To explain the above-described experimental results, especially the effects of the S-shift, the P-shift, and their modifications, it seems necessary to assume the ununiform statistical distribution of the concentration of lattice oscillators which were formed by Si-O bondings in the frequency region from 4.61 x 10^{13} Hz (7.0μ) down to 3.0 x 10^{13} Hz (10μ). And it is necessary to admit the presence of different types of lattice oscillators, their force constant and reduced mass differing from each other.

It is reasonable to consider that the main part of the silica layer consists of silicon dioxide shown as $(SiO_2)_n$ and that they form polyhederon networks. But near the silicon-silica interface, the ratio of concentration of oxygen and silicon atoms is considered to vary because the supply of oxygen atoms to the interface during layer growth is not sufficient to form a saturated silicon dioxide layer. In another type of

situation it is necessary also to assume the surface of the silica layer, because presence of the dangling bond is considerable below the surface. Considering these situations, the variety of Si_xO_y compounds and their configurations which are related to the Si-O oscillator can be summarized as presented in Table I.

The four kinds of lattice oscillators which were formed by the replacement of silicon atoms with oxygen atoms were summarized as type 1 oscillators, and they are classified into four types. Also, six types of dangling bonds which were formed by stripping one, two, and three oxygen atoms from type 1 oscillators were summarized as type 2 oscillators. The configurations of each oscillator mode are shown in Table I. It is reasonable to assume that frequencies of the lattice oscillators of each mode differ from each other as experimentally indicated by Ritter (20) (see Fig. 4).

Considering these situations, the concentration profile of each lattice oscillator inside the silica layer is shown schematically in Fig. 5, where (a) represents the concentration profile of each oscillator. In this figure, type 1 oscillators are visible mainly at the silicon-silica interface and type 2 are seen at the surface of the silica. Furthermore, this figure indicates the structural difference of the surface of the silica which is in an as-grown state and in an as-etched state. From this figure, it is clear that there is a larger concentration of type 2 oscillators on the as-etched surface than on the as-grown. Figure 5b shows the

Table I. Variety of Si-O stretching bondings

In the expression of $(Si_xO_y)_n$, we see with the variation of y/x the frequency of Si-O stretching band changes (15-18). Here, it is reasonable to assume the relation shown as $f_4 > f_3 > f_2 > f_1$ and $f_4 > f'_4 > f''_4 > f'''_4$.

Type 1 oscillator			Type 2 oscillator								
Concentration, cm^{-3}	Frequency	Configuration	Concentration, cm^{-3}	Frequency	Configuration	Concentration, cm^{-3}	Frequency	Configuration	Concentration, cm^{-3}	Frequency	Configuration
N_0	f_0										
N_1	f_1										
N_2	f_2		N'_2	f'_2							
N_3	f_3		N'_3	f'_3		N''_3	f''_3				
N_4	f_4		N'_4	f'_4		N''_4	f''_4		N'''_4	f'''_4	

atomic concentration profile inside the silica and silicon-silica interface relating to the concentration profile of Si-O oscillators.

Assuming the lattice oscillators concentration profile as shown in Fig. 5, the effects which were observed concerning the S-shift can be explained qualitatively as follows;

1. Effect of the S-shift was commonly observed in all samples, which may be due to the presence of type 1 oscillators at the silicon-silica interface and type 2 oscillators on the surface. With the progress of step etching, the contribution of surface oscillators (type 2 oscillators), sensitively related to the occurrence of reflection, increases because the type 1 oscillators are apt to become type 2 oscillators. Thus, the contribution due to more loosely bound oscillators becomes stronger.

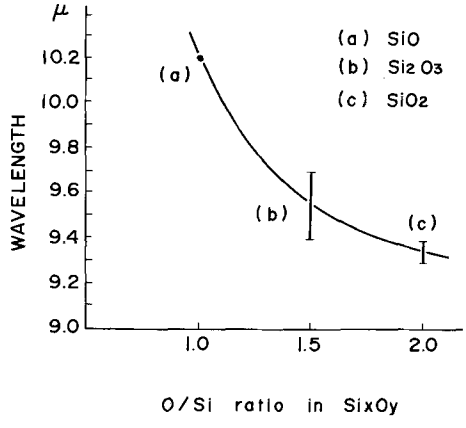

Fig. 4. Relation between wavelength of absorption maximum and O/Si ratio in Si_xO_y (20).

2. As shown in sample A, the wave number of the transmission measurements initially shifts toward the longer wavelength side than that of the reflection measurements. This effect may suggest that reflection intensity is mainly influenced by type 2 oscillators present on the surface, and that transmission intensity is influenced rather strongly by type 1 oscillators. Also, type 1 oscillators are more loosely bound than are type 2 oscillators.

3. When thickness of the silica layer becomes smaller than 3000Å, the S-shift curve of the thermally grown layer returns to the shorter wavelength side by about 10 cm^{-1}, while that of the C.V.D. layer shifts to the longer wavelength side. This effect may be due to a difference in construction of the silica-silicon interface of the two layers.

4. The S-shift curve of sample D shifts toward the shorter wavelength side by about 10 cm^{-1} compared with that of sample C. This effect also suggests that the thin silica layer in an as-grown state is rich in tight bondings, which implies that the concentration of type 1 oscillators is smaller than that of the thick silica layer. This effect can be derived from the fact that the supply of oxygen atoms to form the silica layer at the silicon-silica interface is better as long as the silica layer is thinner.

5. S-shift curves of the C.V.D. silicon layer, samples E and F, shift toward the longer wavelength side by about 30 cm^{-1} from that of the thermally grown silica layer, sample C. This effect may suggest that the C.V.D. layer is rich in loosely bound oscillators throughout the layer thickness. And the S-shift curve of sample F is present at almost the same wave number region as that of sample E, suggesting that there is no special difference in construction between the thin layer and the thick layer regarding the C.V.D. silica layer.

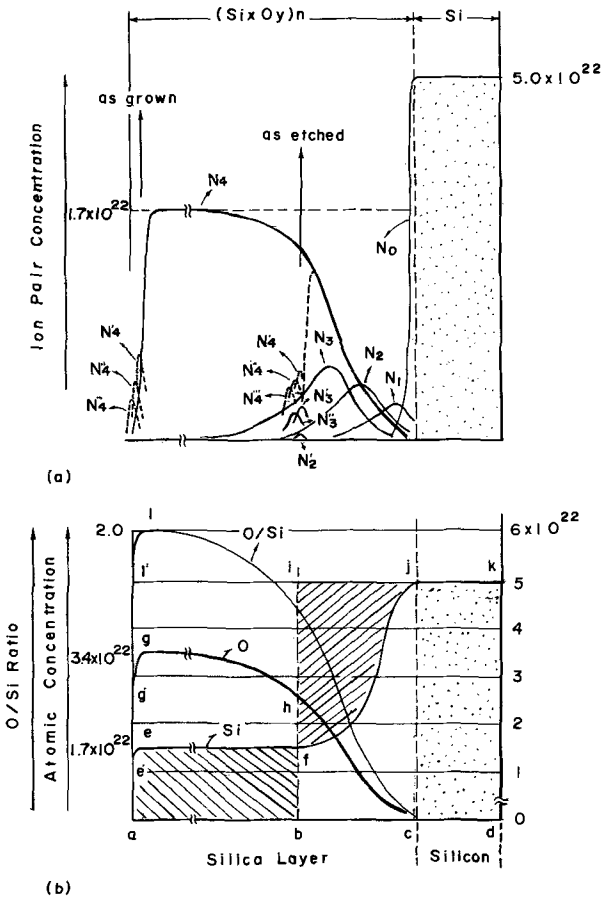

Fig. 5. Distribution profiles of lattice oscillators and atoms inside the silica layer.

a. Lattice oscillator concentration profile. Inside the silica layer, many kinds of lattice oscillator are considered to be present. The type 1 oscillator is rich at the Si-silica interface and the type 2 oscillator is at the surface of the silica layer. With the step etching, the type 1 oscillator is apt to become type 2 oscillators. Type 2 oscillators are sensitively related to the reflection and type 1 and 2 oscillators are to the absorption. It is clear that the concentration profile of the oscillators, N_1, N_2, N_3 and N_4, depends on the ratio N_o/N_{si}.

b. Atomic concentration distribution profile. The number of silicon atoms represented as a area of (ijf) is equal to (feab) and they form the silica layer in the range of (bc) and (ab). The concentration of silicon atom, $1.7 \times 10^{22}/cm^3$ was derived by assuming that the $(SiO_2)_n$ is piled up with pentagonal dodecahedral polyhedrons, whose atomic distance of Si-Si bonding is 3.23Å and that of Si-O is 1.62Å (19). The profile of the curves (gc) and (jf) can be assumed as error functions as

$$N_o(x,t) = \frac{N_o}{2}\left\{1 - erf\frac{x}{2\sqrt{D_1 t}}\right\} \quad [1]$$

$$N_{si}(x,t) = \frac{N'_o}{2}\left\{1 - erf\frac{x}{2\sqrt{D_2 t}}\right\} \quad [2]$$

here, the constants D_1 and D_2 are considered to vary with the conditions for the layer growth. And the ratio N_o/N_{si} varies in the range of 2-0.

6. By thermal treatment at 700°C, the S-curve of the thermally grown silica did not reveal any special changes. On the other hand, the C.V.D. silica displayed shifting toward the shorter wavelength side by about 20 cm^{-1}, suggesting that the loose bondings inside the deposited layer are apt to become tight due to thermal treatments.

Acknowledgments

I express my thanks to Dr. S. Tauchi for his discussions concerning the experimental data and to Messrs. H. Inoue and T. Kiya for preparing the samples and measurements.

Electron Microscopy of Phosphor Raw Materials

P. J. Walitsky and F. M. Vodoklys*

Lamp Division, Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

The reaction of $CaHPO_4$ with the individual activators and modifiers used to produce cool white phosphor was studied using electron microscopy and x-ray diffraction. Electron micrographs were obtained of $CaHPO_4$, $CaCO_3$, CaF_2, Sb_2O_3, $MnCO_3$, $CdCO_3$, and NH_4Cl. Micrographs were also obtained of the material produced by adding one additive at a time to $CaHPO_4$ and firing at ~1200°C in N_2. The conversion of $CaHPO_4$ to β-$Ca_2P_2O_7$ was accompanied by considerable grain growth. Combining with either $CaCO_3$ or CaF_2 enhanced this grain growth. X-ray diffraction was used to identify the products. Particle size data obtained with the Coulter Counter indicated that the size of the final phosphor is determined primarily by the $CaHPO_4$, $CaCO_3$, and CaF_2 components.

The use of electron microscopy to study lamp phosphors has been reported previously by Walitsky (1). The development of a technique for single stage replication was described and examples of calcium halophosphate phosphor shown. A logical extension of this work was the study of the raw materials from which the phosphor is made.

The preparation of calcium halophosphate phosphors is well known and goes back to the nineteen thirties. The starting materials are usually $CaHPO_4$, $CaCO_3$, Sb_2O_3, $CdCO_3$, $MnCO_3$, CaF_2, and NH_4Cl. Wanmaker, Hoekstra, and Tak (2), in 1955, studied the reactions of the various components individually and in various combinations using differential thermal analysis. Many similar studies have been done since. However, as far as can be determined in the published literature, there has been no electron microscopic study of the raw materials or of the various reactions occurring in the calcium halophosphate system. Bodi and Tufts (3) have studied the recrystallization of ZnS phosphor which is primarily a cathode-ray phosphor. Recently Brown has also studied ZnS (6).

While the intent of the work was primarily to obtain electron micrographs, x-ray diffraction data were also obtained. The x-ray diffraction data were especially valuable in pinpointing and explaining structural changes observed in the microscope. They also provided the information necessary to establish correlation with past work.

The electron micrographic study of phosphors mentioned above (1) raised several questions which were unanswered at the time of presentation. Many of the phosphors observed exhibited a surface topography resembling metallurgical structures. It appeared that grain structure covered much of the surface. There was no firm explanation as to its origin. Second, small particles or surface debris were seen on the surface of the large phosphor particles. These were also not fully explained.

Results and Discussion

Samples of each of the raw materials were first studied separately. Following this, samples of $CaHPO_4$ were mixed with each of the separate materials. Samples of $CaHPO_4$ + $CaCO_3$, $CaHPO_4$ + Sb_2O_3, $CaHPO_4$ + CaF_2, etc., were thus obtained. These mixed samples plus a separate sample of $CaHPO_4$ were then fired at ~ 1200°C in a N_2 atmosphere for several hours. The $CaHPO_4$ was studied separately as it is considered the basic structure from which this phosphor forms. The same amounts of material were added as would normally be done when preparing phosphor. The $CaCO_3/CaHPO_4$ mole ratio was approximately 0.5:1, the $CaF_2/CaHPO_4$ mole ratio was approximately 0.13:1, $Sb_2O_3/CaHPO_4$ and $CdCO_3/CaHPO_4$ mole ratios were both approximately 0.01:1, $NH_4Cl/CaHPO_4$ was approximately 0.02:1, and finally the mole ratio for $MnCO_3/CaHPO_4$ was approximately 0.1:1.

$CaHPO_4$.—Figure 1 shows a section of a typical $CaHPO_4$ particle at 10,000X. (All micrographs were at 10,000X.) Figure 2 is a section of a particle from the same lot as Fig. 1 given the heat-treatment described above. Transformation has occurred and grain boundaries are evident. Wanmaker *et al.* (2) state that the transformation of $CaHPO_4$ to β-$Ca_2P_2O_7$ starts at 380°C. The x-ray diffraction data obtained as a part of this investigation indicated that the samples represented by Fig. 2 were indeed β-$Ca_2P_2O_7$.

Comparison of micrographs not shown with Fig. 4 indicates that considerable grain growth has occurred subsequent to the transformation. The development of the grains and their growth is part of a separate investigation which will be discussed in the future. The particle shown in Fig. 4 represents the final result of the grain growth which has occurred.

$CaHPO_4$ + $CaCO_3$.—The next micrograph (Fig. 3) shows a $CaCO_3$ crystal. Some of these particles were observed as almost perfect cubes, while others were

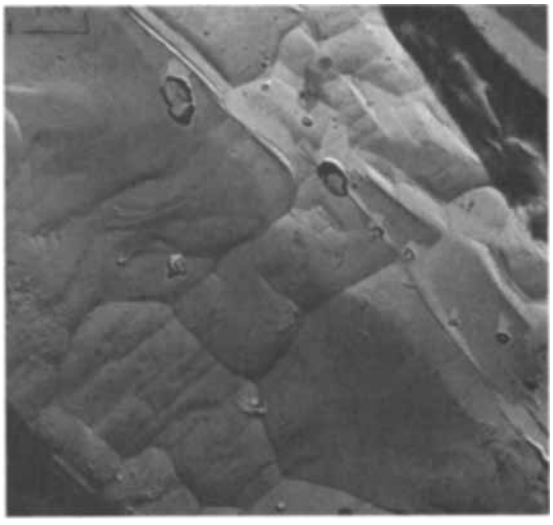

Fig. 2. β-$Ca_2P_2O_7$

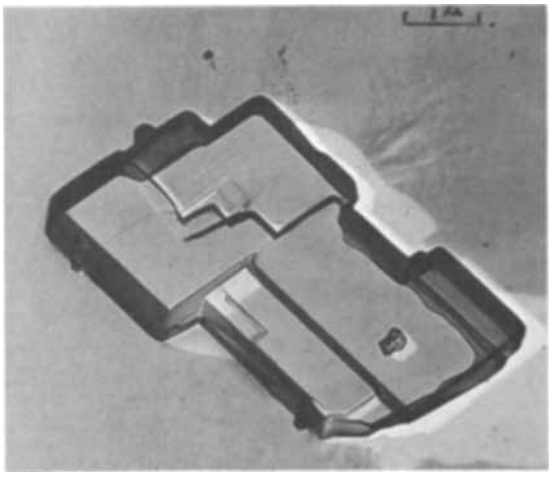

Fig. 3. $CaCO_3$

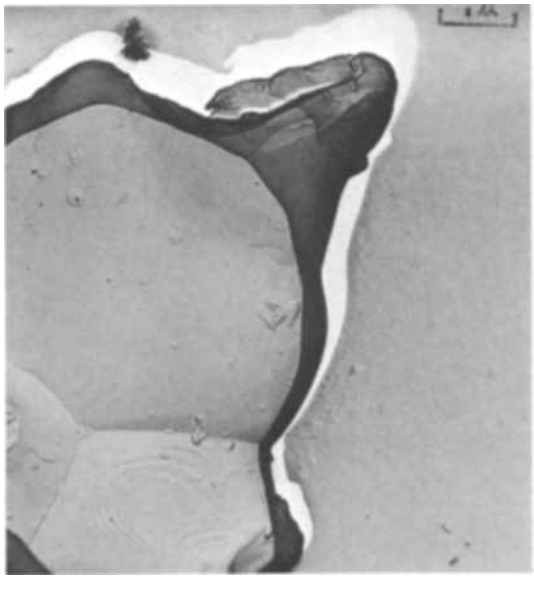

Fig. 4. α-$Ca_3(PO_4)_2$, prepared by heating $CaHPO_4$ + $CaCO_3$

less regular in shape. Combining $CaHPO_4$ and $CaCO_3$ produces a new structure, α-$Ca_3(PO_4)_2$ (Fig. 4). As with the previous reaction, correlation between our x-ray diffraction data and Wanmaker's work was obtained, plus some additional information.

The α-$Ca_3(PO_4)_2$ was indeed the major product found by x-ray diffraction analysis. However a detailed examination of the diffraction pattern revealed the presence of β-$Ca_3(PO_4)_2$ and β-$Ca_2P_2O_7$. Examination of the phase diagram P_2O_5/CaO (7) indicates that these phases will exist if one has a composition slightly richer in CaO than the ratio of 2CaO to $1P_2O_5$. Our starting composition was slightly richer. The temperature to which the sample was heated would suggest that we should also have the phase α-$Ca_2P_2O_7$. This phase was not detected. It may well be that this phase transformed on cooling to β-$Ca_2P_2O_7$.

The grain structure seen in Fig. 4 is somewhat larger than that observed in the transformed $CaHPO_4$. The reaction with $CaCO_3$ apparently changes the final grain size of the α-$Ca_3(PO_4)_2$ from that of the β-$Ca_2P_2O_7$. According to Wanmaker the $CaCO_3$ breaks down to CaO at 900°C, at 1000°C the reaction β-$Ca_2P_2O_7$ + CaO→α-$Ca_3(PO_4)_2$ takes place. (The β-$Ca_2P_2O_7$ had been formed at ~ 380°C.) The reaction is exothermic and perhaps provides a part of the energy necessary for grain growth.

$CaHPO_4$ + Sb_2O_3.—Particles of Sb_2O_3 are seen in Fig. 5. The particle size of this activator apparently covers a fairly wide size range. Combining $CaHPO_4$ and Sb_2O_3 results in formation of β-$Ca_2P_2O_7$ and is seen in Fig. 6. While there is no change in structure as compared to the transformed phosphate there did

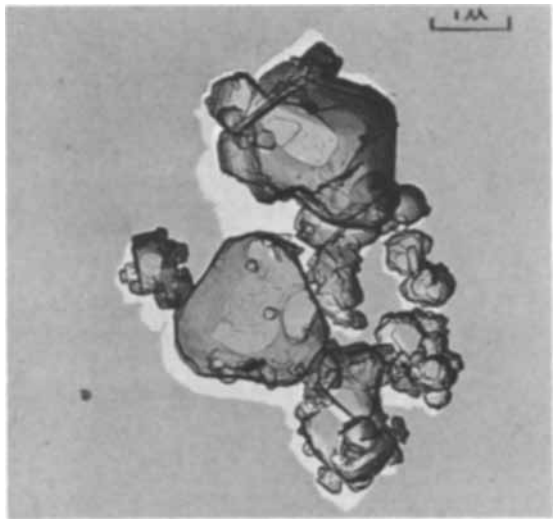

Fig. 5. Sb_2O_3

Fig. 6. β-$Ca_2P_2O_7$, prepared by heating $CaHPO_4$ + Sb_2O_3

appear to be a change in grain structure. The grain size is between that shown in Fig. 2 and 4. There was also evidence of material in the grain boundaries. Stereo electron microscopy indicated that the boundaries were quite deep. From the metallurgical viewpoint two other interesting features were seen: structures resembling twin planes and others strikingly similar to slip lines.

$CaHPO_4$ + $CdCO_3$.—The next material considered was $CdCO_3$. This was revealed as fine material with some agglomeration (Fig. 7). β-$Ca_2P_2O_7$ is again the reaction product and appeared almost identical to the particle in Fig. 6. The only difference was that material was not observed in the grain boundaries. In the preparation of the electron microscope samples $CdCO_3$ was the least soluble in HNO_3 of any of the additions. This necessitated longer dissolution times when preparing the replicas or a change in acid.

$CaHPO_4$ + $MnCO_3$.—$MnCO_3$ is seen in Fig. 8. Platelet growth is the prominent feature of this activator. A few of the particles observed were, however, smooth and did not exhibit this type of structure. As with the preceding two materials, combining it with $CaHPO_4$ does not disturb the transformation to β-$Ca_2P_2O_7$. Its appearance was similar to the $CdCO_3$ and $CaHPO_4$ material and the Sb_2O_3 combination (Fig. 6)

$CaHPO_4$ + CaF_2.—CaF_2 does produce a change in transformation. The material itself is shown in Fig. 9. Its appearance is somewhat similar to the $CdCO_3$, but the CaF_2 is present as much larger particles. Firing produces a mixture of β-$Ca_2P_2O_7$ and Ca apatite [$Ca_5(PO_4)_3F$] as revealed by x-ray diffraction. This

Fig. 7. $CdCO_3$

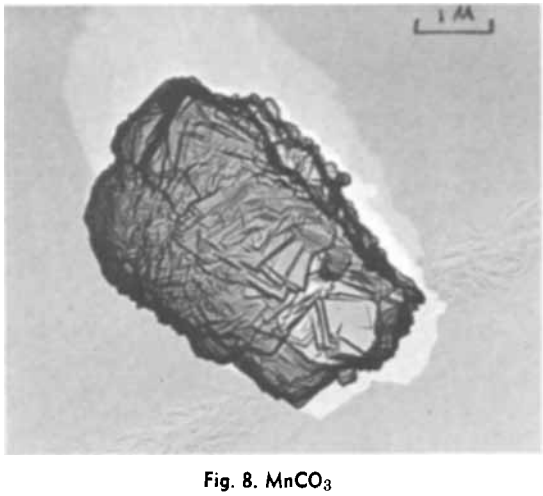

Fig. 8. $MnCO_3$

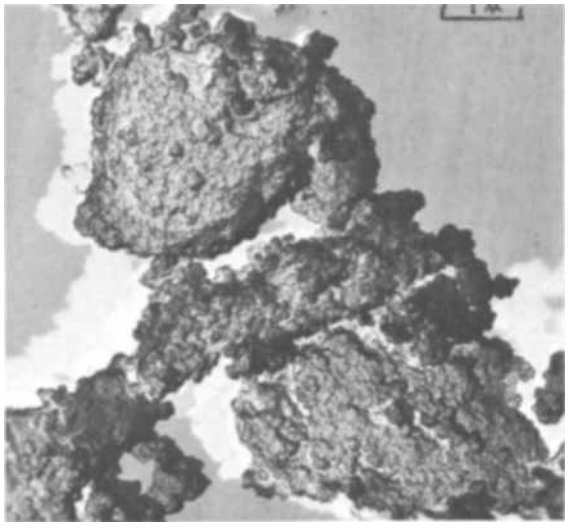

Fig. 9. CaF_2

correlates with Montel (4) who states that $18Ca_2P_2O_7$ + $14CaF_2$ → 5 apatite + $6POF_3(g)$. Rabatin and Gillooly (5) confirmed the reaction using reaction rate studies. They stated that when excess β-$Ca_2P_2O_7$ is present it will appear in the product.

During the microscopic examination it was very difficult to distinguish between β-$Ca_2P_2O_7$ and apatite. Most of the material observed was similar in topography to the β-$Ca_2P_2O_7$. However, examination of the micrographs indicate that some of the particles resembled the final phosphor more than the β-$Ca_2P_2O_7$. As the final phosphor does have the apatite structure it may be that these are apatite particles. An example of this is seen in Fig. 10.

$CaHPO_4$ + NH_4Cl.—The last material examined was NH_4Cl. This material is soluble in water which simplified the replication procedure. A complicating factor was the large size of the particle. It was impossible to obtain micrographs of an entire particle due to folding of the replica film. Fragments were obtained, however, and one is shown in Fig. 11. The material was covered with a very fine step structure. Particles which did not display this structure were generally smaller in size. Combination of NH_4Cl and the $CaHPO_4$ did not disturb the transformation to β-$Ca_2P_2O_7$. Its apearance was similar to Fig. 6 and the $CdCO_3$ combinations.

Phosphor.—A section of a phosphor particle is seen in the last micrograph (Fig. 12). Its topography is

Fig. 10. $Ca_5(PO_4)_3F$, prepared by heating $CaHPO_4$ + CaF_2

Fig. 11. NH_4Cl

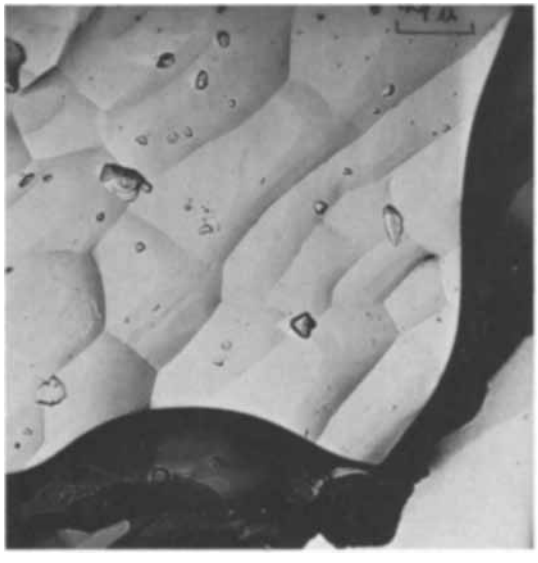

Fig. 12. $(Ca, Cd)_5(PO_4)_3(Cl, F)$:Sb, Mn finished phosphor (cool white).

similar to that seen in many of the earlier micrographs. Quite a few small particles appear on the phosphor surface. These were also observed on the combinations. Examination of the individual components lead us to the conclusion that this material is mostly small bits of activators and modifiers not fully incorporated into the phosphor crystal.

Particle size.—The effects of the different raw materials on the particle size of the finished phosphors were also studied. Calcium dibasic phosphate ($CaHPO_4$) is considered to be the basic "building block" for a calcium halophosphate phosphor, as stated in the introduction. Particle size measurements made with the Coulter Counter indicated that this compound experienced a reduction in particle size when fired to form the β-$Ca_2P_2O_7$ (Fig. 13). The increase in particle size when going from β-$Ca_2P_2O_7$ to the finished phosphor was due mostly to the $CaCO_3$ (Fig. 14).

Also evident was the growth of the β-$Ca_2P_2O_7$ resulting from the reaction with the CaF_2 (Fig. 15). This increase was of lesser magnitude than that caused by the $CaCO_3$. The effects of the other constituents on particle size were insignificant. Thus only those materials which produce a phase change in the β-$Ca_2P_2O_7$ have a significant effect on the final phosphor size.

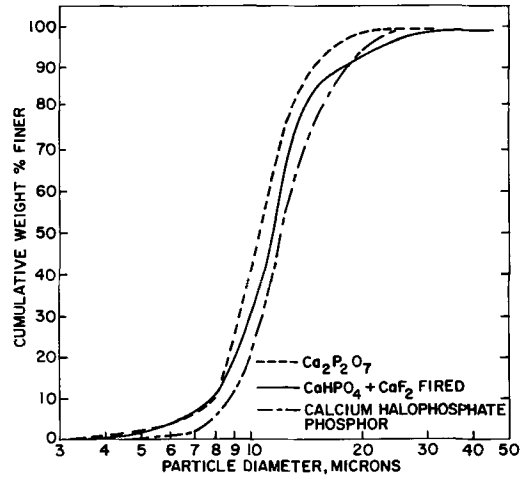

Fig. 15. Particle size distributions, $Ca_2P_2O_7$, $CaHPO_4$ + CaF_2, and $(Ca, Cd)_5(PO_4)_3(Cl,F)$:Sb, Mn.

Conclusion

The question of grain structure on the final phosphor, raised in the introduction, has been explained. It is primarily due to the transformation of $CaHPO_4$ to β-$Ca_2P_2O_7$. Correlation of the micrographs with x-ray diffraction data has provided evidence for supporting several experimental studies done with differential thermal analysis. It is evident that the electron micro-

scope can also provide some new insight into exactly what is occurring during the solid-state reactions involved in the production of lamp phosphors.

Acknowledgment

The authors wish to express their thanks to Miss S. Hamalian who took most of the electron micrographs; appreciation is due also to Dr. C. K. Lui Wei for the x-ray diffraction data, and to Mr. C. E. Oberst for the phosphate-mixture preparations.

A Quasi-Chemical Equilibrium Calculation of the Ge-Si-Sn and Ge-Si-Pb Ternary Phase Diagrams

G. B. Stringfellow and P. E. Greene

Hewlett-Packard Company, Palo Alto, California

ABSTRACT

The ternary phase diagrams Ge-Si-Sn and Ge-Si-Pb have been calculated based on the quasi-chemical equilibrium treatment of the lattice model for both the liquid and solid solutions. The calculation, using temperature independent interaction parameters obtained by fitting the calculated binary liquidus curves to experimental data, agrees to within experimental error with liquidus and tie line data obtained from the steady-state epitaxial growth of Si-Ge alloys from Sn and Pb solutions.

Alloy semiconductors have recently become important because their properties can be tailored for specific applications (1-5). A convenient method for the growth of these alloys is from solutions rich in a metal solvent. One difficulty with this method of crystal growth is the lack of reliable temperature composition ternary phase diagrams. The purpose of this paper is to demonstrate the feasibility of calculating accurate ternary phase diagrams for Ge-Si-M, where M is the metal solvent, using thermodynamic properties of the elements and interaction parameters obtained from the three binary phase diagrams Ge-M, Si-M, and Ge-Si.

The Model

The ternary phase diagram is calculated for the quasi-chemical equilibrium (QCE) model solution which was chosen as the simplest one which is capable of fitting the experimental data for the three associated binary systems. The QCE model has the following properties:

1. Each atom has Z nearest neighbors.
2. Nearest neighbors interact pairwise with the temperature and composition independent interaction parameter, Ω, defined as

$$\Omega_{AB} = H_{AB} - \tfrac{1}{2}(H_{AA} + H_{BB})$$

3. Only the configurational free energy of mixing is considered, *i.e.*, the vibrational free energy of mixing is neglected.
4. The distribution of constituent atoms is calculated using a mass action-like expression

$$N_{AA}N_{BB}/(N_{AB})^2 = \tfrac{1}{4}\exp(2\Omega_{AB}/ZRT) \qquad [1]$$

To test the QCE model, calculated liquidus curves for the binary Ge-M and Si-M systems are compared with the data of Thurmond *et al.* (10) in Fig. 1 and 2. The equations describing the binary liquidus curve for a QCE solution in the case of no solid solubility of B in A are as follows (7)

$$\ln\left[\frac{1}{X_A(1-X_A)\gamma_A\gamma_B}\right] = \frac{\Delta S_A^F}{R}\left(\frac{T_A^F}{T} - 1\right) \qquad [2]$$

$$\gamma_A = \left\{\frac{\beta - 1 + 2X_A}{X_A(\beta+1)}\right\}^{Z/2} \qquad [3a]$$

$$\gamma_B = \left\{\frac{\beta - 1 + 2X_A}{(1-X_A)(\beta+1)}\right\}^{Z/2} \qquad [3b]$$

where

$$\beta = [1 + 4X_A(1-X_A)(\eta^2 - 1)]^{1/2}$$

and

$$\eta = \exp(\Omega_{AB}/ZRT)$$

In these equations A represents Ge or Si and B the metal solvent. ΔS_A^F and T_A^F are the entropy and temperature of fusion of pure A. The interaction parameters were determined by making a best fit to the experimental data. In all cases the calculated liquidus curves are seen to fit the experimental data well.

The Ge-Si binary, both solidus and liquidus, were also calculated treating the solid and liquid as QCE solutions. The method of calculation is the same as that described in the next section with $X_{Sn} = 0$. The calculated liquidus and solidus fit well with the experimental data of Thurmond (16) as shown in Fig. 3.

Calculation of the Ge-Si-Sn Phase Diagram

The first step in the calculation of the ternary phase diagram Ge-Si-Sn is to equate chemical potentials of Ge and Si in the two phases

$$\mu_{Si}^c(T) = \mu_{Si}^l(T) \qquad [4a]$$

$$\mu_{Ge}^c(T) = \mu_{Ge}^l(T) \qquad [4b]$$

Key words: system Ge-Si-Sn, system Ge-Si-Pb, calculated phase diagrams, calculated ternary phase diagrams, system Ge-M, system Si-M.

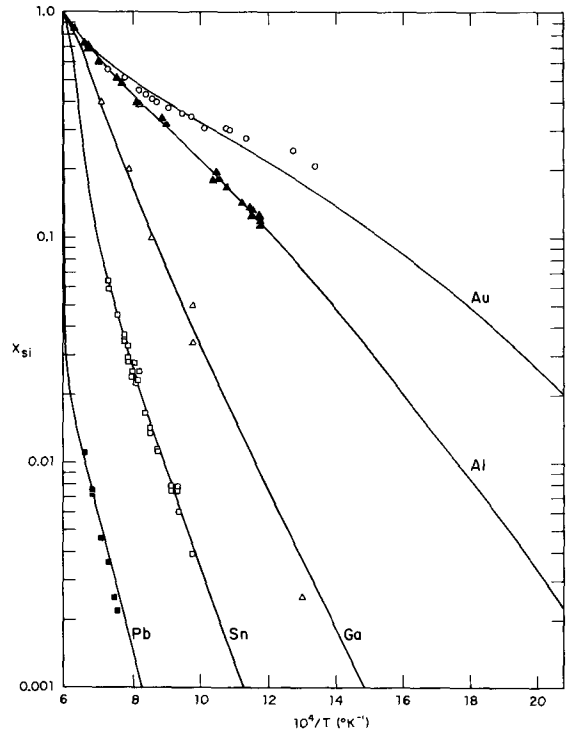

Fig. 1. Liquidus curves for Si-M systems calculated using the QCE model with constant interaction parameters compared to experimental data of Thurmond et al. (10). Values of interaction parameter used were $\Omega_{Si\text{-}Au} = -5020$, $\Omega_{Si\text{-}Al} = -2860$, $\Omega_{Si\text{-}Ga} = 1960$, $\Omega_{Si\text{-}Sn} = 6410$, $\Omega_{Si\text{-}Pb} = 13{,}220$ cal/mole.

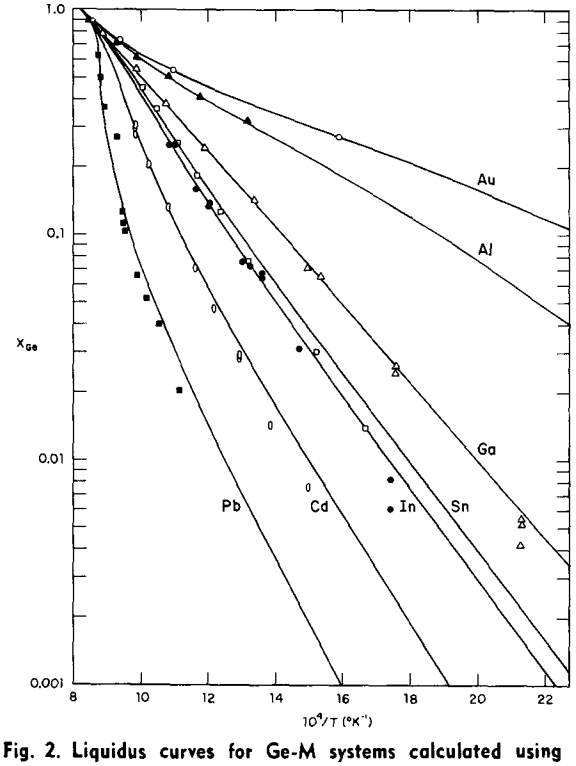

Fig. 2. Liquidus curves for Ge-M systems calculated using the QCE model with constant interaction parameters compared to experimental data of Thurmond et al. (10). Values of interaction parameter used were $\Omega_{Ge\text{-}Au} = -3655$, $\Omega_{Ge\text{-}Al} = -2470$, $\Omega_{Ge\text{-}Ga} = -210$, $\Omega_{Ge\text{-}Sn} = 735$, $\Omega_{Ge\text{-}In} = 1015$, $\Omega_{Ge\text{-}Cd} = 2520$, $\Omega_{Ge\text{-}Pb} = 4675$ cal/mole.

where

$$\mu_i^p(T) = \mu_i^{op} + RT \ln \gamma_i^p X_i^p \quad [5]$$

The superscript p represents the phase and the subscript i represents the component. The chemical potentials of the two phases in the standard state at $T \neq T^F$ are related as follows (14)

$$\mu_i^{oc} = \mu_i^{ol} - \Delta S_i^F (T_i^F - T) + \Delta C_p [T_i^F - T - T \ln (T_i^F/T)] \quad [6]$$

Combining Eq. [4]-[6], neglecting the ΔC_p term in Eq. [6], yields

$$\ln \left[\frac{\gamma_{Si}^c X_{Si}^c}{\gamma_{Si}^l X_{Si}^l} \right] = \frac{\Delta S_{Si}^F}{R} \left(\frac{T_{Si}^F}{T} - 1 \right) \quad [7a]$$

$$\ln \left[\frac{\gamma_{Ge}^c (1 - X_{Si}^c)}{\gamma_{Ge}^l X_{Ge}^l} \right] = \frac{\Delta S_{Ge}^F}{R} \left(\frac{T_{Ge}^F}{T} - 1 \right) \quad [7b]$$

$$X_{Ge}^l + X_{Si}^l + X_{Sn}^l = 1 \quad [7c]$$

These equations assume no solubility of Sn in the Ge-Si solid alloy.

The activity coefficients in the liquid solution may be calculated as a function of temperature and composition using the QCE model. The following six equations specify the thermodynamic properties of the liquid solution.

$$N_{AA}N_{BB}/(N_{AB})^2 = \tfrac{1}{4} \exp (2\Omega_{AB}/ZRT) \quad [8a]$$

$$N_{BB}N_{CC}/(N_{BC})^2 = \tfrac{1}{4} \exp (2\Omega_{BC}/ZRT) \quad [8b]$$

$$N_{AA}N_{CC}/(N_{AC})^2 = \tfrac{1}{4} \exp (2\Omega_{AC}/ZRT) \quad [8c]$$

$$2N_{AA} + N_{AB} + N_{AC} = ZN_A \quad [9a]$$

$$2N_{BB} + N_{AB} + N_{BC} = ZN_B \quad [9b]$$

$$2N_{CC} + N_{AC} + N_{BC} = ZN_C \quad [9c]$$

The equations can be solved to obtain N_{AB}, N_{AC}, and N_{BC}, *i.e.*, the distribution of A, B, and C atoms over the available sites. The total free energy of the system can be calculated and hence the activity coefficients. The details of the numerical calculation can be found in ref. (13).

The activity coefficients in the solid solution assumed to have only two components, are given by Eq. [3a, b]. Z is taken to be 4 for the solid since it has a diamond structure.

Equations [7a]-[7c] can then be solved numerically for a given X_{Si}^l and X_{Ge}^l to yield X_{Sn}^l, the liquidus temperature and the solidus composition in terms of the thermodynamic properties of the elements T_{Si}^F, T_{Ge}^F, ΔS_{Si}^F, ΔS_{Ge}^F, and the four temperature and composition independent interaction parameters $\Omega_{Si\text{-}Sn}$, $\Omega_{Ge\text{-}Sn}$, $\Omega_{Si\text{-}Ge}^l$, and $\Omega_{Si\text{-}Ge}^c$. The first two interaction parameters are obtained by fitting the Si-Sn and Ge-Sn

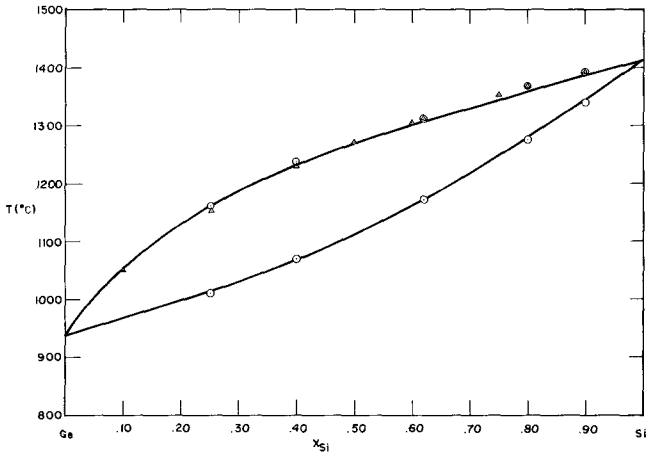

Fig. 3. Comparison of calculated to experimental (16) T-X phase diagram for the Ge-Si system. The QCE calculation used the following interaction parameters $\Omega_{Ge\text{-}Si}^l = 1615$ and $\Omega_{Ge\text{-}Si}^c = 1210$ cal/mole.

Table I. Parameters used for the QCE calculation of the Ge-Si-Sn and Ge-Si-Pb phase diagrams

Parameter	Value used in ternary calculation
T_{Si}^F	1683°K (10)
T_{Ge}^F	1210°K (10)
ΔS_{Si}^F	7.2 eu (10)
ΔS_{Ge}^F	6.7 eu (10)
Ω_{Ge-Sn}	735 cal/mole
Ω_{Ge-Pb}	4675
Ω_{Si-Sn}	6410
Ω_{Si-Pb}	13,220
Ω_{Si-Ge}^l	1615
Ω_{Si-Ge}^s	1210

phase diagrams, Fig. 1 and 2, and Ω_{Si-Ge} for the solid and liquid solutions are obtained by fitting the Ge-Si binary liquidus and solidus data. Fig. 3. The values of the parameters used are tabulated in Table I.

Computed isothermal liquidus lines for the Ge-Si-Sn system are presented in Fig. 4. Iso-(solid composition) lines are presented in Fig. 5. In this figure, each curve represents the liquid compositions in equilibrium with a solid Ge-Si alloy of a given composition. To clarify this somewhat unconventional representation tie lines for the 1200°K liquidus isotherm are included in Fig. 4. By comparing Fig. 4 and 5 it can be seen that tie lines extend from the intersection of the iso-(solid concentration) lines with the 1200°K liquidus to the solid Ge-Si concentration with which the iso-(solid concentration) line is labeled.

Calculation of the Ge-Si-Pb Phase Diagram

The Ge-Si-Pb phase diagram was calculated as described for the Ge-Si-Sn system except for the complication of the liquid immiscibility. The isothermal liquidus curves for the liquid-liquid equilibrium were calculated by equating chemical potentials of Ge, Si, and Pb in the two liquid phases in the same way as for the solid-liquid equilibrium. The two liquidus surfaces were superimposed with the higher temperature liquidus being the equilibrium liquidus surface. This allowed the determination of the monotectic line in the Ge-Si-Pb ternary. The thermodynamic parameters used in the calculation are listed in Table I. The calculated liquidus isotherms are plotted in Fig. 6. In Fig. 7 the iso-(solidus concentration) lines are plotted.

Experimental

Several liquidus isotherms of the ternary phase diagrams were determined by solubility measurement of Si in Ge-M solutions. A schematic of the apparatus used is shown in Fig. 8. The temperature is measured using a Pt/Pt-13% Rh thermocouple enclosed in a fused quartz tube inside the crucible, above the melt. The actual temperature of the melt was determined at several temperatures by inserting a test thermocouple, enclosed in a fused quartz tube, into the melt. It was determined that a correction of +2° is necessary to make the thermocouple located above the melt give the actual melt temperature. The maximum error in measured temperature is estimated to be ±2°. The apparatus is designed so that the Si wafer can be inserted into or removed from the melt at the experimental temperature by tilting the crucible. During the entire experiment the high-purity graphite crucible is in an atmosphere of flowing H_2 purified by diffusion through a palladium membrane.

The experimental procedure is as follows. Appropriate amounts of 6-9's Sn or Pb, Ge, and Si were

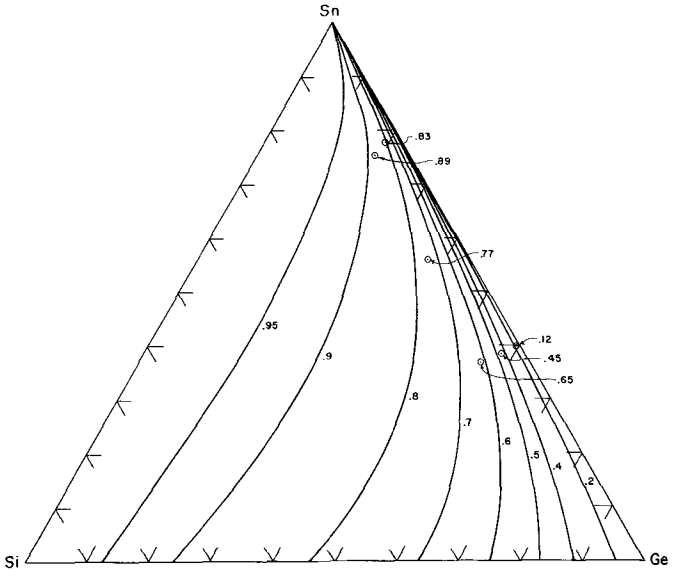

Fig. 5. Calculated iso-(solid concentration) lines for the system Ge-Si-Sn compared with experimental results. Each line represents the liquid compositions in equilibrium with a solid Ge-Si alloy of the given composition.

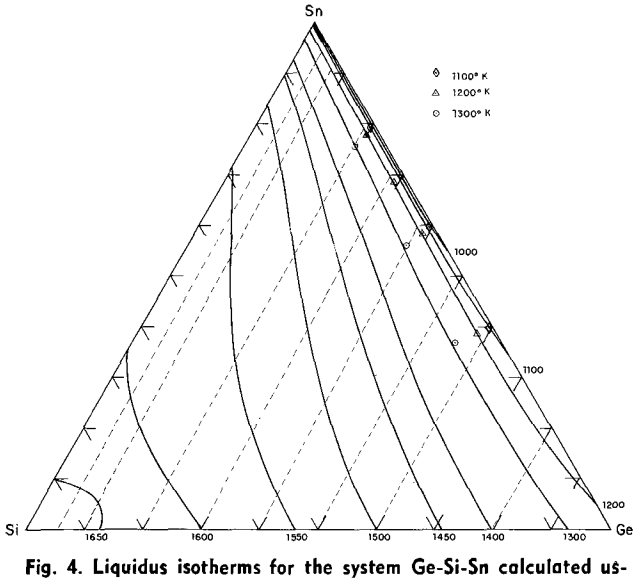

Fig. 4. Liquidus isotherms for the system Ge-Si-Sn calculated using the QCE model compared with experimental liquidus data at 1100°, 1200°, and 1300°K. The dashed lines are tie lines at 1200°K.

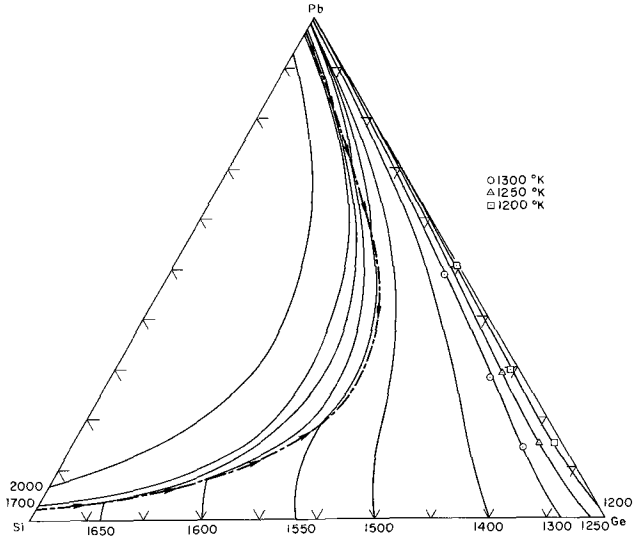

Fig. 6. Ge-Si-Pb isotherms calculated using the QCE model compared with experimental liquidus data at 1200°, 1250°, and 1300°K. The heavy dashed line is the ternary monotectic line.

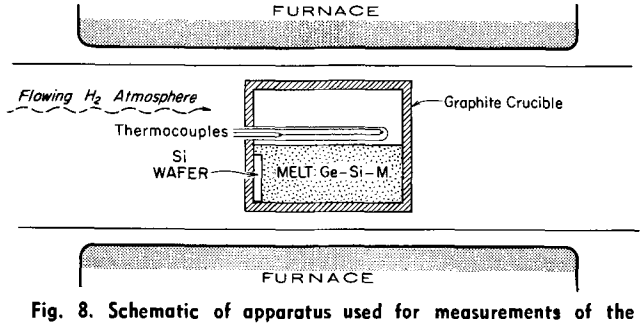

Fig. 8. Schematic of apparatus used for measurements of the solubility of Si in Ge-Sn and Ge-Pb solutions and the growth of Ge-Si alloys from the equilibrium liquidus solutions.

placed in the crucible. A Si wafer was polished mechanically and chemically, weighed, and attached to the holder in the crucible. The crucible was placed in the apparatus. After thorough purging, the crucible was moved into the furnace. The melt was allowed to equilibrate for approximately 1 hr before the Si wafer was inserted into the melt. During the experiment the crucible was slowly rocked to facilitate attainment of equilibrium. After no less than 6 hr, the substrate was removed from the melt and the crucible withdrawn to the cold zone of the apparatus. After allowing the crucible to cool, the Si wafer was removed to determine the weight of Si dissolved.

Due to a slight lateral temperature gradient across the sample, after equilibrium was established, Si would dissolve from one half of the wafer and a Ge-Si alloy crystal would grow epitaxially on the other half. This allowed the composition of the Ge-Si alloy in equilibrium with a given liquid to be determined. In reality crystal growth never occurs under equilibrium conditions but since the crystal growth was very slow, at a constant temperature, and the crystals obtained were homogeneous, as described below, they would be expected to have very nearly the equilibrium solid composition. After each experiment the alloy was removed from the Si substrate and was used to make a Debye-Scherrer x-ray diffraction pattern. This powder pattern was used to obtain the lattice parameter and to determine the homogeneity of the alloy. The half width of the alloy diffraction lines was found to be the same as for pure Si, indicating that the alloys are homogeneous. The composition was determined from the lattice parameter using the a_o *vs.* x data of Dismukes *et al.* (15). The accuracy of the determination of composition is ±1 a/o Si.

The solubility of Si in the Ge-M melt was determined as follows. After the alloy was removed and its weight and lattice parameter determined, the remaining Si was weighed and its dimensions measured. The Si weight was taken as the product of volume and density. This was done to minimize errors due to melt or alloy remaining on the Si surface since Sn, Pb, and Ge all have much higher densities than Si. The amount of Si dissolved in the melt was determined as (original weight of Si added to melt + weight of Si wafer)—(weight of Si wafer after run)—(alloy weight x weight fraction Si in alloy). Since the weight of the Si added to the melt was normally larger than the weight of the Si wafer, errors in determining the final weight of dissolved Si produced only small errors in liquidus composition. The estimated maximum errors resulting from thus determining the weight of Si dissolved are represented by the size of the experimental points on the phase diagrams.

The experimental results are presented on the calculated phase diagram Ge-Si-Sn and Ge-Si-Pb in Fig. 4-5 and 6-7, respectively.

Discussion

The ternary phase diagram is calculated for a model solution which is chosen as the simplest one which fits the experimental data for the three binary systems. Some model solutions which might describe the thermodynamic properties of Ge-Si-M solutions are discussed in terms of a binary solution A-B. All models discussed are based on the lattice model where the constituent atoms are located on a fixed lattice with Z nearest neighbors. The configurational free energy of mixing is determined by pairwise interactions.

The simplest model is the ideal solution where the constituent atoms do not interact so $\Omega_{AB} = 0$.

A second commonly used model is the regular solution (6). In this model Ω_{AB} is nonzero and the A and B atoms are distributed randomly, giving

$$N_{AA}N_{BB}/(N_{AB})^2 = \tfrac{1}{4}$$

The regular solution model is internally inconsistent since, in a system of interacting atoms, certain configurations have lower energy than others, thus the distribution is nonrandom and temperature dependent.

The subregular solution model (8) is similar to the regular solution except Ω_{AB} is taken to be linear in mole fraction A. This model is a specific case of a nonphysical approach where the chemical potential is expressed as a power series in temperature and composition (9). These approaches are useful for extrapolating or interpolating available ternary phase diagram data, but cannot be used to calculate a ternary phase diagram from data on the binary systems.

An internally consistent and more reasonable model is the QCE model described in the second section of this paper. The nonrandom distribution of constituent atoms is calculated using a mass actionlike expression, Eq. [1].

A comparison of calculated *vs.* experimental phase diagram data is necessary to select the appropriate model for the Ge-Si-M systems. Thurmond *et al.* (10) made a systematic study of binary liquidus curves for 14 different elements with Si and Ge. They found that most of the data could be fit using a regular solution model only if Ω were temperature dependent contrary to a basic assumption of the model, *i.e.*

$$\Omega_{AB} = a - bT$$

with a direct relationship between a and b.

Binary liquidus curves calculated using the QCE model with temperature independent interaction parameters, Fig. 1-3, were found to fit the experimental data well. These results suggest that the temperature

dependence of Ω in the regular solution calculation is an artifice to compensate for a failure of the model, in that it does not take into account the temperature dependence of the distribution function. The interaction parameter is forced to include not only $H_{AB} - \frac{1}{2}(H_{AA} + H_{BB})$, but also the changing pair distribution with temperature. This explains the functional relationship between a and b, since the temperature dependence of the distribution function is determined by Ω.

These results in the Ge-M and Si-M systems are similar to those in the Ga-As system which Thurmond (11) and Arthur (12) fitted using the regular solution model with

$$\Omega = a - bT$$

The authors (13) demonstrated that the data could be fit using the QCE model with a temperature independent Ω.

Summary

The Ge-Si-Sn and Ge-Si-Pb ternary phase diagrams, both liquidus isotherms and tie lines, were calculated based on the QCE model for both the liquid and solid solutions. The parameters needed for the calculations were T_{Si}^F, T_{Ge}^F, ΔS_{Si}^F, and ΔS_{Ge}^F, which were extracted from the literature, and the interaction parameters $\Omega_{Ge\text{-}M}$, $\Omega_{Si\text{-}M}$, $\Omega_{Si\text{-}Ge}^c$, and $\Omega_{Si\text{-}Ge}^l$, which were determined by fitting respectively the Ge-M, Si-M, and Ge-Si experimental binary diagram data.

Experimental liquidus data were obtained for the Ge-Si-Sn and Ge-Si-Pb systems by solubility measurements of Si in Ge-M, and tie lines were obtained by growth of Ge-Si alloys from liquid solutions of known composition.

The calculated phase diagrams were found to agree within the experimental data to within the experimental error. This illustrates the accuracy of the QCE calculation of ternary phase diagrams in these particular systems. The results suggest that the calculation would apply to other systems for which the binary liquidus can be fit using the QCE calculation.

Technical Notes

Standing Wave Interference Patterns in Photoresists Observed with a Scanning Electron Microscope

L. J. Fried, R. Flachbart, D. F. Itlen, J. W. Raniseski,* F. W. Anderson, and K. V. Patel

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York

The existence of standing light waves was first demonstrated experimentally by Weiner (1) in 1890, and was used as a basis of a method of color photography by Lippmann (2) in 1891. More recently, the existence of standing wave interference during exposure of photoresists was postulated by Altman and Schmitt (3) to explain the splitting of KTFR[1] films on chromium after development and has been used by Sheridan to produce holograms(4). The objective of this paper is to demonstrate, by use of the scanning electron microscope (SEM), the existence of standing wave interference during photoresist exposure.

Samples were prepared by spinning AZ-1350H[2] photoresist on Si wafers with 5000Å of thermally grown silicon dioxide. The resist was approximately 1.2-1.6μ thick. Patterns were formed in the resist by exposing with an unfiltered 200W Hg arc source with major u.v. lines at 3650, 4050, and 4360Å. Exposure was performed through a silver halide mask for 10-20 sec. The exposed resist was then removed in AZ developer. No post-baking was performed after development. Finally, approximately 500Å of Au was evaporated on the wafers to minimize charging during observation under the scanning electron microscope.

Figure 1 is a SEM micrograph illustrating an edge of one of the resist lands. Of interest are the fringes seen along the thickness of the resist, a higher magnification of which is shown in Fig. 2. These fringes are due to standing wave interference during exposure of the resist.

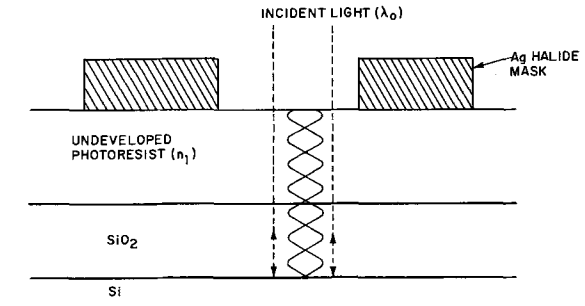

Fig. 3a. Schematic showing formation of standing wave from SiO_2-Si interface. (Change in wavelength between resist and oxide is not shown.)

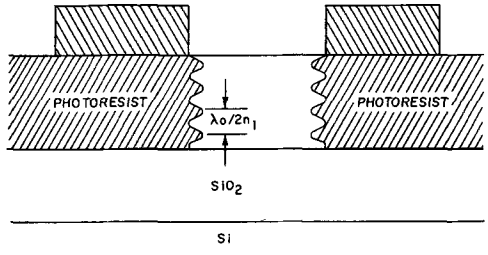

Fig. 3b. Schematic showing resist edge after development

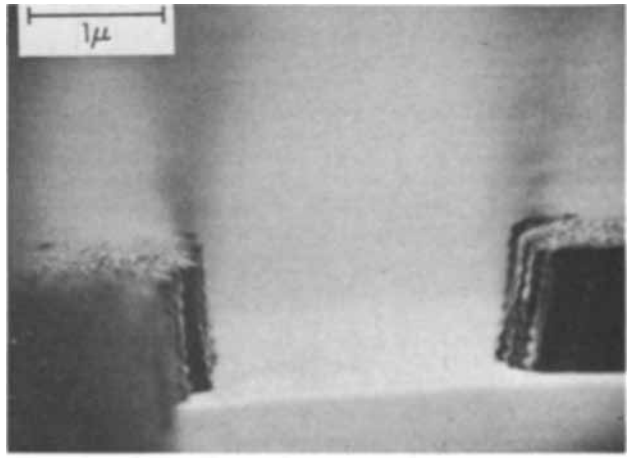

Fig. 4. Edge profile of AZ-1350H

Figure 3a schematically illustrates the formation of the standing wave from the SiO_2-Si interface, and Fig. 3b shows the resulting resist edge after development. Areas where maxima in the resist occur represent nodes in the standing wave where the resist is not adequately exposed and is not removed in the developer. Likewise, areas where minima in the resist occur represent antinodes in the standing wave where the resist is adequately exposed and removed in the developer. The distance between adjacent nodes or antinodes for monochromatic radiation is given by $\lambda_0/2n_1$, where λ_0 is the wavelength of the incident radiation in air, and n_1 the index of refraction of the resist. Figure 4 illustrates the sinusoidal profile of the resist edge.

To determine what contribution was due to a standing wave generated at the photoresist-SiO_2 interface, AZ-1350H was spun onto a glass slide and exposed, with black paper beneath the slide to eliminate a high reflectance substrate. The fringes which were produced were less pronounced than those produced from an SiO_2-Si or photoresist-Si interface; it was therefore concluded that the standing wave was primarily from the Si interface.

To eliminate the possibility that the fringes might have been an inherent structure in the photoresist enhanced by the developer, a resist edge was cleaved, left unexposed, and then immersed in the developer. No fringes were produced.

To determine the effect of the wavelength of the incident radiation on fringe spacing, wafers with AZ-1305H were exposed through band-pass filters, isolating the 3650, 4050, and the 4360Å Hg lines. Table I shows a comparison between the fringe spacing as calculated from the micrographs and that given by

Table I. Comparison between theoretical and measured fringe spacing

Wavelength of incident light, Å λ	n_1*	Fringe spacing, Å Theoretical	Measured
3650	1.70	1070	1100
4050	1.67	1210	1200
4360	1.66	1310	1285

* Index of refraction of photoresist: the indices of refraction were measured (5) on an AZ-1350 polymer (Phenol Formaldehyde Resin), using the laser-VAMFO technique (6).

$\lambda_0/2n_1$. The excellent results are undoubtedly somewhat fortuitous, as the error in the measurements is probably about 10%. However, the change in fringe spacing with wavelength is demonstrated.

It should be emphasized that all of the samples were not baked after development. If postbaking is performed at a temperature such that the resist flows, the fringes wash out.

The existence of fringes due to standing wave interference has been seen in such other positive resists as AZ-1350 and AZ-111 and, to a lesser extent, in negative resists such as KTFR. This difference in extent between positive and negative resists may possibly be due to a swelling of the KTFR during development washing out some of the structure.

To conclude, a scanning electron microscope enabled us to observe fringes along the thickness of the exposed photoresist. These fringes were found to be due to preferential exposure caused by a standing wave originating at the SiO_2-Si interface.

Acknowledgments

The authors would like to thank Drs. H. Levine and W. Pliskin for several helpful discussions; C. Bremmer, G. James, and D. Van Oppens for technical assistance; and A. J. Warnecke for supplying the data on the indices of refraction of AZ-1350H.

Deposition of Epitaxial $InAs_xP_{(1-x)}$ on GaAs and GaP Substrates

H. A. Allen* and E. W. Mehal*,[1]

Texas Instruments Incorporated, Dallas, Texas

There is considerable interest in semiconductors which have band gaps in the near-infrared region of the spectrum (1.4-0.33 eV) for solid-state light-emitting and laser diode, detector, and photoemitter applications. The specific areas of photoemitters and related photocathodes have generated specific interest because of the very high photoemissive yields which have been obtained from Cs_2O activated III-V surfaces (1,2) which show promise of giving a sensitive, high-efficiency photocathode for electromagnetic radiation beyond 0.9 μm, where the quantum efficiency of the classical alkalai-metal photocathodes is less than 1%. However, in order to make photocathodes practical for image-intensifier purposes, the active III-V material must be deposited on a substrate transparent to radiation of wavelengths longer than 0.9 μm.

$InAs_xP_{(1-x)}$ is a III-V alloy system which has band gaps that span this spectral region. GaAs could serve as a substrate window for radiation of 0.9 μm and longer, and GaP could serve as a broader-band window, transmitting light of wavelengths longer than 0.56 μm. The chemical-vapor deposition of $InAs_xP_{(1-x)}$ on InAs substrates, using AsH_3 and PH_3 as the source of As and P, was recently reported (3). A similar process has been used to deposit epitaxial layers of this alloy on chromium-doped and tellurium-doped GaAs and undoped GaP substrates.

Experimental

Materials preparation.—The open-tube deposition system (Fig. 1) used in these studies is constructed of fused quartz. A mixture of anhydrous HCl and purified hydrogen passes over a heated indium reservoir and transports the volatile InCl thus formed to the deposition zone. Purified hydrogen and high-purity AsH_3 and PH_3 (each in hydrogen gas) are mixed in a chamber prior to introduction to the reactor. The composition of the deposited alloys was controlled by the relative flow rates of the AsH_3-H_2 and PH_3-H_2 gases, each of which could be varied continuously from 0 to about 250 cc/min. For these experiments, mixtures containing 4% AsH_3 and 4% PH_3 (each in hydrogen) were obtained from the Matheson Company. Elemental indium (six-nines pure) was purchased from Cominco American, Incorporated.

A two-zone resistance furnace provided independent temperature control (± 2°C) of the indium reservoir and the GaAs or GaP substrate. There was a gradual temperature gradient between the indium zone (maintained between 750° and 850°C) and the substrate (maintained between 630° and 750°C). The seed and indium reservoir were located 3-4 in. apart. In most runs, the seed was held normal to the direction of gas flow by a quartz pin through a hole in the slice.

The GaAs substrates were (100), (111)A, (111)B, and (110) oriented slices (20 mils thick) cut from chromium- or tellurium-doped pulled crystals and chemically polished with 8:1:1 (H_2SO_4:H_2O_2:H_2O) immediately before use. The GaP substrates were grown by chemical-vapor deposition on (111)A GaAs substrates. The substrates were removed by lapping. The as-grown surfaces were used for alloy deposition.

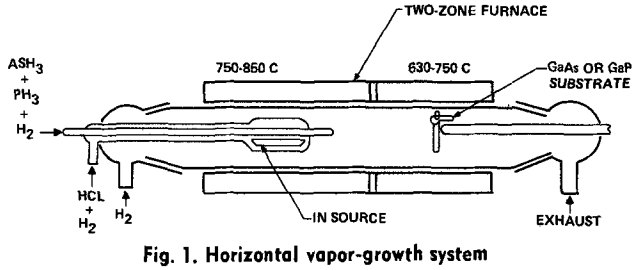

Fig. 1. Horizontal vapor-growth system

[1] Present address: Spectronics Incorporated, Richardson, Texas.

Materials evaluation.—Epitaxial layer thicknesses were determined by either cleave or bevel-lap, and stain. Staining with a 1.5% NaOCl solution in H_2O gave a sharp contrast between the GaAs substrate and the layer; no stain was required for the GaP substrates. Alloy compositions were determined by electron microprobe analysis and/or x-ray diffraction. The sharpness of the diffraction peaks and the reproducibility of microprobe readings (taken in at least four positions on the surface) were used to determine the homogeneity of the layers. Infrared absorption measurements were made routinely to determine the absorption edge and to provide a semiquantitative measure of composition. However, accurate band gap values are difficult to obtain using this procedure because the sharpness of the absorption-edge measurement appears to depend strongly on the method of surface preparation.

Carrier concentrations and mobilities were determined by a-c or d-c Hall and resistivity measurements at room temperature on ultrasonically cut, six-armed samples with indium contacts.

Results and Discussion

Physical properties.—The alloy composition of the epitaxial layers was varied by changing the relative flow rates of the AsH_3 and PH_3 mixtures. The alloy composition (expressed in mole per cent InAs) is plotted in Fig. 2. Against the gas-phase composition calculated from the flow rates (expressed in mole per cent As, taking into account the Group V components only), it is seen that the alloys are systematically higher in arsenic content than the corresponding vapor phase. These results are in close agreement with those of Tietjen *et al.*(3).

Alloy samples grown in a given run were similar in composition. The surface composition did not vary by as much as 1 m/o (mole per cent) for most of the layers grown on (111)A and (110) substrates. The (111)B and (100) layers were less homogeneous for alloys containing more than 50 m/o InAs and were as homogeneous as any other orientation for those having more than 75 m/o InAs. The composition and crystallinity of various samples were checked by x-ray diffraction with compositions being determined by the method described by Howard and Dobrott (4) and the crystalline perfection of the layers was determined by a Laue topographical method developed by Swink(5).

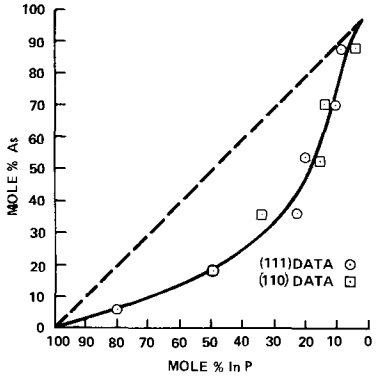

Fig. 2. Per cent InAs in $(InAs)_x(InP)_{1-x}$ deposited *vs.* per cent of As as total V component in the gas phase.

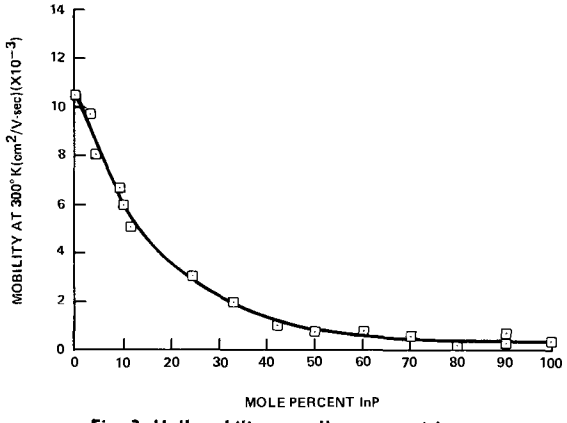

Fig. 3. Hall mobility *vs.* alloy composition

The optimum orientation appears to depend on alloy composition. For InP and alloys with <0.50, the (111)A orientation produced the highest-quality layers. The (100) orientation appeared to become more favorable for alloys having InAs contents of 75 m/o or greater. High-quality layers were grown on (110) substrates up to the middle of the composition range; erratic results were obtained using (111)B substrates. A more complete study of this orientation dependence is under way and will be reported at a later time. The optimum growth temperature appears to increase with InAs composition of the layers from around 640° to 650°C for InP to near 700°C for the InAs layers. Typical deposition rates were 50 ± 10.0 μm/hr.

The deposits on GaP substrates were generally of lower perfection than those of GaAs substrates as evidenced by broader x-ray diffraction peaks. However, some relatively shiny surfaces with a smooth alloy-GaP interface were grown throughout the composition range, but with more difficulty and less reproducibility than on the GaAs substrates. The larger lattice mismatch undoubtedly contributes to the imperfection of the deposits on GaP compared with those on GaAs. However, this might be alleviated by finding a set of growth parameters more favorable to deposition on GaP.

Electrical properties.—The electrical properties of $InAs_xP_{(1-x)}$ layers deposited on chromium-doped semi-insulating GaAs substrates were measured throughout the composition range. The deposits were all N-type having carrier concentrations in the (1-5) X $10^{16}cm^{-3}$ range. The Hall mobilities measured here increase monotonically from about 400 cm^2/V-sec for InP to 10,000 to 11,000 cm^2/V-sec for InAs. It is to be expected that the mobilities for these deposits on GaAs would be considerably lower than those for the deposits on InAs obtained by using the same reactant system (3), due to the large lattice mismatch between the alloy layers and the GaAs substrates. The lower mobilities for the InAs deposits as compared to those of Cronin *et al.* who used $AsCl_3$ and system-generated HCl to prepare InAs layers on GaAs substrates (6,7) are probably due to the incorporation of more compensating impurities originating from the commercial AsH_3 and HCl starting materials. No electrical measurements were made on the $InAs_xP_{(1-x)}$ depositions on GaP.

A Pseudo-Resistance Method for Collating Battery Discharge Data

Olle Lindström*

Department of Chemical Technology, The Royal Institute of Technology, Stockholm, Sweden

ABSTRACT

A pseudo-resistance method is described for transformation of discharge curves obtained with a storage battery into one characteristic curve, which is called the *Ri*-curve. This graphical procedure yields useful figures of merit for storage batteries and is particularly valuable for estimates of battery data at high current and energy drains and for studies of variations and variability in battery performance. Two versions are presented. "Version I," which is sufficient for most purposes, uses three characteristic constants: *a* (the resistance parameter), *b* (the capacity parameter), and *Vr*, where *Vr* is a reference voltage and *a* and *b* are obtained from the regression line $Ri = a + b\ (Ri \cdot D)$, with $Ri = (Vr - V)/I$ and $D = \int I\,dt$ (*V* is the operating voltage, *I* discharge current, and *t* discharge time). The regression line represents the linear part of the *Ri*-curve $Ri = \phi\ (D \cdot Ri)$ which is plotted in the so-called *Ri*-diagram. "Version II," the R&D version, yields four figures of merit: *Vr*, *Dr*, *Rc*, and *Rk*, where *Dr* is a limit capacity, *Rc* a minimum internal resistance, and *Rk* a resistance factor for estimating the fraction of *Ri*, which depends on *D*.

The electric car is expected to become a very demanding application for storage batteries in the future. In contrast to the general level of technology, in this and other novel applications for storage batteries, *e.g.*, on the motor side, the methods for describing the electrical characteristics of the battery itself are unsatisfactory and incomplete. There are very good reasons for this situation. The storage battery is a much more complicated technical system than its electromechanical partner. The motor constitutes an invariant system, whereas the properties of the storage battery change during charge and discharge.

Methods for detailed presentation of the electrical qualities of the storage battery are desired both by the manufacturer and by the user. The manufacturer needs figures of merit in his R&D and for his quality-control functions. The user, *e.g.*, a submarine captain or an "electro-motorist"—a driver of an electric car—needs relevant data presented in an understandable and usable form. This kind of information is needed particularly at high current drains and/or large energy drains, *i.e.*, in the domain of the performance limits of the battery. The user depends less on detailed information of this kind when the battery is in its fully charged condition.

Figures of merit or characteristic parameters for batteries should be derived entirely from the inherent qualities of the battery. The basic relation should, with a minimum of terms, be capable of describing the whole array of discharge curves and associated voltage/current curves with particularly high precision in the domain of the performance limits of the battery. The constants involved should preferably have a physical meaning to help understanding and analysis. The most important goal would, however, be to achieve an efficient reduction of experimental data. This is in line with the purpose of the comprehensive work by Shepherd (1) who derived an equation describing battery discharge. The present approach has much in common with Shepherd's studies. The present work should, however, not be considered an extension of Shepherd's work; rather, the purpose has been to bring to focus the most interesting area from the user's point of view, *i.e.*, the domain of the performance limits of the battery, and to find a more practical procedure for deriving figures of merit for the battery in this domain.

Shortcomings of Present Methods

The performance of storage batteries is today almost universally reported by means of discharge curves. The battery voltage is plotted against the discharge time or the amount of electricity delivered at constant current. The discharge is interrupted at an end voltage, *Vs*, and the obtained capacity figure, *Ds* A-hr, reported as a figure of merit. The choice of *Vs* depends on the application in question and the discharge current.

The familiar Peukert relation is frequently used in lead acid battery studies for estimates of *Ds* at various *I*. Unfortunately, the constants of the Peukert regression line are much influenced by the choices of *Vs* as illustrated by Fig. 1. Figure 1 also includes a Peukert curve for a hypothetical battery with a constant capacity independent of the discharge current. This curve does not deviate too much from the others in the graph.

Key words: battery characterization, *Ri*-curves, *Ri*-diagrams, discharge curves, end voltages, battery parameters, Peukert relation, Shepherd equation, battery variability, voltage-current curves, internal resistance of batteries, electrode structure, overcharging lead acid batteries, sintered iron electrodes.

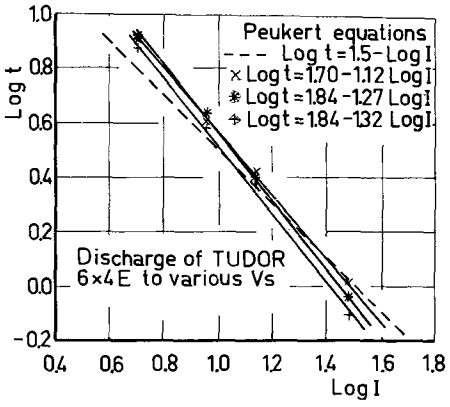

Fig. 1. Peukert curves, $^{10}\log t = a + b\ ^{10}\log I$, derived from discharge curves obtained with a lead acid battery, Tudor 6 x 4E (I, discharge current; t, discharge time; and Vs, end voltage. End voltages, Vs, were chosen according to (a) practice in the laboratory for general evaluation, x; (b) practice for tractionary batteries, ✲; and (c) practice for stationary batteries, +. The dashed line represents a hypothetical battery with constant capacity independent of discharge current.

The concept of end voltage is apparently of little value as a basis for putting up equations describing battery performance because of its arbitrary character. The situation would of course be different if Vs could be related to the electrical properties of the battery and not be decided by the actual application. The following route might, however, be used for defining Vs in a manner which would be satisfactory from this point of view. End voltages plotted against the corresponding discharge currents frequently follow a kind of linear voltage/current curve. The $D = Ds$ curve in Fig. 2 shows end voltages, Vs, against discharge currents. Such V/I curves are also obtained when voltages at constant ratios, D/Ds, are plotted against the current, Fig. 2 (D denotes the number of amperehours that have been delivered at the time of the voltage reading, whereas Ds represents the capacity at the discharge current used). These special V/I curves frequently have the same slopes at different D/Ds ratios. One could then adopt the policy that: (a) end voltages should be chosen so that the Vs/I curve becomes parallel to other V/I curves, valid for various constant D/Ds ratios, and (b) that the constant voltage difference between the Vs/I curve and the V/I curve for $D = 0$ should be related in a simple numerical way to the difference between the V/I curve for $D = 0$ and, *e.g.*, the curve for $D/Ds = 0.5$. This route is fairly complicated, requires that the discussed V/I curves are reasonably parallel, and involves an iteration procedure. The curves in Fig. 2 which are based on present practice to define Vs for tractionary batteries are almost, though not exactly, parallel. The voltage difference between the $D = 0$ and the $D = Ds$ curve is 0.29V. Shepherd considered discharges to be ended at voltages equal to those of the $D = 0$ curve, minus 0.25V.

Shepherd's equation (1) is capable of describing complete sets of discharge curves very efficiently. In spite of this highly desirable feature most laboratories, however, do not seem to use this tool because of (a) the somewhat complex procedures involved in determining the numerical values of the constants of the equation, (b) the diffuse physical meaning of some of the constants, (c) the fact that consistent and good curve fits can be obtained with different sets of constants, and (d) the variability in battery performance which makes any attempt to fit experimental data to any equation over the entire range of discharge curves dubious to the mind of the experimentalist.

The fourth point is particularly relevant when $D < 0.5\ Ds$, as illustrated by the V/I curves in Fig. 3. These V/I curves were obtained with a 260 A-hr stationary lead acid battery. The battery was discharged at various constant discharge currents in the normal way (I = 26, 45, 64 and 111A). The constant current discharge was, however, interrupted for a short time three times during the discharge, at D = 40, 64, and 107 A-hr. On these occasions the load was varied so as to obtain a V/I curve valid for the battery under the prevailing conditions. The battery voltage and the variable load current were recorded after 90 sec of operation at the new current load.

The 12 V/I curves in Fig. 3 obtained in this way (one for each combination of D and I) exhibit three features: (a) linearity, (b) some variability, and (c) fairly small differences—from a practical point of view—between the various runs. The range of the intercepts on the voltage axis for $I = 0$ represents only ± 1.2% of the battery voltage. This domain of battery operation evidently does not provide a good starting point for putting up relations describing battery performance. A better route would be to start at the other end of the discharge profile where more dramatic things happen that are important to the user.

Pseudo-Resistance Method (*Ri*-Method) "Version I"

Obviously, a minimum of three parameters would be required to define the performance of a battery: (a) a capacity parameter, (b) an internal resistance parameter, and (c) a reference voltage. Since the

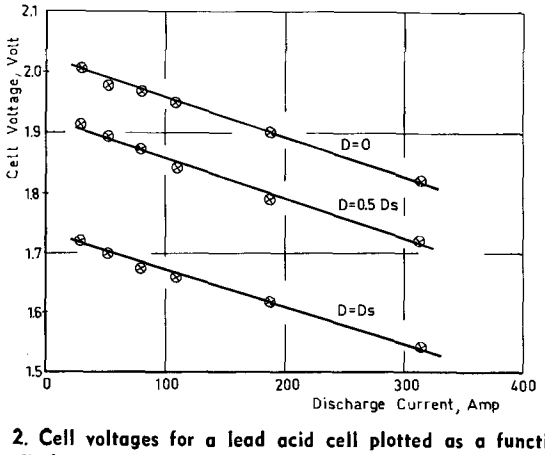

Fig. 2. Cell voltages for a lead acid cell plotted as a function of the discharge current at states of discharges characterized by $D = 0$, $D = 0.5\ Ds$ and $D = Ds$, respectively. Data taken from discharge curves in a battery catalog at the 10, 5, 3, 2, 1, and ½ hr rates (2).

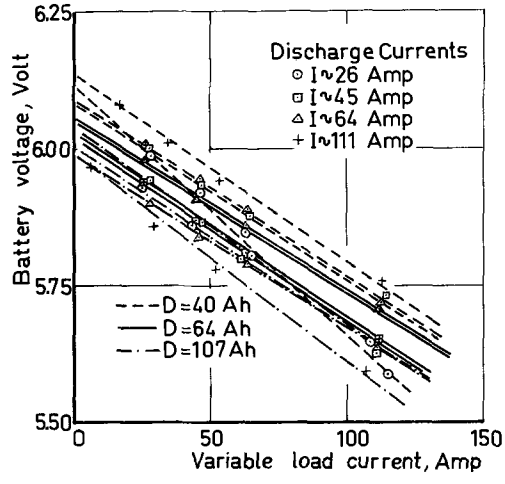

Fig. 3. V/I curves for a 260 A-hr lead acid battery Tudor 3 Spg obtained at D = 40, 64, and 107 A-hr, respectively. The discharge was performed with 26, 45, 64, and 111A, except when readings for the V/I curves were taken.

slope of the V/I curve depends on the state of charge, and the capacities, which can be obtained under various conditions, depend on the shape of the V/I curves, the sought relation should at least include a relationship between these two parameters. The capacity parameter should preferably be related to the capacity found at very small discharge currents, whereas the internal resistance parameter should be related to the properties of the battery in its nearly fully discharged state.

The so called *Ri*-diagrams, introduced in this paper, are in their most simplified version, completely in harmony with the above requirements, and give a good fit of experimental data. This version, here called "Version I," makes use of an apparent resistance term, *Ri*, calculated as

$$Ri = (Vr - V)/I \qquad [1]$$

where Vr is a reference voltage which is estimated as the averaged intercept of the relevant V/I curves extrapolated to $I = 0$, and V is the voltage of operation. *Ri* obtained in this way is plotted against the product $(Ri \cdot D)$ where D is the quantity of electricity, here in A-hr, that has been delivered by the battery at the time of the measurement.

A linear *Ri*-curve indicates that the potential drop, $Vr - V$, increases with discharge time, t, in an accelerated way, being proportional both to $(Vr - V)$ and t. As a matter of fact, the *Ri*-curves, $Ri = \Phi\ (Ri \cdot D)$, most frequently turn out to be linear, except at low energy drains (*i.e.*, early in the discharge). This regression line is here expressed by

$$Ri = a + b\ (Ri \cdot D) \qquad [2]$$

The slope b has the dimension of inverted capacity, $(\text{A-hr})^{-1}$, whereas the intercept on the *Ri*-axis, a, is a characteristic resistance term. Equation [2] is thus based on the three parameters Vr, a, and b. At the moment we consider the *Ri*-diagram, "Version I," to be an empirical relation. We, however, introduce a "Version II" below in which case some remarks of a deductive nature will help in understanding the meaning of the constants a and b.

The *Ri*-diagram in Fig. 4, covering different charge states and discharge currents, shows that this simple route is a fairly efficient procedure for reduction of experimental data into one single curve. Points from different discharges with different currents fall on the same *Ri*-curve. A regression line valid for large energy drains which satisfies [2] is obtained by extrapolating the linear part of the curve toward the *Ri*-axis. In this particular case, $1/b$ corresponds to 45.9 A-hr to be compared with the 15 hr capacity of Ds = 43.5 A-hr.

It is thus realized from Fig. 4 that the *Ri*-diagram could also be useful for a presentation of the electrical properties of the battery for small energy drains even if the linear relation [2] no longer holds in this region.

The *Ri*-diagram is, however, of course no remedy against variability in battery performance. The variability may frequently manifest itself as a variation in the regression constants, a, whereas the slopes, b, of the regression lines in most cases come out fairly constant. This is illustrated in Fig. 5 with four consecutive cycles with a large battery. Clearly the *Ri*-diagram is an excellent tool to study and define this kind of variability, since the variability can often be attributed to one single parameter. It seems quite natural that the well-known variability in battery performance from one cycle to another under seemingly rigorously controlled experimental conditions should be connected with some kind of resistance factor, small in itself but with a large influence on performance. (Variations may occur in the contact between the current-collecting grid and the active

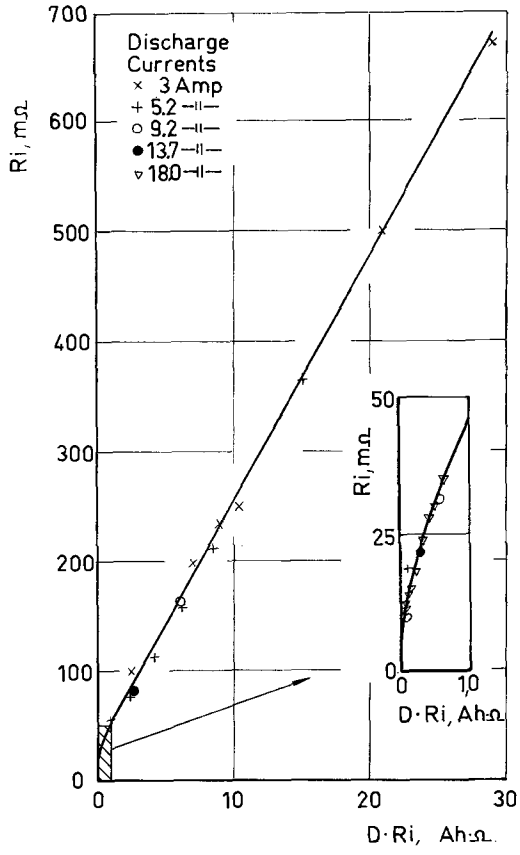

Fig. 4. *Ri*-diagram, "Version I," for a lead acid battery, Tudor 6 x 4E. Constants of the linear regression line are a = 30 mohm b = 0.0223 $(\text{A-hr})^{-1}$. Vr = 2.02V. The section of the diagram near the origin is magnified to demonstrate the typical bend of the *Ri*-curve.

materials due to thin corrosion layers. Minute gas bubbles may remain from the foregoing charging period in the porous structure, etc.)

The different characters of the two regression constants a and b are also evident from the experiments reported in Fig. 6. This lead acid battery was heavily overcharged during many days. The *Ri*-diagram indicates that the slopes in the *Ri*-diagram are quite constant, whereas the regression constant, a, increases with the amount of overcharge. Figure 7 gives a plot of the two regression constants. There is an approximately linear increase of the resistance parameter, a, whereas the capacity parameter, $1/b$, is influenced but slightly by overcharging.

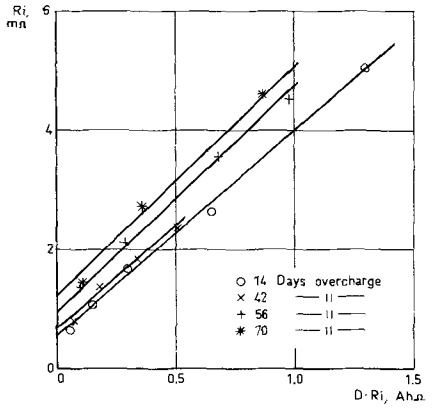

Fig. 6. *Ri*-curves, "Version I," for overcharge experiments with a lead acid battery (Tudor 3 Pg 410). $Vr = 2.02V$.

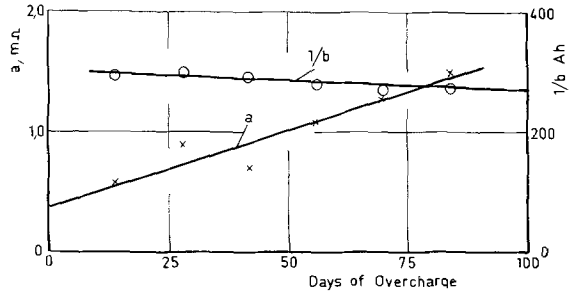

Fig. 7. Parameters *a* and *1/b* from regression lines for *Ri*-curves in Fig. 6.

Figure 8 displays discharge curves taken from a battery catalog (2) in the condensed form of the *Ri*-diagram. The simple method for estimating D at any voltage and discharge current within practical limits is exemplified on the graph. Since one *Ri*-curve is sufficient for one battery, the performance of several batteries can be presented on the same graph for easy comparison. The two constants of the linear part of the *Ri*-curve can be obtained in one single discharge run with two voltage readings at two D (discharge time at constant current to two predetermined voltages recorded). A logarithmic scale makes it possible to accommodate batteries with widely varying properties on the same graph.

By means of values for Ri, taken from the *Ri*-diagram, and the figure for Vr, the V/I curve for the state of charge in question is easily put up according to [1]. Because of the time required to establish steady state in the battery system, V/I curves derived from discharge data at constant current may differ from those obtained with rapid variation of the load.

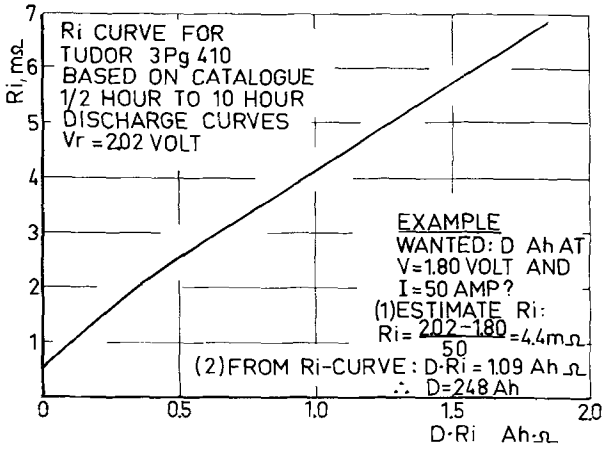

Fig. 8. Use of the *Ri*-diagram, "Version I," for estimates of discharge data.

The *Ri*-Method, "Version II"

So far the *Ri*-method in its "Version I" has been presented as an empirical finding; it is in this respect much like the Peukert relation. The procedure is thus considered to be justified by its practical merits, and can be recommended for any battery system which yields data that give consistent *Ri*-curves.

There must of course be a consistent theoretical background to a consistent *Ri*-curve. Consistent means here that plots taken from discharge runs with different discharge currents fall on the same *Ri*-curve—in the (rare) cases with no variability. This theoretical background may differ in its details from one battery system to another but probably some important elements in the theoretical framework will be common for most batteries. An attempt is therefore made to organize those elements into a formal relationship to get some understanding of some of the features behind the *Ri*-diagram. The result of this treatment is an equation which contains the important elements of the Shepherd equation. The derivation, however, follows a slightly different course and the interpretation of the physical meaning of the constants also differs somewhat. It is shown how the feature of the present paper, the *Ri*-diagram, is related to the type of numerical relationship that was first derived by Shepherd (1).

This treatment suggests a correction which can be applied to "Version I" of the *Ri*-method described above. The somewhat more elaborated "Version II" is useful in R&D work, whereas "Version I" is quite satisfactory from the user's point of view.

Clearly, the concept of a linear voltage/current curve is a logical starting point for the analysis. These curves are characterized by slope and intercept.

From, *e.g.*, Fig. 3, it is realized that two types of voltage drops have to be taken into account: (*a*) $Vo - Vr$, which is a function of the state of charge; (*b*) $Vr - V$, which is the voltage drop due to the passage of current under the prevailing conditions.

The open-circuit voltage of a fully charged battery, Vo, can be defined as the intercept for $I = 0$ from the linear part of the V/I curve for $D = 0$. The actually observed open-circuit voltage could also be used. It is of course important to make clear in numerical work which route is followed.

One might first expect an approximately linear relation between Vr and the state of charge. Shepherd used an equation with log $(Vo - Vr)$ proportional to D. Data in Fig. 2 in Shepherd's paper are, however, fairly consistent with a linear relation; the system was here lead dioxide, zinc, and sulfuric acid. The open-circuit voltage of lead acid batteries at various acid concentrations is, *e.g.*, frequently estimated by means of simple linear relations like voltage equal to (0.84 + density in grams/cm^3), *etc.* Since the density of the acid is approximately linearly related to the state of charge, one might therefore expect a similar linear relation also between Vr and the state of charge even if Vr is not a true open-circuit voltage. Figure 9(a), which is based on data presented in Fig. 3, however indicates that things may not always be that simple. Figure 9 (b) shows furthermore that it is not possible to observe any influence of the discharge current on Vr in this case. Figure 10, which contains data calculated from a battery catalog (2), also indicates a fairly complicated pattern. Vr drops at first with increasing D, but then increases again. There is also a fairly small difference between the maximum and the minimum values for Vr in this graph. The average Vr comes out as 2.02V in this case, which seems to be a good reference value for most lead acid batteries of conventional design.

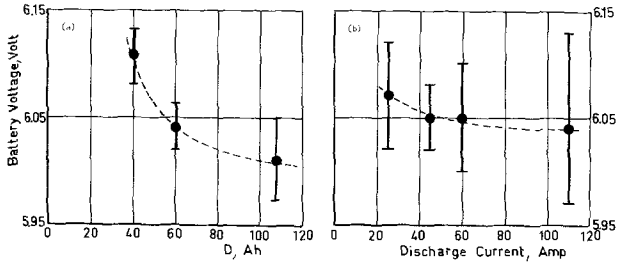

Fig. 9. Averages of *Vr* estimated from *V/I* curves in Fig. 3. Max deviations also shown in the graph. (a) *Vr* as a function of the state of charge (*D* constant in each group, *I* varies); (b) *Vr* as a function of the discharge current (*I* constant in each group, *D* varies).

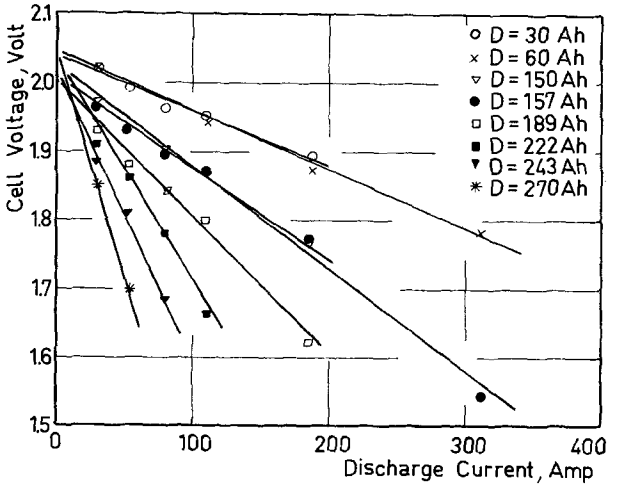

Fig. 10. *V/I*-curves calculated for a tractionary lead acid cell on the basis of catalog data (2).

It is clear that any equation describing the electrical characteristics of a storage battery at low currents and small D is very much influenced by the components of the equation which take care of $Vo - Vr$ since the contribution of $Vr - V$ associated with the current drain as such compared to the total drop $Vo - V$ may be quite small in this region.

The slope of the V/I curve represents an apparent internal resistance of the battery. This resistance should constitute a sum of resistance terms connected with the different process steps in the battery. For comparison it can be mentioned that in fuel cell studies the fairly constant total resistance which in general is observed for an electrode system may be split up in three terms: (*a*) a term associated with the diffusion of gas through the electrolyte film, (*b*) a term associated with the charge transfer step, and (c) a resistance term associated with the migration of ions along the electrolyte film (3).

The empirically found constancy of Ri at a certain state of charge could be due to two causes: (*a*) contributing terms of *any importance* are constant, and (*b*) variations are internally compensated. The fact that practically linear V/I curves are obtained for many different batteries and electrode structures indicates that explanation (*a*) is probably valid.

The apparent internal resistance, Ri, will then be split up in two sums of terms, one representing resistances which are not influenced by the state of charge, *e.g.*, resistance terms associated with the conduction of electrons in the electrode current-collecting structure, and one sum of terms which depend on the state of charge only. These two sums are denoted Rc and Rv, respectively, and thus

$$Ri = Rc + Rv \qquad [3]$$

The state of charge is here defined as $L = (Dr - D)/Dr$, where Dr is the capacity at infinitely low currents, assuming no self-discharge. The resistance term, Rv, can thus be written

$$Rv = \phi(L) = \phi(Dr - D)/Dr \qquad [4]$$

Rc must evidently be smaller than or equal to the minimum value of Ri which can be observed in any measurement. It is realized that it must be possible to find expressions for [4] for any assumed Rc-value satisfying this condition and [3].

Figure 10 illustrated how the apparent internal resistance may depend on the state of charge. We now seek a formal description of this relationship.

The current used in the discharge in general has less influence than generally believed on the structure and conditions of the electrodes of the battery. A general experience with, *e.g.*, lead acid batteries is also that the number of ampere-hours which can be extracted out of the battery when the discharge current is varied during the discharge is fairly constant, within say ± 3%, and approximately equal to Ds for the lowest discharge current in the discharge profile, provided that the final discharge is done at this discharge current. The variation in Ds with the discharge current thus does not reflect differences between the quantities of available active electrode materials due to current-induced effects. The view that the physical state of the electrode is governed mainly by D and not so much by the discharge profile, the course taken to D, is supported by scanning electron micrographs of lead acid battery positive plates which have been discharged at high and low current drains to about the same D. The structure of the plates looks nearly the same, independent of the current used in the discharge, Fig. 11. The appearance of the sintered iron electrodes in Fig. 12 is also in harmony with this view.

It is well known that the active materials in most types of storage batteries with porous electrode structures are not used up entirely in the discharge reaction even if the discharge current is kept very low. Positive and negative materials in the lead acid batteries are thus frequently utilized only to 30-35% (thin electrodes may exceed 50%, however). There are exceptions to this, *e.g.*, the silver oxide electrode which is used to near 100%. The end point of the discharge with, *e.g.*, a lead acid battery at very low current is thus not determined by the amount of active materials present but by the internal resistance which increases to very high values near the end point. A mathematical expression should thus give infinite internal resistance at the end point at very low current drains. The end point, characterized by infinite Ri, could thus represent the maximum available capacity at infinitely low current drains, Dr, assuming no self-discharge. The simplest relation satisfying this requirement is apparently

$$Ri = Rc + Rv = Rc + Rk \cdot Dr/(Dr - D)$$
$$= Rc + Rk/L \qquad [5]$$

The resistance terms which are influenced by the state of charge, and summed as Rv, are thus here assumed to be inversely proportional to the state of charge, which makes $Ri \to \infty$ when $D \to Dr$.

The inverted value of the resistance term Rv, $1/Rv = L/Rk$, is apparently a conductivity term, which thus should be proportional to L, if [5] is valid. It seems quite reasonable that this conductivity term should be proportional to L, at least in a crude way. The active parts of most electrode structures contain well-conducting charged material (in an amount proportional to $Dr - D$) and poorly conducting discharged material (in an amount proportional to D). The resulting conductivity of these active parts of the electrode is then expected to be approximately proportional to $Dr - D$,

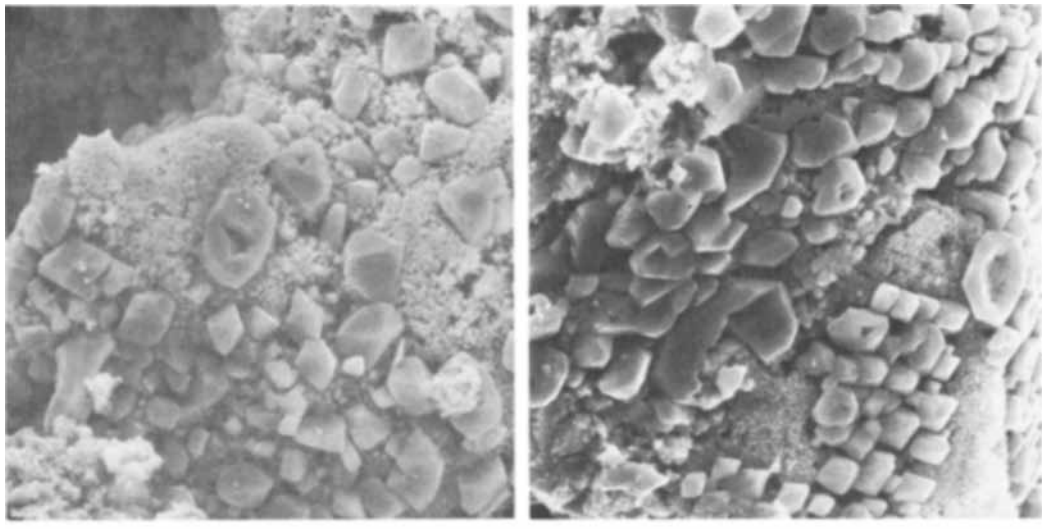

Fig. 11. Micrographs of out layer of tubular positive lead electrodes discharged to ~ 0.6 *Dr* at ½ hr current *(left)* and 20 hr current *(right)*. Lead sulfate crystals in *unreacted* lead dioxide mass.

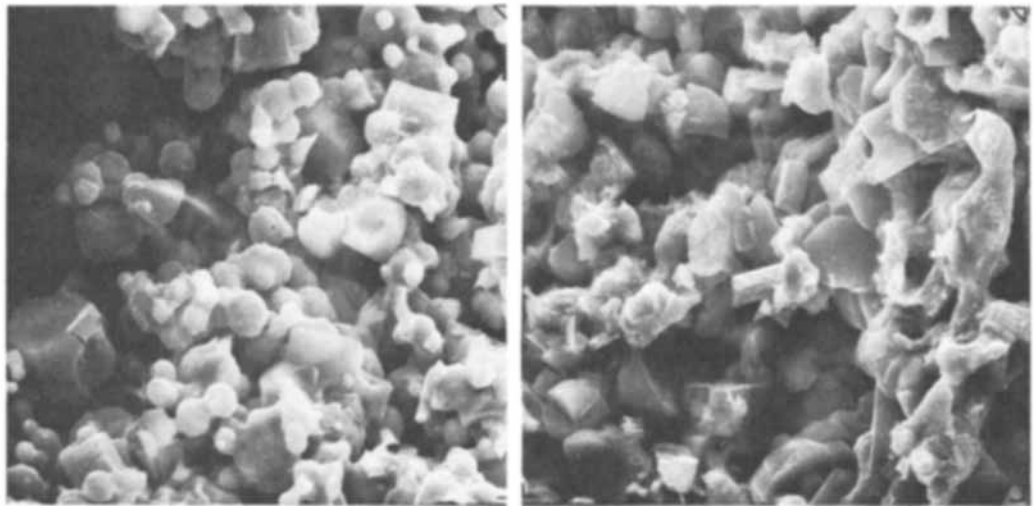

Fig. 12. Micrographs of middle of experimental sintered iron electrode discharged to 0.18 A-hr/g at 12.5 mA/cm^2 *(left)* and 50 mA/cm^2 *(right)*.

i.e., to L. Several other processes in the battery should follow the same pattern. If, *e.g.*, the electrolyte is used up in the discharge, one may expect a linear relation between the conductivity of the electrolyte and L. Actually, most mass transfer processes at play should respond to the change in the state of charge in a related way.

Relation [5] thus seems to exhibit the characteristic features we want to formalize. Shepherd arrived at the same relationship assuming a linear relation between the overpotential and the "active material current density," with the active material current density being inversely proportional to the amount of unused active material in the electrode structure. Shepherd, however, concluded that the successful use of his equations did not necessarily imply that his theoretical deduction did apply. This remark is certainly valid also for the present considerations. The above discussion may thus be summarized

$$\begin{cases} Vo - Vr = \phi\,(L) = \phi\,(Dr - D)/Dr & [6] \\ Vr - V = I\,(Rv + Rc) = I \cdot Rk \cdot Dr/(Dr - D) \\ \qquad\qquad + I \cdot Rc = I(Rk/L + Rc) & [7] \end{cases}$$

In "Version I," Ri was defined as $Ri = (Vr - V)I$. We here start with a more general definition of the apparent internal resistance and refer it to the open voltage of the battery at $D = 0$

$$Ri = (Vo - V)/I \qquad [8]$$

In this case, Ri will vary with the current when $Vo \neq Vr$. Summation of [6] and [7] gives

$$Ri = \phi\,(L)/I + Rk/L + Rc \qquad [9]$$

or

$$Ri = \phi(L)/I + Rk \cdot Dr/(Dr - D) + Rc \qquad [10]$$

Multiplication with $L = (Dr - D)/Dr$ and rearrangement gives

$$Ri = Rk + Rc + 1/Dr\,\{D(Ri - Rc)\} + L/I \cdot \phi(L) \qquad [11]$$

Relation [11] approximates to [2] when $L \to 0$ ($Ri >> Rc$) and at large currents in cases where the expression $L/I \cdot \phi(L)$ in [11] has some significance.

As was mentioned above, it is evidently necessary to know the function $L/I \cdot \phi(L)$ when dealing with nearly fully charged batteries and small currents. The voltage drop, $Vo - Vr$, associated with the state of charge, though in itself small, may be large compared to the drop due to the passage of current under these circumstances. There are no difficulties of a principal nature involved here. One may, *e.g.*, try the relation used by Shepherd; see [13] below. As was mentioned in the introduction, this domain of battery operation is of little significance in this context, however, and we shall therefore drop the term $L/I \cdot \phi(L)$ in [11] and thus put $Vr = Vo$ as was done in the "Version I" treatment. This reduces relation [11] to

$$Ri = Rk + Rc + 1/Dr \cdot D(Ri - Rc) \qquad [12]$$

which may be referred to as the "Version II" equation.

The "Version II" procedure evidently gives a possibility of obtaining two resistance parameters, Rk and Rc, *e.g.*, by solving equation systems of [12] with sets of data for Ri and D. However, this is complicated by

the fact that Rk is not a true constant but frequently varies in the region $D < 0.5\ Dr$. Unfortunately, it is not possible to measure Rc directly since there are also ohmic components in Rk/L. Figure 13 illustrates, however, how differences in Rc show up in the Ri-diagram. In this case the Ri-difference between the two curves, 0.04 mohm, corresponds very well with the calculated differences between ohmic resistances of the two types of grids used in the two batteries.

Most batteries, however, exhibit a fairly flat discharge curve (neglecting the initial drop from the true open-circuit voltage) down to at least $L \sim 0.5$. Thus Ri does not change much during this part of the discharge. This implies that in these cases $Rc >> Rk/L$ in this region. Since Rc is to be considered a correction term in the term $1/Dr \cdot D\ (Ri - Rc)$ of [12], the value for Ri determined from the slope of the V/I curve at $D \sim 0$ could be used as an upper estimate of Rc in [12]. This is the preferred method of calculation in the "Version II" procedure. This is exemplified in Fig. 14, which reports Ri-curves obtained in this way for an experimental sintered iron electrode under development for electric car batteries.

These sintered iron electrodes, 50 mm diameter, were run in half cells in 5N KOH at 50°C. The potential *vs.* a standard Hg/HgO reference electrode was recorded. The discharge current was kept constant at 25 mA/cm². This particular experimental electrode was chosen for this presentation because of the feature exhibited by the Ri-curves in Fig. 14. The first cycle with the new electrode gives peak performance with $Dr = 0.110$ A-hr/cm². Cycle 2 gives $Dr = 0.092$ A-hr/cm² and cycle 3 $Dr = 0.079$ A-hr/cm², whereafter Dr stabilizes at 0.065 A-hr/cm². There is, however, but little variation in the intercepts of the Ri-curves on the Ri-axis. The decrease in performance is thus here attributed mainly to a decrease in the term Dr. This effect may be compared with the overcharge experiments with lead acid batteries reported in Fig. 6 and 7 where decrease in battery performance could be attributed to a change in the resistance parameter, whereas the capacity parameter $1/b$ remained fairly constant. These observations illustrate how the Ri-method can give valuable hints about causes for changes in battery performance.

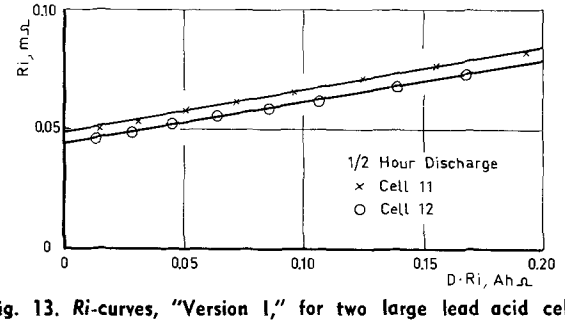

Fig. 13. Ri-curves, "Version I," for two large lead acid cells. Cells identical except for different grid resistance in the positive plates: for cell 11 estimated as 0.002 mohm and for cell 12 as 0.008 mohm.

The calculations involved in the "Version II" procedure are demonstrated for cycle 1 in Fig. 14. A plot of the V/I curves for $D = 0$ showed a fairly small variation of the intercepts, Vr, with the average $Vr = 0.939$V within the limits 0.924-0.954 (± 1.6%). Consequently, use of a constant $Vr = 0.939$V for all Ri-estimates was considered justified. (For comparison, it can be mentioned that the average true open-circuit voltage was $Vo = 0.975$V within the limits 0.960-0.980V). The slope of the V/I curve for $D = 0$ and the discussed cycle 1 corresponds to $Ri = 0.72 \pm 0.10$ ohm-cm², estimated 95% confidence limits. [In this research study, battery parameters are referred to unit area (1 cm²) of the cell section which is carrying the current.] From the discharge curve with voltage plotted as a function of the discharge time at 25 mA/cm², figures for Ri were obtained at various D estimated as $Ri = (0.939 - V)/0.025$ ohm-cm². The figure $Ri = 0.72$ ohm-cm² at $D = 0$ was used as an estimate of Rc to get $(Ri - Rc)$. The Ri-curve was then obtained by plotting Ri against $D(Ri - Rc)$ as shown in Fig. 15. The intercept of the extrapolated linear part of the curve is equal to $Rc + Rk$, which here comes out as 0.93 ohm-cm². The factor Rk is estimated as $Rk = 0.21$ ohm-cm² at $D > 0.5\ Dr$, since Rc was assumed = 0.72 ohm · cm². The factor Rk thus increases from $Rk \equiv 0$ at $D = 0$ to a value which is fairly constant when $D > 0.5\ Dr$ as indicated by the linear course of the Ri-curves in this region. The slope of the regression line corresponds to $Dr = 0.110$ A-hr/cm² to be compared with $Ds = 0.101$ A-hr/cm² for $Vs = 0.700$V.

This method of calculation thus implies a very precise meaning of Rc and Rk. The increase in Ri for increasing D is wholly attributed to the term $Rk \cdot D/(Dr - D)$ of Eq. [10] due to increase both of Rk from zero to a constant value and the increase of $D/(Dr - D)$.

Comparison with the Shepherd Approach

Our Eq. [10] and the evaluation of its constants is compared with Shepherd's Eq. [9] which, with Shepherd's glossary and after minor rearrangement, reads

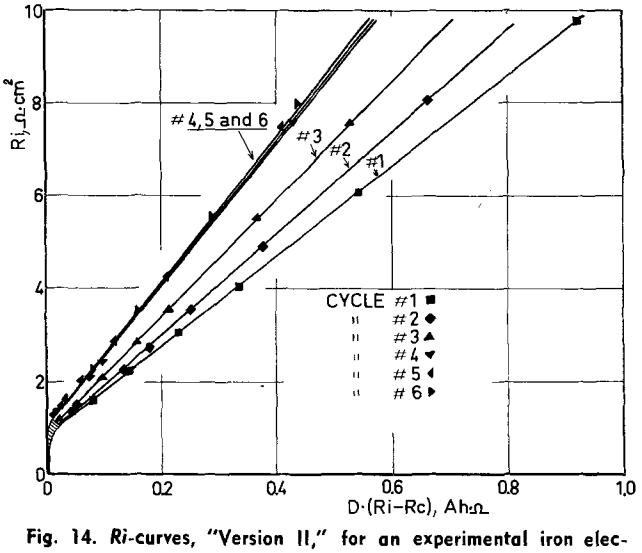

Fig. 14. Ri-curves, "Version II," for an experimental iron electrode.

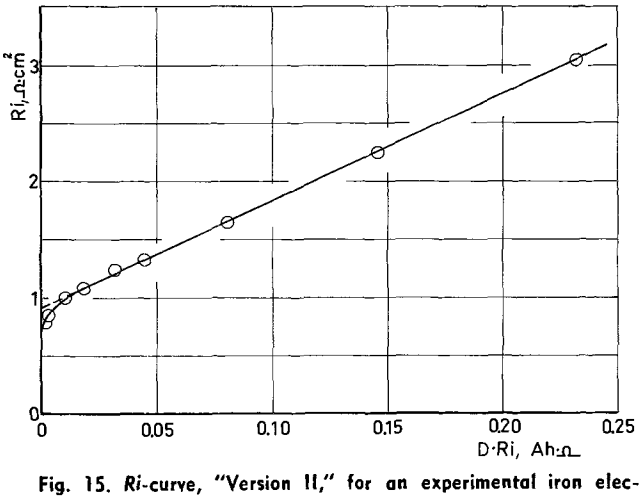

Fig. 15. Ri-curve, "Version II," for an experimental iron electrode (cycle 1 in Fig. 14).

$$(Es - E)/i\ (= Ri) = K \cdot Q/(Q - it) + N - A/i \exp(-BQ^{-1}\, it) \quad [13]$$

This relation is apparently formally identical with the present relation [10], provided $Es = Vr$; $Q = 1/G \cdot Dr$; $N = 1/G \cdot Rc$; $K = 1/G \cdot Rk$ and $-A/i \cdot \exp(-BQ^{-1}\, it) = 1/G \cdot \phi(L)/I$, where G is the area of the cross section through which current is flowing between the electrodes in the battery. However, the above formal identities are not valid from a physical point of view: Shepherd's Q is determined by the amount of available active material on the controlling electrode, whereas our Dr is the capacity at infinite Ri. Shepherd's K is referred to the activation overpotential and N is the internal resistance. Both Rk and Rc as defined above contain ohmic terms; the sole condition is that Rc is independent of the state of charge and Rk is zero at $D = 0$. Shepherd determines his constants by means of an equation system using four points taken from each of two discharge curves, one obtained at a moderately high current density and the other one obtained at a moderately low current density. This procedure uses only a fraction of available experimental data. Physical interpretation is furthermore made difficult by the fact that the internal resistance term frequently comes out as a negative term.

The transformation of [10] into [11], however, seems to give a simple and useful method for graphical reduction of the discharge data. This is the main advantage of the present method. This feature is also demonstrated by means of data taken from lead acid battery curves in Shepherd's paper. The result of the treatment is shown in Fig. 16. Data for this Ri-diagram were taken from discharge curves for a lead acid battery reported in Fig. 9 and 10 in Shepherd's paper.

Shepherd's Fig. 10 is a V/I curve for a fully charged battery, $D = 0$, from which the apparent internal resistance under this condition is obtained as $Ri = 3.8$ mohm. The curves in Shepherd's Fig. 9 give the cell potential as a function of $Q/(Q - D)$ where Q is the amount of active material on the controlling electrode in Ah (Shepherd's glossary) for different current densities. Ri-values were calculated from data from these curves for $Q/(Q - D)$ equal to 6, 4, 3, 2, 1.5, and 1.25. Averaged Ri-values for each D were corrected by subtracting $Rc = 3.8$ mohm and the terms $D(Ri - Rc)$ calculated for the Ri-diagram. The slope of the resulting diagram corresponds to $Dr = 0.9\ Q$, whereas $Rk + Rc$ for large D comes out as 9 mohm. Consequently, it can be concluded that $Rc \sim 4$ mohm, whereas Rk increases from $Rk = 0$ at $D = 0$ to $Rk \sim 5$ mohm at $D > 0.5\ Dr$. These figures plus the estimate of Dr, in this case reported as $Dr = 0.9\ Q$, give a satisfactory description for this particular lead acid battery. (Observe that $Dr \neq Q$!)

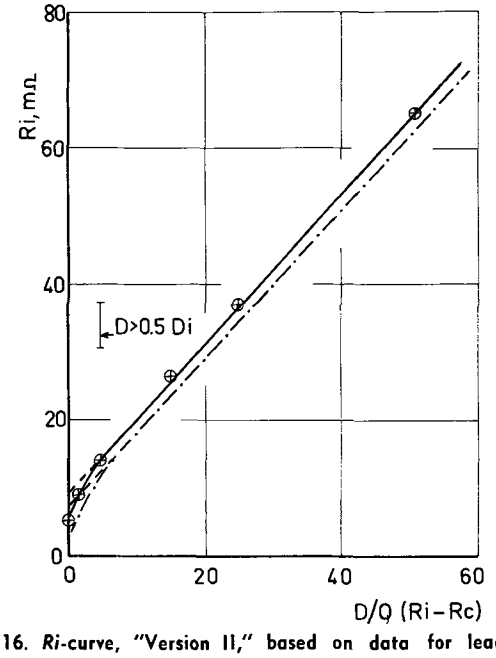

Fig. 16. Ri-curve, "Version II," based on data for lead acid battery reported by Shepherd (1). (Dashed line represents "Version I" procedure.)

Figure 16 also contains for comparison an Ri-curve based on the same data but calculated according to the simplified procedure, "Version I," with no Rc-term. The two curves run in parallel and apparently the "Version I" procedure is as good as "Version II" for the purpose of general battery characterization in this case.

One may also visualize a more refined treatment than the "Version II" procedure described above. The purpose of this procedure, "Version III," should obviously be to establish a relation between Rk and D so as to describe how Rk varies with D. The only, but very serious, limitation is here the difficulty of obtaining sufficiently precise and reproducible experimental data. At present, "Version II" seems to be on the borderline of what is practically feasible.

The Stress of Electroless Nickel Deposits on Beryllium

K. Parker* and H. Shah

General American Research Division, General American Transportation Corporation, Niles, Illinois

ABSTRACT

The residual stress of electroless nickel coatings on one side of 0.01 in. beryllium strips was determined by bow deformation measurements. Different plating conditions can produce either a tensile or compressive stress. The parameters controlling stress are those which determine the phosphorus content of the deposit, of which *p*H is the most important. The stress increases in the negative direction with increase in phosphorus content of the deposit. "As-plated" 4 mil coatings containing more than 8.5% phosphorus are compressively stressed, while those with lower phosphorus content are in tensile stress. Contraction during annealing decreases the compressive and increases the tensile stress of the plate. With close control of the plating parameters, reproducible, essentially "stress-free" electroless nickel coatings can be plated on critical optical beryllium surfaces such as aerospace mirrors.

This investigation was prompted by a recent article (1), which concluded that Kanigen®[1] deposits on beryllium induce significant tensile stresses in the composite: "For diffraction-limited precision optical surfaces, these stresses may produce unacceptable distortions." Precision beryllium mirrors require electroless nickel coating to provide a hard surface for final optical polishing and low scattering reflectivity. The primary purpose of the work was to find the plating conditions inducing the least tensile stress in the plate.

Internal stresses developed in plated deposits are either tensile due to contraction or compressive due to expansion. A tensile stress in the coating will decrease its adhesion, corrosion resistance, and sometimes the fatigue strength of the substrate. It is therefore desirable to minimize tensile stress or produce a slightly compressive plating. Generally the degree of stress decreases with increase in thickness of the deposit.

The stress in plated coatings is most readily measured by plating only one side of thin metal strips. Any residual stress in the coating is released by bending of the strip. The bow at the center is a measure of the internal stress. On thick, rigid substrates no bending can occur and the stress is "locked-in" the deposit. Large stresses exceeding the tensile strength of the deposit will induce cracks, while small stresses may create surface or interphase disturbances such as ripples.

The deformation of metal strips nickel plated on one side only is due in part to the bimetallic effect, *e.g.* the difference in thermal expansion coefficients of electroless nickel (13×10^{-6}/°C) and beryllium (11.6×10^{-6}/°C). If this were the only factor, then an electroless nickel deposit on beryllium would always be in slight tensile stress of about 4000 psi due to its larger contraction, when the composite cools from 95°C plating to room temperature. Other factors such as the plating conditions and bath formulation also produce residual stresses, since they affect the composition and crystal structure of the deposit. Our work was primarily concerned with the effect on stress of two critical plating process variables: *p*H and temperature.

Nickel, which is chemically reduced by sodium hypophosphite, is deposited as a nickel-phosphorus alloy in a metastable state. The phosphorus content in electroless nickel deposits can vary from 3 to 13% depending on the plating conditions and solution employed. Heat treatment above 250°C gradually stabilizes the system by precipitation of nickel phosphide (Ni_3P). This increases the hardness from 50 Rockwell C to a maximum of 70.

Experimental Procedure

To investigate the stresses in electroless nickel deposits, a 10 liter Kanigen® plating system and bath[2] were employed. This process incorporates continuous circulation and filtration, as well as external steam heating of the plating solution. The operating temperature was varied in the range of 82°-97°C and the *p*H of the bath from 3.9 to 5.1. During plating the concentration of all chemicals and the *pH* were maintained by frequent additions to the regeneration tank as indicated by analysis.

The main components of the plating solution were: 0.08M $NiSO_4$ $6H_2O$, 0.23M $NaH_2PO_2 \cdot H_2O$, and 0.36M lactic acid as the nickel chelating agent. Minor amounts of stabilizer, wetting agent, and organic acid promoters were also present. The pH was adjusted with 10% NaOH solution and measured to 0.01 units every 30 min with a Beckman *p*H meter. In the last experiments the hypophosphite concentration was increased to 0.4M.

Beryllium strips, 3 in. long, 0.30 in. wide, 0.01 in. thick, milled and then stress relieved by chemical etching, were used for all plating experiments. Length and width of each strip were determined to 0.01 in.; its thickness to 0.0001 in. Most of the beryllium strips were straight before plating; however, any initial deflection was measured with an optical comparator and recorded. After pretreatment in alkaline cleaner and dilute hydrofluoric acid etch, the strips were plated on both sides under various plating conditions with 0.5-4 mils of electroless nickel. In the first series of experiments, the strips were plated with 3.9-4.3 mils to compare the deformation at similar thicknesses. In most experiments, triplicate or duplicate strips were plated under the same conditions.

In previous stress investigations, the thin metal strips were first masked on one side. After plating, the masking was peeled off. Unless great care is taken, the strips are easily bent when handled during masking or when the masking is removed. A new method to determine the coating stress was therefore employed in which both sides of the strips are plated to minimize handling.

One side of the plated strip was covered with tape before the other side was coated with molten stop-off wax. After removal of the tape the strip was immersed in concentrated nitric acid, which does not attack beryllium. As the nickel alloy is gradually dissolved from the unmasked side, the thin strip assumes a bow shape. After the nickel was completely stripped, the wax was removed by soaking in perchloroethylene. The bow-out at the center (sagitta of the arc) was then accurately measured to 0.0001 in. A concave

[2] The composition and process are covered by U.S. Pat. 2,658,839; 2,658,841; 2,762,723; 2,822,293; 2,822,294; and others assigned to GATX.

nickel surface indicates a tensile (+) stress, while a convex surface shows a compressive (−) stress in the deposit. Any deflection prior to stripping was subtracted to obtain the net change in bow-out (L_1) of the strip due to internal stress in the nickel plating.

After the deflection measurements in the "as-plated" condition, the strips were annealed in an oven for 4 hr at 190°C and the bow-out (L_2) redetermined at room temperature. In some instances the plated strips were annealed a second time to determine any additional change (L_3), which may occur during final stress relief annealing after polishing.

The nitric acid containing the stripped alloy was analyzed for nickel content by EDTA titration, and for phosphorus by the vanadate-molybdate photometric method (ASTM E 156).

Results

The bow measurements of the beryllium strips plated with 4 mils electroless nickel under varying plating conditions are shown in Table I. They are arranged in order of increasing phosphorus content of the deposits. The bow data vary from +0.17 in. (concave) to −0.075 in. (convex). Annealing increases the concave, but decreases the convex curvature.

The internal stresses in the deposits were calculated according to the method of Soderberg and Graham (2), who derived an equation based on a strip rigidly held during plating, and no bending occurs until after deposition is complete. The over-all stress, S, in a compound beam is calculated from the equation

$$S = \frac{E_b I}{r\left(c - \frac{d}{2}\right) dw}$$

E_b = Elastic modulus of basis metal = 44×10^6 psi for Be

I = Moment of inertia of effective section weighted to the base modulus, in psi

$$I = \frac{w}{3}\left[a(d+t)^3 - (a-1)t^3 - 3(t+ad)(d+t-c)^2\right]$$

$$a = \frac{\text{Elastic modulus of coating}}{\text{Elastic modulus of basis metal}} = \frac{20 \times 10^6 \text{ psi}}{44 \times 10^6 \text{ psi}}$$ [3]

c = Distance of neutral axis to outside surface of deposit, in.

$$= \frac{a\,d^2 + 2dt + t^2}{2(a\,d + t)}$$

[3] The modulus of elasticity of electroless nickel "as-plated" is 17×10^6 psi. It increases with heat treatment.

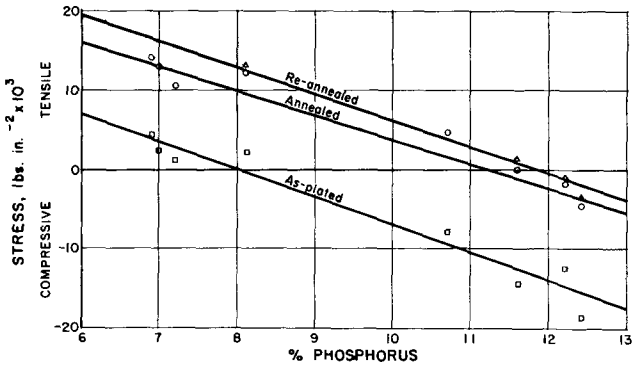

Fig. 1. Stress of electroless nickel on beryllium as a function of phosphorus content of the deposit.

d = Thickness of coating, in.

t = Thickness of the strip, in.

w = Width of the strip = 0.30 in.

r = Radius of curvature, in.

$$= \frac{l^2 + 4L^2}{8L} \simeq \frac{l^2}{8L}$$ (since L is much smaller than l)

l = Length of strip, in.

L = Net change in bow-out, in.

The development assumes that bending of the strip is caused by two kinds of stress, one by the structure of the deposit, the other by the difference in thermal contraction of base metal and the plate, when the plated strip is removed from the hot plating bath. Another assumption is that the net force in the nickel acts in the center plane parallel to the neutral surface of the deposit. The total force or stress in the coating at equilibrium (in bent condition) can be calculated from the measured deformation of the strip. The original force or stress, S, in the unflexed coating is then the sum of this calculated equilibrium force and the additional force necessary to return the coating alone to its unbent condition.

The average stress values vary from +7.9 Ksi [4] tensile for low phosphorus to −18.5 Ksi compressive for high phosphorus deposits in the as-plated condition. After annealing at 190°C, either an increase in the tensile stress or a decrease in the compressive stress is found. Reannealing produced slight additional changes in stress. These results are plotted in Fig. 1.

[4] Ksi = lb in.$^{-2}$ x 10^3.

A decrease of plating pH and/or temperature increases the phosphorus content of the alloy. Thus, at a plating temperature of 88°C the phosphorus increases from 7% at pH 5 to over 12% at pH 4. At a pH of 4 the phosphorus increases linearly from 10.7 to 12.4% with decrease in plating temperature from 97° to 91°C.

The effect of varying the thickness of coatings containing 12.3 ± 0.1% phosphorus is shown in Table II and Fig. 2. In the "as-plated" deposits there is a linear increase in bow-out with increase in thickness and a gradual increase in compressive stress between 1-5 mils thickness. The reannealed stress values varied from +4.9 to −1.2 Ksi. Since thinner coatings became slightly tensile stressed during annealing, a 4 mil thickness is desirable for annealed low stress coatings.

The plating conditions which produce the least stressed coating after annealing slow the plating rate to less than 0.2 mil/hr. The rate can be increased by raising the plating temperature to 93°C; however, it is then necessary to increase the hypophosphite concentration of the bath to 0.4 mole/liter in order to attain the desired 11.5+% phosphorus level in the deposit (4).

As a result of this investigation the plating conditions for the electroless nickel coating of four 13 in. diameter beryllium mirrors (Fig. 3) were adjusted to produce a low stress deposit for precision aerospace experiments. These mirrors were plated at pH 3.95-4.05 and 93°C in a 25 gal Kanigen® system. About 20 hr were required to obtain 4 mils + thickness. Beryllium strips plated at the same time were measured for bow-out and showed a compressive stress in the range of −6 to −16 Ksi as-plated and +1 to −1 Ksi after reannealing.

Discussion

Comparison of the bow data obtained by the old "masking" *vs.* the new "stripping" method shows substantially lower tensile deformation for the latter. Bow measurements of strips plated under the same conditions are generally in good agreement.

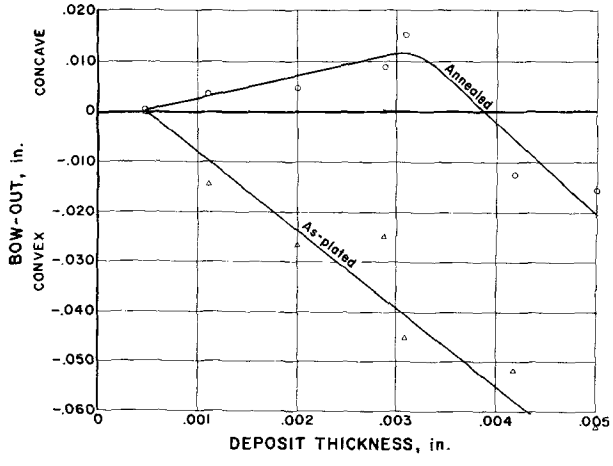

Fig. 2. Effect of deposit thickness on bow-out of electroless nickel (12.3% P) plated beryllium strips.

As shown in Fig. 1 the stress of the electroless nickel deposits is inversely related to the phosphorus content of the deposit. Thus, the tensile stress decreases linearly with increase in phosphorus. At a phosphorus content of about 8.5+%, the "as-plated" coatings are compressively stressed. All coatings with lower phosphorus content show tensile stress. Under "normal" Kanigen® plating conditions of pH 4.5, the phosphorus content of the deposit is 8.5 ± 0.5%.

In electroless nickel plating the phosphorus content of the deposit depends primarily on the pH of the bath. The reaction equilibrium (5)

$$H + H_2PO_2^- \rightleftharpoons P + H_2O + OH^-$$

shifts to the right with decrease in pH—*i.e.*, increase in hydrogen ion concentration. Conversely, raising the pH to 5 lowers the phosphorus content of the alloy. The plating temperature has a smaller effect on phosphorus; however, at pH 4 the temperature should not exceed 93°C to obtain an 11.5% + P deposit.

The higher phosphorus nickel alloys have been found to give more diffuse x-ray diffraction patterns (4, 6) attributed to an "amorphous-like" structure: If in the as-plated alloy the phosphorus is present not only in a supersaturated nickel solution but also at the microcrystallite boundaries, this would move the crystals apart and induce internal compressive stresses.

During annealing the deposits apparently contract, increasing the stress in the positive or tensile direction. Therefore in order to obtain a low-stress annealed coating, a deposit containing 11.5-12% phosphorus is required with a compressive stress of −12 Ksi in

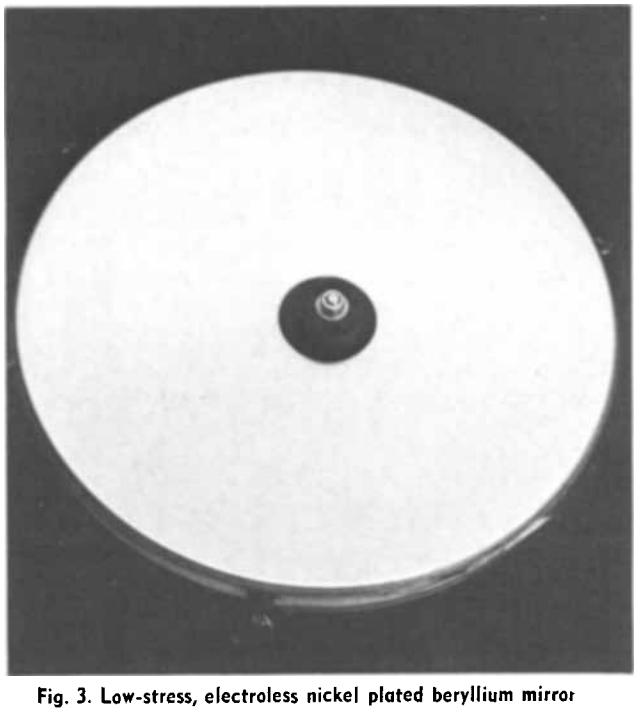

Fig. 3. Low-stress, electroless nickel plated beryllium mirror

the as-plated condition. This apparent shrinkage may be due to the elimination of structural defects and hydrogen from the coating. In any case, during annealing the electroless nickel approaches equilibrium condition and a more orderly lattice arrangement.

These results are in fair agreement with previous findings of Shemenski *et al.* (1). Apparently, all of their coatings contained about 7-8% phosphorus and were therefore in comparatively strong tensile stress after annealing. They also agree with Baldwin and Such (7), who measured at plating temperature a linear increase in mean internal stress from −8 to +16 Ksi with increase in pH of the plating bath from 4.0 to 6.0. Comparison of these results indicates that the bimetallic effect makes only a minor contribution to the internal stress of electroless nickel on beryllium.

The results obtained by Bartlett *et al.* (8) on brass strips plated in a pH 10.5-11.0 pyrophosphate electroless nickel bath should be mentioned. Their nickel deposits contained only 3.2-4.2% phosphorus and showed as much as 50 Ksi tensile stress.

Further plating experiments with metal strips of steel, nickel, aluminum, and titanium are in progress to determine the effect of phosphorus content on the residual stress of the deposit on these substrates.

Summary

On the basis of the results, the following conclusions can be drawn:

1. The difference in thermal expansion coefficients between electroless nickel and beryllium produces a relatively small tensile stress in the composite.
2. The deformation and stress induced by the electroless nickel plating on beryllium varies from compressive to tensile, depending on plating conditions.
3. The plating parameters controlling the residual stress are primarily those which determine the phosphorus content of the electroless nickel deposit.
4. A phosphorus content of 8.5% or higher produces a compressive stress in the as-plated deposit.
5. During annealing at 190°C, the electroless nickel deposits contract with either increase in the tensile stress or decrease in compressive stress.
6. To obtain a "stress-free" annealed electroless nickel coating on beryllium requires an 11.5%+ phosphorus deposit, which is compressively stressed in the as-plated condition.
7. A relatively "stress-free" 4 mil electroless nickel deposit on beryllium mirrors is obtained by close control of plating conditions in a Kanigen® system using a bath adjusted to pH 4.0, containing 0.4 mole/liter hypophosphite and operating at 93°C.
8. A new method for determining the stress of plated coatings by plating both sides of thin strips is shown to give reproducible results.

Electrolytic Removal of P-Type GaAs Substrates from Thin, N-Type Semiconductor Layers

C. J. Nuese and J. J. Gannon

RCA Laboratories, Princeton, New Jersey

ABSTRACT

An electrolytic etching technique has been developed which can remove p-type GaAs substrates from thin (2-10μ) n-type layers of GaAs or $GaAs_{1-x}P_x$, $0 \leq x \leq 1$. Sodium hydroxide is used as the electrolyte, and is sprayed continually over the etching surface to prevent the build-up of "flakes" on the p-type surface as by-products of the etching process. Such flakes serve as an effective mask to the etching process and, unless removed, result in irregular or matte surfaces on the n-type layer after removal of the p-type material. The removal of these flakes by the spray of NaOH leads to shiny, unblemished n-type surfaces over large-area wafers (2-5 cm^2). The extension of this electrolytic etching technique to thin, vapor-grown layers has applications in electron microscopy, luminescence and optical measurements, and in semiconductor device fabrication.

The anodic etching of p-type semiconductors in an appropriate electrolytic solution has been used routinely for polishing and shaping surfaces of germanium (1-5) and silicon (3-6), and for removing damaged material or reducing the active junction area (7) in III-V compounds. However, when an attempt is made to similarly etch n-type samples, a blocking potential barrier is established at the semiconductor surface (3,6), which restricts the passage of electrolytic current, and significantly reduces the etching rate.

This difficulty in electrolytically etching n-type semiconductors, particularly those with a relatively large energy gap (6), and hence a more effective surface barrier, can be used to good advantage for the selective removal of an adjoining p-type layer without significant penetration into the n-type layer. In the present paper, we report a simple electrolytic etching

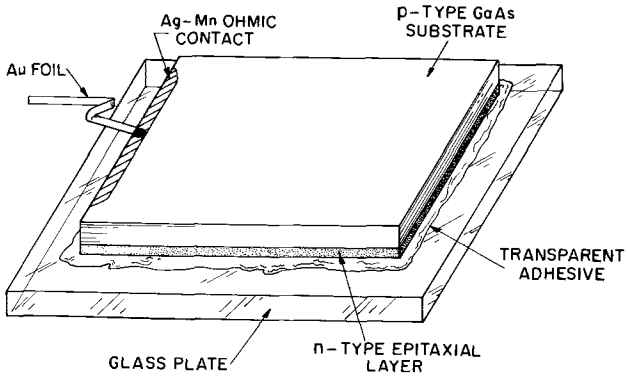

Fig. 1. Geometry of sample used for electrolytic etching. In this case, the sample is mounted permanently on a glass plate for optical transmission measurements.

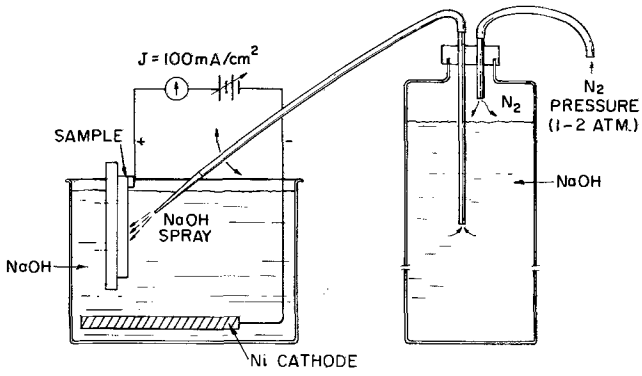

Fig. 2. Electrolytic etching system employing sprayed NaOH electrolyte. Pressurized reservoir of NaOH can be replaced by electric pump for convenience.

technique which has been used successfully for this purpose on large-area p-n junctions in several III-V compounds. This technique has been found to be especially useful for isolating thin (2-10μ) epitaxial layers from thick (250-500μ) p-type substrates, and has been used frequently for this purpose throughout the $GaAs_{1-x}P_x$ alloy system. For such structures, conventional lapping or chemical etching procedures usually cannot be controlled with sufficient accuracy to remove all of the p-type region without penetrating significantly, and often irregularly, into the thin n-type layer.

The thin n-type specimens which can be isolated by this technique have found a variety of applications in electron microscopy, luminescence and optical measurements, and in multilayer device fabrication. Several of these applications are discussed briefly below. It is not our intention in this paper to consider the basic physical or chemical properties of the electrolytic reactions, except where these properties directly affect the extension of our electrolytic etching technique to the large-area layers considered here.

Experimental

Most of the samples used for the etching studies reported here consisted of an epitaxial n-type layer of GaAs or $GaAs_{1-x}P_x$ which had been deposited directly on a <100>-oriented p-type GaAs substrate via a vapor-phase growth technique (8). For such samples the p-n junction was therefore at the substrate-epitaxy interface. In some samples, however, a p-type GaAs or $GaAs_{1-x}P_x$ layer was first deposited on the p-type substrate, followed by the thin n-type layer, in which case the p-n junction was then located within the epitaxial layer. For both cases, the electrolytic technique described below was found to be capable of selectively removing all of the p-type material, leaving only the n-type layer bordering the p-n junction.

The n-type epitaxial layers were typically between 2 and 10μ thick, whereas the substrates were about 500μ thick initially, but were mechanically lapped to a thickness on the order of 200μ to reduce the etching time needed for their removal.

For general sample preparation, an ohmic contact strip of Ag-Mn(9) is evaporated and sintered to the lapped p-type surface (Fig. 1) although, for samples with a heavily-doped p-type substrate, a simple conducting-epoxy contact is often adequate. The wafer for etching is then mounted n-side down on a glass microscope slide by (*a*) tacking a spot beneath the contact area with Apiezon wax,[1] for applications where the n-type layer is to be removed from the slide after etching, or by (*b*) bonding the entire n-type surface to the slide with a clear epoxy (BiPax Tra-Bond)[2] for permanent mounting. Finally, for a current lead, a gold or platinum foil is connected to the p-type contact with silver paste or conducting epoxy.

For the electrolytic etching process, a 3 molar aqueous solution of NaOH has been most commonly used in the system shown in Fig. 2, although the exact degree of dilution does not appear to be critical. Alternately, a simple electrical pump[3] can be used to drive the NaOH spray, in which case the cumbersome pressurized cylinder in Fig. 2 would not be required. In either case, the sample is immersed in the electrolyte to a depth such that the metal contact is just out of solution.

Three conditions were found to be essential for obtaining a smooth, shiny surface on the n-type layer upon the total removal of the p-type layer.

1. Most important, the region being etched must be continually agitated or rinsed during the entire etching process. The electrolytic reactions of GaAs and $GaAs_{1-x}P_x$, unlike those of Ge, produce compounds which are only very slowly soluble in the NaOH solution, and which therefore remain loosely attached to the crystal surface in the form of gray-brown "flakes" (10-12), tentatively identified here as arsenolite, As_2O_3.[4] These flakes have been found to effectively mask the etching process, so that when a sample is etched vertically in the electrolyte, and not intentionally agitated, portions of the flakes drop randomly from the surface under their own weight, causing the etching to proceed irregularly, and resulting in a dull, matte n-type surface upon removal of the p-type material. When a sample is placed horizontally in solution, so that the flakes do not readily fall from the surface, and etched *without agitation*, masking occurs to such an extent that the measured etching current drops by about a factor of four within several minutes. We have found that by continually rinsing away the flakes with a rapidly flowing (0.15 liters/min) stream of NaOH under a pressure head of 3-4 ft of solution, a flat, unblemished n-type surface is usually obtained.

2. A steady d-c current density should be maintained throughout the etching process. Whenever the current density is changed discontinuously (*e.g.*, by dipping the wafer in and out of solution) a distinct etching line appears on the epitaxial surface, probably due to an abrupt change in the etching rate. Best results are obtained by gradually decreasing the etching current as the area of the p-type layer is reduced, so that a current density of approximately 100 mA/cm² is maintained throughout the etching process. A constant *voltage* supply is convenient for this purpose, since the supply current is then automatically determined by the resistance of the layer during etching.

[2] Tra-Con Inc., 55 North St., Medford, Mass.
[3] CRC Vibrostaltic Pulsation Pump, Cat. No. 65/1705; Chemical Rubber Co., Cleveland, Ohio.
[4] This identification results from x-ray powder patterns, which reveal a cubic structure with a lattice constant, a_o of 11.075Å. The x-ray measurements did *not* indicate the presence of GaAs (a_o = 5.653Å) in the flakes, contrary to previous results (11, 12).

3. The cathode should be placed directly *below* the sample. Because of the low-resistance path through the p-type layer (0.1-1 ohm) as compared to that through the electrolyte (~50 ohms), the etching then proceeds most rapidly near its bottom edge, closest to the cathode, and soon becomes noticeably beveled away from the contact. The unetched portion of the p-type material then progresses upward from the bottom, until reaching the surface of the electrolyte near the ohmic contact. Only rarely has the etching been cut off by more rapid etching inward from the sides than upward from the bottom. However, should this be a problem, the wafer can be readily lapped to a bevel, away from the contact, to ensure an upward "travel" of the unetched p-type material.

Results and Discussion

The technique described above has been used frequently to remove thick p-type GaAs substrates from thin n-type epitaxial layers of $GaAs_{1-x}P_x$ over the entire alloy composition range, $0 \leq x \leq 1$. The surfaces of the n-type layers after etching are usually shiny and highly reflecting, as illustrated in Fig. 3 for a 5μ thick $GaAs_{0.5}P_{0.5}$ sample prepared from vapor-phase growth. The surface of this specimen was found to be free of microscopic imperfections at magnifications up to approximately 1000 (see Fig. 4), and was estimated to be flat to within about a micron over most of its surface. A typical etch rate for the electrolytic process here is about 4μ/min.

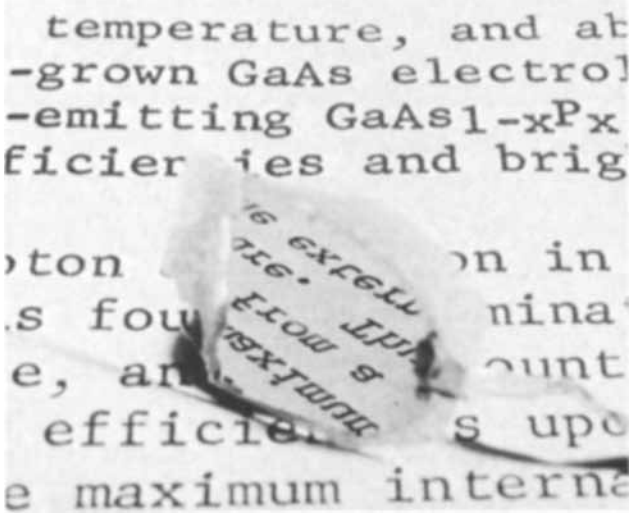

Fig. 3. Reflection from exposed surface of $GaAs_{0.5}P_{0.5}$ n-type layer, 5μ thick, after electrolytic removal of thick p-type GaAs substrate.

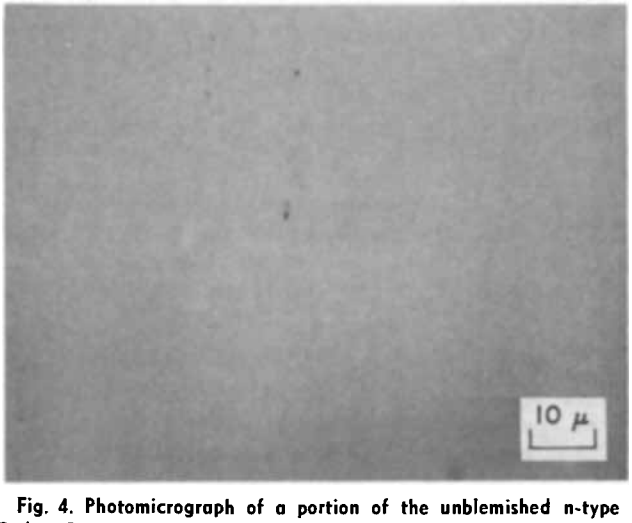

Fig. 4. Photomicrograph of a portion of the unblemished n-type $GaAs_{0.5}P_{0.5}$ surface after electrolytic removal of the adjoining p-type GaAs substrate. Magnification is 1000X. Surface is the same as that shown in Fig. 3.

