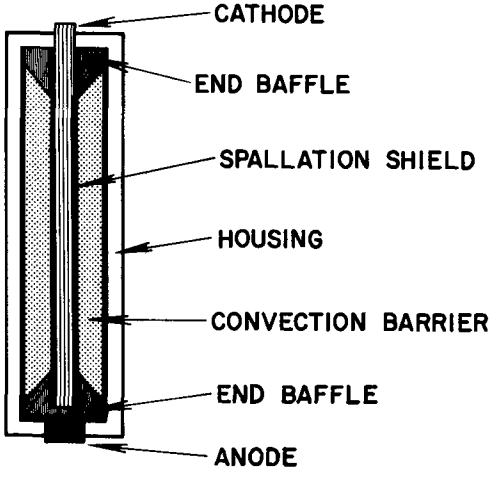

Fig. 1. Schematic diagram of cell

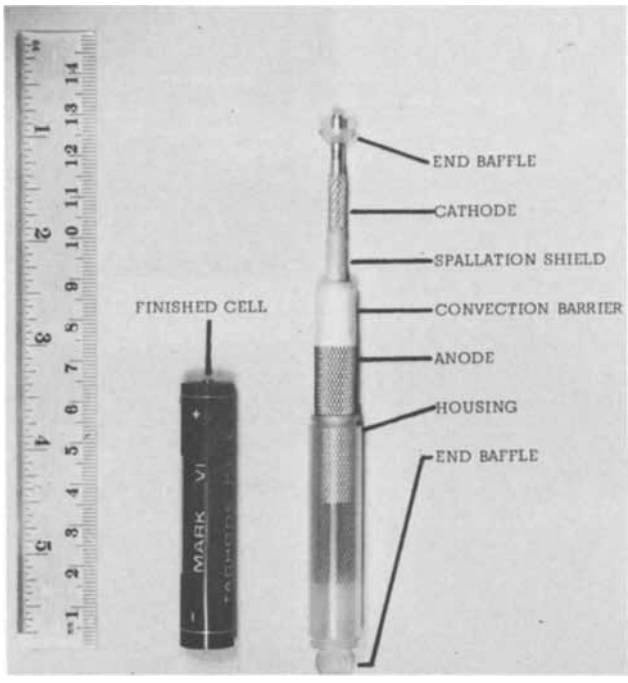

Fig. 2. Assembled cell and component parts

(AR), and an amount of cadmium chloride (AR) sufficient to give a concentration below 0.1 mole/liter on the completion of the charging process. It was necessary to employ the sodium perchlorate as a supporting electrolyte to increase the conductivity of the solution.

The cells were charged and discharged under constant current conditions using a Harrison power supply, Model 6286A, and a Greibach ammeter, Model 700, to measure the cell current with an accuracy of ± 0.5%. The charge-discharge curves were recorded with a Sargent recorder, Model DSRG, and the cell voltage was fed to the recorder *via* a Hewlett Packard d-c null voltmeter, Model 413A.

Experimental Results

The electrochemical evaluation of the cells was performed under ambient conditions at 25° ± 2°C. A typical charging curve is shown in Fig. 3A for a cell charged at the 40°C rate to a capacity of 50 mAh. The voltage remained constant at 2V during the first minute of charge. Then, it increased rapidly and reached 5V at the end of the charge after 1.5 min. The increase in the voltage toward the end of charge was probably due to the increasing resistance of both the silver chloride film and the diffusion layer at the electrode which becomes depleted in charge carriers. The open-circuit voltage of the cell immediately after charge was that of the Zn/AgCl couple, 1.05V, but it decreased to 0.75V on standing as the zinc was replaced by cadmium, Fig. 3B. The Zn/AgCl potential persisted for about half an hour, and the Zn/Cd exchange required slightly less than an hour to reach completion. The discharge curve of a cell discharged at the 2°C rate is shown in Fig. 3C. The load voltage remained constant at 0.6V until the end of discharge approached when it fell to zero at the exhaustion of the cell capacity.

The overvoltage of the cell on discharge is shown in Fig. 4. It increased linearly with the current density which indicated a purely ohmic impedance of 1.5 ohms for the 50 mAh unit.

The cyclability of the cell is represented by the data in Table I for charging rates between 30° and 90°C for cells with capacities of 33 and 50 mAh. The charge recoveries were generally greater than 90% with an average value of 96% throughout ten cycles.

The self-discharge rates of the cells were determined by charging the cells and leaving them on open-circuit

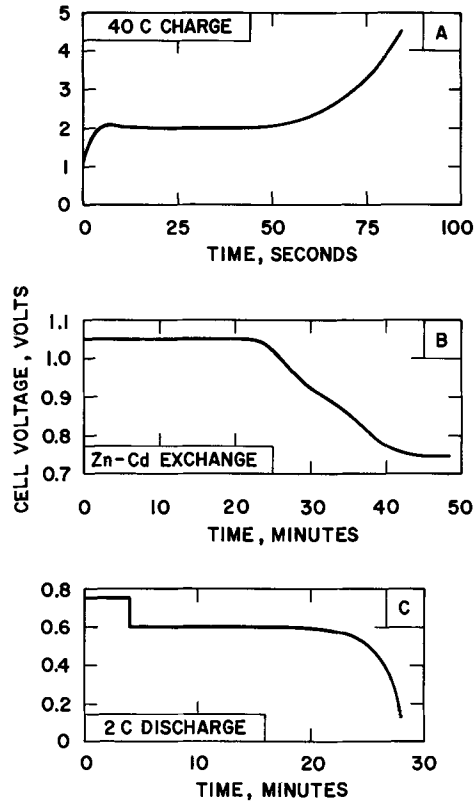

Fig. 3. Voltage characteristics of 50-mAh cell

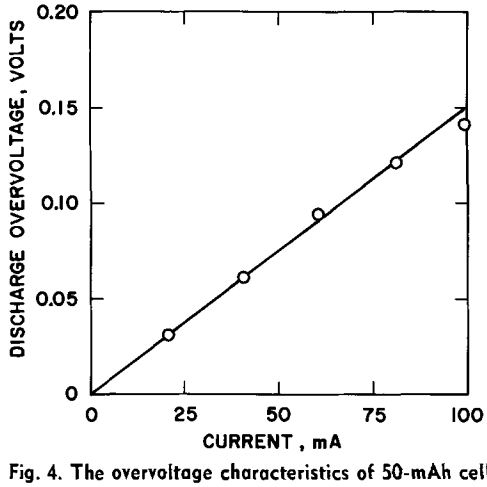

Fig. 4. The overvoltage characteristics of 50-mAh cell

stand for various periods of time before discharge. The results are shown in Fig. 5 for a 50-mAh cell. The data indicated a spontaneous initial rate of loss of capacity of about 0.5 mAh/day. However, the self-discharge rate decreased noticeably after about a month and more than 60% of the capacity remained after 3 months.

Discussion of the Results

The composition of the electrolyte used for the cell was based on a compromise between the various effects discussed on a previous page. A concentration of about 2 moles/liter of zinc chloride appeared to give a sufficient concentration of zinc ions to satisfy the charging rate requirements of the anode, and the associated chloride ion concentration was adequate for the high rate charging of the cathode without causing an unduly high rate of dissolution of the cathode by complexation. The concentration of the supporting electrolyte, 1.5 moles/liter of sodium perchlorate, was close to the maximum permissible concentration for the system which did not cause the precipitation of any solution component. The concentration of cadmium chloride was determined by the requirement that its concentration should not exceed 0.1 mole/liter upon completion of the Zn/Cd exchange and the additional requirements of the total charge of the cell and the volume of electrolyte needed to fill the cell. For the 50-mAh cell, this amounted to 0.365 mole/liter of cadmium chloride.

The dual charging mode was developed to overcome the difficulties associated with the evolution of hydrogen on the zinc electrode on stand. Since the zinc electrode has an active life of about an hour in the cell per cycle, it was of interest to consider the extent of a possible gas accumulation in the cells during extended cycling. The rate of hydrogen evolution calculated from experimental data would, for a 50-mAh deposit of zinc in 2M zinc chloride, amount to less than one tenth of a microliter per hour which suggested that a deleterious gas accumulation would probably not occur except for extended cycling regimes. Furthermore, since the zinc is oxidizing while present on the anode, it is likely that a smaller gassing rate will prevail in the cells.

It was thought that the self-discharge of the cells might be caused by the dissolution of silver chloride due to complexation with chloride ions and its subsequent reduction on the anode. Separate experiments established that this mode of loss of silver chloride amounted to about 0.4 $\mu A/cm^2$ in a 2M zinc chloride solution which agreed well with the low rate of self-discharge reached after a month. However, the observed initial rate of loss was ten times this value, and it is probable, therefore, that another process dominates the initial self-discharge of the cells. It is thought that the slow structural transformation of silver chloride caused by the residual cadmium chloride may contribute significantly to the observed self-discharge rate. A quantitative assessment of the rate of this process is not available.

An attractive feature of the cells is their very long projected shelf life in the uncharged state which can be further enhanced by the use of a silver substrate for the anode.

It is characteristic of the cells we have discussed so far that they can be charged to only low capacities, principally because of their nonporous electrode structures. The energy density of the 50-mAh units is 0.9 whr/lb. Although we have no data on conventional rechargeable cells charged at comparable °C rates, it is probable that energy densities of 1 whr/lb can be

realized with, *e.g.*, nickel-cadmium cells if they are charged at their rated currents for the short periods of time required to give comparable °C rates. However, it is also probable that they will produce gas which the $Cd/ZnCl_2$, $CdCl_2$, $NaClO_4/AgCl/Ag$ cells do not do. The voltage transition associated with the Zn/Cd exchange process may limit the usefulness of the system for some applications.

Conclusions

The rechargeable Cd(Zn)/AgCl cells operated satisfactorily at constant current charging rates between 30° and 90°C *via* the dual charging process involving the primary deposition of zinc and its spontaneous replacement by cadmium from solution.

The fast-charging cells had an open-circuit voltage of 0.75V and an ohmic impedance of 1.5 ohms on discharge. The available data suggest that the half life of charge retention was more than 3 months. The cell capacity was limited to about 50 mAh because flat, nonporous electrodes were used in the configuration discussed in this paper.

It appears that the specific charging rate capability of the Cd(Zn)/AgCl system exceeds that of any other available aqueous system by a considerable margin. However, the realizable energy density of the cell is only 0.9 whr/lb. No parasitic reactions occurred at the high charging rates, and the cells were completely sealed without the need for any venting structures. The average charge recovery through 10 cycles exceeded 95%.

Zinc Sulfide D-C Electroluminescent Displays

A. Vecht, N. J. Werring, R. Ellis, and P. J. F. Smith

Division of Materials and Molecular Science, Woolwich Polytechnic, London, England

ABSTRACT

A study of the materials preparation of zinc sulfide powders activated by manganese and copper has yielded direct-current electroluminescent cells with considerably improved performance. Investigation of the forming process has led to new cell configurations which are described. Some low-voltage characteristics are illustrated, 0.5 ft-L being obtained at 20V. The main problem of deterioration is discussed.

Although the emphasis of research work on the electroluminescence of II—VI compounds has shifted almost entirely from the Destriau type cell (1) to single-crystal junction devices (2), the potential of large-area electroluminescent displays made from powders should not be neglected. The requirement is still for displays and arrays of the order of 100-1000 cm^2. At present, the use of single-crystal devices for these applications must be ruled out. Apart from the prohibitive cost of large arrays of such devices, single-crystal slices greater than 5-10 cm^2 are not available. Furthermore, the current requirements of a junction device working at 1V would be in the region of 50A for a 500 cm^2 display, assuming 1% power efficiency at 500 ft-L. (This represents 500A/500 cm^2 area at a more realistic efficiency of 0.1%.)

The present position of d-c EL phosphors was reviewed recently (3) and it was shown that, with good materials control, both bright and efficient large areas can be produced (4) using powder phosphor layers. It was demonstrated that two different types of powder could be made. The first type is prepared by a slurrying technique, in which the activators are added to prefired ZnS powder (post-activation), and the second type involves the addition of the activator during the precipitation of ZnS (simultaneous-activation). Both types are then fired and may be subsequently copper coated to give high brightness panels which exhibit an electrochemical forming process. The simultaneously activated phosphors were found to be more suitable for low-voltage operation and the present investigation is confined to this type.

Preparative

The phosphors were prepared by the methods previously described in detail (4). Essentially, the powders were doped with manganese and copper during precipitation and were given a copper coating treatment. The activator concentrations were 0.25% manganese and 0.1% copper by weight.

Having prepared the phosphor, the construction of the d-c EL cell is extremely simple. The phosphor is mixed with a fixed weight of organic binder, shaken in an ultrasonic bath, and spread onto a moving plate of tin oxide conducting glass placed on a chromatographic spreader. The thickness of the electroluminescent panel is controlled by the height of the spreader gate over the conducting glass substrate, and usually ranges from 20 to 80 μm. Using this technique, areas up to 6 in. square can be prepared.

Cell Configurations

D-C electroluminescent powder cells have been constructed in two principal configurations: the conventional "through" cell and the gap cell (4). These are illustrated in Fig. 1 and 2. For the "through" electroluminescence cell, a back electrode of evaporated aluminum or a painted layer of colloidal graphite is applied. For experimental purposes, the area of this electrode (normally the cathode) is 0.5 cm^2. The gap electroluminescence cell is prepared by depositing the phosphor layer on an insulating surface between two planar electrodes. The region of light emission (Fig. 2) is dependent on the forming process.

When a d-c voltage is initially applied to a copper-coated phosphor in either a "through" or gap cell structure, the onset of light emission is accompanied by an irreversible fall in current. Similar effects have been observed on thin films (5-7). Upon the completion of the forming process, a line of relatively insulating particles across which most of the voltage drop occurs will have been produced. The "unformed" portions of

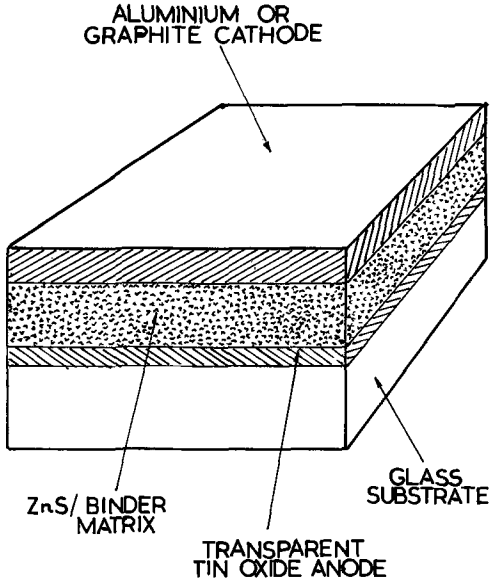

Fig. 1. Conventional powder "through" electroluminescence cell

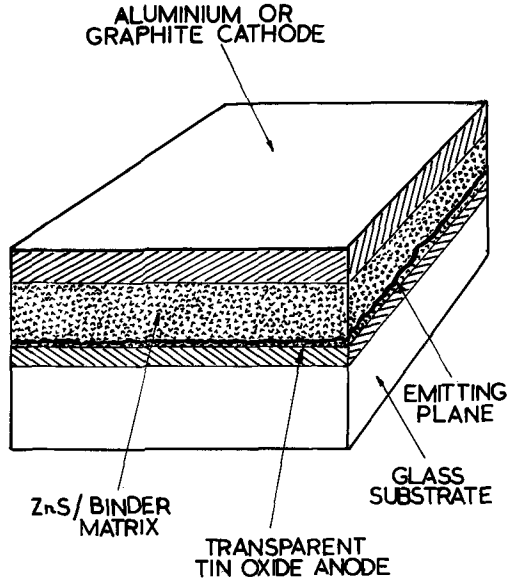

Fig. 3. "Through" cell showing plane of light emission. Thickness of powder-binder layer 50 μm.

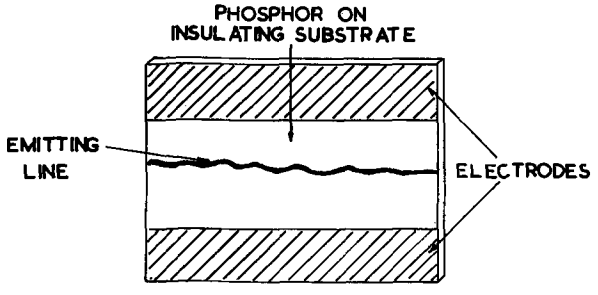

Fig. 2. A simple gap electroluminescence cell on a glass substrate. Graphite electrodes.

the phosphor layer will remain conducting and act as an extension of the electrodes. In the gap cell a similar line of insulating particles will emit light.

The forming process is believed to occur as the result of copper diffusion due to heating in the presence of an applied field. Thus, the power dissipation profile which is dependent on the local variation of defects, thickness and copper concentrations, will determine the path and shape of the emitting area. Similarly, in the "through" cell, a continuous plane or planar area will form that will emit light. Fortunately, this plane is produced adjacent to the conducting glass when this is made the anode (*see* Fig. 3).

Forming also takes place with reversed polarity but, in this case, the plane of emission is near to the back electrode. The efficiency is much lower due to light absorption in the bulk of the phosphor layer. Consequently, to minimize the effects of absorption, cells in the "through" mode must be operated with the conducting glass as the anode.

If a constriction is introduced between the electrodes of an unformed gap cell so that increased voltage stress will occur in a particular region, light emission will subsequently occur at that region. This can be achieved in many ways. For example, if a stylus is run along the surface of a gap cell, the line of light will follow the indentation produced.

A new type (8) of gap cell can be produced simply by making a narrow break in a conducting substrate and painting a layer of phosphor over it. If a voltage is applied, the current will tend to flow through the bulk of the layer as shown in Fig. 4A. Once over the break, the electrons will take the shortest path back to the conducting coating. At a sufficiently high power dissipation, the forming process takes place in the phosphor region adjacent to the conducting substrate and on the positive side of the break (Fig. 4B), and light

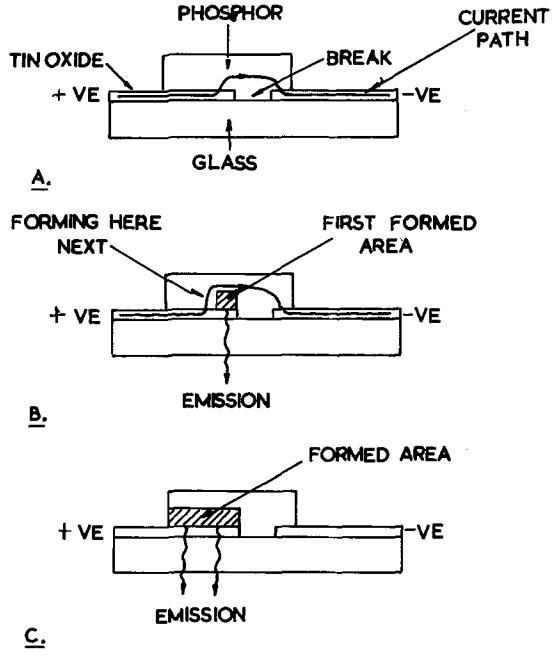

Fig. 4. Stages in the forming process of a modified gap cell

emission occurs. This region now becomes more resistive and the lowest resistance path for current flow moves toward the positive electrode and the forming process is repeated in the adjacent region. Eventually, the band of light emission will extend from the break in the conducting coating to the edge of the phosphor layer (Fig. 4C). Using this technique, simple numerical displays have been constructed (Fig. 5). It can be seen from Fig. 4C that the gap cell is in fact equivalent to a "through" cell, in which the top layer of unformed conducting phosphor acts as the back electrode.

Low-Voltage Operation

In order to be compatible with transistor circuitry, it is preferable that the operating voltage be relatively low (30V). By increasing the surface copper concentration and making thinner panels, the operation voltage has been reduced. As shown in Fig. 6, we have achieved 0.5 ft-L at 20V, increasing to 14 ft-L at 30V. For cross-matrix arrays, the discrimination ratio [defined as the ratio of the brightness at a particular voltage to the brightness at half that voltage (9)] is an

important parameter. Figure 6 indicates a discrimination ratio of 600 at 30V. The dependence of light output on current for the same device is illustrated in Fig. 7. It can be seen that the luminance increases by five orders of magnitude for less than an order increase in current.

Maintenance

The major problem still to be overcome is the short life under continuous operation of these devices. Although the life requirements of at least 5000 hr continuous operation have not yet been realized, improved characteristics are being obtained. At an early stage of the investigation, the devices were sealed in dry air to exclude moisture. These gave relatively poor results. The sealing of the devices in a glass vessel containing dry nitrogen with a powerful drying agent (such as magnesium perchlorate) yielded improved results as illustrated in Fig. 8.

The mechanism of the deterioration process is not yet fully understood. So far, relatively short half lives have been obtained with panels operating at low voltage or high brightness. However, an intermediate range of panels gave promising results. As illustrated in Fig. 9, a half life of 900 hr from 10 ft-L has been obtained.

As with conventional a-c phosphor layers, the impedance increases with operating time. This is not accompanied by a fall in efficiency; therefore the life of the panels can be considerably improved by stepwise voltage application (6). For example, one of our panels which initially emitted 100 ft-L at 60V again yielded this figure at 80V after having reached its half life. Another method of achieving a more useful life is the introduction of an appropriate series resistance. As the resistance of the phosphor layer increases the fraction of the voltage dropped across the layer will rise (10).

Conclusions

The potential of large-area displays made from powdered ZnS phosphors used under d-c excitation has been largely neglected and now affords exciting promise. The main problem to be resolved is that of life. Further improvement in the lifetime can be expected when the factors influencing the diffusion of impurities and defects under an applied field are more fully understood.

Acknowledgments

The authors wish to acknowledge their thanks to the Ministry of Technology and the Governing Body of Woolwich Polytechnic for continued sponsorship of the d-c electroluminescent project. They are particularly indebted to Mr. J. H. Williamson for some device preparation.

Stabilization of Small, Pyrophoric Iron Particles by Surface Polymerization

M. Robbins, J. H. Swisher, H. M. Gladstone, and R. C. Sherwood

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Pyrophoric iron powders, produced by the reduction of α- and γ-Fe_2O_3 in H_2, have been stabilized with respect to air oxidation by a method of surface polymerization which results in the formation of a plastic film around the particles. The polymer-coated iron was subjected to various heat treatments in air and O_2 saturated with H_2O to test its resistance to oxidation. The iron was highly resistant to oxidation as long as the decomposition temperature of the polymer was not exceeded (between 140° and 180°C). Therefore, this method of stabilization holds promise in overcoming a major problem in the use of fine particles of magnetic metals and alloys for permanent magnets and magnetic recording applications.

Submicron particles of magnetic metals and alloys have been of continuing industrial interest, especially for their use as permanent magnets and magnetic tape materials. The main problem in the use of these materials is their tendency to oxidize in air. Iron prepared by the reduction of fine particles of Fe_2O_3 at low temperatures burns upon exposure to air, while fine particles of Fe prepared by other methods, such as reduction from solution (1) or electrolytic reduction (2), oxidize more slowly. Stabilization of Fe particles for a limited period of time can be attained by immersion in organic solvents such as acetone, benzene, *etc.* A different method of stabilizing small metal particles is reported here. This method involves polymerization of a monomer on the surface of the particles which results in their encapsulation in a plastic film.

Experimental

Iron for the initial experiments was prepared from freeze-dried (3) $FeSO_4$ powder which was calcined at 700°C for 5 hr to form α-Fe_2O_3. The average particle diameter of the resulting Fe_2O_3 was about 0.1μ (1000Å), as determined by electron microscopy. Acicular Fe was also employed in the experiments; it was prepared by reducing acicular [Fig. 1(a)] γ-Fe_2O_3 obtained from Charles Pfizer and Company, Inc. (Type MO-4526). The average particle dimensions were 0.1 by 0.5μ.

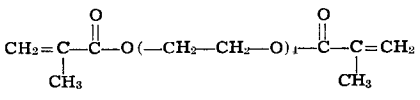
Both the α- and γ-Fe_2O_3 materials were reduced to Fe in hydrogen at 350°C for a minimum time of 3 hr. The resulting iron powder, after cooling to room temperature in H_2, was highly pyrophoric and oxidized immediately upon exposure to air.

For the polymer coating experiments, the iron powder was allowed to cool to room temperature in the H_2 atmosphere. The sample was then lowered into a beaker of the monomer, tetraethylene glycol dimethacrylate,[1] which was contained in the cold end of the reaction tube. This particular monomer has the advantage that there are two polymerizable groups which cause a 3-dimensional structure to form during polymerization.

Dilute monomer solutions were also used to decrease the thickness of the monomer coating and hence the thickness of the polymer. Dilutions of 1:1, 1:6, and 1:15 (monomer to benzene) were used.

Following removal from the furnace, the monomer-coated samples were held for several hours at 60°C in a vacuum oven to remove the benzene. The powder was then placed in a beaker of mineral oil, which was stirred vigorously to avoid clumping of the particles. The mineral oil-coated particle slurries were heated to 110°C and held for 4 hr to effect polymerization of the monomer.

[1] Tetraethylene glycol dimethacrylate



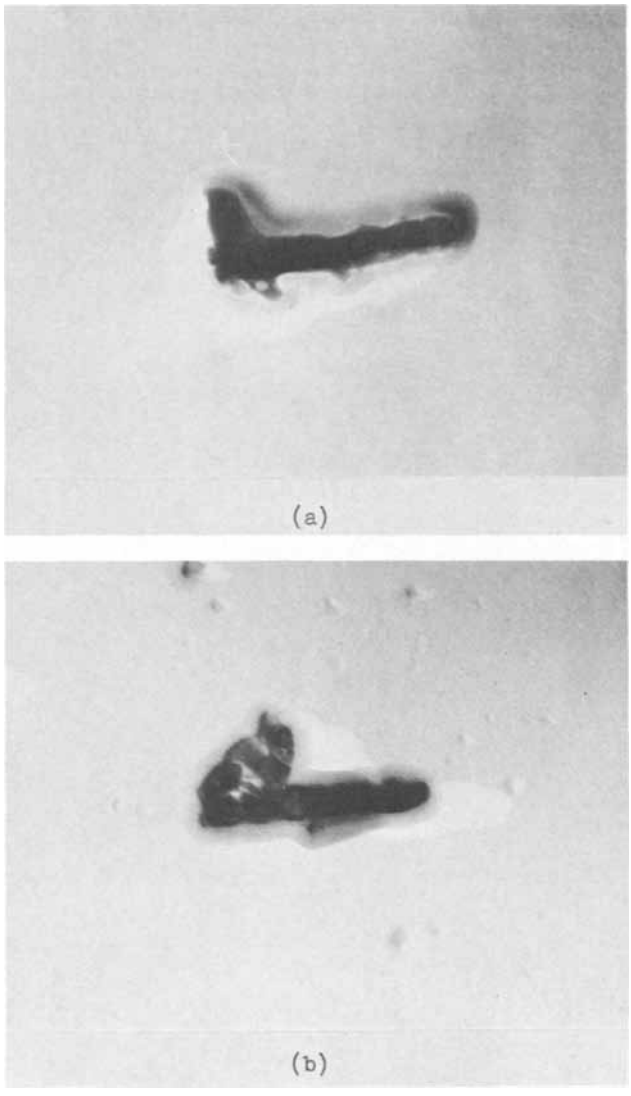


Fig. 1. Electron photomicrographs (27,000X) of (a) γ-Fe_2O_3 starting material and (b) reduced Fe using the γ-Fe_2O_3 as starting material. Polymer coating [gray coating around particle in (b)] was made using 1:15 monomer to benzene dilution.

The slurries were then allowed to cool and the Fe powder removed by filtration. Excess mineral oil was removed by washing the sample with hexane. X-ray diffraction using Cr-Kα radiation indicated the presence of iron with no observable second phase. The electron photomicrographs in Fig. 1(a) and 1(b) show that the shape of the acicular α-Fe_2O_3 was maintained during reduction to iron and that no apparent change in particle size occurred. Some pores in the powders developed, however, because of the difference in density between Fe and Fe_2O_3.

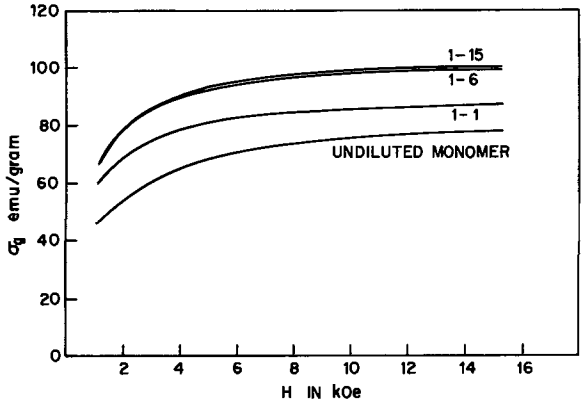

Fig. 2. Magnetic moment (σ in emu/g) vs. applied field for polymer-coated Fe samples using undiluted and diluted monomer solutions.

Results

Results obtained from room-temperature magnetic measurements on iron samples treated in various monomer dilutions are shown in Fig. 2. The observed magnetic moments per gram of material are significantly smaller than for uncoated Fe (σ = 218 emu/g), which indicates that the weight fractions of polymer in the materials are appreciable. With increasing dilution of the monomer with benzene, the polymer film becomes thinner and the magnetic moment increases. Coercivity measurements made on pressed bars of polymer-coated iron yielded coercive forces of $\sim$ 250 oe. Intrinsic coercivities ($I^{H}c$) of $\sim$ 1000 oe have been measured. The bars, which were magnetized after pressing, exhibited a remanent moment, indicating that some alignment of the acicular particles had occurred during pressing.

The results of tests designed to measure oxidation resistance in various media are given in Table I. In these tests, comparisons were made between polymer-coated iron and iron which had been stabilized by flowing a mixture of N_2 saturated with acetone over the sample at room temperature.

After each heat treatment, the samples were examined for oxidation under a microscope. Magnetic moment measurements were also made on many of the samples, which provided a more sensitive means of detecting oxidation. While the sample prepared with a 1:6 monomer dilution showed a 10% change in moment after 40 hr in air at 140°C, the sample prepared with 1:15 dilution was the only one that showed measurable changes in moment at both 140° and 97°C.

Discussion and Conclusions

We have shown that pyrophoric metal particles can be stabilized with respect to air oxidation. Aging tests which were made (Table I) show that this method affords better protection than stabilization with organic solvents. Although magnetic measurements made over time periods longer than those shown in

Table I. Results of oxidation resistance tests on iron powders stabilized with acetone and stabilized by polymer coating

		Test conditions				
Starting material	Passivation treatment	97°C, 67 hr in air	140°C, 40 hr in air	180°C, 18 hr in air	140°C, 24 hr in wet O_2	Immersion in 2*N* HCl
α-Fe_2O_3, γ-Fe_2O_3	None	← Pyrophoric →				
α-Fe_2O_3	Stabilized with acetone	Stable	Oxidized	Oxidized	Partially oxidized	Rapidly oxidized
α-Fe_2O_3, γ-Fe_2O_3	Undiluted monomer	Stable	Stable	Oxidized	Stable	Very slowly oxidized
γ-Fe_2O_3	1:1 Monomer to benzene	Stable	Stable	—	—	Very slowly oxidized
γ-Fe_2O_3	1:6 Monomer to benzene	Stable ($\Delta\sigma$ = 0)	Moderate oxidation ($\Delta\sigma$ = 10%)	—	—	Very slowly oxidized
γ-Fe_2O_3	1:15 Monomer to benzene	Slight oxidation ($\Delta\sigma$ = 3%)	Moderate oxidation ($\Delta\sigma$ = 15%)	—	—	Very slowly oxidized

Table I should be made, the results of oxidation tests at elevated temperatures indicate that room-temperature oxidation should not be a problem.

The room-temperature moment of the sample prepared with a 1:6 monomer dilution (σ = 100 emu/g) is significantly higher than that of γ-Fe_2O_3 ($\sigma \approx 80$ emu/g), which is presently used in magnetic tapes. The coercive force can be increased if desired by substituting Fe-Co alloys for Fe.

An advantage of the monomer used in this experiment is that polymerization can also be brought about by electron beam irradiation (4), which may be of use in some applications. Although we used tetraethylene glycol dimethacrylate exclusively in our study, there are many other monomers which may be used for polymer coatings.

Acknowledgments

The authors would like to thank Mr. E. A. Nesbitt and Mr. E. O. Fuchs for their help in making coercivity measurements. We also thank Miss S. E. Koonce for providing the electron micrographs.

The Optimum Number of Cells in an Amalgam Process Chlorine Plant

Fumio Hine*[1]

Kyoto University at UJI, Japan

ABSTRACT

The optimum number of cells in a chlorine plant has been calculated as a function of a coefficient, α, of the formula: Plant cost = Constant (Plant size)$^{\alpha}$, and the ratio of the a-c power cost, c, to the annual fixed charge, $\overline{Fc}$. The labor cost for plant operation is also discussed, but it is a small factor in deciding the optimum number of cells.

Deciding the plant capacity, the number of cells to be installed, and the optimum conditions of operation in a chlorine plant depends on the market situation, the power cost, the labor rate, the cell type, and other factors. The plant size should meet the market, but too small a plant is not economical. In general, the manufacturing cost decreases with increasing plant size if the plant is operated at nearly full capacity.

The optimum current density of the amalgam-type chlorine cell as a function of the investment and the power cost has been discussed in a previous paper (1).

The number of cells, N, or conversely the cell current load, I, in kiloamperes, is a major factor in optimizing a chlorine plant having the capacity of P metric tons per day by Faraday's law as follows:

$$P = 31.8 \times 10^{-5}\ nIN \text{ (metric tons } Cl_2\text{/day)} \quad [1]$$

where n is the current efficiency of the cell in per cent.

The number of cells to be installed is discussed from the economic point of view in this paper.

Investment

The total investment of a chlorine plant includes the costs of the cell room, the rectifier, the brine purification system, the handling of crude salt, chlorine and caustic, and other auxiliaries. Of these, the investment for the cell room and the rectifier room varies with the number of cells, but other costs are almost independent and are only a function of the plant capacity.

The cell-room cost depends on the plant size, the number of cells, or the amperage of the circuit, and the operating current density of the cells. It increases slightly with the number of cells, because the cost of a small cell is rather high.

The rectifier cost per kilowatt was shown in the previous report to be

$$\text{Rectifier cost per kw} = \text{Constant (Voltage)}^{-\delta}\ (\$/\text{kw}) \quad [2]$$

where δ = 0.15-0.16. Therefore, the rectifier cost is as follows:

$$\begin{aligned}\text{Rectifier cost} &= \text{Constant (kA of cell, } I\text{)} \\ &\quad \times \text{(Number of cells, } N\text{)} \\ &\quad \times \text{(voltage per cell, } v\text{)} \\ &\quad \times (Nv)^{-\delta} \\ &= \text{Constant } (P/n)\ (v)^{1-\delta}\ (N)^{-\delta} \text{ (dollars)}\end{aligned} \quad [3]$$

where v is the voltage of a cell including intercell bus bars in volts.

According to the previous report, the investment, J, consisting of the costs for the rectifier, the cells including graphite anode and mercury, and the cell room including connecting bus and piping, is shown by the next equation:

$$J = J_0 \left(\frac{P}{100}\right)^{\alpha} \left(\frac{i}{100}\right)^{\gamma} \quad \text{(dollars)} \quad [4]$$

where J_0 is the plant cost, in dollars, of a 100-tons/day plant operated at 100 A/dm^2, and i the current density in A/dm^2, and α = 0.926 and γ = −0.740. However, α becomes large for the modern chlorine plant: say 0.96-0.98.

Assume (2) that Eq. [4] is feasible for the cost estimation per unit cell, J_1, in dollars, that is,

$$J_1 = J_0 \left(\frac{P/N}{100}\right)^{\alpha} \left(\frac{i}{100}\right)^{\gamma} \quad (\$/\text{cell}) \quad [5]$$

* Electrochemical Society Active Member.
[1] Present address: Nagoya Institute of Technology, Gokiso-cho, Nagoya 466, Japan.

Since the chlorine plant of P tons/day in capacity has N cells, the plant cost, J, also in dollars, is N times J_1 as follows:

$$J = J_0 N \left(\frac{P/N}{100}\right)^{\alpha} \left(\frac{i}{100}\right)^{\gamma}$$

$$= J_0 (N)^{1-\alpha} \left(\frac{P}{100}\right)^{\alpha} \left(\frac{i}{100}\right)^{\gamma} \quad \text{(dollars)} \quad [6]$$

The total fixed charge, Fc(total), per unit production in \$/ton-Cl_2, which consists of depreciation, tax, maintenance, and supplies, is as follows:

$$Fc(\text{total}) = \frac{J}{365P}\frac{\beta}{100} + Fc' \quad (\$/\text{ton-Cl}_2) \quad [7]$$

where β is a coefficient depending on the location and situation, and is about 15-40%, and Fc' is the fixed charge based on the sum of the investment for brine purification, handling of chlorine and caustic, and other plant facilities not dependent on cell size.

Cost of Electric Power

The cost of electric power per unit of production, Ec, in \$/ton-Cl_2, was also shown in the previous report:

$$Ec = 0.756 \times 10^5 \left(\frac{c'}{n}\right) v$$

$$= 0.756 \times 10^5 \left(\frac{cv}{n}\right)\left(\frac{100}{m'}\right) \quad (\$/\text{ton-Cl}_2) \quad [8]$$

where c' and c are the prices of d-c and a-c power in \$/kwhr, respectively, and m' is the conversion efficiency of the rectifier in %, which is a function of the terminal voltage, V, in volts. It also depends on the type of rectifier. An example of the m' *vs.* V curve of a silicon rectifier is shown in Fig. 1 (3). Therefore, the following equation can be obtained:

$$\frac{100}{m'} = \frac{1}{1 - \frac{m}{V}} \cong 1 + \frac{m}{V} \quad [9]$$

where m is a characteristic value of the rectifier and is 1.45 in this case. Substituting this into Eq. [8],

$$Ec = 0.756 \times 10^5 \left(\frac{cv}{n}\right)\left(1 + \frac{m}{V}\right)$$

$$= 0.756 \times 10^5 \left(\frac{c}{n}\right)\left(v + \frac{m}{N}\right) \quad (\$/\text{ton-Cl}_2) \quad [10]$$

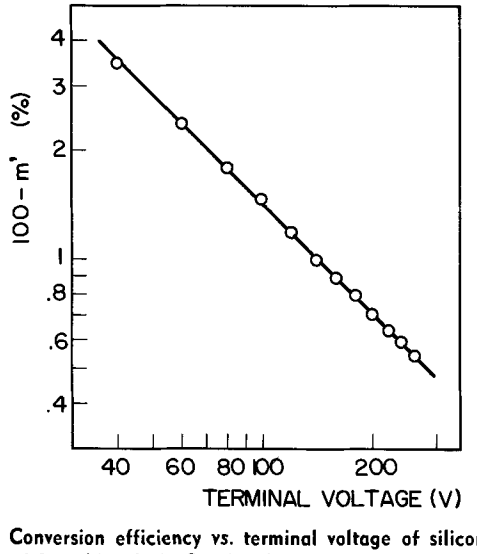

Fig. 1. Conversion efficiency vs. terminal voltage of silicon rectifier (quoted from Mitsubishi Catalog, L30901B, p. 13).

Labor Cost

The labor cost per unit production is greatly affected by several factors such as the size, layout, location and situation of the plant, the type and number of cells, the degree of automation and the labor rate, and the labor quality. Estimation of the labor cost, Lc, is therefore complicated.

A de Nora cell plant is operated by only three men per shift, and the operating man-hours for various sizes of plant up to 36 cells is almost constant according to Monsanto (4). The labor per shift in the de Nora cell plant is surprisingly small, and the layout of the plant is said to be a major factor in reduction of the labor cost.

Gardiner (5) points out that the man-hours per unit of production in an Olin cell plant decrease considerably with increasing the plant capacity, but he also indicates that the labor cost varies with the location and situation even though the plant capacity and the cell size are much the same.

Grosselfinger and Schuecker (6) obtained a relationship between the electric power cost and the labor requirements for anode adjustment in the Uhde cell.

Burt of Olin Mathieson emphasized in private conversation with the author that the labor cost in a chlorine plant is much affected by labor quality; that is, the well-trained workers are able to reduce considerably the direct and indirect costs of operation. A Japanese engineer, Sugino (7), expressed almost the same opinion.

Introduction of automatic process control in a chlorine plant is also effective in cost reduction, but there is an optimum point because the equipment costs are high.

In the past, labor requirements for cell operation were greatly affected by the number of cells, but this is a small factor in a modern plant. A typical 100-tons/day chlorine plant having thirty 100 kA cells requires five men per shift for operating brine purification, cell room, and rectifiers; but, in a 200-tons/day plant, additional labor is only one man per shift.

Since anode adjustment consumes most of the labor for cell operation, the labor cost may increase with the size and number of cells. In practical experience, however, the man-hours for cell operation are almost independent of the size, because a modern large cell is provided with automatic interelectrode control devices and other improved equipment. The effect of the number of cells on labor cost is relatively small for this reason.

The Japanese Ministry of Labor surveyed the trend in man-hours in chlor-caustic plants for the years 1955-1966. Using these data (7), the average man-hours per unit of production have been evaluated as a function of the plant capacity. As shown in Fig. 2, the logarithm of man-hours *vs.* the logarithm of plant capacity is a straight line with a slope of about -1.5, which is a significant result.

Suppose two plants of different sizes: the one having a capacity of 50 tons/day and the other 200 tons/day. The man-hours per unit of production of these plants are 4.5 and 0.4, respectively, according to Fig. 2. Therefore, the total man-hours per day in the small plant should be 4.5 x 50; that is, this plant may require 9-10 men per shift for operation, in contrast with 0.4 x 200 man-hours per day or only 3-4 men per shift in the large plant. It is not unreasonable, because large plants, such as 150-200 tons/day, are new, but several small plants in Japan have operated over 20 years and modernization of these old plants is limited. Some Japanese engineers claim that the slope of the logarithm of man-hours *vs.* logarithm of plant size is about unity according to their experience.

In conclusion, the labor cost, Lc, is roughly shown by the next equation:

$$Lc = \overline{Lc}\left(\frac{P}{100}\right)^{-1} \quad (\$/\text{ton-Cl}_2) \quad [11]$$

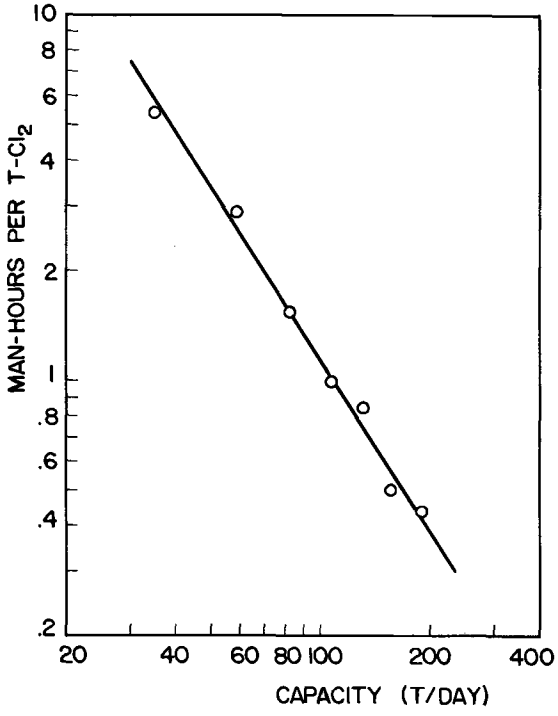

Fig. 2. Man-hours vs. plant capacity in the amalgam-type chlorine plant.

where $\overline{Lc}$ is Lc, also in \$/ton-Cl_2, for a 100-tons/day chlorine plant. The total man-hours for a 100-tons/day plant are about 1.15 per ton chlorine. The labor for the cell room is about 35-40% of the total man-hours. Assuming that the labor rate is \$3.50/hr, the labor cost for the cell room in a 100-tons/day plant is about \$1.50/ton-Cl_2.

Optimum Number of Cells

Assume that the manufacturing cost, Mc, is the sum of the total fixed charge, Fc(total), and the total operating cost, Oc(total), as follows:

$$Mc = Fc(\text{total}) + Oc(\text{total}) \qquad [12]$$

Of these, Oc(total) consists of the power cost, the labor cost, and other expenses, Oc(other), which is almost independent of the number of cells installed, that is,

$$Oc(\text{total}) = Ec + Lc + Oc(\text{other}) \qquad [13]$$

Substituting Eq. [7] and [13] into Eq. [12], we have the optimum number of cells, N(opt), by the differentiation of Mc with respect to N, that is,

$$\frac{dMc}{dN} = \frac{dFc(\text{total})}{dN} + \frac{dOc(\text{total})}{dN}$$

$$= \frac{1}{365P}\frac{\beta}{100}\frac{dJ}{dN} + \frac{dEc}{dN} = 0 \qquad [14]$$

$$N(\text{opt}) = \left[\frac{1-\alpha}{276\times10^5}\frac{J_0}{P}\frac{\beta}{100}\left(\frac{P}{100}\right)^{\alpha}\left(\frac{i}{100}\right)^{\gamma}\left(\frac{n}{cm}\right)\right]^{1/(\alpha-2)}$$

$$= \left[\frac{276\times10^5}{1-\alpha}\frac{cm}{n\overline{Fc}}\right]^{1/(2-\alpha)} \qquad [15]$$

where $\overline{Fc}$ is the annual fixed charge corresponding to J. Thus, the larger the annual fixed charge, the smaller is the optimum number of cells to be installed.

On the other hand, if the cost of d-c electric power is high, the number of cells should be increased. The slope of the investment *vs.* plant capacity curve, α, is also a large factor to N(opt). When α is small, N(opt) becomes small. Since α is close to 1, a small variation of α or $(1-\alpha)$ affects N(opt) very much.

Assuming that $\overline{Fc}$ = \$2000, c = 5 mills/kwhr, n = 95%, and m = 1.5, the optimum number of cells from Eq. [15] is 14 and 51 for α = 0.93 and 0.98, respectively.

Generally speaking, variations of both n and m are small, but c varies from 2 to 10 mills/kwhr. Both $\overline{Fc}$ and α are functions of the cell type, the plant location, the plant layout, and other conditions, and $(1-\alpha)\overline{Fc}$ varies from \$50 to \$400 at present. From Eq. [15], the optimum number of cells is a function of α and the ratio of the a-c power cost to the annual fixed charge. Figure 3 shows N(opt) as a function of $cm/n\overline{Fc}$ or $c/\overline{Fc}$ at constant values of m and n (assuming m = 1.5 and n = 95% in this case) for a reasonable range of α.

It is clear that the value of α for the plant under consideration is most important for discussion of the subject, while it is complicated in practice. Experience in plant design and construction must be depended on for an answer.

The average cost of a-c power in Japan is about 8 mills/kwhr, and the annual fixed charge is \$2000-\$2500; hence, $c/\overline{Fc} \times 10^6$ is 3.2 = 4.0. The coefficient α is not small today as described above. If α = 0.960 and $c/\overline{Fc} \times 10^6$ = 4.0, the optimum number of cells is 36 from Eq. [15] or Fig. 3. Therefore, the 92-kA cells are preferable for the 100-tons/day chlorine plant, assuming 95% current efficiency. The optimum number of cells described by Eq. [15] is independent of the plant size. Then a large chlorine plant, such as 500 tons/day, requires a very large cell. However, a cell up to 300 kA is the largest now available. Consequently, the exact number of cells installed is limited by the cell size also. Larger cells should be developed continuously with increase in production capacity in a plant. The requirement of surprisingly large cells such as 500 kA might not be far away, and reduction of α is an important subject for the design engineer.

Acknowledgments

The author wishes to express his thanks to Dr. W. C. Gardiner, Olin Mathieson Chemical Corporation, and to Dr. Toshiyuki Sugino, Ajino-moto Company, for their helpful advice and supplying useful data for this work.

Oxide Film Studies on Iron in Electrochemical Machining Electrolytes

James P. Hoare*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

Electrodes made from soft iron were polarized potentiostatically in solutions of NaCl, $NaNO_3$, $Na_2Cr_2O_7$, and $NaClO_3$, and the films formed were stripped from the iron surface with constant current stripping pulses. The amount of charge associated with the oxide layer was determined as a function of the potential. In general, the oxide film formed in the passive region is dissolved by the anion in the transpassive region. The Cl^- ion is so efficient in dissolving oxide films on iron that no protective film is formed, and wild cutting is obtained. Such poor oxide-dissolving anions as the chromates protect the surface too well, and machining takes place at high potentials with sparking. Only ClO_3^- ion behaves in such an intermediate way that excellent finishes are obtained with good dimensional control at high metal removal rates.

In the electrochemical machining (ECM) process, the electrolyte is one of the most important considerations for successfully obtaining good dimensional control with an excellent surface finish. LaBoda and coworkers (1, 2) have found that $NaClO_3$ electrolytes produced the best results.

It was questioned why $NaClO_3$ produced good dimensional control and fine finishes, whereas NaCl gave poor dimensional control (wild cuts) and $Na_2Cr_2O_7$ cut at high potentials with poor finishes. From steady-state polarization studies (3, 4) on iron electrodes, an explanation for the ECM behavior of these electrolytes for cutting steel was presented in terms of the build-up and breakdown of an oxide film. According to the literature, the corrosion of iron in solutions of chromates (5, 6), carbonates (7), and phosphates (8) is inhibited by the formation of a passive film of γ-Fe_2O_3. The oxide film present on machined samples of steel in $NaClO_3$ electrolytes was identified as γ-Fe_2O_3 by electron diffraction techniques (4). The differences in behavior of these electrolytes were related to the properties of the passivating film of γ-Fe_2O_3 formed on the steel surface. These conclusions (3, 4) have been criticized by Boden and Evans (9).

In the work reported here, the build-up and the breakdown of the protective film of γ-Fe_2O_3 on iron samples in NaCl, $Na_2Cr_2O_7$, $NaNO_3$, and $NaClO_3$ electrolytes were investigated as a function of potential by means of constant current stripping pulses.

Experimental

The test electrodes were small beads (~0.065 in. in diameter and 0.044 cm^2 in area) melted at the end of soft iron wires (35 mils) and held in the reducing part of a burning H_2 jet to reduce any oxides. These beads were then embedded in polyethylene so that only a hemisphere was exposed to the electrolyte. Teflon spaghetti was used to cover the wire leads. Such electrodes were mounted in triplicate in a Teflon cell (10) along with an α-Pd reference electrode (11). The cell was filled with the proper electrolyte and was preelectrolyzed for 24 hr against removable Pt electrodes. Finally, oxygen was bubbled through the cell at a rate of about 300 cc/min, and the iron electrode was held at a given potential with a 61R Wenking potentiostat until a steady current was reached. At this point, the potentiostat was disconnected by a mechanical switch, and a constant current stripping pulse was applied to the electrode from a pulsing circuit

* Electrochemical Society Active Member.

employing a mercury-wetted relay (12). The trace of the stripping curve was displayed on an oscilloscope and photographed. From the trace, the quantity of charge associated with the oxide-reduction plateaus of the traces was determined.

The following electrolytes, corresponding to those studied under actual conditions, were investigated: NaCl (275 g/liter), $NaNO_3$ (350 g/liter), $Na_2Cr_2O_7$ (100 g/liter), and $NaClO_3$ (350 g/liter). All potentials were recorded with a General Radio Electrometer, Model 1230-A, and reported against the normal hydrogen electrode (NHE). To do this, the potential of the saturated calomel electrode (SCE) against a Pt/H_2 electrode was determined for each solution. The α-Pd electrode is 50 mV more noble than a Pt/H_2 electrode in the same solution, and a value of 245 mV was used as the potential of the SCE *vs.* NHE.

Only the apparent area obtained from the geometric dimensions of the exposed beads was used in this work. Any consideration of a true area was hopeless because each time the bead was held at a given anodic potential the oxide layer formed was reduced by the following cathodic stripping pulse. In this way the true area was continually changed so that only an apparent area can be used as a working device. The transition times were determined from the traces of the stripping pulses by the intersection of the tangents drawn at the points of inflection as described elsewhere (13).

Results

A plot of the steady value of the current for given values of the controlled potential recorded just before the potentiostat was disconnected is presented in Fig. 1. These curves are in good agreement with those previously reported (3, 4). Alongside the curves in Fig. 1 are letters which refer to the traces of the corresponding stripping pulses shown in Fig. 2. Only selected traces are recorded in Fig. 2, but the quantity of charge, Q_{ox}, corresponding to the amount of oxide reduced during the arrests appearing in the traces for all points, was calculated from $Q_{ox} = I\tau A$ and is given in Fig. 3. Here, I is the value of the constant current applied during the stripping pulse, A is the apparent electrode area, and τ is the transition time of the oxide reduction arrest in the stripping pulse.

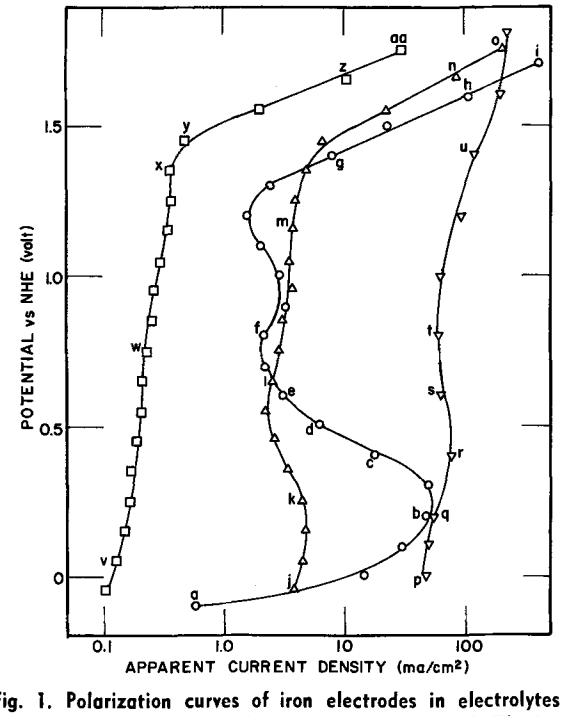

Fig. 1. Polarization curves of iron electrodes in electrolytes of $NaClO_3$, ○; $NaNO_3$, △; NaCl, ▽; and $Na_2Cr_2O_7$, □. The letters correspond to the traces of the stripping pulses shown in Fig. 2.

Discussion

For good dimensional control in the ECM process, it is desirable that the region of the workpiece opposite to and a gap distance away from the cutting face of the tool be corroded while those regions of the workpiece further away, such as the sides, be protected. The protecting agent is a film of cubic oxide which is either Fe_3O_4 or γ-Fe_2O_3 or both, or a mixture of the two (14, 15). In general, most of the traces in Fig. 2 exhibit only one arrest although two may be detected in such traces as Fig. 2d, 2e, 2g, 2z, and 2aa. Nagayama and Cohen (16) found a layer of Fe_3O_4 under the layer of γ-Fe_2O_3 on iron passivated in borate buffer solutions. For the sake of simplicity, we will refer to the protective layer as one of γ-Fe_2O_3 in further discussions.

At the high currents (500-1200 A/in.^{2}) used in ECM, the *IR* drop appearing across the electrolyte gap between the tool and workpiece may assume large values so that the potential drop across the double layer (which controls the rate of the electrochemical corrosion process) at points remote from the cutting face of the tool (such as the sides of a plunge-cut hole) may be much lower than at points directly opposite the cutting face of the tool (such as the bottom of the hole). It is assumed that acceptable cutting rates are achieved when the potential has reached a value corresponding to the transpassive region of the polarization curve (such as points i and o in Fig. 1). This condition exists at the bottom of the plunge-cut hole. If the *IR* drop is large enough, the effective potential at points remote from the tool cutting face will be decreased to a point corresponding to the passive region of the polarization curve (such as point m in Fig. 1). Consequently, how well a given electrolyte provides dimensional control will depend on how sharp the transition from the passive to the transpassive state is with respect to potential. As this transition becomes less sharp, it requires a larger solution path (*IR* drop) to bring the potential into the passive region. As a result, cutting along the sides of the workpiece (wild cutting) results.

In the series of traces, Fig. 2a to 2i, it is seen that the oxide film in $NaClO_3$ begins to form in the region of the critical current at point b in Fig. 1. There is a linear increase in the film thickness with potential (*see* Fig. 3) until point f is reached, followed by a slow thinning of the film up to point g in the beginning of the transpassive region. With increasing potential in the transpassive region, the film is rapidly removed so that at point i the protective film has practically disappeared, and rapid ECM can take place.

In the case of $NaNO_3$ (Fig. 2j to 2o), the oxide film forms at much lower potentials than in $NaClO_3$ but increases more slowly with potential. Also, the oxide is removed in the transpassive region more slowly. Since the polarization curve for $NaNO_3$ lies above that for $NaClO_3$ in the transpassive region, the current at a given potential is smaller in $NaNO_3$ than in $NaClO_3$. This fact is in agreement with the observation that steel is machined more slowly in $NaNO_3$ than in $NaClO_3$. Because the film is removed more slowly in $NaNO_3$, the transition from the passive to the transpassive state is less abrupt, predicting that the dimensional control is not as good as in $NaClO_3$. This conclusion has been verified in actual ECM operation on steel.

A protective film is not formed on iron in NaCl solutions as evidenced by the large currents drawn even at very low anodic potentials in Fig. 1. Although a porous, nonprotecting film is formed at low anodic potentials (*see* Fig. 2p to 2u), it is completely removed at the higher potentials as seen in Fig. 3. Consequently, metal removal can take place at points well remote from the cutting face of the tool. This behavior produces wild cutting with the resultant poor dimensional control.

At the other extreme, iron in chromate solutions is covered by a strongly passivating film (Fig. 2v to 2aa)

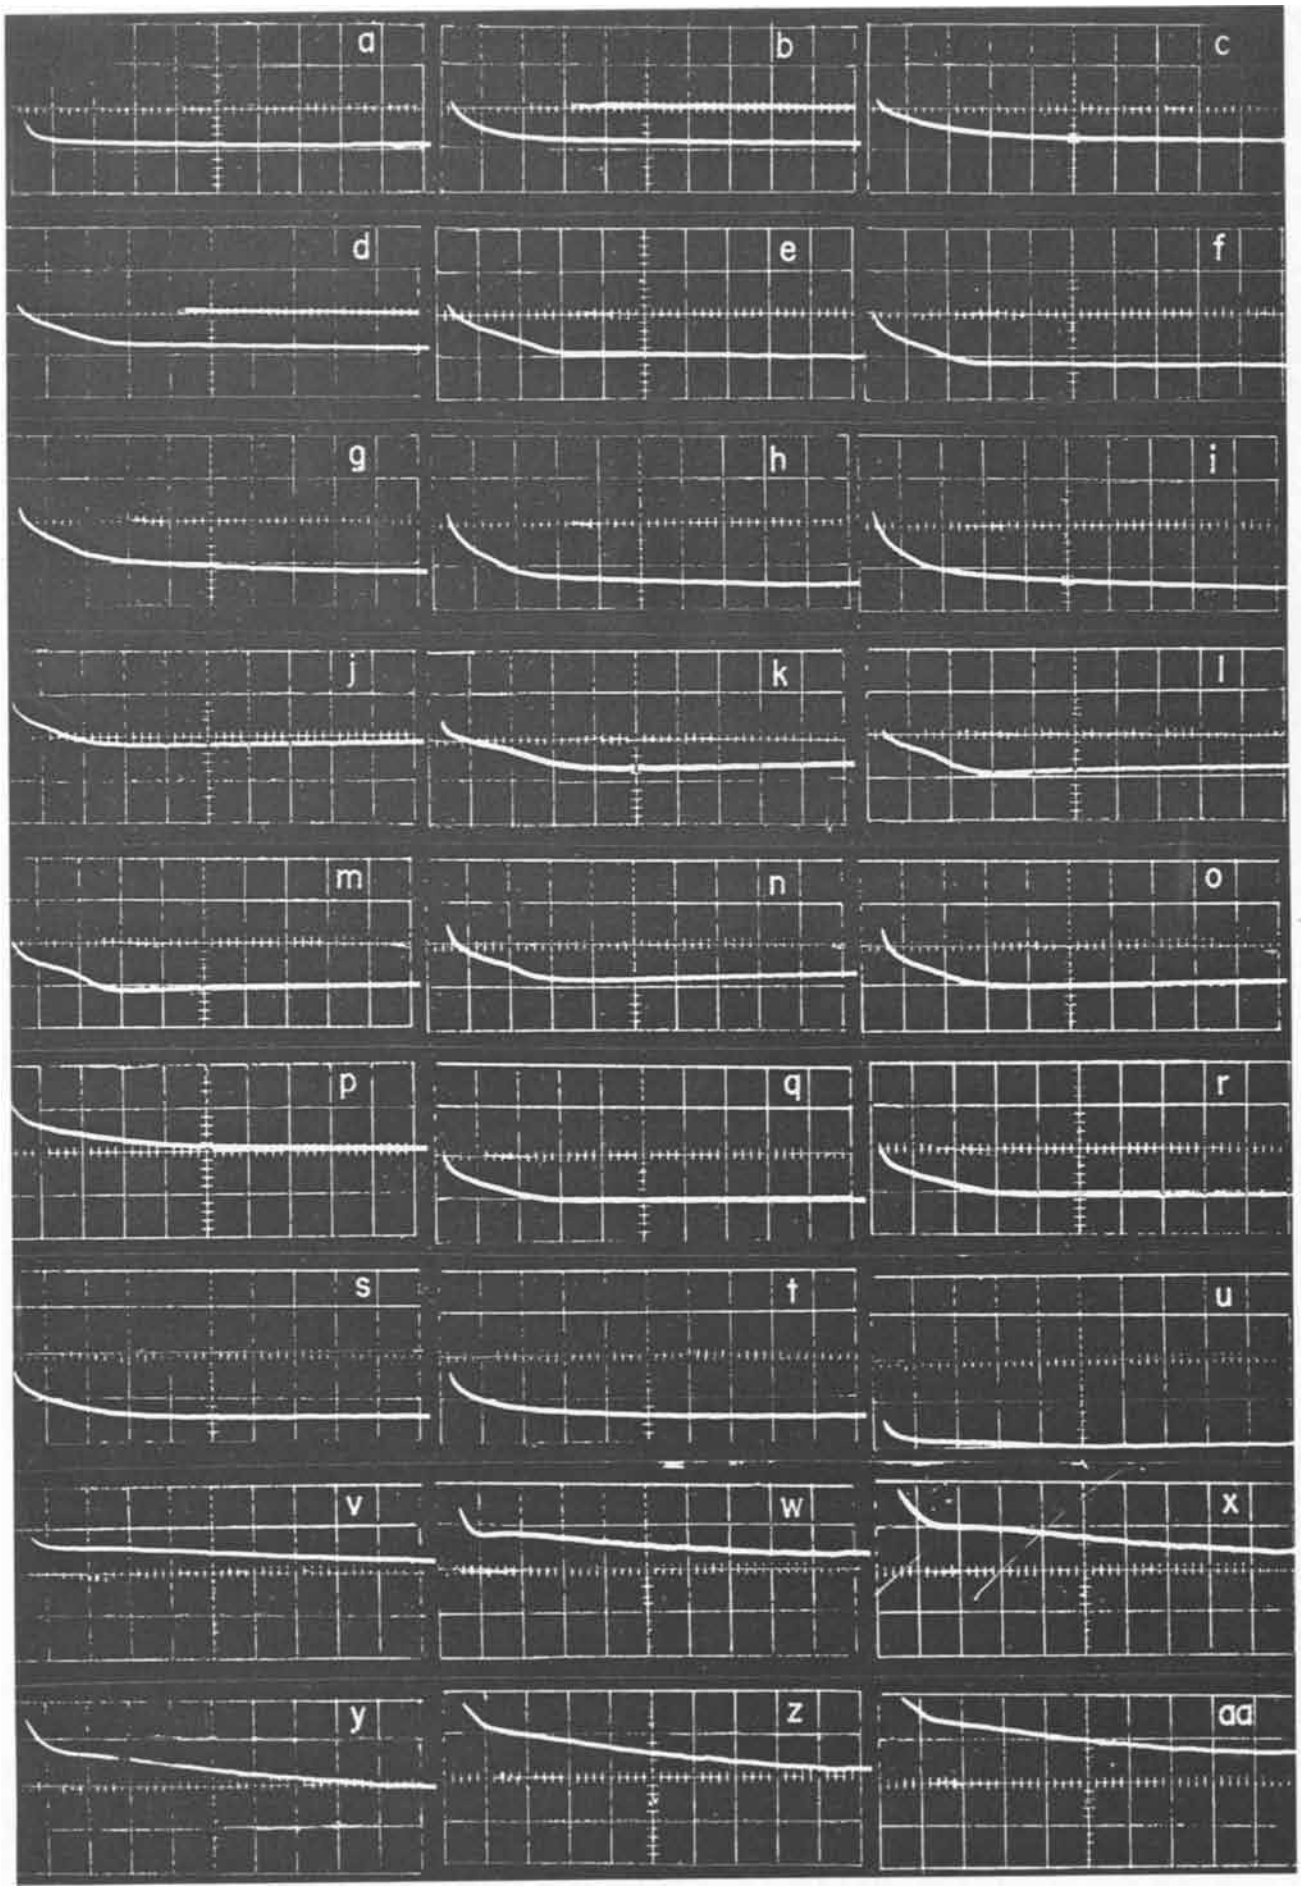

Fig. 2. Trace of the constant current stripping pulses applied to iron electrodes in solutions of $NaClO_3$ (a-i), $NaNO_3$ (j-o), NaCl (p-u), and $Na_2Cr_2O_7$ (v-aa). X-axis = 20 msec/cm; Y-axis = 500 mV/cm; current = 4.2 mA.

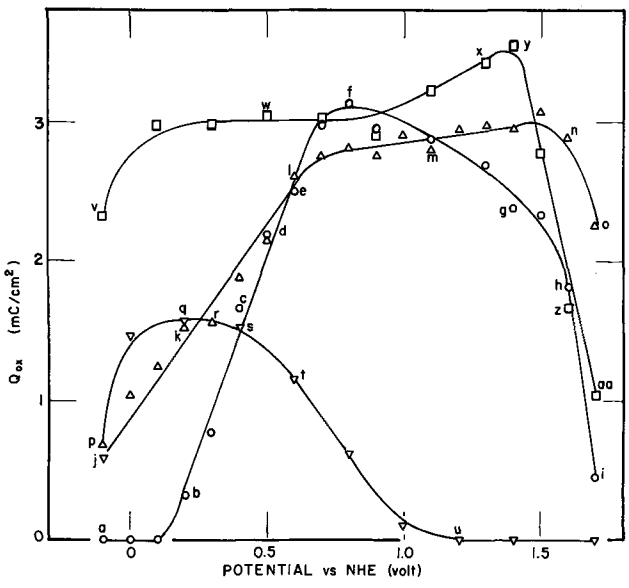

Fig. 3. A plot of the amount of charge, Q_{ox}, formed on the iron surface as a function of the potential in solutions of $NaClO_3$, ○; $NaNO_3$, △; NaCl, ▽, and $Na_2Cr_2O_7$, □. The charge was calculated using apparent area values since true areas could not be estimated. It is the relative shape of the curves that is important.

in most of the potential region studied in Fig. 1 and 3. Although an abrupt removal of the film takes place in the transpassive region (Fig. 3), this effect takes place at much higher potentials than for $NaClO_3$ (Fig. 1). Under such conditions, sparking may take place during the actual ECM operation on steel, and poor finishes are obtained. This conclusion has also been verified in the actual ECM of steel.

For successful ECM operation, it is seen that an electrolyte must be chosen which forms a protecting film on the metal surface but not so protecting that very high anodic potentials are required to remove it as in the case of $Na_2Cr_2O_7$. In addition, the sharper the transition from the passive to the transpassive state takes place, the better is the dimensional control.

As pointed out by Hoar (17), the ability of the anion to penetrate and dissolve a film formed on the metal surface may be the fundamental point in these considerations. The Cl^- ion is a very efficient agent for penetrating and dissolving films of iron oxides so that the iron surface in solutions of Cl^- ion is not passivated by a protective oxide film. In fact, Cl^- ion is so efficient that it has not been possible to achieve acceptably machined steel parts with chloride electrolytes modified by the additions of other anions such as $SO_4^=$ or $CrO_4^=$ ions contrary to that predicted in the literature (9). Anions such as the chromates, phosphates, and carbonates are such poor dissolving agents of iron oxides that, either machining cannot be obtained with such electrolytes, or ECM occurs at such high potentials that poor finishes result from the sparking that takes place.

Intermediate in behavior between chlorides and chromates are electrolytes such as nitrates and chlorates. Of these, the $NaClO_3$ electrolyte is far superior to the other for ECM applications from the standpoint of quality of the surface finish, rate of machining, degree of dimensional control, and economy. The ClO_3^- anion has the fortunate properties of producing a good protective film of γ-Fe_2O_3 on iron surfaces and of producing a sharp transition from the passive to the transpassive state at relatively low anodic potentials.

Technical Note

Diffusion of Zinc through Films of Refractory Metals on GaAs

John C. Marinace*

International Business Machines Corporation, Research Division, Yorktown Heights, New York

To make ohmic contacts of minimal resistance in GaAs injection lasers, one practice has been to alloy plated metals to the GaAs wafer surfaces (1). The alloying must be thorough, otherwise the resistance will be high. When the laser junction is shallow (say, < 3 or 4μ), the alloyed contacts can penetrate the junction, either during the liquid formation of the alloying step or during subsequent laser operation under high current-density conditions.

* Electrochemical Society Active Member.

Another drawback of the alloying method is that the surface tension of the liquid tends to cause it to "ball up," and then freeze into an uneven layer. This hinders subsequent processing of the wafer and mounting of the lasers. The purpose of this paper is to describe a method of overcoming these difficulties, at least on the p-side of a laser wafer.

This method, incidentally, was discovered serendipitously during an investigation of useful maskants against Zn diffusion into GaAs. Instead of being useful maskants, it was found that films of W, Mo, or Cr barely impeded, if at all, the diffusion of Zn into GaAs, GaP, or GaAlAs. Moreover, no liquefaction of the films occurred during the diffusion process.

Other workers at about the same time found that W or Mo could be used effectively as diffusion masks in silicon technology (2, 3).

Experimental

As a result of these findings, the following process was devised for laser fabrication: A chemically polished {100} GaAs wafer (Sn doped, $\sim 2 \times 10^{18}/cm^3$) is coated with 2000-3000Å of W on its polished surface. This filming of W can be done by vacuum evaporation, using an electron gun as a heat source. Alternatively, the W film can be deposited by the hydrogen reduction of WF_6, at about 500°C.

The W-coated wafer is then put through its regular diffusion process. In the case shown in Fig. 1, the coated wafer and 5 mg of $ZnAs_2$ were sealed in a silica ampoule of 11 mm ID and 75 mm length. The ampoule was kept at 750°C for 4 hr and then at 850°C for 0.75 hr. The wafer is lapped on the surface opposite the W film until the wafer is $\sim 100\mu$ thick. Thin layers of Au, Sn, and In are plated on the lapped surface, and in a forming gas atmosphere the wafer is heated rapidly to 450°C and then cooled quickly. Indium is then electroplated on both the alloyed surface and the W film. The wafer is cleaved into bars, which bars are then sawed into lasers. The W does not interfere with the cleaving.

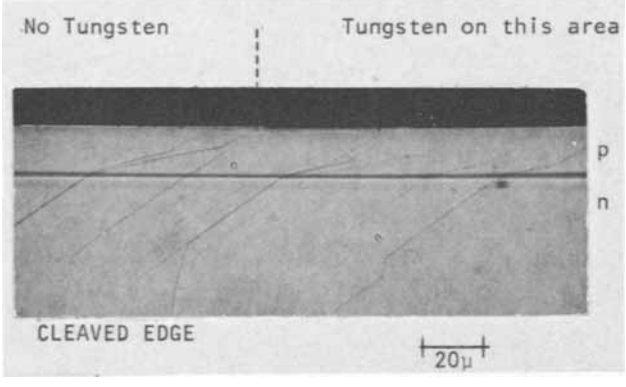

Fig. 1. Cleaved and stained edge of diffused wafer. ~2000Å of W is on wafer surface to the right of the dotted line. Diffusant source was ZnAs; diffusion time was 4 hr at 750°C plus 0.75 hr at 850°C. This wafer was then used in second controlled experiment described in text.

Because the junction profile is substantially unchanged by the presence of the W film, it is very likely that the Zn concentration at the GaAs-W interface is the same as the C_0 of Zn on an uncoated wafer after Zn diffusion. The value of C_0 under conditions of the diffusion procedure set forth above is $\sim 2 \times 10^{20}$; this probably accounts for the observed low electrical resistance at the GaAs-W interface. Nonohmic contacts are observed when W is filmed on n- or p-type GaAs doped in the 10^{18} range or less. When the W is evaporated on an already diffused wafer, the contact is ohmic but of higher resistance than when the Zn is diffused through the W.

Two controlled experiments were carried out to compare the series resistances of lasers using the new W film contacting method. The dimensions of the lasers were nominally of 50μ width, 250μ length, and 100μ thickness and were mounted under compression between In-coated Cu plates.

In one experiment the junction depth was quite shallow (2μ) and the average series resistance was about the same for the two groups: $\sim$ 120 mohm as measured on a Tektronix Model 575 curve tracer at 1A current.

In another experiment in which the junction depth was 17μ (*see* Fig. 1), the average series resistances were as follows:

(*a*) Conventional plating-alloying both sides (1)	100 mohm
(*b*) New W method	70
(c) Indium only on p-side; plating-alloying on n-side	120

The contacts of group (c) above tend to degrade under high current density conditions; that is, the resistance increases slowly. This degradation has not been observed in either the new W-film method contacts or the conventional alloying-plating contacts.

W films have been used successfully on GaP and GaAlAs; Zn was diffused through the films, and a low contact resistance resulted.

Mo and Cr films have not been studied as extensively as have the W films, but their behavior seems similar.

A Kinetic Study of the Electrochemical Reduction of Manganese Dioxide in a Homogeneous Phase

J. P. Gabano, J. Seguret, and J. F. Laurent

Fundamental Research Laboratory, Société des Accumulateurs Fixes et de Traction, "La Pile Leclanché" Department, Poitiers, France

ABSTRACT

The electrochemical behavior of MnO_2 electrodes during cathodic reduction in buffered medium (1M KOH) was studied on the basis of diffusion of protons into the solid phase according to Coleman's theory. The kinetics of the process was followed by means of a diffusion equation which predicts the general form of the discharge satisfactorily during potentiostatic and galvanostatic reductions. A method for determining the product of the active surface area of the electrode by the square root of the diffusion coefficient of protons in the crystal lattice is given and results are compared for various samples of MnO_2.

Numerous studies have been undertaken by various authors for the purpose of studying the electrochemical reduction processes of manganese dioxides. In most cases, such studies have resulted in defining some factors which can influence the performance of galvanic cells using manganese dioxide; unfortunately due to the extreme complexity of the so-called depolarization reaction involved in reduction processes, it is often difficult to find correlations among the properties under study.

However in recent years, new data have appeared, one of the most interesting aspects of which is concerned with the electrochemical reduction of manganese dioxide in a homogeneous phase. The reduction process involves a special mechanism of diffusion in the solid state (1-6). In our previous studies (7), some properties relating to the physicochemical structure of manganese dioxide have been examined by various methods (chemical analysis, thermogravimetric analysis, x-ray diffraction, etc). In the present work the research has been extended to studies of the kinetics of the electrochemical reduction of γ and ρ manganese dioxides from various sources in ordinary use in dry cells of the Leclanché type.

In the course of the present study, the fundamental mechanisms involved in the reduction processes were first reviewed. The basic equations for describing the processes were established, and their possible application was considered in the simple case of reductions carried out under potentiostatic or galvanostatic conditions. The validity of such a treatment has been checked by experimental study of some synthetic and natural manganese dioxides. The electrochemical reductions were carried out in a buffered medium of well-defined composition (1M KOH) by means of the cell described by Appelt (8). Intrinsic constants have been deduced for characterizing the relative electrochemical reactivity of the dioxides under study.

Basic Equations

The electrochemical or chemical reduction of manganese dioxides of the γ and ρ type has already been shown (9) to take place in a topochemical reaction in a homogeneous phase and to progress up to the formation of groutite, MnOOH, according to the simplified reaction mechanism

$$MnO_2 + e + H^+ \rightarrow MnOOH$$

The protons supplied by the electrolytic medium pass into the crystal, whereas, the electrons coming either from the outer circuit (in the case of an electrochemical reaction) or from the oxidation of the reducing agent (in the case of a chemical reaction) allows the valence of an equivalent number of Mn^{4+} ions to change into Mn^{3+} ions so that the electrical neutrality of the lattice is maintained. If it is assumed that the electrons can freely move in the solid phase, only the accumulation of protons in the surface layers of the crystal produces a diffusion toward the deeper layers, thus controlling the reduction kinetics. The two oxides, MnO_2 and MnOOH, cause the formation of only one phase. This reaction proceeds as if the lower oxide forming on the surface of the manganese dioxide particles diffuses to the inside of these particles, thus giving a compound having an intermediate oxidation state when the equilibrium in the phase is reached. Thus for a given degree of reduction, the equilibrium resulting from such a mechanism could be represented by the following equations (10-13)

$$2\left(x-\frac{3}{2}\right)MnO_2,\ 2(2-x)\ MnOOH + 2dxH^+ + 2dxe$$

$$\rightleftarrows 2\left(x-dx-\frac{3}{2}\right)MnO_2,\ 2(2-x+dx)\ MnOOH$$

or

$$MnO_{2(x-1)}(OH)_{2(2-x)} + 2dxH^+ + 2dxe^- \rightleftarrows MnO_{2(x-dx-1)}(OH)_{2(2-x+dx)}$$

x being the oxidation state of the intermediate defined by the ratio O/Mn.

In the kinetic processes of the electrochemical reduction at a dioxide electrode in a buffered elec-

trolyte, the variations in the electrode potential are due to variations in the oxidation state in the surface layers of the crystal. The value of the surface oxidation state x_s can be deduced as a function of time t and reduction current i according to the relation (14-18)

$$x_s = x_o - \frac{V}{FS\sqrt{D}\sqrt{\pi}} i\sqrt{t} \qquad [1]$$

In this expression, x_o is the initial oxidation state of the dioxide, V the average volume occupied by one molecule of the species $MnO_{2(x-1)}(OH)_{2(2-x)}$, F Faraday's constant, S the electrochemically active surface of the electrode, and D the diffusion coefficient of protons in the crystal.

According to the electrical conditions imposed on the electrode, the validity of the above theory may be verified.

Potentiostatic Conditions

The electrode potential being fixed, the surface oxidation state, x_s, remains constant, and in this case relation [1] may be written in the following way

$$x_o - x_s = \frac{V}{FS\sqrt{D}\sqrt{\pi}} i\sqrt{t}$$

that is

$$\log i = \frac{-1}{2}\log t + \log k \qquad [2]$$

with

$$k = \frac{FS\sqrt{D}\sqrt{\pi}}{V}(x_o - x_s) \qquad [3]$$

By determining k at a known x_s corresponding to the imposed potential $E(x_s)$, it is possible to determine the product $S\sqrt{D}$ which is characteristic of the dioxide electrode under study. The value of x_s can be approximately determined in the case of a buffered electrolytic medium, from the following relation

$$E(x_s) = E^{o\prime} - 2.3\frac{RT}{F}\log\left(\frac{2 - x_s}{x_s - \frac{3}{2}}\right) \qquad [4]$$

$E^{o\prime}$ is a constant. $E(x_o)$ is related to x_o by the same relation, that is

$$E(x_o) = E^{o\prime} - 2.3\frac{RT}{F}\log\left(\frac{2 - x_o}{x_o - \frac{3}{2}}\right) \qquad [5]$$

By calculating the difference $\Delta E = E(x_s) - E(x_o)$ representing the polarization imposed on the electrode, x_s can be determined taking the value of x_o into account. However, the application of these various relations implies that the electrode kinetics are controlled only by the diffusion process in the solid phase, and other processes which might cause other electrode polarizations are excluded.

Galvanostatic Conditions

In the case of galvanostatic conditions imposed on the electrode, the previously established relation [1] remains valid. Moreover, if the following relation is assumed

$$K = \frac{V}{FS\sqrt{D}\sqrt{\pi}} \qquad [6]$$

the electrode potential $E(x_s)$ may be written in the following way

$$E(x_s) = E^{o\prime} - 2.3\frac{RT}{F}\log\left(\frac{2 - x_o + Ki\sqrt{t}}{x_o - \frac{3}{2} - Ki\sqrt{t}}\right) \qquad [7]$$

which leads to a linear representation of the coordinate system

$$E(x_s), \log\left(\frac{2 - x_o + Ki\sqrt{t}}{x_o - \frac{3}{2} - Ki\sqrt{t}}\right)$$

Experimental

Manganese dioxides tested.—Three types of manganese dioxide were tested: a common electrolytic manganese dioxide, γ; a ρ manganese dioxide obtained by disproportionation of a sesquioxide in sulfuric acid medium; and a natural manganese dioxide, consisting of mainly ramsdellite.

Electrolytes.—All measurements were carried out in a buffered medium of 1M potassium hydroxide. Some determinations were also made in a 1M solution of deuterated potassium hydroxide (KOD) in heavy water (D_2O). In all cases, the electrolytes were carefully deaerated by previously bubbling purified nitrogen through them.

Reduction cell.—The experimental device described by APPELT and PUROL (8) was used with a constant electrolyte rate of 5 ml/min through the cell. The rate was controlled by a peristaltic pump. With such a mode of operation, concentration polarization was avoided in the electrolyte in the vicinity of the electrode during the reduction. The depolarizing mass distributed on a surface area of 3.2 cm^2 was a mixture of manganese dioxide and acetylene black (6%): its weight varied in the range of 0.05-0.2g. The counterelectrode was a perforated zinc anode through which the electrolyte could flow. The separator was a nylon fabric. The reference electrode employed the Hg/HgO/1M KOH system. In all cases, determinations were carried out at 25°C.

Types of reduction studied.—Potentiostatic reduction.—The equilibrium potential of each kind of manganese dioxide was determined in a separate experiment by recording potential time curves to confirm a steady state.

In a second experiment the sample was first subjected to its equilibrium potential. A TACUSSEL potentiostat of the PRT 20-2Z type with three electrodes was used for this purpose. The current was simultaneously measured by a recorder (TACUSSEL EPL1). The current dropped almost immediately to practically zero, thereby indicating that the electrode was in equilibrium with test solution. A potential more negative than the equilibrium potential was then imposed on the electrode, so that the manganese dioxide was potentiostatically reduced. The current-time curve was recorded.

Galvanostatic reduction.—A suitable potentiostatic polarization was imposed on the dioxide electrode to bring it quickly to the equilibrium potential in the test electrolyte. Then the electrode was subjected to galvanostatic conditions (reduction at a constant current), and the corresponding potential in relation to the reference electrode was recorded as a function of time.

Results and Discussion

Potentiostatic reduction.—Influence of the type of dioxide.—Figure 1 shows various current-time relations obtained from the potentiostatic reductions carried out in 1M KOH medium on the tested manganese dioxides. The weight of depolarizing mix was equal to 0.2g. The reduction time in minutes has been plotted as abscissa, and the corresponding current in milliamperes delivered by the electrode is shown as ordinate. The imposed cathodic polarization is −25 mV.

Examination of this figure leads to the following conclusions. For any type of manganese dioxide, the relationship thus obtained results in lines having a slope of −½ in agreement with the previously established relation [2]

$$\log i = -\tfrac{1}{2}\log t + \log k$$

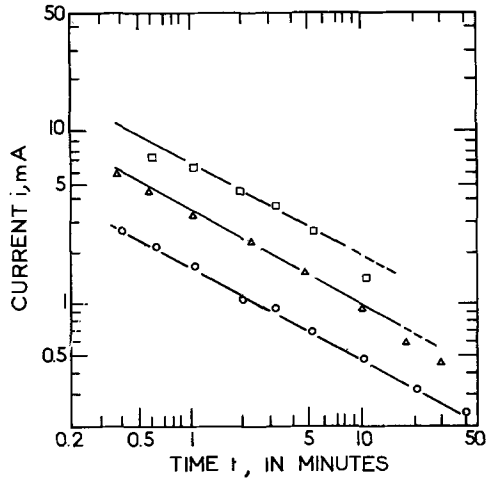

Fig. 1. Potentiostatic reductions carried out on various kinds of manganese dioxide in 1M KOH medium and for a value of the cathodic polarization $\Delta E = -25$ mV. The weight of depolarizing mix is 0.2g. □ Electrolytic MnO_2; △ chemical MnO_2; ○ natural MnO_2 (ramsdellite).

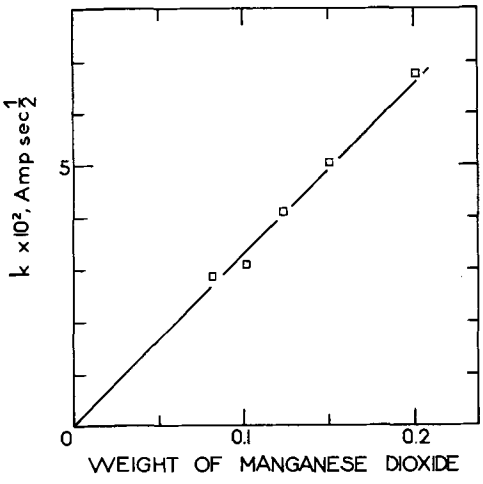

Fig. 2. Variation of k as a function of weight of manganese dioxide used for an electrolytic manganese dioxide and for a cathodic polarization value $\Delta E = -25$ mV.

which shows, that under such conditions, the cathodic reduction phenomenon is limited only by the diffusion process of protons in the crystal of the depolarizer.

The theoretical relationship is even more closely followed as the manganese dioxide becomes well crystallized. With ramsdellite which represents the most highly organized structure, the relation is followed during reduction periods of about 40 min; there is not such good agreement for the more amorphous forms, ρ-MnO_2 and γ-MnO_2. Thus, with electrolytic γ manganese dioxide, deviation from the theoretical relationship appears after a reduction period of 10 min. Such deviations are caused by the fact that the solid wherein the diffusion process takes place can be considered as a semi-infinite medium only as a first approximation, that is only on the scale of the crystallite the dimensions of which limit its continuity. On the other hand, the application of such a theory implies that diffusion takes place in a preferential direction which could, for instance, be one of the better defined crystal orientations of the lattice. This may explain why the best results have been obtained with the most highly crystallized form of MnO_2 (ramsdellite).

The determination of parameter

$$k = \frac{FS\sqrt{D}\sqrt{\pi}}{V}(x_0 - x_s)$$

may be made from the lines obtained for each kind of manganese dioxide tested. Parameter k represents the value of the reduction current intensity at time $t = 1$ sec. In the diffusion equation k has a unit of amp $sec^{1/2}$. It depends partially on the cathodic polarization and partially on the active surface area of the electrode which is directly proportional to the amount of manganese dioxide.

In all cases, the perfect proportionality existing between the value of parameter k and the amount of manganese dioxide present in each test has been verified by varying the weight of the depolarizing mix for a constant polarization of the electrode.

Figure 2 shows the line obtained for electrolytic, γ manganese dioxide by plotting as abscissa the amount of manganese dioxide used in each test, and as ordinate the corresponding value of k for a constant cathodic polarization of -25 mV. By determining the slope of this line, the value of k can be extrapolated to 1g of manganese dioxide which is the selected unit of weight.

Influence of imposed polarization.—The influence of cathodic polarization, ΔE, on the potentiostatic current-time curves has been studied for each type of manganese dioxide tested, at constant depolarizing mix weight. For natural dioxide (ramsdellite), the result was in agreement with the theory for values of ΔE in the -25 to -80 mV range. Figure 3 shows, on a logarithmic scale, the reduction time (in minutes) as abscissa and the corresponding current (in milliamperes) as ordinate for the natural dioxide. The potentiostatic reductions for various values of cathodic polarization have been carried out in 1M KOH medium for a weight of depolarizing mix of 0.2g. Examination of this figure leads to the following conclusions.

At any polarization imposed on the electrode, a series of linear relations of $-\frac{1}{2}$ slope are obtained.

The deviation from the theoretical relationship appears earlier with higher cathodic polarization imposed on the electrode. This may be explained by the fact that the diffusion in the solid phase does not take place in a semi-infinite medium as assumed in the mathematical derivation.

For each value of the cathodic polarization, the parameter k (value of the current at time $t = 1$ sec) has been measured from the preceding experimental determinations. The variation $\Delta x = x_0 - x_s$ corresponding to the imposed variation $\Delta E = E(x_s) - E(x_0)$

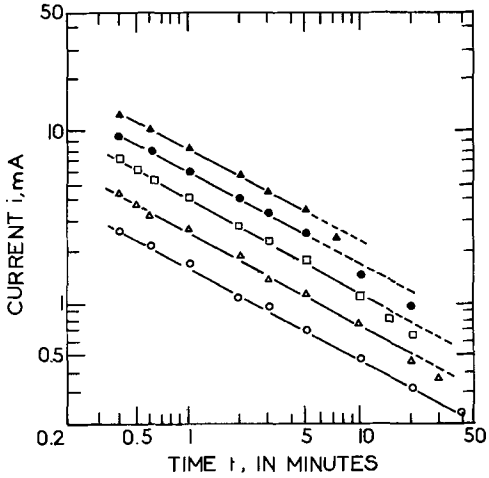

Fig. 3. Potentiostatic reductions carried out on a natural manganese dioxide (ramsdellite) in 1M KOH medium for various values of the cathodic polarization ΔE expressed in mV. The depolarizing mix weight is 0.2g. ▲—80 mV, ●—70 mV, □—50 mV, △—38 mV, ○—25 mV.

has been deduced, taking into account relations [4]-[5] and the value of x_0.

Figure 4 shows Δx as abscissa and parameter k as ordinate. The line thus obtained (white squares) agrees with Eq. [3]

$$k = \frac{\mathbf{F}S\sqrt{\pi}\sqrt{D}}{V}\Delta x$$

The slope of this line

$$\frac{\partial k}{\partial \Delta x} = \frac{\mathbf{F}\sqrt{\pi}}{V} S\sqrt{D}$$

is a means of obtaining parameter $S\sqrt{D}$ which is characteristic of the manganese dioxide electrode tested. This parameter obviously depends on the amount of dioxide involved in the reduction process.

Influence of the electrolyte.—In order to define the influence of the nature of the electrolyte some determinations have been made in a medium consisting of 1M deuterated potassium hydroxide (KOD) in heavy water (D_2O). The potentiostatic reductions were effected on 0.2g of depolarizing mix for cathodic polarization values identical to those described above. However, the natural dioxide used in this test was previously treated for several weeks with heavy water. The solution was renewed several times during the operation, and then the dioxide was dried at 110°C.

Figure 4 also shows (black squares) the relation between k and Δx for this particular case. The line thus obtained shows a lower slope than in the preceding case (reductions carried out in 1M KOH).

The ratio of the slopes $\partial k/\partial \Delta x$ for reductions carried out in 1M KOH in H_2O and 1M KOD in D_2O, respectively, has been found to be 1.4. It is interesting to note that the ratio is very near the theoretical value (1.414) (19).

Practical results obtained with various manganese dioxides.—It has been shown that for each manganese dioxide the electrochemical reduction of which is limited by a diffusion process in the solid phase, a product $S\sqrt{D}$ representing its electrochemical activity can be determined (Eq. [4]).

Several values of the main parameters characterizing these dioxides are shown in Table I, together with the products $S\sqrt{D}$ obtained from potentiostatic reductions carried out in 1M KOH medium.

Values of $S\sqrt{D}$ have been calculated for 1g of dioxide, taking into account the MnO_2 content of the tested samples. The determination of the average molar volume V required for the evaluation of product $S\sqrt{D}$ has been effected from previously obtained (7) results.

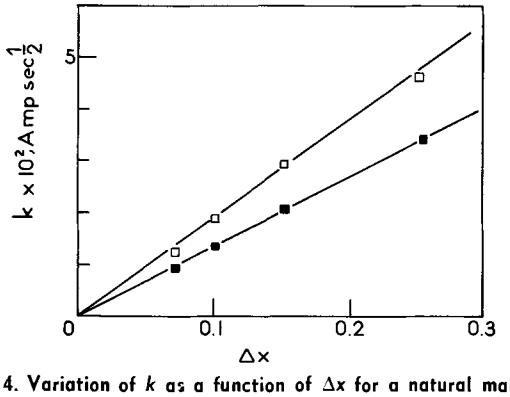

Fig. 4. Variation of k as a function of Δx for a natural manganese dioxide (ramsdellite) and for a depolarizing mix weight of 0.2g. □ Determinations made from potentiostatic reductions in 1M KOH in H_2O; ■ determinations made from potentiostatic reductions in 1M KOD in D_2O.

Table I. Values of the main parameters

Kind of dioxide	% MnO_2	x_0	$E(x_0)$/Hg/HgO/KOH 1M, mV	$S\sqrt{D}$, cm³ sec$^{-1/2}$ g^{-1}
Electrolytic γ MnO_2	90	1.97	+120	5.07×10^{-4}
Chemical ρ MnO_2	81	1.95	+110	2.45×10^{-4}
Natural MnO_2 (ramsdellite)	75	1.96	+95	1.43×10^{-4}

Table II. Diffusion coefficient of protons in the crystal

Kind of dioxide	S BET, m² g^{-1}	$S\sqrt{D}$, cm³ sec$^{-1/2}$ g^{-1}	D, cm² sec^{-1}
Electrolytic γ MnO_2	55	5.07×10^{-4}	8×10^{-19}
Chemical ρ MnO_2	30	2.45×10^{-4}	6.7×10^{-19}
Natural MnO_2 (ramsdellite)	18	1.43×10^{-4}	7×10^{-19}

In Table I, the value of product $S\sqrt{D}$ may be seen to vary from 1 to 5 x 10^{-4} cm³ sec$^{-1/2}$ g^{-1} according to the depolarizing activity of the manganese dioxide tested.

Knowing the BET surface area, it is possible to deduce in first approximation the diffusion coefficient of protons in the crystal, as is shown in Table II.

Galvanostatic reductions.—In order to complete the results obtained by the potentiostatic reductions, some reductions were effected at constant current on the three kinds of manganese dioxide tested.

Figure 5 shows, as abscissa, in a logarithmic scale the ratio

$$\frac{2 - x_0 + Ki\sqrt{t}}{x_0 - \frac{3}{2} - Ki\sqrt{t}}$$

for various values of reduction time, t, as ordinate, the corresponding potential reached by the dioxide electrode in relation to the reference system, after correcting for the ohmic polarization measured by the interrupted current method (20). In order to calculate K, the values of $S\sqrt{D}$ (in cm³ s$^{-1/2}$ g^{-1}) previously determined by the potentiostatic method were used. The i values were calculated for one gram of dioxide.

Examination of Fig. 5 leads to the following remarks.

With any kind of dioxide, the relation gives a line the slope of which is equal to 0.060V, which is in

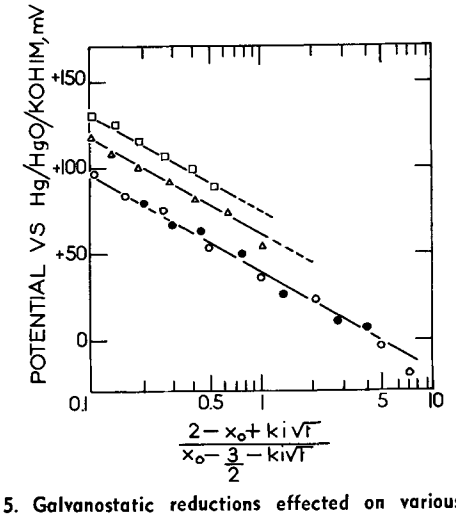

Fig. 5. Galvanostatic reductions effected on various kinds of manganese dioxide in 1M KOH medium for various reduction rates, i, imposed on a depolarizing mix weight of 0.2g. □ electrolytic MnO_2, i = 1 mA; △ chemical MnO_2, i = 1 mA; ○ natural MnO_2 (ramsdellite) i = 1 mA; ● natural MnO_2 (ramsdellite) i = 2 mA.

agreement with theory (2.3 $RT/\mathbf{F}$). The potential is expressed as follows

$$E(x_s) = E^{\circ\prime} - 2.3\frac{RT}{\mathbf{F}}\log\left[\frac{2 - x_o + Ki\sqrt{t}}{x_o - \frac{3}{2} - Ki\sqrt{t}}\right]$$

The theoretical relationship is more closely followed as the manganese dioxide becomes more highly crystallized. This agrees with the hypotheses previously stated from the potentiostatic determinations. The galvanostatic reduction method therefore corroborates the results obtained by the potentiostatic method.

Conclusions

This work has resulted in some general views of the protonic reduction process in the solid phase, which has been mentioned frequently by various authors to explain the mechanisms involved in the electrochemical reduction of γ and ρ manganese dioxides.

The following points have particularly been stressed in this work, which started from theoretical consideration based both on thermodynamics and on the physicochemistry of the solid state.

The behavior of manganese dioxide during its electrochemical reduction may be analyzed to a first approximation by means of an equation representing a diffusion process in the solid state; such equation may be expressed in a particularly simple form if the crystal of the dioxide is assumed to be a semi-infinite medium.

Under the experimental conditions imposed on the system (either potentiostatic or galvanostatic) the validity of this equation can be demonstrated with the restrictions associated with the semi-infinite nature of the crystal of dioxides at the beginning of the electrochemical reduction. The equation is followed more closely as the kind of dioxide tested becomes more highly crystallized.

A characteristic parameter, $S\sqrt{D}$, the product of the active surface area of the dioxide electrode multiplied by the square root of the diffusion coefficient of protons in the crystal, has been determined for 1g samples of dioxides. With such a parameter it has been possible to compare the depolarizing activity of several dioxides of the γ and ρ types. Some determinations were also made in a deuterated electrolyte.

The knowledge of the reduction mechanism gained in this study should be helpful in directing the physicochemical treatments of manganese dioxides in order to obtain a high electrochemical activity for use in galvanic cells.

Discharge Mechanism of the V_2O_5 Electrode

Kenneth R. Newby[1] and Allen B. Scott*

Department of Chemistry, Oregon State University, Corvallis, Oregon

ABSTRACT

The behavior of V_2O_5 single crystals, grown from the melt, during cathodic polarization and recovery, has been investigated. The dependence of potential on *p*H showed that the only plausible reduction product was a solid oxide or oxyhydroxide, polarization being due to the formation of a solid solution. In the *p*H range 2.0-5.5, the curve of electrode potential *vs.* time during both polarization and recovery was accurately predicted by an equation, already applied to MnO_2, derived from the assumption that the product is removed from the surface by diffusion into the electrode. Using tritium as a tracer, it was shown that hydrogen is incorporated in the electrode during discharge at *p*H 4.7. The activation energy for diffusion was found to be 6.7 kcal/mole, which is consistent with bipolar diffusion of protons and electrons.

Vanadium pentoxide as a cathode in electrochemical cells has previously been studied to a limited extent. Watson and Scott (1) studied polycrystalline V_2O_5 electrodes in an acid electrolyte saturated with dissolved V_2O_5. They found that, for low constant-current discharges, polarization curves for this electrode were qualitatively similar to those for MnO_2 in an alkaline medium. These authors were partially successful in applying a theory developed (2) for MnO_2 to these discharge curves. This theory is based on the assumption that polarization is caused by an accumulation of reduced product in solid solution on the electrode surface and that recovery is a result of the subsequent diffusion of the product into the electrode. Its application to MnO_2 has been demonstrated quantitatively (3).

Shukler and Kuz'min (4) studied the cathodic behavior of pressed pellet electrodes made of 80% V_2O_5 and 20% graphite. These authors used H_2SO_4 as an electrolyte and worked at higher apparent current densities than Watson and Scott. They concluded that the V_2O_5 electrode is reduced directly to a second solid phase on the electrode surface. This phase was identified as one containing V(IV).

Here we attempt to determine the discharge mechanism for single crystalline V_2O_5 in NH_4Cl buffered solutions and to show under what experimental conditions the theory applicable to MnO_2 can be expected to predict the discharge and recovery curves.

Experimental

Electrode preparation.—Single crystals of V_2O_5 were grown using a modification of a method originally due to Arsen'eva and Kurchatov (5) and supplied to this laboratory by Boros in a private communication.

The crystals were grown in a platinum crucible in an air atmosphere. Baker analyzed (99.5%) V_2O_5 was melted at 690°C and a small seed of crystalline V_2O_5 was placed on the melt surface. The temperature was then slowly raised until only a single crystallite remained. At this point the melt was cooled at a rate of approximately 1°C/3 min for a total of 10°-20°C. The single crystal grew as a thin, flat sheet on the surface of the melt with the *ac* crystallographic plane parallel to the surface of the melt. The crystal was removed before it reached the edge of the crucible by lifting it from the surface of the melt with a stainless steel spatula.

Crystals could be grown to a diameter of 5 cm (the diameter of the platinum crucible) and a thickness in excess of 3 mm by the above method. However, for convenience a crystal was usually removed from the melt with dimensions of approximately 20 x 10 x 2 mm. The underside of the crystal was covered with polycrystalline material frozen during the process of removal. For the purposes of this study, in which only the top surface of the crystal was presented to the electrolyte, the presence of this material on the back of the crystal was no disadvantage. The top surface was plane, lustrous, and over a large part of its area was, on microscopic examination in reflected light, free of appearances of polycrystallinity. Regions which appeared to be polycrystalline at or near the surface were discarded.

Two methods of attaching leads to the V_2O_5 crystals were used. In one, a hot Pt wire was driven into one end of the oxide crystal which melted and resolidified around the wire. In the other method a copper wire was soldered to a gold leaf which had been deposited on the back of the crystal. After the electrical contact was made, a heavy coat of paraffin was applied to all parts of the crystal except the surface which was to be presented to the electrolyte.

Electrolyte *p*H was measured by means of a Beckman Zeromatic *p*H meter. A Systems Research Corporation Model 5501 differential voltmeter was used to measure the electrode potential with reference to the saturated calomel electrode as a function of electrolyte *p*H. The cell was held in a thermostat at 25° ± 0.2°C.

For counting solutions containing tritium, a 1 ml sample of the solution was pipetted into 10 ml of Bray's solution (6) and counted three times, for periods of 5 min, on a Packard Tri-carb Liquid Scintillation Counting System Model 314 EX. In the original solutions in which electrodes were treated the tritium concentration was such that 28.0 counts/min corresponded to one μ-equivalent of hydrogen. Corrections were made for background and color quenching due to dissolved V_2O_5.

The cell for determining the polarization and recovery curves contained the V_2O_5 cathode, a spectroscopic grade carbon anode, a saturated calomel reference electrode with a Luggin tip having an internal radius less than 0.5 mm placed 2 mm from the cathode, a stirrer, and a gas dispersion tube for either O_2 or N_2. The cell was maintained within 0.2° of any chosen temperature between 0° and 45°C by means of a thermostat. The discharge current was held constant by means of a circuit (7) using a Heathkit Model EUW-194 operational amplifier, and was measured by means of a calibrated microammeter. The potential of the V_2O_5 electrode with respect to the saturated calomel electrode was recorded using a Hewlett-Packard Model 7100 BM recording potentiometer.

Results and Discussion

Effect of pH on electrode potential.—During cathodic discharge in acid medium the reaction may be written

* Electrochemical Society Active Member.
[1] Present address: Bell Telephone Laboratories, Inc., Murray Hill, New Jersey.
Key words: vanadium pentoxide, cathodic polarization, discharge.

$$V_2O_5 + ne^- + n'H^+ + mH_2O = \text{product} + pH_2O \quad [1]$$

where "product" represents the reduced form of the vanadium pentoxide and n, n', m, and p may individually have any value including zero.

At 25°C the Nernst equation for this reaction is

$$E = E_o - \frac{0.059}{n} \log \frac{[\text{product}]\,[H_2O]^p}{[V_2O_5]\,[H^+]^{n'}\,[H_2O]^m} \quad [2]$$

where [ ] represents the activity of the enclosed species.

If the activity of the water is taken as the activity of pure water, and if the activity ratio of the V_2O_5 and the product remains constant when the pH is varied, then Eq. [2] reduces to

$$E = E_o' - 0.059\frac{n'}{n}\text{pH}$$

where E_o' includes E_o and other constants. Thus under these assumptions the slope of the curve of electrode potential *vs.* pH is $-0.059(n'/n)$.

The variation of the V_2O_5 electrode potential with pH, in NH_4Cl solution whose pH was adjusted by addition of NH_3 or HCl, is shown in Fig. 1, for pH between approximately 2.0 and 5.5. When the pH was outside this range, the potential was unsteady. The experiment was conducted both on a freshly prepared electrode which had never been discharged and on electrodes which had been discharged to varying degrees and then allowed to recover for two days.

The slopes of the curves in Fig. 1, determined by least-squares analysis were, for A through D, −0.064, −0.054, −0.058, and −0.060, respectively, with an average value of -0.059 ± 0.005 V/pH unit. This is good evidence that the activities of both V_2O_5 and the product are independent of pH and that $n = n'$.

The data on single crystals confirm the previous result of Watson and Scott (1) on polycrystalline vanadium pentoxide electrodes and also that reported by Shukler and Kuz'min (3) on pressed pellet electrodes.

It has been previously shown (1) that, for the cathodic discharge of V_2O_5 at pH < 5.3, if the number of electrons equals the number of protons the product must be a solid. The reduction may involve loss of oxygen to the electrolyte, exemplified by the reaction

$$V_2O_5 + 2e^- + 2H^+ = V_2O_4 + H_2O$$

or by incorporation of hydrogen and water in the solid electrode exemplified by the reaction

$$V_2O_5 + 2e^- + 2H^+ + H_2O = 2VO(OH)_2 \quad [3]$$

The observation that steady potentials were unattainable outside pH 2.0-5.5 is probably due to the following factors, among others: at pH <2 the product dissolves to an appreciable extent; at pH >5.5 the product is oxidized by oxygen dissolved in the electrolyte.

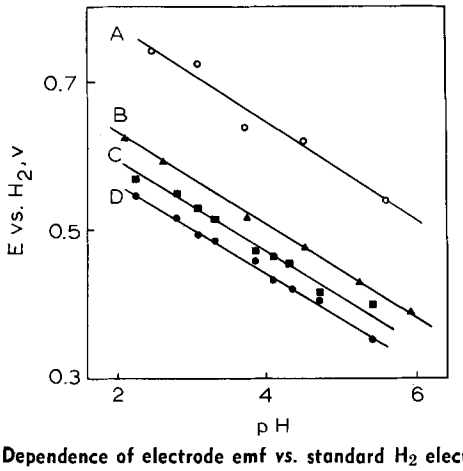

Fig. 1. Dependence of electrode emf *vs.* standard H_2 electrode on pH at 25°C. Curve A is for unreduced V_2O_5; B, C, and D are for partially reduced V_2O_5.

Discharge in tritiated solutions.—In order to demonstrate whether or not hydrogen is incorporated in the V_2O_5 electrode during cathodic discharge, electrodes were discharged in tritium-containing solutions. After a recovery period, the electrodes were anodically charged in a nontritiated electrolyte to recover tritium incorporated during the discharge, and this electrolyte was then counted. Because a considerable amount of tritium was adsorbed or otherwise adhered to the electrode after immersion in tritiated solution even if no discharge current was passed, a standard procedure for rinsing and soaking electrodes was developed to provide suitable "blank" comparisons.

Each electrode initially was allowed to stand for a minimum of 1 hr in 1*N* NH_4Cl solution which contained 25 μc/ml of tritium. The electrode was then rinsed for 1 min with manual agitation successively in each of three 10-ml distilled water baths followed by one 3-hr rinse in a fourth 10-ml distilled water bath. The fourth rinse served as a predischarge blank for the adsorbed tritium on a given electrode. Following the predischarge blank the electrode was returned to the tritiated electrolyte and discharged at a measured current for 3 hr. After discharge the electrode was allowed to recover in the tritiated solution for a minimum of 1.5 hr. At the completion of the recovery period the electrode was rinsed as described above for the blank except that in the fourth distilled water bath the electrode was made an anode and oxidized for 3 hr at a current equal to or slightly less than the discharge current. This charging procedure was undertaken to reverse the discharge reaction and, thereby, aid in the release to the bath of tritium incorporated in the electrode. After the discharge and charge operations, a postdischarge blank was made. The procedure for this was identical to that of the predischarge blank.

Table I shows clearly that tritium was incorporated during discharge, the discharge-charge treatment yielding on the average significantly higher activity than either of the blanks. Some tritium may have been retained in the electrode in most cases even after the charging process, as the postdischarge blank was generally higher than the predischarge blank. An additional cause for higher postdischarge blanks may be an increase in surface roughness caused by charging and discharging which would result in increased adsorption of tritiated solution. From the number of Faradays passed during discharge, and the difference in counting rate between the entries in the discharge-charge column and the predischarge blanks, a rough value for the current efficiency for incorporation of hydrogen during discharge was calculated. It approached 60% in some samples, but was generally lower and highly variable. In part, the low current efficiency may be due to failure to recover all of the tritium during charging; in part it may arise from isotope effects during electrolysis; further in the case of samples 4 and 7 hydrogen gas evolution was ob-

Table I. Comparison of electrode treatments in tritiated solution

Sample	Counting rate, per minute			Current efficiency, %
	Predischarge blank	Discharge-charge	Postdischarge blank	
1	216	526	97	23
2	101	750	268	47
3	64	715	258	37
4	70	374	487	17
5	48	720	98	55
6	26	1397	493	58
7	26	242	210	27
8	26	708	429	52
9	32	640	255	55

served to occur, which would account for the low current efficiency observed.

We conclude from this experiment that the cathodic discharge of V_2O_5 involves largely if not entirely the incorporation of hydrogen in the solid electrode. If the product is in solid solution with V_2O_5, it is meaningless to specify its formula. For some purposes, it may be convenient to represent the reduced material as a solid solution of $VO(OH)_2$ in V_2O_5; however, this representation has the disadvantage that $VO(OH)_2$ cannot diffuse as such in solid solution with V_2O_5 unless oxygen diffuses as well as hydrogen, an unlikely occurrence at the temperatures of interest. The most satisfactory representation is simply a solid solution of hydrogen in V_2O_5.

Polarization and recovery mechanism.—On the basis of the results of the foregoing experiments, we propose that single crystalline V_2O_5 is polarized during discharge by an increasing concentration of hydrogen (probably as an oxyhydroxide) in solid solution; on discontinuing the current, recovery occurs by diffusion of protons, accompanied by electrons, into the interior of the electrode.

Representing the reduction product, as a solid solution of hydrogen in V_2O_5, by the formula $V_2O_5 \cdot H$, the cathode reaction is

$$V_2O_5 + e^- + H^+ = V_2O_5 \cdot H$$

and the Nernst equation for constant pH is

$$E = E_o'' - (RT/F) \ln \frac{[V_2O_5 \cdot H]}{[V_2O_5]}$$

where E_o'' includes E_o and a term involving the pH.

Formulated in this way, the cathode reaction is the formal analogue (8) of the cathode reaction for MnO_2 at moderate current density and pH in the middle range. It must be noted that a different choice of electrode reaction, *e.g.*, Eq. [3], leads to apparent differences in the Nernst equation. These differences disappear if the reference functions for activity are properly chosen on the basis of site-occupancy, as they should, since the representation of solids by molecular formulas is arbitrary.

The dependence of electrode potential upon time should then follow the equation (2, 3)

$$E = E_o'' + 2.303(RT/F) \log \left[\frac{A}{t^{1/2} - (t - \tau)^{1/2}} - 1 \right] \quad [4]$$

where t is the time and τ is the time at which the discharging current is broken. This relation is derived from the solution of Fick's equation for one-dimensional diffusion in a semi-infinite body, with constant flux onto the surface. Provided the proposal above is correct, [4] should apply more accurately to a large single crystal than to the polycrystalline electrodes previously studied.

In obtaining [4], if the activities of V_2O_5 and $V_2O_5 \cdot H$ are replaced by the respective mole fractions, A is given by

$$A = C_o (\pi D)^{1/2}/2\phi \quad [5]$$

with D the diffusion coefficient for the product, C_o the concentration of pure solid V_2O_5 in equivalents/volume, and ϕ the flux of hydrogen through the surface in equivalents/area x time.

Single crystals were discharged and allowed to recover in an NH_4Cl electrolyte, using a range of current densities, temperatures, and pH's. The pH was adjusted by addition of NH_3 or HCl. In previous work with polycrystalline electrodes (1) it was necessary to saturate the electrolyte with V_2O_5 to prevent dissolution of the electrodes; with single-crystal electrodes the rate of dissolution was so small that experiments of several hours duration could be carried out in V_2O_5-free electrolytes with no detectable dissolution provided the pH was within the range 2.0-5.5. This avoided the complication of the possibility of simultaneous reduction of dissolved as well as solid V_2O_5.

Figure 2 shows the polarization during discharge, and the recovery, of a V_2O_5 electrode at pH = 4.7 and current density 48 μA/cm^2. The current was broken at 20 sec.

An apparently instantaneous drop in potential at the start of the discharge, with an approximately equal instantaneous rise on breaking the current, resulted from ohmic polarization, with possibly some contribution due to activation polarization. The original recorder tracings (Fig. 2a) were corrected by removing the segments which appeared to be vertical. The origin of the ohmic polarization was chiefly in the high resistivity (around 100 ohm cm) of the electrode itself, since so-called pseudo-ohmic polarization was made small by use of the Luggin tip. The magnitude of the ohmic polarization was affected by a change in the method of connecting leads (see "Experimental") but there was no other effect of lead location on the shape of the polarization and recovery curves. Due to the extreme initial steepness of the recovery curve, and the finite response time of the recorder, the correction for ohmic polarization at the start of recovery could not be made with accuracy by inspection of the original tracing. However, since the only effect of the correction is to move the recovery curve up or down with respect to the discharge curve, the magnitude of the correction was determined to be that which allowed the same value of E_o'' to be used for both the discharge portion and the recovery portion in fitting the observed data to Eq. [4]. The remaining polarization, shown in Fig. 2b, 3, 5, and 6, is ascribed to solid concentration polarization.

In Fig. 2b, experimental points taken at several values of t from the original tracing, corrected as described, are shown. The constants E_o'' and A of Eq. [4] may be found from the values of E and t at any pair of points on the discharge portion of the curve. The best fit of the experimental points to the equation, during discharge, was given by the constants E_o'' = 0.421V and A = 7.7 sec$^{1/2}$. The recovery curve, *i.e.*, E at $t > 20$ sec, was then calculated with these constants. The full curve of Fig. 2b shows the variation of E with t for both discharge and recovery calculated according to Eq. [4]. The agreement with observation is good.

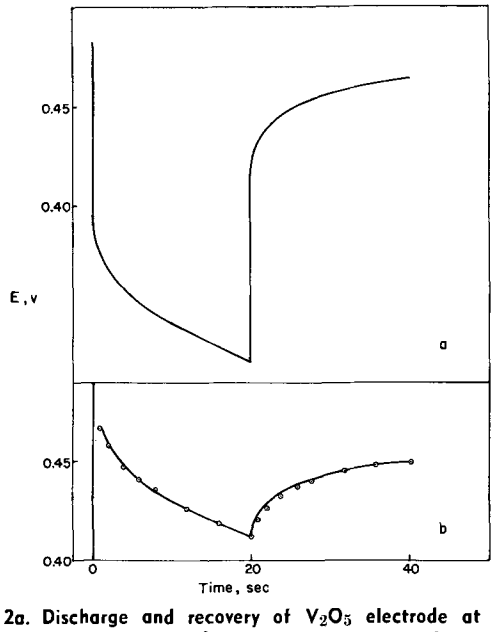

Fig. 2a. Discharge and recovery of V_2O_5 electrode at pH 4.7 and current density 4 μA/cm^2; b after correcting for IR drop on discharge and IR rise on recovery. Points, experimental observations from corrected recorder tracing; full curve, calculated from Eq. [4].

The adherence to Eq. [4] shown in this example is typical of 50 polarization experiments, in which 12 different electrodes were used, provided the *p*H was in the range 2.0-5.5, and the current density and τ were such that τ was somewhat less than $4A^2/9$. At $t \rightarrow 0$, the Nernst equation yields $E \rightarrow \infty$. Except at t near zero, or slightly greater than τ, at which times also the error due to finite recorder response time is apparent, Eq. [4] with constants obtained as above fit the experimental discharge and recovery curves, on the average, within ± 1 mV. The same electrode could be discharged, allowed to recover until E had returned within a few mV of the initial value, and then discharged again; Eq. [4] was followed equally well on the second (and subsequent) discharges as upon the first. We conclude that, under the conditions given, both the polarization during discharge and the recovery are satisfactorily accounted for by the mechanism proposed.

The theory was further tested by examining the dependence of A on the current density. Since A varies as the reciprocal of the flux of the diffusing species onto the surface, it should be linear with i^{-1}, where i is the current density. Figure 3 displays corrected discharge and recovery curves for the same electrode at three different currents. Since the electrode area was maintained constant, the current and current density were proportional. Figure 4 shows the relation between A, found as described above, and the reciprocal of the current, for curves of Fig. 3 and others obtained using additional values of the current. The linearity, and passage through the origin, is satisfactory.

The effects of variation in *p*H, oxygen-content of the electrolyte, stirring, and temperature were next examined.

According to [5], A should be independent of *p*H; however, this was not found to be true. In Fig. 5 are shown the results of discharge at constant current density but varying *p*H. Polarization was made less severe, and recovery more rapid, by lowering the *p*H; this corresponds to an apparent increase in A with decrease in *p*H. There are two probable causes: at *p*H < 2.0 the rate of dissolution of tetravalent vanadium is significant, so that polarization by the mechanism above is minimized by the simultaneous removal of product by dissolution and diffusion into the solid, while the recovery rate is correspondingly enhanced. At all *p*H's the rate of the competing reaction to form H_2 is favored by a decrease in *p*H, so that the actual flux of diffusant may be decreased as a higher proportion of the transferred charge is consumed in H_2 generation.

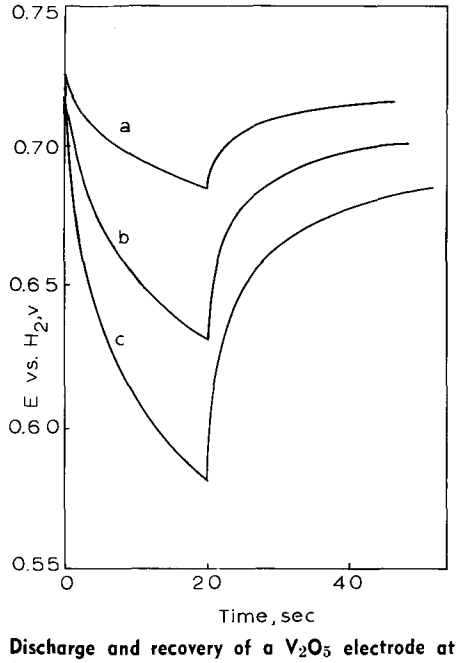

Fig. 3. Discharge and recovery of a V_2O_5 electrode at *p*H 3.1. Current, μA: a, 36; b, 80; c, 123.

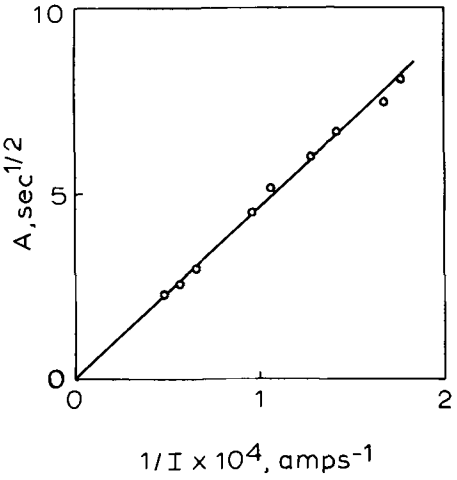

Fig. 4. Dependence of A on current for discharge of the vanadium pentoxide electrode.

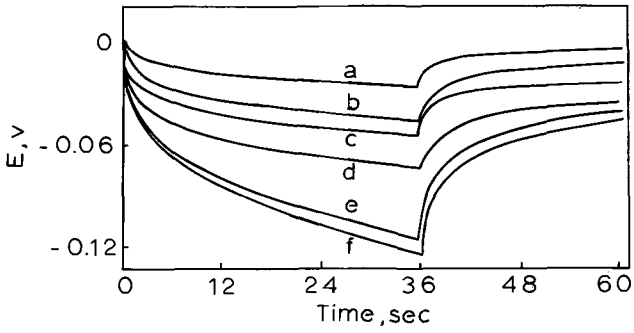

Fig. 5. Effect of *p*H and stirring on the polarization of a V_2O_5 electrode at 61 μA. *p*H: a, 0.7; b, 1.7; c, 3.0; d, 4.5; e, 7.0 stirred; f, 7.0 not stirred. Curves a-d represent both stirred and unstirred discharges. Ordinate of each curve has been shifted so that $E = 0$ at $t = 0$.

At high *p*H's, tetravalent vanadium is oxidized by dissolved oxygen. As shown in Fig. 5, rapid stirring decreased the degree of polarization in an aerated electrolyte of *p*H $= 7$, but had no significant effect at lower *p*H's. It appears that recovery in such a solution is assisted by oxidation of the reduced product and that the rate of oxidation is at least in part governed by the rate of diffusion of dissolved oxygen to the electrode. Several experiments were performed in solutions which had been either freed of oxygen by bubbling N_2 through the solution, or saturated with O_2. In all cases where *p*H ≥ 7 the presence of O_2 in solution clearly reduced the degree of polarization.

The variation of A with *p*H, and the likelihood that evolution of H_2 may compete with the assumed electrode reaction makes the calculation of D from A and ϕ unreliable, since ϕ cannot be related unambiguously to the current density. If it is assumed that ϕ is actually given by $i/\mathbf{F}$, and that the measured surface area is the true surface area, the diffusion coefficient for protons, accompanied by electrons, in V_2O_5 may be calculated for the example shown in Fig. 2, to be $D = 6 \times 10^{-15}$ cm^2/sec. The coefficient for protons alone is one-half this value (11). There are few reported values for other oxides with which to compare this result. The data of Thomas and Lander (12), extrapolated to room temperature, lead to $D \sim 10^{-16}$ cm^2/sec for the bipolar diffusion coefficient for hydrogen in ZnO. The rough value reported above for hydrogen in V_2O_5 appears on this basis to be of a reasonable order of magnitude.

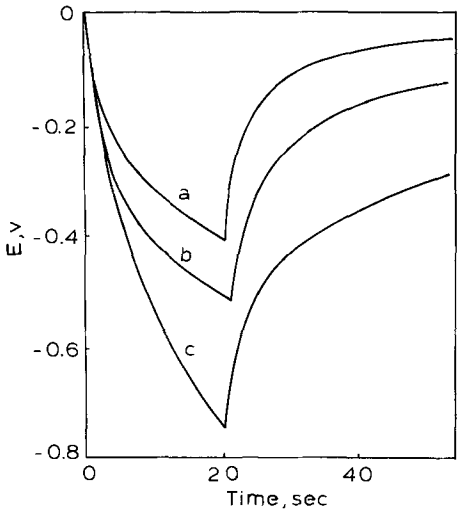

Fig. 6. Effect of temperature on the discharge of a V_2O_5 electrode. Temperature: a, 33°C; b, 16°C; d, 4.5°C; current: 120 μA. Ordinate of each curve has been shifted so that $E = 0$ at $t = 0$.

The effect of temperature upon polarization and recovery is shown in Fig. 6. Letting

$$D = D_0 \exp(-\Delta E/RT)$$

where ΔE is an activation energy for diffusion, it is clear that, provided the current density is constant and the current efficiency for production of the diffusing species is not strongly influenced by temperature, a curve of 2 log A *vs.* T^{-1} should be linear. Figure 7 shows such a relation for the curves of Fig. 6, along with similar data for additional temperatures. From the slope, the value of ΔE was found to be 6.7 kcal/mole.

The magnitude of ΔE is comparable to activation energies reported in some other instances of what is thought to be proton diffusion in oxides, *e.g.*, 3.2 kcal/mole in MnO_2 (9), 13 kcal/mole in α-$Al_2O_3 \cdot H_2O$ (10), and 4.5 kcal/mole in ice (10). For metal ions in oxides, ΔE has been found to be roughly an order of magnitude higher, and it is generally higher still for oxide ions, so that this value of ΔE is consistent with

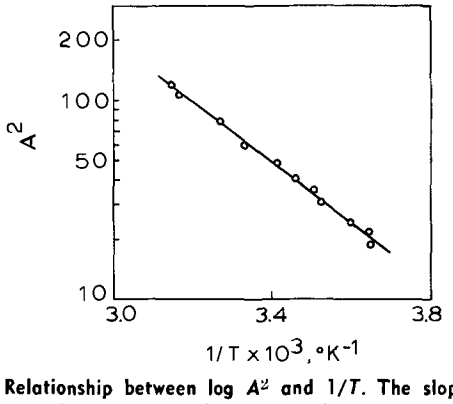

Fig. 7. Relationship between log A^2 and $1/T$. The slope corresponds to an activation energy of 6.7 kcal/mole.

the proposed mechanism involving the diffusion of protons.

A limitation of the simple diffusion theory, already pointed out (2), became apparent when the discharge was carried out for extended periods. Equation [4] predicts that an inflection should occur in the curve of E *vs.* t, during discharge, at $t = 4A^2/9$; further the slope should become infinitely negative at $t = A^2$, that is when the surface is completely reduced. It is evident that A^2 is the analogue of the "transition time" in the chronopotentiometric equation of Sand (13). In fact, both the inflection downward and the later abrupt decrease in potential, where they were observed at all, always occurred at times longer than those predicted. We ascribe this result to the fact that the surface, instead of being a geometrical plane as assumed in the theory, is actually the layer, perhaps a unit-cell edge or more deep, whose composition determines the electrode potential. We are unaware of any satisfactory way to improve the theory by a consideration of the detailed structure of the surface; consequently, in testing the theory we limited ourselves to discharges for times considerably less than $4A^2/9$.

The results reported here differ greatly from those of Shukler and Kuz'min (4). In view of the differences in the electrolyte and apparent current density, and the circumstance that they used polycrystalline material mixed with graphite, this is to be expected. Under the conditions used here, our results all support the conclusion that the reduction product includes hydrogen and forms a solid solution in V_2O_5.

Acknowledgment

The authors wish to acknowledge the assistance of C. Bryden in the preparation of single crystals and D. J. Reed for his aid in the experiments involving tritium. This work was supported in part by the Office of Naval Research. The assistance provided by a NDEA Fellowship is gratefully acknowledged by K. R. Newby.

The Anodic Oxidation of Silicon Nitride Films on Silicon

Terrance B. Tripp

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

The anodic oxidation of silicon nitride films prepared by chemical-vapor-deposition on silicon was studied at six current densities between 4.0 and 13.0 mA/cm^2. It was found that the rate of conversion of silicon nitride to silicon dioxide is independent of time and that the conversion efficiency increases with increasing current density. The onset of film growth from the substrate does not occur until a significant time after the whole film has been rendered easily soluble in HF. It is postulated that the initial product of conversion is an easily soluble, mixed oxide-nitride which must subsequently be converted to oxide before film growth from the substrate can begin. This idea is supported by the behavior of the field strength in the film during the conversion process.

Recently Schmidt and Wonsidler (1) have reported that chemical-vapor-deposited films of silicon nitride on silicon can be converted to silicon dioxide by electrochemical oxidation. The present investigation was undertaken to obtain quantitative data on this anodization process. This information can be used to compare the nature of the conversion of silicon nitride with the formation of anodic oxide films on metals such as silicon and tantalum.

Experimental

The silicon nitride films were grown on 10 ohm cm <111> p-type silicon wafers using the silane-hydrogen-ammonia reaction of chemical-vapor deposition (2). A 1:1000:10 ratio by volume of silane-hydrogen-ammonia was used with a substrate temperature of approximately 900°C. Prior to depositing the nitride, a 12,000Å layer of thermal silicon dioxide was grown on the substrate and a round, 2.5 cm^2 window was opened in this film near the center of the wafer by photolithographic methods (3). This layer of thermal oxide served as an electrically insulating barrier which assured that the anodization was confined to the well-defined area of the window.

The initial thickness of the nitride film was measured by ellipsometry. Samples were selected and matched to give sets with a film thickness variation of less than ± 20Å. Such a set was used for each current density studied. The samples were pressed against a 2 cm ID Viton O-ring mounted in the side of the anodization cell in such a way that the window of silicon nitride was exposed to the electrolyte. In order to reduce heating effects, the plate used to hold the wafer against the O-ring was a block of brass into which cooling fins were machined. During anodization, air was blown over the fins to enhance heat transfer. No temperature rise was detectable with a thermocouple imbedded in the plate very near the surface in contact with the sample. The anodizations were carried out at room temperature using a constantly stirred electrolyte of ethylene glycol + 2% water, 0.4M in KNO_3. Constant current, supplied with an Electronic Measurements Model C633B power supply, was measured with a Keithley 610A electrometer. To measure the voltage drop across the film and substrate a platinum wire, imbedded in glass up to its tip, was placed very near the surface of the sample. The voltage drop between this electrode and the sample substrate during anodization was measured with a Keithley 610A electrometer and recorded with an Esterline Angus Model AW recorder. The contribution to the total voltage by the substrate and contact resistance was about 25V.

The thickness of the converted film and remaining silicon nitride film after anodization was measured interferometrically by taking advantage of the great difference in solubility of the films in HF. First, the surface of each sample was masked with wax to leave two narrow channels of the film exposed, and the film was etched for 2 sec in 48% HF. Next, half the length of each channel was masked with wax, and the film was etched again for several minutes (the etching time varied somewhat with the thickness of the silicon nitride) in 48% HF. After removing the wax, the depth of the channels was measured by interferometry with a Cryolab Model TD-550 thin film thickness determinator. The depth of the channels in the area etched for 2 sec was taken as the thickness of the layer of film produced by the conversion of the silicon nitride. The depth of the channels in the area etched for a longer time was taken as the total thickness of the film.

Results and Discussion

The conversion behavior of 1000Å silicon nitride films at a current density of 7.5 mA/cm^2 (calculated from total current and window area with no roughness factor) is summarized in Fig. 1. The rate of conversion and the total film growth rate were found to be constant also at five other current densities between 4.0 and 13.0 mA/cm^2. Results are summarized in terms of the conversion rate and total film growth rate in Table I. Results obtained from the conversion of a number of samples for the same length of time indicated that the thickness of converted film produced agreed from sample to sample to within about ±20A. Total film thickness was reproducible to within ±50Å.

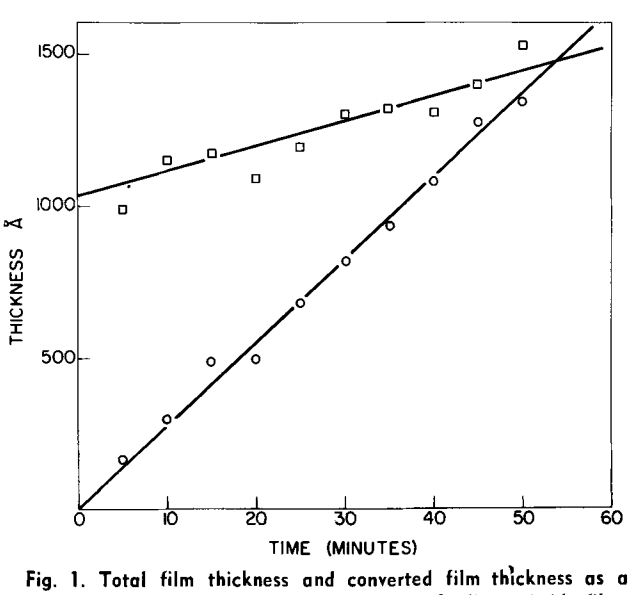

Fig. 1. Total film thickness and converted film thickness as a function of time during the anodic oxidation of silicon nitride films on silicon at a current density of 7.5 mA/cm^2. □ Total film thickness; ○ converted film thickness.

Table I. Conversion rate, total film growth rate, and normalized conversion rate for the anodization of silicon nitride films on silicon at various current densities

Current densities, mA/cm²	Total film growth rate, Å/min	Conversion rate, Å converted film formed/min	Normalized conversion rate ($1/i\ dD/dt$), $\left(\frac{\text{Å converted film}}{\text{formed} \times \text{cm}^2}\right)$ / min × mA
4.0	3.93	13.1	3.28
5.5	5.50	18.9	3.44
7.5	8.20	27.4	3.65
9.0	10.5	35.0	3.89
11.0	12.0	46.4	4.22
13.0	8.0	56.3	4.33

The results from converting 500Å films indicated that the conversion rate is essentially independent of initial film thickness.

Schmidt and Wonsidler (1) report that at a current density of 7 mA/cm² a 1000Å film of silicon nitride is completely converted (presumably as indicated by etch rate) in about 10 min. They used a 7.5 v/o (volume per cent) solution of pyrophosphoric acid in tetrahydrofurfuryl alcohol as electrolyte. In contrast, the present results indicate that it takes about 55 min to convert the same thickness film when the current density is 7.5 mA/cm². The difference in results is most likely due to a difference in the silicon nitride films used or possibly a difference in anodization efficiency of the different electrolytes. In any case, the present results were found to be reproducible for the films studied.

A current efficiency of 1.0% was calculated assuming that the conversion reaction is (1)

$$6\,O^{=} + Si_3N_4 \rightarrow 3SiO_2 + 2N_2 + 12e^{-}$$

The density of the silicon nitride film was taken as 3.1 g/cm³ (see below), and the initial material was considered to be stoichiometric silicon nitride. A similarly low current efficiency has been observed for the anodization of silicon in this electrolyte system (4).

A constant conversion rate is the behavior one would expect for constant current anodization, provided the current efficiency is independent of time and the composition and density of the film are uniform. As the normalized conversion rates ($1/i\ dD/dt$, where i is the current density and D is the converted film thickness) listed in Table I show, the efficiency of conversion increases with increasing current density. In fact, an increase in efficiency with current density has been reported for the anodization of silicon (5). Figure 2 shows the variation with current density of D/D_o, where D is the thickness of the completely converted film and D_o is the initial thickness of the nitride film. This ratio decreases at higher current densities indicating that the increase in conversion efficiency may not be due to a variation in the ratio of ionic to electronic current but to a change in the nature of the conversion, *i.e.*, possibly the initial product of anodization is a mixed oxide-nitride which is easily soluble in concentrated HF and contains a greater percentage of residual nitrogen at higher current densities. Schmidt and Wonsidler (1) have proposed that the conversion reaction involves the evolution of nitrogen gas and, consequently, with increasing current density the increased gas evolution rate produces more porous films. Thus, a given thickness of silicon nitride would produce a thicker converted film with increasing current density, a trend which they reported was observed. Such results are not in agreement with the present study.

In an attempt to detect residual nitrogen in converted films, IR absorption spectra were measured with a Beckman IR 10 spectrometer for films which had been completely converted. No silicon nitride absorption band could be detected. However, the intensity of this absorption band in such films could be below the sensitivity of the instrument or even be absent in a mixed film. The oxide band at 1020-1040 cm^{-1} (6) was present with high intensity.

Figure 3 summarizes the progress of anodization of 500Å films over a time period well beyond the point where the whole film becomes easily soluble in HF. Of interest is the increase in the film growth rate about 5 min after the entire film becomes easily soluble in HF. Some indication of the significance of this change in slope can be deduced from Fig. 4 which shows the voltage build-up during the anodization of both a 500Å silicon nitride film and 10 ohm cm silicon. A change in voltage build-up rate occurs during the anodization of the silicon nitride at a time which corresponds to the break in film growth rate. Furthermore, the build-up rate after the slope change is almost identical to that for the anodization of silicon. Thus, it would appear that the slope change signals the point at which the growth of oxide from the substrate begins. If during anodization, a mixed oxide-nitride film is initially produced as postulated, then what might occur between the time when the film becomes easily soluble in HF and the time when film growth from the substrate begins is the further electrochemical elimination of nitrogen from the film.

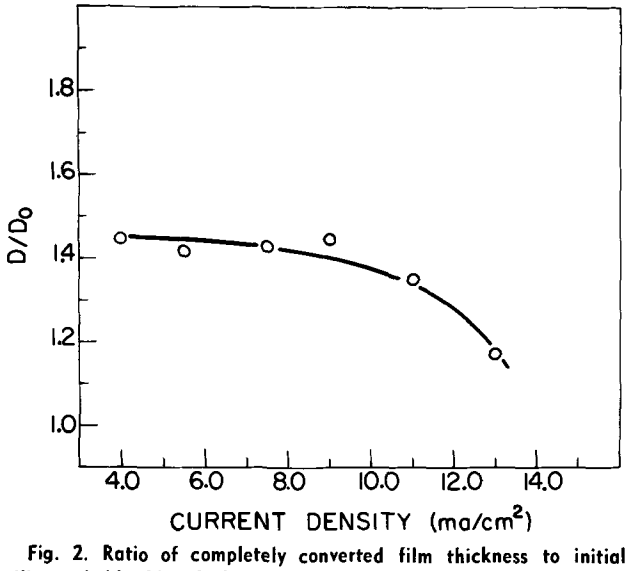

Fig. 2. Ratio of completely converted film thickness to initial silicon nitride film thickness as a function of current density.

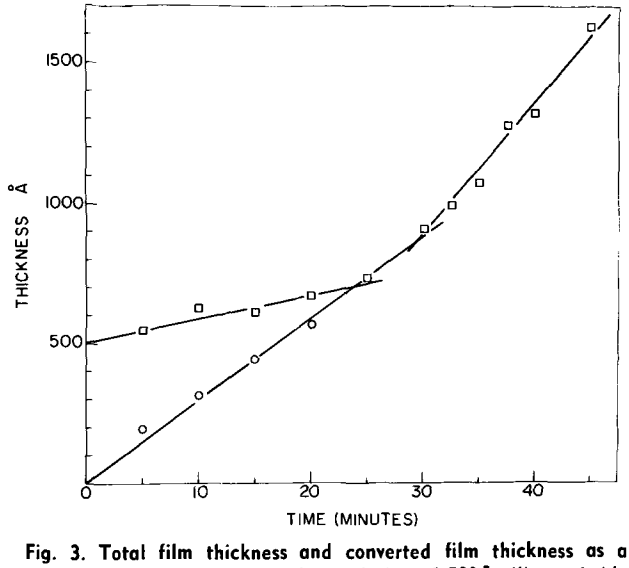

Fig. 3. Total film thickness and converted film thickness as a function of time during the anodic oxidation of 500Å silicon nitride films on silicon at a current density of 7.5 mA/cm². □ Total film thickness; ○ converted film thickness.

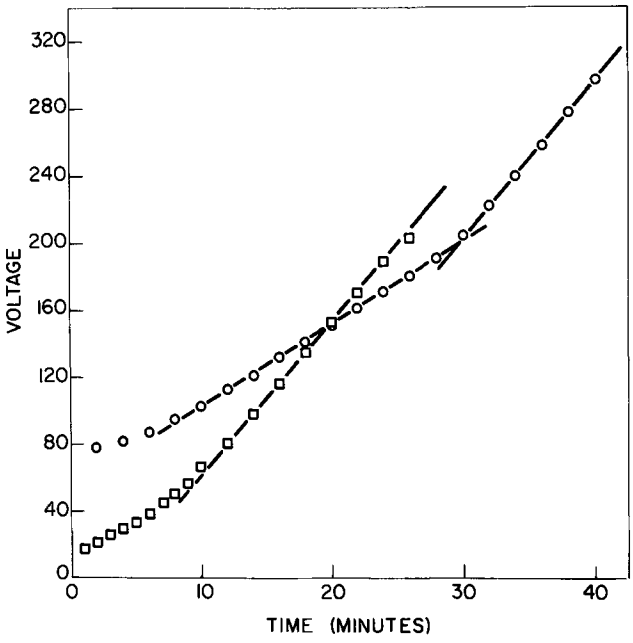

Fig. 4. Voltage as a function of time during the anodic oxidation of silicon and a 500Å silicon nitride film at a current density of 7.5 mA/cm². □ Ten ohm cm silicon; ○ silicon nitride on silicon.

This conclusion is supported by a calculation, based on the densities of silicon nitride and silicon dioxide, of the expected thickness of the converted film to be produced by a given thickness of silicon nitride. Choosing as representative of the limited published data (6-8) on the density of silicon nitride and silicon dioxide films the values 3.1 and 2.2 g/cm³, respectively, one calculates that the complete conversion of a 500Å silicon nitride film should produce a 900Å silicon dioxide film. The change in film growth rate occurs at a thickness of 875Å while the whole film becomes easily soluble in HF at a thickness of 710Å.

It is not possible to calculate from the experimental data the field strength in the converted portion of the film during anodization without making unjustifiable assumptions. Nevertheless, the field in the film being grown directly from the substrate can be calculated if it is assumed that the field in the completely converted silicon nitride film remains constant and is given by the ratio of voltage to film thickness at the point where the change in film growth rate occurs. With these assumptions, the voltage drop across the substrate grown film is simply the difference between the observed voltage and its value at the point where the film growth rate changes. A similar rule applies for the film thickness. The results of such a calculation are summarized in Table II and indicate that the field strength in the new film growing from the substrate is constant at 1.93×10^7 V/cm. Schmidt and Michel (5) observed that the field in the oxide film during the anodization of silicon is constant. Furthermore, this calculated field is in good agreement with the value $1.9 \pm 0.03 \times 10^7$ V/cm² for the field in the oxide film during the anodization of 10 ohm cm p-type silicon. This field was evaluated from voltage build-up and film thickness data obtained in this laboratory by room temperature anodization of silicon at a current density of 7.5 mA/cm² using the electrolyte ethylene glycol + 2% water, 0.04M in KNO_3.

Table II. Calculated field across the substrate-formed-film during anodization of silicon nitride films on silicon at a current density of 7.5 mA/cm²

Anodization time, min	Field × 10^{-7} V/cm
32.0	1.95
34.0	1.93
36.0	1.96
38.0	1.94
40.0	1.93
42.0	1.93
44.0	1.93

A detailed understanding of the progress of the anodization cannot be deduced from the present results alone. Based on unpublished data for the anodization of thermally grown silicon dioxide, Schmidt (9) has suggested that a conversion gradient might be established in the film during anodization by the penetration of hydroxyl ions into the film. Conceivably even the only slightly converted material near the leading edge of this gradient would be easily soluble in concentrated HF. If this is the case, then the whole film would become easily soluble in concentrated HF when the leading edge of the gradient arrives at the silicon surface. A change in film growth kinetics would not occur, however, until complete conversion of the nitride film.

Summary

The rate of conversion of silicon nitride films on silicon was found to be constant in the current density range 4.0-13.0 mA/cm². The initial product of conversion appears to be a mixed oxide-nitride in which the residual nitrogen content increases with increasing current density. This mixed film continues to be converted to oxide for a time after the whole film has been rendered easily soluble in HF. A change in film growth rate and voltage build-up rate then occurs which signals the onset of film growth from the substrate.

Acknowledgments

The author is indebted to Dr. D. M. Smyth and Dr. R. J. Dreiner for many helpful discussions and to Dr. P. F. Schmidt for comments and suggestions. The silicon nitride films were prepared by R. Holmstrom.

Manuscript submitted June 2, 1969; revised manuscript received ca. Sept. 30, 1969. This was Paper 29 presented at the New York Meeting, May 4-9, 1969.

A Calorimetric Study of the Electroless Deposition of Nickel

J.-P. Randin[1] and H. E. Hintermann*

Laboratoire Suisse de Recherches Horlogères, Neuchâtel, Switzerland

ABSTRACT

A calorimetric study of electroless nickel deposition was made, with the aim of establishing the energy balance for the system. The heat of reaction of chemically reduced nickel by hypophosphite, as well as the heats of oxidation of hypophosphite and nickel, and the heat of ionization of water, was measured at 94°C.

A calorimetric study of electroless nickel deposition was performed, with the aim of establishing the energy balance for the system. It was shown in a previous publication (1) that the as-plated alloy is composed of a nickel phase and a nickel phosphide, Ni_2P, phase. Hence, the heat of formation of the Ni_2P must be contained in the heat of reaction of the deposition. The DTA of the deposit showed, indeed, that the energy evolved during heating corresponds almost exactly to the heat of formation of Ni_3P from Ni_2P (2, 1).

