Specimens were mounted in epoxy cold setting resin, polished on silicon carbide papers 200 through 600 grit with kerosene as lubricant, then polished on a wax lap impregnated with 30μ alumina. This procedure resulted in best retention of oxide grains and in obtaining a flat surface. The final polishing was done on 6 and 1μ diamond wheels with napless cloths and kerosene as lubricant. It was necessary to etch the specimens for identification of phases by optical microscopy. A 5% concentrated hydrochloric acid solution in ethyl alcohol was used to preferentially etch wustite in structures containing wustite, spinel, and alloy. A 50% concentrated hydrochloric acid solution in water, which preferentially etched spinel, was used as etchant for structures containing nickel ferrite, nickel oxide, and alloy.

Chemical analyses were carried out by means of a CAMECA electron-probe microanalyzer operating at 15 kev with an x-ray beam take-off angle of 18°. This instrument was calibrated according to the method described by Friskney and Haworth (6, 7). Essentially the method consisted of successively applying atomic number (8), absorption (9, 10), and fluorescence (11, 12) corrections to an assumed set of compositions for a solid phase and calculating the intensity ratio for each metal to that for the pure metal. This procedure yielded iron and nickel calibration curves for each solid. In all cases, the fluorescence correction was significant. The atomic number correction was significant only for the oxides due to the presence of oxygen. Standards used to check the calibration curves for the alloys were alloys of several known compositions. The calibration procedure for the wustite phase could be verified only for pure wustite. For spinel oxide, the calibration procedure was verified for magnetite and nickel ferrite. The homogeneity of each phase in a specimen was determined by subjecting different areas to point counts. In addition, x-ray and electron back-scatter pictures were used for phase identification and to determine qualitatively the metal compositions in the coexisting phases.

Results

The photomicrographs in Fig. 1 and 2 illustrate typical oxide-alloy structures of equilibrated specimens. The structures obtained from both compacts and oxidized alloy plates exhibited an essential feature in that the different phases, which were bonded to one another, were sufficiently large for accurate analyses by the electron microprobe. At the acceleration voltage of 15 kev used for these analyses, the diameter of the x-ray production zone was only about 2μ and hence the minimum size of the particle for accurate analysis was about 5μ. The minimum size of particles analyzed in this investigation was 15μ. Identification of the phases present in a specimen by x-ray diffraction and microscopic observation showed complete agreement.

Information given by the electron probe micrographs was very useful. For example, the micrographs shown in Fig. 3 were obtained from a specimen consisting of spinel containing 1.4 w/o Ni and 71 w/o iron, and an alloy containing 84 w/o Ni. In the electron back-scatter image, the alloy was black and the spinel completely white. Also, the x-ray intensities clearly defined the amounts of iron and nickel in the different phases.

The compositions for the coexisting oxide and alloy phases are recorded in Table I. The mass concentra-

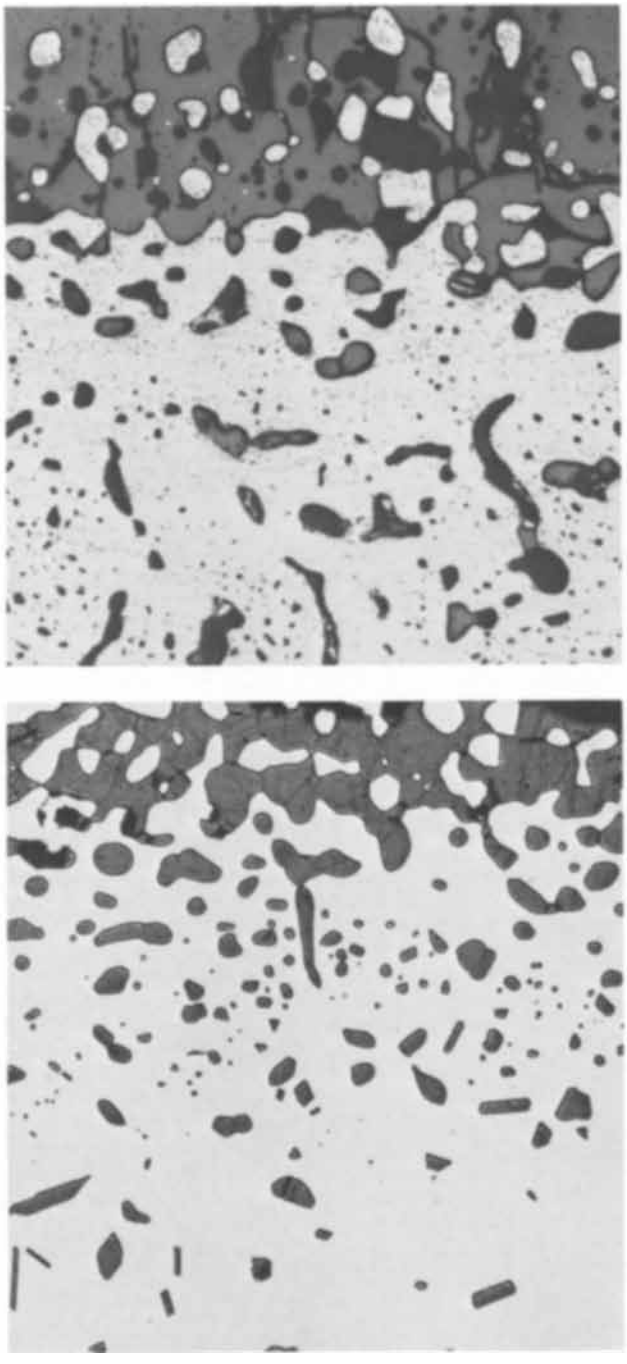

Fig. 1. Equilibrium two-phase fields wustite-alloy and the spinel-alloy. In both micrographs, the dark phases are the oxide phases and the bright phase is the alloy phase: (a) upper micrograph—wustite + alloy etched in 5% HCl in ethyl alcohol, 250X; (b) lower micrograph—spinel + alloy etched in 50% HCl in water, 320X.

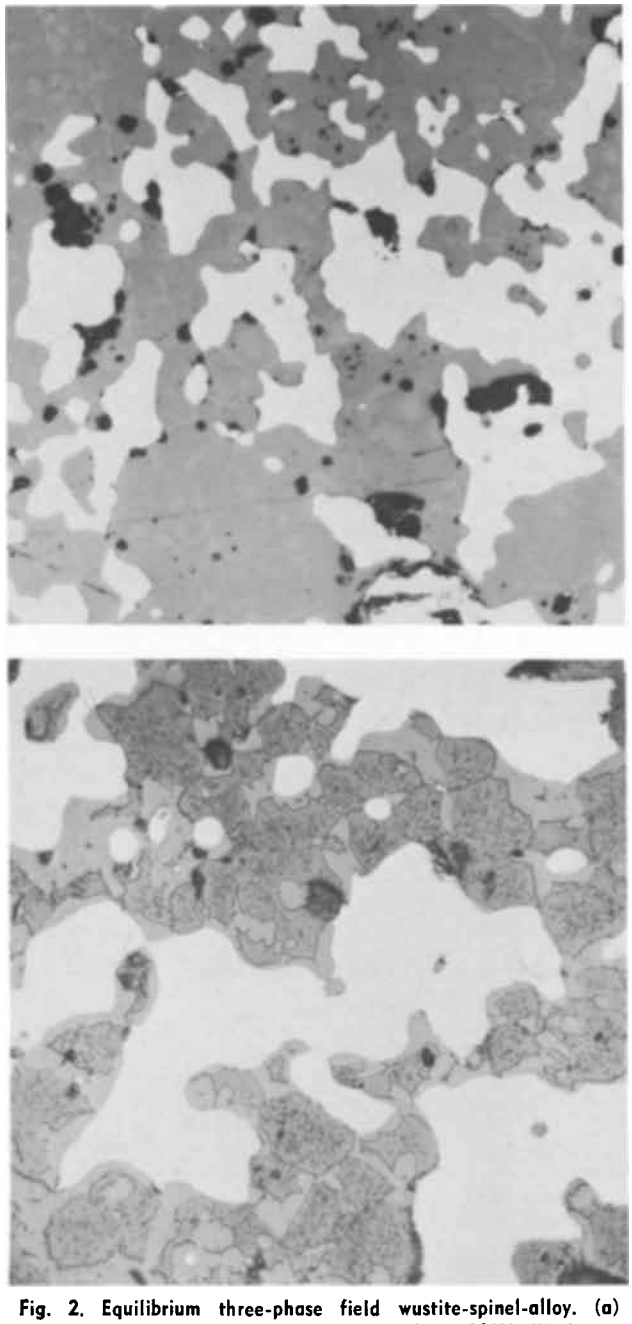

Fig. 2. Equilibrium three-phase field wustite-spinel-alloy. (a) Upper micrograph—microstructure before etching, 200X. (b) Lower micrograph—specimen surface after etching in 5% HCl in ethyl alcohol, 400X; bright phase—alloy, dark matrix phase—wustite, gray precipitates—spinel.

tions obtained experimentally were converted to atomic concentrations which are also given in Table I. Wustite coexisted with alloys containing up to 79.6 a/o Ni, the maximum nickel solubility in wustite being 0.51 a/o. It was found that spinel coexisted with alloys containing from 79.6 to 99.5 a/o Ni. The spinel in equilibrium with wustite and alloy contained 0.6 a/o Ni, while the compositions of the spinel in equilibrium with nickel oxide and alloy corresponded to stoichiometric nickel ferrite. The maximum iron solubility in nickel oxide was 6.5 a/o.

Discussion

The isothermal section of the phase diagram at 1000°C constructed from the compositional determinations is illustrated in Fig. 4. The oxygen solubilities in the alloys have been magnified for clarity and are in fact negligibly small and unknown. The diagram is symmetric about the spinel-alloy field which is bounded by three-phase fields containing wustite-spinel-alloy and nickel oxide-spinel-alloy. These fields are bounded in turn by two-phase fields containing wustite and alloy on the iron-rich side and nickel oxide and alloy on the nickel-rich side of the diagram. Wustite, which exhibits only a small nickel solubility, is stable over a wide range of alloy composition; on the other hand, nickel oxide exhibits a relatively large iron solubility but its stability is confined to a very narrow range of alloy composition. The tie lines in the wustite-alloy and spinel-alloy fields are not proportionately spaced. They fan out from oxide in the iron-rich region and from the alloy in the nickel-rich region of the diagram.

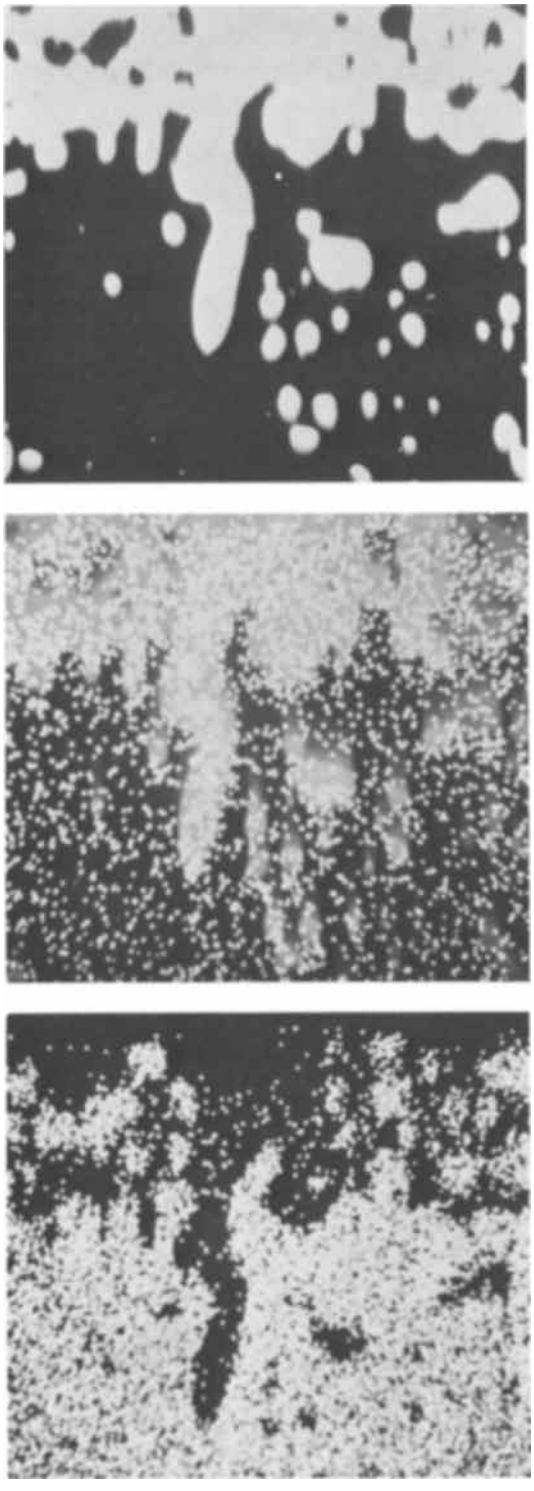

Fig. 3. Electron probe images of sample in the two-phase field spinel + alloy, 1000X. (a) Upper micrograph—electron backscatter image. The spinel phase appears as bright and the alloy phase appears as dark. (b) Middle micrograph—Fe-K_α x-ray image showing distribution of iron in the two phases. (c) Lower micrograph—Ni-K_α x-ray image showing nickel distribution.

A terminal nickel solubility of 0.51 a/o in wustite agrees with a reported value (2) and it lies between two determinations where the nickel contents were reported virtually absent (1) and 1.3 a/o (5). The iron concentration as well as the total metal concentration in wustite decreased with increasing nickel content of the alloy. At the terminal composition, the total amount of metal was 46.7 a/o. Since this value is equal to the iron concentration in wustite upon its equilibration with magnetite, it would appear that there is an isomorphous substitution of nickel for iron in the wustite lattice. The nickel composition of 0.6 a/o for spinel S_1, shows wide divergence from an earlier determination of 5 a/o (1). Magnetite exhibits an inverse spinel structure with ferrous ions occupying octahedral sites and ferric ions occupying both octahedral and tetrahedral sites between oxygen ions (13). Apparently, nickel replaces iron in the divalent sites in the spinel up to the terminal composition corresponding to nickel ferrite (14, 15).

The values reported for the dissociation pressures and nickel contents of wustite are sufficient for thermodynamic evaluation of the solution behavior of nickel in wustite. Values reported for the dissociation pressures of wustite containing nickel in solid solution are compared to that for pure wustite in Fig. 5. The Gibbs-Duhem relationship may be applied to the alloy and oxide phases because these pressures determine oxygen activities

$$N_O{}^A \, d\ln a_O{}^A + N_{Ni}{}^A \, d\ln a_{Ni}{}^A + N_{Fe}{}^A \, d\ln a_{Fe}{}^A = 0 \quad [1]$$

$$N_O{}^W \, d\ln a_O{}^W + N_{Ni}{}^W \, d\ln a_{Ni}{}^W + N_{Fe}{}^W \, d\ln a_{Fe}{}^W = 0 \quad [2]$$

where N is a mole fraction and a is an activity in the alloy (A) and wustite (W) phases. At equilibrium, Eq. [1] and [2] yield the variation of oxygen activity with respect to nickel activity, for

$$\frac{d\ln a_O}{d\ln a_{Ni}} = -\frac{N_{Ni}{}^A - N_{Ni}{}^W N_{Fe}{}^A/N_{Fe}{}^W}{N_O{}^A - N_O{}^W N_{Fe}{}^A/N_{Fe}{}^W} \quad [3]$$

Since the oxygen solubility in the metal is extremely small, 0.0003-0.015 w/o (16, 17), we may neglect the term $N_O{}^A$ in integrating Eq. [3]. Therefore

$$\ln P_{O_2}/P^o{}_{O_2} = 2\int_0^{N_{Ni}{}^A} \left\{ \frac{N_{Ni}{}^A - N_{Ni}{}^W N_{Fe}{}^A/N_{Fe}{}^W}{N_O{}^W N_{Fe}{}^A/N_{Fe}{}^W} \right\} d\ln (\gamma_{Ni}{}^A N_{Ni}{}^A) \quad [4]$$

where $P^o{}_{O_2}$ is the dissociation pressure of pure wustite. This equation was integrated numerically by means of a computer since values are available for the mole fractions of iron, nickel, and oxygen in wustite as well as the activity coefficients of nickel in the alloy (2, 4, 18, 19).

Equation [3] may be simply integrated to the following expression if it is additionally assumed that the small concentration of nickel in wustite approximates to zero and that the mole fractions of iron and oxygen are equal as for stoichiometric wustite

$$\log P_{O_2}/P^o{}_{O_2} = 2 \log (1/1 - N_{Ni}{}^A) \quad [5]$$

This expression is also obtained by comparing the dissociation pressures of pure wustite with that of wustite equilibrated with the alloy

$$FeO^W \leftrightarrows Fe^A + \tfrac{1}{2} O_2 \quad [6]$$

under the approximations of unit activity for wustite and ideal solution behavior of iron in the alloy.

Comparison of the values for the dissociation pressures calculated by means of Eq. [4] and [5] to those determined experimentally are shown in Fig. 5. Although there are large uncertainties in the evaluations of the alloy compositions in the case where dissociation pressures were determined for wustite-alloy compacts (5), both equations serve as a first approximation to the experimental results. The better fit, however, is obtained by Eq. [4] where account has been given to the degree of nickel solubility in wustite and to the activity coefficients for the alloy components. Equation [4] gives the invariant oxygen partial pressures in the wustite-spinel-alloy phase field as 3.26×10^{-14} atm, a value considerably larger than the dissociation pressure of pure wustite, $P^o{}_{O_2} = 1.32 \times 10^{-15}$ atm. Since

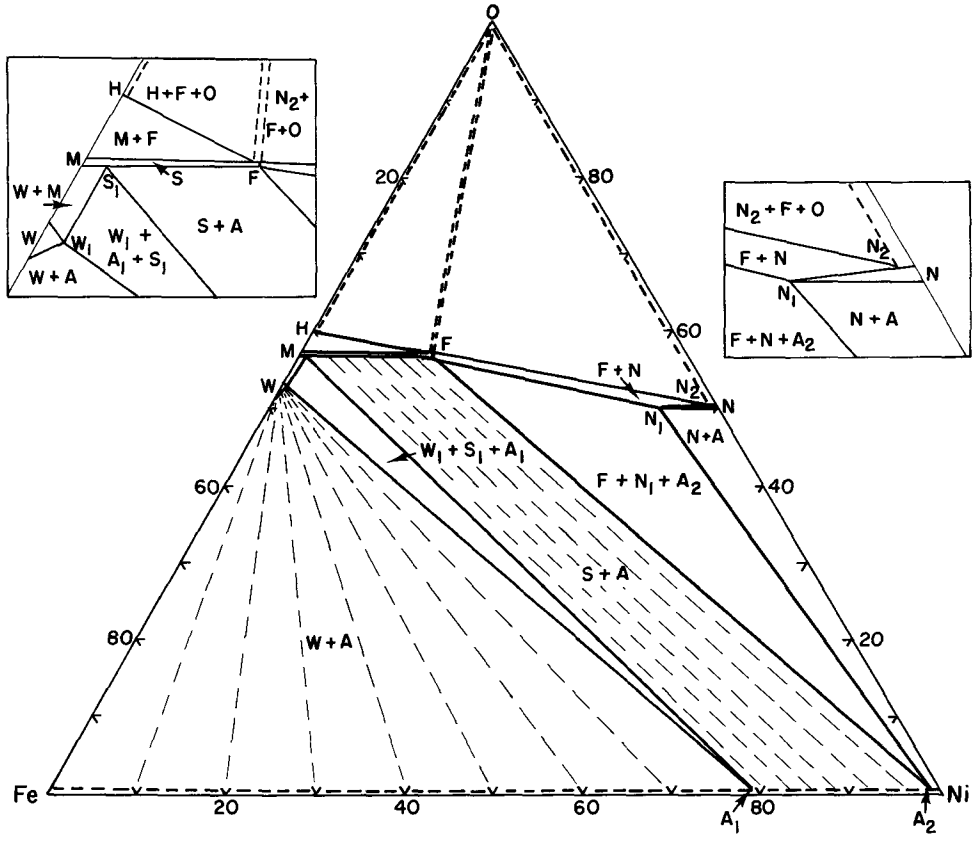

Fig. 4. Iron-nickel-oxygen phase diagram at 1000°C (a/o). W_1—$Ni_{0.01}Fe_{0.87}O$ (wustite); S_1-$Ni_{0.04}Fe_{2.96}O_4$ (spinel). A_1—79.6 a/o Ni, 20.4 a/o Fe (alloy). F—$NiFe_2O_4$ (ferrite); N_1-$Fe_{0.13}$-$Ni_{0.87}O$ (nickel oxide). A_2—99.5 a/o Ni, 0.5 a/o Fe (alloy). N_2—$Fe_xNi_{1-x}O$ where $x \simeq 0.0005$ (nickel oxide). Phase notations: W—*wustite*, $Ni_xFe_{1-(x+y)}O$; M—magnetite, Fe_3O_4. H—*hematite*, Fe_2O_3; N—*nickel oxide*, $Fe_xNi_{1-x}O$. The dashed line across the bottom of the diagram represents oxygen solubilites in the alloy magnified for clarity. Dashed lines in the vicinity of the oxygen corner represent undetermined boundaries of phase fields involving oxygen. The insets on either side represent corresponding phase regions on an expanded scale.

the dissociation pressure of wustite containing the maximum nickel content is less than that for wustite-magnetite equilibrium, 1.62 x 10^{-13} atm, it can be inferred, as was found, that the limiting nickel content of wustite, 0.51 a/o, should be less than the corresponding value for spinel, 0.60 a/o.

A useful approximation to the wustite solid solution may be made by assuming that nickel dissolves in wustite as nickel oxide. The following displacement reaction may then be considered

$$Fe^A + NiO^W \rightleftarrows Ni^A + FeO^W \qquad [7]$$

where

$$K = \frac{a_{Ni}^{(A)} \cdot a_{FeO}^{(W)}}{a_{Fe}^{(A)} \cdot a_{NiO}^{(W)}} = \frac{(\gamma_{Ni} \cdot N_{Ni})_A \cdot (\gamma_{FeO} \cdot N_{FeO})_W}{(\gamma_{Fe} \cdot N_{Fe})_A \cdot (\gamma_{NiO} \cdot N_{NiO})_W} \qquad [8]$$

The value of K is determined to be 186 at 1000°C from electromotive force measurements of Kiukkola and Wagner (20). Since the values of the activity coefficients for the alloy components are known, the nickel oxide content of wustite was calculated for the case of oxide ideal solid solution behavior as a function of nickel content of the alloy phase. This relationship and the experimental relationship are shown in Fig. 6. The curve through the experimental points was determined by a least-squares analysis using a computer. Division of the corresponding values obtained by these two relationships yields the activity coefficient ratio, $\gamma_{NiO}/\gamma_{FeO}$, as a function of equilibrium alloy composition. The curve representing this activity coefficient ratio is also shown in Fig. 6. It can be seen that the ratio of the activity coefficient remains constant at 3.72 for the alloy composition range of 0-40 a/o Ni and then decreases to a value of 2.33 at the limiting alloy compositon for stability of wustite. Consequently, nickel oxide solubility in wustite displays a Henry law be-

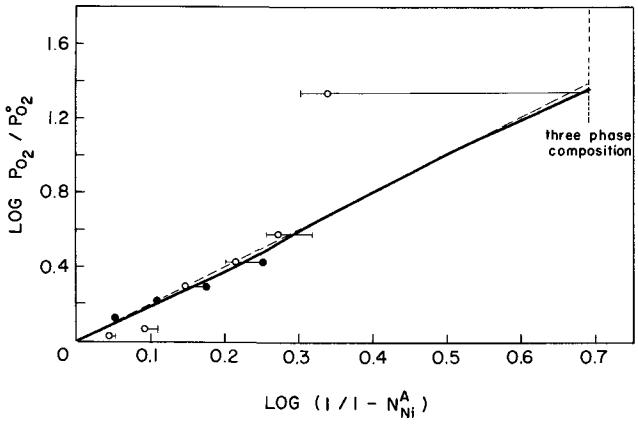

Fig. 5. Equilibrium oxygen partial pressure in the two-phase field wustite-alloy as a function of alloy composition. The solid and dashed curves were calculated according to Eq. [4] and [5], respectively. The data were obtained from Ref. (4) (●) and Ref. (5) (○).

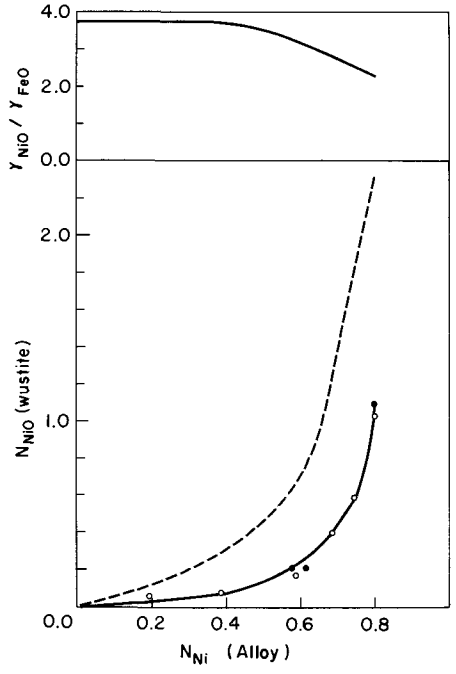

Fig. 6. Solubility of nickel oxide in wustite as a function of equilibrium alloy composition. The dashed curve was obtained with the assumption of ideality for the wustite-nickel oxide system. The data for the experimental curve were obtained from this investigation (●), and from Ref. (2) (○). The activity coefficient ratio $\gamma_{NiO}/\gamma_{FeO}$ for the wustite phase as a function of equilibrium alloy composition was obtained from the above two curves on dividing calculated values obtained on the assumption of ideality by the corresponding experimental values, Eq. [8].

havior only to a mole fraction of 0.008. A similar calculation using Eq. [8] yields $\gamma_{FeO}/\gamma_{NiO} = 4.88$ at the limiting tie line of the nickel oxide-alloy region where the alloy composition is 99.5 a/o Ni, the activity coefficients of nickel and iron in the alloy are 1.0 and 0.78, respectively, and the mole fraction of wustite in nickel oxide is 0.13. Consequently, wustite-nickel oxide solid solutions exhibit positive deviation from ideal behavior at oxygen partial pressures for equilibration with Fe-Ni alloys.

The iron contents of the nickel oxide, N_2, and the alloy, A_2, occurring in the spinel-nickel oxide-oxygen and in the spinel-nickel oxide-alloy regions, respectively, may be evaluated from appropriate standard free energies of formation. The following reactions may be considered

$$NiFe_2O_4 = Ni + 2Fe + 2\,O_2 \quad [9]$$

$$FeO = Fe + \tfrac{1}{2}\,O_2 \quad [10]$$

$$NiO = Ni + \tfrac{1}{2}\,O_2 \quad [11]$$

Since the standard free energies for these reactions at 1000°C are 152, 43, and 30 kcal, respectively (21, 22), we obtain for the equilibrium constants in terms of standard oxygen activities for the pure metals and oxides

$$K_9 = (a_O^{\circ})_9^4 = a_{Ni}\,a_{Fe}\,a_O^4 = 7.65 \times 10^{-27} \quad [12]$$

$$K_{10} = (a_O^{\circ})_{10} = a_{Fe}\,a_O/a_{FeO} = 4.14 \times 10^{-8} \quad [13]$$

$$K_{11} = (a_O^{\circ})_{11} = a_{Ni}\,a_O/a_{NiO} = 7.06 \times 10^{-6} \quad [14]$$

In the three-phase region spinel-oxygen-nickel oxide, $a_O \simeq 1$ and $a_{NiO} \simeq 1$. Therefore, $a_{FeO} \cong 10^{-3}$. Accordingly, the iron content in nickel oxide, N_2, corresponds to approximately 0.05 a/o. In the three-phase region spinel-nickel oxide-alloy, $N_{NiO} \simeq 0.9$ and $a_{Ni} \simeq 1$. Therefore, $a_{FeO} = 0.38$ and $a_O = 6.35 \times 10^{-6}$. Accordingly, the mole fraction of iron in the alloy, A_2, $N_{Fe} = a_{Fe}/\gamma_{Fe} = 0.0047/0.78 \simeq 0.006$. That is, the nickel-iron alloy existing in equilibrium with spinel and nickel oxide contains approximately 0.6 a/o iron. This calculated value is to be compared to the experimentally determined value of 0.5 a/o.

Conclusions

The phase boundaries of the two-phase fields wustite-alloy, spinel-alloy, and nickel oxide-alloy, and the three-phase fields wustite-spinel-alloy and spinel-nickel oxide-alloy were determined at 1000°C. Chemical analyses indicated that nickel solubility in wustite was governed by isomorphic replacement of iron by nickel. It was inferred that, in the spinel phase extending from magnetite to stoichiometric nickel-ferrite, ferrous ions in the octahedral interstitial sites were replaced by divalent nickel ions. The spinel phase in equilibrium with alloys extends from $Ni_{0.04}Fe_{2.96}O_4$ to $NiFe_2O_4$. The wustite-spinel-alloy field consists of wustite containing 0.51 a/o Ni, spinel containing 0.60 a/o Ni, and an Fe-Ni alloy containing 79.6 a/o Ni. The spinel-nickel oxide-alloy field consists of nickel ferrite, nickel oxide containing 6.5 a/o Fe, and an alloy containing 0.5 a/o Fe. The iron content of nickel oxide in equilibrium with spinel and oxygen was calculated to be approximately 0.05 a/o. By means of the Gibbs-Duhem relationship, the dissociation pressures of wustite were related to the compositions of the alloy. Solution of nickel oxide in wustite was shown to exhibit positive deviations from ideal solid solution behavior.

Acknowledgments

This work was carried out by A. D. Dalvi in partial fulfillment of the requirements for award of the Ph.D. degree at McMaster University. He wishes to acknowledge the award of an International Nickel Company of Canada Fellowship for graduate research. Technical Notes

Surface Polarity and Etching of Beta-Silicon Carbide

Robert W. Bartlett* and Malcom Barlow

Stanford Research Institute, Menlo Park, California 94025

Beta-silicon carbide has the zinc blende structure and solution-grown crystals are in the form of octahedral platelets (1). Although the silicon and carbon layers alternate in the stacking sequence, the interatomic spacing in the octahedral direction, [111], is not uniform. The terminating plane for the (111) surface is ideally composed of silicon atoms, while the terminating plane for the $(\bar{1}\bar{1}\bar{1})$ surface is composed of carbon atoms.

If use is made of the anomalous phase shift, differences in x-ray diffraction intensity are detectable and the two opposite sides of noncentrosymmetric crystals can be identified (2). This method has been used by Warekois and co-workers (3, 4) to identify faces of several III-V and II-VI compounds, and Brack (5) has used it to determine polarity in α-silicon carbide.

Polarity Determination

X-ray diffraction intensities from octahedral platelets of β-silicon carbide were measured on a Norelco diffractometer, using filtered CuK_α radiation. The standard sample holder was replaced by a single-crystal goniometer to facilitate orientation and mounting of the crystals, and the x-ray beam was collimated to about 1 mm diameter. Intensities of the scattered beams were determined by a Geiger counter with chart recorder, each reflection being scanned slowly through the Bragg angle. Filters limited the intensities to the linear counting rate region of the counter.

The diffracted intensities are proportional to $|\mathbf{F}(hkl)|^2$. The theoretical ratios of $|\mathbf{F}(hkl)|^2/|\mathbf{F}(\bar{h}\bar{k}\bar{l})|^2$, calculated from the anomalous dispersion correction, are

$$\frac{|\mathbf{F}(111)|^2}{|\mathbf{F}(\bar{1}\bar{1}\bar{1})|^2} = 0.94, \quad \frac{|\mathbf{F}(222)|^2}{|\mathbf{F}(\bar{2}\bar{2}\bar{2})|^2} = 1.00, \quad \frac{|\mathbf{F}(333)|^2}{|\mathbf{F}(\bar{3}\bar{3}\bar{3})|^2} = 1.06$$

Three crystals were examined repeatedly, and the experimental ratios of intensities for the $(111)/(\bar{1}\bar{1}\bar{1})$ reflections were always smaller than 1, while the experimental ratios of intensities for the $(333)/(\bar{3}\bar{3}\bar{3})$ reflections were always larger than 1.

Etching

Etching studies were made on β-silicon carbide platelets grown from solution and on vapor-deposited β-silicon carbide grown epitaxially on platelets (6). Two etchants were used: (*a*) a gas mixture containing 6% chlorine and 26% oxygen in argon at 850° to 900°C and (*b*) a fused salt mixture of 75% NaOH and 25% Na_2O_2 at 700°C. The polarity of the crystals was determined from the ratio of x-ray diffraction intensities. Although the rate of attack was different, the same surface characteristics were observed with both etchants. Etch pits developed on the (111) face but did not develop on the $(\bar{1}\bar{1}\bar{1})$ face. Except for the etch pits, the (111) face remains smooth. These results correspond with the etching of α-silicon carbide in similar etchants (7, 8) where etch pits are observed to form on the smooth face, which was identified by Brack (5) as the (0001) face terminating in silicon atoms, although pits do not usually form on the rough $(000\bar{1})$ face. Similar results have been observed for other zinc blende and wurtzite structures among III-V and II-VI compounds (3, 4).

The depth of etch pits is much less than the thickness of silicon carbide uniformly removed during etching. Uniform etch rates for the chlorine-oxygen gas etchant were obtained by measuring step heights between etched regions and the regions protected by a thermally grown oxide film. On solution-grown crystals the etch rate at 900°C was 0.3 to 0.5 μM/min. Although the etch-pitting characteristics of β-silicon carbide grown epitaxially by vapor deposition were essentially the same as those of the solution-grown platelets, there were marked differences in the uniform etching rates under identical etching conditions. The chlorine-oxygen gas-etching rate of undoped epitaxially grown

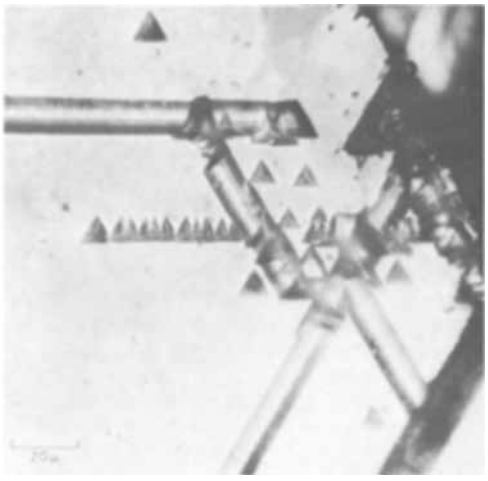

Fig. 1. Solution-grown β-SiC (111) surface etched in $NaOH-Na_2O_2$.

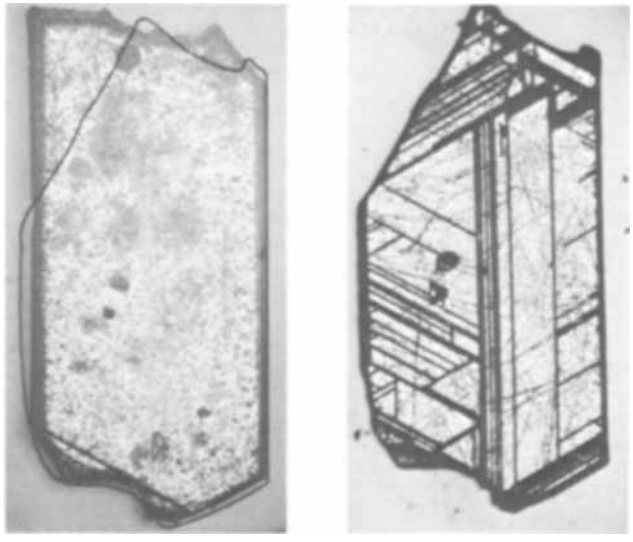

Fig. 2. Etch pit rows extending from the substrate through the epitaxial layer: (left) Etched boron-doped epitaxial layer; (right) after removal of epitaxial layer and re-etching.

crystals was less than 0.02 μM/min at 900°C. The mechanism leading to this difference in rates is not known but may be related to differences in the concentrations of specific impurities present in amounts below the detection limits of neutron activation analysis or emission spectrography.

The etch pits on solution-grown platelets have a marked tendency to cluster in rows as shown in Fig. 1. The pits are frequently sufficiently large and closely spaced to form a groove often running the entire length of the crystal. The axis of these etch pit rows is always a <110> direction. X-ray topographic studies (9) show that the etch pits correspond to surface-terminating partical dislocations with a <112> Burgers' vector that are associated with closely spaced parallel {111} stacking faults.

These dislocations continue in the vapor-deposited silicon carbide grown epitaxially on solution-grown substrates. Etch pits on the surface of the epitaxially grown layer are observed in exactly the same locations as the underlying substrate. This indicates that the stacking faults are also extending from the substrate through the epitaxy layer. This effect is demonstrated by the two micrographs of the same crystal shown in Fig. 2. Correspondence between the etch pit patterns in these micrographs is readily apparent. Both surfaces shown were given identical $NaOH-Na_2O_2$ etching treatments. The lefthand micrograph was taken after lapping off the epitaxial layer with 1μ diamond paste and re-etching the surface. Note that a small section of the crystal was broken during lapping. The epitaxial layer was more resistant to the $NaOH-Na_2O_2$ etchant than was the substrate, which is consistent with the results observed with the chlorine-oxygen gas etchant.

Etch pits that were not extensions from the substrate were also observed on (111) surfaces of epitaxially grown β-silicon carbide. These pits occur in short <110> oriented rows often grouped to form one or more sides of an equilateral triangle, as shown in Fig. 3. These rows are usually no longer than 25μ. The chlorine-oxygen gas etching also causes a few large craters to form in the (111) epitaxial surface, also shown in Fig. 3. Although these craters are oriented in conformance with the octahedral morphology of the smaller etch pits, they are not observed on similarly etched solution-grown substrates. On the $(\bar{1}\bar{1}\bar{1})$ face of epitaxially grown β-silicon carbide the chlorine-oxygen gas etch rounds off twinning hillocks that were formed during vapor deposition. The nodules that result are faintly visible on the back face of the transparent crystal shown in Fig. 3.

Sputtering of Bismuth-Titanium Two-Phase Cathodes

R. T. Shoemaker, C. E. Anderson,*[1] and G. L. Liedl

Purdue University, Lafayette, Indiana 47907

In recent years there has been an increased interest in the development of sputtered films for electronic applications. A wide variety of elements has been investigated in the past with particular emphasis on single element films. Recently more emphasis has been placed on multiple component films produced by a number of methods such as sputtering from multiple component cathodes, reactive sputtering, or some post reaction process.

Winters, Raimondi, and Horne (1) have recently proposed a model for thin film composition by considering only the mechanisms affecting the composition at the substrate. An influence on the flux of atoms leaving the cathode has been illustrated by Anderson (2).

It is also of importance to determine the influence of the cathode morphology on the thin film structure and properties. This study is concerned with the influence of the cathode morphology on the stoichiometry of the resulting thin film. The bismuth-titanium system was selected for this study because of the large difference in the self-sputtering rates of bismuth and titanium (3).

Theory

To relate the composition of the film to the cathode, it is assumed that the number of each type of atom reaching the substrate is a function of the number of atoms of that type leaving the cathode and the probability that these atoms will reach and adhere to the substrate. Therefore, the composition of the film produced on the substrate is given by

$$y_i = N_i P_i \alpha_i / \Sigma_j N_j P_j \alpha_j \qquad [1]$$

where N_i is the number of atoms of element i leaving the cathode per unit area per second, P_i is the probability that atom i will reach the substrate, and α_i is the sticking coefficient.

The number of atoms of element i leaving the cathode is a function of the cathode morphology, the areal coverage of each phase, the composition of each phase, and the sputtering rate of each phase. For a two-element two-phase cathode where the two phases are pure elements, the number of type i atoms leaving the cathode is

$$N_i = x_i f_i \qquad [2]$$

where x_i is the atom fraction of element i in cathode and f_i is the function relating areal coverage to atom fraction and sputtering rate to sputtering parameters.

If we assume a probability function which describes the probability of each species reaching the substrate as

$$P_i = \exp\left[-d(K_{1i}X_i - K_{2i})\right] \qquad [3]$$

where d is the interelectrode separation, X_i is the atomic fraction, and the constants K_{1i} and K_{2i} are dependent on the cathode morphology and atomic collisions.

Therefore, the form of Eq. [1] for the atom fraction composition of the thin film produced from a two-element two-phase cathode is

$$y_1 = \frac{\alpha_1 x_1 f_1 \exp\left[-d(k_{11}x_1 + k_{22})\right]}{\alpha_1 x_1 f_1 \exp\left[-d(k_{11}x_1 + k_{21})\right] + \alpha_2 x_2 f_2 \exp\left[-d(k_{22}x_2 + k_{22})\right]} \qquad [4]$$

which can be rewritten, by assuming that $\alpha_2 f_2/\alpha_1 f_1$ is equal to one, as

$$y_1 = \left[1 + \frac{1 - x_1}{x_1} \exp\left(Ax_1 + B\right)\right]^{-1} \qquad [5]$$

The relationship of the coefficients A and B to the various parameters is dependent on several unknown factors, such as the cathode morphology, sticking coefficients, relative densities of sputtered molecules in the glow discharge, and the energy of the sputtered particles. A detailed model to describe the probability function is currently in progress.

Experimental Procedure

The cathodes were prepared by sintering 100 mesh powders of 99.9 w/o bismuth and titanium powders. Eleven disk-shaped cathodes 2½ in. in diameter and ½ in. thick were prepared with compositions varying from pure titanium to pure bismuth at 10 w/o intervals. The powders were mixed by tumbling and compressed to a pressure of 8000 psi. The green cathodes were placed in capsules which were evacuated to 2 x 10^{-5} Torr and were sintered at temperatures ranging from 250° to 1000°C depending on composition.

The sputtering was carried out in a conventional 4-in., oil-pumped, liquid nitrogen baffled vacuum system. Initially, the system was evacuated to 5 x 10^{-6} Torr. The 99.9% argon sputtering gas was then introduced through a calibrated leak valve at a constant flow rate of about 100 cc/min and the total pressure was set at 20μ by throttling the diffusion pump. The sputtering power source was a 5 kV-d-c source, and sputtering voltages varied from 2.0 kV to 4.5 kV. The sintered cathodes were presputtered for 30 min. The substrates used in this study were soft glass microscope slides.

The segregation of the elements in the thin film were analyzed with an ARL-AMX electron probe microanalyzer, and the composition of the film was determined from the ratio of the bismuth to titanium characteristic x-ray intensities calibrated for films less than bulk thickness (4). Some of the films were stripped from the substrate and examined in transmission with the electron microscope for morphology and structure characterization. The thickness of each film was measured with a multiple beam interferometer.

Results

The sintered cathodes yielded consistent results for longer sputtering times and after presputtering. However, the sintering of the cathodes did result in some problems. It was not possible to get high density sintering because of the wide discrepancies in melting point of the two elements.

Figures 1 through 3 show the relation between the composition of the cathode and the resulting thin film for 2, 3, and 4 kV sputtering potential. These results agree favorably with the predicted form as shown by the fit of Eq. 5 in Fig. 1 through 3. An attempt to fit the data to the model of Winters, Raimondi, and Horne (1) was unsuccessful. The parameters A and B obtained by fitting Eq. [5] to the experimental data are given in Table I. It should be noted that the low bismuth and low titanium composition determinations are inherently the most inaccurate values, and therefore, the intermediate compositions were weighted

more than the low compositions in fitting the equation. Since the probability function is empirical, no particular significance could be applied to the values found for the parameters. However, two factors are apparent. Since bismuth has a higher sputtering efficiency than titanium, bismuth composition in the film should be higher than in the cathode, especially for high bismuth cathodes. This effect contradicts the observed

Table I. Fitted parameters for equation relating titanium composition of sintered cathodes to sputtered film composition

kV	A	B
2	−1.74	2.16

excess titanium in the film for the high titanium cathodes. The observed S-shaped curves, especially for the higher sputtering voltages, could be the result of either a significant variation in the sticking coefficient with composition or, more likely, a net change in the flux leaving the cathode due to shape changes of the phases in the cathode.

The analysis of the electron diffraction patterns showed that the film sputtered from the 30.2 a/o titanium cathode contained at least two phases: a solid solution of titanium in bismuth and an unknown phase or phases. The films sputtered from the 87.8 a/o titanium cathode contained a solid solution of titanium in bismuth and $BiTi_2$, while a very thin film sputtered from the same cathode at the same pressure and voltage contained a solid solution of bismuth in titanium and $BiTi_2$. This result indicates a possible change in the sputtering rates of the two elements during the earlier stages of growth. A third film sputtered from the 96.8 a/o titanium cathode contained a solid solution of bismuth in titanium.

The results of this study verify a selective sputtering in two-phase cathodes and indicate either a composition dependence on the sticking coefficients or a morphology effect in the cathode.

Dielectric Properties of Surface Oxides on Aluminum

S. H. A. Begemann[1] and A. W. Smith

Boeing Scientific Research Laboratories, Box 3981, Seattle, Washington 98124

The impedance of barrier layer oxides on aluminum have frequently been characterized by an equivalent circuit of series-parallel resistor-capacitor combinations or by relaxation processes with a wide spread of relaxation times (1). Work on porous oxides have often used simplified models of the oxide itself while complicating the equivalent circuit with the introduction of pore resistance (2). The present work is an attempt to study the relaxation processes themselves. To make measurements as a function of temperature, a capacitor is formed by evaporating aluminum on top of the surface oxide. Measurements of capacitance and dissipation between 10 Hz and 200 kHz will be reported on both barrier layer and porous oxides between 100° and 500°K.

Experimental

A sample holder was built to allow evaporation of aluminum onto the surface of the oxide and to make measurements of the dielectric properties. This is shown in Fig. 1. The copper sample holder can be cooled with liquid nitrogen and heated electrically. Contact to the outer electrode was made by affixing a wire with a dot of colloidal silver paint at the edge of the area on which aluminum was evaporated. An NRC, Model 3114 vacuum coater was used for the evaporation and as a sample chamber. A General Radio, Type 716-C capacitance bridge was used in combination with a null detector system consisting of a Hewlett-Packard wave analyzer, Model 302A, a low noise preamplifier and filter. This allowed signal amplitudes of 20 mV to be used. The experiment has been discussed in detail elsewhere (3).

Results

Barrier layer oxides.—Aluminum specimens of 99.99% purity, were degreased and etched with 1*N* NaOH for 5 min and rinsed with distilled water. The anodizing was carried out in a 3% by weight ammonium tartrate solution adjusted to *p*H 7. An aluminum cathode was used. The voltage was raised in 10 V steps, and the current allowed to decay to a nearly constant value after each step.

The inverse capacitance/anodizing voltage ratio is close to that obtained by McMullen and Pryor for the same anodizing conditions but measured in the electrolyte solution (4). The frequency dependence of the dissipation for samples formed at several voltages, measured in ambient atmosphere, is shown in Fig. 2. The dissipation factor of these barrier layer oxides is only slightly dependent on atmospheric humidity. The dissipation decreases by at most 20% on application of vacuum and heating to 200°C. The values of the dissipation factor and its decrease with film thickness are similar to that reported by VanGeel and Scholte (5).

Figure 3 shows the temperature dependence of the dissipation factor for a 100V film measured at 1 kHz. Peaks with background subtracted out are shown at 142° and 245°K. At 50 kHz these peaks occurred at 230° and 287°K.

Porous oxides.—The formation of porous oxide layers was carried out on a commercial alloy, 2024-T3. After degreasing and alkaline cleaning, they were etched in a sulfuric acid, sodium dichromate solution. The anodizing was carried out at 36°C, the voltage reaching 40V in 10 min and held there for 30 min. The anodizing solution was a 3% by weight solution of chromic acid.

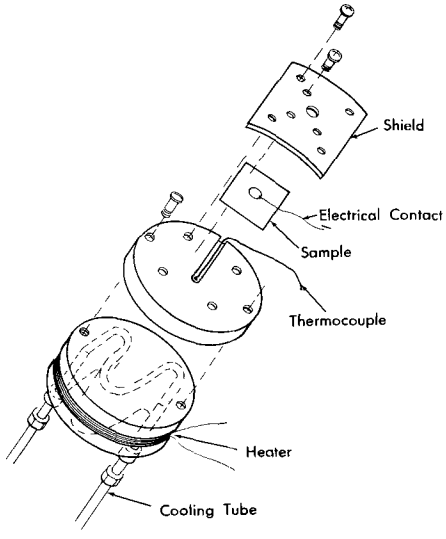

Fig. 1. Schematic drawing of sample holder

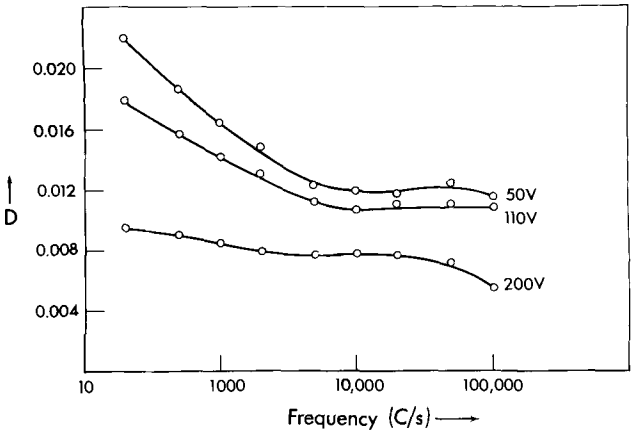

Fig. 2. Dissipation *vs.* frequency for barrier layer films with different anodizing voltages.

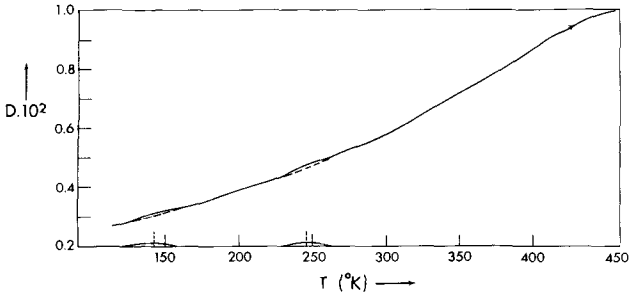

Fig. 3. Temperature *vs.* dissipation for a barrier layer film, anodized in a 3% ammonium tartrate solution at 100V. Measured at 1 kHz in vacuum.

Measurements made with a sodium sulfate solution counterelectrode gave results, agreeing with Dekker and Urguhart (6), that the solution penetrates the porous layer, and the measured capacity depends only on the underlying barrier layer. Results using the evaporated aluminum electrode depend on the porous layer as well, and show the sensitivity to humidity

[1]Present address: Laboratorium voor Technische Natuurkunde, Universiteitscomplex Paddepoel, Groningen, The Netherlands.

Key words: dielectric properties, aluminum oxide, anodic layer, dissipation, hydration.

noted by Jason and Wood (2). This was attributed by them to adsorption of water and consequential conduction down the walls of the pores.

To study the properties of the oxide layer without pore wall conduction, measurements must be made in high vacuum. Figure 4 shows typical results for the variation of dissipation with temperature below room temperature. Similar results to those of the barrier layer oxide were obtained. In one case, peaks occurred at 140° and 214°K for measurements at 1 kHz and at 235° and 270°K for measurements at 50 kHz. As shown in Fig. 4, partial sealing of the oxide with hot water increased the background dissipation with only little increase in the dissipation peaks. Although these dissipation peaks, as well as those for the barrier layer oxides, are small, they occur consistently and the temperature shift with frequency is appropriate for processes with activation energies between 0.1 and 0.5 eV.

Peaks of a much greater magnitude were observed above room temperature with the porous oxide. Figure 5 shows the dissipation factor *vs.* temperature for several frequencies. Two peaks occur, but only one varies in position on the temperature scale with frequency. The higher temperature peak remains at about 405°K.

There is a considerable irreversible decrease in the dissipation due to the first heating cycle. The curves show no hysteresis on further heating, however. It was difficult to remove the background from the lower temperature peak to determine an activation energy, due to overlap with the second peak. The assumption was made (to be discussed later) that the second peak was a decrease in dissipation at 405°K, on a background which increased with temperature. Figure 6 is an example of this background removal.

Figure 7 is an Arrhenius plot of the log frequency *vs.* reciprocal temperature of this dissipation peak. An activation energy of 0.76 eV was obtained.

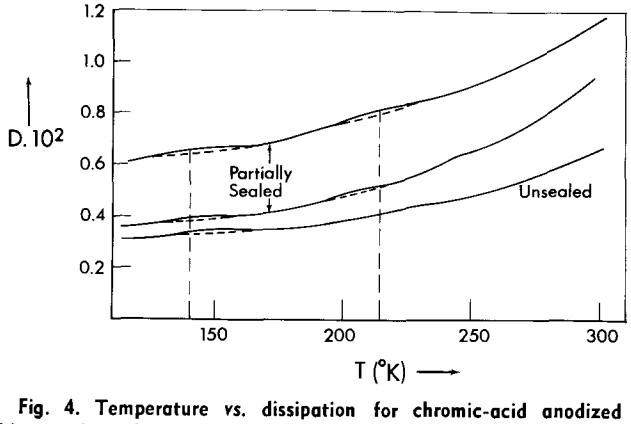

Fig. 4. Temperature *vs.* dissipation for chromic-acid anodized films with different sealing treatments. Measured at 1 kHz in vacuum.

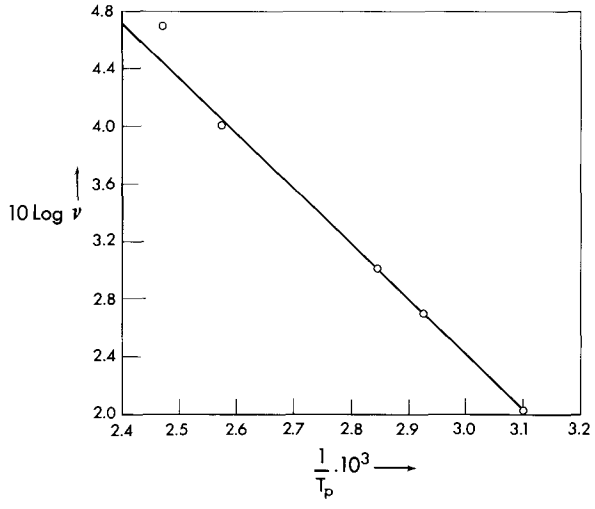

Fig. 7. Log ν *vs.* $1/T_p \cdot 0.10^3$ plot for anodized and partially "sealed" films. T_p = peak temperature.

Discussion

McMullen and Pryor measured the dielectric loss for a barrier layer film at low temperatures (4). Their data also show a peak at about 230°K which they do not discuss. These peaks may be the same as those found here. In addition, they find a large peak just below room temperature in ambient atmosphere which disappears under vacuum. No such peak was found in the present work. However, their apparatus has a thick porous anodic film in parallel with the barrier layer film as an insulator. At high humidities the pore walls would conduct well, and the impedance of this film may become low enough to affect their measurements.

The physical identity of the two species causing the two low temperature peaks is not apparent from the data since they are not very sensitive to humidity or heat treatment. If they are hydroxide groups, then they are stable above the 550°K outgassing used here. Boehmite is stable above this temperature (7).

The 0.76 eV dissipation peak at high temperatures for the porous oxides seems to correspond to the peak for Boehmite for which Mata-Arjona and Fripiat found an activation energy of 0.68 eV (7). Porous oxides do contain some moisture (8). The 0.76 eV relaxation peak is therefore assigned to hydroxide ions as was proposed for Boehmite (7).

It is suggested that the dissipation peak at 405°K is in fact a decrease in dissipation on a rising background curve. This can be due to an order-disorder transition (9). Such an effect was sought by Wickershen and Korpi for Boehmite in dielectric constant measurements (10). Apparently this effect shows up here in the more sensitive dissipation measurements and not in the measurements of dielectric constant.

Diffusional Processes in Solid Electrolyte Fuel Cell Electrodes

R. L. Zahradnik

Department of Chemical Engineering, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213

ABSTRACT

A mechanism is proposed to account for the polarization voltage loss encountered in the electrochemical oxidation of CO at porous, high-temperature, solid-electrolyte fuel cell anodes. The mechanism involves the transport of gaseous CO and oxygen ions to reaction sites, followed by slow electrochemical reaction. The mechanism results in an involved polarization expression, which under certain conditions simplifies to the familiar Tafel form.

High-temperature fuel cells employing either calcia or yttria stabilized zirconia electrolyte have received considerable attention as potential power generators using gaseous fuels derived from coal (1, 2). At the 1000°C operating temperature of solid electrolyte fuel cells, such coal-derived gases as well as prospective fuels such as reformed hydrocarbons will contain large amounts of CO. Oxidation of CO at metallic and mixed oxide fuel cell anodes, however, is accompanied by large polarization losses (3). The presence of hydrogen reduces this loss somewhat, but it is not clear that either the high current densities which are expected from such cells or the complete combustion of CO to CO_2 can be achieved without incurring severe voltage losses. For this reason, it is important to understand in a fundamental way the irreversibilities which occur at solid-electrolyte fuel cell anodes. The purpose of this paper is to propose a possible scheme by which this polarization occurs and to derive the equations which quantitatively relate polarization voltage loss to electrode current density.

Many such analyses for liquid electrolyte fuel cell electrodes have appeared in the literature, and a complete review of the work in this area is not presented here. The pioneering work of Will should be mentioned, however, since it was the first to treat partially immersed electrodes and proposed a method for treating the electrolyte meniscus which considerably clarified the polarization phenomena (4). Will's work has been reviewed and generalized by Lightfoot, who included effects of convection as well as concentration polarization in his analysis (5).

Not all liquid electrolyte fuel cell electrodes follow the thin-meniscus model, however, and analyses of flooded porous fuel cell electrodes have been made, *e.g.* Brown and Rockett (6).

With a liquid electrolyte, it is possible for the gaseous species participating in the electrode reaction to reach the electrode reaction site either through a meniscus film or bulk electrolyte phase, and the reported polarization studies analyze the various ways this transport can occur. In the case of a solid electrolyte, however, such transport is impossible and alternate mechanisms must be responsible for electrode polarization. One possibility is for the reactants (CO and oxygen ions) to counterdiffuse to a mutually acceptable location somewhere on the electrode, and there react. In an earlier paper, Zahradnik analyzed this situation for a one-dimensional electrode (7). In this paper, the analysis is extended to cover two-dimensional effects. In order to simplify the analysis, the concept of a single, rectangular pore is introduced.

Key words: fuel cell, porous electrode, polarization (and/or) overvoltage, diffusion, limiting current, Damkohler number.

A Single Rectangular Pore

Noble metals, nonnoble metals, conducting oxides, and mixtures of oxides and metals have been used at one time or other as high-temperature fuel cell anodes (3). The physical structure of all these materials has been porous, and hence it is reasonable to idealize the structure as a single pore, normal to the electrolyte surface—Fig. 1. In order to simplify the ensuing mathematics and notation, the pore is considered to be rectangular and of infinite extent in the direction normal to the paper. The distance coordinate y is introduced, directed normal to the electrolyte, with origin at the electrode-electrolyte interface and value $y = b$ at the bulk gas phase boundary. The distance coordinate x is introduced, directed parallel to the electrolyte. Its origin is at the centerline of the electrode and it has the value $x = a$ at the pore wall.

The electrode is taken to operate isothermally, and the electrochemical reaction between CO and oxygen

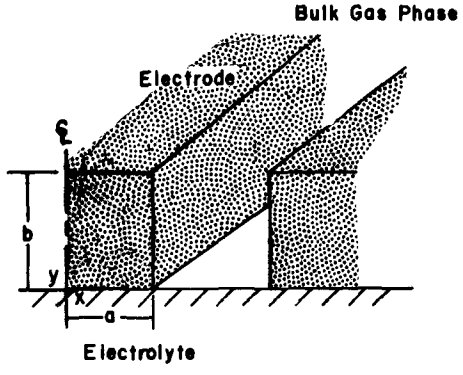

Fig. 1. Idealized pore structure

ions is assumed to occur at the walls of the pore

$$CO + O^{=} \rightarrow CO_2 + 2e^{-} \qquad [1]$$

The rate at which this reaction proceeds per unit of pore wall area, in units of current, is symbolized by $i(y)$.

A number of kinetic expressions have been proposed for $i(y)$ but no generally accepted kinetic description is available (8, 9). At the conditions under which high-temperature solid electrolyte fuel cell anodes operate, however, it seems likely that the following, often proposed, equation is applicable (10)

$$i(y) = 2\mathbf{F}k\, e^{-\left(\frac{\Delta F^{\neq} + \alpha 2\mathbf{F}V}{RT}\right)} [CO]\,[O^{=}] \qquad [2]$$

where k = Constant, including units of rate
$\Delta F^{\neq}$ = Standard state free energy of activation
R = Gas law constant
T = Temperature
α = Fraction of generated voltage which contributes to increasing free energy of activation

Equation [2] represents only the forward rate of reaction [1]. Under most conditions of high-temperature fuel cell operation, the forward rate alone is satisfactory, although provision to include a term for the reverse reaction could be made should electrode operation be near the equilibrium condition of reaction [1].

It is assumed that the oxygen ions diffuse from the electrode-electrolyte interface under the influence only of a concentration gradient. That is, the electrode is assumed to be equipotential, so that no voltage gradient is present as an additional driving force. Under these assumptions, the oxygen ion flow is described by the following steady-state conduction equation

$$\frac{\partial^2[O^{=}]}{\partial x^2} + \frac{\partial^2[O^{=}]}{\partial y^2} = 0 \qquad [3]$$

The nature of the oxygen ion flow need not be completely specified at this time. That is, the diffusion is assumed to be bulk diffusion, such as lattice, grain boundary, or short-circuit diffusion, but no further specification is made. In any case, Eq. [3] would have a similar form (11, 12). Also, the diffusivity of oxygen ions has been assumed to be the same in both the x- and y-direction.

The boundary conditions which apply to Eq. [3] are: at

$$x = 0, \quad \frac{\partial[O^{=}]}{\partial x} = 0 \qquad 0 < y < b \qquad [4]$$

$$y = b, \quad \frac{\partial[O^{=}]}{\partial y} = 0 \qquad 0 < x < a \qquad [5]$$

$$y = 0, \quad [O^{=}] = [O^{=}]_e \qquad 0 < x < a \qquad [6]$$

$$x = a, \quad -D_O = \frac{\partial[O^{=}]}{\partial x} = K[CO]_b\,[O^{=}] \qquad 0 < y < b \qquad [7]$$

where K = A convenient kinetic parameter, representing the terms premultiplying the concentrations on the right-hand side of Eq. [2]
$D_{O^{=}}$ = Diffusivity of $O^{=}$

Equation [4] states that there is no flux across the electrode centerline; Eq. [5] similarly denies oxygen ions admission into the bulk gas phase. At the electrode-electrolyte interface, the oxygen ions have a constant concentration, $[O^{=}]_e$—Eq. [6]. Equation [7] equates the diffusive flux of oxygen ions to the flux due to chemical reaction. In this equation, the concentration of CO is taken to be equal to $[CO]_b$, the bulk gas phase composition. This assumption is reasonable in the light of the high value of diffusivity CO has at cell operating temperatures. However, if so desired, provision could be made to account for small changes in CO concentration due to changes in current level—in the manner used by Zahradnik in his one-dimensional analysis (7). This is not done here, however, since its effect is small.

Solution to Electrode Equations

The solution to the system of Eq. [2]-[7] can be expressed in terms of a Fourier series; the result is from Carslaw and Jaeger (13) (p. 168, Eq. [17])

$$[O^{=}] = 2K\,[O^{=}]_e\,[CO]_b \sum_{n=1}^{\infty} \frac{\cos \alpha_n x \cosh \alpha_n (b - y)}{[(\alpha_n^2 + D_m^2)\, a + D_m] \cos \alpha_n a \cosh \alpha_n b} \qquad [8]$$

where α_n represents the solution to the following

$$\alpha_n a \tan \alpha_n a = D_m = \frac{K\,[CO]_b\,[O^{=}]_e}{\frac{D_{O^{=}}\,[O^{=}]_e}{a}} \qquad [9]$$

The right-hand side of Eq. [9] is the ratio of the maximum reaction rate to a characteristic diffusion rate of $O^{=}$. Such a ratio represents an electrode Damkohler number, and is symbolized as D_m.

The total pore current per unit of length normal to the xy-plane, I, is obtained by integrating the oxygen ion flux at $x = a$ over the entire height of pore wall

$$I = \int_0^b -D_{O^{=}} \frac{\partial\,[O^{=}]}{\partial x}\bigg|_{x=a} dy$$

$$I = \int_0^b D_{O^{=}}\, 2K\,[O^{=}]_e\,[CO]_b \sum_{n=1}^{\infty} \frac{\tan \alpha_n a \cosh \alpha_n (b - y)}{[(\alpha_n^2 + D_m^2)\, a + D_m] \cosh \alpha_n b}\, \alpha_n\, dy$$

This expression can be written as the ratio of I to $I_D = D_{O^{=}}\,[O^{=}]_e/a$, a characteristic oxygen ion flux

$$\frac{I}{I_D} = 2\, D_m^2 \left(\frac{a}{b}\right) \sum_{n=1}^{\infty} \frac{\tanh \alpha_n b}{\alpha_n a\,[\alpha_n^2 a^2 + D_m^2 + D_m]} \qquad [10]$$

Since it is the current-polarization relationship which is of most interest from a fuel-cell point of view, Eq. [10] can be modified slightly to indicate how these two quantities are related.

Current-Polarization Relationship

K is given explicitly by the following

$$K = 2\,\mathbf{F}k\, e^{-\frac{\Delta F^{\neq}}{RT}}\, e^{-\frac{2\alpha \mathbf{F}V}{RT}}$$

At this point it is convenient to utilize the fact that, on an IR free basis, electrode voltage, V, is given by the following thermodynamic relationship

$$V = E_t - \eta = -\frac{\Delta F^{\circ}}{2\mathbf{F}} - \frac{RT}{2\mathbf{F}} \ln \left\{ \frac{[CO_2]_b}{[CO]_b} [O^{=}]_e \right\} - \eta$$

where
η = Electrode polarization
ΔF° = Standard free energy change of reaction [1]

Hence, it is possible to relate D_m to polarization η

$$D_m = D_m^{0}\, e^{\frac{2\alpha \mathbf{F}\eta}{RT}}$$

where D_m^{0} denotes the value of D_m at zero polarization.

Figure 2 is a plot of $\ln (I/I_O)$ *vs.* $\ln D_m = \ln D_m^{0} + 2\alpha\mathbf{F}\eta/RT$, for various aspect ratios.

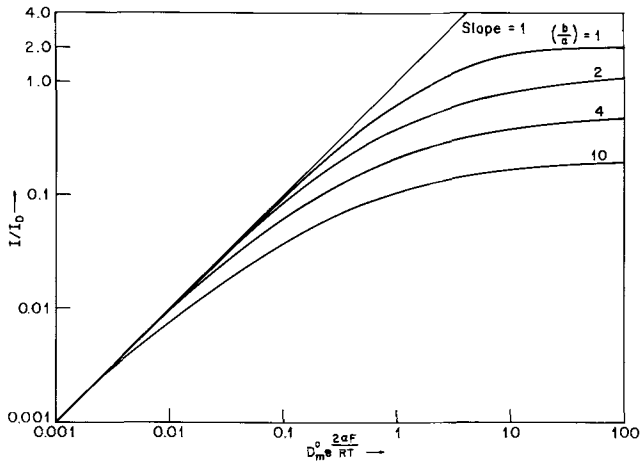

Fig. 2. Current-polarization relationship

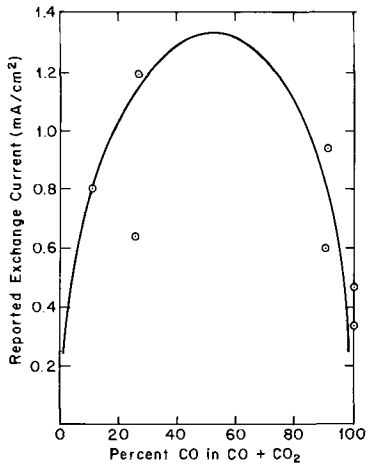

Fig. 3. Reported values of exchange current as function of per cent CO for sintered platinum electrodes (1). Curve is predicted by Eq. [12].

Notice that for small values of current these two expressions are equal, suggesting that

$$\ln I/I_D = \ln D_m{}^0 + \frac{2\alpha \mathbf{F}\eta}{RT} \text{ (small } I\text{)}$$

If $D_m{}^0\ I_D$ is denoted as an exchange current, I_0, this equation reduces to the familiar Tafel form

$$\eta = \frac{RT}{2\alpha \mathbf{F}} \ln I/I_0 \qquad [11]$$

Archer, Elikan, and Zahradnik have obtained polarization data for zirconia-based fuel cells equipped with sintered platinum anodes operating on CO-CO_2 mixtures (3). They report a successful fit of their data using Eq. [11]. Although a consistent value of $\alpha = \frac{1}{2}$ was obtained over a range of compositions, the authors were unable to draw any firm conclusions about trends of the exchange current with composition. However, a simple dependency of (I_0) on bulk gas phase composition may be obtained

$$(I_0) \propto [CO]_b{}^{1-\alpha}\,[CO_2]_b{}^{\alpha}$$

Consider

$$[CO_2]_b = (1 - y_{CO})\ C_b$$

and

$$[CO]_b = (y_{CO})\ C_b$$

where C_b = Bulk gas phase concentration
y_{CO} = Mole fraction CO in bulk gas phase

Then if the value of α is taken to be $\frac{1}{2}$, for a constant C_b, the proportionality between (I_0) and y_{CO} is given by the following

$$\boxed{(I_0) \propto [y_{CO}(1 - y_{CO})]^{1/2}} \qquad [12]$$

The data reported by Archer, Elikan, and Zahradnik are plotted in Fig. 3 *vs.* bulk gas phase percentage of CO in the CO + CO_2 mixture. The relationship suggested by Eq. [12] is also plotted in Fig. 3, with the proportionality constant adjusted to give a best fit to the data. The agreement is quite reasonable, considering the variety of conditions under which the data were obtained. Unfortunately, no data were reported in the 50% CO range.

As I increases, the current-polarization curve starts to deviate from the linear relationship. No other region is encountered where an equation of the Tafel form is a good approximation. This conclusion is different from the one based on a one-dimensional counter diffusion (7), where a second region was observed in which an equation of the Tafel form served as a good approximation to the exact equation.

In order to demonstrate that the current-polarization curve predicted by Eq. [10] does provide a good fit for

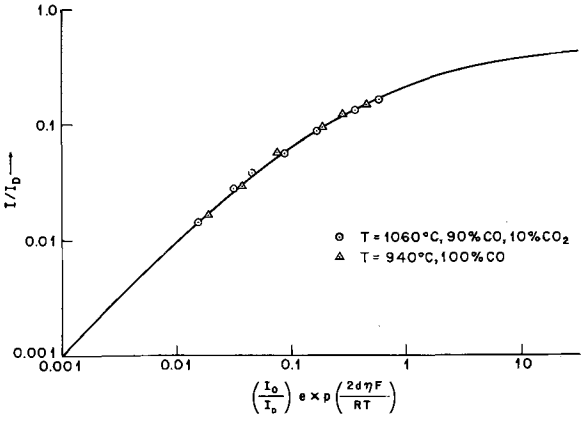

Fig. 4. Experimental data for sintered platinum electrodes (1). Curve is predicted from Eq. [10] with $(b/a) = 4$.

experimental data, some of the results reported by Archer, Elikan, and Zahradnik (3) are plotted in Fig. 4 in the format prescribed by Eq. [10]. The data were obtained at two temperatures, 940° and 1060°C, with a fuel of 100% CO and 90% CO plus 10% CO_2, respectively.

The curve derived from Eq. [10] which is used to correlate these data is for an aspect ratio $(b/a) = 4$. This ratio is felt to be reasonable for the sintered platinum electrodes used in the experiments. The sintering process causes the platinum to coalesce into individual particles whose mean diameter is about one third times the electrode thickness. If the pores are viewed as passages through a matrix of connected particles, then an aspect ratio of four to six would be expected.

The data reported in Fig. 4 were obtained with a test cell whose electrode area was 27.6 cm^2. From Fig. 3, it is noted that exchange current densities of about 0.3 and 0.6 mA/cm^2 can be expected for the 100% CO and the 90% CO fuels, respectively. This would correspond to I_0 values of 8 and 16 mA, respectively, and these were the values used to plot the data. The value of α was taken to be $\frac{1}{2}$.

For the 940°C, 100% CO data, the correlation was obtained with an I_D value of 1500 mA. The 1060°C, 90% CO data was correlated with an I_D value of 1700 mA. It can be seen that only the low current points are in the region of the Tafel kinetics.

The limiting current, I_L, can be obtained from Eq. [10] by letting D_m become large. The result may be expressed as

$$I_L = \left(\frac{D_{O^=}[O^=]_e}{b}\right) \lim_{D_m \to \infty} 2D_m \sum_{n=1}^{\infty} \frac{\tanh\left[(b/a)\,\alpha_n a\right]}{\alpha_n a[\alpha_n^2 a^2 + D_m^2 + D_m]}$$

The first bracketed term shows the limiting current to be inversely proportional to electrode thickness as expected. The exact constant of proportionality depends on the electrode aspect ratio (b/a) as seen from the second term. For (b/a) values larger than 2, this last term is relatively insensitive to (b/a) however.

The data shown in Fig. 4 correspond to limiting currents of 900 mA at 940°C and 1000 mA at 1060°C. While these values are quite low on a current density basis, it should be pointed out that the test cell did employ a thick electrode and that other cells have been operated with much thinner electrodes and consequently much higher limiting currents.

Discussion

The analysis presented here allows a number of interesting conclusions to be drawn about solid electrolyte fuel cell anodes. At low current levels, polarization is controlled by slow chemical reaction, and familiar Tafel behavior is observed. As current increases, the slope of the ln I *vs.* η curve decreases continuously, and no other characteristic region is noted until the limiting current is reached.

Since the object of a properly designed electrode is to support large current densities while sustaining only small polarization losses, it is clear that such an electrode should have large $D_m{}^0$. This requirement means that the kinetics of the electrochemical reaction [1] should be fast. The data reported for platinum electrodes indicate that such is not the case for platinum. However, other materials are suitable as anodes, and one criterion in their selection should be the rate at which reaction [1] proceeds on their surface.

If an anode material of sufficient catalytic level, either natural or induced by special treatment, can be found, the fuel cell behavior would be characterized by large $D_m{}^0$ values. It is interesting to observe what happens to the current distribution in such cases. The net current at any electrode position, $I(y)$, may be obtained directly by differentiating the expression for $[O^=]$, and is given by the following equation

$$\frac{I(y)}{I} = 1 - \sum_{n=1}^{\infty} \frac{\sinh \alpha_n b\,(1-y)}{\alpha_n a[\alpha_n^2 a^2 + D_m^2 + D_m]} \qquad [13]$$

For small values of D_m, this equation is nearly linear (Fig. 5). However, as D_m increases, the relationship is no longer linear, but distinctly curved, as shown in Fig. 5. At high values of D_m, the current is generated largely near the electrode-electrolyte interface and the distribution is distinctly nonuniform. Similar distributions are found along the meniscus of a liquid electrolyte fuel cell electrode (8). However, in the case of solid electrolyte fuel cell anodes, the high current densities that are developed in the vicinity of the electrode-electrolyte interface will produce large heat effects, due to resistance heating in the electrode, which may in turn lead to rupture of the electrode-electrolyte contact. A careful analysis will have to be made of the local heat effects produced in electrodes capable of supporting high current densities.

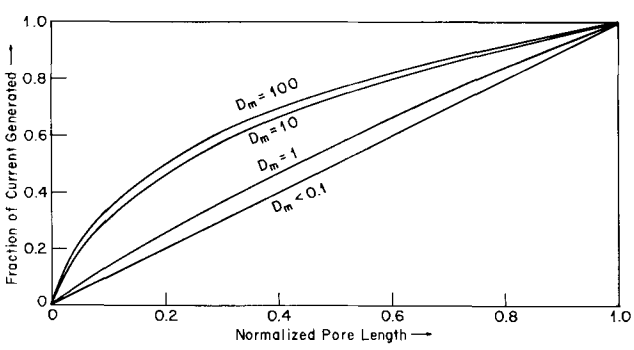

Fig. 5. Current distribution as function of electrode Damkohler number for aspect ratio = 1.

The Corrosion of Titanium Carbide

R. D. Cowling and H. E. Hintermann*

Laboratoire Suisse de Recherches Horlogères, Neuchâtel, Switzerland

ABSTRACT

In 2*N* H_2SO_4, the anodic dissolution of titanium carbide begins at about 0.8V (SHE). Trivalent titanium ions could not be detected in the nitrogen-saturated solution, although this does not rule out the possibility that Ti(III) is formed in the dissolution reaction. However, at 0.8V oxidation to Ti(IV) would readily occur. The results of potentiostatic and galvanostatic experiments indicate that the subsequent passivation of the electrode, which occurs between 1.2 and 1.7V when it is polarized potentiostatically, is due to Ti(IV) oxide. At potentials above 1.7V, oxidation to Ti(VI) occurs. During the initial dissolution of the carbide, both CO and CO_2 were detected.

Although titanium carbide is an important refractory material, characterized by its extreme hardness and its relative inertness, very little attention has been given to its chemical properties. The stability of the Group IV, V, and VI transition metal carbides toward acid and alkali solutions has been examined (1), but, while a patent exists (2) for an anode incorporating titanium carbide, there appear to have been no studies on the anodic behavior of this material. It was felt that one point of interest in such a study would be to determine the nature of products arising from the bonded carbon. Thus Ervin *et al.* (3), in describing the use of titanium carbide anodes for the extraction of titanium metal in molten salt electrolysis, state that the carbide behaves during electrolysis as though it were a metal with high carbon content. From this, one might expect dissolution of titanium, leaving free carbon. On the other hand, various attempts have been made to describe the bonding in carbides (4-6), and it is more reasonable to suppose that the carbon gives rise to at least one gaseous corrosion product.

It was the aim of the present study to investigate the behavior of titanium carbide anode in sulfuric acid solution, to identify the dissolution products, and to define the limit beyond which this material cannot be regarded as inert.

Experimental

Titanium carbide was deposited onto steel disks (C, 1.4%; Cr, 1.3%) by chemical vapor deposition from a mixture of hydrogen, methane, and titanium tetrachloride vapor at high temperature (7).

The nature of the deposit was confirmed by x-ray diffraction studies. Unfortunately this method cannot be used to determine the stoichiometry of the carbide, due to the high degree of scatter in the measured lattice parameter. Chemical analyses have been performed on representative samples of carbide, in order to obtain the stoichiometry. The analysis of metallic impurities was performed by spectrographic and atomic absorption methods. Determination of oxygen and nitrogen was carried out by vacuum extraction and chemical methods, respectively, and of total carbon by oxidation to CO_2 which was subsequently determined by coulometric titration. Free carbon was determined by dissolving the sample in HF and HNO_3, filtering the free carbon on asbestos and burning it to CO_2 in a tube furnace.

Compositions vary between nearly stoichiometric ($TiC_{0.98}$) and about $TiC_{0.9}$. The variation must be due to experimental factors which may be controllable (temperature, gas composition, *etc.*) or not (aging of the apparatus). A systematic study of this problem has not yet been undertaken. Analysis of the impurities showed about 4% each of iron and chromium, which arise either by diffusion from the substrate or by high-temperature attack on the reactor walls by the gas stream. The level of these impurities is not high enough to affect the general characteristics of the corrosion behavior of the carbide, but uncertainties in the stoichiometry and purity made a detailed kinetic study impossible.

Anodes.—Deposits of titanium carbide 10-15 μm thick were obtained on disks of 2 mm thickness. The carbide on one surface was planed away, and the steel then dissolved in warm hydrochloric acid, leaving flakes of titanium carbide.

Cell and instrumentation.—Experiments were performed in a simple cell at room temperature, using Reagent Grade acid solutions. A large cylindrical platinum counterelectrode was used. The basic instrument for both potentiostatic and galvanostatic experiments was a Tacussel[1] type PRT 2000 potentiostat. For potential scans this was coupled to a drive unit, type Servovit 2, and current-potential curves were obtained directly on a Sefram[2] XY recorder.

Results

Potentiostatic measurements.—Figure 1 shows a typical polarization curve for TiC in 2*N* H_2SO_4, obtained at a potential scan rate of 10 mV/min. At about 2V,[3] rapid dissolution of the electrode occurs. The passivation of TiC at about 1V is a process which, at a low rate of scanning, undergoes reactivation when the potential is made progressively less positive. At a higher rate of scan, little reactivation occurs. This is shown in Fig. 2. The *p*H-dependence of the potential of the peak maximum was found to be -0.045 ± 0.005 mV/*p*H unit, the potential becoming more positive as the *pH* decreases. Although plots of log *i* *vs.* *E* during the initial stages of dissolution showed a well-defined Tafel relationship, the slopes were not sufficiently constant to enable reliable kinetic data to be extracted.

Galvanostatic measurements.—When a titanium carbide electrode was charged at constant current in the range 2×10^{-3} to 1×10^{-2} A cm^{-2} in 0.1*N* H_2SO_4, two plateaus in the potential-time curve were found. These occurred at about the same potentials as those at which the two active regions were found during potentiostatic polarization. A typical *E/t* curve is shown in Fig. 3. The process giving rise to the first plateau was assumed to have finished after a time, τ, which was arbitrarily marked by the intersection of two straight lines, extrapolated from the region of rising potential and from the second plateau, in the

manner indicated in Fig. 3. At each current, three charging curves were obtained, each one after prior polarization to the point of hydrogen evolution, and the mean value of τ recorded. At any one current, the reproducibility in the values of τ was generally excellent. Typical results are shown in Table I.

Identification of the dissolution products.—From the titanium.—Several attempts were made to detect the presence of Ti(III) in the solution during the anodic dissolution of titanium carbide. In a standard solution of Ti(IV) in 2N H_2SO_4, containing 5 ppm of Ti and saturated with nitrogen, a platinum wire electrode was polarized cathodically to the point of vigorous hydrogen evolution. After about 5 min, the electrode was charged with a constant anodic current of 3 μA. The *E/t* curve showed a plateau at 0.47V due to the oxidation of Ti(III) to Ti(IV). A titanium carbide electrode was then charged at 500 μA in 2N H_2SO_4 saturated with nitrogen. After a sufficient time had elapsed to put a detectable amount of titanium into solution, a platinum wire electrode in the solution was charged anodically at 3 μA, and the *E/t* curve recorded. No plateau corresponding to the oxidation of Ti(III) could be found. Thus, while this test was not intended to give a quantitative microanalysis of Ti(III), it indicated at least that the concentration of this ion did not build up during the dissolution to a level which was comparable to the concentration of titanium in the solution, and that therefore this titanium is almost certainly in its tetravalent oxidation state.

A similar attempt to detect the presence of Ti(III) as a result of the dissolution of TiC was made by potentiometric titration with a Ce(IV) solution. This also gave a negative result.

From the bonded carbon.—A titanium carbide electrode was charged galvanostatically at 100 μA for 6 days, in 5 ml of 2N H_2SO_4 contained in a tube sealed with a silicon rubber bung. A platinum wire was used as the cathode. The cell voltage was recorded continuously, and was always less than 1.3V. At the end of the charging period, samples of the gas above the solution were taken by direct injection of a 1 ml syringe. This gas was analyzed with a permanent-gas chromatograph,[4] using a silica gel, and a molecular sieve, column. The presence of both CO_2 and CO was confirmed.

Repeat experiments were performed on single crystals of titanium carbide, and in every case both gases were detected.

Discussion

The equilibrium potential-pH diagram for the system titanium-H_2O shows (8) that the most stable species at pH = 0 and at potentials in the region of 1V is the tetravalent ion TiO^{2+}. In fact, at this pH the domain of stability of this ion extends from about zero to about 1.8V. As all attempts to detect the presence of Ti^{3+} during the anodization of titanium carbide failed, it is reasonable to suppose that the initial dissolution produces TiO^{2+}. The actual mechanism cannot be elucidated at this stage, although further work is in progress with pure single crystals of the carbide.

It is quite possible that the dissolution actually produces Ti^{3+}, but that this species is subsequently oxidized to TiO^{2+} at the surface of the corroding

[4] H. Feichtinger, Schaffhausen, Switzerland.

electrode. From Pourbaix (8), the equilibrium potential for the redox couple Ti^{3+}/TiO^{2+} at $pH = 0$ and at $TiO^{2+}/Ti^{3+} = 6$ is about 0.46V. Since the potential of the titanium carbide is above 0.8V during its dissolution, it is clear that any Ti^{3+} formed would be quickly oxidized to TiO^{2+}. Thus, while the present work cannot distinguish whether titanium carbide is oxidized directly to Ti(IV) or whether this occurs through the intermediate formation of Ti(III), the net result is clearly an oxidation to the tetravalent state. Further experiments are planned to examine this question more fully, with the aid in particular of a rotating ring-disk electrode, and it is hoped to report these results in a further communication. It is therefore proposed here that the passivation observed between about 1.2 and 1.7V is due to a tetravalent oxide (or hydrated oxide) of titanium. The peak at about 1V in Fig. 1 can thus be attributed to the sequence

$$TiC(s) \rightarrow TiO^{2+}(aq) \rightarrow TiO_2 \cdot H_2O(s)$$

Figure 4 shows that the formation of the oxide is kinetically possible at potentials above 0.91V. At this point, the i/t curve at constant potential first shows a gradual decay, due to the depletion of active surface by the formation of solid oxide.

During the second active region, one would then expect the oxidation to produce Ti(VI) ions. The potential at which this region begins is in fact in good agreement with that indicated by Pourbaix for the process $TiO_2 \cdot H_2O \rightarrow TiO_2^{2+}$. Direct experimental evidence is given by the fact that, during the dissolution of titanium carbide at about 2V, the solution gradually becomes yellow. It shows exactly the same absorption maximum (410 nm) as the yellow solution formed by the reaction of titanium(IV) ions with hydrogen peroxide, which is due to the ion TiO_2^{2+}.

Figure 2 confirms that this oxide is relatively soluble. Reactivation on the reverse scan occurs only at slow sweep speeds; at higher scan rates, dissolution of the oxide film is not sufficiently fast to allow reactivation. It would appear, then, that passivation is not due to anhydrous TiO_2 (rutile), which has a very low solubility, but rather to the hydrated oxide TiO_2 H_2O.

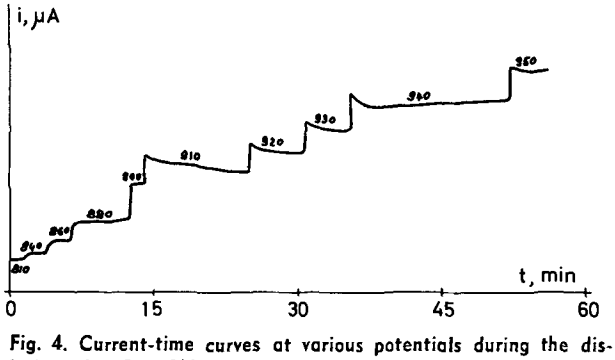

Fig. 4. Current-time curves at various potentials during the dissolution of TiC in 2N H_2SO_4; numbers refer to potential in millivolts.

The gaseous corrosion products being CO_2 and CO, the initial dissolution may proceed according to the reactions

$$TiC + 3\,H_2O = TiO^{2+} + CO_2 + 6\,H^+ + 8e^-$$

and

$$TiC + 2\,H_2O = TiO^{2+} + CO + 4\,H^+ + 6e^-$$

for which dE/dpH is -0.044 and -0.039V, respectively. This corresponds with the observed pH-dependence of -0.045 ± 0.005V.

The potentiostatic experiments therefore indicate that the initial corrosion of TiC produces TiO^{2+}, and that at a certain potential (0.910V in 2N H_2SO_4) the formation of solid oxide ($TiO_2 \cdot H_2O$) begins. At about 1.05V, the rate of formation of oxide exceeds the rate of its dissolution, and the electrode becomes passivated. At about 1.75V, oxidation to TiO_2^{2+} occurs, and severe corrosion of the TiC follows.

This picture is confirmed by the galvanostatic experiments. The charging curve shown in Fig. 3 contains only two plateaus, of which the potential of the first clearly corresponds to the dissolution of TiC as TiO^{2+}. In general during such galvanostatic charging, where the initial corrosion product is freely soluble, the current density, i, and the time, τ, required for passivation to occur are related by: $i\tau^{1/2}$ = constant. In the present case, although the transition times were very long and were rather arbitrarily determined, this relationship held reasonably well above about 6×10^{-3} A cm^{-2} (see Table I).

The second plateau in Fig. 3 occurs at a potential which corresponds closely to that found potentiostatically for the oxidation to Ti(VI). The absence of an intermediate plateau is further evidence that the net reaction during the first active region is an oxidation to the tetravalent state of titanium.

A Comparison of Various 24K Gold Electrodeposits

S. E. Craig, Jr.,* R. E. Harr,* J. Henry,[1] and P. Turner[2]

Chemical Engineering, School of Engineering, College of Engineering Sciences, Arizona State University, Tempe, Arizona 85281

ABSTRACT

Thick electrodeposits of 24K gold were prepared from 14 types of plating solutions in both new and replenished-used conditions. The deposits were examined by x-ray, scanning electron microscope, gravimetric, and electrical techniques. It was found that the purity, microstructure, and apparent density were functions of the plating solution type and age. The crystal lattice constants were found to be independent of both type and age.

Deposit Preparation

Fourteen types of plating solutions were selected as representative of modern commercial plating practice. They contained 8-15 g/liter gold and were operated at 3 mA/cm^2. The bath components are given in Table I. The used baths were taken from various production lines. They had all been "turned over" at least 10 times. The amount of use and degree of contamination could not be precisely determined for these baths. However, a partial determination is given in Table III. Before using the old baths, they were filtered, analyzed, and regenerated by adjusting the pH, density, and gold concentration to the nominal values.

Plating was accomplished in a vigorously agitated 4 liter, constant-temperature tank. The anodes were platinum-plated titanium and had approximately 5 times the area of the cathodes. During plating, small quantities of gold were periodically added to the bath to insure that the gold concentration never fell below 90% of its nominal value. The cathodes were copper plates 2.5 x 5 cm. One side of each cathode was mirror smooth while the other side had a fine mat finish. Four cathodes were used for each bath and the gold was deposited on both sides of each cathode. Immediately after deposition, the samples were cut and the copper etched away with nitric acid. The samples were ultrasonically washed in water, trichloroethylene, and methanol, dried, and stored for later examination.

[2] Present address, Texas Instruments, Inc., Dallas, Texas.
Key words: gold, electrodeposits, purity, crystal structure, resistivity, density.

The deposits were very thick (127 μm) so that effects from the bath could be separated from effects of the copper substrate.

The properties investigated were appearance, density, purity, crystal structure, and preferred orientation. In all cases, the samples from the smooth side of the copper cathodes had the same characteristics as those from the mat side of the copper.

Visual Appearance

The visual appearances of the solution side of the deposits are tabulated in Table I. Except for deposits from baths 1, 13, and 14, the surfaces were fairly similar in appearance. They differed only in relative brightness, smoothness, and fineness of the mat. Bath 13 produced unique, smooth, uniformly brown, dull surfaces. Bath 14 produced bright, shiny, perfectly smooth surfaces. The sparkly, bright appearance of the new hot cyanide deposit is due to its large, individual grains, while the dull, orange or brown color seen in deposits 8u, 11u, and 13 is caused by many small, individual grains. Deposits from used baths tended to be duller and smoother than deposits from new baths. The addition of brighteners and hardeners caused the baths to produce a finer mat surface.

The sides of the deposit adjacent to the copper cathodes were visual replicas of the copper surface even when viewed at 30,000X.

Density

The density of each sample was determined from its weight in air and in diiodomethane. The results, corrected for buoyancy of air and further corrected

Table I. Gold-plating deposits investigated

Bath* No.		Ref.	pH	Density ° Baumé	Visual appearance	Density g/cm^3
1n	Hot cyanide, phosphate, carbonate	(1)	12	15-30	Sparkly bright, very coarse mat.	19.22
1u					Very coarse mat.	19.13
2n	Citrate, phosphate in equal amounts	(2)	5.7-6.0	15-25	Bright, coarse mat.	19.26
2u					Dull, smooth.	19.25
3n	Same as 2 plus 25 g/liter polyamino acid com-		5.7-6.0	15-25	Bright, fine mat.	19.27
3u	plex				Dull, fine mat.	19.27

8n	Phosphate plus 6 g/liter hydrazine sulfate	(4)	5.5-6	14-16	Fine mat.	19.27
8u					Dull, fine mat, orangeish stains.	19.26
9n	Ammonium citrate plus 20 g/liter potassium	(5)	4.5	12	Very fine mat.	19.25
9u	chromium sulfate hardener				Dull, very fine mat.	19.27
10u	Borocitrate plus tetraethylene pentamine		5.0-6.0	20-25	Dull mat.	19.26
11u	Phosphate		6	17-18	Dull mat, orangeish stains.	19.27
12u	Phosphate		9-10	23	Dull, very fine mat.	19.27
13n	Gold sulfite with excess sulfate and sulfite	(6)	9-10	10-12	Very dull, smooth, brownish.	19.23
13u					Dull, smooth, orangeish.	19.25
14n	Same as 13 plus 15 ppm arsenic		9-10	10-12	Bright, shiny, very smooth.	19.13
14u					Bright, shiny, smooth.	19.24

* "n" and "u" signify new and used baths respectively.
Source of gold is $KAu(Cn)_2$ for all baths, except 13 and 14. All unspecified cations are potassium. The conducting salts had concentrations of approximately 100 g/liter as required to provide the lower Baumé for new baths and the higher for used baths.

to 25°C, are shown in column 7 of Table I. Most of these densities are within 0.2% of the density of pure gold. The exceptions are deposits from baths 1, 13, and 14. The low density of deposits from bath 1 is a result of the large pores within the deposits. The lower density of the deposits from bath 13 are caused by the 5 ppm sulfur contained in this deposit and by the microscopic voids barely visible in the photomicrographs. The arsenic in bath 14 further reduces the deposit density.

Electrical Resistivity—Procedure

Strips approximately 1 mm wide and 25 mm long were cut from the deposits and tested for electrical resistivity using a standard four-contact technique. The measurements were made at room temperature, 298°K, and liquid nitrogen temperature, 77°K. The main uncertainty in any individual resistivity measurement resulted from geometric uncertainties. However, when the resistivity at room temperature is divided by the resistivity of the same sample measured at liquid nitrogen temperature, all geometric factors cancel and a ratio. R_{298}/R_{77}, is obtained which is a function of the material only. This ratio does not include the effects of voids, pores, or electrically inactive inclusions. It does include the effect of chemical purity and, to a lesser extent, grain size.

This ratio serves as a sensitive indicator of relative chemical purity. However, it yields no information as to the concentration or types of impurities present.

White and Wood (7) report R_{298}/R_{77} equals 5.0 for 99.999% pure, vacuum-annealed gold. The highest value obtained in this work was 4.91. The difference probably represents a normal amount of dissolved gases, since most of these deposits are 99.999+% pure on a metallic basis.

Deposits from new baths without special additives (baths 1, 2, 7, 8) typically had a resistivity ratio of about 4.9, while used baths without special additives yield deposits with R_{298}/R_{77} in the range of 4.6-4.8. This reduction in purity is typical of the contamination obtained in normal industrial usage.

The high value of R_{298}/R_{77} for the deposits from bath 4 indicates an extremely low amount of codeposition of the brightener.

The addition of hardeners reduced R_{298}/R_{77} into the 4.6 range. However, as the baths were used and the special agents were depleted, the value of R_{298}/R_{77} for deposits from these baths approached the value from used baths without special additives.

Deposits from bath 13 had a lower value of R_{298}/R_{77} than expected. When these deposits were annealed to 400°C for 8 hr, the value of R_{298}/R_{77} increased to about 4.4 which still indicates a fairly high level of impurities. The exceptionally low resistivity level for deposits from bath 14 is a direct result of the 15 ppm arsenic included in the deposit.

The high value of the resistance ratio for deposits from used baths 3 and 10 indicates a very high purity of deposit. This purity can be traced to the low level of contamination of these baths and to the effectiveness of the chelating agent in preventing the deposition of contaminants.

Crystalline Structure

The crystalline structure of the deposits was examined by x-ray diffraction techniques, by Berg-Barret X-Ray Topology (8) and by Scanning Electron Microscopy (SEM). Prior to SEM examination, the sample cross sections were etched in a solution of 2.5% $(NH_4)_2S_2O_8$ and 2.5% KCN for 5-30 min at 25°C to bring out the crystal structure. Typical SEM photomicrographs are shown in Fig. 1 through 8.

Generally, the surface microstructure can be divided into four categories. The first is that produced by the alkaline cyanide baths (Fig. 1). These surfaces are composed of uniform, very large (60-120 μm) grains separated by open grain boundaries which penetrate deeply into the deposit. The second category includes most of the solutions. For this category, nonuniform grains of 5-50 μm are connected by distinct, tight-grain boundaries. Deposits from baths 4, 5, and 6, which contain a codepositing metallic brightener, show more small (1-5 μm) grains. In these first two categories, deposit surfaces made from new baths tended to contain many smooth planes, sharp angles, and straight lines identifiable with the underlying crystal structure (Fig. 2 and 4). Deposits made from used baths exhibited a less-organized structure made up of rounded surfaces and curved lines and often contained randomly distributed small (<1 μm) pits (Fig. 3 and 5). A notable exception to this is the deposit from bath 3 and to a lesser extent the deposit from bath 10, where the chelating agents have caused deposits from used baths to have the surface characteristics of new baths.

The third category of surface microstructure is exhibited by the pure sulfite bath, bath 13, Fig. 7. The grains are small and fairly uniform in size 0.2-5 μm). The grain boundaries are distinct and do not appear to

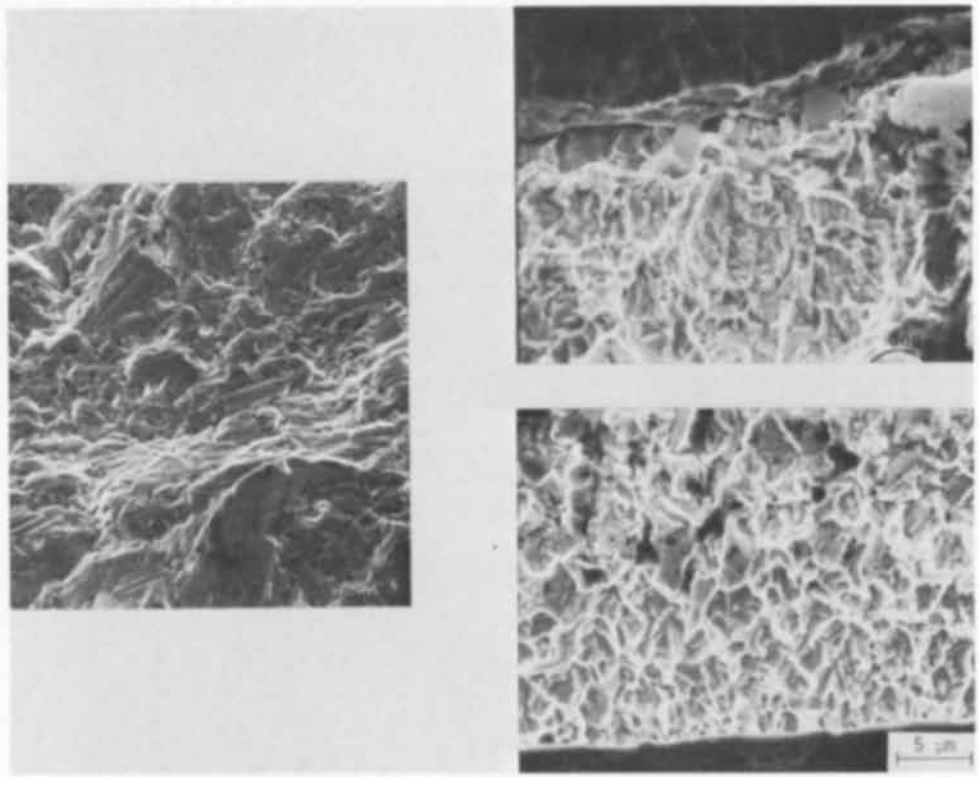

Fig. 3. SEM photomicrographs of deposit 2u.

be tightly closed. The fourth category is exhibited by bath 14. Surfaces from this bath were completely featureless even when viewed at 30,000X.

The SEM photomicrographs of cross sections may also be divided into four categories. The first is the coarse grain structure with deeply penetrating pores found in the hot cyanide bath deposits, Fig. 1. The second category includes the majority of the deposits and shows grains less than 0.5 μm in diameter on the substrate side of the deposit and crystallites 5-30 μm in diameter on the solution side of the deposits. Many of these crystallites can be followed for 20-60 μm through the deposit. Those deposits containing hardeners and brighteners, baths 4, 5, 6, and 9, fall at the lower end of the crystallite size ranges. Deposits from used baths tend to fall in the center of the range, while deposits from new baths which do not contain metallic impurities and from used baths containing chelating agents have crystallites in the upper end of the size range. The two anomalous structures in this group are from new solution 3 which appeared almost amorphous and from new solution 9 which exhibited a distinct columnar structure (Fig. 6).

The third category consists of deposits from the non-cyanide solution, bath 13, which had extremely small grains throughout the deposit (Fig. 7).

The last category is from the non-cyanide solution containing arsenic, bath 14. Cross sections of these

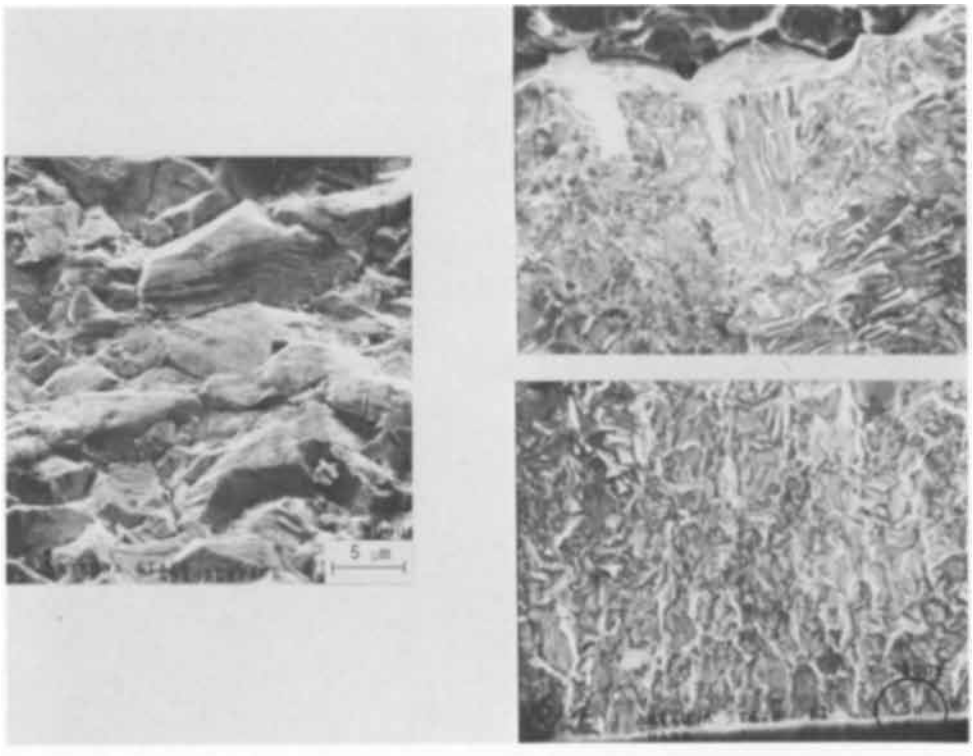

Fig. 4. SEM photomicrographs of deposit 4n. Deposits from 5n and 6n were fairly similar.

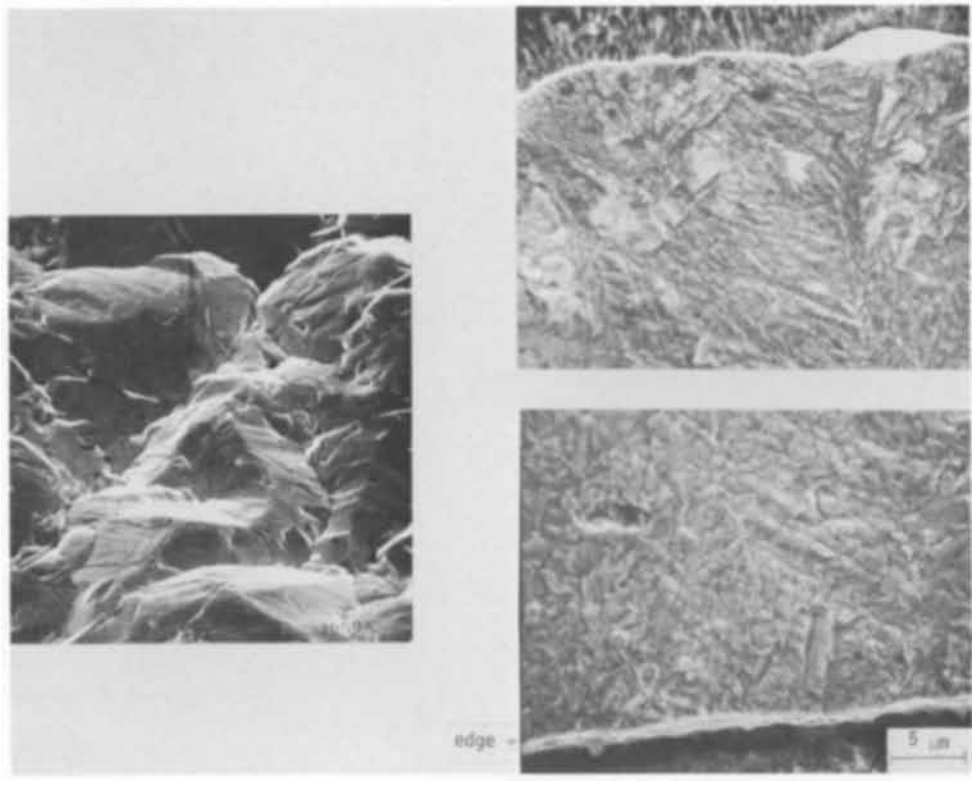

Fig. 5. SEM photomicrographs of deposit 4u.

deposits are amorphous in appearance (Fig. 8). The deposit from the new bath also shows a layered structure similar to those often found for alloy deposits (8). The deposit from a used bath shows only a random porosity.

The crystal lattice parameters were determined by x-ray back reflection. Within the limits of the equipment used, the lattice parameters were those for pure gold. Thus the density variations shown in Table I are caused by impurities, pores, inclusions, *etc.*, but not by lattice expansion.

X-ray line broadening was used to determine the average crystal size (9). This technique is precise for crystallite sizes under 0.1 μm, but for larger values the accuracy degenerates quickly and only a lower limit can be placed on the size. The results of the line-broadening measurements are shown in columns 3 and 4 of Table II.

Berg-Barrett X-Ray Topology (10) was used to determine the maximum crystallite size. With the film used, crystals larger than 3 μm were resolved. The results are shown in parentheses in columns 3 and 4 of Table II. Where values are not reported, no individual crystals could be resolved by this technique.

The first crystals to nucleate from new baths not containing metallic impurities (baths 1, 2, 3) grew to average sizes greater than 0.1 μm. However, the first crystals to grow from all other baths were much

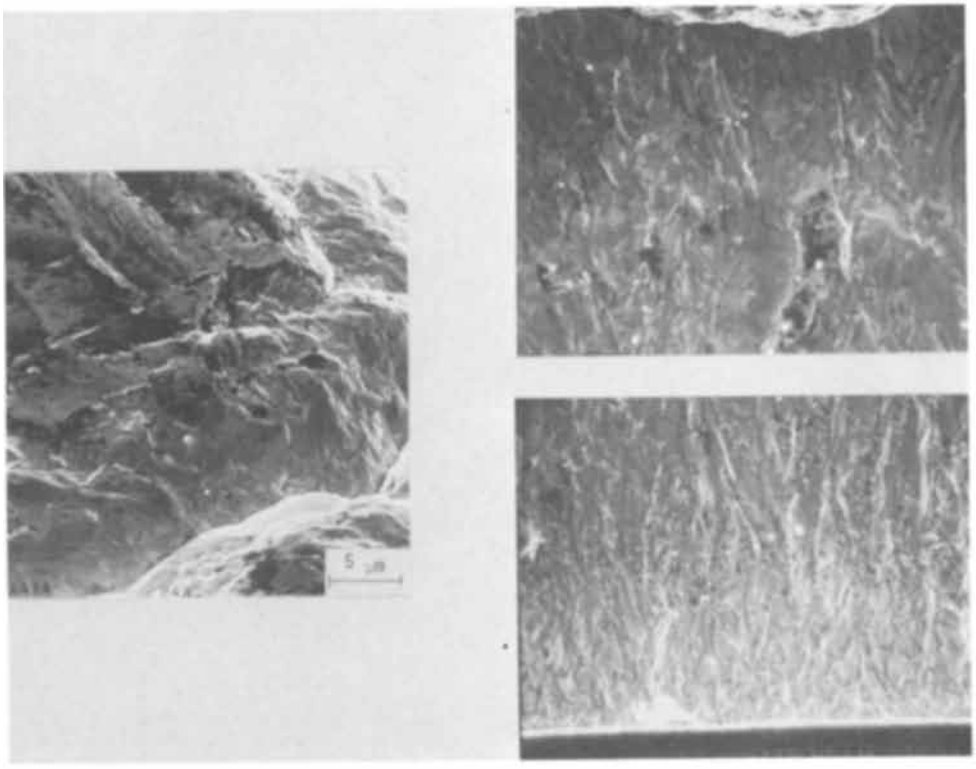

Fig. 6. SEM photomicrographs of deposit 9n.

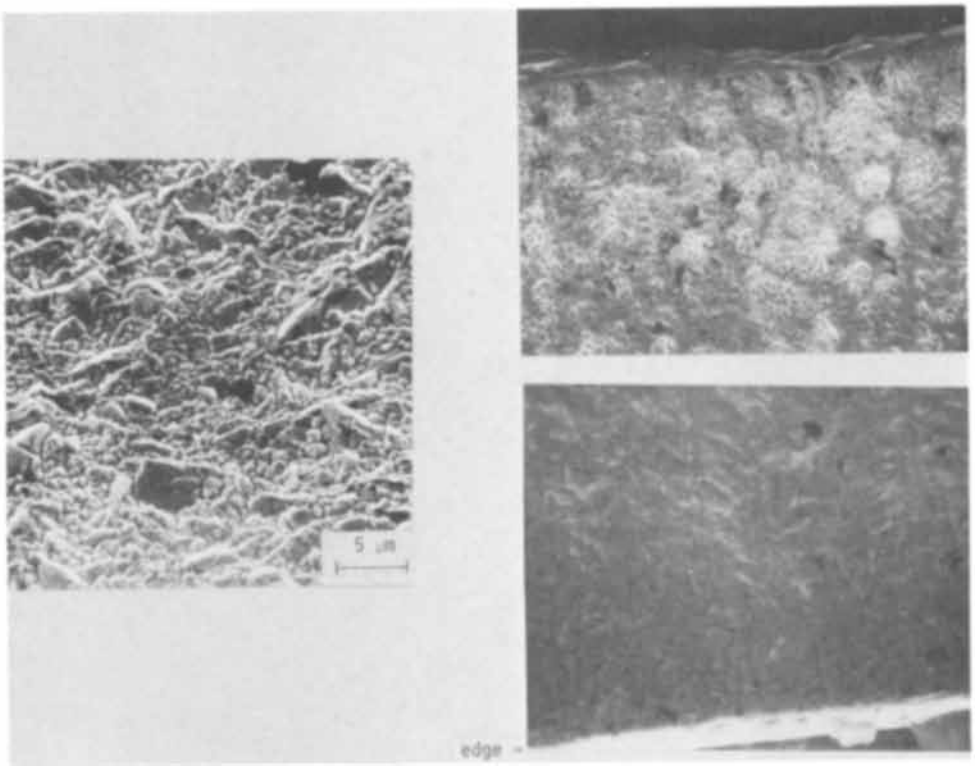

Fig. 7. SEM photomicrographs of deposit 13n. Deposit 13u was similar, but finer grained.

smaller in size (about 0.03 μm). These other baths, with the exception of 7 and 8, all contained metallic impurities either because of normal contamination from use or because of addition of hardeners and brighteners. It appeared that these codepositing metallic impurities facilitated nucleation on the copper substrate so that the average crystal size was smaller. Hydrazine sulfate (baths 7 and 8) performed the same function although the mechanism by which this occurred was not clear.

The average crystallite size on the solution side of the deposit was a good indication of the ability of hardeners and brighteners to control average crystal size. New baths 4, 5, 6, and 9, with these additives, show average solution side crystal sizes of about 0.06 μm, while new baths without these addition agents produce crystals in excess of 0.1 μm. As the baths were used and replenished, the effectiveness of the brighteners and hardeners in controlling crystal size was diminished. This was probably caused by a failure to replenish the baths with these additives at the same rate they were consumed. At the same time, all baths picked up impurities during use. These impurities, unless counteracted with chelating agents as in baths 3 and 10, tended to decrease the grain size. The net result was that baths with and without the

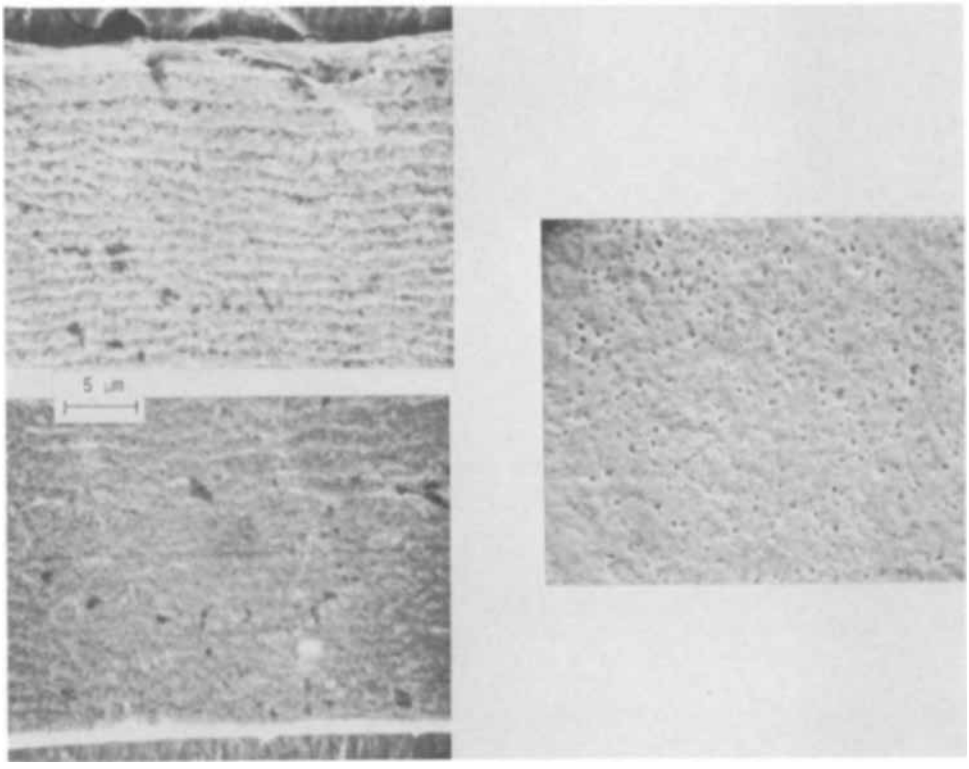

Fig. 8. SEM photomicrographs of sections of deposits 14n and 17u. Surfaces were featureless.

special additives took on the same character as they became contaminated with use.

Except for baths 1 and 14, the maximum crystallite size obtained by the deposits differed only slightly from bath to bath. Bath 14 was the only bath to produce resolvable crystals on the copper side of the deposit. The used bath 14 produced many extremely large single crystals on the solution side of the deposit. These crystals exhibited internal structure, possible parallel slip planes, and long range order between crystals. Since these crystals were not resolved in SEM photomicrographs of either the section or the surface, we conclude that these crystals are extremely thin and oriented parallel to the surface. Crystal platelets of this type are believed to be major contributors to the smooth, shiny surfaces of these deposits.

* "r" signifies a nearly random orientation. Underlined orientations are strongly preferred orientation. Doubly underlined orientations are very strongly preferred. Orientations preceded by a minus sign are significantly diminished.

X-ray diffraction was used to determine the preferred orientation of the deposits. For each side of each deposit, the x-ray intensities of the the first 10 diffraction peaks were measured. These peaks represent crystal orientation from (111) to (511). Intensities for redundant peaks such as (200) and (400) were combined. The intensities were then normalized and compared with NBS data for random deposits (11) and with a pure gold powder sample. The results are shown in columns 5 and 6 of Table II. A major feature of some diffraction patterns was the suppression of a particular peak intensity. This is shown in Table II by a minus sign in front of the associated orientation.

With the exception of the non-cyanide baths and acid phosphate baths, new baths without hardeners or brighteners tended to nucleate and grow (111) initially. As growth of these deposits continued, the (111) orientation was suppressed and higher order orientations, particularly the (311), became dominant. This is in keeping with the general concept that close-packed orientations are natural for heterogeneous nucleation but form the slowest growing crystal faces.

The addition of hardeners, brighteners, or normal operational contaminants usually suppressed the initial (111) nucleation so that both sides of the deposit tended to have a (311) preferred orientation or to be more nearly random. However, two baths, 6 and 9, which contained hardeners, produced deposits with strongly preferred initial (111) orientation. In addition to hardeners and brighteners, bath 6 contained boric acid as a copper conditioner. New bath 9, which contained the hardener and ammonium ion, produced a strong (111) preferred orientation throughout the deposit. The chelating agents in baths 3 and 10 were effective in controlling contaminations so that deposits from these used baths had orientations typical of deposits from new baths. The acid

phosphate baths (8 and 11) were unique in showing a strong tendency to (311) nucleation and growth.

The observations on preferred orientation do not correlate with the observations of crystal size, surface appearance, or grain structure, except in the case of new bath 9. The columnar structure that runs through this deposit is a direct result of the strong (111) preferred orientation for both nucleation and growth.

Conclusions

With the exceptions of the large grain porous structure of deposits from the hot cyanide bath, the very fine grain, brown deposit from bath 13, and the bright shiny deposits from bath 14, the deposits investigated were fairly similar. Special hardeners and brighteners added to new baths decreased the grain size and affected the orientation of the crystals and the surface appearance. However, as the baths were used and regenerated, the differences in deposits tended to diminish. Chelating agents were found to be effective in controlling impurity deposition from used baths.

Electrophoretic Deposition of Luminescent Materials

P. F. Grosso, R. E. Rutherford, Jr., and D. E. Sargent

Applied Physics Department, CBS Laboratories, Stamford, Connecticut 06905

ABSTRACT

Electrophoretic deposition of luminescent materials such as $2CaO \cdot MgO \cdot 2SiO:Ce:Li$ has been accomplished by the adsorption of inorganic cations of Mg^{++}, Ca^{++}, Ba^{++}, Sr^{++}, Al^{+++}, Na^{+}, K^{+}, Li^{+} or NH_4^{+}, from nitrates, chlorides, and bromides, in polar liquids such as isopropyl alcohol with a critical concentration of about 1% H_2O. An explanation of the adsorption charging and the pertinent factors which effect cataphoretic deposition for a calcium magnesium silicate-magnesium nitrate system is presented. Acetone has been found to have a beneficial depolarizing effect, while magnesium salts produce a cementing action on the deposited phosphor layer.

The electrophoretic deposition of powdered phosphors to form fluorescent screens offers several advantages over the usual gravitational sedimentation-cementation processes: (*a*) Curved or irregularly-shaped objects can be coated uniformly; deposition can even be accomplished in an upward direction to prevent the settling out of large phosphor aggregates onto the screen. (*b*) Very fine particle-size screens can be deposited quickly from suspensions that flocculate or settle very slowly (due to the similar charge on each particle); in fact, in electrophoresis, the fine particles move and are deposited more rapidly than larger particles. (*c*) Definite control can be exercised over the amount and character of the final particle cementing agent; desirable cementing agents may be generated simultaneously with particle deposition by combining electrolytic with electrophoretic effects. (*d*) Very smooth screens of uniform and controlled thickness and density can be prepared.

Key words: electrophoresis, deposition, luminescent materials, phosphors, cathode-ray screens.

In these laboratories in the past, phosphor suspensions for electrophoretic deposition have been prepared by stone-milling phosphor powders in polar organic liquids such as alcohols, acetone, *etc.*, for substantial periods of time. Milling does indeed yield "charged" suspensions, but usually also damages the phosphor (light output and efficiency are lower than the original powder). The mechanism of this damage is not completely understood, but appears to result from severe

physical shear, production of many particles below optimum size for efficient fluorescence, thermal damage caused by high local impact temperatures, surface chemistry such as oxidation-reduction reactions, loss or absorption of various substances (*e.g.* analysis shows that phosphors milled with flint stones have absorbed aluminum), *etc.*

During the present study, methods have been sought for "charging" phosphor suspensions without the attendant damage of stone milling. Most attention has been focused on the addition of soluble electrolytes to suspensions of various phosphors in essentially nonaqueous media, but auxiliary means such as stirring, classification by settling (elutriation), and ultrasonic dispersion have also been employed.

In the experimental work described, calcium magnesium silicate (2CaO·MgO·2SiO:Ce:Li) was used.

Experimental Procedure

In order to compare the efficacy of various added electrolytes and various nonaqueous liquid suspending media for promoting the cataphoretic deposition of various phosphors the following test procedure was employed.

The electrophoretic deposition cell consisted of an unstirred vessel of 300 ml capacity, which was provided with a stainless steel frame which supported a 1 in. diameter test blank in a vertical position. The test blanks were either conductive glass or stainless steel. These blanks, one of which was used as the cathode in each experiment, were cleaned ultrasonically with acetone and were weighed before each deposition experiment. Facing the blank cathode and separated from it by a distance of ⅝-¾ in. was a row of three ¼ in. carbon rods held in a vertical position. These rods were the anode in each experiment. Any inert material, such as platinum, can be used as an anode. A variable d-c power supply capable of providing potentials up to 500V and currents up to 250 mA was used to promote electrophoretic deposition.

In typical operation, 250 mg of the phosphor powder under test was added to 250 cc of the fluid suspending media in which the electrolyte under test had previously been dissolved. The phosphor was allowed to equilibrate with the liquid medium by stirring for 5 min, and the resulting suspension was then poured into the test cell. Sufficient potential was immediately applied to yield a current of 10 mA and the deposition was allowed to proceed at 25°C without stirring. The test cathode blank was then withdrawn, dried, and weighed. The appearance of the deposited phosphor layer was examined and noted.

Pertinent Factors

Cataphoretic deposition is a complex phenomenon in which several variables play significant roles. First, the liquid suspending medium must be carefully chosen. It must be a suitable solvent for the added electrolytes under test, but must not yield solutions having high conductivities. It is desirable to maintain a high potential difference between the anode and the cathode, but high current flow with resultant resistance heating is not desirable. Deposition of the suspended powder rather than electrolysis of the liquid medium is desired. In addition, the liquid medium should have a low viscosity so that the charged particle can migrate at the maximum rate under the applied field. For practical reasons, it should be inexpensive, water miscible, and low in toxicity.

Previous work in these laboratories (1-3) and elsewhere (4) has shown that polar liquids such as the water soluble lower molecular weight alcohols and ketones provide good media for electrophoretic deposition. In the present study, isopropyl alcohol and acetone have been used almost exclusively, either separately or mixed together and usually with some water added. Water can be used to advantage in electrophoretic systems, but is very important to carefully control the amount added. This may be illustrated by

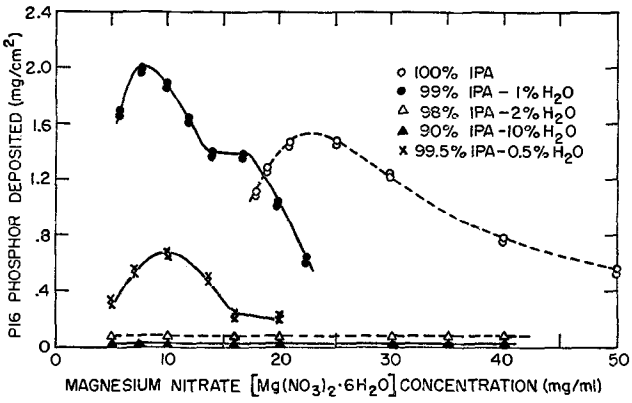

Fig. 1. Effect of magnesium nitrate and water concentrations on amount of phosphor deposited. Deposition conditions: carbon anode-stainless steel cathode; electrode spacing 5/8 in.; current 10 mA, voltage 25-100V; time 5 min; P16 phosphor concentration in suspension 1 mg/ml.

examination of 2CaO·MgO·2SiO:Ce:Li (P16 phosphor) deposition curves shown in Fig. 1. In the experiments represented by the curves, increasing amounts of magnesium nitrate $Mg(NO_3)_2 \cdot 6H_2O$ was added to either 100% isopropyl alcohol, 99.5% isopropyl alcohol +0.5% water, 99% isopropyl alcohol +1% water, 98% isopropyl alcohol +2% water, or 90% isopropyl alcohol +10% water. It will be noted that the highest mass deposition efficiency of phosphor (greater weight deposited during the standard 5 min time interval) occurred when about 8 mg of the magnesium nitrate was added to the 1% water system (250 mg phosphor in 250 cc 99% isopropyl alcohol +1% water). Addition of more or less magnesium nitrate gave less deposition of phosphor. In the experiments in which water was not added, the maximum deposition occurred with approximately 22.5 mg of the nitrate. Addition of more or less than 1% water also gave less deposition of phosphor than 1% water. Use of 98% isopropyl alcohol +2% water, 90% isopropyl alcohol +10% water gave very poor results at all levels of added magnesium nitrate. The higher water concentrations increased the conductivity to allow electrolysis to predominate over electrophoretic deposition. Lower water concentration did not allow satisfactory ionization to take place. It is then evident that the amount of water present, as well as the amount of electrolyte added, is critical.

In the 1% water system, addition of the optimum amount of magnesium nitrate (8 mg) apparently gives good "charging" of the calcium magnesium silicate (P16) phosphor since the weight of deposited phosphor is high. Simultaneously, the conductivity of the system appears to increase, for without the phosphor present 20 mg of magnesium nitrate would be required to give the same conductivity. In order to explain this phenomenon, it may be suggested that the phosphor, known to have excess calcium oxide on its surface, may undergo the following type of absorption-desorption reaction:

$$2(\text{P16}) - \text{SiO} \cdot \text{CaO} - \text{OH} + 2\text{Mg}^{++} + 2\text{NO}_3^- \rightarrow \left((\text{P16}) - \text{SiO} - \text{Mg}^{+} \right)_2 + 2\text{Ca}^{++} + 2\text{OH}^- + 2\text{NO}_3^- \quad [1]$$

The phosphor thus becomes "charged" and the ionic concentration (conductivity) of the suspending medium is simultaneously increased. When less than the optimum magnesium nitrate concentration is added, maximum charging is not attained, and the weight of phosphor deposition is decreased. If greater than the optimum magnesium nitrate concentration is used, the amount of phosphor deposited also decreases because either (*a*) the increase in conductivity causes electrolysis instead of electrophoretic deposition or

(b) the increasing electrolyte concentration may actually diminish the positive charge on the phosphor particles through the increased absorption of negative ions (5). This same type of maximum is noted in the anhydrous system but at higher electrolyte concentrations.

It was also found that acetone is an effective cathode depolarizer, *e.g.*, that when present, it largely prevents the appearance of gaseous hydrogen, presumably by acting as an acceptor of any electrolytic hydrogen generated.

$$2H^+ + CH_3COCH_3 + 2e \rightarrow CH_3CHOHCH_3 \quad [2]$$

Acetone Isopropyl alcohol

When no hydrogen is evolved, very smooth, compact phosphor screens may be deposited. Experiments were conducted to determine the optimum combination of acetone, water, and alcohol.

Excellent results were obtained with 25% isopropyl alcohol +74% acetone +1% water (by volume) as the suspending fluid and electrolyte solvent. Below 70% acetone concentration yielded coarse phosphor screens due to gas evolution during deposition. Above 80% acetone yielded thin, nonuniform phosphor screens of low adherence.

Choice of Added Electrolyte

A large number of inorganic compounds were found to be capable of "charging" calcium magnesium silicate positively so that deposition at the cathode could be achieved. The suitability of these various additives was determined by dissolving 1 mg/ml of the inorganic compound to be investigated to either 99% isopropyl alcohol +1% water or to 74% acetone +25% isopropyl alcohol +1% water (by volume), and then suspending 1 mg/ml of the phosphor in the above fluid and determining whether favorable rates of deposition and good quality screens were obtained. With promising candidate additive compounds, the concentration was varied until the maximum deposition rate and screen quality was established.

Since cataphoresis rather than electroplating was desired, principal attention was given to inorganic compounds having anions which cannot be reduced in aqueous media. Thus soluble salts of magnesium, calcium, barium, strontium, aluminum, sodium, potassium, lithium, and ammonium were evaluated. Divalent magnesium, calcium, and strontium all gave positive results. It is interesting to note that all of these cations form rather insoluble silicates and it is not surprising that they are well absorbed on and "charge" calcium magnesium silicate (probably due to reaction with exposed SiOH or SiO groups). Because of its relatively high ionic charge, low mass, low toxicity, and low solubility in combination with a variety of anions, magnesium was chosen as the preferred cation, with aluminum as a close second choice.

Insofar as the preferred anion is concerned, nitrate and chloride (and to a lesser extent, bromide) appeared to be preferable to several other anions evaluated. While the nitrates and chlorides of magnesium, aluminum, and lithium gave good deposition, the sulfates of these and other metals gave uniformly poor results. It is possible that the sulfate ion was too well removed from solution by the phosphor. When fluoride, phosphate, formate, acetate, citrate, hydroxide, etc., were introduced in the form of acids and bases, the results were also not satisfactory.

P16 phosphor ($2CaO \cdot MgO \cdot 2SiO:Ce:Li$) appears to have a "basic" surface (shown by pH of moist powder against pH paper), probably due to the presence of MgO and/or CaO or the corresponding hydroxides. It may also be "charged" by the addition of hydrochloric acid (presumably by conversion of the oxides and/or hydroxides to magnesium and calcium ions to form the oppositely charged counter layer). The addition of hydrofluoric, phosphoric, sulfuric, formic, acetic, and citric acids do not give favorable "charging." The failure of hydrofluoric, phosphoric, and sulfuric acids may be explained on the basis that the anions of these acids form insoluble calcium salts (the surface is coated with an insoluble compound rather than converted to an ionized double layer), but the failure of formic, acetic and citric acids is more difficult to explain. Perhaps these acids too well "sequester" calcium and magnesium, *i.e.*, actually remove them from the surface of the phosphor, making it impossible for a double layer to form.

The behavior of nitric acid is anomalous. It should yield calcium and magnesium nitrates by reaction with the surface of the phosphor, and these nitrates are known to give favorable depositions. But when nitric acid was added to a system containing isopropyl alcohol, no deposition resulted. Perhaps it is too rapidly consumed in oxidizing the easily oxidized alcohol.

Heavier, more easily reduced cations do not give satisfactory results in general. Thus, the nitrates of lead, iron (ferric), zinc, copper, the chlorides of nickel, cobalt, manganese, palladium, and chromium sulfate either gave no deposit, very discolored deposits (probably containing the respective metals or lower valence compounds), or poorly adhering deposits. This is to be expected in view of the ease of reduction of these metallic ions at a cathode.

Added Advantage of Magnesium and Related Metallic Salts

When magnesium salts are electrolyzed, hydrogen rather than magnesium is liberated at the cathode. In the system we have been investigating, the hydrogen is apparently taken up by acetone (see above). Regardless of the fate of the hydrogen, there is an increase in hydroxyl ion concentration (or pH) in the vicinity of the cathode. This results in the formation (and deposition) of an interesting and adherent form of magnesium hydroxide which can apparently act as a cementing agent for the simultaneously cataphoretically deposited phosphor. The cathode reactions involved may be represented as follows

$$(2CaO \cdot MgO \cdot 2SiO)Mg^{++} + 2HOH + CH_3COCH_3 + 2e \rightarrow (2CaO \cdot MgO \cdot 2SiO) - Mg(OH)_2\downarrow + CH_3CHOHCH_3 \quad [3]$$

That an adherent magnesium hydroxide film is formed under the conditions employed is also indicated by the following: The addition of phenolphthalein to the system with the omission of phosphor gives a very adherent, bright red film on the cathode when current is passed. This is probably a combined film of magnesium hydroxide and the magnesium salt of the phthalein (colored, basic form). Other dyestuff compounds have also been bonded to the cathode by this process, but extensive discussion of these is beyond the scope of this paper.

Conclusions

An electrophoretic deposition process for the formation of luminescent phosphor screens has been developed which does not employ the use of stone milling to disperse and charge phosphor particles. The charging of calcium magnesium silicate phosphor particles is achieved by the adsorption of nonreducible inorganic cations of Mg^{++}, Ca^{++}, Ba^{++}, Sn^{++}, Al^{+++}, Na^+, K^+, Li^+, and NH_4^+ on the phosphor surface. The adsorbed cations cause the phosphor particles to migrate in a suitable suspending media under the influence of an electric field to the electrode of opposite charge. Salts of these cations produce a cementing action between the deposited phosphor layer and the substrate to be coated.

The resulting phosphor coating is tenacious to the substrate, uniform, dense, fine grained, and does not exhibit a decrease in luminous efficiency.

Water concentration is extremely critical with magnesium nitrate as the charging cation. Above and below 1% H_2O decreased the phosphor deposition efficiency.

Acetone has been found to be an effective depolarizing agent, thereby preventing gaseous evolution during the deposition.

Synergistic Effects of Anions in the Corrosion of Aluminum Alloys

A. M. McKissick, Jr., A. A. Adams, and R. T. Foley*

Department of Chemistry, The American University, Washington, D. C. 20016

Aluminum and aluminum alloys are susceptible to pitting and general corrosion in chloride solutions and the fact that nitrate ion can inhibit this corrosion has been reported by several investigators. Callendar (1) measured the corrosion of Al and three Al-Cu alloys in tap water to which were added various concentrations of $NaNO_3$, NaCl, and $K_2Cr_2O_7$. He reported that a critical amount of $NaNO_3$, 0.008% for his tap water, was required to achieve passivation of the Al-Cu alloy and he directly related the rate of reduction of nitrate to the concentration required to achieve passivation. Blanchard and Goucher (2) in their studies of aluminum corrosion in microbial culture media containing a number of salts, including $CaCl_2$ and $FeCl_3$, observed that a 12 mM (millimolar) concentration of KNO_3 protected aluminum alloys 2024 and 7075. At a Cl^-/NO_3^- ratio of 20 there was a slight stimulation of corrosion (about 20% increase). Kassyura and Zaretskii (3) recently reported on the anodic behavior of A-99 aluminum in 1*N* and 3*N* solutions of $NaNO_3$ with various chloride additions. They noted that in a specific concentration range for NaCl the region of the passive state decreased with increased chloride ion concentration. Böhni and Uhlig (4) noted that $NaNO_3$ additions to NaCl solutions moved the pitting potential of 99.99% Al in the noble direction and the relationship between chloride activity and inhibiting nitrate activity followed the equation

$$\log (Cl^-) = 0.65 \log (NO_3^-) - 0.78$$

From the review of the literature it may be concluded that nitrate is an inhibitor for aluminum corrosion in chloride solutions, and that the Cl^-/NO_3^- ratio is important. In connection with an investigation of the chemistry of stress-corrosion cracking of high-strength aluminum alloys we have examined the effect of a number of anions on aluminum and aluminum alloys. Certain effects that have been observed are felt to be sufficiently unusual to warrant a preliminary report. We note, particularly, certain synergistic effects that could not be predicted from a knowledge of the behavior of individual ions.

Experimental

The work reported here consists of immersion tests with three aluminum alloys. Alloy 1199-H14 was supplied by the Reynolds Metals Company and alloys 2024-T3 and 7075-T6 by the Kaiser Aluminum Company. Samples 38 x 26 x 0.81 mm were cleaned in the conventional manner. The strip was immersed in NaOH solution (5 g/100 ml) at 75°-80°C for 1 min, rinsed thoroughly, dipped in NHO_3 (1:3) for 1 min at room temperature, and thoroughly rinsed in distilled water and acetone. Samples were immersed in triplicate in solutions of various salt concentrations for periods of 14 days at 22° ± 1°C. Following exposures, the corrosion product was removed with a stripping solution of 20g of chromic acid and 32.25 ml of 85% phosphoric acid/liter. The weight loss reported was the difference in weight of the sample before the test and that after the stripping. The latter was corrected with the weight loss of an uncorroded metal specimen in the stripping solution.

Results and Discussion

The weight losses for the three aluminum alloys in 0.01*N* NaCl solutions are given in Table I. The corrosion observed with unalloyed aluminum is of the pitting type, whereas that of the alloys progresses rapidly after the first day to a general attack over the entire surface. Also noted here is the inhibiting effect of $NaNO_3$ in concentrations of 0.05*N* and higher in solutions of 0.01*N* NaCl, *i.e.*, a NO_3^-/Cl^- ratio of 5. These two effects, corrosion in chloride solution and inhibi-

Table I. Weight changes of aluminum alloys after 2 week immersion in salt solutions

Alloy	Electrolyte	Weight loss (mg/cm²) (±σ)*
1199	0.01*N* NaCl	0.02 ± 0.007
2024	0.01*N* NaCl	1.17 ± 0.21
7075	0.01*N* NaCl	1.44 ± 0.04
7075	0.01*N* NaCl/0.05*N* $NaNO_3$	0.01 ± 0.01
2024	0.01*N* NaCl/0.10*N* $NaNO_3$	0.14 ± 0.02
7075	0.01*N* LiCl	0.17 ± 0.003
7075	0.01*N* KCl	0.54 ± 0.01

* These are average values. A minimum of three replicates were run but most of these represent averages of about 12 samples run by two different investigators.

Table II. Weight changes of aluminum alloys after 2 week immersion in salt solutions of various nitrate chloride ratios

Alloy	Electrolyte	Weight loss (mg/cm²) (±σ)
2024	0.01*N* NaCl/0.01*N* $NaNO_3$	6.80 ± 0.8
7075	0.01*N* NaCl/0.01*N* $NaNO_3$	10.1 ± 0.75
7075	0.01*N* NaCl/0.005*N* $NaNO_3$	8.8 ± 0.48
7075	0.01*N* KCl/0.01*N* KNO_3	0.31 ± 0.03
7075	0.01*N* LiCl/0.01*N* $LiNO_3$	0.08 ± 0.001
1199	0.01*N* NaCl/0.009*N* $NaNO_3$	0.07 ± 0.03
1199	0.01*N* NaCl/0.003*N* $NaNO_3$	0.07 ± 0.03

tion at some critical NO_3^-/Cl^- ratio have been reported previously, at least qualitatively.

Table II lists typical results wherein the NO_3^-/Cl^- ratio is reduced to one and below. Corrosion is increased by an order of magnitude in the sodium salt solutions. The effect is graphically represented in Fig. 1. The maximum effect is exhibited at a NO_3^-/Cl^- ratio of about 0.7. Tables I and II also indicate that the corrosion rate is not independent of the cation, which is contrary to previously reported observations. The corrosion rate for the 7075 alloy varies, as follows

$$NaCl > KCl > LiCl$$

$$8.5 > 3.2 > 1.0$$

for corrosion under the stated conditions. Also, there is no synergistic effect with potassium or lithium salt solutions.

There is an alloy effect observed here and in other measurements as well. Thus in chloride solution the rates are in the following order

$$7075 > 2024 > 1199$$

$$72 > 59 > 1$$

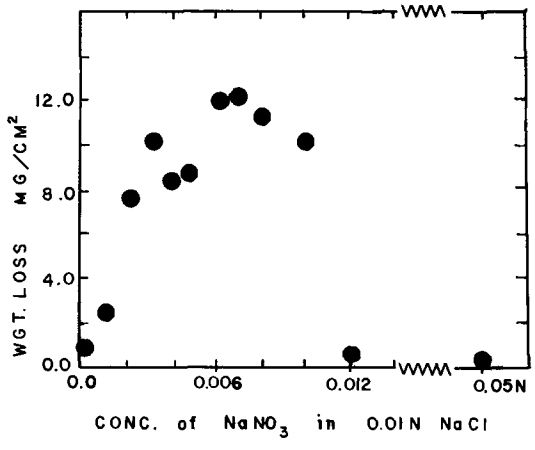

Fig. 1. Effect of $NaNO_3$ additions to 0.01*N* NaCl solutions on the corrosion of aluminum alloy 7075.

The synergistic effect was noted with both alloy types 7075 and 2024 but not with 1199. The physical appearance of the samples corroded in the nitrate-chloride solutions is different from those corroded in chloride solution, being characterized by large blisters suggesting considerable gas evolution during corrosion. After about 1 day's exposure the sample turns black, suggestive of a dealuminification type of attack. Continual exposure over a period of weeks produces a voluminous corrosion product often in the form of streamers (probably hydrated aluminum oxide). Metallographic cross section reveals considerable roughening of the sample.

At this point we are not able to offer a good explanation for these observations. The simple descriptions based on oxide films or competitive adsorption do not appear adequate. We have considered the physical properties of the salts. For example, the activity coefficients at 0.01M are given (5) as

NaCl	0.904
KCl	0.901
LiCl	0.89

These values are not significantly different. The radii of the ions (6) are in the following order

Li^+	0.60
Na^+	0.95
K^+	1.33

This rules out any effect dependent on a trend in size, but not an optimum size for some adsorption process.

The accelerating effect may be related to the reduction of nitrate to nitrite. Nitrite ion is not an inhibitor for aluminum but actually accelerates corrosion. Under conditions comparable to those given in Table II alloy type 7075 exhibits a weight loss in a 0.01*N* NaCl + 0.01*N* $NaNO_2$ of 13.3 mg/cm². This explanation, however, would not account for the cation effect.

We are looking for an explanation of these effects along two lines: The first, potentiostatic experiments to establish the effect of anion ratio on pitting inception time when the alloy is held in the passive range; the second, x-ray and metallographic studies of structural changes in the corrosion product.

Generally, it must be concluded that if these observations are borne out by future experiments we must revise our concept of "anion" effects and include cation effects as well.

Composite Film Metallizing for Ceramics[1]

E. L. Hollar, F. N. Rebarchik, and D. M. Mattox

Sandia Laboratories, Albuquerque, New Mexico 87115

There are two primary approaches to forming a solderable/brazable surface on oxide ceramics: (*a*) react an oxygen active metal on the surface at high temperatures (active-metal metallizing) (1), or (*b*) fuse a glass-metal composite to the ceramic surface (dispersion metallizing) (2).

In the active-metal metallizing technique, the oxygen active metal reacts with the oxide surface at high temperatures to form an interfacial complex oxide system which may act as the intermediate bonding agent, as has been suggested for the glass-on-metal system (3-5). Not all of the active metal is allowed to react with the oxide, thus a brazable metal surface remains. In the dispersion-metallizing technique, the glass phase reacts with the ceramic and, by the selection of the correct coefficients of expansion, provides good bonding to the ceramic. The metal phase which is dispersed in the glass then provides the brazable surface. Both of these techniques require high temperatures to allow chemical reaction and diffusion to take place between the metallizing layer and the ceramic surface. These techniques also allow irregular penetration of the metallizing into the ceramic, particularly in the polycrystalline ceramics having a high glass content in the grain boundaries.

In some cases, design restrictions make these metallizing techniques impractical. Some of these cases are: (*a*) ceramics which cannot withstand high temperatures without decomposition or distortion, (*b*) thin ceramics where the interfacial region must be kept very thin and carefully controlled, (c) ceramic applications where the irregular penetration of the conventional metallizing imposes problems with dielectric breakdown, and (*d*) metallizing techniques which are incompatible with other processing.

The usual method of obtaining an adherent coating in these cases is to sputter, or vacuum evaporate, an oxygen active material on the surface and promote substrate-coating reaction by limited heating (6, 7). Without extensive heating the transitional interface region which is formed is limited in extent and the stress distribution across the interface, which is necessary to obtain a good bond (8), is not developed.

We propose that a transitional interface region, conducive to good bonding, may be formed by deposition of an oxygen-active metal in a controlled gaseous environment. In this technique, the deposition of the active metal is begun in a partial pressure of oxygen to allow partial oxidation of the deposited material and thus form a transition oxide and suboxide interfacial region. By decreasing the partial pressure of oxygen during the deposition, the composition of the interfacial region may be "graded" from the substrate material through a metal oxide-metal composite region to the pure metal. It has previously been noted that better adhesion can be obtained with oxygen active materials on glass when there is a poor vacuum (9, 10). Since the oxygen-active metals are often difficult to braze, a more brazable surface may be formed by the co-deposition of some easily brazed material during the active metal deposition and then grading to the pure brazable metal by gradually decreasing the deposition rate of the active metal.

This investigation was primarily concerned with metallizing fused silica for a high-temperature brazing operation. Fused silica develops large internal strains when other chemical species are diffused into the surface or when recrystallization (devitrification) occurs at high temperature. These strains can crack the fused silica. Therefore, metallizing must be done at moderate temperature with controlled chemical reaction between the metallizing and the fused silica. In addition, the low thermal expansion coefficient of fused silica compared to most glasses and metals causes high stress to be developed in the interfacial region on cooling from high temperatures when conventional metallizing is used. This problem can be averted by using a thin metallizing layer and/or a ductile metal coating.

The choice of materials is dictated by the processing involved. The oxygen-active metal should be insoluble in the braze alloy so that it will not be "scavenged" from the ceramic surface during the brazing operation. In addition, it should not exhibit grain growth at the brazing temperature. The brazable metal should be relatively insoluble in the active metal to prevent excessive diffusion and should not alloy rapidly with the braze material at the brazing temperature.

To prevent scavenging, a refractory material was used in contact with the silica. Of the four refractory metals (niobium, tantalum, tungsten, and molybdenum) investigated, niobium seemed to be the most stable under brazing conditions, and the system niobium-silver with a copper-silver eutectic braze was used. The niobium and silver were deposited in a hot cathode triode sputtering system shown in Fig. 1. The relative sputtering rates were controlled by varying the bias on the sputtering cathodes. The oxygen content in the discharge was controlled using commercial argon-oxygen mixtures and pure argon with valving and a variable leak as shown. The oxygen content in the system was monitored using a differentially pumped mass spectrometer. Recorders were used to monitor the cathode current during deposition.

The sequence of steps in a typical metallizing operation was as follows. The fused quartz substrate was thoroughly cleaned by scrubbing with Alconox until water would wet the entire surface. After multiple rinses in distilled water, the fused silica was etched for 1 min in a 5 v/o (volume per cent) hydrofluoric acid solution and rinsed again. The final precleaning step was air firing at 800°C for 15 min. The cleaned substrate was then placed in the sputtering chamber and the chamber evacuated to 1×10^{-5} Torr. The system was then backfilled with an Ar/5% O_2 mixture to a pressure of approximately 8×10^{-3} Torr while the chamber was continuously pumped. A hot

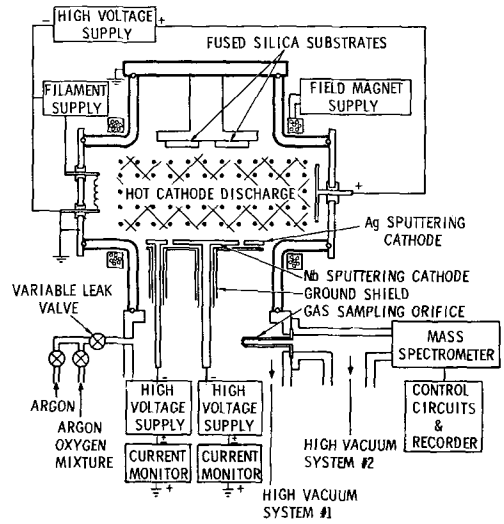

Fig. 1. Hot cathode-dual cathode sputtering apparatus showing disk niobium cathode and concentric ring-shaped silver cathode.

cathode discharge was established, and the substrate was glow-discharge cleaned (11) in the discharge plasma. The sputtering of the niobium was begun by applying a negative 2 kV bias to the niobium sputtering cathode. After a predetermined time necessary to give about 500Å of oxide, the gas flow was switched to pure argon. As the oxygen in the system was pumped out, the film became more metallic and the deposition was continued until about 1500Å of niobium were deposited. At this point, the negative bias on the silver sputtering cathode was gradually increased to codeposit silver with the niobium. The bias on the niobium cathode was then gradually decreased until pure silver was being deposited. The silver deposition was continued until a total thickness of about 10,000Å

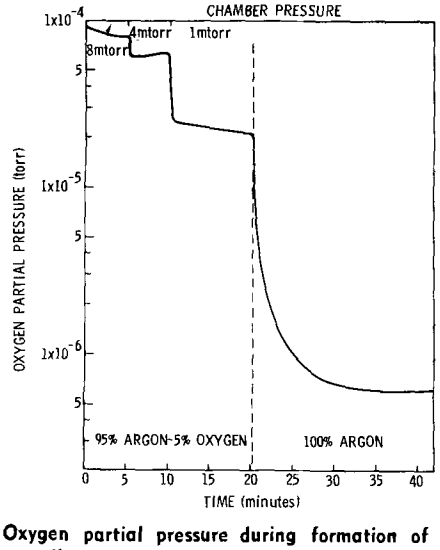

Fig. 3. Oxygen partial pressure during formation of the composite film metallizing.

Table I

Operation	Gas composition and pressure	Sputtering bias	Time (min)
1. Sputter niobium	Ar/5% O_2 @ 8 mTorr	−2 kV	5
2. Sputter niobium	Ar/5% O_2 @ 4 mTorr	−2 kV	5
3. Sputter niobium	Ar/5% O_2 @ 1 mTorr	−2 kV	10
4. Sputter niobium	Pure Ar @ 1 mTorr	−2 kV	30
5. Sputter niobium		−1.5 kV (niobium)	
&	Pure Ar @ 1 mTorr		5
Sputter silver		−0.5 kV (silver)	
6. Sputter niobium		−1.0 kV (niobium)	
&	Pure Ar @ 1 mTorr		10
Sputter silver		−1.0 kV (silver)	
7. Sputter niobium		−0.5 kV (niobium)	
&	Pure Ar @ 1 mTorr		5
Sputter silver		−1.5 kV (silver)	
8. Sputter silver	Pure Ar @ 1 mTorr	−2 kV	90

had been deposited. Figure 2 shows the resulting composition of the composite metallized surface.

The times necessary to deposit the various thicknesses of niobium and silver with a given gas composition, discharge conditions, cathode current density, and cathode bias were determined by stopping the deposition at various stages and measuring the film thicknesses with a Talysurf. Table I summarizes the sequence of steps and the times involved. Care was taken to insure that silver from the previous run was cleaned from the niobium cathode. If this is not done, silver will be deposited on the silica surface and a poor bond will be obtained.

Figure 3 shows the oxygen content of the discharge in a typical metallizing operation. Chemical and ion pumping of oxygen by the discharge substantially reduced the oxygen content of the discharge gas in the initial phase of the process. In order to have excess oxygen available during the initial niobium deposition, high gas pressure was required. The gas pressure was then reduced as the discharge electrodes were saturated and as the discharge chemical pumping decreased.

The fused silica surfaces thus metallized were then brazed with a copper-silver eutectic braze. After being subjected to the brazing operation the seals thus formed were vacuum tight, and when tested to failure the joint fractured in the fused silica.

Where a low temperature–high strengh bond was desired, the aluminum-silver composite system was used. This system provided surfaces which may be soft soldered and is useful for electroding ferroelectric materials and in joining materials having large differences in coefficient of expansion such as alumina and brass.

ABSTRACT

Microscopic investigation of the effect of lignin and $BaSO_4$ on the negative lead electrode showed that lignin was able to modify the lead crystal structure produced during the forming operation, in addition to its effect on the structure of the $PbSO_4$ crystals formed on discharge. The effect of the lignin was to reduce the size and complexity of the dendritic lead crystals in the formed plate. The presence of $BaSO_4$ had no appreciable effect on the microstructure of the formed plate.

At low temperatures and at high discharge rates, the capacity of lead-acid batteries of the pasted plate type is usually controlled by the negative lead electrode. This limiting action is the result of increased polarization at the negative electrode which seriously limits reaction. Of the factors responsible for this polarization, the resistive component is the most serious in its effect. That is to say that low temperature increases the viscosity of the electrolyte, decreases diffusion, lowers conductivity, and otherwise increases the resistance to current flow and reaction at both electrodes. The process at the negative, in addition, produces highly resistive and passivating films of lead sulfate on the reacting lead electrode. Although lead sulfate is also produced on the lead dioxide electrode, the passivating effect in this case is less severe so that the reaction at this electrode can be faster than at the lead electrode.

It has been found that certain substances, called expanders, can decrease the polarization and passivation at the negative electrode. Lamp black, barium sulfate, and certain lignin derivatives have been found to change but not entirely eliminate the limiting character of the negative electrode.

Of these additives, barium sulfate and lampblack have been used almost as long a time as have pasted electrodes and there is now no means of determining if their first use was the result of fortuity or deliberate planning. Lignin, however, was deliberately used to restore desirable properties attributed to products leached from wood separators, as this need became evident when the industry converted from wood to synthetic separators.

The effect of $BaSO_4$ and lignin derivatives on low-temperature, high-rate discharge capacity has been reported by Willihnganz (1), Ritchie (2), Zachlin (3), Popova and Kabanov (4), Kasporov, Yampol'skaya, and Kabanov (5), Barnes (6), Yampol'skaya, Ershova, Astakhov, and Kabanov (7), and Simon (8). The effect of organic materials on the discharge characteristics of the lead electrode has also been the source of many patents claiming specific improvement by certain materials.

While there is disagreement as to the exact mechanism, it is generally agreed that $BaSO_4$ and an organic expander material are most effective when used together. Even here the objection has been made that the effectiveness of the $BaSO_4$ may depend on unidentified organic impurities. The maximum effectiveness of the organic expanders has been reported to occur after a number of charge-discharge cycles, while the effectiveness of the $BaSO_4$ is immediately available (3). Since the size of the $PbSO_4$ crystals has been demonstrated to depend on the size of the $BaSO_4$ crystals added to the original mix, it is generally agreed that the $BaSO_4$ crystals must remain undissolved in the plate to act as nuclei when lead sulfate is being formed. This is thought to prevent or hinder the formation of $PbSO_4$ films on the lead crystals and thus to reduce passivation. As to the function of the organic material, there is less general agreement but such a material seems to require electrolytic oxidation or reduction for maximum effectiveness and it probably then adsorbs on the growing faces

* Electrochemical Society Active Member.

Key words: expander, microstructure, lead-acid, battery, negative plate.

of the $PbSO_4$ crystals, enabling a more porous layer to be formed. There seems to be quite general agreement that a definite small amount of organic material produces expander action and that an excess can be very harmful to the functioning of the electrode. This would appear to indicate a definite adsorption of a monomolecular layer of some portion of the lignin on all or at least the reactive part of the available surface. This adsorbed layer could then produce modification in the crystallization occurring at certain crystal faces.

The foregoing work has emphasized the effect of expanders on the $PbSO_4$ crystals formed on discharge of the lead electrode and has said nothing about any effect on the structure of the lead crystals grown during the charge process. Barnes (6), however, had suggested, without experimental verification, that expanders might also modify the lead crystals formed during charge, leading to an increased surface area. It is, of course, well known that various organic additives have a modifying effect on the growth of specific crystals and this has also been demonstrated for certain metal crystals formed by reduction from solution. There was therefore good reason to expect the same modification in the case of lead crystals.