Whereas n-type layers of $GaAs_{1-x}P_x$ have generally yielded unblemished surfaces, like that shown in Fig. 3 and 4, similar layers of n-type GaAs have occasionally appeared slightly less shiny after etching of the bordering p-type layer. This is thought to be due to a very slight penetration of the etching into the n-type GaAs layer. Since the potential barrier at the interface between the n-type semiconductor and the electrolyte blocks majority carrier electrons, the penetration of the etching into the n-type layer can occur only from the diffusion of minority holes to the semiconductor-electrolyte interface from within the n-type material, or from the generation of electron-hole pairs in the space-charge layer of the interface barrier (13). In either case, the magnitude of the small reverse (etching) current will depend directly on the intrinsic carrier concentration, which in turn varies exponentially with the semiconductor energy gap. Since the energy gap of $GaAs_{1-x}P_x$ can be appreciably larger than that of GaAs, the intrinsic carrier concentration, and hence the magnitude of the etching current, should be much less for n-type $GaAs_{1-x}P_x$ than for GaAs. Furthermore, the diffusion coefficient for holes is somewhat smaller in $GaAs_{1-x}P_x$ than in GaAs, which can further reduce the magnitude of any hole diffusion current responsible for penetration into the n-side of a p-n junction.

The surface perfection of the n-type layer after etching also depends somewhat on the metallurgical perfection of the p-n junction itself, and on the impurity concentrations on the n- and p-sides of the junction. For example, lightly doped n-type ($n \approx 10^{15} - 10^{16}$ cm^{-3}) layers of GaAs and $GaAs_{1-x}P_x$ have consistently been free of surface imperfections, whereas more heavily doped n-type layers have shown slight pitting or matteness, probably due to a breakdown of the potential barrier, which occurs at relatively low voltages for such layers (13).

To the contrary, moderate or heavy doping in the *p-type* substrate or epitaxial layer is desirable to spread the current uniformly across a large area of the wafer. For our applications, p-type layers with acceptor concentrations greater than about 10^{18} cm^{-3} have provided adequate current spreading as well as smooth etching behavior.

Although most of the p-type vapor-grown layers removed by this electrolytic technique have been of $GaAs_{1-x}P_x$, $0 \leq x \leq 1$, the etching process has also been occasionally applied, with success, to p-type layers of InP, $In_xGa_{1-x}P$, and $Al_xGa_{1-x}As$.

Applications.—The thin n-type specimens which can be isolated by the electrolytic technique described below have found a variety of applications. For example, in transmission electron microscopy studies, the region bordering a p-n junction has been consistently located and isolated by selectively etching away all of the bordering p-type layer (14). Such layers are similarly useful for photoluminescent or cathodoluminescent studies, where the n-type region which was originally adjacent to the p-n junction is of interest. In fact, with a photon or electron beam of sufficient intensity, such layers in a suitable material (*e.g.*, GaAs) might well support laser emission within the large-area cavity formed by the two closely spaced surfaces of the n-type layer.

Furthermore, the electrolytic removal of p-type GaAs substrates from thin n-type epitaxial layers of $GaAs_{1-x}P_x$ has been instrumental in measuring the extent of warpage in the epitaxial layers due to the mismatch in the lattice coefficients between the two regions (14). Optical absorption measurements, particularly at photon energies near or above band gap, have also been enhanced by the thin large-area specimens.

A large absorption coefficient (10^4 to 10^6 cm^{-1}) and an ordinarily thick sample usually reduce the transmitted light intensity below normal detection levels.

Finally, a thin n-type base layer sandwiched between two p-type layers of a p-n-p transistor structure has been selectively exposed (for contacting) by masking portions of the uppermost p-type layer from the electrolytic process. Such masking is provided by either a thin film of SiO_2, or by an evaporated array of Ag- or Au-based alloys, which also serve as the ohmic contacts to the emitter. The large array of p-type "mesas" provided over an entire wafer by this masking and etching procedure has also found applications in electroluminescent diodes and in avalanche microwave oscillators(15).

Conclusions

An electrolytic etching techinque has been developed which can remove thick p-types substrates from thin n-type layers of $GaAs_{1-x}P_x$, $0 \leq x \leq 1$. This technique utilizes a spray of NaOH to rinse away "flakes" of arsenolite which form on the p-type surface and which effectively mask the etching process; a constant current density of 100 mA/cm^2; and a cathode located below the bottom edge of the sample, in order to ensure continuous upward etching of the p-type layer. N-type layers of $Ga_{1-x}P_x$ as thin as 2μ and as large in area as 5 cm^2 can be isolated from p-type substrates in this fashion, with exposed surfaces which are shiny and free of surface blemishes under magnifications of $\approx$1000. Light doping in the n-type layer and moderately heavy doping in the p-type material most often yield unblemished surfaces. Such layers of $GaAs_{1-x}P_x$, $x > 0$, have consistently yielded shiny surfaces, whereas similar layers of GaAs have occasionally appeared less perfect. The extension of this technique to thin, vapor-grown layers has applications in electron microscopy, luminescence and optical measurements, and in semiconductor device fabrication.

Acknowledgments

The authors wish to acknowledge the assistance of R. L. Rodgers for preliminary etching experiments, R. J. Paff for x-ray identification of the As_2O_3 "flakes," and H. F. Gossenberger for preparation of the vapor-grown layers used in this investigation. C. J. Buiocchi first simplified the etching system described in this paper by substituting an electric pump for the pressured reservoir of NaOH shown in Fig. 2.

Reaction of Aluminum with Sodium Hydroxide Solution as a Source of Hydrogen

David Belitskus

Aluminum Company of America, Alcoa Research Laboratories, New Kensington, Pennsylvania

Generation of hydrogen for fuel cells by reaction of hydrides with water or aqueous solutions reduces storage weight or volume over high pressure or cryogenic storage (1-3) but is expensive. Reaction of aluminum in aqueous solutions provides an inexpensive, compact source of hydrogen. While 100°-500°F is required for useful rates with mercuric chloride solution (4), room temperature is satisfactory with sodium hydroxide solution.

Experimental Results and Discussion

A shallow Teflon cup holding the aluminum sample was lowered into a sodium hydroxide solution in a flask and the gas evolution-time curve recorded from a gas burette.

Key words: hydrogen, fuel cell, aluminum, atomized powder.

Particular attention was paid to the rate of gas generation from a specific aluminum surface area, since immersion of pellets into a solution provides a convenient form of activation. A prototype portable fuel cell (3) operates under full load with a hydrogen generation rate of 7 ft^3/hr. Assuming that a pellet having a geometric surface area of about 0.5-1 ft^2 is convenient for this purpose, a specific generation rate of 7-14 cubic feet of gas per hour per square foot of surface area (3.5-7 ml of gas per minute per square centimeter of surface area) is required.

Figure 1 shows the reaction rates of 10 cm^2 area cylinders of several aluminum alloys in 200 ml of 10M NaOH at 25°C. The gas volumes reported are for 25°C and 740 Torr. The most rapid reaction (with

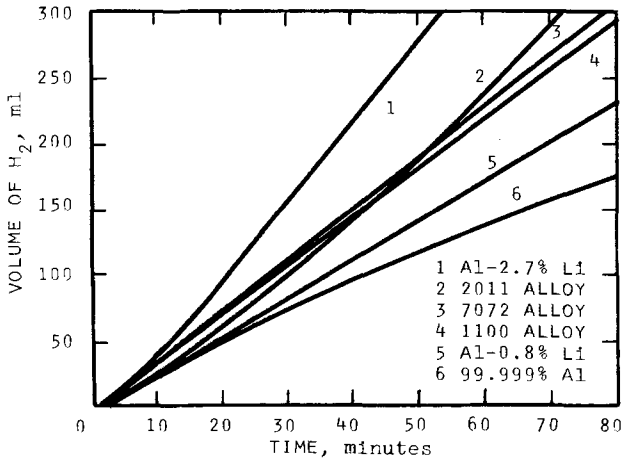

Fig. 1. Hydrogen evolution rate of aluminum cylinders (10 cm^2 geometric surface area) machined from ingots or plates, and immersed in 200 ml of 10M NaOH at 25°C: 99.999% Al, 1100 alloy, 2011 alloy, 7072 alloy, Al-0.8% Li, and Al-2.7% Li.

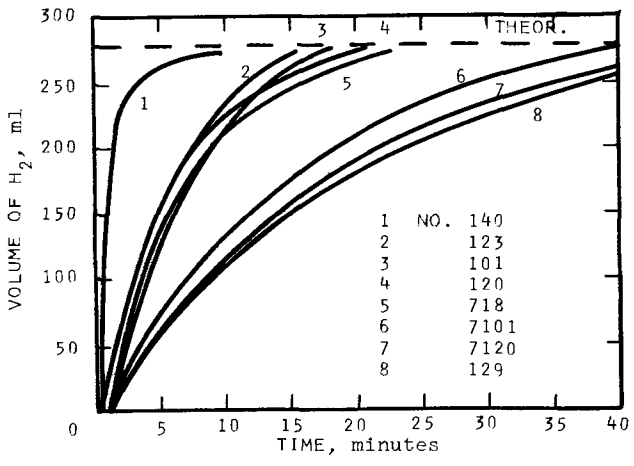

Fig. 2. Hydrogen evolution rate of 0.2g samples of various atomized aluminum powders in 200 ml of 1M NaOH at 25°C.

Al-2.7% Li) had a specific hydrogen generation rate of 0.6 ml/min/cm^2, much lower than desired.

Hence, a more reactive form of aluminum, atomized powder, was tried. Compositions, particle sizes, and surface areas for the powders are given in Table I. Reaction of 0.2g of the highest surface area powder, No. 140, in 1M NaOH proceeded nearly to completion (275 ml of gas) in 10 min. For comparison, reaction in saturated mercuric chloride solution began after a delay of several minutes, but the hydrogen production rate was only 0.06 ml/min. After 40 min of no detectable gas generation in 1M HCl, reaction proceeded at a rate of 0.6 ml/min. Only sodium hydroxide solution seemed suitable for rapid hydrogen generation at room temperature.

Figure 2 shows the gas evolution rates for 0.2g of each powder in 200 ml of 1M NaOH. Relative rates for the powders made from 99.8% Al are as expected from surface area data. High-purity (99.99% Al) powders No. 7101 and 7120 reacted nearly as slowly as No. 129, though having surface areas approximately the same as several 99.8% Al powders which reacted at intermediate rates. This purity effect agrees with the results for ingot samples in 10M NaOH (Fig. 1), but is different from that found by Bobb (4) in comparing alloys of lower purity, 98.8% Al and 99.4% Al in mercuric chloride solution. All unalloyed powders eventually reacted to completion; No. 718 (the Al-12% Si alloy powder) yielded less hydrogen than the unalloyed powders.

The maximum rates of hydrogen generation from 0.2g of No. 140 powder in 10M NaOH, 1M NaOH, and 0.1M NaOH, were, respectively, >500, 130, and 13 ml/min. Rate was directly dependent on sample size for 0.1-0.4g samples of No. 140 powder in 200 ml of 1M NaOH. A delay of about 0.25 min preceded rapid gas generation using No. 140 powder. Delay increased with powders having lower surface areas. When aluminum and solid sodium hydroxide were added to water without mixing, generation of hydrogen was as rapid as, or more rapid than, reaction in predissolved sodium hydroxide solutions.

The gas evolution rates shown in Fig. 3 for compacted 0.75g pellets of No. 140 atomized powder in 200 ml of 1M NaOH decreased with increasing density as might be expected. Even the densest pellet (85% of crystal density) evolved hydrogen rapidly, at 25 ml/min initially or 7 ml/min/cm^2, 17.5 times faster than 1100 alloy ingot cylinder in more concentrated (10M) NaOH. Both higher density pellets remained in one piece during reaction. The lower density pellet broke up and evolved gas at a rate of 500 ml/min or 125 ml/min/cm^2.

Pellet density was more important than surface area of the uncompacted powder in determining the reaction rates of pellets. Three-fourths-gram pellets were compacted at various pressures from samples of powders No. 140, 101, and 129, whose surface areas decrease in this order. Pellets with densities of 2.1 g/cm^3 reacted at similar rates in 200 ml of 1M NaOH. Pellets with densities of 2.3 g/cm^3 also reacted at similar, slower rates. This contrasts with a 12-fold difference in rates found for No. 140 and No. 129 powders in tests with 0.2g samples of uncompacted powder (Fig. 2).

One difference in behavior of the three powders was retained in the pellets. Delay times before rapid

[2] Purity of aluminum before atomization. Typical analysis of powder: Al, 98.7-99.7% (decreasing with increasing surface area of powder); Al_2O_3, 0.1-1.1 (increasing with increasing surface area of powder); Fe, 0.15; Si, 0.07.
[3] Determined by radiochemical method (5) on particular lots of powder used.

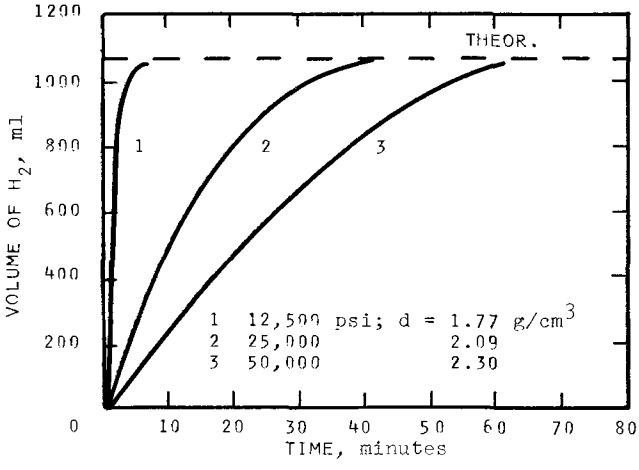

Fig. 3. Hydrogen evolution rate of 0.75g samples of atomized aluminum powder No. 140 compacted at room temperature and the stated pressures into 1.25 cm diameter cylinders and allowed to react in 200 ml of 1M NaOH at 25°C.

reaction were independent of density and were less than 1 min for pellets of No. 140 powder, about 2 min for pellets of No. 101 powder, and 3 min for pellets of No. 129 powder.

Experiments with less than 200 ml solution volume (133 times the stoichiometric amount of water for 0.75g of aluminum) were conducted to observe the effect of reaction heat (14.6 Btu/g Al) on rates and the effect of reduced sodium hydroxide. Reaction of a 0.75g pellet of No. 140 powder (2.1 g/cm^3 density) in 25 ml of 1M NaOH (17 times stoichiometrically required water) proceeded rapidly with 400 ml of gas evolved in 5 min, then gradually slowed to a rate of only 2 ml/min in 35 min. Similar pellets in 25 ml of 2M and 3M NaOH yielded about 300 ml of gas per minute with localized boiling of water. The bulk water temperature rose slowly to a maximum of 70°C when 800 ml of gas had been generated. Delay time decreased noticeably with increased concentration.

The reactions of aluminum in sodium hydroxide solutions are

$$2Al + 6H_2O + 2NaOH \rightarrow 2NaAl(OH)_4 + 3H_2\uparrow \quad [1]$$

$$NaAl(OH)_4 \rightarrow Al(OH)_3\downarrow + NaOH \quad [2]$$

Sodium hydroxide consumed (1.48g NaOH/g Al) in the hydrogen-generating reaction can be regenerated in reaction [2]. The relative rates of reactions [1] and [2] will affect both the rate and the extent of hydrogen evolution if a stoichiometric amount of sodium hydroxide is not present. Reaction [2] is important in both the Bayer process and Al-air batteries (6)

Twenty-five milliliters of 1M NaOH contain 1g of sodium hydroxide, or 90% of the amount required by reaction [1] for 0.75g of aluminum. The rapid decline in rate before the theoretical hydrogen volume (based on weight of aluminum) had been generated in this solution indicates that reaction [2] is not sufficiently rapid to sustain initial gas generation rates.

A final experiment was performed with a 0.75g cylinder (density of 2.1 g/cm^3) of No. 140 powder placed in 2.5 ml of 2M NaOH (or 18% of the stoichiometric amount of sodium hydroxide and 150% the stoichiometric amount of water, according to reaction [1]). The initial rate was very rapid, with boiling of the solution. Within a minute, the volume of gas reached 190 ml; then the rate dropped off sharply, but continued for 20 hr at 0.05 ml/min, the rate at which sodium hydroxide was being regenerated by reaction [2].

After about 20 hr, the hydrogen evolution rate increased to 0.15 ml/min. With time, the aluminum hydroxide precipitate may become a more effective seed surface for regeneration of sodium hydroxide by reaction [2]. Nonetheless, stoichiometric quantities of sodium hydroxide are required for rapid reaction rates. The possibility of rapid gas generation from uncompacted aluminum powder and sodium aluminate solutions has not been tested.

Summary

Hydrogen generation rates from massive aluminum in sodium hydroxide solutions are inconveniently slow for fuel cell use, even in 10M NaOH. Compacts of atomized aluminum powder in sodium hydroxide solutions yield hydrogen at suitable rates without external heating and with a start-up time in the range of 1 min. Rapid hydrogen generation to complete consumption of aluminum requires at least 1.5g NaOH/g Al, but slow generation can continue even with a lower sodium hydroxide to aluminum ratio.

The Electropolishing of Zinc Specimens

R. W. Powers* and E. C. Jerabek

General Electric Research and Development Center, Schenectady, New York

Very smooth, bright surfaces of zinc have been of considerable utility in electrochemical studies. For example, such surfaces were not only helpful in delineating the various anodic films that form on zinc but also were useful in observing the early stages of dendrite formation during the deposition of zinc from alkaline zincate solutions (1-3). The process of electropolishing is often used for producing smooth, bright surfaces in the unworked state. In this note, a new procedure for electropolishing zinc specimens based on a sulfuric acid bath is described. In our experience, it gives rise to a better surface on zinc than that produced by any electropolishing method described previously. A number of such procedures have been summarized by Tegart and by Fedotev and Grilikhes (4). The conditions for optimum polishing given in this note differ significantly from those of Maitak (5). The work of Ovari seems more concerned with brightening zinc rather than with electropolishing (6).

The zinc specimen, usually a disk 0.5-1 in. in diameter, is held in a horizontal plane about 1½ in. off the bottom of a liter beaker that serves as the bath container. The jig on which the specimen is mounted has been described elsewhere (7). The electrolyte consists of about 650 ml of an aqueous solution of sulfuric acid, 20% by weight. The cathode is a 3 in. by 12 in. strip of nickel foil (or, better, platinum foil) with attached tab to serve as the current lead. The cathode foil is arranged along the inside wall of the beaker. For this work, a filtered d-c power supply, Electro Products Laboratories Model NFB, has been used. To prevent hydrogen bubbles, generated at the cathode, from reaching the specimen, a thin porous sheet of material such as Fiberglas, nonwoven nylon, or polypropylene is used as a diaphragm. It is wrapped

* Electrochemical Society Active Member.

about a perforated polyethylene cylinder, 3 in. in diameter by 4 in. high, cut from a polyethylene bottle.

The jig with specimen attached is placed in the electrolyte at room temperature with 2.5V applied between the specimen and the cathode. Because the anodic overpotential comprises most of the cell voltage, the former is controlled adequately by maintaining the cell voltage constant. A value of 2.5V corresponds to a position on the current plateau of the current-potential curve. Smoothing takes place in the presence of a light gray anodic film that covers the specimen surface. Following the initial current surge, the current density is approximately 0.3 A/cm^2. After 1-2 hr of electrolytic smoothing and just prior to removal of the specimen from the bath, the cell voltage is increased to 7-9V. The gray film is removed in 20-60 sec and the specimen surface becomes very lustrous. The specimen is then quickly removed from the bath with voltage applied and immediately plunged into distilled water. It is dried rapidly with a stream of dry gas.

The surface produced according to this procedure is mirrorlike, very lustrous, and smooth as indicated by the Nomarski interferogram shown in Fig. 1. Since the reference plane in the Nomarski technique is formed optically and can be tilted arbitrarily with respect to the specimen surface, only the waviness of the fringes, not the distance between them, is significant in indicating surface smoothness. The photomicrograph shown in Fig. 1 was taken midway between the center and edge of a ¾ in. disk of 99.9999% zinc with yellow light. Grain boundaries are faintly discernible. Slight differences in the heights of individual grains appear to be the cause of the slightly jagged character of the interference fringes.

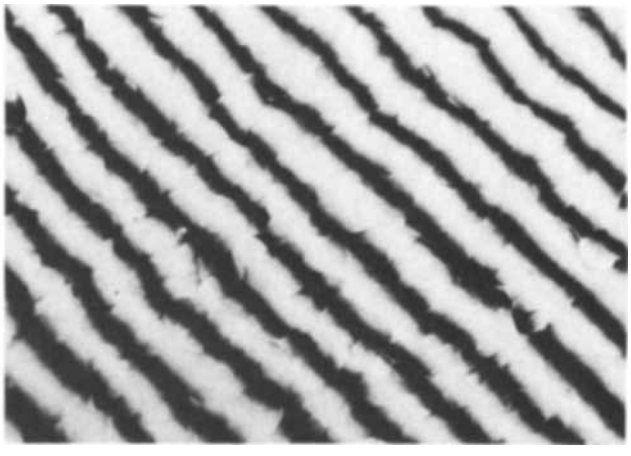

Fig. 1. Nomarski interferogram of zinc specimen after 2 hr of electropolishing. 60X.

The polishing procedure described in this note is not satisfactory for most zinc alloys. Alloying additions evidently increase the conductivity of the gray anodic film. During removal of this film by application of 7-9V, oxygen is evolved on the alloys. This leads to the formation of fine pits.

A Method for the Synthesis of BI_3 for Use as a Dopant Source

M. Berkenblit* and A. Reisman*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York

Although B_2H_6 is generally used as a p-type dopant source for Ge layers grown by the $GeCl_4$ or GeH_4 processes, it was found to have limited applications when used with the GeI_2 disproportionation reaction. Under low growth rate conditions using B_2H_6 as a dopant source in the iodide process (1), Ge epitaxial layers were obtained with resistivities as low as 0.005 ohm-cm. However, under the high growth rate conditions necessary to obtain smooth and shiny epitaxial layers on (110) oriented substrates (2, 3), B addition *via* B_2H_6 presented a problem. The maximum usable p-type doping obtained was 0.02 ohm-cm. With further increase of B_2H_6 concentrations, the surface quality of the epitaxial layer degraded.

At the low temperatures (350°-400°C) used in the disproportionation epitaxial reaction, the incorporation of B into the growing layer was assumed to occur *via* an intermediate formation of BI_3 by the reaction of B_2H_6 with HI in the gas stream. (HI was present as one of the gas species during the deposition process.) The BI_3 yield was limited by the available HI and the efficiency of this reaction at the temperature of the epitaxial reactor. Thus, in order to establish a high BI_3 concentration, a large excess of B_2H_6 was needed, which in turn perturbed the epitaxial reaction.

Substitution of a solid BI_3 source (vendor supplied material) proved to be unsatisfactory because of large variations in purity from lot to lot, and difficulties encountered in transferring the material into the reaction system. It is the purpose here to describe a method for an *in situ* synthesis of BI_3 which yields a reproducible source of boron and enables deposition of low-resistivity Ge single-crystal layers.

The synthesis of BI_3 involved the reaction of B_2H_6 (obtained from the Matheson Company in a H_2-He

* Electrochemical Society Active Member.

Key words: semiconductor materials, doping of semiconductors, p-type dopant source.

carrier gas at 100-1000 ppm level), and HI (delivered from a generator similar to that used for the Ge epitaxy) (4) in appropriate quantities to satisfy the stoichiometry shown in Eq. [1] (5).

$$6B_2H_6 + 6HI \rightleftarrows 2BI_3 + 5B_2H_6 + 6H_2 \qquad [1]$$

Both the B_2H_6 and HI were carried into a furnace by a H_2-He gas mixture and reacted at 250°C. Figure 1 is a schematic representation of the system used. At the output of the reaction chamber, BI_3 was condensed in an ice trap, while other effluent vapors (including B_2H_6) were swept out of the system. Once a sufficient quantity of BI_3 was collected, the synthesis was terminated. Then, using a suitable valving arrangement, the BI_3 was introduced into the epitaxial reactor. During the epitaxial reaction, the BI_3 was maintained at 24°C, and the concentration in the reactor varied by the carrier gas flow rate.

According to calculations made using the JANAF thermochemical data tables, the equilibrium constant for the reaction as written in Eq. [1] varies from 10^{10} to 10^5 in the range 25°-800°C, respectively. The synthesis was attempted at 250°, 450° and 800°C, and only at 250°C was any measurable amount of BI_3 observed. At the higher temperatures, there was no measurable trace of BI_3, indicating that K is much smaller ($\rightarrow 0$)

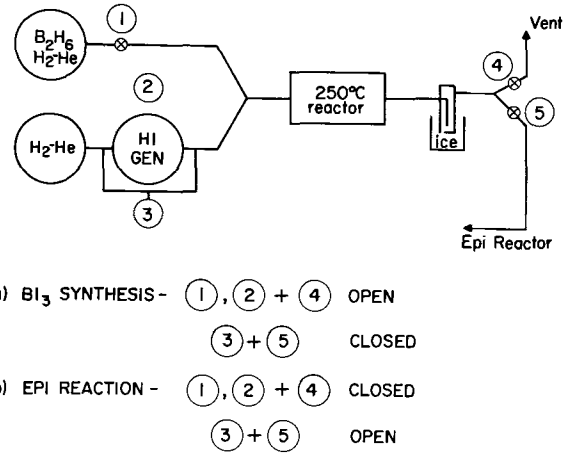

Fig. 1. Schematic representation of the BI_3 synthesis-epitaxial reactor train.

than the calculated value. Since the kinetics of the reaction would increase with increasing temperature, these results do not appear to be due to kinetic limitations, and would indicate that the thermochemical data are in considerable error.

An indication of the applicability of Eq. [1] in describing the over-all reaction and a measure of the reaction efficiency at 250°C were obtained *via* chemical analysis of the reaction products. Thus, if one obtains the ratio of BI_3 to B_2H_6 in the effluent, starting with equimolar mixtures of B_2H_6 and HI, the BI_3/B_2H_6 ratio would be expected to vary between zero when no reaction occurs to 2:5 if the reaction goes essentially to completion. A series of 3 H_2O bubblers were attached to the output of the reaction train (BI_3 and B_2H_6 decompose in water to form B_2O_3 in solution). With the ice trap in place, unreacted B_2H_6 in the exit gas was trapped and decomposed in H_2O while the BI_3 was entrained in the ice trap. After the reaction was terminated, this trapped BI_3 was flushed into a new set of water bubblers and decomposed. The boron content in both solutions was then determined colorimetrically by the methylene blue method (6). Within the precision of the method of analysis (*ca.* 5%), the mole ratio of BI_3 to B_2H_6 was found to be 2:5 indicating that at 250°C the reaction goes essentially to completion.

Acknowledgments

The authors wish to thank M. Sampogna for his assistance with the synthesis and B. L. Gilbert and B. L. Olson for the boron analysis.

Chemical Approaches to the Approximate Prediction of Band Gaps of Binary Semiconductors and Insulators

Ashok K. Vijh*

Hydro-Quebec Institute of Research, Varennes, Quebec, Canada

ABSTRACT

The chemical approaches to the approximate prediction of band gaps of binary inorganic semiconductors and insulators have been briefly reviewed with special emphasis on relatively recent work. These approaches involve establishment of correlations between band gaps and various other quantities, *e.g.* heats of formation, bond energies and electronegativities, *etc.* It has been shown that some of these correlations provide semiquantitative means for the estimation of band gaps of several materials for which it is either too difficult or impossible to compute accurate band gaps on the basis of methods of theoretical physics. The possible theoretical foundations of some of these correlations, as examined previously, have also been presented. Some of the recently proposed correlations, *e.g.* between band gaps and heats of formation per equivalent, even though rough, have universal validity in that they are applicable to all types of binary inorganic compounds covering a wide range of ionicity, crystal type, and band gaps.

It is generally recognized that the methods of theoretical physics are either inadequate or cumbersome for computing the width of forbidden gaps of all but the simplest semiconductors, *e.g.* Ge. The width of the forbidden gap is, of course, an extremely important parameter for the case of semiconducting compounds since it constitutes the basis for the calculation of band structure and the computation of the number of intrinsic carriers, and other properties. This situation has prompted a number of investigators to predict, albeit approximately, the band gaps of semiconductors by chemical approaches involving a variety of correlations (1-8). For example, band gaps have been related to heats of formation per mole (1), heats of formation per equivalent (7), electronegativities (3), atomic numbers (6), heats of atomization per atom (5), single bond energies (4), and average bond energies (8). Many of these correlations are purely empirical in nature. In some cases, however, attempts have been made to present some theoretical justifications (1, 5, 8-10).

In the present article, an attempt is made to present an outline of the more significant of these approaches with special emphasis on relatively recent work. It is assumed that the reader is familiar with the qualitative description of the band theory of solids as presented, *e.g.* in a recent lucid article (11). Other excellent articles on the band theory of solids, at a relatively elementary level, are also available in the literature (2, 3, 12-16).

It may be added that the fundamental contributions of Mooser and Pearson (17), Goodman (18), Suchet (19), and Welker (20) to the subject of prediction of semiconductivity in materials are not included in this article since their work has already been reviewed previously in some detail (10).

* Electrochemical Society Active Member.

Correlation of Band Gaps to Various Quantities

It was demonstrated by Ruppel, Rose, and Gerritsen (1) that band gaps, E_g, of several semiconductors and insulators lie between one and two times the heats of formation per *mole* of the corresponding compounds (Fig. 1). It was pointed out (7), however, following Sanderson (21), that in correlations of the type shown in Fig. 1 the thermodynamic data must be "normalized," *i.e.* the heats of formation should be plotted as per equivalent (*i.e.* neither as per mole nor as per atom but as per atom equivalent). This correlation (Fig. 1) was extended to several more compounds by including this concept of normalization (7), and the results are shown in Fig. 2. It is clear from Fig. 2 that, *roughly*, a very large variety of semiconductors and insulators obey the relation:

$$E_g = 2\,\Delta H_e \qquad [1]$$

where ΔH_e is the heat of formation per equivalent. For the case of polyatomic compounds formed between polyvalent ions, it is particularly glaring that (Table I) the proposal of Ruppel *et al.* (1) is not sustained, whereas Vijh's relation (Fig. 2) gives rather satisfactory predictions of approximate values of the band gaps (Table I).

In a correlation proposed by Hooge (Fig. 3), band gaps of several binary compounds may be satisfactorily estimated from electronegativities by means of an empirical equation. This correlation (3) does not, however, include polyatomic compounds.

In a very interesting paper, Manca related the single bond energies of several compounds, calculated by Pauling's empirical equation (22), to their band gaps,

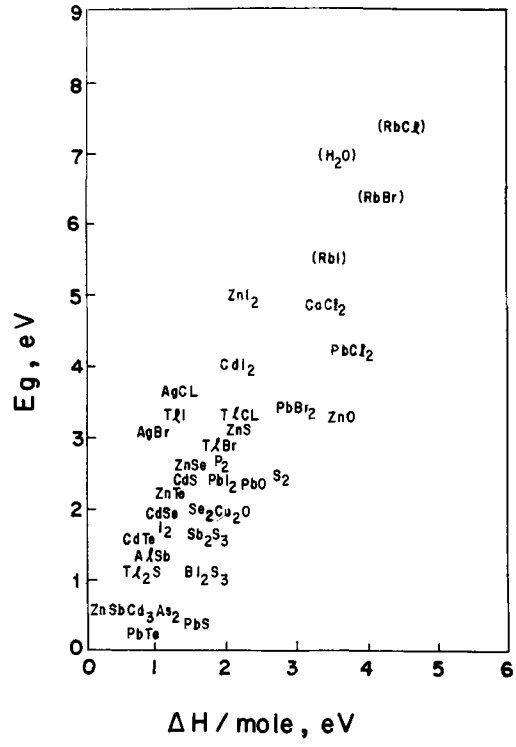

Fig. 1. Correlation between band gaps and heats of formation (standard state) per *mole* for several compounds, after Ruppel, Rose, and Gerritsen (1).

Table I

Compound	E_g (Ruppel *et al.*), eV	E_g (Vijh), eV	E_g (experimental), eV
Al_2O_3	17-34	5.67	7
Ta_2O_5	21.75-43.5	4.35	4.6
TiO_2	9.46-19.92	4.73	3.0
Ga_2O_3	11.19-22.38	3.73	4.4
In_2O_3	9.63-19.26	3.21	2.8

through an empirical relation of the type:

$$E_g = a\,(E_s - b) = 2\,(E_s - b) \qquad [2]$$

where E_g is the band gap value; E_s is the single bond energy; a and b are constants characteristic of a given class (*e.g.* $A^{IV}\,B^{IV}$, $A^{III}\,B^{V}$, *etc.*) of semiconductors. For the compounds examined by Manca, the value of a is roughly equal to 2. Manca's results showing the validity of Eq. [2] for several compounds have been presented in Fig. 4. In another paper, Bailly and Manca (5) have shown that for several compounds the following relation is obeyed:

$$E_g = \overline{A}\,(\Delta G^s - \overline{B}) \qquad [3]$$

Here ΔG^s is the free energy of sublimation per atom of the semiconducting compounds and $\overline{A}$ and $\overline{B}$ are parameters characteristic of each series of semiconducting material. It may be seen from Fig. 5 that Eq. [3] holds for a typical series of compounds. Bailly and Manca have also analyzed the factors that determine the magnitude of parameters $\overline{A}$ and $\overline{B}$ for several series of inorganic compounds (5).

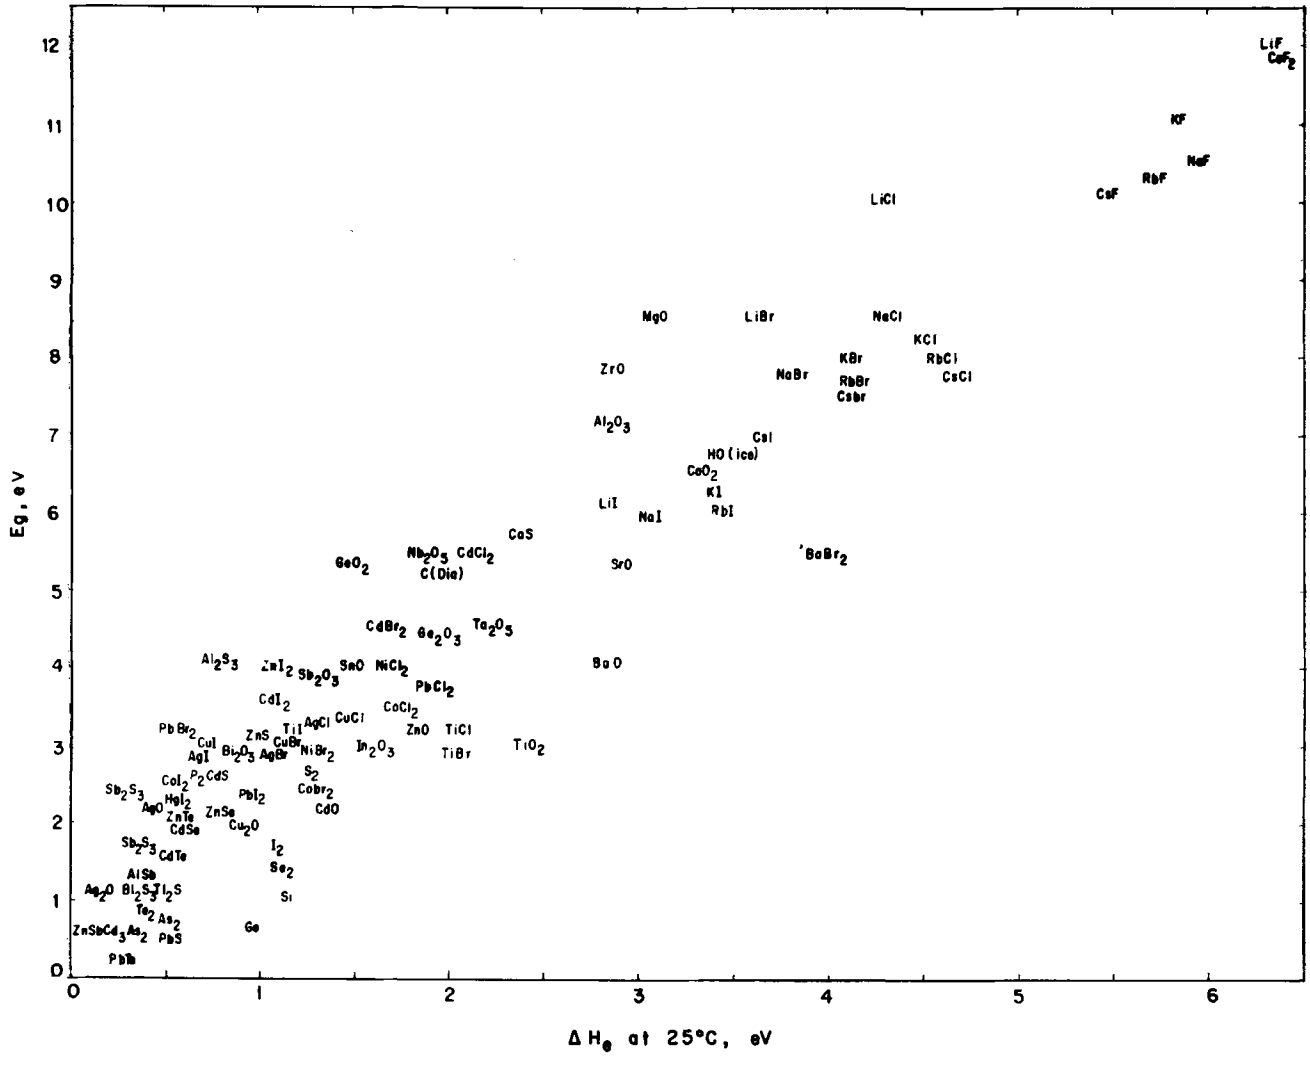

Fig. 2. A plot of band gaps *vs.* heats of formation (standard state) per equivalent for a large number of inorganic binary compounds (7)

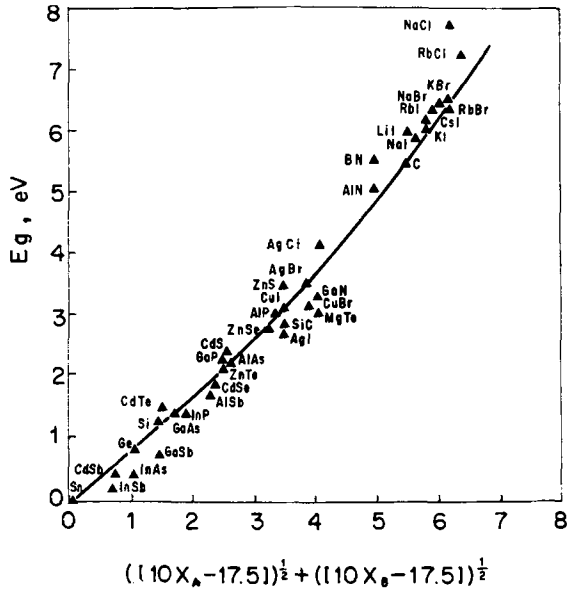

Fig. 3. Hooge's (3) relationship between band gaps and a function of electronegativities, X, for some semiconductors and insulators.

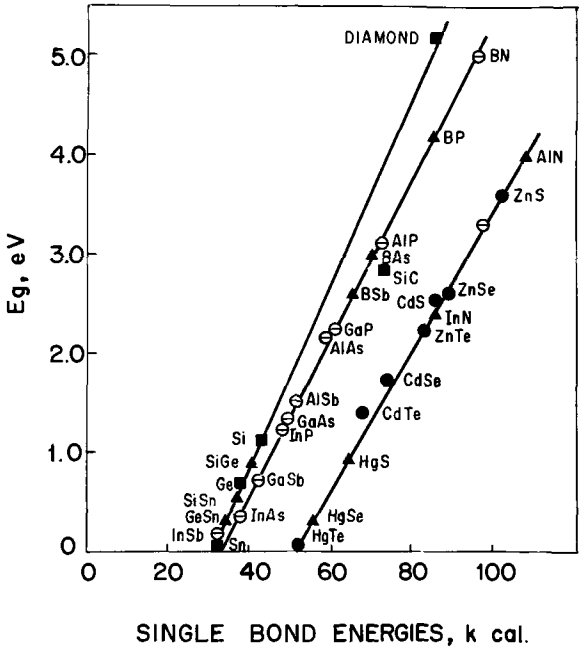

Fig. 4. Manca's correlation between single bond energies, as estimated by Pauling's method, and band gaps for several series of inorganic substances (4).

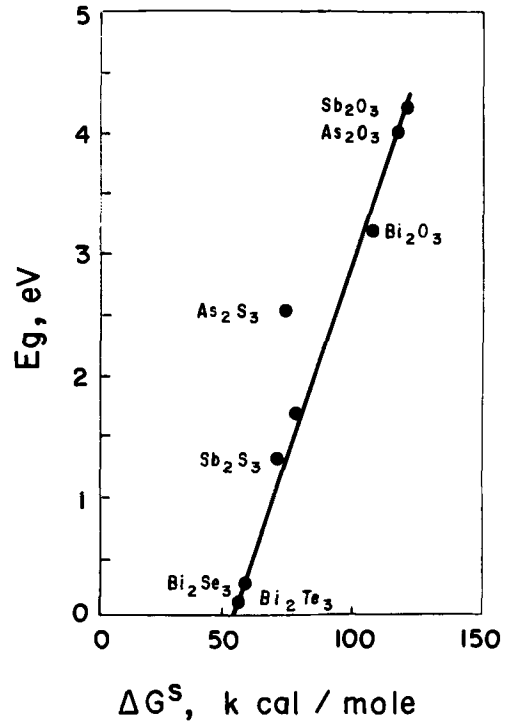

Fig. 5. A typical plot of free energy of sublimation per atom against band gaps for a given series of semiconductors, as presented by Bailly and Manca (5).

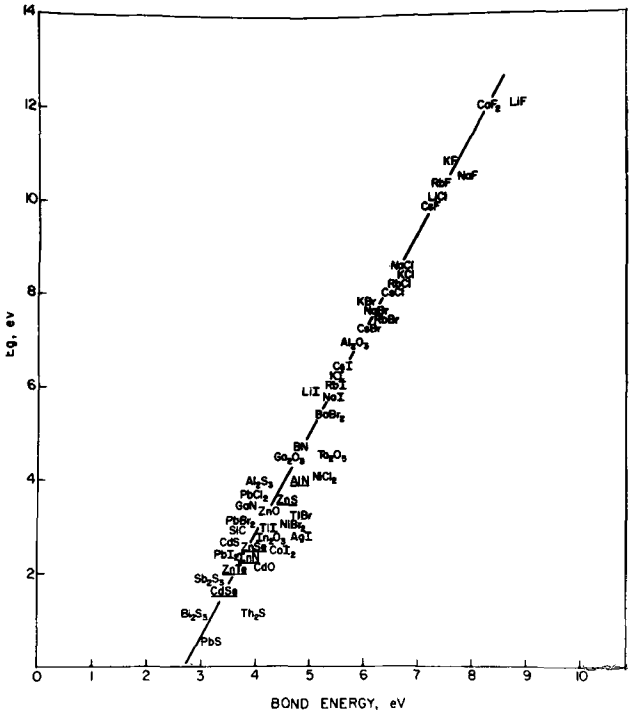

Fig. 6. A plot depicting correlation of average bond energies with band gaps for a wide range of inorganic binary compounds. Bond energies for CdSe, ZnTe, InN, ZnSe, ZnS, and AlN are single bond energies estimated by Pauling's empirical equation since reliable thermodynamic data are not available for calculation of average bond energies (8).

All the foregoing correlations (Fig. 1-5) have a serious limitation in that they are empirical in nature. Further, most of them (Fig. 1, 3-5) are restricted to certain special classes of compounds and lack universal applicability. However, the relationship presented in Fig. 2 is an exception in this particular respect; *i.e.* it has general applicability. A point that may be emphasized here is that most of these correlations are rather approximate in nature.

Recently, Vijh (8) has presented a correlation (Fig. 6) between average bond energies and band gaps, E_g, of several inorganic binary compounds. In fact it has been shown that Manca's Eq. [2] is applicable to a large variety of compounds (Fig. 6) if E_s in Eq. [2] is assumed to denote an average bond energy as calculated by a thermochemical procedure, instead of representing a single bond energy value. It is important to note that this correlation (Fig. 6) is *not* restricted to some particular class of semiconductors and is in fact a general one and includes compounds which cover the following spectrum of behavior:

(i) Inorganic compounds which range from highly covalent (Sb_2S_3) to those which are highly ionic (NaF).

(ii) Semiconductors and insulators representing a rather large range of band gap values, *e.g.* 0.5 to 12 eV.

(iii) There are several substances in Fig. 6 (and Table I) which are polyatomic binary compounds formed between *polyvalent* ions, *e.g.* Sb_2S_3, Bi_2S_3, Al_2O_3, Ta_2O_5, *etc.*

(iv) A wide range of crystal structures as represented in Fig. 6, *e.g.* Wurzite, zinc blende, Corundum, cuprite, fluorite, NaCl, and CsCl.

The relationship presented in Fig. 6 is not only a rather general one but it can also be derived theoretically (8) for the case of ionic compounds, *e.g.* alkali halides. The theoretical basis of Fig. 6 and Fig. 2 has been outlined in the following section.

Some Theoretical Considerations

In this section, an attempt is made to indicate the theoretical basis of Eq. [2] and [1] for the case of alkali halides, assuming that E_s in Eq. [2] represents an average bond energy value. It is important, however, to precede this analysis by a discussion of some matters related to the question of proper definition of bond energies and band gaps.

Bond energies.—There are two procedures frequently used for the calculation of bond energies:

1. *Pauling's method—single bond energies*

The bond energy of an isolated diatomic molecule formed between two univalent atoms, *e.g.* NaCl, may be estimated by Pauling's empirical equation:

$$D(\text{Na-Cl}) = \tfrac{1}{2}\{D(\text{Na-Na}) + D(\text{Cl-Cl})\} + 23(X_{\text{Na}}-X_{\text{Cl}})^2 \quad [4]$$

Here, D(Na-Cl) is the bond energy between Na and Cl in NaCl; D(Na-Na) is the bond energy between Na atoms; D(Cl-Cl) is the bond energy between two chlorine atoms; X_{Na} and X_{Cl} are the electronegativities of Na and Cl, respectively, on the Pauling Scale (22). This method gives fairly accurate estimates of bond energy between two univalent atoms held together by a single bond, *e.g.* NaCl. However, when more than one bond is involved, *e.g.* in CH_4, Pauling's procedure does not give a good estimate of the average C-H bond energy, but only yields a value for the last dissociation energy, *i.e.* C-H bond, when only one H is present on C. When applied to cases involving either divalent or multivalent atoms, *e.g.* Ta_2O_5, Sb_2S_3, GaN, this method gives an estimate of the energy of the last bond in the molecule after all other bonds have been removed. It is believed that such a quantity is not a very good measure of the *general* magnitude of binding in a complex molecule, which must be represented by an average bond energy. The average bond energy thus obtained, it is believed, is more pertinent to the discussion of relation between binding and band gaps in inorganic compounds. This bond energy is calculated from the appropriate thermochemical data, as follows.

2. *Thermochemical procedure—average bond energies*

The bond energy of a compound, *e.g.* NaCl, may be obtained from the equation:

$$D(\text{Na-Cl}) = \Delta H_S + \tfrac{1}{2}\,\Delta H^\circ_{\text{diss}} + H^\circ_f \quad [5]$$

Here, D(Na-Cl) is the required bond energy; ΔH_S is the heat of sublimation of Na metal per *mole*; ΔH_{diss} is the heat of dissociation of Cl_2 molecule into Cl atoms, again, per mole; ΔH°_f is the heat of formation of NaCl in its standard state, again per mole. The quantity given by Eq. [5] (*i.e.* bond energy) is, of course, the heat of atomization of NaCl. In the case of NaCl, only one shared electron pair is involved in the bonding. For complex compounds, *e.g.* Al_2O_3, several bonds (*i.e.* shared electron pairs) are involved and hence an appropriate normalizing factor must be used to obtain from Eq. [5] the bond energy per *bond* and not the total energy for all the bonds in Al_2O_3. This is done by computing, first from Eq. [5], the heat of atomization per mole which is then normalized with respect to the participating valences in order to obtain heat of atomization per equivalent, which is, of course, the bond energy. For example, the heat of atomization per equivalent (*i.e.* the bond energy) for Al_2O_3 is 1/6 of the heat of atomization per mole as calculated from Eq. [5]. Further details on these and related matters are available elsewhere (7, 8, 21-23).

The heat of atomization per equivalent thus obtained, after some second-order corrections (*e.g.* spin correlation stabilization energies, coordinate valence) as discussed by Howald (23), are the actual values of the average bond energies as obtained from the experimental thermochemical data.

These average bond energy values have been used in constructing Fig. 6 (see, however, caption to Fig. 6). The accuracy of these bond energies is limited only by the accuracy of the thermodynamic data which were used in their calculation. These data have been obtained from reliable compilations (23-25). In obtaining these average bond energies, corrections to the heats of atomization per equivalent were applied only for spin correlation stabilization energies (23). The possible presence of coordinate valence has been ignored because unambiguous estimates of the extent of participation of coordinate valence in compounds are not always easily obtained as discussed by Howald (23). Since the theoretical derivation of Eq. [2] and [3] (see below) is claimed to be strictly valid for alkali halides only, this neglect of coordinate valence in the calculation of bond energies is not serious, because alkali halides do not involve any coordinate bonds.

Band gaps.—These band gaps (Fig. 6) refer to k space at $k = 0$. It may be mentioned that precise definition and determination of band gaps involves some real difficulties. For example, in large band gap semiconductors like alkali halides, experimental values quoted are strongly influenced by coulomb effects, even though there is no significant difference between the direct and indirect gap since the bands are very narrow. This is because of the reason that the optical absorption is determined rather by the exciton structure in front of the energy gap than by the energy gap itself (8). In small band gap semiconductors, on the other hand, there are appreciable differences between direct and indirect gaps since the bands are rather wide (8). The significance of values of band gaps used in Fig. 6 must be accepted only in relation to these difficulties. It is believed, however, that the aforementioned difficulties in the precise definition and determination of band gaps are not serious enough to render values of band gaps in Fig. 6 so uncertain as to make the relationship presented invalid.

Derivation of Eq. [2] and [3] for ionic compounds.—As shown previously by Mark (26), the forbidden gap E_g of an ionic compound like NaCl is given by:

$$E_g = 2M - (I_m - A_x) \quad [6]$$

where M is the Madelung energy, I_m is the ionization potential of Na; A_x is the electron affinity of Cl. From Eq. [6],

$$E_g = 2(U - R) - I_m + A_x \quad [7]$$

where U is the experimental (thermochemical) lattice energy and R is an energy term which includes repulsive, London, and other components (*e.g.*, crystal field stabilization energy) of theoretical lattice energy (12) so that

$$M = (U - R) \quad [8]$$

is quite valid.

It may be readily shown, by means of a Born-Haber thermochemical cycle, that (12):

$$\Delta H^\circ_f = \Delta H_s + I_m + \tfrac{1}{2}\,\Delta H_D + A_x + U \quad [9]$$

where,

ΔH°_f is the heat of formation, *e.g.* of NaCl
ΔH_s is the heat of sublimation of Na
I_m is the ionization potential of Na

ΔH_D is the energy of dissociation of Cl_2 (g) into atoms
A_x is the electron affinity of Cl
U is the lattice energy of NaCl

The quantities defined above are all as per *mole* of the corresponding substance.

On obvious rearrangement, Eq. [9] gives:

$$-U = \Delta H_s + I_m + \tfrac{1}{2}\Delta H_D + A_x - \Delta H^\circ_f \quad [10]$$

Now we note that U, A_x, and ΔH°_f are exothermic quantities (hence with $-$ sign) and ΔH_s, I_m, and ΔH_D are endothermic quantities (hence with $+$ sign) for alkali halides. On making these substitutions for exothermicity and endothermicity in Eq. [10], we obtain:

$$U = \Delta H_s + I_m + \tfrac{1}{2}\Delta H_D + \Delta H^\circ_f - A_x \quad [11]$$

Substituting Eq. [11] in Eq. [7],

$$E_g = 2\Delta H_s + 2I_m + \Delta H_D + 2\Delta H^\circ_f - 2A_x - 2R - I_m + A_x \quad [12]$$

or

$$E_g = 2\Delta H_s + I_m + \Delta H_D + 2\Delta H^\circ_f - A_x - 2R \quad [13]$$

On making an approximation that I_m is roughly equivalent to A_x in magnitude, one obtains:

$$E_g = 2\Delta H_s + 2\Delta H^\circ_f + \Delta H_D - 2R \quad [14]$$

or

$$E_g = 2(\Delta H_a - R) \quad [15]$$

where ΔH_a is the heat of atomization per *mole*, and for a diatomic molecule formed between two univalent ions (*e.g.* NaCl) is identical with the heat of atomization per equivalent, which is, of course, the average bond energy (8, 21-23).

When considering a polyatomic compound formed between either univalent or polyvalent ions, Eq. [15] has to be suitably modified. This is owing to the fact that Eq. [6] and [7] refer to the transfer of *one* valence electron only, *i.e.* from Na to Cl; in order to maintain the validitiy of Eq. [12], U in Eq. [11] must also be taken as per valence electron, *i.e.* as per equivalent. As a result, the ΔH_a term in Eq. [15] must be changed from ΔH_a/mole to ΔH_a/eq. for a polyatomic compound. As mentioned earlier, ΔH_a/eq. is, of course, the bond energy E_s. Hence,

$$E_g = 2(E_s - R) \quad [16]$$

For a closely related series of compounds, *e.g.* alkali halides, R may roughly be treated as a constant. Hence, Eq. [15] may be written as:

$$E_g = 2(E_s - b) \quad [17]$$

where "b" is a constant. This Eq. [17] is identical with Manca's equation, *i.e.* Eq. 2 in this paper.

The approximation made in the derivation of Eq. [17] may now be considered. If I_m is not roughly equivalent to A_x, then R in Eq. [16] may be transformed into R' where,

$$R' = R + \tfrac{1}{2}I_m - \tfrac{1}{2}A_x \quad [18]$$

For structurally related compounds, R' may again be assumed as, *roughly*, a constant. For example, for several alkali halides, values of R' lie close to 2.5 ± 0.5 eV. It is obvious, of course, that Eq. [18] must be appropriately modified for compounds involving positive electron affinities.

On the basis of the foregoing analysis, the possible theoretical basis of Fig. 2 may now be explored. Rewriting Eq. [14], by substituting Eq. [18] into it, one obtains:

$$E_g = (2\Delta H_s + \Delta H_D - 2R') + 2\Delta H^\circ_f \quad [19]$$

For several compounds, it turns out, fortuitously, that quantities in the parentheses of Eq. [19] either roughly cancel each other out or assume rather small net value (8). Hence, Eq. [19] may be approximated as:

$$E_g \simeq 2\Delta H^\circ_f \quad [20]$$

As mentioned in the foregoing discussion, in all such discussions the quantities must be properly normalized (7, 8, 21-23), *i.e.* taken as per equivalent which for a diatomic substance formed between uni-univalent ions is, of course, the same thing as per mole. Hence, Eq. [20] may be written as:

$$E_g \simeq 2\Delta H_e \quad [21]$$

Equation [21] is identical with Eq. [1], and it constitutes the possible theoretical basis of Fig. 2.

Limitations of the foregoing theoretical analysis.— It is clear that the foregoing analysis is invalid for elementary semiconductors since lattice energy for these substances has no significance. Also, molecular semiconductors like anthracene are not covered by the foregoing discussions. Further, theoretical foundations of Fig. 2 and 6 for the case of predominantly covalent binary compounds like Sb_2S_3 are not completely clear.

For the case of some covalent compounds, however, *e.g.* those included in Fig. 6, it is possible that the increase in cohesive energy due to homopolar binding approximately cancels out the decrease in lattice energy that may result from partial ionicity of the compound (8, 26). In these cases, experimental lattice energy values, U, will be nearly equivalent to the $(M + R)$ values that would have been obtained, had the compound been predominantly ionic. In some fortuitous cases of this type, the entire analysis presented here would still be valid, despite significant covalent bonding.

In some other cases of covalent compounds, the present analysis may be extended by modifying Eq. [17] to give:

$$E_g = 2(E_s - b) \pm \Delta U \quad [22]$$

where ΔU is the difference between the thermochemical and theoretical lattice energies (12) again taken as per equivalent.

It is important to emphasize that it is rather fortuitous that several covalent compounds obey the relationship shown in Fig. 6, despite the fact that no correction for homopolar bonding has been applied to them.

Concluding Remarks

It has been shown in the foregoing discussion that it is possible to obtain by chemical approaches some significant, semiquantitative correlations between band gaps and other properties, *e.g.* heats of formation and bond energies. The important points that have been brought out in this article are as follows:

(A) These correlations (Fig. 2 and 6) need not necessarily be limited to certain restricted classes of compounds.

(B) They yield semiquantitative results and not just qualitative trends.

(C) These correlations also lend themselves to some theoretical analysis.

It is obvious, of course, that these correlations are not very exact yet and would need considerable improvements and more sophisticated theoretical analysis before yielding procedures for accurate prediction of band gaps of materials.

Manuscript submitted Nov. 3, 1969; revised manuscript received Jan. 19, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

SECTION NEWS

Columbus Section

A symposium on battery separators was held in Columbus, Ohio, on February 18-19, 1970 under the sponsorship of the Columbus Section of The Electrochemical Society. 19 papers covered separator materials and performance in lead-acid, nickel-cadmium, silver-zinc, and silver-cadmium batteries and rechargeable fuel cells. Approximately 100 scientists and engineers from the United States, Canada, England, and Sweden were in attendance.

The proceedings of the symposium will be published in a softbound book in approximately two months. A limited number of copies are still available at $7.00 each. Orders for copies of the proceedings should be sent to Dr. H. L. Goering, Battelle Memorial Institute, 505 King Avenue, Columbus, Ohio 43201. Checks should be made payable to Columbus Section of The Electrochemical Society.

The program consisted of the following papers:

"General Requirements and Characterization of Secondary Battery Separators,"—J. J. Lander, Air Force Aero Propulsion Laboratory, and E. J. Casey, Defense Research Establishment;

"A New Type of Microporous Polymeric Separator,"—Erik Sundberg, Tudor Sweden, and J. Q. Selsor, Ameraace, Esna Corporation;

"Characterization of Anisotropic Films for Battery Separators,"—Michael J. Lysaght, Amincon Corporation;

"The Selection of Textile Fibers and Fabricating Techniques in Separator Design,"—Phoenix N. Dangel, Kendall, Fiber Products Division;

"Characterization and Performance of Separators for Ni-Cd Aircraft Batteries,"—Louis Belove and Paul Scardaville, Sonotone Corporation;

"QC Procedures and Measurements —Polypropylene Separators for Sealed Ni-Cd Batteries,"—T. E. King, Defense Research Establishment;

"Separators for Heat Sterilizable Ni-Cd Batteries," —R. Lutwack, Jet Propulsion Laboratory;

"Ultrafine Porous Polymer Membranes as Battery Separators,"—J. L. Weininger, General Electric Company;

"Cellulosic Separators for Alkaline Batteries—A Review,"—G. A. Dalin, Yardney Electric Corporation;

"Silver-Zinc Battery Separator Material Development,"—E. V. Kirkland, Monsanto Research Corporation;

"Improved Separator Materials for Alkaline Batteries,"—H. E. Hoyt, Borden, Inc., Chemical Division;

"Preparation and Properties of Separators for Silver-Zinc Cells,"—A. Langer and L. C. Scala, Westinghouse Electric Corporation;

"Preparation and Properties of Grafted Membrane Separators for Silver-Zinc Cells,"—V. D'Agostino, RAI Research Corporation;

"Performance of Organic Membranes and Inorganic Coatings as Separators in Silver-Zinc Cells,"—T. J. Hennigan, Goddard Space Flight Center;

"Charged Stand and Cycle Life Test Results on Separator Systems for Alkaline Cells,"—R. S. Bogner, Jet Propulsion Laboratory;

"QC for Heat Sterilizable Silver-Zinc Separator Materials,"—W. von Hartmann, Jet Propulsion Laboratory;

"Chemical and Physical Analysis of Grafted Membranes for Silver-Zinc Batteries,"—E. F. Cuddihy and J. Moacanin, Jet Propulsion Laboratory;

"Separator Developments for Rechargeable H_2O_2 Fuel Cells,"—M. G. Klein, Electro-Optical Systems, Inc.;

"Recent Advances in Ion Exchange Membranes for Use in Rechargeable Fuel Cells,"—A. P. Fickett, General Electric Company.

Concluding the program was a panel discussion chaired by Arthur Fleischer, with panelists T. J. Hennigan, R. Lutwack, T. E. King, and J. J. Lander.

Detroit Section

The Detroit Section held a meeting on March 19, 1970, at the McGregor Memorial Conference Center, Wayne State University. The guest speaker was Dr. C. V. King, Vice-President of the Society, and also President of American Gas & Chemicals, Inc. Dr. King gave a very interesting and lucid account of methods for determining gas leaks. Most of the methods described were chemical tests, involving the use of color-change tapes or papers, which could be used for rocket and missile fuels and oxidizers, for carbon monoxide, ammonia, hydrazine, unsymmetrical dimethyl hydrazine, hydrogen sulfide, for engine fuels, oils, and hydraulic fluids. A simple bubble test for butane lighters was described which involved immersion in water containing a suitable detergent. Dr. King also described a few electrochemical methods for determining leaks. The presentation was illustrated with several demonstrations.

Prior to the technical part of the meeting Dr. King spent fifteen minutes or so discussing Society affairs. The main topics covered were the transfer of the National Office to Princeton, N. J., the running of National Meetings by the National Office, and the Society's membership and financial standing.

Raymond Thacker

naces in the 2000-3000°C range; the use of electric arcs for material synthesis, purification, and crystal growth; and new methods for vapor growth of single crystals of ZnTe, using a "transparent furnace" especially suited for vapor growth of crystals. After a lively period of questions and answers, Dr. Reed demonstrated a model of the transparent furnace. Dr. Carr presented the speaker with a telescoping pocket pointer as a token of the appreciation of the Section for the fine lecture and the meeting was closed with a rising vote of thanks for Dr. Thomas B. Reed.

Dodd S. Carr
Vice-Chairman

North Texas Section

The winter meeting of the North Texas Section was held on January 26, 1970 in the Meadows Building Cafeteria in Dallas.

The speaker was Dr. Charles Tobias of the University of California. Dr. Tobias conducted an informal discussion of several aspects of Electrochemical Society activities such as the new location of the national headquarters. Following this discussion he made a technical presentation on "Electrolysis at High Rates."

Active and transpassive anodic dissolution modes of copper are characterized by different overpotentials and different resulting surface textures. Voltage transients observed during these dissolution processes are related to current densities and electrolyte flow rates. Passivation phenomena and the formation and removal of solid anodic reaction products are likely controlled by mass transport.

David F. Cole
Chairman

Pacific Northwest Section

The Pacific Northwest Section held its third meeting at Andy's Diner, Seattle, Wash., on March 16, 1970. After a social hour and dinner, Robert Glockling, Chairman, introduced David Roe, the guest speaker. Dr. Roe is on the faculty of the Oregon Graduate Center, Portland, Oreg. His illustrated talk was entitled "An Electrochemical and Mass Spectrometric Investigation of Platinum Electrodes."

In spite of their extensive use in electrochemistry, platinum electrodes show some unusual characteristics which eluded thorough explanations. The literature of the past ten years, in particular, is replete with electrochemical investigations of the surface oxidation of platinum and studies of oxidation of organic compounds on "activated" platinum. Deductive development of rigorous, or even consistent molecular models from such information is hampered by incomplete knowledge of, for example, true surface area, "active" surface area, adsorption sites, surface contamination, and the chemical nature of surface oxides.

Further insight in some of these problems has been obtained from combining mass spectrometry with electrochemical measurements. From these results it can be shown how to obtain a clean platinum surface, free of organic adsorbants. Also, anodic oxidation of platinum does not produce an oxide with any of the properties of PtO_2, as noted by decomposition behavior in vacuum. However, exposure of platinum to oxygen and water vapor at 210°C does result in detectable surface oxidation. This oxide can be reduced electrochemically and compared with anodically-formed oxide. Rate and equilibrium measurements of the vapor phase oxidation at 210°C leads to identification of the reaction as requiring one water molecule per atom of oxygen, i.e. $Pt + \frac{1}{2}O_2 + H_2O \rightarrow Pt(OH)_2$.

Sidney Gross
Secretary

1971 Palladium Medal Award, ECS

The tenth Palladium Medal of The Electrochemical Society will be awarded at the Fall Meeting of the Society to be held in Cleveland, Ohio, October 3-8, 1971. The medal was established in 1951 by the Corrosion Division.

The candidate shall be distinguished for his original contributions to theoretical electrochemistry or to fundamental scientific knowledge of corrosion processes. He need not be a member of the Society. There shall be no restrictions or reservations made regarding his citizenship, age, or sex.

To be eligible, the candidate shall agree to receive the award in person at the designated national meeting of the Society. He shall also agree to present a general lecture before the Society, at the above designated national meeting, to be called the Palladium Medal Address. This address will in general describe some area of the candidate's researches, and will be presented at a time and place during the meeting to be specified in each instance by the Board of Directors.

Previous medalists have been: Carl Wagner, Max Planck Institut fur Physikalische Chemie; N. H. Furman, Princeton University; U. R. Evans, Cambridge University; K. F. Bonhoeffer, Max Planck Institut fur Physikalische Chemie (posthumous award); A. N. Frumkin, Electrochemical Institute of the USSR; H. H. Uhlig, Massachusetts Institute of Technology; Norman Hackerman, University of Texas; Paul Delahay, New York University; and Thomas P. Hoar, Cambridge University.

Sections, Divisions, and members of the Society are invited to send suggestions for candidates, accompanied by supporting information, to Mr. Ernest G. Enck, Executive Secretary, The Electrochemical Society, 30 East 42nd St., New York, N. Y. 10017, for forwarding to the Committee Chairman. Deadline for submission of suggestions is August 31, 1971.

BOOK REVIEWS

"Thin Film Technology," by R. W. Berry, P. M. Hall, and M. T. Harris. Published by D. Van Nostrand Co. Inc., Princeton, N. J., 1969. 206 pages; $15.00.

"Thin Film Phenomena," by K. L. Chopra. Published by McGraw-Hill, New York, 1969. 793 pages; $24.50.

Both of the above books are introductions in a way to thin film activities. The former, prepared by the staff of Bell Telephone Laboratories, is perfect for the novice who wishes to engineer a thin film operation. Bare on fundamentals but heavily loaded with specific equations for various topics, it covers the entire gamut, in a surface manner, from the vacuum system itself to generation of the film assembly line. As such it is excellent, but it only covers the thin film capacitors and resistors with its main emphasis on tantalum components. It is, in essence, an engineering manual.

The latter book, by Chopra, could be considered a manual also—but of a different type. Dr. Chopra collects all the phenomena that could occur in thin films, their properties and their experimental aspects, briefly and sparsely covers them and then presents a fantastic amount of references (over 2000). The book is really an encyclopedia of phenomena, techniques and properties. As such it is a surface coverage for someone wishing to enter into thin film research.

Both books serve useful functions. However, I prefer the series on "Physics of Thin Film" published by Academic Press as a more comprehensive starting point.

Growth Processes of the Anodic Crystalline Layer on Potentiostatic Oxidation of Lead in Sulfuric Acid

D. Pavlov and N. Iordanov

Institute of Physical Chemistry, Division of Electrochemical Power Sources, Bulgarian Academy of Sciences, Sofia-13, Bulgaria

ABSTRACT

The dependence of the composition of the anodic layer, the electric capacity, and the current on the quantity of electricity passed on potentiostatic oxidation of lead in sulfuric acid are investigated. Oxidation runs were performed in the lead sulfate, the lead oxide, and the lead dioxide potential regions. It was established that at all oxidation potentials the electrode is passivated by the formation of a dense crystalline layer after passing a given quantity of electricity. Subsequently this layer grows. If the oxidation takes place in the lead oxide region, tetragonal PbO and basic lead sulfate form during the growth of the anodic layer. On oxidation in the lead dioxide region, tetragonal PbO and α-PbO_2 form in the deposit (at -950 mV with respect to the Hg/Hg_2SO_4 electrode). At $+1000$ and $+1100$ mV after the formation of α-PbO_2, $PbSO_4$ is oxidized to β-PbO_2. The change in the composition on oxidation is due to change in ionic conductivity between the $PbSO_4$ crystals. When the current through the anodic layer begins to be transported by O^{2-} at the lead/anodic layer interface, tetragonal PbO is formed. If the oxidation potential exceeds $+950$ mV, α-PbO_2 forms in addition to the tetragonal monoxide. At potentials more positive than $+1000$ mV, the solute Pb^{2+} ions are oxidized to β-PbO_2 at the α-PbO_2/solution interface.

During anodic oxidation of lead in sulfuric acid an insoluble layer is formed whose composition depends both on the potential and the quantity of electricity. In the region lying between the equilibrium potentials of the $Pb/PbSO_4$ and $PbSO_4/PbO_2$ electrodes Lander (1) found tetragonal PbO and explained the formation of this compound in terms of a solid-state reaction between PbO_2 and Pb. Burbank (2) suggested a model of the structure of the anodic layer depending on the oxidation potential. At high oxidation potential Ruetschi and Cahan (3) established the alpha polymorph of PbO_2 and found that $PbSO_4$ is oxidized to β-PbO_2. Ruetschi and Angstadt (4) introduced layers of lead basic sulfates in the model of the anodic deposit. In a previous work (5) we determined the dependence of the composition of the anodic layer on the oxidation potential of the electrode. According to the phases present the potential interval lying between the equilibrium potential of the $Pb/PbSO_4$ electrode -956 mV and $+1400$ mV (with respect to the Hg/Hg_2SO_4 electrode) can be divided into three regions: (*a*) lead sulfate region between -950 and -300 mV. The anodic deposit is constituted by $PbSO_4$ crystals; (*b*) lead oxide region from about -300 to about $+900$ mV. The deposit contains tetragonal PbO and $PbSO_4$ in commensurable amounts as well as minor amounts of basic sulfates of lead; and (*c*) lead dioxide region above approximately $+950$ mV. The anodic layer is built up mainly by the two polymorphs of PbO_2.

Key words: lead sulfate electrochemical formation, lead oxide electrochemical formation, lead dioxide electrochemical formation, lead oxide/lead sulfate layers ionic conductivity, lead oxide/lead sulfate layers x-ray analysis.

In order to elucidate the processes which take place on anodic polarization of the lead electrode in sulfuric acid, it is also necessary to establish the dependence of the composition of the anodic layer on the quantity of electricity passed at constant oxidation potential. This dependence is controlled by the processes which take place on growth of the crystalline anodic layer. This is the purpose of the present paper.

Methods

The following parameters were measured during the potentiostatic oxidation of the lead electrode in sulfuric acid: composition of the anodic layer, current and electric capacity of the electrode. The change in the electrode potential was followed during the first 2 min after interrupting the polarization. The anodic layer was observed by electron microscopy at the end of the measurement.

High-purity 99.9999% lead electrodes with dimensions 16 x 11 x 1 mm were subjected to oxidation in analytical grade electrochemically purified 1*N* H_2SO_4 at 25°C. The oxidation was performed by means of an electronic potentiostat IP-410B Elektroimpex. The electrode potential was measured with respect to a Hg/Hg_2SO_4 electrode by means of a CP-2 voltmeter, Elektroimpex. All values of the electrode potential will be thereafter given with respect to this particular reference electrode. The current and the quantity of electricity were continuously recorded by means of a combined potentiometer-coulometer Goerz R-512.

The determination of the electrode capacity during the potentiostatic oxidation was effected by the method suggested by Pangarov, Christova, Atanasov,

and Kertov (6). To this effect potentiostatic pulses from an IG-3 generator constructed in this Institute were fed to the input of the potentiostat. By means of a C-1-15 oscillograph the quantity of electricity passed either during the potentiostatic pulse or on interrupting the pulse was recorded. The measurement of capacity of the electrode prior to oxidation was performed by applying single rectangular galvanostatic pulses of a duration of 20 μsec. The capacity was determined from the slope of the pulse transient (7). The block diagram of the electric circuit is given in Fig. 1.

The phases present were identified by x-ray diffraction. A Müller Mikro 111 diffraction unit was used. The diffraction patterns were recorded with filtered copper radiation and with the following goniometer settings: goniometer speed 2° 2θ/min, and slits 1°/1°/0.1 mm. The diffractometer traces were measured down to d = 1.60Å. The intensities were measured by the area under the peaks. The x-ray identification of the composition of the anodic layer was performed after 1, 10, and 30 min and 1, 3, 6, 20, 40, and 72 hr potentiostatic oxidation runs. To this effect the electrode was removed from the electrolytic cell, washed, x-rayed, after which the oxidation was continued. This way of determining the composition was adopted after several trial runs which showed that no changes occurred in the phases present during washing and recording of the x-ray diffraction pattern.

After completion of the oxidation at a given potential and after recording the x-ray pattern the electrode was shaded by the platinum-carbon replica technique. The replicas were stripped using a 40% solution of ammonium acetate and observed under the electron microscope Zeiss EF-4.

Experimental Results

Lead sulfate region.—Oxidation runs were performed at −900 and −500 mV. All diffraction lines of the powder pattern of lead sulfate appeared in an interval up to the thirtieth minute. From Fig. 2, it is seen that the intensity increase of the lead sulfate lines is accompanied by a decrease of the lead lines due to the increase in the thickness of the lead sulfate layer.

The capacity and current changes as a function of the quantity of electricity at −500 mV are represented in Fig. 3. Two characteristic stages are observed on the capacity curve. In the first initial stage (ab) the capacity rapidly falls down to 4-5 μF/cm^2. During this stage the electrode is passivated by the anodic layer formed. During the second stage (bc) a slow decrease in capacity and current occurs down to comparatively constant values. At the same time the thickness of the anodic layer increases.

After interrupting the polarization the electrode potential immediately falls down to the Pb/$PbSO_4$ equilibrium potential.

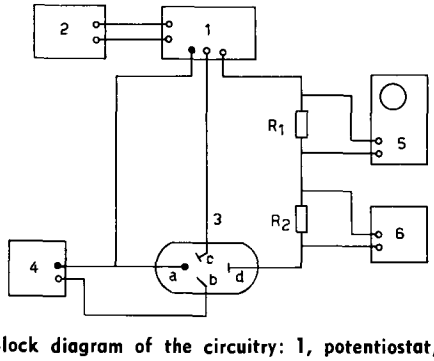

Fig. 1. Block diagram of the circuitry: 1, potentiostat; 2, pulse generator; 3, electrolytic cell (a) working lead electrode, (b) reference Hg/Hg_2SO_4 electrode, (c) reference Pb/$PbSO_4$ electrode, (d) Pt counterelectrode; 4, valve voltmeter; 5, oscillograph; 6, potentiometer-coulometer.

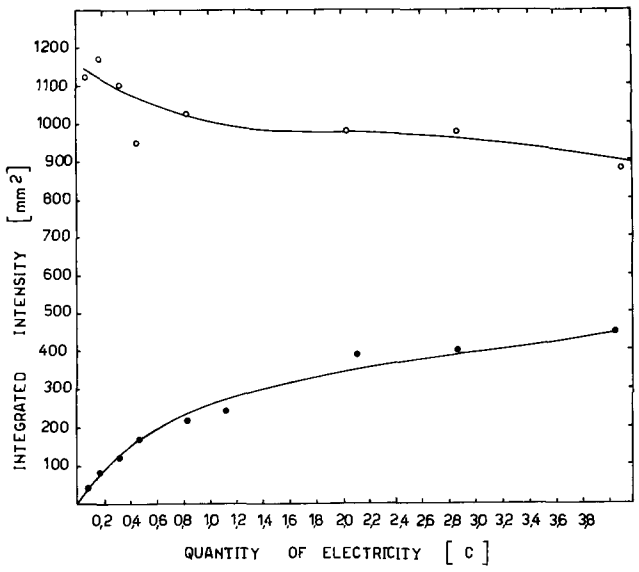

Fig. 2. Change in intensity of diffraction lines of $PbSO_4$ with d = 3.00Å (●) and of Pb with d = 2.85Å (○) as a function of the quantity of electricity after oxidation at −500 mV.

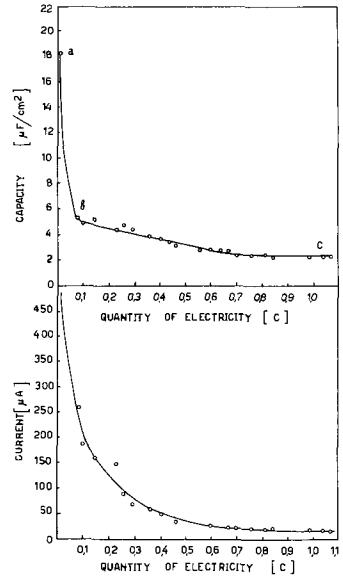

Fig. 3. Change in electrode capacity and current during oxidation at −500 mV.

An electron micrograph of the anodic layer is given in Fig. 4. The deposit is built up by well-defined crystals of different sizes.

Lead oxide region.—Oxidation runs were performed at −200, 0, +300, +700, and +900 mV. The change in the amounts of the phases present in the anodic layer was determined from the changes in the intensities of their diagnostic diffraction lines: for $PbSO_4$, d = 3.00 and 3.33Å (10); for Pb, d = 2.85 and 2.45Å; for tetragonal PbO, d = 3.12Å, 2.80[1] and 1.68Å (5, 11); for PbO·$PbSO_4$, d = 2.95Å (10, 5); for 5PbO·2H_2O, d = 3.08Å (12, 11, 5). The majority of these diagnostic diffraction lines occur in a relatively restricted interval of d-spacings between 2.70 and 3.20Å. Portions of diffraction patterns taken in this interval at different potentials and as a function of the oxidation time (up to 20 hr) are represented in Fig. 5. Only the lower portions of the diffraction peaks are represented since our interest was directed mainly toward the time at which the various compounds ap-

[1] As shown in ref. (5) the intensity of this particular diffraction is enhanced and dominates in the pattern owing to preferred orientation.

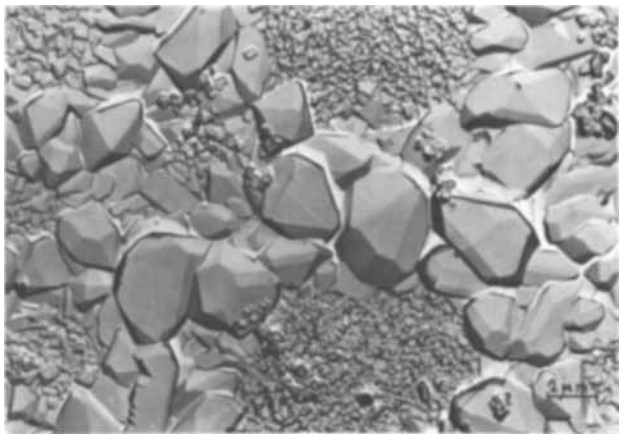

Fig. 4. Electron micrograph of the anodic layer after oxidation at −900 mV. 6500X.

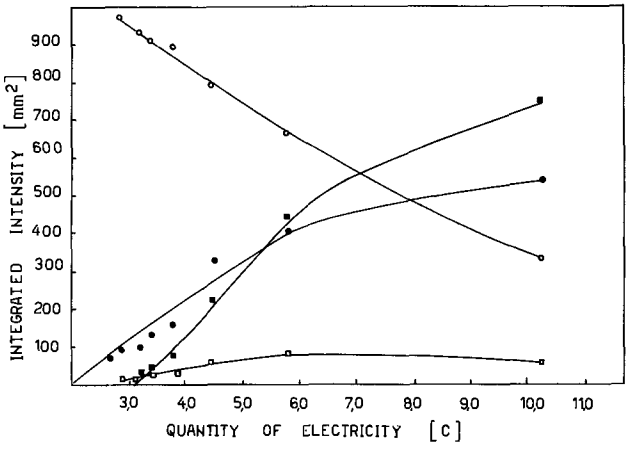

Fig. 6. Change in intensity of diffraction lines of $PbSO_4$ with d = 3.00Å (●), of Pb with d = 2.85Å (○), of tetragonal PbO with d = 2.80Å (■), and of $PbO \cdot PbSO_4$ with d = 2.95Å (□) as a function of the quantity of electricity after oxidation at +300 mV.

pear. Lead sulfate crystals appear during the first minute of the oxidation process. The amount of this compound increases with time. Concomitantly at −200 mV monobasic lead sulfate and tetragonal PbO appear at the sixth hour. The amounts of these compounds in the anodic deposit remain small as compared to that of $PbSO_4$ even after the seventieth hour. Monobasic lead sulfate begins to form at 0 mV after 1-hr oxidation, while after 3 hr tetragonal PbO appears and increases predominantly. At +300 mV monobasic lead sulfate, $5PbO \cdot 2H_2O$ and tetragonal PbO appear at the tenth minute. After a 1-hr polarization the amount of tetragonal PbO rapidly increases. After passing 5-6 coulombs the amounts of $PbSO_4$ and tetragonal PbO become commensurable (Fig. 6). The change in the composition of the anodic layer at +700 and +900 mV (Fig. 5) is similar to that observed at +300 mV, but $PbO \cdot PbSO_4$ appears at the first minute as well as two diffraction lines with interplanar spacings 3.16 and 2.73Å belonging to an unidentified compound. The remaining lines of this compound probably coincide with those of $PbSO_4$. These lines disappear after a 1-hr oxidation. At these potentials the formation of tetragonal PbO becomes the main process after 1 hr. The results obtained show that with the increase of the potential toward the more positive values the time elapsed before the formation of tetragonal PbO

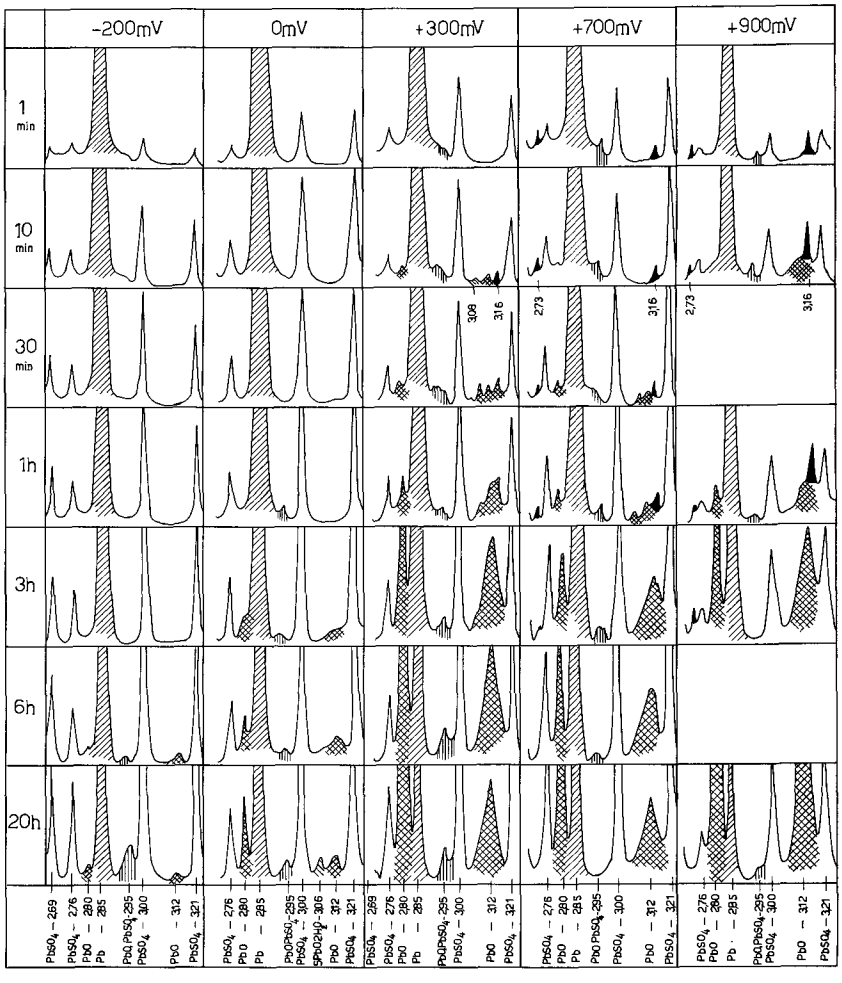

Fig. 5. Portions of diffraction patterns at various potentials after different oxidation times in the lead oxide region.

decreases. The formation of this compound is accompanied or preceded by that of monobasic lead sulfate. Whereas tetragonal PbO begins to predominate the monobasic sulfate remains constant.

From −200 to +900 mV the dependence of the capacity and current on the quantity of electricity passed is similar to that observed at −500 mV but the values are lower. After passing 4-5 coulombs the capacity reaches 0.1-0.3 μF/cm^2.

After interrupting the polarization the electrode potential falls down to the region of the equilibrium potentials of the basic sulfates in 1N H_2SO_4.

Fig. 7 represents an electron micrograph of the anodic layer after oxidation at a potential of +300 mV.

Lead dioxide region.—The change in composition and in capacity was studied at the following potentials: +950, +1000, +1100, +1200, +1300, and +1400 mV. In this potential interval the time for which the electrode acquired the given potential was 3-4 sec.

During the first minutes of oxidation at +950 mV the composition is similar to that found at +700 and +900 mV (Fig. 5). A lead sulfate layer is formed which contains monobasic lead sulfate as well as the unidentified lead compound with diffraction lines d = 3.16 and 2.73Å. After about an hour tetragonal PbO and α-PbO_2 d = 3.12 and 1.84 (13) also appear. The formation of PbO_2 at +950 mV was confirmed by the chemical analysis of the layer. From Fig. 8 it is seen that after passing 2 coulombs three processes occur simultaneously at the electrode. As a result the deposit contains $PbSO_4$, α-PbO_2, and tetragonal PbO. Figure 9 depicts the change in capacity and current changes during the oxidation. After switching on the polarization the electrode capacity falls immediately down to 2.0 μF/cm^2 and remains constant up to 0.25 coulombs of electricity. Subsequently the capacity rapidly increases. The x-ray data indicate that after 2 coulombs a new phase, α-PbO_2, appears. Taking into account the electronic conductivity of α-PbO_2 and the higher sensitivity of the capacity method as compared to x-ray diffraction, it is clear that the increase in capacity is due to the formation of α-PbO_2.

The appearance of the anodic layer obtained on oxidation at +950 mV is shown on Fig. 10. Since lead dioxide is insoluble in ammonium acetate it remains on the replica and is seen on the micrograph as a black deposit.

During the first minutes of the oxidation at 1000-1100 mV the composition is analogous to that found at +950 mV. After 1 coulomb α-PbO_2 and tetragonal PbO form in the anodic layer (Fig. 11). After 18 coulombs β-PbO_2 is detected by diffraction lines d =

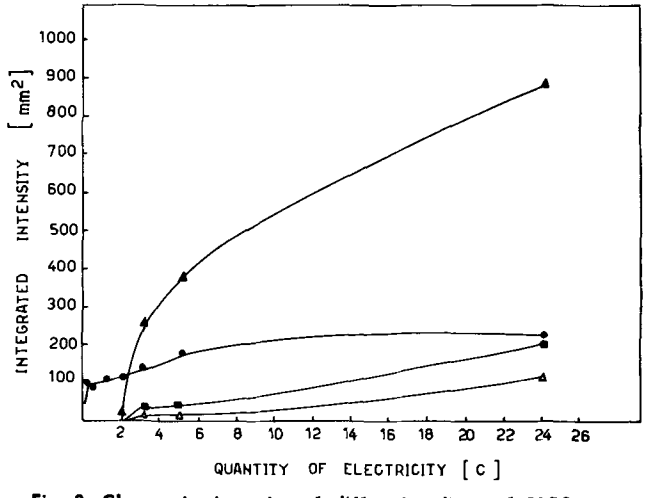

Fig. 8. Change in intensity of diffraction lines of $PbSO_4$ with d = 3.00Å (●); of tetragonal PbO with d = 2.80Å (■); of α-PbO_2 with d = 1.84Å (△), and d = 3.12Å (▲) overlapping with tetragonal lead monoxide as a function of the quantity of electricity after oxidation at +950 mV.

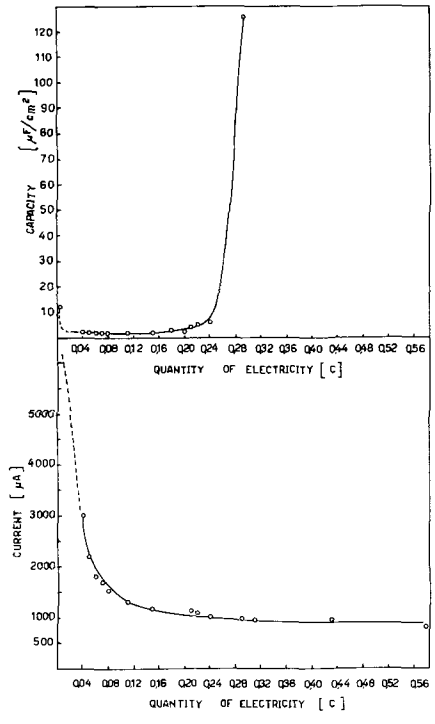

Fig. 9. Change in electrode capacity and current during oxidation at +950 mV.

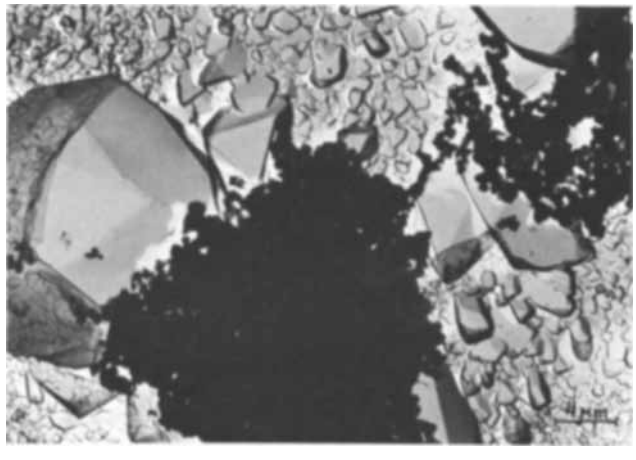

Fig. 10. Electron micrograph of the anodic layer after oxidation at +950 mV. 4000X.

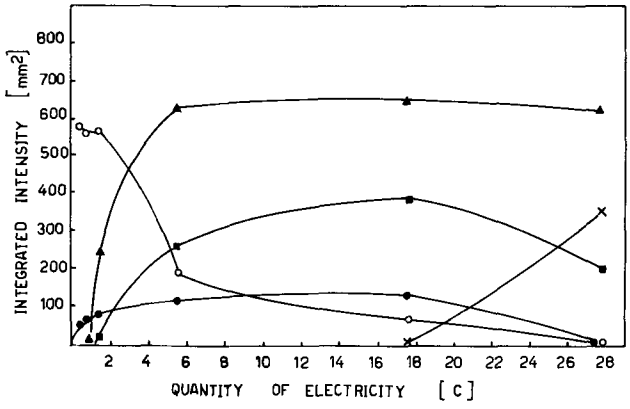

Fig. 11. Change in intensity of diffraction lines of $PbSO_4$ with d = 3.00Å (●); tetragonal PbO with d = 2.80Å (■); of Pb with d = 2.85Å (○); β-PbO_2 with d = 3.50Å (X) and α-PbO_2 and tetragonal PbO with d = 3.12Å (▲) as a function of the quantity of electricity after oxidation at +1000 mV.

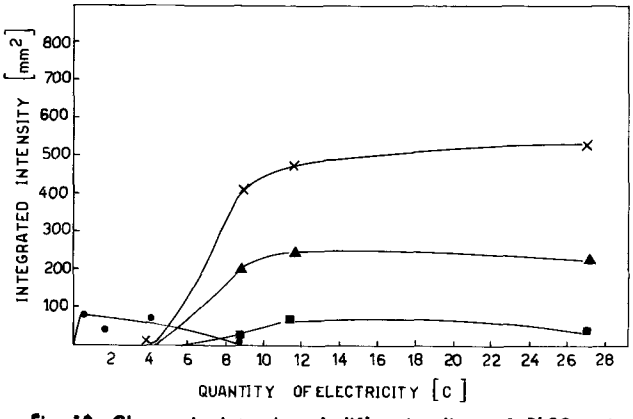

Fig. 12. Change in intensity of diffraction lines of $PbSO_4$ with d = 3.00Å (●); tetragonal PbO with d = 1.68Å (■); β-PbO_2 with d = 3.50Å (X); α-PbO_2 and tetragonal PbO with d = 3.12Å (▲) as a function of the quantity of electricity after oxidation at +1200 mV.

3.50 and 2.78Å, while the line with d = 1.84Å (13) increases. With the progress of the oxidation the amount of β-PbO_2 increases while those of $PbSO_4$ and tetragonal PbO decrease. After 28 coulombs the anodic layer contains α-PbO_2, β-PbO_2, and tetragonal PbO.

Between +1200 and +1400 mV the composition in the first minute of the oxidation is similar to that at +950 mV. After about 4 coulombs α-PbO_2, β-PbO_2, and tetragonal PbO form almost simultaneously (Fig. 12). The sulfate formed at the beginning is oxidized to β-PbO_2 much more rapidly than at +1000 mV. The amount of lead sulfate oxidized is substantially smaller than the β-PbO_2 formed. This means that β-PbO_2 does not form at the expense of $PbSO_4$ only. Tetragonal PbO does not form at +1300 and +1400 mV. At +1300 mV intensive oxygen evolution occurs after 1.6 coulombs when the anodic layer is constituted only by α- and β-PbO_2.

Figure 13 illustrates the capacity and current changes as a function of the quantity of electricity. At higher potentials the time interval elapsed before the increase in capacity becomes shorter. During its increase the capacity reaches values which cannot be accurately determined by the method used. A well-defined maximum is observed on the i/t curve at oxidations above +1200 mV,[2] after the formation of α-PbO_2.

The electron micrograph on Fig. 14 shows the appearance of the lead dioxide at oxidation potential

[2] On repeated oxidation and reduction a maximum in the i/t curves is observed at potentials higher than +1000 mV (17).

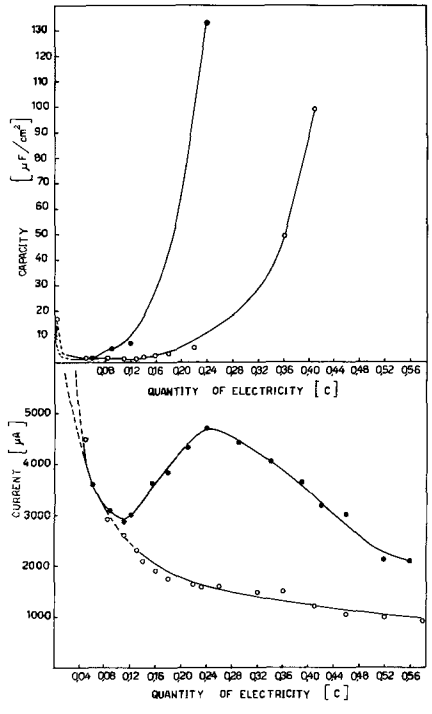

Fig. 13. Change in electrode current and capacity during oxidation at +1000 mV (○) and +1200 mV (●).

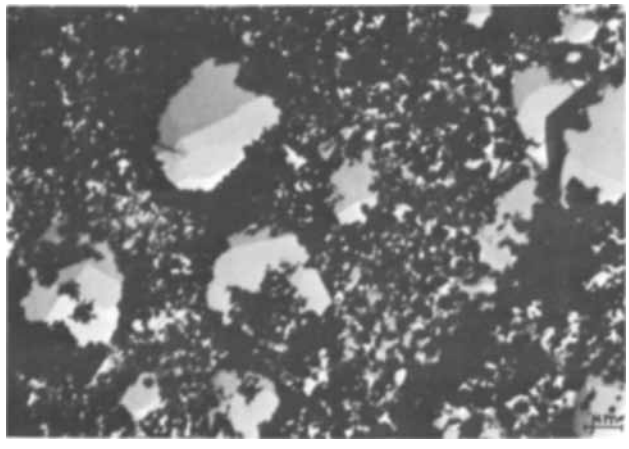

Fig. 14. Electron micrograph of the anodic layer at +1300 mV. 1000X.

+1300 mV. Since the oxidation was interrupted at the beginning of the formation of PbO_2 it is obvious that this compound forms in the intercrystalline spaces left between the $PbSO_4$ crystals.

Discussion of Results

Passivation of the electrode.—On anodic polarization of the electrode at small overvoltages lead is oxidized to Pb^{2+} ions which give, together with the sulfate ions in the solution, $PbSO_4$ crystals. The growth of the lead sulfate crystals hinders the motion of the SO_4^{2-} flow toward the lead surface. The flow of lead ions generated at the lead surface remain uncompensated in the intercrystalline spaces. To remain electroneutral the solution between the crystals is alkalinized and basic sulfates form as a consequence. Thus a continuous dense layer constituted by lead sulfate crystals connected by basic sulfate is formed. This layer passivates the electrode. The time of formation of a dense layer constitutes the passivation stage of the potentiostatic oxidation. These processes were studied in some detail in a previous work (7).

At a given moment of the passivation stage the capacity, C_t, per unit area represents the sum of three

terms: the capacity of the portion of the area, θ_1, occupied by $PbSO_4$ crystals, the capacity of the intercrystalline spaces occupied by basic sulfates, and the capacity of the intercrystalline spaces where the solution is in contact with lead. Therefore the total capacity is given by the equation

$$C_t = \theta_1 \frac{\epsilon_1}{4\pi d_1} + \theta_2 \frac{\epsilon_2}{4\pi d_2} + (1 - \theta_1 - \theta_2) Cd$$

where θ_2 is the portion of the surface occupied by intercrystalline basic sulfates, ϵ_1 and ϵ_2 are the dielectric constants of $PbSO_4$ and the basic sulfates, respectively, and d_1 and d_2 are their effective thicknesses. Cd is the capacity of the double layer at the lead/solution interface. On switching on the polarization the last term in this equation is largest. During oxidation this value rapidly decreases (Fig. 3 ab). It becomes zero when the electrode is covered by a continuous anodic layer. After passivation of the electrode the capacity slowly decreases (Fig. 3 bc). This is brought about by the increase in the effective thickness of the $PbSO_4$ crystals and of the basic sulfate connections between them.

The passivation stage of lead oxidation in sulfuric acid is determined by the quantity of electricity required for building the dense anodic layer. During this period the initial current depends on the overvoltage of the electrode, that is, on the difference between the oxidation potential and the equilibrium potential of the $Pb/PbSO_4$ electrode. The increase in overvoltage gives rise to an increase in the initial current and to a decrease of the duration of the passivation stage. Passivation times and current reach values which exceed the upper limit of the possibilities afforded by modern potentiostats:[3] response time 1-2 μsec at current 10-50 mA.

At overvoltages higher than 1.5V at the first moment the current reaches several hundreds of milliamperes which cannot be accepted by the potentiostat. Thus the passivation stage proceeds at potentials more negative than that fed to the potentiostat. Therefore, x-ray data show that on oxidation above +700 mV (Fig. 8, 11, 12) in the first minute of the run the anodic deposit is constituted by $PbSO_4$ even when the electrode is polarized at potentials lying in the lead dioxide region. After passivation the current decreases and the oxidation takes place at the potential fed to the potentiostat. This potential determines the growth processes of the dense anodic layer.

Growth of the anodic layer.—The object of the present investigation is the study of the changes in the phase composition during the growth of the anodic layer. The growth of the dense anodic layer is determined by its ionic conductivity. It is complicated by the processes of transition through the lead/anodic layer and anodic layer/sulfuric acid interfaces. Owing to the crystallinity of the deposit the ionic conductivity may be achieved in two ways: through the lattice of the lead sulfate crystals and through the basic sulfates connecting them. The lead sulfate crystals are of various sizes. This means that the intensity of the electric field at every point of the anodic layer will be different. The distance between the lead surface and the solution is the smallest in the intercrystalline spaces where the intensity of the electric field is therefore largest. Owing to the very complex conditions of formation of the basic sulfates the latter have probably imperfect structures. These features of the anodic layer require that the motion of the ions take place only through the intercrystalline spaces. This is confirmed by the electron micrograph taken by Grauer, Wehr, and Engel (15) of a lead surface after oxidation in concentrated sulfuric acid and at high temperature. It is seen there that the dissolution of lead occurs at the boundary of the lead sulfate crystals.

[3] This type of potentiostats was used in (14, 4) as well as in the present work.

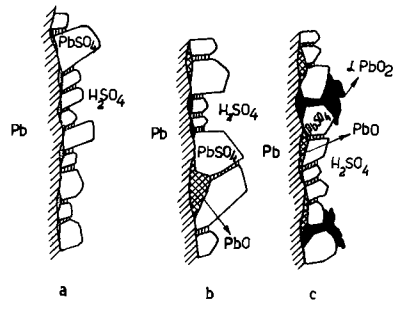

Fig. 15. Model of the anodic layer *(a)* in the lead sulfate region, *(b)* in the lead monoxide region, *(c)* in the lead dioxide region (+950 mV).

The ions which can move upon oxidation up to +900 mV are Pb^{2+} and Pb^{2-}.[4] These ions have equal charges and the same Goldschmidt radii of 1.32Å. The SO_4^{2-} ions have a radius of 2.30Å, *i.e.*, they are very large and do not participate in the current transport through the layer.

Pb^{2+} ions are formed at the lead/anodic layer interface. Under the action of the electric field they reach the second interface and return to the solution. Since the solution is saturated with respect to $PbSO_4$ the Pb^{2+} ions diffuse to the growth front of some of the lead sulfate crystals and are incorporated in it. The ionic current is very small. Therefore the supersaturation of the solution at the surface of the lead crystals is small and the latter have very well-defined faces (Fig. 4 and 7). Owing to these processes of transport of Pb^{2+} through the anodic layer, microvoids are formed between the lead sulfate crystals and the lead surface (Fig. 15a). This gives rise to mechanical stresses in the anodic layer. Under their action some of the lead sulfate crystals are displaced. Sulfuric acid permeates through them and thus reaches the lead surface. Intensive dissolution begins and lead sulfate forms. During growth the lead sulfate crystals come once more closer to one another and the access of the acid to the metal is interrupted. Short abrupt rises in current were observed in the lead sulfate potential region.

The direction of the motion of the O^{2-} ions in the anodic layer is inverse to that of Pb^{2+}. The oxygen ions pass from the solution into intercrystalline spaces. Under the action of the field the O^{2-} ions reach the lead surface. The last stage is related either with the transition of Pb^{2+} which form PbO with the O^{2-} ions or with the inclusion of O^{2-} in the lattice of lead where PbO is also formed. Bode and Voss (16) stressed the close similarities in the structures of lead, tetragonal PbO, and α-PbO_2. The O^{2-} may travel the way indicated in the presence of a corresponding potential drop at the two interfaces and in the layer. Such a drop is created if the electrode has a potential more positive than the given value. This determines the limit between the lead oxide and lead sulfate potential regions. The x-ray diffraction patterns of the anodic layer showed that finely crystalline tetragonal PbO forms above −200 mV.

From Fig. 5 it is seen that the formation of tetragonal PbO becomes the main process after passing a certain quantity of electricity. The detection limit by x-ray diffraction is about a few per cent. Therefore this method is unable to reveal the actual processes taking place at the beginning of the oxidation. Between −200 and +900 mV there is probably at the beginning of the oxidation an ionic current due to the oxygen ions. Therefore the transference number of the Pb^{2+} ions is smaller than unity. During a given time interval this oxygen component of the ionic current brings changes in the structure and composition of the

[4] The solute OH^- ions at the anodic layer/solution interface evolve H^+.

basic sulfates between the $PbSO_4$ crystals. In addition, lead oxide compounds are formed at the metal/anodic layer interface. This change in the nature of the interface and in the structure of the basic sulfates leads to changes in the ionic conductivity. As a result the transference number of O^{2-} increases and that of Pb^{2+} decreases. The formation of tetragonal lead monoxide becomes the main process (Fig. 5 and 6). The appearance and growth of tetragonal PbO underneath the $PbSO_4$ crystals creates internal stresses in the crystalline anodic layer. Under their effect some of the lead sulfate crystals are displaced with respect to one another. The distance between them increases. This makes it possible for the sulfuric acid to intrude between these crystals. The pH decreases. Monobasic lead sulfate and tetragonal PbO are dissolved. The solution becomes supersaturated with respect to Pb^{2+} and SO_4^{2-}. This leads to the further growth of the $PbSO_4$ crystals. The distance between them once again decreases down to sizes which block the flow of sulfuric acid between the crystals. The dissolution of tetragonal PbO stops. Thus the $PbSO_4$ crystalline layer protects the lead monoxide layer from the acid. A two-layer anodic deposit is formed (Fig. 15 b).

As already mentioned, on oxidation at potentials lying in the lead dioxide region first a layer made up of normal and basic lead sulfates is formed owing to the limitations of the potentiostat. Subsequently these compounds as well as the lead are oxidized to lead dioxide (Fig. 11 and 12). In addition another electrochemical reaction takes place, namely oxidation of the OH^- ions of the solution to O_2. This substantially complicates the mechanism of the processes occurring at the electrode and hampers their study.

There are two polymorphs of PbO_2: orthorhombic (α) which is formed on electrolysis from neutral and alkaline solutions and tetragonal (β) obtained in acid solutions. Both polymorphs are electronic conductors.

Tetragonal PbO and α-PbO_2 are simultaneously formed in the anodic layer at +950 mV after a given oxidation time (Fig. 8). This process takes place at given locations of the lead/anodic layer interface (Fig. 10). Since this interface is isolated from the acid the α-polymorph of lead dioxide is formed. The new phases create internal stresses in the anodic deposit which disturb the overlying lead sulfate crystals. Since α-PbO_2 is insoluble in sulfuric acid a new durable interface occurs (Fig. 15c, 10). The total capacity C_t in this case is determined from the expression

$$C_t = C_1 + C_2 + S_t C_{d^1}$$

where C_1 is the capacity of the $PbSO_4$ crystals, C_2 is the capacity of the intercrystalline spaces occupied lead monoxide and basic sulfates, and S_t is the area of the α-PbO_2/H_2SO_4 interface which is in electronic contact with Pb. C_{d^1} is the capacity of the electrical double layer of this surface.

When α-PbO_2 comes into contact with the sulfuric acid the third term of the equation acquires its largest value and becomes capacity-determining. With the proceeding of the oxidation S_t and the total capacity increase (Fig. 9). From the same figure it is easily seen that the current is small and does not change as a result of the formation of alpha lead dioxide. This means that only ionic current passes through the anodic layer as is the case in the lead oxide region.

At potentials more positive than 1000 mV oxidation of Pb^{2+} to Pb^{4+} takes place at the α-PbO_2/electrolyte interface. Since the oxidation is performed in acid medium the β-polymorph of PbO_2 appears (Fig. 11). This process introduces an electronic component of the current which passes through the α-PbO_2 of the anodic layer. With the increase in potential the formation of β-PbO_2 is accelerated (Fig. 12).

Figure 12 shows that the amount of β-PbO_2 is substantially larger than that of the oxidized $PbSO_4$ and tetragonal PbO. This leads to the assumption that prior to the beginning of the oxygen evolution process an ionic current of Pb^{4+} passes through the anodic layer which gives rise to β-PbO_2 at the solution interface. Pb^{2+} ions do not form at these strong high positive potentials. At more positive potentials the ionic Pb^{4+} component of the current is larger while the O^{2-} current, the amount of α-PbO_2, is smaller (Fig 11, 12). An intensive oxygen evolution process begins at potentials more positive than +1200 mV after the formation of the lead dioxide layer. The potential gradient in the layer strongly decreases and tends to zero. Ionic current flows only by diffusion through the layer. The oxygen evolution processes as well as the oxidation of lead through a PbO_2 layer (steady-state corrosion of lead) will be dealt with in future work.

Anionic Inhibition in Electroless Plating

N. Feldstein,* and P. R. Amodio

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

The incorporation of a specific class of oxy-anions in electroless plating baths reveals that above a certain critical concentration limit, a drop in the plating rate takes place. The critical concentration for a specific anion is primarily proportional to those parameters which affect the bath's reactivity. Adsorption of the anions at the electrode-solution interface along with a chemical interaction between the adsorbed layer and the reducing agent is proposed to account for the inhibition effect.

The phenomenon of electroless plating of metals may be best defined as an autocatalytic chemical reduction taking place at heterogenous interfaces. Due to its catalytic and heterogenous character, it is well documented that trace additives may alter the plating process, either to accelerate or decrease the plating rate. Typically, it has been reported (1) that heavy metal ions, such as Pb^{++}, Cd^{++}, and others, as well as sulfur-containing compounds, tend to poison this autocatalytic process. With respect to anionic poisoning, it has been reported that thiocyanate (CNS^-) and cyanide (CN^-) in trace quantity exhibit an inhibiting effect. It has been observed in our laboratory that the presence of nitrate and other oxy-anions may also inhibit electroless plating. The effect was reversible; *i.e.*, samples which did not plate in a nitrate-containing bath would begin plating immediately when immersed in a bath from which nitrate was absent.

This investigation was undertaken to develop a model to account for the inhibition effect and also to test the proposed model against currently accepted theories of electroless plating.

Experimental Procedures

Chemicals.—All chemicals used in preparing the plating solutions with or without the additives were reagent grade. The water used was deionized and then distilled.

Rate.—For comparison of the relative effect(s) of the various anions, standard 2 x 2 in. alumina substrates (American Lava Corporation No. 614 plain) having a geometrical surface area of 52 cm^2 were used. These substrates had a 40 μin. surface roughness. Volume of solutions was held at 200 cc unless otherwise stated. Electroless plating on these substrates was carried out following a tin-palladium sensitization and activation sequence and the weight gain during plating was recorded. No agitation was provided during the plating.

The plating time in all cases was chosen as 10.0 min unless otherwise stated and the temperature was maintained at 25.0° ± 0.1°C. Due to the visible nonuniformities of plating (especially under inhibited conditions) as well as slight variations in induction time, the results are presented as the weight gain per standard area (52 cm^2) for a constant plating time of 10 min. For most of our work, a room temperature electroless Ni-P (2) bath having the following composition was employed: $NiSO_4$, 0.095M; NaH_2PO_2, 0.24M; $Na_4P_2O_7$, 0.11M; and NH_4OH (2.64M), 70 cc/liter. Some of the unique characteristics of this plating bath include: (*I*) The plating rate is strongly dependent on the ammonia content, rising rapidly at first and then falling slowly as the ammonia content increases further. (*II*) Over the *p*H range 9.0-11.5, the plating rate is independent of *p*H, provided the ammonia content is constant. (*III*) For the composition given above, the plating rate is dependent on the hypophosphite ion concentration but independent of the nickel ion concentration.

The inhibition effect for the bath was first checked as a function of the bath composition: *i.e.*, hypophosphite concentration, ammonia content, and *p*H. The *p*H was varied by either changing the ammonia content or maintaining the ammonia content fixed and adding alkali hydroxides.

In monitoring the hydrogen evolved, hydrogen was collected via a simple displacement apparatus. Prior to each run, the plating solution (approximately 500 cc) was saturated with hydrogen. The 2 x 2 in. ceramic substrates mentioned above were used for this work.

Potential measurements.—Potential measurements were carried out using a recording potentiometer. All steady-state potentials (mixed potentials) were obtained using freshly deposited nickel electrodes against SCE at 25°C. Potential measurements were obtained as the concentration of a specific anion varied.

The nitrate activity for different initial concentration levels (10^{-2}-10^{-1}M) was monitored as function of time using a nitrate specific ion electrode (product of Orion Research Model 92-107).

Results and Discussion

Figure 1 shows the over-all inhibition effect associated with each of the oxy-anions. From the results, it can be seen that these anions show inhibition at different concentration levels, leading to the following sequence

Group I: AsO_2^{-1}, IO_3^{-1}, NO_2^{-1}, BrO_3^{-1}, and NO_3^{-1}

The order assigned in group I corresponds to the increasing bulk concentrations required to give inhibition. With the oxy-anions of group II, no inhibiting effects were noted employing concentrations up to 1M.

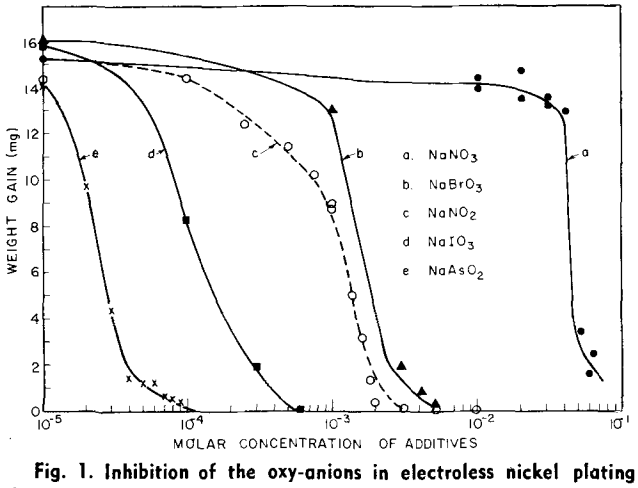

Fig. 1. Inhibition of the oxy-anions in electroless nickel plating bath.

* Electrochemical Society Active Member.

Group II: SO_4^{-2}, HPO_3^{-2}, CHO^{-1}, ClO_3^{-1}, ClO_4^{-1}, AsO_4^{-3}, PO_4^{-3}, CO_3^{-2}, and others

All of the oxy-anions of group I with the exception of the nitrate may be classified as "soft" bases (3), while members of group II are all "hard" bases. Soft bases have donor atoms which are generally easily polarized and oxidized, and are of low electronegativity. Nitrate, the exception, must be present in high concentration in order to yield the inhibiting effect. According to Pearson metal atoms and bulk metals may be classified as soft acids. From the general rule (3) of acid-base interaction, soft pairs have the greatest tendency to interact. On this basis it might be anticipated that soft bases interact with the metallic substrate in an adsorption-type reaction and as a consequence would affect the catalytic nature of the surface. It is interesting to note that the order of effectiveness among the oxy-anions (group I) follows their order of basicity (or degree of softness).

Since the nitrate anion causes the inhibiting effect at a fairly high concentration (10^{-2}-10^{-1}M), its activity for various initial concentrations was monitored as function of time employing a suitable specific ion electrode. This examination was carried out over an interval of several hours with suitable substrates in the plating bath. No change in the nitrate activity was observed. Hence a competing chemical or electrochemical reduction that consumes the nitrate, hindering the main electroless plating process, can be ruled out. Thus the nitrate anion must cause the inhibition through an interfacial adsorption mechanism, even though the interaction is not strong.

With inhibited solutions, if I^-, Br^-, or AsO_4^-, are added, the inhibiting effect can be reversed with I^- addition, but only where NO_3^- or IO_3^- are the inhibitors, provided a thin nickel layer is present on the surface. In other words, the plating rate of a solution inhibited with either nitrate or iodate can be raised greatly if I^- is added to the bath. Typically, it was found that solutions having 8 x 10^{-4}M IO_3^- (Fig. 1d) required at least 6.5 x 10^{-4}M I^- in order to completely nullify the inhibition effect. For inhibited solutions containing the nitrate anion (Fig. 1a), qualitatively it was demonstrated that addition of I^- in a 1:1 molar ratio to the nitrate, caused a reversal of the inhibition effect. Neither Br^- nor AsO_4^- have such an influence on the inhibition.

The dependency of the inhibiting effect on the bath reactivity revealed that the critical concentration required to yield the abrupt inhibition, with the nitrate or the iodate anion, is displaced toward higher concentrations as the bath reactivity is increased. The bath reactivity can be increased by increasing the temperature, the hypophosphite concentration, or the ratio of ammonia to pyrophosphate concentration. To be specific, plating compositions having a hypophosphite content of 0.095, 0.24, and 0.28M required a nitrate concentration of about 2.2 x 10^{-2}, 4.3 x 10^{-2}, and 4.7 x 10^{-2}M, respectively, to yield the onset of inhibition. Similarly, by altering the temperature from 25°, 30°, and 35°C, the nitrate concentration required to yield the inhibition was about 4.3 x 10^{-2}, 5.0 x 10^{-2}, and 7.5 x 10^{-2}M, respectively. No dependency on pH was noted; this is consistent with the kinetic characteristic of the bath, further ruling out any possible competing redox reaction in which the oxy-anions participate, since these reactions are known to be pH sensitive.

Examination of the steady-state potential (mixed potential) as the concentration of the inhibiting ions is increased shows that an abrupt drop occurs at a characteristic concentration. Typical potential variations for different initial nitrate concentrations are shown in Fig. 2. From this figure the potential for the inhibited region is about −570 mV *vs.* SCE. Furthermore, a plating bath without hypophosphite yielded a steady-state potential of about −580 mV *vs.* SCE.

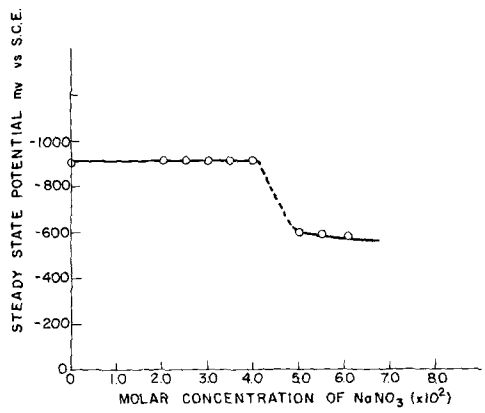

Fig. 2. Steady-state potential vs. nitrate concentration

Examination of the other anions, AsO_2^-, IO_3^-, NO_2^-, and BrO_3^- in their respective inhibition regions (Fig. 1), showed that the steady-state potential at 25°C was in the range of −550 to −600 mV *vs.* SCE. Hence, it can be stated that the addition of nitrate and other inhibiting anions tends to mask the presence of hypophosphite at the electrode solution interface.

In an attempt to characterize the observed phenomena, the data of Fig. 1 was defined as follows

$$\theta = \frac{w_o - w}{w_o}$$

where w_o = weight gain without inhibitor, w = weight gain with added inhibitor, and θ = fraction of inhibition. Figure 3 shows the manner in which θ varies with the concentration of typical additives. Analysis of thiourea inhibition is provided in Fig. 3 for comparison. Since it is reasonable to anticipate that the degree of inhibition is proportional to the fraction of surface sites occupied, Fig. 3 may be classified as an adsorption isotherm. Specifically, the manner in which θ varies with concentration of inhibitors seems to follow the behavior associated with the Frumkin type isotherm (4). Apparently there is an associative enhancement mechanism which accounts for the sudden rapid increase in inhibition taking place over a small concentration change.

The data of Fig. 1 and 3 demonstrate the manner in which the over-all weight gain varies with concentration of inhibiting anions in the bath. Figure 4 shows how each of the main products of the deposition reaction (Ni and H_2) depends on inhibitor concentration. The relative ratio of Ni/H_2 is fairly constant and, in fact, follows closely a 1:1.1 molar ratio (neglecting the hydrogen trapped in the deposit). In contrast to the nickel-hydrogen ratio, the nickel-phosphorus ratio is a variable. The per cent phosphorus in the deposit increases as the inhibitor concentration is increased, typically from 3% without any additives to about 10% with a nitrate concentra-

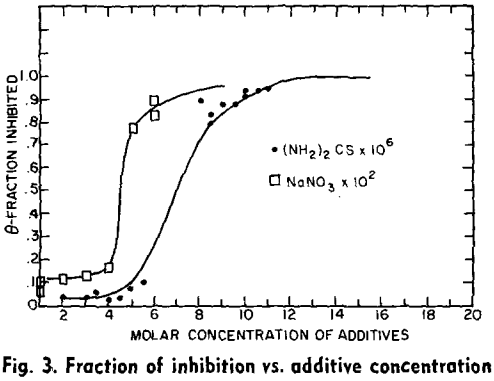

Fig. 3. Fraction of inhibition vs. additive concentration

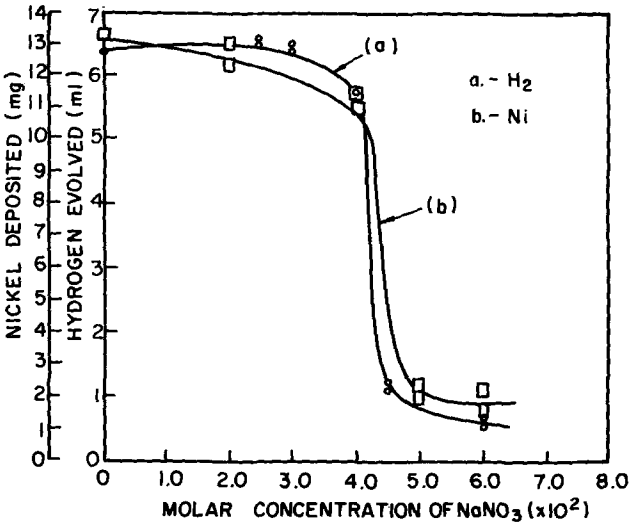

Fig. 4. Nickel and hydrogen deposition vs. nitrate concentration

tion of 5 x 10^{-2}M. Similar behavior was noted when AsO_2^- was employed as the inhibiting anion. For all points along the inhibition curve, the extent of *p*H drop during plating is proportional to the rate of deposition. Since the hydrogen ions come from the anodic reaction of hypophosphite with surface, it can be postulated that the inhibition of the process is related to the anodic reaction(s) leading to the hydride formation rather than to subsequent reactions in which nickel is reduced at the surface. In a recent investigation (5) of Ni/Fe electrodeposition, it was reported that the addition of $NaAsO_2$ up to 0.5 g/l resulted in no effect on the rate of deposition or alloy composition. This result reinforces the belief that the AsO_2^- anion does not interfere with the cathodic process (Fig. 5, reactions 2 through 5) and hence the inhibiting effect must be attributed to interference in the anodic reaction(s).

These observations, while at first sight are puzzling, seem to be consistent with the hydride theory (6) which best accounts for the mechanism of electroless plating of nickel. The hydride theory suggests that the hydrogen evolved is primarily due to the nickel reduction rather than a distinct electrochemical-type reaction. However, the formation of phosphorus in the deposit is best accounted for by separate electrochemical reduction. Since there are two apparent electrochemical redox reactions, *i.e.*, the nickel and phosphorus formation, it is not surprising that each can be altered, but not in the same manner, due to changes in the electrochemical parameters (α, ϕ_2, and η) which affect their reduction kinetics. It is commonly noted in corrosion systems that additives will alter various redox reactions and electroless-plating processes do fall within the general domain of corrosion systems.

In a study of the structure of adsorbed species on metal surfaces (7), application of infrared spectral absorption revealed that nitric oxide when adsorbed

on nickel surfaces yields a preferred configuration whereby the bonding to the surface takes place via the nitrogen part of the oxide. Similar observations on the configuration of adsorption were made with respect to carbon monoxide. These two examples, although they constitute a gas-solid interaction, may also be classified as soft-base soft-acid interactions. They suggest that the preferred configuration for adsorption of the oxy-anions is via the atom which is the most polarizable, easiest to oxidize, and of lowest electronegativity.

In view of the results of this investigation and the fundamentals of hard and soft acids and bases, it is proposed that the inhibition effect associated with the oxy-anions of group I is primarily by a surface adsorption mechanism. For all inhibiting anions, the atom bonded to the surface is As, I, N, and Br rather than oxygen. Due to the adsorption of these anions, the number of vacant catalytic sites decreases, reducing the probability for interaction of hypophosphite with the catalytic sites. Furthermore, due to the preferred orientation associated with the adsorbed anions and, specifically, with the oxygens away from the surface, it is anticipated that the hypophosphite in the proximity of the absorbed layer would also have a preferred orientation. A simple coulombic attraction suggests the models shown in Fig. 6. It is suggested that the formation of hydrogen bonding between the adsorbed layer and the hypophosphite probably accounts for the rapid inhibition taking place within a small concentration range of additives. Whether the chemical interaction between the adsorbed layer and hypophosphite is in a molar ratio of 2:1 or 1:1 is not certain and cannot be resolved with the results of this investigation. Although Fig. 6 utilizes the commonly accepted isomer for hypophosphite, the model proposed is believed to be consistent when employing the other isomer (8) of hypophosphite commonly referred to as the "active form."

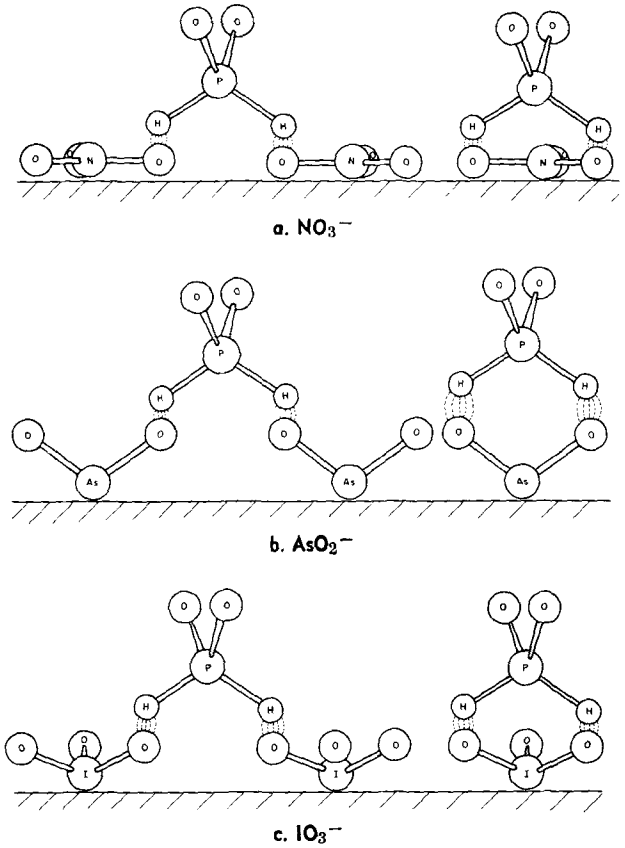

Fig. 6. Proposed model for the interaction of adsorbed oxy-anions with hypophosphite.

Conclusions

The inhibition of the electroless plating of nickel with the incorporation of a specific group of oxy-anions may be best accounted for by an interfacial adsorption mechanism, which reduces the number of catalytic sites for anodic oxidation of hypophosphite. It is further apparent that the abrupt increase of inhibition as the inhibitor concentration increases can be accounted for by any of the following, operating singly or in combination.

I. A chemical interaction between the adsorbed layer and the hypophosphite leading to a strengthening of the P-H bond in hypophosphite.

II. The adsorbed anions alter the structure of the double layer, modifying (or increasing) the degree of surface adsorption and affecting the kinetics of the redox reactions.

III. The number of adjacent pair catalytic sites available for the catalytic dehydrogenation of hypophosphite decreases rapidly once a critical concentration of adsorbed inhibitor is reached.

Although the inhibition effect was examined in detail employing an alkaline room temperature Ni-P bath, additional experiments have shown that the effect also holds for other electroless baths, typically an acidic (9) nickel bath. However, the extent of interaction is not the same. Further study is in progress to determine the applicability of this effect to other electroless plating compositions.

Due to the strong adsorption tendency exhibited by some of the anions, it is anticipated that these anions can be used effectively in the stabilization (10) of electroless plating baths, thereby overcoming major pitfalls associated with some stabilizers (*i.e.*, sulfur-containing compounds), such as their tendency to hydrolyze and the incorporation of sulfur in the deposit.

From the variation of potential as inhibitor concentration increases, and the observed relationship between the onset of inhibition for a given oxy-anion concentration and the hypophosphite concentration, a potentiometric method of analyzing hypophosphite in plating baths is proposed (9). Such a technique would be a rapid and direct method for analyzing the hypophosphite anion concentration in plating baths without interference by the phosphite byproduct, and would closely resemble potentiometric titration methods.

A better understanding of the effects of additives on labile hydrogen (11) in common reducing agents (boraneamine, hypophosphite, formaldehyde, etc.) should lead to a means for accelerating the plating rates of electroless baths.

Electrochemical Oxidation of 2,6-Dithiopurine at the Pyrolytic Graphite Electrode

Reaction Products and Mechanism

Glenn Dryhurst

Department of Chemistry, University of Oklahoma, Norman, Oklahoma 73069

ABSTRACT

At the pyrolytic graphite electrode (PGE) 2,6-dithiopurine is oxidized electrochemically by way of three voltammetric processes. The first pH dependent peak observed is due to oxidation of 2,6-dithiopurine partially in an adsorbed state to give a layer of strongly adsorbed product, bis(6-purinyl)-disulfide-2,2′-dithiol. The second pH dependent peak appears to be further oxidation of the adsorbed product of peak I to a further strongly adsorbed product bis(6-purinyl)disulfide-2,2′-disulfide. The third pH dependent peak is very much larger than the other two and is a $12e/12H^+$ oxidation of 2,6-dithiopurine to purine-2,6-disulfonic acid. In ammonia containing supporting electrolyte systems the evidence suggests that the product of the third peak is purine-2,6-disulfonamide.

There have been several recent reports of the electrochemical oxidation of biologically important purines (1-5) at the pyrolytic graphite electrode (PGE). It is of particular significance that there is an apparent similarity between the modes of electrochemical oxidation and various biological (*e.g.*, enzymic) oxidative processes especially in the case of nonsulfur-containing purines. Purines such as 6-thiopurine (3) which contain exocyclic sulfur groups appear to be oxidized electrochemically by mechanisms which involve the

sulfur grouping, while biological oxidation of this compound consists in oxidation within the purine ring system. However, in view of the very incomplete knowledge of the metabolism and enzymic oxidations of the thiopurines it is probable that the electrochemical mechanisms might aid in understanding the complete and detailed electron transfer reactions of such compounds. In view of the fact that of the thiopurines only 6-thiopurine has been investigated in detail (3) several other important purine systems containing one or more exocyclic thiol groups are being investigated in order to ascertain the generality of the previously observed processes. In addition, electrochemical oxidation of 6-thiopurine results in formation of some interesting products which can otherwise be obtained only by quite complex chemical routes, *e.g.*, purine-6-sulfonamide. Because of our interest in developing electrochemical synthetic routes for such potentially biologically active compounds which are chemically prepared with difficulty or which have never otherwise been prepared it is of interest to further investigate these sulfur-containing systems.

Reported here is the electrochemical behavior of 2,6-dithiopurine.[1]

Only a very limited number of chemical and biochemical studies of 2,6-dithiopurine has been reported. Bergmann and co-worker (6) reported oxidation with the purine oxidizing system *Pseudomonas aeroginosa* which actually had a high xanthine oxidase activity. Oxidation proceeded very slowly at C-8 to give 2,6-dithio-8-oxypurine.

The work reported here indicates that 2,6-dithiopurine is oxidized in three steps. The first peak is due to oxidation probably of weakly adsorbed 2,6-dithiopurine to a product that is very strongly adsorbed. The current density and voltammetric properties of this adsorbed product suggest that it is formed by a 1*e* oxidation of 2,6-dithiopurine to give bis(6-purinyl)disulfide-2,2'-dithiol. The second peak is only observed indistinctly but again the voltammetric behavior suggests that the product is again very strongly adsorbed. In view of the observed voltammetry of this adsorbed product it is likely that it is due to further oxidation of the peak I product to bis(6-purinyl)disulfide-2,2'-disulfide. The third peak which is very much larger than the other two results in formation of a third new compound, purine-2,6-disulfonic acid in a $12e/12H^+$ process. In ammonia containing backgrounds the primary product from the third peak appears to be purine-2,6-disulfonamide.

Experimental

Chemicals.—2,6-Dithiopurine (2,6-dimercaptopurine) was obtained from K & K Laboratories. Buffer solutions were prepared from analytical reagent grade chemicals. Argon (Linde) used for deoxygenating purposes was equilibrated with water; no other purification was necessary.

Chemical synthesis of purine-2,6-disulfonic acid.—Half a gram of 2,6-dithiopurine was dissolved in 8.7 ml of 0.5*M* potassium hydroxide solution. Then a warm solution of approximately 1*M* potassium permanganate was added in a dropwise fashion with vigorous stirring until a permanent slight excess was present (approximately 14 ml $KMnO_4$ required). The excess of permanganate was removed by dropwise addition of dilute sodium bisulfite solution.

The precipitated MnO_2 was filtered at a fine sintered glass funnel. The colorless filtrate was adjusted to *p*H 9 with glacial acetic acid. The resulting solution was evaporated to about 15 ml and, after cooling, was adjusted to *p*H 7.9 with 2*M* acetic acid, when very pale yellow crystals appeared. The solution was chilled for 30 min at −5°C after which the precipitate was filtered and washed sequentially with 85% ethanol, ethanol and ether. Recrystallization was accomplished by reprecipitation from *N* potassium hydroxide with 2*M* acetic acid.

Elemental analysis of the product agreed closely with that expected for the dipotassium salt of purine-2,6-disulfonic acid dihydrate. A yield of about 80% was obtained mp > 300°C.

Ultraviolet absorption data: at *p*H 2.3 λ_{max} = 278.5 mμ; at *p*H 6 λ_{max} = 279.5 mμ; at *p*H 12.6 λ_{max} = 286 mμ.

Electrochemical synthesis of purine-2,6-disulfonic acid.—Approximately 0.2g of 2,6-dithiopurine was suspended in about 190 ml of 1*M* HOAc in a conventional electrolysis cell (2) and with vigorous stirring a potential of 1.4V was applied at the large PGE. Complete electrochemical oxidation usually required 3-4 days and was confirmed by the absence of the characteristic u.v. peaks of 2,6-dithiopurine. At the end of the electrolysis some white precipitate was normally present in the solution and is due to 2,6-dihydroxypurine formed by hydrolysis of the 2,6-disulfonic acid. The water and acetic acid were removed by lyophilization. The resulting solid was dissolved in approximately 15 ml of water and 0.5*M* KOH added until the solution was *p*H 9. The resulting solution was evaporated to very low volume when further white precipitate was produced; this 2,6-dihydroxypurine was removed in a fine sintered glass filter and washed with cold water. The resulting pale yellow filtrate was again evaporated to low volume and the *p*H adjusted to 7.9 with dilute acetic acid. On cooling to 5° a pale yellow precipitate appeared which was filtered and washed sequentially with 85% ethanol, ethanol and ether.

Recrystallization was accomplished in the same way as for the chemically synthesized product. A yield of about 20% was obtained.

The spectra and polarography of this compound were identical to the purine-2,6-disulfonic acid synthesized chemically.

Apparatus.—Apparatus for polarography, voltammetry, cyclic voltammetry, coulometry, macroscale electrolysis, spectral data acquisition, and lyophilization have been described in detail elsewhere (2-5).

Results and Discussion

Voltammetry.—At the stationary PGE 2,6-dithiopurine shows three anodic peaks (Fig. 1). The least positive peak (peak I) is observed between *p*H 1-8; a second peak (peak II) appears at more positive potential between about *p*H 4.7-9, although it is always very poorly formed and is at best merely an inflection on the lower rising portion of the largest and most positive peak (peak III) which itself is observed between *p*H 4.7-12.5. The peak potentials (E_p) for all three peaks shift linearly more negative with increasing *p*H (Fig. 2); $E_p = 0.61\text{-}0.057$ *p*H for peak I, $E_p = 1.26\text{-}0.062$ *p*H for peak II, and $E_p = 1.86\text{-}0.10$ *p*H for peak III.

The current density observed for peak I on average was about 1.0 μa mm^{-2} mM^{-1}; peak II was much too indistinct to allow accurate computation of its current. Wave III showed an average current density at *p*H 4.7 where it was studied most closely of about 10-12 μa mm^{-2} mM^{-1}. By comparison to earlier data (1-3) this would tend to support the view that peak I involved about 1-2*e* and peak III > 10*e* per mole of 2,6-dithiopurine.

Cyclic voltammetry.—Cyclic voltammetry of peak I of 2,6-dithiopurine at a stationary PGE showed that having once scanned peak I on the initial anodic sweep at least one well-formed cathodic peak was observed on the reverse scan (Fig. 3). The peak potentials for these two peaks were separated by *ca.* 0.8V. At low

[1] The *Chemical Abstracts* numbering system is employed throughout this paper.

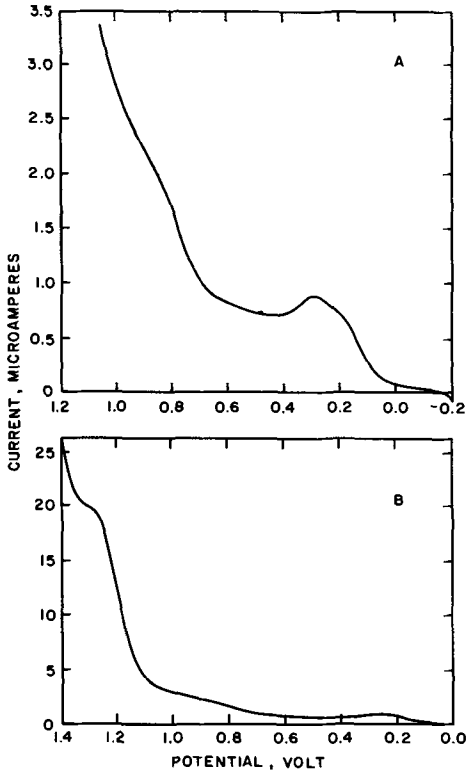

Fig. 1. Voltammograms of *ca.* 0.1 mM 2,6-dithiopurine in acetate buffer *p*H 5.4 at stationary PGE. A, Peaks I and II; B, peaks I, II, and III; scan rate 5 mV sec^{-1}.

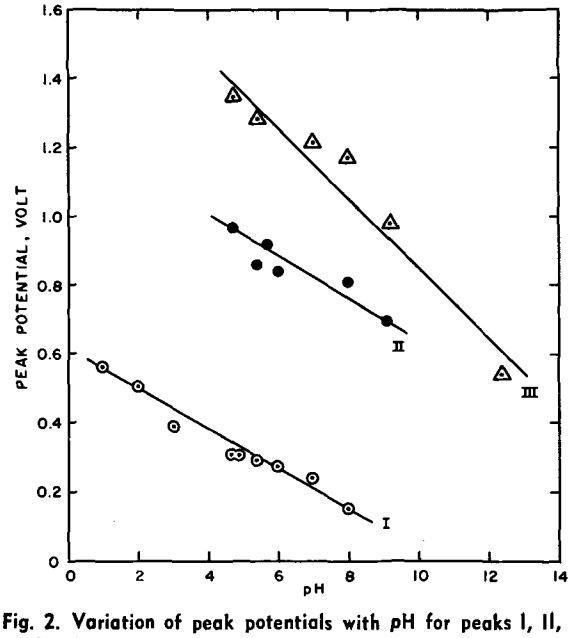

Fig. 2. Variation of peak potentials with *p*H for peaks I, II, and III of 2,6-dithiopurine at stationary PGE.

scan rates and at the higher end of the concentration limit (e.g., at 0.05 m*M*) a small post peak was often observed after the principal cathodic peak. This post peak was clearly observed in acetate buffer *p*H 4.7 (Fig. 3). It was not observed at very low concentrations (*ca.* 0.016 m*M*) or at fast scan rates (*i.e.*, hardly noticeable at scan rates of 50 mV sec^{-1} or above). It was particularly noticeable that the peak current for the main cathodic peak was usually greater than that for the initial anodic peak I and that the cathodic peak was the more symmetrical. Anodic peak I in many

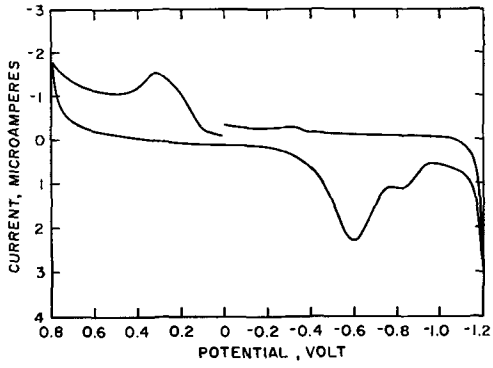

Fig. 3. Cyclic voltammogram of *ca.* 0.1 mM 2,6-dithiopurine in acetate buffer *p*H 4.7. Scan pattern: 0.0V → 0.8V → —1.2V → 0. Scan rate: 5 mV sec^{-1}.

slow scan voltammograms had the appearance of two very close overlapping peaks (*e.g.*, Fig. 1, 3). Such phenomena suggests the involvement of adsorption processes in the current and potential determining reactions.

As the sweep rate increases the value of the experimental equivalent of the peak current function ($i_p/ACV^{1/2}$) (7) increases (Fig. 4). Because of the very limited solubility of 2,6-dithiopurine concentration studies could only be performed over limited concentration ranges. Nevertheless over the range 0.016-0.062 m*M* at scan rates of 20, 50, 100, and 200 mV sec^{-1} in acetate buffer *p*H 4.7 linear i_p-*C* plots were obtained although the graphical plot did not pass through the origin.

With increasing scan rate the peak potential for peak I (anodic) shifted more positive, $E_p = 0.31V$ at 5 mV sec^{-1} and $E_p = 0.48V$ at 500 mV sec^{-1}. The value of E_p for the principal reverse cathodic peak was essentially constant at $E_p = -0.61 \pm 4$ mV over the same scan rate range.

Consideration of the above data in the light of the theoretical data presented by Wopschall and Shain (7) tends in part to support the view that both 2,6-dithiopurine and the oxidation product of peak I are adsorbed. Thus, the symmetry of peak I suggests the presence of two very close overlapping waves, which considered in the light of the increase of the peak current function with scan rate suggests adsorption of the 2,6-dithiopurine. The symmetry, relative peak height, and occasional post-peak formation associated with the reverse cathodic process is indicative of adsorption of the product of oxidation of 2,6-dithiopurine as does the increase of the peak current function with scan rate. At this time the theories of adsorption in

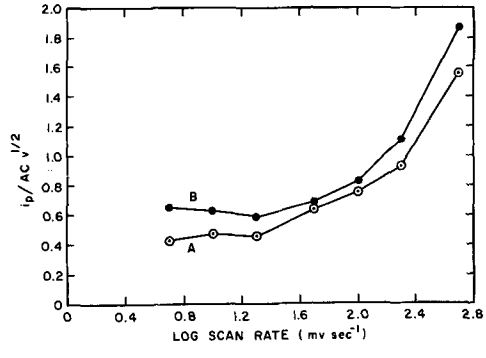

Fig. 4. Variation of experimental peak current function, $i_p/ACV^{1/2}$ in units of $\mu A\ mm^{-2}\ mM^{-1}\ (mV/sec)^{-1/2}$ with scan rate for 0.109 mM 2,6-dithiopurine in acetate buffer *p*H 4.7 at stationary PGE. A, Anodic peak I; B, cathodic peak.

irreversible systems of this type are insufficiently developed to allow calculation of the relative strengths of product and reactant adsorption. The shift of the peak potential for peak I to more positive potential with increasing scan rate is quite the opposite to that expected for a reversible system (7). The disappearance of the occasionally observed cathodic post peak at low concentration or fast scan rate is anomalous, at least as predicted for a reversible system, and accordingly this peak may be a result of secondary chemical processes rather than being specifically associated with adsorption processes.

Cyclic voltammetry embracing anodic peaks II and III did not reveal any significant cathodic peaks.

Coulometry and Macroscale Electrolysis

Peaks I and II.—Attempted coulometric, measurement of faradaic n values at potentials corresponding to peaks I or II of 2,6-dithiopurine were never successful; the current always quite rapidly decayed to a level equal to or less than that observed for background solutions alone. On removal the massive PGE presented a very dull surface unlike that after background electrolysis, which suggested a surface film formation.

In order further to study these processes a clean 4 mm PGE was maintained at a potential corresponding to either peak I or peak II in an acetate buffer *p*H 5.65 saturated with respect to 2,6-dithiopurine. (This buffer system was selected because in it a saturated solution of 2,6-dithiopurine gave a reasonably distinct plateau for peak II.) After 5 min electrolysis the PGE was removed from the electrolysis cell, the controlled potential then turned off, and the PGE thoroughly washed with water for at least 30 sec. Excess water from the glass walls of the PGE was removed with a paper tissue. The electrode was then inserted into a fresh deaerated solution of acetate buffer *p*H 5.65 and various voltammetric scans were run. The voltammetric data can be understood by reference to Fig. 5.

If the PGE was maintained at 0.35V ($\approx$ peak I), after washing and immersion in a fresh buffer solution then on sweeping initially toward negative potential, from a starting potential of 0.0V, two large cathodic peaks were observed at $E_p = -1.05$ and -1.42V (Fig. 5A), the more negative peak being about twice as high as the less negative peak. After scanning the first or both of these peaks then on the subsequent sweep toward positive potential a single anodic peak at 0.35V was observed which corresponds to peak I for 2,6-dithiopurine. Once having scanned this peak then on the next sweep toward negative potential two new cathodic peaks appeared at $E_p = -0.70$ and -1.10V; the peak originally at $E_p = -1.05$V had disappeared and that at $E_p = -1.42$V had decreased to about one third of its original height. If the initial sweep from 0.0V was toward positive potential then no peak corresponding to peak I of 2,6-dithiopurine could be observed, but a peak at 0.85V is observed which corresponds to peak II of 2,6-dithiopurine (Fig. 5B). On the reverse sweep to negative potential two cathodic peaks are observed at the same potentials as outlined for Fig. 5A and the subsequent sweeps to first positive and then negative potentials were also identical to the previously described voltammograms.

If the PGE was maintained at 0.95V for 5 min before washing and scanning, then if the initial scan was toward negative potential, two large cathodic peaks were observed at $E_p = -1.16$ and -1.43V, both peaks being of about the same height (Fig. 5C). Having scanned the first or both of these peaks then on the positive-going sweep a single anodic peak at

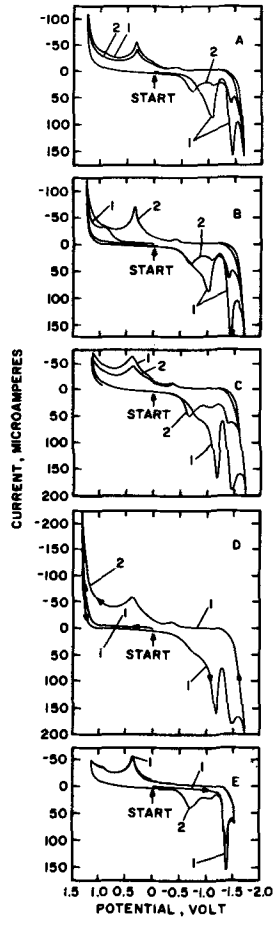

Fig. 5A. Cyclic voltammogram of PGE after electrolysis of 2,6-dithiopurine (saturated) at 0.35V for 5 min in acetate buffer *p*H 5.65. Electrode washed and scanned in fresh, deaerated acetate buffer *p*H 5.65. Scan pattern: 0.0V → −1.65V → 1.25V → −1.65V → 1.25V.

Fig. 5B. Repeat of A but initial scan toward positive potential. Scan pattern: 0.0V → 1.25V → −1.65V → 1.25V → −1.65V.