A study of the literature shows that four principal reaction mechanisms have been proposed to explain the chemical plating of nickel by reduction with hypophosphite:

1. The atomic hydrogen mechanism proposed by Brenner and Riddell (3, 4), then successively supported by several authors, among them Gorbunova and Nikiforova (5), Panchenko and Krokhina (6), Gutzeit (7, 8), Fléchon (9), and Levy (10),
2. The hydride transfer mechanism suggested by Hersch (11), by analogy with the reduction of nickel salts by borohydride ions, and later modified by Lukes (12),
3. The electrochemical mechanism proposed by Brenner and Riddell (4). Machu (13), Müller (14), and Ishibashi (15) adopted this theory with some modifications, while Hickling and Johnson (16) proposed an electrochemical alternative to the atomic hydrogen mechanism,
4. The mechanism involving hydrolyzed nickel with hydroxyl ions proposed by Cavallotti and Salvago (17).

Among these four, only the hydride transfer mechanism and that involving hydrolyzed nickel account for the observed values of the molar ratio Ni^{2+} deposited/$H_2PO_2^-$ consumed, which is always lower than 0.50, as well as the variations of this ratio with pH (18). Further, the results of Sutyagina, Gorbunova, and Glazunov (19), concerning the origin of the hydrogen evolved in the course of the reaction, can be explained also by any of these two mechanisms. The lamellar structure of the deposit, as well as the behavior of baths containing iron, cobalt, and nickel (17), suggests that the most probable mechanism may be that involving hydrolyzed nickel.

In the present work, the heat of formation of the chemically reduced nickel deposit was measured at 94°C, a temperature at which the deposition rate is high. For this temperature, however, heats of reaction cannot be calculated accurately on the basis of the tabulated values at 25°C, since the heat capacities of ions in aqueous media are not known. Therefore, it is necessary to measure the heats of reaction of the oxidation of hypophosphite to orthophosphite and of nickel to Ni^{2+} besides that of the over-all reaction of the chemical deposition of nickel.

In the three principal reactions investigated, hydrogen appears as a reaction product. Therefore measurements were carried out at constant volume and under practically adiabatic conditions to determine the energy content ΔE.

Experimental Procedure

Materials.—The purest sodium hypophosphite[2] was used. Its purity was determined by iodometry (20) and cerometry (21). The average of the two measurements showed that the reagent used was 100 ± 0.5% pure. The accuracy of the titrations was not sufficient to justify a correction, and therefore the hypophosphite was used without further purification, considering it as a 100% pure reagent.

The nickel used was carbonyl-nickel powder,[3] containing: C, 0.05-0.10%; O_2, 0.10%; S, <0.001%; Fe, <0.01%; Ni, balance. This reagent was used without further purification. In the calculations, the impurity proportion was neglected.

Deionized water was used to prepare the sodium hydroxide solutions and to measure the heats of dilution. Prior to use, it was purged for 1 hr at its boiling point with argon to remove traces of CO_2.

In those reactions where hydrogen evolution occurs, the solution was saturated with this gas before being introduced into the Dewar. By this method, the heat of solution of hydrogen did not have to be taken into account.

Other chemicals used were generally "pro analysi" grade.[4]

Apparatus and calorimetric measurements.—The temperature of the thermostat was maintained at 94°C with a relative variation of ±0.005°C. The thermostat was large enough to contain two calorimeters, so that it was possible to work either in a direct, or in a differential mode.

The principal element of the calorimeter shown in Fig. 1 is a Dewar vessel of 1 liter capacity, closed by means of a Teflon stopper, 60 mm thick. The seals were made gas-tight with Viton "O" rings.[6] Stirring was achieved with a glass paddle, turned magnetically at 250 rpm. The magnet was sealed in glass. The thermistors used had a resistance of about 6 kohms at 94°C (100 kohms at 20°C) and were matched to ±1%.[6] The 50-ohm heater was constructed out of Karma alloy[7] wire of 0.10 mm diameter and was insulated from the reaction medium by a glass tube in the form of a coil. Each end of the resistance wire was connected through a short piece of platinum wire, sealed in glass, to the copper leads. Thus, thermal leakage along the copper wires was minimized. The glass bulb containing the reagent was attached to the glass rod by a nylon or platinum wire. The

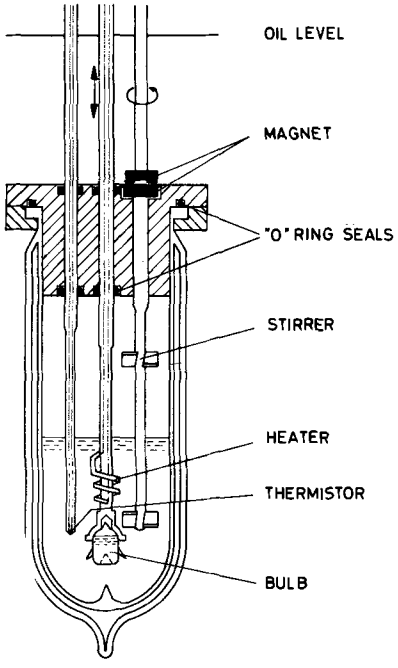

Fig. 1. Calorimeter

platinum wire was used in hydrochloric acid, the nylon wire in electrolytes for the deposition of electroless nickel and for oxidation of hypophosphite, since these reactions are catalyzed by metals.

The calorimeter was allowed to reach equilibrium in the thermostat overnight. The temperature inside the calorimeter was previously brought to the desired initial temperature by the internal heater. The initial temperature of each run was 94.00° ± 0.05°C. The glass bulb was broken by lowering the supporting rod to a glass protrusion welded to the bottom of the Dewar vessel. After the calorimeter had returned to its equilibrium temperature, one or two subsequent calibrations were performed by electrical heating over the same temperature interval. For the determination of the heat of reaction of the nickel deposition the working order was reversed. The calibration preceded the breaking of the bulb to minimize the time during which nickel and orthophosphite could be oxidized.

The temperature change during each experiment was measured by means of unit similar to that described by Nancollas and Hardy (22), consisting of an oscillator, bridge, amplifier, and synchronous detector. The two arms of the bridge included either a thermistor and a reference resistor if the temperature of one Dewar was measured against an external reference, or two thermistors, if the measurement was differential. An a-c bridge was used, and the signal amplified in the usual way, a sensitivity of 16 mV/0.001°C for 1V of the bridge voltage being obtained.

An electronic timer controlled the heating circuit, which was composed of a standard resistance[8] connected in series with the calorimeter heater. The circuit was supplied by a stabilized voltage. The electrical energy dissipated in the heater was determined by measuring the potential drop across the standard resistor and the calorimeter heater, using a digital voltmeter Solartron LM 1420.2.

The volume of liquid used was generally 500 cm³. For measurements of heats of dilution, the accurate volume was calculated on the basis of the weight of the reagent in the bulb to attain the desired dilution. Wherever possible, the proportion of reagents was chosen so as to have an increase of temperature of 0.2-0.3°C. In the measurements of the heat of dilution, the size of the calorimeter did not allow this condition to be realized; therefore, the accuracy of these determinations was less precise.

The calibration of the calorimeter is difficult, because, to our knowledge, no well-authenticated heats of reaction have been measured at 94°C. However, the heat of ionization of water at 25°C is well known (23), and the heat capacity of aqueous solutions of hydrochloric acid, sodium hydroxide, and sodium chloride, between 10° and 120°C, have been studied by Ackermann (24). From the values reported by these authors, the heat of neutralization at 367°K can be calculated to: $\Delta H°_{N(367°K)} = -10.15$ kcal/mole. The error in this value is certainly higher than 1%, because Ackermann extrapolated the heat capacities to infinite dilution from three measurements made at concentrations of 0.5, 1.0, and 2.0M. As is shown below (Table V and VIII), a value of $\Delta H_{(367°K)} = -10.08 \pm 0.05$ kcal/mole, was found within work, for a dilution of $n = 4000$ (n = mole ratio of water to solute), a value which is in good agreement with that calculated at infinite dilution from the data of the literature.

Results and Discussion

Oxidation of hypophosphite.—The oxidation of hypophosphite to orthophosphite and to phosphate is catalyzed by different metals. The data of the literature are limited to the reactions occurring at ambient temperature (25); therefore, the activities of several metals were studied at 94°C to choose the best catalyst for the oxidation of hypophosphite to orthophosphite which, at the same time, would not be too efficient for the oxidation to phosphate. The catalytic activity of Pd, Co, Ni, and Cu was studied in acid, neutral, and alkaline medium. In Table I, the amount of phosphate formed, expressed in per cent of the initial amount of hypophosphite, is reported for each catalyst at different *p*H values. The experiments were performed at constant pressure, with 100 mM hypophosphite in 2 liters of reaction medium. At time O, the catalyst is added, then, at regular time intervals, samples are removed to determine hypophosphite, orthophosphite, and phosphate concentrations. With the amount of catalyst used, all the hypophosphite was oxidized to orthophosphite after about 10 min. In Table I, only the amounts of phosphate formed as a function of the time of reaction are reported.

At *p*H lower than 6, the catalyst dissolves in the reaction medium. Calorimetric conditions were slightly different from those used in the preliminary experiments. The catalyst was added to the reaction medium,

then, after stabilization of the temperature overnight, the bulb containing the hypophosphite was broken. The temperature-time curve was plotted; after the calorimeter had returned to its equilibrium temperature, electrical calibration was carried out. The operation required between 5 and 7 hr, during which no sampling could be made. Results obtained are given in Table II. The approximate duration of the reaction indicates the time interval between the breaking of the bulb and the point at which the temperature, being at its maximum, begins to fall. For copper in alkaline medium, the very slow kinetics observed can be explained by the fact that the catalyst is oxidized and therefore loses its activity. This metal does not offer the best conditions for calorimetric measurements. The same is true of palladium, which catalyzes strongly the oxidation of orthophosphite to phosphate. Raney nickel in alkaline medium is the best catalyst for the oxidation to orthophosphite and the least for the oxidation of this compound to phosphate.

In this work electroless nickel plating in acid media is of interest. For the following reasons the reactions were carried out in alkaline solutions and from the results thus obtained values corresponding to acid media were calculated: (*a*) the amount of phosphate formed by oxidation of orthophosphite is much lower in alkaline than in neutral or acid medium; in fact this amount is low enough to be neglected; (*b*) the catalyst is not oxidized itself to any appreciable amount in alkaline medium, whereas it is in neutral or acid solution; (c) the reaction kinetics is more rapid in alkaline than in neutral or acid medium.

The amount of Raney nickel used was about 25 cm^3 of an aqueous suspension containing about 300 g/l of catalyst. This quantity allows the reaction to proceed to completion in about 10 min. The heat of adsorption of hydrogen on the Raney nickel catalyst was not taken into account. This is justified by the fact that at 94°C the amount of adsorbed hydrogen extrapolated from data measured at ambient temperature, 50° and 80°C (26), is negligible.

Calorimetric measurements were performed with initial concentrations of sodium hydroxide between 0.037 and 0.280*N*, corresponding to a *p*H $\geq$ 12 at the end of the reaction. At lower concentrations of hydroxide ions, the oxidation of orthophosphite to phosphate can no longer be neglected. For example, at a *p*H of about 10, the amount of phosphate formed after 5-7 hr at 94°C corresponds to about 17% of the initial amount of hypophosphite. On the other hand, at *p*H $\geq$ 12 only 0.6% of phosphate was formed during the same time. From this value one can deduce that for the time of the calorimetric measurements of the principal chemical reaction, which was about 30 min, only about 0.05% of hypophosphite was oxidized to phosphate. The initial concentrations of sodium hydroxide used corresponded to $NaOH \cdot 200H_2O$, $NaOH \cdot 750H_2O$, and $NaOH \cdot 1500H_2O$. Table III gives the results of these measurements. Heat values are expressed in defined thermochemical calories, 4.1840 absolute joules. The

errors cited in this table, as anywhere else in this study, are twice the standard deviations of the mean.

Measurements of the heat of reaction at dilutions of sodium hydroxide corresponding to $n = 200$, 750, and 1500 show that the variation of ΔE as a function of n is negligible. The mean of the three sets of measurements can be considered to a good approximation as practically identical with that corresponding to the reaction

$$NaH_2PO_2 \cdot 26H_2O + NaOH \cdot 4000H_2O = Na_2HPO_3 + H_2 + 4026H_2O$$

$$\Delta E_{367°K} = -29.02 \pm 0.11 \text{ kcal/mole} \quad [1]$$

The heat of dilution of sodium hypophosphite corresponds to the reaction

$$NaH_2PO_2 \cdot 26H_2O + 3974H_2O = NaH_2PO_2 \cdot 4000H_2O$$

$$\Delta H_{367°K} = -1.162 \pm 0.015 \text{ kcal/mole} \quad [2]$$

Results are reported in Table IV. By subtracting the heat of dilution of hypophosphite, reaction [2], from the heat of the reaction [1], we obtain

$$NaH_2PO_2 \cdot 4000H_2O + NaOH \cdot 4000H_2O = Na_2HPO_3 + H_2 + 8000H_2O$$

$$\Delta E_{367°K} = -27.86 \pm 0.13 \text{ kcal/mole} \quad [3]$$

and, by addition of ΔnRT, $\Delta H_{367°K} = -27.13 \pm 0.13$ kcal/mole, the heat content of the reaction at constant pressure.

Heat of neutralization of NaOH *by* HCl.—In order to calculate the heat of reaction of the oxidation of hypophosphite to orthophosphite in acid medium from its corresponding value in alkaline medium, the heat of neutralization of hydroxide ions by protons had to be determined. Moreover, this heat of neutralization serves to calibrate the calorimeter, since its heat of reaction is the only one known at 367°K.

Dilutions as above were used, that is $n = 4000$. The reaction corresponds to the equation

Table IV. Heat of dilution of hypophosphite

Run	$H_2PO_2^-$, mM	$q_{obs.}$, cal	$-\Delta H_{367°K}$, kcal/mole
1	6.909	7.869	1.139
2	7.133	8.254	1.157
3	7.046	8.359	1.186
4	6.847	7.990	1.167
5	6.818	7.926	1.162
		Average	1.162 ± 0.015

Table V. Heat of neutralization of NaOH by HCl

Run	HCl 0.996N, mM	$q_{obs.}$, cal	$-\Delta H_{367°K}$, kcal/mole
1	3.389	36.47	10.76
2	3.631	38.82	10.69
3	3.497	37.42	10.70
4	3.492	37.63	10.78
5	3.514	37.60	10.70
6	3.499	37.71	10.70
		Average	10.74 ± 0.04

$$HCl \cdot 55H_2O + 2(NaOH \cdot 4000H_2O) = NaCl + NaOH + 8056H_2O$$
$$\Delta H_{367°K} = -10.74 \pm 0.04 \text{ kcal/mole} \quad [4]$$

Experimental results are reported in Table V. The heat of dilution of 0.996N hydrochloric acid was also measured (Table VIII); it corresponds to the reaction

$$HCl \cdot 55H_2O + 3945H_2O = HCl \cdot 4000H_2O$$
$$\Delta H_{367°K} = -0.663 \pm 0.004 \text{ kcal/mole} \quad [5]$$

Therefore, by subtracting reaction [5] from reaction [4]

$$HCl \cdot 4000H_2O + 2(NaOH \cdot 4000H_2O) = NaCl + NaOH + 12001H_2O$$
$$\Delta H_{367°K} = -10.08 \pm 0.05 \text{ kcal/mole} \quad [6]$$

Finally, the oxidation of hypophosphite to orthophosphite in acid medium follows by subtracting reaction [6] from reaction [3]. This may be expressed in ionic form as

$$H_2PO_2^- \cdot 4000H_2O + H_2O = HPO_3^{2-} + H_2 + H^+ + 4000H_2O$$
$$\Delta H_{367°K} = -17.05 \pm 0.18 \text{ kcal/mole} \quad [7]$$

Oxidation of nickel.—The oxidation of carbonyl-nickel powder was carried out in hydrochloric acid because hydrogen is evolved from it quantitatively (27). The reaction was performed without an accelerator (chloroplatinous acid) which would cause a side reaction (28), whose energy is not known at 94°C. Heats of solution of nickel as a function of the concentration of hydrochloric acid are reported in Table VI. For an acid concentration lower than 1N, the reaction is too slow (1 hr at 0.5N) to allow an accurate calorimetric measurement. The heat of wetting of nickel plus the heat of vaporization of water into the internal bulb volume is positive and equal to 0.43 ± 0.05 cal. The measurement was made with 14 mM nickel in 500 cm³ water. The heats observed, q_{obs}, reported in Table VI are corrected by this value.

The heats of reaction of the oxidation of nickel are of interest at pH values between 4 and 6, since chemical nickel plating occurs within these limits. Although the dilution of protons is then very large, a dilution of $n = 4000$ is adopted as before. In order to refer the values measured at acid concentrations of 1-8N ($n = 55$ to 6), to a value of $n = 4000$, it is necessary to consider the following set of reactions, as Richards *et al.* (28-30) showed.

The heat of the reaction corresponding to the equation

$$a\,Ni + b\,(HCl \cdot cH_2O) = a\,H_2 + [a\,NiCl_2 + (b - 2a)HCl + bc\,H_2O] + q' \text{ cal} \quad [8]$$

Table VI. Heats of reaction for the oxidation of nickel in hydrochloric acid

was measured. On dividing by a in order to find the amount of heat evolved by the solution of 1 mole of nickel

$$Ni + b/a\,(HCl \cdot cH_2O) = H_2 + \left[NiCl_2 + \left(\frac{b}{2a} \Big/ a\right) HCl + bc/a\,H_2O \right] + q \text{ cal} \quad [9]$$

The following additional reactions are necessary in order to reduce the result to the reaction required

$$b/a\,(HCl \cdot cH_2O) + (4000b/a - bc/a)H_2O = b/a\,(HCl \cdot 4000H_2O) + x \text{ cal} \quad [10]$$

$$[NiCl_2 + ((b - 2a)/a)HCl + bc/a\,H_2O] + (4000b/a - bc/a)\,H_2O = \left[NiCl_2 + \left(\frac{b}{2a} \Big/ a\right) HCl + (4000b/a)H_2O \right] + y \text{ cal} \quad [11]$$

$$NiCl_2 \cdot 8000H_2O + \left[\left(\frac{b}{2a} \Big/ a\right)(HCl \cdot 4000H_2O)\right] = \left[NiCl_2 + \left(\frac{b}{2a} \Big/ a\right) HCl + (4000b/a)H_2O \right] + z \text{ cal} \quad [12]$$

From these reactions, by elimination or cancellation, the desired result is

$$Ni + 2(HCl \cdot 4000H_2O) = H_2 + NiCl_2 \cdot 8000H_2O + [q + (y - x) - z] = Q \text{ cal} \quad [13]$$

Table VII gives values of coefficients and energies corresponding to the various dilutions for several hydrochloric acid concentrations. Values of q and y are taken from Table VI and IX. The value x is extrapolated at the concentrations of acid used, from the heats

of dilution reported in Table VIII, and multiplied by the ratio b/a.

The fact that the quantity $(y - x)$ is a difference of similar quantities obtained in precisely the same way increases the ease of determining it accurately. Any systematic errors in x would also appear in y and hence, would be eliminated from the result $(y - x)$. This is also the case in the other principal measurements of this work, since the heat of dilution of the reagent is subtracted from the heats of reaction of the oxidation of hypophosphite and of the neutralization of NaOH by HCl.

The value a being practically the same for all the acid concentrations, the term b/a increases strongly with concentration. Hence, as the apparatus limited the volume to 500 cm^3 and the same dilution had to be maintained, the measurements of the heat of dilution for HCl 4.027 and 7.350N are less precise than those obtained at lower concentrations. At high acid concentrations, the error of the measurement reaches approximately the same value as the difference $(y - x)$; it is for that reason that only the heats of dilution of HCl 1.005 and 2.030N were measured. The experimental results are reported in Table VIII regarding the heats of dilution of hydrochloric acid (reaction [10]), and in Table IX concerning the heat of dilution of the residual solutions (reaction [11]).

The heat of reaction [12] was measured by Richards *et al.* (29) at a dilution of 200, that is to say for the mixture $(1/n\ MCl_n) \cdot 200H_2O$ in an excess of $HCl \cdot 200H_2O$, at 20°C. For the chlorides of Zn, Al, Mg, Cd, and Fe, this heat of mixing is zero. Therefore it can be expected that this energy is also zero or negligible for nickel chloride at a dilution of 4000 and at 94°C. Several measurements of the heat of mixing of $NiCl_2 \cdot 8000H_2O$ in an excess of $HCl \cdot 4000H_2O$ showed that this energy can be considered as being negligibly small.

Finally, for reaction [13], the mean value of the heats of reaction obtained at acid concentrations of 1 and 2N (Table VII), is

$$\Delta E_{367°K} = -17.67 \pm 1.58 \text{ kcal/mole},$$
$$\text{whence } \Delta H_{367°K} = -16.94 \pm 1.58 \text{ kcal/mole}$$

Chemical deposition of nickel.—An acid bath of the following composition was used: $NiCl_2 \cdot 6H_2O$, 30 g/l; $CH_2(OH)COOH$, 30 g/l; $COOH(CH_2)_2COOH$, 10 g/l; NaF, 3 g/l; NaOH to adjust to the desired *p*H. The reducing agent was sodium hypophosphite. Deionized water used for the bath preparation was purged at its boiling point with argon to remove traces of CO_2.

The deposition was performed on seeds of nickel, previously plated chemically to palladium. For each *p*H value of the bath studied, seeds were prepared in an identical solution as follows: 35 cm^3 $PdCl_2$ M/1000 were introduced for each liter of this solution, which was 0.1M in sodium hypophosphite, at 94°C. After about 10 min, the solution was filtered and the seeds of palladium, coated with nickel, were washed and dried at about 100°C. For use in the actual deposition study, these seeds were introduced into the bulb of the calorimeter, which was subsequently broken when the calorimeter temperature reached equilibrium. This method was preferred to the use of a suspension of nickel seeds placed directly in the bath or in the bulb since it avoided partial dissolution of nickel before the run commenced.

The weight of seeds needed for each run to proceed to completion in about 30 min at constant volume was about 1g. This amount was small enough relative to the deposited nickel and phosphorus to determine these quantities with accuracy. At constant pressure, 0.2g were sufficient for the reaction to occur in less than 15 min. The influence of pressure on the electroless deposition process can explain the difference of about one order of magnitude between the amount of catalyst needed to take the reaction to completion in a given time at constant pressure or volume. Sallo, Swenson, and Carr (31) studied this effect and showed that the rate of nickel deposition, from a bath containing little buffer and no complexing agent, decreases with increasing pressure. The reverse is true for the same bath when subjected to ultrasonic vibrations. For a highly buffered bath containing a complexant, the rate of nickel deposition increases with the pressure. Sallo *et al.* concluded that the deposition rate from the former bath is controlled by a diffusion process whereas for the latter the area of hydrogen-free catalytic surface is rate controlling. The effect of pressure is attributed to the influence of the size of hydrogen bubbles formed at the active areas. According to the findings of Sallo *et al.*, it is very likely that the bath used in this study could be controlled by a transport process since the rate of nickel deposition decreases with increasing pressure. On the other hand, one may anticipate the behavior of the bath from Le Chatelier's principle, regarding the reactions which occur during the electroless process (Table XI).

In the experiments described here, the solid area being very large with regard to the plating bath volume, the oxidation of nickel and orthophosphite can occur to a considerable extent. In order to minimize these side reactions, the time during which they could occur must be kept as short as possible. Therefore the usual order of the calorimetric manipulations was inverted; the electrical calibration preceded the measurement of the heat of reaction. After breaking the bulb, the reaction was allowed to continue until the temperature, being at its maximum, began to fall. This generally required between 20 and 40 min. The reaction was then stopped as quickly as possible by quenching, after removal of the calorimeter. The deposit was filtered, washed with water, and dried at about 100°C. The amount of electroless nickel deposited was found from the difference between the initial weight of the seeds and the weight after plating. The phosphorus content of the deposit was deduced analytically in the same way.

The determination of residual hypophosphite in the filtrate of the bath after reaction showed that, in the experimental conditions of this study, 95-97% of the reducing agent was consumed in the experiment. The

* Filtrate from seed preparation used as plating bath.

amount of phosphate in the filtrate being lower than 1% of that of the hypophosphite consumed at $pH \geq 5$ and lower than 2% at $pH \leq 4.5$, this amount has not been taken into account in the energy balance. The orthophosphite concentration of the filtrate was also determined in order to check the material balance concerning phosphorus compounds. In all runs, the hypophosphite consumed corresponded, within experimental error, to the sum: orthophosphite + phosphorus + phosphate.

The calorimetric results of the heat of reaction of electroless nickel deposition are summarized in Table X, which also includes corresponding analytical data. The heats of reaction are referred to the amount of hypophosphite consumed.

For the reaction mechanisms proposed, the total heats of reaction were calculated from the partial heats of reaction stated in Table XI. This table also summarizes the proposed stoichiometries. The experimental results obtained in this work for the heat of oxidation of hypophosphite and nickel, as well as for the heat of ionization of water, were used, through Hess' law, to calculate the heat of deposition of electroless nickel. In Table XI, the electrochemical mechanism is not reported. The stoichiometry of this mechanism is, indeed, the same as that of the atomic hydrogen mechanism given in this table; therefore, values calculated for the second mechanism also are valid for the first one.

Heats of reaction for the deposition of phosphorus indicated in Table XI are estimated on the basis of the most recent data of the literature, which are collected in Table XII. When the heat capacities are known, one can calculate the term $\int_{298°K}^{367°K} C_P dT$, and hence the enthalpy at 367°K. When the heat capacities are not known, one can assume that, to a first approximation, the sum of $\Delta C_P dT$ is zero in the temperature interval considered, that is to say that, for the calculation of the heats of deposition of phosphorus at 367°K, the enthalpies of these substances at 298°K have been used. The error resulting from this approximation is negligible. It might be said, in this context, that some values of enthalpy vary considerably from one author to the other. For example, for orthophosphoric acid H_3PO_3 (aq), the most recent value from NBS tables (32) is $H°_f = -230.6$ kcal/mole, whereas Skinner (33) proposes -226.5 ± 0.8 kcal/mole. In this work, NBS values were adopted, where available.

In the total heat of reaction of the electroless nickel deposition, previous experimental result has been taken into account (1), *i.e.*, that the phosphorus is included in the as-plated deposit as nickel phosphide, Ni_2P, and not as elementary phosphorus. Then, the heat of formation of phosphorus is added to that corresponding to the formation of Ni_2P. For this latter energy, the tabulated value was used (34). Results from DTA (2), for samples containing less than 10% phosphorus, confirm that value, while for samples with more than 10% phosphorus, the adopted value for the heat of formation of Ni_2P would be a little too low. If the experimental heat of reaction corresponds to the calculated one, by taking into account the heat of formation of Ni_2P, this will give supplementary evidence of the existence of a Ni_2P phase in as-plated alloy.

Results of Table X need some comment. The plating bath was studied at several *p*H values, as was the case for the analytical study (18). For values of $pH \leq 4.5$, the behavior of the bath does not correspond to that observed in the previous study, *i.e.*, the phosphorus content is irregular, often higher than that expected, which could mean that, in the present experimental conditions, nickel is dissolved at a relatively high rate. This consideration led to the use of a bath, which was the filtrate of the bath used for the preparation of seeds after readjustment of its *p*H and its Ni^{2+} concentrations. At *p*H 5.0, depositions were carried out in the fresh bath and in that already used. Results show that, at this *p*H, the behavior of these two baths is the same.

The error for the calculated heats of reaction, given in Table X, is the proportion of the errors corresponding to the partial reactions indicated in Table XI. One has to add to it about ±0.1 kcal/mole, to take into account the errors in the analytical determinations of nickel, phosphorus, and hypophosphite. The experimental error is not reported in Table X; it is estimated, on the basis of other measurements of the heats of reaction, to be ±0.2 kcal/mole. The heat of wetting of seeds, as well as the heat of vaporization of water in the bulb volume, is negligible. Heats of oxidation of nickel and hypophosphite are given for a dilution of $n = 4000$. In order to refer the heats of reaction of electroless nickel deposition to this dilution, the heats of dilution of the bath before and after the reaction were measured. The difference between these two determinations is of the order of the limit of error of

the measurement, that is to say about ±0.1 kcal/mole. This contribution to the heat of reaction of the electroless nickel deposition will be neglected.

All experimental results obtained for the heat of reaction of electroless nickel deposition, from pH values of 5.8 to 4.0, correspond, within the limits of error reported in Table X, to the heats of reaction calculated on the basis of the reaction mechanisms proposed. The difference between the observed heat and that calculated, as well as the contribution of the heat of formation of Ni_2P to the total heat of reaction, is reported in Table X. One can see that, for the experiments carried out at high pH values, the contribution of the heat of formation of Ni_2P to the total heat of reaction is of the order of the experimental error. By contrast, for runs 11-24, the contribution of the heat of formation of Ni_2P is clearly greater than this error. If the energy had not been included in the calculation of the total heat of reaction, the experimental heat of reaction would be about 2 kcal/mole $H_2PO_2^-$ more exothermic than the calculated value for runs 11-24. This represents about 15% of the evolved energy for runs 11-15. Therefore, this study is a further confirmation of the existence of Ni_2P in as-plated deposit.

Finally, one can remark that, in practice, when the reaction is performed at constant pressure, the positive heat of vaporization induced by the hydrogen evolution largely counter balances the exothermic heat of reaction of the electroless nickel deposition. Thus, the total phenomenon is endothermic.

Conclusions

Heats of oxidation of hypophosphite to orthophosphite and of nickel to Ni^{2+} were measured at 94°C. They are, respectively, $\Delta H_{367°K} = -17.1 \pm 0.2$ and -16.9 ± 1.6 kcal/mole, at a dilution of $n = 4000$. From the literature data at 25°C given in Table XII, values of $\Delta H°_{298°K} = -16.6$ kcal/mole for the oxidation of hypophosphite and $\Delta H°_{298°K} = -15.3$ kcal/mole for the oxidation of nickel were obtained. The heat of neutralization of NaOH by HCl measured at a dilution of $n = 4000$ is $\Delta H_{367°K} = -10.08 \pm 0.05$ kcal/mole, while the value calculated from (23) and (24) is $\Delta H_{N(367°K)} = -10.15$ kcal/mole.

The energy balance of the over-all system can be established only when the heat of formation of Ni_2P is included in the calculation of the total heat of reaction. This being so, all experimental results obtained for the heat of reaction of electroless nickel deposition, from pH values of 5.8-4.0, correspond to the calculated heats of reaction. From the results of this study, the energy balance of the over-all system can be established. The study of the deposit showed (1, 2) that it contains a nickel phase and a nickel phosphide, Ni_2P, phase. The DTA of as-plated deposits revealed that the energy evolved during heating corresponds approximately to the heat of formation of Ni_3P from Ni_2P. Therefore, the heat of formation of Ni_2P must be contained in the heat of reaction of the electroless nickel deposition in aqueous media. This is precisely the result of this study, since the calculated value of the heat of reaction of electroless nickel deposition, which includes the heat of formation of Ni_2P corresponds within the limits of error to that experimentally obtained. This result constitutes additional evidence for the presence of a nickel phosphide phase in as-plated deposits.

Several authors (39, 40, 41), studying other alloys than NiP, suggested that the principal condition for the formation of "cryptocrystalline" structure is the occurrence of a chemical reaction in the crystallization zone. Solid products of such surface reactions interfere with the normal growth of the crystallite and, therefore, induce the formation of a liquid-like structure. In the electroless nickel deposition, the origin of the liquid-like state of the deposit therefore can be explained in the same way, since the codeposited

Anion Effects in Copper Deposition

David W. Hardesty*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

Preliminary investigation has demonstrated that surface morphology of epitaxial copper electrodeposits is influenced by the anion of the electrolyte. Effects due to the use of sulfate, sulfamate, dimethylsulfamate, methane-sulfonate, benzene-sulfonate, perchlorate, fluoborate, nitrate, chloride, and acetate anions were studied. Observed changes in surface structural details are consistent with adsorption of the anion on the cathode as an important influencing factor, but other factors can and do produce similar results.

It has been observed that iron and chromium can be deposited epitaxially only from singular electrolytes using particular deposition conditions. Iron is so deposited from ferrous chloride electrolyte (1) and chromium from a fluoride "catalyzed" chromic acid solution (2) at temperatures above 80°C. From other electrolytes, deposits of both metals become coarse grained with well-developed preferred orientation. In addition, internal stress decreases as bath temperature is increased. Surface morphology of the plane-facetted epitaxed deposits of iron and chromium is similar in so many respects to that of copper deposits, which have been studied intensively (3-10), that deposition under control of a "bunching mechanism" was concluded to have occurred. It has been shown previously that with similarly specific operating conditions, nickel, cobalt, lead, and zinc (11, 12) are deposited epitaxially with morphologies characteristic of growth by bunching.

The cited work has largely been concerned with deposits from sulfate electrolytes. Limited comparisons with copper deposited from perchlorate and nitrate electrolytes (13, 14) indicated that the habit, or characteristic morphology, developed was correlated with overvoltage during deposition. Very similar habit development was observed in deposits from copper sulfamate solutions, but significant detail differences are observable in illustrative photomicrographs (15).

In the course of an investigation (16) of mechanisms and kinetics of copper deposition from several electrolytes, results obtained were interpreted as indicative of blocking of deposition sites by specific adsorption of anions as one of several factors which influence growth of electrodeposits. In view of the role of adsorbable additives in practical plating processes (17), it is reasonable to expect that such specific adsorption, the effect of which varies with anion size, can result in modifications of the external form and internal structure of electrodeposits.

Since the structure and morphology of iron and chromium are so specifically dependent on the anion used in the electrolyte, the effects of anions of different sizes on the characteristic habit of epitaxial copper deposits were examined. Deposits from acidic copper electrolytes were prepared and their surface forms compared to those obtained from the well-studied sulfate electrolytes.

Experimental

Solutions.—With three exceptions, all solutions contained 0.5M cupric salt and 0.5M excess or free acid. In all cases, the solution was prepared by dissolution of the constituent compounds in distilled water, followed by agitation with 2 g/l activated carbon and filtration after settling overnight. When not in use, the solutions were stored in glass bottles and were filtered before use after storage.

Sulfate, nitrate, chloride, and acetate solutions were prepared from reagent grade salts and acids. Due to limited solubility of cupric acetate, copper concentration was only 0.05M and total cation concentration was adjusted to 0.5M by addition of sodium acetate. Dilute sulfate solutions containing 0.05M $CuSO_4$, 0.45M Na_2SO_4 or $MgSO_4$, and 0.5M H_2SO_4 were also prepared.

Sulfamate (amidosulfonate), citrate, perchlorate, methane-sulfonate, and benzene-sulfonate electrolytes were prepared by slowly adding dissolved acid to a vigorously stirred slurry of reagent grade (assay 55.5% Cu) copper carbonate until effervescence ceased, at which time the remainder of the acid was added. No difficulty was encountered except that solubility limited the benzene-sulfonate solution to 0.35M in the copper salt and free acid.

Dimethyl-sulfamate solution was made with acid prepared by hydrolysis of N,N-dimethylsulfamoyl chloride (18). The twice-recrystallized acid melted at 165°-170°C after washing with ether. Since this acid contained traces of chloride, it was dissolved in water, stirred with a small quantity of AgO, allowed to settle overnight, and filtered. Excess silver was removed by cementation on a spiral of clean copper wire. Chloride ion was not detected by the Bunsen test after this treatment. The copper dimethyl-sulfamate electrolyte was then prepared.

In all cases, deposition at room temperature (25° ± 1°C) was carried out in 500 ml volumes of electrolyte in 600 ml Pyrex beakers. Mild agitation, by a Teflon-coated stirring magnet was held nearly constant by adjusting the stirrer speed to just below that where a visible vortex formed.

Under these conditions of stirring, the apparent limiting current density in the copper sulfate electrolyte was above 100 mA/cm². Without mechanical agitation, the apparent limiting current density was about 10 mA/cm². Above these values, the deposits rapidly became polycrystalline and tended to be powdery or dendritic.

The same anode (2.5 x 8.0 x 0.6 cm) of high-conductivity copper was used throughout. Before placing the anode in any electrolyte, it was cleaned by immersion in 25% (by volume) nitric acid and thoroughly rinsed in distilled water.

Some polarization measurements were made using a copper reference electrode in a Luggin-Haber capillary, positioned at the edge of the cathode. Cathode-to-reference electrode potentials were measured with a high impedance electrometer[1] and recorded, together with the current used, on a two-channel recorder.[2] The potential measurement and recording apparatus were standardized using a laboratory potentiometer.[3]

Electrodes.—After etching in nitric acid, the reference electrodes were prepared by plating (on 20-gauge copper wire) from the studied electrolyte for 2 min at low current density (anode-wire voltage of 10-15 mV).

Current (maintained constant manually to within 0.5 mA) was obtained from a 100-ohm voltage divider across the terminals of a 1.5V dry cell. Current density was usually between 5 and 10 mA/cm^2, and deposit thickness was constant at 15 μm on the copper substrates, areas of 1.0-2.0 cm^2, cut from large-grained, oxygen-free, cast copper anodes and mounted in 3.2-cm diameter epoxy resin[4] castings. These were prepared initially by metallographic grinding and polishing. The disturbed surface layer was removed using a procedure described by Epelboin (19) which consists of a two-step chemical polish followed by electropolishing. Complete removal of the abrasively distorted surface layer is revealed by disappearance of "lines" from the bright copper surface in the second step of the chemical polishing stage. Later, it was found that a flatter surface could be obtained by manual polishing of the cathodes on nonwoven polypropylene cloth[5] (stretched over a plate glass surface) moistened with the second-step chemical polishing solution, then electropolished for 5 min at 1.4-1.8V in 60% phosphoric acid. After examination, deposits were removed by grinding, and the cathodes were repolished before plating again. The columnar structure of the 1-cm thick samples permitted repeated grinding and polishing without requiring redetermination of orientations of individual grains since these are readily recognizable and relocated without undue difficulty. The grains of interest are those with surfaces close (within 10°) to {100} orientations as determined from back reflection Laué photographs. On these grains, the platelet habit found by Pick *et al.* (3) of deposits plated at 10 mA/cm^2 from the sulfate electrolyte provided a convenient, readily reproducible criterion for selection of suitable grains for study.

Microscopy.—Examination of the surfaces of deposits was done on a bench metallograph equipped with a camera.[6] Facet angles were measured, as appropriate, with a microgoniometer.[7] On facets nearly parallel to the surface, interference microscopy could provide limited information on facet contours.

Results

Deposits from the acetate and chloride electrolytes were unsatisfactory, although interesting. In both baths, the initial deposit appeared to be normal, but in a few seconds became rough and powdery in appearance. The acetate electrolyte changed from its original copper blue color to a brilliant, deep blue (comparable to a cobalt blue) and the deposit, under the microscope, was found to consist of extremely small particles, apparently agglomerated into balls. The chloride electrolyte changed from blue to a grass-green and, on standing, became milky with a suspension of finely divided solids. The deposit from this electrolyte was found to consist of octahedral particles, some of which were elongated into blunt needle-like shapes.

The deposits from sulfate, dilute sulfate, perchlorate, and fluoborate electrolytes, at the same current densities, were indistinguishable from each other and compared quite well in appearance with those of Pick *et al.* (3). The deposit from the sulfate electrolyte, in Fig. 1, is typical. The dark material at some of the steps is the first polycrystalline deposit appearing after plating for an hour at 10 mA/cm^2. The apparently planar surfaces actually have slight, irregular curvature which can be seen only by use of the interference microscope. At current densities below 10 mA/cm^2, the pyramidal habit to be seen in Fig. 2a (plated at 5 mA/cm^2 for 2 hr) predominates. This form appears at first glance to be octahedral but is, in fact, non-

planar. Figure 2b shows a corresponding deposit from the fluoborate bath.

Deposits from sulfamate, dimethyl-sulfamate, methane-sulfonate, and benzene-sulfonate baths have forms which, though similar in over-all shapes to deposits from the sulfate electrolyte, appear to be more complex. This is particularly noticeable in the pyramidal forms produced at 5 mA/cm^2, illustrated in Fig. 2c and d. These pyramidal forms and the less prominent, ridged forms show distinct and regular steps. These steps are edges of {100} surfaces and are parallel to <100> directions. In deposits from methane-sulfonate and benzene-sulfonate electrolytes, these forms are much more irregular and, although recognizable, have very different characteristics. In these deposits, pyramids tend to be rounded and steps are very fine and irregular in shape, as illustrated in Fig. 2e.

In deposition from the sulfamate electrolyte over extended periods, it was found that octahedral tipped, branchless "dendrites" grew from the edges of the cathodes, as observed by Kikuchi (20). Also, an acicular precipitate appeared in this electrolyte. When filtered out of the solution, no more of this precipitate appeared until deposition was attempted. The precipi-

tate dissolved readily in dilute (10%) nitric acid to give an initially pale green solution which turned blue in a short time. A comparable precipitate, formed in the methane-sulfonate electrolyte, behaved similarly when dissolved in nitric acid.

Since, in strongly acid solutions (pH <3), sulfamate ion hydrolyzes rapidly to ammonium bisulfate, a sulfate electrolyte containing 0.25M NH_4HSO_4 was prepared. The deposit obtained (Fig. 3) was quite similar in appearance to that from the sulfamate solution. When periodic reverse current (45 sec direct, 15 sec reverse) was used to prepare a deposit from sulfate electrolyte, the appearance was also very similar to a sulfamate deposit as illustrated in Fig. 4a. The effect of periodic reverse current is not very reproducible since another trial yielded the deposit shown in Fig. 4b.

In Fig. 5, the deposit from a citrate electrolyte is seen to consist of isolated or clustered nodules on grain surfaces with grain boundaries shown by lines of larger globular nodules. The current density was initially 5 mA/cm^2 but rapidly decreased to less than 1 mA/cm^2 and could not be restored to the original value by raising the applied voltage.

Overvoltages measured during deposition from sulfate, sulfamate, methane-sulfonate, and benzene-sulfonate solutions were not appreciably different. In all these electrolytes, the final overvoltage was 80-90 mV at 5 mA/cm^2, but in the sulfamate and methane-sulfonate baths, the initial overvoltage was about 50 mV and rose steadily over 20-30 min to the final value.

Discussion

The most important result of this work is that, for solutions of nominally comparable compositions, the surface morphology, or habit, of copper deposits is rather radically affected by the anion present. Bockris and Enyo (16) had found anion effects in their work, but since their investigation was oriented toward study of kinetics and mechanism of deposition, it was not feasible to examine the deposits. It was suggested that the results obtained were consistent with specific adsorption of anions on the copper cathode and that the potential of zero charge for copper is such that this adsorption will occur. It was further suggested that the differences in observed double layer capacities in sulfate or perchlorate and sulfamate electrolytes were

attributable to differences in polarizability, due to differences in the sizes of these ions.

In the work reported here, the results show that deposits from sulfate, perchlorate, and fluoborate have so many surface characteristics in common as to indicate the anions also must have important characteristics in common. The most probable factor is their "shape." All of these ions are regular tetrahedra, with the oxygen atoms in sulfate and perchlorate, and fluorine in fluoborate, equidistant from the central sulfur, chlorine, or boron atom, respectively. These ions are very nearly the same size and have many other similarities (idiomorphic salts, solubilities of salts, dissociation, etc.) (21). Thus, it can be concluded logically that, if specifically adsorbed on copper cathodes, these ions should have similar effects on surface structures.

It appears that changing from sulfate to the sulfamate electrolyte resulted in modifications of the bunching of layers. While the over-all or gross habit remains similar to that of sulfate deposits, details of surface topographies of deposits from the sulfamate and dimethyl-sulfamate electrolytes indicate that uniform steps are formed during growth. It seems reasonable to postulate that the replacement of an oxygen atom in sulfate ion by the amido group (NH_2^-) thus significantly altered the shape or structure of the anion. If, by this substitution, the adsorptive characteristics are enhanced, which is indicated by the double layer capacity of copper in sulfamate solution (16), it is conceivable that step heights could be modified accordingly. The structure of the sulfamate ion is a distorted tetrahedron in which the S-O distances and N-S-O bond angles are smaller than corresponding values in the sulfate ion, presumably due to the electron-deficient NH_2 group (21). Thus, there is reason to believe that this ion has different polarizability and adsorptive behavior than the regular, symmetrical sulfate ion. Replacement of the hydrogen atoms on the amido group by methyl groups to form the dimethyl-sulfamate ion enlarges this ion, and symmetry is even less regular. Distribution of electrons in this ion is a matter of speculation, but its size is such that it could serve, if adsorbed, to block several sites for deposition of copper atoms and thereby account for larger and more uniform step heights. However, addition of ammonium bisulfate to a copper sul-

fate solution produces the same morphological effects observed in sulfamate deposits. In strongly acid solutions (pH <3), sulfamic acid hydrolyzes rapidly to form ammonium and sulfate ions (23, 24). The formation of uniform steps may be due to the presence of the ammonium ion in the sulfamate electrolyte. Presumably, dimethyl-sulfamate ion is subject to similar hydrolytic decomposition [to $(CH_3)_2NH_2^+$?], and the steps observed in these deposits result.

Presence of extraneous or specially structured ions in the electrolyte is not necessary to develop uniformly stepped pyramids or ridges, however, since periodic reverse current (see Fig. 4a) can also produce this result, but not consistently as evidenced by the deposit illustrated in Fig. 4b.

The rather diffuse layering seen in Fig. 2e in deposits from methane-sulfonate solutions, and the even more irregular topography of deposits from benzene-sulfonate electrolyte, do indicate that changes in structure and symmetry of the sulfate ion do affect the surface structure of epitaxial copper deposits. Since overvoltages are not very different from those during depositon from sulfate solution, the effects can be attributed reasonably to differences in adsorption at the cathode.

Another influence which may be operative is the possible effect of ion pairing between the divalent cupric ion and the monovalent sulfamates and sulfonates. In these solutions, the excess acid present may favor the formation of ion pairs such as $[Cu^{++} \cdot CH_3SO_3^-]^+$. Yet another factor which should be considered is the "hydration sheath" of loosely held water molecules which surround ions in solution. The binding forces in these sheaths may also be important in determining the detailed morphological structuring of deposits.

The identical surface morphologies of deposits from the dilute sulfate electrolyte and from the more concentrated solution are of interest. This indicates that it may be feasible to plate copper from these more dilute solutions without impairment of the quality of the deposit. Further, it also shows that the deposition process is essentially independent of cupric ion concentrations, possibly because activity (effective ion concentration) in the more concentrated solutions is not very different from that in the dilute solution.

The behavior of the citrate electrolyte is puzzling. Copper forms complexes with citrate only at relatively high alkalinity. The shape of the small amount of nodules suggests that an inhibiting film formed as the copper was deposited from a complex which may have developed in the high pH cathode film.

The changes which occurred in the acetate and chloride electrolytes may also be due to complexation with the copper species in the electrolyte. Involved could be effects of pH changes in the electrolyte at the electrodes, formation and stability of cupric and cuprous ion complexes, and even more complicated reactions. Proposals of explanations would require investigation of reaction and electrode kinetics, an interesting and difficult exercise obviously outside the scope of this work.

The results obtained in this work are of value, primarily, because several fundamentally interesting problems appear to be involved. Exploration of these may be expected to contribute to improved understanding of electrodeposition processes, provided suitable experimental techniques can be devised. For example, Reddy (25) has analyzed the relationships between electrode kinetics and morphology and pointed out that they are interdependent, thereby furnishing another avenue of attack on the problem.

Electrolytic Reductive Coupling

XVIII.[1] Hydrodimerization of Activated Olefin A *vs.* Cross-Coupling with Activated Olefin B as a Function of Cathode Voltage

Manuel M. Baizer,* John P. Petrovich, and Donald A. Tyssee

Central Research Department, Monsanto Company, St. Louis, Missouri

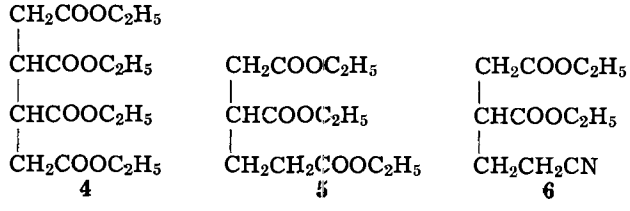
ABSTRACT

It is shown that in mixed reductive coupling of activated olefins A and B, in which A is reduced at the more anodic voltage, the ratio of cross-coupled product HABH to self-coupled product HAAH rises substantially as the controlled potential is made more negative. Diethyl maleate (DEM) was chosen as an example of A and ethyl acrylate (EA) and acrylonitrile (AN) as examples of B. Previously reported fluctuations of voltage along the cathode surface are confirmed and may lead to unexpected formation of HBBH. The results of cyclic voltammetry of DEM in the presence of EA or AN and of a kinetic study of the addition of a carbanion to these same acceptors in bulk are interpreted to indicate that the reductive coupling of DEM with the acceptors occurs largely but not exclusively at the electrode surface.

Among the synthetic advantages amply illustrated for electrolytic reductions at extrinsically controlled potentials are: (*a*) selective reduction of only one of two potentially electroreducible groups in one molecule, as in 9-(*o*-iodophenyl) acridine (2); (*b*) reduction of a molecule to one of two possible major end-products, *e.g.*, a ketone to an alcohol or to a pinacol (3); (c) mixed reductive coupling (4) between activated olefins A and B, in which A is reduced more anodically than B, to yield 1 and 2 without 3 [1]

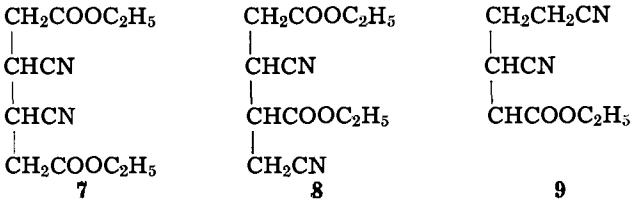
$$A + B \xrightarrow[H_2O]{F} \underset{1}{HA\text{-}AH} + \underset{2}{HA\text{-}B\text{-}H} + \underset{3}{HB\text{-}B\text{-}H} \quad [1]$$

The present paper reports an apparently new phenomenon associated with electrode potential control. In [1] when diethyl maleate (DEM) is an example of A and ethyl acrylate (EA) and acrylonitrile (AN) are examples of B, the ratio of cross-coupled products (**5** or **6**) to hydrodimer (**4**) can be



made to vary considerably depending upon the cathode voltage used; **5** or **6**/**1** increases as the cathode voltage increases (negatively) toward the value needed for reduction of B. By judicious choice of voltage one may, therefore, maximize the yield of **2** or, alternatively, reduce A to **1** even in the presence of B (which might be an impurity) without forming significant quantities of **2**.

It has been reported previously (1) that, when A is *trans*-ethyl-3-cyanoacrylate and B is acrylonitrile, electrolysis of a mixture of A and B leads overwhelmingly to **7** (with a small amount of the isomeric hydrodimer **8**) and to only a trace of the cross-coupled product **9**.



It is shown now that even here the ratio **9**/**7** + **8** increases dramatically as the cathode voltage is made more negative.

Experimental

Reagents.—The diethyl maleate (Matheson, Coleman, and Bell) contained 6% diethyl fumarate according to vpc analysis. Ethyl acrylate and acrylonitrile were high-quality products redistilled and stored over a trace of *p*-nitrosodimethylaniline stabilizer. The dimethylformamide (DMF) and tetraethylammonium *p*-toluenesulfonate were purified as described previously (1). The *trans*-ethyl 3-cyanoacrylate was of the same batch as described previously (1). The preparation of **4** and **6** needed as vpc standards has been reported (1). Compound **5** was obtained by electrolytic reductive coupling of diethyl fumarate and ethyl acrylate. It had the correct elemental analysis, bp 113°-115° (0.15 mm), n^{24}D 1.4380 [reported (5) n^{20}D 1.4390]. Compounds **7** and **9** were available from previous work (1).

Equipment.—The electrolysis cell and associated equipment (6) employed a mercury cathode, area 55 cm^2. The SCE controlling the potentiostat (1.6 ampere Model, Chemical Electronics Company, Newcastle, England) had a salt bridge which was placed at the circumference of the mercury pool. It terminated in a medium porosity sintered disk which was positioned about 1 mm above the surface of the mercury when the stirrer was on. For measurements of the variation of cathode voltage along the mercury surface, the magnetic bar stirrer was replaced by a small glass stirrer in the catholyte. A second calomel cell containing a salt bridge, bent so that it could be positioned under the alundum cup and swivelled to permit readings in an arc from the center of the cell to the circumference, was used along with the "controlling" SCE (Fig. 1).

Analytical methods.—For the experiments with diethyl maleate a vpc analysis was developed, using di-

methyl terephthalate as an internal standard, for the quantitative determination in the mixture of products isolated from the electrolyses of (in order of elution): solvents, diethyl succinate, diethyl adipate, standard, **5**, adiponitrile, **6**, bis-cyanoethyl ether, and **4**. Either of two columns was used: (*a*) a 6-ft, ⅛ in. diameter stainless steel column packed with 80-100 mesh Chromosorb W (N.A.W.) coated with 6% by weight of diethyleneglycol succinate. The instrument was programmed from 180° to 225°C at a rate of 10°/min and held at 225° until all peaks had eluted; (*b*) a similar column packed with 80-100 mesh Chromosorb W (N.A.W.) coated with 10% by weight of Carbowax 20M. The instrument was programmed from 125° to 225° at 50°/min and held at 225° until all peaks had eluted.

In the vpc analysis of the products from ethyl 3-cyanoacrylate a 6-ft, ⅛ in. diameter stainless steel column packed with 10% Apiezon "L" on Chromosorb W (N.A.W.) was used isothermally at 190°. No internal standard was used, and, for comparison purposes, area per cents were taken equal to weight per cents.

Procedures.—The cathode chamber was charged with 50.0g tetraethylammonium p-toluenesulfonate, 5-8 ml of water, a total of 0.75 mole the acceptor olefin(s) (ethyl acrylate, acrylonitrile, or an equimolar mixture of the two) and enough DMF to bring the total volume to *ca.* 150 ml. The anolyte was a saturated aqueous solution of the same salt. The catholyte was stirred and deaerated with nitrogen for 15 min. The cathode voltage was then preset by potentiostat (*vs.* SCE)[2] and from a buret a mixture of 12.9g (0.075 mole) of diethyl maleate and 2.5 ml of acetic acid was added dropwise at a rate sufficient to sustain a current of 0.3-0.5A. Acetic acid was available for dropwise addition from a second buret to maintain the pH in the bulk of the catholyte slightly higher than 7 as measured externally by moist Hydrion paper. After addition was complete, the electrolysis was allowed to proceed at the same cathode voltage until the current fell to 40-60 mA. The catholyte was then diluted with an equal volume of ice water and extracted with five 75-ml portions of methylene chloride. The extracts were washed three times with water and dried over magnesium sulfate. The filtered solution was heated on a water bath at *ca.* 100 mm until no further volatile materials were removed. The residual liquid was analyzed by vpc. Data are summarized in Table I.

The experiment with ethyl 3-cyanoacrylate was conducted similarly except that the catholyte contained 75 ml of AN, 25 ml of DMF, and 6 ml of H_2O; 8.63g (0.069 mole) of ester-nitrile was used in the dropwise addition. After half had been added at −1.450V, a 25-ml sample of catholyte was removed for analysis, the volume replaced by an equal volume of starting catholyte mix, and the remaining half of the ester-nitrile was added at −1.500V. The final catholyte was analyzed in the same manner as the first sample. Suitable arithmetical adjustments permitted the calculation of the quantities of products made in each period. Data are summarized in Table II.

In the experiment in which the variation of the voltage along the mercury surface was measured the catholyte was the same as in runs 4-6 (Table I); small amounts of diethyl maleate were added incrementally in order to achieve the currents at which measurements were desired (Table III). The "monitoring" voltage was read on a DANA Model 5500 digital voltameter fitted with accessory module number 130.

Kinetics (electrochemical).—The method used for obtaining the rate constants is the same as described

[2] In a preliminary experiment the catholyte was charged as in run 1, the cathode voltage preset at −0.51V and increased negatively by small increments while "instantaneous" current readings were made. It was found that between −1.05 and −1.62V a current of only 63-75 mA was sustained (due to reduction of the stabilizer); at more negative voltages reduction of EA began. As discussed later, the conclusion that mixed coupling could safely be carried out at −1.50V without formation of diethyl adipate was, however, incorrect.

[a] At currents greater than *ca.* 100 mA fluctuations of registered cathode voltage were too rapid to permit determination of an average, so that the range is indicated.

previously (7). The concentration of diethyl fumarate was 2 x $10^{-3}M$, EA and AN were 1.0*M* in each run. The solvent was dimethylformamide containing 0.1*M* tetraethylammonium perchlorate.

Kinetics (solution).—The solutions contained 1*M* diethyl ethylmalonate, 0.1*M* EA or AN and 1 x $10^{-4}M$ tetraethylammonium hydroxide in ethanol as solvent. At appropriate times 1 ml of the solution was removed and added to 1 ml of a solution of 0.1*M* diethyl adipate and sufficient acetic acid to stop the reaction in ethanol as solvent. The analysis was done by vpc using diethyl adipate as an internal standard and a 6-ft, 10% Carbowax 20M on Chromosorb W, programmed from 100° to 220° at 15°/min. A plot of ln [product] *vs.* time curved due to the disappearance of base. A smooth curve was drawn through the points and the tangent to the curve at low conversion was used to calculate *k*. The runs were done in pairs, EA and AN, side-by-side at room temperature. The average value for the relative rate constants AN/EA for several runs was 9.2. The maximum value obtained was 11.0 and the minimum was 7.6. All attempts to use dimethylformamide failed due to the extremely rapid disappearance of the catalyst in this solvent. The disappearance of base is due to the facile saponification of diethyl ethylmalonate.

Reductive cyclization of **6** *to* **10**.—Diethyl α-(2-cyanoethyl) succinate (**6**, 47.0g, 2.1 x 10^{-1} moles), Raney cobalt (6.0g), absolute ethanol (120 ml), and ammonia (17.0g, 1 mole) were placed in a 300-ml bomb and heated at 100° under an initial hydrogen pressure of 1500 psi until hydrogen uptake was no longer observed (*ca.* 4 hr) (8). The reaction mixture was filtered, the solvent removed under vacuum, and the residue crystallized from 350 ml of cyclohexene to give 27.2g (1.5 x 10^{-1} moles) of **10**, ethyl 2-oxo-3-piperidineacetate (72%), mp 77°-79°. The infrared spectrum (nujol) has peaks characteristic of ester and amide functions at 1735 and 1650 cm^{-1}, respectively; nmr spectrum (τ, $CDCl_3$): 2.8 (broad singlet, 1H, NH), 5.6 (quartet, J = 7 cps, 2H, OCH_2), 6.4 (unresolved multiplet, 2H, NCH_2), 7.03 (unresolved multiplet, 3H, H α to carbonyl), 8.0 (unresolved multiplet, 4H, ring H), 8.5 (triplet, J = 7 cps, 3H, CH_3).

Anal.—Calcd. for $C_9H_{15}NO_3$: C, 58.38; H, 8.22; N, 7.57. Found: C, 57.88; H, 8.26; N, 7.49.

3-Piperidinethanol.—Ethyl 2-oxo-3-piperidineacetate (9.2g, 5 x 10^{-2} moles) was added in portions to 7.2g (1.9 x 10^{-1} moles) of $LiAlH_4$ in 150 ml of diethyl ether at room temperature over a 2-hr period. After refluxing for 6 hr and cooling, water was slowly added to destroy excess $LiAlH_4$. The mixture was filtered and the solid washed several times with ethanol. The amino-alcohol (3.1g, 2.4 x 10^{-2} moles) was isolated by vacuum distillation: bp 94°-96° (0.28 mm) [lit. (9-11) bp 120°-123° (4-6 mm)]; $n^{24}D$ 1.4897 [lit. (9-11) $n^{21}D$ 1.4880, $n^{25}D$ 1.4920, 1.4888]; nmr spectrum (τ, $CDCl_3$): 6.3 (broad singlet, NH and OH), 6.45 (triplet, 2H, OCH_2), 6.9-8.5 (unresolved multiplet, 11H).

Discussion of Results

In working with the reaction systems described here it is necessary to adopt a series of compromises. One must take cognizance of (*a*) the ready saponification of diethyl maleate (6) (pH and temperature-dependent); (*b*) the electroreducibility of ethyl hydrogen maleate (12); (c) the cyanoethylation of water (pH dependent); (*d*) the anionic oligomerizability/polymerizability of ethyl acrylate and acrylonitrile (proton donor concentration dependent); (*e*) the facile formation of diethyl succinate (proton donor concentration dependent); and (*f*) the facile formation of tetraethyl butanetetracarboxylate (diethyl maleate/water concentration dependent). Conditions were chosen so as to eliminate complicating side reactions [*e.g.*, formation of bis(2-cyanoethyl ether)], minimize the probability of favoring only hydrodimerization (therefore, dropwise addition of DEM), and to accept perhaps higher than necessary yields of DES in order to avoid polymerization. The penalty paid for the last compromise was to increase the possibility of "bulk" rather than electrode reactions (1). Attempts were not made to maximize yields of cross-coupled products at the expense of all other products; the focus of attention was on the ratio of cross-to-self-coupled products. Any DEM anion radical (or derived anion) which ended as DES or any DEM which was saponified was equally unavailable for formation of either coupled product.

Even though the quantity of water added to the catholyte is carefully measured, the concentration of water during a run and from run to run varies due to uncontrollable changes in the porosity of the diaphragm (1). Therefore, as mentioned above, it is not the absolute yield of DES (water dependent) which is significant but the ratio CCP/TEBT.

It is evident from the data in Table I that whether ethyl acrylate or acrylonitrile is the acceptor olefin the yield of reduced cross-coupled product with diethyl maleate compared to the yield of hydrodimer rises sharply as the voltage is made more negative. These results are consistent with our previous suggestion (1) concerning "induced" reactivity of acceptor olefins in electric fields. It is interesting that under certain circumstances (runs 1, 4) very little if any mixed coupling can be made to occur. This may explain reported (13) deviations in the success of obtaining cross-coupled products.

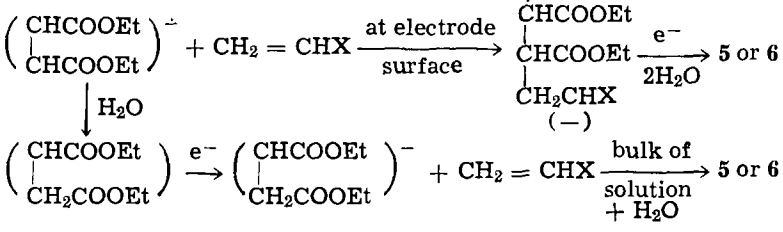
There is another factor affecting the ratio of coupled products: it cannot be ignored but cannot be evaluated clearly. Despite attempts to keep the rates of addition of DEM to the catholyte fairly constant from run to run (6-8 hr) and the effort to maintain comparable current densities (0.3-0.5 A/55 cm^2), the bulk concentrations, although small, of unreduced DEM in the runs at the more positive cathode voltages must have been higher than that at the more negative voltages. The higher concentration *per se* would have favored TEBT formation in the more anodic electrolysis (in accordance with results) but so would the greater reactivity of DEM in the more cathodic electrolyses (not in accordance with results).[3]

The reason for the formation of hydrodimers of the acceptor olefins (runs 3 and 6) as an "apparent" cath-

[3] The coulombs passed in the period between the end of DEM addition and the end of the experiment is a measure of the terminal concentration of DEM in the catholyte. While in run 1 (0.70 A hr) it was higher than in run 2 (0.17 A hr), in run 2 it was lower than in run 3 (0.28 A hr). Likewise, in run 6 (0.61 A hr) it was higher than in run 5 (0.38 A hr).

ode voltage at which they "should" not be reduced is clear from a consideration of the variation of cathode voltage with position of the salt bridge (14) and with current densities (Fig. 1 and Table III). At the currents used in these preparative runs the cathode voltages at certain areas of the mercury cathode may be as much as 0.13V more negative than "apparent" at the more negative voltages and may, therefore, overlap the beginning of the reduction waves of the acceptors. This phenomenon has been reported before (14). This type of preparative cell, otherwise very convenient, must be used cautiously for controlled potential electrolyses in which the desired reduction is < *ca.* 0.2V removed from an undesired reduction. Even at a "fixed" potential, the fluctuations may in some cases be significant (30-40 mV). Since, however, the same geometry was maintained throughout the runs reported in Table I, the conclusions concerning the reductive couplings involving DEM are the same whether one refers to the "apparent" cathode voltage or to the "true" cathode voltage (position 1, Table III).

It will be noted that in similar separate experiments (run 5 *vs.* run 2, run 6 *vs.* run 3) and even more in competitive experiments (runs 7 and 8) considerably more cross-coupled product was formed from AN as acceptor (→ **6**) than from EA (→ **5**). It was of interest to diagnose these results by the most feasible experiments which would differentiate between the reactions of DEM anion radical/diethyl succinate anion with acceptors at the electrode/in the "bulk" of solution.



Cyclic voltammetry provided the answer for the first of these coupled questions. For the second, diethyl succinate anion could, unfortunately, not be used successfully in the Michael reaction; therefore, diethyl ethylmalonate anion, which reacts with acceptors to give only 1:1 products, was chosen for the comparison of AN and EA as acceptors in a "bulk" reaction.[4]

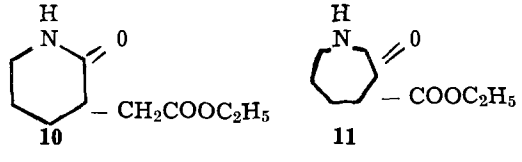
Rate constants for the reaction of EA and AN separately with the anion radical electrochemically generated from diethyl fumarate (DEF)[5] were measured by cyclic voltammetry by the procedure described previously (7). Using 2 x $10^{-3}M$ DEF, the rate constant for the disappearance of the anion radical in the absence of EA and AN is 0.30 sec^{-1} with DMF as solvent and 0.1*M* tetraethylammonium perchlorate as the supporting electrolyte. The rate constant measured in the presence of 1*M* EA was 0.46 sec^{-1}, and in the presence of 1*M* AN was 0.43 sec^{-1}. The ratio of the rate constants for the attack of the anion radical of DEF on AN and EA separately is 0.81. In macroscale cross-coupling electrolysis, if all of the products could be formed at the electrode surface, the cross-coupled product **5** would be formed at 1.2 times the rate of the cross-coupled product **6**. In fact, however, using the TEBT formed as a common denominator, and comparing Runs 2 and 5, **6** predominates by a factor of 1.7.

These results are in apparent contradiction to what would be predicted from cyclic voltammetric data only. However, it must be recognized that in bulk electrolyses the distribution of products obtained must depend not only on the rates of the reactions at the electrode but also on the rates of reaction in the "bulk" of solution outside the influence of the electric field. Cyclic voltammetry yields information exclusively about the first category; a normal Michael reaction "in bulk" yields information exclusively about the second category. The actual product distribution determined experimentally must reflect contributions from both electrode and bulk reactions.

Rate constants for a typical Michael reaction of EA and AN were measured using the diethyl ethylmalonate anion as the donor. The reactions were conducted in ethanol as solvent using tetraethylammonium hydroxide as the catalyst. The ratio of the rate constants for the reaction of AN and EA toward the same donor was 9.2. The fact that the observed rate ratio AN/EA of 1.7 from comparative macroelectrolysis lies between the values of 0.81 for the electrode reaction and 9.2 for the solution reaction again indicates that both of these reactions are occurring in macroelectrolysis.

The demonstrated increased reactivity of each acceptor alone (EA or AN) toward the maleate anion radical donor as the cathode voltage is made more negative must not be interpreted to indicate that their relative separate reactivities will hold when both are present together. Now questions of specific adsorption and cation effects may intervene (17). Examination of the data of runs 7 and 8, Table I, indicates a rate ratio of 6.5 for AN/EA in contrast to the value of 1.7 obtained for runs 2 and 5. The yield of CCP from AN is nearly constant in runs 5, 7, and 8, while the yield of the CCP from EA decreases sharply in runs 7 and 8 from that in run 2. The preferential adsorption of an AN-tetraethylammonium ion complex (17) on the electrode surface, thereby largely excluding EA from the reactive environment, may be the cause of the significant change in relative reactivities observed. The effect may not be unique for AN (17) and may explain the high reactivity of the β-substituted acrylonitriles reported previously (7).

Finally, it should be mentioned that compound **6**, prepared much more conveniently by a one-step electrochemical synthesis than by a multistep chemical route (18), is in itself an interesting intermediate. Catalytic reduction of **6** in ethanol with excess ammonia over Raney cobalt at 100° and 1500 lb gave an almost quantitative yield of ethyl 2-oxo-3-piperidine acetate **10**, mp 77°-79°, (with correct elemental analysis and consistent nmr spectrum) and none of the isomeric 7-membered lactam **11**. Reduction of the



carbethoxymethyl group of **10** with lithium aluminum hydride yielded the corresponding known (9) amino-alcohol whose *p*-bromobenzenesulfonamide melts at 97°-98.5° (correct analysis).

Acknowledgment

We are grateful to John L. Chruma for excellent technical assistance.

Manuscript received Aug. 12, 1969.

[4] It is assumed that steric effects will not influence the relative reactivities of AN and EA toward this model anion. Cf (15).

[5] It has been shown that the same anion radical is formed from either DEF or DEM (16).

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

Densities and Molar Volumes of Molten Alkali Carbonate Binary Mixtures

P. L. Spedding

Department of Chemical and Materials Engineering, The University of Auckland, Auckland, New Zealand

ABSTRACT

Density and molar volumes were determined for the molten lithium, sodium, and potassium carbonate binary mixtures over the complete composition range. Molar volumes of the sodium-potassium carbonate binary exhibit ideal behavior but the lithium binaries show positive deviations in the 0.25 to 0.67% mole lithium carbonate region. An attempt is made to handle the results using thermodynamic reasoning. It is possible to give a detailed explanation of the observed behavior by postulating that inbalances in repulsive cation interactions, caused by the relatively small size of the lithium ion, forces changes in anion-cation bonding in the melt microstructures.

Valuable insight into the nature of liquid structure can be gained from precise thermodynamic data of molten salts. Such information would be particularly relevant at the present time because of the absence of an adequate general theory of liquids. In particular, variations of density and molar volume with both temperature and melt compositions provide information on corresponding changes taking place in melt structure. Furthermore, accurate density data are an essential prerequisite to an adequate interpretation of certain other experimental data, *e.g.*, in the calculation of transport phenomena such as equivalent conductance.

The alkali metal carbonates have been studied extensively in recent years both from an interest in the fundamental structural and transport properties of pure salts and mixtures and also for their importance as electrolytes in the high-temperature fuel cell (1-5). This present study was undertaken as part of an integrated fuel cell research program aimed at obtaining a better understanding of the actual processes involved in the molten carbonate-type cell.

Experimental

The Archimedian single bob densitometer was used because of its simplicity, accuracy, and precision at higher temperatures. The method depends on the availability of suitable surface tension and expansion data (6, 7). If these data were lacking, the two-bob densitometer would have to be used (8). The pycnometer was not used because it was found that a suitable reference liquid for high-temperature work was difficult to obtain. Even when this aspect was avoided by using thermal expansion corrections, the surface tension difficulties encountered made the method unreliable for high-temperature work (9).

The apparatus (Fig. 1) was similar to that used for other molten carbonate studies (5). The densitometer section of the apparatus consisted of a salt bath (K) contained in an 80% Au 20% Pd alloy crucible which was supported on a 25/20 stainless steel frame (O). The crucible was provided with two small lifting holes (J) near its rim to facilitate handling in and out of the furnace. A precision laboratory jack (V), external to the furnace, enabled the crucible and support frames to be moved vertically. A thick pyrophyllite plug (R), fitted with a silicone rubber seal (T) and cooled by external water coils (S), provided a gas seal at the furnace base while still allowing vertical movement. Reproducible depth of bob immersion was ensured by a probe, height-sensing device (M). Ideally the carbonate melts should have been maintained under dry carbon dioxide at a pressure well in excess of their dissociation pressure in order to ensure the melt compositions (5). In practice it was not possible, with this relatively inexpensive type of apparatus, to maintain gas pressure during weight measurements because the bob suspension required free movement during a determination. Conditions were compromised in that a suitable carbon dioxide pressure was maintained during the 5-hr temperature equilibration by sealing the suspension hole at the top of the furnace. During the short time an actual weighing was conducted, carbon dioxide

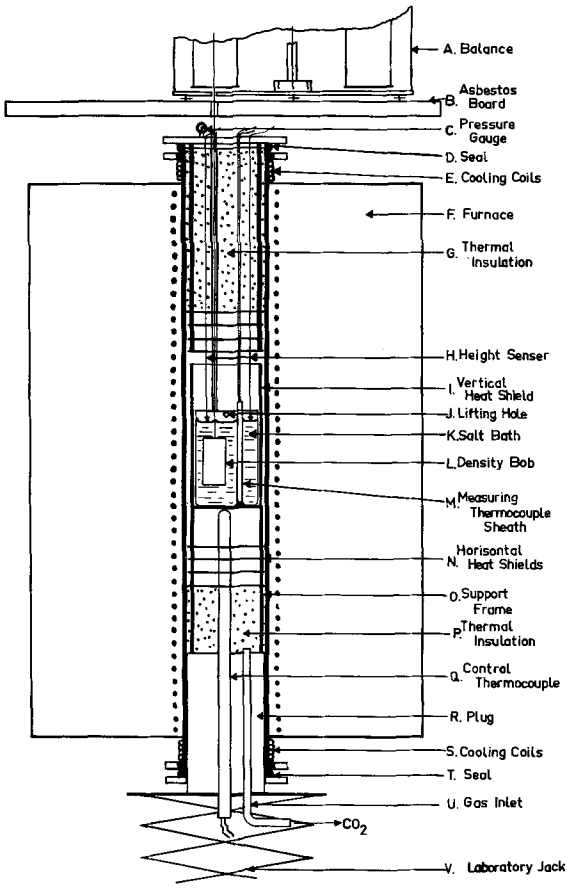

Fig. 1. Archimedian densitometer

was allowed to flow slowly down past the bob suspension wire through a special anticondensation sleeve. The absence of condensation was checked by weighing of the suspension wire after it had been exposed to operating conditions. It has been reported that the gas flow does not adversely affect the results obtained and that any decomposition which may take place during the short measurement period would be on the surface of the salt and so have an insignificant effect on the results (6, 7).

Analytical reagent grade lithium, sodium, and potassium carbonates were used in the preparation of the salt baths. The carbonates were dried initially at 120°C to constant weight and kept in a desiccator prior to weighing of the salt bath material. The salt bath was premelted in a furnace under a carbon dioxide atmosphere, care being taken to ensure that no bubbles were formed in the melt. The bath was solidified slowly and stored in a desiccator until it was used in the densitometer. Density readings were taken at increasing and then at decreasing temperatures. The weights used were calibrated against a substandard set of weights to ensure accuracy. The volume of the density bob was determined by weighing in air of a known density and then in water to a known depth of immersion. The water used was distilled, deionized, and deaerated. The calibration was carried out in a constant temperature room. The following equation applied. Difference between the two weights of masses in air $+ 2\pi r\gamma \cos\theta/g$ = Bob volume $\times$ Difference in density of water and air. Seven separate series of determinations taken at intervals over the molten salt density determinations gave the average volume of the density bob as 2.87675 $\pm$ 0.00027 cc. A further check of the bob volume was made by determining the density of benzene and carbon tetrachloride, and agreement with published data was within $\pm$ 0.01%. Corrections for surface tension (γ) and expansion (10) of the density bob in the melt were applied. In the former case the data of Janz and Lorenz (1) for the pure melts were used and the binary mixture values calculated assuming ideal melt behavior which is of sufficient accuracy for these circumstances (11). One of the most serious sources of error of the density bob method is bubble formation on the bob surface during an actual determination. Bubble formation has been attributed to minute traces of water in the melt, and in the present work this was completely eliminated by use of the premelting technique.

Results

The density data measured for the binary lithium, sodium and potassium carbonate mixtures are detailed in Fig. 2 to 4. The constants for the temperature-density equations were calculated using the method of least squares (12) and are listed in Tables I to III. The calculated accuracy of the determinations was in the region of $\pm$ 0.015%.

Discussion

Comparison with reported data.—Most of the reported data on the densities of molten alkali metal carbonates are incomplete or possess inconsistencies (1, 4, 13-17), Vorobev *et al.* (17) and Janz and Lorenz (1, 4) have suggested this is due to the lack of reasonable precautions being taken in certain instances to prevent thermal decomposition of the melt. The wide scatter and abnormal behavior of much of the data makes it highly probable that this criticism is well justified. When comparisons are drawn between the remaining data it is found that certain inconsistencies exist which are difficult to reconcile. The present work resolve these by showing agreement with the data of Vorobev *et al.* (17) and Janz and Lorenz (1) in the region of the eutectic compositions and the pure components, respectively, but poor agreement elsewhere.

Temperature-density data.—The most notable aspect of the results is the linear relationship which exists between density and temperature even at points quite close to the melting point. The temperature coefficient, *b*, exhibits a reasonably smooth change from one pure component composition to the other. This is in contrast with most other reported carbonate data but seems to be the more reasonable behavior to expect.

Composition-density data.—The sodium-potassium carbonate mixture exhibits a slight negative deviation from lineality. This is the usual behavior to be expected from a mixture of two similar salts. The lithium binary mixtures, on the other hand, show a change in the sign of the deviation from linear behavior at the eutectic compositions. This abnormal behavior of the lithium binary mixtures arises from a clustering of the composition-density data around the eutectic and is in accord with other thermodynamic data reported for these systems (5).

Composition—molar volume data.—Calculated molar volume data are detailed in Fig. 5. The sodium-potas-

sium carbonate mixture exhibits ideal behavior while the lithium binary mixtures show a positive deviation from ideality only in the vicinity of the 50% molar compositions. The deviation is observed to increase as the cation size difference in the melt increases. This nonideal behavior for the lithium mixtures is in line with other reported data for these systems such as the tracer diffusion coefficients (5). In order to explain the diffusion data it was postulated, among other things, that the interionic bonds of the melt were

loosened in the vicinity of the 50% mole compositions as some type of short ranged structure of a covalent nature was formed in the melt. The present density data, in line with density studies of other systems (18, 19), lend further weight to this explanation. In this case the effect is attributable to the widely differing sizes of the constituent cations as there is an increasing deviation from ideality when the cation size difference is increased. The asymmetry is provided either by reason of the large difference in cation polarizing power or from purely geometrical considerations. Phase diagrams for the binary and ternary carbonate systems reveal that compounds are formed from the lithium melts. There is no doubt that the congruently melting compound $LiKCO_3$ is formed in the lithium-potassium system (2) but there is controversy over the formation of a $LiNaCO_3$ compound because, it is argued that the lithium-sodium system shows simple eutectic behavior (2). The present work supports the suggestion of a $LiNaCO_3$ compound being formed in line with evidence from thermal and x-ray analysis data (20, 21). Formation of such compounds would result in a reduction in electrical conduction in the composition region. This is in line with the reported electrical conductance studies of these systems (4, 5).

Partial molar volumes.—The partial molar volumes for the nonideal lithium carbonate binaries were cal-

culated, at convenient temperatures and compositions, by the method of intercepts from the data of Fig. 5. As the nonideality was confined to the 50 m/o (mole per cent) region, the actual intercept determination was applied there only and the values were then extrapolated assuming ideal behavior. The tangents to the curves were constructed using the general method of Hoelscher and Springer (23) and checked by the "squint test" (24). It should be realized that the error of the molar volumes was magnified in the calculation of the partial molar values because of the long extrapolations involved. Values for the partial molor volumes are detailed in Table IV. It can be seen from these data that the solution behaves normally up to the 25 m/o and beyond the 66.7 m/o lithium carbonate compositions. In the intervening region there is initially an increase in partial molar volume of the minor component. The partial molar volume exhibits the usual behavior with respect to temperature.

It is instructive to discuss all changes in molar volume of the melts relative to a chosen reference state (25). For convenience the reference state is taken as the melting point of the higher molecular weight component of the mixture. The implication behind the assumption is that there is a basic microscopic reference lattice structure of the liquid which predominates over the entire region of temperature and composition involved. The molar volume (V) can then be considered to be a function of only two variables, the temperature (T) and the mole fraction of the lower molecular weight component in the mixture (n_2)

$$V = f(T, n_2) \qquad [1]$$

$$dV = (\partial V/\partial T)_{n_2}\, dT + (\partial V/\partial n_2)_T dn_2 \qquad [2]$$

where $(\partial V/\partial T)_{n_2}$ is the rate of change of molar volume with temperature at a fixed composition, *i.e.*, the thermal expansivity. From the density data when n_2 is constant

$$\rho = f(T)$$

i.e.,

$$V = M/f(T) \qquad [3]$$

In the present case

$$(\partial V/\partial T)_{n_2} = bM/(a - bT)^2 \qquad [3a]$$

The second term in Eq. [2], $(\partial V/\partial n_2)_T$, is the isothermal rate of change of molar volume with composition. From molar volume data

$$V = f(n_2) \qquad [4]$$

In the present case

$$(\partial V/\partial n_2)_T = \overline{V}_1 - \overline{V}_2 \quad \text{at} \quad 1 \geq n_2 \geq 0 \qquad [4a]$$

that is, the isothermal rate of change of molar volume with composition is equal to the difference between the partial molar volumes ($\overline{V}$) of the two components in the melt, when the mixture behaves ideally. In the case of the lithium binaries the nonideal section n_2 = 0.25-0.67 can be accommodated by including two new linear functions. Finally, from [2], the change in molar volume above the melting point of the higher molecular weight component can be found

$$\Delta V = \int_{To}^{T} (\partial V/\partial T)_{n_2}\, dT + \int_{n_2=0}^{n_2=n_2} (\partial V/\partial n_2)_T\, dn_2 \qquad [5]$$

and more simply, for convenience

$$\Delta V = \int_{To}^{T} \Delta V_T\, dT + \int_{n_2=0}^{n_2=n_2} \Delta V_{n_2}\, dn_2 \qquad [5a]$$

where ΔV_T and ΔV_{n_2} are the rate change of molar volume with temperature and composition, respectively, used in Fig. 6.

Using this analysis on the data it is possible to separate the respective effect of these two integral terms of [5a] on the molar volume change beyond the standard state. Resulting data are shown in Fig. 6 from which it can be seen clearly that both the change due to temperature and composition are not entirely independent of the other variable; the effect of temperature exhibiting a decrease in volume change with increasing composition of the higher molecular weight component particularly in the vicinity of the pure components, and the effect of composition showing a slight increase in volume change with temperature. The magnitude of these deviations is small, being between 0.5 to 2.0%. In Fig. 6 the effect is shown only for the sodium-potassium carbonate mixtures in order to avoid confusion but the other binaries show a similar effect. It would be expected that the thermal expansivity would alter with composition because it is a property which depends on the nature of the components in the mixtures. However, what is more notable is that the expansion is not regular over the composition range even with ideal melts such as the sodium-potassium carbonate binary. Such variations are in line with studies on binary solids and are presumably connected with interactions in the melt. The same is true of the thermal effects exhibited by the change of molar volume with composition.

It is possible to explain the sudden nonideal volume increase shown in Fig. 5 by reference to the microscopic structural arrangement of the melts along lines suggested by Ward and Janz (4). If the anions are considered as rigid units built up of three interpenetrating oxygen atoms (Fig. 7), then a cation can occupy various contact positions around such a unit (26). These positions, designated as A, B, and C, correspond to symmetrical positions of the cation in contact with, respectively, 2 and 1 oxygen atoms of the anion. The cation can assume intermediate positions depending on the packing of the molecule. The most flexible of these sites is obviously the B and C positions where the cation can move over a relatively large portion of the exposed oxygen atom surface with which it has contact. This type of siting is designated as D cation position. A change in volume of an alkali metal carbonate

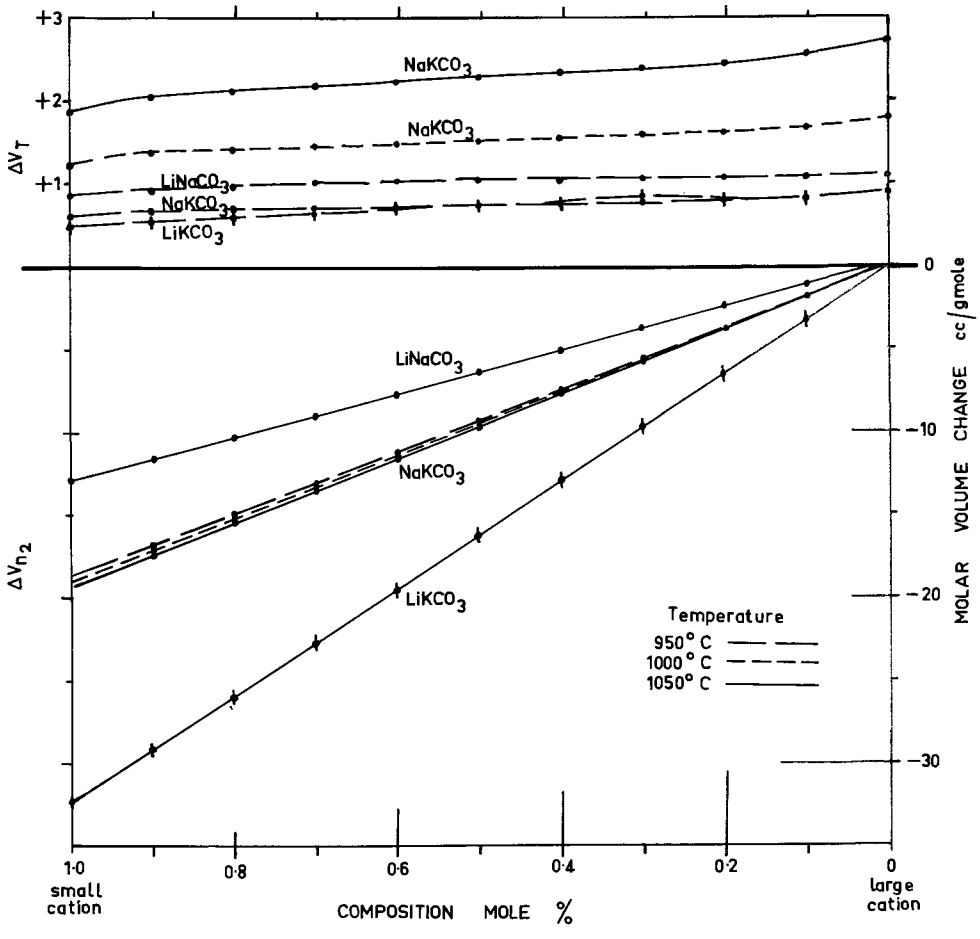

Fig. 6. Molar volume change of the alkali metal carbonate binary mixtures. The temperature effect is shown only for the $NaKCO_3$ mixture.

molecule is possible if a cation is moved from one site to another. With the alkali metal carbonates the anions pack together forming a distorted tetrahedron of four oxygen atoms around an alkali metal ion (27). The cation atoms would then be in a C-3D siting between the anions while every fourth cation in a crystal unit forms an A — A bond. A close examination of the increase in partial molar volume of the lithium binaries reveals that movement of the cations between various sites can provide a feasible explanation for the observed increase in volume of the minor component. For example, with the lithium-sodium carbonates mixtures, the partial molar volume of sodium carbonate increases suddenly by 2.6% at the 66.7 m/o lithium composition and remains constant until about the 50 m/o composition. This corresponds to a shift from A — A bonding of two anions by a sodium atom to an A — D type bonding. Similarly, the lithium carbonate shows a partial molar volume increase of 3.8% at the 25 m/o lithium composition. Again this corresponds to a shift of anion bonding by the lithium cation from A — A to A — D type. In the case of the lithium-potassium binary, corresponding increases in the partial molar volume of the potassium and lithium carbonate of 2.2% and 5.1%, respectively, again aline with A — A to A — D type shift of cation siting. Such a change of bonding of the minor additive in the lithium carbonate binaries implies a drop of coordination number in the particular composition region involved. Determination of such data would provide a positive test of the proposed site change mechanism.

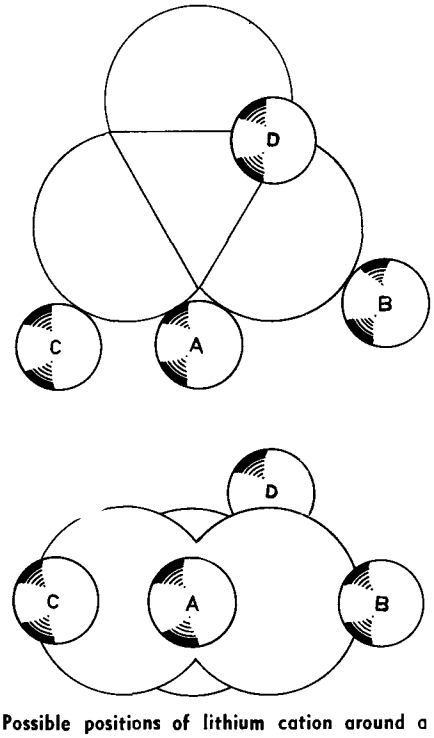

Fig. 7. Possible positions of lithium cation around a carbonate anion.

The flexibility of the D-type bond will depend to a great extent on the size of the cations in both A and D sites. As the size of the cation is increased for the D site and decreased for the A site the flexibility of movement of the cation in the D site will be reduced, *i.e.*, the siting tends toward the B or C positions. Comparison of the lithium-sodium and lithium-potassium binaries shows that the D site tends more toward B or C positions when the size of the diluting cation is increased. This is in agreement with the general predictions regarding cation siting already presented. Another detail of the results which supports the cation siting premise is the almost linear increase in partial

molar volume which is observed for the nonideal region.

Nonideal behavior of these lithium binaries occurs between the small/large cation ratios of 2/1 to 1/3, that is, at definite molar ratios. In the first place the basic reason for the proposed shift in cation siting could well be due to the relatively small sized lithium ion being able to fit between two anions held together by a larger cation in an A — A type bond. This would permit the lithium ion with its greater charge density to influence the larger A — A sited cation. When the small/large cation ratio is above 2/1, the larger cation is, on the average, influenced evenly by lithium ions. As the ratio falls below this point, there is an inbalance of influence because, on an average, large cations are now not influenced by lithium ions alone and an inbalance in repulsive influence forces the larger cation from the A — A site bond. This inbalance continues as the small/large cation ratio falls until it passes below 1/3 ratio. In such circumstances the greater charge density of the lithium ions conceivable would enable them to take the A — A siting thus bringing back ideal behavior to the melt.

Electrode Potentials of Several Redox Couples in Molten Fluorides

H. W. Jenkins,[1] G. Mamantov,* and D. L. Manning

Department of Chemistry, University of Tennessee, Knoxville, Tennessee, and Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

The standard electrode potentials ($E°$) of the following redox couples were determined in molten LiF-BeF_2-ZrF_4 (65.6-29.4-5.0 m/o (mole per cent) and LiF-NaF-KF (46.5-11.5-42.0 m/o) at 500°C from emf measurements on galvanic cells using Ni(II)/Ni reference electrode, contained in a boron nitride compartment. The $E°$ of the Ni(II)/Ni couple was set at 0.000V. In LiF-BeF_2-ZrF_4: Be(II)/Be −2.120V, Zr(IV)/Zr −1.792V (not $E°$), Cr(II)/Cr −0.701V, Cr(III)/Cr(II) −0.514V, Fe(II)/Fe −0.410V, and Fe(III)/Fe(II) 0.166V. In LiF-NaF-KF: Fe(II)/Fe −0.390V and Fe(III)/Fe(II) −0.200V. The more anodic value of $E°$ of the Fe(III)/Fe(II) couple (as compared to the Fe(II)/Fe couple) in LiF-BeF_2-ZrF_4 in comparison to LiF-NaF-KF reflects the higher acidity (modified Lux-Flood concept) of the LiF-BeF_2-ZrF_4 melt.

Electrode potentials give a direct measure of thermodynamic stability of electroactive species relative to one another in a given solvent and provide information useful in electroanalytical chemistry. Interest in electrode potentials in molten fluorides at the Oak Ridge National Laboratory stems from their importance in nuclear reactor technology. A number of electrode potentials have been determined in molten chloride solvents from emf measurements on electrochemical cells (1-3). Few electrode potentials

[1] Oak Ridge Associated Universities Fellow, University of Tennessee.

have been measured in molten fluorides. Grjotheim (4) has measured the potentials of several metal ion/metal electrodes in NaF-KF (40-60 m/o) at 850°C. Baes (5) has calculated electrode potentials in LiF-BeF_2 (66-34 m/o) from ionic equilibria data. Hitch and Baes (6) have measured the potential of a Be(II)/Be electrode *vs.* a HF/H_2 electrode in LiF-BeF_2 (66-34 m/o); the reversibility of the HF/H_2 electrode was studied previously by Dirian, Romberger, and Baes (7). Mellors and Senderoff (8) have estimated several electrode potentials from chronopotentiometric measurements in LiF-NaF-KF (46.5-11.5-42.0 m/o).

Results of other measurements have been summarized elsewhere (9-11).

Experimental

Materials.—Two fluoride salt mixtures were used as solvents in this investigation:

1. LiF-NaF-KF (46.5-11.5-42.0 m/o, liquidus temperature 454°C).
2. LiF-BeF_2-ZrF_4 (65.6-29.4-5.0 m/o, liquidus temperature 434°C).

These two salt mixtures and the following anhydrous fluoride salts were obtained from the Reactor Chemistry Division of the Oak Ridge National Laboratory (12): NiF_2, FeF_2, FeF_3, CrF_2, CrF_3, and LiF-BeF_2 (66-34 m/o). None of these salts received any further pretreatment; however, all were stored in an inert atmosphere until their use. Boron nitride used in the construction of the reference electrode was grade A or HP (Carborundum Company). The boron nitride was kept in a desiccator except for the time required for machining.

Equipment.—The melt (~400g) is contained in a graphite cell which is enclosed in the drybox-furnace system. This system and the Ni(II)/Ni reference electrode contained in a boron nitride compartment that were employed in this investigation have been described previously (13). All emf measurements were made with a Moseley X-Y recorder Model 2D-2A (input impedance 1 megohm). In some cases, in order to expand the recorder scales, the emf was first amplified using a Keithley 600A electrometer.

High-purity nickel and iron wires, coiled several times on the end to increase the surface area, were employed as indicator electrodes for the Ni(II)/Ni and Fe(II)/Fe couples, respectively. Beryllium, zirconium, and chromium indicator electrodes were constructed by attaching a threaded 1 to 1.5 in. long piece of the desired metal to a long, ⅛ in. diameter nickel rod. The beryllium and zirconium electrodes were cleaned with emory paper and rinsed in acetone. The other electrodes were rinsed with acetone and distilled water and then dried.

Procedure.—Voltammetric current-potential curves recorded in each melt were used to identify impurities and approximate their concentrations. Removal of common metal ion impurities, Ni(II), Fe(II), and Cr(II), in the LiF-BeF_2-ZrF_4 melt was accomplished by reduction with zirconium metal. Removal of these impurities in the LiF-NaF-KF melt was accomplished by pre-electrolysis employing either a graphite or platinum cathode.

The emf measurements were made as a function of concentration (except for Be(II)/Be and Zr(IV)/Zr couples); the concentration of the solute species was varied by addition of the anhydrous salt. It was established from the stability of emf measurements and from variations of the voltammetric peak current that homogeneity of solutions was attained by waiting about 1 hr between additions and measurements; the melt was stirred periodically (either manually or mechanically) during that time. EMF measurements were recorded over a 15-30 min period to insure stability of the values.

Solute concentration was determined either by spectrophotometric analysis of a sample taken at the time of the corresponding emf measurement or from a voltammetric current-potential curve recorded at the time of the corresponding emf measurement.

Since a significant junction potential across the boron nitride membrane has been observed (13) (this potential, although stable, was of the order of 100 mV in some experiments), it was necessary to relate the potential of each reference electrode to a common point; in this study, the standard potential of the Ni(II)/Ni couple. This was accomplished by measuring the potential of the reference electrode with respect to a Ni(II)/Ni electrode in the bulk of the melt and extrapolating the measured value by means of the Nernst equation to a value with respect to a unit mole fraction solution of Ni(II).

Results and Discussion

Three concentration scales are commonly employed in molten salts: molality (m), molarity (M), and mole fraction (X). Concentrations are expressed in mole fraction for this study; however, for dilute solutions molality and molarity can be readily related to mole fraction. At 500°C the relationships for LiF-BeF_2-ZrF_4 are given by (14)

$$m = 25.5\,X$$

$$M = 62.2\,X$$

For LiF-NaF-KF the relationships are given by

$$m = 24.2\,X$$

$$M = 52.6\,X$$

The potential of the hypothetical unit mole fraction Ni(II)/Ni electrode was set arbitrarily at 0.000V in these measurements.

Since beryllium metal readily reduces Zr(IV), it was not possible to measure the potential of the Be(II)/Be couple in LiF-BeF_2-ZrF_4. However, the potential of this couple was measured in LiF-BeF_2 (66-34 m/o) by isolating the couple in a boron nitride compartment and measuring the cell emf *vs.* a Ni(II)/Ni electrode in the bulk of a LiF-BeF_2-ZrF_4 melt as the function of the Ni(II) concentration. In these measurements, the emf may have included a junction potential between the two melts plus the previously observed potential drop across the boron nitride wall. Since there was no way to ascertain the magnitude of the junction potential, it was included in the standard electrode potential of the Be(II)/Be couple. The standard state of the Be(II) was taken as the solvent composition, LiF-BeF_2 (66-34 m/o).

The potential of the Zr(IV)/Zr couple was determined by measuring the potential of a zirconium rod immersed in the LiF-BeF_2-ZrF_4 melt. The potential of this rod was stable to ±0.01V over a five day period. The standard electrode potentials of the Fe(II)/Fe, Fe(III)/Fe(II), and Ni(II)/Ni couples were determined in both solvents while the standard electrode potentials of the Cr(II)/Cr and Cr(III)/Cr(II) couples were determined only in the LiF-BeF_2-ZrF_4 melt.

Standard electrode potentials for the various couples were determined from plots of emf *vs.* the logarithm of concentration of the solute species (approximately 5×10^{-5} to 10^{-3} mole fraction) in the bulk of the melt. For each electrode couple, a line having the slope predicted by the Nernst equation was drawn through the data points. These lines were extrapolated to either a unit mole fraction or a Ox/Red ratio of unity to determine the standard electrode potential. Nernstian reversibility was confirmed from a fit of the data points to such lines which was good in all cases except the Cr(II)/Cr couple. For the Cr(II)/Cr couple, the data tended toward a lower slope than predicted by the Nernst equation.

Table I. Standard electrode potentials in molten fluorides*

Electrode couple	Measured,[a] V		Calculated,[b] V
	LiF-BeF_2-ZrF_4	LiF-NaF-KF	LiF-BeF_2
Be(II)/Be	−2.120		−2.211[c]
Zr(IV)/Zr	−1.792[d]		−1.772
U(IV)/U(III)[e]	−1.480		−1.517
Cr(II)/Cr	−0.701		−0.789
Cr(III)/Cr	−0.639		
Cr(III)/Cr(II)	−0.514		
Fe(II)/Fe	−0.410	−0.390	−0.413
Fe(III)/Fe	−0.218	−0.327	
Ni(II)/Ni	0.000	0.000	0.000
Fe(III)/Fe(II)	+0.166	−0.200	

* Temperature 500°C.
[a] Standard state for all solutes except beryllium(II) and zirconium(IV) (see footnote [d]) is the hypothetical unit mole fraction solution. The beryllium(II) standard state is the solvent composition, LiF-BeF_2 (66-34 m/o). The estimated accuracy is ±0.01V.
[b] Values calculated by Baes (5) converted to 500°C.
[c] Experimentally determined value (6).
[d] This potential was not extrapolated to the hypothetical unit mole fraction solution since the activity coefficient of ZrF_4 changes by more than tenfold from 5 m/o to infinite dilution (5).
[e] See ref (15).

The standard electrode potentials determined in this study at 500°C are listed in Table I. Values determined for the Fe(III)/Fe and Cr(III)/Cr couples were calculated from the standard electrode potentials of the Fe(III)/Fe(II), Fe(II)/Fe, Cr(III)/Cr(II), and Cr(II)/Cr couples using a standard approach (16). For the sake of comparison, the standard electrode potentials calculated by Baes(5) in LiF-BeF_2 (66-34 m/o) at 500°C are included in Table I where available. The trend in the values determined in LiF-BeF_2-ZrF_4 agrees well with that calculated in LiF-BeF_2; however, in all instances, the values determined in this study are lower than those calculated by Baes. The 91 mV difference between the two values for the Be(II)/Be couple could be due partially or totally to the inclusion of a junction potential in the value determined in this study. The other differences observed between the two sets of values range from 3 mV for the Fe(II)/Fe couple to 88 mV for the Cr(II)/Cr couple.

These differences may be due to the greater stability of the higher oxidation state relative to the lower oxidation state in LiF-BeF_2 than in LiF-BeF_2-ZrF_4. Such an effect may be caused by the formation of a very stable ZrF_x^{4-x} complex which would make LiF-BeF_2-ZrF_4 a more acidic (using the modified Lux-Flood concept) solvent than LiF-BeF_2 by the reduction of the activity of the basic species, free F^-. The same effect, in a more pronounced example, is observed when comparing the relative stability of Fe(III) to Fe(II) in LiF-NaF-KF and LiF-BeF_2-ZrF_4. In LiF-NaF-KF where all of the F^- is present as free F^-, the standard potential of the Fe(III)/Fe(II) couple is 0.190V anodic to the Fe(II)/Fe standard potential. However, in LiF-BeF_2-ZrF_4 where the free F^- activity is reduced by the formation of BeF_4^{-2} and ZrF_x^{4-x} complexes, the standard potential of the Fe(III)/Fe(II) couple is 0.576V anodic to the Fe(II)/Fe couple. Thus, Fe(III) is 0.386V or 8.8 kcal more stable relative to Fe(II) in LiF-NaF-KF than in LiF-BeF_2-ZrF_4.

Proton Effects in the Electrochemistry of the Quinone Hydroquinone System in Aprotic Solvents

B. R. Eggins and J. Q. Chambers†

Department of Chemistry, University of Colorado, Boulder, Colorado

ABSTRACT

Electrochemical and spectroscopic techniques have been used to study the benzo-, duro-, tetrachloro-, and *p*-xyloquinone-hydroquinone couples in nonaqueous solvents. The proton transfer reactions which are coupled to the electron transfer steps are elucidated. Oxidation of the hydroquinone leads to the protonated quinone species, while reduction of the quinones in the presence of a proton source gives mixtures of the corresponding hydroquinone, its conjugate base, and the free semiquinone, depending on the amount and strength of the proton donor used. Oxidation of the hydroquinones is postulated to proceed *via* a dimer of the one-electron intermediate. Preliminary results are reported on the electrochemical behavior of solutions containing the quinhydrone charge-transfer complex.

The vast majority of organic electrode processes involve proton transfers coupled with electron transfers. Proton transfers are generally very rapid reactions and cannot be studied using conventional polarographic techniques. We have studied the quinone-hydroquinone (Q-QH_2) system which has been considered the classical organic reversible redox reaction (1, 2)

$$Q + 2H^+ + 2e^- = QH_2 \qquad [1]$$

Such systems are often used to test new electrode materials, new electrochemical techniques, and new solvent systems. They are also involved in biological electron transport (3).

Studies by Vetter (4) on the quinhydrone system at platinum electrodes in aqueous solutions using Tafel plots led to the following suggested mechanism

$$\begin{aligned} pH < 5 \quad Q + H^+ &= QH^+ \\ QH^+ + e^- &= QH \\ QH\cdot + H^+ &= QH_2\cdot^+ \\ QH_2\cdot^+ + e^- &= QH_2 \end{aligned} \qquad [2]$$

which can be expressed as a HeHe mechanism. At $pH > 6$ Vetter suggests that the mechanism is eHeH.

There is some conflict between these mechanisms and the work of Hale and Parsons (5) in which polarographic waves at pH 4 were analyzed by the Koutecky method and potential energies of the various species were estimated to elucidate a pathway following the species of lowest energy. These workers suggest that the mechanism is either HeeH or eHeH, and favor the former.

Several researchers including Peover (6), Wawzonek (7), Elving (8), Kolthoff (9), and Osteryoung (10) have studied proton effects on the reduction of quinones in aprotic solvents, but not in great detail. We have studied proton effects in the nonaqueous electrochemistry of the Q/QH_2 system (11) and have characterized the oxidation of QH_2 in acetonitrile (12) using electrochemical techniques over a wide time scale. The products and an intermediate have been detected by cyclic voltammetry (13).

Experimental Section

Most of the experimental procedures were standard and have been described in part elsewhere (14, 15).

Reagent grade chemicals were used. Duroquinone was obtained from Aldrich Chemical Company; *p*-benzoquinone, *p*-xyloquinone, tetrachloroquinone, and *p*-benzohydroquinone were obtained from Eastman Chemical Company. The *p*-benzoquinone was resublimed before use. The hydroquinones were prepared from the corresponding quinones following the method given by Vogel (16). Practical grade pyrrolidine and Analytical Grade pyridine obtained from Matheson, Coleman, and Bell were used without further purification. For most of the studies, acetonitrile of high purity was employed as the solvent.

Two platinum electrodes were used in this study. For measurement at long times a commercial Beckman platinum inlay electrode was used, geometric area: 0.212 cm^2. The other electrode had a geometric area of 0.0134 cm^2 and was used for measurements at short times. The experimental area of this electrode was determined using the known diffusion coefficient of potassium ferrocyanide (17) and found to be 0.0135 cm^2 after correcting for edge effects by the method of Soos and Lingane (18). This electrode was usually polished to a mirror finish using 0.3μ lapping compound before recording individual current-potential (i-E) curves. The mechanical pretreatment gave reproducible results in the nonaqueous systems under study.

The potentiostat was based on the design of Brown *et al.* (19) and provided for compensation of the resistance between the tip of the reference electrode and the working electrode input. At all but the fastest sweep rates employed (*ca.* 2 x 10^3 V/sec), close to 100% iR compensation could be achieved. At the fastest sweep rates the peak potential and current function data contain small contributions from iR terms although qualitative features of the i-E curves are still significant. All peak potential data in this paper are given *vs.* an aqueous SCE.

Controlled potential electrolyses were carried out on 10 mM solutions of hydroquinones by conventional techniques. The product was isolated, after neutralization of the solution (where necessary) with sodium carbonate, by removal of the acetonitrile under vacuum and extraction of the residue with ether or cyclohexane. The quinone products were identified by cyclic voltammetry and melting points. Visible and u.v. spectra were obtained using a Cary Model 14 spectrometer. *In situ* electrolyses were performed in the cavity of a Varian Model V4502 spectrometer following standard procedures.

Results and Discussion

Oxidation of hydroquinone.—The oxidation of benzohydroquinone (QH_2) at platinum electrodes in acetonitrile is irreversible, producing quinone (Q) in a two-electron step.

$$QH_2 \rightarrow Q + 2H^+ + 2e^- \qquad [3]$$

$$Q + H^+ \rightleftharpoons QH^+ \qquad [4]$$

Cyclic voltammograms of QH_2 (Fig. 1) at slow sweep

† Address correspondence to this author at Dept. of Chemistry, University of Tennessee, Knoxville, Tenn. 37916.

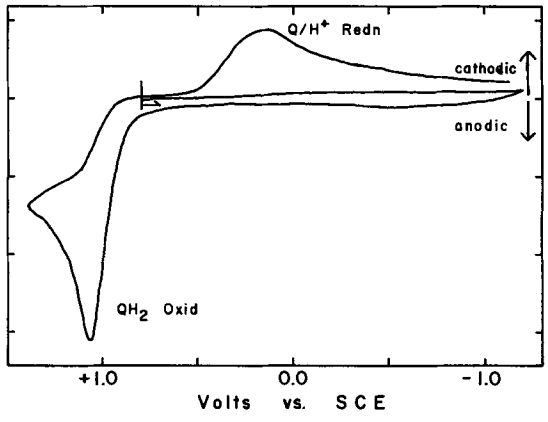

Fig. 1. Cyclic voltammogram of *p*-benzohydroquinone oxidation: 1.82 x 10^{-3}M QH_2, 0.1M TEAP, CH_3CN, 0.12 V/sec, 0.1 mA/division.

rates show one irreversible two-electron oxidation wave (I) followed by one irreversible two-electron reduction wave (II) on the cathodic sweep. The number of electrons involved in each wave was determined by double potential step chronoamperometry (20). The diffusion coefficient of QH_2 is 3.16 ± 0.15 x 10^{-5} cm^2 sec^{-1}. The peak width for wave I at a sweep rate of 0.12 V/sec is 95 mV indicating irreversibility and a transfer coefficient of 0.5. Controlled potential electrolysis of QH_2 and of durohydroquinone gave good yields of the respective quinones.

Wave II involves the reduction of Q/H^+ mixtures to the hydroquinone monoanion, QH^-, which is rapidly protonated in the presence of excess protons.

$$Q + H^+ + e^- \longrightarrow QH\cdot \xrightarrow{e^-} QH^- \xrightarrow{H^+} QH_2 \quad [5]$$

This scheme was established by observation of the effect of proton donors on the cyclic voltammograms of the various quinones. Reduction of a 2:1 mixture of perchloric acid to quinone gives a cyclic voltammogram essentially identical to Fig. 1 in that only the QH_2 oxidation wave is observed on the anodic cycle. With a ratio of 1:1 perchloric acid to quinone, reduction waves can be seen in the cyclic voltammograms corresponding to Eq. [5] and [6]

$$Q + e^- \leftrightharpoons Q\cdot^- \quad [6]$$

followed by oxidation waves on the reverse scan arising from the oxidation of semiquinone ($Q\cdot^-$), QH^-, and QH_2 (see Fig. 2). The peak potential of wave II

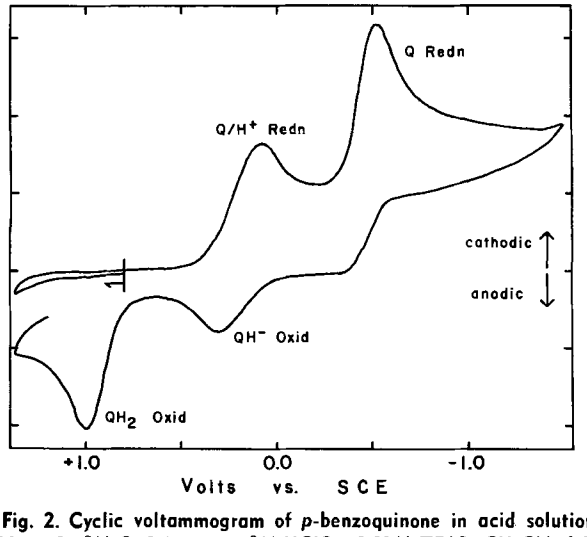

Fig. 2. Cyclic voltammogram of *p*-benzoquinone in acid solution: 1.52 x 10^{-3}M Q, 1.91 x 10^{-3}M $HClO_4$, 0.01M TEAP, CH_3CN, 0.12 V/sec, 0.05 mA/division.

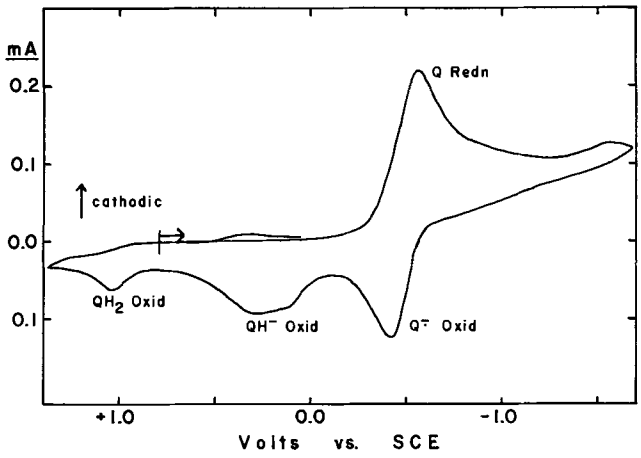

Fig. 3. Cyclic voltammogram of *p*-benzoquinone in the presence of a weak proton donor: 1.87 x 10^{-3}M Q, 2.3 x 10^{-3}M benzoic acid, 0.1M TEAP, CH_3CN, 0.12 V/sec.

(Eq. [5]) varies between 0.0 and 0.2V, depending on the hydrogen ion activity. When *p*-toluenesulfonic or picric acid is used as the proton donor, waves I and II shift to more positive potentials as the acid concentration is increased. The shift is roughly 30 mV in $E_{p/2}$ per tenfold increase in the hydrogen ion activity. A quantitative explanation of this dependence is difficult since the peak widths are also a function of the acidity. The peak width for wave II is *ca.* 0.2V and dependent on sweep rate, suggesting kinetic complications as well as irreversibility.

The diffusion coefficient of the quinone species is 2.9 x 10^{-5} cm^2 sec^{-1}. This was determined by chronoamperometric measurements on wave II in $Q/HClO_4$ mixtures using the Cottrell equation. The apparent *D* value for wave II varies as the quinone ring is substituted by methyl groups. The diffusion coefficient of the solvated proton (H_3O^+?) in acetonitrile/$HClO_4$ mixtures is 2.1 x 10^{-5} cm^2 sec^{-1}.

Evidence for the formation of QH^- in the reduction of Q/H^+ mixtures is as follows. Cyclic voltammograms of quinone in the presence of weak proton donors, *e.g.*, 1:1 benzoic acid to Q, exhibit an oxidation wave at *ca.* +0.3V on the reverse or anodic-going sweep (Fig. 3). This wave is attributed to the oxidation of QH^-. Direct evidence for the oxidation of QH^- was difficult to obtain as addition of excess tetra-*n*-butylammonium hydroxide to QH_2 results in the formation of Q^{2-} and $Q\cdot^-$ (detected by cyclic voltammetry), but not QH^-. With a 1:1 ratio of QH_2:Bu_4NOH a precipitate forms and all electrochemical waves disappear. This precipitate is ascribed to $Bu_4N^+QH^-$ by Badoz-Lambling and Demange-Guerin (21, 22). However, addition of the nonhydroxylic base, pyrrolidine [pK_a in water: 11.27 (23); compared to pK_a's for QH_2 of 9.85 and 11.40 (24)] to QH_2 in acetonitrile results in a decrease in the height of the QH_2 wave and the appearance of an oxidation wave at +0.28V to +0.45V depending on the amount of base added. Assignment of this wave to the oxidation of QH^- is consistent with the acid-base chemistry of QH_2.[1] No Q^{2-} oxidation wave is observed, presumably because pyrrolidine is a weaker base than the dianion. Pyrrolidine itself is oxidized at +1.08V and a product is reduced at −0.88V.

These results can be explained either by a scheme involving "preprotonation" of the quinone to form QH^+ near the electrode surface followed by uptake of an electron or by one-electron reduction of H^+ followed by hydrogen atom transfer to Q. The latter process is feasible since H^+ is reversibly reduced in acetonitrile at a well polished platinum electrode in the region of 0.0V. The pK of QH^+ has been reported

[1] Since this paper was submitted for publication, Parker (42) has reported a similar observation using 2,6-lutidine as the base.

to be −1.0 in aqueous solutions (25). However, there is some dispute over this value since quinone species which are stable in concentrated acid solutions give pK values considerably lower on a Hammett acidity function scale (26, 27). Badoz-Lambling and Demange-Guerin (21) report that benzoquinone is not protonated in N,N-dimethylformamide on the basis of spectrophotometric studies. We find that the absorption spectrum of Q in acetonitrile changes considerably on addition of perchloric acid up to a concentration of 1*M*, showing a new maximum at 353 mμ. These changes are caused by chemical reactions of Q with $HClO_4$, including possible QH^+ formation.

If the basicity of Q is as high as suggested by Biedermann (25), the QH^+ scheme is an attractive explanation for wave II. This scheme is in accord with the kinetic character of the wave and the appearance of the wave at roughly the same potential on both mercury and platinum electrodes. Hale and Parsons (5) have suggested the QH^+ species to explain the reduction of Q in aqueous solutions. Furthermore, the wave seems to be independent of the state of the electrode surface in contrast to the proton wave which varies by several hundred millivolts depending on the platinum electrode pretreatment.

For these reasons, we favor QH^+ as the intermediate in the reduction of $Q/HClO_4$ mixtures. However, in the rest of this paper, this wave (Eq. [5]) will be referred to as the "Q/H^+ wave" which is meant to indicate that the order of proton and electron transfer is open to question.

The process has characteristics similar to catalytic hydrogen waves (28), except that clearly the quinone nucleus is reduced, evidenced by the reduction products detected on the reverse cycle of the cyclic voltammograms. This is similar to the reduction of protonated species in other nonaqueous solvents. For example, Spritzer *et. al.* (29) found that reduction of pyridinium ion in pyridine leads to reduction of the pyridine ring and a coupling product, in contrast to the behavior in aqueous solutions (28).

Chemical complications.—As the sweep rate is increased, wave II disappears completely, and the current function for the QH_2 oxidation wave decreases considerably. This behavior is shown in Fig. 4. However, the corresponding current function for the reduction of Q plus acid (Eq. [5]) remains almost constant with increasing sweep rate on both mercury and platinum electrodes. This result was not expected. We had tentatively ascribed the decrease of the current function of wave II to a slow protonation of Q prior to electron transfer (11).[2] However the observation of a constant current function for the Q/H^+ wave in the $Q/HClO_4$ mixtures implies that protonation of Q, the forward step in Eq. [4], is fast on the time scale of the electrochemical experiment and suggests that the decrease in the current function for wave II shown in Fig. 4 is due to some other kinetic complication.

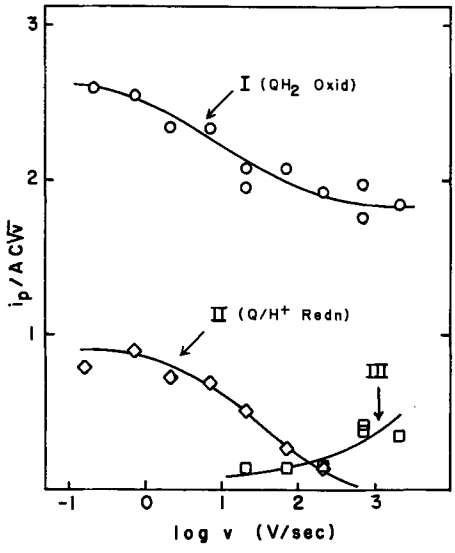

Fig. 4. Variation with sweep rate of current functions for waves I, II, and III of QH_2 cyclic voltammograms. Units: i_p in amperes, A in cm^2, C in moles/liter, and V in volts/sec.

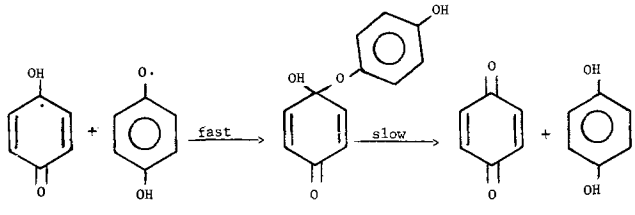
To eliminate the possibility that the difference in the behavior of the current functions for wave II in Fig. 4 and the Q/H^+ wave obtained in a $Q/HClO_4$ mixture was due to the water added with the $HClO_4$, the following experiment was carried out. A 2×10^{-3} *M* QH_2 solution in acetonitrile was exhaustively electrolyzed at a large platinum electrode to produce a "dry" solution, $2 \times 10^{-3}M$ in Q and 4×10^{-3} in $HClO_4$. At slow sweep rates the *i-E* curve obtained on this solution was essentially identical to the reverse cycle of the QH_2 oxidation: one irreversible two-electron Q/H^+ reduction wave was present. However this wave did not disappear at fast sweep rates, but exhibited behavior identical to the $Q/HClO_4$ mixture. In addition several experiments were carried out in which freshly dried molecular sieves were added to the working electrode compartment. Current function data were obtained in agreement with Fig. 4, which indicates that trace amounts of water present in acetonitrile were not producing spurious results.

At a sweep rate of about 10 V/sec a new reduction wave (III) appears on the reverse cycle of the QH_2 oxidation cyclic voltammogram at about −0.3 to −0.4V. This wave becomes more prominent as wave II disappears as is shown in Fig. 4 and the figure in ref. (12). This wave does not correspond to the small Q reduction wave in the cyclic voltammograms of $Q/HClO_4$ mixtures which appears at potentials more negative than −0.5V. Waves II and III were the only reduction processes evident in the cyclic voltammograms at potentials more positive than −2.0V.

The most striking feature of these results is the complete disappearance of the Q/H^+ reduction wave at fast sweep rates. This must mean that the QH· intermediate which is formed in the oxidation of QH_2

$$QH_2 \rightarrow QH\cdot + H^+ + e^- \qquad [7]$$

is not oxidized further by a simple one-electron step at this time scale. Direct evidence for the fate of the protonated semiquinone, QH·, is lacking, but a likely possibility is that it disproportionates to Q and QH_2 *via* a hemiketal intermediate, Eq. [8].



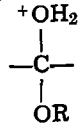
[8]

The hemiketal intermediate, $(QH)_2$, is a dimer of the one-electron intermediate oxidation state, and its formation would account for the decrease of the current function for the main oxidation wave. If the initial concentration of QH_2 is reduced from 2.11 to 0.96 *mM*, the current function for wave I decreases much more rapidly with sweep rate indicating that the chemical step following the initial oxidation process (Eq. [7]) is bimolecular. This is in accord with a dimerization step such as Eq. [8].

Formation of $(QH)_2$ has precedent in the literature. Oxidation of durohydroquinone monomethyl ether by alkaline ferricyanide in benzene mixtures leads to the corresponding dimethoxy derivative which can be isolated as a stable product (30). Also oxidation of substituted phenols leads to products with analogous

[2] This mechanism has been recently suggested by Parker (42).

structures (31,32). The observed half-life of this species, estimated from the decrease of the current function of the Q/H$^+$ wave, is *ca.* 0.1 sec. Under the acidic conditions of the QH_2 electrolysis solutions, the proposed intermediate would be expected to be unstable. Ketals and acetals are known to decompose in an acid catalyzed reaction *via* an intermediate of the type (33):



The half-life of $(QH)_2$ shows qualitatively the expected decrease with increasing hydrogen ion concentration.

In addition to QH_2, the electrochemical oxidation of durohydroquinone (DQH_2), p-xylohydroquinone (XQH_2), and tetrachlorohydroquinone was examined in an effort to extend the generality of the conclusions. The behavior of these hydroquinones is analogous to that of QH_2. The current functions for wave I decrease in each case and waves II and III appear on the reverse cycle for DQH_2 and XQH_2. Cyclic voltammograms of DQH_2 and the corresponding current functions for waves I, II, and III are shown in Fig. 5 and 6. Wave III is observed at lower sweep rates for DQH_2

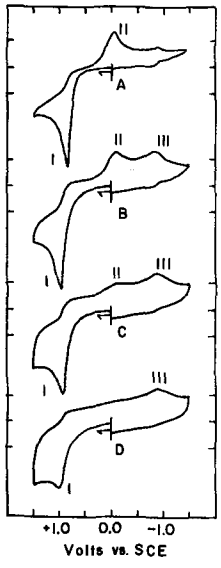


Fig. 5. Cyclic voltammograms of durohydroquinone oxidation: 2.12 x 10^{-3}M DQH_2, 0.1M TEAP, CH_3CN. (A) 1.80 V/sec, 0.02 mA/division; (B) 18.0 V/sec, 0.05 mA/division; (C) 180 V/sec, 0.2 mA/division; (D) 600 V/sec, 0.5 mA/division.

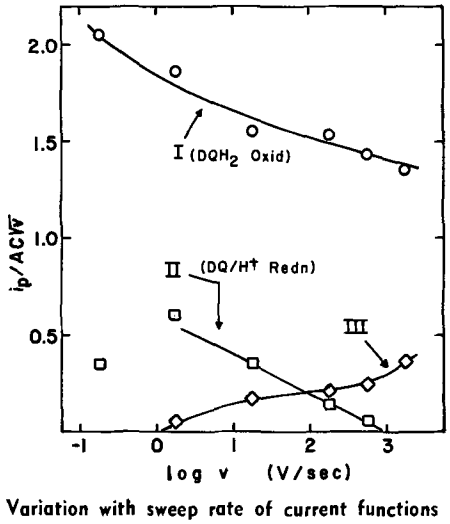

Fig. 6. Variation with sweep rate of current functions for waves I, II, and III of DQH_2 cyclic voltammograms. Units: same as Fig. 3.

and XQH_2 and at potentials fairly close to the reversible one-electron reduction of the corresponding quinone. Wave III occurs at −0.83V for DQH_2 and −0.59V for XQH_2, while the quinones are reduced at −0.83 and −0.54V, respectively, under the same conditions. The intermediates formed from DQH_2 and XQH_2 are more stable than the intermediate formed from QH_2. This conclusion is based on the assumption that wave II disappears when the time scale of the experiment competes with the half-life of the dimer.

The behavior of DQ in the presence of perchloric acid is interesting. First, a considerable excess of acid (6:1) is required to completely eliminate the one-electron DQ reduction wave at −0.83V at a sweep rate of 6 V/sec. With increasing sweep rate the peak potential of the DQ/H$^+$ wave shifts from 0.18V at 0.6V/sec to −0.52V at 600 V/sec and the current function decreases by one half. This suggests that the rate of protonation of DQ is slow.

Nature of wave III.—Identification of the reduction process responsible for wave III is not straightforward. This wave first appears at moderately fast sweep rates and spectroscopic or product identification techniques cannot be applied. However some pertinent observations can be made. First of all, wave III is due to the reduction of some quinone species and not free protons. While protons are reduced in the potential region where wave III appears for QH_2, a proton wave would be expected to occur at roughly the same potential regardless of the hydroquinone oxidized. On the contrary, wave III is dependent on the nature of the hydroquinone in both its peak potential and ease of formation. In an effort to trap the protons released, millimolar concentrations of pyridine were added to the solution. This resulted in the appearance of wave III at slower sweep rates, but the peak potentials still varied considerably with the hydroquinone oxidized. In the absence of pyridine, wave III appears at −0.3V for QH_2 and −0.83V for DQH_2, while $HClO_4$ is reduced in the region of 0.0V. These differences are difficult to rationalize in terms of assignment of wave III to a proton reduction. Furthermore, wave III is observed at a similar potential on a nonaqueous carbon paste electrode (34), in contrast to the proton wave which appears at higher overvoltages on carbon paste than on platinum.

Another possible process for wave III is reduction of the quinone assisted by protons supplied by QH_2 in the diffusion layer. This could proceed by protonation of $Q\cdot^-$ by QH_2

$$Q \overset{e^-}{\rightleftharpoons} Q\cdot^- \xrightarrow{QH_2} QH\cdot \xrightarrow{e^-} QH^- \xrightarrow{H^+} QH_2 \qquad [9]$$

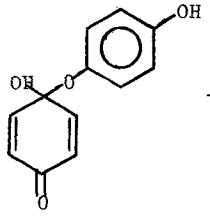
or by the reduction of a Q-QH_2 hydrogen bonded complex to give a preprotonation wave

$$Q\ldots HQH \xrightarrow{e^-} QH\cdot + QH^- \xrightarrow{H^+} 2QH_2. \qquad [10]$$
$$\qquad\qquad\qquad\quad \Big| \xrightarrow{e^-} QH^-$$

Peover (6) has invoked both schemes in the reduction of different carbonyl compounds in the presence of weak proton donors. However, both schemes are somewhat unsatisfactory descriptions of wave III since protons available in the diffusion layer from Eq. [7] would be more effective proton donors than QH_2. In other words, assignment of wave III to either of these processes is not consistent with the mobile equilibrium for the protonation of Q (or the formation of QH·) which is observed experimentally at these time scales. Because this equilibrium is fast, the absence of a Q/H$^+$ wave implies that the concentration of free Q is close to zero in the vicinity of the electrode surface. Quinone solutions containing a large excess of QH_2 do exhibit a wave in the potential region where wave

III is observed. This process is thought to occur according to Eq. [10] and is discussed below.

Reduction of the hemiketal species, $(QH)_2$, formed in Eq. [8] is an interesting possibility for wave III.



$$+ 2H^+ + 2e^- \rightarrow 2QH_2 \qquad [11]$$

Reduction of duroquinone dimethyl ketal in aqueous solutions occurs at more positive potentials than reduction of duroquinone at the same *p*H (35). Hemiketals would be expected to behave similarly and so the assignment of wave III, which is more positive than the quinone wave, to the hemiketal is reasonable.

The appearance of wave III at slower sweep rates in the presence of pyridine is consistent with an intermediate such as the hemiketal whose stability is dependent on the hydrogen ion activity. Invoking this species to explain wave III is also consistent with the behavior of different hydroquinones and the disappearance of the Q/H^+ wave in each case. Moreover its formation by dimerization of $QH\cdot$ is chemically straightforward, and the position (E_p) of the wave relative to the quinone wave is acceptable.

We have proposed that wave III might be due to reduction of quinhydrone on the grounds that in solutions containing 0.02*M* Q and an excess of QH_2, resulting in appreciable equilibrium concentration of quinhydrone, a wave is observed in the region of wave III (12). This suggestion also represents a "one-electron" intermediate state in the oxidation process and explains the decrease of the current function of wave I and the disappearance of the Q/H^+ wave. However, the bonding of quinhydrone in solution is primarily charge transfer in nature (36) and reduction of charge transfer complexes usually occurs at potentials more negative than the reduction potential of the acceptor molecule (37). On this basis alone, assignment of wave III to reduction of quinhydrone species is questionable. *In situ* spectrophotometric observation of the intermediates might permit a distinction to be made between these possibilities since the hemiketal should have a characteristic absorption in the 210 to 230 mμ region (35, 38).

Mechanism.—On the basis of the above discussion we propose the following mechanism for the oxidation of hydroquinones in acetonitrile at a platinum electrode (wave I)

$$QH_2 \rightleftharpoons QH_2^{+}\cdot + e^- \qquad [12a]$$

$$QH_2^{+}\cdot \longrightarrow QH\cdot + H^+ \qquad [12b]$$

$$2QH\cdot \xrightarrow{\text{fast}} (QH)_2 \qquad [12c]$$

$$(QH)_2 \xrightarrow{\text{slow}} Q + QH_2 \qquad [12d]$$

$$Q + H^+ \rightleftharpoons QH^+ \qquad [12e]$$

This mechanism explains the decrease of the current functions for wave I toward values of unity and the disappearance of the Q/H^+ wave. At short times the oxidation proceeds to the one-electron intermediate state, postulated to be $(QH)_2$.

Electrode surface effects.—Experiments were carried out in high concentrations of perchloric acid using both acetonitrile and nitromethane as a solvent in an unsuccessful attempt to detect the $QH_2^{+}\cdot$ or $DQH_2^{+}\cdot$ species by cyclic voltammetry. Occasionally a prominent cathodic wave was observed at +0.6 to +0.7V which could be ascribed to the reduction of a platinum oxide or a solution impurity.

In some experiments QH_2 and DQH_2 were oxidized on a "platinized platinum" surface, prepared by taking the electrode through an oxidation and reduction cycle for 10 min at 100 c/sec. Qualitatively the cyclic voltammograms are similar to those on "smooth" platinum, except that wave III is observed at slower sweep rates and the current function for wave II does not decrease until faster sweep rates. Similar behavior is observed on oxidized electrodes. Gentle polishing with 0.3μ lapping compound restores the electrode to its original activity.

The increase of wave II on a "platinized platinum" surface is difficult to explain in terms of Eq. [12] or any scheme ascribing wave III to an intermediate chemical species. Some chronocoulometric experiments were performed in an effort to detect adsorbed intermediates in the electrode process, but the data did not permit significant conclusions to be drawn. However, these results can be tentatively interpreted by suggesting that the reactions of $QH\cdot$ and $DQH\cdot$ (Eq. [12c]) are partly heterogeneous in nature. A more meaningful explanation awaits further experimental data and a better description of the oxidized electrode surface.

Other solvents.—Cyclic voltammograms of QH_2 were also obtained in dimethylsulfoxide and nitromethane. They are qualitatively similar to those in acetonitrile except that the peak potentials varied as shown in Table I. A detailed study at different sweep rates was made in nitromethane in which current function behavior similar to that in acetonitrile was observed.

Reduction of "quinhydrone solutions".—In low concentrations of quinhydrone the appearance of the cyclic voltammograms is that of a mixture of QH_2 and Q. The QH_2 acts to protonate $Q\cdot^-$ and to suppress the $Q\cdot^-/Q^{2-}$ couple to some extent. Esr indicates that $Q\cdot^-$ radical anions are present in the electrolysis solutions.

However, if the concentration of quinhydrone is sufficiently high, a wave is observed at *ca.* −0.3V. At slow sweep rates no Q reduction wave is observed between −0.5 and −0.6V. On the anodic cycle a broad wave is evident between +0.13 to +0.37V which can be assigned to oxidation of QH^-. No wave corresponding to $Q\cdot^-$ oxidation is seen. This behavior is shown in Fig. 7.

The solution chemistry is complicated in this case since the QH_2 molecule can function both as a donor molecule in a charge transfer complex and as a proton donor. The formation constant for the charge transfer complex between Q and QH_2 in acetonitrile is 0.083 ± 0.004 1 mole^{-1}. This was measured by following the charge transfer band at *ca.* 440 mμ and is in agreement with literature values for other nonaqueous solvents (39). Thus in concentrated quinhydrone solutions or in the presence of a large excess of QH_2 (0.5*M*) there exist an appreciable equilibrium concentration of the charge transfer complex. Assignment of the prewave at −0.3V to reduction of this quinhydrone species could explain the above observations. However, this is unlikely in view of the properties of quinhydrone in solution. The bonding in this species is primarily charge transfer in nature (36). In complexes of this type the acceptor molecule, Q, formally

accepts electronic charge from the donor molecule which will act to decrease the electron affinity of the acceptor and hence its reduction potential. This is the behavior Peover has observed with a series of strong acceptor molecules such as chloranil with hydrocarbon donor molecules (37). Thus the presence of a prewave in the concentrated quinhydrone solutions is more likely to be a result of the proton donor than the charge transfer properties of QH_2. This suggests that a protonation scheme such as Eq. [9] or [10] might be the basis for the prewave at −0.3V.

However there are several features of this reduction process which cannot be explained on the basis of simple schemes such as Eq. [9] and [10]. First, the shift of the prewave from the $Q/Q\cdot^-$ wave is *ca.* 0.25-0.3V which is greater than shifts observed in systems in which Eq. [9] is operative (40). Second, as the sweep rate increases the wave broadens considerably and the peak potential shifts to more negative potentials at *ca.* 0.1V per decade increase in the sweep rate. Even with 10:1 phenol to Q the shift of the prewave is *ca.* 0.18V and a similar shift of 0.1V per decade increase in sweep rate occurs. Little is known about the quantitative aspects of preprotonation behavior such as described by Eq. [10] apart from the brief mention by Peover (6). The properties of this wave are qualitatively similar to those of the previously mentioned duroquinone reduction wave in excess perchloric acid.

In addition the wave at −0.3V does not have the usual shape for a peak voltammogram as can be seen in Fig. 7. At slow sweep rates the *i-E* curve is almost a symmetrical bell curve on both mercury and platinum. Potentiostatic current-time curves also exhibit unusual behavior as the currents fall sharply to zero at long times. The peak current is not proportional to the concentration of Q in solution. A plot of peak current *vs.* concentration exhibits marked positive deviations from linearity at low concentrations. This behavior is to be contrasted with the Q-phenol mixtures which show diffusion controlled waves at all sweep rates. All these phenomena indicate that kinetic as well as adsorption effects are taking place to complicate the electrode process for the reduction of Q− QH_2 mixtures.

Conclusions

The principle mechanistic conclusions of this work are as follows.

1. In the presence of strong proton donors, Q is reduced in a two-electron process, probably *via* the protonated quinone, QH^+. The protonation equilibrium is fast on the time scale of the electrochemical experiment. The duroquinone system behaves in a similar manner, but the protonation of DQ appears to be slower than the protonation of Q.

2. Weak proton donors act to protonate the semiquinone, $Q\cdot^-$, which gives rise to the usual electrochemical protonation scheme first reported by Hoijtink (41). Hydroquinone, QH_2, appears to fall in this category, but the reduction mechanism in the presence of excess QH_2 is complicated and not completely understood.

3. The oxidation of hydroquinones in acetonitrile shows two-electron character at long times but one-electron character at short times when it is postulated to proceed *via* a dimer of $QH\cdot$ which may be a quinone hemiketal.

The Anodic Behavior of Zinc Electrodes in Potassium Hydroxide Electrolytes

M. N. Hull,* J. E. Ellison, and J. E. Toni*

Power Sources Division, Electronic Components Laboratory, U. S. Army Electronics Command, Fort Monmouth, New Jersey

ABSTRACT

The electrochemical oxidation of zinc anodes in potassium hydroxide solutions of 0.5-5.0M has been studied under stationary and hydrodynamic conditions. Linear sweep voltammetry and rotating ring-disk electrode techniques were employed to elucidate the different processes involved in the electrode reaction. Two different surface films are formed on zinc anodes. The first of these causes a small retardation in the rate of dissolution of the electrode in the active region while the second causes passivation. Measurements with rotating ring-disk arrangements indicate that the "dissolution-precipitation" model for the formation of these films may not be correct. The majority of the current passed in those regions where the surface is covered by a film is utilized in direct electrochemical oxidation of the zinc to soluble products and not in processes associated with thickening of the surface layer.

Many previous studies of the anodic behavior of zinc electrodes in alkaline electrolytes have reported the existence of both passivating and nonpassivating films on the electrode surface during electrolysis (1-11). These films have been reported as having a range of colors varying from extremely black (4, 5) in some cases to very white in others (6). It appears, however, that apart from the work of Breiter and Powers (1) and Powers (2), no firm correlation between the effect of these films on the current-voltage (i-v) curves for zinc dissolution, their color, and the nature and convective conditions of the electrolyte has yet been reported. Indeed relatively few studies have been reported of the i-v behavior of zinc anodes recorded under potentiostatic conditions and in these no systematic study of the dissolution process at different scan rates was conducted. In addition, there appears to be no general agreement between different workers as to the exact form of these i-v curves, primarily due to the differing and in some cases, ill-defined convective conditions employed in each case. Thus, Vozdvizhenskii and Kochman (3) reported two peaks in the i-v curves recorded in 2 and 5M KOH solutions before passivation whose relative heights depended on the scan rate (not given) which was employed. These peaks were believed to reflect the formation of two oxides which differed in their degree of hydration, solubility and rate of formation. Again, Breiter and Powers (1) observed distinctly different i-v curves recorded at scan rates of approximately 1.0 mV.sec^{-1} depending on the convective conditions of the 7M KOH solution which they used. Under quiescent conditions the current rose to a peak at -1.27V (Hg-HgO) with increasing anodic voltage and then passed through a small "hump" before the onset of passivity at ~ -1.0V. In stirred solution the current initially rose fairly rapidly to the same potential at which the peak was observed in the unstirred case and from there continued to rise until passivation occurred but with a greatly reduced slope. Elder (12), who also studied the dissolution of zinc in unstirred 7M KOH solution, found that at a scan rate of 2.8 mV.sec^{-1} the current passed through a small peak at -1.12V and then commenced to rise again just before the onset of passivation. The peak potential and current were found to obey the relationship

$$E_p = -0.701 + 0.5246 \log i_p$$

for scan rates within the range 0.56-139.0 mV.sec^{-1}. In contrast, Ashton and Hepworth (10) observed no peaks in the i-v curves recorded in 0.5N NaOH although it is not clear from their work exactly what stirring conditions, if any, were employed. In this case the current rose to a limiting value which was maintained with increasing anodic potential until passivation.

It is therefore evident from the above examples that the i-v behavior of zinc anodes in alkaline electrolytes is very unclear and therefore merits reinvestigation under more clearly defined conditions with regard to both the stirring of the electrolyte and the concentration. In the following work the i-v behavior of zinc wire electrodes in various concentrations of KOH solu-

* Electrochemical Society Active Member.

tions has been studied by the technique of linear sweep voltammetry as a function of both the stirring conditions in the electrolyte and the scan rate. In addition visual observations concerning the nature and color of the various films formed on the surface were made and correlated with the form of the i-v curves recorded at the slower scan rates.

With a knowledge of the general patterns of behavior of the i-v curves and their dependence on both the stirring conditions and the presence or absence of surface films, the dissolution process was further studied using the rotating ring-disk technique which has given added insight into the over-all dissolution process under even more rigorously defined mass transfer conditions. Although this technique would appear to be admirably suited for this type of study only the Russian school appears to have attempted any measurements along these lines. For example, Popova *et al.* (7, 13, 14) have studied the anodic dissolution of passivated zinc anodes by the rotating disk technique but have shed little light on the behavior of zinc anodes during the "active" region of the dissolution process. However, from the i-v curves which they have published one can see that the current rise prior to the onset of passivation did exhibit two distinct regions of differing slope in qualitative agreement with the work of Breiter mentioned above. With regard to the use of a rotating ring-disk arrangement to study the anodic dissolution of zinc, the work of Oshe *et al.* (15) appears to be the only investigation reported to date. No conclusions were drawn from this work concerning the mechanism of the dissolution of zinc, but the results did suggest that in the passive region the nonstationary flow of current caused by a step change in the electrode potential arises from an additional electrochemical dissolution of the zinc and not from processes involved with thickening of the oxide layer.

Preliminary observations are therefore also presented here of sweep measurements obtained with a zinc disk electrode surrounded by either a graphite or a zinc ring, the potential of which was held at a sufficiently cathodic potential that all of the oxidized species transported to the ring were immediately reduced. Some postulations concerning the factors which influence the over-all dissolution process are presented from these two types of study.

Experimental Procedure

The electrical arrangement which was used to obtain the i-v curves with wire electrodes is shown in Fig. 1a. In this the triangular voltage signal was supplied from a Tacussel GSTP-2 function generator to the input of a Tacussel PRT potentiostat and was used to drive the Y-axis of a 564 Tektronix memory oscilloscope which was operated in the X-Y mode. The current flowing through the cell was measured differentially across a resistor in the counterelectrode circuit and was recorded on the X-axis of the oscilloscope.

For measurements with the ring-disk arrangement the circuitry shown in Fig. 1b was used. Since it is not possible to operate two independent electrodes connected to the same ground, *i.e.*, the ring and the disk, at different potentials with respect to a reference electrode, the potentiostats were operated in the reverse mode to that shown in Fig. 1a. In this a large platinum gauze electrode was used as a common counterelectrode for both the ring and the disk and this was connected to "ground." This electrode was polarized cathodically from a second platinum gauze electrode (not shown) to the point of hydrogen evolution and under these conditions maintained a relatively stable potential (±5 mV) as current was passed through it to the ring and the disk. The stability of this electrode was constantly monitored with respect to a Hg-HgO reference electrode. The ring and the disk were connected to the control terminals of separate potentiostats operated in the follower mode and could be held at different fixed potentials or scanned independently with respect to the platinum gauze electrode held at ground potential. A complete discussion of this electrical circuit will be published elsewhere (16). In the experiments described here the ring was held at a fixed potential while the disk was anodically polarized at a scan rate of 10 mV.sec^{-1}. Two memory oscilloscopes, operated in the X-Y mode, were used to record independently the ring and the disk current each as a function of the disk electrode potential. Simultaneously during the potential sweep the collection efficiency N was obtained from a trace of the ring current as a function of the disk current recorded on a Honeywell 550 X-Y plotter.

In the experiments with wire electrodes zinc wire of 99.9999% purity and of 0.076 cm diameter was used. The electrode was sheathed in heat shrinkable Teflon tubing to leave an area of 0.05 cm^2 exposed to the electrolyte. Before a sweep was performed the electrode was pretreated by stepping to a potential of 1.0V positive to the open-circuit rest potential for a period of 1.0 msec. This procedure produced an oxide film on the electrode surface which was then dissolved off when the potential was stepped back to the open-circuit value. The sweep was initiated after the current had decayed to zero (approximately 5 msec.).