An investigation was initiated, using microscopic study and other available means, to determine the nature of the modification produced in the lead sulfate crystallization films through the use of lignin derivatives or barium sulfate. Examination of the negative electrodes which were to be used in this investigation, following their electrolytic reduction to lead from the oxide paste, revealed that the microstructure of the lead crystals was different in the plates with, and in those without, lignin. $BaSO_4$ on the other hand, had no appreciable effect on the electrolytic formation of the negative plate.

Preparation of the Electrodes

The positive PbO_2 electrodes used in these experiments were obtained from Globe-Union factory production and they were of a proprietary formulation. The negative lead electrodes, on the other hand, were of an experimental formulation and the necessary mixing and pasting of these electrodes were done at the Globe-Union Laboratory.

The negative paste was prepared from Eagle-Picher 34U Oxide. Various amounts of $BaSO_4$ and lignin were added to separate portions of this dry oxide, as shown in Table I. These dry mixtures were then mechanically blended for 1 hr to insure thorough mixing. After blending, the portions were individually placed in a mixer and dry mixed for 2 min. Following this, 111 ml of water, at approximately 23°C, were added to 3 lb portions of the oxide during 1 min of mixing, after which the paste was mixed for 4 min more. The required amount of acid, 138 ml (1.325 sp gr., 23°C) was then added over a 5 min period. The paste was then mixed for 15 min more. In the case of paste without lignin, it was necessary to increase the water addition to 121 instead of 111 ml.

Numbered and weighed grids from factory production were then hand pasted to contain approximately the same final weight of paste. After pasting, these plates were cured for a minimum of 72 hr. After curing, the plates were joined together into groups of 4 positives or 5 negatives by burned-on connector straps. The cell groups so produced were then formed electrolytically in 1.050 sp gr acid at 6.6 A/cell, for a period of 20 hr. After formation, the cells were disassembled and the positive and negative groups separated.

Table I. Negative paste mixes used in this investigation (relative amounts of lignin and $BaSO_4$ used in mix)

% $BaSO_4$	% Lignin		
0	0	0.5	1.0
0.5	0	0.5	1.0
1.0	0	0.5	1.0

Both the negative and positive groups were then washed in a stream of water for 3-4 hr. Without further preparation, the positive plates were then dried at 65°C in an oven.

The negative plates, to avoid oxidation, were placed in a drying oven at room temperature which was then purged with nitrogen by three times drawing a vacuum and then releasing it by the introduction of nitrogen. After the third purge, the nitrogen was kept continuously flowing while the temperature was raised to 82°C and maintained for 5 hr. The plates were then cooled to 50°C while still in the nitrogen environment.

After further cooling, the positive and negative groups were then cut apart and the individual plates were analyzed by x-ray diffraction, differential thermal analysis, thermogravimetric analysis, and microscopy. Only the microscopic examination proved of much value in the examination of the formed negative electrode, which consisted almost entirely of lead. Therefore, the present paper deals only with the microscopy of the formed lead electrode.

General and Microscopic Observations of the Formed Lead Electrode

Effectiveness of the lignin in prevention of cracking.—From the preliminary examination of the formed lead electrodes, it was evident that extensive cracking of the active material had occurred only in those electrodes that contained no lignin. Those to which lignin had been added had either no cracks or cracks so small and limited in extent as to make difficult their detection without optical magnification. It was also noted that the electrodes containing no lignin cracked to the same extent whether or not $BaSO_4$ was present.

Apparent variation of electrode surface texture with the amount of lignin present.—Examination of the formed lead electrode by low magnification stereomicroscopy, before the plastic impregnation, indicated that the surface structure varied from electrode to electrode quite noticeably. It seemed that the greatest porosity and the coarsest surface structure was found in plates with 1.0% lignin, while plates containing no lignin appeared to be less porous and to have a finer structure. The presence or absence of $BaSO_4$ seemed to make no difference.

The significance of the above observations was greatly reduced, however, when cross sections of the electrodes were examined at high magnification. To obtain these cross sections, portions of the electrode were impregnated with a polyester, which, after hardening, permitted the sample to be sectioned and polished. Examination at higher magnification of this cross section revealed that the electrodes made from each of the mixes had a structure at the surface and for a few mils below the surface that was quite unlike that which existed in the interior of the electrodes (Fig. 1 and 2). This same difference was found at both plate surfaces. In general, the lead crystals at or near the surface were larger and much further apart than those which were present in the interior.

In addition, there were often large voids just below the surface (Fig. 2). These voids were always a small distance beneath the surface and they were covered over with a layer of surface crystals, so that it is unlikely that these voids could have been seen during the surface examination that took place before the electrodes were impregnated with plastic. Moreover, the electrodes containing 1.0% lignin showed no such voids as appeared in Fig. 2. However, in the actual surface of the 1.0% lignin electrodes the particles

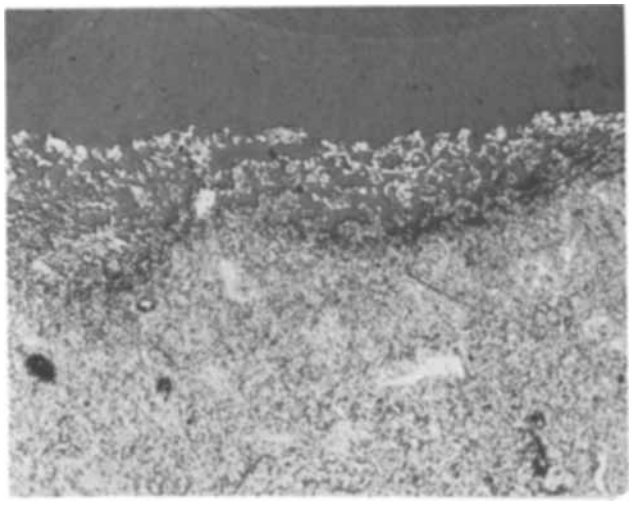

Fig. 1. Cross-sectional view of negative plate, including surface layer. Plate made from paste mix with 1.0% lignin and no $BaSO_4$. Bright particles are lead dendritic crystals. Center of plate is below the lower edge of photograph, while surface of the plate is above the center of the photograph. Dark area at top of photograph is the plastic embedding material. Note different structure at, and just below, surface. Magnification 120X.

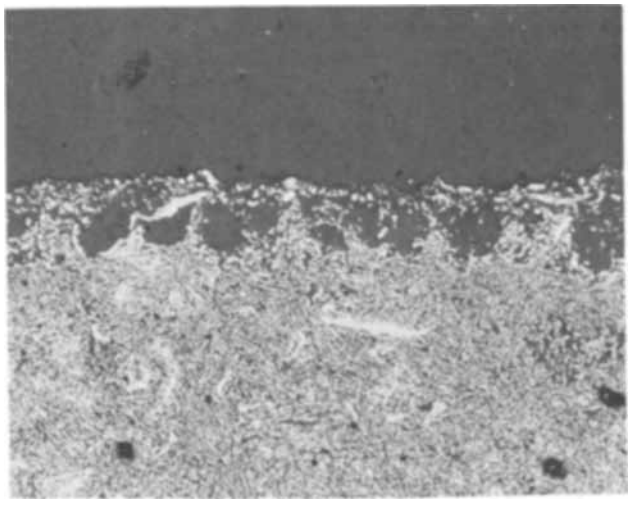

Fig. 2. Cross-sectional view of negative plate, including surface layer. Plate was made from paste mix with no lignin but 0.5% $BaSO_4$. Same relative position as Fig. 1. Note large voids below plate surface. Magnification 120X.

seemed to be larger, or else had formed conglomerates, thus suggesting larger particles, than those that were seen in the other electrodes. Therefore, it seemed likely that in the earlier examination the spaces between these large surface particles had been mistaken for voids when comparison was made with electrodes containing much finer particles. In any case, the differences in size of particles in the surfaces of the different electrodes, as viewed in cross section, were not as obvious as had seemed the case when viewed from above the surface with a stereomicroscope.

It may have been significant that the plates representing mixes with 1.0% lignin had no subsurface voids. It should be noted, however, that there was considerable variation in the appearance of the surface layer, even in the same electrode. It was also true that the amount of material involved in this phenomenon was small as compared with the total area of the cross section. There is also considerable evidence at hand to suggest that the difference at the surface may be, at least partially, the result of the slight sulfation that occurs when the plates stand for a time in the forming electrolyte before the actual electrolysis begins. In this case the phenomenon would probably be independent of the type or amount of expanders being used. Similar differences between the surface and interior of the plate have been noticed in commercial plates of many different manufacturers and have been seen in both positive and negative plates.

Modification of the crystalline lead structure by the presence of lignin.—The most noticeable change in crystalline structure in the presence of lignin was in the central portion of the plate. The thin surface layer of different structure remained unchanged in the presence or absence of $BaSO_4$ and lignin, although this surface layer contained less large holes in the presence of lignin, as previously mentioned.

The interior structure of plates with lignin consisted of smaller and less complex dendritic crystals than that in lignin-free plates. No significant changes of structure could be attributed to the presence of the various amounts of $BaSO_4$ in any of the electrodes. The relative amount of lignin added may have been significant but the effect of changing the amount was small as compared with its complete absence. Therefore, the following description of structure modification by lignin is confined to a comparison of electrodes in which lignin was present and in which lignin was absent, without considering the smaller changes produced by varying the quantity of lignin. It should also be mentioned that the interior microstructure for any given electrode was not entirely uniform and occasional areas were observed in both the electrodes with and without lignin that did not fit the following description. However, the following description represents the structure found in most areas.

In the electrodes containing no lignin (Fig. 3), the individual lead filaments were very long, sometimes with a dozen or more practically parallel filaments extending as a group in straight lines for distances in the range of 200-375μ. This parallel filament structure seemed to be most extensive in the area of the grid bars and to sweep outward from their vicinity. Usually, however, no direct contact with the grid was found. The crystals were randomly oriented except in the vicinity of the grid. They did not seem to grow into the surface layer, so that a distinct boundary could be marked between the surface and the interior. In contrast to the very long, slender lead filaments of the interior, the surface particles were coarse, nondescript, and seldom parallel.

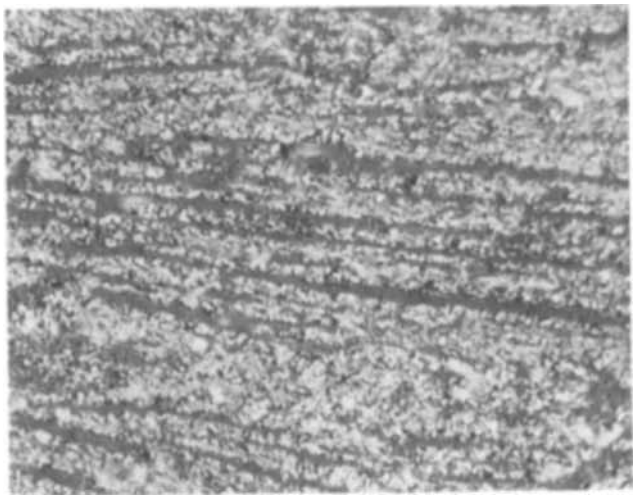

Fig. 3. Formed negative plate cross section, showing the many parallel rows of what appear to be needlelike lead filaments. Paste mix used in the preparation of this plate contained neither lignin nor $BaSO_4$. Magnification 800X.

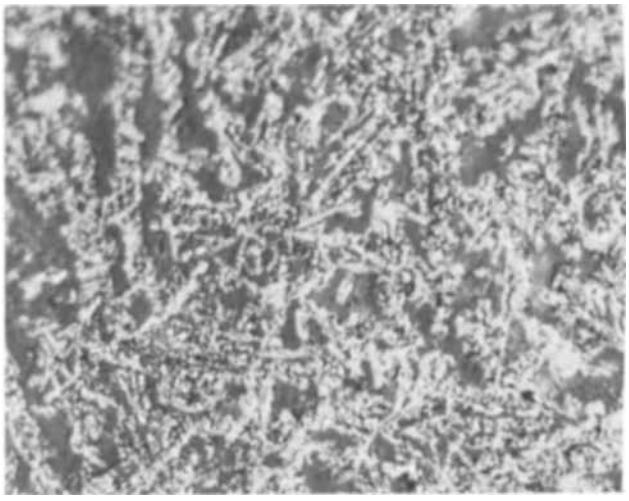

Fig. 4. Cross section of formed negative plate containing 0.5% lignin but no $BaSO_4$. Magnification 800X.

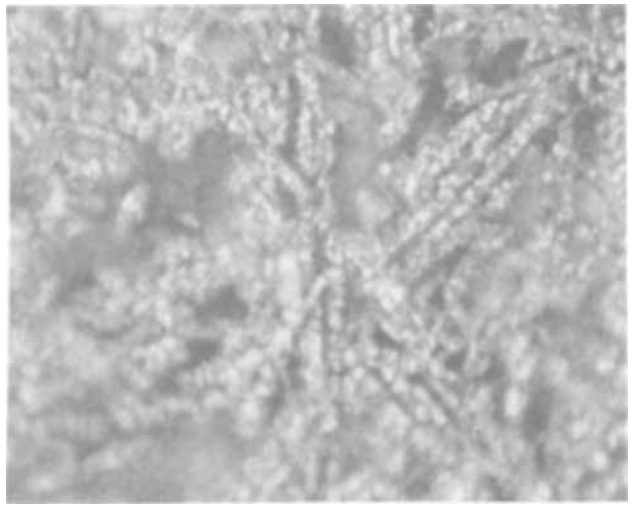

Fig. 6. Same view as Fig. 4, but at the higher magnification of 1600X. Note relatively simple needles as compared with Fig. 5.

In most areas of the plates containing lignin (Fig. 4), on the other hand, parallel filaments of lead were rarely found to exceed 30μ in length and there were rarely more than three or four parallel filaments in a group. Growth direction was also completely random.

Figures 3 and 4 represent a magnification of 800X, about the lowest that could be used to encompass a sufficient area to give an idea of the general structure and yet furnish sufficient detail to enable one to see the individual particles. Figures 5 and 6, taken at 1600X magnification, give a clearer view of the essential differences of the electrodes with and without lignin.

At the magnification of Fig. 4, there seems to be an almost complete lack of parallel filaments, but if one looks closely at Fig. 6, at the higher magnification of 1600X, it is possible to detect very closely spaced parallel filaments. The corresponding photographs of the type of structure found in lignin-free plates (Fig. 3 and 5) very clearly show the many practically parallel filaments of lead that are present in lignin-free electrodes.

Figures 5 and 6 were obtained with an oil immersion objective which not only changes the contrast and general appearance of the lead filaments but also lowers the reflectivity of the polished sample section to some extent. This permits portions of the sample which are beneath the sectioning level to be examined but has the disadvantage that crystal identification by means of differing surface reflectivity is made correspondingly more difficult.

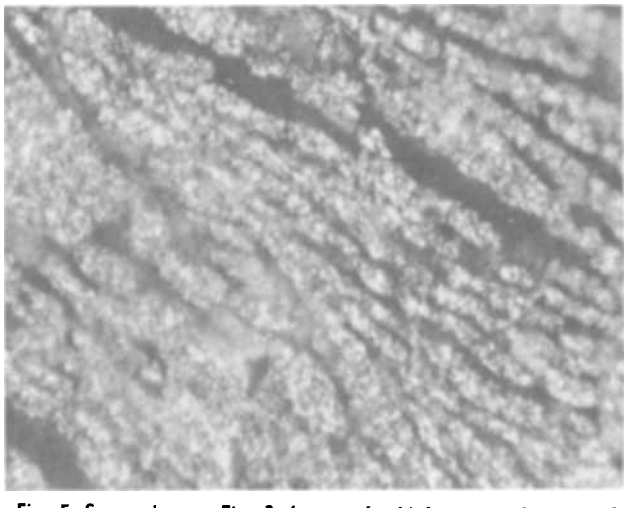

Fig. 5. Same view as Fig. 3, but at the higher magnification of 1600X.

Examination of plates at lower magnifications, such as those of Fig. 3 and 4, seemed to show a number of very small crystals of reflectivity different from that of the lead. This is most evident in Fig. 4. Their general appearance suggested that they were lead sulfate crystals. These crystals seemed to be more numerous in the plates that contained lignin. If true, this might indicate a clue for the reason for the structural differences shown by electrodes containing lignin. Unfortunately, when using oil immersion objectives, for the reasons given above, these crystals could not be clearly differentiated from the lead so that no definite conclusions as to the relative amounts present in lignin-free and lignin-containing plates could be drawn.

It was concluded from the microscopic examination that the complexity of dendritic growth of the lead crystals, and total crystal size, had been reduced by the presence of lignin.

Possibility of lignin migration during forming.—It is the usual practice to add the lignin and $BaSO_4$ to the original paste mix. This mix is then pasted into the grids used for the negative electrodes and is subsequently dried. The negative electrode is then immersed in an acid electrolyte and electrolytically formed to sponge lead. It is not definitely known what happens to the lignin during this process. The $BaSO_4$, on the other hand, because of its lack of solubility, is believed to remain in the negative plate. During the electrolytic forming, the original paste of the negative electrode, consisting of basic lead sulfates, PbO, lignin, and $BaSO_4$, is converted almost entirely to dendritic lead crystals. This conversion presumably liberates the lignin which may either diffuse into the surrounding electrolyte and even to the positive electrode, or immediately deposit on the surfaces of the growing lead crystals as they form.

In the original experimental arrangement, each of the cells contained a positive electrode consisting of four commercial plates and a negative electrode consisting of five plates. The three inside negative plates were laboratory mixes which contained various amounts of $BaSO_4$ and lignin as shown in Table I. In every case, however, the two outside plates were production negatives containing both lignin and $BaSO_4$. After the forming, these two outer plates were discarded and were not given any examination. In the subsequent examination of the experimental plates, the presence of $BaSO_4$ and lignin in the two

outer commercial plates did not seem to have any effect on the structure of the inner experimental plates of the same electrode.

To test the correctness of this observation, however, five additional cells were prepared and electrolytically formed in the same manner as the earlier cells. These additional cells contained the following experimental arrangements in the negative electrode:

(*a*) All five plates were laboratory preparations containing 0.5% $BaSO_4$ but no lignin.

(*b*) Two laboratory prepared plates containing 0.5% $BaSO_4$ but no lignin were sandwiched between three production negatives containing lignin and $BaSO_4$

(*c*) All five plates were production negatives containing $BaSO_4$ and lignin.

(*d*) An electrode was assembled from five laboratory prepared plates containing 0.5% $BaSO_4$ but no lignin. Just prior to formation lignin was added to the electrolyte.

(*e*) An electrode was assembled from five laboratory prepared plates containing 0.5% lignin and 0.5% $BaSO_4$.

The individual plates from each of these electrodes were examined after the formation and their structure was found to confirm the previous conclusions. The structure of the lignin-free plates was the same as that of the two plates containing no lignin which had been sandwiched between production negatives.

The plates which contained no lignin, formed in the electrolyte to which lignin had been added, may have undergone a very slight modification of structure. For the most part the structure found in this electrode was quite similar to that in the electrodes in which all plates were lignin free, except that there seemed to have been a slight reduction in crystal size near the surface of the plate. However, the somewhat different structure usually found at the surface of the plate, as previously noted, made it difficult to be sure. It can only be said that, if lignin added to the electrolyte had any effect on the structure developed during electrolytic forming, such an effect was slight. It was concluded that lignin must remain in the plate and that it is not released into the electrolyte during the formation process.

Discussion and Conclusions

Lignin definitely reduced the complexity of the structure in lead crystals during the original electrolytic formation that produced the so-called "sponge lead" electrode. Therefore, it is important to consider just what is the lead crystal structure. Polished cross sections of electrodes that contained no lignin showed groups of parallel lead filaments extending for considerable distances until their path was interrupted by similar groups of parallel filaments extending in other directions.

What was seen cannot be filaments, however. The possibility would be extremely remote that such small-diameter filaments would extend for any distance parallel to a randomly selected plane section, and for this to occur with the observed frequency would be incredible. Despite their appearance, therefore, the apparent filaments or needlelike lead structures must have represented some other configuration.

The idea of parallel tabular crystals or laminar-like growths suggests itself immediately but was rejected in favor of an ordered dendritic growth for the following reasons:

(*a*) Cross sectioning at any angle through a laminar structure would always produce apparently continuous filaments in the surface of the section. This is not the actual case, however. Sections contained areas both of the needlelike, parallel, pseudo-filaments and areas where small irregular particles appeared, usually roughly circular or ovoid, separated by considerable and usually uniform distances. These particles did not show visible connection with one another. That these irregular particles were dendritic extensions of a larger growth could be easily demonstrated by repeated grinding and re-examination of the same area whereby it was found that particles remained in approximately the same position although the depth of material removed by grinding greatly exceeded their apparent diameters. That they were interconnected at certain levels was also established in this manner.

(*b*) Focusing down through the clear plastic made possible examination of some subsurface areas. It was noted in some cases that pointed projections could be seen below the surface. These appeared to be the ends of dendritic type branched structure, and they were most numerous in areas where the ovoid or circular particles were found. When such areas were ground down, cross sections of these particles were identical with those seen elsewhere and since laminar structure was never noted in this manner it was assumed that the pointed extensions and the sectioned irregular particles were cross sections through a dendritic crystal near a growth boundary. It was indicated that the pointed projections seen beneath the surface were the same as those that had been sectioned, except that growth had stopped short of the plane of section.

(*c*) Disintegration of the plate either by mechanical crushing and grinding, ultrasonic vibration, or the vigorous shaking of suspensions did not reveal any platelets or foil-like structures in the residue. Since lead is malleable, some evidence of such structure should have survived the plate disintegration, if it indeed existed. On the other hand, short lead needles of irregular circumference were abundant in the residue.

(*d*) It has been our experience that sectioning of material containing platelets or tabular crystals gives some evidence of their presence in the polished microsection. The appearance of irregular thin platelets, formed by the sectioning of tabular crystals at angles very close to paralleling their surfaces, is one such indication. Although it is granted that the psuedo-lead filaments seen in the sections of negative plates would indicate very thin laminae, if laminae were indeed present, it would seem that there should be at least an occasional occurrence of such sectioning parallel or nearly parallel to their surfaces. This is especially true since the psuedo-lead filaments occurred in such abundance. Actually no such indications were found, indicating that laminar or tabular forms are not present.

(*e*) The smallness of the psuedo-lead filaments, the closeness of their spacing, and the limited depth to which high magnification objectives are able to be focused below the surface of the section make it impossible to follow inclined surfaces to a sufficient depth below the surface of cutting to obtain much information, but it was noted that such inclined surfaces as could be inspected appeared to have very irregular appearance and that they contained many knoblike protrusions and otherwise more nearly resembled dendritic structure than laminar.

(*f*) Finally, attempts to study the growth of lead crystals by electrochemical reduction from other solutions and from assorted jells has always resulted in a dendritic type of growth rather than a foil-like or laminar one, except where a foil-like structure may eventually develop from a dendritic origin, as is to be discussed.

Much has been learned of lead crystal structure from a study of lead crystals grown by electrolysis from a lead-rich solution, when such crystals were

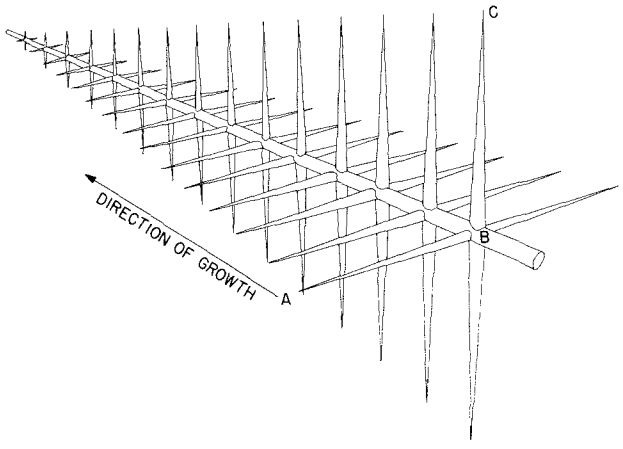

Fig. 7. Simplified drawing of branched structure produced during growth of lead crystals by electrochemical reduction from solution.

grown so that other crystals did not interfere. Figure 7 gives a greatly simplified sketch of such a crystal. The reader is undoubtedly familiar with such skeletal crystals, commonly referred to as dendritic crystals. The observed growth of dendritic lead crystals, however, showed them to be unbelievably complex and far from the simple form shown in Fig. 7. The primary stem, while continuing to grow in a straight line, produced numerous secondary branches growing at right angles to the original growth direction, as in Fig. 7. The process did not stop there, however, because the secondary branches also continued to grow and to produce tertiary branches, at right angles to the growth direction of the secondaries. The process even continued beyond this point to produce branches of an even higher order of branching.

Each branch of such a dendritic crystal grew first into a long, slender needle, much longer in proportion to breadth than shown in Fig. 7. At a later stage numerous platelets or crystallites formed along the length of the needle. These platelets obscured the simple needlelike shape first formed and, when cut, formed very unsymmetrical cross sections. This is illustrated in Fig. 8, which shows an actual photograph of a very small portion of a crystal electrolytically grown from solution. The portion shown does not represent the original primary stem but it was in an area where tertiary branches grew from a secondary. It will be noted that tertiary branches occurred at right angles to one another and at closely spaced intervals along the secondary. Had the process not been stopped at this point, some of the small platelets growing from the tertiary branches may eventually have formed additional branches of higher order. It can be seen that the combination of closely spaced tertiary branches and the growth of the small platelets into the spaces between them produced an almost continuous surface, or foil. In such a structure there are preferred growth directions so that, in essence, parallel laminae result, although with a dendritic origin and without smooth and uninterrupted surfaces. Such a form of growth produces a three-dimensional grid and when cross sectioned at any angle there will be produced in the sectioned surface cross sections of dendritic branches which will be arranged in parallel rows.

This is shown by Fig. 7. If only the quadrant represented by ABC is considered, this can be drawn in slightly greater detail, with some secondary and tertiary branching included, as in Fig. 9. Then imagine that the plane ABCD represents the plane of the electrode cross section. It can be seen how the highly symmetrical branches of the crystal, when intersected in this way, can produce parallel rows of branch cross sections on the surface of the microscopic specimen. Remember also that in the actual crystals the branches are very closely spaced and have overgrowths that not only help to produce cross sections of irregular shape but also help to close up any space left between members of the row. This helps to give the illusion that one is viewing a continuous filament rather than a row of cross sections. In real crystals the dendritic branches were less uniform in diameter, sometimes bent because of their weight, and perhaps with less uniform spacing of branches. Nevertheless, the structure in cross sections would be produced in the same manner as described. (Fig. 10).

This somewhat lengthy description of dendritic growth is not intended to imply that such dendritic growth is unique to lead but only to illustrate how the psuedo-lead filaments are produced that appear in the microscopic cross sections and also how these psuedo lead filaments may indicate the presence of a considerably more complex structure. Whether or not this explanation is correct has no bearing on the reality of the considerably less complex microstructure found in the electrodes containing lignin. Whatever the explanation of the observed microstructures,

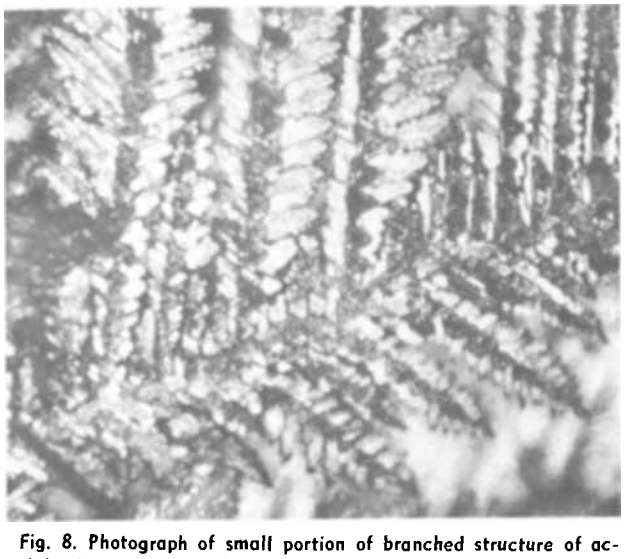

Fig. 8. Photograph of small portion of branched structure of actual lead crystal grown by electrochemical reduction from solution. Magnification 640X.

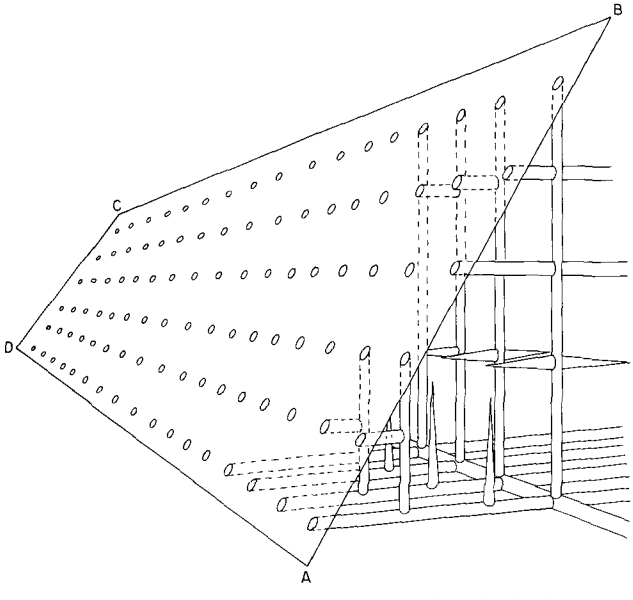

Fig. 9. Drawing made to indicate method by which illusion of parallel lead filaments is created in surface of sections cut through dendritic branched crystals.

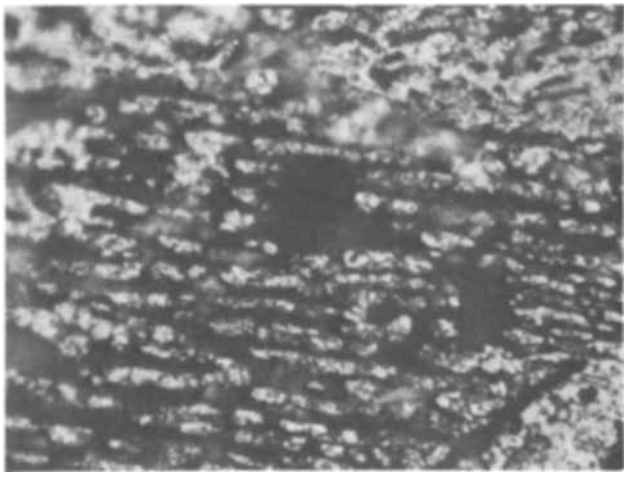

Fig. 10. Photograph of a portion of the psuedo-filaments of lead, indicating the pronounced tendency to be discontinuous even though the individual particles maintain pronounced alignment. Magnification 1600X.

that in the electrodes containing lignin was definitely less complex than that in lignin-free plates.

If this explanation of the observed microstructure is correct, however, the parallel filaments as seen in a lignin-free electrode are evidence of a much more extensive and complex structure either above or below the plane of the cross section made for examination. It should be evident that random sectioning would rarely show the full length of the underlying crystal, so that it would be expected that many of the crystals were actually larger and more complex than the part seen in the section would indicate.

In watching the dendritic growth of lead crystals from solution, it was determined that the diameter was roughly uniform along the entire length of a dendritic branch except at the growing tip where it narrowed to a sharp point. Branch diameter, branch spacing, and total crystal complexity varied with the concentration, current density, temperature, and other factors. Considerable variation in these factors is also noted in different areas of the same formed electrode.

Artistic license is taken in Fig. 7 and 9 which show the branches tapering along their entire length, a completely false impression. Since the branches are all so uniform in diameter, it would appear that added growth to the diameter of the crystal, during the initial rapid stage of growth, is prevented by a sudden depletion of lead ion in the dendritic branch's vicinity as a steep concentration gradient develops.

After the sudden growth of a dendritic branch through a given area, an equilibrium condition is gradually restored and secondary branching occurs. Microscopic examination of dendritic crystals grown in solution showed that the original growth of a branch through the area produced a needlelike cylindrical structure with practically smooth sides. After a time very small crystallites began to form on the original dendritic branches and these continued to increase in size (Fig. 8). At more or less regular intervals along the length of the dendritic branch, some of these crystallites were able to outgrow the others and initiated another sequence of dendritic branching. This in turn set up new concentration gradients that suppressed the growth of the crystallites that remained between those able to outstrip the others.

Very small differences were found in the diameter of dendritic branches of lignin-free and lignin-containing electrodes. This would indicate that lignin exerts little influence in the initial stages of growth during which primary stems are forming. It is apparently the secondary or higher branching that the lignin suppresses. More likely, it is the formation of the small platelets that is suppressed, so that higher order branching is not possible. It is assumed, therefore, that lignin must deposit at once on the newly formed primary stems and further lead growth can occur only by nucleation of new crystals. Presumably, the primary dendritic stem could be as long in a lignin-containing plate as in a lignin-free plate, but no extensive branching would occur. Without a symmetrical and extensive secondary branching, such a long primary stem would probably never be detected, as there would be infinitesimal chance of sectioning so as to reveal the entire length, or even any great portion, of such a long primary stem.

The sections of lignin-containing plates show only short psuedo-filaments and very little paralleling, so that it can be deduced that the underlying crystals are quite simple, close packed, and very numerous.

It is doubtful that the modification in crystal structure brought about by the lignin offers any real advantage at the beginning, although this cannot be definitely ascertained until all phases of this investigation are completed. BET measurement of the surface of the lignin-free and lignin-containing electrodes showed nearly the same surface area to be present in the two cases.

It was noted that lignin seemed to reduce the cracking that occurred during the drying of the formed negative electrodes. This is puzzling since it would seem that the complex lead structure found in the lignin-free plates would form more interlocking and a more coherent plate than would the less intricate crystals of the lignin-containing electrode.

However, perhaps the less complex structure in the lignin-containing plate resulted in more efficient packing so that such a plate was more resistant to the surface tension produced by the evaporation of the electrolyte. Or perhaps the simpler structure of the crystals in the lignin-containing plates is more resistive to compressive forces than are the long, complex, many-branched crystals of the lignin-free plates.

In conclusion, mention should be made of the work of Hauel (9), who studied the change in permeability of the negative electrode during formation and concluded that $BaSO_4$ was beneficial to the process. This conclusion was based on the observed decrease in permeability at the end of formation in plates containing $BaSO_4$ but no organic material, and on the assumption that decreased permeability was the result of the formation of smaller crystals and consequently smaller pores. As mentioned previously, no evidence was found in the present investigation that $BaSO_4$ changed the lead crystal structure in any manner, nor could evidence be found to otherwise explain the decreased permeability in the presence of $BaSO_4$ that was observed by Hauel.

Acknowledgments

The authors wish to thank both the U.S. Naval Research Laboratory and Globe-Union, Inc., for permission to publish this paper, and for their part in the joint effort that has made possible the extensive investigation of lead electrode behavior of which this paper is only a preliminary report. Appreciation is also expressed to the International Lead-Zinc Research Organization, Inc., which has contributed to this and other investigations of electrochemical power sources by maintaining at the Naval Research Laboratory the position of Postdoctoral Research Associate for one of the authors.

Grateful acknowledgment is also made to Dr. Victor R. Deitz of the U.S. Naval Research Laboratory who made the BET surface area determinations.

Manuscript submitted May 7, 1970; revised manuscript received *ca.* Aug. 12, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1971 JOURNAL.

Oxygen and Hydrogen Peroxide Reduction at a Ferric Phthalocyanine-Catalyzed Graphite Electrode

A. Kozawa,* V. E. Zilionis,* and R. J. Brodd*

Union Carbide Corporation, Consumer Products Division, Research Laboratory, Cleveland, Ohio 44101

ABSTRACT

When deposited on graphite, ferric phthalocyanine has been found to be a good catalyst for electrochemical oxygen reduction in near neutral isotonic saline electrolytes (*p*H 7.22). In this study, the electrochemical reduction of oxygen and hydrogen peroxide at the ferric phthalocyanine-graphite electrode was investigated over a wide range of *p*H-values by linear sweep voltammetry in order to characterize the catalyst system. The results are compared with those at platinized platinum and graphite electrodes. The activity of the ferric phthalocyanine-graphite electrode is approximately equal to that of the platinized platinum electrode in 1M KOH. In acid solution, the ferric phthalocyanine-graphite electrode has a fair activity but becomes inactive once a fairly negative potential is imposed.

In the search for a specific catalyst for the oxygen cathode of an implantable fuel cell that could power an artificial heart device, ferric phthalocyanine-catalyzed graphite was found to be an excellent electrode for oxygen reduction in saline solution (1, 2). Metal phthalocyanines such as cobalt phthalocyanine (3, 4) and ferric phthalocyanine (5) have been reported to be good catalysts for the oxygen cathode of a fuel cell. Although the performance of fuel cells or half cells having such catalysts on or in the porous cathode have been reported, basic electrochemical studies of such a catalyst under relatively simple conditions have not been reported. In previous studies, 35% KOH or 4.5*N* H_2SO_4 solutions were used as electrolytes (3, 5). The *pH* range in the present investigation is limited to that between 1M KOH and 0.5M H_2SO_4.

In this study, in order to establish the electrochemical characteristics and capabilities of the ferric phthalocyanine-graphite electrode, the electrochemical reductions of oxygen and hydrogen peroxide were investigated at ferric phthalocyanine-graphite, platinized platinum, and graphite electrodes over a wide *p*H range (*p*H 0.3-13.5). Investigations of the ferric phthalocyanine-graphite electrode in widely varying media should be helpful in defining important characteristics of electrocatalysts, since many catalysts for oxygen cathodes generally do not work equally well in both alkaline and acid solutions.

Experimental Procedure

A platinum or pyrolytic graphite rotating disk electrode described previously was used (1). The areas of the disk electrodes were 0.196 and 0.268 cm^2 for platinum and graphite electrodes, respectively. The cell was a glass vessel having a water jacket to control the temperature. Both the counterelectrode and the reference electrode were saturated calomel electrodes (SCE). All potentials were measured and reported *vs.* SCE. All the current-potential (*i-E*) curves were taken starting at the open-circuit potential and sweeping toward more negative potentials at a rate of 0.1 V/min at 23° ± 1°C. The *i-E* curves were recorded with an X-Y recorder.

Platinum black electrodes were prepared by electrodepositing platinum black on the surface of a polished platinum disk from a chloroplatinic acid solution containing lead acetate. The surface was completely covered with a black deposit. The pyrolytic graphite surface was polished in the usual metallographic manner using a 0.3μ alumina suspended in water, with water on microcloth for the final polish. Ferric phthalocyanine catalyst was deposited on the polished graphite surface from a concentrated sulfuric acid solution by diluting the solution with water. By this method, approximately 1 $\mu g/cm^2$ of ferric phthalocyanine was deposited on the graphite surface. Ferric phthalocyanine was determined spectrophotometrically from the absorbance of pyridine solutions at 655 mμ. The platinized platinum electrode was kept in distilled water and used repeatedly. However, a fresh ferric phthalocyanine-graphite electrode was prepared for each experiment.

The following six electrolytes were prepared from analytical grade reagents:

1. 0.5M H_2SO_4
2. 0.05M H_2SO_4 + 0.15M NaCl (*p*H 1.55)
3. 0.15M NaCl + 0.05M sodium-potassium phosphate buffer (*p*H 7.22)
4. 0.15M NaCl + 0.05M sodium acetate (*p*H 7.7)
5. 0.1M KOH + 0.15M NaCl (*p*H 11.58)
6. 1M KOH.

The *i-E* curves were taken in nitrogen-saturated solution, oxygen-saturated (1 atm) solutions, and in nitrogen-saturated solutions containing hydrogen peroxide. The hydrogen peroxide solution was prepared from 90% hydrogen peroxide (which was a stabilizer-free product supplied by FMC Corporation). The ap-

* Electrochemical Society Active Member.

Key words: oxygen reduction, H_2O_2 reduction, ferric phthalocyanine graphite.

proximate hydrogen peroxide concentration in the nitrogen-saturated solution was 0.001M.

In order to compare the capability of the ferric phthalocyanine-graphite electrode with that of a platinized platinum electrode, the i-E curves for both electrodes were taken in the same solution. Equivalent measurements at an uncatalyzed graphite electrode gave the basic activity of the substrate material since the ferric phthalocyanine catalyst may not completely cover the surface of the graphite electrode.

Results

Figures 1-6 show the i-E curves taken at platinized platinum, ferric phthalocyanine-graphite, and graphite electrodes in various oxygen-saturated, acid, neutral, and alkaline solutions. Regardless of the pH value of the solution used in this work, the current due to oxygen reduction at a graphite electrode is practically zero up to about −0.3V *vs.* SCE. In neutral and alkaline electrolytes, the current at the platinized platinum or ferric phthalocyanine-catalyzed graphite electrodes becomes diffusion limited before that potential.

In acid solutions (Fig. 1 and 2), the loss in activity of the ferric phthalocyanine-graphite electrodes for oxygen reduction is noted once the electrode is swept beyond −0.3V *vs.* SCE. The current is much lower for the second i-E curve than for the initial sweep. In fact, the activity of the catalyzed electrode is reduced to that of a plain (uncatalyzed) graphite electrode after an extended voltage excursion to potentials more negative than −0.8V as noted in curves 2 and 3 of Fig. 2.

It should be kept in mind when examining the i-E curves that essentially all the oxygen reaching the platinized platinum electrode surface by diffusion is reduced to water ($O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$) by a four-electron transfer reaction in the potential range more negative than +0.4V in 0.5M H_2SO_4.

Assuming the plateau current at the platinized platinum disk electrode is the diffusion-limiting current for the oxygen reduction reaction ($O_2 + 4H^+ + 4e^- = 2H_2O$), the maximum current for the ferric phthalocyanine-graphite electrode can be calculated from the ratio of their surface areas. A current value of 300 μA was observed for platinized platinum electrodes. The limiting current value for the ferric phthalocyanine-graphite electrode is calculated to be 400 μA; that is, 0.268 cm^2/0.196 cm^2 x 300 μA = 400 μA.

In neutral and alkaline electrolytes (Fig. 3-6), the ferric phthalocyanine-graphite electrode gives a plateau current value that is close to the diffusion-limiting current as previously calculated over a wide potential range. Also, the electrode maintains its activity upon repeated sweeps, even when it has been swept to very negative potentials.

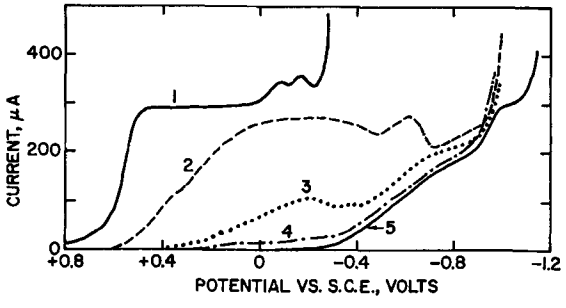

Fig. 1. Current-potential curves in 0.5M H_2SO_4 (oxygen-saturated). Curve 1, platinized platinum electrode (apparent surface area: 0.196 cm^2); curve 2, ferric phthalocyanine-graphite electrode (apparent surface area: 0.268 cm^2), (1st sweep); curve 3, ferric phthalocyanine-graphite electrode (2nd sweep, immediately after curve 2); curve 4, ferric phthalocyanine-graphite electrode (previously swept once in N_2-saturated H_2SO_4 from +0.4 to −1.0V); curve 5, graphite electrode (apparent surface area: 0.268 cm^2).

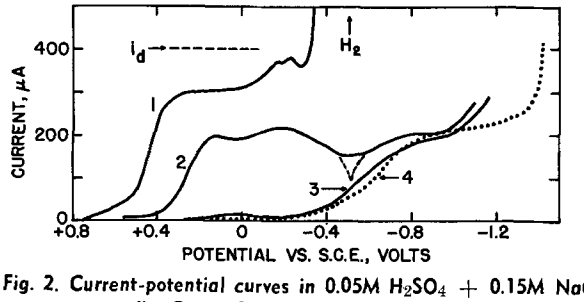

Fig. 2. Current-potential curves in 0.05M H_2SO_4 + 0.15M NaCl (oxygen-saturated). Curve 1, platinized platinum electrode (apparent surface area: 0.196 cm^2); curve 2, ferric phthalocyanine-graphite electrode (apparent surface area: 0.268 cm^2), (1st sweep); curve 3, ferric phthalocyanine-graphite electrode (2nd sweep, immediately after curve 2); curve 4, graphite electrode (apparent surface area: 0.268 cm^2).

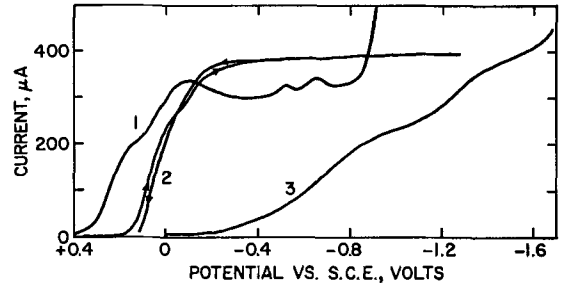

Fig. 3. Current-potential curves in 0.15M NaCl +0.05M phosphate buffer (pH 7.22), (oxygen-saturated). Curve 1, platinized platinum electrode (apparent surface area: 0.196 cm^2); curve 2, ferric phthalocyanine-graphite electrode (apparent surface area: 0.268 cm^2), (arrows show direction of the voltage sweep); curve 3, graphite electrode (apparent surface area: 0.268 cm^2).

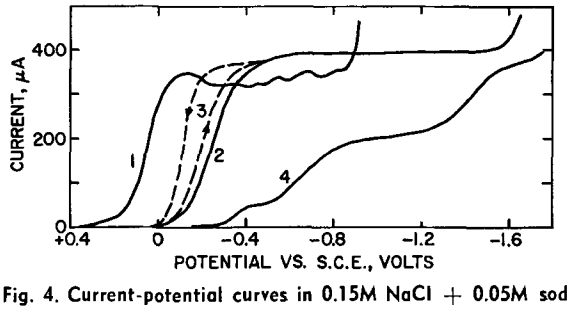

Fig. 4. Current-potential curves in 0.15M NaCl + 0.05M sodium acetate (pH 7.7), (oxygen-saturated). Curve 1, platinized platinum electrode (apparent surface area; 0.196 cm^2); curve 2, ferric phthalocyanine-graphite electrode (apparent surface area: 0.268 cm^2), (1st sweep); curve 3, ferric phthalocyanine-graphite electrode (2nd sweep, immediately after curve 2); curve 4, graphite electrode (apparent surface area: 0.268 cm^2).

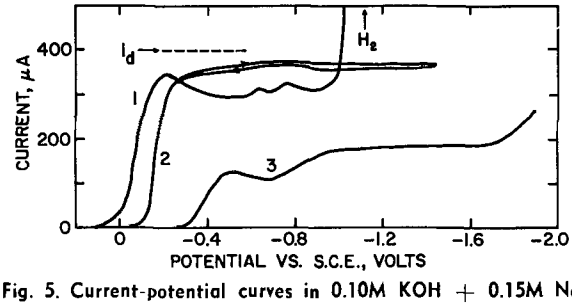

Fig. 5. Current-potential curves in 0.10M KOH + 0.15M NaCl (oxygen-saturated). Curve 1, platinized platinum electrode (apparent surface area: 0.196 cm^2); curve 2, ferric phthalocyanine-graphite electrode (apparent surface area 0.268 cm^2), (arrows show direction of the sweep); curve 3, graphite electrode (apparent surface area: 0.268 cm^2).

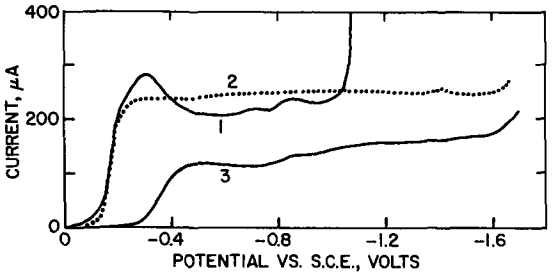

Fig. 6. Current-potential curves in 1M KOH (oxygen-saturated). Curve 1, platinized platinum electrode (apparent surface area: 0.196 cm^2); curve 2, ferric phthalocyanine-graphite electrode (apparent surface area: 0.268 cm^2); curve 3, graphite electrode (apparent surface area: 0.268 cm^2).

An anion effect was noted in the two neutral solutions. It is seen that the i-E curve at the ferric phthalocyanine-graphite electrode is almost reversible in the phosphate-containing solution (curve 2, Fig. 3); that is, the direction of the sweep does not influence the shape of the curve. In the acetate-containing solution, however, the i-E curve is less reversible and the electrode becomes activated (*i.e.*, the i-E curve is shifted toward a more positive potential) when repeated cyclic sweeps are made (curves 2 and 3, Fig. 4).

A well-platinized platinum electrode is considered to be one of the most active electrodes for cathodic oxygen reduction. In neutral and 0.1M KOH + 0.15M NaCl solutions (Fig. 3-5), the half-wave potentials of the i-E curves at the ferric phthalocyanine-graphite electrode are fairly close (100-200 mV) to the value at the platinized platinum electrode. In 1M KOH solution, the half-wave potentials of the i-E curves (Fig. 6) for the ferric phthalocyanine-graphite electrode and the platinized platinum electrode are essentially identical, and there is little difference between the two electrodes in the oxygen reduction capability.

Discussion

Deactivation of the ferric phthalocyanine-graphite electrode in acid.—Deactivation of the ferric phthalocyanine-graphite electrode is seen clearly in acid solution (curve 2, Fig. 2). Around −0.3V the current begins to decrease and passes through a minimum. This may be associated with the oxygen reduction current at a plain graphite electrode which increases around that potential, although the catalyst (ferric phthalocyanine) loses its activity. In order to correlate this behavior with the redox nature of the ferric phthalocyanine-graphite electrode itself, i-E curves were taken in nitrogen-saturated solution (Fig. 7) where the only reactions occurring should be associated with redox reactions of the catalyst. The current values are very low, but four peaks can be seen between −0.3 and −0.8V. Since there are no peaks in the i-E curve (curve 3) taken at a graphite electrode, these four peaks may be attributed to the ferric phthalocyanine catalyst. Although these four peaks are always observed on freshly catalyzed electrodes, they are not exactly reproducible in shape and relative height from one electrode to another. The reduction processes that are responsible for these reduction currents are not known. It is interesting to note that the potential (about −0.3V) at which the first peak begins to appear (see Fig. 7) corresponds to the point where the current decreases in curve 2 of Fig. 2. There may be a correlation between the reduction of the catalyst and the loss of the oxygen reduction activity. This loss of activity in the acid solution was not necessarily permanent. A ferric phthalocyanine-graphite electrode, which was deactivated in acid by sweeping to −0.8V, showed almost full activity when operated in oxygen-saturated 0.1M KOH solution. Therefore, the loss in activity is not associated with loss of the catalyst from the electrode.

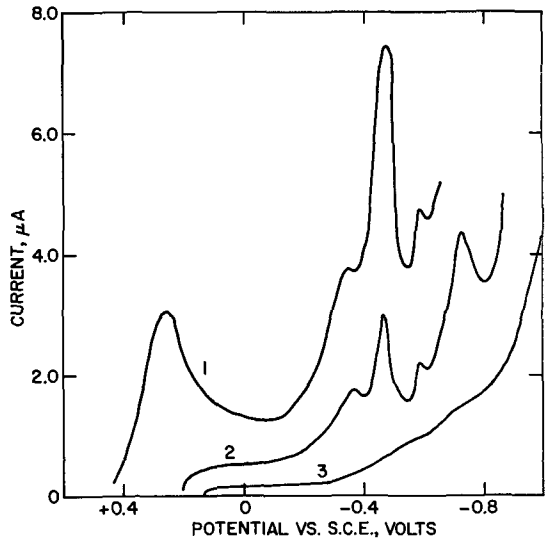

Fig. 7. Current-potential curves in 0.05M H_2SO_4 + 0.15M NaCl (nitrogen-saturated). Curve 1, ferric phthalocyanine-graphite electrode (apparent surface area: 0.268 cm^2); curve 2, ferric phthalocyanine-graphite electrode (2nd sweep); curve 3, graphite electrode (apparent surface area: 0.268 cm^2).

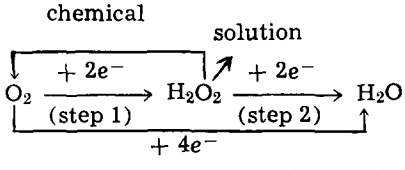
It is possible that the change in activity of ferric phthalocyanine catalyst may be associated with a change in the anion associated with the test. The catalyst is deposited in a thin layer, and an ion exchange which was dependent on the solution composition could occur. It is not clear exactly how the anion would influence the catalytic activity.

Hydrogen peroxide reduction.—Hydrogen peroxide is known to be an intermediate in the cathodic reduction of oxygen at various electrodes (6-8) including graphite and platinum in acid, neutral, and alkaline solutions. A proposed scheme of oxygen reduction is given below.



[1]

A study of hydrogen peroxide reduction in nitrogen-saturated solution should yield some useful information on the kinetics of the electrochemical oxygen reduction. Suppose an electrode does not reduce hydrogen peroxide electrochemically, although oxygen is reduced to water at the electrode. In such a case, oxygen must be reduced either by a direct four-electron step or through a step involving chemical decomposition of hydrogen peroxide.

Figures 8-11 show the results of hydrogen peroxide reduction in nitrogen-saturated acid, neutral, and alkaline solutions. The graphite electrode has little or no ability to reduce hydrogen peroxide electrochemically over most of the potential range studied. The current plateau at the platinized platinum electrode is an experimental measure of the total hydrogen peroxide reduction current. The i-E curves (Fig. 9-11) at the ferric phthalocyanine-graphite electrode in neutral and alkaline hydrogen peroxide solutions contain two steps and differ considerably from the i-E curves taken in the oxygen-saturated solutions. In alkaline and neutral solutions, the ferric phthalocyanine-graphite electrode can reduce hydrogen peroxide, but in acid solution (Fig. 8) the electrode has no activity for hydrogen peroxide reduction. This behavior suggests that step 2 in Eq. [1] does not proceed at reasonable rates at the ferric phthalocyanine-graphite electrode in acid solution. Catalytic decomposition of hydrogen peroxide on ferric phthalocyanine in the absence of

applied potentials has been studied by Cook and George since its structure is similar to hemin and catalase (9, 10). According to Cook's study, ferric phthalocyanine was an outstanding catalyst for decomposing hydrogen peroxide. He attributed the activity to its central iron ion. As yet, the electrochemical oxygen reduction mechanism at the ferric phthalocyanine-graphite electrode is not known. However, a speculative explanation of the two reduction steps could be given here. The hydrogen peroxide decomposition rate should be potential dependent. At low potentials where the rate is small, the spontaneous decomposition of peroxide could produce enough dissolved oxygen to give a significant current. Thus the first step could be attributed to reduction of oxygen produced by the spontaneous catalytic decomposition of peroxide by the catalyst. The second step could be attributed to direct reduction of the hydrogen peroxide molecule to water on the electrode.

In 1M KOH, the current capability of the ferric phthalocyanine-graphite electrode remained fairly close to that of the platinized platinum electrode, as shown in Fig. 12. However, an indication of a kinetic limitation for the ferric phthalocyanine-graphite electrode is noted at the higher rotational speeds. It

Electrode Materials and Catalysts for Oxygen Reduction in Isotonic Saline Solution

A. Kozawa,* V. E. Zilionis,* and R. J. Brodd*

Union Carbide Corporation, Consumer Products Division, Research Laboratory, Cleveland, Ohio 44101

ABSTRACT

The cathode for an implantable fuel cell that could power an artificial heart requires both a specific catalyst and an appropriate electrode material for oxygen reduction. In search of such an electrode structure, various graphites, carbides, metals, and catalytic agents were evaluated using linear sweep voltammetry for oxygen reduction activity in neutral saline solutions. The effect of blood additions on electrode performance was also investigated. An electrode of pyrolytic graphite catalyzed with ferric phthalocyanine was found to be a good specific electrode structure. Characteristics of this electrode in near neutral saline (0.15M NaCl + phosphate buffer, pH 7.22) solution were studied using the rotating disk electrode technique. A kinetic limitation on the limiting diffusion current for oxygen reduction was noted at higher rotational speeds.

An implantable fuel cell that could power an artificial heart requires a specific catalyst for oxygen reduction at the cathode. This means that the catalyst applied on the cathode when used in a blood stream should be selective for electrochemical oxygen reduction and should not promote a direct chemical reaction between molecular oxygen and glucose or other organic substances coexisting in the blood.

In order to fabricate such a cathode to be used in blood, a good oxygen catalyst as well as an appropriate substrate or electrode material having good electrical conductivity is necessary. For this purpose, various possible electrode materials such as graphites, carbides, borides, and a large number of metals, including zirconium and titanium which are known to be corrosion resistant in salt solutions (1), have been evaluated for oxygen reduction in an isotonic saline solution. Also, various organic compounds were tested as possible catalysts. It was noted in the early stage of this work that blood itself contains a substance that promotes oxygen reduction on a graphite electrode. Therefore, our attention focused on iron-containing porphyrin-type compounds such as catalase, hemin, hemoglobin, and metal phthalocyanines. The results of the effect of catalase and hemin on the reduction of oxygen have been reported elsewhere (2) and are not included in this paper.

* Electrochemical Society Active Member.

Key words: oxygen reduction, isotonic saline, ferric phthalocyanine, rotating disk electrode.

Although many papers have been published concerning the electrochemical reduction of oxygen in general (3), these studies were made mostly in concentrated KOH (pH ≅ 16) or H_2SO_4 (pH ≅ 0) electrolytes. Studies of oxygen reduction in neutral salt solutions are very limited [Delahay (4), Kozawa (5), and Laitinen and Kolthoff (6)]. The effect of blood additions on oxygen electrode performance has not been previously reported.

Cobalt phthalocyanines have been reported to be good catalysts for an oxygen cathode in alkaline solution (35% KOH, pH ≅ 16) by Jasinski (7), and iron phthalocyanine in acid solution (4.5*N* H_2SO_4, pH ≅ 0) by Jahnke and Schönborn (8). Neither the activity nor the substrate effect on activity of these compounds for oxygen reduction in neutral salt solution has been reported. In this study, the significance of the substrate effect, particularly the uniqueness of graphite and carbon as substrates for the phthalocyanine compound, are demonstrated.

Experimental Procedure

Electrode materials, chemicals, and blood.—Most of the metals were in the form of wire or a strip and were relatively pure (at least 99.9%). Most of the graphites, carbides, and borides are commercially available items. General information on pyrolytic graphite was published previously (9), and ZTA and other graphites are described in a bulletin (10). Ferric phthalocyanine was obtained from Distillation Products Industries (Division of Eastman Kodak Company) and used as received without purification. The pyridine, used as a solvent for the phthalocyanines, was Fisher Infrared Spectroanalyzed grade. Fresh human blood was obtained from Parma Community General Hospital and stored in a refrigerator at 4°C. The blood contained ethylenediaminetetraacetic acid as an anticoagulant.

Solution.—An isotonic saline solution (0.15M NaCl + 0.05M phosphate buffer, pH 7.22) was prepared from reagent grade chemicals. It was used without further purification. Phosphate buffer was used because it is one of the major pH buffer systems in the blood (11).

Linear sweep voltammetry.—Current-potential (*i-E*) curves were taken in quiescent nitrogen- or oxygen-saturated solution with a Controlled Potential and Derivative Voltammeter (Model ORNL-1988A) (12). The test electrode was placed in one arm of a polarographic H-cell filled with isotonic saline solution. The electrode surface exposed to the solution was about 0.25 cm^2. Paraffin was used to mask off the unused portion of the surface. The potential sweep rate was 0.25 V/min. Usually the *i-E* curve was first taken in a nitrogen-saturated solution, then twice consecutively in an oxygen-saturated solution, and finally in the solution to which blood (10% by volume) was added. All potential measurements were made with respect to a saturated calomel reference electrode (SCE).

Rotating disk electrode.—The rotating disk apparatus used was described in a previous paper (2). The area of the pyrolytic graphite rotating disk electrode was 0.268 cm^2 and that of the platinum electrode was 0.196 cm^2. The electrode was press fitted in a Teflon holder concentric to the rotating shaft. Electrical connection was established by a spring-loaded silver graphite contact in the shaft. Epoxy resin was used to seal the imperfections between the Teflon and the electrode to prevent oxygen from diffusing into the test cell from the back side of the electrode. This also prevented solution from creeping up into the joint.

The rotational speed was varied between 120 and 1980 rpm. The speed was monitored continuously by an electronic counter using a photocell. The voltage scanning rate was 0.1 V/min.

Before deposition of the catalyst, the pyrolytic graphite rotating disk electrode was polished using standard metallurgical techniques. An alumina (0.3μ) suspension in water was used, always ending with a wet polish on the plain microcloth. After deposition of the catalyst, the electrode was washed with distilled water and mounted on the rotating disk apparatus.

Results and Discussion

Oxygen reduction on graphites, carbides, and others.—As noted in Fig. 1 and 2, the shape and the current level of the *i-E* curve are largely dependent on the electrode material. Some of the electrode materials (for example, pyrolytic graphite) gave a two-step *i-E* curve similar to the polarogram of dissolved oxygen at a dropping mercury electrode. Among the electrode materials of this group (Table I), the material which displayed the highest oxygen reduction current at the most anodic potential was ZTA graphite (high density graphite). When blood (10% by volume) was added to the isotonic saline solution, the oxygen reduction current generally increased as shown in Fig. 3 for the case of the ZTA graphite electrode. Table I summarizes the results for all the electrode materials tested of this group. This in-

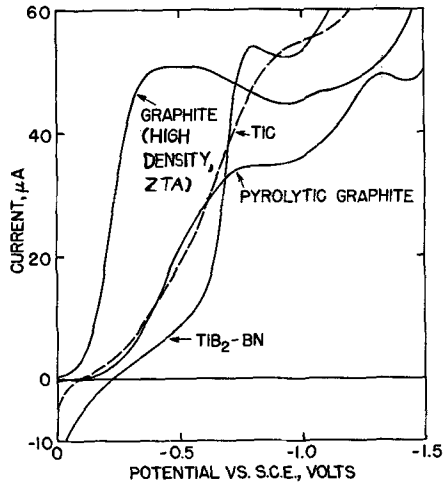

Fig. 1. Current-potential curves taken with various electrodes by linear sweep voltammetry in 0.15M NaCl (+ phosphate buffer, pH 7.22) at 24°C. The solution was saturated with oxygen (1 atm) and the curves were taken in quiescent solution.

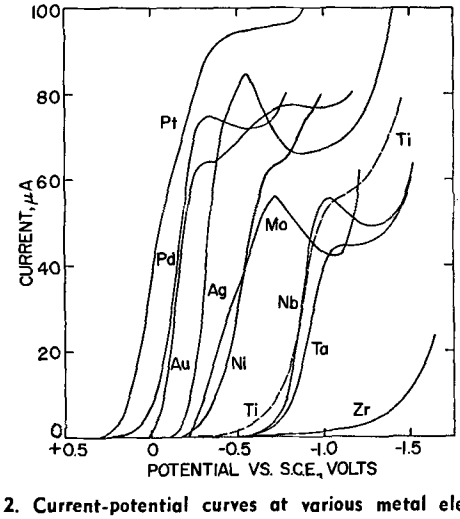

Fig. 2. Current-potential curves at various metal electrodes in 0.15M NaCl solution (phosphate buffer, pH 7.22) saturated with oxygen gas (1 atm) at 23° ± 1°C. The curves were taken in quiescent solution. The electrode surface exposed to the solution was approximately 0.25 cm^2 (not more than 10% deviation).

** In 0.15M NaCl (+ phosphate buffer, pH 7.22) saturated with oxygen (1 atm), and in the NaCl solution to which 10% (by volume) of human blood was added.

creased activity with blood additions suggests that some material present in the blood either acts as a catalyst for the electrochemical oxygen reduction or is itself reduced in the isotonic saline solution. The background current for nitrogen-saturated blood (10% by volume) solutions was negligible, that is, essentially the same as that shown for nitrogen-saturated saline solutions. Therefore, materials present in the blood act as catalysts and are not reduced under the conditions of the experiments.

Oxygen reduction on various metals.—The current level and the potential where the oxygen reduction starts on metal electrodes are widely distributed over the potential range as shown in Fig. 2. The ability to reduce oxygen in neutral saline solution appears to be highly dependent on the nature of the metal. Of the metals evaluated, the best electrode was platinum, as expected. The poorest one was zirconium, on which practically no oxygen reduction took place over a wide potential range. Although all these electrodes were polished with silica powder and water before the experiments, some of the metals, such as zirconium, probably form a surface oxide film under the test conditions which could account for their poor activity.

The effects of blood additions are shown in Fig. 3, 4, and 5 for platinum, graphite, silver, and niobium. In the case of silver (Fig. 4), the oxygen reduction was hindered slightly at the beginning portion of the i-E curve and the plateau current was increased somewhat. The behavior of silver with blood additions was typical of most of the electrode materials studied. The niobium electrode (Fig. 5) is an example of a metal which exhibited a large shift in the i-E curve when blood was added. In the case of the platinum electrode (Fig. 3), not only was the oxygen reduction hindered at the beginning of the i-E curve, but also the plateau current was considerably decreased. This

effect may be caused by a direct chemical reaction between the dissolved molecular oxygen and an organic substance (for example, glucose) present in the blood at the platinum surface and/or due to strong adsorption of blood component(s) on the electrode surface which would hinder the electrochemical oxygen reduction process. In Fig. 3, the results of the ZTA graphite electrode are also shown for comparison with the platinum electrode performance. The oxygen reduction activity for the ZTA graphite and platinum electrodes is almost the same in the solution containing blood.

Search for catalysts.—As noted, some blood components act as a catalyst for oxygen reduction in saline solution. Since it is generally accepted that hydrogen peroxide is an intermediate in the cathodic oxygen reduction process, a catalyst which decomposes hydrogen peroxide rapidly should be a good

catalyst for the oxygen cathode reaction. Therefore, catalase, hemin, hemoglobin, various metal phthalocyanines, and metal porphyrazines were tested by dissolving them in the saline solution or by depositing them on a pyrolytic graphite substrate. Ferric phthalocyanine was the best catalyst of the materials tested. The effectiveness of ferric phthalocyanine as a catalyst appears to be dependent on the nature of the substrate material. The results for catalase, hemin, and various metal phthalocyanines have been presented previously (2).

Substrate effect on the activity of ferric phthalocyanine catalyst.—In these experiments, a small amount of a solution of ferric phthalocyanine in pyridine (50 mg of ferric phthalocyanine in 200 ml of pyridine) was applied to a cleaned nickel or pyrolytic graphite surface. The solvent was evaporated by blowing hot air (70°-80°C) across the electrode surface. The total amount of ferric phthalocyanine on the electrode surface was approximately 45 $\mu g/cm^2$. Figure 6 shows the difference in the activity of the ferric phthalocyanine when deposited on a nickel substrate and on a pyrolytic graphite substrate. In the case of the pyrolytic graphic electrode, the oxygen reduction activity was enhanced considerably when the ferric phthalocyanine was applied; whereas, in the case of nickel, the oxygen reduction activity was decreased

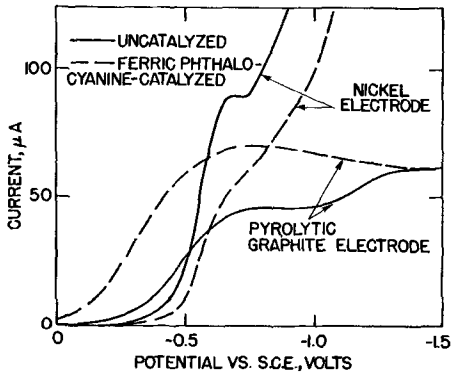

Fig. 6. Current-potential curves at uncatalyzed and ferric phthalocyanine-catalyzed nickel and pyrolytic graphite electrodes in 0.15M NaCl solution (0.05M phosphate buffer added, pH 7.22) at 23°C. Electrode area: 0.27 ± 0.01 cm^2.

somewhat when the ferric phthalocyanine was applied. If a sintered porous nickel plaque, such as is commonly used in fuel cells and nickel-cadmium batteries, was used as a substrate, slightly better activity was observed with the ferric phthalocyanine present than was observed with the nickel plaque substrate alone. The special structure of the carbonyl nickel particles or a nickel oxide film on the surface may be responsible for this effect. In any event, the current increase obtained when ferric phthalocyanine was applied to a nickel plaque was far less than that observed with the graphite substrate. The ZTA graphite electrode itself had a good activity for oxygen reduction as previously mentioned. When ferric phthalocyanine was applied to a ZTA graphite substrate, the oxygen reduction activity was further enhanced as shown in Fig. 7. This behavior is very similar to that noted for pyrolytic graphite.

Various materials (metals, carbides, borides, *etc.*) were tested as substrates for the ferric phthalocyanine catalyst in the same manner as previously described. The results are summarized in Table II. Of these materials, the only substrate that exhibited a substantial current increase in the *i-E* curve was graphite. This suggests that the graphite substrate does not function merely as an electronic conductor for the electrode, but is indispensable in developing the remarkable activity of the ferric phthalocyanine catalyst for electrochemical oxygen reduction. It is well known in the field of catalysis that the supporting substance greatly influences the activity of the catalyst or sometimes determines the specific activity. The graphite and carbon substrates in this case seem to be specific supports and can be considered part of the catalyst system, since neither ferric phthalocyanine nor graphite (or carbon) alone are catalytically active.

Current capability of the ferric phthalocyanine-graphite electrode.—A comparison of the current capabilities of ferric phthlocyanine-catalyzed graphite electrodes and platinum electrodes is found in Fig. 8 and 9.

In the neutral NaCl solution (Fig. 8), the initial oxygen reduction activity at the ferric phthalocyanine-graphite electrode was very good and was close to that of the platinized platinum electrode. It is

The Anodic Polarization Behavior of Copper

H. P. Leckie

Inland Steel Research Laboratories, Inland Steel Company, East Chicago, Indiana 46312

ABSTRACT

The anodic polarization characteristics of copper have been studied under a variety of environmental conditions. In dilute acid solutions at room temperature, copper may dissolve at rates limited by a diffusion-controlled current; increasing the acid concentration results in an increased tendency for passivation. Lowering the temperature promotes the establishment of passivity. A passivation reaction was observed in all the alkaline solutions studied. Galvanostatic charging and decay curves show the existence of several potential plateaus which have been correlated with probable potential-dependent surface reactions.

The present study was undertaken in an attempt to clarify the anodic polarization characteristics of copper, over which controversy has existed for some time. A variety of experimental techniques has been employed in order to gain some insight into the factors affecting the active/passive transition in copper under various environmental conditions.

Key words: oxides, potential current, thermodynamics, kinetics, dissolution.

Anodic polarization of copper may result in either general dissolution or film formation, depending primarily on the pH of the electrolyte. Thus Hickling and

Taylor (1) showed that copper passivated in an alkaline solution forming oxides of Cu_2O and CuO, while in acid solution, copper dissolves to give soluble salts and does not develop a passive protective film. Stolica and Uhlig (2) and Osterwald and Uhlig (3) have studied the effect of alloying elements (nickel and nickel plus zinc) on the anodic behavior of copper in sulfuric acid. These authors showed that the addition of critical amounts of alloying elements to copper would induce passivity in acid solutions. Hedges, (4) however, showed that unalloyed copper could be passivated in acid solutions by lowering the temperature. At −11°C copper became passive in concentrated nitric acid due to the formation of a dark gray film of cupric oxide. In a study of anodic transients for the system copper/hydrochloric acid, Cooper (5) showed the formation of, first solid cuprous chloride followed by cuprous oxide. Copper single crystals immersed in water containing oxygen have been shown by Kruger (6) to oxidize first to cuprous and then cupric oxide. Further studies on the electrochemical dissolution of copper single crystals have been conducted by Jenkins (7). An excellent four-part paper covering the thermodynamic, kinetic, and electrochemical aspects of the corrosion of copper has been written by Ives and Rawson (8).

In the present study, the anodic polarization behavior of copper has been related to *pH*, temperature, galvanostatic current density, and potentiodynamic polarization rate.

Experimental

Copper electrodes (total surface area 10 cm^2) were cut from sheet and prepared by abrasion on 3/0 emery paper followed by a 2-min immersion in 20% nitric acid at 25°C. Each specimen had a tag to which electrical connection could be made.

The all-glass cell used for polarization studies incorporated the following features: (*i*) provision for the centrally located copper anode between and equidistant from two platinum cathodes of the same dimensions, (*ii*) an inlet and outlet for nitrogen agitation, and (*iii*) a further inlet to permit a Luggin capillary from a saturated calomel reference electrode to reach near the anode surface.

Before polarizing, a period of about 15 min was allowed for the specimen to reach a steady open-circuit potential. In the present studies, the electrolyte was exposed to oxygen in the atmosphere and it was noted that the copper electrodes formed a thin surface film during the short time required to reach the open-circuit potential. All potentials quoted are with respect to the saturated calomel reference electrode (SCE). Charging curves were also conducted by first controlling the potential at 1.0V active to SCE and subsequently switching to a preset anodic current density. This procedure eliminated the formation of the oxide film which spontaneously formed under open-circuit immersion conditions.

Solutions were prepared from distilled water made acid or alkaline using sulfuric acid or sodium hydroxide. Low-temperature passivation studies were conducted having the cell enclosed in a freezing mixture of an aqueous calcium chloride solution. This, in turn, was immersed in a bath of acetone to which solid carbon dioxide was added from time to time. By this method, the temperature at −10°C could be maintained within ±0.2°C. In these low-temperature experiments, the calomel electrode was connected to the cell through a bridge. The relatively small potential deviations due to thermal gradients were neglected.

Results

Figure 1 shows the anodic polarization curves for copper in 1M H_2SO_4 at 0° and 25°C. At 25°C only a maximum diffusion-controlled current was observed at noble potentials with no decrease in current density usually associated with passivity. At 0°C, however, there is some evidence of partial passivation as shown

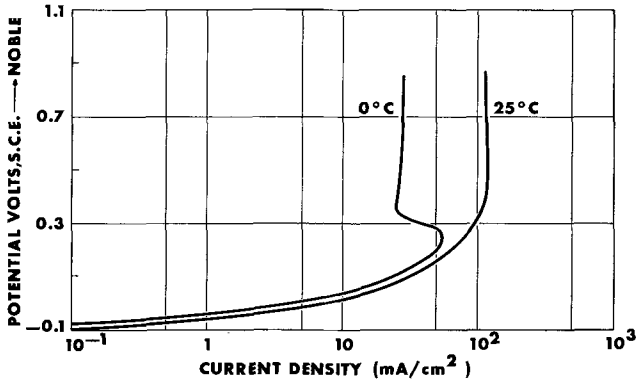

Fig. 1. Potentiodynamic anodic polarization of copper in 1M H_2SO_4 at 0° and 25°C.

by a reduction in the maximum current density as the potential shifts in the noble direction. As the sulfuric acid concentration is increased to 10M, a pronounced passivation reaction is observed even at 25°C (Fig. 2). Lowering the temperature to −11°C further increases the tendency for passivation. Figure 2 also shows that a reduction in temperature from 25° to −11°C lowers the current density for copper in 10M H_2SO_4 at noble potentials by a factor of 4. Anodic polarization curves for copper in a series of sulfuric acid solutions at 25°C ranging from five to ten molar are shown in Fig. 3. It can be seen that the higher the acid concentration, for a given temperature, the more pronounced is the passivation tendency for copper. Between 5 and 6M H_2SO_4, the anodic polarization curves show that copper undergoes a transition from general active dissolution with diffusion-controlled current densities to behavior indicative of film formation. In acid solutions there was no visible film formation at the open-circuit potential.

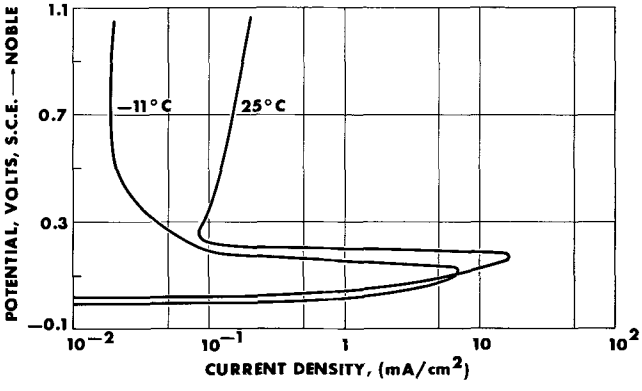

Fig. 2. Potentiodynamic anodic polarization of copper in 10M H_2SO_4 at −11° and 25°C.

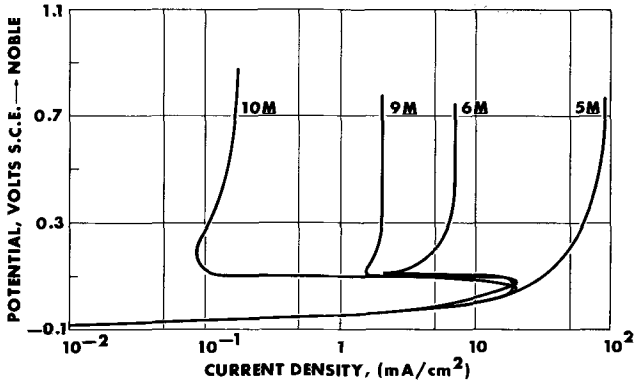

Fig. 3. Potentiodynamic anodic polarization of copper in 5, 6, 9, and 10M H_2SO_4 at 25°C.

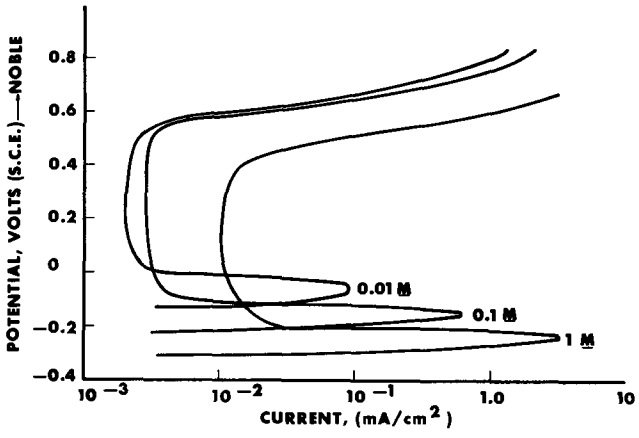

Fig. 4. Potentiodynamic anodic polarization of copper in 0.01, 0.1, and 1.0M NaOH at 25°C.

Figure 4 shows the potentiodynamic polarization curves for copper in 1.0, 0.1, and 0.01M sodium hydroxide solution at 25°C, obtained at a polarization rate of 400 mV/hr. Passivation was observed at all concentrations. The critical current density for passivity in sodium hydroxide solution increases with increase in pH. The passivation potential shifts in the noble direction with decreasing pH according to the relationship $E_{pp} = E^{o}_{pp} - 0.086\ pH$ (Fig. 5).

The anodic polarization curves for copper in the same sodium hydroxide solutions, obtained under galvanostatic conditions, are shown in Fig. 6. A linear relationship was found between pH and the logarithm of the critical current density for passivity

$$\log i_{crit} = KpH + K' \qquad [1]$$

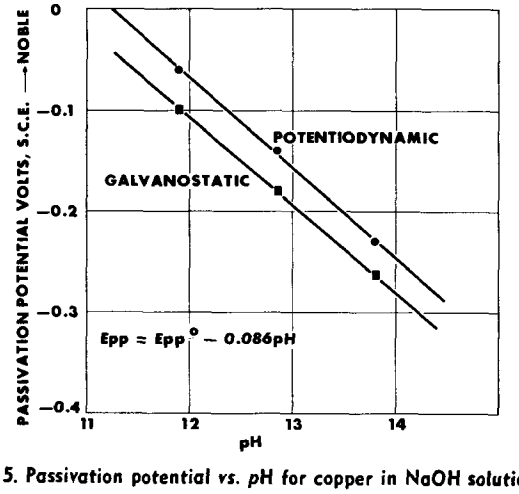

Fig. 5. Passivation potential vs. pH for copper in NaOH solution

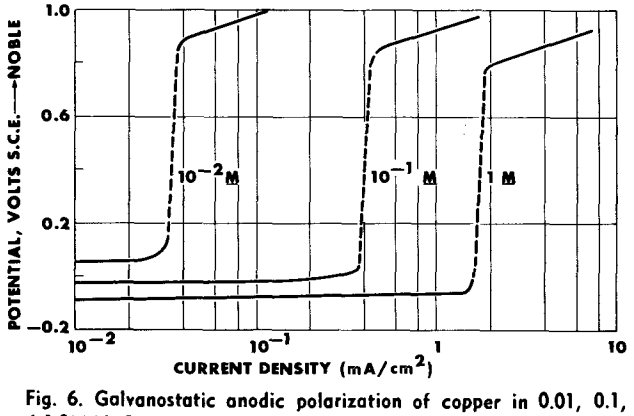

Fig. 6. Galvanostatic anodic polarization of copper in 0.01, 0.1, and 1.0M NaOH solution.

A similar relationship was found for data obtained both from potentiodynamic and galvanostatic techniques. The value of the intercept changes due to differences in the polarization rate. Thus, under galvanostatic conditions, the equation relating critical current density and pH is of the form

$$\log i_{crit} = KpH + K'' \qquad [2]$$

The relationships between pH and critical current density for passivity for copper, obtained from both galvanostatic and potentiodynamic polarization methods are shown in Fig. 7.

Constant current charging curves for copper in 1M NaOH are shown for various current densities in Fig. 8. Three distinct plateaus were observed at −0.57, −0.32, and +0.7V. The exact potential of the plateaus was dependent on applied current density. Potential values quoted here are the most active observed, chosen to minimize overvoltage effects associated with higher applied current densities. Prior to the application of anodic charging currents, specimens were controlled at a potential of −1.0V for a period of 5 min to insure complete removal of all surface films.

With more extended studies of the potential/time behavior of copper in 1M NaOH solution, it was possible to distinguish a further transient plateau in the region of 0 to +0.15V as shown in Fig. 9. In these experiments, polarization was started after the specimen had been allowed to stand at open circuit for some time.

Potential decay curves from the oxygen evolution region, either under open-circuit or forced current decay conditions, show the existence of a plateau at +0.52V. This effect was not observed during anodic charging, probably being obscured by the potential plateau for oxygen evolution. Figure 10 shows the potential decay curves for various current densities from the oxygen evolution potential region to −1.0V. The significance of the various plateaus, each denoting

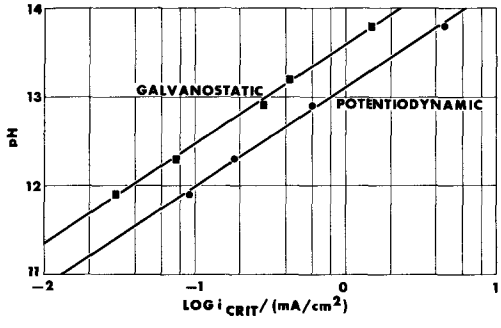

Fig. 7. Critical current density for passivity vs. pH for copper in NaOH solution.

a distinct potential-dependent surface reaction, is discussed in the following section.

Decay curves from the oxygen evolution region after prepolarizing to various potentials are shown in Fig. 11. Prepolarizing to potentials more noble than −0.3V (for a period of 15 min) resulted in a very pronounced plateau at +0.52V, whereas, prepolarizing to more active potentials than −0.3V resulted in a rapid decay to the $Cu_2O/Cu(OH)_2$ potential between −0.3 and −0.35V.

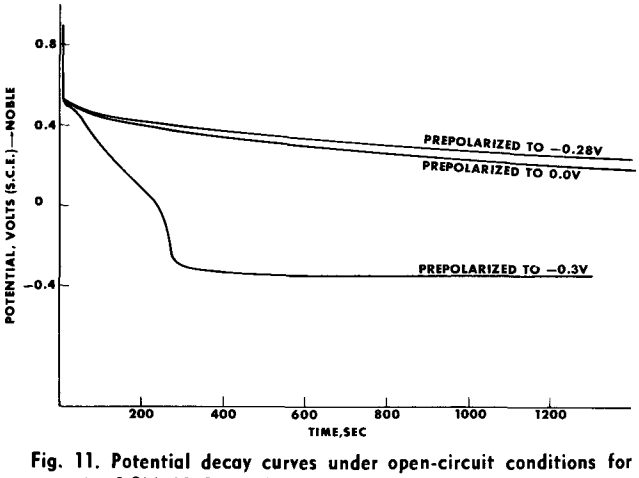

Fig. 11. Potential decay curves under open-circuit conditions for copper in 1.0M NaOH solution at 25°C after prepolarizing to various potentials.

Discussion

The anodic polarization behavior of copper in highly concentrated (10M) solutions of sulfuric acid at room temperature and below shows an active/passive transition characterized by a critical current density and a passivation potential. Lowering the temperature shifts the passivation potential in the active direction and reduces the critical current density. Both of these factors are more conducive to the establishment of passivity.

According to Latimer (9), the free energy of formation of Cu_2O is −34.98 kcal. From thermodynamics the free energy for the following reaction

$$2Cu + H_2O \rightarrow Cu_2O + 2H^+ + 2e \qquad [3]$$

may be calculated to be −21.71 kcal. The equilibrium potential for the formation of Cu_2O according to the above reaction is then 0.23V (SCE).

The passivation potential for copper in 10M H_2SO_4 at 25°C (Fig. 2) occurring at 0.21V, corresponds very closely with the above calculated formation potential of Cu_2O, indicating that the passivation reaction may well be associated with the formation of Cu_2O. The absence of passivity in more dilute acid solutions (1M H_2SO_4) may be attributed to the increased solubility of the corrosion products. In the strongly ionized, more dilute acid solutions, the copper reacts to form $CuSO_4$.

Similarly, the passivation tendency of copper in 1M H_2SO_4 at 0°C may be attributed to the reduced solubility of the corrosion product film at the lower temperature. The fact that such films were readily visible even at very low temperatures, however, indicates that they were porous and offered little protection against further dissolution of the base metal during their initial stages of formation. The increased stability of passivity found in 1M H_2SO_4 at low temperatures is in agreement with the observations made by Hedges (4) on iron, nickel, cobalt, copper, zinc, and magnesium.

In all the alkaline solutions investigated, an active/passive transition was observed. Allmand (10) measured the equilibrium potentials of copper and copper oxide in sodium hydroxide solution and reported the following values (recalculated with respect to SCE): $Cu\text{-}Cu_2O$ = −0.588V, $Cu_2O\text{-}CuO$ = −0.396V, and $Cu_2O\text{-}Cu(OH)_2$ = −0.318V.

It is apparent from Fig. 4 that the potentiodynamic polarization curves do not show the existence of several oxides on the metal surface as only one active/passive transition was observed. Under galvanostatic polarization conditions again only one critical potential was observed where the potential shifted suddenly in the noble direction to the oxygen evolution region. It was therefore not possible to follow the polarization behavior through the various oxidation states of copper by observing the potential/current density relationship utilizing either potentiodynamic or galvanostatic polarization techniques.

The critical current density for passivity *vs.* *p*H dependence in alkaline solutions showed a logarithmic relationship of the form of Eq. [1].

With increasing *p*H, higher critical current densities were required to induce passivity. It is of interest to note that in acid to neutral solutions, King and Uhlig (11) and Leckie (12) have shown, for Fe-25% Cr and various stainless steels, respectively, that the critical current density for passivity decreases with increase in *p*H, but again following a logarithmic dependence.

An increase in the passivation index, $it^{1/2}$ (i = current, t = time taken at all potential steps during polarization), for copper with increase in *p*H has been reported by Shams El Din and Abd El Wahab (13), again showing increased difficulty associated with the passivation of copper at high *p*H values. The difficulty in passivation is probably associated with the dissolution of copper hydroxide in strongly alkaline solutions to form CuO_2^{--}.

The potential/time curves during galvanostatic anodic charging of copper, starting at a potential of −1.0V (to insure a film-free surface) showed three plateaus at potentials corresponding to −0.57, −0.32, and 0.00V. Finally, in all cases, the potentials rose rapidly to some value more noble than 0.7V at which oxygen evolution was observed. The potential plateau close to 0.00V (Fig. 8) was observed only under carefully controlled conditions. With increased current densities, the plateaus corresponding to the various compound formation potentials were shifted in the noble direction, in accordance with the increased overvoltage associated with higher current densities.

The two most active potential plateaus occurring at −0.57 and −0.32V were pronounced and correspond very closely to the thermodynamically calculated formation potentials of Cu_2O and $Cu(OH)_2$ according to the following reactions (calculated for *p*H 14)

$$2Cu + 2\,OH^- \rightarrow Cu_2O + H_2O + 2e \; E_{SCE} = -0.57V \quad [4]$$

and

$$Cu_2O + 2\,OH^- + H_2O \rightarrow 2Cu(OH)_2 + 2e \; E_{SCE} = -0.32V \quad [5]$$

The work of other authors (13) has fairly well established these two reactions as those taking place at the two most active plateaus and the present data is in good agreement with their findings. The existence and nature of the third plateau at approximately 0.00V, however, is the subject of some controversy. Shams El Din and Abd El Wahab (13) found this plateau only after repeated cycling from anodic to cathodic potentials and attribute it to the formation of cuprate ion according to one of the following reactions

$$Cu + 3\,OH^- \rightarrow H\,CuO_2^- + H_2O + 2e \quad [6]$$

or

$$Cu_2O + 4\,OH^- \rightarrow 2H\,CuO_2^- + H_2O + 2e \quad [7]$$

Marcovic and Atlic (14) also attribute this plateau to the formation of cuprate ion according to one of the following equations

$$Cu + 2H_2O \rightarrow H\,CuO_2^- + 3H^+ + 2e \; E^\circ_{SCE} = 1.02V \quad [8]$$

or

$$Cu_2O + 3H_2O \rightarrow 2H\,CuO_2^- + 4H^+ + 2e \; E^\circ_{SCE} = 1.54V \quad [9]$$

where the equilibrium potential of these reactions is both a function of *p*H and $H\,CuO_2^-$ activity. Ohse (15), on the other hand, attributed the potential of −0.01V to the formation of Cu_2O_3. Shams El Din and Abd El Wahab contend that the formation of cuprate ion at approximately −0.01V is a prerequisite to the formation of Cu_2O_3 at the more noble potential of +0.52V according to the reactions

$$2H\,CuO_2^- \rightarrow Cu_2O_3 + H_2O + 2e \quad [10]$$

$$2CuO_2^{--} \rightarrow Cu_2O_3 + \tfrac{1}{2}\,O_2 + 4e \quad [11]$$

The potential plateau found by these authors could be determined only by potential decay curves from the oxygen evolution region and, according to their observations occurred only after sufficient cuprate had formed in the solution by repeated anodic and cathodic polarization cycles.

The potential decay curves shown in Fig. 10 show a distinct plateau commencing at 0.52V. Various experiments were conducted to determine the effect of the presence of cuprate ion on the stability of this plateau. Possible reactions for the oxidation of copper and copper compounds to Cu_2O_3 are according to Eq. [10], [11], [12], and [13].

$$2Cu(OH)_2 + 2\,OH^- \rightarrow Cu_2O_3 + 3H_2O + 2e \quad [12]$$

$$2Cu + 3H_2O \rightarrow Cu_2O_3 + 6H^+ + 6e \quad [13]$$

It is most unlikely, however, that reaction [12] would take place in one step. The formation of Cu_2O_3 probably occurs through the oxidation of either cuprate ion or copper hydroxide. Results from tests where copper was held at various potentials from 0 to −0.3V for various times, instantly polarized to +0.9V and the potential allowed to decay (Fig. 11) show that even at prepolarizing potentials of −0.28V, the potential plateau at +0.52V remained quite pronounced on subsequent decay from the oxygen evolution region. A potential of −0.28V would not appear to be sufficiently noble to sustain the reaction

$$Cu + 2H_2O \rightarrow H\,CuO_2^- + 3H^+ + 2e \quad [8]$$

even at *p*H 14, yet Cu_2O_3 is apparently formed (as shown by the decay curves) without the prior formation of cuprate ion. The prepolarizing potential of −0.28V is sufficiently noble to sustain the formation of $Cu(OH)_2$ from the reaction

$$Cu_2O + 2OH^- + H_2O \rightarrow 2Cu(OH)_2 + 2e \; E_{SCE} = -0.32V \quad [5]$$

Even though cuprate ion will not form directly from copper at such an active potential (−0.28V), it may be possible to form this compound from a direct chemical reaction between $Cu(OH)_2$ and hydroxyl ion at high *p*H values according to the equations

$$Cu(OH)_2 + OH^- \rightarrow H\,CuO_2^- + H_2O \quad [14]$$

$$H\,CuO_2^- + OH^- \rightarrow CuO_2^{--} + H_2O \quad [15]$$

Using neo-cuproine as a complex former, it was possible to detect the presence of soluble copper in the region of the $Cu_2O/Cu(OH)_2$ plateau. This would indicate the presence of cuprate ion (CuO_2^{--}) in this potential range, possibly formed according to reactions [14] and [15]. Table I shows the soluble copper analysis figures for 50 ml aliquots of solution taken at various times during the polarization cycles. Immediately after shifting to the oxygen evolution region, the solution showed a sudden increase in soluble copper. This effect may be accounted for by the copper being polarized through the potential region (plateau at ~0.00V) where $H\,CuO_2^-$ is considered to form directly from copper according to Eq. [5].

Table I. Amount of soluble copper found at various potentials after times shown

Potential, mV	Time, min	Soluble copper, mg/50 ml aliquot
−280	0.25	2.0
−280	8.0	2.5
−280	20.0	10.0
+600	24.0	17.0
+620	35.0	17.0

Cuprate ion may thus be formed during anodic polarization of copper in two ways: first, by the reaction of $Cu(OH)_2$ with hydroxyl ions (Eq. [14] and [15]) and second, at more noble potentials by direct formation from copper.

The present study therefore gives rise to the belief that the primary reactions accompanying the anodic polarization of copper in alkaline solutions may be summarized as follows

$$2Cu + 2\,OH^- \rightarrow Cu_2O + H_2O + 2e$$

$$Cu_2O + 2\,OH^- + H_2O \rightarrow 2Cu(OH)_2 + 2e$$

$$Cu(OH)_2 + OH^- \rightarrow H\,CuO_2^- + H_2O$$

$$H\,CuO_2^- + OH^- \rightarrow Cu_2O^{--} + H_2O$$

$$Cu + 3\,OH^- \rightarrow H\,CuO_2^- + H_2O + 2e$$

$$H\,CuO_2^- + OH^- \rightarrow Cu_2O^{--} + H_2O$$

$$2CuO_2^{--} \rightarrow Cu_2O_3 + \tfrac{1}{2}\,O_2 + 4e$$

Electron Injection into Anodic Tantalum Oxide Assisted by Ionic Interface Polarization

Gerhart P. Klein* and Nils I. Jaeger*

P. R. Mallory & Co. Inc., Laboratory for Physical Science, Burlington, Massachusetts 01803

ABSTRACT

The investigation of electronic conduction processes in anodic tantalum oxide films with electrolytic and solid contacts is generally hampered by parallel ionic conductivity at high fields and the uncertain contributions of flaws, even in the case of high-purity materials. We found that electronic conductivity could be induced reproducibly and with homogeneous current densities in the presence of thin layers of semiconducting oxides, such as Fe_2O_3 and MnO_2 which were deposited by reactive sputtering. Experiments were carried out with electrolyte contact. The electronic current was found to follow log i prop. $V^{1/2}$ in a wide range of current densities. A Poole-Frenkel mechanism is proposed in which the current is controlled by thermionic emission at the Ta_2O_5/MeO-interface. Electronic conductivity increases as a time dependent activation process lowers the emission barrier through ionic interface polarization. The contribution of flaws to the electronic conductivity was investigated by means of the anodic printing technique. The electronic current resulting from the activation process was found to be of uniform density and unrelated to any physical flaws in the anodic tantalum oxide.

Oxide films generated electrochemically by anodic oxidation on valve metals (1), among them tantalum oxide as the relatively best defined, are characterized by high insulation resistance. Their resistivity is dependent on the substrate metal and its degree of chemical purity. The resistivity of anodic Ta_2O_5 on high-purity Ta has been estimated to exceed 10^{15} ohm cm (2). Any lower resistivities found experimentally must be caused by chemical impurities or flaws.

The intrinsic conductivity of anodic Ta_2O_5 is too low to measure, which means that the current-voltage characteristics of Ta/Ta_2O_5-electrodes are usually those of impure Ta_2O_5, after corrections have been made for ionic current contributions. The distribution of electronic conductivity (e.c.) due to impurities is mostly nonhomogeneous (3).

The study of conduction mechanisms in flaws is of some practical, but little theoretical interest, since it is hardly possible to create well-defined experimental conditions. One may ask, however, whether leakage conduction can be understood in terms of explanations such as have been advanced in the literature assuming the existence of fissures (4), and flaws (5), or whether a more fundamental conduction mechanism is at work. Some indication of this was given in an earlier paper (3) which attempted to establish some typical conduction patterns for commonly encountered impurities and physical flaws in Ta_2O_5. Aside from the tentative conclusion that impurities had to be present in all cases where e.c. was observed, we found a behavior of the e.c. which indicated that certain modifications of the Ta_2O_5/electrolyte-interface were responsible for the observed e.c.

The anodization of Ta which had been alloyed with Fe or Ni, among others, resulted in the formation of oxides of the impurities on top of Ta_2O_5. This process was accompanied by sharply increasing e.c. By dissolving the impurity oxide the cause of e.c. was eliminated until, on further anodization, it would gradually return.

In the present investigation we have further explored the conditions under which anodic Ta_2O_5 exhibits e.c. of sufficient magnitude to be measured by electrochemical techniques. Instead of Ta substrates alloyed with metallic impurities we used anodic oxide films on high-purity substrates and deposited thin films of transition metal oxides, *e.g.*, Fe_2O_3 and MnO_2 by means of thermal decomposition of the respective nitrates, or by reactive sputtering. We found on return of the specimens to the electrochemical cell that reproducible, uniformly distributed e.c. could be developed by applying voltage close to the original formation voltage of the anodic Ta_2O_5.

The detailed investigation of this effect revealed an electronic conduction mechanism that is controlled by the properties of the contact between the two oxides. The properties of the contact are modified under the influence of an applied field that leads to ionic migration.

The experimental system, a Ta/Ta_2O_5/MeO-electrode with aqueous electrolyte contact, is shown schematically in Fig. 1. It is in many ways similar to metal/insulator/metal systems which have been studied extensively (6, 7) and for which models have been developed to account for electronic conduction processes. In our system, one of the metal electrodes was replaced by an electronically conducting metal oxide combined with a redox electrolyte that supplies electronic charge to the oxide. Experimentally, metal/in-

sulator/metal systems are hard to work with due to the difficulties of preparing well-defined thin layers of insulators and providing them with electrodes. Nonhomogeneous current distribution, lack of quantitative reproducibility, and current instabilities are common problems which make for a scarcity of unambiguous experimental results.

The advantage of electrolytic contact to insulators, such as insulating anodic oxides, is due to the control of the field distribution in the system by ionic processes. Additional film growth tends to equalize the field in the insulator. Even though this provides an electrically stable condition, the contact properties can be influenced only in a very limited way, *e.g.*, through the redox potential of the electrolyte.

By combining a semiconducting oxide and a redox electrolyte, the advantages of the electrolyte contact are maintained while, at the same time, a means of influencing the contact properties is introduced. The contact remains uniform and the effects of air gaps, dust, etc., are eliminated. At the same time, the oxide limits the ionic processes without entirely blocking them, as would be the case with metal contact, and thus provides some stabilizing effect. In cases where the electronic conductivity of the system is controlled by the contact, this allows one to study the conduction mechanism at fields which in case of metal contact might lead to early breakdown.

The availability of an electrochemical method for the determination of the electronic current distribution (8, 9) on a micro scale is an additional advantage over metal electrodes. A quantitative study of conduction processes in thin films is impossible without detailed information about the density and distribution of the electronic current.

Experimental

Capacitor grade tantalum foil was cleaned in the usual way. Chemical polishing (10) in a mixture of 5 pt H_2SO_4, 2 pt HNO_3, and 1.5 pt HF (all reagent grade, concentrated) was followed by dipping in HF, rinsing in distilled water, and vacuum annealing at 2100°C for 3 hr at 10^{-5}-10^{-6} mm Hg. Anodic oxide films were formed at room temperature in dilute H_2SO_4. Formation current density was 1 mA/cm^2 followed by stabilization at final voltage for 30 min. Film thickness was calculated on the basis of a thickness equivalent of 16.4 Å/V for formation at 1 mA/cm^2 to voltage. The thickness of stabilized films was determined by reforming at this current density and extrapolating the voltage time curve to zero time.

Reactive sputtering of Fe_2O_3 and MnO_2 was carried out in a CVC Bendix D.C. triode sputtering system. The sputtering conditions were, typically: 1000V, 60 mA, 5% oxygen in argon, 12μ pressure, and a target to substrate distance of 8 cm. The deposition rate was approximately 12 Å/min. The target consisted of 9 x 9 cm metal disks without cooling. Iron oxide was sputtered from a high-purity (99.99%) iron target, while manganese targets were prepared by vapor deposition of manganese on a tantalum substrate. The substrate holder was water cooled, and specimens were held in intimate contact with the substrate support by means of a spring loaded mask. Sputter deposition of the metal oxide on the substrate was preceded by sputter cleaning of the target with pure argon. No special treatment was given to the Ta/Ta_2O_5 electrode prior to sputtering. After admission of the sputtering gas mixture, sputtering continued onto a shutter until a stationary sputtering condition had been established. After cleaning the sputtering rate was high, and oxides of low oxidation state were formed. With increasing oxidation of the target the sputtering rate dropped and became constant. The oxides sputtered under this condition were close to Fe_2O_3 and MnO_2 in composition. Electron diffraction experiments showed the films to be polycrystalline. Electron micrographs indicated that the films were continuous. Best results were obtained with oxide films of the order of some hundred angstroms, typically 200Å.

Reactive sputtering of oxides can take place by a number of mechanisms (11). The low sputtering rates prevailing after a stationary condition had been established suggest that the surface of the target was oxidized and that the oxide itself was being sputtered. High energy sputtering may lead to the injection of ions into the anodic oxide. However, in our case the energies of the sputtered ions were relatively low and, in addition, sputtering was done at pressures of 1-10μ and target to substrate distances of 5-8 cm, much greater than the mean free path of any sputtered ions. This made it likely that deposition of MeO took place in the form of neutral molecules by diffusion.

MnO_2 was also deposited by pyrolytic conversion of manganese nitrate. The specimen was coated with a dilute solution of $Mn(NO_3)_2$ in water to which a surface active agent had been added to insure complete wetting of a larger foil area. After thermal conversion to MnO_2 at about 200°C, the foil was carefully rubbed with a cotton swab and water to remove any of the voluminous MnO_2. Only a thin, firmly adherent film was left after this treatment.

After sputtering or pyrolytic deposition the specimen was returned to the electrolyte cell shown in Fig. 2a. It consisted of a glass container with mantle for thermostating, a magnetic stirrer, a platinum counterelectrode, and a saturated calomel reference electrode (SCR). All potentials were referred to the hydrogen electrode in the electrolyte used. The electrolyte was 0.5m standard acetate buffer solution (25°C) in which the sputtered oxides were insoluble.

The electronic circuit (Fig. 2b) consisted of a Kepco Model ABC 200 power supply, a Keithley Model 610C electrometer and a Hewlett-Packard Model 3430A digital voltmeter to measure potential, and a Mosley Model 7100B strip chart recorder to measure current.

Anodic printing, a technique used to make the distribution of the electronic conductivity visible, was described previously (8). For high resolution printing the experiments were performed under the microscope.

The experimental details have been described elsewhere (9).

Results

Anodic activation.—A typical experiment to demonstrate the effect of anodic electronic activation (referred to as activation) was performed as follows: A 200Å film of Fe_2O_3 or MnO_2 was sputtered reactively onto a tantalum substrate which previously had been anodized at 120V for 30 min. The specimen was then returned to the cell shown in Fig. 2 and constant voltage applied. Near the original formation voltage the current increased sharply with time (Fig. 3a-c). For comparison the reformation behavior of a similar Ta/Ta_2O_5 electrode without sputtered oxide on its surface is also shown (Fig. 3d). In the latter case the observed current is largely ionic and decays with time after an initial overshoot. In the former case the current is largely electronic and continually increases with time. Figure 3 gives three examples of "activation curves" (log i_{el} *vs.* time). One for Fe_2O_3 deposited by sputtering, (a) and two for MnO_2 deposited by sputtering (b) and thermal conversion (c) of $Mn(NO_3)_2$. The rate of electronic current increase with time ("rate of activation") is considerably lower for MnO_2. This is attributed to its higher ionic conductivity as compared to Fe_2O_3. This tends to lead to some additional growth of Ta_2O_5 (21) during activation. The activation curves show an initial overshoot which is similar to the overshoot observed with Ta/Ta_2O_5 electrodes. The current goes through a minimum followed by an exponential increase of the electronic current with time to current densities of 10^{-2} A/cm^2 and higher.

In some instances, activation curves with one or several plateaus were observed. This behavior appeared to be related to the composition of the sputtered oxide. The present study is concerned only with the exponential section of the activation curve which is regularly observed with oxides of high oxidation state.

With continuing activation at constant voltage the rate of increase of the electronic current diminished.

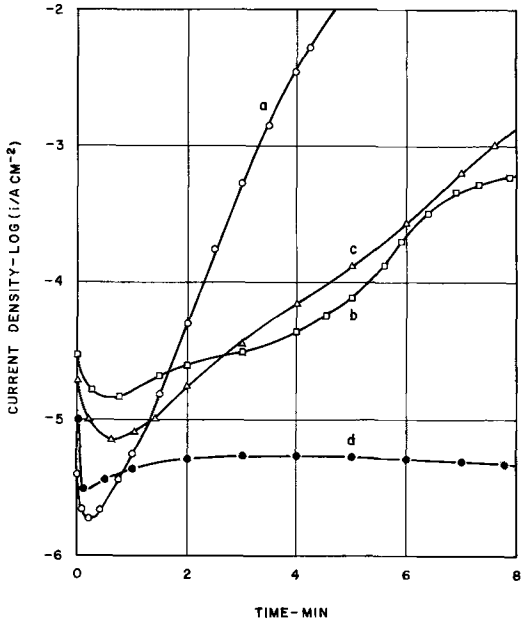

Fig. 3. Current-time characteristic of the activation process for three Ta/(2310Å) Ta_2O_5/MeO electrodes. Anodization of Ta/Ta_2O_5 at 120V, 25°C, 30 min; activation voltage V_A. (a) MeO = sputtered (200Å) Fe_2O_3 film, V_A = 118V, (c) MeO = MnO_2 by thermal conversion of $Mn(NO_3)_2$, V_A = 118V, 75°C; (b) MeO = sputtered (200Å) MnO_x film, V_A = 122V; (d) reanodization curve of Ta/Ta_2O_5 electrode at 118V after activation of the Ta/Ta_2O_5/Fe_2O_3 electrode and subsequent dissolution of the Fe_2O_3 film. This curve is identical to the reanodization trace of the Ta/Ta_2O_5 electrode before deposition of MeO and activation.

This was most pronounced with thin Ta_2O_5 films and was thought to be due to changes in the potential distribution as activation progresses.

The activation process does not destroy the anodic Ta_2O_5 film. In particular, no catastrophic breakdown or scintillations were observed during activation. The current increased steadily with time without giving any indication of noise due to carrier multiplication. After activation and subsequent dissolution of the sputtered oxide film the Ta/Ta_2O_5 electrode could be reformed to voltages in excess of the original formation voltage. Microscopic inspection did not reveal any breakdown or scintillation patterns.

The current-time curve of reformation at constant voltage after dissolution of the Fe_2O_3 film following activation to 10^{-2} A/cm^{-2} was identical to the reformation curve obtained with the original Ta/Ta_2O_5 electrode prior to any deposition of Fe_2O_3 (Fig. 3d). This indicated that the effect of Fe_2O_3 was temporary and that no modification of the bulk of Ta_2O_5 had taken place during activation.

A direct experimental distinction between ionic and electronic current can be made by means of the printing technique. These and all subsequent prints were obtained while increasing the applied voltage at a constant rate. A typical series of prints is shown in Fig. 4 for a Ta/Ta_2O_5/Fe_2O_3 electrode. The example chosen shows both uniform activation near the anodization voltage and nonuniform e.c. at lower voltage. The onset of activation led to the uniform development of opacity due to the formation of the starch-iodine complex. At higher current density levels gassing of the electrode due to oxygen evolution was observed.

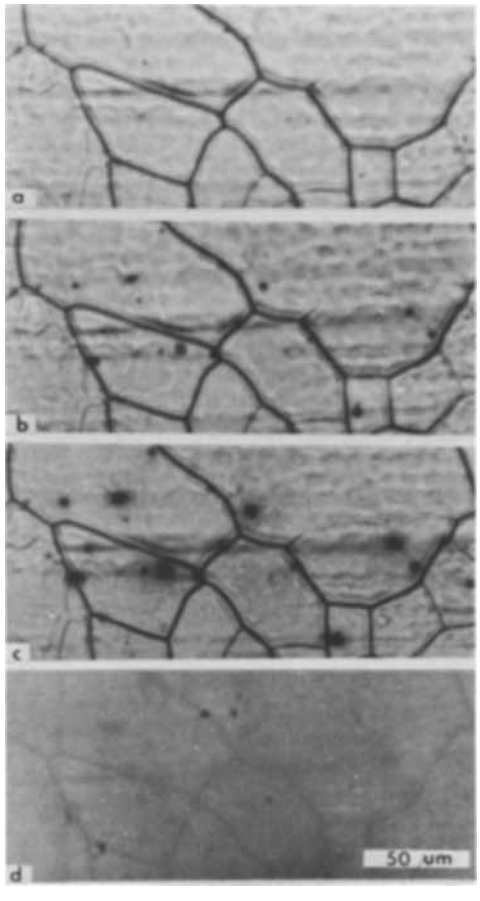

Fig. 4. Series of four anodic prints obtained from a Ta/(2000Å) Ta_2O_5/(200Å) Fe_2O_3 electrode anodized at 100V, 25°C for 1 hr; voltage scan rate 20 V/min; a, at 0V; b, at 80V; c, at 90V; and d, after 30 sec at 95V. Note: Grain boundaries appear dark because they are out of focus.

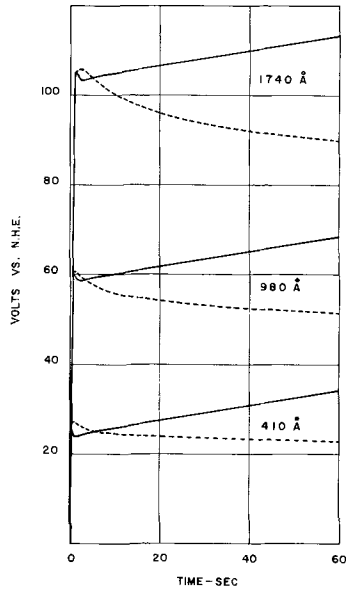

Fig. 5. Activation of three Ta/Ta_2O_5/(200Å) Fe_2O_3 electrodes (- - - -) at constant current (0.5 mA/cm^2). For comparison, the voltage-time curves of anodization for the same Ta/Ta_2O_5 electrodes (————) are also given.

Activation under galvanostatic conditions is shown in Fig. 5 for three Ta/Ta_2O_5/Fe_2O_3 electrodes with different Ta_2O_5 thicknesses. At constant current the voltage increases linearly with time for Ta/Ta_2O_5 electrodes, while it drops steadily toward a constant value when activation takes place in the presence of Fe_2O_3. An initial overshoot is observed in both cases.

Activation as a function of field.—The process responsible for electronic activation depends on the applied field. Figure 6 shows the increase of the electronic current with time for Ta/(1360Å)Ta_2O_5/(200Å)Fe_2O_3 electrodes as a function of the applied voltage (field). The rate of log i increase with time (rate of activation) rises sharply with increasing field strength. The ionic current at these fields is determined by $i_{ion} = A \exp BF$ (1) (F field across Ta_2O_5, A, B, empirical constants). With typical values for A and B given in the literature (2) the ionic current at the highest fields used is estimated to $i_{ion} < 10^{-6}$ A/cm^2. The ionic current is small but finite, and it appears that the activation process shows some correlation with ionic charge displacement.

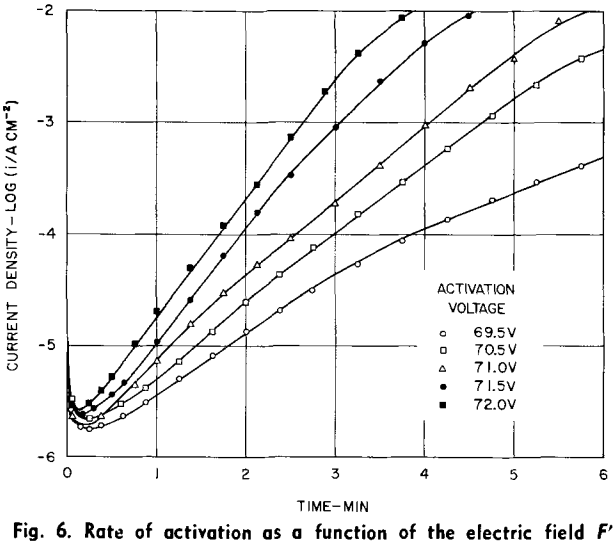

Fig. 6. Rate of activation as a function of the electric field $F' = V/d$ for Ta/(1360Å)Ta_2O_5/(200Å) Fe_2O_3 electrodes. The Ta/Ta_2O_5 electrode was anodized at 70V, 25°C, for 30 min. ○, 5.11 MV/cm; □, 5.18 MV/cm; △, 5.22 MV/cm; ●, 5.26 MV/cm; ■, 5.30 MV/cm.

The activation behavior as a function of Ta_2O_5 thickness is shown in Fig. 7. The Fe_2O_3 thickness was 200Å in all cases. As in Fig. 6, all activation curves were measured at fields that were determined from the actual voltage V as measured against the reference electrode and the thickness d of the particular Ta_2O_5 film. The activation curves of Fig. 7 start out at about the same current level if measured at the same field V/d, but the slopes of the curves increase from the thinnest to the thickest film. The slopes of the activation curves of the thicker films approach a constant value. For the 2310Å film the activation curve is essentially linear over two decades of current. The activation curves of the thin films, *e.g.*, the 410Å film, start out with the lowest slopes, and the slopes decrease further with time of activation.

These differences in the rates of activation may be related to the nonidentity of the applied voltage and the actual potential drop across the Ta_2O_5 film. It was necessary to examine the distribution of the applied voltage over the experimental system shown in Fig. 1 in order to determine whether the activation process was in fact dependent on the field in Ta_2O_5. The constant voltage V does not drop fully across Ta_2O_5 but includes voltage drops across interfaces and the bulk of the MeO film. Also, the potential distribution in the electrostatic condition without ionic or electronic current flow will be different from the distribution during activation. During this transition, the potential drop across Ta_2O_5 may change with a corresponding effect on the rate of activation. For example, the rate of activation would be expected to decline as the field across Ta_2O_5 decreased which, at constant applied voltage, could be caused by increasing interface polarizations, increasing voltage drop across MeO, or by additional growth of Ta_2O_5. Conversely, an increase in the rate of activation could be expected to take place if an electrostatic potential drop across MeO or other parts of the system was shifted to Ta_2O_5.

Potential distribution in the experimental system.— The voltage V measured against a reference electrode is made up of the following contributions: $V = \Delta V + V_4 + \Sigma\psi_{ij} + \Sigma\eta_{ij}$ with ΔV voltage drop across Ta_2O_5, V_4 voltage drop across MeO, $\Sigma\psi_{ij}$ sum of Galvani potential differences, $\Sigma\eta_{ij}$ sum of overvoltages. Any ohmic potential drop (η_Ω) across MeO is also included in this sum. Under electrostatic conditions ($i_{ion} = 0$, $i_{el} = 0$) $\Sigma\eta_{ij} = 0$.

The sum of Galvani potentials is made up of the respective interface Galvani potential differences as indicated in Fig. 1: $\Sigma\psi_{ij} = \psi_{12} + \psi_{23} + \psi_{34} + \psi_{45} + \psi_{56} + \psi_{61}$; with $\psi_{12} = \psi_1 - \psi_2$, $\psi_{23} = \psi_2 - \psi_3$ etc. The sum of overvoltages is similarly composed of the respective contributions from the various interfaces affected by ionic and electronic current passage: $\Sigma\eta_{ij} = \eta_{23} + \eta_{34} + \eta_{45}$.

In a series of experiments at constant field in Ta_2O_5 where only the thickness of the Ta_2O_5 film is being varied a correction of the applied voltage is required which takes into account the potential distribution across the system. This correction which affects the field in Ta_2O_5 becomes the more significant the thinner the Ta_2O_5 film. In the initial phases of the activation process the overvoltage contribution is negligible and the correction is constant. This appears to be the range in which the rate of activation (log scale) is constant. As overvoltages develop in various parts of the system, the rate of activation decreases, and this decrease is again the more pronounced the thinner the Ta_2O_5. Also, additional Ta_2O_5 growth may occur and thus lower the field under constant voltage conditions. Only two factors will be examined more closely in the context of this paper: first, the importance of a redistribution of potential between Ta_2O_5 and Fe_2O_3; and second, an attempt to determine the constant contribution to the applied voltage arising from Galvani potential differences. The contribution from overvoltages other than ohmic potential drop in Fe_2O_3 will not be considered, and the discussion of the activation process will be restricted to the range in which a linear activation characteristic is observed.

Potential redistribution between Ta_2O_5 *and* Fe_2O_3.— The experimental evidence presented so far suggests that the activation process is tied to the migration of ions in Ta_2O_5. This is more clearly demonstrated by Fig. 8 which shows a comparison of the initial parts of an activation curve (e) for a $Ta/Ta_2O_5/Fe_2O_3$ electrode with reanodization curves (a-d) of Ta/Ta_2O_5 electrodes at four constant voltage levels. By varying the reanodization voltage one can find a reanodization curve (c) which closely matches the initial part of the activation curve (e). The two curves match during the initial overshoot and begin to separate only after the current minimum has been reached. The initial overshoot is caused by ionic polarization processes (1, 6) with oxide formation taking place during the overshoot. The identity of the two curves is assumed to signify identical ionic processes in the Ta_2O_5 layer of both specimens. This congruence is regarded as a reference condition for which the field is assumed to be equal in the Ta_2O_5 layer of each electrode. The presence of Fe_2O_3 in one of the electrodes requires a somewhat higher applied voltage to match the reformation curve of the Ta/Ta_2O_5 electrode. From Fig. 8, the difference in the applied voltage was determined to $\Delta V_{Fe_2O_3} = (0.5 \pm 0.5)V$. This represents the initial voltage drop across Fe_2O_3 before electronic conduction sets in. The maximum voltage that could be transferred from across Fe_2O_3 to across Ta_2O_5 would, therefore, be the order of 1V. This will have to be compared to the maximum ohmic drop across Fe_2O_3 as a consequence of the electronic current in order to determine the significance of potential redistribution in the activation process.

The resistivity of Fe_2O_3 as deposited by reactive sputtering is not known, but it can be estimated if it is assumed that the decrease in the rate of activation

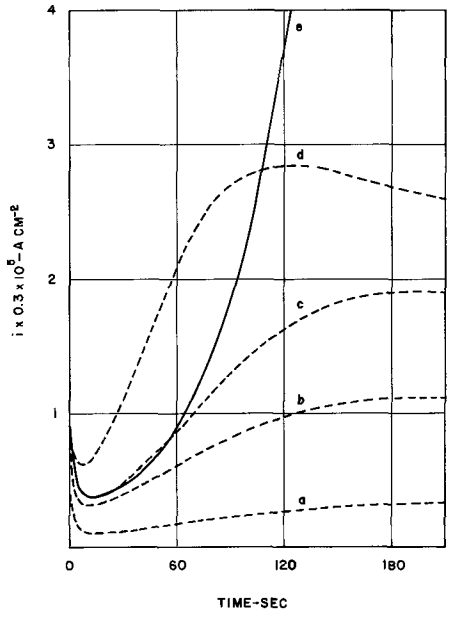

Fig. 8. Comparison of the initial part of the activation curve for a Ta/(1360Å)Ta_2O_5/(200Å)Fe_2O_3 electrode (e) with reanodization curves for Ta/(1360Å)Ta_2O_5 electrodes at different voltages V (a-d). - - -, Ta/Ta_2O_5 (a) 68V; (b) 70V; (c) 70.5V; (d) 72V. ——, $Ta/Ta_2O_5/Fe_2O_3$ (e) 70V.

at high electronic current densities is caused by the ohmic potential drop. It was found that $\sigma_{Fe_2O_3} < 9 \times 10^7$ ohm cm, which leads to a potential drop $\eta_\Omega < 0.9V$ at 5 mA/cm² for a 200Å Fe_2O_3 film. η_Ω becomes significant at current densities of the order of mA/cm² for thin Ta_2O_5 films.

Contribution from Galvani potential differences.—If the rate of activation (log scale) was in fact a function of the ionic processes in Ta_2O_5, as suggested by the experiments presented so far, one would then expect the slopes of the activation curves to be identical for all Ta_2O_5 thicknesses at the same field in Ta_2O_5. Figure 9 shows activation curves with the same slope for the $Ta/Ta_2O_5/Fe_2O_3$ electrodes of Fig. 7. The voltages $V = \Delta V + \Sigma\psi_{ij}$ that had to be used experimentally to obtain equal slopes are given in Table I. The resulting fields $F' = V/d$ are different for all Ta_2O_5 thicknesses. This is attributed to the error made by not taking into account the constant additive voltage arising from $\Sigma\psi_{ij}$. The later is found by computing that value of $\Sigma\psi_{ij}$ that minimizes the difference between the fields. The resulting field $F = (5.06 \pm 0.4)$ MV/cm is then the true field in Ta_2O_5 for all thicknesses. The contribution to the applied voltage from Galvani potentials was found to be $\Sigma\psi_{ij} = (2.35 \pm 0.30)V$.

It was concluded from these estimates that the corrections arising from potential redistributions between Fe_2O_3 and Ta_2O_5 can become significant for thin Ta_2O_5 films. The electrostatic shift appeared to be small in our experiments, but the effect of the ohmic drop was clearly noticeable at the higher electronic current densities. Also, by making allowances for the constant contribution from interface potential drops to the voltage V it was found that the rate of activation (log scale) at constant field in Ta_2O_5 was in fact independent of the thickness of the tantalum oxide.

○ 2310	120, 30	118
△ 1740	90, 30	90
□ 1360	70, 30	71.5
● 980	50, 30	52.5
■ 410	20, 30	23

The continuing decrease in the rate of activation observed in Fig. 7 and 9 which was most pronounced in the curves for the thinnest Ta_2O_5 films is attributed to the effects of overvoltages developing at the various interfaces of the Ta/Ta_2O_5/Fe_2O_3 electrode due to the electronic current and to some additional growth of Ta_2O_5.

Current-field characteristic of the electronic conduction process resulting from activation.—The current-field characteristic of Ta/Ta_2O_5/Fe_2O_3 electrodes was measured after activation to different electronic current levels. The measurements were made at decreasing field. The results for a 1740Å Ta_2O_5 film are shown in Fig. 10 which gives the activation curve and the current-voltage curves related to the activation levels as indicated by horizontal lines. The current-field (voltage) characteristics are linear over several decades of electronic current if log i is plotted *vs.* $F^{1/2}$.

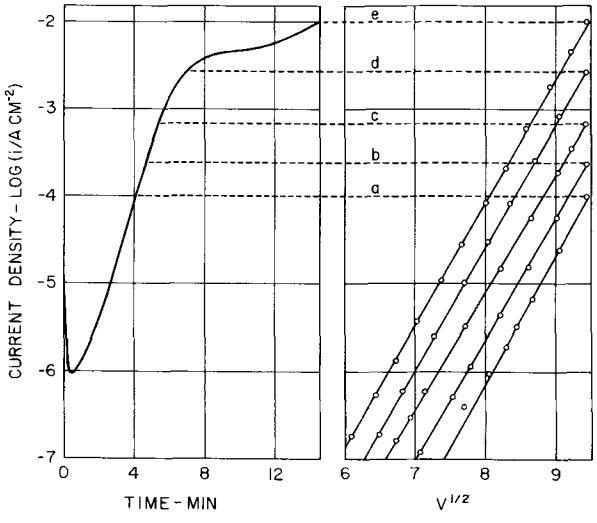

Fig. 10. Activation curve (left) and current-field characteristics (right) for a Ta/(1740Å) Ta_2O_5/(200Å) Fe_2O_3 electrode. Current-field characteristics were measured after activation to the current levels as indicated. Ta_2O_5 was anodized at 90V, 25°C, for 30 min; activation at 89V.

The activation curve shown in Fig. 10 is characterized by a section in which log i *vs.* time is linear, followed by a plateau, and further increase with time. The particular shape of the activation curve is believed to be due to the composition of the sputtered Fe_2O_3 layer. It has no significant effect on the i-F characteristic of the electronic current.

Bulk vs. interface control.—For the interpretation of the activation process and the current-field characteristic of the electronic current to be meaningful it was important to determine the location of the rate-limiting step in the transfer of electrons from the electrolyte to the tantalum substrate. The dependence of electronic current on field would seem to support bulk control. However, there is convincing experimental evidence that it is the injection of electrons into Ta_2O_5 which is rate limiting. In the case of electrolyte contact to Ta_2O_5 the injection rate of carriers is extremely small. In the presence of MeO an electronically conductive state can be created, which must be directly related to a modification of the Ta_2O_5/MeO interface since chemical dissolution of MeO after the active condition had been established removed the cause of electronic conductivity. No indication of any modification of the bulk of Ta_2O_5 as a consequence of the activation process was found.

This behavior of specimens with deposited MeO films is paralleled by the behavior of tantalum that had been alloyed with iron (3). The observations were then interpreted in terms of a competitive migration of tantalum and impurity ions under the effect of the field whereby the impurity ions were faster than tantalum ions. The impurity ion-rich surface layer was thought to be responsible for the observed e.c. Ta_2O_5 layers immediately adjacent to the oxide/electrolyte interface must also have been highly contaminated, but could not be reached by the hydrochloric acid. It is significant that little e.c. was found in an extended interval of continued formation after dissolution of the surface oxide, since it showed that doping of the Ta_2O_5 did not seem to lead to e.c. unless surface oxides were present.

Current distribution.—The question of current distribution is of equal importance for the interpretation of the activation effect since it is well known that high flaw densities can be present in anodic Ta_2O_5 (12). What appeared as uniform e.c. macroscopically could, therefore, be due to large numbers of minute structural flaws. Naturally, assigning the cause for e.c. to flaws would only shift the problem to flaws without solving it. In order to establish the distribution of e.c. one must be able to resolve the current distribution on a microscale. Techniques such as area variation can detect only rather coarse heterogeneity and cannot resolve conduction due to microscopically small flaws of high density. Scanning a surface with various kinds of probes suffers from similar problems. By contrast, anodic printing in its modified form allowed direct observation of the surface of the specimen and, at the same time, its e.c. distribution as revealed by the coloration of the printing electrolyte. It permitted a direct correlation between microscopically visible flaws and their contribution to the electronic conductivity with a resolution of up to 10^8 point flaws/cm^2.

The purpose of the following experiments was to establish the distribution of electronic conduction under the conditions of activation. Macroscopically, the distribution was found to be homogeneous; however, it could not be decided whether this homogeneity was in fact the result of microscopic heterogeneity due to flaws in the anodic oxide.

The following tabulation lists common types of "heterogeneities."

I. Structural	(a) thermal crystalline oxides, nitrides
	(b) "field" crystals
	(c) carbides
	(d) inclusions of foreign phases
	(e) cracks, pores, pinholes, etc.
II. Chemical	(a) metallic impurities in solid solution
	(b) inclusions from electrolyte
	(c) surface impurities

High flaw densities are usually due to structural flaws and those listed under I, a-c are the most common ones. Methods of generating such flaws have been described previously (12-14). In the following high resolution anodic prints obtained with specimens containing various densities of such structural flaws are shown.

Thermal oxide flaws.—Thermal crystalline oxide forms on Ta foil when heated in air at temperatures of 300°-700°C. Different amounts of thermal oxide were generated by heating Ta foil at 500°C in air for 2, 5, 10, and 30 min. Preparation for the printing experiment included anodizing at 80V and sputtering of a 200Å Fe_2O_3 film. Prints for the 5-min sample are shown in Fig. 11. The first of the micrographs shows the Ta foil before anodization with a typical pattern of Ta_2O_5 crystallites. The two anodic prints at 85 and 90V show increasing uniform activation which is most clearly seen at the grain boundaries. These show up quite strongly in the first prints because they are out of focus but disappear gradually as the opacity of the printing electrolyte increases due to the formation of the starch-iodine complex. The prints show homogeneous and uniform opacity and none of the typical distributions of crystallites which vary in density from grain to grain. Uniform opacity was observed even in cases where the anodic Ta_2O_5 contained patches of different color due to high thermal oxide concentration.

"Field"-crystallite flaws.—"Field" crystals in anodic Ta_2O_5 were generated by anodizing Ta foil in 2% nitric acid at 80V, 90°C, for 4 hr. The prints of Fig. 12 were obtained with a sputtered 200Å Fe_2O_3 film. Figure 12a shows the specimen before application of voltage, b at 112V, and c at 117V. Uniform opacity is observed at the highest voltage indicating that the activation proceeded uniformly over the whole surface. At the lower voltage the crystallites led to electronic leakage which could be distinguished clearly from the uniform activation current that occurred at the higher voltage level.

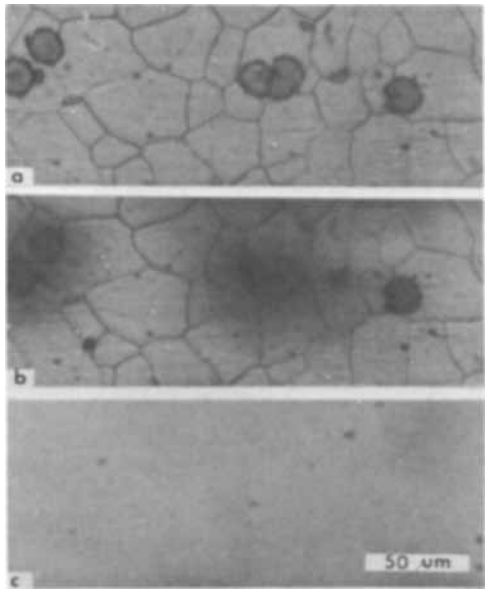

Fig. 12. Anodic microprints of a Ta/(2280Å)Ta_2O_5/(200Å)Fe_2O_3 electrode. "Field" crystals were generated by anodizing in 2% HNO_3 at 80V, 90°C, for 4 hr; voltage scan rate 20 V/min. a, Specimen with "field" crystals, no voltage applied; b, anodic print at 112V; c, anodic print at 117V.

Tantalum carbide flaws.—Carbide flaws were generated in anodic Ta_2O_5 by evaporation of carbon on Ta foil followed by annealing in vacuum at 1800°C for 30 min. Anodization was carried out at 120V, 25°C, for 30 min. The prints of Fig. 13 were obtained after sputtering a 200Å Fe_2O_3 film on Ta_2O_5. The center grain in the specimen shown in Fig. 13 contained the highest car-

Ta_2O_5 anodized at 80V, 25°C, for 30 min; voltage scan rate 20 V/min. a, Ta foil with Ta_2O_5 crystallites before anodization; b, anodic print at 85V; c, anodic print at 90V.

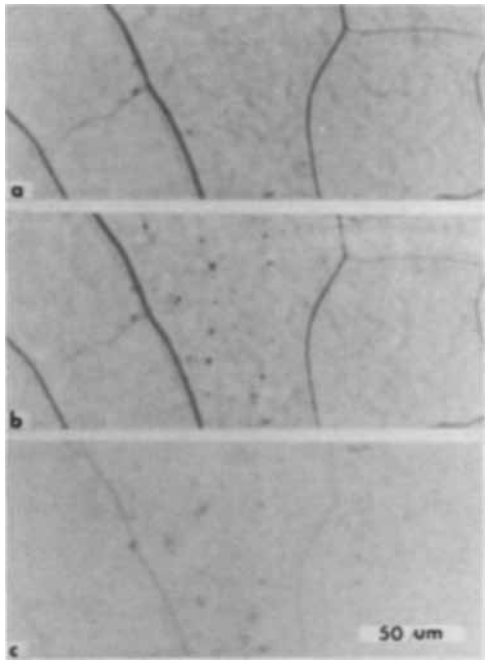

Fig. 13. Anodic microprints of a Ta/(2310Å)Ta_2O_5/(200Å)Fe_2O_3 electrode. Ta foil carburized before anodization at 120V, 25°C, for 30 min; voltage scan rate 20V/min. a, Anodic print at 80V; b, anodic print at 100V; b, anodic print at 115V.

bide concentration which was estimated to be of the order of 10^8 carbide flaws per cm^2. The color of the anodic oxide on this grain was substantially different from that of the surrounding grains. The print at 100V shows discrete electronic leakage sites with a density of about 5 x $10^4/cm^2$. The number of active sites remains constant until uniform activation occurs at 115V. Activation at this voltage was uniform and did not show any variation from grain to grain even though the carbide concentration varied greatly.

Other types of flaws.—Impurities, if present in sufficient quantity, will precipitate under favorable conditions. Tantalum used in these investigations was of high purity and elemental impurities were present in parts per million quantities only after chemical polishing and vacuum annealing. With rapid cooling after annealing conditions were unfavorable for the formation of any precipitates. Such material is characterized by flaw densities of less than $10^4/cm^2$. Anodic prints of less pure $Ta/Ta_2O_5/Fe_2O_3$ electrodes showed the effects of impurity islands with random distribution and shape. In Fig. 5 electronically active flaws are present in a density of 10^4-$10^5/cm^2$. In highly impure material the density of discrete active flaws may increase further. However, high impurity content usually leads to distributed e.c.

Pores, cracks, and pinholes have also been cited as possible contributors to e.c. A sensitive method to detect any of these types of flaws was the deposition of MnO_2 by means of pyrolytic conversion of $Mn(NO_3)_2$ followed by printing. The liquid penetrated pores and cracks and anodic prints revealed any such flaws at low voltage. Since this behavior was rarely, if ever, observed with flat high-purity specimens we could exclude such flaws from further consideration.

Conclusions from printing experiments.—Electronic conduction in flaws could be distinguished clearly from uniform e.c. by means of the high resolution printing technique. Uniform e.c. was observed at the same field strength for all specimens whether they were of highest purity with low flaw density, or whether they were prepared with the highest flaw densities. This was shown most strikingly in samples where different grains of widely varying flaw density exhibited identical activation behavior. Carbide containing samples were of particular interest because nonuniform e.c. was observed within those grains with the highest flaw densities. However, this localized type of e.c. was observed at significantly lower fields and was clearly distinguishable from the uniform e.c. at the activation field strength.

Electronically active sites were usually found to be present in much smaller densities than visible flaws and often appeared in patterns that reflected random contamination rather than distinctive distributions along grain boundaries or definite crystal orientations.

The density of active sites in some grains with high carbide flaw density was higher than in others with lower flaw density. But similar grains in other areas had no active sites at all. Therefore, no direct correlation existed between carbide flaws and e.c.

Thermal oxidation led to vastly greater e.c. occasionally, even though the specimen was thought to be one of high purity. Anodic printing revealed that thermal crystalline oxide was not the source of e.c., but that it originated in typical impurity patterns. This was attributed to the accumulation of impurities at the surface during thermal oxidation. This means that no direct correlation existed between thermal oxide or carbide flaws and e.c. under the conditions of anodic activation. This conclusion should be qualified to the effect that the properties of flaws may depend on the formation voltage. For the purpose of resolving the distribution of the activation current this is of no relevance since activation is observed at all Ta_2O_5 thicknesses.

Typically, electronically active flaws appeared in anodic prints at voltages far enough below the level of uniform activation to be clearly distinguishable. Even though a distribution in size and intensity was usually found to exist it is significant to note that flaws appeared first at rather distinct voltage levels. Their number was, by and large, determined at this level, and no significant increase in number was observed as the voltage increased further. The absence of a voltage dependent distribution of electronically active flaws in these cases allowed one to exclude the possibility that uniform activation was the result of many small flaws of the same kind as the larger ones that had appeared at the lower voltage levels.

Some kinds of flaws can become sources of e.c. in contact with sputtered or pyrolytically deposited MeO. "Field" crystals were one example, cracks, pores and breakdown sites, another. Their density was usually found to be several orders of magnitude smaller than that of oxide or carbide flaws. Again, they were found to conduct at voltage levels below those of uniform conduction and could, therefore, be excluded from consideration in the activation effect.

Summary of experimental results.—The e.c. of Ta/Ta_2O_5 electrodes in aqueous electrolytes was found to be extremely low in the absence of impurities. No obvious correlation between physical flaws as observed microscopically and e.c. was observed. The distribution of e.c. depended on the distribution of impurities present and had to be established experimentally.

With $Ta/Ta_2O_5/MeO$ electrodes (MeO = Fe_2O_3, MnO_2) e.c. was established in a time-dependent activation process on polarization in contact with electrolyte to potentials at which ionic migration set in.

Activation was observed at all Ta_2O_5 thicknesses and was characterized by an exponential increase of the electronic current with time at constant field in Ta_2O_5. In some cases deviations from this behavior were found and attributed to the properties of MeO.

The distribution of e.c. due to activation was found to be uniform and homogeneous. Electronically active flaw sites were found to be active at fields below those required for uniform activation. Therefore, the e.c. observed in the presence of MeO could not be attributed to flaws.

The electronically active condition persisted after activation had taken place and current field characteristics could be measured at fields below those used for activation. The active state slowly reverted to a less active state. The rate was dependent on the nature of MeO.

The dissolution of MeO removed the cause of e.c. The rate-limiting step for electron transport after activation was found to be localized in the Ta_2O_5/MeO interface.

The current-field characteristic of the e.c. was found to be that of thermionic emission, *i.e.*, log i_{el} proportional $F^{1/2}$, over several decades of current.

Discussion

Mechanism of activation.—Any physical model of the experimental system must be able to explain the dependence of the electronic conduction phenomena on the ionic processes preceding them. Experimentally, it was found that the electronic conductivity of the $Ta/Ta_2O_5/MeO$ electrode was as low as that of the Ta/Ta_2O_5 electrode until some ionic conduction had taken place. It is necessary, therefore, to first discuss the ionic processes which take place in Ta_2O_5 with electrolyte and MeO/electrolyte contacts. The two systems are shown in schematic form in the following figures.

The behavior of the Ta/Ta_2O_5 electrode (Fig. 14) is characterized by ionic migration as fields of the order of 10^6-10^7 V/cm are applied (Eq. [1]). Close to 80% of the ionic current is carried by anions (II), the rest by cations (I) (15). Reaction (II) leads to additional oxide growth at the Ta/Ta_2O_5 interface while reaction

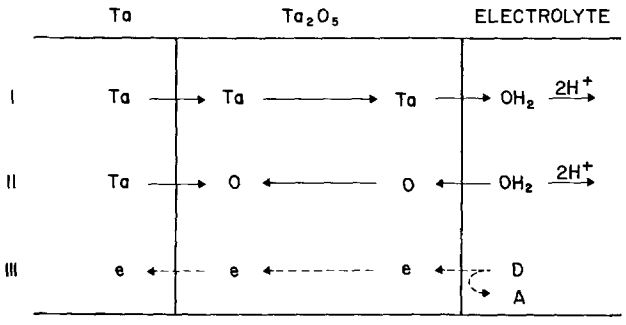

Fig. 14. Schematic of Ta/Ta_2O_5 electrode with electrolyte contact under anodic polarization. D = A + e redox system with D electron donor, A acceptor. Arrows indicate migration currents under a gradient of the electrochemical potential. Charge signs on ions have been omitted.

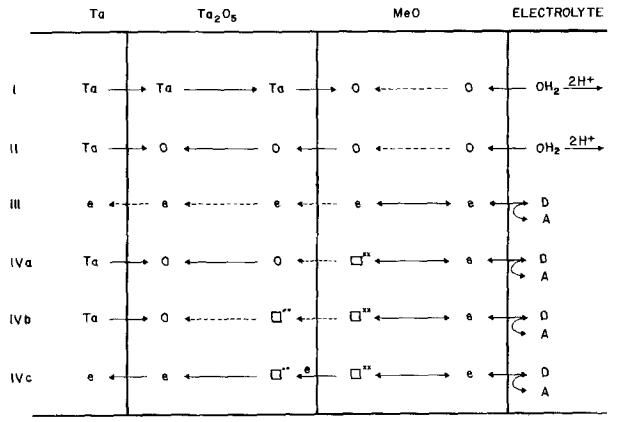

Fig. 15. Schematic of $Ta/Ta_2O_5/MeO$ electrode with electrolyte contact under anodic polarization. MeO = Fe_2O_3, MnO_2. D = A + e, redox system with D electron donor, A acceptor. $\square^{xx}$ oxygen vacancy with positive charge compensated by electrons, $\square^{\circ\circ}$ oxygen vacancy, positively charged. Full line arrows indicate migration currents under a gradient of the electrochemical potential; broken arrows indicate that the reaction is strongly hindered; double arrows indicate equilibrium. Charge signs on ions have been omitted.

(I) leads to growth at the Ta_2O_5 electrolyte interface. (The arrows indicate gradients of the electrochemical potential due to the applied field. Double arrows indicate equilibrium, broken lines indicate that the reaction is strongly hindered.) Oxide growth proceeds with nearly theoretical current efficiency, unless impurities are present in Ta_2O_5. This means in fact that the Ta/Ta_2O_5 electrode is an insulator electrode, since the electronic current even at the highest fields experimentally accessible is small compared to the ionic current.

The properties of metal-insulator electrodes have recently been reviewed (16). They are characterized by the lack of intrinsic electronic charge carriers in the insulator. A steady space charge limited electronic current is observed only if charge carriers can be injected at the insulator-electrolyte interface. An injecting or "ohmic" contact (17) is formed if the electrochemical potential of electrons in the electrolyte (Fermi energy) is sufficiently close to the energy of one of the band edges of the insulator, and if "band bending" allows electron exchange between energy levels in the electrolyte and the surface of the insulator. This condition is not satisfied for the Ta/Ta_2O_5 electrode in aqueous electrolytes as can be concluded from the absence of measurable space charge limited current flow. Also, the absence of measurable electronic current at high fields is evidence of negligible field induced charge injection or carrier generation in the bulk of the oxide. In Fig. 14 the electronic reaction (III) is characterized by the redox system D = A + e in the electrolyte (D donor, A acceptor species), blocked electron injection and a steep gradient of the electrochemical potential in the Ta_2O_5 which sweeps all mobile as well as most of the trapped electrons into the metal substrate. The potential distribution is characterized by a large drop across Ta_2O_5 and polarization at both of its interfaces. The ionic reactions I and II determine the magnitude of these overvoltages. In electrochemical terms the Ta_2O_5/electrolyte-contact is a blocking one for electrons because the overvoltage, as determined by the ion transfer reaction, is insufficient to establish the interface potential difference required for electron injection. Only by increasing the overvoltage of the ionic reaction can this condition for electron injection be met.

In the $Ta/Ta_2O_5/MeO$ electrode (Fig. 15) a second oxide film has been inserted between the insulating Ta_2O_5 and the electrolyte. The consequences regarding the ionic and electronic reactions will now be discussed. MeO (= Fe_2O_3 or MnO_2) is a transition metal oxide which exhibits electronic conductivity according to its nonstoichiometry and impurity content. Two assumptions are made regarding its e.c.

1. Electron equilibrium is established across the MeO/electrolyte interface and throughout MeO.

2. The electronic conductivity of MeO is much larger than its ionic conductivity. This means that the electrolyte contact to MeO is "ohmic" and that a Me/MeO-electrode would correctly measure the redox potential of the electrolyte (18). Electrons will be in equilibrium across MeO as long as its electronic charge carrier concentration is reasonably high and the current drawn remains low.

The effect on the migration of ions of a field applied across Ta_2O_5 will be the same as in the previous case but in contrast to electrolyte contact to Ta_2O_5, oxygen ions will not be readily available at the Ta_2O_5/MeO interface and a metal excess will result at this interface. We assume, for the purpose of this discussion, that the metal excess results from oxygen deficiency. This assumption would seem to be a reasonable one in view of the experimental evidence of amphoteric or n-type behavior of the oxides involved (19, 20). The reactions that lead to a depletion of oxygen ions on either side of the Ta_2O_5/MeO interface are illustrated in Fig. 15, IV a-c. At first, oxygen vacancies are being created on the MeO side as a result of the migration of oxygen ions away from the interface under the influence of the potential gradient across Ta_2O_5 and their limited availability from the electrolyte due to dominant electronic conductivity in MeO. The doubly positive charge of oxygen vacancies is compensated by electrons which are freely available from the redox reaction. This process creates additional electronic energy levels at the MeO side of the MeO/Ta_2O_5 interface.

As the depletion of oxygen ions spreads to the Ta_2O_5 side of the interface, positively charged oxygen vacancies (IV b) are formed inside Ta_2O_5. Their positive charge will remain largely uncompensated as any electrons crossing the barrier will be swept across Ta_2O_5 under the influence of the high applied field. As the oxygen depletion increases on both sides, a double layer charge builds up which is equivalent to saying that the overvoltage at the Ta_2O_5/MeO interface increases. The insertion of the MeO layer between Ta_2O_5 and the electrolyte thus leads to a limitation of the oxygen ion supply required for further Ta_2O_5 growth. The consequence of this limitation is increased interface polarization. This in turn leads to a reduction of the energy barrier for electron injection into Ta_2O_5 and allows larger electronic currents to pass from the electrolyte to the substrate metal. This is the condition that is indicated by reaction (IVc): The electrons are in equilibrium across the electrolyte/MeO interface and MeO and follow the electrochemical potential gradient across the MeO/Ta_2O_5 interface and Ta_2O_5.

Interaction of ionic and electronic processes at the Ta_2O_5/MeO *interface.*—No direct experimental evidence for the modification of the Ta_2O_5/MeO interface due to ion depletion can be given at this time. However, strong support for the contention that ionic migration contributes to the establishment of electronic conductivity comes from the following considerations. First, the activation process takes place at fields where ionic current (1) is known to flow according to

$$i = A \exp BF \quad [1]$$

where A, B = empirical constants and F = electric field. The activation process is time dependent, and the rate of increase of the electronic conductivity is a function of the applied field. Second, in cases where MeO shows some small degree of ionic conductivity, as for example in the case of MnO_2, one can detect some additional growth of Ta_2O_5 underneath MeO (21). Third, after activation has proceeded to a certain conductivity level one finds this condition to persist in the absence of the field for extended periods of time, but with a general tendency to decline over longer periods of time. The reversion to the inactive condition is considerably faster in the case of MnO_2 which shows somewhat higher ionic conductivity than Fe_2O_3. This points to the participation of ionic migration also in the reversion process which proceeds, it is believed, under the driving force of a gradient of the electrochemical potential of the depleted ions.

A quantitative correlation between the ionic current and the activation process as characterized by the increase in electronic conductivity will now be given. The electronic current (i_{el}) follows the current-field characteristic of thermionic emission (7)

$$i_{el} = i_{o,el} \exp (e\beta F^{1/2} - \phi_o)/kT \quad [2]$$

where

ϕ_o = energy barrier at zero field
e = electronic charge
k = Boltzmann constant
T = absolute temperature
β = field lowering coefficient

At constant field

$$\log_{10} i_{el} = D - 0.43\, \phi_o/kT \quad [3]$$

with

$$D = 0.43\, (\log_{10} i_{o,el} + e\beta F^{1/2}/kT)$$

The assumption is made that the ionic polarization at the Ta_2O_5/MeO interface leads to a reduction of the zero field energy barrier ϕ_o, and it is further assumed that the reduction is proportional to the ionic charge that has been displaced. The polarization process can be regarded as the charging of the double layer capacitance in the interface between Ta_2O_5 and MeO by the ionic current as given by Eq. [1]

$$d\eta = i_{ion}\, dt/C \quad [4]$$

$$= A\, (\exp BF)\, dt/C \quad [5]$$

where C = capacitance of polarization double layer formed in Ta_2O_5/MeO interface, η = interface overvoltage. This leads to an expression for the energy barrier as a function of time (t)

$$\phi = \phi_o - et\, d\eta/dt \quad [6]$$

$$= \phi_o - (eAt/C) \exp BF \quad [7]$$

From [7] and [3]

$$\log_{10} i_{el} = D - 0.43\, \phi_o/kT - (0.43\, eAt/CkT) \exp BF \quad [8]$$

From this equation the electronic activation current follows log i_{el} prop exp BF, with B the field constant of the ionic current. B was determined by plotting the slope s of the activation curves ($\log_{10} i_{el}$ *vs.* t, Fig. 6) *vs.* the applied field. From [8]

$$s = (0.43\, eA/CkT) \exp BF$$

$$\log_{10} s = \text{const.} + 0.43\, BF$$

The slope of $\log_{10} s$ *vs.* F yields the field constant of the ionic current. The result that was obtained for three Ta_2O_5 film thicknesses is shown in Fig. 16. The slope of the least-mean-square line gives a value of $B = (4.95 \pm 0.2) \times 10^{-6}$ cm V^{-1}. The close correspondence of this value with $B = 5.2 \times 10^{-6}$, the value given in the literature (1) as determined from studies of the ionic current-field relationship, provides conclusive evidence for the interaction of ionic and electronic processes in the activation effect.

Electronic leakage current due to impurities in Ta/Ta_2O_5 *electrodes.*—The role of impurities in causing electronic leakage in Ta/Ta_2O_5 electrodes may be understood similarly in terms of the activation model. The anodization of contaminated Ta may result in an accumulation of impurity oxide at the Ta_2O_5 electrolyte interface if competitive migration favors this and if the resulting impurity oxide is not dissolved by the electrolyte. This has been found to be the case with Ta contaminated with Fe, for example (3). The surface layer of impurity oxide will now restrict the supply of oxygen ions and thus lead to a degree of interface polarization. This in turn will permit the injection of electrons into Ta_2O_5. As long as the impurity oxide is sufficiently thin and of low electronic conductivity continuing anodization under the impurity oxide will be observed. This mechanism would explain why electronically active sites persist over wide voltage intervals of anodization without significant changes in their relative intensity. In cases where increasingly thicker impurity oxide films are formed the formation of additional anodic Ta_2O_5 will cease and all current will eventually become electronic. Subsequently, excessive current densities may destroy the underlying Ta_2O_5 film.

Impurities may also act as dopants for Ta_2O_5 and thus lead to discrete or quasi-continuous electron conduction levels in the forbidden gap. This would mean that the barrier for electron injection into Ta_2O_5 was reduced under anodization conditions and that conduction took place in impurity levels. A combination of both leakage conduction mechanisms appears possible. However, in the case of Ta contaminated with Fe the experimental observations strongly suggested that doping was not a contributing factor.

The current-field characteristic of impurity conduction will depend on the properties of the impurity oxide, such as its electronic conductivity, thickness, and solubility in the electrolyte, among others. In addition, the energy level distribution in all phases, *i.e.*, Ta_2O_5, the impurity oxide, and the redox electrolyte will also have a major influence.

Mechanism of charge transfer from the electrolyte to Ta *substrate.*—A more detailed discussion of the energy levels of electrons in the Ta/Ta_2O_5/MeO electrode in an aqueous redox electrolyte will now be

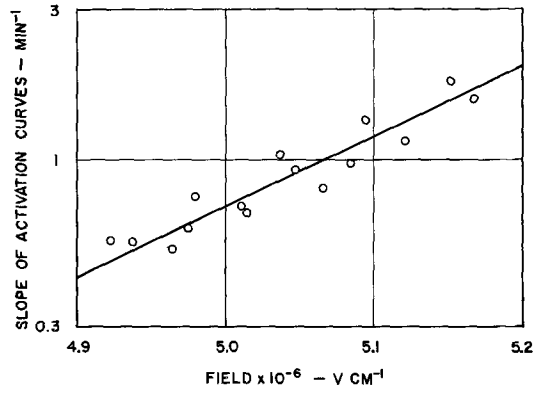

Fig. 16. Slope of activation curves (from Fig. 6) *vs.* the true field $F = \Delta V/d$ in Ta_2O_5.

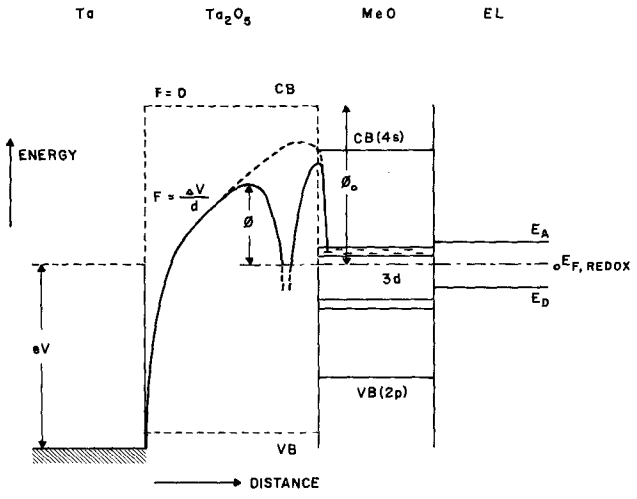

Fig. 17. Electronic energy diagram for $Ta/Ta_2O_5/MeO$ electrode with redox electrolyte contact. For details see text. CB conduction band; VB valence band; redox electrolyte: E_A acceptor level, E_D donor level, $_oE_{F,redox}$ Fermi level; V applied voltage; ΔV potential drop across Ta_2O_5.

given. Figure 17 shows, in schematic form, the electronic energy distribution for the system. The Ta electrode is characterized by its Fermi level E_F (Ta), the anodic Ta_2O_5 by the forbidden energy gap [of the order of 4.5 eV (1)]. The contact is nonblocking with Ta positive. The amorphous nature of anodic Ta_2O_5 may lead to a distribution of quasi-localized energy levels in the forbidden gap (7).

The electronic energy level diagrams of transition metal oxides such as Fe_2O_3 or MnO_2 are not known in any great detail (22-24). For the purpose of this discussion we assume the two transition metal oxides to be characterized by two narrow bands which result from crystal field splitting of the degenerate 3d levels of the transition metal cations under the influence of the strong electric field set up by the oxygen ions. Two wide bands resulting from oxygen 2p and cation 4s electrons are assumed to be too far from 3d levels to affect their occupancy. The location of the 3d energy bands of MeO with respect to the Ta_2O_5 band gap is not known. It is assumed that the 3d band energy levels are far removed in energy from the conduction levels of Ta_2O_5. The Ta_2O_5/MeO electrolyte contact is nonohmic before activation.

The redox system is characterized (25) by its Fermi level, $E_{F,redox}$ which is equivalent to the chemical potential of the electrons in the electrolyte. Donor (E_D) (occupied, reduced) and acceptor (E_A) (unoccupied, oxidized) energy levels show a distribution in energy due to thermal fluctuations of the hydration shell of each ion. The position of the electrolyte Fermi level depends on the redox potential and varies, therefore, with the kind and concentration of the redox system in contact with the $Ta/Ta_2O_5/MeO$ electrode.

In Fig. 17 the effect of an electric field across Ta_2O_5 has been illustrated. With zero field the barrier is rectangular with height ϕ_o. Under a low field the barrier for electrons is of such magnitude and shape that electron transfer is negligibly small. As the field increases the bands in Ta_2O_5 slope sharply downward resulting in a triangular barrier of reduced height. The maximum band bending is obtained when ionic migration sets in. At this point the barrier is still such as to prevent electrons from being injected into Ta_2O_5. As described previously, ionic migration then leads to polarization of the Ta_2O_5/MeO interface and the generation of positively charged centers in Ta_2O_5 close to this interface. The effect of positive ionic charges on the shape of interface barriers has been discussed by Schmidlin (26) and Korzo *et al.* (27). Tunnelling through and/or thermionic emission over a barrier ϕ of reduced height as shown in Fig. 17 must be considered as possible charge transfer mechanisms. The experimental results presented in this study strongly suggest that thermionic emission is the dominant mechanism.