Fig. 5C. Cyclic voltammogram of PGE after electrolysis of 2,6-dithiopurine (saturated) at 0.95V for 5 min in acetate buffer *p*H 5.65. Electrode washed and scanned in fresh, deaerated acetate buffer *p*H 5.65. Scan pattern: 0.0V → −1.65V → 1.15V → −1.65V → 1.15V.

Fig. 5D. Repeat of C but initial scan toward positive potential. Scan pattern: 0.0V → 1.30V → −1.65V → 1.30V.

Fig. 5E. Cyclic voltammogram of a saturated solution of 2,6-dithiopurine in acetate buffer *p*H 5.65 at clean PGE. Scan pattern: 0.0V → −1.50V → 1.15V → −1.50V → 1.15V. Scan rate: 200 mV sec^{-1}.

$E_p = 0.36$V is observed which corresponds to peak I of 2,6-dithiopurine. On the subsequent second negative-going sweep two new peaks at $E_p = -0.70$ and -1.10V are observed along with the most negative of the initial cathodic peaks at $E_p = -1.40$V which was less than one third of its original height (Fig. 5C). If the initial sweep 0.0V was toward positive potential no anodic peaks were noted and the subsequent cathodic and anodic sweeps gave identical traces to those observed if the initial sweep was to negative potentials (Fig. 5D).

Under identical conditions 2,6-dithiopurine at a clean PGE showed only a single cathodic peak on the initial negative-going sweep at $E_p = -1.37$V but having scanned the anodic peak I, $E_p = 0.36$V then two cathodic peaks at $E_p = -0.70$ and -1.08V ap-

peared; the original cathodic peak at $E_p = -1.37V$ had decreased in height (Fig. 5E).

This observed voltammetric behavior can be rationalized as follows: Oxidation of 2,6-dithiopurine at peak I gives rise to a strongly adsorbed and probably highly insoluble product. This latter product can be reduced (stripped) at −1.05V to reform 2,6-dithiopurine. That 2,6-dithiopurine is the result of the latter cathodic process is evidenced by the appearance of a more negative peak at about −1.40V [which is due to partial reduction of 2,6-dithiopurine and partially to catalytic hydrogen discharge (8), the latter process accounting for the major portion of the current] and to the formation of anodic peak I and the normal cathodic peaks at −0.70 and −1.10V on the subsequent cathodic scan, all of which agree with the peaks observed with authentic 2,6-dithiopurine. The adsorbed product from peak I can be further oxidized, this process corresponding to peak II. The product from peak II is also strongly adsorbed; the adsorbed product can be reduced (or stripped) at −1.16V in a process that involves about double the current observed for reduction of the product of peak I (at −1.05V). Again the cyclic voltammetry of the reduction product of the adsorbed peak II product is identical to that of 2,6-dithiopurine.

Peak III.—Coulometry at potentials corresponding to the crest of peak III in acetate buffers pH 2, 3, 4.7, and 5.7 where the peak was most clearly observed gave an average faradaic n value of 10.6. The product of the electrolysis in all of these buffers had a single u.v. absorption peak at $\lambda_{max} = 278$-279 mμ. Polarography of the product solutions showed some very characteristic waves. In 1*M* acetic acid the product showed three waves at $E_{1/2} = -0.85$, −1.05, and −1.23V; in acetate buffer pH 4.7 two waves at $E_{1/2} = -1.14$ and −1.29V were observed. Authentic purine-2,6-disulfonic acid (see Experimental) gave identical spectral and polarographic data. A small scale electrochemical synthesis of purine-2,6-disulfonic acid was successfully carried out (see Experimental) and, although low yields were obtained under the rather crude conditions employed, the product obtained was identical to the chemically synthesized product in terms of melting point, spectra, and polarography in a variety of media. The mechanism of electrochemical reduction of purine-2,6-disulfonic acid is presently under investigation and will be reported in due course (9). It was clear from the polarographic data in particular that purine-2,6-disulfonic acid was the major product; however, several minor polarographic waves also were often observed indicating the presence of less important electrochemical products. No doubt these are sulfinic acids or other sulfur-containing products where the sulfur is in a lower state of oxidation than in the disulfonic acid.

When electrochemical oxidation of 2,6-dithiopurine in ammonia containing background electrolytes was performed extremely erratic faradaic n values were obtained. The major product that was obtained differed spectrally and polarographically from purine-2,6-disulfonic acid. In 1*M* ammonia background the product of oxidation of 2,6-dithiopurine at potentials corresponding to peak III showed two u.v. absorption peaks ($\lambda_{max} = 305$, 225 mμ), while purine-2,6-disulfonic acid showed only a single peak ($\lambda_{max} = 285$ mμ). Macroscale electrolysis of 2,6-dithiopurine in 5*M* ammonia, followed by lyophilization gave a pale yellow product which was extremely insoluble in water (unlike the disulfonic acid) although soluble in strongly alkaline solution and which melted above 300°C. Electrochemical oxidation of a few tenths of a gram of 2,6-dithiopurine in ammonia medium always took excessively long times under the experimental conditions employed, and in fact a product free of 2,6-dithiopurine was never obtained. The product was quite stable to boiling water. The infrared spectrum revealed the characteristic sulfonamide peaks at 1330 and 1153 cm^{-1}. Because of the difficulty of maintaining a sufficiently high ammonia concentration over extended periods of time and the variable coulometric data the exact nature of the products and the mechanism will be reported after more extensive study. Tentatively, however, the evidence suggests that the major product is purine-2,6-disulfonamide, which would be a new and potentially biologically active species.

Mechanism

Peaks I and II.—The voltammetric data supports the view that 2,6-dithiopurine is adsorbed at the PGE and that the products of peak I and peak II are also adsorbed. Cyclic voltammetry of the adsorbed products of peak I and peak II indicates that the products of the two processes are different but that they are reduced directly to 2,6-dithiopurine. The product of peak II is more difficultly reduced than the product of peak I and involves about twice as much current. It is well known that thiols are relatively easily oxidized to disulfides both chemically (10) and electrochemically (3). Electrochemical evidence also suggests that bis(6-purinyl) disulfide, the first oxidation product of 6-thiopurine, is adsorbed at the PGE (3). In view of the magnitude of the anodic current for peak I, the mechanism for peak I is probably formation of bis(6-purinyl) disulfide-2,2′-dithiol (II, Fig. 6) which is strongly adsorbed at the PGE (Fig. 6); the reactant 2,6-dithiopurine being only weakly adsorbed.

The close proximity of the two remaining thiol groups in (II, Fig. 6) suggests that further electrochemical oxidation at peak II would result in further oxidation to the double disulfide, bis(6-purinyl)disulfide-2,2′-disulfide (III, Fig. 6) which is also strongly adsorbed at the PGE. There is only scant evidence for the formation of such complex polysulfides as III (Fig. 6) although 1,4-dithiobenzene is thought to form an analogous species (11), which is also extraordinarily insoluble. Because of the nature of the electrode reaction neither of the above disulfide species has been chemically characterized, their identity being inferred from the observed electrochemical behavior, and by analogy with known chemical and electrochemical properties of thiols.

In view of the insolubility of 2,6-dithiopurine and of the great insolubility of the product of oxidation of 1,4-dithiobenzene (11), it is not unlikely that at least part of the surface coverage of the products of peaks I and II might result from simple precipitation of product.

The third peak in the absence of ammonia is clearly due to oxidation of 2,6-dithiopurine or compounds II and III (Fig. 6) to purine-2,6-disulfonic acid in a 12e/12 H^+ process. The fact that a little less than 12e on average were observed coulometrically is no doubt due to partial formation of derivatives with the sulfur in a lower oxidation state.

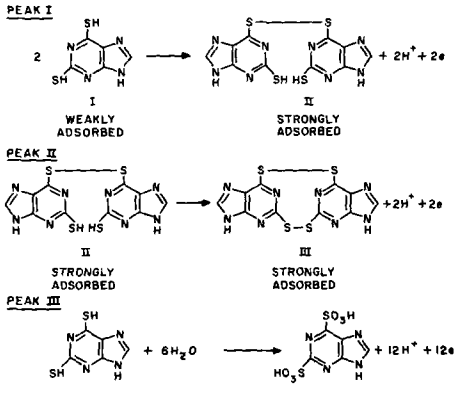

Fig. 6. Interpretation of the observed electrochemical oxidation of 2,6-dithiopurine at peaks I, II, and III.

Electrochemical Reduction of 2,6-Dithiopurine at the Dropping Mercury Electrode and the Pyrolytic Graphite Electrode

Glenn Dryhurst

Department of Chemistry, University of Oklahoma, Norman, Oklahoma 73069

ABSTRACT

The electrochemical reduction of 2,6-dithiopurine has been investigated polarographically at the dropping mercury electrode (DME) and the stationary pyrolytic graphite electrode (PGE). At the DME two reduction waves are observed; the first wave occurs between pH 1-5.7 and is due partly to electrochemical reduction of 2,6-dithiopurine and partly to catalytic hydrogen discharge. The second wave appears between pH 4-8 and is a typical catalytic hydrogen discharge wave catalyzed by adsorbed monoanionic 2,6-dithiopurine. Only a single peak is observed at the PGE between pH 1-7 and again is due to two simultaneous processes, the major process is catalytic hydrogen discharge catalyzed by adsorbed neutral 2,6-dithiopurine accompanied by a minor process which is reduction of 2,6-dithiopurine to a product which is also obtained on reduction of 2-thiopurine under the same conditions; this product is 1,6-dihydro-6-thiopurine.

Recent reports from this group have been concerned with the electrochemical electron transfer reactions of biologically important purines and the relation of these reactions to biological electron transfer processes (1-6), as well as the analytical utility of the electrochemical phenomena (2, 7). Purines containing exocyclic sulfur such as 6-thiopurine are electrochemically oxidized by quite different mechanisms from those observed for the naturally occurring purines; their reduction mechanisms, although complex, were similar to those observed for the non-sulfur-containing compounds. In view of the potential of developing some extremely sophisticated electrochemical syntheses of purines containing sulfur in oxidation states higher than the thiols, such as bis(purinyl) disulfides, sulfinic and sulfonic acids and sulfonamides as a result of oxidation at the pyrolytic graphite electrode, and the very incomplete knowledge of metabolic degradation of the thiopurines, which are often anticarcinogens, as well as a dearth of selective and sensitive analytical procedures, we have continued to examine in detail the electrochemistry of several other thiopurine systems.

Reported here is the electrochemical reduction of 2,6-dithiopurine[1] at both the dropping mercury electrode (DME) and the pyrolytic graphite electrode (PGE).

Horn and Zuman (8) have reported the formation of anodic waves at the DME for 2,6-dithiopurine, while Zuman and Kuik (9) briefly indicate that in ammoniacal cobalt solutions 2,6-dithiopurine gives a catalytic wave for hydrogen evolution.

[1] The *Chemical Abstracts* numbering system is employed throughout this paper.

The work reported here indicates that 2,6-dithiopurine is reduced at the DME and the PGE between about pH 1-6 in a process which partially involves catalytic hydrogen discharge and partial faradaic reduction of the 2,6-dithiopurine. Above about pH 6 at the DME a further large reduction wave appears which is a true catalytic hydrogen wave.

Because of the earlier data (8) no attention was given to the anodic waves reported and expected at positive potential at the DME.

Experimental

Chemicals.—2,6-Dithiopurine and 2-thiopurine were obtained from K&K Laboratories.

Buffer solutions were prepared from analytic reagent grade chemicals. Argon (Linde) used for deoxygenating purposes was equilibrated with water; no other purification was necessary.

Triple distilled mercury was employed throughout the work.

Apparatus.—Apparatus for polarography, voltammetry, cyclic voltammetry, coulometry, macroscale electrolysis, and spectral data acquisition are described elsewhere (3-7).

Results and Discussion

Polarography at DME.—2,6-Dithiopurine exhibits two polarographic reduction waves; the first wave (wave I) occurs between pH 1 and 5.65, the second wave (wave II) occurs between pH 4 and 8. The half-wave potentials for both waves shift linearly more negative with increasing pH (Fig. 1B); $E_{1/2} = -0.79 - 0.076$ pH for wave I and $E_{1/2} = -0.97 - 0.102$ pH for wave II.

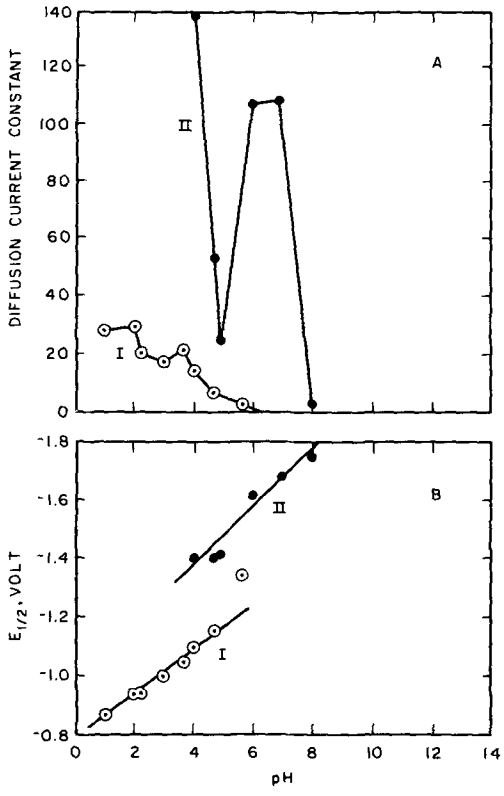

Fig. 1A. Variation of diffusion current constant for waves I and II of 2,6-dithiopurine with pH at the DME.

Fig. 1B. Variation of $E_{1/2}$ for waves I and II of 2,6-dithiopurine with pH at the DME.

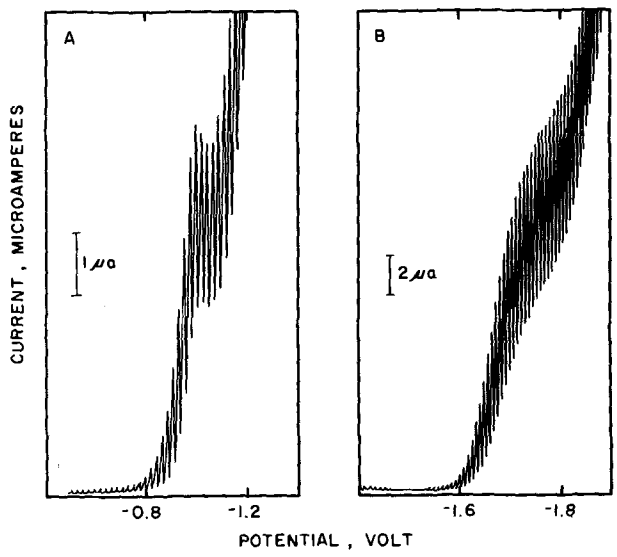

Fig. 2. Polarograms of 0.069 mM 2,6-dithiopurine at the DME in (A) chloride background pH 1.0, and (B) McIlvaine buffer pH 7.

The diffusion current constant for wave I is 28 at pH 1 and decays at pH values above 2 in a more or less regular fashion to zero at about pH 6 (Fig. 1A).

The droptime dependence of wave I in chloride background pH 1.0 is not in accord with a process entirely under diffusion control; for a 0.057 m*M* solution of 2,6-dithiopurine the ratio of $i_l/h^{1/2}$ decreased from 0.526 to 0.36 as h was varied from 32.5 to 92.5 cm, respectively. This decrease coupled with the magnitude of the diffusion current constant indicated that the process was at least partly under catalytic control. In agreement with this conclusion the temperature coefficient of the wave in chloride background pH 1.0 was 3.2%/°C which is larger than expected for a diffusion controlled process, but somewhat smaller for a process solely under catalytic control. The solubility of 2,6-dithiopurine is very low so that although a 0.1 m*M* supersaturated solution can be prepared in water, it slowly precipitates over the course of a few days. Nevertheless, it was found that the current observed for wave I in chloride background pH 1.0 was linearly proportional to concentration over the concentration range 0.02 to 0.10 m*M* with an i_l/C ratio of 57.1 ± 2.4 μA mM^{-1}.

Wave II for 2,6-dithiopurine is first observed at pH 4 as an extraordinarily large wave which occurs close to background discharge. Between pH 4 and 4.9 the diffusion current constant decays steadily from 138 to 25.4 and then increases again to 107 at pH 6 and 108 at pH 7 (Fig. 1A). At pH 8 wave II is extremely small.

In McIlvaine buffer pH 7 (Fig. 2B) the limiting current for wave II appears to increase with decreasing height of the mercury column, but owing to the shift of background discharge to more positive potential in the presence of 2,6-dithiopurine it was very difficult to correct the wave for background current, particularly at low column heights. Nevertheless, the large magnitude of the diffusion current constant and the virtual independence of the limiting current with mercury column height indicated that the wave was effectively under catalytic control.

In McIlvaine buffer pH 7 the temperature coefficient of wave II was —0.98%/°C, *i.e.*, the wave height decreased slightly with temperature. Over the concentration range 6.6 x 10^{-6} to 6.6 x 10^{-5} *M* of 2,6-dithiopurine in the same background the limiting current for wave II increased linearly with concentration although the ratio i_l/C increased from 88 to 162 μA mM^{-1}, respectively.

Voltammetry at PGE.—At the stationary PGE (4 mm diameter) 2,6-dithiopurine gives only a single voltammetric reduction peak, which occurs between pH 1 and 7, the peak potential for which shifts linearly more negative with increasing pH according to the equation $E_p = -0.96 - 0.068$ pH (Fig. 3B). The peak itself is extremely sharp (Fig. 4), more so than expected for a simple diffusion controlled process. The current density decreases in a more or less regular fashion as the pH is increased, ranging from 8.0 μA mm^{-2} mM^{-1} at pH 1.0 to almost zero at pH 7 (Fig. 3A). By comparison with earlier data (1) a current density of 8.0 would indicate an apparent faradaic n value of 13-14 electrons.

In chloride background pH 1.0 the peak current did not increase linearly with concentration (Fig. 5) but over the range 0.02 to 0.10 m*M* at 5 mV sec^{-1} scan rate $i_p - C$ plots are essentially exponential with i_p apparently tending to a limiting value at somewhat above the 0.1 m*M* concentration level. The limited solubility of 2,6-dithiopurine prevented extending the concentration study to higher levels. The ratio i_p/C decreased from 224 μA mM^{-1} at the 0.02 m*M* concentration level to 142 μA mM^{-1} at 0.1 m*M*.

Coulometry at mercury electrodes.—Attempts to determine faradaic n values by macroscale electrolysis of 2,6-dithiopurine at a massive mercury pool electrode in chloride pH 1.0, acetate pH 4.7, and McIlvaine pH 7 backgrounds could not be meaningfully performed because of a quite rapid reaction between 2,6-dithiopurine and mercury to give a gray-black suspension in solution and a gray-black discoloration to the mercury pool surface. This reaction was so rapid, as evidenced by u.v. spectral studies, that within 15 min about 50% of the 2,6-dithiopurine of concentration 0.05 m*M* in acetate pH 4.7 had disappeared. The resultant product was not electrochemically reducible. Accordingly all further information regarding the electrolysis product and electrode mechanism was gained by electrolysis of 2,6-dithiopurine solutions at a large PGE.

Fig. 3B. Variation of peak potential for voltammetric reduction peak of 2,6-dithiopurine at PGE with pH. Area PGE: 12.5 mm^2; concentration: 2,6-dithiopurine 0.10 mM; scan rate: 5 mV sec^{-1}.

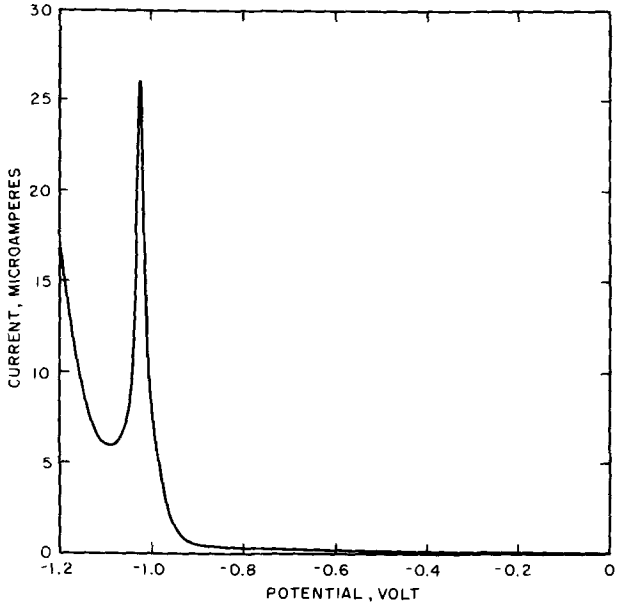

Fig. 4. Voltammogram of 0.10 mM 2,6-dithiopurine in chloride background pH 1.0 at a 4 mm diameter PGE. Scan rate: 5 mV sec^{-1}.

Coulometry at PGE.—Electrolysis of a 0.066 m*M* solution of 2,6-dithiopurine solution in chloride background pH 1.0 on the rising portion of the single voltammetric peak (−0.98V) resulted in the immediate liberation of H_2S (lead acetate paper). The current observed initially was very high (> 50 mA) and did not decay appreciably but remained at an extremely high level. By monitoring the u.v. absorption spectra and

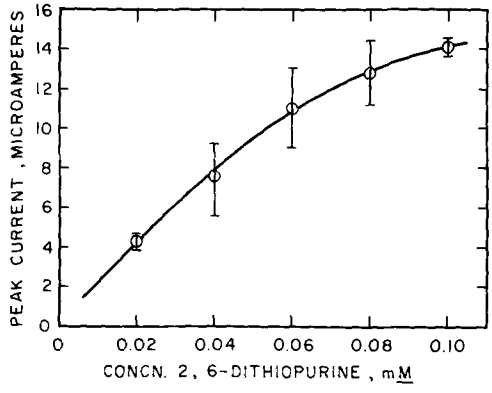

Fig. 5. Variation of peak current with concentration on voltammetric reduction of 2,6-dithiopurine in chloride background pH 1.0 at stationary PGE. Scan rate: 5 mV sec^{-1}.

by employing cyclic voltammetry at PGE it was clear however that the 2,6-dithiopurine was electrochemically reduced. The data accumulated, particularly the cyclic voltammetry, suggested that the product was identical to that obtained upon reduction of 2-thiopurine. Since more extensive data were available on the electrochemical reduction of 2-thiopurine in acetate buffer pH 4.7 (10) where more definitive u.v. spectra and cyclic voltammograms are obtained, a more detailed examination of the reduction of 2,6-dithiopurine in this buffer was carried out.

Attempts to reduce 2,6-dithiopurine in acetate buffer pH 4.7 on the rising portion of the peak (−1.26V) again resulted in formation of H_2S and disappearance of the characteristic spectrum of this compound (λ_{max} = 350, 292.5, 250 mμ) and formation of a species with a quite different absorption spectrum at pH 4.7 (λ_{max} = 282, 246 mμ). Although the observed current was only about one fifth of that observed at pH 1.0 it did not decrease appreciably over the course of several hours, although it was quite obvious from spectral data that all 2,6-dithiopurine had been reduced.

Cyclic voltammetry at PGE of the product revealed that there were no reduction waves remaining (apart from slight traces of 2,6-dithiopurine itself), but a well-formed oxidation peak at E_p = 0.38 → 0.40V was present. Once having scanned this single anodic peak, four cathodic peaks were observed on the subsequent sweep in the negative direction at E_p = −0.77 → −0.78V; −1.02 → 1.03V; −1.27 → −1.29V and −1.52 → −1.54V (Fig. 6C, D). None of these cathodic peaks are observed on cyclic voltammetry of 2,6-dithiopurine itself (Fig. 6A), although at pH 4.7, 2,6-dithiopurine is oxidized at E_p = 0.41V (Fig. 6A, B); the mechanism of this process will be discussed elsewhere. Electrolysis of 2-thiopurine at approximately the same concentration and under otherwise identical conditions did not give rise to H_2S evolution. The characteristic u.v. spectrum of 2-thiopurine at pH 4.7 (λ_{max} 285, 243 mμ) disappeared and a product having an identical spectrum (λ_{max} 282, 246 mμ) to that produced from 2,6-dithiopurine under the same conditions was observed. Cyclic voltammetry of the electrolysis product of 2-thiopurine was essentially identical to that produced from 2,6-dithiopurine (Fig. 6E, F). Complete interpretation of the various peaks observed for these solutions will be reported elsewhere (10).

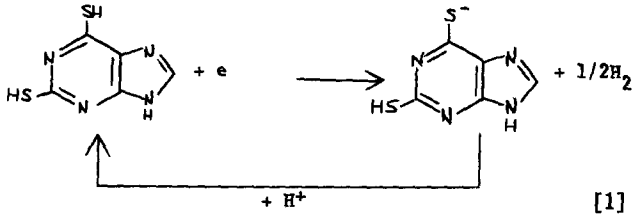
It was thus quite clear that reduction of 2-thiopurine and 2,6-dithiopurine at potentials corresponding to the single reduction peak of the latter compound gave rise to the identical product; this product appears to be extremely effective in facilitating catalytic hydrogen reduction.

Electrochemical Mechanism

Polarography at DME.—As evidenced by the magnitude of the diffusion current constant, the droptime and temperature dependence, and controlled potential

electrolysis data, wave I is due to two simultaneous processes. At low pH the most important of these processes is catalytic hydrogen discharge accompanied by some electrochemical reduction of 2,6-dithiopurine. As the pH increases the decrease in wave height must be related primarily to a decrease in the catalytic process. The decrease in current can be related to the state of ionization of the 2,6-dithiopurine. Viout and Rumpf (11) determined the pK_a values of 2,6-dithiopurine as 5.02 and 10.06 using a potentiometric titration method. Employing a spectrophotometric method based on the three u.v. absorption peaks of 2,6-dithiopurine we have found $pK_{a1} = 4.9$ and $pK_{a2} \simeq 8.8$; the latter figure is of somewhat doubtful accuracy because the peak which was employed for its determination occurred very close to end absorption in most buffer systems employed.

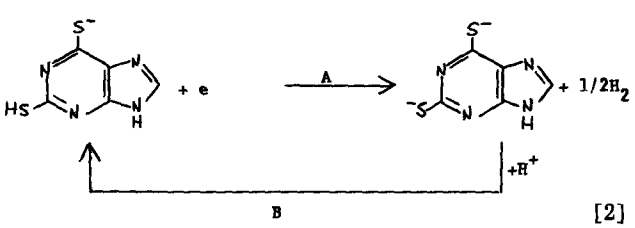
Accordingly, the reaction apparently giving rise to the catalytic contribution is typical of such waves given by many thiols (12) (Eq. [1]).



[1]

As the solution pH increases the concentration of neutral 2,6-dithiopurine decreases as does the proton concentration resulting in a decrease in the current for wave I. Above pH 5 most of the 2,6-dithiopurine will be in the monoanionic form and accordingly the catalytic current would be expected, as observed, to decay to zero. By analogy with the polarographic behavior of 6-thiopurine (4) it might be expected that any true faradaic reduction of 2,6-dithiopurine might decay to zero at pH values much above pK_{a1}, *i.e.*, it is the uncharged species that is reduced. As a result of the reaction (or adsorption) of 2,6-dithiopurine with mercury, coupled with the catalytic processes it is not possible to decide on the nature of the true faradaic process. The very limited solubility of 2,6-dithiopurine does not allow a detailed comparison of the catalytic process proposed for wave I with other systems (12). At the 0.05 m*M* concentration level solutions of 2,6-dithiopurine in acetate and MacIlvaine buffers did not result in any appreciable depression or shifts of electrocapillary curves; at such low concentration levels this was not unexpected.

Wave II shows the typical behavior expected of a normal catalytic wave except for its anomalous temperature dependence. Since wave II is not observed until pH 4 it is likely that it is associated with the monoanionic form of 2,6-dithiopurine which has reached significant concentrations at this pH. Accordingly it is possible to designate the probable catalytic reaction as follows (Eq. [2]).



[2]

The observed shifts in the magnitude of the diffusion current constant (I_d) between pH 4 and 8 may be explained by the fact that at pH 4 (assuming a value of $pK_{a1} = 5.0$) about 10% of the 2,6-dithiopurine exists in the monoanionic form; however, as a result of the high proton concentration and buffer capacity of the buffer employed (MacIlvaine, ionic strength 0.5*M*) a large catalytic current is observed, the current for which is likely limited by reaction [2B], reaction [2A] being a fast electron transfer process. As the pH increases up to pH 4.9 the concentration of the monoanionic 2,6-dithiopurine still accounts for considerably less than 50% of the compound, whereas the proton concentration has decreased an order of magnitude and the buffer capacity has decreased. As a result the systematic current decrease up to pH 4.9 is observed. At pH 6, in excess of 90% of the 2,6-dithiopurine is in the monoanionic form which, as a result of increased catalyst concentration, more than compensates for the decrease in proton concentration and between pH 6 and 7 the catalytic current is again high. At pH 8 the combination of decreased proton concentration and further ionization of the monoanionic 2,6-dithiopurine results in a drastic decay of the observed catalytic current. The anomalous negative temperature coefficient of wave II can only be rationalized by invoking the generally accepted theory that thiols giving rise to catalytic waves do so in an adsorbed state of the catalyst. However, in the case of wave II the catalyst is a negatively charged species and, at potentials of the catalytic wave, the electrode carries a large negative charge. It is not unlikely, therefore, that the thiol adsorption is

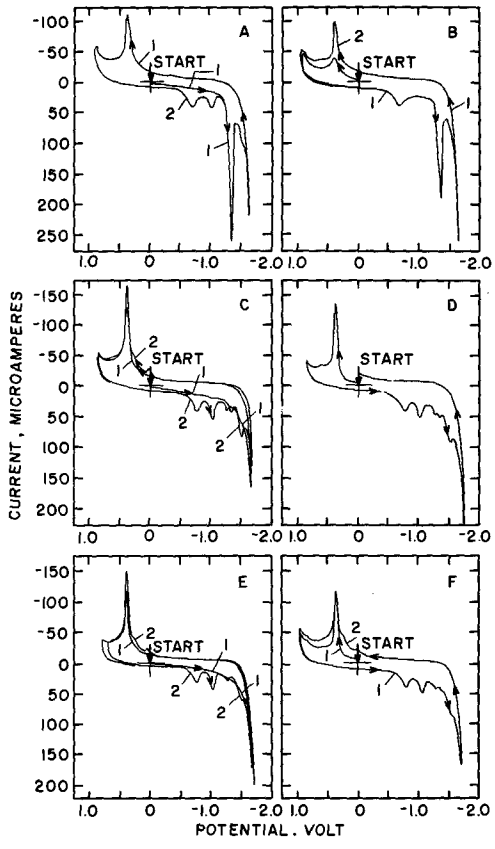


Fig. 6A,B. Cyclic voltammograms of a saturated solution of 2,6-dithiopurine in acetate buffer pH 4.7 at stationary PGE. Scan pattern: A, 0.00V → −1.65V → 0.90V → −1.25V; B, 0.00V → 0.98V → −1.65V → 0.98V → 0.00V.

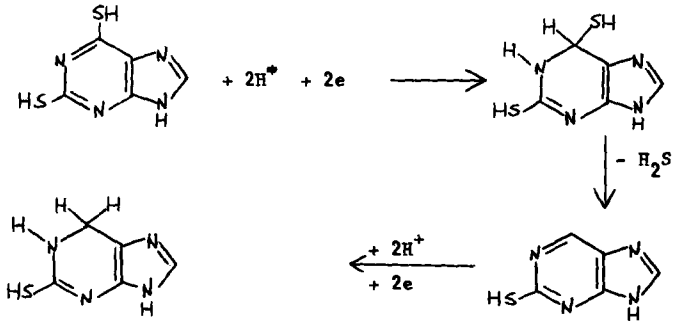
Fig. 6E,F. Cyclic voltammograms of product of electrochemical reduction of 2-thiopurine at −1.26V at PGE in acetate buffer pH 4.7 at stationary PGE. Scan pattern: E, 0.00V → −1.75V → 0.80V → −1.75V → 0.80V → 0.00V; F, 0.00V → 1.00V → −1.70V → 1.00V → 0.00V. Scan rate: 200 mV sec^{-1}; PGE: area 12.5 mm^2.

weak and would have a high temperature coefficient of desorption. The net result being therefore that the usually large positive temperature coefficient of the catalytic process is more than offset by a decrease in catalyst adsorption at elevated temperature. Electrocapillary curves of 0.05 m*M* 2,6-dithiopurine at *p*H 7 showed little difference from the background solution alone.

Voltammetry at PGE.—2,6-dithiopurine is reduced at PGE in a process where apparently the reactant (and possibly product) facilitates catalytic hydrogen discharge. The known pK_{a1} of 2,6-dithiopurine, the variation of E_p and the current density with *p*H, and controlled potential electrolysis data support this view. The product of faradaic reduction of 2,6-dithiopurine appears to be spectrally and voltammetrically identical to that obtained by reduction of 2-thiopurine under the same conditions. The product of this latter reduction of 2-thiopurine appears to be 1,2-dihydro-2-thiopurine (10). Since reduction of 2,6-dithiopurine appears to involve loss of H_2S this must occur by reduction of the 1,6-N=C- double bond in much the same way postulated for 6-thiopurine (4), purine and adenine (13). Accordingly a mechanism for faradaic reduction of 2,6-dithiopurine is proposed (Eq. [3]).



[3]

The process responsible for catalytic hydrogen discharge is no doubt identical to that observed for wave I at DME.

Polarography of Uranyl-Diethylenetriaminepentaacetate Complexes and Adsorption Kinetics at the Dropping Mercury Electrode

Tsai-Teh Lai and Chaur-Shyong Wen

Department of Chemical Engineering, Cheng Kung University, Tainan, Taiwan, China

ABSTRACT

The chelation of uranium(VI) with diethylenetriaminepentaacetate was investigated polarographically over the *p*H range 3.7-8.4 and ligand concentration range 0.005-0.1M. The predominant chelate species was found to be $UO_2(OH)H_2A^{2-}$ with the logarithmic formation constant of 2.96 at *p*H 6.4-7.5 and ionic strength 0.25. In the presence of Triton X-100 <0.003%, a single irreversible and diffusion-controlled wave was obtained. The kinetic parameters were determined (k_s is the order of 10^{-3} cm/sec and $\alpha = 0.42 \pm 0.02$). When the concentration of Triton X-100 is greater than 0.003%, the single wave splits into two irreversible waves, due to the adsorption of surface active substance.

Diethylenetriaminepentaacetic acid (DTPA) is well known to form stable complexes with many metals. Polarographic determinations of copper(II), bismuth(III), and antimony(III) using DTPA as supporting electrolyte have been studied (1). Kalland and Jacobsen have studied the effect of surface-active substances on the polarographic waves of iron-DTPA complexes (2) and also the polarography of copper-DTPA complexes (3,4). The polarographic behavior of europium (5) and thallium(I) (6) in DTPA solution has been reported. The metal ligand ratio of uranyl-DTPA complex has been shown to be 1:1 by spectrophotometry (7).

Since the diethylenetriaminepentaacetic acid is a versatile chelating agent, the polarographic data and the constants of the chelates of uranium(VI) with

Key words: cathodic action, formation constant, kinetic parameters, uranium (VI), DTPA.

DTPA provide an indispensable clue for the extraction, separation, and determination of uranium.

In an attempt to offer this important information, in this paper the polarographic characteristics, the formation constants, and the kinetic parameters due to the adsorption effect of the electrode process for the uranium-DTPA system are reported.

Experimental

Apparatus.—Polarograms were recorded with a Yanagimoto Pen-Recording Polarograph Model p8 at 30° ± 0.1°C. The characteristics of the DME were: m = 1.864 mg/sec and t = 4.53 sec at 74.9 cm mercury height in a 0.15M $NaClO_4$ solution at an applied potential of −0.40V *vs.* SCE.

The pH values of the solutions were adjusted with perchloric acid or sodium hydroxide and determined by a Toa Denpa HM-5A glass electrode pH meter.

Chemicals.—The stock solution of 0.1M uranyl perchlorate was prepared and analyzed as described in the earlier paper (8).

A 0.2M stock solution of DTPA was prepared by dissolving the acid (Aldrich Company) 19.668g and NaOH 6.0g in distilled water and diluting to 250 ml.

Triton X-100 was used as a surface-active substance and 0.15M sodium perchlorate as a supporting electrolyte.

Results and Discussion

Wave characteristics in the absence of surface-active substance.—A well-defined reversible wave was obtained when [DTPA] > 0.02M and 4.35 < pH < 8.40 in the absence of surface-active substance, Triton X-100 (Table I). However, a maximum appeared when pH < 4.35. As shown in Table II, the value of $i_d/h^{1/2}$ is 0.324 ± 0.004 at pH 5.2. This indicates that the limiting current is proportional to the square root of the height of the mercury column and proves that the reductions are entirely diffusion-controlled.

The temperature coefficient of half-wave potential is −0.2 mV/°C and the mean slope of the conventional log plots is 0.059 ± 0.004. These data indicate that the electrode reductions are a one-electron reversible process for the polarographic solutions of [DTPA] > 0.02M at 4.4 < pH < 8.4 in the absence of surface-active substance, Triton X-100.

As shown in curve A of Fig. 1, at pH < 6.4 and pH > 7.5, the slope of $\Delta E_{1/2}/\Delta pH$ is −0.060V showing that one hydrogen ion takes part in the reduction. At 6.4 < pH < 7.5, the half-wave potential is independent of pH. Curve A also shows that the half-wave potential is independent of ligand concentration for a given pH value. It reveals that the reduced complex species, uranium(V)-DTPA, has the same metal-ligand ratio of 1:1 as that of uranium(VI)-DTPA complex. Curve B shows that, in the absence of DTPA, the hydroxylation of uranyl ion occurs at pH > 4.0.

Since the successive pK values of DTPA are 1.75, 2.45, 4.23, 8.50 and 10.02 (9), respectively, the probable chelate species at 4.5 < pH < 8.4 can be deduced to be $UO_2(OH)H_2A^{2-}$ from the half-wave potential relation as had been reported in our earlier paper (10).

It is obvious from Fig. 2 that an anodic wave precedes the normal cathodic wave at pH > 6.0 and the half-wave potential shifts slightly to negative side as the ligand concentration and pH value increase. These phenomena were attributed to the depolarization of mercury by formation of a stable chelate with DTPA.

Formation constants of uranyl-hydroxo and uranyl-DTPA complexes.—It is obvious from curve B of Fig. 1 that in the absence of chelating agent and at pH < 4.0, the half-wave potential remains constant at −0.18V *vs.* SCE; the electrode reduction is

$$UO_2^{2+} + e \rightleftharpoons UO_2^{+} \qquad [1]$$

However, at pH > 4.0, the half-wave potential shifts to more negative side; the slope of $\Delta E_{1/2}/\Delta pH$ is −0.060V indicating that one hydroxyl ion is involved in the electrode reduction. Therefore, it was concluded that the uranyl-hydroxo complex undergoes the following electrode reduction without prior dissociation

$$UO_2(OH)^{+} + e \rightleftharpoons UO_2^{+} + OH^{-} \qquad [2]$$

The half-wave potential can be given as

$$(E_{1/2})_{UO_2(OH)^+} = (E_{1/2})_{UO_2^{2+}} - 0.060 \log K - 0.060 \log [OH^-] \qquad [3]$$

Where K is the formation constant of $UO_2(OH)^+$, which was calculated to be log K = 9.95 (Table III).

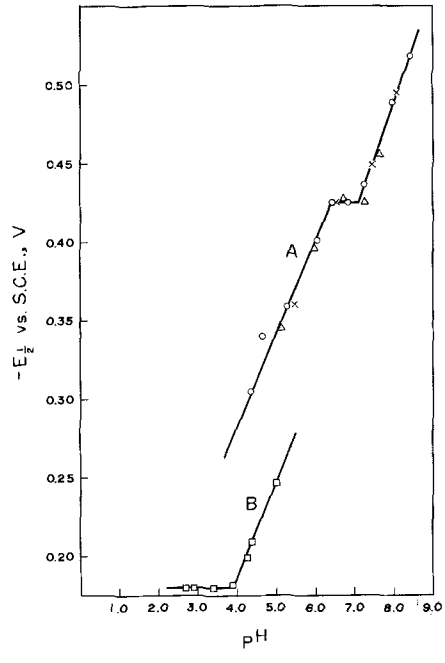

Fig. 1. Effect of pH on the half-wave potential of uranyl-DTPA complex. 1.0 mM $UO_2(ClO_4)_2$, 0.15M $NaClO_4$, 0% Triton X-100, and various ligand concentrations: ○ 0.1M; x 0.02M; △ 0.005M; □ 0.000M.

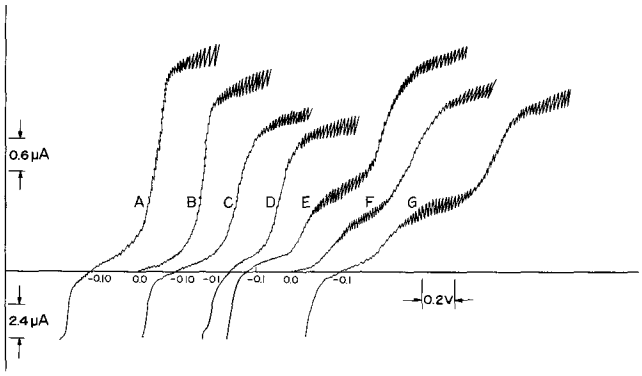

Fig. 2. Polarographic waves of uranyl-DTPA complex. 1.0 mM $UO_2(ClO_4)_2$, 0.15M $NaClO_4$, and varying concentration of DTPA and Triton X-100 at various pH:

	A	B	C	D	E	F	G
pH	5.0	5.0	6.0	6.5	5.0	5.0	6.0
C_{DTPA}, M	0.1	0.02	0.02	0.1	0.1	0.02	0.02
Triton X-100, %	0.002	0.002	0.002	0.002	0.004	0.004	0.004

At $6.4 < pH < 7.5$, the half-wave potential of the complex $UO_2(OH)(H_2A)^{2-}$ is independent of both pH value and ligand concentration (Fig. 1, curve A). Therefore, the half-wave potential of the complex $UO_2(OH)(H_2A)^{2-}$ can be written simply as

$$(E_{1/2})_c = (E_{1/2})_s - 0.060 \log \frac{K_{OC}}{K_{RC}} \qquad [4]$$

where K_{OC} and K_{RC} are the formation constants of the oxidized and reduced forms of the uranyl-DTPA complexes, respectively, and the K_{OC} was determined by the following method which had been reported previously (11).

In the modified Ilkovic equation (12)

$$i_d = 607\, nD^{1/2}m^{2/3}t^{1/6}\left(1 + \frac{AD^{1/2}t^{1/6}}{m^{1/3}}\right)C \qquad [5]$$

the concentration C of the reducible substance can be expressed as the complex species concentration of

$$[UO_2(OH)H_2A^{2-}] = \frac{C_{UO_2(OH)^+} \cdot \alpha_3}{\frac{1}{K_{OC}} + \alpha_3} \qquad [6]$$

where

$$\alpha_3 = \frac{C_{DTPA}}{\frac{[H^+]^3}{k_1k_2k_3} + \frac{[H^+]^2}{k_2k_3} + \frac{[H^+]}{k_3} + 1 + \frac{k_4}{[H^+]} + \frac{k_4k_5}{[H^+]^2}}$$

Substitute the corresponding experimental data for two pH values in the range of pH 6.4-7.5, into Eq. [5] and [6] and by solving the simultaneous equations

$$\begin{cases} (i_d)_1 = f_1(D, K_{OC}) \\ (i_d)_2 = f_2(D, K_{OC}) \end{cases} \qquad [7]$$

the formation constant and the diffusion coefficient of the complex $UO_2(OH)H_2A^{2-}$ can be obtained (Table IV).

Effects of Triton X-100 on the polarograms.—The polarograms were influenced greatly by the addition of Triton X-100. The reversible waves which were observed at $4.4 < pH < 8.4$ and DTPA concentration range of 0.02 to 0.1M were distorted into irreversible waves by the addition of Triton X-100 < 0.003%. Furthermore, when the concentration of Triton X-100 is increased above 0.003%, the wave splits into two more irreversible waves at a more negative potential due to the adsorption of surface active substances (13); the first wave is smaller than the second wave (Fig. 2). The polarographic characteristics of the two waves are shown in Table V.

The electrocapillary curve of mercury, which is illustrated in Fig. 3, shows that the addition of Triton X-100 to the solution causes a large decrease in the drop time of the capillary; the electrocapillary maximum shifts to the positive side with increasing concentration of Triton X-100.

These facts show that an adsorption of Triton X-100 occurs on the mercury electrode; the film formation of surface-active substance can be regarded as a rapid process (14). The inhibiting effect of the adsorbed film of Triton X-100 on the electron transfer renders the current-potential curve more irreversible.

The limiting current of the total wave is independent of the concentration of DTPA but decreases with increasing pH value (Fig. 4). It is interesting to note that the limiting current of the total wave increases with increasing concentration of Triton X-100 and reaches a plateau at 0.008% Triton X-100 (Fig. 4).

Electrode kinetics influenced by the adsorption of surface active substance.—As mentioned above, a single irreversible wave was obtained by the presence

	5.80	0.36	0.095	0.98	0.86	0.138	1.10	2.08

of Triton X-100 < 0.003%. This phenomenon can be attributed to the slower electron transfer in the electrode reduction in the presence of surface-active substance. Therefore the determination of the kinetic parameters of electrode reduction was carried out.

The plots of $E_{d.e.}$ *vs.* log $i/(i_d - i)$ were found to be good straight lines, but the mean slope for the series is 75 ± 5 mV (Table VI). The temperature coefficient of the diffusion current is 0.82%/°C and the value of $i_d/h^{1/2}$ is 0.299 ± 0.020 at pH 5.0. These data show that although the electrode reactions are diffusion-controlled, the process is not reversible.

The corrected reversible half-wave potential $E_{1/2}^r$ for a quasi-reversible system can be expressed by the following relation (15)

$$E_{1/2}^r = \lim_{i \to 0} \left[E_{d.e.} - \frac{RT}{n\mathbf{F}} \ln \frac{i_d - i}{i} \right] \qquad [8]$$

Thus, by plotting $[E_{d.e.} - RT/n\mathbf{F} \ln i_d - i/i]$ against i and by extrapolating it to $i = 0$, the $E_{1/2}^r$ can be obtained (Fig. 5).

The degree of irreversibility of the electrode reduction is expressed by Eq. [9] (15)

$$Z = \text{anti} \log_{10} \left[\frac{n\mathbf{F}}{2.303\,RT} (E_{1/2}^r - E_{d.e.}) - \log \left(\frac{i}{i_d - i} \right) \right] \qquad [9]$$

The standard rate constant k_s and transfer coefficient α can be determined by the following equation

$$\log (Z - 1) = \log \frac{1.13\, D_o^{1/2}}{k_s \sqrt{t_d}} + \frac{(1 - \alpha) n\mathbf{F}}{2.303\,RT} (E_{1/2}^r - E_{d.e.}) \qquad [10]$$

Table VI. Polarographic characteristics and kinetic parameters of uranyl-DTPA chelate

6.60	0.428	0.416	1.44	0.075	0.41	3.09
7.35	0.440	0.418	1.38	0.074	0.40	2.72
8.40	0.500	0.495	0.96	0.071	0.43	2.29

where t_d is the drop time, D_o is the diffusion coefficient of oxidized form.

Equation [10] shows that the plot of log $(Z - 1)$ *vs.* $(E_{1/2}^r - E_{d.e.})$ should give a straight line and the value of k_s and α can be obtained from the intercept and the slope of the plot (Fig. 6). The data obtained at various pH values are listed in Table VI.

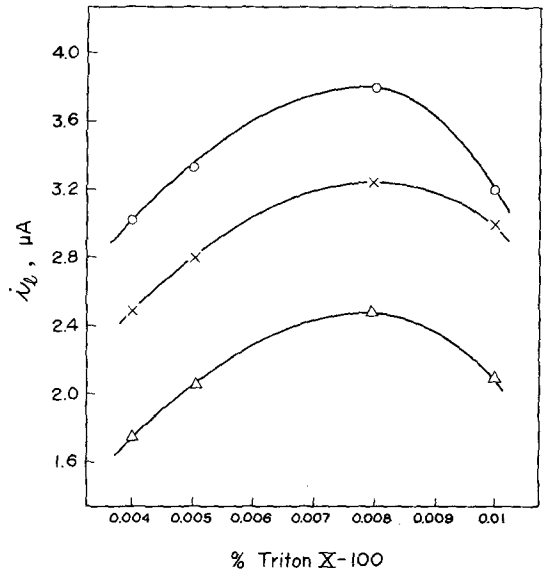

Fig. 4. Effect of Triton X-100 on the total limiting current of uranyl-DTPA complex. 1.0 mM $UO_2(ClO_4)_2$, 0.02M DTPA, 0.15M $NaClO_4$; ○ pH 4.4; x pH 5.0; △ pH 6.0.

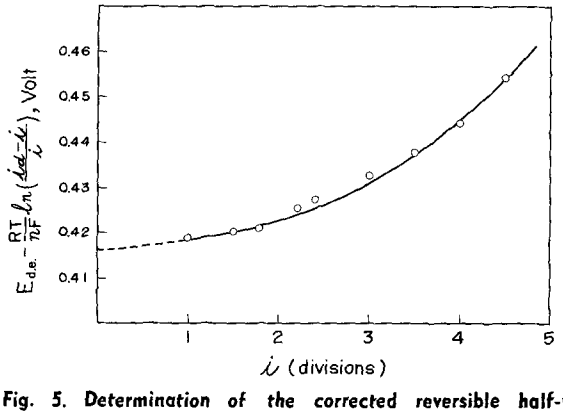

Fig. 5. Determination of the corrected reversible half-wave potential. 1.0 mM $UO_2(ClO_4)_2$, 0.1M DTPA, 0.15M $NaClO_4$, and 0.002% Triton X-100 at pH 6.6.

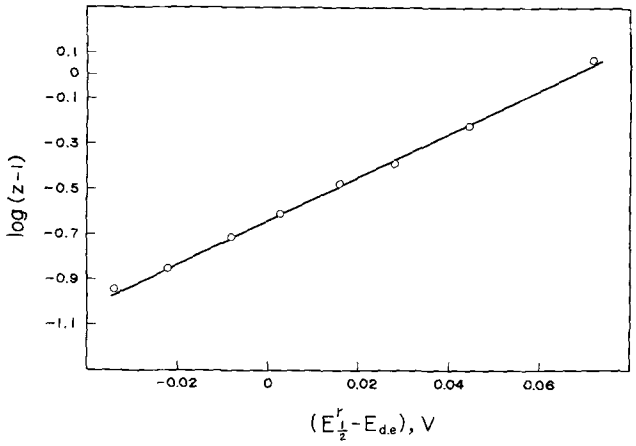

Fig. 6. Plot of log (Z — 1) against ($E_{1/2}{}^r$ — $E_{d.e.}$). 1.0 mM $UO_2(ClO_4)_2$, 0.1M DTPA, 0.15M $NaClO_4$, and 0.002% Triton X-100 at pH 6.6.

The k_s values were found to be of the order of 10^{-3} cm/sec, which indicates that the electrode reduction is quasi-reversible (16). As the pH increases, k_s was found to decrease, showing that the irreversibility increases with increasing pH value. The adsorption of surface-active substance on the dropping mercury electrode inhibited the reaction rate and resulted in the increase of irreversibility. The transfer coefficient α was found to be 0.42 ± 0.02 (Table VI).

Cation Transport Numbers in Molten $AgNO_3$-AgCl Mixtures by Pressure-EMF Measurements

H. E. Townsend*[1] and Paul Duby*[2]

Department of Metallurgy and Laboratory for Research on the Structure of Matter, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

The pressure-emf, or difference in electrode potential which results from a hydrostatic pressure difference, was measured in molten salt cells represented schematically as

$$Ag(s)/AgNO_3, AgCl(l)\ [P_1]//AgNO_3, AgCl(l)\ [P_2]/Ag(s)$$

containing 0-42.8 m/o AgCl, from 200° to 260°C. Measurements of this effect, which depends on the difference between anion and cation mobilities, indicate that the cation transport number increases with increasing AgCl content or with decreasing temperature. Because of the small differences between anion mobilities, the pressure-emf alone is shown to provide a good approximation to all three ion constituent transport numbers in this system.

It has been reported previously (1) that a pressure-emf can be measured in fused salts by applying a pressure difference between two electrode compartments separated by a porous diaphragm and by recording the changes in potential difference between two identical metallic electrodes in equilibrium with the same electrolyte. Equations have been derived (2) which show that this pressure-emf is a linear function of the mass transport numbers of the various components relative to an external reference frame such as the cell or the diaphragm. Although the theory in general applies to any electrolyte, the experiments have so far been limited to single fused salts, and only the results on silver nitrate have been reported in detail (3). The present paper describes a similar investigation which has been carried out with molten mixtures of silver nitrate and silver chloride.

In the general case of a cell, at uniform temperature and composition, containing a mixture of c elemental components (ion constituents), one of which (denoted

* Electrochemical Society Active Member.
[1] Present address: Homer Research Laboratories, Bethlehem Steel Corporation, Bethlehem, Pa.
[2] Present address: Henry Krumb School of Mines, Columbia University, New York, N. Y.
Key words: cation transport numbers, molten salt mixtures, pressure-emf, silver nitrate melts, silver chloride melt, transport number.

by subscript 1) is oxidized or reduced at either of the two identical electrodes, it can be easily shown (2) that as a consequence of Saxen's relation,[3] the pressure-emf is given by the following equation

$$\frac{\Delta E}{\Delta P} = -\frac{1}{\mathbf{F}}\left[\frac{\overline{V}_1^{\circ}}{z_1} + \sum_{k=2}^{c} \tau_k \left(\frac{\overline{V}_k}{|z_k|} - \frac{z_k}{|z_k|}\frac{\overline{V}_1}{z_1}\right)\right] \quad [1]$$

where: ΔE is the electrical potential difference which is caused by the hydrostatic pressure difference ΔP; $\mathbf{F}$ is the Faraday constant (96,487 coulombs); $\overline{V}_1$ and z_1 are the partial molar volume and the oxidation number of the constituent of the electrolyte which reacts at the electrodes; $\overline{V}_1^{\circ}$ is the partial molar volume of the same constituent in the electrode phase; $\overline{V}_k$ and z_k are the partial molar volume and the oxidation number of the remaining elemental components which constitute the electrolyte and which can be determined by chemical analysis.

τ_k is the equivalent mass transport number of the component k relative to an external reference frame, and it is defined as the number of equivalents of the elemental component which would be transported across the diaphragm per faraday of electricity during an electrodiffusion experiment. The transport numbers are algebraic numbers, positive for a transport toward the cathode, and the sum of their arithmetic values equals one.

As discussed previously (2), these definitions, which lead to the above equation by a straightforward thermodynamic calculation, do not require any knowledge or any assumption concerning the ionic species actually present in the melt. The transport numbers are macroscopic quantities that describe the total fluxes resulting from all possible transport mechanisms.

The pressure-emf equation has been derived by the application of theories of thermodynamics of irreversible processes and Onsager's reciprocal relation. It requires only the assumption that the transport numbers and partial molar volumes remain constant within the range of electric field and hydrostatic pressure gradient across the fritted disk, and these conditions are easily verified experimentally. It is also assumed for the purpose of deriving the equation that the chemical composition and temperature remain uniform throughout the system. These conditions are actually fulfilled, even with a mixture as the electrolyte, because the pressure-emf can be measured very fast and because, with a suitable measuring device, no appreciable current is drawn from the cell so that no transport of matter occurs and no concentration gradient builds up.

Equation [1] is readily applied to a mixture of silver nitrate and silver chloride with two metallic silver electrodes. Silver, chlorine, and the nitrate group are the obvious choices as the elemental components, and the oxidation numbers are +1 for the silver and −1 for the chlorine and nitrate. Thus, for the cell which can be schematically represented as

$$\mathrm{Ag(s)/AgNO_3,\ AgCl(1)\ [}P_1\mathrm{]//AgNO_3,\ AgCl(1)\ [}P_2\mathrm{]/Ag(s)}$$

the pressure-emf for uniform temperature and composition is given by

$$-\mathbf{F}\frac{\Delta E}{\Delta P} = V_{Ag} + \tau_{NO_3}\overline{V}_{AgNO_3} + \tau_{Cl}\overline{V}_{AgCl} \quad [2]$$

Experimental

The pressure-emf, or difference in cell potential resulting from a pressure difference between the electrodes, has been measured by continuously recording the voltage of the cell described above and noting the changes that occur as the difference in hydrostatic pressure, $\Delta P = P_2 - P_1$, is alternately applied and released. A glass frit separates the two electrode compartments and allows the pressure difference to be maintained for finite times; 10-15 sec is usually allowed to apply, measure, and release a given pressure difference. Voltage changes were recorded with a Keithley 150 microvoltmeter (10^7 ohms input resistance on the 10 μV range) and a Bausch and Lomb VOM-5 recorder which were calibrated after a series of measurements at a particular temperature by use of a Keithley 260 (better than ± 0.05 μV for a 10 μV output) nanovolt source. The technique employed was with some minor changes identical to that previously described in detail in connection with the measurement of pressure-emf in pure molten salts (3). The modifications which were made as a matter of experimental convenience and do not appear to change the results include the use of silver wire electrodes secured by Teflon seals, instead of silver-plated tungsten wire electrodes sealed in glass, and fine (4-5μ) rather than medium (10-15μ) porosity fritted glass disks.

The pressure-emf has been studied in $AgNO_3$-AgCl mixtures of five compositions (0.057, 0.117, 0.232, 0.345, 0.428 equivalent fraction AgCl) at temperatures extending from the liquidus (indicated by the left-hand termini of the lines on Fig. 1) to the useful limit of the Teflon seals, about 260°C. For each composition, measurements were taken in a random sequence of temperatures. At each temperature which was held constant within ± 1°C by immersion of the cell in a molten Pb-Sn bath, we performed 20-30 individual measurements of the potential changes attending the applied pressure differences which ranged from 5 to 70 cm Hg. The direction of flow was reversed on alternate measurements. Plots of the potential changes, ΔE, against the corresponding pressure differences, ΔP, typically result in straight lines, the slopes of which are the pressure-emf, $\Delta E/\Delta P$. Standard deviations of these slopes were generally within the range 0.05-0.15 μV/atm. This scatter is related to changes in the slope of the background drift (total background generally less than 200 μV) which accompany the flow of salt under the applied pressure difference. Typical recordings of the changes in cell potential as the pressure is applied and released as well as additional experimental details are given elsewhere (3, 11).

The minus sign on the $\Delta E/\Delta P$ values measured in this investigation indicates that in all cases the electrode at the higher pressure became more anodic on application of the pressure difference.

The salt mixtures were prepared from Baker reagent-grade salts, which were fused, mixed, and filtered prior to placing within the cell.

Results and Discussion

The measurements of pressure-emf for mixtures of $AgNO_3$-AgCl are summarized in Fig. 1. At each com-

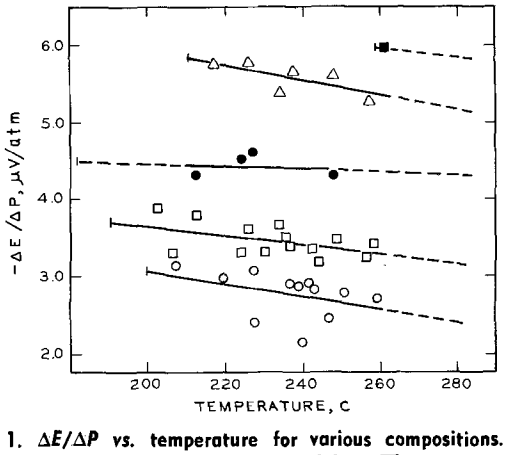

Fig. 1. $\Delta E/\Delta P$ vs. temperature for various compositions. Mole fractions of AgCl are respectively: ○ 0.057, □ 0.117, ● 0.232, △ 0.345, ■ 0.428.

[3] See, for example, G. N. Lewis, M. Randall, K. S. Pitzer, and L. Brewer, "Thermodynamics," 2nd ed., p. 458, McGraw-Hill Book Co., New York, N. Y. (1961).

position (except at $N_{AgCl} = 0.428$, where only one temperature was studied) there appears to be a slight decrease in the absolute value of $\Delta E/\Delta P$ with increasing temperature. The lines drawn through the points at each composition were constructed by a least squares fit.

At those compositions for which measurements were performed at the greatest number of temperatures, it was observed that measurements (those which deviate most from the least squares lines of Fig. 1) at the first few temperatures differed by several standard deviations from the least squares lines. After the initial measurements, however, the results which followed seemed to fit more closely to the downward sloping line. Accordingly, one might be justified in rejecting the initial data on the basis of a possible systematic error.[4] We have chosen not to do this because (*a*) only a few measurements were performed for two of the compositions and (*b*) the salient results of this study, namely, the composition dependence at constant temperature of the pressure-emf and of the transport numbers, are largely unaffected.

At a given temperature, the value of pressure-emf increases markedly with increasing concentration of AgCl. Figure 2 clearly shows the increase of $\Delta E/\Delta P$ relative to the pure salt value (3) as AgCl concentration is increased at 230°C. The error limits associated with each point are based on the standard deviation calculated from the distribution of the data about the least squares lines of Fig. 1.

The composition dependence of $\Delta E/\Delta P$ can now be considered in relation to mass transport in this system. An average anion mass transport number, τ^*_-, can be defined as

$$\tau^*_- = \frac{1}{V_m}\left(\tau_{NO_3}\,\overline{V}_{AgNO_3} + \tau_{Cl}\,\overline{V}_{AgCl}\right) \qquad [3]$$

where $V_m = N_{AgNO_3}\,\overline{V}_{AgNO_3} + N_{AgCl}\,\overline{V}_{AgCl}$ is the equivalent volume of the mixture and N_{AgCl} and N_{AgNO_3} are the equivalent fractions of those components. This allows Eq. [2] to be written as

$$-\mathbf{F}\frac{\Delta E}{\Delta P} = V_{Ag} + \tau^*_- V_m \qquad [4]$$

The broken line shown in Fig. 2 is a plot of Eq. [4] where the assumption has been made that τ^*_- remains unchanged as AgCl is added to pure $AgNO_3$. The slight upward slope reflects the decrease in V_m (4) with increasing N_{AgCl}. The measured values occur significantly above this line, thus indicating that the average anion mass transport number decreases with increasing concentration of AgCl.

[4] Since similar behavior was not observed in experiments with pure $AgNO_3$ (3), we suspect that incomplete mixing in the case of the initial measurements with mixtures may be a possible source of error.

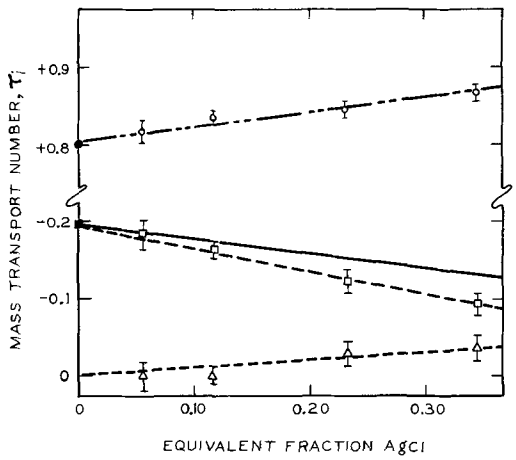

Fig. 3. Mass transport numbers vs. composition, $t = 230°C$. $-\tau^*_-$ calculated from Eq. [4]; ———— $(1 - \tau^*_-)$. ●, ■ pure salt values of mass transport number (ref. 3) of Ag^+ and NO_3^-, respectively; ○ τ_{Ag}; □ τ_{NO_3}; △ τ_{Cl}; – – – $\tau^*_-\,N_{AgNO_3}$ (negative slope) and $\tau^*_-\,N_{AgCl}$ (positive slope).

The decrease in τ^*_- with increasing AgCl is shown explicitly in Fig. 3, where the solid line has been drawn through values computed from Eq. [4]. Correspondingly, there is an increase in the average cation mass transport number, τ^*_+, defined by

$$\tau^*_+ = 1 + \tau^*_- \qquad [5]$$

shown at the top of Fig. 3.

The average anion mass transport number can be related to those of the elemental components by

$$\tau_{NO_3} = \tau^*_-\,N_{AgNO_3} - \phi\frac{V_{AgCl}}{V_m}$$

$$\tau_{Cl} = \tau^*_-\,N_{AgCl} + \phi\frac{V_{AgNO_3}}{V_m} \qquad [6]$$

where

$$\phi = \tau_{Cl}\,N_{AgNO_3} - \tau_{NO_3}\,N_{AgCl} \qquad [7]$$

The function ϕ is a measure of the difference between the mobilities of the two unlike elemental components with the same oxidation number in a binary common-ion mixture. It is often used to summarize results such as those of a Hittorf experiment (5, 6), a measurement of liquid junction potential (7, 8), or a measurement of the potential of a gravity cell (4), which all depend on that difference and are related to the function ϕ. For the system $AgNO_3$-AgCl, it has been previously shown that ϕ is quite small (4) (less than 0.03), which indicates that the values of the mobilities of the two anionic elemental components are nearly equal in these ranges of composition and temperature. Thus, the last term in Eq. [6] may be neglected as a first approximation, allowing computation, within a reasonable degree of precision, of τ_{NO_3} and τ_{Cl}, as well as τ_{Ag} from

$$\tau_{Ag} - \tau_{NO_3} - \tau_{Cl} = 1 \qquad [8]$$

Values of τ_{NO_3} and τ_{Cl} that result from neglecting the last terms in Eq. [6] are plotted as the two lowermost dashed lines in Fig. 3. Exact values of elemental component mass transport numbers, τ_{Ag}, τ_{NO_3}, and τ_{Cl}, which have been computed without approximation using Eq. [4] and [6], with the experimental values of ϕ (4), are also shown on Fig. 3 with the associated uncertainties. Within the cumulative uncertainty, the exact values are coincident with the approximate quantities which have been inferred from the pressure-emf measurements alone, assuming equal anion mobilities. Thus, the approximations

$$\begin{aligned}\tau_{Ag} &= 1 + \tau^*_-\\ \tau_{NO_3} &= \tau^*_-\,N_{AgNO_3}\\ \tau_{Cl} &= \tau^*_-\,N_{AgCl}\end{aligned} \qquad [9]$$

are quite satisfactory; and this system as well as others (8, 9), for which ϕ has been determined to be small relative to the precision with which it can be measured, are amenable to description in terms of a single mass transport number, τ^*_-, determined by the relatively simple experimental technique of pressure-emf.

Without necessarily invoking any microscopic model one can define electrical mobilities which correspond to the quantities τ^*_- and τ^*_+ as

$$U^*_- = \tau^*_- \frac{\Lambda}{\mathbf{F}} \qquad [10]$$

$$U^*_+ = \tau^*_+ \frac{\Lambda}{\mathbf{F}}$$

where Λ is the equivalent conductance. These mobilities have been calculated at 10-degree intervals by use of available conductivity data (10) and are shown in Fig. 4 for each of the compositions studied. Although the slope dU^*_+/dT is greater than dU^*_-/dT, the fractional rate of increase is greater for U^*_-, a fact which is significant for two reasons. First, it indicates that the average cation mass transport number

$$\tau^*_+ = \frac{U^*_+}{U^*_+ - U^*_-} \qquad [11]$$

is decreasing with temperature. Second, it indicates that the activation energies for electrical transport, which can be deduced from an Arrhenius plot of these mobilities, are larger for anion transport. A trend of decreasing anion mobility and hence increasing activation energy with increasing concentration of AgCl is also evident in Fig. 4.

At all temperatures the values calculated for U^*_+ are identical up to 0.232 AgCl as shown on Fig. 4. However, within experimental uncertainty (about 5%, cf. Fig. 3), it would be possible to assume that, with increasing concentration of AgCl. a linear increase in U^*_+ occurs simultaneously with the decrease in U^*_-.

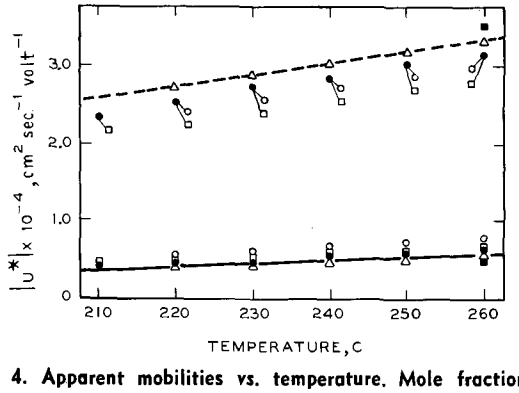

Fig. 4. Apparent mobilities vs. temperature. Mole fractions of AgCl are respectively: ○ 0.057; □ 0.117; ● 0.232, △ 0.345; ■ 0.428. The continuous and the interrupted lines represent U^*_- ———, and U^*_+, – – –, for $N_{AgCl} = 0.345$. Values of U^*_+ for 0.057 and 0.117 are coincident with that at 0.232.

On the basis of the relative anion mobilities as well as the concentration dependence of conductivity and the thermodynamic properties of these mixtures, it has been previously suggested (4) that the process of mixing molten $AgNO_3$ and AgCl could be described in terms of the formation of relatively low-mobility mixed anionic complexes, the simplest example of which is $ClAgNO_3^-$. The results of this investigation, notably (*a*) the decrease in combined anion mobility (as shown in Fig. 3 and 4), and (*b*) the larger (absolute) value of activation energy for anion mobilities, may be consistent with that point of view.

The relationship of item (*a*) above to a model of mixed anionic complexes is obvious enough, particularly when one notes that the values of τ_{NO_3} and τ_{Cl} seem to approach the same value at $N_{AgCl} = N_{AgNO_3}$. Item (*b*) could be related to the same phenomenon in that an additional activation energy is required for thermal dissociation of the complex species as they are formed to an increasing extent with increasing N_{AgCl}. However, any models of complex ion formation based solely on macroscopic transport and thermodynamic information will admittedly remain quite speculative until further information such as self-diffusion, x-ray, and spectroscopic data become available.

One might also inquire as to the generality of the phenomenon of decreased average mobility for the noncommon elemental components in common-ion binary mixtures exhibiting negative heats of mixing. Additional transport measurements in other systems would be useful in this regard.

Thermodynamics of Molten Silver Chloride-Alkali Chloride Solutions by Electromotive Force Measurements

A. D. Pelton and S. N. Flengas*

Department of Metallurgy and Materials Science, University of Toronto, Toronto 5, Ontario, Canada

ABSTRACT

Electromotive force measurements have been made using the reversible formation cell

$$Ag \mid \begin{matrix}\text{AgCl-alkali chloride} \\ \text{(liquid)}\end{matrix} \mid \text{graphite, } Cl_2$$

Various aspects of the cell design are discussed. Measurements were of sufficient precision to give the concentration dependence and the magnitude of the excess free energies, enthalpies, and excess entropies of mixing in the AgCl-ACl (where A = Na, K, Rb, or Cs) systems. The results are discussed in terms of covalent bonding in molten silver chloride. A simple semiquantitative "dual bonding" model is developed in which "ionic" and "covalent" silver coexist.

A knowledge of the thermodynamic properties of molten AgCl-alkali chloride mixtures is of importance in the understanding of the fundamental properties of simple fused salt systems. Accurate enthalpies of mixing in these systems are available from the calorimetric measurements of Hersh and Kleppa (1). Several authors have studied the AgCl-LiCl (2, 3), AgCl-NaCl (4-7), and AgCl-KCl (7-9) systems using electrochemical formation cells. This work is reviewed by Dijkhuis *et al.* (10). Recently, Guion *et al.* (7) have made some measurements in the AgCl-CsCl system. Such measurements in the AgCl-RbCl system have not been reported. From these results, the magnitude of the free energies of mixing are known with reasonable accuracy in these systems. However, asymmetry terms in the concentration dependences of the free energies of mixing are at best poorly defined. The temperature dependences of the measured emf's are of sufficient precision to give only a very approximate estimate of the excess entropies of mixing. A knowledge of the excess entropies of mixing is of prime importance in understanding the solution properties of these mixtures. In the present investigation, measurements of the emf's of formation cells of the following type were made

$$Ag \mid AgCl\text{-}ACl \mid \text{graphite, } Cl_2$$

(where A = Na, K, Rb, or Cs). The measurements were of sufficient precision to permit the calculation of not only the magnitudes but also the asymmetries in the concentration dependences of the excess free energies, enthalpies, and excess entropies of mixing in these systems.

Experimental

A quartz cell was used. A diagram of this cell is shown in Fig. 1. The inner quartz crucible was filled to a depth of about 1½ in. with the melt. The cell was surrounded by a grounded Inconel metal sheath and placed in a tube furnace. Temperatures were read with a calibrated chromel-alumel thermocouple placed as shown in Fig. 1. In a preliminary experiment in which another identical thermocouple was placed in the melt, it was found that the thermocouple in the thermocouple well read the melt temperature correct to within about 0.5°K and also that the temperature gradients over the 1½ in. depth of the melt were of the order of 0.5°K. The total error in temperatures reported is probably about ±1°K. The cell emf and the thermocouple output were tested for induced pickup from the a-c field of the furnace windings by taking readings as the furnace was switched off and on. With the Inconel sheath grounded, no detectable pickup was observed.

A silver electrode of 99.9+% purity and of ⅛ in. diameter welded to a 0.040 gauge silver lead was used. The cell emf was independent of depth of immersion provided that the electrode was immersed deeper than about ¼ in. Only a very small amount of dendrite formation was observed on the silver after operating the cell for a period of two to three days. However, if a finer gauge silver electrode were used, more dendrites formed, and cell voltages were slightly less stable. Possibly, the larger silver wires, having higher thermal conductance, tend to have smaller temperature gradients along their lengths.

The graphite used in the chlorine electrode was ⅛ in. diameter special spectroscopic "SPK" graphite from National Carbon Company. The graphite rods were pretreated by being held at 900°C alternately for 12 hr under vacuum and under an atmosphere of chlorine for a total of 48 hr. A small amount of tar-like im-

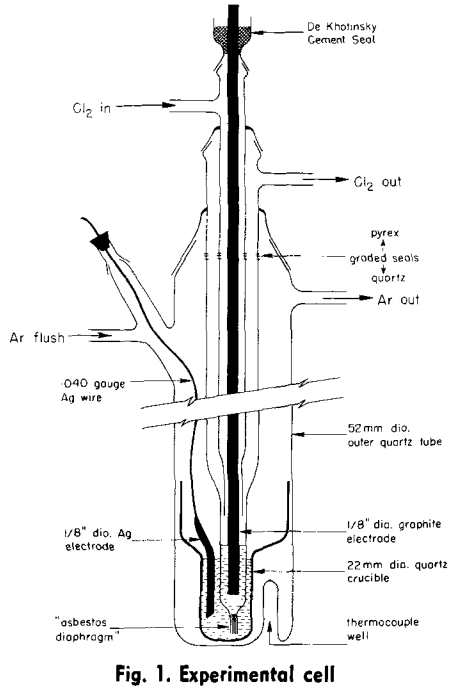

Fig. 1. Experimental cell

Key words: silver chloride, alkali chlorides (sodium chloride, potassium chloride, rubidium chloride, cesium chloride), molten salts (fused salts), formation cells, chlorine electrode, silver electrode, thermodynamics.

purity was removed in this manner. The chlorine used was Matheson "high purity" grade. The chlorine was passed over magnesium perchlorate before being admitted to the cell. It was found that saturation of the melt with chlorine could be achieved without the necessity of bubbling the chlorine through the melt. An arrangement as in Fig. 1 with the Cl_2 inlet tube ending 1 cm above the melt was used.

Of major importance in the present cell design is the "asbestos diaphragm" which separates the two electrode compartments and prevents the diffusion of chlorine to the silver electrode (11). Briefly, these diaphragms are made by tightly rolling a small strand of asbestos string, firing it to a white ash, and then collapsing 6 mm quartz tubing around it with tweezers. Very fine capillary channels result. Cell resistances of 1000 to 20,000 ohms were obtained with these diaphragms. No noticeable attack of the silver electrode after several days of operation was noticed. Most other investigators have used quartz frits or capillary tubes as diaphragms, with cell resistances of about 50 ohms. It is believed that the very stable cell voltages in the present study are, to a large degree, a result of these high resistance asbestos diaphragms.

Reagent grade AgCl, NaCl, and KCl were used. The CsCl (Fisher) was of 99.9% purity, and the RbCl (Matheson) was of 99+% purity. All salts were dried under vacuum and with dry HCl gas at 400°C in the case of AgCl and at 550°C for the alkali chlorides. All salts were stored in a vacuum dessicator.

In a typical experiment, the quartz crucible was filled with the salts and, with the silver electrode in place, the outer cell was capped with a rubber stopper and the salts were melted under vacuum. If melting was not done under vacuum, cell voltages would be slightly less stable for the first 24 hr, possibly because of the effect of dissolved oxygen on the silver electrode. After fusion had occurred, dried purified argon was admitted to the outer cell, and the inner cell, containing the proper amount of salts, was quickly lowered into place. After 2 min, when the salts in the inner cell had melted, the graphite electrode assembly was lowered into place and the inner cell was quickly flushed with dried argon. Cell voltages were found to be slightly more stable if about 12 hr were allowed to elapse before readings were taken.

The chlorine electrode compartment was flushed with chlorine at a high flow rate. After about 1 hr the cell voltage would be stable. Thereafter, readings were taken with the Cl_2 flowing at about 25 ml/min. Voltages were independent of flow rate. The cell emf was measured with a Leeds and Northrup K3 potentiometer. All voltages reported in this work are in absolute volts. No appreciable condensation of salt in the upper part of the apparatus was observed, and so volatility of the salts is not a problem at the temperatures employed in these experiments.

The Cl_2 pressure in the cell was measured with a manometer filled with H_2SO_4. The pressure was about 3 mm Hg above barometric because of the exit bubbler heads. All readings reported were corrected to a Cl_2 pressure of 1 standard atmosphere (1.01325×10^5 newton-m^{-2}). Voltages measured would remain stable to ±0.2 mV for several hours. Response to temperature changes was immediate. Voltages were reproducible on repeated heating and cooling cycles as shown later. All cells were subjected to a polarization test in which about 1 mA was passed through the cell for about 1 min in each direction using an external dry cell. Cell voltages would return to within 0.1 mV of their previous values within 15 sec after the external dry cell was disconnected.

Pressure dependence.—The response of the cell to changes in chlorine pressure was studied. This was done previously, but only over the limited pressure range of 760 to 1050 mm Hg, by Wachter and Hildebrand (12) who observed the expected Nernst behavior.

The chlorine pressure was controlled by mixing the Cl_2 with dry purified argon. Chlorine and argon flow rates were measured using Gilmont "RGI" spherical float flowmeters which were calibrated for the specific gases with a soap-bubble column. Chlorine pressures from 1.0 to 10^{-1} atm could be determined with an accuracy of about ±5%, and from 10^{-1} to 10^{-2} atm with about ±15% accuracy. Calculations show, then, that an accuracy of about ±2 mV at higher Cl_2 pressures and about ±6 mV at the lowest Cl_2 pressures should be obtained at the temperatures of the experiments. At the lowest Cl_2 pressure, when the Ar flow rate was very high, some of the gas mixture was bled off before reaching the cell so that the total flow rate through the cell was about 50 ml/min. Flow rates were kept steady to about ±2% for the duration of a measurement using needle valves.

Five pressure-dependence studies were made, three with pure AgCl electrolyte at different temperatures, and two with fairly dilute solutions of AgCl in NaCl. No hysteresis was observed on increasing and decreasing pressure cycles. The cell voltage responded very quickly to the presure changes. Steady voltages were obtained within about 15 min of a flow rate change, which is about the time one would expect to be required for the gas phase to reach equilibrium. Results are shown in Fig. 2. Theoretical lines calculated from the Nernst equation are also shown. Results are within the error limits expected from the accuracies of the pressure measurements.

Several authors (4, 8, 13-15) have noted that pretreatment of the graphite electrode (usually with Cl_2 at high temperature as in the present study) is necessary for the attainment of stable voltages. It has been suggested that the pretreatment is necessary to saturate the graphite with chlorine. However, the rapid response of the cell emf to changes in Cl_2 pressure as observed in the present study would indicate that saturation is no problem. Perhaps the main effect of the pretreatment is to oxidize impurities (such as ungraphitized binder) in the graphite. Several of these authors have also stated that a pre-electrolysis step was sometimes required to achieve stability. This was not required in the present study.

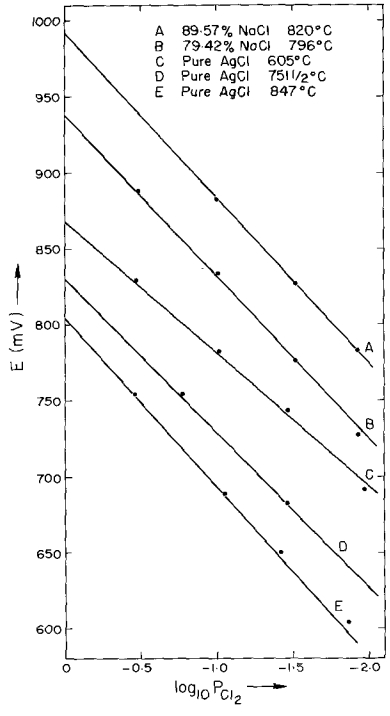

Fig. 2. Results of pressure-dependence studies. Lines shown are calculated from the Nernst equation.

Thermoelectric correction.—The correction for the voltage of the Ag-C couple was determined by measuring the voltage of a cell in which the contact between the silver and the graphite was made with a silver wire instead of the molten electrolyte. Results are shown in Fig. 3. Voltages were quite reproducible on continued heating and cooling. Carbon is negative to silver at the cold junction, and so the thermoelectric potential opposes the emf of the cell. The voltages are very nonlinear with temperature. Voltages as measured by Hamby (16) are also shown in Fig. 3. Panish *et al.* (4) do not give their correction, but state that it was "from 1-9 mV" over the temperature range of interest, which is close to the values obtained in the present study. Literature values (17) give the voltage of the Ag-C couple as varying from 1.2 to 2.6 mV from 500° to 900°C. It would appear that these values are questionable.

The equation of the curve shown in Fig. 3, as obtained by a least squares analysis is

$$V\ (\text{mV}) = 4.36 - 0.08802T + 0.01288T \ln T \quad [1]$$

where T is in Kelvins. This thermoelectric correction only affects the absolute values of E° for the formation of pure AgCl, and does not, of course, affect the differential solution properties.

Results

Formation potential, E°, of pure AgCl.—The formation potential, E°, of pure AgCl was determined in three separate experiments. Results as shown in Fig. 4 are not corrected for the thermoelectric potential. These results were obtained on several heating and cooling cycles.

Recent measurements in this laboratory (18) indicate that the heat capacity, C_p, of liquid AgCl is 13.7 cal/K-mole. Using this value along with literature (19) values of C_p for Ag and Cl_2, ΔC_p for the reaction

$$Ag + \tfrac{1}{2}Cl_2 \rightarrow AgCl_{(liq)} \quad [2]$$

was calculated as

$$\Delta C_p = 4.2 - 2.07(10^{-3})T \text{ cal/K-mole} \quad [3]$$

where T is in Kelvins. (In the present work, 1 calorie is defined as 4.1840J.) Therefore, from the relationship

$$\Delta C_p = nFT\left(\frac{\partial^2 E^\circ}{\partial T^2}\right) \quad [4]$$

(where $n = 1$ for reaction [2] and **F** is the Faraday constant) it may be shown that the expected functional form of E° is

$$E^\circ(\text{mV}) = A + BT + 0.182T \ln T - 4.48(10^{-5})T^2 \quad [5]$$

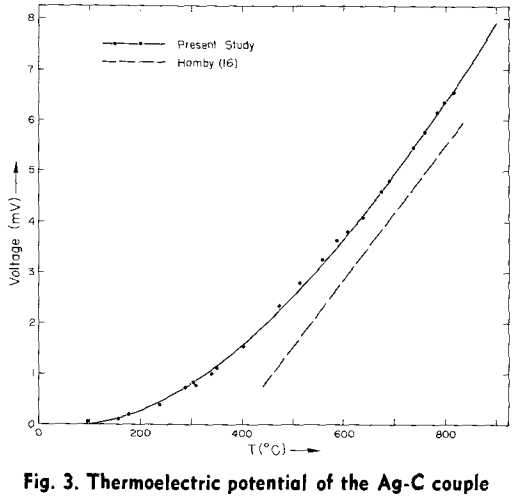

Fig. 3. Thermoelectric potential of the Ag-C couple

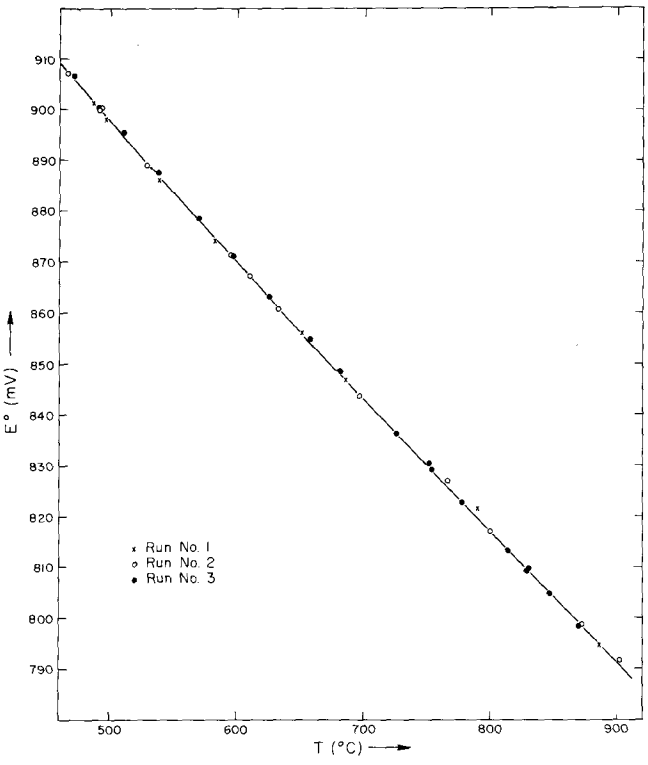

Fig. 4. Formation potential of pure AgCl (uncorrected for thermoelectric potential).

The 39 data points from the three experiments were fitted by a least squares method to an equation of the form of Eq. [5], giving

$$E^\circ(\text{mV}) = 1227.0 - 1.5973T + 0.182T \ln T - 4.48(10^{-5})T^2 \quad [6]$$

The standard deviation was 0.57 mV, and only one point deviated by more than 1.0 mV from the line. The curvature of the experimental curve is thus in very good agreement with that predicted on the basis of heat capacity measurements. In Fig. 4 are shown the experimental points and the fitted curve. Values shown in Fig. 4 are uncorrected for the thermoelectric effect, and the curve shown is Eq. [6] with Eq. [1] subtracted from it.

Hamer *et al.* (20) calculated E° from thermochemical data. If Hamer's calculations are corrected by taking C_p for liquid AgCl as 13.7 (instead of 16.0 as used by Hamer), then the thermochemical curve of E° *vs.* T is very close to the curve measured in the present study and is nearly parallel to it. This is shown in Table I. Agreement between the present results and E° values measured electrochemically by other authors (4, 7, 11, 13, 14, 21) is also reasonable. Values taken from Senderoff and Mellors' (13) curve are listed in Table I. Much of the discrepancy between the present results and those of Senderoff and Mellors probably results from their use of the literature (17) values for the thermoelectric correction. Values measured by Flengas and Ingraham (11) by extrapolating emf's measured in concentration cells are also shown in Table I and are in good agreement with the present values and also with the thermochemical data.

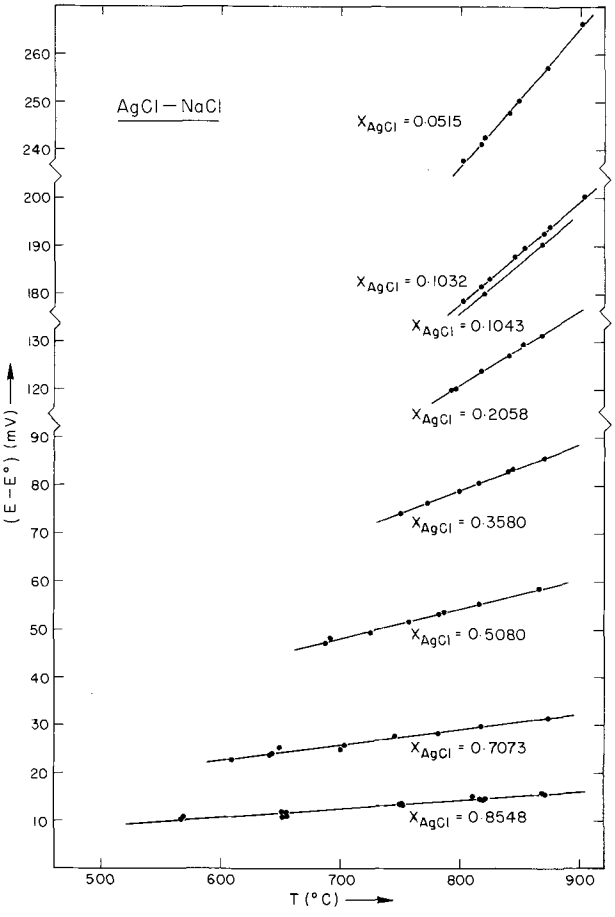

Fig. 5a. (E — E^o) vs. temperature in the AgCl-NaCl system

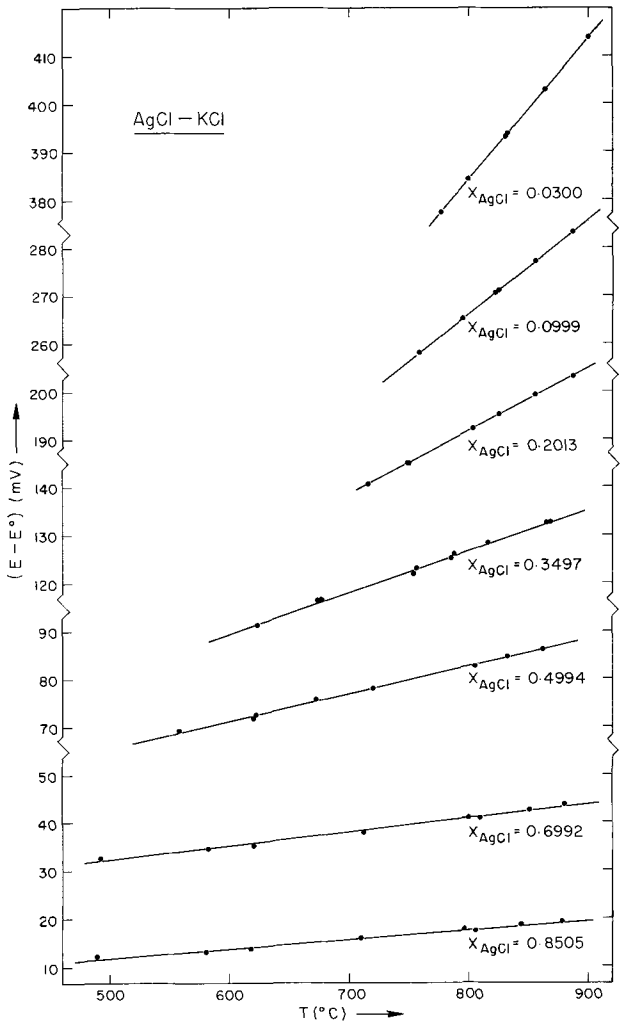

Fig. 5b. (E — E^o) vs. temperature in the AgCl-KCl system

AgCl-alkali chloride solutions.—Cell potentials, E, were measured with electrolytes at several compositions in the AgCl-ACl systems (where A = Na, K, Rb, and Cs). Values of (E — E^o) were calculated for each experimental point using Eq. [6] for E^o. The results are shown in Fig. 5(a-d). The points shown for any one experiment were obtained during at least one, and usually two, heating and cooling cycles. In all cases, the points were well-fitted by straight lines. Least square lines are shown in Fig. 5 (a-d), and the equations of the lines are given in Table II along with the mean and maximum deviations for each line. The mean deviation is never greater than 0.5 mV, and the average maximum deviation is about 0.6 mV.

For a few compositions in the "eutectic wells" of the systems, it was possible to measure values of E at temperatures below the melting point (455°C) of pure

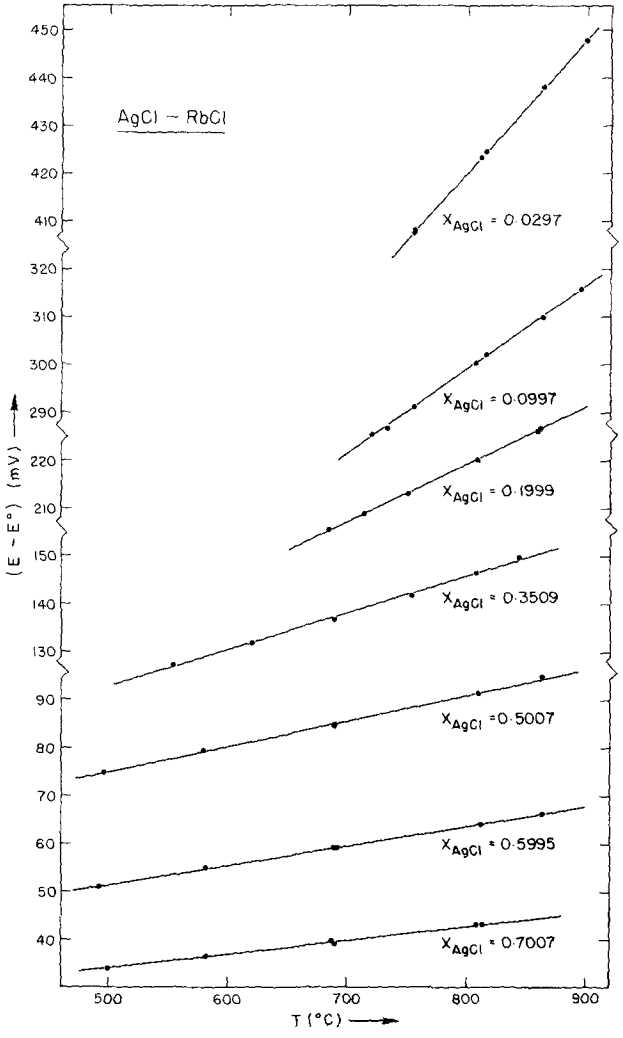

Fig. 5c. ($E - E^o$) vs. temperature in the AgCl-RbCl system

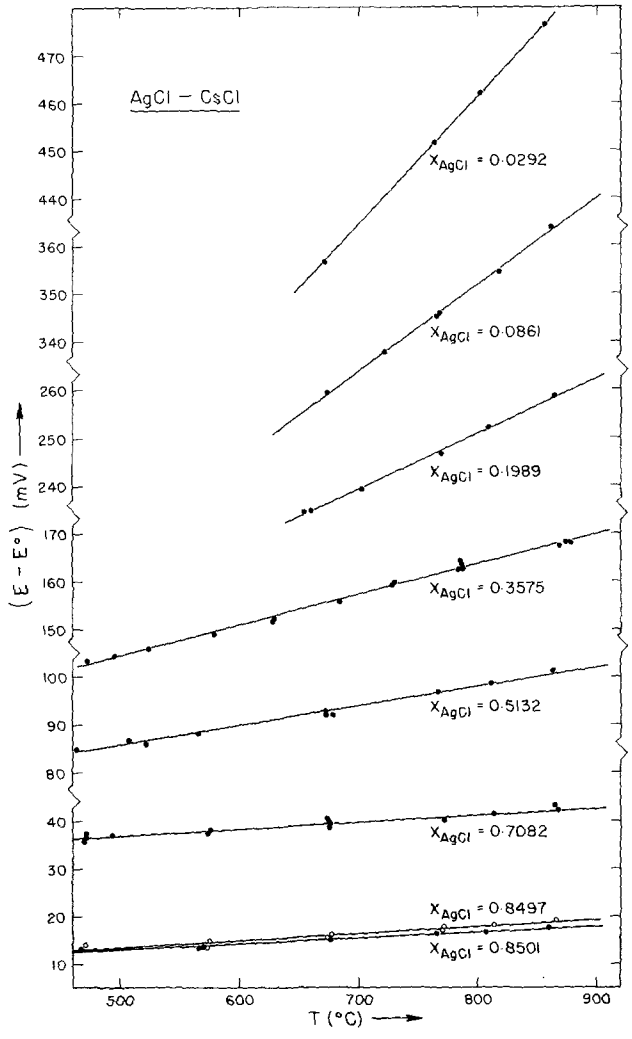

Fig. 5d. ($E - E^o$) vs. temperature in the AgCl-CsCl system

AgCl. From these values of E, and values of $(E - E^o)$ extrapolated using the linear equations in Table II, it was possible to calculate E^o values for pure supercooled liquid AgCl at temperatures down to about 275°C. Calculated values of E^o lay close to the curve obtained by extrapolating Eq. [6]. The disagreement was about 3 mV at 275°C, with the extrapolated curve lying below the calculated points.

In Table II, the partial molar excess free energy of mixing of AgCl, $\Delta\bar{G}^E_{AgCl}$, as calculated from the fitted line, is listed for each composition studied at 800°C. Also listed are the partial molar enthalpy and excess entropy of mixing of AgCl, $\Delta\bar{H}_{AgCl}$ and $\Delta\bar{S}^E_{AgCl}$, calculated from the temperature dependence of $(E - E^o)$. These two properties are temperature independent within experimental accuracy since the $(E - E^o)$ curves are linear within experimental accuracy. (For the composition at $X_{AgCl} = 0.1043$ in the AgCl-NaCl system, there are only two data points, and it was felt that the slope of this line is not sufficiently well defined for partial enthalpies and excess entropies to be calculated.)

For each system, the three partial properties listed in Table II were fitted, using a least squares technique, to power series of the form

$$\Delta\bar{F}_{AgCl} = aX^2_{ACl} + bX^3_{ACl} + cX^4_{ACl} + \ldots \quad [7]$$

where $\Delta\bar{F}_{AgCl}$ is the partial property in question, and X_{ACl} is the mole fraction of alkali chloride. The fitted equations and mean and maximum deviation for each fit are given in Table III. These fits are discussed in detail below. Also in Table III are the fitted equations for $\Delta\bar{G}^E_{AgCl}$ at 700°C for each system.

Excess free energies of mixing.—Values of $\Delta\bar{G}^E_{AgCl}$ at 800°C and of the quantity, $\Delta\bar{G}^E_{AgCl}/X^2_{ACl}$, for the four systems are plotted in Fig. 6(a-d) along with the fitted curves.

It must be remembered when examining the plots of $\Delta\bar{G}^E_{AgCl}/X^2_{ACl}$, that dividing $\Delta\bar{G}^E_{AgCl}$ by X^2_{ACl} greatly magnifies the discrepancy between the fitted curve and the experimental points when X_{ACl} is small. When $X_{ACl} = 0.3$, for instance, errors are magnified about eleven times more than when $X_{ACl} = 1$. The least squares fit is done on the values of $\Delta\bar{G}^E_{AgCl}$, not on the values of $\Delta\bar{G}^E_{AgCl}/X^2_{ACl}$.

In the AgCl-NaCl system, $\Delta\bar{G}^E_{AgCl}$ is positive, and in the AgCl-KCl, AgCl-RbCl, and AgCl-CsCl systems, $\Delta\bar{G}^E_{AgCl}$ is negative. From the plots of $\Delta\bar{G}^E_{AgCl}/X^2_{ACl}$ for the present study, it is seen that 2-coefficient power series fits are justified in the NaCl and KCl systems, and 3-coefficient fits are justified in the RbCl and CsCl systems. Values measured by other authors (4, 7, 8) are also shown in Fig. 6(a, b, d). [Points shown in Fig. 6b from the work of Murgulescu and Sternberg (8) were corrected from lower temperatures to 800°C using partial molar enthalpy data as measured in the present study.] The present study is the first work in which it has been possible to define the second and third coefficients in the power series expansion [7] for $\Delta\bar{G}^E_{AgCl}$.

In order to show clearly the magnitude of the deviations from ideality in these systems, the activities of

using the method of Margules (22) in the form proposed by the present authors (23), are plotted in Fig. 7 for all four systems at 800°C.

Enthalpies of mixing.—The values of $\Delta\overline{H}_{AgCl}$ and of the quantity, $\Delta\overline{H}_{AgCl}/X^2_{ACl}$, are plotted in Fig. 8(a-d) along with the fitted curves. Values measured electrochemically by Guion *et al.* (7) are also shown. Values calculated from the data of Panish *et al.* (4) or of Murgulescu and Sternberg (8) are too scattered to be meaningful.

Enthalpies of mixing are positive in the AgCl-NaCl system, and negative in the other systems studied. From the plots of $\Delta\overline{H}_{AgCl}/X^2_{ACl}$, it is seen that in all systems a 2-coefficient power series fit is justified. (Remember that errors in $\Delta\overline{H}_{AgCl}/X^2_{ACl}$ are greatly magnified at lower values of X_{ACl}.)

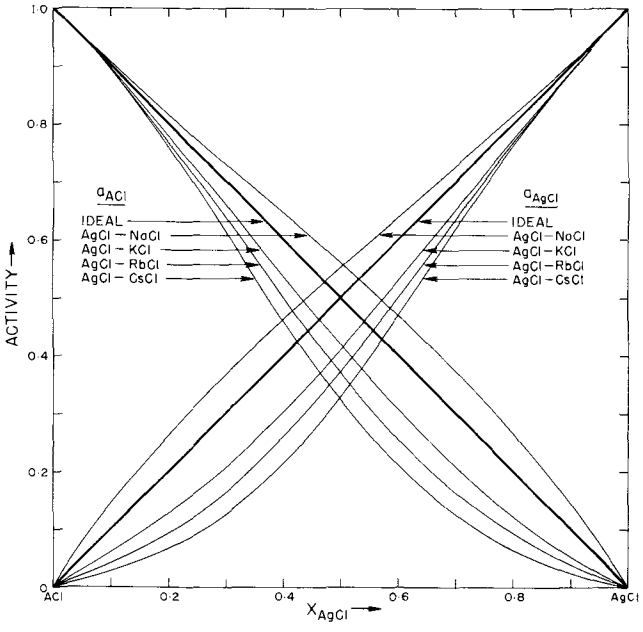

Fig. 7. Activities of AgCl and of alkali chloride (ACl) at 800°C vs. composition in AgCl-alkali chloride systems.

Curves calculated from the calorimetric data of Hersh and Kleppa (1) at 660°C are also shown in Fig. 8 (a-d). Hersh and Kleppa used a 3-coefficient fit to their data in the CsCl system and 2-coefficient fits in the other systems. Agreement between the present results and the calorimetric data is very good. In Fig. 9, the integral molar enthalpies of mixing, ΔH, as measured by Hersh and Kleppa (1) and as calculated analytically from the present data using the Gibbs-Duhem equation are compared. Values of $\Delta H_{0.5}$ (at $X_{AgCl} = X_{ACl} = 0.5$) are in agreement within 100 cal.

Calorimetric measurements made in this laboratory (24) are in good agreement in magnitude with the curves in Fig. 9 for the AgCl-KCl and AgCl-RbCl systems. However, the reported asymmetries, while of the same sign, were much greater than those measured in the present work or in the work of Hersh and Kleppa. In the AgCl-CsCl system, a value of $\Delta H_{0.5}$ of −1600 cal was reported, and this is not in agreement with the curves in Fig. 9. In view of the good agreement between the present work and that of Hersh and Kleppa (1), it would seem that these values are more trustworthy.

Excess entropies of mixing.—Values of $\Delta\bar{S}^E_{AgCl}$ are plotted in Fig. 10 (a, b) along with the fitted curves. Excess entropies of mixing are positive in the AgCl-NaCl system, and negative in the other systems studied. The points were fitted by 2-coefficient power series. Points as measured by Guion *et al.* (7) are also shown.

In Fig. 11a are plotted integral excess entropies of mixing. ΔS^E, calculated analytically from the present

results using the Gibbs-Duhem equation. In Fig. 11b are plots of ΔS^E calculated by using the integral ΔH values at 660°C of Hersh and Kleppa (1) along with integral excess free energies of mixing, ΔG^E, calculated analytically from the present results using the equations for $\Delta\overline{G}^E_{AgCl}$ at 700°C in Table III. Values of $\Delta S^E_{0.5}$ (at $X_{AgCl} = X_{ACl} = 0.5$) in Fig. 11a and Fig. 11b are in agreement to within 0.1 cal/K-mole. The sign of the asymmetry is in agreement for each system. All the systems in which ΔS^E is negative have asymmetries of the same sign, and the asymmetries of ΔG^E, ΔH, and ΔS^E are of the same sign within any one system of the four.

Discussion

From Fig. 12 it can be seen that there is an approximate linear relationship between $\Delta H_{0.5}$ and $\Delta S^E_{0.5}$ for the four systems studied. Furthermore, the line passes approximately through the origin. Hersh and Kleppa (1) measured $\Delta H_{0.5}$ for the AgCl-LiCl system at 660°C as being +490 cal, and this is in the expected direction. By combining the emf measurements of Panish *et al.* (3) at 700°C with the calorimetric data, $\Delta S^E_{0.5}$ was calculated as being almost exactly 0.00 for the LiCl system, whereas in Fig. 12 a value of $\Delta S^E_{0.5} = +0.13$ is predicted. The difference is probably within experimental error limits, but also it may be that, as in many other comparisons of properties involving the alkali

halide series, the very small size of the Li^+ ion causes anomalous behavior.

Reiss, Katz, and Kleppa (25) have developed a conformal solution theory for molten salts having a coulombic-type interionic pair potential. Essentially, the theory is concerned with a dimensional analysis of the partition function and predicts the functional relationship between the enthalpies of mixing and the ionic radii. The theory has been shown (1) to explain the observed trends in various nitrate systems, and also, with an additional term to account for van der Waals-London energy between next-nearest neighbors, the theory has been shown (1) to account for the enthalpies of mixing in solutions of alkali halides. Large discrepancies between theory and experiment resulted, however, when Hersh and Kleppa (1) attempted to explain their values of ΔH in the AgCl-alkali chloride systems. This is evidence, then, that the bonding in AgCl systems has a large covalent character.

The concept of covalent bonding in such solutions was discussed earlier by Thurmond (26) as an explanation of the enthalpies of mixing in the AgBr-alkali bromide mixtures observed by Hildebrand and Salstrom (27). ΔH is positive in the AgBr-LiBr and AgBr-NaBr systems and is negative in the AgBr-KBr and AgBr-RbBr systems, and in all cases the magnitude of $\Delta H_{0.5}$ is very close to the value in the corresponding chloride system. Thurmond suggested that there is a resonance between covalent and ionic Ag-Br bonds. If there is a small cation with a high field strength such as Li^+ or Na^+ on the other side of the bromine, then the resonance is disturbed, resulting in a higher energy for the solution. If however, there is a large weak cation such as K^+, Rb^+, or Cs^+ next to the bromine, the silver can more easily form strong covalent bonds with the bromine, resulting in a negative enthalpy of mixing.

Using the quasichemical method in the manner discussed by Førland (28), it may be shown easily that the negative excess entropies of mixing observed in the present study in three systems are much too negative to be explained by simple ordering on the cation lattice. And such ordering will not, of course, explain the positive values of ΔS^E in the AgCl-NaCl system. However, in view of Thurmond's (26) explanation for the ΔH values, it seems reasonable that the positive and negative ΔS^E values might also be explained as resulting from a decrease or increase in covalency on mixing.

Simple "dual bonding" model.—In order to make these ideas at least semiquantitative, a simple structural model for these systems will be developed.

A very similar model has recently been proposed (29), with much success, to explain the thermodynamic properties of molten $MgCl_2$-alkali chloride mixtures. The essentials of the model for these systems are that there are two bonding configurations for magnesium in solution and in pure $MgCl_2$, with some of the magnesium existing as free Mg^{2+} cations, and some existing in $MgCl_4^{2-}$ complexes. Also, the energy of formation of a complex was shown to depend on the type of cation in its first coordination sphere.

In the AgCl-ACl systems, then, it is proposed that some of the silver exists as "ionic" silver, and some exists as "covalent" silver. Let α be the fraction of silver which is "covalent." It is assumed that the two types of silver can exchange positions with each other and with alkali cations on cation sites. (In this sense the present model differs from the model used for the $MgCl_2$ systems in which the $MgCl_4^{2-}$ complexes exchanged positions with Cl^- anions.)

Possibly, in view of the atomic orbital structure of silver, and from experimental evidence in aqueous and in dilute molten salt solutions (30), the "covalent" silver could be considered to form covalent bonds to two chlorine neighbors through sp digonal hybrid orbitals. However, it is not necessary to know the precise nature of the "ionic" and "covalent" bonding. This is why these terms are placed in quotation marks. It is only necessary that there be two types of bonding configurations available to a silver on a cation site, so that two silver ions, one in each type of configuration, become distinguishable statistical entities.

In one mole of solution, X_{ACl} moles of A^+ ions, αX_{AgCl} moles of "covalent" silver, and $(1 - \alpha)X_{AgCl}$ moles of "ionic" silver ions are randomly distributed over the cation sites. The multiplicity, Ω, of one mole of solution is thus given by

$$\Omega = \frac{N^o!}{(X_{ACl}N^o)!\ (\alpha X_{AgCl}N^o)!\ ((1-\alpha)\ X_{AgCl}N^o)!} \quad [8]$$

where N^o is Avogadro's number. The configurational entropy, S, of one mole of solution is then given by

$$S = k \ln \Omega = -R\,[X_{ACl} \ln X_{ACl} + \alpha X_{AgCl} \ln (\alpha X_{AgCl}) + (1-\alpha)X_{AgCl} \ln (1-\alpha)X_{AgCl}] \quad [9]$$

where k is Boltzmann's constant, and Stirling's approximation has been used. R is the ideal gas constant.

If α^o is the value of α in pure AgCl, then the molar configurational entropy, S^o_{AgCl}, of pure AgCl is given by setting $X_{AgCl} = 1$ in Eq. [11] such that

$$S^o_{AgCl} = -R[\alpha^o \ln \alpha^o + (1-\alpha^o) \ln (1-\alpha^o)] \quad [10]$$

For pure ACl, the configurational entropy, S^o_{ACl}, is zero. Assuming that vibrational contributions to the entropy of mixing may be neglected, the entropy of mixing, ΔS, is given by

$$\Delta S = S - X_{AgCl}S^o_{AgCl} \quad [11]$$

The leading term in the expression for the enthalpy of mixing is assumed to arise from the changes in bond character on mixing and, as in the model for the $MgCl_2$ systems, terms resulting from residual coulombic and polarization interactions not accounted for in the first term are neglected.

Let Δe_1 be the molar energy change for the following process occurring in pure AgCl

$$Ag_{(\text{"ionic"})} \rightarrow Ag_{(\text{"covalent"})} \quad [12]$$

Let Δe_2 be the molar energy change for the same process occurring at infinite dilution in alkali chloride solvent. As discussed earlier, the energy change of this process will depend on the type of cation in the second

coordination shell of the central silver. Thus, if A^+ is a cation with a high field strength such as Li^+ or Na^+, it would be expected that $\Delta e_2 > \Delta e_1$, and if A^+ is K^+, Rb^+, or Cs^+, then the weak alkali cation favors covalency and $\Delta e_2 < \Delta e_1$. In general, the molar energy change, Δe, of process [12] should vary between Δe_1 and Δe_2 depending on the mole fractions of AgCl and ACl. As a first approximation, a linear variation was assumed. That is

$$\Delta e = X_{AgCl}\,\Delta e_1 + X_{ACl}\,\Delta e_2 \qquad [13]$$

Since the pressure-volume work of mixing is negligible, ΔH of mixing may be equated to the change in internal energy on mixing. Since there are αX_{AgCl} moles of "covalent" silver in one mole of solution and α^o moles in one mole of pure AgCl

$$\Delta H = \alpha X_{AgCl}\,(X_{AgCl}\,\Delta e_1 + X_{ACl}\,\Delta e_2) - \alpha^o X_{AgCl}\,\Delta e_1 \qquad [14]$$

Let us define

$$b_1 = \Delta e_1$$
$$b_2 = \Delta e_2 - \Delta e_1 \qquad [15]$$

where b_1 and b_2 are the adjustable parameters in the model and are taken to be independent of temperature and concentration. The parameter b_1 is independent of the type of alkali cation, A^+. The parameter b_2 will have a different value for each binary system. Equation [14] may be rearranged as follows

$$\Delta H = X_{AgCl}\,(\alpha - \alpha^o)\,b_1 + \alpha X_{AgCl} X_{ACl}\,b_2 \qquad [16]$$

The values of α and of α^o which actually occur may be calculated as those which minimize the free energy of mixing. That is, α and α^o may be calculated from the equations

$$\frac{\partial(\Delta G)}{\partial\alpha} = \frac{\partial(\Delta H)}{\partial\alpha} - T\frac{\partial(\Delta S)}{\partial\alpha} = 0 \qquad [17]$$

$$\frac{\partial(\Delta G)}{\partial\alpha^o} = \frac{\partial(\Delta H)}{\partial\alpha^o} - T\frac{\partial(\Delta S)}{\partial\alpha^o} = 0 \qquad [18]$$

Substituting Eq. [12] and [16] into Eq. [17] and [18], performing the differentiations, and rearranging terms yields the following expressions for α and α^o

$$\alpha^o = C_1/(1 + C_1) \qquad [19]$$

$$\alpha = C_1C_2/(1 + C_1C_2) \qquad [20]$$

where

$$C_1 = \exp(-b_1/RT) \qquad [21]$$

$$C_2 = \exp(-X_{ACl}b_2/RT) \qquad [22]$$

If values of b_1 and b_2 are chosen, Eq. [19] and [20] may be used to give values of α and α^o. These values may then be substituted back into Eq. [11] and [16] to give numerical solutions for ΔH and ΔS at any composition.

Numerical solutions were obtained in this manner. Good fits to the experimental data in the four systems studied were obtained with $b_1 = -3.5$ kcal and b_2 values of -4.5, -3.0, -2.0, and $+1.5$ kcal in the CsCl, RbCl, KCl, and NaCl systems, respectively. These values of b_1 and b_2 are reasonable in view of the physical significance attached to them by the model. When $b_1 = -3.5$ kcal, $\alpha^o = 0.836$. Values of α at various compositions in the four systems are listed in Table IV.

Table IV. Values of α calculated from the "dual-bonding" model

b_2, kcal \ X_{AgCl}	0.1	0.3	0.5	0.7	0.9	1.0
				($b_1 = -3.5$ kcal)		
−4.5 (AgCl-CsCl)	0.97	0.96	0.94	0.91	0.86	0.836
−3.0 (AgCl-RbCl)	0.95	0.93	0.91	0.89	0.86	0.836
−2.0 (AgCl-KCl)	0.92	0.91	0.89	0.87	0.85	0.836
+1.5 (AgCl-NaCl)	0.73	0.76	0.78	0.81	0.83	0.836

Calculated curves are shown in Fig. 13 and 14. By comparison with Fig. 9 and 11 it may be seen that the ΔH and ΔS^E curves are simultaneously fitted in magnitude within the limits of experimental accuracy (although ΔS^E calculated for the CsCl system is probably not negative enough). The calculated ΔH curves are almost perfectly symmetric (i.e., parabolic) about $X_{AgCl} = 0.5$. The calculated ΔS^E curves for the KCl, RbCl, and CsCl systems show some asymmetry in the same direction as the experimental curves. For the NaCl system, ΔS^E is calculated as nearly perfectly symmetric.

A good fit to ΔH, as measured by Hersh and Kleppa (1), for the AgCl-LiCl system is obtained with $b_2 = +2.0$ kcal. In this case, $\Delta S^E_{0.5}$ is calculated to be $+0.10$ cal/K-mole. This is as predicted from Fig. 12, but, as discussed earlier, there is evidence that ΔS^E in this system may show anomalous behavior.

Summary

A reversible silver-chlorine formation cell for use in molten salt electrolytes has been built. Voltages are highly stable and reproducible. It is believed that the use of a very high resistance (>1000 ohms) asbestos diaphragm between the two electrode compartments is important in achieving the observed stability. The dependence of the cell potential on chlorine pressure from 10^{-2} to 1.0 atm has been measured. The very fast response of the voltage to changes in chlorine pressure indicates that there is no difficulty in saturating the graphite electrode as was previously thought.

The curvature of the measured E^o *vs.* T curve is in very good agreement with the thermochemical values

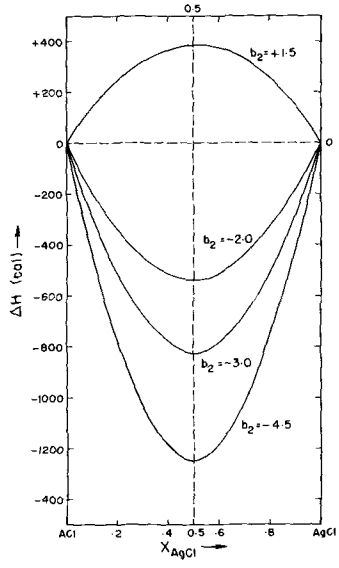

Fig. 13. Integral molar enthalpies of mixing calculated from the "dual bonding" model with $b_1 = -3.5$ kcal and for values of b_2 (kcal) shown.

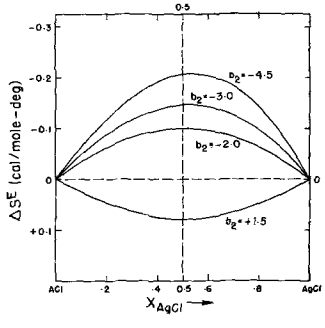

Fig. 14. Integral molar excess entropies of mixing calculated from the "dual bonding" model with $b_1 = -3.5$ kcal and for values of b_2 (kcal) shown.

of ΔC_p for the formation of AgCl, and the curve itself is in very good agreement with the curve calculated from the thermochemical data. Previously noted discrepancies between the thermochemical and electrochemical E° values were the result of the use of an incorrect C_p value for liquid AgCl.

Measurements were made over the total composition ranges in four AgCl-alkali chloride systems. Excess free energies of mixing were in reasonable agreement with values measured by other authors where measurements were available. The precision of the results is such as to give the second and third coefficients in the expansions for the excess free energies as power series in the mole fractions. Enthalpies of mixing, calculated from the temperature dependences of the cell potential, were of sufficient precision to permit 2-coefficient fits as power series in the mole fractions. In all systems, values of $\Delta H_{0.5}$ (at $X_{AgCl} = 0.5$) agreed with calorimetric (1) values within 100 cal, and in all systems the asymmetry of ΔH was also in agreement both in sign and magnitude. Excess entropies of mixing, calculated from the temperature dependences of the cell potential, were of sufficient precision to permit the sign of the asymmetry to be determined. Values of ΔS^E were also calculated using free energies measured in the present work, and calorimetric ΔH values (1). The two sets of curves agreed within 0.1 cal/K-mole at $X_{AgCl} = 0.5$, and in all cases the signs of the asymmetries were in agreement.

Values of ΔG^E, ΔH, and ΔS^E were positive in the AgCl-NaCl system and were negative in the AgCl-KCl, AgCl-RbCl, and AgCl-CsCl systems. Within each system, the asymmetries of ΔG^E, ΔH, and ΔS^E were of the same sign.

It has been shown that the results provide evidence for the occurrence of covalency in molten solutions containing AgCl. A simple "dual bonding" model for these melts was developed in which "ionic" and "covalent" silver coexists. With the use of only one composition-independent adjustable parameter for each system, and one other adjustable parameter for all the systems taken together, it was possible to simultaneously explain the signs and magnitudes of the enthalpies and excess entropies of mixing in all four systems and to explain some of the observed asymmetries.

List of Symbols

A	any alkali metal
T	temperature in Kelvins
ln	natural logarithm
V	thermoelectric potential (mV)
E	reversible cell potential (mV)
E°	reversible cell potential with pure AgCl electrolyte (mV)
C_p	heat capacity (cal/K-mole)
ΔC_p	change in heat capacity for a chemical reaction (cal/K-mole)
n	number of equivalents per mole
$\mathbf{F}$	Faraday constant (23.0610 cal/mV-equiv)
ΔG^E	integral molar free energy of mixing (cal/mole)
ΔH	integral molar enthalpy of mixing (cal/mole)
ΔS^E	integral molar excess entropy of mixing (cal/K-mole)
$\Delta \bar{G}^E_i$	partial molar excess free energy of mixing of component i (cal/mole)
$\Delta \bar{H}_i$	partial molar enthalpy of mixing of component i (cal/mole)
$\Delta \bar{S}^E_i$	partial molar excess entropy of mixing of component i (cal/K-mole)
$\Delta \bar{F}_{AgCl}$	any of the three partial molar properties of mixing of AgCl (excess free energy, enthalpy, or excess entropy)
X_i	mole fraction of component i
a_i	activity of component i
$\Delta H_{0.5}$	integral molar enthalpy of mixing when $X_{AgCl} = X_{ACl} = 0.5$ (cal/mole)
$\Delta S^E_{0.5}$	integral molar excess entropy of mixing when $X_{AgCl} = X_{ACl} = 0.5$ (cal/K-mole)
α	fraction of silver which is "covalent" in the dual bonding model
α°	value of α in pure AgCl
Ω	configurational multiplicity of the solution
N°	Avogadro's number
R	ideal gas constant
k	Boltzmann's constant
S	molar configurational entropy of solution (cal/K-mole)
S°_i	molar configurational entropy of pure component i (cal/K-mole)
Δe	molar energy change for reaction [12], (cal/mole)
Δe_1	value of Δe in pure AgCl (cal/mole)
Δe_2	value of Δe in pure ACl (cal/mole)
b_1	Δe_1 (cal/mole)
b_2	$\Delta e_2 - \Delta e_1$ (cal/mole)

Electrochemical Behavior of 2-(1-Naphthyl)-5-Phenyl- and 2,5-Diphenyloxazole

W. N. Greig and J. W. Rogers

Department of Chemistry, Midwestern University, Wichita Falls, Texas 76308

ABSTRACT

The electrochemical reduction of 2-(1-naphthyl)-5-phenyl- and 2,5-diphenyloxazole in N,N-dimethylformamide has been studied at platinum and mercury electrodes in the presence and absence of proton donors. Polarographic, potentiostatic, voltammetric, and spectrophotometric techniques were employed in the study. Both compounds are reduced via two polarographic steps. The first is a reversible one-electron transfer producing a stable anion radical. The second is a reversible one-electron transfer followed by rapid protonation of the dianion (EC process). The resulting protonated species undergoes a slow irreversible reaction. Addition of hydroquinone as a source of protons enhances the formation of the long term electrolysis product.

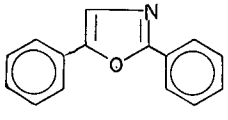
The value of electrochemical measurements in the elucidation of the oxidation-reduction behavior of organic compounds is well documented (1-4). Adams has recently organized and presented a lucid description of mechanisms for the electrochemical oxidation of aromatic hydrocarbons and amines (5). Bard has contributed a great amount of information to the study of electrolytic reduction mechanisms of organic compounds (6-9). Peover has discussed much of the work in this area in a review (10).

However, polarographic data for five-membered, aromatic heterocyclics in aprotic media is very sketchy. There have been no electrochemical investigations of the oxazole nucleus, substituted oxazoles or related compounds in aprotic solvents.

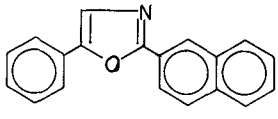
We have undertaken a study of 2-(1-naphthyl)-5-phenyl- and 2,5-diphenyloxazole in N,N-dimethylformamide (DMF) solvent in an attempt to establish a mechanism for their electrochemical reduction. The stability of reduction intermediates and the nature of homogeneous reactions of the intermediates are considered. Polarographic, cyclic voltammetric, potentiostatic, mass electrolytic, and spectrophotometric techniques were employed in the study. The voltammetric behavior of these compounds at mercury and platinum electrodes in the absence and presence of proton donors is described. A reduction mechanism consistent with the electrochemical results is postulated.

Results

Voltammetric methods.—Both 2,5-diphenyl-(I) and 2-(1-naphthyl)-5-phenyloxazole (II) exhibit two well-defined polarographic waves in DMF with 0.1M tetra-N-propylammonium perchlorate (TPAP) as supporting electrolyte. The polarographic half-wave potentials, $E_{1/2}$'s, are −2.13V and −2.47V *vs.* saturated calomel electrode (SCE) for compound I and −1.88V and −2.24 *vs.* SCE for II. The diffusion current (i_d) of both waves of I and II varied as the square root of the height of the mercury head ($h^{1/2}$) above the dropping mercury electrode (DME), indicating that material transfer to the electrode is diffusion controlled. The slope of a plot of potential (E) *vs.* log $i/(i_d-i)$ for the first wave is 60 mV for I and II.



I



II

Key words: Electrochemical reduction oxazole.

The cyclic voltammetric behavior of compound I at a hanging mercury drop electrode (HMDE) is shown in Fig. 1. Voltage excursion and reversal past the first polarographic wave at HMDE yields a voltammogram with a substantial anodic current. The ratio of the cathodic peak current to the anodic peak current $[(i_p)c/(i_p)a]$ is approximately 1.0 at all sweep rates (v), Table I. The cathodic peak potential to half-peak potential separation $[(E_p)c - (E_p)c/2)]$ is 60 mV at all v and the current function $((i_p)c/v^{1/2})$ is invariant to changes in v, Table I. The 60 mV separation is not strictly in accord with the theory for a reversible one-electron transfer. However, the over-all behavior is indicative of such a process producing a radical

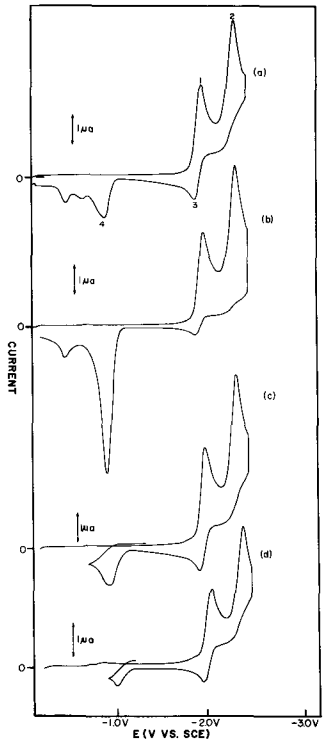


Fig. 1. Cyclic voltammograms of 2,5-diphenyloxazole at HMDE in DMF containing 0.1M TPAP showing sweep range from 0.0V. All solutions were 1 mM in oxazole. Sweep rate was 250 mV/sec in all experiments. (a) Excursion and reversal past second wave, (b) forward excursion held at potential above second peak for 5 sec before reversal, (c) multicyclic voltammogram showing no current peak corresponding to follow-up oxidation current, (d) same as "c" with solution 1 mM in HQ.

[e] Anodic stirring prevented measurement.

species stable during the course of the experiment (11). Similar behavior is observed for the first wave of I at a planar platinum disk electrode (PPDE), Table II.

Voltage sweep and reversal at potentials above the second polarographic plateau yields a second cathodic peak with no corresponding anodic current at sweep rates up to 500 mV/sec., Fig. 1. The $(E_p)_c$ of the second wave shifts approximately 30 mV in a cathodic direction and the current function decreases approximately 20% with a tenfold increase in v, Table I. This behavior suggests a reversible electron transfer followed by a rapid homogeneous reaction of the radical species (EC process) (11).

A second anodic peak current appears at potentials less cathodic than that representing the oxidation of the monoanion radical if sweep excursion is reversed at potentials past the second wave, Fig. 1a, peak 4. This oxidation peak is not present if the voltage excursion is reversed at potentials past only the first cathodic current peak. Multisweep voltammograms exhibit no cathodic current corresponding to peak 4, Fig. 1c. The intensity of the anion radical oxidation current (peak 3, Fig. 1a) is markedly decreased and that of peak 4 is correspondingly increased by pausing at potentials above the second polarographic plateau before sweep reversal, Fig. 1b. These observations suggest that follow-up anodic wave represents the oxidation of a product produced by the EC process occurring at the potential of the second wave. The absence of a cathodic current or any subsequent oxidation-reduction couple is consistent with the regeneration of starting material at the follow-up wave.

[c] Scan reversal 100 mV past $(E_p)_c$. i_p measured by employing the potential hold method (14).

Compound II exhibits similar behavior under the same conditions. Cyclic voltammetric data at a PPDE and a HMDE for compound II are given in Tables I and II. The differences in the current peak potentials and the diffusion $E_{1/2}$ values seem large considering the nature of the substituents and suggest differing reduction mechanisms. However, analysis of all the experimental information strongly indicates similar reduction paths.

Potentiostatic method.—The available electrochemical data show that the first polarographic plateau is representative of a diffusion-controlled one-electron transfer. The number of electrons (n) transferred at potentials above the second polarographic reduction step can be estimated as 2.0 with reference to the ratio of diffusion currents for the first and second polarographic waves. Comparison of slopes of i *vs.* $t^{-1/2}$ plots corresponding to potentials at the first and second polarographic plateaus in experiments carried out on a HMDE yields an n value of 1.0 for the second wave for compounds I and II. The over-all reduction process carried to potentials above the second wave requires two electrons.

The voltammetric and potentiostatic results suggest the following reduction mechanism for I and II

First wave

$$R + e^- \rightleftarrows R^{\cdot -}$$

Second wave

$$R^{\cdot -} + e^- \rightleftarrows R^{=}$$

$$R^{=} + SH \rightarrow RH^- + S^-$$

Regeneration wave

$$RH^- \rightarrow R + H^+ + 2e^-$$

Where R is the substituted oxazole and SH is a proton source. This mechanism has been suggested by Bard (7) for the electrochemical reduction of aromatic azo compounds and is analogous to the behavior exhibited by aromatic hydrocarbons (10).

Effect of proton donors.—To test the postulate of proton addition to the dianion, the polarographic and voltammetric behavior of I and II in the presence of varying amounts of hydroquinone (HQ) was studied (8). The intensity of the first polarographic wave grows at the expense of the second and the second shifts toward more positive potentials with increasing concentration of HQ. At very high concentrations of HQ (0.1M) only one polarographic wave is observed. The pronounced effect of the HQ is consistent with the postulated mechanism and entirely analogous to the behavior of polycyclic aromatic hydrocarbons in the presence of proton donors (10). Hoijtink (12) has shown that this behavior can be explained by the fact that the RH· radical of an alternant aromatic hydrocarbon formed by protonation of the R^{-} ion has a higher electron affinity than the parent compound, R. At potentials above the first polarographic wave the over-all process becomes

$$R + e^- \rightleftarrows R^{\cdot -}$$

$$R^{\cdot -} + HQ \rightarrow RH\cdot$$

$$RH\cdot + e^- \rightarrow RH^-$$

The anodic shift of the second wave with increasing HQ is also suggestive of an increasing rate of the follow-up reaction after the second electron transfer. Addition of HQ has a pronounced effect on the intensity of the product regeneration wave observed in the cyclic voltammetric experiments, Fig. 1d. The anodic current decreases on addition of HQ, and at concentrations as low as 1 mM the regeneration wave is not observed. The behavior suggests a further irreversible reaction of the protonated dianion, RH^-, possibly of the type

$$RH^- + HQ \rightarrow RH_2 + Q^-$$

Mass electrolysis.—Mass electrolysis experiments at a stirred mercury pool working electrode were undertaken to further study the stability of the proposed intermediates and to investigate possible long term reactions. The course of each mass electrolysis experiment was monitored with a PPDE in a three electrode configuration *in-situ* in the electrolysis vessel. Aliquots of the electrolyzed solution were removed and u.v. spectra were recorded at various time intervals.

Electrolysis of 200 ml of a 1 mM solution of I in DMF at potentials above the first polarographic plateau produced a yellow solution containing a paramagnetic species.[1] Electrolysis at this potential for 6 hr produced no detectable change in the anodic current of peak voltammograms corresponding to the oxidation of the 2,5-diphenyloxazole anion radical, Fig. 2a. No decrease in the intensity of the u.v. absorption of the parent compound (λ_{max} = 309 mμ in DMF) was noted after 6 hr of electrolysis, Fig. 3b. Introduction of trace amounts of oxygen destroyed the yellow color.

Increasing the electrolysis voltage to potentials above the second polarographic wave resulted in a purple solution unstable to oxygen. A peak voltammogram of this solution initiated at potentials above the first wave with voltage sweep in the anodic direction exhibited a small current peak corresponding to the oxidation of the anion radical and an intense anodic current at the potential corresponding to the anodic regeneration process, Fig. 2b. Purging the solution with a small amount of oxygen and then degassing with nitrogen destroyed the regeneration anodic current of a peak voltammogram with the potential sweep initiated at potentials above the first polarographic plateau, Fig. 2c. This behavior is consistent with the postulated radical nature of the EC process product.

[1] Analysis of ESR spectrum will be reported later.

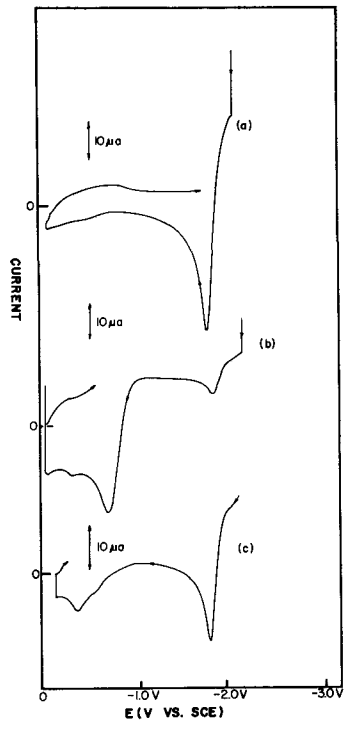

Fig. 2. Single sweep voltammograms at 250 mV/sec at a PPDE of a 1 mM solution of 2,5-diphenyloxazole in DMF undergoing electrochemical mass reduction at various potentials. (a) Single sweep voltammogram initiated at —2.0V; mass electrolysis potential —2.0V for 4 hr, (b) single sweep voltammogram initiated at —2.0V; mass electrolysis potential —2.5V for 30 min. (c) single sweep voltammogram initiated at —2.0V; solution from "b" after introduction of trace O_2 and then degassing with N_2.

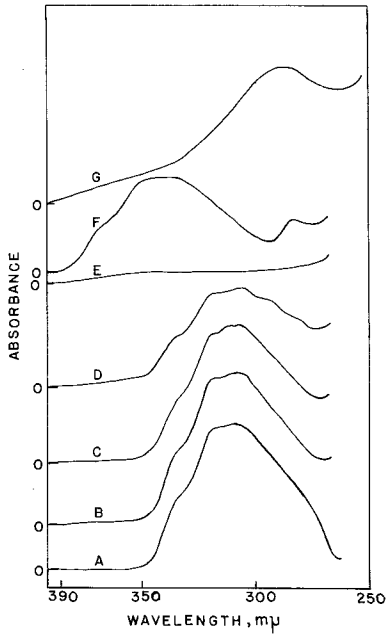

Fig. 3. (a) U.V. spectrum of 2,5-diphenyloxazole in DMF before reduction at a mercury pool electrode, (b) u.v. of solution from "a" after mass electrolysis at potential above first wave for 6 hr, (c) u.v. of solution from "b" after mass electrolysis at potential above second wave for 3 hr, (d) u.v. of solution from "c" after mass electrolysis at potential above second wave for 8 hr, (e) u.v. of solution from "d" after 24 hr of mass electrolysis at potential above the second wave. (f) u.v. of 2-(1-naphthyl)-5-phenyloxazole (II) in DMF, (g) u.v. of mass electrolysis product of II in ether solvent.

Continued electrolysis at potentials above the second wave for 3 hr produced a slight decrease in the intensity of the u.v. absorption of the parent com-

pound, Fig. 3c. No u.v. absorption could be detected after 36 hr of electrolysis at potentials above the second plateau, Fig. 3e. These observations suggest that the radical product of the EC process undergoes a slow, irreversible reaction yielding a product not electroactive at potentials less cathodic than the first polarographic plateau. Mass electrolysis experiments at a mercury pool electrode indicate that compound II behaves in a similar manner with the EC radical product undergoing a slow chemical reaction.

The long term electrolysis products of compounds I and II were extracted from the electrolysis solutions with small portions of benzene until the benzene layers were clear. The benzene solvent was evaporated under vacuum and the brown residue was dissolved in ethanol. The solutions were concentrated by evaporation and then treated with cold anhydrous ether.

The product of II melts at 169°C and exhibits a u.v. spectrum with a λ_{max} of 287 mμ in ether, Fig. 3g. Compound II exhibits a λ_{max} at 333 mμ in ether. The long term electrolysis product of I exhibits a λ_{max} at 276 mμ in ether while the parent substance absorbs at 305 mμ. The u.v. cutoff of DMF does not allow the observation of product production from I during electrolysis.

Discussion

Electrochemical data have been presented that indicate 2,5-diphenyloxazole and 2-(1-naphthyl)-5-phenyloxazole are reduced in two polarographic steps in DMF solvent. The first is a reversible one-electron transfer process producing a stable anion radical. Mass electrolysis experiments indicate that the anion radical does not undergo significant reactions over long periods of time. The second reduction step is a reversible one-electron transfer process producing a dianion which undergoes rapid protonation. The protonated dianion product is oxidizable to the parent compound at potentials more anodic than that corresponding to the oxidation of the anion radical.

The electrochemical reduction mechanism is analogous to that found for polycyclic hydrocarbons in aprotic solvents (10). The analogy is interesting in view of the difference in structure of the oxazole nucleus and an aromatic hydrocarbon.

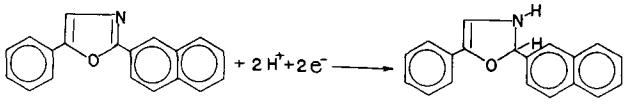
Addition of small quantities of HQ decreases the intensity of the anodic current corresponding to the process

$$RH^- \rightarrow R + H^+ + 2e$$

This suggests that the product of the EC process, RH^-, undergoes further rapid protonation and reduction in the presence of a proton source.

The protonated dianion is found to undergo a slow chemical reaction even in the absence of HQ. Spectroscopic studies show that the λ_{max} of the long term electrolysis product of each compound is at a wavelength less than that of the parent substance. This wavelength shift between the parent substance and the electrolysis product is consistent with decreased conjugation in the product brought about by saturation of the oxazole ring.

Bezuglyi, Shimanskaya, and Peresleni (13) have studied the electrochemical reduction of oxazoles in methanol-water solvent. Their infrared data indicate that 2-(1-naphthyl)-5-phenyloxazole is reduced in the following manner



All other oxazoles were reported to be reduced under similar conditions to a ring-opened product via a 6-electron process. The lack of further reduction of (II) in methanol-water solvent suggests that the reduction should proceed no further in an aprotic medium. The great similarity in electrochemical behavior of (I) and (II) in DMF solvent indicates that the reduction of both proceeds primarily by the above mechanism.

Experimental

Apparatus.—The voltammetric experiments were carried out using a multipurpose instrument with three electrode cell configurations produced by Beckman Instruments, Inc. The instrument consists of a high-speed, high-impedance potentiometric recorder, and an electrolysis module that incorporates a high-gain operational amplifier with circuits for either voltage or current control. All u.v. spectra were recorded with a Perkin Elmer 202 u.v.-visible spectrophotometer.

The platinum working electrode (PPDE) consisted of a platinum disk sealed in a soft glass tube. The PPDE was cleaned in hot nitric acid, washed in distilled water, and hydrogen flamed before each experiment. The area of the electrode was 80 mm^2. The HMDE was a mercury drop suspended on a mercury-coated platinum wire sealed in soft glass. The auxiliary electrode was a coiled platinum wire. The reference electrode in all experiments was an aqueous SCE connected to the test solution by means of an Agar plug and sintered-glass disk. All solutions were deoxygenated with nitrogen gas which was purified by passage over hot copper gauze and then saturated with DMF.

The mass electrolysis experiments were carried out in a 300 ml vessel at a mercury pool cathode having an area of 28 cm^2. The platinum foil anode was oriented 1 cm from the cathode pool and was housed in a fritted glass chamber. The solution was stirred during electrolysis with a stream of purified nitrogen. A Dressen-Barnes regulated power supply was employed as a source of constant potential.

Chemicals.—Compounds (I) and (II) were obtained commercially from Picker Nuclear. They were both recrystallized from pure methanol before use. Compound (I) melts in the range 70°-72°C, compound (II) melts in the range 104°-106°C. Hydroquinone (HQ) was obtained from J. T. Baker Chemical Company and was recrystallized from a 50% water ethylether solution.

Spectroquality N,N-dimethylformamide containing approximately 0.03% water was obtained from Eastman Organic Chemicals. The solvent was vacuum distilled twice from anhydrous $CuSO_4$ before use.

Tetra-N-propylammonium perchlorate was produced by mixing equal molar mixtures of tetra-N-propylammonium hydroxide and perchloric acid. The product was washed with cold distilled water, recrystallized from a 20% acetonitrile-water mixture and dried under vacuum. The hydroxide was obtained from Eastman Organic Chemicals.

Study of the Fluoride Complexes of Antimony(III) in Acidic Media by Rapid A-C Polarography

Evaluation of Complex Ion Systems by A-C Polarography for the Quasi-Reversible Electrode Process

A. M. Bond

Department of Inorganic Chemistry, University of Melbourne, Parkville, 3052, Victoria, Australia

ABSTRACT

The antimony(III)-fluoride complex ion system has been evaluated from data obtained from rapid a-c polarographic measurements. Four complexes are indicated to exist with stability constants of

$$\beta'_1 = 10^3\ (SbF^{++}),\ \beta'_2 = 5 \times 10^5\ (SbF_2^{+})$$

$$\beta'_3 = 2 \times 10^8\ (SbF_3),\ \text{and}\ \beta'_4 = 9 \times 10^{10}\ (SbF_4^{-})$$

where β'_n values refer to equilibria of the type $Sb^{3+} + nF^- \overset{\beta'_n}{\rightleftharpoons} SbF_n^{(3-n)+}$. Before evaluating this system, a detailed study into the nature of the electrode reaction occurring was undertaken and the conditions necessary for convenient polarographic study were ascertained. These conditions, the theory and other aspects of using a-c polarography to examine the system, in which an a-c quasi-reversible electrode reaction was observed, are considered in detail.

Recently (1), the author has shown that rapid polarographic techniques can be applied to the determination of stability constants of metal ion complexes. In this work it was pointed out that the rapid method should be applicable to certain systems which could not be studied by conventional d-c polarography. In other cases, where either conventional or rapid polarography could be used, the rapid method, with its short controlled drop time and fast scan rate of potential, offers the advantages of convenience and considerable time saving.

To verify the usefulness of the rapid polarographic method in the study of complex ion systems, a study of the bismuth(III)-fluoride system was undertaken (2). This particular system necessarily had to be studied in acidic media to prevent hydrolysis of bismuth. In acid media, and under the conditions for polarographic study of complex ions, any fluoride present must be in the form of hydrofluoric acid (HF). HF is especially corrosive toward glass, and conventional polarographic methods with long drop times and fairly slow scan rates of potential cannot be used because the contact time of the glass dropping mercury electrode (DME) with the HF is sufficient for considerable corrosion of the glass DME to occur. The rapid polarographic method, however, because of the fast scan rate of potential which can be used, enables measurements to be made in such a short time that no significant attack on the glass DME occurs. In fact HF concentrations of up to 25% can be tolerated by this method (3).

Key words: fluoride complexes, antimony(III), quasi-reversible a-c polarography.

Antimony, like bismuth, is a lower member of group (V) in the periodic table, and consequently both these elements normally exhibit somewhat similar chemical behavior. Very little, however, is known about the aqueous fluoride chemistry of these two species and information available on the stability or nature of the fluoride complexes formed in solution by Sb(III) or Bi(III) is very limited (4).

If in fact the electrode reaction of Sb(III) at the DME is similar to Bi(III), then use of the rapid polarographic technique and the equation and conditions suggested previously for study of the bismuth(III)-fluoride system (2) should enable the antimony(III)-fluoride system to be studied and thus allow a useful comparison of the two fluoride complexing systems.

As it in fact turned out, the Sb(III) electrode reaction at the DME was not found to be quite identical with that for Bi(III). However, as is discussed later, the use of rapid a-c polarography should still permit a simple calculation procedure being used to evaluate the number and magnitude of the consecutive stability constants of the fluoride complexes of Sb(III) formed in acidic media. This a-c method, the Sb(III) electrode reaction, and the results are discussed in detail in the remainder of this paper.

Experimental

All chemicals used were of reagent-grade purity.

The concentrations of stock solutions from which appropriate aliquots were taken to give the desired concentrations were determined as follows: (*i*) sodium perchlorate by precipitation of potassium perchlorate,

(*ii*) sodium iodide by potentiometric titration against silver nitrate, and (*iii*) perchloric acid by titration against sodium hydroxide.

Fluoride was added as sodium fluoride. Antimony(III) solutions were prepared by dissolving antimony(III) trioxide (Sb_2O_3) in 6*M* perchloric acid.

All measurements were made at 30° ± 0.1°C and at an ionic strength of 2.0 maintained by sodium perchlorate. Oxygen-free nitrogen was used to deaerate the solutions.

The concentrations of Sb(III), sodium iodide, and perchloric acid were 4 x $10^{-4}M$, 3 x $10^{-4}M$, and 1.2*M*, respectively in all solutions measured, unless otherwise stated. The concentrations of fluoride added to each solution are shown in the tables.

Polarograms were obtained using the Metrohm Polarecord E 261. A-C polarography was carried out using the Metrohm A-C Modulator E 393 with an applied a-c voltage of 10 mV, rms at 50 Hz. Rapid polarographic techniques with drop times of 0.16 sec and scan rate of potential of 0.5V/min were used with both d-c and a-c work using Metrohm Polarographie Stand E 354.

To minimize cell impedance, the a-c polarography was carried out with a three-electrode arrangement, with Ag/AgCl as the reference electrode and tungsten as the third or auxiliary electrode.

The DME used in all measurements had a value of $m^{2/3}\,t^{1/6}$ of 1.93 $mg^{2/3}\,sec^{1/6}$ in distilled water at zero applied potential *vs.* the Ag/AgCl electrode.

The method for recording rapid polarograms in aqueous HF was the same as that described previously (2).

All potentials measured in this work refer to a silver/silver chloride reference electrode (Ag/AgCl, 5*M* NaCl) connected to the polarographic solution via a 5*M* $NaClO_4$ salt bridge. No correction was made to the applied potential of the cell for either junction potentials or cell resistance (IR drop).

Antimony(III) electrode reaction at the DME.—Polarographic data for complex formation can most easily be understood and interpreted when reduction or oxidation of species under consideration is reversible.