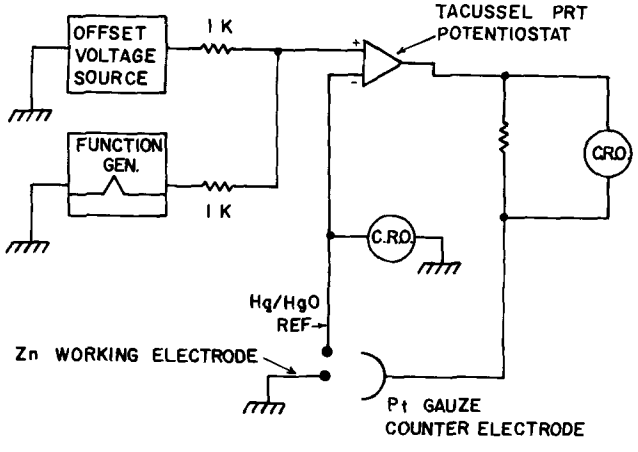

Fig. 1a. Electrical circuitry used for experiments with wire electrodes.

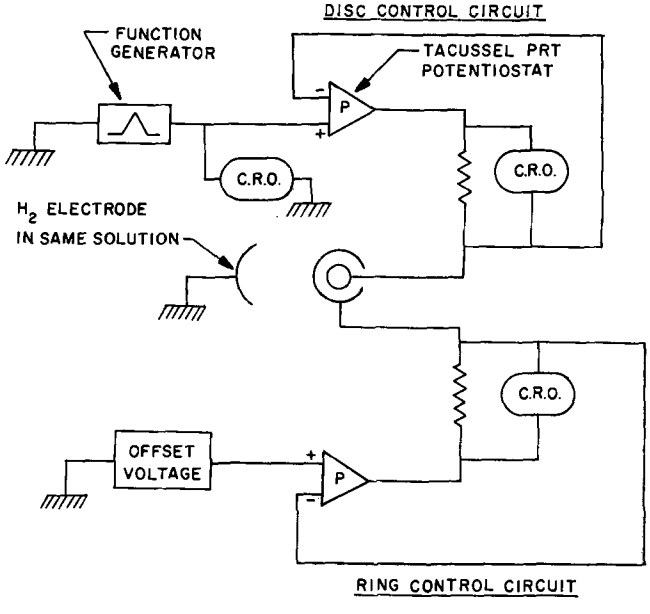

Fig. 1b. Electrical circuitry used for rotating ring-disk experiments.

In the ring-disk experiments two all-Teflon electrode configurations were used. In the first of these a zinc disk (99.99%) was surrounded by a pyrolytic graphite ring and had the dimensions $r_1 = 1.05$, $r_2 = 1.40$, $r_3 = 3.20$ mm ($N = 0.653$). In the second a zinc disk-zinc ring arrangement was used of dimensions $r_1 = 2.55$, $r_2 = 3.30$, and $r_3 = 3.78$ mm ($N = 0.248$). The electrodes were rotated at rates between 50-5000 rpm by means of a servoregulated motor supplied by Electro Devices Inc., and the rotation speed was accurately measured with a General Radio 1153-AP digital frequency meter.

The electrolyte was prepared by dissolving the required weight of Merck reagent KOH pellets in nitrogen-saturated doubly distilled water and was contained in an all-Teflon cell which had provision for the bubbling of nitrogen gas either through or over the electrolyte. Observation of the zinc wire electrodes was performed by means of a Western Electric Laboratory microscope having a maximum magnification of 100 times.

Results

Figure 2 shows the i-v behavior of a zinc electrode in unstirred 5*N* KOH recorded at scan rates of 12.5 and 130.0 V.sec^{-1}. At these sweep rates the form of the curves are independent of the convective conditions in the electrolyte and only one peak is observed on the forward sweep before the onset of passivation. Generally the potential of passivation shifts to more anodic values as the scan rate is increased until eventually at scan rates of the order of several hundred volts per second the point of passivation merges with the current rise associated with the onset of oxygen evolution. Concurrently with the increase in scan rate the total charge passed during the region of active dissolution falls to a minimum value of approximately 20.0 millicoulombs/cm^2 (geometrical area) for scan rates in excess of 500 V.sec^{-1}. Assuming that all of the zinc which is oxidized is utilized as ZnO in passivation of the electrode, then this charge would correspond to an oxide thickness of the order of 70 atomic layers.

At decreasing scan rates the i-v curves begin to show much more detail, and the influence of the stirring conditions in the electrolyte on the form of the curves becomes more pronounced. In Fig. 3 the i-v curves recorded at a scan rate of 82.0 mV.sec^{-1} in both stirred and unstirred 5*N* KOH are shown. The general behavior is that the dissolution current rises steadily with increasing anodic potential to a peak value whose magnitude is strongly dependent on both the electrolyte concentration and the stirring conditions in the electrolyte. After passing through this

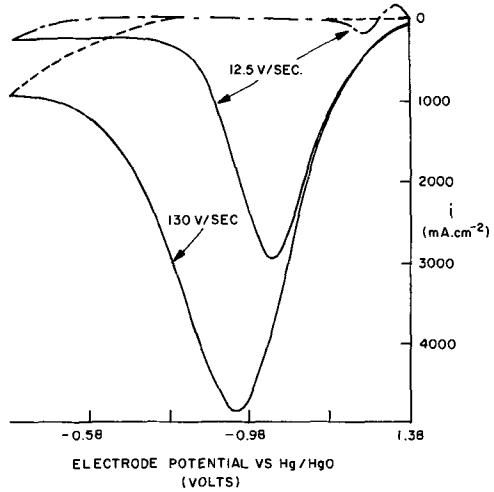

Fig. 2. Current-voltage curves of a zinc wire electrode in unstirred 5*N* KOH at scan rates of 12.5 and 130.0 V.sec^{-1}.

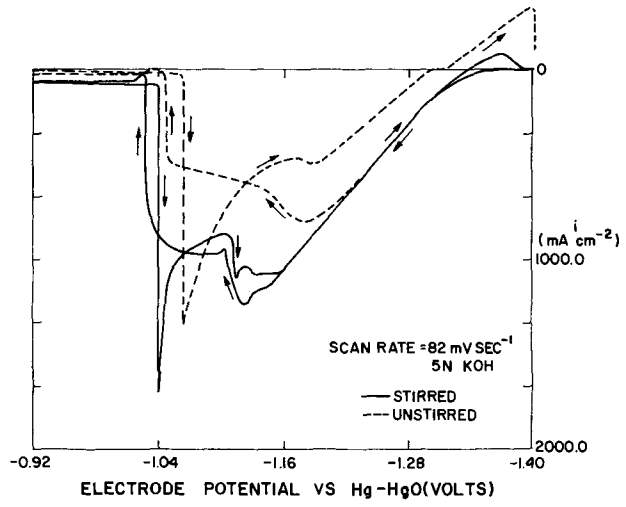

Fig. 3. Current-voltage curves of a zinc wire electrode in both stirred and unstirred 5*N* KOH recorded at a scan rate of 82.0 mV.sec^{-1}.

peak the current is fairly constant in the stirred electrolyte but falls off slowly in unstirred electrolyte until complete passivation occurs at approximately −1.04V.

The reverse sweeps show that the increased rate of chemical dissolution of the passivating film in the stirred electrolyte causes reactivation of the electrode to occur at a more anodic potential than for the unstirred case. Apart from this the general form of the reverse curves are quite similar in that the current falls from the relatively high values attained immediately after reactivation to pass once more through a well-defined peak in the same potential region as that observed during the forward sweep. Near the end of the reverse sweep a broad region is observed where dissolution products remaining close to the electrode surface are reduced.

Interesting changes in the form of these curves take place as both the electrolyte concentration and the sweep rate are decreased. For example, in Fig. 4 the i-v curves recorded at the same scan rate but in 1*N* KOH are shown. One can see as before that in both cases the current rises to a well-defined peak. However, in the stirred electrolyte the current undergoes a further increase in the potential region between that of the peak and the onset of passivity while the slow fall observed in this potential region for the unstirred 5*N* KOH case is less pronounced. In addition the reverse sweeps show that with the decrease in the electrolyte concentration from that shown in the previous figure the rate of dissolution of the passivating film has also decreased and the potential of reactivation

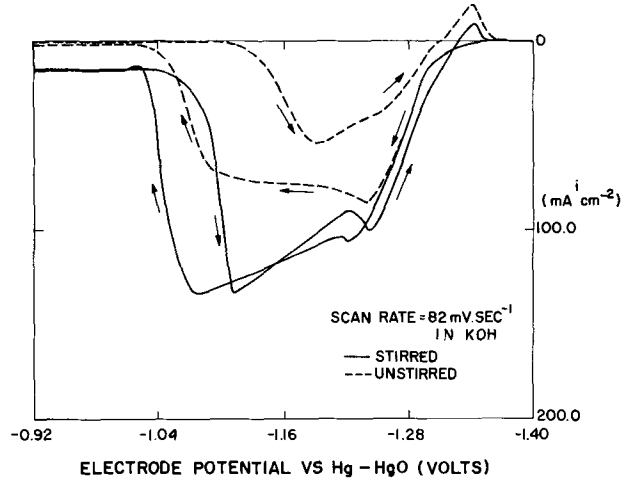

Fig. 4. Current-voltage curves of a zinc wire electrode in both stirred and unstirred 1*N* KOH (scan rate as in Fig. 3).

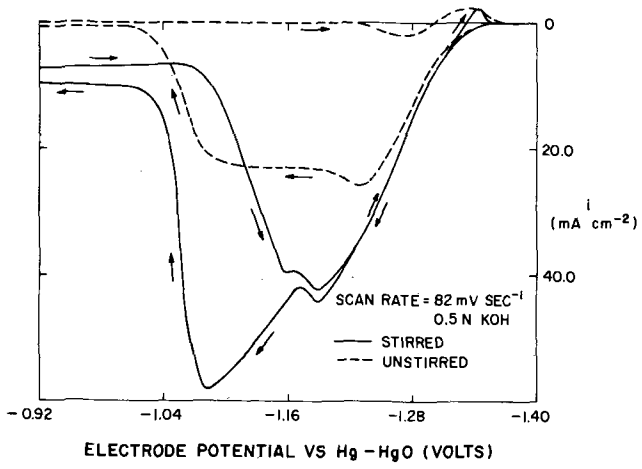

Fig. 5. Current-voltage curves of a zinc wire electrode in both stirred and unstirred 0.5*N* KOH (scan rate as in Fig. 3 and 4).

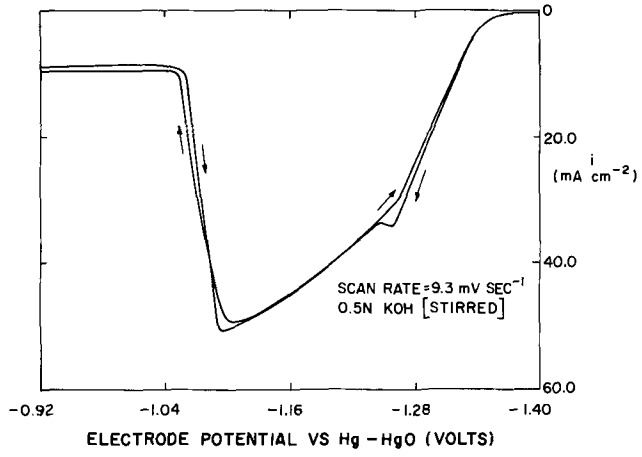

Fig. 8. Current-voltage curve of a zinc wire electrode in stirred 0.5*N* KOH (scan rate as in Fig. 6 and 7).

has therefore moved to more cathodic values particularly in the case of the unstirred electrolyte. These trends are illustrated to a more marked degree in the i-v curves for 0.5*N* KOH shown in Fig. 5. Here the current rise after the peak is now very pronounced in the stirred case and little or no reactivation of the electrode is observed in the time required for completion of the reverse sweep.

Figures 6 to 8 which show the anodic behavior of zinc in these same three concentrations of KOH electrolyte but at the slower scan rate of 9.3 mV.sec^{-1} reveal several additional details. In the 5*N* KOH case shown in Fig. 6 current oscillations are observed to be

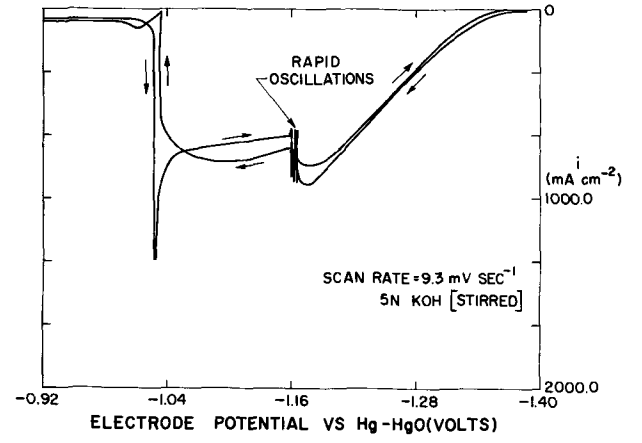

Fig. 6. Current-voltage curve of a zinc wire electrode in stirred 5*N* KOH recorded at a scan rate of 9.3 mV/sec^{-1}.

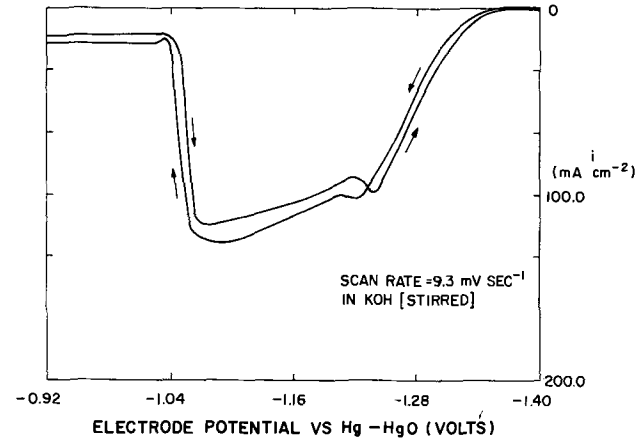

Fig. 7. Current-voltage curve of a zinc wire electrode in stirred 1*N* KOH (scan rate as in Fig. 6).

associated with the peak in both the forward and reverse sweeps in stirred electrolyte while after passivation has occurred the current passes through another small peak before levelling off at a slowly rising value of the dissolution current. In the 1*N* and 0.5*N* KOH electrolytes at this scan rate (Fig. 7 and 8) it is evident that this peak behavior after passivation is less pronounced in the weaker electrolyte.

Figure 9 shows an i-v curve recorded at a scan rate of 1.1 mV.sec^{-1} in unstirred 5*N* KOH and summarizes our observations concerning film formation during the over-all dissolution process. At potentials less anodic than that of the peak (point B) the surface of the electrode remains bright and the development of etch patterns are clearly visible. At B a milky white film forms which in the absence of stirring slowly flakes from the electrode surface in the region C-D. At point D, as the current begins to fall, the surface beneath this film can be observed to be growing dark in color until, after passing through a region of intense current oscillation, the passivated surface at F is very black. This black film however undergoes a rapid lightening of color in the region of the small current peak (FGH) to leave the surface covered by a white crystalline passivating layer. Moreover, this latter color change appears to be somewhat of a reversible process since on the reverse sweep in the region J-K, just prior to complete reactivation of the electrode, the light colored coating begins to darken again and at *K*, where the surface is a mixture of light and dark areas, the current oscillates once more between the active and passive states. Eventually, when a stable current state is attained at *L*, the electrode is wholly covered

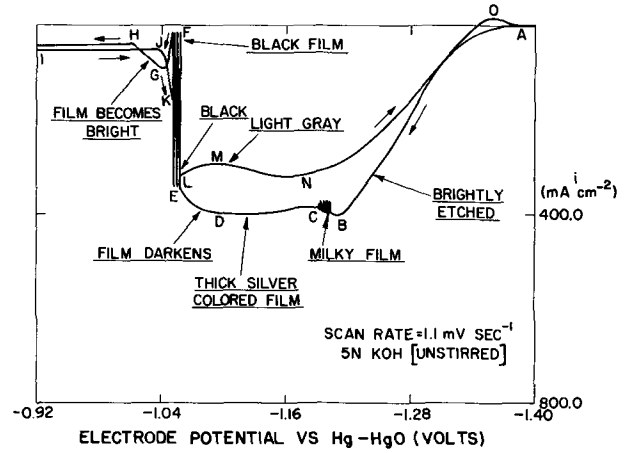

Fig. 9. Current-voltage curve of a zinc wire electrode in unstirred 5*N* KOH recorded at a scan rate of 1.1 mV.sec^{-1}.

by a very black film which now permits active dissolution of the electrode to proceed. This film in the region L-M undergoes another gradual lightening in color to leave the electrode surface with a similar appearance to that observed in the same potential region on the forward sweep.

Using a rotating ring-disk electrode (C-Zn) the i-v curves shown in Fig. 10a were recorded at three different rotation speeds for a scan rate of 10.0 mV.sec^{-1}. The corresponding curves shown in Fig. 10b refer to the reduction current observed at the ring as a function of the disk potential while the ring was maintained at a fixed potential of −1.45V (Hg-HgO), *i.e.*, at a sufficiently cathodic potential to immediately reduce those oxidized zinc species which are swept over from the disk. In general the form of the i-v curves observed at both the ring and the disk are extremely similar if care is taken to maintain reproducible conditions on the surface of the ring by mechanically cleaning off the deposited layer after each sweep. In addition the peak potential is independent of the rotation rate and occurs at a value of −1.2V for a scan rate of 10 mV.sec^{-1}.

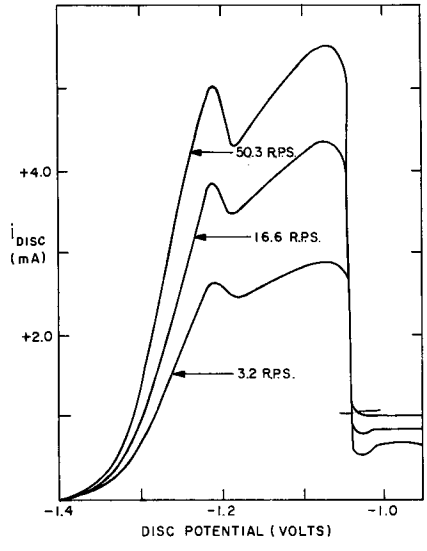

Fig. 10a. Current-voltage curves recorded on the disk of a C-Zn ring-disk electrode at different rotation rates. Scan rate = 10 mV.sec^{-1}; 1*N* KOH; electrode area = 0.035 cm^2.

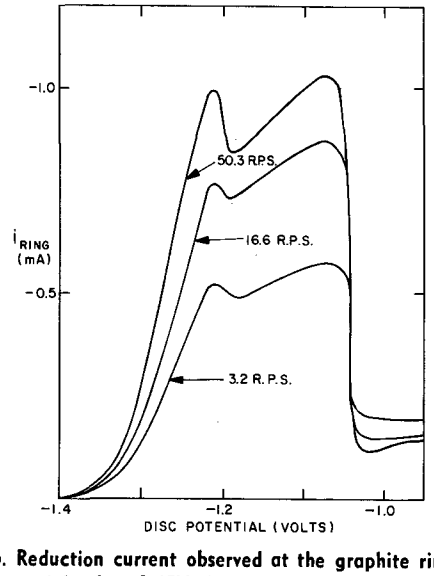

Fig. 10b. Reduction current observed at the graphite ring held at a fixed potential of −1.45V (Hg-HgO) for the current-voltage curves shown in Fig. 10a.

As the rotation rate is increased one can see from the figure that the slope of the i-v curve between the peak and the onset of passivation becomes greater and that the small current peak after passivation disappears. The observed collection efficiency *N* for the two ring-disk systems employed is constant for all regions of the i-v curves, *i.e.*, there is no change in this parameter when measured before the peak, between the peak and the onset of passivity or in that region where the electrode is in a passivated state.

In order to test whether the dissolution process was diffusion controlled for any particular set of experimental conditions, plots of the peak current and also the maximum current observed just prior to the passivation were drawn as a function of the square root of the rotation speed for a fixed scan rate. No significant regions of linearity were observed as is illustrated in Fig. 11 where a plot of the peak current as a function of $\omega^{1/2}$ is drawn. At rotation rates below approximately 600 rpm a straight line is observed which could be indicative of mass transfer control although the linear portion has a positive intercept on the current axis instead of passing through zero as required by the Levich (17) equation. Deviations such as this from the Levich equation have been observed before for other diffusion-controlled reactions at a rotating disk and have been fully discussed by Riddiford (18). It seems clear however that with increasing rotation speed diffusion control of the over-all reaction becomes increasingly less important.

Discussion

The preceding results show clearly that the i-v curves of zinc electrodes in KOH solutions are strongly dependent on the convective conditions in the electrolyte. It is quite evident however that there is only one main peak in both the forward and reverse curves although an additional small broad peak may be identified on the forward sweep immediately following the onset of passivation, particularly in the more concentrated and unstirred solutions. Prior to the peak potential in the active region there does not appear to be any visible films on the electrode surface, and thus unhindered dissolution of the zinc anode occurs. At the peak, however, the dissolution process becomes retarded by the formation of a film on the surface which acts as a barrier layer to either the passage of zinc species from the electrode to the solution or conversely the approach of additional hydroxyl ion species to the unoxidized surface. This barrier layer, which according to Nikitina (8) has the chemical composition of ϵ-$Zn(OH)_2$, is probably formed by the adsorption of the electrolyte anions at the peak potential (19) rather than by a precipitation process from zincate saturated layers adjacent to the electrode surface

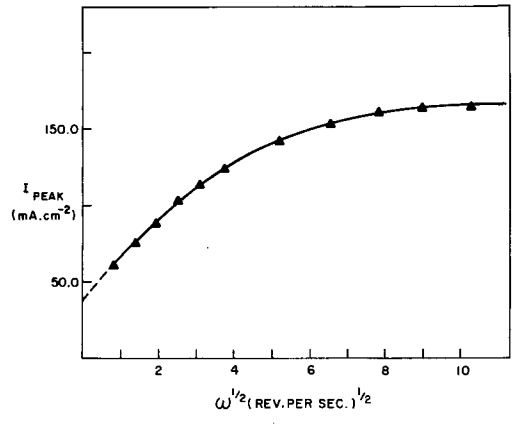

Fig. 11. Plot of the peak current observed at a rotating zinc disk electrode in 1*N* KOH as a function of the square root of the rotation rate.

as suggested before (1). If indeed the previously suggested "dissolution-precipitation model" were valid for the film formation at this point then one would be obliged to explain the further increase in the dissolution current at potentials more positive than that of the peak in terms of thickening of the surface film accompanied by its chemical dissolution at a rate limited by the diffusion of zincate ions away from the electrode surface. In addition one would not expect the current on the ring to undergo any further increase after the peak potential was reached on the disk if the limiting rate of diffusion of zincate ions into the solution had been reached at that point. The evidence is, therefore, that the film of zinc hydroxide is directly formed on the zinc surface once a certain critical potential is exceeded and further dissolution of the electrode is then determined by the thickness and hence by the rate at which transport processes can occur within this layer. One might expect that the layer thickness would be determined by the stirring conditions in the electrode vicinity and in the case of, for example, the rotating disk experiments that the thickness would decrease with increase in the rate of rotation. These conclusions are in agreement with the experimental observations since the slope of the i-v curve in the region between the peak and the onset of passivation increases with increase in the rotation rate reflecting a decrease in the resistance and hence a decrease in the thickness of the film. Further support for these views is found in the lack of linearity of the plots of the peak current *vs.* $\omega^{1/2}$ at rotation rates in excess of 600 rpm. At rotation rates below this value it could be advanced that the thickness of the diffusion layer is such that transport of the zincate species away from the electrode surface is the controlling process. However it is quite evident from the approach of the peak current to a limiting value at higher rotation speeds that the rate-controlling step under these conditions is occurring prior to the diffusive transport of the zincate product into the bulk of the electrolyte. This rate-controlling step is most probably associated with the transport of ions across the surface film under the action of the local electrical field existing across the film between the metal surface and the electrolyte.

At the onset of passivation a definite change on the electrode surface occurs. The sudden drop in the oxidation current with the observed visible changes in the color of the surface film within a narrow and well-defined range of electrode potential is indicative of a sharp change in the nature and conductivity of this layer. This change reflects a change in the composition of the film from that of the hydroxide to that of the oxide. Since, prior to the onset of passivation, it is quite probable that the zinc surface is covered by an adsorbed layer of hydroxide ions, one could postulate that formation of the initial monomolecular layer of oxide on the surface proceeds by a deprotonation reaction accompanied by the formation of water according to

$$Zn(OH^-)_{ads} \rightleftarrows ZnO + H^+ + 2e^-$$
$$H^+ + OH^- \rightarrow H_2O$$

The above reaction sequence can explain the presence of the intense oscillations of the current in this region of the i-v curve at slow scan rates since as the passivation reaction tends to proceed the resulting decrease in the pH of the solution layers adjacent to the electrode surface tends to drive the thermodynamic potential at which the passivating oxide is stable toward more positive values. Attainment of a stable passive state therefore is not reached until a sufficiently anodic potential is achieved that the local pH change in the electrode vicinity does not reverse the passivation step. It is also quite likely that during this region of current oscillation the electrode surface becomes disrupted with the result that a high concentration of interstitial zinc particles become incorporated into the passivating layer and impart to it the characteristic black coloration. That this black surface film does indeed contain an excess of zinc above that of stoichiometrically balanced zinc oxide is borne out by the subsequent electrode behavior after passivation where the current passes through a small oxidation peak (region FGH of Fig. 9) and the film then becomes bright. It is not evident however how the oxide film on the return sweep can again become rich in zinc prior to reactivation of the electrode assuming that the black film formed in this region is indeed one which is rich in zinc. In addition it is also not clear why this black film should permit the metal to dissolve actively after reactivation unless its mode of formation is such that a more porous layer is produced on the surface compared to that formed during the passivation step.

Finally, the constancy of the collection efficiency N over the whole of the i-v curve indicates that the fraction of the current which is utilized in formation of the surface films at either the peak potential or during the onset of passivity is so small that there is no detectable fall in the amount of the reducible species arriving at the ring. Further, one would have expected that, as the applied field across each of the surface films was increased by the increasing anodic voltage, the films would undergo a corresponding gradual increase in thickness. Again the constancy of N between those potential regions where the surface is free of films and those where films are present shows that if, indeed such thickening of the surface layers does occur, it cannot be detected from measurements of this type. Thus the majority of the current produced at the disk for all regions of the i-v curves is utilized in direct electrochemical oxidation of the zinc to soluble products.

During the review stage of the manuscript one of the reviewers questioned the low value of 0.2 for the collection efficiency when the graphite-zinc arrangement was used ($N_{theor} = 0.653$). Since the time we did the experiments reported here we have been able to achieve values very close to the theoretical collection efficiency using much narrower gaps and rings than those reported above. We found that with graphite rings all of the zinc was deposited on the inner circumference of the ring if the gap was very wide and low values of N were obtained. We are now using very thin gaps and rings and the observed values of N come out close to the expected value. We shall be reporting this in more detail in a later publication. The main point is, however, not that N has a low value but that it is constant throughout the whole of the active region of dissolution. Out latest experiments with the redesigned electrode configuration confirm this constancy of N for unamalgamated zinc disk electrodes surrounded by either a graphite or an amalgamated (and nonamalgamated) zinc ring.

Manuscript submitted July 8, 1969; revised manuscript received Sept. 23, 1969. This was Paper 239 presented in part at the New York Meeting of the Society, May 4-9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

Frequency Dispersion in Capacity Measurements at a Disk Electrode

John Newman

Inorganic Materials Research Division, Lawrence Radiation Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California

ABSTRACT

The geometry of an electrode system affects the frequency dispersion of impedance measurements if the primary current distribution on the electrode is nonuniform. This effect is treated for a disk electrode embedded in an insulating plane with the counterelectrode at infinity. The apparent capacity is found to approach zero at large frequencies. The frequency dependence of the apparent capacity will be much smaller for a spherical electrode tangent to an insulating plane. The latter system is also treated briefly.

We investigate here the alternating-current impedance of a disk electrode embedded in an infinite, insulating plane, with the counterelectrode at infinity. The distribution of current over the surface of such a disk electrode is, in general, nonuniform. Figure 1 depicts equipotential surfaces in the medium near a disk, where the solution adjacent to the disk electrode is at a uniform potential; this is the so-called "primary potential distribution," for which the distribution of current on the surface of the disk is given by (1)

$$i = 0.5\, i_{avg}/[1 - (r/r_0)^2]^{1/2} \qquad [1]$$

With an alternating current, the current can pass from the electrode to the solution either by means of a faradaic electrode reaction or by charging the double-layer capacity. Attention here is primarily focused on the double-layer capacity. The impedance can then be represented by an equivalent circuit consisting of a series combination of a resistor and a capacitor (Fig. 2). However, the values of the effective resistance and double-layer capacity of the equivalent circuit are not independent of frequency. Several factors may contribute to this "frequency dispersion."

If the electrode surface is rough, the peaks and valleys will be accessible to a different degree at different frequencies (2). Second, if the frequency becomes large relative to the kinetics of ion sorption in the double layer, then the apparent double-layer capacity will depend on frequency (3). The occurrence of faradaic reactions will also cause a frequency dependence of the values in the equivalent circuit in Fig. 2. Finally, the current distribution will be different at different frequencies, and this will lead to a frequency dispersion, as suggested by Bauer, Spritzer, and Elving (4).

The last factor is investigated theoretically here in order that an experimentally observed frequency dispersion due to this factor will not be erroneously attributed to one of the first factors mentioned. Consequently, the electrode surface is taken here to be smooth, and the true double-layer capacity (per unit area) C is taken to be independent of frequency. Except for large organic ions, the kinetics of ion sorption should not affect the double-layer capacity until frequencies of 1 Mc are reached. The possibility of faradaic reactions will also be included, without, however, consideration of the Warburg impedance due to concentration changes near the electrode.

At low frequencies, the reactive impedance of the double layer predominates over the resistive impedance of the electrolytic solution. Consequently, the current distribution is uniform over the surface of the

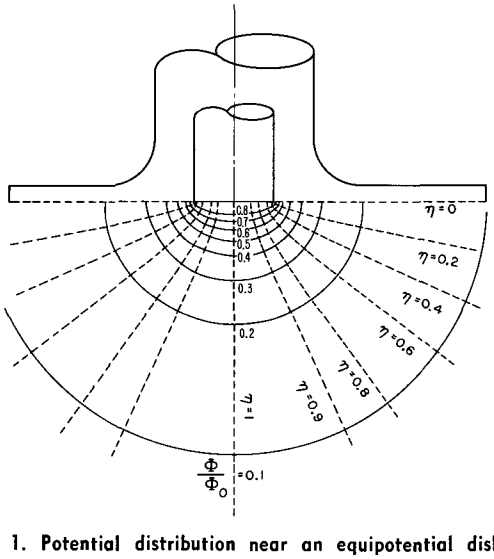

Fig. 1. Potential distribution near an equipotential disk in an insulating plane.

Key words: frequency dispersion, double-layer capacity, current distribution, disk electrode, dropping mercury electrode, polarography.

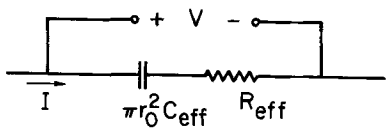

Fig. 2. Equivalent circuit of disk system. Here, C_{eff} and R_{eff} can be regarded as the apparent double layer capacity and the apparent resistance of the electrolytic solution, if faradaic reactions are of negligible importance.

disk, and C_{eff} corresponds to the true double-layer capacity. At high frequencies, the reactive impedance becomes small, and the primary current distribution is a good approximation. Hence, the effective resistance approaches the value for the primary distribution (1)

$$R_{eff} \to 1/4\, r_o\, \kappa \text{ as } \omega \to \infty \qquad [2]$$

As we shall see, C_{eff} approaches zero at high frequencies, in marked contrast to the situation at a hanging mercury drop or dropping mercury electrode.

If, however, faradaic reactions can occur, the low-frequency limit will no longer yield the true double-layer capacity, since the reactive impedance is large compared to the faradaic impedance with which it is in parallel. Information about the true double-layer capacity can then be obtained only at intermediate frequencies with due allowance for the nonuniform current distribution.

For rough electrodes, the low-frequency limit will yield the true electrode area if the true double-layer capacity is known (in the absence of faradaic reactions). However, the determination of the true double-layer capacity from impedance measurements at higher frequencies will not be straightforward.

This investigation is also relevant to the frequency dependence of classical conductivity cells [see, for example, Robbins (5)].

Mathematical Model

The potential in the solution satisfies Laplace's equation

$$\nabla^2 \Phi = 0 \qquad [3]$$

The potential at infinity will be taken to be zero

$$\Phi \to 0 \text{ as } r^2 + z^2 \to \infty \qquad [4]$$

and, since the current density is zero on the insulating plane around the disk electrode, the normal component of the potential gradient will also be zero there

$$\partial\Phi/\partial z = 0 \text{ at } z = 0, r > r_o \qquad [5]$$

At the disk, the normal component of the current density, which contributes to the total current passing to the electrode, is given by

$$i = C\frac{\partial(V - \Phi_o)}{\partial t} + (\alpha + \beta)\frac{i_o ZF}{RT}(V - \Phi_o) = -\kappa\frac{\partial\Phi}{\partial z} \quad \text{at } z = 0, r \leq r_o \qquad [6]$$

where V is the potential of the electrode, Φ_o is the potential in the solution adjacent to the electrode, κ is the conductivity of the solution, C is the true double-layer capacity, and $(\alpha + \beta) i_o ZF/RT$ relates to the kinetics of the faradaic reaction, here taken to be linear. Thus double-layer charging and a faradaic reaction can both contribute to the passage of current from the electrode to the solution. The last equality relates the current density to the normal component of the potential gradient in the solution.

For an alternating current, the electrode potential can be expressed as[1]

$$V = V_o e^{j\omega t} \qquad [7]$$

where V_o is the amplitude of the applied potential. Correspondingly, the potential in the solution can be expressed in terms of a complex potential U which is independent of time

$$\Phi = V_o e^{j\omega t} U(r,z) \qquad [8]$$

The results of the analysis can be expressed in terms of two dimensionless quantities

$$\Omega = \frac{\omega C r_o}{\kappa} \quad \text{and} \quad J = (\alpha + \beta)\frac{i_o ZF r_o}{RT\kappa} \qquad [9]$$

Ω can be regarded as a dimensionless frequency and J as a dimensionless exchange current density. $\Omega = 1$ when, for example, $C = 30\ \mu f/cm^2$, $r_o = 0.25$ cm, $\kappa = 0.05$ (ohm-cm)$^{-1}$, and $\omega = 0.67 \times 10^4$ sec^{-1} (or 10,500 Hz). $J = 0.0194$ when, in addition, $i_o = 0.1$ mA/cm^2 and $(\alpha + \beta)Z = 1$. The results are expressed in terms of C/C_{eff}, the ratio of the true double-layer capacity to the apparent capacity, and $4r_o\kappa R_{eff}$, the ratio of the effective resistance to the resistance for the primary distribution (see Eq. [2]). At low frequencies, $C/C_{eff} \to 0$ unless $J = 0$, and, for small values of J, $4r_o\kappa R_{eff} \to (4/\pi)(1 + 1/J)$.

The secondary current distribution, when $\Omega = 0$, has been discussed before (6).

Analysis

Since Φ satisfies Laplace's equation, U also satisfies Laplace's equation. In rotational elliptic coördinates η and ξ, the solution satisfying the condition at infinity and the condition on the insulating part of the disk can be expressed as (6)

$$U = \sum_{n=0}^{\infty} B_n P_{2n}(\eta) M_{2n}(\xi) \qquad [10]$$

where $P_{2n}(\eta)$ is the Legendre polynomial of order $2n$ and $M_{2n}(\xi)$ is a Legendre function with known properties (6). Since a similar development has recently been used to treat the current distribution on a rotating disk electrode below the limiting current (6), these mathematical details will not be repeated here. In the present case, the coefficients B_n will be complex.

This solution allows the potential and the potential derivative near the electrode to be expressed as

$$U_o = \sum_{n=0}^{\infty} B_n P_{2n}(\eta) \qquad [11]$$

and

$$\left.\frac{\partial U}{\partial z}\right|_{z=0} = \frac{1}{r_o\eta}\left.\frac{\partial U}{\partial \xi}\right|_{\xi=0} = \frac{1}{r_o\eta}\sum_{n=0}^{\infty} B_n P_{2n}(\eta) M'_{2n}(0) \qquad [12]$$

Substitution into the boundary condition [6] on the disk electrode gives

$$(j\Omega + J)\left[1 - \sum_{n=0}^{\infty} B_n P_{2n}(\eta)\right] = -\frac{1}{\eta}\sum_{n=0}^{\infty} B_n P_{2n}(\eta) M'_{2n}(0) \qquad [13]$$

where the dimensionless parameters Ω and J are given by Eq. [9].

This approach derives its economy from the fact that Eq. [10] is an appropriate solution of Laplace's equation. Hence, the problem of solving a partial differential equation is reduced to the determination of the coefficients B_n from Eq. [13]. Multiplication of this equation by $\eta P_{2m}(\eta)$ and integration with respect to η gives an infinite set of equations for this purpose

[1] Strictly speaking, one takes the real part of such complex expressions: $V = Re\{V_o e^{j\omega t}\} = V_o \cos(\omega t)$.

$$B_m = -\frac{4m+1}{M'_{2m}(0)}(j\Omega + J)\int_0^1 \eta P_{2m}(\eta)\left[1 - \sum_{n=0}^{\infty} B_n P_{2n}(\eta)\right] d\eta \quad [14]$$

One can truncate this set of equations by carrying only a finite number of terms in the sum in the integrand. Higher accuracy can, of course, be obtained by carrying more terms.

After the coefficients B_n have been obtained, one needs to calculate the impedance of the system. The total current is given by

$$I = \int_0^{r_0} i2\pi r dr = -2\pi r_0^2 \kappa \int_0^1 \eta \frac{\partial \Phi}{\partial z}\bigg|_{z=0} d\eta = -2\pi r_0 \kappa V_0 e^{j\omega t} B_0 M_0'(0) \quad [15]$$

where the change of variable from r to η is effected by means of the relation

$$r/r_0 = \sqrt{1-\eta^2} \text{ on the disk} \quad [16]$$

Since, furthermore, $M_0'(0) = -2/\pi$, the impedance is

$$Z = V/I = 1/4r_0\kappa B_0 \quad [17]$$

We wish to compare this with the impedance of the series resistor-capacitor combination given in Fig. 2 and supposed to represent the resistance of the solution and the capacity of the double layer. Thus

$$Z = R_{eff} + 1/j\omega C_{eff}\pi r_0^2 \quad [18]$$

Comparison with Eq. [17] allows us to determine R_{eff} and C_{eff} from calculated values of B_0

$$4r_0\,\kappa R_{eff} = B_{or}/(B^2_{or} + B^2_{oi}) \quad [19]$$

and

$$C/C_{eff} = (\pi/4)\Omega B_{oi}/(B^2_{or} + B^2_{oi}) \quad [20]$$

where B_{or} and B_{oi} represent the real and imaginary parts of B_0, respectively.

Results

Table I represents the effective resistance and capacity as a function of the dimensionless frequency Ω and for several values of J, the parameter describing the faradaic reactions. One sees that in the absence of faradaic reactions ($J = 0$) the effective resistance varies by only 8% from the high-frequency limit to the low-frequency limit. The effective capacity gives no high-frequency limit. The presence of faradaic reactions can change considerably the character of the impedance when interpreted in terms of the equivalent circuit of Fig. 2.

Low-Frequency Limit

In the absence of faradaic reactions one obtains at low frequencies a uniform, imaginary current density of small magnitude. As a first approximation

$$B_{ni} \to -\frac{\pi}{4}\frac{\Omega P^3_{2n}(0)}{(2n-1)(n+1)}(4n+1) \text{ as } \Omega \to 0 \quad [21]$$

In particular, $B_{oi} \to \pi\Omega/4$. The real components are of order Ω^2. In particular

$$B_{or} \to \frac{\pi^2}{4^2}\Omega^2 \sum_{n=0}^{\infty} \frac{(4n+1)P^4_{2n}(0)}{(2n-1)^2(n+1)^2} \quad [22]$$

Substitution of these results into Eq. [19] and [20] gives low-frequency limits for the effective resistance and capacity which agree with the appropriate entries in Table I.

High-Frequency Limit

At high frequencies, the surface potential U_0 becomes uniform and real. $B_{or} \to 1$, and $B_{nr} \to 0$ for $n \neq 0$. The imaginary components of the B coefficients are also small. However, the primary current distribution is infinite at the edge of the disk. This is not possible at finite frequencies on account of the impedance of the interface. Hence, a singular-perturbation problem is encountered. The situation is so severe that the value of B_{oi} cannot be determined in a straightforward manner.

Let us examine the singular nature of the problem. The primary potential distribution will be a valid approximation everywhere except in a small region near the edge of the disk. We use rotational elliptic coordinates (6) to investigate this region

$$r = r_0\sqrt{(1-\eta^2)(1+\xi^2)} \text{ and } z = r_0\eta\xi \quad [23]$$

Both ξ and η are small near the edge of the disk, and we can write

$$(r - r_0)/r_0 = \frac{1}{2}(\xi^2 - \eta^2) \text{ and } z/r_0 = \eta\xi \quad [24]$$

These coordinates thus reduce to parabolic coordinates in the region under consideration. (Because this region is small, results obtained for the potential distribution will also be valid near the edge of any electrode at high frequencies if the electrode is flush with an insulating surface at its edge.)

Near the edge of the disk the potential U therefore satisfies the equation

$$\frac{\partial^2 U}{\partial \eta^2} + \frac{\partial^2 U}{\partial \xi^2} = 0 \quad [25]$$

The boundary condition on the surface of the disk, $\xi = 0$, is

$$j\Omega(1 - U_0) = -\frac{1}{\eta}\frac{\partial U}{\partial \xi}\bigg|_{\xi=0} \quad [26]$$

Far from the disk, the potential approaches the primary distribution (1) as approximated for small ξ

$$U \to 1 - \frac{2}{\pi}\tan^{-1}\xi \approx 1 - \frac{2}{\pi}\xi \text{ as } \xi \to \infty \quad [27]$$

Furthermore, on the surface of the insulator

$$\partial U/\partial \eta = 0 \text{ at } \eta = 0 \quad [28]$$

By defining stretched variables as follows

$$\bar{U} = (1 - U)\frac{\pi}{2}\sqrt{\Omega}, \quad \bar{\eta} = \eta\sqrt{\Omega}, \quad \bar{\xi} = \xi\sqrt{\Omega} \quad [29]$$

the problem in the edge region can be made independent of the parameter Ω. The problem then becomes

$$\frac{\partial^2 \bar{U}}{\partial \bar{\eta}^2} + \frac{\partial^2 \bar{U}}{\partial \bar{\xi}^2} = 0 \quad [30]$$

$$j\bar{U}_0\bar{\eta} = \partial\bar{U}/\partial\bar{\xi} \text{ at } \bar{\xi} = 0 \quad [31]$$

$$\partial\bar{U}/\partial\bar{\eta} = 0 \text{ at } \bar{\eta} = 0 \quad [32]$$

$$\bar{U} \to \bar{\xi} \text{ as } \bar{\xi} \to \infty \quad [33]$$

From these results one can conclude that in the original coordinate system the size of this region is of order r_o/Ω, while $1 - U_o$ is of order $\Omega^{-1/2}$ and the (dimensionless) current density $j\Omega(1 - U_o)$ is of order $\Omega^{1/2}$.

The problem posed by Eq. [30] through [33] was solved by finite-difference methods by successive overrelaxation. The results for the surface potential $\bar{U}_o$, which is proportional to the current density, are given in Fig. 3. The current density approaches the primary distribution far from the edge of the disk, but it is more uniform in the edge region where the impedance of the interface prevents the current density from becoming infinite. However, the high currents predicted by the primary distribution are not prevented totally from reaching the disk; the current is just spread out over a larger region. The disturbance of the real component of the current density generates a comparable disturbance in the imaginary component.

The singular-perturbation treatment of the edge region at high frequencies permits these phenomena to be clarified in a definitive manner and permits an economy in the calculations by defining a problem in which no parameters appear. An accurate treatment of the edge region would otherwise require a very fine mesh if Laplace's equation were to be solved by finite-difference methods over the whole disk simultaneously.

As we have seen, the impedance of the system is tied up in the B_o coefficient. This coefficient can be expressed as

$$1 - B_o = \int_0^1 (1 - U_o)\, d\eta \quad [34]$$

and we know that $B_{or} \to 1$ as $\Omega \to \infty$. The primary distribution (see Eq. [1]), which applies over the central region of the disk, can be expressed as

$$1 - U_o = -2j/\pi\Omega\eta \quad [35]$$

We can obtain useful results by proceeding in the following manner. The imaginary part of Eq. [34] is

$$B_{oi} = -\int_0^1 (1 - U_o)_i d\eta = -\frac{2}{\pi\Omega}\int_0^{\sqrt{\Omega}} \bar{U}_{oi} d\bar{\eta} \quad [36]$$

where, in the last expression, we have used the variables appropriate to the edge region. We now break this up into several parts

$$B_{oi} = \frac{-2}{\pi\Omega}\left[\int_0^b \bar{U}_{oi} d\bar{\eta} + \int_b^{\sqrt{\Omega}} \left(\bar{U}_{oi} + \frac{1}{\eta}\right) d\bar{\eta} - \int_b^{\sqrt{\Omega}} \frac{1}{\bar{\eta}} d\bar{\eta}\right] \quad [37]$$

The last integral can be evaluated analytically. The next to the last integral has an upper limit which approaches infinity as $\Omega \to \infty$. Since $\bar{U}_{oi} \to -1/\bar{\eta}$ as $\bar{\eta} \to \infty$, it is permissible to set this limit equal to infinity.

Thus we obtain the following high-frequency limit for B_{oi}

$$B_{oi} = \frac{4A}{\pi\Omega} + \frac{\ln\Omega}{\pi\Omega} \quad [38]$$

where

$$A = -\frac{1}{2}\left[\int_0^b \bar{U}_{oi} d\bar{\eta} + \int_b^{\infty} \left(\bar{U}_{oi} + \frac{1}{\bar{\eta}}\right) d\bar{\eta} + \ln b\right] \quad [39]$$

The value of A should be independent of the value of b. However, it is broken up in this way since the first integral is unbounded as $b \to \infty$ and the second integral is unbounded as $b \to 0$. Evaluation from the information plotted in Fig. 3 gives $A = 0.563$. The high-frequency limit for B_{or} is

$$1 - B_{or} = \frac{2}{\pi\Omega}\int_0^{\infty} \bar{U}_{or} d\bar{\eta} \quad [40]$$

Substitution of Eq. [38] and [40] into Eq. [19] and [20] gives the high-frequency limits

$$4r_o\kappa R_{eff} \to 1 \text{ and } C/C_{eff} \to A + \frac{1}{4}\ln\Omega \text{ as } \Omega \to \infty \quad [41]$$

This asymptotic form for C/C_{eff} and values from Table 1 for $J = 0$ are plotted in Fig. 4. Satisfactory agreement is reached for large values of Ω.

Discussion and Conclusions

The most important result of this work is the fact that there is no high-frequency limit for C/C_{eff}. Consequently, the apparent capacity of a disk electrode embedded in an insulating plane should be expected to vary considerably with frequency. This conclusion is related to the fact that the primary current density becomes infinite at the edge of the disk. Since this effect is related critically to the edge region, the high-frequency behavior will be affected significantly by the detailed geometry at the edge. If the disk is slightly inset in the plane, a finite limit would be obtained.

Since this effect is related to the edge region, a similar conclusion would apply to a flat electrode of any shape embedded in an insulating plane. In contrast, for a mercury drop on an insulating plane, the primary current density does not become infinite, and the frequency-dependence of C/C_{eff} is considerably less (see Appendix).

A similar singular-perturbation problem in the edge region would arise at finite frequencies for large values of J. Since the behavior of the secondary current distribution in the edge region is not of critical interest, there is no compelling reason to pursue this problem. However, the correct determination of the behavior of C/C_{eff} at high frequencies required a consideration of the edge region.

Bauer, Spritzer, and Elving (4) report impedance measurements at a pyrolytic graphite disk electrode.

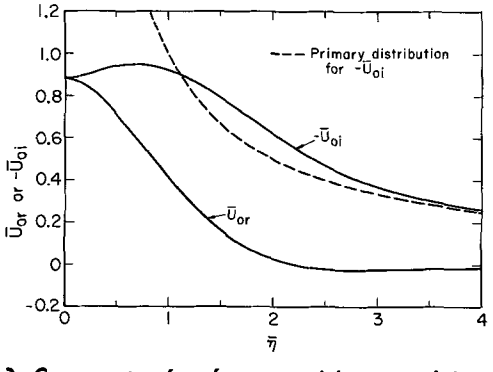

Fig. 3. Components of surface potential expressed in stretched variables for the region near the edge of the disk at high frequencies.

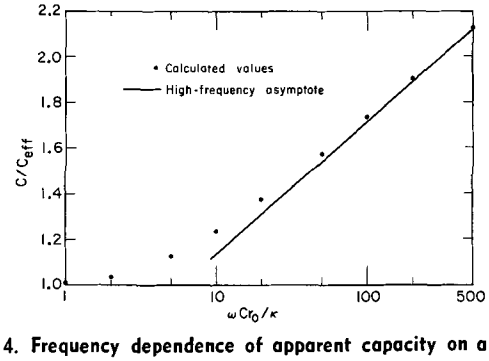

Fig. 4. Frequency dependence of apparent capacity on a smooth disk in the absence of faradaic reactions.

Their results show that the apparent capacity varies by about a factor of 2 while the apparent resistance varies by about a factor of 10. The latter result, interpreted in terms of the present analysis, suggests that faradaic reactions are not of negligible importance.

APPENDIX

A Drop Electrode on a Plane

A mercury drop at the end of a capillary tube is sometimes treated as a spherical electrode tangent to an insulating plane. The frequency dependence of the apparent capacity due to shielding by the capillary tip is inherently much less than that for a disk because the primary current distribution does not become infinite anywhere. The capillary tip can, of course, be designed to minimize the shielding and thus reduce the frequency dispersion further.

Here we use tangent-sphere coordinates (7) ν and μ

$$r = \frac{2r_o\mu}{\mu^2 + \nu^2}, \quad z = \frac{2r_o\nu}{\mu^2 + \nu^2} \qquad [42]$$

where r and z are cylindrical coordinates, with their origin at the *base* of the drop. The surface of the spherical drop is then given by $\nu = 1$. The current density relation on the surface of the drop, analogous to Eq. [6], [13], or [26] becomes

$$(j\Omega + J)(1 - U_o) = \frac{1 + \mu^2}{2}\frac{\partial U}{\partial \nu} \quad \text{at} \quad \nu = 1 \qquad [43]$$

The solution to Laplace's equation satisfying the conditions at infinity and on the insulating plane is expressed as

$$U = (\mu^2 + \nu^2)^{1/2}\int_0^\infty G(p)\frac{\cosh p\nu}{\cosh p} J_o(p\mu)\,dp \qquad [44]$$

The function $G(p)$ is analogous to the B_n coefficients used for the disk, but for the drop no discrete eigenvalues are found. By substitution of this expression into the boundary condition on the drop surface, it is possible to derive a differential equation for $G(p)$

$$2(j\Omega + J)(G - e^{-p}) = p\tanh p\frac{d^2G}{dp^2} + \left(\tanh p + \frac{2p}{\cosh^2 p}\right)\frac{dG}{dp} - \tanh p\left[\tanh p + p + \frac{2p}{\cosh^2 p}\right]G \qquad [45]$$

and $G = 1$ at $p = 0$ and $G = 0$ at $p = \infty$. The impedance Z of the system will then be given by

$$\frac{1}{4\pi\kappa r_o Z} = \int_0^\infty \frac{G(p)\,dp}{\cosh p} \qquad [46]$$

The primary potential distribution, applicable for large values of Ω or J and corresponding to $U_o = 1$, is given by $G(p) = e^{-p}$. The primary distribution has been treated by Maxwell (8) and by Matyáš (9) and has been plotted by de Levie (2). The primary current distribution on the drop is

$$\frac{i}{i_{avg}} = \frac{(1 + \mu^2)^{3/2}}{2\ln 2}\int_0^\infty \frac{J_o(p\mu)p\,dp}{\cosh p} \qquad [47]$$

and is plotted by de Levie. The value of i/i_{avg} at $\mu = 0$ (the bottom of the drop) is here calculated to be 1.3215, in good agreement with de Levie's graph.

For high frequencies we can obtain a second approximation directly from the differential equation

$$G(p) = e^{-p} + j(\tanh p + 2p/\cosh^2 p)/2\Omega\cosh p \qquad [48]$$

Substitution into the integral for the impedance gives the high-frequency limits for the resistance and capacitance of the equivalent circuit.

$$4\pi r_o\kappa R_{eff} = 1/\ln 2 = 1.4427 \text{ and } C/C_{eff} = 1.1352 \qquad [49]$$

The value for the resistance limit can also be inferred from the results of Maxwell. The capacitance in the equivalent circuit of Fig. 2 should now be represented by $4\pi r_o^2 C_{eff}$. Thus, C/C_{eff} is the ratio of the true double-layer capacity to the apparent double-layer capacity and has the same meaning as for the disk. However, the resistance ratio $4\pi r_o\kappa R_{eff}$ is the ratio of the resistance to that for a free sphere not attached to a blunt capillary tube.

Table II. Effective resistance and capacitance for a drop on a plane, in the absence of faradaic reactions (J=0)

$\omega C r_o/\kappa$	$4\pi r_o\kappa R_{eff}$	C/C_{eff}
0	?	1.0
0.1	1.5755	1.0016
1	1.5056	1.0632
10	1.4443	1.1330
∞	1.4427	1.1352

At low frequencies, the current distribution becomes uniform and $C/C_{eff} \to 1$. However, it is difficult to force the current to the surface of the drop near the point of contact, and the effective resistance might be expected to increase considerably more than was found for the disk. The solution for G at low frequencies becomes a singular-perturbation problem. Since little interest in this limit has been expressed, the problem was not pursued.

The drop problem is quite different from the disk problem. Here the high-frequency limit is relatively easy to obtain, but the low-frequency limit is difficult. For the disk the apparent capacity varies considerably with frequency; for the drop the apparent resistance varies considerably. These differences are directly related to the fact that the primary current distribution becomes infinite at the edge of the disk and becomes zero near the point of contact of the drop. Some results for intermediate frequencies are given in Table II. These values are in satisfactory agreement with the experimental results of Tessari, Delahay, and Holub (10). In particular, the factor 1/ln 2 gives a good account of the shielding effect of the capillary on the effective resistance.

Acknowledgment

Henry H. Bauer drew the author's attention to the disk problem. Robert de Levie suggested the drop problem and supplied a copy of Matyáš's paper. The author is indebted to Simon Goren for fruitful suggestions on how to treat the drop problem. In his class he treats the primary distribution by the method used here. This work was supported by the United States Atomic Energy Commission.

Manuscript submitted May 12, 1969; revised manuscript received Oct. 9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

NOMENCLATURE

B_n	coefficients in series expansion of the potential
C	double-layer capacity (f/cm²)
C_{eff}	apparent double-layer capacity in the equivalent circuit
G	distribution function for drop
i	current density (A/cm²)
I	total current (A)
j	$\sqrt{-1}$
J	dimensionless parameter for linear electrode kinetics
J_o	Bessel function of order zero
M_{2n}	Legendre function discussed in ref. (6)
p	separation parameter for drop

P_{2n}	Legendre polynomial or order $2n$
r	radial position from axis of disk (cm)
r_0	radius of disk or drop (cm)
R_{eff}	apparent resistance in the equivalent circuit (ohm)
t	time (sec)
U	complex potential in the solution (V)
U_0	value of U at the disk surface
V	electrode potential relative to infinity (V)
V_0	amplitude of applied potential
z	distance from plane of disk (cm)
Z	impedance of the system (ohm)
η	rotational elliptic coordinate
κ	conductivity of the solution ($ohm^{-1} - cm^{-1}$)
μ	tangent-sphere coordinate
ν	tangent-sphere coordinate
ξ	rotational elliptic coordinate
Φ	potential in the solution (V)
Φ_0	value of Φ at the electrode surface
ω	frequency of applied potential (radian/sec)
Ω	dimensionless frequency

The Electrochemical Reduction of m-Dinitrobenzene in Liquid Ammonia Solutions

William H. Tiedemann and Douglas N. Bennion***

School of Engineering and Applied Science, University of California, Los Angeles, California

ABSTRACT

The reduction of meta-dinitrobenzene has been studied in a NH_4NO_3-NH_3 solution at 0.0°C. Two separate electrochemical techniques, the rotating disk and the potential step, were employed to determine the over-all number of electrons transferred in the first and second waves of the reduction. The first and second waves occurred at −0.08 and −0.25V *vs.* Pb reference electrode, respectively. To within experimental accuracy, four electrons were transferred in each wave. The diffusion coefficient of meta-dinitrobenzene in a NH_4NO_3-NH_3 solution was measured using a modified Stoke's diaphragm cell and found to be a 1.83 x 10^{-6} cm^2/sec.

It has been shown by Spindler and Pritchard (1) that meta-dinitrobenzene (m-DNB) is an effective cathodic depolarizer in several battery systems. The electrochemical reduction of m-DNB has been studied in aqueous media by Jackson and Dereska (2) and by Ehlers and Sease (3). In addition, the possible use of m-DNB in liquid ammonia batteries has prompted studies of m-DNB reduction in liquid ammonia systems by Harris and Matson (4), Schaer (5), and Kuwana and Darlington (6).

In these investigations the following objectives appeared to be of interest: (*i*) the number of electrons transferred in the over-all electrochemical reduction of m-DNB; (*ii*) the number of waves occurring in the reduction; (*iii*) the number of electrons transferred in each wave; (*iv*) the products of each wave; (*v*) the effect of *p*H and solvent on the waves and the products; and (*vi*) a detailed description of intermediate steps in the reaction.

Ehlers and Sease (3) used a combination of potentiostatic and polarographic reduction techniques to study the cathodic reduction of m-DNB among other polynitro aromatic compounds in aqueous media. They were able to show that there are two waves in the total reduction and that eight electrons were transferred in the over-all reaction. However, they were unable to determine the number of electrons transferred in each wave. Of all the polynitro aromatic compounds which they studied, m-DNB is the only compound in which they could not say that four electrons were transferred in each wave.

Harris and Matson (4) studied the constant current reduction of m-DNB in a NH_4SCN-NH_3 solution using a voltage trace technique. From inflections in the voltage trace, the number of equivalents transferred per mole of material reduced can be inferred provided multiple reaction paths do not occur. They reported that m-DNB undergoes two successive four electron reductions. Schaer (5) also studied the reduction of m-DNB in NH_4SCN-NH_3 solutions. He employed constant potential coulometry and reported that eight electrons were obtained in the over-all reduction.

Jackson and Dereska (2) used polarographic and potentiostatic techniques to study the mechanism of the cathodic reduction of m-DNB in aqueous solution at various *p*H values. They obtained two waves with four electrons in each wave. They were able to isolate the product of the first wave as 3-nitrophenylhydroxylamine (3NPHA). However, they were not able to isolate the product of the second wave. The inability of previous researchers (3-5) to isolate the product of the first wave was apparently due to the techniques employed. Jackson and Dereska (2) found that below 100% reduction the product of the first wave is all

** Electrochemical Society Student Associate.
* Electrochemical Society Active Member.

3NPHA. However, near 100% reduction no identifiable product was obtained (the residue turned brown). They proposed that the mixed product observed when 100% reduction is approached for the first wave indicates that reduction of the first nitro group does not occur completely before reduction of the second group begins.

The present study was undertaken in order to clarify some of the previous results obtained in NH_4SCN-NH_3 solutions. Since it has been observed (6) that the SCN^- ion reacts slowly with m-DNB to produce a radical anion, a solution of NH_4NO_3-NH_3 (which does not react with m-DNB) was employed in this study. The m-DNB molecule is protonated in the solution since the solution behaves like a strong acid as shown by Given and Peover (7) and Schaer (5).

To demonstrate consistency and accuracy of results, two separate and independent electrochemical techniques were employed, the rotating disk electrode (8) and the potential step (9). Only the over-all reactions associated with the first and second waves will be considered.

Experimental

Reagents.—Ammonia (NH_3) was obtained from Matheson Company and was further purified by two successive single stage distillations. Conductance was used as a measure of purity of the NH_3 obtained in the final distillation. The conductance was determined as 1×10^{-8} mho/cm. NH_4NO_3 obtained from Sargent Company was vacuum dried at 100°C for 24 hr. A solution of NH_4NO_3-NH_3 (0.37 mole fraction of NH_4NO_3) was prepared by condensing NH_3 from a container which has been previously weighed into a glass vessel containing a known weight of NH_4NO_3. After the desired amount of NH_3 had been condensed, the container of NH_3 was weighed to determine the quantity of NH_3 transferred to the glass vessel. The solution was then stored at 0.0°C. The m-DNB used was Eastman's highest purity and was recrystallized once from chloroform and vacuum dried at 50°C for 24 hr. All solutions of varying concentrations of m-DNB in NH_4NO_3-NH_3 were prepared at the same time by adding a known volume of NH_4NO_3-NH_3 into a flask containing a known weight of m-DNB. The volume of each solution so prepared was about 300 ml. The resulting solutions were light yellow in color.

Apparatus.—A detailed description of the equipment used in the rotating disk and potential step experiments has been given (10). The essential features shall be discussed briefly. A Dumore lathe quill was employed to hold the rotating electrode in a vertical position. A pulley-belt system was used to transmit the desired angular velocity to the rotating electrode via the Dumore quill. The eccentricity at the face of the electrode was determined to be less than 0.001 of an inch. The surface of the electrode consisted of a platinum disk surrounded by Teflon (see Fig. 1). A glass tube was used to connect the cell to a Viton rubber seal. The system was air tight. No NH_3 leak could be detected.

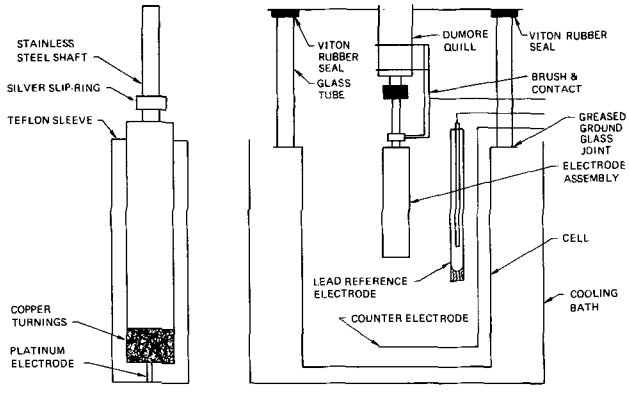

Fig. 1. Rotating disk electrode and electrochemical cell

The spherical platinum electrode used in the potential step experiments was prepared by West Glass Corporation. The average geometrical area of the sphere was determined using an optical comparator. The counterelectrode consisted of a platinum wire mesh cylinder. The cell was sealed with standard, ground glass joints. The cell was air tight, and no NH_3 odor could be detected outside the cell. The rotating disk, after being polished, and the spherical electrode were electrochemically cleaned in chromic acid, washed in redistilled water, and vacuum dried at 150°C for 24 hr.

A cracked-glass lead reference electrode described by Panzer (11) was used in both experiments. The reference electrode consisted of a cracked glass tube filled with NH_3 solution saturated with $LiNO_3$ and $Pb(NO_3)_2$ and contained a strip of lead wire. The ohmic resistance across the cracked glass was about 5×10^5 ohms. Due to this large resistance, a 610B Keithley electrometer which had an internal resistance of 10^{14} ohm was used.

An Anotrol 4700 M potentiostat was used in the potential step experiments as well as in the potentiostatic work with the rotating disk.

A Stokes-type diaphragm cell (12) was used to measure the diffusion coefficient of m-DNB in NH_4NO_3-NH_3 solutions at 0°C. The only modification of significance to Stokes' cell was the replacement of the stoppered ends by Teflon stopcocks.

Procedure.—Approximately 120 ml of a m-DNB-NH_4NO_3-NH_3 solution were used in each experiment. Experiments were conducted on blank solutions of NH_4NO_3-NH_3 to determine the contribution of extraneous reactions to the measured currents. The resulting current was found to be less than 0.5% of the current obtained from the smallest concentrations of m-DNB used. This indicates that the impurity level was low enough not to interfere with the measurements made in these experiments.

Rotating disk electrode.—The electrochemical cell, shown in Fig. 1, which had been cooled to 0.0°C in an ice bath, was flushed several times with NH_3 gas before about 120 ml of solution were added. Several cathodic pulses, lasting about 5 sec, were applied to the electrode before the experiment was begun in order to reduce impurities remaining on the surface. The rotation speed was set by adjusting the control unit which was connected to a d-c motor. The rotation speed was measured with a General Radio Strobotac (Type 1531-A) and recorded. Both galvanostatic and potentiostatic cathodic reductions were performed (which produced the same η *vs.* i curve). When a steady-state condition was reached, the values for the current and potential (*vs.* a lead reference electrode) were recorded and a new setting of the current or potential was made. This procedure was continued until the run was terminated, *i.e.*, a limiting current was reached. Then the rotating speed and/or the concentration of m-DNB was changed and the above procedure repeated.

Potential step.—The same procedure for filling the cell and cleaning the electrode as described above was used in the potential step experiments. The potential (*vs.* a lead reference electrode) sufficient to produce a limiting current at the surface of the electrode was set on the potentiostat. A potential pulse was then applied to the cell. The response was displayed on an oscilloscope and a permanent record was obtained on polaroid film. The potential was changed to determine if a true limiting current had been reached. The oscilloscope was fitted with a projected graticule to eliminate parallax and increase the accuracy of the readings. The concentration was changed and the above procedure repeated.

Diaphragm cell.—The cell was flushed with NH_3 gas. This was done to eliminate entrapment of air in the pores of the diaphragm. A syringe was used to fill the cell. The side containing the dilute solution was filled first. The cell was inverted, and the concentrated solution added to the second compartment. A vacuum pump was connected to the cell so that trapped gas in the pores was removed. A period of several hours was allowed for prediffusion in the diaphragm. The two compartments of the cell were refilled and the experiment begun. The cell was thermostated in a glycol bath at 0.0° ± 0.2°C. The experiment was terminated after 192 hr. The concentration in the bottom compartment changed from 0.0202 to 0.0191M, and the concentration in the top compartment changed from 0.0010 to 0.0023M.

The final concentrations in the two compartments of the cell were analyzed by removing a known volume of solution from each compartment and allowing the NH_3 to evaporate at room temperature. The m-DNB was extracted from the residue by adding spectrograde ether to the residue. The ether was then transferred to a flask, and the ether was allowed to evaporate. The remaining m-DNB was weighed.

The cell was calibrated by Dunning (13). Stokes (12) claimed 0.2% accuracy for this method. Our calibration runs had a mean deviation of 9.2%. This variation is due to small amounts of gas trapped in the diaphragm. Better degassing procedures are needed to improve this accuracy.

Results

Rotating disk.—The equation governing the use of the rotating disk electrode was developed by Levich (8). Riddiford (14), and Newman (15) have since made a Schmidt number correction. Applying their suggested correction to this system, the equation is

$$i_{lim} = \frac{nFD^{2/3}\ C^{\circ}\ \omega^{1/2}}{1.63\ \nu^{1/6}} \qquad [1]$$

where 1.61 in Levich's original derivation is now changed to 1.63 using the Schmidt number correction.

The cathodic reduction of m-DNB in NH_4NO_3-NH_3 solution at 0.0°C on the rotating disk occurred in two waves. The first wave appears at about −0.08V *vs.* a lead reference electrode and the second wave occurred at −0.25V. A typical plot of η *vs.* i as a function of rotation speed is shown in Fig. 2. A plot of i_{lim} *vs.* $\omega^{1/2}$ for the first and second waves resulted in a straight line which passed through the origin as predicted by

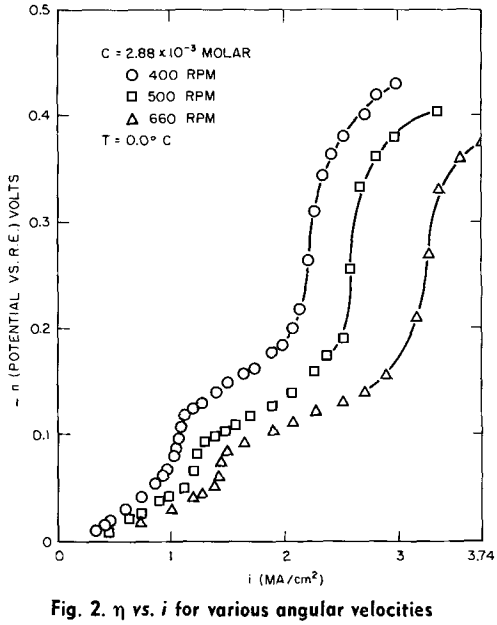

Fig. 2. η *vs.* i for various angular velocities

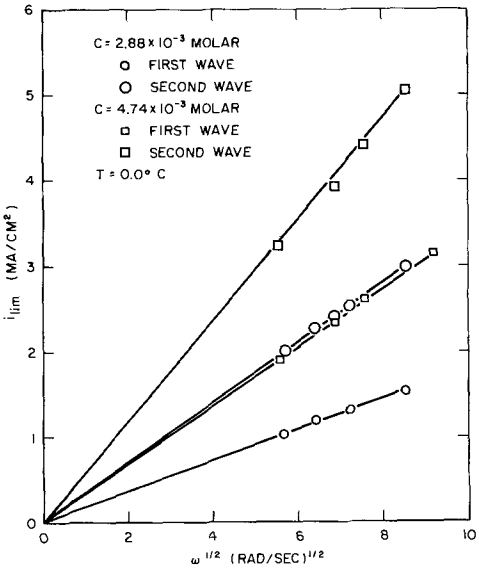

Fig. 3. Effect of varying the disk velocity on the limiting diffusion current for m-DNB reduction.

Eq. [1] (see Fig. 3). A plot of

$$\frac{1.63\ \nu^{1/6}\ i_{lim}}{F\ \omega^{1/2}}\ vs.\ C^{\circ}$$

also resulted in straight lines passing through the origin as predicted by Eq. [1] (see Fig. 4). The slope of the plot in Fig. 4 yields $nD^{2/3}$; n is the over-all number of electrons transferred and D is the diffusion coefficient of the bulk species diffusing to the surface of the electrode. The diffusion coefficient of m-DNB in NH_4NO_3-NH_3 at 0.0°C as measured by the diaphragm cell method was found to be 1.83 x 10^{-6} cm²/sec. The type of species present in the NH_4NO_3-NH_3 solution is the protonated m-DNB molecule (5, 7). Using the value of the diffusion coefficient determined in this work, the values of the number of electrons for the first and second waves were found to be 4.14 and 3.91, respectively.

Potential step.—The equation developed for the limiting current at the surface of a spherical electrode has been presented by Delahay (9) and is shown in Eq. [2]

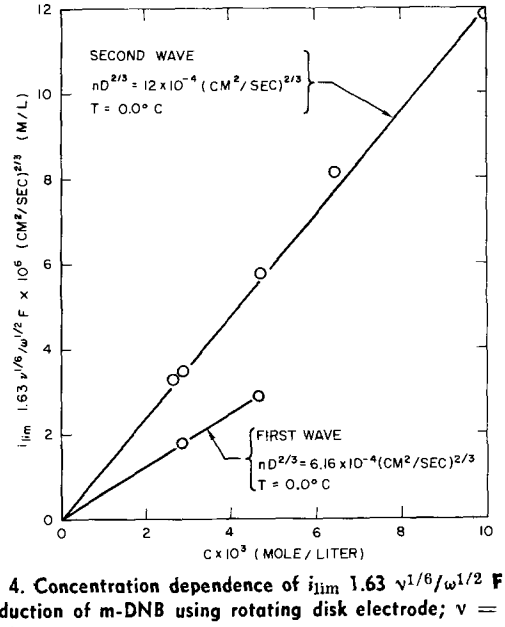

Fig. 4. Concentration dependence of i_{lim} 1.63 $\nu^{1/6}/\omega^{1/2}$ F vs. C° for reduction of m-DNB using rotating disk electrode; ν = 0.0408 stokes (10).

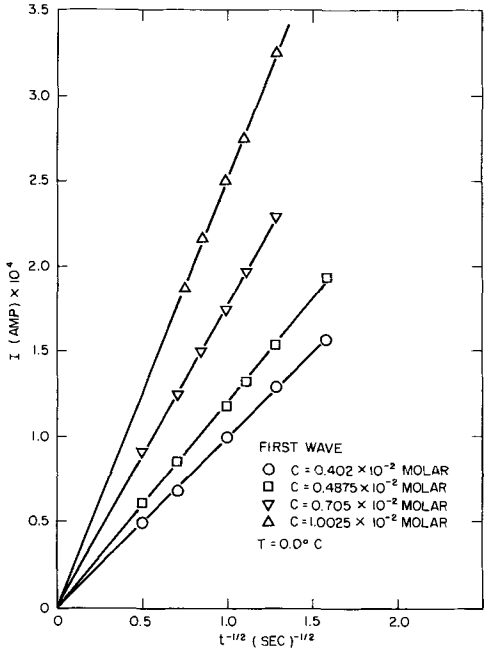

Fig. 5. Variation of the limiting diffusion current with time for the reduction of m-DNB using the potential step for the first wave.

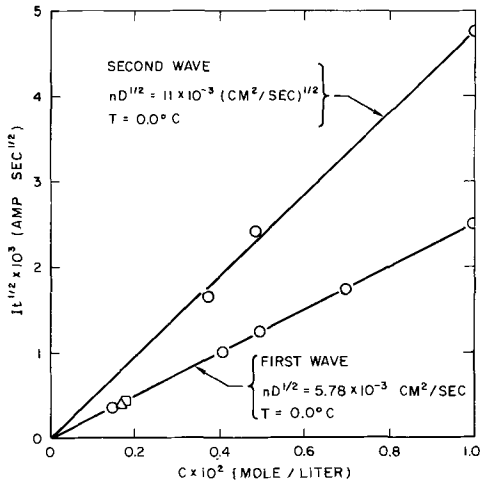

Fig. 6. Concentration dependence of $I\ t^{1/2}$ for the reduction of m-DNB using the potential step.

$$I_{\text{lim}} = \frac{n\mathbf{F}AD^{1/2}\ C^\circ}{\pi^{1/2}\ t^{1/2}} + \frac{n\mathbf{F}AD\ C^\circ}{r^\circ} \qquad [2]$$

For short response times (a few seconds), $(n\mathbf{F}ADC^\circ)/r^\circ$ is negligible compared to

$$\frac{n\mathbf{F}AD^{1/2}\ C^\circ}{\pi^{1/2}\ t^{1/2}}$$

Therefore, for $t < 4$ sec Eq. [2] reduces to the following

$$I_{\text{lim}} = \frac{n\mathbf{F}AD^{1/2}\ C^\circ}{\pi^{1/2}\ t^{1/2}} \qquad [3]$$

The current was plotted *vs.* $t^{-1/2}$ for several concentrations (Fig. 5). The plot produced straight lines which intersected the origin as predicted by Eq. [3]. Figure 6 contains the plots for the first and second wave of

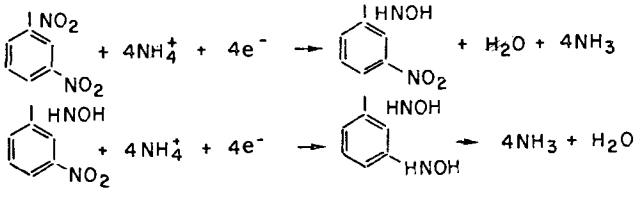
$$I_{\text{lim}}\ t^{1/2}\ vs.\ C^\circ$$

Again it is observed that a straight line results which passes through the origin. The over-all numbers of electrons transferred in the first and second waves are determined from the slopes of the plots in Fig. 6 and the previously determined diffusion coefficient. They were found to be 4.24 and 3.92, respectively.

Discussion

Table I summarizes values of the number of electrons transferred in each wave as determined in this work as well as in the literature cited. As can be seen, the agreement between the results obtained in this paper and that obtained by previous researchers is good.

Based on the similarities between the system of Jackson and Dereska (2) (m-DNB in H_2O with H^+ ions) and that of the system described in this paper (m-DNB in NH_3 with NH_4^+ ions), and the consistency of results, it appears that the over-all reaction mechanism proposed by Jackson and Dereska (2) is the same for ammonia, the system being considered here. Therefore, by replacing H^+ with NH_4^+, we obtain the following



A detailed description of the intermediate steps in the cathodic reduction of m-DNB was not attainable in this study since the NH_4^+ ion concentration could not be varied sufficiently. If one were to use $LiNO_3$ as the supporting electrolyte, the effects of variations in NH_4^+ ion concentration could be examined and details of the reaction mechanism studied.

Rotating Ring-Disk Electrodes

I. Fundamentals of the Digital Simulation Approach. Disk and Ring Transients and Collection Efficiencies

Keith B. Prater[1] and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas

ABSTRACT

A digital simulation technique has been used to treat electrode reactions occurring at the rotating ring-disk electrode (RRDE). The method of treating normal diffusion, normal and radial convection, and homogeneous kinetics at the RRDE is discussed and results for the transient and steady-state currents at the disk and ring electrodes in the absence of kinetic complications are given. Where comparisons are possible, the simulated results were found to be in excellent agreement with previous theoretical treatments.

The rotating ring-disk electrode (RRDE) was introduced in 1959 by Frumkin and Nekrasov (1). The addition of a ring electrode to the rotating disk electrode permitted the detection of products formed by electrode reactions and provided a steady-state method for investigating coupled chemical reactions. However, the mass transfer conditions existing at the RRDE are rather complex, and the mathematical treatment of the RRDE, especially in the presence of kinetic complications, is difficult. A general mathematical treatment was not given until 1966 when a series of papers by Albery and Bruckenstein (2-9) appeared. In these papers, Albery and Bruckenstein presented an exact treatment of the steady-state collection efficiency as a function of electrode geometry in the absence of kinetic complications (3). They also presented approximate treatments of first- and second-order follow up reactions. Unfortunately, as pointed out by Albery (10), the treatment of the first-order case is not applicable to any practical electrode without further approximations. Their second-order treatment is limited to certain regions of rotation rate and rate constant. Furthermore, expansion of these treatments to more complex mechanisms, such as ECE reactions and electrogenerated chemiluminescence (11), seems unlikely.

In this series of papers, we present the results of the application of a digital simulation technique to this problem. This technique is capable of generating a theoretical working curve for any particular electrode under any imaginable kinetic situation. The simulation technique used is a modification of that introduced to electrochemical problems by Feldberg (12) and most fully described in a recent chapter (13). This paper also discusses the mathematical background of the method and gives a detailed description of other applications of this technique.

The principal problem encountered in simulating the RRDE is that, due to the normal and radial convective flow, the concentrations of all species are functions of two spatial variables, X, the normal distance from the electrode surface, and R, the radial distance from the axis of rotation. It is here that this paper differs from those previously presented.

Digital Simulation Method

Digital model.—In a digital simulation of an electrochemical system, one first divides the solution into a number of small volume elements. These volume elements will henceforth be called "boxes" regardless of shape. The shapes of these boxes are chosen in such a way that one can reasonably assume that the solution within each box is homogeneous. For an RRDE, the symmetry of the system suggests the following model. The solution is first divided into thin parallel layers which are Δx cm thick. The electrode is placed in the center of the first layer, parallel to the planes dividing the layers. Then each layer is divided into a cylindrical box of radius $\frac{1}{2}\ \Delta r$ cm which is centered about the axis of rotation, and a series of concentric annular boxes Δr cm wide (Fig. 1). The parameter, Δr, is chosen in such a way that the pertinent radii of

* Electrochemical Society Active Member.
[1] Present address: University of Texas at El Paso, El Paso, Texas.

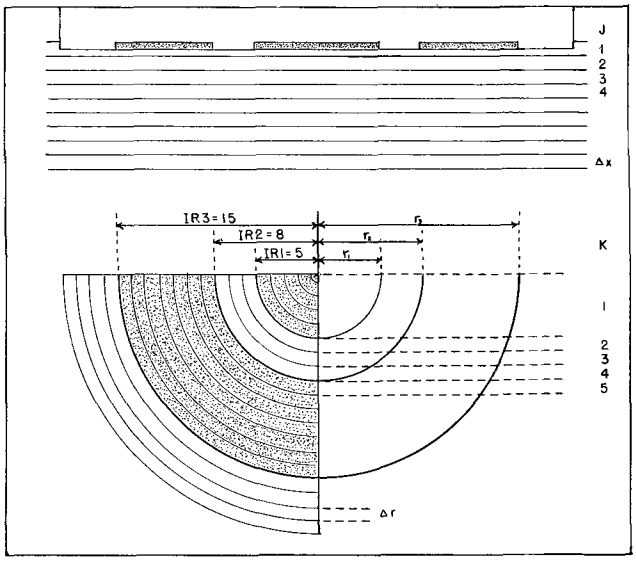

Fig. 1. Digital simulation model of the rotating ring disk electrode.

the electrode, r_1 (the radius of the disk electrode), r_2 (the radius to the inner edge of the ring electrode), and r_3 (the radius to the outer edge of the ring electrode), can be satisfactorily approximated by

$$r_1 = (IR1\text{-}0.5)(\Delta r)$$
$$r_2 = (IR2\text{-}0.5)(\Delta r)$$
$$r_3 = (IR3\text{-}0.5)(\Delta r) \quad [1]$$

where $IR1$, $IR2$, and $IR3$ are integers and correspond to the number of boxes necessary to represent the particular radial distances. Obviously, the smaller Δr is (*i.e.*, the greater the number of annular boxes), the better the approximation is likely to be. Unfortunately, the number of boxes must be weighed against the length of computation time and some compromise reached.

In the interest of minimizing computation time, one can very reasonably assume that the disk electrode is a uniformly accessible surface. This condition holds under usual experimental conditions where an excess of supporting electrolyte is present (14). This means that in each layer, the solution in the cylindrical volume of radius $(IR1\text{-}0.5)(\Delta r)$ centered about the axis of rotation is homogeneous and can be represented by one large cylindrical box.

For the sake of simplicity the following convention is used. Each box is referred to by its layer number, J, and its radial number, K. The layer containing the electrode is the $J = 1$ layer, and all other layers are numbered consecutively outward from the electrode. Within any layer, the large central cylindrical box is called the $K = 1$ box, and all the annular boxes are numbered consecutively outward from this box. The large cylindrical box in the first layer ($J = 1$, $K = 1$) corresponds to the disk electrode. Similarly, the appropriate first layer ($J = 1$) annular boxes correspond to the gap region, the ring electrode region, or the outer insulation region.

A concentration for each of the active species in solution is then assigned to each box. This concentration is associated with the center of each box. Thus, in the particular case of the boxes in the first layer, the concentrations in those boxes correspond to the concentrations at the electrode surface. Before electrolysis begins, all boxes are assigned concentrations which correspond to the bulk concentration of the solution. At the beginning of electrolysis, $t = 0$, the concentrations in those first layer boxes corresponding to the disk and ring electrodes are changed to reflect appropriate boundary conditions. These changes result in a concentration gradient between some of the corresponding boxes in the first and second layers. Using a finite difference representation of Fick's second law, the extent to which the concentrations in these boxes are changed by diffusion across the boundary between them in a time interval, Δt, is calculated. These changes in the original array of concentrations produce a new array reflecting the effects of diffusion during this first time interval. In all calculations we assume, following the arguments of Albery and Bruckenstein (3), that radial diffusion is negligible when compared with radial convection.

In the case of a rotating electrode, convection is also taking place during the same time interval, Δt. From the treatment by Levich (15) of convection to a rotating disk electrode one can calculate the normal and radial components of fluid velocity at any point near the electrode. Thus, one can calculate the distance a given fluid volume will travel in the normal and radial directions in a time, Δt. If, for example, this calculation reveals that the volume element in the Kth ring of the Jth layer at the end of Δt seconds has traveled a distance ΔJ in the normal direction and a distance ΔK in the radial direction, then by replacing the concentration in the J, Kth box in the existing array with the concentration at $J + \Delta J$, $K - \Delta K$, a new array is generated which reflects the effects of both diffusion and convection for a time Δt.

If, in addition, one or more species undergo homogeneous reactions, this can be simulated by calculating, for each box containing the appropriate species, the amount by which each species will be depleted or increased according to the appropriate rate law in a time Δt. This generates an array which represents the expected concentration profile of the simulated system at a time Δt after the initiation of electrolysis. From this profile, the current observed at this point in an experiment can be calculated by assuming that the current is proportional to the difference between the concentrations in the corresponding boxes in the first and second layers, *i.e.*, the flux at the electrode surface. After making the adjustments to the concentrations in the appropriate boxes due to the passage of current, the above process is repeated to give a new concentration profile and current at $t = 2\Delta t$ and so on until the steady state has been attained. In the limit, as $\Delta x \to 0$, $\Delta t \to 0$, and $\Delta r \to 0$, the calculated current-time behavior and the steady-state currents should approach those observed experimentally.

Initial and boundary conditions.—Let us now consider the simulation in greater detail by discussing the following situation. The solution initially contains only species A at bulk concentration C^o_A. At time $t = 0$, the potential of the disk electrode is stepped to a potential on the limiting current plateau for the reaction

$$A \pm ne \to B \quad [2]$$

We consider the case where species B undergoes a first order homogeneous reaction to give some electroinactive species, X, by the reaction

$$B \xrightarrow{k_1} X \quad [3]$$

The potential of the ring electrode is such that all B reaching the ring electrode is instantaneously converted back to A by

$$B \mp ne \to A \quad [4]$$

In digital simulations, to make each computation as general as possible, all calculations are done in terms of dimensionless parameters. Hence, all concentrations are normalized with respect to the initial concentration of bulk species A. Thus, the initial fractional concentration of species A in any box is

$$F_A(J,K) = C^o_A/C^o_A = 1.0 \quad [5]$$

and the fractional concentrations of species B and X are

$$F_B(J,K) = 0.0$$
$$F_X(J,K) = 0.0 \quad [6]$$

At the initiation of electrolysis, $t = 0$, the boundary conditions for the disk box in the case of a potential step to the limiting current region are

$$F_A(1,1) = 0.0$$
$$F_B(1,1) = 1.0$$
$$F_X(1,1) = 0.0 \quad [7]$$

For those first layer boxes which correspond to the ring electrode, the initial boundary conditions are

$$F_A(1,K_R) = 1.0$$
$$F_B(1,K_R) = 0.0$$
$$F_X(1,K_R) = 0.0 \quad [8]$$

where K_R represents all values of K corresponding to the ring electrode region.

Diffusion effects.—These conditions set up a concentration gradient between the first and second layer disk boxes ($J = 1$, $K = 1$) and ($J = 2$, $K = 1$), which gives rise to diffusion across the boundary between these boxes. The amount of material crossing the boundary in Δt seconds can be calculated using the finite difference representation of Fick's second law

$$\Delta F_A(J,K) = DM_A[F_A(J+1) - F_A(J,K)] - DM_A[F_A(J,K) - F_A(J-1,K)] \quad [9]$$

or

$$\Delta F_A(J,K) = DM_A[F_A(J+1,K) - 2F_A(J,K) + F_A(J-1,K)] \quad [10]$$

This states that for any time interval, Δt, the change in the fractional concentration of species A in the J,Kth box is the difference between the amount of A entering from the adjacent box of higher concentration and the amount of A going into the adjacent box of lower concentration. The amount entering or leaving the box is proportional to the concentration gradient across the boundary. The proportionality factor, DM_A is given by

$$DM_A = D_A \Delta t/(\Delta X)^2 \quad [11]$$

where D_A is the diffusion coefficient of species A and ΔX is the width of one layer. The parameter, Δt, is defined below. By applying Eq. [10] to all boxes and then replacing $F_A(J,K)$ by $F_A(J,K) + \Delta F_A(J,K)$, a new array of concentrations is generated which represents the effects of diffusion for a time interval Δt. The concentrations of species B and X are similarly treated. For this technique to converge, DM_A must have a value less than 0.5 (13). In most of these calculations, DM_A was taken to be 0.45.

Convection effects.—The parameter, Δt, is the real time length of one iteration. Thus

$$\Delta t = t_k/L \quad [12]$$

where t_k is some experimentally known time or time dimensioned variable, and L is the number of iterations used to simulate that time. To evaluate the appropriate form of t_k, consider the equation for the velocity of convective fluid flow in the direction normal to the electrode. In the region near the electrode, this is given by (15)

$$v_X = -0.51\,\omega^{3/2}\,\nu^{-1/2}\,X^2 \quad [13]$$

where ω is the rotation rate in radians/second, ν is the kinematic viscosity in square centimeters per second, and X is the distance from the electrode surface. The velocity in the X direction may be represented by the derivative, dX/dt. Thus

$$dX/dt = -0.51\,\omega^{3/2}\,\nu^{-1/2}\,X^2 \quad [14]$$

Solving the above, for X and evaluating between t_2 and t_1, one obtains

$$\frac{1}{X_2} - \frac{1}{X_1} = -0.51\,\omega^{3/2}\,\nu^{-1/2}\,(t_2 - t_1) \quad [15]$$

If we let $t_2 - t_1 = \Delta t$, then X_1 and X_2 represent the distance of a particular solution volume from the electrode surface at the beginning and end of the time interval, Δt. In terms of the layer number, J, the distance from the electrode surface to the center of any box is given by $(J - 1)(\Delta X)$. Let

$$XJ = J - 1 \quad [16]$$

and

$$X_1 = XJ(\Delta X) \quad [17]$$

then X_2 is the position in the old array of the solution volume which will be in the center of the Jth box at the end of the time interval, Δt. It is convenient to let

$$X_2 = (XJJ)\Delta X \quad [18]$$

where XJJ is a nonintegral distance from the electrode expressed in terms of numbers of boxes.

We can now rewrite Eq. [15] as

$$\frac{1}{XJJ} - \frac{1}{XJ} = -0.51\,\omega^{3/2}\,\nu^{-1/2}\,\Delta X\,\Delta t \quad [19]$$

or

$$XJJ = XJ/[1 - (XJ)(0.51\,\omega^{3/2}\,\nu^{-1/2}\,\Delta X \Delta t)] \quad [20]$$

The product $(0.51\,\omega^{3/2}\,\nu^{-1/2}\,\Delta X \Delta t)$ is dimensionless and is designated V_{NAUT}, that is

$$V_{NAUT} = 0.51\,\omega^{3/2}\,\nu^{-1/2}\,\Delta X \Delta t \quad [21]$$

From Eq. [11]

$$\Delta X = (D_A \Delta t/DM_A)^{1/2} \quad [22]$$

Thus

$$V_{NAUT} = 0.51\,\omega^{3/2}\,D_A^{1/2}\,\nu^{-1/2} DM_A^{-1/2} \Delta t^{3/2} \quad [23]$$

Using Eq. [12]

$$V_{NAUT} = 0.51\,\omega^{3/2}\,D_A^{1/2}\,\nu^{-1/2}\,DM_A^{-1/2}\,t_k^{3/2}\,L^{-3/2} \quad [24]$$

Letting

$$t_k = \omega^{-1}\,\nu^{1/3}\,D_A^{-1/3}\,(0.51)^{-2/3} \quad [25]$$

$$V_{NAUT} = DM_A^{-1/2}\,L^{-3/2} \quad [26]$$

then

$$XJJ = XJ/[1 - (XJ)(V_{NAUT})] \quad [27]$$

Note that the above substitutions render the calculation of the effects of convection not only dimensionless, but also strictly in terms of simulation variables. By replacing the concentrations now at the center of each box with the concentrations at the distance calculated from Eq. [27], a new array representing the effects of diffusion and convection normal to the electrode for a time, Δt, is generated.

In a similar manner, the effects of convection in the radial direction can be calculated. Beginning with the equation for fluid velocity in the radial direction near the electrode (15)

$$v_R = -0.51\,\omega^{3/2}\,\nu^{-1/2}\,XR \quad [28]$$

where R is the distance from the axis of rotation, one obtains

$$dR/dt = -0.51\,\omega^{3/2}\,\nu^{-1/3}\,XR \quad [29]$$

Solving Eq. [29] one obtains

$$\ln(R_2) - \ln(R_1) = -0.51\,\omega^{3/2}\,\nu^{-1/2}\,X\,(t_2 - t_1) \quad [30]$$

As before, R_2 and R_1 are the positions of a solution volume at times t_2 and t_1. Rearranging and substituting for X and $(t_2 - t_1)$

$$\ln(R_1/R_2) = 0.51\,\omega^{3/2}\,\nu^{-1/2}\,XJ\,\Delta X\,\Delta t \quad [31]$$

If we let

$$R_1 = RK(\Delta r) \quad [32]$$

and

$$R_2 = RKK(\Delta r) \quad [33]$$

and combine terms, we get

$$\ln(RK/RKK) = (V_{NAUT})(XJ) \quad [34]$$

and finally

$$RKK = RK \exp\left[-(V_{NAUT})(XJ)\right] \quad [35]$$

where

$$RK = K + IR1 - 2 \quad [36]$$

and is the radial distance of the solution volume in the center of the Kth box from the axis of rotation. RKK is the present position of the solution volume which will be at RK at the end of the Δt interval. Equation [35] allows the generation of an array of concentrations which represents the effects of diffusion and both normal and radial convection for a time, Δt.

Kinetic effects.—For a first order disappearance of species B from the J, Kth box, one can write the rate law in the form

$$\Delta C_B(J,K)/\Delta t = -kC_B(J,K) \quad [37]$$

Normalizing the concentrations by dividing both sides of the equation by C^o_A, and remembering that $F_B(J,K) = C_B(J,K)/C^o_A$, we have

$$\Delta F_B(J,K) = -k\Delta t\, F_B(J,K) \quad [38]$$

or substituting for Δt

$$\Delta F_B(J,K) = -[k\omega^{-1}\nu^{-1/3} D_A^{-1/3}(0.51)^{-2/3}]F_B(J,K)/L \quad [39]$$

The dimensionless collection of terms in brackets in Eq. [39] is called XKT, so that

$$XKT = k\omega^{-1}\nu^{1/3} D_A^{-1/3}(0.51)^{-2/3} \quad [40]$$

This is the dimensionless rate parameter which is used in the calculations. Rewriting Eq. [39], we get

$$\Delta F_B(J,K) = -XKT[F_B(J,K)]/L \quad [41]$$

Similarly, the expression for the appearance of species X is

$$\Delta F_X(J,K) = XKT[F_B(J,K)]/L = -\Delta F_B(J,K) \quad [42]$$

By replacing $F_B(J,K)$ with $F_B(J,K) + \Delta F_B(J,K)$ and $F_X(J,K)$ with $F_X(J,K) + \Delta F_X(J,K)$, an array of concentrations which represents the concentration profile one would expect to observe under these conditions after Δt seconds is generated.

Calculation of current.—The fractional flux of a species, Z, moving from a $J = 2$ box into a $J = 1$ box is given by

$$FF_Z(K) = DM_Z[F_Z(2,K) - F_Z(1,K)] \quad [43]$$

The contribution to the current from a given box, K, can be expressed as

$$i(K) = [FF_Z(K)](C^o_A)[A(K)\Delta X](n\mathbf{F})/\Delta t \quad [44]$$

where $A(K)$ is the area of the Kth box (thus $A(K)\Delta X$ is the volume of that box). Rearranging and substituting for ΔX and Δt we get

$$i(K)/n\mathbf{F}C^o_A = FF_Z(K)\, A(K)\, D_Z^{1/2} DM_Z^{-1/2} L^{1/2} t_k^{-1/2} \quad [45]$$

Substituting for t_k and rearranging we have

$$i(K)/(0.51)^{1/3} n\mathbf{F}C^o_A D_Z^{2/3}\omega^{1/2}\nu^{-1/6} = FF_Z(K)\, A(K)\, L^{1/2} DM_Z^{-1/2} \quad [46]$$

If we divide both sides of Eq. [46] by the area of the disk electrode, A_D, we have

$$i(K)/(0.51)^{1/3} n\mathbf{F}A_D C^o_A D_Z^{2/3}\omega^{1/2}\nu^{-1/6} = FF_Z(K) L^{1/2} DMZ^{-1/2} A(K)/A_D \quad [47]$$

Both sides of Eq. [47] are now dimensionless and the simulation variables are all on one side of the equation.

Equation [47] can be used to calculate the current at the disk electrode. That is

$$i_d/(0.51)^{1/3} n\mathbf{F}A_D C^o_A D_A^{2/3}\omega^{1/2}\nu^{-1/6} = FF_A(1)\, L^{1/2} DM_A^{-1/2} \quad [48]$$

In the case of a potential step to the limiting current plateau, since $F_A(1,1) = 0.0$, the fractional flux becomes

$$FF_A(1) = DM_A F_A(2,1) \quad [49]$$

The dimensionless parameters on each side of Eq. [48] are called ZD. Thus, in terms of experimental variables

$$ZD = i_d/(0.51)^{1/3} n\mathbf{F}A_D C^o_A D_A^{2/3}\omega^{1/2}\nu^{-1/6} \quad [50]$$

while in terms of the simulation

$$ZD = DM_A^{1/2} F_A(2,1)\, L^{1/2} \quad [51]$$

Similarly, the current at the ring electrode can be calculated. Using Eq. [47]

$$i_r/(0.51)^{1/3} n\mathbf{F}A_D C^o_A D_B^{2/3}\omega^{1/2}\nu^{-1/6} = L^{1/2} DM_B^{-1/2} \sum_{K_R} FF_B(K)A(K)/A_D \quad [52]$$

where the summation is over all radial boxes, K, corresponding to the ring electrode.

The dimensionless parameter on each side of Eq. [52] are called ZR. Thus, in terms of experimental variables

$$ZR = i_r/(0.51)^{1/3} n\mathbf{F}A_D C^o_A D_B^{2/3}\omega^{1/2}\nu^{-1/6} \quad [53]$$

while in terms of simulation variables

$$ZR = L^{1/2} DM_B^{-1/2} \sum_{K_R} FF_B(K)\, A(K)/A_D \quad [54]$$

If the potential at the ring is such that all B reaching the ring is instantly converted into A, then $F_B(1,K_R) = 0.0$ and Eq. [43] becomes

$$FF_B(K_R) = DM_B F_B(2,K_R) \quad [55]$$

Therefore, Eq. [54] becomes

$$ZR = L^{1/2} DM_B^{1/2} \sum_{K_R} F_B(2,K)\, A(K)/A_D \quad [56]$$

Note that

$$ZR/ZD = (i_r/i_d)(D_A/D_B)^{1/2} \quad [57]$$

The quotient i_r/i_d is the collection efficiency, N. Thus

$$ZR/ZD = N(D_A/D_B)^{1/2} \quad [58]$$

Though it is not necessary to do so, we will assume that $D_A = D_B$, and thus

$$ZR/ZD = N \quad [59]$$

Redefinition of boundary conditions.—At this point, the first iteration in the calculation is completed. It is now necessary to modify the boundary conditions at the disk and ring electrodes as follows.

At the disk

$$F_A'(1,1) = 0.0 \quad [60]$$

$$F_B'(1,1) = F_B(1,1) + DM_A[F_A(2,1)] - DM_B[F_B(1,1) - F_B(2,1)] \quad [61]$$

$$F_X'(1,1) = F_X(1,1) - DM_X[F_X(1,1) - F_X(2,1)] \quad [62]$$

Equation [61] states that the new fractional concentration of B at the disk, $F_B'(1,1)$, is the old fractional concentration of B at the disk, $F_B(1,1)$, plus the amount of A which diffused into the disk and is transformed (with passage of current) into B, less the B which diffuses out.

Equation [62] states that the new concentration of X at the disk, $F_X'(1,1)$, is given by the old concentration less the X which diffuses out.

The new boundary conditions at the ring electrode are

$$F_A'(1,K_R) = F_A(1,K_R) + DM_B[F_B(2,K_R)] - DM_A[F_A(1,K_R) - F_A(2,K_R)] \quad [63]$$

$$F_B'(1,K_R) = 0.0 \quad [64]$$

$$F_X'(1,K_R) = F_X(1,K_R) - DM_X[F_X(1,K_R) - F_X(2,K_R)] \quad [65]$$

At this point the calculation of the effects of diffusion, convection and kinetics are repeated, then currents are calculated at $t = 2\Delta t$, and the process is continued until steady state is reached.

Boundary conditions for constant current.—It is also of interest to simulate the application of a constant current step to the disk electrode. This is done simply by modifying the disk electrode boundary condition in the above simulation. The boundary conditions for constant current at the disk are given by

$$F_A'(1,1) = F_A(1,1) - \text{FLUX} - DM_A[F_A(1,1) - F_A(2,1)] \quad [66]$$

$$F_B'(1,1) = F_B(1,1) + \text{FLUX} - DM_B[F_B(1,1) - F_B(2,1)] \quad [67]$$

$$F_X'(1,1) = F_X(1,1) - DM_X[F_X(1,1) - F_X(2,1)] \quad [68]$$

where F_A', F_B', and F_C' are the new fractional concentrations of species A, B, and C; F_A, F_B, and F_C are the old fractional concentrations. FLUX is the amount of A transformed into B by electrolysis during each Δt interval and is given by

$$\text{FLUX} = (i_{cc}/i_L)\ (0.776)\ (DM_A/L)^{1/2} \quad [69]$$

where i_{cc} is the applied constant current and i_L is the limiting current for species A.

Results

A Fortran program based on the methods of the previous section was written; a listing and discussion of this program is available (16). Calculations for a number of different electrode geometries were carried out on a Control Data Corporation Model 6600 computer and processing times quoted refer to compilation and execution times on this.

Effect of number of iterations.—From Eq. [12] and [22] it is clear that the number of iterations, L, determines the magnitude of Δx and Δt; the larger L, the closer the simulation will approximate the physical system. A simple test of the simulation is to compare the computed steady state current at the disk with that predicted by the Levich equation (15)

$$i_{S.S.} = 0.62\, n\mathbf{F}AC^{o}D^{2/3}\omega^{1/2}\nu^{-1/6} \quad [70]$$

When $L = 50$, the simulated steady-state current at the disk electrode is only 96.5% of the Levich equation limiting current. When $L = 1000$, however, the simulated disk current is 99.5% of the theoretical current. Similar results are obtained for the simulated collection efficiency. A simulation with $L = 50$ yields a collection efficiency 9% higher than that predicted by Albery and Bruckenstein (3) for an electrode with $IR1 = 83$, $IR2 = 94$, and $IR3 = 159$. When $L = 1000$, the simulated collection efficiency agrees to within 0.5% with the theoretical value.

Unfortunately, the computation time required to attain the steady state when $L = 1000$ is prohibitively long, requiring about 25 min of computer time. It was found, however, that identical results could be obtained from a simulation with $L = 50$, which requires only 25 sec of computer time, if a slight modification is made in the calculation of the effects of convection.

If Eq. [27] and [35] are modified as follows

$$XJJ = XJ/[1.0 - (1.11 \cdot XJ \cdot V_{NAUT})] \quad [71]$$

$$RKK = RK \exp[-1.03\,(XJ)\,(V_{NAUT})] \quad [72]$$

the results obtained with $L = 50$ are in close agreement with those using $L = 1000$ and the unmodified convection equations. The introduction of adjustable parameters into digital simulations involving convection has been successful in other cases (13). Note that the factors in Eq. [71] and [72] are valid only for $L = 50$ and $DM_A = 0.45$. There will be slightly different factors for different values of these parameters.

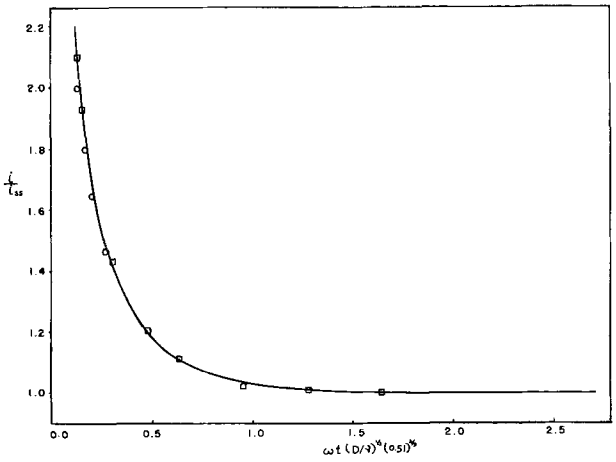

Fig. 2. Simulated disk current transient for potential step at disk: ⊙ theoretical work of Bruckenstein and Prager (17); ⊡ theoretical work of Siver (18).

Figure 2 shows the simulated disk current transient. The solid line is actually two curves, one generated using $L = 1000$ and the other using $L = 50$ and the correction factors. For all practical purposes, they are identical. The simulated curve is also compared with the theoretical and experimental work of Prager and Bruckenstein (17) and the approximate treatment of Siver (18). Both are in good agreement with the simulation.

Figure 3 shows the concentration profile of species A at steady state as a function of distance from the electrode surface in the normal direction. Curves b and c are the results of simulations using $L = 1000$, and $L = 50$ and the correction factors, respectively. On this scale, they are indistinguishable. Curve a is the theoretical concentration profile given by Riddiford (19). The agreement is quite satisfactory and indicates that the correction factors do not adversely affect the concentration profile.

Collection efficiencies.—Table I presents the simulated collection efficiencies in the absence of kinetics for a number of different electrode geometries. In these calculations $L = 50$ and the correction factors given in Eq. [71] and [72] were used. In all cases the simulated collection efficiencies are in excellent agreement with the theoretical collection efficiencies of Albery and Bruckenstein (3). Identical steady-state collection efficiencies are also predicted when the boundary conditions at the disk electrode correspond to a constant current step rather than a potential step. This is as would be expected. Furthermore, the steady-state collection efficiencies are unaffected by the mag-

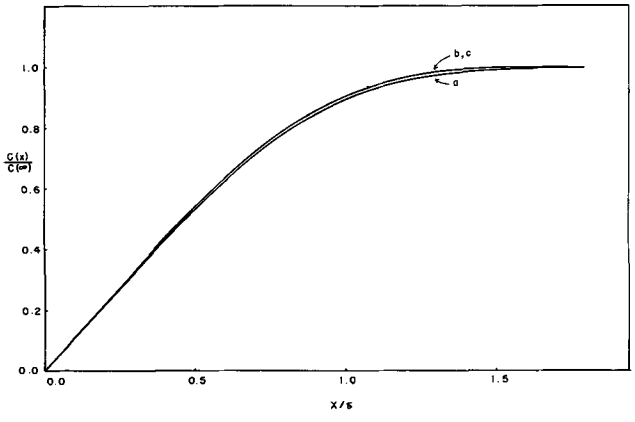

Fig. 3. Concentration profile of species at the disk: a, theoretical curve by Riddiford (19); b, simulated curve, $L = 1000$; c, simulated curve, $L = 50$, correction factors used. $\delta = 1.805\, D^{1/3}\nu^{1/6}\omega^{-1/2}$.

nitude of the current step, provided the current is smaller than the limiting current.

Ring transients.—From an approximate treatment of ring current transients (RCT), Albery (9) suggested that these could be employed to study fast homogeneous reactions of species generated at the disk electrode. Bruckenstein and Feldman (20) introduced the concept of the transit time from disk to ring electrode and suggested its application to the determination of rate constants of homogeneous reactions. Bruckenstein and Napp (21) have also shown that the RCT can be used to determine the amount of adsorption of electrogenerated products.

Figure 4 shows the RCT obtained when either a potential step or a current step is applied to the disk electrode and the ring electrode is held at a potential where all product reaching it is electrolyzed. The computed results for the RCT are identical for L = 1000 or for L = 50 and the modified convection equations.

Note that the current at the ring rises more rapidly when a potential step is applied. This is caused by the large instantaneous current which results at the disk when the potential is stepped (Fig. 2). The RCT, normalized by the steady-state ring current, due to a current step is independent at the magnitude of the current step.

We can compare the simulated RCT's with transit times predicted by Bruckenstein and Feldman (20). The appropriate equation given by them for the transit time (the time interval between the potential step at the disk and the appearance of current at the ring) in the absence of complications is

$$\omega t' D^{1/3} \nu^{-1/3} (0.51)^{2/3} = B[\log (r_2/r_1)]^{2/3} \qquad [73]$$

where ω is in radians/sec, t' is the transit time, and r_1 and r_2 are the radii of the disk and inner edge of the ring, respectively. Bruckenstein and Feldman (20) take B = 2.87, while a slightly different method of carrying out the integration in the derivation yields B = 2.28. Figure 5 shows the simulated RCT's for a potential step at the disk for electrodes of different geometries. Also shown are the transit times calculated from Eq. [73] for B-values of 2.28 and 2.87. A useful definition of the transit time, corresponding to Eq. [73] with B = 2.28, is that time at which the current is approximately 2% of the steady-state ring current. Taking the transit time at a given fraction of the steady-state current seems preferable for many electrodes to methods involving extrapolations of the rising current region of the RCT.

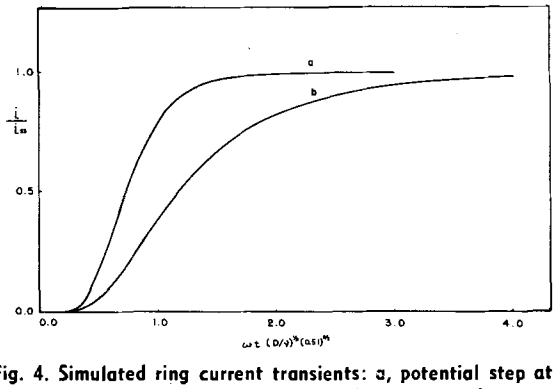

Fig. 4. Simulated ring current transients: a, potential step at the disk; b, current step at the disk; L = 50, correction factors used.

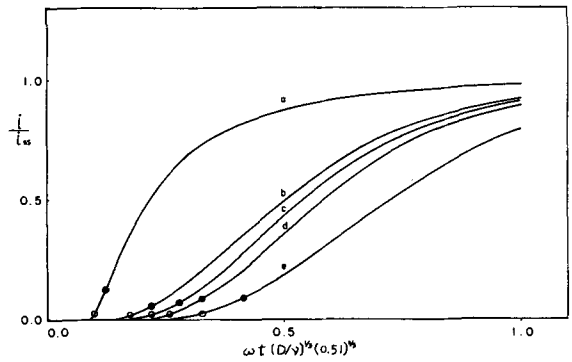

Fig. 5. Simulated transit times: a, $IR1$ = 2000, $IR2$ = 2040, $IR3$ = 2080; b, $IR1$ = 100, $IR2$ = 105, $IR3$ = 147; c, $IR1$ = 100, $IR2$ = 107, $IR3$ = 148; d, $IR1$ = 100, $IR2$ = 109, $IR3$ = 152; e, $IR1$ = 83, $IR2$ = 94, $IR3$ = 159; L = 50, correction factors used. The points correspond to transit times calculated using Eq. [73] with B = 2.28 (open points) and 2.87 (solid points).

We can also compare our results with those of Albery (9) who treated the RCT for the current step condition. For a thin-ring thin-gap electrode, he obtained two approximate equations, one which is valid at long times and the other which is more valid at short times. Figure 6 shows the simulated RCT for the current step condition at a fairly thin-ring thin-gap electrode ($IR1$ = 2000, $IR2$ = 2040, $IR3$ = 2080). Also plotted are points obtained from Albery's equations. The agreement is acceptable and points out the limits within which the approximate equations are valid. Unfortunately, these equations cannot be employed for most practical electrodes which are not of the required thin-ring thin-gap configuration.

Conclusion

The digital simulation technique has been shown to give theoretical results for transient and steady state behavior which are in good agreement with previous theoretical treatments and experiments. The digital simulation approach has the advantage of being directly applicable to situations involving more complex boundary conditions and coupled first and second order homogeneous chemical reactions. Results of dig-

The Equivalent Conductance of Electrolytes in Mixed Solvents

XII. Magnesium Sulfate in Water-Ethanol Solvents

Edward S. Amis and J. F. Casteel

Department of Chemistry, University of Arkansas, Fayetteville, Arkansas

ABSTRACT

The equivalent conductance of magnesium sulfate was measured at 25.00°, 35.00°, and 45.00°C in pure water and in 20.1, 40.7, 60.2, and 80.1 w/o (weight per cent) ethanol. Viscosity, temperature, and dielectric effects are calculated for the conductance process. Also the observed data were compared to the theoretical requirements of the Onsager equation.

Several studies have been made (1-10) in these laboratories of the equivalent conductance of different valence types of electrolytes in various solvent compositions over a range of temperatures. Even the simple salt, potassium chloride (1), has been shown to deviate, depending on the solvent and temperature, from the requirements of the Onsager equation. In other cases interesting suggestions as to the nature of the ions in solution (8) and as to solvent structure and solvation effects (7) have resulted from the conductance data. Since magnesium chloride (10) in ethanol-water solvents gave highly curved phoreograms with corresponding wide deviation from the theoretical Onsager plots, it seemed of special interest to study the conductivity of magnesium sulfate, the anion of which is also bivalent, in order to observe the expected marked curvature of the phoreograms of this salt in the water-ethanol solvent system and to investigate the deviations, also expected to be large, from the Onsager theory. Magnesium sulfate seemed to be of special interest since extensive conductivity work on bi-bivalent electrolytes in water-ethanol mixtures at various temperatures had not been reported.

The conductivity of magnesium sulfate has been studied at various temperatures in water (11) and at 25°C in ethanol-water mixtures ranging from 5 to 50 w/o ethanol (12). This present study includes conductivity measurements at 25.00°, 35.00°, and 45.00°C in various weight per cents of ethanol up to and including 80 w/o, which is the limiting weight per cent of ethanol for measurable concentrations of magnesium sulfate using our conductivity apparatus.

Experimental

All weights were previously standardized against NBS weights. The temperature of the thermostated oil baths were held to ±0.01°C at 25.00°, 35.00°, and 45.00°C. Densities of the mixed solvents were determined with a calibrated arm-pycnometer. In this manner the solvent composition was found within ±0.1%. The viscosities of the solvent mixtures were obtained from the literature (13). Dielectric constants of the mixtures were interpolated from the data of Akerlof (14).

Resistances were measured with a Jones and Joseph 60,000 ohm bridge at a frequency of 1000 Hz. Resistances were accurate to ±1.0 ohm. The L&N conductivity cells had cell constants of 5.3886 and 1.0430.

Conductivity water was prepared in the manner described by Foster and Amis (1). Pure ethanol was prepared by the method of Smith (15). The specific

conductance of pure water (1-3 x 10^{-7} mhos) and ethanol (4-7 x 10^{-8} mhos) agreed favorably with those found by Goldenberg and Amis (6). Solutions were prepared by adding a known amount of magnesium sulfate stock solution to the preweighed solvent. Necessary amounts of pure ethanol were added to restore the solvent composition. Magnesium sulfate (reagent grade Baker's Analyzed) was recrystallized from conductivity water three times, then vacuum dried to the heptahydrate.

Calculation Procedure

Onsager's equation for a completely dissociated bivalent electrolyte is given by

$$\Lambda = \Lambda_o - \left[\frac{4.6085 \times 10^6 \Lambda_o}{(DT)^{3/2}} + \frac{231.52}{(DT)^{1/2}\eta} \right] \sqrt{C} \quad [1]$$

where: Λ = equivalent conductance, Λ_o = equivalent conductance at infinite dilution, η = viscosity of the solvent, D = dielectric constant of the solvent, and T = absolute temperature. The term in the square bracket is called the Onsager slope, γ. Λ_o for all the runs were obtained by the Fuoss-Shedlovsky (16) theory. By application of this theory we determined the equilibrium constant, K, for the dissociation and the correct Λ_o.

The Fouss and Shedlovsky method uses the equation

$$\frac{F(Z)}{\Lambda} = \frac{1}{\Lambda_o} + \frac{C\Lambda f^2}{K\Lambda_o^2 F(Z)} \quad [2]$$

where: K = ionization equilibrium constant

$$Z = \gamma \Lambda_o^{-3/2} \sqrt{C\Lambda} \quad [3]$$

where: γ = Onsager slope and C = concentration in equivalents per liter

$$F(Z) = 1 - Z\,[1 - Z\,(1 - Z\,\{1 - -\}^{-1/2})^{-1/2}]^{-1/2} \quad [4]$$

Redefining C in terms of moles per liter c, the activity coefficient can be expressed as follows

$$-\ln f_\pm = \frac{\dfrac{\epsilon^3}{(DkT)^{3/2}} \left[\dfrac{\pi N_o}{1000}\right]^{1/2} (\nu_+ + \nu_-)^{1/2} (z_+ z_-)^{3/2} (c\alpha)^{1/2}}{1 + \dfrac{G\epsilon^3}{(DkT)^{3/2}} \left[\dfrac{\pi N_o}{1000}\right]^{1/2} (\nu_+ + \nu_-)^{1/2} (z_+ z_-)^{3/2} (c\alpha)^{1/2}} \quad [5]$$

Where $\mathring{a}$ was approximated by $\dfrac{G|z_+ z_-|\epsilon^2}{2DkT}$ and G was a converging factor.

$$\alpha = \frac{\Lambda}{\Lambda_o F(Z)} \text{ (the degree of dissociation)} \quad [6]$$

where: N = Avogadro's number, π = 3.14159, k = Boltzmann gas constant, D = dielectric constant, z_+ = charge of the positive ion, z_- = charge of the negative ion, ν_+ = number of positive ions per molecule, and ν_- = number of negative ions per molecule.

Preliminary values of Λ_o used in the Fuoss-Shedlovsky calculation were obtained with a least squares analysis using an IBM 7040 computer of the log Λ *vs.* $C^{1/2}$, which gave the values in the form

$$Y = a_o + a_1 X + a_2 X^2 + \ldots + a_\eta X^\eta \quad [7]$$

where Y represents log Λ and X the square root of the concentration in equivalents per liter. Initial values of log Λ_o from Eq. [7] were used to calculate the extrapolated values of Λ_o, *i.e.*, Λ_o(extrap). The Λ_o (extrap) values were used as the preliminary values of Λ_o for the Fuoss-Shedlovsky method, Eq. [2] and the most acceptable values of K and Λ_o (F-S) for the electrolyte in each solvent composition were found.

A brief outline of the Fuoss-Shedlovsky method is presented to help clarify the calculation procedure. The left hand side of Eq. [2] is plotted against $C\Lambda f^2_\pm / F(Z)$. The best straight line is obtained by a linear least squares analysis and is extrapolated to abscissa zero, thus obtaining $1/\Lambda_o$. The slope of the straight line is calculated and gives $1/K\Lambda_o^2$. Since Λ_o is known from the intercept, the value of K can be obtained from the slope. Actually, the value of K is calculated only after a reiterative calculation of the best value of Λ_o. The reiterative procedure consists of inserting in Eq. [2] the initial values of Λ_o obtained by use of Eq. [7]. This preliminary value of Λ_o permits a calculation of Z, $F(Z)$, α, and $f_\pm$. The reiteration proceeds from each extrapolated better value of Λ_o to yield better values of Z, $F(Z)$, α, and $f_\pm$. This reiterative procedure continues until Λ_o becomes constant within any desired limits. In the case of our data, the limit of the self-consistent values of Λ_o was chosen to be 0.0001% of the preceding value.

It can be easily seen from Eq. [2] and specifically from Eq. [5] that the numbers of ions per formula of electrolyte and the valence of the ions must be defined in order to calculate $f_\pm$, γ, Z, $F(Z)$, and eventually Λ_o and K. In order to determine the numbers and the valence of the ions produced by an electrolyte in solution, an ionization scheme must be postulated. Whatever ionization scheme is selected, it must result in values of ν_+, ν_-, z_+, and z_- which, when inserted in the equations given above, will permit a computer evaluation of Λ_o and K. Since the Fuoss-Shedlovsky calculation (Eq. [2]) is very discriminatory (8) with respect to the ν and z values used, only a limited number of ionization schemes are available to an investigator. The theory as formulated permits only one choice of type of ionization scheme for any particular set of data. A wrong choice of an ionization scheme for a particular set of data results in one of three objectional features in the calculation:

(*A*) The reiterative calculation will not converge.

(*B*) Impossible values of Λ_o and K will be obtained.

(*C*) $A\sqrt{-1}$ factor will result which generally appears in the $F(Z)$ function, thus making the calculation impossible.

With these limitations in view, the following ionization schemes were finally selected for the different solvent compositions in order to evaluate Λ_o(F-S) and K:

Solvent	Ionization scheme
H_2O	$MgSO_4 \rightarrow Mg^{2+} + SO_4^{2-}$
20.1%	$MgSO_4 \rightarrow Mg^{2+} + SO_4^{2-}$
40.7%	$2MgSO_4 \rightarrow Mg^{2+} + Mg(SO_4)_2^{2-}$
60.2%	$2MgSO_4 \rightarrow Mg^{2+} + Mg(SO_4)_2^{2-}$
80.1%	$MgSO_4 + H_2O \rightarrow MgOH^{1+} + HSO_4^{1-}$

After the values of Λ_o(F-S) and K were calculated, they were substituted into Eq. [1] and a value of Λ, *i.e.*, Λ(calc), was obtained for each concentration. Then these calculated values of Λ were used to recalculate Λ_o(F-S) and K to check for self-consistency in the program and to give an indication of the accuracy of the method of calculation.

Values of Λ_o(F-S) and Λ_o(extrap) were used to calculate the energy of activation of the conductance process by the following procedure. The energy of activation of viscous flow, $\Delta E\eta$, is given by (17)

$$\eta = e^{\Delta E\eta / RT} \quad [8]$$

then

$$\Delta E_\eta = \frac{d(\ln\eta)R}{d\left(\frac{1}{T}\right)} \qquad [9]$$

Pederson and Amis (9) used the following equations for the calculation of $\Delta E_{\Lambda_o exp}$ and $\Delta E_{\Lambda_o cal'd}$

$$\Delta E_{\Lambda_o exp} = -\frac{d(\ln\Lambda_o)R}{d\left(\frac{1}{T}\right)} \qquad [10]$$

$$\Delta E_{\Lambda_o cal'd} = \left[2\frac{d(\ln D)}{d\left(\frac{1}{T}\right)} + \frac{d(\ln\eta)}{d\left(\frac{1}{T}\right)} + 2\frac{d(\ln T)}{d\left(\frac{1}{T}\right)}\right] R \qquad [11]$$

The slopes were calculated by use of Eq. [7] at the temperature of 35°C. $\left[\frac{d(Y)}{d(X)}\right]_x = a_1 + a_2 X$ where $Y = \ln D, \ln\eta, \ln\Lambda_o, \ln T$; where $X = 1/T$, and where $T = 308.15$°K.

Numerical values given by these calculations are presented in the Discussion of Data section.

Discussion of Data

The observed and calculated equivalent conductance data are recorded in Table I. Plots of observed and calculated values of Λ *vs.* $C^{1/2}$, the square root of the concentration in equivalents per liter, are shown in Fig. 1-3. From the figures it can be seen that the agreement between observed and calculated values of Λ is good. In Fig. 1 are included the data from the International Critical Tables (11) for magnesium sulfate in water at 25.00°C. It is obvious from the graph that these data agree well with the present data. The data

of Davies and Thomas (12) for both 20 and 40 w/o ethanol also agree well with our data for both 20.1 and 40.7 w/o ethanol. The agreement between the sets of data can be seen in Fig. 2 for 20.1 w/o ethanol at 25.00°C.

There is good agreement between the values of Λ_0(extrap) and $\Lambda_0(F\text{-}S)$, shown in Table II, in water, 20.1 and 40.7 w/o ethanol, and poor agreement in 60.2 and 80.1 w/o ethanol. The discrepancies between $\Lambda_0(F\text{-}S)$ and Λ_0(extrap) in 60.2 and 80.1 w/o ethanol were not due to imprecision or error in the data but resulted from a failure of the theory in the ethanol rich solvents which is probably due to the formation of more than one complex by association of the ions of the electrolyte. This multiplicity of complexes was not accounted for by one simple ionization scheme; however, the ionizations presented previously, or others comparable to them in the numbers of ions and their charges produced per formula of electrolyte, must have been the predominate ionizations or else the calculations would have run into the problems listed in the calculation section.

In Table II are presented the values of $\Lambda_0(F\text{-}S)$ and $\Lambda_0(F\text{-}S$ calc) and of K and K(calc). The agreement between the two sets of Λ_0 and the two sets of K is good. From the care used in purifying chemicals, making measurements, and performing calculations, the differences between the values of $\Lambda_0(F\text{-}S)$ and K obtained from measured values of Λ and from values of Λ calculated by inserting the values of $\Lambda_0(F\text{-}S)$ and K back into the Fuoss-Shedlovsky equations is certainly indicative of the self-consistency of the data and of the calculations. These differences, which are slight, are perhaps the best indication of the accuracy of the $\Lambda_0(F\text{-}S)$ and K obtained by use of the Fuoss-Shedlovsky method since there are no absolute values of these quantities available for comparison.

The ratio of the observed slope to the Onsager slope is shown for water and 20.1 w/o ethanol. The ratio

becomes so great at weight per cents above 20.1 that they are not considered to be significant. This extreme deviation from the Onsager theory for sulfates in higher weight per cents of ethanol was also noted by Davies and Thomas (12). Also shown in Table II is the product $\Lambda_o\eta$, which is relatively constant for 0.00, 20.1, and 40.7 w/o ethanol. Values of $\Lambda_o\eta$ in 60.2 and 80.1 w/o ethanol show marked decreases compared to the values in the first three solvents. This corresponds to the observation by Than and Amis (10) on the magnesium chloride in the water-ethanol system.

The reasonable consistency of $\Lambda_o\eta$ in the water-rich solvents and its decrease in the ethanol solvents is in harmony with the reasonable ratio of the observed slope to the Onsager slope in the water-rich solvents and the unreasonable values to the ethanol-rich solvents. The plots of $\Lambda_o(F\text{-}S)$ *vs.* viscosity (Fig. 4) show the dependence of equivalent conductance at infinite dilution of magnesium sulfate on viscosity. This dependence has the broad finger shape which has been shown to exist in alkali metals in water-ethanol mixtures (1, 9, 10).

Plots of $-\log K$ *vs.* $1/D$ (Fig. 5) for the three temperatures show a linear relationship from 0.00 to 80.1 w/o ethanol. The plots indicate that the relationship between $pK(-\log K)$ and $1/D$ is independent of temperature. The data of Davies and Thomas (12) are inserted for comparison. The agreement between their measured values of K and our calculated values is good. The values of K show that the presented ionization schemes are reasonable since they decrease very rapidly with decreasing dielectric constant.

If $\log \Lambda_o(F\text{-}S)$ is plotted *vs.* $1/T$ (Fig. 6), straight lines result for water for 20.1 and 40.7 and slightly curved lines for 60.2 and 80.1 w/o ethanol; therefore, the energy of activation must be calculated at a particular temperature for the two latter curves. The Fuoss-Shedlovsky method seems to weigh higher temperatures more heavily; thus, the increase in the value of Λ_o is greater for a given increase in temperature at higher temperature as shown in Table II. Therefore the slope $d(\ln\Lambda_o)/d(1/T)$ is much more negative than one would find by the use of Λ_o's obtained by a simple extrapolation.

The dotted line (Fig. 7) shows the values of $\Delta E_{\Lambda_o\text{exp}}$ (extrap), *i.e.*, calculated from Λ_o(extrap). This is what one would expect considering the values of K. Also, this curve is in agreement with the shape of the $\Delta E_{\Lambda_o\text{exp}}$ curve found by Than and Amis (10). The results of these calculations are recorded in Table III.

Manuscript submitted May 12, 1969; revised manuscript received *ca.* Sept. 12, 1969.

Technical Notes

Thermal Stability of a Propylene Carbonate Electrolyte

Raymond Jasinski and Susan Carroll

Tyco Laboratories, Inc., Bear Hill, Waltham, Massachusetts

Lithium-organic electrolyte batteries are, in principle, superior in a number of aspects to many aqueous electrolyte battery systems. One of the aspects may be prolonged performance at elevated temperatures, *e.g.*, 160°-200°F (71°-94°C). This temperature range is not accessible, for example, to aqueous zinc batteries because of the increased corrosion of this electrode.

Obviously then, one requirement for lithium batteries intended to operate at these temperatures is compatibility of the negative electrode with the electrolyte. In this note are described preliminary studies on the thermal stability of lithium, and other selected battery components with IN$LiClO_4$-propylene carbonate electrolyte, a system employed by a number of groups in developing prototype batteries [see ref. (5) and (2)].

Experimental

The propylene carbonate was distilled and analyzed according to the method described in ref. (1). Sufficient $LiClO_4$ (G. F. Smith, anhydrous grade) was added to make a 1*N* solution which was then further dried by passage down a column of crushed and dried Molecular Sieves. This procedure has been shown to reduce the water content to less than 10 ppm (4). The absence of gassing on insertion of the lithium was consistent with a dry solution.

The first tests were qualitative in nature. Approximately 10 ml of the electrolyte was placed in a 50-ml beaker containing the component of interest. The open beaker was set on a hot plate; a thermocouple, inserted into the bottom of the beaker, was used to monitor temperature. Results are shown in Table I.

In the first run ($LiClO_4$ + PC) the solution was taken to dryness, with no obvious reaction. A second solution was held at 180° for 5 hr with similar results. Heating the electrolyte with lithium metal also provided no obvious reaction. However, the inclusion of acetylene black and sulfur resulted in a violent reaction when the temperature reached the values shown. Only a small amount of electrolyte was lost by evaporation.

Table I. Stability of 1*N* $LiClO_4$-PC solutions

Material	Temperature, °C	Result
$LiClO_4$ in PC	To dryness	Stable
$LiClO_4$ in PC	180 (5 hr)	Stable
$LiClO_4$ in PC + Ni_3S_2	To dryness	Stable
$LiClO_4$ in PC + acetylene black	215	Exploded
$LiClO_4$ in PC + sulfur (flowers)	260	Burned
$LiClO_4$ in PC + lithium (sheet)	240	Stable

To confirm these processes in working cells, a C-size battery was built in a Leclanché-type configuration. The positive was a paste of nickel oxide, sulfur, and acetylene black (10%) with $LiClO_4$-PC). A high current pulse (2A for 30 sec) was applied resulting in immediate explosion.

A more quantitative evaluation of the compatibility of metallic lithium with the electrolyte was made as follows. Three lithium rods, scraped clean of visible nitride and oxide films within an argon atmosphere dry box (Vacuum Atmospheres Corporation) were placed in a three-compartment glass cell. The counter and test electrodes were separated by a glass frit; the reference electrode was separated from the anode by a Luggin capillary. The anode was a cylinder, ⅜ in. diameter.

The test cell was then sealed, removed from the glove box, and placed in an oven thermostatted at + 160°F. A constant current of 1.27 mA was maintained. The effective current density at the anode was 1 mA/cm^2; this is based on using only the area facing the counterelectrode. That this was reasonable was indicated by the fact that pronounced electrochemical dissolution of lithium occurred only on the side facing the center electrode, as would be expected.

The reference electrode-anode voltage was followed continuously with time; these data are shown in Fig. 1. Visual observations were periodically made of the electrode surfaces and the appearance of the electrolyte. The electrolyte remained clear and colorless; no gassing was noted; the anode surface maintained its metallic luster; a slight tarnish was visible on the reference electrode after 800 hr, resembling the form of lithium deposited on the cathode. The appearance of the cathode change markedly. Lithium electrodeposits as an amorphous powder which is only very loosely adherent and not metallic in appearance. It is not possible to judge, from the electrode appearance, whether the electrolyte is stable under such conditions; however the electrolyte in the vicinity of the cathode did remain clear and colorless.

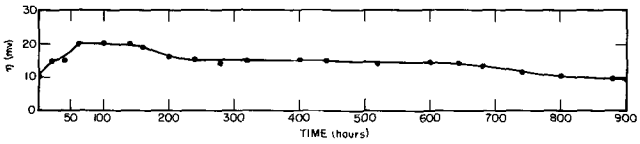

Fig. 1. Time dependence of the reference electrode, anode potential shown for lithium electrodes immersed in 1N $LiClO_4$-PC at +160°F.

Discussion

Consider first the compatibility experiments described by Table I. No gross decomposition was noted in heating the electrolyte alone or in the presence of lithium sheet. More sensitive gas chromatographic evidence indicates some electrolyte decomposition at and above 150°C (1). The electrolyte was not compatible at high temperatures with acetylene black and sulfur. The first material has often been used as a conductive binder in positive plates; sulfur has been suggested as a positive plate material (2, 3). Particular caution should be used in handling positives formed from carbon, sulfur, and lithium perchlorate: This combination resembles closely the classical composition of gun powder.

The electrochemical method is felt to be a particularly severe test of system compatibility, since fresh lithium surface is continuously exposed to the electrolyte at the anode and cathode. Thus, thin but protective films become much less effective in retarding gross decomposition of the electrolyte. As shown in Fig. 1, the polarization of the lithium anode remains relatively constant; there is no indication of any major deterioration in performance with time. The reason for the minor improvement after 600 hr has not been established. Two explanations are possible. First, small amounts of film on the anode are slowly lost by electrochemical dissolution of the electrode and hence it improves with time. Second, small amounts of film deposit on the reference electrode and it slowly deteriorates with time. In either event, the effect is small, a few millivolts over a 900-hr test.

The conclusion to be drawn from these experiments is that there is not a gross decomposition of the electrolyte by anodically discharging lithium metal at 160°F which would prohibit its use in a working battery. This is a necessary although not a sufficient condition for the development of high temperature lithium batteries. Oxidizable materials such as sulfur and acetylene black are not compatible with $LiClO_4$-PC at elevated temperature.

A Laboratory Cell for Testing Anode Materials

A. Tasch, L. E. Vaaler,* and J. M. Finn, Jr.*

Carbon Products Division, Union Carbide Corporation, Cleveland, Ohio

Scaled down diaphragm and mercury cells have been used for many years for the laboratory evaluation of anode materials for chlorine cells. The preparation, operation, and maintenance of these laboratory cells required considerable effort, and, as a result, the present investigation was initiated for the purpose of developing a new laboratory cell that would permit a more precise procedure for the study of the fundamentals of corrosion and the development of improved product. A simple system for depolarizing the cathode was conceived and resulted in a test cell which does not require a diaphragm or brine source. In the new cell the chlorine ion is oxidized to chlorine at the test anode, and the bath is replenished by reduction of chlorine gas bubbled through a porous graphite cathode. Conditions in this cell can be controlled more easily than in the laboratory cell used previously (1).

Apparatus

Figure 1 is a simplified sketch of the cell and the functioning electrodes. The corrosive environment is contained in a battery jar and consists of 30 liters of sodium chloride solution at a concentration of 220 g/l and saturated with chlorine.

Anode and anode support.—Figure 2 is a photograph of the anode parts and assembly.

The anode sample, 1.129 ± 0.002 in. in diameter, provided a corroding surface of 1 in.^{2}. The sample thickness was chosen as a result of corrosion depth measurements (2) which showed that anode graphites may be attacked to a depth of as much as 8 mm below the surface. The thickness of ½ in. (12.7 mm) used in the laboratory cell was, therefore, more than adequate to show the full corrosive attack. The sample edge was drilled and tapped (5-40 tap) to a depth of ½ in. to provide means for attaching an electrical conductor.

A Laboratory Cell for Testing Anode Materials

A. Tasch, L. E. Vaaler,* and J. M. Finn, Jr.*

Carbon Products Division, Union Carbide Corporation, Cleveland, Ohio

Scaled down diaphragm and mercury cells have been used for many years for the laboratory evaluation of anode materials for chlorine cells. The preparation, operation, and maintenance of these laboratory cells required considerable effort, and, as a result, the present investigation was initiated for the purpose of developing a new laboratory cell that would permit a more precise procedure for the study of the fundamentals of corrosion and the development of improved product. A simple system for depolarizing the cathode was conceived and resulted in a test cell which does not require a diaphragm or brine source. In the new cell the chlorine ion is oxidized to chlorine at the test anode, and the bath is replenished by reduction of chlorine gas bubbled through a porous graphite cathode. Conditions in this cell can be controlled more easily than in the laboratory cell used previously (1).

Apparatus

Figure 1 is a simplified sketch of the cell and the functioning electrodes. The corrosive environment is contained in a battery jar and consists of 30 liters of sodium chloride solution at a concentration of 220 g/l and saturated with chlorine.

Anode and anode support.—Figure 2 is a photograph of the anode parts and assembly.

The anode sample, 1.129 ± 0.002 in. in diameter, provided a corroding surface of 1 in.^{2}. The sample thickness was chosen as a result of corrosion depth measurements (2) which showed that anode graphites may be attacked to a depth of as much as 8 mm below the surface. The thickness of ½ in. (12.7 mm) used in the laboratory cell was, therefore, more than adequate to show the full corrosive attack. The sample edge was drilled and tapped (5-40 tap) to a depth of ½ in. to provide means for attaching an electrical conductor.

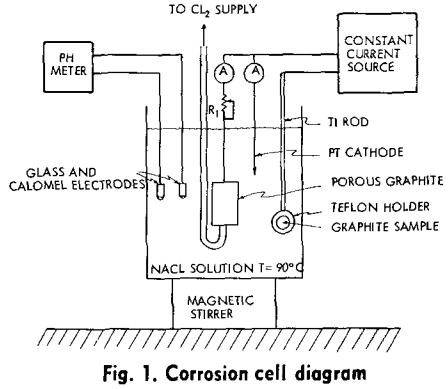

Fig. 1. Corrosion cell diagram

* Electrochemical Society Active Member.

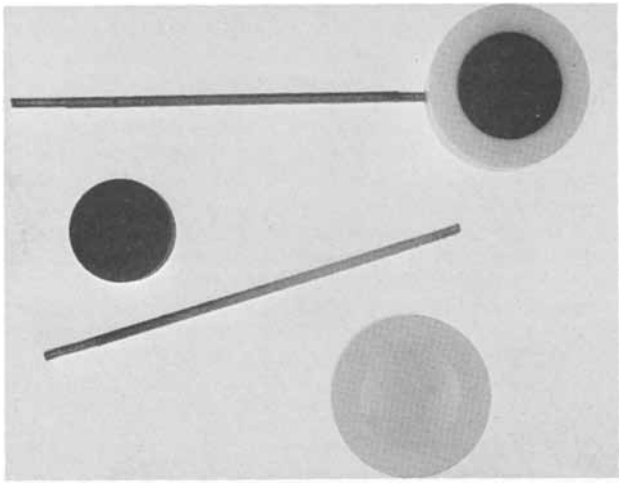

Fig. 2. Anode components and assembly

The test anode was pressed into a cylindrical Teflon holder that protected all but one face of the graphite from attack. The inside diameter of the Teflon can be as much as 0.005 in. larger than the outside diameter of the graphite and still maintain adequate protection. Current was carried to the anode through a ⅛ in. diameter titanium rod which had a 6-40 threaded end to provide an interference fit with the graphite.

Cathode.—The most critical assembly of the laboratory test cell is the chlorine depolarized cathode. This electrode supplies chloride ions to the bath through the reduction of chlorine gas. The cathode consists of a porous graphite block threaded to a ½ in. diameter graphite rod which acts as a physical support as well as an electrical conductor. A glass tube attached to the bottom of the block conducts the chlorine gas to the bath. Porous graphite (PG-25) having the greatest gas permeability was used for the block so that a minimum of gas pressure would provide an adequate supply of chlorine. It was usually found necessary to bubble chlorine through the block for a period of 3-4 days at a pH of 2.0 before normal operation of the cell was initiated. After four to six months of operation, the porous block began to disintegrate rapidly and was replaced. The graphite support rod corroded in the area between the bath level and the cover and also needed periodic replacement.

In addition to the chlorine depolarized cathode, a small platinum wire cathode, connected in parallel, produced hydrogen gas and hydroxyl ions. The platinum cathode simulates, in a controlled manner, leakage of caustic into the anolyte in a diaphragm cell or hydrogen evolution (with OH^- ion formation) on a mercury cathode.

Covers and supports.—The top of the jar was covered with a 1-in. thick Lucite plate which supported the samples, heater, pH electrodes, and cathode and prevented the evaporation of the liquid. The Lucite does not appear to react with the gas or bath and, after one year of operation, there were few signs of deterioration. The cover was drilled with four holes 3½ in. in diameter. Each of four Lucite stoppers made to fit these holes supported four anode assemblies so that 16 samples could be tested simultaneously. Figure 3 shows the cover in place and the location of the various electrodes.

pH Measurement.—The pH of the solution was measured through the use of glass and calomel electrodes by normal techniques and instrumentation. The pH calibration, however, was obtained by using a buffer in a salt solution at 90°C. The two electrodes were located in the center of the cell directly above the cathode block. This position, determined by experimentation, is electrically "neutral" so that the pH

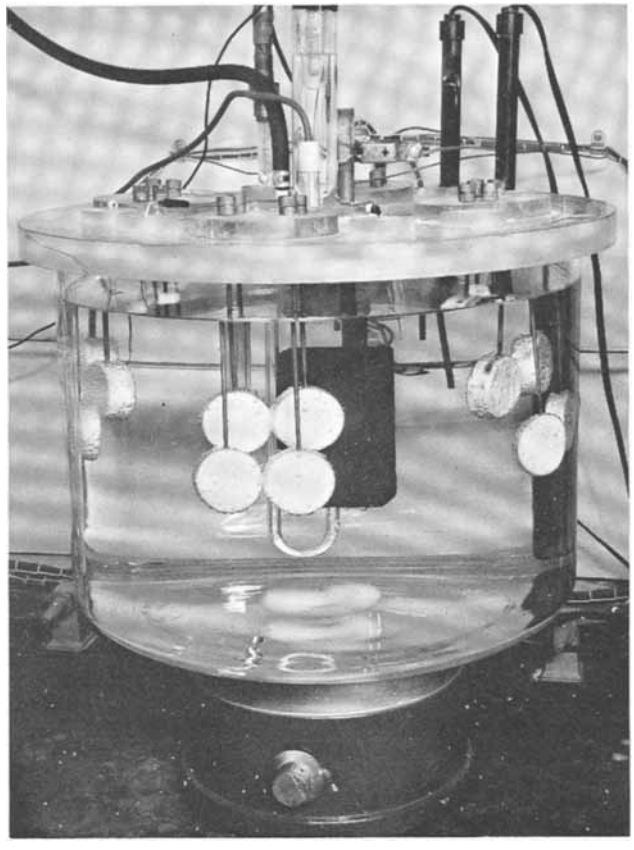

Fig. 3. Photograph of corrosion cell showing location of electrodes.

measurement is affected very little by the electric field associated with the current flow to the anode samples. This arrangement makes it possible to record the correct pH automatically with a recording potentiometer.

Heating and stirring.—The cell bath was maintained at 90°C by means of glass-covered immersion heaters in conjunction with an on-off type control unit. Two 500W units were found to be sufficient even with no thermal insulation of the battery jar.

The uniformity of conditions throughout the bath was insured through the use of a magnetic stirrer under the glass container. Determinations of pH, showed that the variation of this parameter, throughout the bath, is within the error of the measuring instrument (0.1 unit).

Power supply and constant current source.—The electrical current for cell operation was obtained from a rectifier with a variable 30V, 50A, unfiltered output. Filter networks and transistorized constant current circuits were used to produce ripple-free direct current to the anodes. Figure 4 is a schematic of the filter network and the simple one-transistor circuit which maintained the current at a level determined by the setting of R_3. The constant current was obtained by operating the transistor on the flat portion of its col-

lector characteristic. A current density of 0.8 A/in.^{2} was used since this value is typical of commercial diaphragm cell operation. The constant current circuit maintained this level with a tolerance of ±3% when steady-state operating conditions were achieved. Figure 5 shows two test cells in operation, the power source, and control equipment.

Chlorine supply.—The flow of chlorine to the cathode must be great enough to replenish the chloride removed at the anodes and to keep the electrolyte saturated with the gas. To achieve these conditions, chlorine gas was supplied from a stainless steel manifold which was connected to a pressure cylinder containing 150 lb of liquid chlorine. The gas, taken from the manifold, was metered through a Monel valve, passed through a drier of calcium sulfate, and then through a glass bubbler which permitted the flow rate to be adjusted visually. From the bubbler, the Cl_2 passed through a neoprene hose to the glass tube of the cathode assembly. The neoprene hose and graphite cathode block deteriorate in service and must be replaced periodically. Maintenance of the cell, therefore, has been reduced to this simple replacement procedure.