Thermionic current-field characteristic of the electronic activation current.—The experimental results in conjunction with the model of the activation process provide the basis for the interpretation of the current field (voltage) characteristic of the electronic conduction process. The current-field characteristic of the electronic current measured after activation to a certain current level (Fig. 10) showed log i to be proportional to $F^{1/2}$. This characteristic is commonly associated with thermionic emission (Eq. [2]) which may follow one of two mechanisms, which have been reviewed extensively (6, 7, 28).

1. The Schottky effect (S) describes thermionic emission over a field-lowered barrier. The field lowering coefficient β_S is given by

$$\beta_S = (e/4\pi\epsilon_o\epsilon)^{1/2} \quad [9]$$

where ϵ_o = permittivity of vacuum and
ϵ = relative dielectric constant.

2. The Poole-Frenkel effect (PF) is the field assisted thermally activated release of electrons from traps or, more generally, coulombic potential wells. The current-field characteristic of the Poole-Frenkel effect also follows Eq. [2] with a field lowering coefficient which is twice that of the Schottky effect

$$\beta_{PF} = 2\beta_S = (e/\pi\epsilon_o\epsilon)^{1/2} \quad [10]$$

The Schottky effect is normally considered to be an interface effect, while the Poole-Frenkel effect applies to the bulk. The only criterion for an experimental differentiation between the two is the field lowering coefficient which gives the slope of the log i *vs.* $F^{1/2}$ curve. β contains only fundamental constants, with the dielectric constant the only one somewhat uncertain. The slope of the experimental log i *vs.* $F^{1/2}$ curve was used to calculate the dielectric constant. Our measurements for the $Ta/Ta_2O_5/Fe_2O_3$ electrode gave the following results:

ϵ_S	ϵ_{PF}	$\epsilon^{\infty}_{Ta_2O_5}$ (1)	$\epsilon^{\infty}_{Fe_2O_3}$ (29)
1.18	4.7	5.1	~9

There is general agreement in the literature (6, 7) that the high-frequency dielectric constant should apply to both mechanisms. The above comparison of dielectric constants clearly favors the Poole-Frenkel mechanism since there is close agreement between the high-frequency dielectric constant of Ta_2O_5 and the dielectric constant calculated from the Poole-Frenkel field lowering coefficient and the experimentally determined slope of the current-voltage curve.

At first sight it might be surprising that electron emission from an interface should follow the Poole-Frenkel mechanism. In the schematic electronic energy diagram (Fig. 17) it has been assumed that traps are generated inside Ta_2O_5 and that electrons may tunnel freely from the MeO electron levels through the narrow energy barrier at the interface to the traps. The energy barrier of thermionic emission according to Poole-Frenkel would therefore be the barrier seen by electrons trapped in a coulombic potential well as required by the theory. The field in Ta_2O_5 will assist the release of these electrons, and it is believed that it is this step in the electronic conduction process which is rate limiting.

Mechanism of the Electrochemical Reduction of Enolized 1,3-Diketones

Raymond C. Buchta[1] and Dennis H. Evans

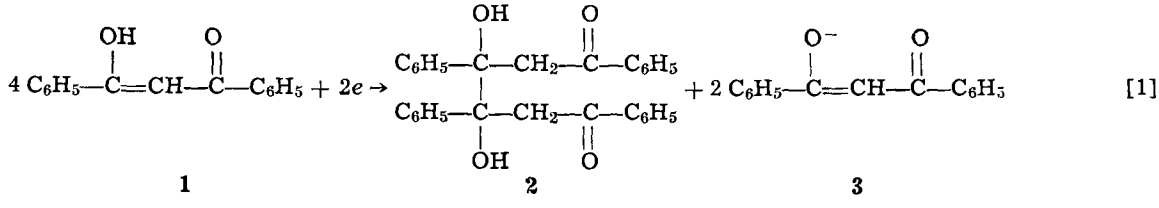
Department of Chemistry, University of Wisconsin, Madison, Wisconsin 53706

ABSTRACT

A mechanism for the electrochemical reduction of 1,3-diphenyl-1,3-propanedione (**1**) and other enolized 1,3-diketones in aprotic solvents has been developed on the basis of cyclic voltammetric studies. The over-all reaction is a 0.5-electron process producing the enolate anion of the 1,3-diketone and the dimeric pinacol. The central feature of the mechanism is a one-electron reversible reduction to the radical anion of the 1,3-diketone followed by a fast, reversible proton transfer from unreacted diketone to the radical anion forming enolate and a neutral radical. The neutral radicals then undergo rapid coupling reactions. The electrochemical behavior of 1,3-diketones existing in the diketo form is contrasted with the above scheme.

Previous investigations have characterized the over-all electrode reactions involved in the electrochemical reduction of representative enolized 1,3-diketones in ethanol-water (1) and dimethylsulfoxide (2). In the present communication the results of detailed studies of the mechanism of the reduction of 1,3-diphenyl-1,3-propanedione **1** (or dibenzoylmethane, DBMH) and other enolized 1,3-diketones in dimethylsulfoxide (DMSO) will be presented.

The reduction of DBMH in DMSO proceeds by an over-all 0.5-electron process (2) with the stoichiometry given in Reaction [1]



[1]

1 **2** **3**

Several chemical properties of 1,3-diketones have proven to be extremely important determining factors in the electrochemical reduction of these compounds. The first and most obvious is the keto-enol tautomerism. Those compounds which exist in the diketo form possess a much different pattern of reactivity (3) than the enolized compounds. The most important difference is the fact that the enol proton in compounds like **1** is sufficiently acidic that the 1,3-diketone acts as a proton donor during its reduction in aprotic solvents leading to the stoichiometry of Reaction [1] in which the conjugate base (enolate ion **3**) of the starting material is one of the products.

Another important property is the tendency for 1,3-diketones to undergo cleavage reactions in basic solution. This is particularly important during the reduction of diketo tautomers in aprotic solvents (3). Metal ions form a variety of complexes with 1,3-diketones

[1] Present address: Jackson Laboratory, E. I. du Pont de Nemours and Company, Wilmington, Delaware 19898.

Key words: cyclic voltammetry, tautomerism, dimethylsulfoxide, dimerization, coulometry.

and the electrochemical behavior of some of these has been reported (4,5). An effect of lithium ions on the electrochemical reduction of DBMH was observed in the present investigation, but the general area of the effect of metal ions on 1,3-diketone electrochemistry remains largely unexplored.

Cyclopropanediols are possible two-electron reduction products of 1,3-diketones. Recently, such products have been isolated after chemical reduction of several cyclic 1,3-diketones (6). Cyclopropanediol derivatives are produced in certain electrochemical reductions (7). However, this particular reaction path appears to be unimportant for the acyclic compounds discussed in this paper.

Experimental

Reagents.—Dimethylsulfoxide (J. T. Baker Reagent, 0.05% or 30 m*M* water) was stirred over calcium hydride for at least 12 hr and distilled under reduced pressure just before use. Tetra-*n*-butylammonium perchlorate (Matheson) was used as received for polarography and controlled potential coulometry. For cyclic voltammetric studies it was recrystallized from ethyl acetate and vacuum dried. Lithium perchlorate (G. F. Smith) was vacuum dried before use. Prepurified nitrogen (Airco) was used for solution deaeration.

Various 1,3-diketones and other materials (Eastman) were used as received: 1,3-diphenyl-1,3-propanedione, 1,3-bis(*p*-fluorophenyl)-1,3-propanedione, 1,3-bis(*p*-methoxyphenyl)-1,3-propanedione, 1-phenyl-1,3-butanedione, isobutyrophenone, acetophenone. Preparations of tetra-*n*-butylammonium dibenzoylmethide (2), 2,2-dimethyl-1,3-diphenyl-1,3-propanedione (8), 2-*t*-butyl-1,3-diphenyl-1,3-propanedione (3), and 1,4-dibenzoyl-2,3-diphenyl-2,3-butanediol (1) have been described.

The nmr spectra of DBMH, 1,3-bis(*p*-fluorophenyl)-1,3-propanedione, 1,3-bis(*p*-methoxyphenyl)-1,3-propanedione, and 1-phenyl-1,3-butanedione were obtained in d_6-DMSO and *d*-chloroform. In consonance with earlier studies (9) these substances were found to exist almost entirely in the enol form. These conclusions were based on the fact that the proper ratios between the integrals of the olefinic proton resonance and the other resonances were found. In addition, no resonance attributable to the methylene protons of the keto form was detected. A broad enol resonance was found for each compound in the 15-17 ppm range. The nmr spectra of 2-*t*-butyl-1,3-diphenyl-1,3-propanedione indicated that it was almost completely in the diketo form. Substitution in the 2-position causes a marked preference for the diketo tautomer as, for example, with 2-methyl-1,3-diphenyl-1,3-propanedione (9c).

Apparatus and procedure.—Instrumentation, cells, electrodes, and procedures for polarography and controlled potential coulometry have been described (2).

Cyclic voltammetric experiments were carried out using an instrument based on conventional circuits (10) and utilizing solid-state operational amplifiers. Philbrick SP65A amplifiers were used for the current follower, voltage sweep, and controller amplifiers. The voltage follower was a Philbrick P25AH. Up to and including a voltage scan rate of 0.3 V/sec, the direction of the scan was changed manually. For voltage scan rates greater then 0.3 V/sec, the triangular waveform of a signal generator (Wavetek Model 112) was employed in conjunction with the above instrument. An X-Y recorder (Hewlett Packard-Moseley Division, Model 2D-2A) was used to record voltammograms up to 0.3 V/sec and for faster scan rates an oscilloscope (Tektronix Type 564 with two Type 2A63 plug-ins) was employed. Oscilloscope traces were photographed (C-12 camera) using Polaroid Type 107 film. Voltage scan rates were measured using the calibrated time axis of the recorder or oscilloscope (Type 2B67 plug-in).

The working electrode was a microburette-type hanging mercury drop electrode (Brinkmann Instruments, Inc.). Necessary precautions in the use of such electrodes have been described (11). The size of the mercury drop was determined from the mass of a known number of drops.

The cell for cyclic voltammetry was the same as that described for polarography (2). The temperature of the test solution was maintained at 25.0° ± 0.1°C using the cell water jacket in conjunction with a pump and controlled temperature bath. The microburette electrode occupied the central inlet of the cell and the other inlets were used for nitrogen deaeration, counter and reference electrodes. The reference electrode was either an aqueous saturated calomel electrode in a cracked glass probe (2) or a platinum quasi-reference electrode (12) sealed in a Luggin capillary. The tip of the capillary could be positioned within one drop diameter of the working electrode. The electrolyte concentration was increased to 0.2*M* to minimize resistance effects. The base line for the measurement of the anodic peak current was obtained by stopping the scan at a convenient potential past the cathodic peak and recording the resulting current-time curve (13). Residual currents were obtained using solutions containing only electrolyte and solvent.

In the cyclic voltammetric studies of the reduction of DBMH it was necessary to use relatively large concentrations (0.5-2.0 m*M*) in order to obtain a significant amount of following chemical reaction at practical scan rates. Consequently, the peak currents were rather large and the cyclic voltammograms were slightly distorted by uncompensated resistance effects. For example, with 2.00 m*M* **1** the cathodic peak current was 56 μA at a scan rate of 5.00 V/sec. The separation of peak potentials was 96 mV compared with 57 mV predicted for a reversible, one-electron process with no distortion due to uncompensated resistance. The effect also manifests itself in a diminished cathodic peak current. Corrections have been discussed by Delahay (14) and Nicholson (15). The approximate correction due to Delahay (14) was applied to all results. The largest correction of the cathodic peak current function was 8%. All corrections were less than 2% for scan rates less than 1.0 V/sec. The efficacy of the correction procedure was demonstrated in a study of the reduction of 2.05 m*M* acetophenone with scan rates varying from 0.050 to 5.00 V/sec and attendant peak potential separations of 70-123 mV. The corrections varied from 3 to 14% and the resulting current functions were constant with an average deviation of 1.0%. The use of this correction procedure assumes that the standard rate constant of the heterogeneous electron transfer reaction is large enough to prevent deviation of the waves from their reversible shape at the highest scan rates employed.

Results and Discussion

Representative cyclic voltammograms of 2.00 m*M* DBMH in dimethylsulfoxide (DMSO) containing 0.2 *M* tetra-*n*-butylammonium perchlorate are shown in Fig. 1. On the cathodic portion of the voltage scan, waves are found having peak potentials of −1.42, −1.72, and −2.28V *vs.* SCE. The first is the main reduction wave for DBMH. The latter two correspond to those observed for the pinacol **2** (−1.73V) and the enolate **3** (−2.27V). On the anodic portion of the voltage scan an oxidation wave occurs at −1.36V. This is due to the oxidation of the primary product formed at the first cathodic wave. If the anodic scan is extended to potentials more positive than those in Fig. 1, a reversible couple at −0.05V is detected. This process is also found with solutions of the enolate **3**. It is probably caused by anodic reactions yielding 1,3-diketone complexes of mercury. It is absent when a platinum working electrode is used.

The cyclic voltammograms in Fig. 1 were recorded at two different scan rates, 0.1(A) and 1.0(B) V/sec. The waves for the pinacol and the enolate show the expected dependence on scan rate, *i.e.*, they are smaller relative to the main wave at faster scan rates. This, of

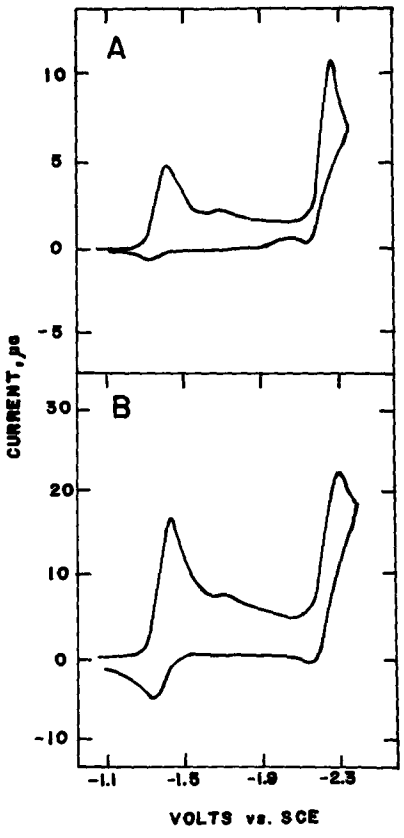


Fig. 1. Cyclic voltammograms of 2.00 mM dibenzoylmethane in 0.2M tetra-n-butylammonium perchlorate in DMSO. A. 0.100 V/sec. B. 1.00 V/sec.

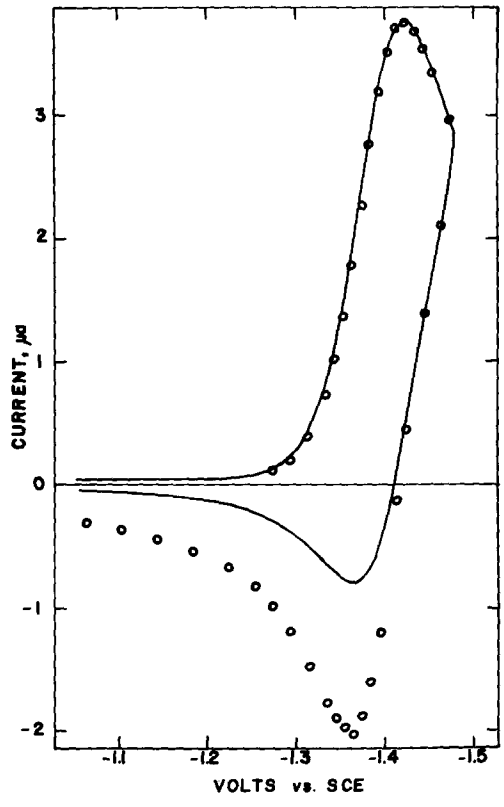

Fig. 2. Cyclic voltammogram of 1.01 mM dibenzoylmethane in 0.2M tetra-n-butylammonium perchlorate in DMSO, 0.100 V/sec. Circles are theoretical points for a reversible one-electron reduction with no following reaction.

course, indicates that given less time for the following chemical reactions to occur, less pinacol and enolate will be formed. It was also found that the pinacol and enolate waves were smaller relative to the main wave at lower DBMH concentrations. This dependence of the rate of the following reactions on concentration indicates that the reactions are of an order higher than first.

The most fundamental process characterizing this system is associated with the main wave at −1.42V. The other waves that have been observed result from products of this reaction. Therefore, experimental efforts were concentrated on the characterization of this process.

Before performing detailed studies of this reaction, it was necessary to establish that Reaction [1] is an adequate stoichiometric description of the process. From earlier studies (2) it was known that controlled potential coulometry of DBMH at −1.50V yielded an average n-value of 0.55. The two products (pinacol 2 and enolate 3) could be detected in the final electrolysis solution by polarography. The yellow color of 3 was completely discharged by the addition of dilute perchloric acid which converted it to DBMH which could then be detected by polarography. The pinacol 2 has been isolated after large scale electrolysis of DBMH in acetonitrile (16), a solvent in which the electrochemical behavior is very similar to that in DMSO.

Finally, the per cent yield of pinacol 2 was determined after controlled potential electrolysis of 49.9 mg of DBMH. A polarographic standard addition method employing the first polarographic wave of the pinacol was developed. Addition of known amounts of pure pinacol resulted in an increase in diffusion current with no change in the wave shape. The yield of pinacol was 107% based on the stoichiometry of Reaction [1]. Thus it is concluded that this reaction is an adequate description of the over-all process occurring at the first wave. Reactions other than [1] can consume no more than about 10% of the DBMH.

The first fact which may be obtained from the cyclic voltammogram of the first wave is the number of electrons in the primary electrode reaction. In Fig. 2 an experimental cyclic voltammogram of the first wave is presented together with the theoretical (13) curve for a reversible one-electron reaction with no following reaction. Excellent agreement is found between experiment and theory except, of course, the anodic peak current is diminished because of the following chemical reactions. Thus the primary product of the electrode reaction is probably the radical anion of DBMH.

There are three major properties of cyclic voltammetry which may be used to characterize a chemical reaction following the electrode reaction. These are the cathodic peak current function, the cathodic peak potential, and the ratio of anodic peak current to cathodic peak current, i_a/i_c (13). For the reaction rates found in this system, the last is the most sensitive and informative measure of the effect of the following reaction.

Representative data for three concentrations of DBMH and scan rates from 0.050 to 5.00 V/sec are summarized in Table I. The values of i_a/i_c increase with increasing scan rate and approach the limiting value of 1.00 at scan rates rapid enough to prevent appreciable following reaction. At a given scan rate the values of i_a/i_c are relatively higher at lower concentrations of DBMH.

To gain some qualitative information about the nature of the reaction, the i_a/i_c values were compared with the predictions for a similar but considerably simpler reaction scheme, *viz.*, a reversible electrode reaction followed by irreversible dimerization of the product (17). The values of k included in Table I are apparent rate constants for dimerization calculated from the i_a/i_c data. The values of k are reasonably independent of scan rate and concentration, although the

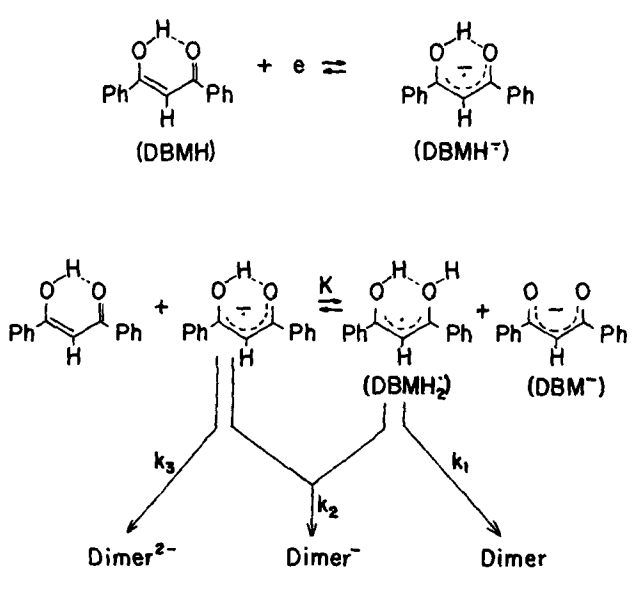
[a] 0.2M tetra-n-butylammonium perchlorate in DMSO. Temperature 25.0° ± 0.1°C. Current functions and peak current ratios are averages (typically 2-3 determinations). Radius of hanging mercury drop electrode: r_o = 0.0485 cm.
[b] Cathodic peak current function × 10^2, A-sec$^{1/2}$ $v^{-1/2}$ M^{-1}. Peak current has been corrected for sphericity effects and small distortions caused by uncompensated resistance. Separation of peak potentials range from 57 mV at low concentrations and slow scan rates to about 100 mV at high concentrations and rapid scan rates. v: scan rate (V/sec).
[c] Apparent second order dimerization rate constant × 10^{-3}, M^{-1} sec^{-1}. Switching time parameter, $a\tau$ (17), was calculated from each voltammogram. Typical values of $a\tau$ were 3.0-4.0.

average apparent rate constant for 0.510 mM DBMH is significantly larger than those obtained with the higher concentrations of DBMH. Thus in terms of i_a/i_c values, the process under study bears resemblance to a simple dimerization reaction. This resemblance is illustrated further in Fig. 3 where additional i_a/i_c data are plotted *vs.* the logarithm of the scan rate. Theoretical curves for an apparent dimerization rate constant of 2200 M^{-1} sec^{-1} are shown and a typical (k = 4 sec^{-1}) theoretical curve for a first-order following reaction (13) is presented for comparison.

The values of the cathodic peak current function are also included in Table I. For the dimerization mechanism, the peak current function will be almost independent of scan rate (17), exhibiting a slight increase at slow scan rates. The experimental values show a significant decrease at slow scan rates. This reflects the fact that the following chemical reactions consume additional starting material (DBMH) leaving less available for the electrode reaction. This effect is largest, of course, at slow scan rates where the extent of the following reaction is largest. The high scan rate limit is about 0.013 A sec$^{1/2}$ V$^{-1/2}$ M^{-1}. This corresponds to a diffusion coefficient of 2.7 x 10^{-6} cm^2/sec for DBMH.

A proposed reaction sequence consistent with the results just discussed is presented in Chart I. The central elements of this scheme are the reversible one-electron reduction of DBMH to its radical anion DBMH$^{\cdot-}$ and the subsequent rapid equilibrium reaction in which unreacted DBMH transfers a proton to DBMH$^{\cdot-}$ producing a neutral radical (DBMH$_2^{\cdot}$) and the enolate 3 (DBM$^-$). Three types of dimerization reaction are included: (*i*) dimerization of neutral radicals characterized by rate constant k_1; (*ii*) coupling of a neutral radical and an anion radical giving an anion of the pinacol. This reaction is characterized by rate constant k_2. It must be followed by protonation of the pinacol anion by DBMH; and (*iii*) coupling of two radical anions characterized by rate constant k_3. Charge interaction considerations suggest that k_3 is smaller than either k_1 or k_2.

Chart I



In this scheme the oxygen atom has been chosen as the site of protonation of the radical anion. Thus the pinacol 2 would be produced in the enol form requiring subsequent tautomerization. Protonation of the radical anion at the central carbon atom cannot be ruled out at this point.

So far no evidence has been found suggesting that reactions of radical species with DBMH to give dimeric radicals (18) are important in this system and such reactions have been omitted from the scheme in Chart I.

This reaction sequence is considerably more complex than the simple dimerization mechanism which was used in the analysis of the i_a/i_c data. It differs in two major ways: (*i*) the species which are dimerizing exist in an equilibrium mixture of two forms, protonated and unprotonated; and (*ii*) the following chemical reactions consume starting material. The latter point is consistent with the observed scan rate dependence of the cathodic peak current function discussed above.

The agreement of the observed i_a/i_c data with the predictions of the simple dimerization model may signify that the theoretical i_a/i_c values corresponding to

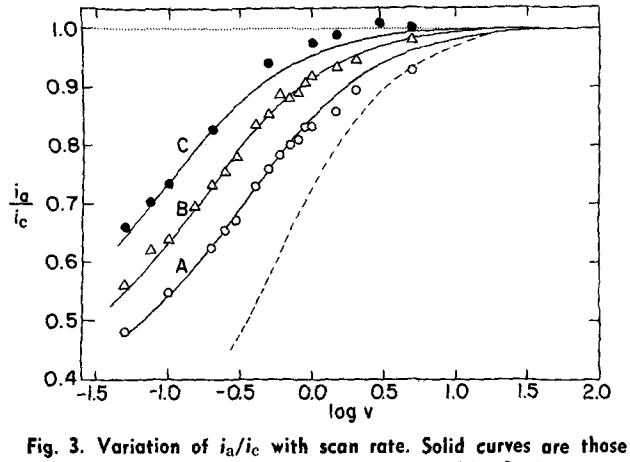


Fig. 3. Variation of i_a/i_c with scan rate. Solid curves are those predicted for a simple dimerization reaction (17). Dashed curve is a typical (k = 4 sec^{-1}) predicted curve for a first-order following reaction (13). The value of the parameter $a\tau$ is 3.4 for all theoretical curves and experimental data. Dibenzoylmethane concentrations: Curve A and ○: 2.00 mM; k = 2200 M^{-1} sec^{-1}. Curve B and △: 1.01 mM; k = 2200 M^{-1} sec^{-1}. Curve C and ●: 2.00 mM + 7.96 mM enolate 3, k = 550 M^{-1} sec^{-1}. Scan rate in V/sec.

the more complex scheme in Chart I would differ only slightly from those for simple dimerization (17). The larger values of apparent rate constant found at the lowest concentration of DBMH studied may signal the breakdown in the similarity of the two schemes. A few double potential step experiments were carried out with 2.00 m*M* DBMH and the disparity between experimental results and theory for a simple dimerization (19) was more readily detected. The calculated values of apparent rate constant showed little dependence on switching time just as they were almost independent of scan rate in the cyclic voltammetric experiments. However, the shape of the anodic portion of the current-time curve was incorrect, causing larger values of the apparent rate constant to be obtained from data points considerably past the switching point. Thus the actual mechanism differs from a simple following dimerization. The apparent rate constants computed from the cyclic voltammetric data should be regarded only as indications of the relative rate of the following reactions.

The succeeding chemical equilibrium plays a central role in the mechanism given in Chart I. The rapid coupling reactions are thought to involve the protonated neutral radical, $DBMH_2^{\cdot}$. Any alteration in experimental conditions which would cause less $DBMH_2^{\cdot}$ to be formed, should cause a concomitant decrease in the rate of the following reactions. One way of effecting such a decrease would be to increase the concentration of the enolate **3** (DBM^-). This should cause the equilibrium to be shifted to the left resulting in less $DBMH_2^{\cdot}$ being formed and a smaller over-all rate of the coupling reactions.

Data for the reduction of 2.00 m*M* DBMH in the presence of various amounts of the tetra-*n*-butylammonium enolate salt of DBMH are summarized in Table II. It is clear that the addition of enolate **3** has a pronounced effect on the rate of the following reactions. Substantial increases in the values of i_a/i_c were observed with an enolate concentration of 1.99 m*M* and again when the concentration was increased to 7.96 m*M*. The effect appears to be leveling off, however, as evidenced by the relatively modest increases in i_a/i_c found when the enolate concentration was increased to 15.0 m*M*. Apparent dimerization rate constants calculated from the data of Table II are roughly 1000 M^{-1} sec^{-1} at 1.99 m*M* enolate and 500 M^{-1} sec^{-1} at 7.96 and 15.0 m*M* enolate. Additional data for 7.96 m*M* enolate are plotted in Fig. 3 along with a theoretical curve for $k = 550$ M^{-1} sec^{-1}. Enolate ion causes a substantial decrease in the rate of the following reactions in consonance with the scheme in Chart I.

The addition of large amounts of enolate has at least one additional effect. The cathodic peak current functions are larger than the *ca.* 1.3 x 10^{-2} A $sec^{1/2}$ $V^{-1/2}$ M^{-1} value (*cf.* Table I) characteristic of DBMH reduction with negligible following reactions. For example, at 0.100 V/sec with 2.00 m*M* DBMH plus 15.0 m*M* enolate the cathodic peak current function was 1.68 x 10^{-2}. This does not signify a change in the over-all reaction scheme because the coulometric *n*-value for electrolysis of 2.0 m*M* DBMH in 15 m*M* enolate was still 0.55. The cause of the increased current functions in the presence of enolate remains to be discovered.

Table II. Effect of enolate on the cyclic voltammetry of dibenzoylmethane[a]

Scan rate, V/sec	i_a/i_c 2.00 m*M* DBMH	2.00 m*M* DBMH + 1.99 m*M* DBM⁻	2.00 m*M* DBMH + 7.96 m*M* DBM⁻	2.00 m*M* DBMH + 15.0 m*M* DBM⁻
0.050	0.478	0.562	0.661	0.695
0.100	0.542	0.632	0.731	0.755
0.200	0.620	0.722	0.826	0.854
0.500	0.757	0.842	0.942	0.954
1.00	0.832	0.904	0.974	0.995
5.00	0.927	0.954	1.00	1.00

[a] Experimental conditions are the same as those given in Table I.

Further evidence that the DBMH radicals are more stable when enolate is present may be found in the fact that an electron spin resonance spectrum may be obtained during electrolysis of DBMH in 0.1*M* tetra-*n*-butylammonium enolate as supporting electrolyte. Unequivocal identification of this radical as the radical anion of DBMH has not been accomplished. A similar spectrum was obtained by reduction of DBMH in tetrahydrofuran at −60°C.

The addition of water has little effect on the cyclic voltammetry of DBMH. When a 2.00 m*M* DBMH solution in DMSO was made 300 m*M* in water, the i_a/i_c ratio decreased only 2% and the cathodic peak current decreased 3% (scan rate: 0.1 V/sec). The acidity of DBMH is about the same as that of phenol (20). DBMH is apparently much more effective than water in donating a proton to $DBMH^{\cdot-}$ in the scheme in Chart I causing water to be relatively ineffective in increasing the rates of the following reactions.

The electrochemical behavior of DBMH is quite similar when 0.1*M* lithium perchlorate is used as supporting electrolyte in place of tetra-*n*-butylammonium perchlorate. The over-all process is still given by Reaction [1]. The pinacol **2** and the enolate **3** were detected in an electrolysis solution. The average *n*-value from controlled potential coulometry was 0.51. Just as was observed in the absence of lithium ion, the pinacol **2** decomposed by an electrolytic autocatalytic process (2) giving benzil[2] and acetophenone. The latter was determined in the electrolysis mixture by a polarographic standard addition technique and was found to be produced in 95% over-all yield from DBMH. The benzil was detected as its radical anion by esr spectroscopy. The somewhat distorted, broad-lined spectrum which was obtained was identical to that obtained during electrolysis of authentic benzil in 0.1*M* lithium perchlorate in DMSO. An exact assignment of splitting constants was not possible. Nevertheless, it was clear that some interaction between the benzil radical anion and a lithium ion (^7Li; $I = 3/2$) was occurring.

Thus the over-all reaction of DBMH reduction in lithium perchlorate is the same as it is in tetra-*n*-butylammonium perchlorate (2). The major difference is that the rates of the following reactions are much greater in the presence of lithium ion. Qualitative evidence for this may be found in the observation that the solution remains colorless during the reduction of DBMH in 0.1*M* lithium perchlorate in DMSO. When the tetraalkylammonium salt is used (2), the solution develops a light green color during the electrolysis presumably because of a higher steady-state concentration of the DBMH radicals.

Even very small amounts of lithium perchlorate have a profound effect on the cyclic voltammetry of DBMH. For example, the addition of 2.0 m*M* lithium perchlorate to 2.00 m*M* DBMH in 0.2*M* tetra-*n*-butylammonium perchlorate completely obliterated the anodic wave for the radical anion at sweep rates less than 0.5 V/sec. The value of i_a/i_c was only 0.534 at 1.00 V/sec and 0.815 at 5.00 V/sec (*cf.* Table I). These i_a/i_c values signify an approximately ten-fold increase in the apparent dimerization rate constant. The increased rates of the following reactions also affect the cathodic peak current function. At slow scan rates the current function is about 0.8 x 10^{-2} A $sec^{1/2}$ $V^{-1/2}$ M^{-1}. These low values (*cf.* Table I) are caused by the fact that the reactions following charge transfer consume DBMH. As the scan rate is increased and the i_a/i_c values approach 1.00, the current function increases toward the limiting value of 1.3 x 10^{-2} characteristic (*cf.* Table I) of insignificant following reactions.

[2] It has been reported that benzil exhibits only a single, two-electron wave in 0.1*M* lithium perchlorate in DMF, whereas there are two separate one-electron waves when tetra-*n*-butylammonium iodide or tetraethylammonium perchlorate is used as supporting electrolyte (21). By contrast, we find two closely spaced one-electron waves for benzil in 0.1*M* lithium perchlorate in DMSO. The half-wave potentials are −1.03 and −1.13V *vs.* SCE.

The effect of lithium ion may be explained in two ways. First the lithium ions may interact with the enolate **3** forming a stable 1:1 complex. The equilibrium in Chart I would be shifted to the right causing relatively more neutral radicals ($DBMH_2^{\cdot}$) to be formed and bringing a commensurate increase in the over-all dimerization rate. This explanation is reasonable in view of the relatively stable lithium-acetylacetonate complex formed in acetonitrile (4).

Second, lithium ions may interact with DBMH radical anions forming ion pairs which may exhibit an enhanced rate of dimerization since electrostatic repulsion has been reduced. The relative importance of these two effects cannot be determined from the present data and available theory.

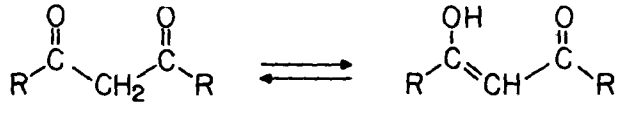
Other symmetrical, enolized 1,3-diketones behave in a manner similar to DBMH. Cyclic voltammograms of 2.00 m*M* 1,3-bis(p-methoxyphenyl)-1,3-propanedione showed i_a/i_c values of 0.592 and 0.676 at 0.100 and 0.200 V/sec, respectively. These correspond to an apparent dimerization rate constant about 60% of that observed for DBMH. On the other hand, 2.00 m*M* 1,3-bis(p-fluorophenyl)-1,3-propanedione gave i_a/i_c values of 0.478 and 0.534 at 0.100 and 0.200 V/sec, respectively. These indicate an apparent rate constant about twice that observed for DBMH.

These relatively small substituent effects do not appear to be related to the ability of electron-withdrawing substituents to lower the unpaired spin density at the coupling site and consequently decrease the rate constant. The effect is actually the opposite. Electron-withdrawing substituents cause increased apparent rate constants.

The effect may be interpreted in terms of a substituent effect on the equilibrium constant of the equilibrium step in Chart I. This equilibrium constant is equal to the ratio K'/K'' where K' is the acidic dissociation constant for DBMH ($DBMH \rightleftarrows DBM^- + H^+$), and K'' is the acidic dissociation constant for $DBMH_2^{\cdot}$ ($DBMH_2^{\cdot} \rightleftarrows DBMH^{\cdot} + H^+$). The electronic properties of the substituents suggest that K' and K'' should be greatest for the difluoro DBMH, less for DBMH, and least for the dimethoxy DBMH. If K' is more susceptible to substituent effects than K'', the equilibrium constants for the difluoro and dimethoxy compounds would be largest and smallest, respectively, in agreement with the observations. Very little is known about substituent effects on radical anion basicity so the above argument can be offered only as a suggestion.

Role of Keto-enol Tautomerism

We may now compare the electrochemical behavior of symmetrical, enolized 1,3-diketones as discussed above with the behavior of symmetrical 1,3-diketones which exist in the diketo form (3). Any of these compounds may exist as the diketo tautomer, **4**, the enol tautomer, **5**, or a mixture of the two.



4 **5**

All of the compounds discussed in the first section are almost completely enolized. By substitution of alkyl groups at the 2-position, compounds may be prepared which cannot exist in the enol form. An example is 2,2-dimethyl-1,3-diphenyl-1,3-propanedione, **6**. Other compounds which conceivably could enolize, show a distinct preference for the diketo form. An example of this class is 2-*t*-butyl-1,3-diphenyl-1,3-propanedione, **7**, which exists almost completely in the diketo form. We have not yet found a compound whose diketo and enol tautomers can be isolated and studied separately.

The diketo compounds differ from the enolized compounds with respect to at least three properties: coulometric n-values, stability of the radical anions, and nature of the reactions of the radical anions.

The n-values obtained by controlled potential coulometry differ markedly for the two kinds of compounds. As was discussed earlier (2) the n-values for reduction of the enolized compounds are all about 0.5 and the over-all reaction is given by [1]. The diketo compounds do not possess the relatively acidic enol proton and the rapid protonation by starting material which is a part of Reaction [1] is no longer possible. Consequently the n-values for the diketo compounds are about one, or specifically, $n = 0.99$ for **6** and $n = 1.1$ for **7**.

The relative stability of the primary product of the electrode reaction, the radical anion, also depends on tautomerism. The radical anions of all the enolized compounds undergo the protonation-dimerization reactions discussed earlier and thus their life-times are relatively short. The radical anions of the diketo compounds have longer lives. For example, the electron spin resonance spectrum of the radical anion of **6** is readily obtained by electrolysis in a cell in the microwave cavity of the spectrometer (3). Under similar conditions the enolized compounds do not give spectra of the primary radical anion, but rather spectra of species formed by subsequent chemical and electrochemical reactions (2). Cyclic voltammetric studies of **6** also indicate an enhanced life-time of the radical anion. The cathodic peak current function was 0.013 $A \cdot sec^{1/2} \cdot V^{-1/2} \cdot M^{-1}$, the same as that obtained for DBMH at fast scan rates (Table I).

The radical anions of diketo compounds are subject to decomposition but the nature of the reactions differs from those of the radical anions of the enolized compounds. The most important reactions are cleavage reactions (3). For example, after the electrolysis of **6** ($n = 0.99$), no polarographic waves for the radical anion can be detected. Instead a wave for a cleavage product, isobutyrophenone, is present and its diffusion current indicates that it has been produced in 80-90% yield. Further evidence of the formation of isobutyrophenone is found in the acquisition of the electron spin resonance spectrum of isobutyrophenone radical anion on further electrolysis of the solution. A cleavage product, 3,3-dimethyl-1-phenyl-1-butanone, is also found after the electrolysis of **7**. No evidence has been found indicating cleavage reactions during the electrolysis of enolized 1,3-diketones. Such reactions may become important under conditions in which the second-order dimerization reactions are slow, *viz.*, low concentrations (*cf.* Table I) and in the presence of added enolate **3** (*cf.* Table II). Another possible reaction of the radical anions of enolized 1,3-diketones is a decomposition to hydrogen gas and enolate ion.[3] Under the conditions utilized in this study, however, Reaction [1] is the major over-all reaction for symmetrical, enolized 1,3-diketones.

One unsymmetrical, enolized compound, 1-phenyl-1,3-butanedione, was studied. Its behavior is more complex. The coulometric n-value for electrolysis on its first wave is 0.75. Some formation of a pinacol is indicated by the characteristic current-time maximum obtained during electrolytic autocatalytic decomposition of pinacols and by the acquisition of an electron spin resonance spectrum for the radical anion of 1-phenyl-1,2-propanedione (2). Yet the high n-value and the formation of acetophenone (2) may indicate that cleavage reactions are also occurring. Further study of unsymmetrical, enolized 1,3-diketones is in progress.

Use of the Potential-Step Method to Measure Surface Oxides

D. E. Icenhower,* H. B. Urbach,* and J. H. Harrison

Naval Ship Research and Development Laboratory, Annapolis, Maryland 21402

ABSTRACT

A new potential-step method was used to determine oxygen coverage on platinum, gold, and rhodium. The procedure was based, in part, on the use of an electronic coulometer. Experimental evaluation of the coverage and its theoretical interpretation was obtained by the use of the potential-step method in conjunction with the potential-sweep method. The advantage of the step method over the potential-sweep method for evaluating the degree of coverage is that the step method gives invariant results regardless of whether the technique is anodic or cathodic. The pH was found to have profound effects on the oxygen coverage. In general, changing the pH alters the degree of coverage by oxygen-containing species probably including carbon dioxide. Changes produced by pH alteration in the potential-sweep patterns of noble metals may be ascribed in part to the adsorption of carbonaceous impurities and to the pH-activated amphoteric character of the surface oxides. The oxygen coverage on platinum, a linear function of potential above 0.8V, may be explained in terms of platinum oxide dipoles.

The literature indicates general disagreement with regard to experimental techniques and results obtained by anodic and cathodic methods (1-4). To resolve questions relative to the merits of these techniques it was decided to measure the oxide coverage by the potential-sweep method and the potential-step method (5-9). The potential-step method employed in this study utilized electronic integration of the current in a way which permitted precision measurements of the oxide coverage and which exhibited no hysteresis in the results regardless of the direction of the potential sweep.

Experimental

Electrochemical cell.—A cell consisting of three compartments separated by sintered glass disks was used for all experiments. Prepurified nitrogen was bubbled through the main compartment and the counterelectrode compartment in order to flush out dissolved oxygen and hydrogen. Giner's (9) dynamic hydrogen reference electrode was used to measure the potential of the working electrode relative to the reversible hydrogen electrode (RHE) in the same solution, and platinum wire was used as the counterelectrode. The individual working electrodes were 5 cm long, 10-mil wires of platinum and gold. They were sealed in soft glass tubing and had small glass balls on the ends to eliminate edge effects.

All solutions were prepared from reagent-grade chemicals and triple-distilled water. Acid and caustic solutions were prepared from sulfuric acid and potassium hydroxide, respectively. Potassium sulfate was added to solutions with pH values of 2.4 and 12.7 to establish approximately constant ionic strength for all electrolytes, which were pre-electrolyzed overnight in a separate vessel prior to use. The pH was

* Electrochemical Society Active Member.

Key words: potential step coulometry, oxide coverage, electronic current integration, platinum oxides, gold oxides.

measured after pre-electrolysis. Measurements were carried out at an average of 27°C.

Electronic equipment.—In the sweep method of studying oxygen adsorption, a Hewlett-Packard Model 3300A, low-frequency function generator produced the triangular potential-time sequences. The function generator programmed a Wenking 61TR potentiostat, which controlled the potential of the working electrode with respect to the reference electrode. The apparatus is shown in block form in Fig. 1. The d-c potential level, the potential span, and rate of change of potential were adjusted easily. The instantaneous potential produced by the passage of the cell current through the calibrated 1000-ohm resistor, was recorded directly on the X-Y recorder as current-potential plots. By insertion of the integrator as shown by the dashed lines, charge-potential rather than current-potential plots were obtained. The integrator consisted of a Philbrick P2 (high common-mode rejection ratio) differential operational amplifier with a 10K input resistor and a 5 mfd output capacitor, which was short-circuited, when desired, by a switch to reset the integrator to zero charge.

Procedure.—Initially the potential was fixed at 1.8V so that oxygen was liberated on the electrode to burn off oxidizable impurities (11). Then the electrode was maintained below the visible oxygen-evolution potential at 1.4V to permit molecular oxygen to diffuse away from the surface. In the third step, the potential was lowered to some empirical value at which the metal oxide was reduced to provide a clean, metal surface. Next, the potential of interest was established. The potential in the last step was the same as that of the third step. The value of the potential employed in the third step was determined from a study of the sweep data on the given electrode at each pH in order to insure that the surface of the metal was indeed free of oxides. The electrode potential in the third step was 0.45V on platinum and 0.5V on gold.

The experimental evaluation of the oxide coverage was performed as follows. Current-time curves associated with the fast potential step similar to that in Fig. 2 were observed by means of an oscilloscope. When the potential was stepped, the current first rose rapidly to some relatively high value and then fell asymptotically to some nonvanishing residual value. This residual current is largely unrelated to the formation of a new state of charge of the surface occasioned by the step in potential, but it arises from the diffusion of oxidizable and reducible impurities to the interface. In order to integrate these current-time plots manually, and thus obtain the total quantity of electricity associated with the desired reaction, some approximation must be made to account for the presence of the diffusion current. Typical plots of the integrated current are shown in Fig. 3. The abrupt rise and fall of the coverage in millicoulombs at 2.5 and 22 sec is due to potential steps. The tangent to the linear sections of the rising curves (between 2.5 and 22 sec) was extrapolated to zero time. This extrapolation to the time of the step (2.5 sec) yielded the coverage in millicoulombs.

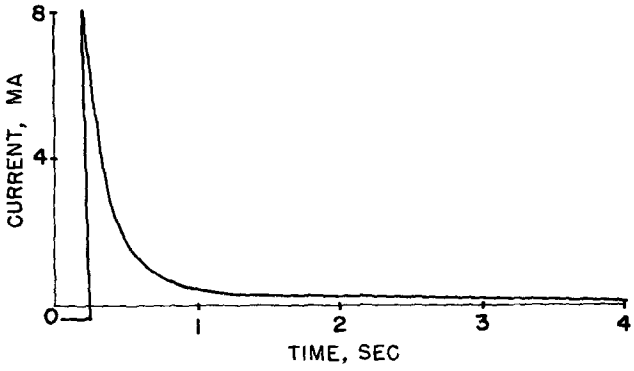

Fig. 2. Typical current-time plot obtained in the potential-step method.

Results

Platinum.—Potential-sweep measurements were employed to eliminate uncertainties with regard to the critical potential region where the oxide layer is reduced without simultaneous formation of a hydrogen layer. Therefore sweep data were obtained to facilitate each study involving the potential steps. Sweep data were obtained for the metals at 0.01 and 0.1 Hz at sweep speeds corresponding to 320 and 32 mV/sec. Some results for these sweep studies at pH values of 0.3, 2.4, 12.7, and 14 are illustrated in Fig. 4.

The sweep curves shown in Fig. 4 represent results previously detailed by Breiter and others (1, 2, 12, 13). The referenced papers furnish adequate discussion. However it is useful to recall that the oxide reduction peak b is flattened in alkaline solutions. It is clear from the above sweep data that a successful potential-step method will require that the cathodic end of the step terminate in the neighborhood of 0.45V at least in acid solution. However in alkaline solution the fusion of the oxide reduction wave with the hydrogen-atom-formation wave would suggest that some error might result due to incomplete reduction. However, use of the 0.45V value in alkaline solution yielded reproducible data independent of step direction indicating

that oxide reduction is complete at 0.45V provided sufficient time is allowed.

The triangular potential-sweep traces were integrated by the electronic procedure described above. Figure 5 represents the integral form of the sweep curves for two speeds. The dashed curve represents data for 0.01 Hz and the solid curve is for 0.1 Hz. The thickness of the double-layer region is greater in the slow sweep because the integral of the constant diffusion current over a longer period of time results in a larger number of coulombs. The charge representative of oxygen adsorption is apparently independent of the sweep time according to the figure, *i.e.*, $Q(0.1) = Q(0.01)$. However, it must be noted that the comparisons are made over different potential limits. The relatively straight line in the oxygen zone (a) represents the oxygen coverage obtained by the potential-step method (to be discussed). The form of these curves is similar to results obtained by Will and Knorr (2) using manual integration of the sweep curves. However, the negative character of the charge in the hydrogen region is explicitly indicated by the present technique. The electronic integration used here measures the double-layer charge (zone b) in addition to charge associated with oxygen coverage. The degree of reversibility in the hydrogen region of the curves is indicated by the fact that the quantities of electricity obtained during the anodic and cathodic sweep (Q_a and Q_c, respectively) differ only by the charge due to diffusion current at the end of the sweep. Careful manipulation of the potential limits is necessary to obtain isocoulombic (closed) curves which in essence bring about the balance of charge due to positive and negative diffusion currents. If the potential span is too far to the right, then $Q_a > Q_c$ due to oxygen evolution and/or oxidation currents of diffusing impurities and the curves shift continuously upward. Similarly, if the potential span lies in the regions too far to the left of the double layer, there is a shift downward due to reduction currents such as those arising from hydrogen evolution. Figure 6 illustrates the latter case for gold electrodes.

The results of the potential-step method on platinum are shown in Fig. 7. A comparison of the results with the sweep method of Will and Knorr has been indicated in Fig. 5. The step data are in better agreement with the anodic rather than the cathodic sweep data. The charge-potential curve representing oxygen coverage is rather linear at all pH values. Effects of pH are noticeable at potentials in the "double-layer" region below 0.8V, where the bend of the charge-potential curve is indicative of substantially more coverage in alkaline solutions than in acid solutions, as was observed in the sweep data.

Gold.—The results on gold (Fig. 8) show several differences from results in platinum. Hydrogen does not electrosorb on gold in the regions of interest in this study (13, 14). Oxygen does not adsorb on the electrode surface below a potential of approximately 1.35V in the acid solution (13, 14).

The reduction of the gold oxide in acid solution is associated with the appearance of a narrow peak near 1.15-1.20V, but in alkaline solution two shallow peaks are observed. The flattened peak at 1.10-1.15V in alkaline solution may correspond with the narrow peak (1.15-1.20V) in acid solution. Anomalous peaks

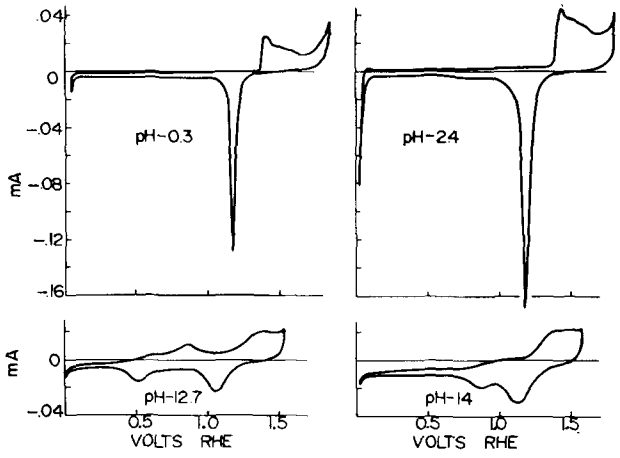

Fig. 8. Potential sweeps on gold

at other values probably represent the oxidation and reduction of organic adsorbates (see Discussion).

The results of the electronic integration of the triangular-potential sweep curves at 0.01 Hz are illustrated in Fig. 6 for gold at a *p*H of 2.4. Gold forms an oxide layer on its surface above the extended double-layer region at about 1.4V. There is a definite fall-off in the rate of oxygen adsorption at about 1.55V corresponding to the fall-off from the first peak in the current-potential plot of Fig. 8 (acid *p*H values). A similar fall-off in the rate of oxygen adsorption has been observed by Brummer and Makrides (14) at 1.45V using a galvanostatic stripping technique. The step method (acid *p*H) indicates a change of slope (Fig. 9) at about 1.55V. The region representative of the reduction and oxidation of hydrogen on platinum is absent in the case of gold (13, 14).

Sweep data on gold (Fig. 8) indicate that at a *p*H of 12.7 there is a broad plateau in the current *vs.* potential curve which may be associated with the adsorption of organic species on the surface of the gold, similar to that of platinum (see Fig. 7). In addition, at alkaline *p*H values the quantity of charge associated with the formation of organic sorbates on the gold appears to be greater at low potentials.

Rhodium.—The potential-sweep data for rhodium (Fig. 10) show a reduction peak at 1.3V in alkaline media. The charge which corresponds to this reduction peak is approximately the same as that for the oxidation peak (see curve for *p*H of 14). The relative magnitude of the oxygen and hydrogen waves in alkaline solution far exceeds the 2 to 1 ratio expected for monolayer coverage in alkaline solution. The

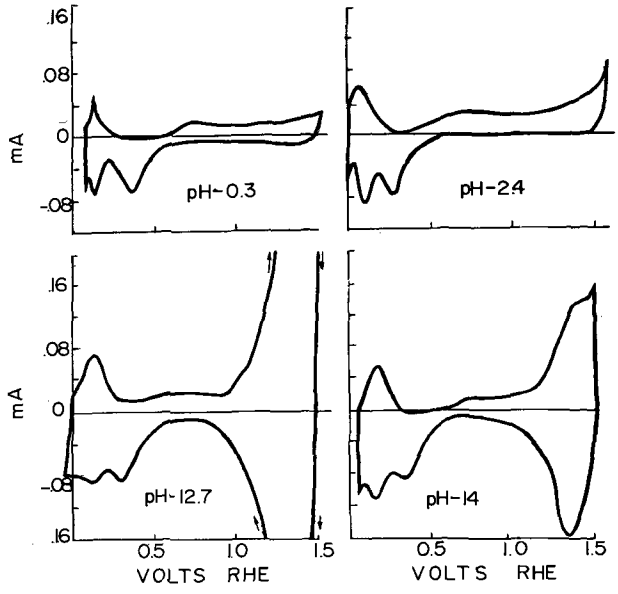

Fig. 10. Potential sweeps on rhodium

normal metal reduction waves between 0.25 and 0.35V appear unchanged in character at all *p*H values.

The hydrogen formation peaks in some cases nearly fuse with the oxide-reduction wave at 0.3V as noted by Bold and Breiter (1). In the *p*H systems corresponding to 2.4 and 12.7 the double-layer region loses the well-defined character shown in the *p*H system at 0.3. Curves obtained at high *p*H for fast sweeps (not illustrated) show less oxidation current relative to hydrogen than do the curves for the slow sweep.

The results of the potential-step experiments on rhodium are illustrated in Fig. 11. The presence of the large, new reduction waves in alkaline media noted in the potential-sweep experiments is confirmed by the very large wave that appears at approximately 1.2V.

Discussion

The experimental results reported here suggest a need for further clarification. An analysis of some areas is presented here, including the theory of the potential-step technique, the nature of the *p*H effects, and the linearity of the charge-potential curves on platinum.

Theory of the potential-step method.—Previous researchers who measured the area under the current-time curves such as that in Fig. 2 have simply terminated the zone of integration arbitrarily in the region where the curve appeared to be leveling. In addition, manual extrapolation to zero time was not

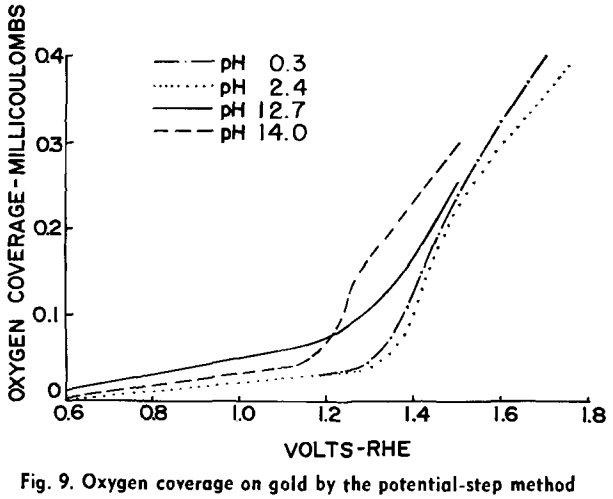

Fig. 9. Oxygen coverage on gold by the potential-step method

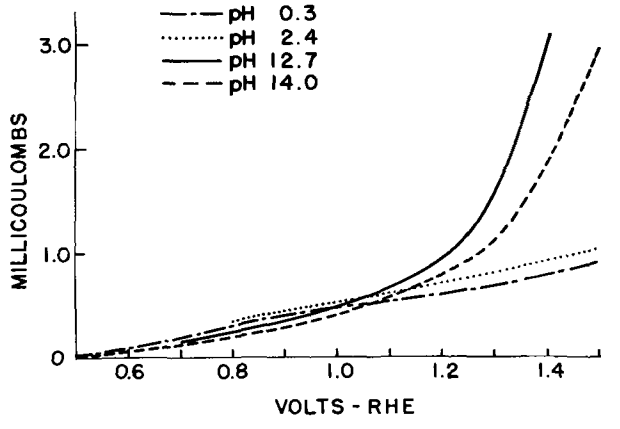

Fig. 11. Oxygen coverage on rhodium by the potential-step method.

performed. This procedure is neither rigorous nor satisfactory. In the typical integrated current-time curves in Fig. 3, the degree of linearity of the plots increases with the length of time from the potential step. Therefore the precision of the extrapolation from the "linear" section increased with time. (In this discussion it is assumed that diffusion currents remain uniform.) If the extrapolation process is repeated for sections of the coulomb-time curve which are doubled in length ad infinitum, the deviations between successive extrapolated values appears to decrease geometrically rather than arithmetically so that the coulomb value converges on some meaningful limit. Therefore this limit is a function of surface area and independent of time in contrast with methods where integration involves measurement of area with arbitrary limits. The quantity of charge, Q, obtained by extrapolating the straight-line portion of the curve back to zero time was found to be independent of the direction of the step. This fact supports the above conclusion that the charge, Q, is also independent of time. At low levels of charging, the scatter between values of Q for the forward and reverse step was as much as 10%. For large levels of charging (large potential steps) values of Q were within 2%.

It is clear from these results that hysteresis between surface charge measurements for anodic and cathodic methods observed elsewhere (3) are not supported here.

The fact that a numerical value close to unity independent of potential and pH is indeed attained must be attributed to the unique ability of the potential-step method to remove from the data extraneous contributions of charge due to residual diffusion currents. If the contributions of the residual currents shown by the dashed extrapolated line in Fig. 3 are subtracted from the experimentally observed charge-time curves, one obtains the corrected curve (short dashes), which rapidly approaches a horizontal asymptote. It is possible to obtain the general behavior of this corrected charge-time curve from the following form of the charge-transfer limited, current-potential relation for the case when the transfer coefficient[15] is 0.5. That is

$$i = 2i_o \sinh\left(\frac{n\mathbf{F}}{2RT}\eta\right) \qquad [1]$$

where i is current density, i_o is exchange current density, n is the number of electrons for the rate-controlling reaction, $\mathbf{F}$ is Faraday's constant, R is the gas constant, T is the absolute temperature, and η is the polarizing potential. The polarization, η, is assumed to be $E_f - E(Q)$, where E_f is the final potential at the end of the potential step and $E(Q)$ is the potential corresponding to the charge, Q, on the surface. Now $E(Q)$ is given by $E_o + Q/C$ where E_o is the starting potential, and where C is the slope of the experimental charge-potential plot of the electrode which is assumed to be constant because of the linearity of the charge-potential curves above 0.8V in Fig. 7. Replacing η by its definition, we obtain

$$\frac{dQ}{dt} = 2i_o \sinh\left(\frac{n\mathbf{F}}{2RT}\right)\left(E_f - E_o - \frac{Q}{C}\right) \qquad [2]$$

An expression involving the quantity of charge on the surface in the argument of an exponential function was derived by Feldberg, Enke, and Bricker (3) in a similar manner. However, they ignored the back reaction which is contained in the hyperbolic sine function. Equation [2] was written only for a step over a linear charge-potential region which in this case requires that E_o be approximately 0.8V. Thus, the equation is applicable only to the anodic sweep on platinum. Integration of Eq. [2] yields

$$-\log\frac{\tanh\frac{n\mathbf{F}}{4RT}\left(E_f - E_o - \frac{Q}{C}\right)}{\tanh\frac{n\mathbf{F}}{4RT}(E_f - E_o)} = \frac{n\mathbf{F}i_o t}{CRT} \qquad [3]$$

Equation [3] behaves like the dashed curve of Fig. 3 which was obtained by subtracting the area due to the diffusion current (the triangle formed by the extrapolation of the coulomb-time curve to zero). Equation [3] has the desirable property that at infinite time the charge, Q, is finite, whereas the mathematical results of previous workers (3) predict an infinite charge. Their charge-time curves showed a logarithmic dependence on the time. A tendency to approach infinite charge has in fact been experimentally observed by Laitinen and Enke (16) at 1.35V and above.

However at 1.25V and below, their results indicate that the charge remains fixed after a finite period (60 sec) of time. Their data and the results reported herein suggest that the coverage (charge divided by true area) is a function of potential rather than time below 1.25V. Two factors associated with the logarithmic increase of charge with time are probably the increase of surface roughness with time and formation of multilayers. Above 1.35V, the charge and coverage increase with time and the coverage approaches infinity, *i.e.*, the pure metal is consumed.

One other aspect of the charge-time curves of Fig. 3 is worthy of attention. The rounding of the curves after the initial jump is indicative of a slow reaction probably associated with the final crystallization steps in oxide formation which is discussed in more detail below. It is clear from the rapid rise of the curves that the majority of the charge transfer takes place within a fraction of a second.

Effects of pH.—Bold and Breiter (1, 12) observed a shift of the triangular potential sweep curves of −0.059 V/pH unit in acid regimes. In addition they noted changes in the structure of the sweep curves when the pH was altered from acid to alkaline character which are similar to those recorded at c in Fig. 4. Gilman (4) and others have suggested that the appearance of such changes in structure arise from the adsorption of carbon dioxide which is generally present in alkaline hydroxides. Radiometric data obtained in this laboratory (17) show that concentrations of less than 10^{-4} molar carbonate yield coverages of the order of 0.05 which can easily account for observed currents. The adsorption of carbon dioxide tends to suppress the magnitude of the current peaks arising from hydrogen adsorption and oxidation (see region a of Fig. 4) below 0.4V.

In the formation of adsorbed metal oxide, hydroxide surface species represent intermediate forms between states representative of water adsorption and those representative of oxygen adsorption.

The formation of oxides on the surface may be analogous to the formation of the bulk oxides of amphoteric metals. In the bulk systems elevation of the pH normally brings about precipitation of the hydroxide. As the pH continues to increase, the metal hydroxides may lose the elements of water. Also, additional hydroxide may be adsorbed with dissolution of hydroxide precipitates. Both insoluble and soluble species may continue to lose elements of water forming oxides (amphoteric acids).

In some cases, the hydroxide is so unstable that on precipitation, it immediately decomposes to the oxide. For each metal the hydroxide will exhibit a pH of maximum stability which for many transition metals will be quite acid. These hydroxides will maintain gelatinous structures or solid structures containing large quantities of water of hydration. These relatively soft structures form quite stable or inert

"hard oxides" through loss of water which may occur not only by dessication but by change of pH. These hard oxides (*e.g.*, silica, alumina, taconite) display a relatively low chemical reactivity compared with the soft oxides since their structures permit considerable resonance stabilization.

Advanced inorganic texts such as Cotton and Wilkinson (18) do not mention the existence of a divalent platinum of the form Pt(II)O. They point out that the divalent hydrous oxide $Pt(II)(OH)_2$ exists, but it is unstable with respect to Pt and PtO_2. It cannot be expected that the divalent surface oxides exhibit different behavior. In the formation of species such as PtO_2 considerable geometric inversion of oxide sites should be anticipated. These inverted species should therefore be part of the basic structure of the hard oxide. These species should account for the great hysteresis between the oxidation and reduction waves of platinum oxide shown in Fig. 4 and 5.

Bold and Breiter have noticed a flattening of the oxide-reduction peak occurring at about 0.8V (see peaks at b in Fig. 4) in experimental triangular sweep curves at high pH values. In fact, they noticed this change at a pH value even as low as 3. A plausible explanation for this behavior may be found in the fact that the cathodic formation of platinum hydroxide is acid catalyzed (see similar discussion under gold below). The thermodynamics of the reduction do not appear to have changed, since the relative position of the peaks shifts 0.059 mV per unit pH. Only the kinetics are affected.

Linearity of the charge-potential curves on platinum.—A significant feature of the charge-potential curves on platinum (Fig. 7) is their linearity above 0.8V. It is possible to explain this linearity by assuming that multilayer formation of the oxide occurs only after a complete monolayer is formed. It is convenient to discuss the charged oxide surface in terms of dipoles (19). The charging process is visualized to begin with a platinum surface on which is adsorbed a layer of water in roughly equal amounts of the "up" and "down" configuration. This surface state is assumed to have little or no charge due to cancellation of dipole fields. Finally the platinum surface is covered by a monatomic layer of platinum hydroxide and oxide. The positive image of the negative oxide species in the platinum represents the positive end of dipoles making up the double layer. We note that the surface potential (20) is given by the expression

$$\chi = 4\pi n\mu/\epsilon \qquad [7]$$

where n is the number of dipoles (represented by the oxide atom and its positive image) per square centimeter, μ is the effective dipole moment of the individual dipoles, and ϵ is the dielectric constant. Now μ is $2rq$ where q is the charge transfer between the metal and the oxide and r is the radius of the oxide species. Substituting μ into Eq. [7] there is obtained

$$\chi = 8\pi rnq/\epsilon = 8\pi rQ/e \qquad [8]$$

where Q is the charge per square centimeter. But this expression represents precisely a linear behavior between charge and potential which was observed. Differentiation of the potential with respect to Q yields a capacitance per square centimeter which represents the process of placing a monolayer of oxide dipoles with moment, μ, on the surface

$$C = \frac{\epsilon}{8\pi r} \qquad [9]$$

(In cgs units this expression represents the capacity per unit area of the oxide region in cm^{-1}.) Using 1.4Å for the radius (21) based on a doubly charged oxide species, we obtained a calculated value of 134 for ϵ which may be compared to the value *ca.* 80 for water. The result suggests a more highly polarized layer in the oxide due to closer stacking of the atoms.

Effects of pH on gold.—Gold also exhibits profound pH effects. As in the case of platinum, the pH effects may be ascribed to various forms of oxide-containing species, *i.e.*, hydrous and hard oxide forms. The step-potential data (Fig. 9) are most easily explained in terms of the mechanisms described above for platinum. However, the sweep data (Fig. 8) are much more complicated. In acid solution one would expect that the abundance of hydrogen ions might lead to rapid formation of hydroxide species in the reduction wave characterized by the peak occurring at 1.20-1.25V. In alkaline solution the formation of this reduction peak is delayed by a lack of hydrogen ions or by reaction of hydroxide ions with the relatively acidic hydroxide species formed by the gold. In other words, the reduction is acid catalyzed. The oxidation is base catalyzed. These effects are illustrated by the following equations

$$e^- + AuO + H_2O \rightleftarrows AuOH + OH^- \qquad [13]$$

$$Au + OH^- \rightleftarrows AuOH + e^- \qquad [14]$$

Thus the cathodic formation of gold hydroxide is hindered by high pH, whereas the anodic formation on gold hydroxide is aided by high pH in agreement with the results.

Areas of uncertainty associated with errant peaks below 0.9V may arise from the presence of organic adsorbates. These adsorbates may be similar to the reduced carbon dioxide species observed on platinum.

Effects of pH on rhodium.—The most unusual feature of the rhodium data is that enormous quantities of charge appear in the anodic sweep at high pH values. There is some evidence of multiple-layer formation, even at a pH of 2.4. At pH values of 12.7 and 14, a new reduction wave characterized by symmetry with the anodic oxidation wave appears. The reduction peak for oxidized rhodium at *ca.* 0.3V is found at all pH's. The magnitude of the oxidation and reduction peaks at high pH's may be explained by assuming multilayer formation (and some dissolution) because the value of 2 characteristic of the monolayer oxide-hydride charge ratio is far exceeded. The different behavior of rhodium at high pH may be attributed to the amphoteric behavior of the rhodium oxides in the manner described above.

Summary

A potential-step method which makes use of an electronic coulometer has been described. The method indicates the extent of oxide coverage on noble metal surfaces without evidence of hysteresis between the data regardless of whether anodic or cathodic steps are employed. The method eliminates arbitrary procedures previously employed in the evaluation of the total surface charge.

The pH profoundly influences the degree of oxide coverage on several metals. Coverage arising from the adsorption of reduced carbon dioxide increases in the double-layer region with increasing pH at least on platinum. The broadening of the oxide reduction wave of platinum with pH is related to the acid catalyzed reduction of the amphoteric oxide.

The hysteresis observed between anodic and cathodic charge obtained by potential sweep methods on platinum may be due to the formation of inert "hard" oxides.

The linear relationship between potential and charge may arise from uniform oxide build-up on platinum. The dielectric constant of the oxide was calculated on this basis.

Acknowledgment

The authors are pleased to acknowledge the helpful discussions of the techniques and theory of the paper

with Dr. E. Gileadi and Dr. J. O'M. Bockris. In addition they give their thanks to R. J. Bowen for his assistance in times of crisis.

Galvanostatic Overpotential Transients and Electrocrystallization Processes on Copper Single Crystals in Solutions of Cupric Sulfate[1]

L. H. Jenkins* and R. B. Durham[2]

Solid State Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

ABSTRACT

Overpotential transients have been measured on copper single-crystal surfaces oriented (100), (110), (111), or (321) which were undergoing galvanostatic dissolution or deposition in acidic solutions of $CuSO_4$. In the current density range below 800 μA cm^{-2}, it is shown that observed overpotential maxima contained both electrocrystallization and charge-transfer components. Deposited material up to the equivalent of $\approx$50 atom layers affected subsequent anodic overpotential-time relationships in a manner related quantitatively to the extent of the deposit. Overvoltage-current relationships are shown to be insensitive to the densities of steps distributed more or less evenly over the various surfaces, but sensitive to orientation and to arrangements and distributions of steps.

Mattsson and Bockris (1) used galvanostatic measurements to demonstrate that, at geometric current densities $>$ 10 mA cm^{-2}, the Cu^{2+}/Cu^{+} redox reaction was rate determining for a system of polycrystalline copper electrodes in acidic copper sulfate solutions. It was suggested that at lower current densities adion diffusion over the electrode surface became kinetically critical. Bockris and Enyo (2) confirmed these observations and assumed further that the factor defining the limits of surface diffusion control was the number of dislocations intersecting electrode surfaces. Studies of the effects of electrode preparative methods on parameters sensitive to the structure of electrode surfaces in the $Cu/CuSO_4$ system were extended by Bockris and Kita (3). Confirmation that at higher current densities in this system the redox reaction indeed was the slowest process was obtained by Brown and Thirsk (4) using another experimental technique.

All these reports cited concerned systems of polycrystalline copper in acidic copper sulfate solutions and the vast majority of the data and observations reported were obtained under experimental conditions such that surface processes were not rate controlling. Damjanovic, Setty, and Bockris (5) examined growth

forms of copper deposited from such solutions on various copper single-crystal surfaces of specific orientation and measured current-potential relationships for the growing surfaces as a function of time. At deposition times corresponding, on the average, to $\sim 10^2$ and 10^5 atom layers of copper over the initial substrate, the overpotentials measured on the surfaces existing at these moments at various geometric current densities indicated the same relationships for electrode kinetics previously reported (1-4). However, small differences due to orientations and/or growth forms were observed and, again, most of the data reported were obtained under conditions such that surface processes could not be considered rate determining. Similar results were obtained by Hayashi *et al.* (6) who also observed effects which were attributed to the "free acid" content in both cupric perchlorate and cupric sulfate solutions. Recently data have been reported for single crystalline copper electrodes in acid cupric perchlorate systems under experimental conditions such that surface processes were rate determining and initial surfaces were not altered appreciably before data pertinent to establishing electrode kinetics were obtained (7). Also, it was shown that relatively thin electrodeposits did not behave exactly as the substrates supporting them. These latter data and their interpretations are in sufficient disagreement with the previously suggested models of surface processes on copper electrodes (2, 3, 5) to make desirable a similar study in copper sulfate solutions at reaction rates lower than were previously examined in detail.

Materials and Experimental Methods

The growth, manipulation, surface preparation, and final electropolishing and washing of the copper crystals used in this work were as previously reported (7-9). Solutions 0.20M in $CuSO_4$, pH adjusted to ≈ 1 by addition of H_2SO_4, were used in all these studies and their preparation, storage, transfer to reaction cells, etc., were also in the manner previously described (7, 10). The two types of reaction cells used, one for obtaining galvanostatic current-potential data and the other permitting microscopic observation and photography of reacting surfaces, were the same as those used in the $Cu/Cu(ClO_4)_2$ systems (7).

Experimental Results

Changes in surface structure.—Observations of changes in surface structures resulting from both dissolution and deposition processes on surfaces oriented (100), (110), (111), and (321) were made and photographed. While data were taken in duplicate for both anodic and cathodic processes on all orientations at 4, 40, and 400 $\mu A\ cm^{-2}$ original surface area, the structural changes observed did not differ enough from those reported for perchlorate systems to warrant extended comment. However, the following comparisons of observations between the two systems are of interest:

(a) Structures developed on the (100) in the sulfate system seemed of about equal size after passage of equivalent charge at the two higher current densities for both deposition and dissolution. This was not observed in perchlorate solutions in which relatively smaller structures with more sharply defined singularities developed on the (100) at progressively higher current densities.

(b) The detailed structure and orientations developed on (110), (111), and (321) were similar in every case in either perchlorate or sulfate systems: Reaction on the (111) occurred by the bunching of steps to form ledges, the (110) developed sharply defined typical ridge-valley arrangements, etc. However, it was noted in sulfate solutions that the relative sizes of structures developed on all orientations other than (100) decreased with increasing current density as compared with those grown under comparable circumstances in perchlorate.

Figure 1 illustrates the structures obtained on the (100) at current densities of 4 $\mu A\ cm^{-2}$. At such low reaction rates, occasional pits or pyramids would develop faster than the rest of the surface. However, as could best be determined, initial deposition or dissolution and early growth stages occurred uniformly over the surface. Note that pit edges, preferred growth direction, etc., are not nearly so well defined in the anodic as in the cathodic case. As stated earlier, structural development of characteristic features at higher current densities occurred completely uniformly over the surface. The figure also illustrates the ledges formed by step aggregation due to deposition at 400 $\mu A\ cm^{-2}$ on the (111). Large, flat areas can be seen clearly separated by relatively low ledges.

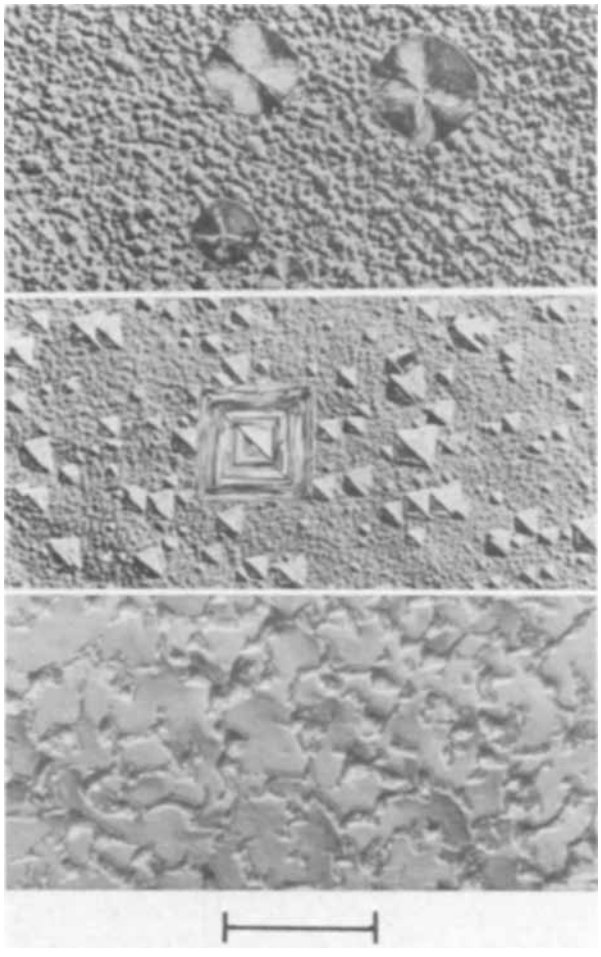

Fig. 1. Upper and middle photomicrographs illustrate structures developed on the (100) due to dissolution and deposition, respectively, at 4 $\mu A\ cm^{-2}$ to the extent of 1.7 coulombs cm^{-2}. The lower illustration is of a (111) after deposition at 400 $\mu A\ cm^{-2}$ to a total of 1.4 coulombs cm^{-2}. The reference mark is equivalent to 4μ in the upper two photographs and to 20μ in the lower.

Current-potential data.—Under galvanostatic conditions, overpotential *vs.* time curves exhibited maxima of the type reported for perchlorate solutions. Also, as in those solutions, a "deposition anomaly" was observed in that times to formation and absolute values of overpotential maxima were changed if the immediately preceding process on the electrode had been deposition. These phenomena are discussed later, but it must be understood that all overpotential relationships discussed as a function of current density are, first of all, values of the observed maxima. Secondly, following every cathodic process on surfaces on which current *vs.* potential data were being determined, an anodic pulse of equal intensity and duration was applied. This latter pulse was disregarded and equilibrium established in the system before the next electrode process of interest was initiated and data recorded.

Figure 2 illustrates the current *vs.* potential relationships obtained for surfaces of the indicated orientations. The treatment given the copper crystals before mounting in the cells was exactly that of those in the previously reported perchlorate systems. The crystals were never annealed after growth and the final pre-experimental treatment consisted of the normal electropolish in an acid copper phosphate bath, followed by standard washing procedures. For purposes of later discussion, these will be termed "standard" surfaces. Obviously it was impossible to focus on these flat, specular surfaces with the microscope in order to obtain meaningful photomicrographs.

Since one of the authors had previously argued that overvoltage *vs.* time and/or current values were changed drastically by the arrangement and distribution of steps over crystal surfaces (7), current *vs.* potential measurements were also obtained on other than standard surfaces. Figure 3 shows such data for surfaces produced by annealing standard surfaces under an H_2 atmosphere at 400°C for 4 hr. Following annealing, all surfaces appeared unchanged to the eye and, while with the optical microscope examinations of these "standard annealed" surfaces showed no observable changes on (100) and (110) orientations, small facets were detected on the (111) and (321). Facet development on the (111) is illustrated in the phase-contrast photomicrograph shown in Fig. 4. The low facet density can be seen and interference fringe shift measurements indicated the average facet to be $\approx 0.1\mu$ high.

Mechanical polishing always leaves fine scratches in the surfaces of soft metals such as copper and these scratches afford sites for possible facet development. Therefore, mechanically polished surfaces, although bright and mirrorlike to the eye, were given a standard electropolish and wash treatment in order to remove $\approx 10\mu$ from the surface in case any impurities were introduced by the mechanical polish. The crystals then were annealed in an H_2 atmosphere at 950°C

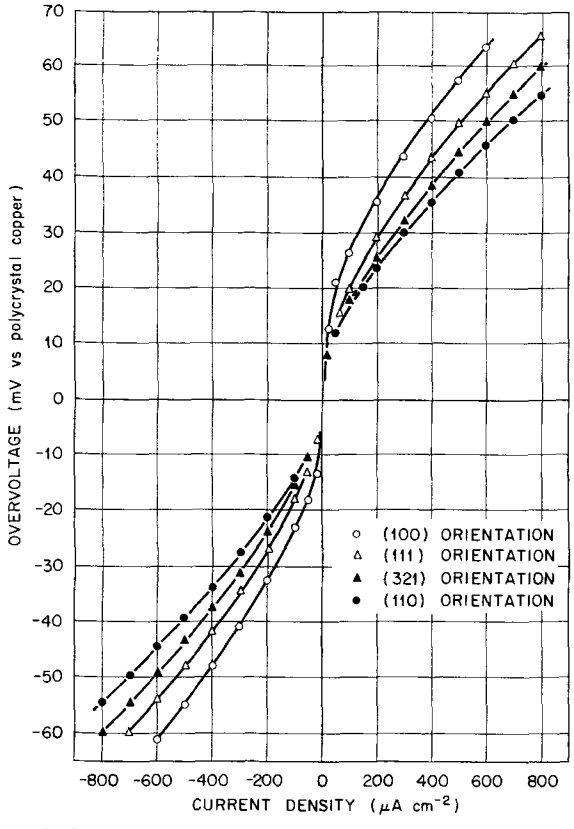

Fig. 2. Overvoltage *vs.* current relationships for "standard" copper single-crystal surfaces in 0.2M $CuSO_4$ + H_2SO_4 (pH $\approx$ 1) at 23°C.

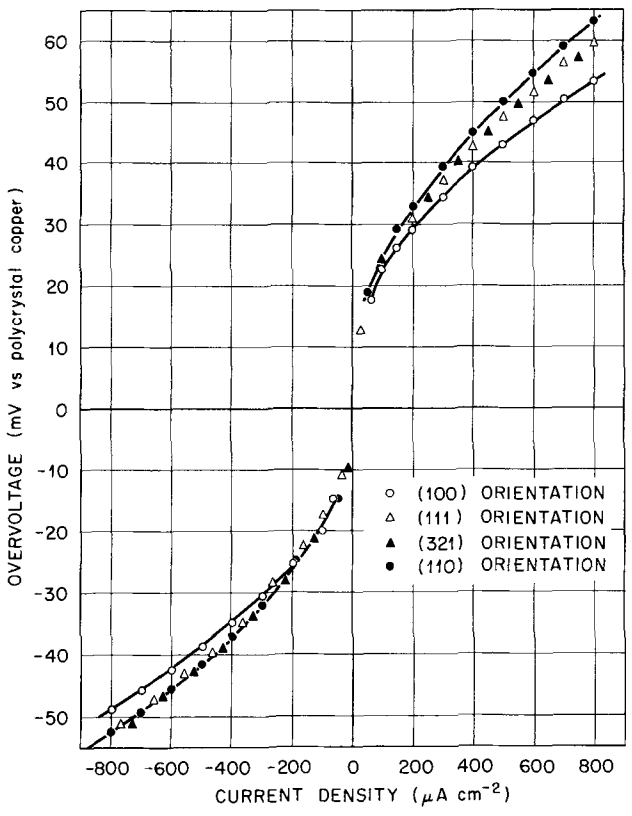

Fig. 3. Overvoltage *vs.* current relationships for "standard annealed" copper single-crystal surfaces in 0.2M $CuSO_4$ + H_2SO_4 (pH $\approx$ 1) at 23°C.

for 16 hr. Following annealing, the samples again appeared bright and flat to the eye, but microscopic examination revealed that all surfaces contained facets whose development was related to, among other things, the mechanical polish. For purposes of comparison, the (111) surface treated in this manner is also shown in Fig. 4. The effects of the mechanical polish are evident in the long, ridged facets. Average structures on all orientations were $\approx 1\mu$ high, although differing markedly, of course, in detail from the (111) illustrated. The current-potential relationships obtained on these "mechanically treated" surfaces are illustrated in Fig. 5.

Finally, in order to develop a high degree of faceting on all surfaces, standard surfaces were vacuum annealed at 950°C for 24 hr so that thermal facets could develop. Following this treatment, all surfaces appeared changed to the eye since facets had grown to such an extent. The (321) and (110) had a milky-pink appearance due to an extremely high density of very small facets estimated to extend less than 0.1μ in any direction and with no preferred orientations developed. Both the (111) and (100) were completely covered by pits which on the (111) were semihexagonally shaped. Pits on the (100) are illustrated in Fig. 4. Pits on the (111) were not quite as well formed as those on the (100) and the former also had a relatively smaller density of the larger pits observed on the latter. The largest pits observed on either surface were less than 2μ deep. The detail in all the illustrations is due to the characteristics of interference-contrast photomicrography, and the sides of the deepest pits on the (100) illustrated in Fig. 4, for example, were only 2° at most from horizontal to the original surface. Current *vs.* potential relationships obtained for these samples are indicated in Fig. 6.

Potential vs. time data.—In general, the potential-time relationships observed for standard crystal surfaces in the sulfate solutions reported here were the same as those previously observed in perchlorate solutions (7) where the same type of surface was used

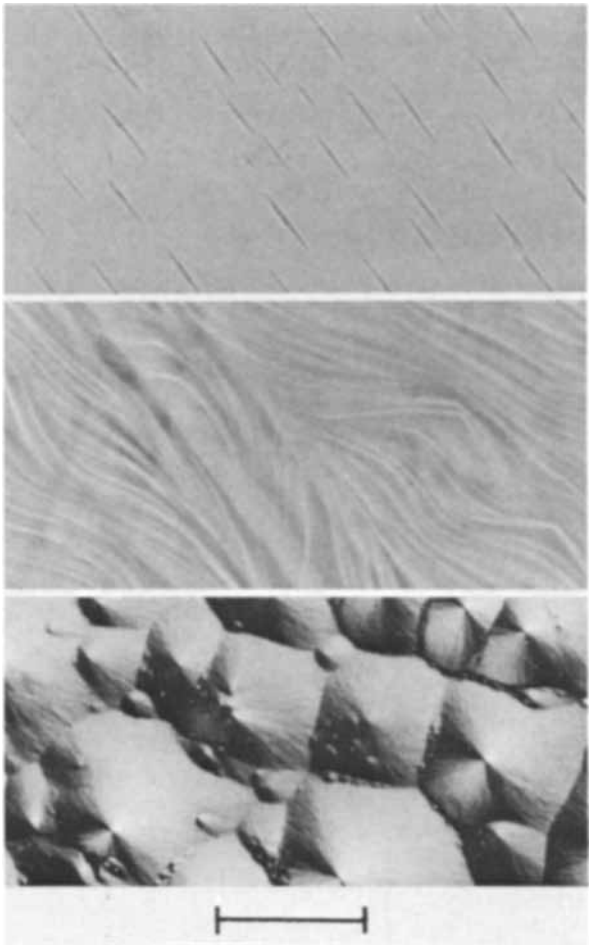

Fig. 4. Upper and middle photomicrographs are of (111) surfaces which were "standard annealed" and "mechanically treated," respectively. The lower illustrates pits on a "vacuum-annealed" (100). The reference mark is equivalent to 25, 50, and 100μ, top to bottom.

exclusively and where it was shown that maxima were established long after the time required to charge the double layer. Also, similar to the latter systems, it was observed that deposition on a standard surface produced anomalous effects on following anodic voltage-time relationships which could persist for periods up to hours unless all the deposited material was removed by an anodic pulse. Not only were times to establishment of succeeding anodic maxima delayed until the time at which the previous deposit had been removed, but also the absolute values of overvoltage maxima were decreased. Since no significant differences were noted in sulfate systems from the well-documented evidence previously reported, oscilloscope traces of voltage-time transients illustrating the phenomena are not shown. However, the effect was observed not only on all standard surfaces, but also on standard annealed and mechanically treated surfaces at current densities of 50, 150, and 450 μA cm^{-2} for deposits equivalent to an average of 50 atom layers. The largest current density or thickest deposit at which the effect could be obtained on these surfaces was not established. However, although the phenomena were observed on all vacuum-annealed surfaces at 50 and 150 μA cm^{-2}, and for all but the (321) at 300 μA cm^{-2}, the effect on all such surfaces ceased to be quantitative at about 150 μA cm^{-2}. Thus it seems established that, also in sulfate solutions, material initially deposited did not diffuse rapidly over the surface to kink-step sites and become indistinguishable from the substrate material.

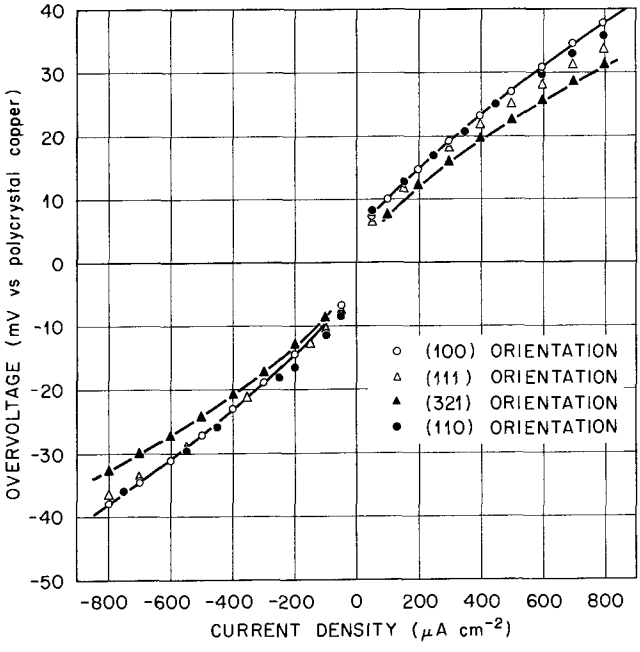

Fig. 6. Overvoltage vs. current relationships for "vacuum-annealed" copper single-crystal surfaces in 0.2M $CuSO_4$ + H_2SO_4 (pH $\approx$ 1) at 23°C.

Discussion

Overpotential maxima and current density relationships.—Three reactions must be examined in the systems reported here: a redox reaction

$$Cu^+ \leftrightarrows Cu^{2+} + e \qquad [i]$$

the reaction between adatoms and cuprous ions

$$A \leftrightarrows Cu^+ + e \qquad [ii]$$

and the exchange of adatoms with the metal lattice

$$M \leftrightarrows A \qquad [iii]$$

Previously (7) it was shown that, although transient processes, maxima treated in the manner of steady-state phenomena would yield the relationship

$$2\eta = \frac{RT}{\mathbf{F}} \ln \frac{(\hat{a}_{Cu2+})}{(\hat{a}_{Cu2+})_{eq}} + \eta_i + \eta_{ii} + \eta_{iii} \qquad [1]$$

where η values are either the total overvoltage measured, or that associated with the reaction appropriate to the subscript notation, and other symbols represent their usual quantities. Also, it should be noted that Vetter's (11) definition of crystallization overvoltage, η_c, is such that

$$\eta_c \equiv \frac{RT}{\mathbf{F}} \ln \frac{(\hat{a}_A)_{eq}}{(\hat{a}_A)} = \eta_{iii} \qquad [2]$$

Others (1-6) have shown that, at higher current densities than those reported here, reaction [i] was the rate-controlling process and, further, that $2\eta = \eta_i$, which as Bertocci (12) pointed out required that $(\hat{a}_{Cu2+})$ not depart from the equilibrium value and that reaction [ii] occur completely reversibly ($\eta_{ii} = 0$). But, obviously, it is also required that $\eta_{iii} = 0$, if the explanation of the data at higher current densities is valid.

On the basis of the deposition anomaly observed in perchlorate systems, which was interpreted to mean that deposited atoms did not occupy half crystal positions and further possessed adatom-like character, and also because of the measured relatively high overvoltages, it was assumed that maxima were established before reaction [iii] had occurred to a significant extent and that $\eta_i \to 0$. The model seemed justified (7) since the data could be treated by the expression

$$i = K\left\{\exp\left[\frac{\alpha z \mathbf{F}\eta_*}{RT}\right] - \exp\left[\frac{-(1-\alpha)z\mathbf{F}\eta_*}{RT}\right]\right\} \qquad [3]$$

where i = current density
K = an orientation-sensitive factor with the dimensions of current density
α = a transfer coefficient which can be orientation sensitive
z = a factor relating the observed overvoltage maxima to the electrocrystallization overvoltage
η_* = value of overpotential maxima

and the remaining terms have their usual significance. In the perchlorate systems $\alpha = 0.50$ for orientation with symmetrical anodic and cathodic current-potential relationships and, of course, z had a value of 2 since the assumptions that $\eta_i \to 0$, $(\hat{a}_{Cu2+}) = (\hat{a}_{Cu2+})_{eq}$, and η_{ii} established that $2\eta = \eta_{iii}$.

Under the experimental conditions reported here, it is only reasonable to assume that certainly the cupric ion activity did not depart from the equilibrium value and that the value of η_{ii} remains zero. Therefore, the expression to be considered is

$$2\eta = \eta_i + \eta_{iii} \qquad [4]$$

and the response of the data to treatment by Eq. [3] will determine whether $\eta_i \to 0$.

Standard surfaces.—However, since the overvoltages measured on standard orientations in sulfate solutions are much lower than those for corresponding conditions in perchlorate solutions, it would seem unlikely that in the range of current densities studied here the situation should be realized in which $\eta_i \to 0$. That this assumption is valid is illustrated by treating the overpotential maxima data from standard surfaces in the manner shown in Fig. 7. (Note that a value of 0.5 is assumed for α since the data illustrated in Fig. 2

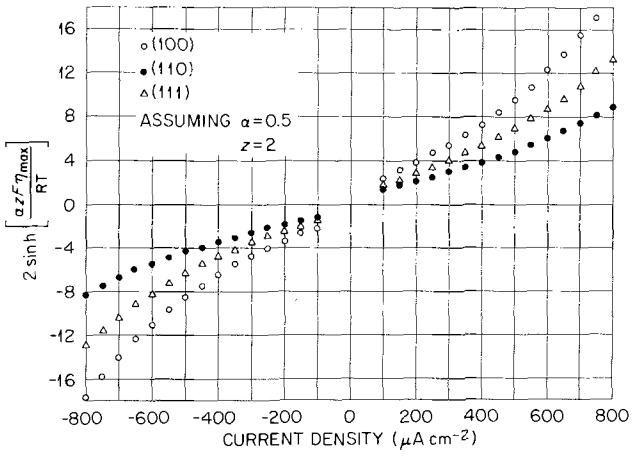

Fig. 7. Relationships between functions of overpotential maxima and current densities for "standard surface" data shown in Fig. 2. All symbols have their usual significance except for z which is a factor relating the crystallization overvoltage to the measured value.

have symmetric anodic and cathodic branches and, therefore, in sulfate systems α is not orientation dependent.) As opposed to the perchlorate case, both anodic and cathodic data from a given orientation do not fall on a straight line passing through the origin. It seems clear that, in sulfate systems, low current density overpotential maxima contain components of both η_i and η_{iii} and that $2\eta \neq \eta_{iii}$. The maxima themselves of course reflect the departures from equilibrium activities of cuprous ions at the interface and adatoms on the metal surface, again as in the perchlorate systems, and the subsequent changes in activities of these two species in an effort to establish the desired steady-state conditions. Other qualitative differences noted between standard data in the two solutions is that, while in both cases higher maxima were established on the (100) than on any other surface, in sulfates the (110) is displaced lower than in perchlorate with respect to the (111) and (321). Also, the asymmetry of (111) and (321) cathodic branches seen in perchlorate systems is not found in the sulfate where all standard orientations had symmetric anodic and cathodic branches. This suggests it would be easier to grow more perfect crystals over these two substrates in sulfate solutions, if the explanation advanced for the cause of asymmetry in perchlorates is correct (7).

Overpotential maxima and surface types.—Although comparison between current-potential curves of a single orientation from different types of surfaces in sulfate systems is difficult due to the manner in which the data are shown, by consideration of Fig. 2, 3, 5, and 6 the following relationships can be verified:

(*a*) Vacuum-annealed surfaces of all orientations yield data considerably different from those obtained on surfaces prepared in other ways.

(*b*) Only standard annealed surfaces produced results which showed a significant asymmetry between anodic and cathodic branches of any one orientation, and all orientations so treated yielded cathodic data which were slightly lower than their anodic counterparts.

(*c*) Both anodic and cathodic branches of (321) data were little affected by any method of surface preparation other than vacuum annealing.

(*d*) Anodic data from standard, standard annealed, and mechanically treated (111) surfaces differ only slightly from each other. However, the cathodic branches of these three surfaces differ significantly, particularly so in the differences of the latter two types from the first.

(*e*) Standard and mechanically treated (110) surfaces yield almost identical data. While cathodic data

from the standard annealed surface do differ from the two former, the anodic portion of the curve shows the highest values observed for any orientation treated in this manner. Indeed, this (110) is the only example observed in which any other than standard treatment created a significant increase in overpotentials over the entire current density range.

(*f*) All other (100) surfaces produced results markedly different from those obtained on the standard (100).

Initially it might be thought that the great differences in current-potential characteristics measured on vacuum-annealed surfaces could be due to changes in surface area. However, consider the extreme case; the dimensions of the pits on the (100) illustrated in Fig. 4, the most heavily faceted surface of all tested, can be shown from simple geometric considerations to increase the surface area from that of the original (considered to lie in the plane of the page) only by $\approx 0.1\%$!

As previously pointed out (7), standard surfaces could not be prepared absolutely flat, but contained gentle long-range undulations such that over the surface the orientation deviated $\approx \pm 0.1°$ from that desired. For purposes of estimation of average monatomic step densities resulting from such slight misorientations, the low index orientations of copper which all contain in excess of 10^{15} atoms cm^{-2} can be considered from the standpoint of fcc hard ball models. Again simple geometric relationships can be used to demonstrate that deviations of 0.1° from a low index plane result in an average monatomic step density of $\sim 10^5$ cm^{-1} due solely to this slight misorientation. Similar relationships show that the average step density arising from misorientation in the pits illustrated in Fig. 4 was $\sim 10^6$ cm^{-1}. However, the hard sphere model reveals that the standard (321) step density approaches 10^7 cm^{-1}; moreover, the steps are continuously kinked such that no atom on a step occupies a half lattice position. Further, neither removal nor addition of material at steps can alter this situation if the orientation is maintained. Thus it seems an unavoidable conclusion that the magnitudes of overpotential maxima were not directly related to average step densities of the various orientations or to the meager changes in surface areas produced by facet formation, and that a barrier exists to reaction at steps. However, large differences related solely to orientation could be observed.

The small differences in anodic data on the (111) surfaces prepared by other than vacuum annealing also suggest maxima were established before significant reaction at steps had occurred. However, the cathodic behavior of other than standard surfaces indicates that deposition occurred over the facets as well as on the (111). The rather extreme sensitivity of both anodic and cathodic processes on the (100) and (110) orientations to method of surface preparation could indicate that facets formed on these orientations serve as preferred sites for supporting the electrode processes. These observations agree with the conclusions reached for perchlorate systems that surface processes such as diffusion and/or step motion seem to be much more difficult over the (100) and (110) than on the (111) and (321).

The observance of the deposition anomaly on the standard (321), as well as on the highly faceted, vacuum-annealed (100), surely must indicate that initial deposition at these low current densities did not occur by the diffusion of adatoms to steps where they were incorporated into the lattice, even on a surface with near maximum step density. Some barrier to diffusion and/or incorporation must be overcome before this can occur. It would appear then that attempts to grow more perfect crystals over like substrates should be made at higher current densities than those reported here, since direct reaction at steps (ledges) under the former conditions is a well-documented phenomenon (13).

It should be said that the term "standard" surface was selected solely because this method of electrode preparation is so universally used. There is no intent to imply that only such surfaces yield data useful in the study of electrocrystallization kinetics. However, it does seem significant that only surfaces prepared in this manner permitted duplication of data from one experimental cell to another. Still, it is quite possible that the practical lower limit of $\sim 10^5$ steps cm^{-1} arising from unavoidable, very slight misorientations from close-packed orientations on any surface prepared in this manner already is too great to afford a true indication of the effects of a few steps spaced more or less uniformly over the surfaces. However, a lack of correlation between average step densities and the magnitude of overvoltage maxima does seem well established. Conversely, it is equally clear that maxima are extremely sensitive to the manner in which steps are arrayed over surfaces, for, although the standard (321) had a higher step density than any other-than-standard surface, all the latter, with but two minor exceptions, exhibited lower overvoltages at comparable current densities. These relationships must have resulted solely from the arrangements of steps over the surface since surface areas remained essentially unchanged in all systems. It is only reasonable to conclude that, given a certain number of steps on a surface, observed overvoltages decrease as step interactions increase to form ledges and/or facets. Since the relative sizes of maxima decrease with decreasing overvoltage such that they also form and decay quite slowly at overvoltages $\simeq$ 10 mV, it is not surprising that they are either unobserved or identified as "pseudo steady state" on surfaces highly faceted as a result of extensive measurements at high reaction rates.

The ranges of higher current densities and overpotentials reported here correspond to the lowest ranges measured by Bockris and Enyo (2) and Bockris and Kita (3), where charge-transfer was not the rate-determining process. Their preparative treatments and the extent of processes necessarily sustained by their electrodes in order to supply the data suggest the research was conducted on surfaces resembling more the vacuum-annealed structures than any others in this present study. Comparison of data in Fig. 6 with those illustrated in Fig. 2, 3, and 5 indicates then that the conclusions of Bockris *et al.* regarding surface processes such as adion diffusion rates, charge-transfer rates on various types of surfaces, relative adion concentrations, predominance of (100) orientations, *etc.*, all must be regarded, at best, as highly speculative because of the uncertainties of the structures of the electrodes yielding the data.

Manuscript submitted July 1, 1970; revised manuscript received *ca.* Aug. 17, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1971 JOURNAL.

Reduction of Oxygen on Teflon-Bonded Platinum Electrodes

W. M. Vogel* and J. T. Lundquist

Advanced Materials Research and Development Laboratory, Pratt & Whitney Aircraft, Middletown, Connecticut 06458

ABSTRACT

By using specially prepared Teflon-bonded electrodes, it was possible to eliminate the internal *IR* drop across the porous electrode and the concentration overvoltage associated with diffusion of oxygen in the gas filled pores of the electrode structure. After this elimination, the apparent exchange current and kinetic parameters for the reduction of oxygen on Pt-black in KOH, H_2SO_4, and H_3PO_4 electrolytes can be determined by using Tafel plots. The data indicate that although the rate of the transfer reaction is the same in the two acids, H_3PO_4 is the poorer electrolyte for an acid fuel cell because of the much slower transport of oxygen. The kinetic data differ only moderately from those reported for smooth Pt surfaces.

A problem common to the development of fuel cell electrodes and to the evaluation of electrocatalysts has always been the difficulty of separating the effects of the electrode structure from the intrinsic activity of the catalyst. In the past this problem has been attacked theoretically by assuming a model.

Generally, the theoretical approach is in effect a method of curve fitting, employing a large number of adjustable parameters. The rather ambiguous results obtained exclusively in this way are, not surprisingly, usually of little value. To reduce the number of these parameters we can use kinetic data obtained on smooth surfaces of the catalyst. Even if such a surface can be prepared, we cannot assume that the catalytic properties, referred to unit true area, are the same for platinum black as for smooth Pt. In addition, of course, it is extremely difficult to eliminate impurities from the electrolyte to such an extent that they no longer influence the O_2 reduction reaction on smooth surfaces. As a result of these difficulties, in many instances neither the intrinsic activity of the electrocatalyst nor the structural details of a given electrode could be determined. There is, therefore, a critical need for additional tools with which to study catalyst blacks and porous electrode structures. This paper describes a new approach to this problem.

The aim was to determine, for a given platinum black, the kinetic parameters of the oxygen reduction free of ohmic and transport limitations. We used Teflon bonded electrodes (1) for this purpose. For very thin electrodes of this type the internal *IR* drop across the electrode and the concentration changes in the gas phase should both be negligible. The electrode thickness should be proportionate to the catalyst loading, *L*, if the Teflon content is constant and if the structure does not change. Under these conditions plots of current density *vs. L* should have linear portions at low loadings. Tafel plots of the initial slopes of these curves (dimension current/unit weight) are the *IR*-free polarization curves, reflecting transfer polarization and concentration overvoltage associated with diffusion of oxygen in the liquid filled pores of the electrode structure. By superimposing the Tafel plots of electrodes of different catalyst content, it is possible to cover a very wide range of current densities. The apparent exchange current and kinetic parameters of the oxygen reduction can be determined from these composite plots.

Experimental

It is essential when employing the procedure just outlined that electrodes be made in such a way that a change in the loading does not produce a qualitatively different structure. Ideally only the electrode thickness should vary. The experimental results indicate clearly whether one is successful in this undertaking. However, we know of no method which will predictably produce the desired results.

It was found that a number of different methods produce satisfactory electrodes. The kind described below were found to be the easiest to make and the most reliable.

A layer of Teflon of approximately 1 mg/cm^2 was sprayed on aluminum foil. The spray mixture was prepared from Teflon 30 (E. I. du Pont de Nemours), containing 60 w/o (weight per cent) solid and 6 w/o Triton X-100, by diluting approximately 1:1 with distilled water. This layer was air dried, vacuum dried, and subsequently sintered to produce a thin porous sheet of TFE. Upon this layer was sprayed catalyst containing Pt-black (Engelhard Industries) and 30 w/o TFE. The catalyst spray mixture was made by first barely wetting the dry Pt-black with water, adding the required amount of Teflon 30 and further adding water to produce a relatively thick soupy consistency of the mix. At 30 w/o TFE content the maximum performance at high currents was obtained, falling off at higher and lower values. The catalyst layer was air dried at 60°C and then lightly compacted with a roller pressed down by hand. Subsequently the electrode was vacuum dried at 150°C for 30 min and finally sintered in air at 250° to 310°C for 5 min. A current collector screen was pressed lightly into the catalyst layer. The screen material was pure nickel (for experiments in KOH) or gold plated tantalum (for acids). Finally the aluminum foil was dissolved by treatment with the respective electrolyte to be used. The electrode was washed with distilled water and dried at 120°C.

The test electrodes were mounted in a screw cap holder, and current pick up was made via a platinum ring in contact with the current collector screen of the electrode. The electrode holder was made of Plexiglas (Rohm and Haas) for use in KOH or of Lexan (General Electric Company) for use in the acids.

The reference was a hydrogen electrode in the same medium used in conjunction with a Luggin capillary.

* Electrochemical Society Active Member.

Key words: cathodes—fuel cell, fuel cell cathodes, porous electrodes, oxygen reduction, platinum black.

The cell was a 500 ml jacketed glass reaction kettle. The temperature was controlled by means of an external circulating constant temperature bath. Reagent grade chemicals were used without further purification and solutions were prepared using singly distilled water. The instrumentation consisted of standard commercially available equipment.

Electrode potentials, E^*, were measured at constant current against a hydrogen electrode in the same medium. The applied current was established in less than 3 μsec and was constant within 1%. The external IR drop between electrode surface and Luggin capillary was determined by the interruptor method.

The electrodes were prepolarized for a few seconds at a potential of approximately 500 mV to remove the initial oxygen coverage from the platinum surface. The potentials were measured after about 1 min and were stable for at least 10 to 15 min.

The specific surface area of the Pt-black is being determined routinely by another laboratory at Pratt & Whitney Aircraft using the hydrogen stripping and the BET methods. Both methods give the same results. The particular black used by us had a surface of (24 $\pm$ 2) m^2/g. This value was rechecked on finished electrodes and found to be the same as for the original Pt-black.

Results

Typical experimental results are presented in Fig. 1-4 for 85% H_3PO_4 at 120°C for oxygen (1 atm) and for air (1 atm) respectively. Similar data were measured in 30% KOH, 20% H_2SO_4 and in 50% H_3PO_4, all at 70°C and with oxygen and air. The data follow the same general pattern as those in Fig. 1-4.

Within the initial approximately linear portion of these curves the internal IR loss is very small, certainly smaller than the reproducibility of the results. This means that the potential does not change across the thickness of the electrode, and it is physically meaningful to normalize the data by dividing the observed currents by the catalyst loading. The resulting specific current, i_m (per mg of catalyst), is proportional to the true current density at the Pt-electrolyte interphase if the concentration overvoltage is negligible, *i.e.* at low currents and especially on pure oxygen.

weight of catalyst $(i_o)_m$ and Tafel slopes, b.

The results are summarized in Table I. Values for $(i_o)_m$ and b were also obtained by analyzing the oscillographic traces after current interruption. For this purpose we assumed that the only process taking place after interruption is the charging of the double layer, assuming constant double layer capacity C^*. We further assumed that the concentration overvoltage remains constant. These two assumptions restrict the analysis to potentials below approximately 800-850 mV and to relatively short times. Under these conditions, the method is that developed by Frumkin (3). This method involves plotting potential E^* *vs.* log $(K_2 + t)$ according to

$$E^* = K_1 + b \log (K_2 + t)$$

$$K_1 \equiv b \log (2.3\ kc/b\ C^*)$$

$$K_2 \equiv (b\ C^*/2.3\ kc) \exp [2.3\ E^*\ (t = 0)/b] \quad [1]$$

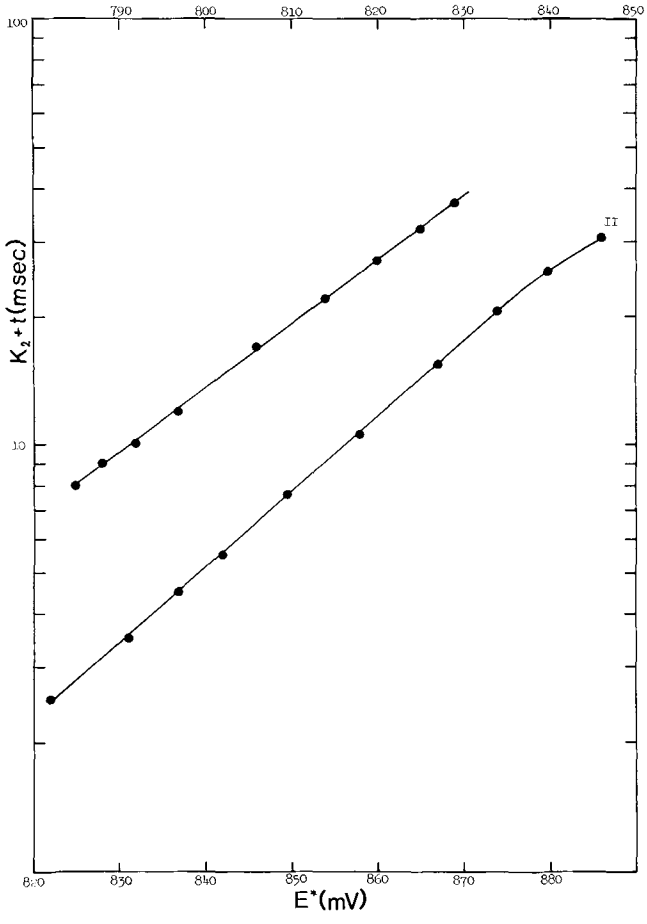

Fig. 7. Determination of kinetic parameters (i_o and b) from oscillographic E^*-t traces after current interruption; curve I (lower E^* scale): 20% H_2SO_4 (70°C), curve II (upper E^* scale): 85% H_3PO_4 (120°C).

log $(K_2 + t)$ *vs.* E^* are given for the following two cases:

(I) 20% H_2SO_4	(II) 85% H_3PO_4
$P_{O_2} + P_{H_2O} = 1$ atm	$P_{O_2} + P_{H_2O} = 1$ atm
70°C	120°C
$L = 4.9$ mg Pt/cm²	$L = 4.9$ mg Pt/cm²
$i = 300$ mA/cm²	$i = 300$ mA/cm²

The parameters of these curves (Fig. 7) are presented in Table II.

The value for the exchange current in H_2SO_4 is for saturation concentration at $P_{H_2O} + P_{O_2} = 1$ atm since the concentration overvoltage in this case was negligible (see Fig. 5). The value for $(i_o)_m$ in Table II for H_3PO_4 refers to an unknown value for the oxygen concentration which, however, was less than the solubility at $P_{H_2O} + P_{O_2} = 1$ atm. This is shown in Fig. 5 where, at the employed current density (61 mA/mg), a deviation from the Tafel line already exists which indicates non-negligible concentration overvoltage. Because of the inherent limitations of the transient method the data for $(i_o)_m$ in Table II are considered less reliable than those in Table I.

Table II. Determination of Tafel parameters from oscilloscopic E^*-t traces after current interruption for Experiments I and II above

	K_1 (mV)	K_2 (msec)	b (mV)	$\left(\frac{dE^*}{dt}\right)_{t=0}$ $\left(\frac{\text{Volt}}{\text{sec}}\right)$	C^* (μf/mg)	kc (mA/mg)	$(i_o)_m$ (mA/mg)

Table III. Exchange currents and Tafel slopes for oxygen reduction on Pt black at $P_{O_2} + P_{H_2O} = 1$ atm

Electrolyte	Temperature	i_o' (A/cm²)	b
30% KOH	70°C	4×10^{-10}	(50 ± 5) mV Steady state
30% KOH	70°C	—	50 mV Transient
20% H_2SO_4	70°C	4×10^{-10}	(64 ± 5) mV Steady state
20% H_2SO_4	70°C	0.9×10^{-10}	66 mV Transient
50% H_3PO_4	70°C	4×10^{-10}	(60 ± 5) mV Steady state
85% H_3PO_4	120°C	4×10^{-10}	(60 ± 5) mV Steady state
85% H_3PO_4	120°C	4×10^{-10}	(60 ± 5) mV Steady state
85% H_3PO_4	120°C	—	57 mV Transient

Similar analyses were performed for all electrolytes. The results are compiled in Table III. Values obtained from steady state data (Fig. 5) are included for comparison.

Discussion

The values for i_o' and b for H_3PO_4 are the same at 70°C and 120°C (Table I). This has probably little theoretical significance because of the different electrolyte concentrations which were used at the two temperatures. For fuel cell applications, however, the independence of temperature is of real significance since different concentrations have to be used to keep vapor pressure and cell resistance small. Thus the activation polarization cannot practically be lowered by raising the temperature.

Somewhat surprisingly, in the region of activation control, phosphoric and sulfuric acid act very similarly as supporting electrolytes. If, as is indicated by the large difference in the values for C* (Table II), the double layer is different in the two acids, it has apparently little or no effect on the rate of O_2 reduction.

All data in Fig. 5 and 6 are practically free of all ohmic polarizations and concentration polarization caused by oxygen depletion in the gas phase. The difference between the extrapolated Tafel lines and the actual polarization curves is therefore caused by the diminishing utilization of catalyst due to oxygen starvation at the interior, flooded portions of the catalyst agglomerates. The current derived from these interior, flooded portions approaches zero for high polarizations. It is in this potential region where the two acids differ. The combination of higher concentration overvoltage and lower Pt utilization makes H_3PO_4 a much poorer electrolyte for fuel cell cathodes, not a higher activation polarization.

The only data for smooth Pt surfaces which are directly comparable with the present data are those of ref. (4). Thus at 116°C and for 85% H_3PO_4 these authors report $i_o' = 5 \times 10^{-9}$ A/cm² and $b = 80$ mV for what they consider oxide-free Pt. Their "active" Pt yielded $i_o' = 1.1 \times 10^{-7}$ A/cm² and $b = 125$ mV. Because of similar prepolarization our data should correspond to their oxide free surface.[1] The remaining difference may reflect a genuine difference between a black and a smooth surface or it may be due to incomplete removal of impurities in the experiments with smooth surfaces. We have no reason to prefer one possibility to the other. Even if the difference reflects entirely the different catalytic activity it is surprisingly small for what are supposedly vastly different surfaces.

At very low potentials the linear range of curves like those in Fig. 1-4 is restricted to very thin electrodes. Such electrodes are difficult to make with the described method of spraying the catalyst on the supporting Teflon film. As a result the present data are insufficient to extend the curves for acids in Fig. 5 and 6. Relatively thin electrodes, although not assuredly free of internal IR drops at the highest currents, nevertheless show defined limiting currents as can be seen in Fig. 8.

[1] Note: At high potentials ($\epsilon^* \gtrsim 950$ mV) an increase in the polarization begins to become noticeable after 10 to 20 min. This change may be due to poisoning by impurities diffusing into the porous electrode from the bulk electrolyte or it may be due to poisoning by the increasing oxygen coverage. At present we cannot distinguish between these two possibilities.

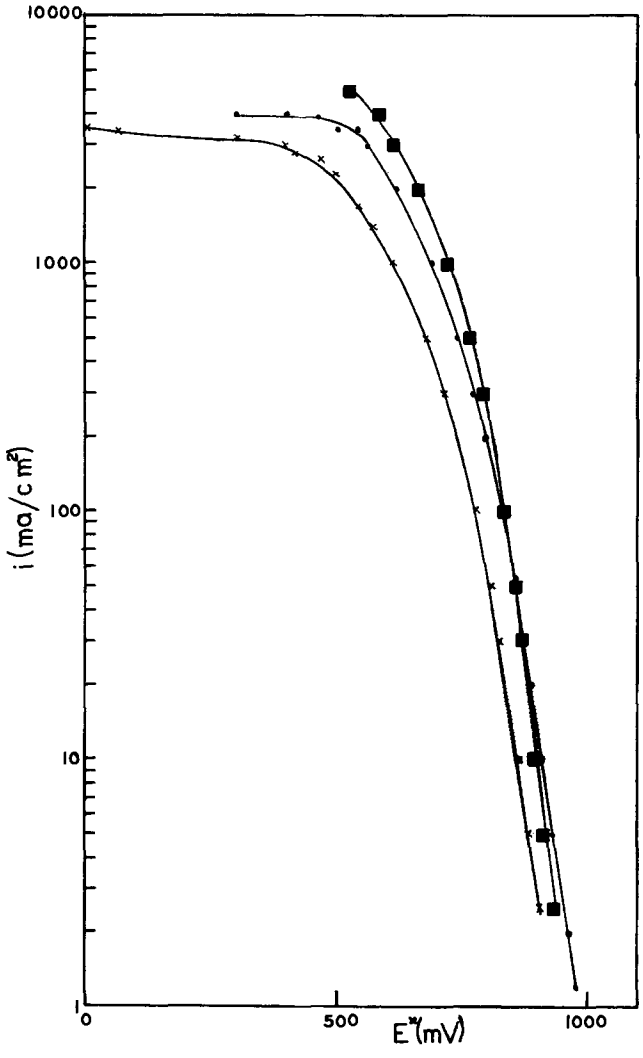

Fig. 8. Polarization curves for single electrodes. ● oxygen, 120°C, 85 w/o H_3PO_4, L = 4.2 mg Pt/cm²; X air, 70°C, 20 w/o H_2SO_4, L = 2.3 mg Pt/cm²; ■ oxygen, 70°C, 20 w/o H_2SO_4, L = 2.3 mg Pt/cm².

Limiting currents on oxygen in H_2SO_4 were not obtained because of the very high current density. If the catalyst loading becomes too high, the current increases slowly without showing a defined limiting current before H_2 evolution begins at the front of the electrode.

An interesting feature of the polarization curves in Fig. 5, 6, and 8 is the shape for KOH. The potential region where the polarization changes from pure activation control with perfect utilization of the catalyst to a limiting current which is obviously controlled by a liquid film is much narrower for KOH than it is for the acids. Although the limiting currents in the acids are at least as high as those in KOH, the starvation of O_2 begins, in the acids, at much lower currents relative to these limiting values. As a matter of fact, the curves for KOH can be described formally by the following equation:

$$\eta - \eta_a = K \log [1 - (i/i_{lim})] \quad [2]$$

where η is the total polarization, η_a is the activation polarization (obtained by extrapolating the linear portions) and i_{lim} is the observed limiting current. Equation [2], of course, describes the behavior of a smooth electrode.

No explanation can be given for this very different behavior of the electrode in acid and in base. The theoretical models proposed for the operation of gas diffusion electrodes usually do not take account of several processes which become important at high current densities. Thus the electrolyte concentration in the catalyst pores changes with the applied current density (5). This change is in opposite directions in acid and in base and depends on the thickness of the electrode. As a result, not only the vapor pressure of the electrolyte changes, but the oxygen solubility and diffusivity become current dependent. In addition, Teflon bonded cathodes in KOH tend to exude electrolyte at their gas-side: The degree of this pumping action increases reversibly with the applied current and the gas-side of the electrode becomes, except in severe cases, immediately dry again at open circuit. This behavior indicates that the catholyte within the catalyst pores is under an overpressure which depends on the current and is sufficiently large to overcome the capillary forces of the catalyst structure. Such an overpressure would tend to increase the thickness of the liquid film on the porous catalyst agglomerates which also would depend on the applied current density.

Rotating Ring-Disk Electrodes

III. Catalytic and ECE Reactions

Keith B. Prater[1] and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Digital simulation techniques were employed to calculate the ring and disk currents at the rotating ring-disk electrode (RRDE) for the cases where the intermediate generated at the disk electrodes undergoes first- or second-order processes producing electroactive species: either the original starting material (a catalytic reaction) or a new species (an ECE reaction). Working curves which allow the detection of these mechanisms and the determination of rate constants of the homogeneous reactions from current-rotation rate data are provided. The determination of the rate constant of the iron(II)-hydrogen peroxide reaction by examination of the reduction of iron(III) in a hydrochloric acid medium at a carbon paste RRDE is described.

A digital simulation treatment of the rotating ring-disk electrode (RRDE) in the absence of following chemical reactions has been presented previously (1). The results of this treatment were in excellent agreement with the work of Albery and Bruckenstein (2). This digital simulation technique has also been applied to those cases in which a following first- or second-order chemical reaction results in a nonelectroactive product (an EC mechanism) (3). These results were in good agreement with the approximate treatments of Albery and Bruckenstein (4-7) within the range of their approximations. In this paper, results of the digital simulation of two mechanisms in which the products of the following chemical reaction are electroactive at the potential of the disk electrode are presented.

In the first mechanism, the ECE (electrochemical-chemical-electrochemical) mechanism, species B, which is generated at the disk electrode by

$$A \pm n_1 e \rightarrow B \qquad [1]$$

undergoes a homogeneous reaction to yield species D which immediately undergoes a further electrochemical reaction at the disk electrode. The homogeneous reaction may be either first- or second-order. In the first-order case

$$B \xrightarrow{k_1} D \qquad [2]$$

while in the second-order case

$$B + C \xrightarrow{k_2} D + Y \qquad [3]$$

In either case, species D is immediately oxidized or reduced at the disk by

$$D \pm n_2 e \rightarrow Z \qquad [4]$$

and species C, Y, and Z are considered to be nonelectroactive at the potentials of the ring and disk electrodes. At the ring electrode, A is regenerated from B by the reaction

$$B \pm ne \rightarrow A \qquad [5]$$

The second mechanism is the so-called catalytic mechanism in which one of the products of the homogeneous reaction is the initial species, A. In the common second-order catalytic mechanism, the intermediate, B, reacts with species C, to yield A and Y, where C and Y are nonelectroactive. That is

$$B + C \xrightarrow{k_2} A + Y \qquad [6]$$

In the limit of large concentrations of species C, the second-order catalytic case simplifies to the first-order case given by

$$B \xrightarrow{k_1} A \qquad [7]$$

In each case, the chemical reaction is instantaneously followed by the re-oxidation or re-reduction of A to B as shown in Eq. [1]. As before, the reaction at the ring electrode is given by Eq. [5].

Digital Simulation

The ECE mechanism.—The general approach to the simulations and the notation to be used has been described in previous communications (1, 3). In the ECE mechanism, the ring current-dependent parameter, *ZR*, calculated for a given value of the rate parameter *XKT* for a first-order reaction or *XKTC* for a second-order reaction, is identical with that calculated for the analogous EC case (3). The difference in the collection efficiency curves for the EC and ECE mechanisms is a result of the effect of the ECE reaction on the disk current parameter, *ZD*. Although the EC reaction does not change the disk current from that observed in the absence of a following reaction, the ECE reaction gives rise to increased disk current. Thus the collection efficiency working curves for the first- and second-order ECE mechanisms can be generated by calculating the ECE disk current for a specified value of the rate parameter and dividing the analogous EC ring current by that disk current.

The simulation of the first- and second-order ECE disk currents is quite similar to the previous RRDE simulation (1, 3) except that only the $K = 1$ boxes need to be considered and thus radial convection can be ignored. The dimensionless rate parameters, *XKT* and *XKTC*, are identical to those for the EC cases. The only major differences between the EC and ECE calculations are that in the ECE case, the boundary conditions at the disk electrode and the current parameter, *ZD*, must take into account the fact that both species A and species D are being consumed at the disk and that both are contributing to the total disk current. Thus in this case the parameter, *ZD*, will be the sum of the currents due to (*i*) diffusion of A into the disk box ($J = 1$, $K = 1$), (*ii*) diffusion of D into the disk box, and (*iii*) electrolysis of any D generated in the disk box. Since the fractional concentrations of A and D in the disk box are zero, the

Key words: digital simulation, electrode reactions, rotating disk electrode.

contribution to the current due to diffusion of A and D into the disk box will be

$$IA = DM_AF_A(2,1)\,(L/DM_A)^{1/2} \quad [8]$$

$$ID_{dif} = DM_DF_D(2,1)\,(L/DM_A)^{1/2} \quad [9]$$

The contribution to ZD due to electrolysis of D produced in the disk box will be

$$ID_{elec} = F_D(1,1)\,(L/DM_A)^{1/2}/2 \quad [10]$$

The factor of 1/2 occurs because the disk box is only $x/2$ wide. Thus in this case

$$ZD = IA + ID_{dif} + ID_{elec} \quad [11]$$

The simulated limiting disk currents as functions of the appropriate dimensionless rate parameters for the first- and second-order ECE mechanisms are shown in Fig. 1. The first-order curve agrees with that simulated by Feldberg *et al.* (8). The disk currents have been normalized by the disk current one would observe in the absence of any following reactions. These disk currents were calculated assuming the stoichiometry given in Eq. [3] and assuming that the number of electrons transferred per molecule is the same for the A to B reaction and the D to Z reaction. In those cases where $n_1 \neq n_2$ or where the stoichiometry is not 1 to 1, the disk current curves can easily be generated by multiplying the amount by which the disk current is enhanced by the appropriate factor. Also shown in Fig. 1 are the associated ring currents from the EC calculations for an electrode with $IR1 = 83$, $IR2 = 94$, and $IR3 = 159$. These, too, have been normalized by the ring current in the absence of any following reaction. The collection efficiency working curves for the first- and second-order ECE mechanisms are shown in Fig. 2. As must be the case, the collection efficiency is lower for an ECE curve than for the analogous EC curve.

The catalytic mechanism.—In the case of the catalytic mechanism, the ring current parameters, ZR, are not the same as the corresponding parameters in the EC mechanism, because the homogeneous reaction regenerating A at the disk is followed by reduction of A to B, so that a greater flux of B to the ring electrode is observed. The simulation, however, is entirely analogous to the simulation of the EC and ECE cases except for the appropriate changes in the boundary conditions and current parameters.

The simulated limiting disk currents for the catalytic mechanism as compared with those in the absence of a following reaction are shown in Fig. 3 as functions of XKT and $XKTC$. The limiting disk currents for this

case have been treated by Koutecky and Levich (9), by Haberland and Landsberg (10), and by Beran and Bruckenstein (11). The treatment by Koutecky and Levich assumed that the reaction layer thickness was very small compared with the diffusion layer thickness, that is, it assumed that k/ω was large. Beran and Bruckenstein treated a rather complex system under pseudo-first order conditions. The simulation results agree very well with the more general treatment of Haberland and Landsberg. This is shown in Fig. 4 in which some of their data for the Fe^{+3}/H_2O_2 system are compared with points calculated from their data in the absence of the following reaction, the rate constant which they calculated, and the simulation results.

While the simulated disk currents are valid for any geometry, the limiting ring currents which are also shown in Fig. 3 were calculated for an electrode with $IR1 = 83$, $IR2 = 94$, and $IR3 = 159$. From the ring and disk currents, one can obtain the collection efficiency working curves shown in Fig. 5.

At this point it is appropriate to compare the simulated collection efficiency working curves for the EC, ECE, and catalytic mechanisms. In all useful ranges of the rate parameters, the ECE curves differ significantly from the analogous EC and catalytic curves. The collection efficiency found for the ECE mechanism for a given value of $XKTC$ and m, where $m = C°_C/C°_A$, is always smaller than that found for the

EC or catalytic mechanisms with the same values of $XKTC$ and m. On the other hand, the EC and catalytic curves are, for most values of the rate parameters, quite similar. In fact, the first-order curves for the two mechanisms are indistinguishable as are the analogous curves for m — 10.0. The m = 1.0 and m = 0.1 curves for the two mechanisms are experimentally indistinguishable for values of $(XKTC \cdot m) < 0.5$. Thus, it is not surprising that Albery *et al.* (6) obtained reasonable results when they treated a pseudo-first order catalytic system with a theory developed for the EC mechanism. Although the collection efficiency data are insufficient for differentiating between the EC and catalytic mechanism, examination of the limiting ring and disk currents allows the two mechanisms to be easily distinguished. The limiting disk current for the EC mechanism is identical to that found in the absence of any following reaction, while the limiting disk current, i_{lim}, for the catalytic mechanism is significantly larger and $i_{lim}/\omega^{1/2}$ varies with ω. Thus, it seems advisable to carry out the RRDE experiment in a manner which yields both collection efficiency and limiting ring and disk current data.

Transient behavior.—The simulated ring current transients for the ECE mechanism are identical to those for the EC mechanism. For the first- and second-order catalytic reactions, the value of $\omega t (D/\nu)^{1/3} (0.51)^{2/3}$ at which the ring current is one-half of the steady-state value is observed to be a function of XKT or $XKTC$ as in the EC case. Unlike the EC transients, however, the catalytic transients do not exhibit maxima.

Results and Discussion

To test the simulation results for a second-order catalytic reaction, the reduction of iron(III) in the presence of hydrogen peroxide was investigated. This reaction, previously investigated at a RDE by Haberland and Landsberg (10), was studied by reduction of ferric ion at the disk and analysis for the ferrous ion at the ring, that is

$$Fe^{+3} + e \rightarrow Fe^{+2} \qquad \text{disk electrode}$$

$$Fe^{+2} + 1/2H_2O_2 \xrightarrow{k_2} Fe^{+3} + OH^-$$

$$Fe^{+2} - e \rightarrow Fe^{+3} \qquad \text{ring electrode}$$

The electrode was a carbon paste RRDE with dimensions r_1 = 0.237 cm, r_2 = 0.268 cm, and r_3 = 0.455 cm. It was calibrated by determining the limiting disk and ring currents in a solution containing 6.4 x $10^{-3}M$ iron(III) and 2M HCl. Typical results are shown in Fig. 6, curves b and c. The experimental collection efficiency, 0.545 ± 0.003, compares quite well to that for the simulation in the absence of perturbing reactions, 0.551. A second determination of the collection efficiency, involving oxidation of 5.7 x $10^{-4}M$ o-dianisidine in 1M H_2SO_4 at the disk electrode yielded a collection efficiency of 0.548 ± 0.003.

The limiting disk currents and corresponding limiting ring currents for the solution which was 6.4 x $10^{-3}M$ in ferric ion and 0.64 x $10^{-3}N$ in hydrogen peroxide were found to be identical to those obtained in a solution which contained 6.4 x $10^{-3}M$ ferric ion and no hydrogen peroxide. This indicated that at this ratio of the concentration of ferric ion to hydrogen peroxide, the rate of the ferrous-hydrogen peroxide reaction was so slow that its effect on the ring and disk currents could not be detected.

When limiting ring and disk currents were obtained for the solution which was 6.4 x $10^{-3}N$ in both ferric ion and hydrogen peroxide, it was obvious that the reaction was significantly affecting the ring and disk currents. These currents along with the collection efficiencies at various rotation rates are shown in Table I. Also shown in Table I are the values of $XKTC$ corresponding to the observed collection efficiencies as obtained from the m = 1.0 working curve in Fig. 5. The

product of the rotation rate and the value of $XKTC$

$$(\omega)(XKTC) = k_2 C^o_A (\nu/D_A)^{1/3} (0.51)^{-2/3}$$

should also be a constant. The values of this product and also the value of k_2 calculated for each rotation rate using a value of the diffusion coefficient, D_A, of 5 x 10^{-6} cm^2/sec and a value of the kinematic viscosity, ν, of 1 x 10^{-2} cm^2/sec, are also given in Table I.

The average value of k_2, 105 liters/mole-sec, compares favorably with reported values which range from $k_2 = 96$ liters/mole-sec in a solution containing $2M$ chloride ion and 4 x $10^{-3}M$ hydrogen ion at 35°C (12), to $k_2 = 145$ obtained in a $1M$ potassium chloride solution (10). This average value of k_2, calculated using the collection efficiencies, can also be employed to compare the predicted values of disk and ring current to the experimental ones. Curves a and d in Fig. 6 are the results of simulations of i_d and i_r at different values of ω employing a k_2 of 105 liters/mole-sec and parameters from the experimental ring and disk currents in the absence of hydrogen peroxide. Also shown in Fig. 6 are the experimental values of i_d and i_r from Table I, which are in satisfactory agreement with the simulated values.

Experimental

The carbon paste RRDE was fabricated from a cylinder of Quickmount (E. H. Sargent Company, Chicago, Illinois) molded onto a precision steel shaft (13). A Motormatic E-550 motor and controller (Electrocraft Corporation, Hopkins, Minnesota) was used as a rotator. A 1/4-in. chuck was mounted directly onto the motor shaft and held the RRDE. A dual-potentiostat similar to that described by Napp, Johnson, and Bruckenstein (14) was used to control the potentials of the disk and ring electrodes independently.

The standard iron(III) solution was prepared by dissolving ferric chloride in $2M$ HCl. This solution, standardized by reducing an aliquot with hydroquinone and determining the ferrous ion spectrophotometrically as the ferrous 1,10-phenanthroline complex, was found to contain $0.064M$ ferric ion.

A stock solution of hydrogen peroxide was prepared by diluting an approximately 30% hydrogen peroxide solution with water to produce about a 5 x $10^{-3}M$ solution. The hydrogen peroxide concentration of this solution was determined shortly before the experiment by reacting an aliquot of this solution with an aliquot of a standard solution of ferrous ammonium sulfate and determining the amount of ferrous ion remaining in solution spectrophotometrically. The hydrogen peroxide solution was found to be 5.9 x $10^{-3}M$ in hydrogen peroxide, or 1.18 x $10^{-2}N$ as an oxidant in the ferrous-hydrogen peroxide reaction. Test solutions were prepared from these stock solutions.

Solutions more concentrated than 6.4 x $10^{-3}N$ in hydrogen peroxide were found to be unstable with respect to decomposition into oxygen and water. Even in a solution which was 6.4 x $10^{-3}N$ in hydrogen peroxide, bubbles were observed at the electrode surfaces. This required wiping the electrode before each measurement and making the measurement as rapidly as possible. All measurements were carried out at 23° ± 0.5°C.

Technical Notes

The Effect of Potential and Time on Deposition Characteristics of Zinc on a Zinc Single Crystal in KOH

F. Mansfeld*[1] and S. Gilman*

NASA/Electronics Research Center, Cambridge, Massachusetts 02139

Employing *in situ* microscopy, Powers (1) demonstrated that the morphology of the zinc electrodeposit in alkaline solutions obtained on the basal plane of a zinc single crystal is markedly different at polarizations in the ranges of −100 mV and −200 mV *vs.* zinc. Details of early growth of the zinc electrodeposit are accessible through the use of the scanning electron microscope (SEM). Although SEM studies have been made of zinc electrodeposits (2, 3), these were not made under conditions of potentiostatic control and are, therefore, not exactly comparable to the results of Powers (1) or to the results obtained by the present authors (4, 5) in their studies of the effect of additives on the morphology of the electrodeposit.

The present studies were performed in a cell similar to that of Powers (1) in a solution of 6*N* KOH containing 20 g/liter of ZnO. Test samples were obtained by cleavage of single crystal rods in a dry box under argon [for details of the experimental procedure, see ref. (4)]. The growth process at a constant potential was followed for a prescribed period of time, employing *in situ* light microscopy. The sample was then removed and examined with the SEM.

Observations of the zinc electrodeposit at −100 mV polarization with the *in situ* light microscope revealed epitaxial growth in the form of hexagonal pyramids. Such pyramids grew in size and decreased in number as already observed by Powers (1). After approximately 15 min, a new growth feature appeared (Fig. 1) at the base of the growth pyramids. These new protrusions appear as black dots and have been called sponge or moss by various authors. They have been observed in the present experiment to be particularly numerous along cracks in the crystal introduced by cleavage. When viewed with the SEM (Fig. 2), it is apparent that these protrusions start to grow directly on the surface of the crystal; still visible are

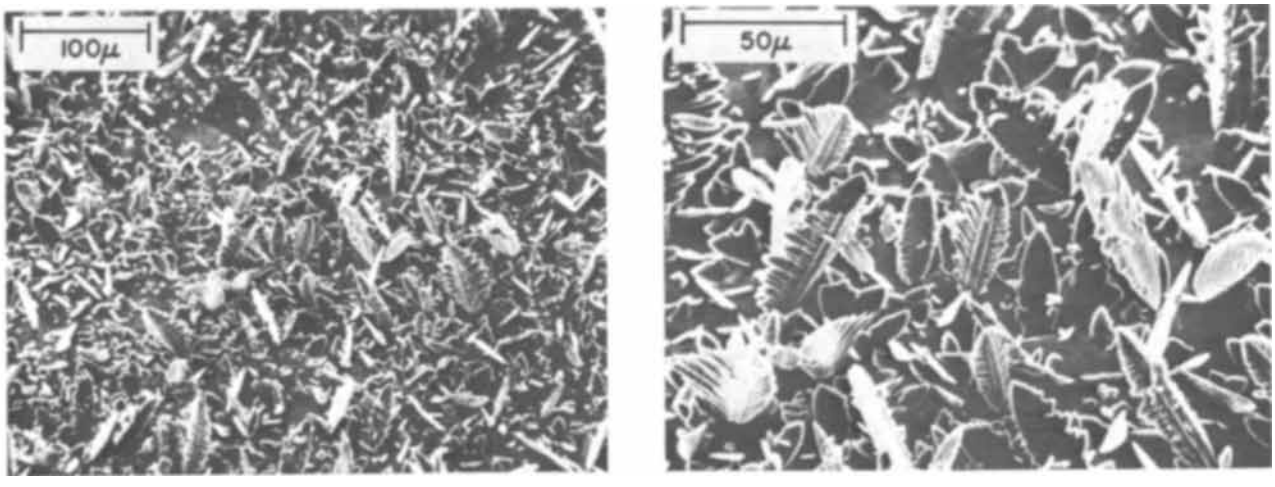

Fig. 4. Deposit at —200 mV from 6N KOH + 20 g/liter ZnO after 10 min. SEM, 34°. (a) (left) 170X; (b) (right) 440X

the layers that formed the growth-pyramids. Fig. 2b shows in more detail the structure of one of the protrusions which were already observed in an earlier study of the authors (Fig. 8 of ref. 4). They consist of many layers with certain crystallographic orientations. It seems reasonable to conclude that both types of growth occur on different sites, which might be screw dislocations in the case of pyramids, while the protrusions seem to nucleate at macroscopic defects or impurity centers (including such regions of macroscopic crystalline disorder as cracks). Comparison of Fig. 2 of this communication with Fig. 6 of ref. 4 reveals the dramatic effect produced by the addition of lead ions to the solution. The epitaxial growth and discrete crystalline protrusions observed here are replaced by microcrystalline hillocks with a pipelike structure in the valleys.

At —200 mV polarization, observation of the zinc electrodeposit with the *in situ* light microscope again reveals initial pyramidal epitaxial growth, the number of pyramids being higher than at —100 mV as observed in ref. 4. As at —100 mV, protrusions appear in the valleys between the growth pyramids, but the protrusions at the more cathodic potential occur early (within minutes) and develop into classical flat dendrites. Features of the dendritic growth are evident in the SEM photographs of Fig. 3 and Fig. 4. Such dendritic growth is suppressed in the presence of additions of lead (4) or tin (5) ions.

The effect of time on morphology of zinc deposits at —200 mV was studied at 5, 10, and 15 min. As can be seen better resolved with the light microscope (Fig. 5) (which in turn does not allow good resolution of the structure of the dendrites), dendrites are initi-

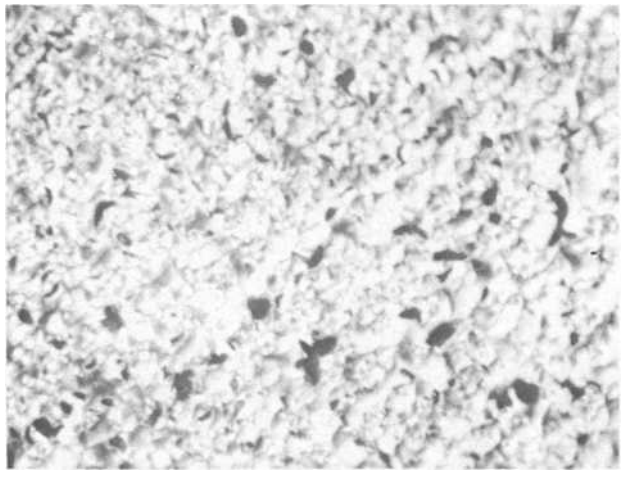

Fig. 5. Deposit at —200 mV from 6N KOH + 20 g/liter ZnO after 5 min. Nomarski Interference Contrast, 110X.

ated at the feet of the growth pyramids, probably at the same sites as the protrusions observed at −100 mV. Figure 3 shows growth after 5 min, and Fig. 4, growth after 10 min. It is obvious that the dendrites not only grow in size but also in number. Often two dendrites start at the same site, producing a heartlike structure. Figure 3b shows details of the observed growth including dendrites at the very early stages of growth. After 10 min of deposition the dendrites already have all features of classical dendrites observed after long plating times—a stem consisting of many plates and sidebranches as can be seen from Fig. 4b at a higher magnification. Examples for deposits after 15 min are shown in Fig. 2 of ref. 5.

In summary our results show that the deposition time and potential play an important role in morphology of zinc deposits on the basal plane of zinc in alkaline solutions. At −100 mV polarization, only epitaxial growth is observed for times below approximately 15 min. For longer times a second structure appears which grows probably from macroscopic defects. At −200 mV dendrites can be observed at times shorter than 5 min, possibly nucleated at the same sites as the protrusions formed at −100 mV. The dendrites grow in size and number with time. A comparison with results in the presence of lead ions (4) and tin or tetraethylammonium ion (5) shows that these additives suppress dendrite growth, although to different extents.

It will be noted that our results do not support a theory concerning the mechanism of dendritic electrocrystallization of zinc proposed by Diggle, Despic, and Bockris (6). In this model the initiation of a dendrite is treated in terms of growing pyramids on the substrate surface. It is assumed that "the rotation of the spiral, within the linear diffusion boundary surrounding the sphere, gives rise to a decrease of the effective radius of curvature of the dendrite tip" until a critical radius is obtained, which is the condition for dendrite initiation (6). In the present work, it has never been found that a dendrite initiated at the top of a pyramid; on the contrary the protrusions at −100 mV always start to grow at the foot of pyramids after these have stopped to grow further (Fig. 2b). At −200 mV, where classical dendrites are observed, these start to grow almost instantaneously between pyramids. It is hard to understand how the heartlike structure as shown in Fig. 3b should grow from the tip of a pyramid after this had reached the critical—very small—radius. It seems more likely that pyramids and protrusions or dendrites grow independently and from different sites.

The Preparation of $FeSn_2$ Coatings by Electrodeposition

Henry Leidheiser, Jr.* and Jyotin Sachdev

Center for Surface and Coatings Research, Lehigh University, Bethlehem, Pennsylvania 18015

$FeSn_2$ is a very corrosion-resistant material (1) and plays a major role at the iron-tin interface in controlling the corrosion behavior of commercial electrolytic tinplate used in container applications. Previous work has shown that small amounts of $FeSn_2$ are formed during the electrodeposition of tin from the alkaline bath on steel substrates (2) and Barry and Phillips (3) have shown that $FeSn_2$ is also formed at the interface during electrodeposition from the acid bath. A method is described herein for the formation of $FeSn_2$ coatings on steel and copper substrates utilizing electrodeposition of an iron-tin alloy followed by heat treatment.

Izmailov and Kudryavtseva (4) have developed an electroplating bath for depositing iron-tin alloys over a wide composition range and have studied the effect of bath composition, pH, and current density on the composition of the alloy. Experiments were carried out which confirmed the essential correctness of their observations. Electron microprobe analysis indicated that the iron and tin were homogeneously distributed throughout the deposit.

Iron-tin alloys of the approximate composition 33 a/o Fe-67 a/o Sn were deposited at 55 ± 5% current efficiency under the following conditions modified from those used by Izmailov and Kudryavtseva: bath composition—$FeCl_3 \cdot 6H_2O$ 27 g/liter, $SnCl_2 \cdot 2H_2O$ 4.0 g/liter, $Na_4P_2O_7 \cdot 10\ H_2O$ 150 g/liter; pH 8.4; temperature, 80°C; current density, 0.5 A/dm^2; graphite anodes. Deposits were typically 0.0002-0.0005 cm in thickness as determined by time of deposition. They were matte, smooth, and dull gray in color. X-ray diffraction analysis indicated the presence of elemental iron, elemental tin, and a small amount of $FeSn_2$. These results are in accord with the phase diagram which indicates that the stable phases at low temperature are iron containing a small amount of dissolved tin, FeSn, $FeSn_2$, and tin (5).

Deposits were heated for 24 hr at 150°-200°C, and the resulting alloy was studied by x-ray diffraction. A small amount of residual tin was present on samples heated at 150°C (residual iron could not be determined because of interference from the steel substrate); complete conversion to $FeSn_2$ occurred at 175°; and small amounts of FeSn were detected on samples heated at 200°C. Presumably above 175°C interaction between the substrate and the deposit becomes significant. Diffraction analysis of deposits formed on copper substrates confirmed that the iron was converted to $FeSn_2$ during heating at 175°C. The use of a copper substrate complicated the analysis since Cu_3Sn was also formed and appreciable amounts of FeSn were observed.

Two forms of $FeSn_2$ are claimed to exist, a tetragonal form and a pseudohexagonal form. Gabe (6) summarizes the diffraction data reported by a number of investigators. Although there are only minor differences between the diffraction patterns of these

* Electrochemical Society Active Member.
Key words: coating, $FeSn_2$, iron-tin, electrodeposition.

two crystalline forms of $FeSn_2$, our data are in better accord with the pattern for the pseudohexagonal form.

The data of Frankenthal and Loginow (7) indicate that one can expect 0.15 mg/cm^2 of $FeSn_2$ to be formed in 24 hr at 175° when tin electrodeposits on steel substrates are heated. In the case of our deposits of thickness equivalent to 3-6 mg/cm^2 there was complete conversion to $FeSn_2$ at 175°C. The higher amount of conversion to the alloy is to be expected in our experiments because of the intimate mixture of iron and tin crystallites in the electrodeposit before heating.

The presence of detectable amounts of FeSn in samples heated at 200°C is interesting because FeSn is not generally observed after commercial tinplate is heated during manufacture.

On the Conductivity of Electrolytes Simulating Those Found in AgCl-Mg, Fresh Water-Activated Batteries

Duane W. Faletti

Applied Physics Laboratory, University of Washington, Seattle, Washington 98105

Experimental determinations were made of the electrolytic conductivity of simulated electrolytes (aqueous $MgCl_2$ solutions) of AgCl-Mg batteries operated in fresh water.

Studies of high-drain, water-activated AgCl-Mg alloy batteries have been conducted. The conductivities of the effluents from such batteries operated in the open sea over the range of concentration (4.5 to 19 °/$_{oo}$ chlorinity) of interest to the battery designer have been presented (1). The development of voltage control systems that maintain a desired battery voltage by recycling a portion of the effluent and adjusting the intake of new electrolytes permits operation of these batteries in both fresh and brackish water. Since fresh water can be thought of as sea water with a chlorinity of zero, the data presented here are not only applicable to the operation of batteries in fresh water, but, by suitable interpolations in chlorinity with the results of Ref. (1), are applicable to operation in brackish water. The rationale for the use of aqueous $MgCl_2$ solutions as simulated effluents of AgCl-Mg alloy batteries when operated in fresh water is given in the following section.

Electrolyte Composition

In addition to the electrochemical reaction

$$2AgCl + Mg \rightarrow MgCl_2 + 2Ag \qquad [1]$$

which has the effect of adding magnesium chloride to the electrolyte, secondary reactions between the anode and water occur:

$$Mg + 2H_2O \rightarrow Mg(OH)_2 + H_2 \qquad [2a]$$

$$Al + 3H_2O \rightarrow Al(OH)_3 + 3/2H_2 \qquad [2b]$$

$$Zn + 2H_2O \rightarrow Zn(OH)_2 + H_2 \qquad [2c]$$

$$Mn + 2H_2O \rightarrow Mn(OH)_2 + H_2 \qquad [2d]$$

$$Pb + 2H_2O \rightarrow Pb(OH)_2 + H_2 \qquad [2e]$$

With pure Mg only reaction [2a] occurs. With AZ61, the most common anode material, reactions [2a] through [2d] occur. With AP65, a recently developed anode, all five of the reactions occur.

Since the hydroxides are insoluble, one would expect them to be quantitatively precipitated, leaving only the $MgCl_2$ from reaction [1] in solution. Analyses of the effluents from batteries that use either AZ61 or AP65 showed that this is the case (2).

The above should be true for any battery using Mg alloy anodes with constituents that form insoluble hydroxides. Therefore, an aqueous $MgCl_2$ solution closely simulates the effluent from a fresh water-activated AgCl-Mg alloy battery.

Experimental Studies

The methods we used to determine the electrolytic conductivities have been reported (2). The electrolytes were prepared from a stock solution made from analytical grade $MgCl_2 \cdot 6H_2O$. Values of the $MgCl_2$ concentration of the stock solution were calculated from chloride and magnesium determinations. The two methods gave results which agreed to within 0.57% of each other. The composition given by the intrinsically more precise chloride determination was used in formulating the electrolytes utilized in this study.

Taking into account uncertainties in cell constant, resistance, temperature, $MgCl_2$ concentration, and the effects of evaporation, maximum uncertainties in electrolytic conductivity ranged from ±1.5% at room temperature or below up to +2.2 to −1.5% at 75°C, where evaporation errors were significant. These uncertainties are based on an error analysis presented in Ref. (1) with a 0.5% maximum uncertainty in the value of $MgCl_2$ concentration in the stock solution.

Results

The electrolytic conductivities obtained from this study are presented in Table I. They agree to within 0.5% or better with the results of Shedlovsky and Brown (3), which should be more precise than those of this study since they used a more accurate method of formulating $MgCl_2$ solutions and since they also used more accurate techniques for determining conductivity.

Kondrat'ev and Nikich (4) determined the electrolytic conductivity of $MgCl_2$ solutions over a temperature range of 25°-300°C (requiring autoclave-type equipment). Their results differed from the results of this study by ±2% at 25°C and ±4% at 35°C. At both temperatures the disagreement decreased from positive values at 5.0 weight per cent (w/o) to negative values at 2.0 w/o, indicating that a systematic error in composition may have existed in their solutions. No systematic error in the concentration was likely in our study as a single stock solution was used to formulate all the electrolytes.

Kondrat'ev and Gorbachev (5) described the cell used by Kondrat'ev and Nikich but did not mention the use of platinized platinum. They simply stated that the electrodes were composed of platinum wire. Thus, the possibility exists that a lack of platinized platinum might also account for the observed discrepancies.

Comparisons were made with the data of Urazov and Tavkesheva (6), who used stock solutions whose concentration was based on the assumption of saturation (great care was taken by them to assure saturation). Good agreement (−1.04%) was observed at 6 w/o $MgCl_2$, but very poor agreement (+6.35% and +8.14%) was obtained at 2.0 and 4.0 w/o, respectively. Since the technique used by Urazov and Tavkesheva to determine the electrolytic conductivity appeared to be reliable, the lack of agreement is more likely due to errors in concentration. As stated previously, Urazov and Tavkesheva diluted their saturated solutions to obtain solutions of the desired concentration. Although they checked the concentrations of their saturated solutions by density determinations, these checks could allow significant errors in concentration, for example, 6% at 4 w/o.

Although the above hypotheses on possible errors in the work of Kondrat'ev *et al.* and Urazov *et al.* cannot be substantiated because the information given in the literature is inadequate, the results presented in Table I are believed to be accurate to within the maximum uncertainties given for this study because (*a*) a proven technique was used, the electrolytic conductivities obtained for sea water using the same method and equipment agreed to within 0.7% with those of Thomas *et al.* (7), and (*b*) the agreement with Shedlovsky and Brown's (3) results was excellent.

On the Relation between Standard Potentials and Activity of Interstitial Silver Ions in AgCl and AgBr

Arnold Hoffman

Research Laboratories of Polaroid Corporation, Cambridge, Massachusetts 02139

There have been several reports (1, 2) indicating that interstitial silver ions, Ag^+_i, are involved in the reduction of a silver halide. Awad (3) recently pointed out that it is likely that the potential of a silver electrode varies with the activity of Ag^+_i in an adhering silver bromide crystal in an analogous manner to the activity of silver ions, Ag^+, in solution.

It is the purpose of this note to show that the difference in the standard potentials between a Ag/AgCl electrode and a Ag/AgBr electrode, $\Delta E°$, can be ascribed to the difference in activity of Ag^+_i in the respective silver halide crystals.

The thermodynamic relations of lattices can be found in textbooks of solid-state physics or chemistry.

Key words: silver chloride, silver bromide, interstitial silver ions, Frenkel defects.

For the sake of clarity these relations will be stated for the special case of silver halides, *e.g.*, AgCl, AgBr, where the defects are mainly of the cationic Frenkel type.

Using the notation of Kröger (4) and Honig *et. al.* (5, 6), a vacant site is denoted by V^{z}_{J-D}, an interstitial ion by J^{z}_{i-D}, and an ion on a normal lattice site by K_{J-D}, where J and K denote chemical species (J and K may be the same chemical species), D the specific silver halide lattice, V vacancy, i interstitial and z formal charge. The number of vacancy and interstitial ions are related by electroneutrality and chemical equilibrium; *e.g.*, for a pure silver halide, the total number of negative defects is equal to the total number of positive defects, *i.e.*

$$[V^{-}_{Ag-D}] + [X^{-}_{i-D}] = [V^{+}_{X-D}] + [Ag^{+}_{i-D}] \quad [1]$$

where

V^{-}_{Ag-D} = silver ion vacancy

X^{-}_{i-D} = interstitial halide ion

V^{+}_{X-D} = halide ion vacancy

Ag^{+}_{i-D} = interstitial silver ion

and

$$V^{-}_{Ag-D} + Ag^{+}_{i-D} \rightleftarrows Ag_{Ag-D} \quad [2]$$

where

Ag_{Ag-D} = silver ion in lattice position (An occupied lattice site is considered to have zero formal charge.)

For a pure silver halide

$$[V^{+}_{X-D}] = [X^{-}_{i-D}] \approx 0 \quad [3]$$

and Eq. [1] becomes

$$[V^{-}_{Ag-D}] = [Ag^{+}_{i-D}] \quad [4]$$

i.e., the number of interstitial silver ions is equal to the number of silver ion vacancies.

The thermodynamics of defects in solids can be treated in a manner analogous to the thermodynamics of solutes in solution. The vacancies and interstitial ions are to be compared to anions and cations, respectively. The silver halide lattice is to be compared to the solvent. On the assumption of ideal behavior, chemical potentials μ_{J-D}, can be expressed as functions of standard chemical potentials μ°_{J-D}, concentration of lattice sites N_{L-D}, of interstitial silver ions N_{i-D}, and of vacant silver sites N_{V-D} (N_i, $N_V \ll N_L$, N can be expressed in mole/cm^3).

The silver ion in a normal lattice position is chosen as the reference point for the thermodynamic scale (5, 6). On the assumption of ideal behavior, a silver ion in a AgCl lattice position is at the same thermodynamic point as a silver ion in a AgBr lattice position. Since this has been chosen as the reference point for the thermodynamic scale, the difference in the chemical potential of silver ions between AgCl and AgBr can be expressed in terms of the respective population of defects, *i.e.*, interstitials and vacancies.