The nature of the polarographic reduction of antimony(III) at the DME has been observed to vary markedly with change in supporting electrolyte. In hydrochloric acid and acidic chloride media, reversible reduction of the type

$$Sb(III) + 3e \rightleftharpoons Sb \text{ (amalgam)}$$

has been observed by many workers [*e.g.*, ref. (5-10)] using conventional d-c methods.

In noncomplexing perchloric acid-sodium perchlorate media, however, reduction of antimony(III) has been found to be irreversible (7, 11). Addition of fairly low concentrations of the halide ions, chloride, bromide, or iodide to these perchlorate solutions leads to the observation of a reversible three-electron reduction wave.

The above features were also observed in this work, by conventional a-c, d-c, and rapid polarographic techniques. Figure 1a shows a conventional d-c polarogram of antimony(III) in 1.2*M* perchloric acid/0.8*M* sodium perchloric media. Two waves close together are observed. The first wave is very small in height and is dominated by the second wave which makes the major contribution to the polarogram. The first wave has a half wave potential, $E_{1/2}$, of −0.07V and the second wave an $E_{1/2}$ value of −0.17V. The complete a-c polarogram also consists of two waves (Fig. 1b) with a very small peak with a summit potential, E_s, of −0.05V and a large, fairly symmetrical peak with E_s of −0.21V being observed.

The half-width of the second wave is about 110 mV, which is significantly larger than the value expected for a reversible three-electron reduction of approximately 90/*n*. The half-width of the first wave cannot be estimated because it overlaps to a large extent with the second wave.

Fig. 1a. Conventional d-c polarogram of antimony(III) in $NaClO_4/HClO_4$.

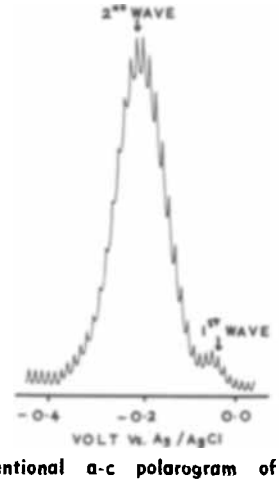

Fig. 1b. Conventional a-c polarogram of antimony(III) in $NaClO_4/HClO_4$.

The rapid d-c and a-c polarograms (Fig. 1c and d) are very similar to the conventional d-c and a-c polarograms. Again the first wave is very small relative to the second and is just discernible. E_s values of −0.05 and −0.22 and $E_{1/2}$ of −0.05 and −0.21 are obtained, respectively, for the first and second waves under rapid polarographic conditions. It can be seen by comparison of Fig. 1a and b with 1c and d that

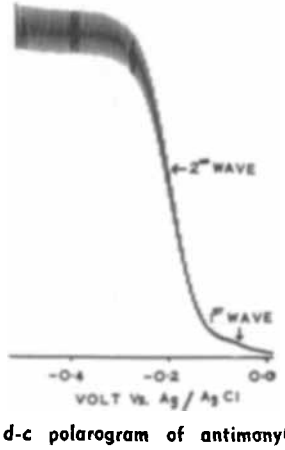

Fig. 1c. Rapid d-c polarogram of antimony(III) in $NaClO_4/HClO_4$.

Fig. 1d. Rapid a-c polarogram of antimony(III) in $NaClO_4$/$HClO_4$.

the very short drop time of the rapid polarographic method does not alter the shape or nature of the polarographic waves significantly.

The addition of a trace of iodide to the $NaClO_4$/$HClO_4$ solutions (Fig. 2a and b) gives reversible polarograms. Plots of $E_{d.e.}$ *vs.* log $(i/id - i)$ are linear with slope 22 ± 2 mV; half-widths of a-c polarograms are 40 ± 2 mV (uncompensated for IR drop); the a-c polarograms are highly symmetrical and $E_{1/2}$ and E_s values are in excellent agreement.

In aqueous solutions, the Sb^{3+} ion has a great tendency to hydrolyze to SbO^+ and even in acidic media the hydrolysis would not be expected to be completely suppressed. In fact, except in concentrated perchloric acid, only a very small concentration of Sb^{3+} could

Fig. 2a. Rapid d-c polarogram of antimony(III) in $NaClO_4$/$HClO_4$/NaI.

Fig. 2b. Rapid a-c polarogram of antimony(III) in $NaClO_4$/$HClO_4$/NaI.

be expected. The two waves in perchloric acid may therefore arise from equilibria of the type $Sb^{3+} + H_2O \rightleftharpoons SbO^+ + 2H^+$. One wave would thus be due to the electrode reaction $Sb^{3+} + 3e \rightleftharpoons Sb$ (amalgam) and the other to an electrode process of the type $SbO^+ + 2H^+ + 3e \rightleftharpoons Sb$ (amalgam) + H_2O. This second process would be expected to be a slow, nonreversible, electrode process as it requires the breakage of a metal-oxygen bond.

When a trace of chloride, bromide, or iodide is added several phenomena could occur leading to the observation of a reversible wave and mechanisms involving adsorption and complex formation have been postulated (8). These halides are readily deformable, and thus adsorbable at the DME on the positive side of the electrocapillary maximum at which the antimony(III) wave occurs. In the absence of a halide the equilibrium concentration of triply charged positive Sb^{3+} ion to be reduced has to move toward a positively charged DME, the kinetics of the electrode reaction are slow, and an irreversible wave due to Sb^{3+} is observed. In the presence of adsorbed halide, the positive charge on the DME is partially neutralized and it could be considered that the rate of the electrode reactions can increase to reversible because it is now easier for the Sb^{3+} to reach the DME. This mechanism implies that at least one of the waves observed in perchloric acid is due to Sb^{3+} and it is this wave which becomes reversible on the addition of halide. Alternatively, complex formation of Sb(III) could occur and give rise to the observed reversible wave.

Formation of $SbX_n^{(3-n)+}$ type complexes in solution could lead to a reversible wave provided that association and dissociation of the complexes is rapid. The electrode reaction could then be considered as a two-stage process with the charge transfer step being reversible and rate determining

$$SbX_n^{(3-n)+} \rightleftharpoons Sb^{3+} + nX^-$$
$$Sb^{3+} + 3e \rightleftharpoons Sb \text{ (amalgam)}$$

As the Sb(III) electrode reaction is similar to that of Bi(III) with regards to the effect of chloride, bromide, and iodide ions, a discussion of the Bi(III) electrode reaction (2, 8, 11) should be consulted for further details as to the possibility of either adsorption or complex formation being the cause of the observed reversible wave. However, it does not appear possible to distinguish between the two possibilities from this or other work.

Addition of fluoride to the 1.2*M* $HClO_4$/0.8*M* $NaClO_4$ solutions leads to rapid a-c and d-c polarograms as given in Fig. 3a, b, c, and d. The $E_{1/2}$ and E_s values become more negative on addition of fluoride and the very small first wave is not observable. The d-c shape of this wave virtually remains unaltered by the addition of fluoride and the a-c wave becomes just slightly broader. (Compare appropriate polarograms from Fig. 1, 2, and 3.)

Fluoride ion, like perchlorate ion, is nondeformable and nonadsorbable at the DME. Furthermore, in acid media most of the fluoride would exist as undissociated HF rather than as free fluoride ion because hydrofluoric acid is a fairly weak acid. Thus neither of the possible adsorption or complex formation mechanisms leading to a reversible wave as observed with chloride, bromide, or iodide could be expected to occur on addition of fluoride.

West and co-workers (12) in 0.5*M* sodium fluoride (*p*H 3.0-4.4) observed a well-defined wave for antimony(III) which had an $E_{1/2}$ value of −0.683V *vs.* SCE. They also observed a prewave. This system would appear to be very similar to that in perchloric acid, where two waves were observed. In the fluoride media the two waves could be attributed to $SbOF_n^{(1-n)+}$ and $SbF^{(3-n)+}$ type complexes, respectively. Comparison with perchloric acid solutions would suggest that

Fig. 3a and b. Effect of added fluoride on the d-c antimony(III)-$NaClO_4/HClO_4$/NaF polarogram. Figure 3b has a higher concentration of fluoride than Fig. 3a and the negative shift in $E_{1/2}$ due to fluoride complexing can be seen.

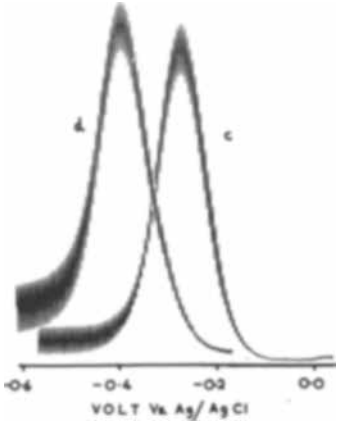

Fig. 3c and d. Effect of added fluoride on the antimony(III)-$NaClO_4/HClO_4$/NaF polarogram. Figure 3d has a higher concentration of fluoride than Fig. 3c and the negative shift in E_s due to fluoride complexing can be seen.

both the SbO^+ and Sb^{3+} waves have shifted to considerably more negative potentials due to fluoride complexing. Pavlov and Lazarov (13, 14) have confirmed the shift in $E_{1/2}$ due to fluoride complex formation. However, their work was carried out using 0.5*M* KCl to maintain constant ionic strength, so somewhat different electrode reactions could be occurring as the chloride would not be an inert electrolyte. In the more acidic medium of 0.1*M* HF-0.1*M* NH_4F, and with a Teflon DME (15) only one irreversible d-c wave was reported with $E_{1/2}$ of −0.65V *vs.* SCE ($E_{1/4}$-$E_{3/4}$) = 90 mV.

Addition of fluoride to the reversible wave found in 1.2*M* $HClO_4$-0.8*M* $NaClO_4$-3 x 10^{-4}*M* NaI causes a negative shift in E_s and $E_{1/2}$ values. Figures 4a and b show that the shape of the d-c and a-c waves also changes slightly with addition of fluoride. In actual fact, the reversible waves are now both a-c and d-c quasi reversible as is shown by the nonlinear d-c plots of $E_{d.e.}$ *vs.* log ($i/id - i$), and the slight broadening of the a-c wave accompanied by the appearance of the shoulder at high fluoride concentrations (16).

The large negative shift in $E_{1/2}$ and E_s could not be, however, completely attributed to change in reversibility and must be partially due to fluoride complexing. The nature and magnitude of the fluoride complexing are discussed in the following sections.

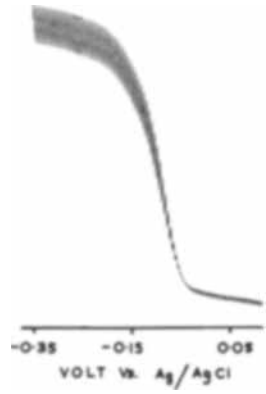

Fig. 4a. D-C polarogram of the antimony(III)-$NaClO_4/HClO_4$/NaI/NaF system at high fluoride concentrations.

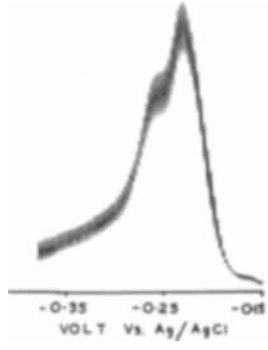

Fig. 4b. A-C polarogram of the antimony(III)-$NaClO_4/HClO_4$/NaI/NaF system at high fluoride concentrations.

Theory

De Ford and Hume (17) have derived an equation for evaluation of consecutive stability constants from polarographic data.

This equation can be written as follows

$$F_o(X) = \text{antilog}\left\{0.4343\frac{n\mathbf{F}}{RT}[(E_{1/2})_F - (E_{1/2})_C] + \log I_F/I_C\right\} = \sum_n \beta_n C^n \quad [1]$$

where the symbol $F_o(X)$ is introduced for convenience to represent the experimentally measurable quantity on the left hand side of the equation. β_n is the formation or stability constant of the n^{th} complex and refers to equilibria of the type

$$M^{x+} + nX^- \overset{\beta_n}{\rightleftharpoons} MX_n^{(x-n)+}$$

The subscripts F and C in Eq. [1] refer to the free ion and complexed ion, respectively. Other symbols are those conventionally used in polarographic terminology.

If fluoride complexing of Sb^{3+} occurs to give rise to $SbF_n^{(3-n)+}$ type complexes, then the electrode reaction occurring can be represented simply as a two-stage process

$$SbF_n^{(3-n)+} \rightleftharpoons Sb^{3+} + nF^- \quad [2]$$

and

$$Sb^{3+} + 3e \rightleftharpoons Sb \text{ (amalgam)} \quad [3]$$

For the De Ford-Hume expression above to be valid the following two conditions must hold: (*A*) The complexed and uncomplexed species are in rapid equilibrium as represented by Eq. [2]. (*B*) Nernstian conditions prevail, *i.e.*, the electrode reaction in Eq. [3] is polarographically reversible. Under these conditions

the half-wave potential measured directly from the polarogram is the reversible half-wave potential, $E_{1/2}{}^r$. Thus Eq. [1] should more correctly be expressed as

$$F_o(X) = \text{antilog}\left\{0.4343\frac{n\mathbf{F}}{RT}[(E_{1/2}{}^r)_F - (E_{1/2})_C{}^r] + \log I_F/I_C\right\} = \sum_n \beta_n C_x{}^n$$

If the electrode reaction is reversible then the a-c summit potential E_s is equal to $E_{1/2}{}^r$ and the De Ford-Hume equation can be solved as

$$F_o(X) = \text{antilog}\left\{0.4343\frac{n\mathbf{F}}{RT}[(E_s)_F - (E_s)_C] + \log I_F/I_C\right\} = \sum_n \beta_n C_x{}^n \quad [4]$$

The first parameter which must be obtained for a successful solution to the De Ford-Hume equation is the $(E_{1/2}{}^r)_F$ value for the free, uncomplexed ion. In this case, this would be for Sb^{3+}.

As previously mentioned, in the presence of a trace of iodide, the d-c electrode reaction was observed to be polarographically reversible by conventional plots of $E_{d.e.}$ *vs.* log $(i/id - i)$.

Reversibility of the a-c polarography was confirmed as follows. With 3 x 10^{-4} NaI the a-c half width was (40 ± 3) mV. Theoretically, at 25°C and for an applied a-c voltage of $\leq 8/n$ mV, (16) the half-width should be approximately $(90/n)$ mV. This work was done at 30°C with an applied a-c voltage of 10 mV, rms at 50 Hz. Under these conditions, with temperature greater than 25°C, and the applied a-c voltage considerably greater than $(8/n = 2.67)$ mV, the theoretical half-width would be expected to be somewhat greater than $(90/n)$ mV, so that the half-width value observed of 40 ± 3 mV, uncompensated for IR drop, indicates a high degree of a-c reversibility. The excellent agreement of $E_{1/2}$ and E_s and the highly symmetrical nature of the a-c wave provides further evidence for the electrode reaction being reversible.

Thus $E_s = E_{1/2}{}^r$, in the presence of a trace of iodide, but whether the value of E_s is $(E_s)_F$ needs to be considered.

If the sole function of the small concentration of the iodide is to provide a reversible electrode reaction by an adsorption mechanism then the necessary equivalence

$$E_s = E_{1/2}{}^r = (E_{1/2}{}^r)_F = (E_s)_F$$

will be satisfied exactly.

If complex formation of iodide is involved then the $E_{1/2}{}^r$ value observed, $(E_{1/2}{}^r)_0$, will be related to $(E_{1/2}{}^r)_F$, by an equation

$$\text{antilog}\left\{0.4343\frac{n\mathbf{F}}{RT}[(E_{1/2}{}^r)_F - (E_{1/2}{}^r)_0] + \log I_F/I_0\right\} = 1 + \beta_1[I^-] + \beta_2[I^-]^2 + \ldots\ldots \beta_j[I^-]^J$$

where β_j is the stability constant of the j^{th} complex derived from equilibria of the type

$$Sb^{3+} + jI^- \overset{\beta_j}{\rightleftharpoons} SbI_j{}^{(3-j)+}$$

Thus, as long as the concentration of iodide is low and β_j complexes are not too strong it can be seen that to a good approximation $(E_{1/2}{}^r)_0 = (E_{1/2}{}^r)_F$. If iodide complex formation is involved in providing the reversible wave, $(E_{1/2}{}^r)_F$ could in fact be calculated provided the β_j values are known. Unfortunately no values for β_j are available (4) and the procedure of neglecting iodide complex formation had to be used. As the concentration of iodide is small, and in fact less than that of antimony, it was hoped that this procedure would not involve a very large source of error. A third possibility, that the reversibility results from a combination of adsorption and complex formation could also be considered. That is, iodide complexation with Sb(III) may occur via a surface reaction or in the immediate vicinity of the electrode surface where the iodide concentration, because of adsorption, would be significantly higher than in the bulk of the solution.

In view of the reversible wave provided by low concentrations of iodide, and the simplifying effect this has on calculations, all the $E_{1/2}$ and E_s values quoted are measured in the presence of 3 x $10^{-4}M$ sodium iodide and the $F_o(X)$ values are assumed to be close to correct whatever the mechanistic effect of iodide on the electrode reaction is, and no correction for iodide complexation was made.

Close examination of the electrode process in fluoride media and in the presence of sodium iodide, showed it to be classified as nonreversible by both a-c and d-c polarography for fluoride concentrations greater than $0.02M$. For concentrations of fluoride greater than this, the nonlinear plots of $E_{d.e.}$ *vs.* log $(i/id - i)$ from d-c polarograms, and the broadening and appearance of shoulders in a-c polarograms, suggested that the electrode process has become quasi reversible.

For fluoride concentrations less than $0.02M$ the electrode reaction was found to be d-c reversible but a-c quasi reversible. Table I verifies the d-c process possesses a high degree of reversibility up to $0.02M$ in fluoride as $(E_{1/4}\text{-}E_{3/4})$ values are within the range 23 ± 1 mV. The a-c half-width, however, increases with added fluoride, indicating a change in rate of electrode reaction is occurring, a fact not observed by the d-c method.

Table I shows the effect of fluoride concentration on (i_d) and $(i_d\sim)$ values. The d-c (i_d) is virtually unaltered by added fluoride but the a-c $(i_d\sim)$ decreases significantly with increasing fluoride concentration. Thus the fluoride complexation reaction is sufficiently rapid so that it does not contribute to rate control in the d-c electrode process. The decrease in $(i_d\sim)$ with increasing fluoride concentration indicates that the a-c electrode process is no longer solely diffusion controlled. If the fluoride complexation reaction is sufficiently rapid so that it does not contribute to rate control in either the d-c or a-c electrode processes, then the experimental observations may be explained entirely in terms of charge transfer effects as follows.

In the absence of fluoride, but in the presence of a trace of other halide ion, the electrode process is diffusion controlled and shows a high degree of reversibility in both the d-c and a-c sense. As the concentration of fluoride is increased, the charge transfer rate is decreased and becomes sufficiently slow so that the a-c electrode process is no longer reversible. For fluoride concentrations less than $0.02M$, the d-c electrode

process is still sufficiently rapid so that it is reversible, as evidenced by the linear plots of $E_{d.e.}$ vs. log $(i/i_d - i)$ with slopes close to the theoretical value. When the fluoride concentration becomes greater than 0.02*M* the charge transfer reaction has become sufficiently slow so that it is no longer reversible in either the d-c or the a-c sense. Under these conditions the quasi-reversible a-c wave becomes significantly broader and may exhibit shoulders (16) (*cf.*, Fig. 4b).

To evaluate the stability constants of the antimony(III)-fluoride system, by the De Ford-Hume method, only d-c results obtained for fluoride concentrations less than 0.02*M* could be used. For this concentration range the d-c electrode reaction is reversible and $E_{1/2} = E_{1/2}^r$. Over this concentration range it was also found that $E_s = E_{1/2} = E_{1/2}^r$ for the quasi-reversible a-c process as shown in Table I, which suggests that a-c polarography can be used despite the fact that an a-c quasi-reversible electrode process is observed.

The theory for a-c polarography involving quasi-reversible electrode processes is rather difficult to solve exactly.

However at low frequency and for $ke^0 \geq 10^{-2}$ cm sec^{-1} it can be shown that E_s approaches $E_{1/2}^r$ (16). Thus, using low frequency a-c polarography, $E_{1/2}^r$ can be calculated directly and simply from the E_s value. A frequency of 50 Hz was used in this work and $(E_{1/2}^r)_C$ values used, were those taken directly from the a-c polarogram as the $(E_s)_C$ value. The previous use of a-c polarography for study of complex ion systems for reversible electrode reactions [1], [2] can thus be extended satisfactorily to the quasi-reversible electrode process. However, care in using the quasi-reversible a-c procedure should be exercised, as only results for which $ke^0 \geq 10^{-2}$ cm sec^{-1} are valid. In this work, solutions of high fluoride concentration which gave shoulders on the a-c polarogram, were not used because ke^0 probably is $< 10^{-2}$ cm sec^{-1}.

The complete $F_0(X)$ function also involves the term log I_F/I_C. For reversible a-c electrode reactions the wave height $(i_d\sim)$ could be used to solve the expression as log $(i_d\sim)_F/(i_d\sim)_C$. However, because of the a-c quasi-reversible reaction this a-c treatment cannot be applied. The d-c treatment, log $(i_d)_F/(i_d)_C$, however, is still valid and can be used for any diffusion controlled reaction. In actual fact, the term log $(i_d)_F/(i_d)_C$ was found to be very small and can conveniently be neglected in calculations of $F_0(X)$.

Thus the equation used to solve the Sb(III)-fluoride complex system was the a-c expression

$$F_0(X) = \text{antilog } 0.4343 \frac{n\mathbf{F}}{RT}[(E_s)_F - (E_s)_C] = 1 + \beta_1[F^-] + \beta_2[F^-]^2 + \ldots \beta_n[F^-]^2 \quad [5]$$

Inclusion of the equilibrium constant K_a, for hydrofluoric acid modifies this equation to give

$$F_0(X) = \text{antilog } 0.4343\,[(E_s)_F - (E_s)_C] = 1 + \beta_1 K_a \frac{[HF]}{[H^+]} + \beta_2 K_a^2 \frac{[HF]^2}{[H^+]^2} \ldots \beta_n K_a^n \frac{[HF]^n}{[H^+]^n} \quad [6]$$

or

$$F_0(X) = 1 + \beta'_1\left(\frac{a}{b-a}\right) + \beta'_2\left(\frac{a}{b-a}\right)^2 + \ldots \beta'_n\left(\frac{a}{b-a}\right)^n \quad [7]$$

where β'_n is the stability constant for the equilibria

$$Sb^{3+} + HF \overset{\beta'_n}{\rightleftharpoons} SbF_n^{(3-n)+} + nH^+$$

and a is the concentration of sodium fluoride added to the solution, initially b *M* in perchloric acid. In the presence of excess acid over added fluoride, and because HF is a weak acid, virtually all fluoride will be present as undissociated HF and the ratio $[HF]/[H^+]$ is given by $(a/b - a)$ as described in a previous paper (2).

If the symbol y is used in place of $(a/b - a)$, the equation has the form

$$F_0(X) = 1 + \beta'_1 y + \beta'_2 y^2 + \ldots \beta'_n y^n$$

If the function $F_1(X) = (F_0(X) - 1)/y$ is now introduced and a graphical plot of $F_1(X)$ *vs.* y is made, then the value of $F_1(X)$ at the intercept equals β'_1. Likewise the value of β'_2 is given by the value of $F_2(X)$ at the intercept when the function $F_2(X) = (F_1(X) - \beta'_1)/y$ is plotted against y and is extrapolated to $y = 0$. The formation constants of higher complexes (if present) may be determined in a similar manner.

As a consequence of the nature of the $F_n(X)$ functions, a plot of $F_n(X)$ *vs.* y for the last complex will be a straight line parallel to the y axis, and this allows the determination of the number of complexes.

In obtaining values of β'_n for the Sb(III)-fluoride system, the extent of error involved in making two approximations must be kept in mind.

First, the β'_n values are to be calculated neglecting any complex formation from iodide. If any occurs, then the electrode reaction should more explicitly be written as

$$\left.\begin{aligned} &SbI_j^{(3-j)+} \overset{\beta_j}{\rightleftharpoons} Sb^{3+} + jI^- \\ &SbF_n^{(3-n)+} + nH^+ \overset{\beta'_n}{\rightleftharpoons} Sb^{3+} + nHF \end{aligned}\right\} \quad [A]$$

$$Sb^{3+} + 3e \rightleftharpoons Sb \text{ (amalgam)} \quad [B]$$

It can be readily shown that β'_n values calculated for fluoride complexes in the manner indicated, by neglect of iodide complexes, will be too low by a factor $(1 + \beta_1[I^-] + \ldots . \beta_j[I^-]^j)$. Thus providing β_1 is not too large for iodide, then at the concentration of iodide used in this work, the approximation of neglecting iodide complexation should be satisfactory. Alternatively, if β_j values were known then the β'_n values could be corrected.

Second, it has been assumed that the fluoride complexes of Sb(III) are of the type $SbF_n^{(3-n)+}$ rather than $SbOF_n^{(1-n)+}$. Both of these can be related by an equilibrium

$$SbF_n^{(3-n)+} + H_2O \rightleftharpoons SbOF_n^{(1-n)+} + 2H^+$$

In this work solutions measured all contained a very high concentration of H^+ which strongly favors formation of $SbF_n^{(3-n)+}$. Furthermore, in this highly acidic media only one wave is observed compared with the two waves at *p*H (3.0-4.4) (12). In the work at higher *p*H (3.0-4.4) the two waves probably result from the equilibrium concentrations of fluoride and oxy-fluoride complexes. In the considerably more acidic media used in this work it is postulated that only the wave from $SbF_n^{(3-n)+}$ is observed because the equilibrium concentration of $SbOF_n^{(1-n)+}$ is now too low to be detected. Analogy of the fluoride system with the corresponding antimony(III)-chloride and the chemically similar bismuth(III)-chloride systems is somewhat hazardous, but for these systems neglecting the $SbOCl_n^{(1-n)+}$ or $BiOCl_n^{(1-n)+}$ complexes at high acidity is satisfactory (4) and they need only be considered at fairly high *p*H. These chloride systems have in fact been successfully investigated polarographically in acid media by assuming formation of simple chloride complexes only (7, 9).

Results and Discussion

Table II and Fig. 5 summarize the results obtained, using the calculation method described previously. Four complexes were observed with values of $\beta'_1 = 10^3$ (SbF^{2+}), $\beta'_2 = 5 \times 10^5$ (SbF_2^+), $\beta'_3 = 2 \times 10^8$ (SbF_3) and $\beta'_4 = 9 \times 10^{10}$ (SbF_4^-). The large errors involved

* a = concentration of sodium fluoride added to solutions initially b M in perchloric acid.

in calculations, by the time $F_4(X)$ values are obtained, could possibly conceal higher but fairly weak complexes. However, at least four can be detected.

Comparison of these results with the bismuth(III)-fluoride system studied previously, for which $\beta'_1 = 26(BiF^{2+})$, $\beta'_2 = 2(BiF_2^+)$ and $\beta'_3 = 500(BiF_3)$ indicate two marked differences in these systems.

First, the stability of Sb(III)-fluoride complexes is considerably greater than for Bi(III)-fluoride species. The very high stability for the Sb(III) complexes is in agreement with the work of Pavlov and Lazarov (13, 14).

Second, an anionic form of Sb(III)-fluoride was detected as SbF_4^-. Such a species was not observed with Bi(III). This difference observed, is in agreement with anion exchange studies made by Faris (17) and Nelson *et al.* (18) in hydrofluoric acid media. In the solid state, SbF_3 is also known to be capable of acting as a Lewis base to form SbF_4^- with the fluoride ion (19), so that detection of an anionic complex in solution containing excess HF could be anticipated.

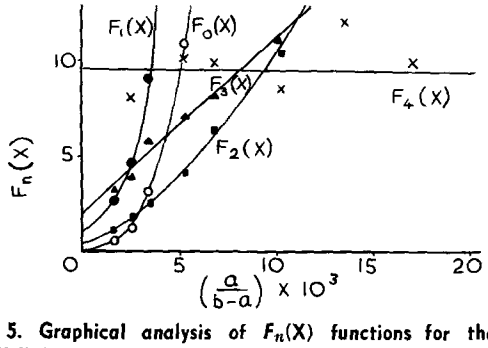

Fig. 5. Graphical analysis of $F_n(X)$ functions for the antimony (III)-fluoride system. ○, $F_0(X) \times 10^{-1}$; ●, $F_1(X) \times 10^{-3}$; ■, $F_2(X) \times 10^{-6}$; ▲, $F_3(X) \times 10^{-8}$; x, $F_4(X) \times 10^{-10}$.

Thus the fluoride complex systems of Sb(III) and Bi(III) exhibit marked differences in aqueous media, both as to the stability and number of complexes formed, according to polarographic data. This idea is also consistent with the rather limited data available from other sources, and this fact at least provides some indication that the theories and ideas used in this work, as well as the assumptions made, are valid.

Technical Notes

A Contribution to the Applicability of Critical Pitting Potentials

H. P. Leckie

Inland Steel Research Laboratories, Coated Products Division, East Chicago, Indiana 46312

Many metals may exhibit passivity or undergo intense localized corrosion in aqueous chloride media depending on the relative position of their open circuit corrosion potential with respect to a "critical pitting potential," V_c. Included in this category are titanium, aluminum, zirconium, nickel, and some of their alloys together with many of the austenitic and ferritic stainless steels. Pitting of these passive metals and alloys is inhibited if the potential, controlled either by local cell action or some outside impressed source, is maintained more active than V_c. Should the metal/solution potential become more noble than V_c localized attack may occur often resulting in environment concentration changes which shift V_c to more active values. Such concentration changes caused by the pitting process itself probably explain the hysteresis effects described by Pourbaix *et al.* (1) who noted both a pitting potential and a "repassivation potential" (occurring at some more active value) for stainless steels in chloride media.

The concept of a critical potential is not new, being first reported in terms of a "breakthrough" potential by Brennert (2) as far back as 1937. Very little follow up to this work took place, save for the work of Mahla and Neilson (3) in 1947, until the last five or six years during which a considerable amount has appeared in the literature (4-9).

From the work of Leckie and Uhlig (8) and Horvath and Uhlig (9) as well as others a considerable amount of information has been obtained relating to the effect of environmental factors on the value of the critical pitting potential for 18-8 stainless steel and aluminum. Other passive materials have been studied to a more limited extent. It is somewhat surprising, therefore, that full utilization of critical potential measurements has not been employed as a more widespread means for rapidly predicting the tendency for localized attack on materials of construction in naturally occurring environments A criticism is often put forth of critical potential measurements as a criterion for predicting localized pitting corrosion under naturally corroding conditions in that such measurements are obtained under short-term dynamic conditions and as such bear no relation to long-term immersion behavior.

It is the purpose of this note to show that critical pitting potentials do indeed provide a valuable criterion in determining passive film stability and may serve as a useful tool in one aspect of materials evaluation for design in much the same way as isothermal transformation curves and pH-potential (Pourbaix) (10) diagrams (although both of these represent "unreal" conditions) serve to provide information regarding the behavior of metals and alloys with respect to thermal and environmental effects, respectively.

Key words: critical pitting potential, pitting potential in chlorides.

Table I. Composition of AISI type stainless steel

Experimental

All experiments were conducted on AISI Type 304 stainless steel and have the composition shown in Table I. Cylindrical specimens cut from rods were abraded to 3/0 emery paper followed by pickling in a solution containing 15% HNO_3, 2% HF, 5% HCl by volume at 60°C for 5 min. Specimens were mounted in a manner previously described (8) such that only the stainless steel was exposed to the environment. The all-glass cell incorporated a platinized platinum counterelectrode, Luggin capillary connected to a saturated calomel reference electrode, and an inlet for gas agitation and deaeration. Electrolytes were deaerated for four or more hours using prepurified nitrogen. All electrolytes were made from double distilled water and Reagent grade chemicals.

Polarization measurements were obtained using a Wenking potentiostat in conjunction with a Wenking potential programmer. The latter permitted sweeps to be conducted over a very wide range of scan rates. An X-Y recorder permitted simultaneous measurement of potential and current. In all cases the stainless steel specimens were activated by holding at a potential of −1.5V SCE for a period of 5 min. The

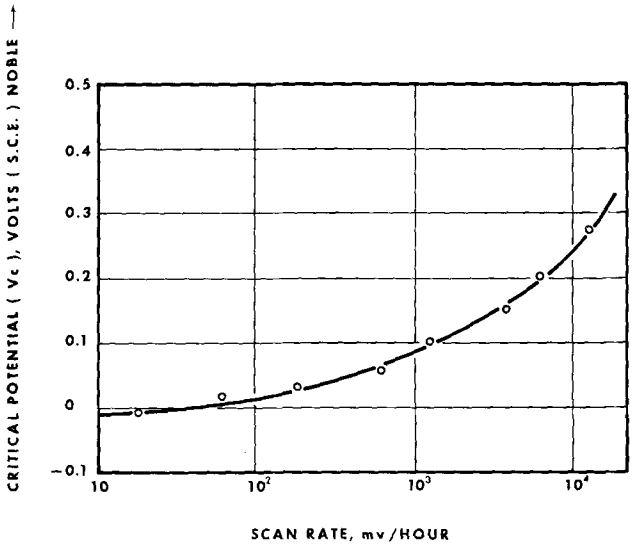

Fig. 1. Effect of potential scan rate on the value of V_c for Type 304 stainless steel in 0.1M NaCl.

potential was then shifted in the noble direction at a scan rate of 10 V/hr and on reaching −0.3V SCE, was held for a further 15 min. Holding at this potential in the passive region allowed the formation of a uniform film. Critical potentials were then measured by again sweeping the potential in the noble direction at various controlled, constant rates.

Results and Discussion

The effect of potential scan rate on the critical potential for pitting for Type 304 stainless steel in 0.1*M* NaCl is shown in Fig. 1. Over a three order of magnitude variation in scan rate, the as-measured critical potential varied by 280 mV. Increasing scan rates resulted in a shift in the critical potential in the noble direction. At lower scan speeds V_c approaches some limiting value. Although no "absolute" value of V_c may be measured on this basis without waiting for an infinite period of time, no breakdown was observed on Type 304 stainless steel held in 0.1*M* NaCl at −0.1V SCE for a period of 14 weeks (2352 hr). This data would indicate that a realistic value for the true critical pitting potential for this material under the described environmental conditions would lie between −0.1 and −0.01V SCE. The latter breakdown potential corresponds to the value measured at the slowest scan rate (18 mV/hr). It would not appear realistic to consider the existence of incubation periods longer than 14 weeks in the confined experimental cell conditions with ready availability of chloride ions.

Under practical conditions the propensity for pitting in a given environment may be determined by measuring the value of the corrosion potential with respect to the critical pitting potential. If the open circuit corrosion potential lies at some value more active than the critical pitting potential (allow a "safety factor" of say 50 mV), it may be reasonably assumed that the passive material under investigation will be immune to pitting corrosion. In this manner the pitting characteristics of passive materials in naturally occurring chloride containing environments may be determined. Any means which will shift V_c in the noble direction (either by alloying or the use of inhibitors) results in a decreased tendency for pitting. Should no pitting occur up to a potential corresponding to the equilibrium oxygen reduction potential, pitting will be inhibited since the corrosion potential arising from local cell action can never be more noble than this value. For this reason titanium having a critical pitting potential ~ + 12V (11), at room temperature can never undergo spontaneous pitting corrosion in chloride solutions in the absence of an externally imposed potential. Therefore, the value of V_c provides a parameter which rates alloys as to their resistance to pitting. In conjunction with a sound experimental design and incorporating multiple regression analysis techniques for data analysis, V_c measurements may be successfully used as a tool in the development of alloys having resistance or immunity to pitting corrosion.

Figure 2 shows the effect of pH on the critical pitting potential as a function of three different chloride ion concentrations. This data was obtained in the manner previously outlined using a scan rate of 500 mV/hr. The data is shown in terms of a nomograph which clearly delineates potential-pH zones corresponding to pitting, general corrosion, inhibition, and immunity. At this scan rate V_c is shifted in the noble direction by 70 mV for each tenfold decrease in chloride ion concentration. Using a potential-step technique Leckie and Uhlig (8) reported a shift of 90 mV for the same change in chloride ion concentration. In all three chloride solutions the critical pitting potential for 18-8 stainless steel was independent of pH in the acid region. At some fairly critical pH in

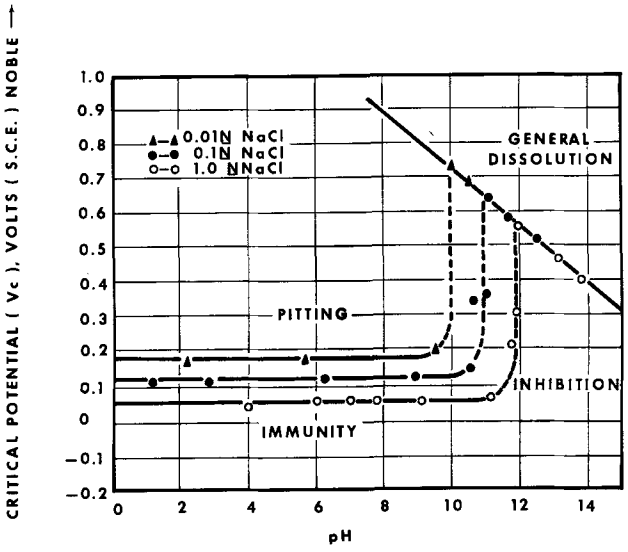

Fig. 2. Effect of pH on V_c for Type 304 stainless steel in 0.01M, 0.1M, and 1.0M NaCl.

the alkaline region V_c shifts in the noble direction. The lines are shown dashed since erratic pitting or general dissolution occurs over a very small pH range and although actual critical pitting potentials may be measured in this transition region these tend to be nonreproducible. The addition of hydroxyl ions thus changes the dissolution behavior from one of pitting corrosion at active potentials to general corrosion and the formation of chromates by the reaction

$$Cr + 4H_2O \rightarrow CrO_4^{--} + 8H^+ + 4e \qquad [1]$$

at noble potentials. Figure 2 shows that the slope of the potential *vs.* pH for this reaction is independent of chloride ion concentration and has a value of −0.082 V/pH unit. The calculated value of slope according to Eq. [1] is −0.079 V/pH. Other inhibitor ions have also been shown to shift V_c in the noble direction at some critical concentration value, dependent on the effectiveness of the inhibitor. Thus, Leckie and Uhlig (8) showed that the efficiency of four ions in inhibiting pitting of 18-8 stainless steel by chlorides decreased in the order $OH^- > NO_3^- > SO_4^{--} > ClO_4^-$.

Nomographs similar in form to that shown in Fig. 2 may be constructed to show the corrosion behavior of other passive metals as a function of chloride and inhibitor ion concentrations.

Conclusion

It is the author's opinion that the critical pitting potential, V_c, has a firm foundation in theory and wide applicability in practice. Measurements of V_c provide a rapid method for predicting the tendency for localized attack in chloride containing environments and serve as a parameter for pitting tendency which may be quantitatively used in the development of pit resistant alloys.

The Effect of Tin and Tetraethylammonium Ions on the Characteristics of Zinc Deposition on a Zinc Single Crystal in Aqueous KOH

F. Mansfeld*[1] and S. Gilman*

NASA/Electronics Research Center, Cambridge, Massachusetts 02139

In a recent paper (1), the authors reported the effect of lead ions added to the electrolyte, on the dissolution and deposition characteristics of a zinc single crystal. The deposit obtained at −200 mV polarization (all potentials refer to the rest potential of pure zinc in the same solution) is converted by the addition of Pb ions from classical dendrites with side branches to compact cylinders with rounded tops consisting of many small crystallites. It was shown that lead blocks most of the sites active for dissolution and deposition of zinc. Growth is nucleated preferentially at sites of macroscopic defects in the crystal, where impurity segregation is also expected. In the present communication, the effect of tin and tetraethylammonium ions on the morphology of zinc deposits at −200 mV is discussed. As a dendrite-inhibiting additive for secondary zinc battery applications, Sn offers the advantage over Pb in that the oxidation potential of Sn is not much higher than that of Zn, as shown by thermodynamic data (2) and potentiostatic polarization curves in 6*N* KOH. On discharge both Zn and Sn may therefore ionize simultaneously making Sn ions available for the recharge process.

In the experiment of Fig. 1, tin was plated out on a polycrystalline zinc rod in 6*N* KOH at −100 mV for 3 min, followed by a linear voltage sweep in the noble direction. The second peak, noble by about +0.19V to the zinc oxidation peak, is not observed in the absence of tin and corresponds to oxidation of that metal

For reference, Fig. 2 obtained using a scanning electron microscope (SEM), illustrates the type of dendritic growth obtained when Zn is electrodeposited on the basal plane of a zinc single crystal from a zincate solution containing no additives [for details of the experimental procedure, see ref. (1)]. Comparison of Fig. 3 and 2 reveals the effect of additions of 10^{-4}M of $SnCl_2$ on the morphology of the Zn deposit. The effect of tin is similar to that of lead (1). The morphology is changed from dendritic (Fig. 2) to a structure consisting of many small crystallites arranged in a spongy array. While the electrodeposit obtained in the presence of Pb (1) was

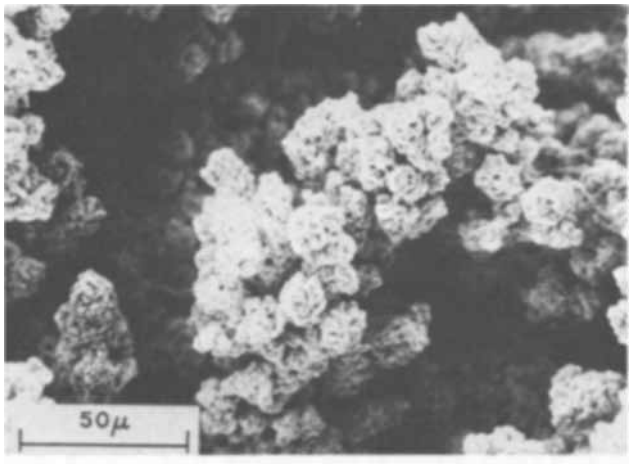

Fig. 3b. 480X.

similarly microcrystalline, the over-all structure was more compact than in the present case.

The effect of tetraethylammonium ion (TEA) was also studied, since a beneficial effect of such ions has been mentioned in (3-5) but no microscopic studies reported. Figure 4 reveals the effect of addition of 10^{-4}M of TEA-ion under the same conditions as in Fig. 2. A dendritic structure is still observed, but dendrites in the presence of TEA ions have become finer with the stem and the side branches shorter and the number of dendrites probably greater. It cannot be shown with these preliminary data whether dendrites are completely suppressed as the concentration of TEA ions is increased or higher members of these compounds added as reported in (4, 5), but the effect of TEA-ions is certainly smaller than that of lead or tin ions at a given potential, concentration, and equal time for deposition.

While it is possible that the slight effect of TEA-ions on the electrodeposit may be due to specific adsorption of the large cations, as suggested by Diggle *et al.* (4, 5) (or of TEA decomposition products which might be present in alkaline solutions), the effect of lead and tin ion additions must more logically be attributed to the codeposition of the corresponding metals with zinc. The foreign metal can be expected to deposit on preferred growth sites blocking further zinc deposition on the particular crystallite and leading to nucleation of new grains.

The effect of lead, tin, and TEA-ions on the corrosion behavior of polycrystalline zinc (99.999%) has been reported recently by the authors (6) for 200-hr tests in 6*N* KOH at 25°C.

Chemical Deposition of Single Crystal Gold Films

Richard Sard*

Bell Telephone Laboratories, Inc., Murray Hill, New Jersey 07974

An electron microscopic investigation has disclosed that epitaxial single crystal gold films can be chemically deposited on copper substrates from aqueous solutions. This unexpected result was observed in the course of an investigation of the growth and structure of gold deposits obtained from the electroless solutions formulated by Okinaka (1).

Initially, annealed copper sheet was used as substrates and the large grained structure, characteristic of recrystallized copper, was copied by gold deposits 0.1-0.2μ in thickness. A series of experiments carried out with single crystal copper substrates that were cut (Servo Met Spark Cutter) and polished parallel to {100}, {110}, or {111} confirmed that the gold deposits were, in fact, epitaxial, *i.e.* they were in parallel orientation with the substrate and exhibited bulk values of the interplanar spacings.

Gold deposits were obtained on at least four single crystal substrates in each orientation as part of the over-all investigation (2) of the structures obtained from electroless solutions. The solutions used for these experiments contained various amounts of the reducing agent, KBH_4, in addition to the other constituents: $KAu(CN)_2$, KOH, and KCN.[1] These solutions will produce gold deposits approximately 1000-1500Å thick in from 2 to 20 min at 80°C, depending on the specific bath composition (1). However, the exact formulations used are not of primary relevance to this note as we are concerned here only with the general features of the initial stages of epitaxial gold deposition on copper substrates. Thus, the fact that autocatalytic solutions were used is not too important because the growth process in this case is due to a displacement mechanism as discussed below. A much more detailed study of the growth, structure and properties of electroless gold deposits has been conducted (2) and will be submitted for publication in the near future.

The gold films were stripped from their copper substrates in a chromic-sulfuric acid solution (3). Stop-off lacquer (Michigan Chrome and Chemical Company) was used to protect the crystals and permit dissolution only at windows on the appropriate surfaces where grid-size regions (2-3 mm) were scribed with tweezers. When the deposits floated free from the substrates they were picked up on grids, carefully washed and dried, then placed in a vacuum dessicator until examination in a Siemens electron microscope operated at 100 kV.

Examples of the single crystal electron diffraction patterns of gold films deposited on {100} and {111} surfaces are shown in Fig. 1 and 2, respectively. These patterns are similar to those observed for epitaxial deposits of face-centered cubic metals prepared by vacuum evaporation (4) and electrodeposition (5, 6). The "satellite" spots in Fig. 1 are due to microtwin faults on the four inclined {111} planes and double diffraction at their boundaries as discussed by previous authors (4, 7, 8). In Fig. 2 the six interior spots in hexagonal array are of the type 1/3 <422> and are due to diffraction at double positioning boundaries (8). Bright-and dark-field observations of the microstructure indicate that the defect densities of these films are quite high; typically $> 10^{10}$ cm^{-2}.

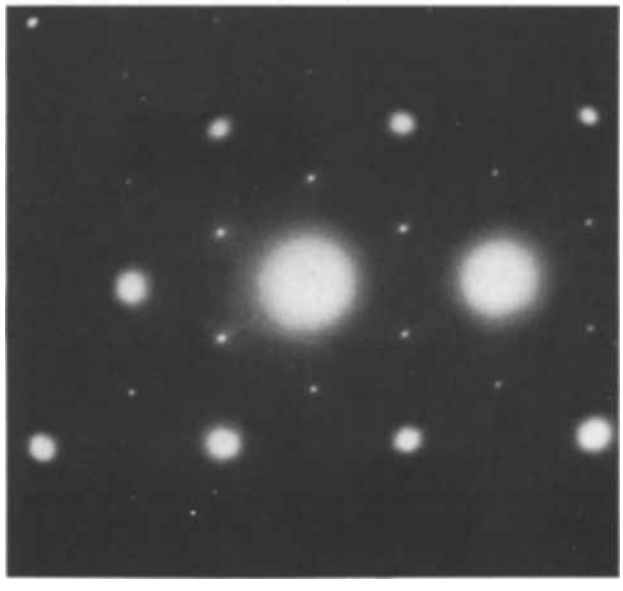

Fig. 2. Transmission electron diffraction pattern of gold deposit on {111} copper single crystal.

As indicated above, a displacement mechanism is responsible for the initial stages of gold deposition on copper substrates. Analytical evidence obtained by atomic absorption spectroscopy indicates that copper dissolves from the surface and goes into solution, presumably to form a more stable cyanide complex. Converting from mass units to equivalent thickness (assuming uniform dissolution over the geometrical area) one obtains values of approximately 100Å for the magnitude of the initial displacement process under favorable conditions, *i.e.*, when pores are sealed by catalytic deposition.

Aqueous solutions that yield deposits of particular metals (*e.g.*, Ag, Cu, Ni, Pd, Pt, Sn) on specific sub-

[1] A typical composition used was: 0.4M KBH_4, 0.02M $KAu(CN)_2$, 0.2M KOH, and 0.2M KCN.

strates have been available for some time (9-11). These deposits are usually termed "immersion" coatings, and they apparently result from galvanic displacement. Unlike electroless solutions, these baths produce relatively thin deposits as the reaction will cease when the solution and original substrate are no longer in contact. Moreover, such deposits are usually quite porous which is why their thickness increases over extended periods of time.

However, it is important to note that the structures of gold deposits obtained from an immersion gold solution (11) and two proprietary (12, 13) solutions were found to be qualitatively similar to those obtained with the electroless solutions. These deposits were obtained at the recommended operating conditions with annealed, polycrystalline copper substrates and the diffraction patterns exhibited single crystal spots corresponding to the various substrate grains.

Thus, it is concluded that the displacement process responsible for the initial deposition of gold films on copper substrates occurs by an epitaxial growth mechanism. There is additional evidence which indicates that such a mechanism may be quite general for the initial stages of displacement processes. This question will be treated in greater detail in a future publication.

Oxygen Reduction on Bright Osmium Electrodes in 85% Orthophosphoric Acid

A. J. Appleby*

Institute of Gas Technology, Chicago, Illinois 60616

Work on the oxygen electrode behavior of osmium has been infrequently reported in the literature. In 1940, Bain[1] reported rest potentials of osmium black films in oxygen-saturated 1*N* H_2SO_4 solution of 0.87V *vs.* hydrogen. Charging curves for —O adsorption on osmium electrodes were studied by Khomchenko *et al.* (2), who noted a general resemblance in properties to those of ruthenium (3), although osmium was observed to go into the solution at lower potentials. Llopis and Vazquez (4) obtained cyclic voltammetric scans in acid solutions on osmium black electrodes. Gnanamuthu and Petrocelli (5) reported steady-state oxygen reduction Tafel slopes of approximately $2RT/\mathbf{F}$ in oxygen-saturated 1*N* H_2SO_4 solution. Electrodes were of comparatively low activity, with overpotentials much greater than those on platinum.

In the present work, oxygen reduction on phase-oxide-free osmium surfaces in 85% orthophosphoric acid was studied as a function of temperature.

Experimental

Osmium electrodes were prepared by electrolytic deposition on 1 cm^2 gold foils from molten cyanides by a previously published method (6). The electrolytic deposits were bright, though somewhat granular. Roughness factors were measured by using a charging-curve technique (2) (see below). Electrodes were suspended on gold wires in the all-silica cell used in previous work (7). A bubbling hydrogen reference electrode was used, to which all potentials are referred. The electrolytic cell contained a gold counterelectrode, so that any contamination of the electrolyte would be confined to traces of nonelectrocatalytic metal. For the same reason, traces of oxidizable material were removed from the electrolyte by hydrogen peroxide treatment rather than by pre-electrolysis.

Apart from the charging curves, all data were obtained by a steady-state galvanostatic technique, allowing sufficient time for less than 0.2 mV/min change in potential at each applied current density. This condition requires 5-15 min at higher current densities; up to 2 hr was required in the 10^{-8}-10^{-9} A/cm^2 range.

Results

Electrode area determinations.—After preparation the electrodes were washed in conductivity water to remove cyanides and were then rinsed in concentrated HCl, conductivity water, and the purified electrolyte.

Electrodes were potentiostated over night at 21.0°C in nitrogen-saturated 85% orthophosphoric acid at 50 mV HRE to ensure reduction of any residual phase oxide, after which chronocoulometric scans were carried out.

Figure 1 shows a typical complete anodic-cathodic charging curve in N_2-saturated 85% orthophosphoric acid at 21°C, at a current density of 200 mA/cm^2 (geometric).

This charging curve is the final one of a series of six, all of which were identical. The curves were terminated at a potential of 0.84V to prevent any

* Electrochemical Society Active Member.
Key words: oxygen reduction, osmium electrodes, electrocatalysis.

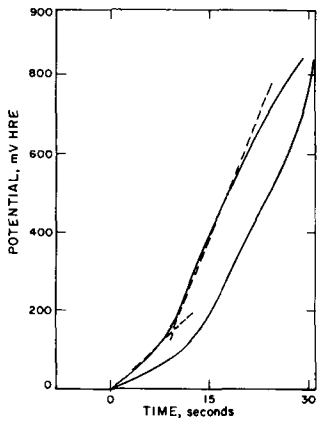

Fig. 1. Charging curve on osmium at 200 mA/cm² in N_2 saturated 85% orthophosphoric acid (21°C).

extensive oxidation of osmium to OsO_2 or OsO_4, or any electrode dissolution.

The electrode shows well-defined hydrogen and oxygen regions, with Q_H about $2Q_O$, where Q_O is the number of coulombs for oxygen. The hydrogen deposition region finishes at about 200 mV; the region of monolayer oxygen deposition starts at about 250 mV and continues through 800 mV.

There is some hysteresis between anodic and cathodic portions, as indicated in Fig. 1, but much less than is shown by platinum (8). The general behavior is close to that of ruthenium (3). The greater hysteresis between anodic and cathodic potential scans on platinum compared with osmium is particularly well shown by Llopis and Vazquez (3).

Preliminary experiments established that the concentration of the acid used has little effect on the charging curves. In addition, results obtained in 1*N* H_2SO_4 and 85% orthophosphoric acid were virtually identical.

Khomchenko *et al.* (2) have shown that electrode areas measured from the hydrogen-charging region agree with BET data on osmium black electrodes. Using 22.48 g/cm³ as the density of osmium and assuming one adsorbed H radical per metal atom, osmium will adsorb 1.73×10^{15} H atoms/cm². If one assumes about 30 μF/cm² for the double-layer capacity in H_3PO_4, then the total charge in going from 0 to about 150 mV (the end of the hydrogen-charging region) is $270 + 30 \times 0.15$ μC/real cm²: *i.e.*, 275 μC/cm².

In Fig. 1 the H-charging region is about 1800 coulombs, indicating a roughness factor of 6.5.

Open-circuit potentials.—Open-circuit potentials were about 850-880 mV HRE 2 hr after immersion of the electrode in oxygen-saturated 85% H_3PO_4 or after cathodic polarization. A complete list is given in Table I.

At 21.0°C the initial value refers to 30 min after polarization: The final value was attained after 12 hr in the solution. Open-circuit potentials rose slowly over several days. This is illustrated by the value at 35.0°C (941 mV) attained after 2 days in the solution.

Tafel plots.—Figure 2 shows a series of steady-state galvanostatic Tafel plots for the osmium electrode at 21.0°, 35.0°, 52.1°, 76.0°, 104.0°, and 136.0°C. In each

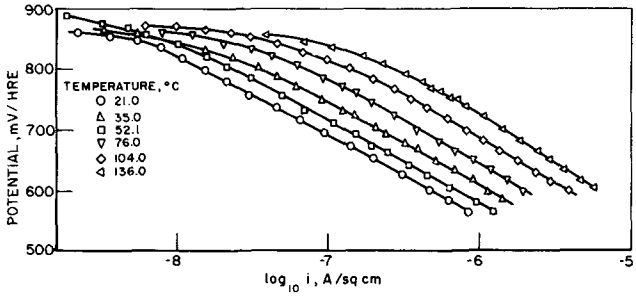

Fig. 2. Tafel plots for oxygen reduction on osmium in O_2 saturated 85% orthophosphoric acid as a function of temperature.

case, the slope is about $2RT/F$. Current densities are corrected for the roughness factor of the electrodeposit.

The Tafel plot at 35.0°C was obtained from the high open-circuit value reported in Table I and is characterized by a more gentle curve into the Tafel region at the high-potential portion of the plot than is observed when results are obtained on electrodes at initially lower open-circuit values. The Tafel region, however, is not affected by the initial open-circuit value.

The above charging curve and polarization results refer to the same electrode. Data obtained on other electrodeposited osmium surfaces were consistently within ±25 mV of the plots shown in Fig. 2, and the discrepancy in each case was not significantly temperature-dependent.

Unlike phase-oxide-free platinum oxygen electrodes, osmium electrodes appear not to be substantially affected by adsorbed impurities, as potentials showed no tendency to decay with time and results are unaffected by preliminary pulsing between 0.9V and 50 mV (9), which should serve to remove any adsorbed impurities (9, 10) that diffuse to the electrode surface from the solution. However, as already indicated, electrodes took a considerable time to come to steady state at any applied current density, indicating that development of equilibrium —O and —OH coverage from water oxidation is slow. However, there was no hysteresis between ascending and descending Tafel plots, provided sufficient time was allowed at each applied current density.

Kinetic data.—Values of i_0 corrected for oxygen partial pressure (assuming a first-order process), roughness factor, $1/\alpha$ values, and Tafel slopes are given in Table II.

An Arrhenius plot of $\log_{10} i_0$ against $1/T$ is given in Fig. 3. Activation energy at the reversible potential on this basis is 13.5 ± kcal/mole.

Discussion

In the potential range 600-850 mV, equilibrium —O and —OH coverage from water oxidation on osmium electrodes may be expected to be high: The charging curve illustrated in Fig. 1 indicates that about one monolayer of —O is adsorbed at 800 mV HRE after 20 sec. On this basis, adsorption of reaction intermediates will take place under Langmuir rather than Temkin conditions.

The Tafel slope of $2RT/F$ is indicative of a primary charge transfer as the rate-determining step, under

Langmuir conditions of adsorption (9). On ruthenium electrodes it has been shown that the primary charge-transfer reaction

$$O_2 + H_3O^+ + e^- \rightarrow (O_2H)_{ads}$$

is rate determining in acid solution (11). In view of the chemical resemblance between ruthenium and osmium and the general similarity of their —O adsorption behavior (2, 3, 4, 11), it is tempting to suggest that the same step is rate determining on osmium electrodes, although precise identification of the process requires reaction-order measurements.

Osmium and ruthenium have similar d-orbital characters (2.2 vacancies) (12) and would be expected to show strong adsorption of oxygenated species compared with gold, on which the same reaction has been shown to be rate determining (13). This is reflected in their measured activation energies at the reversible potential (13.5 kcal on osmium, 11.7 kcal (11) on ruthenium, 23.6 kcal (13) on gold). This demonstrates the effect of heat of adsorption of reaction intermediates on activation energies, first discussed by Horiuti and Polanyi (14) with reference to the hydrogen evolution reaction.

Brief Communication

Oxygen Reduction on Phase-Oxide-Free Platinum-Ruthenium Alloys in 85% Orthophosphoric Acid at High Temperature

A. J. Appleby*

Institute of Gas Technology, Chicago, Illinois 60616

A series of studies conducted by Hoar and Brooman (1, 2) on oxygen reduction in dilute acid solution using Pt-Ru, Pt-Rh, and Pt-Ir alloy electrodes containing low atomic percentages of the alloying metal indicated that such alloys are more active electrocatalysts than pure platinum. Rate enhancement for similar alloys over pure platinum in gas-phase catalysis processes has also been noted. In particular, Bond and Webster (3, 4) showed that Pt-Ru alloys were more reactive than either pure metal for hydrogenation reactions. Other examples of synergistic effects have been noted, both in the gas phase (5) and in electrocatalysis (6).

A recent study by Hoare on Pt-Rh alloys (7) as oxygen reduction catalysts in purified dilute acid

* Electrochemical Society Active Member.
Key words: oxygen reduction, platinum-ruthenium alloys, electrocatalysis.

solution does not confirm Hoar and Brooman's findings: No synergistic effects were noted, and the log exchange current was proportional to the platinum content of the alloy.

In view of the above observations, a study of oxygen reduction on smooth Pt-Ru alloys was carried out in purified 85% orthophosphoric acid at elevated temperature (104°C, approximating to energy conversion device conditions) in a fused-silica electrochemical cell to determine the activity of the alloys under different surface conditions.

Experimental

Polished electrodes of Pt-8 a/o (atom per cent) Ru and Pt-18 a/o Ru were cut from a stock Engelhard alloy sheet of 99.9% purity using a diamond saw. Electrode areas varied between 0.8 and 1.40 cm.^{2} In addition, a 2.0 cm^2 pure platinum electrode of 99.999% purity and a pure ruthenium electrode were studied.

All electrodes were carefully welded to gold wires and after mechanical polishing using alumina powders were degreased with organic solvents and washed with concentrated HCl, conductivity water, and finally the electrolyte (purified 85% orthophosphoric acid).

The electrolyte was purified by treatment with hydrogen peroxide, as described in previous work (8, 9). A thermostatic oil bath maintained the fused silica electrolytic cell (8) at a temperature of 104.0° ± 0.2°C. A stream of high-purity oxygen was passed continuously through the electrolyte at a rate of about 10 ml/min. The reference electrode was an isothermal bubbling hydrogen 85% orthophosphoric acid electrode, to which all potentials throughout this paper are referred (HRE potentials). A gold counter-electrode was used to avoid contaminating the pure ruthenium electrode surface with traces of platinum. Separate batches of electrolyte were used for each alloy.

Results

Rest potentials.—After the preparative procedure described above, each electrode was potentiostated for 2 hr at 50 mV HRE to reduce any superficial oxide that might have been present. Following this treatment, the electrode was allowed to reach its open-circuit potential. Typical values have been plotted as a function of alloy composition in Fig. 1.

In each case, the lower result is the value attained a few minutes after the release of the potentiostatic circuit. The higher values were attained after 2-3 hr. On being left overnight, the value for Pt tended to fall to 980-990 mV; those for Pt-8 a/o Ru and Pt-18 a/o Ru fell to about 990-1000 mV. This may be attributed to the slow adsorption of capillary-active impurities that are not removed by oxidative purification treatment, for example, polyphosphates and traces of organic polymers. Little change in potential was noted for the above electrodes on longer exposures to the electrolyte. On the Pt-40 and 60 a/o Ru alloys, potentials remained essentially constant after 2-3 hr, whereas the value on Ru tended to rise very slowly (5-10 mV/day).

The open-circuit potentials appear to go through a maximum at about Pt-8 a/o Ru (Fig. 1).

Tafel plots.—After equilibration for 8 hr at open circuit in the oxygen-saturated electrolyte, a descending galvanostatic Tafel plot was made for each metal and alloy. In each case, the plot was taken down to the point where diffusion control became apparent; the plotting direction was then reversed. A hysteresis due to desorption of capillary-active material on the electrode surface was observed in each case. The pattern of the hysteresis is changed according to the alloy composition. Plots for each material are shown in Fig. 2 and 3. Plot A for each electrode is the downward plot; plot B is taken in the upward direction. Sufficient time was allowed at each applied current density for the potential to change by less

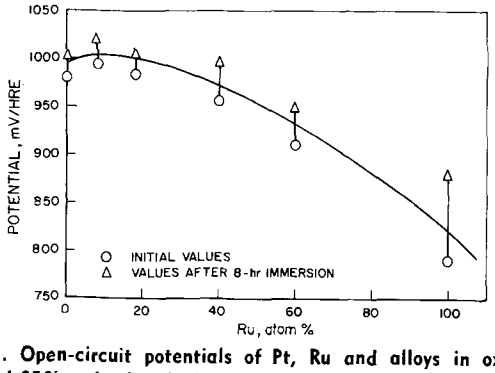

Fig. 1. Open-circuit potentials of Pt, Ru and alloys in oxygen-saturated 85% orthophosphoric acid (104°C).

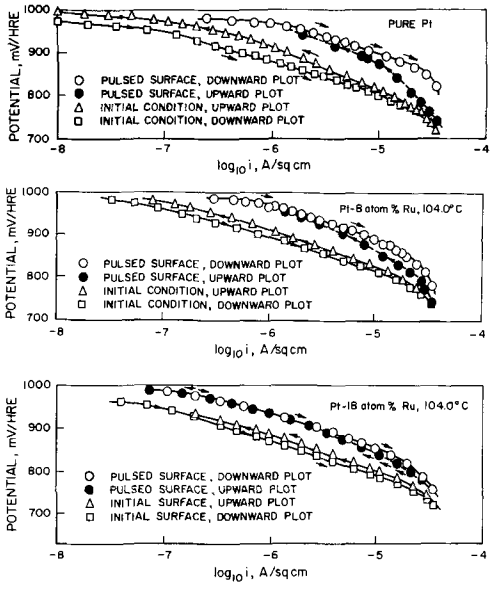

Fig. 2. Tafel plots on Pt and low atom per cent Pt-Ru alloys showing desorption hysteresis in oxygen-saturated 85% orthophosphoric acid (104.0°C).

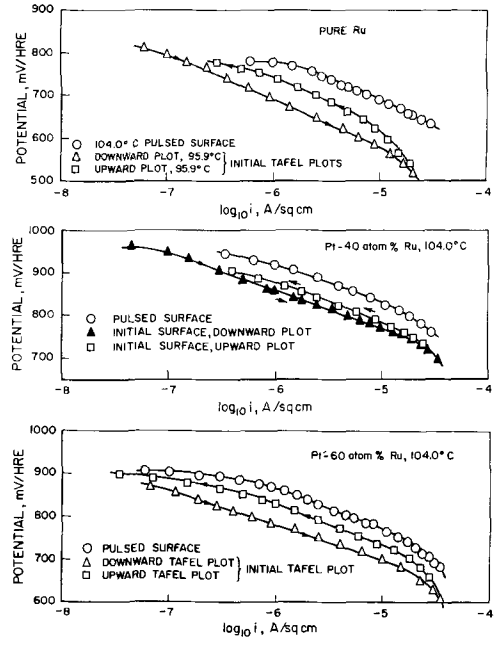

Fig. 3. Tafel plots on Ru and high atom per cent Pt-Ru alloys showing desorption hysteresis in oxygen-saturated 85% orthophosphoric acid (104.0°C).

than 0.5 mV/min. This normally was so within 2-10 min, the time decreasing with increasing current density.

In the case of pure platinum, desorption hysteresis is most marked at about 930-950 mV HRE; the initial plot indicates less activity than for the Pt-8 a/o Ru alloy (Fig. 2). The desorption potential range is broad in the case of the 8 a/o Ru alloy, but desorption becomes marked only below 930 mV HRE on the Pt-18 a/o Ru alloy. For Pt-40 a/o Ru, Pt-60 a/o Ru, and pure[1] Ru, desorption is marked only below 920, 900, and 800 mV, respectively. The enhancement factor of Pt-8 a/o Ru over pure Pt is about 1.5 at 900 mV under these surface conditions. Activities of Pt, Pt-18 a/o Ru, and Pt-40 a/o Ru are similar at 900 mV in plot A.

Tafel plots were also obtained after a standard activation procedure, intended to desorb impurities. Electrodes were pulsed galvanostatically three times between open circuit and 50 mV HRE. The last pulse was always cathodic, and after it a continuous upward plot, starting at about 35 $\mu A/cm^2$, was made. This is represented by plot C in each case in Fig. 2 and 3. Plot D for each electrode in Fig. 2 and 3 is a downward galvanostatic Tafel plot taken from open circuit immediately after completion of plot C. For both plots C and D points were taken after each current density had been applied for 2 min.

For Pt-40 a/o Ru, Pt-60 a/o Ru, and pure Ru, plots C and D were essentially identical. Further pulsing before each point to +1000 and +50 mV led to no further improvement. For pure Ru and the Pt-60 a/o Ru alloy, these plots show deactivation effects (*i.e.*, deviation from linearity) at higher potentials in the ranges above 750 and 850 mV HRE, respectively. Similarly, deactivation effects occur for Pt-40 a/o Ru above about 900 mV HRE. For the platinum-rich compositions, a hysteresis effect is noted between the activated curve plotted in the upward direction and the downward curve (Fig. 3).

It appears that certain adsorbed impurities are not removed from these electrodes by pulsing to +50 mV, but are desorbed at the higher potential end of the plot above about 950 mV. This effect is most marked in the case of pure platinum. On this electrode metal points in the high current density region of curve D are unstable and decayed within a few minutes to values corresponding to those in curve C. Separate pulsing was necessary between each point in curve D to obtain a consistent curve. It was however, established that pulsing to higher anodic potentials (to about 1.4V) led to no further improvement in curve D for pure platinum. This can be considered to be a plot for a clean (*i.e.*, impurity-free) surface. It was established earlier that pulsing of platinum beyond 1.4V leads to surface area changes. Alloys were not pulsed anodically beyond 1000 mV because of the danger of composition changes.

For the Pt-8 a/o Ru alloy, much more stable plot D points were obtained than on pure platinum, and it was possible to trace the whole plot without separate activation for each point. No improvement was noted in individual points by separate activation between points. It therefore appears that pure platinum is much more rapidly deactivated by adsorption of impurities than the Pt-8 a/o Ru alloy (Fig. 2.) The plots for all the impurity-free electrode surfaces (*i.e.*, plot D in each case) are shown in Fig. 4.

[1] The plot for pure Ru is from data at 95.9°C, but may be taken as representative.

Table I. Tafel slopes of Pt-Ru alloy electrodes

	Slope, mV/decade	$1/\alpha$
Pure Pt	77	1.03
Pt-8 a/o Ru	83	1.11
Pt-18 a/o Ru	90	1.20
Pt-40 a/o Ru	95	1.27
Pt-60 a/o Ru	103	1.38
Pure Ru	115	1.54

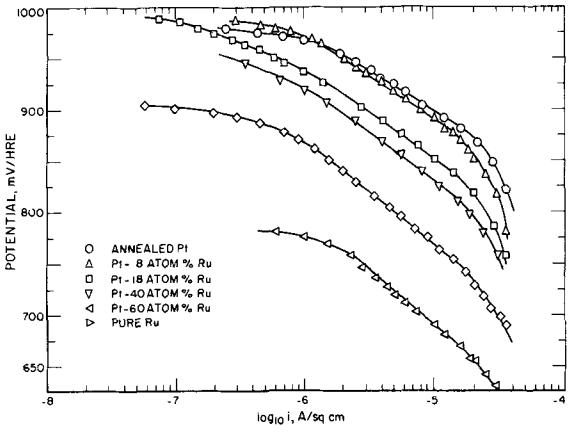

Fig. 4. Tafel plots on pulsed surfaces of Pt, Ru, and alloys in 85% orthophosphoric acid (104.0°C).

Tafel slopes for clean surfaces.—Tafel slopes and $1/\alpha$ values are given in Table I.

There is a definite tendency for the slope to increase as the ruthenium content of the alloy increases.

Discussion

Hoar and Brooman (1, 2) have published work carried out in dilute sulfuric acid to show that Pt-Ru alloys with Ru content up to 9.3 a/o are more active than pure platinum at 25°C. However, the oxide-free platinum electrode data they report indicate that their electrode is considerably less active than the corresponding surface in 85% orthophosphoric acid at 25°C (9) (by about 200 mV at the same current density) and that [from Damjanovic and Brusic's (10) data] it is about 10,000 times less active than the same surface in perchloric acid at the same temperature. According to Hoar and Brooman (1), the inflections in their plots were caused by adsorption of an intermediate. It is more likely, however, that they are due to adsorbed impurities, as only cathodic pre-electrolysis was used for purification. The poor performance of their platinum electrode implies that oxidizable impurities were present in their experiments.

The results of the present experiments show that platinum is more susceptible to poisoning by impurities than alloys containing small amounts of ruthenium, as shown by the initial Tafel plots (Fig. 2 and 3). This is also reflected in the open-circuit potentials and the relative performance of pure Pt and Pt-8 a/o Ru at current densities below 1 $\mu A/cm^2$. The adsorptive properties of Pt-Ru alloys are thus different from those of pure Pt. Their activity in direct hydrocarbon oxidation (6) and their tolerance to poisoning are probably related phenomena.

Results obtained on clean platinum surfaces also decay much more rapidly than on Pt-8 a/o Ru alloy. Hence, in not extensively purified solution, Pt-Ru alloys containing small amounts of ruthenium may be more active than platinum alone, but for clean surfaces at moderate overpotentials activity increases with increasing platinum content.

As may be seen in Fig. 4, the increase in activity is a combination of two factors: improvement in i_o and in Tafel slope. Figure 5 shows the log current at 850 mV HRE plotted against atom per cent Ru. A straight-line relationship is obtained. Similar results have been obtained on the Pt-Rh alloy oxygen electrode system by Hoare (7).

As d-orbital vacancies in solid solutions are proportional to atomic composition, it appears that the energy of activation for the rate-determining step of

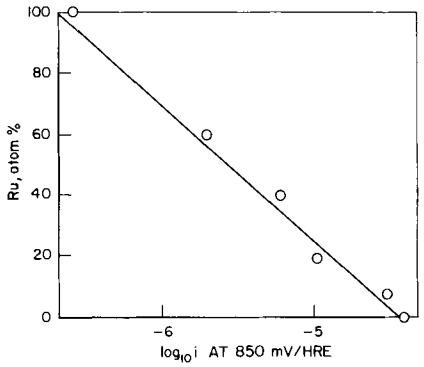

Fig. 5. Correlation between current density at 850 mV/HRE and alloy composition for Pt-Ru solid solutions: oxygen reduction in 85% orthophosphoric acid (104.0°C).

the reaction depends directly on the electronic structure of the alloy.

The Transient Oxidation of Fe-Cr and Ni-Cr Alloys

B. Chattopadhyay and G. C. Wood

Corrosion Science Division, Department of Chemical Engineering, University of Manchester Institute of Science and Technology, Manchester, England

ABSTRACT

The early stages of oxidation of Fe-Cr and Ni-Cr alloys, containing respectively nominally 5, 10, 15, and 30 a/o Cr, in 1 atm oxygen at 600°C have been studied by transmission electron microscopy of stripped films and by electron diffraction. Substantial amounts of iron and nickel oxides, respectively, are produced on all alloys before steady-state, healing, chromium-containing oxide layers are developed. This occurs more rapidly and more completely as the alloy chromium content is increased. For dilute Fe-Cr and very dilute Ni-Cr alloys, grain and subgrain boundaries and other substructural defects of the alloy are covered by thicker oxide. This is due either to their efficiency as cation vacancy sinks or to more local diffusional paths in the oxide above them. Conversely, for alloys richer in chromium (up to 30%), healing is most rapid in these locations due to rapid chromium diffusion to the alloy/oxide interface, leading to thin oxide above the defects. The tendency of rapidly growing iron oxides to overgrow the chromium-containing oxides, and also to undermine them by encroaching on the alloy, is countered by the rapid development of a general healing layer of $FeFe_{(2-x)}Cr_xO_4$ ($O \leq x \leq 2$) for the dilute Fe-Cr alloys and Cr_2O_3 for the concentrated alloys. $NiCr_2O_4$ probably does not form a healing layer for dilute Ni-Cr alloys and the completion of a healing Cr_2O_3 layer is slower than for Fe-Cr alloys. This is largely due to the lower alloy interdiffusion coefficient. However, the slow growth of NiO limits overgrowth and scale encroachment. Cr_2O_3 healing is eventually approached by dense internal oxide formation, resulting partly from the relatively high solubility of oxygen in Ni-Cr alloys.

Relatively little is known about the transient films formed in the initial, nonsteady-state stages of oxidation. Particularly with alloys whose oxidation behavior is borderline between protective and nonprotective, the spatial distribution, amount, composition, and structure of the initial phases determine the oxidation rate and the subsequent approach to steady-state oxidation. A considerable total oxide thickness is often developed before steady-state conditions are established. Wagner (1) has considered presteady-state conditions briefly, and relatively detailed studies of Cu-Ni and Cu-Zn alloys have been made by Whittle and Wood (2, 3). Other papers relevant to the subject have been published on Fe-Cr alloys (4-6, 14) and copper-base materials (7-9).

The present paper is one of a series in which transient oxidation of a wide range of practically important alloys has been studied by transmission electron microscopy and by transmission and reflection electron diffraction of stripped films. By using standard heating and cooling conditions for oxidation in a single oxygen pressure at one temperature, for single-phase Fe-Cr and Ni-Cr alloys of various fixed compositions, the main variables emerge as (*a*) the bulk alloy composition, (*b*) the alloy interdiffusion coefficient, (*c*) the solubility and diffusivity of oxygen in the alloy, and (*d*) the relative growth rates of the doped and complex oxides. The standard free energies of formation for oxides of the relatively noble metals, nickel, cobalt, and iron are so similar, compared with the value for the much less noble metal, chromium, that differences in this factor are insignificant in this series. Complex oxide formation is, however, different in the different systems. Particularly under relatively mild conditions, epitaxy effects and the influence of the substrate substructure must be expected to be significant. Plastic flow of the oxide and substrate may also influence the scale morphology.

A subsidiary object of the paper was to investigate the interrelationship between the substructure of the oxide and the subjacent alloy. This subject is still in its infancy but has been studied for pure metals, for example in ref. (10-21).

Key words: oxidation, Fe-Cr alloy, Ni-Cr alloy.

Experimental Procedure

The alloys were prepared from vacuum-melted materials as cold-rolled strip 0.05 cm thick. The analyses were pure iron, Fe-4.35 w/o Cr (4.7 a/o), Fe-9.4 w/o Cr (10.0 a/o), Fe-15.5 w/o Cr (16.4 a/o), Fe-28.5 w/o Cr (30.1 a/o), pure nickel, Ni-5 w/o Cr (5.6 a/o), Ni-10 w/o Cr (11.1 a/o), Ni-15 w/o Cr (16.6 a/o), and Ni-27 w/o Cr (29.5 a/o). The nominal compositions of 5, 10, 15, and 30 a/o are used throughout the remainder of the paper.

After annealing for 4 hr at 800°C at 10^{-5} Torr, most specimens, 2 x 0.5 x 0.05 cm, were individually electropolished for 5 min in 30 sec pulses at 0.5 A cm^{-2} (25V) in 90% glacial acetic acid, 8% perchloric acid (sp gr 1.61), 2% water (all v/v). This was sufficient to remove about 15 mg cm^{-2} from each side of the specimens. It ensured the complete removal of any

chromium-depleted surface layer developed during fabrication and not removed by annealing. Pure nickel was electropolished under identical conditions in 50% v/v sulfuric acid. All the polished samples were rinsed in water and methanol and dried prior to oxidation.

Oxidation was restricted to 1, 2.5, 5, 10, and 15 min at 600°C. Since the oxidation times were short, the specimens had to be brought to temperature as quickly as possible and then after oxidation cooled very rapidly. The following technique, a refinement of that of Whittle and Wood (2, 3), ensured identical although arbitrary heating and cooling for each specimen. A glass tube, 80 cm long and 3.75 cm in diameter, was suspended by a vacuum-tight joint above a vertical furnace containing flowing oxygen at 1 atm pressure. The furnace inner tube was 66 cm long and 2.85 cm in diameter and the outer tube was 37.5 cm long and 4.5 cm in diameter. The specimen was hung inside the glass tube using a Kanthal hook, 6.25 cm long and 0.05 cm in diameter, passing through a 0.1 cm hole in the specimen. The hook itself was attached to an 18% Cr, 8% Ni stainless steel rod, 60 cm long and 1 cm in diameter, resting freely on an upper suspension rod. Upon release of this suspension rod, the stainless steel rod and attached sample fell 57.5 cm to a second suspension rod, permitting the specimen to reside exactly in the center of the hot zone of the furnace. At the end of the run, the second suspension rod was released, dropping the stainless steel rod and attached specimen directly into a quenching water bath beneath. The oxidation time was designated as the time elapsing between the two releases. The specimens were immediately dried and placed in a desiccator.

Any effects of "overheating" of the sample and the time taken for it to reach 600°C were investigated. A Pt/Pt-Rh thermocouple was spot-welded to the specimen in its usual assembly. Identical temperature/time curves were obtained for iron and Fe-30% Cr. It took about 80 sec to reach the vicinity of 600°C, as shown by automatic recording (Fig. 1). A similar curve was obtained when the thermocouple was attached to the Kanthal hook in the absence of the specimen. If any overheating due to the heat of formation of the oxide occurred, it was masked by the rapid rise to temperature. The other alloys would be expected to give similar curves because iron and Fe-30% Cr were, respectively, the fastest and slowest oxidizing alloys.

After evaporation of carbon onto the surfaces for supporting purposes in some cases, most oxide films were stripped chemically. A saturated solution of iodine in 10% w/v potassium iodide, or sometimes a 12% w/v solution of iodine in absolute methanol, proved successful for Fe-Cr alloys, and a solution of HCl/water/ethanol (10 ml : 30 ml : 40 ml), to which a few milliliters of hydrogen peroxide had been added, proved successful for Ni-Cr alloys. The stripped films

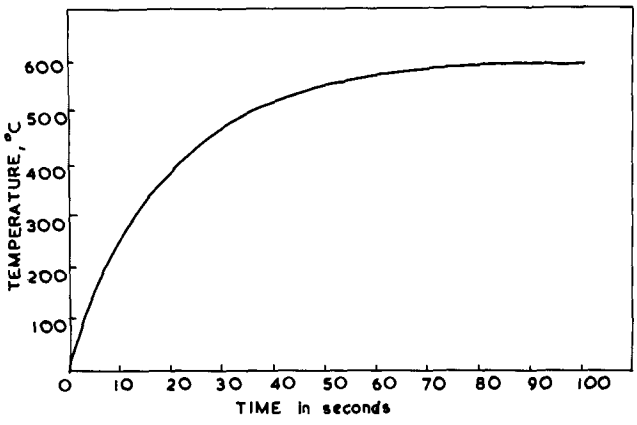

Fig. 1. Temperature of iron or Fe-30% Cr specimen as a function of time during the heating-up period.

were washed in methanol and water prior to examination in an A.E.I-E M6G electron microscope with diffraction attachment at 80 kV.

The top surfaces of films were examined by reflection electron diffraction at grazing incidence, interpretation of the pattern being subject to the usual severe restrictions of this technique. Transmission electron diffraction was applied with greater confidence. Selected area electron diffraction, limited in resolution by the minimum aperture of 1.25 μm, was inadequate to resolve the finely divided phases. Electron probe microanalysis in plan (2, 3) was so near its limits of usefulness, films generally being <1000Å in thickness, that it could not be employed significantly.

Results and Interpretation

Electron diffraction.—The oxides displayed interference colors, often blue to blue-brown, and electron opacity experiments with stripped films indicated them to be in the range 400-2000Å thick. Relative thicknesses between films on 30% Cr alloys could not be judged. It appeared that although for a given oxidation time films were thicker on iron than on nickel, they were thinner on Fe-5 to 15% Cr than on Ni-5 to 15% Cr.

Generally 2 or 3 diffraction photographs were taken from different regions over the surface of every specimen, using large and small apertures as appropriate. The experimental d_{hkl} values were compared with the values obtained from standard x-ray data and the pattern was identified. Some reflection lines were missing in the Fe-Cr patterns which were very diffuse. The diffraction data are summarized in Tables I and II, referring to the phases from the x-ray patterns used in identification. Where an expected oxide (on the basis of general theory and steady-state data) was

Nomenclature as in Table I.

missing, this is indicated in the text. Relative amounts of phases indicated by electron diffraction data must not always be accepted literally. This is because the oxides may be buried in certain cases, missed in random sampling, or present in too small an amount to be detected, particularly if the major lines are in close coincidence with those of another predominating phase. Although it was possible in the Fe-Cr system to differentiate spinel oxides, that is, Fe_3O_4 and $FeCr_2O_4$ from the rhombohedral phases, that is, α-Fe_2O_3 and Cr_2O_3, only with great difficulty could members within each phase group be identified. Thus, identification as $FeCr_2O_4$ or Fe_3O_4 could mean $FeFe_{(2-x)}Cr_xO_4$ ($0 \leq x \leq 2$) rich and lean in chromium, respectively, and Cr_2O_3 and Fe_2O_3 would indicate Cr_2O_3-Fe_2O_3 rich and lean in chromium, respectively. Some evidence of single as well as polycrystalline patterns was observed, but in the absence of alloy attached to the oxide, epitaxy relationships were not identified.

Oxidation of Fe-5% Cr revealed Fe_3O_4 as the only major phase for up to 10 min, with some Cr_2O_3 appearing at 15 min. No $FeFe_{(2-x)}Cr_xO_4$ rich in chromium (usually indexed as $FeCr_2O_4$) was found. However, it is likely that a thin healing layer of the spinel relatively dilute in chromium existed at the scale base, as found for thicker scales produced at high temperatures. The Cr_2O_3 was possibly a healing layer which can develop at the base of the spinel, or internal oxide. A little rhombohedral oxide (probably α-Fe_2O_3) would be expected at the outer surface if the oxidation rate had slowed sufficiently, but this was not detected. For comparison, Phelps, Gulbransen, and Hickman (14) found Fe_3O_4 and perhaps, surprisingly, Cr_2O_3 for Fe-5% Cr after 5 min at 400°C, using reflection diffraction, but only Fe_3O_4 and $FeCr_2O_4$, after cooling by transmission diffraction.

As expected, reflection diffraction revealed Fe_3O_4 with a presumably overlying, rhombohedral layer on Fe-10% Cr at all times. In transmission, the existence of Fe_3O_4 as the major phase was naturally emphasized because the entire film was now being traversed by the electron beam. $FeCr_2O_4$ was occasionally indexed, but again some of the material indexed as Fe_3O_4 could have been spinel dilute in chromium. The weak Cr_2O_3 lines observed in transmission after 5 min could have been a healing layer or possibly a local area where Cr_2O_3 developed from the outset. The latter explanation was supported by the occasional finding of weak Cr_2O_3 lines in reflection patterns. Alternatively this could be a case where an initial Cr_2O_3 layer lifted off the surface, became perforated, and allowed iron-containing oxides to grow beneath it.

For Fe-15% Cr, again, Fe_3O_4 and rhombohedral oxide (probably α-Fe_2O_3 but the presence of Cr_2O_3 after 5 min indicated that some of it could have been α-Fe_2O_3-Cr_2O_3) were detected as the outer phases by reflection electron diffraction. Transmission diffraction revealed additionally Cr_2O_3, which would be expected at the scale base. It is curious that the apparent amount decreased with time. Phelps, Gulbransen, and Hickman (14) also detected Fe_3O_4 and Cr_2O_3 as predominant phases in the stripped film for Fe-13% Cr after 15 min at 600°C.

The presence of Cr_2O_3 as the major phase at all times on Fe-30% Cr was expected, but it is reasonable that minor amounts of Fe_3O_4 (or spinel rich in iron), rhombohedral oxide, and spinel rich in chromium should have been identified. These almost certainly lay at the outside of the films, being the result of the nucleation stages. Further outward diffusion of iron ions, trapped originally in the inner Cr_2O_3-rich layer, toward the location of higher oxygen potential could also occur.

The patterns were much simpler to interpret for Ni-Cr alloys because only three oxides had to be considered. Virtually all the diffraction data were obtained by transmission.

For Ni-5% Cr and Ni-10% Cr, NiO was the major phase, with increasing amounts of $NiCr_2O_4$ as oxidation proceeded. If behavior at higher temperatures was followed here, the spinel did not exist as a complete layer but as particles produced by interaction between the main NiO layer and the Cr_2O_3 internal oxide. It would appear that a healing Cr_2O_3 layer initiated after 10 min for Ni-10% Cr. The low amount of NiO found on this specimen could have been due to very rapid healing or to substantial interaction between the initial NiO layer and the healing Cr_2O_3 layer. The same phenomenon was found after 10 min with Ni-15% Cr, so possibly the second explanation is favored. The extent of NiO formation was still high even with Ni-30% Cr, but the amount of Cr_2O_3 detected, although small, did increase with the alloy chromium content and also became detectable earlier. Apart from the fact that such layers could have been quite thin, these scales tend to crack between the Cr_2O_3 and the outer oxide on cooling. Adhesion between the Cr_2O_3 and the substrate is much better in the Ni-Cr than the Fe-Cr system, due to interlocking. Although most of the oxide would have been stripped from the substrate, some of the Cr_2O_3 may have floated away from the outer layer rich in NiO and containing $NiCr_2O_4$ and not have been detected. There is, however, no direct evidence that a more complete spinel layer did not form at this lower temperature and play a more important role than at higher temperature.

Electron microscopy.—General comments.—Pt/C replicas revealed that electropolished surfaces were smooth and virtually uniform. Etched surfaces of annealed samples showed large grains, of typical diameter 10-50 μm, with relatively uniform surfaces apart from a few minor dimples and some fine columnar grains occasionally grown on grain boundaries. Several areas of each stripped oxide film were studied to ensure representative micrographs.

For pure metals and dilute alloys (very dilute in the Ni-Cr case), the alloy grain boundaries, subgrain

boundaries, and certain other substructural features, which could be dislocation loops and forests, produced thicker oxide. This could have been partly due to impurity segregation in this location but was more likely due to their acting as excellent vacancy sinks. This permitted a high vacancy concentration gradient across the scale and prevented void formation at the scale base, so permitting rapid oxidation (12). Alternatively, the thicker oxide was due to more local paths of easy diffusion, due to lattice disregistry between coalescing epitaxial nuclei in the oxide, the introduction of misfit dislocations, incoherent twin boundaries, mosaic structures, *etc.* (10, 11, 13, 16). The latter explanation also shows why certain grains oxidized faster than others. It appears quite common to make reference to subgrains in the oxide (10, 11), but it is not always easy to differentiate between genuine features and replication effects. Some artifacts may have been introduced on quenching or stripping, but there is no direct evidence of this and most features are considered genuine.

As the alloy chromium content increased, it became progressively more possible for preferential healing of the scale by chromium-rich oxides at the substrate defects. This was due to the more rapid diffusion of chromium to the alloy/oxide interface through such defective regions, permitting the transition from internal to external Cr_2O_3 formation there. There is some evidence that the effect was relatively greater for Ni-Cr alloys, but the situation was complex as discussed later. The term "healing" is used in this paper to mean the development of a compact, slowly growing, oxide layer at the scale base and does not imply closure of cracks and so forth.

Fe-Cr alloys.—Characteristic thickening of the oxide at grain boundaries (up to 1 μm) and other vacancy sinks occurred for pure iron after times of about 2.5 min. Figure 2b-d shows similar features for Fe-5% Cr. Clearly oxidation was most rapid at the main grain boundaries which thickened to different extents due to orientation differences, illustrating that the zone of influence extended beyond the boundaries themselves. Lesser thickening at alloy subgrain boundaries was then followed by the gradual "filling-in" of the areas between the subboundaries. The filling-in was again faster on some grains than others, the process being virtually complete after 15 min. Assuming the subgrains visible in the oxide were not independent features but did replicate the alloy, the subgrains of the alloy appeared equi-axed and about 1-3 μm in size, the small thicker oxide regions usually being 0.5-3 μm. The oxide grain size was, therefore, very much smaller than the alloy grain size even by the time the crystallites formed at the defective regions had thickened, grown, and coalesced to give an opaque oxide.

Figure 2a, typical of several such features, shows an area of thin oxide, probably over a minute healed region of scale (which would be too small to detect by electron diffraction). The features leading radially into the thin oxide could have been dislocations in the oxide, or produced in the replication of dislocation structures in the substrate, or merely have been compositional or contrast effects in the films. The features were still visible on tilting but did not move in the electron beam, probably supporting the replication concept. If they were dislocation arrangements, differential stresses in the oxide or the substrate produced during growth could have been responsible for the distribution. However, the remarkable similarity to the micrographs of Howes (5) and Taylor, Holmes, and Boden (21) suggests they may have been diffraction contrast fringes. Such fringes may have been due to severe strains in the oxide or at the alloy/oxide interface, as a result of epitaxial growth or of stress developed in the oxide at a later stage (5), or electron optical extinction phenomena as a result of rust rosettes (21).

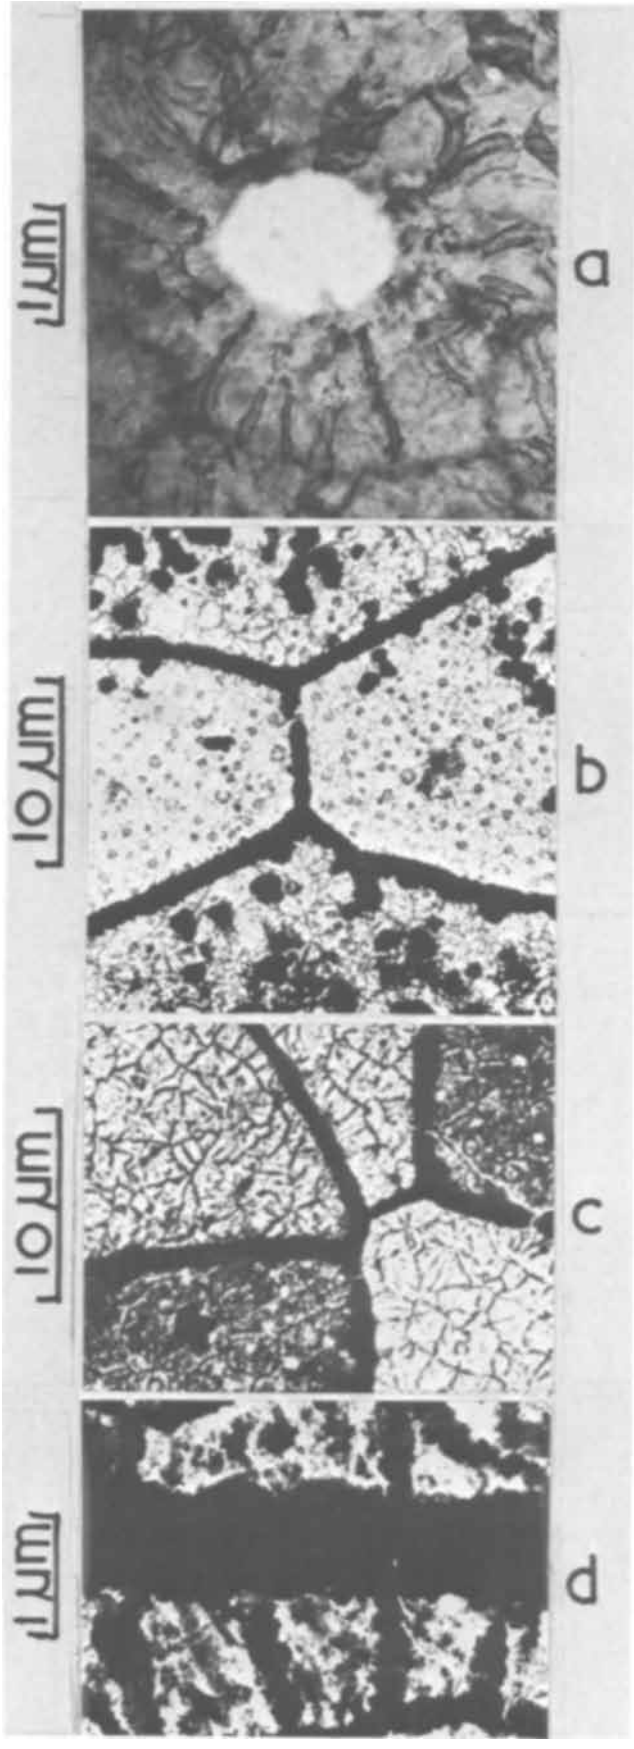

Fig. 2. Transmission electron micrographs of oxide films formed on Fe-5% Cr for (a) 1 min, (b) 2.5 min, (c) 5 min, and (d) 5 min at 600°C; (a) shows radial structural or contrast features leading into a thin oxide disk, (b)-(d) show initial oxide thickening at alloy grain boundaries and other sites and the gradual filling in of the subgrain regions.

Nevertheless, in the present work they were never observed on pure iron.

A similar pattern of boundary growth and the filling in of subgrains was observed on Fe-10% Cr (Fig. 3), the rate appearing to be somewhat similar to that for Fe-5% Cr. The borderline nature of the alloy was illustrated by the fact that in some regions the oxide above the main grain boundaries had thickened everywhere more rapidly than above the grains themselves, whereas, in others (Fig. 4d) oxidation had been slower there due to preferential healing. The intermediate situation is given in Fig. 4a where breaks in the grain boundary darkening indicate localized healing. Remarkable differences in oxide thickness from place to place on this sample may also have been evidence of some localized healing within certain metal grains.

Close scrutiny of certain grains in Fig. 4a reveals a myriad of small disks with dark peripheries, generally separate but occasionally impinging on one another.

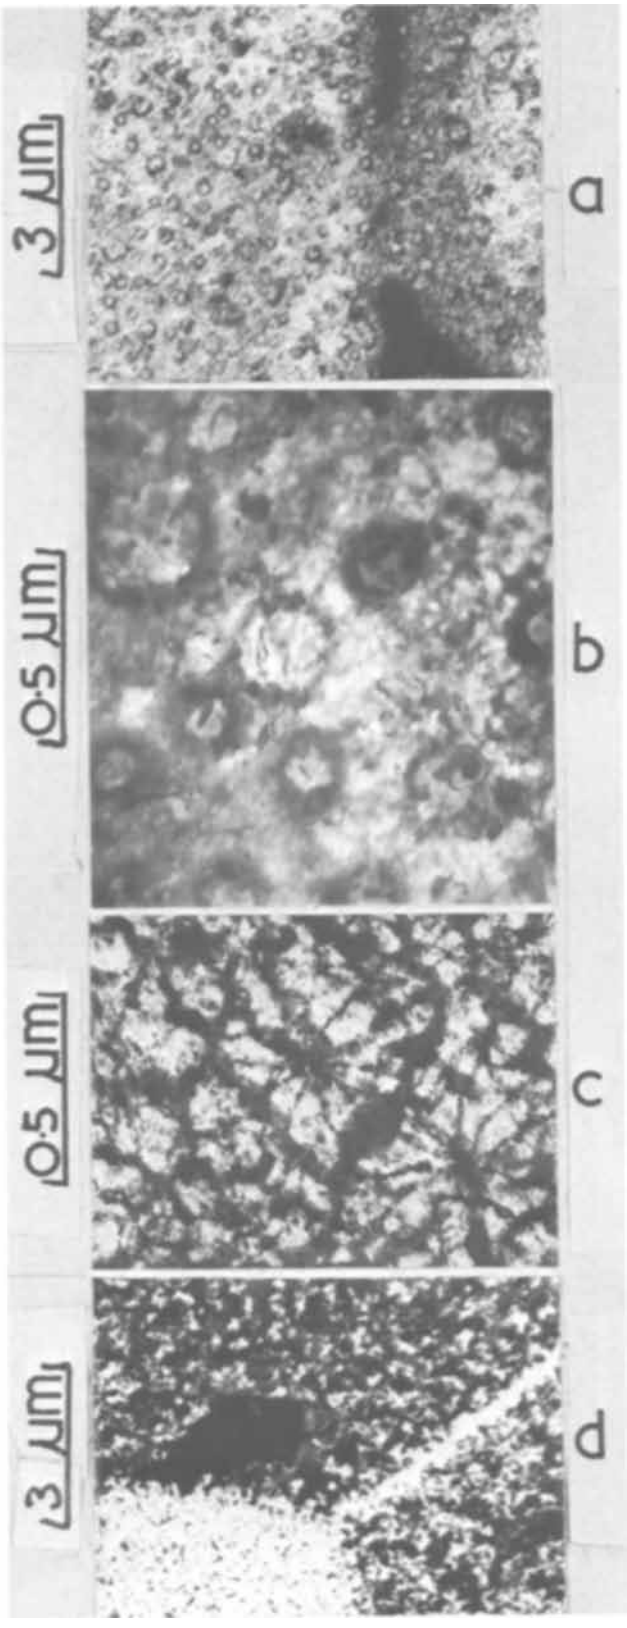

Fig. 3. Transmission electron micrographs of oxide films formed on Fe-10% Cr for (a) 2.5 min, (b) 2.5 min, (c) 5 min, and (d) 10 min at 600°C; (a) and (d) show preferential grain boundary healing in certain locations, with thickening still present elsewhere; (a) also gives the general distribution and (b) the detail of loop structures; (c) shows rosette structures.

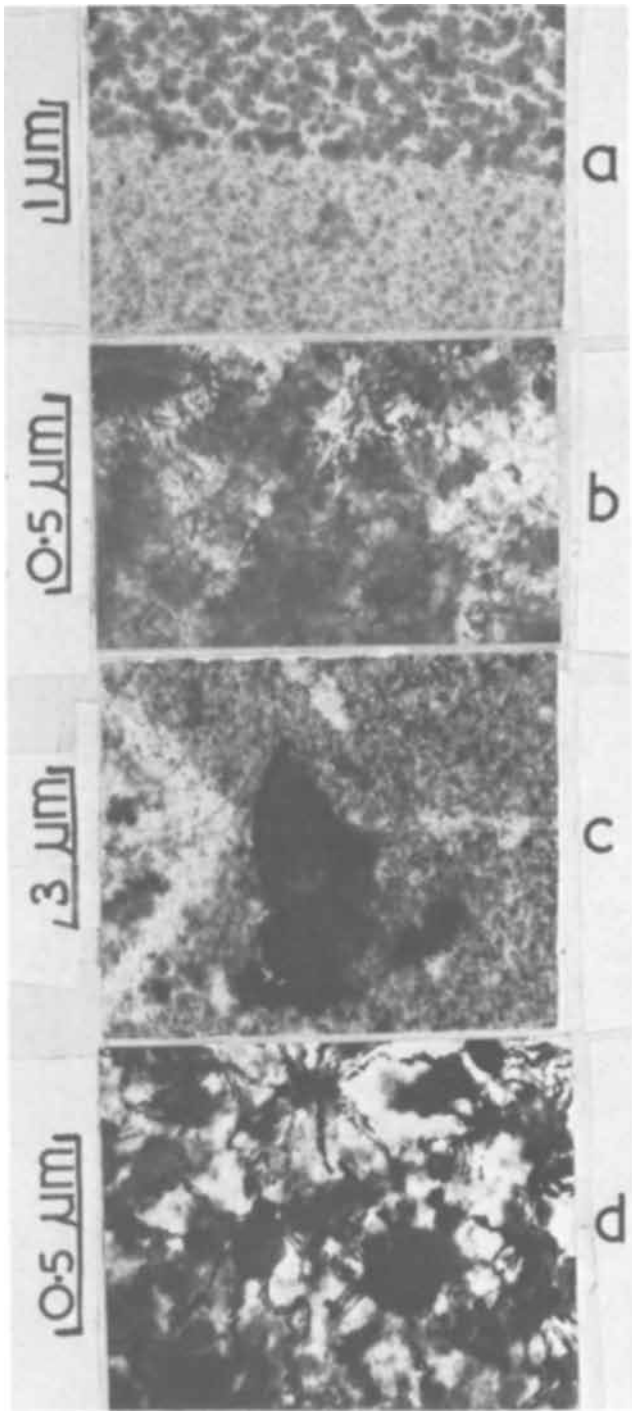

Fig. 4. Transmission micrographs of oxide films formed on Fe-15% Cr for (a) 1 min, (b) 2.5 min, (c) 5 min, and (d) 15 min at 600°C; (c) demonstrates complete preferential healing along grain boundaries; (a)-(c), various local healing features within the grains, and (d), a rosette structure with the "hub" containing thick oxide.

Although they may have been due to minor undulations in the film or local healing within the circles, it appears much more likely that they were genuine features. Figure 4b gives the detail of the disks, the typical diameter being 0.1-0.4 μm and the population 10^9 cm^{-2}. A likely explanation is that the film replicated dislocation loops which were produced in the substrate by rapid cation vacancy injection. Such vacancies, produced by the oxidation process, aggregated and eventually collapsed during the initial stages of oxidation. The peripheries of the loops acted as good cation vacancy sinks, so the oxide thickened above them. Alternatively, the lattice mismatch argument is applicable. Certain loops appear to have been connected with other dislocations. The loops were stable in the beam, which favors the concept that they replicated loops produced in the alloy surface and remained present on tilting. They were also seen in specimens oxidized for 1 min. Similar loops or replicated loops have been observed previously by Howes (5) on Fe-28% Cr, although they were smaller than here, and by Ali and Wood on nickel (22). They have been studied in detail by transmission of thin metal foils covered by thin oxide in the case of magnesium, zinc, and cadmium (17-20).

"Rosette" structures, somewhat similar to those in Fig. 2a except that the central region contained thick rather than thin oxide, were also observed on this alloy (Fig. 3c). The interbranch spacings of the rosettes were thin and bright.

The results for Fe-15% Cr (Fig. 4) revealed complete preferential healing along grain boundaries (Fig. 4c) due to the higher alloy chromium content, with the zones of influence of the boundaries extending more into the grain with certain boundaries than others. Although the oxidation rate still varied from grain to grain, this was somewhat less pronounced than with dilute alloys, with less local scale thickening above substrate defects. The considerable local healing seen in some grains (Fig. 4a-c) could have been due to thin oxide above metal subgrain boundaries or other substrate defects, or due to reduced thickening above chromium-rich oxide which commenced as internal oxide. Features which could have been dislocation forests are visible in Fig. 4b. The rosette structures observed on previous alloys (Fig. 2a and 3c) were again clearly visible, particularly over large areas of the 10 and 15 min specimens (*e.g.* Fig. 4d).

With Fe-30% Cr there was less oxidation at grain boundaries and their peripheries and at certain sites within the grains than over the general surface (Fig. 5a). However, the influence of the grain orientation on the oxidation rate generally appeared less than for the other alloys. As healing by a Cr_2O_3 layer is expected fairly rapidly with this alloy, the mottled oxide was probably mainly the Fe_3O_4 and rhombohedral oxide other than Cr_2O_3 detected by electron diffraction and produced in the initial scale establishment stages. The fine dark particles were almost certainly rhombohedral oxide rich in α-Fe_2O_3, standing proud (Fig. 5a). Perhaps these subsequently acted as centers of rosettes which appeared in ruptured forms. With increasing time, preferential growth at the grain boundaries again began to predominate (Fig. 5b). This is reasonable because once Cr_2O_3 was the major phase over the entire surface and it became thick compared with the outer, residual iron-containing oxides the boundaries could again act as vacancy sinks or enhanced mismatch centers with respect to Cr_2O_3 formation, and local thickening could occur there. The matrix now consisted of fine oxide crystallites up to about 0.2 μm in size (Fig. 5c). Other areas of oxide showed fringes and possible dislocation structures.

Ni-Cr alloys.—Grain boundary thickening of oxide and the variation in oxidation rate from grain to grain also held for pure nickel. The general features were similar to these already described (10-12), with apparent oxide crystallites growing with time and dislocation forests, mosaic structures, *etc.*, visible in the oxide. Many of the oxide films on nickel and the dilute Ni-Cr alloys curled up into rolls on stripping, presumably due to residual stresses within the films.

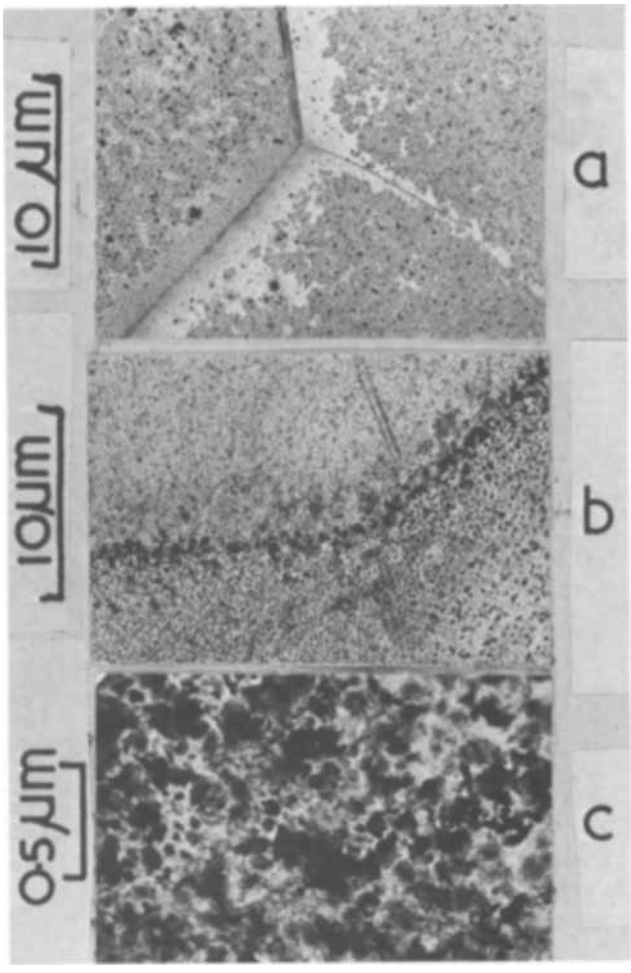

Fig. 5. Transmission electron micrographs of oxide films formed on Fe-30% Cr for (a) 2.5 min, (b) 15 min, and (c) 15 min at 600°C; (a) displays rapid healing at grain boundaries and limited healing within the grains, with a few minor oxide protrusions; (b), local oxide thickening above alloy grain boundaries at a later stage; and (c), the detail of the oxide within the grains.

Oxidation of Ni-5% Cr for 1 min showed a uniform distribution of small, bright, disk-like structures (0.05-0.2 μm in diameter) throughout the matrix, with some evidence of agglomeration of these structures along the grain boundaries (Fig. 6a and b). After 2.5 min and longer times the disks disappeared and larger light regions within the grains and broader grain boundary regions were apparent. The width of the grain boundary bands varied from boundary to boundary and tended to increase with time (Fig. 6c and d). The orientation dependence of the grain boundary zone of influence is presumably related more to the angle at which the boundary has been cut by the surface than to any anisotropy of the alloy interdiffusion coefficient. The extent of thick and thin regions of oxide from grain to grain varied enormously and there were occasional hints of filled-in subgrains and boundary thickening in isolated regions. The general effect of crystallites filling in became more pronounced with time but the evidence of locally healed areas had not always been completely eradicated over the time scale used. Grain boundary healing occurred with much lower alloy chromium contents on Ni-Cr alloys than

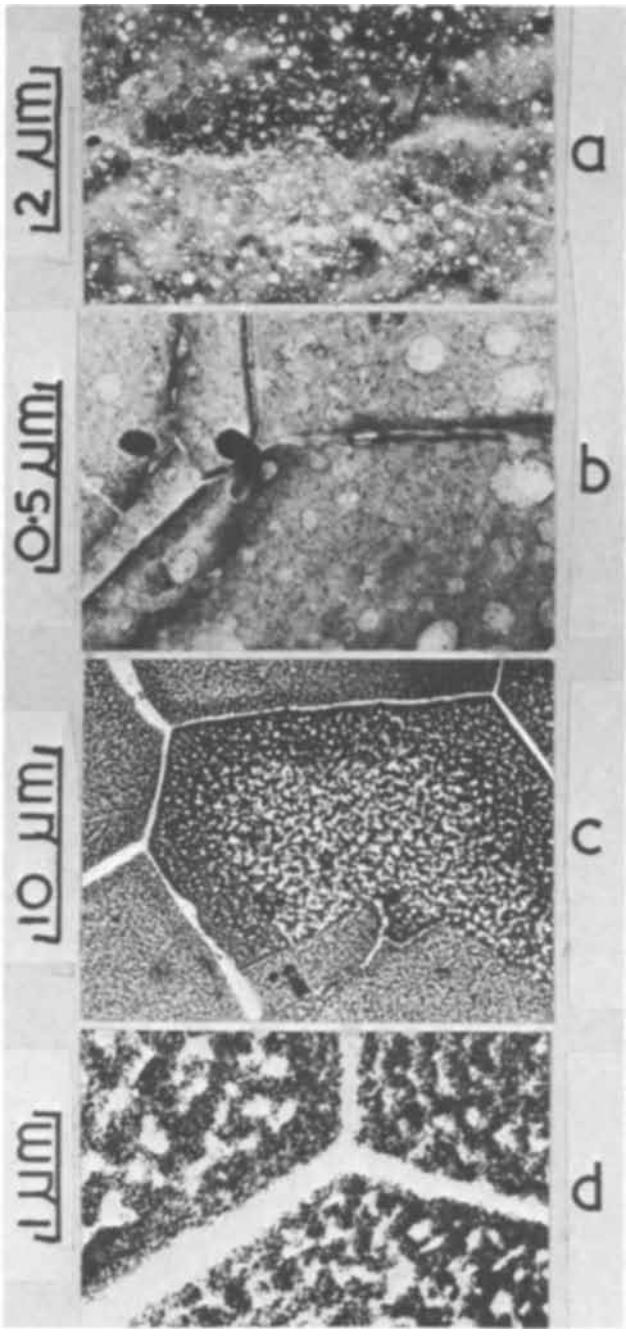

Fig. 6. Transmission electron micrographs of oxide films formed on Ni-5% Cr for (a) 1 min, (b) 1 min, (c) 2.5 min, and (d) 2.5 min at 600°C; (a) and (b) show slow oxidation above disks, probably internal oxide particles or initial nuclei; and (c) and (d), the zones of influence of grain boundaries in producing local healing, as well as local healing within the alloy grains themselves.

on Fe-Cr alloys. Grain boundary thickening, although occurring with dilute alloys, was rare with Ni-5% Cr.

Although possessing a superficial similarity to the disks seen during Fe-Cr oxidation, the present disks were in fact different, showing little peripheral darkening, and were much thinner than the matrix oxide, suggesting local healing. Indeed the explanation is that the NiO could not grow rapidly above internal oxide particles of Cr_2O_3 developed in the alloy for Ni-Cr alloys or above the $NiCr_2O_4$ particles produced on incorporation of the internal oxide into the scale. Such phases could, of course, also have existed as initial nuclei on the surface after only 1 min. Although the disks were not replicated dislocation loops in the present case, it is possible that the first internal oxide nucleated at such sites during the initial stages of oxidation. The disks disappeared after longer oxidation times, partly due to their lateral overgrowth by the rapidly developing NiO and partly due to the development of larger regions of healed oxide (Fig. 6c and d). Despite the evidence of extensive $NiCr_2O_4$ from electron diffraction data, previous work would indicate that healing in this system is usually by Cr_2O_3. Subgrain filling in was much less evident than with Fe-Cr alloys. The nucleation pattern for nickel oxide seemed less related to specific sites than did that of iron oxides on Fe-Cr alloys.

Ni-10% Cr behaved similarly to Ni-5% Cr, healing at grain boundaries being readily apparent, except where they were obscured by lateral overgrowth by NiO. Twin boundaries did not show local thickening or healing, perhaps because such boundaries are coherent (10-11).

Oxidation of Ni-15% Cr showed much more rapid and general healing in the early stages (Fig. 7a), but there was substantial variation from area to area and grain to grain. The areas of the bright regions in Fig. 7b are typically 1-1.5 μm^2. The very fine light areas in Fig. 7b must have been minor grain boundaries, twin boundaries, or, just possibly, slip bands. It is not possible to say categorically whether the light areas were virtually Cr_2O_3 alone or whether they were regions where outer NiO and $NiCr_2O_4$ had become separated from the alloy by healing Cr_2O_3 layers or particles.

The situation was similar for Ni-30% Cr, with even slower oxidation and more pronounced healing at grain boundaries and within the grains (Fig. 8a-c). The width of the healed grain boundary regions visible in the microscope increased with time (Fig. 8b). Certain substructural features where local healing occurred were also revealed within the grains (Fig. 8b). As happened with other alloys, although less clearly (*e.g.*,

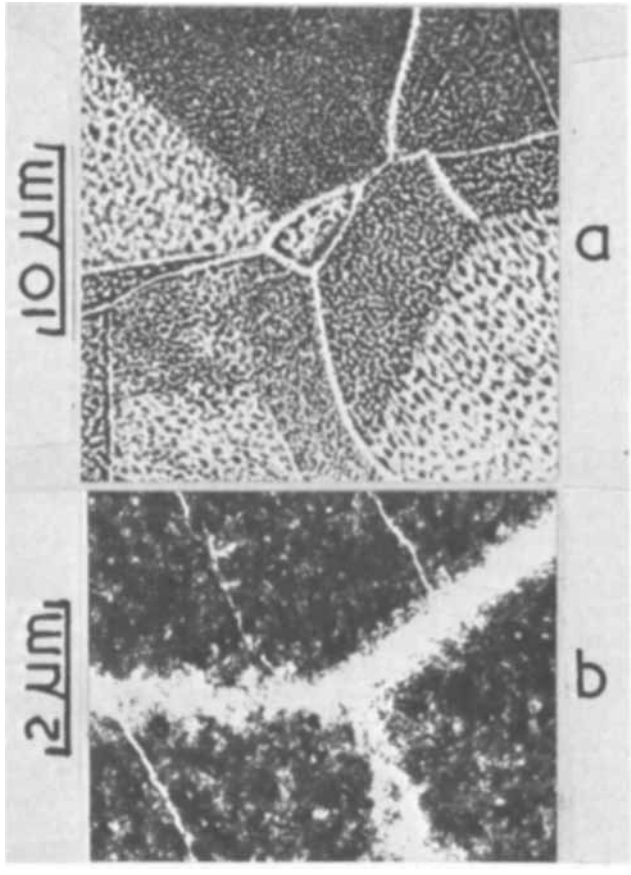

Fig. 7. Transmission electron micrographs of oxide films formed on Ni-15% Cr for (a) 2.5 min and (b) 10 min at 600°C. Preferential healing is most rapid at grain boundaries but is also prevalent within the grains.

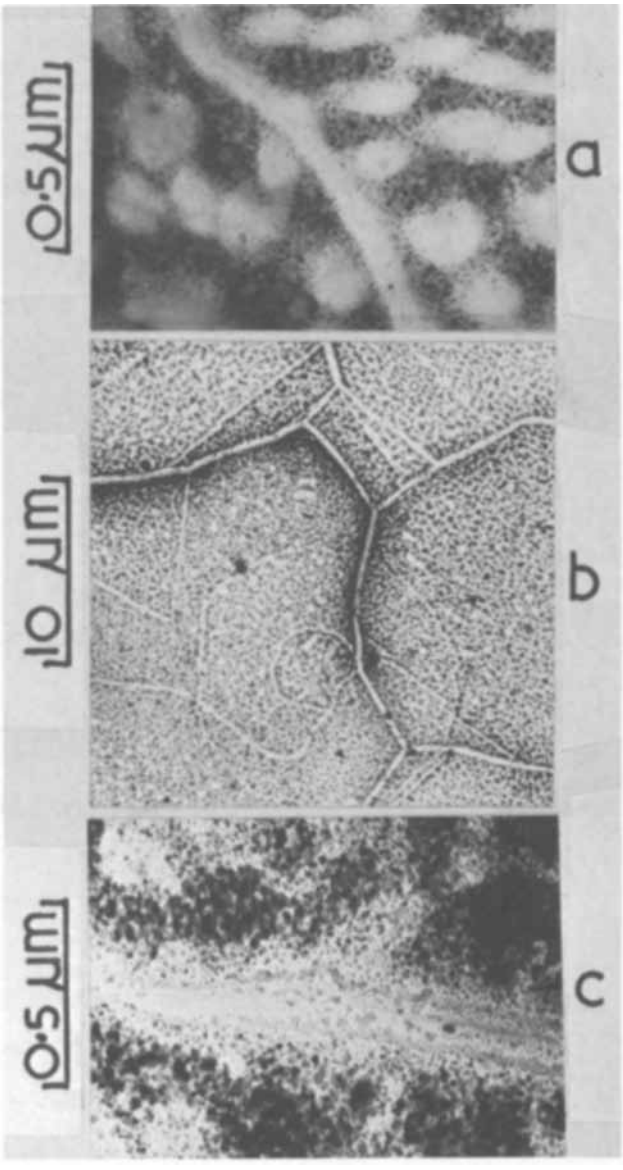

Fig. 8. Transmission electron micrographs of oxide films formed on Ni-30% Cr for (a) 1 min, (b) 15 min, and (c) 15 min at 600°C. Preferential healing sites are clearly visible, as is the grain structure within and adjacent to the healed areas.

Fig. 6b), thickening of the oxide along certain but not all grain margins occurred (*e.g.*, Fig. 8b). This was due to preferential oxidation above a chromium-depleted zone on either side of the grain boundary, lateral diffusion of chromium to the grain boundary occurring to promote continued growth of the chromium-rich oxide there. The width of this zone increased with time due to the inability of the bulk grains to replenish chromium to the margins. A fine oxide grain structure existed within the region over the alloy grain boundaries (Fig. 8c).

General Discussion

The heating and cooling procedure for the specimens was rather arbitrary but is considered to give a good guide to behavior. The slower the heating-up process, generally the greater is the likelihood of establishing the steady state and often the thermodynamically predicted scale at an early stage. The standard free energies of formation of the oxides only predict the thermodynamically stable oxides, not necessarily the steady-state scale, which may be determined by the spatial distribution of phases in the initial film. It is now possible to discuss the influence of the bulk alloy chromium content, the alloy interdiffusion coefficient, the solubility and diffusivity of atomic oxygen in the alloy, and the relative growth rates of the doped sample and complex initial oxide nuclei on the film establishment stages, as far as the limited data on these parameters permit. The data are scattered, often do not refer to 600°C, sometimes depend on material purity, and will be detailed elsewhere (23). Here, for brevity, only order of magnitude values are indicated and the original references are omitted.

The same general pattern of behavior occurs initially for each alloy. The first nuclei of oxide, which rapidly coalesce to give a complete oxide layer, contain particles of the simple and complex oxides of all the alloy components, according to the schematic diagram of Wagner (1) and the observations and theories of Whittle and Wood (2, 3). In principle it should be possible to get scale enriched in the faster growing noble metal oxide. Subsequently a steady-state scaling situation is established, in which the thermodynamically favored oxide (in this case usually Cr_2O_3) attempts to provide a healing layer as the scale base and diffusional factors come more into play. As this occurs the oxidation rate declines, little further noble metal enters the scale and that which is within it redistributes itself in a way determined by the oxygen potential gradient.

It is reasonable to assume that the initial nuclei, rapidly forming from an initial amorphous skin (9), an air-formed film, or a prenucleated surface oxide (15), could be very small indeed and even little above atomic dimensions. However, they rapidly grow into larger crystallites, as observed in the present study, to decrease the interfacial energy. They also tend to interdiffuse to give solid solutions and complex oxides, and noble metal oxides may even be reduced back to metal by the displacement reaction. Particularly at the lower temperature used here, epitaxy effects may be more important than suggested by Whittle and Wood (2, 3) in determining the size, structure, and composition of the initial nuclei. This contribution of epitaxy has been emphasized by various workers (4-6). For example, all the nuclei on Fe-Cr alloys may tend to be cubic (4).

Considering first the 30% Cr alloys in which a healing Cr_2O_3 layer is established relatively quickly, several factors are operative in deciding the thickness of the outer layers containing the simple oxides of iron and nickel and the spinels. For Fe-Cr alloys, the tendency of the very rapidly growing iron-rich oxide nuclei is to overgrow the chromium-rich nuclei and encroach on the alloy, undermining and incorporating any initiating internal oxide particles or layers into the main scale. This is countered by the ease of formation of a healing layer of Cr_2O_3 near the alloy/oxide interface, rather than as internal oxide. As a result of the high alloy interdiffusion coefficient (3-8 x 10^{-10} cm^2 sec^{-1} at 1000°C), and relatively low oxygen solubility (6-80 x 10^{-4} w/o in iron at 700°-800°C) and possibly diffusivity (1 x 10^{-10} cm^2 sec^{-1} at 1000°C), sufficient Cr_2O_3 is precipitated near the surface to prevent further internal oxidation. A further point is that a layer of $FeFe_{(2-x)}Cr_xO_4$ ($O \leq x \leq 2$) may be developed in the initial nuclei and between the outer iron oxides and the developing inner Cr_2O_3 particles or layer. Thus the fast oxidation rate of iron (kp 7.6 to 13 x 10^{-11} g^2 cm^{-4} sec^{-1} at 600°C) would have a chance to show up only in very early stages indeed (kp for Cr is 8 x 10^{-15} at 700°C). Some reaction between residual Fe_3O_4 and α-Fe_2O_3 outside the Cr_2O_3 with the Cr_2O_3 would produce the spinel and rhombohedral oxide detected by electron diffraction.

A similar general picture applies to the oxidation of Ni-Cr alloys where nickel has a higher oxidation rate than chromium. The lower alloy interdiffusion coefficient (1-4 x 10^{-11} cm^2 sec^{-1} at 1000°C) and higher oxygen solubility (200 x 10^{-4} w/o at 600°C) and probably diffusivity (24 x 10^{-10} cm^2 sec^{-1} at 1000°C) com-

pared with the Fe-Cr system mean that the Cr_2O_3 tends to be formed as an internal oxide, although with a very dense population.[1] This possibly coalesces to give a healing layer and is assisted in doing so by the relatively slow overgrowth and encroachment rate of the NiO, (kp for Ni is 3.9×10^{-14} at 600°C) which is much more protective than the iron oxides. The longer time required to "shut off" the growth of the noble metal oxide in the Ni-Cr case means that the initial oxides are of comparable thickness to those on Fe-Cr alloys. It has not been established definitively that $NiCr_2O_4$ does not give a complete layer, but the electron micrographs and higher temperature data possibly tend to favor its presence as particles in the scale. Its relatively fixed composition reduces its amount likely to be found in a scale. No reliable data are available for the formation rates of $NiCr_2O_4$, or indeed for $FeFe_{(2-x)}Cr_xO_4$ ($O \leq x \leq 2$). Really preparabolic oxidation rates of doped oxides should have been used in the above comparisons, but the very limited data suggest similar trends to the kp values (23).

As the alloy chromium content is decreased, the extent of healing becomes more localized in the Ni-Cr system, and within the grains thin oxide often occurs only above Cr_2O_3 internal oxide or recently incorporated $NiCr_2O_4$ particles. Oxidation, determined largely by the rate of thickening of doped NiO, partially blocked by the spinel particles, is still relatively low. It is not as catastrophic as would be expected with dilute Fe-Cr alloys because a healing layer of $FeFe_{(2-x)}Cr_xO_4$, more protective than iron oxides but less protective than Cr_2O_3, is soon developed at the scale base and this determines the oxidation rate. This actually means that the oxidation rate up to 15 min is slower for dilute Fe-Cr alloys than Ni-Cr alloys. Even with the dilute alloys it may become possible to develop a healing Cr_2O_3 layer in the later stages, beneath the $FeFe_{(2-x)}Cr_xO_4$.

The intrinsic diffusion coefficients in the respective Fe-Cr and Ni-Cr system are probably sufficiently similar to avoid any Kirkendall voids in the depleted alloy zone under the oxide as a result of alloy interdiffusion. This is not to say that voids are not eventually produced at the alloy/oxide interface by cation vacancies diffusing in through the scale.

One final point is that it is clear from this study how difficult it is going to be to understand the mechanical properties of oxidizing samples on terms of substructural factors, many of which produce highly localized effects.

Acknowledgments

The authors thank Prof. T. K. Ross for provision of facilities and for encouragement of this study, Mr. B. Vaszko for his collaboration with the electron microscopy and the Science Research Council for a postdoctoral award to one of them (B. C.). They are indebted to International Nickel Ltd. and the British Iron and Steel Research Association for the provision of alloys.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1971 JOURNAL.

[1] If the alloy interdiffusion coefficient is substantially lower at 600° than at 800°C, such densely populated internally oxidized regions may constitute the "healing layer" entirely in some cases. The relative ease of extensive spinel formation at 600°C would thereby be explained by incorporation of such Cr_2O_3 particles into the NiO as oxidation continues.

Ionic Current as a Function of Field in the Oxide during Plasma Anodization of Tantalum and Niobium

W. L. Lee,[1] G. Olive, D. L. Pulfrey, and L. Young*

Electrical Engineering Department, The University of British Columbia, Vancouver 8, British Columbia, Canada

ABSTRACT

The plasma anodization of tantalum and niobium in an oxygen d-c glow discharge was confirmed to be analogous to anodization in aqueous solutions in that evidence was obtained that the ion current J in the oxide was a function of field E in the oxide. Experimental data on $J(E,T)$ were obtained using *in situ* ellipsometry to determine the thickness of oxide D, and hence E (using probe measurements to obtain the potential difference across the oxide) and J from dD/dt. The ellipsometry data are consistent with a two-layer oxide, and this may indicate that both metal and oxygen ion motion is involved in the growth process.

Plasma anodization differs from ordinary anodization in that the electrolyte solution is replaced by an oxygen plasma. As a method of producing dielectric films, it is of particular interest in the fabrication of electronic devices since it is compatible with other vacuum processing steps. In wet anodization the high field ionic conduction in the oxide is believed to be the principal growth mechanism, and little is known to indicate that the electrolyte acts as more than a conducting medium and source of oxygen and contaminant species for the construction of the oxide film. Most authors have assumed that plasma anodization is analogous (1). One exception is Ligenza (2) who has considered, in the case of silicon, a growth mechanism in which implantation in the oxide of energetic ion species from the plasma sets up a concentration gradient leading to diffusion-controlled growth. The analogy may fail for other reasons also. For example, with tantalum and some other metals it is known that in plasma anodization the ion current density is normally a small fraction of the total current density in the oxide, in contrast to ordinary anodization. Under ultraviolet irradiation, however, the ion current in the ordinary wet system may also become a small fraction of the total current due to electronic photoconductivity. In this case the oxide tends to have anomalous properties with regard to homogeneity and refractive index, and the oxide grows faster at a given field strength, *i.e.*, the ionic current at the given field strength is enhanced (3). This might suggest that the photoelectronic current stimulates the ionic current A specific mechanism for electronic current-induced growth was suggested by Fritzsche (4) in connection with yet another case where the ion current is a small fraction of the total current, namely the ordinary anodic growth of oxide films on silicon.[2] Fritzsche's model is that the electronic current involves hot electrons which generate electron-hole pairs by impact ionization. The formation of positive holes, which anodic dissolution experiments on silicon show to have some of the physical attributes of broken bonds, implies the loosening of atoms in the SiO_2 glass which then become mobile. In plasma anodization the large electronic current may be due merely to the presence in the gas of many electrons which are energetic enough to be able to enter the oxide. However, the plasma is itself a source of u.v. radiation so that any effects due directly to u.v. absorption (as opposed to the consequences of electronic photoconduction) may appear in this case also.

Another possible effect of the electron current might be the formation of a net space charge, which would modify the field in the oxide and thus alter the ion current at a fixed mean field. Negative or positive space charge is possible, *e.g.*, electron bombardment of SiO_2 produces positive space charge due to trapped holes (5). Positive space charge would increase the field at the outside of the oxide at the expense of the field near the metal, with obvious consequences according to the kinetics of the process at these interfaces. Finally, if the plasma and wet processes are indeed analogous, then the drastic difference in the conditions at the outer interface must have some observable consequences which may be of help in discovering what part this interface plays. Possibly some limiting growth rate might be expected corresponding to the diffusion limited supply of some participating species in the plasma. There is in fact some evidence that faster growth rates and higher current efficiencies may be obtained in denser plasmas (2, 6) and plasmas of different composition (7), respectively. There is, however, the alternate possibility that the rate of entry into the oxide of electrons from the plasma limits the field which may be set up in the oxide and hence limits the rate of growth, *i.e.*, the different rates in different plasmas may be a function of the relative electron and ion densities.

The aim of the work to be described below was to see whether the ion current density J in the oxide could in fact be identified as a function of the field strength E in the oxide and its temperature T, and in addition, to seek effects on the rates of growth due to a variation of the concentration of plasma species. The growth of the oxide was followed by *in situ* ellipsometry. This indicated that the films were two-layered. J was determined from the rate of growth and E calculated from the thickness and from estimates of the potential difference across the oxide obtained from probe measurements. The calculation involves some difficult points regarding interface p.d.'s and the relation to the free energy of formation of the oxide. These have been discussed elsewhere (8).

Experimental Procedures

The apparatus is shown in Fig. 1. A d-c glow discharge was struck between aluminum disk electrodes of 99.999% specified purity. The cathode (K) was of the "inverse-brush" type, *i.e.*, it had many small holes drilled into the front surface. Musal (9) showed that this gives larger currents and increased plasma stability. The specimen position was fixed by the need for alignment with the windows (O): the light beam of

[2] Silicon differs from tantalum in that the fields for observable ion currents are larger ($1\text{-}2 \times 10^7$ V cm^{-1}) but Fritzche's statement that log J is not dependent on E at low or medium J does not agree with the ellipsometric evidence on wet anodization of Si [ref. (11)].

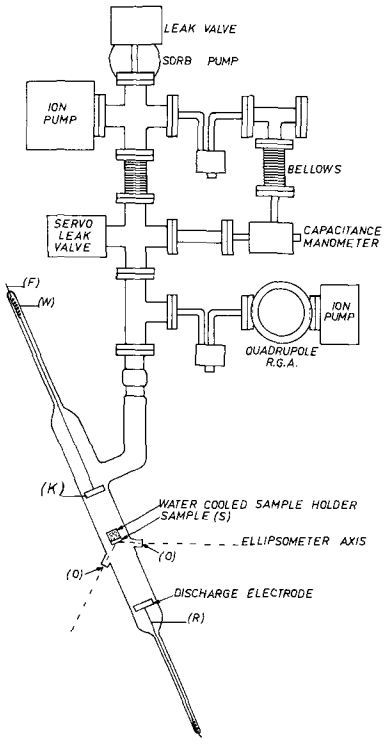

Fig. 1. Schematic diagram of the discharge cell and pumping station.

the ellipsometer should enter and leave the windows at as close as possible to normal incidence in order to minimize polarization errors. The glow discharge could be moved relative to the specimen by adjusting the position of the electrodes with external magnets acting on pieces of iron (not shown) sealed in glass and positioned between the Al rods (R) and coiled Ta wire (W). Connection to a d-c regulated power supply and series resistor was made via the tungsten feedthroughs (F). The discharge cell was a borosilicate glass tube 5 cm in diameter and 30 cm long with tails to allow the motion of the electrodes. It was connected via a metal bellows to a stainless steel pumping system built from standard components with copper gaskets. The whole system was bakeable in a demountable furnace with the sorption pump external. After bakeout at only 110°C the ion pump gave pressures of 10^{-9} Torr as indicated by the ion gauge: organic contamination was shown by the quadrupole residual gas analyzer to be negligible. Matheson 99.999% oxygen was admitted through a leak valve, and the system was normally operated with the sorption pump on.[3] The leak valve could be servo-controlled using a Granville Phillips capacitance manometer and pressure controller. Manual control was also used and, rather than maintain a constant indicated pressure, it was found desirable to control gas inflow to keep constant the potential, with respect to the anode, of a floating probe close to the sample. This procedure was used for the Nb sample and pressure variations of about ±5% around the mean value (60m Torr) were needed.

The specimens were single crystal or polycrystalline sheets about 1 x 1 cm with a tab. These were electropolished in a Teflon cell with circulated solution. Typically current densities of about 150 mA cm^{-2} were used for several minutes with periodic inspection of the surface. The electrolyte was 9 parts by volume of 98 w/o (weight per cent) H_2SO_4 and 10 parts 48 w/o HF for tantalum and 4 parts of 98 w/o H_2SO_4, 2 parts 48 w/o HF, and 5 parts 85 w/o lactic acid for niobium (10). Both were used warm. Single crystal material was preferred because it is easier to obtain a good electropolish, there being no development of ridges or grooves at grain boundaries or of steps due to unequal dissolution rates on different faces.

The samples were fixed to the hollow stainless steel support using a minimum of Ultek high vacuum epoxy with a thin mica sheet for electrical insulation. Water from a thermostatted bath was circulated through the substrate holder and the temperature of the assembly was monitored with a glass-enclosed thermistor embedded in that face of the substrate holder to which the specimen was fixed. The sample holder was supported by a stainless steel crosspiece which was connected to a side-arm of the cell through a metal flange and bellows. During specimen alignment the crosspiece could be adjusted with screws with respect to a metal post which extended from the plate supporting the cell. The water feedthrough tubes were sufficiently flexible to allow the specimen to be rotated for alignment using a bellows-type rotary feedthrough plus bevel gears.

Electrical connections to the thermistor, probes, and specimen entered though an octal header flange on the crosspiece. The probes were tungsten wire with glass sheathing except at the melted spherical tip. Connection to the specimen was via a spot-welded anodized tantalum wire sheathed in small diameter glass tubing.

The ellipsometer was the same as described previously (11), and an angle of incidence of 65° was used. Even with an extra interference-type filter before the photomultiplier the light from the plasma at the wavelength used (5461Å) made balance difficult with the plasma present. A lock-in amplifier as opposed to a tuned amplifier has in later work been used to overcome this.

Normally a constant total current derived from an electronic constant current supply was applied to the specimen and returned via the discharge anode which was grounded. It was found best not to exceed 20% of the total discharge current of 10 mA if unacceptable nonuniformity of oxide thickness was to be avoided.

The potential of the specimen relative to a nearby probe (at zero current, *i.e.*, floating or wall potential) was recorded continuously during growth on a strip-chart recorder using a Keithley-type 602 electrometer with back-off voltage supply as shown in Fig. 2. The potential difference between either the above probe, or one about 1 cm nearer the anode, and the discharge anode was also recorded in similar fashion.

The results to be reported refer to specimens in the negative glow region of the discharge. It was found necessary to have the specimen face away from the cathode to avoid pick-up of aluminum sputtered from the cathode.

Results and Discussion

Ellipsometric evidence for two-layered films.—In wet anodization, see, *e.g.* ref, (1), tracer studies in-

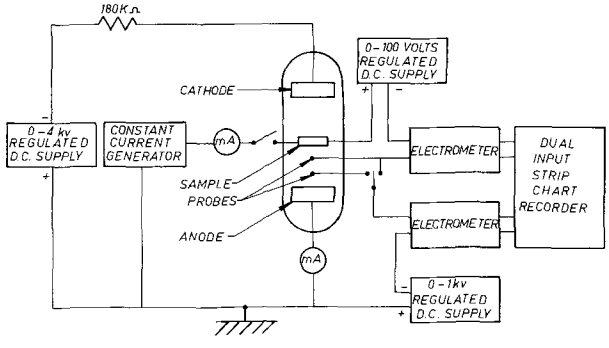

Fig. 2. Schematic diagram of the electrical circuits

[3] In later work (since this paper was submitted) fresh oxygen was flowed through the discharge tube (rather than merely added elsewhere to maintain pressure): there is evidence that this gives increased J at given E.

dicate that metal and oxygen ions move to comparable extents. The film consists of an outer part corresponding to metal ion motion and an inner part due to oxygen motion. With films formed in H_3PO_4, the outer part has a lower refractive index, permittivity, and ionic conductivity. If only slight electrolyte incorporation occurs (*e.g.*, in the case of dilute H_2SO_4 or citric acid), the films are optically homogeneous and nonabsorbing with the possible exception of a very thin outer layer.

The ellipsometric measurements (as illustrated by those in Fig. 3 and 4) on the present films were inconsistent with a homogeneous film with refractive index independent of thickness, but were well accounted for by a two-layer film (12). The inner part had a refractive index close to that of films formed on Ta and Nb in dilute sulfuric acid (11). The outer part in each case had a lower index. This is what might be expected if plasma anodization is analogous in mechanism to ordinary anodization, *i.e.*, if both metal and oxygen ions are mobile. The growth process at the metal/oxide interface would then be the same, and the ellipsometric data were fitted on this basis with, *e.g.*, in Fig. 4, a root mean square error of 0.4° in Δ and 0.12° in Ψ. The different refractive index of the outer film suggests that the reaction at the plasma/oxide interface is affected by the plasma, *e.g.*, bombardment by high energy particles or even u.v. irradiation could lead to a more porous film developing from this interface.

After removal from the cell, the oxide thickness of some samples was mapped out over the surface using ellipsometry. Typically it was 10% greater at the top, presumably due to the nonuniformity of the plasma caused by the substrate holder.[4]

Current efficiency and the growth rate.—Current efficiencies were consistently low, *i.e.*, the amount of oxide produced at 30°C normally corresponded on Faraday's law to about 0.5% of the charge passed, although slightly higher efficiencies (1%) were recorded with Ta substrates at 77°C. Growth rates at the temperatures and current densities used did not usually exceed 3 Å/min.

An obvious factor distinguishing plasma from solution anodization is the absence of water in the former technique and, as it appears that the presence of water can have a catalytic effect in some oxidation processes (13), the plasma anodization of a niobium sample was carried out in a discharge struck in a mixture of O_2 and H_2O. Results are given in Table I, from which it can be seen that the growth rate actually decreases on the addition of water vapor to the system at the same total pressure. A similar result for the anodization of Si in a h.f. discharge has been reported (14), but no explanations were given. However from residual gas analysis results in the present experiment it appears that on striking the discharge the water vapor dissociates into OH, H, and O. The process of dissociative electron attachment in H_2O has a relatively large capture cross section (5×10^{-18} cm^2 as compared with 1.3×10^{-18} cm^2 for attachment in O_2) (15), and H^- ions are probably produced rather than OH^- ions, *i.e.*

$$e^- + H_2O \rightarrow (H_2O^-) \rightarrow H^- + OH$$

Further dissociation of OH according to

$$e^- + OH \rightarrow O + H^-$$

probably occurs and would hence account for the residual gas analysis data. It appears then that, on the addition of water vapor, although a measure of growth control is achieved, some of the electrons usually available for producing the pertinent species for the anodization process are used up in the formation of H^-. In this case, then, the growth rate is reduced, but this does not preclude the possibility of other gas mixtures being effective in increasing growth rates.

[4] More uniform films were obtained in a RF plasma system in which the substrate holder was coaxial with the discharge tube.

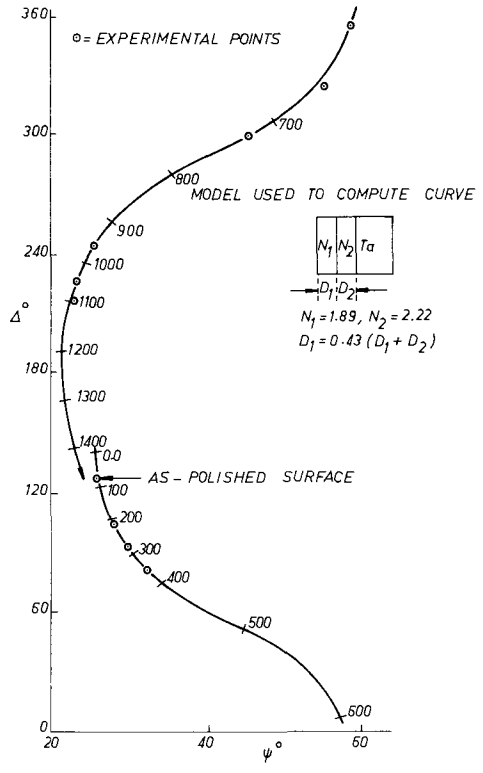

Fig. 3. Ellipsometry results for the plasma anodization of Ta. Experimental conditions: oxygen pressure 80 mTorr, sample temperature 30°C. Values marked on curve are computed total film thicknesses in angstroms.

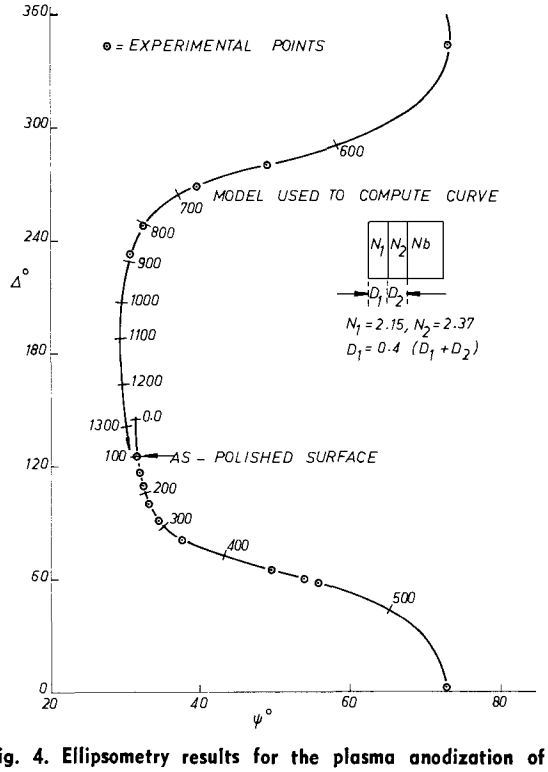

Fig. 4. Ellipsometry results for the plasma anodization of Nb. Experimental conditions: oxygen pressure 60 mTorr; sample temperature 30°C. Values marked on curve are computed total film thicknesses in angstroms.

Table I. Current, field and gas content data for the plasma anodization of Nb in a water/oxygen plasma at 30°C

Formation order	Total sample current, mA	Percentage partial pressure of water vapor, %	Mean growth rate, Å min^{-1}	Estimated field Integral 10^6 V cm^{-1}	Estimated field Differential, 10^6 V cm^{-1}	Ionic current density, 10^{-6} A cm^{-2}	Current efficiency, %
1	0.5	—	0.93	4.0	4.2	2.7	0.53
2	1.0	—	3.6	4.5	4.3	10	1.0
3	1.0	2.2	2.7	4.4	4.4	7.7	0.77
4	1.0	~100	1.7	4.6	4.6	4.9	0.49
5	1.0	~70	(1.4)	4.6	(5.9)	(4.0)	(0.40)*
6	1.0	<70	1.4	4.7	4.7	4.0	0.40

* The sample temperature was greater than 30°C for the first half of formation 5.

Permittivity.—Bridge measurements on plasma-anodized samples after evaporation of gold counter-electrodes gave distinctly lower values of the relative permittivity, *e.g.*, 17 and 34 for Ta and Nb, as compared to 27.6 and 41, respectively, (3) for films anodized in 0.2*N* H_2SO_4 at about 25°C and 10 mA cm^{-2}. It is probable that the permittivity varies with formation conditions, as it does in wet anodization.

The losses of the best specimens were not significantly different from those existing in conventional films, but films with higher losses were met more frequently than is the case for wet-anodized specimens.

Variation of voltage with time at constant total current.—Figure 5 shows a plot of the potential V_{sp} of a niobium specimen relative to a probe during anodization at constant current. The plot is fairly typical of both tantalum and niobium specimens in that the potential rises rapidly when the current is first applied and then settles to a slower, more or less constant rate of rise. The explanation of the fast initial rise is probably as follows. Since the current is mostly electronic the effect is clearly an increase of resistance to electronic current. Electron injection from the plasma appears to occur at comparatively low fields. With little or no space charge in the oxide, the field throughout the oxide is also low. However, electronic space charge develops due to capture of electrons by the heavy concentration of traps present in the amorphous oxide. This would cause the field at the plasma interface to be reduced so that a higher mean field would be required to maintain the given electronic current. Finally, a steady state would be reached in which the slow rise of voltage would be due more or less entirely to the slow rate of growth of the oxide. An alternative explanation is possible in terms of patching of leaky spots in the oxide, but this seems unlikely in view of the fact that the same behavior was exhibited by films prepared by wet anodization and then tested in the plasma.

The type of behavior in Fig. 5 has several implications. First, the ionic current density should be calculated on the basis of total thickness increase during the formation period divided by the total time less the time for the initial transient. This ionic current is then an estimate during the final steady-state period of the formation. Second, the differential field and the integral field may be estimated during this period. Finally, it is evident that, if the space charge explanation is correct, the field distribution in the oxide is modified by space charge so that the situation is expected to differ from wet anodization.