Operation and Experimental Procedure

The best results[1] were obtained by corroding the test samples in the brine solution for five days, washing in hot water for one day, and drying at 110°C for one day. The first five days of corrosion were considered "break-in" time, during which the corrosion rate was highly variable. Conditions were sufficiently stable thereafter to obtain reproducible results during successive five day corrosion periods so that the determination of corrosion rates required a total elapsed time of two weeks.

The test anodes were weighed before installation and following washing and drying after the corrosion period. The weight loss per 1000 A hr of operation is defined as the "corrosion rate" that characterizes the anode material.

The operating parameters of the laboratory cell were selected on the basis of laboratory investigations and commercial operating conditions. The conditions used to obtain the corrosion data presented in this paper were the following: temperature = 90° ± 1°C; current density = 0.8 ± 0.02 A/in.^{2}; brine concentration = 220 ± 10 g/l; I_{pt} = 15% of total cathode current.

The value of I_{pt} (the platinum cathode current) was adjusted by means of R_1 in Fig. 1. By setting this current to various percentages of the total current the pH of the solution could be changed as shown in Fig. 6. In an alternate mode of operation, the platinum cathode was used as an element to control pH at a selected value. For the data presented in this paper the platinum cathode current was adjusted to 15% of the total current because this value produced a pH in the range from 3.0 to 4.0 for the types of graphites examined. This pH is in the range existing in production diaphragm cells.

[1] In an alternate procedure, it was found possible to follow the external corrosion of the anode via changes in its archimedean volume (contained brine and all). The anode was periodically removed and weighed, without washing, above and under a salt solution (220 g/l) of exactly known density. From these data the volume was precisely determined.

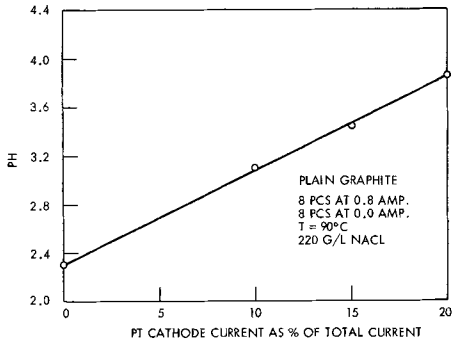

Fig. 6. Effect of Pt cathode current on electrolyte pH

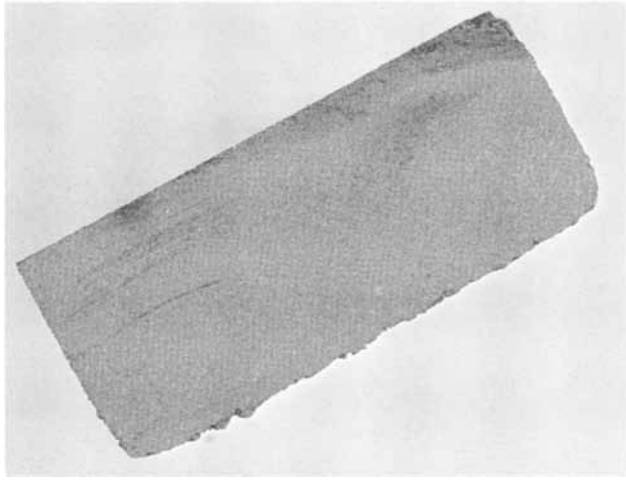

Fig. 7. Cross section of corroded sample

Experimental Results

Figure 7 is a photograph of a cross section through the diameter of a corroded sample indicating that corrosion is reasonably uniform except for some rounding near the circumference. This result indicates that the current density is uniform over most of the surface and somewhat higher at the edges. More elaborate means of assuring a uniform current density could have been provided but would have interfered with free convection and gas escape at the electrode surface.

The corrosion rates of four samples taken from an experimental oil-treated graphite anode are presented in Table I. The average value for the first week was obtained during the "break-in" period and, therefore, should not be compared with the data of subsequent

Table I. Oil-treated anode corrosion rate

σ = Standard deviation.

corrosion periods. The excellent agreement between the average values for the second and third weeks demonstrates the reproducibility of the measurements.

The effect on service life of impregnating graphite with linseed oil is shown in Table II. The samples for the two sets of data involved the same base stock and processing except for the linseed oil treatment. A 20% reduction in corrosion rate was obtained through the use of linseed oil as the impregnating material.

The relatively large standard deviation for the oil-treated graphite was due primarily to the exceptionally low value of corrosion rate of oil-treated sample 2. There was nothing unusual about the appearance of this sample and it is suspected that there was an error in weighing. If sample 2 is omitted, the results show that the cell functions very well in the evaluation of plain and oil-treated graphite and can distinguish between oil-treated graphites as demonstrated by a comparison of the data of Tables I and II.

Samples of oil-treated graphite, through which no current was passed, were immersed in the cell in which the eight oil-treated samples which carried current were being tested. This technique was used to compare the extent of chemical corrosion (no current) with chemical plus electrochemical (current) corrosion. The average weight loss due to chemical corrosion was 28% of the total weight loss of the samples carrying current. This loss is appreciable and does not involve the mechanical erosion that occurs at a conducting electrode at which gas is produced. Conceivably mechanical corrosion could accelerate the corrosion rate on the nonconducting samples.

With the accuracy of control of the meaningful parameters and the simplicity of operation, the apparatus described has become a useful laboratory tool for studying the corrosion of anodes for use in chlorine cells.

Acknowledgment

The authors wish to express their appreciation to N. J. Johnson and M. Janes for the helpful suggestions regarding chlorine chemistry and the discussions of the chlor-alkali industry in general. The assistance of M. G. Swartz in the operation and maintenance of the test cells has been invaluable.

The Electrochemical Decomposition of Propylene Carbonate on Graphite

A. N. Dey* and B. P. Sullivan*

Laboratory for Physical Science, P. R. Mallory & Company, Inc., Burlington, Massachusetts

Propylene carbonate (PC) became one of the most commonly used solvents for organic electrolyte batteries after the successful electrodeposition of lithium (1) from a PC solution of its salt. The solvent was also considered to be relatively stable with lithium. Considerable (2, 3) attention was given to the purification of the solvent to remove the supposedly electroactive impurities, *e.g.*, water. There was no information available regarding the electroactivity of PC itself. We wish to present evidence in this report to show that PC is electrochemically decomposed on the graphite cathode to propylene gas and carbonate ion with almost 100% coulombic efficiency.

Experimental

Propylene carbonate (Eastman Kodak) was vacuum distilled at 120°C, 1.2 mm Hg.

Anhydrous $LiClO_4$ was used as received from G. Fredrick Smith Company.

The graphite rods (⅛ in. diameter), used as working electrodes, were of special spectroscopic type (National AGKSP) supplied by Fisher Scientific Company.

Lithium ribbons (Foote Mineral Company) pressed on stainless steel exmet were used as reference and counterelectrodes.

* Electrochemical Society Active Member.

Perkin Elmer Model 801 gas chromatograph (GC) was used for analysis of the gas and the electrolyte. The column used was Porapak Q with a He flow rate of 20 cc/min, hot wire detector temperature of 200°C, and detector current of 200 mA. The column temperature of 60°C was used for gas analysis.

The water content of our electrolyte was found to be 0.09% (volume).

The cell.—The schematic diagram of the cell is shown in Fig. 1. The working electrode was a graphite rod (A) connected with the platinum wire which was sealed in a glass tube. The electrical connection was made using a copper wire dipped in the mercury pool in the glass tube. The reference (C) and the counterelectrodes (B) were spot welded with the Pt wires from two other glass tubes. The glass container (D) connected with the cell was filled with the PC and the level of the PC in the side arm was adjusted up to the tip of the side arm (as shown in Fig. 1) using dry argon stream, prior to the electrolysis. On electrolysis the evolved gas displaced an equivalent volume of PC from the container (D) and was collected in the container (E) and weighed. The volume of the gas evolved was determined from the weight of the displaced PC. The method was found to be sensitive enough to measure gas volumes of 0.005 cc or more. Also, the PC in

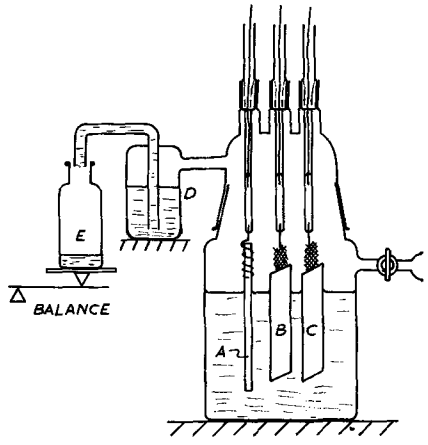

Fig. 1. Cell for the measurement of rate of gas evolution: (A) graphite cathode, (B) and (C) lithium counter and reference electrode, (D) PC container, and (E) container for the weighing of the displaced PC.

container (D) prevented transport of moisture and other impurities from the atmosphere to the cell electrolyte. The cell was assembled in the dry box in an argon atmosphere, and the subsequent gassing experiment was carried out in the open atmosphere. The weight changes due to the evaporation of PC were found to be negligible.

The chemical evolution of gas (H_2) with the lithium electrodes in the electrolyte, was found to be exceedingly low ($< 1\%$ of the gas) during the duration of the gassing experiment. The entire amount of the evolved gas was found to be generated electrochemically at the graphite cathode only.

Experimental Procedure.—Galvanostatic experiments were carried out using Regatron Constant Current Power Supply, Model C-612, (Electronic Measurements Inc.). The electrolyte used was 1(M) $LiClO_4$ in PC. The potential of the graphite working electrode, *vs.* Li reference, and the volume of gas evolved was recorded as a function of time, on passage of a constant current. During electrolysis the graphite rod electrode was found to disintegrate slowly. However, the gassing rate and the potential-time curves were found to be reasonably reproducible when a new graphite rod was used for each run.

At the end of the run the samples of gas and the electrolyte were removed and analyzed by GC. The graphite electrode and the disintegrated materials were collected from the cell on a filter paper (in the dry box) and washed thoroughly with tetrahydrofuran to remove all PC. The electrode along with the disintegrated materials were then acidified with phosphoric acid and the evolved gas was removed by bubbling prepurified argon and was passed first through a cold trap and then through a standard solution of $Ba(OH)_2$. The CO_2 in the gas was quantitatively determined by titrating $Ba(OH)_2$ solutions.

Results and Discussion

A typical chronopotentiogram (corrected for IR) on a graphite electrode in 1(M) $LiClO_4$-PC electrolyte is shown in Fig. 2. The open-circuit voltage of +2.75V *vs.* Li reference dropped sharply on the passage of cathodic current (2 mA/cm^2) and a relatively steady plateau voltage of approximately +0.6V *vs.* Li was observed. During this galvanostatic electrolysis a substantial evolution of gas was observed on the graphite cathode. The rate of gas evolution at an apparent current density of 2 mA/cm^2 is plotted in Fig. 3 for two electrodes of different size. On doubling the total current (same current density) the increase in the rate of gassing was found to be more than double. The

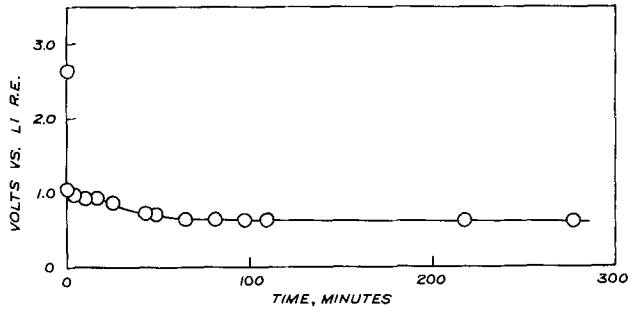

Fig. 2. Chronopotentiogram on graphite electrode in 1M $LiClO_4$-PC electrolyte. Apparent current density = 2 mA/cm^2.

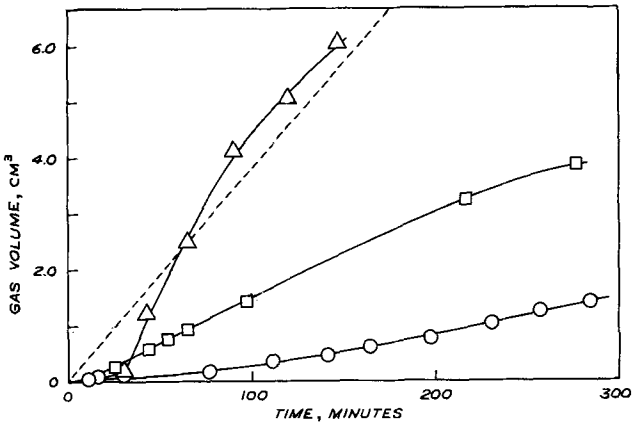

Fig. 3. Rate of gas evolution plots: □ rate of gas evolution at 2 mA/cm^2, total current = 10 mA; in 1M $LiClO_4$-PC; ○ rate of gas evolution at 2 mA/cm^2, total current = 5 mA; in 1M $LiClO_4$-PC; △ rate of gas evolution at 2 mA/cm^2, total current = 5 mA; in 1M $LiClO_4$-PC saturated with propylene; - - - theoretical rate of gas evolution at 5 mA current.

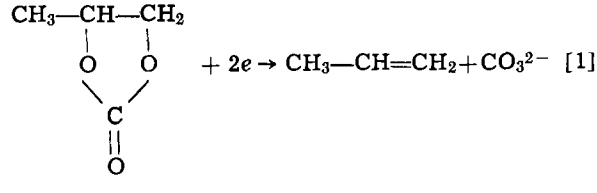
gassing rate was also found to be increased substantially on increasing the current density.

The gas chromatographic analysis of the evolved gas showed that the major ($> 95\%$) component consisted of propylene. The presence of CO_2, H_2, and ethylene in trace quantities ($< 1\%$) was also detected. The G.C. analysis of the electrolyte, after electrolysis, also showed the presence of propylene, as a major new component, and traces of water. No other new component was detected in the electrolyte.

We propose the following electrochemical reaction to explain the formation of propylene.



Based on the above reaction it was possible to determine the coulombic efficiency of gas evolution. The dotted line in Fig. 3 represents the theoretical rate of gas evolution at 5 mA current according to reaction [1]. Apparently, the observed rates are considerably lower. However, we found that propylene was highly soluble in PC. Therefore, the gassing experiment was then carried out in a propylene saturated 1M $LiClO_4$-PC electrolyte. Results in Fig. 3 show that the experimental rate in propylene saturated solution is quite close to the theoretically expected rate.

Reaction [1] also predicts the stoichiometric formation of Li_2CO_3 (insoluble) as a result of the electrochemical decomposition of PC. This was analyzed by determining the amounts of CO_2 evolved on acidifying

Table I. Determination of Li_2CO_3 in the graphite electrode after electrolysis

Apparent current density, mA/cm²	Coulombs passed	Moles of CO_2 observed	Theoretical moles of CO_2 based on reaction [1]	Coulombic efficiency, %
1	185	1.14×10^{-3}	0.96×10^{-3}	118
2	418	2.20×10^{-3}	2.16×10^{-3}	102
2	306	1.63×10^{-3}	1.59×10^{-3}	102
2	393	1.98×10^{-3}	2.04×10^{-3}	97

The coulombic efficiency was again found to be approximately 100%.

the electrode after the electrolysis. Results are shown in Table I.

Formation of trace amounts of H_2 and CO_2 could be due to the chemical and/or electrochemical decomposition of H_2O present in the electrolyte. However, the decrease in the water content did not show any measurable effect on the formation of the main products, *viz.*, propylene and CO_3^{2-}. Thus, the effect of H_2O (0.09% vol) in the above reaction was of minor importance, if any.

It was thus established that PC could be electrochemically decomposed quite efficiently on graphite substrates at potentials substantially positive to that of lithium. However, we found that at higher current densities the potential of the graphite electrode slowly decreased to less than 0V *vs.* Li reference and lithium deposition ensued. Under these circumstances, both the decomposition of PC and the lithium deposition occurred on graphite. This could explain the previously observed (2) inefficient lithium deposition on graphite. On metals like Pt, Ni, Cu, etc., the cathodic chronopotentiogram in 1(M) $LiClO_4$-PC usually consisted of three short voltage plateaus prior to lithium deposition as observed (4) in our laboratory earlier. One of those could be due to the decomposition of PC. On metals like Pt, Ni, Cu, etc., the overvoltage for the lithium deposition could be relatively lower than on graphite and thus lithium deposition became the predominant cathodic reaction, whereas on graphite the decomposition of PC was the predominant reaction at low current densities.

Graphite was one of the most common conductive mixes used for practical battery cathodes. The above finding thus raises a serious question regarding the validity of many cathodic efficiency measurements and also regarding the feasibility of using PC for practical organic electrolyte batteries. Measurements of the kinetics of lithium electrode in PC may also be in error because of the solvent decomposition reaction discussed above.

Similar electrochemical decompositions were observed in other solvents and will be discussed in a future publication.

The Mechanical Behavior of Anodic Coatings on Deformed Aluminum

N. J. Cochrane[1] and R. J. Block

Department of Chemical Engineering and Materials Science, The University of Oklahoma, Norman, Oklahoma

ABSTRACT

Aluminum monocrystals and polycrystalline wire having coatings were deformed in boric acid. The behavior of the coatings was studied using a potential technique to determine the progress of film rupture and by optical metallography. The results suggest that the coating-substrate interface is capable of sustaining significant shear strain.

The rupturing of oxide coatings on metals is believed to play a part in stress corrosion cracking (1) and in the corrosion of cold worked metals (2). As a result, the behavior of barrier-type passive coatings has become a subject of some interest (3-6). In the present paper we describe experiments in which the initiation of fracture in the coating was accurately determined relative to the yield strain of the substrate. The behavior of the coating was studied metallographically to determine its response to the deformation processes. Both aluminum crystals and polycrystalline wire were used as substrate material.

Experimental

The experimental technique, after Logan (1), involved extension of the specimen in a 0.4M boric acid electrolyte while simultaneously measuring its potential relative to a saturated calomel electrode. The specimens, mounted in glass or Lucite balls, were electropolished, stripped of residual films, and either placed open circuited in the boric acid or anodized at 90V prior to extension. The treatments produced barrier coatings 100 and 1300Å in thickness. Coating thicknesses were estimated using the technique of Hunter and Fowle (7), and the usual 14 Å/V relationship.

Results

Figure 1 is a tracing of the load-extension, potential-extension chart records of one of the single crystals tested. The magnitude of the potential difference between specimen and electrode is plotted as a positive value. The crystal was of square cross section ⅛ in. of a side by 1.0 in. gauge length. The orientation of this crystal is given in Fig. 2.

Examination of the 100Å coating after increments 1 and 5 showed only slip plane traces which were apparent on both faces of the crystal. After sufficient extension, the 1300Å coating was found to crack. Cracking always initiated on the crystal surface most nearly perpendicular to the Burgers' vector of the primary slip system. Often a pattern of cracks had developed on the $(\bar{2}\bar{1}0)$ face of the crystal before any cracks had appeared on the $(1\bar{2}2)$ surface. Using round monocrystals, it was verified that displacements causing slip steps rather than surface shears were responsible for crack initiation in the coating. Slip displacements in the absence of corresponding cracks were clearly evident beneath the coating and may be seen in Fig. 3 and 4. Once formed, the cracks always propagated along directions normal to the tensile axis, encircling the crystal.

Conversion of the load-extension data to resolved shear stress-strain curves showed that the crystal ended stage I midway through the second strain increment and deformed in stage II thereafter. Figure 1 shows a small but reproducible delay of about 0.03% extension between yielding of the crystal and onset of film rupture in the 100Å coating. This value is about an order of magnitude less than the maximum extension reported by Bradhurst and Leach (8) for a 20Å film on an aluminum alloy. The difference may be the result of fracture of the coating across fewer but larger slip steps on the monocrystals used here. The delay appears in increments 1 and 5 as well as

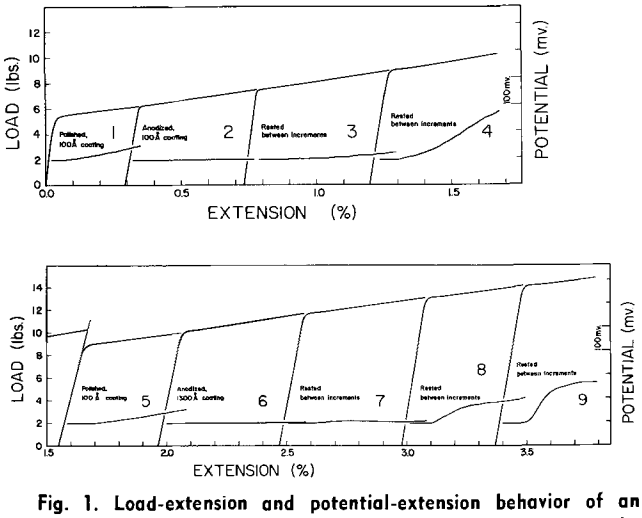

Fig. 1. Load-extension and potential-extension behavior of an aluminum single crystal. Treatment of the specimen prior to the strain increment is indicated.

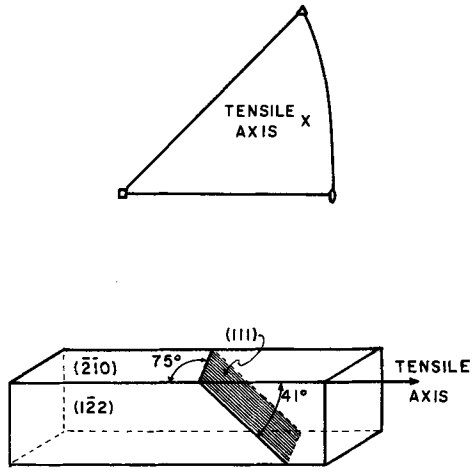

Fig. 2. Stereographic and geometric representation of the crystal used in the sequence of Fig. 1.

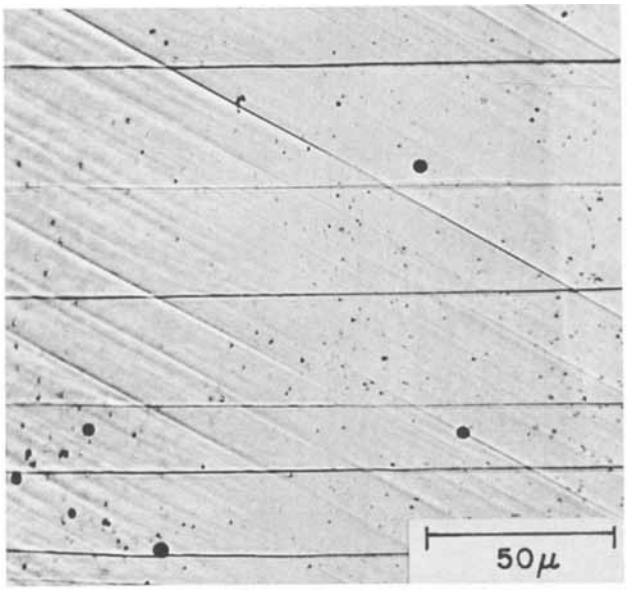

Fig. 3. Photomicrograph of the (2̄10) surface of a crystal having the same orientation as in Fig. 2. The specimen was anodized at 90V and extended 2%. The tensile axis is vertical. Horizontal cracks and diagonal slip plane traces are shown.

increments 4, 8, and 9. In these latter cases flow in the substrate initially caused film rupture where old cracks in the anodized coating had been repaired with the 100Å coating during the rest period between strain increments. Later in these increments new cracks formed in the 1300Å coating.

The surfaces of anodized specimens for which extension had been interrupted before a sharp potential change had occurred (as after increments 2, 3, 6, and 7) showed only slip plane traces equivalent to the diagonal markings visible in Fig. 3. It was verified that a change in specimen potential occurred only with the appearance of circumferential cracks in the coating. Here one is forced to conclude that the coating can remain intact over the shear displacements and slip steps present at the coating substrate interface. The diagonal markings must then be slip plane traces viewed through the transparent coating.

The anodized coating sustained about 1% extension of the substrate before fracture initiated (increments 2-3 and 6-7). Once again one might expect larger extensions with more isotropic substrates. In experiments with annealed aluminum wires having a grain size of 0.002 in., the difference between yielding and the onset of film rupture was about 1.4% extension.

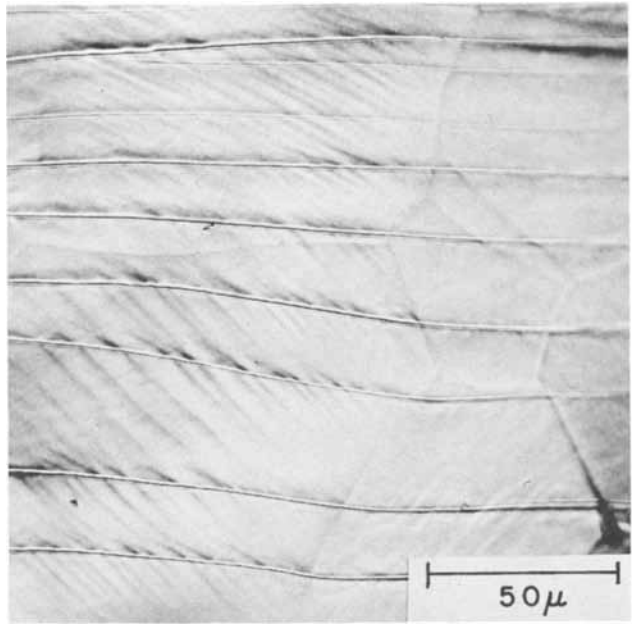

Fig. 4. Photomicrograph of a polycrystalline aluminum wire, anodized at 90V and extended 3.7%. The tensile axis is vertical.

This value is about the same as has been reported elsewhere (8, 9).

Discussion

The results of these studies raise several questions about how thick anodic coatings accommodate deformation of the substrate. Crack propagation appears to be a macroscopic phenomenon in which the film and substrate seem to behave as though they were concentric cylinders under axial load. Cracks which open independent of slip plane traces are most easily pictured as occurring with localized detachment of the coating just ahead of the growing crack. However, the mechanism for crack propagation may also describe how the film accommodates shear of the underlying surface without cracking. The high shearing stresses induced in the coating at slip plane traces could be relieved by interfacial slip, shear of the film or detachment over an area adjacent to the slip plane trace. The first of these mechanisms was invoked by Edeleanu and Law (9) to explain the relaxation of stress between cracks in anodic coatings. Shear of the coating appears to be unlikely in view of the very brittle behavior of isolated coatings observed by Bradhurst and Leach (8) and the present experiments which showed that substrate exposure (potential changes) did not generally accompany the formation of slip lines in the substrate. Shear of the coating may also be eliminated on the basis of observations described below.

Detachment may also be ruled out because of somewhat more indirect evidence. After sufficient extension of the substrate, the thick anodized coatings were observed to buckle, as shown in Fig. 5. Buckling is the result of a decrease in the cross sectional perimeter of the specimen as it elongates. The coating detaches and becomes raised from the surface as indicated by the interference fringes in the micrograph. Buckles in coatings always ran parallel to the tensile axis, and when fully developed, from crack to crack. Figure 5 shows several buckles passing over regions of well defined slip lines where the surface displacements should be fairly large, yet the buckles are not deflected by the slip plane traces. It is also apparent that the coating where raised is unbroken by the slip plane. Therefore, one might conclude that the coating can remain unbroken and adherent to the substrate across slip plane traces even after considerable deformation.

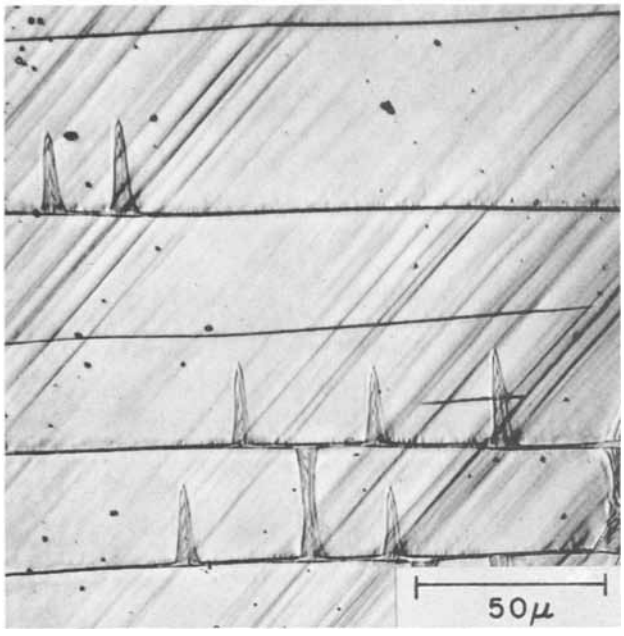

Fig. 5. Photomicrograph of an aluminum single crystal, anodized at 90V and extended 14%. The vertical structures are buckles in the coating.

It appears that the only model which survives is the equivalent of a rather viscous glue which can deform in shear while still firmly bonding the coating to the substrate. The strength of thick coatings was sufficient to require shear of the glue while apparently the opposite situation was obtained with the thinner coating which cracked along the slip plane traces. It seems reasonable to suggest that the characteristics required of the interfacial glue may reside in the misfit dislocations (10) which accommodate film and substrate.

Acknowledgments

The authors wish to express their appreciation to Mr. Parviz Mehdizadeh for his helpfulness throughout the study. Fluorescence and Energy Transfer in $SrZnP_2O_7:UO_2^{+2}$

M. V. Hoffman*

General Electric Company, Lighting Research Laboratory, Nela Park, Cleveland, Ohio

ABSTRACT

An efficient green phosphor has been found in $SrZnP_2O_7:UO_2^{+2}$. Optimum formulation of host matrix, cation substitutions, and activator concentrations have been made and tested in fluorescent lamps. The structure has not been determined, but it is suggested that it may be a UO_2^{+2}-stabilized structure differing from the apparent host matrix of $SrZnP_2O_7$. Efficient energy transfer by radiationless transfer has been found to Eu^{+3} and Nd^{+3}.

The fluorescence of uranium in solids and in liquids is well known and has been thoroughly described in the literature (1, 2). A recent paper by Blasse (3) on the emission characteristics of many uranium-activated compounds with related cubic structures also includes a review of the literature on uranium-activated phosphors. Both green and red emission have been reported for uranium activation, and from these papers, it is apparent that the emission spectra depend on the lattice environment and on the particular uranium-oxygen group. Blasse attributes the green emission in certain phosphors to U^{+6} in octahedral positions, occupying a normal crystallographic site. The spectra of this type of phosphor consist of overlapping bands, varying in peak position and relative intensity, dependent on the structure and influenced by all the surrounding O^{-2} ions.

Another source of green emission is the uranyl group $(O—U—O)^{+2}$, a linear molecular species. These spectra are primarily influenced by the linear or axial U—O bonds, while the equatorial field from the other four U—O bonds exerts only a small influence and does not greatly modify the spectra (4). The emission consists of at least six relatively strong lines, and the absorption contains about 14 lines in the ultraviolet and blue region and a continuum in the ultraviolet. These emission and absorption characteristics are consistent with respect to relative band position, band spacing, and intensity in all matrices in which they are found. By this optical data, the presence of U^{+6} in the uranyl group can be distinguished from U^{+6} in a UO_6^{+6} or UO_4^{+2} group.

* Electrochemical Society Active Member.

Key words: luminescence, $SrZnP_2O_7:UO_2^{+2}$, energy transfer, UO_2^{+2} to Eu^{+3}, uranyl emission, strontium Zn phosphate luminescence.

Rabinowitch and Belford (5) have described the literature on the spectra of UO_2^{+2} in solids such as nitrates, chlorides, sulfates, phosphates, and acetates, and have included much of the earlier work of Dieke and Duncan (6). While it is possible to describe and identify the UO_2^{+2} spectra, little correlation has been possible with the structure in which the ion can be found. In general, the solid materials on which most spectra measurements have been made are hydrates, or formed by decomposition of hydrates, and contain UO_2^{+2} as a major matrix constituent.

The phosphor described here is activated by UO_2^{+2} as determined by its spectra, in a crystalline matrix based on $SrZnP_2O_7$. The structural incorporation of the UO_2^{+2} in this phosphor has not yet been determined.

Procedure.—The starting materials used to prepare the phosphor were standard grades normally used in commercial luminescent materials. These were $SrHPO_4$ and $ZnNH_4PO_4$, prepared for phosphor production, ZnO, $(NH_4)_2HPO_4$, and $UO_2(C_2H_3O_2)_2 \cdot 2H_2O$, purchased as reagent grade material. Uranyl acetate has a flaky consistency which makes uniform mixing difficult. The most satisfactory method was to incorporate the activator by coprecipitation. This was achieved by the addition of NH_4OH to an acid solution containing Zn^{+2}, UO_2^{+2}, and a slight excess of PO_4^{-3} ions. When the precipitate was fired to determine loss on ignition, the product did not retain the uranyl ion, but was arbitrarily calculated as "$(Zn_{1-x}U_x)_2P_2O_7$." Compensation with x or $x + 0.01$ moles ZnO gave the required stoichiometry, showing that the precipitated material had close to the assumed ratio of $Zn/U/PO_4$ even though the oxygen compensation for the uranium was not known. Even though mixing procedures were simplified and were made more efficient by the use of this precipitate, wet mixing in acetone was still found to be necessary to obtain complete diffusion of the UO_2^{+2} during firing.

Firing was in air, in quartz or platinum crucibles, at 800°C for 1 hr followed by 900°C for 2 hr or more. The brightness of the fired material is highly dependent on the preparative technique and formulation, which must include a precise stoichiometry, thorough dispersion of the activator, and a final firing at about 900° ± 10°C.

Formulation and phase relations.—All formulations and activator contents are given as moles per mole of $SrZnP_2O_7$. The identification of the activator as UO_2^{+2} is shown by its absorption and emission in a later section. These characteristic measurements, combined with microscopic examination and x-ray diffraction were used to determine the compositional limitations in the phosphor and the compatibility phase relations of the systems. The phosphor is a matrix of $SrZnP_2O_7$ with the activator, UO_2^{+2}, calculated as additive to the pyrophosphate. The activator can be accepted in amounts up to about 0.10 mole UO_2^{+2} per $SrZnP_2O_7$. Beyond this limit, microscopic examination shows the presence of a second compound. The addition of a full mole of UO_2^{+2} to $SrZnP_2O_7$ results in the formation of this second phase, which is a dark green compound, highly refractory, well crystallized, and easily identifiable by microscopic examination. An orthophosphate formula of $SrZnUO(PO_4)_2$, with U as +4, can be written for this material. Diffuse reflectance measurements showed good agreement with line absorption found for U^{+4} in CaF_2 (7) and no absorption or emission characteristic of UO_2^{+2}.

From optical data, the phosphor can be limited to a material of composition which is variable between $SrZnP_2O_7$ to $SrZnP_2O_7$:0.10 UO_2^{+2}. Above the UO_2^{+2} solid solution limit, the system contains two phases, each containing uranium, but in different oxidation states.

A further requirement of the phosphor is that the SrO=ZnO=P_2O_5=1 ratio must be maintained. Any deviation from this ratio, such as would result from substituting UO_2^{+2} for Sr, for Zn or for P_2O_5, results in the loss of the characteristic UO_2^{+2} absorption and emission. Further, every attempt to provide charge compensation for UO_2^{+2} had the same result. Therefore, the phosphor composition lies only along the join between $SrZnP_2O_7$ and $SrZnUO(PO_4)_2$.

X-ray diffraction patterns of $SrZnP_2O_7$ and of the phosphor show the addition and intensification of new lines with increasing additions of UO_2^{+2}, and a decrease in intensity of some of the host matrix lines. Close to the solid solution limit, a slight shift in a few lines was found. This introduction of new lines with UO_2^{+2} additions could indicate interstitial incorporation of the activator. The x-ray diffraction pattern of the orthophosphate compound closely resembles the additive lines found in the phosphor. For this reason, x-ray diffraction is a poor tool to define compositional and solid solution limits. The XRD patterns of the three materials are compared in Table I. These were obtained on a General Electric XRD 5 using CuKα radiation.

Optical Characteristics

Procedures.—The spectral energy distributions were measured on a direct reading spectroradiometer with a grating monochromator, corrected for photocell response, similar to that described by Brown (8). The spectral slit width is 10Å. The diffuse reflectance spectra were obtained on a Cary 14 recording spectrophotometer and are relative to CaF_2 as a standard. It is modified by the insertion of a 7-54 filter between the sample and detector when measuring between 250 and 360 nm to avoid interference from emission from the sample.

The excitation spectra were obtained by illuminating the sample at 45° normal incidence with a beam of 10-15Å spectral band width obtained from a Cary spectrophotometer, Model No. 14, and focusing the luminescence onto the entrance slit of a ¼ meter JACO monochromator which was set to give the maximum luminescence signal. The light which was chopped immediately before entering the monochromator, was detected by an EMI 9558 QB photomultiplier and the signal was synchronously amplified by a P.A.R. HR-8

lock-in amplifier whose output was recorded on a strip chart recorder. The excitation signal was normalized by dividing by the energy present in the exciting beam which was determined below 330 nm using sodium salicylate phosphor. Between 330 and 600 nm, Rhodamine B was used as the standard. Both have essentially constant quantum efficiencies in the regions specified.

The decay rates of the phosphors were measured by exciting with a brief (2 μsec duration) light pulse (General Radio Strobotac filtered by a 2537Å interference filter). The luminescence was collected by lenses and passed through a JACO ¼ meter monochromator (200Å spectral band width) onto the cathode of a photomultiplier (Amperex 150 AVP). The voltage across the load resistor was displayed *vs.* time on an oscilloscope (Tektronix Type 535A) and photographed with a Polaroid camera. The pictures were measured and the decay data plotted on semilog paper to obtain the decay times.

Measurements.—The spectral distribution of the phosphor at room temperature is shown in Fig. 1, measured against a standard commercial lamp phosphor, Zn_2SiO_4:Mn. The diffuse reflectance is shown in Fig. 2. Comparison of these spectra with the data presented by Bell and Biggers (9) confirm that the absorbing and emitting species is UO_2^{+2} (Table II). The Bell and Biggers data was resolved in the region 3325-5000Å, from spectra of UO_2^{+2} in perchlorate media. At 77°K, the emission spectra of the phosphor retained the relative intensities of the lines, except that the line at 482 nm was quenched, and the side bands on the low energy side were resolved, as the line emission narrowed. The diffuse reflectance spectra did not change in line width or intensity at 77°K.

5	568	17,600	17,917
6	593	16,870	17,081

The excitation was measured by monitoring the 519 nm emission line (Fig. 3 and 4). The excitation follows the absorption with the same band spacing and intensity. The excitation data also show additional small peaks which could indicate the position of vibronic levels. These peaks were not resolved in the diffuse reflectance.

Phosphor evaluation.—The relative intensities of the UO_2^{+2} emission bands do not change with compositional or processing variables, but several factors influence the absolute intensity. Substitutions in the host matrix can be made. When a larger ion is substituted, such as Ba for Sr or Cd for Zn, the brightness is increased. The substitution of smaller ions, Mg for Zn and Ca for Sr, decreases the brightness. This change may reflect the need for a slightly larger crystal lattice to accommodate the UO_2^{+2} ion better. These changes are shown in Fig. 5. The change in brightness with activator concentration is shown in Fig. 6 and is further confirmation of the extent of the solid solution range. A 0.20 substitution Ba for Sr and 0.06 UO_2^{+2} was used in the phosphor formulation for optimum brightness in lamp tests.

The brightness was also found to be dependent on particle size, regardless of whether the size was obtained by milling, classification, or as a result of the

firing procedures used. The best phosphors had an average particle diameter (Fisher SSS) of 12 to 15μ. Firing temperature was the greatest single factor in determining brightness, by its effect on particle size growth. Reduction of the size by milling lowered the brightness by creating very small particles, but classification by separation or refiring did not change the size-brightness correlation. This proved to be a detriment in application in fluorescent lamps, since the particles were too large to make a satisfactory lamp coating without a milling step. The milling necessary to give adequate coating appearance resulted in a loss of brightness of 20-30%.

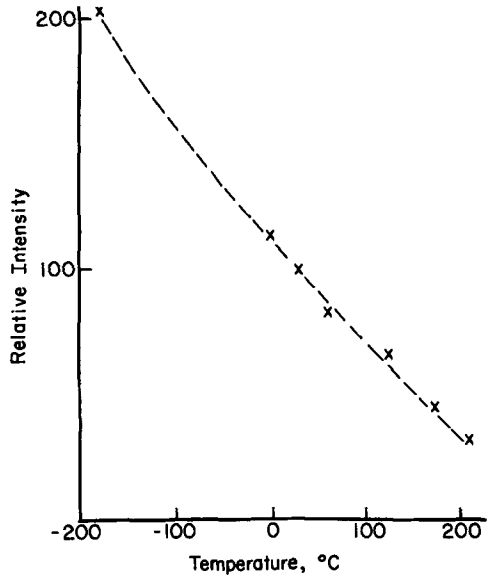

Fig. 7. Peak intensity variation with temperature, 2537 excitation

An additional detriment to lamp application is the decrease in peak intensity with temperature, as shown in Fig. 7. The decrease is large enough to reduce the intensity 8-10% at the operating temperature of a standard fluorescent lamp.

Lamp data were obtained in F 40 T 12 fluorescent lamps, and typical data are shown in Table III. While the lumen level is low for a green phosphor, and below that calculated from relative spectral distributions such as Fig. 1, the lumen maintenance is uniformly good. These results show that the UO_2^{+2} ion can be stable in a fluorescent lamp, if incorporated in a suitable matrix.

Energy transfer.—The transfer of energy from UO_2^{+2} to rare earth ions has been reported in solids, in glass, and in solutions (10-14). The rare earths involved in these systems have included Nd, Eu, Pr, Ho, Er, and Tm. Decay measurements were made by Gandy *et al.* (10) for the $UO_2^{+2} \rightarrow Nd^{+3}$ transfer in barium crown glass and by Zhabotinskii *et al.* (11) in $Cs_2[UO_2Cl_4]$ with transfer to several rare earths. These showed a decrease in the lifetime of the uranyl ion, and the transfer was attributed to radiationless transitions from the resonance level of UO_2^{+2} to the rare earth.

In measuring the $UO_2^{+2} \rightarrow Eu^{+3}$ energy transfer in solutions, Kropp (14) found quenching of the UO_2^{+2} emission with Eu^{+3} enhancement, but the lifetime of the UO_2^{+2} emission was too short to measure. He attributed the transfer to absorption by the $^5D_1$ or $^5D_2$ level of Eu^{+3} of the UO_2^{+2} emission. A similar mechanism was proposed by DeShazer and Cabezas (12) for Eu^{+3} in a glass host.

In this phosphor, efficient energy transfer has been found from UO_2^{+2} to Eu^{+3} and to Nd^{+3}. To a lesser extent, transfer was also found to Sm^{+3}. With Eu^{+3} in $SrZnP_2O_7$ substituting on a Sr site, the emission

Table III. Lamp data, F40T12 lamps

Hours burned	Lumens	LPW

500	1394	35.4

is very weak under all excitations. The spectra, shown in Fig. 8, show evidence of extensive crystal field splitting of the Eu^{+3}. Excitation of the Eu^{+3} emission in $SrZnP_2O_7$ is close to linear between 220 and 280 nm and then decreases to essentially no response at 350 nm. With the incorporation of UO_2^{+2}, the emission, the intensity, and the excitation of Eu^{+3} change. The emission of an optimized sample is shown in Fig. 9, in which the dominant Eu^{+3} emission is the $^5D_0$-$^7F_2$ transition. Changes in relative intensities within the multiplets indicate some change in the Eu^{+3} symmetry resulting from the presence of UO_2^{+2}. The intensity is increased by 60-fold over the Eu^{+3} spectra shown in Fig. 8. The excitation of the Eu^{+3} is now identical to that of the UO_2^{+2} activator, showing the same structure.

This change in Eu^{+3} spectra will occur with as little as 0.002 moles UO_2^{+2} incorporated in the phosphor matrix. Additional UO_2^{+2} does not change the Eu^{+3} transitions, and the spectra of both emitting ions remain the same for all Eu^{+3} and UO_2^{+2} concentrations. Changes in the relative intensities of the two spectra occur as the UO_2^{+2} emission is quenched by the transfer to Eu^{+3}. A typical change is shown in Fig. 10. Optimum Eu^{+3} emission is found between 0.003 and 0.005 Eu, with about 0.06 UO_2^{+2}.

Similar transfer and enhancement was found for Nd^{+3}, in which the emissions at 875 and 1060 nm were measured. The Nd^{+3} spectra did not change with the addition of UO_2^{+2}. A 50-fold enhancement was measured with 0.004 Nd^{+3} in a sample with 0.06 UO_2^{+2}

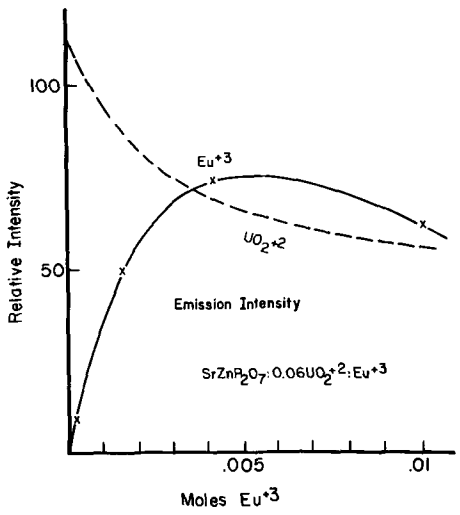

Fig. 10. Relative peak intensity of Eu^{+3} and UO_2^{+2} with Eu^{+2} concentration, 2537 excitation.

added. The excitation of the enhanced Nd^{+3} emission also follows the UO_2^{+2} excitation spectra.

Decay measurements were made on the UO_2^{+2} emission for variations in activator concentration and also with rare earths incorporated. Results are shown in Table IV. This shows energy transfer by a radiationless process from UO_2^{+2} to Eu^{+3} and to Nd^{+3} and Sm^{+3}. No transfer is apparent for Ho^{+3} or Er^{+3} and is questionable for Pr^{+3} from both the decay and the emission measurements.

Discussion

The interesting and perhaps unique aspect of this phosphor is in the incorporation of the UO_2^{+2} ion as an activator in variable amounts, resulting in an efficient phosphor, in a crystalline matrix which does not have a logical site for substitution. The UO_2^{+2} ion has been shown to be linear, with the U—O bond length between about 1.7-1.9Å, depending on the structure in which it is found (4, 15). The full O—U—O^{+2} ion would require 3-4Å distance to be accommodated in the structure, as well as charge compensation. This is a very large ion to be substituted in a matrix containing Sr (1.12Å) and Zn (0.74Å). Several facts indicate that the phosphor is not a substitutional solid solution of UO_2^{+2} in $SrZnP_2O_7$. The stoichiometric requirement of SrO=ZnO=P_2O_5=1, with UO_2^{+2} as an additive must be met. Deviations from this ratio would result in the presence of strontium or zinc phosphates, either metaphosphates or one of several orthophosphates, as a second phase. These compounds when prepared with UO_2^{+2} do not fluoresce efficiently, or absorb unusually. If present in amounts of several per cent, none of these would be expected to greatly reduce the total emission intensity. With this phosphor, this is not the case. Even deviations of a few mole per cent from the exact stoichiometry result in the loss of much of the UO_2^{+2} incorporation in the phosphor. It would appear that the phosphor consists of a structure stabilized by the presence of the O—U—O^{+2} ion, present in a range of up to about 0.10 mole per $SrZnP_2O_7$. Further, this

structure is limited to a narrow composition line along the join between $SrZnP_2O_7$ and $SrZnUO(PO_4)_2$.

Preliminary work on the structures indicates that the unactivated $SrZnP_2O_7$ is possibly orthorhombic and that the phosphor is a monoclinic distortion.

An additional indication that a structural modification of $SrZnP_2O_7$ may be caused by UO_2^{+2} incorporation comes from the differences between the Eu^{+3} spectra in each structure. In the phosphor $SrZnP_2O_7$:UO_2^{+2}:Eu^{+3}, the dominant Eu^{+3} transition is the $^5D_0$-$^7F_2$, while in $SrZnP_2O_7$:Eu^{+3}, the spectra is more complex (Fig. 9 and 8). If the $SrZnP_2O_7$ stoichiometry is not maintained, but with UO_2^{+2} and Eu^{+3} present, the emission is a mixture of the two spectra, with greatly reduced $SrZnP_2O_7$:UO_2^{+2} emission. By analogy to the phase relations, the deviations in stoichiometry could place the composition in a two phase region, identifiable by the emission spectra as $SrZnP_2O_7$:Eu^{+3} and $SrZnP_2O_7$:UO_2^{+2}:Eu^{+3}.

The UO_2^{+2} emission is essentially from a level centered at 20,200 cm^{-1} to the ground state and vibronic levels above the ground state. At 77°K, the emission at 482 nm (20,800 cm^{-1}) is quenched, and side bands of the major emissions are resolved. These are about 250 cm^{-1} lower in energy than the major emission and 5-10% as intense. The existence of this second set of emission lines with a band spacing of about 850 cm^{-1} suggests the possibility of two sites for the UO_2^{+2} ion.

The mechanism of energy transfer as shown by decay measurements agrees with the mechanism proposed by Gandy *et al.* (10) and by Zhabotinskii *et al.* (11). Excitation spectra of Eu^{+3} and Nd^{+3} emission also show that the energy transfer is from the 20,200 cm^{-1} level, however, there is no exact agreement with the rare earth levels. An energy level diagram of this part of system is shown in Fig. 11, and includes the positions of the additional weak UO_2^{+2} levels found in the excitation spectra. The closest levels of Eu^{+3} are about 1000-1300 cm^{-1} from the transferring UO_2^{+2} level. The Nd^{+3} ion has a somewhat better match. The R.E.$^{+3}$ ions listed in Table IV all show a decrease in decay times and, therefore, possible energy transfer, although emission was not found for most of these ions. The three ions showing emission have energy levels at about 19,000 cm^{-1}, showing that this is probably the recipient level. This is the $^5D_1$ level of Eu^{+3} and the $^4G_{7/2}$ level of Nd^{+3}.

No definite evidence of emission from either the $^5D_2$ or $^5D_1$ levels of Eu^{+3} were found in the phosphor. The more probable emissions from these levels would be masked by the UO_2^{+2} emission. No evidence of Eu^{+3} absorption was found in either diffuse reflectance or excitation curves.

Acknowledgments

The author would like to express her appreciation to Dr. R. A. Hewes and Miss E. J. Wilson for the optical and decay measurements, to Miss J. R. Cooper for the x-ray work and for the technical assistance of Diane Karla, Robert Kattler, and Lana Funaro in sample preparation and evaluation.

The Preparation and Crystallography of Cadium Zinc Sulfide Solid Solutions

Paul Cherin, Edward L. Lind, and Edward A. Davis[1]

Xerox Corporation, Rochester, New York

ABSTRACT

Single crystals and powders of $Cd_{(1-x)}Zn_xS$ were grown using chemical transport with iodine. These components form a continuous series of solutions over the entire range of x, 0 to 1. The wurtzite structure was produced over the entire range. The lattice parameters and the composition of the solid solutions were determined to approximately 1% using x-ray diffractometry techniques. The results provide a definitive calibration of lattice constants for the wurtzite structure of solid solutions of CdS and ZnS and allow the analysis of $Cd_{(1-x)}Zn_xS$ samples. The variation of lattice parameters with composition was found to obey Vegard's law. The variation of the c/a ratio with composition was also linear. The ideal ratio, assuming close packing of hard spheres, occurred at 70% ZnS. The volume relationship with composition showed a slightly negative deviation from linearity. A least squares method for refining lattice parameters is described.

Cadmium sulfide and zinc sulfide are of considerable importance as phosphors and photoconductors. Because the size and electronic structure of the cations are so similar, these materials readily form a continuous series of solid solutions. Thus, this is a system in which systematic variation of photoelectronic properties is possible simply by adjusting the composition of the solid solutions.

In this paper we describe a method of preparing single crystals of $Cd_{(1-x)}Zn_xS$ which have uniform composition, show no tendency to order, and are relatively free from strain. Precise measurement of the variation of the lattice parameters with composition was done because of the considerable disagreement existing in the literature (1-5). Future investigators will be able to use the results presented here to determine accurately the composition of their $Cd_{(1-x)}Zn_xS$ single crystals and powders. It will be shown that the solutions are not ideal at room temperature even though the variation of a and c with composition obeys Vegard's law. The c/a axial ratio is computed and plotted as a function of composition. A variety of optical and electrical measurements on these crystals has been published elsewhere (6-9).

Structure

Cadmium sulfide and zinc sulfide can crystallize in two polymorphic modifications, either in a cubic sphalerite structure or as a hexagonal wurtzite structure. Throughout most of the composition range of $Cd_{(1-x)}Zn_xS$, the wurtzite structure is the stable one. Only when the concentration of zinc sulfide nears 100% does the sphalerite form predominate. In this paper, we are concerned only with the wurtzite modification.

The wurtzite phase can be considered as two interpenetrating hexagonal structures, one composed of cations and the other of anions. All the atoms lie in the center of tetrahedra containing unlike atoms at the corners. Regular tetrahedra can pack as efficiently as spheres. For rigid, close packed tetrahedra the ideal c/a ratio is 1.633. Many wurtzite structures deviate from this ideal value. It has been suggested (10, 11) that this deviation occurs because of the partial ionic character of the bonds. Distortion in the c/a ratio can lead to an increase in lattice energy, if the bonds have some ionic character. Within a group of the periodic table, the pairs forming bonds having the most ionic character tend to deviate most from the ideal ratio (10, 11). This empirical rule holds in the case of ZnS and CdS where the c/a ratios are 1.6376 and 1.6238, respectively.

Key words: crystallography, sulfide, solid solutions, cadmium, zinc.

[1] Present address: Cavendish Laboratory, University of Cambridge, Cambridge, England.

Method of Preparation

In the range of temperatures at which these crystals may be grown, the vapor pressure of CdS is so much greater than ZnS at a given temperature, that it is impossible to grow mixed crystals of $Cd_xZn_{(1-x)}S$ (12) from a mixture of the vapors of CdS and ZnS by themselves. However, in the presence of iodine, the equilibrium constants for the reaction of ZnS and CdS with iodine are close enough to result in cotransport. Chemical transport with iodine vapor is, therefore, a convenient means for growth of homogeneous single crystals of $Cd_{(1-x)}Zn_xS$. The crystal sizes achieved by this method were found to be suitable for electrical and optical studies (6-9).

Preparation

Weighed quantities of G. E. luminescent grade ZnS and CdS powders were tumbled in a container overnight and fired in an open boat at 800°C under flowing nitrogen to remove water vapor and volatile salts. A small, but insignificant, amount of the more volatile CdS was lost during this process. The powder was transferred to an 8-in. quartz ampoule and evacuated to 10^{-6} Torr. Sufficient iodine, which had been previously triple sublimed in vacuum to remove permanent gases, was distilled into the ampoule to provide 5 mg iodine per cc of vapor space in the final ampoule (13). The ampoule was sealed off under vacuum and placed in a two-zone furnace. Inadvertent nucleation centers of ZnS or CdS in the growth end of the ampoule were removed by leaving the ampoule overnight with its charge end at a temperature range of 775°-800°C and growth end at a range of 875°-900°C. Subsequently the ampoule was positioned in the furnace so that a suitable growth gradient was obtained. For low proportions of ZnS, the charge end was held at temperatures of 875°-925°C with the growth end at the range 825°-850°C. As the ZnS fraction was increased, the temperatures of both charge and growth ends was increased so that for 95% ZnS crystals the temperature ranges were at 925°-975° and 850°-875°C, respectively. Growth was allowed to proceed from 72 to 80 hr.

Polycrystalline solid solutions were prepared by firing mixtures of the above mentioned ZnS and CdS powders in an open boat at 850°C (controlled to ± 5°C) for 5.5 to 6.5 hr while under a continuous

flow of nitrogen. Samples were slowly cooled in the furnace while the flow of nitrogen was continued.

Determination of Composition

The method of determining the composition of the solid solutions is described in detail elsewhere (15). This technique employed a set of physical mixtures of CdS and ZnS of known composition. The ratio of the intensity of the x-ray emission lines of zinc and cadmium was plotted against the molecular ratio of ZnS to CdS. If care is taken to minimize matrix effects, this plot is virtually linear.

This plot was used to determine the composition of a series of $Cd_{(1-x)}Zn_xS$ solid solutions by x-ray spectroscopy methods, which acted as secondary standards. Debye-Scherrer photographs were taken of the secondary standards, and the distances between the diffraction lines (S) were measured at high values of the Bragg scattering angle. A plot of $(\cos S/4)^{-1}$ *vs.* the composition results in a smooth curve which is nearly linear and which subsequently was used for composition determinations of the crystals and powders.

The purpose of this procedure is twofold. First, when the amount of material available is small, it is not possible to obtain sufficiently high x-ray emission intensities. Then statistical variation in the counts causes considerable error in the composition determined. Second, a higher relative accuracy is obtained by the Debye-Scherrer method. By the techniques described, the composition could be determined absolutely to ± 0.5% and relatively to ± 0.2 m/o (mole per cent) using only 0.1 mg of sample.

It was found that the actual composition and the nominal composition as determined by the known weights of CdS and ZnS in the initial mixture were identical within the limits of error previously stated.

Determination of Lattice Parameters

A North American Philips diffractometer was used to record the lines diffracted from the finely ground solid solution. The solid particles chosen were uniform (between 250-500 mesh). The radiation was CuKα (monochromatic); the scanning speed was (⅛)°/min; a 1° divergence slit was used in conjunction with a 4° preslit and a 1° scatter slit. Diffraction lines were generally recorded out to the limit of the diffractometer, *i.e.* to 145° in 2θ. A NaCl standard was added to the samples to correct for possible minor misalignment.

The diffraction lines were indexed using approximate values of the a and c parameters. These parameters were then refined by fitting the calculated values of $1/d^2$, where d is the lattice spacing, to the observed values using a least squares technique (see Appendix).

Results

The lattice parameters a and c were determined and plotted as a function of composition. These are shown in Fig. 1 and 2, respectively. The variation obeys Vegard's law within the error limits. All the points fall within three times the standard deviation. The relationship between the parameters and the concentration may be expressed as

$$a = 4.1370 - 0.3165x$$
$$c = 6.7168 - 0.4597x$$

where x is the mole fraction of ZnS.

The errors tended to increase toward the high ZnS concentration. This is the region in which the free energy of the wurtzite structure approaches that of the sphalerite structure. Thus, some strain and defects are to be anticipated. The sample containing 95% ZnS did contain some of the cubic sphalerite. The concentration ratio of wurtzite to sphalerite was approximately 9/1. It was assumed that the ZnS concentration was the same in both phases. This assumption was supported by the agreement of the wurtzite a and c parameters with Vegard's law at 95% of ZnS. Additionally, the lattice parameter of the cubic cell containing 95% ZnS agreed with the parameter found assuming a linear relationship with composition.

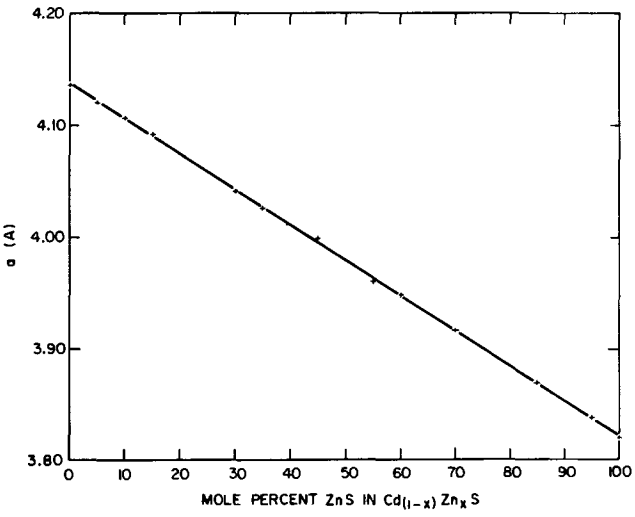

Fig. 1. Lattice parameter a as a function of composition

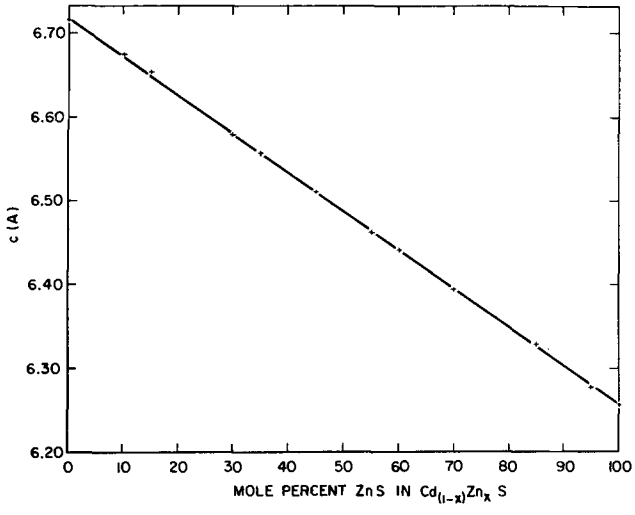

Fig. 2. Lattice parameter c as a function of composition

The c/a ratios were calculated as a function of the composition and are shown in Fig. 3. This variation is linear and may be expressed as $c/a = 1.6238 + 0.01376x$. This relationship is interesting because at $x = 0.70$, $c/a = 1.633$. It was mentioned earlier that distortion in the c/a ratio is related to long range coulombic forces (10, 11). Although the ionic character of the solid solutions does decrease from 0% ZnS to 100% ZnS, there is probably nothing unique in the bonding at 70% ZnS, where $c/a = 1.633$, the ideal ratio. In CdS the tetrahedra tend to be compressed, while in ZnS

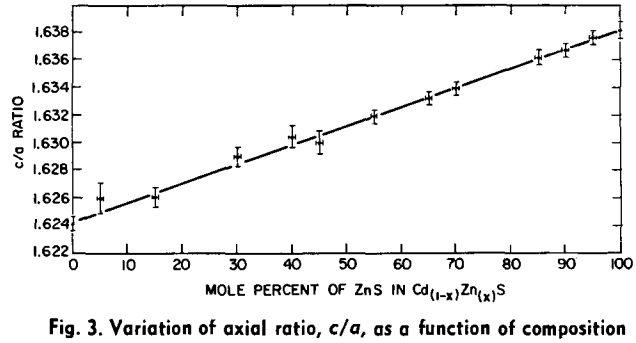

Fig. 3. Variation of axial ratio, c/a, as a function of composition

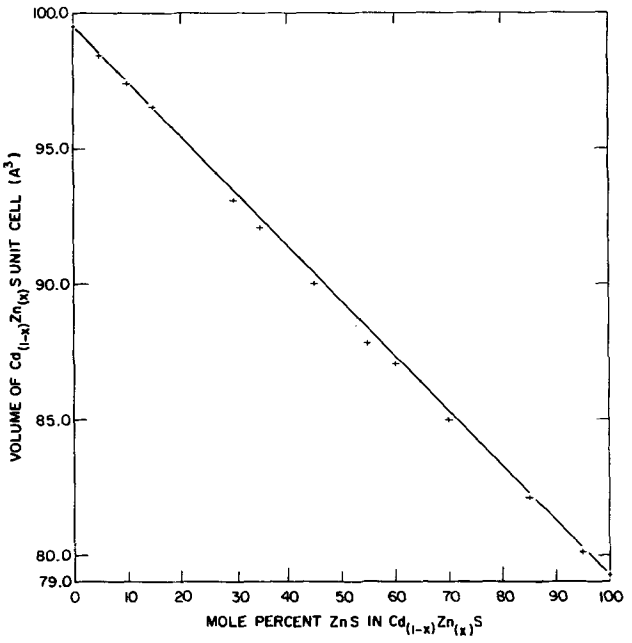

Fig. 4. Unit-cell as a function of composition

the c-axes of the tetrahedra are elongated. At 70% ZnS the average tetrahedron happens to have an axial ratio of 1.633.

The variation of unit-cell volume with concentration has been plotted in Fig. 4. A slightly negative deviation from linearity can be observed. Thus, the solutions are not ideal at room temperature although they might well have been at the temperature of preparation. If the solutions had been ideal, the partial molar volumes would have been additive and the volume variations linear.

The variations of a, c, c/a, and unit cell volume with composition are given in Table I.

Discussion

The variation of the lattice parameters with composition as found by previous investigators (summarized below) is, for the most part, somewhat different than that reported here. Much effort has been expended to make our results as accurate as possible.

The quality of our crystals has been ascertained by other measurements, which would have most probably revealed any imperfections, such as severe strain, inhomogeneity, large concentrations of defects, etc. These measurements include electron microscopy, electron microprobe studies, fluorescence, x-ray precession, Laue measurements, and studies in a polarizing microscope. Spectroscopic analysis for heavy metals shows less than 3 ppm copper and less than 1 ppm of silicon. Fluorescence analysis did not detect the presence of iodine, suggesting that its concentration was no more than 100 ppm. This is in agreement with Beun, Nitsche, and Bölsterli (14). The sharpness of the powder diffraction lines contributed additional evidence.

Table I. Variation of lattice parameters with composition

The standard deviations obtained from the least square computations indicate a rather precise determination of lattice parameters (Table I). The limiting factor is, however, the composition determination. This is the most difficult step, because of the similarity in properties of zinc and cadmium. For this reason, physical methods were utilized instead of chemical techniques. As had been mentioned earlier, much effort was made to determine the composition of the solid solutions (15). The method used is rather sensitive to small changes in composition. Repeated measurements were made and the results were reproducible within 0.5%.

Early measurements of the lattice parameters of the $Cd_{(1-x)}Zn_xS$ system were made by Vitrikhovskii and Mizetskaya (1) using Debye-Scherrer methods. Their results show large positive deviation of a and c from Vegard's law by as much as 0.01A. Their data have considerable scatter, especially for the c parameter. It is not clear what method was used to determine compositions.

Chan's measurements (2) of the variation of the a-axis with composition also reflected more scatter than our data, although a linear relationship was shown. Single crystal techniques were used by this worker. In addition, the voltametry and stripping analysis used to determine composition presented problems, because of interference of one cation with the measurement of the other.

Ballentyne and Ray's (3) measurements indicated very large negative deviations from Vegard's law. They used Debye-Scherrer methods and determined compositions using chemical methods which might explain their different results.

Ortman and Treplow (4) reported that the a and c parameters followed Vegard's law. They plotted their results on a rather compressed scale so that deviations up to 0.01A did not show. Several of their points did not fall on the lines.

In a rather recent effort, Kane, Spratt, Hershinger, and Kahn (5) measured the lattice parameters of evaporated films. Using Debye-Scherrer methods, they found that a and c deviated negatively from Vegard's law. They determined compositions indirectly by monitoring the amount of CdS and ZnS that evaporated from separate boats. Their parameter determinations at high concentrations of ZnS, however, assumed an ideal c/a ratio.

Summary

A continuous series of substitutional solid solutions of $Cd_{(1-x)}Zn_xS$ were prepared. Both the powders and the single crystals appeared to be homogeneous and relatively strain free. The wurtzite structure was the most stable throughout the series at the temperature of preparation. However, some sphalerite phase formed at the 95% ZnS composition. The composition determinations were done using physical methods which avoided problems due to the similarities in properties of zinc and cadmium. The lattice parameter variation with composition was linear. The c/a ratio also showed a linear variation. The ratio reached the ideal value of 1.633, assuming close packing of hard spheres, at 70% ZnS. This was probably due to an averaging effect rather than to any profound change in long range bonding forces. The variation of volume with composition showed a negative deviation from linearity. Thus, the solid solutions are not ideal at room temperature, since the partial molar volumes are not additive.

The pertinent results are given in Table I to enable future workers to easily determine the composition of their solid solutions.

Acknowledgments

The authors would like to thank Fred Knier for his help in preparing the solid solutions, Chester Bielan for his aid in determining the compositions, and George

Fekete and Phyllis Unger for their aid in collecting and analyzing the diffraction data.

APPENDIX

Least squares fit of $(1/d_c)^2$ *to* $(1/d_o)^2$

In reciprocal lattice parameters, $1/d^2$ is linear, *i.e.*,

$$1/d^2 = S_{11}h^2 + S_{22}k^2 + S_{33}l^2 + S_{12}hk + S_{23}kl + S_{31}lh,$$

where

$$S_{11} = b^2c^2\sin^2\alpha/V^2$$
$$S_{12} = 2abc^2(\cos\alpha\cos\beta - \cos\gamma)/V^2$$
$$S_{22} = c^2a^2\sin^2\beta/V^2$$
$$S_{23} = 2a^2bc(\cos\beta\cos\gamma - \cos\alpha)/V^2$$
$$S_{33} = a^2b^2\sin^2\gamma/V^2$$
$$S_{31} = 2ab^2c(\cos\gamma\cos\alpha - \cos\beta)/V^2$$

a, b, c are the unit cell lengths, α, β, γ are the angles, and V is the volume of the cell.

The sum of the squares minimized is

$$\sum_{i}^{N} W_i[1/d_i^2 - (S_{11}h_i^2 + S_{22}k_i^2 + \text{--------} + S_{31}l_ih_i)]^2$$

where N is the number of diffraction peaks observed. The weights, W_i, were taken as

$$W_i = 1/\sigma_i^2$$

$$\sigma_i = \left[\frac{d(1/d^2)}{d(2\theta)}\right]\Delta(2\theta_i), = \frac{8\sin 2\theta_i\,\Delta(2\theta_i)}{\lambda}$$

and $\Delta(2\theta_i)$ was taken to be the uncertainty in reading the peak position due to broadness or noise.

Broad Emission and Excitation Bands in Y_2O_3 and YVO_4

S. Z. Toma and D. T. Palumbo

Sylvania Electric Products Inc., Chemical and Metallurgical Division, Towanda, Pennsylvania

ABSTRACT

Pure yttrium oxide has three x-ray-excited emission bands in the blue-u.v. region of the spectrum. Addition of thallium gives a broad emission peaking at about 580 nm with a decay time of less than 20 nanosec and Eu^{3+} emission in this matrix can be sensitized with thallium and bismuth absorption bands. On lowering the temperature from room to liquid N_2 both Y_2O_3:Bi and YVO_4:Bi show new emissions as well as complex differences in the excitation spectra. The results in Y_2O_3:Bi are discussed on the basis of bismuth occupying two centers in this matrix.

Numerous studies on the optical properties of rare earth-activated Y_2O_3 and YVO_4 have appeared (1-7). Considerably less work, however, has been reported on activators with broad absorption and emission bands in these matrices, the emphasis being primarily on bismuth activation at room temperature (8-12), and more recently on indium in YVO_4 (13). In both YVO_4:Bi (8, 9, 11) and Y_2O_3:Bi (10-12) only some of the bands arising from bismuth addition are experimentally established and their corresponding electronic transitions are not clearly understood. As will become evident below, two factors contribute to this: (*a*) in Y_2O_3:Bi, the large number and strong overlap of the observed emission and excitation bands makes difficult the isolation and study of the individual bands, with a similar problem existing in YVO_4:Bi where the matrix absorption overlaps that obtained on Bi^{3+} addition; and (*b*) the differentiation of Bi-matrix from predominantly free ion transitions ($6s \rightarrow 6p$) is difficult since host luminescence exists in the absence of any activators. The problem is analogous to the case of $CaWO_4$ and $CaWO_4$:Pb where the luminescence on addition of Pb^{2+} is usually considered to arise from Pb-perturbed tungstate groups (14, 15).

The present work concerns a study of Y_2O_3:Bi and YVO_4:Bi at liquid nitrogen temperature with a comparison to the results obtained at room temperature. The optical properties of Y_2O_3, Y_2O_3:Tl, Y_2O_3:Eu,Tl, and Y_2O_3:Eu,Bi were also investigated.

Experimental

Phosphors were prepared from intimate mixtures of high-purity raw materials by solid state reactions. For activated and pure YVO_4, proper amounts of Y_2O_3 and Bi_2O_3 were blended with recrystallized NH_4VO_3 and fired for 2 hr at 950°C.

Phosphors with Y_2O_3 as a matrix were synthesized by acetone blending appropriate amounts of thallium (ic) oxide, bismuth oxalate, and yttrium oxalate. The mix was first-step fired at 700°C and refired for 2-3 hr at 1200°C. In europium-containing phosphors, Y^{3+} and Eu^{3+} were coprecipitated as oxalates before addition of bismuth or thallium. This coprecipitation and the high firing temperatures were necessary to obtain high efficiency phosphors. All samples were prepared in air atmosphere unless specified otherwise. The data discussed below were obtained with the following concentrations of various activators: $Y_{0.95}Bi_{0.05}VO_4$, $(Y_{0.995}Bi_{0.005})_2O_3$, $(Y_{0.98}Tl_{0.02})_2O_3$, $(Y_{0.99}Eu_{0.01})_2O_3$, $(Y_{0.983}Eu_{0.01}Bi_{0.007})_2O_3$, $(Y_{0.95}Eu_{0.05})_2O_3$, and $(Y_{0.93}Eu_{0.05}Tl_{0.02})_2O_3$, where the concentrations are for the formulated compositions. In Y_2O_3:Tl a substantial amount of activator is lost on firing and the various thallium-containing phosphors showed more than 90% loss as measured by atomic absorption analysis.

Excitation and emission spectra were obtained with a Perkin-Elmer Model 195 and Hitachi-Perkin-Elmer MPF-2A spectrophotofluorimeters. The Perkin-Elmer Model 195, a prism instrument (16), provided energy-corrected emission and excitation spectra (Fig. 4 and 5) and was used to obtain quantum efficiency data by comparing the phosphors to NBS $MgWO_4$ (17). The Hitachi instrument, though uncorrected (see Fig. 10 and 14 for energy correction factors), provided better separation of the overlapping excitation and emission bands due to its grating optics (Fig. 1 and 7-14). Reflectance spectra were obtained with a Bausch and Lomb Spectronic 505 instrument. A TRW Model 31A instrument was used for decay time measurements.

X-ray-excited emission spectra were recorded using radiation from a tube with a molybdenum target operating at 50 kV and 30 mA. One gram samples were pressed into pellets 1 cm in diameter and the emission measured from the excitation side of the sample. An EMI 9558B photomultiplier and a 1-meter Jarrell-Ash monochromator were used to record the spectra.

Results

YVO_4, YVO_4:Bi.—Pure YVO_4 shows a blue emission peaking at about 440 nm at both room and liquid N_2 temperature. YVO_4:Bi at room temperature gives a broad, yellowish emission peaking at 560 nm under both short and long wavelength ultraviolet excitations. The emission color at liquid N_2 temperature, however, is determined by the energy of exciting radiation. A blue emission peaking at 440 nm dominates under short wavelength excitations (< 300 nm), whereas only the yellowish emission of bismuth appears at longer (340 nm) wavelengths. Figure 1 shows the excitation spectra for both these emissions. As the emission wavelength, at which the excitation spectrum is measured, is gradually increased above 440 nm, an increase in peak height of the excitation band at about 340 nm occurs relative to that of the higher energy band. Figure 1 also shows the excitation spectrum for the peak emission of pure YVO_4 at 440 nm and liquid N_2 temperature.

Y_2O_3.—Three x-ray-excited emission bands are observed with maxima at approximately 340, 365, and 400 nm. The spectrum appears in Fig. 2. Possible contribution of chemical impurities to this matrix emission is difficult to rule out. However, several samples of Y_2O_3, considered to be of high purity by the suppliers and by our own analysis, gave similar spectra. On converting the same materials to YVO_4, a high intensity emission, characteristic of the vanadate matrix, was always observed.

Y_2O_3:Tl *and* Y_2O_3:Eu, Tl.—The reflectance, emission and excitation spectra of Y_2O_3:Tl prepared in air are shown in Fig. 3, 4, and 5. Varying thallium concentrations formulated up to 10 a/o (atom per cent) gave an optimum brightness at about 2% added thallium, with a quantum efficiency of 25% under 254 nm excitation.

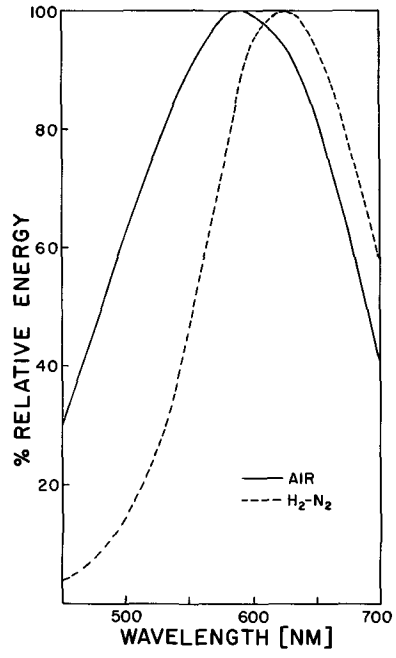

Fig. 4. Y_2O_3:Tl emission spectra: solid line (air) with 254 nm excitation; dashed line (H_2-N_2) with 365 nm excitation.

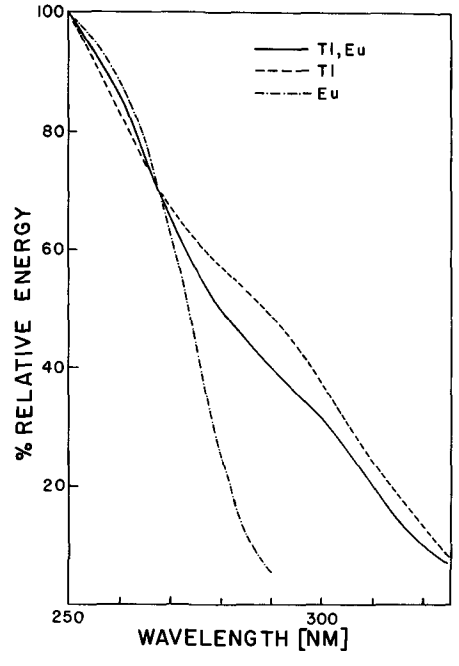

Fig. 5. $(Y_{0.95}Eu_{0.05})_2O_3$, $(Y_{0.95}Eu_{0.05})_2O_3$:Tl, and Y_2O_3:Tl excitation spectra: dashed line for 580 nm emission, solid and dot-dashed lines for the europium emission at 611 nm. The latter's weak (f-f) excitation lines are not shown.

A fluorescence decay time of less than 20 nanosec was observed. Refiring for 1 hr at 1000°C in N_2-H_2 (10%) atmosphere gives a material with distinctly different optical properties, the absorption and emission bands extending to longer wavelengths (Fig. 3, 4) and the emission intensity decreasing.

Addition of thallium to Y_2O_3:Eu alters the excitation spectrum of Eu^{3+} emission at 611 nm (Fig. 5). The broad excitation band for this emission (5, 12) is extended to longer wavelengths. A decrease in emission intensity is observed under 254 nm excitation whereas enhancement is seen at longer (*e.g.*, 290 nm) excitation wavelengths. The effect is gradual, increasing with increasing amounts of added thallium. Figure 5 shows the spectrum of the phosphor formulated with 2 a/o Tl. A comparison of the relative brightness of Y_2O_3:Eu and Y_2O_3:Eu,Tl at various excitation wavelengths can be made by comparing the corresponding excitation curves after a 20% scaledown of the Y_2O_3:Eu,Tl curve.

Energy transfer from Tl to Eu is demonstrated in Fig. 5, where the excitation spectrum for the 611 nm Eu^{3+} emission in Y_2O_3:Eu,Tl is in the same energy region and similar to that observed for Tl emission in Y_2O_3:Tl. Further indication of the transfer is provided by the observed decrease in intensity of the broad-band thallium emission on addition of increasing amounts of europium (0.1-1.0 a/o) at constant, 2 a/o thallium concentration.

Y_2O_3:Bi *and* Y_2O_3:Eu,Bi.—At room temperature Y_2O_3:Bi has two emission bands in the visible at about 405 and 500 nm. Their respective excitation band maxima, three for each emission (12), are shown schematically in Fig. 6 and labeled as g bands for the green emission at 500 nm and b bands for the blue emission at 405 nm.

Exact positions of some of these band maxima are difficult to ascertain due to strong overlap with adjacent bands. Furthermore, from the measurement standpoint, it is difficult to establish the "pure" bands associated with each emission, also due to this overlap. The problem is common to most measurements on this phosphor and some of the excitation and emission spectra shown below are for wavelengths slightly displaced from the proper maxima in efforts to isolate the bands of interest.

The reflectance spectrum of Y_2O_3:Bi appears in Fig. 3. A quantum efficiency of about 40% was obtained at room temperature using 340 nm exciting radiation. The 500 nm emission, which was the only band we were able to isolate using Corning filter CS3-74, has a decay time of 5×10^{-7} sec at room temperature.

Figure 7 shows a comparison of Y_2O_3:Bi emission at room and liquid N_2 temperature under 371 nm excitation. A similar comparison appears in Fig. 8 with 350 nm excitation. The effect on the excitation bands of lowering the temperature appears in Fig. 9 for the 500 nm emission. Note the decrease in intensity of 330 (2 g) relative to the 344 nm (1 g) band with decreasing temperature. Simultaneously, excitation in the energy region of the 2 g band (325 nm) gives a new emission in the visible at about 430 nm (Fig. 10). The excitation spectrum of the 430 nm band (Fig. 11) is dominated by the 330 nm band but with some contribution from the 371 (1 b) and 338 nm (2 b) bands of the 405 nm emission. This contribution decreases when excitation spectra are measured for emissions at longer wavelengths than 430 nm (further away from the 405 nm emission to minimize overlap) and at 500 nm (Fig. 9) very little of the 1 b and 2 b bands remain.

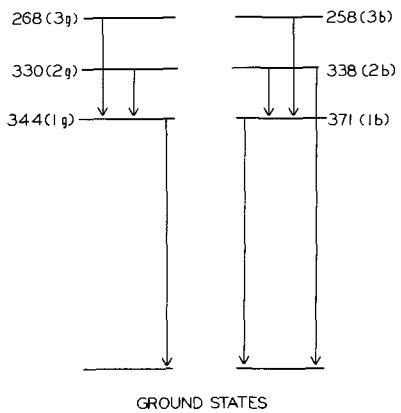

Fig. 6. Schematic representation of the excitation band maxima in nanometers for the 500 nm (g bands) and 405 nm (b bands) emissions in Y_2O_3:Bi. Arrows indicate electronic transitions at room temperature discussed in the text. The g and b designations also represent the electronic states responsible for the corresponding excitation bands.

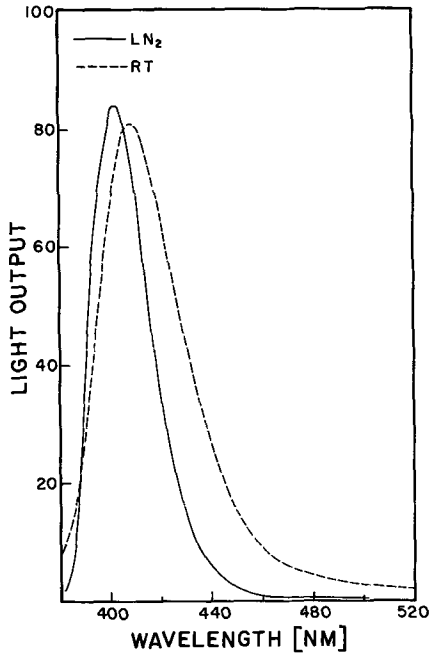

Fig. 7. Emission spectra of Y_2O_3:Bi excited at 371 nm

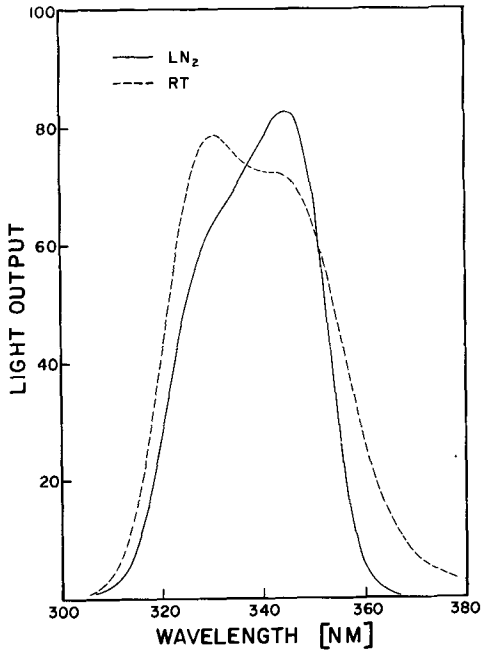

Fig. 9. Excitation spectra of Y_2O_3:Bi for the 500 nm emission

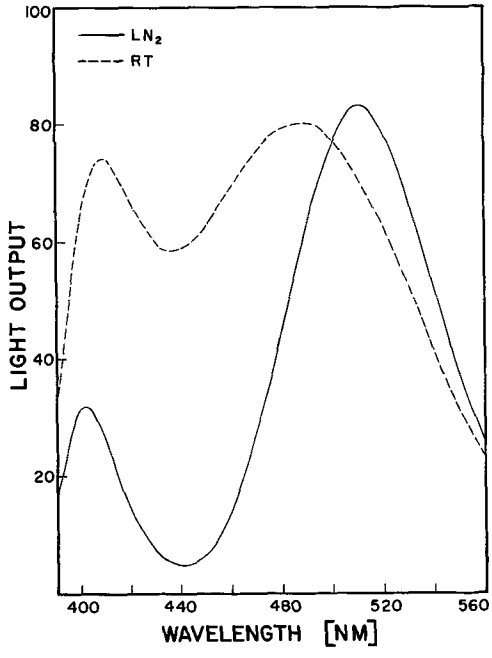

Fig. 8. Emission spectra of Y_2O_3:Bi excited by 350 nm radiation

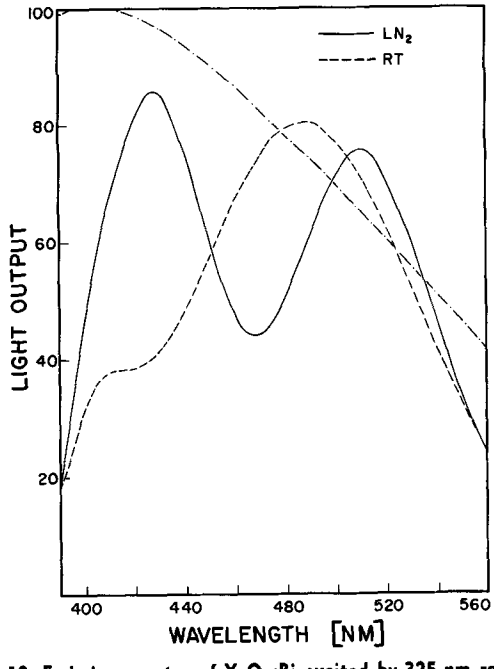

Fig. 10. Emission spectra of Y_2O_3:Bi excited by 325 nm radiation. The dot-dashed curve shows the relative sensitivity of the grating-photomultiplier combination used.

Qualitatively similar effects are observed on comparing the excitation spectra for the 405 nm emission at room and liquid N_2 temperatures (Fig. 12 and 13). Note that the excitation band at 338 nm (2 b) in Fig. 12 decreases in intensity relative to that at 371 nm (1 b) on cooling to liquid N_2 temperature. At the same time (Fig. 13) the emission band at about 355 nm, under 338 nm excitation, now dominates the emission spectrum. This u.v. emission can also be ascertained at room temperature but with considerably weaker intensity than the 405 nm band and less resolved from it.

Energy transfer from Bi to Eu has been reported, considering only the 500 nm emission (10). Figure 14 gives the excitation spectra of Y_2O_3:Eu,Bi measured at 611 nm for the Eu^{3+} emission and at 450 nm, where both the 405 and 500 nm emissions of Bi contribute. Both the b and g excitation bands of bismuth are shown to sensitize the Eu^{3+} emission, this being a further similarity between the two sets of bands.

Discussion

The room temperature excitation spectrum of YVO_4:Bi extends to longer wavelength than that for the pure matrix. However, no structure can be ascertained at these long wavelengths. At liquid N_2 temperature (Fig. 1), bismuth addition introduces a discrete band peaking at about 340 nm. It is interesting to note that this is the energy region of the 1 g (344 nm), 2 g (330), and 2 b (338) excitation bands in Y_2O_3:Bi. The appearance of higher energy emission peaking at 440 nm in YVO_4:Bi may be compared to similar results obtained on rare earths additions to this matrix. Palilla *et al.* (2) observed that although additions of 0.5 m/o (mole per cent) of Dy^{3+}, Tm^{3+}, Sm^{3+}, or Eu^{3+} almost completely quench the luminescence of YVO_4 at room temperature, it reappears with high intensity on cooling these phosphors to liquid

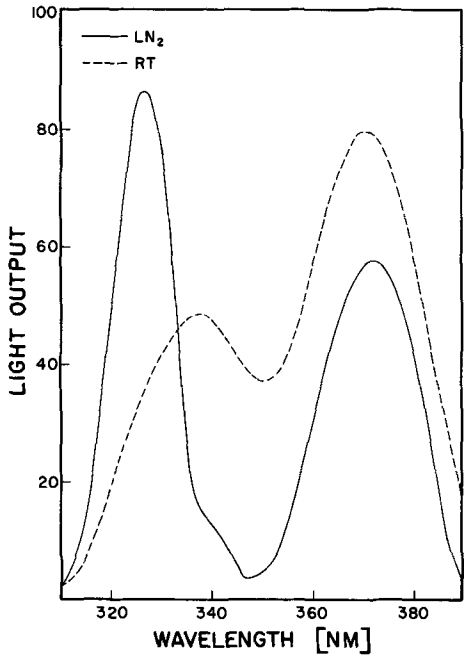

Fig. 11. Excitation spectra of Y_2O_3:Bi for the 430 nm emission

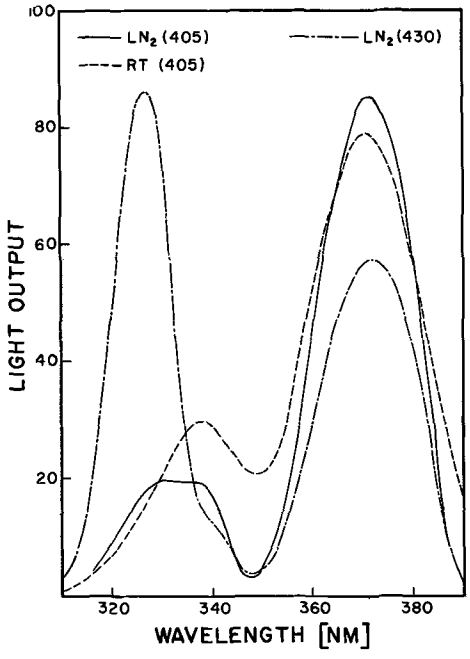

Fig. 12. Excitation spectra of Y_2O_3:Bi for the 405 nm and 430 nm emissions.

N_2 temperature. This suggests that the 440 nm emission observed in YVO_4:Bi at liquid N_2 temperature may be due to host luminescence since the maximum of the emission band of pure YVO_4 is also at 440 nm. However, the difference in the energies of the maxima of the excitation bands for the 440 nm emission in YVO_4 and YVO_4:Bi (Fig. 1) is not understood if in both phosphors the luminescence arises from the common host.

The absorption of pure Y_2O_3 has been reported at wavelengths lower than 225 nm (3,18). In this and the similar oxides of scandium and lanthanum the bands are generally ascribed to electron transfer transitions from oxygen to the trivalent cations (18-20). Further study of the three emission bands observed with x-ray excitation in Y_2O_3 was difficult since attempts to observe any u.v.-excited luminescence, within our instrumental capabilities, were not successful.

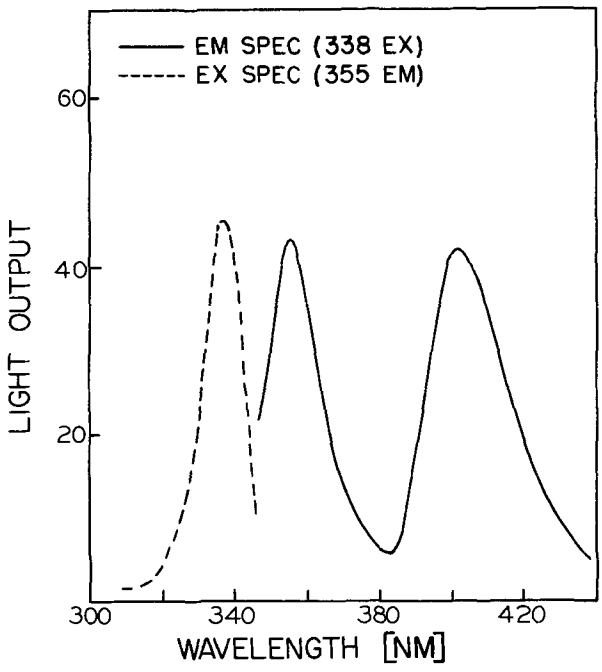

Fig. 13. U.V. emission in Y_2O_3:Bi at liquid N_2 temperature with its corresponding excitation band.

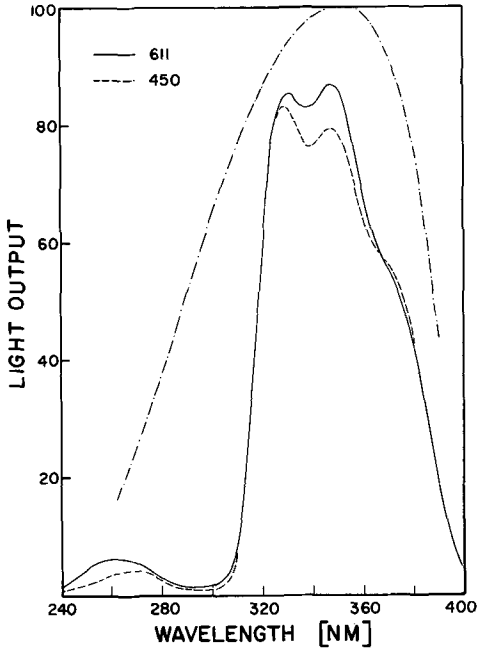

Fig. 14. Excitation spectra for the 611 and 450 nm emissions in Y_2O_3:Eu,Bi at room temperature. The dot-dashed curve shows the relative intensity of the grating-xenon lamp combination used.

Although monovalent thallium is well known as an activator, its trivalent state with $5d^{10}$ configuration is not commonly considered as such. The question of the particular oxidation state of thallium in the matrix with a trivalent cation is, then, of some relevance. Comparing the size and charge of Tl^+ (1.49Å) and Tl^{3+} (1.05) to Y^{3+} (1.06) and considering that Tl_2O_3 is isomorphous with Y_2O_3, the trivalent state of thallium can be favored in nonreduced Y_2O_3:Tl. Further evidence for this is the change in optical properties observed on refiring in H_2-N_2 atmosphere, which presumably can be due to a reduction in the oxidation state of Tl^{3+}. It is also interesting to note that the reduced material absorbs in the same energy region as trivalent bismuth (Fig. 3), the latter being isoelectronic with Tl^+.

Absorption of a trivalent thallium ion in Y_2O_3 can arise either from transitions in the thallium-oxygen bond or the free ion $d^{10} \rightarrow d^9s$. The latter have been considered in alkali halides containing Cu^+ and Ag^+ (21). Their absorption coefficients are smaller by one or two orders of magnitude than those of Pb^{2+} and Ti^+. If the spectra arise from $d^{10} \rightarrow d^9s$ (forbidden) transitions, then their energy in alkali halides is larger than the corresponding transitions in the gaseous state (21). The spectra of nonreduced Y_2O_3:Tl are difficult to understand as arising from such $d^{10} \rightarrow d^9s$ transitions, since their lowest energy in gaseous Tl^{3+} is at 75052 cm^{-1} (22), whereas the absorption of Y_2O_3:Tl occurs at appreciably longer wavelengths. This absorption, however, may be compared to that observed for the hexachlorocomplexes of Pb^{4+} (23), the latter being isoelectronic with Tl^{3+}. Two broad and intense absorption bands are observed at 307 and 208 nm with the high molar extinction coefficient of 9700 and 24000, respectively. These have been interpreted as possibly due to an electron transfer from a predominantly ligand orbital to the empty s orbital of Pb^{4+} which is filled in Pb^{2+} complexes (23). Similar allowed transitions may occur in the thallium-oxygen center in nonreduced Y_2O_3:Tl and the observed short decay time is compatible with such transitions.

The spectra of Y_2O_3:Bi at room temperature show that the green emission at 500 nm can be excited with three bands (1-3 g). Thus, the electronic states responsible for the 3 g and 2 g excitation bands are not the emitting states, since the same emission is observed with the lower energy 1 g band. Radiationless transitions, then, from the 2 g and 3 g to the 1 g state must occur and these are indicated schematically in Fig. 6. The probability for such transitions at temperature T may be considered as proportional to an exponential factor containing T and other parameters pertaining to the configuration coordinate curves of the respective electronic states (24). On lowering the temperature to that of liquid N_2, the probability for transitions, as for example from 2 g to 1 g, can decrease and allow at least some emission from 2 g state, *i.e.*, direct radiative transition from 2 g to the ground state. The new emission at 430 nm (Fig. 10) can be understood as arising from such a transition and is consistent with related excitation spectra given earlier. A similar interpretation applies to the origin of 355 nm emission band, *i.e.*, a radiative transition from 2 b to the ground, electronic state.

In prior work (12), the 405 and 500 nm emissions of bismuth were assumed to arise from different centers in Y_2O_3, for example the C_2 and S_6 sites. The additional emission bands at 355 and 430 nm as well as their corresponding excitation spectra are quite compatible with such an assignment; one center for the 500 and 430 nm emissions and a differing one for the 405 and 355 nm emissions.

Diffusion of Manganese in Single Crystalline Manganous Oxide

J. B. Price[1] and J. Bruce Wagner, Jr.*

Materials Research Center, Northwestern University, Evanston, Illinois

ABSTRACT

The self diffusion of $^{54}_{25}Mn$ in monocrystalline manganous oxide has been studied in order to investigate the predominant lattice defect in MnO_{1+x} in the low oxygen pressure region of the phase field. In the low oxygen pressure region of the MnO_{1+x} phase field the material exhibits apparent n-type behavior. A graph of log D^{T}_{Mn} *vs.* log P_{O_2} for a temperature of 1032°C exhibits a constant slope of $+1/5.4$ for $10^{-18} \leq P_{O_2} \leq 10^{-8}$ atm. This pressure dependence is consistent with the model for doubly ionized cation vacancies over the range of composition studied.

The oxide, MnO_{1+x}, is nonstoichiometric with a maximum deviation from stoichiometry of approximately 15% (1-4). The high temperature region of the MnO_{1+x} phase field is shown in Fig. 1. In regions B and C the oxide is oxygen excess (1, 4) according to the following quasi-chemical reaction

$$\tfrac{1}{2}\, O_2(g) \rightleftarrows O_{xs} + V_{Mn}^{m'} + m\oplus \qquad [1]$$

where O_2 is an oxygen molecule, O_{xs} is an excess oxygen atom on a regular oxygen site, $V_{Mn}^{m'}$ is a negatively charged manganese vacancy, $\oplus$ is an electron hole (4), and m is the degree of ionization of the vacancy. Classically m takes on a value of 0, 1, or 2. In region B, m equals 2 (1, 4), and m equals 1 in region C (1, 4). In regions B and C the electrical conductivity (1, 4) is proportional to the concentration of electron holes, $[\oplus]$ or p. In the region of the MnO_{1+x} phase field shown in Fig. 1, $0.05 < \sigma < 8.0$ (ohm-cm)$^{-1}$. For dilute solutions the ideal mass action law predicts that

$$p = [\oplus] = (m)^{1/(1+m)}\, P_{O_2}{}^{+1/2(m+1)} \exp\{-\Delta G°_f/(1+m)RT\} \qquad [2]$$

where the brackets, [], denote concentration, P_{O_2} is the oxygen partial pressure, $\Delta G°_f$ is the Gibbs free energy for reaction [1], R is the gas law constant, and T is the absolute temperature, In regions B and C the electrical conductivity is

$$\sigma = e\mu_{\oplus}\, p \qquad [3]$$

where the conductivity, σ, is in reciprocal ohm-cm, e is the electronic charge in coulombs, the electron hole mobility, $\mu_{\oplus}$, is in cm^2/v-sec, and p is the number of holes/cm^3, given by Eq. [2]. In regions B and C the differential form of the oxygen pressure dependence of the conductivity is

$$\left[\frac{\partial \log \sigma}{\partial \log P_{O_2}}\right]_T = \frac{1}{2(1+m)} \qquad [4]$$

where it is assumed that $\mu_{\oplus}$, $\Delta G°_f$, and m are not functions of concentration (4). Data from the thesis Eror (1) and from Hed and Tannhauser (4) are shown in Table I. Both Eror and Hed found satisfactory agreement between the value of $1/2(m+1)$ determined from conductivity studies and the value of $1/2(m+1)$ determined from thermogravimetric studies in regions B and C. The concentration of cation vacancies and the deviation from stoichiometry may be computed from thermogravimetric data (1, 4). The oxygen pressure dependence of the deviation from stoichiometry is

$$\left[\frac{\partial \log x}{\partial \log P_{O_2}}\right]_T = \frac{1}{2(1+m)} \qquad [5]$$

where x, $0 < x < 1/3$, is the deviation from stoichiometry in MnO_{1+x}. The oxidation studies of Fueki and Wagner (9) further substantiate the predominance of the cation vacancies in region B.

The apparent p-n boundary (1-4) occurs at approximately $P_{CO_2}/P_{CO} = 1$ in the temperature range 800°-1500°C. For ratios less than $P_{CO_2}/P_{CO} = 1$, the value of $1/2(m+1)$ derived from conductivity studies is negative. Eror (1) and Hed (4) were unable to correlate their conductivity and thermogravimetric data in region A because neither was able to detect weight changes in region A. Hed and Tannhauser (4) showed that the weight change between the p-n boundary and the Mn-MnO boundary would be less than 25 μg/g if cation vacancies predominated in region A. The limit of resolution for the systems used

by Hed and Eror is 25 μg/g, or 25 x 10^{-4}%. Hed and Tannhauser (4) demonstrated that MnO_{1+x} in region A could be n-type, electronically, if $\mu_{\ominus} > 10\ \mu_{\oplus}$. Using the analysis of Becker and Frederikse (10), Hed computed the oxygen pressure dependence of p from his own conductivity data for the oxygen pressure range $-2.5 \leq \log P_{CO_2}/P_{CO} \leq +2$ at 1100° and 1300°C. He found no inflection point or minimum in log (const. p^2) *vs.* log P_{O_2} at or near the apparent p-n boundary. He concluded that at the p-n boundary $n\mu_{\ominus} = p\mu_{\oplus}$ and that $p > n$. As p decreases, the electron contribution to the conductivity eventually dominates because $\mu_{\ominus} > \mu_{\oplus}$ even though $p \geq n$. Gvishi, Tallan, and Tannhauser (11) confirmed that $\mu_{\ominus} > \mu_{\oplus}$ by Hall measurements on single crystals of MnO.

Self diffusion studies with the $^{54}_{25}$Mn isotope would be more sensitive to small changes in the deviation from stoichiometry than thermogravimetric analysis and would therefore compliment the conductivity studies made in region A. Accordingly the present study was carried out.

Boundary Value Problem

An infinitesimally thin layer of $^{54}_{25}$Mn placed on the surface of a thin slab of MnO_{1+x} will have the following distribution after t seconds (12)

$$N(\xi,t) = \frac{Q}{\sqrt{\pi Dt}} \exp\ (-\xi^2/4Dt) \qquad [6]$$

where Q is the number of $^{54}_{25}$Mn atoms initially on the surface per square centimeter of surface, D is the diffusion coefficient, $N(\xi,t)$ is the number per cubic centimeter ξ centimeter below the surface after a diffusion anneal of t seconds. It is assumed that all the $^{54}_{25}$Mn diffuses into the sample, that it does not change the composition of the sample, that it diffuses through the bulk only, that $I(\xi,t) = \text{const. } N(\xi,t)$, and that $I_o = \text{const. } Q$. Then

$$I(\xi,t) = \frac{I_o}{\sqrt{\pi Dt}} \exp\ (-\xi^2/4Dt) \qquad [7]$$

where $I(\xi,t)$ is the number of counts per second per cubic centimeter at a depth of ξ cm, and I_o is the number of counts per second per square centimeter initially at the surface. The tracer diffusivity, $D_{Mn}{}^{T}$ (hereafter simply, D), may be calculated from the tracer distribution, $I(\xi,t)$; it may be calculated also from the integrated distribution

$$I_k = I_o \operatorname{erfc} \frac{k}{\sqrt{4Dt}} \qquad [8]$$

where k is the thickness of material removed prior to counting. Equation [8] may be rearranged (13) so that it is amenable to graphical solution

$$50\left(2 - \frac{I_k}{I_o}\right) = 50\left(1 + \operatorname{erf}\frac{k}{\sqrt{4Dt}}\right) \qquad [9]$$

A graph of 50 $(2 - I_k/I_o)$ *vs.* $k/\sqrt{t}$ yields a straight line with intercept at 50 $(2 - I_k/I_o)$ equal to fifty on probability paper. Analysis via Eq. [7] is the sectioning method (12), and analysis via Eq. [8] is the Gruzin method (12). It was experimentally verified that absorption corrections to Eq. 8 were unnecessary because the 0.84 m.e.v. radiation emitted by $^{54}_{25}$Mn is relatively unattenuated in MnO_{1+x}.

Experimental Procedure

Rectangular slabs approximately 200 x 100 x 30 mils were cleaved from single crystal boules of MnO_{1+x}. Two typical analyses are presented in Table II. The samples were equilibrated at a given oxygen pressure and temperature in a vertical tube furnace. The oxygen pressure was fixed with a flowing mixture of CO_2 and CO. The time required to equilibrate a sample at a given oxygen pressure and temperature was computed from the appropriate value of the chemical diffusivity. Using an electrical conductivity technique (14) the composition dependence of the chemical diffusivity of MnO_{1+x} was determined before the radiotracer studies were initiated. It was assumed that the as-received MnO_{1+x} boules were highly nonstoichiometric; to test the assumption, several as-received samples were equilibrated to a composition near the MnO_{1+x} — Mn_3O_4 boundary, P_1 in Fig. 2. The equilibration was monitored with d-c conductivity readings.

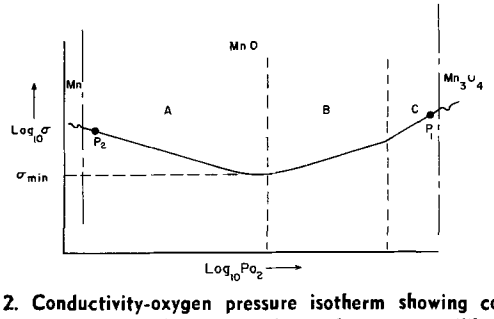

Fig. 2. Conductivity-oxygen pressure isotherm showing composition, P_1 to which several as-received samples were equilibrated to determine the approximate composition of as-grown samples.

The characteristic curve of Fig. 2 shows the conductivity variation with oxygen pressure at constant temperature. If the as-grown sample composition were in region A, *e.g.*, P_2 in Fig. 2, the conductivity would initially decrease, reach a minimum, and then increase to the equilibrium value corresponding to P_{O_2} final, *e.g.*, P_1 in Fig. 2. If the initial composition were in region B, the conductivity would increase monotonically to the final value. If the initial composition were in region C to the right of, or at a higher deviation from stoichiometry than the final equilibrium composition of this experiment, the conductivity of the sample would monotonically decrease with time until it reached the equilibrium value (P_1 in Fig. 2). The latter behavior was found with all as-grown samples tested. Therefore, the as-received samples were oxygen-rich, the composition being close to the MnO_{1+x}-Mn_3O_4 boundary, corresponding to a composition near P_1 in Fig. 2.

Radiotracer diffusion samples were equilibrated and diffused in pairs in platinum baskets. The oxygen pressure and temperature combinations at which samples were equilibrated are given in Table III. The equilibrated samples were polished on one face with 500A silicon carbide paper. On the polished face was placed a drop of neutral, aqueous $^{54}_{25}MnCl$ solution containing about 2 μcuries of $^{54}_{25}Mn$. The drop of $^{54}_{25}MnCl$ was dried under a lamp in approximately 30 min. The pair of samples was then placed, active faces together, in a platinum basket in the cold zone of the diffusion anneal furnace. The same CO_2/CO mixture which was used for the prediffusion anneal was used for the diffusion anneal. The samples were lowered into the hot zone via a magnetic coupling between a magnetic drive wheel inside the gas system and a concentric magnetic ring outside the gas system. The minimum diffusion anneal was 100 min, and the maximum diffusion anneal was 1300 min. The diffusion anneal was terminated by raising the sample from the hot zone to the cold zone of the furnace in about 5 sec. Prior to mounting, at least one diffusion length of material was lapped from each edge and from the back face of each sample to minimize errors from surface diffusion. The diffused samples were mounted in a room temperature setting plastic inside a magnetic stainless steel ring.

A microscope was focused on the top surface of the sample, and an attached dial gauge was zeroed. After each successive layer was lapped from a sample the amount removed was read on the dial gauge after the microscope was refocused. The initial count rate was I_o. Succeeding activity measurements were made of the total remaining sample, I_k, and of the grindings, $I(\zeta,t)$.

Results

In Fig. 3 are the results of twenty-two radiotracer experiments. The oxygen pressure dependence of the cation diffusivity, $[(\partial \log D_{Mn}{}^T)/(\partial \log P_{O_2})]_T$, is given in Table IV. Lacombe *et al.* (2) have presented direct experimental data from which the activation energy

$$Q^* = \left[\partial \log D_{Mn}{}^T / \partial \log \frac{1}{T} \right]_{P_{O_2}} \quad [10]$$

may be calculated. From their manganese oxidation experiments Fueki and Wagner (9) have calculated $D_{Mn}{}^T$ *vs.* $\log P_{CO_2}/P_{CO}$; from these data and the equilibrium constant for the dissociation of CO_2, Q^* may be calculated. By assuming parallel isotherms the

1141°, 935°, and 852°C data of the present study were extrapolated so that an approximate value of Q^* could be calculated for comparison with the data of Fueki (9) and of Lacombe (2). The results are given in Table V.

Approximately half of the diffusion profiles did not extrapolate to the point 50 $(2 - I_k/I_o)$ equal to fifty, see Fig. 4. Where the data did not extrapolate to fifty the profile was translated so that it would intercept 50 $(2 - I_k/I_o)$ equal to fifty, the dotted line in Fig. 4. The differences between the corrected profile and the experimental profile are due to the experimental errors in the location of the plane k equal to zero and in the measurement of I_o as discussed below. Referring to Eq. [9]

$$50\left(2 - \frac{I_k}{I_o \pm \delta}\right) = 50\left(1 + \text{erf}\frac{k \pm \Delta}{\sqrt{4Dt}}\right) \quad [11]$$

the data in Fig. 5 may be interpreted on the basis that δ and Δ of Eq. [11] are not equal to zero. There is a constant error in the measurement of I_o and k. The error in the location of k equal to zero was due to the occasional presence of a very thin layer of the plastic mount on the top surface of the crystal. The plastic mount had to be removed before the measuring microscope could be focused on the top surface of the crystal. One or two microns of the crystal were inadvertently removed with the excess cold mount so that the point k equal to zero was one or two per cent uncertain. Because of evaporation losses during the diffusion anneal the measured value of I_o was approximately 10% uncertain. For experimental data containing nonzero values of Δ and δ the profile extrapolates to some value of $I_k/I_o \neq 1$ at k equal to zero. The appropriate way to adjust the profile for the nonzero values of Δ and δ is to translate the curve as shown in Fig. 4, curve B. The appropriate value of D was calculated from the translated curve. See the dashed curve in Fig. 4. For the data in Fig. 4 the value of D

calculated from the translated curve differs from the value of D calculated from the experimental curve by 20%. All the samples were sectioned to a depth of at least twice $\sqrt{Dt}$, and it was found that in most samples the γ intensity did not go to zero; it dropped to a constant value of approximately 10% of I_0. This residual activity, or tail (15), was subtracted point by point from the profile. If the ratio of the residual activity to I_0 was two tenths or less there was no measurable difference between D computed from data including the tail and D computed from data with the tail subtracted out. If the ratio of the residual activity to I_0 exceeded two tenths the experiment was repeated on another sample.

Only one experiment was conducted so that both Eq. [7] and [8] could be used to analyze the data for D on the same sample. The sample was lapped and counted using the Gruzin method, but at 30μ intervals, layers approximately 4μ thick were removed on circular grinding paper and counted. The counting errors in the sectioning data were appreciable because the net count rate from the grindings was always less than the background count rate. However, the difference between D computed from the sectioning data and D computed from the residual activity data, 23%, was close to the average experimental error of 18%.

The linear absorption coefficient for the $^{54}{}_{25}Mn$ γ radiation was also measured. Slabs of monocrystalline MnO_{1+x} were placed over an active diffusion sample, and the decrease in count rate per each slab added was measured. The area of the absorber slabs was at least twice the area of the source. The experimental value of the linear absorption coefficient, μ, was comparable to the value computed from reference data (17)

$$\mu \text{ (calc)} = 0.3 \text{ cm}^{-1}$$

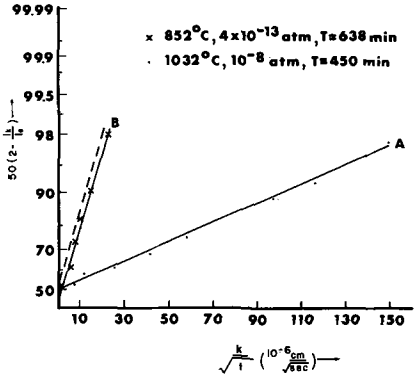

Fig. 4. Two radiotracer profiles of 50 $(2 - I_k/I_0)$ vs. $k/\sqrt{t}$ from which $D_{Mn}{}^T$ was determined to be: (A) 3 x 10^{-9} cm²/sec for 1032°C, 10^{-8} atm P_{O_2}, t = 450 min, and (B) 5 x 10^{-11} cm²/sec for 852°C, 4 x 10^{-13} atm $P_{O}{}^2$, t = 638 min. Curve A intercepted the ordinate at 50 $[2 - I_k/I_0]$ = 50 as required by theory, see text. Curve B did not. It was translated as shown by the dashed line to intercept the ordinate at 50. This offset indicates an experimental error. See text.

$$\mu \text{ (exp.)} = 0.1 \text{ cm}^{-1}$$

Therefore the absorption correction to Eq. [8] was not necessary as was noted previously.

The average percentage deviation of the experimental data about the $\log_{10} D - \log_{10} P_{O_2}$ regression line at 1032°C was 16%. The data computed from a least squares analysis of $\log_{10} D$ vs. $\log_{10} P_{O_2}$ at 1032°C are given in Table VI. Each datum point studied corresponded to some fixed value of temperature and oxygen pressure. At many of the data points several repeat experiments were conducted, each on a different sample. At all data points at least two samples were analyzed. Each experimental value of D was compared to the average value at that datum point to compute a per cent deviation in the sense of Eq. [12]

$$\% \text{ deviation} = \frac{\Delta D}{D(\text{avg})} \times 10^2 \qquad [12]$$

where

$$\Delta D = D(\text{avg}) - D(\text{exp.}) \qquad [13]$$

and

$$D(\text{avg}) = \sum_{i=1}^{j} D_i/j \qquad [14]$$

The average per cent deviation was 18%. The standard deviation in the log $D_{Mn}{}^T$ vs. log P_{O_2} data at 1032°C is 0.1.

Discussion

The oxygen pressure dependence of the electronic conductivity of MnO_{1+x} in region A could yield a model involving a manganese interstitial

$$MnO(s) \rightleftarrows \frac{1}{2} O_2(g) + Mn_i{}^{m\cdot} + m\ominus \qquad [15]$$

where $Mn_i{}^{m\cdot}$ is an ionized interstitial, $\ominus$ is an electron, and m is an integer, either one or two. With this model the differential form of the oxygen pressure dependence of the electrical conductivity is

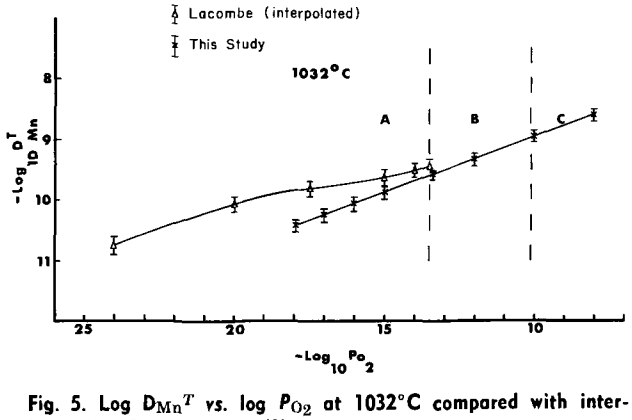

Fig. 5. Log $D_{Mn}{}^T$ vs. log P_{O_2} at 1032°C compared with interpolated data from Lacombe (2).

$$\left[\frac{\partial \log \sigma}{\partial \log P_{O_2}}\right]_T = -\frac{1}{2(m+1)} \quad [16]$$

An oxygen vacancy would yield the same oxygen pressure dependence for the conductivity

$$MnO(s) \rightleftarrows \frac{1}{2} O_2(g) + V_O^{m\cdot} + m\ominus \quad [17]$$

where $V_O^{m\cdot}$ is an oxygen vacancy with m positive charges.

As suggested by Hed and Tannhauser (4) a doubly ionized cation vacancy would yield a similar oxygen pressure dependence for the electrical conductivity if

$$\mu_- n >> \mu_+ p \quad [18]$$

and

$$np = n_i^2 = n_{io}^2 \exp(-E_g/RT) \quad [19]$$

where n_i is the intrinsic concentration of carriers, n_{io} is a constant, and E_g is the band gap expressed here in cal/mole. The conductivity is given by

$$\sigma = e(\mu_- n + \mu_+ p) \quad [20]$$

and

$$p \propto P_{O_2}^{1/2(m+1)} \quad [21]$$

so that combining [18], [19], [20], and [21] yields

$$\sigma \propto P_{O_2}^{-1/2(m+1)} \quad [22]$$

for n-type MnO. With their conductivity data and the analysis of Becker and Frederikse (10), Hed and Tannhauser substantiated this latter model.

The self diffusivity of manganese is proportional to the concentration of defects responsible for the mobility of the manganese, presumably either cation vacancies or cation interstitials. In regions B and C of the T-P_{O_2} diagram (Fig. 1), the predominant defect is the cation vacancy (1-4), the concentration of which is proportional to $P_{O_2}^{1/2(m+1)}$. In region B the data of this study, of the study of Lacombe *et al.* (2), and the study of Fueki and Wagner (9) verify that D is proportional to $P_{O_2}^{1/2(m+1)}$, where m equals approximately two. For region A Eq. [15] predicts that D should be proportional to $P_{O_2}^{-1/2(m+1)}$, the oxygen pressure dependence of the concentration of manganese interstitials if manganese interstitials were the predominant defect. There would necessarily result a minimum value of D near the composition corresponding to the boundary between regions A and B. Both the data of Lacombe and the data of the present study show no minimum value for D. If Eq. [17], the oxygen vacancy model, were valid for region A, the mobile cation defect in region A would be the low concentration vacancy. There would be an intrinsic region near the region A-region B boundary because the material would be transforming from oxygen excess in region B to oxygen deficit in region A. The cation diffusivity, D, would decrease monotonically across the phase field with an inflection point in the intrinsic region. The oxyyen pressure dependence of D would be $P_{O_2}^{-1/2(m+1)}$. Although Lacombe has rejected the oxygen vacancy model, his data seem to support it. Reasoning that if the oxygen vacancy were the predominant point defect in region A there would be appreciable oxygen transport in an electric field, Lacombe *et al.* (2) eliminated the oxygen vacancy model by showing that the ionic conductivity was dominated by the cation contribution. By assuming parallel isotherms we have interpolated Lacombe's radiotracer diffusion data for comparison with the data of the present study, see Fig. 5. The error bars on the interpolated data points of Lacombe were taken from equivalent data points at 1000° and 1100°C. The experimental data points of the present study are given with the computed regression line. The agreement between the two sets of data is very satisfactory. The diffusion activation energy, Q^*, is also consistent with the cation vacancy model. The differences in the data, Fueki's at 10^{-10} atm ($Q^* = 22$ kcal/mole), Lacombe's (interpolated) at 10^{-10} atm ($Q^* \cong 19.3$ kcal/mole), and our extrapolated value at 10^{-11} atm ($Q^* \cong 36$ kcal/mole), are attributed to experimental error and extrapolation.‡ The data of Lacombe, Q^* *vs.* P_{O_2} from 10^{-10} to 10^{-22} atm, will be discussed further because they require the least interpretation and extrapolation. For a vacancy diffusion model it is known that $Q^* = [\Delta H^\circ_f/(m+1) + \Delta H_m]$ where ΔH°_f is the enthalpy for reaction 1, the enthalpy of formation of an ionized vacancy and m electron holes and ΔH_m denotes the enthalpy of movement of the manganese ions. This is the notation of Eror, and it is consistent with the notation of Hed and Tannhauser if one notes that $\Delta H^\circ_f = \Delta h^\circ_f + E_1 + E_2$ where Δh°_f is the enthalpy of formation of a neutral cation vacancy, and E_1 and E_2 are the first and second ionization energies of the cation vacancy. The enthalpy of motion for diffusion will show a discontinuity when plotted *vs.* composition or P_{O_2}, wherever there is a change in diffusion mechanism. If $\Delta H^\circ_f/(m+1)$ may be determined for each value of P_{O_2} at which Q^* has been calculated, it would be possible to calculate ΔH_m at each value of P_{O_2}.

In the p-region of the phase field

$$\sigma = \mu_{\oplus} p\, e = \text{const}\, P_{O_2}^{\frac{1}{2(m+1)}} \exp\left\{-\frac{\Delta H^\circ_f + (m+1)\,\Delta H^\ddagger_{\oplus}}{(m+1)RT}\right\}$$

and

$$\left[\frac{\partial \ln \sigma}{\partial\, 1/RT}\right]_{P_{O_2}} = -\left(\frac{\Delta H^\circ_f}{m+1} + \Delta H^\ddagger_{\oplus}\right) \quad [23]$$

These data are available from Eror (1, 16) and are reproduced in Table VII. At 7×10^{-10} atm $[\Delta H^\circ_f/(m+1)]$ is -6 kcal/mole, and from Lacombe's data at 10^{-10} atm Q^* is 19 kcal/mole. Therefore, at 7×10^{-10} atm, ΔH_m is 25 kcal/mole. In the n-region of the phase field

$$\sigma = ne\mu_{\ominus} = [n^2_{io}/p]\, e\mu_{\ominus} \exp(-E_g/RT)$$
$$= \text{const}\, P_{O_2}^{-1/2(m+1)} \exp\left\{\left[\Delta H^\circ_f - (m+1)\left(E_g + \Delta H^\ddagger_{\ominus}\right)\right]\Big/(m+1)RT\right\} \quad [24]$$

where ΔH°_f is the enthalpy of formation of a doubly ionized cation vacancy, E_g is the intrinsic energy gap

** Probable error.
‡ Because only one datum point of Q^* at a given P_{O_2} was available, it was not possible to assign confidence limits to these energy values.

(4), and $\Delta H^{\ddagger}_{\ominus}$ is the enthalpy of motion of an electron. Then

$$\left[\frac{\partial \ln \sigma}{\partial\, 1/RT}\right]_{P_{O_2}} = + \left(\Delta H^{\circ}_f/(m+1) - E_g - \Delta H^{\ddagger}_{\ominus}\right) \quad [25]$$

and from Hed and Tannhauser (4), $E_g + \Delta H^{\ddagger}_{\ominus} = 2.49$ eV or 57.4 kcal/mole. From the data of Eror we have at 10^{-19} atm O_2, $\left(\Delta H^{\circ}_f/(m+1) - E_g - \Delta H^{\ddagger}_{\ominus}\right) = -51.7 \pm 0.8$ kcal/mole. Combining the data one calculates $\Delta H^{\circ}_f/(m+1) = 5$ kcal/mole. At 10^{-20} atm O_2 $Q^* = 26$ kcal/mole and ΔH_m is then calculated to be 21 kcal/mole at approximately 10^{-20} atm O_2. Within experimental error ΔH_m is 22.2 kcal/mole and is shown to be a representation of the same diffusion process in both regions A and B. Also it is evident that the temperature dependence of the conductivity is dominated by the term E_g in the n-regions of regions A. In regions B and C, σ is almost independent of temperature. The above calculations probably yield only approximate agreement owing to the large errors in each energy term. Nevertheless, the magnitude of the energy terms is reasonable. A similar calculation assuming diffusion via interstitial jumps in the n-region yields clearly unreasonable values for the energy terms as can be seen in what follows. If the predominant lattice defects are interstitials at low oxygen pressures, then a plot of log conductivity *vs.* reciprocal temperature at constant oxygen pressure yields a slope whose value gives $\left[\Delta H^{\circ}_f/(m+1) + \Delta H^{\ddagger}_{\ominus}\right] = +51.7 \pm 0.8$ kcal/mole at 10^{-19} atm where $\Delta H^{\ddagger}_{\ominus}$ denotes the migration enthalpy of electrons and ΔH°_f denotes the enthalpy for the ex-solution of oxygen (formation of interstitials) according to Eq. [15]. Under this assumption, combining the value, $Q^* = [\Delta H^{\circ}_f/(m+1) + \Delta H_m] = 26$ kcal/mole, and $\left[\Delta H^{\circ}_f/(m+1) + \Delta H^{\ddagger}_{\ominus}\right] = 51.7$ kcal/mole yields $\left[\Delta H_m - \Delta H^{\ddagger}_{\ominus}\right] = -26$ kcal/mole or $\Delta H_m = -26 + \Delta H^{\ddagger}_{\ominus}$ where ΔH_m denotes the migration enthalpy of interstitial cations for the purposes of this calculation. A reasonable value of ΔH_m is ≈ 35 kcal as it should be larger than the similar energy term for the enthalpy of motion via vacancies. If so, the enthalpy of migration for electrons would amount to ≈ 61 kcal/mole which is clearly unreasonable. Again the evidence points to cation vacancies as the predominant lattice defect in MnO.

The temperature dependence of the electrical conductivity at constant P_{O_2} does not provide data for a straightforward calculation of $\Delta H^{\circ}_f/(m+1)$ in the intrinsic region. Thermogravimetric data would provide values of $\Delta H^{\circ}_f/(m+1)$ in the intrinsic region, but these data are not available. Other data are not available then for a consistency check of the temperature dependence of Lacombe's diffusion data in the intrinsic region. However, the inflection points in the diffusivity isotherms are not consistent with a cation vacancy model.

If the majority lattice defect in region A were a cation vacancy, via Eq. [1] the oxygen pressure dependence of the cation diffusivity would be $P_{O_2}{}^{+1/2(m+1)}$. There would be no minimum or inflection point in the log D_{Mn^T} — log P_{O_2} data. The diffusion data of the present study are thus consistent with the model wherein cation vacancies are the predominant lattice defect in MnO.

Summary

The data, log D_{Mm^T} *vs.* log P_{O_2} at 1032°C, of this study are consistent with the cation vacancy model proposed by Hed and Tannhauser (4).

In region C there is agreement between conductivity and thermogravimetric analysis. In region B all studies of conductivity, thermogravimetry, oxidation, and radiotracer diffusion yield an oxygen pressure dependence of approximately +1/6. The predominant defect in region C is a singly ionized cation vacancy, and in region B the predominant defect is a doubly ionized cation vacancy. In region A the oxygen pressure dependence of the conductivity is −1/6, there is no measurable weight change, and the oxygen pressure dependence of the cation diffusivity is +1/6. The computed oxygen pressure dependence of the electron hole concentration is +1/4 in region C and +1/6 in regions A and B, with no inflection point at the region A-region B boundary. Further, the oxygen pressure dependence of the cation diffusivity is +1/5.4 throughout regions A and B, and the activation energy for motion, ΔH_m, is the same in both regions. Therefore, we conclude that throughout the high temperature region of the MnO_{1+x} phase field, MnO_{1+x} is oxygen excess with cation vacancies, including region A. Further arguments supporting this conclusion are presented by F. A. Kröger (18) who showed that the thermodynamically stable forms of MnO, FeO, CoO, and NiO are all oxygen excess.

The Equilibrium and Free Surface Sublimation Pressures of Oriented Single Crystals of Bismuth Telluride

Iraj Y. Kashkooli and Zuhair A. Munir

Department of Materials Science, School of Engineering, San Jose State College, San Jose, California

ABSTRACT

The equilibrium and free surface sublimation pressures of bismuth telluride were determined by the torsion-effusion and torsion-Langmuir techniques, respectively. Based on a least-square fit, the expression for the equilibrium pressure in the temperature range of 722°-828°K was found to be: $\log P$ (atm) $= (7.579 \pm 0.373) - (1.020 \pm 0.029)\ 10^4/T$, where T is the absolute temperature and the given uncertainties are the standard deviations. A similar treatment of the results of free surface pressure over basal plane oriented single crystals gave the following expression for the apparent total pressure in the temperature range of 741°-793°K: $\log P$ (atm) $= (10.312 \pm 0.693) - (1.280 \pm 0.053)\ 10^4/T$. Assuming the sublimation reaction Bi_2Te_3 (S) = 2 BiTe (g) + ½ Te_2 (g), average third-law enthalpies and activation enthalpies of sublimation at 298°K were found to be 127.4 ± 1.2 and 133.1 ± 1.8 kcal/mole, respectively. Calculated values of the sublimation coefficient varied from 0.14 at 722°K to 0.39 at 828°K.

Probably because of its thermoelectric properties, the telluride of bismuth, Bi_2Te_3, has been the object of considerably more thermodynamic investigations than the corresponding compounds of other group V elements (1-3). However, until the recent studies of Gorbov and Krestovnikov (4), and Boncheva-Mladenova *et al.* (5) no vapor pressure measurements had been reported on this compound.

Based on the assumption that the sublimation of bismuth telluride is according to

$$Bi_2Te_3(S) = Bi(g) + BiTe(g) + Te_2(g) \qquad [1]$$

Gorbov and Krestovnikov (4) calculated the sublimation pressures from weight loss determinations. In an added note, however, these authors suggested that better agreement between calculated and measured thermodynamic functions can be achieved if the sublimation reaction of bismuth telluride is written as follows

$$Bi_2Te_3(S) = 2\,BiTe(g) + 1/2\,Te_2(g) \qquad [2]$$

Assuming an identical reaction, Boncheva-Mladenova *et al.* (5) reported sublimation pressures of polycrystalline bismuth telluride employing the Knudsen and Langmuir techniques.

Mass spectrometric studies by Porter and Spencer (6) showed the presence of the gaseous species BiTe, Bi, and Te_2 over liquid bismuth telluride. However, lack of similar mass spectrometric information regarding solid bismuth telluride renders sublimation pressure values calculated from weight loss data subject to considerable doubt. In this paper we report results of sublimation studies on bismuth telluride using the weight-loss-independent torsion-effusion and torsion-Langmuir methods for the experimental conditions of equilibrium and free surface sublimations, respectively.

Experimental

The torsion-effusion and torsion-Langmuir methods have been discussed in several publications (7-9), and the apparatus used in this study has been described in a recent paper (10).

The torsion cells used in this investigation, which were made of National Carbon ZT101 grade graphite, have similar geometric configurations to those described earlier (8, 9).

Single crystalline bismuth telluride used in this study had been previously prepared from 6-nine pure tellurium and bismuth by the Bridgman technique. X-ray examinations of an ingot prepared by this technique showed it to be a single crystal with an easy cleavage basal plane parallel to its major axis. To be used in the torsion-Langmuir experiments, wafers of bismuth telluride, about 1.5 mm thick, were cleaved off the ingot following a liquid-nitrogen quench. When x-rayed these wafers were found to be single crystalline with facial orientations corresponding to the basal plane [Bi_2Te_3 has the tetradymite type hexagonal lattice (11)].

In agreement with others (5) the sublimation of bismuth telluride was found to be congruent. X-ray examinations of samples which had previously been heated in vacuum at temperatures and for periods of time corresponding to no less than 30% weight loss gave patterns identical to those obtained from unheated samples. Furthermore, metallographic examinations of the heated samples proved the absence of any second phase which may have not been detected by the x-ray analyses, *e.g.*, amorphous tellurium.

Temperatures were measured by means of a calibrated Pt-Pt/10% Rh thermocouple imbedded inside a dummy cell situated about 2 cm below the torsion cell. Determination of the temperature profile of the heating element indicated that the torsion and dummy cells are well within the constant temperature portion of the profile. Calibration of the thermocouple was accomplished by redetermining the freezing point of pure samples of aluminum, silver, and copper which were placed inside the dummy cell.

Ambient pressures, as measured in the vicinity of the heating element, were maintained at 2×10^{-5} Torr or less throughout this study.

As a check on the reliability of pressure results obtained using the present apparatus, the vapor pressure of silver was redetermined in the range of 10^{-3} to 10^{-6} atm. From over 30 vapor pressure determinations the third-law heat of vaporization of silver was calculated to be 68.3 ± 0.4 kcal/mole which is in good agreement with the value reported by Hultgren *et al.* (12) of 68.1 ± 0.3 kcal/mole.

Results

Equilibrium sublimation.—Figure 1 shows the results of equilibrium pressure determinations, calculated from torsion deflections in the temperature range of 722°-828°K, and plotted as $\log P$ vs. $1/T$, where P is the total sublimation pressure of bismuth telluride

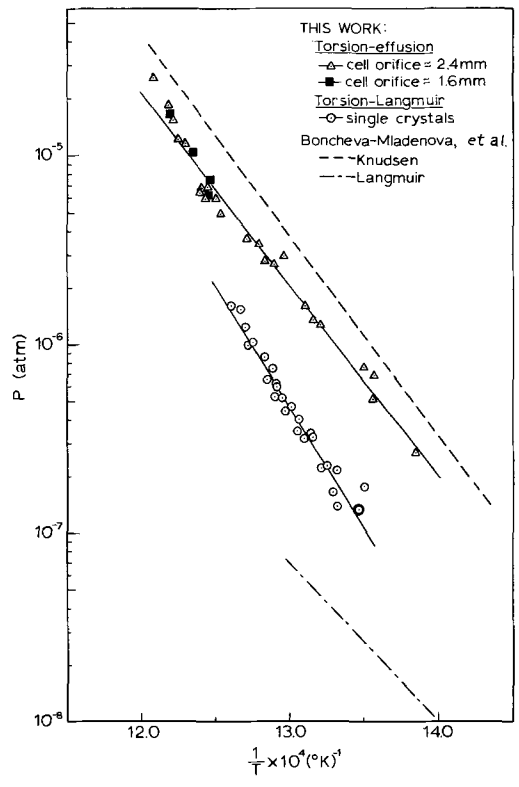

Fig. 1. Sublimation pressure of bismuth telluride

and T is the absolute temperature. Employing a least-square method of analysis these results can be expressed as

$$\log P\ (\text{atm}) = (7.579 \pm 0.373) - (1.020 \pm 0.029)\ 10^4/T \qquad [3]$$

where the quoted uncertainties are the standard deviations. If the reaction given by Eq. [2] is assumed to be the one describing the sublimation process of bismuth telluride, then the expression for the equilibrium constant becomes

$$K = (P_{BiTe})^2 \cdot (P_{Te_2})^{1/2} \qquad [4]$$

where P_{BiTe} and P_{Te_2} are the partial pressures of the gaseous species BiTe and Te_2, respectively. From kinetic theory considerations the relationship between these partial pressures is

$$\frac{P_{BiTe}}{P_{Te_2}} \frac{2}{1/2} \left[\frac{(\text{m.w.})Te_2}{(\text{m.w.})BiTe}\right]^{1/2} \qquad [5]$$

where (m.w.)Te_2 and (m.w.)BiTe refer to the molecular weights of the two species. Finally, since the total pressure is the sum of these partial pressures, *i.e.*,

$$P_T = P_{BiTe} + P_{Te_2} \qquad [6]$$

an expression (similar to that of Eq. [2]) relating the equilibrium constant, K, with temperature can be derived. From such an expression second-law heat and entropy of sublimation were calculated and corrected to 298°K using reported thermodynamic functions (13). These calculations gave values of $\Delta H°_{298}$ and $\Delta S°_{298}$ of 121.6 ± 5.0 kcal/mole and 93.5 ± 6.3 eu, respectively.

Third-law calculations, based on Eq. [2] and using reported free energy functions for Te_2(g) (14), BiTe(g) and Bi_2Te_3(S) (4, 13), are shown in Table I. Table I also shows the results of mean-free-path to orifice diameter calculations, which were based on a molecular diameter of BiTe(g) of 3.48Å, and the assumption of ideal gas law. The average value of the third-law $\Delta H°_{298}$ of sublimation was found to be 127.4 ± 1.2 kcal/mole.

Free-surface sublimation.—The free surface sublimation pressures of oriented single crystals of bismuth telluride, which were obtained from torsion-Langmuir deflection measurements, are shown in Fig. 1. Least-square analysis of these results obtained in the temperature range of 741°-793°K gave the following expression for the apparent total pressure over basal-plane oriented bismuth telluride crystals

$$\log P\ (\text{atm}) = (10.312 \pm 0.693) - (1.280 \pm 0.053)\ 10^4/T \qquad [7]$$

where T is the absolute temperature and the given uncertainties are the standard deviations. Again using the procedure outlined by Eq. [4] through [6], second-law activation heat and entropy values were calculated with the resulting values for $\Delta H^{\pm}_{298}$ and $\Delta S^{\pm}_{298}$ of 151.3 ± 6.4 kcal/mole and 124.6 ± 7.5 eu, respectively.

Calculations of the third-law heat of sublimation, which were based on reported free-energy functions (13, 14), are shown in Table II. An average $\Delta H^{\pm}_{298}$ of 133.1 ± 1.8 kcal/mole was obtained from these calculations. From results obtained in this study the sublimation coefficient, defined as the ratio of the free-surface-to-equilibrium pressures, was found to vary from 0.14 to 0.39 over the corresponding temperature limits of 722°-828°K.

Discussion of Results

The assumption of equilibrium conditions inside the torsion-effusion cells was based on examinations of theoretical factors governing effusion cells (15, 16). Use of two cells with orifice areas differing by a factor of about two showed no dependence of measured pressures on the orifice size. Moreover, the calculated third-law heats of sublimation showed no deviation with a decrease in the λ/d ratio reported in Table I. Thus in accordance with the cited theoretical considerations, the reported torsion-effusion pressures are the equilibrium sublimation pressures of bismuth telluride.

The reasonably good agreement (within 5%) between the calculated third-law and second-law equi-

librium heats of sublimation suggests that the sublimation mechanism of Bi_2Te_3 is in accordance with Eq. [2]. Agreement between published pressure results (4, 5), which were calculated from weight loss data assuming the reaction of Eq. [2], and those measured directly in this work can be taken as additional support for the plausibility of the assumed mechanism. Reported $\Delta H°_{298}$ values (4, 5) are within 2% of the value calculated in this paper.

On the other hand, the relatively large discrepancy ($\sim$ 14%) between second-law and third-law activation enthalpies may be interpreted as suggesting a mode of sublimation under free-surface conditions which is somewhat different from that under equilibrium. That it is possible to have differences in the mode of sublimation under free surface and equilibrium conditions, has been shown in at least one investigation (17). The existence of a layer structure in Bi_2Te_3 (18) (Te — Te — Bi — Te — Bi — Te — Te — Bi .....) may possibly contribute to a dual nature in the sublimation modes of this compound.

In addition to the ease with which cleavage takes place along basal planes of Bi_2Te_3, choice of this orientation in the free surface sublimation study was based on previous experience on other hexagonal systems in which the sublimation rates of basal planes were found to be lower than those of prismatic planes (19) and thus offer a greater degree of departure from equilibrium. Rates of sublimation from these basally oriented crystalline faces, which were constant at any given temperature, thus represent a state of "apparent" or pseudo-equilibrium. Such low rates of sublimation may result from the formation or desorption energetics of the two gaseous species leaving the surface.

Selected Area Electron Diffraction Study of α-Fe_2O_3 Platelet Growths Twinned on Twist Grain Boundaries

R. L. Tallman* and E. A. Gulbransen*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

Broad, rounded draperylike platelet growths result from the oxidation of unannealed iron in dry oxygen at 400°C. Their skewed sandwich structure is a new type of twinning in which the composition plane is a twist grain boundary. This twin interface and the platelet faces are on the basal plane. A 13.174° twist angle is common; 21.787°, 26.66°, and 35.22° were also found. Such a rounded platelet would be expected to result from the proposed internal diffusion mechanism.

Three distinct families of α-Fe_2O_3 growths have been observed in the gaseous oxidation of relatively pure irons (1, 2). These are whiskers, bladelike platelets, and broad, rounded platelets. Whiskers have been found to show the axial twist characteristic of an axial screw dislocation (3, 4). The bladelike platelets are contact twins with the composition plane parallel to the blade face and to the mirror plane relating the two orientations (4, 5). The blade face is on the rhombohedral plane, (010) of the primitive structural rhombohedron.

This paper presents the structure, or structures, of the broad, rounded platelets together with all the selected area electron diffraction patterns important to the determination of these structures. Comments on some features of the probable growth mechanism and their broader significance are also provided.

* Electrochemical Society Active Member.

Experimental

The broad, rounded platelets examined in this work were chosen from many produced in oxidation experiments which were part of some earlier studies (1, 2). The iron wire, 0.007 in. thick, obtained from the National Bureau of Standards, contained <200 ppm metallic impurities and about 140 ppm carbon. The unannealed wire was washed, degreased, and rinsed with ethyl alcohol. Then the wire was oxidized 48 hr at 400°C in an atmosphere of oxygen which had been dried by a trap cooled by solid carbon dioxide in acetone. Broad, rounded platelets have also been observed in oxidations in dry oxygen at up to 500°C of Battelle iron wires of higher purity.

Conditions determining growth of whiskers, bladelike platelets, and broad, rounded platelets.—The broad, rounded platelet growths predominated among the growths on the unannealed wires. Areas of platelets and areas of whiskers developed on annealed wires; whisker growth seems likely to be the growth to be expected for annealed wires under the least complex conditions. The broad, rounded platelet growth seems to be associated with some plastic deformation of the iron, but this may involve an undetermined impurity effect. The 10 μm breadths of the platelets may be permitted by the preferred orientation (texture) of the grains always found in the surface of fine iron wires.

The whisker and broad, rounded platelet growths are replaced by bladelike platelet growths (1, 2, 5) when the atmosphere is water vapor (with at least some oxygen). The absence of bladelike platelets among the whiskers and broad, rounded platelets indicates that the water vapor concentration is less than some unknown limit. Experiment (2) has shown this limit to be smaller, itself, than 3%.

Selected Area Electron Diffraction Study of Broad, Rounded Platelet Structures

Earlier work (1, 2) has established that the broad, rounded platelets are α-Fe_2O_3. This was accomplished with a simple electron diffraction camera. Patterns from a standard were taken alternatively with patterns from 0.007 in. iron wires densely covered with broad, rounded platelets of α-Fe_2O_3. The d-spacings measured were all α-Fe_2O_3 d-spacings, and the intensities compared satisfactorily with x-ray powder diffraction intensities. The patterns also compare satisfactorily with electron diffraction patterns of fine α-Fe_2O_3 powder. The spot shapes and intensity distributions of such platelet patterns are consistent with the shape and preferred orientation of the platelets. The large, thin total cross section of these growths results in an extreme predominance of their diffraction in such patterns.

The platelets themselves having been adequately proved to be α-Fe_2O_3, selected area diffraction patterns of large numbers of platelets were measured to determine the instrument constant for selected area diffraction. The satisfactory indexing of such patterns further confirms that the broad, rounded platelets are α-Fe_2O_3.

In this paper a set of three indices will refer to the face-centered rhombohedral (morphological) unit cell; a set of four, to the structural (triple) hexagonal unit cell. Information concerning these unit cells and the d-spacings and transformations of indices can be found in the associated previous publications (3-5).