Hence, for a silver halide crystal, with mole fractions $X_{J-D} = N_{J-D}/N_{L-D}$ introduced, we may write

$$\mu_{i-D} = \mu^{\circ}_{i-D} + RT \ln [X_{i-D}/\beta] \quad [5]$$

where β denotes the number of available interstitial sites per silver ion. (For AgBr and AgCl $\beta = 2$.)

$$\mu_{V-D} = \mu^{\circ}_{V-D} + RT \ln X_{V-D} \quad [6]$$

$$\mu_{AgAg-D} = \mu^{\circ}_{AgAg-D} + RT \ln X_{AgAg-D} \quad [7]$$

but,

$$X_{AgAg-D} \approx 1$$

and

$$\mu^{\circ}_{AgAg-D} \equiv 0 \qquad \text{(reference state)}$$

therefore

$$\mu_{AgAg-D} = 0 \quad [8]$$

If equilibrium has been attained for reaction [2], then the difference in the chemical potential of silver ions in the product and reactant states, $\Delta\mu_D$, equals zero, *i.e.*

$$\Delta\mu_D = \mu_{AgAg-D} - (\mu_{i-D} + \mu_{V-D}) = 0 \quad [9]$$

Substituting [8] into [9]

$$\Delta\mu_D = -(\mu_{i-D} + \mu_{V-D}) = 0 \text{ (at equilibrium)} \quad [10]$$

Substituting [5] and [6] into [10]

$$\mu^{\circ}_{i-D} + RT \ln[X_{i-D}/\beta] + \mu^{\circ}_{V-D} + RT \ln X_{V-D} = 0 \quad [11]$$

but from Eq. [4]

$$X_{i-D} = X_{V-D} \quad [12]$$

Substituting [12] into [11]

$$(\mu^{\circ}_{i-D} + \mu^{\circ}_{V-D}) = -RT \ln [(X_{i-D})^2/\beta] = (\mu^{\circ}_{I} + \mu^{\circ}_{V})_D \quad [13]$$

If D represents AgBr, then

$$\tfrac{1}{2}(\mu^{\circ}_{i} + \mu^{\circ}_{V})_{AgBr} = RT \ln (1/X_{i-AgBr}) + \tfrac{1}{2}RT \ln \beta \quad [14]$$

For AgCl (assuming $\mu^{\circ}_{AgAg-AgCl} = \mu^{\circ}_{AgAg-AgBr} = 0$, Eq. [8] is applicable).

$$\tfrac{1}{2}(\mu^{\circ}_{i} + \mu^{\circ}_{V})_{AgCl} = RT \ln (1/X_{i-AgCl}) + \tfrac{1}{2}RT \ln \beta \quad [15]$$

The difference in standard chemical potential of silver ions between AgCl and AgBr is given by

$$\tfrac{1}{2}(\mu^{\circ}_{i} + \mu^{\circ}_{V})_{AgCl} - \tfrac{1}{2}(\mu^{\circ}_{i} + \mu^{\circ}_{V})_{AgBr} = RT \ln [X_{i-AgBr}/X_{i-AgCl}] \quad [16]$$

The electrical work done on a charge, q, when its potential is changed ΔV, is $q\Delta V$. In transferring positive charge (interstitial silver ions) from the negative (AgBr) electrode to the positive (AgCl) electrode, electrical work is done on the cell. The work is equal to $+ nF\Delta E^{\circ}_s$, where nF is the number of charges per mole ($n = 1$), and ΔE°_s is the potential difference between AgCl and AgBr. Therefore, in the cell

$$(-)\ Ag/AgBr/Br^{-}//Cl^{-}/AgCl/Ag(+)$$

Eq. [16] becomes

$$\Delta E^{\circ}_s = [\tfrac{1}{2}(\mu^{\circ}_{i} + \mu^{\circ}_{V})_{AgCl} - \tfrac{1}{2}(\mu^{\circ}_{i} + \mu^{\circ}_{V})_{AgBr}]/F = RT/F \ln [X_{i-AgBr}/X_{i-AgCl}] \quad [17]$$

The values of $(\mu^{\circ}_{i} + \mu^{\circ}_{V})_{AgCl}$ and of $(\mu^{\circ}_{i} + \mu^{\circ}_{V})_{AgBr}$ [as obtained from application of the Boltzmann distribution law to data of ionic conductivity *vs.* temperature (7)] are 1.4 and 1.1 eV, respectively, or 1.4 and 1.1 volt-faradays per mol (1 $V\mathbf{F}$ = 96487 joules = 23061 calories). Substituting these values into Eq. [17] gives

$$\Delta E^{\circ}_s = RT/n\mathbf{F} \ln[X_{i-AgBr}/X_{i-AgCl}] = +150 \text{ mV} \quad [18]$$

This value is in excellent agreement with the difference in the standard Gibbs-Stockholm potentials between Ag/AgCl and Ag/AgBr electrodes: + 0.2222V and + 0.0713V, (*vs.* standard hydrogen electrode), respectively (8). Thus, the difference in standard potentials reflects the differences in equilibrium population of interstitials. It would seem, therefore, that the suggestion above, that the potential of a silver electrode varies with the activity of Ag^{+}_{i} in an adhering silver halide crystal in an analogous manner to the activity of silver ions, Ag^{+}, in solution, is correct.

Rapid Mass Transport to Electrodes in Foamed Electrolyte

Leonard Nanis* and Frank McLarnon[1]

School of Chemical Engineering, University of Pennsylvania, Philadelphia, Pennsylvania 19104

Foamed electrolyte, prepared by adding commercially available foaming agents to KOH and H_2SO_4 solutions has certain potentially attractive features. Gas saturation should proceed rapidly by diffusion into the foam bubble walls. The open foam structure should also permit ready removal of reaction products. By comparison, the porous electrodes used in conventional fuel cells must permit the transport and reaction of fuel gases as well as waste products removal within the complex pathways of the pore structure. Foam may be readily produced by the dispersion of fuel gas in concentrated electrolytes containing nonelectrochemically active foaming agents. Overpotential-current density studies have been made with smooth platinum electrodes immersed completely in the liquid electrolyte which is stirred by the entry of fuel gas to provide a comparison for similar measurements with electrodes totally in foam.

Experimental

The apparatus consisted of two standard Pyrex reaction kettles (500 cc) joined by a simple inverted U-tube electrolyte bridge. The kettle tops were fitted with rubber stoppers through which passed the bridge, reference and working electrodes, and a gas inlet (hydrogen, oxygen, helium) connected to a standard dispersion tube (15-20μ pore size). The anode compartment is shown in Fig. 1. The working platinum electrodes were spot-welded to a Pt wire sealed into a glass tube which was vertically movable to permit electrode positioning. A platinized-platinum electrode in contact with hydrogen saturated anolyte (either liquid or foam) provided a hydrogen reference electrode (shown schematically as the probe in Fig. 1) for the anode studies. A silver electrode was used for convenience in the cathode compartment and was frequently checked for stability against the hydrogen reference. For background studies with helium gas, a hydrogen reference electrode was separated from the anolyte by a fritted glass barrier, obtained conveniently by the use of a gas dispersion tube. The cell was operated in a driven mode in a simple constant current circuit obtained with a d-c power supply with current regulated with a decade resistance box. Electrode overpotentials were measured with a Hewlett-Packard 3430A digital voltmeter (10^7 ohm input impedance).

Electrolytes were prepared with once-distilled water and technical grade reagents without further purification. The pretreatment sequence consisted of purging each cell for about 1 hr with helium gas at about 15 cc/min through each of the 500 cc compartments. Midway through this purging, the platinum electrodes were activated with a current of about 20 mA/cm^2 reversed once a second for about twenty seconds as recommended by Petrii and Shchigorev (2). The same pretreatment sequence was used for H_2 and O_2 bubbled through the anode and cathode compartments, and for background current determinations in the presence of helium stirring. Gas purities were: H_2, 99.8%; O_2, 99.5%; He, 99.995. All gases were used without further purification.

In 4*N* H_2SO_4, the current reversal treatment gave an open circuit cell potential of 1.0V within a few minutes

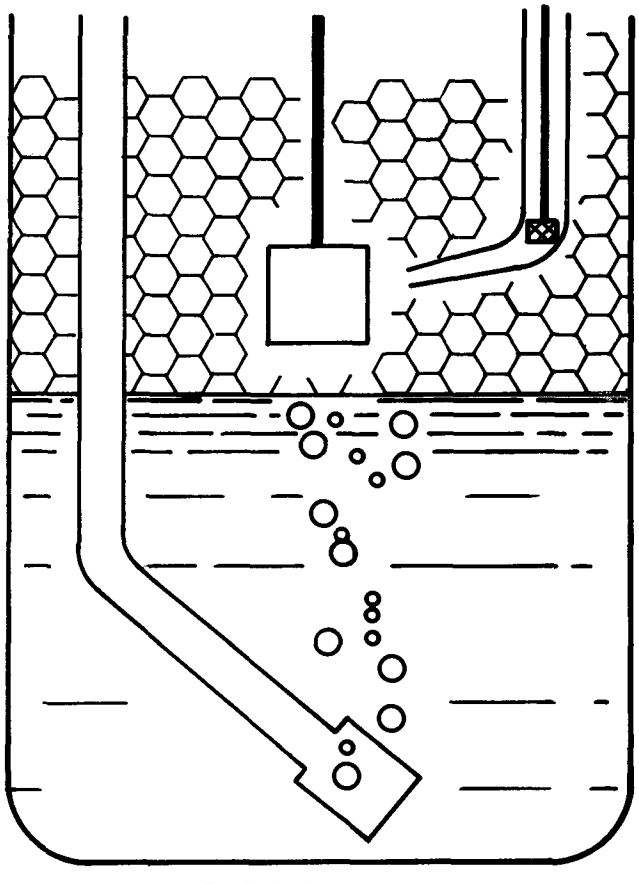

Fig. 1. Anode compartment

[1] Present address: Department of Chemical Engineering, University of California, Berkeley, California 94720.

after treatment, declining gradually to about 0.85V after 5-10 min. In KOH (2-6*N*), the potential reached about 1.0-1.1V within 1-5 min after activation, changing very little thereafter.

Following helium pretreatment, a blank test with helium stirring was conducted. Anode and cathode overpotentials were recorded for current density steps of 10 μA/cm^2 up to 100 μA/cm^2 both in the electrolyte well-stirred by helium bubbles and in the foam above the electrolyte. After H_2 and O_2 pretreatment, anode and cathode overpotentials were recorded for 0.1 mA/cm^2 steps to 1.0 mA/cm^2 for the electrolyte immersed completely in the well-stirred liquid electrolyte, and at 0.5 mA/cm^2 intervals up to 12 mA/cm^2 for the electrode withdrawn completely into the foam. At each current, steady potentials were recorded with the time for attainment of steady overpotentials usually less than 30 sec except near the limiting current density where times on the order of one minute were needed. For studies of the anode (square electrode, Fig. 1) immersed in liquid, stirring was provided by positioning the electrode directly in the ascending stream of hydrogen bubbles.

For a typical run (using 0.2 weight per cent [w/o] Carboxane TW-100, Textilana Corp., Hawthorne, Calif.) in 4*N* H_2SO_4 electrolyte at 22°C, the foam height measured from the liquid-foam interface increased from 3 cm to 10 cm as the gas flow rate was increased from 0.5 cc/min to 20 cc/min. As the temperature was increased from 7° to 65°C, the foam level (for a flow rate of 4 cc/min) decreased from 5 cm to 1 cm. However, the anodic limiting current density remained at 9 ± 0.5 mA/cm^2 over the temperature range. For foam height under 2 cm, the upper section of the 2 x 1.4 cm smooth platinum electrode was uncovered by foam.

For studies with 0.2 w/o Actrasol PSR foamant (A. C. Trask Co., Chicago, Illinois), the foam level at constant gas flow rate decreased from 5 cm to essentially no foam (even at gas flow rates greater than 100 cc/min) as the KOH electrolyte concentration was increased from 2 to 6*N*.

Results and Discussion

Various foaming agents were initially tested in both 4*N* H_2SO_4 and 2*N* KOH. Oxidizable or reducible agents, as determined by current passage in the blank helium test, were rejected. Foaming agents chosen for study generally produced an order of magnitude improvement in current when the electrodes were withdrawn from the liquid electrolyte into the foam.

In 4*N* H_2SO_4, best results were obtained with Carboxane TW-100, an alcohol ethoxylate, which gave a nearly constant foam level and essentially invariant overpotential-current density response at foamant concentrations ranging from 0.02 to 1.0 w/o. In KOH, the agent giving the greatest current increase was Actrasol PSR, potassium sulfo-ricinoleate, used at 0.2 w/o in 2-6*N* KOH. Comparison of various foamants is shown in Table I.

The current density-overpotential behavior for H_2 oxidation in liquid and in foam for Carboxane TW-100 in 4*N* H_2SO_4 is shown in Fig. 2. The lowest curve, designated "in foam" (triangle points), was obtained for foam produced by helium bubbling. A nearly similar curve (not shown) was obtained for the helium-stirred liquid background anode determination. Clearly defined anode limiting current densities (*cf.* Fig. 2) were obtained for hydrogen oxidation in all solutions tested and were used to compute an equivalent mass transfer boundary layer thickness, assuming uniform current density distribution. Hydrogen diffusion and solubility data (uncorrected from 30°C) of Ruetschi (1) were used in the expression

$$J_{lim} = \frac{nF\mathcal{D}C_b}{\delta} \qquad [1]$$

Results are shown in Table I. Clear resolution of cathodic limiting current densities was not generally obtained, so that δ values were not calculated. However, cathodic currents were always greater in foam than in bubble-stirred electrolyte. An index of the foam effect is the ratio of cathodic oxygen reduction current in foam to current in stirred liquid at a potential of 0.4V with respect to the hydrogen reference electrode of the anode compartment. The foam-liquid current ratio ranged from 26 for Actrasol PSR in 4*N* KOH to low values of 3.7 for Aromox T/12 in 2*N* KOH and 1.6 for BRIJ 30 in 4*N* H_2SO_4. At a potential of 0.1V, the foam-liquid current ratio for BRIJ 30 in 4*N* H_2SO_4 increased to 3.4, while the ratio for Aromox T/12 in 2*N*

KOH was 5.8. It should be noted that the foam-liquid current ratio for Actrasol PSR in 4*N* KOH was essentially constant over a wide potential range (32 at 0.65V, 30 at 0.1V). Cathode current density in foam ranged from 3 mA/cm^2 at 0.65V to 9 mA/cm^2 at 0.1V. Table I shows that boundary layer thickness for the anode immersed in electrolyte stirred by hydrogen varies between 46 and 83μ as the flow rate varies from 9 to 4 cc/min in 500 cc of liquid, *i.e.*, as expected, smaller δ was associated with high flow rates. In the foam, the equivalent boundary layer thicknesses are very much less than for the well-stirred electrolyte, with the calculated values grouped chiefly around 3-4μ with an apparent second range of 10-14μ.

The 3-4μ values (Table I) may be explained in terms of a thin film of electrolyte covering the electrode when it is in the foam. Many researchers (3-8) have noted a similar increase in current when electrodes were partially withdrawn from liquid electrolyte into a gas atmosphere. For instance, Will (5) has determined that for a partially withdrawn platinum electrode, the rate-controlling step for hydrogen oxidation is the diffusion of the gas through a thin electrolyte film completely covering the electrode. Also, Burshtein (4) and Müller (9) have optically determined the establishment of an electrolyte film thickness on the order of several microns covering an electrode partially withdrawn from solution. Since present electrochemical determination indicates a mass transfer layer of a few microns in thickness in the foam region, it may be considered that the foam acts to stabilize an electrolyte film on the electrode. Insufficient data are presently available for speculation about the interaction of foamants in electrolytes which produce the 10-14μ range of computed layers.

Will (5), Bennion and Tobias (7), and Burshtein *et al.* (4) have determined that most of the current on a partially immersed electrode is passed in a critical reaction zone, on and near the meniscus. In the foam, since the electrode is completely withdrawn from the solution, there can be no conventional meniscus, and the more uniform film permits more useful electrode surface to be available for reaction.

Further studies of foam conductivity, current distribution and applications of the foam method to electrode reactions will be reported shortly.

Acknowledgments

Financial support of NASA (NSG-316), the NSF Undergraduate Research Program and Matthey-Bishop is gratefully acknowledged as well as the generous loan of platinum electrodes from Matthey-Bishop Inc., Malvern, Pennsylvania, and of foaming agents from the various companies cited in Table I in the text.

Manuscript submitted April 6, 1970; revised manuscript received *ca.* July 30, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1971 JOURNAL.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 116, No. 7 and 11, July and November, 1969, and Vol. 117, No. 1 and 5, January and May, 1970.

Study of the Lithium Oxide-Nickel Oxide System. I. Thermodynamics of Dilute Solid Solutions

S. Pizzini, R. Morlotti, and V. Wagner
(pp. 915-920, Vol. 116, No. 7)

J. Deren and **G. Róg**[1]: By measurements of emf of appropriate solid galvanic cells Pizzini *et al.* determine in their work the thermodynamic properties of solid solutions of Li_2O in NiO. There are some remarks which we would like to make in connection with this problem.

1. In their work Pizzini *et al.* assume the possibility of only one mechanism of incorporation of lithium in an oxidizing atmosphere

$$0.5\,Li_2O + 0.25\,O_2 \rightleftharpoons Li^{\cdot}_{Ni} + O_o + h \qquad [1]$$

As we showed in 1964[2] the mechanism of lithium incorporation is more complicated. In the region of low concentrations of lithium, up to about 0.1 a/o, a number of phenomena have been observed which can be explained only by accepting another mechanism of lithium incorporation in this concentration region. The possible ways of formation of low-concentration solutions of Li_2O in NiO have been suggested also.[2,3] Recent studies on the emf of the appropriate solid cells confirmed the different behavior of the low- and high-concentration solutions.[4,5]

2. In our laboratory we carried out the methodological investigations of measurement of solid galvanic cells given by the scheme

$$Pt|Ni, NiO_{pure}||\text{solid electrolyte}||NiO_{doped}, Ni|Pt \qquad [2]$$

with the use of the lime-zirconia electrolye/0.85 ZrO_2 + 0.15 CaO.[6] In contrast to Pizzini we did not observe the drop of the voltage with time to values close to zero. As may be seen from the data listed in our Table I, a very good constancy of the emf value is observed during the measurement carried out for 10 hr at 900°C.

3. The suggestion of the authors ascribing the observed drop of the voltage (see above) to irreversible migration of lithium from the left-hand compartment to the right-hand one, when $x_2 > x_1$, is not clear to us. As is known, the zirconia-lime electrolyte is defective practically solely in the anion sublattice. It is possible that incorrect sintering of the electrolyte caused the possibility of lithium migration along the grain boundaries. The reproducibility of our results amounted to 0.02 mV.[4,7]

4. Application by the authors of α-Li_2SO_4 as the solid electrolyte raises the question whether, during heating of the samples in the course of measurements conducted at temperatures 570°-850°C, the diffusion of

lithium from the electrolyte to solid solutions of lithium in nickel oxide did not take place. If such diffusion were possible, the cell would then become irreversible. Relatively poor reproducibility of the emf measurements, 5-10 mV, observed in experiments in which this value was low, up to 80 mV, may imply the occurrence of such processes. The studies carried out by us[5,7] on the solid cell given by the scheme

$$Pt|Ni, NiO||0.85ZrO_2 + 0.15CaO||NiO, Li_2O, Ni|Pt \quad [3]$$

indicate that for these temperatures incorporation of Li into the parent lattice of NiO occurs relatively fast, resulting in the formation of the appropriate electromotive force.

5. It appears from the paper that the authors regard solid solutions of lithium oxide in nickel oxide containing below 1.5 a/o Li as ideal solutions. Our studies show that even in this concentration range the solutions cannot be classified as ideal. However, they behave as the regular solutions. In the region of concentration under discussion the activity coefficients depend only slightly on the concentration of Li incorporated, $f_1 \approx f_2$.[7] This is illustrated by the data of our Table II. In our opinion it is due to this fact that the Nernst equation

$$E = \frac{RT}{F} \ln \frac{a_1}{a_2} = \frac{RT}{F} \ln \frac{f_1 x_1}{f_2 x_2} \approx \frac{RT}{F} \ln \frac{x_1}{x_2} \quad [4]$$

is obeyed.

S. Pizzini[7a] and **R. Morlotti:** The work of both Professor Deren and ourselves on the lithium oxide-nickel oxide system was concluded in the same month and independently so we learned only later, unfortunately of the alternative approach used by the authors in footnote 4.

[7a] Now at the Institute of Electrochemistry, University of Milano, Italy.

Table I. Effect of lithium diffusion

	Li ppm in the electrode	Li ppm in the electrolyte	Li ppm in the electrode
Before the experiment	91	—	1860
After the experiment	243	320	1430

With regard to the first point of Professor Deren's remarks, about the possibility that other defect mechanisms, different from the purely substitutional one, which is described by our Eq. [1]

$$0.5\ Li_2O + 0.25\ O_2 \rightarrow Li_{Ni} + O_O + h^{\cdot} \quad [1]$$

could be operative in the range of dilute solutions, we stress the point that we carried out our measurements in a concentration range of dissolved lithium ($x_{Li} > 0.1$ a/o) where also according to footnotes 9 and 10 only the mechanism described by Eq. [1] is active. The omission of comments about other mechanism, however, could have raised some misunderstandings about the role of other defects, such as nickel vacancies in the range of the very dilute solutions. As to the second point, we would like to mention that the cell used by Deren and Rog[8,11,12] is different from that used preliminarily by us, since we fitted lime zirconia (in oxidizing atmosphere) with two electrodes which did not contain any metallic nickel. Table I, published here, which was omitted in our paper, shows the effect of lithium diffusion in the electrolyte, after having operated the cell for some days at 1000°C. Lower temperature (900°C) and excess nickel in the reducing atmosphere might well be responsible for the reduced reactivity of the system, so that we do not see any contradiction between our results and those of Deren and Rog.

We do not exclude the possibility that lithium migration could have taken place along grain boundaries, but this, in our opinion, has nothing to do with the incorrect sintering of the electrolyte. In all polycrystalline materials, and when the temperature is lower or of the order of magnitude of the Tamann temperature, one could never exclude contributions from surface or grain boundary migration. Moreover, it has been demonstrated recently that protons[13] could diffuse with the interstitial mechanism in stabilized zirconia, the order of magnitude of the diffusion coefficient being 10^{-6} cm^2 sec^{-1} at 900°C.

It seems therefore not entirely surprising that a small size ion such as lithium ion is, could diffuse in stabilized zirconia.

As to the other points, it is our opinion that it is rather difficult to compare directly our results with those of footnotes 8, 11, 12. Our results, in fact, refer to samples with known lithium content and known Ni^{3+} content (for details see footnotes 14 and 15 as well as the paper now in discussion) which have been never equilibrated with metallic nickel. Analysis of lithium and Ni^{3+} content before and after each measurement permits the care of the negligible influence of the Li_2SO_4 decomposition in oxygen atmosphere on the lithium content in the electrodes and of the negligible deviations from the 1:1 ratio between the lithium added and entirely dissolved and Ni^{3+} found.

Professor Deren's results, on the contrary, all refer to samples of known lithium content (but possibly not entirely dissolved) and of unknown Ni^{3+} content,

which is presumably inadequate over the 1:1 ratio, due to the presence of metallic nickel.

In our opinion, so far there is no experimental evidence that excess nickel does not influence the 1:1 ratio within the dissolved lithium and localized electron holes (or Ni^{3+}); one has to treat the solutions with and without nickel excess as different solutions. We also raise some doubts on the reliability of the regular solution approach used by Professor Deren and colleagues, just on the basis of the experimental temperature coefficients of concentration cells, calculated with the classical Hildebrand approach from the results reported in footnote 12, which largely differ from the theoretical purely configurational values.

On the Breakdown of Passivity on Stainless Steels in Halide Media

B. E. Wilde and E. Williams, (pp. 1539-1540, Vol. 116, No. 7)

N. D. Greene[16] and **W. D. France, Jr.**[17]: The authors explanation that slight changes in critical pitting potentials are "related to the presence of nonionic, nonelectroactive constituents in the corrodent" prompts this discussion. In our recent study[18] of the critical breakdown potential, E_c, we noted that oxygen produces effects different from other oxidizers because its reduction yields hydroxide. Oxygen reduction can occur during anodic polarization in aerated solutions because of the noble redox potential of the O_2/OH^- couple. As a result, the pH increases at the metal-electrolyte interface which shifts the breakdown potential in the noble direction.[19] Thus, our theoretical model predicts that E_c should become more noble as the O_2 content increases.

Our concept is qualitatively confirmed by the results of Mueller and Greener.[20] The experiments of Wilde and Williams also can be viewed as supporting this mechanism, that is, E_c is more noble in oxygenated solutions than in deaerated media. However, the Wilde-Williams data do not exhibit a direct correlation between E_c and oxygen levels at low concentrations where it appears that the reported oxygen contents are beyond both the accuracy and repeatability of the Beckman Model 778 Process Oxygen Analyzer[21] employed. The accuracy of this instrument is limited by its polarographic sensing probe to $\pm 1\%$. At the lowest range, 2.5 ppm, this introduces an error of ± 0.025 ppm. Consequently, we would be interested in learning more about the author's measurements of oxygen in solution, especially any refinements that were used to obtain the degree of accuracy reported.

B. E. Wilde and **E. Williams:** We would like to thank Drs. Greene and France for their interest in our paper and their comments. In reply, we shall clarify the issues raised in two parts: 1, details regarding the analysis of dissolved oxygen, and 2, the effect of oxygen on the critical pitting potential.

1. Since we made no statements regarding the accuracy of our measurements in our communication, we can only assume that Drs. Greene and France are referring in their discussion to the sensitivity[22] of the oxygen probe measurements. In this regard in connection with other work, one of us (BEW) has determined the limits of sensitivity of an identical polarographic probe to oxygen in pressurized water using an independent method of analysis[23] modified to operate in the range of 0.01-0.1 ppm O_2. Briefly, we exposed a Beckman probe to recirculating pure water at 1200 psig, the oxygen content of which was controlled in the range 0.01-0.1 ppm O_2 by conventional gas sparging techniques.[24] It was found, by using a recorder connected to the Beckman amplifier output, that changes in oxygen concentration in the range 0.025 to 0.05 ppm and up, could be detected, although the absolute accuracy was no better than $\pm 25\%$. However, in no case was a reading observed where the probe output was not qualitatively related to the oxygen content of the water. That is, readings always reflected incremental increases and decreases of oxygen in a qualitative manner. As a matter of interest, the above correlation was not confined to one probe, but was observed on a number of probes used throughout the investigation.

In view of this, we feel that the reported oxygen contents in our paper are qualitatively correct, *e.g.*, more dissolved oxygen resulted after purging with hydrogen than that resulting from argon, etc. We have to concede that the absolute magnitudes of the oxygen concentrations may be somewhat different than the reported values at the lowest levels, but we feel that this point is of minor significance in view of the over-all objectives of our communication.

2. The purpose of our communication was to draw attention to the fact that experimental values of the critical pitting potential could vary (in the case of Type 430 stainless steel in 1*N* NaCl at 25°C) from -0.185 to -0.035 V_{SCE}, depending on whether hydrogen or oxygen, respectively, were employed to purge the corrodent. It was also noted that apparently such nonionic and nonelectroactive substances as argon and nitrogen could also affect E_c by a significant amount rather than a "slight change" as described by Greene and France.

In an attempt to explain this behavior, we suggested that (*a*) hydrogen could be oxidized to H^+ on the anode surface, and (*b*) oxygen could be reduced; these reactions may account for the variation in E_c. More recent studies[25] have shown that the effect of oxygen is due to local pH changes at the metal/electrolyte interface following cathodic reduction of oxygen, a fact which apparently Greene and France surmized in a footnote in their recent paper,[26] yet overlooked in their conclusions regarding the correlation between electrochemical and chemical pitting tests. We could not and still cannot explain the effect of argon and nitrogen.

While there may be some uncertainty about the absolute magnitude of dissolved oxygen resulting from purging with argon and hydrogen as discussed earlier, we feel that two significant facts emerge from the data: (*a*) the variations in E_c observed in argon and nitrogen purged solutions cannot be explained on the oxygen content of the solution alone and (*b*) more importantly we have shown[27] that the pronounced effect of oxygenation on E_c is the cause of the reported lack of correlation between electrochemical and chemical accelerated pitting tests on stainless steels.

Oxidation of C-25 w/o Cr at High Temperatures

which is presumably inadequate over the 1:1 ratio, due to the presence of metallic nickel.

In our opinion, so far there is no experimental evidence that excess nickel does not influence the 1:1 ratio within the dissolved lithium and localized electron holes (or Ni^{3+}); one has to treat the solutions with and without nickel excess as different solutions. We also raise some doubts on the reliability of the regular solution approach used by Professor Deren and colleagues, just on the basis of the experimental temperature coefficients of concentration cells, calculated with the classical Hildebrand approach from the results reported in footnote 12, which largely differ from the theoretical purely configurational values.

On the Breakdown of Passivity on Stainless Steels in Halide Media

B. E. Wilde and E. Williams, (pp. 1539-1540, Vol. 116, No. 7)

N. D. Greene[16] and **W. D. France, Jr.**[17]: The authors explanation that slight changes in critical pitting potentials are "related to the presence of nonionic, nonelectroactive constituents in the corrodent" prompts this discussion. In our recent study[18] of the critical breakdown potential, E_c, we noted that oxygen produces effects different from other oxidizers because its reduction yields hydroxide. Oxygen reduction can occur during anodic polarization in aerated solutions because of the noble redox potential of the O_2/OH^- couple. As a result, the pH increases at the metal-electrolyte interface which shifts the breakdown potential in the noble direction.[19] Thus, our theoretical model predicts that E_c should become more noble as the O_2 content increases.

Our concept is qualitatively confirmed by the results of Mueller and Greener.[20] The experiments of Wilde and Williams also can be viewed as supporting this mechanism, that is, E_c is more noble in oxygenated solutions than in deaerated media. However, the Wilde-Williams data do not exhibit a direct correlation between E_c and oxygen levels at low concentrations where it appears that the reported oxygen contents are beyond both the accuracy and repeatability of the Beckman Model 778 Process Oxygen Analyzer[21] employed. The accuracy of this instrument is limited by its polarographic sensing probe to $\pm 1\%$. At the lowest range, 2.5 ppm, this introduces an error of ± 0.025 ppm. Consequently, we would be interested in learning more about the author's measurements of oxygen in solution, especially any refinements that were used to obtain the degree of accuracy reported.

B. E. Wilde and **E. Williams:** We would like to thank Drs. Greene and France for their interest in our paper and their comments. In reply, we shall clarify the issues raised in two parts: 1, details regarding the analysis of dissolved oxygen, and 2, the effect of oxygen on the critical pitting potential.

1. Since we made no statements regarding the accuracy of our measurements in our communication, we can only assume that Drs. Greene and France are referring in their discussion to the sensitivity[22] of the oxygen probe measurements. In this regard in connection with other work, one of us (BEW) has determined the limits of sensitivity of an identical polarographic probe to oxygen in pressurized water using an independent method of analysis[23] modified to operate in the range of 0.01-0.1 ppm O_2. Briefly, we exposed a Beckman probe to recirculating pure water at 1200 psig, the oxygen content of which was controlled in the range 0.01-0.1 ppm O_2 by conventional gas sparging techniques.[24] It was found, by using a recorder connected to the Beckman amplifier output, that changes in oxygen concentration in the range 0.025 to 0.05 ppm and up, could be detected, although the absolute accuracy was no better than $\pm 25\%$. However, in no case was a reading observed where the probe output was not qualitatively related to the oxygen content of the water. That is, readings always reflected incremental increases and decreases of oxygen in a qualitative manner. As a matter of interest, the above correlation was not confined to one probe, but was observed on a number of probes used throughout the investigation.

In view of this, we feel that the reported oxygen contents in our paper are qualitatively correct, *e.g.*, more dissolved oxygen resulted after purging with hydrogen than that resulting from argon, etc. We have to concede that the absolute magnitudes of the oxygen concentrations may be somewhat different than the reported values at the lowest levels, but we feel that this point is of minor significance in view of the over-all objectives of our communication.

2. The purpose of our communication was to draw attention to the fact that experimental values of the critical pitting potential could vary (in the case of Type 430 stainless steel in 1*N* NaCl at 25°C) from -0.185 to -0.035 V_{SCE}, depending on whether hydrogen or oxygen, respectively, were employed to purge the corrodent. It was also noted that apparently such nonionic and nonelectroactive substances as argon and nitrogen could also affect E_c by a significant amount rather than a "slight change" as described by Greene and France.

In an attempt to explain this behavior, we suggested that (*a*) hydrogen could be oxidized to H^+ on the anode surface, and (*b*) oxygen could be reduced; these reactions may account for the variation in E_c. More recent studies[25] have shown that the effect of oxygen is due to local pH changes at the metal/electrolyte interface following cathodic reduction of oxygen, a fact which apparently Greene and France surmized in a footnote in their recent paper,[26] yet overlooked in their conclusions regarding the correlation between electrochemical and chemical pitting tests. We could not and still cannot explain the effect of argon and nitrogen.

While there may be some uncertainty about the absolute magnitude of dissolved oxygen resulting from purging with argon and hydrogen as discussed earlier, we feel that two significant facts emerge from the data: (*a*) the variations in E_c observed in argon and nitrogen purged solutions cannot be explained on the oxygen content of the solution alone and (*b*) more importantly we have shown[27] that the pronounced effect of oxygenation on E_c is the cause of the reported lack of correlation between electrochemical and chemical accelerated pitting tests on stainless steels.

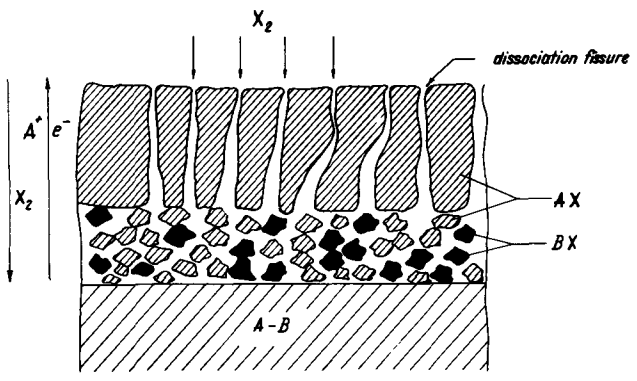

Fig. 2. Schematic representation of outward lattice diffusion of the basis metal and of inward diffusion of the oxidant.

eral problems involved in the theory of oxidation of metals and alloys. In particular these authors pay much attention to the mechanism of transport of matter through the scale in the course of oxidation of Co-Cr alloys. This problem has been extensively studied also in our laboratories.[32-41] On the basis of model studies carried out on the Ag-Zn-S, Cu-Zn-S, Ni-Cr-S, and Fe-Cr-S systems we proposed a new model for the mechanism of formation of double layer, heterophase scales on binary alloys. The model pertains to the systems in which the oxidation products of the alloy components do not form solid solutions, and the defect structure of which is confined solely to the cation sublattice. It was shown that the heterophase scale grown on the alloys of this type (Cu-Zn, Fe-Cr, Ni-Cr, Co-Cr, etc.) is composed as a rule of two layers: the outer monophase layer and the inner heterophase layer. The outer layer is built of the compound of the base metal with an oxidant, the base metal being in the alloys of this type the nobler one. The inner layer on the other hand is built of the heterophase mixture of compounds of both alloy components with an oxidant, and in the case when these compounds form the spinel phases, the inner scale layer may by triple or even multiphase. The scales of this type show as a characteristic feature a complete or practically complete lack of the plastic flow of the reaction products, which is reflected in the characteristic morphologic cross section of the scale. The boundary between the two scale layer corresponds, irrespective of the reaction time and the shape and size of the element under oxidation, to the initial surface of the alloy specimen. Another proof of the lack of the plastic flow of the scale is provided by the location of a marker, which, irrespectively of the reaction time, *i.e.*, of the scale thickness, is found at the boundary between the two scale layers. On the other hand in the case of monophase scales on pure metals, or on alloys, the scale in the region of flat surfaces undergoes considerable plastic deformation, resulting in the shift of the marker together with the scale toward the metallic core. The two limiting cases mentioned above are illustrated schematically in Fig. 1.

Lack of plastic flow in the case of the heterophase scale on alloys constitutes the main reason for the different mechanism of the scale formation in this case as compared with the mechanism of formation of the monophase scales. The islets of phase BX formed on the core surface made impossible, practically from the first moments of the reaction, preservation of the full contact between outer AX layer and the metallic core. This leads to dissociative decomposition of the outer layer, which occurs mainly along the perpendicular to the core grain boundaries of the scale crystals. Since dissociation commences in the case under discussion practically instantaneously after formation of the primary outer layer, the anisotropic decomposition results in the instantaneous destruction of the layer compactness in its entire cross section. Further growth of the scale proceeds then due to the outward lattice diffusion of the basis metal A and the inward diffusion of the oxidant as shown schematically in Fig. 2. As mentioned above the dissociative model of the mechanism governing formation of the double-layer heterophase scales on alloys, is based on the results of model experiments carried out with the use of radioactive isotope of sulfur ^{35}S.[32-41] Veracity of this model with respect to oxide scales was confirmed in experiments with the use of the stable isotope of oxygen ^{18}O.[42]

Extensive studies by Hed and Kofstad concerning morphologic structure of heterophase scales on Co-Cr alloys allow one to suppose that the mechanism of formation of these scales is in accordance with the dissociative model proposed by Brückman, Mrowec, and Werber, Fig. 2. Such a conclusion is supported particularly by the fact that the boundary between the two scale layers corresponds to the initial surface of the alloy. In contradiction to Hed and Kofstad's suggestions we believe that this fact implies the absence of the plastic flow of the scale. Further proof for the dissociative mechanism of formation of the scales under consideration is provided by the porosity of both scale layers observed by Hed and Kofstad. They indeed ascribe the porosity of the outer layer to the existence of the dissociative mechanism; however, they do not draw consistent conclusions from this fact. The works of Hed and Kofstad contain a number of experimental proofs confirming the dissociative mechanism proposed by us. Some of their facts cannot even be explained satisfactorily in terms of the other theories. In particular these authors have shown the presence in the outer scale layer of micropores situated perpendicular to the core, grouped mainly along grain boundaries (Fig. 14[29] and Fig. 13a[31]). A further experimental fact which has not been explained satisfactorily consists of the formation at the corners of the alloy sample Co-25% Cr, oxidated at low pressures of oxygen, of the heterophase scale, whereas at the same time in the region of flat surfaces the monophase scale composed of chromic oxide was observed. Such a structure of the scale results evidently from the dissociative mechanism. At the sample corners namely, plastic

deformations of the monophase scale are considerably hindered owing to geometrical rigidity of the system.[34-39] Therefore in this region anisotropic dissociation leads practically instantaneously to the destruction of the compactness of the primary Cr_2O_3-layer and consequently to the formation of the heterophase scale. In the region of the flat surface on the other hand, the monophase scale is subjected to plastic deformations, which ensures its considerably longer contact with the metallic core, and thus good compactness of the scale during the longer reaction time.

We would like to conclude that the results of the studies by Kofstad and Hed may be readily interpreted in terms of the dissociative model of the mechanism governing formation of heterophase scales on binary alloys.

Solid Ionics—Solid Electrolyte Cells

T. Takahashi and O. Yamamoto (pp. 1-5, Vol. 117, No. 1)

G. Pistoia and **B. Scrosati**[43]: The authors report that the x-ray diffraction pattern of $RbAg_4I_5$, prepared according to the method described by Owens and Argue,[44] showed lattice parameter identical with that reported in literature. Nevertheless the authors found a $RbAg_4I_5$ specific conductivity of 0.170 ohm^{-1} cm^{-1}, a value which is 0.090 ohm^{-1} cm^{-1} less than that found by Oxley and Humphrey.[45] Since this difference in conductivity values cannot certainly be included in the experimental errors, do the authors have some explanation for their low conductivity data? In this respect it may be useful to report an observation made in our laboratory when measuring the specific conductivity of $RbAg_4I_5$ pellets in function of the compression pressure. We found that the conductivity depends to a certain extent on the compression pressure of the electrolyte pellets.[46] Since Takahashi and Yamamoto report that the electrolyte pellets utilized in their solid state cells were compressed at 5 tons/cm^2, it seems reasonable to believe that also the pellets for the conductivity measurements were compressed at the same pressure. If this assumption is valid, the relatively low conductivity value found by the authors may find its explanation since we have found that at 5 tons/cm^2 the $RbAg_4I_5$ conductivity is of the order of 0.178 ohm^{-1} cm^{-1}.

For a cell using a mixture of $Te,RbAg_4I_5,Ag_2Te$ and graphite as cathode, the authors claim an internal resistance of 1 ohm at room temperature. From the cell discharge curves, reported in Fig. 8 of the paper, however, the internal resistance results in average to be of the order of 15 ohms, a value which seems to be more realistic.

Furthermore, from the polarization curve at 25°C of Fig. 3 it results that at 10 mA/cm^2 the anodic polarization becomes severe. Nevertheless flat discharge curves at 10 mA/cm^2 are reported in Fig. 9. It seems very difficult to give an explanation of this point unless considering that the charging process has some depolarizing effect on the anode.

In conclusion our opinion is that the work of Professors Takahashi and Yamamoto is interesting because it shows the feasibility of selenium and tellurium as cathode materials in $RbAg_4I_5$ solid electrolyte cells, and therefore we would appreciate some comments on the relatively low value of the conductivity of the electrolyte, on the discrepancy between the reported internal resistance value and the one derived from the discharge curves, and finally, on the discharge curves at 10 mA/cm^2.

T. Takahashi: The difference between the conductivity values of $RbAg_4I_5$ measured by us and by Oxley and Humphrey seems to be due to the difference of the state of the electrode used. We used a silver plate as the electrode while Oxley used a mixture of silver powder and $RbAg_4I_5$. This sort of discrepancy in conductivity value has been pointed out by Owens and Argue[47] comparing their value with that obtained by Bradley and Greene.[48] We have obtained a conductivity value of 0.24 ohm-cm^{-1} at 25°C using the mixture of silver powder ond $RbAg_4I_5$ as electrode. This value is somewhat smaller than that obtained by Oxley, and this is considered to be due to the difference of the contact resistance between the electrode and the electrolyte and the difference of the moulding pressure of the specimen as pointed out by Professor Scrosati.

The internal resistance 1 ohm of the cell Ag/$RbAg_4I_5$/Te, $RbAg_4I_5$, graphite was the value measured by 1,000 Hz a-c bridge, and the internal resistance obtainable by Fig. 8 should be higher than 1 ohm owing to the polarization resistance at anode and cathode being added. The value of the resistance measured by the interrupter method was 1 ohm.

In the anode polarization measurement shown in Fig. 3, the silver plate electrode was used, while in the cell shown in Fig. 9, a mixture of silver powder and $RbAg_4I_5$ was used as the electrode. This is the reason why the appreciable polarization was not found in the case of Fig. 9 at the apparent current density of 10 mA/cm^2.

Galvanostatic Overpotential Transients and Electrocrystallization Processes on Copper Single Crystals in Solutions of Cupric Perchlorate

L. H. Jenkins (pp. 630-640, Vol. 117, No. 5)

R. Piontelli, B. Rivolta,[49] **G. Poli,**[50] and **G. Serravalle**[51]: The systematic work on the single crystal electrodes carried out by Dr. Jenkins, with the aim of throwing some light on the dark mystery of the kinetics and morphology of the electrocrystallization and electrodemolition processes of metals, is fully acknowledged. No doubt, the use of single crystal electrodes is an indispensable step in view of any true progress along this route.

The very extensive research work carried out here in this field[52] has clearly shown, however, the difficulties encountered in controlling: (*a*) the nature and density of the defects interesting the electrode surface, and (*b*) the surface states.

As a matter of fact, the most carefully prepared surfaces appear to be especially sensitive to the various contamination sources, arising not only from the preparation and handling of the electrodes, but from traces of organic matter on the walls of the measurement cells or present in the solution.

The influence of the ensuing contamination may concern both morphology and kinetic laws (especially in the low current density range). It is a predominant source of the appearance of transient overvoltage maxima in galvanostatic conditions with single crystal electrodes and especially with perchlorate baths.

Overvoltage maxima have been observed by us too at the start of our work: (*a*) in the deposition on foreign cathodes,[53] and (*b*) in anodic and cathodic exchange processes of the ions of the electrode metal.

A test of credibility for the meaning of these phenomena appeared to us to be the quite regular obedience to the (generalized) Tafel-law.

We noticed moreover a conspicuous influence of the anion, a point deserving successive comments.

For (b), however, the decisive progress in experimental techniques, successively attained here[54] have led to the systematic disappearance of the maxima from our oscillographic recordings, together with a strong reduction of the quasi-steady overvoltages.

Among the necessary cares, we recall: (i) the use of only glass-metal cells, whose form and interior wall-surface must allow a very radical cleaning before use, and (ii) the prolonged galvanic prepurification of the solution[55] in a separate compartment of the cell, from which the solution may be successively introduced (by inert gas pressure) in the measurement compartment, where the electrode has been previously placed, in accurately controlled surface conditions.

For the $Cu/Cu(ClO_4)_2$ electrodes, the Jenkins result may be compared with those obtained here, with the techniques above, by G. Poli and B. Rivolta.[56]

The bath utilized by Poli and Rivolta was $Cu(ClO_4)_2$ 0.5M + $HClO_4$ 1M [for Jenkins: $Cu(ClO_4)_2$ 0.2M; pH 1] and the explored c.d. range 2-100 A/m^2 (instead of 0.01-4 A/m^2 for Jenkins.

Our experiments[57] indicate:

1. dissymmetry between anodic and cathodic overvoltages (higher for the last) on all of the studied orientations: (111), (110), (100) (in the Jenkins experiments only for (111));
2. the anodic quasi-steady cathodic overvoltages decrease in the order: (100) > (111) > (110) according to both Jenkins and our experiments;
3. on the cathodic side, at c.d. lower than about 40 A/m^2, the overvoltages (in absolute value) decrease in the order (100) > (111) > (110), while, in the c.d. range over 40 A/m^2, the order is (111) > (100) > (110); while Jenkins finds (100) > (110) > (111);
4. for (100), at 2 A/m^2, the quasi-steady anodic overvoltage lies in the range of 3 mV, while the oscillographic records of Jenkins at 1.5 A/m^2, indicate overvoltages in the order of 35 mV.

Again for (111), at 2 A/m^2, the anodic and cathodic quasi-steady overvoltages lie in the range of 1.2 and 1.4 mV, respectively, as compared with values in the order of 25 mV at 1.5 A/m^2 for Jenkins.

Jenkins finds moreover at this c.d. transient maxima: for (100) in the order of 50 mV, and for (111) 38 mV on the anodic side and −33 mV on the cathodic one.

In our experiments, the above mentioned cares lead to a total disappearance of the transient maxima, previously found by us also.[58]

Of course we do not exclude the occurrence of transient overvoltage maxima (sometimes strong) in cases in which nucleation may assume a kinetically very decisive role, for instance on foreign cathodes in the absence of alloy formation, or on nearly ideal surfaces. Quite modest maxima may be foreseen in various conditions. One may thus consider the hypothesis the surfaces investigated by Jenkins to be ideally flat.

On the basis of our results, concerning not only Cu but also Ag, Pb, Cd and other single crystal electrodes, however, we are forced to consider the intervention of contamination sources in a part at least of these results.

A special comment appears to deserve the influence exerted, in this field, too, like every one of the electrochemistry of metals[59] by anions.[60]

In the usual inorganic-anion series, the perchlorate baths utilized by Jenkins and by Poli and Rivolta, among the various investigated, are quite peculiar. In these baths the highest quasi-permanent galvanostatic overvoltages and transient maxima are encountered as a rule; moreover, the baths themselves are especially sensitive to the prepurification policy.

The last in this case leads to the strongest (absolute and relative) reduction of these effects.

One could attempt, of course, simply correlating the high quasi-steady overvoltages with the high transients by admitting a direct inhibitive influence of the perchlorate ions themselves.

This does not explain the influence of the purification policy. On the contrary, the general phenomenological results and the comparison with the other anions (among which chlorides are, in general, at the opposite extreme, as well known in corrosion), appear to suggest a more convincing explanation.

Due to their want of selective adsorption on the electrode surface, perchlorate anions are also the less able to exert a "competitive adsorption,"[61] by which the anions may displace from the electrode surfaces the contamination sources or other adsorbed species.[62]

In our opinion, the differences in the sensitivity of the different baths in respect to the purification policy is the most convincing evidence of the importance the competitive adsorption may assume in deciding the influence of anions in the kinetics of electrode processes (either anodic or cathodic).

L. H. Jenkins: It was an awareness of the pioneering work of Professors Piontelli, Poli, Rivolta, and Serravalle which aided in the decision of the Surface Studies Group at Oak Ridge National Laboratory to investigate electrocrystallization phenomena as a means of understanding the effects of structure on the reactivity of metal surfaces. Since much of the group effort has been concerned with other than electrochemical phenomena, it might be useful to call attention to some of this work. Members of the group were the first to grow metallic crystals (copper) with a dislocation density conclusively proven to be as low as $\simeq 50$ cm^{-2}. From crystals of such high perfection it was possible to obtain Borrmann x-ray transmission stereotopographs and to demonstrate a correspondence between dislocation images in the topographs and etch pits at sites where dislocations intersected specimen surfaces.[63] The use of electron microscopy of surface replicas[64,65] and interference and phase-contrast optical microscopy,[66,67] as well as neutron irradiation hardening as an aid in handling and manipulating samples,[68] are some of the many techniques routinely used by the group. The group's ability to prepare specifically oriented surfaces and to characterize them in terms of their structure is well documented.[66,67,69,70] Therefore,

[55] Following our purification policy, the prolonged electrolysis is carried out at low current-density with cathodes, or both electrodes, of the same metal to be utilized in the measurement. The especially good results thus obtained may be credited to the progressive elimination (by adsorption and occlusion) at least of those contamination sources, and also of oxygen, in respect of which the measurement electrode may result specifically sensitive.

[56] *Rend. Ist. Lomb.*, 93, 262 (1959).

[57] In all of these experiments the electrode surfaces examined by electron diffraction gave very neat Kikuchi lines while the details of the diffractograms confirm the surfaces are usually exempt from any distortion or covering films and are smooth.

[58] The influence of the prepurification is different for the different orientations, being definitely greater for (100), that is, the orientation corresponding to the highest overvoltages, a result which appears to be in line with our general views on the kinetics of the electrode processes.

[60] For Cu, however, on the cathodic side, the overvoltages are a little greater in sulfate bath than in perchlorate, a result that may indicate an inhibitive influence of the sulfate ion. This last hypothesis finds support in the systematic study carried out here on the influence of addition of neutral salts including potassium sulfate. Also the influence of the "free" acid in sulfate baths could thus find a partial explanation.

it does not appear unjustified to conclude that the surfaces discussed here were exceptionally well characterized in terms of the density and nature of the defects intersecting the electrode surface. No comment can be made regarding control of "surface states" since the meaning of the term used by Piontelli *et al.* is not clear in this context.

As for the experimental systems, we also have noted a pronounced "anion effect." If nothing else, the observations demonstrate quite conclusively that the usual model of adatoms diffusing over a bare surface to monatomic steps is inappropriately simplistic. All surface processes must be affected by the water, anions, adatoms, etc., on the electrode surface. However, it is difficult to say more than that it is possible impurities adsorbed in sufficient quantity at significant sites should contribute to the effect. Moreover, the concept of selective or competitive adsorption in solutions assumed to contain minute quantities of unidentified impurities is such a general argument that it is of limited usefulness. From completely reasonable assumptions of values for adsorption coefficients, number of sites, impurity levels in solution, etc., it can be used to demonstrate that (*a*) no system can be properly purified, or (*b*) any system is sufficiently pure unless containing a measurable quantity of specific inhibitors, or (c) any stage between these two extremes is a proper description. This concept applied to data obtained in "clean" systems at different laboratories does have the virtue of supplying a vague, nonspecific means for rationalization of conflicting results.

In the work under discussion here very careful precautions were taken to ensure the cleanliness of all components of the system.[71] Certain aspects of the experimental results such as the quantitative relationships between the extent of deposition and time-to-formation of maxima, long-lived aspects of this deposition anomaly, asymmetry of cathodic and anodic branches of the (321) and (111) current *vs.* potential relationships, as well as the near coincidence of their cathodic values, symmetry of the two processes on the (100) and (110), and other data and arguments presented in the paper led to the conclusion that in this case maxima could not result from impurities adsorbed on the crystal surfaces. As a matter of fact, much of the earlier stages of investigation not reported in the paper were spent establishing the fact that use of all the cleaning techniques of Piontelli *et al.*, did not eliminate maxima from these systems. In attempting to understand this discrepancy the following observations were made:

1. Maxima were extremely sensitive to the presence of dissolved oxygen and were altered when absolutely all oxygen was removed. This phenomenon could be understood on the basis that, by oxidizing the cuprous ions to cupric, equilibrium was destroyed in a system in which the observed overvoltage was extremely sensitive to the cuprous ion concentration (*see* Eq. [8] in original text). Moreover, it was demonstrated[72] that while singular orientations of copper crystals reacted completely uniformly over the surface when the sole driving force for the reaction was an applied external emf, the same systems undergoing corrosion at reaction rates even an order of magnitude greater due to the reactions

$$\frac{1}{2}O_2 + H_2O + 2Cu^+ \rightleftarrows 2Cu^{++} + 2OH^- \quad [1]$$

$$Cu^{++} + Cu^\circ \rightleftarrows 2Cu^+ \quad [2]$$

were not uniformly attacked over the surface. Therefore, it was concluded that nonuniform attack due to corrosion and the concomitant effects on interfacial cuprous ion activities, at the very least, affected the formation of maxima in oxygen-containing systems. However, it was soon established that the complete removal of dissolved oxygen changed the absolute values of observed maxima, but did not cause them to disappear.

2. Nevertheless, after many measurements at current densities in excess of ~ 1 mA/cm^{-2} had been made on any one surface it was observed that overvoltage values decreased markedly. Initially this was assumed to be due to an attendant increase in surface area. However, examination of such surfaces by optical and surface replication electron microscopy revealed that no change in surface area had occurred, but rather that the steps initially evenly distributed over electropolished surfaces due to even slight ($\sim$0.1°) misorientations from low-index planes had interacted and bunched into ledges and facets. This suggested that in systems initially at equilibrium overvoltages were extremely sensitive to the arrangement and distribution of steps over a surface. Extensive investigations of various step distributions on different orientations of copper crystals in solutions of copper sulfate unequivocally confirmed this to be the case.[73]

It is well known and easily demonstrated that on an electropolished copper surface in either perchlorate or sulfate solutions a current of 10 mA/cm^{-2} flowing for as little as 5 sec will produce a change in surface structure sufficient to be easily observable with an optical microscope. Therefore, when extensive data are obtained in such systems at current densities $\gtrsim$1 mA/cm^{-2} they are from surfaces whose structures are changing constantly during the course of observations. Because of the deposition anomaly demonstrated in the paper under discussion, this is particularly true of surfaces on which measurements have resulted in a net deposition, an observation confirmed by the results of Bockris and Enyo.[74] Moreover, as facet and ledge formation increase, the overvoltage decreases markedly even though the faceting is to a degree much too small to alter the surface area.[73] Also, it is well known that maxima decrease with the overvoltage such that at $\lesssim 10$ mV they are quite small and slow both to form and decay. This last fact seems to be acknowledged by Piontelli *et al.* who refer to their observed overvoltages as "quasi-steady."

For all these reasons it seems completely justifiable to conclude that the experimental data of all the many researchers discussed here were obtained from "clean" systems. As concluded in the paper under discussion and confirmed by work currently in press,[73] it seems to the author that experimental evidence supports the opinion that many of the differing results obtained in various laboratories reflect differences in surface structures yielding the data rather than indeterminate differences in ill-defined trace impurity levels.

A New Class of High-Conductivity Solid Electrolytes: Tetraalkylammonium Iodide-Silver Iodide Double Salts

Boone B. Owens*

Gould Ionics Incorporated, Canoga Park, California 91304

ABSTRACT

Double salts, formed by the combination of silver iodide with tetraalkylammonium iodide salts, have been found to exhibit very high ionic mobilities in the solid state over the temperature range from 100° down to −50°C. In the system AgI-diethyldimethylammonium iodide, the composition dependence of the ionic conductivity at 22°C passes through a maximum value of 0.06 $(\text{ohm-cm})^{-1}$ at a composition of 87 m/o (mole per cent) AgI. Results are presented for a number of related salts in the silver tetraalkylammonium iodide class.

Takahashi and Yamamoto (1-6) have extensively investigated the electrolyte Ag_3SI and the solid electrolyte cell $Ag/Ag_3SI/I_2$. This system has been of especial interest because the electrolyte has a specific electrical conductivity of 0.01 $(\text{ohm-cm})^{-1}$ at 20°C, orders of magnitude more conductive than most other solid electrolytes at ambient temperatures. However, this electrolyte has the disadvantage of a low decomposition emf (7). Another solid-state battery was reported by Gutmann, Hermann, and Rembaum (8); however, no completely dry, high-conductivity solid electrolyte was reported, and the cell discharge reaction has recently been re-evaluated (9).

The highly conducting group of salts KAg_4I_5, $RbAg_4I_5$, and $NH_4Ag_4I_5$ was more recently reported to have ionic conductivities of 0.2 $(\text{ohm-cm})^{-1}$ at 20°C (10, 11). This group of electrolytes suffers from a thermodynamic instability at 20°C, with respect to the reaction

$$2MAg_4I_5 \rightarrow M_2AgI_3 + 7AgI \qquad [1]$$

where $M = K$, Rb, or NH_4 (10, 12). The MAg_4I_5 electrolytes can be quenched in at very low temperatures; however, at temperatures near to or below ambient they may decompose, according to Eq. [1], in the presence of H_2O vapor or upon being ground.

Because of the number of silver halide or silver halide containing salts that exist in structures that permit high Ag^+ ion mobility, it appeared that new high-conductivity solid electrolytes would be complex salts of the type $MX \cdot nAgI$ where MX represents an unspecified salt and n is the mole ratio of AgI to MX in the conducting compound. In considering other iodide salts that might form high-conductivity products with AgI, substituted ammonium iodide compounds were investigated (13). The initial successful experiments on this group were carried out prior to Bradley and Greene's conflicting report that Me_4NI did not combine with AgI to form a conductive product (10). The present paper reports the properties of high-conductivity solid electrolytes formed by the combination of silver iodide with the tetraalkylammonium iodides.

The new set of solid electrolytes has ionic conductivities of 0.01-0.06 $(\text{ohm-cm})^{-1}$ at 20°C. Furthermore, these materials appear to be thermodynamically stable at subambient temperatures, and as such they represent the most conductive stable solid electrolytes known at temperatures below 25°C.

Experimental

Materials.—The quaternary tetraalkylammonium iodide salts (QI) were obtained from Eastman Kodak or prepared from the tertiary amines and the alkyl iodide; the silver iodide was supplied by Mallinckrodt Chemical. The double salts were prepared by the combination reaction

$$QI + n\ AgI \rightarrow QAg_nI_{n+1} \qquad [2]$$

where n is the mole ratio of AgI to QI.

The reactants were intimately mixed, compacted, and then annealed in closed Pyrex vessels under an inert Ar atmosphere at elevated temperatures ranging from 125° to 165°C. Multiple compactions and anneals were carried out to permit the system to come to equilibrium.

Alternately the products were prepared by adding a small amount of H_2O to the reactants to form a paste. This material was vacuum dried at 80°C, ground, pelletized, and then annealed at 120°C for 8-16 hr in a sealed tube under an Ar atmosphere. The compaction and annealing were repeated once.

Compositions were prepared with n values varying from 0 to about 20. The conductivities of these compositions were determined and from the variation in conductivity with composition the approximate stoichiometry of the conducting phase was determined.

Resistance measurements.—The method for measuring the pellet resistance of ½ in. diameter cells Ag, $RbAg_4I_5$/Sample/Ag, $RbAg_4I_5$ has been described elsewhere (11, 14). The temperature dependence of the resistance was also determined, following essentially

* Electrochemical Society Active Member.

Key words: conductivity, quaternary ammonium iodide, silver iodide, solid electrolyte, solid-state electrochemistry, substituted ammonium iodide, tetraalkylammonium iodide.

the same procedure as previously reported (11, 14). The low-temperature environment was maintained by placing the conductivity cells in a Missimer environmental chamber that had been adapted to have a flowing Ar atmosphere and external electrical contacts for reading the resistance of samples within the atmosphere. The temperature range was from −80° to 200°C.

Density.—Densities were determined by pressing the products into ½ in. diameter pellets at pressures of 45,000 psi. The pellet dimensions were determined with a micrometer and the weight was determined with an analytical balance.

Results and Discussion

Me_4NI-AgI *system.*—The composition of the tetramethylammonium iodide-silver iodide samples varied from 0 to 97.5 m/o AgI. Generally, the products would contain two phases; a single phase product would be formed only at compositions corresponding to compounds stable at the synthesis temperature. The one intermediate compound reported to form in this system is $(Me_4N)Ag_2I_3$ at 66 2/3 m/o AgI (15). The density results are reported in Table I, with those for the Me_2Et_2NI and Et_4NI systems.

The specific conductivities for samples of composition ranging from 0 to 100 m/o AgI are reported in Table II, column 2. In the composition range from $(Me_4N)I$ to $(Me_4N)Ag_2I_3$ there is no evidence of a high-conductivity electrolyte having been formed. However, between the compounds $(Me_4N)Ag_2I_3$ and AgI, the conductivity passes through a maximum at 87 m/o as shown by the plot in Fig. 1 of specific conductivity *vs.* mole per cent AgI. Smyth, Tompkins, and Ross (16) recently reported that silver iodide, comelted with Me_4NI, at a mole ratio of 6 to 1 forms a solid product with conductivity of 0.04 $(ohm\text{-}cm)^{-1}$, in good agreement with the results shown in Fig. 1. The position of the maximum indicates that the formula of the conducting compound is close to $(Me_4N)Ag_{6.7}I_{7.7}$. However, this method of measurement is not precise enough to determine the exact formula. An x-ray structure determination has been carried out by Geller and Lind who found the compound stoichiometry to be $(Me_4N)Ag_{6.5}I_{7.5}$ (17).

Table I. Density of pelletized polycrystalline salts QAg_nI_{n+1} at 22°C[a]

m/o AgI	Density in g/cc, where QI is		
	Me_4NI[b]	Me_2Et_2NI	Et_4NI
0	1.84 (1.83)	1.54	(1.56)

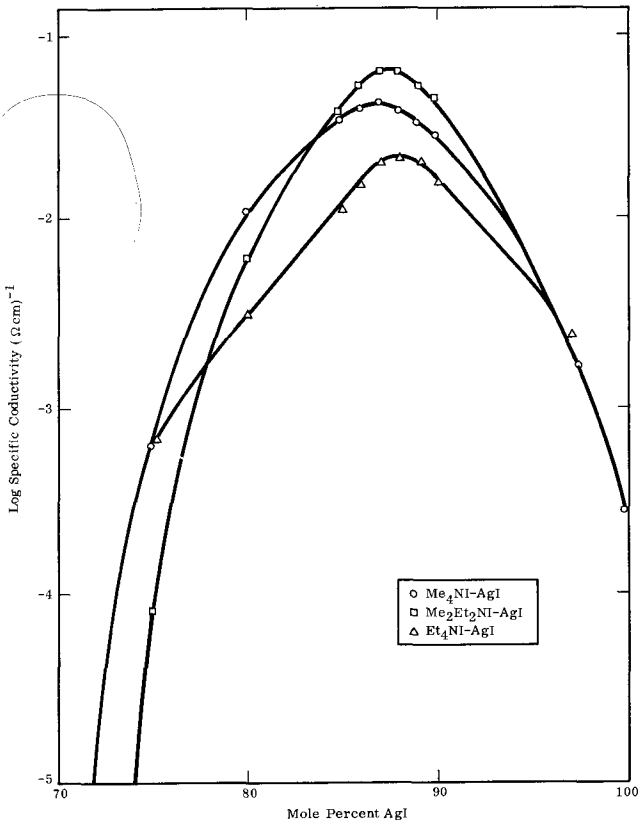

Fig. 1. Composition dependence of the specific conductivity of the binary solid electrolyte systems Me_4NI-AgI, Me_2Et_2NI-AgI, and Et_4NI-AgI, at 22°C.

In the present investigation some of the initial syntheses were carried out at 160°C. From both conductivity measurements and powder pattern analysis of the products evidence was obtained for another high-conductivity compound forming at a composition near 80 m/o AgI. When syntheses were carried out at 120°C this compound was not formed; it therefore appears to be a high-temperature compound, unstable at temperatures below 120°C. The conductivity at 22°C of quenched samples of this high-temperature phase was about 0.01 $(ohm\text{-}cm)^{-1}$.

The conductivity curves of Fig. 1 were not corrected for contact resistance. These corrections were obtained for the 87 m/o AgI composition following the procedure previously described (14). The specific conductivity of the 87 m/o AgI-Me_4NI composition at 22°C is $4.2 \pm 0.7 \times 10^{-2}$ $(ohm\text{-}cm)^{-1}$.

Other high-conductivity electrolytes have been found to be thermodynamically unstable at and below ambient temperatures (10-12). No thermodynamic data for the $(Me_4N)_2Ag_{13}I_{14}$ compound have been reported, and therefore its stability with respect to decomposition reactions such as

$$(Me_4N)_2Ag_{13}I_5 \rightarrow 2\ (Me_4N)Ag_2I_3 + 9\ AgI \qquad [3]$$

is unknown. However, the conducting compound has not exhibited any tendency to decompose during storage under ambient conditions, in contrast to the behavior of the MAg_4I_5 group of high-conductivity electrolytes (10, 11). In addition, a sample of the $(Me_4N)_2Ag_{13}I_{15}$ compound was prepared out of water by refluxing a slurry of AgI in a solution of Me_4NI and then cooling the reaction vessel to 0°C. The solid phase that was then isolated was predominately $(Me_4N)_2Ag_{13}I_{15}$ as evidenced by x-ray powder analysis, indicating that this compound is stable at least over the temperature range from 0° to 120°C.

Me_2Et_2NI-AgI *system.*—The investigation of the diethyldimethylammonium iodide-silver iodide system

was carried out, following the same procedures as just described for the tetramethylammonium iodide-silver iodide system. The results are shown in Tables I and II and Fig. 1. This system is analogous to the preceding one in that there appears to be a nonconducting compound QAg_2I_3, and a conductive compound at a composition near 87½ m/o AgI. The maximum conductivity observed was 6.4 x 10^{-2} $(ohm\text{-}cm)^{-1}$. The precise formula of the conducting compound is unknown. The conductivity results suggest $(Me_2Et_2N)Ag_7I_8$ (87½ m/o AgI); however, the formula may be the same as that of the preceding system, $(Me_2Et_2N)_2Ag_{13}I_{15}$ (17). No structural results have been reported for the high conducting compound.

Et_4NI-AgI *system.*—The tetraethyl ammonium iodide-silver iodide system was similarly investigated, and a maximum in the conductivity curve was found at 88 m/o AgI. Results are also shown in Tables I and II and Fig. 1. The maximum value of 2.2 x 10^{-2} $(ohm\text{-}cm)^{-1}$ was observed at 88 m/o AgI.

Conductivity of QAg_6I_7 *as function of* Q.—The results thus far reported have shown that high-conductivity electrolytes are formed between AgI and the tetraalkylammonium iodide salts Me_4NI, Me_2Et_2NI, and Et_4NI. In order to investigate the extent to which other tetraalkylammonium iodide salts will combine with AgI to form conductive products a series of different QI salts were combined with AgI in the mole ratio of 1 to 6. The conductivity of these products (which would generally be expected to contain two phases) was then determined, and these results are given in Table III. The conductivity of the pure AgI determined by the present procedure was 3 x 10^{-4} $(ohm\text{-}cm)^{-1}$. Conductive products were formed by all the salts from tetramethylammonium iodide through butyldiethylmethylammonium iodide. The most conductive compound was formed with the diethyldimethylammonium iodide. As the tetraalkyl group changed from butyldiethylmethyl to butyltriethyl a sharp decrease by a factor of 10^4 was observed in the conductivity. This result suggests that these larger quaternary ammonium ions are forming new nonconductive compounds with AgI. If no compound formation were occurring, then the dilution effect of a second phase on the conductivity of AgI should result in a specific conductivity of about 10^{-4} $(ohm\text{-}cm)^{-1}$, as was observed for the very large asymmetric hexadecyltrimethyl ammonium ion.

Temperature dependence of conductivity.—The temperature dependence of the resistance was determined for samples of Me_4NI, Me_2Et_2NI, and Et_4NI combined with AgI in the mole ratio of 1/7. The results of several temperature cycles are shown in Fig. 2, where the conductivity curves are compared to those of AgI, Ag_3SI, and $RbAg_4I_5$. The Me_4NI and Me_2Et_2NI compounds remained conductive down to −50°C, with Arrhenius activation energies of 4.0 and 3.6 kcal/mole, respectively. The Et_4NI compound has an activation energy of 5.7 kcal/mole at 20°C. It gave some indication of transforming into a nonconductive phase, as the conductivity dropped to less than 10^{-4} at −50°C, as shown in Fig. 2. Contact resistance contributes to the total resistance measured on these cells; the contribution was determined for samples at 22°C but not at other temperatures. This effect could modify the slopes of the curves in Fig. 2. The log conductivity-reciprocal temperature plots for these three compounds are compared to those of other high-conductivity electrolytes in Fig. 2. Below 27°C this new group of electrolytes contains the most conductive, thermodynamically stable solid electrolyte known (12).

Table III. Electrical conductivity of tetraalkylammonium iodide-silver iodide compositions of empirical formula QAg_6I_7 at 22°C

Tetraalkylammonium ion	σ $(ohm\text{-}cm)^{-1}$
Tetramethyl	4 × 10^{-2}
Ethyltrimethyl	4 × 10^{-2}
Diethyldimethyl	6 × 10^{-2}
Trimethylisopropyl	4 × 10^{-2}
Trimethylpropyl	3 × 10^{-2}
Triethylmethyl	3 × 10^{-2}
Tetraethyl	1 × 10^{-2}

Triethylpropyl	2 × 10^{-3}
Butyldiethylmethyl	8 × 10^{-4}
Butyltriethyl	6 × 10^{-8}
Methyltripropyl	3 × 10^{-8}
Tetrapropyl	3 × 10^{-8}
Tributylmethyl	3 × 10^{-7}
Butyltripropyl	2 × 10^{-7}
Tributylethyl	3 × 10^{-7}
Tetrabutyl	1 × 10^{-7}
Hexadecyltrimethyl	1 × 10^{-4}

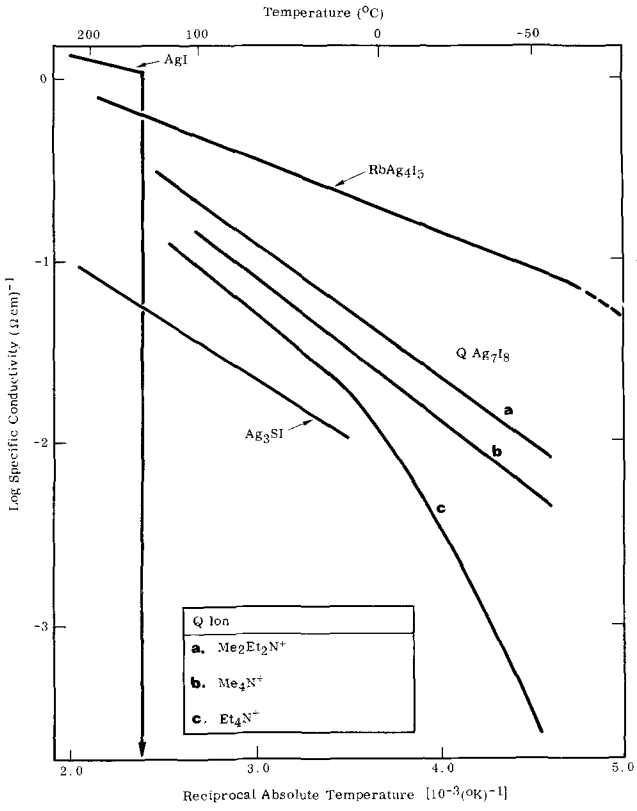

Fig. 2. The temperature dependence of the specific conductivity of $(Me_4N)Ag_7I_8$, $(Me_2Et_2)NAg_7I_8$, and $(Et_4N)Ag_7I_8$ from −50° to 100°C.

Electronic conductivity.—Measurements of the electronic conductivity in some of these compounds have been carried out by Oxley and Humphrey (18). Polarization cells Ag/electrolyte/Pt were analyzed by their current-voltage relationships. Results indicate the electronic conductivities are less than 1 x 10^{-10} $(ohm\text{-}cm)^{-1}$ in these materials.

Transport number measurements.—The ionic transport numbers in the electrolyte compositions Me_4N-Ag_7I_8 and $Et_4NAg_7I_8$ were determined by Topol (19). The Hittorf method of correlating weight changes in the electrodes of cells of the type

$$Ag/QAg_7I_8/C$$

with the transport of current was used, as previously described (12). The result for both materials was that Ag^+ ion carried all of the current. Thus, it is probable that in this entire class of electrolytes Ag^+ ion carries all of the current as it does in the previously reported high-conductivity electrolyte class MAg_4I_5 (10, 12).

Conclusions

The results indicate that the formation of conductive quaternary ammonium iodide-silver iodide compounds is a fairly general phenomenon, including all ions from $C_4H_{12}N^+$ to $C_9H_{22}N^+$. It is probable that under non-

ambient conditions of pressure and temperature there will be not only transformations from conductive to resistive phases (as observed for $Et_4N\,Ag_7I_8$ at low temperatures), but also some transformations from resistive to conductive phases by the compositions containing the larger tetraalkylammonium ions. Structural studies have shown that in the $RbAg_4I_5$ crystal lattice the Ag^+ ions (16 per unit cell) are distributed over a large number of sites (20, 21). Geller reported there are 56 iodide tetrahedra per unit cell, which share faces to permit rapid Ag^+ ion diffusion within the immobile lattice of iodide anions (20).

Geller and Lind (17) have recently reported the crystal structure of $(Me_4N)_2Ag_{13}I_{15}$. The hexagonal unit cell contains 39 Ag^+ ions distributed over 123 tetrahedral sites. These sites are formed by iodide tetrahedra that again share faces in a manner to permit Ag^+ ion diffusion throughout the anion lattice.

In the solid electrolyte group KAg_4I_5, $RbAg_4I_5$, and $NH_4Ag_4I_5$ the compounds are isomorphous and form complete solid solutions (11). A comparison of powder photographs of the present series of tetraalkylammonium silver iodide electrolytes gives no evidence for isomorphous structures. However, the similarity of ionic transport suggests there should be similar diffusion paths in these crystals. Structural studies of this series should prove to be very enlightening as to the detailed processes involved in the Ag^+ ion transport.

Acknowledgment

The author wishes to thank Mr. Louis D. Hermo who carried out much of the experimental phase of this investigation. The work was performed under the North American Rockwell Corporation Independent Research and Development Program.

Manuscript received May 25, 1970. This was Paper 331 presented at the Los Angeles Meeting of the Society, May 11-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1971 JOURNAL.

Oxidation of an Fe-30% Ni Alloy in Oxygen at 700°-1000°C

I. A. Menzies and J. Lubkiewicz[1]

Corrosion Laboratories, Department of Chemical Engineering, The University of Manchester Institute of Science and Technology, Manchester 1, England

ABSTRACT

The oxidation of an Fe-30% Ni alloy has been studied at 700°-1000°C using thermogravimetric, metallographic, and electron probe microanalysis techniques. At all temperatures, parabolic kinetics was observed and the activation energy for the process was 37.8 ± 5 kcal $mole^{-1}$. At all temperatures, $Ni_xFe_{3-x}O_4$ and Fe_2O_3 were present in the external scale and oxidation was accompanied by a progressive Ni enrichment of the underlying alloy. In this alloy, the Ni enrichment reached values of ~60% even after short periods of oxidation at 700°C and Ni concentrations of 75-85% were recorded after longer times and at higher temperatures. The Ni concentration in the $Ni_xFe_{3-x}O_4$ scale layer rapidly attained concentrations corresponding to $x > 0.5$. There was no internal oxidation at 700°C although some was observed at 800°-900°C. Considerable internal oxidation was observed at 1000°C. In this alloy, there was relatively uniform precipitation of internal oxide particles with no evidence of intergranular oxidation. The mechanism of oxidation of the alloy is discussed in the light of present knowledge concerning the Fe-Ni-O system.

It was clear from a detailed review of the literature (1, 2) that there was considerable disagreement concerning the growth morphology and composition of oxide scales formed on Fe-Ni alloys containing ≤ 30 w/o (weight per cent) Ni in air and in oxygen. Furthermore, there was little information concerning the kinetics and scaling of Fe-Ni alloys in CO_2 or CO_2/CO mixtures. Since that time, considerable information dealing with the behavior of alloys containing ≤ 50 w/o Ni in CO_2 and CO_2/CO mixtures has been given (3-6). The present study is a continuation of more

recent investigations of the behavior of an Fe-12% Ni alloy in oxygen at atmospheric pressure at 700°-1000°C (7) and deals with scale development and internal oxidation as a function of time and temperature. Since completion of the present investigation, additional information concerning the behavior of Fe-Ni alloys at 0.2 atm and 200 Torr oxygen pressure at 977°-1000°C has become available (8) and these recent observations are discussed with the present results.

Experimental

The alloy used was of high purity and was supplied by the British Iron and Steel Research Association in the form of cold-rolled strips. The composition of the alloy was as follows: Ni, 30.2%; C, 0.006%; S, < 0.03%; Sb, < 0.005%; Bi, < 0.005%; Pb, < 0.005%; P, 0.001%; Si, 0.004%; CW, < 0.05%; Nb, < 0.05%; Sn, < 0.01%; Cr, 0.008%; Co, 0.014%; Mo, < 0.01%. Specimens 0.5-0.8 cm x 1.0 cm x 1.6 cm were cut from the sheet and a small suspension hole drilled in each specimen for a fine Pt suspension wire.

All specimens were abraded on 600 SiC paper and chemically cleaned in an acid mixture as previously described (3-5). After water washing, the specimens were dipped in a mixture of 2 parts of H_2SO_4 and 1 part HNO_3 and again rinsed thoroughly. The specimens were then allowed to stand in a solution containing 50 g/liter KCN for 1 hr. They were then washed in water, rinsed in acetone, and allowed to stand in this solvent until required.

Weight gain determinations were made continuously using a quartz spring thermobalance as previously described (9). Oxygen containing $\not>$10 ppm hydrocarbons, $\not>$50 ppm Ar, $\not>$0.15 g/m^3 H_2O, 5 ppm CO_2 was further purified before use to remove CO_2 and to reduce the moisture level to <10 ppm. In all runs, the chemically etched specimen was suspended in the cool part of the balance while the chamber was evacuated and flushed with purified oxygen for 15-30 min. The specimen was then lowered into the hot zone of the furnace by means of a winching device, and cathetometer readings were commenced as soon as possible. All experiments were carried out in an atmosphere of oxygen at atmospheric pressure. At the end of each run, the specimen was winched out of the furnace over a period of 2-3 min and cooled in oxygen in the top section of the balance.

All specimens for metallographic examination and electron probe microanalysis were vacuum impregnations mounted in an Araldite resin with powdered calcite as a hardener (10). Specimens for electron probe microanalysis were then given a thin (100-500Å) coating of carbon to render them electrically conducting. Iron and nickel profiles were measured using a Cambridge Mk II Misroscan at several scanning speeds in the range 4-40 μm/min and the peak values of Ni enrichment were checked by direct measurement of Bragg angles at these points. An accelerating voltage of 25 kV was used throughout and the results were corrected for background radiation, paralysis time, absorption, and fluorescence. The quantitative traces for Fe and Ni shown in the various figures have been fully corrected at the points indicated and the complete curves adjusted accordingly. In all cases, several traces were obtained at various scanning speeds to insure appropriate sensitivity of measurement and allow elimination of statistical errors. All values of interfacial contents of oxides and metal with respect to Ni are accurate to within ±2% of the measured value and were obtained from the corrected line scans.

Results

Kinetics of oxidation.—The specimen weight gains are given in Fig. 1 as a function of time. The results shown are the average of at least five experimental runs at each temperature. The parabolic law was obeyed throughout the entire exposure period and no rate transitions were apparent. The parabolic rate constants are given in Table I. An Arrhenius function was plotted using the method of least mean squares and the value obtained for the activation energy was 37.8 ± 5 kcal mole^{-1}. The value of the rate constant at 900°C was lower than expected from the over-all pattern of results at other temperatures.

Oxide morphology and composition, and Ni *redistribution in the alloy.*—To facilitate comparison with other studies (7), the main investigations were carried out at 700° and 900°C. In addition, specimens oxidized for 46 hr at 800°C and 3 and 7 hr at 1000°C were also examined.

Examination of specimens oxidized at 700°C.—Specimens oxidized for 0.25, 3.5, 9.0, and 40 hr were examined. Similar morphological features were found throughout the entire exposure period and details of all major features are presented collectively in Table II. The outer scale consisted of a two-layer oxide, the layers being of almost the same thickness (Fig. 2). Beneath the external scale in each specimen was a Ni-rich rim which increased in thickness with time of exposure, being ~2 μm thick after 0.25 hr oxidation and ~10 μm thick after 40 hr. No internal oxidation was detected within this rim. Linear scans for Fe and Ni along lines normal to the metal-oxide interface in Fig. 2 yielded the profiles shown in Fig. 3. The spinel compositions at the inner interface in contact

with the metal were as follows: 0.25 hr—$Ni_{0.29}Fe_{2.71}O_4$; 9 hr—$Ni_{0.33}Fe_{2.67}O_4$; and 40 hr—$Ni_{0.66}Fe_{2.34}O_4$. In specimens oxidized up to 9 hr there was a Ni concentration gradient across the spinel phase (*cf.* Fig. 3a), whereas after 40 hr (Fig. 3b) the spinel phase in contact with the metal showed little change in Ni concentration over a thickness of ~7 μm. Thereafter there was a concentration gradient to the hematite interface.

The metal rim always contained ≥60% Ni but the apparent rise in Ni concentration with increasing amounts of oxidation may be due to an increase in the accuracy of the analyses with increasing thickness of the enriched zone.

Table III. Major features of specimens of an Fe-30% Ni alloy oxidized at 900°C

Duration of oxidation (hr)	Wt gain (mg/cm²)	Scale thickness (μm)	Ni content of $Ni_xFe_{3-x}O_4$ Inner interface %	Inner interface x	Outer interface %	Outer interface x	Ni concentration in enriched alloy (%)	Composition of internal oxide Fe, %	Ni, %

46	18.4	90	19	0.78	19	0.78	85	69	3

Examination of specimens oxidized at 900°C.—Overall, the results at 900°C were similar to those at 700°C except that some internal oxidation occurred. The major features are summarized in Table III. After all exposures, the external scale consisted of two oxides of approximately the same thickness.

After 0.25 hr oxidation (0.9 mg/cm²), a few isolated oxide particles were apparent within the metal rim beneath the external scale (Fig. 4). The Ni enrichment behind the external scale was 65% even at this stage (Fig. 5). The Ni concentration in the spinel layer decreased from ~20% at the scale/alloy interface to <1% at the spinel hematite interface and thus the inner region of the external scale corresponded to oxide compositions in the range $Ni_{0.82}Fe_{2.18}O_4$ to $Ni_{0.04}Fe_{2.96}O_4$. The internal oxide particles were too small to allow accurate analysis. After 1 and 4 hr, similar features were observed (Table III) and the internal oxide particles were 1-2 μm diameter still too small for accurate analysis.

After 9 hr oxidation, the general features of the specimen were similar but, contrary to previous speci-

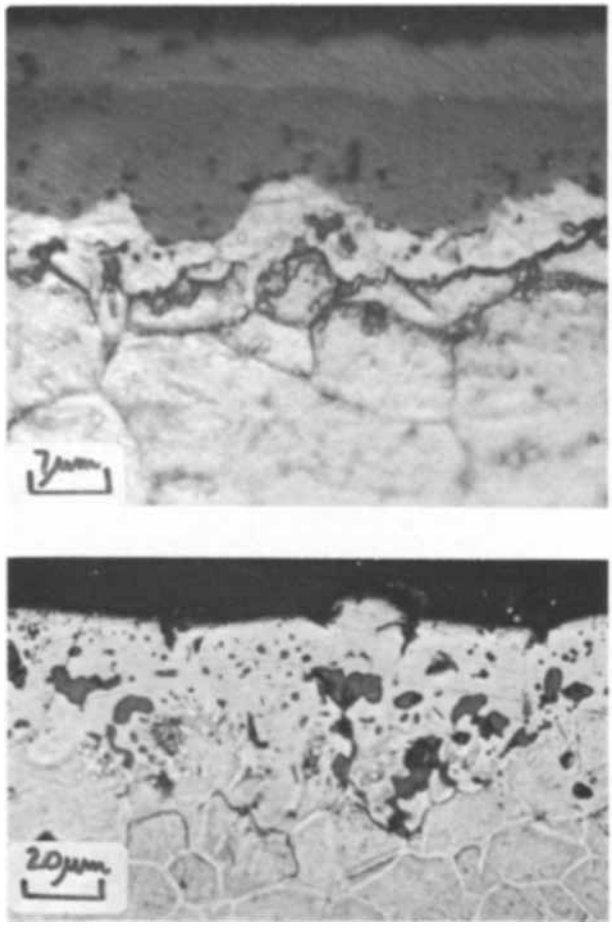

Fig. 4. Cross sections of an Fe-30% Ni alloy oxidized at 900°C (2% nital etch): *(a) top*—0.25 hr, *(b) bottom*—46 hr. (Internal oxide particles.)

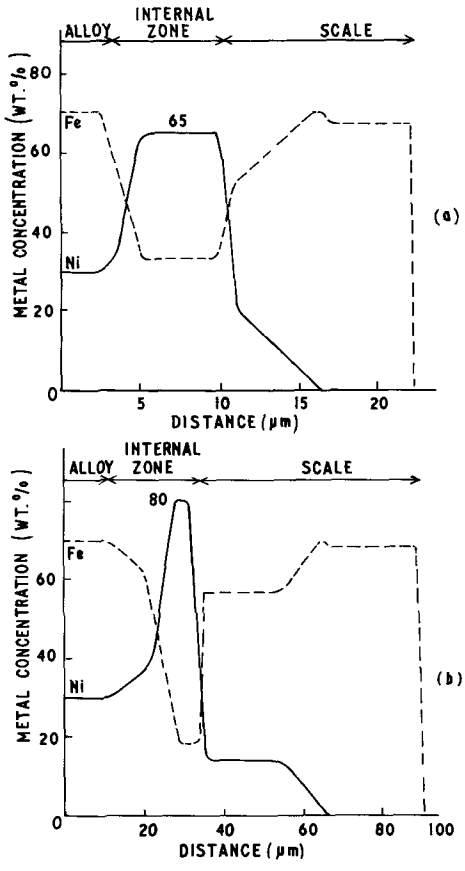

Fig. 5. Concentration profiles across an Fe-30% Ni alloy oxidized at 900°C: *(a)* 0.25 hr, *(b)* 9 hr.

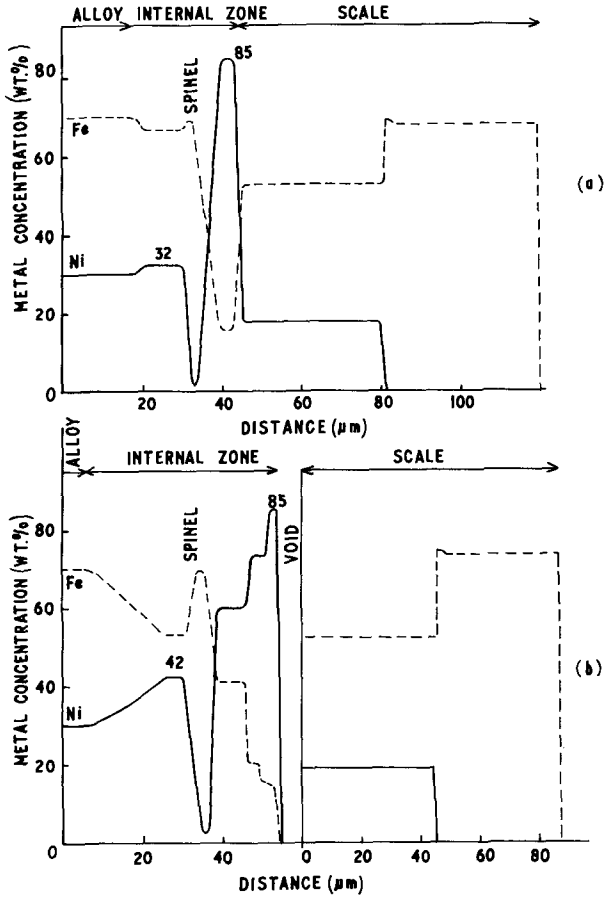

Fig. 6. Concentration profiles across an Fe-30% Ni alloy oxidized at 900°C: *(a)* 21.5 hr, *(b)* 46 hr.

mens at this temperature, the Ni concentration profile in the spinel region of the external scale showed little change in Ni concentration in the innermost 15 μm of this layer (Fig. 5b), although there was a gradient in the outermost regions of the layer. In specimens oxidized for longer periods (21.5 and 46 hr), there was little evidence of concentration gradients anywhere across the spinel layer (Fig. 6). Metallographic examination of cross sections of specimens exposed for 9-46 hr indicated that the size of the internal oxide particles increased with increasing exposure time. The particles were of irregular shape, discontinuous, and randomly distributed (*cf.* Fig. 4b). These internal oxide particles contained surprisingly little Ni having compositions corresponding to: 9 hr—$Ni_{0.12}Fe_{2.88}O_4$; 21 hr—$Ni_{0.04}Fe_{2.96}O_4$; 46 hr—$Ni_{0.1}Fe_{2.9}O_4$. After 9 hr exposure, the Ni enrichment in the alloy was recorded as a single peak (Fig. 5b), whereas after long exposures (Fig. 6) the Ni build-up was in the form of steps ~5 μm long indicating some stratification of the Ni enrichment of the alloy.

Clearly Ni concentration gradients were observed in the spinel in the outer scale. When the Ni build-up had attained ~80% in the internal zone of the alloy, uniform Ni profiles were recorded in the spinel region of the external scale.

Examination of specimens oxidized at 800° and 1000°C.—The early stages of oxidation were not investigated at either temperature. The major results are summarized in Table IV. Again, features similar to those observed at 700° and 900°C were evident at 800°. The external scale and degree of internal oxidation were similar to those observed in specimens oxidized for 9-21.5 hr at 900°C (*cf.* Fig. 7). The internal zone contained a number of small (1-2 μm diam) particles and the concentration profiles obtained were similar to those in Fig. 6a. Thus, results from the terminal specimen at 800°C were consistent with those obtained at 700° and 900°.

In general, the scale morphology at 1000°C was similar to that at 700°-900°C (Table IV), the major difference being the pattern of internal oxidation at 1000°C (*cf.* Fig. 7b,c). Here the proportion of oxide (~50%) in the internal zone was considerably greater in specimens exposed at 1000°C than in specimens of corresponding weight gain at 900°C (*cf.* 3 hr at 1000°C and 46 hr at 900°C). The internal zones of the specimens oxidized for 3-7 hr at 1000°C were analyzed along lines normal to the metal/oxide interface. In the 3 hr specimen (Fig. 8), three different spinel areas were analyzed and found to have the following compositions: (*A*) $Ni_{0.78}Fe_{2.22}O_4$; (*B*) $Ni_{0.24}Fe_{2.76}O_4$; (*C*) $Ni_{0.29}Fe_{2.71}O_4$. In the 7 hr specimen, the internal oxide particles had the composition $Ni_{0.12}Fe_{2.88}O_4$. The Ni enrichment in the alloy within the internal zone was recorded in both specimens as 70-80%. These

concentrations may in some instances have been low due to excitation of iron from immediately adjoining areas of spinel oxide. The nickel concentration profiles in the outer spinel phase in both specimens oxidized at 1000°C were uniform.

Discussion and Interpretation

Satisfactory reproducibility in the kinetic studies was achieved by careful attention to surface preparation of the specimens prior to exposure, in agreement with previous work (1-5, 7). The observed oxidation rates at 900° and 1000°C were close to those reported by Foley and Guare (11), whereas those at lower temperatures were somewhat higher than those reported previously (11). The activation energy of 37.8 ± 5 kcal mole^{-1} is in agreement with the values of 41.8 kcal mole^{-1} obtained for an Fe-30% Ni alloy in air (11). Thus, although the establishment of the morphological pattern of oxidation is more important than the oxidation kinetics, the kinetic data and their reproducibility and agreement with other work in the literature give confidence that the observed morphological features are typical of the system.

One of the main features of the oxide scales was the absence of FeO in agreement with recent work (7, 8) but contrary to results reported earlier by Bénard and Moreau (12, 13). Under all conditions of exposure, the scale consisted of an inner layer of nickel ferrite spinel ($Ni_xFe_{3-x}O_4$) and an outer layer of hematite (Fe_2O_3). It should be made clear that the structures of the oxides of composition $Ni_xFe_{3-x}O_4$ have not been examined in detail. It seems most likely from the evidence available in the literature, however, that this is a reasonable assumption (14, 15). Lattice parameter measurements in oxides across gradients of the type shown in Fig. 3, 5, 6, and 8 would be difficult to interpret because of the variations in Fe:O ratio in magnetite and in the Fe:Ni ratio in nickel ferrite. In the case of the Fe-30% Ni alloy, nickel entered the spinel layer from the commencement of oxidation and rapidly increased in concentration to values of x in $Ni_xFe_{3-x}O_4$ close to or greater than 0.5. Indeed, at temperatures >700°C, values of x significantly less than 0.5 were not observed even after relatively short periods of exposure. This is in agreement with the rapid rise in Ni concentration in the underlying alloy to >60% at lower temperatures and >80% at higher temperatures. Thus, from known equilibria in the Fe-Ni-O system (14-17), FeO would not be expected to be present, in agreement with the experimental observations. Oxide growth was regular and the additional oxide phase, NiO containing 10-20% Fe, reported (8) for the oxidation of an Fe-35% Ni alloy at 1000°C did not appear which suggests that 30% Ni is probably closer to the true composition limit for

Type 2 alloys of the Wulf, Carter, Wallwork classification.

Internal oxidation was of quite a different pattern from that observed for an Fe-12% Ni alloy (7) where grain boundary precipitation predominated. In the Fe-30% Ni alloy there appeared to be no preferential sites for internal oxidation (Fig. 7) at 1000°C and at all temperatures <1000°C the amount of internal oxidation in the 30% Ni alloy was very much less than that observed after similar exposures of an Fe-12% Ni alloy (7). Indeed, with the Fe-30% Ni alloy there was no internal oxidation at 700°C, whereas internal oxidation of the Fe-12% Ni was considerable. Thus the decrease in the amount of internal oxidation with increasing Ni content of the alloy corresponds with greater Ni enrichment in the alloy behind the oxide scale and a rapid enrichment of the spinel scale layer in Ni to compositions of $Ni_xFe_{3-x}O_4$ where $x \geq 0.5$. This is of particular interest since it has been reported (18) that solid solutions of $NiFe_2O_4$ in Fe_3O_4 are ideal solutions up to Ni concentrations corresponding to $Ni_{0.5}Fe_{2.5}O_4$, whereas at higher Ni concentrations (*i.e.*, $x > 0.5$) nonideal behavior occurs. Thus there may be some changes in diffusion or transport processes which take place when Ni concentrations exceed the limits of ideality and this may be of particular significance in relation to the reduction in internal oxidation as compared with the Fe-12% Ni alloy (7), particularly at lower temperatures (700°-900°C). Initially, preferential oxidation of iron occurs and in the case of the Fe-30% Ni alloy there is a rapid uniform build-up of Ni in the underlying alloy. There was no evidence of grain boundary enrichment in nickel although the general increase in nickel concentration would be expected to lead to an increase in the solubility of oxygen in the underlying Ni-enriched zone and possibly to the presence of oxygen gradients, assuming that oxygen becomes available. It seems clear that in the case of the Fe-30% Ni alloy sytem at 700°-900°C there is much less oxygen mobility than in the Fe-12% Ni alloy (7). This may be due to changes in interfacial equilibria between Ni-enriched metal and Ni-rich Ni ferrite as compared with the situations in the Fe-12% Ni alloy (7) where the spinel phase contains much less Ni. It has previously been suggested (7) that some anion diffusion may occur in $Ni_xFe_{3-x}O_4$ where $x < 0.4$ and that this may contribute toward providing a supply mechanism for oxygen which then goes into solution in the alloy and gives internal oxidation. In the present work, the observations for the Fe-30% Ni alloy suggest that at 700°-900°C when $x > 0.5$ such anion diffusion processes no longer contribute to internal oxidation which consequently decreases. The position is less clear at 1000°C where internal oxidation takes place to a considerable extent in alloys containing 12-30% Ni although there is some evidence of a change in the form of the internal oxide. Clearly, further data are required to substantiate these views which must be regarded as tentative.

Over-all, however, despite those possibilities of changes in anion diffusion in the spinel phase and their possible significance in relation to internal oxidation, such processes are of limited significance in relation to the over-all rate-controlling process. This is clearly the rate of cation diffusion in the nickel ferrite spinel phase. This work also indicates that for alloys containing ~30% Ni the problem of internal oxidation at lower temperatures (~700°C) is much less severe than that encountered in lower alloys (~12% Ni) under similar conditions where the total amounts of oxidation involved are similar. This is of considerable practical significance since the presence of internal oxide may be extremely damaging under service conditions.

Acknowledgments

We wish to thank Professor T. K. Ross for the provision of laboratory facilities and one of us (J.L.) wishes to acknowledge the receipt of Departmental Research Bursary. We also wish to thank Mr. B. Lambert for his valuable assistance and advice concerning the electron probe microanalyses.

Ellipsometric Studies of Anodic Oxide Films Formed on Tantalum in Dilute Phosphoric Acid

C. J. Dell'Oca** and L. Young*

Department of Electrical Engineering, University of British Columbia, Vancouver 8, British Columbia

ABSTRACT

Further ellipsometric data which confirm the two-layer nature of the anodic oxide films grown on tantalum in dilute phosphoric acid are reported. The two layers are believed to arise, respectively, from growth at the oxide/solution interface due to metal ion transport and from growth at the metal/oxide interface due to oxygen ion transport. The outer layer has a lower refractive index and dielectric constant due to phosphate incorporation. The effects have been observed in dilute phosphoric acid but not in the previous work in dilute sulfuric acid and citric acid of comparable concentration since phosphate is incorporated relatively strongly during the growth process. A model with a linear gradient of index is shown not to give an adequate representation of the optical results.

One of the most unexpected experimental findings in the study of the growth of anodic oxide films on tantalum is that both metal and oxygen ions are mobile to comparable extents. The situation as shown by the most recent tracer studies of Pringle (1) is especially puzzling in that the results are, as he pointed out, quite inconsistent with conventional models of ionic transport. Thus it was found that layers of rare gas marker atoms embedded in thin oxide films were spread out during subsequent growth of the films. The amount of spreading was greater the lower the mass of the rare gas atoms. However, the position of center of the distribution with respect to the metal surface was independent of the mass of the atoms. The amounts of new oxide produced on either side of the marker layer were determined by Pringle and used to calculate the metal ion transport number for anodization in 0.2*N* sulfuric acid at various current densities. It appears that the film grows simultaneously at the metal/oxide and oxide/solution interfaces: thus, tracer studies by Randall, Bernard, and Wilkinson (2) showed that the outer part of the film contains a uniform and in some cases a quite large amount of species from the electrolyte. The effect was particularly marked with phosphoric acid, and it was shown that the incorporated phosphate decreased the permittivity and ionic conductivity of the oxide compared to films made in dilute sulfuric acid. The oxide produced at the metal/oxide interface was found to be free from incorporated electrolyte species, as would be expected if the incorporated species are not mobile within the film. Ellipsometric measurements already reported (3) and further extended below give a clear confirmation of this picture of two homogeneous layers for films made in dilute phosphoric acid. In 0.2*N* sulfuric acid the effect of incorporated sulfate is less and optical methods (4-7) have either indicated a homogeneous film or have detected a deviation from a uniform oxide only in the form of an apparent very thin outer absorbing layer for films made in dilute sulfuric acid (5) although marked optical inhomogeneity through the thickness of the film was found for films made in more concentrated acid. Recent ellipsometric measurements by Muth (8) on films made in citric acid and dilute sulfuric acid have also indicated an optically uniform film and have given a permittivity close to that found for films made in 0.2*N* sulfuric acid (4) as compared to the lower value found by Klerer (9) using "Talysurf" measurements for the thickness.

Experimental Procedures

The polycrystalline Fansteel capacitor grade tantalum specimens were prepared by abrasion with metallurgical papers followed by either (*a*) mechanical polishing with alumina on a polishing wheel followed by a 5-sec dip in 48% HF, (*b*) electropolishing (5), or (*c*) mechanical polishing followed by electropolishing. It is believed that large-scale deviations from flatness should introduce only an averaging error due to the range of angles of reflected light accepted by the ellipsometer. Small-scale deviations would make the metal behave as though it were "tapered" in density but should disappear due to the smoothing inherent in anodizing. In practice electropolishing gave 1 or 2% higher current efficiencies for oxide production but a more wavy surface than did mechanical polishing. More careful empirical optimization of procedures is needed to obtain a good electropolished surface with polycrystalline than with single crystal metal.

Formation procedures and ellipsometry measurements were essentially as described in previous papers (3, 7). A detailed analysis of ellipsometric errors was made (thesis by Dell'Oca).

Results and Discussion

Two layer nature of the films.—The evidence from the tracer work is that the transport number is independent of total thickness at constant current density. To the extent that one may assume as a first approximation that the thickness of oxide formed per coulomb is the same for the two parts of the film, then the ratio of increments in the thickness of the outer layer to increments in total thickness is equal to the metal ion transport number. The ellipsometric results were fitted on the basis of the ratio of the thickness of the two parts being constant at constant current density. The parameters were initially chosen by comparison of experimental ellipsometric curves with computer curves. Later a program was used which adjusted the parameters in turn to minimize the mean square deviation of the experimental points from the computed curve with the Ψ values weighted by a factor of 4.[1]

The characteristic feature of the two layer model is that, with two layers which are nearly equal in index and thickness, when the thickness of the film has been increased so that the phase change of light traversing the whole film in-and-out has increased by 2π, the exponential terms in the ellipsometry equation which involve the phase changes in the individual parts of the film have changed corresponding to an approximate π change of phase, *i.e.*, have changed sign. After a fur-

[1] Ellipsometry gives the ratio of the complex reflectivities in p and s light: $R_p/R_s \equiv \tan\psi \exp i\Delta$.

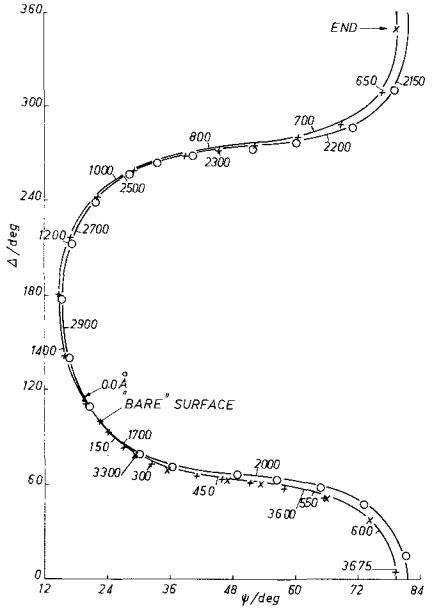

Fig. 1. Experimental results and calculated curve for *in situ* ellipsometric measurements on tantalum specimen anodized in dilute H_3PO_4 (Table I, line 7). Successive cycles denoted + O X. Wavelength 5461Å, angle of incidence 67.5° (also applies to Fig. 2, 4).

ther 2π total phase change these terms have nearly returned to their original values. Hence the plot of Ψ *vs.* Δ tends to return close to its original track on what would be the third cycle for a uniform film. This is illustrated by calculated and experimental data in Fig. 1.

Some numerical results are given in Table I which contains the values of the parameters which gave the best fit to each of a set of specimens for both two layer and single layer films. The root mean square deviation in Δ and Ψ is also given and clearly confirms a better fit with the two layer model. The qualitative aspect of "recycling" on the third cycle (3) is, however, perhaps the most conclusive feature.

With electropolished surfaces a value of 3.3-2.3*j* for the refractive index of the metal (5-7) gave the best fit, but with mechanically polished metal a lower value of absorption index 2.25 was preferred. However, the optical properties of the oxide seemed unaffected by method used in surface preparation of the metal. The index of the inner oxide was found to be 2.22, *i.e.*, close to the value at this wavelength found in previous work (7) for films made in 0.2*N* H_2SO_4. The index of the outer layer depended on both the concentration and nature of the electrolyte, since these things affect the nature and amount of incorporated electrolyte species. As in previous work, no evidence for two layers was found in 0.2*N* H_2SO_4.

What might seem an obvious alternative model is that involving a continuous monotonic gradient of index through the film rather than two individually homogeneous layers. Physically this might correspond to the incorporated species continuously moving inward as the film grew, and in this case fixed values of index at the interfaces might be expected. The case of a linear gradient with fixed end values was computed using a stepwise approximation with 56 steps, *i.e.*, 56 thin homogeneous layers. This model fairly unequivocally does not fit the data since on the third cycle there is no tendency to return to the curve traced out on the first cycle (Fig. 2.).

Experimentally, there is clearly no reason why the measurement errors should produce the recycling effect.

Table I. Parameters giving best fit to ellipsometry data for oxides grown in various ways using a one or two layer optical model for the oxide. For oxides grown in H_3PO_4 both the double and single layer fit is given. (Single layer is distinguished by absence of values for n_2 and G where G = thickness of outer part divided by total thickness.) The value $n_m = 3.3$ is assumed

Table II. Comparison of goodness of fit by a single layer and by a two layer model of measurements at three angles of incidence on a single film. The index of the metal was taken as $3.3 - 2.3j$ and the other parameters were varied to obtain the best fit. The best values were: single layer; $n = 2.17$; two layers $n_1 = 2.15$, $n_2 = 2.22$, $G = 0.52$ (= outer film thickness/total film thickness). ϕ = angle of incidence, T = thickness

	Experimental		Single layer fit			Two layer fit		
ϕ	ψ	Δ	ψ	Δ	T (A)	ψ	Δ	T (A)
75°	50.04	10.6	49.956	10.287	1924.71	49.986	10.435	1894.25
67.5°	54.71	4.64	54.718	4.575	1924.70	54.786	4.683	1895.3
60°	60.03	339.98	60.094	339.916	1923.81	60.143	339.876	1895.67

Measurements were also made on each of three films at three angles of incidence to test the two layer model. As might be expected the data for each film can *a priori* be fitted equally well by a single layer model, as illustrated for one film in Table II.

The relative permittivity of the outer layer of films formed in 0.23*N* phosphoric acid was determined by assuming that the inner layer has the same permittivity as the effective value 27.6 found for films formed in 0.2*N* sulfuric acid under specified conditions (4). This is justified by the model in which the oxide formed at the metal/oxide interface is not affected by the nature of the electrolyte, and provided that the effect of the incorporated sulfate in films made in dilute sulfuric acid may be neglected, as is confirmed by the interpretation of the ellipsometer data in which the refractive index of the inner layer of films made in phosphoric acid was equal to the effective value for films made in dilute sulfuric acid. The value obtained was 25 for formation at 1 mA/m^{-2} and 25°C, measured at the same temperature.

Metal ion transport member.—Ellipsometry provides a nondestructive method of estimating transport number. The values obtained for 0.23*N* phosphoric acid at 25°C were 0.51 to 0.52 at 1 mA/cm^{-2} and 0.56 at 10 mA/cm^{-2}. These, as shown in Fig. 3 are in excellent agreement with the tracer data of Randall *et al.* (2), as might be expected since both methods use the incorporated electrolyte species as markers. It is perhaps worth noting that the only case for which both the method using inert gas and that using the electrolyte species as markers have been applied is formation at 1 mA/cm^{-2} at 25°C in 0.2*N* sulfuric acid and that the results were in disagreement [0.256 (1) as compared to 0.48 (2)].

Sequential Formation in Different Electrolytes

If a film is formed first in concentrated and then in dilute acid it is expected that the oxide produced consists of three layers. An inner layer which represents the inner undoped portion of the oxide formed in each anodization. A middle layer containing a uniform high concentration of phosphate typical of formation in concentrated H_3PO_4 and an outer layer typical of the outer layer formed in the dilute acid; this is provided

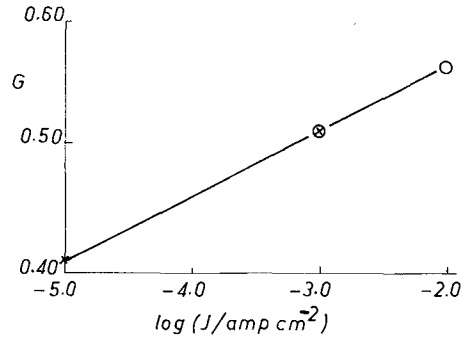

Fig. 3. Ratio of thickness of outer layer to total thickness vs. current density for film grown in dilute H_3PO_4 at 25°C. X Randall *et al* (2); O present work.

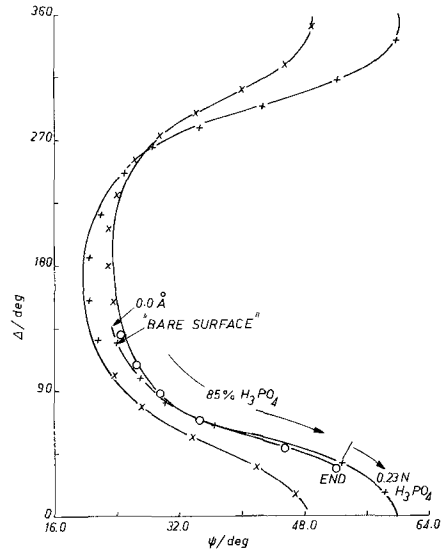

Fig. 4. Experimental points and computed curve for anodization in concentrated followed by dilute phosphoric acid. The computer curve is based on the model that the already existing oxide is unchanged by further anodization, the oxide produced is determined by the electrolyte in use. Cycles denoted + X O.

that the incorporated species are immobile. Knowing the thickness of each layer of the oxide produced in the concentrated acid anodization and assuming that the refractive index of each portion of the oxide for the two anodizations would be the same as for formation entirely in each electrolyte, then the ellipsometry results of the second anodization could only be fitted if the separate layers occur in the sequence outlined above. Figure 4 shows fitted and observed data for the case where 0.23*N* H_3PO_4 was the second electrolyte. In curve fitting, values from Table I of $n_1 = 2.14$, $n_2 = 1.98$, and $n_3 = 2.22$ for the index of refraction of outer, middle, and inner layers were used, and the best fit to the data was found by varying G, the ratio of the outer layer to total new oxide produced in the second electrolyte, where the initial oxide now acts as a marker layer. A G of one half was found which agrees well with formation entirely in dilute H_3PO_4 as in Table I. Similar results were obtained from fitting the previously reported data (3) where the second electrolyte was 0.2*N* H_2SO_4 (except $n_1 = 2.22$ was used). All formations were at 1 mA/cm^2 at 25°C.

It might be pointed out that oxide formation in concentrated phosphoric acid is supported to about 95V at 1 mA/cm^2. The range of oxide thickness obtained is not sufficient to produce a complete ellipsometry cycle (3); however, a model of two nonabsorbing layers fits these results better than a single absorbing layer (1 aCPA Table I) and much better than a single nonabsorbing layer (not shown). Furthermore, the fit to the results from sequential formation in different electrolytes was obtained only if the initial oxide formed in concentrated acid consisted of two nonabsorbing layers.

High Field Ionic Conduction in Tantalum Anodic Oxide Films with Incorporated Phosphate

C. J. Dell'Oca and L. Young***

Department of Electrical Engineering, University of British Columbia, Vancouver 8, British Columbia

ABSTRACT

The dependence of the ionic current density J on the mean field $\overline{E}$ in oxides grown on tantalum in H_3PO_4 electrolyte was studied using ellipsometry to estimate the thickness. The field in the outer layer which is believed to grow due to metal ion motion is higher because of phosphate incorporation. The field in this layer was estimated by assuming that the field in the inner undoped layer was the same as the mean field at the same current density and temperature in films made in dilute sulfuric acid, which are less affected by electrolyte incorporation. The results indicate that the effect of phosphate on the ionic conductivity may be due to its reducing the permittivity and hence the effective field. It is pointed out that electrolyte incorporation gives two effects which contribute to the nonlinearity of log J *vs.* $\overline{E}$ plots. Thus, since the metal ion transport number increases with J so does the proportion of the film which contains phosphate and requires a higher field. Also the concentration of phosphate increases with J. The incorporation leads to history effects which are not removed by subsequent formation, since the profile of phosphate records the sequence of current densities used. The time dependence of the field on changing the electrolyte is consistent with the field locally determined by the local film material.

An investigation is reported on the effects of incorporated phosphate (1) on the ionic conduction process using the ellipsometer techniques described in the preceding paper.

In the earlier work on ionic conduction in anodic oxide films the current density J was expected to depend on the field E according to $J = J_0 \exp(-(W - \alpha E)/kT)$. Experimental results were at one time thought to show an anomaly of the type that $\partial \log J/\partial E$ was independent of the temperature (2). Later (3) it was claimed that the steady state J could be described by $J = J_0 \exp(-(W - \alpha E + \beta E^2)/kT)$ *i.e.*, the slope of log J *vs.* E plots varied as expected with temperature at constant E but was not independent of E. The earlier anomaly arose because experimentally a mean slope over a fixed range of J was calculated. The rationale of this form of expression was that the activation energy for sufficiently large fields should be detectably nonlinear in the field. Several mechanisms have since been proposed by various authors which must lead to this type of effect with homogeneous oxide, whether or not they are experimentally significant. The theory of ionic conduction is based on the idea that the potential energy of the moving ion can be written as a periodic function of its own position coordinates only, plus a ramp due to the applied field. This model gives nonlinearity as a second order effect as was noted in the above paper (2) where it was supposed to be small. (It depends on the shape of the potential energy function.) Random variations in activation energy from site to site such as are expected in an amorphous oxide were shown to be capable of giving this effect but not the analogous one in the transient case where the sudden changes in J due to sudden changes in E are observed (4).

Later it was suggested that electrostriction might be responsible (5), but Dignam (6) and later Dignam and Gibbs (7) showed that, if so, the electrostriction must be much greater than in halide crystals. It is certainly likely to be greater, and electrostriction has been claimed and disputed to dominate the electro-optic effect shown by these films (8, 9). Dignam, Goad, and Sole (10) have found a similar experimental behavior with aluminum. Dignam (6) and Dignam and Gibbs (7) have considered in some detail the question of the effects of the shape of the periodic potential energy function and conclude that the curvature may be accounted for by this. Young and Zobel (12), who extended the experimental result to niobium, suggested that an expected model for these oxides would be ions moving fairly freely down channels with occasional coulombic traps. This model corresponds to $J = J_0 \exp(-(W - \gamma E^{1/2})/kT)$ which represents the data quite well with one less parameter. It is a mistake to suppose (7) that this model is incorrect because the quadratic expression gives a better fit. One cannot expect an accurate fit for an approximate treatment of a simplified model; the point is whether the fit is accurate enough to suggest that the model contains the essential features of the real system. Further theoretical treatments have been based on the shape of the potential energy-distance relation and on dielectric effects treated by transition state theory (13, 14). Dreiner and Tripp (15)

Key words: tantalum, anodic oxide films, ellipsometry, ionic conduction at high fields, dielectric films.

[*cf.* Dreiner (16)] have recently confirmed experimentally the quadratic form for tantalum over an extended temperature range using a pressure vessel.

Most of the work has been done on films made in dilute solutions of electrolyte which are not strongly taken up by the oxide. It will be shown in the present paper that two effects, due to the incorporation of electrolyte, lead to curvature of log J *vs.* $\bar{E}$ plots where $\bar{E}$ is the average field in the oxide. This has not been noted before although in the first report of the effect (3) it was shown that the curvature is larger for films made in more concentrated sulfuric acid solutions which were known to be inhomogeneously taken up.

The experimental procedures were as described in the accompanying paper which also deals with the ellipsometric techniques used.

Results and Discussion

The constant field required for a constant ionic current up to quite large thicknesses suggests that the bulk of the oxide is electrically neutral at fields which give ionic conduction. The field required for a given current must then, according to conventional models, be determined by the concentration of the mobile species in the electrically neutral oxide. However, this concentration could be controlled by the nature of the bulk oxide or by interface effects, *e.g.*, if space charge compensation occurred due to double injection of positive and negative ions. A partial test is provided by formation successively in two electrolyte solutions. In the case of bulk control, if the existing oxide is not modified by the change of electrolyte, then the mean field is a function of the thicknesses and characteristic fields of the various layers. Thus for formation in 14.7M phosphoric acid followed by formation in 0.23*N* phosphoric acid, an inner layer which is essentially pure oxide, a second layer containing a high concentration of phosphate and a third, outer layer containing a lower concentration of phosphate are produced. Ellipsometric data were fitted well by this model as shown in the previous paper. Figure 1 shows that the computed and observed fields are consistent with the idea that the field in each individual layer is characteristic of that layer and independent of whatever other layers were present. In the computation 8.15 x 10^6 V/cm and 6.46 x 10^6 V/cm, respectively, represent the fields typical of formation in the first and second electrolyte and the oxide produced in the first electrolyte was 552Å.

In previous work with 0.2*N* sulfuric acid (3), experiments were made in which films were grown either completely at a given current density to a given final voltage, or partly at a higher current density and then finally at the same lower current density to the same final voltage. The optical thickness was found to be indistinguishable provided a quite small minimum charge was passed at the final current

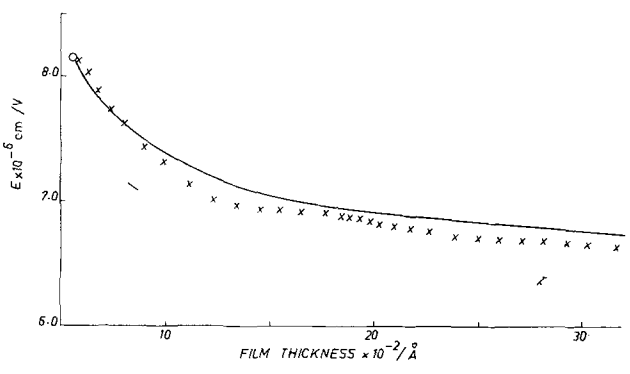

Fig. 1. Average field as function of thickness after changing electrolyte. The line is calculated on the basis that the field in each part of the film is characteristic of the material in that region.

density. Also the relation between J and $\bar{E}$ was indistinguishable within 1% of field values for formation at constant voltage and constant field, respectively (12). On the present model one should expect the distribution of incorporated electrolyte to be a function of the formation procedures, and, since the incorporated phosphate is thought to be immobile, no amount of formation at a final current density should bring the film into the same state as complete formation at this current density. If this is indeed the case, the effect went undetected in dilute sulfuric acid only because it was too small. In 0.23*N* phosphoric acid the effect was detected as shown in Table I.

Dependence of ionic current density on field.— Figure 2 shows the mean field in the oxide *vs.* the ionic current density for growth of films in 0.23*N* phosphoric acid. The data were obtained by first growing to 99V at 10 mA/cm^{-2} giving about 1400Å of oxide. A constant 100V was then applied. The thickness was estimated using ellipsometric measurements made during successive interruptions of film growth. A two layer model with the metal ion transport number taken as 0.56 was employed as an approximation,

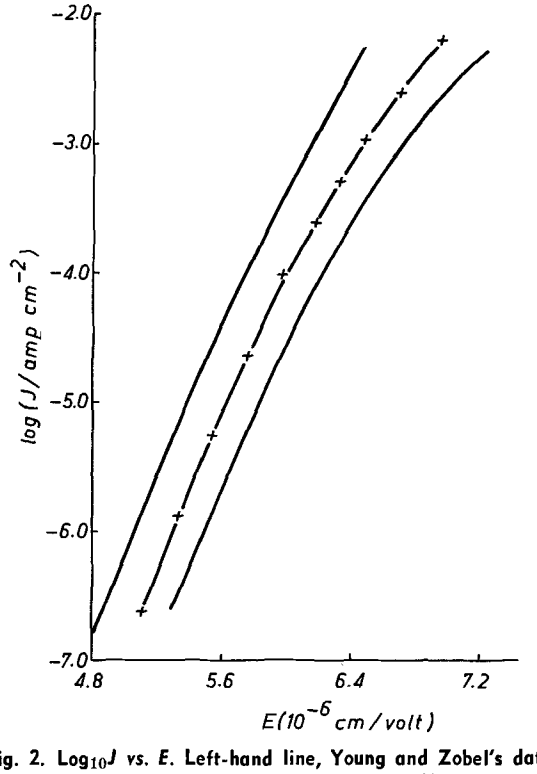

Fig. 2. $\text{Log}_{10}J$ *vs.* E. Left-hand line, Young and Zobel's data for 0.2*N* H_2SO_4; middle line, present data for 0.23*N* H_3PO_4; right-hand line, field in outer part of film obtained from middle line by assuming that the field in the inner part is the same as the mean field for formation in 0.2*N* H_2SO_4.

since most of the film was grown at the high current densities for which this transport number was found. The total ionic current density was found by differentiating the thickness-time data. Also shown in Fig. 2 is a curve which represents the data of Young and Zobel (12) for formation in 0.2N H_2SO_4 with the same procedure except that a uniform film was assumed.

In agreement with Randall *et al.* (1) the mean field is higher with the phosphoric acid due to the greater effects of phosphate compared to sulfate.

The results at 25°C are described by

$$J = J_1 \exp (q(\alpha E - \beta E^2)/kT)$$

where $q = 5e$ and

$J_1 = 10^{-38.42}$ A/cm^{-2}, $\alpha = 10.69$Å, $\beta = 6.51$ Å/10^{7}vcm^{-1}

as compared to

$10^{-28.71}$A/cm^{-2}, 6.995Å, 3.34 Å/10^{7}vcm^{-1}

for 0.2N H_2SO_4. To obtain the field in the outer layer, the field in the layer near the metal was approximated by the mean field for formation in 0.2N sulfuric acid, analogous to what was done in the accompanying paper to estimate the permittivity. The result is shown in Fig. 2. Changes during the constant voltage formation in the ratio G of the thickness of the outer film to the total thickness were estimated by assuming that the instantaneous transport number at a given J was the same as the steady-state value at this J (see preceding paper).

Curvature of log J vs. $\bar{E}$ plot.—Two effects associated with electrolyte incorporation cause curvature. First, the metal ion transport number has been found experimentally to increase with J. Thus the higher J the larger the fraction of the film that requires a higher field because of phosphate incorporation. Second, concentration of incorporated electrolyte is found to increase with J. The precise curvature produced depends on the conditions, *i.e.*, constant voltage or constant current formation. If the assumptions made in dissecting the film to evaluate the field in the outer layer were correct, then any curvature in the plot in Fig. 2 would be due to this second effect plus any curvature shown by homogeneous oxide.[1]

It is interesting to note that the fields in the two layers are roughly inversely proportional to their permittivities. This is shown in Fig. 3 when log J is plotted against $\epsilon_r E = D/\epsilon_0$ (D = electric displacement). This continuity of D across the interface between the two layers is not the result of an electrostatic boundary condition between dielectrics as assumed by Dignam (17) and by the reviewers: the layers act as conductors not dielectrics and the boundary condition is continuity of current density. There is no reason why charges should not accumulate at the interface to give any required change in D.

[1] It is perhaps useful to give some trivial equations showing that (for constant J formation) curvature is implied by the empirical facts of dependence of transport number, and concentration of incorporated phosphate on J, and of the constancy of D. Thus, experimentally (1) at constant temperature $G = A + B \ln(J/C)$ where A, B, C and further similar quantities below are temperature dependent parameters. Clearly, this relation can be valid only over a limited range of J. The mean field is $\bar{E} = E_i(1 - G) + E_0 G$ where E_i and E_0 are the fields in the inner and outer layers. We assume that the permittivity may also be taken as linearly dependent on $\ln(J/C)$ and that the effect of phosphate is solely on the effective field, *i.e.*, $J = C \exp HE_i = C \exp KE_0$, where $K = (1 - L \ln(J/C))M$. Hence, $\bar{E} = \left(\frac{1-A}{H} + \frac{A}{M}\right)\ln\left(\frac{J}{C}\right) + \left(\frac{B}{M} - \frac{B}{H} + \frac{AL}{M}\right)\left(\ln\left(\frac{J}{C}\right)\right)^2 + \left(\frac{BL}{M}\right)\left[\ln\left(\frac{J}{C}\right)\right]^3$ provided $1/(1 - L \ln(J/C)) \simeq 1 + L \ln(J/C)$. In Fig. 3 the difference in curvature between the plots for the inner and outer layers, on the assumptions made, is due to no allowance having been made for L. Also, in this experiment the concentration of phosphate in the outer layer will not have been constant, since the current density and mean field were decreasing throughout as the thickness increased at constant voltage.

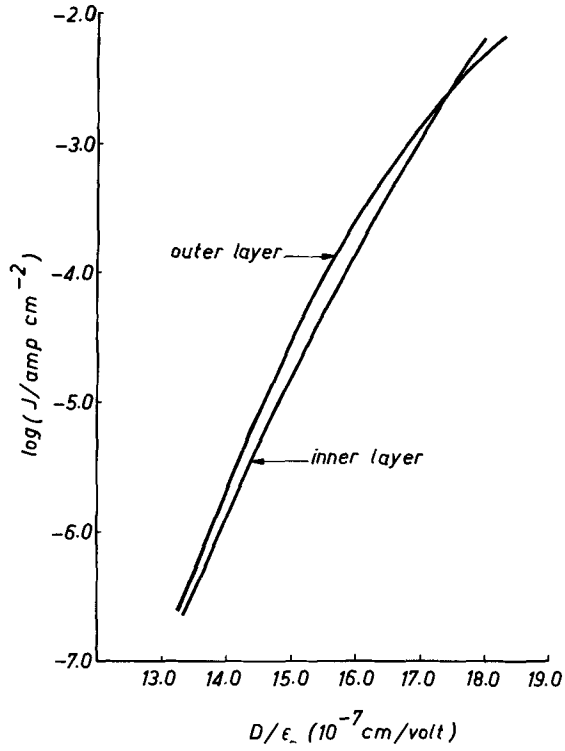

Fig. 3. $\text{Log}_{10} J$ vs. $\epsilon_r E = D/\epsilon_0$ for inner and outer parts of films made in 0.2N H_3PO_4.

Charges are supposed to exist close to the metal/oxide and oxide/solution interfaces to adjust the fields at these interfaces with respect to those in the interior of the film.

The near-equality of D seems to mean that an effective field should be taken as driving the ions in the ordinary model. For high ϵ_r the effective field will be essentially proportional to ϵ_r. The long-noted parallelism (1, 18) between ϵ_r and ionic conductivity cannot be ascribed to both being due to lattice point defects since little change occurs with phosphate doping in the audio frequency dielectric dispersion. The difference in permittivity is partly due to ultraviolet frequency effects (as shown by the change in refractive index) and most of the rest must be due to infrared polarization processes.

Both sources of curvature are indicated by the tracer results (1) to be present in films made in 0.2N H_2SO_4. The question is, therefore, whether any detectable curvature would be present in truly homogeneous oxide. To resolve this question, experiments are needed on films made in very dilute solutions of electrolytes which have minimum tendency to be incorporated. However, some clues are possibly as follows. First the idea of nonlinear activation energy removes the temperature anomaly in $\partial \log J/\partial E$ for both steady-state (3) and transient experiments (4). Second, the history of current densities was found experimentally to have little effect with 0.2N H_2SO_4 on the $\bar{E}$ for a given J provided a quite small charge was passed at the final J. Finally, it is surprising that the curvature effects should be shown by tantalum, aluminum, and niobium. In all these considerations a basic difficulty is that, in our opinion, no theory, which would be at all convincing in the absence of the experimental data, explains the comparable order of mobility of metal and oxygen ions. Possibly some momentum transfer process, such as is required (4) to explain the time development of J at constant E with films previously made at low J, will eventually explain this, but such a process is not taken account of in the ordinary theories of steady-state ionic con-

duction. We refer to Pringle's (19) and Dignam's approaches to this problem (20).

Thermal recrystallization.—Another process which involves atomic movement is the thermal recrystallization of the films (21-24). In this case local electric fields and concentration gradients near the crystalline nuclei drive the transport process. It might be expected that electrolyte incorporation effects might be seen also in this process although the facts that the inner layer is thought to be free of electrolyte, and that ion movement occurs more freely in this layer, might equally be expected to cancel out the effect. Brandon *et al.* in the discussion of their paper (24) have in fact reported observing electrolyte effects on thermal recrystallization.

Films of about 500Å were made on tantalum which had been chemically polished. The films were detached by the cathodic technique (2), mounted on platinum grids, and annealed at temperatures in the range of 650°-750°C in groups on a silica support in a silica-tube furnace in an atmosphere of oxygen. They were then examined in a Hitachi 11AB electron microscope at 100 kV. The reproducibility as regards the absolute amount of recrystallization was poor. However, the percentage of recrystallization was consistently greater for films made in dilute sulfuric acid than for films made in dilute phosphoric acid. The general appearance of the recrystallized films was also different.

A Doped Oxide Deposition System for Antimony Diffusion

F. L. Gittler* and R. A. Porter

Bell Telephone Laboratories, Inc., Allentown, Pennsylvania 18103

ABSTRACT

A doped oxide diffusion system for antimony diffusion is described. The system has been shown to be feasible for base diffusion in PNP transistors. It appears to be superior to presently used systems for buried layers in integrated circuit slices.

The apparatus consists of a hot plate which heats a turntable on which slices to be deposited are placed. The associated gas train is automatic and can be programmed to deliver $(CH_3)_3Sb$ (the antimony source), SiH_4 and oxygen, to make the oxide, and nitrogen. The gas reaches the slice through an inverted fritted funnel. The deposition occurs at the desirably low temperature of 315°C and typically takes less than 5 min. The layer before the drive-in diffusion consists of an Sb_2O_5 or mixed SiO_2-Sb_2O_5 layer. This is then capped with an SiO_2 layer to prevent Sb evaporation from the surface. The drive-in is accomplished at normal diffusion temperatures.

The diffusion coefficient at 1200°C of 8.3×10^{-13} cm^2 sec^{-1} was calculated using an erfc distribution. A surface concentration of 5×10^{19} cm^{-3} was determined from published curves (13). The diffusion coefficient is somewhat higher than published values, which may be due to the availability of excess Sb_2O_5 at all times during the diffusion run.

The system is recommended for silicon device processing and has recently been shown to be useful for germanium diffusion.

Antimony diffusions have customarily been accomplished by use of solid Sb_2O_3 in a two-zone furnace (1). Some of the surface problems generated by use of the solid source were described by LaRocque *et al.* (2). The surface eroded during diffusion due to high concentration Sb areas. Runyan has used $SbCl_5$ as a diffusion source with some success (1). A liquid source has also been reported (3) which performs well.

The dopant used in this investigation is $(CH_3)_3Sb$, trimethylstibine. It was diluted in nitrogen and pur-

chased from Air Products and Chemicals Company, Allentown, Pennsylvania. Methods of preparation are cited in Morgan (4). $(CH_3)_3Sb$ is a colorless liquid, boiling point—80.6°C, melting point—87.6°C.

In the work described here, the source is admitted in the vapor state mixed with nitrogen. The apparatus used is an improved modification, described below, of the version used by Conser *et al.* (5).

The major advantages of this diffusion system are the preservation of surface perfection, inexpensive deposition apparatus, and a furnace system in which gas flow patterns are inconsequential, because only the drive-in is accomplished in the high temperature furnace. Flow patterns in the deposition apparatus may be important, when mixed Sb_2O_5-SiO_2 is deposited. However, this deposition is a low temperature, 300°, procedure. $(CH_3)_3Sb$ was chosen for this application, because the hydride H_3Sb, is unstable and $(CH_3)_3Sb$ was the volatile compound with the highest antimony content available (6). The most important use of the method described here is for "buried layer" applications for integrated circuit designs and for base layers in PNP transistors. The method works equally well for germanium.

Experimental Procedure

In Fig. 1 is a schematic representation of the experimental apparatus. The gas flow is controlled automatically by timers. Entering at the top of the reaction chamber are the reactants SiH_4 and $(CH_3)_3Sb$. The cylinders containing the gases are shown on the left. The silane used was a 3% mixture in nitrogen and the trimethylstibine was a 1% mixture in nitrogen. These concentrations were not checked.[1] The only other reactant required, oxygen, entered on the left and right of the reaction chamber. The temperature of the hot plate was 360° ± 0.5°C stabilized by the controller. The slice temperature, determined by means of a color changing indicator was 315°C. It can easily be seen that all or any combination of the 3 reactants can be admitted to the reaction chamber.

The object of this procedure was to deposit the dopant onto the slices located on the turntable. Subsequent treatment in a furnace at temperatures in excess of 1200°C resulted in a diffused silicon layer in a slice. When only $(CH_3)_3Sb$ or SiH_4 was admitted, no deposition occurred. In order to make a run, the hot plate turntable was lowered from the reaction chamber. Slices were placed on the turntable as shown, the turntable raised to meet the reaction chamber, timers set for desired time, and the start button pushed. After completion of the prescribed automatic cycle, the slices were removed by lowering the turntable. Between runs, N_2 was usually allowed to flush to keep the system dry.

The reactions presumed to occur are

$$SiH_4 + 2\,O_2 = SiO_2 + 2\,H_2O$$
$$2\,(CH_3)_3\,Sb + 13\,O_2 = Sb_2O_5 + 6\,CO_2 + 9\,H_2O$$
$$SiH_4 + 2(CH_3)_3Sb + 15\,O_2 = SiO_2 + Sb_2O_5 + 6\,CO_2 + 11\,H_2O \quad [1]$$

[1] The concentration of SiH_4 was obtained by mixing the pure gases. The $(CH_3)_3Sb$ was weighed in an ampoule, which was then broken in the nitrogen contained in the cylinder. All runs were made by use of a single cylinder of each of the gas mixtures.

Experimental Results

Deposition experiments.—The purpose of this series of experiments was to find the rate of deposition of SiO_2 and Sb_2O_5 on silicon substrates. Six runs were made with flow conditions given in Table I. Shown in Fig. 2 is a plot of weight gain *vs.* time of deposition for pure or mixed oxides on silicon substrates at 317°C. The volume ratios shown are flow rates of $(CH_3)_3Sb$-N_2 and SiH_4-N_2 mixtures. Note that to obtain the volume ratios 0.3, 0.5, and 1, the flow rate of SiH_4-N_2 was maintained constant and the flow rate of $(CH_3)_3Sb$-N_2 varied. The run at volume-ratio-of-2 was made at one-half the SiH_4 flow.

One would expect that weight gains of runs 2, 3, and 4 with additional $(CH_3)_3Sb$ would be larger than for pure SiH_4. This is not the case as shown by the results in Fig. 2. The maximum weight gain per minute if complete reaction occurred and all products deposited on one slice only, is given in Table II. Of course, not all reaction products deposit on one slice, but the relative amounts should be in proportion with Table II.

A plot normalized at volume ratio of 0.3 is shown in Fig. 3. It is not clear how the added $(CH_3)_3Sb$ could cause such a decrease in deposition rate. The layer deposited with equal volumes of SiH_4 and $(CH_3)_3Sb$ was analyzed and found to be 95% Sb_2O_5 and 5% SiO_2. Several explanations are plausible. The addition of $(CH_3)_3Sb$ may act as a chain breaker in the oxidation of SiH_4 believed by some to be a chain reaction. Or the surface, which is required for deposi-

tion of SiO_2 and Sb_2O_5, catalyzes the Sb_2O_5 formation but not the SiO_2 formation. Or, even though oxygen was in excess, SiO_2 molecules did not deposit with the same efficiency as Sb_2O_5 and, therefore, unreacted SiH_4 and nondeposited SiO_2 left the reaction chamber.

The molecular species deposited in the silicon slice was determined by microprobe analysis (7). As noted above, Sb_2O_5 and SiO_2 were found, hence Eq. [1] is consistent with the analysis.

Diffusion experiments.—One of the problems with Sb_2O_5 is its volatility since Sb_2O_5 evaporates during the diffusion necessary to redistribute the Sb from

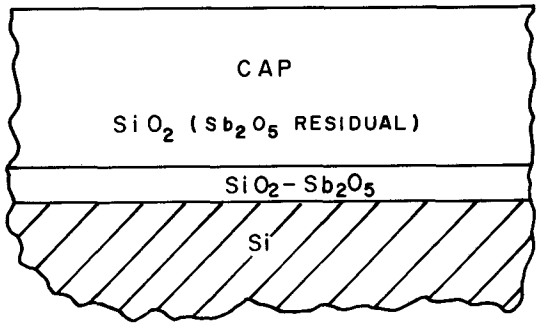

Fig. 4. Structure after deposition

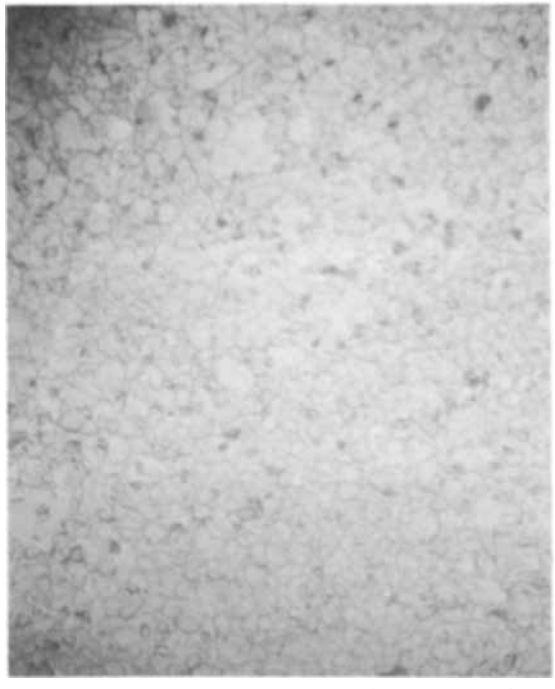

Fig. 5. Surface of slice after diffusion, when excessive deposition times are used.

the surface into the silicon to avoid the escape of Sb_2O_5 during drive-in-diffusion, an "oxide-cap" is grown as shown in Fig. 4. Such a structure is produced by first admitting a mixture of $(CH_3)_3Sb$, SiH_4 and oxygen and then only SiH_4 and oxygen. If very low sheet resistances were desired, pure $(CH_3)_3Sb$ and O_2 were admitted. The SiO_2 cap is directly responsible for the success of this method; however, in addition to the cap, it was necessary to restrict deposition times to less than 3 min or poor surfaces resulted. An example is shown in Fig. 5. Thin deposition layers resulted in no visible surface deterioration during diffusion.

A wide range of sheet resistivities can be obtained by varying the trimethylstibine to silane ratio. Sheet resistivities from 15 to 290 ohm-square^{-1} were obtained by changing the flow ratios from 0.03 to 1.0 and drive-in temperatures from 1200° to 1284°C as shown in Fig. 6. An example of a typical run is given in Table III.

The deposition time of 4 min is favorable for mass processing. Since only a flat temperature-profile-furnace is required for drive-in diffusion, a number of hot plates can be used to deposit the slices and several hundred slices can then be driven-in at the same time. Junction depths can easily be predicted as shown in Fig. 7. The junction depth is a function of $\sqrt{t}$.

Reproducibility of the runs is shown in Table IV. Each run consisted of 4 slices deposited with pure

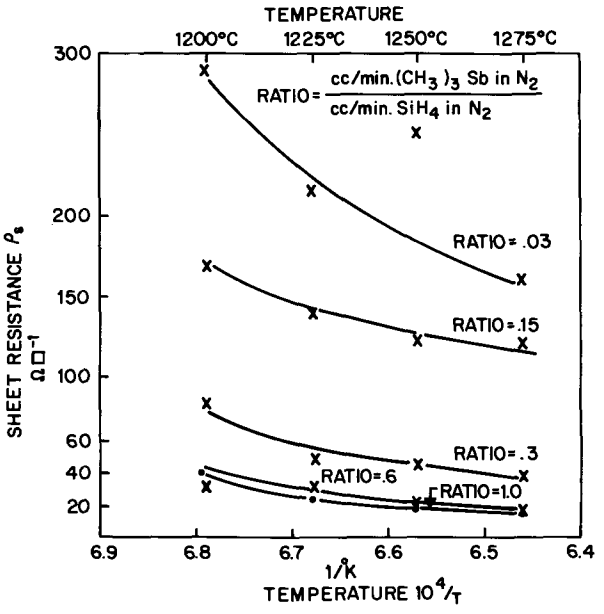

Fig. 6. Resistivity as a function of stibine ratio and diffusion temperature.

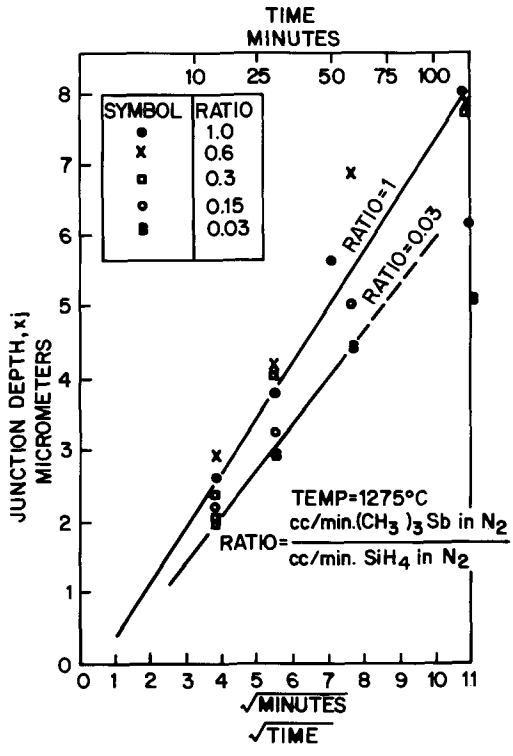

Fig. 7. Junction depth as a function of diffusion time

$(CH_3)_3Sb+O_2$, capped with SiO_2, and diffused for 2 hr at the temperatures indicated. One slice was angle lapped in each run and surface concentrations were computed using the complementary error function profile. The resistivities measured on each of the 4 slices in each run were 2% of the average resistivity for that run.

The error function distribution was assumed in the solution of the diffusion equation, though an infinite source may not actually have been available. Rather a rate-limiting step may have to be assumed, because the antimony in the silicon diffuses faster than in the oxide. Smits and Miller derived a solution for a rate-limiting transfer step which they solved for the gaseous case (8). In the situation at hand, diffusion occurs both into the oxide cap and the silicon. For simplicity and since no diffusion constants in the oxide were known, a complementary error function in the silicon was assumed. This is a good assumption, since diffusion occurred from pure Sb_2O_5.

Since diffusion times are known, it is possible to calculate effective diffusion coefficients, which are shown in Table V. The higher diffusion coefficient found in this work may be due to the more concentrated source used.

Many device slices have been diffused using the doped oxide deposition system and both good surfaces and good device yields have been produced.

Exposure of Photoresists

II. Electron and Light Exposure of a Positive Photoresist

Barret Broyde

Engineering Research Center, Western Electric Company, Inc., Princeton, New Jersey 08540

ABSTRACT

Less energy is required to solubilize AZ-1350 when the exposure is accomplished with kilovolt electrons than when light is used to expose the photoresist. In contrast to overexposure with light, overexposure by electrons causes an insoluble cross-linked product to form. The solubilization reaction is enhanced by the addition of small amounts of benzotriazole, indazoles, and imidazoles, while the cross-linking reaction is inhibited by these additives.

Photosensitive materials called photoresists are used during the manufacture of semiconductor devices to protect selected areas of semiconductors and other surfaces against chemical attack. Conventionally, the desired pattern in the photoresist is obtained by exposing the photoresist-coated surface to light through a mask. However, electron beam pattern generators, in which a controlled electron beam writes on the photoresist, offer the advantage of exposing narrow sharp lines. After exposure with either electrons or light, the pattern is developed by rinsing the photoresist with a solvent. Negative resists are those that are insolubilized on exposure while positive resists are solubilized.

The light and electron flux necessary to expose resists has been reported by several workers (1-3). It appears that positive resists are less sensitive to both light and electrons than are negative resists. In conventional positive photoresist processing this lower sensitivity sometimes requires that exposure times be longer than desirable. But, more important, the low sensitivity usually leads to very long exposure times when either projection photolithography or writing electron beams are used to pattern the resist.

This work reports that members of the benzotriazole, imidazole, and indazole families decrease the flux and hence energy required for the light and electron exposure of a high resolution positive photoresist, AZ-1350.[1] The energy required can be determined from the flux if the fraction absorbed is known. Previous work at Western Electric has shown how this can be calculated for electron exposure (4) while absorptivity data are reported here for the experiments involving light exposure.

Experimental

Layers of AZ-1350, 6000Å thick, were prepared by spinning techniques. The resist was then baked at 60°C for 10 min, allowed to cool, exposed and then dip-developed for 4 min in the Shipley AZ-Developer (full strength). The thickness of the resist before and after development was measured by profilometer techniques described previously (4). Electron exposure was carried out at 2×10^{-5} Torr with an electron beam focused to give a 2.5 cm^2 spot. The current was measured with a Faraday cup before and after exposure. Light exposures were carried out with a 150W xenon lamp held 1m from the resist. Glass filters allowed only wavelengths longer than 3100Å to irradiate the resist. Chromium-coated glass plates were used as the substrates for the electron exposure experiments, while quartz plates were used to study the light exposure.

When the effects of additives were examined, the additive was dissolved in the photoresist solution at least 16 hr before use. Occasionally, it was found that films of the resist with additive required shorter development times.

Key words: photoresists, electron beams, light exposure.

[1] A proprietary product of the Shipley Company, Newton, Massachusetts.

Results and Discussion

Electron exposure of AZ-1350.—Typical behavior of 6000Å thick layers of AZ-1350 after exposure to 15 keV electrons and development is given in Fig. 1, curves A and B. The electron flux required to expose unsensitized AZ-1350 depends on the energy of the exposing electrons as well as the time that the resist has been stored. Typically, 6 $\mu coul/cm^2$ of 15 keV electrons are required to expose newly purchased solutions while the same resist 4 months later requires about 40 $\mu coul/cm^2$ for exposure. The loss of sensitivity of the resist on storage may arise from the same cause as the loss in sensitivity of the resist when it is heated (5). When AZ-1350 is overexposed to the extent that it has absorbed about 20×10^{21} eV/cm^3, it cannot be removed by AZ-Developer. This overexposed spot is also insoluble in acetone and benzene.

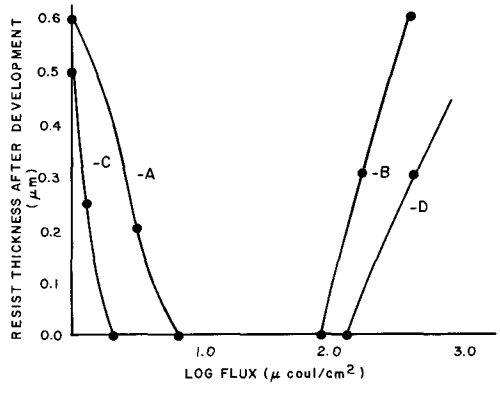

Fig. 1. Exposure of AZ-1350 by 15 keV electrons. Curves A and B, newly purchased resist; curves C and D, newly purchased AZ-1350 containing 2% benzotriazole. The initial thickness of resist was 0.6 μm.

Varying the electron accelerating potential between 5 and 20 kV changes the flux required to expose newly purchased AZ-1350 from 3 to 9 μcoul/cm^2. Using the model previously described (4) to calculate the amount of energy transferred from the beam to thin layers, the amount of absorbed energy required to solubilize fully newly purchased resist is 1.5 $\pm$ 0.05 x 10^{21} eV/cm^3. The range of 5 keV electrons in AZ-1350 has been measured here as 6500 $\pm$ 200Å, and this value was used for this calculation.

Harwood and Hunter have identified the reactive moiety in AZ-1350 as 3,4-dihydroxybenzophenone-4-[naphthoquinone-(1,2) diazide (2)] sulfonate and have found that it constitutes 23% of the weight of the solids in the photoresist (6). Since the density of dried AZ-1350 films is 0.9, there are 1.6 x 10^{16} sensitizer molecules in a square centimeter of film 6000Å thick. If all the sensitizer molecules have reacted when the film is fully solubilized, then the G value (number of molecules that react per 100 eV absorbed) for solubilization is about 18. This rather high value implies that energy transfer from the electron beam to a reactive site in AZ-1350 is much more efficient than in negative resists.

The mechanisms of the reactions involved in the response of AZ-1350 to electron radiation have not been determined yet, but it is likely that a cross-linking reaction of its phenol-formaldehyde polymer (6) leads to the insoluble product (*see* below). It is also likely that the solubilization reaction is the same one that occurs with light; quinone diazide groups are converted to carboxylic acids (7). Solubilization arising from a scission reaction of the phenol-formaldehyde polymer in which indiscriminate bond breakage occurs and soluble low molecular-weight compounds result cannot be fully excluded, but it is not probable because scission would have to predominate at low exposures and cross-linking at high exposures.

Exposure of AZ-1350 by light.—Htoo has shown that an exposure of 3.6 x 10^{18} eV/cm^2 is needed for a 6000Å-thick film of the resist with 3654Å radiation (1). Since K. H. Cho of this laboratory has shown the absorptivity of these films to be 0.32 at this wavelength, this exposure corresponds to an absorbed energy of 1.7 x 10^{18} eV/cm^2 and a quantum yield of 0.032 for the solubilization process. Absorbed light energy therefore is only 5% as efficient in causing solubilization as is electron energy. The higher efficiency of solubilization during electron exposure is unexpected, since the primary process of electron energy absorption leads to a large variety of excited bonds and molecules, while during light absorption only the quinone diazide groups are excited.[2] Overexposure by wavelengths greater than 3100Å does not lead to an insoluble product, but when the resist is exposed to 2537Å radiation it forms an undevelopable spot. Since the phenol-formaldehyde polymer absorbs radiation at this wavelength but not at the longer wavelengths, it is probably undergoing a cross-linking reaction.

Sensitization of AZ-1350.—When dilute solutions of benzotriazole in AZ-1350 are prepared and spun to films, it is found that a lower flux of both electrons and light is required to solubilize the resist. Typical results for electron exposure are shown by curve C of Fig. 1 and, for light exposure, by Fig. 2. Benzotriazole also inhibits the cross-linking that occurs with high electron fluxes (curve D, Fig. 1). The edges of exposed and developed lines in the photoresist both with and without sensitizer were examined under an optical microscope. The resolution of the microscope is about 0.33 μm which is insufficient to distinguish any difference in edge gradients.

[2] Htoo has shown that less than 8.1 x 10^{15} eV/cm^2 of light are needed for the exposure of 6000Å KTFR films, while 4.6 x 10^{16} eV/cm^2 of electron energy are needed, so that light exposure of KTFR is more efficient than electron exposure. In ref. (4), Htoo's work is incorrectly quoted.

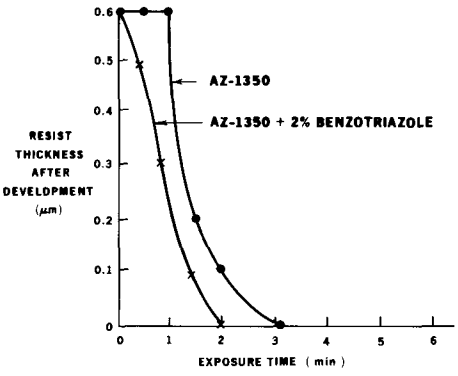

Fig. 2. Effect of benzotriazole on the exposure of AZ-1350 by light. The initial thickness of resist was 0.6 μm. A 150W xenon lamp 100 cm from the sample was used.

Benzotriazole is not the only efficacious additive. All members of the benzotriazole, imidazole, and indazole families that are soluble and that have a hydrogen atom bonded to a nitrogen atom also decrease the flux needed to expose AZ-1350. These additives also sensitize the response of other quinone diazide resists *e.g.*, AZ-1350-H (a Shipley product) and KAR-3 which is manufactured by Eastman Kodak.

The mechanisms in sensitizing the solubilization reaction and in inhibiting the cross-linking reaction are still being investigated. Since neither the absorption spectrum nor the penetration range of electrons of the resist change significantly when low levels of benzotriazole additives are added to the resist, sensitization of the solubilization probably involves better energy transfer from the site of absorption to the reaction site. Benzotriazole-type additives also cause energy to be transferred away from cross-linking sites, since 2% solutions in KTFR cause an increase in the electron energy needed to reach the gel point from 2.5 x 10^{20} eV/cm^3 to 11 x 10^{20} eV/cm^3. Benzophenone and hexaphenyldilead, which reduce the electron flux needed to reach the gel point of KTFR, also cause a reduction in the flux that cause overexposure in AZ-1350.

Conclusions

1. Electron exposure is more efficient in solubilizing AZ-1350 than is light exposure.
2. Overexposure by electrons causes a cross-linking reaction which renders AZ-1350 undevelopable.
3. Benzotriazole-type additives increase the efficiency of the solubilization reaction caused by both electron and light absorption while retarding the cross-linking reaction caused by electrons.

Properties of Cathodochromic Sodalite

William Phillips

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Cathodochromic behavior of iron-doped sodalites containing Br, I, or mixtures of halogens has been investigated in addition to that of chloride sodalite. Ultraviolet excitation of these materials produces an optically bleachable absorption band whose peak moves from 5250 to 6025Å as the halogen composition is changed from Cl to I. Electron beam excitation produces nearly identical absorption, but exposures above a certain threshold produce, in addition to optically bleachable absorption, residual absorption that is insensitive to light. Residual absorption is at a minimum in iodide sodalite.

Cathode-ray tubes utilizing a cathodochromic screen material instead of a phosphor have a number of valuable attributes in display-storage applications. The behavior of tubes of this type made with sodalite as the screen material has been described earlier (1). In this publication we describe in some detail the properties of iron-doped sodalite materials that have been synthesized for cathodochromic applications.

Sodalite is an aluminosilicate compound having the ideal formula $Na_8Al_6Si_6O_{24}Cl_2$. The basic structural unit consists of a cage formed of AlO_4 and SiO_4 tetrahedra linked together by their oxygen atoms. In the center of this cage is a Cl^- surrounded by four Na^+ ions. The sodalite cage can, and often does, accommodate a number of anions other than Cl^-. Br^-, I^-, OH^-, and SO_4^{2-} are frequently occurring substitutions. Sodalite usually occurs in nature as a blue-colored mineral. A photochromic variety of sodalite also occurs and is known as hackmanite.

The synthesis of sodalite for photochromic studies was reported by Medved in 1953 (2) and 1954 (3). He used a powder sintering technique and found that his sodalite had to be reduced, preferably in a hydrogen atmosphere, before photochromic properties appeared. Medved suggested a model for the switching of sodalite in which electrons were transferred from U-centers to F-centers under the influence of uv excitation. Also in 1954 a paper by Kirk (4) appeared emphasizing the role of sulfur as an activator in sodalite. Further work on sodalite was reported by Radler and others in 1962 through 1964 (5). Radler reported that the color of the switched sodalite could be altered by substituting other halogens for the chlorine.

The ESR spectrum of the photochromic color center of sodalite was reported in 1967 by Hodgson, Brinen, and Williams (6) and found to be consistent with the F-center model. The photochromic properties of this material were described in a subsequent paper by the same authors (7). They found, in agreement with Kirk, that photochromic behavior appeared only when sulfur was present in their materials. Cathodochromic properties of sulfur-doped sodalite have been reported recently by Forrester *et al.* (8).

In this paper we describe the photochromic and cathodochromic behavior of sodalites containing Cl, Br, I, and mixtures of these halides. These materials differ from those reported in ref. (6) through (8) in that they are activated by the presence of iron. Sulfur does not appear to play a significant role in their switching behavior.

Synthesis and Optical Properties

Most of the material used in the present research was prepared by a hydrothermal synthesis method at the Airtron Division of Litton Industries. The pressures utilized were considerably higher than those reported in ref. (7) (25,000 psi instead of 4000 psi), and a temperature gradient was applied to the apparatus to encourage transport and crystallization of the sodalite at the top of the vessel. The resultant material has the form of a coarse crystalline gravel, containing well-formed dodecahedra with faces occasionally as large as 5 mm across. In order to induce photochromic properties the material is crushed, if necessary, to smaller than 12 mesh, then annealed in a reducing atmosphere, usually hydrogen, for several hours at 850°-950°C.

Reduced sodalite prepared as described above is colorless, but develops a magenta coloration when exposed to uv or to electron beam excitation. The coloration is nearly identical for the two types of excitation, but we find that little or no coloration can be induced or bleached by optical excitation unless the material contains appreciable amounts of iron (see section on the Influence of Dopants).