Voltage vs. thickness for steady-state conditions.—Figure 6 (which is for niobium) shows voltages with respect to a nearby probe recorded at the end of each of a series of formations at the same total current, plotted against the corresponding thickness of oxide. The corresponding ionic current density, as deduced from the change of thickness during the anodization period, is recorded beside each point. Clearly the linear dependence of voltage on thickness indicates a constant mean field strength in the film. This constant field gave a more or less constant ionic current. This is analogous with wet anodization, but does not mean necessarily that the field was constant through the thickness of the film. The intercept H_I at zero thickness gives information on the net work function corrections but with an unknown error due to any changes in the drop in plasma potential between the probe surface and the oxide surface.

Relation between log J, E, and T.—Figure 7 is for niobium and shows values of log *J* for various estimated fields. We included here all "integral" fields for one final specimen, in which it was believed that the control of pressure had been very precise, plus data at low anodizing currents for films greater than 450Å thick from two earlier specimens. (With thicker films the zero error in voltage has less effect on the estimate of field.) Differential fields ($\Delta V/\Delta D$) have been omitted since they were prone to scatter, as is

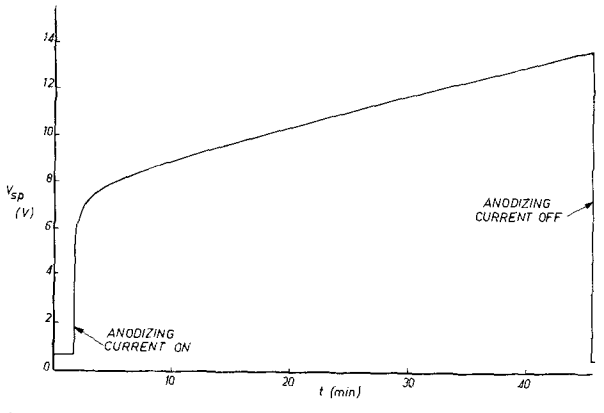

Fig. 5. Typical variation of the potential of a Nb sample (with respect to a floating probe) during plasma anodization at constant current.

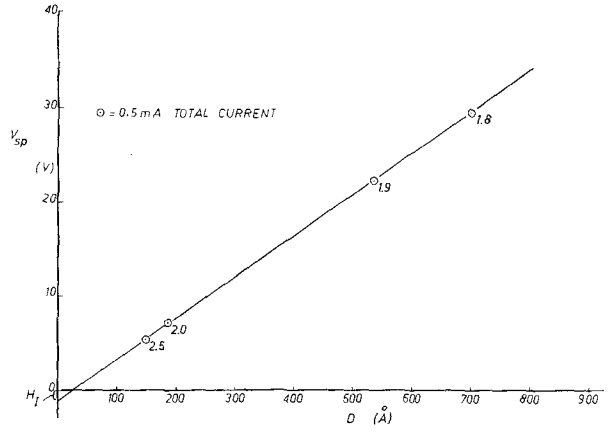

Fig. 6. Variation of the potential of a Nb sample (with respect to a floating probe) with oxide thickness for a series of formations at 0.5 mA total current.

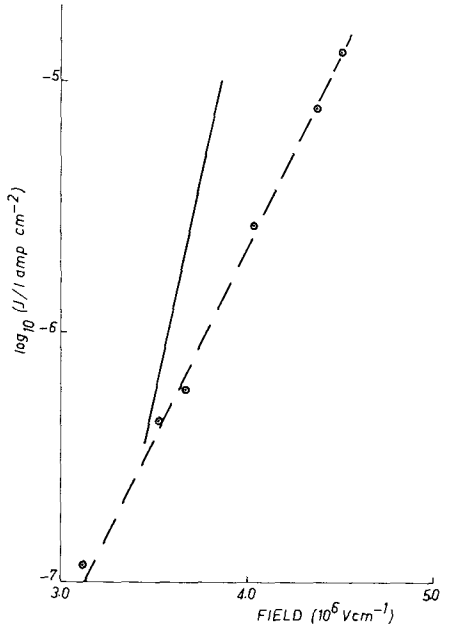

Fig. 7. Variation of ionic current with field in the oxide for the anodization of Nb. ⊙, plasma anodization—oxygen pressure 60 mTorr, sample temperature 30°C; continuous line, solution anodization, Young and Zobel (11), sample temperature 25°C.

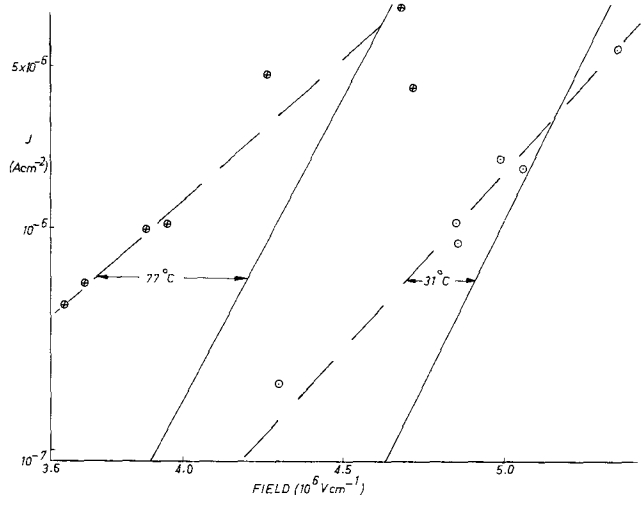

Fig. 8. Variation of ionic current with field in the oxide for the anodization of Ta. ◯ ⊕, plasma anodization—oxygen pressure 80 mTorr, sample temperature as indicated; continuous line, Young and Zobel (11).

to be expected from the discussion above. Also included is a line referring to the anodization of Nb in 0.2N H_2SO_4 (11). Figure 8 shows log J *vs.* E at two temperatures for Ta, plus equivalent data for growth in 0.2N H_2SO_4 (11).

The data in Fig. 7 and 8 appear to show that ionic current is indeed determined by the field in the oxide. The same type of change from wet anodization is shown for both Ta and Nb, *i.e.*, for plasma anodization the value of $d \log J/dE$ is less and $J_0 \exp -W/kT$ in $J = J_0 \exp(-W/kT) \exp(+\beta E)$ is greater than for the wet case.

These two changes are what might have been predicted from the lower refractive index and permittivity of the plasma oxide, or at least of the outer layer. The lower refractive index probably indicates a less dense film so that the zero field activation energy W should be less, thus giving the higher intercept on the log J axis at zero field. Also, as has been noted in conventional anodization for some time, there appears to be a correlation between permittivity and ionic conductivity. The most acceptable model is that ionic conduction is controlled by an effective field, *e.g.*, the Lorentz field $1/3\ (\epsilon_r + 2)E$. This would predict the change of slope. However, the latter could also be explained by the previously mentioned effect of a negative space charge in reducing the oxide field near the oxide/plasma interface below the mean (estimated) field.

It is perhaps worth noting by way of caution that, if the ionic current was in fact controlled by the electronic current, which was itself controlled by the field, then once again log J would show some dependence on E. This possibility could perhaps be evaluated by varying the plasma conditions so that different electronic currents were obtained at the same field.

Acknowledgments

Grateful acknowledgment for financial support is given to the Defence Research Board of Canada (ECRDC project C91) and the United States Air Force, Avionics Laboratory, Wright-Patterson Air Force Base (contracts F33615-68-C-1704 and F33615-70-C-1225). The authors are also grateful for the assistance received from Dr. C. J. Dell'Oca in developing the computer programs for the two layer model.

Manuscript submitted Feb. 16, 1970; revised manuscript received May 25, 1970. This was Paper 22 presented at the New York Meeting, May 4-9, 1969. The work on niobium is based on a M.A.Sc. thesis by one of the authors (G.O.).

Any discussion of this paper will appear in a Discussion Section to be published in the June 1971 JOURNAL.

Sealing Effects near the Barrier-Porous Layer Interface of Anodic Aluminas

G. A. Dorsey, Jr.

Kaiser Aluminum and Chemical Corporation, Center for Technology, Pleasanton, California 94566

ABSTRACT

Effluent gas detection, infrared analysis, impedance measurements, and gross weight changes were used to study the effects of boiling water exposures on anodic oxide films: the "sealing" reaction. Certain changes in film structure and composition were found to be significant with regards to the effectiveness of the sealing treatment. Particularly important were transitions leading to an effect localized at the interfacial region between the barrier and porous layers. In retrospect, hydration and structural changes at the outer surface of the porous layer (generally regarded as the only effect of sealing) may contribute little to at least the initial impedance increase, on sealing. Alloy 1199 foil was anodized in 0.3M sulfuric acid at 1.08 A/dm^2 (10 A/ft^2) and 30°C. Anodizing times varied from 1 to 18 min, and a detailed study was made of coatings prepared in the 3.0-to-4.6μ thickness range. Unsealed, as well as sealed, foils were examined.

The term "sealing" probably originated with the observation that dyes were permanently retained within an anodic coating if, following the dye operation, the anodized workpiece was subjected to a brief immersion in boiling water. Then too, it was found that the same immersion treatment rendered the anodic coating more durable than unsealed films and subsequently more protective to the substrate metal. Sealing was first considered to be a pore-closure mechanism that was limited to the outer surface of the film and caused by oxide swelling due to the formation of the monohydrate boehmite. And while this basic view can still be substantiated, later work has shown the sealing process to be relatively complex. The electron microprobe work of Wood *et al.* (1) shows that at least some bulk effects, in addition to surface hydration, are involved, while Spooner (2) found hydration and structural changes taking place for at least the first 50 hr of sealing. More recently (3) an anion exchange mechanism (hydroxide replacing incorporated sulfate, within the oxide structure) was proposed, while the streaming potential measurements of Yokota (4) and others (5) seem to indicate that trihydrates, rather than monohydrates, are formed on sealing. Further background may be found in a detailed review by Diggle, Downie, and Goulding (6).

Earlier (7) we found that sealing appeared to produce a decrease in the amount of barrier layer oxide, in keeping with the earlier observation of Hunter and Fowle (8). At the same time, however, the amount of porous layer cross-linking was found to increase. This led to the speculation that at least one important effect of sealing involved a structural transition at the interface between the barrier and porous layers. The barrier layer was proposed to consist of two layers [confirmed by electronoptical data (9), also by the recent work of Vol'fson and Pilyankevich (10)], and it was the more permeable open-structured secondary phase barrier layer that appeared involved in this transition. Schematically, this might be represented as shown in Fig. 1.

Conventionally, the effects of sealing are measured by observations regarding the changed nature of the porous layer surface, for example, by dye rejection tests (11, 12). Certainly, the outer surface of the porous layer is changed, structurally hydrated, by the sealing process. However, it may be that an equally important change is that which takes place at the barrier layer-porous layer interface.

Key words: anodic aluminas, sealing.

Experimental

Sample preparation. —Cleaned alloy 1199 aluminum foils (99.99% Al) were chemically brightened, then anodized in 0.3M H_2SO_4 at 30°C and 1.08 A/dm^2 (10 A/ft^2) with an anode-cathode potential of 20V. These conditions were employed to slow down structural transitions that normally (1.7M H_2SO_4 at 1.3 A/dm^2) take place too quickly to allow a detailed study. Anodizing times varied from 1 to 18 min. Afterward, the foil coupons were cut in half, and one-half of each was sealed in pH 6.0 boiling distilled water for either 10-, 15-, or 20-min periods. These coupons were then tested, along with the unsealed halves, after air drying but without any further delay.

Nonanodic aluminas were also prepared to illustrate a comparison between the structure of acid gel aluminas and the anodic barrier layer. These were formed by adding $AlCl_3$ to dilute HCl solutions, adjusted to various pH levels with NaOH. Each solution was centrifuged before the *IR* examination of (*a*) the clear and water-white supernatant liquid, in Irtran cells *vs.* a water blank and (*b*) the precipitate (formed above pH 4) after air drying this, then preparing a KBr pellet for use *vs.* a KBr blank.

Test methods.—The samples were examined within the 4000-600 cm^{-1} range of the Beckman *IR*-7, as before (13) using, for the anodized foils, a reflectance attachment set at 45° angle of incidence. The amount of barrier layer present was taken from the absorbance of the 900-to-1000 cm^{-1} band. The amount of porous layer was based on the absorbance of the 1325 cm^{-1} Al=O band (13); actually, this is probably an Al=O←S band associated with structurally incorporated sulfate. We did not use far infrared here since,

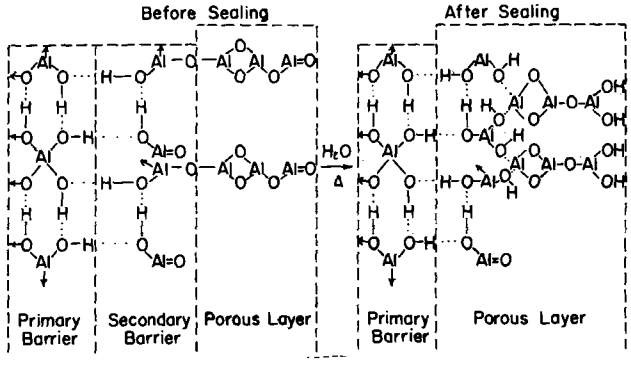

Fig. 1. Proposed sealing effect caused by barrier layer transition

for thin films, this 1325 cm^{-1} band provides as reliable a measure of porous layer quantity as does the far infrared Al-O-Al stretch. This may be seen by comparing these data with those given in ref. (7).

The effluent gas detection (EGD) data were taken in the usual manner, described earlier (14). Impedance measurements were made immediately after anodizing and air drying the same films from which sections were taken for examination by the other techniques. The data reported are average values from multiple readings obtained with a Twin City Testing Corporation Z-Scope (1 kHz impedance bridge), using a 3.5 w/o NaCl media (15).

Coating weight and weight gain on sealing measurements were made in the standard manner, using the chromic-phosphoric acid stripping technique (15) for the coating weight determinations. Film thicknesses were obtained by metallographic cross sectioning.

Results and Discussion

Earlier (17) we suggested a two-phase oxide structure for the anodic barrier layer. This was proposed to consist of a primary barrier layer phase (seemingly, a cyclic trihydrate) and a secondary phase with a lower polymer weight than the primary, apparently less dense and comprised of μ-hydroxy linkages (as opposed to the apparent hydrogen bonding of the primary phase). There was some limited precedence for this already in the literature, but a recent article (18) by Vedder and Vermilyea puts forth an excellent alternative to this earlier *IR* interpretation.

They propose that the substrate metal produces a polarization effect on a translational mode Al-O-Al lattice vibration, thereby leading to a 950 cm^{-1} absorption band that would otherwise occur at longer wavelengths. While their interpretation also contains elements of speculation, it offers many interesting possibilities. We would like to point out, however, that elemental aluminum need not be present to sustain this ~950 cm^{-1} absorption. If the earlier interpretation (17) has some basis, and apart from other data then presented, then acid gel aluminas should also have this same structural feature. Grunwald and Fong (19) recently did in fact suggest a similar structure for acid gel aluminas.

In connection with this it should again be noted that the ~950 cm^{-1} absorption band is found both in soluble aluminic acids and in the solid gels corresponding. Figure 2 shows the *IR* spectra of aqueous solutions prepared by dissolving $AlCl_3$ in dilute HCl. Figure 3 shows *IR* spectra of the gels precipitated from these solutions at higher pH values, along with representative spectra of the primary and secondary phases of the anodic barrier layer. One principal difference between these two alumina types is that the nonanodic alumina undergoes complete dehydration at or below 250°C, whereas the anodic aluminas

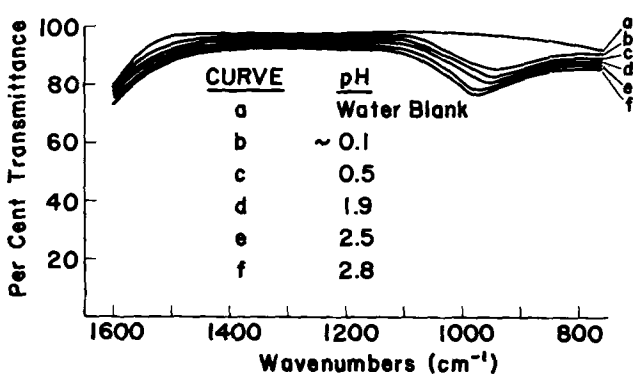

Fig. 2. Infrared spectra of aqueous solutions prepared from $AlCl_3$ and HCl: in Irtran cells *vs.* matching water blank.

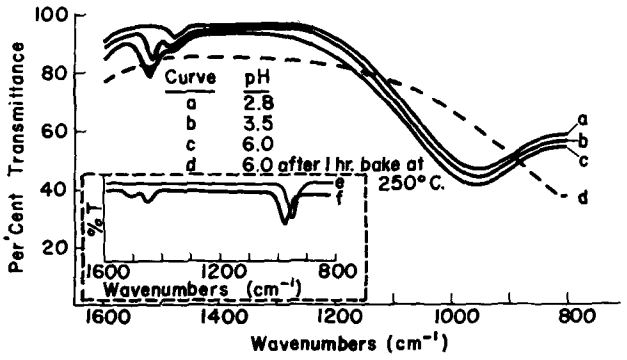

Fig. 3. Infrared spectra of hydrous and dehydrated (curve d) alumina gels precipitated from $AlCl_3$ solutions: in KBr *vs.* KBr blank. Spectra for primary phase (curve e) and secondary phase (curve f) anodic barrier layer oxides are included.

apparently require far higher temperatures (14), possibly owing to a higher degree of polymerization.

Returning to the subject now at hand. Figure 4 shows the linear relationship that was obtained between the anodic coating thicknesses and the anodizing times, in the 0.3M H_2SO_4 electrolyte at 1.08 A/dm^2 and 30°C. However, as has been noted earlier (7), the composition of the coating did not remain constant but changed as anodizing progressed. Figure 5 shows *IR* data for changes in the amounts of barrier and porous layers with respect to anodizing time. These again illustrate the transitions within the barrier layer, and from barrier layer to porous layer,

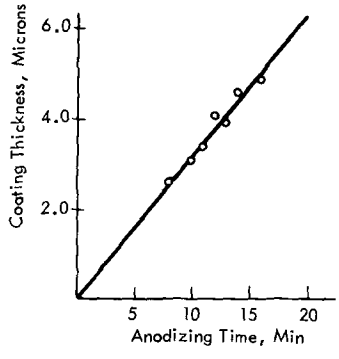

Fig. 4. Coating thicknesses for increasing anodizing time in 0.3M H_2SO_4 at 1.03 A/ft^2 and 30°C.

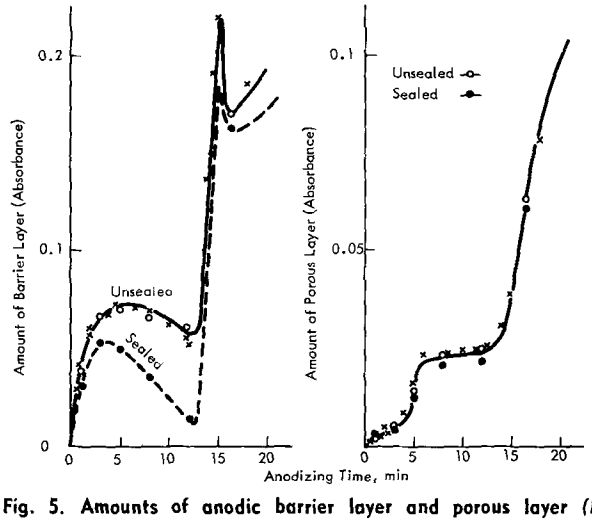

Fig. 5. Amounts of anodic barrier layer and porous layer (*IR* data) for sealed and unsealed films. Open and filled circles are data points obtained for this report. The X points were obtained earlier (14) for unsealed films also prepared by these same anodizing conditions.

that were discussed earlier (7,9,14). Most pertinent is the transition from primary to secondary barrier layer phase that begins at the end of 4 min of anodizing, under these conditions. This transition is rapid in the 10-15 min region, being complete after 15 min. Figure 6 also illustrates this transition, using the characteristic band position shift from 930 to 980 cm^{-1}. We would, therefore, expect the film prepared in this transition region (films anodized between 10 and 15 min, 3.0-4.6 μm) to be structurally unstable. There was no structurally established barrier phase here, no established equilibrium between primary and secondary barrier layer phases. The sealing effect, which alters both the amount and nature of the barrier layer, might therefore be most pronounced in this region.

As before, sealing decreased the amount of barrier layer (Fig. 5), the decreased amount of barrier layer being caused by the sealing-affected transition (an "inner seal" effect) consisting of a structural change from barrier layer to porous layer oxide. As anticipated, the magnitude of this effect was greatest for films within the ~10-15 min range, and was less elsewhere. The *IR* spectra themselves serve better to illustrate such effects in the film transition region. The differences between an unsealed and sealed film spectrum, for a 12-min film (center of transition zone) is shown in Fig. 7.

Note the nearly complete transition from secondary barrier phase (unsealed) to porous layer trihydrate (sealed). For films prepared outside this transition zone (with less than 10 min or more than 15 min of anodizing time) such a change was far less pronounced (Fig. 8).

Data from another technique, to illustrate the same structural sensitivity to sealing, are shown in Fig. 9. These are effluent gas detection (EGD data) obtained for the transition zone films, and with the ratio of partial water contents for sealed and unsealed films (water removable to 350°C, with helium purge) plotted *vs.* anodizing time. Note that this ratio

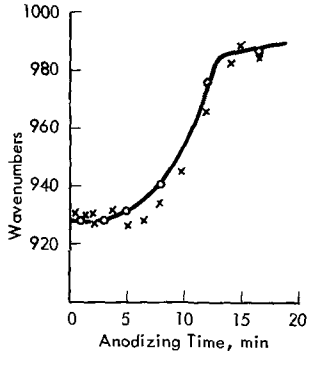

Fig. 6. Placement of barrier layer band center showing transition from primary barrier phase (930 cm^{-1}) to secondary barrier phase 980 cm^{-1}). Open circles are data points obtained for this report (there was no detectable change in wavenumber between sealed and unsealed films of the same thickness). The X points were obtained earlier (14), with these same anodizing conditions.

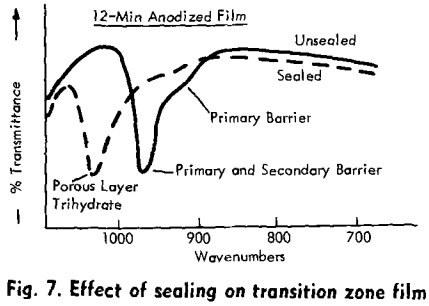

Fig. 7. Effect of sealing on transition zone film

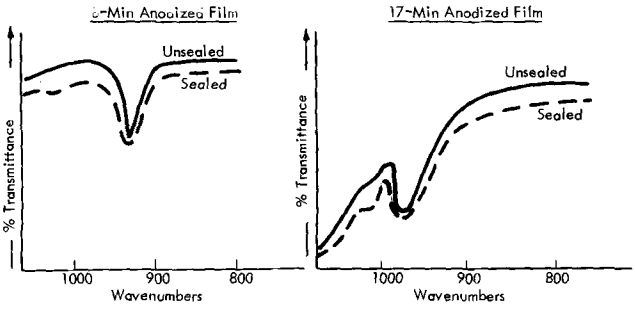

Fig. 8. Effect of sealing on films outside of transition zone

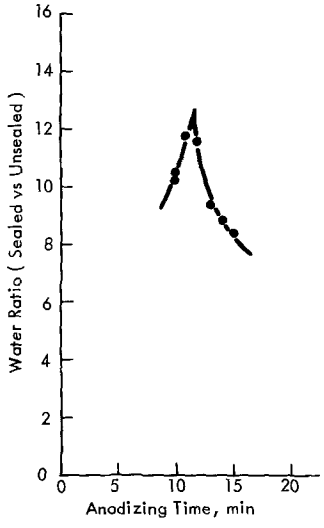

Fig. 9. Ratio of water contents between sealed and unsealed films (EGD data) when baked to 350°C.

(degree of change, on sealing) reached a peak near 12 min of anodizing time. Beyond 15 min of anodizing time, the ratio decreased. A correlation between the *IR* data and the EGD data themselves may be seen by a comparison of Fig. 10 and 5.

The porous layer Al=O←S bond data do not reflect any such change as a result of sealing however, since the increase in porous layer cross-linking [as a result of sealing (7)] did not materially alter the Al=O←S band absorbance. We would expect,

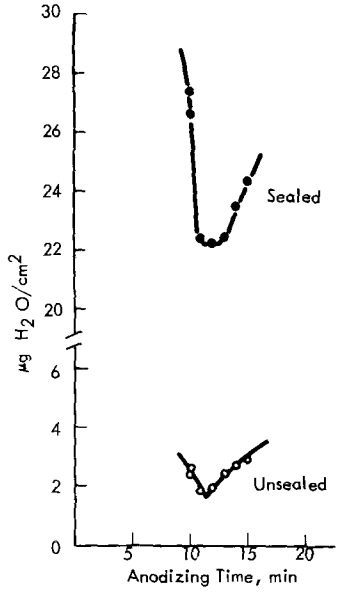

Fig. 10. Micrograms per square centimeter water released from sealed and unsealed films (EGD data) when baked to 350°C.

however, to find a large amount of physically sorbed water in the porous layer after sealing, due to surface hydration and to effects other than those occurring near the interface between barrier and porous layers.

The weight gain on sealing data (Fig. 11) shows such an increase. Note, first, that the total quantity of water in the sealed film was far more than that indicated by the EGD technique. Earlier (14), it was suggested that at least some of the water removed by the EGD technique (below 350°C) corresponded to barrier layer hydroxide. The comparison between total weight gain, on sealing, and the EGD-measured hydrate would seem to lend some further support toward this speculation. That portion of the porous layer hydrate which is not related to the barrier layer, or to its transition product, must then be removable only by baking above 350°C, under the conditions of the EGD technique (10°C/min heating rate, with helium purge).

Figure 11 also shows that the total weight gain on sealing, plotted *vs.* anodizing time, does not extrapolate back to 0 min. Instead, an extrapolated 0 weight gain falls on the plot at approximately 7 min anodizing time. However, but perhaps only by coincidence, this correlates nicely with the *IR* data for the porous layer. Note (Fig. 5) that the porous layer only begins to form, in any appreciable quantity, after 4 min of anodizing time, and its growth rate reaches an equilibrium (plateau) after 6-7 min. If the porous layer is responsible for the bulk of the water taken up during sealing, and if only a trivial amount of porous layer was formed before the 6-7 min anodizing time, we would not expect to find a gross weight gain, on sealing, that was linear with respect to film thickness (or to anodizing time).

Thus, these *IR*, EGD, and gross weight change data have demonstrated the apparent transition zone that exists during anodizing, and within which zone the anodic oxide structure is highly vulnerable to changes caused by sealing. On either side of this zone, sealing effects appear lessened. Some physical significance to this can be given, now, by an examination of impedance data.

The 1 kHz impedance values (kilohm/cm²) are usually at least two to fivefold higher with sealed films than with unsealed films. Explanations of this are usually given in terms of changes relating to film porosity (a physical plugging of the outer pore surface, a leaching of electrolyte from the pore volume, etc.) which may be hard to reconcile with the over-all linear increase of impedance with increasing sealed-film thickness. When equal sealing conditions are employed, any surface effects should be approximately equal in magnitude and relatively independent of minor changes in film thickness. Current reasoning now seems to fall along the lines of Wood *et al.* (20, 21): that sealing effects are not limited to pore blockage at the coating surface, but are also due to structural rearrangement and agglomeration processes that take place within the bulk of the coating as well.

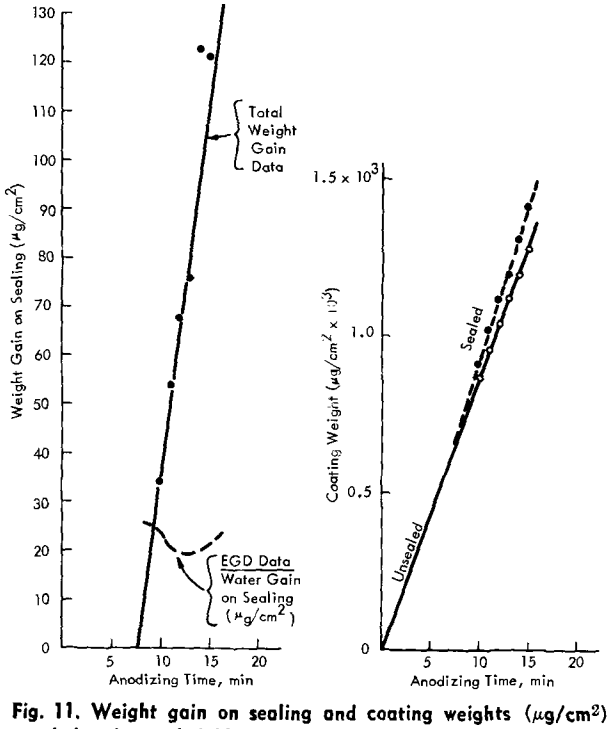

Fig. 11. Weight gain on sealing and coating weights (μg/cm²) for sealed and unsealed films.

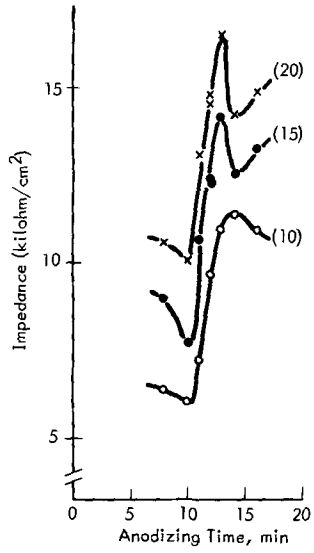

Fig. 12. Coating impedance data for sealed films, plotted as a function of anodizing time. Curves are for 10, 15, and 20 min sealing times, respectively.

Figure 12 shows impedance data for these same anodic coatings, and again in the transition region of from 10 to 15 min anodizing time. Note the peak at 12 min where the preceding data have shown the inner seal effect to be at its maximum. If the only factors altering impedance values were a combination of surface effects and a linear increase in bulk film thickness, then a more nearly linear relationship should have been obtained. This would be especially so if the effective barrier layer thickness were constant, with only bulk and surface porous layer effects to influence impedance values. This is not meant to imply that only inner seal effects are important in the mechanism of sealing, but that they are a potentially equal contributor to whatever effects sealing may produce.

Structural Features of Anodic Aluminas Adjusted to Influence the "Degree-of-Seal"

G. A. Dorsey, Jr.

Kaiser Aluminum & Chemical Corporation, Center for Technology, Pleasanton, California 94566

ABSTRACT

Different two-step current density programs were used to prepare 7.4 μm anodic oxides in an attempt to determine a set of anodizing conditions best suited to properly sensitize the oxide structure for maximum sealing effect. Effluent gas detection, infrared analysis, and impedance measurements were used to study these films. The desired structure was achieved, in a 1.7M H_2SO_4 electrolyte, by anodizing to a 4.84 x 10^2 coulomb/dm^2 current quantity using a current density of 1.3 A/dm^2, then rapidly increasing the current density to 3.5 A/dm^2 for a total current quantity of 13.9 x 10^2 coulomb/dm^2 (yielding 7.4 μm films). Sealed and unsealed coatings were examined.

In the preceding paper (1) a structural transition was described that takes place, as a result of sealing, near the interfacial region between the secondary phase barrier layer and the porous layer of anodic coatings on aluminum. However this sealing effect was limited to films of ~4 μm thickness, using the anodizing conditions then employed: 0.3M H_2SO_4 at 1.08 A/dm^2 and 30°C. A proposed requirement for this sealing transition, or "inner seal effect," was that the structure of the anodic barrier layer should be in a transition form that represents approximately 50% conversion of primary into secondary phase oxide. With the more commonly used porous layer anodizing conditions of 1.7M H_2SO_4 at 1.3 A/dm^2 and 25°C, such a transition zone would be expected to be limited to films of only ~2 μm thickness. This is supported by data presented earlier (2) and shown again here for purposes of comparison, in Fig. 1. The apparently required structure occurred at 12 min anodizing time (~4 μm film thickness) with the 0.3M H_2SO_4 electrolyte, using 1.08 A/dm^2 and 30°C, and at 5.7 min (~2 μm film) with 1.7M H_2SO_4, using 1.3 A/dm^2 and 25°C

We now seek to bring about this same structural feature in the anodic coating, in order to maximize the inner seal effect, but with thicker, 7.4 μm films prepared in 1.7M H_2SO_4 at 25°C. A two-step current density sequence seemed to be a feasible approach, in order to first develop the necessary oxide structure, then to "freeze" this structure by using a high current density, which nevertheless allows the film to thicken to the desired value. This would amount to a reversal of the normal transitions of the anodizing process, so as to produce a 7.4 μm thick film with the same structural proportions of a threefold thinner coating.

Experimental

Sample preparation.—Alloy AS32 (alloy 1100 clad with 1100:99.2% Al) sheet coupons were cleaned and chemically brightened, then anodized in 1.7M H_2SO_4 at 25°C for a total current quantity of 13.9 x 10^2 coulombs/dm^2. One group was anodized at a current density of 1.3 A/dm^2. The remainder were anodized at 1.3 A/dm^2 for the first 4.84 x 10^2 coulomb/dm^2 (6.25 min), then the current density was immediately increased to a higher value, which was maintained for the balance of the anodizing program. In the latter case, final current density values ranged from 2.16 to 4.32 A/dm^2. One coupon from each set of anodizing conditions was left in the unsealed condition, while the other was sealed for 10 min in boiling pH 6.0 distilled water, buffered with acetic acid and sodium hydroxide. Coupons intended for impedance measurement were also sealed for 20 and 30 min, respectively. Table I lists these various anodizing conditions, together with the final voltage values and the coating thicknesses that resulted.

Test methods.—The samples were examined within the 4000 - 35 cm^{-1} ranges of the Beckman *IR*-7 and *IR*-11 spectrophotometers, according to procedures

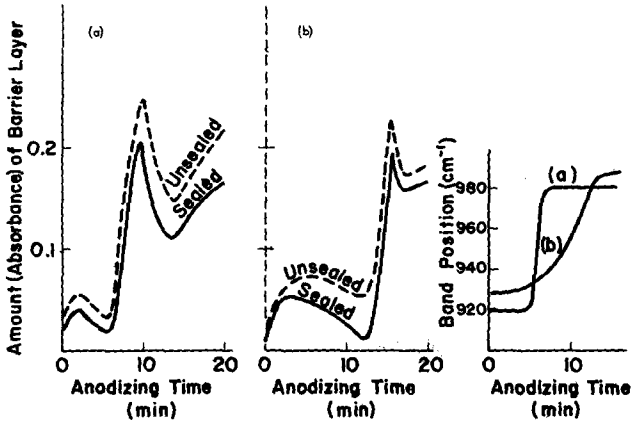

Fig. 1. Amount of barrier layer vs. anodizing time, produced in (a) 1.7M and (b) 0.3M H_2SO_4 electrolytes, also showing *IR* band position. Anodizing conditions were: (a) 1.7M H_2SO_4-1.3 A/dm^2, 25°C and (b) 0.3M H_2SO_4-1.08 A/dm^2, 30°C.

already described (2). Infrared absorbance values and band positions were then determined, to measure (*a*) the amount and type of barrier layer, (*b*) the amount of porous layer cross-linking, and (*c*) the amount of structurally incorporated porous layer sulfate (1325 cm^{-1} infrared band).

Effluent gas detection (EGD) data were obtained as before (3), and impedance values were measured with a 1 kHz. impedance bridge (1). Coating thicknesses were obtained by metallographic cross sectioning. With the exception of these thickness measurements, all sample analyses were made immediately after air drying the sample, without any storage period.

Results and Discussion

As shown in Table I, all coatings were of the same thickness: 7.4 ± 0.2 μm. The data that follow should therefore show no effects that might be caused by gross differences in coating thickness.

As discussed earlier, we sought to achieve a certain steady-state coating structure, the nature of which, and modes of transition, are described in more detail elsewhere (1, 2). Briefly, we sought to find the two-step current density program that would produce an anodic coating which was highly receptive to sealing effects near the barrier-porous layer interface. There should be a current density range within which the coating is in this desired state. Current densities on either side of this range might then produce coatings of lower sealing sensitivity.

Figure 2 shows the kilohm per square centimeter impedance values that were obtained with these 7.4 μm films; plotting kilohm/cm^2 impedance values *vs.* final current density, with each film having been prepared with 1.3 A/dm^2 for at least the first portion (4.84 x 10^2 coulomb/dm^2) of the anodizing program. A nearly 80% improvement in coating impedance (film impermeability) was realized with a final current density near 3.46 A/dm^2, *vs.* 1.3 A/dm^2, with films sealed for 10 min. More prolonged sealing times decreased this factor to about 40%. Effluent gas detection (EGD) and infrared data confirm this by showing the same correlatable trends that were reported earlier (1) for nearly threefold thinner films.

Figure 3 presents the EGD partial water contents (water removable to 350°C, with helium purge), again for both sealed (10 min) and unsealed films. These data indicate, however, that the optimum second current density value lies closer to 3.24 A/dm^2. The minimum inflection in the curve at this point is an indication of inner seal effect (1). It can be seen more clearly in Fig. 4: the water ratio (μg H_2O/cm^2, sealed *vs.* unsealed) plotted against second current density values. With reasonable justification, we can make the assumption that these EGD data apply directly to the inner seal effect, and not to hydrate structures that occur elsewhere in the porous layer or at its surface (1).

The infrared data, Fig. 5 through 8, are equally definitive, but require interpretation. We seek a coating structure whose barrier layer is undergoing a transition, and where neither the primary nor the secondary phase barrier layer is the established

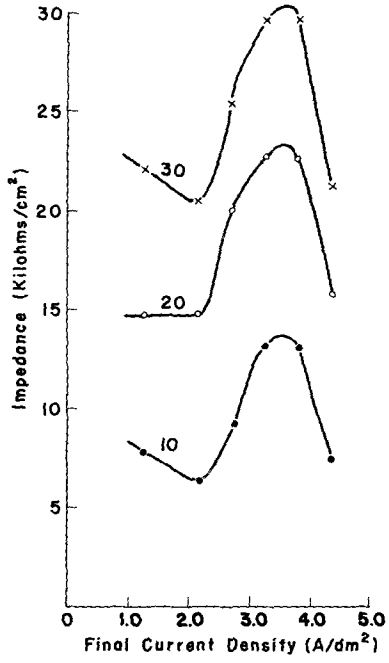

Fig. 2. Coating impedance for sealed films as a function of final current density. Curves are for 10, 20, and 30 min sealing time, respectively.

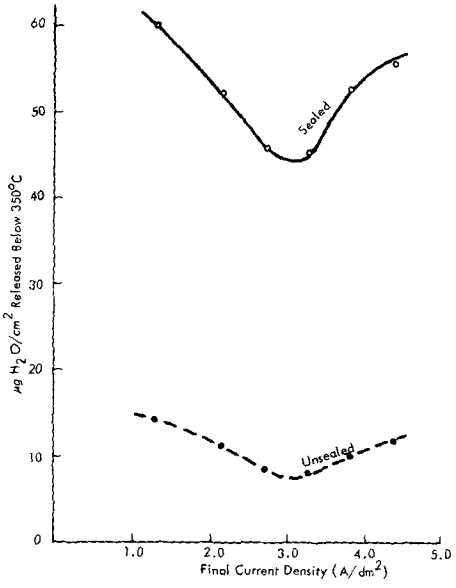

Fig. 3. Micrograms per square centimeter of water released from sealed and unsealed films (EGD data) when baked to 350°C.

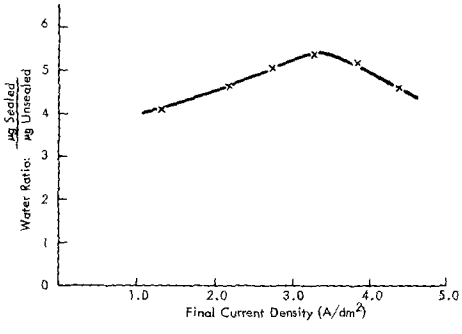

Fig. 4. Ratio of water released (EGD) from sealed *vs* unsealed films, plotted against final current density.

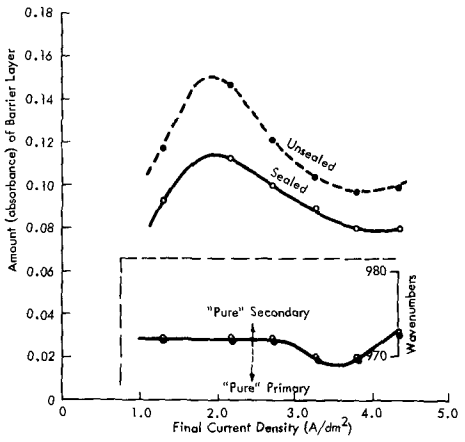

Fig. 5. Amount of barrier layer in sealed and unsealed films, also showing placement of *IR* band.

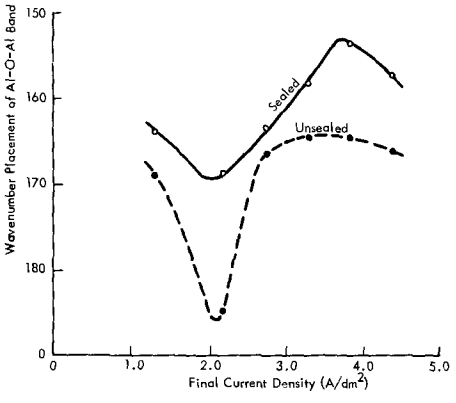

Fig. 6. Placement of porous layer Al-O-Al far *IR* band center, showing effect of sealing transition.

structure. As noted earlier (1, 2), this would require that the wavenumber peak position of the barrier layer be somewhere within the region near 965 cm^{-1}, and the amount (absorbance) of the barrier layer should be at a minimum. Figure 5 shows that these conditions are best met with a second, or final, current density whose value is between 3.24 and 3.78 A/dm^2.

Far infrared data are equally well suited, but indirectly, to measure the extent of this transition-state property of the barrier layer. Although the far *IR* data are strictly a measure only of the porous layer, the barrier layer sealing transition produces a direct result in the porous layer. Sealing transforms a portion of the secondary-phase barrier layer into porous layer hydroxide. This transformation increases the amount of porous layer cross-linking, thereby shifting, to lower wavenumbers, the peak placement of the porous layer Al-O-Al stretching vibration. Figure 6 illustrates such a shift in band position, which is at its minimum (most favorable) value with a final current density in the region 3.24-3.78 A/dm^2.

Figure 7 is a plot of amount (absorbance) of porous layer cross-linking, for sealed and unsealed films, and again (2) shows that, for unsealed films, the amount of porous layer cross-linking follows an inverse relationship with the amount of barrier layer The minimum inflection near 3.24 A/dm^2, in Fig. 7, is an indication that the barrier layer structure has undergone a change that puts it back into the inner seal transition zone. The inflection shows that, in this region, the

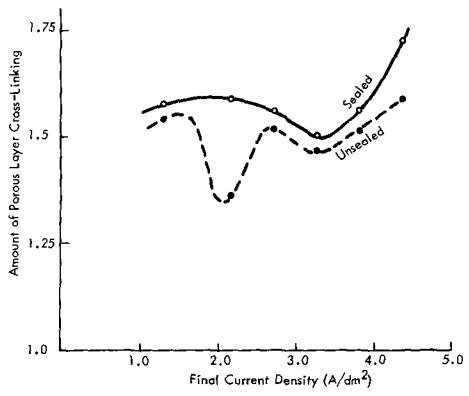

Fig. 7. Amount of porous layer cross-linking (far *IR* data) for sealed and unsealed films.

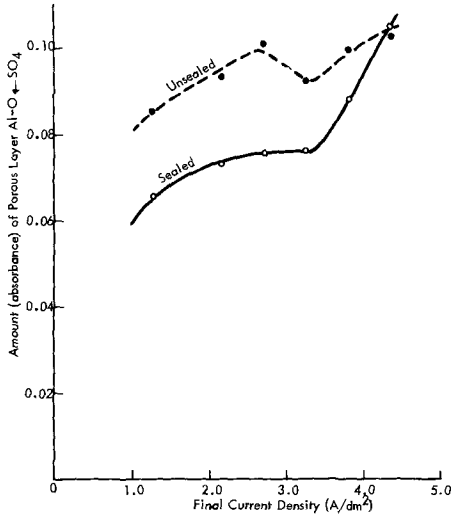

Fig. 8. Amount of porous layer incorporated sulfate (Al=O—S band at 1325 cm^{-1}) for sealed and unsealed films.

barrier layer has reverted from predominantly secondary phase (which gives rise to the porous layer) to a primary-secondary transition zone, within which the growth of the porous layer subsides slightly.

Figure 8 shows a plot of structurally incorporated porous layer sulfate (Al-O-S linkage) plotted *vs.* final current density. Sealing removes some of the incorporated electrolyte anion and probably replaces it with an hydroxyl group (4). Less directly, since the Al-O-S bond is insensitive to changes in porous layer cross-linking, these data also show some of the effects that were discussed earlier in connection with Fig. 5.

Electronic States of Mn^{2+}-Activated Phosphors.

I. Green-Emitting Phosphors

ABSTRACT

The electronic states of Mn^{2+} are derived from excitation spectra for five green-emitting phosphors: (*i*) $MgGa_2O_4$:Mn, (*ii*) Zn_2SiO_4:Mn, (*iii*) $ZnAl_2O_4$:Mn, (*iv*) Zn_2GeO_4:Mn, and (*v*) $Li_2ZnGe_3O_8$:Mn. Only $MgGa_2O_4$:Mn is found to give a spectrum consistent with octahedral (or tetrahedral) symmetry of Mn^{2+}; the other four phosphors show spectra typical of Mn^{2+} in symmetry lower than octahedral. Solution of the Tanabe-Sugano energy matrices using the $MgGa_2O_4$:Mn levels as input gave Racah parameters of $B = 624$ cm^{-1} and $C = 3468$ cm^{-1}.

Most studies of the optical spectra of Mn^{2+} compounds have been concerned with aqueous solutions of Mn salts, hydrated crystals, and Mn^{2+} halides. Where studies of Mn^{2+}-activated phosphors have been made, the principal concern was to account for observed differences in emission color, the phosphors falling in two classes, those with green emission and those with orange-to-red emission. In similar fashion, we catalog the spectra of Mn^{2+} phosphors in two parts. In this paper we give spectra for five phosphors with green emission and reserve for a later paper presentation of spectra for the orange-to-red emitters. Aside from the obvious division based on color difference, the division follows naturally from the observed position of the ^4A-^4E level for the two classes. For the green emitters the level is found at about 23,500 cm^{-1}, while for the orange-to-red emitters, the level is found at about 24,700 cm^{-1}.

We give below, then, excitation and emission spectra for $MgGa_2O_4$:Mn, Zn_2SiO_4:Mn, $ZnAl_2O_4$:Mn, Zn_2GeO_4:Mn; and $Li_2ZnGe_3O_8$:Mn, give assignments for the observed levels, compare our observations, where possible, with previously reported results, and, finally, fit the observed levels of $MgGa_2O_4$:Mn for given values of the Racah parameters and crystal field strength.

The energy levels of the $3d^5$ Mn^{2+} ion in an octahedral crystal field have been given by Orgel (1), Tanabe and Sugano (2), and Druzhinin (3). Moore (4) gives the free-ion levels. In brief, the free-ion levels, in order of increasing energy are ^6S, ^4G, ^4P, ^4D, and ^4F. In the octahedral field the designations are $^6A_{1g}(^6S)$, $^4T_{1g}(^4G)$, $^4T_{2g}(^4G)$, ^4E_g-$^4A_{1g}(^4G)$, etc., where the free-ion level origins are given in parentheses. The labels A, E, and T refer to single, double, and triple orbital degeneracies, respectively. For completeness, Orgel's crystal field diagram is reproduced in Fig. 1.

The theory has been applied by Pappalardo (5) to $MnCl_2$ and $MnBr_2$, by Goode (6) to $MnCl_2$ complexes, by Ford *et al.* (7) to MnS, by Medlin (8) to naturally occurring minerals, by Heidt *et al.* (9) to $Mn(ClO_4)_2$, by Cotton *et al.* (10) to tetrahalo anions, by Lawson (11) to Mn^{2+}-halo hydrates, by Bingham and Parke (12) to glasses, and by Curie (13), McClure (14), Ryskin *et al.* (15), and Langer (16) to ZnS. In the above systems, the position of the ^4E-$^4A(^4G)$ level varied from 21,237 cm^{-1} (ZnS:Mn) to 25,550 cm^{-1} (MnF_2). In general, no splitting of the two lowest-lying ^4T levels was observed.

With particular reference to the phosphors we report on below, Klick and Schulman (17) give the excitation spectrum of Zn_2SiO_4:Mn. They note three broad bands in the visible. Kostantinova-Schlezinger (18), and Konstantinova-Schlezinger and Kabakova (19) give excitation spectra for green and red emitters; in particular, for green-emitting Zn_2SiO_4:Mn and Zn_2GeO_4:Mn they show three bands in the visible for each. For $ZnAl_2O_4$:Mn, Kroger (20) indicates one band in the visible. Schrader (21) and Vlam (22) report fine structure on the emission band of Zn_2SiO_4:Mn at low temperature. Butler (23), Nagy (24), and Makai (25) fit the silicate emission spectrum with Gaussian bands. Brown (26) discusses the luminescence of $MgGa_2O_4$:Mn and Grisafe (27), the luminescence of $Li_2ZnGe_3O_8$:Mn. Klick (28) gives a brief summary of the Mn^{2+} luminescent center.

A knowledge of expected site symmetry of Mn^{2+} in each of the lattices considered here serves as basis for comparison of observed spectra with group theoretical predictions. In all five phosphors the site symmetry is expected to be either octahedral or tetrahedral. $ZnAl_2O_4$ (20), $MgGa_2O_4$ (29), and $Li_2ZnGe_3O_8$ (27) are spinels with both octahedral and tetrahedral sites. Zn_2SiO_4 (30, 31) and Zn_2GeO_4 (32) have tetrahedral sites. For the $3d^5$ configuration Orgel's diagram applies for both octahedral and tetrahedral symmetry (33).

Experimental Procedures

Excitation and emission spectra were measured at room and liquid-N_2 temperature using a Hitachi-Perkin Elmer MPF-2A spectrofluorimeter. Liquid-He spectra were taken on the same instrument using an Air Products "Cryo-Tip" dewar. The excitation source was a 150-W xenon-arc lamp for measurements below 380 nm and a 1000-W quartz-iodine (tungsten) lamp for measurements above 380 nm. The line structure of

the xenon arc in the region of 430 to 500 nm interferes with accurate determination of band positions. The spectra obtained were uncorrected for energy.

The compounds measured were formulated with Mn^{2+} concentrations designed to give maximum quantum efficiency as determined by extensive empirical testing, except as noted below, where Mn^{2+} concentration variations revealed additional band structure. Preparative techniques were typical of usual solid state phosphor synthesis and are given in the literature (20, 21, 26, 27, 32).

In deriving band locations, no attempt was made to resolve overlapping bands into Gaussians to obtain a more precise value of wavelength. Values quoted for these bands are therefore only estimates.

Results and Discussion

A few comments are in order before detailing the results, summarized in Table I for ready reference: (*i*) only $MgGa_2O_4$:Mn gives the expected spectrum for octahedral (or tetrahedral) symmetry, *i.e.*, no splitting of degenerate E and T levels, (*ii*) the position of the ^4A-$^4E(^4G)$ level is relatively constant in all five samples at about 23,500 cm^{-1}, (*iii*) where splittings of the degenerate E and T levels occur, some of the expected levels are not observed, and (*iv*) Orgel's criterion that the levels with minimum slope (A and E levels) show the narrowest bandwidth is used as the starting point for assignments.

The spectrum for $MgGa_2O_4$:0.02 Mn is given in Fig. 2. Not shown is the weak lowest-lying $^4T_1$ level at 478.7 nm. The sharp level at 424.7 nm is the ^4E-$^4A(^4G)$. The remaining assignments are given in Table I. Levels above the $^4E(^4D)$ are not observed; they are masked by the charge transfer band. The structure observed at about 415.0 nm is not uniquely assigned. A possible assignment would be a $^2T_2(^2I)$ level, not shown in Orgel's diagram, but which Tanabe and Sugano indicate crosses the lower-lying levels (2). An alternative assignment, as a splitting of the ^4E-^4A level, is not consistent with the observed band intensities for Zn_2GeO_4:Mn and Zn_2SiO_4:Mn, noted below.

In contrast, Zn_2GeO_4:0.03 Mn shows complete splitting of the $^4T_1(^4G)$, $^4T_2(^4G)$, and ^4E-$^4A(^4G)$ levels. The spectrum is given in Fig. 3. Not obvious in the figure is the third band of the ^4E-^4A level, but shown in greater detail and higher resolution in Fig. 4. The $^4T_2(^4D)$ level lying above the ^4E-$^4A(^4G)$ level is not a distinct triplet as might be expected. Only two of the expected three bands are well-resolved. Higher lying levels, again, are masked by the main broad excitation band.

Zn_2SiO_4:0.06 Mn gives splittings paralleling those of Zn_2GeO_4:Mn. Here, the third band of the $^4T_2(^4G)$ level is not observed. The triplet character of the ^4E-$^4A(^4G)$ level is shown in Fig. 4; the complete spectrum is shown in Fig. 5. Attempts to resolve the third band of the $^4T_2(^4G)$ level at lower (down to 0.5 m/o [mole per cent] and higher Mn (up to 12.0 m/o) contents were fruitless. The possibility that one of the three assigned ^4E-$^4A(^4G)$ levels belongs to the $^4T_2(^4G)$ triplet was considered, but rejected as inconsistent with assignments for the Zn_2GeO_4:Mn spectrum.

The spectrum of $Li_2ZnGe_3O_8$:0.035 Mn is given in Fig. 6. Here, the lowest-lying $^4T_1$ level was not observed. The $^4T_2(^4G)$ level splits into a triplet. Only doublet character appears in the ^4E-$^4A(^4G)$ and the $^4T_2(^4D)$ levels, where we might expect triplets in analogy with the complete splitting of the $^4T_2(^4G)$ level. The $^4E(^4D)$ level shows the expected doublet. At lower Mn content (0.5 m/o) no splitting of the

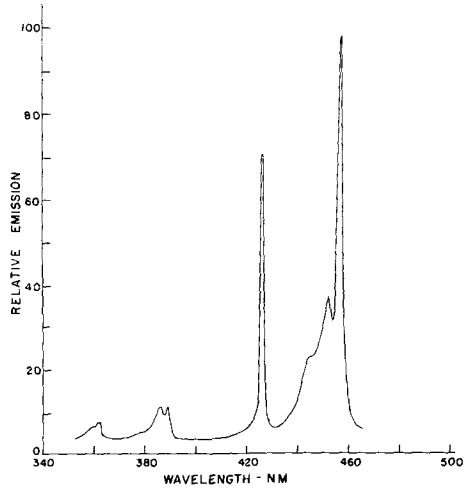

Fig. 7. Excitation spectrum of $ZnAl_2O_4$:0.02 Mn at liquid-N_2 temperature.

^4E-$^4A(^4G)$ level is noted, although the rest of the levels split as given in Fig. 6.

For $ZnAl_2O_4$: 0.02 Mn, no structure is resolved in the ^4E-$^4A(^4G)$ level although the $^4T_2(^4G)$ level is a distinct triplet. The spectrum is given in Fig. 7. The $^4T_1(^4G)$ level was not observed; the $^4T_2(^4D)$ and the $^4E(^4D)$ levels split into the expected triplet and doublet, respectively. We attribute the apparent structureless nature of the ^4E-$^4A(^4G)$ level to instrumental limitations; our maximum resolution for excitation spectra is about 0.6 nm. We note fine structure appearing in the $^4T_2(^4D)$ level (not shown in Fig. 7) at 384.3, 385.6, 386.3, and 387.2 nm. Goode (6) attributes similar structure in $MnCl_2 \cdot 2H_2O$ to spin-orbit splittings. The splittings here ($\sim$65 cm^{-1}) are consistent with his calculated values.

We noted above failure to observe the $^4T_1(^4G)$ level in $ZnAl_2O_4$:Mn and $Li_2ZnGe_3O_8$:Mn. Either the levels are too weak to observe or they lie so near the emission band (small Stokes shift) they cannot be measured in the excitation mode. We favor the latter explanation based on the observed magnitude of splitting of the $^4T_2(^4G)$ level from the ^4E-$^4A(^4G)$ level. Larger splittings are observed for $ZnAl_2O_4$:Mn and $Li_2ZnGe_3O_8$:Mn than are observed for the remaining three phosphors. We expect then the $^4T_1(^4G)$ level in these two compounds to be found at lower energy than the $^4T_1(^4G)$ level of the silicate, gallate, and orthogermanate, hence closer to the emission band and possibly overlapping it. The predicted position of these $^4T_1$ levels, derived from calculations indicated below and plotted in Fig. 11, supports the interpretation.

The spectral characteristics of the emission bands of the five phosphors vary from simple to complex. $MgGa_2O_4$:Mn and Zn_2GeO_4:Mn show no fine structure. At liquid-N_2 temperature the gallate peaks at 508 nm and has a 27 nm bandwidth at half-maximum intensity (spectrum not shown). Zn_2GeO_4:Mn peaks at 524 nm and has a 30 nm bandwidth; the spectrum is given in Fig. 8. Also shown in Fig. 8 is the $ZnAl_2O_4$:Mn spectrum; it is almost a mirror image of the $^4T_2(^4G)$ excitation band (Fig. 7). However, one extra band is observed in emission. Since the emission transition is presumably $^4T_1(^4G) \rightarrow {}^6A_1(^6S)$, complete splitting of the triplet can account for only three of the observed bands. Alternatives are that the structure results from superposition of vibrational modes or that spin-orbit coupling produces the additional splitting. Goode (6), in his calculations including spin-orbit coupling, gives splittings of the $^4T_1(^4G)$ level of about 62 cm^{-1}, smaller than we observe in emission ($\sim$150 cm^{-1}). At present we can make no definitive assignment for the origin of the fine structure.

Similar considerations apply to the Zn_2SiO_4: 0.005 Mn spectrum shown in Fig. 9. We observe more structure than reported by Schrader (21), but less structure

than reported by Vlam (22). The marked asymmetry and fine structure observed suggest that more than one mechanism is operative here.

For $Li_2ZnGe_3O_3$:Mn, Fig. 10, the spectrum broadens with increased Mn content and at 3.5 m/o Mn shows a series of seven fine-structure components superimposed on a broad asymmetric band; the fine-structure levels occur at 520.1, 522.8, 525.8, 528.0, 530.6, 533.7, and 536.6 nm. The regularity of the fine-structure separations about the 528.0 nm level suggest vibrational structure as their origin; the average separation in levels is about 100 cm^{-1}.

As a final exercise, we use the Tanabe-Sugano matrices to fit the $MgGa_2O_4$:Mn levels. We use the ^4E observed levels (23,578 and 27,948 cm^{-1}) to derive values of the Racah parameters, using the $^4\Gamma_3$ matrix, which is independent of the crystal field strength. The values of B (624 cm^{-1}) and C (3468 cm^{-1}) obtained are then used in the crystal-field-dependent matrices to determine the remaining levels. The results are shown in Fig. 11, where we include the observed levels of the other four compounds for qualitative comparison. A value of 10 Dq of 5200 cm^{-1} gives a reasonable fit for the gallate levels. A more accurate fit can be obtained by a least squares procedure, using B and C as adjustable parameters. However, in the absence of experimental values for the higher-lying levels, the refinement seems unwarranted. Table II gives a comparison of our derived values for B, C, and 10 Dq with those reported in the literature. Our values are in fair agreement with those reported for Mn^{2+} complexes (9-11).

We noted above that Mn^{2+} is expected to be in an octahedral or tetrahedral site in all five compounds

Table II. Value of B, C, and 10 Dq in cm^{-1} for Mn^{2+} systems

studied (1). If so, no splitting of degenerate E and T levels is expected (2). However, only $MgGa_2O_4$:Mn gives the expected spectrum, *i.e.*, no splitting of degenerate levels. Two mechanisms may account for observed splittings; either the symmetry is lower than is expected, or Mn^{2+} occupies both octahedral and tetrahedral sites in the $Li_2ZnGe_3O_8$:Mn and $ZnAl_2O_4$:Mn spinels, and both (unequivalent) tetrahedral sites in Zn_2SiO_4:Mn (31). The latter mechanism would, at most, account for doubling the number of expected levels, but would not account for the observed triplets (Fig. 11). We assume, therefore, that the splittings result from a lowering of the site symmetry. The point group symmetries consistent with complete lifting of the degeneracies are C_2v, C_2h, D_2, or D_2h (33).

The apparent dependence of the ^4E-$^4A(^4G)$ level-splitting in $Li_2ZnGe_3O_8$:Mn on Mn^{2+} concentration is unexpected and deserves further study. (The observation is not an artifact attributable to spectra measured at different instrumental resolutions.) Group theoretical arguments require that complete splitting of the $^4T_1(^4G)$ level be reflected in complete splitting of the remaining levels. Until additional data are available, we forgo explanations that must be couched in speculation.

On emission spectra we have said little and can say little more. Where structure is observed in a phosphor emission spectrum, it usually follows that structure is also observed in the excitation spectrum. The converse statement may or may not be true. In particular, the Zn_2GeO_4:Mn emission spectrum shows no fine structure, while the excitation spectrum does (Fig. 3 and 8).

Summary

Of the five compounds examined, only $MgGa_2O_4$:Mn shows the expected behavior for Mn^{2+} in octahedral (or tetrahedral) symmetry. The complete splitting of at least one of the ^4T levels in all the remaining compounds requires distortion of the expected octahedral (or tetrahedral) symmetry down to C_2v, C_2h, C_2, or D_2h symmetries (33). The question of the effects of spin-orbit coupling and vibrational modes on splittings and fine structure we leave unresolved, requiring additional experimental data taken at higher resolution and embracing a wider range of Mn concentrations for more definitive conclusions.

Luminescence of Divalent Europium in Ba-Ca, Ba-Sr, and Ca-Sr Orthophosphate and Pyrophosphate Compositions

Costas C. Lagos*

Phosphor Research Laboratory, Sylvania Lighting Center, Danvers, Massachusetts 01923

ABSTRACT

Divalent europium was used as an activator in Ba-Ca, Ba-Sr, and Ca-Sr orthophosphate and pyrophosphate compositions. Luminescence was observed in most of the compositions and spectral energy distribution measurements were made on all samples. Changes in the mixed cation ratios produced variations in emission band intensities, shifting of emission peak positions, and changes in emission band widths A new compound with the formula $Ba_2Ca(PO_4)_2$ was found.

Compositions along the binary joins between the orthophosphates and pyrophosphates of Ca-Sr, Ba-Sr, and Ca-Ba were doped with divalent europium and examined for luminescence under 2537Å excitation. Many of the compositions fluoresced quite strongly and emission band peak positions varied from 407 to 550 nm. During the course of the investigation, a previously unreported orthophosphate compound with the composition of $Ba_2Ca(PO_4)_2$ was found.

Other papers (1-6) have previously reported on the divalent europium activation of alkaline earth orthophosphates and pyrophosphates, but in most cases the authors either presented data primarily on the substitution of Mg for Ba, Ca, or Sr, or they did not report extensively on their results. In this paper we shall endeavor to present a more comprehensive picture on the divalent europium activation of the mixed alkaline earth orthophosphates and pyrophosphates with the major emphasis being placed on empirical results.

Experimental

The samples were prepared using luminescent grade Ba, Ca, and Sr carbonates, $BaHPO_4$, $CaHPO_4$, and $SrHPO_4$, and 99.99% pure Eu_2O_3. After dry mixing, the blends were fired in air and then mixed again prior to a final reduction firing in a 1% H_2-99% N_2 atmosphere. The firing temperatures used were varied and were determined by the particular composition join being studied. A concentration of 0.02 gram atom of Eu were added per gram atom of alkaline earth cation and a slight excess of phosphate (0.02 gram atom) was also used.

X-ray diffraction data were obtained on all samples. Spectral energy distribution data (SED curves) using 2537Å radiation were also obtained on all luminescent samples, and emission peak height intensities were compared as described previously (3).

Results and Discussion

Orthophosphates

Ca-Sr *compositions.*—The only noteworthy luminescence observed in these compositions was that of the pure end members, $Ca_3(PO_4)_2$ and $Sr_3(PO_4)_2$. Each end member has two polymorphic forms, α and β (7, 8). $Ca_3(PO_4)_2$ has a β to α transition temperature of 1180°, while the β-form of $Sr_3(PO_4)_2$ is not stable at room temperature unless it is stabilized by the addition of a number of various foreign cations of which Ca is one (8).

Calcium was substituted for strontium in $Sr_3(PO_4)_2$:Eu^{+2} in 0.5 mole increments and samples were fired at 1100° and 1250°C. X-ray diffraction data of the mixed Ca-Sr compositions from both firing temperatures showed only the presence of either β-$Sr_3(PO_4)_2$, β-$Ca_3(PO_4)_2$, or some solid solution between them. The end members were found to be β-$Ca_3(PO_4)_2$ at 1100°C, α-$Ca_3(PO_4)_2$ at 1250°C, and α-$Sr_3(PO_4)_2$ at both temperatures.

Figure 1 shows the emission curves for α and β-$Ca_3(PO_4)_2$:Eu^{+2} and α-$Sr_3(PO_4)_2$:Eu^{+2}. The latter had an intense narrow emission band peaking at 415 nm, while β-$Ca_3(PO_4)_2$:Eu^{+2} had a similarly narrow emission band peaking at 408 nm. An extremely wide emission curve peaking at 488 nm was obtained with α-$Ca_3(PO_4)_2$:Eu^{+2}. This phosphor, because of its wide emission curve, appeared to be a moderately bright whitish green when visually observed under 2537Å excitation, but its peak intensity was only about 6% of the 1200°C fired α-$Sr_3(PO_4)_2$:Eu^{+2} phosphor, the brightest of this particular orthophosphate group. Table I lists the emission properties of these end-member phosphors which were the only significant phosphors found in the Ca-Sr orthophosphate compositions. Data on some standard phosphors are also included for reference.

As Ca was substituted for Sr in α-$Sr_3(PO_4)_2$, the β-form of $Sr_3(PO_4)_2$ was formed. The only luminescence observed here was an extremely weak reddish-orange emission. On examination by the spectral energy distribution radiometer, the red portion of the luminescence was found to be weak trivalent europium emission. Apparently, the trivalent europium in the β-$Sr_3(PO_4)_2$ compound could not be reduced to divalent europium.

In addition to the weak red Eu^{+3} emission, there was also observed an extremely weak orange emission

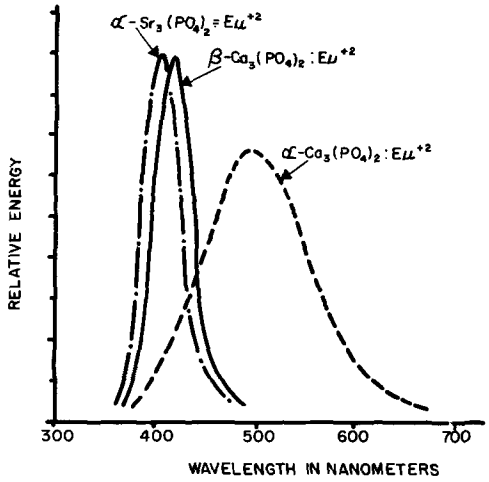

Fig. 1. Spectral energy distribution of the emission of α-$Ca_3(PO_4)_2$:Eu^{+2}, β-$Ca_3(PO_4)_2$:Eu^{+2}, and α-$Sr_3(PO_4)_2$:Eu^{+2}. 2537Å excitation.

Plus other lines.

in the vicinity of 510-660 nm which had also been reported previously by Gorbacheva (5).

Ba-Ca *orthophosphates.*—Calcium was substituted for barium in $Ba_3(PO_4)_2$:Eu^{+2} in 0.5 mole increments and samples were fired at 1000° and 1200°C. As in the case of Ca-Sr orthophosphate compositions, the brightest phosphors obtained in this binary system were the pure end members, α- and β-$Ca_3(PO_4)_2$:Eu^{+2}, which were mentioned previously in the discussion of the Ca-Sr orthophosphate compositions, and $Ba_3(PO_4)_2$:Eu^{+2} which had an intense emission band at 415 nm.

Figure 2 shows the emission curve for the $Ba_3(PO_4)_2$:Eu^{+2} phosphor and Table I lists its emission properties.

Also included in Fig. 2 is the emission curve for the new compound that was discovered during this investigation. This compound had the formula $Ba_2Ca(PO_4)_2$, with an emission peak intensity about 10% of the $Ba_3(PO_4)_2$:Eu^{+2} end member, but it appeared a moderately bright pale yellow-white under 2537Å excitation because of its extremely wide emission band. The emission properties of this phosphor are also given in Table I.

The presence of the two emission peaks in the SED curve of this $Ba_2Ca(PO_4)_2$:Eu^{+2} phosphor appeared to indicate that a mixture of two phases was present. X-ray diffraction data, however, showed extremely sharp and well-defined lines of a single compound whose x-ray pattern did not correspond to any single pattern or combinations of patterns of any other known compounds in either the BaO-P_2O_5 or CaO-P_2O_5 binary systems. Table II gives the x-ray diffraction data for the new $Ba_2Ca(PO_4)_2$ compound.

The $Ba_2Ca(PO_4)_2$:Eu^{+2} phosphor was also inspected under 2537Å excitation with a microscope. The emission color of all particles was identical. SED curves of some individual luminescent particles were obtained using a modified fiber optic single particle microspectroradiometer which was previously described by Bouchard (9). The single particle SED curves were identical to the SED curve shown in Fig. 2 which was obtained from a powder sample. The two peaks in the emission curve are probably the result of the activator being in two different crystallographic sites.

Figure 3 shows the variation of emission peak intensity with composition for the 1200°C firing. As Ca was substituted for Ba, there was a drastic decrease in emission intensity until the composition of $Ba_2Ca(PO_4)_2$ was reached. Further Ca substitution resulted only in a small gradual increase in intensity until the wide band pale green-white emitting α-$Ca_3(PO_4)_2Eu^{+2}$ end member was reached.

It also can be seen from Fig. 3 that there was a substantial increase in the width of the emission band as Ca was substituted for Ba. The emission band width began to increase at $Ba_{2.5}Ca_{0.5}$ and continued to increase quite rapidly until the $Ba_{1.5}Ca_{1.5}$ composition was reached. X-ray diffraction of compositions in this region ($Ba_{3.0}$ to $Ba_{1.5}Ca_{1.5}$) showed the presence of (*a*) $Ba_3(PO_4)_2$, (*b*) a mixture of $Ba_3(PO_4)_2$ and $Ba_2Ca(PO_4)_2$, (c) $Ba_2Ca(PO_4)_2$, and (*d*) lower *d*-spacing values of $Ba_2Ca(PO_4)_2$, respectively.

At concentrations of Ca greater than $Ca_{1.5}$ larger *d*-spacing values and line intensities of α-$Ca_3(PO_4)_2$ began to appear in increasing amounts in the x-ray diffraction data, the rate of increase of the emission band width began to level off, and the peak of the weak emission curve began to shift from 500 nm for $Ba_{1.5}Ca_{1.5}$ to 554 nm, 560 nm, and 530 nm for the next three Ba-Ca compositions until finally the emission peak position of 488 nm for α-$Ca_3(PO_4)_2$:Eu^{+2} was obtained.

Emission results of samples fired at 1000°C were similar to those obtained at 1200°C except for slightly reduced emission intensities which were due to decreased reactivity. This was confirmed by the x-ray data which showed x-ray diffraction lines of reduced intensity and sharpness. Here again as was the case in the 1200°C firing, α-$Ca_3(PO_4)_2$ was found to be the only phase present in the compositions from $Ba_{0.25}Ca_{2.75}$ to $Ba_{1.0}Ca_{2.0}$. This was quite surprising since the 1000°C firing temperature was considerably lower than the normal β to α transition temperature of 1180°C, as determined by differential thermal analysis in our lab-

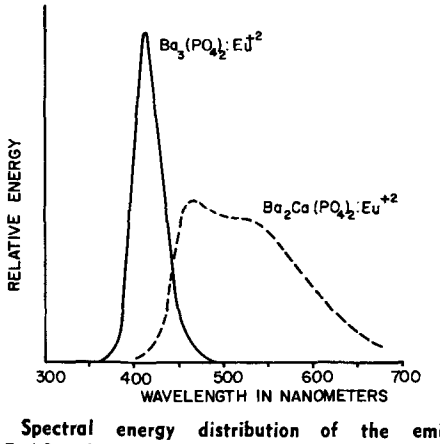

Fig. 2. Spectral energy distribution of the emission of $Ba_3(PO_4)_2$:Eu^{+2} and $Ba_2Ca(PO_4)_2$:Eu^{+2}. 2537Å excitation.

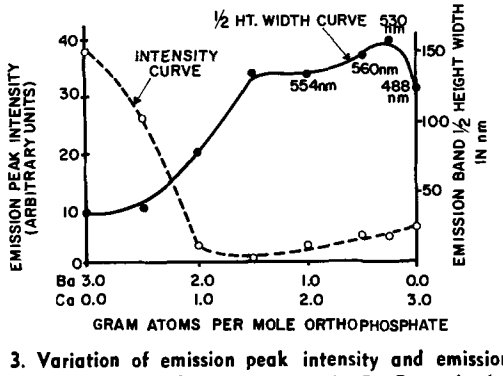

Fig. 3. Variation of emission peak intensity and emission band half-height width with changing cation in Ba-Ca orthophosphate compositions.

oratory. Apparently, the substitution of the larger Ba ion for Ca up to the compositions of Ba_1Ca_2 tended to stabilize the α rather than the β-form of $Ca_3(PO_4)_2$ even at as low a temperature as 1000°C.

Ba-Sr *orthophosphates.*—Ba-Sr orthophosphate compositions were fired at 1000° and 1200°C, and substitutions of Ba for Sr were made in 0.5 mole increments. X-ray diffraction data indicated that there was a complete solid solution formed between $Ba_3(PO_4)_2$:Eu^{+2} and α-$Sr_3(PO_4)_2$:Eu^{+2}. Because of this complete solid solution and the intense brightness of the end-member phosphors, the intermediate Ba-Sr compositions were also quite bright. The emission curve of $Ba_3(PO_4)_2$:Eu^{+2} was shown in Fig. 2 and that of α-$Sr_3(PO_4)_2$:Eu^{+2} in Fig. 1. Table I gives the emission properties of α-$Sr_3(PO_4)_2$:Eu^{+2} and $Ba_3(PO_4)_2$:Eu^{+2}.

Figure 4 shows the variation of emission peak intensity and the shifting of the emission peak with changing composition for the 1000°C firing. The change in intensity for compositions between the two end members was almost a straight line which was as expected because of the complete solid solution between the Sr and Ba orthophosphates. As Sr was substituted for Ba, there was a slight shifting of the emission band toward the longer wavelengths before it began to shift toward the 407 nm peak of the α-$Sr_3(PO_4)_2$:Eu^{+2} phosphor.

Because Ba was not one of the cations which stabilized the β-form of $Sr_3(PO_4)_2$, there were no results to be reported on β-$Sr_3(PO_4)_2$-$Ba_3(PO_4)_2$ compositions.

Pyrophosphates

Ca-Sr *pyrophosphates.*—There are three polymorphic forms of $Ca_2P_2O_7$, α, β, and γ (7), and two polymorphic forms of $Sr_2P_2O_7$, α and β (10). The γ-form of $Ca_2P_2O_7$ was not studied, because it was only stable at low temperatures (320°-340°C). The transition temperature from β-$Ca_2P_2O_7$ to α-$Ca_2P_2O_7$ was at 1140°C, and Ca-Sr compositions were fired at two different temperatures of 1050°C and 1250°C in order to study the effect of β-$Ca_2P_2O_7$:Eu^{+2}-α-$Sr_2P_2O_7$:Eu^{+2}, and α-$Ca_2P_2O_7$:Eu^{+2}-α-$Sr_2P_2O_7$:Eu^{+2} compositions.

A weak blue emission at 424 nm was obtained with β-$Ca_2P_2O_7$:Eu^{+2}, while strong emission peaks at 419 and 422 nm were obtained with α-$Ca_2P_2O_7$:Eu^{+2} and α-$Sr_2P_2O_7$:Eu^{+2}, respectively. β-$Sr_2P_2O_7$:Eu^{+2} was dead to 2537Å excitation. Table III lists the emission properties of these phosphors along with those of the various Ca-Sr compositions fired at 1050° and 1250°C. The emission properties of a standard $CaWO_4$:Pb phosphor were also included for reference.

Sr was substituted for Ca in $Ca_2P_2O_7$:Eu^{+2} in 0.25 mole increments and samples were fired at 1050° and 1250°C, as mentioned previously. Longer firing times of 8-12 hr were needed for these particular compositions since the normal firing times of 2-4 hr produced nonequilibrium conditions and erroneous results in emission intensities and emission peak positions.

For the 1050°C firing, x-ray diffraction data showed only the presence of either β-$Ca_2P_2O_7$, and/or α-$Sr_2P_2O_7$ in all compositions. The $Ca_2P_2O_7$ and

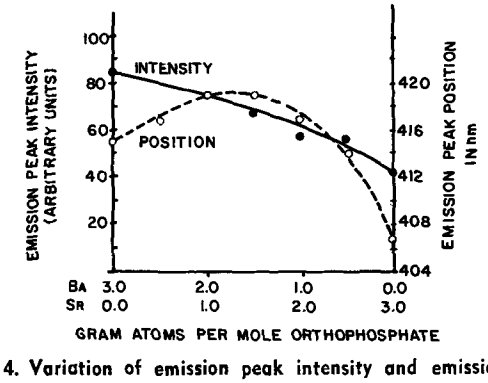

Fig. 4. Variation of emission peak intensity and emission peak position with changing cation in Ba-Sr orthophosphate compositions.

Table III. Emission properties of Ca-Sr pyrophosphate compositions

Composition	Peak position, nm	Band width at ½ height, nm	Peak height intensity as % of Zn_2SiO_4:Mn
	1050°C Firing		
β-$Ca_2P_2O_7$:Eu^{+2}	424	39	7
$Ca_{1.75}Sr_{0.25}P_2O_7$:Eu^{+2}	420	43	44
$Ca_{1.50}Sr_{0.50}P_2O_7$:Eu^{+2}	420	46	57
$Ca_{1.25}Sr_{0.75}P_2O_7$:Eu^{+2}	430	45	60
$Ca_{1.0}Sr_{1.0}P_2O_7$:Eu^{+2}	430	43	70
$Ca_{0.75}Sr_{1.25}P_2O_7$:Eu^{+2}	431	40	72
$Ca_{0.50}Sr_{1.50}P_2O_7$:Eu^{+2}	429	38	82
$Ca_{0.25}Sr_{1.75}P_2O_7$:Eu^{+2}	426	35	119
α-$Sr_2P_2O_7$:Eu^{+2}	422	32	149
	1250°C Firing		
β-$Ca_2P_2O_7$:Eu^{+2}	419	30	86
$Ca_{1.75}Sr_{0.25}P_2O_7$:Eu^{+2}	423	40	70
$Ca_{1.50}Sr_{0.50}P_2O_7$:Eu^{+2}	431	48	79
$Ca_{1.25}Sr_{0.75}P_2O_7$:Eu^{+2}	439	43	94
$Ca_{1.0}Sr_{1.0}P_2O_7$:Eu^{+2}	440	39	110
$Ca_{0.75}Sr_{1.25}P_2O_7$:Eu^{+2}	438	37	123
$Ca_{0.50}Sr_{1.50}P_2O_7$:Eu^{+2}	434	35	145
$Ca_{0.25}Sr_{1.75}P_2O_7$:Eu^{+2}	430	35	162
α-$Sr_2P_2O_7$:Eu^{+2}	422	30	156
$CaWO_4$:Pb (Reference)	446	124	39

$Ca_{1.75}Sr_{0.5}P_2O_7$ compositions were β-$Ca_2P_2O_7$ with the intensity and sharpness of the β-$Ca_2P_2O_7$ diffraction lines being drastically reduced in the latter composition. In the $Ca_{1.5}Sr_{0.5}$, $Ca_{1.25}Sr_{0.75}$, and the $Ca_{1.0}Sr_{1.0}$ compositions, α-$Sr_2P_2O_7$ was present, but with diffraction lines of greatly reduced intensity and sharpness. The remaining compositions, $Ca_{0.75}Sr_{1.25}$ through $Sr_2P_2O_7$ were also α-$Sr_2P_2O_7$ but with moderately strong diffraction lines of increasing sharpness as the concentration of Sr was increased.

Table III lists the emission properties of the 1050°C fired compositions. The most intense phosphor of the group was the unsubstituted α-$Sr_2P_2O_7$:Eu^{+2} phosphor, and it appeared that with increasing Ca substitution the good phosphor was simply being diluted with the poor β-$Ca_2P_2O_7$:Eu^{+2} phosphor resulting in steadily decreasing emission intensities. No important changes occurred in the emission peak positions and widths at half height as the Ca-Sr compositions were varied.

At the 1250°C firing temperature x-ray diffraction data showed that α-$Ca_2P_2O_7$ was formed and that it was present in the compositions from $Ca_2P_2O_7$ to $Ca_1Sr_1P_2O_7$. In the $Ca_{1.75}Sr_{0.25}$ and the $Ca_{1.5}Sr_{1.5}Sr_{0.5}$ compositions, the α-$Ca_2P_2O_7$ had higher d-spacing values. In the $Ca_{1.25}Sr_{0.75}$ and the $Ca_{1.0}Sr_{1.0}$ compositions mixtures of decreasing amounts of α-$Ca_2P_2O_7$ and increasing amounts of α-$Sr_2P_2O_7$ were found, while in the $Ca_{0.75}Sr_{1.25}$ through the $Sr_2P_2O_7$ compositions only α-$Sr_2P_2O_7$ was found with lower d-spacing values in the former composition.

The emission properties of the 1250°C fired Ca-Sr compositions are also given in Table III. All of these phosphors were moderately intense, but again as in the 1050°C firing the brightest phosphors were in the Sr-rich compositions. There was, however, a slightly larger change in the emission peak positions from about 420 for the end members to 440 nm for the Ca_1Sr_1 composition, as compared to the 1050°C firing temperature where the peak position change was from about 422 nm for the end members to 431 nm for the $Ca_{0.75}Sr_{1.25}$ composition. The widths at half-height for the 1250°C temperature were about the same as those obtained at the 1050°C firing temperature.

Ba-Sr *pyrophosphates.*—There are two polymorphic forms of $Ba_2P_2O_7$, α and δ (11), and two forms of $Sr_2P_2O_7$, α and β (10). The α and δ-$Ba_2P_2O_7$:Eu^{+2} and β-$Sr_2P_2O_7$:Eu^{+2} compositions resulted in virtually dead phosphors. As reported previously, α-$Sr_2P_2O_7$:Eu^{+2} was a very bright phosphor whose emission properties were given in Table III.

Sr was substituted for Ba in $Ba_2P_2O_7$:Eu^{+2} in 0.25 mole increments and samples were fired at 1000° and 1200°C. X-ray diffraction data of the 1000°C fired samples showed: (a) δ-$Ba_2P_2O_7$ and α-$Sr_2P_2O_7$ for the end members; (b) solid solution of α-$Sr_2P_2O_7$ in δ-$Ba_2P_2O_7$

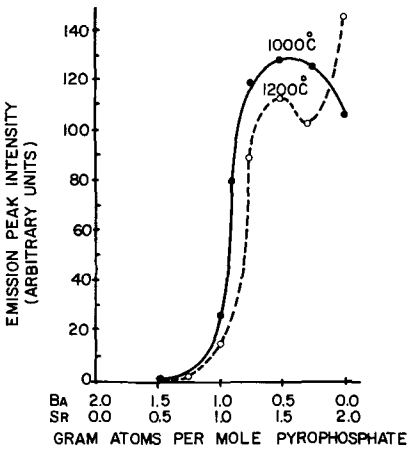

Fig. 5. Variation of emission peak intensity with changing cation in Ba-Sr pyrophosphate compositions fired at 1000° and 1200°C.

in the $Ba_{1.75}Sr_{0.25}$ and $Ba_{1.5}Sr_{0.5}$ compositions; (c) solid solution of δ-$Ba_2P_2O_7$ in α-$Sr_2P_2O_7$ in the $Ba_{0.75}Sr_{1.25}$, $Ba_{0.5}Sr_{1.5}$, and $Ba_{0.25}Sr_{1.75}$ compositions; and (d) mixtures of δ-$Ba_2P_2O_7$ and α-$Sr_2P_2O_7$ in the $Ba_{1.25}Sr_{0.75}$ and Ba_1Sr_1 compositions.

Figure 5 shows the variation of emission peak intensity of the Ba-Sr pyrophosphate compositions at the two firing temperatures of 1000° and 1200°C. At 1000°C there was no substantial luminescence until the area of the Ba_1Sr_1 composition was reached. At this point further substitution of Sr for Ba led to a rapid increase in emission intensity which reached a maximum at $Ba_{0.5}Sr_{1.5}$ before decreasing slightly at the $Ba_{0.25}Sr_{1.75}$, and the α-$Sr_2P_2O_7$:Eu^{+2} phosphor compositions.

The shape of the emission intensity curve for the 1200°C fired samples was quite similar to the 1000°C fired samples except at the pure α-$Sr_2P_2O_7$:Eu^{+2} composition. Here the intensity of the 1200°C sample was increased substantially over that of the 1000°C fired sample and this increased intensity was considerably out of line with the intensities from the remaining 1200°C fired compositions. A repeat test with new samples gave the same results.

A possible explanation for this irregularity is that the emission intensity of the unsubstituted α-$Sr_2P_2O_7$:Eu^{+2} phosphor is instrinsically higher at 1200°C, but when Ba is substituted for Sr, a substantial decrease occurs in the general level of emission intensity of the Ba-containing samples causing a discontinuity in the intensity curve between these samples and the α-$Sr_2P_2O_7$:Eu^{+2} composition.

This effect did not occur at 1000°C probably because of the decreased reactivity between the Ba and Sr ions at this lower firing temperature. Indeed, x-ray diffraction data of the 1200°C samples did show sharper lines and better crystallinity, although the compounds present in the various compositions were identical to the compounds present in the same compositions at the 1000°C firing temperature.

No shifts in emission band positions or changes in band widths were observed at either firing temperature. The luminescence observed for all samples was due entirely to the emission of the bright α-$Sr_2P_2O_7$:Eu^{+2} phosphor, which was simply being diluted by the nonluminescent δ-$Ba_2P_2O_7$:Eu^{+2} phase.

Ba-Ca *pyrophosphates.*—The end-member phosphors of the Ba-Ca pyrophosphate composition series, α and δ-$Ba_2P_2O_7$:Eu^{+2} and α and β-$Ca_2P_2O_7$:Eu^{+2} were discussed previously, and the emission properties of the latter two phosphors were given in Table III.

Increasing amounts of Ba in 0.25 mole increments were substituted for Ca in $Ca_2P_2O_7$:Eu^{+2} and the compositions fired at two different temperatures, 1000° and 1120°C. Bright phosphors with emission peaks in the 430-450 nm spectral region were found in the Ca-rich half of the composition join. In these high emission intensity compositions α-$Ca_2P_2O_7$ with higher d-spacing values was found by x-ray diffraction to be either the predominant or only phase present at both firing temperatures.

For the 1000°C firing α-$Ca_2P_2O_7$ with higher d-values was found in the range of compositions from $Ba_{0.25}Ca_{1.75}$ to $Ba_{0.75}Ca_{1.25}$ while mixtures of α-$Ca_2P_2O_7$ and predominantly δ-$Ba_2P_2O_7$ were found in composition range from $Ba_{1.0}Ca_{1.0}$ to $Ba_{1.5}Ca_{0.5}$. δ-$Ba_2P_2O_7$ was found for the pure Ba end member and the $Ba_{1.75}Ca_{0.25}$ composition, while β-$Ca_2P_2O_7$ was found for the pure Ca end member.

For the 1120°C firing temperature α-$Ca_2P_2O_7$ with higher d-values was found in the composition range from $Ba_{0.25}Ca_{1.75}$ to $Ba_{1.0}Ca_{1.0}$ and was also the predominant phase in the $Ba_{1.25}Ca_{0.75}$ composition. β-$Ca_2P_2O_7$ and δ-$Ba_2P_2O_7$ were found for the end members, and mixtures of α-$Ca_2P_2O_7$ and predominantly δ-$Ba_2P_2O_7$ in the remaining compositions, $Ba_{1.75}Ca_{0.25}$ and $Ba_{1.5}Ca_{0.5}$.

It appears that the partial substitution of Ba for Ca in $Ca_2P_2O_7$ leads to the stabilization of α-$Ca_2P_2O_7$ at temperatures where one would normally expect β-$Ca_2P_2O_7$ (β to α transition temperature approximately 1140°C) (7).

Table IV lists the emission properties of the Ba-Ca pyrophosphate compositions fired at the two different temperatures. Also included for comparison are the emission properties of unsubstituted α-$Ca_2P_2O_7$:Eu^{+2} prepared by firing at 1200°C and a reference phosphor, $CaWO_4$:Pb. The last column in this table lists the intensities of the Ba-stabilized α-$Ca_2P_2O_7$:Eu^{+2} phosphors, which even though fairly intense, are only about two-thirds of the intensity of the unstabilized α-$Ca_2P_2O_7$:Eu^{+2} phosphor obtained from a 1200°C firing.

Also in Table IV are the data for changes of emission peak positions and changes in band widths at half-height for varying compositions at the two firing temperatures. For the compositions fired at 1000°C, there was a shifting of the emission peak from 424 nm for β-$Ca_2P_2O_7$:Eu^{+2} to 460 nm for the $Ba_{1.25}Ca_{0.75}$ composition as Ba was substituted for Ca. There was also a substantial increase in the band width at half-height changing from 40 nm for β-$Ca_2P_2O_7$:Eu^{+2} to 97 nm for the $Ba_{1.25}Ca_{0.75}$ composition. Peak positions and widths at half-height of compositions with a greater Ba concentration of 1.25 could not be measured because of low emission intensity.

The changes that occurred in the emission peak positions and the emission band widths at half-height for the 1120°C fired compositions were considerably less than those that were fired at 1000°C. Emission peaks shifted only over a range from 428 nm for β-$Ca_2P_2O_7$:Eu^{+2} to 447 nm for both the $Ba_{0.5}Ca_{1.5}$ and $Ba_{0.75}Ca_{1.25}$ compositions, and the band widths at half-height ranged from 40 nm for β-$Ca_2P_2O_7$:Eu^{+2} to 61 nm for

Table IV. Emission properties of Ba-Ca pyrophosphate compositions

$Ba_{1.5}Ca_{0.5}$ with the majority of the compositions having a width at half-height between 52 and 56 nm.

Summary

Bright Eu^{+2} activated phosphors exist in the Ba-Ca, Ba-Sr, and Ca-Sr orthophosphate and pyrophosphate compositions. In the orthophosphate compositions the brightest phosphors were $Ba_3(PO_4)_2:Eu^{+2}$ and α-$Sr_3(PO_4)_2:Eu^{+2}$, and various composition mixtures of the two. α- and β-$Ca_3(PO_4)_2:Eu^{+2}$, and β-$Sr_3(PO_4)_2:Eu^{+2}$ resulted in either low intensity or dead phosphors, as did the majority of the phosphors that were obtained from composition mixtures of these poor phosphors with the two bright phosphors.

The substitution of small amounts of Ba in $Ca_3(PO_4)_2$ had a tendency to stabilize α-$Ca_3(PO_4)_2$ rather than β-$Ca_3(PO_4)_2$ even at temperatures considerably below the normal β to α transition temperature of 1180°C. A new compound with the formula $Ba_2Ca(PO_4)_2$ was also discovered in the $Ba_3(PO_4)_2$-$Ca_3(PO_4)_2$ system.

In the pyrophosphate compositions the brightest phosphors were α-$Ca_2P_2O_7:Eu^{+2}$ and α-$Sr_2P_2O_7:Eu^{+2}$. Weak or dead phosphors were obtained with α and δ-$Ba_2P_2O_7:Eu^{+2}$, β-$Ca_2P_2O_7:Eu^{+2}$, and β-$Sr_2P_2O_7:Eu^{+2}$. Mixtures of α-$Ca_2P_2O_7:Eu^{+2}$ and α-$Sr_2P_2O_7:Eu^{+2}$ resulted in bright phosphors, while composition mixtures of either of these two bright phosphors with any of the weak or dead pyrophosphate phosphors resulted in phosphor compositions with reduced intensities caused by the dilution of the good phosphors by the poor phosphors.

The brightest phosphors found in the present study, α-$Sr_3(PO_4)_2:Eu^{+2}$, $Ba_3(PO_4)_2:Eu^{+2}$, α-$Sr_2P_2O_7:Eu^{+2}$, and α-$Ca_2P_2O_7:Eu^{+2}$ were all from 200 to 400% more intense than the $CaWO_4$:Pb reference phosphor. Many of the partially substituted phosphors were also considerably more intense than $CaWO_4$:Pb, but, in almost every case, less intense than the unsubstituted materials.

Acknowledgments

The author wishes to thank Mr. Allen Rudis and Miss Marion Skeadas for the spectral energy distribution and x-ray diffraction measurements and Dr. K. H. Butler and Dr. M. J. B. Thomas for helpful discussions and suggestions.

Preparation and Properties of Bulk $In_{1-x}Ga_xAs$ Alloys

John W. Wagner

Electronic Materials Division, Bell & Howell Company, Pasadena, California 91109

ABSTRACT

Single crystals of $In_{1-x}Ga_xAs$ have been grown by Czochralski techniques for $0.0 \leq x \leq 0.2$ and $0.8 \leq x \leq 1.0$. Polycrystalline single-phase $In_{1-x}Ga_xAs$ material has also been pulled for $0.2 < x < 0.8$. Two Czochralski techniques were employed: (*i*) the sealed system or Gremmelmaier technique, and (*ii*) the liquid encapsulation technique. Mass spectrographic data have been correlated with alloy lattice parameter determinations on the as-grown material to yield information on the solidus curve of the InAs-GaAs system. Hall measurements were made and impurity analyses were performed using the spark source mass spectrometer.

Since Woolley and Smith (1) initially demonstrated that continuous solid solution occurs in the InAs-GaAs system, a number of investigators have prepared homogeneous, single-phase $In_{1-x}Ga_xAs$ alloys throughout the entire range of composition using directional freezing techniques (2-4), zone-leveling techniques (5, 6), and vapor-growth techniques (7-10). These material investigations have been generated by the attractive thermoelectric properties of the InAs-GaAs alloys and by their light-emitting capabilities. Of the above studies, only the vapor epitaxial experiments have produced single-crystal alloys throughout the entire composition range. Diodes fabricated from these epitaxial layers have exhibited coherent light emission from 0.84μ for GaAs to 3.1μ for InAs.

Bulk single crystals of $In_{1-x}Ga_xAs$ are desirable for many applications. The work reported herein involves the growth of such single crystals by Czochralski pulling from the melt. When growing volatile materials from the melt at high temperatures, the Czochralski technique has several advantages (and disadvantages) when compared with directional freezing and zone leveling. The most important advantage is the direct three-dimensional observation of the growth process. One can therefore observe if the growing material is a single crystal or is polycrystalline, and can then determine whether to continue growth or to reseed and begin again. Visual observation is extremely difficult to achieve in directional freezing and zone-leveling processes when volatile materials at high temperatures are involved.

Key words: semiconductor, alloys, indium-gallium arsenide, crystal growth, Czochralski method, phase diagram, electrical properties.

Crystal Growth

The growth of $In_{1-x}Ga_xAs$ crystals from the melt required the use of special growth techniques in order to contain the volatile arsenic in the melts. Two tech-

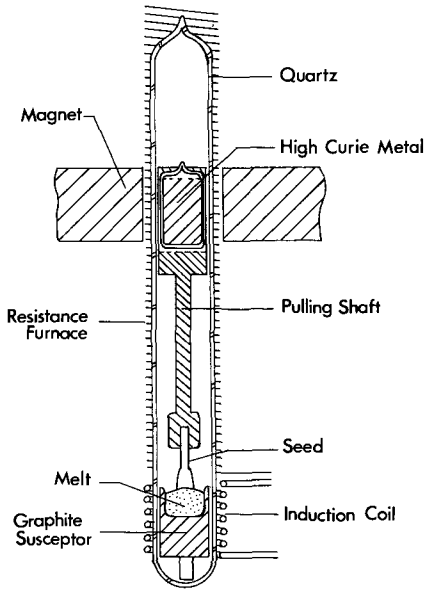

Fig. 1. Diagram of apparatus used for pulling crystals by the Czochralski technique [after Gremmelmaier (11)].

niques were used in this study: (*i*) Czochralski growth by maintaining a partial pressure of arsenic throughout the growing chamber (Gremmelmaier technique), and (*ii*) Czochralski growth by covering the melt with a transparent liquid (liquid encapsulation).

Sealed system.—In order to maintain a partial pressure of arsenic throughout the growing chamber, adaptations were made on the sealed all-quartz pulling apparatus used by Gremmelmaier (11). Figure 1 is a diagram of this system. Quartz was used as the growing chamber due to the reaction of the volatile arsenic with most other materials. Since the growing chamber is completely sealed, rotation and pulling were accomplished by magnetic coupling through the quartz tube. The entire growing chamber was enclosed in a resistance-heated furnace in order to hold an excess amount of arsenic in the vapor state and thus establish the required partial pressure. In order to grow from a stoichiometric melt, the partial pressure of arsenic had to be varied when growing different compositions of the alloy by changing the amount of the excess arsenic in the system. The partial pressures of arsenic over the InAs and GaAs melts were 0.2 and 1.0 atm, respectively. The partial pressures were calculated by using a two-to-one ratio for the As_4 to As_2 molecules. It was assumed that the partial pressures of arsenic necessary to maintain approximately stoichiometric melts for the alloys would vary linearly over this 0.2-1.0 atm range, *i.e.*, a melt containing 50 m/o (mole per cent) InAs and 50 m/o GaAs would need a pressure of 0.6 atm.

The indium-gallium alloy was melted by rf coupling (450 kc) and then was allowed to react with the arsenic at high temperature. Invariably, quartz crucibles were used. During the initial experiments, the rf was allowed to couple directly to the melts. However, direct coupling was found to yield unwanted thermal fluctuations in the melt (as evidenced by polycrystalline boules containing very small grains, less than 100μ in the largest dimension). Therefore, a graphite susceptor was placed around the quartz crucible. By allowing the rf to couple to the graphite susceptor, improved thermal stability was attained in the melt. All boules reported herein which were grown using the Gremmelmaier technique were pulled from melts heated indirectly via a graphite susceptor. In order to minimize contamination problems from the graphite (Grade UT-6, Ultra Carbon Corporation), the susceptor was baked out for several hours under vacuum at high temperatures, typically 1000°C and sealed in quartz. The temperature sensing device was a sapphire rod which transmitted the radiant energy from the base of the crucible to a thermopile. The growth temperatures ranged from 938°C for InAs to 1238°C for GaAs.

Liquid encapsulation.—The alternative to establishing a partial pressure of arsenic over the melt to maintain stoichiometry is to contain the arsenic using the liquid encapsulation technique (12-14). By covering the melt with liquid boric oxide (B_2O_3) and maintaining on the outer surface of the liquid an inert gas pressure, which was greater than the vapor pressure of the arsenic at the melt surface, volatilization was suppressed. Boric oxide was chosen in this study because it was less dense than the melts, was optically transparent, and was virtually nonreactive with the melt constituents. The hygroscopic nature of the boric oxide necessitated vacuum heat treating (10^{-4} Torr) at approximately 1000°C for 24 hr. If the heat treatment was not performed, numerous gas bubbles existed on the melt surface while trying to pull.

A schematic diagram of the liquid encapsulation growth apparatus is shown in Fig. 2. The quartz tube is sealed at both ends by O-ring flanges so that a vacuum or a positive pressure may be maintained in the growth chamber. The pull rod and the crucible may both be rotated. Heating was by resistance furnace (rf coupling is also possible with this technique), and the temperature was sensed by a thermocouple. The thermocouple was placed near the heater element so as to obtain as high a sensitivity as possible. The temperature near the element was controlled to within $\pm\frac{1}{4}$°C. The seed was lowered through the boric oxide to the melt surface and the crystal was pulled slowly through the B_2O_3. Often the boric oxide was so viscous that a thin layer remained on the crystal as it was pulled out of the B_2O_3. This was actually desirable, since if the boric oxide were permitted to flow off the crystal too rapidly, the crystal would still be in a relatively hot zone and would lose a substantial amount of arsenic from the crystal surface by vaporization. This arsenic would then cause a problem with visibility as it deposited on the cooler sections of the quartz tube. The thin layer of B_2O_3 remaining on the crystal was not a problem, since it was easily removed by dissolution in hot water.

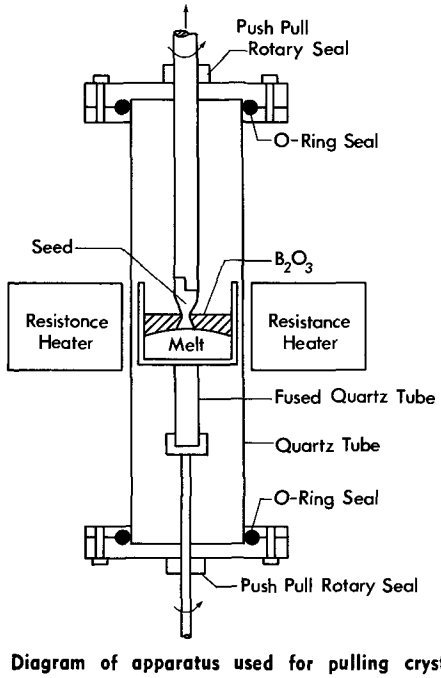

Fig. 2. Diagram of apparatus used for pulling crystals under B_2O_3 glass.

The liquid encapsulation technique offers several advantages over the Gremmelmaier technique. First, the boric oxide glass provides thermal insulation at the surface, minimizing gaseous convection currents, and yielding greater thermal stability at the melt surface. Second, the liquid encapsulation allows pulling and rotating by direct mechanical means, thereby ensuring less vibration in the system. Third, the boric oxide layer tends to allow the establishment of better thermal gradients across the melt surface (as judged by the relative ease of obtaining a nearly flat growth interface).

General.—Single crystals of $In_{1-x}Ga_xAs$ were prepared for $0.0 \leq x \leq 0.2$ and $0.8 \leq x \leq 1.0$ using both the Gremmelmaier and liquid encapsulation techniques. All of the single crystals were grown in the {111} direction. The crystals were typically 10-30g in weight and were 5-10 mm in diameter. The melts used ranged in size from 100 to 300g. Polycrystalline, single-phase material was also produced for $0.2 < x < 0.8$. For crystals grown using the Gremmelmaier technique pulling rates were varied from 1 cm/hr to as low as 1 mm/hr. Crystals grown using the liquid encapsulation technique were pulled at rates of 1-3 mm/hr. In both techniques, seeding required undercutting of the seed diameter to 1-2 mm for a length of up to 3 cm in order to reduce crystal strains. This is especially important in growing the alloys, since strains due to initial lattice mismatch between the seed and the first portion of the alloy to be grown are quite important.

Phase Diagram

The phase diagram of the InAs-GaAs system has been reported by several investigators (6, 15, 16). Agreement is lacking between the investigators and, therefore, in order to have control of the composition of each crystal grown, the InAs-GaAs phase diagram was investigated in this study.

The compositions of the first-to-freeze portions of several $In_{1-x}Ga_xAs$ ingots grown in this study were determined using spark-source mass spectrographic analyses. The estimated accuracy of these compositions is ±10% of the values given. The lattice parameters, a_o, from these first-to-freeze sections were determined from x-ray powder photographs using the $\sin^2\theta$ extrapolation technique. The accuracy of these parameters is estimated to be ±0.001Å. The resulting data are listed in Table I. Correlation of the mass spectrographic data with the lattice parameters indicates that Vegard's law is followed in this system, a fact which has been previously shown by several investigators (1, 6, 7). Therefore, the final composition of each first-to-freeze portion was determined under the assumption that Vegard's law holds in the InAs-GaAs system throughout the entire range of composition.

Once the composition of the first-to-freeze portion of each crystal had been determined, the solidus points of this system were then plotted using the liquidus curve given by Van Hook and Lenker (16). The resulting phase diagram is shown in Fig. 3. Also shown are the solidus data of Van Hook and Lenker (16), Woolley and Smith (15), and Hockings *et al.* (6). Our solidus data are seen to be in good agreement with those of Woolley and Smith (15) and Hockings *et al.* (6) who also used Vegard's law for composition determinations. Since we have used the liquidus curve of Van Hook and Lenker (16) in plotting the solidus, the good agreement between our solidus and that of Woolley and Smith (15) (who used an anneal-quench-x-ray technique to obtain these solidus values) and Hockings *et al.* (6) suggests that this liquidus is essentially correct. However, the solidus curve of Van Hook and Lenker (16) is believed to be incorrect for temperatures of less than 1025°C due to nonequilibration of their alloy samples at the relatively low temperatures. Stringfellow and Greene (17) have calculated the pseudobinary phase diagram of the InAs-GaAs system and their calculated solidus curve is in reasonable agreement with that shown here of Woolley and Smith (15), Hockings *et al.* (6), and the present paper.

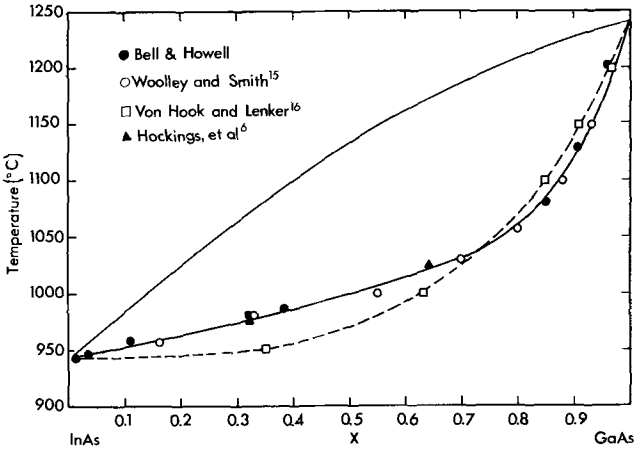

Fig. 3. Phase diagram of the $In_{1-x}Ga_xAs$ system

Characterization

As previously mentioned, x-ray powder patterns were used to determine the lattice parameter of each $In_{1-x}Ga_xAs$ ingot grown, and these parameters were compared with the Vegard line to determine the compositions of these ingots. X-ray Laue patterns were made to yield a qualitative indication of crystal perfection and to verify the single-crystal nature of several of the ingots. Most of the powder photographs and Laue photographs had sharp lines and spots, respectively, which indicate that the materials are relatively free of strains and compositional inhomogeneities.

Electrical measurements were made using conventional d-c potentiometric techniques to determine Hall coefficients and resistivities. The Hall mobilities and carrier concentrations were then calculated using the equations $\mu = R\sigma$ and $n = 1/Re$. The standard Hall sample was a bridge-type rectangular parallelopiped with dimensions of ~1 mm thickness, ~1 mm width, and ~1 cm length. These samples were always taken from the area of the boule just below the "crown" and were all representative of the "first-to-grow" section of the ingot. The sample was ultrasonically cut so as to have several arms to which the electrical contacts were attached. The resulting data are shown in Table II, and the electron mobilities at 300° and 77°K of our best $In_{1-x}Ga_xAs$ samples are plotted *vs.* composition in Fig. 4. Also plotted in Fig. 4 are electron mobility data at 300°K taken from Conrad *et al.* (9) which were measured on vapor-epitaxially deposited InAs-GaAs alloys on GaAs substrates. The data of Conrad *et al.* (9) indicate a minimum in electron mobility near the midrange of composition, which was suspected to be due to alloy scattering. However,

our room temperature (and also 77°K) data do not indicate a minimum in the mobility curve. Also, the electron mobilities of our InAs-GaAs samples increase from 300° to 77°K in contrast to the results reported by Conrad *et al.* (9) This implies that scattering from an unknown charged center (which was apparently seen in the vapor epitaxial material) is not present in melt-grown material.

Several of the $In_{1-x}Ga_xAs$ crystals were analyzed for impurities using the spark-source mass spectrometer. An impurity analysis which is typical for crystals containing 0.05-0.10 mole fraction GaAs is given in Table III. Silicon and sulfur are the most important of the major electrically active impurities. Analyses of the elemental arsenic show both of these impurities in quantities of such a magnitude as to account for their concentration in the $In_{1-x}Ga_xAs$ after consideration of the appropriate distribution coefficients. Both the silicon and sulfur can be removed from the arsenic by several purification steps, and in our laboratory such purification has yielded GaAs crystals having Si and S levels of an order of magnitude lower than those given in Table III for the alloys. In fact, GaAs crystals have been grown from quartz crucibles with carrier concentrations as low as 2×10^{15} cm^{-3} and room temperature mobilities of 8600 cm^2 V^{-1} sec^{-1}. These results indicate the quartz crucible and chamber do not significantly add silicon to the melt. However, care must be taken not to allow the melt temperature to exceed 1260°C. At 1300°C silicon pickup from the crucible can exceed 1 ppm. No difference was seen in the levels of electrically active impurities in crystals grown by the two techniques, *i.e.*, they typically contained approximately 1 ppm of such impurities.

Conclusion

Single crystal $In_{1-x}Ga_xAs$ alloys have been pulled from the melt using both the Gremmelmaier and liquid encapsulation techniques. Although only polycrystalline materials were prepared for $0.2 < x < 0.8$, it is believed that single crystals can be pulled from the melt throughout the entire composition range if greater mechanical and thermal stability is provided, slower growth rates are employed, and higher quality seeds are generated, *i.e.*, single-crystal seeds with compositions matching that of the crystals to be grown. The solidus for the InAs-GaAs system was determined and our results are in agreement with Woolley and Smith (15) and Hockings *et al.* (6). The electron mobilities of the InAs-GaAs crystals did not show a minimum with respect to composition and increased on cooling from 300° to 77°K.

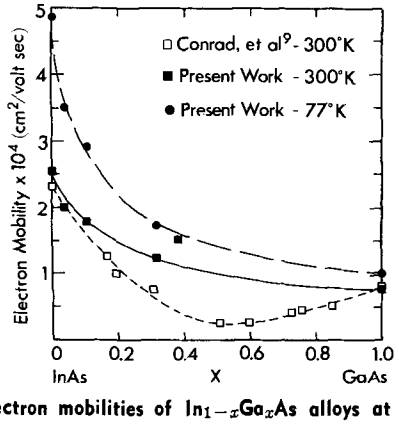

Fig. 4. Electron mobilities of $In_{1-x}Ga_xAs$ alloys at 300°K and 77°K.

Table III. Typical impurity analysis of InAs-GaAs (parts per million atomic)

Element*	Detection limit**	Concentration in crystal
Li	0.03	5.0
C	0.3	5.0
N	0.3	1.0
O	0.3	5.0
F	0.3	0.4
Al	0.1	0.2

Technical Notes

Argon Content in (111) Silicon for Sputtering Energies below 200 eV

J. Comas and E. A. Wolicki

Naval Research Laboratory, Washington, D. C. 20390

A technique for detecting implanted argon in silicon by the neutron activation of argon has been described and data have been given in the 200 to 2200 eV bombarding range (1). These data showed that the argon content rises very sharply from around 225 eV and appears to approach a plateau around 2200 eV. We have been able to extend the low energy implantation data well below 200 eV by improving the shielding and the counting system for the radioactive argon. In addition absolute calibration of the counting system has been obtained from standard Ar-Si samples. In this communication we present data on argon implanted in (111) Si below 200 eV for bombarding currents of 1 and 2 mA and from 50 to 2200 eV at 1 mA. The low energy, high beam intensity, range is of special interest in sputtering experiments and the argon trapping presented go much lower in energy than most studies. The bombarding argon energies as stated do not include corrections due to the plasma potential; this would increase the argon bombarding energies by about 5.0 eV.

The targets used were thin (111) Si wafers about 25 mm in diameter. The bombarded surface area, defined by a graphite guard ring, was 3.14 cm^2. Prior to being bombarded, the wafers were chemically etched in a modified CP_4 solution and rinsed with ethyl alcohol. The etching produced a shiny smooth surface and reduced the sample thickness to about 0.060 in. Thin Si samples were used in order to minimize the interference from the Si^{31} beta activity produced by the neutron irradiation, which introduces counting errors, as well as being a considerable health hazard.

The bombarding apparatus for the bombardment at 200 eV and above is similar to that previously described (1). An argon ion beam is drawn through a screen placed at the edge of a thermionically sustained, magnetically confined, arc discharge. Argon ions that pass through the screen are further accelerated between the screen and the target by applying a negative potential on the target with respect to the screen. For bombardments below 200 eV the screen is removed and the target is placed in its position mounted on a graphite holder (2). The target is biased negatively with respect to the arc discharge and bombarded normally with argon ions drawn from the arc. In this position the target acts like a large Langmuir probe placed in a plasma, and low energy, high intensity, bombarding beams can be readily obtained. The bombarding times of 10 min were long enough to produce an equilibrium condition between the incident argon beam and the trapped argon being released as the Si surface is sputtered away. The accuracy of the bombarding current measurement is 3.5%.

After argon bombardment the targets were removed from the sputtering apparatus and placed in NRL's nuclear reactor for activation. A lithium-drifted germanium detector was used to obtain the gamma ray spectrum of the radioactive Ar^{41} and Si^{31} produced (1.293 and 1.265 MeV, respectively). A small Ar background, due to the activation of natural argon in the air by the reactor, was eliminated by shielding of the detection system. A graded shield made of ⅛ in. plates of lucite, lead, and aluminum [aluminum plate against the Ge(Li) detector] greatly reduced the "cooling" time. The procedure more than doubled the number of events from Ar^{40} recorded in the gamma ray spectrum.

Absolute calibration of the counting efficiency was accomplished by using Si samples which were bombarded at 3.0 MeV with a known number of argon ions, and which were otherwise similar to the samples used for the sputtering runs. It is reasonable to assume that all the Ar ions at this energy are trapped, since the sticking probability approaches unity for energies above 20 KeV (3). Less than 10^{-5} % of the implanted argon in a Si wafer undergoes transmutation for each 1 hr exposure in the reactor. The prepared Si-Ar calibration standard was then activated and counted under the same conditions as the low energy argon sputtered targets; in this way a calibration for the system was obtained which required no further corrections.

The NRL Van de Graaff accelerator was used to produce the 3.0 MeV beam of Ar^{40} ions. The beam was magnetically analyzed before striking the target and, to insure uniform irradiation over the bombarded area, the beam spot was scanned electrostatically. Tests were made for the presence of a neutral beam component which would contribute to the implanted Ar content, but not be measured as part of the integrated beam charge. The neutral component was obtained by comparing the coloration produced in LiF by a given dose of 3.0 MeV Ar^{40} ions (4), to the coloration produced when the charged beam was removed from the target by a deflecting voltage. Three permanent magnets were also placed along the beam transport tube between the deflecting plates and the target in order to remove any particles which were ionized after passing through the deflecting plates. The neutral beam component obtained from the coloration measurements was found to be less than 3% of the total charge delivered to the target.

The number of incident 3.0 MeV Ar ions was obtained from the total electrical charge which was collected in a Faraday cup arrangement and integrated during bombardment. A negatively biased guard ring was placed at the entrance of the chamber to suppress secondary electrons. The beam size (as measured on a quartz plate) was about 1.6 cm^2 and the bombarding beam current was 1.5 μA. For each of three samples, 9.59×10^{15} argon ions were implanted; a fourth sample was bombarded with 3.84×10^{16} argon ions as a test for saturation and none was observed. The (111), (110), and (100) orientations were used in different bombardments to test for any orientation dependence which might occur; as would be expected in the MeV range, no orientation dependence was observed in the argon content. The argon content in a 3.0 MeV Ar implanted Si sample was also examined as a function

Key words: ion implantation, activation analysis, ion-atom collisions, surface interactions, ion trapping.

of temperature. The sample was heated in vacuum for 15 min in 100°C steps. No significant change in the argon content was observed until near melting temperatures were reached. This is consistent with the observations of Kelly and Brown (5) on the release of 40 KeV Xe^+ ions injected into Al, Ta_2O_3, and Al_2O_3.

The argon content in each Si target was obtained by considering the initial argon activity, integrating the argon signal, and using the counter efficiency as measured from the 3.0 MeV Ar-Si standards. Results of a series of bombardments from 12 to 200 eV for a bombarding beam of 2 mA and from 50 to 200 eV for a 1 mA beam are shown in Fig. 1. The argon content rises very sharply from approximately 7.6 x 10^{13} Ar/cm^2 at 12 eV to approximately 1.1 x 10^{16} Ar/cm^2 at 85 eV for the 2 mA curve. The same sharp initial increase is seen in the 1 mA case. Above 85 eV the rise is not as drastic and at 200 eV the amount retained is approximately 2.15 x 10^{16} Ar/cm^2. In Fig. 2 the argon content for a 1 mA beam is shown for a series of bombardments from 50 to 2200 eV; data in the 50-200 eV range was taken from Fig. 1. Above 800 eV there is a gradual increase in the argon content to about 7.0 x 10^{16} Ar cm^2. It appears from the above results that the threshold for the trapping of argon in Si is in the same range as the threshold for sputtering, around 20 eV, as estimated by extrapolation of Ar-Si yield curve of Wolsky and Zdaunk (6).

The above curves resemble the rapid rise in the W(100) sticking probability *vs.* ion energy curves of Ne, Ar, Kr, and Xe of Kornelsen and Sinha (7). The

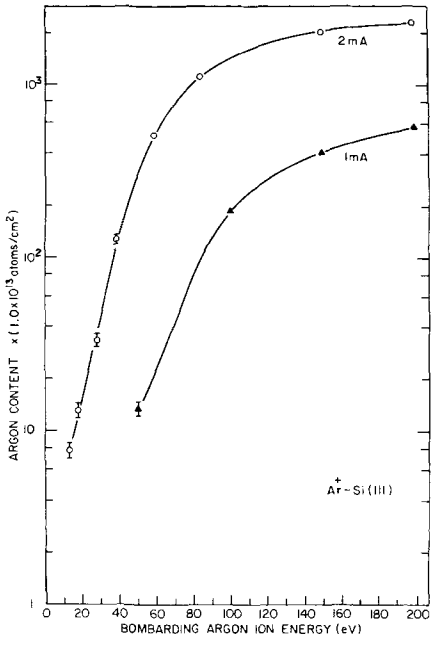

Fig. 1. Argon content in (111) Si *vs.* argon ion energy from 12 to 200 eV for a 2 mA beam and from 50 to 200 eV for a 1 mA beam. Absolute calibration was obtained by using an Ar-Si standard with a known number of trapped argon atoms.

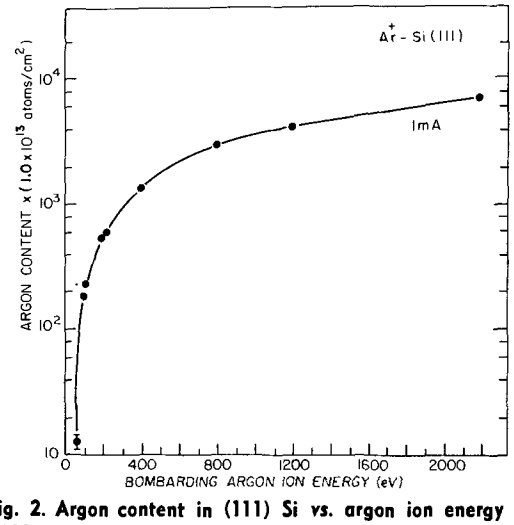

Fig. 2. Argon content in (111) Si *vs.* argon ion energy from 50 to 2200 eV for a 1 mA beam.

sticking probability of Ar goes from about 1.5 x 10^{-3} at 100 eV to about 0.41 at 1 KeV. They obtained desorption spectra from W(100) bombarded with Ne, Ar, Kr, and Xe from 40 eV to 5 KeV. The desorption spectra at low energies shows the influence that the surface has in the trapping process. The Ne desorption spectrum at 40 eV for a dose of 1.5 x 10^{13} ions/cm^2 showed no detectable desorption. Ne was the lowest energy spectrum presented and had a Ne detection limit of ~3 x 10^{10} atoms/cm^2. Distinct Ne desorption peaks were observed, however, from the 60 eV bombardment.

Our results cannot be compared directly since the doses in our bombardments are considerably higher (1.9 x 10^{19} ions/cm^2 for the 2 mA case), and the argon is detected *in situ*. We, however, observe significant trapping for the 2 mA bombardment below 60 eV. The difference in the argon content between the 1 and 2 mA curves is believed due to the trapping of argon at sites on or near the surface which are created during the bombardment, as well as bombarding argon-trapped argon collisions on the surface.

Negative Surface Charge in Ge MOS Structures

T. O. Sedgwick* and S. Krongelb

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

It has been reported (1, 2) previously that Ge surfaces covered with deposited SiO_2 films and subjected to hydrogen annealing exhibit a midgap surface acceptor state, and either a second acceptor state near the valence band or fixed negative charge in the oxide. This second negative charge center was observed to appear prominently only after hydrogen annealing at 800°C, although it could be removed simply by inert gas annealing. Such formation and removal conditions are somewhat different from those for the hydrogen-induced midgap acceptor state. We have recently found that negative oxide charge also appeared in Al-SiO_2-Ge MOS devices, but not in Au-SiO_2-Ge MOS structures, when they were annealed with the metal in place. This note presents this data and indicates that the negative charge is due to exposure of the surface to atomic hydrogen. It also shows that the negative charge appears in high density on Ge <110> surfaces and only in moderate density on Ge <111> surfaces. Si samples do not show any negative surface charge formation when subjected to equivalent processing.

Experimental

Samples were prepared by coating 1 to 10 ohm-cm p-type Ge or Si wafers with 300-2000Å pyrolytic SiO_2 (3).

Final premetallization annealing.—All samples were then annealed in 10% H_2-90% N_2 at 800°C for 17 min, henceforth referred to simply as H_2 annealing. Some of these samples had a final anneal in air at 230°C for about 17 hr or for shorter times in dry O_2 at 420°C, henceforth referred to as O_2 annealing. A few Ge <110> samples received a final anneal in dry N_2 at 650°C for 5-60 min. Finally, approximately 5000Å Al or Au field plate dots about 30 mil in diameter were evaporated (metallization) onto the oxide (the samples were not intentionally heated during evaporation and their temperature probably did not exceed 75°C for more than a few minutes). The fixed charge density, Q_{fc}, of these MOS devices was determined by capacitance-voltage measurements and the results are shown in Fig. 1.

Post metallization annealing.—After the above-mentioned annealing steps and initial measurements, some of the same samples were then annealed with the Al or Au dots in place for about 17 hr in air at 230°C. The fixed charge density Q_{fc} was remeasured and the results are shown in Fig. 2.

It was necessary to use a variation (1, 2) of the usual MOS measurements technique to measure Q_{fc} in the Ge samples. In this method, capacitance voltage curves are determined at 150 kHz and at 77°K. The advantage of this technique is that the midgap surface acceptor states introduced by hydrogen annealing cannot follow the a-c measuring signal, and do not therefore introduce excess capacitance[1] which would cause an error in the Q_{fc} determination. Q_{fc} is determined simply by measuring the voltage shift at the flat band point. The inability of this technique to distinguish between surface states lying very close to the valence band and fixed oxide charges has been discussed previously (1). The silicon samples were measured at 150

[1] This excess capacitance in the case of some Ge samples is so large that at room temperature the normal MOS capacitance "dip" is not seen at all.

kHz and room temperature[2] and exhibited the normal MOS capacitance "dip."

Results

Figure 1 shows the effect of the final premetallization annealing ambient on Q_{fc} for <110> and <111> oriented Ge and Si surfaces. Large negative Q_{fc} values only occur on Ge <110> surfaces exposed to H_2. Ge <111> surfaces subject to H_2 annealing show a small tendency toward negative Q_{fc} values. Note that Ge <110> samples subjected to the usual hydrogen anneal, but then finally annealed in dry N_2 show the usual positive Q_{fc} found for O_2 annealed samples. Si samples show a shift of opposite sign in Q_{fc} after hydrogen annealing.

Figure 2 shows the effect of post-metallization annealing, and the dependence of this effect on the last premetallization annealing ambient for the two Ge orientations. The lines connect before and after results on the same device. All samples show some negative shift of Q_{fc} on annealing with Al dots. The largest shifts are observed on samples which have received H_2 treatment as their final premetallization annealing with Ge <110> surfaces showing shifts of 5×10^{12} and Ge <111> surfaces exhibiting the slightly smaller change of 3×10^{12}. O_2 annealed samples show the smallest negative Q_{fc} shift (approximately 1×10^{12}), and this shift has saturated and does not increase on further post-metallization annealing. The increase in negative Q_{fc} for the H_2 annealed samples, on the other hand, was found not to be saturated after the 17 hr post-metallization anneal. Thus on further post-metallization annealing there is further significant increase in the negative fixed charge. For example, an additional 11-day anneal (not shown in Fig. 2) at 230°C increased the negative Q_{fc} of two samples by an additional $3.5\text{-}4.5 \times 10^{12}/cm^2$.

In neither Fig. 1 nor 2 was there a correlation between measured Q_{fc} and oxide thickness in the range 300-2000Å, although an attempt was made to find such a correlation.

Samples provided with Au dots and subjected to the same annealing cycles as indicated in Fig. 2 showed very small shifts in Q_{fc}. In one case, samples provided with Au dots showed no increase in negative charge, and in a second case Au dot samples showed a factor of ten smaller increase in negative charge than the control sample which was an identically treated Al-SiO_2-Ge MOS device.

Discussion

The appearance in Fig. 1 of a large but variable negative Q_{fc} on Ge <110> and to a lesser extent on Ge <111> surfaces correlates clearly with hydrogen exposure. Since we observe the same pattern of occurrence in Fig. 2 for samples annealed with Al (but not Au!) dots in place, we hypothesize that this effect is also due to hydrogen which has presumably been produced by the reaction of Al with residual water or hydroxyl groups in the SiO_2 layer. There are two additional pieces of evidence which lend support to this same hypothesis. First, it has been shown that SiO_2 films on Ge which contain water have an abnormally high dielectric constant. Annealing such films with Al dots reduces the dieletric constant, an effect which is attributed to the removal of water by reaction with Al (4). Second, in the Si planar transistor technology, a similar annealing is believed to produce atomic hydrogen which diffuses through the oxide and eliminates fast surface states at the Si interface (5).

A p-type electrical effect due to hydrogen exposure was noted by Heiland and Handler (6) who observed a strong increase in the p-type surface conductivity on clean <111> Ge after exposure to atomic hydrogen which could be removed readily by vacuum annealing at 550°C for ½ hr. Molecular hydrogen seems to have no effect electrically on clean surfaces at room temperature (7), and it is essentially completely desorbed above 280°C (7, 8). Therefore, it is suggested that atomic hydrogen is the active species which is physically trapped at the interface by the oxide layer. The trace of atomic hydrogen present at equilibrium in hydrogen gas at 800°C (9) could account for the results of Fig. 1, and the reduction of hydroxyl or water at 230°C by Al to yield atomic hydrogen could account for the results of Fig. 2. The fact that the negative Q_{fc} is very rapidly removed by an inert gas anneal at 650°C suggests that the hydrogen is loosely bound near the Ge surface and readily out-diffuses through the SiO_2 layer, although much more slowly than would occur from a Ge surface not covered with a deposited oxide layer.

It does not seem possible to postulate a convincing structural model for the interaction of atomic hydrogen with Ge surfaces. We note, however, that a similar p-type shift in Ge surface potential has been observed by Gerischer *et al.* (10) and Memming and Neumann (11). They observe a p-type surface potential shift from capacitance voltage measurements after the surface has been reduced by cathodic polarization in aqueous solution. They postulate that the reduced surface is covered with →GeH groups.

We have also not been able to satisfactorily explain why only Ge <110> surfaces show a marked negative surface charge effect, while Ge <111> surfaces show a smaller effect. Neither can we offer the reason why Si <111> and <110> surfaces exposed to the same reducing treatments show no effect whatsoever.

[2] Since the p-type Si samples were measured at room temperature, the charge density results may be in error by indicating a too large negative (or too small positive) oxide charge. This does not influence our conclusions, however.

On the Origin of Diamagnetism in MgO and CdO

T. Mookherji

Physical Sciences Research Laboratories, Teledyne Brown Engineering, Huntsville, Alabama 35807

The solid state properties of semiconductors have been the subject of many studies from both experimental and theoretical points of view. Group II-Group VI semiconductors have been studied by many workers because of their interesting properties and some, for example ZnO, have space applications as thermal control coating pigment. The magnetic susceptibility of some of these has recently been measured (1, 2).

The present investigation includes the accurate measurement of the diamagnetic susceptibility of MgO and CdO and a description of the type of bonding in these substances by a theoretical calculation of the susceptibility. This is part of a program to find other materials suitable for space application which will supplement ZnO.

The susceptibility at room temperature is measured with a quartz-microbalance (3) by the method of Mookherji (4), the sensitivity and accuracy of which are already established. The chemicals used were Matheson Coleman & Bell's Reagent grade which meets the ACS specifications. The substances, in the form of powder, were packed in small glass ampoules for measurement. The susceptibility of the ampoules was predetermined and taken into account in the calculation. This was necessary since diamagnetic susceptibility of CdO and MgO is very small. Two types of calibration standards were used: freshly prepared triclinic single crystal of $CuSO_4 \cdot 5H_2O$, whose susceptibility, χ_1, along the c-axis is accurately known (3), is used where the total susceptibility of the system is paramagnetic; and very pure carbon tetrachloride (4), where the total susceptibility is diamagnetic. The measured susceptibility values are shown in Table II.

There is some difference between our measured values and that reported in the literature (5, 6) where the measurements were made using Gouy method. The microbalance technique employed for the present measurements is free from the sources of errors encountered with Gouy method and has much higher sensitivity and accuracy. Moreover, ref. (5, 6) used KCl as standard substance. The measured values given in (5, 6) are always less than that measured by the author and given in (2). This difference is probably due to the increased sensitivity and accuracy of the present method.

In a semiconductor, the total magnetic susceptibility is the net effect of the susceptibility due to the lattice, χ_L, the free charge carrier susceptibility, χ_c, and the susceptibility of the impurity atoms χ_i and is expressed as

$$\chi = \chi_L + \chi_c + \chi_i$$

The lattice susceptibility can be expressed as

$$\chi = \chi_1 + \chi_2$$

Key words: diamagnetism, metal oxide, covalent bond, partial ionic character.

O	$1s^2$, $2s^2$	$2p^{4.45}$	−1.45	−5.48	−6.93

where χ_1 is the susceptibility of the inner electrons of the lattice atoms and χ_2, the susceptibility due to the valence electrons of the lattice atoms.

There are different methods to calculate each of these susceptibilities separately. At present, we only consider χ_L as it contributes most to the diamagnetic susceptibility.

Calculations were first made by assuming that both inner and valence electrons obey the Langevin equation

$$\chi = -\frac{Ne^2}{6mc^2}\sum \overline{r_i^2}$$

where the symbols have their usual meaning. The values of $\overline{r_i^2}$ were calculated by the method of Slater (7), as modified by Angus (8). This calculation was carried out for the electronic structures $A^{++}B^{--}$ and $A^{--}B^{++}$, where A is the metal atom and B is the nonmetal atom. The susceptibility values thus obtained are found to be very different from the experimental values.

Since the experimental susceptibilities could not be accounted for by the above method, the method of covalent bonding with partial ionic character was tried, with the inner electron susceptibility, χ_1, calculated as before, since this method gives fairly good results for some II-VI compounds.

Following Pauling (9), the amount of ionic character, I, can be found from the electronegativities of the metal and the nonmetal atoms, x_A and x_B, respectively, using the equation

$$I = 1 - \exp\left[-\tfrac{1}{4}(x_A - x_B)\right]$$

This gives an ionic character of 73% for MgO and 55% for CdO corresponding to an effective charge of ±0.27 and ±0.45, respectively. As a result, the effective number of valence electrons on Mg, O, Cd, and O will be 1.73, 4.27, 1.55, and 4.45, respectively

The valence electron susceptibility, χ_2, is calculated using the Langevin equation, but tetrahedral radii of Pauling (9) are used instead of calculating by the Angus method (8), as the calculation of $\overline{r_i^2}$ by the Angus method gives a high value for the calculated susceptibility. Table II shows the comparison between experimental and calculated susceptibilities, and Table I gives the values of the ionic susceptibilities calculated. The susceptibilities are in cgs emu.

From the agreement between experimental and calculated susceptibility for the covalent model with partial ionic character, it is felt that this method can well be applied in the case of MgO and CdO.

Acknowledgments

The author wishes to express his thanks to W. C. Snoddy and G. M. Arnett of the Space Thermodynamics Branch for allowing the use of their magnetic susceptibility balance and to Dr. H. J. Watson for continued interest during the progress of the work.

Liquidus Isotherms in the Ga-In-As System

M. B. Panish

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

Recently several temperature-composition points on the liquidus surface of the $Ga_xIn_{1-x}As$ primary phase field of the Ga-In-As system were determined in this laboratory. They were obtained by a simple technique in which dissolution of crystals of the solid phase was observed visually and which has been described elsewhere for studies of the II-VI-Bi systems (1), the In-P system (2) and the Ga-In-P system (3). The experimental data for two cuts along constant Ga concentration lines [25 and 55 a/o (atom per cent) Ga] in the ternary system are presented in Table I and Fig. 1 and 2.

Somewhat more difficulty is encountered in using the observational technique for this system than was encountered with any of the other systems mentioned, primarily because the precipitated solid appears to remain under the surface of the liquid. This accounts for the greater scatter in these data than in those obtained for the other systems. The experimental data could only be checked against one other experimental determination of the liquidus temperature in this ternary, that is the GaAs-InAs pseudobinary data of Van Hook and Lenker (4). The intersection of their data for that pseudobinary and the data obtained here at the highest experimental temperature is shown in Fig. 2. The agreement of the two experimental points is within 2°K, although the precision of the data obtained here appears to be closer to ±10°K.

Recently Stringfellow and Greene (5) have used a quasichemical model for the liquid and for the solid solutions, along with phase and thermodynamic data for the Ga-As, In-As, GaAs-InAs (pseudobinary), and Ga-In systems to calculate a ternary phase diagram for the Ga-In-As system. In Fig. 1 and 2 curves for the liquidus temperatures which were obtained by picking points from isotherms in their ternary phase diagram are shown.

The experimental curves of Fig. 1 and 2, have been used with the liquidus curve plotted by Thurmond (6) for Ga-As, the data of Hall (7) and Koster and Thomas (8) for In-As, and the data of Van Hook and Lenker (4) for the GaAs-InAs pseudobinary to plot experimental liquidus isotherms in the Ga-In-As ternary phase diagram of Fig. 3. Since experimental data were obtained only along two cuts in this ternary, the experimental isotherms thus obtained are shown partially as dashed curves. Also plotted is the 1200°K quasichemical curve of Stringfellow and Greene. The shapes of these isotherms are similar to those which have previously been described for other III-V systems such as Ga-Al-As (9), Ga-Al-P (10) and Ga-In-P (3). Such isotherms are characteristic of ternary sytems in which there is only one high melting III-V binary compound for each III-V binary with a

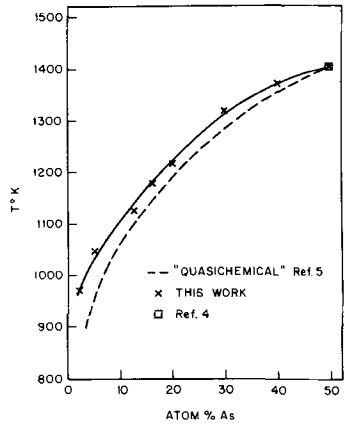

Fig. 2. Liquidus temperatures along the 25 a/o gallium cut of the Ga-In-As system.

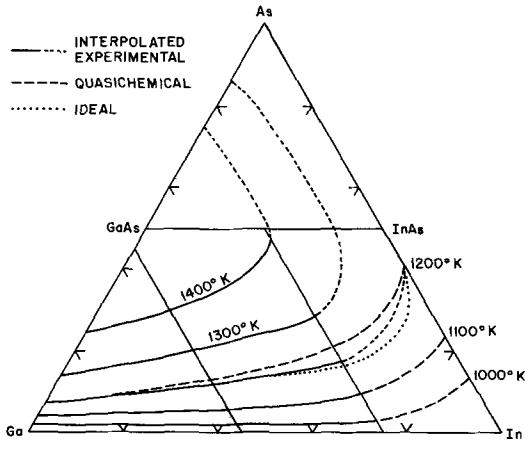

Fig. 3. Liquidus isotherms in the Ga-In-As ternary system

complete or extensive series of solid solutions between the two binary compounds.

It is interesting and instructive to compare the isotherms obtained experimentally with those computed with the quasichemical model and simply on the basis that the entire system is ideal. This latter assumption leads to the relation (9)

$$K_{InAs}(X_{Ga} - X_{Ga}^2 - X_{Ga}X_{In}) + K_{GaAs}(X_{In} - X_{In}^2 - X_{Ga}X_{In}) - K_{InAs}K_{GaAs} = 0 \quad [1]$$

where the X's are the atom fractions of Ga and In in the liquid at the liquidus composition and the K's are the ideal equilibrium constants

$$K_{III\,V} = X_{III}X_V \quad [2]$$

for the liquidus of the binary. An "ideal" 1200°K isotherm has been calculated with K(1200°K, GaAs) = 0.067 from Thurmond's liquidus for Ga-As (6) and K(1200°K, InAs) = 0.242 from a smooth curve drawn through the liquidus data of Hall (7) and Koster and Thoma (8) for In-As. This isotherm is plotted in Fig. 3 and can be seen to approximate the experimental data at least as well as the quasichemical isotherm.

Conclusion

The liquidus temperatures along two cuts in the Ga-In-As ternary system have been used with phase data for the boundary binary systems to plot the positions of the liquidus isotherms in that system. Isotherms of 1200° which were estimated on the basis of a quasichemical model and on the assumption of total ideality are shown to be in fair agreement with the experimental curve. This degree of agreement between the positions of isotherms calculated on the basis of these two different assumptions about the thermodynamic properties of the liquid and the solid emphasizes that in the III-V systems the shapes of the isotherms are primarily determined by the differences in the free energies of formation of the binary compounds (3, 9, 10). Any model which includes this difference as a major contributor to the behavior of the system will yield isotherms in fair agreement with the true isotherms. This does not, however, imply that the model selected is a true description of the system, but merely that the shapes of the liquidus isotherms are insensitive to the model.

Testing Batteries for Vehicular Applications

I. Test Facility

B. Agruss*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

A versatile facility was required to test a variety of batteries applicable to vehicular propulsion. Such a facility was designed and built to characterize all types of batteries in the 1-10 kW range. It was built around a motor-generator set and load bank. The unique features of this test facility are that it can be operated either manually or automatically at constant *power*, *current*, or *voltage* whether charging or discharging a test battery.

Battery capacity is determined today almost exclusively by varying constant current discharges. Vehicle loads, however, are expressed as constant power requirements. The ability of batteries to fulfill these requirements cannot be determined directly from the usual battery tests at constant current or voltage. What has been required is a versatile test facility to test a variety of batteries applicable to vehicular propulsion. It had to supply, directly, battery characteristics at constant power as well as at constant current and voltage.

Early power plants may be hybrid battery systems consisting of an energy battery and a power battery connected together through some type of charging device whereby the power battery is charged at idle or cruise speeds by the energy battery. Each battery operates under different conditions and needs different characteristics. The energy battery provides energy and power for range at cruise speeds and for charging the power battery. It must have a good energy density but not necessarily a good power density. The power battery must provide the bursts of power required for acceleration and other short-duration, high-power requirements. So it must have a good power density but not necessarily a good energy density. Constant power and constant current tests will characterize the energy battery. However, for the power battery these tests must be augmented by a test which will show the ability of this battery to give repeated acceleration power pulses. The test facility, too, must reveal how the two batteries interact when operated in a hybrid mode.

For both types of batteries, it is important to know the charge acceptance at varying depths of discharge. These data will show the power and energy requirements for recharging both types of batteries.

A versatile battery test facility was built from available items to perform all of the enumerated special tests plus the usual battery tests. Data are provided to characterize all types of batteries in the 1-10 kW range. The facility was built around a motor-generator set and a load bank. The unique feature is that the motor-generator set can be operated manually or automatically at constant power, current, or voltage whether charging or discharging a test battery. Repeated acceleration power pulses can be obtained also, manually or automatically.

Description of Facility

An over-all view of the test facility is shown in Fig. 1. All areas are self-explained. The relationship among the several parts of the facility is shown in the block diagram of Fig. 1(a) which also lists the figure numbers where detailed schematics for each part may be found.

Load bank.—The load bank shown in Fig. 2 consisted of ¼ in. stainless steel tubes clamped at varying lengths to give varying resistances. The tubes were water-cooled internally to remove heat. Currents of 100-500A could be carried by these pipes by using one or more in parallel. This was done by means of contactors actuated by pushbuttons, as shown in Fig. 3. Fine adjustment was made by having the motor-generator set buck or aid the battery current.

Fig. 1. Battery test facility

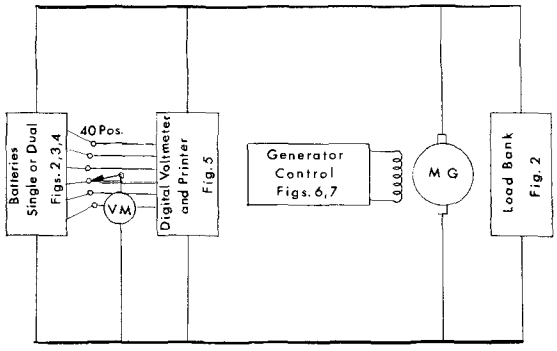

Fig. 1(a). Facility block diagram

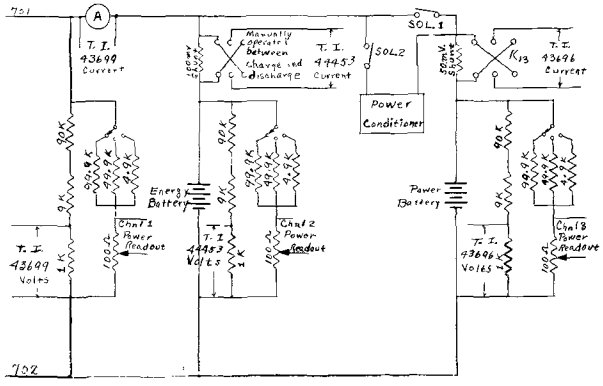

Fig. 4. Dual battery instrumentation schematic

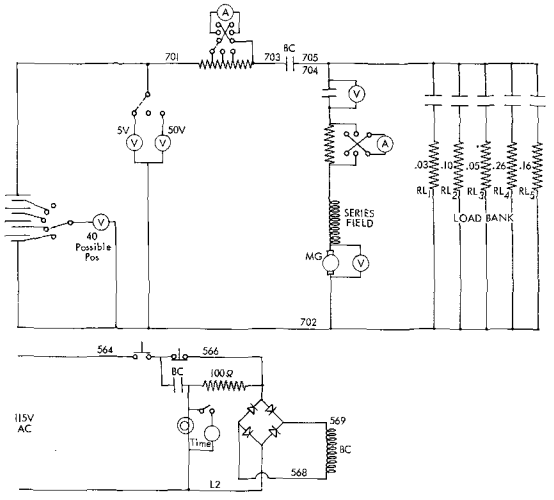

Fig. 2. Load bank schematic

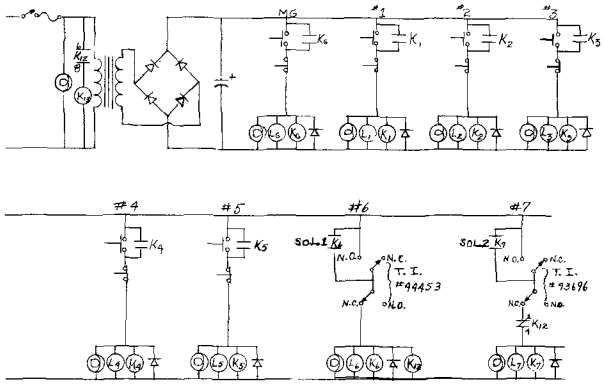

Fig. 3. Relay and switch schematic

Dual battery operation.—Early experimental electric power plants may be dual battery systems consisting of an energy battery and power battery. The energy battery charges the power battery during low-power periods when no power is required from the power battery. The energy battery, at exhaustion, is charged with the motor-generator set. Voltage limits, depending on battery type and characteristics, govern the charge-discharge operation.

Figure 4 shows the means by which this operation is accomplished. Adjustable cams on the servomotor shaft of two Texas Instrument Servo-riters actuate microswitches which open and close solenoids No. 1 and 2 at the proper voltage levels. Stations No. 6 and 7 in Fig. 3 show how the microswitches are connected to actuate the solenoids.

Normally, solenoid No. 2 is closed since the upper cam on T.I. 43696 is set to make contact on N.O. at battery open circuit and lower voltages. This causes the power battery to be charged at a rate determined by the conditioner. The lower cam on 43696 is set to open N.C. and close N.O. when the battery reaches maximum charge voltage. This opens solenoid No. 2 and charging stops.

When power is called for at the load, the voltage of the energy battery falls. At the set voltage, the upper cam on T.I. 44453 closes N.O. and opens N.C. This causes solenoid No. 1 to close and also energizes K_{12} whose normally closed contacts open, opening solenoid No. 2. Now both batteries are supplying power to the load. When the load demand drops, the energy battery voltage will rise. Now the lower cam on T.I. 44453 will open at N.C., de-energize solenoid No. 1, and allow T.I. 43696 to take over. The power battery voltage will be low, so solenoid No. 2 will close. Now the power battery is being charged by the energy battery. The power conditioner limits the high charge current to a discharged battery and by a voltage sensor reduces the charge current to the end of charge rate at the end of charge voltage.

Voltage dividers are used, as shown, to limit the signals to the Servo-riters. The reversing relay (K_{13}) attached to the 50 mV shunt shown in Fig. 4 is actuated in unison with solenoids No. 1 and 2 through relay K_{12} in Fig. 3.

Power measurement and recording.—A novel means was used to measure and record power without resorting to expensive electronic multipliers or d-c wattmeters. A 100 ohm retransmitting slide wire was attached to the shaft of the servomotor being actuated by the current shunt signal in each of the Servo-riters. This slide wire formed one leg of a voltage divider system which was placed across the battery as shown in Fig. 4. A three-position switch changed resistors so that battery voltages from 0-5, 5-50, and 50-100V would yield reasonable signals, yet limit the drain on the battery to 1 mA.

The position of the wiper on the slide wire is directly proportional to the current. The drop across the slide wire is directly proportional to the battery voltage. Hence, the voltage signal from wiper to one end of the slide wire is directly proportional to the product of current and voltage or power. This signal can be read with a high impedance millivoltmeter or recorded as shown. The channel numbers in Fig. 4 refer to channels in the four-channel recorder shown in Fig. 1 labeled "Power Readout." Any one signal can be used to control the motor-generator set at constant power as is described later.