General description of the platelets.—Figure 1 shows a broad, rounded platelet with a typical S-curve. Stereoscopic images have also shown platelet S-curvature. A dark field image showing three approximately parallel bend contour lines has been obtained from another platelet. Since only one diffracted beam passed the objective aperture, there were at least two points of inflection in the cross section normal to the bend

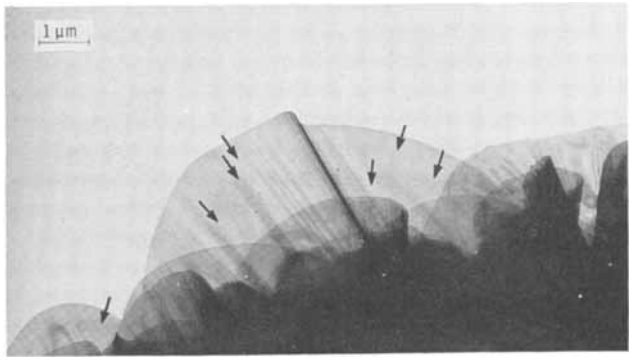

Fig. 1. Broad, rounded platelets of α-Fe_2O_3 on a 175 μm diameter iron wire after 48 hr in dry O_2 at 400°C. Each arrow indicates a step in thickness tracing the edge at a stage in the platelet growth.

contours. This draperylike curvature is common, but some broad, rounded platelets are nearly flat.

Figure 2 is an artist's attempt to show the curved surfaces and twinned structure of the broad, rounded platelets. The arrows indicating the [$\bar{1}$10] directions of the two crystals show the relative twist about [111] which relates the two crystal orientations. The approximate [$\bar{1}$10] growth direction and bend axis is common.

Heights of the broad, rounded platelets range to 4 μm and breadths to 10 μm. Both in thickness and in thickness uniformity, the broad, rounded platelets appear to be similar to the bladelike platelets (1, 2, 4, 5). Thicknesses are estimated to be commonly in the range 150-300Å.

The four structures determined suggest that all broad, rounded platelets are contact twins with one twin interface. The twin interface, or composition plane, is a twist grain boundary on the basal plane, parallel to the platelet faces. This could be called a skewed sandwich structure.

The four structures found are different in that their twist angles are different. Other differences between the platelets, such as differences in shape, thickness, bend contours, etc., might be expected to accompany the difference in structure. However, these differences have not been correlated with the twist angle

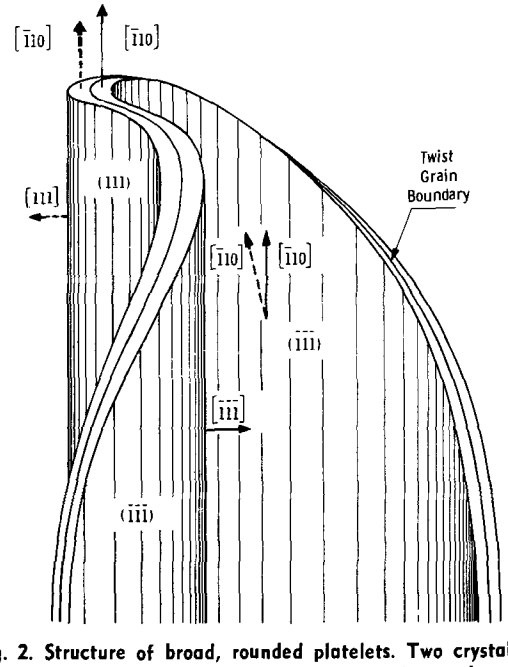

Fig. 2. Structure of broad, rounded platelets. Two crystal orientations indicated by rhombohedral indices; thickness shown exaggerated by a factor of five or more.

variation, primarily because such features have not been studied sufficiently.

Special twist angles.—Two of the twist angles have special significance in that they rotate lattice point rows in the basal plane into coincidence. This results in a repeating pattern in the boundary structure with a small two-dimensional hexagonal unit cell. If the twist angle were small, one could imagine the boundary to consist of a hexagonal array of islands of coherency separated by axial screw dislocations. This is the common picture of small angle twist grain boundaries (6, 7). Then the special twist angles would introduce long-range translational symmetry into such an array. The fact that the special twist angles are found suggests that this concept has some validity unexpected for such large twist angles. That is, the interface structure has some special stability (reduced energy).

Common twist angle.—Figures 3 and 4 indicate the indexing of the diffraction patterns obtained from two platelets which show the most common twist angle. That angle is calculated to be 13.174° = 2 arc csc$\sqrt{76}$. The calculation is based on the coincidence of the double diffraction patterns about the $2\bar{2}0$ spots and the incident beam. The planes $(32\bar{5}0)$ and $(23\bar{5}0)$ of the two crystals, as well as the directions $[32\bar{5}0]$ and $[23\bar{5}0]$, are rotated into coincidence by this twist angle.

Each drawing in Fig. 3 and 4 shows the diffraction from one face crystal. In each figure the two hexagonal patterns of circles are related by the twist angle, 13.174°.

The rotation indicated in the diffraction pattern of each face crystal results from the curved nature of the broad, rounded platelets. Both showed bend contours roughly perpendicular to the iron wire surface, and, therefore, along what might be considered the growth directions. This is the most common bending. The bend contours lie parallel to the projection of the axis of the rotation of the bending. For these two platelets the bending seems to be nearly exactly about $[\bar{1}10]$ for the platelet faces whose pattern drawings do not show the indices. (That is why these patterns are more symmetrical than those showing the indices.) That this $[\bar{1}10]$ direction, toward eight o'clock in the drawings, lies parallel to the bend contours is confirmed by the relative rotation of image and diffraction (determined with asbestos fibers).

The growth directions of the broad, rounded platelets are in the region of the $[\bar{1}10]$ directions of the two faces. This $[\bar{1}10]$ direction (face-centered rhombohedral, morphological indices) is also the growth direction of the whiskers and bladelike platelets (3-5).

In both Fig. 3 and 4 the beam is nearly parallel to the threefold axis near one extreme of the bending. This orientation is indicated by the hexagonal patterns of open circles. The patterns differ in that the bending brings (001) parallel to the beam in Fig. 3 and (110) parallel in Fig. 4.

Of nineteen platelets for which the selected area diffraction patterns were available and suitable, thirteen gave patterns indicating the 13.174° twist angle. Other twist angles have been determined for three of the remaining six.

Uncommon twist angle.—Figure 5 indicates the indexing for the one platelet with the special twist angle 21.787° = 2 arc csc$\sqrt{28}$. The angle is that required to rotate $3\bar{3}1$ of the drawing at the right of Fig. 5 into

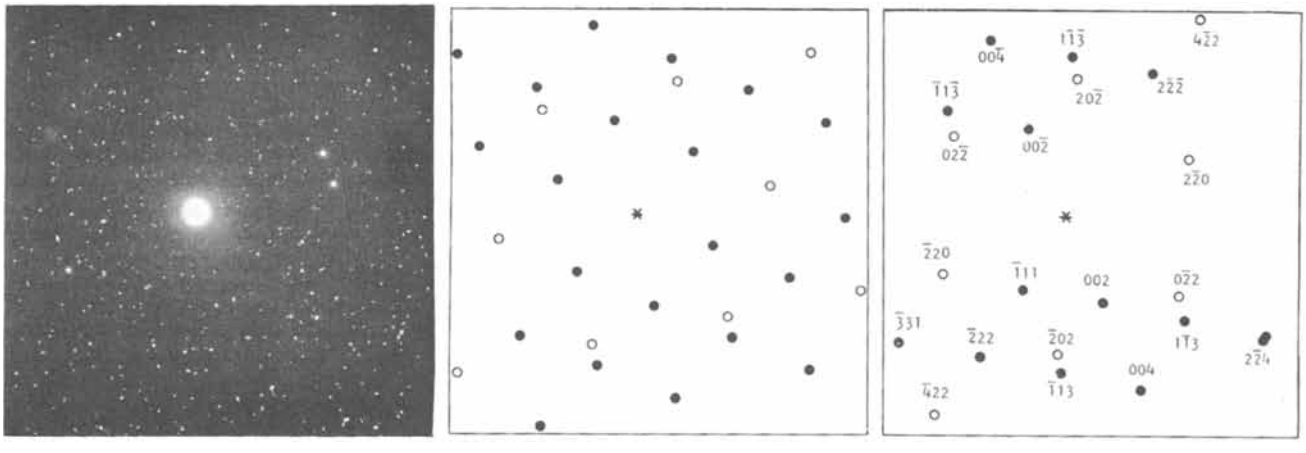

Fig. 3. Broad, rounded platelet, α-Fe_2O_3, twist angle 13.174° = 2 arc csc$\sqrt{76}$. The pattern is the sum of the drawings

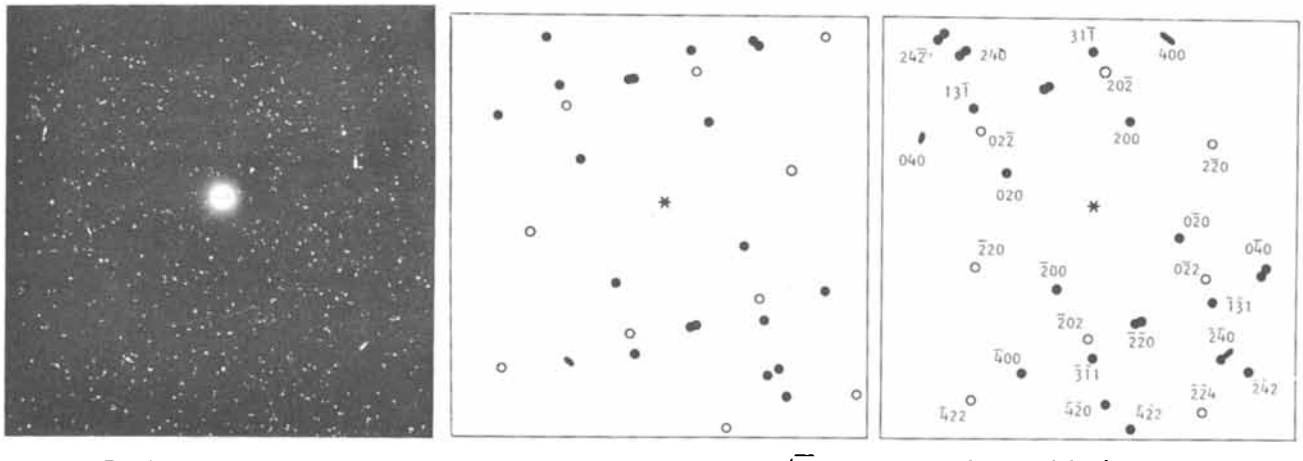

Fig. 4. Broad, rounded platelet, α-Fe_2O_3, twist angle 13.174° = 2 arc csc$\sqrt{76}$. The pattern is the sum of the drawings

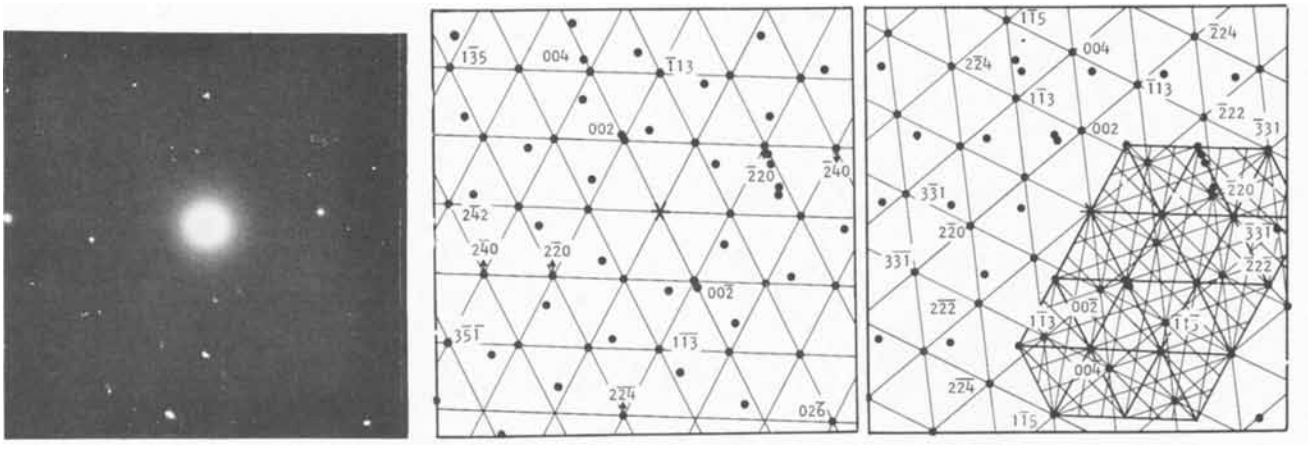

Fig. 5. Broad, rounded platelet, α-Fe_2O_3, twist angle 21.787° = 2 arc csc$\sqrt{28}$

its position in the row of reciprocal lattice points including 2$\bar{4}$0, of the drawing at the left. This rotation brings the direction [21$\bar{3}$0] into coincidence with the direction [12$\bar{3}$0] [and the planes, (21$\bar{3}$0) and (12$\bar{3}$0), into coincidence as well].

A portion of the array of the left drawing is drawn in heavier lines at the lower right of the drawing at the right. In this area the regular array of intersections of the additional finer lines indicates the positions of the spots of the double diffraction pattern, which is too weak to reproduce satisfactorily. As in the case of the 13.174° twist, the pattern of the double diffraction spots is continuous and includes the incident beam spot and the indexed spots for both orientations. The special twist angle results in coincidences among the reflections from the two platelet faces. These are the intersections common to the two arrays.

Not so special twist angles.—Figure 6 represents the indexing of the one diffraction pattern indicating a measured twist angle of 35.22 ± 0.2°. This pattern is the second of three in a series. The specimen was rotated approximately 8° for the second pattern, and approximately 4° more for the third. The rotation was about an axis normal to the beam and to the arrows on the drawing. Arrows pointing to positions at smaller Bragg angles indicate the positions of spots most intense in the first pattern. Arrows pointing to larger Bragg angles indicate spots most intense in the third. The rotation is out of 5 o'clock, into 11 o'clock on the patterns. With this information, the orientation of the platelet is apparent from the effect of the rotation on the spot positions and intensities.

The unindexed weak spots and the changes in spot position with platelet orientation in the beam indicate diffraction that can be described by continuous reciprocal lattice rods normal to the platelet face. The diffraction from bladelike platelets was also characterized by continuous relrods (4, 5).

Figure 7 indicates the indexing of the pattern for the only platelet having a measured 26.66 ± 0.2° twist angle. Some of the double diffraction pattern is shown in the drawings. In these drawings, as in Fig. 5, the same spots are shown in two drawings, each of which shows the indexing for one face of the platelet.

The bending of this platelet has produced streaked reflections. The long streaks indicated by the fine lines of the drawing are observed on the original plates. Such streaks are also describable by continuous relrods.

The arrows from the 131 and 13$\bar{1}$ spots of the left-hand drawing indicate the positions, on the lines of the drawing, of the intersections of the axial rows of reciprocal lattice points containing the 13$\bar{1}$ and $\bar{1}$31 points. The other arrows of the two drawings indicate directions to the positions at the correct Bragg angles for the diffraction indexed at the arrows. The bending of the crystal was such that this diffraction was "bypassed"; furthermore, as a result of this bending, angles in the reciprocal lattice are not faithfully presented by the pattern.

The angles 26.66° and 35.22° do not approximate angles required to rotate to coincidence rows of lattice points sufficiently closely spaced (*i.e.*, along directions with sufficiently small indices) that some special significance is indicated. However, it may be of some significance that 13.174° + 13.174° = 26.348°, and 13.174° + 21.787° = 34.961°. The possibility of two interfaces in these platelets, with twist angles that sum to give the measured twist angles, has not been substantiated

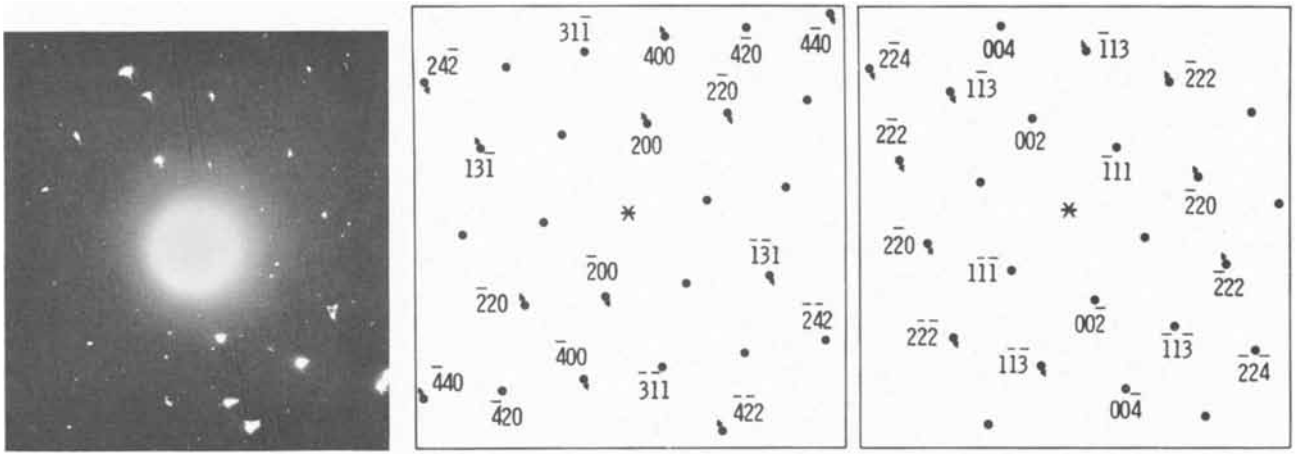

Fig. 6. Broad, rounded platelet, α-Fe_2O_3, twist angle 35.22 ± 0.2°

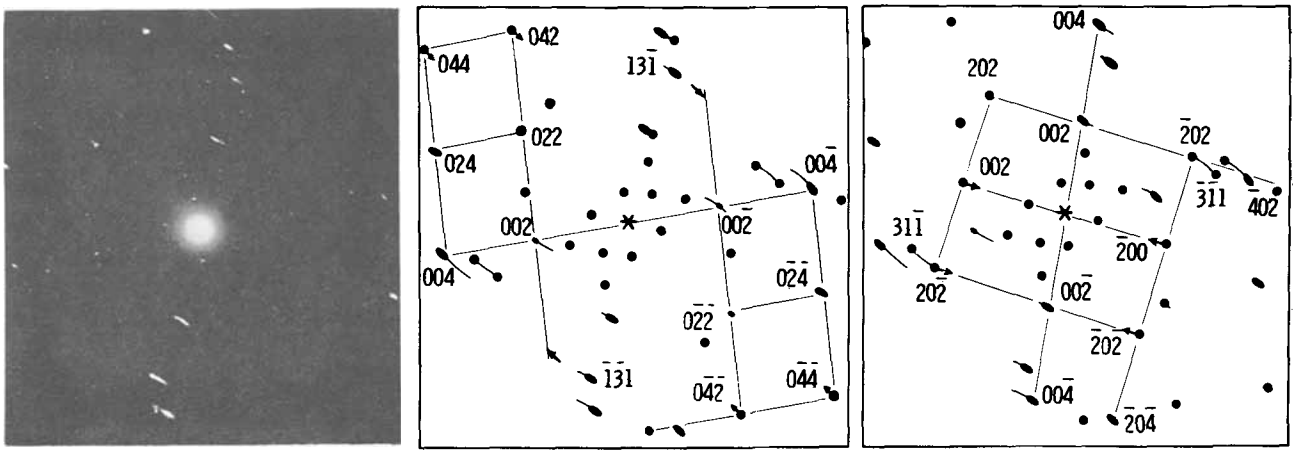

Fig. 7. Broad, rounded platelet, α-Fe_2O_3, twist angle 26.66 ± 0.2°

by the observation of diffraction from a third, intermediate orientation. Furthermore, two twist boundaries, even if relatively stable, one would expect to have more energy than one nondescript twist boundary on a parallel plane.

Curvature and stresses in the platelets.—A dark field image for the four reflections $0\bar{2}2$ and $\bar{1}3\bar{1}$ of Fig. 4, measures 6.7 μm between the bend contours $0\bar{2}2$ and $\bar{1}3\bar{1}$ for the crystal rotated about [2$\bar{2}$0] by the bending. The approximate radius of curvature, 12 μm, is given by 6.7 μm/2sin(ϕ/2), where ϕ = 32.35°, the rotation between the positions for the $0\bar{2}2$ and $\bar{1}3\bar{1}$ reflections. For a 300Å thickness, maximum tensile strain (at the surface) of 1.25 x 10^{-3} results from this curvature. The strain is multiplied by the appropriate stiffness constant (8), c_{11} = 2.42 x 10^{12} dyne cm^{-2}, to calculate the maximum tensile stress, 3.0 x 10^9 dyne cm^{-2}, or 44,000 psi.

Maximum shear stresses of the order of 10^6 dyne cm^{-2} can be estimated to result where such curvatures are involved in draperylike folds. The appropriate shear modulus (8) is c_{44} = 0.85 x 10^{12} dyne cm^{-2}. For some crystalline materials (9, 10), critical shear stresses have been measured to be smaller than the shear modulus by a factor of 10^5. The shear stresses resulting from the bending of the platelets should be sufficient to produce slip on the composition plane, for which the critical shear stress is likely to be less than the estimated 10^7 dyne cm^{-2}. Edge dislocations at the twist boundary should result from this slip. The many images of dislocations in the platelets have not been studied in this work, however, nor have the apparent dislocation loops.

The bend contours of many platelets show the platelet edges less curved, or partially straightened, relative to the base of the platelet. The unrelieved stresses associated with the bent crystals should cause their edges to straighten. The configuration of the growth sites must be curved when the growths are examined after oxidation. Presumably, growth sites are curved initially. However, they may change in curvature during oxidation or cooling. The cracks and discontinuities observed in some platelets may have resulted from stresses occurring after their growth, possibly on cooling. A further consideration is that the curvature of a platelet would vary with a variation in twist angle. The twist angle might change (in time, or with further growth) so as to increase the interface area having a special, low-energy twist angle.

Special defects, Moire fringes, and further contrast effects, possibly resulting from magnetic structure, have not been studied.

General Discussion of the Platelet Structures

Some further general comments can be made about these platelets. The twist angles have all been given as positive, but a distinction could be made as to which face is rotated in the positive sense relative to the other. The two possibilities, which could be indicated by negative and positive values of the same twist angle, are enantiomorphs, or mirror images of one another.

The composition plane very likely has islands of coherency for the 13.174° twist such that the structure is repeated through each island, from one twin through into the other (with the twist distributed over several layers on the basal plane). This most simple structure can be thought of as the result of a rotation on the interface plane of half a single crystal relative to the other half.

However, evidence is not available to prove, for any of the twist angles, that the structure is so simple. Two further possible operations may be necessary. The rotation, most likely on a plane of octahedral positions, may be accompanied by a translation over the interface by some fractional distance. Furthermore, a layer of oxygen ions and a layer of iron ions may be missing at the interface.

That absence of two such layers and only two such layers need be considered can be shown as follows: Number the oxygen layers in the unit cell 1, 3, 5, 7, 9, and 11. Lattice points are at center ($\bar{3}$) on levels 0, 4, and 8 (twelfths of the hexagonal c dimension), in the even-numbered (iron) layers. The lattice translation relates layers 1, 5, and 9. But these are in mirror orientation to 7, 11, and 3 by the operation of the c-glide planes on {11$\bar{2}$0}. Removing layers 2 and 3 (or 3 and 4) puts 1 in contact with 5, and no rotation with translation will bring the ordered structure back. Removing 2, 3, 4, and 5 (or 3, 4, 5, and 6) puts 1 in contact with 7; but 7 is related to 3 by translation, and so the structure obtained can be ordered by a translation in the basal plane. Similar arguments handle the question of iron positions and other possible numbers of missing planes of atoms. The removal of layer 3 is enantiomorphic to the removal of layer 9, however. Consequently, if layers are missing, each twist angle represents four possible enantiomorphic structures.

Moiré patterns and screw dislocation arrays.—The broad, rounded platelets can be expected to give rotational Moiré patterns (6, 7). However, micrographs at sufficiently high resolution have not yet been obtained for the broad, rounded platelets. Such observations of Moiré fringes on twist grain boundaries may be confused with the images of the screw dislocations to be expected where the twist angle α is not too great (11).

The distance H between parallel screw dislocations (the diameter of the hexagon of screw dislocations about an island of coherency) is given by $H = b/2\sin(\alpha/2)$ where b is the magnitude of the Burgers vector of the screw dislocations. Hexagons 21.9 and 13.3Å

across are calculated for the 13.174° and 21.787° twist boundaries, respectively. That some order can exist between such screw dislocations so close together is evidenced by the relative stability of these structures indicated by their existence.

Twist grain boundaries with translational symmetry on planes of threefold symmetry.—Rotations about the threefold axis by angles $\alpha = 2 \text{ arc sin } (h - k)/2\sqrt{h^2 + hk + k^2}$ bring lattice point rows into coincidence. The angles 21.787° and 13.174° bring the point rows $k\bar{h}O$, $2k2\bar{h}O$, $3k3\bar{h}O$, . . . into coincidence for hk values 21 and 32, respectively, for which $h - k = 1$.

Discussion of growth mechanisms.—Tip and edge growth.—Observations by Takagi (12) indicate that whiskers and bladelike platelets grow from the tip. He observed their further growth from the "stumps" of broken growths and also some effects of temperature changes. The further growth of broken broad, rounded platelets has not been observed.

However, some broad, rounded platelets are marked by thickness variations at what appear to be outlines of the platelet outer edge as it was at various times during growth by addition at the outer edge. Figure 1 shows such markings in two platelets. The outlines are such as would result if the growth rate normal to the platelet edge had been approximately uniform over the length of the platelet edge. That is, any one outline is everywhere approximately at the same distance from the platelet edge. The only alternative, growth by addition at the base edge, would not be expected to produce such markings, which indicate smooth, rounded outlines of areas decreasing in breadth as the growth progresses. Except for thickening growth, the shape (outline) of thin crystal growths in general must result from edge growth. In the case of these rounded platelets, growth must be at the outer edge.

A precedent for the consideration of growth from the base as a possible alternative mechanism lies in the observation by Markali (13) of evidence suggesting that Nb_2O_5 whiskers grow from the base by a mechanism involving plastic deformation of the oxide layer.

Iron transport.—We apply here the arguments for internal iron diffusion mechanisms, some of which have been presented previously (3-5). Iron must be transported from the base to the tip or edge to produce the growth of the α-Fe_2O_3 whiskers and platelets. Internal diffusion mechanisms involving linear and planar defects are proposed primarily on the basis of the arguments against other transport mechanisms:

Lattice diffusion coefficients (14) are nearly isotropic at higher temperatures and are far too small to account for significant growth in the range 400°-500°C.

Caplan and Cohen (15) have failed to detect a weight loss in measurements on Fe_2O_3 in flowing atmospheres at 1200°C. Vapor transport of iron oxides or hydroxides at lower temperature is severely limited by these experiments and by common experience with turbines, steam generators, etc.

Coble (16) determined that the α-Fe_2O_3 compaction on sintering at 750°C proceeds at a rate determined by the iron lattice diffusion coefficient. His results provide an upper limit on the surface diffusion coefficient because surface diffusion is a competing process which produces no compaction. This upper limit is too small, by a factor of at least 10^4, to supply the iron incorporated in the whisker and bladelike platelet growths at rates of 1 to 100Å sec^{-1}. Growth rates of the broad, rounded platelets are likely to be comparable; they are known to exceed 0.1Å sec^{-1} from heights found after 48 hr oxidations. It seems excessive to propose both surface transport by an unknown mobile iron-oxygen species (somehow absent in the sintering experiments) and the poisoning of competing surface growth sites.

The shapes of the three growth types observed (whiskers, bladelike platelets, and broad, rounded platelets) can be qualitatively understood to result from the internal diffusion of iron because the shapes match the symmetry of the internal defects. This is a point in favor of the internal diffusion mechanism.

Large twist angles.—One may question why only platelets with large twist angles have been observed. The calculated density of dislocations increases with twist angle, indicating increasing disorder. It may be that the larger twist angles we have found on observing only the tall growths result in larger diffusion coefficients for iron at the twist grain boundary.

Base structures.—The symmetry and perfection of the platelet growths suggest the presence of unknown special structures at their bases. The ability of these special structures to supply the iron diffusing in the platelets is a feature of the internal diffusion hypothesis. Future studies of iron oxidation and of mechanisms for the transformation of Fe_3O_4 to α-Fe_2O_3 might well include a search for the structures and mechanisms associated with the growths of α-Fe_2O_3.

Conclusion

The structures of the broad, rounded platelets have been successfully deduced from electron diffraction patterns. These platelets and their growth have been described to the extent permitted by the available information. The diffusion of iron in the internal twist boundaries of these platelets is the only transport mechanism against which we find no strong arguments.

It seems self-evident that crystal growth resulting from diffusion along internal defects will predominate in general when lattice diffusion is small and the external paths of vapor transport and surface diffusion are precluded. Grain boundary and lattice defect diffusion should be especially important to oxide growth in metal oxidation at ordinary temperatures.

Technical Notes

The Effect of Emitter Perimeter-to-Area Ratio on Current Gain after Temperature Treatment

C. C. Mai and T. S. Whitehouse

Semiconductor Division, Sylvania Electric Products Inc., Woburn, Massachusetts

It is well known (1-3) that the d-c current gain of a transistor increases after treatment in hydrogen at temperatures above 300°C. From this experiment it was found that this change of d-c current gain is directly related to the perimeter-to-area ratio of the emitter. This indicates that the mechanism causing this change is the variation of generation-recombination current at the intersection of the junction and the silicon-silicon dioxide interface.

Experiments and Results

Four different sets of transistors with emitter perimeter-to-area ratios in the range of 2.7-6.7 mil^{-1} were employed. They were typical npn planar transistors with boron and phosphorus diffusions. The surface oxides, about 0.6μ thick, were grown by steam oxidation at 1050°C.

Ten transistors from each set were annealed for 1 hr at 450°C in a nitrogen ambient. Ten other transistors from each set were annealed for 1 hr at 450°C in a forming gas ambient (95% nitrogen, 5% hydrogen). The d-c current gains were measured at collector currents ranging from 10 μA to 10 mA. The data are plotted in Fig. 1, 2, 3, and 4. It is evident that the current gain, h_{FE}, is greater for transistors treated with forming gas and that the degree of difference is directly related to the perimeter-to-area ratio of the emitter. Also, the difference in h_{FE} is dependent on collector current, as expected.

In Fig. 5 the ratios of h_{FE} of forming-gas-treated units to h_{FE} of nitrogen-treated units are plotted against the perimeter-to-area ratios of the emitter at a collector current of 10 μA and at the peak current gain. The curves show that there is a relatively greater effect of forming-gas treatment at low current levels, but the effect also appears at peak gain.

In a second experiment one set of ten transistors was treated in the sequence listed in Table I. h_{FE} was measured after each treatment. The data indicate that the high value of h_{FE} due to a previous forming-gas treatment can be reduced by baking in nitrogen. h_{FE} does not decrease further with additional baking. When the transistors were treated in forming gas again, h_{FE} rose to the same high value obtained before. Further forming-gas treatment did not effect h_{FE} further.

Discussion

The reciprocal of d-c current gain ($1/h_{FE}$) is a function of three factors: emitter efficiency, base transport, and recombination on the surface. At a fixed current level the surface term is proportional to (4)

$$\frac{S\,As}{A}$$

where S = surface recombination velocity
A = area of the emitter and
As = surface area where recombination takes place. The term As is proportional to the emitter perimeter and hence the surface term is proportional to the perimeter-to-area ratio of the emitter.

Since S is multiplied by As/A, any change in S becomes magnified as the perimeter-to-area ratio becomes greater. Thus, the fact that h_{FE} increases with this ratio with forming-gas treatment shows that the surface recombination velocity was decreased. Also, the surface contribution to h_{FE} has its greatest effect

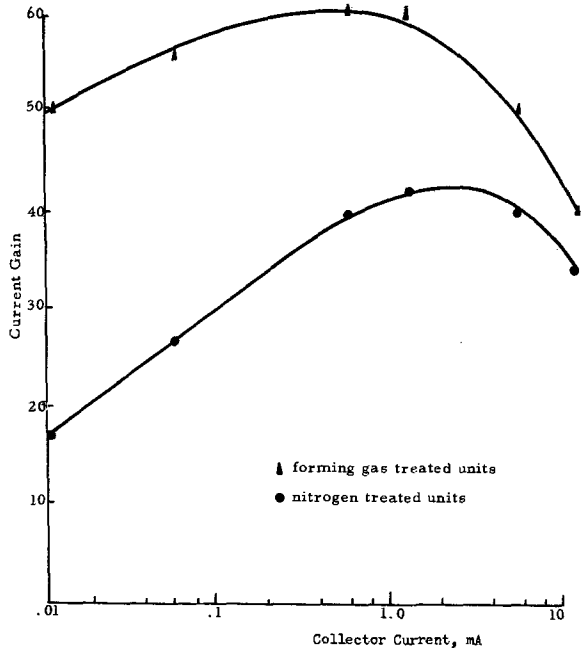

Fig. 1. Current gain vs. collector current for emitter perimeter-to-area ratio of 6.7, mil^{-1}.

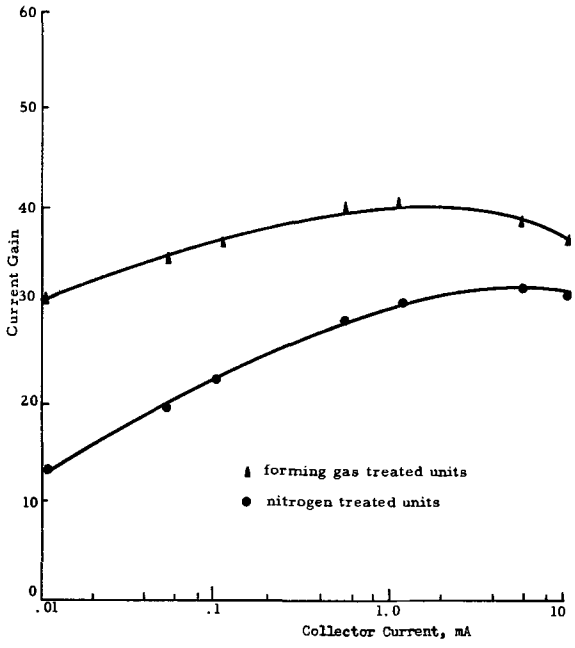

Fig. 2. Current gain vs. collector current for emitter perimeter-to-area ratio of 4.5, mil^{-1}.

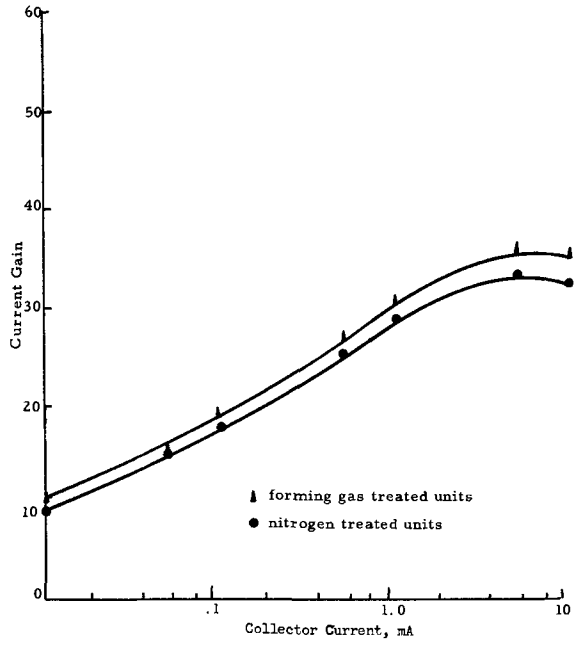

Fig. 4. Current gain vs. collector current for emitter perimeter-to-area ratio of 2.7, mil^{-1}.

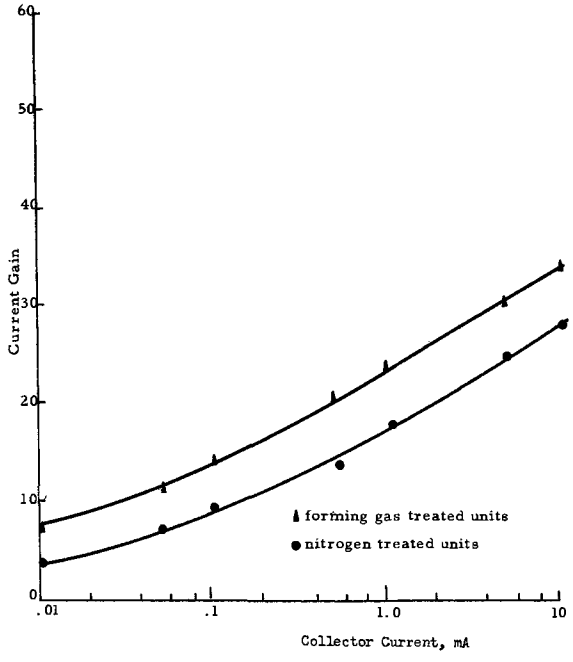

Fig. 3. Current gain vs. collector current for emitter perimeter-to-area ratio of 3.7, mil^{-1}.

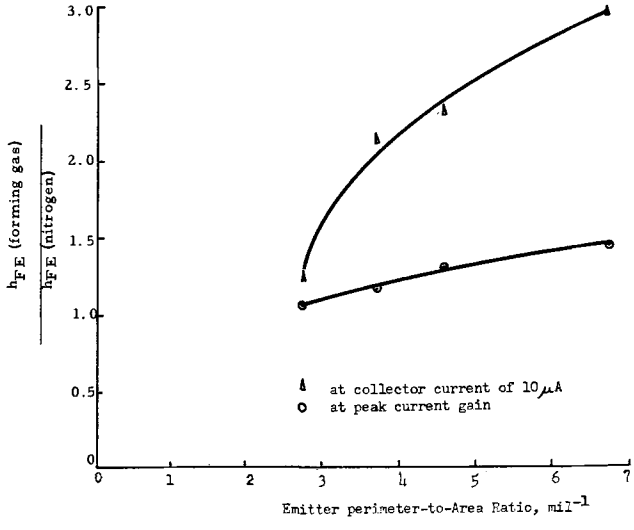

Fig. 5. Ratios of current gain of forming-gas-treated units to that of nitrogen-treated units vs. the emitter perimeter-to-area ratio.

on h_{FE} at low currents (4). Figure 5 shows that the forming-gas effect is greatest at low currents, giving added evidence that surface recombination velocity is being decreased by the forming-gas treatment.

The experimental result that the increase is h_{FE} in forming-gas-treated transistors is directly dependent on the perimeter-to-area ratio suggests that the hydrogen in the emitter base junction at the silicon-silicon dioxide interface decreases the surface recombination velocity. One possible explanation for the effect of forming gas is that the hydrogen in the gas combines with the unsaturated bonds at the interface, lowering the surface recombination velocity and hence increasing h_{FE}.

This paper has also shown that the h_{FE} changes due to baking in forming gas in nitrogen are reversible, which demonstrates that the hydrogen can be removed from the junction by out-diffusion.

Table I. Sequential treatment

Temp, °C	Time, hr	Ambient	h_{FE}
450	1	Forming gas	58.0
200	1	Air	57.5
450	1	N_2	50.5
450	1	N_2	50.5
450	0.25	Forming gas	58.0
450	2	Forming gas	58.0

Conclusion

When transistors are heat-treated in forming gas at temperatures above 300°C, the surface recombination velocity decreases and the current gain increases. The current gain increase is greater as the perimeter-to-area ratio of the emitter increases and the collector current decreases. The effect can be reversed by baking the transistor in nitrogen.

Further Verification of a Model for Diffusion from Doped Oxides

M. L. Barry* and J. Manoliu

Fairchild Semiconductor, Research and Development Laboratory, Palo Alto, California

In a recent article (1) we presented and verified a model describing the diffusion from a deposited doped oxide into a semiconductor substrate. Subsequently, in related work dealing with diffusion into polycrystalline silicon, we found additional experimental evidence verifying this model. In short, we find that junctions after diffusion from a deposited oxide are deeper in polycrystalline silicon than in single-crystal silicon because the diffusivity of the dopant is higher in the polycrystalline material. However, the sheet conductivities are the same for both types of silicon since the diffusion process is limited by diffusion within the oxide source.

Figure 1 shows a general one-dimensional case for diffusion of a dopant from a uniformly doped oxide into a semiconductor substrate. In the work to be described, the layer of undoped barrier oxide has been reduced to a minimum and may be disregarded. We have shown previously that for the case where the deposited oxide is thick compared to the diffusion length in the oxide, the concentration of dopant in the semiconductor after diffusion is given by

$$C_2(x,t) = C_s \operatorname{erfc}\,(x/2\sqrt{D_2 t}) \qquad [1]$$

and

$$C_s = \frac{C_o\sqrt{D_1/D_2}}{1 + (1/m)\sqrt{D_1/D_2}} \qquad [2]$$

where C_o is the initial concentration of dopant in the oxide, D_1 and D_2 are the diffusivities of the dopant in the oxide and in the semiconductor, respectively, and m, the segregation coefficient, is the ratio of the surface concentration of the dopant in the semiconductor to the surface concentration in the oxide. If the substrate is silicon with a reasonably high resistivity (about 2 ohm-cm for most cases) of opposite type from the diffusing dopant, Eq. [1] and [2] can be manipulated to yield

$$x_j = 2\sqrt{D_2 t}\ \text{argerfc}\ (C_B/C_s) \qquad [3]$$

and

$$I/V = 8.15 \times 10^{-23}\,\bar{\mu}\,C_s\sqrt{D_2 t} = 8.15 \times 10^{-23}\,\bar{\mu}\,\frac{C_o}{1 + (1/m)\sqrt{D_1/D_2}}\sqrt{D_1 t} \qquad [4]$$

where x_j is the junction depth resulting from the diffusion, I/V is the sheet conductivity as measured with a standard 4-point probe, C_B is the bulk concentration of carriers in the substrate, $\bar{\mu}$ is the effective mean mobility of the carriers, and the constant, 8.15×10^{-23}, contains the electronic charge and the spreading-current factor for the 4-point probe.

Since argerfc (C_B/C_s) is only a weak function of C_s, the junction depth for a given diffusion time depends primarily on the diffusivity of the dopant in the semiconductor; on the other hand, if $(1/m)\sqrt{D_1/D_2}$ is small compared to 1 (and this appears to be the case for both boron and phosphorus in silicon), the I/V will depend primarily on the diffusivity of the dopant in the oxide. The same analysis applied to Eq. [2] indicates the surface concentrations will vary inversely with the diffusivities in the silicon. Equations [2], [3], and [4] then predict that if diffusions are made from the same deposited oxide into silicon substrates in which the diffusivities of the dopant vary widely, the resulting junction depths and surface concentrations will reflect this variation while the sheet conductivities will remain nearly the same. Another way of describing this is to say that for the ratios of D_1 and D_2 which occur in silicon oxide and silicon, the process is limited by the total quantity of dopant which can diffuse out of the oxide, and this total quantity is nearly independent of the sink into which it is diffusing.

Experimental verification of the above conclusions has been found for the case of diffusion from a doped oxide into intrinsic polycrystalline silicon with a typical crystallite size of 0.3μ. The silicon was deposited by the thermal decomposition of silane, and the phosphorus-doped oxide was deposited at 400°C by the oxidation of silane and phosphine. In all cases, the polycrystalline silicon was much thicker than the junction depth after diffusion, so there was no problem of saturating the polycrystalline layer. As Table I

Table I. Diffusion from phosphorus-doped silicon oxide into polycrystalline and single-crystal silicon

Temp, °C	I/V polycrystalline / I/V single-crystal	x_j polycrystalline / x_j single-crystal
1000	0.8	2.8
1100	0.9	2.6
1200	0.9	3.0

shows, there is a very large enhancement of the junction depth in the polycrystalline silicon compared to single-crystal silicon, but very little difference between the sheet conductivities, or I/V's, for the two substrates. That this is not just due to decreased carrier mobilities in the polycrystalline silicon is shown by the enhancement of both x_j and I/V in polycrystalline material after a normal gaseous-source predeposition where the diffusion is not oxide limited.

This type of diffusion appears to offer an improved technique for measuring the diffusivity of dopants in the oxide, since as shown in Eq. [4] the sheet conductivity is relatively insensitive to D_2, the diffusivity of dopant in the polycrystalline silicon. However, before quantitative results can be reported, the effective mobilities of carriers in polycrystalline silicon must be determined. This information, as well as the mechanism of the diffusion of dopants in polycrystalline silicon in relation to the structure of the silicon will be described in a subsequent paper.

Recombination-Generation Centers Caused by 60°-Dislocations in Silicon

M. C. Collet

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven-Netherlands

The importance to device fabrication of the dislocation density in semiconducting material has been recognized more and more in recent years.

Many experiments have been carried out on the influence of dislocations in silicon on device parameters such as leakage current, breakdown voltage, and noise. This field has been reviewed recently by Queisser (1). In the methods used in these experiments to introduce the dislocations the samples had to be at 800°C or higher for at least half an hour. This treatment is quite sufficient to enable impurities to diffuse through the crystal and to interact with the dislocations. Because of this it is impossible to know whether the measured effects are caused only by dislocations or by impurities interacting with these dislocations.

An exception can be made for the experiments of Glaenzer and Jordan (2) on the influence of dislocations on lifetime in silicon, where the interaction between the dislocations and slow diffusants like O, C, B, and P was avoided. However these lifetime measurements were carried out on bulk silicon. Here the dislocations are surrounded by space charge cylinders. According to the authors this makes it very difficult for majority carriers to reach the dislocations, so that the recombination rate is strongly decreased and astonishingly high lifetimes of about 200 μsec at room temperature are found for silicon with a dislocation density of 10^7 cm^{-2}. Nevertheless they were able to measure the energy levels associated with edge dislocations.

In the experiments we are reporting here the generation rate of minority carriers was measured in depletion layers. Dislocations occurring in these regions will not be shielded by space charge cylinders, and their influence on recombination-generation rates can be assumed to be much more pronounced. This is a typical situation for most devices containing p-n junctions, because their characteristics are strongly influenced by recombination-generation centers present in the depleted region of the junction.

The depletion layer was obtained by biasing the gate of a MOS capacitor made on our samples. This bias induces an inversion layer at the silicon surface with a depletion layer underneath. A sudden increase in bias causes an instantaneous increase of the depletion layer thickness followed by a slow relaxation to the equilibrium value. The relaxation time is governed by the rate at which minority carriers are generated in the depletion layer and it can be measured by monitoring the high-frequency capacitance of the MOS during the relaxation of the depletion layer. Because one starts the measurement with an inversion layer at the surface the influence of surface states on generation is negligible. A more complete description of this method can be found in the literature (3-5).

Introduction of the Dislocations

Dislocation-free, Czochralski grown, (111) oriented, 10 ohm cm phosphorus doped silicon slices, with a 1.5 in. diameter were lapped and polished to a final thickness of 300μ. The slices were etched 40μ on each side and cleaned by repetitive boiling in HNO_3 alternated with rinsing in deionized water and dipping in HF. This treatment was directly followed by oxidation at 1200°C in dry oxygen in a double walled quartz tube. The oxide thickness was 0.25μ. The oxide layer was stripped from the back face of the wafer, and a phosphorus diffusion at 1100°C was carried out. Such a diffusion is known to getter metallic impurities from silicon.

Next the slices were scribed and broken into four quarters. By means of two pressure contacts a voltage was applied to such a sample. The current flowing through the sample heated it. When a part of the sample became intrinsic, because of thermal generation, that part showed a negative temperature coefficient of resistivity, and it attracted most of the current. This part reached a temperature of about 900°C while the rest of the sample remained at a relatively low temperature. The stresses caused by the temperature gradient were sufficient to cause plastic deformation.

Figure 1a shows a sample during deformation and Fig. 1b shows an x-ray topograph of a sample after the treatment. The deformation has caused slip along (111) planes. Points at the edge of the crystal acted as dislocation sources. The dislocations ran from the edge into the crystal up to the point where the crystal was too cold to permit further glide. This caused the (111) slip planes to be densely packed with dislocations. The slip bands are visible as white stripes in the topograph.

The dislocations in those slip planes were lying along <110> directions in a herring bone pattern. The Burgers vector, which is the same for all dislocations in one such slip plane, could be determined by the contrast criterion for x-ray diffraction. Dislocations crossing the depletion layers of the MOS capacitors with which we measured the generation rate were found to be of the 60° type.

Using this method mean dislocation densities of 10^7 cm^{-2} were created in less than 5 sec, including

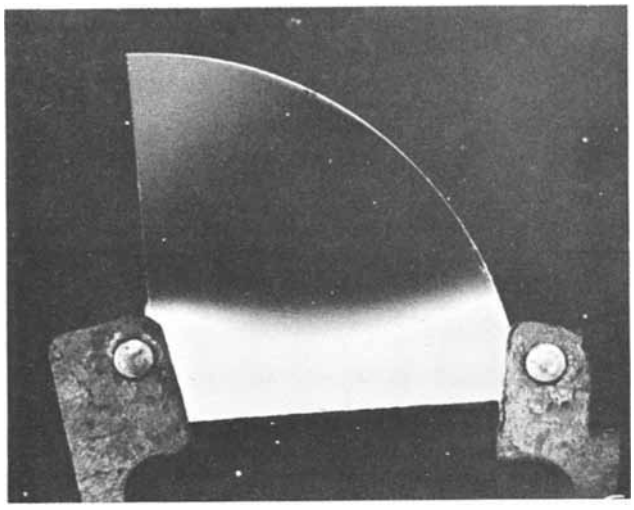

Fig. 1a. Photograph of a sample during deformation. Hot zone between the pressure contacts is at about 900°C.

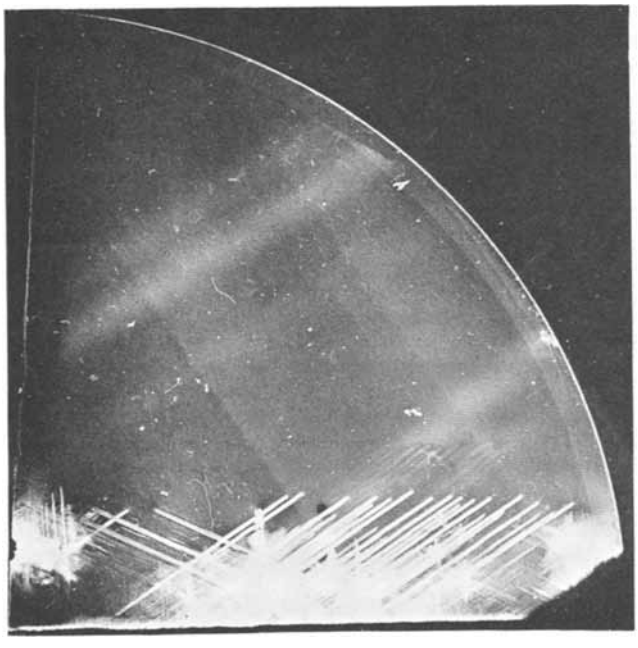

Fig. 1b. X-ray topograph of a deformed sample

heating and cooling times. The short duration of the heat-treatment prevents impurities such as O, C, B, and P from diffusing toward the dislocations. Fast diffusants like Cu, Au, and Fe could diffuse to the dislocations from within a radius of 100μ. As mentioned above, we tried to keep their concentration as low as possible by means of gettering by phosphorus diffusion.

After the introduction of the dislocations the MOS capacitors needed for the generation rate measurements were completed by the evaporation of 0.5 mm diameter aluminum dots on top of the oxide layer.

Results of Generation Rate Measurements

Figure 2 shows an x-ray topograph of a sample with dislocations. Spots where the generation rate of minority carriers has been measured are indicated by numbers. At 4, 5, and 6 the crystal is still dislocation free, although at 5 the temperature reached 900°C during deformation and at 6 an elastic strain field is present, caused by one of the pressure contacts used for heating the sample. Notwithstanding these differences the same low generation rate was found at these three places. But whenever the generation rate was measured on parts of the crystal containing high dislocation densities significant increases in generation rate were found. Spots 1 and 2, for example, showed a 300-

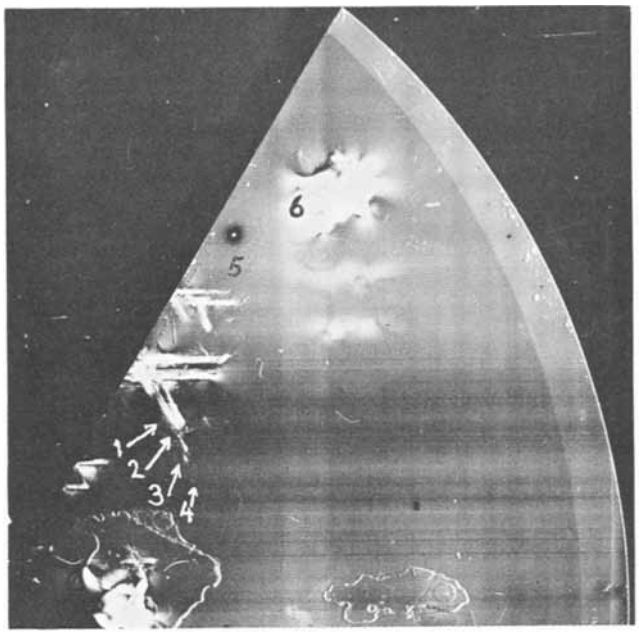

Fig. 2. X-ray topograph of one of the samples on which generation rate measurements were performed.

fold increase and spot 3 a 30-fold increase in generation rate.

The correlation between increased generation rate and the presence of dislocations proves that plastic deformation introduces generation-recombination centers. It does not prove that the dislocations are responsible for these centers, because plastic deformation introduces not only dislocations, but also vacancies, divacancies, vacancy impurity complexes, and possibly interstitials. Such point defects may also cause an increase in generation rate.

The energy levels associated with these point defects are known, mostly from measurements on electron-irradiated samples (6). If we can determine the energy levels of the centers which cause the increase in generation rate in the samples, the possible contribution of those point defects can also be identified.

For this purpose the temperature dependence of the generation rate was measured. To interpret these measurements the Shockley-Read theory for recombination-generation was applied (7).

In Fig. 3 the ratio of generation rate and intrinsic charge carrier concentration is plotted logarithmically against the inverse of absolute temperature. Curves A, B, and C have been measured on spots on three different samples where 60°-dislocations were present. Curve D was measured on the same sample as curve A but on a dislocation free spot.

Each of the drawn curves in Fig. 3 has been constructed by the summation of two straight lines, whose slopes are indicated.

According to the Shockley-Read theory the generation rate in a depleted layer is equal to

$$U = n_i \left[\tau_{n_0} \exp \frac{q}{kT} (E_t - E_i) + \tau_{p_0} \exp \frac{q}{kT} (E_i - E_t) \right]^{-1}$$

$E_t - E_i$ = distance in eV between the center of the energy gap and the recombination-generation center's level. For $E_t - E_i > 0$ the recombination-generation center's level is in the lower half of the energy gap and *vice versa*. The other symbols have their usual meaning.

For the material containing 60°-dislocations energy levels are found at $|E_t - E_i| = 0.20$ eV and at $|E_t - E_i| = 0.06$ eV.

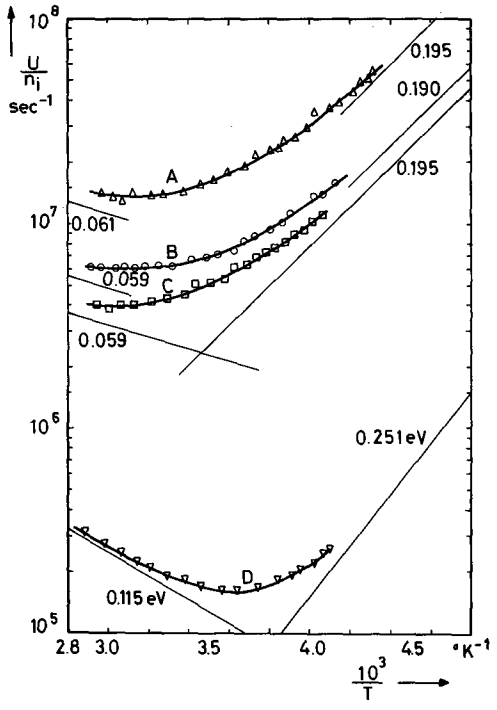

Fig. 3. Ratio of generation rate and intrinsic carrier concentration plotted logarithmically against the inverse of absolute temperature.

The line associated with the 0.20 eV level has a positive slope. If $|E_t - E_i| > 0$ it follows from the above equation that $\tau_{p_0}/\tau_{n_0} >> 1$ and the center is a donor. If $|E_t - E_i| < 0$, $\tau_{n_0}/\tau_{p_0} >> 1$, in this case the center is an acceptor. These data fit the second acceptor level of the divacancy, and they also fit the acceptor level of the vacancy-phosphorus complex. Because the energy levels associated with 60° dislocations have not been reported, the 0.20 eV level found here can be explained as being due to divacancies, vacancy-phosphorus complexes, or dislocations. The experimental evidence allows no choice between these possibilities.

For the 0.06 eV level the combinations $E_t - E_i > 0$ and $\tau_{n_0}/\tau_{p_0} > \frac{1}{4}$ or $E_t - E_i < 0$ and $\tau_{p_0}/\tau_{n_0} > \frac{1}{4}$ are found. The monovacancy and iron cause centers which fit these data. But the monovacancy is known to be mobile at very low temperatures (6) and thus should have been annealed out. If iron causes the high generation rates in the deformed part of our samples, we should have found it in the dislocation-free part of the same sample as well.

Curve D, however, shows that iron is not present in this part of the crystal. Thus the 60°-dislocations remain as the most probable explanation of the 0.06 eV level.

Conclusion

Dislocations of the 60°-type are able to cause an increase of several orders of magnitude in generation rate. In n-type silicon this behavior can be described by one Shockley-Read type recombination-generation center with an energy level at a distance of 0.06 eV from the center of the energy gap. If this level is situated in the upper half of the energy gap, it probably acts as a donor, if in the lower half, it probably acts as an acceptor.

Also present after plastic deformation was a center with a level at 0.20 eV from the middle of the energy gap. This level may be due to divacancies, vacancy-phosphorus complexes or dislocations.

Acknowledgments

It is a pleasure to thank M. V. Whelan for the adaptation of the generation measurements to our purpose and for many stimulating discussions and L.M.C. Goossens for his valuable assistance during these experiments.

A New Striation Etch for Silicon

Manfred Kämper

Siemens AG., Wernerwerk für Bauelemente, Werk Halbleiter Laboratorium, Pretzfeld, Germany

A new method has been worked out to reveal a striation etch in silicon crystals in a fast and definite way. The method is fast, furnishes a shining surface, and works on silicon of a very wide range of resistance. Previous etchants are slower (1-4), give a more or less rough surface (1, 3), and work mainly on highly doped material (1-4).

The silicon wafer is lapped on one side with 800 SiC or Al_2O_3 grit with the assistance of 3% NaOH in the slurry on a cast iron plate. The lapped wafer is then chemically polished by a mixture of 2 parts hydrofluoric acid 38%, 5 parts acetic acid 96%, and 3 parts nitric acid 100%. It would be preferable to let the wafer roll in a polypropylene beaker during the etch. The temperature of the etchant initially should be 20°C and should be allowed to warm up during the etch. Under these conditions the etching time would be 10-15 min, and the resulting surface is shining.

After these lapping and polishing processes a special treatment precedes the actual striation etch. The wafer is treated with a mixture of 1 part acetic acid 96% and 1 part nitric acid 100% for 1 min at about 50°C, rinsed with deionized water, and warmed up with 50% KOH solution until hydrogen is evolved over the whole surface. This should take from 15 to 30 sec. The wafer is then rinsed at once with deionized water and finally with acetic acid 96%, under which the wafer should be kept up to the actual striation etch. The time between the last treatment and the following striation etch should not be too long.

The etchant for the striation consists of, e.g., 20 ml hydrofluoric acid 48% and 10 ml acetic anhydride, to

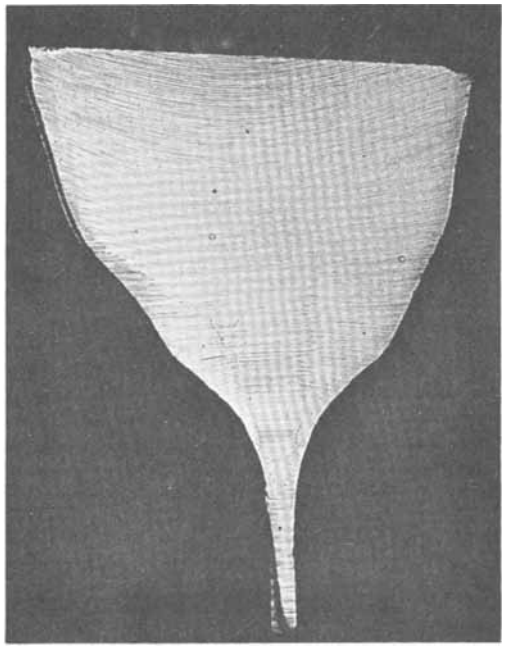

Fig. 1. Longitudinal section out of the cone of a dislocation free single crystal silicon rod with the seed. The center facet above the seed vanishes when the rotation is switched from concentric to excentric.

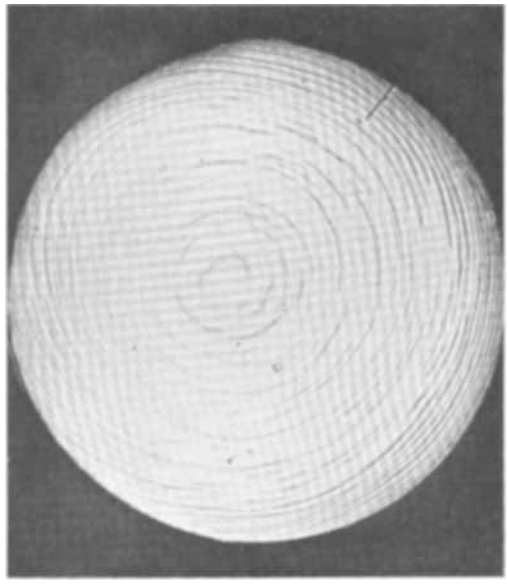

Fig. 2. Transverse section out of a dislocation free single crystal silicon rod. Some swirls can be seen parallel to the striation spiral.

which 10 drops of a 0.5M $NiSO_4 \cdot 7H_2O$ solution in HF 48% and 4 drops of a 10M HNO_3 solution in HF 48% are added. The 4 drops of 10M HNO_3 solution can be substituted by 20 drops of 1M V_2O_5 solution in HF 48%. The latter gives a somewhat more shining surface than the former, but the sensitivity is not as large.

The striation etch is carried out under strong illumination, the exact intensity of which is not critical. The etching time is 10-20 min. During the etch one can follow the development of the striation which becomes visible after 2 min.

During the etch the surface will stain, revealing continuous color changes. The formation of that colored film indicates the start of the etch. Should no film form on the surface, one can start the formation by adding 1 more drop of the oxidant (HNO_3 or V_2O_5 in Hf) to the solution while stirring, causing the local concentration of the oxidants to be increased at the surface for a short time. After the etch, the wafer is rinsed with water, methanol, 50% KOH solution, water, and finally methanol in the given order. The KOH solution takes off the colored film.

The essentials of this method seem to be the special treatment of the surface before the actual striation etch and the composition of the striation etchant. Treatment of the surface includes the passivation with $CH_3COOH:HNO_3$ 1:1 and the activation with 50% KOH. Passivation leads to a more even evolution of hydrogen on the surface in the second step. Use of acetic acid to wet the surface after the KOH treatment is better than the proposed (2) use of methanol, because methanol reacts with the striation etchant and furnishes a cloudy surface at times. Concerning the reaction mechanism the addition of acetic anhydride to the striation etchant seems to lower the surface tension. The concentration of HF is not lowered much by the addition of acetic anhydride as it would be in the case of use of acetic acid. The efficiency of other species (like acetylfluoride) in the solution cannot be excluded for the practical effect, that nearly no bubbles form on the surface during the etch. Bubble formation has been a major problem with previous etchants.

The addition of Ni^{2+} ions in most instances furnishes a more shining and reflecting surface. In special cases as with p-materials, which sometimes are not etched as readily as n-materials, the quantity of $NiSO_4$ can be increased. The method works for crystals with resistivities ranging from 10^{-3} ohm cm up to 2 to $3 \times 10^{+3}$ ohm cm. For higher resistivities, the etching time may be somewhat longer.

Usually a longitudinal test piece out of a silicon rod is etched better than a transverse test piece. This is because the gradient of the resistivity generally is steeper in the former than in the latter.

A more detailed discussion of the mechanism will be given elsewhere.

Technology of Solid Electrolyte Coulometers

John H. Kennedy, Fred Chen,* and John Willis

Department of Chemistry, University of California, Santa Barbara, California

ABSTRACT

A pulse discharge technique for reading solid electrolyte coulometers was studied and found to be superior to constant current readout. The technique can be applied to any solid electrolyte system which holds an open-circuit voltage for several seconds. A double-cell configuration for information storage with cyclic use was investigated. An initial charge setting could be retained for a number of cycles, but conditions are extremely critical. Any slight coulometric error will continue to add to or subtract from the initial charge so that after several cycles errors become quite large. Coulometers containing Ag_3SBr show excellent characteristics at temperatures as low as −70°C, but are poor at temperatures above ambient. Palladium and graphite do not offer any electrochemical advantages over gold as an indicator electrode other than the extremely sharp voltage rise on graphite.

In previous publications, it was demonstrated that solid electrolyte cells could function as moderately accurate coulometers (1, 2). However, this work concentrated on material and cell preparation, cell resistance, electronic conductivity contribution, and coulometric accuracy at constant current. It was shown that highest accuracy was obtained when the cells were "read" (*i.e.*, determining the amount of silver plated on an inert gold electrode by anodic stripping) under the same conditions that they were plated. In order to achieve accurate integration of a varying current, other methods besides constant current readout have been examined.

In this paper, considerations that are necessary for practical solid state electrolytic integrators are explored. These include integration readout with pulse discharge, use of double-cell configuration for information storage, operating temperature range, and possible substitutes for the gold indicator electrode.

Experimental

Materials.—Silver iodide.—Commercial silver iodide (B and A) was used as received.

Silver sulfide bromide.—Ag_3SBr was prepared according to the procedure described in a previous publication and designated as method II (2).

Silver sulfide iodide.—Ag_3SI was prepared according to a procedure analogous to that developed for Ag_3SBr using potassium iodide in place of potassium bromide.

Rubidium silver iodide.—$RbAg_4I_5$ was prepared according to the method described by Owens and Argue (3). It should be noted that our material had the same chemical composition as that reported by Owens and Argue, but our material was not handled in a dry box. The material was stored in a desiccator, and pellets were coated with Microshield plastic to minimize hydrolysis. However, the material is quite sensitive to moisture, and the poor results presented below may be partially due to decomposition taking place while the cell was under test.

Silver metal.—Engelhard Type G-3 fine silver powder.

Gold metal.—Wilkinson 99.99%, 5-15μ gold powder.

Procedures.—Cell preparation.—Cells in the form of pellets were prepared by powder compression described previously (1, 2). Double cells for cycling were prepared with a layer of silver followed by a layer of electrolyte, a layer of gold, a second layer of electrolyte, and finally a second layer of silver. These cells were 0.5 in. in diameter and weighed about 2.0g.

Graphite electrodes.—Hexamethylenetetramine, Durite D-5143, and powdered graphite were mixed together in ethanol in the ratio 2:10:88. The ethanol was then evaporated under vacuum and the graphite dried at 235°C overnight. The mixture was reground and pressed in the same manner as the powdered metal electrodes. Hexamethylenetetramine, which catalyzes the curing of the Durite binder, could have some effect on the graphite electrode. However, in its absence the graphite did not press properly yielding cells with little mechanical strength. The normal amount was 2% of the total weight, and changes in this ratio did not appear to affect the electrochemical properties of the graphite cells.

Pulse discharge readout.—A Bissett-Berman Corporation EDR-300 E-Cell Digital Readout was used for pulse discharge readout of cells. Either 5000 or 10,000 ohms resistance was used in series to decrease peak currents. A schematic diagram is shown in Fig. 1.

Temperature control.—An Associated Testing Laboratory SW-5101 environmental chamber was used for temperatures other than ambient.

Constant current readout.—A Bissett-Berman Corporation E-Cell Digital Coulometer was used for constant current charging of cells and for those experiments designated as constant current readout. This unit has a built-in trigger which cuts off the constant current supply when cell voltage reaches a predetermined value.

* Electrochemical Society Student Member.

Key words: coulometer; coulometry; electrolyte, solid; silver sulfide bromide; silver sulfide iodide; rubidium silver iodide; silver iodide; integrator, electrolytic; pulse discharge.

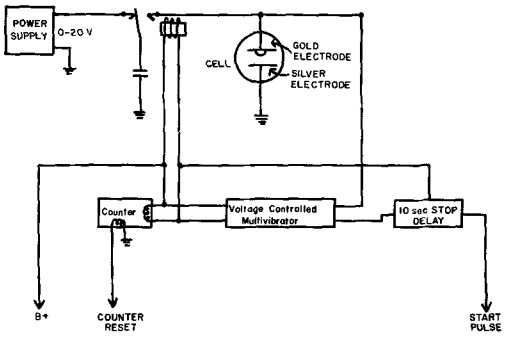

Fig. 1. Capacitative discharge current/time monitor. Courtesy of Bissett-Berman Corporation.

Charge setting for double cells.—A Harrison 6112A d-c power supply was used to clean by anodic stripping the gold surface *vs.* each of the silver electrodes with the use of a needle probe. The probe consisted of a copper wire, sharpened at the end and held or clamped on the center gold layer while the cell was clamped in place. After anodic stripping, a predetermined amount of silver was plated on the gold by applying a constant current between one silver electrode and the needle probe to the gold electrode. A Bissett-Berman E-Cell Digital Coulometer was used for this procedure.

Cycling.—A constant current was applied between the two silver electrodes until the voltage across the cell reached a preset cut-off value. After noting the time, the current was then reversed either manually or automatically and run until the voltage again reached the cut-off value. As an example, odd-numbered cycles were cut off at +0.5V while even-numbered cycles were cut off at −0.5V. For automatic reversal, after the cell reached the preset voltage and the current was disconnected, the cell polarity was rotated by a stepping relay and current reapplied to initiate a new cycle. The cycle times were recorded by following the cell voltage on a Moseley Model 7100B dual channel recorder.

Controlled potential electrolysis.—Samples of potassium iodide in 0.5F H_2SO_4 were electrolyzed at +0.70V *vs.* SCE for 30 min using a Beckman Electroscan 30. The 0.5F H_2SO_4 supporting electrolyte was pre-electrolyzed for 5 min and showed less than 1 mcoulomb of charge on the coulometers.

Results and Discussion

Pulse discharge method for reading solid electrolyte coulometers.—It was shown previously that, when constant current readout was used for solid electrolyte cells, the charge recovered was a function of the current level. As the current was increased, the error became more negative. The main reason for inaccurate readout for these devices is that the actual experimental function normally observed, applied voltage at the operating current, is not the function indicating the complete stripping of silver from the gold electrode, which is a gold electrode potential *vs.* a reference. Although three-electrode systems have been used for basic studies, current must be interrupted for each measurement to eliminate polarization. Applied voltage includes silver electrode potential, silver electrode/electrolyte polarization, electrolyte *IR* drop, and gold electrode/electrolyte polarization in addition to the desired gold electrode potential. The polarization voltages and *IR* drop vary with current and, thus, it is easy to see why readout accuracy varies with current level. It was also shown that accuracy improved with succeeding cycles under the same operating conditions as the cell appeared to become "conditioned" to these conditions (2). If the operating conditions such as current or temperature changed, new conditioning cycles were required to regain high readout accuracy.

The pulse discharge method circumvents these problems by measuring, at least approximately, the gold electrode potential, and triggers a cutoff when a potential develops indicative of complete silver stripping. In principle, a capacitor is discharged through the cell equivalent to 0.100 mcoulomb of charge. The voltage across the cell is monitored as is done in the conventional constant current mode. However, after the pulse, the voltage drops rapidly as the *IR* drop and polarization voltages decay, and when the cell voltage falls below 0.25V another pulse of charge is delivered. While silver remains on the gold electrode, the potential is essentially zero since it is being measured against the counter silver electrode. When all the silver has been stripped by the pulses of charge, a gold electrode potential develops which does not decay rapidly with time. Actually, since the measurement is still a two-electrode case as opposed to a cell containing a reference third electrode, the auxiliary silver electrode will not be strictly a reference potential. However, polarization which develops during the pulse will have 10 sec to decay which is sufficient time to consider the auxiliary silver electrode as a reference potential. As soon as the cell potential remains above 0.25V for 10 sec, the circuit is inactivated, and the number of pulses which were delivered can be read on a counter. The values of 0.25V and 10-sec time period for voltage decay were established for liquid electrolyte timers, but turn out to be convenient for the solid electrolyte coulometers reported here. The only modification necessary was the addition of 5000-10,000 ohms resistance in series with the cell to slow down the capacitor discharge. The equipment is designed to deliver peak currents of 10 mA which led to shorting for some of our solid electrolyte cells. The resistors cut the pulse peak currents to about 1 mA or less, although the slower pulses do require a somewhat longer running time. The actual time for readout is not inversely proportional to pulse current since a major fraction of time is associated with the final few pulses when the voltage is decaying slowly, but still reaching 0.25V in less than 10 sec. The 10-sec delay is arbitrary, but for most of our experiments the difference between 5, 10, or 20 sec was 1-2% and often just a pulse or two.

Accuracy of the pulse discharge readout method was checked by charging the cells at constant current and using the pulse discharge for stripping. The pulse discharge equipment was calibrated to ±0.5% by the manufacturer and was reproducible to ±0.2%. Since the output is digital, there is an absolute uncertainty of ±0.1 mcoulomb. This need not be an inherent limitation since the instrument could be designed to give pulses of 0.01 or 0.001 mcoulomb. The constant current source used for checking the pulse discharge method was calibrated to ±0.1%. The results in Table I show that this method is as accurate and reproducible as the constant current method results given in Table III of Ref. (2). In addition, it was noted that very little "conditioning" was required (Table II) contrary to the results when constant current readout was em-

ployed in which the first few cycles were usually 3-8% away from succeeding charge-discharge cycles [*see* Fig. 9, Ref. (2) for typical results]. This behavior for pulse discharge supports the concept that this method of readout is less dependent on previous history and charging conditions than the constant current method. To emphasize this difference, a cell was cleared at 100 μA, charged at 100 μA, and read out at various constant currents. At currents above 100 μA, the cell was cleared at 100 μA before the next charge was applied. The results in Table III show how a cell conditioned at 100 μA will give low results at higher currents and high results at lower currents. As the current level is increased, polarization and *IR* drop increase, causing the 0.5V cutoff voltage to be reached sooner. A cell conditioned at 100 μA will be most accurate when subsequent stripping is performed at 100 μA. At currents lower than 100 μA less polarization and *IR* drop will allow the cell to run longer, while at currents above 100 μA the cell will run short.

A small effect was even noted when various charging currents were employed with a constant readout current. This was unexpected from the concept that polarization and *IR* depend only on the stripping current level. However, silver deposition conditions do play a part in the polarization observed during stripping and would account for this observation.

To illustrate the use of solid electrolyte cells as coulometers, a program of various amounts of charge applied at various current levels was used followed by pulse discharge readout. Table IV shows results of a series of integrations on one cell. To date, over 20 cells have been operated as coulometers with similar results. Again the readouts were accurate to 1-2%, although occasionally a higher error was observed suggesting that some silver had become separated from the gold electrode. Contrary to constant current readout, the pulse discharge showed no tendency for values to reach some limiting value when several integrations under the same conditions in a row were performed (*see* Table IV which lists a set of runs in the order performed). Also, there was no evidence for different results because of different previous runs. An example is seen in Table IV in which integration No. 13 was the same as No. 8 with essentially the same result even though the preceding integrations were different. Thus, integration of a variable current input can be accomplished with the solid electrolyte systems using the pulse discharge technique. However, the cells still show changes in charge setting when a hold period between charge and discharge is present, similar to the constant current results. Also, high-temperature results (> 50°C) were poor even for immediate readout. In fact, at elevated temperatures, the open-circuit voltage fell so rapidly that pulse discharge could not be employed. Even when fully stripped, the gold electrode would not retain an open-circuit potential > 0.25V for 10 sec, which is necessary for cutoff. At constant current, large positive errors were observed. The inability of the cell to hold a charge during an idle period and the inability of the gold electrode to hold an open-circuit potential is related to the residual current of the cell which is also a measure of electronic conductivity in the electrolyte (2). As temperature is increased, the electronic contribution increases rapidly explaining the open-circuit decay as well as the extra time required to bring the cell to 0.5V. This obvious shortcoming could limit the device to ambient or lower temperatures with only short idle periods. However, as preparation techniques for Ag_3SBr improved, the residual current was decreased an order of magnitude and further improvement may still be possible.

To illustrate the use of a solid electrolyte coulometer for controlled potential electrolysis, iodide solutions were oxidized at +0.70V *vs.* SCE. The solid electrolyte cell was in series with the electrolysis and, after the current decayed to background level, the coulometer was read using pulse discharge. The results are shown in Table V.

Low-temperature studies.—Conductivity of Ag_3SBr as a function of temperature is given in Ref. (2). The cells exhibit reasonable resistances of < 100 ohms as low as −70°C. Timing accuracy at constant current for cells at low temperature is shown in Table VI. Negative errors which were observed in general prob-

ably result from the higher polarization voltages and *IR* drop leading to premature cutoff. Precision was excellent although the results at −70°C definitely showed less precision than the higher temperatures. Charge hold showed a slight negative drift at −70°C reaching −7.5% at 25 hr. In general, charge hold characteristics were better at low temperature.

With pulse discharge, positive or negative errors were observed at −70°C, depending on plating current, and again showed poor precision. However, an experiment at −70°C gave excellent results which are given in Table IV. Results at −25°C were similar to constant current readouts with an average of −1.9% when a charge of 400 sec at 36 μA was applied to the cell.

It should be noted that behavior at low temperature was markedly better than at elevated temperature with extremely sharp cutoff both at constant current and pulse discharge. Constant current cutoff depends on sulfide oxidation effects which are less at low temperatures. Sharper pulse discharge cutoff coincides with the slower decay of open-circuit potential at low temperature after silver has been stripped from the gold electrode. Solid electrolyte coulometers operated well at room temperature or below, including better charge storage and sharper cutoff characteristics as the temperature was decreased. Accuracy and precision became somewhat poorer below −25°C, but cutoff characteristics and general performance remained good to −70°C, the lowest temperature studied. Cells could be operated at 35°-50°C using constant current readout, but pulse discharge could be employed only below 35°C.

Double-cell configuration for information storage.— The normal mode of operation of these coulometers (*i.e.*, plating a certain amount of silver on a gold electrode and subsequent stripping) destroys the information which was stored on the gold indicator electrode. In developing a device which stored the original information, a double-cell configuration has been used and tested. The cell consists of a silver, solid electrolyte, gold, solid electrolyte, silver five-layer pellet in which the center gold indicator electrode is given an initial charge setting *vs.* one of the silver electrodes. Current is then passed through the entire pellet which strips silver from one side of the gold while plating an equivalent amount on the other side. When the cell reaches a preset cutoff voltage (normally 0.5V), the current is reversed. Some of the pellets have undergone several thousands of such cycles. A recorder trace showing voltage *vs.* time is shown in Fig. 2,

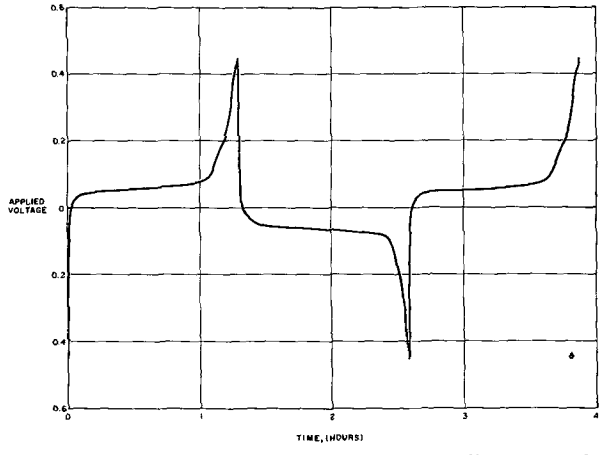

Fig. 2. Cell voltage *vs.* cycle time. Ag_3SBr pellet operated at 36 μA, 25°C with 0.5V automatic cutoff and current reversal. Cycle time approximately 4000 sec. (Note: The voltage across the cell was measured from the output of a VTVM because the recorder impedance was only 1 megohm. The voltage rise across the cell from 0.45 to 0.5V was more rapid than the VTVM response which appears on the recorder trace as a cutoff of 0.45V.)

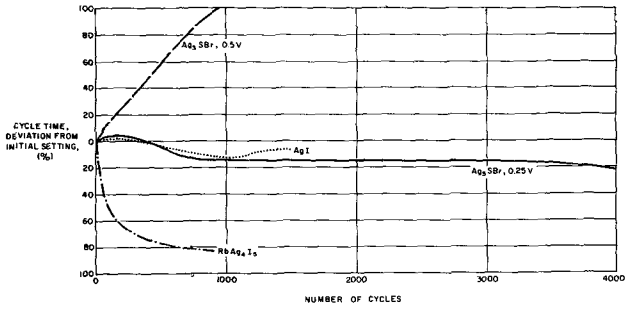

Fig. 3. Cycle time changes with number of cycles.

Ag_3SBr	0.5V	100 μA	216 sec initial
Ag_3SBr	0.25V	100 μA	166 sec initial
$RbAg_4I_5$	0.5V	100 μA	340 sec initial
AgI	0.5V	3.6 μA	425 sec initial

while cycle time *vs.* cycle number is shown for some of the pellets in Fig. 3.

The results for Ag_3SBr were interesting in that, with 0.5V cutoff, the cycles ran long (+0.1%/cycle) while, with 0.25V cutoff, the cycles ran short (−0.02%/cycle). This difference can be explained by the sulfide oxidation which occurs at 0.35V (2). In driving the voltage to 0.5V, some oxidation of sulfide occurs on one side of the gold, while an equivalent amount of silver is plated on the other side. When the current is reversed, this silver is stripped on the second side, but will cause an equivalent amount of silver to be plated on the first gold side. Silver is plated in preference to sulfur reduction because the sulfide cycle is irreversible. Thus, every time some sulfide is oxidized, more silver plate enters the system and the cycle time gets progressively longer. The effect would be even more dramatic except for the tendency to run short (seen at 0.25V cutoff and probably the same type of effect with $RbAg_4I_5$) which tends to compensate for the sulfide effect. This balance between low and high results is also affected by temperature; the cycle time increases at higher temperature and decreases at lower temperatures. Another operating problem with Ag_3SBr was encountered using manual cycling. Any time the pellet was left idle for long periods of time, such as 1-3 days, the cycle time would increase significantly. Manual cycle drift averaged +0.80%/cycle at 36 μA but only +0.09% when cycled automatically. However, when changes associated with idle periods were subtracted, the cycle drift averaged +0.11/cycle in good agreement with automatic cycling.

Results for AgI in Fig. 3 show that, under these specified conditions, AgI can be used for over a thousand cycles without large changes in charge setting, indicating the 100% coulombic efficiency. It should be noted that lower currents (3.6 *vs.* 100 μA) had to be used with AgI since its conductivity is nearly 1000 times smaller than Ag_3SBr or $RbAg_4I_5$.

Negative errors are normally encountered with solid electrolyte cells during anodic stripping. Silver may lose contact with the electrolyte or the gold electrode, and thus is not oxidized during stripping. Silver iodide exhibits this same effect with larger amounts of charge, but the very small amounts of charge used in these experiments could be repeatedly cycled with little loss.

Cycle time for $RbAg_4I_5$ pellets decreased rapidly, but these results may only be reflecting the fact that the tests were not carried out in a dry box. It is known that $RbAg_4I_5$ is a satisfactory electrolyte when protected from the atmosphere (4), although experiments of this type have not been reported before.

It appears that with careful choice of operating conditions, such as 0.25V cutoff voltage for Ag_3SBr, the double-cell configuration can be used to store initial information and to use this information for determining cycle time for many cycles. However, the

latitude of these conditions is much more limited than for single shot timing or integration.

Indicator electrodes.—The primary requirement for an indicator electrode is that it be sufficiently more noble than the metal used for tabulating charge so that an observable voltage rise can be observed when the indicator electrode is clear. When silver is used for coulometry, only a few materials exhibit this nobility including gold, platinum group, and carbon (1, 2, 5, 6). When normal trigger circuits are used, the voltage rise should be at least 0.2-0.3V and preferably $>$ 0.5V. Voltage rises for palladium and graphite are given in Fig. 4.

In addition to this primary requirement, the open-circuit voltage must not decay so quickly that a cutoff cannot be achieved when pulse discharge is considered. Open-circuit voltage decays after stripping for palladium and graphite electrodes are also shown in Fig. 4. Only graphite with Ag_3SBr electrolyte gave sufficiently slow voltage decay for pulse discharge.

Timing accuracy at constant current was checked for currents of 10-360 μA and for periods of 36-360 sec for Ag_3SBr and Ag_3SI using palladium and graphite electrodes in place of gold. Although readouts were quite reproducible with standard deviations of about 1-3%, accuracy was poor with average errors ranging from −40% to +131%. Pulse discharge gave similar poor results. The only advantage graphite exhibited over gold was its very sharp cutoff. This was caused by two effects. First, there was no voltage plateau at 0.35V which has been attributed to sulfide oxidation (2). Evidently, the irreversible oxidation of sulfide on gold is even more irreversible on graphite. The second effect appeared to be poor electrode/electrolyte contact which would mean less effective area for the same size pellet. The smaller area would have less capacitance and, thus, a sharper voltage rise. The poor contact, however, also led to low results. At this time, there does not appear to be an indicator electrode more suitable than gold for solid electrolyte silver coulometers.

Accurate Temperature Control for Laboratory Furnaces Using Thermocouple Modulation

John G. Burt

Nuclear Engineering Department, The Ohio State University, Columbus, Ohio

ABSTRACT

A solid state circuit utilizing field effect transistors in a free running multivibrator configuration is discussed as a method for improving temperature regulation of galvanometer movement controllers. The circuit when used in conjunction with on-off controllers will maintain temperature to ±0.2°C at 1000°C.

Frequently it is necessary to maintain the temperature of a muffle or tube furnace at a set point with control accuracy of ±1°C at 1000°C for extended periods of time. This small tolerance is generally far beyond the limit of on-off galvanometer temperature controllers presently available. The proportioning controllers which will satisfy this requirement are generally quite expensive and this high cost very often precludes their use in many experiments conducted in the laboratory. This work deals with a reasonably simple and inexpensive modification to on-off galvanometer controllers which will greatly improve the short- and long-term temperature fluctuation about the set point.

With most laboratory furnaces and their associated galvanometer on-off controllers, there are two effects which contribute to the variation above and below the set point temperature: thermal inertia of the furnace and galvanometer pivot friction. The first factor is the result of furnace winding and thermocouple proximity, while the second comes from the finite friction present in the galvanometer movement (1). The result of these two factors is a dead zone about the set point where the galvanometer movement is not affected by slight changes in the thermocouple signal, and an oscillation in furnace temperature having a period of 5-15 min depending on the location of the thermocouple relative to the heating elements.

Reid has discussed a method for reducing the short- and long-term temperature fluctuation by modulating the thermocouple signal with a low-frequency a-c voltage (2). The superposition of the a-c signal on the d-c thermocouple output results in a voltage that drives the galvanometer above and below the dead zone that surrounds the set point. This effectively turns the controller on and off once during each modulated cycle, the ratio of "on" to "off" time being determined by the average d-c signal. The power delivered to the windings is proportioned in time such that the furnace cannot oscillate with its natural frequency, and the effect of the dead zone is minimized.

The original method used to obtain this "Guoy" modulation was mechanical, using resistance wire and a rocking pool of mercury, and as such is subject to breakdown when used for extended periods of time. This effort has been directed toward replacing the mechanical modulator with a solid state electronic circuit, which is not as susceptible to failure. During the last few years, field effect transistors have been developed to the point where very high input impedances can be obtained at low cost; thus oscillators and multivibrators having extremely low frequencies can be constructed using moderate-sized capacitors. In this particular circuit, two n-channel FET's are used in a free running multivibrator configuration to obtain a square wave having a period of about 10 sec. Ten seconds was chosen since the galvanometer movement is damped and cannot follow any signal having a period of less than 5 sec/cycle.

The circuit shown in Fig. 1 functions as follows. When power is applied, both FET's are in the "on" mode as the gates are at essentially the same potential as the sources. As S_1 is closed, capacitor C_1 is charged through Q_2 to the full supply voltage of the battery. When this switch is released (a push button is used for S_1), the source of Q_1 immediately returns to near ground and C_1 drives the gate of Q_2 about 4V negative with respect to ground. This negative pulse turns Q_2 off as the gate is now negative compared to the source of Q_2. C_1 discharges through R_2 according to the R_2C_1 combination allowing the gate of Q_2 to return to ground. At this point, Q_2 will turn on driving the gate of Q_1 negative *via* coupling capacitor C_2, turning Q_1 off. The RC decay at the gate of Q_1 eventually turns Q_1 on and the sequence is repeated. The square wave obtained from the two FET's is integrated by the 1-meg resistors and the 4-μf capacitor to obtain a double ramp function which is more suitable for driving the galvanometer. Q_3 and Q_4 are pnp silicon transistors used in a common collector mode to drive the low impedance load which will be added to the galvanometer circuit. The 1-ohm resistor added to the galvanometer was chosen for two reasons; the addition of more than 1-2 ohms will alter the dampening of the galvanometer and require recalibration of the temperature scale, while any load of less than 1 ohm is difficult to drive with the output transistors. The two trimpots are incorporated into the circuit in order to adjust the magnitude of the modulating signal for optimum results. This adjustment also makes it possible to use the circuit to drive various types of thermocouples since the output voltage varies from one type to the next. When platinum-rhodium thermocouples are used, the modulating signal need only be about 1/10 mV, while for chromal-alumal it must be about 1 mV in order to sweep through the dead zone at 1000°C.

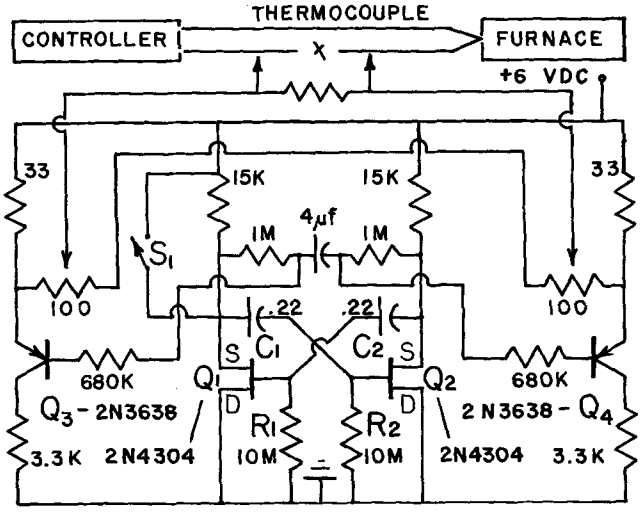

Fig. 1. Solid state circuit utilizing field effect transistors

In summary, it is recommended that mercury relays be used for switching power to the furnace windings as the frequent switching due to the modulation will quickly wear out ordinary metal contactors. Improved performance will also be obtained by switching from a low-to high-power mode at more elevated temperatures rather than complete on-off operation. The best regulation has been observed when the maximum power is applied about 60-70% of each cycle, and the modulating signal set for minimum amplitude which allows switching once during each modulated cycle. Good long-term regulation will require a reference junction which is maintained to ±0.05°C or better, and an ice bath in a vacuum Dewar has been found quite satisfactory. Using these precautions it has been possible to take a controller that maintained 1000° ± 4.0°C prior to this modification, and obtain regulation of ±0.3°C at this operating temperature for 4-6 hr. Short-term fluctuations over a period of 15-20 min are less than 0.2°C. Experimental runs were conducted at 1020°C using a Marshall 10-in. OD tubular furnace in conjunction with a Leeds & Northrup speedomax H-AZAR strip recorder. Span and zero suppression were adjusted for a 20°C span at this operating temperature and fluctuations of 0.10°C were observable. The furnace was operated without modulation to observe temperature variation and oscillation. Modulation was then imposed on the thermocouple and the regulation recorded for extended periods of time.

Electrodeposition of Lead-Antimony Alloys

J. W. Dini and J. R. Helms

Material Science Division, Sandia Laboratories, Livermore, California

ABSTRACT

Two fluoborate solutions capable of producing sound, thick lead-antimony deposits are described. One contains peptone and resorcinol in addition to lead and antimony fluoborates, while the other contains beta-naphthol in place of the peptone and resorcinol. Property data for some deposits are presented as well as influence of operating conditions and bath composition on antimony concentration of deposits.

Sound, thick lead electroforms have been produced by electroplating in fluoborate solution (1). However, as expected, the lead deposits were quite soft (hardness of 8 Knoop with a 5-g load) and highly subject to marring and scratching during handling. In an effort further to improve lead electroforms, a method was sought for increasing their hardness and strength. The method investigated, codepositing antimony with lead in a fluoborate solution, was chosen because antimony and/or tin is frequently used as an alloy to increase the strength of lead castings, and, of the two metals, antimony imparts the most hardness and strength to the lead (2). The fluoborate solution was chosen because past experience indicated that this solution was the best possible choice for electrodeposition of lead-antimony alloys (1, 3, 4-9).

The study revealed that fluoborate solutions are indeed capable of producing sound, thick electroforms of lead-antimony alloys, and that these alloys are harder and have higher tensile strengths than pure lead. In general, the study showed that as the antimony composition of a deposit is increased the deposit becomes harder and stronger.

During the course of the study, it was found that:

To obtain an alloy with a fixed antimony composition required the use of a pure lead anode wrapped tightly in filter paper and bagged with Dacron.

Although fluoborate solutions containing either resorcinol and peptone or beta-naphthol functioned equally well, deposits produced with the resorcinol-peptone bath bubbled when quickly heated to the melting point. There were no supplemental studies of the effects of addition agents.

An increase in the antimony concentration of the plating bath increased the antimony concentration of the deposit.

For a given bath composition, an increase in current density or a decrease in temperature lowered the antimony concentration of the deposit.

Preliminary Experiments

Antimony content of deposit.—Initially, a 1-liter bath was used that contained 460 ml/liter lead fluoborate concentrate, 0.23 g/liter peptone, and 0.23 g/liter resorcinol. Antimony was added in small amounts as antimony fluoborate (*see* Table I for composition of lead and antimony fluoborate concentrates). The anode was chemically pure lead and of the same dimensions as the cathode (2¼ x 4 in.). Panels were plated for 30 min at 30 A/ft², and the antimony content of the deposit was determined by using a copper coulometer during the plating operation and the calculation technique described by DuRose and Hutchison (10). As shown in Table II, the antimony content of the deposit increased as the antimony content of the solution increased.

Immersion deposition.—During testing, it became obvious that antimony was being deposited on the lead anode by displacement when the bath was not electrolyzed. At the end of the first day of plating, the lead anode was left in the bath overnight. The next morning there was a bright displacement coating of antimony on the anode. The antimony content of the alloy produced in the bath after the antimony was removed from the anode was 7.8%, whereas the previous evening it was 18.0%. Since the plating times were short enough that the amount of antimony deposited out of solution was minimal, it was evident that most of the antimony had been removed from the solution by displacement on the lead anode.

Displacement deposition of antimony on anodes in alloy plating baths has been discussed in the literature. Booe noticed the immersion with lead-tin anodes in a solution containing lead, tin, and antimony fluoborate (11). He obviated the phenomenon by wrapping the anodes with paper to limit the amount of solution coming in contact with the anode. Schaefer and Mohler also had the same trouble when plating lead-tin-antimony alloys, but decided the problem was not that serious because the rate at which antimony immersion plated on the anode was only about one fourth of the rate at which the antimony was electrodepositing at the cathode (12).

Because both the data from the test under discussion and past experience indicated that immersion deposition could be a problem, the anodes in all following experiments were wrapped tightly with two layers of Whatman #42 filter paper and bagged with Dacron. This did not completely prevent immersion plating but minimized it by limiting the amount of solution coming in contact with the anode. In addition, when the baths were not being used, the anodes were removed from the solution.

[A]Solution contained 460 ml/liter Harshaw Lead Fluoborate concentrate, 0.25 g/liter peptone, and 0.25 g/liter resorcinol. Volume was 1 liter, plating current density 35 A/ft², and temperature 27°C.

Antimony vs. lead anode.—In a second experiment similar to the one described earlier, an antimony anode was used instead of the lead one. A small amount of antimony was added to the plating solution and then a series of panels were plated. As time progressed, the antimony content of the deposits increased even though no more antimony was added to the bath as antimony fluoborate. This increase occurred because antimony went into solution at the anode faster than it plated out at the cathode, thereby gradually increasing the antimony content of the bath (*see* Table III). With a 93% lead-7% antimony anode, preferential electrolytic dissolution of antimony was noted, thus gradually increasing the antimony content of the bath.

The work with the various anode systems showed that the best approach for obtaining an alloy with a fixed antimony composition was to use a pure lead anode and additions of antimony fluoborate as the solution was depleted of antimony. Use of anodes containing antimony precluded keeping the antimony content of the deposit at fixed levels.

Physical Properties

Experimental procedures.—To determine the effect of the antimony content on the physical properties of the electrodeposited alloy, electroforms approximately 30 mils thick were produced by plating for 8 hr at 25 A/ft² in a 40-liter solution (*see* Table II for composition). (Thicker deposits were not produced because the process would have required more than the 8 hr of a typical working day.) The mandrels were 3- by 6-in. aluminum panels, and a Mohler-Schaefer box was used to assure uniform deposition during plating (13). Prior to plating, the mandrels were zincated and given a cyanide copper strike. The antimony content of the deposits was increased by adding antimony fluoborate to the plating bath. The solution was continuously filtered through a unit containing a Dacron filter tube, and an electric stirrer with a plastic stirring rod provided the agitation. The anodes were of chemically pure lead, wrapped with filter paper and bagged with Dacron. The anode-to-cathode ratio was about 2 to 1. During plating, the alloy composition was determined with a copper coulometer (10). Tensile specimens were prepared by using a Tensilkut template, as described by Dini and Helms (1).

Results

The electroforms produced appeared to be quite sound. Those low in antimony content had the dull, gray appearance typical of lead. As the antimony content of the alloy increased, the deposits became brighter and their tensile strength and hardness increased in a relatively linear fashion (*see* Fig. 1 and 2). The tensile data shown agree fairly well with published data for cast lead-antimony alloys (2). Elongation of the electroformed alloys was essentially *nil* in all cases, and the structure of the alloys, examples of which are shown in Fig. 3, was fine grained.

Peptone-Resorcinol vs. Beta-Naphthol Bath

When the alloy deposits were quickly heated to their melting point, vigorous outgassing and bubbling occurred, and an odor similar to that of burnt peptone was evident. In addition, a carbonaceous film would occasionally appear on the surface of a heated part. This phenomenon was attributed to decomposition of organics which had been occluded in the deposits during plating. A few experiments revealed that, of the two organic additives used in the solution, peptone was the major culprit in the heating problem. Attempts at producing deposits without either one or both of the organic additives resulted in rough, noduled deposits that were completely unacceptable.

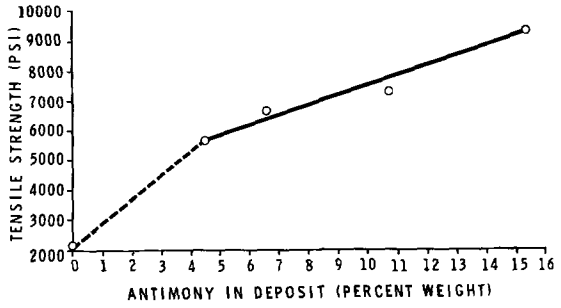

Fig. 1. Effect of antimony content in the deposit on tensile strength.

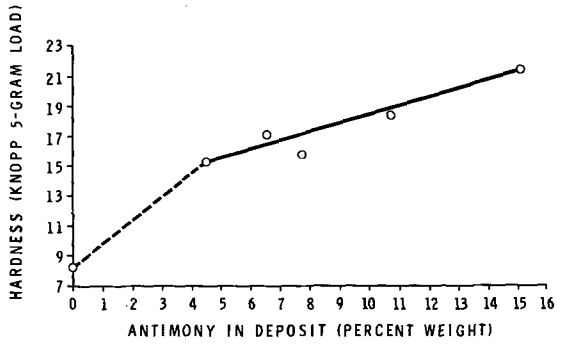

Fig. 2. Effect of antimony content in the deposit on hardness

At this point, it should be mentioned that this bubbling phenomenon was also obtained with tin-lead electrodeposits produced in a standard fluoborate bath containing peptone and resorcinol as additives (14). This finding led to the conclusion that this type of reaction is probably prevalent for most deposits produced in fluoborate solution containing organic additives. For thin deposits, the problem is probably not of consequence; however, when deposits are thick and joining or soldering operations have to be performed, difficulties could be experienced.

A few other organic additives, including catechol, hydroquinone, and beta-naphthol, were evaluated in the lead-antimony solution. It was found that smooth, thick deposits could be produced in a solution containing beta-naphthol, and when these deposits were heated the bubbling was not nearly as extensive as with the peptone-resorcinol system. Figure 4 compares a deposit produced in the peptone-resorcinol bath with one produced in the beta-naphthol bath. Both were quickly heated to their melting points shortly after plating. Because the beta-naphthol bath produced good deposits that did not bubble when heated, the physical properties of the deposits obtained with this bath were further investigated.

Beta-naphthol bath.—To evaluate the effect of current density and temperature on the antimony concentration of deposits produced in the beta-naphthol bath, a series of experiments was run with a 40-liter solution containing beta-naphthol as the organic additive (*see* Table IV). The antimony concentration of the plating solution was checked after each plating test by Langford's permanganate technique (15) and then readjusted with additions of antimony fluoborate. Cur-

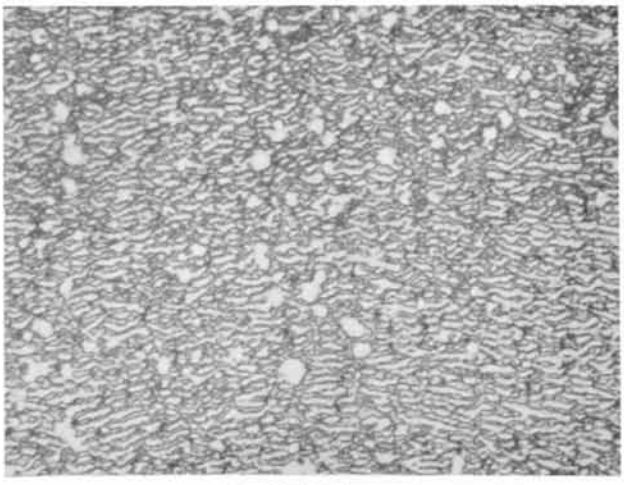

Fig. 3. Cross sections of deposits produced in solution containing lead fluoborate, antimony fluoborate, peptone, and resorcinol. Etchant was a solution containing acetic acid, nitric acid, and glycerol. Magnification was 1000X. Current density was 25 A/ft².

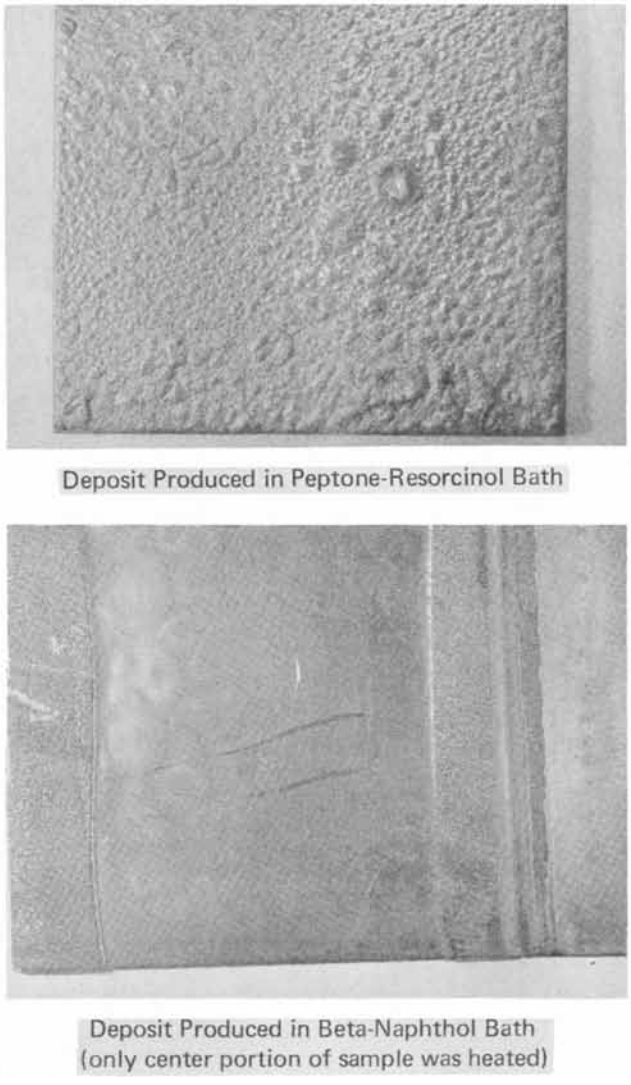

Fig. 4. Comparison of deposits produced in peptone-resorcinol and beta-naphthol baths. Note the bubbling effect on the deposit produced in the peptone-resorcinol bath.

rent density effects were checked at two antimony concentration levels, 0.43 and 0.98 g/liter.

The results, included in Table IV, show that for both series evaluated the antimony concentration increased as the current density decreased. As expected, the bath containing the higher amount of antimony in solution produced deposits higher in antimony content. The temperature data (*see* Table V), which were obtained only on the bath containing 0.43 g/liter antimony, showed that as the temperature increased the antimony content of the deposit increased.

These trends for lead and antimony are typical for less noble and more noble metals in a normal alloy plating system.

Table IV. Effect of current density on antimony concentration of alloy

The Effect of a Silicon-Boron Phase on Thermally Grown Silicon Oxide Films

William A. FitzGibbons,[1] Thomas Kloffenstein,*[2] and Karl M. Busen*[3]

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

It is shown in the present paper that silicon oxides etch more slowly when they are thermally grown on samples with a silicon-boron phase, whereas oxides grown on samples without a phase exhibit the normal etching rate of SiO_2. One also can observe that the maximum variation in etching rates is different for samples with and without a phase. A removal of the phase prior to oxidation reduces variation of the etching rate considerably (by a factor of five in some cases).

In the processing of silicon planar devices or integrated circuits, dopants are being used which convert predetermined regions of a silicon wafer from one conductivity type to another. The dopants enter the wafer *via* openings in a protective silicon oxide mask. To form the openings, photoresist processes are utilized where silicon oxide is coated with a layer of light-sensitive photoresist material and where in subsequent steps this material is exposed, developed, and selectively removed in places which conform to a device pattern. At these places, the silicon oxide can be etched off so that the openings for the dopants are formed.

The etching must be controlled carefully to avoid residues in the openings and/or undercuttings. This phenomenon commonly arises when part of the silicon oxide has been adulterated by a glass-forming substance as phosphorus oxide. Pliskin and Gnall (1) have reported that in this case one finds a faster etching rate for glass than for the oxide itself. Such a difference in etching rate can lead to undercutting.

The appearance of residues in openings is another phenomenon which can be related to a difference in etching rates between a glass and SiO_2. For formation of the openings, timed etching is normally applied and the duration is often adjusted to etching rates of pure silicon oxide. If boron glass occupies the openings, timed etching may not be sufficient to remove all of it, because, as is demonstrated later, boron glass has a lower rate than SiO_2. This residue can be related directly to contact resistance problems.

The present article deals specifically with conditions under which a boron glass is formed and with the etching behavior of the glass and its influence on device fabrication. Generally the glass forms in an oxidizing atmosphere on top of samples which are composed of a silicon substrate and a boron-rich surface layer. Such a layer can be observed after execution of a deposition step, during which a boron source is generated for subsequent drive-in diffusion. In this step, a silicon slice is exposed to high concentrations of diborane (B_2H_6). The layer consists most likely of a silicon-boron phase. Its formation and its nature have been described recently (2, 3). For convenience, some details concerning the phase are repeated here. The phase was observed to form on silicon substrates which were exposed for 5 min and more to an ambient of $N_2 + O_2 + B_2H_6$ (300-1000 ppm) with a total flow of 2 liters/min. The temperature ranged from 930° to 1100°C and the oxygen concentration was 1% at all times. Glass etches such as buffered HF or diluted HF did not attack the phase; however, a mixture of $HF:HNO_3:CH_3COOH = 1:2:6$ or a low-temperature oxidation with subsequent etching in diluted HF removed it. The oxidation was carried out at 600°C in a flow of wet oxygen.

The phase acts as a source for the diffusion of boron into silicon. This diffusion, which takes place together with the formation of the phase, is called prediffusion. For the processing of semiconductor devices, normally an additional heating cycle, the drive-in diffusion is applied in order to obtain a deeper penetration of the prediffused boron into the substrate. During the drive-in diffusion, the sample is exposed to an oxidizing atmosphere and it is this processing step which produces the boron glass we are discussing.

Experimental

For the experiments, several lots were prepared with each lot having three samples. To make condi-

tions for the investigations "realistic," the samples were structured as if they were going to be used for circuit processing, which means that p-type silicon substrates were n-type diffused (with high surface concentration), overgrown with an n-type epitaxial layer, oxidized, covered with photoresist, exposed, developed, stripped of photoresist, subjected to a glass etch, and exposed to different boron depositions as described in Table I.

All samples were then treated by a glass etch. After that, the samples in each deposition cycle were divided into two groups with one group going through ellipsometric measurement #1, phase removal, ellipsometric measurement #2, drive-in, and the other group going through ellipsometric measurement #1 and drive-in. The procedures are summarized in Fig. 1(a).

Data for the deposition cycle have been given in the introduction. The etch, applied after deposition, consisted of $HF:H_2O = 1:10$. The first ellipsometric measurement was done for identification of the boron-silicon phase. For an identification, the relative phase change Δ was determined from the polarizer setting of the ellipsometer. The instrument used was a Gaertner Model L119. A phase layer was considered to be present when the Δ values, as read by the ellipsometer, were different from Archer's value for a cleanest etched silicon surface ($\Delta = 175°$) (4). Under the conditions in this experiment, a Δ of 160° represents a thin-phase layer while a Δ of 130° can be considered a thick phase. The phase removal was achieved by either the low-temperature oxidation with subsequent HF etching [Ref. (3)] or by a special process. To see how effective the removal was, a second ellipsometric measurement was taken. For drive-in, the samples were heated at 1130°C in an oxidizing atmosphere until about 5000Å-thick oxide layers were obtained. No evidence of any silicon-boron or other unetchable phase was apparent after any drive-in cycle used.

The oxides which formed during drive-in were investigated for their etching rate [Fig. 1(b)] by measuring their thicknesses ellipsometrically before and after 3-min etching in a slow glass etch (700 ml of 40% NH_4F solution + 100 ml of 49% HF at 23°C). A special computer program was set up (5) to determine the oxide thickness from ψ and Δ values (change in amplitude ratio and relative phase change) measured at 5461Å under an angle of incidence of 70° and assuming that the index of refraction was $n_1 = 1.456$ for the oxide and $n_2 = 4.05 - 0.028\,i$ for the silicon substrate; n_1 was obtained by comparison of measurements at two different angles of incidence (50° and 70°).

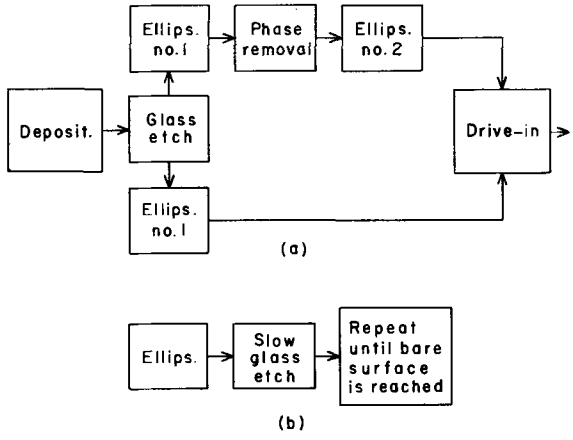

Fig. 1. Procedures for sample evaluation: (a) preparation of samples for drive-in; (b) determination of the etching rate.

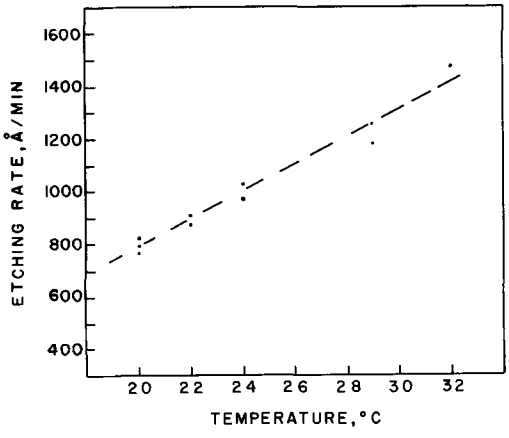

Fig. 2. Etching rate of thermally grown pure silicon oxide vs. temperature.

The results of the measurements are summarized in Table II. The Δ values show that the phase grows with an increase in B_2H_6 concentration. Oxides on samples, where a phase layer existed had on the average about 10% lower etching rates (lots C and D) than oxides which were grown on samples where the phase layer was either very thin or had been removed. One can further observe that the samples with a thicker-phase layer (lot D) acquire thicker oxides after drive-in. For comparison, etching rates as a function of temperature were determined for thermally grown SiO_2. Figure 2 shows that the etching rate of SiO_2 at 23°C is 950 Å/min which is about the same as that for the oxides in lot A and lot B in Table II. This indicates strongly that, for samples with nearly nonexistent phases or for samples without a

phase, the grown oxide is SiO_2. We find also that for boron glasses there is a larger variation among the etching rates than for SiO_2. The maximum variation for etching rates within a given lot has been entered into the last column of Table II. The extremely large variation of etching rate has been verified by special investigations which have shown that depending on the flow conditions and on the position of the samples the phase can vary from slice to slice in a particular lot or can even vary over a single slice.

After this trend had been established, 36 more samples were prepared with varying phase thicknesses. Of the samples in each group, six samples were subjected to low-temperature oxidation and etching, six samples to the special process for phase removal, and six samples were left untreated. Half of the samples in each subgroup of six were then subjected to a drive-in cycle with wet/dry oxidation, the other half to a cycle with dry/wet/dry oxidation. Again etching rates and their variations were evaluated for oxides grown during drive-in. In Table III are found the results for this part of the investigation. For reasons of economy, individual samples and drive-in cycles (it was found that the cycles had no influence on the etching rate) are not listed in Table III, but only lots of samples which underwent the specified processes. For each lot, the maximum variations in etching rate are found in the last three columns. The trend shown in Table II is now substantially confirmed; namely, that a silicon boron phase leads to an oxide, which etches about 10% slower than pure silicon oxide does and that oxides grown on a phase have a higher maximum variation in etching rate than SiO_2 has. The structure of this oxide has not been investigated but it is tentatively assumed that the substance which forms the oxide is a boron glass.

In a final experiment to provide additional information on the nature of the investigated oxides, oxides of various thicknesses were thermally grown on silicon slices. The oxide-covered slices were then exposed to a B_2H_6 concentration of 1000 ppm for 5 min and were post-annealed in the same furnace for 15 min in an N_2 + 2% O_2 flow. Table IV shows the oxide thickness before and after the B_2H_6 exposure. The thicknesses which were measured with the ellipsometer increased from 500 to 700Å during the B_2H_6 treatment. The etching rate of the oxide was found to change with depth. The upper 2000Å had a rate of 2/5 of that of the remaining oxide. The latter had the same rate which clean, thermally grown SiO_2 has. The effect of the changing etching rate can be seen by etching a step in the oxide and taking interference pictures. They show undercutting. The smaller etching rates, common to oxides grown on phase layers and to oxides prepared by deposition of boron oxide on SiO_2, are indicative of the boron glass nature of the oxides grown on phase layers.

5	Wet O_2	5675	6420

Summary and Discussion

In the preceding section, it was shown that oxides grown on a silicon-boron phase have a lower and more erratic etching rate than pure SiO_2. When and if a silicon-boron phase does exist, the lower temperature oxidation prior to drive-in will remove all traces of it. This procedure reduces the etching rate variations by a factor of 3 to 5. High variations in etching rates for samples of the same lot can be related to variations of the phase. It was, furthermore, shown that exposing pure silicon oxide to diborane results in a glass which etches at about twice the rate as does SiO_2.

The last observation explains the undercutting during photoresist processes when one assumes that there are two discrete oxide layers under the photoresist layers. When an opening in such a layer is exposed to a glass etch, the difference in lateral etching rates between SiO_2 and the boron glass causes uneven erosion.

The formation of a boron glass on top of a phase layer during drive-in oxidation can lead to another disturbing effect. When such a glass forms in openings for contacts of a planar device, times etching which is normally adjusted to pure silicon oxide may not be sufficient to remove all of the glass from the openings. In this case, contact resistance problems can result. It was actually observed that upon removal of the phase such problems ceased to exist. Because the appearance of the phase is erratic under certain conditions, one can expect that without phase removal procedures there can be an erratic appearance of contact problems, too, even for the same lot or slice. Thus, phase removal offers a good tool for control of yield. It should be pointed out that according to the investigations the contact resistance problem is not directly associated with an unetchable silicon-boron phase but follows from the formation of the boron glass during drive-in.

Cell Voltage during the Electrolytic Production of Manganese Dioxide

F. R. A. Jorgensen

Division of Mineral Chemistry, C.S.I.R.O., Port Melbourne, Victoria, Australia

ABSTRACT

The components of the cell voltage (*viz.*, anodic potential, *IR* drop through the deposit, *IR* drop through the electrolyte, and cathodic potential) are discussed for a range of operating conditions and the discussion illustrated with a record of pilot cell data obtained over a period of 32 days of operation. Growth of the deposit was found to occur from the deposit/electrolyte interface and electrical transport through the deposit was by semiconduction.

Gamma manganese dioxide for use as a depolarizer in high-capacity dry cells can be prepared by the electrolysis of a hot aqueous manganese sulfate solution (1). During this operation, manganese dioxide forms as a massive deposit at the anode and hydrogen is liberated at the cathode. A typical voltage drop across an operating cell has not been discussed in detail in the literature and, apart from a few isolated measurements by Kissin (2) and Steinhoff (3), little is known about the individual electrode processes in these electrolytes. The mechanism of deposition is also not completely understood. Marx (4) concluded that the deposit formed at the actual electrode surface, while both Marx and Schrier and Hoffman (5) concluded that the deposit was nonconducting and electrical transport was *via* pores through the deposit. Van Arsdale and Maier (6), however, treated the electrode processes as occurring at the deposit/electrolyte interface and stated that the deposit was conducting. In view of this lack of information and doubt as to the actual mechanism of formation of the massive deposits, advantage was taken during the operation of a small pilot plant electrolytic cell to conduct a series of experiments to further our understanding of this electrolytic process.

Experimental

In the pilot cell, high-density oil-impregnated graphite was used as the electrode material for both anodes and cathodes, the relative arrangement of which is shown in plain view in Fig. 1. The electrodes were housed in a polypropylene-lined steel tank through which the heated cell liquor was circulated at the rate of 2 gpm by a peristaltic pump. Fresh feed was metered to the cell, displacing spent electrolyte through an overflow pipe to maintain a constant level. The cell was operated under the following conditions: T, 95°C; H_2SO_4, 50-55 g/liter; Mn^{2+}, 55-60 g/liter; anode C.D., 10.0 A/ft² (10.8 mA/cm²); cathode C.D., 6.8 A/ft² (7.3 mA/cm²). Figure 1 also shows the position of a polypropylene strip which was suspended in the electrolyte some distance in front of one of the anodes. This strip served the same purpose as a marker in high-temperature oxidation experiments and was used to detect whether the deposit grew from the graphite or the electrolyte interface.

The cell was operated for 32 days during which time the deposit attained a thickness of 1 in. The deposit was remarkably uniform in thickness, thus indicating a uniform distribution of current to all parts of the anodes. After a 2-hr start-up period, measurements were made of the potential at the surface of the growing deposit relative to a Hg-$HgSO_4$ reference electrode. The latter was sited external to the cell and was connected to one of the anodes *via* a probe which was filled with 1N H_2SO_4. After each measurement, the probe was rotated away from the electrode to prevent incorporation in the deposit. A current interrupter, employing high-current switching transistors, was used when required to remove the current for approximately 10^{-4} sec. The *IR*-free potential measurements were made at the moment of interruption using a cathode ray oscilloscope as null indicator. The equipment is shown in schematic form in Fig. 2.

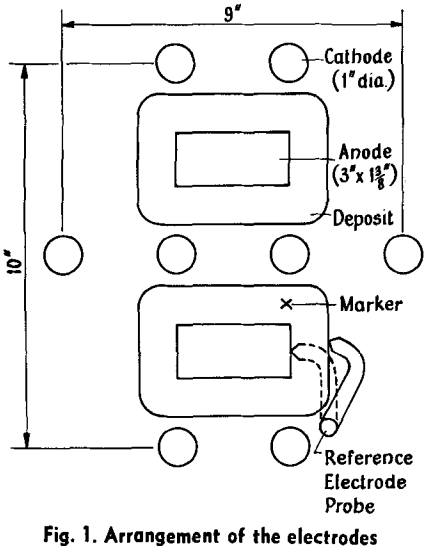

Fig. 1. Arrangement of the electrodes

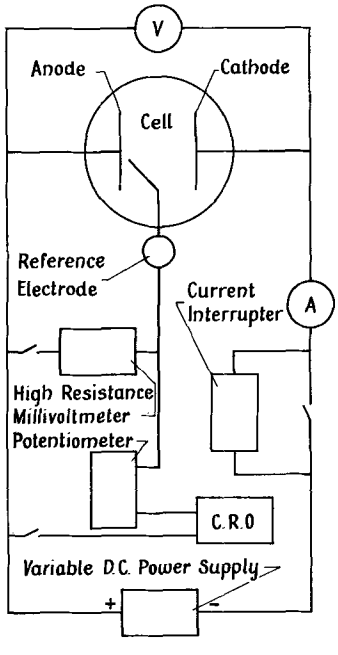

Fig. 2. Cell instrumentation

On completion of the run the anodes were quickly removed from the cell and washed, the deposit was stripped from the anodes, and samples retained for chemical and x-ray diffraction analysis. Samples of the material were subsequently sectioned on a diamond saw and the individual sections analyzed for total manganese (7) and available oxygen (8). These figures were used to establish the value of "n" in the formula MnO_n.

Results and Discussion

Figure 3 shows point values of the cell voltage as a function of time. The results were characterized by the initial rapid rise to a level of 2.75V and thereafter by a slow decrease to 2.60V at the end of the run. Fluctuations occurred due to cracking of the deposit and to a lesser extent to minor variations in the electrolyte composition during the course of the run. In the following discussion, the over-all cell voltage has been broken down into the following components: anodic potential, *IR* drop through the deposit, *IR* drop through the electrolyte, and cathodic potential.

Anodic reaction.—At the end of the run, inspection of the anodes revealed that the polypropylene marker had become incorporated in the deposit and had not been pushed ahead of it. This shows conclusively that deposit formed at the electrolyte and not at the graphite interface. The deposit on one of the anodes was also noted to be touching a cathode. No short-circuiting of the cell had occurred, however, so that if the deposit was conducting it must be concluded, in agreement with Nichols (9), that the presence of a very high contact resistance prevented the leakage of a significant amount of current. Further inspection revealed the presence of some pores in the deposit. They were few in number, however, and appeared to have resulted from the healing of cracks. In many cases, the pores were blind and did not lead to either face of the deposit. These observations discount the suggestions made by Schrier and Hoffman (5) that the formation of the deposit took place by a mechanism involving pores through the deposit and support the view that a reaction of the type proposed by Vetter (10) occurs at the deposit/electrolyte interface. This electrochemical reaction may be represented by the following equation

$$Mn^{2+} + (n + m)H_2O \rightarrow MnO_n \cdot mH_2O + 2nH^+ + 2(n - 1)e \quad \ldots (A)$$

Figure 4 shows anode potential, corrected for *IR*, as a function of the electrolysis time. It can be seen that in the first 50 hr there was a rapid polarization to potentials in excess of 1400 mV *vs.* NHE, after which the potential decreased and thereafter remained practically constant at 1330 mV *vs.* NHE. Unfortunately, the point values shown in Fig. 4 do not allow the full magnitude of the polarization to be determined as this occurred over a week end when the cell was unattended. Separate tests indicated, however, that during this phase of the electrolysis polarizations of as high as 1800 mV *vs.* NHE were attained. In a limited number of tests, graphite anodes were found to exhibit the initial polarization on every occasion that they were tested; for platinum anodes, however, the effect was not always observed but appeared to be dependent on surface preparation. A possible explanation of the above behavior is that the initial oxide film formed on the surface of the anodes was incapable of maintaining the reaction at the rate of the impressed current and the electrodes polarized to potentials where alternate reactions were possible. At these high potentials, the initial oxide film either underwent a dissolution or was recrystallized, the net effect being that nuclei of the desired form were created on the surface after which the potential settled to a level characteristic of electrolysis conditions.

Additional information concerning the final steady state anodic reaction was obtained from a series of laboratory scale tests carried out at constant anode potentials. The form of the potential *vs.* steady state current density relation is shown in Fig. 5 from which it is evident that for the electrolyte (*i.e.*, one containing 50 g/liter H_2SO_4 and 50 g/liter Mn^{2+} as $MnSO_4$), and degree of agitation used in these tests, a limiting diffu-

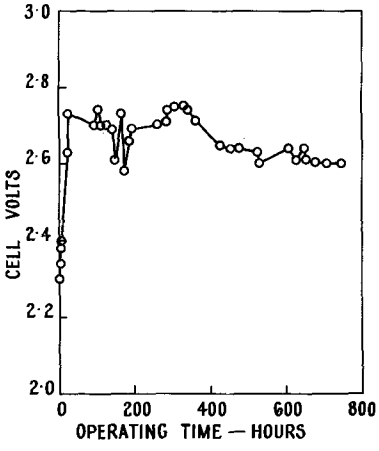

Fig. 3. Cell volts as a function of operating time

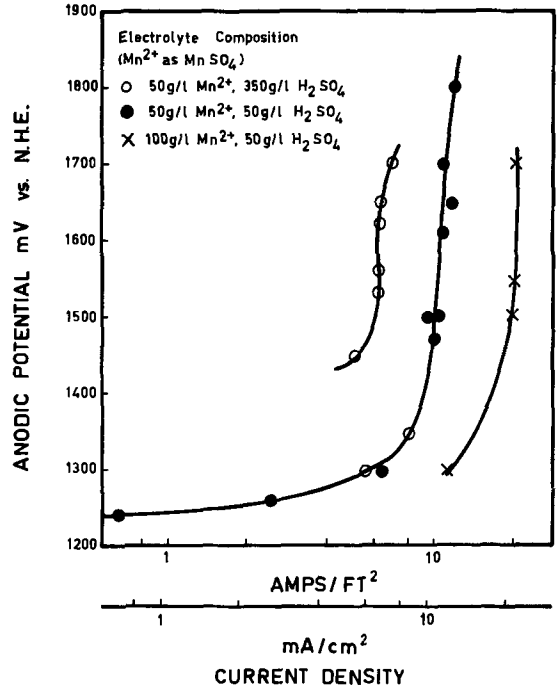

Fig. 5. Anodic current density, at the surface of the deposit, as a function of the potential of formation.

sion condition was approached at values of the current density exceeding 10 A/ft² (10.8 mA/cm²). Increasing the manganese concentration of the electrolyte to 100 g/liter Mn^{2+} approximately doubled the limiting diffusion current, while an increase of the acid content to 350 g/liter was found to halve the limiting current density. For the electrolytes containing 50 and 100 g/liter of Mn^{2+}, anodic current efficiencies of close to 100% were attained until the potential exceeded 1400 mV *vs.* NHE after which the efficiency declined. For the electrolytes containing 350 g/liter of acid, however, the anodic current efficiencies were only of the order of 50%.

X-ray diffraction analysis of ground samples of the deposit confirmed the γ structure and chemical analysis of thin sections revealed the presence of a composition gradient through the deposit which reflected the effect of variations in the anode potential on the composition of the deposited material. The composition gradient is shown in Fig. 6. Chemical analysis also showed the presence of a very thin layer of degraded material, having an *n* value of 1.83, at the electrode surface. This material was in contact with ⅛ in. of partially oxidized graphite. Additional pilot plant tests which involved the removal of anodes after 50 and 400 hr of operation showed that most of the attack on the graphite occurred during the first 50 hr of operation when the electrodes were polarized to high potentials. Extension of the operating time to 780 hr did not produce any measurable increase in the deterioration of the anodes.

Conductivity of the deposit.—The voltage drop associated with the passage of the current through the deposit is shown in Fig. 7. During the first 50 hr of operation, the *IR* drop over the deposit rapidly increased to approximately 300 mV, after which there was a steady increase as the deposit thickened. Fluctuations evident in the record were probably caused by the formation and subsequent healing of cracks in the deposit. The initial rise in the graph is associated with the first 50 hr of operation when the electrodes were polarized to high potentials and represents a high resistance contact at the electrode surface due to the presence of a layer of partially oxidized electrode material and degraded MnO_2. Deposits produced on platinum electrodes which experienced the initial polarization to high potentials did not show the sudden rise in *IR* component. These observations support the above view.

There is a lack of information concerning the semiconducting properties of γMnO_2. Pons and Brenet (11) have, however, reported a value of 13 ohm-cm for the

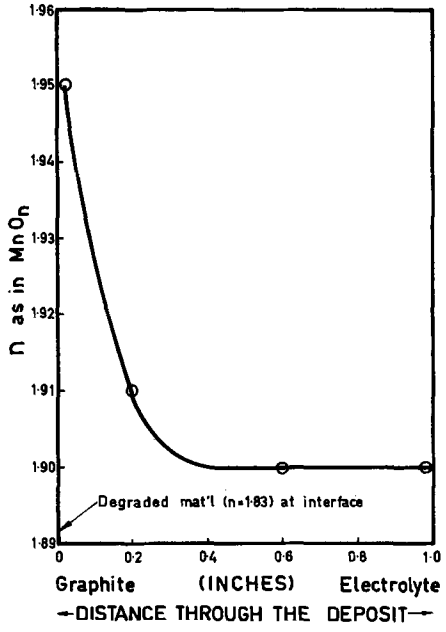

Fig. 6. Composition gradient through the deposit

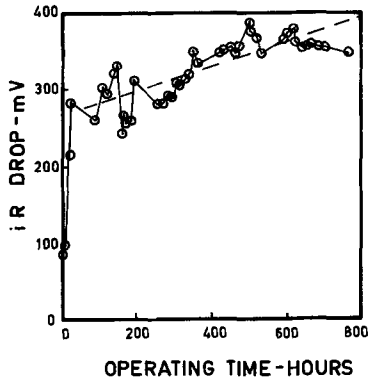

Fig. 7. *IR* drop across the deposit as a function of operating time.

resistivity measured at room temperature and Gabano and his associates (12) have determined semiconduction activation energies for a wide range of composition. Calculations utilizing these data show that under the present conditions (*T*, 95°C; average *n* value of the deposit 1.91) the conductivity of γMnO_2 should be 0.4 ohm^{-1} cm^{-1}. This agrees fairly well with the value of 0.25 ohm^{-1} cm^{-1} obtained from the steadily increasing *IR* values. The latter, which correspond to the increase in *IR* due to the growth of the deposit, are indicated on Fig. 7 by the dashed line.

The above discussion was based on measurements carried out with the reference probe at a fixed distance of 8 in. above the bottom of an anode. Two hours before the completion of the run, however, the probe was traversed over the whole of the 19½ in. of the anode that was submerged in the electrolyte. The *IR*-free potential was independent of position and constant at 1330 mV *vs.* NHE, while the potential drop across the deposit was found to vary from 344 mV at the bottom to 333 mV at the top of the electrode. Calculations taking the current and conductivity of the graphite (8.5 x 10^3 ohm^{-1} cm^{-1}) into account showed the voltage drop, associated with the flow of current through the graphite, to be approximately 10 mV. When allowance was made for this factor, the voltage drop across the deposit was also found to be independent of position.

Conductivity of the electrolyte.—The conductivity values of various manganese sulfate/sulfuric acid solutions were determined in a heated conductivity cell and the results are shown in Fig. 8. It can be seen that, over the range of concentration used in the present work, conductivity of the electrolyte was independent of manganese concentration but increased linearly with increasing acid concentration. It is also apparent that the conductivity of the electrolyte was less than that of the deposit (0.16 *cf.* 0.25 ohm^{-1} cm^{-1}). Hence,

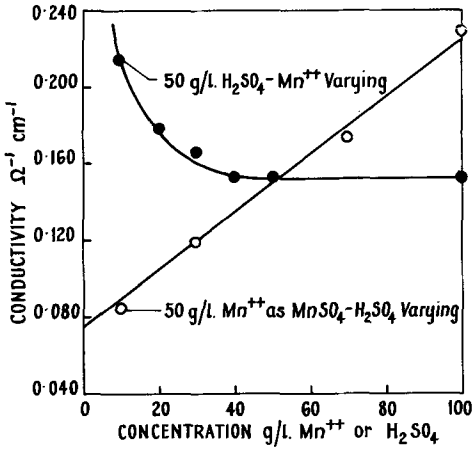

Fig. 8. Conductivity of manganese sulfate electrolytes at 95°C

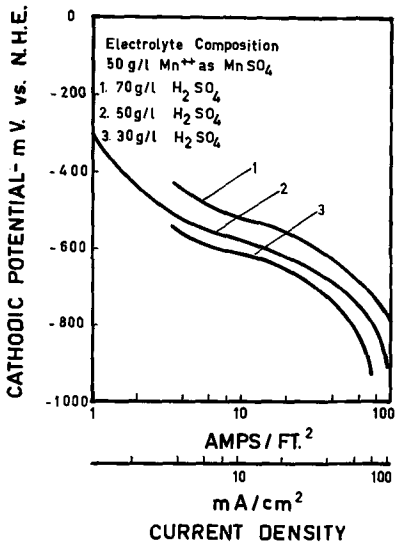

Fig. 9. Cathodic current density as a function of potential

as the deposit increased in thickness it reduced the length of the solution path and there was a net reduction in the over-all cell resistance.

Some of the decrease in cell volts, evident from Fig. 3, could also have been due to the reduction in current density at the surface of the growing deposit. It was shown however that, after the initial polarization had passed, the *IR*-corrected anode potential remained practically constant at 1330 mV *vs.* NHE. This is consistent with electrolysis conditions in the pilot cell corresponding to the flat portion of Fig. 5 where the anode potential is relatively unaffected by variations in current density. Hence under the present conditions the decrease in cell volts was due solely to the reduced length of the solution path.

Cathodic reaction.—Electrolytes containing from 30 to 70 g/liter of H_2SO_4 and Mn^{2+} as the sulfate were used in a well-stirred laboratory cell to determine the effect of electrolyte composition on the overvoltage associated with the hydrogen evolution reaction at the cathodes. As would be expected, manganese concentration had little effect but varying the acid concentration made appreciable differences to the potential of the reaction. From Fig. 9 it can be seen that under the conditions used in this work the cathodes would have been operating at a potential of −560 mV *vs.* NHE.

Conclusions

1. Evidence has been presented to show that massive electrodeposits of manganese dioxide function as semiconductor electrodes; that is, the anodic reaction occurred at the interface between the deposit and the electrolyte, while electrical transport through the deposit was by semiconduction.
2. Results obtained from the operation of a small pilot plant cell showed that for most of the run the cell operated at a voltage of from 2.75 to 2.60V. Analysis of the results showed that the combined anodic and cathodic electrochemical reactions accounted for 1.90V, and that the remaining 0.85-0.70V was associated with the passage of the current through the deposit and the electrolyte. The conductivity of the electrolyte was less than that of the deposit, and as the deposit thickened there was a resultant slight decrease in the over-all cell voltage.

Acknowledgments

The author wishes to thank Dr. W. T. Denholm and Mr. R. Dorin, members of the Division of Mineral Chemistry, C.S.I.R.O., the former for devising the system of *IR* measurement and the latter for assistance with the experimental program. The financial support of the Electrolytic Zinc Company of Australasia Limited is also gratefully acknowledged.

Conductivity of Sodium Chlorate-Sodium Chloride-Water System at High Temperature

R. A. Crawford,* W. B. Darlington,[1] and L. B. Kliever[2]

Research Department, Industrial Chemicals Division, PPG Industries, Barberton, Ohio

ABSTRACT

The conductivity of the $NaClO_3$-NaCl-$H_2O_{(l)}$ system for temperatures above 80°C was investigated. The $NaClO_3$ concentration ranged from 412 to 1354 g/1000g H_2O and the NaCl concentration varied from 74 to 177 g/1000g H_2O. Temperature and $NaClO_3$ concentration were both significant variables in affecting the conductance of the salt solution. Regression analysis was used to determine the coefficients for a series of empirical conductance equations. These model equations used various concentration terms, as square root, linear, square, and logarithmic, and are compared to experimental results. Only two equations are reported and these equations predict the experimental data within ±0.005 mho cm^{-1} for the concentration ranges and temperatures studied.

A common method for the industrial preparation of sodium chlorate uses a solution containing around 600 g/liter $NaClO_3$ and 120 g/liter NaCl at a temperature of 45°C. With the development of newer electrode systems and improved cell design, $NaClO_3$ may be produced using solutions having higher $NaClO_3$ concentrations and cells operating at higher temperatures. The objective of this work was to obtain contour maps at various temperatures so optimum salts concentrations could be used. Since the over-all production system may determine the concentration of one of the salts, a range of values, or a contour surface, was required. The range of salts concentrations reported here varies from 328g $NaClO_3$/liter (412 g/1000g H_2O) to 842g $NaClO_3$/liter (1354 g/1000g H_2O) and from 57g NaCl/liter (74 g/1000g H_2O) to 120g NaCl/liter (177 g/1000g H_2O).

Shedlovsky (1), using the theoretical equations developed by Onsager, found an empirical equation for the determination of $\Lambda°$. Lorenz (2) replaced the original square root concentration term with an empirical parameter that was characteristic for each group of electrolytes. The Lorenz equation is shown in Eq. [1].

$$\Lambda = \Lambda° - AC^n \qquad [1]$$

Knibbs and Palfreeman (3) studied the $NaClO_3$-NaCl-H_2O system for temperatures up to 80°C, $NaClO_3$ concentrations up to 600 g/liter, and NaCl concentrations up to 250 g/liter. They did not attempt to correlate their data to empirical equations. As with the study of Knibbs and Palfreeman, the system in this paper is not a simple or a dilute system. There are two anions and one cation present and the total ionic strength is much greater than allowed by any of the empirical equations developed. Because of this, we are attempting to find empirical equations that best fit our data.

Experimental

After determining the area of interest with preliminary studies, two series of runs were made using the following procedure. A conductance cell was constructed by sealing a commercial pipette-type conductivity cell with platinized electrodes in a 1-liter Erlenmeyer flask. The connection was made near the bottom of the flask so a sample of the electrolyte solution could be drawn up between the electrodes for a conductance measurement. A Teflon stopcock at the top of the pipette cell allowed it to be sealed from the atmosphere. The Erlenmeyer flask was fitted with an "O" ring joint in which a circle of hydrophobic membrane material[3] was held in place by Viton "O" rings. This membrane permitted air to escape from the cell (because the cell contents expand after placing in the constant temperature bath) but was impermeable to water vapor. A 24/40 joint was modified so it could be fitted with a rubber septum and this was inserted in the top of the Erlenmeyer. Additional solution was added to the cell from a hypodermic syringe equipped with a 6-in. long 20-gauge needle that was inserted through the rubber septum. This allowed us to introduce the sample near the bottom of the cell. Stirring in the cell was done with a Teflon covered magnetic stirring bar that was actuated by an air driven magnetic motor immersed in the constant temperature bath. The conductivity cell was calibrated with 1.0 demal KCl at 25°C using the data of Jones and Bradshaw (4). The cell constant was 98.98 cm^{-1}. The cell was connected, using a grounded, shielded cable, to a Beckman Model RC-18 conductance bridge with an accuracy of 0.1%.

The solutions to be measured were prepared gravimetrically by weighing the correct amount of salts and water into the Erlenmeyer flask described earlier. All weights were corrected to vacuo. The flask was placed in the constant temperature bath and after the desired temperature had been attained, the conductance cell was filled with sample. The conductance was monitored for a period of time until the conductance did not vary by more than ±5 μmhos on successive measurements.

If a dilution was to be made for another conductance measurement at a different concentration, the following procedure was used. The solution to be added was drawn into the syringe, the syringe weighed, the contents added to the cell as previously described, and the empty syringe reweighed to give a tare weight. The solution was thoroughly stirred and the conductance obtained as described above.

The constant temperature bath used for these studies was an oil-filled recirculating bath. The temperature was regulated to ±0.02°C by a mercury-in-glass thermoregulator and its associated relay. The regulator activated a 250-w infrared heat lamp mounted above the bath, thereby avoiding thermal lags obtained with immersion heaters.

The temperature was measured with a Beckman thermometer calibrated in increments of 0.01°C. This

thermometer was calibrated using a laboratory platinum resistance thermometer which in turn had been calibrated against a National Bureau of Standards reference.

Chemicals.—The KCl was recrystallized J. T. Baker reagent grade assaying 99.7% KCl before recrystallization.

The $NaClO_3$ was J. T. Baker reagent grade assaying 100.0% $NaClO_3$.

The NaCl was Fisher ACS reagent grade.

All materials were dried at 110°-120°C under a pressure of 1-2 Torr for at least 24 hr prior to use. The chemicals were stored over P_4O_{10}. The conductivity water used for preparing all solutions was obtained by redistilling water in a quartz still.

Results

These runs were performed at 90.00° ± 0.02°C and 97.50° ± 0.02°C at several NaCl and $NaClO_3$ concentrations. Some effort to statistically balance these data points was tried, but complete balance was not possible because of solubility limits. The data points are given in Table I. There was randomization within a series to help remove bias. In the 90.0°C series, runs No. 5, 9, and 10 were replicated and gave an average conductance value of 0.44341 ± 0.00451 mho cm^{-1}. In the 97.5°C series, runs No. 14 and 15 were replicated and gave an average value of 0.48088 ± 0.00030 mho cm^{-1}.

Since our objective was to obtain the best empirical equation from our data and to obtain contour maps from these equations, many different models were tried. Acceptable models were subject to the following restrictions:

(*a*) A significant regression mean square[4]
(*b*) The two series of data had to be compatible indicating no temperature interaction[5]
(*c*) The R Square term should be close to 1 indicating that most of the data were included in the regression sum of squares[6]
(*d*) The standard error term should be small

The data were analyzed using regression analysis. In this technique, the parameters associated with a model equation containing one dependent and one or more independent variables per equation are estimated using a least-squares technique. Using these results, one estimates the random error associated with the response (standard error) and places confidence limits on the parameters.

Many models, from very simple models utilizing only linear concentration terms to complicated models using a combination of half power, linear, quadratic, logarithmic, and interaction terms, were tried. All calculations were performed on an IBM 360 or a time-sharing computer. All calculations have the concentrations in molal units and temperature in °C, either as original or coded data.

The simple models did not fulfill all of the above criteria and the complicated models did not improve the R^2 or reduce the standard error sufficiently to warrant their use. Therefore, only two models are described in this paper.