The optically induced and electron beam induced absorption spectra measured by transmission through an iron-doped chloride sodalite single crystal are shown in Fig. 1. The optical samples used to obtain this and the following figure were cut from the largest available hydrothermal crystals. To obtain the cathodochromic spectrum the reduced samples were aluminized and then colored (on both sides) in a demountable electron beam apparatus at approximately 30 kV. The aluminum was removed and the crystals measured within about 10 min of coloration.

When bromine is substituted for the chlorine in sodalite the resultant photochromic material develops a purple color rather than magenta, because the position of the induced absorption band is moved to a longer wavelength (5550Å instead of 5250Å). The shape and intensity of the induced absorption band are similar to those of chloride sodalite (*see* Fig. 2). In sodalite synthesized with iodine as the halogen, the absorption peak occurs at even longer wavelengths (6025Å) as shown in Fig. 3. Intermediate positions for the peak of the induced absorption band are produced in sodalites containing mixtures of halogens.

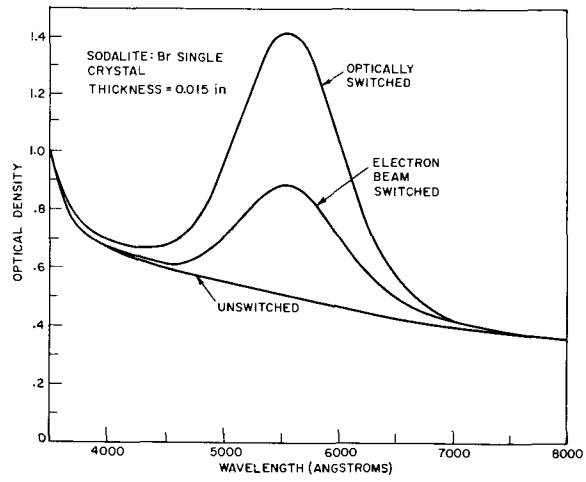

Fig. 2. Unswitched, uv switched, and electron beam switched absorption spectra of a sodalite:Br single crystal.

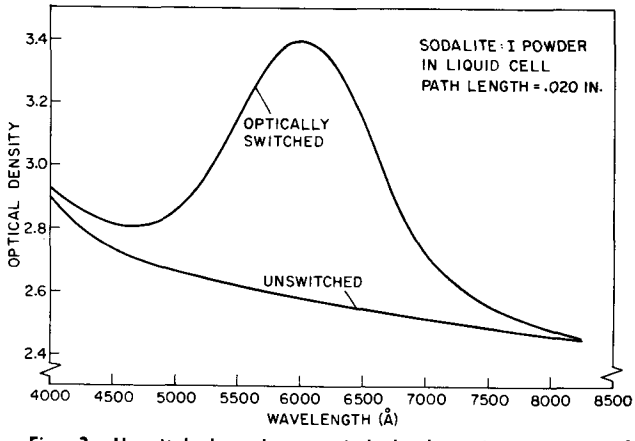

Fig. 3. Unswitched and uv switched absorption spectra of sodalite:I powder dispersed in an index-matched liquid.

The position of the photochromic absorption band in sodalite in fact appears to be determined by the lattice constant of the material as is the case for the F-band in alkali halides (9). Figure 4 shows the position of the peak of the induced absorption band as a function of lattice constant for the materials mentioned above, and also for sodalites having the compositions $Na_8Al_6Si_6O_{24}ClBr$ and $Na_8Al_6Si_6O_{24}BrI$. The linewidths for the latter materials are about the same as for pure chloride and bromide, *i.e.*, 1000-1100Å. The dependence of wavelength on lattice constant found in Fig. 4 is much steeper than that found for alkali halides. The results in Fig. 4 are in general agreement

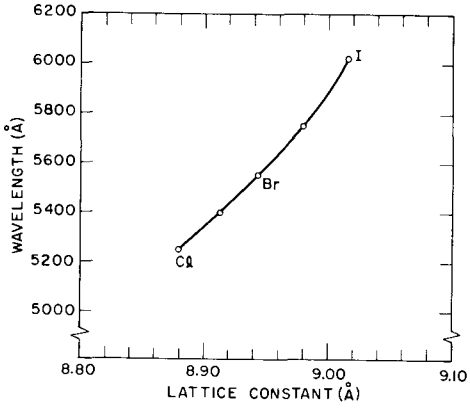

Fig. 4. Position of the peak of the photochromic absorption band of sodalite vs. the lattice constant of the material.

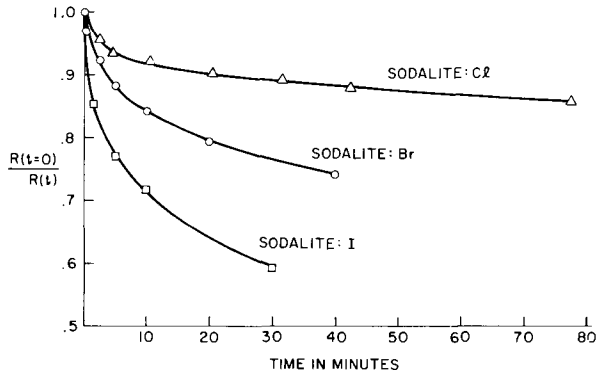

Fig. 5. Thermal decay of the induced change in reflectance of chloride, bromide, and iodide sodalite powdered samples measured at room temperature. $R(t=0)/R(t)$ is the reflectance immediately after coloring the sample divided by the reflectance at time t.

with those reported in ref. (8), except that the positions of the absorption peaks in the present work consistently occur at 80-160Å shorter wavelengths. This may result from the absence of sulfur from the present materials.

The thermal decay rate of the materials also changes with composition. The decay of the optically induced reflectance change of powdered chloride, bromide, and iodide sodalites was measured, at the peak of the induced absorption band, on a spectrophotometer equipped with integrating spheres. The results are reproduced in Fig. 5 (10).

The induced absorption coefficient inferred from Fig. 1 for sodalite:Cl is $\alpha = 68$ cm^{-1}. This value is typical of chloride and bromide sodalite crystals and powdered specimens excited to saturation with 3650Å radiation. Iodide sodalite crystals and powders are usually found to be less strongly absorbing when optically excited, for reasons that are not clearly understood (*see* Table I). Using the Smakula equation and assuming that the oscillator strength of the photochromic transition if $f = 0.5$ (about the same as for the F center in alkali halides), one can estimate the density of color centers in the materials. These estimates are shown in Table I.

Bleaching of the optically induced coloration in sodalite is accomplished by irradiation with light within the induced absorption band. This is also the case for the electron beam induced coloration provided that the degree of coloration is held below a particular level. If this level is exceeded in many sodalite specimens, a portion of the induced coloration is found to linger after optical bleaching is attempted. The residual coloration of chloride and bromide sodalites cannot be removed by optical irradiation nor does it show any significant thermal decay at room temperature. It can, however, be removed by heating the crystal to 200°-250°C. The extent to which residual coloration occurs varies with the material composition. It will be discussed in greater detail in the following section.

Electron Beam Coloration of Sodalite Powders

The major portion of the study of the cathodochromic behavior of sodalite has been performed using powdered material. The procedure has been to prepare 2 in. square glass slides by settling the powder from aqueous suspension in much the same manner as phos-

Table I. Typical optical properties of sodalites

Sodalite type	Absorption peak, Å	Absorption coefficient at peak, cm^{-1}	Density of color centers, cm^{-3}
Cl	5250	70	5×10^{17}
Br	5550	70	5×10^{17}
I	6025	40	3×10^{17}

phor CRT screens are formed. Early experimentation established approximate optimum powder parameters for these slides. The values used for sodalite usually fall in the range 10-37μ for the particle size and 3-7 mg/cm^2 for the screen weight. The slides are aluminized to increase their whiteness and to render them completely opaque.

Test slides are evaluated by mounting them in a demountable electron beam apparatus and exciting them over a known area with a measured electron beam current. The accelerating voltage is held at 28 $\pm$ 1 kV, and the exposures are typically made at current densities ranging from 0.05 to 5 μA/cm^2 for 1, 2, or 5 sec. The slides are illuminated with a regulated tungsten light source at an angle of 45°. The source intensity is adjusted until the diffuse reflected screen luminance, as measured by a spot brightness meter normal to the slide, reaches a convenient value, usually 1 or 10 ft-L. At these illuminations the contrast ratio is essentially independent of light level, and the decay rate of the coloration is long compared with the exposure time. After electron beam exposure the luminance is again determined and the contrast ratio calculated from the relation

$$C.R. = \frac{\text{reflectivity unswitched}}{\text{reflectivity switched}} = \frac{\text{luminance unswitched}}{\text{luminance switched}}$$

Successively larger exposures are made, and the slides are erased after each exposure. In this way a curve of contrast *vs.* electron beam exposure is obtained. As the exposure is increased one usually reaches a point where residual coloration begins to appear. The contrast ratio measured on a slide after the optically erasable portion of the coloration is removed is referred to as the residual contrast. A typical electron-beam exposure curve, showing the onset of residual coloration, is shown in Fig. 6. (The accumulated residual coloration in Fig. 6 and 7 is shown as a function of the sum of those exposures which exceed the residual coloration threshold.)

The coloration behavior illustrated in Fig. 6 is characteristic of chloride and of bromide sodalites as well. The behavior of iodide sodalite differs in several important respects. As shown in Fig. 7, the residual coloration in iodide sodalite is much smaller than in chloride and bromide sodalites at any given exposure level. Under continuous excitation at current densities typical of many CRT applications (3 μA/cm^2), the residual contrast ratio of some iodide samples saturates between 1.1 and 1.2. The residual coloration built up under these circumstances can be removed by exposure to a high intensity visible light source (7500 ft-c) for a period of about 1 hr. An iodide sodalite CRT of this nature has been in operation for many months. Although it needs occasionally to be flooded with light from a slide projector to remove residual images, there has been no permanent degradation of its contrast capabilities or background screen color.

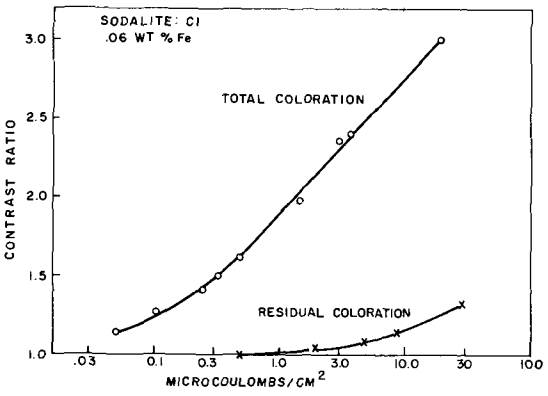

Fig. 6. Electron beam exposure curve for a chloride sodalite test slide.

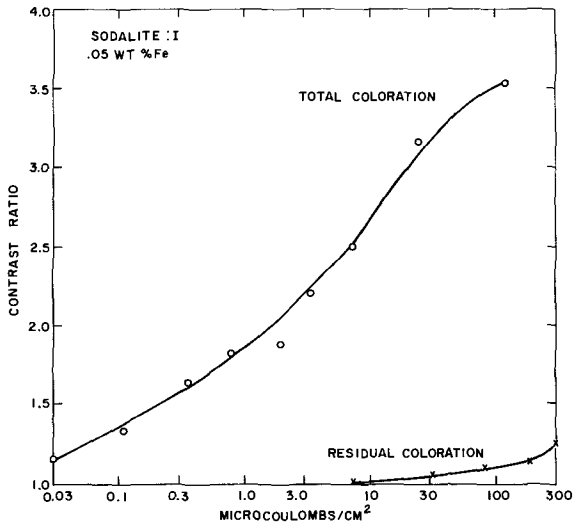

Fig. 7. Electron beam exposure curve for an iodide sodalite test slide.

Influence of Dopants

The role of iron.—Iron-free sodalite colors in a manner comparable to iron-doped sodalite under electron beam excitation. However, residual coloration begins to appear at very low exposure levels in the iron-free material. The results of electron-beam measurements on a number of sodalite samples, having a variety of iron concentrations, are summarized in Fig. 8. Except for the points marked with an S (*see* Role of Sulfur below), the materials have sulfur concentrations less than or about equal to 0.012 w/o.

The data points represent the contrast ratio at which residual coloration first appears during exposure curve measurements, as a function of the measured or estimated iron concentration in the sample. The filled-in points represent materials for which iron concentrations were determined by atomic absorption spectroscopy. The open points represent estimated iron concentrations based on the nominal doping and checked by emission spectrographic analysis. The estimated concentrations are usually found to agree with the measured concentrations to within 20%. Exceptions occur in the low concentration range, where residual iron levels (typically 0.001-0.005 w/o) become comparable to or exceed the intentional doping.

The data of Fig. 8 indicate a rapid rise of the residual coloration threshold with increasing iron concentration to about 0.03 w/o, followed by a slower rise at higher concentrations. At low concentrations the optically induced contrast capabilities of the materials

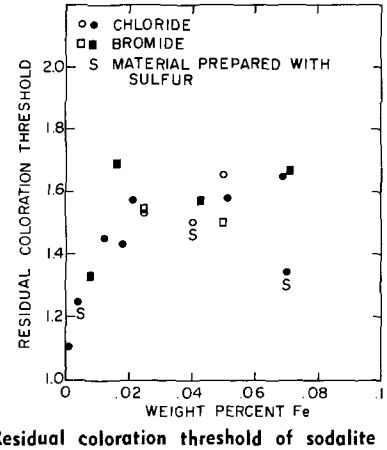

Fig. 8. Residual coloration threshold of sodalite test slides *vs.* amount of iron in the sodalite. Closed points; iron concentration determined by atomic absorption spectroscopy; open points, estimated iron concentration.

are quite similar to the results shown in Fig. 8. The sodalites prepared for this study containing 0.001 w/o or less iron show little or no photochromism. At iron concentrations greater than 0.03 w/o, however, the optical switching tends to fall off somewhat (10, 11), whereas no fall-off is discernible in Fig. 8. The reasons for this discrepancy are not clear.

It has not been possible to extend this investigation to iron concentrations higher than about 0.07 w/o because the solubility of iron, at least under the synthesis conditions used until now, appears to saturate in this region. It is expected, however, that in future work this solubility limit can be raised by charge-compensation techniques.

The Role of Sulfur.—The data of Williams *et al.* (7) show a strong correlation between the amount of photochromic coloration of chloride sodalite and the amount of sulfur present in the material. These authors find that the optimum concentration of sulfur lies between 0.3 and 0.6 w/o, and the lowest concentrations for a measurable effect are "less than .014 percent."

Most of the iron-doped sodalite samples studied in the present work have residual sulfur concentrations of about 0.012 w/o as determined by mass spectroscopy. In spite of this low concentration, it was necessary to rule out the possibility that some or all of the reversible switching properties of these materials derive from the presence of sulfur. To determine if the residual sulfur concentration does indeed contribute to the switching we evaluated sodalite prepared with highly purified starting materials and doped with iron in the normal way. In these samples the sulfur concentration was measured to be about 0.0015 w/o, yet they colored and bleached at least as well as the nonpurified sodalite, both under optical and electron-beam excitation.

To extend the tests in the direction of high sulfur concentrations, a few samples were prepared containing approximately the optimum sulfur concentration, 0.5 w/o as reported in ref. (7). The performance of these samples under electron beam excitation is indicated in Fig. 8 by the points marked with an S. They tend to have residual coloration thresholds lower than or about equal to the materials containing an equal amount of iron but no added sulfur.

From the available data it appears that sulfur does not contribute to the cathodochromic switching performance of the iron-doped sodalite synthesized in the present study and that its presence may in fact be detrimental in materials with high iron concentrations.

On the other hand Forrester *et al.* (8) have synthesized sodalites activated by sulfur and containing very little iron, with properties closely resembling the present iron-doped materials in many respects. It is probable that both iron and sulfur can play the role of activators in sodalite and that the synthesis conditions used in the present study tend to be favorable for the formation of iron-activated sodalite and rather unfavorable for sulfur-activated sodalite.

Density Changes and Fused Salt Anneals

During the reduction of sodalite in hydrogen (the step that induces cathodochromic behavior) a considerable amount of HCl and NaCl is evolved, leading to a large change in the density of the material. These changes were measured by floating batches (typically 4-8g) of the material in question on mixtures of S-tetrabromoethane and methanol (densities 2.96 and 0.73). As additional methanol is titrated into the mixture and stirred, some of the floating material goes into suspension and finally sinks. Histograms such as those shown in Fig. 9 and 10 were plotted from visual estimates of the amount of material remaining afloat after discrete amounts of methanol are added.

Some density loss occurs for all types of sodalite, but the amount that occurs varies from one batch to the next. It is found that for given hydrogen reduction

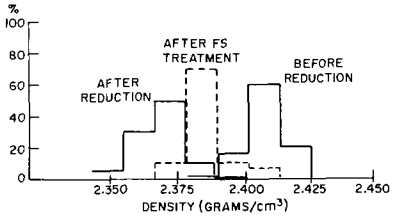

Fig. 9. Density history of a typical sodalite:Br sample

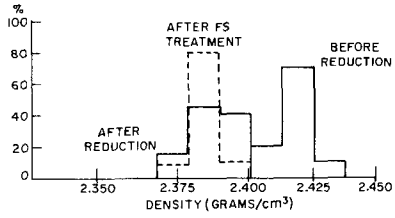

Fig. 10. Density history of a sodalite:Br sample that underwent a relatively small density decrease during reduction.

conditions, the density loss is at a minimum for sodalite batches containing particularly clear and well-formed crystalline material. This type of material is characterized by occurring at the high end of the density spectrum of the unreduced sodalite (*see* Fig. 9 and 10). It is also found that this type of material yields cathodochromic screens with the highest residual coloration thresholds. The mean densities before reduction and the minimum density losses observed for chloride, bromide, and iodide sodalites are shown in Table II.

The density data may be used to estimate the number of halogen vacancies generated in the reduction process. This has been done for two limiting cases, one in which it is assumed that all the loss is due to halogen evolution and another in which it is assumed that all the loss is due to sodium halide evolution. The results are summarized in the last two columns of Table II. In some cases lattice expansion is responsible for a significant portion of the density deficit, but this does not alter the fact that at least two orders of magnitude more halogen vacancies are created than actually participate in the switching process. An iron-doping level of 0.05 w/o corresponds to a density of 1.25×10^{19} iron atoms/cm^3 in chloride sodalite. Thus, considerably more iron is present in these materials than is required to account for the number of reversible color centers.

A series of experiments was performed in which sodalite samples were annealed in fused NaCl or NaCl-NaBr baths. The anneals were generally carried out at a temperature of 850°-950°C for 4 hr in a hydrogen atmosphere. It was found that this treatment could restore a portion of the density loss. This is illustrated in Fig. 9 for a rather typical sodalite:Br sample. About half of the lost density of the reduced material has been replaced in the fused salt anneal. A different situation is illustrated in Fig. 10. This material underwent a relatively small density decrease during reduction, and the fused-salt treatment does not produce any significant change in its density.

Regardless of whether or not the reduced material undergoes an increase in density during the fused-salt

Table II. Halogen vacancy density in reduced sodalites

Sodalite type	Density before reduction, g/cm^3	Minimum density change, %	Lattice volume expansion, %	Vacancy density, cm^{-3}	
				Halogen lost	Sodium halide lost
Cl	2.27	0.73	~0	2.9×10^{20}	1.7×10^{20}
Br	2.41	1.0	0.41	1.1×10^{20}	8.5×10^{19}
I	2.55	0.55	0.25	3.7×10^{19}	3.2×10^{19}

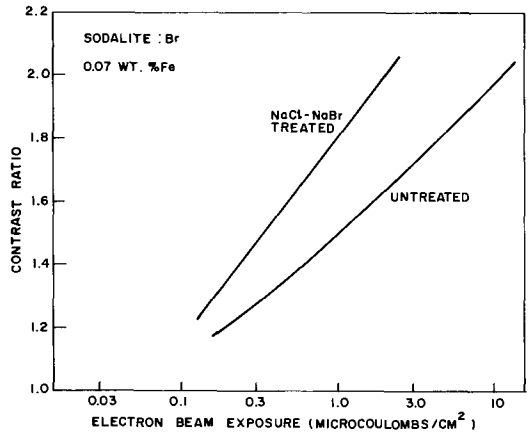

Fig. 11. Electron beam exposure curves for the material of Fig. 10 before and after fused-salt treatment.

anneal, there is usually a large increase in the electron-beam sensitivity of the material. Figure 11 shows a sensitivity curve for a sample of the material of Fig. 10 untreated, compared to material that was treated. Approximately six times more electron beam exposure is required to color the untreated material to a given contrast than is needed to color the treated material. Similar results are obtained for most other samples, with the exception of those which already have high sensitivities (*i.e.* 1.5 microcoulomb/cm² or less required to achieve a 2 to 1 contrast ratio). The sensitivity increase is accompanied by an increase in the residual coloration threshold as shown in Fig. 12. The data points in Fig. 12 that are linked by lines represent the residual coloration thresholds for the same material untreated and fused-salt treated (marked FS). In most cases there is an increase in the threshold for the treated material. These effects appear to be most profound for materials with high iron concentrations.

Conclusions

Sodalites synthesized with Cl, Br, I or mixtures of these halides form a family of photochromic and cathodochromic materials whose properties can be varied continuously as a function of composition and doping. These materials are of particular interest because they can be used to fabricate display-storage devices having uniquely simple configurations. Therefore, it is of importance to try to further improve their contrast capabilities and other pertinent properties.

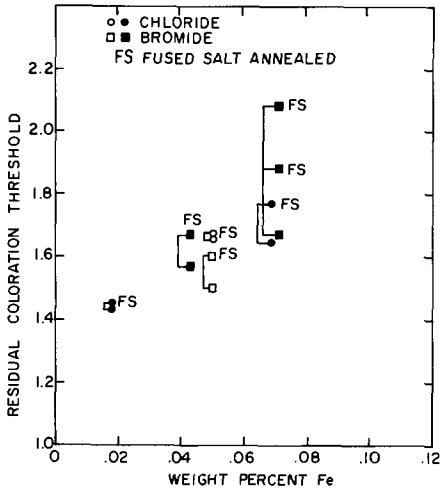

Fig. 12. Residual coloration thresholds of samples of sodalite materials before and after fused-salt treatment.

The photochromic switching of the sodalites involves the reversible transfer of an electron from a thermally stable level which may be provided by iron or sulfur, to a halogen vacancy in which it is thermally unstable. Optically reversible cathodochromism appears to involve the same centers, and the cathodochromic electron transfer process is thought to be closely related to the photochromic process (11, 12). From the data on the relative densities of halogen vacancies and reversible color centers it appears that the number of thermally stable centers limits the degree of reversible switching that occurs. A more serious practical limitation of sodalite, however, is the occurrence of residual coloration. A detailed understanding of this phenomenon would be most helpful to increase the usefulness of the sodalites in cathodochromic display applications.

Reflection X-Ray Topography of GaAs and GaP Cleavage Faces

G. A. Rozgonyi and S. E. Haszko

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

X-ray topography has been applied to cleaved cross sections of GaAs and GaP wafers. Experimental procedures for cleavage face x-ray topography are described in this paper, and the wide range of use for this method is shown. Using this technique a measure of the depth of damage introduced into the material during cutting and polishing, as well as during device fabrication, *e.g.*, the application of ohmic contacts, is obtained. The relative defect density in GaP substrates and epitaxial layers can be determined from the topographs. Damage introduced at the substrate-epitaxial layer interface can also be readily identified.

The relation between crystal imperfections and the performance of semiconductor devices has been well established during the last decade (1). Although most of this work has been on silicon, there is plenty of evidence that defects play an equally important role in compound semiconductors as well (2). One of the more powerful techniques for the analysis of defects in semiconductors has been x-ray topography (XRT) (3). Recently several workers have applied XRT techniques to the study of imperfections in GaAs substrates as well as in GaAs and $GaAs_xP_{1-x}$ epitaxial layers (4-6). Both the reflection (Berg-Barrett) and transmission (Lang) geometries have been employed to study surface and bulk defects of wafers during processing and after epitaxial thin film growth. Attempts have been made (6) to analyze selectively the defects as a function of depth by adjusting the diffraction conditions such that only the top 5-20μ of the sample are active in the diffraction process. There are several factors limiting the usefulness of this approach. For example, in samples with deep surface damage, the diffraction contrast is overpowered by enhanced diffraction from the deformed surface regions. In this case the depth of damage can only be determined after the damaged layer is removed. Also, for studies of film-substrate interfaces, the region of most interest, the interface itself, is not explicitly delineated and may actually be deeper than the penetration depth of the x-rays, which is generally 6-12μ for Cu $K_{\alpha 1}$ depending on the angle of incidence of the x-rays with the surface (6).

An alternate approach to the problem of obtaining a profile or "in-depth" analysis is to cleave the wafer. Since (100)- and (111)-oriented samples are used for practically all devices, it is easy to obtain cleavage faces which expose a cross section normal to the large area growth surface of the wafer. A reflection x-ray topograph of the cleavage face will, therefore, yield the following information:

(*i*) a profile of the strain field at the free surface,
(*ii*) the distribution and density of defects in the bulk and in the layer, and
(*iii*) the imperfection density at the film-substrate interface.

Considering the amount of information obtained with a single topograph it is surprising how little cleavage face topography has been used. Aside from a recent report by Schiller (7) and a single XRT in a paper by Howard and Dobrott (6) the technique has been neglected. In the present report we wish to show that once the sample alignment procedures are optimized there are many phenomena associated with thin film-substrate processing steps that can be readily observed and studied with cleavage face XRT. This information can then be used in conjunction with the electrical or optical evaluation of the material to relate the effectiveness of a particular processing step, or type of defect, with the final performance of specific devices.

Key words: defects, III-V compounds, semiconductor processing.

Equipment and Sample Alignment Procedures

A Jarrell-Ash microfocus x-ray unit with a line focus and Cu $K_{\alpha 1}$ characteristic radiation has been used. A standard Jarrell-Ash Lang camera was adapted for use in the reflection mode to obtain Berg-Barrett topographs of $(\bar{1}10)$ and $(1\bar{1}0)$ cleavage faces of GaAs and GaP wafers. Figure 1 shows schematically the relation between x-ray source, cleavage face, and photographic plate. The x-ray beam is ~3 cm high and 1 mm in cross section when it reaches the sample. Since the sample is at a small angle to the incident radiation it is quite easy to image reasonably large cleavage faces. In fact, using this geometry for normal

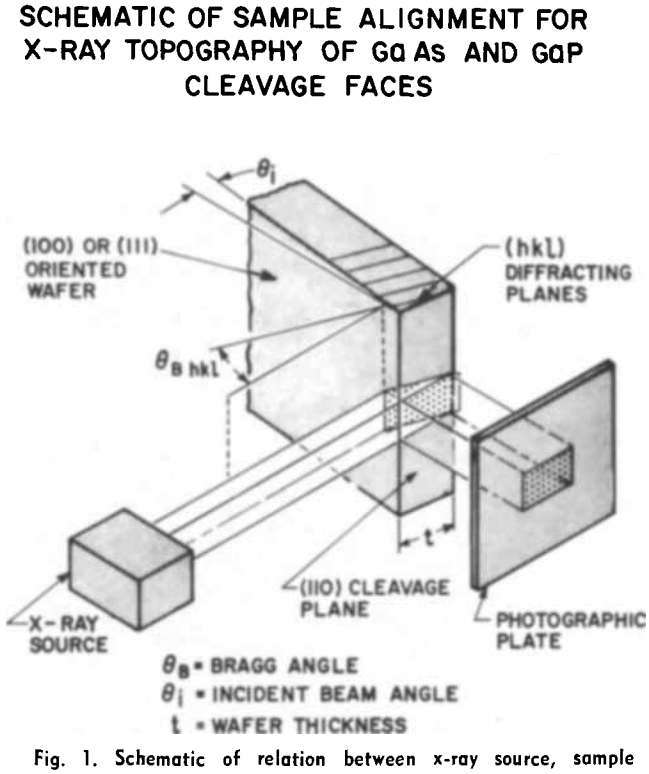

Fig. 1. Schematic of relation between x-ray source, sample cleavage face, and photographic plate.

Table I. Crystallographic data for alignment of GaAs and GaP cleavage faces using Cu $K\alpha_1$ radiation

Material	Orientation of wafer surface	hkl Diffracting planes	$\theta_{110/hkl}$	$\theta_{B_{hkl}}$	θ_i	$2\theta_{B_{hkl}}$	θ_{roll}
GaAs	111	531	44.18	53.71	9.53	107.42	11.0
		422	30.0	41.87	11.87	83.74	19.47
	100	333	35.26	45.07	9.81	90.14	Zero
GaP	111	531	44.18	56.74	12.56	113.48	11.0
		422	30.0	43.82	13.82	87.64	19.47
	100	333	35.26	47.26	12.00	94.52	Zero

Berg-Barrett XRT of plane wafer surfaces, it is possible to image 5 x 30 mm samples without scanning.

In order to obtain topographs of maximum resolution with minimum distortion it is necessary to place the photographic plate close to the sample and also have it intercept the diffracted beam at 90°. Therefore, the (hkl) diffracting planes are chosen such that the angle of incidence, θ_i, is small, *i.e.*, less than ~20°, and the diffracted beam is as close to the normal to the cleavage face as possible, *i.e.*, $2\theta_B - \theta_i \approx 90°$. θ_i is easily calculated as the difference between θ_{Bhkl} and the angle between the $(1\bar{1}0)$ cleavage face and the (hkl) planes. Table I lists the data necessary to select a suitable diffraction plane for (100) and (111) oriented wafers of GaAs and (111) wafers of GaP. It should be mentioned that it is sometimes necessary to tilt or "roll" the sample about the $[1\bar{1}0]$ axis in order to obtain a zero-layer reflection. That is, for minimum distortion of the XRT image, it is necessary to keep the incident and diffracted beams and the cleavage face normal in the same plane. For example, from Table I it is seen that for a (111) oriented wafer of GaP the $(4\bar{2}2)$ reflection gives $2\theta_B = 87.64°$ and $\theta_i = 13.82°$. However, referring to the $(\bar{1}10)$ stereographic projection of Fig. 2 it is found that the $(4\bar{2}2)$, or equivalently the $(2\bar{1}1)$, does not lie along the line from $(1\bar{1}0)$ to (111). Since the GaP was oriented (111), the sample must be rolled 19.47° toward the (001) until it coincides with the (112) zone. The sample is now properly aligned for a zero-layer $(4\bar{2}2)$ topograph.

The diffracted beam is initially recorded on dental x-ray film with a 3-5 min exposure to check the sample alignment. With thin wafers this is quite important because the samples bend and overlapping

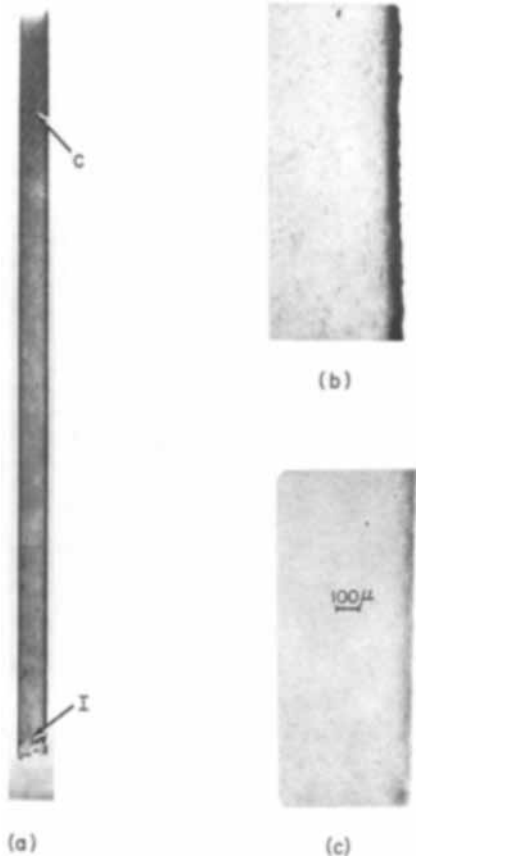

Fig. 3. CF-XRT of saw-cut GaAs wafers: (a) Czochralski crystal (~6X); (b) Czochralski crystal (~35X); (c) boat-grown crystal (~35X).

spurious images may occur. Ilford nuclear plates, either type G-5, exposure times ½-1 hr, or type L-4, exposure times of 2-4 hr, are then used depending on the resolution required for the sample. The distance between x-ray source and exit slit is ~42 cm, while a power level of 200W was used.

As examples of cleavage face x-ray topography (CF-XRT), several topographs from Czochralski and boat-grown GaAs substrate wafers are shown in Fig. 3. The wafers have been cut to ~0.030 in. on an ID saw and then cleaved with a razor blade. Aside from localized damage at the impact point of the razor blade, marked I in Fig. 3(a), and the cleavage steps in the upper portion of the sample, marked C in Fig. 3(a), the cleaving operation does not seriously affect the major portion of the wafer. The dark region on the right-hand side[1] of the higher magnification CF-XRT's in Fig. 3(b) and 3(c) represents the surface damage and associated strain field introduced by the sawing operation. The photographs have the same contrast as the original plate; therefore, defects show up as dark areas. The intense dark areas arise because the angular range of Bragg reflection by a perfect crystal is small compared to the divergence of the incident beam. Therefore, a distorted, damaged, or dislocated region reflects a larger fraction of the incident flux in the diffracted beam direction than does the more perfect surrounding material.

An estimate of the dislocation density can be obtained by counting the strain fields in the center of the crystal, *i.e.*, the number of dark lines per unit area. A value of 10^3-10^4/cm^2 has been seen in most of the GaAs Czochralski crystals, *see* Fig. 3(b), while boat-grown material is much lower and approaches zero for some

[1] The surface of interest is always presented as the right-hand edge of our CF-XRT's since the left-hand or "leading edge" side is often over-exposed due to x-rays which enter the front face of the wafer and exit from the cleavage face, see Fig. 1. Therefore, we generally trim the left-hand side of our pictures, where practical.

ingots, *see* Fig. 3(c). It should be noted that the saw damage and associated strain field in the low dislocation, boat-grown material is substantially less than that in the Czochralski crystals, and that both bulk imperfections and surface damage can be examined in the single CF-XRT.

Applications of Cleavage Face XRT

Polishing damage in GaP substrates.—Figure 4 is a composite of 3 CF-XRT of GaP wafers cut from a Czochralski crystal grown by the liquid encapsulation method. The right-hand edge of Fig. 4(a) shows the surface of a wafer cut with an ID saw which shows greatly enhanced diffraction to a depth of ~1 mil. There is also a gray area extending ~2 mils deeper, which is most likely the extent of the elastic strain field due to the gross surface damage. In Fig. 4(b) the sample has been mechanically polished on both sides to a mirror finish, initially with American Optical Type 305 abrasive, followed by 3.0μ and then 0.1μ diamond paste to remove a total of 3 mils. There is a corresponding reduction in the depth of heavy damage at the surface, but the crystal is still obviously highly strained. In order to remove the surface damage and associated strain field and still maintain a flat, highly polished surface we had the wafers chemically polished. A total of ~1.2 mils was removed from the "B" or phosphorous-face. The uniform contrast of the topograph in Fig. 4(c) shows that the chemical treatment does in fact remove the saw damage and leave the surface strain free. These observations can be related to the electroluminescent properties of liquid phase epitaxial layers subsequently grown on chemically and mechanically polished substrates (8).

LPE layer—substrate profiles.—Two examples of film-substrate combinations which are well suited to examination by CF-XRT are shown in Fig. 5 and 6. The films are GaP and have been deposited by liquid phase epitaxy (LPE) onto Czochralski GaP substrates. A thin dark line can be seen at the film-substrate interface in Fig. 5, while a region of gross deformation exists at the outer surface of the LPE layer. The strain field due to interfacial defects is readily detected and, for this film, it is on the order of 5-10μ in width. Note that the film-substrate interface does not act as a barrier to line defects which readily cross over from substrate to film. We would, therefore, expect the LPE film defect concentration to be comparable to that in the substrate. The origin of the large surface damage or "skin effect" is not understood at present. However, we note that the surface damage is now comparable to that in the raw cut wafer shown in Fig. 4(a). We might expect that an ohmic contact or the growth of another LPE layer would be severely influenced by this type of surface. Application of chemical polishing

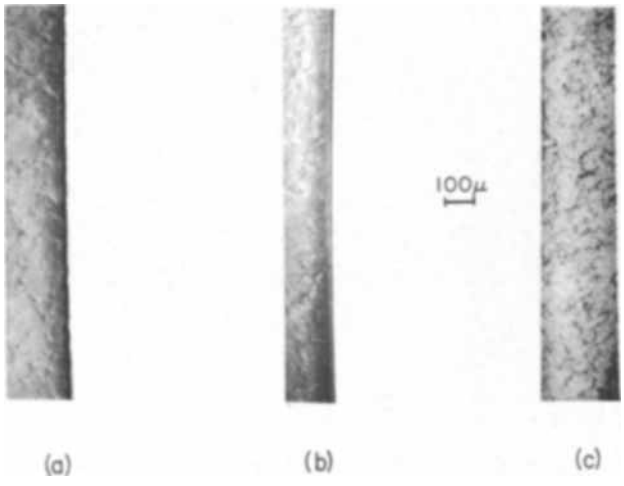

Fig. 4. CF-XRT of GaP wafers (~45X): (a) saw-cut; (b) mechanically polished; (c) chemically polished.

Fig. 5. CF-XRT of GaP substrate — single LPE film profile (~90X).

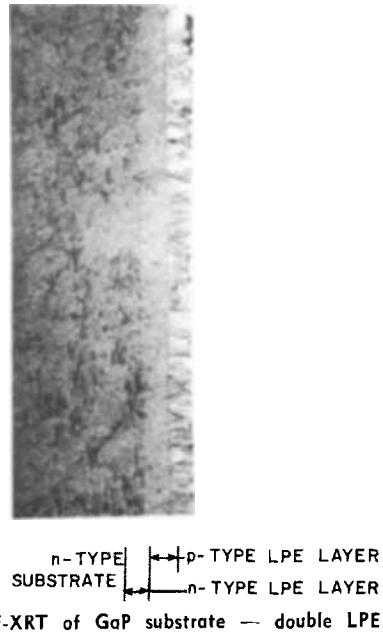

Fig. 6. CF-XRT of GaP substrate — double LPE film profile (~75X).

to remove 20μ of surface removed the damage and a CF-XRT revealed uniform contrast across the LPE layer.

A "double tipped" layer, *i.e.*, a p-type LPE layer on a previously grown n-type LPE layer, is shown in Fig. 6. In this example we note a large difference in the defect concentration in the first layer when compared to the substrate. Also, the film substrate interface is not a distinct line as in Fig. 5 but shows up as a barrier for the defects in the substrate. Unfortunately, the p-n interface is not nearly as good, and a continuous line of defects appears. In addition, a series of large strain fields are observed traversing the width of the p-type layer. A subsequent powder x-ray diffraction analysis of the outer layer revealed the presence of polycrystalline Ga_2O_3 which is not detected in samples free of this particular contrast feature. We have, therefore, attributed these defects to the strain field around precipitated inclusions of Ga_2O_3 (9).

Ohmic contacts to GaAs thin films.—A recurring problem with the device fabrication of Gunn and LSA oscillators is the quality of ohmic contacts. A popular contacting procedure is the evaporation of Ag and/or

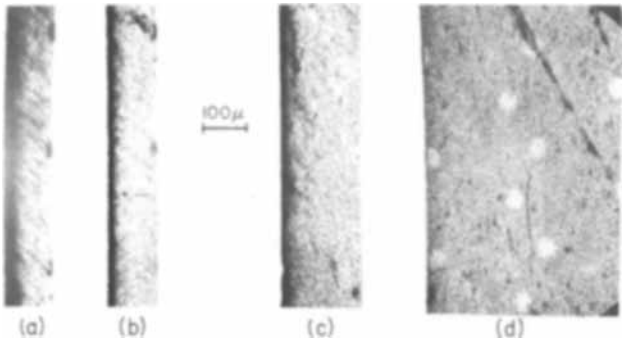

Fig. 7. CF-XRT of ohmic contacts to GaAs thin films (~60X). (a) Sn-Ag; (b) Ag; (c) Au-Ge; (d) (100) wafer surface.

alloys of Ag with Sn, In, and Ge followed by heating to 600°C in forming gas at a pressure of 5×10^{-3} Torr. Because of the rather high temperature involved and the variety of Ag compounds under consideration it was decided to supplement the normal electrical measurements with CF-XRT. Typical results illustrating good and bad alloy contacts and also a new lower temperature vacuum evaporated Au-Ge contact are shown in Fig. 7. The contacts are initially evaporated on the GaAs through a mask with a staggered array of 0.002 in. diameter holes. A CF-XRT of a poor contact is expected to show excessive damage whenever the cleavage face intercepts a contacted region of the wafer. A Sn-Ag contact on a 6μ thick epitaxial GaAs layer vapor deposited on a substrate now thinned to 0.004 in. is shown in Fig. 7(a). It is readily seen that the processing damage and associated strain field extends up to 20μ below the surface. This is considerably deeper than the 6μ thick epitaxial film. A defective, high resistance device resulted from this procedure. A CF-XRT from an Ag contact, also heated to 600°C, is shown in Fig. 7(b). Once again the location of the damaged regions near a contact is quite evident. However, in this case the extent of damage is substantially reduced, and an ohmic contact was obtained. Finally, an Au-Ge alloy evaporated in vacuum at 250°C onto an outgassed GaAs film-substrate combination was examined. The result is a topograph with no evidence of a strain gradient due to the contact, see Fig. 7(c). A normal Berg-Barrett XRT of the array of 0.002 in. dots is shown in Fig. 7(d) alongside the CF-XRT in order to pinpoint the location of the contacts. As expected the electrical properties of the evaporated Au-Ge contact have proven to be consistently better than the Ag alloys (10).

Discussion and Conclusions

The examples presented above have been chosen to illustrate the range of applicability of cleavage face x-ray topography to everyday problems in semiconductor device processing. Obviously many other examples could have been presented, but these cover the range from cutting a substrate wafer to the contacting of a layered device. It has been our experience that many attempts at device fabrication involving a series of materials preparation and device processing steps have been unsuccessful because the quality of the initial material or the effectiveness of a processing step is judged primarily by the operation of the device itself. We believe that CF-XRT when used in conjunction with other metallurgical, electrical, optical, etc., tests offers a means of establishing optimum semiconductor shaping processes and a meaningful in-process quality control.

It should be pointed out that by concentrating on a profile of a cross section we have sacrificed one of the usual advantages of XRT, *i.e.*, the ability to obtain information over the entire surface or bulk of the sample. Therefore, a CF-XRT should be coupled with a Lang or Berg-Barrett XRT if any doubt exists as to the general applicability of the results. This dual-XRT approach was taken in the present paper, see Fig. 7(c) and 7(d), in locating the GaAs contacts. Figure 7(d) also shows that the cleavage operation does not affect the surface of the sample. In terms of sample preparation, cleaving is the only step required.

The results presented above were obtained from cleavage faces normal to the large area surface of the wafer. In the future we plan to cleave along the (101) plane, which leaves an angle of 35° and 45° with the (111) and (100) surfaces, respectively, *see* Fig. 2. In this way interfacial defects, such as misfit dislocations, which would appear as a dot or a line in a normal cleavage, would be exposed as a cross grid network.

Another possible area of improvement is in reducing exposure times by diffracting off more intensely reflecting planes. The use of Cr radiation in place of Cu and an analysis similar to that in Table I would reveal the (311) plane as the most favorable diffracting plane for (111) oriented wafers. This should reduce the exposure times for L-4 plates to less than an hour. A (311) reflection would also reduce θ_{roll} to zero.

In conclusion, it has been shown that CF-XRT is a powerful technique for examining defects in GaAs and GaP substrates and epitaxial layers as a function of thickness. As a consequence of this initial study several results have already been obtained which have aided in the improvement of GaAs and GaP device fabrication. Specifically, ohmic contacts to GaAs thin films are now made by vacuum evaporation of Ge-Au in place of the high-temperature Ag and Ag(In, Sn, Ge) procedures previously used. Also, by using a chemical polishing procedure it has been possible to improve the electroluminescent properties of LPE GaP diodes over that obtained from mechanically polished substrates. In addition, a qualitative means of estimating the depth of damage due to saw cutting and evaluating the most effective polishing technique for its removal has been described. Similarly, residual surface damage in GaP LPE layers has been observed and subsequently removed by chemical polishing. Other applications to problems related to defects introduced by ion implantation and thermal diffusion are obvious and will be pursued in the future.

Acknowledgments

The authors would like to thank A. A. Bergh for initially suggesting they examine cleavage faces and for his comments on this work. The GaP Czochralski crystals were supplied by H. W. Verleur and chemically polished by A. J. Sayko. The contacts to GaAs films were provided by T. Riley and B. Pruniaux. Comments on the initial manuscript by B. Schwartz, R. H. Saul, and T. Iizuka are appreciated. The authors would also like to acknowledge numerous discussions with F. B. Koch on x-ray phenomena.

ABSTRACT

The concentration of carbon in semiconductor silicon and the behavior of carbon in the fusion and crystallization of silicon have been studied by the use of charged particle activation analysis. The solubility of carbon in solid silicon has been found to be 3.5 x 10^{17} at./cm^3 or slightly less at the melting point, and the equilibrium distribution coefficient of carbon between solid and liquid silicon has been determined to be 0.07 ± 0.01. Carbon content over the above solubility value has seldom been observed in silicon single crystals produced by modern industrial techniques. The content appears to depend more on the growth conditions of the single crystal than on the chemical purification method. The phase diagram of the C-Si system in the extremely low carbon concentration range is given, together with a discussion of the kinematics of the carbon behavior in zone melting. Also, a new technique for studying the evaporation of carbon from the silicon melt is shown.

Although reliable information about the concentration and behavior of carbon in semiconductor silicon has been required, analytical results reported for carbon vary anomalously according to the analytical method used (1). We have proved that charged particle activation analysis by the $^{12}C(^3He, \alpha)^{11}C$ reaction is the most sensitive and most reliable for this analysis (2). Using this method, we have analyzed semiconductor silicon of various origins and specifications, and determined the following two constants: (*i*) the solubility of carbon in solid silicon at the melting point, and (*ii*) the equilibrium distribution coefficient of carbon between solid and liquid silicon.

Experimental

Analytical method.—Details concerning the charged particle activation analysis for carbon, nitrogen, and oxygen in semiconductor silicon are described in a separate paper (2). This technique has a lower limit of sensitivity for carbon down to 1 x 10^{15} at./cm^3. For carbon concentrations between 4 x 10^{16} and 3.5 x 10^{17} at./cm^3, this method has given results which agree fairly well with those of the infrared absorptiometry (3), as will be shown in a separate paper. (The former method gave results smaller by a factor of 0.7 than the latter.) About 160 samples including device-grade silicon and carbon-doped silicon have been analyzed. Uncertainty in the results of the activation analysis is estimated to be about 10 and 30% for carbon concentrations of 2 x 10^{17} and 5 x 10^{15} at./cm^3, respectively. The lowest result obtained for the apparent carbon content has been 2.0 x 10^{15} at./cm^3, indicating that the various possible interferences in this analysis are not serious for carbon concentrations over 5 x 10^{15} at./cm^3 (2).

When the carbon is precipitated as silicon carbide, the activation analysis involving the chemical separation usually gives lower results because the precipitate is not readily decomposed by the chemical treatment. This was found by measuring the ^{11}C activity formed in some carbon-doped samples before and after the chemical separation. For carbon concentrations up to about 3.5 x 10^{17} at./cm^3, results of the nondestructive measurement have always agreed with those of the separation and measurement, but for higher concentrations, the latter has given distinctly lower results than the former. However, as will be made clear later, carbon concentrations under about 3.5 x 10^{17} at./cm^3 is usually not precipitated.

Key words: concentration of C in semiconductor Si, solubility of C in solid Si at its mp, equilibrium distribution coefficient of C between solid and liquid Si, phase diagram of C-Si system.

Preparation of carbon-doped silicon.—Commercial semiconductor silicon usually does not contain enough carbon for the reliable measurement of its solubility in solid silicon and its equilibrium distribution coefficient. Various quantities of carbon (10, 30, and 100 ppm) in aqueous suspension (Aquadag) were painted uniformly on silicon rods (2.5 cm diameter, 30 cm length), and molten zones were passed through them (about 7 mm width, 3.5 mm/min traveling velocity). Then, in several parts of one of the resultant rods, molten zones (7 mm width) were passed with various traveling velocities to give a sample from which distribution coefficient measurements were made. All the zone meltings were carried out in a vacuum, and the above sample was not exposed to air in the intervals between the zone meltings. Also, Czochralski crystals were pulled from pyrolytic graphite crucibles.

Results

Solubility of carbon in solid silicon at the melting point.—When passing molten zones through the carbon-covered silicon rods, silicon carbide powder appeared on the surfaces of the melts; the larger the quantity of carbon, the sooner the appearance of the particles. The resultant carbon distribution in one of the samples is shown in Fig. 1. Carbon concentration just prior to the appearance of silicon carbide was always found to be 3.5 ± 0.4 x 10^{17} at./cm^3 regardless of the quantity of carbon painted on the rod. This is explained clearly by the phase rule. When three condensed phases, *e.g.*, solid silicon, liquid silicon, and silicon carbide, coexist in equilibrium in a two-component system, *e.g.*, silicon and carbon, the composition of each phase should be uniquely determined. Therefore, 3.5 ± 0.4 x 10^{17} at./cm^3 is an observed value for the solubility of carbon in solid silicon at its melting point. Also, this value is consistent with the following experimental results: (*i*) Czochralski crystals from graphite crucibles exhibit approximately the same carbon content; and (*ii*) as described in the preceding section, when carbon exceeded this concentration, different behavior was observed in the chemical treat-

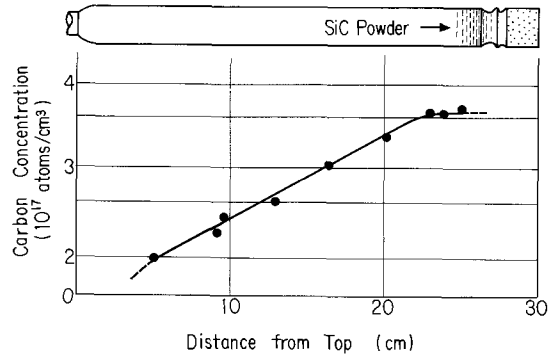

Fig. 1. Carbon distribution after a single zone pass through a carbon-painted silicon rod.

ment. This value, however, may be slightly overestimated, as the solid-liquid boundary could be dendritic and thus the growing solid phase would capture a small fraction of the liquid phase.

Equilibrium distribution coefficient of carbon between solid and liquid silicon (K_{eq}).—The solubility of carbon in liquid silicon has been reported by several authors (4-6). This value can be regarded as about 35 x 10^{17} at./cm³, or slightly higher, at the melting point of silicon. Thus, K_{eq}, which is the ratio of the solubility in the solid to that in the liquid, is calculated to be about 0.1, or slightly less.

By another method, K_{eq} was obtained with more certainty. Carbon distributions in the sample described above are shown in Fig. 2. From these distributions, the effective distribution coefficients, K_{eff}, are obtained in relation to the zone velocities, as shown in Fig. 3. By extrapolating the curve in Fig. 3 to zero velocity, K_{eq} is obtained as 0.06 or 0.07. This value may be slightly underestimated, due to the evaporation of part of the carbon from the molten silicon in the course of the zone pass. This evaporation, however, can be regarded as insignificant because no notable amount of oxygen was available to form carbon monoxide (see below). Therefore, K_{eq} has been determined to be 0.07 ± 0.01.

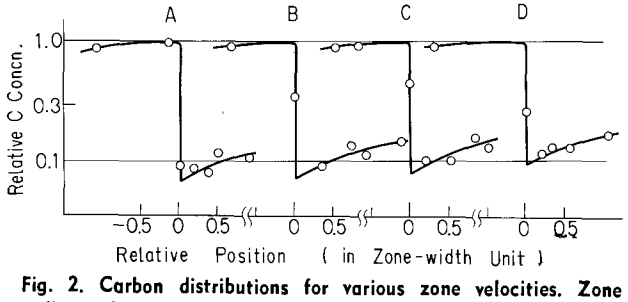

Fig. 2. Carbon distributions for various zone velocities. Zone traveling velocity: A, 0.4 mm/min; B, 0.8 mm/min; C, 1.2 mm/min; D, 1.6 mm/min.

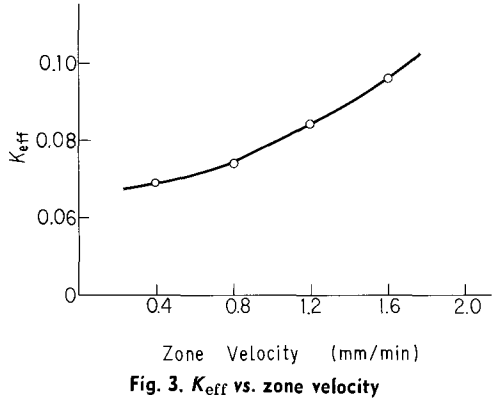

Fig. 3. K_{eff} vs. zone velocity

Carbon content of commercial semiconductor silicon.—The carbon content of various kinds of commercial semiconductor silicon produced by modern industrial techniques is shown in Table I, together with their oxygen content as measured by the charged particle activation analysis (2). All values are below the solubility in solid silicon at the melting point. In general, the carbon content of single-crystal silicon appears to depend more significantly on the conditions in the single-crystal formation than on the chemical purification method. The carbon content of dislocation-free samples shows no obvious difference from ordinary float-zone silicon. The high carbon and oxygen contents of the Czochralski crystals can be explained as contaminations from the graphite heating device and silica crucible used in the process.

Change of the carbon content in an industrial process.—Table II shows the change of the carbon and oxygen content in the course of the production of single-crystal silicon. The polycrystalline silicon used as the raw material for all the single crystals, was produced by the monosilane process in Komatsu Electronic Metals Company, Japan, and carbon content was very uniform and constant.

Single crystals with the lowest carbon and oxygen content were obtained by float-zone melting in a vacuum. After multiple zone passes, the concentrations have been found to be reduced, but reach a value which seems to be determined by several conditions in the process. For example, in order to reduce the carbon content below about 5 x 10^{15} at./cm³, special care should be taken to prevent the back diffusion of vacuum pump oil. Silicon crystals after float-zone melting in argon have been found to contain varying quantities of carbon, although the concentrations are always lower than the polycrystal content. Probably, the purity of the argon is a critical factor in determining the carbon content.

Discussion

Phase diagram of C-Si *system.*—From the information described above, the phase diagram of the C-Si system in the extremely low carbon concentration range can be drawn (*see* Fig. 4). The lowering of the melting point was calculated by the formula: $\Delta T = RT^2_m x/\Delta H$, which is an integrated form of the Clausius-Clapeyron equation using Raoult's law, and allowing for a dilute solution $\ln(1-x) \approx -x$ where x is the mole fraction of the solute. R is the gas constant, T_m is the melting point, x is the mole fraction of solute, and ΔH is the molar heat of fusion.

Table I. Carbon and oxygen content of commercial semiconductor silicon

	Carbon content, 10^{17} at./cm³	Oxygen content, 10^{17} at./cm³
Polycrystal	0.20 ~ 0.50 [0.82]*	0.80 ~ 3.0 [0.04]*
Single crystal		
FZ in argon	0.080 ~ 0.35	0.05 ~ 0.20

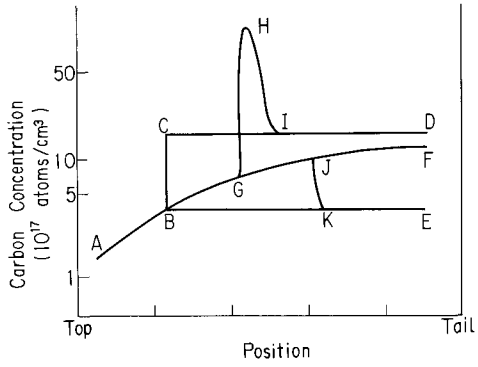

Fig. 5. Various possible carbon distributions after a single zone pass. ABCID, no supersaturation of the liquid phase and no removal of the silicon carbide; ABKE, no supersaturation but complete removal; ABGJF, supersaturation throughout; ABGHID, supersaturation up to G and then no removal; ABGJKE, supersaturation up to J and then complete removal.

The technique described above, *i.e.*, combination of charged particle activation analysis with zone melting, will provide useful information concerning the phase diagrams of carbon, nitrogen, and oxygen in ultrapure substances. More detailed thermodynamic discussions concerning these impurity elements in semiconductor silicon will be forthcoming in a separate paper.

Kinematical considerations of the carbon behavior.—In the solidification of the liquid eutectic C-Si mixture, it is quite natural for carbon to behave differently from the one component of an ordinary binary alloy due to the phenomena: (*i*) usually silicon carbide will not precipitate immediately when the liquid phase has become supersaturated; and (*ii*) silicon carbide appearing on the solid-liquid boundary can be removed to the liquid-gas surface, leaving only the solid silicon rather than the solid eutectic mixture.

In order for the carbon to precipitate, many carbon atoms must condense. The probability of their encounter, however, should be quite small because of their low concentration. This is especially true in the float-zone melting process where none of the nucleation centers, such as foreign substances, imperfections in the solid phase, and special spots on container walls, are readily available. Therefore, the liquid, and also the solid phases are likely to become supersaturated.

We have actually observed phenomenon (*ii*). In general, the van der Waals' attraction between the surface of a solid phase and the surrounding liquid phase is much smaller when the solid is only slightly soluble in the liquid as compared to the highly soluble conditions. The silicon carbide powder, therefore, can be positioned on the liquid-gas surface with more stability in free energy than on the solid-liquid boundary. Turbulence in the molten zone caused by the radio-frequency heating carries the silicon carbide powder to the more stable position.

According to whether the removal of the silicon carbide and the supersaturation of the liquid phase take place or not, varying types of the resultant carbon distribution are possible after a single zone pass of a silicon rod with a relatively high original carbon content. This is shown in Fig. 5. The original carbon content is about 15 x 10^{17} at./cm^3, and the liquid phase has become saturated at Location B. The carbon level at C, I, and D should be equal to the original carbon content. Practically, distributions corresponding to the partial removal of the silicon carbide probably occur more frequently than those in Fig. 5.

From these kinematic considerations, carbon contents of silicon single crystals exceeding the solubility in the solid at the melting point can be explained. Such high carbon concentrations were sometimes found in old silicon crystals, but rarely in modern products. This is probably due mainly to the difference in the carbon content of the raw polycrystals. It is natural that silicon carbide precipitates when silicon containing over 3.5 x 10^{17} at./cm^3 of carbon is kept at 1100°C (7).

Evaporation of carbon.—A parallel can be found between the carbon and oxygen concentrations in Table I and Table II. This suggests the evaporation of carbon as carbon oxide from the molten silicon. In order to obtain proof of this evaporation, the following new radiochemical technique has been devised: (*i*) bombard semiconductor silicon of known carbon and oxygen content with ^{3}He particles accelerated over 40 MeV energy to produce ^{11}C in the silicon by the reaction of the matrix itself (2); (*ii*) fuse the bombarded silicon by radio-frequency heating, and analyze the evolved gas for the ^{11}C by radio gas chromatography; and (*iii*) measure the ^{11}C remaining in the silicon. The evaporation of the carbon has thus been proved, although data are still being acquired in this study.

Future problem.—Effects of the carbon on the semiconductor properties still remain obscure, although a correlation between the lattice parameter and the carbon concentration has been reported (8). At the present, any remarkable effect on the electronic properties has not been documented. In more elaborate and elegant uses of the semiconductor, however, it is possible for the carbon to play some role. This will be the topic of future study.

Acknowledgment

The authors would like to express their thanks to the Cyclotron Group of the Institute of Physical and Chemical Research for their bombardment services, and to Mr. Yoshiyuki Endo, of the Komatsu Electronic Metals Company, for his aid in the analytical practice.

ABSTRACT

The effect of substrate temperature on the preferred orientation of polycrystalline silicon films deposited on thermally grown silicon dioxide has been investigated. The films were deposited by the pyrolytic decomposition of silane and were examined by x-ray diffraction and scanning electron microscopy. For films grown to a thickness of 16μ, the preferred orientation first increased in the <110> direction as deposition temperature was increased to 1000°C; as deposition temperature was increased above 1000°C the preferred {110} orientation decreased. The measurement of preferred orientation as a function of film thickness indicated that the strong {110} preferred orientation at 1000°C was due to accelerated {110} growth and not preferred {110} nucleation orientation.

The deposition of silicon on oxidized silicon wafers is of interest in microelectronic applications of dielectric isolation and selected area epitaxy. Silicon may be deposited on these surfaces by physical or chemical methods. Chemical deposition of silicon from the halide onto the oxidized surface has been reported as often needing a nucleating agent, such as a sodium salt, to produce a uniform coating of polycrystalline silicon (1). Silane has been used to deposit polycrystalline silicon on silicon dioxide covered silicon wafers, but no information was given on the structure of the films (2).

Silicon wafers used in microelectronic applications are polished single crystals and are usually sliced parallel to a low index crystallographic plane, but silicon oxide grown on the single crystal surface is amorphous with a short range crystobalite structure (3, 4). Hence, deposition on oxidized single crystal silicon is deposition on an amorphous substrate. Previous papers, where silicon was vacuum evaporated onto heated fused quartz substrates, report that the deposited film habit has a strong temperature dependence. Random polycrystalline silicon films were reported at substrate temperatures above 550°C, and evidence of (111) preferred orientation above 1000°C was shown (5, 6). Mountvalla (7) reports random films in the range between 700° and 765°C with a preferred {110} orientation between 765° and 900°C. At 1000°C Mountvalla (7) reports a mixed {110} and {111} orientation.

The purpose of this paper is to report the use of silane for silicon deposition on oxidized silicon wafers and to report the effect of substrate temperature on the preferred orientation of the deposits.

Experimental

The wafers were polished 0.005 ohm-cm boron doped single crystal silicon orientated within 2° of the {111} face. They were then oxidized in a quartz tube furnace at 1100°C by bubbling nitrogen through a heated water bath. The final oxide was approximately 1μ thick.

The deposition apparatus was an induction heated silicon horizontal tube epitaxial reactor (Fig. 1). Pure (50 ohm-cm) silane was fed through a flowmeter and mixed with sufficient hydrogen to produce a silane atmosphere of 0.37% by volume in the 7-cm-diameter by 75-cm-long quartz glass reaction chamber. The oxidized substrates were placed on either a silicon carbide coated graphite susceptor or a quartz envelope containing a graphite susceptor. The susceptor was placed in the quartz reactor tube at a point midway in the induction coil and at a small angle with respect to the horizontal.

The primary control variable for these experiments was substrate temperature which was varied from 840° to 1265°C (corrected from optical pyrometer readings). Silane flow rate was a constant 50 cc/min which produced a deposition rate of 0.8 μ/min. In a standard run the substrate was rapidly brought to temperature and then held at temperature for 7 min before introducing the silane gas for a 20-min run. A hydrogen atmosphere was used during both preheat and cooling periods. The preheat conditions and deposition time were varied for some runs, as will be described in the section "Results."

The preferred orientation was examined using an x-ray diffractometer. The {111} oriented silicon wafers did not produce a diffraction pattern since they were slightly misoriented. To give accurate comparison of preferred orientations of the different samples, all x-ray scans were run at identical settings, except for the counts-per-second scale.

Results

A total of 18 samples were prepared under various processing conditions. Table I shows sample identification numbers, process conditions, and relative x-ray intensities.

Macroscopically flat layers of polycrystalline silicon were deposited on the oxidized silicon substrates for all test temperatures except 1265°C. At a substrate temperature of 1265°C, the reduction and erosion of the silicon dioxide was too rapid to hold the deposited silicon. Examination of the wafer after the run showed that all oxide had been removed, and random crystallites had nucleated and grown on the single crystal surface (Fig. 2). The remainder of this paper will be a discussion of test results for substrate temperatures of 840°-1170°C only.

The texture of the 16μ-thick deposits was strongly temperature dependent. The absolute x-ray intensity

of the {110} crystal planes showed an increase with increasing temperature until 1000°C, and then the {110} intensity decreased with further increases in temperature (Fig. 3). The relative intensities of the other low index crystallographic planes increased as the absolute {110} intensity decreased (Table I). That is, the films have an increasing preferred {110} orientation for deposition temperatures up to 1000°C; and even though the {110} orientation predominates, it reduces in strength at higher temperature to approach the surface coverage of {100} orientated crystallites. Even in the high-temperature deposits the relative intensities of the {111}, {311}, and {331} orientations are depressed from the standard ASTM (8) values. It should be noted that in an x-ray diffraction pattern, a {400} peak which is 13.5% of the {220} peak implies that there are as many {100} oriented crystallites on the wafers as there are crystallites oriented in the {110} direction.

An example of the x-ray diffractometer data is shown in Fig. 4 where the diffraction peaks from sample 2-3 are compared to the peaks in sample 2-4 (see Table I). Both patterns were taken with identical machine settings. The upper curve shows a very strong {220} peak, and the lower curve shows a weaker {220} peak, but the relative (and in this case, the absolute) intensities of the {111}, {400}, and {331} peaks have increased. The surfaces on samples 2-3 and 2-4 were examined by scanning electron microscopy. The surface of sample 2-4, which has the more random distribution of the crystallites, is shown in Fig. 5. Sample 2-3, which has a strong {110} preferred orientation, is similar to Fig. 5 except that the surface appears more uniform.

To test for possible causes of preferred orientation, the standard deposition run, as described above, was perturbed. The methods of perturbation and the results are described below:

1. Sample 2-9 which was deposited initially at 990°C was heat-treated in hydrogen at 1165°C for 30 min. The purpose of this test was to see if a high-temperature treatment would produce an orientation similar to a high-temperature deposition. The x-ray diffraction pattern was not changed by this treatment.

2. The oxide coated substrate was preheated at 1125°C for approximately 8 min before deposition; the

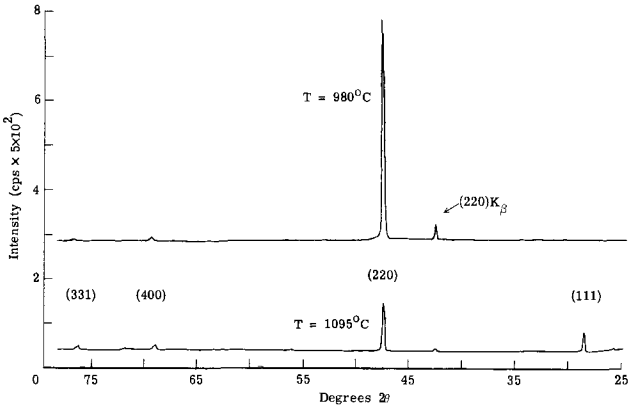

Fig. 4. X-ray diffraction intensity of low index planes for deposits made at 980° and 1095°C.

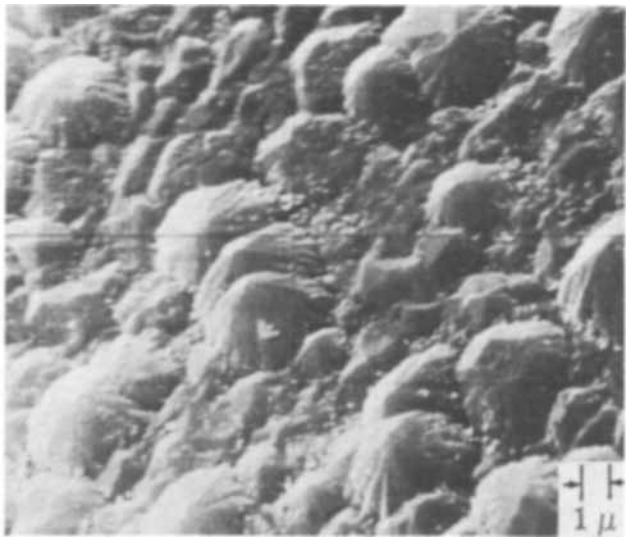

Fig. 5. SEM photomicrograph of film deposited at 980°C

temperature was then lowered to 970°C for normal deposition. This test was made to see if the preferred orientation was due to the oxide heat-treatment or to the actual deposition temperature. This test resulted in a stronger {110} preferred orientation than would normally be obtained at a deposition temperature of 970°C (see data on sample 2-14 in Table I).

3. Two sets of samples were made by depositing each at two different temperatures. That is, on one set of samples deposition was started at 985°C and continued for 5 min, then deposition was stopped and the temperature was raised to 1165°C, in the hydrogen atmosphere, and deposition proceeded for the remaining 15 min of the 20-min run. In another run the above temperatures were reversed, except that the high temperature was 1150°C. These tests were conducted to see if the temperature of the initial deposition would be controlling for future changes in temperature. The data, obtained from the high-temperature start, fell on the curve of {220} peak *vs.* substrate temperature as though the entire run was made at 1150°C; however, the run started at 970°C, had a low intensity {220} similar to a run made at 1165°C and a relatively strong {400} peak indicating a {100} preferred orientation (see data on samples 2-15 and 2-13 in Table I).

4. Data were taken in which deposition time was the independent variable, and temperature was held constant at approximately 980°C. Deposition times of 1, 5, and 8.5 min were used. These data were taken to see if the preferred orientation was due to nucleation orientation or growth orientation. The x-ray data for the 1-min run gave no distinguishable diffraction pattern. The 5-min run had a combination {110} and {100} preferred orientation with the {100} being the stronger of the two. Finally, in the 8.5-min run the {110} peak was clearly showing its strong preferred orientation (see data on samples 2-19, 2-21, and 2-17 in Table I).

Discussion

The preferred orientation of thin silicon films deposited on thermally grown silicon dioxide by the pyrolytic decomposition of silane is both temperature and thickness dependent. Substrate temperatures of approximately 1000°C produced a very strong {110} preferred orientation when the films were grown to a thickness of approximately 16μ, but thinner films ($t \simeq 4\mu$) tend to have a near random orientation with the {100} crystallographic plane predominating. This thickness dependence of preferred orientation indicates that the films have a preferred {100} nucleation orientation, but the {110} orientated crystallites have more favorable growth conditions in the intermediate temperature (970°-1000°C) range. The strongest {100} preferred orientation for all samples was produced by starting deposition at 985°C and then going to 1165°C for the majority of the run (see data for sample 2-15). These data not only indicate that the lower temperature produces a greater nucleation {100} orientation than a higher temperature, but that the growth {100} orientation is greater at the higher temperature.

However, in a deposit started at a high temperature ($T \approx 1150$°C), and continued at an intermediate temperature ($T \approx 980$°C), the preferred {110} orientation was weak as compared to deposits made entirely at 980°C. This implies that the nucleation orientation may be random at high temperatures. The preferred {110} orientation that does exist in this sample is due to growth orientation at the reduced temperature, but there were less {110} oriented nuclei to start with due to initial growth at the higher temperature.

A high-temperature (1125°C) predeposition treatment of the substrate tends to enhance the nucleation orientation of {110} crystal planes since sample 2-14 has the strongest {110} orientation of all runs. A post deposition heat-treatment ($T \approx 1165$°C, initial run at $T \approx 990$°C) had no measurable effect on the crystallography of the deposits.

In summary, both nucleation and growth contributions to preferred crystallographic orientation of silicon deposits on silicon dioxide appear to be temperature dependent. Temperatures in the neighborhood of 1000°C produce a preferred {100} nucleation orientation but strongly favor the {110} orientation in growth kinetics. Substrate temperatures in the range of 1150°C appear to favor a more random distribution of oriented nuclei and favor a {100} growth orientation.

Reaction Equilibria in the Growth of GaAs and GaP by the Chloride Transport Process

D. J. Kirwan[1]

Monsanto Company, St. Louis, Missouri 63166

ABSTRACT

The equipment and procedures used for the measurement of high temperature heterogeneous reaction equilibria are described. The results of these measurements for four reactions of primary importance to the epitaxial growth of GaAs and GaP by the chloride transport process are reported and compared with literature values.

The epitaxial growth of III-V compounds is based upon the departure from equilibrium of reactions of the type

$$3GaCl(g) + 1/2As_4(g) = 2GaAs(s) + GaCl_3(g)$$

with a similar reaction applying for GaP. Also, in the presence of hydrogen the reaction

$$GaCl_3(g) + H_2(g) = GaCl(g) + 2HCl(g)$$

is important. The crystal growth rate will be dependent upon the departure of the above reactions from equilibrium, and the equilibrium constants are temperature dependent. The purpose of this work was the experimental determination of the equilibrium constants for the above reactions and others pertinent to the manufacture of GaAs and GaP.

The results of a literature survey of available reaction equilibria data for reactions involved in the growth of GaAs and GaP from the vapor by the chloride transport process are presented in Table I. In all cases the standard state is taken as the pure material at one atmosphere pressure. In the last column the references for the data are given as well as whether the equilibrium constant was obtained by direct experimental observation or calculated from thermochemical data. Redundant reactions are included for the convenience of the user.

[1] Present address: Department of Chemical Engineering, University of Virginia, Charlottesville, Virginia 22901.

Key words: gallium arsenide, gallium phosphide, vapor transport, epitaxial growth, reaction equilibrium.

The thermochemical data tabulated by Fergusson and Gabor (1) are used in Table I when available. There is a significant discrepancy between their value of the standard heat of formation of GaCl and that reported in (2) (−16.2 kcal/mole *vs.* −19.0 kcal/mole). The equilibrium constants for reactions 17-21 involving GaP were obtained by computing the chemical potential of GaP from the vapor pressure measurements of Johnston (3).

Direct experimental observations are available for only three of the reactions listed in Table I and in one case (reaction 4) the value is not in agreement with that calculated from thermochemical data. Also, the extreme sensitivity of the value of the equilibrium constant to the accuracy of the standard enthalpy and entropy of reaction (at 1000°K an uncertainty of 5 kcal in the enthalpy of reaction changes the equilibrium constant by more than an order of magnitude) makes direct measurement of equilibrium constants of interest advisable. In this work the equilibrium constants for reactions 4, 6, 12, and 20 in Table I are measured as a function of temperature.

Experimental

Since the reactions of interest have a net change in the total number of moles of gaseous species, the equilibrium constants can be obtained from closed tube pressure-temperature measurements similar to those of Silvestri and Lyons (4) and Zeugel (5). In this method the total pressure in the reactor is measured as the reactor is heated to various temperature levels.

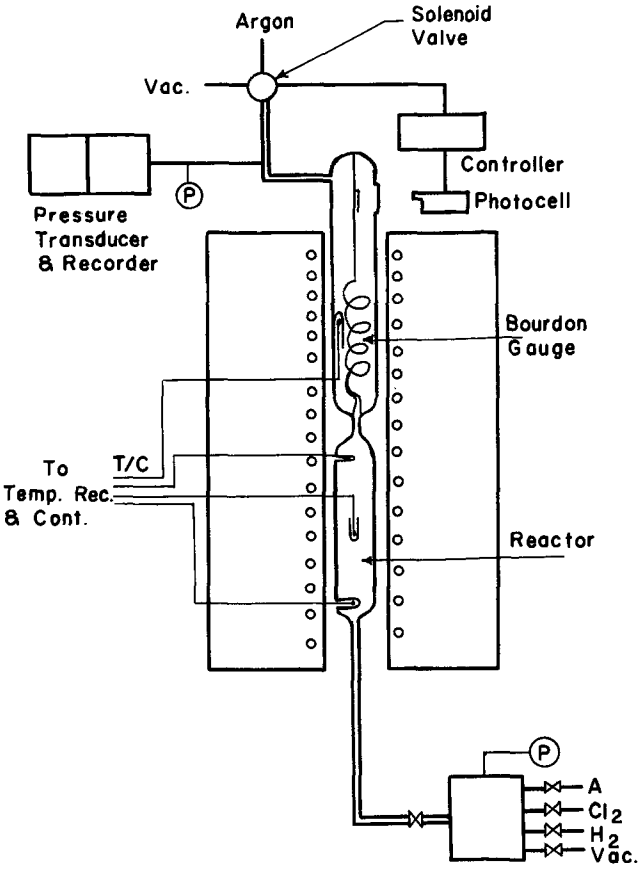

Fig. 1. Closed reactor system

From atom balances, a knowledge of the initial charge of reactants, and the temperature and pressure measurements, the partial pressure of each species may be calculated; hence, the equilibrium constant can be obtained at each temperature.

Equipment.—The experimental system selected was a batch reactor consisting of a quartz tube placed within a furnace capable of reaching approximately 1200°C. The principal items of equipment shown schematically in Fig. 1 included:

1. A reactor pressure sensing system consisting of a quartz helix bourdon tube attached to the reactor through a capillary tube, a photocell and a controller. The quartz bourdon gauges are manufactured by Worden Quartz Products, Inc., Houston, Texas. A mirror attached to the end of the helix rotated when the pressure within the tube changed causing a deflection of a light beam coming from the photocell. The reflected light beam was received by a photocell assembly coupled to a controller which operated a solenoid valve which restored the mirror to the null position by adjusting the argon gas pressure in the enclosure about the helix. The pressure in the enclosure was then read from a Wallace and Tiernan absolute pressure gauge and continuously recorded using a potentiometric type pressure transducer.

Some further comment on the quartz bourdon gauges is perhaps in order. Since condensed phases (GaAs, GaP, Ga) were present during these reactions even at the highest temperatures, it is necessary that the pressure measuring system be capable of being heated above the temperature in the reactor to prevent deposition. These all quartz gauges can be heated to above 1100°C in a corrosive atmosphere. They do have some drawbacks. The quartz helix is very fragile and quite easily broken from mechanical shock. Quartz is subject to weakening and eventual breakdown due to devitrification at high temperatures. This process is hastened by water vapor and basic oxides. Hence it is necessary that the quartz be kept clean and not handled with the hands or fingers before placing in the furnace. To obtain reproducible readings it is necessary to anneal the gauges prior to use. For the gauges used in this work approximately 30 hr at 1070°C were required.

2. As shown in Fig. 1, a muffle furnace having three separately controlled windings was used to maintain a uniform temperature along the reactor with the bourdon tube about 20°C higher than the reactor.

3. A gas handling system was used for evacuating the reactor and charging the gaseous reactants. Two Wallace and Tiernan absolute pressure gauges (0-1800 and 0-800 Torr) were used for pressure measurements.

4. Temperatures were measured and controlled by Type K, Iconel sheathed, thermocouples placed in wells at three locations along the length of the reactor and in a well in the bourdon gauge.

5. The reactor, a 24 mm ID quartz tube approximately 7 in. long, was designed to insure separation of gaseous and liquid or solid reactants until the reactor had been sealed and the initial charge of gas determined. This was accomplished by sealing the solid or liquid within a quartz ampoule with a breakaway tip. The ampoule was placed at the bottom of a vertical tube within the reactor. An iron rod, encased in quartz, was placed on top of the ampoule. At the start of the run, this rod was raised by an external magnet and then allowed to drop breaking the tip and allowing reaction to begin.

Procedure.—The determination of an equilibrium constant consisted of the following steps:

1. An ampoule containing the appropriate solid or liquid reagent was placed in the reactor with the bourdon assembly attached.

2. The reactor was evacuated and heated with a torch to remove any adsorbed species. After a number of alternate fillings and evacuations with argon and then with the gaseous reactants, the reactor was filled to the desired pressure and sealed with a torch.

3. The exact gaseous charge was determined by observing the pressure in the reactor as a function of temperature with the ampoule unbroken. At these low pressures (50-200 Torr) all the gases of interest behave ideally. This determination was carried out in a constant temperature air bath operating between room temperature and approximately 250°C. When the material in the ampoule was nonvolatile, *e.g.* GaAs, the muffle furnace was used, permitting higher temperatures to be obtained and a more accurate calculation of the molar density of gas charged.

4. With the reactor in the furnace, the pressure sensing system was nulled at the true pressure in the reactor as determined in step 3. The ampoule was broken and the total pressure observed at a series of temperatures. The pressure transducer used with a recorder was useful for determining when the total pressure had become constant and the reading could be taken. Data were taken during both heating and cooling to insure that equilibrium had been attained in the reactor.

Further details of the procedure will be given when the individual reactions are discussed.

Results and Discussion

Reaction A: $3GaCl(g) + \frac{1}{2}As_4(g) = 2GaAs(s) + GaCl_3(g)$.—The measurement of the equilibrium constant of this reaction follows the method of Zeugel (5). It consisted of charging a known amount of chlorine gas (>99.5%) and a sealed ampoule containing an excess of GaAs (Monsanto, melt grown) to the reactor. At low temperatures the chlorine completely reacts with GaAs forming chlorides of gallium and arsenic (possibly free arsenic also). Above approximately 600°C these reactions are complete and the only species present are $GaCl_3$, GaCl, As_4 (small amounts of As_2)

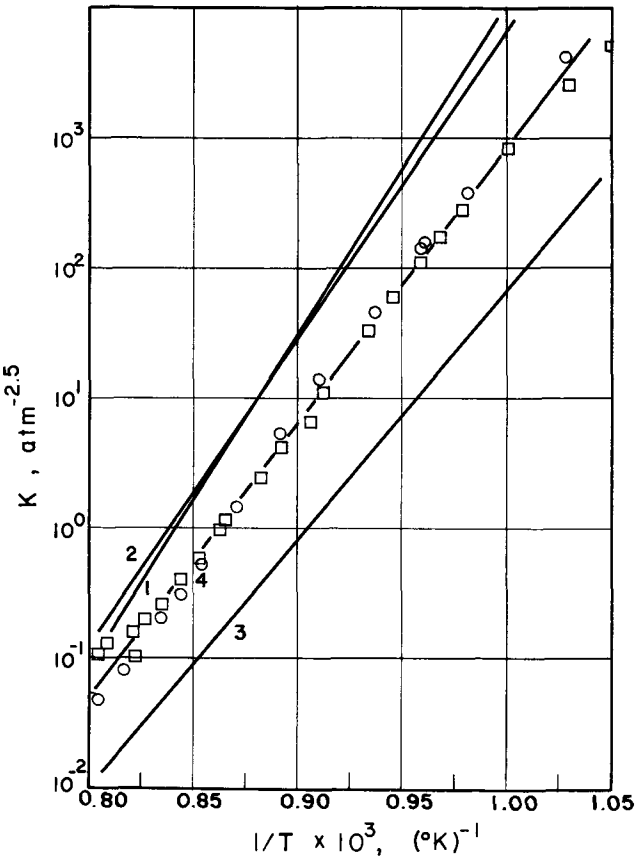

Fig. 2. Equilibrium constant: $3GaCl + \frac{1}{2}As_4 = 2\ GaAs + GaCl_3$. Curve 1, (5); curve 2, (1); curve 3, (2); curve 4, this work (two runs).

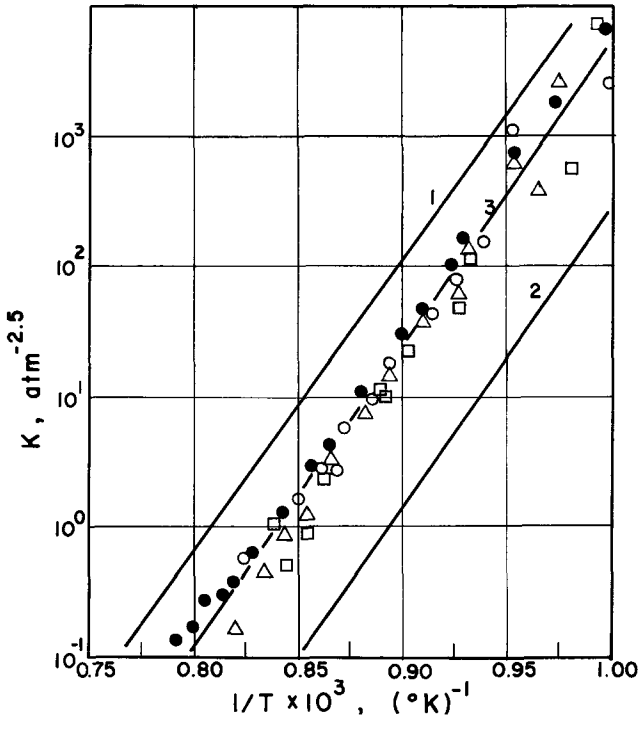

Fig. 3. Equilibrium constant: $3GaCl + \frac{1}{2}P_4 = 2GaP + GaCl_3$. Curve 1, (1, 3, 6); curve 2, (2); curve 3, this work (four runs).

and GaAs. A correction for the amount of arsenic present as As_2 in equilibrium with As_4 was made using the data of Stull and Sinke (6) as correlated by Zeugel (5). The equilibrium constant for the reaction was then calculated from total pressure measurements as the temperature was raised in steps from 600°C to about 1000°C and then lowered. The calculations were performed on a CDC 6400 computer.

The values of the equilibrium constant obtained in this work are presented in Fig. 2. Also shown are a correlation of the experimental results of Zeugel (5) and two sets of values calculated from thermochemical data. As mentioned earlier, the only difference between the literature curves is due to the use of different values for the standard heat of formation of GaCl(g). The least squares correlation of the equilibrium constants measured in this work is given in Table II along with information on the uncertainty of the correlating equation and the temperature range over which it applies.

Zeugel's experimental values are in good agreement with values calculated from Fergusson and Gabor's (2) thermochemical data while the results of this work lie between the two literature curves. Some recent results obtained in this laboratory on the growth and etching rates of GaAs support the equilibrium constant reported here (7). Finally, as has been previously noted, the value of the equilibrium constant calculated from thermochemical data is very sensitive to small changes in the heats and entropies of reaction. For example, if Thurmond's (8) value for the heat of formation of GaAs, which is only 700 cal less than that of Fergusson and Gabor, were used, the literature curve would be much closer to the experimental values obtained here.

Reaction B: $3GaCl(g) + \frac{1}{2}P_4(g) = 2GaP(s) + GaCl_3(g)$.—The procedure for measuring equilibrium constants for this reaction is analogous to that for reaction *A* except, of course, excess GaP (Monsanto, melt grown) was placed in the quartz ampoule. A correction for the presence of $P_2(g)$ was made using the equilibrium data of Stull and Sinke (6) for the dissociation of $P_4(g)$ to the dimer. It was noted that chlorine did not react very rapidly with GaP at room temperature. To increase the reaction rate the temperature was raised to about 1000°C and data taken during cooling first and then taken during heating. This also had the effect of removing material from the ampoule and distributing it throughout the reactor which reduced mass transfer resistance in the reactor and thereby shortened the time required to come to equilibrium at a given temperature.

The results of four runs on this system are presented in Fig. 3. Similar to those of GaAs, the equilibrium constant data lie between the two literature curves which again differ only in the value used for $\Delta Hf°_{298}$ of GaCl(g). The equilibrium constants measured in this work were correlated and the resulting equation is given in Table II.

Reaction C: $GaCl_3(g) + H_2(g) = GaCl(g) + 2HCl(g)$.—The equilibrium of this reaction is of importance because epitaxial deposition of GaAs, GaP or $GaAs_xP_{1-x}$ occurs in the presence of a high partial pressure of hydrogen. Under such conditions the partial

Table II. Experimental equilibrium constant data

Reaction	$Log_{10}K_p$ (atm units)	Var. of slope	Std. error of estimate	Temperature range (°K)
$3GaCl(g) + 1/2As_4(g) = 2GaAs(s) + GaCl_3(g)$	$2.10 \times 10^4/T - 18.0$	4.5×10^4	0.11	900-1300
$3GaCl(g) + 1/2P_4(g) = 2GaP(s) + GaCl_3(g)$	$2.20 \times 10^4/T - 18.6$	1.8×10^5	0.21	1000-1250
$GaCl_3(g) + H_2(g) = GaCl\ (g) + 2HCl(g)$	$-1.00 \times 10^4/T + 8.5$	3.6×10^4	0.14	900-1330
$GaCl_3(g) + 2Ga(l) = GaCl_3(g)$	$-1.16 \times 10^4/T + 14.0$	6.2×10^4	0.11	720-920

pressure of $GaCl_3$ is so reduced by reaction C that the deposition reaction is often written as

$$2GaCl(g) + \tfrac{1}{2}As_4(g) + H_2(g) = 2GaAs(g) + 2HCl(g)$$

The equilibrium constant for this reaction is simply the product of the equilibrium constants of reactions *A* and *C*. It is not possible to determine the equilibrium constant of the above reaction directly using a closed reactor system; hence the equilibrium constant for reaction *C* was measured and combined with that of reaction *A* to obtain the desired result.

The reactor was charged with hydrogen gas (>99.9%) and $GaCl_3$ (Monsanto produced, purity ~98%) crystals in a quartz ampoule. The amount of $GaCl_3$ charged was determined by an analysis of the reactor pressure between 550°K and 750°K where the reaction with hydrogen has not yet begun, but all of the $GaCl_3$ is in the vapor phase. The analysis is complicated by the presence of $GaCl_3$ in both monomer and dimer forms in the vapor. The equilibrium constant for the dissociation of the dimer as measured by Laubengayer and Schirmer (9) was used in the calculation of the amount of $GaCl_3$ present.

The total pressure measurements were complicated by high temperature diffusion of hydrogen through the thin-walled quartz helix of the bourdon gauge and the reactor walls themselves. Since in this system no condensed phases exist above about 250°C (a temperature where the diffusion rate is negligible), the bourdon tube was maintained at this temperature throughout a run. Diffusion through the reactor walls was slower but significant at the higher temperatures when the hydrogen partial pressure is high. To minimize this effect a large $GaCl_3/H_2$ ratio was used so that at the higher temperatures most of the hydrogen has reacted. This, of course, makes the calculation of the hydrogen partial pressure and, therefore, the equilibrium constant more uncertain in the high temperature region.

In a number of runs the data were not reproducible and log *K* *vs.* 1/T plots did not give straight lines. These problems were attributed to contamination of the $GaCl_3$. Gallium trichloride is strongly hygroscopic and easily contaminated if contacted with air. Data from such runs were, of course, disregarded.

In Fig. 4 are presented data from two runs in which the $GaCl_3/H_2$ ratio was large, the data reproducible during heating and cooling and no evidence of contamination was observed. Also shown are the literature values calculated from the data of Fergusson and Gabor (1) and that using the NBS value for $\Delta Hf°_{298}$ of GaCl(g). The data indicate a heat of reaction 15 to 25 per cent higher than the literature values and do not agree with either literature curve. The observed equilibrium constants were correlated and the resulting equation is given in Table II.

The growth rate studies, mentioned previously (7) as supporting the equilibrium constant values for reaction *A*, actually gave values of the equilibrium constant for the reaction,

$$2GaCl(g) + \tfrac{1}{2}As_4(g) + H_2(g) = 2GaAs(s) + 2HCl(g)$$

The values obtained were in agreement with the combined values of the measured equilibrium constants for reactions *A* and *C*. Consequently, those studies give support to the results obtained here for both reactions *A* and *C*.

Reaction D: $GaCl_3(g) + 2Ga(l) = 3GaCl(g)$.—As well as providing further thermodynamic information on the chlorides of gallium, the equilibrium of this reaction is important to the epitaxial growth of GaAs in two ways. First, gallium is commonly supplied to an epitaxial reactor by bubbling HCl through a gallium contactor held at high temperature. The reaction of interest is

$$2HCl(g) + 2Ga(l) = 2GaCl(g) + H_2(g)$$

whose equilibrium constant is simply the equilibrium constant of reaction *D* divided by that of reaction *C*.

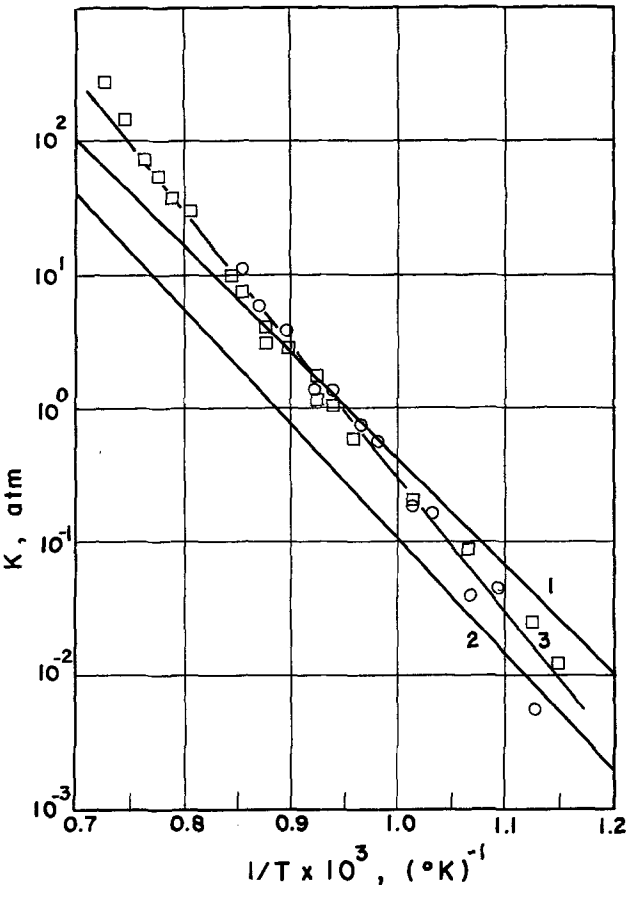

Fig. 4. Equilibrium constant: $GaCl_3 + H_2 = GaCl + 2HCl$. Curve 1, (2); curve 2, (1); curve 3, this work (two runs).

A knowledge of this equilibrium constant provides the value of the maximum conversion to GaCl to be expected in the contactor. Second, the disproportionation of GaCl(g) to free gallium and GaCl(g) has been suggested as a step in the mechanism of the growth of GaAs by the chloride transport process.

The procedure for carrying out the measurement of this equilibria consists of charging chlorine gas and an ampoule containing excess liquid gallium (99.99%) to the reactor. At lower temperatures the chlorine completely reacts forming a mixture of $GaCl_3$ and $GaCl_2$. The $GaCl_2$ decomposes above 300°C to Ga(l) and $GaCl_3$(g). Above approximately 400°C the reaction of interest then occurs.

The results of the two runs made are compared with the literature data in Fig. 5. The data are in excellent agreement with the experimental measurements of Zeugel (5) and lie between the literature curves using different values for $\Delta Hf°_{298}$ of GaCl. The values obtained in our work were correlated with the equation listed in Table II.

Thermochemical data.—We had hoped that the equilibrium constants of these four reactions would permit the calculation of new values of the more uncertain thermochemical data, particularly that of GaCl. Inspection of Fig. 2-5 suggests that, since the measured values lie between the two literature curves corresponding to different values of $\Delta Hf°_{298}$ of GaCl, the thermochemical data of GaCl may be in error. The only other species common to all four reactions is $GaCl_3$; however, since it is stable at room temperature, it would be expected that its thermochemical properties would be more easily measured and therefore more reliable.

The chemical potential of GaCl as a function of temperature was calculated from each of the measured equilibrium constants assuming that the literature values of the entropies and enthalpies of all other

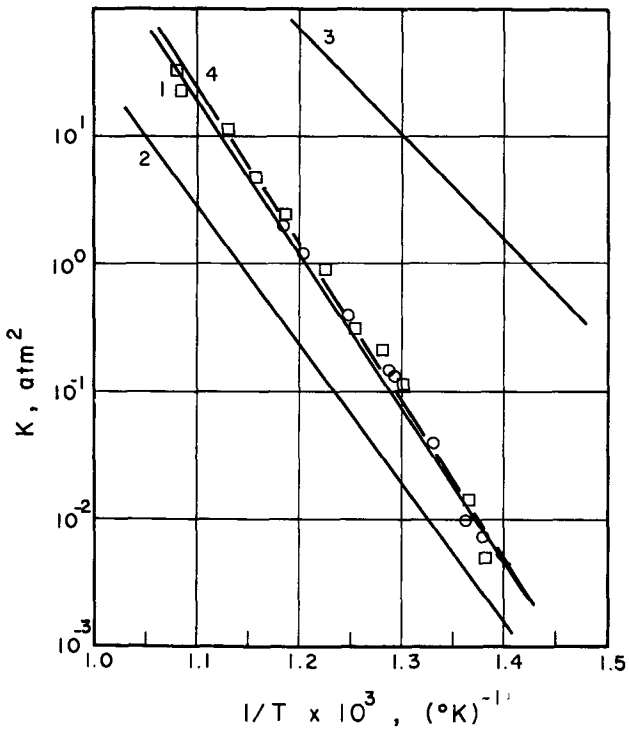

Fig. 5. Equilibrium constant: 2Ga + $GaCl_3$ = 3GaCl. Curve 1, (5); curve 2, (1); curve 3, (2); curve 4, this work (two runs).

species were correct. The results, which generally lay between the two literature values, varied, at most, by 4 kcal/mole (out of approximately 80 kcal/mole) depending upon which reaction was used. $\Delta Hf°_{298}$ for GaCl calculated from these data also varied as much as 4 kcal/mole with an average value of 17.5 kcal/mole. The discrepancy in $\Delta Hf°_{298}$ and hence in the chemical potential of GaCl between the two literature values [Ref. (1) and (2)] is 2.8 kcal/mole. Although the measured equilibrium data are reasonably self-consistent, they are not accurate enough to settle the discrepancy in the literature values. The true value of $\Delta Hf°_{298}$ of GaCl probably does lie between the literature values.

Equilibrium alloy composition.—The equilibrium constants for the reactions depositing pure GaAs and GaP may be used to predict the composition of a mixed crystal, $GaAs_{1-x}P_x$, in equilibrium with a vapor of given composition.

Consider the formation of a solid solution of GaP and GaAs. The condition of thermodynamic equilibrium of the deposition reactions yields the equations

$$\frac{P_{GaCl_3}(\gamma_A X_A)^2}{P^3_{GaCl}\, P^{1/2}_{As4}} = K_A \qquad [1]$$

$$\frac{P_{GaCl_3}(\gamma_P X_P)^2}{P^3_{GaCl}\, P^{1/2}_{P4}} = K_B \qquad [2]$$

where γ_A and γ_P are the activity coefficients of GaAs and GaP in a solid solution of mole fraction, $X_A = 1 - X_P$, of GaAs and of mole fraction, X_P, of GaP. K_A and K_B are the equilibrium constants of reactions A and B discussed previously. Equation [2] divided by [1] yields a relation between the phosphorous composition in the solid and that in the vapor.

$$\frac{\gamma_P X_P}{\gamma_A(1 - X_P)} = \left(\frac{K_B}{K_A}\right)^{1/2} \left(\frac{p_{P4}}{p_{As4}}\right)^{1/4} \qquad [3]$$

In the absence of better information it is reasonable to assume that the solid solution is approximately ideal ($\gamma = 1$). Equation [3] can be solved for the mole fraction of GaP in the solid.

$$X_P = \frac{(K_B/K_A)^{1/2}\,(P_{P4}/P_{As4})^{1/4}}{1 + (K_B/K_A)^{1/2}\,(P_{P4}/P_{As4})^{1/4}} \qquad [4]$$

The partial pressure ratio, p_{P4}/p_{As4}, is not simply the ratio of phosphorus to arsenic in the feed because these species partially dissociate into the dimer forms at the temperatures of interest. The true ratio of tetramers, accounting for the dissociation, is given by the equation

$$\frac{P_{P4}}{P_{As}} = \frac{y_P P_V + K_P/8 - (K^2_P/64 + y_P P_V K_P/4)^{1/2}}{(1 - y_P)P_V + K_{As}/8 - (K^2_{As}/64 + (1 - y_P)P_V K_{As}/4)^{1/2}} \qquad [5]$$

where y_P is the fraction of group V element that is phosphorus, P_V is the total pressure of group V elements computed as if all were in the tetramer form, and K_{As} and K_P are the equilibrium constants for the dissociation reactions: $As_4 = 2As_2$, $P_4 = 2P_2$. Equations [4] and [5] may then be used to calculate the equilibrium alloy composition for a given temperature, group V partial pressure and fraction of group V elements that is phosphorus, provided the temperature dependencies of the equilibrium constants are known. In Fig. 6 are presented some calculated values of the equilibrium alloy composition for typical conditions of epitaxial growth of $GaAs_xP_{1-x}$ (T = 800°, 850°C, 1 atm pressure and 0.375 mole per cent group V elements).

Summary and Conclusions

The equilibrium constants measured in this work are listed below.

1. $3GaCl(g) + \frac{1}{2}As_4(g) = 2GaAs(s) + GaCl_3(g)$

$$\log_{10} K\ (atm^{-2.5}) = 2.10 \times 10^4/T - 18.0$$

2. $3GaCl(g) + \frac{1}{2}P_4(g) = 2GaP(s) + GaCl_3(g)$

$$\log_{10} K\ (atm^{-2.5}) = 2.20 \times 10^4/T - 18.6$$

3. $GaCl_3(g) + H_2(g) = 2HCl(g) + GaCl(g)$

$$\log_{10} K\ (atm) = -1.00 \times 10^4/T + 8.5$$

4. $2Ga(l) + GaCl_3(g) = 3GaCl(g)$

$$\log_{10} K\ (atm^2) = -1.16 \times 10^4/T + 14.0$$

On the Redistribution of Boron in the Diffused Layer during Thermal Oxidation

J. S. T. Huang and L. C. Welliver

Solid State Electronics Center, Honeywell, Inc., Plymouth, Minnesota 55427

ABSTRACT

This work is concerned with the investigation of the impurity redistribution process in a two step p-type diffusion. A simple theoretical model is formulated from which a closed form expression for the impurity profile is obtained. The experimental results verify the theoretical prediction of the profile. From these results, the segregation coefficient of boron at the oxide-silicon interface is determined, and the total number of impurity atoms that have escaped into the oxide can also be estimated.

In integrated circuit technology, two step boron diffusion involving a deposition step followed by a drive-in step is commonly encountered. The drive-in process is usually performed in oxidizing atmosphere, resulting in redistribution of boron within the semiconductor. This redistribution process during thermal oxidation was studied by Grove *et al.* (1) using uniformly doped substrates of semi-infinite extent. Their model is therefore not applicable to the case where diffused layers are used. For instance, their conclusion that the concentration at the interface is independent of the oxidation time certainly will not hold true for the diffused layer. Kato and Nishi (2) studied the redistribution of the boron diffused layer over a limited temperature range, but their analysis was so complicated that a computer was needed to obtain numerical results. In this paper, a simple theoretical model is first developed. A closed-form solution is then obtained for the impurity profile. The only unknown is the segregation coefficient at the interface which is determined by fitting the experimental result to the theoretical plots for various values of the segregation coefficient.

With the mathematical form of the impurity distribution available, many semiconductor properties such as the Hall coefficient and piezoresistive coefficient of a diffused layer can be characterized by effective values averaged over the impurity distribution in the layer.

Key words: semiconductor, diffusion, oxidation.

Theoretical Model

The boron deposition process gives rise to a complementary error function distribution of impurities. The total impurity atoms per unit area is given by

$$Q = 2C_s\sqrt{\frac{D_1 t_1}{\pi}} \qquad [1]$$

where C_s is the surface concentration usually limited by the solid solubility of the diffusant; D_1 and t_1 are the diffusion constant during the deposition and the time of deposition, respectively. The subsequent oxidation and drive-in will result in a total oxide thickness of x_o. The corresponding thickness of silicon oxidized is mx_o, where m is experimentally determined to be 0.38 (3). Figure 1 shows the diffusion model. At $t = 0$, the original Si surface is at $y = 0$ and the oxide-silicon interface as a function of time is indicated by $y_o(t)$.

The problem can be divided into two parts. First, consider that there is no flow of impurity atoms into

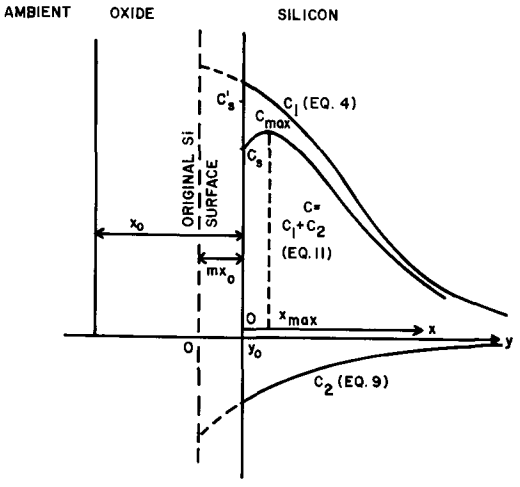

Fig. 1. Diffusion model

the oxide from the silicon, and the original Si surface is impermeable. The oxidation will cause an amount of impurity contained within mx_o to be absorbed by the oxide. The impurity distribution is then given by the solution of the diffusion equation

$$\frac{\partial C_1}{\partial t} = D\frac{\partial^2 C_1}{\partial y^2} \qquad \text{for } y > y_o \qquad [2]$$

where D is the boron diffusion constant in silicon during the drive-in. Since the extent of junction penetration of the deposited profile is small compared to that of the final profile after the drive-in, the total impurity distribution may be approximated by a delta function. The solution is then

$$C_1(y,t) = \frac{Q}{\sqrt{\pi Dt}}\exp(-y^2/4Dt) \qquad \text{for } y > y_o \quad [3]$$

Let x be the distance measured from the oxide-silicon interface as shown in Fig. 1, then $y = x + mx_o$. The oxide growth is assumed to be parabolic, *i.e.*, $x_o = \sqrt{Bt}$ where B is the growth rate constant. By the coordinate transformation $y = x + m\sqrt{Bt}$, [3] can be written as

$$C_1(x,t) = \frac{Q}{\sqrt{\pi Dt}}\exp\left[-\left(\frac{x}{2\sqrt{Dt}} + \frac{m}{2}\sqrt{\frac{B}{D}}\right)^2\right] \quad [4]$$

There is a net flow of impurities across the silicon-oxide interface because of the segregation coefficient at two solid interfaces, the finite diffusion probability of the dopant in the oxide, and the mass transfer at the oxide-ambient interface. For simplicity, assume that the diffusion constant of boron in oxide is negligible compared to that in silicon. Consider a small time interval dt during which a layer of silicon $m dx_o$ is converted into oxide of thickness dx_o. The amount of impurity in the original silicon was $C_s(y_o,t)\,m dx_o$ and the amount in the oxide is

$$C'_s(y_o,t)\,dx_o = kC_s(y_o,t)\,dx_o \qquad [5]$$

where k is the segregation coefficient. The difference, $(k-m)C_s(y_o,t)\,dx_o$, must outdiffuse from the semiconductor. Hence, the rate of flow is

$$D\frac{\partial C_2}{\partial y}\Big]_{y=y_o} = (k-m)\,C_s(y_o,t)\frac{dx_o}{dt} = \frac{(k-m)\,C_s(y_o,t)}{2}\sqrt{\frac{B}{t}} \quad [6]$$

The conditions for the second part of the solution are $C_2(y,0) = 0$ and $C_2(\infty,t) = 0$. Initially, assume zero impurity concentration in the silicon. The subsequent outdiffusion of the boron into the oxide will result in a mathematically negative concentration at the oxide-silicon interface. The solution of the diffusion equation is

$$C_2(y,t) = A\,\text{erfc}\left(\frac{y}{2\sqrt{Dt}}\right) \qquad [7]$$

where A is a constant to be determined. From [6] and [7], and $y_o = m\sqrt{Bt}$, the constant A can be expressed as

$$A = -\frac{k-m}{2}\sqrt{\frac{\pi B}{D}}\,C_s(y_o,t)\exp\left(\frac{m}{2}\sqrt{\frac{B}{D}}\right)^2 \qquad [8]$$

With reference to the x-coordinate, [7] and [8] can be combined to give

$$C_2(x,t) = -\frac{k-m}{2}\sqrt{\frac{\pi B}{D}}\exp\left(\frac{m}{2}\sqrt{\frac{B}{D}}\right)^2 \times C_s\,\text{erfc}\left(\frac{x}{2\sqrt{Dt}} + \frac{m}{2}\sqrt{\frac{B}{D}}\right) \quad [9]$$

The solutions $C_1(x,t)$ and $C_2(x,t)$ are sketched in Fig. 1. Since the diffusion equation and its associated boundary conditions are linear, the resulting impurity distribution is obtained by adding [4] and [9] to give

$$C(x,t) = \frac{Q}{\sqrt{\pi Dt}}\exp\left[-\left(\frac{x}{2\sqrt{Dt}} + \frac{m}{2}\sqrt{\frac{B}{D}}\right)^2\right] - \frac{k-m}{2}\sqrt{\frac{\pi B}{D}}\exp\left(\frac{m}{2}\sqrt{\frac{B}{D}}\right)^2 \times C_s\,\text{erfc}\left(\frac{x}{2\sqrt{Dt}} + \frac{m}{2}\sqrt{\frac{B}{D}}\right) \quad [10]$$

By setting $x = 0$ in Eq. [10], the surface concentration $C_s(0,t)$ is determined from [10]. Finally, the expression for the concentration profile is given by

$$C(x,t) = \frac{Q}{\sqrt{\pi Dt}}\exp\left[-\left(\frac{x}{2\sqrt{Dt}} + \frac{m}{2}\sqrt{\frac{B}{D}}\right)^2\right] - \frac{k-m}{2D}\sqrt{\frac{B}{t}} \times \frac{Q}{1 + \frac{k-m}{2}\sqrt{\frac{\pi B}{D}}\exp\left(\frac{m}{2}\sqrt{\frac{B}{D}}\right)^2\text{erfc}\left(\frac{m}{2}\sqrt{\frac{B}{D}}\right)} \times \text{erfc}\left(\frac{x}{2\sqrt{Dt}} + \frac{m}{2}\sqrt{\frac{B}{D}}\right) \quad [11]$$

Equation [11] is not as complex as it appears because the coefficient of the second term is independent of x. The distance at which the maximum concentration occurs is found by differentiating [11] to give

$$x_{\text{max. conc.}} = \sqrt{\frac{B}{D}}\sqrt{Dt} \times \left\{\frac{k-m}{1 + \frac{k-m}{2}\sqrt{\frac{\pi B}{D}}\exp\left(\frac{m}{2}\sqrt{\frac{m}{D}}\right)^2\text{erfc}\left(\frac{m}{2}\sqrt{\frac{B}{D}}\right)} - m\right\} \quad [12]$$

By setting $x = 0$ in [11] and also substituting [12] into [11], the ratio of maximum concentration C_{max} to surface concentration C_s is found to be independent

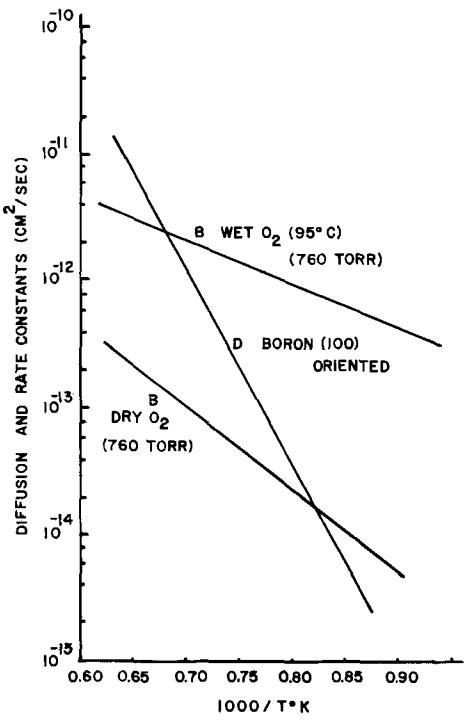

Fig. 2. Temperature dependences of oxide growth rate and diffusion constant of boron.

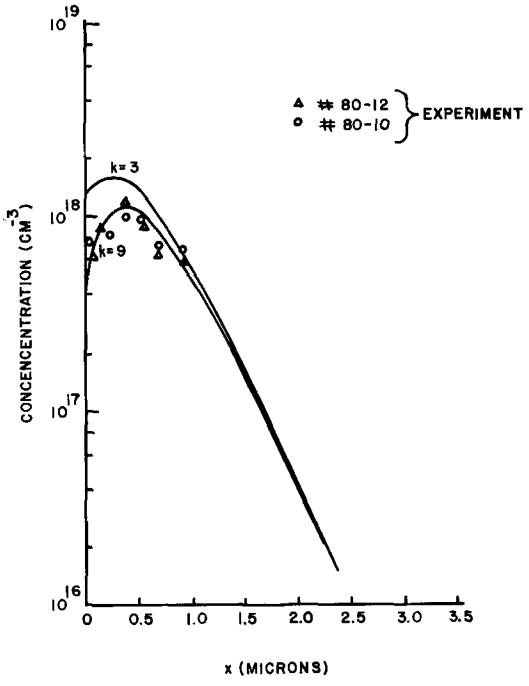

Fig. 3. Impurity profiles after oxidation in wet O_2 at 1100°C for 2 hr.

of the diffusion time and the total impurity Q prior to oxidation. However, the values of C_{max} and C_s depend critically on the diffusion temperature and the oxidation condition (wet or dry). Figure 2 shows the oxidation rate constants in dry and wet oxygen together with the diffusion constant of boron in (100) orientation. The diffusion constant of boron is taken from the measurements of Kurtz and Yee (4) corrected for (100) orientation based on the experimental results of Wills (5).[1] For cases in which both wet and dry cycles are involved, the effective rate constant is given by

$$B = \frac{B_w t_w + B_d t_d}{t_w + t_d} \qquad [13]$$

where the subscripts w and d indicate wet and dry oxidations, respectively.

The total impurity left in the silicon after oxidation can be found by integrating [11] from $x = 0$ to $x = x_j$ where x_j is the junction depth. Thus

$$Q' = Q\left\{\operatorname{erfc}\left(\frac{m}{2}\sqrt{\frac{B}{D}}\right) - \frac{\frac{k-m}{\sqrt{\pi}}\sqrt{\frac{B}{D}}\exp\left[-\left(\frac{m}{2}\sqrt{\frac{B}{D}}\right)^2\right] - \frac{m(k-m)}{2}\frac{B}{D}\operatorname{erfc}\left(\frac{m}{2}\sqrt{\frac{B}{D}}\right)}{1 + \frac{k-m}{2}\sqrt{\frac{\pi B}{D}}\exp\left(\frac{m}{2}\sqrt{\frac{B}{D}}\right)^2\operatorname{erfc}\left(\frac{m}{2}\sqrt{\frac{B}{D}}\right)}\right\} \qquad [14]$$

For a typical oxidation process, the impurity lost to the oxide, *i.e.*, $(Q - Q')/Q$, is generally greater than 60%.

Experimental Results

The materials used in this work were all 2-5 ohm-cm (100) n-type silicon wafers polished on both sides. The deposition was accomplished by heating boron nitride disks and the silicon wafers together at 925°C. The sheet resistivity, as measured by a four-point probe, was 80 ohm/□. The total impurity concentration was determined to be 6.3 x 10^{14} at./cm^2. The wafers were then divided into three groups subject to wet oxidation (oxygen bubbled through 95°C water) at 1100°, 1200°, and 1250°C for 2, 1, and ½ hr, respectively.

To obtain the experimental profile the oxide was stripped off each wafer and the wafer was then subjected to successive etching in KOH at 60°C. After each etch, the weight loss of the slice was found to determine the depth of the etch, and the sheet resistivities were measured using a four-point probe.

The surface concentrations of the diffused layer were obtained independently from the capacitance-voltage characteristics of MOS structures (6). By comparing the surface concentration obtained this way with the change of resistivities after the first etching step, the effective mobility value for the diffused layer was obtained from which the impurity concentration was determined for the subsequent etches. The mobility values used in the calculation are listed in Table I together with other results discussed later.

The theoretical profile is given by [11] for which appropriate values of the diffusion and oxidation rate constants corresponding to the oxidation temperature are to be found in Fig. 2. The theoretical profiles for different oxidation temperatures are plotted in Fig. 3 through 5 for two values of the segregation coefficient:

Table I. Comparison of results

Oxidation temperature	1100°C	1200°C	1250°C
Oxidation time	2 hr	1 hr	½ hr
Oxidation conditions	wet O_2	wet O_2	wet O_2
Diffusivity, cm²/sec	3.5×10^{-13}	1.9×10^{-12}	4.2×10^{-12}
Growth constant, cm²/sec	1.55×10^{-12}	2.3×10^{-12}	2.8×10^{-12}
Mobility, cm²/V-sec	145	135	130
Resistivities, ohm/□ (calculated)	410	250	210
Resistivities, ohm/□ (measured)	440	280	200
Initial boron cnc Q cm⁻²	0.63×10^{15}	0.63×10^{15}	0.63×10^{15}
Remaining boron, cm⁻²	0.11×10^{15}	0.19×10^{15}	0.22×10^{15}
% Boron lost	83%	70%	65%
Segregation coefficient	9	9	9

[1] The boron diffusion constants plotted in Fig. 2 are in good agreement with the experimental result recently reported in a paper by Chan and Mai, *Proc. IEEE*, pp. 588-589, April, 1970.

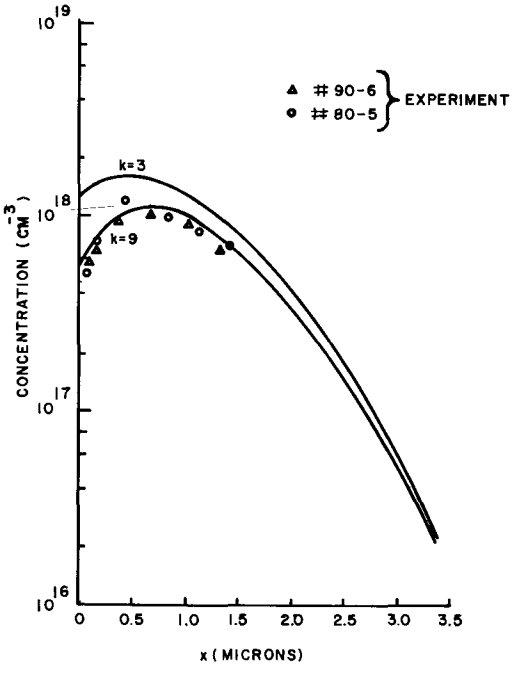

Fig. 4. Impurity profiles after oxidation in wet O_2 at 1200°C for 1 hr.

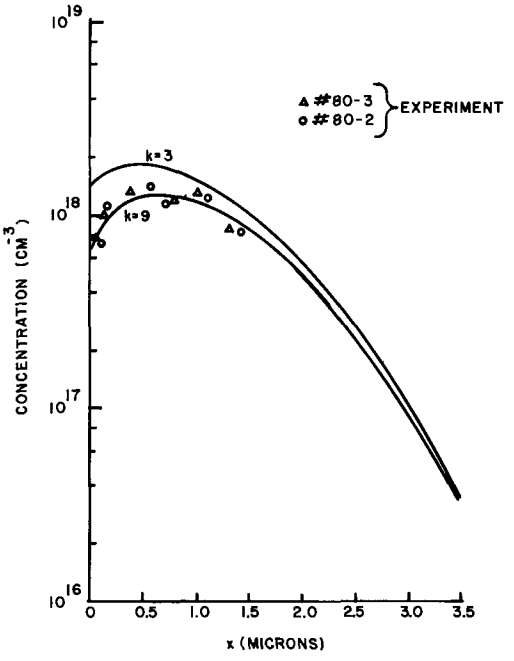

Fig. 5. Impurity profiles after oxidation in wet O_2 at 1250°C for ½ hr.

$k = 3$ and $k = 9$. The experimental results are also shown as points is these figures. It is seen that the experimental points fit quite well to the curves with $k = 9$. Thus it may be concluded that, for boron, the segregation coefficient is approximately 9 and is independent of oxidation temperatures and conditions. This value is in general agreement with the value of 10 found by Kato and Nishi (2) for dry oxidation conditions with diffused layers. It should be noted that had redistribution of boron in the oxide been ignored, the surface concentration as calculated from [3] would be about an order of magnitude higher than the actual surface concentration.

The total impurity atoms that remained in the silicon are calculated from [14]. The results are shown in Table I indicating that the amount of boron lost during oxidation is so large that it more than compensates for the increase of mobilities.

Discussion of Results

The scattering of experimental points is to be expected because errors arising from measurements of this type are unavoidable. Some deviations of the experimental result from the theoretical prediction can also be explained by uncertainties in diffusion and rate constants used in our calculations. It should be pointed out that there exist discrepancies in mobility values reported in the literature. However, in our work, uncertainties in mobility values are mitigated because they are measured by the MOS capacitance technique. Inspection of the results shown in Fig. 3 through 5 indicates generally good agreement between theory and experiment thus validating the diffusion model we proposed.

This model, together with Fig. 2, furthers the understanding and control of the redistribution process in p-type diffused layers. For example, at low temperatures the oxidation rate is higher than the diffusion rate resulting in large depletion of boron at the interface. Silicon surfaces with low boron concentrations are prone to inversion. For oxidation at 1250°C, faster diffusion and slower oxidation rates have brought about a decreased depletion of boron and less loss of total boron atoms even though the junction is deeper.

Technical Notes

High Resolution Print-Out of the Electronic Conductivity Distribution of Anodic Tantalum Oxide

Gerhart P. Klein*

P. R. Mallory & Co. Inc., Laboratory for Physical Science, Burlington, Massachusetts 01803

The distribution of the electronic conductivity (e.c.) of valve metal oxides and other thin film dielectrics is frequently nonuniform on a microscale. This may be due to impurities or flaws arising from many causes. Experimental results, *e.g.*, current-voltage characteristics, cannot be interpreted meaningfully unless the current distribution is known. In many instances it is desirable to identify the sources of e.c., especially when arising from heterogeneities on a microscale, such as grain boundaries, inclusions, *etc.*

This communication reports on some recent improvements in the resolution of the redox print-out technique which has been described elsewhere (1). Originally, the potassium iodide/starch printing gel was spread on the specimen while hot and filter paper was used as a backing material. The paper with a thin film of gel which contained the image of the e.c. distribution was lifted off the specimen after current had been passed through the oxide film. The coloration on the print provided a direct replica of the electronic charge that had been passed through the specimen. In this form, the print-out technique is particularly well suited for replicating relatively large areas.

In the study of oxide films, one is frequently interested in determining whether or not there is a direct correlation of the e.c. with microscopically visible surface features. In this case, the microdistribution of the e.c. might provide clues as to its source. In other cases, the interpretation of the electronic current-voltage characteristic of oxide electrodes may depend on whether the current is truly homogeneous on a microscale or whether it is in fact heterogeneous but only appears uniform due to high flaw density.

Experimental

To obtain high resolution, the printing experiments were performed under the microscope. This allowed one to observe, at the same time, the surface of the specimen and the passage of electronic charge as reflected in the coloration of the starch/potassium iodide gel electrolyte. The distribution of the e.c. could be followed as a function of time and voltage without the need to reapply the electrolyte as was required in the older technique if interval prints were desired.

In the micro redox print-out technique, the specimen was masked with tape and provided with a counter-electrode, as shown in Fig. 1. For masking, pressure-sensitive polyester tape with silicone adhesive was used. Pressure-sensitive aluminum tape served as the counterelectrode. Holes punched through both tapes exposed circular areas of the specimen. A drop of liquid printing gel was applied to the test area and a cover glass was pressed on the masking tape. A thin layer of printing gel was thus formed in the test area. The edge of the aluminum tape acted as the counter-electrode (negative). The specimen itself was connected to the positive terminal of a suitable power source.

The experiments were carried out by applying linearly increasing voltage to the specimen. In some cases, it was desirable to follow the change in e.c. with time at constant applied voltage.

A LEITZ Ortholux microscope was used with automatic Orthomat camera and an achromatic objective 32X/0.60 with a free working distance of 5.7 mm. A magnification of 100X on 35 mm film was obtained, before additional photographic magnification. Photographic reproduction of the prints in black and white posed serious problems since the substrate, when anodized, provided a colored background which reduced the contrast between it and the coloration of the printing gel in areas of current flow. Color prints or slides would be more satisfactory in this regard than black and white prints.

Results and Discussion

The following examples of microprints were obtained with tantalum foil. They have been selected to illustrate the capability of the micro print-out technique to resolve the electronic conductivity distribution on a micro scale, to correlate its distribution with structural features of the substrate, and to identify sources of leakage current after introducing defined heterogeneities in the anodic oxide film or subjecting the specimen to characteristic pretreatments.

Detection of impurities in substrate.—Tantalum foil in the "as-rolled" condition did not show grains either before or after chemical polishing. In the course of heating in vacuum (*e.g.*, 1 hr at 2100°C and 10^{-5} mm Hg), a grain structure was developed with the grain boundaries clearly delineated. Surface impurities were plentiful in the "as-rolled" condition; however, after the vacuum-annealing treatment, very few electronically active flaws remained.

The e.c. of flaws is often low which makes detection by the print-out technique difficult. Recently (2), it was shown that uniformly distributed e.c. could be developed in high-purity Ta_2O_5 after depositing thin layers of certain metal oxides, Fe_2O_3 and MnO_2

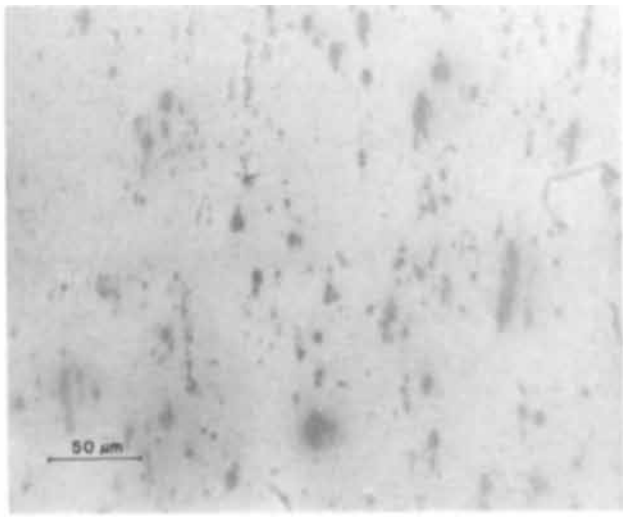

Fig. 3. Print-out of Ta/Ta_2O_5 specimen without special pretreatment.

among others, on the anodized substrate and reanodizing at a voltage close to the original anodization voltage of the oxide film. In addition, certain kinds of flaws in the oxide showed leakage at voltage levels below those at which uniform e.c. was found when such additional impurity oxide films were present. This method was employed in some of the examples shown here to enhance the e.c. of any flawed areas and thus increase the sensitivity and contrast of the micro print-out technique.

Figure 2 shows the print-out of Ta foil that was prepared as follows: Metallurgical grade Ta foil after chemical polishing and annealing in vacuum at 2100°C for 1 hr was oxidized for 5 min at 500°C in air, anodized at 100V for 1 hr, and sputtered with a 200A film of Fe_2O_3 (2). The print obtained at 90V shows randomly distributed leakage sites. The grain boundaries stand out because they are out of focus. At the grain boundaries, no electronic current was observed in any of the specimens studied. The density of electronically active sites in the specimen of Fig. 2 was of the order of $6 \times 10^4/cm^2$.

Chemical polishing and vacuum heating had removed many of the impurities of the rolled stock leaving a reasonably clean surface which did not show a sufficient density of leakage sites when evaluated by means of the print-out technique.

Thermal oxidation of tantalum in air was found to bring out sources of e.c. buried below the cleaner surface which were not in evidence after heating in vacuum. This is attributed to the preferential oxidation and diffusion of impurities to the surface. Thermal oxidation caused leakage sites to appear in a pattern typical for random contamination. The additional deposition of Fe_2O_3 served to amplify the intensity of the electronic current at such impurity sites.

The print-out shown in Fig. 3 was obtained with tantalum foil as used above, however without chemical polishing or vacuum heating. The surface was sufficiently contaminated to yield a high density of electronically active sites. In this case, additional thermal oxidation and Fe_2O_3 deposition would have increased their density beyond the limits of resolution and was thus omitted. The density of leakage sites was of the order of $5 \times 10^5/cm^2$ after anodization to 40V. Most conducting sites are unrelated to any surface features visible before or after anodization.

Anodic crystals.—In the print-out shown in Fig. 4, physical heterogeneities were generated deliberately in the anodic oxide by anodically crystallizing the

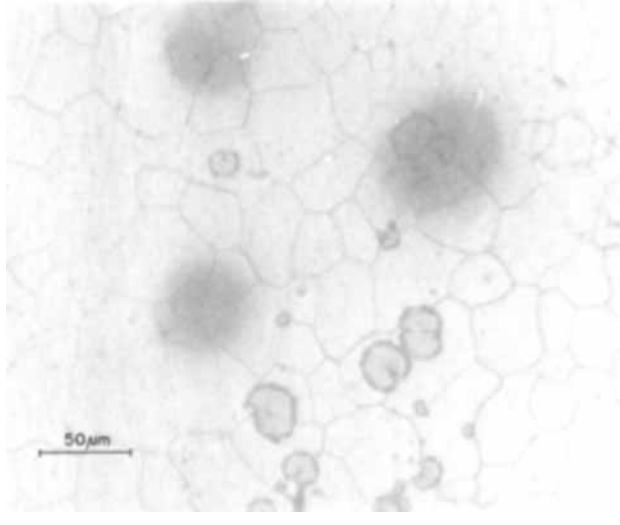

Fig. 4. Print-out of Ta/Ta_2O_5 specimen with "field" crystals

specimen (3) (no chemical polishing or vacuum heating) at 100V, 90°C, for 2 hr in 2% nitric acid solution. A print-out of the sample after crystallization revealed few sites with electronic conductivity within the sensitivity of the technique. After deposition of a 200A Fe_2O_3 film, the print shown in Fig. 4 was obtained at 90V. The striking feature of this print is that there seems to be some correlation between anodic crystals and electronic conductivity. Three dominant conducting sites happen to be on crystal sites; however, many more crystals show no e.c. at all at this voltage. In addition, the e.c. in the areas around the crystals is distributed over an area much larger than the crystals themselves. Observation of the growth of the spots revealed that they did not spread out from the crystals but intensified uniformly over the whole area. This, together with an observation of the over-all leakage pattern led to the conclusion that the three crystals located within the electronically conducting areas had to be associated with impurities in the substrate, while crystals by themselves did not exhibit any noticeable e.c. at the voltage applied in this print.

Tantalum carbide.—In the following example, chemically polished and vacuum-treated Ta foil was carburized by vapor deposition of a 1000A carbon film and subsequent heat treatment in vacuum at 1800°C for 30 min. After anodization at 80V, the interference

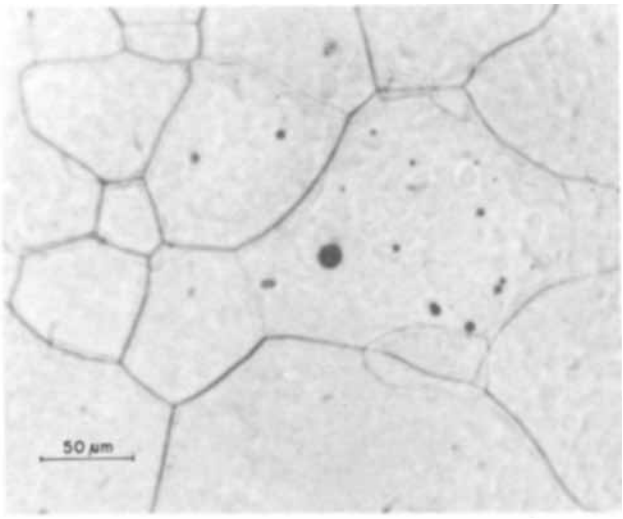

Fig. 5. Print-out of Ta/Ta_2O_5 specimen containing tantalum carbide.

color of the oxide film varied from grain to grain depending on the concentration of tantalum carbide crystals intersecting the surface of the grains. The large grain in the center of Fig. 5 showed the highest concentration of carbide. Under high magnification (1000X), individual flaws (4) could be identified by their color. Their density was estimated to exceed $10^8/cm^2$. The grains surrounding the one with the highest flaw concentration still contained fairly high concentrations of carbide flaws but the effect on the color of the anodic oxide was less visible.

The print-out after anodization to 80V (not shown) revealed only weak e.c. in isolated spots. After the deposition of a 200A film of sputtered Fe_2O_3, the print-out shown in Fig. 5 was obtained. A limited number of electronically active sites were found, being most numerous within the grain with the highest flaw density. However, their density was of the order of 10^4-$10^5/cm^2$ as compared to 10^8 for tantalum carbide flaws.

The examples given in Fig. 4 and 5 should caution one when trying to infer the cause of e.c. from the kind of pretreatment given to the specimen. Figure 4 shows that the e.c. is not associated with field crystallization even though the print shows leakage at some of the crystals. In the case of Fig. 5, the presence of tantalum carbide in high concentration did not lead to quasi homogeneous electronic leakage as one might expect considering the high concentration of carbide flaws present. Although e.c. was observed, its distribution did not correspond to the distribution and density of carbide flaws which was about four orders of magnitude higher than the density of leakage sites. Still the number of leakage sites tended to be highest in grains with the highest carbide concentration, but not consistently so. No attempt is made to resolve this apparent contradiction. It illustrates convincingly the need for high power resolution of the distribution of e.c. in all studies of the effects of impurities and flaws on the e.c. of anodic oxide films.

Sensitivity.—The maximum resolution of anodic micro prints was estimated to be of the order of 10^7-10^8 electronically conducting sites per square centimeter. This estimate is based on the analysis of prints such as the one shown in Fig. 3. Obviously, the resolution depends on the nature of the sources of e.c., their size, and distinctness. Additional processing of the photographic image using microdensitometric techniques could increase the resolution further.

The sensitivity of the print-out technique depends on the size and the intensity of the electronically active sites that can be detected at the limit of resolution. It was found that a charge density of 10 mcoulombs/cm^2 let to a pronounced coloration of the printing gel. Using this charge density, the electronic current was estimated for the spots in Fig. 2. With a printing time of 60 sec and an average spot diameter of 7 μm, the apparent geometric current density was 3.5×10^{-6} A/cm^2, and the current per electronically active site was of the order of 10^{-10} to 10^{-11}A. This should not be considered an absolute limit since smaller spots can still be resolved under favorable conditions.

Measurement of P-Etch Rates for Boron-Doped Glass Films

Ahmed H. El-Hoshy

General Electric Research and Development Center, Schenectady, New York 12301

Pliskin (1) has pointed out that glasses that are rich in either lead or boron have faster P-etch[1] rates than glasses with no lead or boron oxide in them. Earlier, he used the selective etching property of the P-etch to establish that oxygen is the diffusing species when silicon dioxide is grown thermally (2). Recently use has been made of pyrolytically deposited boron-doped glasses as a diffusion source in semiconductor processing (3). For a specific diffusion time and temperature, both the surface concentration and junction depth are determined by the glass composition. The boron-doped glasses are particularly useful in MOS processing where their properties match those of the thermally grown silicon dioxide, while providing additional insulation for subsequent metallization steps.

In the course of using boron-doped glass, two aspects requiring elucidation were found: (a) the need to monitor glass composition and (b) the necessity of providing a fast etch. Both spectrophotometry (4) and infrared absorption (5) have been used successfully to determine glass composition. The following experiment demonstrates that etch rate measurement can serve the same purpose. During the experiment P-etch rates were found to be much faster than those of buffered HF, thereby providing a basis for mixing fast etches for boron-doped glasses.

[1] 15 parts HF (49%), 10 parts HNO_3 (70%), and 300 parts H_2O.

Key words: P-etch rates, boron-doped glass films.

Experiment

One ohm-cm, P-type (100) silicon wafers are coated with boron-doped glass of variable composition at 300°C. The ratio of boron oxide to silicon dioxide is controlled by the ratio of diborane to silane in the main gas stream. The deposited glass thickness is a few thousand angstroms. Subsequent to glass deposition the wafers are fired in argon at ~1050°C for several minutes. Half the wafer is then masked by dipping it into molten glycol-phthalate. The glass is dissolved from the unmasked half. After removal of the glycol-phthalate, the sample is ready for etch rate measurement.

The height of the deposited glass is measured using a Sloan Dektak instrument. A series of immersions in P-etch, each followed by a measurement of the step height, is made for each sample. Figure 1 shows a set of such measurements. The accuracy of height measurement is better than 25Å.

Results and Discussions

Figure 2 shows the etch rate in Å per minute as a function of the molar fraction of diborane to diborane and silane in the reaction chamber. Spectrophotometric measurements indicate an increase of the molar fraction of B_2O_3 in the deposited glass from 14 to 34% with the increase in molar fraction of $B_2H_6/B_2H_6 + SiH_4$ from 15 to 42% (6). The etch rate is observed to increase markedly with diborane concentration; in particular, it seems to have an exponential dependence on the diborane molar concentration.

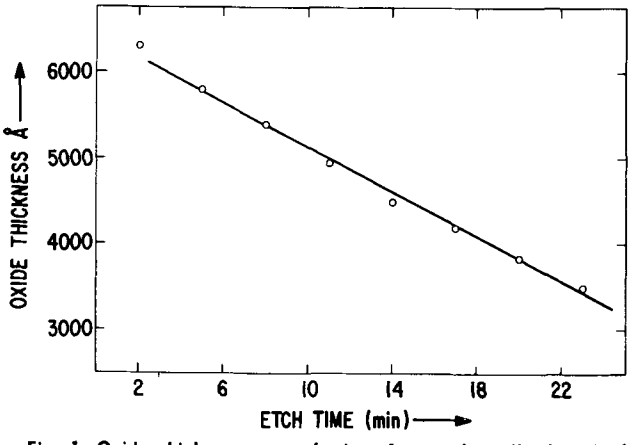

Fig. 1. Oxide thickness vs. etch time for pyrolytically deposited undoped glass.

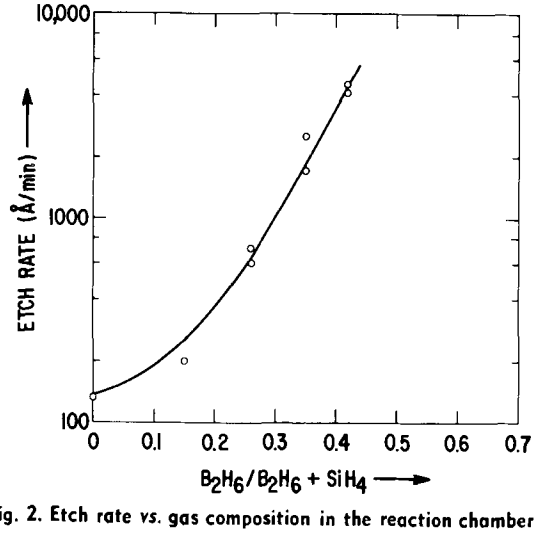

Fig. 2. Etch rate vs. gas composition in the reaction chamber

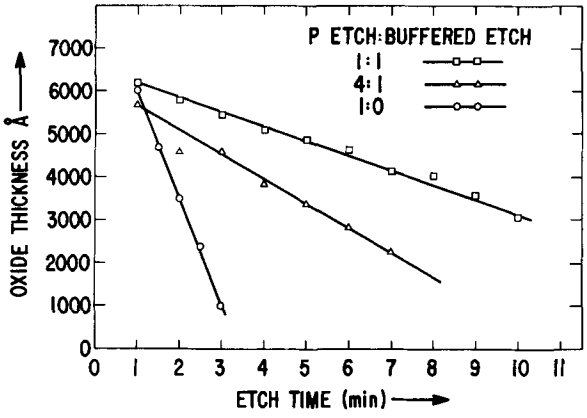

Fig. 3. Oxide thickness vs. etch time for three different etches $\left(\frac{B_2H_6}{B_2H_6 + SiH_4} = 0.35 \text{ for the glass}\right)$.

The increase in P-etch rate with boron content seems to indicate that the dissolution rate is limited by the amount of silicon dioxide present in the glass. This conclusion is further supported by measured dissolution rates of B_2O_3 in dilute HNO_3 solutions of about 10^4 Å/sec at room temperature (7). The reported decrease in buffered HF etch rates with boron content strongly suggests that the etch rate in this case is limited by the dissolution of B_2O_3 present in the glass. It is, therefore, possible to control the etch rate of boron-doped glasses by using an etch that varies in composition from 100% P-etch to 100% buffered HF. Figure 3 shows the effect of etch composition on etch rate.

Summary

P-etch rates can be used as a sensitive measure of boron concentration in pyrolytically deposited boron glasses. By mixing P-etch with buffered HF, fast etches are obtainable for boron glasses.

Brief Communication

Chemical Transport Epitaxy of Silicon by Organic Compounds

Y. Avigal and M. Schieber

Department of Physics, Hebrew University, Jerusalem, Israel

Epitaxial growth of silicon by chemical transport is performed mainly by the reaction: $SiCl_4 + 2H_2 = Si + 4HCl$ (1-3) which takes place at about 1200°C. Besides the high temperature (4) the process has the disadvantage of handling corrosive products.

More recent investigations use the pyrolytic decomposition of silane to deposit silicon: $SiH_4 = Si + 2H_2$. This reaction takes place at somewhat lower temperatures of about 1100°C but is considered to be hazardous due to the presence of H_2. It should be mentioned that both the hydrogenation of $SiCl_4$ and the decomposition of SiH_4 take place at relatively low temperatures of about 600°C while the epitaxial reaction occurs above 1100°C. Recent work has proved both theoretically (5) and experimentally (6) that absorption of hydrogen is responsible for the high temperature used for the epitaxial crystallization of silicon. So, for instance, in order to remove mechanically the adsorbed hydrogen, it was possible to obtain epitaxial (6) growth of silicon at temperatures below 1000°C. The present work describes an intrinsic way to avoid the presence of H_2 during the epitaxy of silicon. The following chemical reaction is used:

$$Si(CH_3)_4 = Si + \text{byproducts}$$

The first experiments were performed at relatively high temperatures of 1100°C because we used H_2 to clean the substrates. It is anticipated that etching with HCl (7) should lower the crystallization temperature below 1000°C because it would avoid the use of hydrogen in any stage of the epitaxial process.

Experimental Method

The apparatus used to prepare epitaxial films by the pyrolysis of the organic compound of silicon (shown in Fig. 1) consists of a source of pure hydrogen and a source of pure helium, a saturator, reaction chamber, and a radio frequency generator for external heating.

Key words: epitaxy, thin films of silicon, chemical transport deposition, MOS technology.

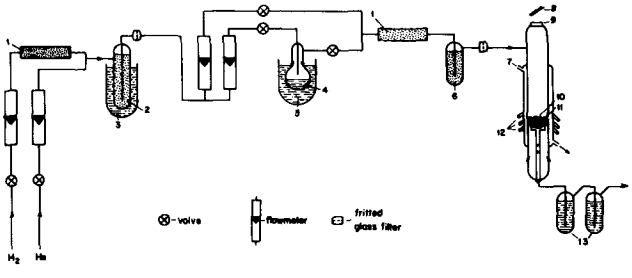

Fig. 1. Apparatus for the preparation of thin films of silicon by the pyrolysis of $Si(CH_3)_4$: 1—Palladium deoxo; 2—Linde molecular sieves; 3—liquid air trap; 4—$Si(CH_3)_4$; 5—cooling solution; 6—phosphor pentaoxide; 7—water sleeves; 8—mirror; 9—optical flat window for inspection; 10—substrate; 11—pedestal; 12—R.F. coil; 13—silicon oil traps.

The hydrogen and helium gases are purified by passing through a trap of "palladium deoxo" to remove oxygen. A trap of molecular sieves type-5A refrigerated with liquid air to remove water and another "palladium deoxo" purifier and a trap containing phosphorpentaoxide in order to remove any traces of water.

A mixture of hydrogen diluted with helium passes directly to the reaction chamber to etch the substrate. After etching, one part of the helium used as a gas carrier of the $Si(CH_3)_4$ is mixed with free flowing helium and introduced in the reaction chamber for epitaxy. The temperature of the saturator and the ratio between the two parts of the helium gives the desired mole fraction of $Si(CH_3)_4$ in the gas mixture. The pyrolytic reaction takes place in a water-cooled quartz tube. The substrate is supported in a graphite pedestal acting as a susceptor. The (111) mirror polished silicon substrate wafers are etched by 40% HF solution and then washed with deionized water and dried under an inert gas. Prior to film deposition the silicon wafer is etched in dry hydrogen at about 1300°C for half an hour after which the temperature is lowered to about 1100°C, and a mixture composed of $Si(CH_3)_4$ and He is introduced in the reactor. The parameters which control the deposition rate are temperature, $Si(CH_3)_4$/He molar ratio, flow rate, and time of reaction. A typical example for an epitaxial growth is: 1150°C, molar ratio, $Si(CH_3)_4/He = 0.05$ and 17 min during which a thickness of 7μ is obtained.

The film thickness was measured by polishing a 5° bevel on the coated surface of the wafer, stained with a mixture of $HF\text{-}HNO_3$ 100:1 which delineated the film region at the top of the bevel. The thickness is then determined by measuring the width of the film region under microscope and calculating the film thickness accordingly.

Monocrystalline films were grown in the temperature range of: 1100°-1300°C. At the upper part of this range of temperatures the film surfaces were of mirror perfection. Experiments using HCl etching to replace H_2 and heteroepitaxial growth on spinel and sapphire substrates and doping experiments with phosphine and borane in both homo- and heteroepitaxy are progressing and will be reported separately. The carbon contamination of thin films produced by this method is published elsewhere (8).

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 116, No. 7, July 1969, and Vol. 117, No. 4, 5, and 7, April, May, and July 1970.

Infrared Reflection Studies of the Oxidation of Copper and Iron

G. W. Poling (pp. 958-963, Vol. 116, No. 7)

Robert R. Rahn[1]: I have studied the oxidation of copper with a technique similar to that used by Poling, the main difference being the angles of incidence. Poling used 73° and I used near grazing incidence, 85°-90°. Poling's statement that "Infrared oxide band intensities were found to be directly proportional to film thickness over the range of about 0-5000Å" is not supported by his data for an oxide thickness greater than 1000Å. My data,[2] on Cu films oxidized at 145°C and an oxygen pressure of 175 Torr, show that the band intensity at 655 cm^{-1} (close to Poling's maximum at 640 cm^{-1}) is linear to about 1000Å, is maximum at about 2000Å, and then decreases. For incidence angles of 85° and 89°, calculations by Schwartz[3] indicate that there is an optimum oxide thickness for which this band intensity is a maximum. The apparent disagreement between Poling's statement and my observations may very well be due to the complicated and critical dependence of band intensity on the angles of incidence.

Poling does not mention the copper oxide, $CuO_{0.67}$, which is a defect structure of Cu_2O. At a temperature of 150°C and an oxygen pressure of 100 Torr, the defect oxide should be formed on the copper surface rather than Cu_2O.[4-6] Since some of Poling's samples were oxidized at 140°C in air, $CuO_{0.67}$ must have been present in those oxide films. I mention this defect oxide because many people are not aware of its existence. This does not change Poling's conclusions, because the defect structure and Cu_2O both have the same strong absorption band.

I would like to acknowledge the contribution to this work by Professor Robert Greenler. The work was supported by a research grant from the National Science Foundation.

G. W. Poling: R. Rahn's data on *IR* band intensity *vs.* copper oxide film thickness for incidence angles of 85°-90° cannot be compared directly with our data obtained using 73° incidence. It is to be expected that the range of "approximate" linearity between band intensity and film thickness will decrease as the incidence angle increases. We have many data indicating that at 73° incidence good linearity is observed up to film thicknesses of approximately 2500Å. Results of one experiment indicated that reasonable linearity extended up to about 5000Å film thickness. This latter result should certainly be checked.

There seems little doubt that, as Mr. Rahn pointed out, several of the oxide films that we studied would better have been described as $CuO_{0.67}$ and not Cu_2O. Although we referenced the paper of Wieder and Czanderna [Ref. (24) in subject paper] which initially reported the occurrence of $CuO_{0.67}$, we did not distinguish between Cu_2O and $CuO_{0.67}$ in our paper. Neither the infrared spectra, x-ray diffraction patterns, nor electron diffraction patterns that we observed could distinguish Cu_2O from $CuO_{0.67}$ since the latter is a defect structure of Cu_2O. Although our paper did not contribute data on film stoichiometry, we should nevertheless have mentioned this aspect and thank Mr. Rahn for his reminder.

Structure and Electrical Properties of $FeO-P_2O_5$ Glasses

D. L. Kinser (pp. 546-548, Vol. 117, No. 4)

Mary Splann Mizzoni[7]: In his study of an iron-phosphate glass system, Dr. Kinser has attributed the dielectric dispersions that he observed to a Maxwell-Wagner-Sillars heterogeneous loss mechanism. He was able to do this because he observed no dispersion in two specimens—one with no observable crystallites and one with large crystals. He presents his data as evidence that the dispersions cannot be attributed to an electron-hoping mechanism which Dr. K. W. Hansen and I had previously proposed in our paper[8] on the same glass system.

Dr. Kinser could not have come to his conclusions had he found dispersion peaks in his noncrystalline specimen and in his large-crystal specimen (Fig. 2 and 5 of his paper). Most likely, he would have found these peaks if he had subtracted the d-c conductivity from the total a-c conductivity. He claims that this is not necessary. However, an approximation of the total a-c conductivities of these two specimens indicates that the d-c conductivities are an appreciable part of these totals. Approximations were made, as Kinser reported no capacitance or dielectric constant data.

[8] K. W. Hansen and M. T. Splann, *This Journal*, 113, 895 (1966).

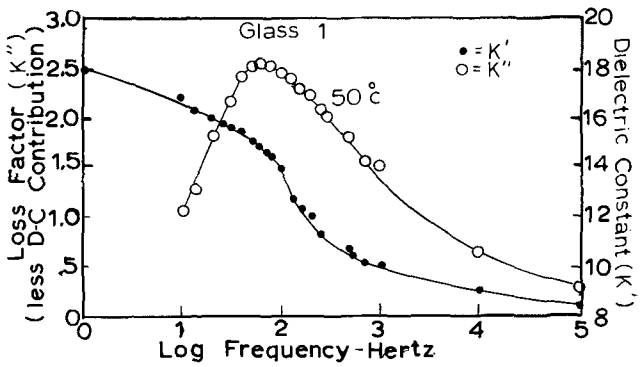

Fig. 1. Dielectric constant and loss factor (minus the d-c contributions) *vs.* the logarithm of frequency for Glass 1 at 50°C.

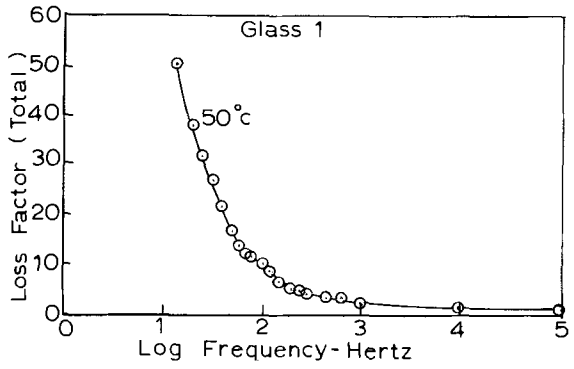

Fig. 2. Loss factor (total) vs. the logarithm of frequency for Glass 1 at 50°C.

To illustrate more exactly the effect of the d-c conductivity on the total a-c conductivity, I have plotted data presented in our paper and that same data *without* the d-c contributions removed, as shown in Fig. 1 and 2, respectively. It is readily seen that the d-c conductivity masks the dispersions in our data. There were no observable crystals in our glasses.

Kinser reports that the oxidation of the glassy matrix was altered by the formation of crystals, thereby changing the electrical properties. Without forming crystals, we obtained this change in oxidation of the glassy matrix, accompanied by changing electrical properties. It appears that *this* is the difference in our work, rather than an explanation for the conduction mechanism.

D. L. Kinser: The comments of Mrs. Mizzoni with reference to my possible conclusion as to Maxwell-Wagner-Sillars loss behavior in these glasses are quite true and they are appreciated. As a result of discussions with her, I have subtracted the d-c contributions from all the data reported. These calculations have not revealed any dielectric dispersions in any samples where none were observed in the $\tan\delta_{Total}$ observations.

Several of these calculations were made prior to publication, and these were taken to be representative of all these glasses because of the relatively small d-c conductivity changes upon thermal treatment. My original assertion that this calculation is unnecessary thus stands unmodified. No dielectric dispersion was observed in either $\tan\delta_{Total}$ or $\tan\delta_{a.c.}$ in the as cast or 1 hr at 600°C samples. From this I concluded that the mechanism of the loss is M-W-S in origin and not a result of electron hopping. To further substantiate this conclusion, I might add that an electron resonance—even of a partially bound electron—seems unlikely in the audio-frequency range.

Examination of Mrs. Mizzoni's uncorrected loss factor data (Fig. 2, Discussion Mizzoni) reveals a clear indication of the dispersion at about 100 Hz. This dispersion is clearer and obviously easier to handle after the calculation, but nonetheless it is evident without corrections. Most of my reported results are at higher temperatures and are considerably clearer without correction.

Analogous behavior with thermal treatment was observed by the author (Ref. (3), abstract only) in a Na_2O-V_2O_5-P_2O_5 glass, and this result is also cited as an independent argument that the loss is M-W-S in origin rather than electron resonance.

Recent continuation of this work by A. Dozier and myself to other $Fe^{3+}/Fe^{3+} + Fe^{2+}$ glasses has revealed analogous behavior in all compositions examined. This work is being prepared for publication at this time.

With reference to Mrs. Mizzoni's final comment regarding an explanation for the conduction mechanism, I had no intention of disputing the electron-hopping model for conduction in these systems. I did assert and now reaffirm that the dielectric dispersion which she observed can be attributed to a heterogenous loss mechanism rather than an electron resonance.

The Theory of Anomalous Diffusion in Solids Near Diffusant Saturation Concentrations: Example—Phosphorus in Silicon

P. E. Bakeman, Jr. and J. M. Borrego

(pp. 688-690, Vol. 117, No. 5)

D. Shaw[9]: Bakeman and Borrego have proposed a model, referred to here as the BB model, to explain the concentration dependence of the chemical diffusion coefficient of P in Si. The authors supported the validity of their model by fitting it to the radiotracer data of Tannenbaum.[10] There are however further consequences of the BB model which appear to make it untenable:

1. According to the BB model, D (in the notation of the model) is independent of P concentration, yet two values of D ($4{\cdot}8 \times 10^{-13}$ and $7{\cdot}4 \times 10^{-13}$ cm^2/sec) were required in order to fit Tannenbaum's results on two samples diffused under identical conditions. It is implicit in the BB model that at one temperature there should only be one value of D.

2. Tannenbaum's[10] radiotracer data are rather unsatisfactory because (*a*) It is not clear whether radiotracer concentrations were measured right up to the surface or whether a considerable extrapolation was involved (*e.g.* Fig. 7 of Tannenbaum's study);[10] (*b*) It is not known to what extent the neutron activation affected the P distribution; there is evidence that neutron irradiation can cause an enhanced penetration of an impurity;[11] (*c*) It is not known what effect the anneal (3 min at 1050°C) following the neutron activation had on the P distribution.

Maekawa's[12] experiments avoided these three difficulties and application of the Matano method of analysis[13] to the data in his Fig. 3 gives the variation of the chemical diffusion coefficient of P in Si with P concentration shown in Fig. 1. It is manifest that this variation cannot be explained by the BB model, which predicts a monotonic dependence of diffusion coefficient on concentration.