Non Linear Systems monitor.—A Non Linear Systems 20-point scanner, digital voltmeter and printer was used to monitor individual cell voltages. The period between print-outs could be varied from 5 to 30 min. The event marker on the Servo-riters would show just when the readings were being taken. Each timer was wired to start the other when its time ran out and thereby actuate the scanner advance and start relays. Print-out would continue indefinitely at the

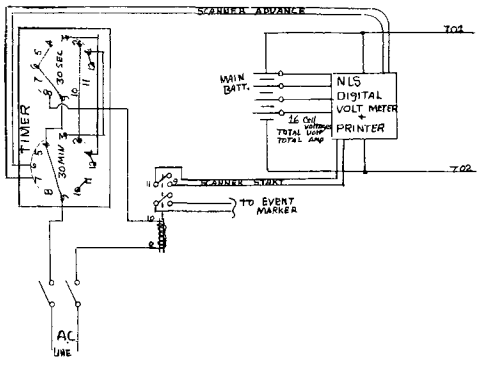

Fig. 5. Print frequency timer for NLS system electrical schematic

desired intervals until the a-c line switch was opened (Fig. 5).

Generator output control.—Figure 6 is a schematic of the d-c generator output control panel. The upper half of the figure relates to manual control only. The coupled exciter furnishes field current, the magnitude of which is controlled by the field rheostat and the series resistor. This mode is used for gross testing or where pulses are desired.

The bottom half of Fig. 6 relates to automatic control at constant voltage, current, or power. In this mode, the field current is supplied by a Sorenson 150V, 5A power supply with remote control tabs. The electronic control presents a controlled varying resistance to the remote control tabs of the power supply, thus controlling the field current. The electronic control can sense either three levels (5, 50, 100V) of battery voltage from the voltage dividers, current from the shunt signal, or power from the retransmitting slide-wire signal described previously. Each mode of operation is selected by the six-position selector switch and the two-position sensor switch. To reverse the generator output, the field current is reversed. The four-pole double-throw switch shown reverses both the field current and the shunt signal to the sensor so it can operate properly. The battery voltage does not reverse on charge or discharge; hence, no reversing switch is necessary.

Electronic motor-generator control.—The heart of the generator control system is the electronic controller diagrammed in Fig. 7. This is a simple feedback loop which compares an input voltage to an internally generated one, and applies the difference to make a transistor more or less conducting. In parallel with the base and emitter of the transistor is a resistor which is the remote control for the field power supply. A millivolt signal proportional to voltage, current, or power is applied at terminals 1 and 2 of the shunt

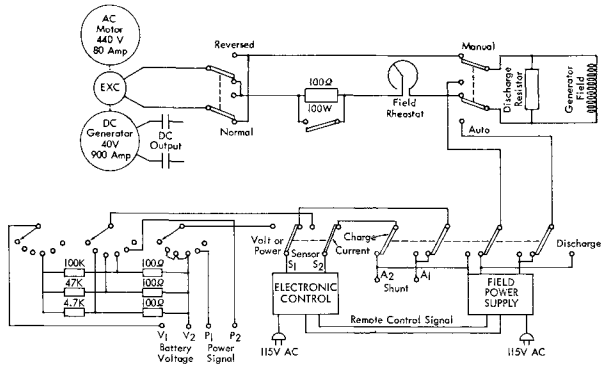

Fig. 6. D-C generator output control

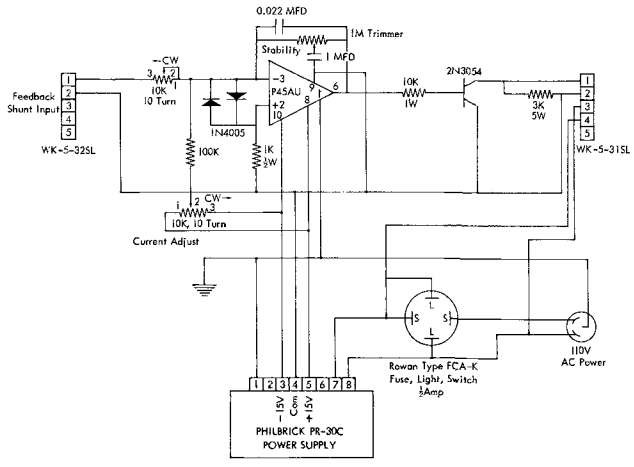

Fig. 7. Current control-motor generator

input. This signal voltage is bucked by an interval voltage whose magnitude is varied by the current-adjust potentiometer. The error signal is applied to operational amplifier P45AU, which controls the conductance of transistor 2N3054.

Across terminals 1 and 2 of WK-5-31SL is a 3K resistor. The same terminals are connected to the remote control tabs of the power supply. The specifications for remote control are 20 ohms/V; hence, 3000 ohms will bring the power supply to 150V, and 300 ohms to 15V. Thus, by varying the resistance, the voltage of the power supply can be varied. By varying the conductance of the transistor in parallel with the 3K resistor, the resistance, seen by the power supply, is varied.

To accomplish constant generator output, the current-adjust potentiometer is adjusted until the desired voltage, current, or power is obtained. If the input signal decreases, the error signal decreases, reducing the conductance of the transistor, which then increases the field current; this, in turn, increases the generator output, so that the error signal is brought up to its original level. The opposite occurs if the input signal increases—the generator output decreases to bring the signal back to its former level. Hence, constant generator output is achieved for either voltage, current, or power.

A big advantage of this control is that it can be programmed for an infinite variety of charge-discharge profiles. By having a number of current-adjust potentiometers connected to appropriately programmed switches, the output of the generator can be programmed to a variety of profiles. Each potentiometer can be infinitely adjusted to any charge or discharge level desired. This allows excellent versatility.

Conclusions

1. A versatile battery test facility was constructed from a motor-generator set and load bank.
2. The facility has the capability to provide hitherto unavailable battery data for vehicular applications.
3. Besides the standard constant current battery tests, constant power and acceleration pulse tests can be performed also.
4. By appropriate programming, an infinite variety of charge and discharge profiles are available.

Manuscript submitted Dec. 22, 1969; revised manuscript received ca. May 11, 1970. This was presented in part as Paper 42 at the Detroit Meeting, Oct. 5-9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1971 JOURNAL.

Testing Batteries for Vehicular Applications

II. Tests on Some Commercially Available Energy Batteries

B. Agruss*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Using a versatile test facility previously described (1), a number of commercially available Pb-acid batteries were tested. Typical test results are presented, especially those most meaningful to vehicular applications. It is shown that at varying power discharges the energy capabilities are additive. By this means, performance, range, and capability of batteries under varying duty cycles can be ascertained. Power density *vs.* energy density curves are obtained almost by inspection from constant power discharges. Voltage-current characteristics, both for charge and discharge, at varying capacity levels are presented. It is shown that Pb-acid batteries can be charged rapidly to 80-85% of their capacity before battery voltage rises rapidly.

The ability of batteries to fulfill vehicular requirements cannot be determined directly from the usual battery tests at constant current or voltage. Vehicle loads are expressed as constant power requirements; hence battery characteristics at constant power as well as constant current and voltage are needed.

Early power plants may be hybrid systems consisting of an energy battery and a power battery connected together through some type of charging device whereby the power battery is charged at idle or cruise speeds by the energy battery. The energy battery provides power for range at cruise speeds and for charging the power battery. It must have good energy density but not necessarily a good power density. The power battery must provide the bursts of power required for acceleration and other short-duration, high-power requirements. So it must have a good power density but not necessarily a good energy density.

This paper concerns itself with energy batteries. Constant power and constant current tests characterize the energy battery. Also, it is important to know the charge acceptance at varying depths of discharge. These data show the power and energy requirements for recharging the batteries.

Battery data are shown which were obtained on several commercially available Pb-acid batteries which may be generalized as energy batteries. Power battery data will be reported at a later date in another paper.

Battery Tests

Two diesel batteries were connected in series for check-out tests on the previously described test facility (1). These batteries had 205 A-hr, 20 hr capacity, and could deliver up to 5 kW so that sufficient power and capacity were available. After the check-out tests, several commercially available S.L.I. batteries were characterized as energy batteries. Between each capacity test, the batteries were fully charged to constant voltage and specific gravity at the finishing rate. All battery tests were carried out at ambient temperature.

In the following discussion, each kind of test is listed separately. The data obtained for each respective test are shown. Useful information derived from these data are described.

Constant current tests.—Figure 1 shows the results of the usual constant current discharges obtained during check-out on the diesel batteries. These discharges give the capacity of the battery at different current drains. These data may be replotted to give capacity *vs.* current as shown in Fig. 2 for the S.L.I. batteries. The first capacity on each curve at the lowest current was taken at the nominal 5 hr rate. In some S.L.I. applications, a voltage *vs.* current curve with time as a parameter might be helpful. These curves do not readily yield power output results except by an iterative process. For S.L.I. use these capacities are sufficient, but for vehicular applications they do not suffice.

Constant power tests.—Of much more practical value are the constant power discharges. Battery voltage is the limiting factor in vehicle operation. A minimum cut-off voltage is normally specified. Hence, voltage *vs.* ampere-hours or time is plotted as shown in Fig. 3 and 4 for the diesel batteries. It has been found (as shown later) that voltage *vs.* time curves are more useful; hence the S.L.I. battery data have all been plotted that way in Fig. 5-7 inclusive. All of these curves have somewhat the same shape as the constant current curves, but the slopes are much steeper since both voltage and current are changing.

The usefulness comes in directly obtaining range at any road load (power level). For instance, in Fig. 5, if

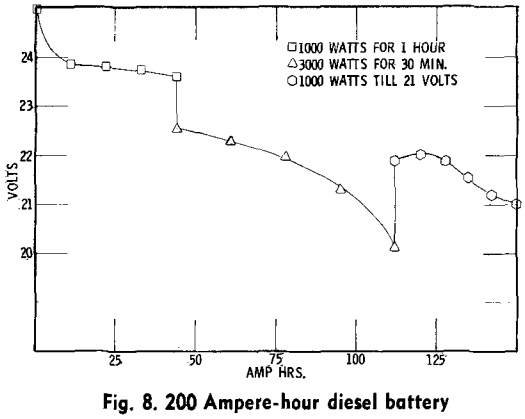

Fig. 8. 200 Ampere-hour diesel battery

the 400W level meant 30 mph, then the vehicle could travel 42.5 miles before recharge. This is a simple calculation by inspection rather than a time-consuming iterative process.

A description of several duty cycles further shows this usefulness. Also, the principle of additivity of ampere-hours or time is described, and how this principle can be used to construct duty cycles. In Fig. 8 is shown a duty cycle of 1000W for 1 hr, followed by 3000W for 30 min, then 1000W again to the 21V cutoff. The versatility of this facility allows a rapid change from one power level to another. Thus, any duty cycle can be applied to the battery. The additivity principle can be illustrated now. Comparing Fig. 3 and 8, it is seen that, within experimental error, the two 1000W portions of Fig. 8 coincide with the 1000W curve of Fig. 3, both at the low and high ampere-hour ends; *i.e.*, from 0 to 45 A-hr and from 100 to 150 A-hr. The 3000W portion of Fig. 8 between 45 and 100 A-hr coincides with the same portion of Fig. 3. The same coincidence was noted for voltage *vs.* time constant power discharge curves.

The coincidence of all of these profiles illustrates the principle of additivity. The capacity removed at any power level in ampere-hours or time may be added to that removed at a different power level to determine total amount consumed and amount remaining before the battery cutoff voltage is reached.

Plots of projected duty cycles show at what portion of the cycle the battery reaches cutoff voltage and limits performance. Incidentally, Fig. 8 shows also the ability of a Pb-acid battery to supply useful energy at decreasing power levels.

To use the principle of additivity more effectively, the data of Fig. 5, 6, and 7 were replotted as capacity *vs.* time in Fig. 9, 10, and 11, respectively. Now it is possible to determine battery capability, performance, and range. First, all of the limiting points were connected, as shown, with a dotted line. Capacities beyond this line are not attainable because cutoff voltage is reached at this line. Assume that the constant power curves represent road loads at specified vehicle speeds. Now assume a duty cycle specifying time at various vehicle speeds. It is very easy to ascertain the ability of

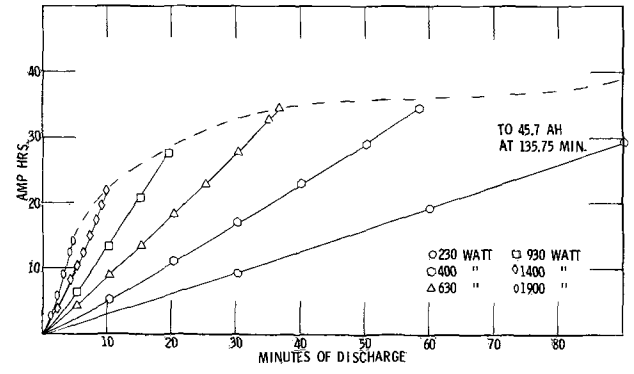

Fig. 10. 39 Pound battery (plastic case), constant power discharge capacity *vs.* discharge time.

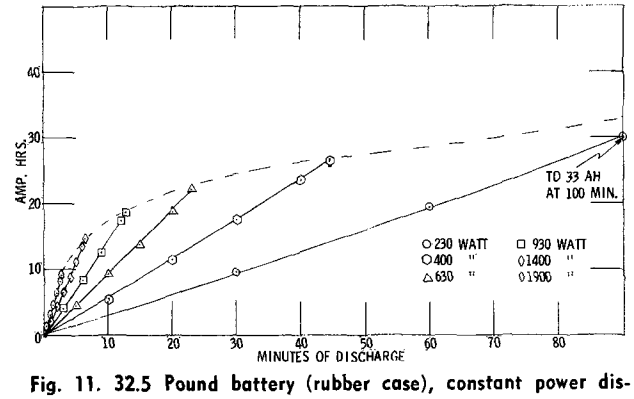

Fig. 11. 32.5 Pound battery (rubber case), constant power discharge capacity *vs.* discharge time.

any battery to perform that cycle. For instance, suppose a duty cycle of 30 min at 230W, 10 min at 1400W, 10 min at 630W, and finally 15 min at 400W were imposed upon the battery in Fig. 9. After 30 min at 230W, 9 A-hr were consumed. This is equivalent to 5 min at 1400W. An additional 10 min brings the time of discharge to 15 min where a total of 32 A-hr have been consumed. This is equal to 35 min discharge at 630W. An additional 10 min at 630W (45 min) brings the ampere-hours consumed to 42. Now this is equivalent to 73 min discharge at 400W. The limit at 400W is 85 min. This means the battery can deliver only 12 min at 400W instead of the 15 min assumed. Battery voltage at each point, if desired, can be obtained from Fig. 5 at the appropriate power and time of discharge intersections. It is also seen that only a maximum of 12 min can be obtained at 1400W after 30 min at 230W. Thus, performance limits are obtained. A summation of the products of vehicle speed and time at that speed gives the vehicle range. Performance at power levels other than those portrayed may be interpolated between the appropriate power curves.

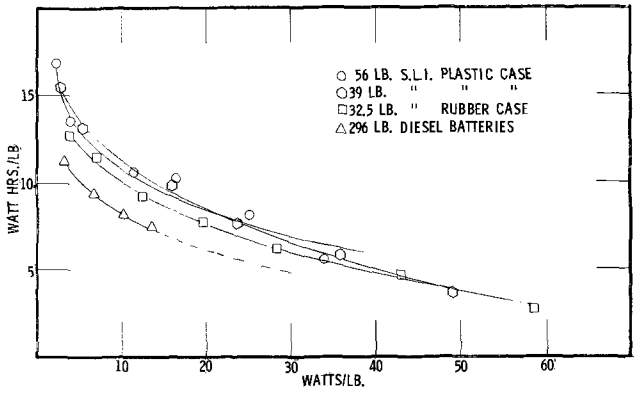

Fig. 12. Energy density vs. power density, various Pb-acid batteries.

The curves in Fig. 9, 10, and 11 are very close to straight lines. The 10-20% change in voltage and current is not seen on this small scale. An expanded scale would emphasize the curvature. It just so happens that, for these batteries, these curves can be approximated by straight lines. However, for other types of batteries, the curvature is pronounced enough so that the data cannot be approximated easily by straight lines.

Energy density-power density.—A very useful application of Fig. 4-7 inclusive is in the construction of energy density *vs.* power density curves. The time to cutoff voltage for any constant power discharge multiplied by the power gives the watt-hour capacity at that power level. This value divided by the battery weight gives the energy density. The power divided by the weight gives the power density. Thus, each constant power discharge yields one point for the energy density *vs.* power density curve. The curves in Fig. 12 were made this way. This is a fast, easy method to construct these much valued curves. Constant current discharges do not yield such data readily.

The two plastic-case batteries show almost identical energy and power densities in spite of their large difference in ampere-hour capacity. This shows that the gain in capacity was due to the gain in weight which was largely active material and lead supporting structure. A larger plastic container contributes very little extra weight.

The plastic case batteries show a 10-20% gain in energy density over the rubber-case battery at the low power levels. At the high power levels, there was very little difference in energy density between the differently contained batteries.

The rugged construction of the diesel batteries shows up in their low energy and power densities.

Voltage-current characteristics.—The test facility lends itself to fast, easy determinations of voltage-current characteristics. The electronic generator control makes it easy to pass smoothly from charge to discharge, or *vice versa*, through open circuit (V at zero I). The current adjustment control can be manipulated so that the generator voltage exceeds, equals, or is less than the battery voltage. Thus, the battery is charged, at open circuit, or discharged, respectively.

Voltage-current curves obtained in this manner are shown in Fig. 13 through 16, inclusive, for varying states of charge. Note the smooth passage through open circuit. At high current drains, the voltage readings had to be taken instantly since the reading would change rapidly with time. At low drains, the voltage would remain stable for ½ to 1 min.

All the S.L.I. batteries had about the same discharge characteristics. At the 25% capacity level, the slope with increasing current was somewhat greater for the lower capacity batteries.

It is interesting to note that, except for a fully charged battery, the battery will accept a charge easily; that is, the voltage does not rise abruptly with an

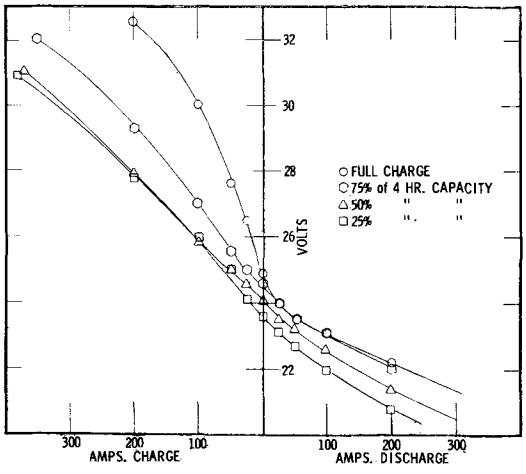

Fig. 13. 200 Ampere-hour diesel batteries, charge discharge, voltage *vs.* current.

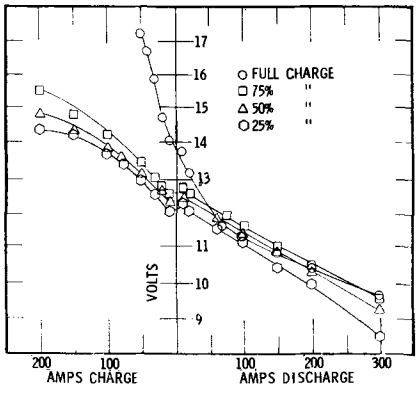

Fig. 14. 56 Pound battery (plastic case), charge discharge, voltage *vs.* current.

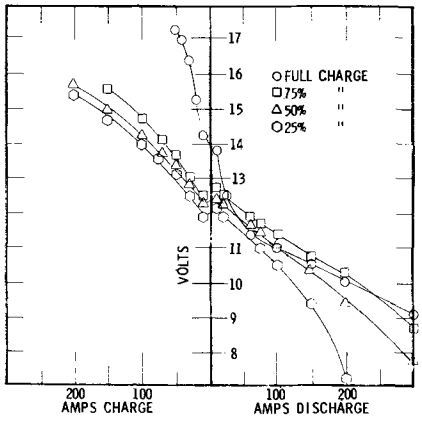

Fig. 15. 39 Pound battery (plastic case), charge discharge, voltage *vs.* current.

increase in current. The rapid rise in charge voltage for a fully charged battery shows poor charge acceptance, as expected, and the onslaught of gas evolution. There is no rapid rise in charge voltage even at 75% capacity. Further data, which will be reported at a later date, seem to indicate that the rapid rise begins about 80-85 capacity.

Except for the fully charged battery, the charge and discharge curves are nearly projections of one another. The slight rise in slope for the charge portion may be due to the higher specific gravity acid within the pores of the plates. There is a greater slope for the rubber-

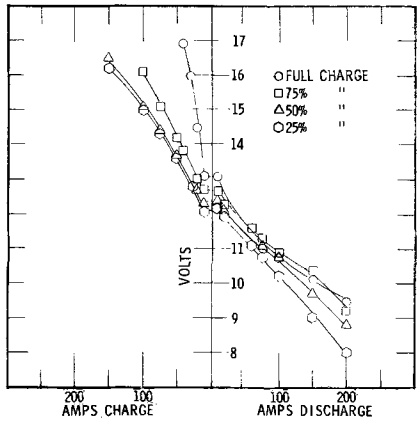

Fig. 16. 32.5 Pound battery (rubber case), charge discharge, voltage *vs.* current.

cased battery. This can be caused by differences in call design and active material make-up, especially negative plate expander.

Comments.—The data contained herein cover a good range of S.L.I. batteries. Although curves for only one battery would be sufficient to explain all the tests and describe the principles involved, much more confidence is obtained if more than one size battery follows the same trend, especially with lead-acid batteries. There is an added advantage in including all the data. The performance of any other battery as an energy battery may be ascertained by judicious interpolation or extrapolation of the data herein.

Future work.—It is planned to repeat these tests at −18°C (0°F) and 71°C (160°F) and find the effect of temperature on duty cycle capacities.

In forthcoming reports, other types of batteries will be characterized; acceleration power pulses will be included.

Conclusions

1. It was found that a few power profiles, a voltage-current test, the usual constant current tests, plus charging data with state-of-charge as a parameter, provided our data needs for vehicular applications.
2. During any varying power discharge, the principle of additivity was followed; *i.e.*, the capacity removed at any power level expressed in ampere-hours or time may be added to that removed at a different power level to determine total amount consumed and amount remaining before the battery cutoff voltage is reached.
3. By applying the additivity principle, the ability of batteries to perform varying duty cycles can be obtained rapidly, and the range is easily calculated.
4. Constant power capacity discharges readily yield energy density-power density relationships.

Surface Chromium on Chromate Treated Tin Plate

Joseph J. Becker*[1]

Jones & Laughlin Steel Corporation, Graham Research Laboratory, Pittsburgh, Pennsylvania 15230

ABSTRACT

The surface chromium composition of tin plate treated cathodically in sodium dichromate solution was analyzed by three methods: (*a*) alkali stripping, (*b*) acid stripping, and (*c*) treatment with bromine methanol solution. It is suggested that the surface chromium insoluble in alkali is anhydrous chromic oxide, while that soluble in alkali is hydrated chromic oxide. The potential time curves from galvanostatic anodic treatment of tin plate cannot be interpreted in the simplistic manner commonly accepted for tin-free steels with a chromium-chromium oxide coating.

By far the largest percentage of commercial tin plate is given a cathodic treatment in dichromate solution with current densities in the region of 25-35 A/ft^2 and treatment times of the order of 1 sec. The concentration of the solution is about 3% sodium dichromate. Traditionally, acid stripping or alkali plus acid stripping (1, 2) has been used to remove and estimate the quantity of surface chromium[2] deposited on the tin plate during the chromate treatment. Such procedures give total surface chromium concentration.

A coulometric method for the estimation of surface chromium on passivated tin plate was proposed by Britton (3). The sample is made the anode of a cell with sodium phosphate solution as the electrolyte. The potential difference between the sample and a reference electrode is monitored as a function of time for a galvanostatic treatment. According to Britton, during the potential arrest shown on the potential time curves, Cr^{3+} is oxidized to Cr^{6+} with about 56% current efficiency.

A coulometric method basically the same as that suggested by Britton for tin plate is generally employed for the determination of metallic chromium on TFS (tin-free steels with a chromium-chromium oxide coating) (4, 5). Although Britton recommended a neutral phosphate solution for tin plate, sodium hydroxide solutions are generally used for TFS. However, curves may be obtained for passivated tin plate using either solution with no very significant difference in results. The question, therefore, arises as to whether or not such curves from tin plate samples can be used to demonstrate and estimate surface metallic chromium concentrations.

This question is central to a disagreement which has recently arisen concerning the detailed chemical nature of the surface chromium on commercial CDC (cathodic dichromate) tin plate. Much of the work involved is unpublished; however, the suggestion has been made (6, 7) that metallic chromium is present on the surface of commercial CDC tin plate, and that this concentration can be estimated from potential time curves.

From Britton's work it was already evident that the quantity of charge passed during the potential arrest from "as-received" tin plate was too large for the potential arrest to be interpreted in terms of 100% current efficiency for the reaction $Cr^{3+} \rightarrow Cr^{6+}$. Since not all the surface chromium could be metallic chromium this is also true for the reaction $Cr^0 \rightarrow Cr^{6+}$. Britton cited the work of Shah and Davies (8) indicating oxidation of tin at these potentials. However, it has been suggested that the smaller quantity of charge passed during the potential arrest obtained during galvanostatic, anodic treatment of CDC tin plate which had been previously treated in hot KOH (8.5M KOH at 180°F for 2 min) is entirely used for the oxidation of metallic chromium. This suggestion was associated with the contention that the surface chromium which is insoluble in hot alkali is metallic chromium (6). According to Rocquet and Aubrun (7), the potential arrest from plate previously treated in hot 1*N* NaOH cannot be interpreted in terms of 100% current efficiency for the reaction $Cr^0 \rightarrow Cr^{6+}$. However, these workers claim that the potential arrest from plate previously treated in a NaOH-H_2O_2 solution can be so interpreted.

The present work was undertaken to further the knowledge of the chemical composition of the surface chromium on commercial CDC tin plate. We sought first a chemical method which would inform us as to whether or not metallic chromium was one of the constituents on the surface of CDC tin plate. The method adopted was to treat samples with bromine methanol solutions. Chromic oxides are insoluble in these solutions, whereas chromium trioxide and metallic chromium are soluble. By analyzing the insoluble residue from attack by bromine methanol on samples previously subjected to one of the stripping methods, as well as samples in the as-received condition, it was possible to determine whether or not the surface chromium is soluble in bromine methanol.

Methods

Details of each of the methods used are given below. Most of the results were obtained using disks of 8 in.^{2} surface area.

Alkali stripping.—The sample was placed in 20 cc of 8.5M (48%) KOH at 180°F for 2 min. The sample was removed and rinsed into the solution. Twenty cubic centimeters of 10% sulfuric acid and 10 cc of 85.5% phosphoric acid were added. One to two drops of saturated potassium permanganate were added and the solution boiled for 5 min. Ten cubic centimeters of 38% HCl were then added to reduce the excess permanganate and obtain again a colorless solution. Diphenylcarbazide reagent (9) was added, the solution was brought to 100 cc, and the chromium content determined colorimetrically. The solutions have a *p*H lower than the preferred range for use with this reagent. Nevertheless, meaningful and consistent results were obtained. In later work, the method has been modified to give solution of higher *p*H with no difference in results.

Acid + alkali stripping.—The method used was a modification of that described by Hill (1). The sample was placed in 25 cc of sodium hydroxide-sodium phosphate solution (40g NaOH + 50g Na_3PO_4/liter). The solution was heated and allowed to boil for 2 min. The sample was removed and rinsed into the solution. This procedure was repeated in 25 cc of 1:3 sulfuric acid, the solution being allowed to boil for 1½ min.

[1] Present address: 44 West 63 St., New York, N. Y. 10023.

[2] In this paper, chromium is used as the name of an element without prejudice to its valence state, *e.g.* as the pure metal or in a compound. When metallic chromium is specifically meant, the paper so states.

The alkali and acid solutions were mixed. Potassium permanganate was added and the procedure given above for colorimetric determination of chromium was followed.

Bromine methanol attack.—The sample was placed in a solution of 12 cc of bromine and 25 cc of methanol. After all reaction had ceased, the solution was filtered using a Millipore suction filtering apparatus and a Gelman Metricel filter of pore size 0.45μ supported by a Whatman No. 42 filter paper. The residue was rinsed free of all bromine, then ignited and fused with borate and carbonate in a platinum crucible. The fusion was dissolved in 30 cc of 13% H_2SO_4. The solution was brought to 50 cc and the chromium content determined by atomic absorption. An alternative procedure sometimes used was to add 30 cc of the alkali-phosphate solution to the sulfuric acid solution of the fusion, followed by 10 cc of phosphoric acid. This was followed by oxidation with permanganate and colorimetric determination of chromium.[3]

Coulometry.—The procedure used closely followed Britton's work. Samples were subjected to anodic galvanostatic treatment at a current density of 25 μA/cm^2 in a solution of 7.5 g/liter disodium phosphate buffered to a *p*H of 7.4 with phosphoric acid. A saturated calomel electrode was used as the reference electrode and the variation of sample potential with time was recorded.

Results

In one set of experiments, samples were first stripped according to the acid plus alkali method and then subjected to bromine methanol attack. In other cases the samples were subjected to attack by bromine methanol in the "as-received" condition. Tables I-III show the results of these experiments.

Figure 1 shows the results of two experiments in which different sized samples (the sample weight being proportional to surface area) were subjected to complete attack by bromine methanol. The results are used in Table II. It is apparent that for three different lots of commercial CDC tin plate the sum of the surface chromium removed by the alkali plus acid stripping plus the remaining chromium insoluble in bromine methanol was equal to the total chromium insoluble in bromine methanol for the "as-received" samples. This means that all, or very nearly all, the surface chromium removed by the alkali plus acid stripping was insoluble in bromine methanol. The chromium, insoluble in bromine methanol, that was found for samples that had previously been treated by the alkali plus acid stripping is contributed by the base steel.

[3] Extra special precautions to minimize hydrolysis reactions due to the presence of water during the bromine methanol attack on samples were not necessary since we were interested only in the chromium content of the residue. However, samples which were stripped in acid or alkali and then were subjected to bromine methanol attack were rinsed free of water with methanol prior to the latter treatment.

Tables IV and V show the results of similar experiments in which the samples were first stripped in hot concentrated KOH and then subjected to bromine methanol attack. The consistency of the data in Tables IV and V with those in Tables I and II should be noted.

The total is the same whether the sample is first treated by the KOH method or by the alkali plus acid method. The surface chromium removed by each method is insoluble in bromine methanol, but more is removed by the alkali plus acid stripping method than by the KOH method.

Figure 2 shows the results of a series of experiments in which sample disks of 8 in.^{2} area of lot 2 plate were subjected to bromine methanol attack to different weight losses, the reaction not being allowed to go to completion. The weight loss was plotted against the quantity of chromium found in the insoluble residue from that weight loss. The results confirm by extrapolation to zero weight loss that about 32 μg/8

in.^{2} of chromium insoluble in bromine methanol are on the surface of this plate. Also shown in Fig. 2 are the results of similar experiments for a sample size of 18 in.^{2} surface area. The low chromium values associated with the lower weight loss arise from the fact that, since the surface chromium measured is insoluble in the medium, it must be released by undercutting. The base steel has a lower concentration of chromium insoluble in bromine methanol than the surface, so preferential attack of the base produces results below the linear relationship. The latter represents complete release of the surface chromium plus an amount proportional to the extent of attack on the base steel.

The results in Table VI show that about half the surface chromium remains on the surface of the CDC tin plate after the anodic treatment in phosphate solutions. This is in agreement with Britton's (3) observation. Table VII shows that this surface chromium is insoluble in bromine methanol solutions after the anodic treatment.

Figure 3 shows a typical potential time curve for a sample that had been previously treated in hot concentrated KOH (curve b). For comparison, a curve from "as-received" plate is also shown (curve a). The numerical results obtained by interpreting the potential arrests, as measured by AB, AC, and DC, from KOH-treated samples in terms of the oxidation of Cr^0 to Cr^{6+} are shown in Table VIII. The sample area used

to obtain the curve was 2.2 cm^2, and each side of the plate was run separately. The results given in Table VIII have been calculated for 4 $in.^2$ of both sides and thus are comparable with the results of the chemical analyses. Also shown in Fig. 3 is a typical potential time curve (curve c) for plate which had been baked (15 min at 350°F) and then treated in KOH prior to anodic polarization. Numerical results obtained from such curves are also shown in Table VIII. Following the suggestion of Rocquet and Aubrun (7), potential time curves were also obtained from plate which had been treated in $NaOH-H_2O_2$ solutions, and results from such experiments are also included in Table VIII.

Discussion

Chemical analysis.—Despite the limitations on accuracy that are apparent, for example in Fig. 1, the results clearly indicate that all, or very nearly all, the surface chromium removed by the alkali plus acid strip is insoluble in bromine methanol. Thus, it had been demonstrated that the surface chromium on these commercial CDC samples that is alkali insoluble and acid soluble is insoluble in bromine methanol, and, therefore, is not metallic chromium.[4] Since metallic chromium is soluble in hot sulfuric acid, it is evident that there is no appreciable quantity of surface metallic chromium on these plates. The literature (10) indicates that the solubility in acid of anhydrous chromic oxide is dependent on the thermal history of the chromic oxide. It is possible for anhydrous chromic oxide to have a slight solubility in acid. Thus, we have found that after treatment of samples of commericial anhydrous chromic oxide in sulfuric acid, chromium could be detected in the solution in concentrations considerably greater than the concentrations occurring in our analyses. After treatment of the anhydrous chromic oxide with 25 cc of hot 8.5M KOH, not even microquantities of chromium could be found in the solution. This suggests that the alkali insoluble surface chromium on commercial CDC tin plate may be anhydrous chromic oxide, which is, of course, insoluble in bromine methanol solutions.

The alkali soluble portion of the surface chromium is indicated by our results also to be insoluble in bromine methanol and is, therefore, not a simple hexavalent chromium compound. The suggestion here is that the alkali soluble surface chromium is a hydrated chromic oxide. Concentrated solutions of caustic are used to remove and estimate the hydrated chromic oxide on the surface of TFS materials (4, 5).

It is, of course, possible that, rather than anhydrous and hydrated chromic oxide, there may be two forms of hydrated oxide with different degrees of hydration, one soluble the other insoluble in alkali.

It will be noted that there is a large percentage of variation in the quantity of chromium found in the alkali stripping solutions from different samples of the same plate. This has been generally found to be true in our work. This may represent the limit of reproducibility in these experiments, and it may be due to a certain amount of undercutting through etching of the tin. However, it may reflect genuine variations in the surface concentration of alkali soluble chromium oxide.

Although we have concluded that there is no metallic chromium on the commercial CDC plates we have examined, we cannot say that metallic chromium is not deposited during the CDC process. It may be that the CDC process does deposit metallic chromium but that the chromium is subsequently oxidized, resulting in a product which has no surface metallic chromium.

[4] Experiments using metallic chromium have shown that under the experimental conditions about 200 mg of chromium dissolve in the bromine methanol solution in 20 min, the shortest time employed. For the plate with the highest content of metallic chromium in the base, the quantity of metallic chromium per 8-sq.-in. sample was about 1.6 mg. Thus, surface metallic chromium in concentrations equivalent to the total surface chromium concentration on CDC tin plate would still leave the quantity of metallic chromium well within the practical solubility limit.

Potential-time curves.—It is realized that, if treatment in hot concentrated KOH removed surface chromic oxide leaving behind metallic chromium, some, if not all, of this metallic chromium would oxidize when the samples were re-exposed to the atmosphere. Thus, when subsequently subjected to anodic treatment as in the work to which reference has been made, the sample would have some surface chromium oxide. However, this oxide is not necessarily involved in any electrolytic reaction during the galvanostatic anodic treatment. For example, in the case of TFS materials it is claimed (4) that the same charge is passed during the potential arrest whether or not the chromic oxide is first removed by treatment in hot KOH. A less ambiguous consideration is that we have already shown that the alkali insoluble and acid soluble surface chromium is not metallic chromium. Nevertheless, in view of the various interpretations that have been applied to the potential time curves from anodic treatment of tin plate, we felt it of interest to examine these curves briefly.

It may be noted that the original suggestion that the curves from KOH-treated samples could be used to estimate surface metallic chromium on CDC tin plate defined the potential arrest as portion DC of the curve (Fig. 3). The results so obtained, Table VIII, are inconsistent with the results of the chemical analyses discussed above. The accuracy of the results reported in Table II is not sufficient to rule out with certainty the possibility of 5 μg of metallic chromium per 8 $in.^2$ indicated in the first line of Table VIII. However, our results show this possibility as unlikely, and the larger numbers obtained from baked plate show that the potential arrest is not correctly interpreted in terms of 100% current efficiency for the reaction $Cr^0 \rightarrow Cr^{6+}$. An increase in surface metallic chromium on baking is hardly a reasonable interpretation and, in any case, the data in Table I show that there is no loss of chromic oxide on baking. Quite clearly, it cannot be assumed *a priori* that the potential arrest, however measured, from samples previously treated in KOH is due only to the oxidation of metallic chromium. A possible explanation of the larger potential arrest from the baked plate is an increase in the amount of chromic oxide not removed by the KOH treatment. However, we have not been able to confirm this experimentally.

The large concentrations of surface metallic chromium calculated from the curves from samples treated in $NaOH-H_2O_2$ solution are, of course, inconsistent with the results of the chemical analyses discussed above. Thus, also in this case, we conclude that the potential arrest cannot be interpreted only in terms of the oxidation of metallic chromium.

Conclusions

1. The surface chromium on the commercial CDC tin plate was insoluble in bromine methanol. It was retained on the surface not as metallic chromium but as a chromic oxide, probably a mixture of hydrated and anhydrous chromic oxide or possibly a mixture of two different hydrated forms.

2. The potential time curves from anodic treatment of CDC tin plate cannot be interpreted in the simple manner employed in the case of TFS materials, even if the plate be first treated in hot concentrated KOH.

3. Anodic polarization of samples previously treated in $NaOH-H_2O_2$ solution does not yield potential arrests that may be interpreted entirely in terms of the oxidation of Cr^0 to Cr^{6+}.

Improvements in the Etching of Hard Aluminum Electrolytic Capacitor Foil

M. S. Hunter*

Alcoa Research Laboratories, Aluminum Company of America, New Kensington, Pennsylvania 15068

ABSTRACT

Improved procedures are described for etching hard electrolytic capacitor foil for low and intermediate voltage applications. For low voltage formation (0-100V), high capacitance was obtained by etching at high current density in a solution containing a high NaCl concentration and 10 g/liter Na_2SO_4. For intermediate voltage formation (100-250V), optimum etching conditions consisted of a lower current density and NaCl concentration, along with the sulfate addition. In both applications, the combination of hard foil and the sulfate addition in the etch bath were particularly advantageous.

The continuing demand for aluminum electrolytic capacitors has been for units of greater capacity and smaller size. This demand can be met by improving etching techniques, with special aluminum foils, and through the selection of optimum combinations of foil and etch process for specific applications.

The ability of hard-rolled aluminum foil to produce capacitor anodes of greater capacitance was discovered over 30 years ago (1), but no use was made of this discovery for almost 25 years. In 1962, it was stated that, since dislocations act as preferred sites for etch attack, the large number of dislocations in a work-hardened foil should lead to a finer etch (2). Such an etch would be expected to have a greater surface area and, hence, higher capacitance. Shortly thereafter, it was shown that this actually was the case, although this fact did not appear in the literature for several years (3).

Two of the most significant advancements in electrolytic etching technology have been: (*a*) the discovery that etching current density has a profound effect on capacitance with both high and low formation voltages (2-3), and (*b*) the discovery that the addition of sodium sulfate to the electrolytic etching bath increases greatly the capacitance of annealed foil at low formation voltages (4-6). Present work describes additional improvements in electrolytic etching technology in sodium chloride solutions, which can be used to obtain considerably higher capacitance at both low and intermediate formation voltages.

Low Voltage Formation

In experiments involving low voltage formation (0-100V), 0.003-0.0035 in. thick foils of 99.99, 99.93, and 99.88% aluminum in both the annealed (0) and hard (H19) tempers were used. In evaluating the effect of NaCl concentration, a current density of 0.99A/cm^2 (6.4 A/in.^{2})[1] was employed because high current density has proven to be advantageous in etching foil for low voltage applications. NaCl concentrations from 80 to 310 g/liter were evaluated since this is the range over which relatively high current densities can be obtained conveniently. Formation was in an aqueous solution containing 30 g/liter tartaric acid and adjusted to *p*H 5.5 with NH_4OH. Measurement was at 60 Hz in a solution having a resistance of 30 ohms, using 3 in. x 1½ in. samples centered between stainless steel cathodes 1 in. apart.

NaCl concentration affected capacitance with all purities and both tempers of foil, as shown by the data for 30V formation in Table I. Capacitance increased progressively with NaCl concentration throughout the range. The effect was more pronounced with hard foil than with annealed foil. With annealed foil, the improvement over the concentration range was greatest with highest purity foil. With hard foil, however, the improvement was greatest with lowest purity foil.

[1] All areas are projected area; *e.g.*, 2 in. × 2 in. sample has 4 in.^{2} area.

Table I. Effect of temper and NaCl concentration[1] on 30V capacitance[2]

Purity	Temper	NaCl concentration, g/liter 80	120	200	310
99.99	Annealed	40.0	43.1	44.0	49.9
99.99	Hard	59.3	62.0	68.0	72.8
99.93	Annealed	40.1	41.8	41.3	45.4

[1] 200 g/liter C.P. NaCl at 90°C; 6.4 A/in.² for 7.2 A-min/in.².
[2] mfd/in.² after room-temperature formation in 3% ammonium tartrate solution at pH 5.5.

In evaluating the effect of sulfate, the same etching current density was used, along with various combinations of NaCl and sodium sulfate concentrations. It was found that the maximum benefit from the sulfate addition was achieved at a concentration of about 10 g/liter. With this sulfate content, best consistency of etch and highest capacitance were obtained with NaCl concentrations in the range of 200-230 g/liter. Data for the 200 g/liter solution are listed in Table II.

The data in this table show the beneficial effect of sulfate with annealed foil that has been described previously in patents (4-6). They also show that the beneficial effect of sulfate is considerably greater with hard foil, which increased 4.8-5.3 mfd/cm² (31-34 mfd/in.²), than with annealed foil, which gained 1.24-1.55 mfd/cm² (8-10 mfd/in.²). In addition, the combined effect of temper and sulfate is decidedly synergistic. For example, with 99.99 foil, the improvement in capacitance of annealed foil from the sulfate addition is 1.24 mfd/cm² (8.0 mfd/in.²). The improvement from annealed to hard foil, without sulfate in the etch, is 3.7 mfd/cm² (24 mfd/in.²). On the simple assumption that effects would be additive, it might be expected that the combination would increase capacitance by about 5 mfd/cm² (32 mfd/in.²). The actual improvement, however, was 9 mfd/cm² (58.2 mfd/in.²), 80% greater than expected. This improvement is particularly impressive because the increase in capacitance with the hard foil-sulfate combination is over 130% with the two higher purities of foil and almost 100% with the lowest purity foil.

Electron microscope examinations revealed the changes in etch configuration associated with changes in NaCl concentration and the addition of sulfate to the etch bath. These observations supported the principles stated previously (2) that capacitance is determined not only by the surface area developed during etching, but also by the degree of smoothing during formation which results from the consumption of aluminum to form the oxide dielectric film. For this reason, relatively coarse etches are best for high voltage formation because the surface area is retained better during formation. On the other hand, in low voltage applications, advantage can be taken of finer etches, which develop greater surface area, because so little metal is consumed during formation.

Electron microscope examinations were made using plastic-carbon replicas. These showed that hard foil developed a much finer etch configuration under all etching conditions. Increasing NaCl concentration and adding sulfate to the etch bath also produced a finer etch. Thus, the optimum combination for low voltage formation was hard foil, high current density, high NaCl concentration, and sulfate addition in the etch bath.

The effects of temper and sulfate addition on the etch configurations of 1199 foil are shown in Fig. 1 and 2. In these micrographs, the etch facets are the (100)

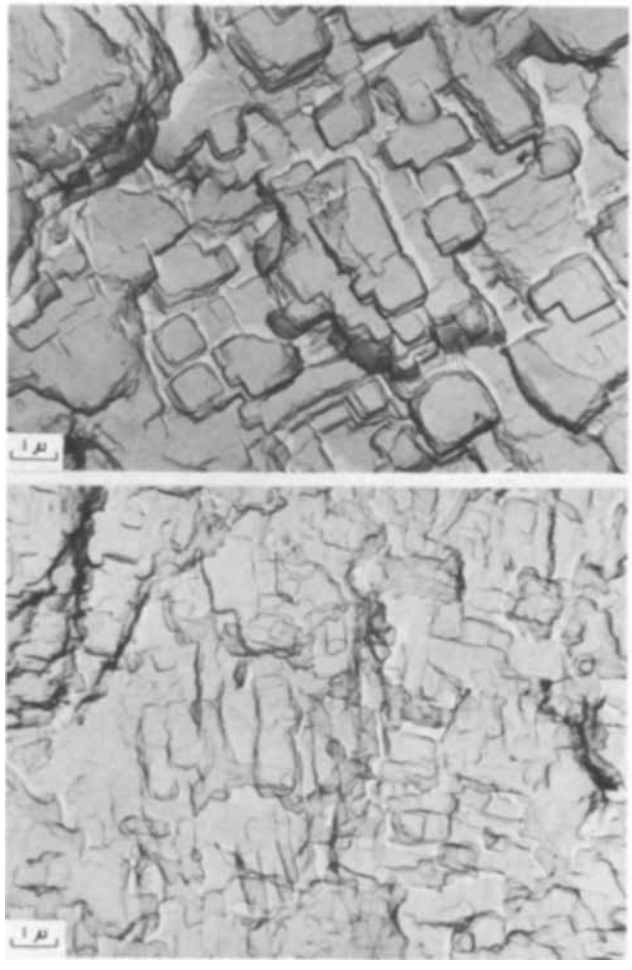

Fig. 1. Etch configurations developed by etching 1199 foil at 4.8 A/in.² in 200 g/liter NaCl solution (X6000). *Top*—annealed foil, 45.8 mfd/in.² at 30V formation. *Bottom*—hard foil, 82.4 mfd/in.² at 30V formation.

planes of the aluminum lattice. In annealed samples, these form a regular array because the fields shown are within single grains. With hard-rolled foil, the etch facets are arrayed more irregularly because of the highly fragmented structure of the foil. Sulfate addition (Fig. 2) brought about further refinement of the general etch configuration and, in addition, developed additional smaller steps and facets superimposed on the larger facets.

In the lower micrograph of Fig. 2, a very fine speckling of the metal surface is apparent. This configuration has been noted with sulfate-bearing etches and has tended to be more prevalent with hard foil and with high NaCl concentrations.

Intermediate Voltage Formation

The investigation of the potentialities of hard foil for use in the intermediate forming voltage range (100-250V) was concerned primarily with defining optimum etching conditions. Foils of 99.99, 99.93, and 99.88% minimum purity, in the 0 and H19 tempers, were used. Basing the choice of etch parameters on the principles defined previously, and the known effect of the possible etch variables, samples were etched at current densities from 0.25 to 0.75 A/cm² (1.6-4.8 A/in.²), in solutions containing from 40 to 240 g/liter NaCl, both with and without an addition of 10 g/liter Na_2SO_4. Formation was in an aqueous solution containing 1 g/liter $NH_4H_2PO_4$ operated at 90°C. Measurement was the same as for low voltage formation except that a measuring solution having a resistance of 1440 ohms was used.

It was found, as had been expected, that optimum conditions for intermediate voltage formation were

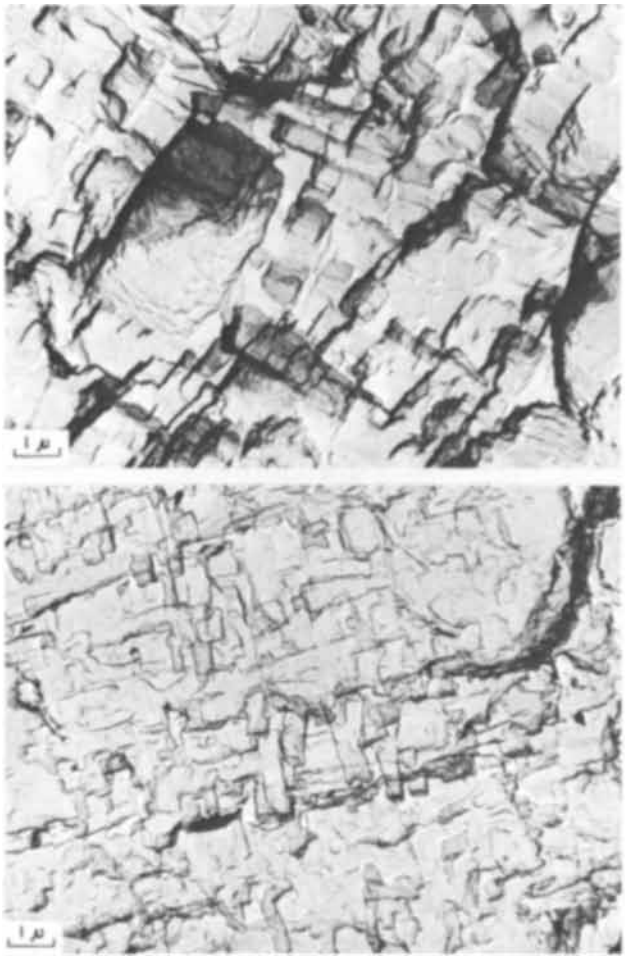

Fig. 2. Etch configurations developed by etching 1199 foil at 4.8 A/in.^{2} in solution of 200 g/liter NaCl + 10 g/liter Na_2SO_4 (X6000). *Top*—annealed foil, 56.7 mfd/in.^{2} at 30V formation. *Bottom*—hard foil, 114.2 mfd/in.^{2} at 30V formation.

different from those for either high-voltage or low-voltage applications. Without sulfate addition, moderately high NaCl concentrations (160-240 g/liter) and current density (~3.2 A/in.^{2}) were optimum. Under these conditions, hard foil of all purities showed some advantage over annealed foil at 125V formation (Table III). As formation voltage was increased, however, this advantage decreased rapidly, particularly with lowest purity foil.

With sulfate addition to the etch solution, the etch-refining effect of the sulfate had to be offset somewhat for maximum capacitance. This was done by reducing NaCl concentration to about 80 g/liter. With this modification, the combination of hard foil and sulfate addition produced greatly increased capacitance as shown by the values in Table III. At these capacitance levels, hard foil showed an advantage over annealed foil with all purities and at all forming voltages.

A further increase in wet-cell capacitance was obtained by hydrating the etched samples prior to formation as shown by the data in Table IV. These higher values could be utilized only if the alpha-alumina-monohydrate formed during hydration had no adverse effect on other capacitor characteristics.

[1] Ten minutes in boiling distilled water.
[2] Etched at 3.2 A/in.[2] for 7.2 A-min/in.[2] in 80 g/liter NaCl + 10 g/liter Na_2SO_4 at 90°C.
[3] Formation in 1 g/liter $NH_4H_2PO_4$ solution at 90°C.

Electron microscope examinations were made to show the character of the roughness found optimum for intermediate voltage formation. The roughness of annealed and hard foil samples etched under conditions optimum for hard foil are shown in Fig. 3. The difference in general roughening between the two tempers is apparent, although the basic facet size is somewhat larger than that found optimum for low voltage formation. The larger facet size results from lower NaCl concentration used. Superimposed on general roughness is the finer faceted pattern, apparently generated by sulfate addition.

Summary and Conclusion

For low voltage formation, hard foil develops maximum capacitance with high NaCl concentration, high etching current density, and a sulfate addition to the etch. For intermediate forming voltages, optimum conditions involve lower current density and somewhat lower NaCl concentration. With proper etch parameters, hard foil is superior to annealed foil up to 250V formation.

Mechanism of Operation of a Voltage-Sensitive Switch

John J. Randall, Jr., Ernest N. Urfer, Henry F. Puppolo, and William S. Goruk*

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts 01247

ABSTRACT

Electron microscopy and electron microprobe analysis have shown that discrete iron-rich impurity sites in aluminum foil cause the formation of voids 2-40μ in diameter in the porous part of a duplex porous-barrier anodic film used as the insulating element in a voltage-sensitive switch. It is postulated that the existence of these voids allows the counterelectrode material to penetrate the porous layer and contact the underlying barrier layer. Since the cross-sectional area penetrated is very small, the probability of direct contact to imperfections in the barrier layer is much lower than would be the case with a simple metal-barrier oxide-metal system. As a result, breakdown strength of a device made with the duplex oxide is more uniformly reproducible than that of the latter and is also more nearly characteristic of bulk aluminum oxide.

A single-shot, voltage-sensitive switch with extremely reproducible breakdown characteristics can be prepared on an aluminum substrate by anodizing the aluminum sequentially in a porous film forming electrolyte and in a barrier film forming solution and then applying an appropriate counterelectrode. This device is designed to short-circuit when a pulse voltage of a predetermined magnitude is applied across the electrodes. Prior to closure the characteristics of the device are those of a low-leakage, low-capacitance capacitor, while after breakdown it behaves as a low-resistance conductor. The devices used for this study were designed to close at low voltages (5-15V), but higher closure voltages can be achieved by increasing the thickness of the barrier portion of the porous film formed by the duplex anodization. Closure time for the device is dependent on the height of the voltage pulse applied, but can easily be controlled to within a few microseconds.

Although it has been recognized that films containing porous aluminum oxide of the type which is

* Electrochemical Society Active Member.
Key words: voltage sensitive switch, aluminum oxide, breakdown strength.

formed in chromic acid anodizing electrolytes give more reproducible results for this switching application than do films of the pure, compact barrier type oxide which is used in electrolytic capacitors (1, 2), the reasons for the different behavior have not been elucidated. In this communication we describe our attempts to establish the mechanism of operation of switches utilizing porous oxide by means of optical and electron microscopical examination of the system before and after breakdown had occurred.

Experimental

Aluminum foil for the base electrode was either 99.88, 99.99, 99.999, or 99.9999% pure and was electropolished in a perchloric acid-acetic anhydride solution prior to anodization. Specimens were carefully washed in distilled water after polishing. In the few experiments where evaporated substrates were used, the source material was 99.999% aluminum.

Anodization in aqueous 1.5% chromic acid was carried out at constant current at 38°C for a predetermined length of time. Under the experimental conditions used, anodization in chromic acid solution is known to produce a porous type of aluminum oxide with a layer of compact barrier oxide at the base of the pores. At the current densities used here ($\sim$ 0.5 mA/cm^2), the barrier layer reaches a limiting thickness in less than 10 min, as evidenced by the constancy of the cell voltage beyond that time. The porous layer, however, continues to grow.

Following the anodization in chromic acid, all specimens were anodized at a constant voltage which was slightly higher than the terminal voltage in the CrO_3 solution in 0.1% aqueous ammonium dihydrogen phosphate solution (ADP) at 85°C. This second anodization has been shown to improve the uniformity of closure voltage (2), presumably by healing imperfections in the compact portion of the original film formed in CrO_3. Some increase in the thickness of the compact layer also occurs during this step, but the amount of oxide formed is very small compared to that formed during the first anodization.

The usual counterelectrode material was a relatively heavy coating of silver paste which was dried at 125°C after application, but, for purposes of revealing the appearance of the film after breakdown, in some cases a thin silver paste was applied to the oxide to form a relatively transparent counterelectrode.

Observations

Figure 1 shows low magnification appearances of aluminum foil of three different purities after electropolishing and anodization in chromic acid solution. Anodization in ADP did not noticeably change the appearance of the foil. The spots which appear on all specimens, which will hereafter be referred to as defects, are most obviously prominent on the lowest purity foil; 99.9999% foil showed no evidence of the presence of defects. In no case was it possible to see defects of this type when samples had been electropolished but had not been anodized in chromic acid. It was further observed that variations in the density of sites occurred from one manufacturer's product to the next even with metal foil specimens which had the same over-all purity.

Electron microprobe examination of the defect sites showed that a concentration of metallic impurities occurs at these locations. The roughly circular sites, which are about 2-40μ in diameter, have, as may be seen in Fig. 2, a central core which is 1-2μ across which appears to contain the bulk of the impurity. In the case of 99.88 and 99.99% metal, the impurity was primarily iron in amounts of 0.5 and 0.1%, respectively, in the volume of material analyzed by the microprobe; a small amount of nickel was also present. In the 99.999% foil about 0.05% chromium was found. At high magnification in the optical microscope, it was easily determined that the central region was lower by several microns than the surrounding site area and

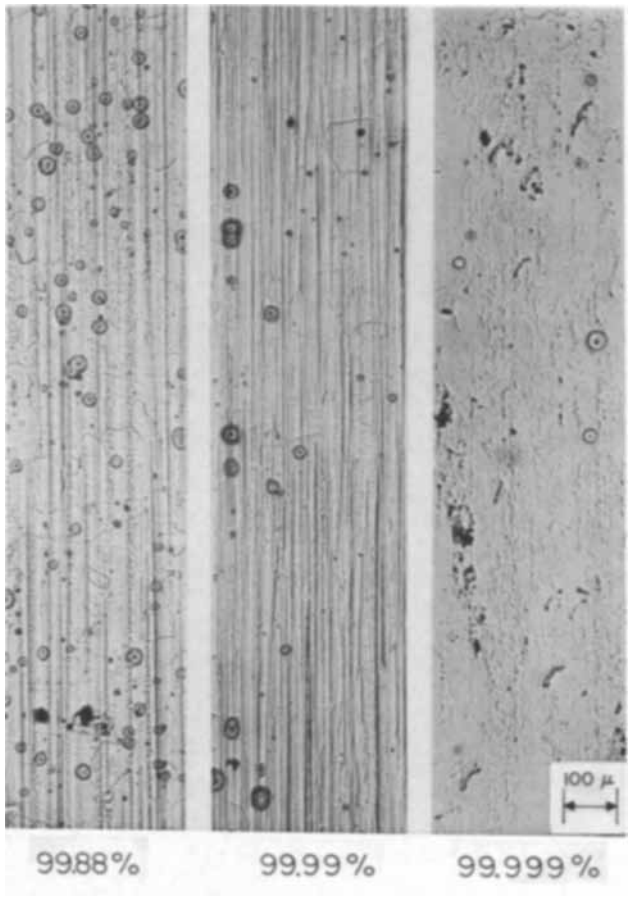

Fig. 1. Appearance of aluminum foil of three different purities after electropolishing and anodizing in chromic acid solution.

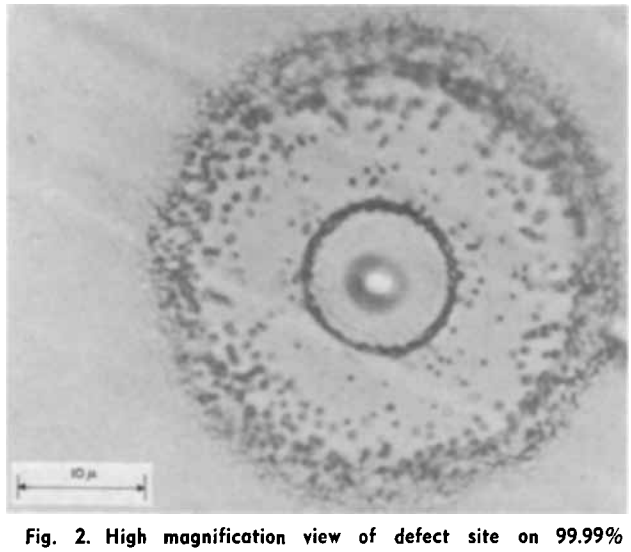

Fig. 2. High magnification view of defect site on 99.99% aluminum.

that the whole site was somewhat lower than the rest of the foil surface.

Switches made using thin silver electrodes were closed by applying the appropriate pulse voltage in order to observe the appearance of specific breakdown locations; Fig. 3 shows one such specimen. From the similarity of appearance of the specimen which had been broken down to that seen in Fig. 2, it seems obvious that breakdown is localized at the impurity sites.

Oxide films were then isolated from anodized foil by the use of an aqueous mercuric chloride solution which amalgamates with the aluminum and allows the film to float free. Pieces of film were rinsed and then

Fig. 3. Defect sites where breakdown has occurred. Black material is thin silver counterelectrode.

picked up on copper screens for examination in the electron microscope. Figure 4 contains a selection of transmission micrographs of areas of oxide which (presumably) were located above defect sites in the metal. The darker areas are thicker than the lighter and indicate the presence of porous Al_2O_3, while the lighter areas, as can be seen particularly in Fig. 4(b), have a structure more typical of barrier-type oxide. In several cases, the thin-film area has apparently separated from the thicker film and left a hole in the specimen.

When the anodization time in chromic acid is greatly increased, the sites have a slightly different appearance as is shown in Fig. 5. It appears that the porous oxide on both sides of the annular void has begun to grow across the barrier oxide region. It seems possible that these growths might ultimately form a bridge across the thin-film area when the film is grown to still greater thickness, but this was not verified directly due to the fact that the electron beam could not penetrate a film much thicker than that of Fig. 5.

Correlation of Physical Structure with Electrical Characteristics

Typical ramp-type closure data (applied voltage was increased at 0.1 V/sec until breakdown occurred) for films formed on two different purity substrates are plotted in Fig. 6 as a function of anodization time in chromic acid (which is roughly proportional to the total film thickness). For both purities, a plateau is observed for short anodization times and a sharply increasing slope thereafter. On the plateau region of the curves closure voltage is very reproducible, while beyond that region breakdown is erratic.

Since the breakdown voltage in the plateau region is roughly the same as the ADP anodization voltage, and since it can be demonstrated that the porous layer continues to grow throughout the plateau regions of these curves, it is apparent that the porous portion of the film does not contribute to the breakdown voltage until it has grown beyond a critical thickness, which thickness is larger for lower purity aluminum. Effectively, anything less than the critical thickness of porous oxide is shorted-out by the defect sites so that it makes no contribution to the closure voltage. The more sites that are present, or perhaps the larger or deeper they are, as is probably the case with 99.88% metal, the thicker the layer of oxide which can be affected, and the longer the plateau region of the curve.

From the appearance of the film over the impurity sites and the known structure of porous oxide films on aluminum, we deduce the cross-sectional structure of the sites shown in Fig. 7 and the following explanation for device performance. The nonhomogeneity of the

iron impurities appears to be due to the low solubility of iron in aluminum, which causes segregation of an iron-rich phase at specific sites. From the transmission photographs it appears that porous oxide does not

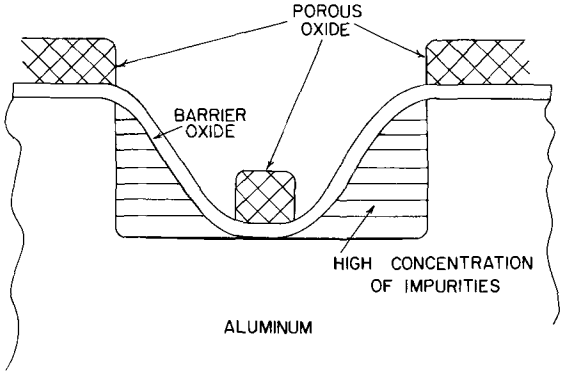

Fig. 7. Proposed cross-sectional structure of defect site

form over an annularly shaped region on top of these discrete iron locations in the original foil. However, barrier oxide apparently does form in the annular region, as can be seen in Fig. 4(b), where the thinner barrier oxide has broken and rolled back on itself. The barrier layer has the typical "orange peel" appearance which has often been observed on electropolished aluminum and on thin dielectric Al_2O_3 films (3, 4). The reasons for the formation of porous oxide over the very center of the site but not around its periphery are not known, but may indicate that iron is absent from the most central region. Unfortunately, the diameter of the electron beam in the microprobe was too large to tell precisely whether the impurity was located in the exact center of the site or in the annular ring, so that a complete correlation was not possible.

Because of the presence of these annularly shaped voids in the porous layer it is possible for the counterelectrode material to penetrate through to the barrier film at a considerable number of locations, particularly when a liquid or semiliquid vehicle is used for application of the counterelectrode. Since the total insulator thickness is then less at these points than at the surrounding locations, the switch is most likely to break down at the defect sites. In fact, electron microprobe analysis of devices made from 99.99% aluminum showed that iron was present at every shorted area in a closed switch. This explains why the closure voltage on the plateau sections in Fig. 6 is characteristic of the barrier layer alone rather than of the barrier-porous combination. The fact that closure voltage rises sharply as anodization time is further increased is taken as evidence that counterelectrode penetration of the voids becomes less likely either because of "bridging" mentioned above or to the increased vertical height of the void. The former could perhaps come about as a result of the complete consumption of the iron impurity by the anodic oxidation.

The total area of contact to the barrier layer is rather small; in 99.99% aluminum, the approximately 600 sites/cm^2 occupy only an estimated 0.05% of the geometric surface area of the specimen. Hence, most of the barrier layer is covered by porous oxide, and other types of defects, such as those caused by surface contamination or roughness (5, 6), which are present in much larger numbers and which are known to give rise to low-voltage breakdown of dielectric films (7) are, for the most part, insulated from the counterelectrode. (Conceiving of the porous layer and the barrier layer as two distinct entities, the result is not unlike the improved insulation resistance achieved when two layers of paper are utilized in a paper capacitor, for the probability of a defect in one layer being exactly aligned with one in the second layer is extremely small.) It is this insulation of defects having low breakdown strengths which is thought to account for the more uniform breakdown behavior of the duplex film, as compared to that of a barrier oxide film of the type used in capacitors.

As might be predicted, switches prepared on evaporated aluminum substrates had considerably higher breakdown voltages than foil-based devices. This is presumably due either to the fact that the evaporation nearly totally separates the iron and other high melting point impurities from the aluminum, or to the homogenization of impurities which would be expected to occur during the process of deposition. Since the evaporated substrates have no discrete impurity sites, the porous part of the duplex insulator makes a positive contribution to the breakdown strength regardless of its thickness, and plots of closure voltage *vs.* anodization time (or total film thickness) do not exhibit the plateau region of Fig. 6.

Technical Notes

Mounting Specimens in Teflon for Electrochemical Studies

Z. Nagy* and J. McHardy*

The Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pennsylvania 19104

Electrochemical studies frequently involve the use of strong acids or alkalies which attack most mounting materials (epoxy resins, waxes, *etc.*) (1) to some extent and result in contamination of the test solution. In our experience, only Teflon has proved fully satisfactory as a mounting material. Three techniques have been described for mounting specimens with Teflon (2-4), but each one has certain shortcomings. The method described here has proved sufficiently versatile for mounting both brittle, irregular crystals of so-called "sodium tungsten bronze" (5) and wires of pure zinc.

1. Sodium tungsten bronze.—Crystals of the nonstoichiometric compound Na_xWO_3 (where $0.4 < x < 1$) are prepared by electrolytic deposition from a $Na_2WO_4 + WO_3$ melt onto a gold wire. A short length of the wire is left projecting from the crystal for making electrical contact. The crystal is placed in a clean metallographic mounting mold (the use of Teflon eliminates the need for mold lubricants) as shown in Fig. 1. The mold is partially filled with a pre-established amount of molding powder (Teflon 8 granular TFE resin) and pressed at about 5000 psi (compression ratio 3:1) to form a ½ in. diameter, ¾ in. long pellet. At this point, the compact has sufficient mechanical strength to be handled easily. The tip of the gold wire is exposed by cutting away a few millimeters of Teflon, then the compact is sintered in a stream of pure nitrogen for 2 hr at 380°C. Between 280° and 380°C, the warm-up and cool-down rates are controlled at 50°C/hr. TFE Teflon undergoes large dimensional changes in this range and rapid heating or cooling can result in cracking. Slow cooling also produces a high degree of crystallinity in the finished piece, a characteristic needed for good creep resistance and low gas permeability (6). Below 280°C, the rates are not critical.

A wire is soldered to the gold contact, and the specimen is mounted in the Teflon and glass assembly illustrated in Fig. 2. The Teflon part of the assembly is a "Straight Union Reducer" (Fluorocarbon Incorporated).

2. Zinc wire electrode.—A somewhat different approach is used in this case. A pellet of Teflon is pressed as before, then a hole, about 3% under size, is drilled in the center, and the zinc wire (1/32 in. diam) is forced into the hole. The compacted pellet has the re-

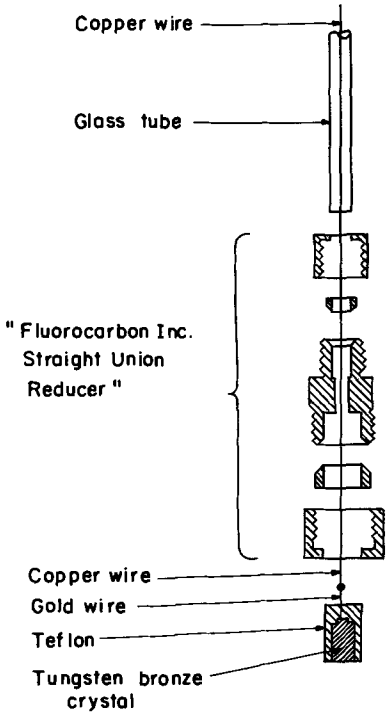

Fig. 2. Electrode assembly for tungsten bronze specimens

Table I. Comparison of four Teflon specimen mounts

Mount	Compression gasket	Hot-pressed FEP	Shrink-fit tubing	Sintered TFE
Source	Stern & Makrides (2)	Mannan (3)	Alwitt & Vijh (4)	Present work
Specimen requirements	Drilled and tapped rod	No limitation	Simple shape	No limitation
Versatility	Limited to machinable materials	Unsuitable for reactive materials	Good but not well suited for repeated polishing	Good
Convenience	Good	Poor, requiring simultaneous application of heat and pressure	Good	Good, but requires care during sintering

quired mechanical strength to allow these operations with only occasional failure. The pellet is sintered under the same conditions as described in case 1 and then machined to fit the glass part of a "Lab-Crest Solv-Seal Joint" (Fischer & Porter Company). The electrical contact to the zinc wire is made by spot welding a platinum foil to it, which in turn is spot welded to copper wire. (Spot welding the zinc to copper was found to be difficult.) The full assembly is shown in Fig. 3. The working face of the assembly is mechanically polished before each test.

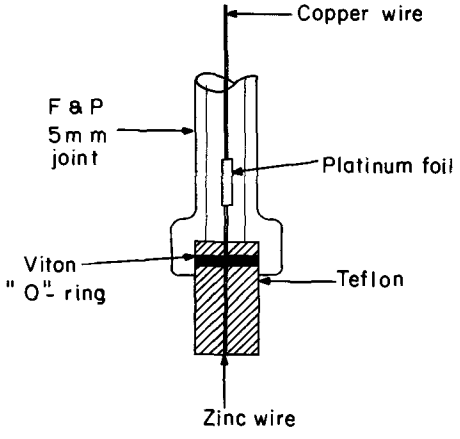

Fig. 3. Electrode assembly for zinc wire specimens

Each of the four types of Teflon mount fulfills the primary requirement of a clean, leakproof electrode. The differences among them lie in such considerations as convenience and versatility (*cf.* Table I). The present technique was developed for applications requiring greater versatility than the three earlier methods could provide.

The Sulfur Cathode in Liquid Ammonia

M. H. Miles*

Department of Chemistry, Middle Tennessee State University, Murfreesboro, Tennessee 37130

and W. S. Harris*,[1]

Naval Weapons Center, Corona Laboratories, Corona, California 91720

ABSTRACT

Electrochemical studies of sulfur-H_2S solutions in acid liquid ammonia electrolytes on silver and platinum surfaces over the temperature range of +20° to −50°C show that sulfur is a useful cathode for low-temperature fuel cells and batteries. The maximum theoretical coulombic efficiency of two electrons per sulfur atom can be obtained. The potentiostatic reduction of the sulfur species in stirred solutions shows that even at subzero temperatures the reactions achieve rates limited only by mass transport. The reaction on platinum apparently involves physical adsorption of the reacting sulfur species, while the reaction on silver involves chemical bonding of the sulfur species and formation of Ag_2S. Insoluble, electronically conducting Ag_2S should prove useful as a rechargeable cathode in batteries and fuel cells.

Solutions of elemental sulfur in liquid ammonia have been proposed for use as cathodes in low-temperature batteries (1-3). The actual species present when sulfur is dissolved in ammonia is still in question, especially since recent work has refuted the existence of S_4N_4 to any appreciable extent (4-8). The high solubility of sulfur in ammonia (5, 7) makes this inexpensive element attractive for use as the oxidant in low-temperature fuel cells and batteries using liquid ammonia electrolytes. A fuel cell consisting of liquid lithium ammoniate as the fuel and sulfur as the oxidant gives a theoretical energy density comparable to that of the H_2/O_2 fuel cell and, furthermore, shows promise of operation at subzero temperatures. Studies on the liquid lithium anode are in progress; results presented here are restricted to electrochemical investigations of sulfur solutions in liquid ammonia.

Experimental

The chemicals used include Matheson N.F. sublimed powder sulfur, Baker reagent NH_4NO_3 and $LiNO_3$, and Matheson anhydrous ammonia (99.99%), each used without further purification.

Potentiostatic measurements were made in liquid ammonia solutions stirred by a stream of ammonia gas. The current between the working and counterelectrodes was recorded *vs.* time and usually appeared to be fairly constant after several minutes. Measurements were made in the direction of both increasing and decreasing potentials, and the average value is reported.

Solution preparation, electrochemical cells, reference electrodes, temperature control, and electronic equipment is described elsewhere (9-10).

Key words: ammonia, cathode, electrocatalysts, platinum, polysulfides, silver, silver sulfide, reduction, sulfur.

Results

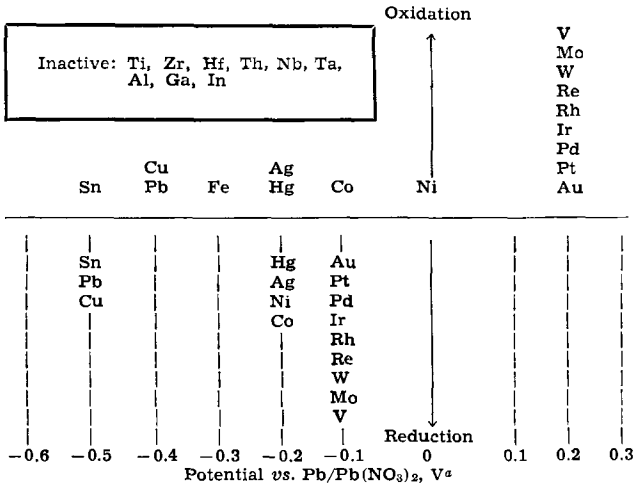
Rate of solution.—Although sulfur is soluble in ammonia solutions in excess of 30% by weight (10M), the rate of solution is often slow; for example, in attempting to prepare a 0.1M sulfur solution in concentrated NH_3-$LiNO_3$ a dichroic blue-red solution formed which changed gradually to a yellow solution, but some of the sulfur remained undissolved even after ten days. During potentiostatic reduction, the color of this solution changed to a deep brownish red, and the excess sulfur dissolved. When H_2S is present even in low concentrations, however, the rate of solution of sulfur in ammonia is very rapid.

Electrocatalysts.—The electrochemical oxidation or reduction reactions of the sulfur-H_2S solution in acid liquid ammonia depend markedly on the nature of the metal electrode used. The platinum metals tested (Pt, Pd, Ir, Rh) along with Re, Au, W, Mo, and V show a large (over 0.3V) difference in the potentials at which significant electrode oxidation and reduction of the sulfur solution occur. For Ag, Hg, Cu, Pb, and Sn the oxidation reactions of the sulfur-H_2S solution are observed at potentials considerably more negative than for the Pt metals, and the reduction occurs at potentials close to those of oxidation. Results for Co and Ni are intermediate to those for Ag and Pt. For Fe, a large oxidation peak is observed, but no subsequent reduction peak could be detected.

The metals Ti, Zr, Hf, Th, Nb, Ta, Al, Ga, and In are completely inert toward any electrochemical reaction of the sulfur solution.

The results for the various metals are summarized in Table I by listing the metal at the potential (to the nearest 0.1V) where the oxidation and reduction currents due to sulfur or H_2S attain a value of 2 mA/cm^2 when the sweep rate is 125 mV/sec. Oxidation is repre-

Table I. Sulfur reactivity on various metals in NH_3-NH_4NO_3 at 20°C from cyclic voltammetric experiments



[a] The potential where the current density for the sulfur reaction is 2 mA/cm² at a sweep rate of 125 mV/sec (0.02M S + H_2S).

sented above and reduction below the center horizontal line.

Cyclic voltammetric experiments.—Figures 1-3 show cyclic voltammograms of sulfur-H_2S solutions in acid liquid ammonia. Figure 1 shows a typical cyclic voltammetric trace for sulfur on a platinum electrode with the dashed line indicating the background current of the NH_3-NH_4NO_3 solution alone.

Figure 2 shows the effect of the potential sweep rate on the oxidation and reduction peaks when a silver electrode is used. Making repeated sweeps with no wait time between successive sweeps gave very reproducible results. The anodic and cathodic peak currents are proportional to the square root of the sweep rate. The displacement of the peak potentials with increasing scan rates suggests uncompensated iR effects (11, 12) due to the large currents obtained. From Fig. 2, this effect is about 1.5 V/A, suggesting that the uncompensated resistance between the reference and working electrodes is a reasonable value of about 1.5 ohms. Figure 3 shows the sulfur reactions on the silver

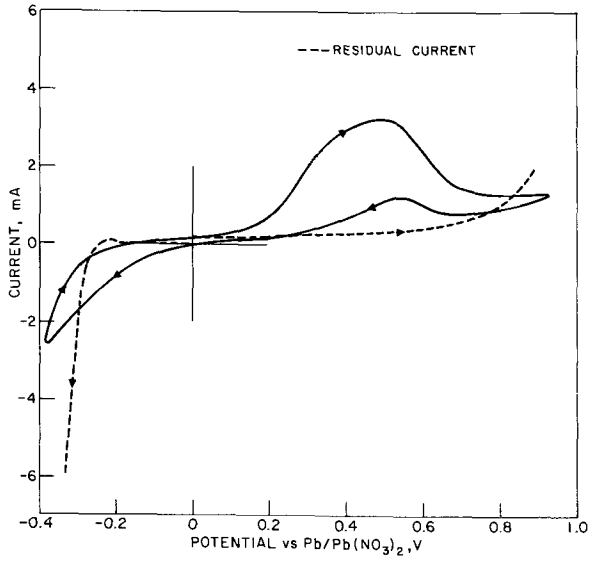


Fig. 1. Cyclic voltammogram for 0.1M sulfur, H_2S solution in NH_3-NH_4NO_3 at 15°C using platinum wire electrode with geometrical area = 0.3 cm². Potential sweep began at 0.0V and swept first in the anodic direction. Sweep rate = 100 mV/sec.

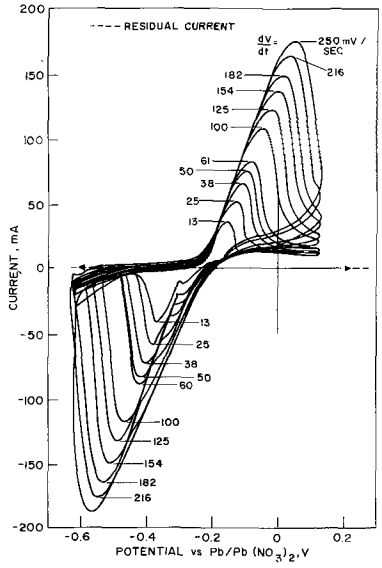

Fig. 2. Effect of potential sweep rate on cyclic voltammograms for 0.1M sulfur, H_2S solution in NH_3-NH_4NO_3 at 15°C using silver wire electrode with geometrical area = 0.3 cm².

electrode at −50°C as a function of the anodic sweep range limit during continuous potential sweeps.

Constant current experiments.—Typical curves for the constant current reduction of sulfur in stirred acid ammonia solutions at 15°C on silver and platinum electrodes are shown in Fig. 4. A sharp inflection in potential is observed when 2 electrons are consumed in the reaction per atom of sulfur initially present. A similar study at −10°C on silver also gave nearly 2 electrons per sulfur atom. Constant current studies on nickel show evidence for sulfur reduction but gave no clear inflection, while tantalum showed complete inactivity toward any sulfur reduction.

Potentiostatic experiments.—Potentiostatic studies of the electrochemical reduction of sulfur solutions on silver and platinum surfaces in stirred acid liquid ammonia solutions at 15° and −35°C are presented in Fig. 5-6. The residual current shown is the current obtained before sulfur and H_2S were added and results mainly from the reduction of NH_4^+ to hydrogen gas. The rest potential in the 0.1M sulfur, H_2S solution was −0.15V with the silver electrode and 0.0V for the

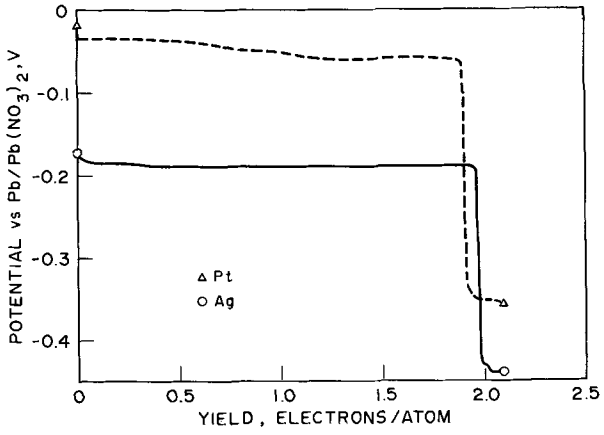

Fig. 4. Constant current reduction of sulfur, H_2S solutions in stirred NH_3-NH_4NO_3 on platinum and silver electrodes of about 50 cm^2 geometrical area. I = 1.00 mA; T = 15°C.

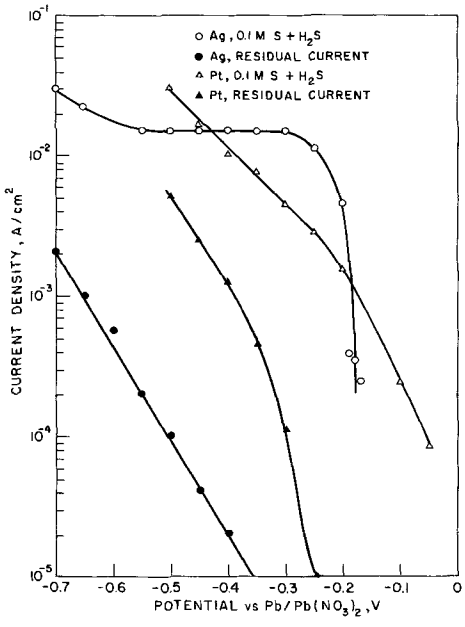

Fig. 5. Potentiostatic reduction of 0.1M sulfur, H_2S solutions in NH_3-NH_4NO_3 on silver and platinum electrodes. T = 15°C.

platinum electrode, both potentials measured at 15°C against a Pb/saturated $Pb(NO_3)_2$ reference electrode. The reaction rate for the reduction of sulfur appears to be faster on silver than on platinum since with the silver electrode there is a sharper increase in reduction current density with overvoltage (Fig. 5). The reduction of sulfur on silver achieves mass transport limitation since a limiting current is reached which is markedly dependent on the rate of stirring. Stopping the stirring action causes the current to fall suddenly; recovery is quick when stirring is resumed. The reduction current for the sulfur reaction on platinum at high overvoltage is also affected by the rate of stirring. Note that the limiting current attained on silver is higher at −35°C (Fig. 6) than at +15°C, probably resulting from the lower viscosity of the less concentrated 1M NH_4NO_3 solution.

Neutral solutions.—Thus far the results have all been for acid (NH_4NO_3) ammonia solutions to which H_2S was added to accelerate the rate of solution of the sulfur. The results are quite different for sulfur dissolved in neutral ($LiNO_3$) ammonia solutions where no H_2S is used. Cyclic voltammetric experiments on the sulfur dissolved in neutral liquid ammonia showed no evidence for any electrochemical oxidation or reduction of sulfur on silver or platinum electrodes. Con-

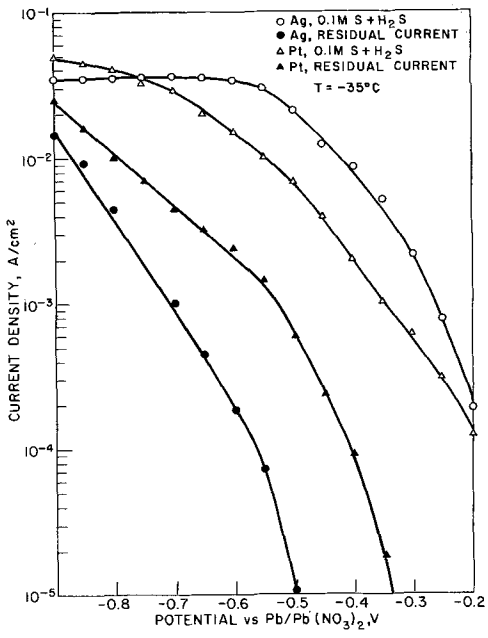

Fig. 6. Potentiostatic reduction of 0.1M sulfur, H_2S solutions in NH_3-1M NH_4NO_3 at −35°C on silver and platinum electrodes.

stant current experiments in stirred neutral ammonia solutions on silver and platinum electrodes showed similar negative results. Unlike the behavior shown in Fig. 4, when reduction begins, the potential quickly drops to about −2.3V, indicating that the sulfur remains unreacted, and lithium ions are being reduced. Addition of Li_2S produced no change in these experiments, but the addition of H_2S quickly rendered the sulfur reducible. Similarly, potentiostatic measurements showed very little reduction of sulfur until H_2S is added to the solution.

These very different effects of Li_2S and H_2S on the sulfur solution in neutral ammonia supports the findings of Nelson and Lagowski (8) that H_2S in ammonia forms a hydrogen-bonded species, $[SHNH_3]^-$, but produces no free sulfide ions, while sulfide ions added to ammonia do not undergo ammonolysis to HS^-. Apparently, the species $[SHNH_3]^-$ is necessary to render the dissolved sulfur electrochemically active. The reactive forms of sulfur probably are polysulfides since solutions of sulfur and H_2S in liquid ammonia have been shown to produce polysulfides, and the compound $(NH_4)_2S_5$ has been isolated (5, 13).

Discussion

In evaluating the sulfur cathode for fuel cell or battery use in liquid ammonia electrolytes, the constant current studies are a measure of the coulombic efficiency. The constant current studies of sulfur reduction on platinum and silver (Fig. 4) show that, within experimental error, the maximum theoretical coulombic efficiency of two electrons per sulfur atom can be obtained on these two metals. This indicates that there are no detrimental side reactions or decomposition of the reactant during the 40-hr time span of the experiments. Similar studies on silver at −10°C gave approximately the same results as obtained at +15°C, showing that this high coulombic efficiency does not decrease appreciably with decreasing temperature.

The potentiostatic investigations in the stirred solutions are a measure of the dynamic performance of the sulfur cathode in a flowing electrolyte feed fuel cell. Figures 5 and 6 indicate that the dynamic performance of the sulfur cathode is at least as good on silver as on platinum. The rest potential of the sulfur cathode is more negative on silver than on platinum, but a limiting current is reached at considerably lower overvoltages on the silver electrode. The dynamic performance of the sulfur cathode at −35°C (Fig. 6) indicates

satisfactory low-temperature operations, especially considering that the reactions achieve rates limited only by mass transport, and that much higher sulfur concentrations are feasible. Using the expression (14)

$$i_L = nFD\delta^{-1}C \qquad [1]$$

for the limiting current dsnsity, i_L, where D is the diffusion coefficient, δ is the thickness of the diffusion layer, C is the bulk concentration of reactant, and n and $\mathbf{F}$ are the usual electrochemical quantities, we calculate from the results on silver (Fig. 5 and 6) that $D\delta^{-1} = 10^{-3}$ cm sec^{-1}. Since δ is usually about 10^{-3} cm in stirred systems, the diffusion coefficient of the reacting sulfur species is roughly 10^{-6} cm^2 sec^{-1}, a reasonable value (10), indicating that the reaction is indeed limited by mass transport.

A probable general reaction mechanism for the sulfur reactions in ammonia is

$$xM + yS \rightleftharpoons M_x \ldots S_y \underset{-2ye^-}{\overset{+2ye^-}{\rightleftharpoons}} xM + yS^= \qquad [2]$$

where M represents the electrode metal and S and $S^=$ are likely part of a polysulfide ion, $S_x^=$. The $M_x \ldots S_y$ bond may range from simple electrode absorption to an actual metallic sulfide compound. Both Ag_2S and PtS, like most sulfides of the electrode metals tested, are black compounds which are insoluble in liquid ammonia, and therefore readily detectable if formed in significant amounts. During the electrochemical studies on platinum of the sulfur-H_2S solutions in liquid ammonia, the platinum electrodes maintain a bright, metallic luster indicating very little build-up of any metallic sulfide compounds. However, when a silver electrode remains at open circuit in the sulfur-H_2S solution, or during electrochemical oxidation of the solution on silver, the silver electrode becomes black, indicating formation of Ag_2S from the chemical reaction

$$2Ag + S \rightleftharpoons Ag_2S \qquad [3]$$

or from the electrochemical reaction

$$2Ag + S^= \rightleftharpoons Ag_2S + 2e^- \qquad [4]$$

Constant current coulometry experiments show that the electrochemical oxidation of ammonia-H_2S solutions on silver produces insoluble products which can be quantitatively reduced. An acid ammonia solution saturated with H_2S was oxidized on silver for 1800 sec at 0.500 mA, turning the electrode black. The solution was then stirred for 30 min to allow any soluble sulfur products to dissolve, then the electrode was transferred to a separate compartment with fresh electrolyte. Reduction at the same current, 0.500 mA, produced a gradual fading of the black color with a sharp inflection in potential after 1815 sec, indicating that the silver had been oxidized to insoluble Ag_2S and then was quantitatively reduced. Figure 7 shows the results of this test and results for a silver control electrode in a similar solution showing that the reduction is not observed without first forming silver sulfide. Similar tests on platinum showed oxidation of the ammonia-H_2S solution at about 0.0V with the electrode remaining bright. Reduction in a separate compartment showed only hydrogen evolution, indicating that no insoluble platinum sulfide compounds were formed on the platinum electrode during oxidation of the ammonia-H_2S solution. These experiments suggest that in reaction [2], $M_x \ldots S_y$ represents chemical bonding with formation of a metallic sulfide compound on silver while the bonding on platinum is of a different nature.

The very different peak potentials and peak currents observed in the cyclic voltammetric experiments on platinum and silver (Fig. 1 and 2) reflect the different nature of the sulfur reactions on these two surfaces. On the silver electrode, formation of the electronically conducting Ag_2S greatly increases the

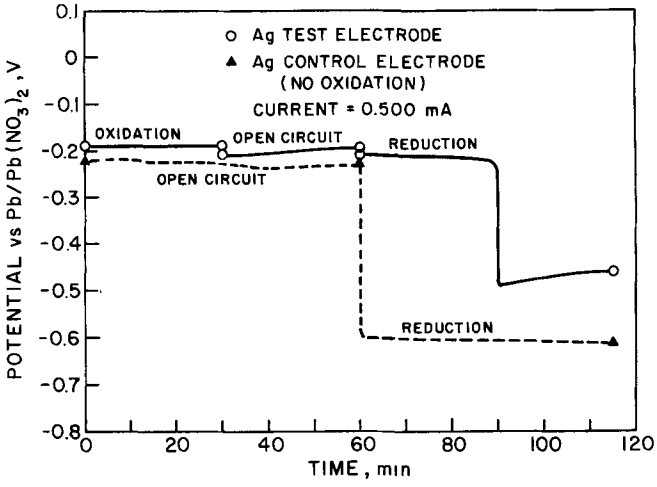

Fig. 7. Constant current coulometry experiments on silver in NH_3-NH_4NO_3 solutions containing H_2S using constant currents of 0.500 mA. Electrode area = 2 cm^2, T = 15°C.

effective electrode area, resulting in higher currents. The peak currents on the silver electrode in sulfur-H_2S solutions are quite insensitive to the bulk sulfur concentration; also the number of coulombs involved in the reaction peaks (Fig. 2) are independent of the potential sweep rate, indicating that we are essentially observing reaction [4] involving insoluble Ag_2S. The reversibility of this reaction suggests use of Ag_2S as a rechargeable cathode in liquid ammonia batteries or fuel cells. Figure 3 indicates that reaction [4] occurs readily even at −50°C, indicating good performance of the Ag_2S cathode at subzero temperatures.

Table II gives the free energy of formation, ΔG_f°, for several metallic sulfides along with the calculated standard electrode potential for the reaction $M_xS_y + 2ye^- \rightleftharpoons xM + yS^=$ in aqueous solutions. The variation in the standard potentials from that for silver, E°-$E^\circ_{Ag_2S}$, reflects solely the differences in ΔG_f° for the metallic sulfide, hence the variation should be the same in liquid ammonia solutions for the above reaction. The difference in the potentials in Table I at which electrochemical oxidation of the sulfur-H_2S solution in ammonia is observed may reflect such thermodynamic effects when the $M_x \ldots S_y$ bond involves chemical bonding. Comparing Tables I and II indicates that the sulfur reactions on Hg, Fe, Cu, Pb, and Sn probably involve chemical bonding as found for silver since, as thermodynamically expected, the reactions are observed at potentials negative to the reaction on silver. The sulfur oxidation reactions on Pt, Ir, Mo, Ni, and Co are observed at potentials considerably more positive than thermodynamically expected,

Table II. Thermodynamic data[a]

Compound	ΔG_f°, kcal/mole[b]	E°, V[c]	$E^\circ - E^\circ_{Ag_2S}$, V

[c] Standard electrode potential at 25°C for the reaction $M_xS_y + 2ye^- \rightarrow xM + yS^=$ in aqueous solution. For $S^=$(aq), ΔG_f° = 20.5 kcal/mole from the above reference.
* ΔH_f° (ΔG_f° is not given).

indicating that metallic compounds are not involved in these reactions. Much weaker $M_x \ldots S_y$ bonds are apparently formed on these metals. From the difference in rest potentials for the Ag and Pt electrodes in sulfur-ammonia solutions (0.15V), it is estimated that $\Delta G_f^\circ = -3$ kcal/mole for the Pt . . . S bond formed in the electrochemical reaction. This small value suggests that weak, adsorption bonding of the sulfur species to the platinum surface is involved.

Other metals which form weak, adsorption bonds with the sulfur species would be expected to show electrochemical behavior similar to platinum. The metals inactive toward the sulfur-ammonia solution apparently do not form either chemisorption or physical adsorption bonds with the sulfur species. This inactivity may be due to oxide or nitride films on the metal which persist during the electrochemical experiments.

Summary

1. The reduction of sulfur in platinum and silver electrodes in acid ammonia solutions yields the maximum theoretical coulombic efficiency of two electrons per sulfur atom.

2. Potentiostatic measurements in stirred solutions show that even at subzero temperatures the reactions achieve rates limited only by mass transport.

3. The electrochemical reactions of sulfur on platinum and silver are different in nature. Apparently, physical adsorption is involved on platinum, while chemisorption and Ag_2S formation occurs on silver.

4. Electronically conducting Ag_2S may be useful as a rechargeable cathode in liquid ammonia batteries and fuel cells. The oxidation and reduction reactions involving this compound occur readily even at −50°C.

5. Cyclic voltammetric screening of various metals indicates their activity toward the sulfur reactions. Interpretations of these results are given in terms of the thermodynamics of the metal-sulfur bond.

Anodic Polarization of Passive Electrodes

D. A. Vermilyea*

Surfaces and Reactions Branch, Physical Chemistry Laboratory, General Electric Company, Schenectady, New York 12301

ABSTRACT

Anodic current flow at a passive electrode lowers the surface *p*H and increases the corrosion and film dissolution rates. Analytical expressions are obtained to permit the calculation of the rates of formation of new film and soluble species. It is shown that when equilibrium is achieved between the film and the solution, as with magnesium, polarization of only a few tens of millivolts can result in current densities of the order of 1 A/cm². For metals forming films which dissolve more sluggishly it is often necessary to exceed the oxygen evolution potential before large currents can be achieved. Thick anodic films can be formed when the film blocks oxygen evolution and when the film dissolution rate constant is small. Buffers suppress the *p*H change at the surface and may prevent rapid dissolution and corrosion.

The purpose of this paper is to discuss the effects on the current and corrosion rate of the application of anodic currents to passive metals. Passivity is difficult to define adequately, and for this discussion a passive metal is one covered with an oxide or hydroxide film which substantially impedes corrosion. Such a film will often comprise a dense barrier layer of a poorly crystallized material next to the metal and a porous layer of a better crystallized product next to the solution. Application of an anodic current will usually lower the *p*H at the electrode surface, and that in turn will effect the rate of dissolution of the protective film. It is this effect of *p*H on film dissolution which is to be considered. Localized attack is outside the scope of this paper.

* Electrochemical Society Active Member.
Key words: corrosion, films, dissolution.

The Initial Condition

Consider a film covered specimen in a nearly steady state, with a barrier layer of constant thickness and a porous layer whose thickness is changing slowly. Corrosion at this specimen produces more film (which could be oxide or hydroxide) at a rate r_{fo} according to a reaction like

$$M + zH_2O \rightarrow M(OH)_z + z/2\ H_2 \qquad [1]$$

where z is the metal valence, and soluble species at a rate r_{so} according to

$$M + zH_2O \rightarrow M^{+z} + zOH^- + z/2\ H_2 \qquad [2]$$

the total rate being r_o.

Application of Current

Upon application of an external current, additional hydroxide will be formed at a rate r_f according to

$$M + zH_2O \rightarrow M(OH)_z + zH^+ + ze \quad [3]$$

and additional metal ions at a rate r_s according to

$$M \rightarrow M^{+z} + ze \quad [4]$$

It may be noted that, as far as soluble species are concerned, metal ions are generated by r_s and r_{so}, hydroxyl ions are generated by r_{so}, and protons are generated by r_f.

For simplicity it will be assumed that the solution is sufficiently concentrated that electrical transport can be neglected and the Nernst approximation will be used to describe diffusion near the specimen. Equations for mass balances are then the following

$$\dot{n}_M + z = \frac{10^{-3} D_{M+z} \Delta C_{M+z}}{\delta} = r_{so} + r_s \quad [5]$$

$$\dot{n}_{H+} = \frac{10^{-3} D_{H+} \Delta C_{H+}}{\delta} = zr_f - zr_{so} \quad [6]$$

if there is a net production of protons in an acid solution

$$\dot{n}_{H+} = \frac{10^{-3}[D_{H+}(C_{H+})_i + D_{OH-}C_{OH-}]}{\delta} = zr_f - zr_{so} \quad [7]$$

if there is a net production of protons in a solution containing C_{OH-} hydroxyl ions per liter

$$\dot{n}_{OH-} = \frac{10^{-3} D_{OH-} \Delta C_{OH-}}{\delta} = zr_{so} - zr_f \quad [8]$$

if there is a net production of hydroxyl ions in a basic solution; and

$$\dot{n}_{OH-} = \frac{10^{-3}[D_{OH-}(C_{OH-})_i + D_{H+}C_{H+}]}{\delta} = zr_{so} - zr_f \quad [9]$$

if there is a net hydroxyl ion production in an acid solution with a proton concentration C_{H+}. In Eq. [5]-[9] the $\dot{n}$'s represent rates of generation or removal of the various species, the D's represent diffusion coefficients, δ (assumed the same for all ions) is the thickness of the Nernst layer, the ΔC's represent the concentration difference in moles per liter between the surface and the bulk solution, and the subscript i indicates an interface concentration.

The total external current density, i, is given by

$$i = \sum_j m_j \mathbf{F} \dot{n}_j \quad [10]$$

in which the summation is over all species, and where m_j is the charge on each particle. It can readily be verified that $i = z\mathbf{F}(r_f + r_s)$. Equations [5]-[10] can now be used to find out how an external current will influence the corrosion of the metal. There are two situations of interest, depending on whether or not equilibrium is achieved at the film-solution interface.

Case I. Equilibrium at Film-Solution Interface

For this case the equilibrium conditions are given by

$$K_s = (M^{+z})(OH^-)^z \quad [11]$$

and

$$K_w = (H^+)(OH^-) \quad [12]$$

where the quantities in brackets represent activities. From Eq. [11] and [12], approximating activities with concentrations

$$(C_{M+z})_i = \frac{K_s (C^z_{H+})_i}{K_w{}^z} \quad [13]$$

Equation [10] can now be used with Eq. [13] to find the current density in situations of interest.

Two examples of the use of the equations will illustrate their utility. Consider first magnesium with a film of $Mg(OH)_2$,[1] with $z = 2$, $\delta = 10^{-2}$ cm, $D_{Mg+2} = 10^{-5}$ cm^2/sec, $D_{OH-} = 3 \cdot 10^{-5}$ cm^2/sec, $D_{H+} = 10^{-4}$ cm^2/sec, $\mathbf{F} = 10^5$ coul/eq., $K_s = 10^{-11}$, $K_w = 10^{-14}$, and in the bulk solution $C_{OH-} = 10^{-4}$ moles/liter. In this example there is a net production of protons in an alkaline solution, assumed to contain an excess of supporting electrolyte. Equations [5], [7], [10], and [13] give for the current density

$$i = \frac{10^{-3}\mathbf{F}[D_{H+}(C_{H+})_i + D_{OH-}C_{OH-}]}{\delta} + \frac{10^{-3} z\mathbf{F}}{\delta} D_{M+z} \frac{K_s}{K_w{}^z} (C^z_{H+})_i \quad [14]$$

For a current density of 10^{-1} A/cm^2 the surface concentrations of magnesium ions and protons are found to be 0.5M and 2.24 x 10^{-9}M (pH 8.65), respectively, and nearly all the current is carried by Mg^{+2}. Previous studies of corrosion of magnesium and of dissolution of $Mg(OH)_2$ (2) have shown that a dissolution or corrosion rate of 10^{-10} moles/cm^2 sec can be expected at about pH 9. Using that rate for r_{so} in Eq. [7] we find $zr_f = 2.14 \times 10^{-10}$ moles/cm^2 sec, or $i_f = 2.14 \times 10^{-5}$ A/cm^2. Thus a very small fraction of the applied current produces more film.

Magnesium does actually behave in solutions with pH > 5 as predicted by these equations. The hydroxide layer covering the surface is porous and its growth slows the reaction only moderately (1). Presumably this porous film can readily accept the additional small amount of reaction product corresponding to r_f without blocking the reaction. As a result of this film formation, however, the pH is reduced and the magnesium ion concentration becomes large enough to carry a high current. The end result of anodic corrosion of thin magnesium specimens is a very porous, fragile, but coherent hydroxide replica of the original specimen, which shows that hydroxide is indeed formed by the passage of current.

As a second example consider beryllium, with a film of $Be(OH)_2$ having $K_s = 10^{-26}$ in a pH 5 solution containing excess supporting electrolyte. Taking $D_{Be+2} = 10^{-5}$, Eq. [5], [6], [10], and [13] show that for $i = 10^{-1}$ A/cm^2 $C_{H+} = 0.05$ moles/liter, $C_{Be+2} = 0.25$ moles/liter. If r_{so} is assumed to be 10^{-14} moles/cm^2 sec, a value calculated from the solubility product of $Be(OH)_2$ assuming that the spontaneous reaction is diffusion controlled in the pH 5 solution, then Eq. [6] gives $zr_f = 5 \times 10^{-7}$ moles/cm^2 sec so that $i_f = 0.05$ A/cm^2 and $i_s = 0.05$ A/cm^2. In this example a very large change in pH is required to produce a high current density, so that a large amount of new film must be produced, and both protons and metal ions carry a significant fraction of the current. The experimental situation is not so well known for beryllium as for magnesium, and in particular it is not known whether equilibrium is achieved at the solution-film interface.

Discussion of Case I.—Constancy of r_{so} was assumed and in the examples given the values of r_{so} were so low compared to other rates that the approximation is reasonable. Usually anodic polarization would decrease the spontaneous cathodic reaction and hence decrease r_{so}, and for some situations a good approximation may be to ignore r_{so} in Eq. [5]-[9]. On the other hand, strong anodic polarization and a large decrease in pH may decrease the barrier film thickness significantly and result in an enhanced cathodic reaction and increased r_{so}.

It is possible that the specimen may become film free as a result of anodic polarization. For example, for a metal which is relatively unreactive in a thermodynamic sense the hydrolysis of metal ions may produce a pH low enough to make the film unstable at

[1] There may be a MgO layer between this film and the metal, but at long times the $Mg(OH)_2$ layer controls the corrosion behavior.

the applied potential. The present analysis does not apply to such a situation.

Finally, the current-potential behavior is of interest. If equilibrium is achieved at the interface, and if the solution is very concentrated so that no changes in the total ion concentration take place in the Nernst layer, then only a resistive polarization occurs. In a less concentrated solution concentration polarization occurs in the Nernst layer and some additional polarization will be present. Such concentration polarization can be calculated from the equation (3)

$$E = \frac{RT}{z\mathbf{F}} \ln\left(1 + \frac{i\delta}{z\mathbf{F}D \cdot 10^{-3}C_o}\right) \qquad [15]$$

in which E is the potential difference and C_o is the bulk anion concentration. If $C_o = 1$ mole/liter, for a current density of 1 A/cm^2 $E = 0.023$V for a divalent anion. It can be seen that the electrode polarization (exclusive of iR drop) for such anodic corrosion can be very small.

Case II. Equilibrium Not Achieved at Film-Solution Interface

If equilibrium is not achieved it is convenient to use the relationship

$$i = z\mathbf{F}(r_f + r_s) \qquad [16]$$

It has been predicted theoretically (4) and observed experimentally (2, 5) that the relationship between dissolution rate and hydrogen ion concentration for oxides and hydroxides has the form

$$r_s = k\,C^n{}_{H+} \qquad [17]$$

in which k is the dissolution rate constant and n has values which differ markedly for various systems and range from 0 to 4/3. For the situation in which Eq. [6] is valid, Eq. [6], [16], and [17] give

$$i = z\mathbf{F}\left[r_f + k\left\{\frac{\delta}{10^{-3}D_{H+}}(zr_f - zr_{so})\right\}^n\right] \qquad [18]$$

A slight rearrangement, the substitution of values for δ, D_{H+} and $\mathbf{F}$, and of i_f for $z\mathbf{F}r_f$ and i_{so} for $z\mathbf{F}r_{so}$ gives

$$i = i_f + z\mathbf{F}k(i_f + i_{so})^n \qquad [19]$$

Three ranges of values of n are of interest:

(a) $n = 0$.

It has been observed (5) that the rate of dissolution of anodic Al_2O_3 films in aqueous solutions at 100°C is nearly independent of pH between pH 1 and pH 10, so that $n = 0$.[2] Then

$$i = i_f + z\mathbf{F}k \qquad [20]$$

In such a situation, if k is small, most of the current produces more oxide and the film simply thickens. The case $n = 0$ is of great practical importance in anodic oxidation, for if $n = 0$ and k is small then large currents and low pH can be tolerated without the disruption of film formation.

(b) $0 < n < 1$.

Magnesium hydroxide dissolves with $n \sim \frac{1}{2}$ at pH < 5 (2), and it is expected theoretically (4) that many oxides and hydroxides would have n between 0 and 1. Note that equilibrium is not achieved for $Mg(OH)_2$ at pH < 5, where a surface reaction controls the rate. Figure 1 shows the behavior of various currents as functions of i_f for a hypothetical material with $n = \frac{1}{2}$ and $k = 10^{-7}$ (the value of k for $Mg(OH)_2$ is 10^{-7}), and for which $r_{so} = 0$. The dissolution current, i_s, increases less rapidly than does i_f, and the total current may produce mostly ions at low current density and mostly film at high current density. Having most of the applied current produce ions as in this example at low currents does not necessarily mean that

[2] The rates in ref. (5) are initial rates and decrease with time at pH 4-10 due to the formation of a porous AlOOH layer. This example is thus only valid for pH < 4. For other systems this restriction may not be present.

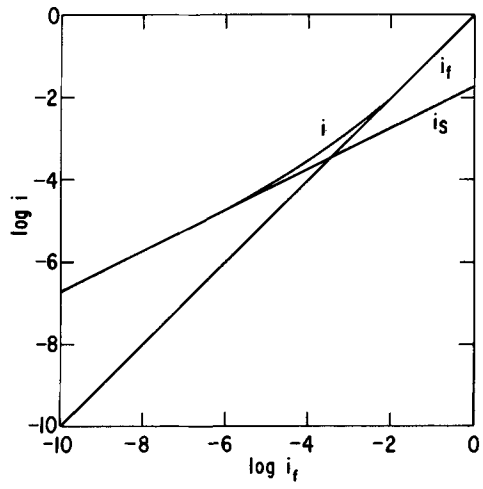

Fig. 1. Relationship between total current density i, the current density of formation of metal ions i_s, and the current density of film formation i_f, for a hypothetical metal covered with an oxide whose rate of dissolution is given by Eq. [17] with $k = 10^{-7}$ and $n = \frac{1}{2}$.

there is a net film dissolution and eventual cleaning of the specimen in a real situation, for the spontaneous corrosion rate may be high enough to keep the specimen covered with a film.

(c) $n > 1$.

For $n > 1$ the dissolution rate increases faster with total current than does the film formation rate. Depending on the value of k, therefore, it is possible that film formation could predominate at low currents with mostly dissolution at high currents. A practical example is not known.

Discussion of Case II.—Absence of surface equilibrium is probably the situation existing with many metals forming dense barrier films having low values of spontaneous corrosion (r_o). Such dense barrier films grow by high field ion conduction, and as the film thickness increases a considerable potential drop occurs in the film. In order to reach the large currents needed to lower the pH sufficiently to increase the film dissolution rate it is necessary to raise the potential to a point where some proton producing electrode reaction other than film formation occurs. A common situation is that large currents are not found until oxygen evolution occurs in the transpassive region. Rapid corrosion of the metal usually accompanies such oxygen evolution, possibly because of the enhanced proton concentration. When the film is a good insulator or blocks current for any reason so that no oxygen evolution occurs then application of very large potentials and growth of thick anodic films may be possible, as with Al, Ta, Zr, Nb, etc.

General Discussion

Two major problems in predicting results of anodic polarization are that it is not now possible to predict (except from experience) what will happen to any new film which is produced, and it is not possible to predict when surface equilibrium may be achieved or what values of k and n will be encountered when equilibrium is not achieved. If the new film is added to the dense barrier, then application of an additional anodic potential may simply thicken the barrier and the current may remain low. It seems generally true that metals yielding films with low values of k (the dissolution rate constant, Eq. [17]) are also the ones which give dense barrier films, but evidence is fragmentary. Future progress requires studies of the character of reaction products and of their reactivity.

The role of anions in these phenomena is important. Buffers, for instance, may prevent any large pH change until a critical film forming current is reached. If the hydroxyl ion or a buffer ion is the only anion present,

then current flow may concentrate the ion in the solution near the specimen so that little pH change can occur despite large polarization. For example, when magnesium is polarized to +1.2V on the standard hydrogen electrode scale in a 10^{-2}M solution of KOH the current is only a few microamperes per square centimeter, while in 10^{-2}M Na_2SO_4 a current of 0.1 A/cm^2 is reached at a potential of −1.26V (open-circuit potential −1.39V). The explanation for this fact is the following. Most of the large potential difference in the KOH solution is doubtless applied across the film. Should any break occur in the film so that a large local anodic current starts to flow the concentration of hydroxyl ions near the break would be increased by the current so that further precipitation of $Mg(OH)_2$ would occur and the break would be healed. In the Na_2SO_4 solution, on the other hand, any rupture of the film and accompanying current flow concentrates sulfate ions which are not effective buffers. The pH is then free to fall, and the dissolution rate can become very large.

The Anodic Behavior of Zn-Cd Binary Alloys in 1M Sulfamic Acid-Formamide Solutions

I. A. Menzies, R. A. Brodie, D. Gearey, and G. W. Marshall

Corrosion Laboratories, Department of Chemical Engineering, University of Manchester Institute of Science and Technology, Manchester 1, England

ABSTRACT

The anodic behavior of zinc, cadmium, and Cd-Zn binary alloys has been studied in 1M sulfamic acid-formamide solution. The anodic polarization curves for the single metals and alloys containing 90, 81.9, and 40% Cd are typical of electropolishing systems. In all cases a-c impedance measurements indicate the formation of solid anodic films at the onset of polishing. Under steady-state conditions of dissolution (300 coulombs) of the alloys the ratios of metal dissolved anodically are similar to those in the original alloys. All current efficiencies were 100 ± 2.5%. All of the alloys are deeply etched under appropriate conditions and considerable phase contrast is found during polishing conditions. Here there is a small amount of preferential dissolution of Cd-rich phases which give rise to phase contrast while film formation suppresses crystallographic etching. The effects of anode shape and method of polarization on polarization data in sulfamic acid-formamide solutions are also discussed.

The present work is a continuation of previous studies (1-4) of the anodic dissolution and polishing of metals in organic electrolyte solutions. Among the organic systems which have been investigated, a solution of sulfamic acid in formamide has proved to be a highly versatile polishing medium producing good results on Cu, Sn, Pb, Zn, Cd, and Ag. It has also been shown that Mo, W, and Ti can also be polished at high overpotentials. Zinc and cadmium have both been found to polish well in sulfamic acid-formamide solutions, dissolving at current efficiencies close to 100%. Most recently (4) evidence has been obtained from viscosity and a-c impedance measurements which indicate that anodic dissolution of Zn is under diffusion control and that polishing occurs by random dissolution through an anodic film with suppression of crystallographic etching. The present study is concerned with a number of aspects of the behavior of Zn-Cd alloys. In choosing an alloy system for this initial work on dissolution in organic electrolytes the Zn-Cd system was selected since both of the single metals were known to electropolish and the associated limiting current densities were similar. Furthermore the alloy system is a simple eutectic system.

Key words: anodic dissolution, zinc-cadmium alloys, organic electrolytes, electropolishing, electro-etching, formamide.

The objectives of the work were: (*a*) to obtain preliminary data concerning the polarization characteristics of a range of Zn-Cd alloys; (*b*) to confirm and extend previous investigations (4) concerning the presence of films using a-c impedance techniques; (*c*) to determine metal dissolution ratios and current efficiencies and to relate the nature of the surfaces produced to conditions of polarization. Since previous investigations (3-4) had shown that in this particular system potentiostatic and galvanostatic polarization curves were similar, the galvanostatic technique used previously (4) was used again.

Experimental

Preparation and purification of materials.—Alloys.— The alloys were prepared from 99.9999% purity zinc and cadmium by melting in Pyrex glass tubes under an argon atmosphere. After the alloys had melted, the tubes were vigorously agitated and the contents maintained in the molten state for some time to ensure homogeneity of the liquid. After cooling the alloys were placed in 'Pyrex' casting tubes with a little 'Analar' $ZnCl_2$ to act as a flux. This improved the quality of the cast rods by reducing porosity and oxide inclusions. During heating the casting tube was evacuated and flushed with purified argon twice, and after

melting of the alloys the tubes were evacuated to remove residual gas. Finally, the alloy was allowed to solidify slowly under dry argon. Samples of the castings were removed for metallographic examination. Two diameters of rod (1 and 0.75 cm) were prepared and the larger rods were rolled to sheet while the smaller ones were used as electrodes in galvanostatic polarization studies.

Solute and solvent.—Microanalytical reagent grade sulfamic acid was supplied by British Drug Houses Ltd., to the following specification: acidimetric assay >99.9% moisture <0.1%; sulfate <0.05%; nonvolatile matter <0.05%. This material was stored in a vacuum desiccator before use. Formamide was purified as described elsewhere (1, 3).

Apparatus and experimental methods.—Electrolyte preparation and metering systems.—The electrolyte preparation and metering systems used were as described previously (1, 5, 6). A weighed quantity of sulfamic acid was placed in the electrolyte vessel, and the required volume of purified formamide to give a 1N sulfamic acid solution was metered from the burette. These operations were carried out under dry nitrogen flow, and on completion the electrolyte vessel was sealed, removed, and shaken at intervals. After complete dissolution had taken place the solution was ready for transfer to the electrolysis cell.

Constant current measurements.—Cells of the pattern previously described (1) were used for these measurements. The alloy anode Fig. 1A was 1.5 x 1.0 cm and approximately 0.1 cm thick, and the surrounding cathode was a Ta cylinder of ~84 cm^2 surface area. For the measurement of anodic current efficiencies at constant current density a Wareham Measuring Systems Ltd. galvanostat type C223 capable of delivering 1A at 80V was used with a copper coulometer in series. In all experiments a total of 300 coulombs was passed. The anodes were gently abraded to 600 grade SiC paper, pickled lightly in 10 v/o (volume per cent) HNO_3 to remove surface films, washed with distilled water and acetone and finally dried in a stream of warm air, weighed and placed in the cell. All measurements were carried out at 25° ± 0.1°C in an atmosphere of purified and dried nitrogen.

A.C. impedance measurements.—These measurements were made using the same type of cell but with a central anode of the type shown in Fig. 1B, all details of the method of measurement and bridge circuit being as previously described (4). Various current densities in the range 1-100 mA/cm^2 were applied using a 120V dry battery and the corresponding readings of resistance and capacitance recorded.

Galvanostatic measurement of polarization curves.—The cell used for these measurements was similar to that described previously (3) and used for potentiostatic measurements. The technique used in the present work was similar to that in previous work (4) all potentials being measured with respect to the Cd/$CdCl_2$, KCl (satd)-formamide reference electrode. In the polishing region it was found that potential fluctuations tended to occur irregularly, and potential readings were taken at fixed time intervals. The current was raised in increments of 5 mA by means of the calibrated control, and the potential reading was noted 15 sec later and the current again increased. A fresh solution was used for each experiment.

Analytical procedures.—The metal dissolution ratios were determined by atomic absorption spectrophotometry (7) and over-all current efficiencies from weight loss measurements. There was some random scatter in the results of atomic absorption measurements, and total metal dissolution was found to be more accurately represented by weight loss measurements. However, the metal dissolution ratios were considered to be sufficiently accurate for the results to be meaningful.

Results

Anodic polarization curves measured galvanostatically with respect to the reference electrode.—Excellent reproducibility was obtained except in the very high current density regions where considerable oscillations of potential tended to occur. For each metal or alloy all of the points obtained during four separate measurements were plotted on a large scale, the best line drawn through the experimental points, and the resulting smoothed lines are shown in Fig. 2. At all current densities in the etching range zinc and cadmium had lower overpotentials for normal dissolution than any of the alloys. The transition from etching to polishing was sharp in all cases. The limiting current density for zinc was ~54 mA/cm^2 while that for cadmium and the alloys was 65-70 mA/cm^2. Although the transitions and limiting current densities were well defined the upper parts of the polishing regions were much less well defined. However, the anodic overpotential ranges

Table I. Polishing voltage ranges for Zn, Cd, and binary alloys of these elements in sulfamic acid-formamide solutions at 25°C

Material	Galvanostatic anodic overpotential, V
Zinc	11.0
Alloy 1 (60% Zn)	8.0
Alloy 2 (18.1% Zn)	6.0
Alloy 3 (10% Zn)	5.5
Cadmium	3.0

at the limiting current density decreased with increasing cadmium content of the alloy (Table I).

A-C impedance measurements.—The curves for resistance as a function of current density are shown in Fig. 3, the main feature in all cases being the sudden extremely large increase in resistance (5-150 ohm-cm^2) coinciding with the onset of polishing conditions. When no net current was flowing through the electrode the resistances, with the exception of cadmium, were ~4 ohm-cm^2. On applying a net current the initial resistances all fell to slightly lower values which rose again with increasing current density until the limiting current density was reached when the very large increase in resistance was observed. After the limiting current density, the resistances for zinc and alloy 1 (60% Zn 40% Cd) increased slowly with current density whereas materials with a cadmium content of >40% the resistance became completely unstable and violent oscillations of the null detector made it impossible to obtain more than one reading for each specimen. The limiting current densities from these measurements were 50-60 mA/cm^2 for Zn, alloy 1, and alloy 3, 65 mA/cm^2 for alloy 2 (18.1% Zn, 81.9% Cd) and 80 mA/cm^2 for cadmium.

The initial capacitance for all specimens was ~10 μF/cm^2 Fig. (4), and initially there was a rapid rise to ~100 μF/cm^2 with increasing applied current density. Following this there was a slight increase in capacitance with increasing current density until the limiting current density was attained when the capacitance fell sharply to values ~0.5 μF/cm^2. Since the bridge could not be balanced at current densities high in the polishing region for specimens containing >40% cadmium, curves for such specimens have only one point in this region.

Over-all it is clear from these measurements that the anode resistance is extremely high in the polishing region and that under these conditions the capacitance is correspondingly low.

Anodic dissolution ratios and dissolution efficiencies at constant current density.—After each anodic dissolution experiment the electrolyte was analyzed for zinc and cadmium and the proportions of each metal dissolved was calculated for comparison with the proportions present in the alloy (Table II). For alloy 1 (60% Zn 40% Cd) there is some evidence that at the lowest current density (8 mA/cm^2) the Zn:Cd ratio in solution was slightly greater than that in the alloy whereas at current densities >70 mA/cm^2 the ratio was lower. For alloy 2 (18.1% Zn 18.9% Cd) the dissolution ratio was 17 Zn : 83 Cd, *i.e.*, slightly lower than that in the alloy. In the case of alloy 3 the ratio in solution was 11 Zn : 89 Cd and hence a slightly higher proportion of Zn appears in solution than that nominally present in the alloy (10% Zn 90% Cd). Overall, however, it is clear that the metal dissolution ratios are similar in all cases to the ratios initially present in the alloys. The total metal dissolution efficiencies did not vary significantly with anodic current density or alloy composition since all were within the range 100 ± 2.5%. There was some indication that the current efficiencies increased slightly (~1%) with increasing cadmium content of the alloy.

Observations of surface features after treatment at constant current density.—The surface features of all three alloys were recorded as a function of current density.

Alloy 1. (60% Zn 40% Cd).—This alloy has a composition midway between the eutectic composition and pure zinc and in the as-cast condition (Fig. 5a) is composed of primary dendrites of Zn-rich solid solu-

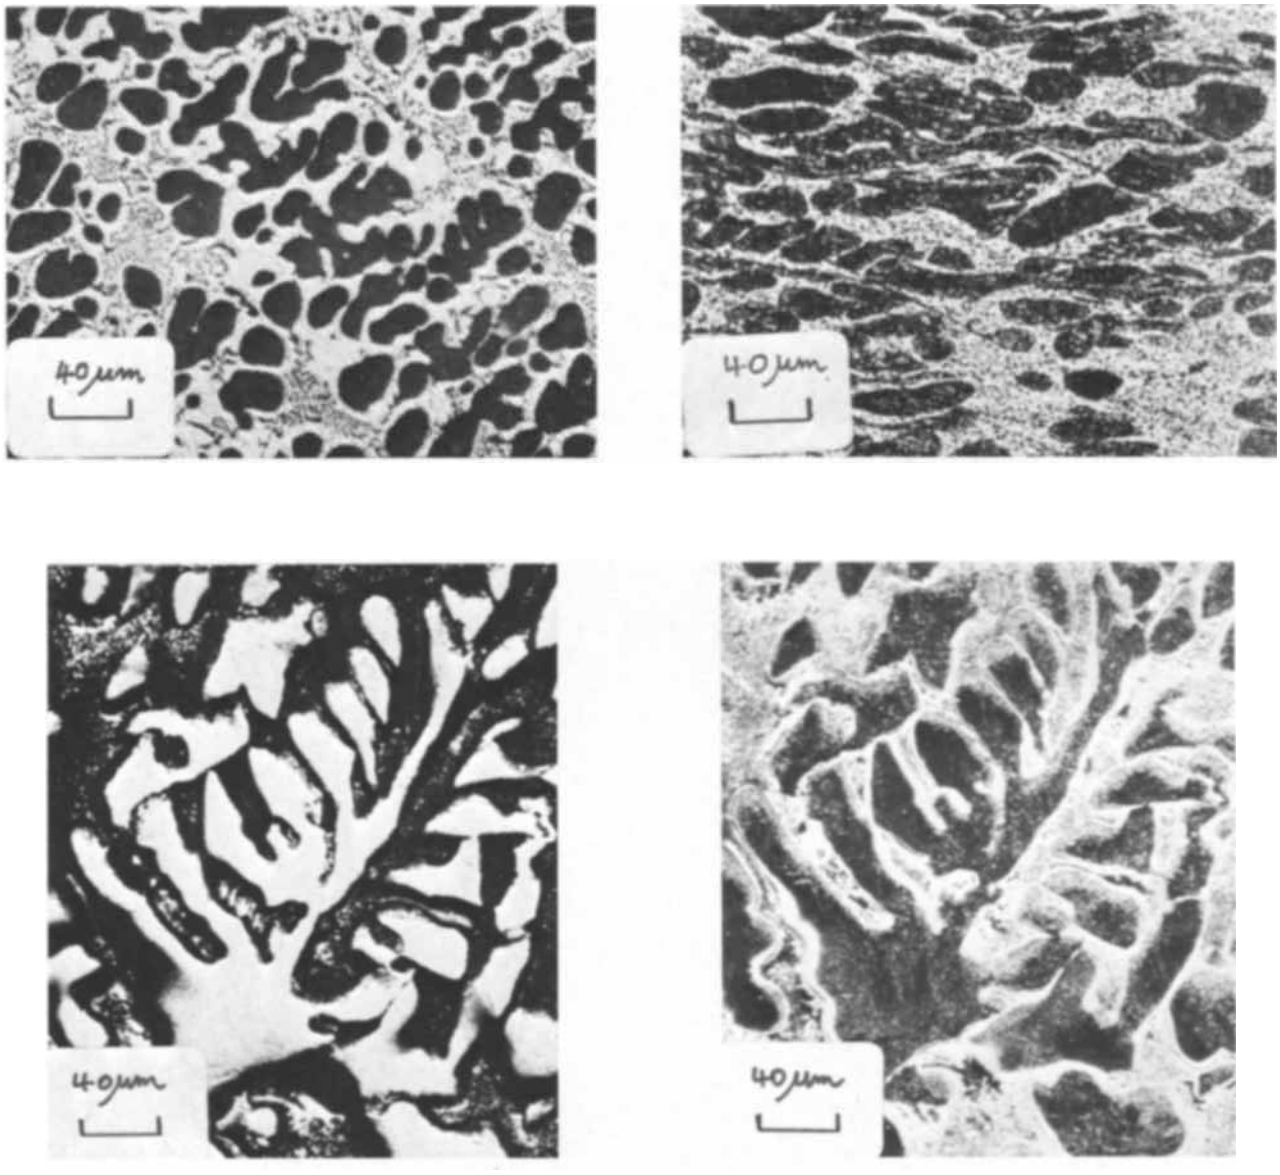

Fig. 5. Photomicrographs of specimens of alloy 1 (60% Zn) (a) as-cast structure; (b) as-rolled structure; (c) polished zinc dendrites (72 mA/cm²); (d) polished zinc dendrites (72 mA/cm²) dark ground illumination.

tion (dark phase) in a matrix of eutectic composed of the cadmium-rich solid solution (light phase) and the zinc-rich phase. After rolling into strips the dendritic pattern was distorted but still recognizable (Fig. 5b).

Anodic treatment of sheet specimens of the alloy at constant current density resulted in two distinct types of surface. At current densities <32 mA/cm² the specimen surfaces were dull matt gray and etched. However, pits were also present and these were found to correspond in shape, size, and depth (12-20 μm) to areas of zinc-rich phase present in the alloy. At intermediate current densities (32-56 mA/cm²) polishing specimens where the local current density was highest was evident on the lower corners and edges of the specimens where the local current density was highest due to rather poor current distribution. Completely bright and reflective surfaces were obtained at current densities >56 mA/cm². A fine relief pattern was apparent even to the naked eye. Examination of the specimen surface under oblique illumination (Fig. 5c) indicated by the shadows produced that either the height of the eutectic phase was lower than that of the zinc-rich phase or that a groove was present at the boundary between the two phases. By changing to dark ground illumination (Fig. 5d) all light directly reflected from the specimen surface was eliminated, and at the same time scattered light was brought into focus producing an image of all surfaces which were not plane and perpendicular to the optical axis. The light areas in Fig. 5d thus represent the hollows or grooves at the edges of the zinc-rich phase. Most of the central areas of the dendrites were polished to a smooth highly reflective surface.

Alloy 2. (18.1% Zn *81.9%* Cd).—This alloy was close to the eutectic composition (17.4% Zn) and the as-cast structure was almost completely eutectic (Fig. 6a), the presence of a few small particles of zinc-rich phase confirming that the zinc content was slightly in excess of the true eutectic composition. Rolling of the alloy did not change the structure significantly. Overall, the general relationship between structure and current density observed with alloy 1 was also observed with this alloy. At current densities ≤ 32 mA/cm² there was poor definition of grain boundaries and in this case no etch pits were observed. The first signs of polishing were observed on the lower corners and edges of specimens exposed at 32 mA/cm² and increasing the current density from 32 to 56 mA/cm² progressively increased the area of the specimen which was polished. At current densities >56 mA/cm² the whole specimen surface became bright and polished although relief

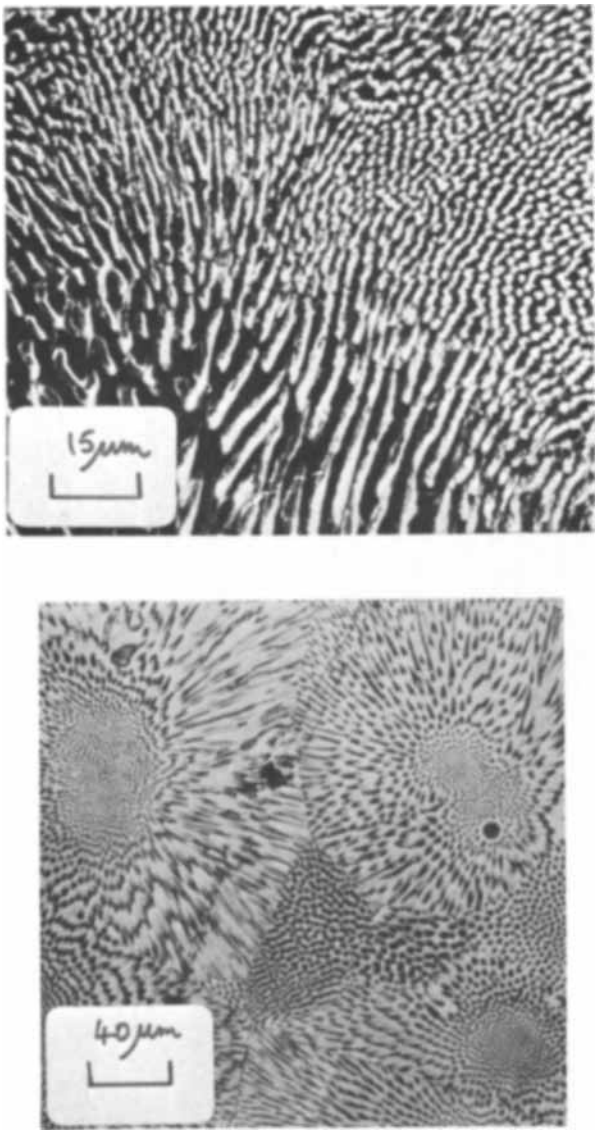

Fig. 6. Photomicrographs of specimens of alloy 2 (18.1% Zn-eutectic) (a) (top) as-cast structure (b) (bottom) polished surface (72 mA/cm^2) showing selective removal of one component during polishing.

effects were observed (Fig. 6b), the Zn-rich phase being proud of the eutectic. This was, however, best observed under dark ground illumination at relatively high magnifications, and under normal direct illumination at moderate current densities only a low degree of relief was observed due to the relatively fine structure and uniformity in the alloy.

Alloy 3. (10% Zn 90% Cd).—The composition of this alloy was intermediate between that of the eutectic and pure cadmium and in the as-cast condition (Fig. 7a) it consisted of primary dendrites of cadmium-rich phase set in a fine eutectic mixture. The lens-shaped markings on some of the dendrites are probably deformation twins induced during metallographic preparation. After rolling the cadmium-rich phase was irregularly shaped.

Again the over-all anodic behavior of this alloy was similar to that of alloys 1 and 2. Deep etching occurred at current densities up to ~32 mA/cm^2, and the individual phases could not be readily distinguished. Again the first signs of polishing appear round the bottom edges and corners of the specimen at 32 mA/cm^2, and the area of polished surface increased with increasing current density up to 56 mA/cm^2. The surfaces resulting from anodic treatments at 56-96 mA/cm^2 were completely polished although slight relief effects were observed. The cadmium-rich phase was generally

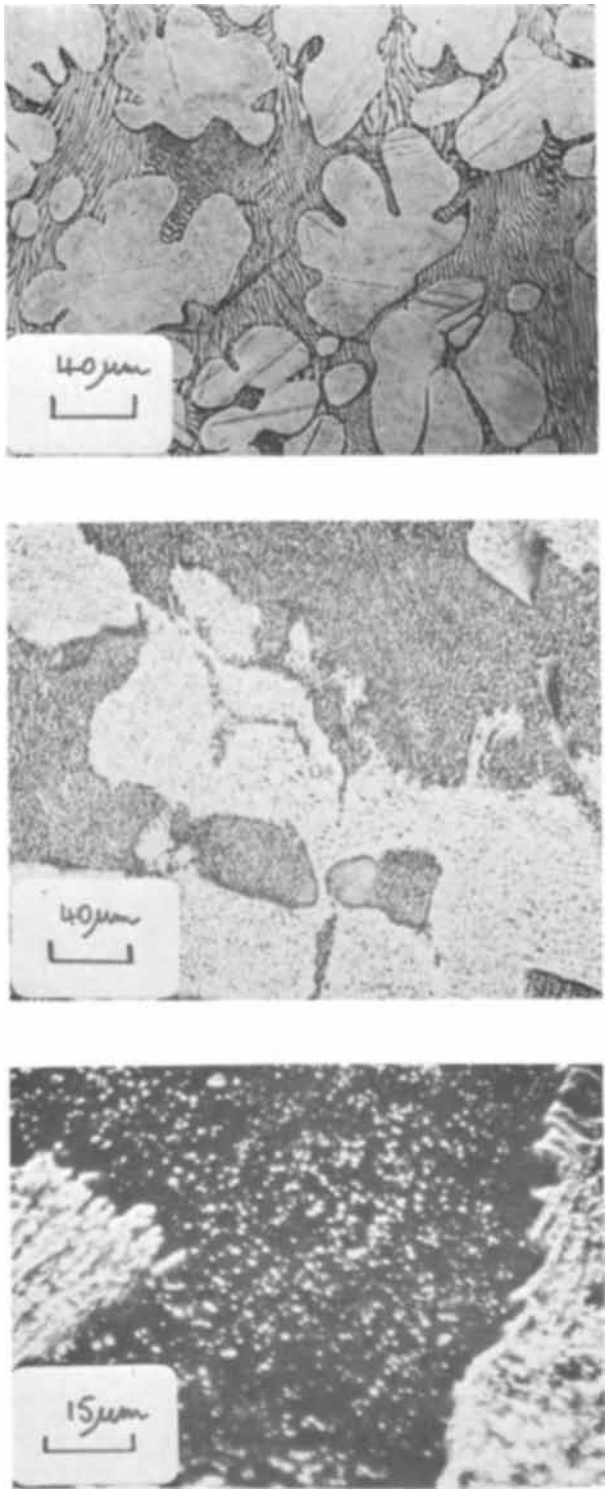

Fig. 7. Photomicrographs of specimens of alloy 3 (10% Zn): (a) (top) as-cast structure; (b) (center) polished surface (72 mA/cm^2) showing depression of Cd-rich phase; (c) (bottom) as (b) dark ground illumination, showing rounded pits in cadmium phase as light spots.

1-2 μm below the general level of the eutectic as can be seen by the shadows in this phase in Fig. 7b. The surfaces of the cadmium-rich dendrites, although highly reflective, were covered with minute pits (0.25-1.50 μm diameter), and this could best be seen at higher magnification under dark ground illumination where the pits are seen as light spots on a dark background. (Fig. 7c)

Additional general observations.—Polished specimens after removal from the solution very rapidly formed a dull gray film on the surface if they were not washed

immediately after breaking the electrical circuit. These films were studied using electron microscopy. Black particles with angular shapes (cf. Fig. 8a) were found associated with the fine two-phase material of the eutectic, the single phase zinc-rich areas being free of such particles. This close association of the particles with the intimate mixture of phases in the eutectic is seen in more detail in Fig. 8b where it is clear that they appear to propagate from the rods of the dispersed phase. An extensive study of the particles was made using transmission electron diffraction, but diffractograms of sufficient quality to permit measurement and calculation of lattice parameters could not be obtained. The material was certainly crystalline, often opaque to electrons, and probably metallic. A particularly interesting dendritic formation is shown in Fig. 8c, and despite the lack of direct evidence it seems almost certain that crystals of cadmium were deposited on the surface by an exchange reaction between zinc in the eutectic phase and cadmium ions in solution.

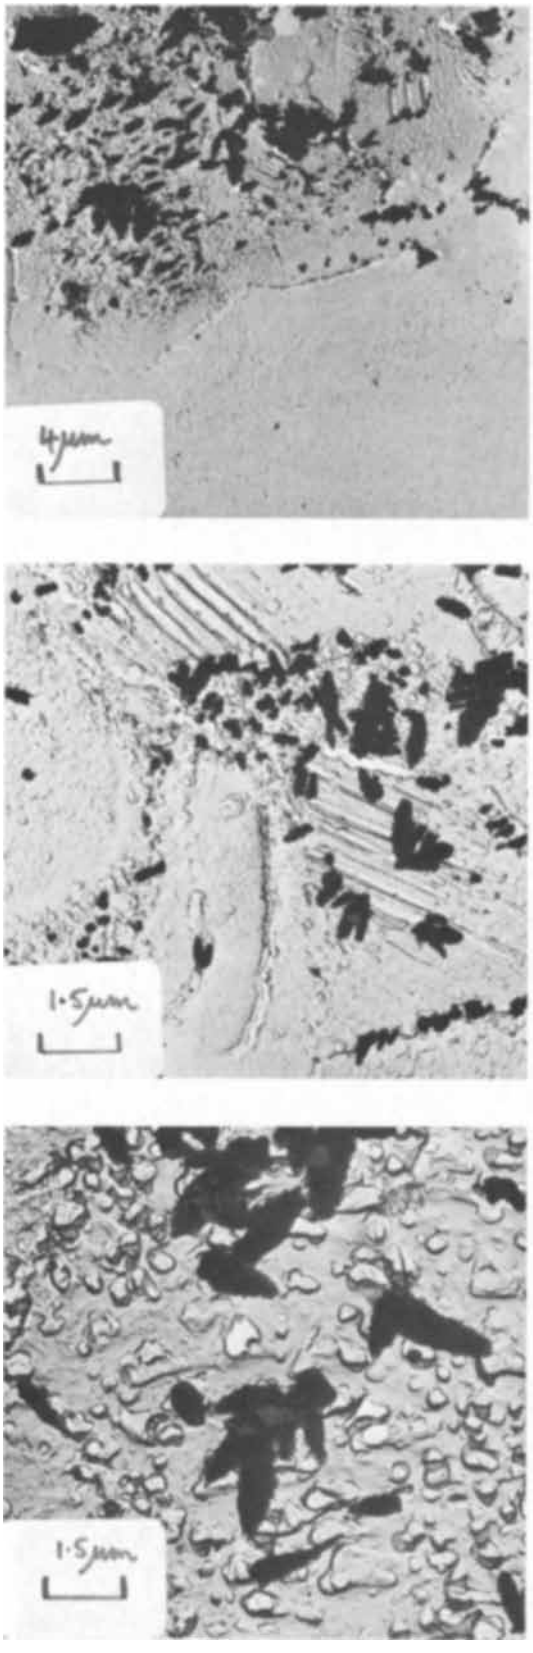

Fig. 8. Electron micrographs of precipitates on polished specimen: (a) (top) presence of particles only on eutectic areas; (b) (center) association of particles with rods of dispersed phase; (c) (bottom) metallic dendrites.

During anodic dissolution of the alloys qualitatively similar viscous layers were observed streaming from the electrode surfaces and these were observed during both etching and polishing. Since there was evidence of film formation during polishing some of the polished specimens were subjected to electron probe microanalysis for sulfur in plan, but the presence of this element could not be confirmed.

Discussion

The present work represents one of the first investigations of the anodic behavior of alloys in organic electrolyte solutions and as such must be regarded as exploratory and rather general in nature. It must however be pointed out at the outset that the anodic dissolution ratios and the metallographic features represent long-term steady-state conditions and not the early stages of dissolution. Caution is therefore necessary in discussing these features in relation to the galvanostatic polarization curves.

Dissolution of alloy 1 (60%) Zn at 16 mA/cm^2 within the etching range resulted in deep pitting and metallographic examinations suggested that this was associated with preferential dissolution of Zn-rich dendrites. Clearly although preferential dissolution of zinc may occur in the early stages cadmium dissolution also occurs, and only at the lowest current density (8 mA/cm^2) was there significant evidence of preferential dissolution of zinc under steady-state conditions. At 72 mA/cm^2 there was evidence that the Zn-rich dendrites were raised above the matrix of Cd-rich eutectic. There was also some indication (Table II) that the solution contained a slightly higher proportion of cadmium than the alloy. This is no doubt associated with the higher limiting current density for cadmium dissolution (Fig. 2 and 3).

In the case of alloy 2 it was not possible because of the fine eutectic structure to determine which phase was preferentially dissolved during etching and polishing. Again under steady-state conditions there was little preferential dissolution of either metal (Table II). With alloy 3 the metallographic evidence suggested some slight preferential dissolution of cadmium.

Under the etching conditions used in the present work good metallographic contrast apparently was not obtained. This was most probably due to excessive surface roughening during steady-state dissolution. A much higher degree of contrast was obtained during polishing, the difference in height between the phases being 4-8 x 10^{-5} in. In the polishing region the differentiation ratio for cadmium (D_{Cd}) as defined by Greene, Rudlaw, and Lee (8), is given by $(i_{\lim Cd}/i_{\lim Zn})_E$ at any potential (E) where $i_{\lim M}$ are the observed limiting current densities for dissolution of Zn and Cd. At almost all potentials in the polishing region D has values of ~1.2. Thus under steady-state conditions during polishing there appears to be a difference in height ~10^{-4} in. and phase contrast with a dissolution ratio somewhat lower than that specified as necessary by Greene, Rudlaw, and Lee. This is not surprising as their criteria were derived for short-time etching conditions. It must however be made clear that in the present work crystallographic etching was sup-

pressed in the polishing region. It is noteworthy that long-term dissolution (300c) results in a Zn/Cd dissolution ratio the same as the Zn/Cd weight ratio in the alloy over a range of current densities in both polishing and etching regions. Generally accepted theory (9-11) indicates that in the initial stages of dissolution the two constituents in the alloy dissolve independently of each other at the current density appropriate to the potential or overpotential setting (heterogeneous or homogeneous alloys) as derived from the polarization data for the single constituents. Then, taking the fraction of the alloy surface occupied by each component to be proportional to its volume fraction in the alloy and assuming two constituents 1 and 2 with molecular weights M_1, M_2, dissolution valencies Z_1, Z_2, and current densities of dissolution i_1, i_2 under set conditions we have

$$\frac{\text{Weight of 1 dissolved}}{\text{Weight of 2 dissolved}} = \frac{i_1 M_1 x_1 \rho_2 z_2}{i_2 M_2 x_2 \rho_1 x_1} \qquad [1]$$

where x_1, x_2 are weight fractions of 1 and 2 in the alloy and ρ_1, ρ_2 are respective specific gravities.

In the polishing range in the present results the rates in Eq. [1] becomes approximately

$$\frac{\text{Weight of Cd dissolved}}{\text{Weight of Zn dissolved}} \approx 3\,\frac{x_{Cd}}{x_{Zn}}$$

since $i_{Cd} \sim 7/5\ i_{Zn}$ (Fig. 2), $Z_{Cd} = Z_{Zn}$, $\rho_{Cd} \approx \rho_{Zn}$, and $M_{Cd} \approx 2M_{Zn}$. Thus the ratios of metal dissolved according to Eq. [1] are a factor of ~3 different from that actually observed.

Several modifications of the above behavior have been suggested usually in connection with the protective properties of components in strongly passivating systems. Thus it has been suggested that modification results from the accumulation of the less active component on the surface by re-orientation of the latter after dissolution of the more active atoms, or alternatively by re-precipitation of less active atoms after primary dissolution (11). In the present results the remarkable consistency of the dissolution ratios in etching and polishing regions despite a variety of alloy structures seems to indicate a more general explanation. In any case, on a geometrical basis it can easily be appreciated that there must be a tendency for less active atoms to accumulate on the surface. Thus if the dissolution rates of the two components are at all comparable long-term dissolution will not result in over-all preferential dissolution of one component, although at any time a certain amount of preferential dissolution, of the order of the grain or particle size, of the more active component would be expected. Hence in the polishing region a rather fine etch of the eutectic is noticed, Fig. 6b, although it must be stressed again that crystallographic etching is suppressed. This is indeed an attractive demonstration of the primary importance of the suppression of crystallographic etching in polishing phenomena. The larger scale component etching (which, of course, would not be suppressed by the polishing film) does not prevent the appearance of a visually polished surface.

The results of the a-c impedance measurements on the alloys and cadmium were generally similar to those previously obtained (4) for zinc. The magnitude of the increase in resistance corresponding to the onset of the limiting current and the associated decrease in capacitance are again best interpreted in terms of formation of anodic films. Over-all anodic dissolution is controlled by diffusion processes in solution at higher potentials, and this may well be true at potentials in the etching range. Most theoretical treatments of alloy dissolution processes (9-12) are based on short-term activation controlled processes, and it is not possible to discuss the present system in detail until further studies of dissolution as a function of time have been completed.

The solutions produced by the anodic dissolution of alloys 2 and 3 (Cd-rich) frequently contained a cloudy yellow precipitate which was shown to be cadmium sulfide. The cathodic reaction in 1M sulfamic acid-formamide must therefore include the reduction of sulfamic acid to sulfide ion either directly or by means of cathodic hydrogen. Redeposition, presumably of Cd, the more noble metal, was also a problem with polished specimens unless these were removed from the electrolyte while they were still connected to the power supply and washed immediately in pure formamide. Similar difficulties have been reported by Moulen (13) during the electropolishing of Pb-Sn alloys in aqueous fluoboric acid.