The first model equation was a full polynomial in the variables. In order to separate the quadratic effects from the linear effects, that is decrease the confounding, and at the same time improve the determinant of the correlation matrix, the data were coded. This involved transforming the coordinates of the system so the centroid of the data points approximately correspond to the origin of the transformed variables. The transformed model equation is given in Eq. [2].

$$K = 4.6028 \times 10^{-1} + 8.5861 \times 10^{-5} \cdot C_1 + 1.296 \times 10^{-6} \cdot C_1^2 - 8.7904 \times 10^{-5} \cdot C_2 - 5.5571 \times 10^{-8} \cdot C_2^2 - 6.7264 \times 10^{-7} \cdot C_1 \cdot C_2 + 4.1267 \times 10^{-3} \cdot T \quad [2]$$

where:

K = Specific conductance in mho cm^{-1}
T = [°C − 93.75°C]
C_1 = [NaCl concentration − 130 g/1000g H_2O]
C_2 = [$NaClO_3$ concentration − 870 g/1000g H_2O]

This model gave a statistically significant regression equation and the equation had a standard error of 4.66 x 10^{-3} mho cm^{-1}. The plot back is shown in Table II. It is observed that the maximum error is only slightly greater than 1%, with most of the errors less than 1%.

Contour maps of these data were obtained and the one for 97.5°C is shown in Fig. 1. The contour map for the 90.0°C is not shown; however, it has the same form except that the specific conductance values were smaller. Equation [2], when reduced to its canonical form, is the equation for a hyperbola with the center of the plateau at a coded NaCl concentration of −98 g/1000g H_2O and a coded $NaClO_3$ concentration of −200 g/1000g H_2O. The specific conductance at this point is calculated to be 0.44526. The experimental

[4] The preliminary data indicated that at least $NaClO_3$ concentration was significant in affecting specific conductance.
[5] The preliminary data indicated that specific conductance was linearly related to temperature.
[6] The R Square = Regression SS/Total SS.

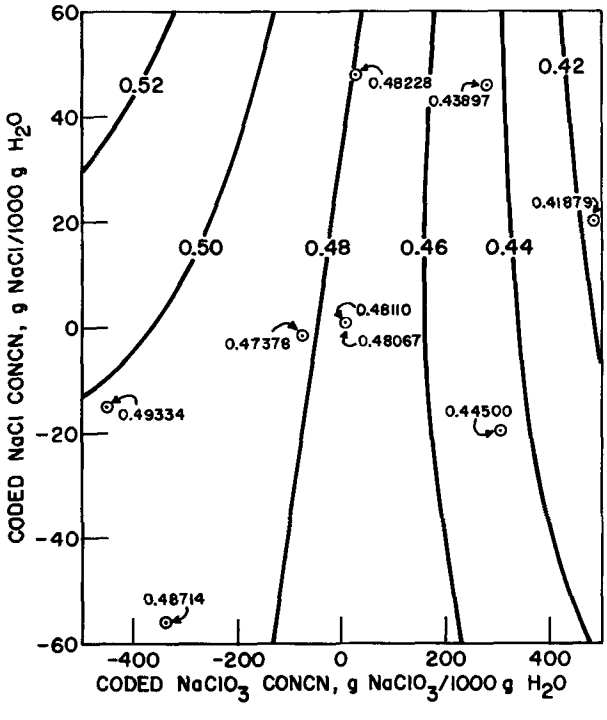

Fig. 1. Contour surface, using Eq. [2], for specific conductance as a function of NaCl and $NaClO_3$ concentration and a coded temperature of +3.75°C (97.5°C).

points are included in Fig. 1 and it is observed that the fit, in most cases, is quite good.

This model equation, unfortunately, has some inherent errors. The first is that it predicts continually increasing conductance values at: (*a*) high NaCl concentration and low $NaClO_3$ concentration, and (*b*) low NaCl and high $NaClO_3$ concentrations. We know this is incorrect because association at high concentrations should decrease the conductance. This equation also predicts continually decreasing values of conductance at high NaCl and $NaClO_3$ concentrations and at low NaCl and $NaClO_3$ concentrations, which would be expected. Solubility effects are ignored in this and subsequent analyses. Another difficulty with this equation is that the specific conductance should approach zero as the actual NaCl and $NaClO_3$ concentrations approach zero. This equation predicts a specific conductance of 0.281 mho cm^{-1} at zero salts concentrations.

Since the constant term and coded data in Eq. [2] prevented the specific conductance from approaching zero, the constant term in the second model was deleted. This change would force the equation to go through zero if the data were not coded.

A model that fits the theoretical equation a little better is given in Eq. [3] and [4]. Equation [3] gives the 90.0°C model

$$K = 4.0292 \times 10^{-2} \cdot C_1^{1/2} + 1.6577 \times 10^{-2} \cdot C_2^{1/2} - 1.3221 \times 10^{-3} \cdot C_1 - 3.2127 \times 10^{-4} \cdot C_2 - 4.2414 \times 10^{-7} \cdot C_1 \cdot C_2 \quad [3]$$

and Eq. [4] gives the 97.5°C model

$$K = 4.227 \times 10^{-2} \cdot C_1^{1/2} + 2.2105 \times 10^{-2} \cdot C_2^{1/2} - 1.8805 \times 10^{-3} \cdot C_1 - 4.7733 \times 10^{-4} \cdot C_2 + 7.1351 \times 10^{-8} \cdot C_1 \cdot C_2 \quad [4]$$

where

C_1 = NaCl concentration in g/1000g H_2O
C_2 = $NaClO_3$ concentration in g/1000g H_2O

The model represented by these equations gives a standard error of 5.55 x 10^{-3} mho cm^{-1} and a statistically significant regression equation. The plot back data are shown in Table II and it is observed that the fit is about as good as the fit obtained with Eq. [2]. This is very satisfying because we have forced this model to give a zero specific conductance at zero NaCl and $NaClO_3$ concentration.

A contour map of 97.5°C data is shown in Fig. 2. The contour map for the 90.0°C data is not shown, but will have the same general shape as Fig. 2. Equation [4] predicts a maximum specific conductance of 0.498 mho cm^{-1} at a NaCl concentration of 135 g/1000g H_2O and a $NaClO_3$ concentration of 565 g/1000g H_2O.

Equations [3] and [4] obviously predict that the specific conductance goes to zero as the salts concentrations go to zero. Also, as the salts concentrations get extremely large, the specific conductance goes to zero, and of course, goes negative beyond this point. This zero specific conductance value is well beyond solubility limits, however. These equations also predict that when one of the salts is constant at zero concentration and the other is steadily increased, the specific conductance passes through a maximum. This behavior would be expected experimentally.

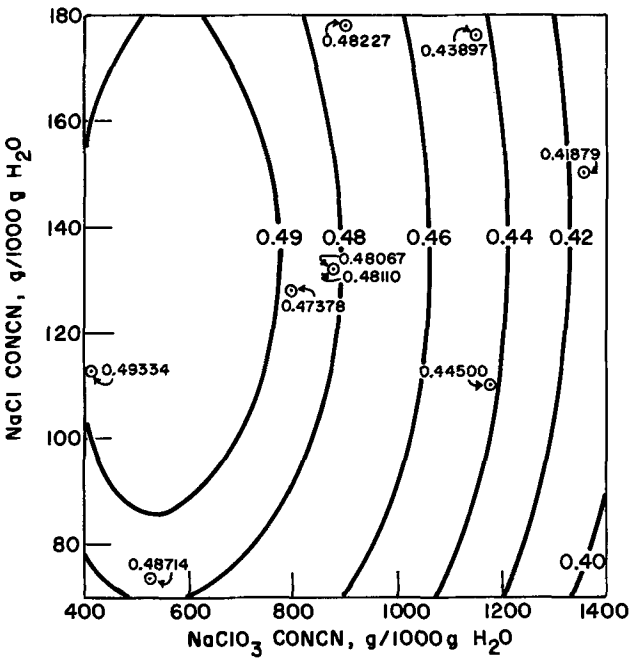

Fig. 2. Contour surface, using Eq. [4], for specific conductance as a function of NaCl and $NaClO_3$ concentration and a temperature of 97.50°C.

There is no justification for using our equations to predict specific conductance of solutions far removed from the range of our experimental data. The only reason for doing this was that we felt the best equation would be one that, at least approximately, predicted specific conductances throughout the entire soluble region, in addition to predicting accurately specific conductance within the range of experimental data. Then, if at some later date we or some other investigators extended the range of experimental data points, only minor changes in the parameters of Eq. [3] or [4] would be required to make it an acceptable equation.

Discussion

From a practical point of view, our equations allow one to calculate specific conductance for a wide range of temperatures and concentrations. Of all the empirical models tried, those given in Eq. [2], [3], or [4] predict the specific conductance best for the concentrations encompassed by the experimental data. Equation [3] or [4] appears to predict the specific conductance best for any NaCl or $NaClO_3$ concentration within the range of solubilities. Since we lack data for extended ranges of concentrations, the above is our best estimate of the contour surface. A major discrepancy between Eq. [2] and [4] is in the area of low $NaClO_3$-high NaCl concentration. In this area, Eq. [2] predicts a continuously increasing specific conductance, a condition we know cannot exist. On the other hand, Eq. [4] predicts an absolute maximum and its value is less than 0.50 mho cm^{-1}, a phenomenon we would, *a priori*, expect. Within the experimental concentration range, Eq. [2] yields a smaller standard deviation when experimental data points are compared to calculated data points; whereas, Eq. [4] appears to predict the expanded concentration range better. Our

data do not determine which equation describes the surface more accurately.

One major problem with all of these models is that the standard deviations of the regression coefficients are, in some cases, large when compared to the regression coefficient. In these cases, some of the terms in our various models may have been zero, or at least we could not have proven it to be non-zero statistically. As mentioned earlier, this could only be resolved by additional experimental work, specifically more replicated experiments.

In conclusion, we have used statistical methods to determine acceptable empirical equations for predicting specific conductance values for concentrated $NaClO_3$ and NaCl solutions at elevated temperatures. We have shown two equations; one gives accurate specific conductance values for a limited range of NaCl-$NaClO_3$ concentrations and the other gives less accurate specific conductance values over a more extended range of concentrations. It is hoped that additional experimental data can be generated so more correct and accurate equations may be found to describe this system.

Acknowledgments

The authors wish to express their gratitude to Mr. David Kirbawy who wrote the computer programs and obtained the statistical analysis of these data.

The Calculation of Cathode Current Efficiency and Metal Loss in a Small Alumina Reduction Cell

V. Anthony Cammarota, Jr.,* and David Schlain*

College Park Metallurgy Research Center, Bureau of Mines, United States Department of the Interior, College Park, Maryland

ABSTRACT

Experimental data from a small Hall cell were used to show the relationship between the cathode current efficiency and the carbon monoxide-carbon dioxide content of the anodic gas. The equation, $CE = 0.45\ (\%\ CO_2) + 47.6$, was developed and shown to give reliable estimates of aluminum production. In this equation, the volume per cent of carbon dioxide is corrected for the Boudouard reaction which varies in amount with anode type and operating conditions. A second and equally effective equation is, $CE =$ Anode $CE - EL$, where Anode CE is based on the oxygen in the anodic gases and EL is metal efficiency loss resulting from solubility and vaporization. The minimum value of EL is the solubility of metal in the electrolyte, which in the small cell was estimated to be 0.12%. Calculations made with experimental and literature data show that under industrial conditions the Pearson and Waddington equation gives good estimates of cathode current efficiency, because the lower efficiency indicated by the excess carbon monoxide from the Boudouard reaction compensates for the EL factor.

The Pearson and Waddington equation, developed as a means of relating the cathode current efficiency in commercial aluminum cells to the anodic gas composition (1), is

$$CE = 0.5\ (\%\ CO_2) + 50 \qquad [1]$$

Equation [1] is based on the following reasoning: (*a*) At the cathode, aluminum-bearing ions are reduced to metal with 100% current efficiency; an equivalent quantity of oxygen is liberated at the anode, and all of the oxygen combines with carbon to form CO_2. The over-all reaction is expressed by

$$2Al_2O_3 + 3C \rightarrow 4Al + 3CO_2 \qquad [2]$$

(*b*) All of the CO which appears in the anodic gas results from the reaction between various reduced species and CO_2. In terms of equivalent aluminum, this is

$$2Al + 3CO_2 \rightarrow Al_2O_3 + 3CO \qquad [3]$$

If there is no reoxidation of aluminum as expressed by reaction [3], then the anodic gas is 100% CO_2 and the cathode current efficiency, as calculated by means of Eq. [1], is 100%. If all the CO_2 reacts with reduced species, then the anodic gas is 100% CO and the current efficiency is 50%. In commercial practice, the gas contains 60-80% CO_2 which is equivalent to a current efficiency of 80-90%.

Work by other investigators led to the conclusion that the relationship between gas composition and cathode efficiency as expressed in Eq. [1] was valid but inaccurate because it did not account for certain other reactions which also occur. Beck (2), with an experimental alumina reduction cell, correlated gas analysis data with current efficiency. The results showed that more CO was generated than can be accounted for by reaction [3], and that this excess CO is the product of the reaction between carbon dioxide and carbon, commonly referred to as the Boudouard reaction

$$CO_2 + C \rightleftarrows 2CO \qquad [4]$$

The equilibrium is strongly displaced to the right at 950°-1000°C. Accordingly, Beck introduced the g term, the ratio of carbon in the gas to carbon theoretically

* Electrochemical Society Active Member.

Key words: Hall cell, anodic gas, alumina, reduction, current efficiency, metal loss, solubility, vaporization, specific carbon consumption.

oxidized to CO_2. Another correction term, Z, was added that accounts for the oxidation or loss of cathode products by reactions other than that with CO_2 and also for electronic conduction. The equation, as modified by Beck, becomes

$$CE = g[50 + 0.5\ (\%\ CO_2)] - Z \qquad [5]$$

This was later amended to include electronic conduction as a separate entity (3)

$$CE = \{g[50 + 0.5\ (\%\ CO_2)] - Z\}\left\{1 - \frac{Z'}{100}\right\} \qquad [6]$$

where Z' is the percentage of electronic loss.

Kostukov (4) derived the formula

$$CE = [50 + 0.5\ (N_{CO_2} + n_{CO_2})]n_c \qquad [7]$$

where N_{CO_2} is the volume per cent of CO_2 in the anodic gas, n_{CO_2} is the portion of CO_2 that reacts with hydrogen gas from the cracking of hydrocarbons in the baking zone of Soderberg anodes, and n_c is the Boudouard correction term.

An equation which corrects for air leakage was derived by Hamlin and Richards (5).

Saakyan (6) did not apply correction terms, and a plot of his cathode current efficiency *vs.* CO_2 content yielded the equation

$$CE = 0.22\ (\%\ CO_2) + 73 \qquad [8]$$

An excellent discussion on methods of determining current efficiency by the use of equations such as those given above and on variables affecting current efficiency was given by Thonstad (7).

One of the objectives of the work at the Bureau of Mines was to design a cell which would operate at high cathode current efficiencies for evaluating anode materials. During the course of this work, it was found that the data obtained in the small experimental cell would fit the Beck modification of the Pearson and Waddington equation if values for g and Z were first determined for that temperature and current density. With the use of g and Z, two general equations have been derived which give accurate predictions of cathode current efficiency. A third equation, similar to Saakyan's, was also derived, but it is less acceptable.

Experimental

The alumina reduction cell (Fig. 1) differed in construction and operation from a commercial cell—it was externally heated, electrolysis was conducted under an argon atmosphere so that there was no possibility for reaction of carbon with air, and there was no crust over the electrolyte and no layer of solid electrolyte next to the cell wall. There were no periodic additions of alumina during the operation of the cell.

The cell was located on a graphite support in a gas-tight 6-in. diameter vertical Inconel[1] tube through which the purified argon flowed. The argon entered the cell through orifice, H, or through the anode bus bar slip-hole and carried the gaseous reaction products out through the gas exit tube, B, to the gas collection bottles. The cell liner, L, cover, F, splash baffle, G, and anode sleeve, I, were machined from dense, premium-grade boron nitride, which is inert to the molten electrolyte. The splash baffle collected anode dust and prevented splashing into the gas exit tube. The anode sleeve ensured a specific exposed anode surface area. The anode, K, had an area of 3.80 in.^{2} and was placed 1.5 in. from the cathode and about 1 in. below the electrolyte surface. The cell, M, was machined from dense, fine grained graphite and was continuous with the 2-in. diameter cathode, N, which fitted snugly into the liner bottom. The cell voltage was measured between the anode potential rod, C, and the inside control thermocouple, O. The anode and cathode bus bars, D and P, extended to points near the electrode surfaces, and contained within them Chromel-Alumel thermocouples, E and Q.

[1] Reference to specific brands is made to facilitate understanding and does not imply endorsement of such items by the Bureau of Mines.

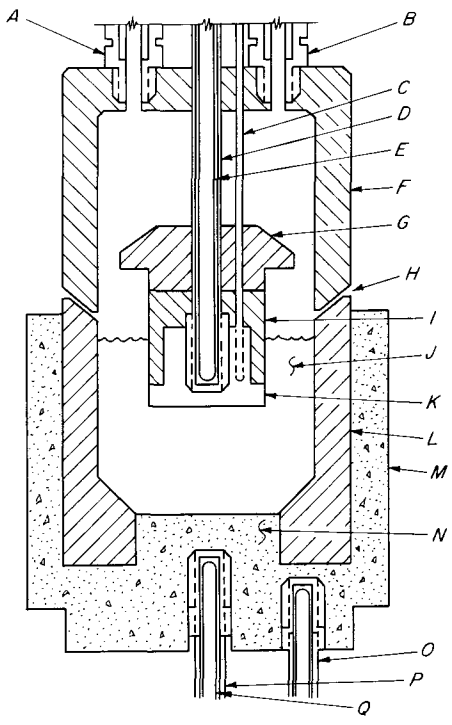

Fig. 1. Reduction cell assembly: A—manometer tube, B—gas exit tube, C—anode potential rod, D—anode bus bar, E—anode thermocouple, F—boron nitride cover, G—splash baffle, H—orifice, I—sleeve, J—electrolyte, K—anode, L—boron nitride crucible liner, M—graphite crucible, N—cathode, O—control thermocouple, P—cathode bus bar, Q—cathode thermocouple.

The anodes were either machined from large industrial anode blocks or were prepared from raw materials in the laboratory. The raw materials were either commercial coke and pitch or experimental coke and pitch binder made from lignite.

The furnace was heated by six silicon carbide resistance rods equally spaced around the tube. Temperatures were measured with Chromel-Alumel thermocouples and the anode and cathode temperatures were recorded to within 1°C on an adjustable zero-adjustable range recorder. The cell temperature was controlled through a proportional reset controller by the inside control-thermocouple and the furnace-thermocouple connected in parallel. The furnace was equipped with a fan to cool the furnace tube and cell quickly after a run. The electrolyte was normally frozen within 3-4 min, and the aluminum within 15-17 min after the run was completed. A copper coulometer with stainless steel cathodes was used to measure the quantity of electricity passing through the cell.

The electrolyte was composed of 85.6% natural Greenland cryolite, 7.4% reagent-grade CaF_2, and 7% anhydrous reagent-grade aluminum oxide. The cell, completely assembled in the furnace tube with 440-600g of charge, was dried overnight at 500°C under flowing argon. After the electrolyte had been brought to operating temperature, the anode was lowered to within 1.5 in. of the cathode. The anode and cathode temperatures were adjusted to within 1°C of electrolysis temperature before the beginning of each reduction.

Reductions were performed at anode current densities of 2.5, 5, and 10 A/in.^{2} (asi) and at 980° and 1000°C. The total current for each run was 38 A-hr. For the purpose of anodic gas collection and analysis, the electrolysis time was divided into six equal portions; gas composition was essentially constant in periods two through six. The cell gases first passed through scrubbers to remove water, dust, halides, and cyanides; then through CO_2 absorption bottles; and finally through copper(II) oxide at 600°C to oxidize the CO

to CO_2 and the H_2 to water. Immediately after the electrolysis ended, the cell was quickly fan-cooled. In this way, the quantities of CO_2, CO, and H_2 evolved during each electrolysis were determined.

After each run, the electrolyte, including the material machined from the cathode surface and from the liner, was analyzed for aluminum by the standard hydrogen evolution method. The anode and all carbonaceous material on the cell interior and electrolyte surface were analyzed for carbon to give a material balance check and anode consumption values.

Results

Initially, experiments were conducted in the alumina reduction cell with anodes cut from large industrial anodes in order to determine the effect of cell variables and the reproducibility of results. For a series of standard runs at 980°C and 5 asi anode current density, the cathode current efficiency based on aluminum produced was 81-83%. Anode current efficiency, based on the oxygen evolved as CO_2 and CO was 91-92%. The volume ratio of CO to CO_2 in the anodic gas was 0.389-0.419. Specific carbon consumption calculated from carbon in the anodic gas is a measure of the excess carbon oxidized over the theoretical amount, assuming 100% CO_2 formation at the anode. Specific carbon consumptions ranged from 1.06 to 1.08. These results showed that the cell could be operated at a high current efficiency with a variation of 1-2 percentage units.

The Pearson and Waddington equation is based on the assumption that the anode and cathode current efficiencies are equal. Therefore, a plot of anode current efficiency *vs.* % CO_2 in the anodic gas should give a straight line according to Eq. [1]. However, Fig. 2 shows that data obtained in the experimental cell do not form the straight line relationship unless the gas volume and the composition are corrected for the amount of CO_2 reacting with carbon to form CO as shown in reaction [4]. The correction factor for the Boudouard reaction is the g term in Beck's Eq. [5]. We therefore have the relationship

$$\text{Anode } CE = g[50 + 0.5\ (\%\ CO_2)] \qquad [9]$$

The g term is equal to the specific carbon consumption as defined above. Data obtained in the experimental cell at College Park show that the value of the specific carbon consumption is dependent on variables such as anode current density, temperature, the raw materials, and anode manufacturing processes. Some typical values associated with electrolysis conditions or anode type are shown in Table I.

In order to obtain data for a cathode current efficiency equation, electrolyses were conducted under standard conditions at 980° and 1000°C and at 5 and 10 asi. The cathode current efficiencies from these runs were plotted (Fig. 3) against the volume per cent of CO_2 after correcting it for the Boudouard reaction.

Table I. Effect of anode material and electrolysis conditions on specific carbon consumption

Anode type	Electrolysis °C	Electrolysis asi	Specific carbon consumption (g)
Cut from industrial anode blocks	980	5	1.06
Laboratory, commercial coke and binder	980	2.5	1.13
	980	5	1.11
	980	10	1.06
	1000	2.5	1.20
	1000	5	1.11
	1000	10	1.11
Laboratory, commercial coke and lignite binder	1000	5	1.19

1000°C	13.4	6.5	5.4

(a) Based on one electrolysis.

The points fall along a line which is almost parallel to the Pearson and Waddington line as obtained from Eq. [1], but 6-7 current efficiency units below it. This difference in cathode current efficiency is equal to the metal loss by mechanisms other than reaction with CO_2, and it will be called *EL*. An attempt will be made to break *EL* into component losses. The Beck equation, written with *EL* substituted for *Z*, is

$$\text{Cathode } CE = g[50 + 0.5\ (\%\ CO_2)] - EL \qquad [10]$$

Substituting Anode *CE* according to Eq. [9]

$$\text{Cathode } CE = \text{Anode } CE - EL \qquad [11]$$

Data obtained earlier in electrolyses done at several temperatures and current densities and with an average cell pressure differential of 15 cm water or less were used to evaluate the *EL* term. Since a total of 38 A-hr was used in each experiment, electrolysis times were shorter at the higher current densities. The average values of *EL* are given in Table II. The term *EL* decreases with increasing current density because there is less vaporization during the shorter electrolysis times. The *EL* values at electrolyte temperatures of 980° and 1000°C are substantially the same. It was assumed that in this cell there is no electronic conduction and hence no correction is necessary.

With these predetermined *EL* values for the electrolysis conditions used, it is possible to use Eq. [11]

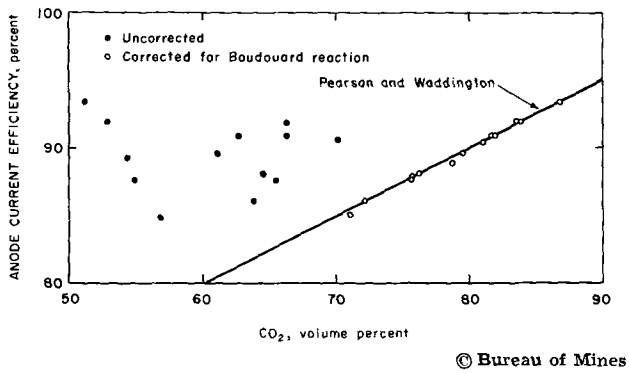

Fig. 2. Anode current efficiency as a function of carbon dioxide content of anodic gas.

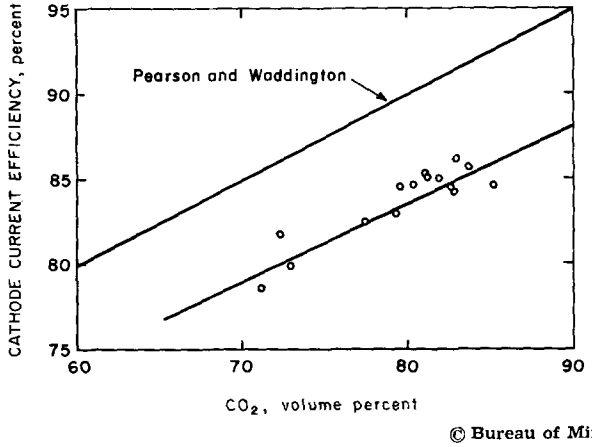

Fig. 3. Cathode current efficiency as a function of corrected volume per cent carbon dioxide.

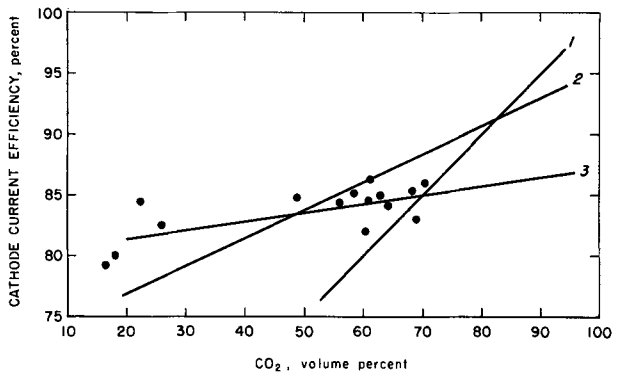

Fig. 4. Cathode current efficiency as a function of uncorrected volume per cent of carbon dioxide: 1—Pearson and Waddington, 2—Saakyan, 3—Bureau of Mines Eq. [13].

to calculate cathode current efficiencies and to compare them with those based on the aluminum actually produced. This was done with a set of experiments performed in the small cell. The data given in Table III show very good agreement between experimental and calculated cathode current efficiencies, the average difference being only 1.0 unit.

A least-squares fit of the cathode current efficiencies and corrected volume per cents of CO_2 given in Fig. 3 results in the general equation

$$CE = 0.45\ (\%\ CO_2) + 47.6 \qquad [12]$$

The data used in Fig. 3 were replotted in Fig. 4 (line 3) except that the values for per cent CO_2 were not corrected for the Boudouard reaction. In this case, the points fall along a line for which the equation is

$$CE = 0.076\ (\%\ CO_2) + 79.9 \qquad [13]$$

The line for Eq. [13] varies greatly from the Pearson and Waddington line because in the experiments on which Eq. [13] is based the specific carbon consumption was 1.07-1.50, whereas the Pearson and Waddington equation is based on the assumption that the specific carbon consumption is 1.00. Equation [13] is more similar to Saakyan's Eq. [8] which is also based on experimental data but, obviously, with different specific carbon consumptions. It is apparent that Eq. [13] is insensitive to small changes in the CO_2 content of the gas.

The cathode current efficiencies were calculated for the experiments in Table III by using Eq. [12] and [13], and compared in Table IV with the experimental values and with those obtained by Eq. [11]. Efficiencies calculated by Eq. [11] agree well with those calculated from Eq. [12]. Equation [13] often results in large deviations in current efficiency because it is relatively insensitive to changes in the CO_2 concentration in the gases, and the gas composition is not indicative of cathode current efficiency if the specific carbon consumption is high.

Figure 5 compares the manner in which Eq. [12] and [13] reflect the change in current efficiency with time during a single experiment. The data are for a 3-hr experiment at 980°C and 5 asi using an anode cut from a large industrial anode. The insensitivity of Eq. [13] to changes in anodic gas composition is well illustrated by its linearity almost from the beginning. On the other hand, Eq. [12] shows a gradual increase in efficiency for about the first hour, after which a steady state is reached at 85-87% efficiency. During this time, the specific carbon consumption is increasing from 1.02 to 1.10, where it remains for the duration of the run. Current efficiency based on oxygen recovered increases from 72 to 92%. This means that the initially high CO content of the gas is produced from reoxidation of aluminum and not from the Boudouard reaction.

A possible explanation for this high initial rate of oxidation is that, at the beginning of an experiment in the small cell, there is no pool of aluminum on the graphite cathode. Initially, the aluminum product is in the form of many tiny globules, or a mist, and has not yet coagulated into larger globules with less surface area. Because of bath convection caused by the anode heating about 10°C more than the cathode, there is an excessive amount of aluminum being carried into the vicinity of the anode where reoxidation occurs. In almost every electrolysis conducted, this pattern is evident.

An attempt was made to improve the estimation of efficiency by splitting *EL* into a solubility component and a vaporization component. The solubility of aluminum has been reported at 0.1% (11). Taking the nominal value of 0.1%, the amount of aluminum dissolved was calculated for each of a series of runs, at 1000°C and 5 asi, in which the cell pressure differential varied between 6 and 35 cm water. The calculated soluble aluminum in each electrolyte was divided by the theoretical aluminum produced and expressed in current efficiency units. This solubility component was subtracted from *EL* in each of these runs to give the vaporization component, which was plotted *vs.* average cell pressure differential in Fig. 6. In the range of 8-12 cm water, where most of the electrolyses for the data in Table IV were conducted, the vaporization varies between 1 and 4, but most of the time is in the 2-3

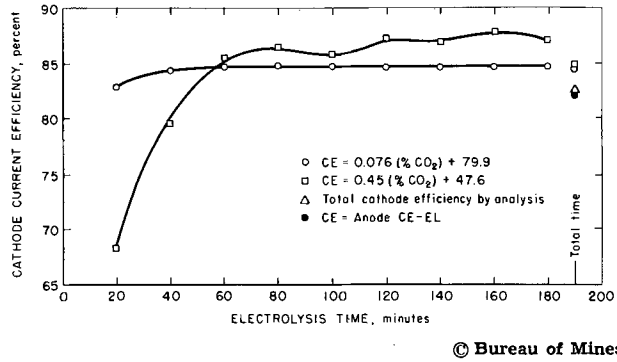

Fig. 5. Change in calculated cathode current efficiency with time for an extended electrolysis at 980°C, 5 asi.

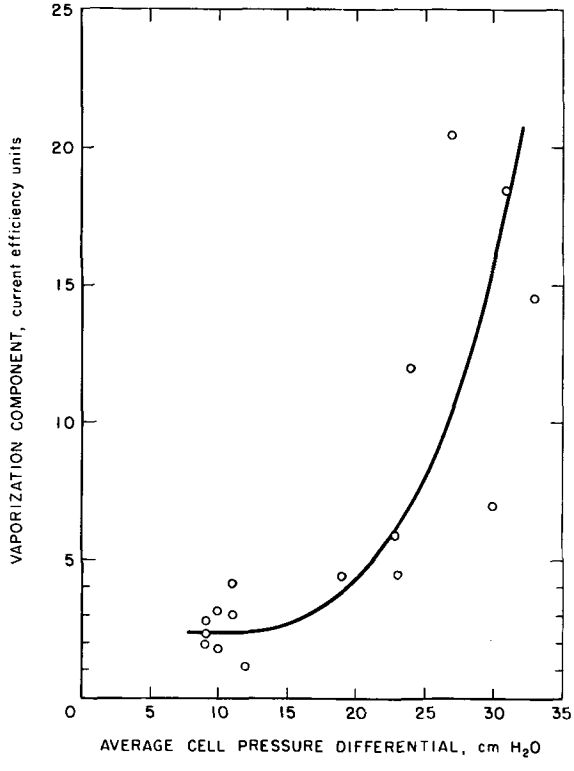

Fig. 6. Vaporization component as a function of cell pressure differential at 1000°C, 5 asi.

range. In subsequent electrolyses, the value for the vaporization component was taken as 2.5 at 1000°C and 5 asi for pressure differentials up to 15 cm water. The solubility component, estimated as described above, varied from 3.9 to 4.6 current efficiency units. The individual values for *EL*, calculated by adding vaporization and solubility components, varied from 6.4 to 7.1. The *EL* value for experiments at 1000°C and 5 asi is 6.5 current efficiency units (Table III). Hence, the use of *EL* values obtained from estimates of solubility and vaporization would not significantly improve the calculation of current efficiency. These components are not known accurately enough and, in addition, pressure fluctuations affect vaporization enough so that it overshadows any small changes in solubility.

Discussion

Although the Pearson and Waddington equation does not contain any of the correction terms used in the more recent equations, it has been found to give reliable current efficiency values under normal commercial operating conditions; Bureau of Mines' work with the small experimental cell has verified this. The corrections for vaporization and solubility on one hand and for the Boudouard reaction on the other are opposite in sign and have approximately the same value in the small cell under the usual operating conditions.

The manner in which the corrections *g* and *EL* in Eq. [10] may offset each other to make the Pearson and Waddington equation a reasonably good approximation is illustrated with a set of data obtained in the small cell. Considering that, in the Boudouard reaction the volume of CO produced is twice that of the CO_2 that reacts, the CO_2 content of the anodic gas can be corrected for the Boudouard reaction in the following way

$$\% CO_{2c} = \frac{CO_{2a} + CO_{2b}}{CO_{2a} + CO_a - CO_{2b}} \times 100 \qquad [14]$$

where CO_{2c} is the corrected volume, CO_{2a} and CO_a are experimentally determined, and CO_{2b} is involved in the Boudouard reaction. The results of these calculations are shown in Table V. The last column is the

Table V. Relative magnitude of corrections

Experimental cathode current efficiency, %	*g*	% CO_{2a}	% CO_{2c}	Corrections in Eq. [10], per cent cathode CE: *EL*	½(% CO_{2c}-% CO_{2a})
82.3	1.13	57.7	78.4	6.9	10.4

83.0	1.06	69.0	79.3	6.7	5.2

apparent decrease in cathode current efficiency resulting from the Boudouard reaction, on the basis of one-half unit change in aluminum current efficiency per one unit change in volume per cent of CO_2 according to Pearson and Waddington.

The relationship between apparent decrease in cathode current efficiency, as indicated by the change in gas composition, and specific carbon consumption is shown in Fig. 7. Also plotted, as the right-hand ordinate, is the *EL* term for each of these electrolyses. The value of *EL* is usually 4-7 units. The intersection of this range with the apparent decrease in cathode current efficiency from the Boudouard reaction gives a value for *g* of 1.04-1.08. This means that, in electrolyses is which *g* ranges from 1.04 to 1.08, the Pearson and Waddington equation should give reliable results because the Boudouard reaction and *EL* corrections will offset each other.

In Fig. 8, the experimental cathode current efficiency is plotted *vs.* the experimental CO_2 content. For values

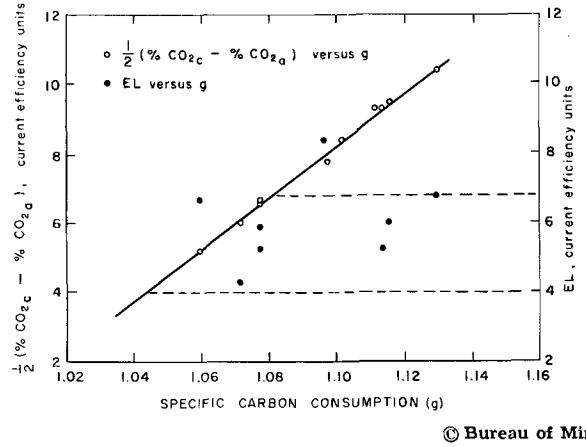

Fig. 7. Relationship between errors in Pearson and Waddington equation introduced by Boudouard reaction and by losses of metal.

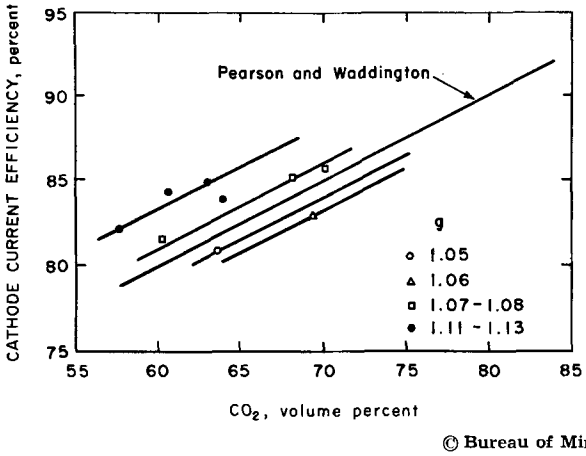

Fig. 8. Experimental data showing ranges of specific carbon consumption in which the Pearson and Waddington equation gives good results. (The volume per cent of CO_2 is uncorrected.)

of g between 1.05-1.08, the actual current efficiency is within 1.5-2 percentage units of the value calculated by the Pearson and Waddington equation. As g increased to 1.11-1.13, the deviation became greater. The EL value for all of these experiments was about 6-7.

An examination of the literature also supports these findings. Beck (2) found that for g equal to 1.04-1.07 there was good agreement between the experimental current efficiencies and those calculated from the Pearson and Waddington equation. As g became less than 1.04, the experimental value was significantly below the calculated one. This agrees with the conclusions derived from Fig. 7. When g is less than 1.04, the amount of Boudouard reaction corresponds to an EL value of less than 4, so that aluminum loss is not sufficiently accounted for, and the calculated efficiency is greater than the actual one.

An analysis was also made of the data presented by Saakyan (6). These data show specific carbon consumption values of 1.05-1.08 that correspond to his correction factor, K, of 4-6. Subtraction of a nominal value of 5.0 from Saakyan's current efficiency yields the plot shown in Fig. 9. Very good agreement occurs when the specific carbon consumption is 1.05-1.08. The deviations from Pearson and Waddington with changes in specific carbon consumption are well illustrated. Again it is shown that the Boudouard reaction fortuitously accounts for metal loss in the cell. It is interesting to note that our value for metal loss varies between 6 and 7, which is slightly above that indicated in Saakyan's work and the value of 5 taken by Beck.

The value of the specific carbon consumption is significant in that it serves as an indicator of anode reactivity. For example, the data in Table I show that the coke which results from lignite pitch is more reactive than that which comes from coal-tar pitch. It seems specific carbon consumption or g can be used as an index number to signify relative anode quality.

An attempt was made to correlate the experimental values of EL with those that could be calculated from physical data available in the literature. The reactions that may take place are given below

$$Na_3AlF_6 \rightleftarrows 2NaF + NaAlF_4 \quad [15]$$

$$5\,NaAlF_4 \rightarrow Na_5Al_3F_{14} + 2AlF_3 \quad [16]$$

$$6NaF + Al \rightarrow 3Na + Na_3AlF_6 \quad [17]$$

$$3Na + 2AlF_3 \rightarrow Al + Na_3AlF_6 \quad [18]$$

Reaction [15] represents the dissociation of cryolite at 1000°C (8). The volatile sodium tetrafluoroaluminate, upon slow cooling in the gas exit tube, forms chiolite and aluminum (III) fluoride as in reaction [16] (9). As aluminum is formed in the electrolyte, it can react according to Eq. [17] with sodium fluoride to form sodium vapor (9). This sodium vapor reacts [18] at about 600°C with aluminum (III) fluoride in the gas exit tube to form aluminum and cryolite (9).

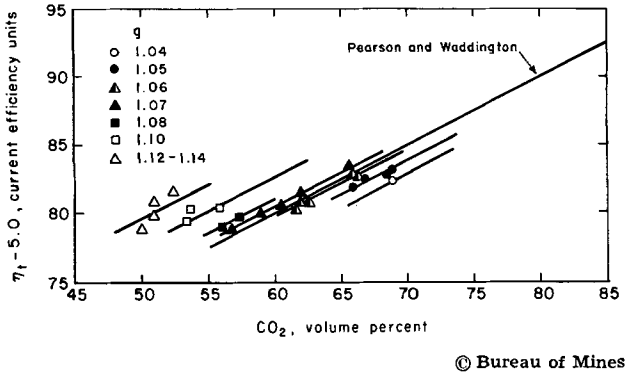

Fig. 9. Data taken from Saakyan (6) to show values of g for which Pearson and Waddington equation gives good results. (Volume per cent of carbon dioxide is uncorrected.)

Thus, aluminum is lost from the cell. This may also explain why sodium is not detected when the system is opened.

The experimental values for EL in Table III were compared to calculated values based on the solubility of aluminum in the melt and on vaporization losses resulting from reactions summarized in reactions [15] through [18]. First, an estimate was made of aluminum lost in the small cell by using electrolyses conducted for 1 hr. In 1-hr, vaporization loss would be at a minimum. The total metal loss was the difference between aluminum theoretically produced and the sum of aluminum actually produced and aluminum lost by reoxidation. The metal lost in six experiments at 1000° or 980°C and at 10 asi was an average of 0.15% of the weight of the electrolyte. Second, an estimate was made of vaporization losses. The data for vapor pressure of sodium over cryolite-aluminum melts is given by Stokes (10). Taking the partial pressure to be about 20 Torr at 1000°C, the number of moles of sodium (n_{Na}) is

$$n_{Na} = \frac{P_{Na}}{760} = 2.63 \times 10^{-2}\ \text{moles/molar volume} \quad [19]$$

This corresponds to a sodium loss of 0.33 g/hr of electrolysis, which is equivalent to about 0.13g aluminum. Expressed as current efficiency units, this is 1 unit lost per hour of electrolysis. Subtraction of 0.13g aluminum equivalent from the total of 0.15% loss (0.68g) gave an estimated solubility of 0.12%. This value is in good agreement with solubilities reported in the literature (11, 12).

Average EL values were calculated on the basis of a vaporization loss of one current efficiency unit per hour and a solubility of 0.12%. These values are compared with experimental values for EL in Table VI.

The agreement between calculated and experimental EL values is excellent for 2-hr electrolyses, but poor for the 4-hr run. In the latter case, volatilization may be greater than expected because of longer time at slowly changing electrolyte composition. For the 1-hr electrolysis, only one run was available at low pressure differential.

Conclusions

Data obtained in a small batch-type, externally heated Hall cell show that cathode current efficiency equations based on CO_2 content of the anodic gas are valid, provided corrections are made for the reaction of CO_2 and carbon to form CO, and for metal losses. Two equations provide accurate estimates of aluminum production

$$\text{Cathode } CE = \text{Anode } CE - EL$$

where Anode $CE = g\,[50 + 0.5\ (\%\ CO_2)]$, and

$$\text{Cathode } CE = 0.45\ (\%\ CO_2) + 47.6$$

where % CO_2 is corrected for the Boudouard reaction. The value of EL and the constants in the second equation vary somewhat with current density and temperature. EL is primarily a correction for losses resulting from solubility of aluminum in the electrolyte and for vaporization of metal values.

The specific carbon consumption (g) is a measure of anode reactivity.

Table VI. Comparison of experimental and calculated values of EL

Temp, °C	Time, hr	EL	
		Calculated	Experimental
980	1	5.6	6.7[a]
980	2	6.8	7.1
1000	2	6.6	6.5
1000	4	8.5	13.4

[a] One electrolysis.

The Pearson and Waddington equation gives good estimates of cathode current efficiency in commercial cells because under normal operating conditions the metal losses resulting from solubility and vaporization, which amount to 4-7 cathode current efficiency units, are fortuitously balanced by the results of the Boudouard reaction.

The estimate of volatilized and soluble aluminum derived for the small cell are in good agreement with physical data in the literature. These estimates together with the estimate for aluminum loss by reaction with CO_2 seem to account for all losses in the small cell.

On the Oxidation-Reduction Mechanism of the Cadmium Metal-Cadmium Hydroxide Electrode

Yutaka Okinaka*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Electrochemical oxidation-reduction processes of the $Cd/Cd(OH)_2$ electrode in concentrated alkaline solutions were investigated by using a rotating ring-disk electrode as well as a stationary electrode. Results support the mechanism that the anodic oxidation of Cd to $Cd(OH)_2$ in the active potential range proceeds entirely through the dissolution-precipitation sequence, while the cathodic reduction of $Cd(OH)_2$ takes place both through the solution phase and by a direct solid-state mechanism.

The mechanism of anodic oxidation of cadmium metal and cathodic reduction of the oxidation product in strongly alkaline solutions is of interest in understanding the behavior of the cadmium electrode in nickel-cadmium batteries. In spite of much effort in recent years by a number of investigators, the reaction mechanism is still incompletely understood. For example, two radically different mechanisms have been proposed in the literature for the anodic reaction: the dissolution-precipitation mechanism (1-6) and the solid-state oxidation mechanism involving ionic transport through the $Cd(OH)_2$ film (7-9). The formation of CdO has been the subject of discussion of many investigators. Croft (7), Falk (10), and Armstrong *et al.* (11) found no evidence of CdO formation, whereas Huber (2), Huber and Stucki (2a), Breiter and Weininger (12), and Breiter and Vedder (13) reported experimental results indicating the formation of CdO. It has been suggested that CdO is formed as the primary product before its conversion to $Cd(OH)_2$ (3, 3a, 5) or as a result of a secondary reaction that occurs after $Cd(OH)_2$ is formed (12, 14). Most recently, Devanathan and Lakshmanan (6) proposed a mechanism in which the CdO formation occurs in parallel with the formation of $Cd(OH)_2$. Rozentsveig *et al.* (1), Huber (2), Lake and Casey (3, 3a), Breiter and Weininger (12), and Devanathan and Lakshmanan (6) suggested that it is the CdO layer, and not $Cd(OH)_2$, that causes the passivation which limits the extent of anodic oxidation of cadmium metal. Milner and Thomas (15) state that even if CdO does form, it will not play any significant role under the normal operating conditions of nickel-cadmium batteries, because they are not ordinarily negative-limited and passivation ought not to occur. It is recognized, however, that under certain conditions the cell does become negative-limited on discharge, even when significant excess of charged cadmium is present. Thus, understanding the cause of the passivation of cadmium metal is of great practical interest. The mechanism of the cathodic reduction of $Cd(OH)_2$ has been studied to a much lesser degree than its anodic counterpart (7, 12, 13, 16) in spite of its importance in relation to the charging process of the battery cadmium electrode. Croft (7) and Rubin (16) believe that the cathodic process occurs by a solid-state mechanism without involving the solution phase.

The present investigation using a rotating ring-disk electrode was undertaken in order to obtain information on the role of soluble cadmium species during the anodic as well as the cathodic process. The technique is now well known as a powerful method for detecting and determining the concentration of soluble intermediate species formed at an electrode surface (17).

Experimental

Both the disk and ring were made of 99.99% pure cadmium metal. Epoxy resin was used as the insulating material. The electrode had the following dimensions: r_1 (disk radius) = 4.7 mm, r_2 (r_1 plus the thickness of insulating ring) = 5.1 mm, r_3 (r_2 plus the thickness of cadmium ring) = 5.7 mm, and r_4 (radius to the outer edge) = 6.4 mm. Before each experiment, the surface of the electrode was polished mechanically with 4/0 emery paper wetted with methanol, cleaned with methanol and water, and cathodized in 6.9M KOH at 0.5 mA for at least 1 hr to obtain an oxide-free surface. The electrode was kept immersed in deaerated water when not in use. The speed of rotation was 2100 rpm unless otherwise stated.

A half-charged cadmium electrode of sintered-plate-type served as the reference electrode to control and measure the potential of the disk electrode. It was placed in a compartment which was connected to the main part of the cell through a salt bridge with a capillary tip. A platinum coil served as the counterelectrode. A second, half-charged cadmium electrode placed in a compartment separated by a fine sintered glass disk served as the reference-counterelectrode for the ring electrode circuit. A constant voltage of -0.2V was applied to the ring electrode against the reference-counterelectrode from a battery-voltage divider arrangement. Because the ring current was always small (< 0.3 mA) as compared to the charge

Key words: cadmium, cadmium hydroxide, anodic oxidation, cathodic reduction, anodic film, rotating ring-disk electrode.

capacity of the reference-counterelectrode (200 mA·hr), the polarization of the latter was negligible. By taking current-potential curves in 6.9M KOH saturated with $Cd(OH)_2$, it was confirmed that the potential of −0.2V lies well within the mass transfer limiting current region for the reduction of dissolved cadmium species.

The stationary cadmium electrode used in the experiments for the calculation of ionic conductivity of the anodic film was constructed by press-fitting a pure cadmium rod in Teflon. The electrode surface was polished first mechanically with 4/0 emery paper and then chemically in concentrated nitric acid and in a 1:1 mixture of concentrated phosphoric acid and 30% hydrogen peroxide. The apparent surface area of the electrode was 0.317 cm^2.

A Wenking 64TR potentiostat with an MP64 motor potentiometer was used in both galvanostatic and controlled-potential experiments. Potassium hydroxide was of analytical reagent grade (Baker, low chloride and low iron) and used without further purification. The solution was deaerated by bubbling purified nitrogen. All experiments were conducted at room temperature.

Results and Discussion

Potential scan experiment.—Anodic process.—The disk potential was scanned at a speed of 100 mV/min first in the anodic direction to various potentials and then in the cathodic direction, while currents at both the disk and the ring electrode were being recorded. In the anodic scan (Fig. 1, solid line) the disk current (i_{disk}) — disk potential (E_{disk}) curve exhibited a sharp peak due to the active oxidation of the disk followed by a passivation process. The corresponding ring current (i_{ring}) — E_{disk} curve also showed a sharp maximum at the disk potential where i_{disk} became maximum. The magnitude of i_{ring} at the peak was equal to 230 μA in this experiment. The concentration of dissolved cadmium at the disk surface, c^o, can be calculated from this value with the aid of the following equation (17)

$$c^o = \frac{i_{ring}\,\delta}{nFAND} \qquad [1]$$

where

$$\delta = 1.61\left(\frac{D}{\nu}\right)^{1/3}\sqrt{\frac{\nu}{\omega}} \qquad [2]$$

and A is the area of the disk electrode in cm^2, N the collection efficiency (17, 18), D the diffusion coefficient of the dissolved cadmium species in $cm^2 \cdot sec^{-1}$, δ the diffusion layer thickness in cm, ν the kinematic viscosity of the solution in $cm^2 \cdot sec^{-1}$, and ω the angular velocity of rotation of the electrode. By using the numerical values $n = 2$, $\mathbf{F} = 96500$ coulombs, $A = 0.677$ cm^2, $N = 0.311$ [calculated from electrode geometry with the aid of the Albery-Bruckenstein Eq. (6.1) in ref. (18)], $D = 0.51 \times 10^{-5}$ $cm^2 \cdot sec^{-1}$ for $Cd(OH)_3^-$ in 6.9M KOH (19), $\nu = 1.67 \times 10^{-2}$ $cm^2 \cdot sec^{-1}$ [calculated from density 1.2854 and viscosity 2.147 centipoise (15)], and $\omega = 219.8$ sec^{-1} (2100 rpm), the value of c^o at the peak potential was calculated to be equal to 1.06×10^{-3}M. The equilibrium solubility of cadmium hydroxide in 6.9M KOH at 25°C determined by various investigators (19-23) ranges from 1.2 to 1.6×10^{-4}M. Thus, the concentration of dissolved cadmium species at the disk surface at the peak potential was about 7 to 9 times larger than the equilibrium solubility of cadmium hydroxide. Such a large degree of supersaturation can be understood only in terms of the dissolution-precipitation mechanism, in which cadmium metal first dissolves anodically and the dissolved species subsequently form a precipitate of $Cd(OH)_2$ on the metal surface. Supersaturation is required to form nuclei in the initial stages of precipitation.

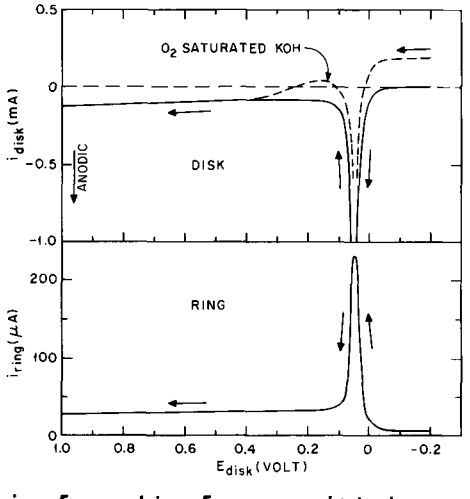

Fig. 1. i_{disk}-E_{disk} and i_{ring}-E_{disk} curves obtained on anodic scan of E_{disk} at 100 mV/min in 6.9M KOH. Speed of rotation, 2100 rpm. Broken line, same electrolyte saturated with oxygen.

The cause of passivation was the subject of discussion of the papers by Rozentsveig *et al.* (1), Lake and Casey (3, 3a), Breiter and Weininger (12), and Devanathan and Lakshmanan (6). These authors postulated that passivation is due to formation of a thin continuous film of CdO, although the different groups of authors suggested different mechanisms for the film formation. The ring-disk electrode experiment does not provide any conclusive information on the mechanism of passivation. However, there are evidences which show that passivation is not simply due to complete coverage of the cadmium surface with $Cd(OH)_2$ crystals. First, a simple microscopic observation of the passivated surface shows the coverage with crystalline products to be incomplete. Second, the reduction of oxygen continues after passivation up to about +0.4V as shown by the dotted line in Fig. 1. This curve was obtained in 6.9M KOH saturated with oxygen at atmospheric pressure. The rate of potential scan had no effect on the oxygen current between 100 and 1 mV/min. If the cadmium metal surface were completely covered with an insulating layer of $Cd(OH)_2$ on passivation, no oxygen reduction would continue to such a positive potential. The result supports the view that the passivation is due to the formation of a thin film of CdO, which appears to have a relatively high electronic conductivity under the present conditions of film formation. [Conductivity values ranging from 100 to 500 $ohm^{-1} \cdot cm^{-1}$ have been reported for bulk CdO (24).] In agreement with Breiter and Weininger (12), the structure of the entire film may be pictured in such a way that a number of $Cd(OH)_2$ crystals are imbedded in an extremely thin passivating layer of CdO. As will be discussed later, this passivating layer appears to be insoluble or only very slowly soluble in alkali, whereas $Cd(OH)_2$ in the film is soluble in the electrolyte to a significant extent.

Figure 1 also shows that the disk current after passivation increases slightly as the potential becomes more positive than about +0.4V and approaches +1.0V, while the ring current in the corresponding potential range decreased slightly. It is considered that the disk current in the passive potential range consists of two components: the current necessary for replenishment of the dissolved part of the $Cd(OH)_2$ crystals by further oxidation of the metal, and that for the growth of CdO. The former component is expected to be determined by either the equilibrium solubility or the rate of chemical dissolution of the $Cd(OH)_2$ crystals and hence independent of potential, while the latter component may be potential-dependent. The results of infrared spectroscopic investigation recently reported by Breiter and Vedder (13) indicate that an increasing amount of CdO is formed at more anodic potentials. On the other hand, the magnitude of i_{ring} after passivation of the disk (about 30 μA at +0.2V) corresponds to a concentration of the dissolved cad-

mium species at the disk surface equal to 1.4 x 10^{-4}M, as calculated from Eq. [1]. This concentration agrees with the equilibrium solubility of $Cd(OH)_2$ under the conditions of the present experiment. The observed decrease in i_{ring} with E_{disk} apparently indicates a slight decrease in the rate of chemical dissolution of the film during the potential scan.

Cathodic process—The $i_{disk} - E_{disk}$ curves 1 and 2 in Fig. 2 were obtained by reversing the direction of potential sweep immediately after terminating the anodic sweep (Fig. 1) at +1.0 and at +0.2V, respectively. In curve 1 a prewave is noted prior to the large cathodic peak. This prewave was first reported by Breiter and Weininger (12) in more dilute KOH solutions (0.2 and 1M). In 6.9M KOH we observed that the prewave appeared only after the sweep reversal was made at a potential more positive than about +0.4V. In curve 2, which was obtained by reversing the potential sweep at +0.2V, the prewave was totally absent, while a very small prewave was visible when the potential scan was reversed at +0.5V (not shown in Fig. 2). Breiter and Weininger attributed the prewave to the reduction of CdO on the basis that the reduction of $Cd(OH)_2$ is not thermodynamically possible at about +0.04V where the prewave begins to appear. It is of interest to note in Fig. 2 that the ring current exhibited no marked change in the potential range of the prewave, while it decreased rapidly as the disk current increased further toward the peak. This result clearly shows that the reduction of the substance yielding the prewave, presumably CdO, does not proceed through the formation of soluble intermediates. In view of the relatively high electronic conductivity, it is not surprising that CdO is reduced directly without an intermediate dissolution step. It is considered that the reduction of an electronic conductor can take place on its surface, and, when the molar volume of the reduction product is smaller than that of the oxidized material, it can continue to completion with all ionic motions in the solution phase. Thus, the reduction of CdO to Cd does not require ionic conductivity of CdO. The fact that a larger prewave appears on reversal of potential sweep at a more positive potential is consistent with Breiter and Vedder's finding (13) that a greater amount of CdO is formed at a higher anodic potential.

That the reduction of $Cd(OH)_2$ takes place, at least partially, through the formation of a soluble intermediate is indicated by the rapid decrease in i_{ring} starting at about 0 volt and the increase in i_{ring} observed when the disk circuit was opened after the termination of potential sweep at −0.2V (see Fig. 2). This subject will be discussed further in subsequent sections.

Galvanostatic experiment.—Anodic process.—When the disk was made an anode at a constant current, the ring current rapidly increased to a maximum and then decreased gradually until the disk passivated. As an example, the result obtained at i_{disk} = 0.5 mA is shown in Fig. 3. The disk was at open circuit before application of the current. The magnitude of i_{ring} during the active oxidation of the disk (up to 8 min, and $E_{disk} < 60$ mV) was always greater than 40 μA, which corresponds to a concentration of soluble cadmium species at the disk surface greater than 1.8 x 10^{-4}M. Comparison of this value with the equilibrium solubility 1.2 to 1.6 x 10^{-4}M shows that supersaturation persisted during the entire period of active anodic oxidation of the disk. The result clearly demonstrates that the dissolution-precipitation mechanism was operative during the galvanostatic anodic oxidation. The decrease in i_{ring} with time shows that the concentration of dissolved cadmium at the disk surface decreases as the latter becomes covered with $Cd(OH)_2$. This may be anticipated for two reasons. First, the ring current is proportional to the "average" concentration of the dissolved species over the disk surface. Hence, even if the dissolution reaction and the precipitation reaction continue at a constant rate, the uncovered area of the disk surface at which the dissolution reaction takes place should decrease with time, resulting in a decrease in the "average" concentration. Second, as the disk surface becomes covered to an increasing extent, more sites for precipitation become available; thus, the rate of precipitation of $Cd(OH)_2$ on the disk surface is expected to increase with time. This also should result in a decrease in the surface concentration of the dissolved species.

Cathodic process.—After the anodic polarization at 0.5 mA, the disk was open-circuited and then cathodically polarized at the same current. During the cathodic polarization, the disk current was interrupted a few times to see the effect of opening the circuit on the ring current. Results are shown in Fig. 4. During the initial reduction of the anodic film, the disk electrode was only slightly polarized, while the ring current continued to decrease. It is significant to note that when the disk current was interrupted, the ring current rapidly increased. This increase in ring current clearly shows that the reduction of the $Cd(OH)_2$ film takes place at least partially through the dissolved cadmium species. After the disk current was turned on again and the potential reached the hydrogen evolution region, the disk current was interrupted for the second time. This again caused a sharp rise in ring current, indicating that $Cd(OH)_2$ was still present on the disk surface in spite of the fact that hydrogen evolution was taking place. The existence of $Cd(OH)_2$ during the hydrogen evolution is also seen from the result that cathodic polarization at 0.05 mA after the 0.5 mA experiment permitted further reduction of $Cd(OH)_2$ without hydrogen evolution (Fig. 4, right half). It is noteworthy that the final current inter-

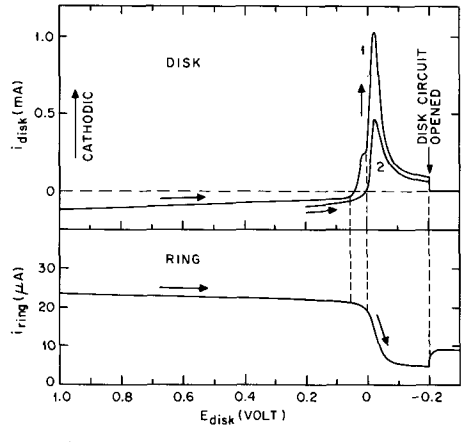

Fig. 2. i_{disk}-E_{disk} and i_{ring}-E_{disk} curves obtained on cathodic scan of E_{disk} after anodic scan. 2100 rpm. (The behavior for 60 sec after opening the disk circuit is shown to the right of −0.2V.)

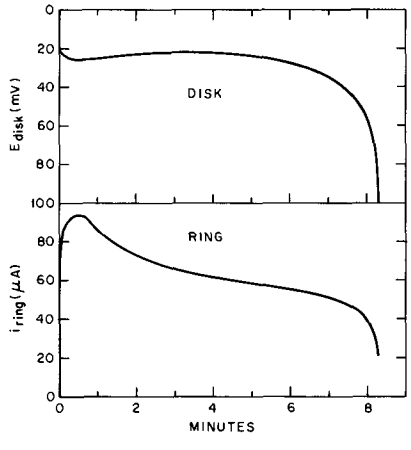

Fig. 3. Galvanostatic anodization of disk in 6.9M KOH at 2100 rpm, i_{disk} = 0.5 mA.

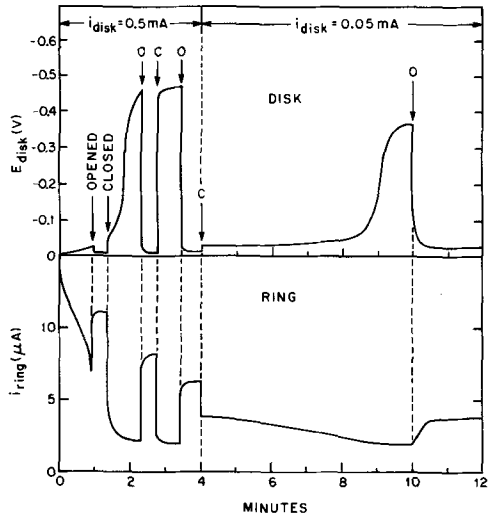

Fig. 4. Galvanostatic cathodic reduction after anodic oxidation at 0.5 mA, 2100 rpm.

ruption after 10 min still caused an increase in ring current. Evidently, the rate of solution of the $Cd(OH)_2$ film is quite slow.

Potentiostatic experiment.—Anodic process. Current-time curves obtained on applying various anodic potentials to the disk electrode are reproduced in Fig. 5. Again, from the magnitude of i_{ring} it is clear that the anodic reaction proceeds through the dissolution-precipitation sequence.

An attempt was made to calculate the rate constant for the precipitation process from these current-time curves. In order to carry out the calculation, it is necessary to formulate the reaction scheme. The form of dissolved cadmium species present in equilibrium in concentrated alkaline solutions has been studied by several investigators (19-22). Visco and Sonner (19) recently reinvestigated the subject and established that the dissolved cadmium species exists in the form of $Cd(OH)_3^-$ in solutions of KOH from 2 to 15*M*. Thus, in agreement with Milner and Thomas (15) we shall write

$$Cd + 3\,OH^- \rightleftarrows Cd(OH)_3^- + 2e^- \qquad [3]$$

$$Cd(OH)_3^- \xrightarrow{k} Cd(OH)_2 + OH^- \qquad [4]$$

where k is defined as the heterogeneous rate constant for the precipitation reaction. The current consumed in the formation of CdO, if any, at the small anodic potentials (<40 mV) is negligible. Suppose that the electron transfer reaction [3] is sufficiently fast that the disk current, except during the short initial transient period, is controlled by the rate of the precipitation reaction [4] and/or the rate of mass transfer of $Cd(OH)_3^-$. The former is given by kc^o while the latter by $(D/\delta)\ c^o$; thus the total rate of disappearance of $Cd(OH)_3^-$ is given by $(k + D/\delta)\ c^o$. Assuming that the disk current flows only through the uncovered area, we can write

$$i_{disk} = 2FA(1 - \theta)\left(k + \frac{D}{\delta}\right) c^o \qquad [5]$$

where θ is the fraction of the disk surface covered by $Cd(OH)_2$. Combination of this expression with Eq. [1] yields

$$i_{disk} = \frac{\delta}{ND}(1 - \theta)\left(k + \frac{D}{\delta}\right) i_{ring} \qquad [6]$$

The values of i_{disk} and i_{ring} being known at various times from the experimental current-time curves, it should be possible to calculate k provided that θ is known. Since θ cannot be determined readily, we calculated k at various times with θ set equal to zero and plotted it against time to find the value of k at $t = 0$ by extrapolation. The result is shown in Fig. 6. The two curves obtained at 35 mV at 1000 and 3950 rpm show that k is practically unaffected by the speed of rotation, which constitutes a partial check of Eq. [6]. The observed increase of k with time is partly due to the fact that the surface coverage was ignored in the calculation, but it is attributable mainly to an increase in the number of nuclei for the precipitation with increasing coverage and hence with time. The precision and reproducibility of this experiment was not very good; it was especially sensitive to the surface preparation. Therefore, no quantitative significance should be attached to the observed effect of potential on $k_{t=0}$. The results simply show that the method can be used, in principle, to calculate the rate constant of the precipitation reaction, and that $k_{t=0}$ was approximately 1 to 3 x 10^{-3} cm · sec^{-1} under the particular conditions used in this experiment.

Cathodic process.—The disk electrode was first anodized at +40 mV for 10 min at 6.9M KOH at 2100 rpm. The potential was then suddenly switched to −40 mV while both i_{disk} and i_{ring} were being recorded. Results are shown by curves 1 and 2 in Fig. 7. When the rotation was stopped during the reduction, both i_{disk} and i_{ring} decreased, and they increased again when rotation was resumed. The ring current more than doubled when the disk circuit was opened after 90 sec. These results clearly show that the anodic film does dissolve in the electrolyte, and the reduction of the dissolution product takes place at the disk electrode. This is also clear from comparison of the ring current-time curve during the reduction of the film (curve 2) with that

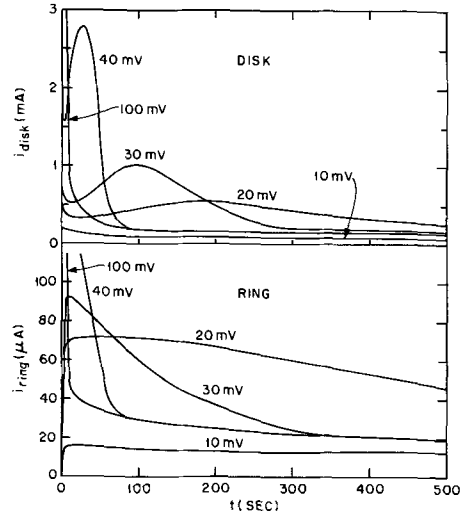

Fig. 5. Potentiostatic anodization of disk in 6.9M KOH at various potentials, 2100 rpm.

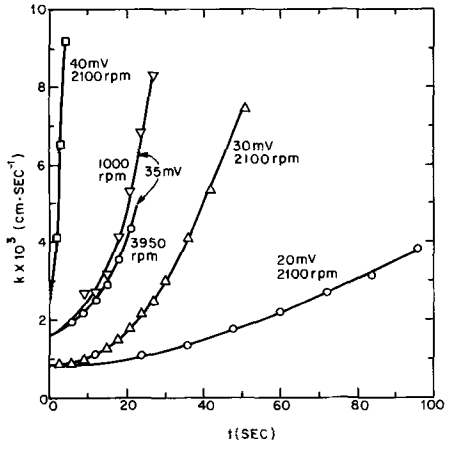

Fig. 6. Heterogeneous precipitation rate constant calculated from i_{disk}-t and i_{ring}-t curves.

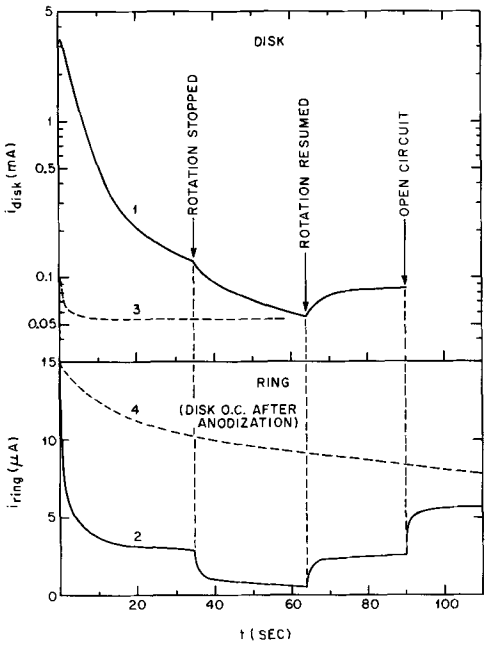

Fig. 7. i_{disk}-t (curve 1) and i_{ring}-t (curve 2) curves during potentiostatic reduction at −40 mV of the film formed at +40 mV on the disk in 6.9M KOH. Also included are (curve 3) i_{disk}-t curve for reduction of $Cd(OH)_3^-$ at −40 mV in 6.9M KOH saturated with $Cd(OH)_2$, and (curve 4) i_{ring}-t curve during free dissolution in 6.9 KOH at open circuit of the film formed on the disk at +40 mV. 2100 rpm for all curves.

during free dissolution of the film at open circuit (curve 4). The latter was obtained by first preanodizing the disk electrode under the same conditions as for curve 1 and then opening the disk circuit. While these experimental results show that the reduction of the anodic film takes place at least partly through the solution phase, this mechanism alone does not seem to be sufficient to account for the very large disk current observed during the initial period of reduction in curve 1. The steady-state reduction current measured in 6.9M KOH saturated with $Cd(OH)_2$ was only 53 μA at −40 mV (curve 3 in Fig. 7). Clearly, if the reduction proceeded solely through the dissolved intermediate, the dissolution of the anodic film would have to be extremely fast to account for the large initial disk current. Actually, however, the dissolution rate of the film was found to be rather slow. For example, the ring current due to the free dissolution of the film (curve 4) continued to decrease slowly for about 1.5 hr until the current finally reached zero. We also found that during the initial period of about 10 sec, the disk current was unaffected by stopping and resuming the rotation.

These experimental results suggest that in the initial stages the cathodic reduction of the film proceeds to a significant degree by the direct mechanism without going through the solution phase, while in the later stages the contribution of the solution-reduction mechanism becomes more significant. It may be speculated that when the cadmium metal is mostly covered with the film, the reduction takes place largely by the direct mechanism involving no soluble intermediate. As the reduction progresses, an increasing portion of the cadmium metal surface becomes exposed to the electrolyte, which increases the contribution of the reduction through the solution phase. It would be desirable to have more quantitative information as to the extent of contribution of each of the two mechanisms to the over-all reduction process. However, the experimental technique employed here could not yield such information.

On the basis of their current-interruption experiment during the galvanostatic anodic oxidation of cadmium metal in KOH, Farr and Hampson (9) reported that the solubility of the anodic film in the electrolyte is negligible. They observed that the total passivation time was independent of the duration of current interruption up to 80 hr. It would appear that the result of our ring-disk electrode experiment is at variance with that of Farr and Hampson's current interruption experiment. This apparent contradiction can be understood if it is assumed that the passivation occurs because of the formation of a thin insoluble film, which may consist of CdO as postulated by Breiter and Weininger (12), while the major oxidation product, $Cd(OH)_2$, dissolves in the electrolyte to give rise to the reduction current at the ring electrode. Thus, the result of current interruption experiments reported by Farr and Hampson does not necessarily mean that the entire film is insoluble.

Electrical conductivity of the film.—The solid-state growth mechanism originally postulated by Croft (7) and supported by Farr and Hampson (9) requires the rate of transport of ions such as Cd^{++}, OH^-, or H^+ in the film to be large. These ions may migrate or diffuse through the interior of the crystalline lattice, through defects in the film, or through grain boundaries or pores in the film. In order to obtain some information on the magnitude of the ionic conductivity of the film, potentiostatic anodic current-time curves obtained at a stationary planar cadmium electrode were analyzed according to the method described by Franck (25) and also by Fleischmann and Thirsk (26). The analysis should be regarded as only very approximate because the actual film is not uniform in composition as well as in thickness.

Suppose that a metal electrode given is already covered entirely with an anodic film of a uniform thickness. If an anodic current i flowing for time dt results in an increase in film thickness by $d\delta_f$ by a solid-state ionic transport mechanism, the following equation should hold

$$\frac{d\delta_f}{dt} = \frac{m}{n\mathbf{F}A\rho} i \qquad [7]$$

where m is the molecular weight of the substance composing the film, A is the area of the electrode, and ρ the density of the film. If the film dissolves during its growth, the total current i must be corrected for the current corresponding to the rate of dissolution of the film. This correction is unnecessary if the solution is presaturated with the material of the film, because no further dissolution of the film will take place during the solid-state growth in such a solution. The total potential drop between the metal and the solution can be written as

$$\Delta V = i\left(R_{m/f} + \frac{\delta_f}{\sigma A} + R_{f/s}\right) \qquad [8]$$

where $R_{m/f}$ and $R_{f/s}$ are the resistances of metal-film and film-solution interfaces, respectively, and σ is the specific conductivity of the film. It is assumed here that all three components of the total potential drop vary linearly with current. Under potentiostatic conditions (ΔV = const.), the following relation can be derived readily from [7] and [8]

$$\frac{1}{i^2} = \frac{1}{i_o^2} + \frac{2m}{n\mathbf{F}A^2\sigma\rho(\Delta V)} t \qquad [9]$$

where i_o is the current at $t = 0$. It is expected from this equation that plotting i^{-2} against t should yield a straight line, and its slope should permit calculation of σ.

An experiment was carried out with a stationary cadmium electrode with $A = 0.317$ cm² in 6.9M KOH saturated with $Cd(OH)_2$. The electrode was first anodized at +0.100V for 90 min, at which time the electrode surface was assumed to be completely covered

with a film. The potential was then stepped up to +0.300V. The i^{-2} — t plot at the two potentials is shown in Fig. 8. At +0.100V the relation was not linear as may be expected, whereas a good straight line was obtained at +0.300V except for the first several minutes. Since the amount of CdO formed in this potential range is believed to be negligibly small as indicated by the absence of cathodic prewave in the potential scan experiment (see Fig. 2), it may be assumed that the current observed at +0.300V was consumed entirely for the growth of $Cd(OH)_2$ by a solid-state ionic transport mechanism. In calculating the ionic conductivity σ from the slope of the straight line, the actual surface area of $Cd(OH)_2$ crystals which is in contact with the electrolyte should be used for A. However, since this is an unknown quantity, we are compelled to use the apparent electrode area for A to find the order of magnitude of σ. With $n = 2$, $A = 0.317$ cm^2, $m = 146.43$, $\rho = 4.79$ g · cm^{-3}, and $\Delta V = 0.2$V, we obtain $\sigma = 1.7 \times 10^{-10}$ ohm^{-1} · cm^{-1}. The experiment was repeated by forming the initial film at +0.0952V and stepping up the potential to +0.196V. The i^{-2} — t plot at the latter potential yielded a straight line with $\sigma = 2.0 \times 10^{-10}$ ohm^{-1} · cm^{-1} in good agreement with the value found from Fig. 8. The conductivity value is comparable to that found for anodic films of $PbSO_4$, 3.5×10^{-10} (26) or 1×10^{-9} ohm^{-1} · cm^{-1} (27).

The increase in "average" film thickness due to the solid-state growth at +0.300V in the experiment of Fig. 8 was calculated from the integration of the current-time curve over the 70-min period. It amounted to 0.044μ. On the other hand, the average film thickness prior to application of the potential step was estimated to be approximately 0.14μ. This value was calculated by integration of the current-potential curve which was obtained in a separate experiment by scanning the potential from +0.1 to −0.3V at a speed of 0.1 V/min after potentiostatic film formation at +0.1V. Thus, the increase in film thickness due to the solid-state growth at +0.3V corresponds to about 30% of the thickness of the film formed at +0.1V.

The results described above show that in the potential range after passivation, the film does grow by the solid-state ionic transport mechanism. In the potential range of active oxidation (<0.05V), however, the contribution of ionic transport process to the film formation is negligible. It can be estimated that the solid-state film growth is limited to only about 0.01μ for $\Delta V = 0.05$V.

Summary and Conclusion

1. The formation of a dissolved intermediate species during the anodic and cathodic processes of cadmium metal in concentrated alkaline solutions was demonstrated by using the ring-disk electrode technique.

2. The dissolution-precipitation mechanism prevails in the active range of potential. The contribution of solid-state growth mechanism is negligible in this potential range, and practically all current flows through exposed areas of the cadmium metal.

3. The result of this investigation supports the view expressed by previous investigators (1-3a, 6, 12) that passivation is not the result of complete blocking of the cadmium metal surface by $Cd(OH)_2$ crystals but rather is due to the formation of a thin, continuous film of CdO next to metallic cadmium. This passive film appears to be insoluble or only very slowly soluble in alkali.

4. In the passive range of potential the $Cd(OH)_2$ crystals grow on top of the passive layer by a solid-state ionic transport mechanism. The ionic conductivity of the $Cd(OH)_2$ film is of the order of 10^{-10} ohm^{-1} · cm^{-1}.

5. The quantity of CdO formed increases with increasing anodic potential, and in 6.9M KOH it becomes detectable by cathodic reduction if the anodization potential is brought to a value more positive than +0.4V *vs.* the equilibrium potential of $Cd/Cd(OH)_2$.

6. The cathodic reduction of CdO occurs at a potential about 40 mV less cathodic than that of $Cd(OH)_2$ without forming a soluble intermediate.

7. The reduction of $Cd(OH)_2$ occurs both by a direct mechanism and through the solution phase. The contribution of the latter mechanism increases as the reduction progresses and as the area of exposed cadmium metal increases.

Kinetics of the Solid Lithium Electrode in Propylene Carbonate

Robert F. Scarr*

Union Carbide Corporation, Consumer Products Division, Research Laboratory, Cleveland, Ohio

ABSTRACT

Kinetic parameters for solid lithium electrodes have been evaluated at 23° ± 1°C for $LiClO_4$ in propylene carbonate at several concentrations between 0.1 and 1.0M. Polarization data obtained by the interrupted current method agree with that obtained by a pulse technique. Depending on its treatment, the electrode exhibits one of two levels of activity. This phenomenon is believed to be due to the presence of a film formed by reaction between lithium metal and the solvent or impurities. The film is broken down at higher current densities, effecting an increase in electrode area. The area increase has been corroborated by double-layer capacitance measurements. Standard exchange current of a film-free electrode in $LiClO_4$ is 1.78 ± 0.33 mA/cm².

Lithium metal is a promising material for use as an anode in nonaqueous battery systems. Besides being one of the more active metals and possessing a very low equivalent weight, lithium has been shown, at least in the case of its amalgam, to be a highly reversible electrode. Cogley and Butler (1) have evaluated the so-called "true" exchange current for lithium amalgam in LiCl-dimethyl sulfoxide electrolyte at approximately 3 mA/cm².

The present investigation is a study of the kinetics of the solid lithium electrode in another solvent of current interest, propylene carbonate. The electrolyte was $LiClO_4$, a soluble lithium salt commonly used in nonaqueous battery studies. Due to the nature of experimental conditions and the existence of interfering processes, the results obtained should be considered preliminary. At this early stage of our understanding of this system, rigorous measures, such as correction for double-layer effects of activity coefficients, were not used in analysis and interpretation of experimental results.

Experimental

Most of the current-voltage data for the lithium electrode reaction were obtained by the interrupted current technique. This type of measurement represents steady-state conditions for the test electrode, and permits the polarization to be corrected for ohmic drop. A pulse method was also used.

Cell current was controlled by a Tacussel Model PIT 20-2X potentiostat in a galvanostatic mode. The control signal was supplied from a variable-gain inverting adder which summed a constant d-c potential and a single 100-μsec pulse from a Tektronix Model 160 Pulse Generator.

The pulse amplitude was initially adjusted to counterbalance exactly the d-c potential. The result was a signal wherein the d-c level corresponded to closed-circuit operation and the pulse period to the open-circuit condition. For the pulse experiments, the d-c level was nulled. Variation in the closed-circuit current was achieved by changing the gain of the adder. Steady-state cell voltages were measured on a Dana Model 5400 digital voltmeter. Transient cell potential and cell current were observed on a Tektronix Model 564 Storage Oscilloscope with a Model 3A3 dual channel differential amplifier using the a.c.-coupled input. The settling time for the current interruption, defined as 97% of the full step, was less than 2 μsec, as shown in Fig. 1.

The cell for this work was a 50-ml Pyrex beaker with a tight-fitting Teflon top which held the three electrodes with vertically oriented surfaces. All electrodes, test, counter, and reference, were pieces of

99.96% lithium foil obtained from Foote Mineral Company. This foil was known to contain 100 ppm potassium, 200 ppm sodium, and 150 ppm calcium. The test electrode was a flat plate, 0.5 x 1.0 cm, exposed to electrolyte on both sides, and surrounded by the counterelectrode which was suspended around the perimeter of the cell. Though nearly cylindrical, this geometry may have led to nonuniform distribution of the current at the electrode surface. According to Wagner (2), the current density at the edges of the electrode could, for the conditions employed in this particular experiment, be as much as twice that of the average based on a parallel-plate model for the cell. The effects of nonuniform current distribution should, however, largely cancel in the determination of the kinetic parameters from the average current, and, in view of the preliminary nature of the work, this effect shall be disregarded.

The reference electrode was situated adjacent to and in the same plane as the test electrode. Lithium metal is known to be a stable reference electrode, and in the present work was found not to vary more than 1 mV from an auxiliary twin reference electrode, even after prolonged use. The area of the test electrode was controlled and known. Prior to their use, the surfaces of the electrodes were cleaned by brushing with Carborundum cloth.

During the earliest work, those parts of the test electrode not intended to contact the electrolyte were coated with Microtex masking lacquer. Later, this substance was shown by gas chromatography (g.c.), to introduce trace quantities of unknown organic contaminants into the electrolyte. Consequently, the use of the masking lacquer was discontinued, and the electrode area was controlled instead by cutting away all unwanted metal. The electrode of the desired size was suspended just below the surface of the electrolyte by a thin thread of lithium metal remaining from the original piece. The results obtained using this type electrode were, however, no different than those where the lacquer was used.

The entire cell and associated work area were incorporated in a glove box containing a purified, continuously renewed argon atmosphere. Oxygen was removed from the argon by passing it over hot copper turnings and water vapor was removed with Linde 13X Molecular Sieve. During quiescent periods, the argon flow rate was 0.8-1.3 std ft^3/hr, which corresponds to an hourly rate of 15-23% of the box capacity. The flow rate was considerably higher at times when the transfer chamber was opened. The humidity in the box was monitored by a Panametrics Hygrometer, Model 1000, and throughout the course of the work was progressively reduced to about 5 ppm water vapor. The nitrogen content of the atmosphere was below limits detectable by g.c. Under these conditions, lithium metal remained visually bright and clean indefinitely. Ambient temperature within the box was 23° ± 1°C.

Propylene carbonate was purified by vacuum distillation from a Podbielniak column at 8 mm Hg and 100°-105°C column head temperature. The resulting product still contained some low level contamination, probably 1,2-propanediol. It is known (3) that the glycols are virtually impossible to remove completely. Ultrapure lithium perchlorate made by vacuum fusion was obtained from Anderson Physical Laboratories, and was used without further purification. After preparation, electrolytes were stored over Linde 4A Molecular Sieves and occasionally also stored in the presence of lithium wool.

The normal procedure was first to obtain data at increasing levels of anodic polarization, followed by decreasing the current back to open circuit, each point requiring 3-8 min to establish. This pattern was then repeated in the cathodic direction. Nonohmic steady-state polarization was evaluated by extrapolating the initial region of the potential-time curves back to the initiation of the pulse, then subtracting the obtained ohmic drop from the steady-state cell voltage. The electrode potential could be determined with an error of ±2% of the IR drop or 1 mV, whichever was the greater.

Current-voltage data were then plotted according to the Allen-Hickling method (4). In this technique, polarization data are corrected for the back reaction by plotting the logarithm of the function $I/1 - \exp(\eta/\beta)$ *vs.* the overvoltage, η, where I is the current density and $\beta = RT/F$. A one-electron process is assumed. This permits data points very close to equilibrium to be taken into account. In addition, cathodic and anodic branches are colinear, thereby reinforcing one another.

Results and Discussion

The current-voltage behavior of the electrode seemed to depend in part on the humidity of the glove-box atmosphere. During the initial phases of this work, the water vapor content of the glove box was approximately 30 ppm. A current-voltage plot typical of these conditions is given in Fig. 2, where the circles represent data taken under increasingly positive polarization and the triangles the opposite direction. The cathodic branches of these plots were seldom colinear with the anodic branches, and usually fell away (to higher polarization) as the current density increased. The lithium deposits corresponding to this region were loose, granular, and poor in quality.

The average exchange current density, I_0, for 1M $LiCO_4$ at this stage of the work was found to be about 0.64 ± 0.04 mA/cm^2, and the cathodic transfer coefficient, α, about 0.63 ± 0.02. The corresponding kinetic parameters for 0.2M $LiClO_4$ were 0.32 ± 0.01 mA/cm^2 and 0.69 ± 0.01, respectively. The cathodic transfer coefficient calculated from the dependency of exchange current on lithium-ion concentration was in good agreement with the slope of the Allen-Hickling plots.

At this point, glove-box conditions were improved to the extent that water vapor was reduced to about 15 ppm. All measurements were then repeated using new batches of materials. A pronounced change in polarization behavior was found to occur. Although the water vapor was thereafter reduced even further to 5 ppm, no additional change in results occurred.

Current-voltage curves characteristic of those obtained are illustrated in Fig. 3. Data points taken under the initial increasing anodic polarization indicated very clearly the usual linear region with an exchange current approximately equal to the previous measurements. At a point midway in the series, however,

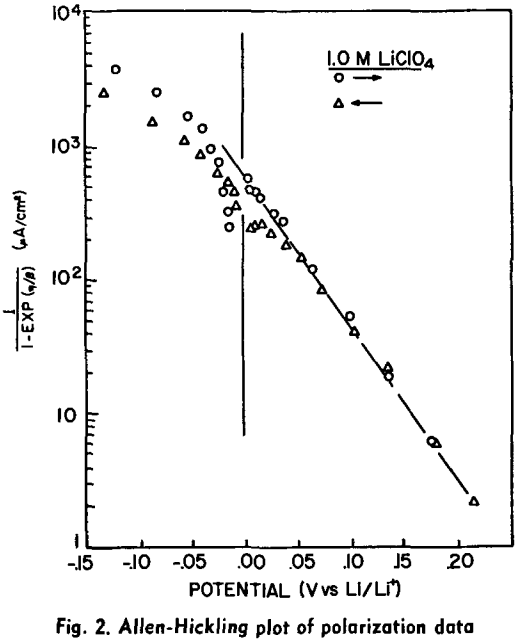

Fig. 2. Allen-Hickling plot of polarization data

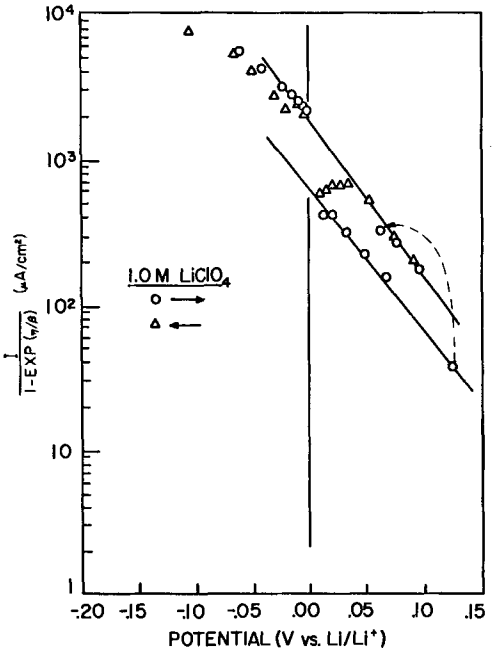

Fig. 3. Allen-Hickling plot of polarization data; later results

usually in the range of 2-5 mA/cm², the overpotential suddenly diminished, as shown by the dashed line. These latter data points, as well as those taken under subsequent decreasing current, define a second linear region with a higher exchange current. The extension of the upper line was often colinear with the cathodic branch, as illustrated in Fig. 3. After an electrode had once achieved the active condition, subsequent anodic treatments resulted in retracing the upper curve, as shown in Fig. 4 for 0.2M $LiClO_4$.

The linearity of the anodic branch of the current-voltage plot indicates that electron transfer is the rate-determining phenomenon in this region. Steady-state conditions are superseded at current densities above 15 mA/cm² where diffusion polarization is presumed to take effect.

The dual Tafel behavior is believed to be due to the existence of an insulating film on the electrode surface which initially covers many of the active sites available for reaction. Such a film is not the normal product of anodization of lithium metal but is probably the result of a side reaction with the solvent or an impurity. This interpretation is supported by the observation by Cogley and Butler (5) of a waxy film deposited on lithium amalgam in propylene carbonate electrolyte.

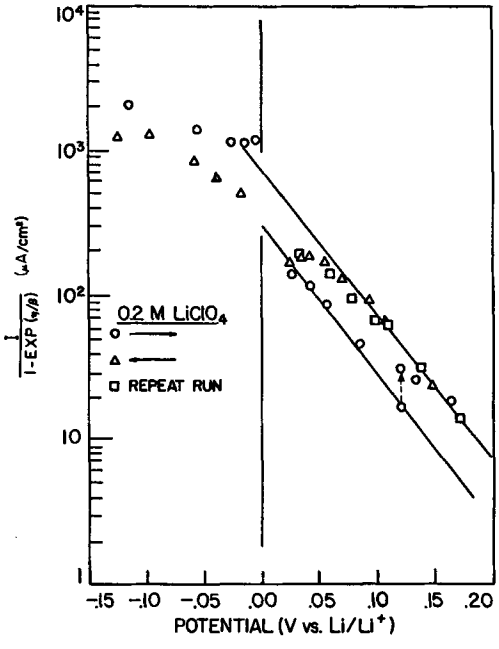

Fig. 4. Allen-Hickling plot of polarization data showing retracing of upper curve.

As the current is increased under interrupter conditions, the effect of the film can be overcome, causing the effective area of the electrode to be abruptly increased. This point occurs when the rate of creating new sites through either dissolution or deposition exceeds that of film formation. Film formation is probably limited by the rate of diffusion of reactant through solution.

Film formation may be catalyzed by the presence of water, hence the dependence on the humidity of the glove box. Of the two levels of activity, the upper is probably more representative of the intrinsic properties of the electrode because of the absence of the film. The electrode remains in this enhanced mode as long as the current appreciably exceeds the rate of film formation. Below this point, the film is reformed, causing the downward decay of the Allen-Hickling plots.

Independent evidence has been obtained that a reactive substance which might lead to film formation is present in the electrolyte system. Linear sweep voltammetry of propylene carbonate solutions of various electrolytes has revealed the presence of two cathodic peaks between 0.0 and 1.0V with respect to Li/Li^+. These peaks might be attributed to formation of lithium intermetallic compounds with the substrate. The peaks have been observed in this laboratory, however, even in the complete absence of lithium ion, or where lithium compounds are not expected to form, such as for nickel electrodes shown in Fig. 5. Furthermore, it may be shown from thermodynamic data that propylene carbonate may be expected to decompose in this potential region.

The film formation theory was further confirmed by applying current pulses rather than current interruptions to the electrode. In the case of pulses, the amount of material removed from the electrode is negligible, hence the film would be expected to maintain its integrity. Figure 6 shows the results of an electrode which was subjected to both pulse and current interruption techniques. The circles, open and solid, represent the first pulse experiment for ascending and descending current, respectively. The usual shift in polarization was not observed, indicating that the film remained intact.

The current interruption run, denoted by the triangular data points, was made the next day. The first few points are therefore considerably lower than the pulse series due to further film formation which occurred overnight. Nevertheless, midway through the run, the electrode switched to the enhanced state and remained

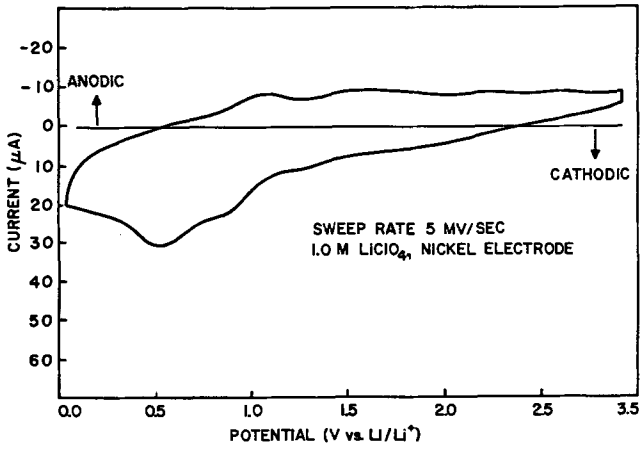

Fig. 5. Voltammetric sweep of nickel electrode in $LiClO_4$ electrolyte.

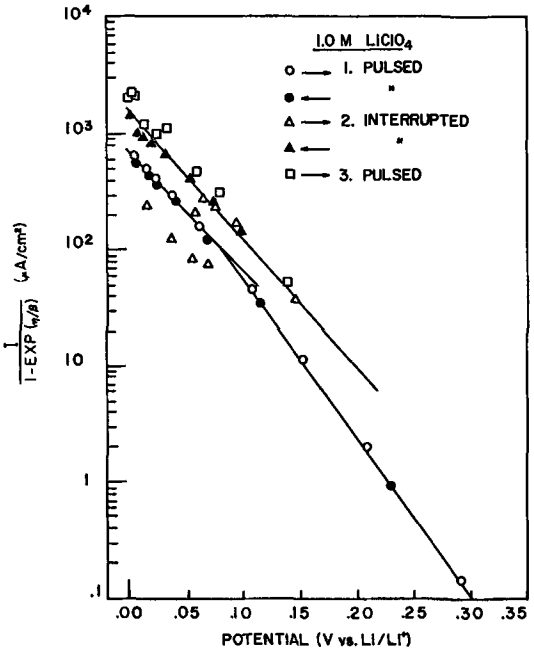

Fig. 6. Allen-Hickling plot for combined current interrupter/pulse procedure.

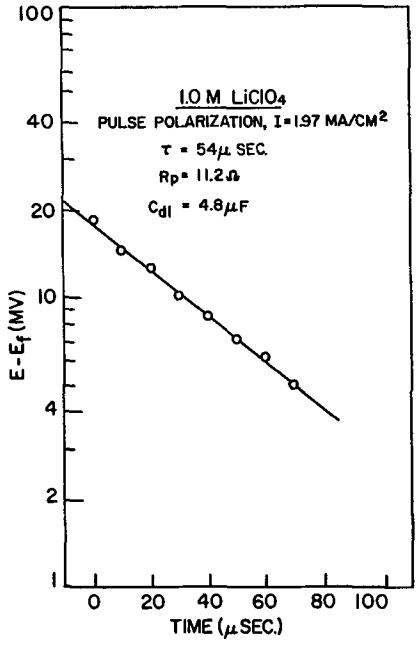

Fig. 7. Log plot of potential response after pulse

in that condition for the balance of the experiment. The square points are for another pulse series immediately following the interrupter run. It is seen that the activity of the electrode remained high during this period. The agreement between the pulsed and interrupted results indicates further that there was no temperature increase during the interrupter series due to resistive heating of the electrolyte.

Table I. Double-layer capacity and polarization resistance for pulsed runs, 1M $LiClO_4$

	C_{dl} $\mu F/cm^2$	R_p ohm
Lower curve	2.4	20.4
Upper curve	5.2	9.3

As further characterization of the insulating effect of the film, an indication of the area change was obtained by evaluating the double-layer capacity (C_{dl}) from pulse data, both before and after the interrupter run. Using a parallel resistor-capacitor equivalent circuit as a model for the double layer, C_{dl} was evaluated from the slope of log potential *vs.* time plots, as in Fig. 7. Because of the experimental difficulties in making such measurements under film-forming conditions and because of the marginal fitness of the model in this range of overpotential, C_{dl} values should be considered valid only for purposes of comparison. As shown in Table I for 1M $LiClO_4$, the double-layer capacity, hence electrode area, does increase roughly in proportion to the increase in exchange current while the polarization resistance (R_p) is seen to decrease. The exchange current calculated from R_p, 2.7 mA/cm^2, is in good agreement with that obtained from the interrupted current measurements, *vide infra.*

Due to the irreproducibility and nonlinearity of the Allen-Hickling plots for the cathodic data, kinetic parameters were determined largely from anodic measurements. Only where the cathodic data tended to substantiate anodic results were they utilized. The character of the results from the cathodic region may probably be attributed to a mixed-electrode process involving both metal deposition and solvent decomposition. Convection is ruled out as an explanation for the nonlinearity because of the agreement between interrupter and pulse data.

The combined pulse-interrupter measurements were carried out at several concentrations of electrolyte. The exchange currents evaluated by this means, as well as those obtained by the conventional interrupter procedure, were combined to give the results listed in Table II. As one means of determining the transfer coefficient, α, these data are plotted *vs.* log concentration in Fig. 8. The straight lines represent the data according to a least-squares analysis; the numerical parameters for the least-squares lines are given as the last entry in Table II. The data obtained by the pulse technique are solid points, while those obtained by interruption are shown as open points. The relationship of the upper and lower curves is seen very clearly. The data from the earliest experiments obtained before the dual effect was encountered are represented by the crosses and the dashed line, and are in good agreement with the lower curve.

The transfer coefficient has been determined both from the polarization slope and from the concentration

Table II. Li/$LiClO_4$ electrode kinetic parameters at 23°C

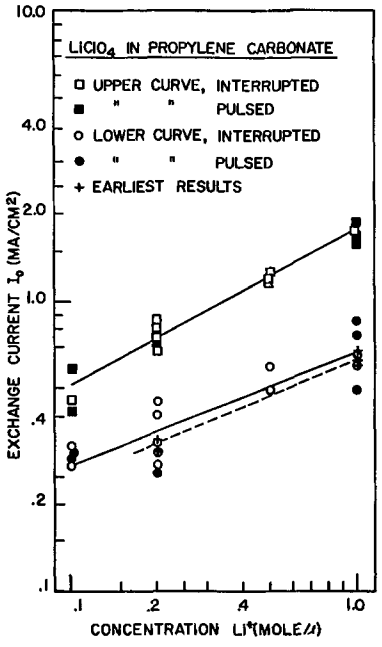

Fig. 8. Exchange current-concentration plot for $LiClO_4$

dependence of exchange current. The first method, while normally preferred, suffers from the influence of surface films and interfering corrosion processes at low currents. The second method may produce erroneous results because no correction has been made for double-layer effects or for activity coefficients. For the majority of cases, an average value for the transfer coefficient of 0.62 is obtained, but for the reasons stated the reliability of this figure is somewhat in question. The standard exchange current obtained by both methods is *ca.* 1.8 mA/cm². Standard deviations for these values are given in Table II. The principal factor in the scatter of the kinetic parameters from run to run is probably the irreproducibility of the film. This is supported by the qualitative observation that the data scatter for the lower state of electrode activity is somewhat greater than for the more active state where the film is supposedly absent. The above kinetic parameters may be compared with those of Cogley and Butler (5) who obtained values of 0.75 and 8.6 mA/cm², respectively, for Li(Hg)-LiCl in DMSO.

It is concluded that the solid lithium electrode is indeed active enough to compare favorably with other electrodes presently utilized in primary battery applications. While the formation of a film with some component of the electrolyte may reduce the apparent activity of the metal, the electrode discharge performance should improve under continuous drain conditions which tend to remove the film. In the final analysis, such a film may actually prove beneficial as a protective layer during idle periods.

Acknowledgments

The author is pleased to acknowledge the assistance of Mr. Peter Briedis in obtaining the experimental data, and the helpful discussions of Professor Ernest B. Yeager, Case Western Reserve University.

Manuscript submitted Aug. 6, 1969; revised manuscript received Nov. 17, 1969. This was Paper 161 presented at the New York Meeting, May 4-9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

PbO_2 in the Lead-Acid Cell

II. Cycling and Overcharge on Pure and Antimonial Lead Grids

ABSTRACT

Three representative lead oxides were used in fabricating lead-acid cells with pure and antimonial lead grids. The cells were cycled and overcharged. Positive plates were removed at intervals and the active material was examined by x-ray diffraction, electron microscopy, and by spectroscopy. Bulk densities of the active materials were also determined. The cells with pure lead grids usually had somewhat lower capacities than the corresponding antimonial cells, and lost approximately 80% of their initial capacity between 5 and 10 cycles. None of the antimonial cells suffered major capacity loss during the 21 cycles comprising the test. The rate of loss in bulk density of the PbO_2 was higher in the pure lead cells. This and the loss in capacity have been attributed to the grain growth and anhedralization that take place more rapidly when antimony is absent. Antimony appears to act as a nucleating catalyst for the PbO_2 and inhibits crystal growth.

The fully charged positive electrode of the lead-acid cell is a porous polycrystalline aggregate of PbO_2. The individual crystallites are usually of submicroscopic dimensions (1), and the aggregate must retain its mechanical strength and electrical continuity under stringent requirements: percolation of H_2SO_4 throughout the mass, cyclic volume changes between PbO_2 and $PbSO_4$ during electrode operation, and vigorous O_2 gas evolution during overcharging. The ability of

* Electrochemical Society Active Member.

the working electrode to withstand such use is the combined result of several factors. Voss and Huster (2) have shown that, in antimonial cells, the durability of the PbO_2 mass is related to the depth of discharge during cycling, with deep or complete discharges most destructive. The composition of the supporting grid alloy has an effect on the cycle life of the active material. Under usual conditions, plates made with antimonial alloy grids have significantly longer cycle life than those with nonantimonial lead grids (3, 4).

In general, the strength of polycrystalline aggregates has been shown to be related to their microstructures (5, 6), and it has been suggested that the durability of a PbO_2 aggregate is related to the morphology of the particles as seen in the electron microscope (3, 7).

In the first phase of this study, electrodes fabricated from three representative lead oxides were oxidized while supported on pure and antimonial lead grids (8). The resultant PbO_2 was examined by x-ray diffraction and electron microscopy, and it was concluded that the freshly anodized mass comprised compound spikes of crystals of approximately 0.5μ average diameter, which were overgrown with smaller sessile crystallites, 0.1μ or less in diameter. The descriptive terminology was selected because botanical analogy is frequently employed to describe crystal formations. Such a geometrical morphology readily explains the difference in surface area of the polycrystalline mass when measured by gas absorption methods, about 7 m^2/g, and the value of 14 to 24 m^2/g, calculated on the basis of x-ray line broadening (4, 9). The very small sessile crystallites lie within the range that gives rise to a limited degree of x-ray line broadening (10). Since the smaller crystallites cover the larger crystals, and because the specific x-ray absorption of lead is high, the entire mass appears to consist of the smaller crystallites. In such a specimen, the underlying larger crystals contribute little to the x-ray diffraction pattern, although the larger crystals may make up the major fraction of the total weight of the sample. Kordes (4) determined from neutron diffraction that the interior portions of the crystals or agglomerates of PbO_2 electrodes appeared to have better "crystallinity" than the outer layers or grain boundary material. This was borne out by the direct examination of PbO_2 by electron microscopy (8). In further agreement with the conclusions of Kordes (4), it was observed that the initial oxidation, or formation of PbO_2, was not significantly different when antimonial or pure lead supporting grids were employed.

It was also found that there was no significant difference in the initial morphology of the active material among the three representative oxides employed, although the oxide that originally contained Pb_3O_4 gave rise to the largest individual crystals (8).

Table I. Cell characterization*

* Pastes of each oxide were applied to pure and 7% antimonial lead grids, and positive and negative plates were pasted with the same materials at the same time.
** Materials used in fabrication of these cells are characterized in Ref. (11).
*** Materials used in fabrication of these cells are characterized in Ref. (8).
† Symbols signify: *D*—wet paste density in g/in.^{3}; *F*—sp gr H_2SO_4 used in formation; *G*—sp gr H_2SO_4 used in the cycling and overcharging routines, Table II.

The present phase of the study was undertaken to determine: whether electrochemical cycling and overcharge in H_2SO_4 has an effect on the crystal morphology of PbO_2, whether differences in active material morphology attributable to the presence of antimony in the grid metal could be observed, as indicated by earlier studies (3, 4), and whether differences could be ascribed to the original oxides from which the electrodes were fabricated.

Materials and Methods

Three representative lead oxides, designated *A*, *C*, and *H*, were used in this study. The metals and individual oxide production batches were characterized in detail in earlier reports (8, 11). Conventional battery plates were hand pasted and cured following standard practice for each of the oxides using pure and antimonial lead grids, nominally 7% Sb by weight. No additives were used in plate fabrication, and positive and negative plates were pasted with identical materials. From these plates, 12 full-sized 9-plate cells were assembled for electrochemical cycling and overcharge tests (12). Six small 3-plate cells (2 negatives and 1 positive) were manually cycled a few times. These experiments are summarized in Tables I and II.

Two each of the positive and negative plates were removed from six of the 9-plate cells after 11 cycles. These were replaced by heavy plastic sheets to retain approximately the normal element-electrolyte balance

Table II. Capacity cycling and overcharge procedures

9-Plate cells						3-Plate cells*

* The 3-plate cells were cycled at ambient room temperature which varied between 20°-30°C. A positive plate potential *vs.* Hg/Hg_2SO_4 of 0.75-0.8V was used as the cut-off voltage.
** The 20-hr rate at 26.67°C (80°F).
*** Cycles 2, 9, and 12 were run at −17.78°C (0°F). All others were run at 26.67°C (80°F).
† Following 11 cycles, 6 cells (one of each type oxide and grid) were removed from the cycle test. After removal of two each of the positive and negative plates, these cells were placed on the following overcharge regime: overcharge, 120 hr at 2.5A; stand, 48 hr less the time required for; high rate discharge, 75A at 37.78°C (100°F) to a cut-off voltage of 1.00V. Failure was reached when the cell capacity fell below 40% of the initial capacity at the 75-A discharge rate.
Note: The charging schedule for the 9-plate cells was to restore 135% of the capacity discharged on the previous discharge. The schedule for the 3-plate cells was to restore 125% of the capacity discharged on the previous discharge at constant current. If the on-charge voltages or the specific gravity of the electrolyte were not stable, charging was continued until the readings indicated a fully charged condition or a defective cell.

and cell packing, prior to continuing with the overcharge phase of the study. After reassembly as 5-plate cells, the pure lead cells were placed on the overcharge test for 2 weeks, and the antimonial cells for 5 weeks. The remaining six 9-plate cells were continued on the cycle test for a total of 21 cycles.

The small 3-plate cells were assembled in polyethylene bags which were shimmed externally to approach a normal element-electrolyte balance. A Hg/Hg_2SO_4 reference electrode was placed in each 3-plate cell, and current, positive plate, and cell voltages were recorded continuously. After formation, these pure lead cells were given 4 cycles, and the antimonial cells 8 cycles.

Fully charged positive plates were removed from the cells at selected intervals and, after blotting off excess electrolyte, the plates were dried in air at room temperature or at 60°-71.1°C (140°-160°F). The plates were weighed before and after removal of the active material. The PbO_2 was examined by x-ray diffraction and electron microscopy by the same techniques described earlier (8). Positive active materials from the 9-plate cells were analyzed spectrographically for antimony, and their bulk densities were measured by the method of Dittman and Sams (13).

Results and Discussion

During operation of a PbO_2 electrode in H_2SO_4, changes in capacity (2, 14), electrical continuity (15-17), bulk density (13), and particle size (4) take place in the electrode mass. Ultimately it fails to deliver adequate electrical capacity, and must be replaced. Some of these changes have been examined in this study to determine the nature of the difference in behavior of PbO_2 when supported on pure and antimonial lead grids, and to compare the behavior of three representative lead oxides.

Capacity.—Discharge capacities of the cells used in this study are given in Table III, and Fig. 1 shows the change in actual cell capacity at the 20-hr rate with cycling at 26.67°C (80°F). The cells with pure lead grids usually had somewhat lower capacities than the corresponding antimonial cells, and lost approximately 80% of their initial capacity between 5 and 10 cycles. High rate discharges showed less difference between antimonial and pure lead cells, and this may be attributed to the relatively small amount of active material required to take part in such cycles (14, 18). It has also been suggested (12) that in the pure lead cells a barrier layer may form between the grid and active material and may offer less resistance at high than at low discharge rates. None of the antimonial

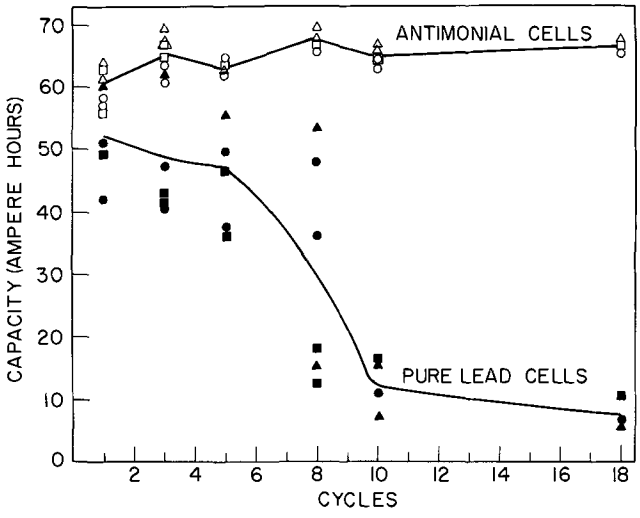

Fig. 1. Actual cell capacities at the 20-hr rate discharged at 26.67°C (80°F). Three of the pure lead cells had failed by the 8th cycle and all had failed by the 10th. None of the antimonial cells had failed at the conclusion of the test at 21 cycles. ●, Oxide *A*; ■, oxide *C*; and ▲, oxide *H* on pure lead grids. ○, Oxide *A*; □, oxide *C*; and △, oxide *H* on 7% Sb-Pb grids.

cells suffered major capacity loss in the cycle tests of this investigation. Visual examination of the positive plates at the conclusion of the cycle tests indicated that the pure lead cells failed by degradation of the active material, while the antimonial cells would have failed because of grid corrosion although none reached failure during these cycles (12).

Overcharge.—During the first week of the overcharge test, Table II, there were indications that the soft lead cells were beginning to short out. These cells were opened and the lead whiskers and bridges removed, and the cells returned to the line. During the second week the shorting problem became general, and the soft lead cells were removed from test at the end of the second week. The antimonial cells did not begin to show shorting troubles until the end of the fourth week, and their test was discontinued after 5 weeks.

The combination of 11 deep capacity cycles and overcharge is evidently a very severe regime for the lead-acid cell. Visual examination of the positive plates indicated that in the pure lead cells the active material failed, while in the antimonial cells the grids limited cell life. In addition, it appears that antimonial grids grow to a greater extent than pure lead grids in the overcharge test, whereas the pure lead grids grow to a greater degree than the antimonial ones during cycling.,

Utilization of PbO_2.—During cycle operation of the positive plate of the lead-acid cell, only a fraction of the active material is actually used. Nominally every kilogram of PbO_2 is capable of giving 224 A-hr capacity. The coefficient of use varies with the rate and ambient conditions of discharge, usually lying in the range of 10-50% of theory (14). The coefficient of use also appears to depend on the grid metal, with the same active material paste yielding less capacity with pure lead grids than when supported on antimonial grids. Representative values of the coefficient of use for the cells in this study are given in Table IV. The values of 18-63% utilization obtained with the plates and conditions of this study lie within the accepted operating range. Differences among the three oxides were less on antimonial than on pure lead grids.

Bulk density.—The bulk or apparent density of the positive active material decreases with cycling (13). Figure 2 shows the change in bulk density of plates fabricated with the three oxides on pure and antimonial lead grids. On pure lead, the rate of density loss

was greater than for the same active material supported on antimonial lead grids. The rate of change in the bulk density is more significant than the actual magnitude since it is the change that is of interest. Changes occurred with all oxides on both pure and antimonial lead grids; however, the rate of density loss was greater on the pure lead grids.

The bulk density of a porous granular aggregate depends on the degree of close packing of the individual solid particles. Within the mass, pores may be opened by actual removal of material throughout the structure. This mechanism does not alter the over-all volume of the mass. Decrease in the apparent density may also result from an over-all volume expansion of the aggregate with a corresponding increase in the internal pore volume. In such an expanded mass, the individual particles are less closely packed. This is the characteristic of granular masses that gives rise to the phenomenon known as dilatancy (19-21). Dilatancy was first described and named by Reynolds in 1885 (19) who noted the most familiar example: the drying out of an area of wet beach sand around each step as a person walked along the shoreline, followed by a resurfacing of the water after the weight was removed. Reynolds demonstrated that application of force to a granular mass, not rigidly contained, caused an expansion or dilation of the mass, and an increase in internal porosity. The disruption of an unconfined granular mass resulting from a localized stress is not limited to nearest-neighbor particles, but is propagated through the structure for considerable distances (19-21).

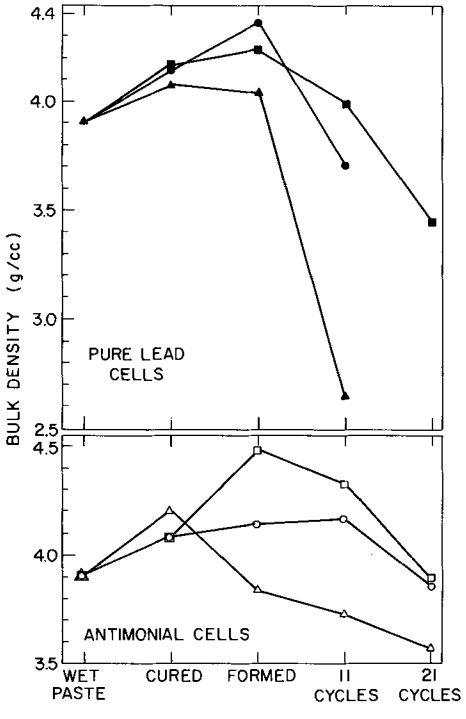

Fig. 2. Bulk density of the positive active material at various stages of the study. The rate of density loss is markedly greater for the pure lead cells. The plates containing oxide *H* were considerably less dense than the other two oxides and this may be attributed to the growth of the largest crystals of PbO_2 in these plates, and dilatant behavior of the active material. ○ and ●, oxide *A*; □ and ■, oxide *C*; △ and ▲, oxide *H*.

The volume contraction of a granular mass upon pulverization is also a very familiar effect, but the reverse action, the expansion of a close-packed granular array upon growth of the individual particles, is less commonly appreciated.

The decrease in bulk density of the cycled PbO_2 electrode probably results from both the opening up of internal voids by conversion of relatively low density materials to the high density PbO_2 during formation, and by an over-all volume increase owing to an increase in individual particle size. It may well be that the growth of the individual particles exerts sufficient force to cause the granules to shift from their initially more close-packed configuration. This suggests that it is grain growth that causes the expansion of the apparent volume of the PbO_2 electrode during cell operation. The relation of this expansion process to positive plate life, warping, and grid fracture has been pointed out by Dittman and Sams (13).

X-ray diffraction examination.—The major solid phase of the fully charged electrodes was identified by x-ray diffraction to be rutile type β-PbO_2 in all positive plates. Some plates showed one broad extra diffraction peak of low intensity in the vicinity of the position of the strongest line in the diffraction pattern of α-PbO_2. It is not possible to make an identification on the basis of a single diffraction line; therefore, the plates used in this study may or may not have contained a small amount of α-PbO_2. Tetragonal PbO, Sb, Sb_2O_3, and several other lead oxides also have strong diffraction peaks in this position. During cycling of the plates, this extra line disappeared from the diffraction patterns.

It has been reported earlier (4, 8, 22) that there is some evidence of a small degree of preferred orientation in freshly formed PbO_2 electrodes. This is suggested by the deviation in relative intensities of the diffraction lines from those of the standard pattern. This effect was not eliminated by hand grinding of the specimens in a mortar and pestle and sieving through 125-μ mesh screens; however, electrochemical cycling of the electrodes gradually eliminated this deviation. It may be that the deviation from standard intensities is caused by crystal anisotropy of a degree insufficient to give the usual mixture of broad and slender peaks in the diffraction patterns. The intensity of the diffraction patterns also increased with cycling, and this can be attributed to an increase in crystal size to give more efficient diffraction of x-rays. The degree of crystallinity did not, however, become sufficient to give good resolution of the K_α doublet. The small sessile crystallites of the freshly formed PbO_2 appeared to be about 10^{-5} cm in average diameter (8). Line broadening is present but slight in the range 10^{-5} to 10^{-6} cm, and line broadening resulting from

anisotropy of the small crystallites would not necessarily be distinguishable in such a specimen (10). Distortion of the lattice may also give rise to similar effects in the diffraction patterns of the freshly formed PbO_2 electrodes. It is not feasible in these specimens to distinguish between these possible causes of the peculiarities in the diffraction patterns, and all factors may be present in the electrochemically formed PbO_2 mass.

Geometrical morphology and the effect of antimony.—The particle morphology of the PbO_2 undergoes marked change during cycling in H_2SO_4. In addition, the presence of antimony in the grid metals appears to have a most significant effect during cycle operation of the cells. All three oxides included in this study underwent similar changes with cycling, and for this reason only selected electron micrographs of changes in oxide *A* on both pure and antimonial lead grids are presented here as representative of the three oxides. Oxide *H*, that initially gave rise to the largest crystals upon formation (8), again produced the largest PbO_2 crystals in this study. This greater grain growth is reflected in the greater loss of bulk density of oxide *H* compared to oxides *A* and *C*, Fig. 2.

Figure 3 shows an electron micrograph of freshly formed PbO_2 electrode material made from oxide *A*. The agglomerates are believed to be true spherulites made up of very small crystals that have grown on the surfaces of somewhat larger skeletal crystals (8). This structure changes with cycling, and Fig. 4 (*a*) shows the morphology after four cycles on pure lead supporting grids. The increase in particle size is clearly apparent. The smallest crystallites are no longer present, and the spherulitic character has largely disappeared. The spiney growth on the surface of a larger grain in the center of the photograph appears to be a stage in the alteration of a spherulitic formation. The same oxide supported on antimonial lead, Fig. 4 (*b*), shows a marked loss of spherulitic morphology after 8 cycles; however, the particle size is smaller than when pure lead grids were used as in Fig. 4 (*a*). The accumulation of antimony in the electrode mass is progressive, Table V, and the change shown by comparing Fig. 3, 4 (*b*), 5, and 6 (*b*) is believed to be the result of the gradual increase in the antimony content of the positive active material. This is further borne out by comparing the appearance of the active materials after 11 capacity cycles plus overcharge, Fig. 6 (*a*) and (*b*). Here the effect of antimony on the

Fig. 3. Electron micrograph of a carbon replica of PbO_2 from oxide *A* after formation on 7% antimonial lead grids. These agglomerates appear to be true spherulites of small sessile crystals overgrown on spikes of larger crystals. Marker equals approximately 1μ.

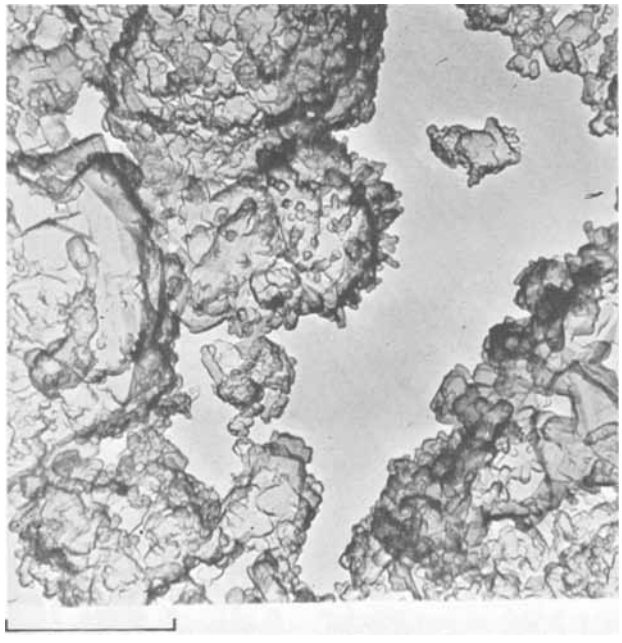

Fig. 4(*a*). Electron micrograph of a carbon replica of PbO_2 from oxide *A* after 4 cycles on pure lead grids. The smallest sessile crystallites have disappeared and the particle size is larger than the freshly formed material, Fig. 3. The spiked formation at the center of the photograph suggests that the smallest crystals are consumed in discharge, and the recharge process involves deposition on the residual crystals of PbO_2 so that they become larger with each cycle.

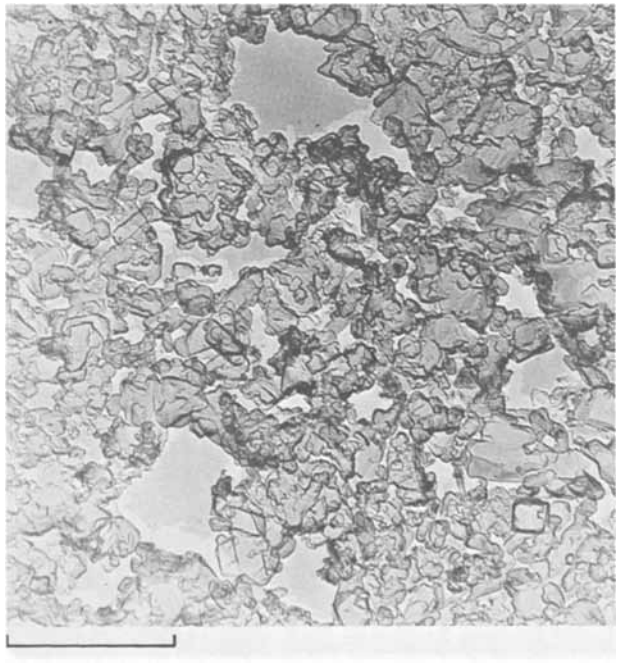

Fig. 4(*b*). Electron micrograph of a carbon replica of PbO_2 from oxide *A* after 8 cycles on 7% Sb-Pb alloy grids. Cycling has produced considerable grain growth and the small crystallites originally present after formation have been consumed; however, the 11 cycles have not resulted in grains of the size seen in Fig. 4(*a*) after 4 cycles on pure lead. Many of these crystals appear to have surface and edge defects that may serve as active sites for the discharge reaction. Markers equal approximately 1μ.

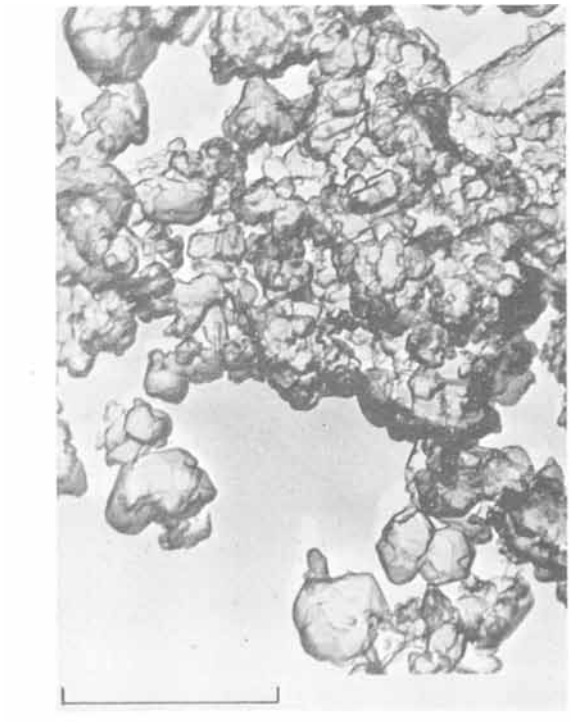
active material is especially apparent. In the pure lead cell, there has been marked grain growth and anhedralization of the PbO_2 particles. The small crystallites present after formation have disappeared, and the particles have the smooth surfaces and rounded outlines associated with so-called normal crystal growth (23, 24). The active material from the antimonial cell, on the other hand, has regained its spherulitic form, the individual crystallites are larger than those in the freshly formed material, Fig. 3, but smaller than those in the pure lead cell, Fig. 6 (*a*). They have irregular convoluted surfaces and edges. The



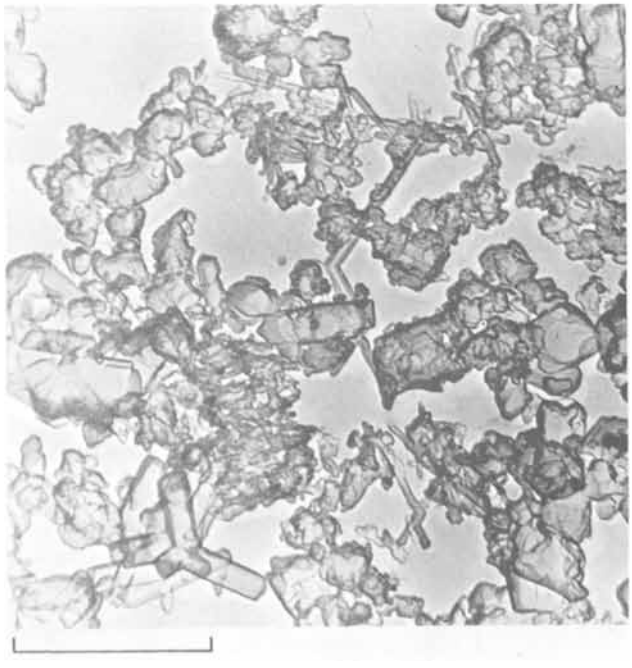


Fig. 5. Electron micrographs of carbon replicas of PbO_2 from oxide *A* after 21 cycles on 7% Sb-Pb alloy grids. *(a) Top:* The accumulation of Sb in the active material, Table V, has apparently acted as a growth inhibitor for the PbO_2 so that the individual crystals do not grow significantly in size after 8 cycles. *(b) Bottom:* A considerable fraction of this active material is made up of very slender prismatic crystals that have in some instances been overgrown with small sessile crystals. Markers equal approximately 1μ.

Table V. Spectrographic analysis for Sb in positive active material

	7% Sb	0.075	0.120	0.28	0.35

* BL—below the limit of the method used, or less than 0.001% Sb.

** Accumulation of the relatively small amounts of antimony in the pure lead cells may be the result of contamination inadvertently introduced during testing.

PbO_2 taken from the antimonial cells was a lighter brown than that from the pure lead cells which was very dark brown, almost jet black.

These direct observations are in agreement with conclusions of earlier studies (3, 4) comparing antimonial and nonantimonial cells. The increase in particle size and change from spherulitic to regular crystal growth appear to be the cause of the early disintegration of the positive active material in nonantimonial cells. It appears that during cycling the larger crystals grow at the expense of the smaller ones. The initial electrical capacity of the electrodes has been attributed to the large surface area of the small crystallites (4). As grain growth occurs, the surface area and electrical capacity would decrease. In addition, the structural strength of the granular mass would be expected to decrease owing to dilatant behavior as mentioned previously.

The PbO_2 particles in the pure lead cells grow more rapidly and to a larger size than those in the antimonial cells, resulting in more rapid paste disintegration and failure. Antimony retards the crystal growth rate so that these effects are less rapid. However, even in antimonial cells, the bulk density of the mass gradually decreases, Fig. 2, and the autoradiographic studies of Bode *et al.* (15-17) indicate that, at the end of life of antimonial cells, pockets of PbO_2 become electrically isolated so that they may not be discharged. This is readily explained by the long-range effects of stresses in granular masses.

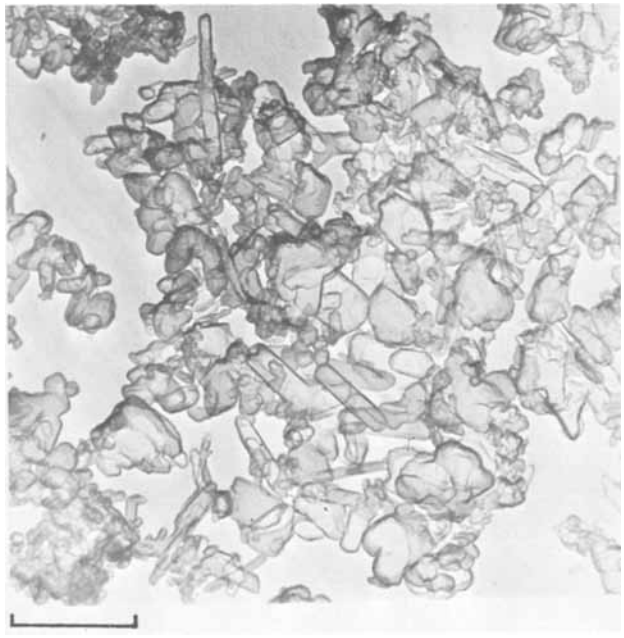

Fig. 6(*a*). Electron micrograph of a carbon replica of PbO_2 from oxide *A* after 11 cycles plus 2 weeks' overcharge on pure lead grids. Marked grain growth and anhedralization are visible in this example. The crystals have smooth surfaces and edges.

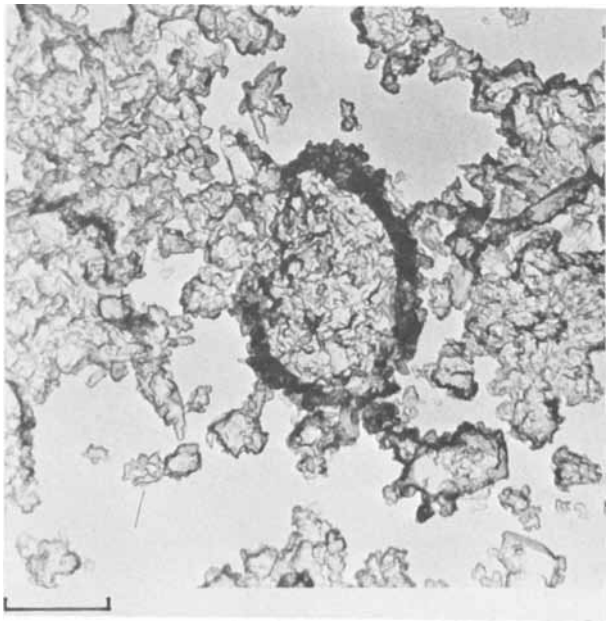

Fig. 6(*b*). Electron micrograph of a carbon replica of PbO_2 from oxide *A* after 11 cycles plus 5 weeks' overcharge on 7% Sb-Pb alloy grids. The Sb present in this active material appears to have promoted the nucleation of many small crystals and to have inhibited the growth of larger crystals. The surfaces and edges of the individual crystals contain many flaws that may indicate a high degree of electrochemical activity. This cell had failed on the overcharge test by grid corrosion. Markers equal approximately 1 μ.

The mechanism by which antimony has the above effect on the morphology of PbO_2 is not defined. It may be concluded that essentially it acts as a nucleating agent for PbO_2, simultaneously inhibiting crystal growth. It may accomplish this by entering the PbO_2 lattice by substitutional solid solution. This could give rise to an increased number of nucleating centers on the surfaces of the PbO_2 crystals. Incorporation into the lattice has been suggested as the cause of a similar effect of Sb_2O_3 on crystallization of rutile type CrO_2 (25). Up to 2% by weight of the antimony oxide can enter the CrO_2 lattice with no detectable change in lattice parameters. In this case, the antimony has been said to act as a nucleating catalyst producing small highly acicular crystals. Electrochemically, pentavalent antimony is the stable species at the potentials of the PbO_2 electrode in acid solutions (26). In crystalline oxides, the oxygen coordination is the same for Pb^4 and Sb^5 (27), and the spectrographic results, Table V, and radioactive tracer analyses (28, 29) indicate that antimony remains associated with the PbO_2 electrode mass. Thus it seems likely that antimony can enter the PbO_2 lattice, occupying Pb^4 positions in the oxygen octahedra. Quite another mechanism is also possible. The antimony may be adsorbed at the growth sites on the PbO_2 crystal surfaces, probably preferentially on the fastest growing faces, and act as a growth inhibitor. Under these circumstances, nucleation would be a secondary effect. The complexities of full mechanism definition and coordination of electrochemical and crystallization processes have been emphasized by Bockris and Razumney (24). It is apparent that further effort is required to define the mechanism by which antimony promotes nucleation of PbO_2 and inhibits crystal growth. When this is understood, it may be possible to select another material that will serve the same functions and at the same time be free of the detrimental side effects of antimony in the lead-acid cell (14).

The Adsorption of Vanadium(III) on Mercury from Thiocyanate Solutions and Its Electrochemical Consequences

Fred C. Anson* and Josip Caja[1]

Gates and Crellin Laboratories of Chemistry, California Institute of Technology, Pasadena, California

ABSTRACT

The adsorption of V(III) on mercury electrodes in thiocyanate electrolytes has been measured chronocoulometrically. The adsorption is not strongly dependent on potential except in the vicinity of the V(III)/V(II) half-wave potential. The adsorbing species is a V(III)-thiocyanate complex containing one or more thiocyanates. The adsorption of V(II) also occurs, but is much weaker than that of V(III). A minimum value for the exchange current for the V(III)/V(II) couple in the adsorbed state has been estimated coulostatically. Although this exchange current is quite large, 0.5 A/cm^2, its magnitude can be largely accounted for by the enhancement of the reactants' surface concentrations produced by their adsorption.

The spontaneous adsorption of electrochemical reactants on the surface of electrodes often produces complications in the study of the kinetics of their electrode reactions. An electrode process that can proceed by more than one pathway, *e.g.*, via both the adsorbed and unadsorbed reactants, corresponds to a complex equivalent circuit which contains elements that cannot be evaluated in separate experiments in the absence of the reactants. As a result, a larger number of kinetic parameters must be extracted from the rate data, and confidence in the accuracy and uniqueness of the resulting kinetic parameters is weakened. Under these circumstances, it is advantageous to have independent quantitative information on the extent of adsorption of the reactants because the kinetic data can then be analyzed with one less adjustable parameter.

The technique of chronocoulometry (1) is well suited to provide the desired quantitative adsorption data. It has been applied in the present study to evaluate the adsorption of V(III) and V(II) on mercury electrodes in thiocyanate solutions. The V(III)/V(II) system was chosen for several reasons. It offered an opportunity to compare the adsorption of a transition metal redox couple with the extensively studied anion-induced adsorption of white metal cations (2-6) [Cd(II), Zn(II), Pb(II), In(III)]. Second, the equilibrium adsorption of V(III) and V(II) could be measured in poised solutions containing both halves of the redox couple, thus allowing the potential dependence of the adsorption in the vicinity of the half-wave potential to be determined. Analogous data for the white metal cations are less straightforward to obtain because of the difficulties associated with the preparation and storage of metal amalgam electrodes. Finally, the V(III)/V(II) system was attractive because the electrode kinetics of the couple have been extensively studied (7-14) in electrolytes where no reactant adsorption occurs. It was hoped that a comparison of these rates with those measured with adsorbed reactants would contribute to an understanding of the effect of adsorption on the rate of electrochemical charge transfer for a simple redox reaction.

Experimental

Techniques.—The adsorptions of V(III) and V(II) (which shows very little adsorption) were evaluated at potentials removed from the half-wave potential by double potential-step chronocoulometry (1). The theory and practice of this technique have been described (15, 2). To measure V(III) adsorption the electrode potential was stepped from various initial values, E_i, to −900 mV, where the rate of reduction of V(III) is diffusion limited, and then back to E_i. To search for V(II) adsorption the potential was stepped from various initial values, well cathodic of $E_{1/2}$, to −300 mV where the oxidation of V(II) is diffusion limited in thiocyanate solutions.

Data acquisition and analysis were performed by means of the computer-based apparatus previously described (16). In most cases, data points (*i.e.*, the value of the charge passed up to each time) were recorded (automatically) every 400 μsec. Typically, 100 such points were obtained during the first potential step and another 100 following the return of the potential to its initial value. The amount of adsorbed V(III) was evaluated, as before, (3, 16) from regression analysis of the two sets of data points according to the theoretical equations of double potential-step chronocoulometry (15).

The double potential-step technique was not useful at values of E_i near $E_{1/2}$, where both V(III) and V(II) are present, because the coupling between the mass transfer process and the Nernstian limit on the electrode reaction rate greatly complicates the theoretical analysis. A modified single potential-step chronocoulometric method was employed to evaluate the adsorption in these cases. Details are described in the section on Results and Discussion.

To evaluate q^m, the charge density on the mercury electrode, in solutions where the electrode was ideally polarizable, *i.e.*, when only V(III) or V(II) was present, the charge flowing into a potentiostated dropping mercury electrode (dme) was measured and analyzed as previously described (2, 17, 18). The same experimental procedure was also employed with poised solutions containing both V(III) and V(II) in which the dme behaved as a nonpolarizable electrode. As is explained later, these experiments yielded values of q^m plus a fraction of the amounts of adsorbed V(III) and V(II) rather than q^m alone. Measurements of q^m with the dme were also performed by means of the computer-based data acquisition and analysis system (16).

Coulostatic experiments designed to measure large electrode reaction rates were performed with conventional circuitry (19). The potential-time transients were obtained photographically with a Tektronix Type C-12 camera and a Type 531 CRO with a Type W preamplifier. This combination recovered from being driven off scale within 1.0 μsec or less, but experimental data free from ohmic perturbations were usually not available at times shorter than 1.5 μsec.

Reagents.—All solutions were prepared from reagent grade salts and triply distilled water. Recrystallization of the salts produced no changes in the experimental results. Evidence for the quality of the reagents was

the good agreement between values of the electrode charge measured in these experiments and those previously obtained (by others) for the same electrolytes from double layer capacitance measurements. Solutions of V(II) were prepared by controlled potential reduction of V(V) at a stirred mercury pool at −1100 mV in the same cell employed for the subsequent electrochemical measurements. Solutions of V(III) were prepared by oxidation of V(II) at the mercury pool at −300 mV. With supporting electrolytes containing more than 0.01M thiocyanate the spontaneous reaction between V(V) and SCN^- was not negligible. Therefore, with these solutions V(V) was reduced to V(IV) by reduction at the mercury pool at −100 mV before any thiocyanate was added.

The concentrations of V(III) and V(II) were determined polarographically. The source of V(V) was V_2O_5 dissolved (after prolonged stirring) in 0.5M perchloric acid. All test solutions were 0.01-0.02M in $HClO_4$. Higher acidities were avoided to minimize the slow acid catalyzed decomposition of thiocyanate. Calculations show that the hydrolytic dimer of V(III) (20) constituted less than 1% of the total V(III) present in all solutions studied.

Solutions were deoxygenated with prepurified nitrogen that had been passed successively through copper turnings at 350°C and a trap maintained at −77°C. The ionic strength of all solutions was adjusted to 1.0M with $NaClO_4$. Measurements were carried out at 25° ± 2°C. All potentials are referred to the saturated calomel electrode.

Apparatus.—The hanging mercury drop electrode was a commercially available unit (Brinkman Instruments, Inc.) modified to improve the electrical contact (21). The mercury pool electrode used for the controlled potential generation of V(III) and V(II) served as the auxiliary electrode in the chronocoulometric and coulostatic experiments.

The electronic control device used to impose potential perturbations on the indicator electrode and to measure the current and coulomb responses consisted of appropriately connected operational amplifiers (Philbrick Type SP 656), mercury wetted relays, bias potentiometers, and switches. Its design and operation were essentially identical to previously described units (16, 22).

Results and Discussion

Two major aspects of the electrochemistry of the V(III)/V(II) couple have been studied: the adsorption of V(III) on mercury and the kinetics of the V(III)/V(II) couple in the adsorbed state. In order sensibly to address the second aspect the results of the adsorption studies are required so these will be discussed first.

V(III) *adsorption in the absence of* V(II).—The adsorption of V(III) was searched for in perchlorate, bromide, iodide, and thiocyanate electrolytes by double potential step chronocoulometry (1, 2). Only in thiocyanate solutions was significant adsorption detected. The standard double-step chronocoulometric technique depends on the assumption that the product of the electrode reaction is not adsorbed on the electrode. Two lines of evidence indicated that the adsorption of V(II) in thiocyanate solutions is very small: (*i*) single potential-step chronocoulometry with pure V(II) solutions gave intercepts of charge *vs.* $(\text{time})^{1/2}$ plots which matched (within ±0.5 $\mu C/cm^2$) the charge change obtained between the same two potentials in the absence of V(II); (*ii*) when reactant but not product is adsorbed, the slopes of the chronocoulometric plots for the forward and reverse potential steps are unequal, the reverse slope being larger. The ratio of the slopes can be calculated from a knowledge of the amount of adsorbed reactant (15). Thus, if products were adsorbed, the calculated and observed slope ratios would disagree. As the data in Table I show,

Table I. Calculated and observed slope ratios for double potential step chronocoulometric measurements with 1 mM V(III) in thiocyanate[a]

$-E_i$, mV	$F\Gamma_{V(III)}$, $\mu C/cm^2$	Reverse slope/forward slope	
		calculated[b]	observed

300	14.2	1.27	1.27
350	13.6	1.26	1.27
400	13.0	1.25	1.24

[a] Supporting electrolyte was 0.1M NaSCN-0.9M $NaClO_4$-0.01M $HClO_4$. The potential was stepped from E_i to −900 mV and back. [b] Slope ratios were calculated from $S_r/S_f = 1 + a_1 F\Gamma_{V(III)}/S_f\tau^{1/2}$, where S_r and S_f are the reverse and forward slopes, respectively, τ is the duration of the first potential step, and a_1 is defined in (15); for the experimental conditions employed $a_1 = 0.966$.

the calculated and observed slope ratios are in good agreement indicating little or no adsorption of V(II).

Table II summarizes the data obtained on V(III) adsorption at various potentials and thiocyanate concentrations. The rather slight dependence of the adsorption on the electrode potential is evident. The values of q^m in Table II were obtained in two ways: (*i*) the charge flowing into a dme potentiostated in the V(III)-SCN solution of interest was determined (17, 18); (*ii*) the value of q^m at −900 mV, the potential to which the electrode was stepped, was measured as in (*i*). Then the difference in charge between the initial potential and −900 mV was obtained, in the usual way (15), from the intercept of the chronocoulometric plot for the reverse step. Subtraction of the value of q^m at −900 gave the value of q^m at the initial potential in the presence of the adsorbed V(III). Both procedures gave the same values for q^m, but the chronocoulometric method was preferable because of difficulties in eliminating traces of reducible or oxidizable impurities which contributed undesirably large faradic components to the total charge consumed in the dme experiments with the V(III) solutions.

Figure 1 shows that the adsorption of V(III) is only weakly affected by changes in the amount of adsorbed thiocyanate ions. Values of Γ_{SCN^-} used in Fig. 1 were evaluated from the data of Wroblowa *et al.* (23) obtained in pure thiocyanate solutions by assuming that the adsorption of thiocyanate in pure and mixed electrolytes would be the same at corresponding salt activities (24).