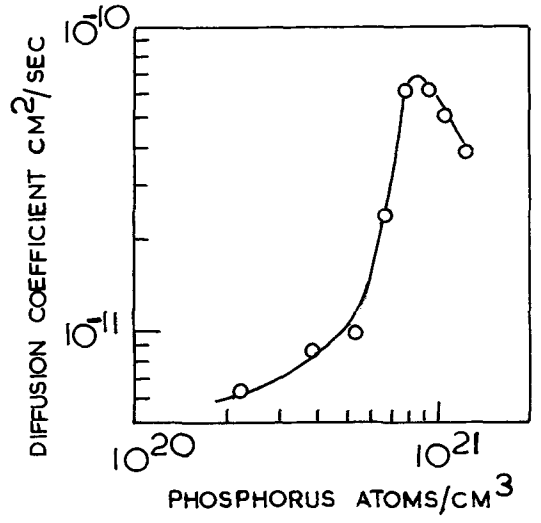

Fig. 1. The variation of the chemical diffusion coefficient of P in Si with P concentration at 1200°C from the data of Maekawa.[12]

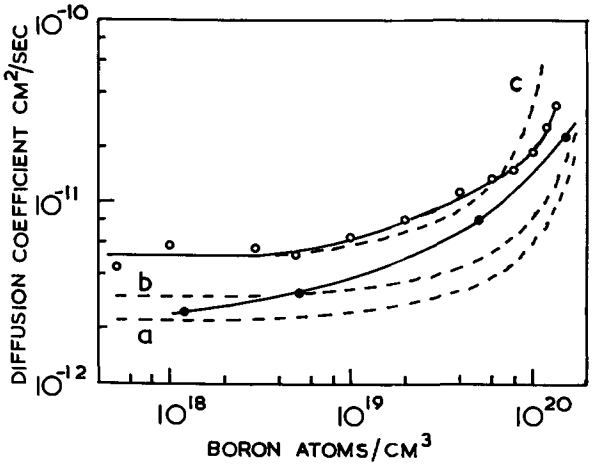

Fig. 2. The variation of the chemical diffusion coefficient of B in Si with B concentration. The solid lines represent the data of Vick and Whittle[14] (●) and Okamura[15] (○). The dashed curves show the variations according to the BB model with (a) $D = 2{\cdot}2 \times 10^{-12}$ cm²/sec, surface concentration $= 2{\cdot}2 \times 10^{20}$ cm^{-3}; (b) $D = 3 \times 10^{-12}$ cm²/sec, surface concentration $= 2{\cdot}2 \times 10^{20}$ cm^{-3}; (c) $D = 5 \times 10^{-12}$ cm²/sec, surface concentration $= 1{\cdot}35 \times 10^{20}$ cm^{-3}.

3. It is stated in the paper discussed that the results of Vick and Whittle[14] for B chemical diffusion in Si are also in accord with the BB model. In Fig. 2 an attempt has been made to fit the BB model to the data of Vick and Whittle[14] at 1150°C (their Fig. 4). In this case the surface concentration is well defined ($=2{\cdot}2 \times 10^{20}$ cm^{-3}). Okamura[15] has also studied B diffusion in Si and shows that the chemical diffusion coefficient of B varies as the square root of B concentration (his Fig. 8). Objection however can be made to his method of evaluating the concentration dependence of the diffusion coefficient which basically assumes that the diffusion coefficient is independent of concentration! Application of the Matano analysis[13] to the B distribution given by Okamura[15] in his Fig. 7 gives the dependence shown in Fig. 2. The surface concentration is again well defined at $1{\cdot}35 \times 10^{20}$ cm^{-3}, and an attempt to fit the BB model is shown. The best that can be said about the BB model and the chemical diffusion of B in Si is that it shows the same trend as the experimental data.

4. As propounded it would seem that the BB model should apply equally well to the radiotracer distribution in isoconcentration diffusion experiments whereas it is well known that in such experiments the radiotracer distribution is given by a complementary error function, *i.e.*, a constant diffusion coefficient.[16]

Although there is general agreement in the literature that in the chemical diffusion of P and B in Si the diffusion coefficient is concentration dependent, there seems to be a lack of agreement on the form of this dependence which obviously must be established before a proper theory can be advanced.

P. E. Bakeman, Jr. and **J. M. Borrego:** We thank Professor Shaw for his comments and will answer them in the same order as they are presented. It should be noted that the BB model is an attempt to incorporate impurity atom interaction into diffusion theory in a physical way. Other effects which undoubtedly also occur have been neglected, but we feel that the theory properly accounts for many of the anomalous high-concentration diffusion results presented in the literature.

1. In short high-concentration diffusions such as the phosphorus diffusions performed by Tannenbaum, the rate of impurity dissolution is extremely high. It is probable, therefore, that the density of vacancies in the host material is less than the equilibrium density characteristic of the host material at the diffusion temperature. This vacancy deficiency is expected to vary from run to run causing differing reductions in low-level diffusion constants throughout the crystal.

2. (*a*) Concentration *vs.* depth data is required to obtain the results presented in Tannenbaum's Fig. 9. As the samples were anodically sectioned in approximately 400Å layers, it is probable that the appropriate data were used.

(*b*) Koifman and Niyazova consider the case of exposing a silicon wafer coated with metallic gold to a neutron flux. The conclusion generated from their work cannot be generalized to cover the case in hand.

(*c*) Further, Tannenbaum indicates that the sheet resistivity of the samples was identical before irradiation and after annealing. Any change in the phosphorus profile would have lowered the sheet resistivity of the samples.

Maekawa's experiments do not show that Tannenbaum's results were incorrect. In fact, there is acceptable agreement between Maekawa's results as presented by Shaw, in his Fig. 1, and the BB theory for concentration of less than 8×10^{20} phosphorus atoms/cm³. It is quite possible that a second phase formed at concentrations higher than this.

3. As there are no radioactive isotopes of boron, impurity profiles of sufficient accuracy to determine concentration-dependent diffusion coefficients are not available.

4. The BB model does apply to the radiotracer distribution in isoconcentration diffusion experiments. The diffusion coefficient is concentration-dependent and given by

$$D' = D\frac{C_{max} + C(x)}{C_{max} - C(x)}$$

where $C(x)$ is the sum of radioactive and nonradioactive diffusant concentrations. As $C(x)$ is not a function of x, a complementary error function diffusion profile is expected.

Growth and Characterization of Lead Telluride Epitaxial Layers

John W. Wagner and Alan G. Thompson

(pp. 936-940, Vol. 117, No. 7)

A. J. Crocker and **D. C. L. Wiffen**[17]: Wagner and Thompson state that the solubility of Te in molten Pb

[17] Zenith Radio Research Corporation (U.K.) Ltd., Stanmore, Middlesex, England.

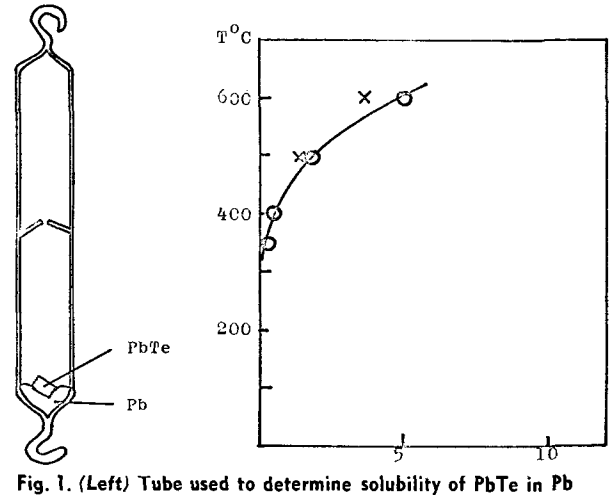

Fig. 1. *(Left)* Tube used to determine solubility of PbTe in Pb
Fig. 2. *(Right)* Liquidus curve of the Pb-Te system for low concentrations of Te. ○ = Crocker and Wiffen. X = Wagner and Thompson.

has not been reported in the more recent literature. We have investigated methods of fabricating diodes similar to those of Wagner and Thompson and thought it would be of interest to describe our method of determining this solubility.

A weighed cube of PbTe (6 mm edge, p-type $\sim 10^{18}$ cm^{-3}) was sealed in an evacuated tube (Fig. 1) together with a known weight ($\sim$10g) of Pb (99.99% pure). The Pb and PbTe were heated at various temperatures for 24 hr with occasional shaking. The tube was then inverted and shaken and kept inverted at the temperature in question for 30 min. The assembly was then cooled at $\sim$40°C/hr.

The contents of the tube were etched in a solution of H_2O_2/acetic acid. This solution rapidly dissolves Pb but has little or no effect on PbTe. The original PbTe source was reweighed after etching. From the change in weight of the lead telluride source and the original weight of Pb, the solubility of PbTe (*i.e.* Te) in Pb could be determined and is shown in Fig. 2. Good agreement with the data of Wagner and Thompson is found. Since a closed tube was used, there is no loss of Te such as that reported by Wagner and Thompson.

The solution grown crystals, grown from the highest temperature were cage and solid cubes together with some dendrites. As the starting temperature decreased the size of the crystals decreased and there was an increased tendency to form dendrites.

Catholyte Studies in Copper Oxide-Magnesium Thermal Cells

Lawrence H. Thaller*

Lewis Research Center, National Aeronautics and Space Administration, Cleveland, Ohio 44135

ABSTRACT

The present investigation concludes the study of the performance of copper oxide-magnesium thermal cells operating at 450°C. The objective of this present study was to investigate the cause of the 0.25V step drop in open-circuit voltage that occurred during the latter stages of discharge of these cells.

The investigation consisted of two parts:

(*A*) Cells were equipped with a reference electrode between the anode and cathode and discharged. These tests showed that the step drop in the open-circuit voltage was due to a sudden drop in the activity of the cuprous ion in the vicinity of the cathode. This two-order-of-magnitude drop in the cuprous ion activity was attributed to the formation of a complex. Other cells were discharged which had additions of either magnesium chloride or lithium oxide in the electrolyte. Additions of lithium oxide brought about the formation of this complex, and additions of magnesium chloride retarded the formation of this complex at the expense of a much higher rate of self-discharge. (*B*) Potentiometric titrations were performed to more fully investigate the stoichiometry of the complex. These titrations were performed in solutions of the lithium chloride-potassium chloride eutectic. When 1.5 moles of lithium oxide were added per mole of cuprous oxide, an end point in the titration occurred. The difference in electromotive force (emf) of a copper electrode placed in a saturated solution of cuprous oxide and one placed in a saturated solution of the cuprous complex was the same as the emf difference that occurred at the voltage step during discharge of complete cells. Additions of magnesium chloride to this solid complex returned the cuprous ion to solution by precipitating the oxide ion (as MgO) associated with the complex.

Based on these and our previous findings, a model is presented that explains essentially all the significant features of cell behavior during discharge. This model suggests that, during the initial stages of discharge, magnesium ions move to the catholyte, where they are precipitated as magnesium oxide. During the latter stages of discharge, lithium ion predominates in the charge neutralization process and creates conditions favorable for the formation of the cuprous complex. This lowers the open-circuit and operating voltages of these thermal cells.

A continuing program (1-4) at Lewis has been directed toward the investigation of a high-temperature primary cell having an operating time of several days at a temperature of 450°C. The anodes used are magnesium; the cathodes, mixed copper oxides; and the electrolyte, the eutectic mixture of lithium chloride and potassium chloride. One of the objectives of this program was to understand the over-all electrochemical and chemical reactions that take place during the discharge of these cells and how they are influenced by mass-transport processes.

In the first phase of these studies (1), the open-circuit voltage during the early stages of discharge of complete cells was shown to be the result of the following half-cell reactions:

$$Mg \rightarrow Mg^{+2} + 2e^- \qquad \text{at anode}$$

$$Cu^{+1} + e^- \rightarrow Cu \qquad \text{at cathode}$$

The cupric ion is chemically reduced to the cuprous state by reaction with copper according to the reaction

$$Cu^{+2} + Cu \rightarrow 2Cu^{+1}$$

In the second phase (2), methods of reducing the self-discharge rates of these cells were investigated. It was determined that the rate of transport of copper ions from the cathode to the anode controlled the over-all rate of self-discharge. In the third phase (3), the performance of two different cell designs was investigated as a function of the amount of electrolyte, discharge rate, and electrode geometry. One of the important findings of this study was that cell failure under the test conditions was probably due to freezing of the electrolyte. This must have been caused by a change in electrolyte composition during the course of the discharge; specifically, an increase in magnesium ion content.

This situation was investigated more completely in anode half-cell studies (4) employing electrolyte compositions which simulated different stages of discharge in actual cells. It was shown that under certain conditions of temperature, composition, and current density, the electrolyte adjacent to the anode (anolyte) partially froze next to the anode and thus caused extreme concentration and *IR* polarization.

One of the remaining unanswered questions in the study of this thermal cell was the origin of the 0.25V

* Electrochemical Society Active Member.

Key words: thermal cell, battery, molten salts.

drop in the open-circuit voltage that was observed at greater than about 45% depth of discharge of complete cells (1-3). It had already been shown (2) that, in the latter stages of discharge, lithium oxide was one of the products of reaction in the vicinity of the cathode. Also, a compound of unknown composition (compound X) was located in the region of the discharged cathode (catholyte) in cases which showed the 0.25V drop in open-circuit voltage. It was suggested that this unknown compound may be a complex species of lithium oxide and cuprous ion or cuprous oxide, which could explain the abrupt drop in the open-circuit voltage.

This present study was undertaken in order to explore this point in more detail. It consisted of two sets of experiments:

(*A*) A study of the anode and cathode polarization during the discharge of complete cells by means of a reference electrode.

(*B*) Potentiometric titrations to explore the complex ion chemistry of the electrolyte in the catholytes.

Materials

The electrolyte used was the eutectic mixture of lithium chloride and potassium chloride. This material, purified according to the modified Laitinen process (5), was ground to a suitable particle size (<3 mm). A nitrogen-filled (from liquid boiloff) drybox was used to store the materials and to carry out all the experimental procedures (weighing, mixing, heating, *etc.*). The cathode material was the wire form of cupric oxide (a mixture of cuprous and cupric oxide), and the anodes were primary magnesium. The chemical compositions of the materials used, determined by analytical techniques already described (1), are listed in Table I. In some of the experiments, reagent-grade, anhydrous powders of cuprous oxide, lithium oxide, and magnesium chloride were used. It was assumed that water in the cuprous oxide and magnesium chloride accounted for the discrepancy from 100.0%.

The reference electrodes (6) were of the disposable type. Silver wire (99.99% Ag) was immersed in a 0.13*M* (molal) silver chloride solution of the lithium chloride-potassium chloride eutectic. This mixture was contained in a glass melting point tube which acted as a membrane between the reference electrolyte and the cell electrolyte.

Procedure

Cell discharge studies.—Open-top vertical cells, shown in Fig. 1, were discharged in a small, electrically heated, temperature-controlled furnace located inside the drybox. The cells, with reference electrodes placed between the anode and cathode, were discharged for 2 hr in a regime programmed as follows:

(*a*) Fixed external resistance equal to R_1, 100 min
(*b*) Fixed external resistance equal to $R_1 + R_2$, 10 min
(*c*) No load, 10 min

Table I. Composition of materials[a]

Material	Content, w/o	Material	Content, w/o
Cuprous oxide:		Cupric oxide (wire form):

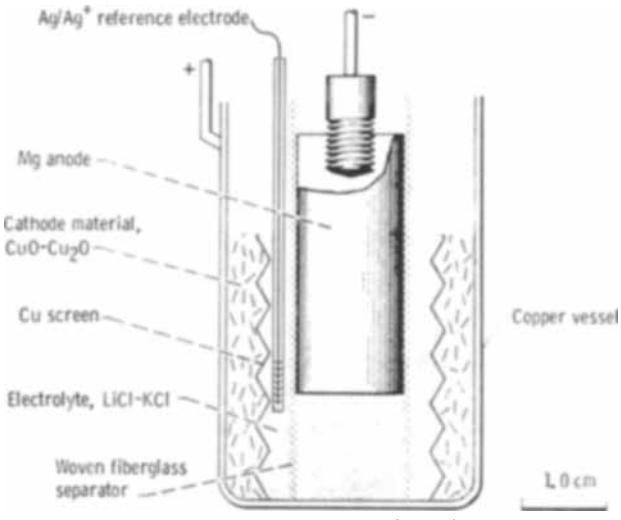

Fig. 1. Cell with reference electrode

This program was repeated as necessary until the cell voltage dropped to the arbitrary cutoff voltage of 0.5V. The voltage of the cell, as well as the current flowing through the discharge circuit, was recorded continuously. The details of the discharge circuit are described in Ref. (2). For the sake of this discussion, the term open-circuit voltage is defined as the cell voltage at the end of each 10-min no load period.

The cells were assembled for discharge with weighed amounts of anode and cathode material. The anode was covered with two layers of tightly woven glass fabric to reduce the possibility of internal short circuits. The cell, minus electrolyte and reference electrode, was placed in the furnace and allowed to preheat to 450°C. The desired amount of powdered electrolyte was added to the cell and melted. At this point, electrolyte additives (lithium oxide or magnesium chloride) were mixed with the molten electrolyte. After insertion of a reference electrode, the discharge was begun and was continued until the cell voltage dropped below the 0.5V cutoff point.

Potentiometric titration studies.—Figure 2 shows the details of the cell used for the potentiometric titrations. The copper vessel (identical to those used for the discharge studies) served as the indicator electrode (Cu/Cu^{+1}) and contained the mixture to be titrated. About 30g of the lithium chloride-potassium chloride eutectic was the solvent. After a weighed amount of the cuprous salt had been added to the solvent, the cell was placed inside the furnace (the same as used for the discharge studies) and allowed to equilibrate for ½ hr after melting. Either the saturated solutions of cuprous oxide with excess solid on the bottom of

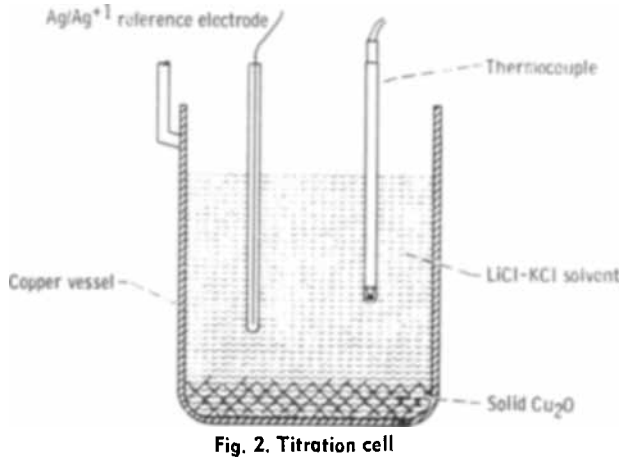

Fig. 2. Titration cell

the vessel or the unsaturated solutions of cuprous chloride were used as starting mixtures for the titrations.

After a silver/silver ion reference electrode was placed in the cell and the emf between the reference electrode and the coper electrode became constant within 2 mV, the titration was begun. Weighed additions of lithium oxide or magnesium chloride were made to the electrolyte, and the emf of the Cu/Cu^{+1} electrode was followed relative to the Ag/Ag^{+1} reference electrode. Between additions, ample time was allowed for the re-establishment of equilibrium conditions. Electromotive force was recorded continuously on a strip-chart recorder fed from a high-impedance ($>10^{14}$ ohms), battery-operated electrometer.

Results and Discussion

Cell discharge studies.—As pointed out in the introduction, previous studies indicated that the origin of the 0.25V drop in open-circuit voltage was the formation of a cuprous ion complex which would reduce the cuprous ion activity in the vicinity of the cathode. Further, it was indicated that lithium oxide was implicated in some way with the complex formation. For these reasons, cells were discharged that had a reference electrode placed between the anode and cathode so that individual electrode potentials could be obtained.

Figure 3 shows the open circuit voltages between the anode and the reference electrode and between the cathode and the reference electrode recorded during the discharge of a cell. Clearly evident is the 0.3V change in the emf of the cathode at about 70% depth of discharge. This change in the cathode potential, together with the gradual decline of 0.05V in the anode emf, leads to a net decrease in cell potential of about 0.25V at the step. Based on this information this potential drop is associated with decreased cuprous ion activity at the cathode.

The chemical analytical work described previously (2) had revealed that lithium oxide, as well as compound X, was present in large amounts in the catholyte during the latter stages of discharge. Based on these facts it was speculated that the lithium oxide was in some way responsible for the change in the cathode half-cell potential. To verify this hypothesis, another cell was discharged that had 1g of lithium oxide dissolved in the 20g of electrolyte prior to discharge. Figure 4 compares this discharge to the previous one in which no lithium oxide was added. Only the open-circuit anode-to-cathode voltages are plotted as a function of depth of discharge. The drop in open-circuit voltage of the cell with the added oxide occurred at a much smaller depth of discharge. These two cells differed only in electrolyte composition. They contained about the same amounts of active materials, were discharged through the same fixed external resistance, and delivered essentially the same number of ampere-hours of electricity. This amounted to about 95% of their theoretical capacity (based on the cathode) (see Table II). So, although the activity of the cuprous ion was reduced about two orders of magnitude, as evidenced by the change in open-circuit voltage, there was no decrease in the electrochemical accessibility of this complex form of the cuprous ion.

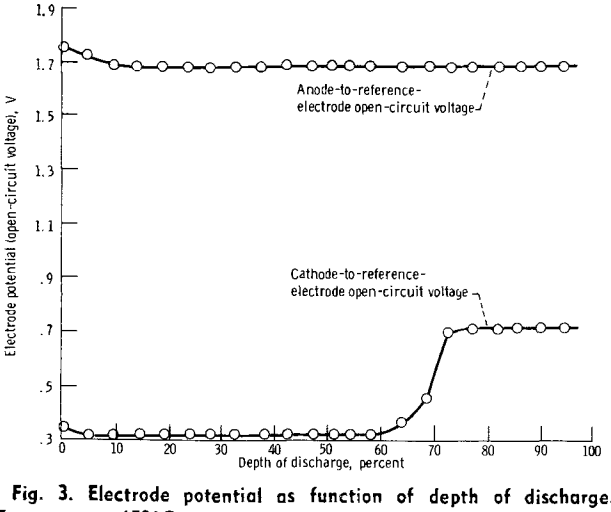

Fig. 3. Electrode potential as function of depth of discharge. Temperature, 450°C.

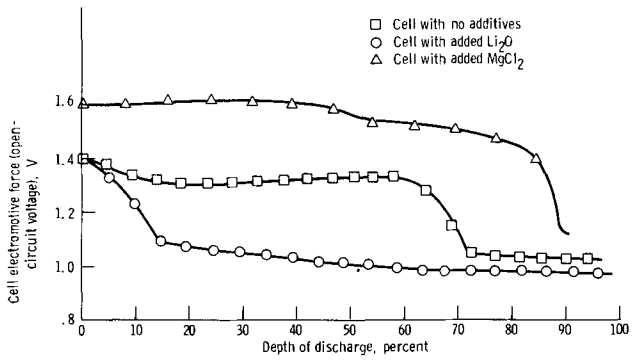

Fig. 4. Cell voltages (open-circuit voltage) as function of depth of discharge.

If the addition of lithium oxide accelerates the appearance of the step in the open-circuit voltage, the addition of magnesium chloride should have the opposite effect. This can occur because soluble magnesium ion should precipitate more of the oxide ion freed by the discharge of the copper oxides than the amount of magnesium ion diffusing over from the discharging anode. Also shown in Fig. 4 are the open-circuit voltages of a cell discharged with 3.7g of magnesium chloride dissolved in the electrolyte prior to discharge. It should be noted that the predicted behavior is observed; namely, that the step in the open-circuit voltage is delayed to the end of the discharge.

In connection with these results, it is important to compare several other aspects. In Table II, all the pertinent parameters are listed for the three cells. The two most important parameters to compare are (*a*) the step placement factor, χ, defined previously (3), which is the depth of discharge at which the voltage step occurs; and (*b*) the average rate of self-discharge. As the amount of soluble oxide in the cell is reduced, χ increases. However, the addition of the magnesium chloride leads to a 34-fold increase in the rate of self-discharge when compared with the cell that had no additives. This is caused by a shift in the copper oxide solubility equilibrium to favor dissolution as the soluble oxide ions are removed by precipitation. The resulting increase in concentration of copper ions leads to an increase in the rate of self-discharge.

Titration studies.—Although the cell discharge studies were fully adequate to detect the presence of the cuprous complex and identify lithium oxide as one of the constituents, there was no way of ascertaining the stoichiometry of the complex species. Potentiometric titration studies were undertaken to investigate this matter.

Table II. Cell operating parameters

Parameter	Cell 1	Cell 2	Cell 3
Weight, g:			
Mg anode (initial)	5.87	6.13	6.10
CuO-Cu_2O cathode (initial)	10.0	10.0	10.0
LiCl-KCl	19.0	19.0	19.0
Li_2O	0	1.0	0
$MgCl_2$	0	0	3.7
Cell life (to 0.5V), hr	42	42	22
Cell output (to 0.5V) A-hr	6.07	5.97	3.25
Average cell current, mA	145	142	148
Average self-discharge current, mA	3.1	15	102
Step placement factor, χ	0.68	0.10	0.87

In the titrations described in this section, the emf (relative to the Ag/Ag^{+1} reference) of the copper indicator electrode is plotted against what is referred to as the oxide ratio. The oxide ratio is defined as the moles of oxide that are either in solution or can be forced into solution (by shifts of equilibrium) for every 2 moles of cuprous ion. When the data are plotted in this manner, inflection points in the emf at certain oxide ratios will denote the composition at which a large change in cuprous ion activity has occurred. It is presumed that this corresponds to complex formation. It must be re-emphasized here that only the cuprous ion can be in equilibrium with metallic copper. Copper in any higher oxidation state is reduced by the metal to form cuprous ion (Cu^{+1}). Hence, only cuprous compounds were investigated.

Figure 5 shows a typical titration curve. The starting mixture was a saturated solution of cuprous oxide with excess solid on the bottom of the container. Slightly soluble cuprous oxide has an oxide ratio of 1.0 (1 mole $O^{=}$/2 moles Cu^{+1}) and this is the starting point of the titration curve at about 0.32V relative to the 0.13*M* silver-silver ion reference electrode. The circular data points represent the successive additions of lithium oxide. A very strong complex is formed at an oxide ratio of about 2.5; that is, 1.5 moles of lithium oxide and 1 mole of cuprous oxide are required for its formation. The extent of the emf shift from the solution saturated with cuprous oxide to that saturated with respect to the complex is about 0.3V, which is identical to the magnitude of the cathode potential shift in the cell discharge studies. This complex was a light-green solid material that was partially soluble in the melt. The squares in the figure represent back-titration data points using magnesium chloride, which is very soluble. It appears that the very low solubility of magnesium oxide shifts the complex formation equilibrium so that the complex is quantitatively dissociated. During the course of this back titration, one insoluble material (MgO) is being formed at the expense of another insoluble material (stoichiometric $Cu_2O \cdot 1.5\ Li_2O$). The exact composition of the cuprous complex has not been determined, but the preceding representation is convenient for the purposes of discussion. These reactions are summarized as follows: Complex formation:

$$Cu_2O_{(S)} + 1.5\,Li_2O \rightarrow Cu_2O \cdot 1.5\,Li_2O_{(S)}$$

Complex dissociation:

$$Cu_2O \cdot 1.5\,Li_2O_{(S)} + 1.5\,Mg^{+2} \rightarrow Cu_2O_{(S)} + 1.5\,MgO_{(S)} + 3\,Li^{+}$$

This evidence for complex formation was by no means unexpected considering the changes that took place in the cathode potentials during cell discharge, which have already been discussed. However, further studies of this cuprous complex did lead to some unexplainable results. Figure 6 shows another titration that started with excess cuprous oxide as before. Magnesium chloride was added first to force the cuprous ions into solution as magnesium oxide was precipitated; that is

$$Cu_2O_{(S)} + Mg^{+2} \rightarrow MgO_{(S)} + 2Cu^{+1}$$

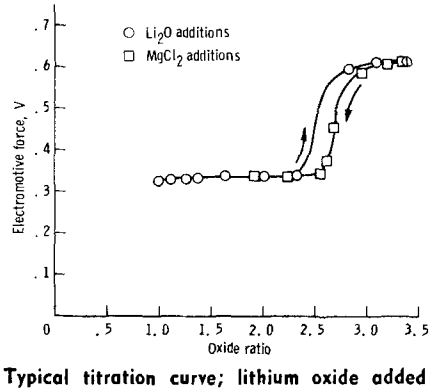

Fig. 5. Typical titration curve; lithium oxide added first, then magnesium chloride. Temperature, 450°C.

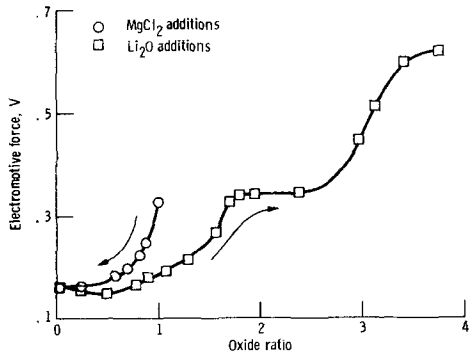

Fig. 6. Further titration study; magnesium chloride added first, then lithium oxide. Temperature, 450°C.

Note here that oxide in the form of magnesium oxide does not contribute to the oxide ratio since it is too insoluble. Enough magnesium chloride was added to reduce the oxide ratio from 1.0 to almost zero (0.012). Starting from this point, lithium oxide was added. The emf from an oxide ratio of about zero to 1.0 was not retraced, but two inflection points were obtained: one at an oxide ratio of about 1.5 and the other at about 3.0. A simple precipitation of cuprous ion $2Cu^{+1} + O^{=} \rightarrow Cu_2O_{(S)}$ would have resulted in an inflection point at an oxide ratio of 1.0. Clearly, cuprous ion does not precipitate as the oxide in a simple manner, but forms at least two different species as lithium oxide is added to the solution.

From the values of emf at an oxide ratio of 1.0 in the two titration curves, namely 0.18V (Fig. 6) and 0.32V (Fig. 5), it can be noted that the activity of cuprous ion is greater when lithium oxide is added to cuprous ion alone than when cuprous oxide itself is placed in the melt. This indicates that the solution process of cuprous ion is itself coupled with complex formation involving lithium ions from the melt.

In contrast to the differences noted at oxide ratio of 1.0, at ratios of 2.0 both titration curves show a rather constant emf of about 0.34V. Also, both titrations show the final formation of a complex that has an emf of about 0.62V.

This information on the complex forms of the cuprous ions may now be added to the information obtained from the discharge of complete cells to form a more accurate concept of the over-all chemical and electrochemical reactions that take place inside an operating thermal cell. Figure 7 depicts the over-all reactions as they are now understood. There are essentially two limiting cases, depending on whether the magnesium ion or the lithium ion carries the current (*i.e.*, has a transport number of 1.0). In actual cell operation, there will, of course, be a combination of these two processes, depending on such factors as the current drain and the depth of discharge. It is assumed here that the transport numbers of the chloride ion and oxide ion are zero. This is justified since no magnesium oxide was ever found in the anolytes of discharged cells (2). Although it is not proven that the transport number of the chloride ion is zero at all times, the point is irrelevant to the following argument.

First, the case where the transport number of the magnesium ion is 1 is discussed. For lack of evidence to the contrary, it is assumed that cupric oxide dissolves in a simple manner at the cathode. The cupric ion then oxidizes metallic copper to form cuprous ions which are electrochemically reduced. Meanwhile, in the anode compartment, a magnesium ion is generated and migrates to the catholyte where it precipitates the oxide ion liberated when the cupric oxide dissolved.

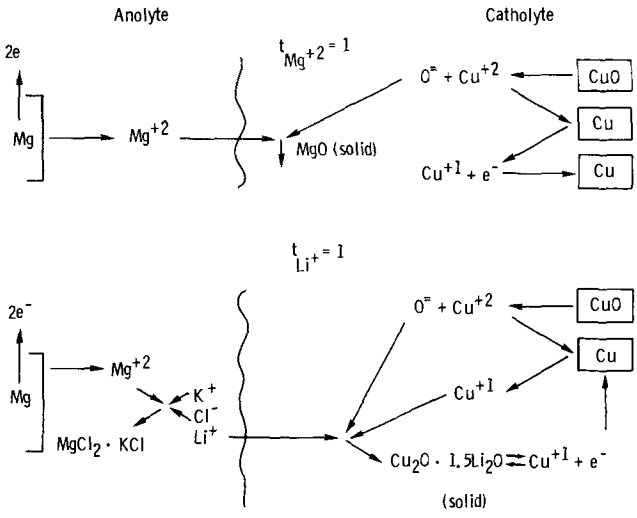

Fig. 7. Over-all reactions involved during cell discharge

This over-all situation would be characterized by a cell open-circuit voltage of 1.5-1.3V. The distribution of reaction products and cell emf agrees with that observed during the early stages of cell discharge (2). Since the data agree with the proposed model, the assumption that chloride ion plays little or no part in the charge neutralization process appears to be valid.

Later in the discharge, as it becomes more difficult for the magnesium ions to move through the layer of discharge products, the smaller lithium ion predominates in the charge neutralization process. As a consequence, a solid cuprous complex is formed in the catholyte. This results in a cell emf of 1.1-0.9V. It also results in a magnesium ion enrichment of the anolyte causing an increase in the melting point (4), which leads eventually to partial freezing of the electrolyte next to the discharging anode. Once again, the model is consistent with experimental facts and provides an explanation for the 0.25V drop in the open-circuit voltage of cells in the later stages of discharge and the sharp cutoff at the end of their service lives which occurs before all the active materials have been consumed.

Summary of Results

This is the conclusion of a program to evaluate the performance of copper oxide-magnesium thermal cells at 450°C. The present study was conducted to verify the presence of solid cuprous complexes in the vicinity of the cathode during the latter stages of discharge of complete cells and, further, to study these complexes using potentiometric titrations. The significant findings are as follows:

1. Cells that were discharged with a reference electrode placed between the anode and cathode revealed that the step drop in the open-circuit voltage during the latter stages of discharge was due to a change in the half-cell reaction at the cathode.
2. This change in half-cell reaction could be brought about earlier in the discharge by the addition of lithium oxide to the cell electrolyte.
3. This change in half-cell reaction could be made to occur later in the discharge by the addition of magnesium chloride to the cell electrolyte. This addition caused a very large increase in the rate of self-discharge of otherwise identical cells.
4. In the titration studies, the addition of 1.5 moles of lithium oxide per mole of cuprous oxide in a lithium chloride-potassium chloride solvent brought about the formation of an insoluble cuprous complex compound. The difference in electromotive force (emf) of a copper electrode placed in a saturated solution of cuprous oxide and one placed in a saturated solution of the cuprous complex was the same as the emf difference that occurred at the voltage step during the discharge of complete cells.
5. Cuprous ions that were precipitated by lithium oxide in the lithium chloride-potassium chloride solvent formed two different complexes, indicating that cuprous oxide does not dissolve in a simple manner.
6. Finally, based on this and our previous studies, a model is presented that explains essentially all the significant features of cell behavior during discharge.

Efficiency of Hydrazine-Peroxide Fuel Cells[1]

H. B. Urbach* and R. J. Bowen*

Naval Ship Research and Development Laboratory, Annapolis, Maryland 21402

ABSTRACT

Studies of the efficiency of single hydrazine-hydrogen-peroxide fuel cells were undertaken as part of a continuing program on electrode materials providing input data for hydrazine-peroxide-fuel-cell power. Experimental results for single fuel cells constructed of pressed platinum-Teflon electrodes indicate that oxygen-purge rates equivalent to 1-2 A/ft^2 are adequate. Most significant is the fact that coulombic efficiencies of both fuel and oxidant exhibit a broad maximum exceeding 88% between 60 and 100 A/ft^2. Thus, a minimum reactant weight-energy ratio appears to lie between these current density limits.

Hydrazine fuel cells may be a contender in some future applications of fuel-cell power. However, the precise evaluation of the hydrazine fuel cell relative to other cells requires a knowledge of their realizable experimental coulombic efficiencies which are hitherto unreported. Losses in efficiency result largely from the self-decomposition of the hydrazine, from cross diffusion of hydrazine and oxygen through the porous structure of the cell, and by purge of oxygen from the cell. A general procedure necessary for the determina-

Key words: fuel-cell efficiency, fuel-cell purge requirements, hydrazine anode, oxygen cathode, efficiency, coulombic.

tion of such inefficiencies is presented here based on laboratory studies employing a single 6- by 6-in. cell. Coulombic and power efficiencies as a function of purge rate, hydrazine concentration, oxygen pressure, load, total pressure, and temperature are reported in detail. The results will be useful in the engineering evaluation of hydrazine fuel-cell plants and systems. However, the specific assignment of numerical values of efficiency to other systems should be employed only with the knowledge that considerable variation exists not only between different systems but within individual systems.

Experimental Equipment and Procedure

Most of the studies of experimental efficiencies were performed at atmospheric pressure. Cells 6- by 6-in. square (232 cm^2) were employed in all studies. The anodes were commercially (American Cyanamid, Type AB-6) supplied electrodes prepared from pressed Teflon-platinum powders on gold-plated nickel screens with platinum loadings of 9 mg/cm^2. The cathodes were the same except that the platinum loadings were 40 mg/cm^2. The electrodes were separated by an electrolyte-saturated, 0.030 in. thick asbestos matrix. Expanded metal nickel screen was used as manifolding behind both electrodes. The anolyte consisting of 5M KOH and hydrazine was circulated behind the anode by a magnetically coupled polypropylene centrifugal pump. High-purity (Matheson "gold label" grade) oxygen was maintained at a 3 psi differential pressure relative to the electrolyte by a diaphragm regulator. The study is based on the anticipated decomposition of hydrogen peroxide into oxygen before feed to the cathode. Oxygen use was measured by a calibrated float-type flowmeter. Oxygen purge and anolyte gas-evolution rates were measured by wet test gas meters at room temperature and atmospheric pressure. Analyses of the gases were obtained by means of a Beckman oxygen analyzer and a Fisher-Hamilton gas partitioner.

To analyze losses resulting from pressurized operation, studies were performed using similar cells exposed to typical oxygen pressures and hydrazine concentrations. High ambient pressures were developed in a system described previously (1) employing high-pressure argon and oxygen compressed above cylinder pressure by diaphragm compressors. The cross-diffusion of oxygen and hydrazine through the 0.030 in. electrolyte matrix was measured as a function of oxygen pressure and hydrazine concentration by potentiostatic procedures referenced previously (1).

Polarization data were obtained by programming the current sweep of a 30 ampere Kordesch-Marko-type current interrupter and gate, and recording sequentially by means of a stepping switch the cell potential and cell potential corrected for ohmic losses. The hydrazine coulombic efficiencies calculated from gas-evolution data were verified by comparing the number of coulombs measured on a current integrator with the change in hydrazine concentration after a period of cell operation.

Experimental Results

The inefficiencies in the hydrazine-oxygen fuel cell are derived from self-decomposition of the fuel, from cross diffusion of the oxidant and fuel, and from purge of the oxidant. The experimental data on self-decomposition are illustrated in Fig. 1. The arrows associated with the experimental points indicate the rate of gas evolution during increasing or decreasing load (current density). Gas-evolution rates include both hydrogen and nitrogen evolution normalized to 1.0 ft^2 of electrode area. The dashed line showing increasing gas evolution with load represents the theoretical nitrogen evolution discussed below. The ascending solid line was constructed parallel to the theoretical line of nitrogen evolution in the manner which best approximates the experimental points. The descending solid

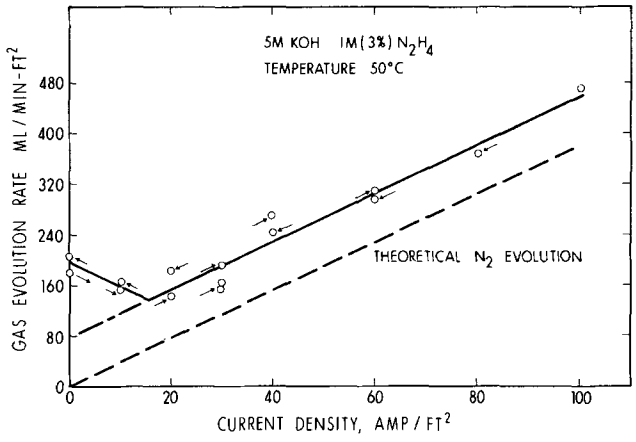

Fig. 1. Gas evolution at platinum-Teflon anodes exposed to hydrazine solution.

line, by construction a straight line which best fitted the points, approaches, at its junction with the ascending branch, a minimum at approximately 128 ml/min-ft^2, almost 67% of the open-circuit value of 200 ml/min-ft^2.

Figure 2 is a graph of experimental data for the cross diffusion of hydrazine from the anolyte through the anode and cell matrix to the cathode compartment where the hydrazine reacts with oxygen to form water and nitrogen. The cross diffusion is measured by analysis of the evolved gases rather than by electrochemical analyses (1). The diffusion is dependent on the applied load as well as the hydrazine concentration. The hydrazine loss is given in ml N_2/min-ft^2 and in the equivalent current density. Gas volumes are reported in the water-saturated condition at 25°C in all graphs and tables.

The most significant fact relative to efficiency is that the cross-diffusion losses of hydrazine decrease rapidly with increasing load. At low concentrations of hydrazine the ratio of cross-diffusion losses at open circuit and at load is much higher than the ratio at high concentrations of hydrazine. For example, at 1% hydrazine

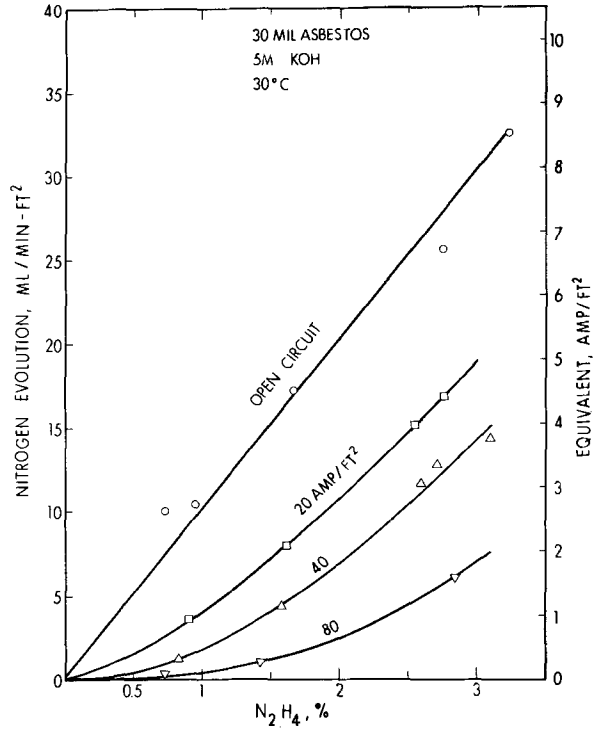

Fig. 2. Effect of hydrazine concentration on the nitrogen evolution rate (resulting from hydrazine diffusion) at the cathode.

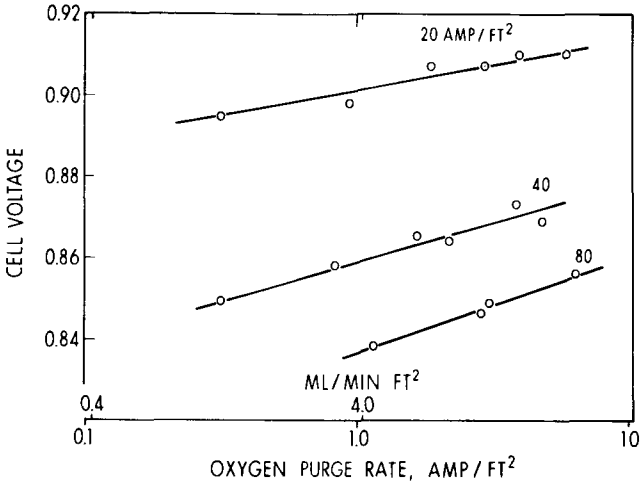

Fig. 3. Effect of load and oxygen purge rate on the output potential of a hydrazine-oxygen cell.

the ratio is approximately 20, whereas at 3% the ratio is approximately 4.5.

Figure 3 illustrates the effect of steady oxygen-purge rates on the cell potential at various loads. The cell potential is logarithmically dependent on the purge rate within the experimental limits of study. However, the logarithmic dependence is not uniform with current density, exhibiting increasing slope with the load. Thus, purge rates increase cell output most strongly at high loads.

Discussion

Self-decomposition losses.—Experimental gas-evolution data for hydrazine decomposition have been reported previously (2). It is possible to rationalize such experimental data if it is assumed that the mechanism of self-decomposition of hydrazine proceeds according to the following half-cell and over-all reactions:

$$N_2H_4 + 4\,OH^- \rightarrow N_2 + 4H_2O + 4e^- \quad [1]$$

$$4H_2O + 4e^- \rightarrow 2H_2 + 4\,OH^- \quad [2]$$

$$N_2H_4 \rightarrow 2H_2 + N_2 \quad [3]$$

Others have proposed electrochemical mechanisms (3-12).

Equation [1] for the anodic reaction is not reversible. Although reaction [2] is reversible, there is no hydrogen except that arising from the decomposition of hydrazine to produce the reverse of Eq. [2]. Polarization curves for the reactions of Eq. [1] and [2] may be approximated by dashed curves shown in Fig. 4. The open-circuit potential is of course a mixed potential, E_m, which occurs when the anodic and cathodic currents are equal in accordance with Eq. [4]. The superscripts (see glossary for meaning of symbols)

$$I_a^\circ = I_c^\circ \quad [4]$$

of Eq. [4] indicate the values of the anodic and cathodic current at the mixed potential. To assist in the analysis it is assumed that the polarization curves are linear and parallel.

The linear cathodic hydrogen line is drawn through the reversible hydrogen potential, 0.0V at vanishing current. The anodic line is constructed parallel to the cathodic hydrogen curve. These assumptions are quite crude as Fig. 4 shows, but the procedure is easily generalized to take into account the precise functional relationship between the half-cell currents and potential. The assumptions are justified if they facilitate analysis utilizing unsimplified experimental data.

The observed external current, I, is given by Eq. [5]

$$I = I_a - I_c \quad [5]$$

The relationship between the number of moles of nitrogen, hydrogen, and current is given by Faraday's

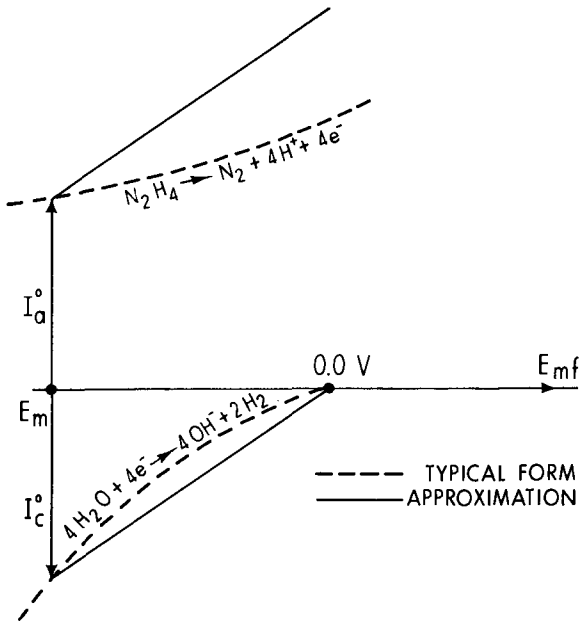

Fig. 4. Form of polarization curves for the half-cell reactions of Eq. [1] and [2].

law as written in Eq. [6] and [7], where K is (298/273) (22.4 x 60)/96.5

$$V_n = \frac{KI_a}{4} \quad [6]$$

$$V_h = \frac{KI_c}{2} \quad [7]$$

As the potential becomes anodic, the anodic and cathodic currents may be expressed in terms of the current at the mixed potential. By construction from Fig. 4

$$I_a \doteq I_a^\circ + \frac{I}{2} \quad [8]$$

$$I_c \doteq I_a^\circ - \frac{I}{2} \quad [9]$$

where the coefficient ½ arises from the assumption of parallel polarization curves. (Employing the actual unsimplified polarization curves, the coefficients of I in Eq. [8] and [9] would be r and $-(1-r)$ where $0 \leq r \leq 1$ and r is a function of I. Equations [8] and [9] would then be precise.) Employing either approximate or precise coefficients of I, Eq. [8] and [9] are consistent with Eq. [5].

Inserting Eq. [8] and [9] in Eq. [6] and [7] yields

$$V_n = V_n^\circ + \frac{KI}{8}; \quad I \leq \frac{8V_n^\circ}{K} \quad [10]$$

$$V_h = 2V_n^\circ - \frac{KI}{4}; \quad I \leq \frac{4V_h^\circ}{K} \quad [11]$$

When $I > 8V_n^\circ/K$, I_c vanishes. The total gas evolution is given by the sum of Eq. [10] and [11].

$$V_t = 3V_n^\circ - \frac{KI}{8}; \quad I < \frac{8V_n^\circ}{K} \quad [12]$$

$$V_t = \frac{KI}{4}; \quad I > \frac{8V_n^\circ}{K} \quad [13]$$

Equations [12] and [13] yield the theoretical gas evolution. They predict a minimum gas evolution obtained by equating [12] and [13] whence

$$2V_n^\circ = \frac{KI}{4} \quad [14]$$

which states that the minimum gas evolution is 2/3 its value at open circuit.

Thus, Eq. [12], [13], and [14] predict a gas-evolution-current curve with a descending branch, an ascending branch which has the theoretical faradaic slope, and a minimum which is 67% of the open-circuit gas evolution. These predictions are in agreement with the data of Daniel'-Bek and Vivitskaya (2). Likewise, they are in agreement with the data of this study (Fig. 1). The slope of the ascending branch is in agreement with the theoretical value of $KI/4$ in conformity with Faraday's law.

An area of divergence between theory and experimental result exists in the fact that the extrapolated ascending branch of the curve does not pass through the origin. This result suggests that some self-decomposition takes place on metallic or catalytic surfaces which cannot accommodate electrochemical discharge of the evolved hydrogen. This self-decomposition is independent of the current passed through the external circuit. The amount of the self-decomposition can be calculated from the deviation of the actual experimental curve from the theoretical curve in Eq. [13].

The approximate procedure described here suggests that precise measurement of gas evolution from hydrazine cells may be used to define the true anodic hydrazine polarization curves.

Cross-diffusion losses.—The results of Fig. 2 obtained by analysis of purged gases may be compared with previous studies of cross diffusion (1) obtained by a potentiostatic analysis of hydrazine under open-circuit conditions. The potentiostatic data, interpolated to 30°C, yield an equivalent cross-diffusion loss of approximately 9.5 A/ft² in good agreement with the value of 8 A/ft² obtained from Fig. 2 (at 3% hydrazine) considering the differences in the experimental conditions.

The significant features of the data in Fig. 2 (namely, that losses arising from cross diffusion decrease with load) arise from the fact that under load part of the available hydrazine is anodically consumed. Most interesting is the fact that the cross-diffusion loss at lower concentrations of hydrazine is significantly less than half the loss at higher concentrations. In particular, for example, at 80A loads, the loss at 2% hydrazine is only 35% of the loss at 3%.

The possibility that cross diffusion of oxygen decreases with load is suggested by these results.

Purge losses.—The data of Fig. 3 represent not only purge losses but cross diffusion of hydrazine. The nitrogen which is observed in the purged oxygen was originally part of the hydrazine which was transported by diffusion from the anolyte flowing past the back side of the anode through the asbestos separator. Convection plays a negative role in the transport of this hydrazine because the pressure gradient in the cell is normally against the direction of hydrazine flow.

The logarithmic dependence of the cell potential on oxygen-purge rate suggests that the cathode potential is exhibiting a Nernst-like response to the oxygen concentration which therefore should be linearly related to the purge rate. While logarithmic proportionality may exist, the slopes of the curves do not correspond to expected values for typical Nernst behavior. In addition, the slopes change with current density, indicating more complex relationships.

Hydrazine fuel requirements.—A formulation of fuel and oxidant requirements is simply stated if it is assumed that there are only four significant elements of fuel-cell inefficiency: the diffusion of hydrazine to the cathode, D_h; the diffusion of oxygen to the anode, D_o; the purge of oxygen from the cathode space, P; and the decomposition of hydrazine, S. The weight per kilowatt-hour of hydrazine, W_h, in terms of the weight per kiloampere-hr, M_h (0.663 lb/kA-hr for pure hydrazine), is

$$W_h = \frac{M_h}{E}\left(\frac{I + D_h + D_o + S}{I}\right) \qquad [15]$$

Table I. Fuel requirements

where E is the cell potential. The oxygen-purge term does not enter into the expression for fuel requirements.

Table I is a compilation of raw laboratory and derived data used in subsequent calculations and figures. Losses have been expressed in amperes per square foot for consistency. The loss due to diffusion of oxygen, D_o (see column 3 which contains the sum of D_o and S), is obtained from Fig. 5 which is reproduced from Ref. (1). The value of D_o is negligible at atmospheric pressure. The value of the self-decomposition term, S, is 6.5 A/ft² and is derived from Fig. 1 in accordance with the discussion above. The average values for the cross diffusion of hydrazine, D_h (namely, 5.7, 3.7, and 3.8 A/ft² corresponding to the 20, 40, and 80 ASF level), were obtained experimentally and deviate from the values 7.8, 5.5, and 2.6 obtained from Fig. 2 and corrected for temperature. The results of Fig. 2 represent a separate independent study at 30°C. The disparities result from aging processes and from difficulties associated with maintaining constant oxygen-purge, hydrazine diffusion rates, and differential pressures in a dynamic system. The results of Fig. 2 exhibit a larger fall-off in the cross-diffusion rate as load increases than is apparent from column 2 of Table I. In fact, according to Table I, the average cross diffusion, D_h is slightly higher at 80 than at 40 A/ft². Figure 2 indicates that such behavior is anomalous. The data of Table I represent measurements over a period of several hours in contrast with the data of Fig. 2. Thus,

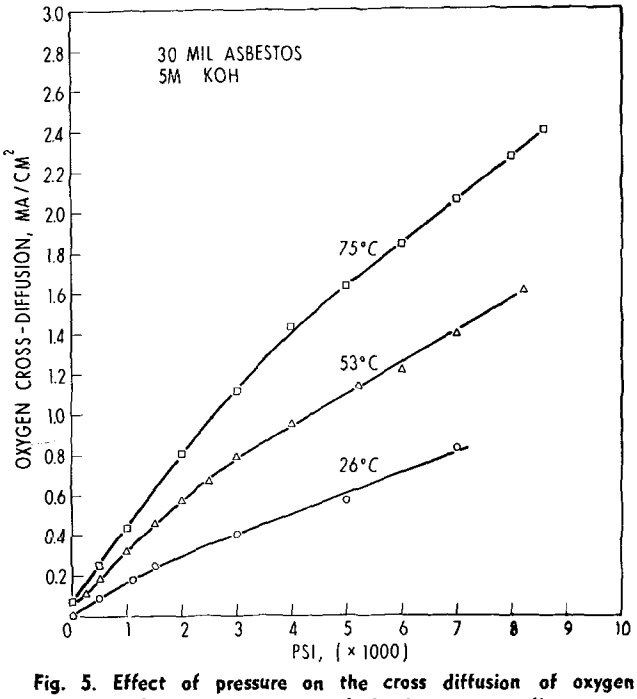

Fig. 5. Effect of pressure on the cross diffusion of oxygen through an asbestos separator in a hydrazine-oxygen cell.

they may represent changes in the nitrogen bubble content of the asbestos matrix and changes in the differential pressure between anode and cathode spaces which modify the diffusion processes by superposition of convective flow patterns.

In the following analysis, the values of hydrazine diffusion, D_h, employed in subsequent calculations are those listed in Table I. The inconsistency described in the previous paragraph colors the results of the following analyses to the extent of +4% to +2% in the most discrepant cases. The discrepancy is on the conservative side in the most likely operating ranges.

Columns 6 and 7, the hydrazine fuel requirement calculated by use of Eq. [15], are plotted as a function of the purge rates (column 8) in Fig. 6. The immediate conclusion to be drawn is that the oxygen-purge rate within the range of 1-5 A/ft² does not change the fuel requirement by more than 1.5% and is therefore not the most significant factor in hydrazine fuel requirements.

Peroxide requirements.—A formulation of peroxide requirements is given in Eq. [16] based on an anticipated 100% conversion of peroxide to oxygen. The weight per kilowatt-hour of peroxide, W_o, in terms of the weight of peroxide required per kiloampere-hour, M_o (1.398 lb/kA-hr for 100% peroxide), is

$$W_o = \frac{M_o}{E}\left(\frac{I + D_o + D_h + P}{I}\right) \qquad [16]$$

The self-decomposition term, S, in Eq. [15] is replaced by the oxygen-purge rate, P, in Eq. [16]. The value of D_o is again negligible at atmospheric pressure. The values of D_h and P are taken directly from the measured raw data of Fig. 3. See Table II for a compilation of the input raw data and calculated values of weights per kilowatt-hour. The required weights are plotted against purge rate in Fig. 7. The significant fact again is that, at current densities where operation is likely because of high efficiency, purge rates between 1 and 4 A/ft² have negligible effect.

Fuel-oxidant requirements.—Figure 8 indicates that fuel-oxidant requirements per kilowatt-hour (derived from Fig. 6 and 7 and listed in Table III) exhibit broad minima with respect to oxygen-purge rate. The significant conclusion, as before, is that the oxygen-purge rate is not a significant factor at operating current densities such as 40 A/ft² or greater which would be desirable for reasonable coulombic efficiency.

Figure 9 represents the specific fuel-oxidant requirements per kilowatt-hour under varying load as determined by Fig. 8. The effect of purge rate is again seen to be small compared to the effect of load. In contrast with behavior observed in hydrogen-oxygen fuel cells, the fuel-oxidant weight-energy ratio decreases with load to approximately 80 A/ft². The specific fuel-oxidant requirements probably increase above 80 A/ft² where life characteristics of hydrazine fuel cells represent an uncertain area. Assuming acceptable life characteristics, a minimum reactant weight-to-energy ratio appears to occur between 60 and 100 A/ft².

Table II. Peroxide requirements

Coulombic efficiencies.—Figure 10 shows that the coulombic efficiency of the peroxide (oxygen) cathode is a function of purge rate. On the other hand, Fig. 11 shows that the coulombic efficiency of the hydrazine anode is independent of oxygen-purge rate over the range studied. Figures 12 and 13 show again that load rather than purge is the significant over-all factor in coulombic efficiency as in the weight-energy ratio.

Summary

The coulombic efficiency and material requirements per energy unit of a hydrazine-peroxide single cell

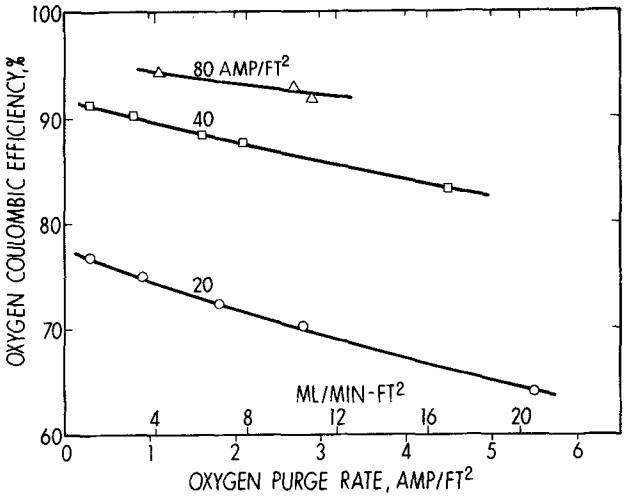

Fig. 10. Effect of oxygen purge rate on the coulombic peroxide (oxygen) efficiency.

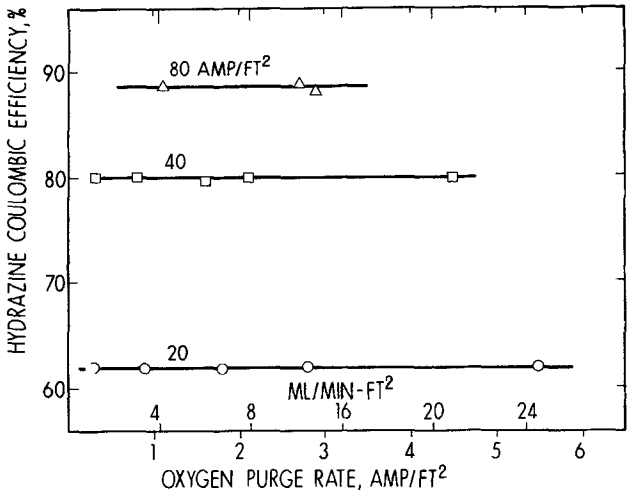

Fig. 11. Effect of oxygen purge rate on the coulombic hydrazine efficiency.

were studied. Electrodes were a commercially supplied variety prepared from pressed platinum and Teflon powders in 6- by 6-in. squares. Analysis of the gas evolution at hydrazine anodes indicates that at high load the self-decomposition losses of hydrazine may be negligible. Cross diffusion of hydrazine (and possibly oxygen) decreases rapidly with load. Increased oxy-

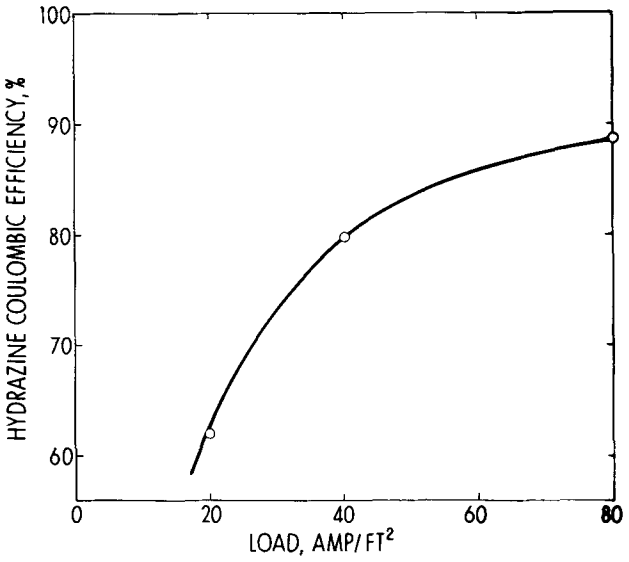

Fig. 13. Effect of loading on the coulombic hydrazine efficiency

gen-purge rates increase the cell potential most strongly at high load.

Hydrazine requirements decrease only slightly with oxygen-purge rate. On the other hand, peroxide requirements increase with purge rate although at high loads the increase is small. Combined fuel-oxidant requirements per energy unit show broad minima with respect to oxygen-purge rate. Moreover, at high current densities where operation is most efficient, the fuel-oxidant requirements are essentially independent of purge rate. However, they are strongly dependent on load. Minimum reactant weight-energy ratios and maximum coulombic efficiency may occur between 60 and 100 A/ft^2.

The results are peculiar to the particular system studied. In any systems analysis, numerical assignment of efficiencies should be based on experimental evaluation of the fuel-cell modules actually contemplated for application.

The results suggest that hydrazine-peroxide fuel cells of the type studied should be operated at current densities of the order of 60 and 100 A/ft^2 to achieve minimum reactant weight-energy ratios.

Acknowledgments

This work is part of a program of exploratory development sponsored by the Naval Ship Systems Command under the management of Bernard B. Rosenbaum and the technical cognizance of Ronald R. Nilson of the Naval Ship Engineering Center. The authors are pleased to acknowledge the support and encouragement of their supervisor, John H. Harrison.

GLOSSARY OF SYMBOLS

D_h	Diffusion loss of hydrazine in amperes per square foot
D_o	Diffusion loss of oxygen in amperes per square foot
E	Cell potential in volts
I	Current density in amperes per square foot
I_a	Current density for the anodic reaction
I_c	Current density for the cathodic reaction
I^o	Current density at the mixed potential
K	A constant
M	Mass requirements per kiloampere-hour
M_h	Weight of pure hydrazine per kiloampere-hour
M_o	Weight of pure peroxide per kilowatt-hour
P	Purge loss of oxygen in amperes per square foot
S	Self-decomposition loss of hydrazine
r	The fraction of the external current which produces a change in the anodic current
V_h	Volume of hydrogen in milliliters produced per minute per square foot
V_n	Volume of nitrogen in milliliters produced per minute per square foot
V_t	Volume of all gases in milliliters produced per minute per square foot
V^o	Volume of gas produced at the mixed potential at open circuit
W_h	Weight of hydrazine per kilowatt-hour
W_o	Weight of peroxide per kilowatt-hour

Electrochemical Characteristics of Armco Iron in Acidic Solutions Containing Benzoic Acid—Effect of pH and Chloride Ions

D. L. Piron* and Ken Nobe**

School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The effect of chloride ions and solution pH on the electrochemical behavior of Armco iron in sulfuric acid in the absence and presence of benzoic acid has been investigated. The corrosion rate of inhibited and uninhibited iron decreased with increase in solution pH. The capacitance increased linearly with immersion time although the corrosion rate remained essentially constant. The slope of the capacitance-immersion time curve was less for inhibited than for uninhibited iron and decreased with increase in solution pH. A minimum in the corrosion rate was observed for inhibited and uninhibited iron in pH 0.3 solutions containing 0.01M NaCl. This minimum was not observed for solutions of pH 1.0 and 1.7.

This paper reports on the effects of benzoic acid and chloride ions on the electrochemical behavior of Armco iron in acidic sulfate solutions at various pH values. Workers in this laboratory have previously investigated the electrochemical behavior of Armco iron in 1*N* H_2SO_4 containing ring-substituted anilines (1) and benzoic acids (2).

Experimental

The electrodes of Armco iron were cut from a ½ in. diameter rod and a thin layer of the cylindrical surface was milled off on a lathe to remove the scale. Electrodes were degreased with benzene in a soxlet extraction apparatus for 3 hr and finally vacuum annealed at 900°C for 1 hr and cooled slowly to room temperature in about 7 hr while still under vacuum.

The electrochemical cells and the electrode assembly have been described previously (3). All solutions were prepared from 1*N* H_2SO_4 and the pH was adjusted by addition of a concentrated NaOH solution. For solutions containing the inhibitor, benzoic acid, the concentration of the organic compound was maintained at 0.02M. The specific concentrations of chloride ions were obtained by addition of sodium chloride in the desired amounts to the solution. Sodium chloride concentrations of 0.01, 0.02, 0.1, and 0.2M were used in this study. All solutions were deaerated with the prepurified nitrogen for at least 3 hr before insertion of the electrodes. The electrodes were activated in 5*N* H_2SO_4 for 10 min immediately before immersion in the electrolyte. All experiments were performed at room temperature.

Five second current pulses, which were sufficient to reach steady state, were utilized for cathodic polarization. The corrosion current was determined by extrapolation of the cathodic Tafel line to the corrosion potential. The differential capacitance was determined by the d-c pulse method.

Results

The corrosion potential of inhibited iron in the absence of chloride ions shifted to slightly more noble potential indicating a greater effect of the benzoic acid on the anodic dissolution reaction than on the cathodic process, the hydrogen evolution reaction [see Ref. (4)]. With the exception of pH 1.7 solutions, the corrosion potential of iron was not appreciably affected by chloride ions. In pH 1.7 solutions, there was a small but consistent shift in the corrosion potential in the noble direction with increase in concentration of chloride ions.

The cathodic polarization of inhibited and uninhibited iron in sulfuric acid at pH 0.3, 1.0, and 1.7 in the absence of chloride ions is shown in Fig. 1. For solutions of pH 0.3 and 1.0, the rate of the hydrogen evolution reaction (h.e.r.) on iron was less in the presence of benzoic acid. However, no effect of the inhibitor on the rate of the h.e.r. was observed for iron in pH 1.7 solutions.

Tafel lines were obtained for both inhibited and uninhibited iron with cathodic Tafel slope of 80 mV as shown in Fig. 1. The electrochemical reaction orders of the h.e.r. with respect to the hydrogen ions were determined by plots of log i_c *vs.* pH. For both inhibited and uninhibited iron

$$\left(\frac{\partial \log i_c}{\partial \text{pH}}\right)_{\psi} \approx -1$$

The effect of chloride ions on the rate of the h.e.r. on both inhibited and uninhibited iron in pH 0.3 solutions is shown in Fig. 2. It is seen that the h.e.r. rate on iron in 0.01M NaCl was less than in 0.02M benzoic acid compound. Comparison of the decrease in the rate of the h.e.r. on iron in solutions containing 0.01M NaCl and 0.02M benzoic acid separately and together suggest that at these concentrations the inhibition of the h.e.r. is the result of adsorption of both chloride ions and benzoic acid. Iron in pH 0.3 solutions containing chloride ions of 0.02, 0.1, and 0.2M NaCl behaved similarly; *i.e.*, chloride ions decreased the rate of the h.e.r. on both inhibited and uninhibited iron. The same effect of chloride ions was observed for iron in pH 1.0 solutions. However, for pH 1.7 solutions the

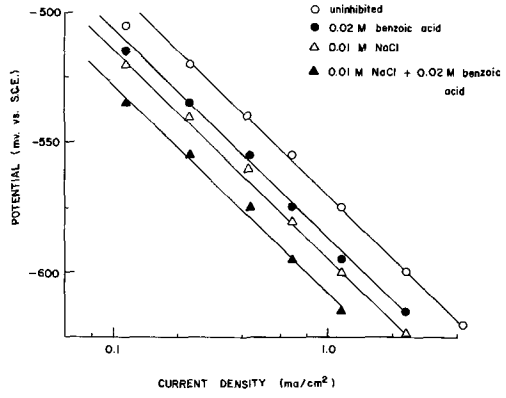

Fig. 2. Effect of low concentrations of chloride ions on the cathodic polarization of iron.

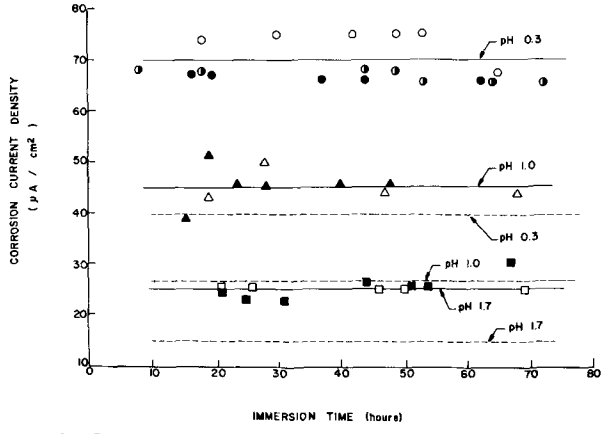

Fig. 3. Corrosion rate of iron in H_2SO_4 vs. immersion time. Points and continuous line represent uninhibited iron. Dashed line represents inhibited iron (0.02M benzoic acid).

rate of the h.e.r. on inhibited and uninhibited iron was stimulated by the presence of chloride ions.

The corrosion rates of uninhibited iron in sulfuric acid solutions of *p*H 0.3, 1.0, and 1.7 as a function of immersion time are given in Fig. 3. The corrosion rates were essentially constant with immersion time, and the averaged rates were 70, 44, and 25 μA/cm^2, respectively.

The corrosion rates of iron in sulfuric acid solutions of *p*H 0.3, 1.0, and 1.7 containing 0.02M benzoic acid were also constant with immersion time. The averaged corrosion rates were 40, 27, and 15 μA/cm^2, respectively, and are shown in Fig. 3. For both inhibited and uninhibited iron, the corrosion rate decreased with increase in the solution *p*H.

Table I shows the effect of chloride ions on the corrosion rate of inhibited and uninhibited iron. It is seen that a minimum in the corrosion rate was observed for both inhibited and uninhibited iron in 1*N* H_2SO_4 + 0.01M NaCl. Corrosion inhibition of iron by benzoic acid was maintained for all concentrations of chloride ions studied in this work ($\leq$0.2M NaCl). A minimum in the corrosion rate was also observed by Mazza and Greene (5) who investigated the corrosion of 304 stainless steel in 1*N* H_2SO_4 containing sodium chloride of various concentrations. The sharp minimum and subsequent increase in corrosion rate observed for iron in *p*H 0.3 solutions was not observed for iron in *p*H 1.0 and 1.7 solutions. For *p*H 1.0 solutions, the corrosion rate decreased with introduction of chloride ions but leveled off to a reasonably constant value with increase in chloride ions. For *p*H 1.7 solutions, the corrosion rate increased slightly with introduction of chloride ions and leveled off to an approximately constant value with increase in concentration of sodium chloride. Table I shows that the effect of chloride ions on the corrosion rate of inhibited and uninhibited iron in sulfuric acid solutions is influenced by the solution *p*H.

Table I. Averaged steady-state corrosion rate (μA/cm^2)

NaCl conc (M)	Uninhibited pH			Inhibited pH		
	0.3	1.0	1.7	0.3	1.0	1.7
0.00	70 ± 6	44 ± 1	25 ± 1	40 ± 7	27 ± 6	15 ± 2
0.01	40 ± 8	30 ± 7	28 ± 2	20 ± 4	22 ± 4	20 ± 1
0.02	48 ± 15	19 ± 4	31 ± 1	30 ± 5	23 ± 7	20 ± 1
0.10	66 ± 4	21 ± 4	33 ± 3	37 ± 3	20 ± 4	20 ± 1
0.20	70 ± 2	25 ± 5	35 ± 1	47 ± 6	22 ± 3	20 ± 2

The initial capacitance of inhibited and uninhibited Armco iron in sulfuric acid in the presence and absence of chloride ions ranged from 30 to 35 μf/cm^2. Thus, there was no significant effect of benzoic acid and chloride ions on the initial capacitance of iron.

For *p*H 0.3 and 1.0 solutions, the capacitance of inhibited and uninhibited iron in H_2SO_4 increased linearly with immersion time as shown in Fig. 4 and 5, respectively. The slope of the capacitance *vs.* immersion time curve decreased with increase in *p*H and with addition of benzoic acid. For *p*H 1.7 solutions, the capacitance remained constant with immersion time and was not affected by the presence of benzoic acid. The capacitance increase with immersion time of Armco iron in 1*N* H_2SO_4 in the absence and presence of benzoic acid has been reported previously (2, 6).

Figures 4 and 5 also show a typical effect of chloride ions on the capacitance of inhibited and uninhibited Armco iron in *p*H 0.3 solutions. For uninhibited and inhibited iron in *p*H 0.3 solutions, the rate of increase of capacitance with immersion time decreased with addition of chloride ions. However, the rate of increase in capacitance of inhibited and uninhibited iron

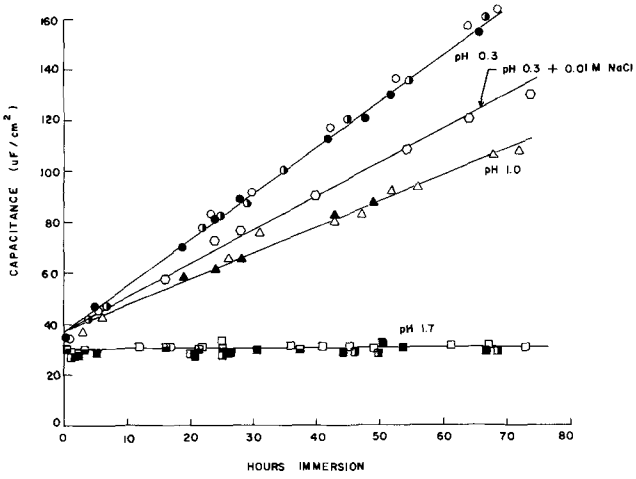

Fig. 4. Open-circuit capacitance of iron in H_2SO_4 vs. immersion time.

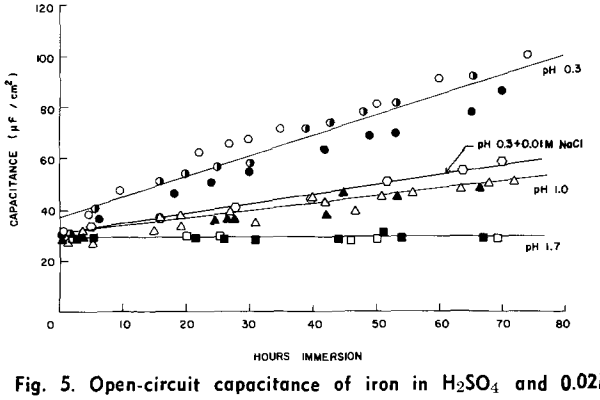

Fig. 5. Open-circuit capacitance of iron in H_2SO_4 and 0.02M benzoic acid vs. immersion.

in pH 1.0 and 1.7 solutions was not appreciably affected by chloride ions.

Discussion

The open-circuit capacitance of iron in 1*N* $HClO_4$ and HCl solutions did not increase appreciably with immersion time in contrast to the capacitance increase observed for iron in sulfuric acid solutions of less than pH 1.7. The results of the open-circuit capacitance experiments indicate that the anion, HSO_4^-, plays a significant role in the capacitance-immersion time behavior of Armco iron in H_2SO_4 of pH 0.3 and 1.0. Since the corrosion rate of both inhibited and uninhibited Armco iron remained constant with immersion time as shown in Fig. 3, it is apparent that the increase in capacitance with immersion time was not due to an increase in surface roughness.

In a separate series of experiments, it has been observed that the large capacitance (pseudocapacitance) obtained after long immersion times can be substantially reduced by prolonged cathodic polarization. Furthermore, it has been observed previously that, after removal of the electrode from the solution for a prolonged period of time and then reimmersion in electrolyte, the Armco iron resumed the capacitance increase with immersion time (7). Sayano (8) observed that the large open-circuit capacitance after a long immersion time could be reduced to the original value by anodic passivation of iron at +600 mV *vs.* SCE and subsequent self-activation to the corrosion potential. After activation the initial capacitance value was attained again and, subsequently, the capacitance increased linearly with immersion time as observed previously. These results provide further evidence that the capacitance increase was not due to an increase in surface area, but rather to the formation of a surface species which involves the anion, HSO_4^-.

In view of the above experimental observations, a possible mechanism to account for the anodic dissolution and open-circuit capacitance behavior of iron in H_2SO_4 is as follows:

$$Fe + H_2O \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [FeOH]_{ads} + H^+ + e \qquad [1]$$

$$[FeOH]_{ads} \xrightarrow[k_2]{\text{RDS}} FeOH^+ + e \qquad [2]$$

$$[FeOH]_{ads} + HSO_4^- \underset{k_{-2a}}{\overset{k_{2a}}{\rightleftharpoons}} [FeOH_2SO_4]_{ads} + e \qquad [2a]$$

$$FeOH^+ + H^+ \xrightarrow[\text{fast}]{k_3} Fe^{++} + H_2O \qquad [3]$$

$$[FeOH_2SO_4]_{ads} \xrightarrow{k_{3a}} Fe^{++} + HSO_4^- + H_2O \qquad [3a]$$

where k_1, k_{-1}, and $k_3 >> k_2 >> k_{2a}$

Bockris *et al.* (9) proposed reaction steps [1], [2], and [3], with step [2] the rate-determining step, as the mechanism for the anodic dissolution of iron. Step [2a] is similar to one of the reaction steps in the mechanism proposed by Florianovich *et al.* (10). The slow but steady increase in the open-circuit capacitance with immersion time is surmised to be an adsorption pseudocapacitance due to formation of an electroactive surface complex intermediate, $FeOH_2SO_4$, as in step [2a], which is a parallel reaction to the rate-determining step [2]. Pseudocapacitance due to adsorbed hydrogen atoms has been precluded in light of Devanathan and Stachurski's results (11). A plausible alternative mechanism would include a slow reaction step, a reaction between Fe and the bisulfate ion to form an electroactive surface intermediate, parallel to step [1]. The depletion of the surface complex during passivation of iron at +600 mV and the subsequent reattainment of the initial capacitance, as observed by Sayano (8), may be ascribed to a reaction as step [4]

$$[FeOH_2SO_4]_{ads} \xrightarrow{k_4} Fe^{+++} + SO_4^= + H_2O + e \qquad [4]$$

The Preparation of Dithionites by the Electrolytic Reduction of Sulfur Dioxide in Water

Colin Oloman

B.C. Research, Vancouver 167, Canada

ABSTRACT

This paper reports the results of experimental studies on the cathodic reduction of sulfur dioxide in water solution. The system is discussed in terms of the chemical and electrochemical reactions which accompany the flow of current. Experimental results demonstrate the effect of principal process variables on current efficiency and chemical yield. The work described is directed toward the development of an electrolytic process for the production of dithionite solution for industrial use.

Background

The dithionites are strong reducing agents which are commercially valuable as bleaching chemicals. Consequently, the preparation of these salts has received considerable attention.

The common method of making dithionites is through the direct reduction of a solution of sulfur dioxide or sodium bisulfite in water with metallic zinc (1, 2). The reduction can be carried out successfully using sodium amalgam (3) and metallic iron has been considered for the same purpose (4). Dithionites can also be made by the reaction of such reducing agents as sodium borohydride with sulfur dioxide.

Apart from chemical reduction, the electroreduction of sulfurous solutions has long been recognized as a source of dithionites.

In 1857 Schonbein (5) observed the reddish brown color formed by the electrolysis of sulfur dioxide solutions and noted that the resulting liquid is a strong reducing agent. In 1877 Gerout (6) reported the electrolysis of sulfurous acid to obtain a yellow solution of "hydrosulfurous" acid and the electrolysis of sulfur dioxide in water was adopted by Worsley (7) in 1924 as a method of producing "hydrosulfurous" acid for bleaching purposes. However, dithionous acid is very unstable and, since this early work, the electroreduction of simple solutions of sulfur dioxide in water has received little attention.

The decomposition of dithionite in an electrochemical cell can be partly avoided by using as the catholyte nearly neutral solutions of sulfites and bisulfites. This technique has been the subject of investigations since about 1900 (8-12) and is the basis of several patented processes for the electrochemical manufacture of dithionites (13, 14).

Despite considerable work on the subject, the electroreduction process has not been made to compete commercially with the conventional zinc reduction process for dithionite manufacture. In an evaluation written in 1924 (15), McKee and Woldman explain how limitations on chemical yield and current efficiency impair the value of the electrochemical process. Their concise summary of the situation is probably still pertinent today.

Nevertheless, the potential cost reduction through the direct use of electric power in the preparation of dithionite makes a successful application of the electrochemical method an attractive goal. The work described in this paper has been directed toward the development of a useful process for producing dithionite solutions by the electroreduction of sulfur dioxide in water.

Cathode reactions.—The standard electrode potentials for the reduction of sulfurous solutions to dithionite under acidic and basic conditions are given by Latimer (16) as

$$2H_2SO_3 + H^+ + 2e^- \rightarrow HS_2O_4^- + 2H_2O \qquad -- E_o = -0.08V$$

$$2SO_3^= + 2H_2O + 2e^- \rightarrow S_2O_4^= + 4\,OH^- \qquad ---- E_o = -1.12V$$

The corresponding hydrogen discharge potentials are 0.0 and −0.83V, respectively. However, the existence of a hydrogen overvoltage of a few tenths of a volt on most metal cathodes will allow the preferential formation of dithionite in acid solution. With rising *p*H, dithionite formation should be possible only with high overvoltage cathodes at relatively low current densities.

Apart from the discharge of the hydrogen ion, further secondary reactions at the cathode can involve the reduction of dithionite itself to thiosulfate

$$S_2O_4^= + 2H^+ + 2e^- \rightarrow S_2O_3^= + H_2O \text{ ---- } E_o \approx +0.88V$$

and possibly the reduction of thiosulfate to free sulfur. The existence of these alternative electrode reactions explains, in part, the difficulty of obtaining useful concentrations of dithionite in the electroreduction process.

The stoichiometry of dithionite formation in the electrolytic process is commonly given as

$$2HSO_3^- + 2H^+ + 2e^- \rightarrow S_2O_4^= + 2H_2O$$

This equation implies that the bisulfite ion is the reactive species in the primary cathode reaction. However, from their study of the reduction of sulfurous solutions at a dropping mercury electrode, Kolthoff and Miller (17) conclude that sulfur dioxide or sulfurous acid is the depolarizer in the primary cathode reaction.

It follows that dithionite is formed most easily through the electroreduction of a solution of low *p*H containing a high concentration of sulfur dioxide.

Chemical decomposition of dithionite.—The principal barrier to the efficient electrolytic preparation of dithionites lies in the chemical instability of dithionous acid. Practical current densities can be attained only in acid conditions which promote decomposition of the product dithionite and consequently limit the process yield.

The mechanism of the decomposition of dithionite is complex. McKee and Woldman (18) summarize the work of early investigators of this subject and present data which show the decomposition of dithionite in neutral and acid sulfite solutions to be a simple reaction, second order with respect to dithionite concentration. This reaction is presented as

$$H_2O + 2S_2O_4^= \rightarrow S_2O_3^= + 2HSO_3^-$$

More rigorous examinations of the decomposition kinetics (19, 20) have showed that in the *p*H range

Key words: *primary*—dithionites; *co-term*—electrolytic, preparation, reduction, sulfur dioxide. *Primary*—sulfur dioxide; co-*term*—dithionites, electrolytic, reduction.

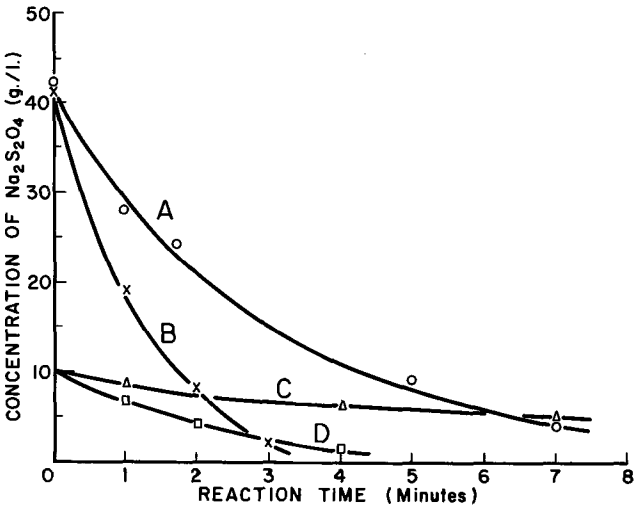

Fig. 1. Decomposition of dithionite in solution with sulfur dioxide and thiosulfate. Temperature 18°C; SO_2 concentration, 8 weight per cent (w/o); pH, 0.8; nitrogen purge; initial $[S_2O_3^=]$, A, 0.008M; B, 0.04M; C, 0.002M; D, 0.04M.

4.5-7 the rate is raised by increases in the concentration of dithionite, bisulfite, thiosulfate, and hydrogen ions. Under some circumstances, the decomposition of dithionite is autocatalytic.

Both zinc (21) and cadmium (22) have been observed to stabilize dithionite, while transition metal ions are generally believed to increase the rate of decomposition.

It is certain that the rate of decomposition of dithionite increases with decreasing pH. However, published studies give no quantitative account of the decomposition of dithionite in solutions with a pH below 4. Specific data on the decomposition of dithionite in a strong solution of sulfur dioxide is given here in Fig. 1. The 8% sulfur dioxide solution has a pH of about 0.8 and under this condition the dithionite disappears very rapidly. Thiosulfate appears to be an autocatalytic agent and the decomposition rate is largely determined by an interaction between the effects of dithionite and thiosulfate concentration. The form of this dependence is not known.

Similar studies have shown that the rate of decomposition of dithionite in an 8% sulfur dioxide solution is increased about fivefold by raising the reaction temperature from 10° to 28°C.

The Electrodeposition of Sulfur Dioxide in Water

Process.—The production of dithionites by the cathodic reduction of sulfurous solutions always involves a competition between the rate of formation of dithionite at the cathode and the rate of decomposition of dithionite in the bulk of the catholyte.

In such a process, the dithionite yield and the current efficiency for production of dithionite depend on the interaction of several factors. Most important of these are:

(*a*) The concentration of depolarizer in the catholyte, the condition of turbulence at the cathode surface, and the cathode material, which together determine the current density that can be usefully applied to the cathode.

(*b*) The ratio of cathode area to cathode chamber volume, which together with the current density gives the current concentration and hence the rate of dithionite formation within the catholyte.

(*c*) The concentration of dithionite and thiosulfate, the pH, and the temperature of the catholyte, which determine the rate of dithionite decomposition.

When a simple solution of sulfur dioxide is used as the catholyte in this process, the rate of dithionite decomposition is very high but the presence of free sulfur dioxide allows the application of a correspondingly high current density. Under these conditions, dithionite can be obtained in reasonable yields from a reactor with a high ratio of cathode surface area to cathode chamber volume which operates at a low temperature and employs a low catholyte residence time.

The method adopted for the preparation of sodium dithionite by the electroreduction of sulfur dioxide in water is represented in Fig. 2. In this process, sulfur dioxide in water is converted to dithionite in a single pass across an active cathode plate. A cation specific membrane separates the anode and cathode chambers of the cell and sodium ions are supplied to the catholyte from a recycling anolyte solution of a convenient sodium salt. The primary electrode reactions occurring in the cell are:

at the anode

$$4NaOH \rightarrow 4Na^+ + O_2 + 2H_2O + 4e^-$$

at the cathode

$$4SO_2 + 4e^- \rightarrow 2S_2O_4^=$$

net reaction

$$4NaOH + 4SO_2 \rightarrow 2Na_2S_2O_4 + O_2 + 2H_2O$$

The balance between the rate of formation and decomposition of the dithionite makes it impractical to carry the sulfur dioxide conversion to 100%. Thus the catholyte solution leaving the reactor contains sodium dithionite, sodium bisulfite, and sodium thiosulfate, together with unconverted sulfur dioxide which must be neutralized to preserve the dithionite.

Apparatus and procedure.—The conditions required for the preparation of sodium dithionite by electroreduction of sulfur dioxide in water are fulfilled by the

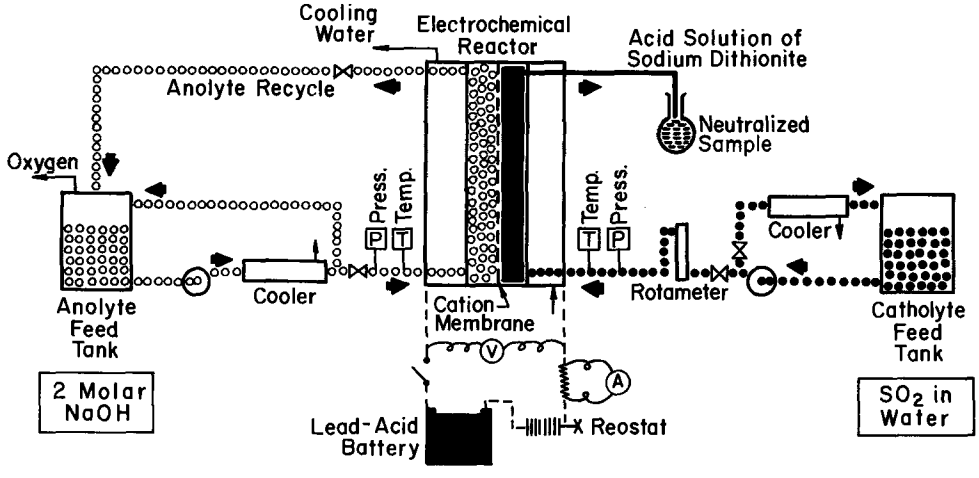

Fig. 2. Apparatus used in experimental production of sodium dithionite.

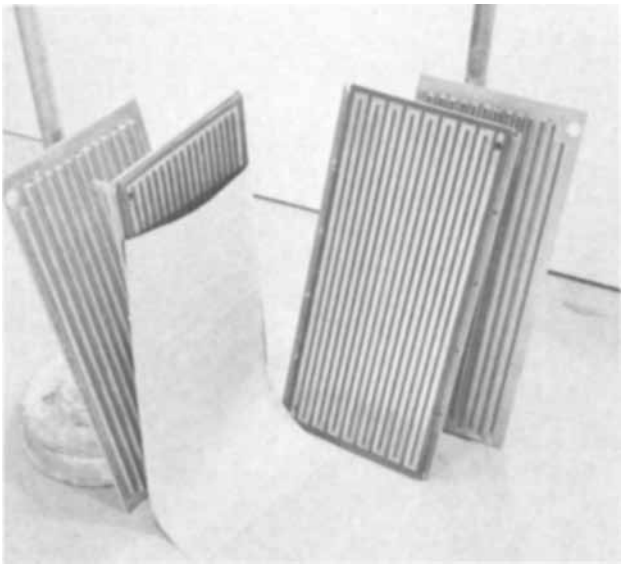

Fig. 3. Single cell used in electroreduction of sulfur dioxide in water.

electrochemical cell shown open in Fig. 3. This cell consists of a cathode and anode plate, both of 316 stainless steel, separated by a cation membrane. The membrane is supported by a nylon mesh not shown in the photograph. Cathode and anode chambers are formed on the electrodes by fingered neoprene gaskets which direct the solutions across the electrodes so that the catholyte flows through the cathode channels in series while the anolyte moves through the anode channels in parallel. The channels are all 1 cm wide and about 0.15 cm deep and the total active cathode area is 1000 cm^2 for a single cell or 800 cm^2 for each cell used in series. Electrode plates are 1/32 in. thick and are backed by 1/16 in. aluminum current distribution plates which in turn are cooled by water flowing through external chambers. Several of these cells may be put together in series to increase the cathode area of the reactor.

In operation of the reactor, a catholyte solution of 2-12% sulfur dioxide in water was precooled to 10°C and pumped through the cathode chamber. The anolyte consisted of a 2M (molar) solution of sodium hydroxide which was kept at a temperature between 10° and 15°C while recycling around the anode circuit at a rate of about 1 liter/min/cell. With a flow of 100 ml/min of a catholyte solution containing 95 g/liter of sulfur dioxide, the decomposition potential of each cell was 1.2V and the electrical resistance some 24 ohm · cm^2.

Both the anolyte and catholyte were made up with water from the city mains containing about 0.5 ppm of both iron and copper. However, in the experiments the anode was dissolved slowly at the higher current densities and this was responsible for the presence of transition metal ions in the catholyte product up to concentrations of about 10 ppm.

Direct current was supplied to the reactor from a set of lead-acid batteries and controlled to individual cells through separate carbon block rheostats.

In each of a series of experimental runs, the reactor produced a continuous flow of a reddish-brown solution of sodium dithionite with unconverted sulfur dioxide. This product stream was sampled directly into an excess of sodium hydroxide solution and analyzed within 30 min. Routine analysis for dithionite alone was done by titration into an acid indigo carmine solution under a nitrogen purge (23), while the complete analysis for dithionite, thiosulfate, and sulfite was carried out by a detailed iodometric method (24). No systematic account was made of the sulfide content of the product solutions but occasional checks showed sulfide to be present in relatively small amounts.

The dithionite yield from sulfur dioxide and the current efficiency for the process were calculated as:

$$\text{Dithionite yield} = \frac{2[S_2O_4^{=}] \text{ in product}}{[SO_2] \text{ in feed}}$$

$$\text{Current efficiency} = \frac{\text{Mole/min of } S_2O_4^{=} \text{ in product}}{\text{Applied current}} \times \frac{193{,}000}{60}$$

Results and discussion.—(a) Effects of catholyte flow rate, sulfur dioxide concentration, and cathode current density.—The effects of flow rate, sulfur dioxide concentration, and current density on the current efficiency and chemical yield for dithionite are illustrated by the factorial results of Tables I and II. The corresponding equations are the results of a stepwise multiple linear regression analysis of the data and contain the factors which were shown to be significant up to the 10% level.

From the statistical analysis, most of the variation in current efficiency and yield could be attributed to the effects of the primary variables and their linear interactions. Residual errors are probably due to experimental error to the uncontrollable variation of the process temperature between 10° and 15°C.

In Table I it is apparent that the current efficiency is increased with sulfur dioxide concentration and flow rate. This is a consequence of the independent effects that these variables have on the concentration of reactive species at the cathode surface. Increasing current density always lowers the current efficiency as the cathode becomes polarized with respect to sulfur dioxide and the cathode potential favors the occurrence of secondary reactions. This effect is diminished with increasing sulfur dioxide concentration.

Other interactions are indicated in Table I but their analysis is confused by chemical decomposition effects due to the varying composition of the catholyte.

Table I. Current efficiency for dithionite in electroreduction of sulfur dioxide in water

Catholyte flow rate (cc/min)	SO_2 concentration—w/o: 3.5, Current density, A/cm^2			7.2, Current density, A/cm^2			11.5, Current density, A/cm^2		
	0.025	0.05	0.1	0.025	0.05	0.10	0.025	0.05	0.10
	Current efficiency—per cent								
60	42	6	1	62	41	14	69	61	34

100	16	5.5*	5*	9	14	15*	6	12	18
200	10	10	6.7*	5	8	9	3.5	6	11

* Indicates appearance of H_2 gas and free sulfur.
Catholyte temperature = in 15°C; out 10°C.
Cathode area = 1000 cm^2.
Cathode chamber volume = approx 150 cm^3.
Dithionite yield = 15 + 0.35 (flow) − 193 (current density) − 0.98 (SO_2 conc) (flow) + 27 (SO_2 conc) (current density).
Correlation coefficient = 0.82.

The results for chemical yield (Table II) are also complicated by several interactions. The observed effects and the natural result of a process in which the dithionite yield is determined by a competition between formation and decomposition reactions in the catholyte.

An increase in current density should generally improve the dithionite yield as it raises the rate of dithionite formation at the cathode. However, this effect is limited by the polarization of the cathode, which promotes alternative and/or destructive cathode reactions. Consequently, the positive effect of current density is only seen at a high sulfur dioxide concentration. Similarly, the negative effects of flow rate and sulfur dioxide concentration are reversed at a high current density because increases in flow or concentration restore the balance of cathode reactions to favor dithionite accumulation.

The curves of Fig. 4 and 5 described the action of the cell in more detail. Figure 4 shows how an increasing current density on the cathode causes the current efficiency to fall due to the effects of secondary electrode reactions and chemical decomposition. Corresponding results for dithionite yield from sulfur dioxide show that with increasing current density the dithionite yield rises until it reaches a maximum at a critical current density. Higher current densities lead to a loss of yield through secondary electrode reactions. Experimentally, the critical current density is that at which hydrogen bubbles appear in the product catholyte, higher current densities give free sulfur and cause the disappearance of the typical orange color in the product dithionite solution.

The effect of sulfur dioxide feed concentration and catholyte flow rate on the critical current density is reflected in Fig. 6 and 7. These results are indicative of the importance of mass transfer to the kinetics of dithionite accumulation in the catholyte during the electroreduction of sulfur dioxide in water.

The utilization of electric current in the various cell reactions is shown in Fig. 8. At low current densities dithionite is the principal product of the cathode reaction, with small amounts of thiosulfate and hydrogen. As the current density increases thiosulfate formation becomes more important, until hydrogen and dithionite degeneration products are the only results of current applied in excess of the critical current density.

Figure 8 also shows the value of lead as a cathode material. Lead has a higher hydrogen overvoltage than stainless steel, but it appears that the lower hydrogen loss is compensated by increased thiosulfate formation. The maximum dithionite yield is not increased by using a lead cathode, although the critical current density is somewhat higher than that obtained with a stainless steel cathode.

(b) Effect of ratio of cathode surface to cathode chamber volume.—Figure 9 demonstrates that increasing the ratio of cathode surface area to cathode cham-

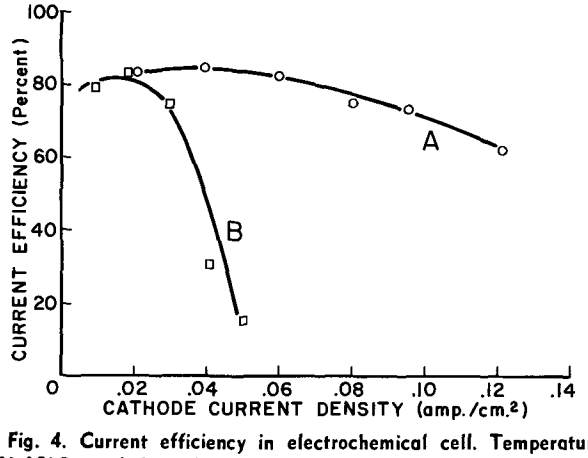

Fig. 4. Current efficiency in electrochemical cell. Temperature, 10°-15°C; catholyte flow, 100 ml/min; cathode area, 1000 cm^2; cathode area/chamber volume, 15 cm^2/cm^3; SO_2 feed concentration: A, 95 g/liter; B, 26 g/liter.

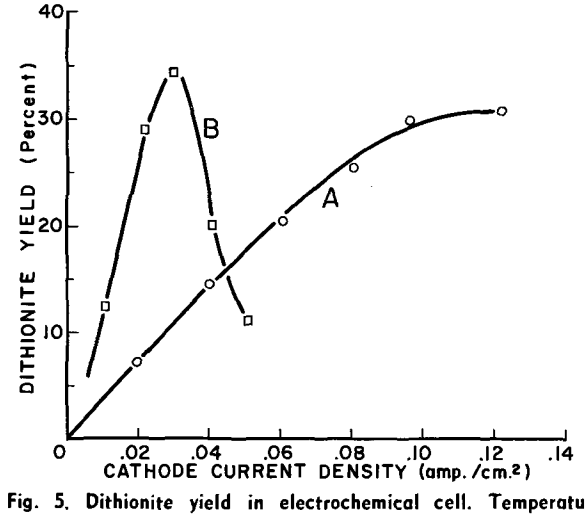

Fig. 5. Dithionite yield in electrochemical cell. Temperature, 10°-15°C; catholyte flow, 100 ml/min; cathode area, 1000 cm^2; cathode area/chamber volume, 15 cm^2/cm^3; SO_2 feed concentration: A, 95 g/liter; B, 26 g/liter.

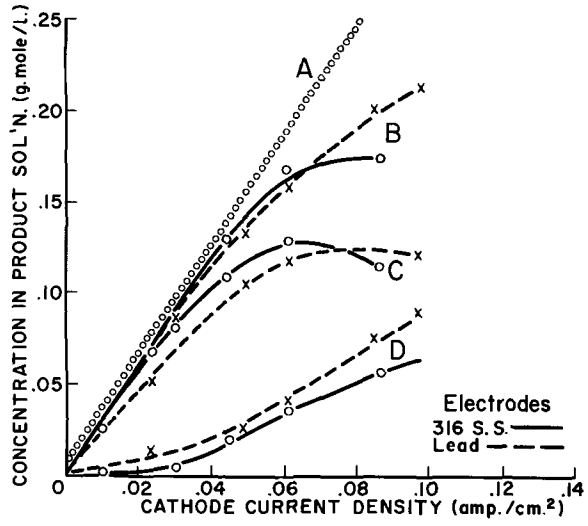

Fig. 8. Current utilization in electrochemical cell. Temperature, 10°-15°C; catholyte flow, 100 ml/min; SO_2 feed concentration, 50 g/liter; cathode area 1000 cm^2; cathode area/chamber volume, 15 cm^2/cm^3: A, applied current; B, thiosulfate + dithionite; C, dithionite; D, thiosulfate.

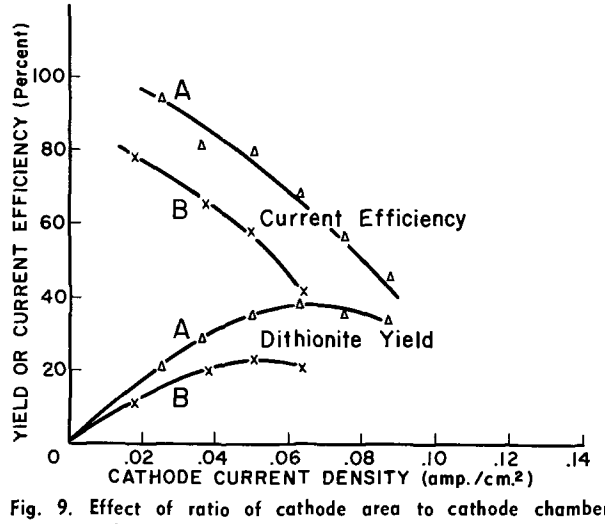

Fig. 9. Effect of ratio of cathode area to cathode chamber volume on yield and current efficiency for dithionite. Temperature, 15°C; catholyte flow, 50 ml/min; SO_2 feed concentration, 80 g/liter; cathode area, 800 cm^2. Ratio of cathode area to chamber volume: A, 15 cm^2/cm^3; B, 8 cm^2/cm^3.

ber volume increases the maximum dithionite yield from a single cell. This ratio is raised from 8 to 15 cm^2/cm^3 by packing the cathode chamber with inert beads and is responsible for increasing the maximum dithionite yield from 28 to 38%. The effect here is that of increasing the rate of dithionite formation relative to its rate of decomposition and possibly of helping sulfur dioxide transfer through increasing the turbulence in the catholyte.

(c) Effect of total cathode area.—The conversion of sulfur dioxide can be increased, while still employing subcritical current densities, through using more than one cell in series. The result of using two cells in series, thus increasing the total cathode area from 800 to 1600 cm^2, is shown in Fig. 10. In the experiments represented by Fig. 10, the current was supplied to the two cells in parallel with the same potential drop across each cell and the current density averaged over the total electrode area.

The effect of doubling the cathode area was to increase the maximum yield of dithionite from 38 to 48%, while the corresponding total applied current was raised from 50 to 70 A.

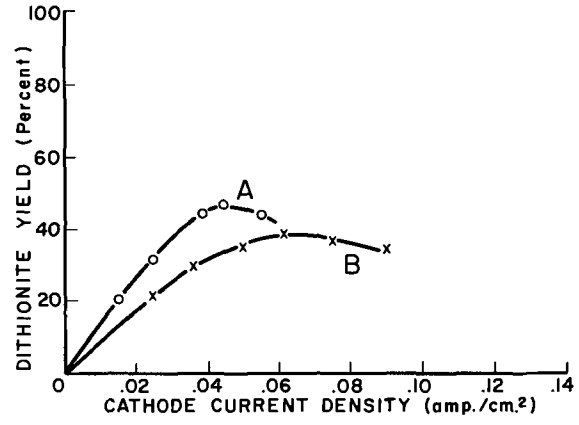

Fig. 10. Effect of cathode area on dithionite yield. Temperature, 15°C; catholyte flow, 50 ml/min; SO_2 feed concentration, 80 g/liter; cathode area/chamber volume, 15 cm^2/cm^3. Cathode area: A, 1600 cm^2; B, 800 cm^2.

It is apparent from these results that, as the sulfur dioxide conversion rises, the current density which can be usefully applied to the catholyte must fall. This decreasing current density means a decreasing rate of dithionite formation but coincides with an increasing rate of dithionite decomposition. The difficulty is compounded by the high order kinetics of dithionite decomposition but is balanced by the rising catholyte *p*H shown in Fig. 11. The consequence of these interactions is an area of diminishing returns where the use of greater cathode areas eventually leads to a loss of dithionite yield.

Within the limitations of the experimental apparatus, the dithionite yield obtained with four cells in series was no greater than that obtained from two cells, and sometimes less. The highest dithionite yield measured was 48% and corresponded to a current efficiency of 72% with a product concentration of 52 g/liter of sodium dithionite.

(d) Effect of catholyte pH.—The consequence of increasing the catholyte feed *p*H with a constant total sulfurous sulfur content is illustrated in Fig. 12. For a given current density, the current efficiency on a stainless steel cathode falls with increasing catholyte *p*H. These curves are some evidence that the formation of dithionite is favored by the presence of free sulfur dioxide and that the bisulfite ion, which in Fig. 12 has its highest concentration at a *p*H of 2.1, is not relevant to the primary cathode reaction.

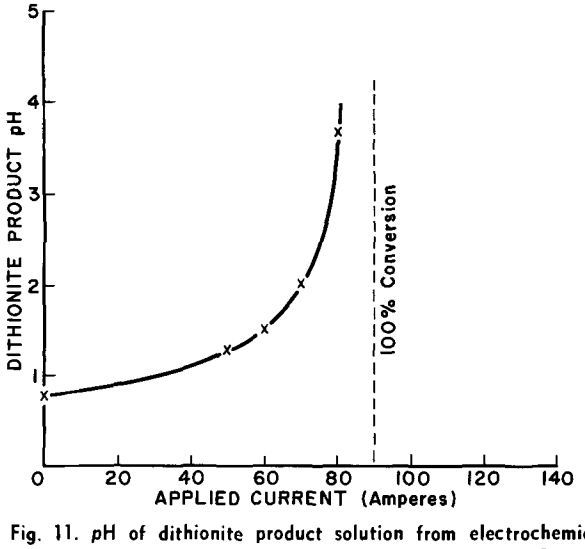

Fig. 11. *p*H of dithionite product solution from electrochemical reactor. Temperature, 15°C; catholyte flow, 50 ml/min; SO_2 feed concentration, 80 g/liter; cathode area, 800 cm^2.

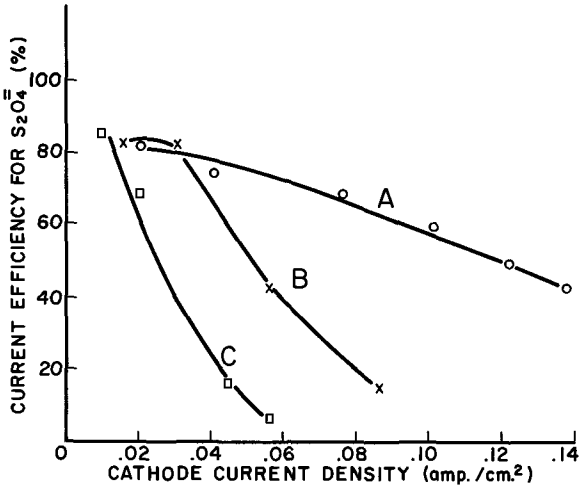

Fig. 12. Effect of catholyte *p*H on current efficiency in electrochemical cell. Temperature, 10°-15°C; catholyte flow, 100 ml/min; cathode area, 1000 cm^2; cathode area/chamber volume, 8 cm^2/cm^3. Catholyte composition: A, 95 g/liter SO_2; *p*H = 0.75; B, 95 g/liter SO_2 + 60 g/liter NaOH, *p*H = 2.1; C, 95 g/liter SO_2 + 90 g/liter NaOH, *p*H = 6.0.

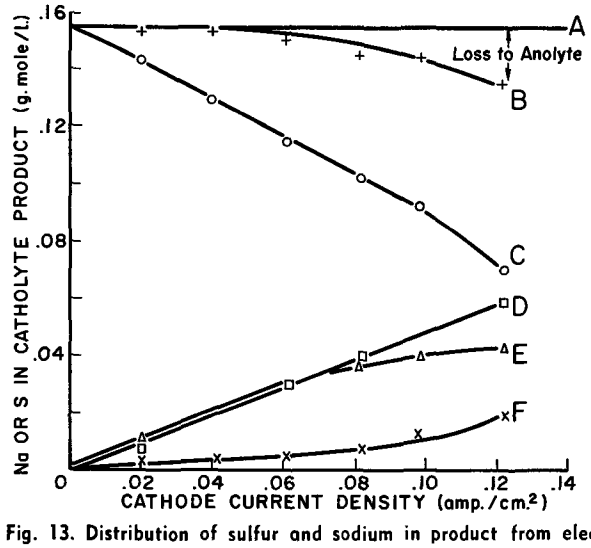

Fig. 13. Distribution of sulfur and sodium in product from electrochemical cell. Temperature, 10°-15°C; catholyte flow, 100 ml/min; SO_2 feed concentration, 95 g/liter; cathode area, 1000 cm^2, cathode area/chamber volume, 15 cm^2/cm^3. A, total S in feed; B, total S in product; C, S in sulfite; D, Na^+ in product; E, S in dithionite; F, S in thiosulfate.

(e) Sodium and sulfur balance.—The movement of sulfur and sodium across the membrane is an important aspect of the operation of the electrolytic cell. Figure 13 shows the effect of current density on the quantities of sulfur and sodium appearing in the catholyte product. That the membrane is selective for cations is evident in the relation between total sulfur in the catholyte feed and that in the catholyte product. These lines are identical for low current densities, but at high current densities they show a gap, corresponding to a loss of negative sulfur radicals into the anolyte. Sodium ions appear to be the principal current carrier across the membrane.

Conclusion

Sodium dithionite can be made by the electroreduction of a simple solution of sulfur dioxide in water in a divided cell.

In this process, the formation of dithionite is favored by the presence of free sulfur dioxide in the catholyte. However, the low *p*H of the catholyte promotes the decomposition of dithionite, which effect is compounded by the catalytic influence of thiosulfate in the product solutions.

The natural difficulties in producing dithionite through the electroreduction of sulfur dioxide in water can be partly overcome in the design of the reactor used for this purpose. A continuous bench-scale reactor, operating at 10°C on a catholyte feed of 8% sulfur dioxide in water, has been made to give a solution containing 52 g/liter of sodium dithionite with a corresponding current efficiency for dithionite of 72%, and a dithionite yield of 48%.

The process is one of diminishing returns in which the yield is limited by the increasingly unfavorable balance between dithionite formation and decomposition with rising sulfur dioxide conversion.

Technical Notes

Electroplating of Osmium

A. J. Appleby*

Institute of Gas Technology, Chicago, Illinois 60616

Although electroplating of the remaining platinum-group metals has been widely studied, there are no references in the literature to bright osmium plating. When the subject was last reviewed (1), a number of methods were available for bright ruthenium plating, including aqueous (for instance, nitrosochloride) baths, and a high-temperature process originally described for noble metal stripping by Atkinson (2) and for iridium electrodeposition by Withers and Ritt (3), and extended to platinum and ruthenium coatings by Rhoda (4). A fused alkali cyanide bath is used in the latter method, with dissolving noble metal anodes. Electrodeposited coatings were described (4) as being of much better quality than those available from aqueous ruthenium or platinum baths, and could be produced in flaw-free layers up to several mils in thickness. Owing to the instability of the cyanide complexes of palladium and apparently also of rhodium, no satisfactory results were obtained with these metals. No attempts were made to plate osmium by a similar method.

Khomchenko and co-workers examined aqueous osmates or perosmates (5), together with hexachlorosmates (6) for preparing electrodeposited osmium black catalyst electrodes. Although previous studies by the same workers (7) showed that bright ruthenium deposits could be prepared under certain conditions from analogous ruthenium baths (ruthenates), they report no work on obtaining bright osmium deposits. Black deposits were also obtained by Llopis and Vasquez using a similar method (8).

In the present work, an osmium electrode for oxygen electrode and redox studies was required. A bright deposit with the lowest possible roughness factor was most desirable, as this is easier to interpret kinetically. Gold foils of 1 cm^2 area were used as the substrate.

Some initial experiments were carried out in 2% aqueous hexachlorosmate solutions using a gold cathode and carbon anode at current densities varying from 1 to 20 mA/cm^2. At low current densities (lower than about 4 mA/cm^2, no osmium was deposited. At higher current densities, black nonadherent deposits resulted. At low current densities, it appears that Os^{2+} is formed.

Accordingly, an attempt was made to obtain a bright electrodeposit on gold using a modification of the molten salt method (2-4). A mixture of 8% osmium trichloride in equal parts of KCN-NaCN was heated to 600°C under nitrogen in an alumina crucible.[1]

Not all the osmium salt appeared to be soluble; some decomposition occurred. Using a gold cathode and a graphite anode, current densities in the range 1-50 mA/cm^2 were explored. Below about 5 mA/cm^2 no deposit appeared, but at about 10-20 mA/cm^2 a bright and adherent, though granular, deposit (*i.e.*, showing many-faceted crystals) was obtained. At higher current densities, black deposits again resulted.

In the present work, no attempts were made to make deposits thicker than 2-5μ, as this was sufficient for the purpose of making an electrode. Initial current efficiency was on the order of 20-40%, based on Os^{3+}. Attempts to obtain thicker coatings in the apparatus used were not successful, owing to deterioration of the bath. It would appear that more careful control of the atmosphere over the melt than was possible with nitrogen flow over an open crucible is necessary to prevent loss of osmium as OsO_4. It was observed that electrodeposited osmium films dissolved in the bath when small anodic currents (~1 mA) were applied.

Roughness factors of the electrodeposited coatings were measured by the electrolytic hydrogen-charging method, using constant current chronocoulometry in nitrogen-saturated dilute sulfuric acid. This method has been shown to give results that are consistent with BET measurements (5), and it is not affected by the presence of gold, which does not adsorb hydrogen in this potential range (9). Typical roughness factors for the granular bright deposits were 6-7.

It thus appears that bright osmium electrocoatings, using dissolving osmium anodes in molten cyanides, are a practical proposition.

Key words: osmium, electrodeposition of osmium, fused-salt osmium baths.

[1] The osmium electrodeposits obtained during the course of this work were only for the purpose of making test electrodes for experimental redox and oxygen electrode studies. For these experiments a thin coating of osmium was satisfactory. No facilities were available to extend the study to examination of the conditions for obtaining thicker coatings. The control of atmosphere above the melt was not particularly satisfactory, and this probably accounts for the instability of the bath. However, we were able to show that bright osmium flash coatings can be produced by this method and, with more careful control of atmosphere and using dissolving osmium anodes to insure a constant concentration of Os ions in the melt, it seems probable that more satisfactory coatings of considerable thickness can be obtained.

Observations on Imperfections in Silicon Material Using the Spreading Resistance Probe

D. C. Gupta,* J. Y. Chan, and P. Wang*,[1]

The Bayside Research Center of General Telephone & Electronics Laboratories Incorporated, Bayside, New York 11360

The spreading resistance probe is a versatile technique for measuring resistivity, resistivity profiles, resistivity variations, mobility, and the hardness of silicon (1-7). In this paper, the applications of this probe to study resistivity striations and lateral variations in resistivity are described. Further, it is shown that the probe can also be used to locate strain regions and various imperfections in bulk and epitaxial silicon which affect the electrical properties of the material.

The spreading resistance probe technique, as discussed elsewhere (1, 2), is based on the measurement of the total contact resistance or conductance of a metal-to-semiconductor point contact. The radius of contact is influenced by mechanical vibration, the pressure on the probe, the specimen surface preparation, and the damage of the region under the contact due to Joule heating during measurement. It is, therefore, necessary to control all these parameters to make the measurements reproducible. The measurements reported in this paper were made by using a semiautomatic spreading resistance probe in a constant output voltage mode and with a constant impact of the probe to the specimen as described by Gupta and Chan (1). With this probe, the reproducibility of the resistivity measurements on (111)-oriented n-type bulk silicon was found to be $\pm$ 0.39% (3σ) over a wide range. Similar reproducibility was also obtained on p-type silicon material.

Application of the Technique to Study Imperfections

The technique is applicable for locating regions of resistivity striations and impurity segregation in highly doped bulk silicon. It has also been shown to be useful in identifying deformed regions and strain areas. Figure 1 shows striations in a low-resistivity phosphorus-doped silicon slice cut in (111)-plane as depicted on an x-ray topograph; the numbers represent resistivity values obtained by spreading resistance probe and normalized such that the value at the center of the slice was one. As the spiral grew out from the center, higher resistivity values were obtained.

Figure 2 shows the x-ray topograph of a slice cut in (110)-plane from a low-resistivity phosphorus-doped silicon grown in a <111> direction. The striations were in the form of closely spaced lines because of the angle in which the crystal was cut. Resistivity measurements were made with the spreading resistance probe and values represented a variation of up to 14%.

Figure 3 is a photograph of strain field on the back side of a n/n^+ silicon epitaxial wafer as seen through the scanned Infrared Laser Microscope (8). The substrate of the wafer was Sb doped to approximately 0.008 ohm-cm or 7×10^{18} atoms/cm^3, the solubility limit. Darker areas in the photograph represented high absorption areas where free carrier concentrations were higher. These dark regions did not result from strains in the silicon due to lattice mismatch because regions with greater strain should be more transparent to infrared radiation. High concentration areas were also verified by the spreading resistance probe measurement data taken on the back side surface. These areas on the slice could actually be located by carefully mapping the resistivity values as shown in normalized form on this micrograph; low values were obtained in the darker areas and high values in the light-shaded areas.

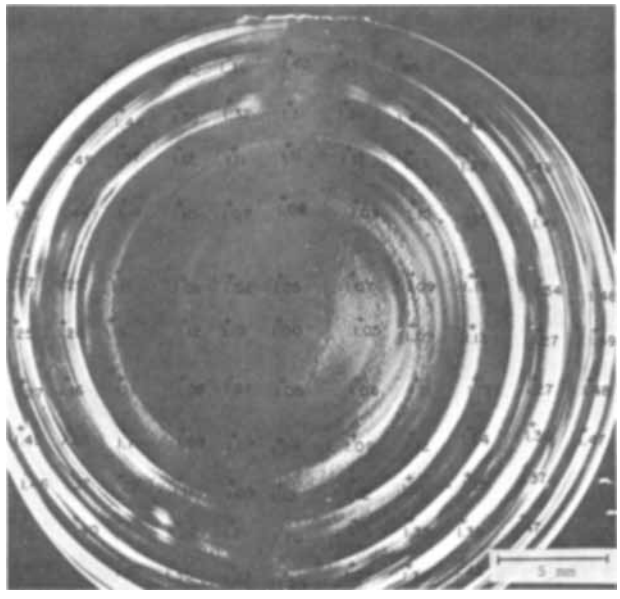

Fig. 1. Numbers showing resistivity values in normalized units as measured with the spreading resistance probe (1.0 represents 0.004 ohm-cm) superimposed on an x-ray topograph of the striations in a low-resistivity phosphorus-doped silicon slice cut in (111)-plane.

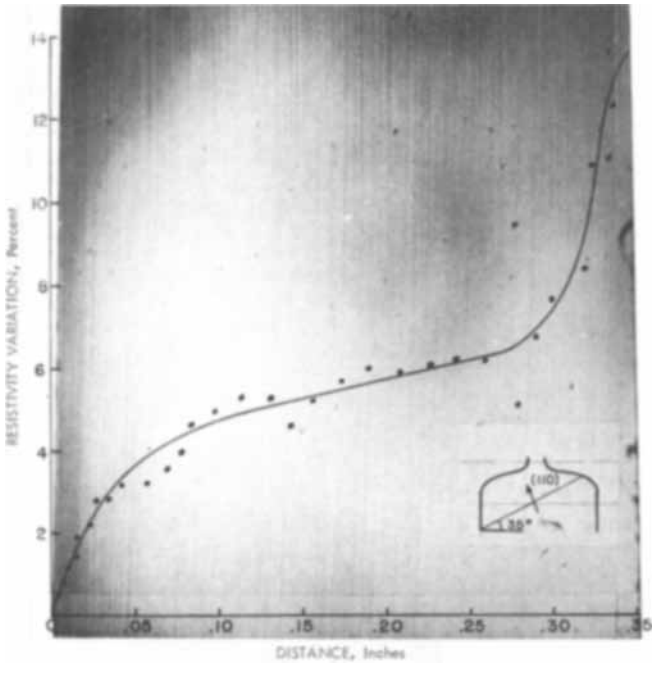

Fig. 2. Measured resistivity variations are superimposed on an x-ray topograph of a low-resistivity phosphorus-doped silicon slice cut in (110)-plane from a crystal (diam 1 in.) grown in <111> direction.

[1] Present address: Texas Instruments, Inc., Dallas, Texas 75222.

Key words: silicon, spreading resistance probe, resistivity inhomogeneities, growth imperfections, micro-defects in bulk and epitaxial silicon.

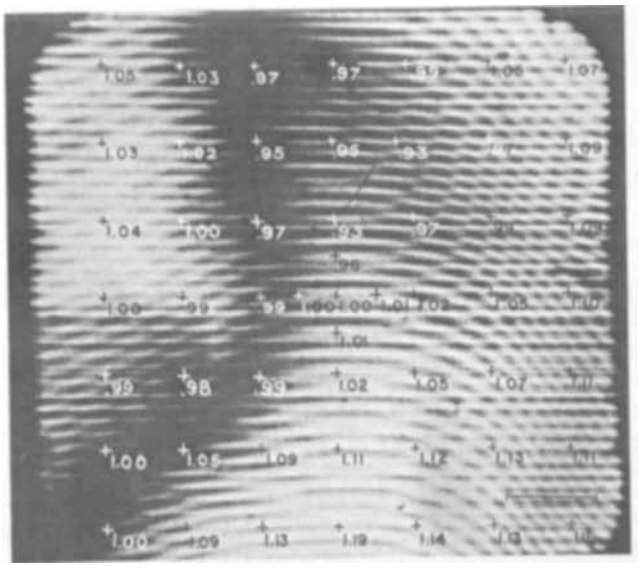

Fig. 3. Photograph of strain field on the backside of n/n$^+$ silicon epitaxial wafer with Sb-doped substrate as seen through the Scanned Laser Infrared Microscope (8). Numbers show resistivity values in normalized units, 1.0 represents 0.0089 ohm-cm, $\Delta\rho/\rho \simeq$ 26%.

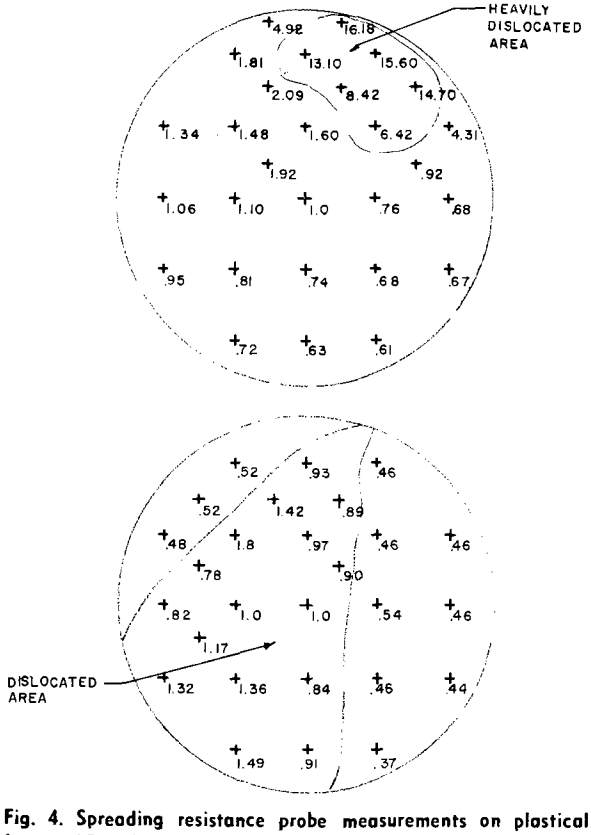

Fig. 4. Spreading resistance probe measurements on plastically deformed IC-wafers after isolation diffusion: (a) severely deformed specimen, (b) not-so-severely deformed. Numbers show resistivity values in normalized units.

Spreading resistance probe measurements made on an epitaxial wafer that contained a large number of stacking faults did not reveal any significant variations in resistivity. Either these stacking faults were not electrically active or this spreading resistance probe was incapable of locating the microvariations due to stair-rod dislocations (9).

Normalized spreading resistance measurements data on two partially plastically deformed silicon slices are shown in Fig. 4. The wafer shown in Fig. 4(a) was more severely deformed than that shown in Fig. 4(b). In the more severely deformed wafer, high-resistivity values were found to correspond to regions with high dislocation density observed by x-ray transmission topography. In the less severely deformed specimen, the regions with high dislocation densities still yielded higher resistivities, but the change in the resistivity values in deformed and not-deformed areas was relatively minor. These results may be explained partly in terms of Read's theory modified to include the scattering of carriers. The scattering results in a reduction of mobility as shown experimentally by Glaenzer and Jordan (10). Their results, however, are not directly applicable here because the dislocations in the silicon samples used in their work were intentionally aligned in one direction, whereas the dislocations in the silicon wafers used in the present work were not oriented in any particular direction.

Figure 5 is an x-ray transmission topograph of an integrated circuit wafer taken after isolation diffusion. This wafer was severely deformed by the high temperature and high surface concentration boron diffusion step for formation of the isolation junctions. The extent of plastic deformation in five different regions is shown in the enlarged micrographs strategically placed on the over-all view. The spreading resistance probe measurements taken on the back side surface were normalized and are plotted on this micrograph. Several features are prominent in this figure:

(a) Higher resistivities corresponded to higher dislocation density.
(b) The deformation was due to localized stress caused thermally or mechanically rather than to the high boron surface concentration used in the diffusion.
(c) The bright spot, a strain region probably due to probe damage, had no effect on resistivity, supporting our previous observation.

Conclusions

The spreading resistance probe is shown to be useful in detecting inhomogeneities and strain areas in bulk and epitaxial silicon without the use of sophisticated photographic techniques. To detect these, however, the probe needs to be a precise instrument capable of high spatial resolution. Such a probe can be designed with the careful consideration of all the parameters that affect spreading resistance measurements (1, 3). The quality of the surface of the specimens is required to be the same as that of the bulk calibration standards. Wherever possible, vapor-etched or chemically mechanically polished, mirrorlike surfaces should be used. These surfaces yield reproducible results (11). The technique is simple, speedy, and nondestructive. As with all electrical measurements, the technique has the drawback of being nonspecific as to the characteristics of the defects.

Acknowledgments

The authors acknowledge the assistance of the late John Sciola for the x-ray topography work and E. D. Jungbluth for the investigations on the Scanned Laser Infrared Microscope.

Plating Stresses from Electroless Nickel Deposition on Beryllium

R. M. Shemenski, J. G. Beach, and R. E. Maringer
(pp. 402-409, Vol. 116, No. 3)

E. Meisler and **D. Banerjee**[1]: Messrs. Shemenski, Beach, and Maringer have applied the theory of bimetallic beams in order to determine the stress resulting from electroless nickel plating on beryllium. For the problem considered by the authors, the failure to satisfy continuity and equilibrium conditions simultaneously leads to an unduly high value for both the resulting loads and stresses. The results of this investigation indicate that in this case the authors' use of the theory is inapplicable. Before this theory can be successfully applied, one must investigate its applicability and limitations.

The theory presented by Timoshenko[2] as applied by the authors is valid if the following conditions are met:

(*a*) The resulting deflections are small with respect to the thickness of the beam
(*b*) The elastic moduli and the thicknesses of the respective metals must obey the relationship that

$$E_1 t_1^2 = E_2 t_2^2$$

The impact of these conditions can be shown as follows. The free body diagram of the plating and the basis material is shown in Fig. 2 published here. In order that there be no separation at the interface, the relationship between the radii of curvature of the plating and the substrate must be

$$\rho_2 = \rho_1 + \frac{t_1 + t_2}{2} \qquad [i]$$

If the deflections are small, the resulting radii of curvature are very large with respect to the term

$$\frac{t_1 + t_2}{2}$$

Hence, the following approximation can be made

$$\rho_2 \approx \rho_1 = \rho \qquad [ii]$$

Using the beam equation for beam 1 and 2, results in the following relationships

$$\frac{P_1 t_1}{2} = \frac{E_1 I_1}{\rho_1} \qquad [iii]$$

$$\frac{P_2 t_2}{2} = \frac{E_2 I_2}{\rho_2} \qquad [iv]$$

Substituting [ii] in [iii] and [iv] and solving for P results in

$$P_1 = \frac{E_1 b t_1^2}{6\rho_1} \qquad [v]$$

$$P_2 = \frac{E_2 b t_2^2}{6\rho_2} \qquad [vi]$$

Equilibrium considerations demand that P_1 be equal to P_2. No separation at interface demands $\rho_1 = \rho_2$. Hence, in order to satisfy both the condition of continuity, *i.e.*, no separation at the interface and the condition of equilibrium, the following must be satisfied

$$E_2 t_2^2 = E_1 t_1^2 \qquad [vii]$$

One way of satisfying Eq. [vii] is to have $E_1 = E_2$ and $t_1 = t_2$.

The values presented by the authors show that the substrate is approximately twice as thick as the plating and that the elastic modulus of the substrate is 1.5 times the elastic modulus of the plating which results in the following

$$E_2 t_2^2 = 6.0 E_1 t_1^2$$

The immediate inference from this result is that conditions of equilibrium and nonseparation at interface are not satisfied simultaneously. This means that, if one assumes a common radius of curvature for beams 1 and 2, one cannot have a common P for both of them and *vice versa*. The authors, however, ignore this inherent contradiction in the theory and proceed to calculate a common P for beams 1 and 2 while assuming a common radius of curvature (Eq. [A-15]). The effect of this erroneous assumption is illustrated by the values of P in the authors' Table II. It shows values of P as high as 44 lb. A simple experiment performed during the course of this investigation demonstrated that a mere 350g axial load caused buckling and a permanent bow-out of 0.39 in. on a 0.010 in. thick, 0.5 in. wide, and 4 in. long beryllium strip. A simple computation of Euler buckling loads for the type of strip considered by the authors shows the first critical buckling load to be about ½ lb, second critical buckling load to be about 2 lb, and so on. All these clearly show that Eq. [A-15] used by the authors for computing P

[2] S. Timoshenko, *J. Opt. Soc. Am.*, **11**, 233 (1925).

for the present problem is not valid and gives unrealistically high values. Consequently, the stress equations, [A-16], [A-17], [A-18], and [A-19], will give erroneous stress values.

The discrepancy is further corroborated if one computes the bow-out based on the authors' Eq. [1] and [2] by using the values of $\Delta\alpha$ from Fig. 4 and compares it with measured values of bow-out presented in Table II. The computed values differ by as much as 100% from the measured values and are on the lower side.

Ignoring the basic assumptions leads the authors to compute stress and load values which are very high and totally unrealistic.

A Simple Procedure for Mounting Sodium-Tungsten Bronze Electrodes

R. S. Alwitt and A. K. Vijh (pp. 413-414, Vol. 117, No. 3)

A. Belanger, G. Belanger, and A. K. Vijh[3]: We have recently applied the suggested procedure of electrode mounting to graphite rod electrodes (National "Spectroscopic Electrodes" obtained from the Carbon Products Division of Union Carbide of U.S.A.; diameter of the electrodes 1/16 in.) and found that some modifications are needed. The graphite rod electrodes were initially prepared as described in the above publication (with contact to a copper wire through a mercury drop) and were tried as anodes for the electrolysis of aqueous sodium chloride solutions. It was observed that the chlorine evolved migrates through the graphite rod and attacks severely the mercury contact and the copper wire forming chemical compounds which are presumably insulating, thus giving rise to terribly bad contact, in addition to creating unwanted, solid-state electrochemical couples. The ease with which chlorine migrates through this graphite electrode suggests presence of some porosity in the graphite. The porosity, however, is definitely not high enough to allow diffusion of the electrolyte solution through the graphite. In any case, if a corrosive gas diffuses through the bulk of an electrode material (with or without porosity) the procedure of Alwitt and Vijh has to be somewhat modified. For graphite rod electrodes, we have changed this procedure slightly in the following way: A platinum wire was first flame-sealed into the Pyrex "trubore" tubing; the outer end of this platinum wire was heated into a small bead and was mechanically fitted into a matching tiny vertical hole drilled into the graphite rod. The bead is unnecessary if a thicker platinum wire which fits tightly into the drilled hole is available. The glass-(platinum)-graphite boundary was masked by the Flotite Teflon tubing (as in the paper under discussion). The mechanical seal between graphite and platinum, though far from being a perfect electrical connection, yields a contact which is satisfactory for most of the laboratory experiments since the ohmic resistance is less than *ca.* 0.2 ohms. A graphite electrode thus mounted is shown schematically in Fig. 1 published here. This electrode assembly has been found to be quite satisfactory for prolonged anodic evolution of chlorine.

Physical and Mechanical Properties of Electrodeposited Copper

III. Deposits from Sulfate, Fluoborate, Pyrophosphate, Cyanide, and Amine Baths[1,2]

Vernon A. Lamb,[3] Christian E. Johnson,[4] and Donald R. Valentine[5]

National Bureau of Standards, Washington, D. C. 20234

ABSTRACT

This paper is the third published report on the results of a broad program on properties of electrodeposited copper, sponsored jointly by the American Electroplaters' Society, The International Copper Research Association, Inc., The Copper Development Association, and the National Bureau of Standards. The first paper is a comprehensive review of the literature to 1965. The second paper is an interim report on experimental results. The present and final paper, which incorporates the data in the second, includes data from the baths designated in the title, for deposits prepared under a wide range of operating conditions and with use of a variety of addition agents. Properties measured include tensile strength, yield strength, elongation, modulus of elasticity, fatigue strength, hardness, internal stress, density, electrical resistivity, and thermal expansivity. Properties were measured for as-plated deposits, deposits after annealing at several temperatures, after cold-working, and at low and high ambient temperatures. Structure of deposits was examined by optical, electron micrograph, and x-ray methods. Content of impurities in deposits was determined. Correlations are developed among properties, structure, impurity content, type of bath, and operating conditions.

I. Introduction

The properties of wrought metals can be varied over wide ranges by alloying, by various heat treatments, or by mechanical working. By these procedures, properties are tailored to fit various applications. Electrodeposited metals are often and increasingly used for electroforming and other engineering applications for which specific properties are required or would be advantageous. As with wrought metals, properties of a particular electrodeposited metal can also be varied over wide ranges. This may be done by varying the type and composition of the plating bath, by use of addition agents or alloying constituents in the bath, or by varying the operating conditions, *e.g.* current density, bath temperature, agitation, or use of modulated current. Properties of electrodeposited metals may also be modified subsequent to formation by heat treatment or mechanical working. Although interest in properties of electrodeposited metals is not new, early applications of plating were such that the need for data on properties was limited, and therefore no comprehensive data had been reported. Special military applications during World War II stimulated work in this area and led to an extensive study of the properties of electrodeposited chromium (1). From 1948 to 1952, a comprehensive project on determination of the properties of electrodeposited nickel was carried out under joint sponsorship of the American Electroplaters' Society and the National Bureau of Standards (2).

Except for nickel, more copper is electrodeposited for technical and engineering applications than any other metal. A considerable amount of data on properties of electrodeposited copper was available prior to the present program. However, there were many gaps and inconsistencies. A broad program to determine physical and mechanical properties of electrodeposited copper was therefore initiated at the National Bureau of Standards, sponsored jointly by the American Electroplaters' Society, the International Copper Research Association, the Copper Development Association, and the National Bureau of Standards.

Key words: electrodeposited copper, copper electrodeposits, copper-electrolytic sulfate, copper-electrolytic fluoborate, copper-electrolytic pyrophosphate, copper-electrolytic cyanide, copper-electrolytic amine, physical properties-electrolytic copper, mechanical properties-electrolytic copper, tensile strength-electrolytic copper, yield strength-electrolytic copper, ductility-electrolytic copper, modulus-electrolytic copper, fatigue strength-electrolytic copper, hardness-electrolytic copper, internal stress-electrolytic copper, density-electrolytic copper, electrical resistivity-electrolytic copper, thermal expansivity-electrolytic copper, annealing-electrolytic copper, cold working-electrolytic copper, hot properties-electrolytic copper, low temperature properties-electrolytic copper, structure-electrolytic copper, impurity content-electrolytic copper.

FOOTNOTES TO TABLE I

[a] Agitation. Air agitation was used for all baths except cyanide baths, except as noted in the "other variable" column in the table. Agitation of cyanide baths CN-1 through CN-4 was effected by pumping the solution upward past the specimen panel. Baths CN-5 through CN-9 were agitated by a combination of pumped solution and propeller stirring, except as noted in lines 136 and 137.
[b] Deposit thickness. Deposits from sulfate, fluoborate, and pyrophosphate baths are 15-20 mils (375-500 μm) thick, except as noted.
[c] Bath symbols are defined in Tables II, III, and IV.
[d] Abbreviations: EA + M, ethyl alcohol plus molasses; LA, lactic acid; β-NQ, β-naphthoquinoline; NDS, 1, 5-naphthalenedisulfonic acid; PSA, phenolsulfonic acid; TU, thiourea; TIPA, triisopropanolamine; Prop. A, proprietary brightener for sulfate bath, containing a sulfonate and an azo dye; Prop. B, proprietary brightener of the selenium type for cyanide bath; PR, periodically reversed current.
[e] One pound per square inch (psi) = 0.000704 kilogram per square millimeter (kg/mm²).
[f] 0.05% offset.
[g] KHN = Knoop hardness number.
[h] Negative values represent compressive stresses.
[i] Determined from beam deflection measurements.
[j] Determined from stress-strain curve. Values not designated [i] or [j] determined by measuring strain with resistance strain gauges.
[k] Per cent elongation in 1 in.
[m] Copper sulfate concentrations in the proprietary baths were in the range specified by the vendor, 225 and 200 g/l, respectively, of $CuSO_4 \cdot 5H_2O$.
[n] Values for tensile strength for thin deposits from the cyanide bath, measured by the bulge method, are based on the initial thickness of the deposits. They are, thus, approximately comparable with values measured by tensile pull.
[o] Tensile and yield strengths and elongation for these thick deposits were measured by tensile pull. Strains are elongation, % in 2 in.

The objectives of the project were as follows: to obtain data on the more important mechanical and physical properties of electrodeposited copper, prepared from all of the commonly used types of plating baths under a range of operating conditions; to correlate the properties with these conditions and with the structure and chemical composition of the deposits; and to examine correlations among the various properties.

Availability of systematic data of this character will make it possible for designers and producers of items incorporating engineering-type copper deposits to select and control optimum types of baths and operating conditions, and should stimulate uses of copper deposits for this kind of application. In addition, extensive data of this sort are likely to reveal relationships and disclose questions that will stimulate basic or theoretical researches in the field.

The following properties have been measured in the present study; tensile strength, yield strength, elongation, Young's modulus of elasticity, fatigue strength, internal stress, hardness, density, electrical resistivity, thermal expansivity, tensile strength and ductility at low (−78°C) and elevated (150° and 325°C) temperatures, and effects of annealing and cold-working on several of the preceding properties. In addition, concentrations of impurities and structures have been determined for a representative sampling of deposits.

The values of most of these properties for as-plated deposits are summarized in Table I. Data showing effects of temperature, annealing, and cold-working are summarized in Table XXVII (to be published in November).

This is the third and final paper based on the work done under this project. The first paper was a comprehensive survey of the literature through 1965 on properties of copper electrodeposits (3). The second was a preliminary report on properties of deposits from the sulfate bath (4). In the present paper, in order to make a complete and consistent presentation, we have included the data previously published in Ref. (4). In addition, the present paper includes data from fluoborate, pyrophosphate, cyanide, and amine types of baths.

II. Preparation of Plating Solutions and Deposits

A. Solutions

Composition and operating conditions for all of the baths used are given in Tables II, III, and IV. The black areas in Table II represent conditions under which deposits from sulfate baths were made. They were chosen so as to give several 2-4 point compari-

* The copper metal concentration in F-1 is the same as in the Cu-2 sulfate baths.

sons for a given variable with all other variables constant. Variables not included in Table II, such as addition agents, periodic current reversal, *etc.*, are covered in other tables that are discussed in subsequent sections.

The range of conditions investigated with the fluoborate, pyrophosphate, and amine baths (Table III) is much smaller than with the sulfate bath, but sufficient sets were used to show the effects of the major variables. Cyanide baths, Table IV, were extensively studied. Basis for choice of levels of variables and other details regarding these baths are discussed in the sections containing the results for the respective baths.

Sulfate baths were prepared either from analytical reagent or National Formulary grades of chemicals. The copper fluoborate concentrate, the copper pyrophosphate, and the copper cyanide were plating-grade salts from reliable suppliers. Analytical grade chemicals were used to provide the minor constituents in these baths. Distilled water was used in all cases for both original make-up and maintenance of bath level.

Data in the literature indicate that chloride as an impurity in sulfate baths may have marked effects on deposit properties (3). These baths were therefore checked after purification and periodically during use for chloride content. In new purified baths, chloride was not detected (<1 ppm).[6] In used baths, 2-3 ppm were occasionally found. At this level, chloride has no measureable effect (5).

All baths were purified before use by treatment with 10 g/l of activated carbon, followed by filtration through filter paper. Some of the sulfate baths were also treated with hydrogen peroxide, 1 ml/l, followed by heating to 60°C prior to filtering. Deposits from baths purified by either procedure had the same tensile strength. Following the above treatments, all baths were pre-electrolyzed with a corrugated copper cathode for approximately 10 A-hr/l, at a current density of 0.5 A/dm^2.

As a check on adequacy of purification, spectrographic analyses of several typical deposits were made[7] (Table V). It is seen that only a few metallic impurities were detected, and that these were present at concentrations of only a few parts per million. In a bath that has been operated for some time, equilibrium with the anodes is approached, and bath and deposit purity may depend more on the purity of the anodes than on that of the original bath. Therefore, samples of two of the types of anodes that we used were also analyzed (Table V). No impurities were found at levels that would be expected to cause significant contamination of deposits.

B. Control of Operating Variables

1. Bath concentrations.—Concentrations of the major constituents of each bath were determined by standard analytical procedures (6, 7). The aim was to control the concentration of constituents in operating baths to ±2%. For the most part, this was achieved. In a few cases, slightly larger deviations occurred but were insufficient to produce significant effects on deposits.

2. Temperature and current density.—Temperature was controlled to ±1°C with automatic equipment. Consistent use of vigorous agitation insured uniformity within this range throughout the bath. Current density was controlled to ±5%. Current for most overnight runs was monitored with a recorder.

C. Equipment

1. Tanks.—Plating baths were contained in glass battery jars. Two shapes were used, 8 x 13 in. and 12 x 12 in. in horizontal section. Filled to a depth of 14 in., they contained 27 and 30 liters of solution, respectively. A few panels (serial No. 68-77, addition agent phenolsulfonic acid) were plated in a polypropylene tank.

[6] ppm signifies parts per million by weight.
[7] Determinations were made by Virginia C. Stewart, Analytical Chemistry Division, NBS.

[a] Values were determined by semiquantitative spectrographic analysis. Where no value is shown, the content was less than 0.0001%. The designation 0.000X indicates a probable trace in the range 0.0001-0.001%. Other elements checked for but not detected in the deposits, *i.e.* if present their levels were less than 0.0001%, include Al, As, Au, B, Ba, Be, Bi, Cd, Ce, Co, Cr, Ga, Ge, Hf, Hg, In, Ir, La, Na, Nb, Os, Pd, Pt, Rh, Ru, Sb, Sc, Sn, Sr, Ta, Te, Th, Ti, Tl, U, V, W, Y, Zn, Zr.
[b] Deposited with periodically reversed current, 15-5 sec cycle.

2. Cathode boxes.—Uniform current distribution and deposit thickness were obtained on specimen panels by boxing them closely with a nonconducting shield. In the jar with 8 x 13 in. horizontal section, boxing was supplied by the bottom and sides of the jar itself, with the 8 x 14 in. panel set against one short side of the jar. In the jar with 12 x 12 in. horizontal section, the panel was enclosed in a cathode box, open at the top and toward the anodes. The width of the sides was 6 in. An air distribution channel was built into the lower front edge of these boxes. It contained six evenly spaced outlet holes, 1/16 in. in diameter. The line of holes was parallel to the panel and spaced 4 in. from it. Discharge of air or liquid through these holes provided agitation that was uniform along the width of the specimen panel.

Early preliminary experiments with the sulfate bath yielded panels that varied in hardness from top to bottom if the air was discharged close to the panel (*e.g.*, 1 in.) or if the rate of air flow was appreciably less than that given in the next paragraph. Various box materials were used, namely, methyl methacrylate polymer, polypropylene, and Teflon. The methylmethacrylate was used only in the sulfate baths. Experiments described in Section III showed that contact of the baths with these resins did not affect properties of deposits.

3. Heating, cooling, pumps, filters, and agitation.—Heaters were quartz electric units.

A 1 hp commercial chilling unit was used for maintaining the bath temperature during high current density operation and for operation at 20°C. The chiller maintained a low temperature in a water ballast tank. Ballast tank water was circulated with a thermostatically controlled pump through a water jacket surrounding the plating tank when cooling was required.

Pumps for circulating the plating solution, and filter bodies, were made of either polyvinylchloride or polypropylene. In the early work with sulfate baths (panel serial No. 1-67), solution was pumped continuously into a large glass funnel containing a paper filter. For subsequent deposits from sulfate baths, a commercial filter-pump unit was used with a cotton filter cartridge. The reason for the choice of the cotton is discussed later. A cotton filter was also used for the fluoborate baths, but for all other baths cartridge filter units of polypropylene were used.

For the early sulfate deposits, air for agitation from the building supply line was filtered through a 4 ft long column of cotton. Air for all subsequent deposits was obtained from an oil-less blower, with the output filtered through a mixture of cotton and granular carbon, packed in a 20 liter bottle. The rate of flow of the air was approximately 10 l/min. This provided vigorous agitation, judged to be comparable to what would normally be used in a commercial installation. In general, air was used for agitating all baths except the cyanide types, though it was also used for the latter for a few deposits from the high-efficiency bath (CN-8). Some exceptions are noted in Table I.

For cyanide baths CN-1 through CN-4, agitation was provided by pumping plating solution through the same cathode-box distribution holes that were otherwise used for air distribution. Flow rate was approximately 4 l/min. This agitation was supplemented by the natural flow induced by evolution of hydrogen at the panel surface. For deposits from cyanide baths CN-5 through CN-9, additional agitation was found to be necessary to prevent excessive top-to-bottom variation of deposit thickness. It was provided by a non-

conducting propeller blade, 3 in. diameter, located about 1 in. below the center of the panel, rotated at about 400 rpm.

4. *Anodes and anode bags.*—Three types of anodes were used: electrolytic sheet, oxygen-free, and phosphorized. There were no significant impurities in the first two types (Table V). Phosphorized anodes were not analyzed because they were used only in the proprietary bright sulfate bath, in accordance with the vendor's recommendation. The electrolytic sheet anodes were used in all sulfate baths. Before use, they were heated to 600°C for 1 hr to carbonize any organic inclusions that might be present, such as glue. The oxygen-free anodes were used in all cyanide baths.

Anode bags made of polyvinylchloride fabric were used for the early sulfate deposits and bags made of napped polypropylene for all later baths. Before use, bag materials were thoroughly freed of weaving lubricants by a combination of solvent cleaning and leaching with portions of plating bath which were discarded. (Filter units were treated similarly.)

D. Deposits

The standard thickness of specimen deposits was 18-20 mils (500 μm). A few thinner deposits were made for determining the effects of thickness on properties. Deposits were formed on Type 304 stainless steel starting sheets, 8 x 14 x 0.03 in. The sheets were polished as required to remove surface imperfections, buffed with a fine emery compound, degreased, scrubbed with fine pumice, and dipped for 1 min in 1:1 nitric acid to passivate the surface. A flash plate of nickel about 0.1 mil thick was applied from a Watts bath and the panel transferred after rinsing with distilled water to the copper plating bath.

The nickel starting plate was used because it covered the stainless steel more uniformly and quickly than did copper, and separated easily, whereas copper plated directly on the stainless steel, at least from the acid baths, occasionally exhibited sufficient local adhesion to make separation difficult. On completion of plating, the copper deposit was freed from the starting sheet by trimming the edges. It separated easily. The nickel flash, which adhered to the starting face of the copper, was removed by stripping it anodically in a solution containing, in parts by volume, 50 of conc H_2SO_4, 50 of 85% H_3PO_4, and 5 of water. The stripping operation removed about 0.01 mil of copper. This did not affect the measured values of tensile strength and elongation. A band 1 in. wide all around the panel was trimmed and discarded. The remaining portion, with dimensions of 6 x 12 in., was uniform in thickness within ±5% for most deposits. It was more difficult to obtain uniform top-to-bottom thickness of deposits from cyanide baths. In general, these varied in thickness about ±10%.

The various specimens required for measurements of properties were cut from these panels.

III. Deposits from Sulfate Baths

A. Mechanical Properties

1. *Methods of measurement: tensile and yield strengths, elongation, Young's modulus of elasticity, and hardness.*—Tensile specimens were made by milling a stacked bundle of specimen stock that had been sheared to ¾ x 6 in. Dimensions of finished specimens conformed to ASTM specifications except for a shorter grip length (8). The width of the reduced section of a standard specimen was 0.5 in. and gauge length 2 in. The specification also describes a subsize specimen with a reduced section ¼ in. wide and 1 in. gauge length. A few subsize specimens were used, identified in Table I by listings of elongation as per cent in 1 in. Ultimate tensile strengths were determined by testing specimens in a standard tensile machine, which plotted load and elongation. Yield strengths were determined from these curves. The linear speed of loading for the tensile test was 0.030 in./min. Cross-sectional area of a specimen was determined from its width, measured by micrometer caliper, and its thickness calculated from its weight and area. Three specimens were usually made from each panel, from top, center, and bottom zones.

For triplicate specimens from the same panel, the deviation of tensile strength from the mean for about 80% of the panels was within ±5%. For the remaining 20% of the panels, deviations ranged from ±6 to ±15%.

Elongation measurements were more variable. Again, for triplicate specimens from the same panel, the deviation from the mean for about 80% of the panels was within ±5%. For the remainder, the deviation ranged up to ±33%. The high deviations were mainly for specimens having a low elongation, so that a relatively small absolute deviation corresponded to a large relative deviation. It is therefore more meaningful in the case of elongation to express deviation in absolute rather than relative terms. A deviation of ±5 absolute percentage points encompassed all but two of the panels.

Three procedures were used for obtaining modulus of elasticity, namely, measurement of the slope of the initial part of the stress-strain curve plotted by the tensile machine, measurement of beam deflection, and measurement of strain for small loads with resistance strain gauges. For the beam deflection procedure, a strip of specimen stock 1 x 15 cm was mounted as a cantilever and its vertical deflection with dead-weight loads measured with a microscope. In the strain-gauge method, gauges were cemented to both sides of a standard tensile specimen, using the manufacturer's recommended adhesives and procedures. The specimens were stressed in a sensitive, small-capacity pulling unit and strain measured in terms of change of resistance with a Mueller Bridge having a sensitivity of 0.0001 ohm. Elongation sensitivity was about 1 μin. In calculating the modulus, allowance was made for the contribution of the gauge and cement to the strength of the assembly. The strain-gauge method was the most accurate and reliable of the three and was used for obtaining most of the values given in Table I and the various subtables. Data that were obtained by the other methods are noted in the tables.

The values reported for modulus of elasticity are judged to be accurate to ±1 x 10^6 psi.

Hardnesses of deposits were measured on metallographically mounted and polished cross sections. A Tukon microhardness tester was used, with a Knoop indentor. For the thicker deposits, a 200g load was used. For most of the thin deposits from the cyanide baths a 100g load was used, but for a few of the thinnest deposits a 50g load was used. Where intercomparisons between hardnesses determined with different loads are made in some of the subsequent tables and figures, corrections have been made to place all values on a 200g load-basis, by substracting 11 hardness units from values determined with a 50g load, and 6 hardness units from values determined with a 100g load. These difference factors for load effect were determined from comparative measurements on our specimens.

Hardnesses were usually run in duplicate, with specimens from top and bottom zones of a panel. Most of the individual values were within ±5 KHN[8] units of the tabulated average values.

2. *Reproducibility of properties.*—It is important that a deposit obtained from a particular type of bath under particular operating conditions be representative of those conditions and that observed properties can be reproduced under like conditions at any time. The purification and control procedures described above were thought to be adequate to achieve reproducibility, but evidence was required. Among properties that we considered for monitoring the reproducibility of deposits were tensile strength, hardness, electrical resistivity, and polarization. Hardness, which served this

[8] Knoop hardness number, kg/mm².

purpose for nickel (2), was found to be unsuitable for deposits from the sulfate bath because of low correlation with other properties. Our preliminary measurements showed this, as did the results of our literature survey (3) and the work of Read (9). Electrical resistivity was found to vary too little with change of independent variables to provide a good criterion of reproducibility. Polarization measurements should, in principle, serve the purpose, but we found them impractical because of the time and effort required to check their reliability and reproducibility. Tensile strength appeared to be the property best suited as a monitor of reliability and reproducibility of baths and deposits.

Results of some checks on reproducibility of properties are shown in Table VI, in which comparable members of pairs are juxtaposed. In the cases of lines 18-19 (line numbers refer to serial positions in Table I), 24-25, and 54-55, the compared specimens were made at different times with different bath preparations. Panels represented in lines 14-15 and 85-86 were made from the same baths and at close time positions. Tensile strengths and elongations are seen to agree closely for members of pairs. The exception of elongation on line 26 is discussed below.

Reproducibility of hardness was good for pairs on lines 14-15 and 85-86, but poor on lines 24-26 and 54-55. The variation for lines 24-26 is related to that for elongation and is also discussed below. The poor agreement on lines 54-55 may be an addition agent effect. Baths containing naphthalenedisulfonic acid (NDS) require prolonged pre-electrolysis, which causes a change in composition of the addition agent, associated with a change of color, and may be also related to deposit hardness even though tensile strength and elongation were not affected.