A Rapid Anodic Porosity Test for Ni-Fe Electrodeposits on Copper Wire

W. O. Freitag*

UNIVAC, Division of Sperry Rand Corporation, Blue Bell, Pennsylvania 19422

ABSTRACT

A 10-min semiquantitative polarographic test is described which measures the area of copper substrate left exposed by pinholes or defects in electrodeposited memory wire. The wire sample is made the anode in an electrolytic cell, the Ni-Fe outer film is rendered passive with a controlled potential sequence, and the anodic current due to oxidation of exposed copper is recorded as a function of potential. The height of a copper passivation peak is measured, and this height is shown to be proportional to exposed Cu area. The method is useful in quality control and in following the course of corrosion in environments when the attack at local defects is the major mechanism.

The occurrence of pinholes or other plating defects which leave some of the substrate exposed is a familiar problem with decorative or protective electrodeposits. As a part of the development of plated wires for computer memories, it became necessary to measure the porosity of thin magnetic alloy films on copper. The test developed for this purpose is described, and we believe that the same general approach might be applicable to other situations.

The plated wire memory elements consist of a substrate of beryllium-copper wire 0.005 in. in diameter coated with an electrodeposited film of permalloy. Wires of this type were prepared first by Long (1) and the process was described more recently by Sagal (2). The alloy films have an average composition near 80% Ni and are generally about 8000Å in thickness. Usually, a layer of pure copper is interposed between the substrate and the magnetic alloy. Pinholes or other defects which leave part of the copper substrate exposed affect the magnetic performance of the wires. Furthermore, pinholes could provide sites for corrosion and so affect the long-term stability and reliability of the elements.

Tests for porosity in electrodeposits usually consist in rendering the pores visible by means of some chemical reaction which is specific to the substrate material and leaves the deposit unchanged. Evaluation is then carried out by visual or microscopic examination. In electrography, the test panel is made anodic in a cell and is held in contact with filter paper which is saturated with an appropriate electrolyte so that ions from the exposed substrate areas produce a colored precipitate. These methods are not easily applied to cylinders of small diameter, such as plated memory wire.

The literature describes methods wherein anodic currents are measured which represent metal dissolution from the basis metal at pores in the deposit under conditions at which the deposit is passive. Ehrhardt (3) applied this approach to gold on copper by measuring the diffusion limited anodic current of copper dissolution in 5% H_2SO_4 at a potential at which no other electrode reaction was occurring. Khan recently reviewed this method (4) and found that the gold layers were not sufficiently passive during this treatment and gave background currents which rendered the tests inaccurate. Shome and Evans (5) reported on the use of a corrosion cell for determining porosity of nickel deposits on iron. They used a large auxiliary cathode of copper and measured either the corrosion current or the amount of iron accumulating in the electrolyte after a period of time. Clarke and Britton (6), dealing with tin, nickel, or copper on steel, related the slope of E *vs.* i curves to the resistance of electrolyte within the pores. Their approach, however, depends on certain conditions being valid which are difficult to achieve experimentally, and is not applicable to very thin deposits in any event.

In the present work, pores in nickel-iron alloy films on copper are detected by measuring the anodic passivation current peaks from exposed copper areas after a prescribed polarization sequence which leaves the Ni-Fe areas passive.

Pinhole Test Sequence

The wire sample is made the working electrode in a polarographic cell using dilute sodium pyrophosphate as electrolyte. Figure 1 summarizes the polarization sequence and diagrams the currents observed.

First, a negative potential, −1.8V *vs.* SCE, is applied to reduce surface oxides and effect a certain degree of cathodic cleaning. Then the sample is brought to +800 mV whereupon passivating films grow on both the permalloy and the copper areas. After the observed current falls to a very low level, usually 0.6 to 0.8 μA/cm of sample length (in about 4 min) the cell is placed on open circuit.

The anodic film which formed on copper is soluble and dissolves within 2 min after removing the potential (the "reactivation" time), while the anodic film on the magnetic alloy remains intact. After this reactivation step, the potential scan is begun at −200 mV and run to about +300 mV at a rate of 200 mV/min. An anodic current peak is observed as the copper

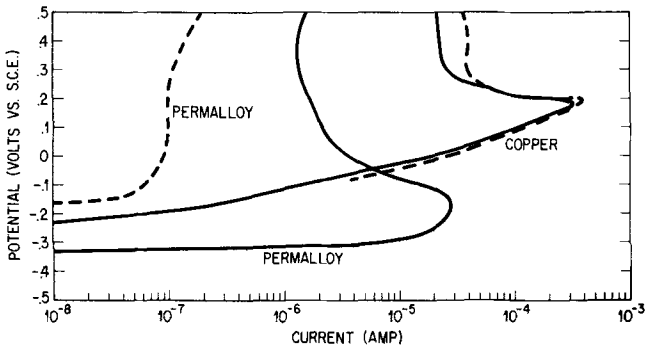

Fig. 2. Anodic traces of unplated copper and solid permalloy wires in the active condition (solid lines) and after polarization as in Fig. 1 (dashed lines). The electrolyte is 0.085M $Na_4P_2O_7$ at pH = 5.2.

areas repassivate, and the height of this peak is measured.

Apparatus and Procedure

Two kinds of electrolytic cells were used in this work. One was a simple "H-cell"[1] one leg of which was a saturated calomel electrode with a mercury surface about 1 in. in diameter. The calomel cell was used as the counterelectrode under the assumption that up to 400 μA of current (the upper limit of the polarograph) would not polarize it, and that any polarization which might occur would not alter test results. Potentials are not measured more accurately than $\pm$10 mV. The H-cell could accommodate sample lengths up to 5 cm. When longer lengths of wire were tested, a three-electrode cell was used which consisted of a platinum foil counterelectrode and a standard calomel reference electrode.[2] The relative location of the three electrodes was not controlled since, again, critical voltage control was not necessary. A Fisher Elecdropode with recorder was used with both cells, but an operational amplifier circuit was added to drive the three-electrode cell.

Wire samples were masked top and bottom with Scotch Electroplater's Tape (3M Company) making sure that the immersed end was completely insulated. There was no evidence that impurities from the tape interfered in any way with the test.

The electrolyte was 0.085M $Na_4P_2O_7$ adjusted to a pH of 5.2 with H_3PO_4. The tests were carried out at room temperature. A very few test runs were done with the electrolyte saturated with O_2 or swept with N_2, but no significant differences were immediately apparent, and virtually all of the work was done under ambient conditions.

Identification of Passivation Current Peaks

The passivation behavior of copper and permalloy in this electrolyte are shown in Fig. 2. The solid lines are taken from current voltage traces while scanning 0.005 in. diameter solid permalloy wire[3] (1 cm) and copper plated beryllium-copper wire (0.2 cm). Voltage scanning was started at -500 mV (*vs.* SCE) at $+200$ mV/min. The cathodic currents are not shown.

The dashed lines in Fig. 2 are traces of scans of the same samples run according to the procedure in Fig. 1; the permalloy is passive but the copper was virtually unchanged.

The passivation behavior for the alloy is similar to that described for Fe-Ni alloys by Economy *et al.* (7) in sulfuric acid solutions. The passivation current density for permalloy in Fig. 2 is on the order of 1 mA/cm^2, compared to a value less than 25 mA/cm^2 extrapolated from Economy's results, which covered a pH range only up to 3.7. The location of the current peak is about -0.18V (SCE) in pyrophosphate at pH = 5.2 compared to -0.15V (SCE) in H_2SO_4 at pH 2.7, *i.e.*, in fair agreement and not much affected by pH.

Figure 3 shows a trace made on a plated wire before and after the alloy deposit was deliberately nicked with a razor blade. The resulting scratch was sufficient to render that point on the wire useless for memory application. The occurrence of the copper passivation peak is clearly evident at $+100$ mV. In practice, the copper peak occurs at $+20$ to $+120$ mV (SCE), with larger copper areas usually peaking at the higher potentials. This shift is expected to be related to the voltage scanning rate. The method used to measure the peak height is also illustrated in Fig. 3.

The scan is started at a potential such that little or no cathodic current flows. Cathodic current will, of course, reduce some of the nickel passivation and a current peak due to the repassivation of nickel will appear. However, some nickel passivation current can be tolerated since the Ni peak usually does not interfere with observations of the Cu peak.

The electrode reaction mechanisms are doubtlessly complex. In broad terms, the rate of formation of the passivating copper pyrophosphate film is determined by competition between a precipitation reaction

$$Cu^{++} + P_4O_7^{----} \rightarrow \text{insoluble salt}$$

and a dissolution reaction:

$$\text{insoluble salt} + P_4O_7^{----} \rightarrow \text{soluble complex}$$

The existence of insoluble salts and complex ions in the copper pyrophosphate system at pH 5.2 is well known (8-11), but no attempt is made here to identify the species involved. Above a pH of about 6, where no copper-pyrophosphate precipitate is found, the present method fails. On the other hand, below pH 4 passivity is difficult to obtain, direct attack on the nickel is excessive, and samples are rapidly destroyed.

Area Calibration of the Copper Peak Current

In order to validate the test sequence, it is necessary to prove that a direct correlation exists between the height of the copper passivation peak and the area of exposed copper. Electrodes of known area were prepared by potting 1-mil diameter copper wires so that only polished cross sections were exposed to the electrolyte. The peak heights of assemblies containing from 1 to 25 wires were measured. The results are shown in line A, Fig. 4, which has the expected slope of 1. Similarly potted electrodes containing single wires of larger diameter yielded curve B, which has a slope of about 0.8.

Neither of these lines can properly be extrapolated to lower currents to provide a quantitative calibration curve. The peak current is at least partially controlled by diffusional processes whose rate is maximized by multiple small-sized copper electrodes which permit essentially three-dimensional supply of reactants to the electrode. Large cross-section electrodes undergo a transition from three- to one-dimensional diffusion behavior with an expected reduced over-all rate or

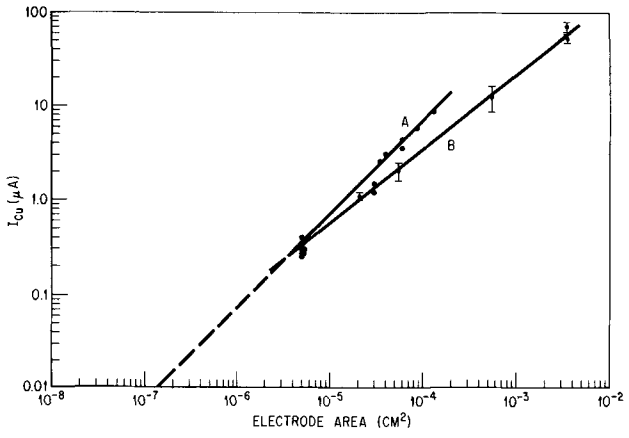

Fig. 4. Copper peak current vs. electrode area correlation curves for multiple electrodes comprised of 1 mil diameter sections (curve A) and single electrodes of larger diameters (curve B).

current. Pinhole arrays in actual plated wires will behave as isolated multiple electrodes of various diameters. The smaller pinholes will contribute disproportionately large partial currents to the total current until other effects predominate, such as high electrolyte resistance in very small pinholes, failure of the previously formed anodic film on copper to dissolve in the allowed two minutes, or failure of the electrolyte to penetrate very small pinholes. A true calibration curve would lie to the left of the extrapolation of line A, Fig. 4, and would be parallel to line A only if the pinholes have approximately the same diameter.

The repeatability of the measurement on sanded electrodes consisting of a single 1-mil diameter copper wire was slightly better than ±20%. Eleven measurements taken from four different electrodes gave an average I_{Cu} value of 0.30 μA, with a standard deviation of 0.05 μA. Standard derivations of measurements using the larger diameter single-wire electrodes are indicated by the error flags in Fig. 4. Most of this error arises from real surface area variations due to roughness of the copper cross sections. The peak heights found for a 25-mil diameter copper section were consistently lower when the surface was prepared by electropolishing than when it was sanded.

The advantage of this method over Ehrhardt's (3) is that the effects of solution convection, which must be dealt with when measuring a diffusion limited anodic current, are minimal. Copper wire calibration samples gave essentially the same distribution of peak heights when the copper electrode faced downward in the electrolyte, or was inverted to face upward. The peak of the copper current is reached in 15-30 sec, a time apparently too short for the buildup of density gradients which are sufficient to cause local convection. Furthermore, any Ni-Fe passivity that is lost between the initial passivation and the measuring sweep, is quickly re-established during the sweep before the copper dissolution potential is reached. Thus the passivation peak for copper stands out unambiguously.

The repeatability of measurements on plated wire samples could not be determined because of the cumulative destructive effects described below. It is believed that except for the occurrence of gross defects, most acceptable wire deposits are characterized by microfissures which are relatively uniformly distributed. All-in-all the method yields useful data over a range of five orders of magnitude. Acceptable plated wires display copper peaks of 0.03-0.005 μA or less per centimeter of wire length, while poorly plated wires ranged from 0.1 to 1 μA. Variation of the thickness of the permalloy deposit from 3000 to 10,000Å, plated under "acceptable" conditions, had little or no effect on the observed defect area. Badly corroded wires have been observed with currents up to 400 μA, or about 50% exposed substrate area.

Effect of Repeated Scanning

Some of the charge passed during the initial passivation step represents active dissolution of nickel and iron. Thus, there exists the possibility that high results would be obtained if the passivation stage removes some of the magnetic alloy. Existing pinholes could be enlarged or thinly plated areas could be stripped and a pinhole generated.

To estimate the magnitude of this source of error, the cumulative effect of repeated pinhole test cycles was examined. Figure 5, line A, shows that when passivation is carried out as in Fig. 1, there is indeed a slow increase in the measured copper peak height, but that this levels off after about 8–10 test cycles. The increase in copper peak height from the first to the second scan of a given sample was usually found to be about 20 to 30%. It is estimated, therefore, that the true copper height would lie about 20-30% below that measured by the first scan. The test is clearly partially destructive, but the error is no greater than other uncertainties.

Line B in Fig. 5 shows the effect of using a passivation technique which permitted much greater anodic currents to flow. Instead of polarizing at a constant +800 mV, passivation was done by scanning from −200 to +800 mV at 200 mV/min. This provided greater opportunity for active dissolution of nickel, and the more rapid sample destruction is evident in curve B. The passivation of a normal wire requires passage of about 6 x 10^{-4} to 30 x 10^{-4} coulombs/cm length. If all of this charge represents dissolution, distributed uniformly, a layer of magnetic alloy 50-250Å is lost. As a check, a portion of electrolyte that has been used to test a total of 90 cm of wires was analyzed by atomic absorption and found to contain Ni in an amount equivalent to the dissolution of 20 ± 20 Å/cm of wire. The dissolution is almost surely not uniform, and pinhole enlargement has not been preventable.

Dissolution is even more serious when impurities are present which prevent the passivation of the Ni-Fe. Such impurities are provided, for example, by tarnish layers which form under certain conditions during corrosion tests in sulfur-containing atmospheres. A dip in 1:1 HCl was found adequate for removing the tarnish layers, but this operation also removes up to 300Å of alloy.

Selection of Sample Length

Production wire batches consisting of 20 to several hundred 20-in. long wires, are characterized by apply-

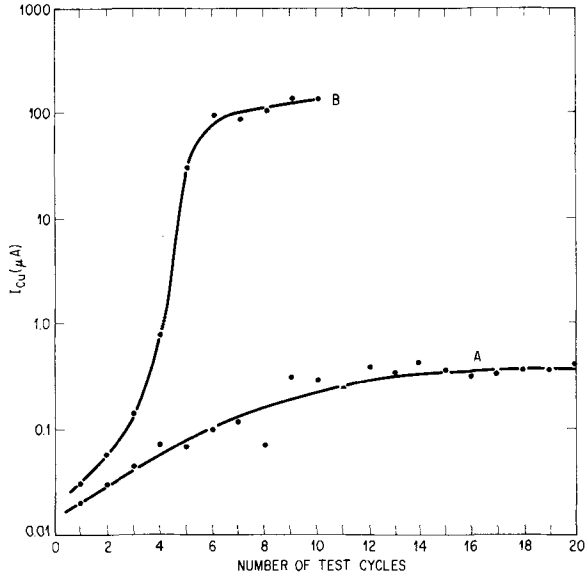

Fig. 5. Effect of repeated test cycles on the observed copper peak height, I_{Cu}. Curve A, procedure as in Fig. 1; curve B, first passivation done by slow scan to +800 mV.

ing the test to a 10-cm length from each of several wires, and copper peak currents range from <0.005 to 0.03 μA/cm. When plating defects other than microfissures occur, they are scattered at random along the length of the wire. A short sample could obviously lead to erroneous interpretations if it happens to fall between defects. Too long a sample, on the other hand, could cause an infrequent defect to be averaged over too long a length with an equally erroneous underestimation. For example, when one 38-cm length was tested 1 cm at a time, all sections fell in the range of 0.01-0.1 μA except one with the abnormally high reading of 0.7 μA. The same wire taken as a whole showed an average current of 0.04 μA/cm which would have been considered only slightly outside the "normal" range. While the statistically ideal sample length was not determined, a length of 10 cm was selected as a good working compromise and in general two such lengths were cut from each production wire tested.

Conclusions

A porosity test has been worked out which gives a measure of the substrate area left exposed by plating defects or pinholes in Ni-Fe alloy films plated on copper. Even with the errors discussed above, the test is useful in quality control of the plating process and in following the course of corrosion reactions. The accuracy has proved more than adequate for measurements of exposed substrate area ranging from less than 0.0004 to 50% and can undoubtedly be improved by optimizing the test conditions.

The method makes use of the current peak associated with a metal being anodically passivated during a potential scan. The technique might be adaptable to other metal pairs if an electrolyte can be found in which the two passivating layers have widely different rates of dissolution.

Acknowledgments

The writer wishes to express his appreciation to Dr. Leonard Nanis for much helpful discussion and to Mr. Andrew Sloss who spent many tedious hours before the polarograph.

The Approach to Limiting Current in a Stagnant Diffusion Cell

Limin Hsueh and John Newman*

Inorganic Materials Research Division, Lawrence Radiation Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The transient behavior of surface concentration and current density in a stagnant diffusion cell has been worked out with consideration of surface and concentration overpotentials and the ohmic resistance of the solution. Both theoretically and experimentally, the current density is found to overshoot the limiting current density during part of the transient.

A stagnant diffusion cell is a capillary cell with an electrode at one end of a capillary filled with solution and open at the other end into a container with solution and containing the counterelectrode. Such a cell is commonly used for diffusivity measurements (1, 2) because of its simple experimental setup and the easy measurement of current and time.

Early analyses (3, 4) showed that, for a constant concentration at the electrode surface, the current decreases in inverse proportion to the square root of time in an unsteady, one-dimensional diffusion, or $i\sqrt{t}$ is a constant for a given concentration of solution. Accordingly, the current would be infinite at zero time. Actually, for a constant applied potential, the current is finite and remains more or less constant until the reactant concentration at the electrode surface approaches a value of zero. The time required for this depends on the potential difference applied across the two electrodes and the properties of the solution itself. It may range from less than 100 sec in a well-supported solution to several tens of thousands of seconds in a solution of a single electrolyte.

Davis, Horvath, and Tobias (2) have included the surface overpotential for linear electrochemical kinetics in their treatment. In the present work, the analyses is extended to include the ohmic resistance of the solution, as well as nonlinear electrochemical kinetics.

This work was motivated not so much by the ohmic and kinetic limitation at short times but more by the shape of the logarithmic current-time curves obtained in the measurement of integral diffusion coefficients (5), the study of the effect of ionic migration on limiting currents (6), and attempts to obtain limiting currents in cupric sulfate solutions in the absence of sulfuric acid (7). Under certain conditions, the current overshoots the limiting current. A similar phenomenon was predicted in the analysis of the current distribution on a rotating disk electrode (8-10) and on

* Electrochemical Society Active Member.
Key words. mass transfer, current distribution, copper sulfate-sulfuric acid system, polarization.

plane electrodes in the walls of a flow channel (11, 12). Experimental confirmation obtained in the present work may thus lend support to those analyses. The similarity to polarography in a binary salt solution (13) should also be noted. No overshoot was predicted in that work, but a recalculation for that system shows that there can be an overshoot for large applied potentials.

Analysis

With the assumption of constant physical properties, the equation for unsteady diffusion in a stagnant diffusion cell for a solution without supporting electrolyte or with an excess of supporting electrolyte reduces to

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial y^2} \qquad [1]$$

where $c = c_+/\nu_+ = c_-/\nu_-$ and

$$D = \frac{z_+u_+D_- - z_-u_-D_+}{z_+u_+ - z_-u_-}$$

for a solution of a single electrolyte, and where c and D represent the concentration and effective diffusion coefficient of the reactant for a solution with an excess of supporting electrolyte.

Equation [1] should be solved with the initial condition that the concentration is uniform, $c = c_\infty$, throughout the capillary at $t = 0$. The concentration at the electrode surface can be taken, for the moment, to be an unknown function of time, $c = c_0(t)$ at $y = 0$. By taking the Laplace transform of Eq. [1] with respect to time and solving the resulting ordinary differential equation, one obtains for the transform of the concentration

$$\bar{c} = \frac{c_\infty}{s} + \left[\bar{c}_0(s) - \frac{c_\infty}{s}\right] e^{-y\sqrt{s/D}} \qquad [2]$$

where s is the Laplace transform variable. The length of the capillary has been taken to be much greater than the thickness of the diffusion layer. Differentiation of Eq. [2] with respect to y, setting y equal to zero, and inversion by means of the convolution integral produce an equation relating the concentration gradient at the surface to the variation of the surface concentration

$$\left.\frac{\partial c}{\partial y}\right|_{y=0} = \frac{-1}{\sqrt{\pi D}}\int_0^t \frac{dc_0(t')}{dt'}\frac{1}{\sqrt{t-t'}}\,dt' \qquad [3]$$

This equation is useful because the current density is also related to the concentration gradient at the surface

$$i = \frac{n\mathbf{F}D}{1-t_R}\left.\frac{\partial c}{\partial y}\right|_{y=0} \qquad [4]$$

where t_R is the transference number of the reactant ($t_R = 0$ with an excess of supporting electrolyte). The current density is further related to the surface overpotential η_s by

$$i = i_o\left(\frac{c_0}{c_\infty}\right)^\gamma\left[\exp\left\{\frac{\alpha Z\mathbf{F}}{RT}\eta_s\right\} - \exp\left\{-\frac{\beta Z\mathbf{F}}{RT}\eta_s\right\}\right] \qquad [5]$$

where i_o is the exchange current density, αZ and βZ are the transfer coefficients, and γ expresses the concentration dependence of the exchange current density.

The ohmic drop in a capillary of length L is

$$\Delta\Phi_{ohm} = iL/\kappa_\infty \qquad [6]$$

and the concentration overpotential is (14)

$$\eta_c = \frac{RT}{Z\mathbf{F}}\left[\ln\left(\frac{c_0}{c_\infty}\right) + t_R\left(1 - \frac{c_0}{c_\infty}\right)\right] \qquad [7]$$

where $Z = -z_+z_-/(z_+ - z_-)$ for reaction of a cation from a solution of a single electrolyte, and $Z = -n$ for a solution with an excess of supporting electrolyte. For the case of metal deposition from a solution of a single electrolyte, the concentration overpotential expressed by Eq. [7] includes an ohmic contribution due to the variation of the conductivity in the diffusion layer (14). Hence, it is appropriate to use the conductivity of the bulk solution in Eq. [6]. The total potential difference V^* applied between the electrode and the solution outside the capillary (as measured by a reference electrode of the same kind as the working electrode) is the sum of the concentration overpotential, the surface overpotential and the ohmic potential drop

$$V^* = \eta_c + \eta_s + \Delta\Phi_{ohm} \qquad [8]$$

It seems appropriate to define a dimensionless current density I and a dimensionless exchange current density J as

$$I = \frac{Z\mathbf{F}L}{RT\kappa_\infty}i, \quad J = \frac{Z\mathbf{F}L}{RT\kappa_\infty}i_o \qquad [9]$$

to define a dimensionless applied potential V and total overpotential η as

$$V = \frac{Z\mathbf{F}}{RT}V^*, \quad \psi = \frac{Z\mathbf{F}}{RT}(\eta_c + \eta_s) \qquad [10]$$

and a dimensionless surface concentration θ as

$$\theta = c_0/c_\infty \qquad [11]$$

Then Eq. [5] through [8] can be rewritten as

$$I = V - \psi = J[\theta^\gamma e^{-\alpha E} - \theta^\gamma e^{+\beta E}] \qquad [12]$$

where

$$E = \psi - t_R(1-\theta) \qquad [13]$$

and Eq. [3] and [4] can be combined to read

$$I = \frac{NL}{\sqrt{\pi D}}\int_0^t \frac{d\theta(t')}{dt'}\frac{1}{\sqrt{t-t'}}\,dt' \qquad [14]$$

where

$$N = -\frac{nZ\mathbf{F}^2Dc_\infty}{(1-t_R)RT\kappa_\infty} \qquad [15]$$

If we now define a dimensionless time τ by

$$\tau = t/t_c \qquad [16]$$

where

$$t_c = N^2L^2/\pi D \qquad [17]$$

then Eq. [14] can be written as

$$I = \int_0^\tau \frac{d\theta(\tau')}{d\tau'}\frac{1}{\sqrt{\tau-\tau'}}\,d\tau' \qquad [18]$$

Equations [12], [13], and [18] constitute four equations for the determination of the time dependence of I, θ, and ψ, as well as E. They can be solved numerically when the six parameters, α, β, γ, J, V, and t_R are known for a given system. One more parameter, V, could be eliminated, but this might obscure the physical significance of the results.

Numerical Calculation Method

The integral in Eq. [18] was approximated by a sum by an adaptation of the method of Acrivos and Chambré (15). Since Eq. [18] involves an indefinite integral, it is only necessary to solve a nonlinear set of equations at each time step. By the nature of the problem, $\theta = 1$ at $\tau = 0$. For the details of the calculation method, one may refer to ref. (16).

Theoretical Results

The dimensionless current density I is plotted against the dimensionless time τ in Fig. 1 with V as a parameter. The values of α, β, γ, J, and t_R are all taken to be equal to 0.5. The higher the total applied potential V, the shorter the flat part of the curve. For high values of V, the current density overshoots the limiting cur-

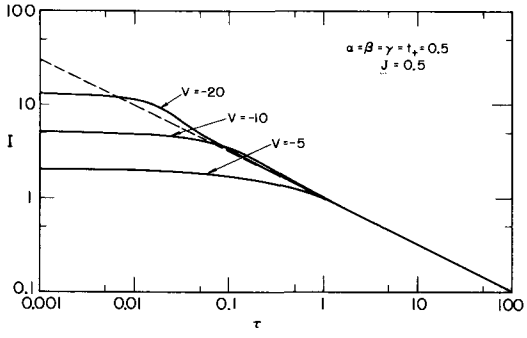

Fig. 1. Decrease of current density in a stagnant diffusion cell

rent, a phenomenon that has been observed experimentally in many of our curves of log current *vs.* log time. For a given value of V, the flat part of the curve persists longer for larger values of the characteristic time t_c. A high value of t_c results from a high transference number of the reactant and a low conductivity of the solution.

For a capillary tube of $L = 10$ cm, some estimated values of t_c for copper sulfate and sulfuric acid at 25°C are

$[CuSO_4]$ M	$[H_2SO_4]$ M	t_c sec
0.05	0	3.0×10^6
0.5	0	6.7×10^6
0.05	1.0	5.6×10^2

In the calculations, $Z = 1$, $t_R = t_+ = 0.4$ for copper sulfate only. $Z = 2$, $t_R = 0$ for the solution with sulfuric acid as supporting electrolyte.

The decrease of surface concentration θ with time is plotted in Fig. 2 with identical parameters. The higher the applied potential, the faster the surface concentration drops to zero. The time required for the surface concentration to drop to 10 and 1% of the bulk value is plotted in Fig. 3.

Experimental Results

Figure 4 shows the transient behavior of the current density with various amounts of supporting electrolyte. These curves have qualitatively the same shape as the theoretical curves in Fig. 1, particularly with regard to the transient overshooting of the limiting current.

The surface concentration was also measured optically for an unsupported, 0.0385M cupric sulfate solution at 25°C; the results are shown in Fig. 5 for two values of the applied potential, 0.80 and 0.60V. The measured variations of the surface concentration are compared with the theoretical predictions in Fig. 5. The following data were used for the calculations:

		ref.
Conductivity κ_x	4.13×10^{-3} mho/cm	(17)

2	0.0998	0.100	0.355	71.2
3	0.0999	0.050	0.355	198
4	0.1001	0.020	0.350	553

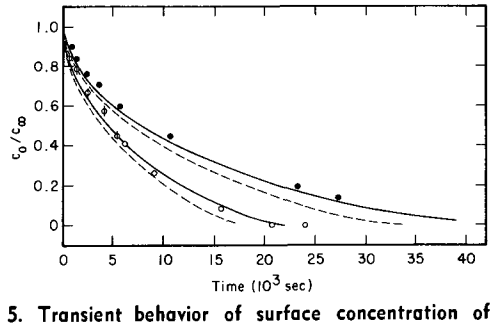

Fig. 5. Transient behavior of surface concentration of copper sulfate (0.0385M) in a stagnant diffusion cell: ● 0.60V; ○ 0.80V; dashed lines, $i_o = 1.0$ mA/cm², solid lines, $i_o = 0.1$ mA/cm²).

The length of the cell L was 15 cm, the area of the electrode was 0.178 cm², and the calculated characteristic time t_c was 5.60 x 10^6 sec. There are no exchange current density data available in the literature for an unsupported $CuSO_4$ solution, a reasonable estimate being that it lies between 0.1 and 1.0 mA/cm². The solid lines are theoretical calculations at an exchange current density of 0.1 mA/cm², and the dashed lines

are calculated at 1.0 mA/cm². The solid lines represent a satisfactory fit to the experimental results.

An unexplained observation should be recorded here. For a solution 0.1*M* in $CuSO_4$ and 1.375*M* in H_2SO_4, the current time curves in Fig. 6 were obtained. The current drops suddenly at about 0.3 sec. This phenomenon was fairly reproducible in a well-supported electrolyte. No such step change was observed for solutions with little or no supporting electrolyte.

Before the runs, the electrode was predeposited with copper at 0.1V for 1 to 3 min. Values of the parameters for the theoretical calculations are $\alpha = 0.75$, $\beta = 0.25$, $\gamma = 0.5$, $t_R = 0$, $\kappa_z = 0.4925$ mho/cm, $Z = 2$, $L = 7.0$ cm, $D = 5.09 \times 10^{-6}$ cm²/sec, $t_c = 740$ sec, $V^* = 0.225$V, and the exchange current density is estimated to lie between 1 and 10 mA/cm² for a cathode surface prepared by electrodeposition (20).

Before the step change of current density, the horizontal part of the curve was found to fall between the curves for theoretical predictions of exchange current of 1 and 10 mA/cm². The charging of the electrode double layer should be complete in a time of about 0.5 msec.

A reviewer suggests the following possible explanations for the step change of current density: (*a*) cuprous ions are initially present in the solution in equilibrium with cupric ions and will tend to react before the cupric ions due to kinetic factors (20); (*b*) crystallographic defects in the deposit may be different from those in the substrate metal and thus lead to a change of kinetic parameters with time; and (*c*) adsorption of inhibitors or impurities may lead to changes of kinetic parameters although the effect would not be expected to be reproducible. However, calculations based on the equilibrium concentration of cuprous ions suggest that the transition time for their concentration to drop to zero at the electrode surface would be much smaller than the time at which the step change in current density occurs.

Conclusion

In this work, the transient behavior has been worked out for a stagnant diffusion cell. The resulting time dependence of the surface concentration for an unsupported electrolyte agrees with the theoretical predictions within the uncertainty of the available electrochemical kinetic parameters. The current density is found, experimentally and theoretically, to overshoot the limiting current, in harmony with predictions for the current distribution on plane and disk electrodes.

Stoichiometry of Anodic Copper Dissolution at High Current Densities

K. Kinoshita,*[1] D. Landolt,*[2] R. H. Muller,* and C. W. Tobias*

Inorganic Materials Research Division, Lawrence Radiation Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The influence of current density, flow rate, and electrolyte composition on the stoichiometry of anodic copper dissolution was investigated under conditions comparable to those of electrochemical machining. Weight loss measurements, x-ray diffraction, and chemical analysis were used for the characterization of the dissolution reaction. A sharp change in dissolution mechanism coincided with the transition from active to transpassive dissolution. For active dissolution, an apparent valence of the dissolution process of two was found in sulfate and nitrate electrolytes, and of one in chloride electrolytes. For transpassive dissolution, mixed valences lying between 1 and 2 were found in all electrolytes. The mixed valences are interpreted to result from the simultaneous production of monovalent and divalent reaction products, some of which are in solid form.

Anodic dissolution of metals at current densities of up to several hundred amperes per square centimeter and with electrolyte flow velocities of many meters per second is being carried out on a technical scale in the process of electrochemical machining (ECM). In an attempt to provide quantitative information on the electrochemical processes under high current densities, the anodic dissolution of copper is being investigated (1-3). Copper was chosen because its electrochemical properties are reasonably well understood (4-8). In a previous paper (1), the role of mass transfer in determining the occurrence of passivation phenomena during copper dissolution in K_2SO_4 and KNO_3 solutions has been reported. It was found that apparent anode potentials and surface textures resulting from dissolution changed drastically while going from a low voltage (active) to a high voltage (transpassive) mode of dissolution.[3]

In the present study, the valence of the electrode reaction and the composition of reaction products of copper have been investigated in nitrate, sulfate, and chloride electrolytes. Weight loss measurements of the anode, x-ray diffraction analysis of solids, and chemical analysis of the solution were used for the characterization of the dissolution reaction. Current densities employed ranged from 0.1 to 80 A/cm^2. Experiments were performed under forced convection conditions in a flow channel at flow rates from 30-700 cm/sec, as well as in unstirred solutions under free convection conditions.

Experimental

Most experiments were carried out under forced convection conditions in an experimental flow system similar to that described in a previous study (1) and schematically shown in Fig. 1. The electrolyte was pumped by a positive displacement pump,[4] and the flow rate was measured with a rotameter.[5] One half inch stainless steel pipes were used throughout the system.

A 30 cm long rectangular flow channel of 1 x 3 mm cross section, constructed of laminated polyvinyl chloride, was positioned upstream of the experimental cell to establish fully developed velocity profiles at

[5] Type 18410, Schutte and Koerting Company, Cornwall Heights, Pennsylvania.

the electrodes (1). The electrolysis cell is shown schematically in Fig. 2. The cell body (B) was made of epoxy resin with the two glass side walls (H) held together by plates (C). The cell was connected to the inlet and outlet channel by end flanges (G). Optical observation of the interelectrode gap could be performed through the glass walls. Back-side capillaries (K) which enter the channel walls next to the electrodes were used for electrode potential measurements and, in some experiments, for the sampling of solution on the downstream side of the electrodes. The copper electrodes (D) (purity ≧99.9%) had a geometrical surface area of 3 x 3 mm. The electrodes could be advanced manually by turning micrometer head (M). The electrode assembly was pushed back against insert (F) by sprint (O). Silicone rubber gaskets[6] cast between glass wall and epoxy cell body were used for sealing the cell.

Measurements of cell voltage, electrode potentials, and current were made simultaneously on a multi channel light beam oscillograph.[7] Electrical power connections to the cell were made by threaded connections screwed into aluminum cap (E). The current was recorded by measuring the voltage drop across a shunt. Anode and cathode potentials were measured with respect to saturated calomel reference electrodes, which were placed in small glass containers connected to the capillaries by Tygon tubing. The electrolysis current was provided by an electronically controlled constant current supply.[8]

Prior to each run, the electrodes were ground on 600 grit emery paper and washed with aqueous detergent. Following a dip in concentrated HCl, they were rinsed with distilled water and reagent grade acetone and stored in vacuum until use. The electrodes were aligned with the channel wall by using a microscope with 20X magnification. During electrolysis, the 1 mm electrode gap was approximately maintained by manual adjustment of the micrometer.

During a typical experiment, 25 mg of copper were dissolved, which corresponded to an average depth of dissolution of about 0.3 mm. After each run, the anode was removed from the cell, rinsed with water, dried with acetone, and weighed on an analytical balance. The accuracy of the weight loss determination is estimated at ±1-2%. The amount of charge passed during the experiment was determined from the oscillographically recorded current trace. The accuracy of the charge measurement is estimated at ±2-3%.

From the measurement of charge and weight loss, an apparent valence n of the dissolution process was calculated according to Eq. [1]

$$n = \frac{ItM}{\Delta W \mathbf{F}} \qquad [1]$$

where I is the current passed during time t, M is the atomic weight of copper, ΔW is the anode weight-loss, and $\mathbf{F}$ is the Faraday constant.

Solid reaction products formed during the anodic dissolution of copper were analyzed by x-ray diffraction. Initial analyses were made using a 11.46 mm Debye-Scherrer powder camera mounted on an x-ray diffraction unit.[9] Ni filtered Cu radiation (40 kV, 20 mA) was used.

A sample of the anodic reaction product from the flow cell was collected by rubbing a glass fiber through the precipitate adhering to the wet surface. Diffraction patterns obtained were, however, difficult to analyze because of the faintness of the diffraction lines. Also, because of the small samples, exposure times to the x-ray beam from 6-12 hr were necessary.

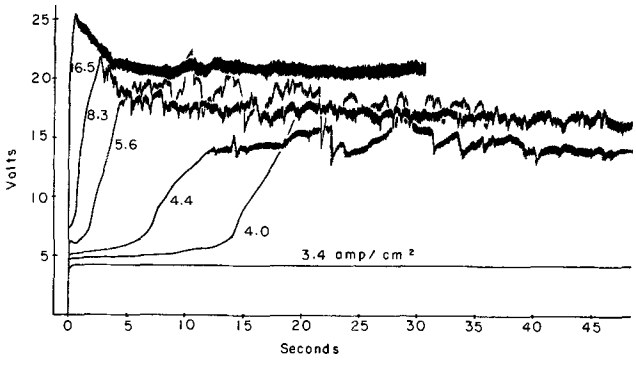

Fig. 3. Cell voltage transients measured in 2N KNO_3 at different current densities, flow rate 30 cm/sec.

To provide a larger specimen, a continuous sampling technique was developed. An x-ray diffractometer[10] using a Ni filtered Cu radiation (40 kV, 14 mA) could then be used. Solution escaping through the (0.014 in. diameter) capillary on the downstream side of the anode was collected on a Whatman No. 41 paper by continuous vacuum filtration. Without washing, the filter paper with adhering precipitate was dried under vacuum, mounted on a Lucite sample holder using double-sided adhesive tape, and placed in the diffractometer. A preliminary x-ray pattern of the blank showed strong diffraction peaks at low θ values which did, however, not interfere with the diffraction peaks of possible compounds present in the precipitate.

In order to substantiate the apparent valence determination carried out under forced convection conditions, some experiments were performed in a stagnant electrolyte which allowed quantitative determination of dissolved Cu^+ and Cu^{2+} ions. Since Cu^+ is unstable in aqueous solution unless complexing agents are present, only chloride electrolytes were analyzed this way. The electrolysis was carried out in an H cell with a glass frit separating anode and cathode compartments (2). In contrast to the highly diluted dissolution products obtained in the flow channel, concentrations which can be determined by simple analytical techniques could be obtained in this system. The analytical determination of Cu^{2+} and Cu^+ was based on that given by Vogel (9). Cuprous ion was oxidized with ferric ammonium sulfate, and the resulting ferrous ion was titrated with ceric sulfate. The cupric ion concentration was obtained as the difference between total copper concentration and cuprous ion concentration. The total copper concentration was determined iodometrically after oxidation of cuprous ion to cupric ion by sodium peroxide.

Results

Current-voltage behavior.—Figure 3 illustrates the transient cell voltage behavior during galvanostatic copper dissolution in 2N KNO_3 under a given flow rate (30 cm/sec). At low current density (3.4 A/cm²), the dissolution proceeds indefinitely in a low voltage (active) mode. Above a critical current density, which is shifted to higher values by increased flow rates, the dissolution process switches to a high voltage (transpassive) mode, after a transition time with active dissolution. The length of the transition period decreases with increasing current density and decreasing flow rate (not shown). Figures 4 and 5 are examples of transient cell voltage behavior with K_2SO_4 and KCl solutions. In all cases, dissolution in the transpassive mode occurs at a cell voltage which is 10-20V higher than in the active mode. Voltage fluctuations are observed in the transpassive region and, at the higher current densities, a voltage maximum occurs before steady state is reached.

Apparent valence.—Average steady-state values of the cell voltage and apparent valence values are

plotted *vs.* current density in Fig. 6 to 8. The behavior in 2*N* KNO_3 and 1*N* K_2SO_4 solutions is very similar. With the transition from active to transpassive dissolution, a sharp drop in apparent valence occurs. The apparent valence value of $n = 2$ observed in the active region indicates that copper is dissolved almost exclusively to divalent cupric ions. This is consistent with expectations based on thermodynamic considerations of the reversible potential of a copper electrode in contact with dissolved mono and divalent copper ions (8). In the transpassive region, on the other hand, the apparent valence depends on the value of the applied current density with respect to the current density at which passivation occurs. A limiting value of $n \simeq 1.5$-1.6 is reached at high current densities. In order to account for this value of n, it has to be assumed either that part of the copper is dissolved to a monovalent form, or that part of the metal disintegrates during the dissolution process. Since *p*H might have an influence in determining the reaction path (8), additional experiments were performed in a 2*N* KNO_3 solution adjusted to *p*H 1 by the addition of concentrated nitric acid, and also in a 1*N* H_2SO_4 solution. Voltage readings and apparent valences obtained in both of these electrolytes corresponded within experimental accuracy to those of the nitrate and sulfate solutions, respectively. This indicates that, within the range studied, *p*H has a negligible influence on apparent valence of the dissolution process. As illustrated by Fig. 8, the behavior in KCl solutions was quite different from that in KNO_3 and K_2SO_4 solutions. A sharp transition between active and transpassive dissolution was absent. Instead, periodic fluctuations occurred (indicated by dotted lines in Fig. 8) in the transition region. Such oscillations in the copper/chloride system have also been reported in the literature for low current density conditions (6, 10). Periodic oscillations have also been observed during high rate copper dissolution in sulfate and chlorate electrolytes under certain conditions (1-3). The apparent valence, in the case of chloride solution, is $n = 1$ at low current densities. A maximum of $n = 1.4$ is observed at intermediate current densities, and the apparent valence drops to $n \simeq 1.2$ in the range of high current densities. While it appears that the observed changes in apparent valence are related to the occurrence of passivation, the relationships are not as clear cut as in

Table I. X-ray analysis of anode solid reaction products

Electrolyte	Compounds identified
2N KNO_3	Cu_2O, Cu
2N KNO_3 + HNO_3 (pH 1)	Cu
1N K_2SO_4	Cu_2O, Cu
1N H_2SO_4	Cu

nitrate and sulfate solutions. For example, at the highest flow rate (606 cm/sec), the maximum value of n was attained at much higher current density than that corresponding to the active-passive transition derived from cell voltage measurements.

Analysis of solid reaction products.—Anode precipitates were found during transpassive dissolution only. X-ray analysis of precipitates collected from experiments performed in KNO_3 and K_2SO_4 solutions showed Cu_2O to be the principal copper compound. Diffraction peaks for metallic copper were also present in some experiments. The metallic copper contents of precipitates from acidified solutions was increased at the expense of the cuprous oxide contents (Table I). No analysis of anodic precipitates in chloride solution was possible because precipitates could not be collected in sufficient amounts. A typical diffraction pattern of anode precipitate is given in Fig. 9 together with patterns of known samples of Cu_2O and Cu. Precipitates collected in the drain tank showed a different composition from those collected close to the anode. They contained basic oxides of complex composition, owing to contact with the alkaline solution produced at the cathode.

Analysis of dissolved reaction products.— Apparent valence determinations in chloride solution were also carried out in a separate cell under absence of forced convection. In these experiments, values of apparent valence obtained from weight loss measurements could be compared with those obtained by chemical analysis of dissolved reaction products. Calculation of the chemically determined apparent valence n^* was based on Eq. [2]

$$Cu \rightarrow xCu^+ + yCu^{2+} + n^*e \qquad [2]$$

where x and y are the fractional amounts of Cu^+ or Cu^{2+}, respectively. Since, from the mass balance $x + y = 1$ and from the charge balance $x + 2y = n^*$, one gets Eq. [3]

$$n^* = 2 - x = 1 + y \qquad [3]$$

The results given in Table II illustrate the good agreement between the valence determined by chemical analysis with that derived from weight loss measurements for a wide range of current densities. In all cases a mass balance could be established within 1-2%. Changes in apparent valence with current density in chloride solutions are therefore indeed due to different ratios of Cu^+ and Cu^{2+} produced. No oxygen evolution was observed during the experiments. The experiments also confirmed that the anodic behavior, *i.e.*, the occurrence of active and transpassive dissolution, was essentially the same in stagnant as in flowing solutions,

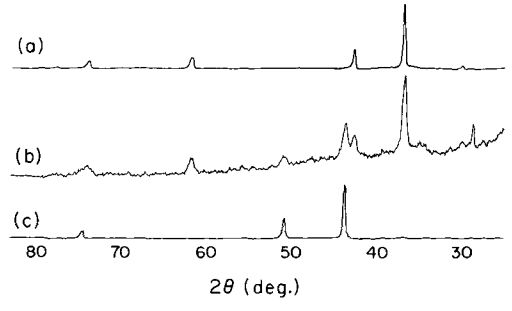

Fig. 9. X-ray diffractometer trace of anode precipitate (b) compared to known samples of Cu_2O (a) and Cu (c). Anode precipitate obtained at 11.1 A/cm² and 50 cm/sec in 1N K_2SO_4.

Table II. Chemical analysis of dissolved reaction products in 3N KCl solution after passage of 60 coul, anode area 1 cm²

with the exception that passivation sets in at much lower current densities in the absence of external convection.

Discussion

Nitrate and sulfate solutions.—Two dissolution modes, active and transpassive, were found differing in overvoltage and apparent valence of dissolution. The transition between active and transpassive dissolution depends on mass transfer conditions. Using the mass transfer correlations for channel flow discussed earlier (1), the interfacial concentration of ionic dissolution product at the onset of transpassive dissolution was estimated from the passivation current density for different flow rates and electrolytes. (A diffusion coefficient of 5×10^{-6} cm²/sec was assumed for this calculation.) A comparison of the results shown in Table III with solubility data given in Table IV indicates that the onset of transpassive dissolution coincides, at least qualitatively, with the limiting transport of dissolved reaction products by convective diffusion. This substantiates the validity of previous results (1) which were obtained in a different flow system, mostly at higher current densities and flow rates. In addition, it was found here that passivation current densities in 1N H_2SO_4 were essentially the same as in 1N K_2SO_4. This suggests that limitations in the transport of cupric salt, rather than the formation of oxide or hydroxide, initiates the change to transpassive dissolution.

The present study also demonstrates that the transition between active and transpassive dissolution is associated with a drastic change in current efficiency for the metal removal process, with more copper being

Table III. Calculated interfacial concentration of copper salts at onset of transpassive dissolution

	3N KCl	1.9	(17), (18)

dissolved for a given amount of charge in the transpassive region. A mechanism involving the formation of monovalent copper species at the anode, especially cuprous oxide, rather than anodic disintegration by grain boundary attack (11, 12), seems to be the cause for the apparent increase in current efficiency. The above conclusion, although it cannot be rigidly proven on the grounds of our results, is supported by the following experimental observations: (*A*) Cuprous oxide has been found to be the main constituent of anodic films. (*B*) Substantial amounts of metallic copper were observed in the x-ray patterns in acidic solutions only, consistent with the fact that Cu_2O disproportionates in these solutions into Cu^{2+} and Cu. (*C*) No grain boundary attack was observed microscopically in the transpassive region. Instead, the surfaces after transpassive dissolution had a shiny appearance and were almost randomly pitted (1, 2). (*D*) At least in the case of chloride solutions, the presence of cuprous ion could be verified quantitatively. All these factors indicate that a distintegration mechanism, which has been proposed primarily for more reactive metals (beryllium, magnesium, cadmium, zinc) at low current densities (13-16), is not likely to be of importance in the present anodic dissolution process.

Measured apparent valences tended to reach a constant limiting value at high current densities. No satisfactory explanation for this phenomenon can be given at the present time. From a purely kinetic point of view we would expect a continuous variation of n with current density. A possible explanation of the observed constancy of n may, perhaps, be sought in a model viewing the surface as an ensemble of small surface area elements randomly fluctuating between active and passive states. Such active-passive fluctuations, which are most pronounced in chlorate electrolytes (2, 3), are now being studied in this laboratory.

Chloride solutions.—The dissolution behavior in chloride electrolytes is different because the monovalent ionic state becomes thermodynamically more favorable than the divalent state due to the formation of cuprous ion complexes (17, 18). Thus, disproportionation of Cu^+, which usually occurs in aqueous solutions is avoided. Since a variety of different complexes may be formed, depending on the local chloride concentration, the dissolution process in chloride solutions is expected to be much more complicated than in nitrate and sulfate solutions. For example, due to the effect of chloride concentration on the solubility of cuprous ion, the formation of precipitate layers depends not only on the rate of departure of cations from the interface, but also on the rate of arrival of anions. In addition to the mass transport of the dissolution product, the mass transport of chloride ion may therefore become a limiting factor, since chloride ions are consumed at the anode by complex formation. Such a mechanism has, for example, been reported by Landsberg *et al.* (19) for the dissolution of gold in HCl. During the course of stoichiometric determinations in stagnant solution, a number of transient measurements were performed in 3*N* KCl solutions at constant current density. Table V summarizes the transition times determined for the onset of transpassive behavior. In spite of that the geometrical arrangement was not ideal to exclude free convection completely, the application of Sand's equation is justified because of the short times involved. From the average measured quantity $i\sqrt{\tau}$, a value for ΔC, the rate-limiting concentration difference, was calculated according to Eq. [4]

$$\Delta C = \frac{2i\sqrt{\tau}}{n\mathbf{F}\sqrt{\pi D}} \qquad [4]$$

assuming $D = 5 \times 10^{-6}$ cm²/sec and $n = 1$. The resulting value of $\Delta C = 3.6$ mole/liter is similar in magnitude to the solubility of CuCl in 3*N* KCl [1.9 mole/liter (17)]. This indicates that, under the conditions of these experiments, passivation may have been caused by a similar precipitation mechanism as in nitrate and sulfate solutions.

Table V. Transition times τ for copper dissolution at different current densities i in 3*N* KCl without external convection

i, A/cm²	τ, sec	$i\sqrt{\tau}$
0.10	38.90	0.62
0.16	11.60	0.56
0.21	9.20	0.69
0.26	5.63	0.62
0.51	1.85	0.70
0.82	0.65	0.68
1.00	0.48	0.69
1.31	0.28	0.69
1.58	0.20	0.70
1.87	0.16	0.75
1.98	0.15	0.77

The increase in apparent valence n on passivation (Fig. 8) is consistent with the fact that at higher anode potentials, the reaction $Cu \rightarrow Cu^{2+}$ becomes thermodynamically possible. No true anode potential measurements were possible under the conditions of this study; therefore, a discussion has to remain qualitative. The subsequent decrease in n at still higher current densities may then be explained by assuming formation of Cu_2O, as observed in the case of nitrate and sulfate solutions. The oozing of a reddish brown, finely dispersed dissolution product from localized anode areas which changed their positions during electrolysis was observed visually in stagnant KCl solutions in the transpassive region (2). This solid might have been Cu_2O, but it was not possible to collect the precipitate due to its chemical instability in the chloride electrolyte. The formation of cuprous oxide during copper dissolution in chloride media has also been reported in the literature (20-23). The formation of a thin cuprous chloride film during transpassive dissolution in chloride solution was indicated by the white appearance of the surface.

Summary and Conclusions

1. The present study has confirmed earlier findings (1) obtained under different experimental conditions that in nitrate and sulfate electrolytes the transition from active to transpassive dissolution of copper is controlled by the mass transfer of dissolved dissolution products.

2. Although the details of copper dissolution in chloride solution are probably different from those in nitrate and sulfate, the gross current-voltage behavior is similar. Ionic mass transfer limitations seem, therefore, to be the dominating factor determining the onset of passivation in chloride solutions, too.

3. The apparent valence of the dissolution process undergoes a noticeable change with the transition from active to transpassive dissolution. In nitrate and sulfate solutions, active dissolution proceeds with an apparent valence of 2. Transpassive dissolution leads to a lower apparent valence, which reaches a limiting value of 1.6 at high current densities. This drop in apparent valence is interpreted to be caused by the anodic production of monovalent copper species, rather than by anodic disintegration.

4. Active dissolution in chloride solution occurs with an apparent valence of one. This is due to the stabilization of cuprous ion by complex formation. Upon passivation the apparent valence increases, going through a maximum of 1.4 with increasing current density before reaching a limiting value of 1.2. This increase in apparent valence on passivation is due to part of the copper being dissolved in divalent form.

5. No significant oxygen evolution occurred during copper dissolution under all the experimental conditions employed.

6. The formation of solid anodic dissolution products during transpassive dissolution has been demonstrated in agreement with earlier optical observations. Anal-

ysis of the precipitates by x-ray diffraction has shown Cu_2O to be the main constituent produced in potassium nitrate and sulfate solutions. Metallic copper, resulting from disproportionation of Cu_2O, is found in acidified solutions. In chloride solutions optical observation indicated the formation of cuprous chloride films.

Comparative Activity of (111), (100), (110), and Polycrystalline Platinum Electrodes in H_2-Saturated 1M H_2SO_4 under Potentiostatic Control

Sigmund Schuldiner,* Murray Rosen,*[1] and David R. Flinn*[1]

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C. 20390

ABSTRACT

Potentiostatic measurements of the three principle faces of oriented single Pt crystals and polycrystalline Pt showed some interesting comparisons. True areas are based on Pt atom densities, and under the electrochemical treatment used, no changes in these areas were found once the initial surface cleaning was completed. The hydrogen overvoltage was independent of crystal orientation or other metallurgical factors; however, the passivation of the hydrogen oxidation reaction and the oxygen generation reactions were different for each single crystal orientation with a large difference between these faces and a polycrystalline bead electrode. Steady-state relations between potential and amounts of associated H atoms and number of sites available for coverage with O atoms were determined also. These steady-state values are generally less than the comparative amounts found under transient conditions. Oxygen evolution on the Pt faces was not observed below a potential of 1.8V. It appears that grain boundaries, stress, and impurity inclusions may have more effect in determining the catalytic activity for some reactions than does the actual atomic density or geometry of Pt atoms.

Although there have been numerous investigations of the hydrogen reaction on polycrystalline Pt electrodes and of the potentiostatic behavior of Pt in H_2-saturated solutions, our knowledge of the effects of the geometry of Pt atoms on such behavior is very limited. Using the voltage sweep method, Will (1) studied the relationship between hydrogen adsorption and potential on single Pt crystals of (111), (100), and (110) orientations.

Our approach was to conduct a comparative investigation of polycrystalline Pt with Pt single crystal orientations with respect to reactivity for steady-state hydrogen generation, hydrogen oxidation, and oxygen generation reactions. In addition, steady-state relations between surface coverage with potential were determined, both in the presence and absence of dermasorbed oxygen.

Experimental

The high-purity, gas-tight electrochemical system, the experimental conditions, and the method of measurement were the same as used in ref. (2). Three single crystal Pt electrodes with orientations (111), (100), and (110) were in the cell. A fourth Pt electrode, polycrystalline bead, similar to previous ones (2), was substituted for one of the single crystal electrodes to confirm that the experimental conditions

used for the single crystal electrodes duplicated the previous work.

The single crystal Pt electrodes were prepared and mounted in the following way. Three high-purity (99.999%, 3 pass electron beam zone refined) single crystals were welded to Pt wires and then were spark cut to the three principle faces (111), (100), and (110).[2] The faces were then electropolished in a melt consisting of equal weights of KCl and NaCl at 700°C in accordance with the procedure reported by Brouillet and Epelboin (3). After rechecking the orientation by x-ray diffraction, each crystal was mounted by placing a thin cylinder of virgin polyethylene (this polyethylene gave a water-clear melt) snugly against the sides of each crystal. A tightly fitting heat-shrinkable TFE Teflon tube was then placed over the polyethylene sleeve. Upon heating with an electric heat gun the polyethylene melted and the Teflon tube shrunk. Upon cooling the single crystal is tightly enclosed in a Teflon-polyethylene envelope. During heating some molten polyethylene covered part of the oriented Pt face. This polyethylene was largely removed by carefully cutting with a razor around the edge of the squeezed out polyethylene and carefully stripping the excess polyethylene from the Pt surface. Photomicrographs[3] showed that tiny particles of polyethylene remained on the surface; however, these were removed during the initial electrolysis as was shown by photomicrographs taken after such treatment. (A polyethylene particle is shown in the encircled area on Fig. 1a as a dark gray fragment. Similar fragments are apparent).

The Pt wire connected to the single crystal, which is covered by the Teflon tube, is sealed through a glass cap. Upon insertion of the electrode into the cell, the glass cap, which has a ¼ in. standard glass pipe connector, is connected to the cell via a Viton-A ring and screw clamp which gives a gas-tight seal.

The initial set of three oriented faces was carefully wiped with a fine soft paper and then cleaned with concentrated nitric acid and rinsed with triply distilled water. Upon close examination scratches were noted on these electrodes, and after the electrochemical measurements were made, photomicrographs showed many fine scratches on each crystal face. These crystal faces were re-electropolished, and after mounting great care was taken not to contact the exposed faces with anything but nitric acid, triply distilled water, and electrolyte. This careful treatment avoided scratches on the soft exposed Pt face. Potentiostatic measurements on each face were repeated after another polishing, and for the scratch-free surfaces, the results were essentially the same. However, the scratched surfaces showed some important variations which will be discussed.

The first measurements on the Pt bead (mounted in glass) were taken after the forming of the bead by melting the end of a Pt wire in a H_2/O_2 flame, cleaning in nitric acid, rinsing, and pre-electrolysis. To assure that the electropolishing procedure itself did not cause changes or leave a residue on the single crystal surfaces which could affect their electrochemical properties, a second set of potentiostatic measurements was made on the bead after electropolishing it under the same conditions used for the single crystals. The electropolished Pt bead, after the usual cleaning treatment, gave essentially the same results as were initially obtained before electropolishing.

All of the Pt electrodes had mirror bright surfaces, but as Fig. 1 shows they were by no means flat surfaces. Mechanical means of flattening the surface were avoided since it was felt that scratching or the inclusion of polishing agents could have strong effects. It seems obvious that atomically smooth surfaces are not feasible at the present time, and it is felt that the predominant orientation of surface atoms is influenced by the underlying Pt atoms of the given orientation.

True area (4) was calculated on the basis of a one-to-one correspondence between each Pt atom and O_{ad}. Since different crystal orientations were used, it was necessary to determine the number of Pt at./cm^2 for each face and bead. Atom densities for perfectly smooth electrodes of the (111), (100), and (110) orientations were calculated to be 1.5×10^{15}, 1.31×10^{15}, and 0.92×10^{15}, respectively, using 3.9231Å (5) as the lattice parameter. The atom density for the bead was assumed to be 1.31×10^{15} (2). On this basis and correcting for double layer charging (36 μC/cm^2), the number of μC/cm^2 for a 1 cm^2 true area electrode for each face and bead was calculated. The experimental true area of each electrode was then determined, and Table I shows areas of unscratched electrodes. All areas given in this paper are so-defined true areas.

Two types of electrochemical measurements were performed. The first was the type of potentiostatic measurement previously reported (2) for a bead electrode and gave the steady-state current density *vs.* potential relation for each electrode in H_2-saturated 1M H_2SO_4 under conditions of very rapid stirring with H_2 gas (> 1000 ml H_2/min).

The second type of measurement gave anodic charging curves taken by applying galvanostatic pulses (1.2-2 A/cm^2) after potentiostating the electrodes until steady state was reached. In this case steady state refers to no change in the number of coulombs of charge

[2] The orientation, spark cutting, and x-ray diffraction confirmation of the orientation was done by C. L. Vold, Metallurgy Division, Naval Research Laboratory.

[3] Photomicrographs of the Pt electrodes were made by A. C. Simon, Electrochemistry Branch, Naval Research Laboratory.

Table I. Pt electrode true areas

Electrode	$\mu C/cm^2$	Area,* cm^2
Bead	420	0.54 ± 0.01
Bead, electropolished	420	0.60 ± 0.01
(111), first electropolish	484	0.15 ± 0.01
(111), second electropolish	484	0.125 ± 0.01
(100), first electropolish	420	0.20 ± 0.01
(100), second electropolish	420	0.15 ± 0.01
(110), first electropolish	294	0.048 ± 0.001
(110), second electropolish	294	0.043 ± 0.006

$$* \text{ Area} = \frac{\text{current } (A) \times \mu\text{sec to form one monolayer of } O_{ad}}{(\mu C + 36)/cm^2}$$

required to oxidize sorbed H atoms and/or to saturate the surface with O_{ad}. The steady state obtained in the first type of measurements meant no change in current density with time. The times required in most cases to reach coulombic steady state was shorter than the time required to reach steady-state current densities. However, under conditions of initially high dermasorbed O content followed by a lowering of potential to a value that resulted in a large loss of dermasorbed O, overnight potentiostating was necessary. After steady state was reached, the high-speed switching arrangement previously reported (6) was used to switch from potentiostatic control to a galvanostatic anodic charging pulse. These measurements were carried out under initial electrode conditions of either no dermasorbed O (by first taking the potential to 0V for at least 5 min) or fully charged with dermasorbed O (by first taking the potential to 1.8V for at least 30 min). After the initial treatment, the electrode was potentiostated to a set value.

The determination of the amounts of sorbed H atoms oxidized and O atoms formed during galvanostatic anodic charging was done in the following way. Anodic charging curves applied at the H^+/H_2 equilibrium potential for each electrode were determined at the beginning and end of each set of measurements. The end of the hydrogen region and the length of the linear atomic oxygen adsorption, O_{ad}, region were determined in the standard way (4) by drawing a straight line through the linear O_{ad} region and finding the intercepts with straight lines drawn from the slope of the so-called double layer region (from about 0.5 to 0.9V) and from the linear extrapolation of the O_2 generation region starting at about 1.75V. Dropping a perpendicular line from the intercepts at the beginning and end of the O_{ad} linear region to the anodic charging curve gave potentials that were considered to be the end of the H oxidation region and the end of the O_{ad} formation region, respectively. The voltages determined in this way varied from 0.8 to 0.95V for the end of the H oxidation region and varied from 1.65 to 1.85V for the end of the O_{ad} formation region. The specific voltages for a given run were very reproducible, and the actual values were directly dependent on the actual current densities used in the anodic charging pulse. The voltages determined in this way were used to calculate the number of coulombs, q_H and q_O [after correcting for double layer charging (4)], of sorbed H and O_{ad} formation for each anodic charging curve for each electrode at the various potential settings. This method of determining the H and O regions differs from the procedure used in earlier work (7) where these regions were always determined by intercepts from the linearly extended O_{ad} region. Although the linear extrapolation method is basic in determining the area of the Pt electrodes (4) and is a reliable technique, under anodic potentiostatic control the H associated with the Pt is low at potentials above 0.3V and the linearity of the O_{ad} region decreases. Therefore, the difficulty of determining the length of the O_{ad} regions increases. Although a determination of coverage of O_{ad} is possible by the method used in ref. (7), we feel that the present technique is less subjective and better defines the method of determining surface coverage. Later in the paper data will be given which can be compared with the data given in Fig. 2 of ref. (7). Such a comparison will show fairly good correspondence for the two methods. Although our measurements do not assure an absolute relation of amounts of H and O_{ad} and potential, the values obtained do give a valid comparison of the four different Pt electrodes. The temperature was 25° ± 1°C, and all measurements were made in H_2-saturated (1 atm) 1M H_2SO_4.

Results and Discussion

Area determinations.—Will (1) concluded from his experimental results that the areas (roughness factors) of his Pt single crystal faces increased with increased number of potential sweeps. Recently, Biegler (8) reviewed the problem of area increases on polycrystalline Pt and also concluded from his own work that there are significant increases in electrode area under repetitive, cyclic treatment that involved fast reduction of surface oxide and that smoothening can occur under slow reduction of oxide. Our own experience with Pt electrodes over a period of many years showed that under our experimental conditions no significant changes in electrode areas were found either in the pre-electrolysis treatment or in use of polycrystalline electrodes over long periods of time. Taking into consideration the findings of Will and Biegler, we decided to investigate carefully the problem of surface roughening and to determine if recrystallization or significant changes in surface atom arrangement occurred.

We point out that our electrodes were not subjected to rapid repetitive, cyclic treatment and that the only rapid potential changes experienced by the electrodes were during anodic charging and switching. Figure 1a is a photomicrograph (100X) of the (111) Pt face electrode. This picture was taken immediately after electropolishing and placing the electrode in the Teflon-polyethylene mount. The encircled area shows a typical remnant of the polyethylene film stripped from the surface during electrode mounting. Many other similarly shaded and appearing particles of polyethylene can be observed on the surface. After cleaning the electrodes and placing them in the cell, the equilibrium hydrogen potential was obtained on each electrode before any electrolysis was applied. Upon applying an anodic charging pulse to each electrode, it was observed that the hydrogen regions were very short and indistinct and that the oxygen regions were somewhat rounded. After applying about 10 pulses, the hydrogen region lengthened and the oxygen region became less rounded. Each electrode was then potentiostated to 1.5V for a period of at least 16 hr. After this time the anodic charging curves for each face showed a normally clean linear oxygen region. Significant increases in area were observed over a period of several days. The largest change was experienced in one run with the (110) electrode which underwent a change from 0.0264 to 0.047 cm^2 over a period of one week. After these inital area changes frequent area determinations showed that each electrode experienced no further significant change.

Figure 1b is a photomicrograph (135X) of the same electrode shown in Fig. 1a after that electrode (111) was in the cell for a period of two months. During that time the electrode underwent potentiostatic polarization ranging from −0.04 to 2.1V for eight days and was subjected to potentiostatic control and anodic charging during a period of four more days. Figure 1b shows the complete removal of the bits of polyethylene and further shows no significant change in the Pt surface. The same dendritic areas, pits, terraces, and structure are apparent in both photos.

Our interpretation of the initial area changes and shape of the anodic charging curves is that the polyethylene residue in contact with the electrodes is being

removed primarily by being scrubbed off by the formation of oxygen. Some oxidation of the polyethylene in close contact with the surface may occur. It may take quite a bit of time (possibly as long as a week) to remove the last trace of polyethylene. Once this initial cleaning of the surface occurs, photomicrographic evidence and electrochemical area determinations show that actual roughening or structure changes on the electrode surface do not occur under the conditions of our experiments. Our findings do not mean that roughening could not occur under Biegler's (8) or Will's (1) experimental conditions. However, there is a possibility that Will's polishing of the single crystal faces with alumina powder did result in an incorporation of some alumina in the surface layer. The two hundred or more sweeps required to get a reproducible surface may be related to the removal of some, if not all, of the alumina by a scrubbing action by hydrogen and oxygen.

Hydrogen overvoltage.—Hydrogen overvoltage data are shown in Fig. 2 and 3. The interesting feature of these curves is that there is no significant difference between the bead and (111), (100), and (110) faces. The Tafel b slope is -0.025, and the i_o for the equilibrium hydrogen/hydrogen ion exchange is 1.9 mA/cm^2. The assumed atomic densities of the four electrodes in terms of atoms per square centimeter are: 1.5 x 10^{15} for (111), 1.31 x 10^{15} for (100), 0.92 x 10^{15} for (110), and 1.31 x 10^{15} for the polycrystalline bead. Hence, since the calculated true areas are based on these numbers of Pt atoms per square centimeter, one can conclude that Pt atom density and spacing do not determine the kinetics. It may be argued that diffusion is the rate-controlling process; however the true areas include a roughness factor, and since the geometric area is the important consideration in diffusion, it would be necessary to show that the roughness factor for all the electrodes are essentially the same. The method we used to mount the single crystals left an uneven rim of polyethylene around the edge of the electrode so that accurate determination of the geometric area was difficult. However, several determinations of geometric area by use of a Bausch and Lomb Measuring Magnifier showed differences in roughness factor. For example, for the (110) face the roughness factor after the first electropolishing was 2.1, whereas after the second electropolishing it was 1.4. However, the hydrogen overvoltage results, based on true area, were essentially the same.

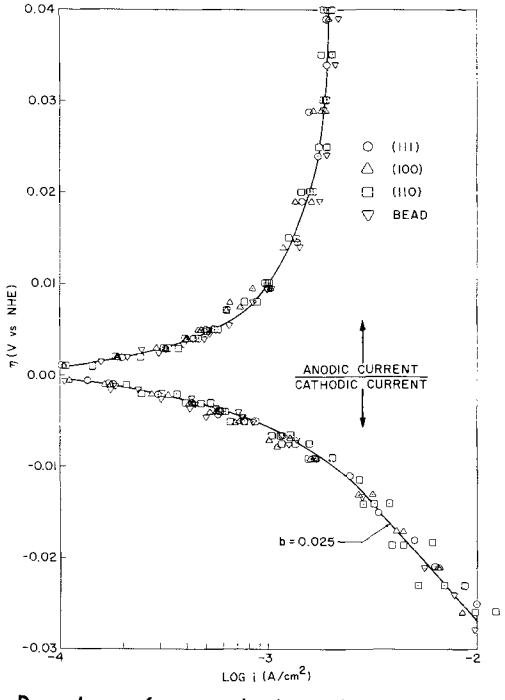

Fig. 2. Dependence of current density on hydrogen overvoltage

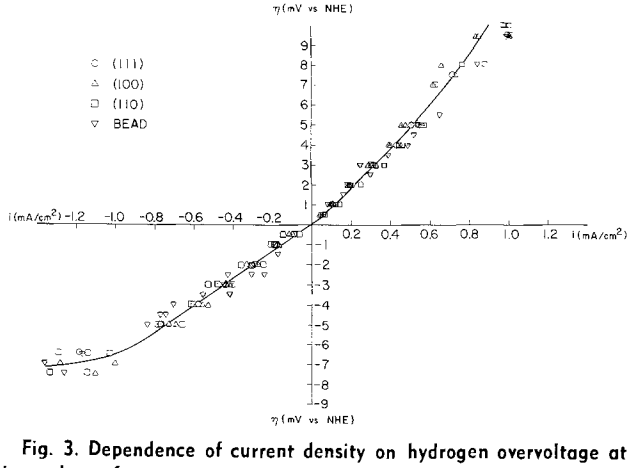

Fig. 3. Dependence of current density on hydrogen overvoltage at low values of η.

The data in Fig. 3 satisfactorily compares with data previously obtained [(9) Fig. 4], however, the Fig. 3 data are on a more expanded potential scale. This expansion clearly illustrates that for $\eta > 0.5$ mV the experimental data points do not fit on an extrapolated linear curve from -6 mV through zero. This deviation shows that the amount of adsorbed H which is in rapid equilibrium with H^+ and H_2 dissolved in solution is very small.

Potentiostatic anodic current density vs. voltage relations.—Figures 4-6 show the potentiostatic anodic current density *vs.* voltage relations for the (111), (100), and (110) faces. Figures 7 and 8 compare the three crystal faces with previous results (2) for a polycrystalline bead electrode for the increasing and decreasing potential sequences, respectively. The former bead electrode results were checked with a new bead electrode, both before and after the same electropolishing used on the single crystal faces. The present results confirmed the previously reported values and further demonstrated that effects due to electropolishing and differences in solution composition were negligible. In addition, Fig. 9 and 10 compare three lightly scratched (by rubbing with soft tissue paper) principle faces and a Pt bead electrode.

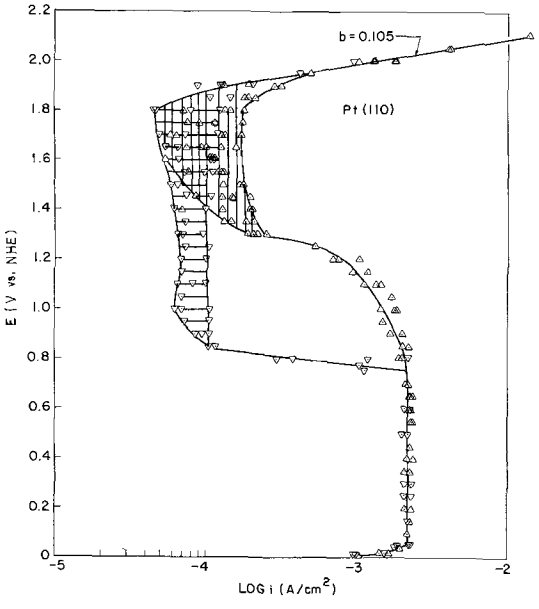

Fig. 6. Potentiostatic dependence of current density on potential for Pt (110): △ increasing potential sequence; ▽ decreasing potential sequence.

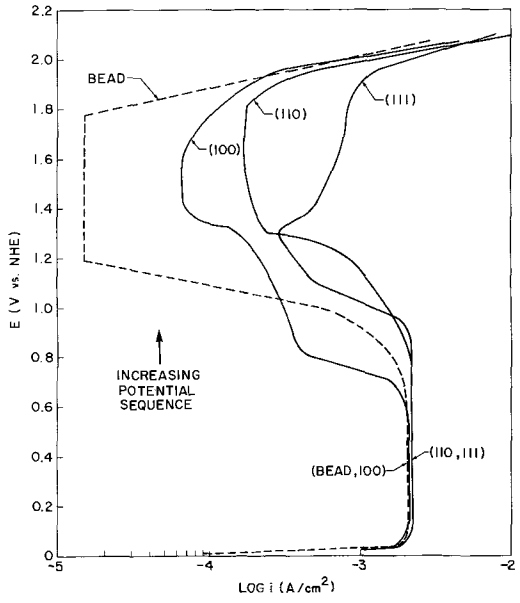

Fig. 7. Comparative potentiostatic relations for increasing potential sequence. Curves are lines shown in Fig. 4-6.

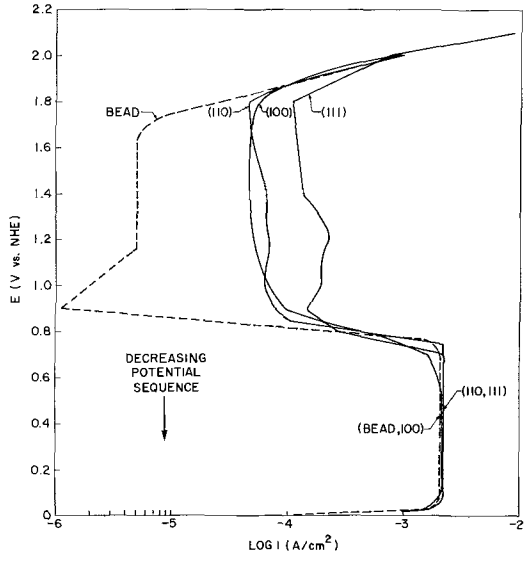

Fig. 8. Comparative potentiostatic relations for decreasing potential sequence. Curves are lines shown in Fig. 4-6.

The data in Fig. 4-10 show that the limiting H_2 oxidation reaction is esssentially independent of crystal orientation. Small differences are noticeable for the bead and the (100) face which had about 10% lower limiting current densities than the (111) and (110) faces (see Fig. 7 and 8). Small differences can also be seen for the lightly scratched faces (Fig. 9 and 10). These differences are just about within the limits of the experimental error (about 10%), and even though these differences were consistent after two electropolishings, they are too uncertain to be considered significant. The fact that the scratched electrodes which would, of course, have higher roughness factors than the smooth electrodes gave virtually the same limiting current densities further demonstrates that the limiting current density is not primarily diffusion-controlled. This conclusion holds because the data in Fig. 4-10 are plotted on the basis of true area (4) which means that if the data were plotted on the basis of geometric area, there would be significant differences between the scratched and unscratched Pt faces.

The really significant differences in the three principle faces and the bead are in the passive (decreased rate of H_2 oxidation) region and the transpassive (oxygen evolution) region. Figure 7 shows that the onset of passivity and the shape of the passive region is very much dependent on the orientation. For example, the potential at which passivity commences increases in the order (100), bead, (110) and (111), whereas for the decreasing potential sequence, Fig. 8, the activation (increased rate of H_2 oxidation) of each electrode has little dependence on orientation. The differences for the scratched electrodes (Fig. 9 and 10) are significantly less.

The differences in behavior shown in the shapes of the passive regions and the Tafel slopes of the oxygen generation region are at the same time remarkable and unexplicable on the basis of Pt atom geometry. Figure 4 shows that for the (111) face at potentials between 1.4 and 1.9V the current density, for both the increasing and decreasing potential sequences, is cyclic (at about 20-min intervals) over one order of magnitude. At and below 1.4V, dermasorbed oxygen

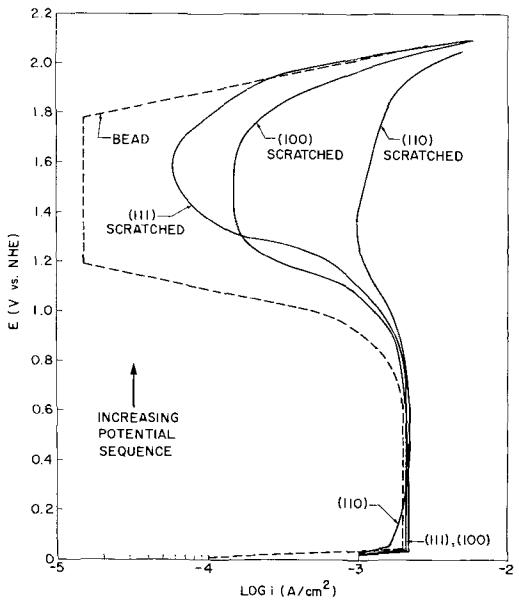

Fig. 9. Comparative potentiostatic relations for scratched single crystals. Increasing potential sequence. Curves represent maximum current densities. Bead electrode is unscratched.

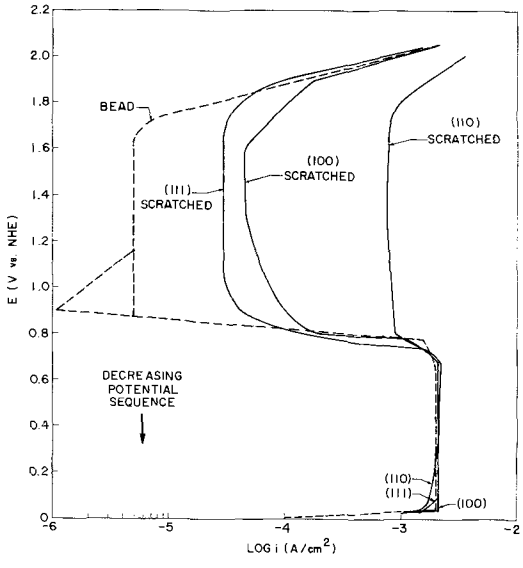

Fig. 10. Comparative potentiostatic relations for scratched single crystals. Decreasing potential sequence. Curves represent minimum current densities. Bead electrode is unscratched.

(decreasing potential sequence data) reduces the rate of hydrogen oxidation until 0.7V where the dermasorbed oxygen is removed. The Tafel slope of the oxygen evolution reaction is 0.180 for the increasing potential sequence and 0.095V for decreasing potentials. The Tafel slope for both the increasing and decreasing potential sequence for the bead was 0.13 (2).

The (100) face, Fig. 5, shows no cyclic behavior at potentials above 1.4V, but the differences in the rates of oxidation between 1.4 to about 1.7V is small. Dermasorbed oxygen appears to only have a significant effect from 1.4 to 0.8V. For this electrode, the O_2 evolution Tafel b value is 0.100 for both the increasing and decreasing potential sequence.

For the (110) face, Fig. 6, there is a great deal of overlap and scatter of points from 1.4 to 1.9V for the increasing and decreasing potential sequence. Below 1.4V the separation due to dermasorbed oxygen is apparent down to 0.75V. The O_2 evolution Tafel b value for both the increasing and decreasing potential sequence is 0.105.

Figures 7 and 8 show that the passivation of the oriented single crystals are all significantly less than that of the bead, but there is no order as far as Pt atom densities are concerned. All that one can say is that the presence of grain boundaries or stress in the beads or differences in impurities in the bead and the single crystals greatly enhance passivation. Figures 9 and 10 for the scratched oriented crystals also show enhanced activity over the bead. In this case the (110) scratched face is the least passivated of all the electrodes investigated. For this electrode the change in activity above 0.7V was small for both the increasing and decreasing potential sequences. In fact, the presence of dermasorbed oxygen (Fig. 10) has only a minor effect on the activity of this electrode.

Another interesting observation that was made during the course of the potentiostatic measurements on the unscratched faces was the potential at which visible oxygen evolution occurred. Each of the faces was mirror bright so that under bright illumination, if gas evolution occurred, the formation of extremely small bubbles would be obvious. On the three oriented faces it was noticed that bubbles of oxygen were not observed unless the electrodes were potentiostated at 1.8V or above. Figures 4 to 8 showed that at potentials from 1.4 to 1.8V, the current densities for each crystal face did not vary greatly, and at potentials down to 0.7V the current densities generally increased. In addition, Fig. 7 shows that at the three faces the current densities varied considerably at, and immediately below, 1.8V. If the net reaction were an electrochemical generation of O_2, the potential at which this reaction occurs should be detected easily, especially since measurements at potentials above 0.7V took anywhere from an hour to hours to reach steady state. The fact that no oxygen bubbles were evident below 1.8V shows that the net reaction below this value was not the formation of O_2.

This conclusion means that there must have been some interaction of molecular hydrogen with whatever current-consuming reaction occurred. The following possibilities are apparent:

$$H_2 \rightarrow 2H^+ + 2e \quad [I]$$

$$2H_2O + Pt \rightarrow 4H^+ + Pt - O_2 + 4e \quad [IIa]$$

$$Pt - O_2 + 2H_2 \rightarrow Pt + 2H_2O \quad [IIb]$$

$$H_2O + Pt \rightarrow 2H^+ + Pt - O + 2e \quad [IIIa]$$

$$Pt - O + H_2 \rightarrow Pt + H_2O \quad [IIIb]$$

$$H_2O + Pt \rightarrow H^+ + Pt - OH + e \quad [IVa]$$

$$2Pt - OH + H_2 \rightarrow 2H_2O + 2Pt \quad [IVb]$$

Other oxygenated species can be visualized also.

The important conclusion that one can derive from the observation that O_2 bubbles are not formed until a potential of 1.8V is reached is that for the oriented single crystals, and as was previously concluded for a heterogenous Pt electrode (2, 7, 10), H_2 in solution reacts with oxygen or oxygenated products of water in the passive region. Only when the rate of oxygen generation (1.8V) exceeds the rate of the interaction of H_2 with the oxygenated species is the net reaction the formation of O_2. This conclusion does not, of course, mean that oxygenated products of water may not exist on the surface of Pt (or O be dermasorbed in Pt) in the passive region below 1.8V, but it does imply that below 1.8V saturation of the surface with oxygenated species of water is infeasible. In addition, support is given to the previously reported conclusion from this laboratory (2, 7, 10) that the cause of the initiation of passivation at 0.7V on a Pt bead is not due to surface coverage with oxygen or an oxygenated product of water, but rather by anion adsorption. As the potential is increased above the value where passivation is initiated, the amount of oxygen or oxygenated products of water is increased, but sulfate ions also play an important role. In summary, the fact that a high voltage of 1.8 is required before visible O_2 evolution occurs is strong evidence that under steady-state conditions, the net accumulation of water oxida-

tion products on the Pt surface is strongly restricted both by the interaction with H_2 and by the presence of sulfate ions.

Relation between potential and amount of associated H atoms.—Figure 11 shows the relationships obtained for the dependence between the amount of hydrogen, q_H, oxidized by a high current density anodic pulse and the potentiostated steady-state potential for all electrodes. Figure 12 compares the four electrodes on a normalized scale, $q_H/q_{H,E=0}$. Since on the normalized scale, the q_H of each electrode is compared to its q_H at the H^+/H_2 equilibrium, the amount of coulombs is related to the number of Pt atoms per square centimeter for each electrode since the ratio q_H/q_O was about the same for all three faces. Thus the atom densities for the three faces and for the bead are normalized, and the curves in Fig. 12 show the fraction of the number of the equilibrium associated H atoms at each potential. On the normalized scale, the differences between the four electrodes are small. Only at potentials of 0.1V and below does there appear to be a significant difference between the (111) and (100) compared to the (110) and bead. However, Fig. 11 shows that on the defined (4) true area scale, there are considerable differences in the amounts of H associated with each electrode. It is interesting that Fig. 11 shows that under steady-state conditions small amounts of hydrogen are associated wtih Pt at potentials above 0.35V.

The dashed line for the bead data in Fig. 11 is the q_H *vs.* E relation for a single anodic charging curve from the H^+/H_2 equilibrium. This dashed curve shows that transient and potentiostatic H content do not have the same dependence on potential. The steady-state amount of H associated with Pt at any potential above 0V is always less than the high current density transient values.

Will (1), using a cyclic voltametric technique, obtained a normalized $q_H/q_{H,E=0}$ separation between the three faces in the order (100) > (111) > (110). Our comparative data (Fig. 12) gives (100) = (111) > (110) = bead.

Relation between potential and amount of O atoms formed by anodic charging.—A series of anodic charging curves typical for any of the electrodes is represented in Fig. 13 by a (100) electrode. Figure 14 gives the q_O *vs.* potential data for all electrodes and Fig. 15 gives the normalized $q_O/q_{O,E=0}$ data for all electrodes. As brought out in the experimental section of this paper, q_O is the number of coulombs per square centimeter of oxygen atoms formed on the electrode surface with a high current density galvanostatic pulse under the given potentiostatic conditions.

All of the open symbols signify that the electrode was taken to open circuit (zero volt) for at least 5 min before the given potential was applied. The closed symbols signify that the electrode was taken to 1.8V for at least 30 min. Thus, for the open symbols, the initial electrode condition was the equilibrium hydrogen electrode free of dermasorbed oxygen, whereas

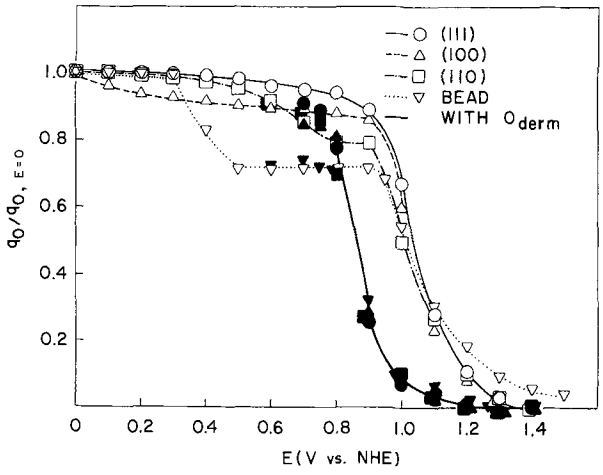

Fig. 15. Normalized ($q_O/q_{O,E=0}$) amounts of O atoms formed on each Pt electrode when an anodic galvanostatic pulse is applied at given steady-state potentials. Open symbols are values for initial potentiostating at 0V. Closed symbols are values for initial potentiostating at 1.8V.

for the closed symbols the initial electrode condition was saturation with dermasorbed oxygen.

The data in Fig. 14 and 15 show that for all of the oriented faces, there is a relatively small decrease in the amount of O atoms required to form a monolayer with the anodic charging pulse from zero to 0.9V. On the other hand, the data for the bead is similar to previously reported data (7) and shows a significant decrease in the required amount of O to form a monolayer at 0.4V, followed by a plateau to 0.9V and then a sharp drop similar to the oriented faces. The hysteresis (closed symbols) is believed to be caused by dermasorbed oxygen. The data in Fig. 14 and 15 show that dermasorbed oxygen is virtually completely removed at a potential of 0.8V. About 16 hr of potentiostating at 0.8V (after saturating the electrode at 1.8V with O) was required before the steady-state q_O was found for all electrodes. This q_O at 0.8V, as were closed symbol values at lower potentials, corresponded to the open symbol, initially dermasorbed O-free cases.

The dashed line for the bead in Fig. 14 shows the linear q_O *vs.* E relation for a single anodic charging curve beginning at the H^+/H_2 equilibrium. The amount of O_{ad} which can be formed by an anodic pulse starting at a given E above 0.5V is always less than the O_{ad} formed under high current density transient conditions starting at zero. The rapid decrease in the deposited quantity of O_{ad} at E above 0.9V supports the conclusion that sulfate ion adsorption does decrease the number of sites available for O_{ad}.

Because under steady-state potentiostatic conditions H_2 will react with oxygen and/or oxygenated water species, the large decreases in the amounts of O required to form a monolayer under galvanostatic charging are believed to be due to anion (sulfate ion) adsorption (2, 7). Further, from kinetic considerations (2), it is felt that anion adsorption not only initiates passivation, but is the major cause of the rapid decrease in the rate of H_2 oxidation up to at least 1.2V. The data in Fig. 7 and 8 correspond sufficiently well with the sharp drop at 0.9V to show a real relation between increased surface coverage and decreased rate of H_2 oxidation. The most pronounced difference in the four electrodes is the comparison of the bead to the three oriented faces. Both the drop in q_O at 0.4V and the much lower minimum current densities shown in Fig. 7 and 8 indicate that such differences as grain boundaries, stress, or differences in impurities in the Pt play an important role both in anion adsorption and passivation. The differences in the three faces are too small to be highly significant, but several trends are apparent. There is a sharper decrease in q_O at potentials in excess of 0.4V for the (110) face (Fig. 15), and at potentials from 0.7 to 0.9V, its behavior is intermediate to the (111), (100), and the bead. The q_O for the (100) face drops significantly at 0.1V but then changes very little until 0.9V.

In summary, differences in behavior of the various orientations are apparent, but they are small and follow no logical sequence, such as atom density or spacing. The really significant differences are those between the oriented single crystal faces and the polycrystalline bead. This difference indicates that factors such as grain boundaries, stress, and possible variations in impurities in the Pt can play an important role in some adsorption phenomena and may influence the catalytic activity of some reactions. Another possible variation may be differences in the potential of zero charge between the bead and single crystal faces.

The open-circuit rate of reaction of a rapidly generated monolayer of Pt-O formed by an anodic galvanostatic charging pulse with H_2 in solution (11) was determined in the hope that single crystals, which would be in an essentially ideally annealed state, would differ significantly from a bead electrode which would contain strains. The rates of the $Pt - O_{ad} + H_2$ reaction for all four electrodes varied from about 1 to 5 mA/cm^2. These differences were random and were independent of orientation or polycrystallinity. Actually, previous work (11) with bead electrodes gave rates which ranged both lower or higher than these values, so that no particular relation between the metallurgical state or single crystal orientation of Pt and the rate of the reaction of $Pt - O + H_2$ was obtained.

Conclusions

Figure 16 shows photomicrographs at magnification of 325X of (111), (100), and (110) faces after prolonged electrochemical measurements. These photomicrographs show no particular metallurgical changes on the electrode surface as compared to those taken before electrochemical treatment (see Fig. 1 also). The present study has shown that there are areas of marked differences in electrochemical behavior of single crystal orientation as compared with a polycrystalline electrode, and that for some reactions (*i.e.*, hydrogen overvoltages below 0.7V) the effects of metallurgical fac-

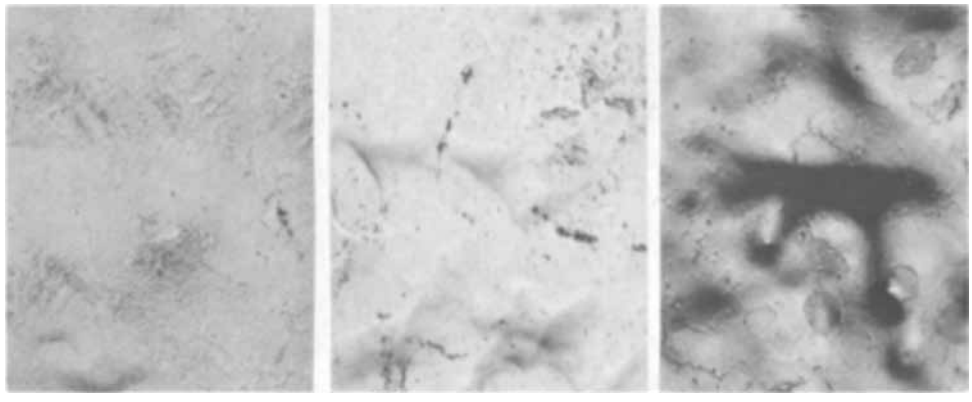

Fig. 16. Photomicrographs of (a) (left) Pt (111), (b) (center) Pt (100), and (c) (right) Pt (110) after electrolysis (325X).

tors are minor. Changes in electrode area or in character of the electrode surfaces were not found. Undoubtedly an improved technique for polishing the electrode to give orientations that approach atomic smoothness would be desirable as would observations of surface atomic arrangement by such techniques as LEED. It is apparent that grain boundaries, stress, and impurity inclusions in the electrode may be of much more importance in determining catalytic activity for some reactions than is the actual atomic density or geometry of platinum.

Surface defects on oriented single crystals caused by scratching had marked effects on the passivation of Pt electrodes for hydrogen oxidation starting at about 0.7V. Comparisons with a polycrystalline bead showed large differences which were most likely caused by grain boundaries, stress, and possibly metallic impurities. It is believed that the passivity behavior is due to anion (sulfate ion) adsorption and that the various defects somehow influence this factor.

The primary conclusion that this investigation has led to is that there is no simple correlation between atomic geometry and electrode behavior. Investigations of other more complex electrochemical reactions and better definition and control of metallurgical factors are required before generalizations concerning atomic geometry should be made.

Electrochemical Oxidation of Guanine at the Pyrolytic Graphite Electrode

Glenn Dryhurst and Gerald F. Pace[1]

Department of Chemistry, The University of Oklahoma, Norman, Oklahoma 73069

ABSTRACT

The electrochemical oxidation of guanine at the pyrolytic graphite electrode was investigated by linear and cyclic scan voltammetry between pH 0-12.5 and by controlled electrode potential electrolysis in aqueous 1M acetic acid solution. Guanine is oxidized by an initial $2e/2H^+$ potential determining attack at the —N(7) = C(8)— double bond followed by a further $2e/2H^+$ oxidation of the —C(4) = C(5)— double bond to give 2-amino-6,8-dioxypurine-4,5-diol which, being unstable, undergoes further reaction by two routes: (*a*) further electrochemical oxidation to parabanic acid, guanidine, and carbon dioxide; and (*b*) hydrolysis to oxalyl guanidine and carbon dioxide. The exact nature of intermediate species in the electro-oxidation of guanine and uric acid were more thoroughly established by extensive use of fast sweep cyclic voltammetry. In particular it appears that in ammonia buffers at moderately high pH, the intermediate is a 4,5-diamine rather than a 4,5-diol.

Guanine (2-amino-6-oxypurine) is one of the two principal purines found in nucleic acids and as such is involved in many biological processes. Previous work has indicated a similarity between the heterogeneous electrochemical and enzymatic oxidation of naturally occurring purines such as adenine or uric acid (1, 2), although this parallelism does not appear to extend to purines with exocyclic sulfur atoms (3, 4). Nevertheless, the observed electrochemistry of these latter compounds might aid in interpreting the very incompletely understood biological oxidation. Fast scan cyclic voltammetry of several nonsulfur-containing purines has indicated that a general mechanism might be operative involving formation of a common ultimate primary electrochemical product which has been postulated to be a dicarbonium ion or a 4,5-diol (5). However, recent results on some methylated xanthines (6) which will be published shortly indicates that if the N-7 position is methylated, then no intermediate comparable to those observed for other purines can be detected or is much smaller than for other compounds. Faradaic n values also support this idea. In view of these latter findings and the importance of guanine in biological systems, it was felt that the electrochemical oxidation mechanism for this compound should be elucidated in detail rather than arbitrarily assuming that its oxidation proceeded by a route essentially identical to uric acid. A further reason for studying guanine was that if parabanic acid was an electrochemical product, then as a result of the effective labeling of the pyrimidine ring by the 2-amino group, it should be possible to assign correctly the ring origin of this acid which was not possible with adenine and uric acid.

Many of the biological and chemical reactions of purines are presented in the reviews of Lister (7) and Robins (8). Little, however, appears to be known of the mechanism of biological oxidation of guanine. Generally, biological oxidation processes are characterized only in terms of the major or most easily detected products. In many animals guanine is converted

[1] Present address: Continental Oil Company, Ponca City, Oklahoma.

Key words: guanine, electro-oxidation, 2-amino-6-oxypurine, bioelectrochemistry, pyrolytic graphite.

to uric acid and allantoin (9) although in xanthinuric man, guanine ingested as yeast RNA or as 3′-guanylic acid appears to be converted primarily to xanthine (10). Guanine is oxidized only slowly in the presence of very large excesses of xanthine oxidase to uric acid. Wyngaarden (11) has suggested that this process might be brought about by traces of guanase present in the xanthine oxidase. In rat liver, guanine is converted to hypoxanthine (12). Photodynamic inactivation of DNA on irradiation with visible light in the presence of the dye lumichrome is due to breakdown of guanine (13). Using tracer techniques, the photodynamic degradation of guanine involved formation primarily of guanidine and parabanic acid. Urea has also been detected as a photo-oxidation product (14). Chemical oxidation of guanine by MnO_2 in aqueous suspension at 100° gave guanidine and urea (15).

The study reported here of the electrochemical oxidation of guanine at controlled electrode potential at the pyrolytic graphite electrode (PGE) indicates a mechanism whereby guanine is oxidized in a primary 4e process to give an unstable compound which has been characterized as 2-amino-6, 8-dioxypurine-4, 5-diol or -4, 5-diamine in ammonia containing backgrounds [equivalent to the dicarbonium ion intermediate postulated for uric acid and adenine (1)]. The subsequent chemical or electrochemical reactions of this primary product decides the final nature of the over-all reaction. Again, it appears as if the initial sites of electrochemical and biological oxidation are similar, but the normal biological deamination reaction at C-2 does not occur under electrochemical conditions.

Experimental

Chemicals.—Chemicals were obtained from the sources listed; guanine (Nutritional Biochemicals); parabanic acid, guanidine sulfate, 4-chloro-meta cresol (Eastman); guanidine hydrochloride (Matheson); 2, 3-butanedione monoxime (Fisher). Buffer solutions were prepared from reagent grade chemicals.

Argon (Linde) used for deoxygenating purposes was equilibrated with water; no other purification was necessary.

Apparatus.—Polarograms and voltammograms were recorded on a Sargent Model XVI Polarograph using a water-jacketed three-compartment cell maintained at 25° ± 0.1°C and containing a saturated calomel reference electrode (SCE) and a platinum gauze counterelectrode in saturated potassium chloride solution. All potentials are referred to the SCE at 25°C. The dropping mercury electrode had normal m and t values. The preparation of the various pyrolytic graphite electrodes was described earlier (1). Apparatus for cyclic voltammetry, controlled potential electrolysis, coulometry, and lyophylization are described elsewhere (3, 5). Ultraviolet absorption spectra were recorded on a Perkin Elmer-Hitachi Model 124 Spectrophotometer; infrared spectra were recorded on a Beckman IR8 spectrophotometer.

Voltammetric procedure.—Because of the low solubility of guanine, saturated solutions in appropriate buffers were prepared, the excess of guanine removed by filtration, and the concentration computed by measurement of the u.v. absorbance. A portion of these solutions was then placed in the polarographic cell and deaerated with argon for about 10 min. Once in position, the 4 mm diameter PGE was allowed to stand for about 30 sec without applied potential; the starting potential was then applied for 5 sec (usually 0.00V) and the voltammetric scan commenced.

The PGE was resurfaced before every run by polishing on a 600 grade silicon carbide paper disk mounted on a motor driven rotating disk. The electrode was washed thoroughly with a jet of distilled water; the surface was then very gently touched onto a clean paper tissue to remove excess of water.

Coulometry.—A measured volume of background solution was electrolyzed at the appropriate potential in the working electrode compartment until the titration coulometer (16) gave a small constant titration rate. Then, between 0.1 to 0.2 mmole of guanine was introduced. The electrolysis was then continued until all of the suspended guanine had disappeared and the current had decayed to the background level. Completion of the electrolysis was always confirmed by the disappearance of the characteristic guanine u.v. absorption peak.

Macroscale electrolysis.—The same apparatus was used for macroscale electrolysis as for coulometry except that between 1 and 2 mmoles of guanine was suspended in 200 ml of 1*M* HOAc. Electrolysis was continued until no suspended guanine remained and the characteristic u.v. absorption of guanine had disappeared. At completion of the electrolysis, the solution in the working electrode compartment was shell frozen onto the walls of a 1 liter flask and lyophilized which resulted in a white fluffy powder.

Thin layer chromatography.—With the exception of urea, which was spotted as a solution (1 mg/ml), all reference compounds and the lyophilized electrolysis product were applied to thin layer sheets as very small crystals and were dissolved by repeated addition of water. Two different solvent systems were employed, n-butanol, acetic acid, water (120-30-50) and n-propanol, water (70-30). Two thin layer supports were employed, silica gel with fluorescent indicator (Eastman Chromogram 6060) and alumina (Eastman Chromogram 6062).

Parabanic acid was identified as a major product as a spot on the fluorescing silica gel plate having an r_f value in butanol, acetic acid, water solvent of 0.83, and 0.70 in propanol, water both being identical with authentic parabanic acid.

Urea was detected as a very minor product using butanol, acetic acid, water as solvent, and the silica gel adsorbent with Ehrlich's reagent ($r_f = 0.68$). Allantoin was not detected under the same conditions.

Ammonia was tested for on silica gel in the same solvent with Nessler's reagent but was not detected.

Guanidine was identified in the product on an alumina plate using propanol, water as solvent with sodium nitroprusside reagent (17) (r_f of 0.43), and on silica gel in butanol, acetic acid, water with the same reagent ($r_f = 0.63$).

Ion exchange isolation and identification of guanidine.—Thin layer chromatography indicated that guanidine was a product of electro-oxidation. Since all other products or potential products except urea, which was only a very minor product, were acidic or could be hydrolyzed to salts in strong base, isolation of guanidine was attempted.

One hundred milligrams of lyophylized electrolysis product was dissolved in 30 ml water and passed through a Dowex X-8 ion exchange column (hydroxide form) and washed with 150 ml water. The effluent was neutralized with hydrochloric acid and lyophylized. The infrared spectrum of the product was essentially identical to authentic guanidine hydrochloride.

Ion exchange isolation and identification of parabanic acid.—One hundred milligrams of lyophylized electrolysis product was dissolved in 30 ml water and passed through a column of Dowex 50W-X8 ion exchange resin (strongly acid form) and washed with 150 ml of water. The product was lyophylized. The infrared spectrum of the product was essentially identical to that of authentic parabanic acid.

Parabanic acid was further confirmed by the polarographic behavior of the product in 1M acetic acid ($E_{1/2} = -0.68$V) and ammonia buffer pH 9 ($E_{1/2} = -1.06$V) and from the fact that in the latter solution it rapidly decomposed to oxaluric acid ($E_{1/2} = -1.60$V) (18).

Determination of parabanic acid.—At completion of the electrolysis, parabanic acid was determined by transferring about 20 ml of the electrolysis solution to

a polarographic cell, and after deaeration a polarogram was run between 0 and −1.4V. The height of the wave at *ca.* −0.7V was compared with a calibration curve prepared from authentic parabanic acid.

Determination of guanidine and guanidyl residues.—Guinidine or guanidyl residue was determined by modification of the procedure described by Staron *et al.* (19). In our hands the sensitivity of this procedure was about five to ten times lower than claimed. In order to overcome this low sensitivity, the solution produced on electrolysis of 0.1-0.2 mmole guanine was lyophylized and the resulting solid product dissolved in 10.0 ml water. To 2.0 ml of this latter solution was added 2.0 ml of a 10% solution of 4-chloro-meta cresol in 95% ethanol. After agitating, 2.0 ml of *N* sodium hydroxide was added followed by 1.0 ml of freshly prepared sodium hypobromite solution (1 ml Br_2 in 99 ml *N* NaOH). The absorbance of the yellow color which developed was measured at 440 mμ in a 1.0 cm stoppered quartz cell. Calibration curves were prepared with guanidine sulfate solutions which contained between 0.2 and 2 mg guanidine in the initial 2.0 ml aliquot of solution.

Determination of oxalyl guanidine.—Oxalyl guanidine, allantoin, or any other similar species capable of being quantitatively hydrolyzed to glyoxylic acid by sequential base then acid hydrolysis responds quantitatively to the method of Young and Conway (20). The experimental procedure is described elsewhere (1) except that under the present conditions, a 3.0 ml aliquot of the electrolysis solution diluted to 5.0 ml with 1*M* HOAc was employed.

Results and Discussion

Voltammetry.—Guanine shows a single well-formed anodic voltammetric peak at the stationary PGE between *p*H 0 and 12.5. Above *p*H 11 there was some indication of a small second wave close to background discharge. Because these latter waves appeared only occasionally at very high *p*H, they were not examined further. The peak potential, E_p, for the main guanine wave shifts linearly more negative with increasing *p*H

$$E_p = 1.115 - 0.065\ pH$$

at 3.33 mV sec^{-1} scan rate. The shift of peak potential of 65 mV per *p*H unit is in fairly close agreement with that expected for a process where the rate-controlling step involves an identical number of protons and electrons. Considering the guanine peak observed over the whole *p*H range study, an average current density of 3.72 μA · $mmole^{-1}$ mm^{-1} was obtained. However, between *p*H 2.3-10 guanine is rather insoluble so that the data in these regions corresponds to that observed for essentially saturated solutions, and in these regions the current density was much more variable, no doubt reflecting contributions of adsorbed guanine to the total current. Below *p*H 2 where guanine is somewhat more soluble and solutions well below the saturation limit were employed, the mean current density was 2.72 μA · $mmole^{-1}$ mm^{-2}. This latter figure is in good agreement with that expected for involvement of 4e per guanine molecule. In 2*M* H_2SO_4 guanine shows linear ip-C curves between 0.005-1.0 m*M* which indicates that the electrochemical reactions are probably diffusion controlled.

Coulometry.—At *p*H 2.3, coulometry at a potential corresponding to the crest of the guanine oxidation peak gave faradaic *n* values ranging from 4.2 to 4.7e. At completion of the electrolysis, the characteristic u.v. absorption spectra of guanine (λ max = 275 mμ) had disappeared.

Preparative electrolysis.—Exhaustive electrolysis of guanine at fixed anodic potential allowed the preparation of sufficiently large amounts of products to permit their isolation, identification, characterization, and quantitative determination. Several isolation and detection approaches were employed including lyophylization (freeze drying), ion exchange, thin layer chromatography, polarography, u.v. and *IR* spectrophotometry, and other physical measurements. These revealed the presence of guanidine and parabanic acid as major products along with a slight trace of urea. Neither allantoin nor ammonia was detected. A species was detected, however, which when subjected to a sequential base then acid hydrolysis gave rise to glyoxylic acid; the latter compound is readily detected and quantitatively determined by formation of its condensation product with phenylhydrazine which is oxidized by ferricyanide to the characteristic red chromophore (20).

Quantitative analysis (typical) of a solution after complete electrolysis of 0.22 mmole of guanine in 200 ml of 1M HoAc revealed that 1 mole of guanine yielded 0.35 mole parabanic acid (polarography), 0.90 mole of guanidyl residue [procedure of Staron *et al.* (19)] and 0.55 mole of a species which could be hydrolyzed to glyoxylic acid [Young and Conway procedure (20)]. It was noted that the value of the measured *n* value in excess of 4.0 was numerically twice the moles of parabanic acid produced per mole of guanine.

Cyclic voltammetry.—The involvement of about 4e per molecule of guanine in the oxidation suggested a mechanism similar to that observed for adenine (1), *i.e.*, initial oxidation at C-8 followed by further oxidation of the C(4)-C(5) double bond. In order to gain more detail into these processes, cyclic voltammetry, at fast scan rates, was employed.

Scanning from 0.0V at a clean electrode toward positive potential only a single anodic peak (peak I_a) is observed for guanine. Once having scanned this peak and then sweeping toward negative potential, however, at least two cathodic peaks are observed. The first (peak I_c) always occurs at potentials more positive than zero, the second (peak II_c) occurs at much more negative potential. On the second sweep toward positive potential a new anodic peak (peak II_a) appears before the peak I_a and forms an almost reversible couple with peak I_c.

Figure 1A shows a voltammogram for these first and second cycles. In order to detect peaks I_c and II_a, it is necessary to employ high sweep rates, *i.e.*, > 300 mV sec^{-1} (5), indicating that the product of the main oxidation peak I_a is very unstable. Earlier reports of the electro-oxidation of uric acid (2) and adenine (1) postulated that the primary electrochemi-

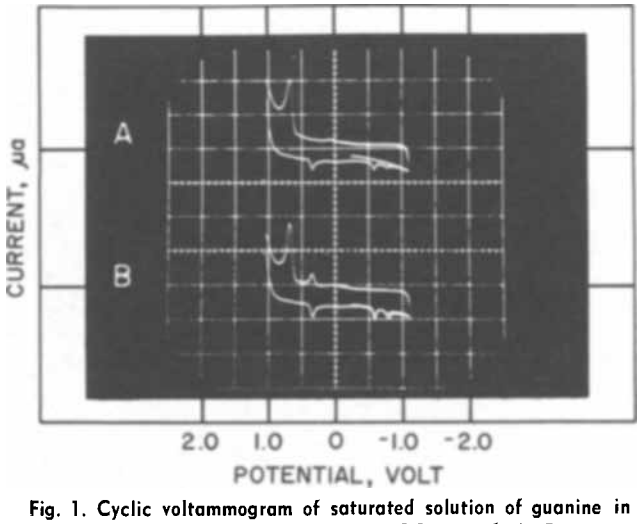

Fig. 1. Cyclic voltammogram of saturated solution of guanine in MacIlvaine buffer *p*H 6 at PGE. Scan rate 8.8 $Vsec^{-1}$. A, First scan at a clean electrode, sweep started at 0.0V and run toward negative potential; scan pattern, 0.0V → −1.1V → +1.05 → −1.1V. B, Second scan. Scan pattern: 0.0V → −1.1V → +1.05V → 0.0V. Calibration marks on current axis indicate zero current for the appropriate voltammogram. Current above the calibration mark is anodic (—). Current sensitivity 200 μA per div.

cal product was a dicarbonium ion formed by removal of two π electrons from the —C(4) = C(5)—double bond. However, since the peak potential for uric acid oxidation was shown to be *p*H dependent, although only two *p*H values were examined (2), and involved direct attack at the 4,5 position unlike adenine and guanine which must involve attack elsewhere in the molecule before the 4,5 bond is oxidized (*vide infra*), then protons must be involved in the energy (*i.e.*, potential) controlling process. This led to the suggestion that the intermediate in uric acid oxidation was in fact 2,6,8-trioxypurine-4,5-diol (5). We have confirmed that uric acid is oxidized in a *p*H dependent process and that the cathodic peak due to reduction of the unstable 4,5-diol is also *p*H dependent. At a scan rate of 8.8 $Vsec^{-1}$ the primary uric acid oxidation peak followed the relation

$$(E_p) = 0.83 - 0.071\ pH$$

between *p*H 1 and 12.5. The reversible cathodic peak followed the relation

$$(E_p)_{red} = 0.68 - 0.061\ pH$$

although it was only observed distinctly between *p*H 1 and 8.

All of the peaks observed for guanine are *p*H dependent at 8.8 $Vsec^{-1}$ being described by the relations: $E_p = 1.20\text{-}0.077\ pH$ for peak I_a; $E_p = 0.72\text{-}0.059\ pH$ for peak I_c; $E_p = -0.54\text{-}0.026\ pH$ for peak II_c, and $E_p = 0.9\text{-}0.077\ pH$ for peak II_a. A peak of similar appearance and *p*H dependence to peak II_a was also observed for uric acid. Actually one or occasionally two additional cathodic peaks were also observed at many *p*H values. These usually occurred at more positive potential than peak II_c except occasionally at high *p*H. An example is shown in Fig. 1B where a clear peak at −0.6V is observed before peak II_c at −0.75V. These additional peaks were most clearly observed at *p*H 2.3 (acetate), 3.0 (MacIlvaine), 4.0 (MacIlvaine), 4.9 (MacIlvaine), and 6.0 (MacIlvaine).

In ammonia background *p*H 9.1 the cyclic voltammetry of guanine was considerably different to that observed at all lower and higher *p*H values (Fig. 2). Thus, after scanning peak I_a the primary oxidation peak, a peak corresponding to peak I_c at positive potential did not appear (from the *p*H dependence of peak I_c it should have occurred at +0.19V). Instead, a new peak at −0.55V appeared followed by three more negative peaks one of which corresponded to peak II_c. Then on the second anodic sweep a new anodic peak at −0.52V appeared forming a reversible couple with the cathodic peak at −0.55V. In addition, however, a peak corresponding to peak II_a also appeared (E_p = 0.13V)

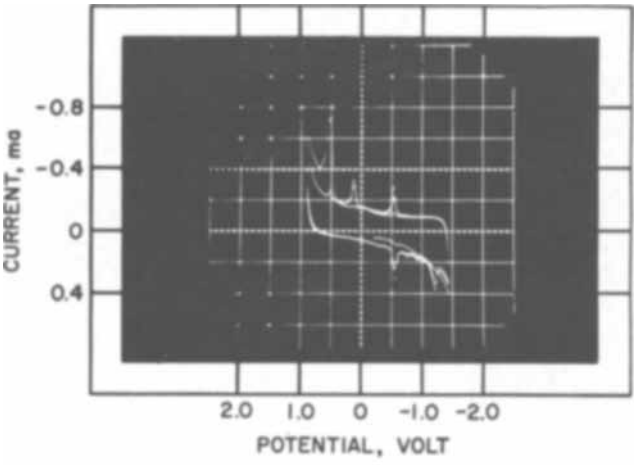

Fig. 2. Cyclic voltammogram of a saturated solution of guanine in ammonia-ammonium chloride buffer *p*H 9.1 at PGE. Scan rate 10 $Vsec^{-1}$. First scan started at 0.0V and swept toward negative potential.

although under no conditions did the reversible $II_a - I_c$ couple appear. Uric acid showed similar behavior, namely after scanning the primary oxidation peak; no reversible cathodic peak was observed but a new reversible couple at $(E_p)_{cathodic} = -0.55V$ and $(E_p)_{anodic} = -0.52V$ appeared.

Mechanism

The characteristic uv absorption spectrum of guanine (λ_{max} = 275 mμ in 1M HOAc) is due to the —C(4) = C(5) — C(6) = 0 chromophore (21, 22). In view of the disappearance of this spectrum and consideration of the adenine and uric acid mechanisms it is likely that the —C(4) = C(5)—double bond is oxidized.

Removal of 4e from guanine along with the observed *p*H dependence of the anodic peak suggests that the process proceeds by two sequential two-electron, two-proton oxidations. Enzymes such as xanthine oxidase, always preferentially attack an —N=CH— double bond. In guanine only the —N(7)=C(8)H— bond of this type is available. Theoretical calculation of the nucleophilic localization energy of this same bond predicts that it will be preferentially oxidized (23). Accordingly it appears that the —N(7)=C(8)— bond is that which would be initially attacked electrochemically. It is observed experimentally (1-5, 24) and predicted theoretically, from the energies of the highest occupied molecular orbitals (23), that the ease of electron removal from purines increases with the number of ring substituted oxygen groups in the molecule. Accordingly, once the initial potential controlling oxidation at —N(7)=C(8)— has occurred, further oxidation should take place; since the u.v. spectrum of guanine is lost, it must take place at the —C(4)=C(5)— double bond.

Fast sweep cyclic voltammetry clearly allows observation of the reduction of the unstable product (peak I_c) of the primary electrochemical reaction (peak I_a) and re-oxidation in turn of the product (peak II_a) of this secondary reduction at a less positive potential than required for the initial oxidation of guanine. These latter redox processes are essentially reversible and are *p*H dependent to an extent indicative of the involvement of an identical number of protons and electrons. The reversible couple occurs at potentials very similar to those observed for the uric acid oxidation-reduction couple. Accordingly, the electrochemistry of the cyclic voltammetry of guanine (I, Fig. 3) can be interpreted as an initial two-electron, two-proton rate-determining oxidation to 2-amino-6,8-dioxypurine (II, Fig. 3) followed by a further rapid two-electron, two-proton oxidation to 2-amino-6,8-dioxypurine-4,5-diol (some of which is even further electrochemically oxidized to parabanic acid and guanidine III) (Fig. 3) which corresponds to peak I_a. Provided a fast enough sweep rate is employed, reduction of III to II can be observed and corresponds to peak I_c, and on the next anodic sweep, peak II_a is observed which corresponds to oxidation of II back to III.

The cathodic peak (peak II_c) observed for both guanine and uric acid is probably due to reduction of a product of partial further oxidation of III, namely, parabanic acid (V, Fig. 3) (25). Authentic parabanic acid shows a similar *p*H dependence to peak II_c although the peak potential for its reduction generally occurred at somewhat more negative potential. A possible explanation of this effect is that the parabanic acid produced by breakdown of intermediate III (Fig. 3) is situated very close to the electrode surface and is reduced under *p*H conditions which are quite appreciably lower than those extant in the bulk solution owing to the liberation of protons as a result of reaction I → II, the result being therefore a shift in the peak to more positive potential. The peak observed at more negative potential than II_c at high *p*H is no doubt due to oxaluric acid which is known to the hydrolysis product of parabanic acid at high *p*H and

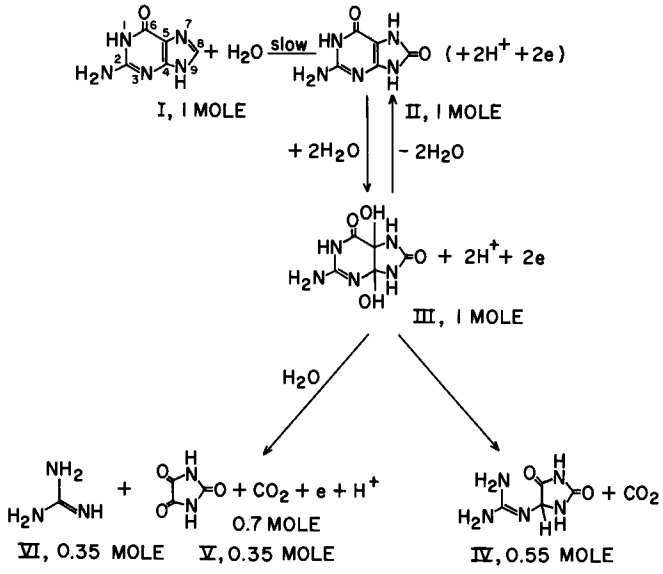

Fig. 3. Proposed pathways for electrochemical oxidation of guanine in moderately acidic solution. The molar quantities refer to the amount involved per mole of guanine. Compounds listed are as follows: I, guanine; II, 2-amino-6,8-dioxypurine; III, 2-amino-6,8-dioxypurine-4,5-diol; IV, oxalyl guanidine; V, parabanic acid; VI, guanidine.

which is electrochemically reducible at more negative potential (26).

The nature of the processes giving rise to other cathodic peaks at various *p*H values is difficult to assign. It is possible that intermediates such as the so called "Behrend Compound" postulated for uric acid oxidation (2) might exist at certain *p*H values and be electroactive. However, saturated solutions of guanine were employed at most *p*H values for cyclic voltammetry; the presence of adsorption or capacitive peaks is also likely. The reversible redox couple observed for guanine and uric acid in ammonia buffer at *p*H 9 is not observed at any other *p*H in the absence of ammonia and hence must be specifically associated with this latter species. The likely explanation of the effect is shown in Fig. 4, namely, that the primary potential controlling step is identical to that at other *p*H values, *i.e.*, two-electron, two-proton oxidation of the —N(7)=C(8)—bond to give 2-amino-6,8-dioxypurine (II, Fig. 4). However, in the presence of ammonia two-electron, two-proton oxidation results in formation of 2-amino-6,8-dioxypurine-4,5-diamine (III, Fig. 4). It would then seem that it is this latter species

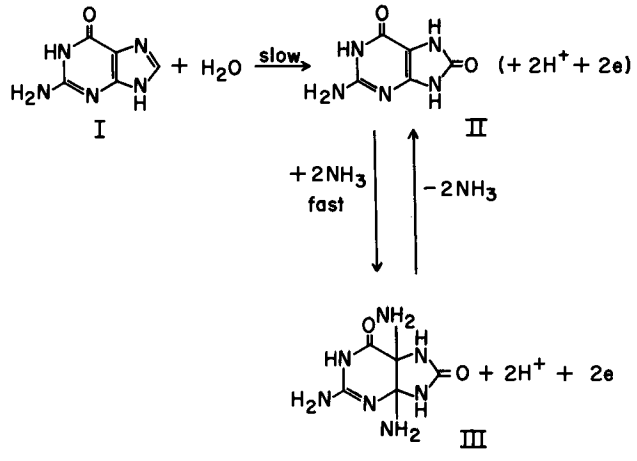

Fig. 4. Proposed primary electrochemical pathways for electrochemical oxidation of guanine in ammonia buffer *p*H 9.1. Compounds listed are as follows: I, guanine; II, 2-amino-6,8-dioxypurine; III, 2-amino-6,8-dioxypurine-4,5-diamine.

which forms the reversible redox couple at *ca.* —0.5V. The explanation of the anodic peak at 0.15V, which is the potential expected for the normal peak II_a is difficult to decide. A possible cause is decomposition of the 4,5-diamine (III, Fig. 4) to an electroactive species capable of being oxidized in this potential region. The most negative cathodic peak ($E_p = -1.4$V) most probably is due to oxaluric acid. In moderately acid solution, it is clear that the primary 4,5-diol product (the most usual product) is unstable and under conditions of constant potential oxidation decomposes by two routes, the first by further electro-oxidation to parabanic acid, guanidine, and carbon dioxide. Solution analysis supports this view since the faradaic n value and parabanic acid produced are in agreement with theory, *i.e.*, 0.35 mole parabanic acid per mole of guanine with an n value of 4.7e. In addition, the total guanidyl residue found per mole of initial guanine accounts for 0.9 mole, while oxalyl guanidine (IV, Fig. 3) determined by hydrolysis to glyoxylic acid accounts for only 0.55 mole, which therefore by difference indicates that 0.35 mole of free guanidine (VI, Fig. 3) is produced. This latter figure is in accord with the 0.35 mole of parabanic acid detected. These data further support the view that the parabanic acid is derived exclusively from the imidazole ring of guanine.

The material balance achieved accounts for only 90% of the initial guanine. No doubt additional hydrolysis of the above products accounts for the remaining 10%.

Conclusions

Guanine is electrochemically oxidized by a mechanism very similar to that observed for other naturally occurring purines such as uric acid and adenine. The evidence put forward supports the view that the locus of initial electron removal is the same for enzymic and electrochemical processes and is in accord with theoretical molecular orbital predictions. Unlike most enzyme reactions where the 2-amino group of guanine is removed, this group remains intact under electrochemical conditions, and further electrochemical reaction is centered at the —C(4)=C(5)—bond.

It is particularly striking that the photodynamic degradation of guanine and indeed DNA appears to be identical to the electrochemical degradation.

Technical Notes

Effect of Sb_2O_3 on the Microstructure of the PbO_2 Electrode

A. C. Simon* and S. M. Caulder*[1]

Naval Research Laboratory, Washington, D. C. 20390

and E. J. Ritchie*

Eagle-Picher Industries, Incorporated, Joplin, Missouri 64801

Unusual properties have been attributed to battery plates which contain lead-antimony grids. The supposition is that antimony dissolves from the grid and then reacts in some manner with the active material.

In a comparison of lead-calcium *vs.* lead-antimony grids (1), it was reported that the presence of antimony increased the amount of α-PbO_2 during formation, helped to retain the active material and capacity during cycle tests, and modified the crystal structure of the PbO_2. Electron micrographs indicated that, in plates containing antimony in the grid metal, the PbO_2 material was in the form of complex clusters of prismatic crystals. In plates containing lead-calcium grids, however, the PbO_2 particles were nondescript globules. It was suggested that the prismatic morphology was required to maintain a firm texture in the active material of the $PbO_2/PbSO_4$ electrode. It has also been suggested (2) that antimony may act as an inhibitor of PbO_2 crystal growth, the assumption here being that increasing growth size decreased surface area and structural strength of the active material.

In the present investigation another phenomenon has been noted which is directly attributable to the antimony oxide and which offers a clue for attaining greater strength in the active material without the necessity of using lead-antimony grid alloys. A number of cells were prepared in which various oxides or oxide blends had been used in the preparation of the plates. Duplicate cells were prepared from each of these paste compositions, one with plates containing grids of lead and the other containing grids of lead-antimony. Optical microscopy was used to determine the microstructure of the cured plates, formed plates, and plates that had received a number of cycles.

Key words: antimony trioxide, Sb_2O_3, microscopy, lead dioxide electrode.

In the preparation of the plates for microscopic examination, use was made of a polyester resin for impregnation. After this hardened, the plates were cut and the cross section was polished.

Usually, such polished sections, particularly of cured plates, are quite stable. It was noticed, however, that in samples taken from two of the cured plates, the polished surface had been etched by the atmosphere, after a considerable time on the shelf. The remainder of the cured plate sections were then reexamined and none was found with a similar etch pattern.

The etch pattern was quite distinct and suggested that long, needlelike crystals had been present in the polished surface that were completely invisible until the etching took place (Fig. 1). When polarized light was used to examine the specimen at the same location, it was found that crystals were present at the areas where an etch pattern was seen. These crystals were colorless, transparent, and indistinct and blended into the surrounding material, so that their outline was blurred (Fig. 2). Nevertheless, they could be seen sufficiently well to determine that they usually coincided with the etched portions of the surface and that they were actually acicular rather than cross sections through tabular crystals.

Because they had given no indication of their presence in the polished surface when examined by vertical illumination (unpolarized light) before the etching had occurred, these crystals had been completely overlooked in the original examination. This invisibility in the polished section also indicated that the crystals consisted of material different from the usual constituents found in the uncured plate which indicate their presence by differences either in reflectivity or in the amount of relief polishing.

The acicular crystals, showing atmospheric etching, were found only in cured plates to which 0.10% of

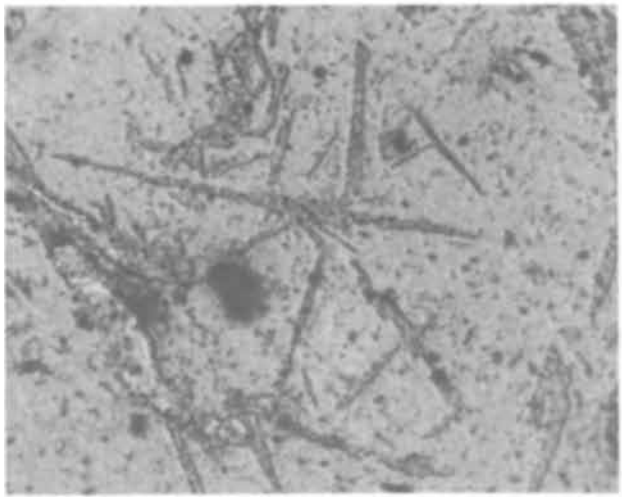

Fig. 1. Distinct etch pattern suggesting the presence of long, needlelike crystals.

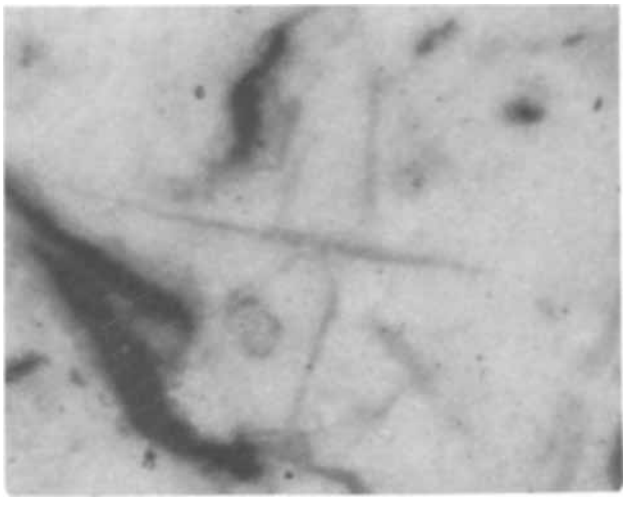

Fig. 2. Colorless, transparent, indistinct crystals found at areas where an etch pattern was seen.

Sb_2O_3 had been intentionally added to the paste during mixing. Two batches had contained this added Sb_2O_3 and both were otherwise identical except for a difference in the paste density. In the one case this was 64 g/in.^{3} and in the other, 69 g/in.^{3}. Both of these formulations had been pasted on lead grids, and both showed similar crystals and surface etching.

The same paste formulation, without the added Sb_2O_3, did not show any indication of such crystals as have been described, even when pasted on lead-antimony alloy grids. All indications were that this crystal type appeared only when Sb_2O_3 was a constituent of the paste mix.

The most interesting point, however, was that needles with very similar acicular shapes were also found in the formed plate (Fig. 3). These were composed of PbO_2 and were easily seen in the polished

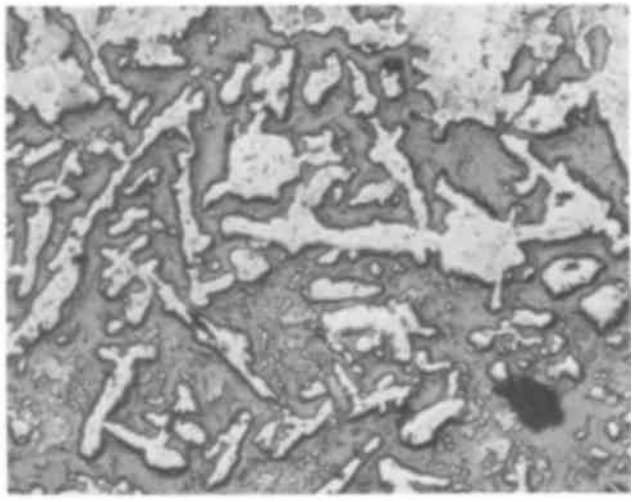

Fig. 3. Acicularly shaped needles found in the formed plate

sections and in size and shape suggested a relationship with those in the cured but unformed plate. These areas of PbO_2 with acicular external form were found only in the formed plates to which Sb_2O_3 had been added in the original mixing.

The lack of these needlelike crystals of PbO_2 in the formed plates with lead-antimony grids indicates that the amount of antimony that can be obtained from the grid is insufficient for the formation of such crystals. This is particularly true because the type of crystal responsible for the acicular PbO_2 crystals in the formed plate was first formed in the cured plate. Under curing conditions the electrolytic action necessary for solution and transport of the antimony is missing.

In the samples examined which contained 0.10% Sb_2O_3, the number of needlelike PbO_2 groups formed seemed insufficient to bind the plate active material together, either by intergrowth at contacts (such as seems to have occurred at several points in Fig. 3) or by the formation of an interlocking structure.

It would seem advisable to investigate this phenomenon further by using various amounts of Sb_2O_3 in the paste and combining this with capacity and life-cycle tests to see if this type of structure can be improved and whether it proves to be beneficial.

Mass Transport Limitations in Lithium-Cupric Fluoride Cells

R. Keller*

Research Division, Rocketdyne,
A Division of North American Rockwell Corporation, Canoga Park, California 91304

The lithium-cupric fluoride battery system which has an excellent theoretical energy density has been studied by various investigators (1). Severe performance limitations were encountered in regard to discharge rates. Such limitations appeared to depend on the electrolyte, *e.g.*, they were significantly greater in propylene carbonate electrolytes than in those based on methyl formate.

It appears that the performance of the cathode generally is the factor limiting the performance of lithium-cupric fluoride batteries under study. Factors possibly limiting cathode performance include (*a*) internal conductance of the cathode material, if reduction occurs *in situ;* (*b*) dissolution rate of the electroactive material, if reduction of dissolved copper species occurs; (*c*) formation of complexed copper species causing changes in discharge potentials and/or loss by diffusion and migration; (*d*) blocking of discharge sites by reaction products, particularly insoluble lithium fluoride; and (*e*) mass transport in the electrolyte. Mass transport limitations are being scrutinized in this note. It is shown below that, in certain cases, mass transport in the electrolyte alone may account for the observed performance limitations. It should not be implied, however, that the factors limiting the performance of prototype cells in actual discharge tests have been identified.

The lithium-cupric fluoride cell, *e.g.*, with a $LiClO_4$ electrolyte, is somewhat unique inasmuch as the cation of the electrolyte is being precipitated at the cathode during cell discharge, according to

$$CuF_2 + 2Li^+ + 2e = \underline{Cu} + \underline{2LiF} \qquad [1][1]$$

Lithium fluoride has generally a very low solubility in aprotic solvents and solutions; some solubility values obtained in our laboratory are given in Table I. Because of this very low solubility of LiF, and since lithium is the only cation present (disregarding copper), practically all fluoride ions potentially formed at the cathode are readily precipitated. This causes a depletion of the electrolyte at the cathode. Under limiting conditions, this depletion will be complete, and mass transport cannot be increased by higher electric fields (higher *IR*-drops). A similar effect, incidentally, can occur also in aqueous systems, *e.g.*, when insoluble hydroxide forms at the anode; in such "conventional" cases, this effect is, however, much less critical because of higher diffusion coefficients and because a higher amount of electrolyte solute (as reservoir) can be tolerated without severely jeopardizing the energy density of the cell.

In the following, a lithium-cupric fluoride cell with a 1M $LiClO_4$ in propylene carbonate (PC) electrolyte shall be considered as an example. At a discharge under mass transport limitations, an electrolyte concentration profile, shown schematically in Fig. 1, will eventually result. The electrolyte concentration at the anode will correspond to a saturated $LiClO_4$ solution and will be practically zero at the cathode.

Table I. Solubility of LIF

Solvent/solution	Temp, °C	Solubility of LiF, moles/liter
Propylene carbonate	25; 60	$<5 \times 10^{-6}$
1M $LiClO_4$/PC	25	1×10^{-4}
Dimethyl formamide	25	3×10^{-5}
Dimethyl formamide	60	5×10^{-5}
Acetonitrile	25	2×10^{-6}
Methyl formate	25	3×10^{-5}

Table II. Calculation of limiting current

Li precipitated as LiF at cathode:	$j_{Li,c} = -\frac{i}{F}$
Li^+ transported by migration:	$j_{Li,m} = \frac{i \cdot t_+}{F}$
Li^+ transported by (linear) diffusion:	$j_{Li,d} = -D\frac{dC_{Li}}{dy}$
Li^+ transported by convection:	Zero

$$j_{Li,c} + j_{Li,m} + j_{Li,d} = 0 = -\frac{i_l}{F} + \frac{i_l \cdot t_+}{F} - D\frac{\Delta C_{Li}}{\Delta y}$$

$$i_l = -D\frac{F\,\Delta C_{Li}}{t_- \cdot d}$$

The diffusion limiting current for such a case is calculated for a simplified, linear model where: (*a*) no separator is present; (*b*) the distance between anode and cathode is $d = 1$ mm; (*c*) convection is negligible; (*e*) the diffusion coefficient, D, is constant throughout the cell; and (*f*) the solubility of $LiClO_4$ at the anode is 2.1 moles/liter, the solubility of LiF at the cathode is negligible, and a linear concentration profile for $LiClO_4$ forms between anode and cathode. The concentration gradient for the lithium ion can then be represented by

$$\frac{dC_{Li}}{dy} = \frac{\Delta C}{d} = \frac{-2.1 \times 10^{-3}}{0.1} \text{ moles cm}^{-4} \qquad [2]$$

Lithium ions are transported by migration and diffusion (convection neglected). At steady-state limiting conditions, the amount of lithium ions reaching the cathode equals the amount of lithium ions precipitated at the cathode. The limiting current, i_l, can be calculated as shown in Table II.

$$i_l = -D\frac{F \cdot \Delta C_{Li}}{t_- \cdot d} \qquad [3]$$

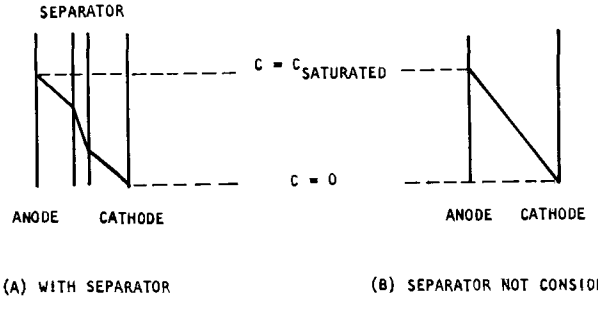

Fig. 1. Schematic electrolyte concentration profile

Key words: lithium cells, copper fluoride cathode, mass transport, nonaqueous battery.

[1] According to solubility studies, the reaction $2LiClO_4 + CuF_2 = \underline{2LiF} + Cu(ClO_4)_2$ may occur on open circuit, although such studies have indicated that it may progress very slowly. It is not certain how far such a reaction would extend, i.e., if $Cu(ClO_4)_2$ would form in significant amounts beyond the solubility of this compound in an actual electrode. Such a process would cause a depletion of the electrolyte, but, overall, an excess of CuF_2 would have to remain because in a practical system a stoichiometric amount of ClO_4^- could not be permitted without jeopardizing the high-energy density feature of the cell. After an initial discharge of $Cu(ClO_4)_2$, the limiting conditions would therefore occur as discussed.

Selecting the value of $D = 2.6 \times 10^{-6}$ cm^2 sec^{-1} determined as the integral diffusion coefficient for a 1M $LiClO_4$/PC solution at 25°C in this laboratory (2), and a value of $t_- = 0.75$ based on transference and conductance measurements (3), a value of

$$i_l = 7 \times 10^{-3}\ \text{Acm}^{-2}$$

results for $d = 0.1$ cm and $\Delta C = -2.1$ moles/liter.

By assuming a simple cell model, some factors have not been considered:

1. Convection has been neglected. It was found experimentally by Boehm and Ibl (4) for an aqueous system that convection was negligible at electrode distances smaller than about 0.4 to 0.6 mm. Because the distances between walls in the presence of a separator should be assumed to be smaller than 0.5 mm, and, in addition, the viscosity of the propylene carbonate electrolyte is higher than the viscosity of aqueous solutions, disregard of convection effects is indeed appropriate.
2. The diffusion coefficient in the separator material is lower than in the electrolyte, and somewhat lower values for limiting currents should result if the presence of separators is considered.
3. Increases in cell temperatures during discharge cause higher diffusion rates and hence higher limiting currents; a temperature increase from 25° to 70°C might be expected to approximately quadruple the limiting current in analogy to aqueous solutions (5).
4. A reservoir of electrolyte may be contained in the cathode. However, such excessive amounts of electrolyte solution or solute depress the total cell energy density.
5. A layer of saturated $LiClO_4$ solution may build up at the anode if sufficient $LiClO_4$ is available and hence increase the concentration gradient by reducing the distance between saturated solution and cathode.
6. Higher currents will be obtained in the transition period before diffusion limitation will be reached.

Conclusions

Limitations to low or moderate discharge rates can be predicted for certain lithium cells because of transport limitations in the electrolytes. It appears essential to consider such factors.

Limitations by mass transport as discussed may be reduced by:

1. Use of electrolytes with higher diffusion coefficients;
2. Use of an electrolyte or a cathode material which does not form insoluble cathode discharge products;
3. Use of excess electrolyte solute as ion reservoir at the cathode;
4. Proper choice of separator to minimize separator action as diffusion barrier;
5. Reduction of the electrode spacing.

Rapid Determination of Electronic Conductivity Limits of Solid Electrolytes

D. A. J. Swinkels*

Central Research Laboratories, The Broken Hill Proprietary Company Limited, Shortland, N. S. W. 2307, Australia

Solid oxide-ion conductive electrolytes have found many applications for the determination of oxygen activities at elevated temperatures. However, at low oxygen activities and high temperatures, such as for example in the determination of dissolved oxygen in liquid steel (1), the onset of electronic conductivity causes a reduction in cell emf from that calculated from the simple Nernst equation.

Schmalzried (2, 3) has treated the emf relationships for solid electrolyte cells in which the electrolyte shows mixed ionic and electronic conductivity. Free electrons may be generated by the reaction

$$O_o = O_2(g) + 2V_o^{\cdot\cdot} + 4e^- \qquad [1]$$

where O_o is an oxygen atom in a regular oxygen site, $V_o^{\cdot\cdot}$ is a doubly ionized oxygen vacancy, and e^- is an excess electron. For heavily doped materials such as $(ZrO_2)_{0.9}(Y_2O_3)_{0.1}$ or $(ZrO_2)_{0.88}(CaO)_{0.12}$, O_o and $V_o^{\cdot\cdot}$ are approximately constant, and hence the electronic conductivity at a given temperature will vary with oxygen pressure according to

$$\sigma_e = \sigma_e^{\circ} P_{O_2}^{-1/4} \qquad [2]$$

The resulting cell emf for a cell with oxygen pressures P_1 and P_2 is then given by

$$E = \frac{RT}{\mathbf{F}} \ln \frac{P_\ominus{}^{1/4} + P_2{}^{1/4}}{P_\ominus{}^{1/4} + P_1{}^{1/4}} \qquad [3]$$

where P_θ is the oxygen pressure at which the electronic conductivity becomes equal to the ionic conductivity, *i.e.*, the ionic transport number $t_i = 0.5$. Equations similar to [2] and [3] are available for materials showing hole conductivity and for materials showing both electron and hole conductivity. The current analysis is limited to materials showing only ionic and electron conductivity. Values of $P_\ominus$ have been determined from resistance measurements as a function of P_{O_2} (4), from emf measurements on cells with known oxygen activities (5, 6), from polarization measurements between a reversible and a nonreversible electrode (4), and by

* Electrochemical Society Active Member.

Key words: oxide ion conductor, oxygen pump, coulometric titration.

coulometric titration procedures (7). Resistance measurements result in limited precision values of $P_\ominus$ since extreme experimental difficulty exists in fixing the very low P_{O_2} values which are required. At high temperatures, errors due to changes in surface and gas conduction and to contact resistances can readily occur. Methods involving emf measurements all require quite impervious electrolyte specimens and mountings since otherwise the resulting lower emf values are due to gas permeability, but may be interpreted as being due to electronic conductivity.

A new technique similar to the coulometric titration method (7) or the oxygen pumping approach of Yuan and Kröger (8) is proposed. Such a method can be used with both porous and dense samples, and $P_\ominus$ values, over a wide range of temperatures are determined in a single run. An emf cell is made up, from the sample of the electrolyte to be tested, with a Pt-air electrode on one side and a liquid metal electrode on the other side (see Fig. 1 for typical geometries). Fine silver (99.95%+ Ag) was used in our measurements since the temperature range of interest was 1000°-1650°C, but other metals can be used at lower temperatures. Contact to the liquid silver was made *via* an iridium wire.

Oxygen is pumped from the metal side of the cell by passing a d-c current in the appropriate direction, and the cell becomes polarized to an extent determined by the rate of oxygen removal with the current and by the leak rate of oxygen back into the system through the sample or its mounting or from the argon cover gas. The current is increased until it exceeds the total leak rate. The oxygen level in the metal is then reduced to an extremely low level. Further increases in current rapidly increase the proportion of the electronic current through the sample. Under these conditions $P_2 >> P_\ominus >> P_1$ and hence Eq. [3] may be simplified to

$$E_m = \frac{RT}{4F} \ln \frac{P_2}{P_\theta} \qquad [4]$$

where $P_2 = 0.21$ atm. E_m is obtained by momentarily interrupting the current and measuring the cell emf without *IR* drop and correcting for the Ir-Pt thermal emf. The open-circuit emf decays at a rate determined by the total leak rate of oxygen back into the silver.

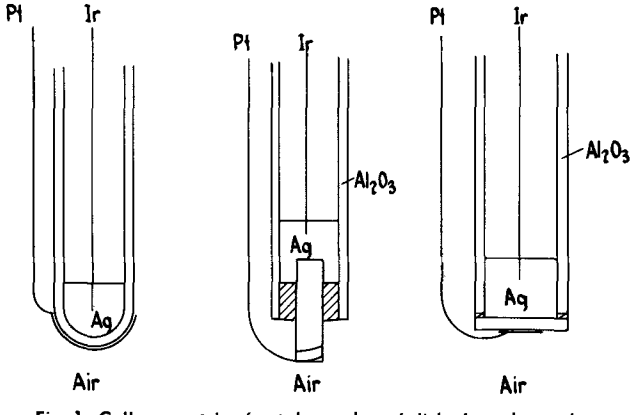

Fig. 1. Cell geometries for tube, rod, and disk shaped samples

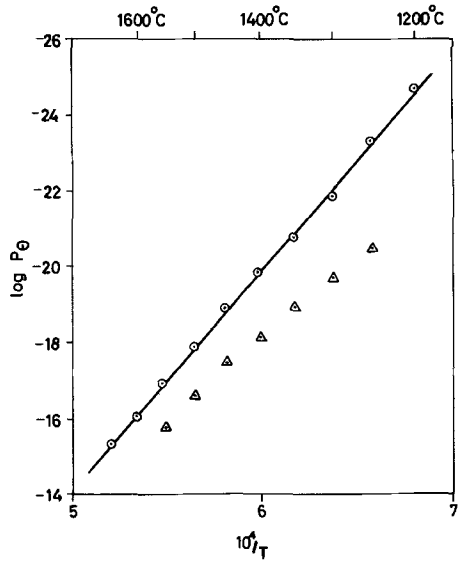

Fig. 2. Values of log $P_\ominus$ determined from resistance measurements (△) and by the present polarization technique (○).

i.e., the sum of molecular oxygen flow (through pores) and O^{--} flow (balanced by electronic flow).

Results obtained for a high-purity 7 m/o Y_2O_3 stabilized zirconia material prepared by coprecipitation, calcining, pressing, and sintering (9) are shown in Fig. 2. The sample consisted of a ⅛ in. diameter 1 in. long cylinder mounted in an alumina tube using Ceramabond 503 alumina cement. The polarizing current was interrupted for 0.5 msec at 50 msec intervals and the emf was measured by a track-store circuit synchronized with the interruptions and displayed on a DVM. $P_\ominus$ values calculated from 2 terminal resistance measurements in air and in H_2/H_2O atmospheres at 1592 Hz are shown for comparison. The resistance measurements were reproducible to ±1 in the value of log $P_\ominus$ calculated while the polarization measurements were generally reproducible to ±0.2 in log P_θ.

Manuscript submitted April 13, 1970; revised manuscript received June 25, 1970.