The data in Table II and Fig. 1 contrast with similar data for the thiocyanate-induced adsorption of Cd(II) (2) and Zn(II) (25, 26) in that the adsorption of V(III) is less affected by changes in potential, electrode charge, and adsorbed thiocyanate than are the white metal cations. We believe these smaller dependences reflect a difference in the mode of adsorption of V(III). The white metals are believed to be adsorbed as uncharged, cation-anion complexes by bond

[a] All solutions contained 0.01M $HClO_4$ and were adjusted to an ionic strength of 1.0 with $NaClO_4$.

formation with additional anions which are specifically adsorbed on the electrode (2, 5, 6). Vanadium(III), on the other hand, is more likely to be adsorbed by means of the same thiocyanate anions with which it is complexed in the bulk of the solution. This assertion is based primarily on related experiments with Cr(III) thiocyanate complexes (27) which, because of their substitution inertness, can be studied in the absence of any free thiocyanate anions. The adsorption of these Cr(III) complexes is decreased monotonically by the addition of thiocyanate anions as the latter compete for the available electrode surface. Thus, the adsorption of the Cr(III)-thiocyanate complex results exclusively from the interaction between the coordinated thiocyanate and the mercury surface.[2]

An analogy has been drawn (27) between the adsorption of Cr(III)-SCN complexes on mercury electrodes and the homogeneous reaction

$$CrNCS^{2+} + Hg^{2+} = CrNCSHg^{4+} \quad [1]$$

which proceeds extensively from left to right (28, 29). The V(III) analog of reaction [1] cannot be observed because of the substitution lability of V(III), but the adsorption of the V(III)-thiocyanate complex on mercury can be observed, and it shares too many of the behavioral aspects of the Cr(III)-thiocyanate adsorptions to ignore the likely connection.

The adsorption of the Cr(III) complex is thought to arise from increases in the ligand field strength of the nitrogen atom in the coordinated thiocyanate molecule when a mercury-sulfur bond is formed at the sulfur atom in the same molecule (27, 30). The driving force for adsorption according to this scheme would be less for the doubly charged V(II) than for triply charged V(III) because of the smaller ligand field splitting, Δ, and similarly less for the d^2 V(III) ion than for the d^3 Cr(III) ion; the observed relative adsorptions of these three ions are in this order.

[2] Adsorption of metallic ions on mercury via coordinated ligands was proposed by O'Dom and Murray (4) in the case of indium adsorption from iodide electrolytes. We have argued against this mechanism for adsorption in the case of white metal cations (3), but we favor it in the case of transition metal cation adsorption induced by thiocyanate (27).

Identity of the adsorbed-V(III) *species.*—Attempts to determine the composition of the adsorbed V(III) complex were largely unsuccessful. The adsorption reaches a maximum at a concentration of thiocyanate near 0.1M (see Table II), but it does not seem justified to identify this adsorption maximum with the maximum concentration of a particular V(III)-thiocyanate complex because increasing the thiocyanate concentrations also increases the adsorption of free thiocyanate anions which compete for the available electrode surface with all V(III)-thiocyanate complexes. Furthermore, the available data on the formation constants for complexation of V(III) with thiocyanate are not adequate to allow the relative concentrations of the various possible V(III)-thiocyanate complexes to be calculated. Furman and Garner (31) showed that $VNCS^{2+}$ is the predominate complex formed in solutions 5 mM in V(III) and SCN^-, but evidence for higher complexes was clear at higher thiocyanate concentrations, such as prevailed in the present experiments.

Experiments with the Cr(III)-thiocyanate complexes, where the identities of the adsorbing species were certain (27), showed that the adsorption increased considerably as the number of coordinated thiocyanate ions increased from one to three. Similar behavior in the substitution-labile V(III)-thiocyanate system could lead to the preferential adsorption of a complex containing more than one thiocyanate, even if the higher complex were a relatively minor constituent in the solution.

In several previous studies (3, 6, 20), information on the charge of the adsorbing species was obtained from measurements of the changes in the rates of irreversible electrode reactions produced by the adsorption. This approach failed in the present instance for the lack of suitable electrode reaction whose rate could be measured in the narrow potential "window" between the reduction of V(III) and the oxidation of mercury in the thiocyanate supporting electrolytes.

V(III) *adsorption in the presence of* V(II).—In solutions containing mixtures of V(III) and V(II) the standard double potential-step chronocoulometric

techniques is not applicable because the separation of double layer charging from faradaic reduction of adsorbed V(III) is no longer possible by means of the intercepts of the two plots of charge *vs.* appropriate functions of time. This inseparability of double layer and faradaic charge has been subjected to extensive analysis and discussion by Delahay and co-workers (32-34) and Sluyters and co-workers (35, 36). Review articles with treatments of this topic have also appeared (37-39). The ramifications of charge inseparability for the present experiments become clear if a single potential-step chronocoulometric experiment is contemplated: suppose the potential of a mercury electrode is stepped from its equilibrium value in a V(III)-V(II) mixture to −900 mV where the reduction of V(III) is diffusion limited. Plots of the total charge passed at time, t, *vs.* $t^{1/2}$ are linear and have intercepts on the charge axis equal to the sum of the amount of V(III) adsorbed at the equilibrium potential and the difference in the charge on the electrode between the initial potential and −900 mV. If the usual chronocoulometric analysis were applied, the charge on the electrode at the initial and final potentials would be measured in independent experiments and the resulting difference in charge subtracted from the observed intercept to obtain the amount of adsorbed V(III). The value of the charge on the electrode, q^m, at −900 mV can be obtained, as described in the Experimental section, from measurements of the charge flowing into a dme potentiostated at −900 mV in a solution containing V(II) but no V(III). However, if the same procedure is followed at the equilibrium potential with the mixture of V(III) and V(II), the value of q^m at the initial potential is not obtained. Instead, the sum of q^m plus a fraction of the amounts of V(III) and V(II) adsorbed at the equilibrium potential is obtained. This result has been anticipated in previous work by others (40, 41), but it has, so far as we are aware, never been explicitly tested by experiment. For this reason, it seems useful to give a, largely unoriginal, thermodynamic analysis of the expected results along with those obtained experimentally.

We shall consider a mercury electrode at equilibrium in a solution containing the salts NaNCS, $V(NCS)_2$, and $V(NCS)_3$. The electrocapillary equation for this system is (42)

$$-d\gamma = q^m\,dE^- + \Gamma_{Na+}d\mu_{NaNCS} + \Gamma_{V(III)}(d\mu_{V(NCS)_2} + \mathbf{F}\,dE^-) + \Gamma_{V(II)}d\mu_{V(NCS)_2} \quad [2]$$

where it has been assumed that the V(II)-V(III) couple functions as a reversible redox couple; *i.e.*

$$d\mu_{V(NCS)_3} = d\mu_{V(NCS)_2} + \mathbf{F}\,dE^- \quad [3]$$

And where γ is the interfacial tension, q^m is the charge density on the mercury, E^- is the potential of the mercury electrode with respect to an electrode reversible to thiocyanate ion, the μ's and Γ's are the chemical potentials and surface excesses of the subscripted species, respectively, and $\mathbf{F}$ is the Faraday. Suppose a series of measurements of the interfacial tension are made in solutions containing varying ratios of V(III) to V(II) but with a constant total concentration of vanadium, C^*.

$$C_{V(III)} + C_{V(II)} = C^* = \text{const.} \quad [4]$$

Under these conditions Eq. [3] and [4] can be combined to yield

$$d\mu_{V(NCS)_2} = -\mathbf{F}\left(\frac{C^* - C_{V(II)}}{C^*}\right)dE^- \quad [5]$$

Substituting [5] into [2] and rearranging gives (2)

$$-d\gamma = \Gamma_{Na+}d\mu_{NaNCS} + \left[q^m + \mathbf{F}\Gamma_{V(III)} - \mathbf{F}(\Gamma_{V(III)} + \Gamma_{V(II)})\left(\frac{C^* - C_{V(II)}}{C^*}\right)\right]dE^- \quad [6]$$

which leads to

$$-\left(\frac{d\gamma}{\partial E^-}\right)_{\mu_{NaNCS}} = q^m + \frac{\mathbf{F}}{C^*}(\Gamma_{V(III)}C_{V(II)} - \Gamma_{V(II)}C_{V(III)}) \quad [7]$$

Thus, a measurement of the slope of the electrocapillary curve at potentials where both V(II) and V(III) are present does not give q^m, but a more complex quantity dependent on the concentrations and surface excesses of V(III) and V(II).

The measurement of the charge flowing into a potentiostated dme in a V(II)-V(III)-thiocyanate mixture, according to the procedure described in the Experimental section (2, 17, 28), amounts to an experimental evaluation of the slope of the electrocapillary curve. This assertion seems quite reasonable because the time scale of the experiment is several seconds and the heterogeneous rate constant for the V(II)/V(III) couple in thiocyanate media is greater than 10^{-2} cm/sec so that there is no reason to doubt that thermodynamic equilibrium prevails throughout the data collection. Note also that so long as the thiocyanate concentration is large compared with the total vanadium concentration, as the ratio of V(III) to V(II) is changed, the derivative with the respect to E^- is essentially the same as the derivative with respect to E_{ref}, the potential measured *vs.* a fixed-potential reference electrode.

An experimental test of this analysis is given in Fig. 2 which gives "charge"-potential curves for two supporting electrolytes in the absence and presence of V(III) and V(II). With the sodium perchlorate electrolyte the values of charge obtained from the dme experiment are the same, within experimental error (±0.4 μC/cm²), whether or not the V(III)/V(II) couple is present. This accords with the chronocoulometric result that no adsorption of V(III) or V(II) could be detected in pure perchlorate electrolytes; the second term in Eq. [7] is thus zero at all potentials and the true charge on the electrode, q^m, is obtained in the presence, as well as in the absence of the V(III)/V(II) couple. [This conclusion ignores any nonspecific adsorption of V(III) and V(II) in the diffuse layer, but this is negligibly small at the ionic strength (μ = 1.0) and vanadium concentrations (C^* = 1 mM) employed.]

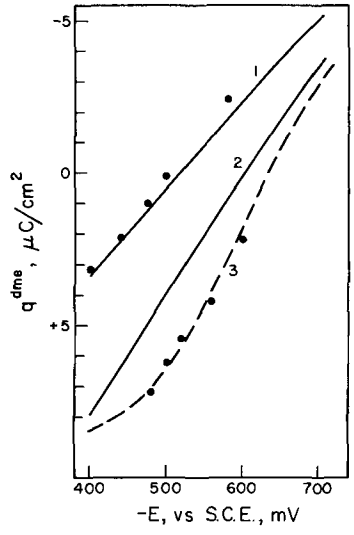

Fig. 2. Potential dependence of the values of q^{dme} obtained with a dropping mercury electrode. Solution compositions: 1, 1M $NaClO_4$; 2, 3, 0.1M NaNCS-0.9M $NaClO_4$. Solid lines are for the pure supporting electrolytes; plotted points represent values obtained in the same electrolyte in the presence of vanadium: [V(III)] + [V(II)] = 1.0 mM. All solutions also contained 0.02M $HClO_4$.

A different result is obtained with the mixed perchlorate-thiocyanate electrolyte (Fig. 2). With this supporting electrolyte the charge-potential curves do not coincide in the absence and presence of V(III) and V(II). Again, this behavior accords with the chronocoulometric result that substantial V(III) adsorption occurs from 0.1M NaNCS solutions. Equation [7] predicts that in a solution where $C_{V(III)} = C_{V(II)} = \frac{C^*}{2}$, the value of "charge" resulting from the dme experiment should be given by $\left[q^m + \frac{\mathbf{F}}{2} (\Gamma_{V(III)} - \Gamma_{V(II)} \right]$. Values of $\mathbf{F}\,\Gamma_{V(III)}$ and $\mathbf{F}\,\Gamma_{V(II)}$ obtained chronocoulometrically for a solution containing 0.5 mM V(III) and 0.5 mM V(II) are 7 ± 1 μC/cm^2 and 0 ± 1 μC/cm^2, respectively. Thus, if q^m were unaffected by the adsorption of V(III), the expected value of charge resulting from the experiment with a dme poised at the equilibrium potential would be 3.5 μC/cm^2 greater in the presence of 0.5 mM V(III) and V(II) than in their absence. The observed difference (Fig. 2, $E = -520$ mV) is 3 μC/cm^2. Comparable agreement was obtained at other potentials in the vicinity of the half-wave potential which supports the analysis given above. The inseparability of faradaic from nonfaradaic charge with poised electrodes in Nernstian systems where substantial reactant adsorption occurs is also clearly demonstrated.

One may inquire why more total charge is supplied by the potentiostat to the dme in the presence of V(III) and V(II) even if the (not directly measurable) value of q^m is not changed by the adsorption of V(III). The explanation is that as the drop grows some of the V(III) at its surface is "consumed" by being adsorbed on the electrode. The Nernstian balance of V(III) and V(II) at the electrode is thereby disturbed, and the potentiostat supplies the additional charge necessary to oxidize enough V(II) to restore the ratio V(III)/V(II) to its initial value. This faradaic charge will be supplied at just the same rate as is the nonfaradaic charge needed to maintain the charge density, q^m, because both charge-consuming processes are proportional to the rate of change of the electrode's area. It is just this indistinguishability in time that renders the two kinds of charge experimentally inseparable.

The comparison made above of the separation near $E_{1/2}$ of the two charge-potential curves for the thiocyanate electrolyte in Fig. 2 with the separation calculated on the basis of Eq. [7] depended on a knowledge of $\Gamma_{V(III)}$ and $\Gamma_{V(II)}$ at potentials near $E_{1/2}$. However, the inseparability of the faradaic and nonfaradaic charges just described prevents the direct measurement of the double layer charging corrections which must be subtracted from the observed intercepts of chronocoulometric charge-(time)$^{1/2}$ plots to obtain values for $\Gamma_{V(III)}$. This leaves the question of how the values of $\Gamma_{V(III)}$ and $\Gamma_{V(II)}$ quoted above as prevailing at potentials near $E_{1/2}$ were obtained. In two ways: the simplest was to assume, on the basis of the behavior observed at potentials removed from $E_{1/2}$, where separation of faradaic and nonfaradaic charges is no problem, that a negligible change in q^m at potentials near $E_{1/2}$ is produced by the adsorption of V(III). Then the charge change measured in the absence of vanadium for a potential step from initial potentials near $E_{1/2}$ to -900 mV could be subtracted from the chronocoulometric intercept obtained in the presence of vanadium to obtain $\Gamma_{V(III)}$. The reasonableness of the assumption on which this method is based was checked by evaluating $\Gamma_{V(III)}$ by a second method and comparing the results.

The second route to values for $\Gamma_{V(III)}$ took advantage of the fact that measurements of q^m at -900 mV by the dme procedure gave the same result, -9.5 μC/cm^2, in the presence and absence of V(II). The intercepts, I, of chronocoulometric (charge *vs.* $t^{1/2}$) plots for potential steps to -900 mV from initial equilibrium potentials in solutions containing both V(III) and V(II) are therefore given by Eq. [8]

$$I = \mathbf{F}\,\Gamma_{V(III)} + q^m{}_{-900} - q^m{}_{E_i} = \mathbf{F}\,\Gamma_{V(III)} - q^m{}_{E_i} - 9.5 \quad [8]$$

An independent relation between the same quantities results from the dme charge measurements with the poised solution at E_i. From Eq. [7]

$$-\left(\frac{\partial \gamma}{\partial E}\right) = q^{dme}{}_{E_i} = q^m{}_{E_i} + \beta\,\mathbf{F}\,\Gamma_{V(III)} \quad [9]$$

where $q^{dme}{}_{E_i}$ is the charge supplied to the growing drop at a rate proportional to its change in area and $\beta = C_{V(II)}/C^*$. Equations [8] and [9] can be solved simultaneously to yield values for $\mathbf{F}\Gamma_{V(III)}$ (as well as $q^m{}_{E_i}$).

Both of the methods were applied to obtain values of $\Gamma_{V(III)}$ at potentials near $E_{1/2}$, and the resulting data are summarized in Table III. The agreement between the values of $\Gamma_{V(III)}$ obtained by the two methods is only fair presumably because the assumption that q^m is unaffected by the adsorption of V(III) is not strictly valid and also because of the relatively large uncertainties associated with the values of $q^{dme}{}_{E_i}$ obtained from the dme experiments in poised solutions. However, the data do demonstrate unambiguously that a substantial amount of V(III) is adsorbed in the vicinity of the half-wave potential for the couple.

The strong potential dependence of $\Gamma_{V(III)}$ near $E_{1/2}$ reflects the fact that the concentration of V(III) is very potential dependent near $E_{1/2}$ (Nernst equation). A similar dependence on the concentration of V(III) is also observed at potentials well anodic of $E_{1/2}$ (Table II).

With reference to the ideas of Delahay *et al.* (32-34), it may be worth noting that in the present instance, the evaluation of $\Gamma_{V(III)}$ by the combination of the chronocoulometric intercept with the dme charge measurement (Eq. [8] and [9]) accomplishes a separation of the total charge into faradaic ($\mathbf{F}\Gamma$) and nonfaradaic ($q^m{}_{E_i}$) components. However, this separation is not *a priori* because it resorts to the non-thermodynamic chronocoulometric measurements. Nevertheless, this tactic can be helpful in evaluating the "true double-layer capacitance"; *i.e.*, $\left(\frac{\partial q^m}{\partial E}\right)$, in the presence of reactant adsorption. Just such use is made of this possibility in the experiments on the kinetics of the V(III)-V(II) couple in thiocyanate solutions to be described next.

Effects of V(III) *adsorption on the kinetics of the* V(III)-V(II) *couple.*—The problem of measuring the rate of a rapid electrode reaction when the reactant is adsorbed on the electrode has long plagued electro-

Table III. Comparison of the values for $\Gamma_{V(III)}$ obtained by two different methods

Supporting electrolyte: 0.9M $NaClO_4$-0.1M NaNCS-0.01M $HClO_4$
[V(II)] + [V(III)] = 1.0 mM

$-E$, mV *vs.* SCE	$\mathbf{F}\Gamma_{V(III)}$,[a] μC/cm^2, from intercept	$\mathbf{F}\Gamma_{V(III)}$,[b] μC/cm^2 from intercept and dme measurements
480	9.7 ± 0.4	7.2 ± 1.5
500	8.9	7.3
520	7.2	7.6
550	3.9	2.4

[a] These values were obtained by subtracting from the intercepts of chronocoulometric charge-(time)$^{1/2}$ plots the charge consumed in stepping the electrode from the same initial equilibrium potential to -900 mV in the supporting electrolyte alone. The reproducibility of each value was *ca.* ±0.4 μC/cm^2.

[b] These values were calculated by combining Eq. [8] and [9] to give $(1 - \beta)\mathbf{F}\Gamma_{V(III)} = I - q^{dme} - 9.5$. The reproducibility of each calculated value was *ca.* ±1.5 μC/cm^2.

chemical kineticists. A large number of theoretical analyses and experimental attacks on the problem have been made [ref. (43-50) are a representative but not comprehensive set of examples]. They all boil down to extrapolations to infinite frequencies or vanishingly small times where, it is assumed, only adsorbed reactant can be reacting because of the finite times required to transport unadsorbed reactant from the solution to the electrode surface. This philosophy was applied to the V(III)-V(II) couple in thiocyanate solutions in the present experiments by means of the coulostatic technique (19): small charges were injected into a hanging mercury drop electrode initially at its equilibrium potental in a solution containing approximately equal concentrations of V(III) and V(II). The resulting, open-circuit, potential-time transients were observed on an oscilloscope, recorded photographically, and analyzed to obtain information about the kinetics of the electrode reaction. To carry out the analyses of the transients, values of the differential double-layer capacitance are required (51, 52) and the appropriate value of the capacitance is that for solutions containing the reactant couple. When no reactant adsorption occurs the double-layer capacitance measured at the same potential in reactant-free supporting electrolyte is usually an excellent approximation of the capacitance in the presence of reactant. When reactant adsorption is known to occur, as with V(III) in thiocyanate solutions, the approximation that there is no change in double-layer capacitance is much poorer. Furthermore, the *a priori* inseparability of faradaic current and double-layer charging current referred to earlier complicates attempts to evaluate the true double-layer capacitance in the presence of reactant adsorption (47-50).

The approach adopted in the present experiments was as follows: values of $q^m{}_{E_i}$ at various values of E_i were obtained by simultaneous solution of Eq. [8] and [9] as described earlier. A plot of these values of $q^m{}_{E_i}$ *vs.* potential in the vicinity of $E_{1/2}$ was made. The slope of the resulting line gives the appropriate differential double-layer capacitance for use in analyzing the coulostatic potential-time transients. The experimental errors involved in obtaining the values of $q^m{}_{E_i}$ leave some uncertainty in the value of the double-layer capacitance in the presence of vanadium as is indicated in Fig. 3. It seems likely that the capacitance is actually about the same, 46 μF/cm^2, in the presence of vanadium as in the pure supporting electrolyte. However, the slope of the dashed rather than the solid line in Fig. 3 was used to evaluate the

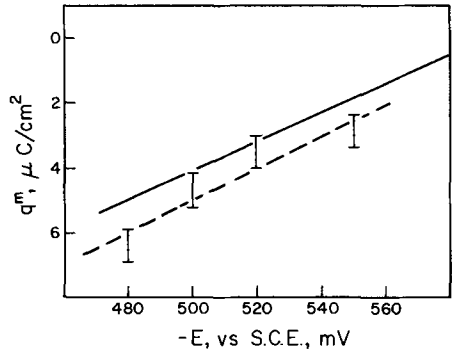

Fig. 3. Charge-potential curves. The solid line is the result of measurements of q^m with the dme procedure in pure supporting electrolyte

0.1M NaSCN-0.9M $NaClO_4$-0.02M $HClO_4$

Its slope corresponds to a double-layer capacitance of 46 μF/cm^2. The four points marked with bars were obtained from the corresponding points in Fig. 2 by subtracting the appropriate fraction of $\Gamma_{V(III)}$ as calculated from Eq. [7]. The length of the bars indicates the range of the values obtained in replicate experiments. The dashed line through the four points corresponds to a double-layer capacitance of 50 μF/cm^2.

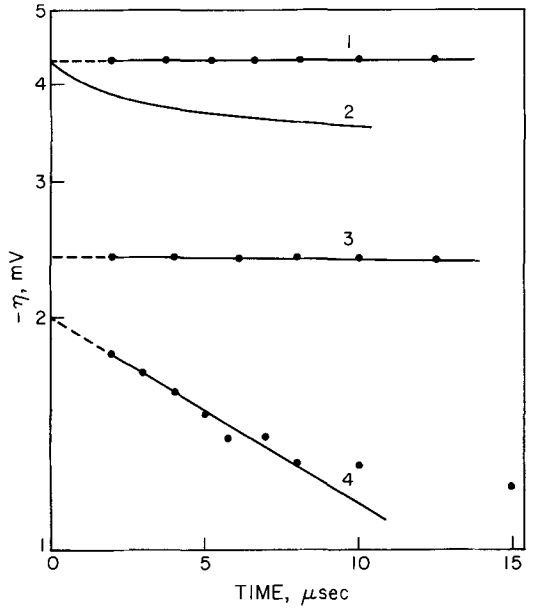

Fig. 4. Cathodic coulostatic relaxation transients for V(III)/V(II) in thiocyanate. 1, Supporting electrolyte alone: 0.1M NaSCN-0.9M $NaClO_4$-0.02M $HClO_4$; 2, calculated diffusion limited relaxation transient in the same electrolyte as 1 for [V(III)] = [V(II)] = 0.5 mM; 3, experimental transient in the same electrolyte as 1 with [V(III)] = [V(II)] = 0.5 mM; 4, as in 3 except [V(III)] = [V(II)] = 5 mM. The overvoltage, η, is plotted on a logarithmic scale. In each case, the initial potential was −520 mV and the charge injected was −0.176 μC/cm^2.

capacitance as 50 μF/cm^2 in the presence of V(III) and V(II). The true value of the capacitance should be bracketed by these two values.

Curve 3 in Fig. 4 shows a typical cathodic potential-time relaxation transient obtained with 0.5 mM V(III) and 0.5 mM V(II) in a 0.1M NaNCS-0.9M $NaClO_4$ supporting electrolyte. It is unusual in that even at the shortest times at which measurements could be made, the observed potential is well below the value that is obtained in the same electrolyte without vanadium, curve 1. Curve 2 is the calculated transient that would be observed for a diffusion limited electrode reaction with the same bulk concentrations of V(III) and V(II) and the double-layer capacitance of the supporting electrolyte. It is clear from curve 2 that very little of the difference between curves 1 and 3 can be attributed to the reaction of the bulk reactants, especially at the shortest observable times. The potential difference between curves 1 and 3 could arise either from a large difference in the double-layer capacitance for the two solutions or from the very rapid faradaic reaction of adsorbed V(III). However, the double-layer capacitance has been shown to increase by no more than 4 μF/cm^2 (from 46 to 50 μF cm^2) in the presence of V(III) and V(II) (Fig. 3), while a change of 30 μF/cm^2 would be required to account for the difference between curves 1 and 3 in Fig. 4. Thus, the faradaic reaction of adsorbed V(III) seems clearly to be the source of this difference.

As a check on these conclusions, a set of coulostatic experiments was also carried out in a bromide supporting electrolyte where substantial anion adsorption occurs, but no evidence of V(III) adsorption was obtained in chronocoulometric measurements. Figure 5 shows the results: essentially no difference at the shortest times between the curves obtained in the presence and absence of V(III) and V(II). These results with the bromide electrolyte confirm that V(III) adsorption in the thiocyanate electrolyte is the reason for the differences between curves 1 and 3 in Fig. 4. It seems reasonable, therefore, to use the difference between these two curves to calculate a value for the exchange current for the adsorbed V(III)/V(II) couple. Unfortunately, only a lower limit on the rate

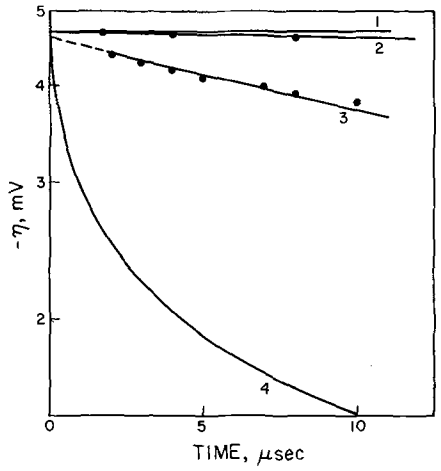

Fig. 5. Cathodic coulostatic relaxation transients for V(III)/V(II) in bromide. Supporting electrolyte: 1M NaBr-0.02M $HClO_4$. 1, Supporting electrolyte alone; 2, experimental transient with [V(III)] = [V(II)] = 0.5 mM; 3, experimental transient with [V(III)] = [V(II)] = 5 mM; 4, calculated diffusion limited transient for [V(III)] = [V(II)] = 5 mM. The overvoltage, η, is plotted on a logarithmic scale. In each case, the initial potential was −470 mV and the charge injected was −0.239 $\mu C/cm^2$.

can be obtained because the essentially constant level of the potential-time transient at the shortest accessible times (curve 3, Fig. 4) indicates that the reduction of the adsorbed V(III) is completed by the time the ohmic potential drop decays to negligible values, *ca.* 1.5 μsec. At $t = 1.5$ μsec, the difference between curves 1 and 3 amounts to 1.8 mV which corresponds (on the basis of the double-layer capacitance in the presence of adsorbed V(III) obtained from Fig. 3) to 0.090 $\mu C/cm^2$ of charge. This charge difference can be attributed to the reduction of the same amount of adsorbed V(III). Thus, 0.090 $\mu C/cm^2$ of V(III) were reduced within 1.5 μsec. The minimum average faradaic current flowing during this period was thus 60 mA/cm^2 and the average overvoltage during this period was 3.4 mV. If the same linearized current-potential relation commonly used to analyze the kinetics of unadsorbed reactants (53) is applied to the present case, a value of the minimum exchange current can be calculated

$$I = I_o \frac{\mathbf{F}}{RT} \eta \qquad [10]$$

where I is the faradaic current, I_o is the exchange current, η is the overvoltage, and $\mathbf{F}/RT = 0.0392$ mV^{-1} at 25°C. Equation [10] leads to $I_o = 0.50$ A/cm^2 as the minimum value of the exchange current for the adsorbed reactants.

If positive instead of negative charge is injected in the coulostatic experiment, the resulting anodic transient duplicates the cathodic transient. This indicates that sufficient V(II) is adsorbed to provide a symmetrical relaxation pathway via the adsorbed reactants. The chronocoulometric value for V(II) adsorption at $E_{1/2}$ was 0 ± 1 $\mu C/cm^2$, but the coulostatic measurements are more sensitive for detection of small quantities of adsorbed reactant. Hence, 0.5 $\mu C/cm^2$ was taken as a reasonable value for the amount of adsorbed V(II).

The rather large minimum exchange current obtained for the V(III)/V(II) couple in the adsorbed state contrasts with the smaller exchange currents previously measured for this couple in electrolytes where no reactant adsorption was involved (7-14). This large difference might be regarded as an instance of true catalysis by the electrode surface, *i.e.*, electrocatalysis. Before reaching this conclusion however, it is necessary to compare the exchange currents for the homogeneous (no reactant adsorption) and heterogeneous (both reactants adsorbed) cases with equivalent concentrations of reactants. "Equivalent concentrations" for these two cases implies homogeneous concentrations that expose the electrode surface to the same amounts of reactants per square centimeter as are adsorbed in the heterogeneous case. The molar reactant concentration that is required to match the cross-sectional concentration in the bulk of a homogeneous solution with a surface concentration of adsorbed reactant, Γ_i, can be calculated from Eq. [11]

$$C_i = \frac{C_{H_2O}}{\Gamma_{H_2O}} \Gamma_i \qquad [11]$$

where C_i is the required molar reactant concentration, $C_{H_2O} = 55.5$M, and Γ_{H_2O} is the number of moles of water per square centimeter in the bulk of the solution; for pure water $\Gamma_{H_2O} = 2.7 \times 10^{-9}$ moles/cm^2 (54).

For the V(III)-V(II) system under consideration the surface concentrations of the two oxidation states at −520 mV estimated from chronocoulometric measurements of their adsorptions are $\Gamma_{V(III)} = 7.5 \times 10^{-11}$ moles/cm^2 and $\Gamma_{V(II)} = 5.2 \times 10^{-12}$ moles/cm^2. The matching homogeneous bulk concentrations calculated from Eq. [9] are $C_{V(III)} = 1.5$M and $C_{V(II)} = 0.10$M. It is the exchange current that would be measured in an (hypothetical) experiment with a solution containing these calculated concentrations of V(III) and V(II) that must be compared with the exchange currents observed with adsorbed reactants in order to assess whether the adsorption has had an effect on the electrochemical reactivity of the V(III)/V(II) couple.

To make this comparison a value for the homogeneous exchange current for the V(III)/V(II) couple in the same electrolyte is needed. Coulostatic relaxation transients for solutions 0.5 mM in V(III) and V(II), such as curve 3 in Fig. 4, are not suitable for this purpose at any accessible times because the corrections for mass-transfer contributions to the relaxation are sizeable and complex with reactant concentrations this low (51). For this reason, the coulostatic experiment was repeated with a solution ten times more concentrated in vanadium ([V(III)] = [V(II)] = 5 mM). The resulting transient is shown as curve 4 in Fig. 4. The slope of the straight line drawn through the points at the shortest times (before mass transfer begins to slow down the relaxation) with the double layer capacitance obtained from the data in Fig. 3 lead (51) to an exchange current of 69 mA/cm^2.

To check on the reasonableness of this value the experiment was repeated in a 1M NaBr electrolyte where there are no complications from adsorbed reactants. Curve 3 in Fig. 5 shows the relaxation transient that resulted. Its slope corresponds to an exchange current of 29 mA/cm^2 which makes the exchange current obtained in the thiocyanate electrolyte seem reasonable.

Taking the value of 69 mA/cm^2 for a solution 5 mM in V(III) and V(II) and assuming that the transfer coefficient, α, is 0.5, one calculates that the exchange current that would correspond to a solution containing 1.5M V(III) and 0.1M V(II) is 5.4 A/cm^2. This value is ten times greater than the estimated minimum exchange current with adsorbed reactants in the 0.1M NaNCS-0.9M $NaClO_4$ electrolyte. It is, therefore, not possible to observe any electrocatalytic effects if they are present. The increase in rate arising merely from the increased concentrations of reactants is so large that it effectively masks any enhancement (or depression) in the electrochemical reactivity of the complexes resulting from their adsorption.

The much higher reaction rates (exchange currents) observed with adsorbed reactants are to be expected because of the large increase in their surface concentrations which are produced by even rather weak adsorption (10^{-12} moles/cm^2 or less). This fact may often permit the reaction rate for both the adsorbed and nonadsorbed reactants to be evaluated because the

characteristic relaxation times for the two kinetic pathways may be sufficiently different for two distinct relaxations to be observed. The present case is such an example: the adsorbed V(III) is reduced so much more rapidly than the dissolved V(III) that the latter's rate of reduction can be measured without serious contributions from the reaction of the adsorbed species (curve 4, Fig. 4). Some complications might be anticipated from contributions of the adsorbed reactant to the slower relaxation of the dissolved reactant because the overvoltage which controls the rate of both processes continues to change. It is likely that curve 4 in Fig. 4 departs from linearity at longer times (lower overvoltages) for this reason. Nevertheless, the initial slope of this curve should provide a reasonable estimate of the exchange current for the homogeneous reaction.

Nürnberg (55) has suggested recently that weak adsorption of V(III) and V(II) may occur in perchlorate electrolytes. We could find no evidence for this chronocoulometrically nor even in the much more sensitive coulostatic experiments. Relaxation transients obtained in 1M $NaClO_4$ extrapolated to the same initial overvoltage as was obtained in blank experiments, *i.e.*, they resembled curve 3 in Fig. 5 rather than curve 4 in Fig. 4, and the calculated exchange currents [I_o = 250 $\mu A/cm^2$ with 0.5 mM V(III) and V(II)] agreed with previous measurements (7-9).

Sluyters and co-workers have reported on the kinetics of a number of metal/metal amalgam electrode reactions in which weak reactant adsorption occurs (35, 36, 56-58). In every case, the exchange currents were too large to be measured (with the a-c bridges employed) when reactant adsorption was evident. Similar behavior has also been observed by others (46, 59) and this apparent generality lead Sluyters and co-workers to speculate recently (60) as to whether there might not be "a causal connection between (electrochemical) reversibility and specific adsorption" of reactants. One conclusion arising from the present investigation is that concentration enhancement rather than true catalysis may often be the source of the much larger electrode reaction rates observed with adsorbed reactants. Essentially the same point has been made by Mairanovskii in discussing the polarography of adsorbed organic reactants (61, 62).

It seems likely that electrode reactions which are inherently slower than those so far investigated may permit a clearer distinction to be made between rate enhancements due to true catalytic adsorption and those arising only from concentration enhancement by adsorption. Kinetic studies of a number of transition metal thiocyanates are presently under way in this laboratory to explore this possibility.

Thermogalvanic Cells: Equations for Special States and Ionic Mobilities

Philip B. Lorenz

Bartlesville Petroleum Research Center, Bureau of Mines, U. S. Department of the Interior, Bartlesville, Oklahoma

ABSTRACT

Linear phenomenological equations for processes in thermogalvanic cells are set up in two forms. One form is used for examining the nature of six special states: the thermal and shorted initial states, and the isothermal, thermal, shorted, and adiabatic steady states. With aqueous electrolytes the following are predicted: a large variation in the Soret effect and a moderate variation in the Peltier heat with changes in electrical state; a difference between electrical and thermal transference numbers; and a small temperature gradient set up by the flow of current under adiabatic conditions. The other form of the equations is used for examining the mobility of ions in a thermal field and a comparison with the mobility in an electrical field or a concentration gradient. Introduction of electrostatic potential as a variable suggests a way of measuring thermodynamic properties of individual ions.

The thermogalvanic cell serves as a prototype for processes involving electric potentials of chemical and thermal origin. The spontaneous electric potentials in the earth are of considerable importance in logging of oil wells and other geophysical analytical methods. With ordinary geothermal gradients, the thermal component of a measured potential can amount to many millivolts. This part of the potential has received less than its share of attention, although electrochemical and electrokinetic potentials have been considered extensively.

For all kinds of potentials, a systematic formulation by means of linear phenomenological equations provides a sound basis for further understanding of the processes. A variety of formulations has been presented (1-5), but some are more convenient for making predictions than others. It is illuminating to compare the work that has been done with the isothermal concentration cell.

For the latter system, one formulation in particular has been used for describing the behavior of the cell under a variety of experimental conditions (6). The variables in this formulation are current, potential, diffusion rate, and gradient of chemical potential, which are closely related to experimental quantities. A special state is the steady state when electrical current maintains a constant concentration gradient. This state is relatively unfamiliar, but has been used as a basis for a separation procedure (7).

The more abstract formulation in terms of electrochemical potentials (8) leads to a relation between electrical and diffusion mobility that amounts to an extension of the Nernst-Einstein equation to finite concentrations.

The purpose of the present work is to extend the same treatment to the thermogalvanic cell. From the formulation in terms of experimental quantities, we find that there are six special states. The characteristics of two of these states have long been considered, *viz.*, the steady state of "Soret equilibrium" and the "initial" state of uniform concentration when the temperature gradient is first established. However, when the various possible electrical and thermal constraints are permuted, there are three other steady states and one other initial state.

From the formulation in terms of electrochemical potentials, we gain more information about the individual properties of the migrating ions. This information is of theoretical interest and, moreover, is needed for a knowledge of the behavior of mixed electrolytes.

Key words: initial state, ionic activity coefficient, ionic entropy, ionic mobility, Peltier heat, Soret coefficient, steady state, thermal emf, thermogalvanic cell.

The Cell

The salient features of the analysis can be seen in the simple case of a cell with a single electrolyte in a single solvent, with all the gradients in one dimension. The electrodes are reversible to one of the ions according to the reaction

$$(1/z_r)\,[M] \rightarrow (1/z_r)\,r^z + e^- \qquad [1]$$

where [M] is a substance, or a group of substances, *e.g.*

$$[M] = [\tfrac{1}{2}H_2],\ [AgCl - Ag],\ [\tfrac{1}{2}PbO + \tfrac{1}{2}H_2O - \tfrac{1}{2}Pb]$$

$$r = H^+, \qquad Cl^-, \qquad OH^-$$

For definiteness, the cell will be oriented so that reaction [1] takes place as written at the left, and in reverse at the right. All fluxes and forces will be taken as positive from left to right (Fig. 1). Thus, the cell emf

$$E = \tilde{\Delta\mu_r}/z_rF \qquad [2]$$

is positive when the right-hand electrode has the sign of the r ion. E is a difference function that is formally converted to a gradient in the subsequent treatment.

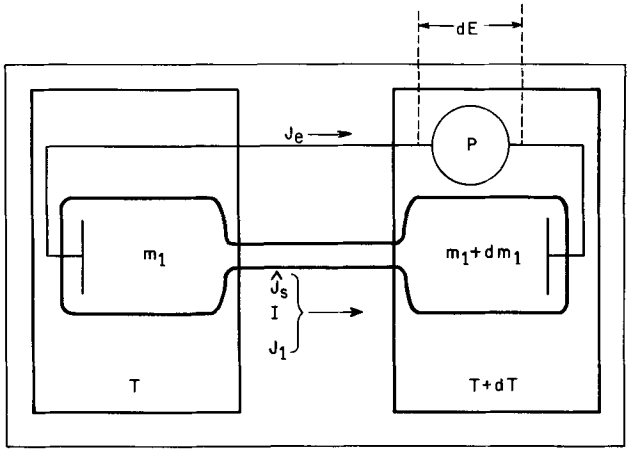

Fig. 1. Schematic diagram of thermogalvanic cell

Phenomenological Equations and Experimental Coefficients

The flux of solvent is eliminated by assuming the Hittorf convention. The electrolyte flux is then a straightforward experimental quantity in a cell such as that shown schematically in Fig. 1. The thermal flux will be represented by the flux of entropy. The reason for this choice is that the coefficients of the equations can be more conveniently interpreted than when heat flux is used directly.

The total entropy flux includes a convective term for bulk transport that results from the frame of reference anchored to the solvent. However, it is the nonconvective portion of the flux, $\overline{J}_s$, that is conjugate with the temperature gradient (5), and moreover the quantity

$$\hat{J}_s = \overline{J}_s - \Sigma_i \overline{S}_i J_i$$

is the conjugate flux when ordinary chemical or electrochemical potentials are used in place of the total chemical potentials that include the temperature variation.[1] For the processes under consideration, $\hat{J}_s$ is unaffected by the frame of reference; it is the "reduced heat flow" divided by the temperature (5). The reduced heat flow is measured calorimetrically as the heat accumulation on one side of the cell and depletion on the other. (The two quantities are not equal, but the difference is a second order effect.)

By the use of [2] and transformations that have been discussed previously (6), the phenomenological equations for the thermogalvanic cell can be put into the form

$$\begin{aligned} \hat{J}_s &= L_{11}\nabla T + L_{12}\nabla E + L_{13}\nabla\mu_1 \\ I &= L_{12}\nabla T + L_{22}\nabla E + L_{23}\nabla\mu_1 \\ J_1 &= L_{13}\nabla T + L_{23}\nabla E + L_{33}\nabla\mu_1 \end{aligned} \qquad [3]$$

The Onsager reciprocal relations have been incorporated into Eq. [3]. A modificaton of these equations is less symmetrical but more closely related to familiar experimental quantities

$$\begin{aligned} \hat{J}_s &= C_{11}\nabla T + C_{12}\nabla \ln m_1 + C_{13} I \\ J_1 &= C_{21}\nabla T + C_{22}\nabla \ln m_1 + C_{23} I \\ E &= C_{31}\nabla T + C_{32}\nabla \ln m_1 + C_{33} I \end{aligned} \qquad [4]$$

where m_1 is the molal concentration of the electrolyte. In this case $C_{21} = C_{12}/A$, $C_{32} = -C_{23}A$, and $C_{31} = -C_{13}$, where $A = \nu RT(1 + d \ln \gamma_\pm/d \ln m_1)$. Expressions for the coefficients of [3] and [4] in terms of conventional experimental quantities are given in Table I.[2] Extra terms appear in the L-coefficients because diffusion and thermal conductivity are measured with no electric current rather than with no electric potential. Table II gives examples of numerical values.

[1] For the system under consideration, $\hat{J}_s$ can be expanded to $\overline{J}_s - \overline{S}_M J_M - \overline{S}_1 J_1$, where J_M is a fictitious flux of electrode material; or $\hat{J}_s$ can be transformed to $J_{sk} + \hat{S}_r J_r + \hat{S}_g J_g + \hat{S}_e J_e + [\overline{S}_e + \overline{S}_r/z_r - \overline{S}_M/z_r]J_e$, where the term in brackets is the calorimetric entropy of the electrode reaction.

Table I. Coefficients of [3] and [4]

Subscript	$-L$	$-C$
11	$(K + \pi_{sm}^2\kappa/F^2T)/T$	K/T
12	$-\pi_{sm}\kappa/TF$	$\hat{S}_1 m_1 D$
13	$(\hat{S}_1 m_1 D/A) + (\pi_{sm} t_g \kappa/n_g F^2 T)$	π_{sm}/TF or ϵ
22	κ	$m_1 D$
23	$t_g\kappa/n_g F$	$-t_g/n_g F$
33	$(m_1 D/A) + (t_g/n_g F)^2\kappa$	$1/\kappa$

A 4.73×10^3	Proportional to ν	Small	(11)

Special States

There are three "initial" states: the isothermal initial state (IIS); the thermal initial state (TIS), in which a temperature gradient is established in the absence of electric current and before material fluxes have produced a significant concentration gradient; and the shorted initial state (SIS), which is the TIS with electrodes short-circuited. There are four steady states, two induced by the flow of current and two by a temperature gradient. In the former category belong the isothermal steady state (ISS) and the adiabatic steady state (ASS), the later produced by an adiabatic flow of current until the fluxes of solute and entropy both cease. The steady states produced by a thermal gradient are the thermal steady state (TSS) or Soret equilibrium in the absence of current, and the shorted steady state (SSS), which is the TSS with electrodes short-circuited.

Expressions equal to the various ratios under these special conditions are listed in Table III. Expressions is braces are included only for completeness. To get expressions compact enough for tabulation, it was necessary to develop the shorthand portrayed in Table IIIa. Examination of Tables II, III, and IIIa leads to the following conclusions:

1. The effect of electrical state (SIS and SSS) on thermal conductivity of aqueous electrolytes is very small, 1 part in 10^5 for 0.01N KCl and not over 1% in extreme cases. In fused salts or semiconductors this effect could be quite substantial, as much as 30%.

2. The Peltier heat of 0.01N KCl is increased about 6% by the establishment of ISS. This varies in sign and magnitude with electrolyte species. It depends on a large Soret coefficient and reasonable gegenion transference number. The increase is larger at low concentration; however, both the steady state and the low

[2] The thermal and electrical conductivities of the external circuit contribute to the over-all process, and the coefficients of Table I are, to a slight extent, approximations.

Table III. Expressions equal to various ratios

	0 =	IIS $\nabla T, \nabla m_1$	TIS $\nabla m_1, I$	SIS $\nabla E, \nabla m_1$	ISS $J_1, \nabla T$	TSS J_1, I	SSS $J_1, \nabla E$	ASS J_s, J_1
Thermal conductivity × $1/T$	$\hat{J}_s/\nabla T$		C_{11}	$C_{11}W_{13}$		$C_{11}W_{12}$	$L_{11}(1 - L^2_{13}/L_{11}L_{33})$	0
Peltier coefficient × $1/T$	$\hat{J}_s/I$	C_{13}		$\left\{\frac{C_{13}W_{13}}{W_{13}-1}\right\}$	$C_{13}U_{13}$		$\left\{\frac{C_{13}W_{13}}{W_{13}-1}X\right\}$	
Thermal emf	$\nabla E/\nabla T$		$-C_{13}$			$-C_{13}U_{13}$		$\{-C_{13}Z\}$
Electrical resistivity	$\nabla E/I$	C_{33}			$C_{33}W_{32}$			$C_{33}W_{23} + Y$
Soret coefficient	$\frac{\nabla \ln m_1}{\nabla T}$					$-C_{21}/C_{22}$	$-\frac{C_{21}}{C_{23}}\frac{U_{12}}{W_{23}}$	$\left\{-\frac{C_{21}U_{32}}{C_{22}U_{13}(U_{23}-1)}\right\}$
Transference	J_1/I	C_{23}		$\frac{C_{23}U_{12}}{U_{12}-1}$	0	0	0	0
Steady-state concentration	$\nabla \ln m_1/I$				$-C_{23}/C_{22}$		$\left\{-\frac{C_{23}U_{12}}{C_{22}U_{13}(U_{12}-1)}\right\}$	$-\frac{C_{23}}{C_{22}}\frac{U_{23}}{W_{12}}$

concentration increase the power required to transfer heat.

3. The foregoing effect in 3 is numerically equal to the difference in thermal emf between initial state (TIS) and Soret equilibrium (TSS).

4. The electrical resistance as usually measured with alternating current depends only on the distributed resistivity due to distributed concentration. Values in Table III refer to an increase in current flow and the simultaneous adjustment of the system to a new steady state. In this case $\nabla E/I$ is almost double the normal resistivity.

5. The Soret effect is defined for TSS, but, if the concept is extended to other steady states, the coefficient for 0.01*N* KCl is reversed in sign and increased eightfold in magnitude by short circuiting (SSS). This change is large for any system with a large Peltier coefficient and a reasonable gegenion transference number. It varies greatly with the electrolyte species; the sign is not always reversed.

6. The transference of electrolyte by current in 0.01*N* KCl is about 6% smaller when the current is generated by a thermal gradient than when it is generated by an applied emf. This means that a larger portion of the current is carried by the reversible ion when the current is thermally generated.

7. The concentration gradient in the current-induced steady state is virtually the same under isothermal (ISS) and adiabatic (ASS) conditions. In the adiabatic case, the temperature gradient is $-C_{13}U_{13}/C_{11}W_{12}$, which for 0.01*N* KCl is an increase in the direction of current flow of 0.33 deg m^{-1} A^{-1} (0.0033 deg cm^{-1} A^{-1}). This value depends primarily on the Peltier coefficient, but it also increases significantly with an increase in the Soret coefficient.

Phenomenological Equations and Mobilities

The other form of the equations to be considered is

$$\hat{J}_s = \Omega_{ss}\nabla T + \Omega_{sr}\nabla\tilde{\mu}_r + \Omega_{sg}\nabla\tilde{\mu}_g$$

$$J_r = \Omega_{sr}\nabla T + \Omega_{rr}\nabla\tilde{\mu}_r + \Omega_{rg}\nabla\tilde{\mu}_g$$

$$J_g = \Omega_{sg}\nabla T + \Omega_{rg}\nabla\tilde{\mu}_r + \Omega_{gg}\nabla\tilde{\mu}_g \quad [5]$$

Table IIIa. Shorthand for Table III and values (dimensionless) for 0.01*N* KCl

$1 - W_{12} = C_{12}C_{21}/C_{11}C_{32}$	$+0.96 \times 10^{-7}$
$1 - W_{23} = C_{23}C_{32}/C_{22}C_{33}$	-0.94
$1 - W_{13} = C_{13}C_{31}/C_{11}C_{33}$	-2.82×10^{-6}
$1 - U_{12} = C_{13}C_{32}/C_{12}C_{23}$	$+16.6$
$1 - U_{23} = C_{21}C_{13}/C_{23}C_{11}$	-1.7×10^{-6}
$1 - U_{13} = C_{12}C_{23}/C_{13}C_{22}$	-5.7×10^{-2}
$L_{13}^2/L_{11}L_{33}$	$+1.20 \times 10^{-5}$

$X = (1 - L_{13}^2/L_{11}L_{33})/(1 - L_{13}L_{32}/L_{12}L_{33})$
$Y = (1 - U_{23}/W_{12})(1 - W_{23}) + (W_{13} - 1)U_{13}/W_{12}$
$Z = 1 + (W_{23} - 1)U_{23}/(W_{13} - 1)U_{13} + (W_{13} - 1)U_{13}/W_{12}$

These equations emphasize the contributions of the separate ions to the cell process. Here the coefficients are thermal and electrochemical mobilities.[3] Their relation to the coefficients of Eq. [4] are

$$\Omega_{ss} = C_{11} + C_{13}^2/C_{33} = -(K + \pi^2_{sm}\kappa/T\mathbf{F}^2)/T$$

$$\Omega_{sr} = \nu_r[(C_{12}/A) + C_{13}(C_{23} + 1/n_r\mathbf{F})/C_{33}] = t_{r\kappa}\pi_{sm}/Tz_r\mathbf{F}^2 - \nu_r\hat{S}_1 m_1 D/A$$

$$\Omega_{sg} = \nu_g[(C_{12}/A) + C_{13}C_{23}/C_{33}] = t_{g\kappa}\pi_{sm}/Tz_g\mathbf{F}^2 - \nu_g\hat{S}_1 m_1 D/A$$

$$\Omega_{rr} = \nu_r^2[(C_{22}/A) + (C_{23} + 1/n_r\mathbf{F})^2/C_{33}] = -t_r^2\kappa/z_r^2\mathbf{F}^2 - \nu_r^2 m_1 D/A$$

$$\Omega_{gg} = \nu_g^2[(C_{22}/A) + C_{23}^2/C_{33}] = -t_g^2\kappa/z_g^2\mathbf{F}^2 - \nu_g^2 m_1 D/A$$

$$\Omega_{rg} = \nu_r\nu_g[(C_{22}/A) + C_{23}(C_{23} + 1/n_r\mathbf{F})/C_{33}] = -t_r t_g\kappa/z_r z_g\mathbf{F}^2 - \nu_r\nu_g m_1 D/A \quad [6]$$

To develop a relation among mobilities, a special symbol is defined for the entropy of transfer when the electric current is carried by one ion alone

$$\hat{S}_{Ir} = (\hat{J}_s/J_r)_{J_g=\nabla T=0} \quad [7]$$

$$\hat{S}_{Ig} = (\hat{J}_s/J_g)_{J_r=\nabla T=0} \quad [8]$$

By use of the relations

$$J_g = \nu_g J_1 \quad [9]$$

$$J_r = \nu_r J_1 + I/z_r\mathbf{F} \quad [10]$$

it is found that

$$\hat{S}_{Ir} = z_r\mathbf{F}[C_{13} - C_{12}C_{23}/C_{22}] = t_g\hat{S}_1/\nu_r - z_r\pi_{sm}/T \quad [11]$$

$$\hat{S}_{Ig} = z_g\mathbf{F}[C_{13} - C_{12}(C_{23} + 1/n_r\mathbf{F})/C_{22}] = t_r\hat{S}_1/\nu_g - z_g\pi_{sm}/T \quad [12]$$

From Eq. [6], [11], and [12], it follows that

$$\Omega_{sr} = \Omega_{rr}\hat{S}_{Ir} + \Omega_{rg}\hat{S}_{Ig} \quad [13]$$

$$\Omega_{sg} = \Omega_{gg}\hat{S}_{Ig} + \Omega_{rg}\hat{S}_{Ir} \quad [14]$$

The left-hand side of each equation represents the mobility of the ion under the sole influence of a thermal gradient. From a thermodynamic point of view, $-\hat{S}_{Ir}\nabla T$ is the "thermal force" for the migration of

[3] $\Omega_{rr} = (c/z_r\mathbf{F})u_r$ where c is equivalent concentration and u_r = (migration speed)/(voltage gradient).

r-ions accompanied by the electrode reaction. Thus, $\hat{S}_{Ir}$ serves to convert the electrochemical mobility, Ω_{rr}, into a part of the thermal mobility. This first term is the principal term. The second term involves Ω_{rg}, which is sometimes called a drag coefficient, and represents a kinetic interaction between the two ions. This interaction introduces a correction term into the thermal mobilitites, so that they are not identical with the electrochemical mobilities.

A similar situation exists in the relation between electrical and diffusion mobility. For the electrolyte, it is seen from Eq. [6] that

$$m_1 D/A = (t_r t_g \kappa/n_r^2 \mathbf{F}^2) - \Omega_{rg}/\nu_r \nu_g \quad [15]$$

and for the self-diffusion of a single ion, it can be shown that, approximately

$$m_r D_r/\nu_r RT = (t_r \kappa/z_r n_r \mathbf{F}) - \Omega_{rg}/\nu_g \quad [16]$$

In both cases, the second term on the right is a correction to the ideal Nernst equation. It has been shown (8) that Ω_{rg} is proportional to $\sqrt{m}$ at high dilution, so in the limit, thermal, electrical, and diffusion mobilities of the i-ion are all equal to Ω_{ii}. The nonequality of mobilities at higher concentration is introduced by the differing conditions of measurement.

Properties Associated with Individual Ions

The quantities $\hat{S}_{Ir}$ and $\hat{S}_{Ig}$ represent a composite of processes in the solution, in the external circuit, and at the electrodes. When $\hat{S}_{Ir}$ is expanded to show the entropy contribution of each process

$$\hat{S}_{Ir} = (\bar{\bar{S}}_r + z_r \bar{\bar{S}}_e - \bar{S}_M) \quad [17]$$

where $\bar{\bar{S}}_r$ is the entropy transported by the r-ion in solution, $\bar{\bar{S}}_e$ is the entropy transported by the electron in the wire, and $\bar{S}_M$ is the aggregate of molar entropies in the group [M]. The right-hand side of [17] is the same as the expression (3) for the thermoelectric power of the cell in Soret equilibrium, since by reciprocity

$$(\hat{J}_s/J_r)_{J_g=\nabla T=0} = -z_r \mathbf{F} (dE/dT)_{J_1=I=0} \quad [18]$$

Equations [17] and [18] are of value in developing expressions that suggest a measurement of thermodynamic properties of individual ions.

For illustration of the reasoning, consider first the electron in the wire. The differential of its total potential in the thermal gradient at zero electric current is (3)

$$d\bar{\mu}_e = -\bar{\bar{S}}_e dT \quad [19]$$

But if the temperature of a charged, isolated conductor M is raised, the increase in the total potential of the electrons is $d\bar{\mu}_e = -S_e dT$. If the conductor is connected with a sample of the same material at the original temperature, there will be a slight shift of charge because of the decreased escaping tendency at higher temperature. The electrons migrate from the cold end to the hot end until the thermal and electrical fields balance. The total potential is determined by the change in electrostatic (Volta) potential, ψ, as well as the temperature

$$d\bar{\mu}_e = -\bar{S}_e dT - \mathbf{F} d\psi \quad [20]$$

Equating [20] and [19]

$$d\psi = (\hat{S}_e/\mathbf{F}) dT \quad [21]$$

The electrostatic potential is measurable in principle, although a comparison of values at different temperatures would be less simple than measurements of isothermal changes. Table IV gives calculations from Eq. [21] for copper and platinum. The thermally induced electrostatic potential is a few microvolts per degree. This effect would probably be masked by the variations in local electrostatic potential due to inhomogeneous surfaces.

Table IV. Electrostatic potentials (μV/deg) on metals calculated from electronic entropies (joule/deg)

	Pt	Cu
$\bar{\bar{S}}_e$[a]	0.10	−0.045
$\bar{S}_e$[b]	0.05	+0.033

[a] Temkin and Khoroshin (14).
[b] Statistical value based on 1.0 free electron per atom for Cu and 0.6 for Pt (15).

Now the differential of the total potential for the r-ion can be easily derived by setting up the condition for equilibrium, *i.e.*, reversibility, at the electrodes. The expression is (3)

$$d\bar{\mu}_r = z_r \mathbf{F} dE + [z_r \bar{\bar{S}}_e - \bar{S}_M] dT = d\tilde{\mu}_r + [z_r \bar{\bar{S}}_e - \bar{S}_M] dT \quad [22]$$

Then, by use of

$$d\bar{\mu}_1 = \nu_r d\bar{\mu}_r + \nu_g d\bar{\mu}_g = \nu_r d\tilde{\mu}_r + \nu_g d\tilde{\mu}_g - \bar{S}_1 dT \quad [23]$$

it follows that

$$d\bar{\mu}_g = d\tilde{\mu}_g + [z_g \bar{\bar{S}}_e - (z_g/z_r) \bar{S}_M - \bar{S}_1/\nu_g] dT \quad [24]$$

When the thermogalvanic cell is in an initial state (IIS), $dE/dT = \pi_{sm}/T\mathbf{F}$, and this can be combined with [11], [17], and [22] to give

$$d\bar{\mu}_r = (-\bar{\bar{S}}_r + t_g \hat{S}_1/\nu_r) dT = -\bar{S}_r dT + z_r \mathbf{F} d\psi \quad [25]$$

Here ψ is to be taken as the electrostatic potential at the surface of the solution. Thence

$$(d\psi/dT)_{in} = (-\hat{S}_r + t_g \hat{S}_1/\nu_r)/z_r \mathbf{F} \quad [26]$$

Example calculations from Eq. [26] are given in Table V. Separate calculations (a) and (b) are made from different estimates of $\hat{S}_r$. The chief difference lies in the choice of a value for $\bar{S}_r$ for the hydrogen ion, which was −4.5 eu in (a) and −5.5 eu in (b). This makes an appreciable change in the predicted surface potential difference. In principle, since $\bar{S}_H$ is the basis for all conventional ionic entropies, measurements of surface potentials could be used to get actual ionic entropies (16).

When a cell is in Soret equilibrium, according to [17] $dE/dT = -\hat{S}_{Ir}/z_r \mathbf{F}$, and [25] is replaced by

$$d\bar{\mu}_r = -\bar{\bar{S}}_r dT = -\bar{S}_r dT + RT\, d \ln \gamma_r m_r + z_r \mathbf{F} \psi \quad [27]$$

Table V. Electrostatic potentials (μV/deg) on 0.01*N* electrolytes calculated from entropies of transport (joule/deg)

		KCl	HCl	KOH

t_g		0.490	0.175	0.735
$\hat{S}_1$[a]		7.1	43.9	63.5
$\hat{S}_r$	(a)[a]	7.5	40.6	0.0
	(b)[b]	2.1	43.2	7.1
$(d\Psi/dT)_{in}$	(a)	−41	−341	484
	(b)	+14	−368	409
$(d\Psi/dT)_{st}$	(a)	−40	−193	329
	Δ	3.5	22.0	32.0

[a] According to de Bethune (1).
[b] According to Agar (3).

where the second term on the right is the variation of Lange's "real potential" with concentration, and γ_r is some function of concentration that amounts to an activity coefficient for the reversible ion. Under the same conditions

$$d \ln m_1/dT = -\hat{S}_1/A \quad [28]$$

Now since $m_r = \nu_r m_1$

$$(d\psi/dT)_{st} = -\hat{S}_r + (S_1/\nu)[(1 + d \ln \gamma_r/d \ln m_1)/(1 + d \ln \gamma_\pm/d \ln m_1)] \quad [29]$$

Values given in Table V are based on the assumption that the quantity in square brackets is unity, *i.e.*, that the ionic activity coefficient is directly proportional to the mean activity coefficient of the electrolyte. The last line of the table shows differences that would result from a 10% change in the square brackets. This suggests a possible way of getting a numerical comparison of the activity coefficient of an electrolyte with an activity coefficient for its ions.

Thermodynamic Properties of Molten Mixtures of Cobalt Chloride with Some Alkali Halides

Drannan C. Hamby[1] and Allen B. Scott*

Department of Chemistry, Oregon State University, Corvallis, Oregon

ABSTRACT

Thermodynamic properties including the activity coefficient, and the partial molar free energy, enthalpy, and entropy of mixing have been determined for the solute $CoCl_2$ in the solvents KCl, NaCl, LiCl, and 1:1 NaCl-KCl. Values of the properties were established by measuring the reversible emf of cells of the type

$$Co|CoCl_2, MCl|Cl_2,C$$

where M represents an alkali metal cation. Cell emf's were determined over a range of concentration from approximately 10^{-4} to as high as 8.3×10^{-1} mole fraction of solute and temperatures ranging from the melting points of the solvents to 900°C. Experimentally determined values of the quantity $\Delta G°$, the standard change in Gibbs function for the reaction

$$Co(c) + Cl_2(g) \rightarrow CoCl_2(l)$$

have been found to agree to within 1 kcal with values calculated on the basis of Brewer's (19) tabulation: the agreement with values calculated from other data in the literature is not as close, but is still within the stated limits of uncertainty of the data. Reference electrodes of the type

$$Ag|AgCl, MCl||$$

which utilized solid porcelain as a bridge, were immersed in the same melts and allowed continuous monitoring of chlorine electrode potentials as solute concentrations varied.

This report concerns electrochemical cells which may be designated

$$Co|CoCl_2(N), MCl\ (1 - N)|Cl_2, C$$

where

$$N = \frac{\text{moles solute}}{\text{moles solvent} + \text{moles solute}}$$

and MCl is KCl, NaCl, 1:1M NaCl-KCl or LiCl. Reference electrodes of the type

$$Ag|AgCl\ (N), MCl\ (1 - N)||$$

similar to those described by Lamb and Labrie (1) and Littlewood (2) were also placed in the melts of the cells described above. The solvent, MCl, was always the same on both sides of the membrane. This arrangement allowed continuous measurement of the quantity

$$\Delta E' = E'_{Ag} - E_{Ag}$$

where E'_{Ag} and E_{Ag} are emf's for the cell

$$Ag|AgCl\ (N_{AgCl}), MCl||MCl, CoCl_2(N_{CoCl_2})|Cl_2, C$$

in the respective cases $N_{CoCl_2} \neq 0$ and $N_{CoCl_2} = 0$. The magnitude of $\Delta E'$ is useful in determining the limits of $CoCl_2$ concentration over which one may convert potentials measured with the Ag reference electrode to potentials based on the chlorine reference electrode without correcting for junction effects.

Cell emf's were determined over the ranges of solute concentration and temperature shown in Table I.

Experimental data have been extrapolated to unit mole fraction of $CoCl_2$ to establish a basis for the calculation of solute activities and partial molar free energies, enthalpies, and entropies of mixing of $CoCl_2$ in the various solvents.

Experimental

Several experimental details have been described in a previous paper and will not be repeated here (3). These include cell envelope and chlorine electrode design; cleaning procedures; gas metering method; furnace, temperature control, and temperature measurement; emf measurements and instrumentation; measurement of thermoelectric emf's developed by electrode pairs; details concerning preparation of the Ag|AgCl reference electrodes; and source and treatment of metal electrodes.

The chlorine, argon, and HCl gases were Matheson Company "high purity." The HCl and chlorine gases were passed over $Mg(ClO_4)_2$ and hot (500°C) powdered graphite (Ultra Carbon UF-4-S) before entering the cell. The argon was passed over $Mg(ClO_4)_2$ or P_2O_5 and then over hot Cu at 500°C; the Cu was in the form of pellets formed by reduction of CuO with H_2. The gas delivery system was glass except for a few inches of rubber tubing near the cell top.

The salts used in this work were:

NaCl *and* KCl.—Reagent grade materials were further purified by passage through ion exchange columns (4, 5). The salts were then vacuum desiccated and oven dried at 120°C in air for 48 hr. After two moles of salt were weighed into the cell crucible, the salts were subjected to two days vacuum-oven treatment at temperatures up to 200°C and pressures of approximately 10^{-2} mm Hg. The crucible was then transferred to the cell, in air, and the salt was again held at a pressure of approximately 10^{-2} mm Hg while being slowly brought to near its melting point over a two day period. Fusion was carried out under dry HCl and the salt was then chlorinated in the presence of carbon (6).

Table I. Concentration and temperature ranges

Cell	Solvent	T, °C	Solute range, N_{CoCl_2}
I	KCl	800-900	9.7×10^{-4}-4.8×10^{-1}
II	NaCl	800-900	1.4×10^{-4}-5.3×10^{-1}
III	1:1 NaCl-KCl	700-900	5.0×10^{-4}-5.4×10^{-1}
IV	LiCl	700-800	1.1×10^{-3}-8.3×10^{-1}

[1] Present address: Linfield College, McMinnville, Oregon.
* Electrochemical Society Active Member.

LiCl.—Reagent grade was used. Drying procedure was the same as for NaCl and KCl.

$CoCl_2$.—Reagent grade $CoCl_2 \cdot 6H_2O$ was initially vacuum oven dried at approximately 10^{-2} mm Hg at 200°C. The salt was subsequently dried for at least 4 hr under flowing dry HCl at 400°C. It was then transferred to weighing bottles in a glove bag under nitrogen, capped, and stored in a desiccator over P_2O_5 until used.

A schematic diagram of the cell envelope and electrodes is shown in Fig. 1. Each cell contained one Ag|AgCl reference electrode housed in a ½ in. diameter McDanel PT 38 MV30 porcelain tube, a Vycor sheathed chromel-alumel thermocouple, two chlorine electrodes, and one 6 mm Vycor tube, constricted to a capillary at the lower end, which protected the Co electrode from direct attack by dissolved chlorine (7). The Co electrode was immersed in the melt several minutes before its use in an emf determination. At other times it was positioned above the melt inside the protection tube where it was protected by a dry argon atmosphere. Equalization of melt concentration inside and outside the metal electrode compartment was achieved by purging with dry argon and allowing the compartment to refill.

After solvent preparation was complete and the electrodes were immersed, continuous monitoring of the chlorine electrode potential with respect to the Ag|AgCl reference electrode was begun. Subsequently, solute was added, either by electrolysis at low concentrations ($N < 10^{-3}$) or as the bulk anhydrous $CoCl_2$ powder at higher concentrations; transfer to the cell involved brief exposure to the atmosphere. Cell emf's were measured as a function of temperature, the usual sequence being high, low, and intermediate temperatures.

At any nominal bath concentration three samples of the melt were taken through the vacuum port by means of an acid-washed, flamed, 6 mm Vycor tube. Cobalt in the samples was determined spectrophotometrically at 520 nm in aqueous solution as the soluble red complex anion formed by Co^{++} and nitroso-R salt (sodium 1-nitroso-2-hydroxynaphthalene-3,6-disulfonate) (8). Aqueous solutions of known concentration of $CoCl_2$ were used to establish a curve of absorbance per cm *vs.* concentration. The limit of error (99% confidence level) of bath concentration, based on deviations of the original 10 standardizing absorbances from the least squares line, and also on the deviations of 10 other absorbance values for samples made up from the original standard solution, is taken to be +3% of bath concentration. This estimate is based on dilutions to yield absorbance values in the range 0.2 to 0.7 cm^{-1}.

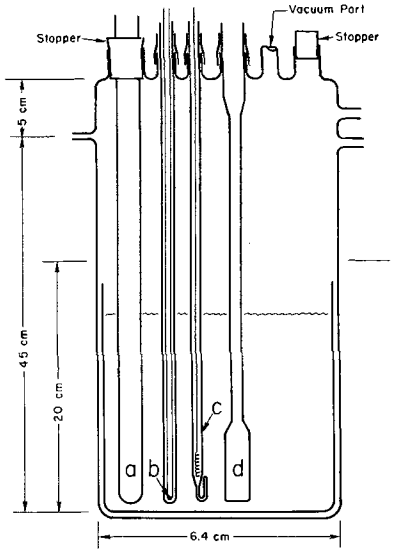

Fig. 1. Schematic diagram of cell envelope and electrodes: a, Ag reference electrode; b, thermocouple; c, Vycor protection tube; d, chlorine electrode.

Results

Reversibility of Co and chlorine electrodes was verified as reported previously (3). The treatment of the primary cell data is illustrated in Fig. 2 for cell III, solvent 1:1 NaCl-KCl. All emf's have been corrected for thermoelectric effects. In all cases the relationship of cell emf to temperature was assumed to be linear. The uncertainty in the determination of the slopes was estimated to be 5 x 10^{-5} V/degree. From Fig. 2 and similar plots cell emf's were read at constant temperature to prepare the curves shown in Fig. 3. Straight lines, giving the best fit by least

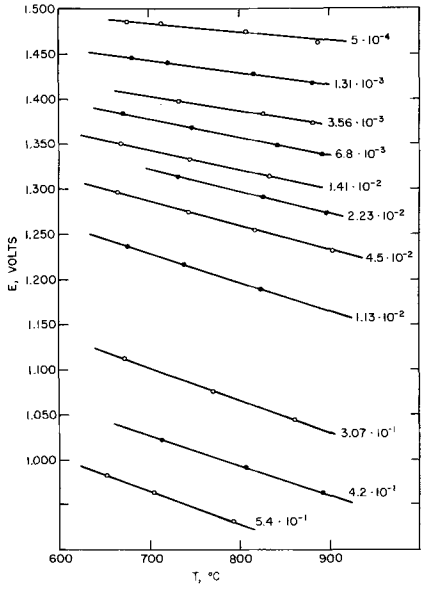

Fig. 2. Primary data for cell III, 1:1 NaCl-KCl solvent. Solute concentrations are indicated.

squares analysis, for the low concentration data are shown, and the slopes of these lines are compared with the Nernst equation value, 2.303 $RT/2\mathbf{F}$, in Table II.

The data of Fig. 3 have been extrapolated to unit mole fraction, using Raoult's law to predict a limiting slope as $N \rightarrow 1$, in order to establish the values of E° at 700° and 800°C. The thermodynamic functions for the assumed cell reaction

$$Co(c) + Cl_2(g) \rightarrow CoCl_2 \text{ (in liq. soln. at conc. } N) \quad [1]$$

have been calculated on the basis of the definitions

$$\lim_{N \rightarrow 1} \frac{a}{N} = 1$$

$$a = N\gamma$$

where a, N, and γ refer to the solute, $CoCl_2$. Thus, the standard and reference states of the solute are chosen as the pure liquid with the properties of the pure liquid at the temperature of the experiment and one atmosphere total pressure. The standard state for Cl_2 was taken as the pure gas at one atmosphere pressure. Corrections for variation in barometric pressure and depth of immersion of the Cl_2 electrode were estimated to be definitely less than 1 mV and were neglected. The reference function for the metallic reactants is mole fraction and the reference and standard states for the metals are taken as the pure elements in their stable modification at one atmosphere total pressure, at 1 atm pressure, and the temperature of the experiment. Thus, for Co the stable phase and standard state is the β phase, stable from 718°K to 1400°K at 1 atm pressure (11). The partial molar Gibbs function of mixing and the partial molar enthalpy and entropy of mixing are given by

$$\overline{G} \equiv \Delta G - \Delta G^\circ = -2\mathbf{F}E - \Delta G^\circ$$
$$\overline{H} \equiv \Delta H - \Delta H^\circ$$
$$\overline{S} \equiv \Delta S - \Delta S^\circ = 2\mathbf{F}\left(\frac{\partial E}{\partial T}\right)_p - \Delta S^\circ$$

where ΔG°, ΔH°, and ΔS° are the standard changes for reaction [1]. The excess free energy of mixing is given by

$$\overline{G}^E \equiv \overline{G} - RT \ln N = RT \ln \gamma$$

The values of $\Delta G^\circ = -2\mathbf{F}E^\circ$ determined in this study are given in Table III along with values calculated from data in the literature (9, 10, 11).

The quantity $\Delta S^\circ = 18.5$ eu was determined by extrapolating a curve of ΔS *vs.* log N to $N = 1$; the scatter of the data indicate an uncertainty of at least ±2 eu in this quantity.

Emf values were read at selected concentrations from the curves of Fig. 3 and used to calculate the values of the functions given in Tables IV through VII. Values of $\overline{S}$ given in the table are smoothed values based on graphs of ΔS *vs.* log N_{CoCl_2} and the value of ΔS° mentioned above.

The Ag|AgCl reference electrodes incorporated in cells I through IV are described in Table VIII. E'_{Ag} was found to be independent of N_{CoCl_2} up to $N_{CoCl_2} = 10^{-2}$. The values of E'_{Ag} given in the tables are average values, corrected for thermoelectric emf's, taken over the duration of the experiments with $CoCl_2$ concentrations up to $N = 10^{-2}$. The maximum deviation from the average is given. Nonzero values of $\Delta E' = E'_{Ag} - E_{Ag}$ were observed at higher concentrations; these values are plotted in Fig. 4 along with similar data for nickel electrodes and the solute $NiCl_2$ taken from an earlier paper (3).

Discussion

The cobalt electrode has been studied in fused salts by Flengas and Ingrahm (12), Laitinen and Liu (13), Stromatt (14), and Trzebiatowski and Kisza (15). Flengas and Ingrahm used the reference electrode

$$Ag|AgCl\ (N), 1{:}1\ NaCl\text{-}KCl||$$

where the double line represents an asbestos fiber, to measure the potential of the Co electrode as a function of $CoCl_2$ concentration up to $N = 6.12 \times 10^{-2}$ at 710°C in 1:1 NaCl-KCl. In an independent experiment the potential of the reference was established with respect to the chlorine electrode in the same solvent. Thus, the cell emf's for the $CoCl_2$ formation cell may be calculated from Flengas and Ingrahm's data. Corrections for thermoelectric effects of 4-5 mV were included in a later paper; however, as discussed previously (3) for the case of Ni, the polarity of the correction is in doubt. Flengas and Ingrahm's earlier data points without thermoelectric correction for the Ag-Co couple all lie within ±6 mV of the least squares line given in Table II. The majority of the points lie above the least squares line, and it is believed that proper inclusion of the thermoelectric correction would leave the two sets of data in good agreement.

Stromatt has carried out a rather extensive but unpublished study of solvent effects on nickel and cobalt electrodes at fixed solute concentration. Measurements of cobalt electrode potentials with respect to a chlorine electrode were taken at or near 0.1M and normalized to 0.1M at 670°C. Solvent composition was varied over wide ranges for the mixtures NaCl-KCl, LiCl-KCl, and LiCl-NaCl; however, measurements were not

Table VIII. Ag|AgCl, MCl reference electrodes

Cell	N_{AgCl}	Solvent	E'_{Ag} (volts) 700°	800°
I	5.5×10^{-3}	KCl		1.131 ± 4 mV
II	6.0×10^{-2}	NaCl		1.030 ± 2 mV
III	6.6×10^{-3}	1:1 NaCl-KCl	1.074 ± 2 mV	1.074 ± 2 mV
IV	7.3×10^{-2}	LiCl	0.975 ± 2 mV	0.969 ± 2 mV

carried out utilizing the pure alkali metal chlorides as solvents. Comparison of Stromatt's data with the present data require, in the case of 1:1 NaCl-KCl, both a temperature and a thermoelectric adjustment of data. Temperature coefficients of emf from the present study and Handbook (17) thermoelectric values were used to make the necessary corrections. The value 1.378V at $N_{CoCl_2} = 6.63 \times 10^{-3}$ calculated from Stromatt's data is in good agreement with that found in the present study, 1.375V.

Trzebiatowski and Kisza (15) have studied the cells

$$Co|CoCl_2(N), MCl\ (1 - N)\,|Cl_2,C$$

where MCl is KCl, NaCl, or LiCl. Five concentrations were studied in the case of KCl, three for NaCl, and only two for LiCl. Both the cell emf's and temperature coefficients may be compared with the present work. The emf values reported by Trzebiatowski and Kisza are higher in all cases than those reported here; the magnitude of the disagreement ranges from 7 to over 30 mV. Trzebiatowski and Kisza (31) made no corrections for thermoelectric effects, the magnitude of which would depend on experimental arrangement and can, in this case, be as high as 20 to 30 mV. Correction for thermoelectric effects might improve the agreement between the two sets of data; however, it must also be noted that their slopes, $dE/d \log N$, for KCl deviate rather strongly from the Nernst values, indicating the possibility of mixed electrode reactions. Values of dE/dT determined by Trezebiatowski and Kisza are uniformly lower than those determined in this study, the two sets of data differing by a factor of about 1.5.

The apparent lack of agreement between certain values of $\Delta G°$ reported in Table III requires comment. Values in columns a, b, and c are calculated from thermochemical data and are all based on $\Delta H°_{298} = -77.8$ kcal, given by Rossini (18). The uncertainty in this quantity is given by Kubaschewski (10) as ±4 kcal. Brewer *et al.* (19) obtained $\Delta H°_{298} = -74 \pm 1$ kcal, using the heat of solution given by Bichowsky and Rossini (20) and the data of Jellinek and Uloth (21) for the heat of reaction of $CoCl_2$ with H_2. Our directly determined values of $\Delta G°$, which are generally about 4 kcal less negative than those in columns a, b, and c, support the values of $\Delta H°_{298}$ given by Brewer *et al.* At the same time the agreement of our values with the others listed is, in general, not outside the uncertainty quoted for Rossini's $\Delta H°_{298}$.

Quite clearly, additional differences appear among the values of $\Delta G°$, arising from the considerable spread in the values chosen for the heat capacity and heat of fusion of $CoCl_2$.

Egan (22), from measurements on the cell

$$Co|CoCl_2(c)|BaCl_2(c), AgCl\ (N = 0.2)\,|Ag$$

found $\Delta G°$ at 400° and 450° to be, respectively, 2.7 and 2.5 kcal less negative than that calculated by Wicks and Block, which again suggests that $\Delta H°_{298}$ should be less negative than the value given by Rossini.

A small error may arise in the present work from the dilution of Cl_2 by vapors of the melt. At 800°C the vapor pressures of NaCl, KCl, and $CoCl_2$ are 4.5×10^{-4}, 9.1×10^{-4}, and 4.0×10^{-2} atm, respectively; at 900°C the pressures are, respectively, 2.7×10^{-3}, 5.0×10^{-3}, and 1.7×10^{-1} atm (23, 24, 25). No data are available for mixtures. The error from this source would increase with solute concentration and temperature. Two cases are considered: $N = 0.83$ at 800°C and $N = 0.5$ at 900°C. Assuming Raoult's law to apply (which seems unlikely as $CoCl_2$ is known to form complexes with the alkali halides which should markedly reduce its vapor pressure), and taking $a_{Cl_2} = P_{Cl_2}$, the errors arising from dilution of Cl_2 by $CoCl_2$ vapor would be 1.6 and 4.5 mV, respectively. The latter amount is an upper limit for the error from this source, and it has been assumed that at lower temperatures and concentrations the error could be disregarded. No attempt was made to correct the data, since vapor pressures over the mixtures are not known.

The negative deviations of the solute from Raoult's law observed in this work follow a well established pattern with respect to solvent cation, *i.e.*, the magnitude of $\overline{G}^E$ becomes greater in the order LiCl < NaCl < 1:1 NaCl-KCl < KCl. In the case of the solute $CoCl_2$ it is reasonable to attribute the observed deviations, at least at low concentrations, to the formation of the tetrahedral complex anion, $CoCl_4^=$. The existence of this ion has been demonstrated spectroscopically at low concentration in a number of fused chlorides (26-28). There is also evidence (27) which would indicate tetrahedral coordination for this particular solute even at high concentrations.

A comparison of the degree of departure from ideality of the solutes $NiCl_2$, $CoCl_2$, and $MgCl_2$, as measured by $\overline{G}^E$, is of interest. Values of $\overline{G}^E$ for these solutes in KCl at 800° are given in Fig. 5. At concentrations below $N = 0.1$ there are significant differences in the degree of departure of the solutes from ideality. $CoCl_2$ exhibits the greatest departure followed by $NiCl_2$ and $MgCl_2$. The same order is exhibited by these solutes in the solvent 1:1 NaCl-KCl at 800°C (13, 16). It is interesting to note that the order, $CoCl_2 > NiCl_2 > MgCl_2$, is reflected by the hexacoordinate crystal radii of Co (II), Ni (II), and Mg (II). These radii are 0.72, 0.69, and 0.66Å, respectively (32). However, it is not suggested that the observed ordering should be attributed simply or even primarily to differences in ionic radii.

In Fig. 6 the variation of the partial molar entropy of mixing of $CoCl_2$, $\overline{S}$, is shown as a function of log N_{CoCl_2}. The solid curve corresponds to the equation

$$\overline{S} = -R \ln N$$

that is, the value predicted by ideal mixing (Raoult's

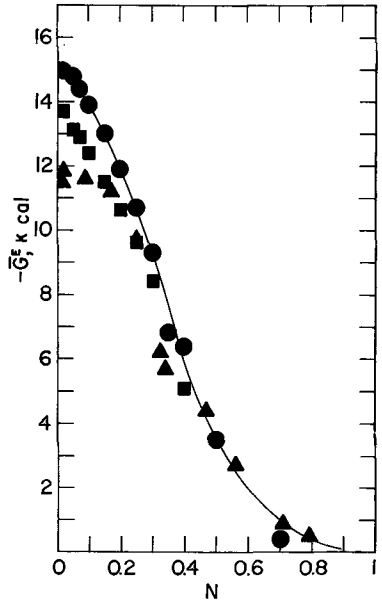

Fig. 5. Excess partial molar free energy, $\bar{G}^E$, vs. mole fraction for the solutes $MgCl_2$ ▲, $NiCl_2$, ■, and $CoCl_2$, ●, in KCl at 800°C. The $MgCl_2$ data are those of Niel and Clark (16).

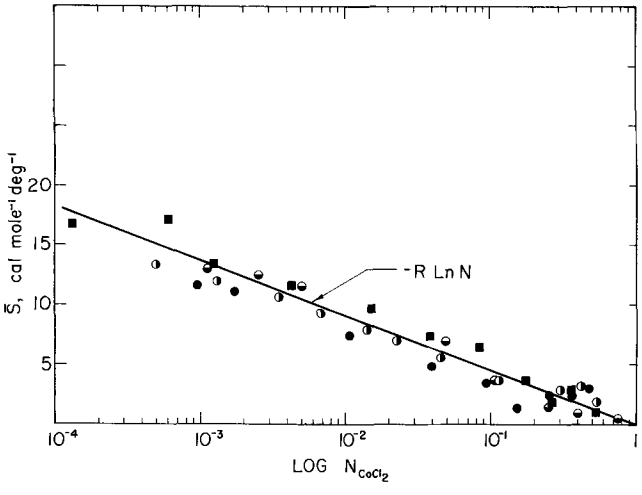

Fig. 6. Partial molar entropy of mixing for $CoCl_2$, $\bar{S}$, as a function of log N_{CoCl_2}. Solid line is $\bar{S} = -R \ln N$. Symbols are related to cells and solvents as in Fig. 3.

law) or the Temkin model (30).[2] Within the uncertainty in $\bar{S}$, the solutions follow this relation. The entropy of mixing for a number of models have been discussed previously for $NiCl_2$ solutions (3) and the conclusion was reached that, while some models (such as the vacancy model) may be ruled out on the basis of the observed entropy of mixing, the data are insufficiently accurate to allow one to select unambiguously the most representative model.

The calculation of the potential of a particular metal electrode, R, with respect to the chlorine electrode from data available on the cells

$$R|RCl_2(N), MCl(1-N)||AgCl(N'), MCl(1-N')|Ag$$
$$Ag|AgCl(N'), MCl(1-N')||MCl|Cl_2,C$$

is frequently of interest. Detailed consideration of cell reactions (29) indicates that an error $\Delta E'$, defined above, is involved in the calculated potential.

Provided the two surfaces of the membrane each act as an electrode reversible to the M^+ ion (which would be expected, for example if transport through the membrane were solely by means of the M^+ ion), it may be shown that

$$\Delta E' = -(RT/F) \ln a_{MCl}$$

where a_{MCl} is the activity of MCl in the RCl_2 (N), MCl ($1 - N$) solution. The solid curve in Fig. 4 gives the value of $\Delta E'$ calculated from this relation assuming that $a_{MCl} = N_{MCl}$. Experimental results for the solutes $CoCl_2$ and $NiCl_2$ are in good agreement at $N_{RCl_2} < 5 \times 10^{-2}$ and in fair agreement in most of the solvents up to $N_{RCl_2} = 0.1$.

If this result, valid for both $NiCl_2$ and $CoCl_2$, is taken also to be valid for $FeCl_2$, the Ag|AgCl,MCl|| reference electrode may be used reliably in place of the chlorine electrode to study low-concentration solutions of $FeCl_2$, which otherwise would undergo oxidation by chlorine. In this case E_{Ag} may be determined (*i.e.*, with $N_{FeCl_2} = 0$) by comparison with the chlorine electrode; E'_{Ag} may then be taken as

$$E'_{Ag} = E_{Ag} - (RT/F) \ln N_{MCl}$$

for $N_{FeCl_2} \lesssim 0.1$.

Acknowledgments

The initial encouragement by W. J. Kroll to undertake this research, and his continued interest is acknowledged with thanks. The authors are also indebted to D. A. Nissen, K. Stern, R. D. Walker, and Robert Stromatt for useful discussions and information, to Linda Schuerman for help in salt preparation, and to the Tektronix Foundation and Linfield Research Institute for valued support.

Manuscript submitted July 22, 1969; revised manuscript received Nov. 10, 1969. This was Paper 189 presented at the New York Meeting of the Society, May 4-9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

Thermodynamics of Lithium Iodide in Anhydrous Dimethyl Sulfoxide

Mark Salomon

National Aeronautics & Space Administration, Electronics Research Center, Cambridge, Massachusetts

ABSTRACT

The thermodynamic properties of LiI in dimethyl sulfoxide have been determined by the emf method. Results are consistent with the concept that anions are less solvated in the aprotic solvent, but that the order of increasing solvation is $Cl^- < Br^- < I^-$. The significance of individual ionic solvation energies is (qualitatively) discussed.

Previous thermodynamic studies in dimethyl sulfoxide (DMSO) have involved either the LiCl (1-3) or LiBr (4) salt-solvent systems. The present work extends the measurements to the LiI-DMSO system. The work was carried out by emf measurements on the cell

$$\text{Li}|\text{LiI-DMSO}|\text{TlI, Tl(Hg)} \qquad [1]$$

These emf measurements were transferred to emf's for the solid thalium cell

$$\text{Li}|\text{LiI-DMSO}|\text{TlI, Tl} \qquad [2]$$

by reference to the cell

$$\text{Tl}|\text{Tl}^+|\text{Tl(Hg)} \qquad [3]$$

The relation between the emf's of cells [1]-[3] is

$$\mathcal{E}_2 = \mathcal{E}_1 - \mathcal{E}_3$$

and the values for $\mathcal{E}_3$ as a function of temperature were obtained from the data of Richards and Daniels (5).

The standard potential of cell [2], $\mathcal{E}_2^\circ$, was obtained from

$$\mathcal{E}_2 = \mathcal{E}_2^\circ - \frac{2RT}{\mathbf{F}} \ln (m_\pm \gamma_\pm) \qquad [4]$$

where $\gamma_\pm$ was evaluated from (6)

$$\ln \gamma_\pm = -\frac{A\, m^{1/2}}{1 + m^{1/2}} + 2\beta m \qquad [5]$$

In Eq. [4] and [5], $m_\pm$ and $\gamma_\pm$ are the mean molalities and activity coefficients, respectively; A is the Debye-Hückel constant; β is a constant and all other terms have their usual significance [*e.g.*, see ref. (4)].

Finally by reference to the cell

$$\text{Li}|\text{Li}^+|\text{Tl}^+|\text{Tl} \qquad [6]$$

the solubility product for TlI can be calculated from

$$\ln K\,\text{sp (TlI)} = (\mathcal{E}_2^\circ - \mathcal{E}_6^\circ)\mathbf{F}/RT \qquad [7]$$

In DMSO at 25°C, $\mathcal{E}_6^\circ = 2.641$V (4).

Experimental

All cells, solutions, and equipment used were identical to those reported earlier (4, 7). Reagent grade $LiI \cdot 3H_2O$ was dried at 240°C under vacuum for 24 hr [cf. ref. (11), (12)]. One batch of 2.73% Tl (by weight) amalgam was used for all the runs. The potentials of cell [1] were recorded over a period of 3 to 4 days and a constant potential (to within 0.1 mV) was usually attained on the second day. Below solution concentrations of 0.1*M*, the emf's of cell [1] exhibited continual drift, decreasing slowly over the entire time the cells were studied. Stable potentials were not reached, and no data are reported for these small concentrations.

Results

The cells were studied at 25°, 35°, and 45°C. To evaluate $\mathcal{E}_2^\circ$, the Guggenheim approximation was used (6). This approximation was found to fit other very similar systems quite well (1-4, 7, 8). In this method a plot of $\mathcal{E}'$ *vs.* m is extrapolated to infinite dilution. Here $\mathcal{E}'$ is defined as

$$\mathcal{E}' = \mathcal{E}_2 + \frac{2RT}{\mathbf{F}}\left\{\ln m_\pm - \frac{A\, m^{1/2}}{1 + m^{1/2}}\right\}$$

A typical plot is shown in Fig. 1 for the data at 25°C. Results for all three temperatures are shown in Table I. Energies and enthalpies in Table I were obtained as follows: calculated $\mathcal{E}_2^\circ$ values were fitted to a second order polynomial, *i.e.*

$$\Delta G_2^\circ\ (\text{DMSO}) = -39.313 - 0.11172 \cdot T + 2.1637 \cdot 10^{-4} \cdot T^2\ \text{kcal/mole}$$

and ΔH_2° and ΔS_2° are obtained by differentiating this relation with respect to temperature. A similar treatment for cell [2] in aqueous solutions (9) gives the following relation

$$\Delta G_2^\circ\ (H_2O) = -44.771 - 0.04387 \cdot T + 5.7264 \cdot 10^{-5} \cdot T^2\ \text{kcal/mole}$$

Activity coefficients of LiI for the three temperatures are given in Table II. These $\gamma_\pm$ values were calculated

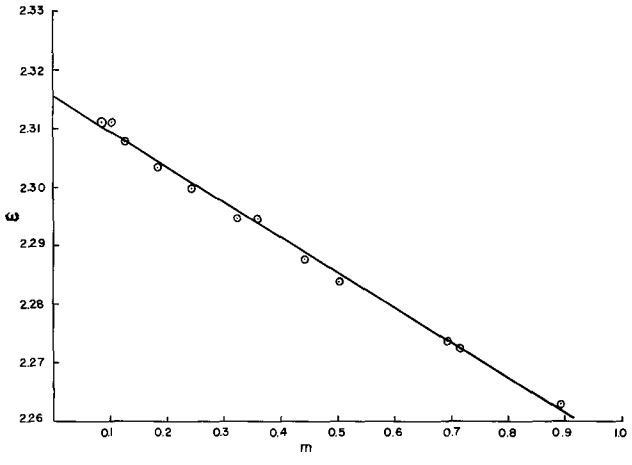

Fig. 1. Plot of E' vs. molality at 25°C

from Eq. [4] using the $\mathcal{E}_2°$ values listed in Table I. Finally a value for the TlI solubility product was calculated from Eq. [7]. It is found that K_{sp} (TlI) $= 3.1 \cdot 10^{-6}$, and this value can be compared to K_{sp} (TlBr) $= 6.0 \cdot 10^{-7}$ (4) and K_{sp} (TlCl) $= 5.9 \cdot 10^{-7}$ (3).

Discussion

The solvation of ions in dipolar aprotic solvents differ significantly from aqueous systems (10, 4, 7, 8). Evidence for specific ion properties comes mainly from solubilities (10) and free-energy and enthalpy data (4, 7, 8, 11, 12). Significant insight into the nature of solvation processes in DMSO can be achieved by comparing free energies, enthalpies, and entropies of transfer, $\Delta G_t°$, $\Delta H_t°$, and $\Delta S_t°$, respectively, from water to DMSO. Comparisons of these quantities involving many solvents has been made elsewhere (4, 7, 8). Tables III and IV list those quantities for the transfer of the Li-halide salts from water to DMSO.

Inspection of Tables III and IV reveal information supporting previous interpretations (4, 7, 8, 10) that the degree of solvation of the anion increases in the order $Cl^- < Br^- < I^-$. This is dramatically demonstrated by plotting ln $\gamma_\pm$ *vs.* $m^{1/2}$; such a plot is shown in Fig. 2. The shape of these plots are very similar to the aqueous data [*e.g.*, see (13)] with the exception that (*i*) the aqueous data is shifted upward by about 0.2 — 0.4 lnγ units and, (*ii*) the lnγ plot for LiCl in H_2O shows a minimum at about $m = 0.4$ whereas no such minimum is observed for LiCl in DMSO. Since this minimum is associated with solvation effects (13),

Table I. Thermodynamic quantities for cell [2]*

°C	$\Delta G_{2,m}°$	β	$\Delta H_{2,m}°$	$\Delta S_{2,m}°$	$\mathcal{E}_{2,m}°$
25	−53.39	0.581	−58.55	−17.30	2.3152

it is apparent that the solvation of LiCl in DMSO is smaller than it is in H_2O as proposed earlier (4, 7, 10). This can now be demonstrated (qualitatively) as follows. It is well known that the "true" molality, m', of a given solution differs from the conventional molality, m, by (13)

$$m' = m/(1 - 0.001\ hm) \qquad [8]$$

In Eq. [8], h is the solvation number and arises from the fact that in a solution containing m moles of solute in 1000g of solvent, there are 1000/mw — hm moles of free solvent (mw is the molecular weight). The corresponding relation between the "true" and conventional activity coefficients is therefore

$$\ln \gamma = \ln \gamma' - \frac{h}{\nu} \ln a_1 - \ln (1 - 0.001\ hm \cdot \mathrm{mw}) \qquad [9]$$

where ν is the total number of ions into which the solute molecule dissociates and a_1 is the solvent activity. We assume [cf. Robinson and Stokes, ref. (13)] that lnγ' is given by the Debye-Hückel relation

$$\ln\gamma' = -A\sqrt{m'}/(1 + Ba_i\sqrt{m'}) \qquad [10]$$

where m' is obtained from Eq. [8]. The solvent activity coefficient can be calculated from the observed activity coefficients (ln$\gamma_\pm$) by use of the Gibbs-Duhem equation

$$\ln a_1 = -\int_0^{X_2} \frac{X_2}{1 - X_2}\, d \ln a_2$$

In this equation a_1 and a_2 are, respectively, the solvent

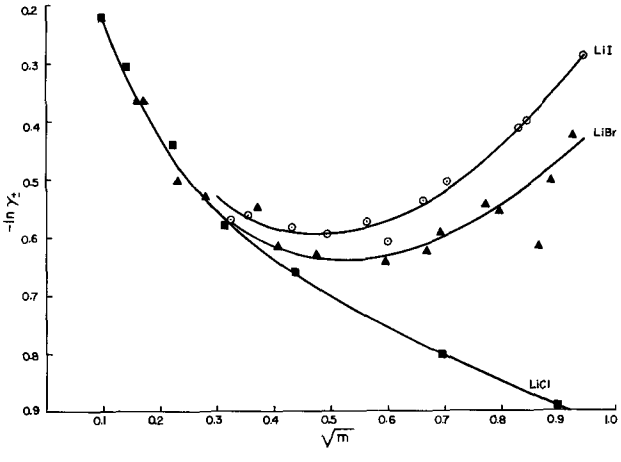

Fig. 2. Plot of *ln* $\gamma_\pm$ *vs.* $m^{1/2}$ for lithium halides in DMSO: ○, present data for LiI, ▲, LiBr (4), ■, LiCl (1, 2).

and solute activities, and X_1 and X_2 are the corresponding mole fractions. To obtain an exact integral, the $\ln a_2$ term was fit to the polynomial

$$\ln a_2 = \alpha + \beta X_2 + \gamma X_2^2$$

so that

$$\ln a_1 = \beta (X_2 + \ln X_1) + \gamma (X_1^2 - 4X_1 + 2\ln X_1 + 3.0)$$

Finally in order to evaluate the solvated radii term (a_i in Eq. [10]) we use the approximate relation [cf. ref. (13)]

$$a_i = [3V (h - \Delta)/4\pi]^{1/3} + r_+ + r_- \qquad [11]$$

where V is the volume occupied by 1 solvent molecule ($1.185 \cdot 10^{-22}$ cc for DMSO), r_+ and r_- are the crystal radii of the cation and anion, respectively, and Δ is an adjustable parameter called the "penetration distance." In the present calculations, values of 0.1 and 1.0 were taken for Δ in the aqueous and nonaqueous systems. It should be pointed out that several serious limitations exist in this calculation (see below) and the results, while qualitative, do in fact reflect the differences in solvation between the solvents H_2O and DMSO. Equation [9] was easily solved by an iteration procedure on an IBM 7094 computer by slowly increasing h from 0 in steps of 0.05. The iteration was carried out until the calculated $\ln\gamma_\pm$ (Eq. [9]) equaled the observed value to within ± 0.001 units. The results of these calculations are shown in Table V. The effect of changing Δ from 0.1 to 1.0 is small as indicated in this table. While the calculations are not, by any means, quantitative, they are significant in the sense that they do demonstrate that the various Li-salts are less solvated in the organic solvent than they are in water. The fact that h in Table V increases from Cl^- to I^- in both solvents is fortuitous and results from the simplified treatment for a_i (Eq. [11]) used in these calculations (13). A more exact treatment (14) equates the experimental activity coefficient, γ, to three contributions, *i.e.*

$$\log \gamma = \log f_c + \log f_h + \log f_{so}$$

where the f's are rational activity coefficients and the subscripts c, h, and so refer, respectively, to coulombic, hydration, and mutual salting-out interactions. The first two terms can be calculated simply as discussed by Conway (14), but the salting-out term requires specific knowledge of partial molal volumes. The lack of such data prevents the accurate determination of solvation numbers.

Single ion contributions to ΔG_t°, ΔH_t°, and ΔS_t° are of interest since they are important in comparing solvent kinetic effects (10, 11, 15) as well as distinguishing between specific solvation effects between anions and cations. In Table IV, it is seen that both the enthalpy and energy of transfer of the anion become more negative in going from Cl^- to I^-. This is demonstrated for the enthalpy of transfer in the last column of Table IV where $\partial\Delta H_t^\circ$ is the relative (to Br^-) enthalpy of transfer of the anion from H_2O to DMSO, *i.e.*

$$\partial\Delta H_t^\circ = \Delta H_t^\circ(X^-) - \Delta H_t^\circ(Br^-)$$

The fact that ΔS_t° is almost independent of the nature of the anion indicates that the increase in solvent structure in transferring the salt to DMSO is largely a cation effect. Using the approach described by Feakins (16), where individual energy contributions are given by

$$\Delta G_t^\circ(MX) = \Delta G_t^\circ(M^+) + k/r_- \qquad [12]$$

or

$$\Delta G_t^\circ(MX) = \Delta G_t^\circ(X^-) - m/r_+ \qquad [13]$$

it was found that Eq. [13] gave satisfactory results for the alkali-chloride-N-methyl formamide system (7). In these equations, k and m are constants and the intercept of a plot of $\Delta G_t^\circ(MX)$ *vs.* $1/r$ gives the single ion value for the free energy of transfer. However in the course of the present work, use of Eq. [12] has led to values for $\Delta G_t^\circ(Li^+)$ of the order of -30 kcal/mole, $\Delta G_t^\circ(Cl^-)$ values of $+35$ kcal/mole, and $\Delta H_t^\circ(X^-)$ values which were in complete disagreement with those more reasonable values found by Arnett and McKelvey (23). This demonstrates the complete breakdown of Eq. [12] for the present data but does not indicate that the use of Eq. [13] is invalid. Indeed the use of Eq. [13] over [12] is to be preferred (16) especially when one is transferring salts to solvents more basic than water. It has been suggested (17) that the use of equations such as [12] and [13] should be corrected for mutual polarization arising from dispersion forces, *i.e.*

$$\Delta G_t^\circ = \Delta G_t^\circ(\text{el}) + \Delta G_t^\circ(\text{neut})$$

where ΔG_t°(el) is given by Eq. [12] or [13] and ΔG_t°(neut) is proportional to r^2 and can be estimated from solubility data of rare gases in the two solvents (17). ΔG_t°(neut) contributions can be evaluated by use of Henry's law

$$p/c = \exp\{(\mu_s^\circ - \mu_g^\circ)/RT\}$$

Here μ_s° and μ_g° are the chemical potentials of the solute (unit concentration) in solution and gas phase, respectively, p is the partial pressure, and c is the concentration in solution. Using this equation together with the data for rare gas solubilities in DMSO (18) and H_2O (19), it is found from a plot of ΔG_t°(neut) *vs.* r^2 that ΔG_t°(neut) for Li^+, Cl^-, Br^-, and I^- is 244, -285, -390, and -551 cal/mole, respectively (values are based on molal units). The resulting plot of $\Delta G_t^\circ(MX) - \Delta G_t^\circ$(neut) *vs.* $1/r_-$ still gave $\Delta G_t^\circ(Li^+)$ values close to -30 kcal mole^{-1} and $\Delta H_t^\circ(Li^+)$ values close to 20 kcal/mole thereby indicating that ΔG_t°(el) in Eq. [14] cannot be evaluated simply by a $1/r$ (Born)-type law. In fact in highly polarizable solvents such as DMSO (10), the possibility of ion-quadrupole and ion-induced quadrupole probably become significant. For example in H_2O, which has a lower polarizability than does DMSO, the interaction energy between an ion and the H_2O quadrupole is, for a linear alignment

$$E_\theta = e\theta/d^3$$

where θ is the quadrupole moment ($\sim 2.10^{-26}$ esu); e is the electronic charge and d is the diameter of the water molecule ($\sim 3.10^{-8}$ cm). E_θ is therefore of the order of 5 kcal/mole and is by no means insignificant [cf. ref. (20)]. In the aprotic solvents such as DMSO and propylene carbonate, dipole moments are high (10) and are attributed to the highly charged oxygen center and a very diffuse negative charge spread out over the remainder of the molecule. The success of applying Eq. [13] to evaluate $\Delta G^\circ(X^-)$ from a series of salts such as LiCl, NaCl, KCl would appear to arise from the fact that the cations are very much less polarizable and that the major interaction energy is an ion-dipole one whereas anions, which must interact with the polarizable end of the solvent molecule, do not behave so simply. Further demonstration of this cation *vs.* anion effect can be seen from work on other solvent systems where individual ionic contributions to ΔG_t° are always made on the basis of some extrathermodynamic assumption involving the cation (21, 22). This effect is also significant for transfers between hydrogen-bonded (protic) solvents as individual ΔG_t° values between H_2O and methanol were always significantly

Table V. Solvation numbers in H_2O and DMSO at 25°C

Salt	H_2O^1	H_2O^2	$DMSO^1$	$DMSO^2$
LiCl	4.2	4.5	0.2	1.0
LiBr	4.5	5.0	0.2	1.0
LiI	7.5	7.7	1.5	1.8

[1] $\Delta = 0.10$.
[2] $\Delta = 1.00$.

higher for the anion plot (Eq. [12]) than for the cation plot (Eq. [13]) as discussed by Feakins (16).

Oxygen Reduction on Oxide-Free Platinum in 85% Orthophosphoric Acid: Temperature and Impurity Dependence

A. J. Appleby*

Institute of Gas Technology, Chicago, Illinois

ABSTRACT

Oxygen electrode kinetics in 85% orthophosphoric acid have been studied as a function of temperature and impurity level in the electrolyte. It is shown that the mechanism of reaction is the same as that in N perchloric acid, and that rate constants and Tafel slopes are dependent on impurity adsorption. Hydrogen peroxide is not a significant reaction product, at least at high temperatures. The activation energy of the reaction at the reversible potential was determined to be 22.9 ± 0.9 kcal.

Work carried out in recent years on the oxygen electrode on platinum in acid solution has stressed the importance of the surface oxides on the metal whose half-wave reduction potential is close to that for oxygen reduction at all pH values (1). Some workers have noted inhibition of the oxygen reduction process by oxides of platinum (2-6); in other cases the reaction was accelerated (1).

The majority of workers consider that a two-stage reduction takes place, with hydrogen peroxide as an intermediate (4-7). This product was either reduced or spontaneously decomposed (8) on the platinum surface at the same potentials as those of its formation. However, in other cases no hydrogen peroxide was detected as a reaction product (3, 9).

Recent work has shown that oxide-free platinum (10, 11) under high-purity conditions is more active than oxidized platinum (12) for oxygen reduction in dilute acid and is kinetically quite different (11, 12). It has also been shown that under these conditions impurity adsorption is associated with the formation of hydrogen peroxide (13) which is produced in a process parallel to the main reaction of oxygen reduction direct to water (14).

As it is evident from the literature that a wide variation of results has been obtained in the past under different conditions in acid electrolytes, an examination of oxygen reduction on oxide-free platinum under different conditions of impurity level and temperature in 85% orthophosphoric acid has been carried out to determine the effect of these variables on kinetics.

Experimental

To reduce the possibility of attack by the electrolyte (85% orthophosphoric acid), especially at the highest temperatures of study, all parts of the electrochemical cell in contact with the acid were constructed from fused silica. The reference electrode was a dual bubbling hydrogen electrode in the same electrolyte as that used in the cell. All potentials quoted in this paper are referred to this electrode (HRE potentials). The counterelectrode was a large-area platinum grid. Working electrodes were 1 cm^2 platinum foils of zone-refined (nominal 99.999%) grade hung on platinum wires. They could be moved up or down as required

* Electrochemical Society Active Member.

by means of sliding seals. All gaskets and seals in the equipment were of Teflon or Viton A. A general description of the layout of the cell and ancillary equipment together with the cleaning procedure used has been published (15).

Hydrogen for the reference electrodes and oxygen or oxygen-nitrogen mixtures for the working compartment of the cell were passed through presaturators containing 85% orthophosphoric acid before being led into the cell. The cell and presaturators were maintained at the required temperatures in the range 25.1-136.1°C in a thermostatic oil bath. The hydrogen and oxygen used were of Matheson ultrahigh-purity-grade, and the nitrogen was of 99.997% purity. All gases contained less than 0.1 ppm oxidizable organics, but as a further precaution the hydrogen and oxygen or oxygen-nitrogen mixture were passed over a bed of platinized asbestos at 300°C before going to the cell. Reproducible oxygen-nitrogen mixtures of known oxygen partial pressure were made using capillary flowmeters and a mixing chamber. During experiments, oxygen or oxygen-nitrogen mixtures were normally bubbled through the cell at the rate of approximately 10 ml/min.

The platinum foil or disk electrodes were degreased, and washed with HCl, conductivity water, and the electrolyte itself before use. The electrolyte was normally prepared by a succession of hydrogen peroxide treatments to remove oxidizable matter, although in some experiments untreated analytical reagent-grade 85% (14.6M) orthophosphoric acid was used.

The majority of measurements were carried out galvanostatically using a conventional battery-operated, high-resistance circuit, although with the rotating ring-disk electrode a potentiostat was used. The ring-disk electrode was used to investigate the role of hydrogen peroxide in the oxygen reduction reaction. Its construction will be discussed elsewhere.

Results

Electrode activation.—The work of Damjanovic and Brusic (11) has emphasized the difference in kinetic character for the oxygen reduction reaction between "bare" or "reduced" platinum surfaces, and platinum which has been subjected to anodizing or other intensive oxidation (12). The importance of obtaining a reproducible surface has been often stressed in the literature. Accordingly, it was decided in these experiments to use a standard electrochemical method of surface preparation for all the working electrode specimens.

After preparation of the electrodes by the method described above, the platinum specimens were hung until required above the electrolyte level in a pure oxygen atmosphere in the cell. After specimens were lowered into the cell, they were subjected to an anodic galvanostatic pulse, followed by a series of about three anodic and cathodic pulses between 1.0V and 50 mV at a current density of 10^{-3} A/cm^2. The final pulse was in every case cathodic, after which the electrodes were allowed to reach their rest potentials. In the initial anodic pulse the electrodes were allowed to reach a maximum potential of 1.2-1.3V. A series of preliminary experiments established that the maximum potential of this activation procedure, provided it was above about 1.1V and below approximately 1.4V, was unimportant. Pulsing above 1.4V led to electrodes of slightly increased activity. This may be attributed to an increase in surface energy (increase in the number of surface defects) on reduction of the phase oxide monolayer formed at these potentials (16, 17).

The major purpose of this activation procedure was to desorb impurities on the electrode surface (18). Any phase oxide or adsorbed oxygen radicals formed at high potentials are reduced in the cathodic portion of the pulse. It was established that potentiostating the electrodes at 0.25V for long periods, a procedure which should slowly remove any "dermasorbed" oxygen initially present in the platinum (19), made no difference to the final behavior of the electrode. This activation method is essentially similar to the electrochemical treatment used by Damjanovic and Brusic (11). However, their procedure involved exposing the electrode to a potential of 1.7V for a period of several seconds, which produced an electrode with similar kinetic character but higher activity (by a factor of 2) than chemically treated or thermally reduced electrodes.

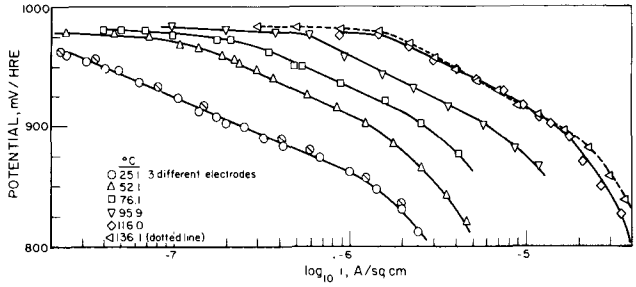

Fig. 1. Cathodic Tafel plots on oxide-free platinum, pure electrolyte.

Rest potentials.—In clean (hydrogen peroxide treated) electrolyte saturated with oxygen at 1 atm pressure, the platinum electrodes after pulsing attained rest potentials in the range 985-1000 mV. A slow rise was noted over a period of several hours, when a maximum potential of about 1010-1015 mV was reached. A slow decay followed; a final potential of about 990-1000 mV was noted after 24 hr, which would remain constant[1] thereafter. The rest potentials were not significantly temperature-dependent, but at the highest temperatures studied they tended to be a few millivolts lower. Values of rest potentials, generally close to those noted in other aqueous media, are considered to be due to a mixed potential mechanism to explain the low value of the rest potential compared with the thermodynamic value for the oxygen electrode (about 1.2V at 25°C). In this mechanism, the cathodic process is oxygen reduction, and the anodic process is considered to be either platinum oxidation (20) or the oxidation of impurities (21).

Tafel plots.—Galvanostatic Tafel plots were made immediately after electrode activation at six different temperatures in the range 25.1°-136.1°C. They are illustrated in Fig. 1. Equilibrium was quickly attained at each point within 1-2 min, after which the potential remained steady for 15-20 min. This period was followed by a very slow decay of potential at constant current, which was more rapid at lower potentials. This may be attributed to the slow deactivation of the electrode by impurities diffusing in from the solution. It was noted that deactivation was most rapid at high oxygen bubbling rates, which would indicate a diffusion-controlled process. A similar effect has been noted, though at lower potentials, in 0.1*N* sulfuric acid using a rotating disk electrode when the electrolyte had been similarly purified (13). The original potential could then be restored by pulsing to either 1.0V or 50 mV, which desorbed the impurities responsible.

Results thus obtained were very reproducible; the data for three different electrodes cut from the same sample of platinum foil are shown together on the plot for 25.1°C (Fig. 1). Results at higher temperatures for different electrodes were within 10 mV. It may be seen in each case that a high-potential region exists in which there is little change of potential with current density, followed by a Tafel region, followed by a region of higher slope leading to the limiting-current region. Results are generally simlar to those reported by Damjanovic and Brusic (11) in 0.1*N* perchloric acid at room temperature. It should be noted that the Tafel lines at 116.0° and 136.1°C are prac-

[1] Over a period of weeks.

tically coincident because of the rapid increase in water vapor pressure over phosphoric acid, and hence the fall in oxygen partial pressure in this temperature range. Table I lists the Tafel slopes and extrapolated exchange current values, together with values of $1/\alpha$, where α is the transfer coefficient. In each case, the exchange current values have been obtained by extrapolating back to the value of the reversible potential at the temperature of experiment, calculated for gaseous water from the data of Lewis and Randell (22), and corrected for the water vapor pressure over 85% orthophosphoric acid (23). The figures quoted in Table I refer to the theoretical emf of the cell

$$H_{2(1-p)\ atm} \quad 85\%\ \text{orthophosphoric acid} \quad O_{2(1\ atm)}$$

where p is the water vapor pressure over the electrolyte. The exchange current values have been corrected for the oxygen partial pressure and are expressed for a standard pressure of 1 atm. The correction has been made on the basis of first-order oxygen reduction kinetics at constant potential (see below). It is apparent from Table I that the Tafel slopes, at least above 900 mV, are very close to RT/F.

Kinetic data in analytical-grade acid.—A number of experiments were carried out in analytical-grade acid to determine the effect of traces of oxidizable impurities on the system. Such impurities have been detected in orthophosphoric acid and have been identified as traces of phosphorous and hypophosphorous acids (24). On immersion, chemically cleaned electrodes generally took up rest potentials of about 750 mV (at 25°C) to 920 mV (at 136°C) in analytical-grade electrolyte.

After cathodic polarization, higher values were noted: 886 mV at 25.1°C, 916 mV at 76.1°C, and 941 mV at 116.0°C. Within 24 hr, these values had fallen considerably, to about 600 mV at 25°C and 800 mV at 136°C.

Galvanostatic Tafel plots.—A steady-state galvanostatic Tafel plot was made at each temperature on electrodes that had been allowed to stay on open circuit in the solution for 1 hr so that equilibrium could be reached between the electrode surface and the residual impurities in the solution. A high current density in the appropriate range was applied to the electrode, and an ascending steady-state Tafel plot was made. The electrode was left at each point for sufficient time for less than 1 mV change in 5 min to occur. Normally, steady state was achieved within 10 min.

Downward Tafel plots were similar, but had somewhat lower slopes, registering lower potentials in the low current density part of the plot. Downward plots taken on electrodes which had been in the solution 24 hr were normally steep (slope $\sim 2RT/F$), and showed more evidence of electrode deactivation (higher polarizations at low current densities).

To show the effect of impurity desorption by pulsing to 50 mV, a second plot was made at each temperature. These are illustrated in Fig. 2 for 25°-95°C. For these Tafel plots the electrode was activated by pulsing before each point since it was noted that slow deactivation over a period of some minutes took place. The potential eventually returned to values close to the initial curve for each current density studied. A much more effective method of electrode activation

was shown to be a method of pulsing between 50 mV and 1.2V before each galvanostatic point. Results of this method are also shown in Fig. 2. Deactivation was in this case exceptionally rapid compared with a purified solution, and was dependent upon the rate of stirring of the solution. A typical potential-time curve for such an activated electrode (after pulsing to 50 mV) is shown in Fig. 3. The electrode surfaces obtained by this technique are probably essentially free from adsorbed impurities after pulsing, as the plots of maximum potential reached after pulsing against log current density (Fig. 2) are close to the steady-state plots obtained in purified electrolyte (Fig. 1).

Tafel slopes, $1/\alpha$ values, and extrapolated apparent exchange current values for the steady-state plots in analytical-grade acid are given in Table II.

Order of reaction for oxygen.—The effect of oxygen partial pressure in the Tafel region at 52.1°C in purified electrolyte has been published (25). For this experiment oxygen was diluted with nitrogen to give the partial pressure required before being led into the cell. The results obtained indicate that the reaction is essentially first order for oxygen at constant potential.

Hydrogen peroxide formation.—An examination of the contribution of oxygen reduction to hydrogen peroxide to the over-all process was carried out using a rotating ring-disk electrode at 3140 rpm in the purified electrolyte at 76.1° and 116.0°C. The electrode disk had an area of 0.212 cm² and was treated before use in the same way as the platinum for electrodes. During the experiments, the lightly platinized electrode ring was maintained at a potential of 1.3V, at which oxidation of any hydrogen peroxide produced in the oxygen reduction reaction at the disk will be diffusion-controlled.

The shapes of the oxygen reduction waves obtained at 76.1° and 116.0°C are shown in Fig. 4. At 76.1°C, the reduction wave has the appearance of a double wave as noted for instance on mercury in dilute acid solutions (26). In the latter case, the first wave corresponds to oxygen reduction to hydrogen peroxide, and the second wave corresponds to oxygen reduction direct to water.

The data obtained on hydrogen peroxide oxidation at the ring as a function of disk potential are also shown on Fig. 5. As the collection factor of the ring electrode in the apparatus used is 0.35, hydrogen peroxide production only accounts for a maximum of approximately 16% of the total oxygen consumed, the figure being considerably less (under 5%) at 116.0°C. It is clear that the double-wave effect cannot therefore be attributed to oxygen reduction to hydrogen peroxide.

It was noted that pulsing of the disk between 1.2V and 50 mV would restore the disk current to about 60 μA in the potential range 0.75-0.3V, corresponding to the value of limiting current for the 4-electron process of oxygen reduction. The limiting current value then gradually fell, over a period of some minutes, down to the values in Fig. 2, the rate of fall being most rapid in the potential range 400-500 mV. In the

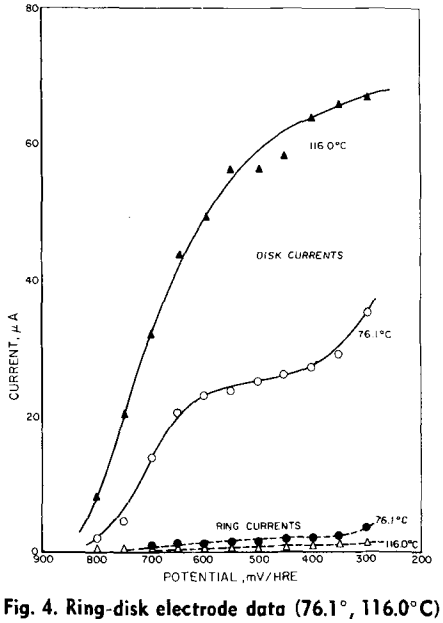

Fig. 4. Ring-disk electrode data (76.1°, 116.0°C)

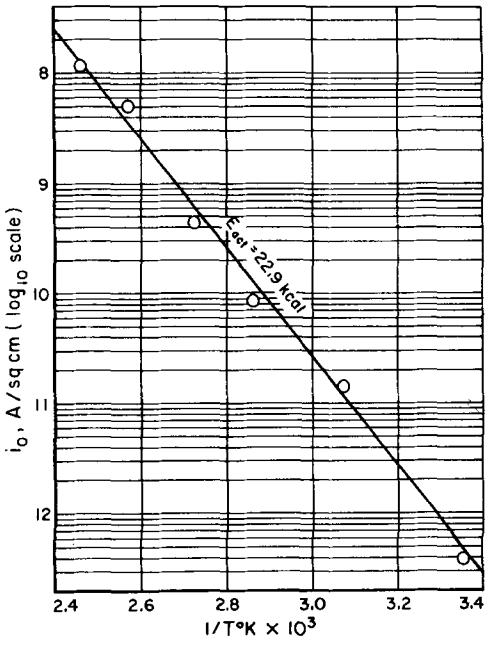

Fig. 5. Arrhenius plot for exchange current values on oxide-free platinum.

Tafel region the rate of deactivation of the electrode was very small. These results are similar to those noted by Müller and Nekrasov (27) in dilute sulfuric acid, which these authors attributed to anion adsorption in the double-layer region (below about 800 mV), so that oxygen reduction sites on the electrode surface are blocked. Damjanovic, Genshaw, and Bockris (13) have recently shown that in dilute sulfuric acid this deactivation effect only occurs in the presence of nonoxidizable impurities which are not removed by extended pre-electrolysis or by hydrogen peroxide treatment. They conclude that anion adsorption is not directly responsible as deactivation is apparently controlled by the slow diffusion of some species to the electrode surface. This species can only be removed from the electrolyte by the use of a large-area platinum adsorber electrode potentiostated for extended periods at the potential of maximum deactivation (about 300-400 mV in dilute sulfuric acid), which is removed from the solution taking with it the impurities at the end of the operation. The nature of these capillary-active impurities is open to question; they may be traces of organic greases or adsorbable foreign ions.

Müller and Nekrasov (27) have shown the deactivating effect of chloride ions in acid solutions, and Müller and Sobol (28), the corresponding effect of divalent cations on oxygen reduction in alkaline solutions. It is certainly possible that polyphosphates are responsible in this present case.

Damjanovic *et al.* (13) have shown that hydrogen peroxide production in acid solution is associated with the presence of these capillary-active materials, and they attribute this to the blocking of high-energy sites on the electrode surface, where O-O bond dissociation (and direct reduction of O_2 to water) takes place. When impurities are eliminated, little H_2O_2 results.

In the present case, very little peroxide was detected as a reaction product, but it is certainly possible that catalytic decomposition of hydrogen peroxide takes place during the time occupied in diffusion from the disk to the ring, so that the collection factor of the electrode is effectively reduced. The precursor of hydrogen peroxide produced in the reaction is, according to Nekrasov (29), the O_2H^- ion adsorbed on the electrode. This material may be expected to become progressively more unstable (and liable to dissociate) with rise in temperature, so that

the yield of hydrogen peroxide will fall, even in the presence of adsorbed impurities.

At 116.0°C the oxygen reduction wave shows much less the influence of any impurities in the solution. It is therefore apparent that their heat of adsorption on platinum is comparatively low.

We may conclude from these data that hydrogen peroxide is only a minor product of oxygen reduction on oxide-free platinum in concentrated phosphoric acid at temperatures of interest in the operation of fuel cell cathodes.

Activation energy for oxygen reduction.—The activation energy for oxygen reduction on oxide-free platinum at the reversible potential has been obtained from the Arrhenius plot (Fig. 5) of the extrapolated exchange current values (corrected to atmosphere oxygen pressure) in purified electrolyte. The value obtained is 22.9 ± 0.9 kcal. This is considerably higher than the value on oxidized platinum (13.1 kcal) (15) and is close to the value reported for the oxygen electrode reaction in alkaline solution (12, 30). No activation energy correction has been made in the present case for changes in oxygen solubility or water activity of the electrolyte, but such corrections are small.

As has been already noted, the nonoxidizable capillary-active material has no effect on Tafel slopes and exchange currents (13), so further purification is not expected to significantly influence these quantities or the activation energy.

Discussion of Mechanism

In pure solutions, oxygen reduction on oxide-free platinum is first-order, and the Tafel slope is $RT/\mathbf{F}$. Under the conditions of the experiment it is not possible to obtain any other relevant kinetic parameters which might further clarify the mechanism. It is not possible to obtain the order of reaction for (H^+) at constant ionic strength in concentrated phosphoric acid; as oxygen evolution takes place on an oxidized surface, no direct determinations of the stoichiometric number are possible as the near-equilibrium and anodic regions are not accessible.

Under Langmuir adsorption conditions, we may use the following relation for α, the measured transfer coefficient (12, 31-33)

$$\alpha = \beta n + \frac{n_a}{\nu}$$

where β is the symmetry factor of the rate-determining step, ν is the stoichiometric number of the rate-determining step, n is the number of electrons transferred in the rate-determining step, and n_a is the total number of electrons transferred before the rate-determining step. Assuming that the rate-determining step is a charge transfer with $\beta = \frac{1}{2}$ and that only one electron is transferred in the rate-determining step,[2] with the experimental value of α equal to 1

$$n_a/\nu = \tfrac{1}{2}$$

The only solution is $n_a = 1$, $\nu = 2$. $n_a = 2$, $\nu = 4$ is not possible as only 4 electrons are involved in the over-all reaction.

However, if $\nu = 2$, *i.e.*, two identical charge-transfer reactions occur for one unit of the over-all process, then the chemical order of reaction for O_2 must be ½, not 1 as is experimentally observed. Hence, under Langmuir conditions the rate-determining step cannot be a charge-transfer unless β has the nonphysical value of unity.

If the rate-determining step is a chemical process

$$n = 0, \text{ and } n_a/\nu = 1$$

Again, for unit oxygen reaction order, ν must be 1, hence $n_a = 1$; that is, the data are consistent with a chemical step following a 1-electron transfer.

The above analysis applies only to 1:1 coupled mechanisms (31). For more complex paths in which chemical steps control without preliminary charge-transfer other possibilities exist. Gnanamuthu and Petrocelli (34) have provided a useful list of possible oxygen reaction mechanisms, which includes 1:1 and more complex paths, with kinetic parameters evaluated assuming Langmuir adsorption.

Tafel slopes of $RT/\mathbf{F}$ appear in certain complex paths, which also satisfy the experimental oxygen reaction order requirement. Again neglecting paths involving 2-electron charge transfers, the only reactions which satisfy the above conditions are as follows, "S" in each case being an undefined surface site. The calculated Tafel slope follows each reaction

A. $O_2 + S + S - H_2O \rightarrow SOH + SO_2H$	∞
(rds) $SO_2H + SH_2O \rightarrow SOH + SH_2O_2$	$RT/\mathbf{F}$
[the "hydrogen peroxide path" (35)]	
B. $O_2 + S + SH_2O \rightarrow SOH + SO_2H$	∞
(rds) $SO_2H + S \rightarrow SO + SOH$	$RT/\mathbf{F}$
["metal peroxide" (35) or Conway and Bourgault (36) paths]	
C. $S + O_2 + e^- \rightarrow SO_2^-$	$2RT/\mathbf{F}$
(rds) $SO_2^- + H^+ \rightarrow SO_2H$	$RT/\mathbf{F}$[3]
[Ives (37) or Hoare's (38) paths].	

Damjanovic and Brusic (11) have pointed out that their H^+ reaction order data (rate $\propto [H^+]^{3/2}$) for dilute perchloric acid are inconsistent with mechanism C, which is first order in H^+. Similarly, the complex (nonconsecutive) mechanisms A and B, which are zero-order in H^+, are not in agreement with their experimental data.

Consequently, it appears that the present results, and the results of Damjanovic and Brusic (11), are not explicable assuming Langmuir adsorption. These authors have, however, noted that in the potential range in which results are obtained, platinum is covered by less than monolayer quantities of water oxidation fragments [—OH and —O, with the latter predominating (21)].

Experimentally, a linear relationship between steady-state coverage and potential holds in N perchloric and sulfuric acids (11, 21). This coverage-potential relationship implies that the heat of adsorption of the oxygen radicals on the platinum surface falls off linearly with increasing potential and increasing coverage (21). If one assumes that the intermediates in the oxygen electrode process follow a similar isotherm to that of the adsorbed water fragments (11), then it is possible to show the experimental data are consistent with the mechanism

$$S + O_2 \rightarrow SO_2$$

$$\text{(rds)} \qquad S - O_2 + H^+ + e^- \rightarrow SO_2H$$

followed by

$$SO_2H + 3H^+ + 3e^- \rightarrow 2H_2O$$

which proceeds by unknown (though rapid) steps.

The isotherm which describes the adsorption of intermediates in the reaction is thus the Temkin isotherm, in which the heat of adsorption of a particular species is dependent on the total coverage of all species on the electrode (39). As Böld and Breiter (40) have shown, it is necessary to assume that Temkin adsorption of oxygen and —OH radicals takes place on platinum in order to explain the experimental cyclic voltammetric scans in dilute perchloric and sulfuric acid. Similar plots are obtained in concentrated phosphoric acid (41), and hence it is reasonable to assume that the same isotherm applies in this case. A complete analysis of this mechanism is given as the Appendix.

[2] It is assumed that a two electron transfer would require too high an activation energy.

[3] Gnanamuthu and Petrocelli (34) point out that the slope may be greater than $RT/\mathbf{F}$ if the plane of closest approach for the adsorbate and the Helmholtz plane are not identical.

One may only speculate on steps following the rate-determining step. As shown by Damjanovic, Genshaw, and Bockris (13), hydrogen peroxide production in dilute sulfuric acid is accompanied by impurity adsorption, which results also in lower reaction rates. The same has been shown here to take place in concentrated phosphoric acid. The next steps of the reaction therefore probably are

$$(a) \qquad SO_2H \rightarrow SO + SOH \xrightarrow{3H^+} 2H_2O + 2S$$

or

$$(b) \qquad SO_2H + H^+ + e^- \xrightarrow{3e^-} SH_2O_2 \rightarrow S + H_2O_2$$

[or perhaps $2SO_2H \rightarrow 2S + H_2O_2 + O_2$ ref (1)]

The first reaction will take place only preferentially if the heats of adsorption of the product are sufficiently high. In the presence of adsorbed electron-donating impurities the net heat of adsorption of negative species (for instance —O_2H) on the electrode surface should be lowered. From the previous discussion, this will reduce the over-all reaction rate and make reaction (*b*) above the preferred step.[4]

It should be noted that in absence of impurities the reaction

$$S - O_2 + H^+ + e^- \rightarrow S - O_2H$$

will take place under Langmuir conditions of adsorption, with low total coverage of adsorbate, in the double-layer region (below about 750 mV HRE). In the presence of impurities, again Langmuir conditions will occur, now involving high coverages of capillary-active adsorbate. In this case, however, much lower rate constants would be expected, as the adsorbed material will depress the heat of adsorption of the reaction product —O_2H.

We have noted that in the presence of gross amounts of oxidizable impurity (untreated electrolyte) the rest potential is depressed. This is to be expected if the rest potential is a mixed potential, with anodic process diffusion-controlled impurity oxidation and the cathodic process oxygen reduction. The effect of pulsing the electrode desorbs impurities from its surface (18) and leaves more sites available for reaction. If the heat of adsorption of impurities is potential-dependent, the final Tafel plot will appear to be the locus of a family of normal (Langmuirian) Tafel plots of $2RT/\mathbf{F}$ slope, but with changing rate constant, according to impurity coverage. If coverage falls with increase in overpotential, a slope of less than $2RT/\mathbf{F}$ will occur. If a rise in coverage with increasing potential occurs, a net slope greater than $2RT/\mathbf{F}$ results.

Slopes between $RT/\mathbf{F}$ and $2RT/\mathbf{F}$ are frequently observed on oxygen reduction electrodes, and have been observed in impure solutions during the course of this work, on the electrodes which have been in contact with the solution for 1 hr. After 24 hr in the solution, high coverages of strongly bound impurities may be considered to be present. These materials probably do not appreciably desorb during the Tafel plot so that slopes close to theoretical for a 1-electron charge transfer, with no previous charge transfer, under Langmuirian conditions ($2RT/\mathbf{F}$) occur, although at high overpotential.

It is interesting to note when large amounts of strongly adsorbable anion are present (*e.g.*, in HCl solution) slopes appreciably greater than $2RT/\mathbf{F}$ occur (8), probably indicating progressively increasing adsorption of anion with overpotential. In addition, the adsorbed anion effectively prevents SO_2H breakdown on the electrode surface, as H_2O_2 appears to be the primary reaction product (8, 44).

[4] This is perhaps equivalent to saying high energy sites for direct reduction of O_2 to H_2O are blocked.

On this basis, it is possible to rationalize past data for oxygen reduction on bare platinum in acid solutions. When electrodes are given a preparative treatment consisting of anodic and cathodic pulsing (or hydrogen pretreatment at high temperature), slopes close to $RT/\mathbf{F}$ are obtained. In other cases, slopes are obtained which depend more on potential-dependent impurity adsorption than on oxygen electrode kinetics as such.

Similarly, due to the higher slopes of Tafel plots obtained under impure conditions, apparent exchange current values might be higher (Tables I and II) than under pure conditions. This does not imply higher rate constants, but indicates that the observed slope is too high due to potential-dependent electrode deactivation.

Finally, the rate-determining step for oxygen reduction on phase-oxide-free platinum

$$S - O_2 + H^+ + e^- \rightarrow SO_2H$$

appears to be common to all aqueous acid electrolytes which are stable at oxygen-electrode potentials, regardless of temperature or concentration. In acids with anions which are not strongly adsorbed, this reaction will take place under Temkin conditions at potentials above 750 mV, with an approximate slope of $RT/\mathbf{F}$.

APPENDIX

Oxygen Reduction under Temkin Adsorption Conditions

The arguments for the derivation of a Temkin-type rate-controlling equation are as follows. Consider the above reaction taking place at a potential V, under charge-transfer control, at a potential sufficiently far from equilibrium to make the backward reaction negligible.

The rate equation would be

$$i_{\text{forward}} = \mathbf{F}\frac{kT}{h}(\theta^*)[H^+]\left(\exp -\frac{[\Delta G^{\neq} + (1-\beta)(\Delta G_p - \Delta G_r)]}{RT}\right)\cdot \exp\left(\frac{-\beta\mathbf{F}V}{RT}\right) \quad [1]$$

where k, h, and $\mathbf{F}$ have their usual meanings, θ^* is the oxygen coverage on the electrode, $\Delta G^{\neq}$ is the free energy of activation in absence of adsorption, ΔG_r is the free energy of adsorption of reactants (O_2 only, as we assume H^+ is not specifically adsorbed), ΔG_p is the free energy of adsorption of products (—O_2H), and β is the symmetry factor.

Assuming $\beta = \frac{1}{2}$

$$i_{\text{forward}} = \mathbf{F}\cdot\frac{kT}{h}\theta^*[H^+]\left(\exp -\frac{[\Delta G^{\neq} + \frac{1}{2}(\Delta G_p - \Delta G_r)]}{RT}\right)\exp\left(\frac{-\mathbf{F}V}{2RT}\right) \quad [2]$$

If we write $\Delta G = \Delta H - T\Delta S$ in each case

$$i_{\text{forward}} = \text{const.}\ \theta^*[H^+]\left(\exp -\frac{[\Delta H^{\neq} - T\Delta S^{\neq} + \frac{1}{2}(\Delta H_p - \Delta H_r) - \frac{1}{2}T(\Delta S_p - \Delta S_r)]}{RT}\right)\exp\left(\frac{-\mathbf{F}V}{2RT}\right) \quad [3]$$

We make the assumption that a potential-dependent adsorption of reactants and products occurs, which may be reasonably described by a Temkin isotherm in the range of $0.2 > \theta_T > 0.8$, where θ_T is the total coverage on the electrode of strongly bonded adsorbed species (39). These constitute primarily O radicals at high potential (21). We then obtain

$$i_{\text{forward}} = \text{const.}\ \theta^*[H^+]\left(\exp -\frac{[\Delta H^{\neq} - T\Delta S^{\neq} + \frac{1}{2}(\Delta H_p + q_p\theta_T - \Delta H_r + q_r\theta_T) - \frac{1}{2}T(\Delta S_p - \Delta S_r)]}{RT}\right)\exp\left(\frac{-\mathbf{F}V}{2RT}\right) \quad [4]$$

where ΔH_r and ΔH_p are the heats of adsorption at low coverage, and q_r and q_p are enthalpy-coverage factors for reactants and products. It is understood that q is positive for a reduction in heat of adsorption; $\Delta H^{\neq}$ and $\Delta S^{\neq}$ are the enthalpy and entropy of activation in absence of adsorption.

$$i_{forward} = \text{const. } \theta^* \cdot [H^+] \left(\exp - \frac{[\tfrac{1}{2}(q_p - q_r)\theta_T - \tfrac{1}{2}T(\Delta S_p - \Delta S_r)]}{RT} \right) \exp\left(\frac{-FV}{2RT}\right) \quad [5]$$

We must now substitute a relation for θ^* in terms of P_{O_2}. It is reasonable to assume that θ^* is very low, and that oxygen adsorption follows a Langmuir isotherm, so that

$$P_{O_2} = A \frac{\theta^*}{1 - \theta_T} \exp(\Delta G/RT) \quad [6]$$

where ΔG is the free energy of adsorption of oxygen.[5] However, according to our previous postulate, that heat of adsorption of the reactants depends on θ_T, we may write

$$P_{O_2} = A \left(\frac{\theta^*}{1 - \theta_T}\right) \exp \frac{(\Delta H_r - T\Delta S_r + q_r\theta_T)}{RT} \quad [7]$$

Assuming changes in entropy of adsorption with coverage are negligible (42) we may write

$$P_{O_2} = A \left[\frac{\theta^*}{1 - \theta_T}\right] \exp\left[\frac{\Delta H_r - T\Delta S_r}{RT}\right] \exp\left[\frac{q_r\theta_T}{RT}\right] \quad [8]$$

which is basically a modified Frumkin isotherm.

We have seen from Eq. [5] that

$$i \propto \theta^*$$

and we have found experimentally that

$$i \propto P_{O_2}$$

Now, from Eq. [8]

$$P_{O_2} \propto \theta^*$$

for small values of θ^* provided that the expression

$$\exp[(\Delta H_r - T\Delta S_r + q_r\theta_T)/RT] \quad [9]$$

from Eq. [8] does not substantially change with θ_T.

Assuming that ΔS_r does not depend on total coverage (42) and, as we noted experimental first-order dependence between $\theta_T = 0.1$ (at low potentials) and $\theta_T \sim 0.2$ (at about 1000 mV) to within 10%, then

$$\exp(\Delta H_r/RT) > 0.9 \exp[(\Delta H_r + q_r\theta_T)/RT] \quad [10]$$

This inequality gives the upper limit of q_r, the lower limit being 0. Thus,

$$\exp - 0.1\, q_r/RT > 0.9$$

giving

$$0.1\, q_r/RT < 0.1$$

Hence

$$q_r < 0.6 \text{ kcal/mole}^6$$

We may conclude, therefore, that q_r is small; it has been shown that q_p is about 23 kcal/mole in N perchloric and sulfuric acids (11, 21).

Assuming θ^* is small

$$\frac{\partial}{\partial P_{O_2}}\left(\frac{\theta^*}{1 - \theta_T}\right) \sim \partial\theta^*/\partial P_{O_2}$$

and, substituting Eq. [8] in Eq. [5] we have

$$i = \text{const. } P_{O_2}[H^+] \left[\exp - \frac{[\tfrac{1}{2}(q_p - q_r)\theta_T - \tfrac{1}{2}T(\Delta S_p - \Delta S_r)]}{RT}\right] \exp - \left(\frac{[\Delta H_r - T\Delta S_r + q_r\theta_T]}{RT}\right) \exp\left(\frac{-FV}{2RT}\right) \quad [11]$$

which gives, as ΔH_r is constant

$$\text{const. } P_{O_2}[H^+] \exp - \left[\frac{\tfrac{1}{2}(q_p + q_r)\theta_T - \tfrac{1}{2}T(\Delta S_p + \Delta S_r)}{RT}\right] \exp\left(\frac{-FV}{2RT}\right) \quad [12]$$

Again, assuming that changes in θ do not influence ΔS_p or ΔS_r, we obtain

$$i \propto P_{O_2}[H^+] \exp - \left(\frac{\tfrac{1}{2}(q_p + q_r)\theta_T}{RT}\right) \exp\left(\frac{-FV}{2RT}\right) \quad [13]$$

It should be noted that this is basically the same equation as that derived by Damjanovic and Brusic (11) except that their equation predicts that weaker adsorption of reactants would cause an increase in the reaction rate; that is, they have $-q_r$, not $+q_r$ in their equation.

Damjanovic and Brusic (11) have shown that for platinum an approximately linear variation of coverage exists in the intermediate coverage region ($0.2 < \theta < 0.8$) and that the potential for unit coverage changes by 60 mV per unit of pH.

Hence, where K is constant, we obtain

$$\theta(V, pH) = K \cdot V + K(RT/F) \cdot pH + \text{const.} \quad [14]$$

Substituting in Eq. [13] we obtain

$$i \propto P_{O_2}[H^+] \left(\exp - \frac{[\tfrac{1}{2}(q_p + q_r) \cdot (KV + K(RT/F)pH)]}{RT}\right) \exp\left(\frac{-FV}{2RT}\right) \quad [15]$$

From published data (11, 21) we find that $q_p \approx 23$ kcal/mole. Hence we may write, as $q_r << q_p$

$$i \propto P_{O_2}[H^+] \left(\exp - \frac{\tfrac{1}{2}q_p[KV + K(RT/F)pH]}{RT}\right) \exp\left(\frac{-FV}{2RT}\right) \quad [16]$$

Under equilibrium conditions, neglecting pre-exponential terms in the forward and backward Temkin rate expressions (21) and as "q" is large (43)

$$q\,\delta\,\theta = F\,\delta\,V$$

That is, the change in heat of adsorption in the interval ΔV is equal to the change in electrochemical potential.[7]

Hence

$$q = F\left(\frac{\partial V}{\partial \theta}\right)_{pH} \quad [17]$$

and, from Eq. [14]

$$(\partial V/\partial\theta)_{pH} = \frac{1}{K} \quad [18]$$

where q refers to any strongly bound species.

Substituting Eq. [17] and [18] in Eq. [16], we obtain

$$i \propto P_{O_2}[H^+] \left(\exp - \frac{[\tfrac{1}{2}FV + \tfrac{1}{2}RT(pH)]}{RT}\right) \exp\left(\frac{-FV}{2RT}\right) \quad [19]$$

or

[5] The constant A has been introduced in Eq. [6] to allow ΔG to represent the free energy of adsorption of oxygen at low coverage.

[6] This implies also that ΔH_r is small, which is reasonable as oxygen is adsorbed as molecules.

[7] It should be noted that it may perhaps be more accurate to write

$$F\delta V = \Delta\Delta G$$

where $\Delta\Delta G$ is the equilibrium change in free energy of adsorption of the intermediate in the interval δV. If we substitute this quantity in Eq. [2], it is not then necessary to suppose that the entropy of adsorption is coverage-independent (42).

$$i \propto P_{O_2}[H^+]^{3/2} \exp\left(-\frac{FV}{RT}\right) \quad [20]$$

This equation has a Tafel slope of RT/F, and has the correct oxygen partial pressure and pH-dependence (11).

Rotating Ring-Disk Electrodes

II. Digital Simulation of First and Second-Order Following Chemical Reactions

Keith B. Prater[1] and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas

ABSTRACT

A digital simulation technique has been employed to treat the steady-state and transient ring current behavior at the rotating ring-disk electrode (RRDE) for cases where the intermediate generated at the disk electrode undergoes a first- or second-order homogeneous chemical reaction leading to a nonelectroactive species. Where comparisons were possible, the results were found to be in good agreement with previous approximate theoretical treatments. Working curves are provided which allow determination of rate constants of the homogeneous reactions from ring-current-rotation rate data.

The rotating ring-disk electrode (RRDE) was introduced by Frumkin and Nekrasov (1) as a means of detecting intermediates of electrode reactions. An intermediate, B, is generated at the disk electrode by the reaction

$$A \pm ne \rightarrow B \quad [1]$$

and B is detected at the ring electrode by applying a sufficient potential such that all B reaching the ring is transformed back to A by the reaction

$$B \pm ne \rightarrow A \quad [2]$$

If B is a stable species, then the ratio of the current at the ring electrode to the current at the disk electrode is a function only of the geometry of the electrode (2). This ratio is called the collection efficiency, N, and is given by the expression

[1] Present address: University of Texas at El Paso, El Paso, Texas.
* Electrochemical Society Active Member.

$$N = -i_r/i_d \quad [3]$$

If species B undergoes a chemical reaction which depletes its concentration as it passes from the disk to the ring, then the observed collection efficiency under these conditions, N_k, (the kinetic collection efficiency) will be smaller than that found in the absence of these reactions. In this case, the collection efficiency is a function, not only of electrode geometry, but also of the rate constant of the reaction, the rotation rate, ω, and other solution parameters.

Albery and Bruckenstein (3) have given an approximate treatment of steady-state kinetic collection efficiencies for the first-order EC mechanism (where EC denotes an electron transfer followed by a chemical reaction)

$$B \xrightarrow{k_1} X \quad [4]$$

in which B reacts to give an electro-inactive species X. This treatment is valid only for extremely thin-ring thin-gap electrodes and then only for certain values of k_1/ω. In a later paper, Albery, Hitchman, and Ulstrup (4) modified the previous treatment to make it applicable to a wider range of electrode geometries. Albery (5) has also treated the ring current transients for this mechanism in the case of a constant current at the disk electrode.