We concluded from such comparisons that reasonable reproducibility was achieved with the purification and control procedures that had been adopted. However, at a point about one year along in the project, difficulties were encountered. Baths that had given deposits with properties as in lines 18-19 began to yield deposits with properties like those in line 89 (last line in Table VI), characterized by very low strength and ductility. In appearance these deposits had a coarsely faceted, spangly surface, whereas the deposits that had been obtained previously had a relatively fine-grained, smooth surface. The degree to which this effect occurred varied. The deposit of line 89 was intermediate. Some deposits were more coarsely faceted than this and so weak that they bent under their own weight. On bending such a deposit to a short radius, cleavage occurred between facets. Others, only slightly faceted, showed perhaps half the reduction of strength seen for panel No. 78C (line 89). To identify these deposits, we refer to them in succeeding discussion as "spangled." A few deposits of this type had been obtained early in the program. At that time we ascribed the cause to accidental impurities, because a repurified bath generally yielded the fine-grained deposits that we considered to be normal. Spangled deposits became a persistent problem when we put into operation a new plating installation that we thought would improve the maintenance and control of baths and operating conditions and permit faster production of specimen stock. The plating had previously been done in the 8 x 13 in. glass jar units with continuous filtration of the plating solution through a paper filter in a large funnel, as described above (Par. II-C-3).

The new installation employed a 12 x 24 x 18 in. deep polypropylene tank, equipped with a high-speed polypropylene filter-pump unit containing a polypropylene filter cartridge, a methacrylate resin cathode box, polyvinylchloride piping, and an anode diaphragm of polyvinylchloride fabric. A new air supply from an oil-less compresser was also used. All of the polymeric materials were reputed to introduce no contamination into plating baths. However, the obvious hypothesis, which we assumed initially, was that one or more of these polymers, large areas of which contacted the bath, was introducing a harmful impurity that caused spangling.

Many experiments were performed to locate the source of the supposed contamination. Without describing all of the details, it may be said that the general procedure and results were as follows. Starting with a bath that was yielding the smooth strong type of deposit, it was subjected in turn to contact with all of the suspect materials; alternatively, a bath producing spangled deposits was repeatedly purified after each of the suspect materials was removed from contact with the bath, one by one. The conclusion reached from these experiments was that none of these materials caused the trouble. In the course of the experiments, it was observed on several occasions that a bath freshly repurified with activated carbon and batch-filtered through filter paper yielded a few normal deposits and then reverted to spangling. After the batch filtration, subsequent filtration was done through a polypropylene cartridge. A related observation made about the same time was that, when the filter paper previously used in the funnel for continuous filtration of a bath in our smaller original unit was replaced with a napped polypropylene cloth filter, spangling soon developed.

The conclusion, or hypothesis, that we have reached as a result of these experiments is as follows. The natural form of a deposit from a highly purified copper sulfate bath approaches a mixture of separate crystals, such as is characteristic of deposits of silver or lead from nitrate baths or cadmium from a sulfate bath. Traces of impurities in the plating solution, which act as grain-refining addition agents, are necessary to prevent coarse, faceted deposits. In our case, the impurity was a cellulosic derivative of the filter paper, perhaps a sulfonate. In commercial baths, muslin or wool fabrics (6) have commonly been used as filter media. Hydrolysis of wool would introduce small concentrations of glue-type compounds. Furthermore,

addition agents have been almost universally intentionally added to commercial baths. Thus, the conditions that we encountered that caused spangling would be rarely observed.

Similar coarsely faceted deposits were obtained by Shreir (10). He reported a correlation with cathode polarization, with low polarization for faceted, and high for smooth, deposits. A higher polarization is the expected effect of an addition agent. However, Shreir's interpretation was different. He believed that the smooth deposits were "normal," and that the coarse deposits, which he obtained after working of a bath, were the result of the presence in the bath of cathodic reduction products of the sulfate ion that caused a lowering of cathode polarization. However, his data were not all consistent with this interpretation. Barnartt (11) has reported copper deposits from a sulfate bath for which he claims a purity of 99.999% which were smooth and fine grained at a thickness of 7 mils. However, it is conceivable that an unsuspected grain-refining impurity may have been present.

Our experiences described above led us to the conclusion that we could not complete the work with the sulfate bath without using a grain-refining addition agent. One alternative would be to continue the slight contamination with cellulose extract to control spangling. The cellulose has a mild effect, producing deposits with nearly the same strength as annealed wrought copper.

A second alternative was to search for an addition agent in the form of a definite compound that would have a mild effect similar to that of the cellulose, but preferable because of its definite characterization. For this purpose we tried dextrin, dextrose, glycerol, glycine, and sorbitol. The results are shown in Table I, lines 43, 44, 48, 49, and 68, respectively. Tensile strengths for the last three were in the correct range and none of them produced appreciable grain refinement. However, they all caused significant embrittlement. We, therefore, returned to the use of a cellulosic filter. However, at this point we were well along with production of deposits from other types of baths, had abandoned the funnel-type filter, and were using solely the equipment consisting of the 12 x 12 in. glass jar with a high-speed filter pump unit. We, therefore, completed the preparation of deposits from sulfate baths in this unit, using a cotton-wound filter cartridge. All deposits from sulfate baths with panel serial numbers of 274 or higher were made in this manner. In Table VI we show a comparison of physical properties as affected by this change in conditions. The deposits averaged in line 26 are duplicates of lines 24-25, except for the more drastic exposure to cellulose of the bath from which the deposits of line 26 were made. It is seen that the later deposits (higher cellulose) are about 20% stronger, are much more ductile, and somewhat softer.

The effect on structure of the difference in the degree of exposure to cellulose is shown in Fig. 1-1 and 1-2. The structures of both deposits are of similar columnar type, but the grain size in panel No. 322 (line 26), which had the more drastic exposure to cellulose, is appreciably smaller than that in panel No. 25.

The structure in Fig. 1-3 (Table VI, line No. 18) is the typical columnar type, whereas the spangled deposit in Fig. 1-4 (Table VI, line No. 89) contains smaller equiaxed grains, reminiscent of an annealed structure. Although the structure of the spangled deposit is distinctly different from that of the other deposits in Fig. 1, it is not obvious from its structure that it should be so much weaker.

The starting surface of the deposits in Fig. 1, and in all succeeding photomicrographs, is at the bottom of the photomicrograph.

3. Effect of thickness on properties of deposits.—The initial layers of an electrodeposit tend to continue the structure of the basis metal for a short distance. If this structure is fine, a transition zone occurs where the deposit grains grow with thickness from the initial fine structure to a coarser structure characteristic of the deposit (12). Properties therefore tend to change with thickness. Examination of the structures of deposits from sulfate baths in Fig. 1 and in later structure figures shows this fine initial grain and the transition zone extending for 3-5 mils. Beyond this zone, the structure changes little with increase in thickness.

A few experiments were conducted to determine the effect of thickness (Table VII, Fig. 2 and 3). Thin deposits, 1-6 mils, are significantly stronger but less ductile than deposits 18 mils thick (Fig. 2). Because of lack of data for intermediate thicknesses or for thicknesses greater than 18-20 mils, the curves in Fig. 2 are drawn as straight lines. Actual curves are probably similar in form to the dotted curves at the top and bottom of Fig. 2. This postulate is reinforced by the form of the resistivity curve in Fig. 3 (curve No. 4) for which a value at an intermediate thickness was

[b] Determined from stress-strain curve.
[c] Metric conversions; one mil (0.001 in.) = 25 μm; one pound per square inch (psi) = 0.000704 kilogram per square millimeter (kg/mm²).

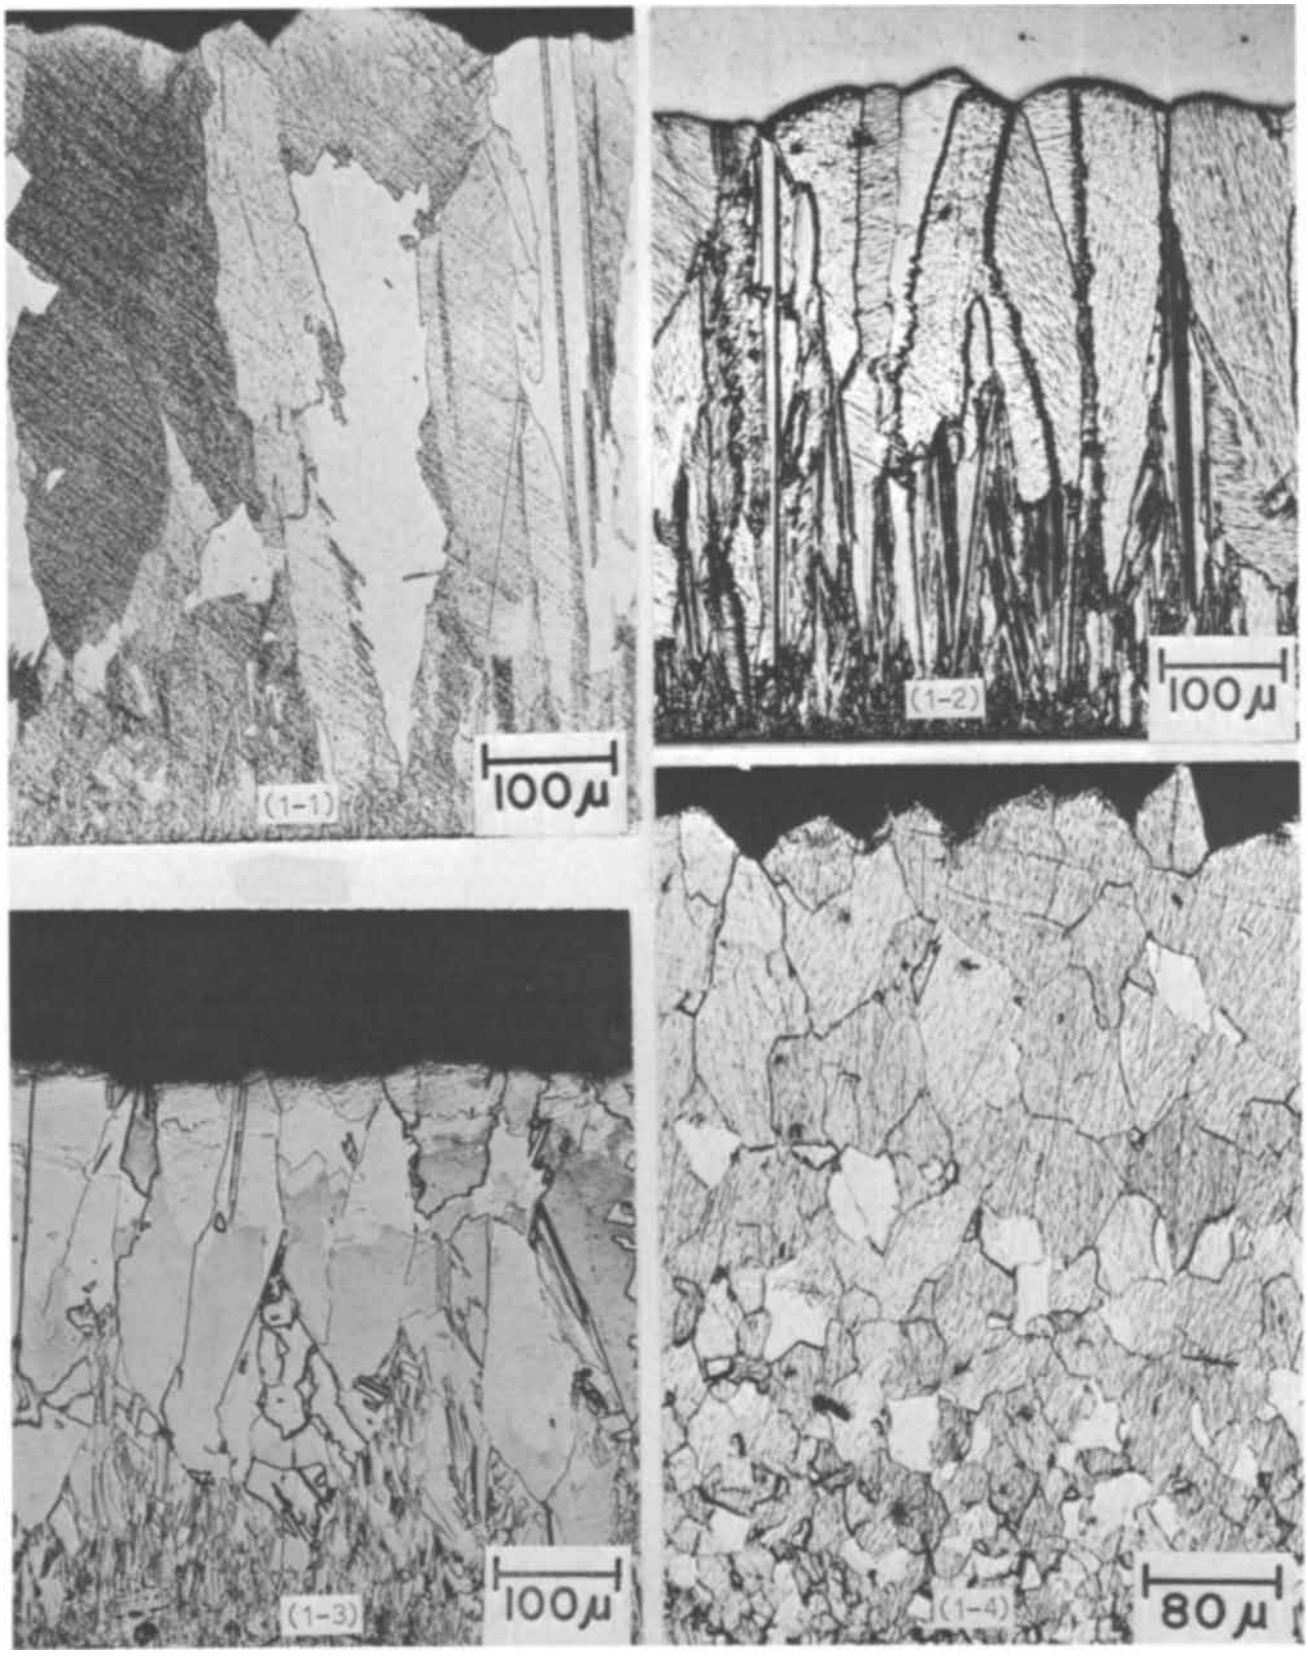

Fig. 1. Effect of contact of sulfate plating baths with cellulose on the structure of copper deposits: Cu2-H2, 30°C, 2 A/dm²—(1-1) Mild exposure to cellulosic filter; (1-2) severe exposure to cellulosic filter. Cu2-H2, 20°C, 2 A/dm²—(1-3) Mild exposure to cellulosic filter; (1-4) Spangled deposit from highly purified bath, no known exposure to any grain-refining agent.

determined. The effect of thickness on tensile strength, elongation, and resistivity is consistent with the transition from the fine-grain structure of the deposit at the starting surface to large grains at a thickness of about 5 mils (Fig. 1).

From Table VII it is seen that the modulus of elasticity is independent of thickness. Data presented later show that there is some variation of modulus with strength, but variations in strength in the present data are too small to reveal an effect on modulus.

Variation of hardness with thickness is indeterminate from our data. If thickness has an effect on hardness, it is minor.

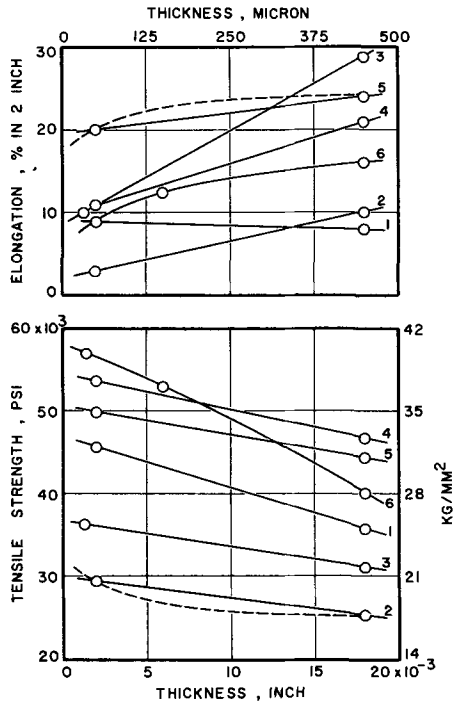

Fig. 2. Relationships between thickness, tensile strength, and elongation of copper deposits from the Cu2-H3 bath at 30°C, 2 A/dm², and containing addition agents as follows: 1—0.1 g/l β-naphthoquinoline; 2—0.05 g/l lactic acid; 3—1.8 g/l 1,5-naphthalenedisulfonic acid; 4—10^{-4} g/l Se; 5—10^{-3} g/l Se; 6—3.5 g/l triisopropanolamine.

Changes of properties with thickness also occur in deposits from standard cyanide baths, but probably for a different reason, to be discussed later. Because of their uniform grain size, one would not expect thickness to affect the properties of deposits from pyrophosphate, amine, or high efficiency type cyanide baths to the same extent as it does those of deposits from sulfate baths (see Fig. 34 and 59).

If an addition agent had sufficient effect to completely suppress a columnar structure (see Fig. 20-9, 20-10), one would not expect properties to vary with thickness. However, none of the addition agents shown in Table VII completely suppressed the columnar

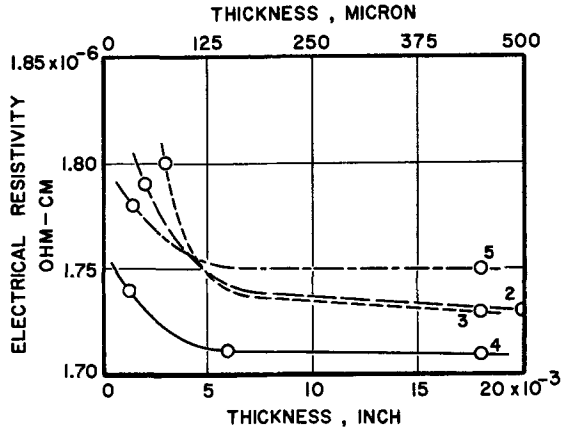

Fig. 3. Relationship between thickness and electrical resistivity of copper deposits from the sulfate bath: 2—Cu2-H2, 30°C, 2 A/dm²; 3—Cu2-H2, 20°C, 2 A/dm²; 4—Cu2-H3 plus naphthalenedisulfonic acid, 1.8 g/l, 30°C, 2 A/dm²; 5—Cu2-H3 plus triisopropanolamine, 3.5 g/l, 30°C, 2 A/dm².

structure of sulfate bath deposits (Fig. 20-2 to 20-8), with the result that the properties of these deposits, as well as those from nonaddition agent baths, vary with thickness.

4. Effect of operating conditions and bath composition.—a. Bath temperature.—Data on the effect of bath temperature on mechanical properties of deposits from sulfate baths are collected in Table VIII. Variation of tensile strength and elongation with temperature is plotted in Fig. 4. Both of these properties decrease with increase in bath temperature in most cases. The reverse effect for tensile strength, seen in two curves in Fig. 4 and in lines 39-41 and 80-86 of Table VIII, has a maximum magnitude of ±9.5%; thus, its significance is doubtful (Section III-A-1). A similar analysis applies to the data for elongation. We conclude that increase of temperature generally causes a decrease of tensile strength and elongation. Since the magnitudes of the effects are small, they may be obscured by minor variations in other conditions or by inherent errors of measurement.

Values of yield strengths as a function of temperature are given in Table VIII. In general, yield strength parallels tensile strength, and is similarly related to bath temperature.

The data for hardness in Table VIII are analyzed as follows. Out of nine sets of data, hardness decreases with increase in temperature in six of the sets and is unaffected in two. In three of the 3-member sets, minor reversals of effect occur, smaller than the ±5 KHN units shown in Section III-A to be the variability range of duplicates. These reversals are therefore not significant. In only one set (lines 18-29) do the data deviate significantly from the general trend. Thus, the statement made above regarding tensile strength and ductility also applies to hardness; namely, the predominant trend is a decrease of hardness with increase in bath temperature. However, the effect is generally small and it may be obscured in specific cases by the effect of other variables or by inherent errors of measurement.

b. Current density.—Data on the effect of current density on properties are assembled in Table IX. Variations of elongation and tensile strength with current density are shown in Fig. 5. The dominant trend is increase of both elongation and tensile strength with increase of current density, but the effects are not large. A few deviations from the dominant trend occurred.

The reversed relationship noted in comparing the data on lines 41 and 42 requires explanation. It was evident from the appearance of panel No. 297 (line 42) that the deposit approached a "burnt" condition. The current density of 20 A/dm² at 60°C was obviously too high to yield a sound deposit. The decrease of tensile strength and ductility with current density is therefore real and significant in this case. The abnormality of this deposit (panel No. 297) may be seen

[d] Measured by beam deflection method.

in its structure (Fig. 17-C-4) and in its high content of impurities (Table XXXII), in comparison with the normal deposit (panel No. 323).

Data on the effect of current density on hardness given in Table IX indicate no definite relationship between current density and hardness. However, it is shown later that, if *all* nonaddition agent deposits from the sulfate bath are considered, there is a loose correlation between tensile strength and hardness (Fig. 15). Since tensile strength was shown above to have a small positive correlation with current density, it follows that there must be on the average a small increase of hardness with increase of current density. However, the effect is too small to be evident from examination of individual cases.

c. Concentration of copper sulfate.—It is seen from Table X that copper sulfate concentration does not have a significant effect on tensile strength or hardness. There is a sufficient predominance of cases where elongation increased with increase of concentration of copper sulfate to indicate a real effect.

In Table X some properties of commercial wrought copper have been included for comparison with those of electrodeposits from the sulfate bath. It is seen that the tensile strengths of the electrodeposits are nearly the same as that of annealed tough-pitch copper. The latter has a tensile strength of 31,000 psi, whereas the average for all nonaddition agent deposits is 29,000 psi. On the other hand, the average elongation of the electrodeposits, 24%, is considerably less than the 45% of the annealed tough-pitch copper, and the average hardness of the electrodeposits, 60 KHN, is significantly higher than the value of 45 KHN for the annealed tough-pitch copper.

d. Concentration of sulfuric acid.—The effect of the concentration of sulfuric acid on properties of deposits is shown in Table XI. Several sets of data relating tensile strength and elongation to concentration of sulfuric acid are plotted in Fig. 6. There is a consistent trend to increase in strength and elongation for an increase from the intermediate to the high concentration of acid. In the two cases where data were obtained relating the low to intermediate acid concentration, the reverse effect occurs. Thus, the curves in Fig. 6 pass through a minimum. We hesitate to conclude that this is a true relationship without additional evidence. The generally observed parallelism between tensile strength and ductility that occurs with nonaddition agent deposits from the sulfate bath is well illustrated in Fig. 6.

One sees on examining the results for hardness in Table XI that, again, the correlation with the composition variable is equivocal. However, the preponderant

effect is an increase in hardness with increase in acidity.

e. Addition agents.—Data relating addition agents to properties are summarized in Tables XII and XIII and Fig. 7. In both tables, data for the corresponding non-addition agent deposits are shown so that a direct evaluation of the effects of the addition agents can be made. We refer to these as "control deposits." As little as 3 mg/l of gelatin are seen to produce a significant effect on strength, more so than any of the operating or composition variables discussed in the preceding sections. This concentration of gelatin also produces a moderate decrease in ductility and increase in hardness. The effects of concentration of gelatin are shown graphically in Fig. 7. Concentrations of gelatin between 0.003 and 0.1 g/l cause a regular change of ductility and yield strength, with the effect leveling off at about 0.1 g/l. However, tensile strength passes through a maximum, probably at a concentration of gelatin somewhat higher than 0.01 g/l. The high ratio of yield strength to tensile strength at 0.1 g/l is abnormal and probably indicates that the true tensile strength was higher than that observed, and that premature failure occurred due to brittleness (the elongation was nearly zero).

The higher concentrations of gelatin produced a marked increase in hardness (148 KHN at 0.1 g/l).

Phenolsulfonic acid (Table XII, PSA) was used at a concentration of 1.0 g/l and deposits were made over a range of operating conditions. The average tensile strength for all of these deposits was 33,000 psi *vs.* 28,000 psi for the control deposits. The increase is small, but is probably real because it is consistent. PSA has a comparable small but consistent effect in raising ductility and a more definite effect on hardness, with an increase from an average hardness of 57 KHN for the control deposits to 88 KHN for the PSA deposits.

[a] All deposits were made from the Cu2-H3 bath.
[b] Addition agent symbols are defined as follows: EA + M, ethyl alcohol + molasses; β-NQ, β-naphthoquinoline; LA, lactic acid; NDS, 1,5-naphthalenedisulfonic acid; TIPA, triisopropanolamine; Prop. A, proprietary bright acid copper bath containing a sulfonate and an azo dye.
[c] One pound per square inch (psi) = 0.000704 kilogram per square millimeter (kg/mm²).
[d] 0.05% offset.
[e] Negative values represent compressive stress.
[f] Per cent elongation in 1 in. (2.5 cm).

Lines 58-62 in Table XII show the effect of bath temperature on tensile strength and ductility of deposits from baths containing PSA. The decrease in tensile strength is more pronounced than for corresponding nonaddition agent deposits, with the effect of the PSA largely lost at 40°C. Bath temperature has a smaller effect on ductility.

The effects of a variety of other addition agents are shown in Table XIII. Most of these addition agents have only small effects on tensile strength. Dextrin, lactic acid, and thiourea cause small decreases, especially thiourea. Ethyl alcohol plus molasses is neutral in its effect. The addition agents that were most effective in increasing strength were selenium dioxide, triisopropanolamine (13) (TIPA), and the proprietary brightener designated as "A."[9] TIPA was most effective at a relatively high current density. It is possible that the effects of some of the other addition agents might be larger at higher current densities. All of these addition agents resulted in smoother deposits with a visual appearance of grain refinement, but none except Proprietary A yielded bright deposits. TIPA tended to yield deposits peppered with small nodules on a fine-grained background. Efforts to eliminate this defect were not entirely successful. The tendency to cause nodules appears to be an inherent characteristic of this addition agent. Its concentration was also difficult to control due to rapid depletion. Control of selenium dioxide was also difficult. This is natural because of its very low concentration in the bath.

Selenium dioxide and 1,5-napthalenedisulfonic acid (NDS) caused increases in ductility. The effects on ductility of thiourea plus NDS and of Proprietary A were not significant. The other addition agents resulted in significant decreases in ductility, but in no case to the extent of extreme brittleness.

All the addition agents caused significant increases in hardness. β-Naphthoquinoline, selenium dioxide, TIPA, and Proprietary A were most effective, yielding hardnesses in the range of 120-140 KHN.

f. Periodic current reversal (PR).—Plating with periodically reversed current, as developed by Jernstedt (14) and applied to high efficiency copper cyanide baths, results in marked improvements in physical properties, smoothness, and ability to form thick deposits. Periodic current reversal (PR) has less pronounced, but significant, effects on deposits from acidic baths. Applications of PR have been reviewed in previous publications (3, 15).

A clock-type timer system and a large-capacity relay unit were used to control the periodically reversed current. Cycle periods were adjusted to ±5%. A thorough investigation of the effect of PR would require variation of the PR cycle and other operating conditions. We intended only a limited study, to show whether PR significantly affects properties. The cycle used was based on information in the review references cited above.

Our data on the effect of PR on properties of copper deposits are given in Table XIV for deposits from both sulfate and cyanide baths. At this point we consider only the former. Comparing the data in line 79 with that in the next two lines, it is seen that tensile and yield strengths and hardness are increased significantly by use of PR. Comparisons are made with direct current deposits formed at both 2 and 4 A/dm² because, while the instantaneous plating rate with PR is 4 A/dm², the net plating rate is only $4(5 - 2/5 + 2) = 1.7$ A/dm².

The elongation of the PR deposit is between those of the two direct current deposits. The data in Table XIV by themselves are not sufficient to permit a definite conclusion regarding effect of PR on elongation. However, in conjunction with other elongation data shown in Fig. 14, discussed in Section III-E, we conclude that tensile strength and elongation vary inversely for PR deposits.

B. Internal Stress in Deposits from Sulfate Baths

1. Method of measurement and reproducibility.—Data on internal stress are of interest from the theoretical standpoint and are of practical concern in engineering applications, where excessive stress may cause warping and cracking of an electrodeposit. Stress was measured with the Brenner-Senderoff spiral contractometer, using the precautions described by these authors (16). The estimated accuracy of individual determinations of stress is ±300 psi (0.21 kg/mm²).

2. Effect of Thickness of Deposit.—Partly for convenience and partly because internal stress in sulfate deposits, with which we worked first, did not usually increase significantly with increase in thickness beyond 1 mil, this was chosen as the thickness on which to base our measurements. Variation of stress with thickness for several representative types of deposit is shown in Fig. 8 and 9. The curve in Fig. 8 for a deposit from a sulfate bath containing naphthalenedisulfonic

[9] This proprietary addition agent is reported to contain a cationic azo dye and an organic sulfonic acid.

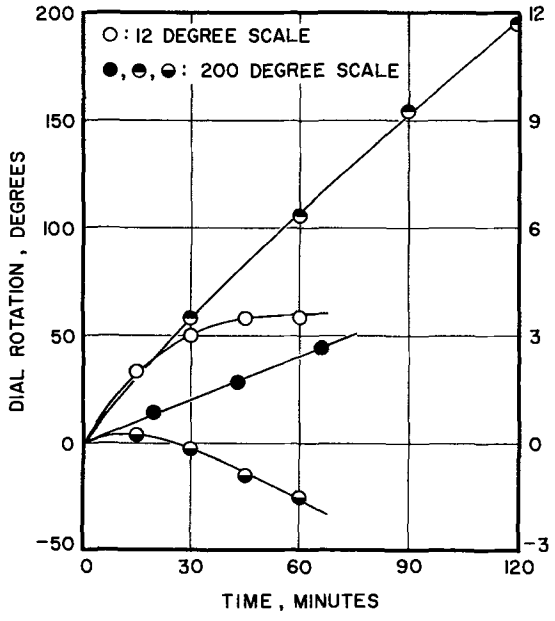

Fig. 8. Increase of internal stress with thickness (plating time) for various types of copper deposits. Dial rotation of 1° equals 70±20 psi, depending on thickness. Negative rotation designates compressive stress. The terminal point of each curve corresponds to a deposit thickness of approximately 1 mil (25 μm). ○—Cu2-H3 containing 1.8 g/l 1,5-naphthalenedisulfonic acid, 30°C, 2 A/dm²; ●—Cu2-H3, 30°, 4 A/dm², PR cycle 5-2 sec; ◓—CN-2, 40°, 1 A/dm²; ◒—pyrophosphate, 50°, 2 A/dm².

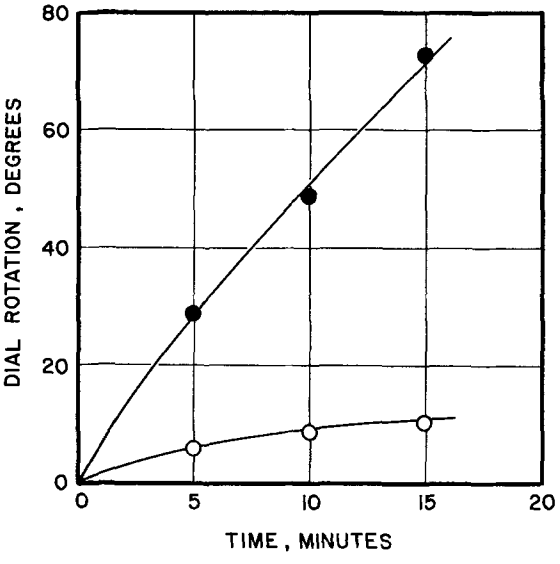

Fig. 9. Increase of internal stress with thickness (plating time) for copper deposits from a sulfate and a fluoborate bath. Dial rotation of 1° equals approximately 65 psi. The terminal point of each curve corresponds to a deposit thickness of approximately 1 mil (25 μm). ○—F-1, 30°C, 8 A/dm²; ●—Cu2-H3, 30°, 8 A/dm².

acid is fairly typical of low-strength deposits from sulfate baths. It is seen that the rate of increase of stress has become nearly zero at a thickness of about 1 mil. This was also the behavior of the deposit from a fluoborate bath (Fig. 9). Stress was still changing at a significant rate at this thickness in deposits of the other types illustrated in Fig. 8 and 9. In these latter deposits, the stress ultimately developed is higher than the value we have reported. However, we conclude on qualitative grounds that the increase in stress, with one exception, soon ceases to increase with thickness, because deposits, after separating from the starting sheet, did not warp and curl. This indicates that either the stress-free later "layers" of the deposit were more predominant in thickness or that stresses were relieved by room-temperature annealing.

The one exception was the deposit made from a sulfate bath with periodic current reversal (Fig. 8 and Table I, line 79). Residual stress was evident in this deposit, causing warping of the 18 mils thick panel. Apparently, reversal of current causes each new layer, cycle after cycle, to deposit with stress comparable to that in the initial layer of a continuous deposit. In general, the deposits that show continued increases in stress at a thickness of 1 mil and which have the higher reported levels of stress have small-grain structures (Fig. 20, 21, 34, 59).

The pyrophosphate deposit (Fig. 8), in which stress is compressive, first went through a brief period in which the stress was tensile. This may be caused by an abnormal initial structure induced by the substrate, with conversion to a structure typical of the conditions as thickness increases.

3. Effect of operating conditions and bath composition.—a. Bath temperature.—Increase of bath temperature causes the internal stress of deposits from sulfate baths to decrease. This is true in an algebraic sense; *i.e.*, if the stress is compressive, increase of temperature makes it more compressive. This is illustrated in Table VIII and Fig. 10 and 11.

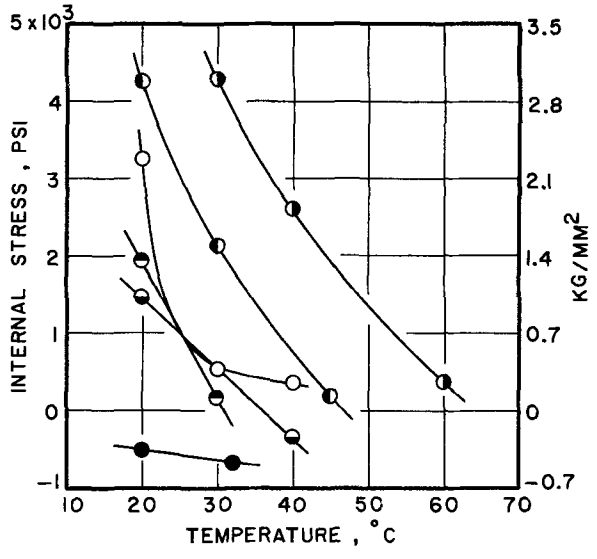

Fig. 10. Relationship between bath temperature and internal stress in copper deposits from sulfate baths. Negative stress is compressive. ○—Cu1-H2, 2 A/dm²; ●—Cu2-H2, 0.5 A/dm²; ◒—Cu2-H2, 2 A/dm²; ◐—Cu2-H2, 4 A/dm²; ◓—Cu2-H3, 2 A/dm²; ◑—Cu2-H3, 8 A/dm².

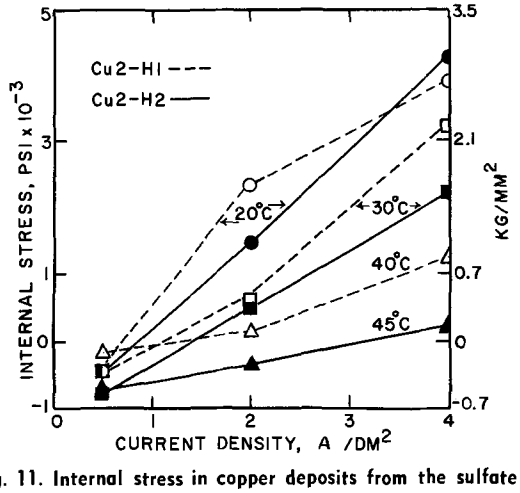

Fig. 11. Internal stress in copper deposits from the sulfate bath: effect of bath temperature, current density, and concentration of sulfuric acid. Negative stress is compressive.

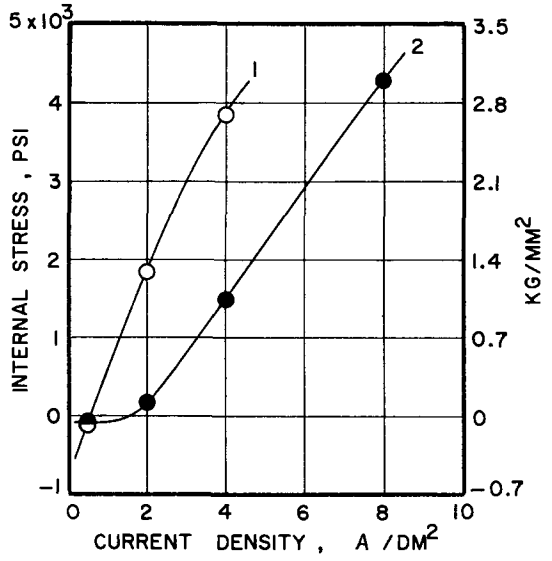

Fig. 12. Relationship between current density and internal stress in copper deposits from sulfate baths. Negative stress is compressive. 1—Cu1-H3, 30°C; 2—Cu2-H3, 30°.

b. Current density.—The effect of current density on internal stress is shown in Table IX and in Fig. 11 and 12. The effect is unequivocal, with significant and consistent increase in stress with increase in current density in each instance.

c. Concentration of copper sulfate.—If the concentration of copper ions in the cathode film is relatively low, this might be expected to cause small grain size and high stress. However, the effect might be small in magnitude unless limiting current conditions were approached. On these hypotheses, one might expect minor effect from change of concentration of copper sulfate in a high concentration range, but that, in passing from an intermediate to a low concentration, increase in stress would be larger. On the other hand, this conclusion is modified by consideration of current density and temperature. If current density is sufficiently low or bath temperature sufficiently high, the tendency for stress to increase with decrease in concentration of copper ion might be nullified. These hypotheses fit the data tabulated in Table X rather closely. Thus, in the first set of data (lines 5, 18, 20), where bath temperature is low, stress increases significantly with decrease of copper sulfate from the intermediate (Cu-2) to the low concentration (Cu-1). In the second set (lines 8, 35, 81), stress does not change significantly with change of copper sulfate concentration and this insensitivity is associated with a very low current density. In the third, fourth, and seventh sets (lines 2-12; 6-24, 25; and 7-28, 29), differences in stress are not significant and this is associated with high bath temperatures (relative to the first set). In the fifth set (lines 9-82), the difference due to the change from Cu-2 to Cu-3 is not significant (less than ±300 psi), in agreement with the hypothesis. There is a significant increase in stress with decrease of copper from Cu-2 to Cu-1. In this case, the concentration of sulfuric acid is high, and this would tend to depress the copper ion concentration by means of the common-ion effect, thus causing an increase in stress. In the sixth set (lines 10-38) the situation is similar to that for the first pair of the fifth set, except that one would expect the effect to be larger because the current density is higher in the sixth set, and a larger effect did occur. Finally, in the eighth set (lines 41-87), due to the high bath temperature and high range of copper concentration, we might anticipate that stress would be little affected by the change of copper concentration, and this is what is observed.

The data in Table X have been discussed in this detail to emphasize that, in all of the interrelationships we have attempted to simplify, many variables interact with complex effects. This may result in apparent discord which might disappear if the effects of all variables could be simultaneously analyzed.

d. Concentration of sulfuric acid.—Data showing the effect of concentration of sulfuric acid on stress are summarized in Table XI and Fig. 11. Counting sets of three as two pairs, there are 17 pairs of data for deposits made with different acid concentrations in Table XI and Fig. 11, jointly. In 13 of these pairs, differences in stress are within or nearly within our estimate of reproducibility of ±300 psi. Two pairs show a small but significant increase of stress with increase of acidity, and two a decrease. We can only conclude that, within the range of concentrations of sulfuric acid that we used, the effect of change of concentration of sulfuric acid is small and its direction undetermined.

One might predict a dual effect: *e.g.*, if conditions are borderline with respect to maintenance of an ample concentration of copper ions in the cathode film, due to a low concentration of copper in the bath, high current density, or low temperature, increase of acidity might, due to the common ion effect referred to in Section III-B-3-c, cause sufficient further reduction of concentration of copper ion in the cathode layer to result in significant grain refinement and increase of stress. Another situation would be that in which the concentration of acid was sufficiently low that basic material codeposited, causing high stress. Increase in acidity might then cause *decrease* of stress. Additional experiments would be required to evaluate this speculation.

e. Addition agents. Effects of addition agents on stress are shown in Tables XII and XIII and Fig. 13.

A concentration of gelatin in the plating bath of 0.003 or 0.01 g/liter results in an increase in stress, whereas with 0.1 g/liter the stress has a large compressive value (Table XII, Fig. 13). Thiourea and Rochelle salt have been reported to have a similar effect (17, 18). The concentration of thiourea that we used (Table XIII) was not large enough to produce stress reversal.

The effect of phenolsulfonic acid is shown in Table XII. Comparing the values of stress in pairs, lines 12 *vs.* 16, 24-26 *vs.* 33, 36-37 *vs.* 59-60, and 82 *vs.* 88, we see that phenolsulfonic acid consistently causes a reduction of stress. This is analogous to the effect of organic sulfonates in nickel baths. On the other hand, 1,5-naphthalenedisulfonic acid (line 54-55, Table XIII) causes a small but not significant increase in stress. The stress value in line 58, Table XII, shows that

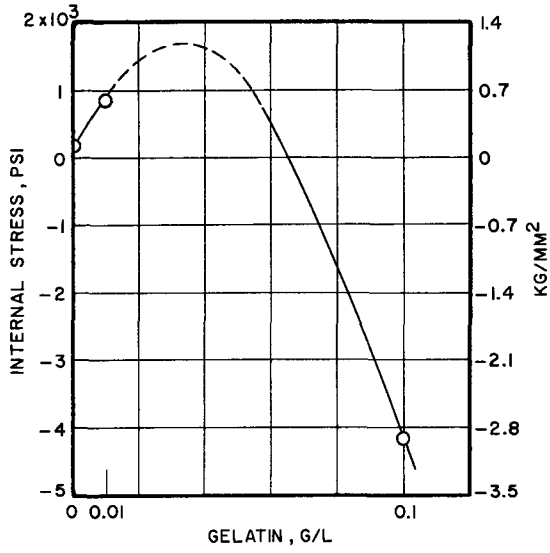

Fig. 13. Relationship between gelatin concentration in the bath and internal stress in copper deposits from sulfate baths (Cu2-H3, 30°C, 2 A/dm²).

decrease of temperature from 30° to 20°C causes a significant increase in stress of a deposit from a bath containing phenolsulfonic acid ($\Delta psi = +1500$). Thus, the effect of temperature is the same as in a non-addition agent bath.

The addition agents listed in Table XIII that are not referred to in the preceding paragraph all caused significant increases in stress. The largest effects were produced by β-naphthoquinoline, selenium dioxide, triisopropanolamine (TIPA), and the proprietary addition agent. However, none of the stresses seen in Table XIII is high enough to cause trouble in most applications of electrodeposits.

f. Periodic current reversal.—Effect of periodic current reversal on stress is shown in the first three lines of Table XIV. It is seen that PR causes a marked increase of internal stress. This has already been discussed in Section III-B-2 in its relation to deposit thickness. It is hypothesized that the high stress may be the result of forming deposit, layer after layer because of the cycling, that has the high stress characteristic of the fine-grained zone next to the substrate in d-c deposits.

C. Density of Deposits from Sulfate Baths

1. Method of measurement and reproducibility.—Knowledge of density is of interest primarily because it depends on purity and structure of deposits. Density was measured by obtaining the mass of a specimen by weighing in air and the volume of the specimen by measuring the buoyant force on it when immersed in a liquid. Precautions required for precision density measurements have been described (19) and were followed with some abridgments. For deposits through panel serial No. 96, the immersion liquid used was water containing a wetting agent. The immersion liquid for subsequent panels was tetrabromoethane. Specimens were made from broken segments of tensile specimens or from rectangular strips ¾ x 5 in. A comparison of the density of a pulled and unpulled specimen showed that the cold-working of a tensile specimen did not affect its density measurably. Triplicate specimens were usually used, each taken from a different position on the panel; from some panels only duplicates were used. No significant effect of position on the panel was found.

Weighings were made to 0.05 mg. Balance case temperature was constant to ±1°C. Temperature of the submersion liquid was measured to 0.1°C. All data were corrected to 25°C. The average variation among duplicate or triplicate sets was ±0.001 and the maximum ±0.004 g/cm³. The accuracy of the reported values is judged to be ±0.005 g/cm³.

2. Results.—Examination of the data in Tables VIII to XI shows maximum variations within given sets of pairs or triplets of ±0.002, ±0.004, ±0.004, and ±0.002 g/cm³ due to the largest applied variations of bath temperature, current density, concentration of copper sulfate, and concentration of sulfuric acid, respectively. Corresponding average densities, respectively, are 8.924, 8.924, 8.923, and 8.923 g/cm³. These data illustrate the remarkably small change of density with change of bath composition or operating conditions.

One exception to this constancy appears in Table IX, line 42, panel 297. This is the high current density deposit referred to in Section III-A-4-b. Its low density of 8.86 correlates with its other abnormal properties.

Some addition agents cause marked lowering of density, while others have little, if any, effect. As little as 3 mg/liter of gelatin cause a significant lowering, while 0.1 g/liter results in the very low value of 8.86 g/cm³ (Table XII). Among the other addition agents used (Tables XII and XIII), only triisopropanolamine at 5 A/dm² caused significant reduction of density.

Periodically reversed current has no measurable effect on density of deposits from the sulfate baths (see Table XIV, first three lines).

Densities of deposits from sulfate baths are summarized in Table XV, in which comparative values for other preparations of copper are also assembled.

D. Electrical Resistivity of Deposits from Sulfate Baths

1. Method of measurement and reproducibility.—Specimens used for measuring electrical resistivity were strips 0.5 x 15 cm. They were clamped in a jig with current contacts at the ends and intermediate voltage contacts 10 cm apart. Two methods were used for the electrical measurements. In the first method, conventional equipment was used for measuring voltage between the two contacts while a measured current was passed. This method was used for specimens from all panels through No. 96. Measurements on specimens from panels made subsequent to No. 96 were made with a commercial milliohmmeter, which operated on the same principle as above, and which had an accuracy of ±1% in the range of resistance within which measurements were made. In both procedures, the equipment was calibrated and measurements of experimental specimens were directly intercompared with a 1 mohm standard resistor. The resistance of experimental specimens was of this order. Two, or usually three, specimens were taken from each panel, from top, middle, and bottom positions. Position did not affect resistivity. Cross-sectional area of specimens was obtained from length and mass. Small corrections were made for surface roughness, as described previously (4). The average deviation from the mean within sets of duplicates or triplicates was ±0.8%, considering all thick deposits (84 sets; thin deposits from cyanide baths excluded). Among these 84 sets, variation exceeded ±1% for only eight sets. Calculated values of resistivity reported in Table I and in the various subtables have been corrected to 25°C by assuming that the temperature coefficient of resistivity of the deposits is the same as that for pure copper (0.0068×10^{-6} ohm-cm/°C) (20).

2. Results.—Variation of electrical resistivity with thickness of deposits from sulfate baths has already been discussed (Section III-A-3, Table VII).

Analysis of resistivity data in Tables VIII to XI shows the following:

	Electrical resistivity, μohm-cm	
	Maximum variation within sets	Average, all sets
Table VIII, effect of bath temperature	±0.035	1.73
Table IX, effect of current density	±0.02	1.73
Table X, effect of concentration of copper sulfate	±0.005	1.73
Table XI, effect of concentration of sulfuric acid	±0.005	1.73

The variations are too small to permit definite conclusions as to the effects of the various parameters. It is seen in these tables that the few cases of maximum resistivity (1.75-1.78 μohm-cm) correspond to either a low temperature (20°C) or a high current density (8 A/dm²) and this is probably significant.

Not included in the above analysis is the deposit made at 60°C and 20 A/dm² (line 42, Table IX) which has been referred to in previous sections as abnormal. It also has an abnormally high resistivity, 1.90 μohm-cm.

Periodic reversal of current caused a small increase in resistivity of a deposit from a sulfate bath (Table XIV, line 79). This is consistent with the fine-grain structure of the deposit and with the higher resistivity of thin deposits (Section III-A-3, Table VII).

Relationships between the resistivity of deposits and addition agents in sulfate baths are shown in Tables XII and XIII. It is seen that gelatin, 0.1 g/l, triisopropanolamine, and the proprietary addition agent produce significant increases in resistivity. Gelatin, 0.003 or 0.01 g/l β-naphthoquinoline, SeO_2, sorbitol, and thiourea cause an increase of about 0.04 μohm-cm, only slightly larger than possible measurement variability, but probably real. Effects of phenolsulfonic acid, ethyl alcohol plus molasses, lactic acid, and naptha-

lenedisulfonic acid on resistivity are smaller than the sensitivity of our measurements.

Some comparative values of resistivity for wrought copper are shown in Table X. The average resistivity of the deposits from nonaddition agent sulfate baths is about the same as that of annealed electrolytic tough-pitch copper (1.73 and 1.74 μohm-cm, respectively). Resistivity values of many individual deposits in Tables VIII to XI are in the range of 1.70-1.72 μohm-cm, which compares with 1.71 reported for high-purity copper (3). Resistivity data therefore indicate a high degree of purity for most of the deposits from nonaddition agent sulfate baths.

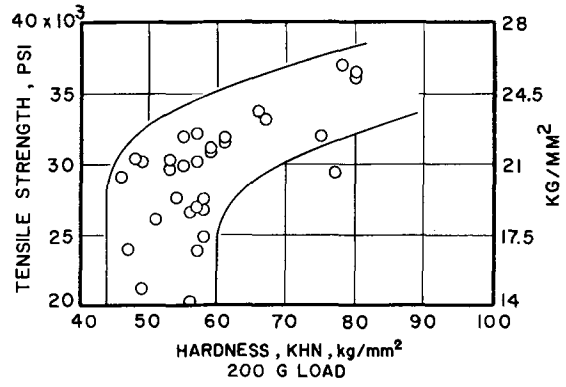

Fig. 15. General relationship between hardness and tensile strength of copper deposits from all nonaddition agent sulfate baths at various operating conditions.

E. Relationships between Properties of Deposits from Sulfate Baths

1. Tensile strength and elongation.—The usual relationship between tensile strength and elongation for wrought metals is inverse; *i.e.*, a high tensile strength is associated with a low ductility and *vice versa*. In Fig. 14 we have plotted values of tensile strength and elongation for all as-plated deposits from sulfate baths, including those containing addition agents. The points fall into three main groups: those enclosed by envelopes A and B, and the group in the intermediate area designated as C.

With a few minor exceptions, the "A" envelope includes all deposits from nonaddition agent baths (except for thin deposits) and deposits from baths containing addition agents that have little effect on tensile strength. These addition agents are dextrin, lactic acid, the two sulfonic acids, and thiourea, 0.005 g/l.

Contrary to the usual relationship, the ductility of these deposits increases with increase in tensile strength. This anomalous relationship has been previously noted by Safranek (21), Read (9), and the present authors (4). The points enclosed in envelope "B" show the expected inverse relationship between tensile strength and elongation. It is seen that this group includes deposits from baths that contain effective addition agents, such as triisopropanolamine and Proprietary A. The deposit made with periodic current reversal is also in this group.

Area C may be referred to as a transition zone. In this zone are found points representing deposits from baths containing addition agents of intermediate effectiveness and points for thin deposits.

Examination of the photomicrographs in Fig. 16-21 reveals that size and type of grain is correlated with these differences in relationships between tensile strength and ductility. The deposits represented in envelope A are composed predominantly of relatively large columnar grains. Those represented by points in envelope B have a fine grain structure and in area C an intermediate grain size. It is assumed that the thin deposits, represented in both envelope B and area C, have a relatively fine structure similar to that of the initially formed portion of the structures seen in Fig. 16-21.

The direct relationship between tensile strength and ductility exemplified by envelope A in Fig. 14 is also seen in Fig. 4, 5, and 6 for nonaddition agent deposits. The inverse relationship corresponding to envelope B in Fig. 14 is further illustrated in Fig. 2. Again, the influence of the finer grain of thin deposits is noted.

It is clear from Fig. 14 and the above discussion that a consequence of the dual relationship between tensile strength and elongation is that low ductility may be associated with either high tensile strength and fine grain structure, or with low tensile strength and coarse grain structure. On the other hand, high ductility is associated with a narrow range of tensile strength. The association of low ductility with either very fine

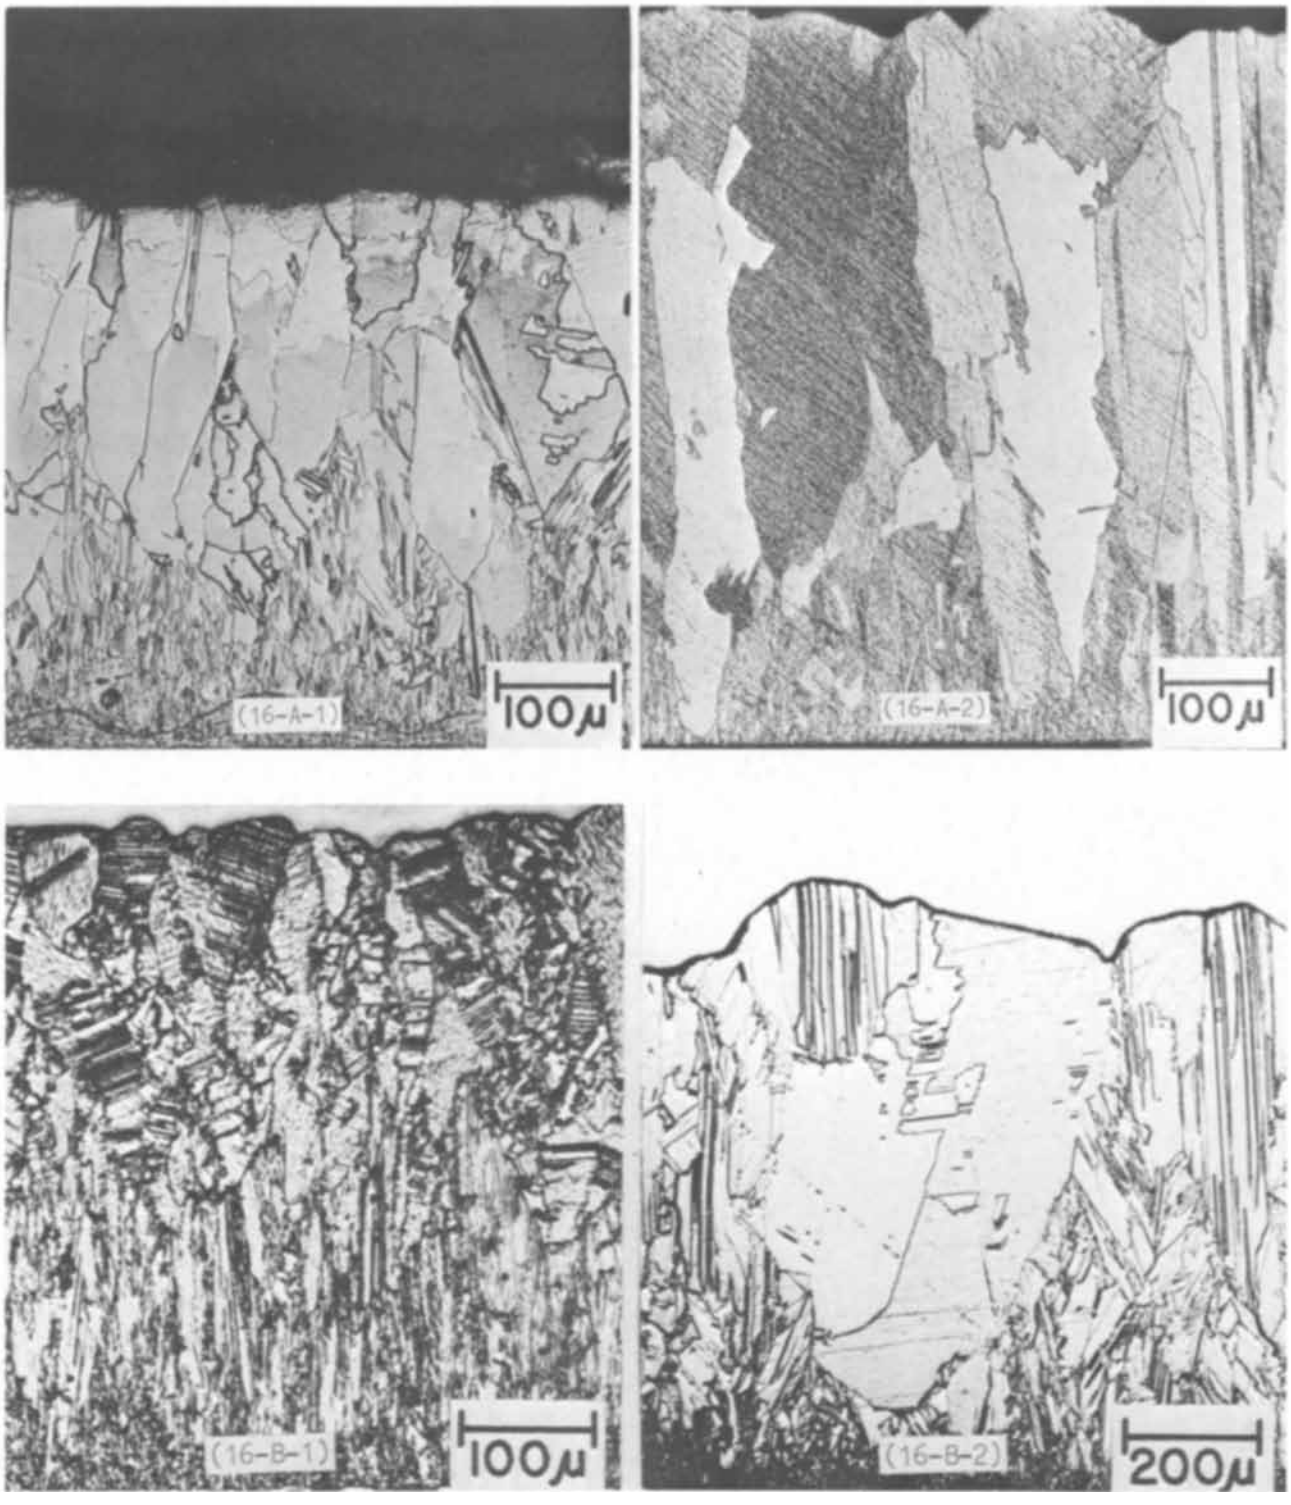

Fig. 16. Effect of bath temperature on the structure of copper from sulfate baths. Part A: Cu2-H2, 2 A/dm^2—(16-A-1) 20°C; (16-A-2) 30°C. Part B: Cu3-H3, 4 A/dm^2—(16-B-1) 20°C; (16-B-2) 60°C.

or very coarse grain structure has been noted by others.[10]

2. Tensile strength and hardness.—Hardness usually increases linearly with the tensile strength of wrought metals. The same relationship has been observed for electrodeposited nickel (2). In Fig. 15 tensile strength is plotted as function of hardness for all deposits from nonaddition agent sulfate baths. It is seen that in the range of tensile strength of 20,000-30,000 psi and hardness from 46 to 60 KHN, distribution of points is quite random, with no apparent correlation. At higher strengths and hardnesses, there is an approximate direct correlation. Data for three deposits that are abnormally hard in combination with low strength, due to a small degree of spangling, were omitted from Fig. 15. In Table XIII, it is seen that deposits made with some addition agents, such as lactic acid (line 50) and thiourea (line 69) have relatively high hardness but abnormally low strength. On the other hand, the addition agents that have been described in preceding sections as "active" or "effective," such as triisopropanolamine and proprietary A, cause increase of both hardness and strength. Thus, addition agents affect hardness and tensile strength independently, so that no general correlations are seen.

F. Structure of Deposits from Sulfate Baths

1. General.—Structure of copper electrodeposits has been more extensively studied than any other property. However, in much of this work there has been no effort to correlate structure with mechanical and physical properties of deposits. The literature on this subject was reviewed in the first paper of this series (3). An extensive study of structure was not a part of this research, although photomicrographs of a sufficient sampling of deposits were prepared to show broad interrelationships.

Standard metallographic procedures were used for preparing specimens. To avoid changes of structure caused by annealing during mounting, the specimens were mounted in a room-temperature curing thermosetting casting resin. Most specimens were given a thick back-up plate of electrodeposited nickel prior to mounting, to protect edges during polishing. Approved polishing procedures were used (20, 22). The final polishing of most of the specimens was mechanical, but several were electropolished also and the structures obtained by the two methods compared to make sure that structure alterations due to surface working were not occurring. Good agreement of structure was obtained. Some of the specimens were etched with an ammonia-peroxide etch (NH_4OH, conc, 5; H_2O_2, 3% grade, 5; water, 5 parts by volume) and some with a dichromate etch (K_2CrO_7, 5g; H_2SO_4, conc, 3 ml; water, 100 ml).

2. Effect of operating variables and bath composition.—*a. Bath temperature.*—Structures for two pairs of deposits with temperature the only variable are shown in Fig. 16. Increase in grain size and decrease in the thickness of the fine-grained basal layer with increase of temperature are seen in both pairs.

b. Current density.—Microstructures for three sets of deposits with current density the only variable within each set are shown in Fig. 17. The series in part A shows a decrease of grain size with increase in current density. Between 0.5 and 2 A/dm² (17-A-1 and 17-A-2), the difference is most marked in the basal zone of Fig. 17-A-2. A significant change of structure to a randomly oriented fine grain is seen on going to 4 A/dm² (17-A-3). This is the only deposit of this character among those we examined from nonaddition agent baths. A minimum concentration of copper, a maximum acid concentration, and a moderately high cur-

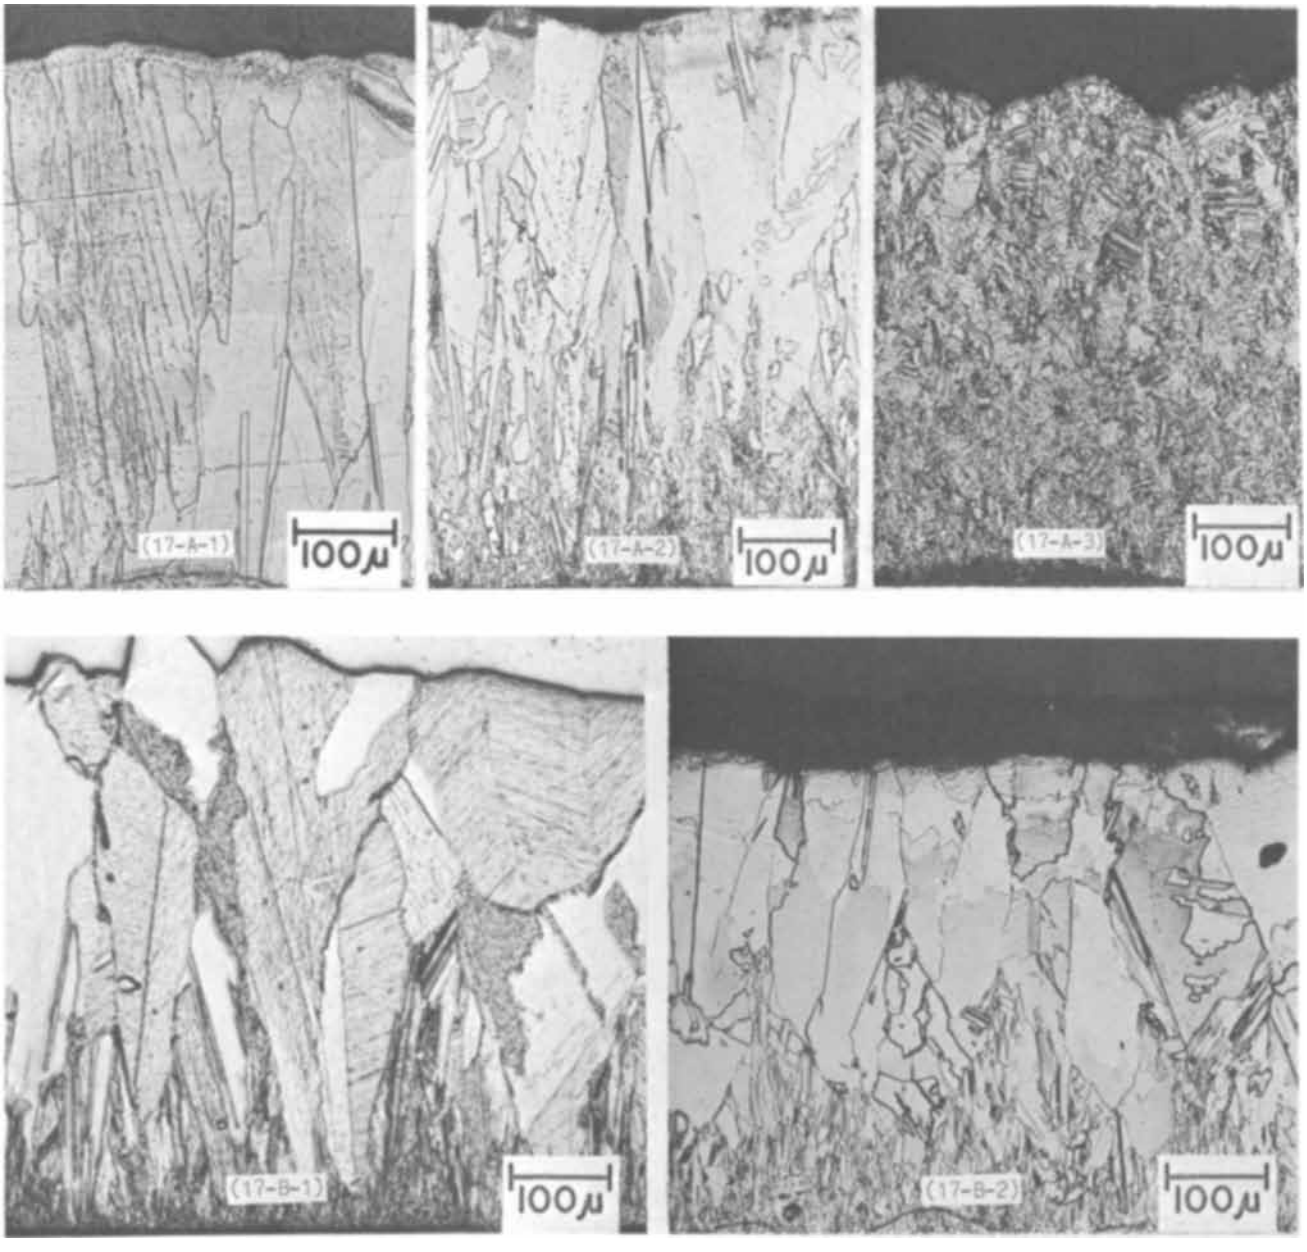

Fig. 17. Effect of current density on the structure of copper from sulfate baths. Part A: Cu1-H3, 30°C—(17-A-1) 0.5 A/dm²; (17-A-2) 2 A/dm²; (17-A-3) 4 A/dm². Part B: Cu2-H2, 20°C—(17-B-1) 0.5 A/dm²; (17-B-2) 2 A/dm².

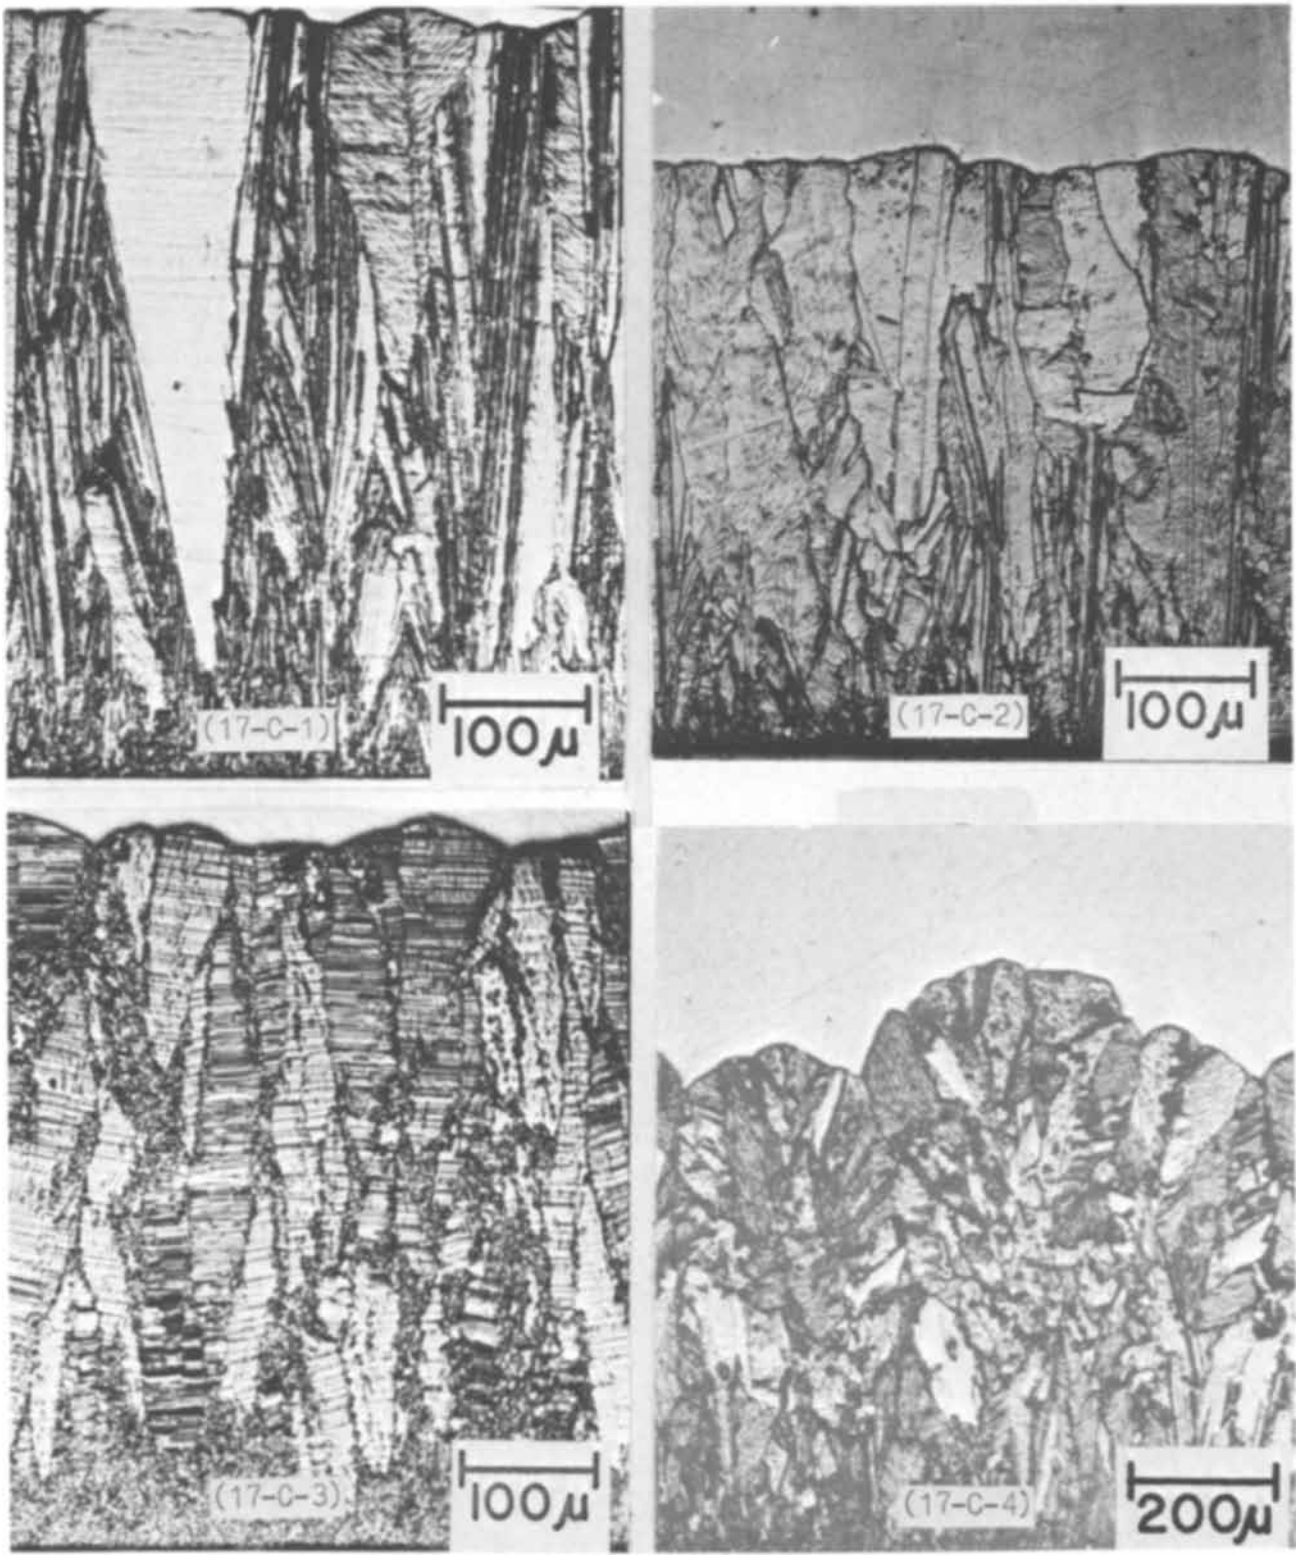

Fig. 17 (contd.). Effect of current density on the structure of copper from sulfate baths. Part C: Cu2-H3, 30°C—(17-C-1) 0.5 A/dm^2; (17-C-2) 2 A/dm^2; (17-C-3) 8 A/dm^2. Part C: Cu2-H3, 60°C—(17-C-4) 20 A/dm^2.

rent density probably combine to produce this effect. Decrease of crystal size with increase of current density is confirmed in Fig. 17-B and 17-C-1 to 3. Figure 17-C-4 is not strictly part of this series but is included here to show the contrast due to a very high current density (20 A/dm^2). This deposit, though not fine grained, is seen to be very nodular. To the naked eye it had a "burnt" appearance and was very weak, as discussed previously in Section III-A-4-b.

c. Concentration of copper sulfate.—The effect of the concentration of copper sulfate on structure is shown in Fig. 18. Even though the structures of the various deposits in this figure are not identical, they are similar to the extent that all of them contain large columnar grains, with no characteristic shift of structure with increase of concentration of copper ion. We conclude that, within the range studied, copper concentration has little effect on structure.

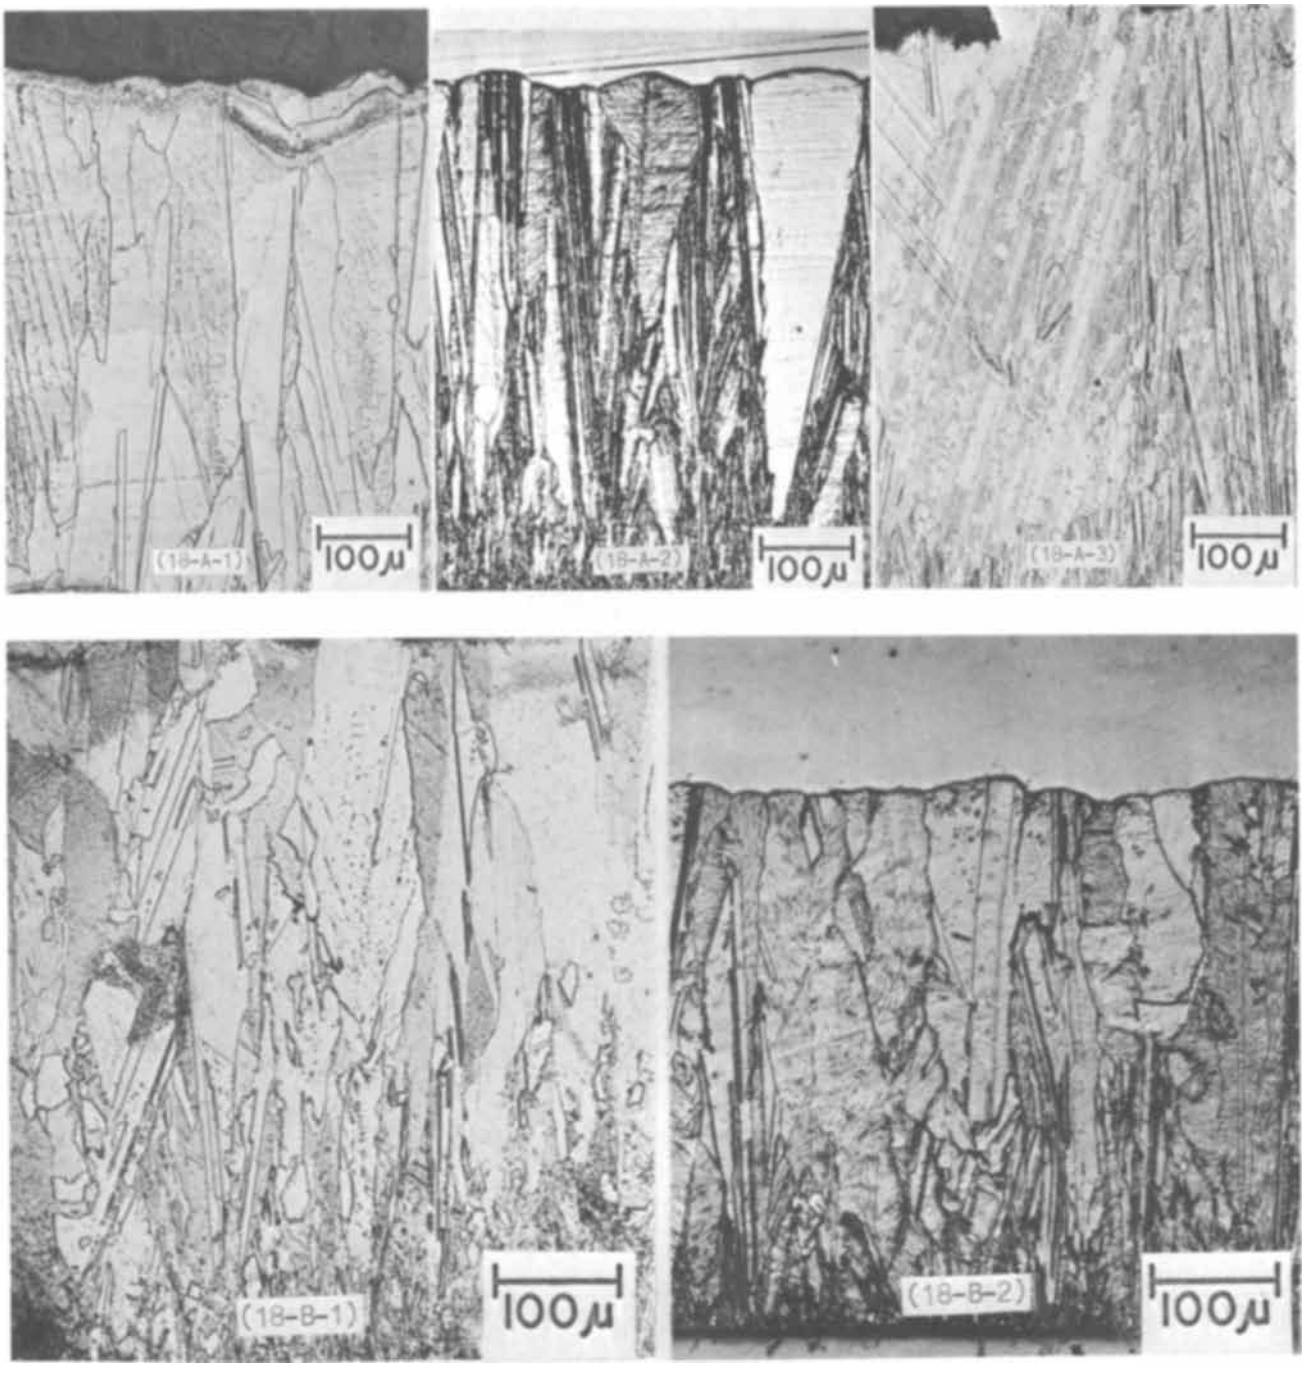

Fig. 18. Effect of concentration of copper in the bath on structure of deposits from sulfate baths. Part A: H-3, 30°C, 0.5 A/dm^2—(18-A-1) Cu-1; (18-A-2) Cu-2; (18-A-3) Cu-3. Part B: H-3, 30°C, 2 A/dm^2—(18-B-1) Cu-1; (18-B-2) Cu-2.

d. Concentration of sulfuric acid.—Figure 19 shows the effect of concentration of sulfuric acid on structure. In both Part A (sulfuric acid, 0.25 and 0.75 molar, respectively) and Part B (sulfuric acid, 0.4 and 0.75 molar, respectively) there is a shift from long columns to somewhat broken columns, but no marked change in grain size.

e. Addition agents.—Effects of addition agents are shown in Fig. 20. Figure 20-1 shows the structure of a nonaddition agent deposit from the Cu2-H3 bath, temperature 30°C, current density 2 A/dm^2. It is included for comparison since all of the other deposits were made under the same conditions except for the presence in the bath of the addition agent (Fig. 20-10, a deposit made from a bath containing the proprietary addition agent, is an exception with respect to both composition and operating conditions. (See line 77, Table I).

Two addition agents that had minor effects on properties are lactic acid and naphthalenedisulfonic acid (NDS) (Fig. 20-2 and 20-3, respectively). Lactic acid causes the structure to be somewhat acicular, but the grain size is nevertheless rather large. NDS causes a change in crystal form but does not appear to reduce the grain size. The small effects of these addition agents on structure are thus correlated with their small effects on properties. All of the other addition agents result in marked grain refinement, especially triisopropanolamine and proprietary A (Fig. 20-9 and 20-10, respectively). Figure 20-7 shows an unusual structure; it is a deposit from a bath containing a mixture of thiourea and NDS. It shows cyclic lamina-

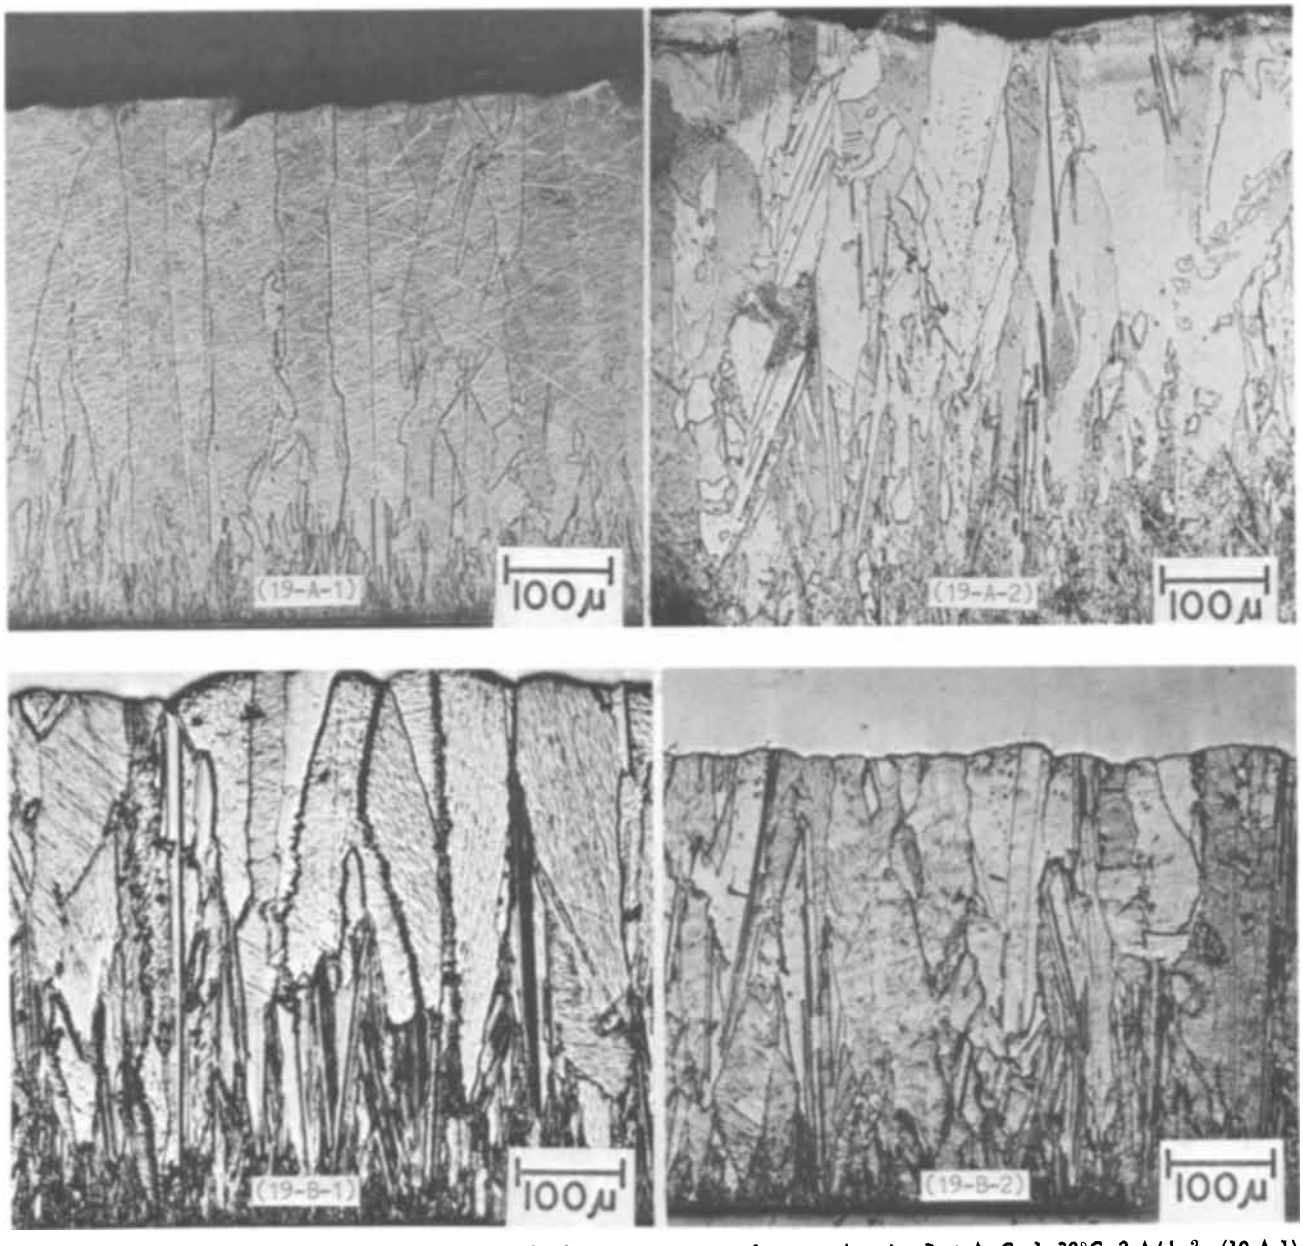

Fig. 19. Effect of concentration of sulfuric acid in the bath on structure of copper deposits. Part A: Cu-1, 30°C, 2 A/dm^2—(19-A-1) H-1; (19-A-2) H-3. Part B: Cu-2, 30°C, 2 A/dm^2—(19-B-1) H-2; (19-B-2) H-3.

tions parallel to the base and simultaneously a fine columnar structure that persists through the laminations. A structure of this type has been reported previously in a cobalt-tungsten alloy deposit (23). The deposit was examined by electron probe measurements to see whether a cyclic concentration of carbon or sulfur could be detected corresponding to the visible laminar structure.[11] The average lamination width is about 3 mils and the probe resolution was less than 1 mil. The probe was therefore adequate with respect to resolution. Neither carbon nor sulfur was detected. This result was not unexpected, because the probe sensitivity was only of the order of 1-2% for carbon and 0.1% for sulfur. It is probable that cyclic concentrations of these impurities would be less than these sensitivity limits.

The structures of several other deposits from addition agent baths were examined visually and are briefly described as follows:

[11] Electron probe measurements were made by D. L. Vieth, Analytical Chemistry Division, NBS.

Line No. Table I	Addition agent	Character of deposit: Crystal form	Character of deposit: Average grain diameter (mil)
43	Dextrin	Broken columnar	~3
48	Glycerol	Regular columnar	~4
49	Glycine	Regular columnar	~4
68	Sorbitol	Broken columnar	~4

f. Periodic current reversal.—The structure of the sulfate deposit made with periodic current reversal (Table XIV, line 79) is shown in Fig. 21-3, together with direct current deposits for comparison. The deposit in Fig. 21-1 was made at the same temperature and current density and approximately the same plating rate as the net rate for the PR deposit. The deposit in Fig. 21-2 was made at the same instantaneous rate as the PR deposit. Other conditions do not quite match, but the effect of the differences on the structure of Fig. 21-2 should be small. It is seen that PR causes a marked reduction in grain size to yield a fine fibrous structure (Fig. 21-3). The nodule seen in this view is characteristic. In appearance, these deposits were semi-bright but marred by a fairly high density of small

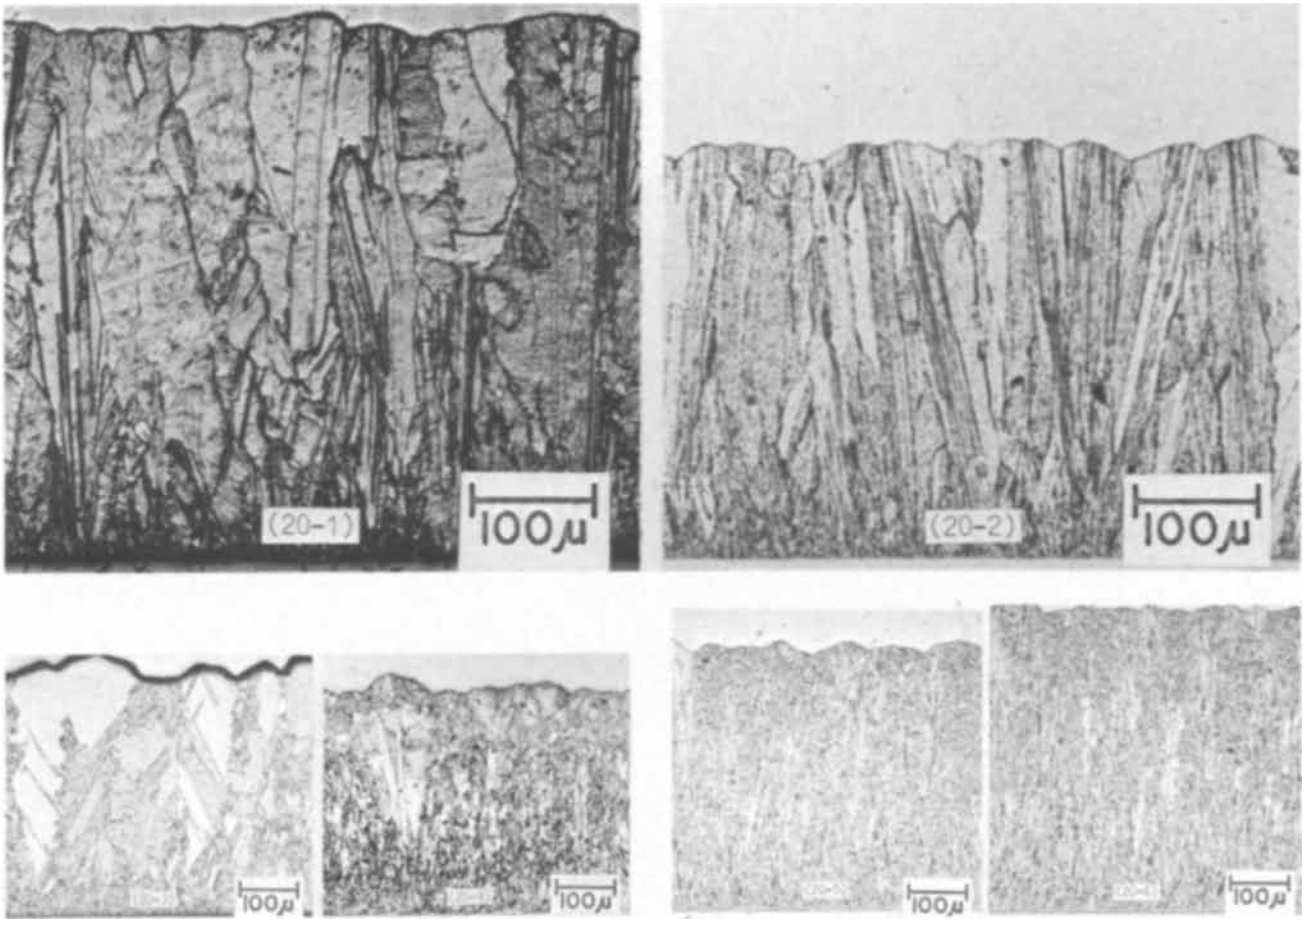

Fig. 20. Effect of addition agents on structure of copper deposits from sulfate baths. All deposits are from bath Cu2-H3 operated at 30°C and 2 A/dm^2, except as noted under 20-9 and 20-10: (20-1) No addition agent; (20-2) 0.05 g/l lactic acid; (20-3) 1.8 g/l naphthalenedisulfonic acid; (20-4) 0.1 g/l β-naphthoquinoline; (20-5) 10^{-4} g/l selenium; (20-6) 10^{-3} g/l selenium.

nodules that we were unable to eliminate and that seemed to be characteristic. No laminations corresponding to PR cycles can be seen at the magnification of 200X, which is to be expected, since with an over-all cycle period of 7 sec, the thickness per cycle is less than 2 μin.

3. Correlation of structure with properties.—It has already been shown (Section III-E-1) that there is a correlation between structure and tensile strength and elongation. Correlation between structure and hardness is inconsistent. Among the nonaddition agent deposits, there is no consistent correlation. Among the fine-grained addition agent deposits, higher hardness is associated with a fine-grain structure.

In Section III-B-2 it was shown that there is a correlation between internal stress and structure, with a higher stress associated with the finer structure in the basal zone of a deposit. In Sections III-F-2-a and b, a decrease in grain size with decrease of temperature or with increase of current density was demonstrated, and in Sections III-B-3-a and b the latter two variables were seen to cause an increase of stress. One would therefore deduce that decrease of grain size is associated with increase of internal stress. When one considers addition agents, the same relationship exists in some cases, *e.g.* for deposits from baths that contain β-naphthoquinoline or selenium dioxide (Table XIII). On the other hand, gelatin in higher concentrations causes deposits to have a very fine grain structure (24), yet they are compressively stressed. Other instances of anomalous structure-stress relationships have been reported (3).

The significant lowering of density and increase of resistivity noted in Sections III-C and D, caused by the addition agents that produce significant grain refinement, indicates that there is a correlation between these properties and grain size.

Manuscript received April 8, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1971 JOURNAL.

Physical and Mechanical Properties of Electrodeposited Copper

III. Deposits from Sulfate, Fluoborate, Pyrophosphate, Cyanide, and Amine Baths[12]

Vernon A. Lamb, Christian E. Johnson, and Donald R. Valentine

National Bureau of Standards, Washington, D. C. 20234

IV. Deposits from Fluoborate Baths

A. General

The compositions of the fluoborate baths are shown in Table III. The concentration of copper metal (molarity) in the low-concentration bath (F-1) was the same as in the Cu-2 sulfate baths. The high-concentration bath (F-2) was similar to a bath described by Diggin (21) and by the commercial suppliers of fluoborate concentrates. Control of the concentration of copper fluoborate was based on chemical analysis. Fluoboric acid control was based on measurement of *p*H with sensitive *p*H paper. Equipment used was the same as for sulfate baths with one exception. To avoid attack of the glass tank by fluoborate, a lining of polyethylene sheet was used. A cotton filter, the same as used in the later sulfate baths, was used for the fluoborate baths. Air agitation was used.

B. Effect of Operating Conditions and Bath Composition on Properties of Deposits

1. Bath temperature.—Data on the effect of bath temperature on tensile strength, elongation, hardness, and internal stress, tabulated in Table XVI, are plotted in Fig. 22. Each of these properties decreases with increase of temperature. Attention is directed to the fact that, as with non-addition agent sulfate baths, ductility decreases with decrease of tensile strength.

Neither density nor electrical resistivity undergoes significant change with change of bath temperature (Table XVI).

2. Current density.—Effect of current density is also shown in Fig. 22. Increase in current density causes tensile strength, elongation, hardness, and internal stress to increase. Again, elongation parallels tensile strength.

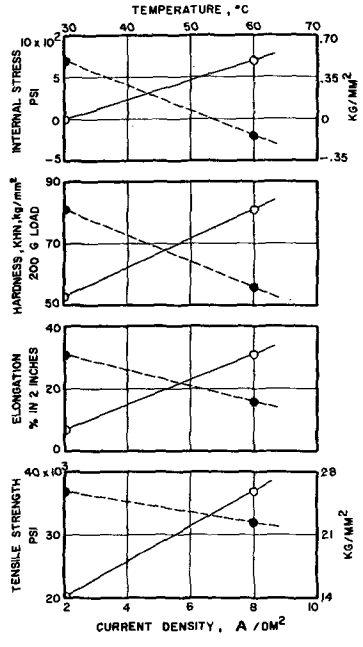

Fig. 22. Relationships of current density and bath temperature to tensile strength, elongation, hardness, and internal stress of copper deposits from a fluoborate bath (F-1). ○—current density, ●—bath temperature.

As with temperature, current density has no significant effect on either density or electrical resistivity.

3. Concentration of copper fluoborate.—The effect of concentration of copper fluoborate on properties may be seen by comparing lines 91 and 93 in Table XVI. The differences due to concentration are insignificant for all of the properties shown except hardness. The small

[a] No addition agent in either bath; identical air agitation.
[b] 0.05% offset.
[c] One pound per square inch (psi) = 0.000704 kilogram per square millimeter (kg/mm^2).

decrease from 81 to 71 KHN with increase of concentration is in the expected direction. It is possible that larger effects exist at lower bath temperatures or at higher current densities.

C. Comparison of Deposits Made with High Current Densities from Fluoborate and Sulfate Baths

A comparison between properties of deposits from fluoborate and sulfate baths, both made at a high current density, 20 A/dm^2, is shown in Table XVII. The general character and properties of the deposit from the fluoborate bath are nearly the same as those of the deposits shown in Table XVI that were made at lower current densities. On the other hand, the deposit from the sulfate bath was weak, brittle, had a very low density and high resistivity, and a high impurity content (see Section VIII-G), properties indicating that the limiting current density was exceeded. These results confirm the reputed high current density capability of the fluoborate bath in comparison with the sulfate bath. The comparison is in one sense unfair, since the concentration of copper ion in the fluoborate bath is nearly twice that in the sulfate bath. However, the solubility of $CuSO_4$ makes it impractical to operate the sulfate bath with a significantly higher concentration than we used, whereas operation of the fluoborate bath with a concentration of copper ion equal to that shown in Table XVII or higher is practicable.

D. Structure

The structure of the deposit represented on line 91, Table XVI, is shown in Fig. 59-2. It has a more fibrous character than the deposit from the corresponding non-addition agent sulfate bath (Fig. 59-1). It is possible, however, that under other conditions fluoborate baths may yield large-grained deposits. Thus, if grain size correlates with strength, one might expect the very weak deposit on line 90, Table XVI, made at a low current density, to have a coarse structure.

V. Deposits from the Pyrophosphate Bath

A. General

Only one bath composition was used for making deposits from the pyrophosphate bath (Table III). The selection of the concentrations of the various constituents was based on recommendations made by several authors (25-27). No addition agents were used. Deposits were bright as plated.

B. Effect of Operating Conditions on Properties of the Deposits

1. Bath temperature.—Comparing lines 98 and 100 in Table XVIII, it is seen that the only property that is affected significantly by a change of temperature of 10°C is internal stress. The change from 1700 psi tensile to 1900 psi compressive with increase of temperature is in the same direction as has been observed for the sulfate and fluoborate baths but is larger.

2. Current density.—The data on lines 95 and 98 of Table XVIII show that increase of internal stress is the only significant change of property due to increase of current density from 2 to 4 A/dm^2.

3. Agitation.—Propeller agitation was tried initially in the pyrophosphate bath. Since the deposits were not uniformly bright over the entire area and tended to be nodular, other means of agitation were tried, as described in Table I, lines 95-100. Air agitation gave the best results, and was used for the deposits for which data are given in Table XVIII. However, several properties of the deposits prepared with other modes of agitation were measured. The results appear in Table I. It is seen that these properties were not affected appreciably by the variations in agitation.

C. Structure

Photomicrographs of the deposit on line 95, Table XVIII, are shown in Fig. 59-3 and 59-4. The structure differs markedly from that of deposits from sulfate or fluoborate baths. There is indication of large columnar crystals with a very fine substructure. Tensile strength and other properties of these deposits vary from those of large-grained sulfate deposits in the direction that one would expect if the grain size were smaller, but the effect is not as large as it is with the finer-grained deposits from addition agent sulfate baths.

Additional data on the structure of these deposits are discussed in Section VIII-F.

VI. Deposits from the Amine Bath

A. General

Several researches have been reported on attempts to develop commercially useful baths based on copper-

Table XVIII. Effects of temperature and current density on properties of deposits from the pyrophosphate and amine baths

amine complexes (27-29). Although the baths that have been described have not achieved significant use, it was thought that since the amine bath is a rather different type than the others used in this project it deserved a limited investigation to see whether the deposits had any unusual properties. Several of the baths described in the literature were tried. Most of them did not yield sound thick deposits. Sound deposits were obtained from the bath shown in Table III, which is similar to one described by Greenspan (29). Deposits were fairly smooth at a thickness of 10 mils, but became excessively rough, with a tendency for filamentary growths to start at larger thickness.

B. Effect of Current Density on Properties of Deposits

Because current density is a relatively uncontrollable variable when irregularly shaped objects are plated, it seemed most important in a limited study to include current density as a variable. This was the only variable studied. The results shown in Table XVIII indicate that a change of current density from 2 to 4 A/dm^2 does not significantly change the properties of the deposits.

It is seen that the deposits are fairly strong and very hard. However, their low ductility is adverse. Their high compressive internal stress is noteworthy. Their low density and high electrical resistivity indicate a probable high content of impurity, but this was not investigated.

C. Structure

A photomicrograph of the deposit on line 151, Table XVIII, is shown in Fig. 59-6. The structure is seen to be very fine, with unresolved grains at a magnification of 500X.

VII. Deposits from Cyanide Baths

A. General

Concentrations of the various constituents of the cyanide baths and levels of operating variables were chosen on the basis of a review of the recommendations made in various publications (6, 26, 27). The brightener system identified in Table IV as "Proprietary B" is reported by the vendor to be a selenium type (26).

B. Mechanical Properties

1. The bulge method for measuring tensile strength and ductility.—a. Apparatus.—It is difficult to prepare, handle, and test deposits in the thickness range of 0.001-0.002 in. by the standard tensile pull method. To avoid these difficulties, Read and co-workers have adapted the hydraulic bulge test to the measurement of tensile strength and ductility of thin electroformed deposits (30, 31). Since most of our deposits from cyanide baths were 0.001-0.002 in. thick, the bulge test was the preferred test method. Besides avoiding the technical difficulties referred to above, the method has the advantage that specimens can be made very easily and at low cost by simply cutting out a disk of the material with scissors.

The basic principle of the bulge tester is illustrated in Fig. 23, Part I. The test specimen, in the form of a disk cut from a specimen panel, is clamped between the thick steel base plate and the clamp ring. Oil is pumped through the opening under the copper disk, causing it to expand into the opening in the clamp ring. In our apparatus, the diameter of the disk is 2⅜ in., and of the hole in the clamp ring, 1.5 in. Tensile strength can be calculated from the fluid pressure and bulge height, and degree of elongation or ductility can be determined from the linear stretch of a unit length at the top of the bulge at rupture. We constructed the apparatus that we used. It is the same in principle as the apparatus described by Read and co-workers but differs in details of design. A photograph is shown in Fig. 23, Part II, in which the major components are identified. The gear pump, with a capacity of 1000 psi, was powered by a 1/6 hp integrally coupled motor. Oil was drawn from the reservoir through the filter and pumped through the throttle valve into a parallel

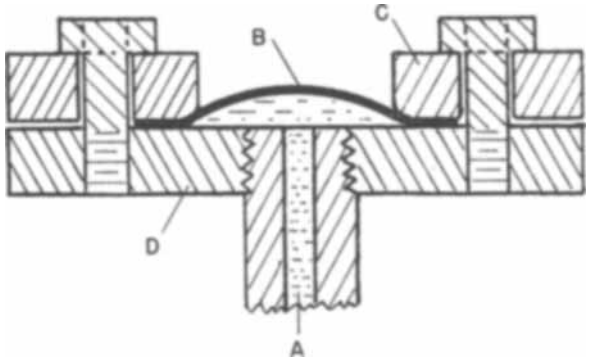

Fig. 23-I. Cross section of head of bulge tester: A—oil inlet, B—bulged disk, C—clamping ring, D—base plate.

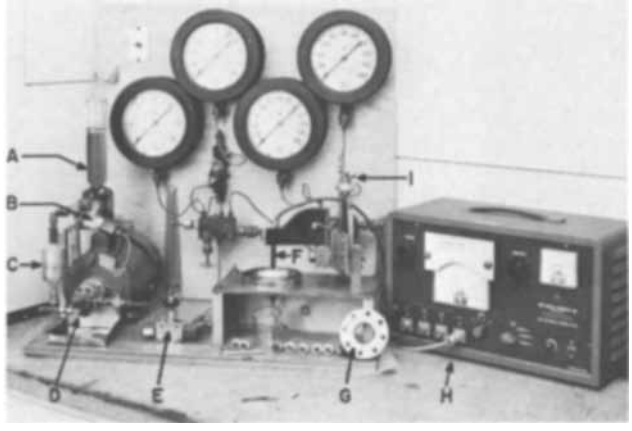

Fig. 23-II. Photograph of complete bulge tester: A—oil reservoir, B—bypass valve, C—oil filter, D—pump, E—throttle valve, F—Dermitron probe, G—clamping ring, H—Dermitron unit, I—vertical micrometer.

array of tubing, one to the bulge and one to each of the four gauges. The line to each gauge was equipped with a cut-off valve. If the pressure limit for the first gauge (30 psi) was exceeded, its valve was closed and pressure read on the second gauge (100 psi), *etc.*, through the third (300 psi) and fourth (1000 psi). Good sensitivity of pressure measurement was thus obtained for any magnitude of pressure encountered. Flow rate and bulge growth were controlled by combined settings of the bypass valve and throttle valve.

An expanded disk is shown in place on the base plate. Oil released on rupture of the disk is caught in the shallow tray surrounding the base plate and flows into the small beaker. The height of the bulge is measured with the Dermitron[13] unit (32) in the following manner. A dummy specimen is laid on the base plate and the probe is lowered with the probe-height control screw until it just touches the specimen, then raised about 0.005 in. The Dermitron controls are then adjusted so that, at this arbitrary distance between the probe face and the specimen, the Dermitron thickness meter reads at the midpoint of the scale and the sensitivity is about 0.001 in. for full-scale needle deflection. Without changing the Dermitron adjustments, the probe is raised sufficiently by the screw to permit placement and clamping of the test specimen. The probe is then returned to its former position, minor readjustments in Dermitron control settings are made if necessary, and the starting height of the probe is read on the micrometer screw. The bulge is then slowly expanded. As it grows, the probe is raised simultaneously with the screw so that the original clearance between the probe face and the specimen is maintained, as indicated by a constant reading at the center point of the Dermitron meter. When the specimen ruptures, growth stops, and, simultaneously, advance of the

[13] An eddy current type of thickness gauge.

screw is stopped. The difference between the reading of the probe-height micrometer screw at this point and at the beginning gives the height of the bulge. The advantages of this height-measuring procedure are (*a*) that the bulge is not mechanically contacted by the measuring device and, hence, not mechanically damaged and (*b*) the procedure is sufficiently simple that one operator can control bulge growth and height measurement simultaneously. We estimate that the measured values of bulge height are accurate to about ±0.001 in. and those of pressure to about ±5% of the observed value. A minimum of six replicate disks from each panel was tested. Variations in pressure among the six were often as much as ±25%. The large variation is judged to result from premature failure of some of the specimens because of the presence of flaws. However, within a given set of specimens, bulge height and pressure were usually closely correlated. The formulas in the next section show that tensile strength is approximately proportional to the ratio of pressure to bulge height and, therefore, even though variations of pressure and height among replicates were rather large, calculated values of tensile strength seldom varied more than ±5%.

b. Bulge test relationships.—(i) Basic relationships.— The following relationships for obtaining tensile strength and ductility values from bulge measurements are stated without development. For more detail the reader is referred to Read and co-workers (30, 31):

$$\text{Nominal tensile strength} = \frac{PR}{2t} \qquad [1]$$

where P is pressure at fracture, R is the radius of curvature of the bulge at fracture, and t is the initial thickness of the specimen, which was determined from area and mass.

$$\text{True stress} = \sigma = \bar{\sigma} = \frac{PR}{2t_i} \qquad [2]$$

in which true stress, σ, is equal to the load divided by the simultaneously measured cross-sectional area. Use in Eq. [2] of t_i, the simultaneously measured thickness, yields true stress. "Significant stress," $\bar{\sigma}$, is a generalized function which is a measure of the stress under any type of loading. The equality shown in Eq. [2] applies to isotropic material tested either in simple tension or in balanced biaxial tension; the latter is the situation in the bulge test (30).

To obtain values for t_i for substitution in Eq. [2], a grid was printed on the flat specimen before bulging. From the elongation of the grid after bulging, t_i can be calculated on the assumption that the volume of metal underlying an initial grid square remains constant. The radius of curvature, R, is obtained from

$$R = \frac{r^2 + h^2}{2h} \qquad [3]$$

where r is the radius of the hole in the clamp ring and h is the height of the bulge.

Nominal tensile strength (Eq. [1]) is calculated and tabulated in all of the succeeding tables of data obtained by bulge testing. The values are thus approximately comparable to those already discussed which have been determined by tensile pull, which are calculated on the basis of the initial cross section of the test specimen. In one exception, Fig. 25, discussed later in this section, significant stress is used.

Ductility was determined from bulge measurements by measuring the amount of stretch at fracture of a grid printed on the specimens. The grid pattern was transferred with printer's ink from an intaglio engraving in a steel block. Line spacing was 0.05 in. The lengths of four or five grid squares near the peak of the bulge were measured, after bulging, with a microscope. Both axes of grids were measured. The average length of the bulged grid, calculated from these measurements, is designated as L. The initial grid length is designated L_o. "True strain," δ, is defined by the relation

$$\delta = \int_{L_o}^{L} \frac{dL}{L} = \ln \frac{L}{L_o} \qquad [4]$$

The following remarks are intended to show in a brief manner the significance of δ. Consider a uniaxial tensile test, *i.e.* a test of a standard pull specimen. For small values of elongation, *e.g.* up to 10%, $\Delta L/L_o$ is nearly equal to $\ln L/L_o$, where ΔL is the difference between initial and final length of a grid unit. Therefore, for a brittle material that elongates uniformly and does not undergo necking, true strain from Eq. [4], multiplied by 100, is approximately equal to elongation expressed as per cent of a given gauge length such as 2 in. However, for a ductile material with a nominal elongation larger than about 10%, the arithmetic and logarithmic ratios deviate significantly. Also, necking may occur, resulting in a much larger true elongation at the point of rupture than the average over the gauge length. Therefore, while true strain and per cent elongation are both measures of ductility, they are, in general, not numerically comparable.

In tensile pull, strain occurs in only one direction. In bulge testing, strain occurs in all directions radially from the center of the disk. The ability of the metal to elongate in a given radial direction is reduced by its simultaneous elongation in other radial directions. Thus, δ for a bulge specimen will be less than the strain obtained with the same stress applied to a tensile pull specimen. Read shows that a quantity designated as $\bar{\delta}$, significant strain, is identical to true strain in the case of a specimen pulled in simple tension, but that in the case of the biaxial loading of a bulge specimen

$$\bar{\delta} = 2\,\delta \qquad [5]$$

Significant strain from bulge measurements is comparable to true strain from tensile pull, but is not comparable to nominal elongation for the reasons given in the preceding paragraph.

As already indicated above, bulge height and, hence, $\bar{\delta}$ for individual specimens within sets of six sometimes varied as much as ±25%, especially for the relatively brittle deposits. This is comparable to the situation in tensile pull, where, *e.g.*, the difference between 5 and 10% elongation in our measurements (a relative variation of ±50%) is scarcely significant. It is, therefore, not feasible for us to assign a definite evaluation of accuracy to our data on significant strain. However, small differences, *e.g.* ±10%, cannot be considered to be significant.

(ii) Data relating significant stress and significant strain for several types of baths.—It was not practicable to print grids and measure elongation directly for every specimen. Therefore, grids were printed on a substantial sampling of disks from deposits of a given type of bath. Values of $\bar{\delta}$ calculated from the grid data were then plotted as a function of bulge height. The same curves were then used to obtain $\bar{\delta}$ from bulge height for unprinted specimens.

A plot of $\bar{\delta}$ *vs.* bulge height is shown in Fig. 24. The curves for most of the deposits are closely clustered, showing that there is not much difference in what may be termed, by analogy with tensile pull, as their necking characteristics. Curves for two types of deposits do not fit the main pattern. The deposits from a sulfate bath containing 1,5-naphthalenedisulfonic acid addition agent (curve 2, panel No. 114A-E) had significantly higher $\bar{\delta}$ for a given bulge height than the other deposits; *i.e.*, for a given height of bulge, the degree of stretch at the peak of the bulge was abnormally high and, hence, thickness at the peak of the bulge abnormally low. In other words, this deposit showed a pronounced "necking" tendency. Deposit No. 303 (curve

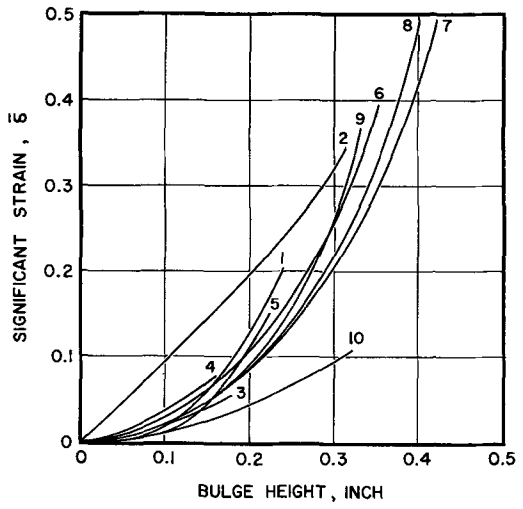

Fig. 24. Relationship between bulge height and significant strain for thin copper deposits from various baths: (1)—Cu2-H3 containing 3.5 g/l triisopropanolamine, 30°C, 2 A/dm^2; (2)—Cu2-H3 containing 1.8 g/l 1,5-naphthalenedisulfonic acid, 30°C, 2 A/dm^2; (3)—CN-2, 60°C, 2 A/dm^2; (4)—CN-5, 80°C, 4 A/dm^2; (5)—CN-4, 80°C, 2 A/dm^2; (6)—CN-6, 60°C, 2 A/dm^2; (7)—CN-7, 60°C, 2 A/dm^2; (8)—CN-8, 80°C, 6 A/dm^2; (9)—CN-8, 80°C, 6 A/dm^2, PR, cycle 15-5 sec; (10)—CN-9, 80°C, 6 A/dm^2.

10), a deposit from the high efficiency cyanide bath containing the proprietary selenium-type addition agent, showed the opposite effect, indicating relatively uniform stretch over most of its area, or lack of necking. One might expect this property to be associated with brittleness, yet specimens from panel No. 303, while of low ductility, were not as brittle as specimens from panels 146 or 195 (Table XXII), which fall in the central group in Fig. 24.

Relationship between significant stress and significant strain for a variety of deposit types is shown in Fig. 25. Most of them show a nearly linear stress-strain relationship up to a fairly definite yield point. Two of them, specimens represented by curves 3 and 4, show brittle failure. A very wide range of ultimate strength is seen, from a low of 28,000 psi for the proprietary high efficiency deposit (curve 10, panel No. 303) to 85,000 psi for a deposit from a standard cyanide bath (curve

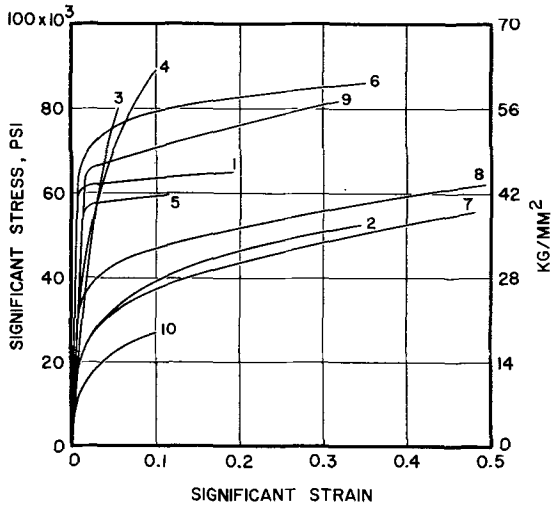

Fig. 25. Relationship between significant strain and significant stress for thin copper deposits from various baths: (1)—Cu2-H3 containing 3.5 g/l triisopropanolamine, 30°C, 2 A/dm^2; (2)—Cu2-H3 containing 1.8 g/l 1,5-naphthalenedisulfonic acid, 30°C, 2 A/dm^2; (3)—CN-2, 60°C, 2 A/dm^2; (4)—CN-5, 80°C, 4 A/dm^2; (5)—CN-4, 80°C, 2 A/dm^2; (6)—CN-6, 60°C, 2 A/dm^2; (7)—CN-7, 60°C, 2 A/dm^2; (8)—CN-8, 80°C, 6 A/dm^2; (9)—CN-8, 80°C, 6 A/dm^2, PR, cycle 15-5 sec; (10)—CN-9, 80°C, 6 A/dm^2.

4, panel No. 195). Only one cyanide-type deposit with a higher strength was encountered in this research (not included in Fig. 25), namely, a deposit made with periodic current reversal from a bath containing thiocyanate (line 143, Table XIV).

c. Comparison of tensile properties obtained by pull and bulge methods.—Table XIX contains comparative values of tensile strength and elongation from pull and bulge measurements. Except for the deposits from cyanide baths on lines 141 and 146, all deposits from both sulfate and cyanide baths were in the range of thickness from 1 to 3 mils.

The first group of data, lines 53-75, is for deposits from sulfate baths. It is seen that, for each deposit, both pull and bulge methods yield the same value for tensile strength, within the normal range of variability of the measurements. On lines 57 and 75 are shown comparisons between our results and those obtained by Read[14] from measurements on specimens from duplicate panels that we supplied to him. Close agreement is seen.

The strength values measured by tensile pull for the deposits from cyanide baths on lines 101 through 125 are seen, with one exception, to be consistently lower than the bulge values. This is probably because premature rupture occurs during tensile pull. As discussed above, tensile pull specimens, when thin and brittle, are more subject to damage in preparation and handling than are bulge disks, and premature failure may be expected. Good agreement is seen in lines 140-146 between tensile pull values of strength for thick cyanide deposits and bulge values for corresponding thin deposits. Good agreement is seen in lines 119 and 121 between our values and those determined by Read.

Turning to comparisons of ductility determined by the two methods (Table XIX), agreement cannot be expected in light of the preceding discussion in Section VII-B-1-b. In both the sulfate and cyanide groups, per cent elongation from tensile pull is significantly less than 100 x $\bar{\delta}$, with one exception in each group. The tensile pull specimens in the sulfate group underwent varying degrees of necking, which would cause differences between the two methods in the direction that is seen. In the cyanide group the differences are probably due mainly to premature rupture of the tensile pull specimens, since the latter were relatively brittle and did not undergo noticeable necking. Good agreement is seen between our values of significant strain and those determined by Read.

2. Effect of thickness on properties of deposits from cyanide baths.—Effects of deposit thickness for several deposits from cyanide baths are shown in Table XX and Fig. 26. Tensile strength and significant strain increase with increase of thickness, while electrical resistivity decreases. The directions of the effects for tensile strength and significant strain are opposite to those for sulfate deposits (Section III-A-3, Table VII, Fig. 2, 3). However, the comparisons are made in a somewhat different range of thickness. The thinnest sulfate deposit was 0.5 mil and most of the thin deposits were 1.0-2.0 mils, whereas the thicknesses of several of the thinnest cyanide deposits are 0.2-0.3 mil. Our explanation of the effects in the case of the cyanide deposits is that these very thin deposits contain pores and defects which cause them to have abnormally low strength and ductility and high resistivity. At a thickness of about 2 mils these effects were diminishing.

3. Effects of operating conditions and bath composition on mechanical properties of deposits from cyanide baths.—a. Bath temperature.—The effect of bath temperature on tensile strength is shown in Table XXI and Fig. 27. Counting sets of three in Table XXI as two pairs, there are 12 pairs. The data for all of these are plotted in Fig. 27. It is seen that for four pairs the effect is minor and for one pair tensile strength decreases with increase of temperature. For the other seven

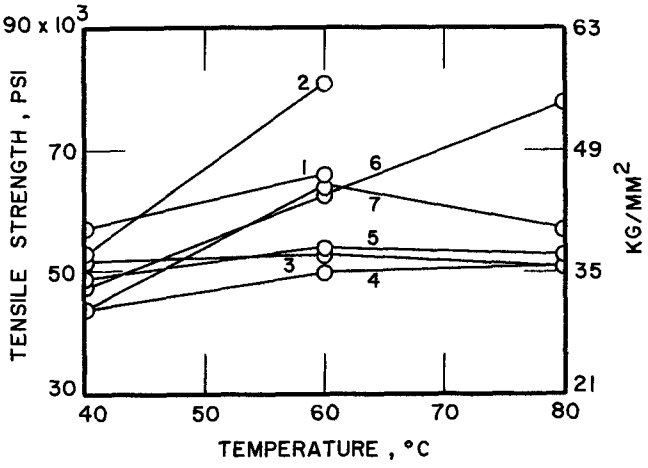

Fig. 27. Relationship between bath temperature and tensile strength of copper deposits from cyanide baths: (1)—CN-2, 1 A/dm²; (2)—CN-2, 2 A/dm²; (3)—CN-4, 2 A/dm²; (4)—CN-4, 4 A/dm²; (5)—CN-5, 2 A/dm²; (6)—CN-5, 4 A/dm²; (7)—CN-6, 2 A/dm².

pairs tensile strength increases with increase of temperature. With one exception, the effect is smaller between 60° and 80°C than between 40° and 60°C. We judge that the predominant effect, increase of deposit strength with increase of bath temperature, which is unexpected, is real. The following hypothesis may explain the effect: In cyanide-type baths current efficiency, and, hence, plating rate, increases markedly with increase in bath temperature. Thus, with other conditions constant, increase in temperature may lead to depletion of copper ions in the cathode film, with consequent decrease of grain size and increase of strength. This effect would be countered by increase in rate of diffusion of complex cyanide ions into the cathode film with increase of temperature, but the latter might be the minor effect because of the large size of the complex ions.

The effect of bath temperature on significant strain is indefinite, as seen in Table XXI. Most of the values vary randomly in the range of 0.1-0.25. The only clues to a relationship are seen in the second and sixth sets of data (lines 106-110 and 123-127, respectively) which show an appreciable decrease of significant strain with increase in temperature.

Variation of modulus with temperature is in the range $(16 \pm 1) \times 10^6$ psi, not a significant variation.

Hardness is not markedly affected by bath temperature. However, there is a small but predominant trend toward increase of hardness with increase of bath temperature. The relationship is, thus, parallel to that between tensile strength and bath temperature, and our explanation is the same.

b. Current density.—Complete data on the effects of current density on mechanical properties are shown in Table XXII. Figure 28, which contains data for those cases where the effects were significant, shows that the predominant tendency is for tensile strength and hardness to increase with increase in current density, and for significant strain to decrease. Several cases

where there was no appreciable effect are seen in Table XXII.

The range of variation of the modulus is (16 ± 1) x 10^6 psi; *i.e.*, change of current density does not affect the modulus significantly.

c. Concentration of copper cyanide.—The effects of concentration of copper cyanide on mechanical properties are shown in Table XXIII and Fig. 29. There is a consistent decrease of tensile strength and hardness and a trend toward increase of ductility with increase

[a] One pound per square inch (psi) = 0.000704 kilogram per square millimeter (kg/mm²).

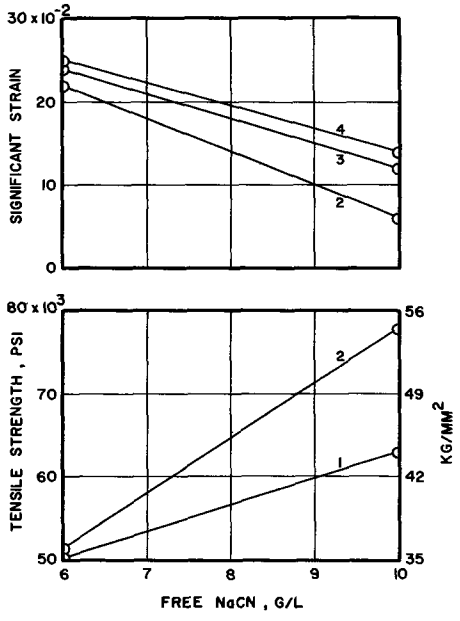

Fig. 30. Relationships between free cyanide concentration, tensile strength, and significant strain of copper deposits from cyanide baths: (1)—CN-4 and CN-5, 60°C, 4 A/dm²; (2)—CN-4 and CN-5, 80°C, 4 A/dm²; (3)—CN-4 and CN-5, 60°C, 2 A/dm²; (4)—CN-4 and CN-5, 80°C, 2 A/dm².

of concentration of copper cyanide. The modulus of elasticity is unaffected.

d. Concentration of free cyanide and sodium carbonate.—Increase in concentration of free cyanide results in increase in tensile strength and decrease in significant strain in most instances. The cases in which a significant effect occurs are shown in Fig. 30. However, examination of Table XXIV shows several cases in which the effect was negligible. Neither modulus of elasticity nor hardness were affected significantly (Table XXIV).

The data in Table XXIV also show that a twofold increase of concentration of sodium carbonate did not produce an appreciable effect on any of the properties except significant strain, which was increased.

e. Concentration of Rochelle salt and effect of potassium ion.—Examination of the data summarized in Table XXV does not give a clear conclusion regarding the effect of Rochelle salt on mechanical properties. Differences are small and tend in both directions. We can only conclude that the effects are minor.

Effect of an all-potassium bath may be seen by comparing lines 130 and 133 in this table. Potassium ion, as compared with sodium, causes significant decreases of strength, ductility, and hardness.

f. pH.—Table IV shows the variation of pH with duration of electrolysis of cyanide baths. Variation of pH is not normally controlled in these baths, which operate at a "natural" pH. It is seen that the initial pH for all except bath No. CN-8 is in the range 11.4-11.8 and increases after working to a stable value in the range 12.6-12.8. This is the direction of shift to be expected due to the low cathode efficiency. Bath No. CN-8 is initially higher in pH due to its high content of KOH, and does not change with working, due to its high cathode efficiency. Under the above circumstances, effect of pH on properties of deposits is of only academic interest. However, a few measurements were made to compare the tensile strength and ductility of panels made at the lower limit of the pH ranges shown in Table IV with those of panels made at the upper limit of the range. No measurable effect was observed.

g. Proprietary brightener.—Baths No. CN-8 and CN-9 are fairly similar in composition, as may be seen in Table IV, except for the presence in CN-9 of the proprietary addition agent of the selenium type. Both are based on potassium salts and have the same copper content. CN-9 is higher in free cyanide and lower in KOH but it is probable that effects of these differences on properties of deposits are less than that of the addition agent.

Comparing lines 135 and 138 with lines 145 and 147 of Table XXII, we see that tensile strength, ductility, and hardness are all significantly smaller for the deposits from the bath containing the selenium-type addition agent. The value of the addition agent lies in its effect on smoothness and brightness rather than in its effect on properties.

h. Periodic current reversal (PR).—The effects of periodic current reversal on properties of deposits from baths CN-8 and CN-9 are summarized in Table XIV. Comparing line 140 with 135-138 we see that PR produces a marked increase in tensile strength. Addition of KCNS (line 143) produces a further significant increase. Deposits from bath No. CN-9 made with PR (line 148) are more than twice as strong as non-PR deposits (lines 145-147). Neither change of current density nor change of PR cycle had significant effects on strength (lines 140 *vs.* 142 and 143 *vs.* 144, respectively). Under none of these conditions used by us was the tensile strength as high as has been claimed by some authors (3).

Effects of PR on ductility are less consistent, but the conclusion in summary is that, for deposits from bath CN-8, the stronger PR deposits are less ductile than the weaker non-PR deposits (*cf.* line 138 with 140-141 and line 135 with 143-144). The strongest deposits (lines 143, 144) have the lowest ductility. On the other hand, the moderately strong PR deposit from bath CN-9 (line 148) has the very high elongation of 45%, which is evidently due to a specific effect of the addition agent.

Hardness is much increased by PR for deposits from baths CN-8 and CN-9 (Table XIV). Whereas variation of the PR cycle had no effect on strength and ductility, the deposit made with the 30-10 sec cycle is significantly harder than that made with the 15-5 sec cycle. The PR deposit from bath CN-9 (line 148) is the hardest encountered in this research, namely, 224 KHN.

[b] One pound per square inch (psi) = 0.000704 kilogram per square millimeter (kg/mm²).

C. Internal Stress in Deposits from Cyanide Baths

1. Effect of thickness.—The uppermost curve in Fig. 8 shows that the cumulative internal stress of a deposit from bath CN-2 (line 105, panel 136, Tables XXI-XXIII) increases nearly linearly with time (*i.e.*, with thickness) to the limit of thickness over which stress was measured (approximately 1.5 mil). With respect to internal stress, this deposit is fairly typical of deposits from cyanide baths. This relationship between stress and thickness is in marked contrast to that for deposits from sulfate baths, such as the deposit from a bath containing naphthalenedisulfonic acid. Internal stress in the latter deposit levels off, with no further increase after reaching a thickness of about ¾ mil (Fig. 8). These contrasting effects correlate with the increase in grain size with increase of thickness for the sulfate deposits (Fig. 20-3), and with the constancy of grain size of the cyanide deposits (Fig. 34).

2. Effect of operating conditions and bath composition on internal stress of deposits from cyanide baths.—*a. Bath temperature.*—Effect of bath temperature on internal stress is shown in Fig. 31 and Table XXI. At first sight the results, shown fully in Fig. 31, appear to form no consistent pattern. However, some relationships may be deduced as follows. Consider first the deposits from baths CN-2, CN-4, and CN-5. The general pattern is that, for these deposits, stress tends to go through a maximum with increase of bath temperature. Of 10 pairs of data involved, only one (curve No. 1) has a contrary trend. Deposits from bath CN-6 (Rochelle type, curve No. 7) have significantly lower stress than the deposits from the other baths and their stress is nearly unaffected by bath temperature.

b. Current density.—There is no consistent relationship between internal stress and current density and in no case is the effect very large (Table XXII). There is indication that the effect of current density on stress tends to be lost at the higher operating temperatures.

c. Concentration of copper cyanide.—The preponderant effect indicated by the data summarized in Table XXIII is decrease of internal stress with increase of concentration of copper cyanide. The effect is definite for lines 101 *vs.* 105 and 127 *vs.* 135. However, there is a borderline reverse effect in lines 110 *vs.* 113.

The high value of stress seen in line 145 is an addition agent effect, discussed in paragraph *f* below.

d. Concentration of free cyanide and sodium carbonate.—There is consistently no significant effect on internal stress due to changes of concentration of either free cyanide or sodium carbonate (Table XXIV).

e. Concentration of Rochelle salt and effect of potassium ion.—The data in Table XXV show that addition of Rochelle salt to a cyanide bath consistently causes a decrease of internal stress.

Comparison of lines 130 and 133 shows that converting a sodium to a potassium Rochelle bath results in a significant increase in internal stress of the deposits. The same change caused decreases of tensile strength, ductility, and hardness, illustrating the lack of correlation of these properties with stress.

f. Proprietary brightener.—Comparison of the values for internal stress on lines 135 and 145 of Table XXII shows that addition of the proprietary selenium-type brightener to a high efficiency bath causes a marked increase in internal stress.

g. Periodic current reversal (PR).—Data relating the effect of PR to internal stress of deposits from cyanide baths are available only for bath No. CN-8 (Table XIV). Comparing lines 140 and 143 with lines 135 and 138, it is seen that stress is only slightly higher in the PR deposits. The large effect observed with sulfate deposits does not occur with cyanide deposits because, as seen in Section VII-C-1 above, stress does not decrease with increase of thickness of the latter.

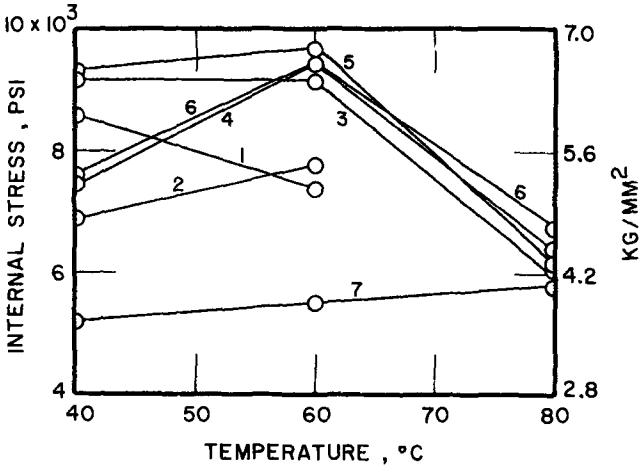

Fig. 31. Relationship between bath temperature and internal stress in copper deposits from cyanide baths: (1)—CN-2, 1 A/dm²; (2)—CN-2, 2 A/dm²; (3)—CN-4, 2 A/dm²; (4)—CN-4, 4 A/dm²; (5)—CN-5, 2 A/dm²; (6)—CN-5, 4 A/dm²; (7)—CN-6, 2 A/dm².

D. Density of Deposits from Cyanide Baths

Excluding the deposits from baths CN-8 and CN-9, which will be referred to subsequently, the average density of all deposits listed in Tables XXI through XXV is 8.911, with extremes of 8.898 and 8.920 g/cm³. For these thin deposits, the accuracy of our measurements (±0.01 g/cm³) was not sufficient to enable us to detect any effect of temperature, current density, and bath composition on density.

It is noted in Table XXII that the densities of the deposits from the high efficiency baths (lines 135, 138, and 146) range from 8.919 to 8.925 g/cm³, significantly higher than the average 8.911 of the low-copper cyanide baths. We believe that these higher values of high-efficiency deposits, in the same range as the densities of deposits from sulfate baths, are real, particularly since some of these high values were obtained from measurements on thick deposits for which accuracy of measurements is judged to be ±0.005 g/cm³ (*e.g.*, line 146, Table I).

E. Electrical Resistivity of Deposits from Cyanide Baths

An analysis similar to that given above for density leads to the following conclusions regarding the effects of various variables on electrical resistivity:

Table No.	Variable	Effect on resistivity
XIV	PR	None
XIV	Added KCNS + PR	Significant increase
XIV	Added proprietary addition agent + PR	Significant increase
XXI	Temperature increase	Variable, minor
XXII	Current density increase	Very small increase
XXII	*Added proprietary addition agent (without PR)*	*None*
XXIII	CuCN increase	None
XXIV	Free CN increase	None
XXIV	Na_2CO_3 increase	None
XXV	Rochelle salt addition	Small increase
XXV	Potassium ion (*vs.* sodium)	Significant decrease

F. Relationships between Properties of Deposits from Cyanide Baths

1. Tensile strength and ductility.—Tensile strength as a function of significant strain is plotted in Fig. 32, which contains points representing all deposits from cyanide baths. In general, significant strain decreases with increase in strength. This is the relationship that usually occurs for wrought metals, and was observed for certain addition agent sulfate deposits. It is the opposite of the relation between strength and ductility for nonaddition agent deposits from sulfate and fluoborate baths (Fig. 14 and Fig. 22, respectively). The two deposits that most conspicuously fail to conform to the general pattern are (*a*) the deposit from the proprietary high-efficiency bath made with direct current, which has low ductility for its strength, in comparison with the main pattern; and (*b*) the corresponding PR deposit, which has abnormally high ductility.

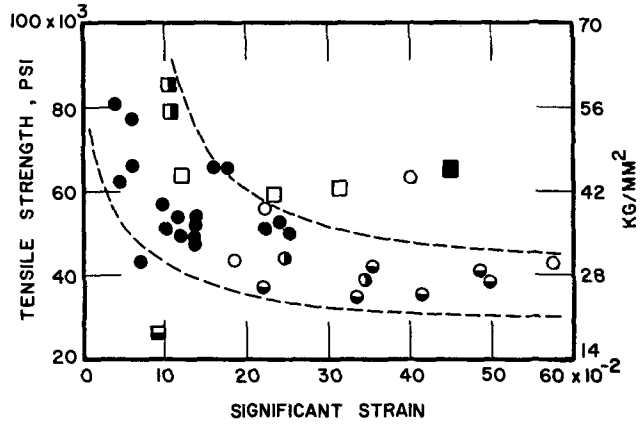

Fig. 32. General relationship between significant strain and tensile strength of copper deposits from various cyanide baths. ●—CN-1 through CN-5, all operating conditions; ○—CN-6, sodium Rochelle salt bath, all operating conditions; ◑—CN-7, potassium Rochelle salt bath, all operating conditions; ◒—CN-8, all operating conditions; □—CN-8 with periodic current reversal (PR), no addition agent; ◧—CN-8 plus 2 g/l KCNS, with PR; ▣—CN-9, proprietary bright bath; ■—CN-9 with PR.

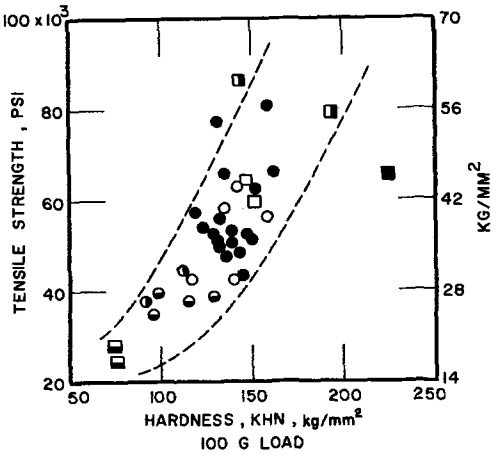

Fig. 33. General relationship between hardness and tensile strength of copper deposits from various cyanide baths. The code defining deposits is the same as for Fig. 32.

2. Tensile strength and hardness.—The general relationship between tensile strength and hardness for all deposits from cyanide baths is shown in Fig. 33, in which there is seen to be a positive correlation between hardness and tensile strength. The relationship is more definite than that for sulfate deposits (Fig. 15).

G. Structure of Deposits from Cyanide Baths

1. Effect of type of bath on structure.—Optical micrographs of several typical deposits from cyanide baths are shown in Fig. 34. Included for comparison are a strike bath deposit, a deposit from a typical low-concentration bath, deposits from both sodium and potassium Rochelle-type baths, a deposit from a standard high-efficiency bath, and a deposit from a high-efficiency bath containing a selenium-type proprietary brightener. The deposits from the low-concentration baths (Fig. 34-1 and 34-2) show a fine columnar structure, which is surprising, because literature references commonly refer to deposits from these baths as being extremely fine grained (33). On the other hand, a cyanide deposit with a structure similar to that of Fig. 34-1 has been reported by R. R. Bair and A. K. Graham [Ref. (26), p. 167]. To verify the structure seen in Fig. 34-1 and to check the possibility that it might be an erroneous work-induced structure, an entirely new section was prepared and examined by both optical and electron micrography. The electron micrographs, shown in Fig. 36, were made from a specimen prepared by a deep electropolish. The same results were obtained, indicating that the observed structure is a true representation of the deposit. The significant features noted in the electron micrographs are:

a. Small micro-twin and columnar grains extending the thickness of the deposit.

b. Surface rippling in the areas below nodules on the upper surface (Fig. 36-2). The electron micrographs were made for us by D. B. Ballard of the NBS Metallurgy Division. Details are given in section X, Appendix.

The addition of Rochelle salt (Fig. 34-3) is seen to cause grain refinement. The deposit from the potassium Rochelle bath (Fig. 34-4) does not contain the nodular structures of the deposit from the sodium salt bath and shows some indication of the presence of fairly large equi-axed grains. The deposit from the high-efficiency bath (Fig. 34-5) is fine grained, whereas that from the proprietary bright bath (Fig. 34-6) shows large columnar grains extending the thickness of the deposit. This structure correlates with its low strength and ductility (Table XXII).

2. Effect of periodic current reversal on structure.—Effect of periodic current reversal on structure is

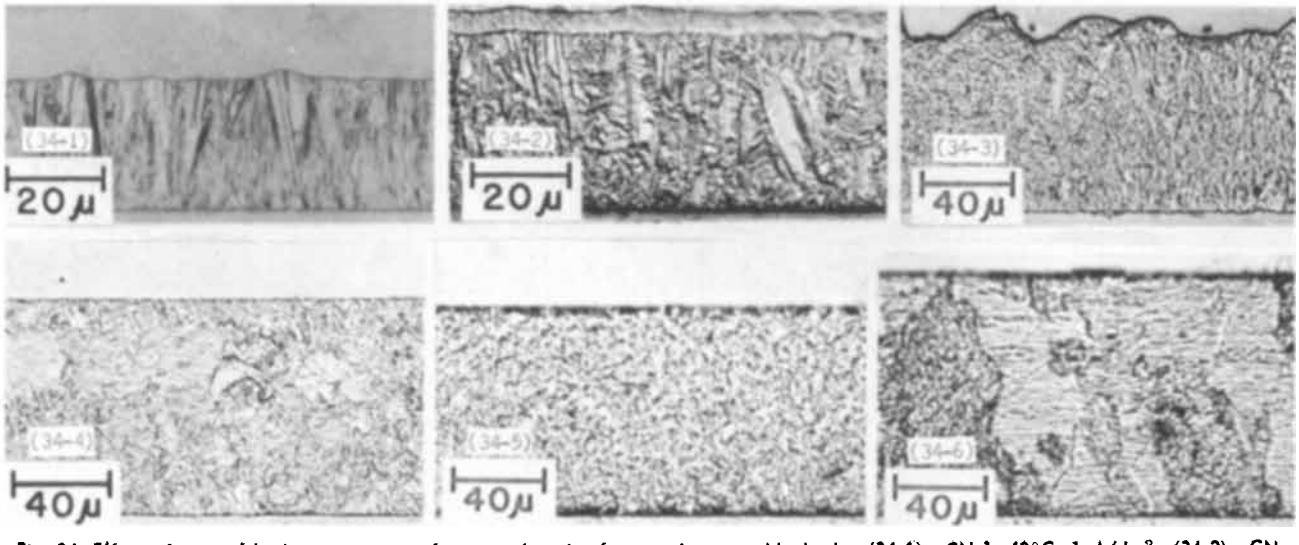

Fig. 34. Effect of type of bath on structure of copper deposits from various cyanide baths: (34-1)—CN-1, 40°C, 1 A/dm²; (34-2)—CN-5, 60°C, 2 A/dm²; (34-3)—CN-6, 60°C, 2 A/dm²; (34-4)—CN-7, 60°C, 2 A/dm²; (34-5)—CN-8, 80°C 6 A/dm²; (34-6)—CN-9, 80°C, 6 A/dm².

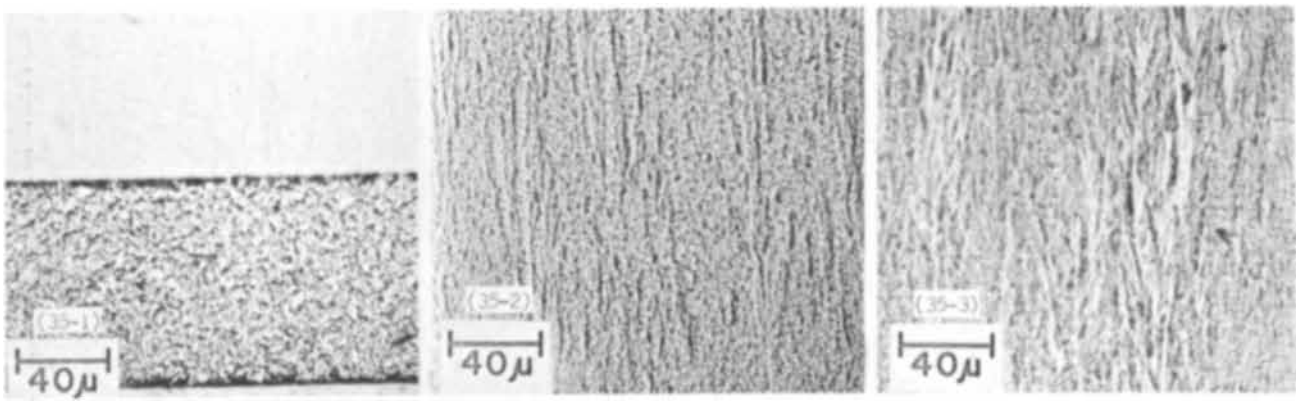

Fig. 35. Effect of periodic current reversal (PR) on structure of copper deposits from a high-efficiency cyanide bath: (35-1)—CN-8, 80°C, 6 A/dm^2, continuous current; (35-2)—CN-8, 80°C, 6 A/dm^2, no addition agent, PR, 15 sec cathodic, 5 sec anodic; (35-3)—CN-8 plus 2 g/l KCNS, 80°C, 6 A/dm^2, PR, 15 sec cathodic, 5 sec anodic.

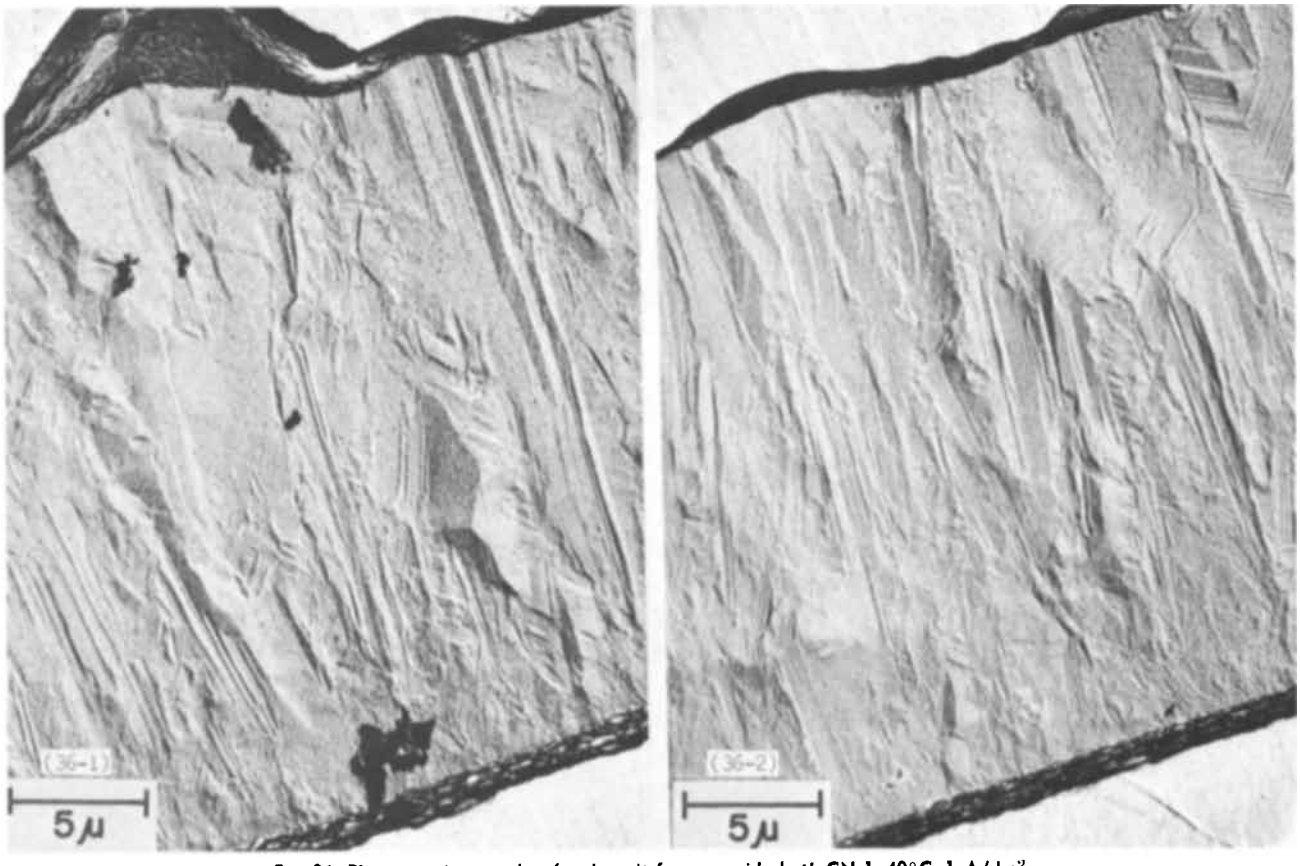

Fig. 36. Electron micrographs of a deposit from cyanide bath CN-1, 40°C, 1 A/dm^2

shown in Fig. 35. Figure 35-1 is a deposit from bath CN-8 made without PR, 35-2 the same with PR, and 35-3 the same as 35-2 except for addition of potassium thiocyanate to the bath. The latter two deposits were both built to a thickness of 18 mils. The addition of the thiocyanate resulted in a brighter final surface and less tendency for nodules to form. Both of the PR structures appear to be finer than the non-PR but with a distinct fibrous character. This shift of structure is consistent with the higher strength and hardness of these deposits (Table XIV). The laminations in Fig. 35-2 and 35-3 due to current interruption are not as distinct as have been shown in other published PR structures (14, 26). This is because the short cycle time that we used (15 sec cathodic, 5 sec anodic) resulted in a thickness per layer of only about 0.04 mil, which is resolvable and faintly visible in the original photographs at 500X but may not show in published prints.

Chlorine-Caustic Soda

I. Production.—The production of chlorine increased in 1969 to a new record of 9,427,000 tons in the United States, according to The Chlorine Institute, Inc. (1). This tonnage represents a gain of approximately 11.2% over the 1968 production of chlorine gas. The 1969 production of chlorine in Canada also reached a new high, 887,000 tons, which is up 14.4% over 1968 figures. During the period 1959-1969, the average annual growth rate has been 8.0% in the U.S. and 11.5% in Canada.

From December 1968 to December 1969, daily capacity increased 12.2% to 28,276 tons in the U.S. and increased 6.4% to 2636 tons in Canada.

Manufacturing in the U.S. operated at 95.6% of capacity, while Canadian producers operated at 93.3% in 1969.

During 1969, the unusual situation of a snug caustic soda market was the rule rather than the exception. Although generally caustic has experienced a slower growth trend than chlorine, lower prices have brought other markets into range (2). Caustic has already taken over most of the alumina processing market, and is making inroads into pulp and paper production at the expense of soda ash. There is some hope that the trend will extend to the glass industry, but most feel business in this area will come slowly.

A 7.5%/yr growth prediction for caustic soda and an 8.0%/yr growth for chlorine would indicate that supplies of caustic will continue to exceed market growth. In addition, theoretical yield of caustic is about 1.1 tons per ton of chlorine. Production figures, however, do not indicate that this yield is achieved in practice.

Some chlorine, approximately 4%, is a by-product of making metallic sodium from salt, with no coproduction of caustic. Production of lithium chloride, soda ash, potassium hydroxide, and in-plant use of caustic account for most of the rest of the discrepancy between the theoretical and the actual output ratio for chlorine and caustic.

Dow Chemical leads U.S. producers of caustic with 30% of the total capacity, followed by PPG with about 9%, Allied and Diamond Shamrock with about 8% each, Olin Mathieson and Hooker with about 6%, Wyandotte 5%, and with FMC, Stauffer, Pennwalt, B. F. Goodrich, Alcoa, and Kaiser rounding out the list of major companies in the industry.

In marked contrast to chlorine, exports of caustic grew at 12%/yr during the period 1960-1967. Most of this production was tied to bauxite processing.

No attempt is made to pinpoint caustic prices due to the many grades, type, and volume of shipments, *etc.*, but it does appear that discounting has been eliminated to a great extent. Most major producers announced \$3-\$4/ton increases, to the \$66/ton range, effective the third quarter of 1969 (3).

II. Expansions.—The best estimates of The Chlorine Institute, Inc., indicate that by the end of 1970 projects now under way will increase combined U.S. and Canadian daily capacity by about 6.5% or to approximately 12 million tons (4, 5).

Company & location	Type of cell	Capacity (tons/day)	Completion date
(A) Shutdown			
Arkla Chemical Corp., Pine Bluff, Ark.	Hooker S-1 Diaphragm	75	Oct. 1969
Stauffer Chemical Co., Huntsville, Ala.	Hooker S-1 Diaphragm	100	Aug. 1969
Stauffer Chemical Co., Dominguez, Calif.	BASF Mercury	150	
(B) Production started			
General Aniline and Film Corp., Linden, N. J.	BASF-Krebs Mercury	250	Nov. 1969
Interprovincial Cooperative Ltd., Saskatoon, Saskatchewan	Kureha HD-4 Mercury	70 Exp.	Jan. 1969
Kaiser Aluminum & Chemical Corp., Gramercy, La.	Hooker S-3B Diaphragm	300 Exp.	May 1969
PPG Industries, Lake Charles, La.	DeNora Mercury	600	Feb. 1969
Reactive Metals, Inc., Ashtabula, Ohio	Downs	50% Exp. metallic sodium-chlorine	Dec. 1969 1st stage
Velsicol Chemical Co., Memphis, Tenn.	Hooker S-4 Diaphragm	Hooker S-1 removed	June 1969
Wyandotte Chemicals Corp., Geismar, La.	Hooker S-4B Diaphragm	350	April 1969
C. Building or planned			
American Magnesium, Snyder, Texas	Magnesium cells	30,000 tons/yr	Bal. 1970
Conso Chemicals Ltd., Abercrombie Point, Nova Scotia	ICI Mercury	\$8 million	Early 1970
Dow Chemical Co.,	Dow	24,000 tons/yr	Late 1971
Dallesport, Wash.	Dow	24,000 tons/yr Magnesium (100,000 tons/yr Cl_2)	Late 1973
Dow Chemical Co., Freeport, Texas	Dow Diaphragm	Expansion planned	
Dow Chemical Co., Midland, Mich.	Dow Diaphragm	Modernization planned	1971-1972
Dow Chemical Co., Pittsburg, Calif.	Dow Diaphragm	450	Mid-1970
Dow Chemical Co., Plaquemine, La.	Dow Diaphragm	\$2.2 million	2nd Quarter 1970
National Lead Co., Grantsville, Utah	BASF	45,000 tons/yr Magnesium	Late 1971
Oregon Metallurgical Co., Albany, Ore.	Alcan	10,000 tons/yr Magnesium	1st Quarter 1970
PPG Industries Inc., Guayanilla, Puerto Rico	DeNora Mercury	500	Late 1970
Standard Chemical Ltd., Beauharnois, Quebec	Uhde Mercury	220	1970
Stauffer Chemical Co., St. Gabriel, La.	Uhde 30 m^2 Mercury	500	1st Quarter 1970

III. New developments.—A. Pricing.—In the last quarter of 1969, the price of chlorine was raised \$2/ton to the \$75/ton range, in single unit tankcars, F.O.B. plants, freight equalized. Higher manufacturing and distributing costs were given as the reason for the increase. For that small percentage of total production sold in ton containers, the price was also increased \$2 to \$97/ton (6, 7).

B. Mercury.—Mercury consumption increased 5% during 1969 with the larger users being the manufacturers of chlorine and caustic soda, catalysts, pulp and paper, and pharmaceutical products.

Mine production was estimated at 29,000 76-lb flasks; secondary production was 50% less than 1968, mainly as a result of a drop in government sales. California and Nevada supplied 63% and 28%, respectively, of the mercury produced in the U.S., with the balance from Alaska, Arizona, Idaho, Oregon, and Texas. The value of primary production was placed at \$14,600,000 (8).

Imports of mercury increased approximately 20%. Spain is the largest producer with British Columbia,

[1] This report is sponsored by the Industrial Electrolytic Division of The Electrochemical Society. While it is primarily a summary of production and developments in the chlor-alkali industry, reports of other electrolytic industries are included.

The material presented herein has been gathered from many sources, noted in the References, and does not necessarily represent the opinions of the authors.

* Electrochemical Society Active Member.

Algeria, Turkey, and Yugoslavia also contributing to the world production.

The price of mercury has been as low as $182/flask in August 1963, and as high as $700/flask in June 1965. Lately it has fallen from about $585 to less than $500/flask (9).

Government officials recently said they would like to sell about 73,700 flasks from surplus stockpiles eventually; however, opposition is expected from the domestic industry and through diplomatic channels. The government has been offering stockpiled mercury this year at the rate of 1500 flasks a month.

C. BASF-Wyandotte.—Badische Anilin and Soda-Fabrik AG of Ludwigshafen, West Germany, announced that it is acquiring 98.5% of the outstanding stock of Wyandotte Chemicals Corporation, Wyandotte, Michigan. This represents an investment of about $95 million. In the next three or four years, BASF expects to spend around $105 million on plant expansions and modernization.

In 1968 BASF had sales of $1.4 billion, while Wyandotte's sales were $147 million (10).

Other Alkalies and Electrolytic Processes

Sodium Chlorate.—Production of sodium chlorate in the U.S. was approximately 183,000 tons in 1969, with a projected demand of 244,000 tons by 1973. Of this, 72% goes to the pulp and paper industry, 14% is used in the manufacture of chlorates and perchlorates, and 9% is used for herbicides. The pulp and paper industry employs chlorates for the generation of chlorine dioxide to bleach paper. Cotton defoliation and clearing railroad rights-of-way account for most of the herbicide use.

The domestic producers of sodium chlorate are listed (11):

Producer	Capacity (short tons/yr)
American Potash and Chemical Corp., Hamilton, Miss.	23,500
American Potash and Chemical Corp., Henderson, Nev.	30,000
Brunswick Pulp and Paper Co., Brunswick, Ga.	7,000
Georgia-Pacific Corp., Bellingham, Wash.	5,000
Hooker Chemical Corp., Columbus, Miss.	55,000
Hooker Chemical Corp., Niagara Falls, N. Y.	15,500
Reigel Paper Corp., Butler, Ala.	4,000
Reigel Paper Corp., Reigelwood, N. C.	7,000
Pacific Engineering and Production Co., Henderson, Nev.	6,000
Penn-Olin Chemical Co., Calvert City, Ky.	31,000
Pennwalt Corp., Portland, Ore.	15,000
PPG Industries Inc., Lake Charles, La.	15,000
	214,000 Total

Caustic potash.—Caustic potash facilities currently operable in the U.S. are shown below (12):

Producer	Capacity (short tons/yr)
Allied Chemical Co., Syracuse, N. Y.	30,000*
Diamond Shamrock Corp., Delaware City, Del.	16,000
Diamond Shamrock Corp., Muscle Shoals, Ala.	40,000
Dow Chemical Co., Pittsburg, Calif.	10,000
Hooker Chemical Corp., Niagara Falls, N. Y.	36,000*
International Minerals and Chemical Corp., Niagara Falls, N. Y.	23,000*
Monsanto Co., Sauget, Ill.	45,000
Pennwalt Corp., Calvert City, Ky.	25,000
PPG Industries, Inc., Corpus Christi, Texas	7,000*
PPG Industries, Inc., New Martinsville, W. Va.	8,000
	240,000 Total*

* Includes solid or flake production.

Published price for liquid, in carload or truckload quantities, was $3.80/cwt., F.O.B. producing plant. Flake prices increased during the year from $11.10/cwt. to $11.60/cwt.

Soda ash.—Natural soda ash production reached a total of 2,500,000 tons in 1969; this quantity was valued at $47,800,000 (13). The production rate noted reflects continued price degradation, as the quantity increased 23%, but the value dropped 14% compared to last year. While some production came from the dry lake beds in California, the bulk of U.S. needs was supplied by Green River, Wyoming, as in previous years. Food Machinery Corporation's three shafts in Green River are operating at near capacity of 1,250,000 tons/yr; a fourth shaft is planned, commencing a $5,000,000 expansion program (14). In addition, nearly 2,000,000 tons of sodium carbonate were produced synthetically (15).

Year-end price for both dense and light 58% soda ash climbed 5% from 1968, listing: bagged, $2.20/cwt. and bulk, $1.65/cwt. (16).

Aluminum.—Primary aluminum production in the U.S. increased to 3,800,000 tons in 1969, up from 3,250,000 tons in 1968. Canadian production of aluminum was reported to total approximately 1,063,000 tons in 1969.

Apparent use of aluminum in the U.S., based on shipments of primary metal, net imports, and recovery from scrap, increased to approximately 4,800,000 tons. This year of relatively steady production served to reduce imports of aluminum metal to a level less than 1968, when strikes at plants of two major domestic producers forced consumers to rely on foreign supply (17).

Aluminum ingot capacity under construction or planned for 1969 was as follows (18):

Producer	Capacity (short tons/yr)
Aluminum Co. of America, Rockdale, Texas	50,000
Aluminum Co. of America, Evansville, Ind.	50,000
Gulf Coast Aluminum Corp., Lake Charles, La.	35,000
Kaiser Aluminum & Chemical Corp., Tacoma, Wash.	20,000
Reynolds Metals Co., Longview, Wash.	40,000
National-Southwire Aluminum Co., Hawesville, Ky.	180,000

The price of unalloyed primary aluminum ingot, which had been raised to 27¢/lb early in January 1969, was raised again to 28¢/lb in mid-October.

Domestic production of bauxite rose to 1,800,000 long tons, while imports were 12,000,000 long tons. Approximately 60% of the bauxite imports in 1969 came from Jamaica, 20% from Surinam, and the majority of the balance from the Dominican Republic, Haiti, and Guyana. It is estimated that 67% of the alumina imports were from Australia and about 25% from Surinam (19). Generally speaking, 4 tons of bauxite are required to produce 2 tons of alumina which will yield 1 ton of primary aluminum.

Beryllium.—This year marks the fifth straight year that the use of beryl (a beryllium-aluminum-silicate) has increased, and the U.S. consumption for 1969 exceeded 6000 tons (20). Nearly half of the beryllium metal consumed is used in high-speed aircraft, and the remainder employed in missile components, the nuclear industry, and copper and nickel alloys (to impart fatigue resistance) (21, 22).

Domestic sources for beryllium production are the states of South Dakota, Maine, and Colorado, in that order, for hand-sorted beryl; and Utah for mined bertrandite (another beryllium-aluminum-silicate). General imports of beryl for 1969 should exceed 6400 tons, valued at $2,600,000; interestingly, while the tonnage is nearly a 40% increase over 1968, the foreign value of this material dropped 15%.

The industrial activity evident in 1969 is probably in response to the steadily growing beryllium market. Kawecki Berylco Industries, Inc., and Brush Beryllium Company processed hand-sorted beryl into beryllium metal and alloys; and some concentrates have been shipped from the new (September) Brush Beryllium's Spor Mountain processing plant near Delta, Utah. General Astrometals Corporation has leased the electrofining facilities of Beryllium Metals and Chemicals Corporation. Topaz Beryllium Company (subsidiary of The Anaconda Company) has acquired land in Juab County, Utah, for a proposed beryllium ore concentration plant.

Government inventories at mid-year listed 7387 tons of beryllium-copper master alloy and 229 tons of beryllium metal (exactly the amounts reported for

mid-year 1968); the 11% BeO-bearing beryl figure was 26,559 tons, which is slightly down from a year ago. The General Services Administration sales of beryl in 1969 (including a December 1968 sale) totaled 3475 tons; the price varied from $50.52 to $52.67/short ton unit.

Chromium.—The three leading consumers of chromite increased their usage during the year, as inventories dropped. The metallurgical industry used 739,000 tons in 10 months, an 8.5% increase over 1968, reflecting the high level of stainless steel production. The chemical and refractory industries consumed 175,000 and 253,000 tons, respectively. This was a 5% increase in chromite use by the chemical industry, while the 8% decrease in use for the refractory group continued last year's trend (23).

The metallurgical industry had to turn to surplus chromite from government stockpiles to supplement supply, with the continued economic sanction against Southern Rhodesia imposed in early 1967. The General Services Administration has sold 789,000 tons since January 1967 with 206,000 tons delivered in the first 10 months of 1969.

Negotiations for a plant to produce ferroalloy in Puerto Rico were announced by Air Reduction Company. The plant is to have two furnaces with a combined rating of 40,000 kW; full production is estimated for late 1971 or early 1972. A chromium chemical plant to be built in Wilmington, North Carolina, was announced by Diamond Shamrock Corporation.

Metallurgical-grade chromite prices moved upward for the third successive year. Quoted prices per long ton at Atlantic ports were as follows: Russian, 48% Cr_2O_3, 4-1 ratio $49-$52; Russian 54-56% Cr_2O_3, 4-1 ratio, $55.10-$59.60; and Turkish 48% Cr_2O_3, 3-1 ratio, $47.50-$48.50.

Copper.—In its first full year of operation since 1966, the U.S. Copper Industry posted significantly optimistic gains in 1969.

A record 9% jump in mine production of recoverable copper was recorded, up to 1,560,000 tons over the 1,429,000-ton 1966 previous high (24). Of this amount, more than half (51%) came from Arizona with the states of Utah, New Mexico, Montana, and Nevada contributing another 40% which accounts for the bulk of U.S. production. The U.S. share of free world mine output is now up to about 30% (25).

Based on tonnages of domestic primary material only, smelter production was up almost 32% over 1968, to a projected total for 1969 of 1,520,000 tons. Refinery output of domestic material jumped 35% over last year, and is expected to post 1,450,000 tons for 1969.

Reversing a two-year trend, consumption of refined copper increased (over 2,000,000 tons used in 1969), but fell short of the 2,400,000-ton record year of 1966. Wire and cable alone accounted for 1,300,000 tons (up 9% over 1968); defense programs, primarily for ammunition, took 225,000 tons of copper.

In conjunction with increased U.S. mine production, imports of blister and refined copper dropped this year and are estimated below 1968 receipts by 8% and a plummeting 69%, respectively.

Primary world copper prices have risen 200% in the past ten years, using the London Metal Exchange as a measure; domestic wholesale price indexes show a 60% rise. For the year 1969, the LME average price per pound for copper went from 56¢ to 72¢; U.S. prices mirrored this increase, going from 42¢ to 52¢ in three steps. However, a balance in the copper market is anticipated with the expected elimination of World-U.S. price differentials.

In the recovery field, Powdered Metals Corporation of Phoenix, Arizona, has announced construction plans for the first plant which will employ the new Harlan (George E. Harlan) Process to obtain copper powder from oxide ores (26). The ore is leached with a demineralized water-sulfuric acid solution and the leach liquor is then filtered and electrolyzed. The process is said to reduce the cost of present smelting and electrowinning techniques by 40%. Most of the reduction results from utilization of inexpensive equipment and avoiding costly milling, flotation, and furnacing units. In addition, the components are so simple and light that a portable plant can be trucked to operate on-site at ore deposits once considered too small or remote. Ore-to-powder requires only 4 hr compared to several days using conventional means.

Lithium.—The following companies are involved in processing lithium raw material to lithium primary products: Foote Mineral Company at Sunbright, Virginia, and Silver Peak, Nevada; American Potash and Chemical Corporation, Trona, California; and Lithium Corporation of America, Bessemer City, North Carolina (27). Production data are not available.

Use of lithium in 1969 was at an all-time high. Products employing lithium in their manufacture include: ceramics and glass, greases, welding and brazing fluxes, air conditioning equipment, rubber, and pharmaceuticals. Some newer uses include aluminum reduction cells, and bleaches and sanitizers.

Lithium metal was priced at $7.75/lb in 1000-lb lots; lithium carbonate at $0.46/lb in carload lots; and lithium chloride at $0.85/lb.

The reports on cesium and rubidium, normally included in this section, are omitted this year since the Mineral Industry Survey fails to make any mention of these metals.

Magnesium.—For the year 1969, production of primary magnesium is projected at 89,500 tons, up 2% over 1968; and shipments at 107,000 tons, up 16%. Secondary magnesium recovery is expected to be 15,000 tons. While there was only a minimal rise in exports (4500 tons), imports increased 43% netting about 24,000 tons. The U.S. accounts for over 60% of the world 162,000-ton annual production figure.

The consumption of primary magnesium in 1969 was 100,000 tons, which represents a 3% drop from the 103,000 tons in 1968, as reported by the U.S. Bureau of Mines (28). In contrast, *Business Week* reports 1969 as the sixth consecutive year that magnesium demand has risen, and the third year in a row that demand has exceeded capacity (29). However, all sources agree that magnesium is on the verge of a Cinderella boom; expansions of present capacity are predicted to double by 1971 and reach 300,000 tons/yr in 1972 (30).

The ultimate target of the expanding magnesium industry is an anticipated 400,000-ton potential automotive market within 10-15 years. In the near term, the largest single market for magnesium is in the aluminum-magnesium alloys used in commercial aircraft; machinery is next, and the chemical industry third. The lightweight metal is making a strong bid to replace aluminum; while it still costs more than aluminum, the price differential may shrink with the activity the magnesium producers are exhibiting. New products include rapid transit systems, motors, cameras, power tools for home use, photoengraving, corrosion-resistant paint, and battery casings.

One big name in the industry dropped out in the third quarter of 1969: Alamet Division of Calumet and Hecla Corporation shut down its dolomite (highest grade magnesium, but most expensive process) plant at Selma, Alabama. The major producers now in the field are: Dow Chemical Company, with a 48,000-ton/yr plant to go on stream the last half of 1971 and reach design capacity in 1976 at Dallesport, Washington (31, 32); National Lead Company with a 45,000-ton plant under construction at Salt Lake, due for completion in 1971 (33, 34); American Magnesium Company began operation of its scheduled 30,000-ton plant at Snyder, Texas; and Oregon Metallurgical Corporation at Albany, Oregon, plans to complete its 10,000-ton plant in early 1975 (35). In addition, two large aluminum producers, Alcoa and Kaiser, own property in the magnesium-rich Salt Lake area (36); and two steelmakers, USS and National are taking a close look at producing magnesium themselves (37).

Magnesium compound production increased over 1968 by 14% in volume and 16% in value. Imports of refractory magnesium declined about 20% for the year.

Manganese.—In 1969, approximately 1,800,000 tons of manganese ore containing 35% or more manganese were imported from Brazil, Gabon, Australia, and the Congo. Ferromanganese imports increased to 300,000 tons for the year, primarily from the Republic of South Africa, France, India, and West Germany. Manganese metal imports were down to 1428 tons for the first three quarters, with the majority from the Republic of South Africa.

Domestically, approximately 2,300,000 tons of ore were produced. Montana and New Mexico continued to mine ore containing 35% manganese, but at lower levels than in 1968. International Minerals and Chemical Corporation shut down their blast furnace in Sheridan, Pennsylvania, and stopped producing ferromanganese. High imports and large inventories were given as reasons for this change (38).

December quotations for ore with a content of 46-48% manganese were 49-53¢/long ton. Foote Mineral announced price increases effective January 1, 1970 on all grades of electrolytic manganese, with a typical increase being No. 1 chip to 31.25¢ from 30.25¢/lb (39).

Deepsea Ventures Inc., a subsidiary of Tenneco Inc., was active in carrying on the deep-sea mineral investigations formerly pursued by Newport News Shipbuilding and Dry Dock Company. This work, off the Georgia and Florida coasts, has yielded over 40 tons of manganese nodules that are to be treated in process pilot plants.

Nickel.—International Nickel Company of Canada, Ltd. (Inco) operations in Ontario were closed by a strike of the United Steelworkers of America from July 10 until November 17, 1969. While Inco's Manitoba facilities continued to produce nickel, these account for only 30% of the company's total capacity. In addition, Falconbridge Nickel Mines, Ltd., was out of operation from August 21 until November 22, 1969, because of a strike by the Mine, Mill, and Smelter Workers Union (40). These two stoppages reduced the free world's production of nickel approximately 50%. Upon resumption of work, the increased wage and fringe benefits (worth $1.35/hr) increased Inco's employment costs by approximately 35% (41).

A total of 29 million pounds of nickel has been released from Government stockpiles thus far, compared to the 150 million pounds International Nickel claims to have lost during the four month strike. The stocks must be replaced with the government by July 1972, so it seems certain the shortage will continue (42).

World production of nickel was estimated at 530,000 tons. Imports into the U.S. from all sources were expected to be 125,000 tons with exports at 30,000 tons.

The producer price for cathodes started the year at $1.03/lb F.O.B. shipping point. Following settlement of the 128-day strike, Inco raised the price to $1.28 which was followed by other major producers. Quotations for dealer cathodes according to *Metals Week* were $1.65-$1.75/lb early in the year, but reached $6.65-$7.15 in October. Prices in the $8-$10/lb range were said to have been obtained for small quantities of special forms.

A hydrometallurgical nickel refining process, developed by Sherritt Gordon Mines, Ltd. (Toronto, Canada), has come to the attention of others due to the nickel shortage. Sherritt Gordon has been using this process since 1954 and recently licensed the process to Western Mining Corporation of Australia. A 50-million lb/yr refinery was announced for completion in 1971 or 1972 by The Philippine's Marinduque Mining and Industrial Corporation, using a modified version of the process (43).

International Nickel announced construction of an $80-million refinery marking the first commercial use of the Inco Pressure Carbonyl (IPC) process. This highly automated plant at Copper Cliff, Ontario, is scheduled for completion in 1971. Capacity is stated to be 100 million lb/yr of pellets and 25 million lb/yr of powder (44).

Sodium.—The use of sodium metal was up slightly over 3% in 1969 compared to last year; the 3% figure confirms the growth estimated in this industry for the next 3 years (45). While the sodium business recovered from the 1967-1968 drop, projected quantities based on 8-month figures show the 1969 total at 162,000 tons, which is still under the 1966 165,000-ton high. Of the sodium metal produced, 83% was used to manufacture tetramethyl and tetraethyl lead, 6% was used as a reducing agent in the production of titanium sponge, and the remaining 11% found miscellaneous uses (peroxide production, sodium hydride descaling of metals, chemical and drug intermediaries, and coolant in nuclear power stations) (46).

All major producers increased metallic sodium prices effective on spot in mid-November and on January 1, 1970 for contract business. Brick price (drummed, in 18,000-lb lots) rose 2¢/lb to 24½¢; reactor grades increased to 29¢; and carload lots increased to 18¾¢/lb.

Titanium.—Titanium sponge metal (refined ore) production rose 12% in 1969; sponge consumption leaped 35% over 1968, to about 19,500 tons (47). Foreign sponge imports for the first 9 months indicated a total receipt of 6230 tons. At year's-end, domestic sponge of 99.3% purity held at $1.32/lb, while import (from Japan and the United Kingdom, principally) dropped 0.05 to $1.20/lb (48). Only a small amount of titanium sponge was sold by the General Services Administration in 1969.

Through October, titanium metal (unwrought, waste, and scrap) was imported for consumption in an amount projected to equal 6500 short tons at a value expected to exceed $10,500,000. The bulk of the imports came from Japan (70%), with Russia (15%) and the United Kingdom (10%) making up most of the remainder. Exports, mostly scrap, were up 20%, totaling 3400 tons for 1969.

The price reduction reported last year (49) seems to have produced the desired result as the burgeoning consumption in 1969 indicated. Gains in chemical and construction uses are difficult to measure accurately, but aerospace and the aircraft industry are still prime markets.

No rutile was produced domestically in 1969, and imports increased 15%. To expand domestic rutile production, in June of 1967 the Office of Emergency Preparedness (OEP) reduced the war stockpile of rutile from 200,000 to 100,000 short dry tons. In 1969, import price for 96% TiO_2 rose to a high of $160 per short ton over last year's close at $125.

Ilmenite imports of the mineral concentrate rose 50% over 1968 in the face of a 3% drop in domestic production. Ilmenite is used mostly in making titanium oxide pigment. Quoted prices for 1969 held firm at $30-$35 per short ton for domestic 60% TiO_2-content stocks; and at $20-$21 per long ton for imported 54% TiO_2 material.

Zinc.—Reversing a three-year trend, U.S. mine production of zinc for 1969 rose 4%, to 546,000 tons (50). In conjunction with the expanding lead industry, 33,000 tons of zinc supplied from new mines alone placed Missouri as one of the country's leading zinc producers. While the historically higher zinc producing states increased their output, zinc production in others dropped, which offset the potential gain.

Smelter production of slab zinc zoomed the first half of 1969, but fell off the last half; still, projected output was up from the previous record year of 1966 by 5% and exceeded 1968 by 8%, totaling 1,160,000 tons. To add to this bright picture, shipments led production by a net 9000 tons for the year, considering customer's stores accumulation. Zinc imports of ore and metal approximated those of 1968. The principal suppliers were Canada, Mexico, Australia, and Peru.

Total consumption of zinc for 1969 was 1,800,000 tons with slab accounting for 1,400,000 and the other 400,-

000 tons made up of direct ore use (135,000) and scrap (265,000). In line with the increases noted in production, consumption also equalled the record year 1966. The largest advances in the industry were posted by zinc-base alloys (585,000 tons), zinc oxide (44,000), and in copper-base alloys as a result of full-year operation of brass mills (184,000 tons).

The General Services Administration sales amounted to 25,440 tons from the existing zinc disposal authorization; 22,610 tons remain in inventory.

Prime Western Grade zinc price rose 2¢ during the year, in three steps, to finish 15½¢/lb. The London Metal Exchange price, after fluctuating throughout the year, ended at 14¢/lb.

Electrical Energy

U.S. Generation.—The utility companies and industrial plants in the U.S. combined to produce 1.43 trillion kilowatt hours (kWhr) of electricity this year (51). Reflecting ever-increasing power consumption, this represents an 8.8% gain over 1968, substantially greater than the 5.2% growth in 1968, and the 7.4% average for the 5-year period ending 1967.

Utility production (representing 93% of the nation's total electrical energy capacity) held at the same 9.3% increase over the previous year, to a new record total of 1.33 trillion kWhr. The breakdown by production means shows: 16.7% hydroelectric, 82.7% by steam electric plants, and the balance (0.6%) by internal combustion engines and gas turbines. Each category reached a new high, exceeding 1968 levels by 0.3, 11.2, and 16.9%, respectively.

Steam electric generation using nuclear fuel showed a gain compared to 1968, of from 7.7 to a total of 12.3 billion kWhr; this increase (60%) is still only 0.86% of the country's total energy need. However, it is predicted that, by the year 2000, 50% of the nation's electrical energy requirements will be met by nuclear facilities (52). In 1969, consumption of coal reached 297 million tons, gas nearly 3.15 trillion cubic feet, and oil 188 million barrels. In keeping with the production increases, use of each fuel also rose. Hydroelectric generation also set a record high of 52.8 million kW, topping 1968 by 3.3%. It is estimated that, of the country's total hydroelectric potential (178.5 million kW), only 48.8 million kW, or 27%, has been developed.

There has been some concern regarding the rate at which present resources are being dissipated. Coal, gas, and oil have been carefully studied, and it is estimated that existing supplies will suffice for from 200 to 1000 years (53).

Utility generating capacity posted a record 8.1% increase this year, adding 21,806,000 kW, to a new high of installed capacity totaling 291,058,000 kW. This total capability is ample to supply current U.S. needs. Looking to the future, however, demand for electricity in the U.S. is expected to match the growth rate of the past three decades, which means doubling the generating capacity each ten years (54).

Coupled with the capacity and consumption increases seen in 1968, the industry also experienced delays. Some generating plants and transmission lines were not put into service on schedule, primarily as a result of shortages of skilled labor.

Nuclear Power.—In the U.S. Generation section of this report, it was reported that the total percentage of electrical energy derived from nuclear sources was very small (less than 1%). The past year still succeeded in chalking up a 60% production increase over 1968, even though it was a declining year for orders in the nuclear business. Furthermore, though recent rising construction costs (now about $1.45/kW for conventional *vs.* $2.00/kW for nuclear) have made utility companies hesitate to go the nuclear route, 1972 is predicted as the turning point for the swing to nuclear power (55, 56).

Historically, fossil-fueled steam generating plants have been the major source of electrical energy (57). In 1957, a government-sponsored program to develop and demonstrate the feasibility of nuclear reactors for civilian application was introduced to the electric utility industry. By 1964, $3 billion in study had indicated the cost advantage of a nuclear installation as typically slightly over 5 mills/kWhr, compared to 5-6 mills/kWhr for a fossil-fired plant. In addition, nuclear plants will require considerably less expense for pollution control. Following these findings, a rash of orders were placed for nuclear plants in 1966 and 1967. The explanation for the difference between the fast start and the current restrained status of the nuclear power industry is simply growing pains.

The power plant supply industry was pushed beyond its capacity, as neither facilities nor trained workmen were available to begin; construction costs and inflation have been steadily rising; and delays were experienced in educating a public concerned with thermal and radiation effects. On-stream service has been postponed as much as two years, and the original five years have been stretched to the present 6½-7 years for expansion planning.

The U.S. is well established as the world leader in enriched-uranium light water type nuclear power reactors, but the present generation of nuclear reactors employ less than 2% of uranium's potential energy. For this reason, the government and private industry are actively investigating fast (breeder) reactors for electrical power generation. Breeder reactors will utilize 50% of the latent energy in uranium and will, in fact, produce or "breed" more fissionable material than they consume. The major effect of the fast reactors will be to stabilize the supply and price of uranium; however, commercial exploitation of fast reactors is not expected to begin before the 1980's. Accordingly, power rates will probably fluctuate little in the next ten years, and only begin to drop as a result of breeders in the succeeding ten years.

D-C power.—In evaluating the power transmission figures of the last few years, the recent use of extra-high-voltage (EHV) lines must be taken into account. Power transfer capability increases as the square of the voltage, so comparing only miles of transmission line installed is not comprehensive. The decrease in actual miles from 18,452 in 1968 to 14,555 in 1969 illustrates the point well; in terms of voltage-miles, power transmission installation increased 32% in 1969 (58).

Currently, utility transmission installations are limited to 500-kilovolt (kV) lines, but this year saw the first 765-kV line become operable. Tests are in progress to utilize 1100- and even 1500-kV lines. Also, additional exploration is under way to examine the benefits directly related to direct current EHV transmission systems working in conjunction with alternating current systems.

There was a delay in completing the 853-mile, 750-kV[2] d-c transmission line between the Dalles Substation (on the Columbia River in Oregon) of the Bonneville Power Administration and the Slymar Substation of the Los Angeles Department of Water and Power. Start-up service was rescheduled for Spring of 1970.

Developments of Interest

Petrochemicals by electrolysis.—Electrolysis in organic syntheses has been studied for many years; however, very few processes have reached a commercialized scale. Electrolytic routes to organics may be applicable where product selectivity may be superior to known chemical methods (59).

A good example is the Monsanto process for electrohydrodimerization of acrylonitrile producing adiponitrile in a single, high-selectivity step; it is recognized that existing thermal and catalytic dimerization methods give inferior yields and/or lower conversions. Asahi Chemical of Japan is reported to be planning a 20-million-lb/yr adiponitrile facility. BASF is also said to be working on a similar process.

[2] Erroneously reported as an 825-mile, 800-kV line in the Report for 1968.

When objectional co-products may be avoided, the electrolysis method may have merit. An example would be the electrolytic chlorohydrin process for propylene oxide, eliminating the unwanted production of calcium chloride.

Conversion by chemical means may require reaction conditions so severe in terms of pressure, temperature, residence time, catalyst life, or corrosivity that the cost of the electrolysis system is justified. Direct handling of troublesome reagents may be eliminated, as in 3M's electrolytic fluorination process, and the bromination process developed by Sohio. The use of lower cost raw materials and useful products from both anode and cathode reactions may provide economic advantages.

Continued research in this area is indicated and, when any of the above advantages or a combination of them offset the high power and cell cost, an attractive process will result.

The Kel-Chlor process.—At the April 1969 American Chemical Society meeting in Minneapolis, Dr. Alex G. Oblad, Vice-President of Research and Development for the M. W. Kellogg Company (New York), presented the chemistry involved and the potential market impact of a breakthrough nonelectrolytic process for the manufacture of chlorine (60-62). Essentially, the Kellogg development provides a successful way to oxidize hydrogen chloride to chlorine.

The basic idea is not new. In the same manner, chlorine was first produced in the laboratory by the Swedish chemist Karl Wilhelm Scheele (63), and the concept was refined to commercial use about a century ago by Deacon and Hurter. They employed solid copper chloride as a catalyst; but, by using air as the oxidizing medium, the resultant chlorine was highly diluted with nitrogen, though acceptable for those times. More recent attempts to upgrade the process include increased catalytic activity, which has not proved attractive, or introduction of an organic molecule to react with chlorine and thus drive the reaction equilibrium toward more complete oxidation. The latter are generally termed oxychlorinations, and are useful but limited in application.

With the present-day availability of cheap oxygen, the Kellogg process employs two novel keys to push its descendant of the Deacon reaction to completion: nitrogen oxides as homogeneous (gas phase) catalysts, and sulfuric acid to absorb oxides and steam (64). Briefly, gaseous hydrogen chloride is reacted with hot recycled nitrosyl sulfuric acid to form nitrosyl chloride; in the first oxidation chamber, nitrosyl chloride with oxygen breaks down to chlorine and nitric oxide; conversion is completed in a second oxidizing step, where sulfuric acid absorbs water (steam) and reacts with the nitrogen oxides to yield nitrosyl sulfuric acid, which is recycled. The product chlorine is quite pure and relatively dry and meets the specifications of some applications as is; for more stringent uses, it can be easily upgraded.

In the past, attempts to commercialize hydrogen chloride oxidation processes have stumbled on economically insurmountable corrosion problems. Kellogg reports, however, that in its new process corrosion is not a difficulty and that "available" materials are utilized. Continuous operation of a one-ton/day unit is said to have proven the Kel-Chlor process, and Kellogg is prepared to offer it for license. Operating costs will vary, depending on plant size, from $17 to $10/ton of chlorine produced.

Dr. Oblad points out that, for the first time, the production of chlorine is exceeding that of caustic, dumping more caustic in an already saturated market. In addition, by-product hydrogen chloride from organic chlorinations is also creating an increasing disposal problem. Its developer offers the Kel-Chlor process as the solution to this situation. Neither the electrolysis of aqueous hydrogen chloride nor the electrolysis of magnesium chloride is geared to American market requirements, according to Dr. Oblad.

Two major areas are suitable targets: the production of elemental chlorine itself, and the use of chlorine in chlorination reactions (the largest of which is manufacture of vinyl chloride). As to the hydrogen chloride charge, four processes are listed as adequate sources: 1—steam hydrolyzed magnesium chloride, 2—the by-product from Solvay Process ammonium chloride, 3—the reaction of sulfuric acid with sodium chloride, and 4—the fertilizer industry's conversion of potassium chloride to the more potent potassium phosphate or nitrate.

Manuscript received June 11, 1970. This report was presented at the Industrial Electrolytic Division Luncheon at the Los Angeles Meeting of the Society, May 10-15, 1970.

Any discussion of this report will appear in a Discussion Section to be published in the June 1971 JOURNAL.

F. M. Becket Memorial Award

The Electrochemical Society will offer the F. M. Becket Memorial Award to a qualified graduate student for the summer of 1971. This Award commemorates F. M. Becket, a man of great research and administrative ability and a former President of the Society, whose accomplishments in science and industry were outstanding. The stipend valued at $1500 provides a grant-in-aid toward a summer's (at least two months) research and study overseas in the laboratory of a recognized research institute or institution of higher learning, selected from the approved list maintained by the F. M. Becket Memorial Award Committee.

The objectives of this Award are to stimulate and encourage education and participation in the fields of electrochemical science and industry concerned with specialty materials and processes as follows:

a) **Materials** such as refractory metals and compounds, intermetallics, graphite, fused salts, and rare earth metals;

b) **Equipment** for the utilization of electrical energy in materials synthesis;

c) **Processes** using arcs, vacua, plasmas, and electron and ion beams; and

d) **High temperature kinetics and thermodynamics phenomena** such as melting, vaporization, reactions, sintering, diffusion or oxidation occurring at high temperatures, high pressures, or vacua involving high temperature materials.

To be eligible for the Award, the entrant must qualify in one of the two following categories. He must be either (1) a graduating senior of demonstrated ability, regularly enrolled in any recognized college, university, or institute of technology in continental United States or Canada, who intends to seek an advanced degree, or (2) a graduate student, similarly enrolled, who is seeking an advanced degree. No limitations of sex, race, nationality, or religion are to be imposed by the Award Committee in determining the recipient of the Award.

The Award shall be presented on the basis of the following material:

1. A complete transcript of the student's academic record.

2. Two copies of a letter, over the signature of the head of the College or Department in which the student is enrolled, describing briefly his academic work, his campus activities, and presenting an estimate of his abilities.

3. Two copies of a letter, over the student's signature, containing a brief biographical sketch, a detailed description of the nature and extent of his academic work, particularly as it may relate to the field of the Award, and an outline of his plans for the future. The student shall indicate, from the list provided by the Award Committee, his choice of a place of residence under the Award.

Application forms are available from the Executive Secretary, Mr. Ernest G. Enck, The Electrochemical Society, Inc., 30 East 42nd Street, New York, N. Y. 10017. Deadline for receipt of completed applications will be February 1, 1971; and the Award winner will be announced on April 1, 1971.

Physical and Mechanical Properties of Electrodeposited Copper

III. Deposits from Sulfate, Fluoborate, Pyrophosphate, Cyanide, and Amine Baths*

Vernon A. Lamb, Christian E. Johnson, and Donald R. Valentine

National Bureau of Standards, Washington, D. C. 20234

VIII. Comparisons of Deposits from All Types of Baths: Fatigue Strength, Thermal Properties, Cold Working, Structure, Composition, and General Correlations

A. Fatigue Strength

1. Introduction, method, and apparatus.—Fatigue strength is of interest primarily in applications in which vibration or other cyclic stressing of plated or electroformed parts may cause fracture. Several studies of the effect of plating on the fatigue strength of a basis metal have been reported, but very little information on fatigue properties of separated deposits has come to our attention [Ref. (2) for nickel, Ref. (21), p. 55, for copper].

The method that we used for measuring fatigue strength was designed by J. A. Bennett of the NBS Metallurgy Division. It is an adaptation of the Amsler "Vibrophore" test method[15] to thin sheet stock (34). Specimens were milled from panel stock to the form shown in Fig. 37. They were then bent into a "U" as shown at "1" in Fig. 38. The bending procedure was as follows. A ¼ in. diameter rod was placed transversely across the center of the flat specimen, which was supported on a deep (2-3 in.) sponge-rubber pile which acted as a female mandrel. With a small press, the rod and sheet were forced into the sponge-rubber pile. The action of the test machine is illustrated in Fig. 38. The formed specimen was attached to blocks 2 and 3 with screws through clamping plates (not shown). Block 2 was rigidly attached to the frame of the machine. Block 3 oscillated vertically, driven by the force, *P*. This produced lateral oscillation of the top of the specimen, as indicated by the arrows above "1." Thus, each of the four faces of the specimen was alternately stressed in tension and compression, with maximum stress at the position of minimum width. The mean load was zero; *i.e.*, the maximum deflections of the specimen to either side of the zero-load position were equal. Oscillation rate was 1800 cycles/min. The maximum load, *P*, was determined from machine adjustments; lateral displacement of the top of the specimen, illuminated with a stroboscope, was measured with a micrometer microscope. The relationships by means of which stress and strain in the specimen are determined from *P* and the lateral displacement of the specimen are developed in the Appendix, paragraphs X-B-1 and X-B-2.

2. Results.—The fatigue characteristics of several typical kinds of copper deposits are shown in Fig. 39, in which stress amplitude is plotted as a function of the number of cycles required to produce failure by cracking. The character of the curves is typical, similar to those obtained for wrought metals. The pertinent data from these curves are summarized in Table XXVI. Stress-strain parameters for three types of copper representing high and low extremes and a mid-value of

* AES Project 21 Report. Sections VIII-X published here are the third and last installment of this paper. Part 1 (Sections I-III) appears on pages 291C-318C of the September issue, and part 2 (Sections IV-VII) on pages 341C-352C of the October issue.

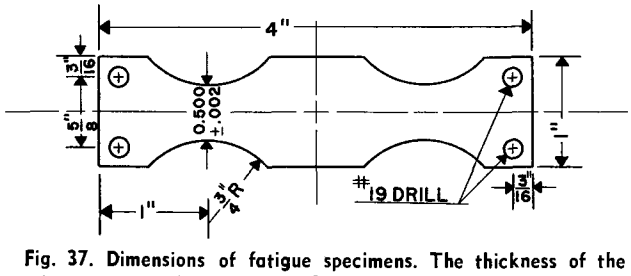

Fig. 37. Dimensions of fatigue specimens. The thickness of the specimens ranged from 0.015 to 0.02 in. (375-500 μm).

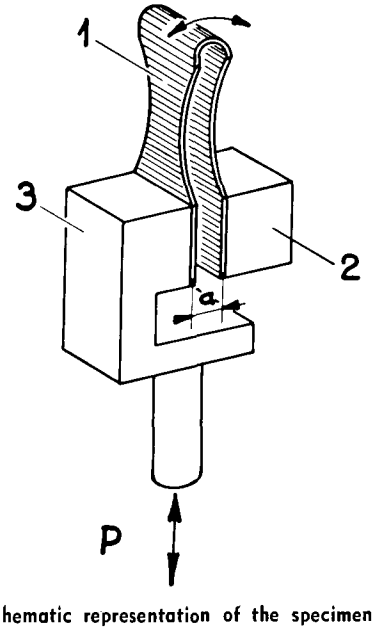

Fig. 38. Schematic representation of the specimen mounting for fatigue testing of electroformed copper. The specimen, 1, is attached to holders, 2 and 3, with screws and clamping plates (not shown). Holder, 2, is rigidly attached to the frame of the machine. Application of the pulsating force, *P*, causes holder, 3, to oscillate vertically, resulting in lateral oscillation of the specimen as indicated by the curved arrows. The distance "*a*" is 0.300 in. (7.5 mm).

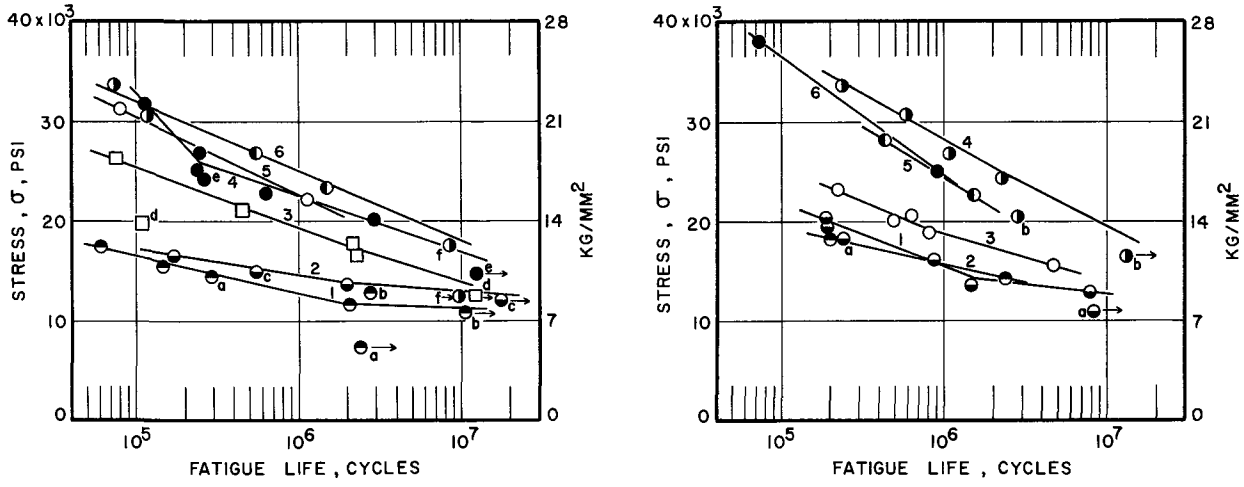

Fig. 39. Relationship between fatigue life (cycles) and stress for electroformed copper. *Part A (left):* (1) Cu2-H2, mild cellulosic exposure, 30°C, 2 A/dm^2; (2) Cu2-H2, severe cellulosic exposure, 30°C, 2 A/dm^2; (3) Cu2-H3 containing 1 mg/liter selenium, 30°C, 2 A/dm^2; (4) pyrophosphate, 50°C, 2 A/dm^2; (5) pyrophosphate, 50°C, 4 A/dm^2; (6) Cu2-H3 containing 3.5 g/l triisopropanolamine, 50°C, 5 A/dm^2. *Part B (right):* (1) F-1, 30°C, 8 A/dm^2; (2) F-2, 50°C, 20 A/dm^2; (3) Cu3-H3 containing 1 g/l phenolsulfonic acid, 30°C, 2 A/dm^2; (4) CN-8 containing 2 g/l KCNS, 80°C, 6 A/dm^2, PR, cycle 15 sec cathodic, 5 sec anodic; (5) CN-8 containing 2 g/l KCNS, 80°C, 6 A/dm^2, PR, cycle 30 sec cathodic, 10 sec anodic; (6) CN-8, 80°C, 6 A/dm^2, no addition agent, PR, cycle 15 sec cathodic, 5 sec anodic. Specimens that did not fail are indicated by a letter and an arrow. These specimens were tested further with larger loads. The point representing the retest conditions is designated by the corresponding letter.

fatigue strength are plotted in Fig. 40.[16] The curves for the non-addition agent sulfate deposits and for the pyrophosphate deposits are linear, indicating that in testing these deposits the elastic limit was not exceeded. The small deviation from linearity at the top of the stress range for the deposit from a sulfate bath containing triisopropanolamine has questionable significance.

In Table XXVI, the stress level at failure is shown for two life periods, 10^6 and 10^7 cycles. For 10^6 cycles, two values of stress are shown for lines 76 and 147, designated as σ_c and σ_m. σ_c represents a "calculated" value, obtained from the basic mechanical relationships developed in Appendix B-1. σ_m represents a "measured" value, determined from direct microscope measurements of strain on statically displaced specimens. The procedure is described in Appendix B-2. The magnitudes of the fatigue strength obtained by the two methods are in reasonable agreement.

The value of σ_c will first be considered in relation to the yield strength (Table XXVI). Fatigue failure would be expected to occur rapidly if the yield strength were exceeded. It is seen that several of the deposits were stressed beyond our values for yield strength, but nevertheless had fatigue lives of 10^6 or 10^7 cycles. This indicates that the tabulated values of yield strength, which are based on the arbitrarily selected offset of 0.05%, may be too low, or that dynamic yield strengths are higher than static yield strengths. Whatever the explanation, the results show that at the stress levels applied for lives of 10^6 to 10^7 cycles, plastic deformation must not have occurred.

It is of interest to intercompare the endurance ratio, *i.e.*, the ratio of the fatigue strength to the tensile strength, for the various plated coppers and for wrought copper. The ratio varies from a low of 0.32 for a PR deposit from bath CN-8 to a high of 0.61 for a deposit from the pyrophosphate bath. Ratios for deposits from the sulfate and fluoborate baths are close

[16] Explanation of stress-strain parameters in Fig. 40: From Eq. [12] of Appendix B-1, it is seen that stress is proportional to P/t^2 since a and b are constants. From Fig. 72 it can be readily shown that $\delta = t/2R$, where δ is the strain in the surface fibers of the specimen. Since R is approximately inversely proportional to the horizontal deflection of the top of the specimen, we have $R = K/D$, where K is the proportionality constant and D the deflection. Substituting this value of R in the preceding equation gives $\delta = tD/2K$. Thus, surface strain is approximately proportional to tD. See Appendix B-1 for definitions of symbols.

to 0.5, about the same as the ratios for wrought copper.

With respect to quality of deposits as measured by fatigue strength, deposits from non-addition agent sulfate and fluoborate baths are about the equal of annealed wrought copper, but poorer than cold-worked wrought copper. On the other hand, deposits from the sulfate baths containing addition agents and from the cyanide and pyrophosphate baths are equal or superior in fatigue strength to cold-worked wrought copper.

For a given type of bath, variation of operating conditions did not affect the fatigue strength significantly (Table XXVI). For example, changes in the following variables produced either no change or negligible change: degree of exposure of the sulfate bath to cellulose (lines 24, 26); bath temperature and current density (fluoborate bath, lines 91, 94 and pyrophosphate bath, lines 95, 98); and PR cycle (lines 147, 148).

Residual tensile stress adds to deformation stress to produce a higher total stress, which may be expected to hasten fatigue failure. One might, therefore, expect a relationship between fatigue strength and internal stress (Table XXVI). There are some positive correlations. For example, compare lines 26 and 88. The tensile strength is nearly the same, but the fatigue strength of the latter, with a compressive stress, is significantly higher. On the other hand, two of the highest values of fatigue strength appear in lines 76 and 147, both associated with high internal stress. At first sight this appears to be a reversal of the expected effect. However, we note that these high stress values corrrelate with the lowest endurance ratios. It is thus probable that, if these deposits were to retain their high strength and also had a low internal stress, the endurance ratio would be in the "normal" range of 0.5 and the fatigue strength would then be about 40,000 instead of 25,000-28,000 psi. The difference is a measure of the reduction due to the high internal stress. The correlation with internal stress fails in the case of the pyrophosphate deposits, where an apparently significant variation in internal stress does not affect the fatigue strength.

Several failed specimens were examined by J. A. Bennett to determine the character of the failure cracks, with the following results:

Panel No.	Structure type	Character of cracks
13	Large columnar, fairly fine starting grain	Cracks started on final (coarse) surface, propagated between dendrites
295	Fine uniform grain	Cracks started on both sides. Grain too fine to evaluate position of cracks with respect to grains at magnification used.
345	Like No. 13, U-bend with final surface outside	Like No. 13, cracks started on outside surface.
345	Same as above, but U-bend with final surface inside	Like No. 13, but cracks started on inside surface, in this case also the coarse surface.

The above results are what one would expect. The comparison between the two specimens from Panel No. 345 shows that the characteristics of the machine and the test procedure were such that inside and outside surfaces of the "U" were equally stressed.

B. Properties of Annealed Deposits

1. *Annealing procedures.*—Specimens were made from panel stock before annealing, *i.e.*, operations such as machining and stripping of nickel were carried out on the as-plated stock. Annealing[17] was done either in vacuum or in an argon atmosphere. Specimens were held at temperature for the times indicated in Table XXVII. They were put into and removed from a cold furnace, so the actual total annealing period was longer than the nominal period. The heat-up and cool-down periods ranged from about 15 min for 150°C to 45 min for 500°C.

Since it was not feasible to procure the extended data shown in Table XXVII for a large number of copper deposits, a representative sampling was chosen, including typical soft deposits from sulfate and fluoborate baths, deposits of a hard strong type from a sulfate bath containing an addition agent, typical pyrophosphate deposits, and PR deposits from bath CN-8 containing KCNS as an addition agent. The latter was chosen because it has good properties as plated and can be produced as thick electroforms. Limited measurements were also made with thin deposits from other cyanide baths, namely CN-2, a typical low-concentration bath, CN-8 without an addition agent or PR, and CN-9, the proprietary high-efficiency bright-plating bath.

[17] Annealing was done in part by G. E. Hicho of the Metallurgy Division, NBS, and in part by the authors.

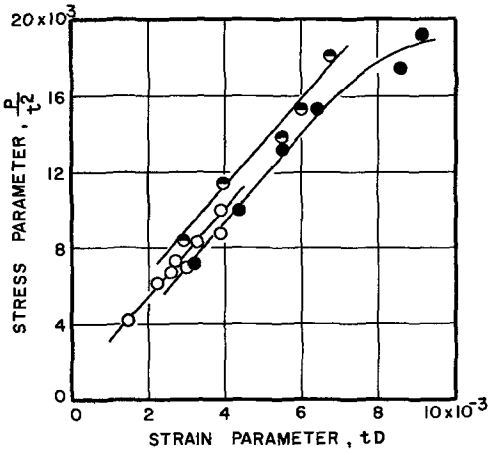

Fig. 40. Relationship between stress and strain at the surface of copper fatigue specimens from three types of baths at the point of minimum width: ○—Cu2-H2, 30°C, 2 A/dm²; ●—Cu2-H3 containing 3.5 g/l triisopropanolamine, 30°, 5 A/dm²; ◓—pyrophosphate, 50°, 2 A/dm². The specimen thickness is represented by "*t*", the magnitude of the horizontal deflection of the top of the specimen by "*D*," and the applied load by "*P*."

2. *Effects of annealing on mechanical properties.*—Data are summarized in Table XXVII and in Fig. 41, 42, and 43. In Fig. 41, it is seen that in general annealing caused decrease of tensile strength and increase of ductility. However, the changes are small for deposits that are initially soft and ductile, namely those from the non-addition agent sulfate bath, the fluoborate bath, and the pyrophosphate bath. The deposit from the sulfate bath containing triisopropanolamine resists change to a fairly high annealing temperature (325°-400°C), then abruptly loses strength and gains ductility. The PR cyanide deposit, on the other hand, undergoes significant changes in the same directions at the lowest annealing temperature of 150°C. The tensile strength and elongation of all of the deposits tend to the same values after annealing at 500°-550°C.

Effects of both annealing and cold rolling on modulus and hardness are illustrated in Fig. 42 and 43. In general, cold rolling has less effect on modulus than does annealing. The magnitude of the shifts due to cold rolling is within our estimated accuracy of $\pm 1 \times 10^6$ psi and the direction is random. On the other hand, annealing at 500°C causes a significant decrease of modulus in all but one case (PR deposit from bath CN-8).

The effect of annealing on hardness (Fig. 43) is similar to its effect on tensile strength. The deposits that are initially soft or fairly soft (non-addition agent sulfate, fluoborate, and pyrophosphate) undergo minor additional softening. The deposits from the triisopropanolamine sulfate bath (TIPA) and the PR CN-8 bath undergo marked reduction of hardness. The abnormally low hardness, 32 KHN, of the TIPA deposit is an "apparent" value due to an "exploded structure" of the deposit resulting from heating to 500°C. This has other related effects that are referred to subsequently.

Cold rolling in all cases causes a significant increase of hardness.

[o] One pound per square inch (psi) = 0.000704 kilogram per square millimeter (kg/mm²).
[p] All mechanical properties of annealed deposits were measured at room temperature.

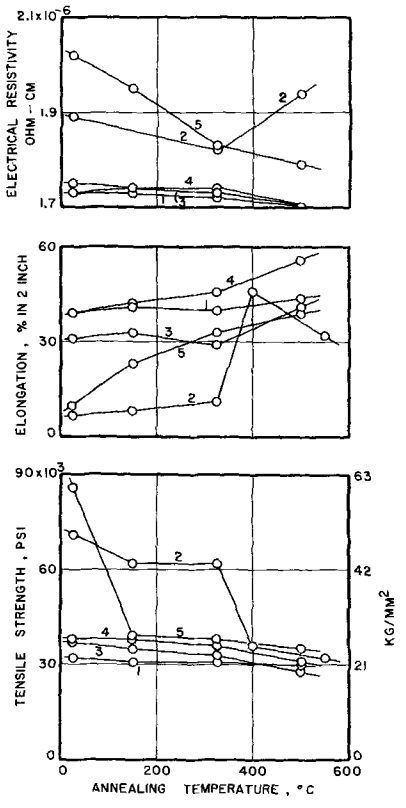

Fig. 41. Relationships between annealing temperature and tensile strength, elongation, and electrical resistivity of copper deposits from various baths: (1) Cu2-H2, 30°C, 2 A/dm²; (2) Cu2-H3 containing 3.5 g/l triisopropanolamine, 30°C, 5 A/dm²; (3) F-1, 30°C, 8 A/dm²; (4) pyrophosphate, 50°C, 2 A/dm²; (5) CN-8 containing 2 g/l KCNS, 80°C, 6 A/dm², PR, cycle 15 sec cathodic, 5 sec anodic.

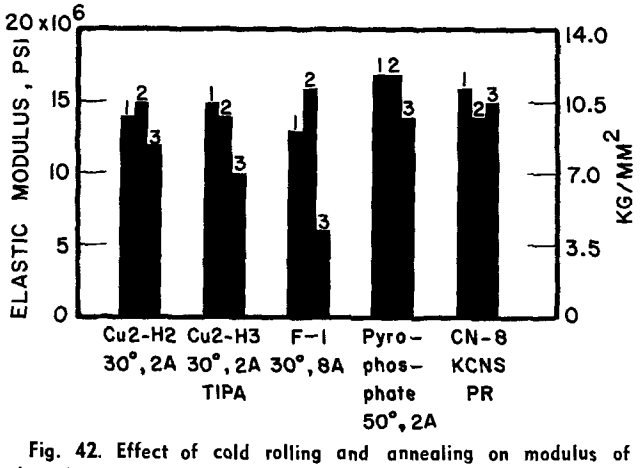

Fig. 42. Effect of cold rolling and annealing on modulus of elasticity of copper deposits from various types of baths: 1—deposits as plated; 2—deposits cold rolled, 50% reduction; 3—deposits annealed at 500°C for 15 min.

Yield strength decreases with annealing for all of the deposits, reaching the extremely low value of 3000 psi for the fluoborate deposit annealed at 500°C (Table XXVII).

3. Effect of annealing on density.—Since the effects of annealing on density were in general small, data were obtained only for deposits annealed at 500°C. The results are compared with as-deposited values in Table XXVII. No measurable effect was found except for the TIPA deposit. It underwent a very large decrease of density, 18%, due to "explosion" and formation of interior voids. (The effect of the same

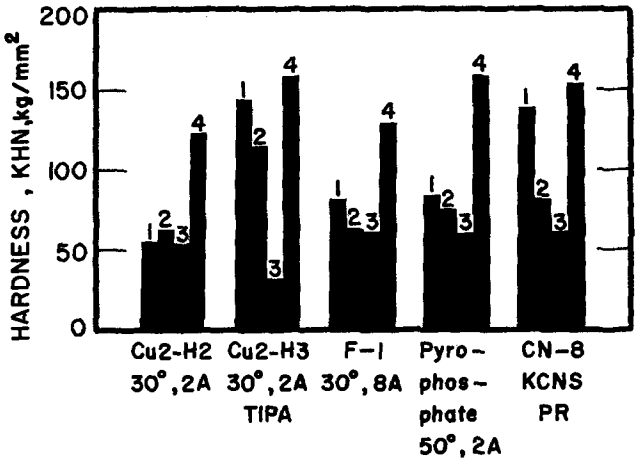

Fig. 43. Effect of annealing and cold rolling on hardness of copper deposits from various types of bath: 1—deposits as plated; 2—deposits annealed at 325°C for 15 min; 3—deposits annealed at 500°C for 15 min; 4—deposits cold rolled, 50% reduction.

phenomenon on hardness was described above in Section VIII-B-2.) The voids are shown in Fig. 45-3.

4. Effect of annealing on electrical resistivity.—Effect of annealing on electrical resistivity is shown in Fig. 41. As in the cases of the other properties already discussed, the deposits that are soft and have low resistivity as plated undergo little change, although their resistivity does decrease slightly. The anomalous behavior of the TIPA deposit is seen again. Its resistivity is high as plated and undergoes significant decrease after annealing at 325°C. However, after annealing at 500°C, its resistivity *increases*. Our interpretation is that, after heating at 325°C, the deposit still has a normal structure, with grain growth that correlates with the lower resistivity. After heating at 500°C, void formation has occurred which causes the true cross section of the deposit to be less than the nominal cross section, hence, the resistivity increases. The PR deposit from the CN-8 bath undergoes a marked regular decrease of resistivity as the annealing temperature is increased, but even after heating at 500°C its resistivity is higher than that of high-purity copper.

5. Effect of annealing on the structure of various deposits.—*a. A deposit from a non-addition agent sulfate bath.*—In Fig. 44 are shown the structures of specimens from panel No. 322-323 (Table XXVII, line 26), as plated, annealed at 325°C, and annealed at 500°C. At 325°C recrystallization and grain growth have involved mainly the originally fine-grained basal portion of the deposit. After annealing at 500°C, complete recrystallization has occurred, with large grains extending through the entire thickness of the deposit. The columnar character of the structure is retained.

It was seen in the preceding Sections VIII-B-2, 3, and 4, that properties of this type of deposit varied but little as a result of annealing. The change of structure is sufficient that a somewhat larger effect on properties might have been predicted.

b. A deposit from a sulfate bath containing an addition agent.—In Fig. 45 are shown the structures of an as-plated deposit from a sulfate bath containing 2 g/l of triisopropanolamine, the same deposit after annealing at 500°C, and a deposit from a bath containing 3.5 g/l of the addition agent after annealing at 500°C. The deposit from the bath containing the low concentration of addition agent has equiaxed grains of medium size after annealing, whereas the deposit from the bath containing the high concentration of addition agent contains many voids (black areas). This condition is discussed in detail in subsequent Section VIII-E-2. It causes the abnormally low hardness and density already described.

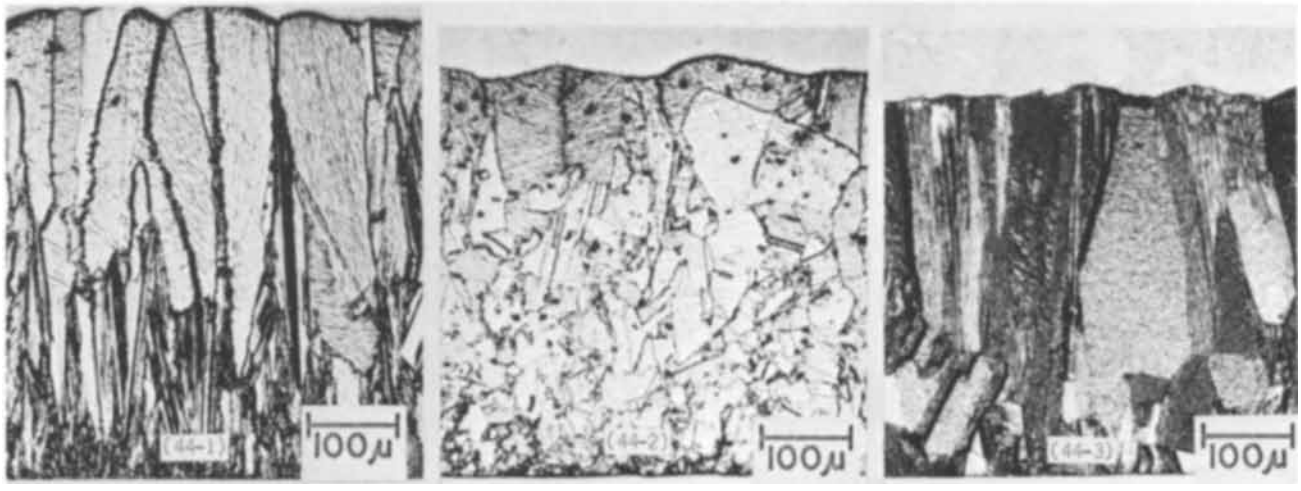

Fig. 44. Effect of annealing on structure of a copper deposit that is coarse grained as plated; from sulfate bath Cu2-H2, 30°C, 2 A/dm^2: (44-1) as plated; (44-2) annealed 15 min at 325°C; (44-3) annealed 15 min at 500°C.

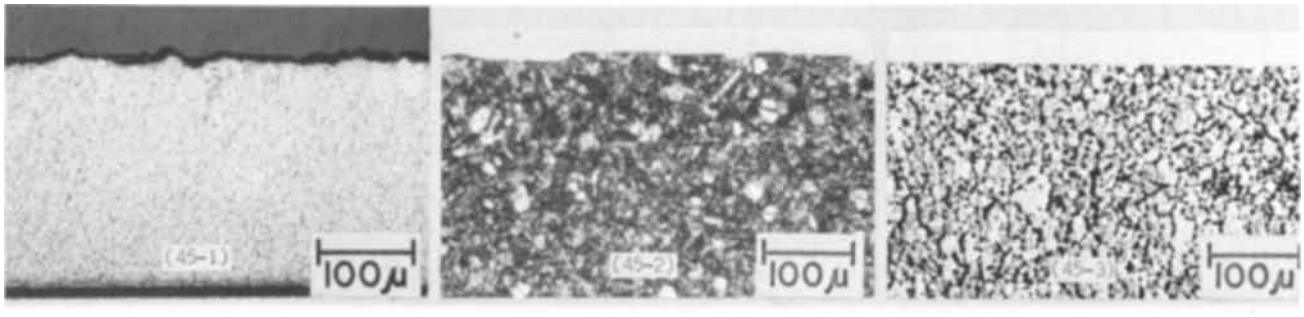

Fig. 45. Effect of annealing on structure of copper deposits that are fine grained as plated. Deposits made in a Cu2-H3 bath containing triisopropanolamine (TIPA), 30°C, 5 A/dm^2. Note voids caused by gas-forming impurities entrapped in the deposit from the high-TIPA bath. (45-1) 2 g/l TIPA, as-plated deposit; (45-2) 2 g/l TIPA, deposit annealed 15 min at 500°C; (45-3) 3.5 g/l TIPA, deposit annealed 15 min at 500°C.

Fig. 46. Effect of annealing on structure of a copper deposit from fluoborate bath F-1, 30°C, 8 A/dm^2: (46-1) as plated; (46-2) annealed 15 min at 325°C; (46-3) annealed 15 min at 500°C.

In Table XXVII we see that the hardness of the deposit shown in Fig. 45-2 is normal (footnote[n]), which correlates with the absence of voids.

c. *A deposit from the fluoborate bath.*—The effect of annealing on the structure of a deposit from a fluoborate bath is shown in Fig. 46. The character of the changes is so similar to those for the non-addition agent sulfate deposit discussed above in paragraph "*a*" that the same remarks apply. However, there is a larger difference in grain size before and after annealing at 500°C, which correlates with a somewhat larger effect on properties than occurred in the case of the sulfate deposit.

d. A deposit from the pyrophosphate bath.—The effect of annealing of a deposit from a pyrophosphate bath is shown in Fig. 47. There is scarcely any effect at 150°C (47-2) and only a small effect at 325°C (47-3). However, the specimen annealed at 500°C shows marked grain growth. The same specimen at a higher magnification (500X) is shown in Fig. 47-5. Large columnar grains with a fine substructure are seen. The magnitude of the properties and the relatively small

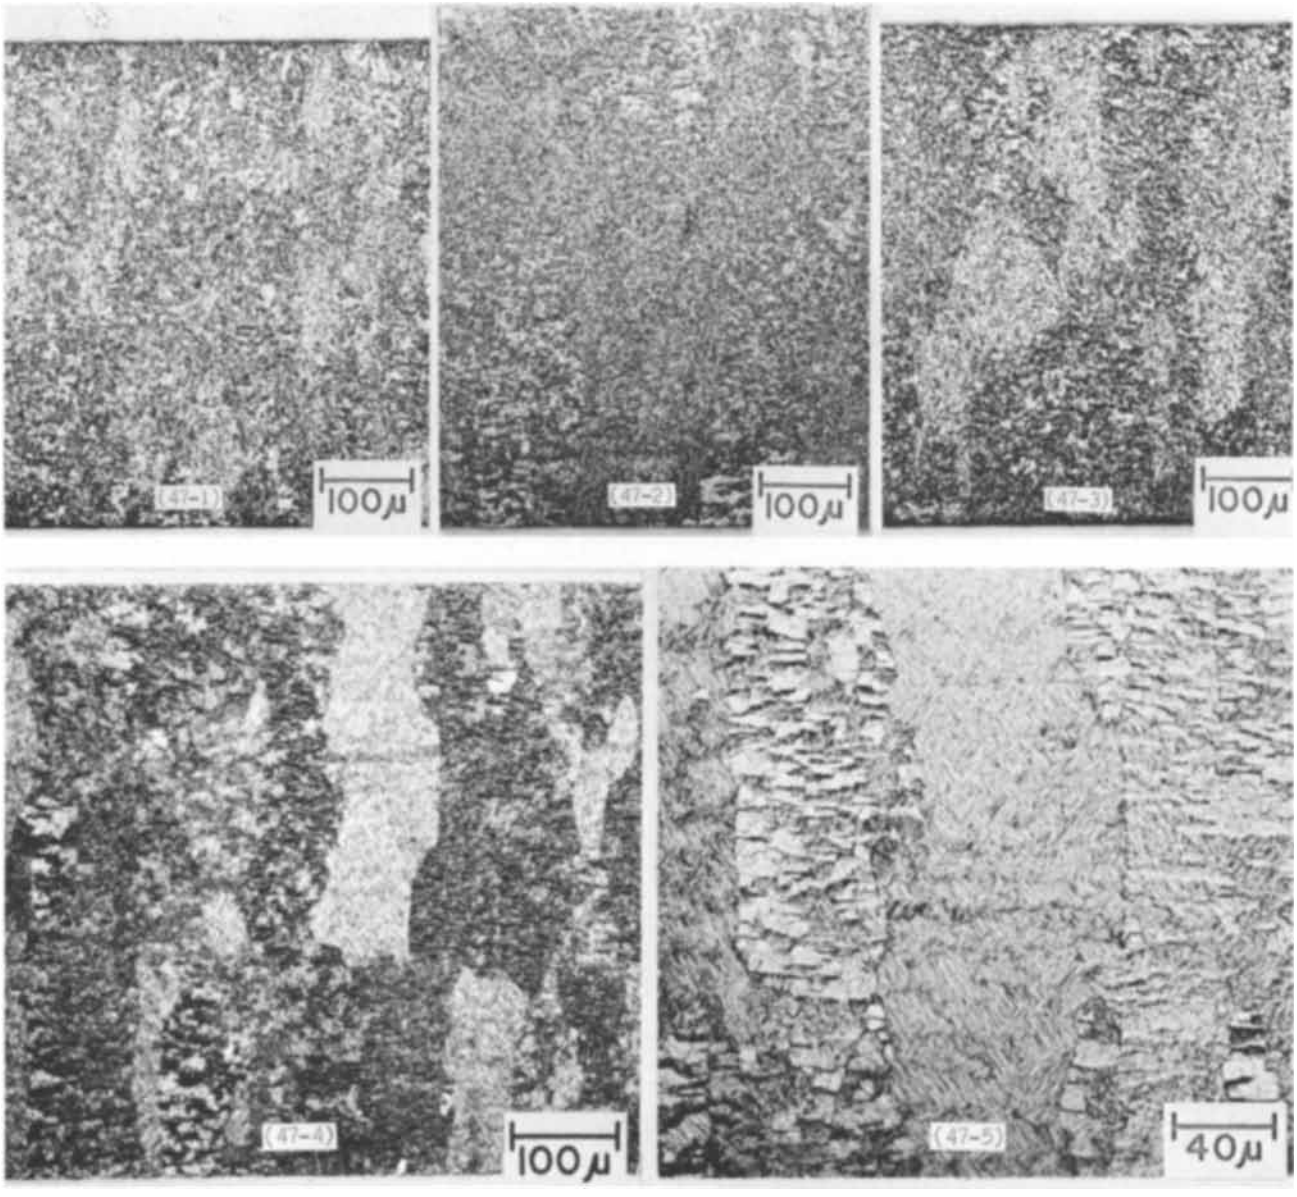

Fig. 47. Effect of annealing on structure of a copper deposit from the pyrophosphate bath, 50°C, 2 A/dm^2: (47-1) as plated; (47-2) annealed 2 hr at 150°C; (47-3) annealed 15 min at 325°C; (47-4) and (47-5) annealed 15 min at 500°C.

degree of change on annealing, in comparison with the TIPA and the CN-8 deposits (Section VIII-B-2, 3, 4; Table XXVII), indicate that possibly fairly large grains as seen in Fig. 47-5 are present in the unannealed deposit and that annealing delineates the boundaries.

e. A deposit from cyanide bath CN-8, made with periodically reversed current.—The effect of annealing on the structure of a deposit made with PR in bath CN-8 is shown in Fig. 48. Annealing at 325°C (48-2) has resulted in the loss of the fibrous character of the as-plated deposit, but no distinct grains can be seen. After annealing at 500°C, fairly large equiaxed grains appear. The black spots are apparently an etch effect and do not represent voids, since the density did not change with annealing (Table XXVII, line 143). The marked changes of properties of this deposit due to annealing, seen in Table XXVII and discussed in Sections VIII-B-2, 3, and 4, correlate with the large increase of grain size.

C. Properties of Cold-Rolled Deposits

1. Cold-rolling procedures.—Cold rolling was done with a small hand mill. Strips of panel stock 1 in. wide, with the nickel flash removed, were rolled to 50% and 10% of their original thickness. Rolling to 10% (90% reduction) was done primarily to determine whether the deposits were sufficiently malleable to permit such drastic reduction. All of the deposits in Table XXVII did submit to this treatment, without annealing and with no edge-cracking apparent to the naked eye. However, reductions were not carried out in one pass. About three passes were used for 50% reduction, with additional fine-adjustment passes to obtain the exact thickness desired and to straighten the strips. Specimens for measurements of properties were cut from the reduced strips.

2. Effects of cold rolling on several properties and on structure.—a. Mechanical properties.—Results are shown in Table XXVII and Fig. 49. Division of deposits into the same type-groups that occurred with annealed deposits is noted for cold working. Thus, the soft as-plated sulfate, fluoborate, and pyrophosphate deposits undergo significant strengthening and embrittlement due to cold reduction (Fig. 49). The initially strong deposits from the sulfate TIPA bath and the CN-8 bath with PR are only slightly affected.

The effects of cold reduction on yield strength are closely parallel to the effects on tensile strength. All deposits acquire a yield strength in the range of 45,000-50,000 psi after 50% reduction, essentially the

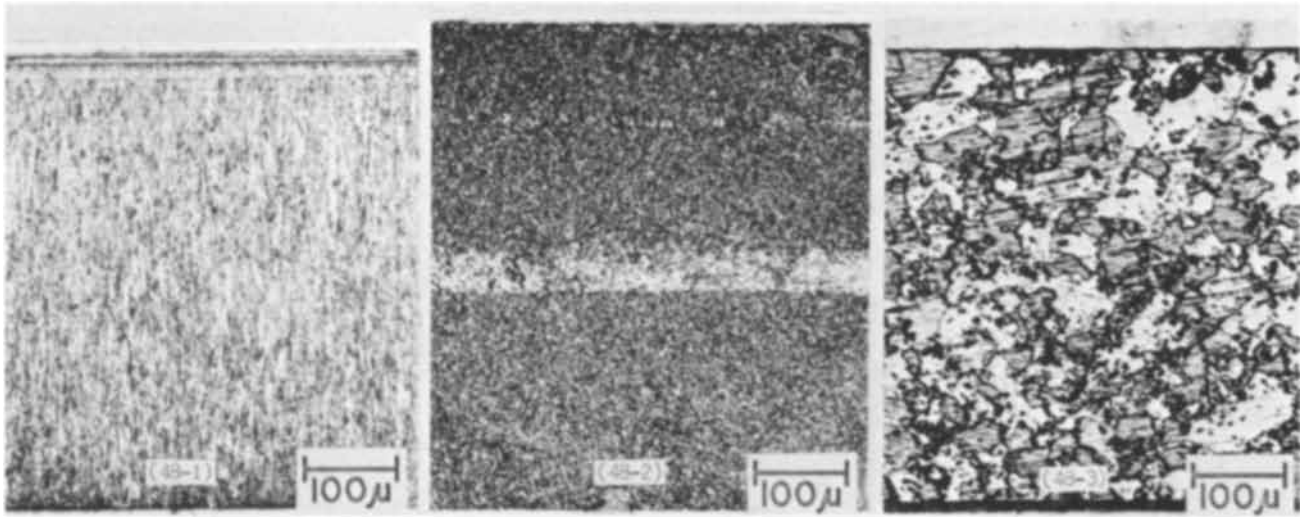

Fig. 48. Effect of annealing on structure of a copper deposit from cyanide bath CN-8 containing 2 g/l KCNS, 80°C, 6 A/dm², PR, 15 sec cathodic, 5 sec anodic: (48-1) as plated; (48-2) annealed 15 min at 325°C; (48-3) annealed 15 min at 500°C.

same as that of similar wrought copper (48,000 psi).[18]

The effects of cold rolling on modulus and hardness were already discussed above (Section VIII-B-2, Fig. 42 and 43).

b. Density.—Only one determination of the effect of cold rolling on density was made (Table XXVII, line 26). The decrease of 0.001 g/cm³ for a soft sulfate deposit is not a significant change. Data from the literature for wrought copper (Table XXVII, last line) indicate that cold working causes a small decrease of density.

[18] The values in Table XXVII from the literature for cold reduced wrought copper that have no temper designation are for material that has been cold reduced 50%. Temper designation for this degree of reduction is *extra hard*. The values included for half-hard materials (21% cold reduction) are for comparative purposes. For example, the material cold reduced 50% is appreciably stronger than that reduced 21%, or half hard, namely, 54,000 and 45,000 psi, respectively. Magnitudes of effects on yield strength, elongation, and hardness also depend on degree of cold reduction.

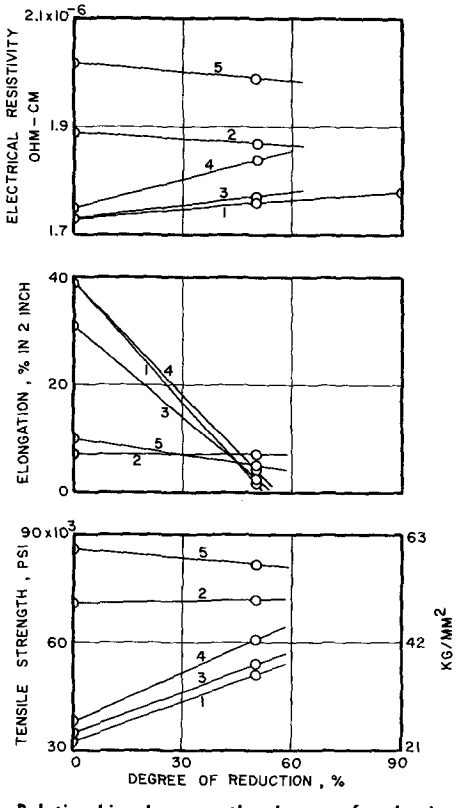

Fig. 49. Relationships between the degree of reduction by cold rolling and tensile strength, elongation, and electrical resistivity of copper deposits from various types of baths: (1) Cu2-H2, 30°C, 2 A/dm²; (2) Cu2-H3 containing 3.5 g/l triisopropanolamine, 30°C, 5 A/dm²; (3) F-1, 30°C, 8 A/dm²; (4) pyrophosphate, 50°C, 2 A/dm²; (5) CN-8 containing 2 g/l KCNS, 80°C, 6 A/dm², PR, cycle 15 sec cathodic, 5 sec anodic.

c. *Electrical resistivity.*—Resistivity is increased by cold rolling of the three soft-type deposits (Fig. 49). The resistivity of the soft sulfate deposit (Table XXVII, line 26) is slightly higher after 90% reduction than after 50% reduction. The hard deposits (TIPA and CN-8, PR) undergo a small decrease of resistivity with cold rolling. However, the change is of borderline significance. The small effect is what might be expected of deposits that have very fine grain and high resistivity as plated.

d. Structure.—The effects of cold rolling on structure are shown in Fig. 50-54, inclusive, for the five types of deposits appearing in Table XXVII. The soft sulfate and fluoborate deposits (Fig. 50 and 52, respectively) show elongation of grains in the direction of rolling, and irregular crumpling of columnar grains, but little reduction of grain size.

In general appearance, the effects of cold rolling on the deposit from sulfate TIPA bath, the pyrophosphate bath, and the CN-8 bath with PR are similar (Fig. 51, 53, and 54, respectively). The cold-rolled specimens in Fig. 51 and 53 show a hint of conversion from a perpendicular to a longitudinal fiber, and Fig. 54 shows a conversion from a perpendicular fiber to an equiaxed, slightly finer structure. It will be noted that the reduced specimens are not exactly half the thickness of the as-plated specimens. This is because the two were made from different but duplicate panels which were not identical in thickness.

D. Tensile Strength and Elongation of Deposits at Low and High Ambient Temperatures

1. Methods of measurement. Tensile strength and elongation were measured by the tensile pull method. Specimens were pulled with the same test machine that was used for measurements of modulus (Section III-A-1). Three temperatures were used, −78°, 150°, and 325°C. The specimens pulled at 150°C were preannealed at 150°C for 1 hr to avoid the necessity of holding them for this period at 150°C in the test machine before pulling. The specimens pulled at 325°C were held at this temperature in the test machine for 15 min before pulling. Specimens pulled at −78°C were pulled immediately with no hold at temperature. To provide the various ambient temperatures, a lightweight aluminum can was attached to the lower specimen grip and extended upward to sufficient height to enclose the specimen and the upper grip. The inside

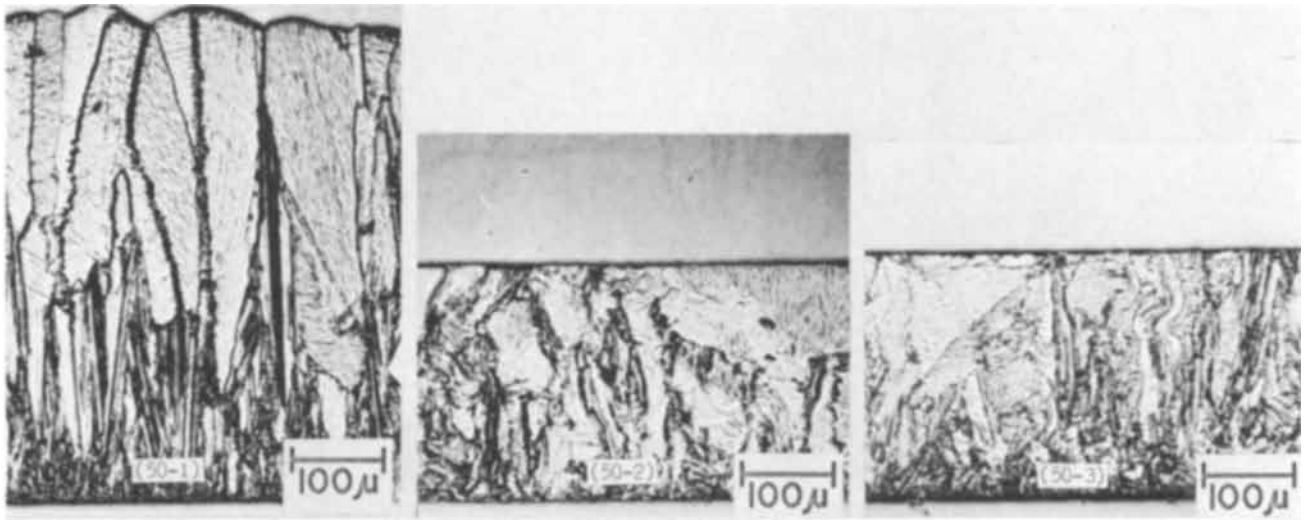

Fig. 50. Effect of cold rolling on structure of a large-grained type of deposit from copper sulfate bath Cu2-H2, 30°C, 2 A/dm^2: (50-1) as plated; (50-2) 50% reduction, cross section parallel to direction of rolling; (50-3) 50% reduction, cross section normal to direction of rolling.

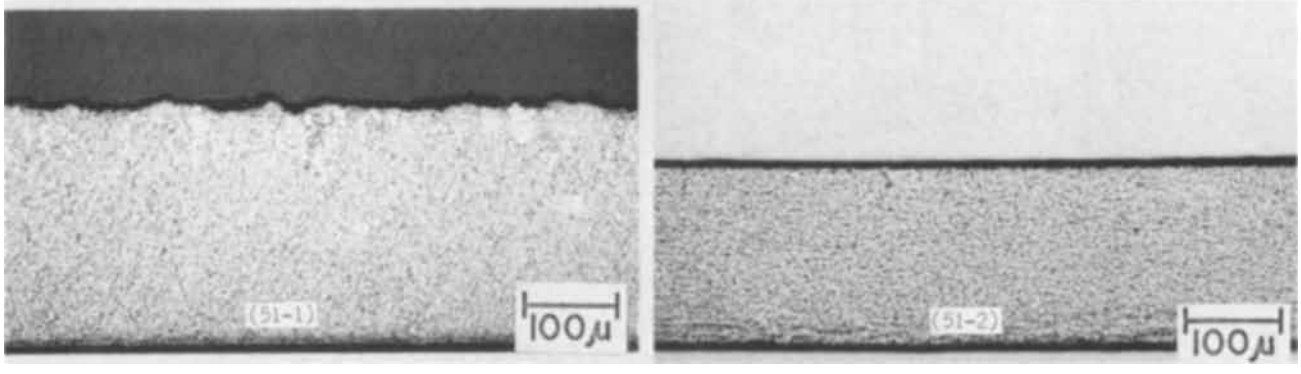

Fig. 51. Effect of cold rolling on structure of a fine-grained copper deposit from sulfate bath Cu2-H3 containing 2 g/l triisopropanolamine, 30°C, 5 A/dm^2: (51-1) as plated; (51-2) 50% reduction, cross section parallel to direction of rolling.

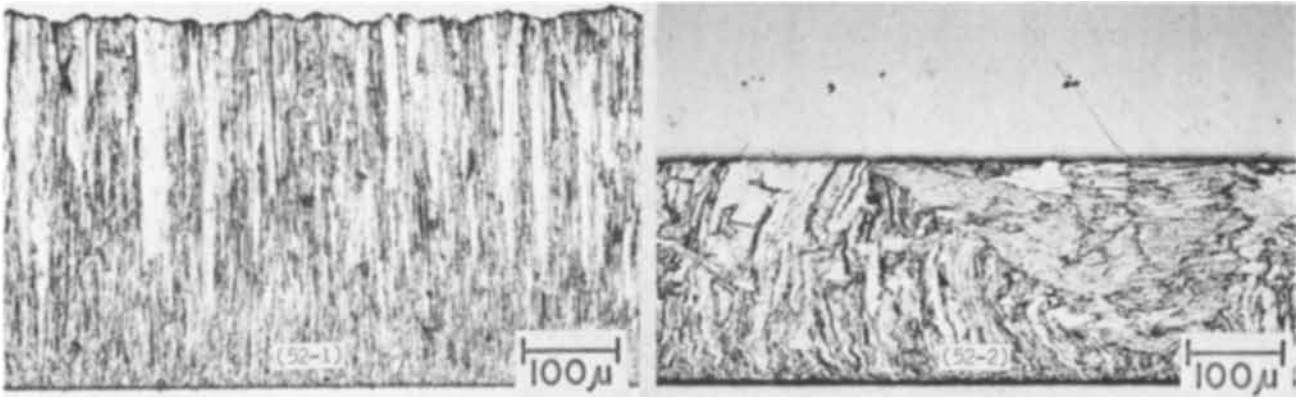

Fig. 52. Effect of cold rolling on structure of a deposit from fluoborate bath F-1, 30°C, 8 A/dm^2: (52-1) as plated; (52-2) 50% reduction, cross section parallel to direction of rolling.

diameter of the can was 2 in. A Nichrome winding and thermal insulation surrounded the can. Controlled current through the winding provided the elevated temperatures. Tubes with an outside diameter of ¼ in. were welded to the lower and upper ends of the can to provide inlet and exit, respectively, for argon, to provide a nonoxidizing atmosphere. A thermocouple close to the center of the tensile specimen was used to measure its temperature, which was maintained constant to ±1°C. Prior determination of vertical temperature gradient within the can showed that vertical variation over the active length of the deposit was not more than 2°C. For pulling at −78°C, the can was filled with a cryogenic mixture of solid carbon dioxide and absolute alcohol.

2. Effects of low and high ambient temperatures on tensile strength and elongation.—The data on tensile strength and elongation at the ambient temperatures listed in Table XXVII are plotted in full in Fig. 55. Several relationships of interest may be seen. Tensile strength of all deposits increases as ambient temperature decreases from 325° to −78°C. The one exception in the case of the deposit from the CN-8 bath, between 25° and −78°C, is probably not significant, because the difference between 80,000 and 86,000 psi is within our normal accuracy range of ±5%. The same type-grouping of deposits occurs as was seen above in Sections VIII-B and C. The soft sulfate, fluoborate, and pyrophosphate deposits remain close together in strength with parallel decreases with increase in tem-

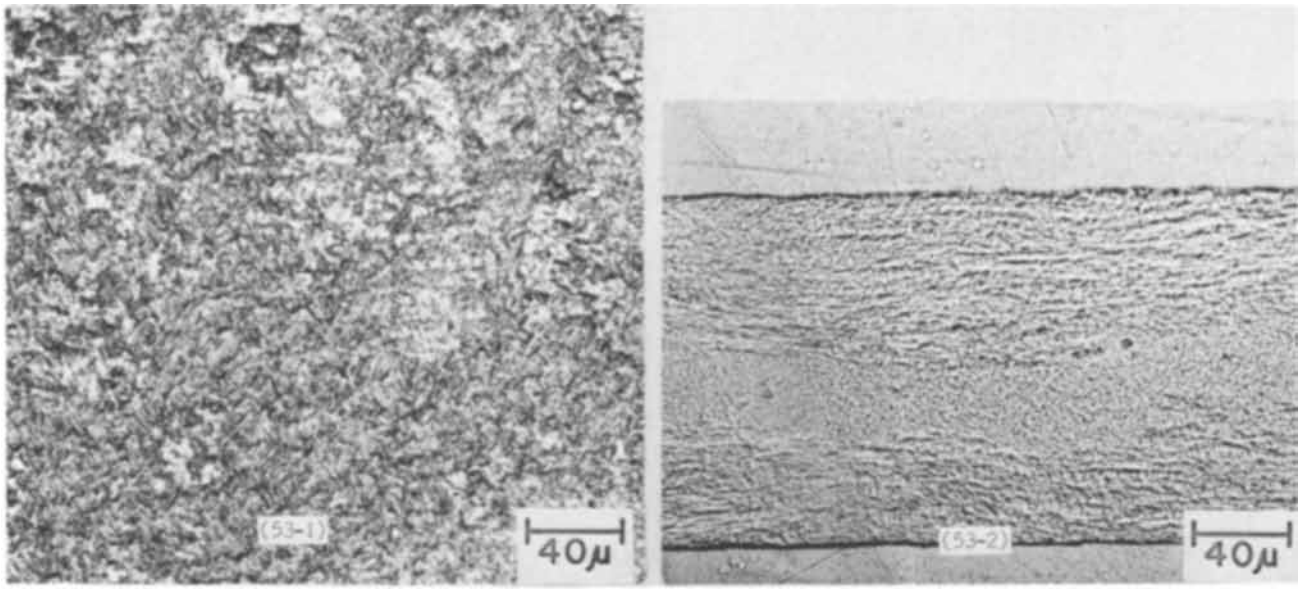

Fig. 53. Effect of cold rolling on structure of a copper deposit from a pyrophosphate bath, 50°C, 2 A/dm^2: (53-1) as plated; (53-2) 50% reduction, cross section parallel to direction of rolling.

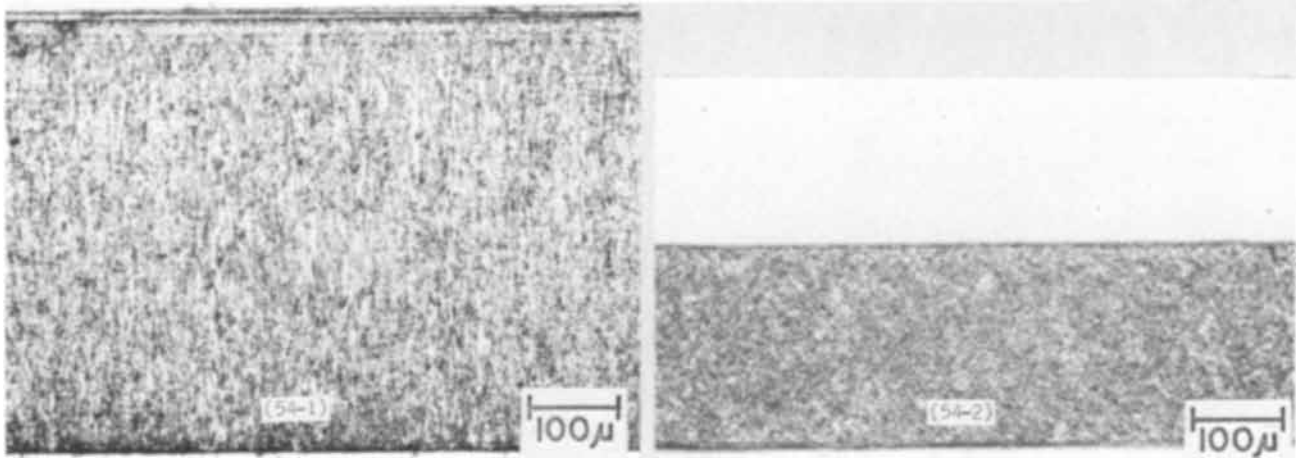

Fig. 54. Effect of cold rolling on structure of a copper deposit from cyanide bath CN-8 containing 2 g/l KCNS, 80°C, 6 A/dm^2, PR, 15 sec cathodic, 5 sec anodic: (54-1) as plated; (54-2) 50% reduction, cross section parallel to direction of rolling.

perature. The deposits of the other group (TIPA; CN-8, PR) have higher strengths at room temperature, but lose strength more rapidly with increase of temperature; thus, deposits of both groups approach the same strength at 325°C. The CN-8 deposit, with a strength of 20,000 psi at 325°C, remains slightly stronger than the other deposits at this temperature.

The relationship between tensile strength and elongation of deposits tested at ambient elevated temperatures is opposite to that for deposits that are annealed and then tested at room temperature. In the first case, *both* tensile strength and elongation decrease with increase of ambient temperature. In the second case, annealing causes tensile strength to decrease, but elongation to increase, with increase of annealing temperature. The same relationships have been reported for wrought copper (35).

The type-grouping referred to above is seen again with respect to elongation. Except for two partial aberrations, ductility for both groups decreases with increase of ambient temperature. However, the soft-type deposits, which at low temperature have markedly higher ductility, decrease in ductility more rapidly with increase of temperature so that, at 325°C, all but the pyrophosphate deposit have very low and nearly equal elongation (Fig. 55).

The deviation of the elongation of the pyrophosphate deposit from the main pattern is large enough that it is probably real and indicates that a difference in structure or a difference in rate of annealing exists that accounts for its significantly higher ductility at 325°C.

E. Thermal Expansivity

1. Introduction and method of measurement.— Knowledge of thermal expansivity may be needed in cases where distortion might occur due to differential expansion of coating and basis metal or of electroformed assemblies made of more than one kind of metal. Cracking due to differential thermal forces, which may occur with chromium or brittle nickel deposits, is not likely in the case of copper deposits. We know of no published data on thermal expansivity of as-plated copper (3).

Specimens were made from sheet panel stock cut into pieces ¾ in. x 6 in. These were made into 6 in.-long tubes, ¼ in. diameter, by forming over a mandrel. Several small holes were drilled adjacent to each long edge of the sheet before forming. A lacing of fine copper wire through these holes, inserted after forming, bound the edges together and prevented deformation of the tube during heating.

To measure thermal expansivity, we used an apparatus of fused quartz described by Hidnert and Souder (36). Length changes were measured with a dial gauge accurate to 0.1 mil. It was calibrated against a standard gauge block. An inert atmosphere was

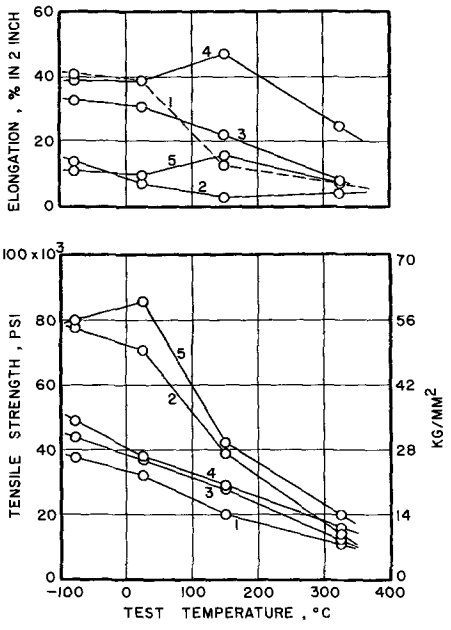

Fig. 55. Relationships between actual test temperature at which properties were measured and tensile strength and elongation of copper deposits from various types of baths: (1) Cu2-H2, 30°C, 2 A/dm²; (2) Cu2-H3 containing 3.5 g/l triisopropanolamine, 30°C, 5 A/dm²; (3) F-1, 30°C, 8 A/dm²; (4) pyrophosphate, 50°C, 2 A/dm²; (5) CN-8 containing 2 g/l KCNS, 80°C, 6 A/dm², PR, cycle 15 sec cathodic, 5 sec anodic.

maintained in the specimen container while it was heated. Calibrated thermocouples were located near each end and at the center of the specimen. End-to-end temperature variation was not more than 2°C and average temperature of a specimen over its length was known to within less than 1°C. Measurements were made at two temperatures, 200° and 400°C. Measurements were made during both heating and cooling portions of the cycle, and several of the specimens were measured through more than one cycle.

We estimate the accuracy of our measured expansivities to be ±1%, equivalent conservatively to an uncertainty in the coefficient of expansion of ±0.2 x 10^{-6} parts per unit length per °C.

As described below, the deposit from the sulfate TIPA bath underwent a large permanent expansion as a result of heating. We, therefore, decided that a limited study of the expansivity characteristics of other deposits from addition agent baths, the amine bath, *etc.*, should be made, to determine whether permanent changes in length occur due to heating. For these limited measurements, specimens were flat strips, ¼ in. x 6 in. Their as-plated lengths were measured accurately, after which they were heated at 500°C for 15 min. After cooling to room temperature, their lengths were again measured.

2. Measured values of thermal expansivity.—The types of deposits selected for expansivity measurements are the same as were used for annealing, cold rolling, *etc.* Complete expansivity data for these deposits are given in Table XXVIII. Hysteresis curves are shown in Fig. 56, 57, and 58.

The expansivity of the soft deposit from the sulfate bath (Table XXVIII, line 26) is seen to be nearly identical with the values obtained by us for cold-rolled commercial sheet and with the values reported in the literature for high-purity electrolytic copper, melted, cast, and cold drawn (37). There is indication that the expansivity of this deposit is slightly higher on first heating after annealing at 500°C, but it reverts to the "normal" value on second heating.

The expansivities of the fluoborate, pyrophosphate, and CN-8 deposits are about 2% less than that of the sulfate deposit.

[a] TIPA = triisopropanolamine.
[b] Estimated concentration.
[c] Due to the large absolute expansion it was necessary to limit the temperature in these two cases to about 325°C to avoid exceeding the limit of our gauge. This effect and the large permanent elongation is caused by formation of voids. See Fig. 45-3 and corresponding value for density, Table XXVII.
[d] Values measured by authors of present research.

The expansivities of the deposits from the sulfate TIPA bath were quite irregular. The irregular behavior of these deposits was first noted when a large permanent expansion of a specimen from panel No. 224 caused loss of data because the range of our micrometer dial gauge was exceeded. The bath from which this deposit was made contained approximately 2 g/l TIPA, whereas the bath from which panel No. 339 was made contained 3.5 g/l. It is seen that the specimen from panel No. 224 had normal expansivity after heating to 470°C, but still underwent an additional small permanent expansion. A specimen from panel No. 339 yielded very high expansivities and underwent large permanent expansion. Annealing at 550°C stabilized the specimen so that no further permanent expansion occurred, but the expansivity is about 5% higher than for the other deposits. Figure 58 shows expansion curves for two cycles for the deposit from the sulfate TIPA bath. The first cycle shows the large permanent expansion. This behavior is undoubtedly due to incorporation of addition agent or other gas-generating impurities into the deposit during plating. Gas generation on heating expands the deposit (Fig. 45-3) and causes decrease of density, hardness, and strength as noted in previous sections. The expansivity specimen from panel No. 339, after final heating, was distorted, brittle, and friable.

The pyrophosphate and cyanide deposits, which had low expansivities, underwent small permanent con-

Curve B shows third cycle after specimen was annealed at 550°C for 1 hr—use scale on right. Permanent expansion of 0.12 in. occurred between heatings represented by curves A and B. Specimen length, 6 in.

tractions. The contraction and the low expansivity are undoubtedly related. The pyrophosphate deposit on second heating had nearly normal expansivity. Expansion curves for these deposits are shown in Fig. 56 and 57. They show the small hysteresis effect associated with the slightly smaller expansivity always noted on the cooling cycle. The effect is larger for the CN-8 deposit (Fig. 57) than for the pyrophosphate deposit (Fig. 56).

3. Qualitative tests of thermal expansion.—The results of the qualitative tests described above in Section VIII-E-1 are tabulated in Table XXIX. The amine deposit undergoes significant permanent expansion, but only about 1/15 that of the TIPA deposit (Table XXVIII). The proprietary bright sulfate deposit undergoes about 50% more permanent elongation than the TIPA deposit and is quite brittle after heating. The deposit from the sulfate bath containing 0.1 g/l gelatin is the only other deposit that underwent marked permanent expansion. It was very brittle, but this was also its condition before heating. None of the deposits in Table XXIX showed distortion of shape except the amine deposit, which was severely blistered.

It is probable that the deposits in Table XXIX that undergo only a small permanent expansion have thermal expansivities very close to the value for the deposit in Table XXVIII, line 26.

F. Structure of Deposits

1. Optical micrographs.—Structure in relation to various parameters has already been illustrated with many optical micrographs in preceding figures. In this section we restrict the consideration of optically determined structure to comparisons between typical deposits from various types of baths (Fig. 59).

In Fig. 59-1 and 59-2, deposits from non-addition agent sulfate and fluoborate baths are compared. The concentration of copper was the same in each bath, and operating conditions (bath temperature, current density, and cellulose filter) were the same for each deposit. The finer, more fibrous structure of the deposit from the fluoborate bath must, therefore, be ascribed to some unique effect of the fluoborate anion. The finer

structure is associated with slightly better mechanical properties than those of the sulfate deposit.

The pyrophosphate deposit, Fig. 59-3 and 59-4, appears to have a fine random structure. However, this conclusion is in conflict with the magnitudes of the properties of this deposit, with its behavior on annealing (already discussed in Section VIII-B-5-d), and with the results of x-ray diffraction examination presented in the next section.

The deposit from the high-efficiency cyanide bath, the structure of which is shown in Fig. 59-5, is similar to that from the pyrophosphate bath and involves similar contradictions. It appears to have a fine random grain, in conflict with its properties and with the x-ray data. An explanation for these anomalies is suggested in the next section following the presentation of the x-ray data. Similar contradictory data on grain size, as determined optically and by x-ray, have been noted by Read.[19]

The deposit from the amine bath, shown in Fig. 59-6, appears to have a very fine, random structure with no resolved crystals. The properties of this deposit, such as fairly high strength, low ductility, and high hardness, summarized in Section VIII-H, confirm the reality of its fine structure.

2. X-ray diffraction.—a. Back-reflection patterns.— Back-reflection patterns were obtained from both the final and starting faces of the six deposits listed in Table XXX to obtain information on grain size. Ilford CX film was used to enhance resolution. Specimens were used as plated; *i.e.*, the faces were not polished. Specimens were positioned normal to the beam, with 6 cm between specimen and film. Filtered radiation from an iron target was used, collimated to a beam diameter of 1 mm.

Grain size is estimated from the degree of resolution of spots in the back-reflection patterns (Fig. 60). However, accurate values of grain size cannot be determined by this method unless the following conditions are met: (*a*) specimens must be free of internal stress; (*b*) grain orientation should be random; (*c*) grain size should be uniform. While some as-plated electrodeposits approach these criteria, most fail in one or more of them. Furthermore, grain size estimated by the x-ray method and by optical methods under ASTM standards is not comparable because a twin is not regarded as a new grain in optical determinations, but does give rise to a new x-ray spot. Because of these factors, the grain sizes given in Table XXX can be regarded only as qualitative and as showing relative fineness of grain for the various deposits.

In Fig. 60, the diffraction index of the outer ring is 311 (Kα), middle ring 222 (Kα), and inner ring 400 (Kβ). The absence of the resolution of the Kα doublets may be due to internal stress or to very small grain size.

Following are interpretations of the patterns shown in Fig. 60:

1—Panel No. 323 (line 26), a soft-type deposit from a sulfate bath. Figure 60-1-F shows the pattern for side F, the final plated surface. It shows blurring to very large spots, indicating a wide range of grain size. Figure 60-1-B shows the pattern for side B, next to the basis metal. It contains continuous rings with doublets resolved, indicating very small grain size and low stress.

2—Panel No. 337 (line 76), a hard, strong deposit from a sulfate bath containing triisopropanolamine. Figures 60-2-F and 60-2-B show the patterns for sides F and B, respectively. The rings are continuous, with doublets unresolved, indicating a uniform fine grain throughout the deposit.

3—Panel No. 343 (line 91), a soft-type deposit from a fluoborate bath. Figure 60-3-F shows the pattern for side F. The 222 and 400 lines are absent, indicating texture. The 311 line contains 2 large spots and a very faint continuous line, indicating a mixture of fine and large grains. The rings for Fig. 60-3-B, with no resolution of spots and poor resolution of doublets, indicate a very fine structure of the fluoborate deposit in the basal zone. These x-ray results for panels No. 323, 337, and 345 confirm the grain sizes seen in the optical micrographs, Fig. 59-7, 59-8, and 59-2, respectively.

4—Panel No. 320 (line 95), a deposit from a pyrophosphate bath. Figures 60-4-F and 4-B show the patterns for the final and starting surfaces of the deposit, respectively. Both show large isolated spots with some faint blurring, indicating large grains intermixed with some fine grains. The indicated grain size in the basal zone is not quite as large as in the final plated zone. The absence of the 222 reflection indicates that the deposit is textured.

The x-ray evidence in the preceding paragraph, physical property data, and behavior on annealing (Section VIII-B) indicate that the pyrophosphate deposit has a large grain size. However, contradictory evidence was found by optical examination (Fig. 59-3 and 59-4). Since evidence for a relatively large grain

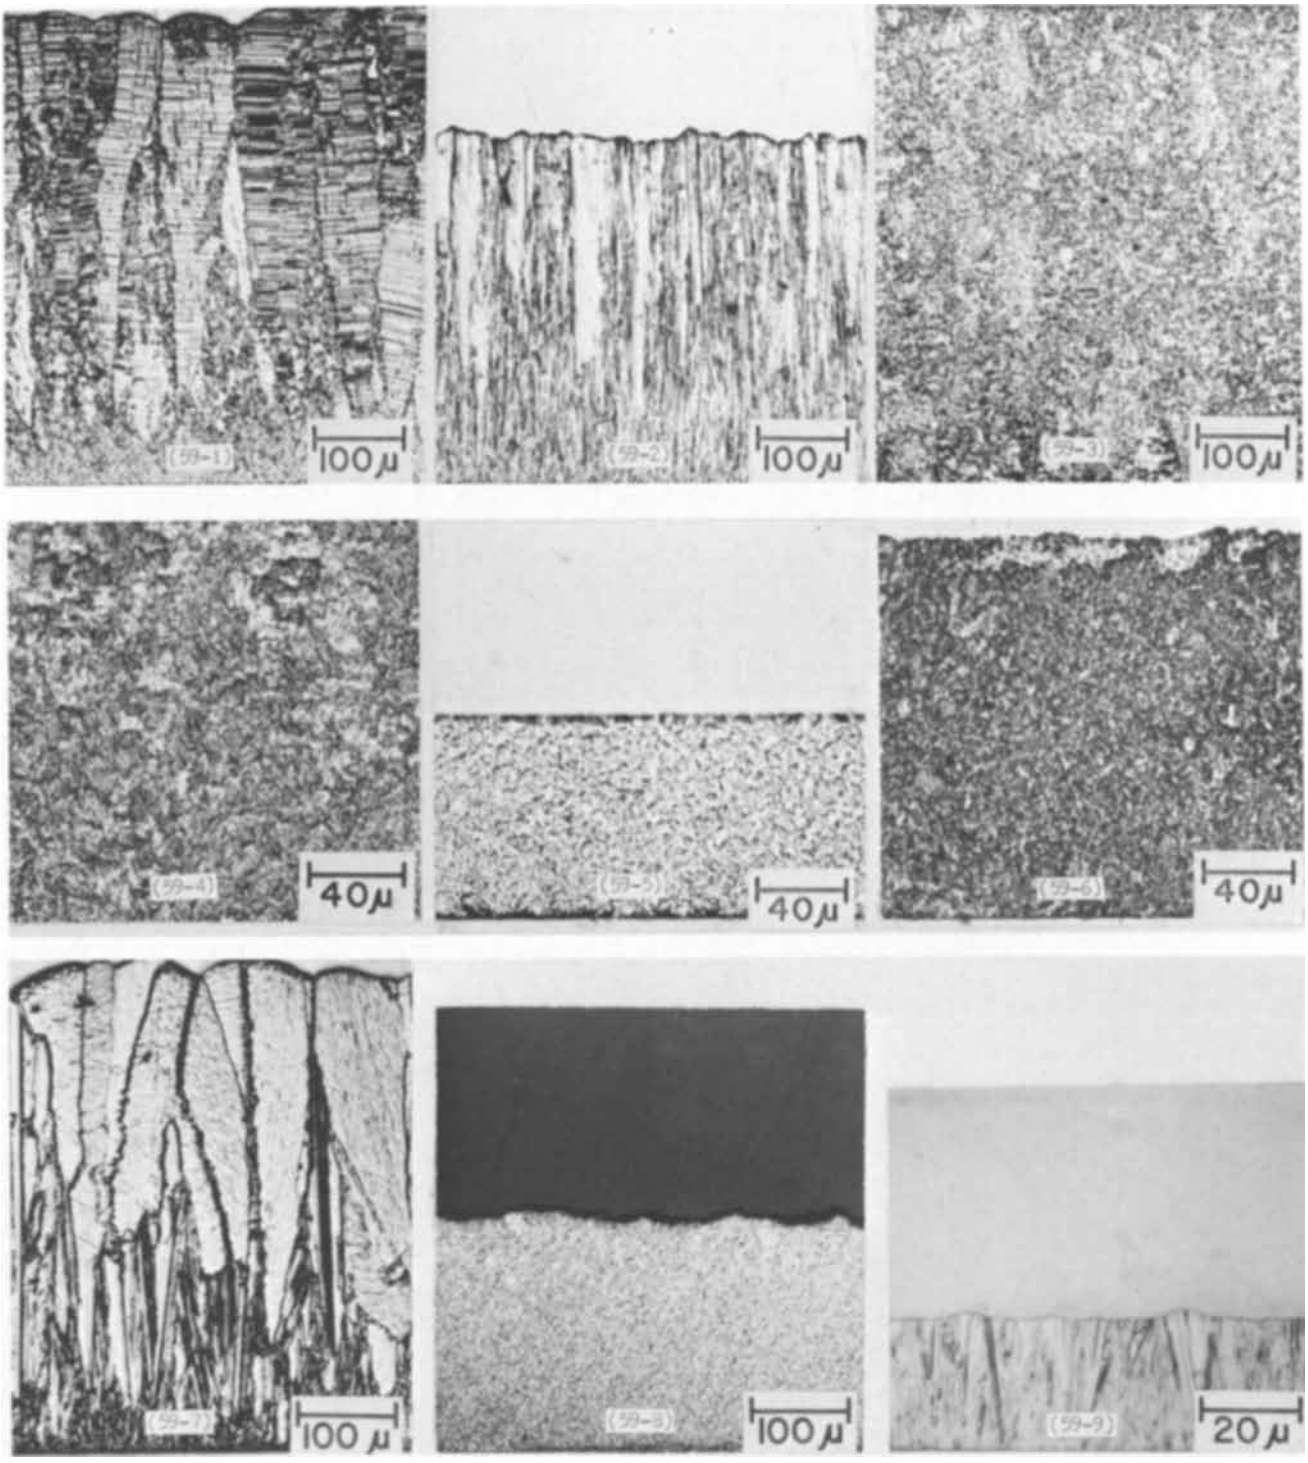

Fig. 59. Comparison of structure of deposits of copper from all types of baths: (59-1) Cu2-H3, 30°C, 8 A/dm^2; (59-2) F-1, 30°C, 8 A/dm^2; (59-3) and (59-4) pyrophosphate, 50°C, 2 A/dm^2; (59-5) CN-8, 80°C, 6 A/dm^2; (59-6) amine bath, 55°C, 4 A/dm^2; (59-7) Cu2-H2, 30°C, 2 A/dm^2; (59-8) Cu2-H3 containing 2 g/l triisopropanolamine, 30°C, 5 A/dm^2; (59-9) CN-1, 40°C, 1 A/dm^2.

size is preponderant, we conclude that the optical structure is misleading. We suggest the following two theories to account for the apparent discrepancy: (*a*) A columnar structure such as seen in Fig. 47-4 and 47-5 after annealing may be present in the as-plated deposit, but the etching technique used for preparing the photomicrograph specimen was inadequate to reveal it. (b) The fine structure seen in Fig. 59-3 and 59-4 represents an end-view of crystals whose main axes lie in the plane of the deposit. The pyrophosphate photomicrographs would thus be analogous to a view normal to the surface of, *e.g.*, the fluoborate deposit, Fig. 59-2. This theory would require that the grains in the pyrophosphate deposit grow in a directional parallel to, or nearly parallel to, the plane of the deposit. This could occur by a mechanism in which shallow crystal steps are located with their faces nearly normal to the plane of the deposit, with growth occurring by build-up on these faces (38). We favor this theory, as it is also in accord with the semibrightness of the pyrophosphate deposits.

5—Panel No. 128 (line 101), a deposit from a strike-type cyanide bath, CN-1. The diffraction lines, Fig. 60-5-F and 5-B, which are continuous, indicate fine grain size on both the final plated side and in the basal zone of the deposit. The photomicrograph (Fig. 59-9) and the electron micrographs (Fig. 36) show columnar grains, of the order of 1 μm in diameter, in agreement with what the x-ray sees in a view normal to the plane of the deposit.

[a] F, x-ray beam directed at final plated surface; B, beam directed at starting surface, *i.e.*, the surface that was adjacent to the basis metal.
[b] Estimated values of crystal size are qualitative.
[c] The magnitude of the number for a given plane indicates the ratio of the intensity of diffraction by that plane to the intensity that would occur if orientation were random. If the orientation were random, the number would be unity for all planes.
[d] One pound per square inch (psi) = 0.000704 kilogram per square millimeter (kg/mm²).
[e] Values from Table XXXI. For panel 337, sulfur was taken as the same as that for panel 323. For panel 320, phosphorus was estimated by analogy with 323. For panel 128, impurity content is assumed to be similar to that of panel 145 (line 110 in Table XXXI), which was made under similar conditions.

6—Panel No. 268 (line 138), a deposit from a high-efficiency cyanide bath, CN-8, containing no addition agent, made without periodic current reversal. Individual spots in the back-reflection patterns are resolved, although smaller than those in the patterns of the large-grained deposits. There is no significant difference between the final plated side and the basal side (Fig. 60-6-F and 6-B). An intermediate grain size is indicated, as shown in Table XXX.

The optical micrograph for this deposit, Fig. 59-5, shows a very fine grain. Thus, for this deposit we have the same contradictions as for the pyrophosphate deposit, and the discussion above in paragraph 4 applies.

b. *Texture analysis.*—A preferred orientation, or fiber texture, of crystals in electrodeposits has been noted and studied by many authors. The results of these studies of copper deposits were reviewed briefly in the first paper of this series (3). Most deposits from sulfate baths have been reported to contain a predominance of crystals oriented with the (110) plane in the plane of the deposit. Quantitative measurement of the angular distribution of the degree of preferred orientation of the (110) plane about the normal to the surface of a copper deposit was made by Ogburn and Newton (39). Under certain conditions, (100) and (111) textures occur in deposits from sulfate baths (40-42). According to the results of a recent publication (43), a shift of orientation from (110) to (113) to (210) planes parallel to the plane of the deposit occurs with increase in current density. The (113) and (210) orientations were obtained at current densities in the range of 60-200 A/dm² with violent agitation. In the upper part of the range the deposits were arboreal and very weak. Most nickel deposits have a (100) texture (2).

The present measurements were made with a diffractometer, using a cobalt target. The radiation was monochromated with the (111) plane of a lithium fluoride crystal at the receiving detector. The front and back surface of each specimen was step-scanned over the diffraction peaks indicated, at 0.05 deg 2θ steps, with a counting period at each step of 100 sec. Background was substracted and area integrated by the Simpson 1/3 rule. A number representing the relative intensity of the diffraction peak from the planes listed in Table XXX to its expected intensity was then calculated. This number, given in Table XXX, is the ratio of the intensity of diffraction by a given plane to the intensity that would occur if orientation were random. If orientation were random, the number would be unity for all planes.

Since the 220 diffraction peak is the second order of the (110) plane, the results in Table XXX show a fairly strong preferred orientation of the (110) plane in the plane of the deposit for panel No. 323, the non-addition agent sulfate deposit, and still stronger identical orientation in the fluoborate deposit. The basal zone of both of these deposits shows a small preferred orientation of the same plane. The strike-type deposit from the cyanide bath, which shows a columnar grain orientation, shows a small degree of preferred orientation, also of the (110) plane.

Orientation in the deposit from the sulfate bath containing triisopropanolamine is nearly random, with just a hint of preferred (110) orientation.

The deposits from the pyrophosphate and high-efficiency cyanide baths depart from the above pattern in that the former shows a high degree of preferred orientation with the (111) plane in the plane of the deposit, and the latter the (200) plane, equivalent to the (100) plane, in the plane of the deposit. The latter is unusual in that the orientation is strong in the basal zone but has become random at the final surface.

It was noted that the intensity of diffraction from the oriented plane in the final plated surface of specimens No. 323, 320, and especially 345, approached that from a single crystal. It should be noted that the method used did not give a complete survey of all

[a] and [b] Values designated [a] and [b] were determined at the laboratories of American Metal Climax, Inc., and E. I. du Pont de Nemours & Co., Inc., respectively. All other determinations were made at NBS.
[c] TIPA: triisopropanolamine; Prop. B: proprietary brightener, selenium type.

possible preferentially oriented planes. For example, the (211) plane was not examined.

We are indebted to C. J. Bechtoldt of the NBS Metallurgy Division, Lattice Defects and Microstructure Section, for the x-ray measurements and for interpretation of the results.

3. Correlations among structure, properties, and impurities.—The deposits in Table XXX fall into two distinct groups, those with medium to large grain size (non-addition agent sulfate, fluoborate, pyrophosphate, and high-efficiency cyanide), and those with fine grain (sulfate-TIPA, and cyanide, CN-1). The deposits in the coarse-grained group have low to medium tensile strength, hardness, and resistivity, and a small content of impurities. The deposits in the fine-grained group have high tensile strength, hardness, resistivity, and impurity content.

As discussed by Brenner (2) and others, the primary factor that determines properties of electrodeposits is impurity content. A high content of impurities interferes with crystal growth, causing fine grain and associated high values of properties. Impurity content in turn is determined primarily by type of bath and by the kind and concentration of addition agent used. Variations in operating conditions of baths, in the normal range, have minor effects in comparison with type of bath and addition agent. This theory is confirmed for copper by the results summarized in Table XXX. Thus, the total impurity content of the four large-grained deposits is in the range of 0.003-0.005%, whereas that of the fine-grained deposits (lines 76 and 101) is much larger, namely, 0.022 and 0.01%, respectively.

G. Composition and Impurity Content of Deposits

1. Introduction.—It is generally recognized that impurities in deposits may significantly affect their structure and properties. About 20 papers dealing with this aspect of electrodeposited copper were reviewed in the first paper of this series (3). In the present work we have determined metallic and nonmetallic impurities in several representative types of deposits.

Determinations of metallic impurities in both anodes and deposits were made, mainly to monitor the effectiveness of our purification procedures. The results of these determinations, already presented in Table V, were discussed in Section II-A.

In this section we consider nonmetallic impurities in several typical kinds of deposits.

2. Results of determinations of nonmetallic impurities in copper deposits.—a. Hydrogen and oxygen.—Content of hydrogen and oxygen in various deposits is shown in Table XXXI. Values of oxygen designated "*a*" in Table XXXI were determined in the laboratories of American Metal Climax, Inc.[20] The other values of both oxygen and hydrogen were determined at NBS.[20] Reasonable agreement is seen between values determined at the two laboratories.

The ratio of O/H in nickel and chromium deposits has been found to be close to 8 on the average, indicating that they enter these metals in the form of adsorbed water or hydrated salts (1, 2). Ratios of O/H for copper deposits calculated from our data range from 4 to 40, with 5 out of the 10 values equal or close to 8 (Table XXXI). One might conclude that in a significant proportion of deposits the hydrate theory is indicated, but that in several kinds of deposits other factors must be acting. For example, the high value of 40 for the sample from panel No. 297 (line 42) is shown below to be probably caused by the inclusion of sulfate ion in the deposit.

With one exception, only 1/10 to 1/2 as much oxygen is present in the three soft-type deposits (non-addition agent sulfate, fluoborate, and pyrophosphate) as in the addition agent and cyanide deposits.

[20] Determinations at American Metal Climax, Inc., were made by courtesy of G. C. Van Tilburg. Oxygen, hydrogen, and nitrogen were determined by J. T. Sterling of the Analytical Chemistry Division, NBS, by a vacuum fusion method.

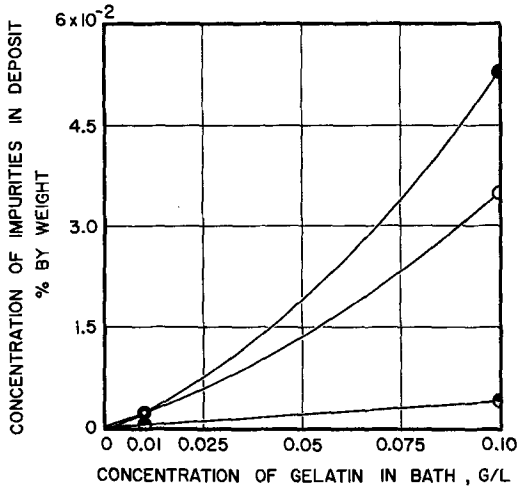

Fig. 61. Relationship between concentration of gelatin in a sulfate bath and concentration of impurities in deposits from the baths. Bath: Cu2-H3, 30°C, 2 A/dm². ○—oxygen; ●—nitrogen or carbon; ◓—hydrogen.

One would expect the concentrations of oxygen and hydrogen in deposits from acid-type copper baths to be lower than in deposits from nearly neutral nickel baths. This is the relationship that occurs. On the average, we found the content of oxygen and hydrogen in copper deposits to be less than 1/10 of that reported in nickel deposits (2).

The effect of concentration of an addition agent in the bath on concentration of impurities in the deposit is seen in Fig. 61. The concentration in the deposit increases more rapidly than that in the bath. This relationship implies that part of the impurities in the deposit may be entrapped by a mechanism other than adsorption, because, as is well known, the amount of a material adsorbed on a surface increases less rapidly than its concentration in the contacting fluid.

b. Nitrogen.—The possibility exists that nitrogen will enter deposits from sulfate baths that contain a nitrogen compound as an addition agent (gelatin, TIPA) and from pyrophosphate and cyanide baths, both of which contain nitrogen compounds. Nitrogen was found in these deposits in reasonable relative concentrations (Table XXXI). It is surprising that nitrogen was found in the deposits from the non-addition agent sulfate bath or from the fluoride bath. The source of the small amounts in the latter deposits could be accidental, e.g., contamination of the surface of the samples that were analyzed, although precautions were taken to minimize surface contamination.

c. Carbon.—The relatively high content of carbon[21] in the gelatin and TIPA deposits is to be expected, due to adsorption of these carbon-containing addition agents (Table XXXI).

The amount of carbon in the cyanide deposits is small, indicating that the amount of cyanide ion adsorbed by the deposit is small. If the carbon in the cyanide deposits does enter *via* adsorption of CN ion, the ratio C/N might be expected to be close to 12/14 = 0.86. Since the deposits in lines 138 and 141 are similar, it is valid to use the concentration of carbon in one and nitrogen in the other to obtain C/N, which is seen to equal 1.05. This is close enough to 0.86 to indicate that carbon and nitrogen do enter the deposit as CN ion. On the other hand, the ratio for the deposit from bath CN-5 (line 127) is about 7, a large deviation. Not much weight can be given to this speculation, based on only two determinations.

d. Boron and fluorine in deposits from the fluoborate bath.—The very low concentrations of boron[22] and fluorine[22] in the deposits from the fluoborate bath indicate that there is very little inclusion of fluoborate ion in the deposits (Table XXXI).

[21] Determinations of carbon were made in the laboratories of E. I. du Pont de Nemours and Company, Inc., by courtesy of O. B. Mathre. Carbon was also determined, by combustion, by J. R. Baldwin of the Analytical Chemistry Division, NBS.

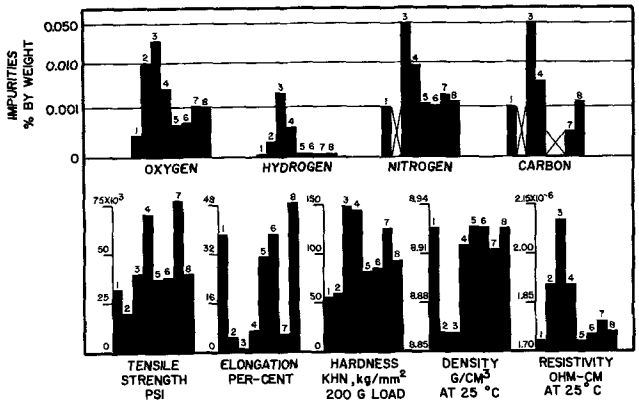

Fig. 62. Correlations between impurities in deposits and properties of deposits for various types of baths: 1—sulfate bath Cu2-H2, 30°C, 2 A/dm²; 2—sulfate bath Cu2-H3, 60°C, 20 A/dm²; 3—sulfate bath Cu2-H3 containing 0.1 g/l gelatin, 30°C, 2 A/dm²; 4—sulfate bath Cu2-H3 containing 3.5 g/l triisopropanolamine, 30°C, 5 A/dm²; 5—fluoborate bath F-1, 30°C, 8 A/dm²; 6—pyrophosphate bath, 50°C, 2 A/dm²; 7—cyanide bath CN-5, 80°C, 4 A/dm²; 8—cyanide bath CN-8, 80°C, 6 A/dm². Note pseudo-logarithmic impurity scale. Metric conversion: one pound per square inch (psi) = 0.000704 kilogram per square millimeter (kg/mm²).

e. Selenium in deposits from baths containing selenium compounds as addition agents.—Selenium[23] is present in the deposits from the sulfate bath containing SeO_2 and in the deposit from the high-efficiency cyanide bath containing the proprietary selenium-type brightener (Table XXXI). Evidently very small concentrations of selenium in copper deposits produce marked effects on structure and properties. (Sections III-A-4-e, III-B-3-e, III-F-2-e, VII-B-3-g, VII-C-2-f, VII-G-1, and Fig. 20 and 34).

f. Sulfur in deposits from sulfate baths.—The low concentration of sulfur[24] in the deposit from the non-addition agent sulfate bath (Table XXXI, line 26) indicates very little inclusion of sulfate ion in normal deposits. The high current density deposit (line 42) contains more than three times as much, which correlates with the high value of the ratio, O/H, for this deposit.

3. Correlations between concentrations of impurities and properties of deposits.—Correlations between impurity content and properties for eight representative types of deposit are shown in the bar graphs in Fig. 62, from which one can visualize the interrelationships. While some variations from regular correlations will be noted, there are, in general, fairly close correlations between, on the one hand, concentrations of the various impurities, and, on the other hand, between these impurities and the various properties. It should be noted that the correlations with impurities are inverse in the case of elongation and density. Close study of this figure will reveal many details regarding correlations that we leave to the reader to ferret out. Relationships between total impurity content, structure, and properties were discussed above (Table XXX, section VIII-F-3).

H. Summary of Properties and General Correlations

In this section we present a general analysis and correlation of all properties for all as-plated deposits.

[22] Boron was determined by quantitative spectrography by Virginia C. Stewart and fluorine by a wet method by J. R. Baldwin, both of the staff of the Analytical Chemistry Division, NBS.

[23] Selenium was determined by neutron activation analysis by D. A. Becker of the Analytical Chemistry Division, NBS.

[24] Sulfur was determined by combustion by J. R. Baldwin of the Analytical Chemistry Division, NBS.

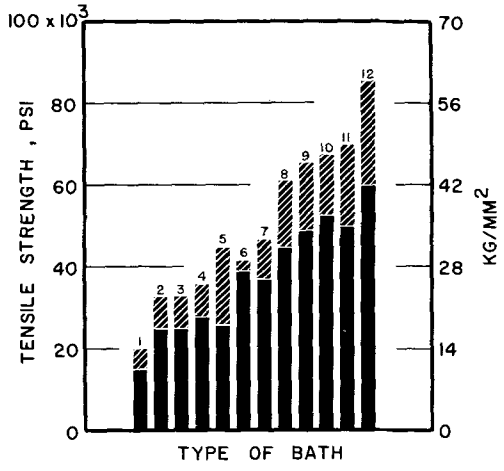

Fig. 63. Ranges and comparative magnitudes of tensile strength of copper deposits from various types of baths: 1—Sulfate baths: plus thiourea (0.005 g/l) and spangled deposits. 2—Sulfate baths, no addition agent, all conditions. 3—Sulfate bath plus addition agents with small effect on strength: dextrin, ethyl alcohol and molasses, glycerol, glycine, lactic acid, 1,5-naphthalenedisulfonic acid, sorbitol, thiourea (0.015 g/l). 4—Fluoborate baths, all conditions. 5—Cyanide baths that yield deposits with lower strengths than those from low-concentration baths: CN-7, CN-8, CN-9. 6—Pyrophosphate bath, all conditions. 7—Sulfate baths plus addition agents or other conditions that cause a moderate increase in strength: gelatin, β-naphthoquinoline, phenolsulfonic acid, selenium dioxide, thiourea plus 1,5-naphthalenedisulfonic acid, thin deposits (2 mils), periodic current reversal (PR). 8—Cyanide bath, sodium ion Rochelle salt type, CN-6. 9—Cyanide baths, all low-concentration types, CN-1 through CN-5, all conditions. 10—Amine bath. 11—Sulfate baths plus addition agents or other conditions that cause a large increase in strength: proprietary A, selenium dioxide (thin deposits, 2 mils), triisopropanolamine. 12—Cyanide baths plus addition agents or other conditions that cause a large increase in strength: CN-8 plus PR, CN-8 containing KCNS plus PR, CN-9 plus PR.

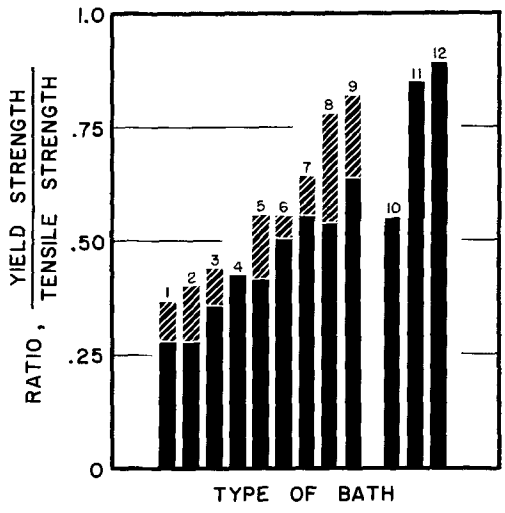

Fig. 64. Ranges and comparative magnitudes of the yield ratio of copper deposits from various types of baths: 1—Sulfate baths, non-addition agent, all conditions. 2—Sulfate baths plus addition agents that cause minor change in yield ratio: lactic acid, β-naphthoquinoline, 1,5-naphthalenedisulfonic acid, phenolsulfonic acid, selenium dioxide, thiourea (0.005 g/l), thiourea plus 1,5-naphthalenedisulfonic acid. 3—Fluoborate baths, all conditions. 4—Cyanide bath, CN-9. 5—Sulfate baths plus addition agents or other conditions that cause a moderate increase in yield ratio: ethyl alcohol plus molasses, thiourea (0.015 g/l), triisopropanolamine, periodic current reversal (PR), thin deposits (2 mils) from bath containing 1,5-naphthalenedisulfonic acid. 6—Pyrophosphate bath, all conditions. 7—Cyanide bath, CN-8 plus PR. 8—Sulfate baths plus addition agents or other conditions that cause a large increase in yield ratio: gelatin, proprietary A, thin deposits (2 mils) from a bath containing selenium dioxide. 9—Amine bath. 10—Commercial wrought copper, annealed. 11—Commercial wrought copper, half hard (21% reduction). 12—Commercial wrought copper, extra hard (50% reduction).

1. Correlations between tensile strength and types of deposits.—In Fig. 63, values of tensile strength are plotted for all deposits that we studied. The data are shown for groups of deposits, classified in part on the basis of bath and in part on magnitude of tensile strength, arranged with increasing strength from left to right on the graph. The limits of the shaded zones at the tops of the bars represent minimum and maximum values of tensile strength for the group. The limits plotted for each group are based mainly on the average deviation from the mean within the group. However, if several deposits within the group had values appreciably lower or higher than the limits defined by the average deviation, the range plotted was enlarged to take account of these deviant deposits. The plotted values are thus somewhat subjective, but in our judgment best represent the group. This procedure was followed for determining the plotted values of upper and lower limits for Fig. 63-65 and 67-70, inclusive.

Figures 63 to 70 were prepared primarily to serve as a convenient visual reference summary, and are therefore discussed only briefly. For example, it is seen in Fig. 63 that the over-all range of strength varies by a factor of four, with spangled sulfate deposits the weakest and PR cyanide deposits the strongest. Changes of tensile strength due to large-effect variables, such as type of bath or addition agents, are readily seen. However, changes in strength due to small-effect variables, such as current density, are not revealed. For the latter type of information, the reader must refer to the appropriate preceding section.

2. Correlations between the yield strength-tensile strength ratio and types of deposits.—The ratio, yield strength/tensile strength, is very low (about 25%) for soft-type deposits, considerably lower than that of annealed wrought copper (55%). The ratio increases progressively with strength, approaching that of cold-worked wrought copper for the strongest electrodeposits.

3. Correlations between elongation and types of deposits.—Figure 65 discloses a general inverse relationship between elongation and type of bath, as compared with Fig. 63 for tensile strength. Thus, the deposits from the amine bath, among the highest in tensile strength, are the most brittle, and the soft-type sulfate deposits, next to weakest, are third from most ductile. The deposits from the pyrophosphate and high-efficiency cyanide baths, with the highest ductilities, are somewhat more ductile than would be predicted from their position in Fig. 63. This could be the result of the crystal orientation hypothesized in Section VIII-F-2-a.

4. Correlations between modulus of elasticity, tensile strength, and types of deposits.—A general correlation between tensile strength and modulus is seen in Fig. 66. However, the higher range of modulus, 16 and 17 x 10^6 psi, embraces a rather large range of tensile strength (40,000-86,000 psi). Modulus values for wrought copper are seen to be located in the mid-range of the correlation band. Correlations between modulus and type of deposit are similar to those between tensile strength and type of deposit, although the fluoborate and sulfate-TIPA deposits deviate conspicuously from the predominant pattern, having abnormally low moduli.

5. Correlations between hardness and types of deposits.—The type-grouping for hardness, Fig. 67, is closely parallel to that for tensile strength, Fig. 63.

6. Correlations between internal stress and types of deposits.—Examination of the groupings in Fig. 68 shows many deviations from the group order that

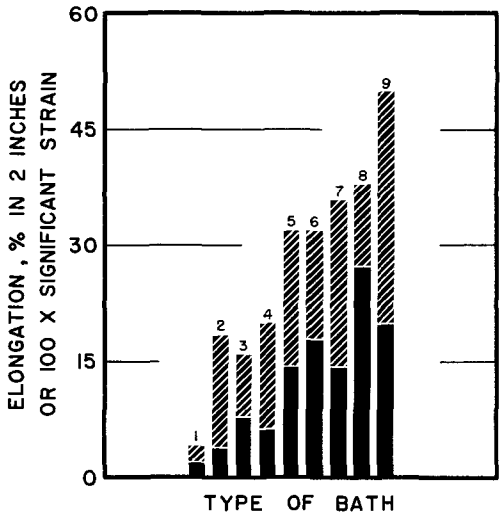

Fig. 65. Ranges and comparative magnitudes of elongation of copper deposits from various types of baths: 1—Amine bath. 2—Sulfate baths plus addition agents or other conditions that cause significant lowering of ductility: dextrin, ethyl alcohol plus molasses, glycerol, glycine, lactic acid, β-naphthoquinoline, sorbitol, thiourea (0.005 and 0.015 g/l), triisopropanolamine, proprietary A, non-addition agent thin deposits (2 mils), thin deposits (2 mils) from baths containing 1,5-naphthalenedisulfonic acid or selenium dioxide, spangled deposits. 3—Cyanide baths, all low-concentration types, CN-1 through CN-5, all conditions. 4—Cyanide baths, high concentration types that yield deposits with ductility nearly the same as those from low concentration baths: CN-8 containing KCNS plus periodic current reversal (PR), CN-9. 5—Fluoborate baths, all conditions. 6—Sulfate baths plus addition agents or other conditions that cause minor effect on ductility: gelatin (0.003 g/l), 1,5-naphthalenedisulfonic acid, phenolsulfonic acid, selenium dioxide, thiourea plus naphthalene disulfonic acid, PR. 7—Sulfate baths, no addition agent, all conditions. 8—Pyrophosphate bath, all conditions. 9—Cyanide baths that yield deposits that are significantly more ductile than those from low-concentration baths: CN-6, CN-7, CN-8, CN-8 plus PR, CN-9 plus PR.

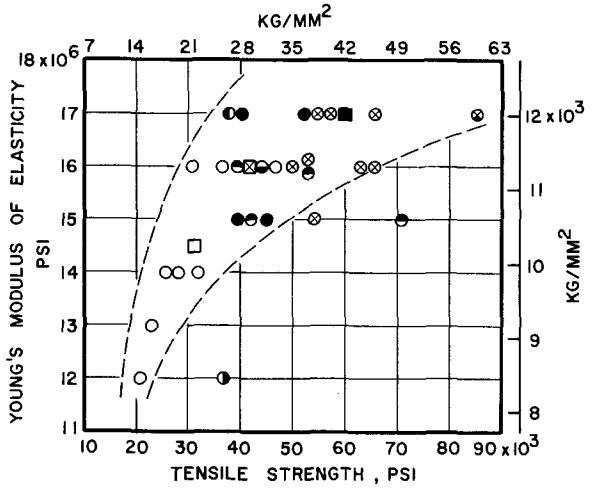

Fig. 66. Relationship between tensile strength and modulus of elasticity of copper deposits from various types of baths: ○—non-addition agent sulfate baths; ●—sulfate baths containing gelatin; ◒—sulfate bath containing selenium dioxide; ◓—sulfate bath containing triisopropanolamine; ◑—fluoborate bath; ◐—pyrophosphate bath; ⊗—cyanide baths, CN-1 through CN-5; ⊗—CN-8 containing KCNS plus periodic current reversal (PR); □—commercial wrought copper, annealed; ⊠—commercial wrought copper, half hard (21% reduction); ■—commercial wrought copper, extra hard (50% reduction).

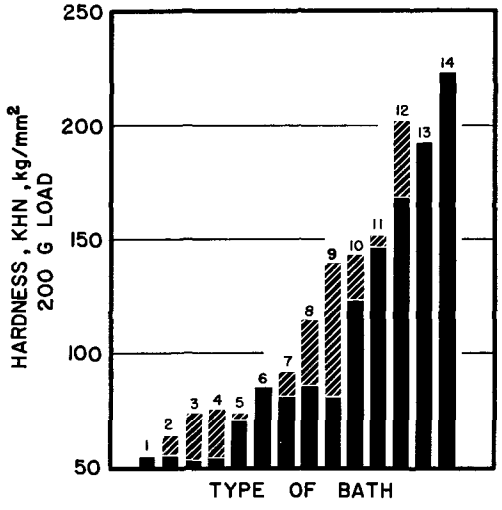

Fig. 67. Ranges and comparative magnitudes of hardness of copper deposits from various types of baths: 1—Sulfate bath, Cu2-H3, 30°C, 2 A/dm^2, severe exposure to cellulose. 2—Sulfate baths plus addition agents that have minor effect on hardness: dextrin, ethyl alcohol plus molasses, glycerol, sorbitol. 3—Sulfate baths, no addition agent, all conditions. 4—Fluoborate baths, all conditions. 5—Cyanide bath, CN-9. 6—Sulfate bath, spangled deposit. 7—Pyrophosphate bath, all conditions. 8—Cyanide baths, CN-7 and CN-8, all conditions. 9—Sulfate baths plus addition agents: includes all addition agents in Table XIII except those in "2" above. 10—Cyanide baths, CN-1 through CN-6, all conditions. 11—Cyanide baths: CN-8 plus periodic current reversal (PR); CN-8 plus KCNS plus PR, cycle 15 sec cathodic, 5 sec anodic. 12—Amine bath. 13—Cyanide bath, CN-8 plus KCNS plus PR, cycle 30 sec cathodic, 10 sec anodic. 14—Cyanide bath, CN-9 plus PR.

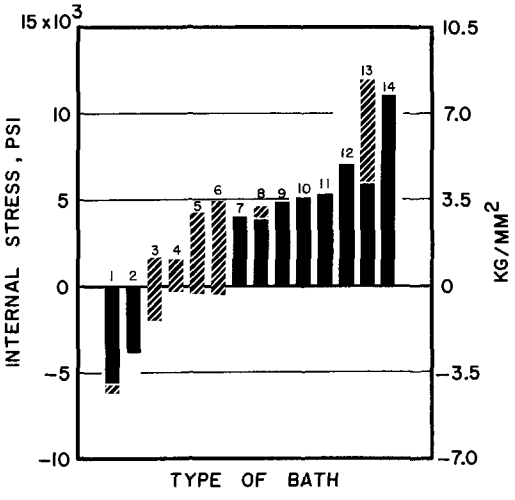

Fig. 68. Ranges and comparative magnitudes of internal stress in copper deposits from various types of baths. Negative stress is compressive. 1—Amine bath. 2—Sulfate bath containing 0.1 g/l gelatin. 3—Pyrophosphate bath, all conditions. 4—Fluoborate baths, all conditions. 5—Sulfate baths, no addition agent, all conditions. 6—Sulfate baths plus all addition agents in Table XIII except gelatin (0.1 g/l), β-naphthoquinoline, triisopropanolamine (30°, 5 A/dm^2). 7—Sulfate bath plus periodic current reversal (PR). 8—Cyanide baths: CN-8, CN-8 plus PR. 9—Cyanide bath, CN-6. 10—Cyanide bath, CN-8 plus 2 g/l KCNS plus PR. 11—Sulfate bath plus β-naphthoquinoline. 12—Sulfate bath plus triisopropanolamine (30°, 5 A/dm^2). 13—Cyanide baths: CN-1 through CN-5, CN-7, all conditions. 14—Cyanide bath, CN-9.

exists in the other graphs in this set (Fig. 63-70). This individuality of internal stress, or lack of consistent relationships with other properties, has been previously noted.

7. Correlations between density and types of deposits.—Except for the low values of density seen in

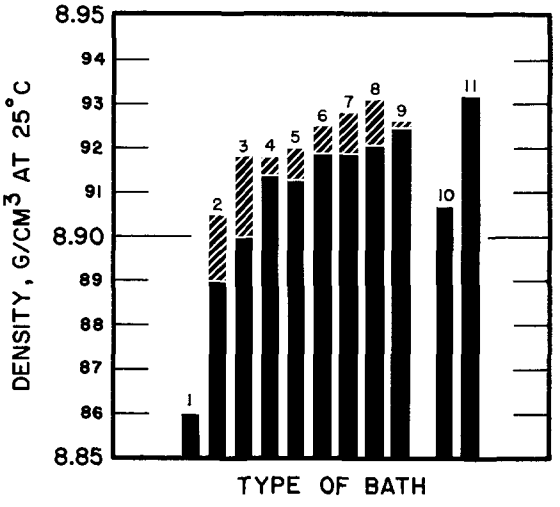

Fig. 69. Ranges and comparative magnitudes of density of copper deposits from various types of baths: 1—Sulfate baths plus addition agents or other conditions that cause a large decrease of density: gelatin, 0.1 g/l; Cu2-H3, 60°C, 20 A/dm^2 (high current density). 2—Amine bath. 3—Cyanide baths: CN-1 through CN-5, all conditions. 4—Sulfate baths plus addition agents that have slight lowering effect on density: gelatin, 0.003 g/l; triisopropanolamine, 30°, 5 A/dm^2; proprietary brightener A. 5—Cyanide baths: CN-6 and CN-7, all conditions; CN-8 plus KCNS plus periodic current reversal (PR). 6—Cyanide baths: CN-8, CN-9. 7—Sulfate baths, no addition agent, all conditions. 8—Sulfate baths plus addition agents or other conditions that have no significant effect on density: ethyl alcohol plus molasses, lactic acid, 1,5-naphthalenedisulfonic acid, β-naphthoquinoline, phenolsulfonic acid, selenium dioxide, thiourea, thiourea plus naphthalenedisulfonic acid, triisopropanolamine, 30°, 2 A/dm^2; periodic current reversal; spangling. 9—Fluoborate and pyrophosphate baths, all conditions. 10—Commercial sheet, half hard (21% reduction). 11—Single crystal.

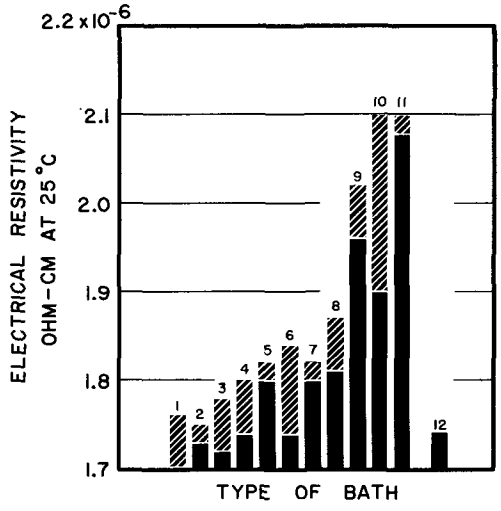

Fig. 70. Ranges and comparative magnitudes of electrical resistivity of copper deposits from various types of baths: 1—Sulfate baths, no addition agent, all conditions. 2—Fluoborate and pyrophosphate baths, all conditions. 3—Sulfate baths containing addition agents that have minor effect on resistivity: ethyl alcohol plus molasses, β-naphthoquinoline, gelatin (0.003 and 0.01 g/l), lactic acid, naphthalenedisulfonic acid, phenolsulfonic acid, selenium dioxide, thiourea, thiourea plus naphthalene disulfonic acid, triisopropanolamine (30°C, 2 A/dm^2), periodic current reversal (PR). 4—Cyanide baths: CN-7 and CN-8, all conditions; CN-8 plus PR. 5—Sulfate baths plus factors that have medium effect on resistivity: thin deposits (2 mils); proprietary brightener A. 6—Cyanide baths: CN-1 through CN-5, all conditions. 7—Cyanide bath: CN-9 (proprietary B). 8—Cyanide baths: thin deposits (0.25 mil) from CN-1 through CN-3; CN-6, all conditions. 9—Cyanide baths: CN-8 plus KCNS plus PR; CN-9 (proprietary B) plus PR. 10—Sulfate baths plus addition agents or other factors that have large effect on resistivity: Cu2-H3, 60°, 20 A/dm^2 (high current density); gelatin (0.1 g/l); triisopropanolamine plus high current density (5 A/dm^2); spangling. 11—Amine bath. 12—Commercial wrought copper: annealed electrolytic tough pitch.

the first two groups of Fig. 69, all deposits have rather high density, with only small differences between groups. Nevertheless, the lower density of cyanide deposits and the reduction of the density of sulfate deposits due to "active" addition agents is apparent.

8. Correlations between electrical resistivity and types of deposits.—Type groupings for electrical resistivity, Fig. 70, are quite parallel to those for tensile strength and hardness (Fig. 63 and 67, respectively).

9. General correlations among properties and types of deposits.—Some of the properties of the main types of deposits are represented in Fig. 71. In the first group, the seven types of deposits are arranged in increasing order of tensile strength. The same order, type 1 to 7 serially, is maintained in the representations of the other properties, so that deviations from regular correlations will be apparent. There is general parallelism between tensile strength, hardness, and resistivity, and to some extent internal stress, and inverse correlation of these properties with elongation and density.

The higher than "normal" elongation of the deposits from the high-efficiency cyanide bath and pyrophosphate bath is apparent, as is the inverse relationship between ductility and tensile strength of the deposits from the amine bath and from sulfate baths containing high-effect addition agents. The average hardness of the latter group of deposits is lower than normal. This is the only significant deviation from a regular hardness pattern.

We have remarked several times that internal stress is the most unique property in that it is least correlated with other properties. While this is true, Fig. 71 does show several regular correlations. Abnormally low stress of the pyrophosphate and amine baths is the main deviation from normal correlation.

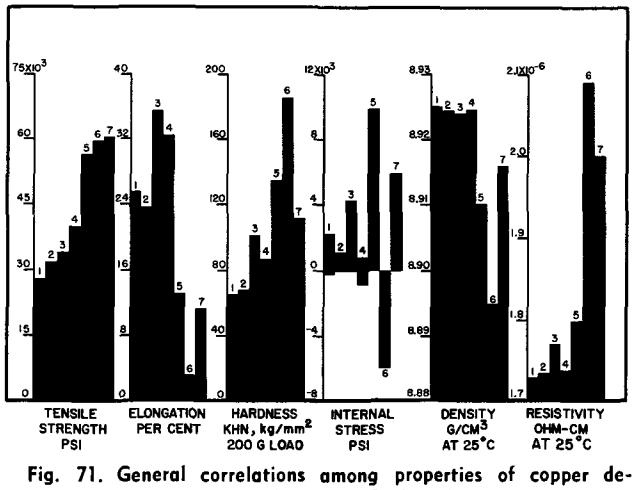

Fig. 71. General correlations among properties of copper deposits from various types of baths: 1—Sulfate baths, all non-addition agent deposits. 2—Fluoborate baths, all conditions. 3—Cyanide bath, CN-8, all conditions except no addition agent nor periodic current reversal (PR). 4—Pyrophosphate bath, all conditions. 5—Cyanide baths, CN-1 through CN-5, all conditions. 6—Amine bath. 7—Sulfate baths plus large effect addition agents. Notes: Elongation is in per cent in 2 in. except for column "5" which is 100X significant strain. Negative values of internal stress represent compressive stress. Metric conversion: one pound per square inch (psi) = 0.000704 kilogram per square millimeter (kg/mm^2).

Considering density, correlation is regular except for the same reversed positions between the deposits from the amine bath and the sulfate bath containing high-effect addition agents, also noted for elongation

and hardness, and repeated again for electrical resistivity. The low value of resistivity of the pyrophosphate deposit is also apparent. The consistent deviation of the properties of the pyrophosphate deposits from the normal, in general in favorable directions, is the most apparent phenomenon shown in these comparisons. It is quite likely that it is associated with a unique structure, as hypothesized in Section VIII-F-2-a.

IX. Acknowledgments

The authors acknowledge the assistance of the following for help with experimental work: J. F. Berkeley and G. I. Reid of the Electrolysis and Metal Deposition Section, NBS, for preparation of metallographic specimens, measurements of expansivity, and preparation of photomicrographs, and T. R. Shives of the Metallurgy Division, NBS, for measurements of hardness. The assistance of many other members of the staff of NBS has been acknowledged at appropriate points in the text.

We also acknowledge the valuable help and advice given by the following: C. H. Sample, District Supervisor, Project 21; R. A. Ehrhardt and A. M. Max, previous and present chairman of the Project 21 committee; and members W. Blum, A. Brenner, S. Lyman, O. B. Mathre, C. W. Ostrander, H. J. Read, D. A. Swalheim, G. C. Van Tilburg, M. L. Whitehurst, and C. I. Whitman.

We gratefully acknowledge the donation of anodes by American Metal Climax, Inc.

Financial support for the project was supplied jointly by the American Electroplaters' Society, Inc., through the Research Board, and by the International Copper Research Association, Inc., the Copper Development Association, and the National Bureau of Standards.

X. Appendix

A. Procedures Used for Preparation of Electron Micrographs (Fig. 36)[25]

Mechanically polished cross sections were electropolished in a commercial electropolishing unit with a proprietary polishing solution containing H_3PO_4, 250 ml; distilled water, 500 ml; ethanol, 250 ml; propanol, 50 ml; urea, 5g; proprietary constituent, 2 ml. Conditions were: time, 5 sec; temperature, 25°C; current, 0.6A. Contact to one specimen was made with a solder spot at the base of the mount and to another with silver paint. No significant difference in structure was seen due to the brief heating during soldering. After electropolishing, chemical etching was done in the etch mixture: NH_4OH, 30 ml; H_2O_2-3%, 30 ml; H_2O, 30 ml; 5 sec, 25°C.

Replicas were made with cellulose acetate tape. The negative replicas were rotary shadowed at an angle of 25° with palladium and backed with carbon at an angle of 90°.

B. Development of Fatigue Relationships

1. Calculation of σ_c in Table XXVI.—The fatigue specimen is represented in Fig. 72 with exaggerated thickness and curvature and with the U-bend at the top replaced with an equivalent rigid bar so that the rotational moments may be visualized. The lower end of the right-hand strip is rigidly fixed. The vertical force, P, causes bending as shown. We consider the bending of only one arm, recognizing that the same forces are present in both. Thus, the force, P, may be thought of as divided in two equal parts, $P/2$, each part causing the bending of one arm. Therefore, the moment causing rotation about O and corresponding bending about O' is

$$\frac{P}{2} \cdot a = M \qquad [1]$$

M, the moment about O', is also equal to the integral

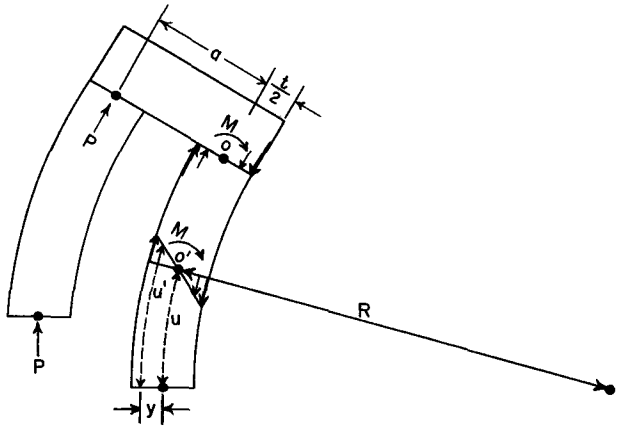

Fig. 72. Stresses and moments in a flexed fatigue specimen

over the cross section of the specimen of the product of the fiber stresses (represented by the small arrows) and their respective moment arms. It is thus expressed as

$$M = \int \sigma y \, dA \qquad [2]$$

where σ is the fiber stress at distance y from the neutral plane of the strip and dA is an element of area in a normal plane. By definition

$$\sigma = E\delta \qquad [3]$$

where E is Young's modulus of elasticity and δ is strain. From Fig. 72, $\delta = (u' - u)/u$. Substituting in [3]

$$\sigma = E\left[\frac{u' - u}{u}\right] \qquad [4]$$

Again from Fig. 72

$$\frac{R}{R + y} = \frac{u}{u'} \qquad [5]$$

from which

$$u' = u + \frac{yu}{R} \qquad [6]$$

Substituting u' from [6] in [4]

$$\sigma = \frac{Ey}{R} \qquad [7]$$

Substituting for σ from [7] in [2]

$$M = \frac{E}{R}\int y^2 dA = \frac{EI}{R} \qquad [8]$$

where $I = \int y^2 dA$, the geometrical moment of inertia around O'.

For a rectangular beam of width b and thickness t, $dA = b\,dy$; hence

$$I = b\int y^2 dy = 2b\left|\frac{y^3}{3}\right|_0^{t/2} = \frac{bt^3}{12} \qquad [9]$$

Equation [7] gives the actual stress in any given plane at distance y from the neutral plane. The distance y to the outer plane is $t/2$. Therefore the surface stress is given by

$$\sigma = \frac{E}{R} \cdot \frac{t}{2} \qquad [10]$$

From Eq. [8], $E/R = M/I$. Substituting this in [10]

$$\sigma = \frac{M}{I} \cdot \frac{t}{2} \qquad [11]$$

Substituting the value of M from [1] and the value of I from [9] in Eq. [11] gives

$$\sigma = \frac{Pa}{2} \cdot \frac{12}{bt^3} \cdot \frac{t}{2} = \frac{3Pa}{bt^2} \qquad [12]$$

Equation [12] gives surface stress, and is the relation

[25] Electron micrographs were made by D. B. Ballard, NBS Metallurgy Division, Lattice Defects and Microstructure Section, who also supplied the data on procedures used.

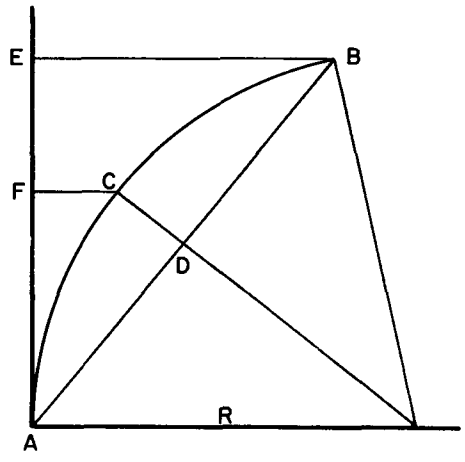

Fig. 73. Relationship between radius of curvature and deflection of an arc.

used for calculating σ_c in Table XXVI. P is obtained from the machine calibration, a is 0.30 in. for our specimens, b is 0.50 in., and t is the measured thickness of the specimen.

2. Calculations of σ_m in Table XXVI.—The arc ACB in Fig. 73 represents an edge view of a short segment of one arm of a flexed fatigue specimen. C is the longitudinal center, *i.e.*, the point of minimum width. Index marks were placed on the edge of the specimen at C and at points A and B, with $\overline{AC}$ and $\overline{CB}$ each equal to 1/8 in. The variation in width of the specimen over the span $\overline{AB}$ is small, so that the curvature is nearly uniform. The specimen was statically flexed and clamped in the flexed position in a jig. The distances $\overline{EB}$, $\overline{FC}$, $\overline{AE}$, and $\overline{AF}$ were then measured with a micrometer microscope to an accuracy of 0.1 mil. Their values were then plotted on large paper on a magnified scale of 100X. From the plot, $\overline{CD}$ and $\overline{AD}$ were measured. The following right triangle relationship is apparent from Fig. 73

$$(R - \overline{CD})^2 + \overline{AD}^2 = R^2 \qquad [13]$$

Expanding [13] and solving for R gives

$$R = \frac{\overline{CD}^2 + \overline{AD}^2}{2\overline{CD}} \qquad [14]$$

From Eq. [10] in the preceding Section X-B-1

$$\sigma = \frac{E}{R} \cdot \frac{t}{2} \qquad [10]$$

Substituting in [10] the value of R from [14]

$$\sigma = \frac{Et}{2}\left[\frac{2\overline{CD}}{\overline{CD}^2 + \overline{AD}^2}\right] \qquad [15]$$

This is the value of σ designated as σ_m in Table XXVI. The values of E (modulus) used in [15] were determined by us or estimated from values for similar deposits. $\overline{CD}$ and $\overline{AD}$ were determined from the direct measurements and graphical evaluation just described.