Albery and Bruckenstein (6) have also given an approximate treatment of the second-order EC mechanism

$$B + C \xrightarrow{k_2} Y + Z \quad [5]$$

where C, Y, and Z are electro-inactive species. Unfortunately, the treatment of this mechanism is valid only for very small values of the parameter $k_2C^\circ_A/\omega$ where C°_A is the bulk concentration of species A.

Albery, Hitchman, and Ulstrup (4) have presented experimental work to support the modified treatment of the first-order case, and Johnson and Bruckenstein (7) have investigated the second-order case. In both of these studies, however, the systems chosen did not strictly conform to the above mechanisms in that in all cases one product of the homogeneous following reaction was the starting species, A. Thus, the experimental studies were more related to the catalytic reaction mechanism; a theoretical treatment of that case will be given in a later paper.

In this paper, we present the results of the application of a digital simulation technique (8) to the first- and second-order EC mechanisms. In addition to steady-state kinetic collection efficiencies, ring current transient behavior is presented. This simulation technique can be applied to any electrode and the results are valid for any value of the rate parameters, k_1/ω and $k_2C^\circ_A/\omega$.

Digital Simulation Method

The basic method for the digital simulation of the RRDE including the simulation of the first-order EC mechanism has been presented in a previous paper (8). Only two modifications of the simulation technique previously presented are necessary in order to simulate the second-order EC mechanism. First, the collection efficiency for such a process will be determined not only by the value of the rate constant, k_2, the rotation rate, ω, and the bulk concentration of species C, C°_C. For the second-order case, then, an additional parameter, m, given by

$$m = C^\circ_C/C^\circ_A \quad [6]$$

must be specified. Thus in setting up the initial conditions, the fractional concentration of species A in any box will be

$$F_A(J,K) = 1.0 \quad [7]$$

and the initial fractional concentration of species C in any box will be

$$F_C(J,K) = m \quad [8]$$

A second difference between the treatment of the first- and second-order cases concerns the form of the dimensionless rate parameter. The pertinent rate law for the second-order mechanism is

$$-dC_C/dt = -dC_B/dt = k_2C_BC_C \quad [9]$$

In terms of the simulation this becomes

$$-\Delta C_C = -\Delta C_B = k_2C_BC_C\Delta t \quad [10]$$

Dividing through by C°_A and letting

$$C_C/C^\circ_A = F_C \quad [11]$$

and

$$C_B/C^\circ_A = F_B \quad [12]$$

then Eq. [10] becomes

$$-\Delta F_C = -\Delta F_B = k_2F_BC_C\Delta t \quad [13]$$

Replacing C_C by $F_CC^\circ_A$ and using the equation (Eq. [12] and [25], ref. (8))

$$\Delta t = t_k/L = \nu^{1/3}D_A^{-1/3}\omega^{-1}L^{-1}(0.51)^{-2/3} \quad [14]$$

one obtains

$$-\Delta F_C = -\Delta F_B = k_2t_kC^\circ_AF_BF_C/L \quad [15]$$

The product $k_2t_kC^\circ_A$ is the dimensionless rate parameter applicable to this mechanism and is called XKTC. Thus

$$XKTC = k_2t_kC^\circ_A = k_2C^\circ_A\omega^{-1}\nu^{1/3}D_A^{-1/3}(0.51)^{-2/3} \quad [16]$$

where as before ν is the kinematic viscosity and D_A is the diffusion coefficient of species A.

The effects of kinetics on the concentration in any box may be taken into account by replacing the existing concentrations of B and C, F_B and F_C by

$$F'_B(J,K) = F_B(J,K) - \Delta F_B(J,K) \quad [17]$$

$$F'_C(J,K) = F_C(J,K) - \Delta F_C(J,K) \quad [18]$$

Other than these two modifications, the simulation is identical to that previously presented.

A digital computer program based on the digital simulation model with the appropriate modifications was used to obtain the results which will be presented. These results were obtained by first selecting a value for the appropriate dimensionless rate parameter

$$XKT = (0.51)^{-2/3}k_1\omega^{-1}\nu^{-1/3}D_A^{-1/3} \quad [19]$$

for the first-order case or XKTC for the second-order case. In the second-order case, a value for the parameter m was also specified. The computation was then carried out until a steady state was attained. This computation yields both steady-state kinetic collection efficiencies, N_k, and the ring current transients as functions of the dimensionless rate parameters and m. In all cases unless otherwise stated, L = 50 and D_m = 0.45 and the appropriate correction factors were used.

First-Order Results

Steady-state behavior.—The simulated collection efficiency *vs.* XKT curve for an electrode approximating the thin-ring thin-gap electrode treated by Albery and Bruckenstein is shown in Fig. 1 and 2. In Fig. 1, the simulation is compared with Albery and Bruckenstein's Eq. [6.4] (3) in the region of small XKT. The entire simulated curve is shown in Fig. 2 as is the comparison with their Eq. [5.8] (3). These graphs show clearly the regions in which the approximate treatments of Albery and Bruckenstein apply for an electrode of this geometry. These regions of applicability are quite close to those suggested by Albery and Bruckenstein.

In a later paper (4), Albery pointed out that the thin-ring thin-gap treatment is not valid for most

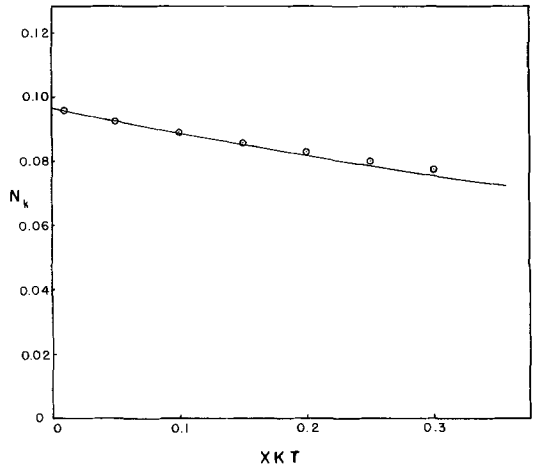

Fig. 1. Collection efficiency vs. XKT for a first-order following reaction at a thin-ring thin-gap electrode (IR1 = 2000, IR2 = 2040, IR3 = 2080). ⊙ Comparison with Albery's Eq. [6.4] (2). XKT = $k_1\omega^{-1}D^{-1/3}\upsilon^{1/3}(0.51)^{-2/3}$.

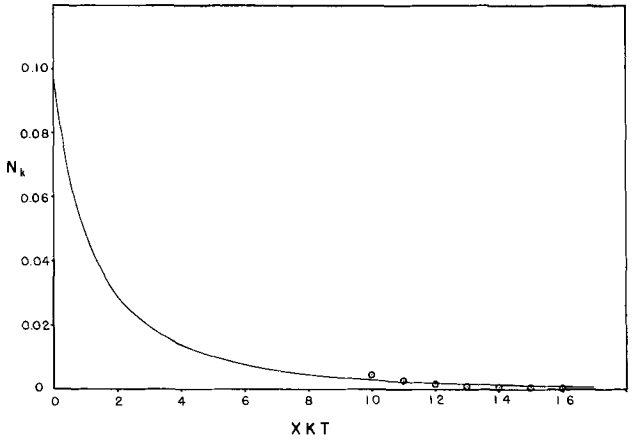

Fig. 2. Collection efficiency vs. XKT for a first-order following reaction at thin-ring thin-gap electrode (IR1 = 2000, IR2 = 2040, IR3 = 2080). ⊙ Comparison with Albery's Eq. [5.8] (2). XKT = $k_1\omega^{-1}D^{-1/3}\nu^{1/3}(0.51)^{-2/3}$.

practical electrodes, and he presented a modified theory which should be applicable to a wider range of electrode geometries. The results of the simulation of the two electrodes for which Albery presented his calculations are shown in Fig. 3 as well as Albery's calculated values for the collection efficiency as a function of $(XKT)^{1/2}$. The agreement over this range of XKT values is excellent.

It is interesting to consider the effect of electrode geometry on the range of applicability of different electrodes to studies of first-order following reactions. The results of the simulation of three different electrodes are given in Fig. 4. Electrode A is the electrode previously presented which approximates the thin-ring thin-gap electrode. Electrode B is one of Albery's electrodes. It has a fairly thin gap and a moderately thin ring. Electrode C which has been used in these laboratories has a comparatively wide gap and ring. The simulated working curves show, as expected, that the thin-ring thin-gap electrode (A) is the most applicable of the three for studying extremely fast reactions, while electrode C, with a wider gap is more useful for slow reactions. The point to be made here is that while electrodes similar to electrode A should be used for studying fast reactions, they are not useful for slow reactions ($k \leq 0.1$) because even at the lowest usable rotation rates such a reaction does not proceed to any detectable extent in the time required for species B to reach the ring electrode. In these cases, electrodes with gaps as wide as that in electrode C or even wider should be used

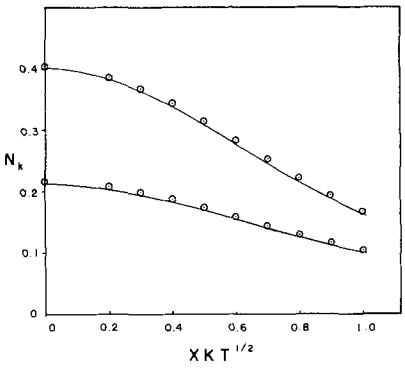

Fig. 3. Collection efficiency vs. $(XKT)^{1/2}$ for a first-order following reaction for two electrodes of different geometries

a. $r_1 = 0.3635$	$r_2 = 0.3777$	$r_3 = 0.4835$
IR1 = 200	IR2 = 208	IR3 = 266
b. $r_1 = 0.4770$	$r_2 = 0.4869$	$r_3 = 0.5222$
IR1 = 820	IR2 = 837	IR3 = 898

⊙ Comparison with Albery's Fig. 2 (4). XKT = $k_1\omega^{-1}D^{-1/3}\upsilon^{1/3}(0.51)^{-2/3}$.

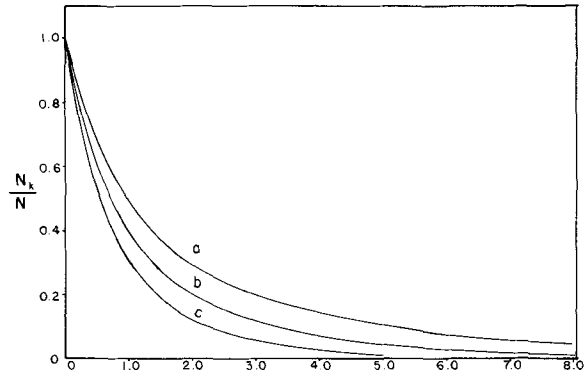

Fig. 4. Collection efficiency vs. XKT for a first-order following reaction for three electrodes of different geometries. XKT = $k_1\omega^{-1}D^{-1/3}\upsilon^{1/3}(0.51)^{-2/3}$. a, $r_2/r_1 = 1.02$, $r_3/r_2 = 1.02$; b, $r_2/r_1 = 1.04$, $r_3/r_2 = 1.28$; c, $r_2/r_1 = 1.14$, $r_3/r_2 = 1.70$.

For this first-order case, identical steady-state collection efficiencies are predicted when the boundary condition at the disk electrode corresponds to a constant current step instead of a potential step. The constant current boundary condition at the disk affects only the transient and not the steady-state behavior of the collection efficiency.

Transient behavior.—The simulated ring current transients (RCT) for this mechanism due to a potential step at the disk are shown in Fig. 5. Each curve represents the RCT for the specified value of the dimensionless rate parameter, XKT. As must be the case, the steady-state currents are seen to decrease with increasing values of XKT. An interesting feature of these curves is that, unlike the RCT in the absence of a following reaction, the ring current passes through a maximum before attaining steady state. This is because under the potential step condition, a very large instantaneous flux of species B is generated at the initiation of electrolysis [see Fig. 2, ref. (8)]. The short time interval between the generation of this large flux of B and the detection of B at the ring does not permit the homogeneous reaction to reduce the concentration of B to its eventual, lower steady-state value. Hence a maximum in the ring current is observed. Identical simulation results are obtained if the simulation is carried out with L = 1000 and no correction factors. This effect is more clearly shown in

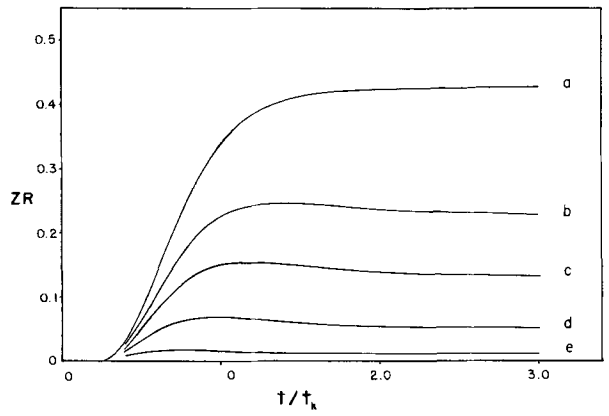

Fig. 5. Ring current transients for a first-order following reaction for different values of XKT. a, 0.0; b, 0.5; c, 1.0; d, 2.0; e, 4.0. Zr $= i_r/(0.51)^{1/3}nFA_DC^\circ {}_AD_B^{2/3}\omega^{1/2}\upsilon^{-1/6}$. XKT $= k_1\omega^{-1}D^{-1/3}\upsilon^{1/3}(0.51)^{-2/3}$. Simulated with IR1 = 83, IR2 = 94, IR3 = 159.

Fig. 6 in which the RCT's have each been normalized by the eventual steady-state current for each value of XKT. This plot also points out that the value of $\omega t\ D^{1/3}\nu^{-1/3}(0.51)^{2/3}$ at which the ring current is one-half (or any other fraction) of the steady-state value is a function of XKT and could in principle be used to determine the rate constant, as has been suggested by Albery (5).

These results can be compared with those obtained using a constant current boundary condition at the disk. The results of two simulations which differed only in the boundary condition at the disk are shown in Fig. 7. Note that no maximum is observed when a constant current is applied to the disk. The effect of the rate parameter on the normalized RCT's with a constant current step at the disk is shown in Fig. 8. As before, the value of the time parameter, $\omega t\ D^{1/3}\nu^{-1/3}(0.51)^{2/3}$, at a specified fraction of the steady-state current is a function of the rate parameter, XKT. It should also be pointed out that these normalized curves are independent of the value of the applied constant current.

Second-Order Results

Steady-state behavior.—A series of curves of N_k *vs.* (XKTC) (m) for different values of m, for a following second-order reaction and for the disk electrode held at a potential where the limiting current for the conversion of A to B occurs, is shown in Fig. 9. Also shown in Fig. 9 is the simulated collection efficiency

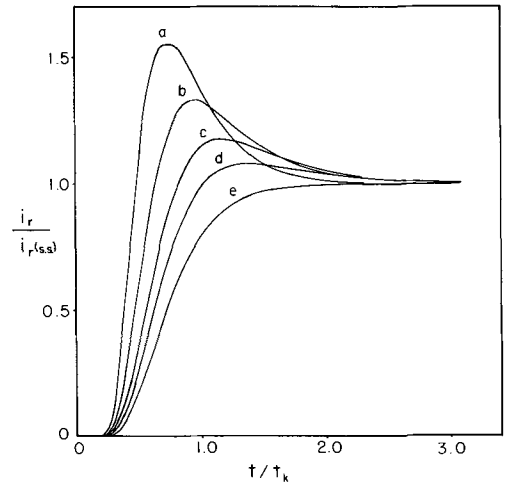

Fig. 6. Ring current transients for a first-order following reaction for different values of XKT. a, 4.0; b, 2.0; c, 1.0; d, 0.5; e, 0.0. Curves are normalized by the steady-state current at each value of XKT. Simulated for IR1 = 83, IR2 = 94, IR3 = 159. XKT $= k_1\omega^{-1}D^{-1/3}\upsilon^{1/3}(0.51)^{-2/3}$.

curve for a first-order following reaction. Note that when C is in tenfold excess, the second-order curve is almost indistinguishable from the first-order curve; thus when m = 10.0, the second-order process can be treated as a pseudo-first-order one.

In the case of this second-order mechanism, unlike that of a following first-order reaction, the simulated collection efficiencies presented here are valid only for the case $i_d = i_{lim}$. If a constant current less than the limiting current were applied to the disk, differ-

ent collection efficiencies would be observed as pointed out by Albery and Bruckenstein (6). The simulation of the effects of a constant current less than the limiting current can easily be done, but there seems to be little reason to do so.

In the treatment of this case by Albery and Bruckenstein (6), the current at the disk electrode is adjusted to a value where the concentrations of B and C are equal at the inner edge of the ring electrode. Under these conditions, the current at the ring due to species B will be dependent on the rate of the reaction between B and C and is given by the following equation

$$i_r = BnF\pi r_2^2 D_A \omega^{3/2} \nu^{-1/2} k_2^{-1} \quad [20]$$

The constant, B, was originally calculated to be 590 (6) but more recently has been given as 210 (7). The disk current necessary to produce the appropriate conditions is given by

$$i_d = 620nF\pi r_1^2 D_A^{2/3} \omega^{1/2} \nu^{-1/6} C^\circ_C (1 - F(\alpha))^{-1} \quad [21]$$

where $F(\alpha)$ is a geometrical parameter of the electrode which has been tabulated by Albery and Bruckenstein (2). Note that for the particular value of m, given by

$$m = C^\circ_C / C^\circ_A = 1 - F(\alpha) \quad [22]$$

Eq. [21] becomes

$$i_d = 620nF\pi r_1^2 D_A^{2/3} \omega^{1/2} \nu^{-1/6} C^\circ_A \quad [23]$$

This is precisely the limiting current due to species A as predicted by the Levich equation. Thus from Eq. [20] and [23], N_k in this case is given by

$$N_k = (B/620)(r_2/r_1)^2 \omega k_2^{-1} C^\circ_A{}^{-1} D^{1/3} \nu^{-1/3} \quad [24]$$

or

$$N_k = (B/620)(r_2/r_1)^2 (0.51)^{2/3} (XKTC)^{-1} \quad [25]$$

Note that Eq. [24] must at best be valid only as $\omega/k_2 C^\circ_A$ approaches zero where it accurately predicts that, under these conditions, N_k approaches zero. At the other limit, as $\omega/k_2 C^\circ_A$ approaches infinity, Eq. [24] predicts that N_k should increase without bound, while in reality the actual upper limit is N, the collection efficiency in the absence of kinetic complications.

To compare the digital simulation results with those of Albery and Bruckenstein (6), an electrode of a given geometry was chosen, and m was adjusted according to Eq. [22]. Values of N_k at various values of XKTC with i_d at its limiting value can then be used to investigate the useful range of Eq. [24].

Simulated collection efficiencies *vs.* 1/XKTC are shown in Fig. 10 for one of Albery's electrodes under these conditions. Also shown is the line predicted by Eq. [25] using B = 210. The simulation yields curves which approach the proper limits (zero or N) for the extreme values of $\omega/k_2 C^\circ_A$. In the region of small $\omega/k_2 C^\circ_A$, the simulated curve is approximately linear, but the agreement with Eq. [25] depends on the particular geometry. The slope of the simulated curve as $\omega/k_2 C^\circ_A$ approaches zero yields a value of B of about 260, but it seems that the use of the entire simulated working curve would be preferable to an approximate linearization near $\omega/k_2 C^\circ_A = 0$.

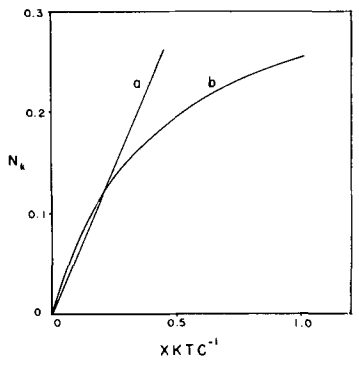

Fig. 10. Collection efficiency *vs.* $(XKTC)^{-1}$ for a second-order following reaction. m = 0.60. IR1 = 200, IR2 = 208, IR3 = 266. $XKTC = k_2\omega^{-1}C^\circ_A D^{-1/3}\upsilon^{1/3}(0.51)^{-2/3}$. Curve a is a plot of Eq. [25]; curve b is the simulated curve.

Albery and Bruckenstein's recommended experimental procedure involves variation of i_d at values below the limiting current and at constant ω to obtain the i_r values used in fitting Eq. [24]. It appears that a more straight forward procedure when working curves such as those in Fig. 9 are available, would involve maintaining i_d at its limiting value and studying the variation of N_k with ω and m. The value of k_2 is then obtained by fitting the experimental results to these working curves.

Transient behavior.—A description of RCT's for second-order following reactions has not been given previously. The simulation shows that the RCT's for the second-order mechanism are similar to those for the first-order case. As shown in Fig. 11, the extent to which a maximum is predicted in the potential step case is a function of the ratio of the bulk concentrations of species A and C. If A is in excess, then the maximum is small because very little B disappears on its way to the ring and the RCT approaches the RCT in the absence of a following reaction. If C is in excess, then the maxima are similar to those obtained for the first-order case.

Conclusion

The digital simulation technique is capable of describing both the steady-state and transient behavior at the RRDE for systems involving homogeneous reactions following the electrode reaction for a wide range of electrode geometries, ω and R. Although the simulation technique permits the calculation of the transient behavior of the ring current, there are many experimental problems involved in measuring these transients. The most important problem is that adsorption of the intermediate, B, on the disk electrode will delay and smear out the RCT while desorption of B produced from adsorbed A will produce a maximum similar in form to the one predicted for this kinetic case, even in the absence of kinetic effects. Bruckenstein (9) has considered cases like this and their effects on transients. Since adsorption of either product or reactant is so frequently found, the observation of the maxima predicted by the simulation will be difficult. For the same reason, the use of RRDE transient measurements to investigate the kinetics of homogeneous reactions is probably less profitable and more difficult, than the corresponding steady-state measure-

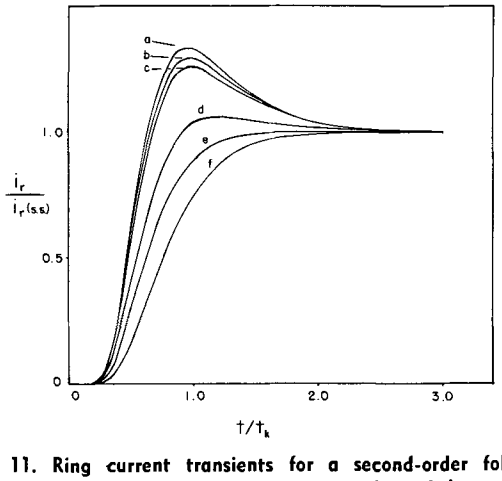

Fig. 11. Ring current transients for a second-order following reaction with a potential step at the disk. $t_k = \omega^{-1}D^{-1/3}\upsilon^{1/3}(0.51)^{-2/3}$. IR1 = 83. IR2 = 94, IR3 = 159. The curves are all generated for $(XKTC)(m)$ = 2.0 at different values of m; also shown is the first-order curve. a, First-order; b, 10.0; c, 5.0; d, 1.0; e, 0.5; f, 0.1.

ments. We might point out that adsorption interferes in a similar way in other types of electrochemical transient measurements (*e.g.*, cyclic voltammetry and chronopotentiometry).

The method of obtaining rate constants proposed here involves setting the disk current at its limiting value, observing the ring current as a function of ω, and fitting the results to working curves for the particular RRDE employed. This technique should prove just as useful, and operationally somewhat easier, than the technique suggested by Albery and Bruckenstein (6). The relatively small value of m which yields essentially pseudo-first-order behavior ($m > 10$) suggests that a good fit to the first-order working curves does not necessarily indicate that a second-order reaction is not involved.

Technical Notes

Ultrafine Porous Polymer Membranes as Battery Separators

Joseph L. Weininger* and Fred F. Holub

General Electric Research and Development Center, Schenectady, New York

In nonaqueous galvanic systems, based on organic solvents, it is important to keep soluble ions of the cathodic reactant from the anode. Conventional ion exchange membranes have been used (1, 2) for this purpose, but have not been able to support appreciable current densities. In solvent exchange only an insufficient amount of organic solvent, *e.g.* propylene carbonate or dimethyl sulfoxide, replaces water in the ion exchange resin. To obviate this problem and obtain a separator for organic electrolyte cells, an alternate method of ion exclusion is reported in this note.

It is possible to restrict migration of solvated ions by reducing the pore size of microporous membranes below a certain limit. Different methods are known of producing microporous polymers by the introduction of additives into a thermoplastic resin and following this by the removal of the additive to leave a porous structure. For example, Sargent and Safford (3) introduced anionic surfactants into polyethylene and processed the mixture. After the additive is leached out, there remains a microporous structure. Similarly, in the present method ultrafine porous polymer membranes are prepared. These membranes are flexible, about 50% porous, and, most importantly, have extremely fine pore size. The average pore size is between 40 and 120Å.

Membranes were prepared by adding sodium benzoate or other salts of benzoic acid to the melted polymer in a weight ratio of 70-85 parts of benzoate to 30-15 parts of polymer. The salt does not dissolve in the polymer, but forms a dispersion or colloidal suspension. In processing, the polymer was milled on differential rolls with the benzoate salt at 140°-160°C for polyethylene or 170°-180°C for polypropylene. The mixtures were then cooled close to the softening point of the polymer and sheeted into 0.005-in. thick films. The final leaching of the sheets occurred in water at 20°-55°C. The salt was generally extracted in 1-16 hr. However, leaching is almost complete within 5-10 min.

In some cases the polymers were also irradiated with high energy electrons of 20 Mr at a dose rate of 10 Mr/min before or after extraction of the salt. This irradiation step was employed to improve the thermal and mechanical properties of the porous polymer for possible later use at greater than ambient pressures and temperatures. Irradiation after leaching was more effective in strengthening mechanical and thermal properties, but by this treatment the smallest pores were closed by cross-linking.

Membranes were tested routinely for porosity, gas permeability, and electrolytic conductivity. The porosity was determined by density measurements, the gas permeability from nitrogen flow as a function of applied pressure, and the electrolytic conductivity was measured at 1 kHz with a conductance bridge after filling the membrane with 1M KCl.

The known porosity of 40-50% corresponds to the initial weight ratio of polymer and additive. The conductivity is of the same order of magnitude as that of the solution filling the membrane. This shows an open continuous pore structure. Finally, small gas permeability is a measure of small pore diameters.

From the magnitude of the conductivity, a tortuosity factor can be calculated. It is the ratio of the actual electrolytic conductance to that expected at the given porosity and thickness for a structure with straight pores, normal to the surfaces.

The properties of three membranes are listed in Table I. They are given as examples of the magnitudes

involved and are representative of the very large number of membranes which were prepared from high-density polyethylene and highly crystalline polypropylene together with salts of benzoic acid as the additives.

The median pore size of these membranes is about 40-120Å. Materials of different pore size are illustrated in Fig. 1, 2, and 3. Figure 1 is an electron micrograph of a porous polyethylene sheet prepared by dissolving an anionic surfactant in polyethylene and subsequently removing the additive (3). Figures 2 and 3 show porous polyethylene and polypropylene prepared by the present method. In Fig. 1 the pores have a dimension of about 1μ (10,000Å), whereas in the other membranes most of the visible pores are about 100Å large. The majority of pores are smaller than 100Å median upper limit.

To obtain a quantitative estimate of the pore distribution, the following widely divergent physical methods were used to determine the pore sizes:

1. Electron microscopy.
2. Capillary flow—mercury intrusion porosimetry.
3. Capillary flow—liquid permeability.
4. Gas diffusion—Knudsen flow.
5. Small angle x-ray scattering.

Each of these methods has its specific limitation so that the quantitative values obtained indicate the limits of pore sizes rather than their distribution. However, a distribution curve can be constructed, combining the results of the above physical methods. Figure 4 shows the qualitative distribution of pore diameters on a logarithmic scale. The distribution ordinate, $\Delta N/N$, is

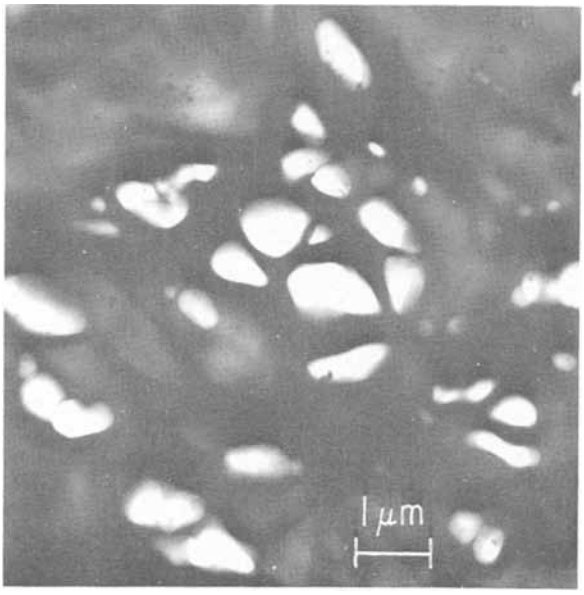

Fig. 1. Electron micrograph of porous polyethylene membrane, prepared with anionic surfactant as additive. 10,000X.

Fig. 2. Electron micrograph of ultrafine porous polyethylene membrane. 100,000X.

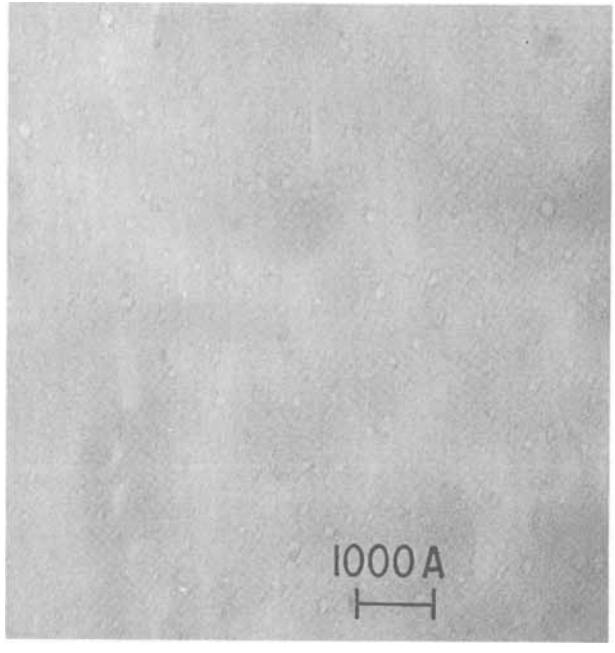

Fig. 3. Electron micrograph of ultrafine porous polypropylene membrane. 100,000X.

a qualitative estimate of the abundance of pores with different diameters. The numbered bars and the single point above the curve correspond to the different methods and the range of pore diameters obtained with them.

These membranes are now being used as separators in rechargeable organic electrolyte systems, containing a negative lithium electrode and a positive bromine electrode: $\ominus$ Li(on Ni)/0.2M LiBr + 0.8M $LiClO_4$ in propylene carbonate(PC)/porous polyethylene membrane/1.5M Br_2 + 1.6M LiBr in PC/porous C $\oplus$. With excess bromine solution, the cell is limited in current efficiency by lithium utilization, which, therefore, becomes a measure of self-discharge caused by bromine diffusion to the negative electrode. Table II shows the utilization of lithium as a function of cycle life. These results were obtained by charging and discharging the cell in 45-min half cycles, charging the cell at 4.2V and 1 mA/cm², discharging it at approxi-

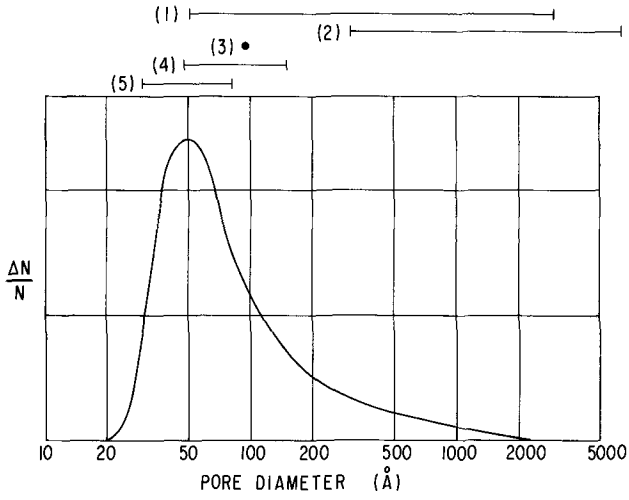

Fig. 4. Distribution of pore diameters in ultrafine porous membrane.

mately 3.2V and at a current density to match complete discharge in each cycle; for example, 0.9 mA/cm^2 for 90% utilization in the first 100 cycles.

Such use of the galvanic system as a secondary cell is made possible by the presence of the porous membrane as separator. Electro-osmotic measurements indicate that each tribromide ion and bromine molecule is associated with 4-6 molecules of the solvent. The solvated entity is less than 20Å in size, but this size in combination with its polar character, and the larger transport number of the positive ion, prevents bromine from reaching the lithium electrode compartment, except through the largest pores of the separator. Additional evidence for this is adduced from comparable experiments with porous Vycor glass which has a uniform pore diameter of 60Å. In this latter case, no bromine diffusion or migration occurs.

The alternative of using ion exchange membranes as separators in the nonaqueous system fails, because it has not been possible to exchange the solvent water in the ion exchange membrane with a sufficient amount of organic electrolyte to render it conducting. For example, a conventional cation exchange membrane was equilibrated with lithium ions, vacuum dried, and equilibrated with organic solvent (PC), or water was replaced stepwise by PC. In both cases, the conductivity of the cation exchange membrane in its organic form was about 2 x 10^{-9} mho/cm as compared with 0.46 x 10^{-3} mho/cm for the ultrafine porous separator in operation of the lithium-bromine cell, and 1.5 x 10^{-3} and 0.94 x 10^{-3} mho/cm, respectively, for the initial solutions in the positive and negative electrode compartments of the above cell.

Electroreduction of β-Diketones on Mercury

E. Kariv, J. Hermolin, and E. Gileadi

Institute of Chemistry, Tel-Aviv University, Ramat-Aviv, Israel

The electroreduction of ketones has been widely reported in the literature (1-6). Dimers formed by reductive coupling are often found, in particular in the presence of mercury or amalgams (1). β-Diketones are of special interest since they can follow several reduction pathways when reduced electrochemically (7). The polarography of some β-diketones has been studied (7-11) and different products were obtained by varying the conditions of electrolysis (7). Cyclopropandiols formed by intramolecular reactions have been proposed as intermediates in chemical reduction (12-14) and recently such compounds formed during electroreduction have been isolated (15).

The reduction of dimedone (I) on a mercury cathode was studied. Butanol, methanol, isopropanol, or DMF were used as solvents. Tetraethyl-ammonium-p-toluene sulfonate which was used as the electrolyte increased the solubility of the reactant and reduced the rate of simultaneous hydrogen evolution.

The product of the reaction has been separated and identified as the dimer (III), formed by a single electron transfer per molecule of dimedone (I). The same product was proposed before (8) on the basis of a polarographic determination of the number of electrons transferred in the reaction. However, no attempt was made to separate and identify the product in this previous study. The dimer (III) is a β-hydroxy-ketone which loses two molecules of water easily to yield the dimer (IV) with a conjugated double-bond system.

Electroreduction of β-Diketones on Mercury

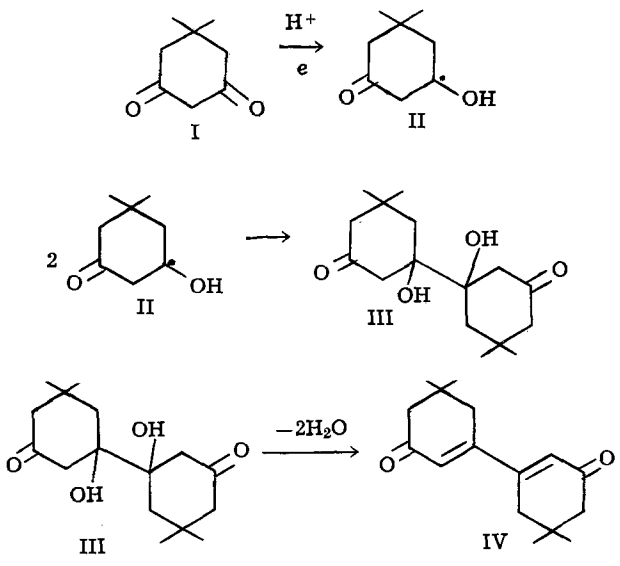
E. Kariv, J. Hermolin, and E. Gileadi

Institute of Chemistry, Tel-Aviv University, Ramat-Aviv, Israel

The electroreduction of ketones has been widely reported in the literature (1-6). Dimers formed by reductive coupling are often found, in particular in the presence of mercury or amalgams (1). β-Diketones are of special interest since they can follow several reduction pathways when reduced electrochemically (7). The polarography of some β-diketones has been studied (7-11) and different products were obtained by varying the conditions of electrolysis (7). Cyclopropandiols formed by intramolecular reactions have been proposed as intermediates in chemical reduction (12-14) and recently such compounds formed during electroreduction have been isolated (15).

The reduction of dimedone (I) on a mercury cathode was studied. Butanol, methanol, isopropanol, or DMF were used as solvents. Tetraethyl-ammonium-p-toluene sulfonate which was used as the electrolyte increased the solubility of the reactant and reduced the rate of simultaneous hydrogen evolution.

The product of the reaction has been separated and identified as the dimer (III), formed by a single electron transfer per molecule of dimedone (I). The same product was proposed before (8) on the basis of a polarographic determination of the number of electrons transferred in the reaction. However, no attempt was made to separate and identify the product in this previous study. The dimer (III) is a β-hydroxy-ketone which loses two molecules of water easily to yield the dimer (IV) with a conjugated double-bond system.



Product identification.—The dimer (III) has been isolated as sparingly soluble white crystals (methanol), mp 226°C (corr.). It had no absorption in the u.v. region. *IR* (KBr) 3440 (OH) and 1690 cm^{-1} (C = 0); mass spectrum m/e 282, 264, 246; molecular weight (by bp elevation) 280.

The dimer (IV) has been isolated as yellow platelets, mp 180°C (corr.). U.V. max (95% C_2H_5OH) 286 mμ (ε21900); *IR* (KBr) no absorption in the OH region, 1655 cm^{-1} (C = 0); nmr ($CDCl_3$) δ 1.08 (singlet 12H), 2.31 (singlet 4H), 2.4 (doublet 4H) and 6.28 ppm (multiplet 2H); mass spectrum m/e 246; molecular weight 247. Upon very mild dehydration on florisil at room temperature, pure dimer (III) yielded exclusively the dimer (IV).

The combined Faradaic yield for the dimers (III) and (IV) was 30-70% depending on both potential and the concentration of reactant in solution.

Kinetic studies.—Current-potential measurements were taken on a dropping mercury electrode equipped with a tapper which knocks off equal sized drops at equal intervals of time (*ca.* 0.2 sec). The maximum current (observed just before the drop is knocked off) was measured, and the current density was calculated from the average drop weight, assuming that the drops were hemispherical.

A wave due to reduction of dimedone is observed at −1.5 to −1.8V *vs.* SCE, depending on the concentration of reactant in solution, as shown in Fig. 1. The shape of the curves and the reduction potentials are not essentially affected by changing the solvent. The reaction is first order at lower concentrations and potential, but tends to zero order as the concentration and/or potential are increased. A limiting current is observed at higher potentials, as shown in Fig. 2, where the values of the current, corrected for background current, are plotted *vs.* potential. This behavior implies a rate-determining surface reaction, with reaction limited currents, as found also by Conway *et al.*

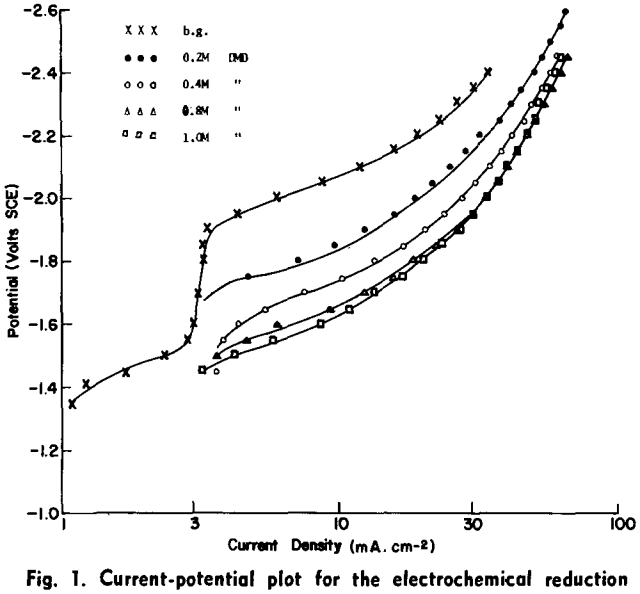


Fig. 1. Current-potential plot for the electrochemical reduction of dimedone on mercury. 1M tetraethyl p-toluene-sulfonate in n-butanol.

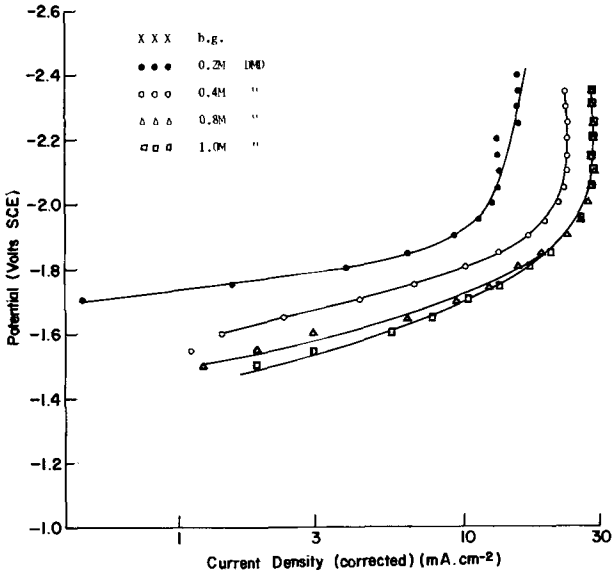

Fig. 2. Data of Fig. 1 corrected for background current

(5) for the reduction of acetophenone on mercury. It is also consistent with the product (III) formed by combination of two radicals (II) which are unstable in the homogeneous phase and can only have a substantial steady-state concentration on the electrode surface.

Preparation of Single Crystals of Cuprous Oxide in an Arc-Image Furnace

Dan Trivich* and **Gordon P. Pollack**[1]

Department of Chemistry, Wayne State University, Detroit, Michigan

ABSTRACT

A crucible-free technique for pulling single-crystal cuprous oxide from the melt has been developed, involving the use of an arc-image furnace to form a melt on the top of a cylindrical ingot of cuprous oxide. Single crystals approximately 1 cm in diameter and 3.5 cm long were grown along [111], [110], and [111] directions by the use of oriented seeds. The crystals were found to cleave preferentially along (111) planes. A count of chemical etch pits on (111) faces indicates a dislocation density of 10^4 to 10^5 cm^{-2}.

Cuprous oxide has been the subject of a number of investigations mainly because of its interesting electrical properties which depend on a departure from stoichiometry. It has been only recently that single crystals have become available for these investigations. These single crystals of cuprous oxide have been prepared by grain growth from polycrystalline cuprous oxide (1-4), by careful oxidation of single-crystal copper (5), and by hydrothermal methods (6). However, while these single crystals are useful for many studies, the methods have the disadvantage of giving usually thin samples with a limited control of orientation.

Attempts to grow cuprous oxide from the melt in our laboratory and elsewhere have been hampered by the reactivity of molten cuprous oxide with the standard crucible materials. Zucker (7), who used the Czochralski method to grow single crystals of Cu_2O from the melt, investigated a number of crucible materials of which sintered magnesia was found to be least reactive.

Because of this reactivity problem, it would be preferable to dispense with the use of crucibles. We have developed a crucible-free method of growing cuprous oxide single crystals from the melt by use of an arc-image furnace. We report here some details of this procedure and of the quality of the crystals obtained.

Crystal Growth Procedure

Essentially, the method consists of the use of focused radiation from a carbon arc to form a melt on top of a cylindrical ingot of cuprous oxide. The surface tension of the molten cuprous oxide is sufficient to hold the melt in place. Single crystals are then pulled from this melt by the Czochralski technique which consists of partial immersion and withdrawal of a seed crystal. Since the present method dispenses with the use of crucibles, the crucible contamination problems associated with past methods have been eliminated.

The basic design of the arc-image furnace used in these experiments has been described by Poplawsky and Thomas (8). The source of the radiant energy is a high-intensity carbon arc powered by an a.c.-d.c. motor generator supplying 150A d.c. at 78V. Imaging is accomplished by a double-paraboloid system (9) using two 150-cm parabolic mirrors set on a vertical axis with the carbon arc at the focus of the lower mirror and the partially molten ingot at the focus of the upper mirror. The crystal pulling mechanism provides for both rotation and vertical translation of the seed and the bulk material. Final temperature control is obtained by varying the position of the melt in relation to the focused image of the arc. The rotation and translation functions are motorized but final control of the position and rotation is attained by manual adjustment of the motor controls according to the judgment of the operator who views the work stage through a telescope.

The starting material for the preparation of the bulk material in the experiments reported here was high-purity copper metal (99.999+% pure, supplied by the American Smelting and Refining Company) usually in the form of 9-mm rods or sometimes 0.3- x 0.3- x 15-cm^3 strips. These were oxidized completely to Cu_2O by heating in air in a separate furnace at 1030°C for 3 days. The rods of Cu_2O were then transferred to the arc-image furnace where they were fed from above into the focus of the upper mirror and thus melted and deposited onto a high-purity copper base. By gradual feeding in of the source rods and downward withdrawal of the work stage from the melt zone, an ingot of bulk material 3.5 cm in diameter and 3 cm high could be built up. The work stage could also be surrounded by a Pyrex envelope to provide for control of the atmosphere. Usually the ingot build-up procedure was carried out under reduced pressure (2 Torr) in order to aid in the removal of gas bubbles trapped in the melt.

For the crystal growth process, the above procedure was essentially reversed so that material was transferred upward from the ingot to a Cu_2O seed crystal, but with more stringent control requirements. The crystal growth was begun by properly adjusting the power to the arc and the position of the ingot of bulk material in relation to the focal point so that a melt of the correct size and temperature was produced. A seed crystal, cut from a plate of cuprous oxide grown by the grain growth method (1), was then

* Electrochemical Society Active Member.
[1] Present address: Texas Instruments, Inc., P.O. Box 5936, M.S. 147, Dallas, Texas 57222.

merged with the melt. Material was transferred to the seed by upward vertical translation of both the seed and the bulk material at the correct relative rates. The crystal growth was usually carried out in air at 1 atm with a seed withdrawal rate of 1.5-2.0 cm/hr and rotation rates of 32 and 12 rpm in the same direction for the seed and bulk material, respectively.

Results and Evaluation of Crystals

The crystals obtained by this method were typically about 8-10 mm in diameter and 3-5 cm long. Difficulties with obtaining larger stable molten zones have thus far limited the maximum obtainable diameter to about 10 mm. Also, the length of the samples obtained is presently limited by the burning time of the carbon arc. No preference for direction of growth was observed since equal success was obtained for growth along the [100], [110], and [111] directions. The crystals were found to cleave preferentially along the (111) planes. Some typical samples are shown in Fig. 1.

The single-crystal character of the samples was evaluated by examining ground faces for grain boundaries and by back-reflection Laue x-ray diffraction. Grain boundaries when present were revealed by grinding a flat surface on the sample and then etching the surface with 0.5*N* NaCN solution. Under adequately controlled conditions the first portion of the sample pulled from the melt was invariably single crystal in character, but there was frequently a tendency for the growth to become coarsely polycrystalline toward the end of the sample. On the average, grain boundaries were found to appear approximately ¾ of the way down the sample. This deterioration of the structure toward the bottom end of the sample was further confirmed by x-ray analysis in that secondary diffraction spots became apparent. However, it was possible with care to grow samples which were single crystal in character over the entire length.

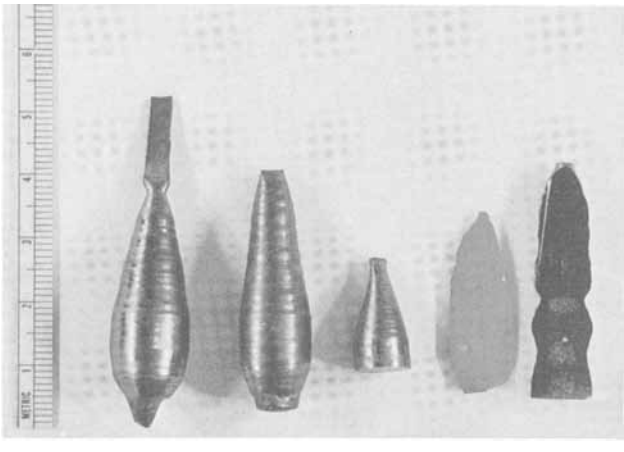

Fig. 1. Samples of Cu_2O as grown by the arc-image furnace method. The two samples at the left are single crystals as grown; the first has the seed still attached. The third sample was cut to reveal a cross section for examination. The fourth sample shows the ground surface of a lengthwise slice, showing the absence of grain boundaries. The fifth sample shows polycrystalline regions in a ground and etched slice.

Examination of cross sections of the samples revealed a number of pinhole-size voids which apparently originated from gas bubbles trapped in the viscous melt and subsequently transferred to the crystal. Subjecting the melt to a moderate vacuum before a run diminished but did not eliminate the voids. It is possible that these bubbles provided nucleation sites for the secondary crystallization that occurred. Another factor that probably contributed to the poor structure at the bottom of the samples is the basic instability of the carbon arc as a heat source.

In order to obtain a measure of the dislocation density in these samples, the density of chemical etch pits on the (111) planes was determined. Samples were prepared by first grinding a flat surface on the sample and then chemically polishing in a solution containing 17% HNO_3, 41.5% H_3PO_4, and 41.5% HAc (5) to remove the surface damage. The etch pits were developed by immersion of the sample for 30 sec in a solution containing 12% copper nitrate and 10% nitric acid (10). The etch pit density was found to vary across a plane perpendicular to the growth axis, typical values being 10^4 to 10^5 cm^{-2} near the center. The density of etch pits was also found to increase down the length of the sample.

The increase in etch pit density toward the center of the sample was probably due in part to the temperature distribution in the melt zone during the crystal growth. As shown for the double-paraboloid type of arc-image furnace (8), the melt-zone has a large radial temperature gradient which leads to a highly concave liquid-solid interface. Samples formed by solidification through such an interface could contain large stresses which would lead to the production of the dislocations.

Fast-Decay Phosphors

A. Bril, G. Blasse, and J. A. de Poorter

Philips Research Laboratories, N.V. Philips' Gloeilampenfabrieken, Eindhoven, The Netherlands

ABSTRACT

Decay times, efficiencies, and spectral energy distributions of a number of Ce^{3+}-activated phosphors have been determined. Decay times as short as 25-30 nsec are found for YPO_4-Ce, YOCl-Ce, and $YAl_3B_4O_{12}$-Ce; the two first-named phosphors show a weak, the last a strong, afterglow. The techniques of measurement have been described.

Ce^{3+}-activated phosphors are known as phosphors with very short decay times. The emission is ascribed to a 5d → 4f transition in the Ce^{3+} ion. The decay time is found to be shorter than 100 nsec due to the fact that an allowed transition is involved. Recently Ropp (1) summarized the results previously obtained and gave new data on Ce^{3+}-activated rare earth phosphates. The decay times of the latter phosphors are about 30 nsec, *i.e.* shorter than reported previously for Ce^{3+} phosphors. Awazu and Muto (2) described sensitization of YPO_4-Ce by the incorporation of thorium ions, leading to a higher photoluminescent efficiency.

The emission band of Ce^{3+}-activated phosphors has a doublet character due to the splitting ($\approx$2000 cm^{-1}) of the ground state ($^2F_{7/2}$,$^2F_{5/2}$). The emission is nearly always located in the blue or ultraviolet region of the spectrum. An exception is the yellow emission of the phosphor $Y_3Al_5O_{12}$-Ce which has been recently described (3).

In this paper, decay times, efficiencies, and spectral energy distribution of the emissions are given for several Ce^{3+}-activated phosphors, especially yttrium, scandium, and lanthanum phosphates and borates and yttrium oxychloride.

The cerium-activated phosphors find application in: (*a*) Flying-spot cathode-ray tubes for the TV transmission of films and slides. For color TV, an emission is required covering the whole visible spectrum. (*b*) A special type of color-TV receiving tube, the so-called index tube where an ultraviolet emitting phosphor is required in order to obtain the index signal (4).

Experimental

The preparation of the phosphors has been described by us earlier (5). The cerium concentration is 1-2%.

The decay times are measured both with ultraviolet and cathode-ray excitation. With cathode-ray excitation, a square pulse of voltage is displayed to the grid of the electron gun of a demountable cathode-ray tube, so that the phosphor can be irradiated during a variable time and with a variable repetition frequency. The method is analogous to that described previously by Bril and Klasens (4), but now much shorter times can be measured due to the use of a square-wave oscillator giving short pulses with a very short rise time (Tektronix Type 109, rise time 0.25 nsec, repetition frequency 550-720 pulses/sec) in combination with an oscilloscope with a wide frequency band (Philips No. 3330, bandwidth 70 MHz). The oscilloscope pictures were photographed with the aid of a Polaroid camera. To find all decay components, it is necessary to irradiate the phosphor with a wide range of excitation times in succession. Suppose a short and a long decay time component of equal efficiency are present, of *e.g.* 50 nsec and 1 msec. When the phosphor is then irradiated with a pulse of about 50 nsec duration, the maximum height of the rise and decay curve of the 1 msec component is negligible with respect to that of the 50 nsec component (the areas under the curves being equal). As a consequence, the long decay time component may be overlooked. This difficulty is avoided by exciting the phosphor for longer times also.

With ultraviolet excitation, use was made of two methods. (*a*) The TRW Nanosource instrument shown schematically in Fig. 1. The radiation source is a hydrogen discharge lamp for short-wavelength u.v. or a nitrogen discharge lamp for long-wavelength u.v.; the duration of the exciting pulses is 4 nsec or 9 nsec, the rise time less than 1.6 or 4 nsec, respectively, while the repetition frequency can be varied from zero to 5 KHz. The exciting radiation is filtered in such a way that the desired u.v. region is transmitted and imaged on the phosphor. The emitted radiation passes a filter transmitting only the fluorescence and is then collected by a photomultiplier with fast response time. With this instrument, the excitation time cannot be prolonged beyond a few nanoseconds which is a disadvantage as mentioned above. (*b*) Therefore, an additional method is used: longer decay times with u.v. radiation can be measured with the aid of a set-up described previously (6), using a cathode-ray tube with a fast, u.v.-emitting phosphor. In this case, u.v. pulses of shorter and longer duration can be obtained by modulation of the electron beam with a square-wave oscillator.

The spectral energy distributions were measured with the aid of a Jarrell-Ash 0.50m grating monochromator (15000 g/in., blazed at 750 nm). In the blue and ultraviolet region, the measurements were carried out in second order of the grating. As a detector, a photomultiplier with S20 photocathode was used (EMI 9558 Q), the current of which is amplified with the aid of a phase-sensitive a-c amplifier. To obtain the emitted power as a function of wavelength from the measured photocurrent, a correction for the varying instrumental response G as a function of λ has to be made (G consists of the variation of the response of the photomultiplier and of the transmission of the monochromator). This correction has been applied automatically, using a circuit whose diagram is given

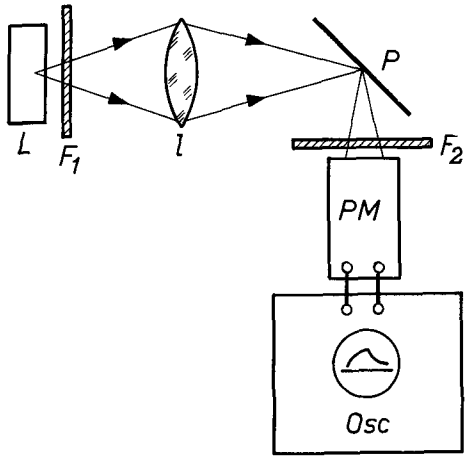

Fig. 1. Schematic diagram of the Nanosource instrument for decay time measurement: L = lamp, F_1 = ultraviolet transmitting filter, l = lens, F_2 = ultraviolet absorbing filter, PM = photomultiplier, Osc = oscilloscope, P = phosphor.

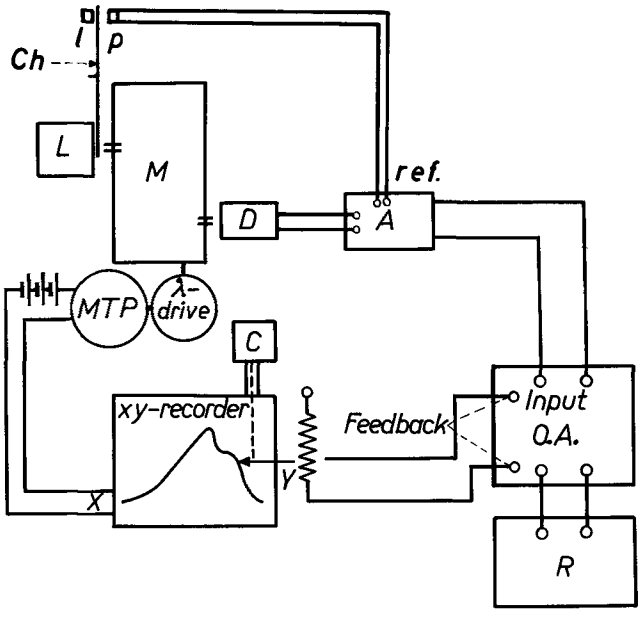

Fig. 2. Schematic diagram of automatic correction for instrumental response in spectral energy distribution measurements: *L* = light source, *M* = monochromator, *D* = detector, *Ch* = chopper (770 Hz), *l* = lamp, *p* = photodiode, *ref.* = reference signal, *A* = phase sensitive amplifier, *O.A.* = operational amplifier, *R* = recorder, *MTP* = multiturn potentiometer, *C* = curve follower.

in Fig. 2. On the axis of the wavelength drive, a multiturn potentiometer is fixed, to which a voltage of a few volts are applied. The variable voltage of the multiturn potentiometer is fed to the X-circuit of a flat-bed XY recorder. On this recorder, a piece of paper is placed on which the instrumental response $1/G = f(\lambda)$ is drawn. This curve is read with the aid of a curve follower. In this way a variable resistance, proportional to the value of $1/G(\lambda)$, taken from the built-in Y-potentiometer, is displayed to the feedback channel of an operational amplifier (Hewlett-Packard-Dymec). The normal signal $i(\lambda)$ of the photomultiplier is fed to an input channel of this amplifier. The output of the operational amplifier then gives the product of the two signals $I(\lambda) = i(\lambda) \cdot 1/G(\lambda)$, representing the emitted radiant power per constant wavelength interval (in arbitrary units). In the u.v. region, the correction factor $G(\lambda)$ proved to be nearly constant. Apparently, the instrumental response did not change much in this wavelength region.

Results and Discussion

In Table I, the decay times, the efficiencies and the maxima of the emission bands are given, both for cathode-ray and ultraviolet excitation. Some of the data, together with excitation and reflection spectra,

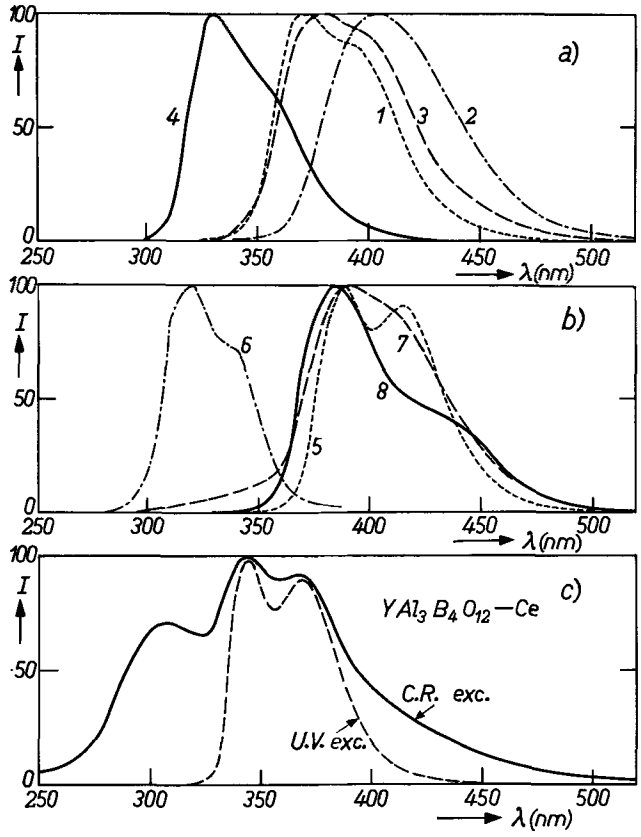

Fig. 3. Spectral energy distribution of the fluorescence. Along the ordinate, the radiant power per constant wavelength interval (*I*) in arbitrary units is given: (*a*) (cathode-ray excitation) 1. $Ca_2MgSi_2O_7$-Ce, 2. $Ca_2Al_2SiO_7$-Ce, 3. YOCl-Ce, 4. YPO_4-Ce. (*b*) (cathode-ray excitation) 5. YBO_3-Ce, 6. $LaPO_4$-Ce, 7. $Sc_2Si_2O_7$-Ce, 8. $ScBO_3$-Ce. (c) $YAl_3B_4O_{12}$-Ce, ——— cathode-ray excitation, - - - - u.v. excitation.

have already been published but are given here for completeness (7). In Fig. 3, the spectral energy distribution curves with cathode-ray excitation for some phosphors are given.

Generally, the doublet character of the emission (see introductory paragraphs) can be observed. However, sometimes a third, very short wavelength u.v. band is present, which has been ascribed to fluorescence from higher 5d-levels (6). For $Y_3Al_5O_{12}$-Ce, $ScBO_3$-Ce, and $Sc_2Si_2O_7$-Ce, this very short wavelength emission is present with u.v. excitation, but is absent or only weakly present with cathode-ray excitation. On the contrary for $YAl_3B_4O_{12}$-Ce such a third band is found with cathode-ray excitation but is absent with u.v. excitation. For $LaBO_3$-Ce, this very short wavelength

τ : Decay time, where the 1/*e* value of the initial intensity is reached (excitation pulse < 10 nsec).
δ : Percentage of the initial intensity 80 μsec after the end of the pulse of 20 μsec duration.
η : Radiant efficiency (energy conversion efficiency), C.R. excitation (20 kV).
q : Quantum efficiency, U.V. excitation.
* : Nonexponential decay.
** : The Ce concentration is 1-2%.

band is present for both types of excitation. The reason for the difference in behavior of the two types of excitation is not understood.

For u.v. excitation, the decay time τ is given, defined as the time at which the $1/e$-value of the initial intensity at the end of the pulse is reached. These values for τ are obtained for short-duration pulse excitation (less than 10 nsec), leading generally to exponential decay curves.

In some Ce-activated phosphors, more decay components are present. For $Ca_2Al_2SiO_7$-Ce, for example, it is well known that in the freshly prepared phosphor at least two decay components are present, from which the slower component disappears during life (8). Moreover, this phosphor and many other Ce^{3+}-activated phosphors show a strong deviation from the exponential law at much longer times (see Fig. 4). A long afterglow occurs, milliseconds even. This may be due to release of excitation energy stored in traps as a consequence, *e.g.* of impurities or imperfections in the host lattice. This long afterglow is troublesome in some applications such as the index-color-TV receiving tube. Therefore, for cathode-ray excitation we give not only the decay time τ ($1/e$-value), but in the 4th column of Table I also a value δ, defined as the percentage of the initial intensity 80 μsec after the end of an excitation pulse of 20 μsec duration. From the table it can be seen that δ varies considerably for the phosphors measured: it is 18% for $YAl_3B_4O_{12}$-Ce, while only 1.5% is found for YOCl-Ce, YPO_4-Ce, and $LaPO_4$-Ce. These latter phosphors are therefore suitable in cases where not only a short decay time but also a low-intensity afterglow is required (9).

For $LaPO_4$-Ce, Ropp (1) gives a value of 32 nsec close to our value of 35 nsec. For calcium magnesium silicate, Ropp gives 114 nsec for cathode-ray excitation ($1/e$-value), while we find a value of 80 nsec for our $Ca_2MgSi_2O_7$-Ce. This difference may be due to another composition of the substance, so that the long decay time components are different (moreover, these depend also on the duration of the excitation pulse). In this respect, it is remarkable that for our $Ca_2MgSi_2O_7$-Ce we measure a decay time of 50 nsec with an exponential decay curve for u.v. excitation when a very short excitation pulse of less than 10 nsec is used. With cathode-ray excitation, however, the curve is found to be nonexponential when extended over long enough times, *e.g.* 500 nsec (see Fig. 4; excitation pulse also less than 10 nsec). For the $1/e$ value, we find $\tau = 80$ μsec.

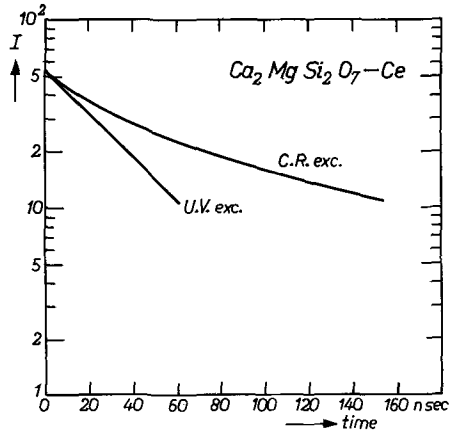

Fig. 4. Decay curves of $Ca_2MgSi_2O_7$-Ce for cathode-ray and u.v. excitation.

The Efficiency of Cathode-Ray Phosphors

I. Measurement

G. W. Ludwig* and J. D. Kingsley

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

The cathode-ray efficiency of a variety of phosphors has been studied, including (ZnCd)S:Ag, Zn_2SiO_4:Mn, ZnO:Zn, and oxide hosts activated with Eu^{3+}, Tb^{3+}, and other rare earths. In addition to the basic measurement of efficiency at 10 kV, the voltage dependence was measured over the range 0.2-20 kV and analyzed following Gergely.

One of the most important parameters of a cathode-ray phosphor is its power efficiency: the watts of radiant output per unit power in the incident electron beam. The measurement of absolute efficiency has been discussed by Bril (1). He determined the incident power by measuring the accelerating voltage and the sample current. A thermopile having a flat spectral response was used to detect the emitted radiation. To calibrate the thermopile and obtain an absolute efficiency measurement, Bril replaced the phosphor plaque with MgO of known reflectivity, irradiated it with a standard lamp, and measured the detector output. (If, instead, the radiated power is detected with a photomultiplier, one must calibrate its spectral response and measure the spectral energy distribution

* Electrochemical Society Active Member.

from the phosphor.) Bril found efficiencies ranging from 0.2 to 21% for a set of standard phosphors obtained from the National Bureau of Standards.

Many workers have contented themselves with measurement of relative efficiency. For example, Buchanan *et al.* (2) used a set of commercial phosphors as standards (accepting published efficiency figures for them) to calibrate the response of their detection system. The booklet "RCA Phosphors" (3) quotes relative radiant energy (*i.e.*, efficiency) of phosphors taking the output from RCA Phosphor No. 33-W-2A (Zn_2SiO_4:Mn) to be 100.

Only scattered values for the efficiencies of many of the newer phosphor materials are available in the literature. Moreover, the efficiency of a particular phosphor may be substantially influenced by preparatory and/or handling techniques. Therefore, it was deemed worthwhile to investigate the efficiency of a sizable number of phosphors, both new and old. The measurements on the older ones form a basis of comparison for the newer ones. We have measured commercial phosphors, the standard phosphors from the NBS studied by Bril, YVO_4 doped with rare earths, Eu-doped oxide phosphors such as Gd_2O_3 and Y_2O_2S, etc.

In addition to the basic measurement of efficiency at 10 kV, the relative efficiency has been studied over the range 0.2-20 kV. The resulting curves have been analyzed in terms of a formula suggested by Gergely (4) for de-excitation associated with the surface of the phosphor particles. From the analysis one obtains three parameters characterizing a phosphor, including a characteristic (or "dead") voltage. Of course, such measurements are of considerable interest for evaluating phosphors for low voltage applications, and have not been available for most phosphors hitherto.

For some hosts, such as YVO_4, there is reason to expect that the ratio of the cathode ray to u.v. efficiency will be a constant independent of the activating impurity or its concentration. To allow a check on this expectation, the absolute efficiency of many of the phosphors has been measured under excitation at 2537Å.

We have been interested in correlating the cathode-ray efficiency with other phosphor parameters. In a companion paper (5) we discuss the processes involved in cathode-ray excitation, and the use of photons of energy up to ~25 eV to simulate fast electron excitation. Comparison is made there between cathode-ray efficiency and efficiencies observed under u.v. excitation. Experimental techniques and results are presented and discussed in this paper.

Experimental Techniques

Preparation of phosphor plaques.—Phosphor powders for investigation under cathode-ray excitation were obtained from several sources including the General Electric Company Chemical Products Business Section, Cleveland; The National Bureau of Standards; and commercial sources. Shortly before use, the powders were sieved through a 400 mesh screen, or a coarser screen for relatively coarse powders.

Phosphor plaques were prepared having a phosphor weight in the range 8-14 mg/cm². Such a weight was adequate to produce plaques having no areas covered so lightly that the electron beam could penetrate completely through the phosphor layer.

The phosphor plaques were prepared by settling the powdered phosphor in a 3 in. diameter cylinder onto 1 x 2 in. pure silver (or aluminum) plates. Silver was chosen because it is an excellent electrical and thermal conductor, minimizing electrical charging and temperature rise, and is an excellent reflector for visible light from the settled phosphors. Some plaques were prepared by settling in water without binder, while for others a LiOH binder was used. In the latter case 380 cc of barium acetate solution (0.060 g/liter) was first poured into a cylinder containing a silver plate.

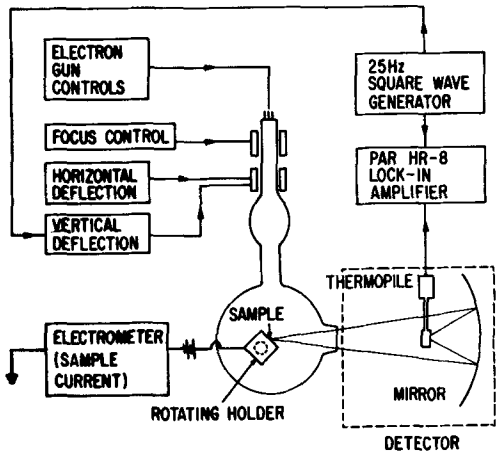

Fig. 1. Apparatus used to measure cathode-ray efficiency of phosphors.

A suspension of the phosphor in 240 cc of lithium hydroxide solution (0.4 g LiOH/liter) was then added. The phosphor was allowed to settle, the liquid slowly drained through an outlet, and the plaque allowed to air-dry at room temperature.

Cathode-ray excitation.—The plaques were excited using the apparatus shown in Fig. 1. The demountable cathode-ray tube will accept four plaques. The sample holder is a copper block which is thermally isolated by a length of stainless steel tubing, so that measurements may be made in the temperature region 77°-420°K. An electron beam from a commercially available oxide cathode gun (10FP4) was magnetically focused onto a plaque and magnetically deflected to produce a raster of the desired size. The plaque was oriented at 45° to the incident beam, while the emitted light passed through a quartz port at 90° to the beam. The beam voltage was adjusted in the range 0.2-10 kV by applying the potential to the electron gun. Post-acceleration of the beam was used to obtain voltages up to 20 kV. The sample holder, which was near ground potential, was biased positive relative to nearby parts of the tube so that secondary electrons were collected and the measured sample current was equal to the total incident electron beam current, the measurement error being a few per cent.

Absolute efficiency measurements were made at 10 kV or occasionally 20 kV beam voltage. For such measurements a thermopile[1] was used as the detector element. To high accuracy such detectors produce a response which is proportional to the total incident radiant energy independent of its wavelength. The electron beam was swept vertically at a frequency of 25 Hz, and a spherical mirror was used to focus the light on the active surface of the thermopile. Since the image of the phosphor was twice as long as the active surface of the detector, the thermopile signal was square wave modulated at the vertical scan frequency. This signal was synchronously detected using a Princeton Applied Research Model HR-8 lock-in amplifier. A 25 Hz square wave was used both to synchronize the vertical scan and as an input to the lock-in amplifier operated in the selective external mode. When a measurement was completed, the sample holder was rotated to position a new sample in the electron beam, and micrometer drives were employed to so reposition the thermopile as to maximize the signal from it.

The thermopile is sensitive to radiant energy from the phosphor in the infrared and ultraviolet as well as in the visible portion of the spectrum. In cases where information concerning the spectral distribution of the radiation was of interest, energy ranges were isolated by interposing appropriate filters in the light path to the thermopile.

[1] The thermopile was a Model RSL-6S obtained from Charles M. Reeder and Co., Detroit, Mich.

The relative efficiency of phosphors was measured as a function of beam voltage over the range 0.2-20 kV. In these measurements, use of the thermopile detector was abandoned in favor of the greater sensitivity of a photomultiplier such as a 1P21. In order to maintain a raster of standard size, it was necessary to adjust the focus coil voltage and the horizontal and vertical deflection coil voltages at each value of beam voltage. The photomultiplier tube used as the detector was positioned directly in front of the quartz window with no collecting optics for the light.

Phosphor emission spectra were also taken with cathode ray excitation. A lens in front of the quartz window served to focus the emitted light on the entrance slit of a ½ meter Jarrell-Ash spectrometer.

Ultraviolet efficiency at 2537Å.—The absolute radiant efficiency of a phosphor under u.v. excitation customarily is defined as the emitted radiant power divided by the power absorbed from the incident beam. We have measured this efficiency by a technique similar to that of Bril and Hoekstra (6). A block diagram of our apparatus is shown in Fig. 2. Radiation from a 4w germicidal lamp, consisting largely of the mercury line at 2537Å, was mechanically chopped at 13 Hz. A narrow band interference filter passed a band centered near 2537Å and suppressed other components. The radiation was reflected from an MgO plaque onto a thermopile and synchronously detected using a Perkin-Elmer Model 107 amplifier. The MgO plaque then was replaced by a geometrically similar phosphor plaque. Readings of the thermopile signal were taken both with and without interposing a filter (which removes 2537Å radiation) between the plaque and thermopile. The absolute efficiency, η_{2537}, and reflection coefficient, r_{2537}, of the phosphor were then calculated from the formulas (6)

$$r_{2537} = \rho(V_P - V_{PF}\tau^{-1})/V_{MgO} \quad [1]$$

$$\eta_{2537} = \frac{\rho}{\tau(1-r)}\frac{V_{PF}}{V_{MgO}} \quad [2]$$

In [1] and [2] V_{MgO}, V_P, and V_{PF} are the thermopile signals from the MgO plaque, the phosphor with no filter interposed, and the phosphor with attenuating filter for 2537Å interposed, respectively. The parameters ρ and τ are the reflectivity of the MgO and the transmission of the filter for the fluorescent radiation. The formulas assume equal transmission of the quartz window of the thermopile for 2537Å and the fluorescent radiation.

Results

The relative light output of phosphors under cathode-ray excitation was studied from 0.2 to 20 kV. Typical results for the light output per unit current are shown in Fig. 3. At high voltage the output approaches a straight line through the origin, while at low voltage it falls substantially below the line. As the voltage is lowered the incident electrons penetrate

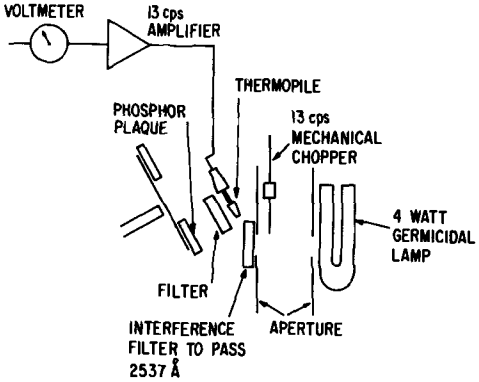

Fig. 2. Apparatus used to measure absolute efficiency of phosphors under 2537Å excitation.

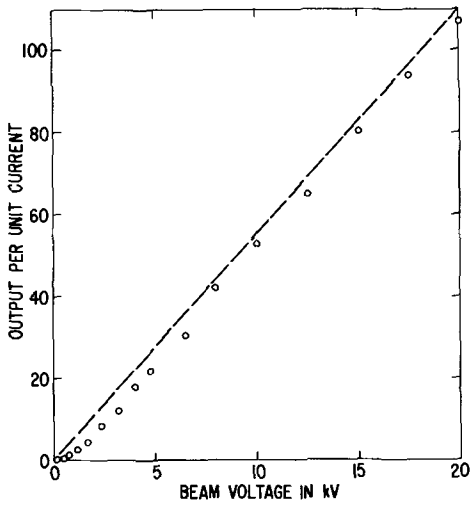

Fig. 3. Relative light output of a Gd_2O_3:Eu phosphor as the beam voltage is varied.

the phosphor grains less and less. It is generally accepted that the decrease in power efficiency at low beam voltage is associated with surface loss.

Gergely (4) has analyzed the voltage dependence of cathodoluminescence under a set of simplifying assumptions. He assumes a range for the incident electrons of the form

$$R = KV^b \quad [3]$$

where K and b are material constants. He approximates the excitation density as uniform throughout the range. He assumes that free carriers are produced which diffuse through the phosphor and recombine at the surface, characterized by a surface recombination velocity. The result of his analysis is that the efficiency, normalized to 1 at high voltage, is given by [*cf.* his Eq. (8)]

$$\eta_N = 1 - Q\left[\frac{1-\exp(-\beta R)}{\beta R}\right] \quad [4]$$

where β is the inverse of the diffusion length and Q is a surface recombination loss parameter. However, we can use the range relation of Eq. [3] to express η_N in terms of the beam voltage V and a characteristic voltage V_0

$$\beta R \equiv (V/V_0)^b \quad [5]$$

$$\eta_N = 1 - Q\frac{1-\exp[-(V/V_0)^b]}{(V/V_0)^b} \quad [6]$$

Plots of η_N for $b = 1.5$ and different values of Q are shown in Fig. 4. For $Q = 0$ (no surface loss) η_N is in-

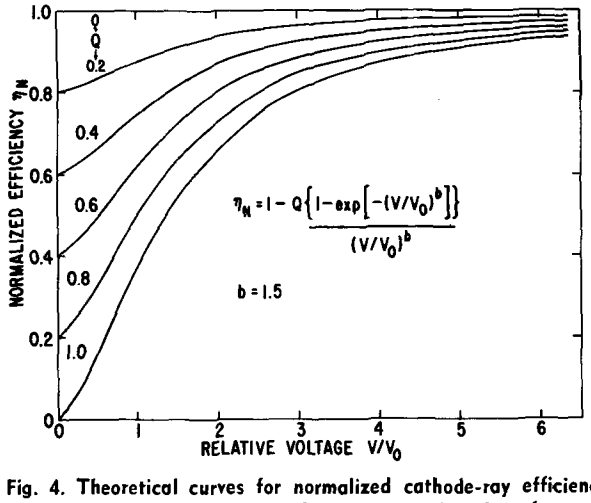

Fig. 4. Theoretical curves for normalized cathode-ray efficiency as a function of voltage for different strengths of surface recombination.

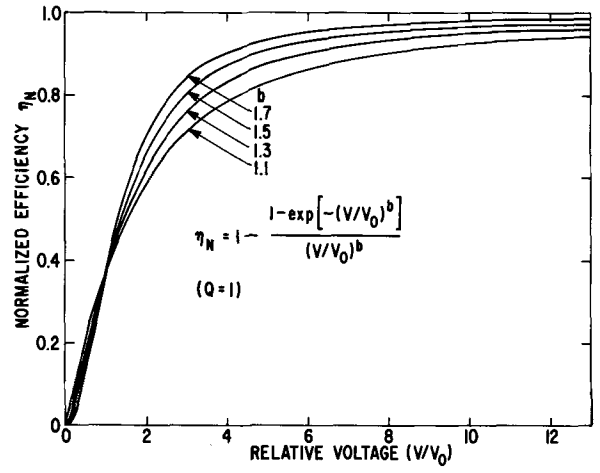

Fig. 5. Theoretical curves for normalized cathode-ray efficiency for different range-voltage relations.

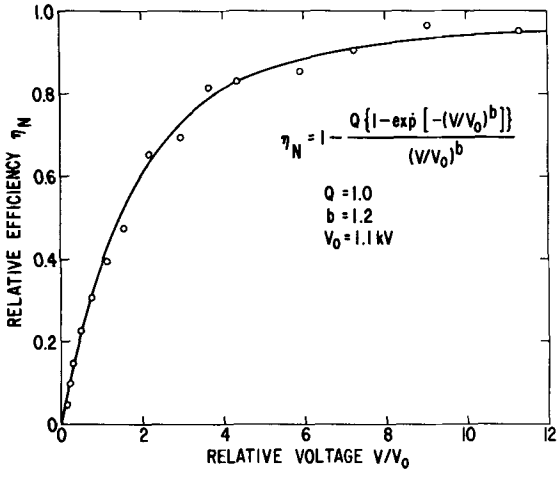

Fig. 6. Normalized efficiency of a Gd_2O_3:Eu phosphor compared with Eq. [6] of the text.

dependent of voltage. As Q increases toward 1, the limiting efficiency at low voltage approaches zero. In all cases, the η_N approaches unity at high voltage.

In Fig. 5 η_N is plotted for $Q = 1$ and different values for b. Large b implies that the range rises rapidly with voltage. Correspondingly, for b large the efficiency rapidlly approaches unity as the voltage increases.

Gergely's assumption that energy transport in the phosphor grain is by diffusion of free carriers may not apply to many of the phosphors of present interest. However, it does seem possible to fit the experimental data rather well by a curve of the form Eq. [6] with judicious choice of the parameters V_0, b, and Q. Data were matched to that equation in the following way: We normalized the efficiency to 1 at high voltage and extrapolated the efficiency to zero voltage to find $Q = 1 - \eta_N(0)$. V_0 can be found by realizing that at V_0, $\eta_N = 1 - Q(1 - e^{-1})$, while the parameter b is found by matching curves such as those of Fig. 5.

The experimental data of Fig. 3, normalized at high voltage, were replotted as normalized efficiency *vs.* normalized voltage in Fig. 6. There is reasonable agreement between the experimental points and the calculated curve for η_N.

The efficiency of the phosphors at 10 kV was measured using the thermocouple detector.[2]

[2] No correction was applied for absorption of the emitted light internal to the phosphor or on reflection by the metal backing plate. It can be shown that the correction factor needed to convert measured to intrinsic efficiencies is approximately $2/(1 + R)$ where R is the reflectivity of the phosphor-backing plate combination [*c.f.* ref. (7)]. For sulfide phosphors, settled on aluminum, we find $R \sim 0.8$, while for most other phosphors, settled on silver, $R > 0.9$.

The absolute efficiency and reflection coefficient under excitation at 2537Å were calculated using Eq. [1] and [2], assuming at value $\rho = 0.91$ for the reflectivity of MgO (1) and using a measured value $\tau = 0.92$ for the visible transmission of the Pyrex filter used to attenuate 2537Å radiation.

Values for the cathode-ray efficiency at 10 kV, η_{cr}, the parameters V_0, b and Q describing the voltage dependence of the efficiency, and the parameters η_{2537} and r_{2537} describing the efficiency and reflection coefficients under 2537Å radiation are given for various phosphors in Tables I-V. Unless otherwise indicated, samples were obtained from J. Rabatin.

Comments and discussion.—Cathode-ray efficiencies of commercial and NBS standard phosphors (Tables IA and II).—Bril (1) has published efficiency values for a number of standard phosphors obtained from the National Bureau of Standards. The booklet, "RCA Phosphors" (3) lists the efficiency of a series of RCA commercial phosphors relative to a Zn_2SiO_4:Mn phosphor. We have used Bril's (1) and Hardy's (8) published efficiency for Zn_2SiO_4:Mn to set the absolute efficiency scale for the RCA phosphors: a relative efficiency of 100 apparently corresponds to an absolute efficiency of 6%.

Figure 7 shows our detector reading for a number of phosphors along with the efficiency as published by Bril or as derived above for RCA phosphors. The efficiency scale for our detector readings can be set by drawing a straight line on the basis of the experimental points. The substantial deviations from the line are attributed partly to random errors, partly to differences in measurement conditions (beam voltage and current, plaque preparation, etc.), and partly to real differences in efficiency between different phosphor lots. Our measurements on the same phosphor lot are repeatable to ±5% or so; that is for two successive measurements η_1 and η_2 it generally is true that

$$0.95\,\eta_1 - 0.5 < \eta_2 < 1.05\,\eta_1 + 0.5$$

where η_1 and η_2 are expressed in per cent.

We have also made an independent determination of the efficiency scale for our detector readings. The thermopile was irradiated with light from a standard lamp, the energy output of which previously had been calibrated by the National Bureau of Standards. The light

*The booklet "RCA Phosphors" (2) lists the total relative radiant energy from phosphors under cathode-ray excitation. η_{PB} is the cathode-ray efficiency calculated assuming that a total relative radiant energy of 100 corresponds to an efficiency of 6% [see A.E. Hardy, ref. (10)].

was mechanically chopped at 26 Hz and the detector output read with the lock-in amplifier. In this way we obtained a value for the detector sensitivity for 25 Hz square wave modulation. The absolute efficiency scale could then be set by estimating the fraction of the total emitted light from the phosphor gathered by the mirror and focused onto the thermopile. The efficiency scale estimated in that way agreed within about 10% with the scale as estimated in the preceding paragraph from measurements on standard phosphors.

Ultraviolet efficiency of NBS phosphors (Table IB).—A comparison between our measurements of u.v. efficiency and those of Bril and Hoekstra (6) on the NBS standard phosphors is given in Table IB. Our measurements tend to be slightly higher. The average could be made to agree more closely if a lower value for the parameter ρ, the reflectivity of our MgO plaque for 2537Å radiation, were assumed.

YVO_4:RE *phosphors (Table III).*—The cathode-ray efficiency of all the YVO_4:RE samples fell in the range 1-7%, with YVO_4:Eu being the most efficient. All of the phosphors showed high surface loss ($Q \cong 1$), and the parameter b in the range-voltage relation ($R \sim V^b$) was measured to be 1.4 ± 0.2. The characteristic voltage V_0 is a measure of the voltage (and hence depth within the phosphor grain) at which surface de-excitation is still important. We find that V_0 varies somewhat with the activator and is largest in the unactivated sample where one might expect energy transport over relatively large distances, since there are no purposely added activators to trap the excitation.

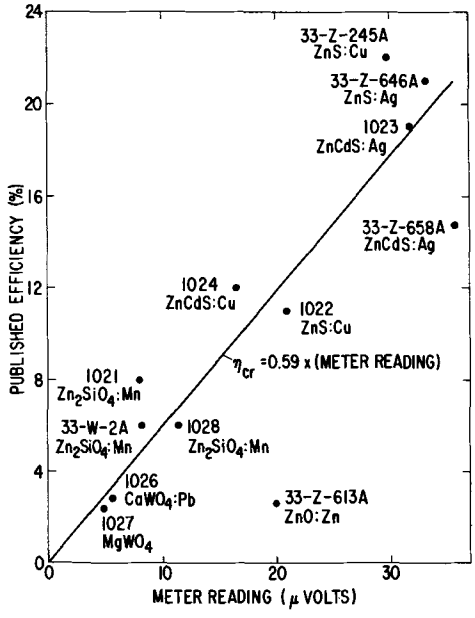

Fig. 7. Calibration of the cathode-ray efficiency scale using standard and commercial phosphors.

It is generally accepted that YVO_4 phosphors are host-sensitized in both cathode-ray and u.v. excitation; the excitation energy is absorbed by the lattice and transported to activators via the VO_4^{-3} groups. Thus, both the cathode-ray efficiency and the u.v. efficiency at 2537Å are expressible as the product of two efficiencies, one describing the excitation of VO_4^{3-} groups by fast electrons (or 2537Å photons), and the other the production of luminescence from VO_4^{3-} excitation. The latter efficiency will depend on the activator and other impurities present in the sample, but should be the same for cathode-ray and 2537Å excitation. The former efficiency differs for cathode-ray and 2537Å excitation, but may not be sensitive to the impurities and defects in the sample unless they produce traps which intercept the excitation energy before the VO_4^{3-} groups are excited. In the absence of such traps we expect the ratio η_{cr}/η_{2537} to be the same for all samples and activators. Indeed, we find $\eta_{cr}/\eta_{2537} = 0.16 \pm 0.03$. On the other hand, Kano and Otomo report on impurities, such as Mo, W, and Ta which apparently produce traps such that the cathode-ray efficiency is reduced while the photoefficiency at 2537Å is largely unaffected (9).

Eu^{3+} *activated oxide, oxysulfide, and oxyhalide phosphors (Table IV).*—Except for the oxyhalides, all of the Eu^{3+} activated phosphors which we investigated are at least as efficient as YVO_4:Eu, the most efficient being Gd_2O_3:Eu and Y_2O_2S:Eu. All show strong surface losses ($Q \simeq 1$) and are reasonably efficient under 2537Å excitation.

Tb^{3+} *activated oxyhalide and oxysulfide phosphors (Table V).*—Except for YOCl, the phosphors in Table V are at least moderately efficient under both cathode ray and 2537Å radiation.

The Efficiency of Cathode-Ray Phosphors

II. Correlation with Other Properties

J. D. Kingsley and G. W. Ludwig*

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

In cathode-ray excitation of a phosphor the energy of the fast electrons appears, in an intermediate stage, as excitation of the valence shell electrons. We have used photons of energy up to 25 eV to simulate cathode-ray excitation. Attempts to account for cathode-ray efficiencies on the basis of the photoexcitation efficiencies give agreement in some cases and substantial lack of agreement in others. A correlation between high plasma resonance energy and low cathode-ray efficiency is pointed out.

In the preceding paper (1) we have presented measurements of the cathode-ray efficiency of a variety of phosphor materials. In this paper we discuss the processes involved in cathode-ray excitation (2). We then seek to correlate the cathode-ray efficiency with results of other experiments, notably with the photoefficiency observed under u.v. excitation.

When a fast electron enters a phosphor it loses energy predominantly by ionizing electrons from the inner shells of atoms. The penetration of fast electrons and the processes whereby the excitation energy is transferred to valence-shell electrons and from them to the activator atoms are discussed. Photons of energy up to ~25 eV have been used to simulate the excitation of phosphors by fast electrons. Comparison is made between observed cathode-ray efficiencies and expectations based on the photoexcitation measurements. In addition, a correlation between low cathode-ray efficiency and high plasma resonance energy is pointed out. While our crude models meet with some measure of success in accounting for observed cathode-ray efficiencies, there is substantial lack of agreement in other cases. Thus, the understanding of cathode-ray efficiency still is in a primitive state and much remains to be done.

* Electrochemical Society Active Member.

The penetration of fast electrons into phosphor materials is summarized, and the host excitation thereby produced is discussed. We present and discuss methods for estimating cathode-ray efficiency on the basis of photoexcitation efficiency in the u.v. and make some concluding comments.

Penetration of Fast Electrons (3)

As a fast electron passes through a medium it interacts with nearby atoms via Coulomb forces. An electron with a kinetic energy in the 20 kV range is not sufficiently energetic to displace nuclei from their lattice sites. Rather, it is scattered elastically by the nuclear potential as screened by the electrons of the medium. However, in passing near an atom a fast electron can impart a sufficient electromagnetic pulse to a bound electron to cause it to ionize. The energy loss of a fast electron is predominantly by ionization of electrons from inner shells of atoms, and is given approximately by Bethe's formula (4)

$$-\frac{dE}{dX} = \frac{2\pi Ne^4}{E} \ln\left[\frac{E}{E_i}\sqrt{2.717/2}\right] \qquad [1]$$

Here E is the electron energy, X is the path length, N

is the density of bound electrons, e is the electronic charge, 2.717 is the base of natural logarithms, and E_i is an average ionization energy for the bound electrons. Since the logarithmic term is slowly varying, dE/dX is approximately inversely proportional to the electron energy, and the maximum excitation density occurs near the end of the electron's path. Equation [1] is only valid as long as the energy lost in an ionization event is small compared with the electron's energy ($E_i << E_j$). With the reservation that the initial energy must be large compared with E_i, Eq. [1] can be integrated to give the relation between electron energy and integrated path length.

In estimating the spatial distribution of the energy dissipated by incident fast electrons, account must be taken of the deflections suffered by the electrons in elastic scattering events. The problem is a difficult one because the electrons suffer multiple collisions and undergo both small and large angle deflections. Thus, the initial trajectory of an electron is completely lost before it dissipates its energy.

Spencer (5) has made numerical calculations of the energy dissipation in a series of different elements for the experimentally important case of a plane perpendicular source of fast electrons of a given energy. His numerical results include values for the electron range and for the excitation intensity as a function of depth. The excitation intensity shows a peak which moves deeper into the material as the initial electron energy is increased.

Ehrenberg and King (6) have made an interesting experimental study of the penetration of electrons into a phosphor crystal. They focused a narrow electron beam onto a flat crystal face. The luminous glow through an adjacent face at right angles to the first was enlarged with a microscope and photographed using a series of different exposures. Contours of equal brightness could be traced out, giving a direct measure of the distribution of excitation within the crystal. At high incident electron energy the excited volume resembled a sphere joined to the surface by a narrow neck. As the electron energy was decreased, the neck shortened until at low energy the excited volume was roughly hemispherical. From measurements at different energy Ehrenberg and King were able to deduce to range-energy relation. For a range of different phosphors they found a practical range $P \propto E^{1.7\pm0.1}$.

The penetration of fast electrons in nonluminous materials has also received much experimental attention (7).

There is a close correspondence between the experimental and the theoretical determinations of the spatial distribution of energy loss. For example, the determinations of the voltage-range relation are consistent. Thus, a reasonable understanding of the basic features of the penetration of electrons into matter has been achieved.

Lattice Excitation Produced by the Fast Electrons

From Eq. [1] we see that to first approximation a sufficiently fast electron loses energy to each bound electron of an atom at the same rate. Since there are more inner shell electrons than valence shell electrons, the former account for the major part of the energy loss. Thus, the major primary excitations produced by a fast electron are fast secondaries and excited ions.

In the second stage of the excitation process, excited ions lose energy by Auger transitions in which one outer shell electron is ejected from the ion, while a second such electron falls into the hole in the inner shell. Energetic secondary electrons can also cause ionization. Thus, a shower of energetic secondaries and ionized atoms is formed. As more and more ionization of the medium is produced by repetition of the above processes, the average energy of each excitation of course decreases. A fraction of the incident primary electrons and their secondaries leave the solid, resulting in a back-scattering loss which typically

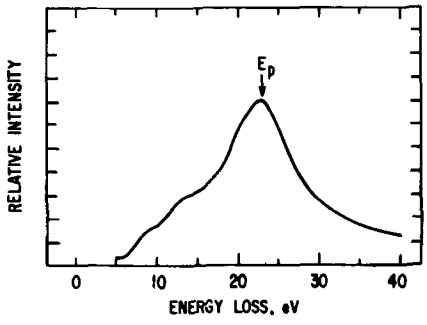

Fig. 1. Energy loss spectrum for fast electrons incident on an Al_2O_3 film [after Swanson (12)].

amounts to about 10% of the energy of the primaries. In addition, a very small fraction (~1%) of the excitation is lost by x-ray emission.

As the average energy of the secondary electrons falls below the binding energy of deep inner shell electrons, energy loss to valance shell electrons becomes relatively more important. Loss to these electrons has been described in terms of the longitudinal dielectric function, $\epsilon^L(k,\omega)$, which is dependent on both the energy lost, $\hbar\omega$, and the momentum transferred, $\hbar k$. The complex longitudinal dielectric function

$$\epsilon^L(k,\omega) = \epsilon_1{}^L(k,\omega) + i\epsilon_2{}^L(k,\omega)$$

and the energy loss to the valence-shell electrons are related by

$$-Im\frac{1}{\epsilon^L(k,\omega)} = \frac{\epsilon_2{}^L}{(\epsilon_1{}^L)^2 + (\epsilon_2{}^L)^2} \qquad [2]$$

Energy loss of relatively energetic electrons (~20 keV) to valence-shell electrons can be determined directly by the characteristic energy loss measurement (8, 9).[1] A thin foil of the solid under investigation is prepared. The foil is irradiated with monoenergetic electrons, and the electrons passing through it are analyzed in energy. In addition to the electrons which pass through without loss, one observes electrons which have lost energies characteristic of the solid. For some metals, the loss occurs mainly at one reasonably well-defined energy and multiples thereof; for Al such a loss occurs at about 15 eV. No optical absorption band occurs at this energy, and it thus does not represent an interband transition. The loss peak rather occurs at the resonant energy for longitudinally polarized, collective oscillations in the density of the Al valence electrons. These oscillations are the so-called plasma oscillations.

Plasma resonance phenomena[1] have been discussed by Bohm and Pines (10) and Nozieres and Pines (11). They arise from the Coulomb interaction between electrons. One can show that plasma resonance occurs near an energy given by

$$E_p \equiv \hbar\left(\frac{4\pi N_v e^2}{m}\right)^{1/2} \qquad [3]$$

Here N_v is the valence electron density and m is the mass of a free electron.

Swanson's measurement (12) of the energy loss spectrum of an oxygen-dominated lattice, Al_2O_3, is shown in Fig. 1. The loss peak occurs near the plasma resonance energy as calculated from Eq. [2]. However, the great width of the peak indicates that any collective oscillation is very short lived, soon decaying to other forms of host excitation. The bumps on the broad loss peak presumably represent interband transitions and/or exciton transitions.

Characteristic energy loss measurements have been made for CdS (13), but not for most other phosphor lattices.

[1] References (8) and (9) are review articles discussing plasma resonance phenomena and the characteristic energy losses of electrons in solids.

The energy loss of fast electrons to valence-shell electrons can also be estimated from the optical properties of the material (14, 15). The optical properties are described by the transverse complex dielectric function $\epsilon^T(k,\omega)$. For $k \simeq 0$ excitations $\epsilon^T \simeq \epsilon^L$, and ϵ^T can be used in place of ϵ^L in the loss function [2].

Figure 2 shows Swanson's comparison (12) between $\epsilon_2^L[(\epsilon_1^L)^2 + (\epsilon_2^L)^2]^{-1}$ as deduced from energy loss of fast electrons in Al_2O_3 and $\epsilon_2^T[(\epsilon_1^T)^2 + (\epsilon_2^T)^2]^{-1}$ determined from the optical constants of the material.

We have measured the optical constants of single crystals of the phosphor host YVO_4 as a function of photon energy in the region 3-25 eV (16). The real and imaginary components of the transverse dielectric function were determined by a Kramer's-Kronig analysis of the reflectivity data. They are shown in Fig. 3 along with the energy loss function as estimated from ϵ^T.

The loss function has a broad maximum near the plasma resonance energy as given by Eq. [3]. The structure on the curve is attributed to interband and/or exciton transitions.

Of major concern in cathodoluminescence are the excitations produced by relatively low energy secondary electrons. Since the momentum loss varies as $E^{-1/2}$, there will be comparatively large momentum transfer associated with energy loss of slow electrons.

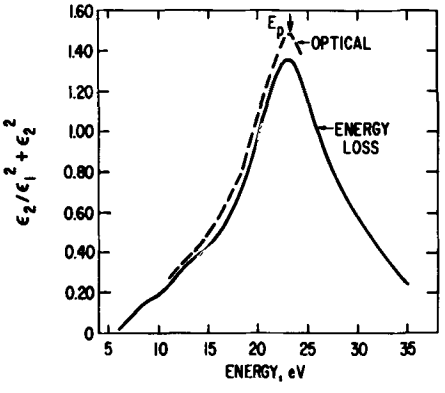

Fig. 2. Energy loss function $\epsilon_2/(\epsilon_1^2 + \epsilon_2^2)$ of Al_2O_3 as determined from optical and from energy loss measurements [after Swanson (12)].

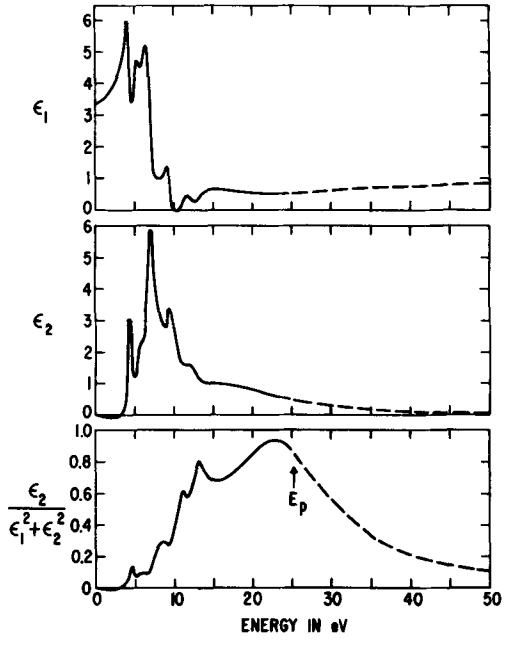

Fig. 3. Real and imaginary parts of the dielectric constant, ϵ_1 and ϵ_2, respectively, and the energy loss function $\epsilon_2/(\epsilon_1^2 + \epsilon_2^2)$, as deduced from a Kramer's-Kronig analysis of reflectivity data for a YVO_4 single crystal.

Unfortunately, there is no direct information on $\epsilon^L(k,\omega)$ for k appreciably different from zero. As k increases, plasmon creation tends to be suppressed in favor of interband transitions. No estimates are available on how severely the loss function is affected. It is likely, however, that in most phosphors the energy of fast electrons ultimately goes to exciting valence-shell electrons in a fundamental loss band similar to that shown in Fig. 3.

Estimation of Cathode-Ray Efficiencies

The excitation of luminescence by energetic electrons can be described by the following sequence of steps:

1. The primary electrons lose energy predominantly by exciting electrons from inner shells of ions, thereby leaving a trail of fast secondaries and excited ions. They also excite valence-shell electrons.

2. The excited ions decay, principally by Auger transitions, producing additional secondary electrons and excited ions. A small fraction (about 1%) of the excitation is lost through x-ray emission.

3. The processes of 1 and 2 continue, each successive step reducing the average energy of the secondaries and excited ions, and increasing the excitation of the valence shell electrons.

4. Except for the roughly 10% lost by back-scattering and x-ray emission, all of the energy of the primary electrons ultimately appears as excitations of the valence-shell electrons in the "fundamental energy loss region" from a few electron volts to several 10's of eV. The excitations initially formed may consist of a mixture of free electrons and holes, plasmons, and excitons. We will neglect the excitons, since probably few are formed initially. Moreover, the plasmons decay, principally into interband excitations, almost immediately. It is as though energetic-hole pairs were excited directly by the energetic primary and secondary electrons.

5. The total excitation energy of a typical electron-hole pair is 20-30 eV. This energy consists of the band gap energy plus the energy of the energetic electron relative to the conduction band minimum and that of the energetic hole relative to the valence band maximum. An energetic electron (or hole) can excite an additional electron-hole pair if its energy exceeds a threshold energy E_t. It can also excite phonons. Theoretical calculations (17) by Kane and Mahan show that a very energetic charge carrier loses much more energy to pair creation than it does to phonon excitation. However, as its energy decreases, the cross-section for pair creation decreases, while the phonon cross-section remains essentially constant. Obviously, a carrier with a kinetic energy less than E_t can excite phonons but not pairs. It may also excite defects or impurities, including activators. (However, we assume that the excitation of activators at this stage is negligible.) Carriers having insufficient energy to excite additional electron-hole pairs eventually thermalize by phonon emission.

6. Activators are excited by thermalized pairs. One possible mechanism is through successive capture of an electron and a hole. This mechanism is very likely operative in II-VI compounds and other semiconductors. A second mechanism involves the initial formation of an exciton, which then migrates to an activator and excites it. This mechanism is thought to be important in YVO_4, $CaWO_4$, and similar materials. The activator relaxes to the emitting state and fluoresces, usually with the emission of part of the energy as phonons.

The loss of potential excitation energy occurs principally in steps 5 and 6. The energy available from one thermalized electron hole-pair is E_g, the band gap energy. In all cases for which information is available, one pair produces at most one emitted photon, with energy $h\nu_e$, so that the energy efficiency of step 6 is

no greater than $h\nu_e/E_g$. Let us make the assumption that the number of emitted photons per thermalized pair produced under cathode-ray excitation is equal to the quantum efficiency η_q, which is observed for photoexcitation just above the absorption threshold. Then the radiant efficiency of step 6 will be that which is observed for excitation with u.v. radiation; $\eta_{u.v.} = \eta_q \frac{h\nu_e}{h\nu}$, with $h\nu \simeq E_g$. If the mean energy required to make a pair is E_x, the efficiency of step 5 is E_g/E_x, and the over-all cathode-ray energy efficiency is given by (18)

$$\eta_{c\text{-}r} = (1 - \eta_{back}) \frac{E_g}{E_x} \frac{h\nu_e}{E_g} = (1 - \eta_{back}) \frac{E_g}{E_x} \eta_{u.v.}(E_g) \quad [4]$$

where η_{back} is the fraction of the energy lost by backscattering.

Equation [4] is useful only if we have an independent means for determining E_x. In principle, E_x could be calculated if the dielectric function $\epsilon^L(\omega,k)$ were known out to large values of k, corresponding to appreciable momentum transfer. However, as mentioned previously, at best $\epsilon^L(k,\omega)$ is known for small k, where it can be deduced from optical measurements. Mahan (17) has calculated E_x for YVO_4 by neglecting any dependence of the loss function on momentum and assuming that the energies of the hole and electron produced in each pair creation event are equal. Under these assumptions, he estimates E_x to be about two times the threshold energy for optical absorption.

A simple model which allows us to estimate E_x describes the host as having parabolic valence and conduction bands. It assumes that the probability of an energetic electron (or hole) creating a pair is much larger than the probability of its losing energy to phonons if and only if its energy exceeds some threshold energy, E_{te} (or E_{th}). Then, as is shown in the appendix, it is generally true that the maximum energy an electron-hole pair can have without being able to excite additional pairs is $E_g + E_{te} + E_{th} = 4E_g$. This value, $4E_g$, is an upper limit for E_x which would be realized only if both charge carriers were produced with energies just under their respective thresholds in each excitation event. The minimum value E_x can have is E_g. This occurs if the energy of the high energy electrons is channelled entirely into creation of electron-hole pairs in which both carriers have zero kinetic energy. We thus find $E_g < E_x < 4E_g$.

Various estimates of E_x have appeared in the literature (19, 20).[2] Such data as are available are consistent with E_x values between $2E_g$ and $4E_g$.[3]

Information on the efficiency of a phosphor under photoexcitation in the photon energy range up to ~40 eV is of interest relative to an understanding of its cathode-ray efficiency for several reasons:

(*a*) Measurement of the radiant efficiency at the band gap energy, $\eta_{u.v.}(E_g)$, may be combined with estimates of E_x/E_g and $(1 - \eta_{back})$ to yield a prediction of the cathode-ray efficiency from Eq. [4].

(*b*) The region up to ~40 eV is the energy range in which the excitation energy of fast electrons eventually shows up as excitations of the valence shell electrons. If excitations of a given energy are sufficiently similar, whether produced optically or by fast electrons, then one expects the cathode-ray efficiency to be a weighted average of the photoexcitation efficiency over this energy range. The weighting function to be used is the relative amount of excitation produced by fast electrons at each energy; the energy loss function as determined optically might be a suitable approximation.

We have studied the photoexcitation efficiency of a number of phosphors in the range of photon energies $3 < h\nu < 25$ eV by exciting them with u.v. from a vacuum monochromator. (Experimental limitations have thus far prevented us from extending the measurements to higher energy.) The luminescent output was compared with that from a sodium salicylate plaque assumed to have a quantum efficiency which is independent of photon energy over the range of interest. Measurement of the absolute radiant efficiency at 2537Å and a value of the average emission energy $h\nu_e$ could then be used to compute the absolute quantum efficiency and absolute radiant efficiency as a function of photon energy. Several representative quantum efficiency curves are shown in Fig. 4.

The energy dependence of the quantum efficiency is most readily interpreted for Zn_2SiO_4:Mn samples. Between 4 and 5.5 eV the photoexcitation appears to be associated with absorption by the Mn activator, since the strength depends on the Mn concentration. Host absorption apparently sets in at about 5.5 eV. From 6 to 14 eV the quantum efficiency remains roughly constant between 70 and 90%. We interpret this to mean that each absorbed photon yields either one or no emitted photons. At 14 eV the quantum efficiency begins to rise, indicating that some of the absorbed photons yield more than one emitted photon. A 14 eV photon produces an electron and a hole at least one of which has sufficient energy to excite a second electron-hole pair. Thus, for one or both carriers $5.5 < E_t < 14 - 5.5$ or $5.5 < E_t < 8.5$.

The quantum efficiency curves for YVO_4:Eu, Gd_2O_3:Eu, and $CaWO_4$:Pb shown in Fig. 4 are not as readily interpreted. For energies slightly greater than the absorption threshold, the efficiency reaches values of 80-100%. At intermediate energies (~8 eV) the quantum efficiency falls. We believe that this decrease in efficiency occurs partly because of surface de-excitation and partly because the intrinsic or bulk efficiency of the excitation produced in this energy range is less. The absorption coefficient $\alpha(h\nu)$ for far u.v. photons is high for the phosphors in question. For example, for YVO_4 $\alpha \sim 10^6$ cm^{-1} for $h\nu > 7$ eV, and the bulk of the u.v. radiation is absorbed within 100Å of the surface. The depth over which surface deactivation

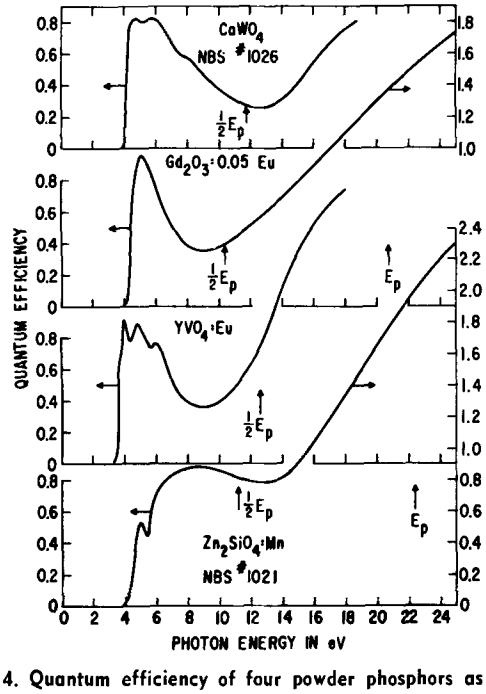

Fig. 4. Quantum efficiency of four powder phosphors as a function of the energy of the incident u.v. photons.

[2] Shockley (19) and Klein (20) have given estimates of E_x. However, their estimates are based on a model wherein the incident fast electrons (of perhaps 20 keV energy) continually lose energy by phonon emission as well as by electron-hole production. According to Mahan (17), such a model is unrealistic.

[3] Data on pair production summarized by Klein (20) is consistent with values $2.7 \leq E_x/E_g \leq 4.0$ for the semiconductors Ge, Si, GaAs, SiC, PbO, and CdS.

is important, for electron excitation, is given approximately by the electron range $R(V_0)$, where V_0 is the characteristic voltage as determined from the voltage dependence of the cathode-ray efficiency. As estimated from the voltage-range relation,[4] 40Å < $R(V_0)$ < 1000Å for most phosphors, and $R(V_0) \sim$ 130Å for YVO_4:Eu. Consequently, a substantial part of the dip in the quantum efficiency curve may be due to surface de-excitation, assuming that u.v. produces the same kind of excitation as fast electrons.

The decrease in quantum efficiency near 8 eV may also be due to a change in the excitation mechanism. Near the excitation edge it is likely that excitons are formed directly by the absorption of the u.v. photons. As the photon energy is increased, one expects to encounter a threshold for the formation of free electrons and holes. The quantum efficiency for fluorescent emission may be lower for free carriers, because they are susceptible to nonradiative trapping processes which do not effect neutral excitons. The increase in efficiency at 10-12 eV is believed due to internal multiplication.

Parameters describing the photoexcitation and cathode-ray excitation of several phosphors are summarized in Table I.[5]

Let us compare the measured cathode-ray efficiency of several phosphors of Table I with an estimate based on Eq. [4]. Taking $1 - \eta_{back} = 0.9$ and $1 < E_x/E_g < 4$, we estimate that $0.22 < \eta_{c\text{-}r}/\eta_{u.v.}(E_g) < 0.9$. For a typical value $E_x/E_g = 3$, $\eta_{c\text{-}r} = 0.3\ \eta_{u.v.}(E_g)$. Unfortunately, E_g is not known for most phosphors, and perhaps the best we can do is to assume that $\eta_{u.v.}(E_g) \simeq \eta_{u.v.}^{max}$, where $\eta_{u.v.}^{max}$ is the maximum radiant efficiency in the near ultraviolet. Figure 5 shows experimental values of $\eta_{c\text{-}r}$ plotted *vs.* 0.3 $\eta_{u.v.}$. There is rough agreement for Gd_2O_3:Eu and $Na_2OGd_2O_3$:Eu, while the remaining materials have $\eta_{c\text{-}r} << 0.3\ \eta_{u.v.}^{max}$. One source of the discrepancy may be the assumption that $\eta_{u.v.}(E_g) = \eta_{u.v.}^{max}$; the maximum in $\eta_{u.v.}$ may correspond to the excitation of excitons rather than free carriers. It is also possible that our assumption of a sharp threshold E_t for pair creation is at fault. If the probability of pair creation increases slowly above threshold, the effect would be to raise E_x and decrease the expected $\eta_{c\text{-}r}$.

Let us now make the assumption that excitations in the fundamental loss region produced optically yield the same luminescent efficiency as the excitations of the same energy produced by fast electrons. Since we do not know the spectrum of excitations produced by fast electrons in the phosphors in question, we simply compare $\eta_{c\text{-}r}$ with 0.9 $\eta_{u.v.}$, where $\eta_{u.v.}$ denotes the range of photoexcitation efficiencies observed between 9 and 25 eV, and the factor 0.9 takes into account the back-scattering loss in fast electron excitation. (No correction for surface de-excitation has been applied.) The comparison is made in Fig. 6. There is rough agreement for several phosphors including Gd_2O_3:Eu and Y_2O_3:Eu. For $MgWO_4$, $CaWO_4$:Pb, and Zn_2SiO_4:Mn $\eta_{u.v.}$ is high compared with $\eta_{c\text{-}r}$, and application of a surface correction would only worsen the agreement.

[4] The voltage-range relation was calculated by assuming that the range $R = 0.4I$, where I is the integrated path length. In turn, I was calculated using the formula given on p. 753 of ref. (6).

[5] See Ref. (1) for additional information concerning these parameters and their measurement.

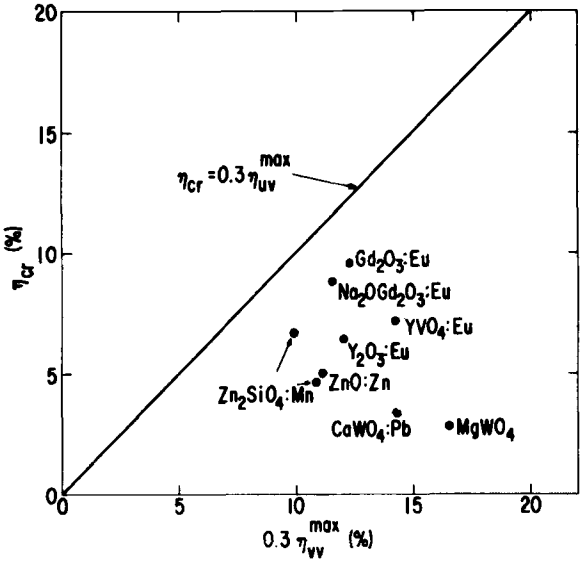

Fig. 5. Comparison between maximum photoexcitation efficiency in the near u.v. and cathode-ray efficiency.

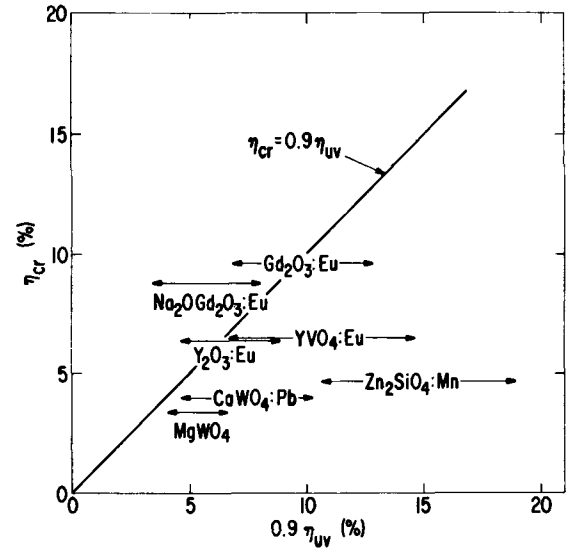

Fig. 6. Comparison between the photoexcitation efficiency in the range $\frac{1}{2}E_p < h\upsilon_{incident} < E_p$ and the cathode-ray efficiency.

The above attempt to relate $\eta_{c\text{-}r}$ to the vacuum ultraviolet photoexcitation efficiency has thus met with very limited success. But the excitations made by photons and electrons may have different momenta and a different division of energy among electrons and holes. Thus, there may be a fundamental difficulty in relating the two kinds of measurement. The cathode-ray efficiency seems to be more variable and sensitive to phosphor preparation than the near u.v. photoefficiency. For example, by incorporation of certain impurities, Kano and Otomo (21) were able to substantially reduce the cathode-ray efficiency of YVO_4:Eu while leaving the near u.v. efficiency largely un-

Table I. Parameters describing the luminescence of selected phosphors

affected. Pairs having appreciable energy and momentum may undergo trapping and nonradiative decay processes which pairs having low energy and momentum avoid (perhaps because the latter pairs quickly form excitons). Further progress in understanding cathode-ray efficiency is made difficult by a lack of knowledge of how important undesired trapping processes may be, and thus how high the efficiency might be in their absence. Additional knowledge about the excitations produced by fast electrons and about exciton formation, surface de-excitation, band gap energies, etc., would be useful.

We have noticed a correlation between high plasma resonance energy of a phosphor host and low cathode-ray efficiency (see Fig. 7). We know of no phosphor having $E_p > 21$ eV and $\eta_{c\text{-}r} > 8\%$. The very efficient phosphor hosts (Zn,Cd)S:Ag and Gd_2O_3:Eu have $E_p \approx 15.4$ and 20.8 eV, respectively. One simple model for phosphor excitation is that the energy of the fast electrons is used exclusively to produce plasmons and that each plasmon decays to form one electron-hole pair, with no further multiplication ($E_x = E_p$). Assuming $\eta_q = 1$, we find $\eta_{c\text{-}r} = (1 - \eta_{back})h\nu_e/E_p$ from Eq. [4]. This relation is obeyed to within ±30% for about one third of the samples for which we have made the comparison. However, other phosphors (such as ZnS:Ag) show a higher $\eta_{c\text{-}r}$ than the above model predicts, indicating that $E_x < E_p$.

Concluding Comments

We have presented several models of the excitation mechanisms involved in cathodoluminescence. Each of these models is capable of "explaining" the efficiencies of only a fraction of the materials we have investigated. We thus do not have, as yet, a generally applicable picture of cathodoluminescence. The reasons for the failure of our models in many instances are understandable, but the means for improving them are not obvious.

A thorough understanding of cathodoluminescence appears to require a more detailed knowledge of the band structure, excitation processes, and decay processes in the energy range from the band gap to the plasmon energy. This knowledge is not easily acquired either experimentally or theoretically. Determination of the optical constants of more phosphor materials and a more detailed understanding of the vacuum u.v. excitation spectra and surface de-excitation may be useful.

There are some comparatively certain conclusions which one can draw, however. Specifically, the more efficient phosphors are expected to be, and in practice turn out to be, those with small band gaps and low

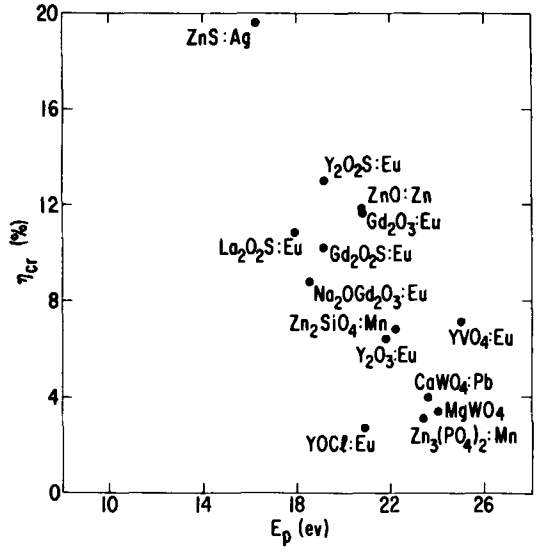

Fig. 7. Cathode-ray efficiency and calculated plasma resonance energy $E_p \equiv \eta(4\pi Ne^2/m)^{1/2}$ of a series of phosphors.

Table II. Some compounds having low plasma resonance energy (see Eq. [3])

$GdCl_3$	18.0

plasma resonance energies. Thus, an empirical search for new phosphor hosts may be more fruitful if the materials investigated are those which tend to have small E_g and $\eta\omega_p$. Obviously, the band gap cannot be arbitrarily small if a material is to emit visible emission efficiently at room temperature. As a guide, we have listed a number of materials with low E_p in Table II.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

APPENDIX

Threshold Energies for Pair Creation by an Energetic Carrier

We assume that the host has parabolic conduction and valence bands, and use the subscripts e and h to denote electron and hole, respectively. The smallest possible energy for pair creation corresponds to the case where the momenta of all the particles are parallel or antiparallel. We assume that momentum is conserved without the aid of phonons or impurities and equate the momentum loss of the energetic carrier to the total momentum of the pair

$$\Delta p = p_e + p_h \qquad [A\text{-}1]$$

Furthermore, we equate the energy loss of the energetic carrier to the total energy of the created pair

$$[p_0^2 - (p_0 - \Delta p)^2]/2m = E_g + p_e^2/2m_e + p_h^2/2m_h \qquad [A\text{-}2]$$

Solving for p_0 and eliminating p_h we find

$$p_0 = \frac{m}{\Delta p}\left[E_g + \frac{\Delta p^2}{2m} + \frac{p_e^2}{2m_e} + \frac{(\Delta p - p_e)^2}{2m_h}\right] \qquad [A\text{-}3]$$

The minimum value of p_0 can be found by differentiating Eq. [A-3] with respect to Δp, and with respect to p_e, and equating each to zero and solving the pair of simultaneous equations. The minimum occurs for $\Delta p = 2m(m_e + m_h)E_g/(m + m_e + m_h)$ and $p_e = 2m(m_e)^2E_g/[(m + m_e + m_h)(m_e + m_h)]$. The threshold energy for pair creation is then given by

$$E_t = [1 + m/(m_e + m_h)]E_g \qquad [A\text{-}4]$$

For $m = m_e = m_h$, $E_t = 3/2\ E_g$. For $m_e << m_h$, $E_{te} = E_g$, $E_{th} = 2E_g$. We find that $E_{te} + E_{th} + E_g = 4E_g$, independent of the effective masses.

Anomalous Thermal Behavior of Boron-Doped Low-Temperature Ge Epitaxial Layers

M. Berkenblit,* T. B. Light, and A. Reisman*

IBM Watson Research Center, Yorktown Heights, New York

ABSTRACT

Recently, conditions have been defined for the growth of mirror-smooth layers of Ge on either Ge or semi-insulating GaAs by the GeI_2 disproportionation reaction. In attempting to dope such layers with p-type impurities under the defined surface-rate-limited growth conditions, it was observed that order-of-magnitude decreases in resistivity occurred on heating the grown layers to temperatures higher than the original growth temperature. This indicated that impurities were initially incorporated in an electrically inactive state. Results are presented which show this behavior to be increasingly pronounced for fast growth rates and low substrate temperatures. and growth conditions to minimize the effect are defined.

Recently, conditions were defined for the growth of mirror-smooth layers of Ge on Ge or semi-insulating GaAs (110) substrates by the GeI_2 disproportionation reaction (1). In attempting to fabricate devices in layers that were boron doped and grown under defined surface-rate-limited growth conditions, a marked thermal instability was detected. It was observed that material grown at 350° exhibited an order of magnitude decrease in resistivity as a consequence of a process step which required temperatures higher than the original growth temperatures (*e.g.*, 700°C As diffusion for diode fabrication). As a consequence, it was difficult to achieve control of resistivities of 0.1 ohm-cm or greater. Initial attempts at preparing As-diffused diodes in B-doped Ge layers grown at 350°C under the surface limiting conditions described in reference (1) resulted in devices with soft reverse characteristics.

Investigation of the anomalous behavior demonstrated that the thermal instability is a function of the temperature at which the layer is grown, the growth rate and to some degree the concentration of the added impurity. The results presented in this paper are mainly concerned with B-doped Ge. Ga-doped samples, prepared using a solid source of $GaCl_3$, were shown to exhibit a similar resistivity change following heat treatment. Within the limits of the experiment, As-doped layers did not behave in this manner. In the following, conditions are defined for layer growth and annealing which permit stabilization of the electrical behavior and the maintenance of the desired surface smoothness.

Experimental Procedure

Germanium epitaxy.—The Ge layers were grown in a horizontal reactor under the required high-velocity and high-GeI_2-concentration conditions described previously by the authors (1). Substrate temperature was varied from 350° to 410°C, and the velocity and concentration of the carrier and reactant gases were adjusted upwards with increasing temperature in order to maintain surface-reaction-rate limiting conditions. The Ge source bed was held at 600°-620°C. A 15% H_2-85% He mixture was used as a carrier gas at an input flow rate of 900-1500 cc/min [room-temperature average linear-gas-stream velocity (l.g.s.v.) at the substrate equal to 190-320 cm/min]. The I_2 source temperature for the HI generator was varied from 65° to 85°C (±0.2°C at a given temperature), which is equivalent to a range of HI pressures of 11.0-39.2 Torr.

Purification of the carrier gas, preparation of the substrates, and the use of a vacuum chuck substrate holder to protect the surface during Ge deposition have been described in detail previously, as have a number of general considerations regarding the low-temperature disproportionation reaction (1-4).

Doping.—The prime source for p-type doping was BI_3. The use of BBr_3 and $GaCl_3$, as well as elemental Ga with which HI was reacted, were tested and found to be unsuitable as a means of introducing a controlled impurity concentration into the reactive gas stream. During the course of the investigation, a method was developed for the *in situ* synthesis of BI_3 which made available a reproducible source of boron and eliminated the problems of handling a highly reactive material (5). Arsenic as an n-type impurity was obtained from the *in situ* decomposition of AsH_3 carried into the reactor as a dilute mixture in 15% H_2-85% He.

Annealing.—Germanium layers, grown by the iodide process as well as by other deposition techniques, and bulk Ge wafers were annealed at 500°C for 16 hr in a

* Electrochemical Society Active Member.

Table I. Resistivity of bulk Ge and epitaxial Ge layers on Ge or GaAs substrates annealed at 500°C for 16 hr

Deposition process	Deposition temperature, °C	"As grown" resistivity of Ge layer	Resistivity after 16 hr at 500°C
GeI_2 (BI_3)	350	0.1 to >12 ohm-cm, p-type and n-type (low BI_3)	p-type ~0.02 ohm-cm
Bulk Ge wafers (n-or p-type)	—	—	No change
$GeCl_4$ (B_2H_6)	800	~0.1 ohm-cm, p-type	No change
GeH_4 (B_2H_6)	650	~0.1 ohm-cm, p-type	No change
GeI_2 (no BI_3)	350	n-type	Slight change

quartz tube furnace in a 15% H_2-85% He ambient. A comparison was made between the iodide process and the other deposition methods, and with bulk material, to obviate the possibility of an impurity present in the annealing furnace causing the resistivity shift, and to determine whether the method of deposition influenced the results.

Measurement of electrical characteristics.—A 3-point-probe spreading-resistance technique was used to determine the resistivities of the "as grown" layers and to follow the changes resulting from the various anneal cycles. Van der Pauw samples were prepared from a number of samples for Hall-mobility and active-impurity-concentration determinations. Planar diodes were fabricated by As diffusion at 700°C for 30-60 min through openings in vapor-deposited SiO_2 layers. The diode area was about 1.8×10^{-5} cm^2. The reverse characteristics of the diodes were measured from 0.2V to breakdown.

Results and Discussion

Table I shows the variation of resistivity with annealing for samples of Ge from various sources. It may be observed that B-doped Ge layers (approximately 0.1 ohm-cm), grown at 350°C at a rate of 5 μm/hr, exhibit a very pronounced decrease in resistivity to <0.02 ohm-cm as a result of a heat treatment at 500°C. Such behavior was found to be characteristic of the p-type Ge grown by the iodide process and was not observed in Ge deposited at higher temperatures by other methods (pyrolysis of GeH_4 at 650°C and the reduction of $GeCl_4$ at 800°C). Ge wafers cut from bulk grown material, both p- and n-type, showed no change following heat treatment. In layers grown by the iodide process without BI_3 or any other intentionally added impurity present in the vapor stream, only a slight shift in resistivity could be detected after heat treatment.[1] Similar slight changes were observed some years earlier by Marinace *et al.* (6, 7), and were attributed by them to incorporated iodides. From the above results it is clear that iodide contamination in the grown layers does not contribute significantly to the anomalous resistivity effect. Finally, the instability of the deposited-Ge layer was similar whether the substrate used was Ge or GaAs.

The major conclusion from the information in Table I is that boron appears to be incorporated to a large degree in an electrically inactive state at 350°C under the nonequilibrium growth conditions employed, and is subsequently activated by an annealing process. Significantly, in previous work, B-doped Ge layers, grown at 350°C under flux conditions approaching equilibrium, did not exhibit a resistivity shift. All of the above indicate that the resistivity changes observed are a consequence of the growth parameters, primarily, and the attendant mechanism of impurity incorporation during the specific growth procedure used.

The extent to which growth rate affects the observed stability of B-doped Ge was studied in a series of depositions at 350°C. It was found that the resistivity change following annealing at 500°C was large (approximately an order of magnitude) for layers grown at rates of 2-10 μm/hr. For layers grown at 1.2 μm/hr the effect was somewhat diminished, and at an 0.8 μm/hr growth rate there was less than a 10% change in resistivity. It should be noted that, as the growth rate was reduced, the epitaxial-layer surface quality deteriorated and the layers were less suitable for fine-line device fabrication. Consequently, as equilibrium growth conditions were approached, electrical stability was gained at the expense of surface quality.

The resistivity change, after annealing the deposited Ge layers, was reduced markedly also as a result of a relatively small increase in substrate temperature. In order to retain surface-rate-limiting growth conditions and attendant surface smoothness, it was necessary to increase the vapor phase concentration and velocity as the substrate temperature was increased. This, of course, resulted in an enhanced growth rate with increasing temperature; for example, at 385°C it was necessary to employ a growth rate of approximately 20 μm/hr in order to obtain surfaces comparable to those obtained at 350°C at a rate of 5 μm/hr. At 400°C deposition temperatures, the growth rates were of the order of 25-30 μm/hr. In this range, however, some degradation of surface quality resulted, since the maximum practical concentration and velocity obtainable in the system employed was only marginally adequate.

A summary of the deposition parameters is shown in Table II. The flux requirements in terms of HI vapor pressure, carrier gas input, and average linear-gas-stream velocity at the substrate site are listed together with the resulting growth rates. The BI_3 concentration is an approximate value required to provide an "as grown" resistivity of 0.1 ohm-cm.

A numerical comparison of the relative stabilities of layers deposited at various substrate temperatures was estimated by calculating a ratio of inactive boron in the "as grown" layer to the total boron in the layer. Spreading resistance values for resistivity were converted to carrier concentration using the curves of Sze and Irvin (8). The total boron concentration, C_T, was obtained from the resistivity of the annealed sample (neglecting corrections for charge carrier compensation and mobility). The concentration of inactive boron, C_T-C_I, was taken as the difference between the annealed value, C_T, and the value derived from the "as grown" resistivity, C_I. $(C_T\text{-}C_I)/C_T$ represents the fraction of the boron that is incorporated into the "as grown" Ge layer in an electrically inactive state. Figure 1 is a plot of this ratio as a function of substrate temperature. The inactive boron fraction is seen to decrease from 0.83 to 0.12 in the substrate temperature interval 350°-400°C, respectively. This is consistent with the observed decrease in the BI_3 concentration required in the gas phase (Table II).

A further evaluation of the effect of substrate temperature during growth and annealing was made from Hall mobility data. Van der Pauw samples were prepared from Ge layers grown on semi-insulating GaAs substrates at 350° and 385°C. The insulating substrates were used to provide isolation of the epitaxial film. Half of each Ge/GaAs structure was given an extended anneal (48 hr at 500°C) to insure complete equilibration of the Ge layer. The results are shown in Fig. 2a

Table II. Deposition parameters used to obtain smooth surfaces as a function of temperature

Substrate temperature, °C	HI vapor pressure, Torr	Flow rate, cc/min	L.G.S.V. cm/min	Growth rate, μm/hr	BI_3 concentration, ppm	$\frac{C_T - C_I}{C_T}$
350	11.0	900	190	5	90	0.83
385	27.6	1200	250	20	70	0.58
400	27.6	1500	320	25	50	0.12

[1] "As grown," undoped layers were high resistivity n-type (of the order of 2 ohm-cm), and they remained high resistivity after annealing (some samples converted to p-type high resistivity and others remained n-type, but with a higher resistivity).

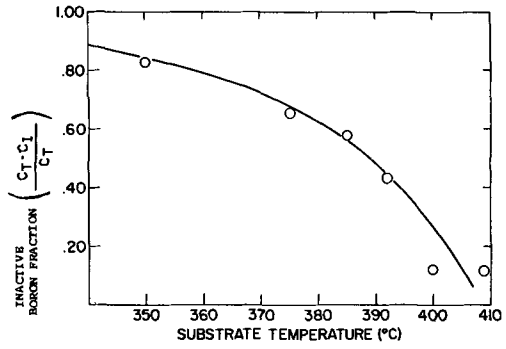

Fig. 1. Variation of the fraction of inactive boron with substrate temperature.

and 2b as plots of mobility *vs.* carrier concentration. The solid lines represent published data for bulk mobility (9). The shape of the curves at the high carrier concentration end (dashed portions) was obtained from values determined by Woods (of these laboratories) on bulk material. Samples grown at 385°C exhibit a Hall mobility close to that of bulk mobility at room temperature. Following annealing at 500°C, the resistivity of these samples decreases slightly and is accompanied, as expected, by a similarly small decrease in Hall mobility. Samples grown at 350°C exhibit a Hall mobility considerably smaller than the bulk value. Following annealing there is a considerable resistivity change accompanied by a somewhat smaller Hall mobility change. The Hall mobility of such samples at room temperature following annealing is still, however, considerably smaller than the bulk value.

For these same samples measured at 77°K, the following is observed: the mobility of the sample grown at 385°C and annealed at 500°C is essentially the bulk value, whereas that of the sample grown at 350°C and annealed at 500°C shows a significant increase from the "as grown" value, but is still less than the bulk value. Unaccountably, when measured at 77°K, the layer grown at 385°C exhibited essentially bulk mobility following annealing, but the carrier concentration decreased after annealing. In view of the results for both the annealed and unannealed layers deposited at 385°C, this last result is unexpected and as yet unexplained. What does appear to be clear, however, is that with a slight increase in growth temperature of the layers, one obtains Hall mobilities more nearly approximating bulk values. As we shall show below, diodes fabricated from layers grown at different temperatures show leakage characteristics that correlate with Hall data in the sense that, as Hall mobilities approach bulk values, diode characteristics improve.

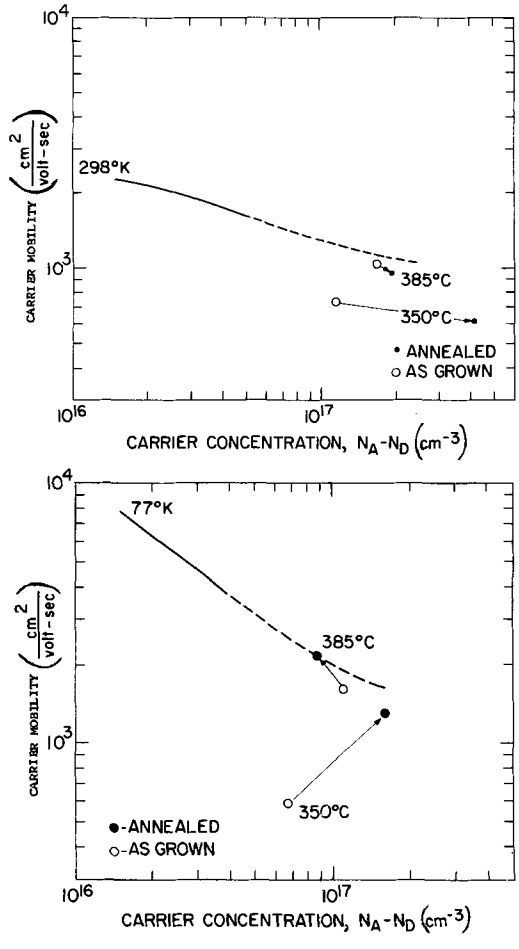

Fig. 2. Hall mobility *vs.* carrier concentration, as-grown and after annealing at 500°C. a, Room temperature; b, liquid nitrogen temperature.

The characteristics of diffused diodes made in Ge layers grown under various conditions of growth rate, substrate temperature, and annealing time were compared. All of the Ge layers were given at least a standard annealing treatment of 500°C for 16 hr before diode fabrication.

Typical reverse characteristics are shown in Fig. 3 for diodes in bulk Ge, and in high- and low-temperature epitaxial layers of Ge deposited on Ge and GaAs substrates. Diodes formed in bulk Ge and in Ge epitaxial layers, deposited by the reduction of $GeCl_4$, were indistinguishable from one another. The Ge layers deposited on GaAs substrates by the pyrolytic dissociation of GeH_4 were more heavily doped, with the result that they had a lower breakdown voltage; below breakdown, the characteristics are equivalent to those for bulk Ge.

As seen from Fig. 3, the B-doped layers formed by the disproportionation of GeI_2 at 350°C yielded soft reverse *I-V* characteristics, whether deposited on Ge or on GaAs substrates. As the reverse voltage increases, it eventually reaches a saturation value at about the expected breakdown voltage.

The major difference between diodes fabricated in layers grown at higher and lower temperatures is seen in the slope, n, of the log I *vs.* log V characteristic in the pre-breakdown region. Thus, $n = \Delta \log I/\Delta \log V$. If $n \rightarrow 0$, then this is indicative of what is normally termed a hard diode characteristic. If $n \rightarrow 1$, a resistance-like or soft characteristic is indicated.

Figure 4 gives a summary of the values of n for typical diodes in epitaxial layers formed by different high- and low-temperature epitaxial processes. The B-doped layers produced by the high-temperature processes ($GeCl_4$ and GeH_4) yield acceptable diodes, even when deposited on GaAs substrates (via the GeH_4 process). It should be noted that Ge layers deposited on GaAs using the GeH_4 process are plastically deformed (10). Consequently, the question of crystal perfection influencing these results was tested. An As-doped layer on Ge, produced by the low temperature process (GeI_2

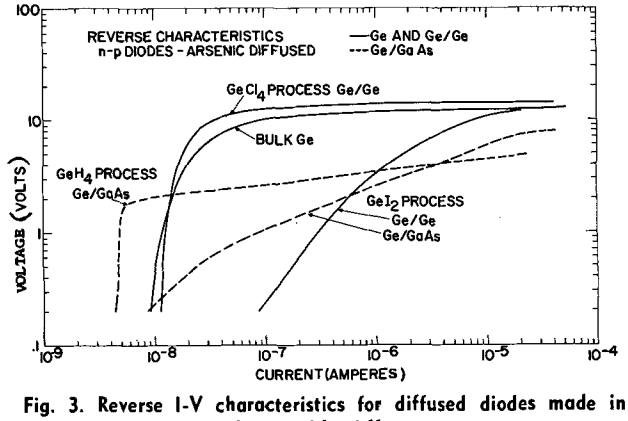

Fig. 3. Reverse I-V characteristics for diffused diodes made in bulk Ge and in Ge layers deposited by different processes.

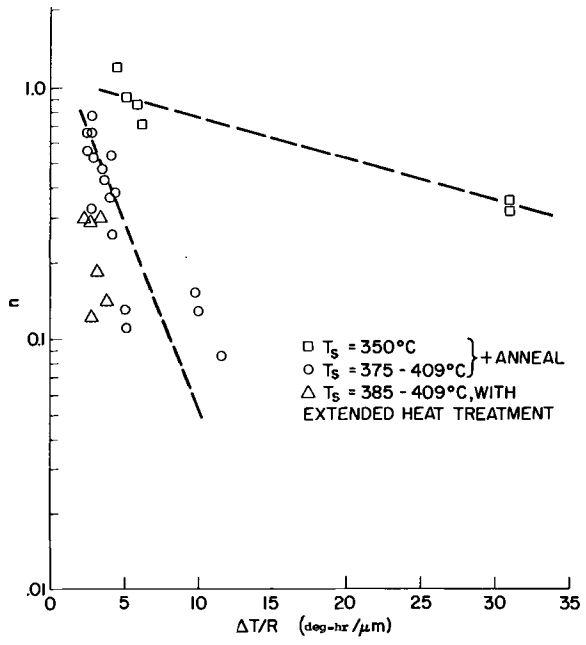

Fig. 5. Measured values of the pre-breakdown slope (n = Δlog I/Δlog V) of V-I characteristics for diodes made in Ge layers deposited under different conditions of substrate temperature, T_S, and deposition rate, R.

at 350°C substrate temperature), also yielded acceptable diodes. We can see from the data of Fig. 4 that neither substrate type nor plastic deformation are important factors leading to high values of n, but that low deposition temperatures combined with the use of B doping does result in high values of n.

The effects of substrate temperature and growth rate on n are shown in Fig. 5. Log n is plotted against the ratio $\Delta T/R$, where ΔT is defined arbitrarily as the substrate temperature, T_S, minus 325°C, and R is the growth rate in μm/hr. The ratio $\Delta T/R$ is used, since it is expected that the incorporation of active B would be enhanced by larger ΔT or smaller R. Most of these data are for layers grown on Ge substrates.

As mentioned previously, all of the Ge layers from which these data were obtained were annealed at 500°C for 16 hr prior to diode fabrication. Some of the samples were given extended heat treatments at 500°C for 32-48 hr or at 800°C for 45 min. The n-values for these samples were about a factor or two lower than would be expected from the substrate temperature, growth rate, and standard anneal.

It can be seen, then, that the growth conditions which lead to minimal changes in resistivity also lead to improved diode reverse characteristics. The resistivity data indicate that the B dopant present in the 350°C layers is not all incorporated into electrically active sites in the Ge lattice. The mobility data indicate that there is an extra scattering mechanism taking place in these layers. The inactive B may be associated with imperfections which adversely affect the mobility.

Summary

1. The resistivities of Ge layers deposited at the lower substrate temperature (350°C), using high GeI_2 concentrations and high carrier gas velocities, were thermally unstable (exhibiting resistivity decreases of a factor of 10) and the mobilities were low.

2. The resistivities of Ge layers deposited at the higher substrate temperatures (>375°C) showed much less thermal instability (10% decrease in resistivity at 400°C) and yielded satisfactory diodes after annealing.

3. The thermal instability is attributed to incomplete incorporation of electrically active B in the Ge lattice.

Acknowledgments

The authors wish to thank M. Sampogna for assistance in growing the Ge layers, M. E. Cowher for the Hall measurements, S. A. Sharpe for making diode measurements, and R. A. Laff for many helpful discussions.

Manuscript received Sept. 9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.