Evidence for a Complex Chloromolybdate Ion in a Molten Salt Medium from Transference Experiments

Vernon A. Lamb

National Bureau of Standards, Washington, D. C. 20234

Considerable indirect evidence exists for the presence of anionic chloro complexes of molybdenum in molten alkali chloride media, based mainly on emf measurements (1-4). It was thought that experiments that would provide direct evidence for the existence or absence of such complexes would be worthwhile. A transference technique was chosen for this purpose. The molten system was a solution of K_3MoCl_6 in KCl-LiCl eutectic.

If, at a particular temperature, the equilibria between Mo(III) ions and chloride ions lie predominantly in the direction of negative Mo-containing species, Mo should be electrically transported from the cathode compartment to the anode compartment of a transference cell. A blank experiment (no current) run under similar conditions should give the amount of transport by diffusion. A positive difference between Mo in the anode compartment resulting from electrolysis and from diffusion would indicate the presence in the molten system of a preponderance of negatively charged complex ions. On the other hand, if no electrical transport to the anode compartment were found, it would indicate that either the transference number of the complex is zero, or that it is dissociated to such a degree that neutral $MoCl_3$ or positive chlorocomplexes of Mo(III) predominate. In the latter case, electrical transport of molybdenum into the cathode compartment could be detected by electrolysis of a cell in which the molybdenum salt was initially present only in the anode compartment.

Experimental

Preliminary experiments showed that it was necessary to pass a large number of coulombs through a cell to produce transport of sufficient molybdenum to permit its measurement with reasonable accuracy. The cell shown in Fig. 1 was, therefore, designed to permit a large coulomb flow. Silver chloride is used in cathode compartment D. This arrangement prevents deposition of molybdenum from cathode compartment E that would occur if compartment D were absent and the cathode were placed directly in compartment E. The diaphram, C, between the two sections of the anode compartment prevented large amounts of nickel from entering compartment B-C. The number of coulombs that could be passed was limited by the amount of silver ion in the cathode compartment and the mass of nickel anode in contact with the eutectic melt in the anode compartment. These had capacities of about 7000 coulombs, whereas 2600 was the largest amount passed (Table I).

Key words: hexachloromolybdate complex ion, molten salt, transference numbers.

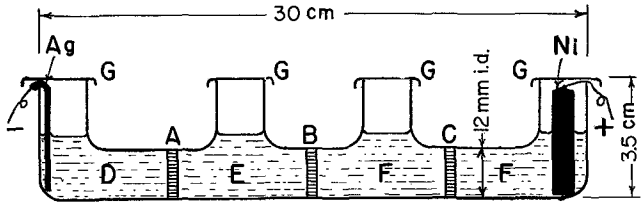

Fig. 1. Design of Vycor transference cell. A, B, C, porous quartz diaphrams; D, LiCl-KCl eutectic + AgCl, 25% by wt; E, K_3MoCl_6 + LiCl-KCl eutectic; F, LiCl-KCl eutectic; G, caps to reduce evaporation of salt.

The quartz disks shown in Fig. 1 were 1.5 mm thick and had a nominal pore diameter of <15 μm. As obtained from the manufacturer they had pore volumes ranging from 33 to 45%. Under a pressure differential of approximately 1 atm, the flow of water through these disks was 10-15 ml/min. To reduce the porosity of the disks and, hence, the interdiffusion rate between the contents of the cell compartments, the disks were partially plugged with silica by treating successively with ethyl silicate and hydrochloric acid, followed by baking at 800°C (5). Disks so treated to give a water flow under suction of about 0.5 ml/hr were used by Lunden (6), who estimated their effective total pore cross section to be about 0.3 to 0.4%. In our experience, disks this tightly plugged were extremely difficult to impregnate with molten salt, passed only a very small current at several hundred volts, and showed evidence of conductance by arcing. Most of the runs were therefore made with cells containing disks plugged to a flow under 1 atm pressure of 3-10 ml/hr. Such disks were estimated to have a pore cross section of about 3%. They permitted passage of currents of the order of 100 mA at cell potentials in the range of 5-10V, and interdiffusion was adequately reduced, as shown by the data in Table I.

Preparation of salts.—Potassium and lithium chlorides were purified by the method of Maricle and Hume (7). Potassium chloromolybdate was prepared by the method of Senderoff and Brenner (8) and purified by heating in vacuum at 150°C for ¾ hr, followed by successive washes in water, HCl-methyl alcohol, methyl alcohol, and ethyl ether, followed by vacuum removal of the ether. Analysis gave Mo, 19.95%; Cl, 49.6%. Theoretical: Mo, 23.1%; Cl, 51.2%.

Table I. Summary of experiments on transport of molybdenum

Exp. No.	Temp, °C	Current, mA	Time, hr	Coulombs	Disk flow at 1 atm, ml/hr	Initial location of K_3MoCl_6	Mo found in opposite compartment, mg	$t_{MoCl_6^{3-}}$
				Part A. Control experiment				
16B	720	None	53	None	12	—	0.55	
				Part B. Transport experiments				
5	800	80	1.8	520	42	Cathode	2.1	0.012
14	800	23	5	410	2.2	Cathode	1.5	0.011
8	800	140	4	2,000	3.5	Cathode	4.9	0.0074
15	800	180	4	2,600	10	Cathode	5.3	0.0062
12	800	100	2.8	1,000	4.0	Anode	0.9	—
							Arithmetic mean	0.009
							Standard deviation	0.0028

The found analysis is approximately accounted for if the preparation contained 12% of excess KCl. A eutectic mixture of LiCl and KCl plus potassium chloromolybdate was prepared that contained LiCl, 40%; KCl, 47%; K_3MoCl_6, 13% by weight (57, 41, and 2 m/o, respectively) of the constituent salts. On melting the molybdenum salt-eutectic mixture, a small amount of black precipitate formed, which was probably a molybdenum oxide or a higher valent chloride. It was separated by settling, freezing, and mechanical removal. Transfer and mixing operations were done in a dry-box.

Procedure.—The cells described above were filled in a dry-box and stoppered during transfer to the furnace tube. They were exposed to air only briefly while inserting the electrodes, capping the openings, and placing in the furnace tube. The Vycor furnace tube, 6 cm OD, was then sealed, evacuated, filled with argon, and heated in a horizontal tube furnace. When the salt had melted, several successive evacuations and pressurizations were usually required to cause filling of the disk pores, indicated by good electrical conductivity. Coulombs passed were measured by integrating the current-time curve recorded on a strip-chart.

After electrolysis was completed, the cell was allowed to cool in the furnace and was then removed. To recover the salt from the segment B-C (Fig. 1), the cell was broken at the respective disks and the salt dissolved in water in a beaker. Molybdenum in the portion of salt from segment B-C was determined spectrophotometrically by the thiocyanate method. Separate experiments with known mixtures showed that nickel from the anode compartment did not interfere. The accuracy of the molybdenum determinations is judged to be within ± 3%.

Results.—The results are summarized in Table I. The control experiment, 16B, shows that the amount of molybdenum transferred by diffusion to the adjacent section of the cell that initially contained no molybdenum salt is negligible (0.01 mg/hr). The amounts of molybdenum found in the anode compartments, B-C, in experiments 5, 8, 14, and 15 definitely indicate transport of molybdenum by a negative molybdenum-containing complex ion.

The data in the last line of Table I, experiment 12, show that there was no significant transport of a molybdenum-containing ion from the anode to the cathode compartment. This result reinforces the evidence of experiment No. 5, 8, 14, and 15 and indicates that any positive chloro complexes of Mo(III), if present, are in rapid equilibrium with the predominant negative complexes. (The small amount of molybdenum found in the cathode compartment in this experiment is ascribed to diffusion and to trace contamination from the adjacent Mo-containing compartment, which is difficult to avoid completely when the frozen salt is salvaged for analysis.)

The values for the transference number in the last column of Table I were calculated from

$$t_- = \frac{(96500)\,(\text{mass of Mo transferred})}{(\text{coulombs})\,(\text{Equivalent wt. of Mo})} \quad [1]$$

The undissociated hexachloro complex ion is assumed for calculating the tabulated transference numbers; hence, the equivalent weight of molybdenum is 1/3 of its molecular weight.

Conclusions

With the apparatus and procedure described, direct evidence for the existence of an anionic chloromolybdenum complex at 800°C has been obtained. Its transference number of approximately 1% in the KCl-LiCl solvent has been determined with an accuracy of about ±30%. This value of the transference number of the complex shows that alkali and free chloride ions carry most of the current, and its magnitude is reasonable in view of the mol fraction of molybdenum in the melt (2%).

The Electrodeposition of Nickel from Heavy Water

F. E. Ammermann, S. Ghosh, J. A. Larson, and C. R. Lewis

Research Office, Product Planning and Development, Chrysler Corporation, Detroit, Michigan 48231

Since no information was available concerning the effect of substituting deuterium for hydrogen in electroplating solutions, a short experiment was undertaken to determine the effects of this substitution. Nickel was deposited from baths identical except for the presence of hydrogen in one and deuterium in the other, and the resulting deposits were subjected to metallographic and x-ray diffraction examination.

Procedure

For the electrodeposition experiment, two solutions were made, each containing 2.4g of nickel chloride ($NiCl_2$) and 13.9g of nickel sulfate ($NiSO_4$) as dessicated salts. One was dissolved in 100 ml normal water and the other in a like amount of heavy water. One drop of hydrochloric acid was added to each solution to suppress hydrolysis and each was allowed to stand for 24 hr. Anodes were prepared from rolled electrolytic nickel. Cathodes, 1 in.^{2} were cut from polished brass sheet. The anodes were bagged in filter paper.

Electrolysis was performed in glass jars at room temperature. The electrodes were spaced 1 in. apart. The systems were connected in series and current supplied from a rectifier at the equivalent density of 30 A/ft^2 at the cathode. Each jar contained one cathode

Key words: deuterium, electroplating, stresses, nickel.

and anode arranged so that the opposed surfaces carried the principal amount of current and the backs were shielded. It was recognized that the conditions of high pH, low temperature, and lack of buffer (usually boric acid) would yield a burned and brittle plate, but it was felt that the unfavorable circumstances were more likely to emphasize any significant differences in deposition.

At the onset of deposition it was noted that hydrogen evolution was much reduced in the deuterium oxide solution. The cathodes were periodically examined in order to note significant alterations in appearance. As expected, the deposits were cracked and burned but that from the deuterium oxide much less so. Deposition was stopped when a sufficient thickness of nickel had been deposited to permit further examination. The total plating time was 2.5 hr during which the current was kept constant by periodic adjustment. Visual inspection showed the deuterium plate to be relatively smooth and metallic, whereas the normal system had produced the expected scaled and discolored surface. Somewhat unexpected was the appearance of the anodes. The anode from normal water appeared uniformly pitted but the heavy water anode was distinguished by large widely spaced holes in the surface.

Metallurgical Results

Both anodes and cathodes were given a detailed metallurgical examination. Because the deposits, especially from the normal water, were curled and fragmented, superficial hardness measurements were not taken. Figures 1 and 2 show the microscopic aspects of the anode dissolution. Since both the anodes and plating conditions were the same, any differences must be attributed to the presence of the heavy water in the electrolyte. The internal cavity structure and the nature of localized, uniform, tri-axial dissolution, irrespective of grain orientation, appears to be the same in both cases. Therefore, the difference lies in the behavior of the anode surface layer in the presence of the two electrolytes. In the heavy water solution, the surface characteristics of the anode appear to present no problem for dissolution (Fig. 4), whereas in the normal water solution, the surface layer appears to be passivated (Fig. 3) to a high degree. The improved anode utilization in the heavy water cell is apparent.

Figures 5 and 6 show cross sections of the deposits from heavy and normal water, respectively. The following observations can be made:

1. Both systems produced a deposit almost similar in appearance except for depth, uniformity, and tenacity with the substrate.
2. Both deposits are difficult to etch, basically columnar in nature and similar in microstructure except for the grain size difference.
3. The deposit from the heavy water system shows more ductility and better metallurgical bond with the substrate than the deposit from normal water.
4. In both systems, the structural continuity is broken by intermittent plating, indicating perhaps the effect of oxidation. Electron microscopic investiga-

tion of the structure of both the anode and the plating is being pursued and may reveal further information.

X-Ray Results

Since distinct differences in grain size and stress levels were apparent in the two deposits, Fourier analysis of the x-ray diffraction peak shapes was undertaken to make these differences more quantitative. The analysis was performed on the (200) and (400) lines using copper radiation. Since the Rachinger (1) technique for doublet separation depends heavily on the tails of the diffraction lines, an interfering line from the brass substrate (which was evident in the tail of one diffraction line), made doublet separation difficult. Therefore, a computer program based on the unresolved doublet was used (2). The correction for instrumental broadening was made with the method devised by Stokes (3), using annealed nickel powder as the instrumental standard. The separation of the broadening into microstrain and particle size terms was accomplished utilizing the Warren and Averbach technique (4). The results of this analysis are shown in Table I.

The values of De and microstrain shown in Table I are in order-of-magnitude agreement with those given

Table I. X-ray results

Plating solution	Effective particle size De_{200}, A	Microstrain $\langle E^2_{50A} \rangle^{1/2}_{200}$	Microstrain $\langle E^2_{100A} \rangle^{1/2}_{200}$

D_2O	140	Very small	Very small

by Hinton (5) for electrodeposited silver. The general conclusion from the results shown is that the observed physical difference between the two plates can be attributed primarily to microstrains. In interpreting these microstrain differences, one must keep in mind that, since the Fourier analysis was carried out centered on the mid-point of the annealed peak, the microstrain values obtained must be corrected for any macrostrain which may be present. *i.e.*, the observed values are actually equal to $[\langle E_L^2 \rangle - \langle E_L \rangle^2]^{1/2}$. However, due to the poor adherence of the plates, it can probably be assumed, in this case, that any macrostrains have been relieved. It should also be noted that it is apparently possible for hardness (or ductility) differences to be accounted for by twin faults (5), and these were not evaluated in this case. However, it is felt that the large differences in microstrains are the primary cause of the ductility variation between the two plates, and twin fault variations are probably small.

It is apparent that visual, structural, and physical differences do exist in nickel deposited from normal and heavy water under the conditions described. The major effects are a lower stress level and smaller grain size in the nickel deposits and a more uniform removal of the anode surface from the heavy water solution. It is likely that these differences would diminish under conditions conducive to a more normal deposit such as higher temperatures, although the effects on anode dissolution should not depend strongly on this particular plating condition. The anode effect may represent a combination of D_2O as a solvent and the changes relative to H_2O during a plating cycle.

There are certain difficulties inherent in plating experiments using deuterium oxide that arise from the necessity of excluding normal hydrogen and the fairly high cost of deuterium oxide. However, the interesting results achieved in a simple experiment suggest that further investigation of deuterium oxide in both the deposition and etching of metals would be fruitful.

A Kinetic Study of the Fluorination of Silver

Patricia M. O'Donnell*

Lewis Research Center, National Aeronautics and Space Administration, Cleveland, Ohio 44135

ABSTRACT

The effect of the variables, temperature, and pressure, on the kinetics of the reaction of fluorine with silver were studied. The temperature range of the investigation was from 25° to 300°C, and the reaction was measured at fluorine pressures of 50-600 Torr. The reaction was found to be pressure dependent. Three reaction products are identified: silver subfluoride, silver monofluoride, and silver difluoride. No simple rate law could describe the data over the entire time interval of the reaction.

The majority of the kinetic studies on heterogenous systems that have appeared in the literature in general discuss metal-oxygen systems. There have been some kinetic studies reported on metal-fluorine systems (1-15); however, the majority of the research on metal-fluorine systems has been compatability studies. In the present investigation the fluorination of silver was studied by exposing silver coupons to fluorine gas and following the reaction by the pressure drop method. The effect of both temperature and pressure on the rate of reaction are presented.

Experimental

The system used to study the fluorination of silver is shown in Fig. 1. Fluorine is brought from the tank through copper tubing into the system which is Pyrex throughout except for the reaction furnace which is made of quartz. A cold trap using a methylcyclohexane slush (−116°C) was used to remove any hydrogen fluoride impurity from the fluorine. The fluorine is analyzed by reaction with mercury in the still (1). Analysis of the fluorine indicated 99.83% fluorine plus 0.17% HF before purification and 100% fluorine after purification. Enough purified fluorine for one run is stored in the storage bulb. The mercury manometers in the system indicate the pressures in the storage and reaction sections of the apparatus. A layer of fluorocarbon oil is floated on top of the mercury to prevent it from reacting with the fluorine. All readings are corrected for density differences between the oil and the mercury. The metal samples are silver plates 1.27 x 15.24 x 0.012 cm. Spectrographic analysis gave a purity of 99.999%.

A plate is inserted into the cold reaction furnace under flowing argon and is positioned upright in the center of the furnace. The end plug is put in place and the argon pumped out. The furnace is turned on and the reaction section brought up to the appropriate temperature. Temperature profiles have been run with an instrumented metal sample, and the results show that the temperature variation across the sample is not more than 1°C. Meanwhile the storage section is filled with fluorine. The general experimental method used to determine the rate of fluorine consumption by silver was to measure the pressure decrease in a vessel of known volume containing the silver sample. In order to maintain approximately constant fluorine pressure, the pressure was allowed to drop only about 2 Torr and then more fluorine is introduced to return the pressure to its initial value. Pressures are recorded automatically by the pressure transducer and recording system. The perfect gas law was used to calculate the amount of fluorine consumed from the incremental pressure drop, the vessel volume, and the temperature. From the calibrated volume of the system, pressure changes on the time trace can be converted to milliliters of fluorine consumed at STP. After approximately a 4-hr exposure time the heaters were turned off, the system was allowed to cool to 25°C, and then the fluorine was pumped out of the system through the two soda lime scrubbers. The system is then brought up to atmospheric pressure with argon. A dry box is connected to the end of the furnace and the sample is pulled into it under flowing argon to prepare it for chemical and instrumental analysis.

Results and Discussion

The fluorine consumption by the silver samples was measured at several temperatures and pressures. The reaction was followed as a function of time and is reported as milliliters of fluorine consumed at STP per square centimeter of silver surface based on the geometrical area of the silver surface.

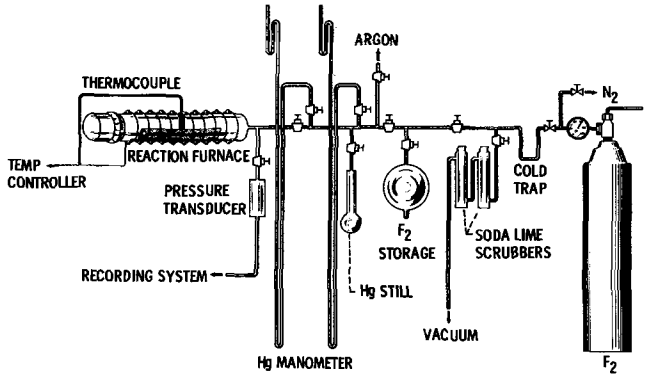

Fig. 1. Fluorination apparatus

* Electrochemical Society Active Member.

Key words: kinetics of fluorination of silver, fluorination of silver.

The effect of temperature on the reaction at a constant fluorine pressure of 50 and 200 Torr is shown in Fig. 2 and 3, respectively. The effect of pressure on the reaction at a constant temperature of 100° and 200°C is shown on Fig. 4 and 5. Note that at both temperatures there is a pressure reversal. This observed reversal in pressure dependency is not unique to this system but has been observed in other fluorination studies where multiple products are formed (16).

Data were not obtained at $t = 0$, the initial contact time of fluorine with the silver, because it takes a finite period of time to pressurize the apparatus with fluorine.

No simple rate law will describe the silver-fluorine reaction over the entire time interval studied. A linear rate law is applicable at short times, but as the time interval increases the data points deviate from a straight line as illustrated in Fig. 6. The data at the longer time intervals can best be described by a parabolic rate law as shown in Fig. 7.

Several products are formed when silver is reacted with fluorine at the temperatures and pressures studied. The products were identified by x-ray diffraction and by chemical and physical analysis as the subfluoride Ag_2F, the monofluoride AgF, and the difluoride AgF_2. Where more than one fluoride appeared the films were layered with the fluoride richest in silver adjacent to the metal and the one richest in fluorine at the gas-fluoride surface. The monofluoride was found as the middle layer. The relative amounts of

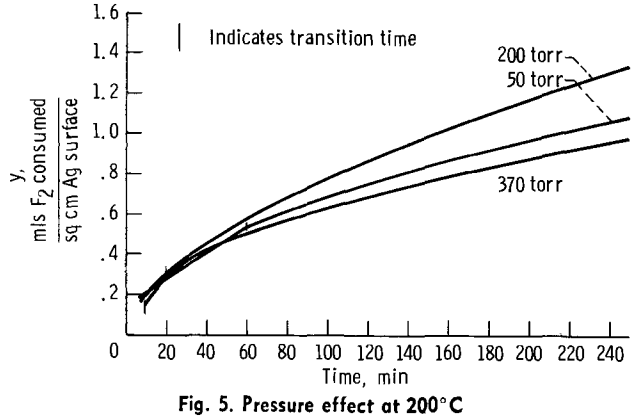

Fig. 5. Pressure effect at 200°C

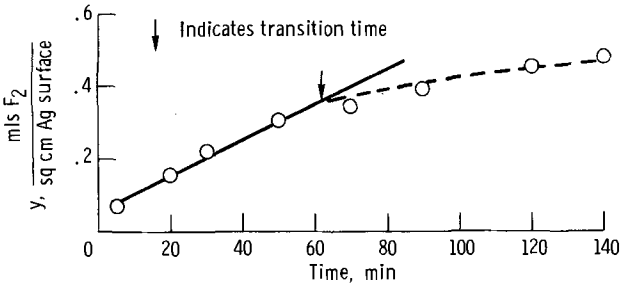

Fig. 6. Linear plot of fluorine consumption (100°C, 300 Torr)

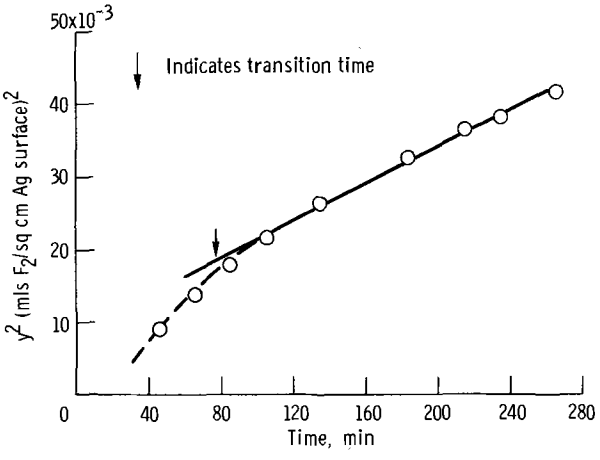

Fig. 7. Parabolic plot of fluorine consumption (50 Torr, 100°C)

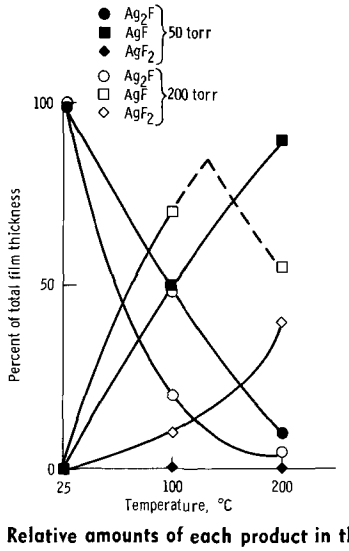

Fig. 8. Relative amounts of each product in the film

each product in the film, obtained from cross-section microscopy are shown in Fig. 8 for two pressures as a function of temperature. The amount of Ag_2F is shown by the circular symbols. As the temperature increases the amount of Ag_2F decreases. At 25°C only Ag_2F is formed at both pressures. The amount of AgF, shown by the square symbols, seems to increase to a maximum amount and then decrease as the temperature increases. The amount of AgF_2 is shown by the diamond symbols. No AgF_2 is formed at 50 Torr regardless of the temperature while at 200 Torr the amount increases as the temperature is increased. Not only temperature but pressure also affects the products formed. At 25°C and all pressures studied the only product formed was the subfluoride Ag_2F. As the temperature is increased, one or more reactions are possible including the decomposition of the subfluoride.

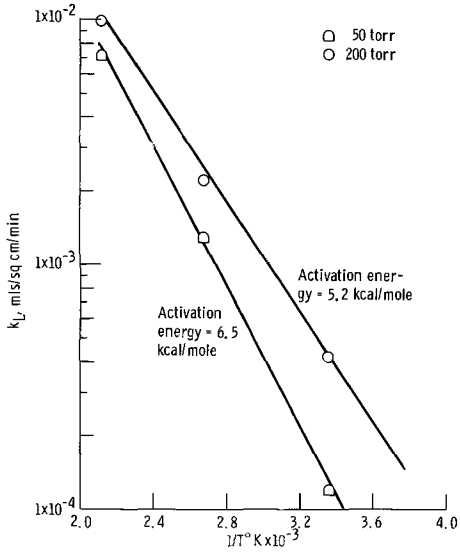

Fig. 9. Effect of temperature on rate constant in the boundary controlled region.

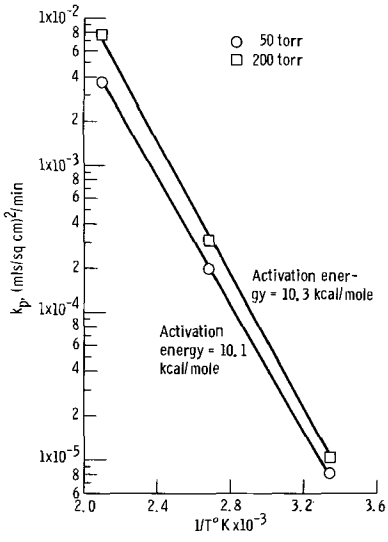

Fig. 10. Effect of temperature on rate constant in the diffusion controlled region.

At 300°C the product melted even though the temperature was well below the reported melting points of the monofluoride (435°C) and the difluoride (690°C) This could be due to the formation of a known low melting eutectic $AgF \cdot AgF_2$ (17).

Reaction rate constants are plotted against $1/T$ on Fig. 9 and 10. The data on Fig. 9 show a pressure effect. Brown and Crabtree (1) observed a pressure effect on the activation energy, but could offer no explanation.

The reaction of silver and fluorine is a complex reaction and the applicability of different rate laws is difficult to explain in the absence of definitive solid-state data.

Summary

The experimental results presented in this paper point to the fact that the reaction between fluorine and silver is a complex reaction, and the kinetics are not simple. In a study of this type it is the over-all rate that is determined, and no attempt was made to determine individual specific rates.

Effect of Sealing Variables on the Degree-of-Seal

G. A. Dorsey, Jr.

Kaiser Aluminum & Chemical Corporation, Center for Technology, Pleasanton, California 94566

ABSTRACT

At least three separate effects occur during sealing (*a*) gross water adsorption by the bulk and surface of the porous layer, probably also accompanied by anion loss (as in the case of H_2SO_4-anodized films), (*b*) an oxide transition near the barrier-porous layer interface, which results in a net decrease in the amount of barrier layer and a net increase in the amount of porous layer cross-linking, and (*c*) a seemingly thin-layer effect that takes place with aging and may be localized in the pore base region of the porous layer. A two-step current density program was used to prepare 7.4-7.6 μm (0.3 mil) anodic films on alloy 1100, using a 1.7M H_2SO_4 electrolyte at 25°C. These coatings were then sealed for from 10 to 65 min, at temperatures from 65° to 95°C, in weakly buffered sealing baths whose *p*H was adjusted within the region of 5.0 to 6.5. Corresponding films were also left in the unsealed condition. Data for these films were obtained using 1 kHz impedance measurement of coating permeability, effluent gas detection (EGD technique) of partial water contents, and infrared determinations of coating structures. For these 7.4-7.6 μm (0.3 mil) coatings, the greatest benefit was derived with the following sealing conditions: sealing *p*H range, 6.15 ± 0.15; seal time, 30 min, but not more than 40; sealing temperature, 95°C-to-boiling, or higher, as might be achieved by pressurized steam sealing.

References (1) and (2) describe the "inner seal" effect and point out its potential importance in the over-all mechanism of sealing. This involves a structural transition that appears to take place, as a result of sealing, near the interfacial region between the secondary phase barrier layer and the anodic oxide porous layer. It seemingly is an hydration effect that has the nature of a structural hydrate rearrangement, the net result being a forming together (or agglomeration) of oxide at the base of the individual alumina fibrils that comprise the porous layer. This is apart from surface hydration changes and anion loss that occur elsewhere in the porous layer oxide.

Earlier work dealt with the "effect" itself, and not with factors introduced by changes in sealing variables. Only one set of sealing conditions was employed for this: *p*H 6.0 boiling water, with a seal time of 10 min. Now we seek to determine the varying results that are brought about by employing different sealing temperatures, seal times, and *p*H values.

This sealing effect was limited to only thin films (~2 μm) when conventional anodizing conditions were employed (2): 1.3 A/dm², 1.7M H_2SO_4 and 25°C. However, the same effect could be achieved with three-fold thicker films (7.4 μm) when the proper oxide transition structure was obtained with a two-step anodizing current density program (2) in this same electrolyte. An initial current density of 1.3 A/dm² was used to develop a near-optimum oxide structure. This structure was then "frozen" by a higher current density (3.5 A/dm²) that allowed the film to thicken normally while nevertheless maintaining the oxide structure characteristic of the thinner ~2 μm film. In this manner, at least for ~7 μm (0.3 mil) films, the inner seal effect could be realized independent of actual film thickness.

However, this sealing transition, or inner seal effect, is undoubtedly sensitive to changes in sealing variables, although in this regard it should be no different from films prepared by more common practice. High-temperature sealing conditions may rapidly create surface blockage that could close off otherwise reactive sites, or the effect that we describe could be a slow reaction and relatively independent of surface effects: dependent only on temperature, in a nondehydrating environment. Additional boiling water seal times might be required, beyond the 15-min time period normally employed with ~7 μm films, in order to realize the completion of a slow reaction. There is, too, the potential effect of sealing *p*H, which may also be a factor if the mechanism of this transition involves hydrogen or hydroxyl ion from the sealing medium.

Key words: anodic aluminas, sealing.

Experimental

Sample preparation.—Alloy AS32 (alloy 1100 clad with 1100: 99.2% Al) sheet coupons were cleaned and chemically brightened, then anodized in 1.7M H_2SO_4 at 25°C. The initial current density of 1.3 A/dm² was maintained for the first 4.84 x 10^2 coulombs/dm² of current quantity (6.25 min at 1.3 A/dm²), then the current density was immediately raised to 3.46 A/dm² and maintained at that level for the balance of the anodizing period. The total current quantity expended was 13.9 x 10^2 coulombs/dm², equivalent to a 7.4 μm film thickness.

The various seals were prepared from distilled water containing 5 x 10^{-6}M acetic acid as a buffering additive and were adjusted to the desired *p*H with sodium hydroxide. The *p*H value was measured at the temperature selected for operation of the seal. Four *p*H values were employed: 5.0, 5.5, 6.0, and 6.5. Sealing temperatures were 65°, 75°, 85°, and 95°C. Sealing times ranged from (*a*) unsealed, to (*b*) 10, 20, 30, 50, and 65 min. Impedance and EGD values were determined immediately, and the same coupons were then re-examined periodically over storage periods of up to 100 days, stored in a clean environment, at ambient room humidity. Infrared data were obtained after an approximate 30-day storage period following sample preparation.

Test methods.—Effluent gas detection (EGD) data were obtained as before (3). The anodized sample was placed in a leak-tight chamber within the oven of a gas chromatograph, then continuously purged with helium which passed on to a thermal conductivity detector. The chamber was heated from ambient temperature to 350°C, at a rate slightly less than 10°C/min (3). As volatile materials, in this case, water, are evolved from the sample, the water-bearing helium effluent is carried on to the detector which then provides a continuous plot of evolved water *vs.* temperature. The result is exactly the same as a thermobalance operated in differential mode, but provides far more sensitivity.

Impedance values were measured with a 1 kHz impedance bridge (Twin City Testing Corporation's Z-Scope), using a 3.5 w/o NaCl media. The data re-

ported are average values taken from multiple readings with each anodized coupon. Infrared spectra were obtained within the 4000-35 cm^{-1} ranges of the Beckman IR-7 and IR-11 spectrophotometers, according to procedures already described (4).

Results and Discussion

Effluent gas detection (EGD).—A limitation of this technique is its failure to allow for baking temperatures above 350°C, which is usually insufficient to allow complete dehydration of most types of anodic coatings. Nevertheless, it has been shown (1-3) that the partial water content, measured by the lower-temperature EGD method, has value. This fraction of the films' total water content apparently corresponds directly with that portion of the oxide that is altered by the barrier layer sealing transition; EGD data are seemingly a reliable indicator for the degree of completion of the inner seal effect. The partial water measured by the EGD technique is independent of total porous layer oxide thickness and is independent of total water content, with neither of these two factors directly influencing the inner seal effect. The EGD data provide isolated data pertaining only to the inner seal effect itself and, when coupled with data sensitive to other changes within the coating structure, should provide a clearer picture of over-all sealing mechanisms.

The EGD technique proved not to be sensitive to effects related to the aging of sealed coatings (Fig. 1), and these sealed films were therefore stored, for convenience, prior to EGD measurement. Unsealed films are, however, affected by aging (Fig. 1), and subsequent coatings were tested immediately after air drying. Figures 2 through 5 show these EGD data plotted *vs.* sealing time, and including the effects of different sealing *p*H and temperatures. These curves

are symmetrical except for the low-*p*H seal data (Fig. 2, *p*H 5.0) which show what might be regarded as a solubility effect, with prolonged seal times, that becomes more pronounced as sealing temperature is increased toward boiling. This would indicate that, except for *p*H 5.0 seals, the apparent solubility effects did not penetrate down to that portion of the oxide that is responsible for the EGD data, the barrier-porous layer interface.

Figures 3-5 show (with seals at pH 5.5 or higher) a plateau or maximum endpoint in the sealing reaction. Beyond this point, further sealing times had no effect. This maximum value (63 μg H_2O/cm^2) represents the apparent completion of the sealing reaction, at least so far as the inner seal is concerned.

Earlier (4) the inner seal effect was proposed to be a structural conversion of pre-existing aluminum hydroxide. It was proposed that the secondary phase barrier layer hydroxide converted into a lower polymer form of hydroxide that was incorporated into the porous layer at the base of its individual alumina fibrils. If such was the case here, there should be a plateau or maximum endpoint in the sealing reaction, since all oxide (secondary phase barrier layer) available for this transition would have been converted. If the EGD technique is sensitive only to the quantity of this transformed oxide and not to other sealing reactions such as gross water content, then these data should show (as is seen in the data, Fig. 3-5) a maximum value that remains unchanged by further sealing.

With freshly anodized unsealed films, the 1 kHz a-c impedance correlates with the primary phase barrier layer thickness, giving the following relationship: 14.2 Å/kohm/cm^2 impedance. This places the average primary phase barrier layer thickness for these coatings at 180Å. Similarly, using earlier *IR* data (2, 5), and the current *IR* data to be discussed later, the average unsealed (initial) secondary phase barrier layer thickness may be calculated as 1.12 x 10^4Å. Using densities of 2.7 and 2.4 g/cm^3 for these oxides, respectively, complete dehydration to the monohydrate should release, at most, a quantity of water corresponding to 23% of the initial oxide weight. This would be 63 μg H_2O/cm^2, exactly the value of the plateau (endpoint) region shown in Fig. 3-5. Assuming, still speculatively, an initial trihydrate composition for the unsealed secondary phase barrier layer, and assuming that the plateau maximum value corresponds to an endpoint in the depolymerization reaction for this oxide, as one result of sealing, then the following interpretation can be made:

(*A*) Initially and before sealing, the EGD technique detects only a small fraction of the trihydrate water that is actually present in this oxide sublayer: about 10%.

(*B*) After a short but inadequate seal time, some of this trihydrate has undergone the depolymerization transformation. While its composition remains unchanged, the partial transformation increases the percentage of water driven off from this oxide by the temperature-limited EGD technique.

(*C*) Correspondingly more water is detectable *via* EGD as more of the oxide is converted by further sealing. Eventually, sealing consumes all of the oxide that is available for transformation. Beyond this point, the EGD data show no further increase in apparent water content as a result of further sealing. A maximum-value plateau has been reached.

(*D*) While the initial EGD data show only about 10% of theoretical water content for unsealed samples, this percentage increases as the degree of sealing becomes complete. Samples that have reached the maximum value plateau region should release (via EGD) an amount of water corresponding to 2 moles of water for each mole of sublayer oxide.

This does not mean that this particular water has been gained as a result of sealing. It may already have been present but needed the impetus of sealing to transform the oxide structure into one that dehydrates more readily: into an oxide that dehydrates under the low-temperature conditions (to 350°C) of the EGD technique.

Similar plots (unpublished) of water released *vs.* sealing *p*H for varying seal times at 95°C show a maximum value that appears to lie near *p*H 6.0. The 10-min seal data show this more clearly, since data in the plateau region mask out the effect of *p*H. The transformation, once complete, is unaltered by changes in seal *p*H (except for what might be solubility effects near *p*H 5.0). While sealing is ordinarily carried out in the *p*H range of 5.5 to 6.5 (6), there may be more advantage to sealing near *p*H 6.0. This is consistent with Bogoyavlenskii and Belov (7) and may also be seen with impedance data to be discussed shortly.

An attempt at kinetic data, using Van't Hoff's differential method, provides another tool for the interpretation of these data. Ordinarily, such data are obtained by measuring the decrease in reactant concentration as a function of time, with varying initial reactant concentrations. Where c_1 and c_2 denote two different initial concentrations and where n denotes the apparent order of the reaction with k being the rate constant, or specific reaction rate, then

$$-dc_1/dt = kc_1^n$$

and

$$-dc_2/dt = kc_2^n$$

and

$$n = \frac{\log(-dc_1/dt) - \log(-dc_2/dt)}{\log c_1 - \log c_2}$$

A plot of log $(-dc_1/dt)$ *vs.* log c, will be linear and the slope will be the apparent order of reaction, n, if the reaction proceeds without complication. Extraneous features in the reaction will, on the other hand, yield a curved plot to indicate that the reaction proceeds without a simple order.

Sealing eventually produced the same maximum-value plateau (end point) in the EGD data: 63.4 μg H_2O/cm^2, a value which remained unchanged with further seal times. Unsealed samples, prepared in an identical fashion, also gave a constant EGD value of 8.54 μg H_2O/cm^2. Therefore we assumed that the amount of alumina being transformed, on sealing, was equivalent to the difference between these two values, or 54.9 μg H_2O/cm^2. This value serves as "initial reactant" for the Van't Hoff concentration term "c". After, for example, a 10-min seal at *p*H 5.5, the EGD technique detected 22.8 μg H_2O/cm^2 indicating a "reactant" concentration equivalent to 40.6 μg H_2O/cm^2 remaining. Then one point on the plot would be represented by log $(-dc_1/dt)$ = log (54.9-40.6/10), with log c_1 = log (54.9). Similar calculations led to the values that are plotted in Fig. 6 through 8; calculations were prevented for the *p*H 5.0 data, because of what appear as solubility effects (Fig. 2) in this low *p*H seal.

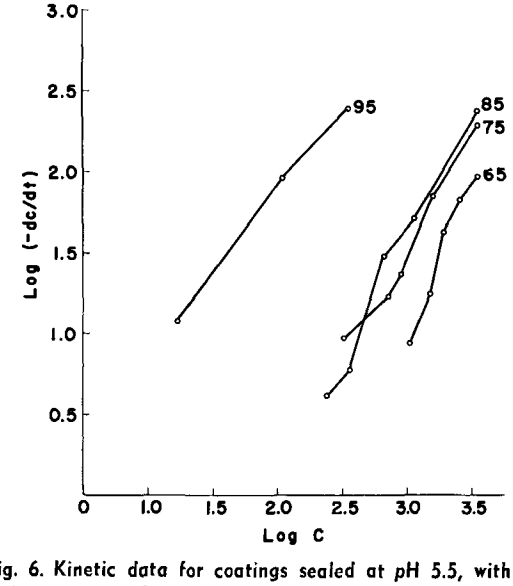

Fig. 6. Kinetic data for coatings sealed at *p*H 5.5, with tie line notation giving seal temperature: °C. The apparent reaction order was, at 65°C, 1.7; at 75°C, 1.4; at 85°C, 1.5 and, at 95°C, 1.0.

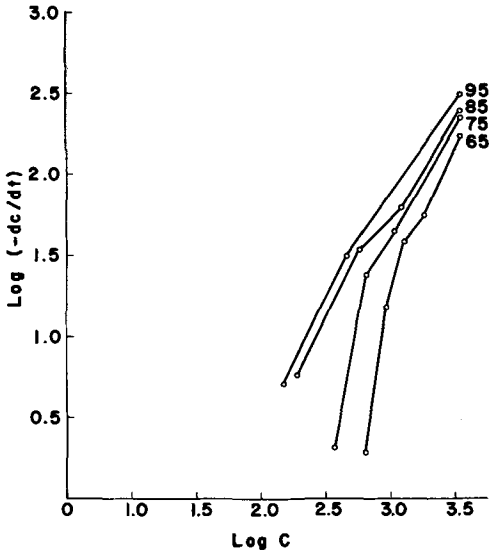

Fig. 7. Kinetic data for coatings sealed at pH 6.0, with tie line notation giving seal temperature: °C. The apparent reaction order was, at 65°C, 2.0; at 75°C, 1.8; at 85°C, 1.2 and, at 95°C, 1.2.

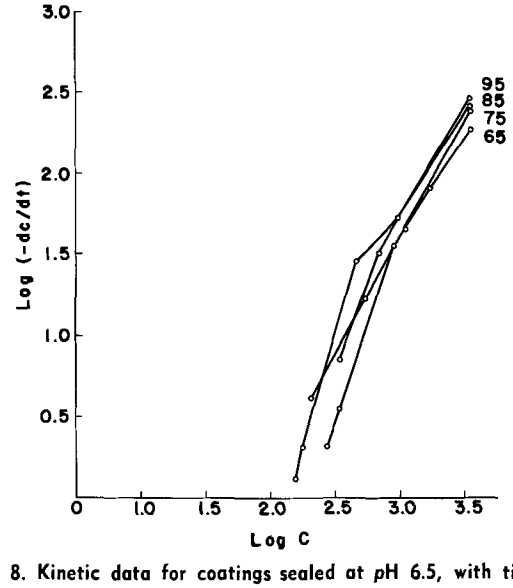

Fig. 8. Kinetic data for coatings sealed at pH 6.5, with tie line notation giving seal temperature: °C. The apparent reaction order was, at 65°C, 1.3; at 75°C, 1.7; at 85°C, 1.5 and, at 95°C, 1.5.

The apparent order of the sealing reaction was generally greatest (as high as $n = 2$) for the low temperature (65°C) seals. The reaction order approached unity as the seal temperature increased. This could be interpreted in at least two different manners

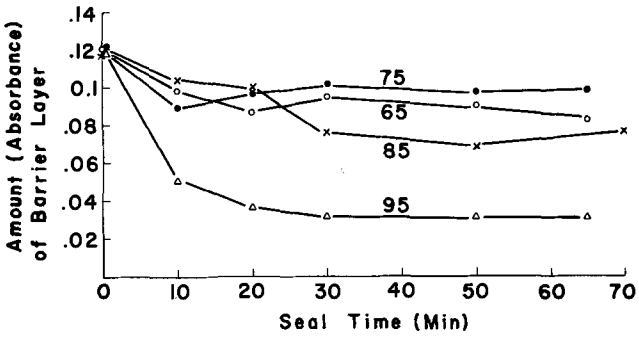

Fig. 9. Infrared absorbance (amount) of barrier layer for coatings sealed at pH 6.5; tie line notation gives seal temperature: °C.

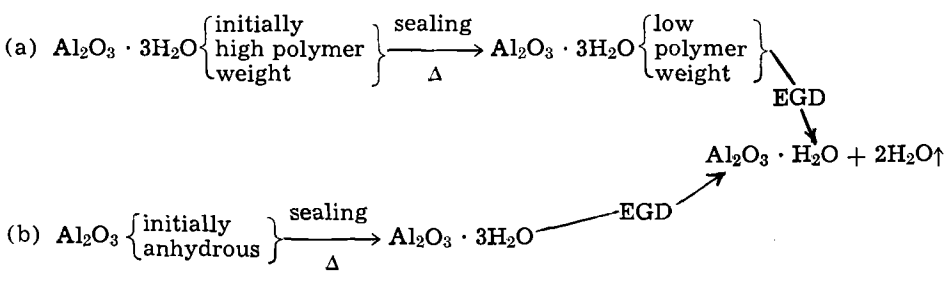
hydration reaction (*via* EGD technique) has some complicating feature. This would tend to favor sealing reaction' (a), which employs a depolymerization reaction on sealing rather than simple water sorption. That portion of the hydrated alumina which is detected by the low-temperature EGD technique then appears to be hydrated before sealing, and releases progressively more water (on baking via EGD) as its structural cross-linking is progressively lowered by sealing. Eventually, sealing lowers this cross-linking to a minimum value that (with the EGD technique) releases a stoichiometric amount of water, as did the mineralogical trihydrates gibbsite and bayerite (8). Further, the data show that after this point sealing produces no further change in the amount of water released (with EGD baking) by the coating. Such behavior is consistent with earlier *IR* data (1, 2, 4) which served as the basis for describing this same sealing effect. When this, the inner seal effect, is complete, the apparent order of the reaction is near unity.

Intermediate and far infrared analyses.—Ordinarily, *IR* data show much better precision than was obtained here. Since this poor interrelationship shows only for sealed coatings, and not for unsealed samples, it seems likely that these samples should have been analyzed immediately after preparation. As it was, they were stored at random for approximately 30 days prior to analysis. In any event, the observable trends are still valid, but what might be poor structural reproducibility (for sealed samples) makes quantitative interpretation difficult.

Figure 9 shows the amount of barrier layer plotted *vs.* sealing time. These data include each of the various sealing temperatures at pH 6.5 and are representative of the entire group. Initially, each coating (unsealed) had the same amount of barrier layer: total amount of barrier layer being comprised of both primary and secondary barrier layer phases. After sealing, the amount of barrier layer decreased due to the secondary barrier-to-porous layer conversion. At pH



However, as seen in Fig. 6-8, the plots of log $(-dc/dt)$ *vs.* log c are more nearly linear only for the 95°C sealing conditions. This implies the possibility that, at least at lower sealing temperatures, the EGD dehydration reaction proceeds with complexity: that the de-

5.0 the extent of this conversion was less at 65°C than at 75°C; the 85°C and 95°C data show approximately equal conversion and at about the same rates. Similar data obtained at pH 6.5 (Fig. 9) show a better differentiation between 85°C and 95°C data: the 95°C seal

causing the greater degree of transformation. At a given temperature, the pH 6.5 seal gave a greater degree of barrier-to-porous transformation than did the pH 5.0 seal.

Figure 10 shows the amount of porous layer cross-linking plotted *vs.* sealing time for each sealing temperature and at pH 6.5. Before being sealed, each coating had about the same amount of porous layer cross-linking. After sealing, this amount varied greatly depending on seal time, pH, and temperature. However, just as the amount of barrier layer always decreased on sealing, due to the secondary barrier-to-porous layer transformation, the amount of porous layer cross-linking always increased on sealing.

Figure 10 also shows the generally adverse effects of too prolonged a sealing time, although this decrease in cross-linking was usually more pronounced for the 95°C seals. These data show that maximum sealing benefit is obtained near a sealing time of 30 min. Sealing at a lower temperature tended to retard the apparently detrimental effect due to oversealing, but lower temperatures also gave lesser amounts of porous layer cross-linking. These porous layer data are, of course, not specific for changes that occur near the barrier-porous interface, but would include cross-linking changes in the bulk of the porous layer as well. While these data show the advantages of 95°C and 30-min sealing conditions (as did the EGD data) there is still reason to suggest that still higher seal temperatures would further accelerate the sealing process, perhaps a pressurized steam seal at 150°C, with condensate pH controlled.

Impedance.—Figure 11 shows the initial impedance values plotted *vs.* sealing time and temperature at a sealing pH of 5.5. These values were obtained immediately after air-drying the coatings and before any storage period. At 95°C (and regardless of seal pH) the impedance increased almost linearly with seal times of up to 30 min. After 35 min, the rate of impedance change lessened to form a plateau beyond which the impedance change (with further seal time) was comparatively slight. This point (~38 kohms/cm^2 impedance) would correspond to the total impermeability of this oxide and would reflect changes taking place both in the barrier layer region of the film and elsewhere in the porous layer, and also at the oxide surface (9, 10).

At progressively lower sealing temperatures, there appeared to be an initial period during which minimal impedance change took place. Afterward, the impedance increased quickly. The time span of this initial period was greatest at low temperatures but showed no obvious dependence on pH. This is seemingly indicative of a temperature-dependent reaction rate, consistent with the "inner seal effect" mechanism described earlier. A plot of log impedance *vs.* sealing temperature is essentially linear for most of these data.

Figure 12 shows the effect of sealing pH on impedance levels. For each sealing time period, the impedance increased as the seal pH increased toward pH 6.0, then decreased beyond that. Extrapolation would seem to indicate that optimum results (highest impedance) were obtained at pH 6.15 ± 0.15.

Aging also alters (increases) the 1 kHz a-c impedance of sealed films but, as seen in Fig. 13, aging produces little change in unsealed films. The same figure also shows data for marginally sealed films: films sealed at pH 5.0 and 65°C, also showing only a minor increase in impedance with aging. In contrast, films sealed at the same pH (pH 5.0) but at 95°C and for 30 min, showed a pronounced change in impedance value on aging. Figure 14 shows other such data for these sealing temperatures at pH 6.0 with 30-min sealing time.

Generally and exclusive of unsealed and marginally sealed films, impedance values increased most rapidly during the first 5 days of aging. The impedance increase, with aging, then lessened but continued until the film had aged ~30 days. Afterward, comparatively little or no further change in impedance took place. There are also the following additional observations that may be made for the generalized effect of aging on sealed films.

1. Aging prior to exposure has no recognized, or at least reproducible, effect on the results of outdoor service testing of sealed films.

2. Similarly, aging does not alter the results of aggressive laboratory-accelerated corrosion tests: pitting corrosion tests such as CASS, or acid solubility tests such as Kape (sulfurous acid solubility).

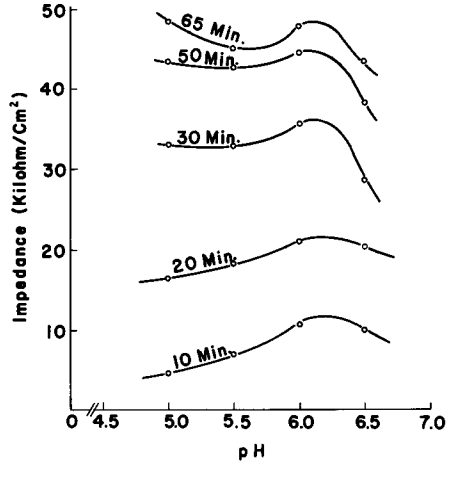

Fig. 12. Initial impedance values for coatings sealed at 95°C, with the tie line notation giving sealing times: minutes.

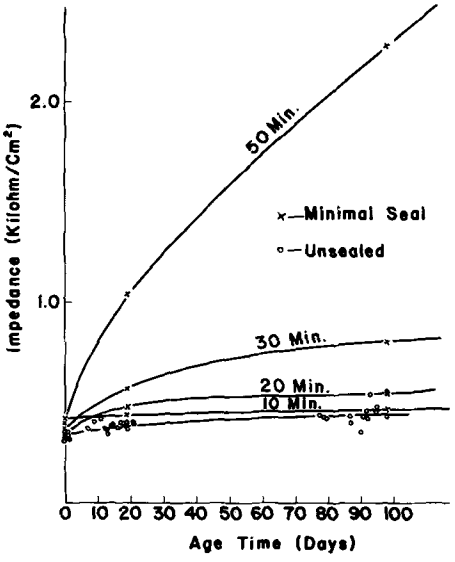

Fig. 13. Effect of aging on impedance values for (a) unsealed coatings and for coatings marginally sealed, at pH 5.0 and 65°C, by immersion for: (b) 10 min, (c) 20 min, (d) 30 min, and (e) 50 min.

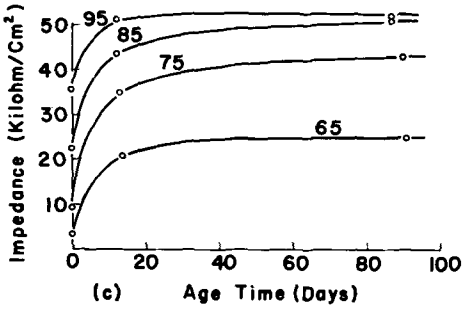

Fig. 14. Effect of aging on impedance values for coatings sealed at pH 6.0 for 30 min.

3. Aging (with sealed films only, not the case with unsealed films) does not alter the EGD test results, which would detect changes related to the barrier layer sealing transition, or inner seal effect.

4. Aging does alter (increase) the results of tests that are surface sensitive. The FACT test (dielectric breakdown in an acidic copper-containing electrolyte) is one such example (9).

5. While aging doubles the impedance value of sealed films, this effect may be virtually eliminated (and the impedance restored to approximately the initial value) by a brief exposure to a mildly aggressive environment (10). A few seconds in boiling distilled water, or immersion in room temperature dilute acid, will suffice.

It seems reasonable, therefore, to suggest that aging is a short-ordered effect that is of little consequence, when the anodic film is placed in a mildly aggressive environment where it is rapidly degraded. The effect of aging might be speculated to be equivalent to the formation of a thin film, from agglomerate particles. If such a filmlike thin layer were at the outer surface

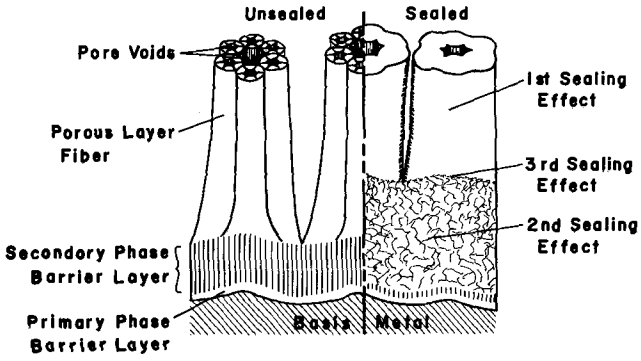

Fig. 15. Illustration of proposed sealing effects: 1st sealing effect [according to Wood et al. (11, 12)]: A pore closure mechanism that probably does not alter gross pore (large central pore) diameter to point of closure. Pores that are affected are micropore channels or permeable sites that lie within the fiber itself. 2nd sealing effect: An oxide transition, from barrier into porous layer oxide that results in a relatively impermeable gel formation at the base of the porous layer. 3rd sealing effect: A short-ordered thin film effect of glazing at the surface of the porous coating gel layer.

of the anodic coating, however, impedance values would likely have been increased far more than was observed; no more than a twofold increase was found on aging. By contrast, a thin oil layer at the outer coating suface raises impedance beyond the range of our instrument. Thus, instead of a surface condition, it seems reasonable to suggest that the aging effect might represent a coalescence of fibrils at the base of the porous layer, equivalent to a film at the surface of any agglomerate particles created by the inner seal effect.

A summary illustration of these sealing effects is shown in Fig. 15.

Side Reactions during the Anodization of Aluminum in a Glycol Borate Electrolyte

Robert W. Santway and Robert S. Alwitt*

Sprague Electric Company, Research and Development Laboratories, North Adams, Massachusetts 01247

ABSTRACT

A study of the anodization of aluminum in a glycol borate electrolyte at voltages sufficiently high for side reactions to occur, but below the sparking voltage, showed that the formation of barrier oxide was accompanied by solvent oxidation, aluminum dissolution, and production of a thick oxide that grew in cracks of the barrier film. Surprisingly, the presence of the crack network has little effect on electrical properties. It is believed that side reactions initiate at flaws in the barrier oxide.

In suitable electrolytes, anodic oxide films can be grown on metals such as aluminum or tantalum at 100% current efficiency. For an anodization at constant current a film thickness is finally reached, characteristic of each system, above which current is consumed in other anodic reactions and the rate of film growth decreases. Continued passage of current may ultimately result in sparking (scintillation) over the anode surface.

Some observations on the sparking process have been presented recently (1), but it is still not a well understood phenomenon. Little information appears to have been published on the processes preceding sparking (2). This region is of practical importance to the operation of electrolytic capacitors since the onset of side reactions limits the maximum voltage of these devices. In this paper we report our observations of the secondary reactions that occur at an aluminum anode in a glycol borate electrolyte. The nature of the reactions and their effect on surface morphology and electrical characteristics are considered.

This type of electrolyte was chosen for several reasons. It is typical of systems used in electrolytic capacitors. Oxide can be formed at 100% current efficiency and contains little incorporated matter from the electrolyte (3). For some electrolyte compositions there is a wide voltage range in which side reactions can be studied prior to the onset of sparking. A disadvantage of using this electrolyte is that the chemical species in solution are not well defined. Borates react with glycol to produce coordination compounds, esters, and water (4).

Experimental

Anodizations were performed in an electrolyte of 17.2 w/o (weight per cent) ammonium pentaborate ($NH_4B_5O_8 \cdot 4H_2O$) in ethylene glycol (17% APB-EG). High-purity (99.97%) aluminum foil and wire were used as anodes. These were prepared by chemical polishing in a HNO_3-H_3PO_4 mixture (15 ml of 70% HNO_3, 85 ml of 85% H_3PO_4) for 2 min at 85°C, followed by a 10-min etch in 1M NaOH at room temperature. Anodization was at room temperature at constant current densities in the range 0.1-1.2 mA/cm^2.

Series capacitance and RC of anodized foils were measured at several frequencies using a conventional resistance ratio arm bridge with an a-c signal less than 100 mV. Measurements were against platinized electrodes in either aqueous 0.8M H_3BO_3 with sufficient NH_4OH added to give a resistivity of about 225 ohm-cm, or aqueous ammonium formate with a resistivity of 10 ohm-cm (*ca.* 2*N*).

In some experiments gas generated at the anode was collected and analyzed in a dual column, programmed temperature gas chromatograph, using a molecular sieve column. Aluminum in solution was measured using a previously established photometric procedure (5).

Results and Discussion

Description of side reactions.—A typical voltage-time recorder trace is shown in Fig. 1. The voltage at which dV/dt started to decrease was little affected by current density. For example, in one experiment it was about 247V at 1.0 mA/cm^2 and increased to 260V when the current density was dropped to 0.10 mA/cm^2. Weight measurements showed that during the initial voltage rise all the charge can be accounted for by production of an anodic Al_2O_3 film. In the region of reduced dV/dt the following events were observed:

1. Sharp decreases in voltage accompanied by equally rapid return. The frequency and intensity of these excursions increased as the voltage increased.
2. Gas bubbles were evolved at points on the anode surface.
3. Weight measurements showed that anodic oxide was produced at less than 100% efficiency.
4. The anode surface appeared blemished. At low magnification it was seen that the oxide had cracked,

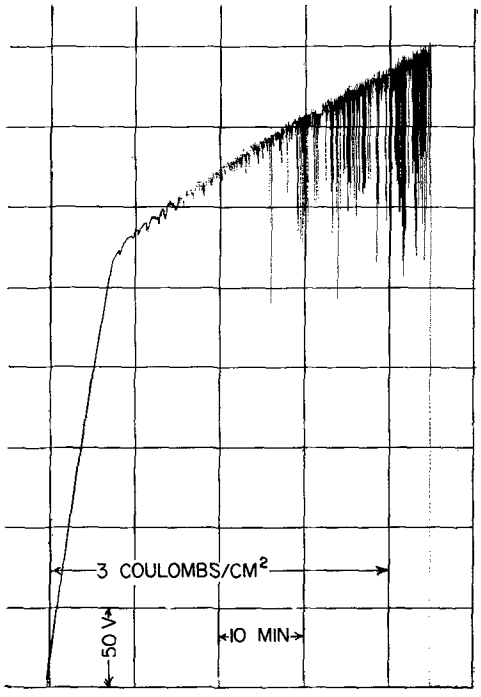

Fig. 1. Typical voltage-time trace for anodization in 17% APB-EG at 1.24 mA/cm^2.

* Electrochemical Society Active Member.

Key words: anodic oxides, aluminum, breakdown, electrolytic capacitors.

and in the cracks had grown a new solid many times thicker than the barrier film.

5. Analysis of the electrolyte showed the presence of dissolved aluminum.

6. The solution turned yellow and eventually sparking took place at about 450V.

These observations will now be described in more detail.

Gas evolution.—In a typical experiment, a current density of 0.33 mA/cm^2 applied overnight resulted in the production of a volume of gas equivalent to 0.013 ml/coulomb. Gas collection was halted prior to the onset of sparking. Analysis of the gaseous products from two experiments gave an average composition of 40% CO, 10% CO_2, and 50% H_2. The carbon monoxide and carbon dioxide must have been the products of glycol oxidation. The hydrogen did not come from the cathode compartment but was a true anode product. Since it could not be produced electrochemically at the anode, the hydrogen most likely was the result of some subsequent chemical reactions at the anode.

Cracks and new oxide growth.—Cracks in the oxide started at apparently random points on the surface and then spread in a network pattern. In Fig. 2a and 2b an early and a later state of crack development are illustrated. Examination of a number of specimens showed that in general crack initiation is not associated with grain boundaries of the substrate metal (6). Even after prolonged anodization the cracks never covered more than a few per cent of the surface.

The cracks were filled with a white solid many times thicker than the surrounding barrier oxide film. In the metal substrate was found a pattern of deep grooves identical to that of the cracks, suggesting that the new phase extended below, as well as above, the level of the original barrier film. The cracks were bounded by what appeared to be small tight cylinders of curled barrier film. The light outline of the empty cracks in Fig. 2c is believed to be an optical effect of this curled film.

No positive identification of the new solid material could be made. It was white, translucent, and gave no x-ray diffraction pattern. It was not soluble in some common organic solvents and heating for 2 hr at 900°C produced no change in appearance. We believe it to be an aluminum oxide. Perhaps it is similar to the material observed on aluminum after prolonged exposure to this 17% APB-EG electrolyte at high temperature (5).

An important observation was that during anodization gas bubbles were produced only at the tips of cracks. This indicates that the new oxide material was not a good electronic conductor, and that it maintained intimate contact with barrier film along the length of the cracks. It suggests that the secondary reactions took place only at the growing tip of a crack, a potentially complex region in which four phases could be in contact, viz., metal, barrier film, new oxide, and electrolyte.

Some of these observations are similar to those made by Vermilyea on the field crystallization of amorphous anodic Ta_2O_5 films (7). In that case, under the influence of a strong electric field, crystalline Ta_2O_5 nucleated at the metal/film interface, broke through the barrier film, and spread over the surface as irregular polygons until the amorphous film was completely replaced.

Dissolved aluminum.—During anodization up to about 250V no significant amount of aluminum was detected in solution. Coincident with a decreased dV/dt and the onset of gas evolution, the aluminum concentration began to increase uniformly with time. For a specimen that was anodized at 1.24 mA/cm^2, dissolved aluminum accounted for 10% of the charge passed following the onset of secondary reactions.

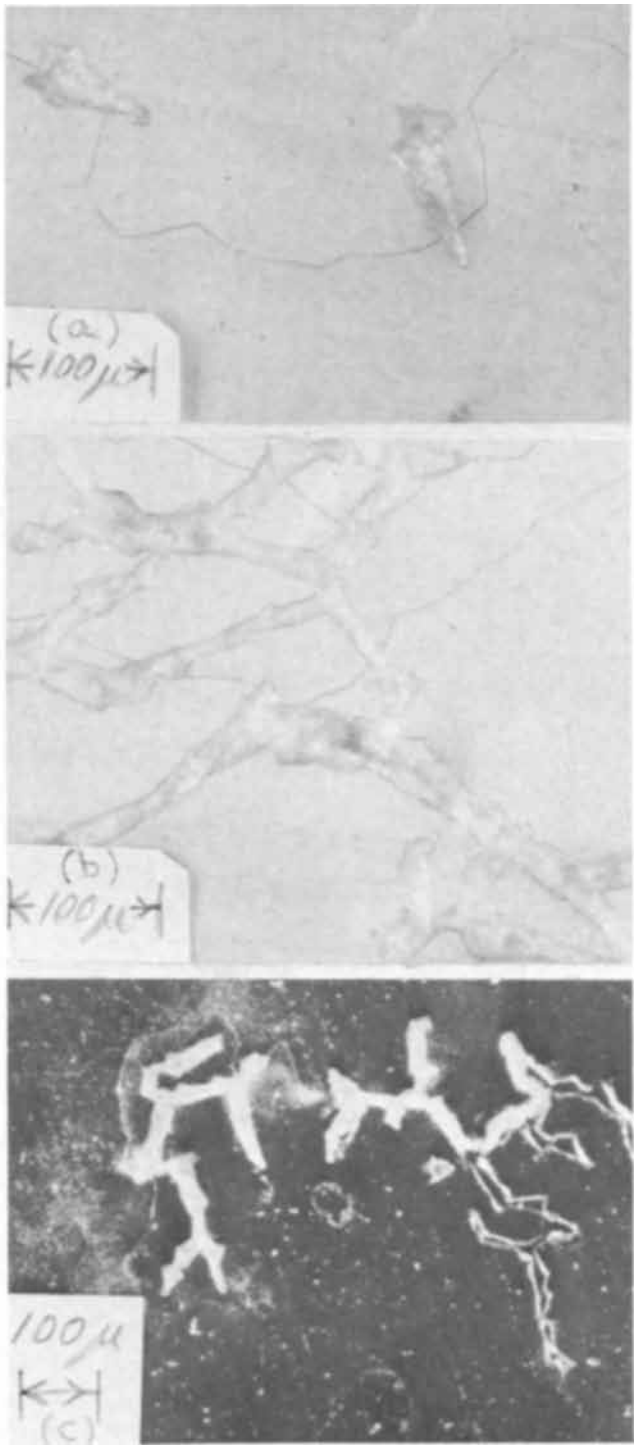

Fig. 2. Micrographs of Al foil anodized in 17% APB-EG at 0.27 mA/cm^2 to 320V. (a) Early state of crack development; (b) later state; (c) transmitted light through isolated oxide. Dark background is barrier film, white network is new oxide. Outlined pattern on right resulted from loss of new oxide during handling.

Distribution of aluminum oxidation reactions.—The amount of charge consumed in each of the aluminum oxidation processes (barrier film formation, new oxide growth, and metal dissolution) was estimated from measurements made on specimens anodized at 1.24 mA/cm^2. A typical voltage-time curve is shown in Fig. 1. The charge passed during the initial period of 100% barrier film production and the sample weight at the end of this period were measured. After further anodization the specimens were again weighed

and finally the weight was obtained after stripping oxide in H_3PO_4-CrO_3 solution. Oxide stripping was done in two stages, an initial room temperature immersion followed by one at 85°C. The new oxide was removed much more rapidly than the barrier film and the two materials could be easily distinguished at room temperature during a series of successive stripping measurements. The remaining barrier film was removed at 85°C. The weight of aluminum consumed in all oxidation reactions was determined as the difference between the specimen weight after stripping and the weight of base metal at the onset of side reactions. This latter figure was obtained by subtracting from the specimen weight at that point the calculated weight of anodic oxide produced at 100% efficiency.

The results are listed in Table I. The charge consumed in aluminum dissolution was taken as the difference between that calculated for metal consumption and that used in oxide formation. For the purpose of calculating charge consumption the thick oxide was assumed to be Al_2O_3.

It appears that these measurements were made in a region where the barrier film continued to thicken at a steady though reduced rate. This is indicated by the constant fraction of charge used for film formation. The weight of the new oxide was only about 4% of the total barrier film weight. The fraction of the surface covered by this material would be even smaller.

Other reactions.—The details of the glycol oxidation reactions resulting in CO and CO_2 production are not known, but the maximum charge consumed in these reactions was estimated by assuming that no more than three electrons were transferred per mole of CO and five electrons per mole of CO_2. From the volume and composition of gas collected it was calculated that these reactions could account for up to 9% of the charge passed in the region of low dV/dt. Since total metal oxidation accounted for less than 30% of the charge, clearly other anodic reactions took place.

In a recent study in our laboratory (8), Vijh found that in acidic aqueous solution the major products of glycol oxidation at a smooth Pt electrode were glyoxal and oxalic acid. The gaseous product accounted for only 1-2% of the total charge passed and was composed of roughly equal volumes of CO and H_2 with a slight amount of CO_2. The similarity in the compositions of the gas phases produced at the smooth Pt and the oxidized aluminum electrodes and the fact that in both cases the gaseous products accounted for only a small part of the total charge, suggested that at the aluminum electrode the remainder of the charge might be accounted for by production of glyoxal and oxalic acid. However, any glyoxal produced in the glycol borate electrolyte would be complexed by borate (9) and hence escape detection, and no test for carboxylates was found that was sufficiently sensitive in this solution. Thus, we were unable to verify the reactions that consumed more than half the charge passed during side reactions.

Effect of side reactions on electrical properties.—It was expected that the heterogeneous nature of the cracked oxide film would have a significant effect on dielectric properties. Young has suggested that the presence of fissures can be demonstrated by a dependence of impedance on measuring electrolyte resistivity (10). To investigate this, foil specimens were anodized in the 17% APB-EG electrolyte at 1.0 mA/cm² to several voltages up to 400V. At the higher voltages cracks had developed to a considerable extent. The series capacitance and resistance were measured at several frequencies in electrolytes with resistivities of 230 and 10 ohm-cm.

The frequency dependence of reciprocal capacitance and series resistance for a 400V specimen are shown in Fig. 3 and 4. The frequency dependence of $1/C$ was unaffected by electrolyte resistivity. Although a higher resistance was obtained in the low resistivity solution at low frequencies, the increase was small and no greater than was encountered with normal barrier films. Thus, at these ambient conditions there appeared to be no significant electrolyte penetration through the cracked areas.

Table I. Aluminum oxidation reactions during period of side reactions

Charge,* coul/cm²	Weights,* μg/cm² Barrier oxide	New oxide	Total Al consumed	Per cent of charge Barrier oxide	New oxide	Al diss.†	Total
1.59	45.7	4.2	37.3	16.3	1.5	7.4	25.2
2.02	56.1	5.8	51.8	15.7	1.6	10.1	27.4
2.51	73.2	6.2	69.6	16.6	1.4	11.7	29.7

* Measured from onset of side reactions.
† By difference.

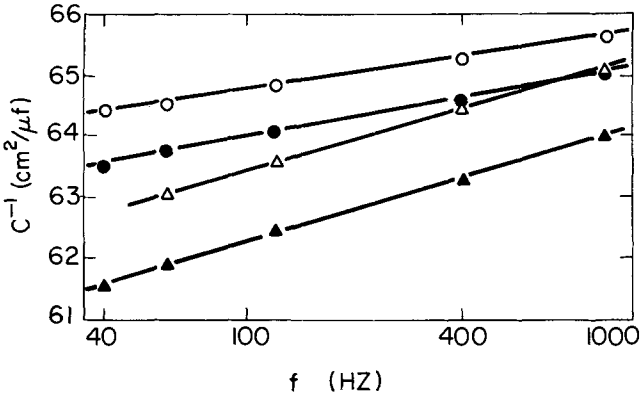

Fig. 3. Frequency dependence of series capacitance of 400V films formed in two electrolytes and measured in two solutions. Triangles = 17% APB-EG anodization; circles = 39% APB-EG anodization. Open symbols = 230 ohm-cm measuring solution; filled symbols = 10 ohm-cm measuring solution.

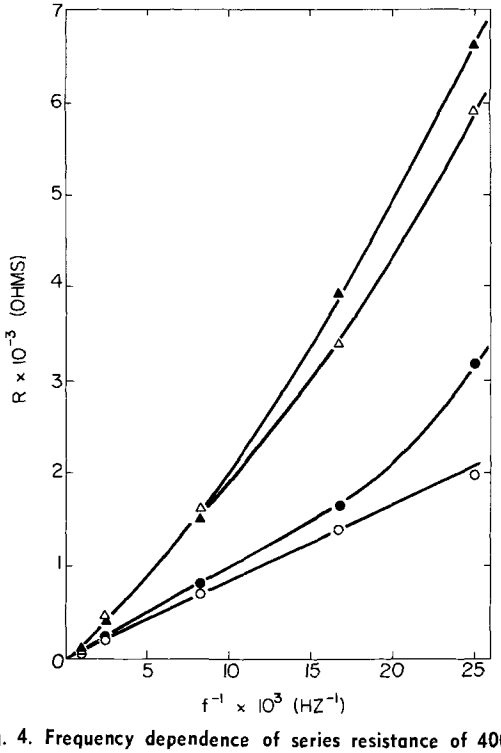

Fig. 4. Frequency dependence of series resistance of 400V films formed in two electrolytes and measured in two solutions. Same symbols as Fig. 3.

The presence of the new thick oxide within the cracks could make the film behave like a two-phase dielectric which might have different properties than a normal barrier film. To examine this, use was made of another glycol borate electrolyte. A solution of 39% APB in ethylene glycol will support anodization at 100% current efficiency up to 450V. Specimens were anodized in this electrolyte at 1.0 mA/cm^2 to 400V, forming barrier films free of cracks. The frequency dependence of these samples is also shown in Fig. 3 and 4.

A comparison of the results obtained with the cracked and crack-free oxides shows that the capacitance level of the films is about the same but the cracked film exhibits a slightly greater frequency dependence of capacitance and a much greater frequency dependence of series resistance. At the lowest measuring frequency the resistance of the film formed in 17% solution was more than twice that of the film formed in 39% electrolyte.

The effect of the crack network on leakage current was examined by comparing results obtained with films formed in the two electrolytes. Foils were anodized to 400V at 0.28 mA/cm^2 in both of the APB-EG electrolytes. The samples anodized in the 17% solution have well-developed cracks whereas those processed in the 39% solution were free of cracks. Leakage currents were measured in the 39% electrolyte at several voltages up to 350V. At all voltages, the leakage current decreased slightly with time for both sets of samples, and the current was somewhat lower for the cracked oxide. For example, after 3 hr at 350V the leakage current was 1.8 μA/cm^2 for the uniform film and 0.7 μA/cm^2 for the cracked oxide.

From the a-c and d-c properties it can be inferred that the oxide in the cracks is in sufficiently intimate contact with the barrier film to prevent electrolyte paths through the film. Also, the new oxide is an inferior dielectric, though a relatively good insulator.

Some details of anodization with side reactions.—An important observation was that when foils with uniform, thick (*e.g.*, 400V) films formed in the 39% APB-EG electrolyte were anodically polarized in the 17% solution, side reactions took place at voltages as low as 250V. After such treatment the appearance of thick films was the same as that of films grown in the 17% electrolyte (compare Fig. 5 with Fig. 2). Thus, side reactions in a particular electrolyte started at a voltage that was independent of film thickness. This is not an unusual observation, since many workers in this field have observed that anodization electrolytes appear to have a limiting voltage, as measured by leakage current, gassing, etc., that is not very dependent on barrier oxide thickness.

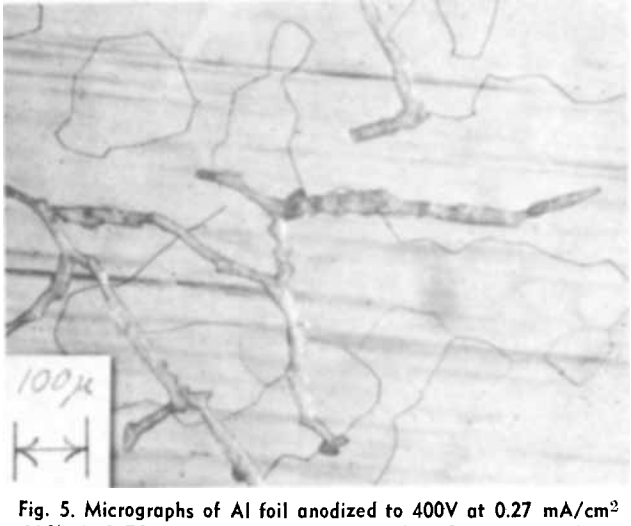

Fig. 5. Micrographs of Al foil anodized to 400V at 0.27 mA/cm^2 in 39% APG-EG and then held at 0.27 mA/cm^2 in 17% APB-EG for 140 min. Final voltage was about 300V.

The rate of the side reactions seemed to depend on film thickness and current density of formation. Foils were anodized in the 39% APB-EG electrolyte to three film thicknesses at each of three current densities. Reciprocal capacitance was the measure of film thickness. These specimens then were polarized anodically in the 17% electrolyte for 3 min at 350V. This was sufficient for new oxide growth to start at a number of points on the surface. The density of growth spots seen at 150X was taken as a measure of the extent of side reactions. The results are listed in Table II. Samples with the smallest initial film thickness had the greatest spot density. Moreover, the current density of film formation affected the extent of side reactions, with films formed at the lowest current density exhibiting the smallest amount of growth of new oxide. It should be noted that the initial films were all formed at 100% current efficiency, and bridge measurements showed no differences in dielectric properties among these samples other than those expected on the basis of film thickness.

The films formed in 39% APB-EG could be uniformly thinned in H_3PO_4-CrO_3 stripping solution at 85°C, as determined from the correlation between capacitance increase and weight loss. The films on some 400V specimens were thinned to approximate the thickness (weight basis) of 350 and 300V films. When these were immersed in 17% APB-EG electrolyte for 3 min at 350V the spot density was an order of magnitude greater than for comparable unthinned samples. The results are shown in Table III. It appears that chemical thinning exposed many points for subsequent side reactions.

Behavior of cracked oxides.—Some experiments were done using foil that was first anodized to produce a uniform film and then the oxide was cracked by bending the specimen. On re-anodizing such samples, three observations were made. First, any thick oxide growth was seen only within these cracks or in cracks that had obviously initiated at these induced cracks. Second, when re-anodization was done at constant current, thick oxide was observed only when the current density was relatively high. At low current densities the cracks appeared to be healed with normal barrier film, although voltage fluctuations accompanying this process indicated the possibility of other side reactions. For example, a 200V cracked film re-anodized to 200V in 17% APB-EG had thick oxide growth in the cracks when the C.D. was 280 μA/cm^2 (based on total area) but exhibited no signs of the new oxide when the C.D. was 28 μA/cm^2. This example also illustrates the third important observation. There was evidence of side reactions on these flexed specimens at voltages much lower than encountered during normal anodizations. In the above case, voltage fluctuations were observed at 75V when

280	385	3.300	327
280	325	2.838	838

* Thinned in H_3PO_4-CrO_3 solution.

the C.D. was 280 μA/cm^2 and at 120V when the C.D. was 28 μA/cm^2.

From these observations we infer that the growth of the thick oxide occurs preferentially in cracks and is promoted by high current density. Furthermore, under normal anodizing conditions cracks must not develop until high voltages are reached, for example, 250V in 17% APB-EG and 450V in 39% APB-EG.[1]

Conclusions

It is likely that the sites for the initiation of side reactions are flaws in the barrier oxide film similar to those found in anodic Ta_2O_5 films (11). Although direct evidence for this is lacking, it does seem significant that slight chemical thinning of the oxide resulted in an order of magnitude increase in subsequent growth centers (Table II). This corresponds to Vermilyea's observation that flaws in Ta_2O_5 films were preferential sites for chemical dissolution (11).

It would be expected that reactions at a cracked flaw would be like those at a crack produced by flexing in that the resulting high local current density would result in production of thick oxide rather than barrier film. This more voluminous oxide would cause a strain in the surrounding barrier film sufficient to crack the film and side reactions would then occur in this region. The cycle would continue until the crack reached a point where the growth of new oxide sealed off the tip of the crack before the strain in the surrounding barrier film produced further extension. It is believed that the immediate cause of the formation of thick oxide rather than barrier film is the occurrence of the glycol oxidation reaction. This parallel reaction might change the local electrolyte composition so that normal barrier film could not be produced.

The high degree of reproducibility of the voltage at which side reactions start is apparently a characteristic of the initial film fracture process. From the experiments with flexed specimens it is evident that side reactions can occur over a wide range of lower voltages if cracks are present. It is surprising that the critical voltage for side reactions was independent of average film thickness in these experiments. It is reported that flaw thickness increases less rapidly with formation voltage than does the average thickness (11). Perhaps some flaws reach a limiting thickness which is maintained as the formation voltage increases.

[1] Further support for this came from an anodization in the 39% solution which was followed with an oscilloscope set at a sweep rate of 50 μsec/cm and a sensitivity of 20 V/cm. No discontinuities in the voltage trace were observed up to 350V, at which point the anodization was stopped.

Reactions at flaws may play a role in all aluminum anodizations when the eventual decrease in current efficiency occurs. Other features of the present case, such as the development of a crack network, are probably specific to the particular system. For example, one can picture a side reaction in which no product is formed that affects the composition of the growing oxide. In that case barrier film formation and side reaction would proceed in parallel at the cracked flaw until film growth stifled the side reaction. The net effect would be growth of barrier oxide at reduced current efficiency.

Apparently the presence of the thick oxide network might not be objectionable in an electrolytic capacitor since it only affects the series resistance. It is the growth process which is undesirable in a device since it would give rise to high leakage currents and inability to support a steady voltage. Moreover, the gas generated at both anode and cathode during side reactions would contribute to other failure modes (12).

Acknowledgments

The authors are grateful to Mr. J. Barry for performing the gas analyses and to Mrs. E. Vigna for obtaining many of the laboratory results reported here.

Effects of Material and Processing Parameters on the Dielectric Strength of Thermally Grown SiO_2 Films

N. J. Chou and J. M. Eldridge

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The influence of several material and processing parameters on the dielectric strength of thermally grown SiO_2 films on silicon has been assessed. This was accomplished by statistically analyzing the breakdown characteristics of a large number of MOS capacitor structures, which had been fabricated in various ways. Although the results of this investigation are only qualitative, they clearly demonstrate that the effective breakdown strength of these films is strongly dependent on: SiO_2 purity, structural perfection and thickness; the presence of a passivating phosphosilicate glass layer; the presence and reactivity of the metal electrode; and, the duration of the post-metallization heat treatment. The morphology of certain micron-size defects which develop in the MOS structure during annealing is described in some detail, since these faults are apparently responsible for oxide shorting in some instances.

Since the oxide layer under the gate electrode in MOSFET's is subjected to very large electric fields (up to 2 MV-cm^{-1}), its dielectric strength has an important bearing on the reliability of these devices. Although interest in electrical breakdown phenomena in such films has increased in recent years, along with the rapid development of MOSFET technology, the effect of various process and material variables on the effective dielectric strength of thermally grown SiO_2 films has not yet been well characterized. This is due to the extreme sensitivity of this property to changes in oxide composition and structure, which are, in turn, quite dependent on device fabrication procedures. An additional uncertainty is introduced by the dependence of the breakdown characteristics on the particular testing technique employed.

The dielectric strength of thermally grown SiO_2 has been reported by Deal (1) to increase with the density of the insulating film, going from 4.8 to 5.5 MV-cm^{-1} as the density was raised from 2.04 to 2.22 g-cm^{-3}. Breakdown strength values of 4 to 6 MV-cm^{-1} for 2000Å thick SiO_2 films on silicon were found by Ainger (2), who also observed that lower values were encountered on oxide films grown on more heavily doped, p-type silicon. A more thorough investigation of breakdown phenomena in Al-SiO_2-Si structures has been made by Klein (3,4), who found that a succession of breakdown events could be initiated at low fields (< 2 MV-cm^{-1}) when the applied voltage was slowly increased. These events produced visible spark discharges which created individual macroscopic holes in the capacitor, due to localized evaporation of oxide and metal. Such events were labeled "single-hole" or "self-healing" because the test capacitor was still operational after they occurred. When the applied field reached the 5 to 9 MV-cm^{-1} range, the dielectric failure was accompanied by arcing or by propagation of single-hole events to adjacent sites. This resulted in permanent destruction of the capacitor. Consequently, Klein's data indicate that the effective breakdown strength of SiO_2 films does not have a well-defined value but increases as the weak spots in the oxide are eliminated by continued testing, until the ultimate value (in the range, 5 to 10 MV-cm^{-1}) is reached. It should be noted that this range of ultimate strength values is appreciably higher than those observed in earlier studies where unspecified measurement and testing techniques were employed (1, 2).

Key words: dielectrics, dielectric strength, MOSFET devices, morphology of SiO_2.

In a different approach, Fritzsche (5) examined the statistical distribution of breakdown strength values of a large number of Al-SiO_2-Si capacitors. Here, the breakdown field was taken as the value at which the first breakdown event occurred in a capacitor, self-healing or otherwise. His results are typically shown in Fig. 1, where the fraction ($\Delta N/N$) of capacitors tested, which break down in a small interval of field, is shown as a function of the corresponding field. Maxima were observed which consistently fell into three ranges: 0-0.6, 1-3, and 7-9 MV-cm^{-1}. According to Fritzsche: the peak labeled "primary" represents the intrinsic (or electronic) breakdown strength of the oxide; the "secondary" one is attributable to the presence of small, randomly distributed, crystallized regions (structurally similar to quartz, too minute to be detected by conventional techniques but large enough to cause breakdown by serving as flaws in the otherwise amorphous dielectric); and the "tertiary" to the effect of gross structural defects such as pinholes. Note that the primary strength corresponds to the ultimate dielectric strength values reported by Klein and his co-workers (3, 4). Fritzsche's interpretation was supported by the following observations: (*i*) the temperature dependences of the primary and secondary peak positions are similar to those of amorphous silica and crystalline quartz, respectively; (*ii*) as-grown anodic SiO_2 is amorphous and fails to exhibit a secondary-type peak until it has been subjected to heat treatment probably capable of inducing recrystallization; (*iii*) the tertiary failure mode is promoted by mechanically damaging the oxide; and (*iv*) the expected random nature of oxide defects can be inferred by the increase in secondary and tertiary breakdown with the electrode area (5).

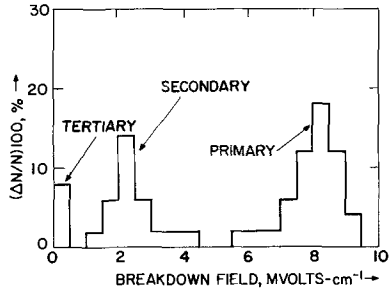

Fig. 1. Typical breakdown strength distribution curve for Al-SiO_2-Si (after Fritzsche).

Fritzsche found that the primary mode of breakdown in SiO_2 was electronic in nature, thus exhibiting no dependence on the duration of the applied field. In contrast, Worthing (6) found that when a constant, positive voltage was applied to the metal for the time required to cause breakdown, the breakdown field of SiO_2 films on n-type, degenerate Si was proportional to $(\text{time})^{-1/4}$. This particular time dependence has been frequently observed for bulk insulators where it is known as Peek's law (7). This has the effect of lowering the dielectric strength of the SiO_2 film from 6.7 MV-cm^{-1} for fast stressing rates to approximately 3 MV-cm^{-1} for a testing voltage applied at an infinitely slow rate. However, no time dependence was observed by Worthing when the metal was negatively biased.

The present investigation was undertaken to ascertain the influences of various processing and material parameters on the dielectric strength of oxide films and to resolve the apparent differences in the findings of some of the above investigations. An attempt was made to separate the effects of these variables, in view of the fact that they were found to interact frequently to alter the breakdown characteristics. Since the breakdown behavior is also affected by measurement technique, this separation was facilitated by employing a standardized testing procedure. The statistical approach (5) was then utilized to evaluate the dependence of the dielectric strength of the thermally grown oxide on SiO_2 purity and thickness, phosphosilicate glassing, electrode metal reactivity, and post-metallization heat treatment. Although most of the results of this investigation are of a semiquantitative nature, many of these will be seen to be quite relevant both to the development of MOSFET technology and to the understanding of the mechanism of oxide breakdown.

Experimental Procedure and Results

Specimen preparation.—Various types of oxide films were prepared in the following ways on Monsanto chemically-mechanically polished, <100>- and <111>-oriented silicon substrates of 2 to 10 ohm-cm resistivity.

"Regular" SiO_2 preparation.—The as-received substrates were cleaned in transistor grade reagents according to the following sequence: boiling trichloroethylene, boiling isopropyl alcohol, de-ionized (DI) water, boiling nitric acid, DI water, dilute hydrofluoric acid, DI water, and blown dry in N_2. Thermally grown SiO_2 films of so-called "regular" quality were formed with the desired thicknesses (in the 200-2000Å range) at 1100°C in a single-walled, high-purity silica tube in a resistance-heated furnace. As will be seen later, SiO_2 films prepared in this manner under normally clean laboratory conditions have quite reproducible dielectric breakdown characteristics and, as such, provided a convenient reference material for this investigation; hence, they have been designated to be of "regular" quality. The mobile cation (presumably Na^+ ions) concentration of such films, as established by measuring the flat-band voltage shift upon bias-temperature stressing (8), was typically $\sim 2 \times 10^{11}$ Na^+ ions-cm^{-2}. It should be emphasized that this concentration (assuming the mobile species is Na^+ ions) represents only a fraction of the total sodium content of the oxide (9).

"Ultraclean" SiO_2 preparation.—Ultra-pure SiO_2 films were prepared also by using extremely clean conditions. The silicon substrates were vapor-etched first in a very pure and dry HCl-H_2 ambient, followed by an *in situ* oxidation at 1100°C in dry O_2. Heating was accomplished using a silicon carbide-coated graphite susceptor placed inside a water-cooled, fused silica jacket. The mobile cation concentrations of these films was established to be $\lesssim 2 \times 10^{10}$ cm^{-2}; *i.e.*, about an order of magnitude less than that of "regular" SiO_2.

Phosphosilicate glass preparation.—Other specimens were prepared by alloying the surface of "regular" SiO_2 with P_2O_5 to form phosphosilicate glass (PSG)-SiO_2 layered structures. These glass films were typically thin and relatively low in phosphorus content [*e.g.*, 125Å thick with 4 m/o (mole per cent) P_2O_5] (10). Since these thin PSG-SiO_2 composite layers are particularly effective for preventing threshold drifts in MOSFET devices (11-13), such structures are termed "stabilized" in this paper.

Metallization and annealing.—Sixty-four metal electrodes of a given area (in the range 0.05-1.3 mm^2) were deposited through metal masks onto each wafer. The high purity metals (99.999+% aluminum, for example) were evaporated, using an electron gun heat source. Finally, the completed structures were heated for 5 min at 500°C in a nitrogen ambient in order to anneal out the E-gun induced radiation damage at the oxide-semiconductor interface. Any departures from the above preparation procedures will be detailed when necessary.

General testing procedure.—In order to select appropriate breakdown testing conditions, the following series of measurements were carried out on Al-SiO_2 (1000Å, regular)-Si structures. Large numbers of capacitors (typically 100 to 200 samples) were tested by applying a voltage, which was made to increase linearly with time, to each electrode until breakdown (self-healing or otherwise) occurred. In this technique, the development of breakdown causes the appearance of an abrupt departure from linearity in an otherwise smooth voltage *vs.* time trace. The breakdown field is evaluated at this point which corresponds to a current density on the order of approximately 10^{-6} A-cm^{-2}. The resultant breakdown distributions were then displayed as bar graphs, wherein those fractions ($\Delta N/N$) of capacitors failing in a small interval (0.5 MV-cm^{-1}) of field are plotted against the corresponding breakdown fields.

Electrode area.—Typical breakdown distributions for regular SiO_2 films are shown in Fig. 2, where it may be seen that the secondary failure mode increases with electrode area (F). As shown in the Appendix, the oxide defect concentration can be estimated from this areal dependence. When this is done, a value of ~10 defects-cm^{-2} is obtained, which is significantly lower than the estimated value (~80 cm^{-2}) (5) for the SiO_2 film shown in Fig. 1. In view of their better perfection, it is not surprising that the films in Fig. 2 do not show a tertiary peak. In general, the 0.5 mm^2 electrode seems to provide a useful reference distribution for further work because the secondary failure mode is significant with this area although most of the breakdown is still intrinsic.

Field application rate.—Both the intrinsic strength and the mode of breakdown of 1000Å, regular SiO_2 films are unaffected by decreasing the rate of field application over the range from 1 to 0.01 MV-cm^{-1}-sec^{-1}. Only for films with much higher defect con-

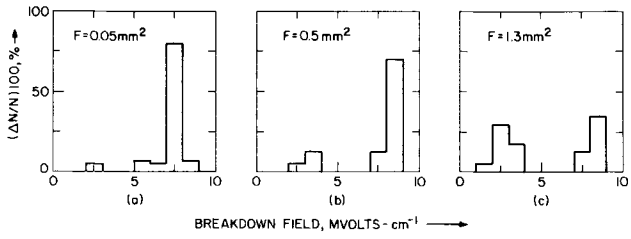

Fig. 2. Area dependence of the breakdown strength distribution for regular oxide in Al-1000Å SiO_2-Si structures.

centrations (>90 defects-cm^2) was a significant shift of the primary peak toward lower field values observed to occur with decreasing ramp speed. We believe that this effect of defect concentration on the rate dependence of breakdown strength may account for the discrepancy between the findings of Fritzsche (5) and Worthing (6). However, the relationship between the extent of this shift and the ramp speed (or biasing time) was not established in the present investigation because this would have required the preparation of oxide films with reproducibly high defect densities. Since the specimens to be tested were of a lower defect density, it was feasible to use the highest ramp speed tested (*i.e.*, 1 MV-cm^{-1}-sec^{-1}) in order to minimize the measuring time.

Temperature.—A limited amount of testing indicated that the statistical distributions of breakdown strengths were relatively insensitive to changes in the testing temperature, in the 25°-150°C range, for regular oxide and for phosphosilicate glass-SiO_2 composite layers. Hence, all subsequent measurements were done at room temperature.

Polarity.—In order to avoid loss of field across a depletion region in the semiconductor, breakdown measurements in this investigation were carried out with a field polarity such that an accumulated silicon surface was always maintained.[1] This was accomplished by biasing the metal positively for n-type and negatively for p-type substrates. When breakdown data were taken under this polarity restriction, the distribution curves for the Al-SiO_2 (1000Å, regular)-Si structures showed no significant dependence on the duration of the applied field.

Effects of material and processing parameters on oxide breakdown.—Type of oxide film.—In contrast with that observed for regular oxide films, the breakdown distribution curves for ultraclean SiO_2 exhibited no measurable areal dependence (*cf.* Fig. 2 and 3a). Although the intrinsic strengths of both grades of SiO_2 are the same (*i.e.*, 6 to 9 MV-cm^{-1}), the higher purity films exhibited no noticeable defect-related breakdowns. It is important to note that when HCl vapor-etched Si substrates are thermally oxidized in a resistance-heated, fused silica tube, the resultant breakdown properties are generally quite similar to those of regular oxide. These results suggest that the lower impurity (most likely sodium) concentrations that are typically attained in the oxidation step of the ultraclean processing procedure lead to superior SiO_2 breakdown characteristics. To understand this impurity effect, it may be instructive to note that the structure of thermally grown SiO_2 is apparently quite similar to that of fused silica. That is, it is comprised of SiO_4 tetrahedra (with Si^{+4} ions in their centers) which are linked together at the corners or oxygen sites to form a three-dimensional network essentially devoid of long-range order. Although phase transformations are very sluggish in this oxide, they are greatly accelerated by the addition of small quantities of network modifiers, such as sodium (14). For example, sodium contamination has been reported (15) to result in the formation of locally crystallized regions in thermally grown SiO_2 films, thereby causing defect-related breakdown. Depending on the magnitude of this phase transformation, it should first appear as an increase in secondary breakdown [in accord with Fritzsche's model (5)] and eventually as a rise in the incidence of tertiary oxide failures. It will also be seen that shorting can develop as a result of a solid state reaction between the metal electrode and the oxide during post-metallization annealing.

In the case of PSG-stabilized specimens, the glass addition was found to virtually eliminate defect-type breakdown in regular SiO_2, and to raise its primary strength to 9-12 MV-cm^{-1} (*cf.* Fig. 2 and 3b). The first improvement may be accounted for by the fact that the phosphosilicate layer is liquid at its temperature of formation (10, 16), and therefore would form a continuous film over the underlying SiO_2. The second beneficial effect can be largely attributed to the higher dielectric strength of the PSG itself (17).

Oxide thickness.—For regular and stabilized films prepared with various total oxide thicknesses (in the 200-880Å range), the likelihood of defect-related breakdown was found to increase appreciably with decreasing insulator thickness (see Fig. 4). The addition of a PSG layer is again seen to substantially reduce the frequency of defect-related breakdowns.

A quantitative determination of the oxide defect density (ρ, cm^{-2}) was carried out for the data in Fig. 4. The predicted proportionality between ln P (P being the fraction of primary breakdowns) and F was obtained for several thicknesses (Fig. 5). The apparent departure from linearity for the 200Å, regular SiO_2 at the largest electrode area may be due to the use of too small a sampling. Defect densities of the films were estimated from the slopes and are listed in Table I. It may be seen that the density of defects of regular SiO_2 increases by a factor of approximately sixty as the thickness is reduced from 630 to 200Å.

The enhancement of the intrinsic strength by PSG is again evident in Fig. 6. The rise in dielectric strength, on going from 880 to 410Å, can be attributed to the relative increase in the PSG-to-SiO_2 thickness ratio. However, the primary breakdown strength for both oxides decreases significantly for thinner (< 400Å) films and shows a marked dependence on area, in contrast to the thicker oxides. Thus, the

[1] Numerous comparative tests have shown that inflated values of dielectric strength are obtained when Si surfaces are depleted during breakdown measurement since part of the potential drop occurs in the semiconductor.

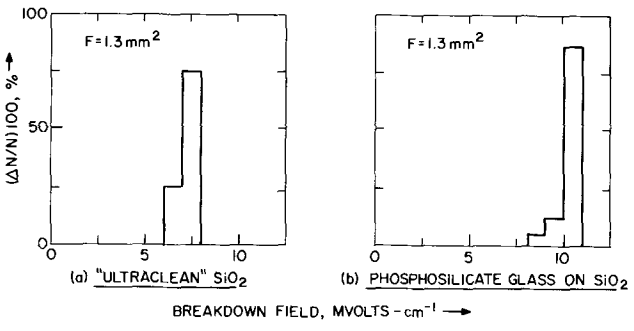

Fig. 3. Dielectric strength distributions for: *(a)* Al-SiO_2 (1000Å, ultra-clean)-Si; and *(b)* Al-PSG (125Å, 4% P_2O_5)-SiO_2 (900Å, regular)-Si structures. Note absence of defect-related breakdown in both oxides.

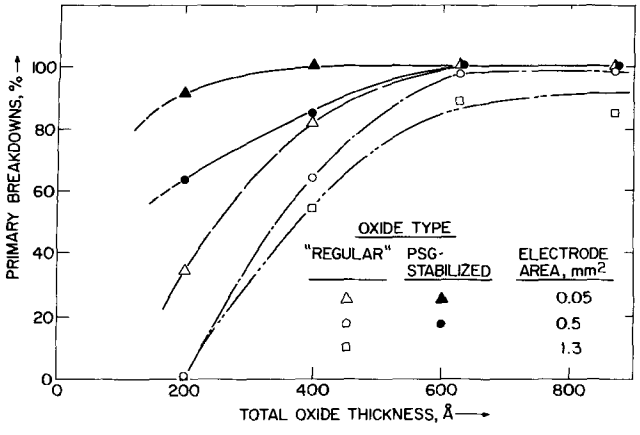

Fig. 4. Dependence of breakdown mode for regular and phosphosilicate glassed oxides on thickness. Note that the PSG addition is relatively most beneficial for the thinnest films.

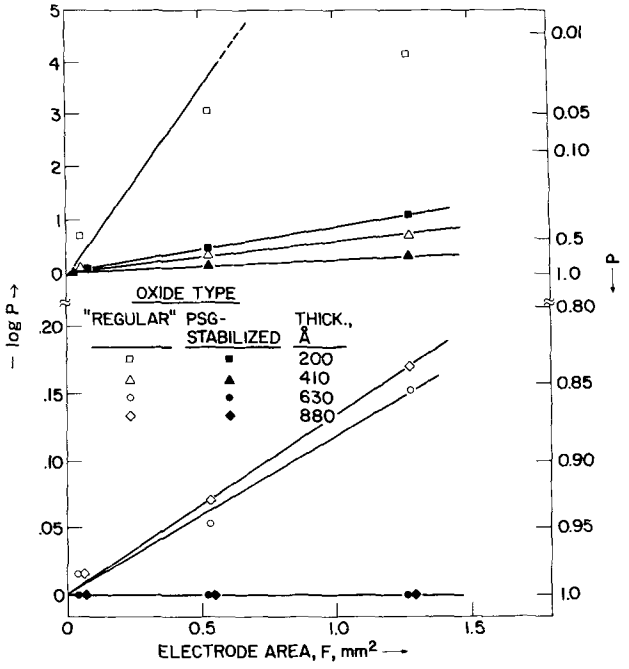

Fig. 5. Dependence of the fraction (*P*) of the total film area exhibiting primary breakdown on insulator thickness and electrode area for regular and phosphosilicate glassed oxide.

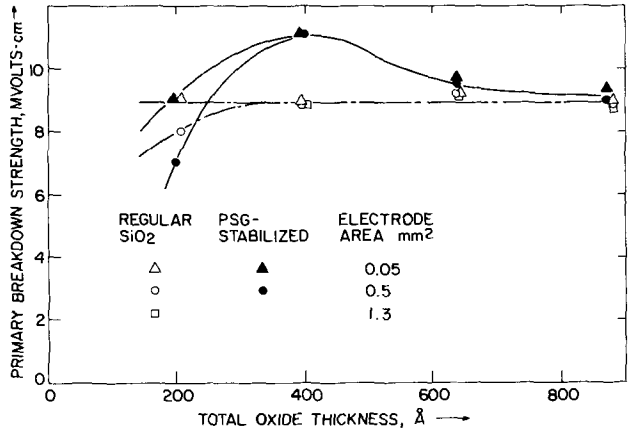

Fig. 6. Dependence of primary breakdown strength on total thickness of regular and phosphosilicate glassed SiO_2 films, where the thickness of the PSG layer is held constant at 125Å. Note that this strength is independent of electrode area, except for films thinner than 400Å.

mechanism responsible for primary-type breakdown is apparently no longer electronic in nature for these highly defected, very thin films. This change is consistent with the development of field-induced thermal instabilities at weak spots (3,4) and may well give rise to a time-dependence of the strength (6).

Impurities introduced after formation of SiO_2.—Protracted, post-metallization annealing treatments (viz., on the order of 30 min at 500°C) can promote extensive, tertiary-type breakdown (18) (see Fig. 7). The catalytic effect of certain cationic impurities in accelerating the devitrification of SiO_2 (14, 15), prob-

Oxide \ d, Å / ρ, cm⁻²	200	410	630	880
"Regular" SiO_2	750	65	12	12
PSG-stabilized	120	30	<1	<1

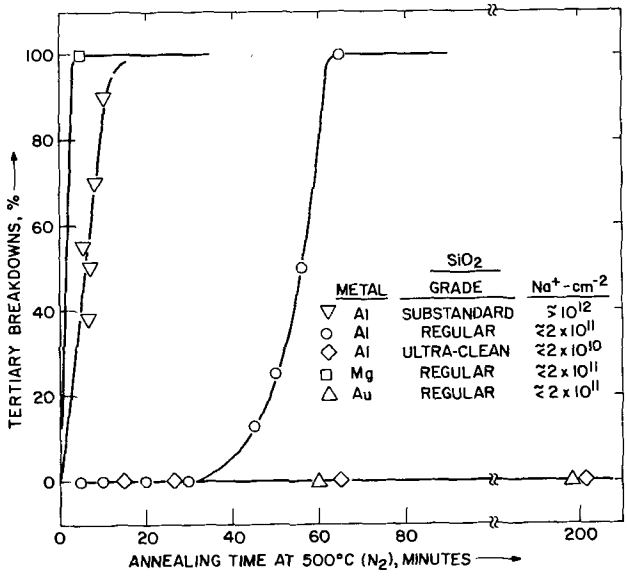

Fig. 7. Combined effects of electrode metal reactivity and post-metallization annealing on the development of electrode shorts in metal-1000Å SiO_2-Si structures, where the purity of the oxide is varied.

ably accounts for most of this behavior since it is most severe for films grown with a high sodium content and when highly reactive metal electrodes are used. In fact, electrical shorts (*i.e.*, tertiary breakdown) were rarely observed in oxide areas that were not covered by metals, or when noble metal electrodes such as gold were used, even after many hours of heating at 500°C. Mechanical stresses, arising from steps in the oxide thickness or from differences in the thermal expansion coefficients of the components on the MOS structure, may also contribute to oxide deterioration. Protracted annealing at 500°C also results in the growth of gross structural defects, under the edge of the metal electrode (18), which are probably responsible for the shorting. This particular type of tertiary failure mode will be described later.

The role of the metal electrode on the development of tertiary breakdown in stabilized film was evaluated by depositing 0.5 mm² dots of several metals on PSG (125Å, 4 m/o P_2O_5)-SiO_2(900Å, regular)-Si substrates, followed by determinations of the statistical breakdown distributions in both the unannealed and annealed (100 min at 500°C in N_2) conditions. From the results in Fig. 8, it is apparent that Mg, Ti, and Ni markedly promote oxide failure, while Al and Au have essentially no effect for PSG-stabilized struc-

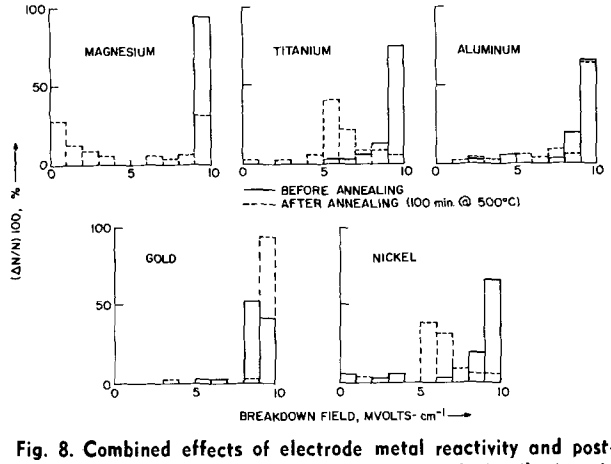

Fig. 8. Combined effects of electrode metal reactivity and post-metallization annealing on the breakdown strength distributions in PSG-stabilized, 1000Å oxide films.

tures. A comparison of the results for aluminum electrodes on regular and PSG-stabilized SiO_2 indicates that the PSG layer has the effect of retarding the development of electrical shorts due to extended annealing treatments. This retardation effect of the glass is more pronounced for structures with magnesium electrodes (*cf.* Fig. 7 and 8).

It is well-known that impurity ions can be introduced into the oxide in ways other than by electrode-oxide interactions. Thus, it is important to evaluate the possible effects of this type of contamination on breakdown. It was found in this investigation, for example, that when sodium (in concentrations of approximately 5 x 10^{12} cm^{-2}) was added after oxide formation (by boiling the oxidized wafers in NaCl-H_2O solutions prior to aluminization), relatively little additional deterioration was observed relative to the untreated, regular SiO_2 control material, for heating times up to approximately 50 min at 500°C. Therefore, it would appear that Na^+ ions which are introduced after SiO_2 formation, do not have much of an effect on crystallizing the oxide during subsequent post-metallization annealing at these temperatures.

In order to investigate the effect of localized damage in the insulator and at the insulator-semiconductor interface on tertiary breakdown, ultraclean SiO_2 films were irradiated with various O^+ dosages (using a constant beam energy of 75 keV). After deposition of 0.5 mm^2 Al dots, the capacitors were annealed for various times at 300°C in N_2 and tested in the usual way. Although the unannealed specimens exhibited the usual primary strength and essentially no indication of oxide deterioration, extensive shorting appeared after a very modest anneal of 20 min at temperatures as low as 300°C (see Fig. 9). Oxide failure was markedly increased by a small rise in the O^+ dosage and by a reduction in the oxide thickness. As in the earlier cases, oxide deterioration is intimately related to the presence and reactivity of the metal electrode. That is, electrical shorts were not observed in areas not covered by metal during heating [as subsequently established by using a removable mercury probe (19)] or when deposited gold electrodes are used. The network damage, due to implantation, apparently accelerates the metal-oxide reaction, thereby promoting shorting (18).

Glassing of Na^+-contaminated SiO_2.—Since sodium can be introduced inadvertently into SiO_2 during MOSFET processing before the PSG protective layer is added, it is very important to know what such contamination can do to the dielectric strength of the resulting layered oxide. This is of particular concern

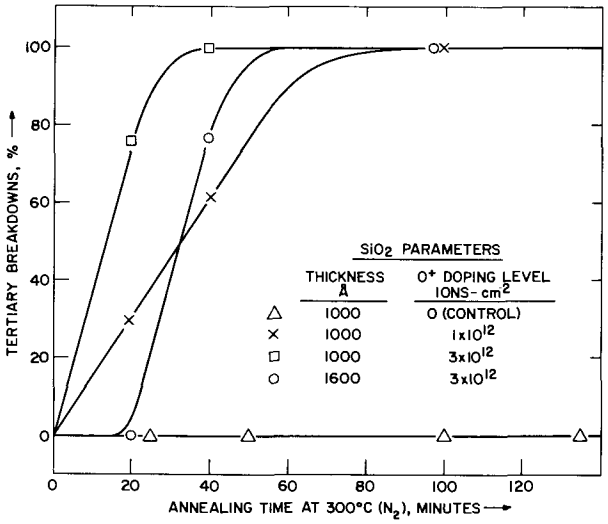

Fig. 9. Development of electrical shorts on annealing at 300°C in ultra-clean SiO_2 films, implanted with various O^+ ion dosages.

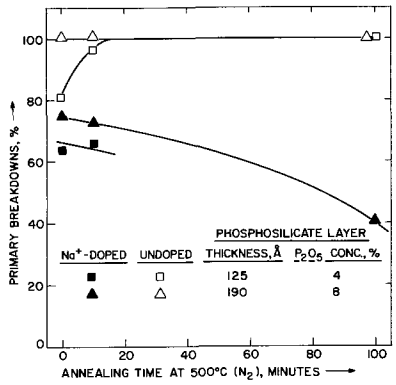

Fig. 10. Effect of post-metallization annealing on the breakdown characteristics of 1000Å SiO_2 films, deliberately contaminated with sodium, prior to phosphosilicate glassing. Characteristics of uncontaminated films are included for comparison.

because the glassing is carried out at temperatures, (800°-1100°C) where the promotion of crystallization by sodium is at a maximum (14). Therefore, the breakdown distributions were determined for oxide films prepared by: (*i*) growing 1000Å SiO_2 films of regular quality, (*ii*) immersing these oxidized substrates for 15 min in boiling NaCl-H_2O solutions to incorporate Na^+ ions in the oxide (8), (*iii*) diffusing P_2O_5 into the outer SiO_2 surfaces (at 800°-1000°C) to form phosphosilicate films, (*iv*) depositing 0.5 mm^2 aluminum dots, (*v*) annealing at 500°C (N_2) for various times, and (*vi*) breakdown testing. The severe deterioration of oxide quality due to Na^+ contamination is quite apparent in the results shown in Fig. 10. Experiments on regular SiO_2 films, subjected to the salt-water and subsequent high-temperature treatment (30 min at 1000°C in O_2) before aluminization, indicated that this oxide exhibited much more deterioration than the glassed ones. It may be concluded that even the addition of a PSG layer cannot prevent the formation of oxide faults at high temperatures when appreciable sodium concentrations are present in the SiO_2.

Morphology of annealing-induced defects.—The gross structural features of large defects, produced by extended annealing of Al-SiO_2-Si structures (see section on Impurities introduced after formation of SiO_2), are described below. It may be seen that these defects are quite massive, relative to the thickness of the insulating film. As such, they are probably mainly responsible for most of the tertiary breakdowns, even for the case where the capacitors have been subjected to a normal post-metallization heat treatment (*e.g.*, 5 min at 500°C).

Metallographic examination of shorted capacitors reveals the presence of well-defined, oriented defects on the periphery of the aluminum. Although partially covered by metal, their shapes are clearly rectangular and triangular for <100>- and <111>-oriented silicon, respectively, while their sides coincide with the (110) family of directions in the substrate. Evidently, the heating required to produce such defects decreases with a lowering of oxide perfection. Thus, they are readily visible at 500X magnification after an hour of annealing 1000Å, regular SiO_2 capacitors at 500°C, and ion-implanted oxide at 300°C. While becoming larger and more numerous with annealing time, they only develop under or in close proximity to reactive metal electrodes. The defects do not appear in regions away from the aluminum, for example, or in gold-deposited capacitors.

Conventional collodion replicas were made of the oxide surface for examination by electron microscopy, after removing the aluminum in a dilute HCl etchant. For specimens previously subjected to severe annealing treatments for aluminized structures (*e.g.*, ~ 2

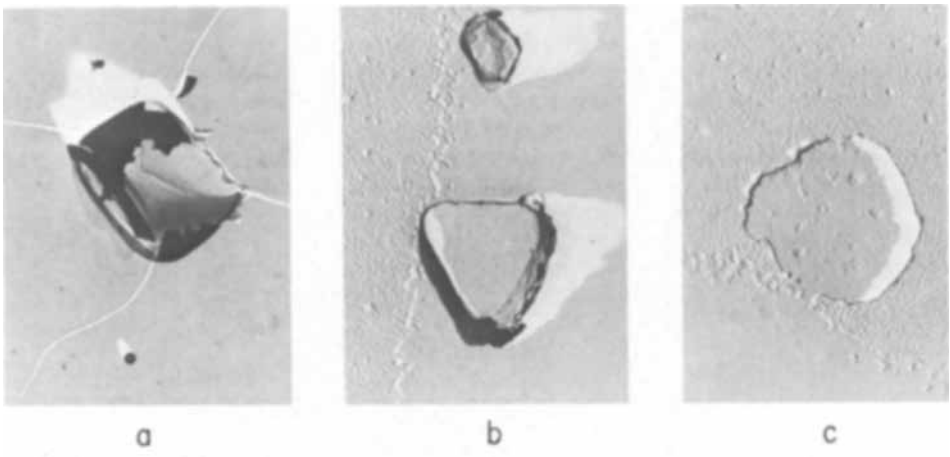

Fig. 11. Electron microscope replicas (at 9000X) of gross defects, developed in Al-SiO_2-Si structures during protracted annealing, as they appear after the aluminum is etched off. (a) and (b) show the faceted pits developed in <100>- and <111>-oriented Si, respectively, where pit sizes can be compared with that of ½μ latexsphere visible in (a). A typical, irregularly shaped raised area in the substrate is shown in (c).

hr at 500°C), the metallized oxide region was readily discernible, since considerable surface roughening had occurred as a result of a solid state reaction between the SiO_2 and Al. Electron micrographs of the replicas show that these defects are faceted pits, 1-10μ on a side and extending 1-2μ into the silicon (see Fig. 11a and b). With the aluminum removed, it was apparent that the pits are preferentially located along the perimeter of the metallized region, rather than in the center. Based on crystallographic considerations, it is evident that the facet faces are (111) planes.

Black films line the (111) faces of the pits. Since this material adheres to the collodion, it was possible to identify it as γ-Al_2O_3, using electron diffraction and microprobe analyses. Electron microprobe measurements, on specimens still covered with aluminum (*i.e.*, unetched), indicated that the faceted pits are filled with metallic aluminum, while the adjacent electrode region is depleted of metal. Finally, large irregularly shaped plateaus (approximately half a micron high) were frequently observed to occur in the substrate, adjacent to the pits (see Fig. 11c). Thus, the growth of pits and plateaus in close proximity and the presence of γ-Al_2O_3 in the pits suggests that a rapid transfer of mass occurs during annealing. It appears that silicon atoms can diffuse away from the receding faceted planes to form raised areas in the substrate covered by aluminum, while aluminum can penetrate the relatively thin oxide barrier to fill the γ-Al_2O_3 lined pits in the silicon. It is expected that large flaws in the oxide layer would also result from the development of the plateau regions. One effect of this mass rearrangement is the appearance of extensive shorting in MOS structures subjected to severe post-metallization heat treatments. As such, it constitutes another mode of tertiary failure, in addition to the presence of pinholes which develop during oxide growth.

Summary

Electrical breakdown characteristics of SiO_2 films thermally grown on silicon have been found to depend strongly on oxide preparation and various subsequent treatments:

1. While a lowering of the concentration of mobile impurities reduces the occurrence of defect-related breakdowns, it does not change the magnitude of the intrinsic breakdown strength of SiO_2. Appropriate phosphosilicate glassing, on the other hand, not only effectively obliterates oxide defects but also raises the intrinsic strength of the composite films.

2. Under identical SiO_2 growth conditions, reduction of film thickness is accompanied by an increase in the density of oxide faults. Excessively high defect density in the oxide gives rise to a time dependence of the breakdown characteristics and can therefore lower the magnitude of the primary breakdown strength under certain testing conditions. The addition of a PSG layer removes this dependence by eliminating the effect of oxide weak spots on breakdown. The amount of glassing required for this purpose is greater for SiO_2 films which have initially a higher defect density.

3. Sodium contamination can result in severe oxide deterioration, especially during film growth at temperatures in the 1000°-1200°C range. In contrast to this, sodium contamination after SiO_2 growth has much less of an adverse effect on the dielectric properties.

4. Protracted annealing of MOS structures (*e.g.*, 30 min at 500°C) can cause oxide deterioration by promoting a solid state reaction between certain electrode metals and SiO_2. This effect is more pronounced for oxides having a higher defect concentration. When aluminum is used, micron-size structural defects develop, concurrently with increased defect-related breakdown. These results suggest that another mechanism for oxide shorting can be operative, in addition to the breakdown which can be attributed to pinholes produced during oxide growth. This newer mode involves a rapid redistribution of massive quantities (relative to the dielectric thickness) of aluminum and silicon during the annealing process.

5. Lattice defects created by ion implantation have virtually no effect on the breakdown strength prior to annealing. Deterioration of implanted oxide during annealing at 300°C may be attributed to either an accelerated injection of electrode metal ions into the film, or by local crystallization facilitated by the presence of lattice defects.

The above observations are consistent with Fritzsche's breakdown model (5) which implies that processing steps promoting local crystallization of the oxide will result in an increase in defect-related breakdown, while glassing has an opposite and beneficial effect. Furthermore, the structural mismatch between the crystallites and the oxide matrix, which provides rapid diffusion paths, may also account for the observed annealing failure mode in Al-SiO_2-Si structures.

APPENDIX

The defects are assumed to be randomly distributed and have a size roughly comparable to the film thickness (therefore, much smaller than the electrode area, F). The total area (A) of the film may be subdivided into N cells of an area a, which is just large enough to accommodate a defect if it happens to be there. It follows that the probability (p) of randomly selecting an occupied cell is equal to $n/N = \rho \cdot a$, where n is the total number of occupied cells. Conversely, the probability (q) of picking an unoccupied cell is equal to $(1-p)$.

When an electrode is deposited, the number of cells covered by metal is $n' = F/a$. Consequently, the probability (P) for the electrode to not cover a defect is

$$P = q^{n'} = (1 - p)^{F/a} \quad [1]$$

Since $n << N$, it can be shown that

$$\ln P = -F \cdot \rho \quad [2]$$

A fraction P, of the total film area, will consequently exhibit primary-type breakdown. Equation [2], which was also used by Fritzsche, was derived here to give the reader a better appreciation of the significance of the results that can be determined by its application.

Acknowledgments

The authors are indebted to Dr. F. X. Montillo for providing the ultraclean SiO_2 specimens, to Dr. B. L. Crowder for ion implantation of SiO_2 films, to Dr. P. Balk and Dr. T. O. Sedgwick for their comments on this manuscript, and to Messrs. R. J. Dendall, W. Gordon, Jr., R. Hammer, and D. Johnson for their invaluable assistance with the breakdown measurements, and C. F. Aliotta for the electron microscope work.

Preparation, Forming, and Aging of Electroluminescent ZnS:Mn,Cu,Cl Films

W. Riemer*[1] and R. E. W. Lake

Department of Electrical Engineering, University of Toronto, Toronto, Ontario, Canada, and Canadian Westinghouse Company, Hamilton, Ontario, Canada, respectively

ABSTRACT

The d-c characteristics (luminance-voltage-current) of electroluminescent films of ZnS:Mn,Cu,Cl prepared by two different methods were investigated during the operating life of the films. For the devices investigated a shift in the characteristics and an increase in the efficiency with operation time was observed. It is suggested that the terms forming and aging do not describe the time-dependent changes in the characteristics, but rather reflect practical aspects of the properties of the films.

Electroluminescence (radiative emission on application of an electric field) in activated ZnS has been recently reviewed in general (1, 2) and for the case of thin film devices (3). The usual configuration for investigating the electroluminescence of thin films of ZnS resembles a capacitor in that it consists of a film of ZnS sandwiched between two parallel electrodes, of which one is transparent to permit the observation of the emitted light.

Under operation ZnS:Mn,Cu,Cl films undergo time-dependent changes in the observed characteristics which are commonly referred to as forming and aging. Forming (4, 5) describes the observation that, on first applying a voltage to a film of this composition, a large current flows but no emission occurs. With the subsequent gradual decrease in current electroluminescence commences and increases in luminance. The duration of this process depends on the fabricating method and is typically a few seconds to as much as an hour (6, 7). One of the reasons that electroluminescent devices have not been more successfully applied is the aging effect or deterioration of emission on operation (8). The longest half-life (time to half initial luminance) for a ZnS thin film was reported to be just over a thousand hours (9) under a-c excitation. The d-c half-life of thin films is considerably shorter than that obtained under a-c conditions, and in some instances the devices are unstable (10).

In common terminology forming and aging are used to designate apparently distinct periods in the operating life of ZnS:Mn,Cu,Cl films. This paper describes the results of an investigation to determine whether a significant change in the d-c device characteristics can be associated with forming and aging, and whether these two phenomena are affected by the method of preparing the devices.

Experimental

The devices investigated consisted of a layer of phosphor sandwiched between two electrodes in a capacitor arrangement, and supported by a glass substrate. The phosphor used as source material for these experiments was ZnS:Mn,Cu,Cl with the following impurity concentrations determined by activation

* Electrochemical Society Active Member.
[1] Present address: Institut für Angewandte Physik, Universität Basel, Basel, Switzerland.
Key words: aging, electroluminescence, forming, thin films, vacuum deposition, zinc sulfide.

analysis: Cu 1.6%, Mn 0.2%, and Cl less than 0.1%. It was not possible to establish the corresponding concentrations in the films. A tin oxide layer on the substrate constituted the transparent electrode, and a matrix of 1 mm square aluminum electrodes on the phosphor film completed the array of devices. All evaporations of materials other than metals were performed in an Edwards High Vacuum Ltd. Model 12EX coating unit. The equipment had been modified to accommodate the special requirements for the production of uniform thin films. In pre-evaporation pumpdown the pressure observed on the dry air calibrated ionization gauge was approximately 1×10^{-5} Torr. A range of phosphor film thicknesses between 0.2 and 2.0μ was investigated. Interferometric measurements were used to determine the thickness of the films and also to calibrate the crystal monitor used for rate control.

Two methods were employed for the preparation of phosphor films. A procedure that gives good control over the impurity incorporation and satisfactory recrystallization is based on diffusing the impurities from a relatively large bulk of powder of desired impurity content into the film, previously deposited, contiguous to the powder under equilibrium conditions (11). The substrate with the evaporated ZnS film is embedded in the activated powder and the combination is heated in a double crucible (12) to approximately 750°C for a brief period. Using diffusion-activation relatively good films can be made, although only certain types of glass substrate and tin oxide layer survive this treatment.

The alternate method, deposition-activation, is based on the crystallization and activator incorporation during the deposition of the film (13). The source material, sintered pressed pellets of phosphor, was deposited onto a heated substrate. A very efficient method of substrate heating consisted of using the tin oxide layer on the substrate (subsequently used as transparent electrode) as a resistive heater (14). In preliminary experiments it was found that the characteristics of devices prepared by deposition-activation were primarily sensitive to the substrate temperature and the deposition rate. With increasing substrate temperature, the condensation rate decreased as in Fig. 1. A series of films were deposited under similar conditions, but the deposition rate was varied over a range from 5 to 45 Å/sec by varying the source temperature. For deposition rates in excess of 10 Å/sec the breakdown field of the film decreased and reduced the attainable luminance of the device (Fig. 2). For deposition rates less than 5 Å/sec, presumably as a consequence of the residual gas at the vacuum prevailing during evaporation, the maximum attainable luminance also decreased. The properties of the deposited film depend on the constitution of the vapor from which it condenses. For the given vacuum environment and boat design an optimum substrate temperature of approximately 240°C and deposition rate of 5 Å/sec were used in the preparation of films on which change in characteristics measurements were made.

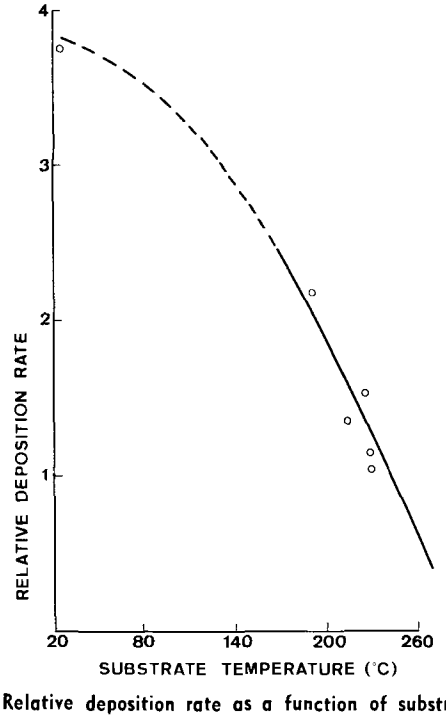

Fig. 1. Relative deposition rate as a function of substrate temperature.

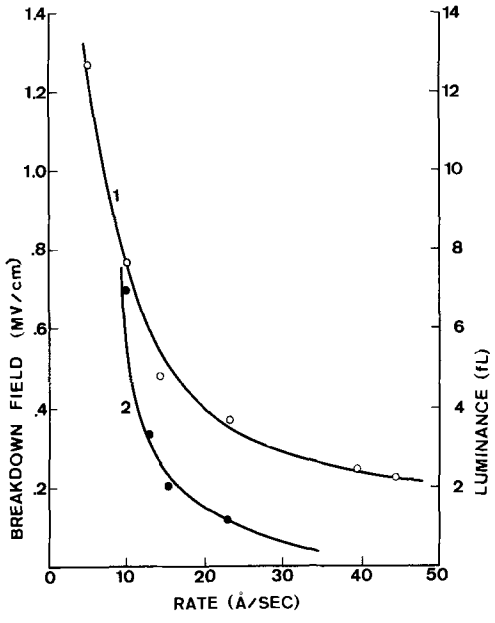

Fig. 2. Effect of film deposition rate on: 1, break-down field; 2, luminance.

The three variables that describe the operation of an electroluminescent film are the voltage (V) applied to the tin oxide and aluminum terminals, the current (I) through the device, and the luminance (L). The electrodes were connected in series with a large resistor to a stabilized voltage supply. The voltage across the film was monitored with a Keithley 601 electrometer. A small series resistor was used to record the current. Reproducible luminance results were obtained with a Spectra Pritchard photometer. The characteristic curves, L-V-I, were recorded with a Honeywell 550 recorder.

Observations

Both deposition-activated (80 films) and diffusion-activated (44 films) films were investigated. Although, under d-c operating conditions, diffusion-activated films generally showed a higher luminance (maximum observed 240 fL) than deposition-activated films (maximum observed 50 fL) the change in characteristics on operating was qualitatively similar, and consequently only representative results for deposition-activated films are presented.

In preliminary experiments it was observed that, for the devices investigated, emission was most effective when the aluminum electrode was made positive. In order to investigate the change on operation in d-c characteristics this polarity (aluminum positive) was therefore used. From first turn-on to the final breakdown of the device the current was maintained constant at 1 mA.

The voltage across the device and the luminance were continually monitored as a function of time. The voltage and luminance history for film 5-31 is described in Fig. 3. For constant current the voltage increases continuously. The actual trace, from which this graph is constructed, shows that as the break-

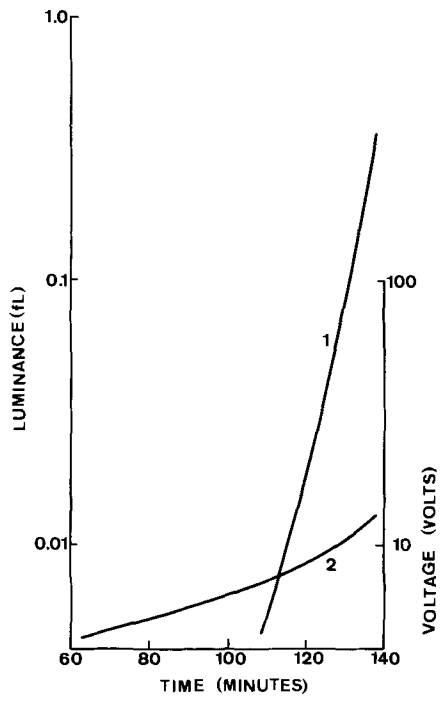

Fig. 3. Time-dependence of voltage and luminance for constant current for film 5-31. 1, Luminance; 2, voltage.

down voltage is approached the device becomes very noisy and final destructive break-down is preceded by numerous voltage spikes to low resistance values. Near break-down the luminance reaches a maximum value and decreases again. This decrease can be explained by the observation that near break-down individual portions of the device extinguished. Consequently the photometer, integrating over a large portion of the device, records a decreasing luminance.

In order to determine the change of the device characteristics as a result of operation, the V-L-I characteristics were plotted periodically. In earlier experiments it had been established that interrupting the current through a device did not result in a relaxation to a lower voltage on turning the current back on. It could be assumed, therefore, that the characteristics at any point in time described the degree of change in the device. To ensure that the measurements of the V-L-I curves did not affect the device significantly the current was limited to a range less than 1 mA.

The variation of voltage with current is shown in Fig. 4. It appears that the device was initially linear, but with operation became increasingly nonlinear and asymmetrical. Measurable emission started as the device became nonlinear and was macroscopically uniform over the entire electrode area.

Electroluminescent devices are often described by their L-V curve. The interpretation of the electroluminescence mechanism is also often based on this relationship. For the film already described the L-V graph at various points during its operating life is given in Fig. 5. It is noticed that the curves are parallel and progressively displaced to higher voltage values.

The L-I characteristics are shown in Fig. 6. It is observed that emission efficiency (in fL/mA) increases both with time of operation and, for small values of current, with current. For large currents near break-down, as for example curve 4, the efficiency decreases presumably as active areas of the device are eliminated.

In order to determine to what extent the change that had occurred during operation was irreversible, several films were operated under conditions where the voltage polarity was regularly reversed. At no point could the previous characteristics be regained. Although a minor degree of recovery occurred, a permanent change had been established that modified the device characteristics.

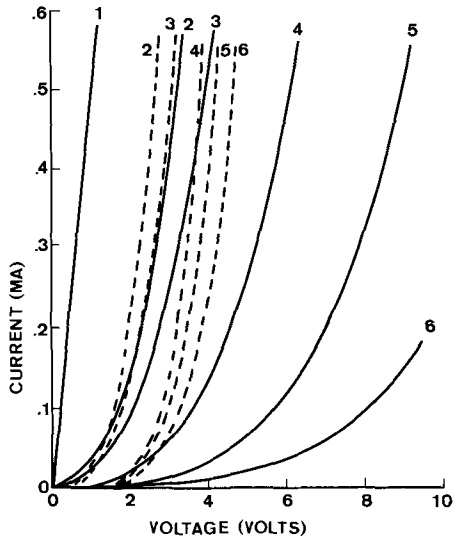

Fig. 4. For film 5-31, voltage variation with current after operating device for the following period: 1, start; 2, 72 min; 3, 117 min; 4, 133 min; 5, 141 min; 6, 157 min. Solid line: aluminum electrode positive; dashed line: aluminum electrode negative.

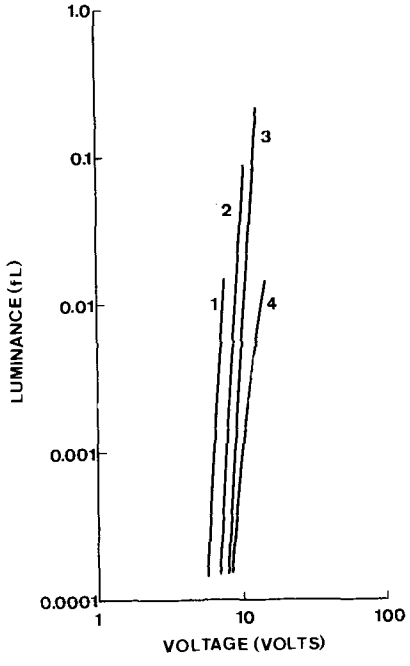

Fig. 5. For film 5-31, luminance variation with voltage after operating device for following period: 1, 117 min; 2, 133 min; 3, 141 min; 4, 157 min.

To establish whether the time-dependent effects observed could be associated with the formation of an oxide between the film and the aluminum electrode (15) the measurements were repeated on a matrix of devices which included a SiO layer between the film and the opaque electrodes, for which a number of different metals were used. For this case it was observed that emission commenced on first applying a voltage to the device, but that the same shift in characteristics occurred as with devices that did not have an oxide layer, and that in the presence of the oxide layer metals other than aluminum also led to electroluminescence.

Discussion

The terms forming and aging, as applied to thin films of ZnS:Mn,Cu,Cl, are commonly used to refer to apparently identifiable distinct processes. Thus, the virgin device on first application of a voltage under-

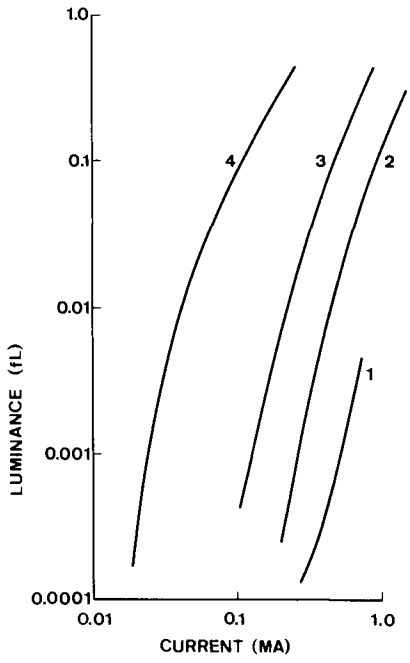

Fig. 6. For film 5-31, luminance variation with current after operating device for following period: 1, 117 min; 2, 133 min; 3, 141 min; 4, 157 min.

goes forming, whereupon electroluminescence is possible. Once emission has been achieved, the film is subject to aging, or decrease in luminance on constant voltage operation. The observations reported in this paper suggest that forming and aging are two labels that are convenient but arbitrary in the description of the time-dependent behavior of the devices under operation, since they reflect practical aspects of the devices rather than any distinct phase of device change.

For every device investigated electroluminescence was associated with nonlinear I-V characteristics. The initial linear I-V curve, not observed in the experiments with an additional oxide layer, is probably caused by parasitic conductive paths which must be eliminated for electroluminescence to occur.

Two possible explanations for the shift in device characteristics suggest themselves: the growth of an oxide layer at the aluminum electrode, and a change in the bulk of the film. The observation that, in the presence of a SiO layer, the shift in device characteristics occurred with metals other than aluminum would indicate that the formation of an aluminum oxide layer probably serves to eliminate parasitic conductive paths, but that changes in the film bulk cause the observed shift.

The nature of the change in the ZnS:Mn,Cu,Cl films has not been conclusively demonstrated. In the fabrication of certain types of rectifiers and transistors an electronically active region is created by a "forming" process that involves substantial ionic current (16). It is proposed that, in view of the concentration of copper in the films greatly in excess of the solubility (17), copper ions diffuse to capturing boundaries creating electronically active phases of Cu_xS (18, 19) and leading to an electroluminescence mechanism described by Vlasenko and Gergell (20). The constancy of slope of the shifted I-V curves and the increasing efficiency with operation of the devices support this interpretation.

Acknowledgments

This investigation was made possible by the support received from the Canadian Westinghouse Company, and by the encouragement and advice given by Professor G. Dick of the University of Toronto.

Luminescence of Pr^{+3} Activated Y_2O_2S

Lyuji Ozawa* and Philip M. Jaffe*

Zenith Radio Corporation, Chicago, Illinois 60639

ABSTRACT

The luminescent properties of the green emitting $Y_2O_2S:Pr^{+3}$ have been studied. The emission lines in the visible region are assigned to the transitions from $^3P_0$ to ^3H_J and to $^3F_2$ of Pr^{+3}; the main green emission lines around 514 nm are attributed to the transition $^3P_0 \rightarrow {}^3H_4$. There was a small shift, about 160 cm^{-1}, of the emission lines to higher energy with an increase in host cation radius (Y to Gd to La). The two broad excitation bands in $Y_2O_2S:Pr^{+3}$, centered at 255 and 290 nm, are due, respectively, to host excitation and to excitation associated with an interaction of activator and host. The optimum activator concentration of $Y_2O_2S:Pr^{+3}$ phosphor is at about 1×10^{-2} mole Pr_2O_2S per mole of phosphor. Quadrupole-quadrupole interaction is involved in the concentration quenching of the green emission.

Y(Gd and La)$_2O_2S:Pr^{+3}$ phospors[1] emit a green emission under cathode-ray or ultraviolet excitation (1, 2). The energy levels of Pr^{+3} in $PrCl_3$ (3, 4), in $LaBr_3$ (5, 6), in YCl_3 (7), in other crystals (8, 9), and in the vapor state (10) have been studied in detail from their absorption and fluorescent spectra. However, it is somewhat difficult to assign the electronic transitions within the Pr^{+3} ($4f^2$) configuration which are responsible for the emission and excitation lines in Y(Gd and La)$_2O_2S$ because there is some discrepancy, about 400 to 1800 cm^{-1}, between the positions of the observed emission and excitation lines of Y(Gd and La)$_2O_2S:Pr$ phosphors and the positions of the lines reported in ref. (3)-(10).

In this paper, the assignment of the emission and excitation lines of $Y_2O_2S:Pr$ phosphor is made by comparison with the energy levels of Pr^{+3} in YCl_3. The small shift of the Pr^{+3} emission lines with a change in host cation radius, the origin of the two broad excitation bands, the optimum activator concentration, and the concentration quenching mechanism of the Pr^{+3} emission in Y_2O_2S are also reported.

Experimental

The rare earths used[2] were yttrium oxide 6*N*, gadolinium oxide and lanthanum oxide 5*N*, and praseodymium oxide 3*N*. The rare earth oxide as host component and praseodymium oxide were dissolved in hot nitric acid and precipitated with oxalic acid. The precipitate was dried, then heated in air at 900°C for 2 hr to convert to the oxide, using alumina crucibles. This mixed oxide (1 mole) plus sulfur (3 moles) and sodium carbonate as flux (1 mole) were mixed in a mortar and then fired at 1100°C for 2 hr in air. After firing, the samples were washed with hot deionized water several times. By this treatment, residual sulfur and sodium compounds were removed from the phosphors. The samples obtained were confirmed as the oxysulfide by x-ray diffraction analysis.

The emission, excitation, diffuse reflectance spectra, and cathodoluminescence data were obtained with the equipment described elsewhere (11). No correction of the emission spectra was made for the spectral response of the monochromator and photomultiplier. The concentration dependence of the intensity of selected lines was determined from the recorded emission spectra by measuring their amplitudes.

[1] The Pr^{+3} was substituted for a portion of the rare earth host cation in all preparations as for example $(Y_{1-x}Pr_x)_2O_2S$. However, the conventional phosphor notation will generally be used, *i.e.*, $Y_2O_2S:Pr$. Unless indicated otherwise, Pr is always trivalent.

[2] Obtained from Lindsey Division, American Potash and Chemical Corporation.

Results and Discussion

Assignment of lines of Pr^{+3}.—The emission and excitation spectra of $Y_2O_2S:Pr$ phosphor were similar to the spectra of $Gd_2O_2S:Pr$ and of $La_2O_2S:Pr$ phosphors. For this reason, the spectrum of the $Y_2O_2S:Pr$ phosphor is primarily discussed in this paper. The small differences between the emission spectra of the Y(Gd and La)$_2O_2S:Pr$ phosphors will be discussed in the section on Effect of host cation radius on the emission line wavelength.

The emission spectrum of $Y_2O_2S:Pr$ phosphor under 254 nm radiation from a low-pressure mercury lamp is shown in Fig. 1. No change of the emission spectrum was observed under excitation by other wavelengths or by cathode rays. In Fig. 1, the weak emission lines at wavelengths longer than 540 nm are also shown with higher magnification (about 10 times). The emission spectrum consists of lines ranging from about 470 to 700 nm. The main group, which consisted of many lines, peaks at about 514 nm, so that the emission color of the phosphor appears green. The $Y_2O_2S:Pr$ emission spectrum is due to the transitions between the energy levels of the $4f^2$ configuration of Pr^{+3}.

The position of the lines and bands in the excitation spectrum of the 514 nm emission was coincident with the position of the lines and bands in the excitation spectrum of the 670 nm emission. Since the direct excitation spectrum of the 670 nm emission clarified to a greater extent the distinctions between the excitation lines, a study of the excitation spectrum of the 670 nm emission was made.

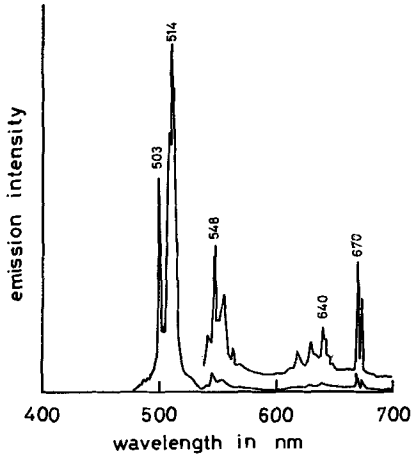

Fig. 1. Emission spectrum of $Y_2O_2S:Pr^{+3}$ phosphor. Above 540 nm the highly magnified spectrum is also shown.

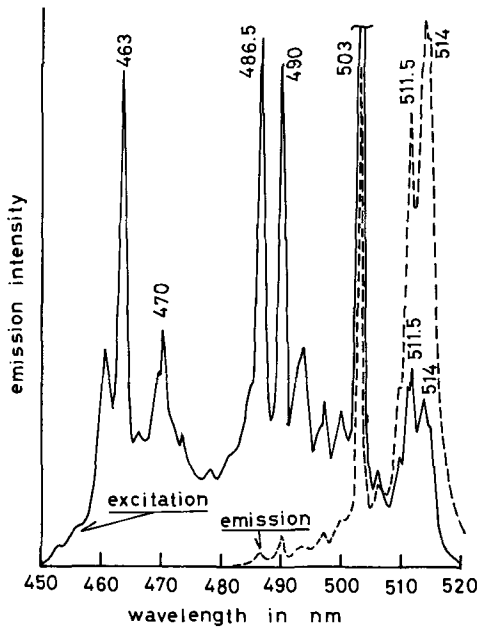

Fig. 2. Detail excitation and emission spectra of $Y_2O_2S:Pr^{+3}$ phosphor. The lines are assigned as the transition between ground level $^3H_4$ and excited levels.

The excitation spectrum of the 670 nm emission consisted of two broad and strong bands centered at about 255 and 290 nm, respectively, and of several weak lines at wavelength longer than 450 nm. The broad excitation bands are described in more detail below. The direct (line) excitation spectrum is shown in Fig. 2. Figure 2 also gives the green emission spectrum of $Y_2O_2S:Pr$ obtained with 290 nm excitation. The emission lines coincided in position with the excitation lines for the 670 nm emission. The direct excitation spectrum of $Y_2O_2S:Pr$ was classified into three groups: 463, 486.5, and 503 nm. These excitation lines may be attributable to direct transitions from the $^3H_4$ ground level to the excited levels of the Pr^{+3} ion. However, as shown in Table I the positions of the lines were about 1800 cm^{-1} lower in energy from those for the free ion (12). The large differences of the energy level positions between free Pr^{+3} and Pr^{+3} in Y_2O_2S is due to the fact that the position of the J levels of Pr^{+3} in crystals depends on bonding character of Pr^{+3} with the nearest neighbor anions and that the separation decreases in energy with an increase in covalent bonding (5, 9). Ionic character of bonding increases with an increase in electronegativity of the elements.

The Pr^{+3} energy levels which participate in the direct excitation and emission lines of $Y_2O_2S:Pr$ phosphor are comparable to the energy levels of Pr^{+3} in YCl_3 which may have a little more ionic bonding than Y_2O_2S. By assuming that the position of the energy levels of ^3P_J Pr^{+3} in Y_2O_2S is about 400 cm^{-1} lower than the corresponding position of the energy levels of Pr^{+3} in YCl_3 (7) because of more covalent bonding than in the chloride, the groups of the direct excitation lines of $Y_2O_2S:Pr$, 463, 486.5, and 503 nm, can be attributable to the transitions from the Pr^{+3} ground level $^3H_4$ to the excited levels $^3P_2$, $^3P_1$, and $^3P_0$, respectively. The strong excitation lines at 486.5 and 490 nm in Fig. 2 may be due to transitions to the sublevels of $^3P_1$ which is split by the crystal field. There may be a line around 480 nm which corresponds to the transition $^3H_4 \rightarrow {}^1I_6$ but it is too weak to verify. The weak excitation lines at wavelengths longer than 503 nm in Fig. 2 are attributable to the transitions from the $^3H_4$ ground level, which is split into many levels by the Stark effect, to the $^3P_0$ which is not split.

Table I. ^3P_J and $^1I_6$ excited energy levels of free Pr^{+3} and Pr^{+3} in yttrium compounds

Energy levels	Free ion* cm⁻¹	nm	YCl_3* cm⁻¹	nm	Y_2O_2S cm⁻¹	nm
$^3P_0$	21,390	466	20,214	495	19,460†	514
					19,880	503
$^3P_1$	22,007	455	20,831	480	20,400	490

$^1I_6$	22,211	450	21,076	474		
$^3P_2$	23,161	431	21,867	457	21,320	469

* From ref. (7).
† Fluorescent main line.

In the emission spectrum of $Y_2O_2S:Pr$ shown in Fig. 1, there are no emission lines originating from the levels above $^3P_0$ because there is no change of the emission spectrum of $Y_2O_2S:Pr$ under direct excitation of the $^3P_0$, $^3P_1$, or $^3P_2$ levels, *i.e.*, with 503, 486.5, and 463 nm radiation, respectively. The emission lines of the $Y_2O_2S:Pr$ spectrum consisted of four main lines, 514, 548, 640, and 670 nm. These were attributable to the transitions from $^3P_0$ to $^3H_4$, $^3H_5$, $^3H_6$, and $^3F_2$, respectively.

The transition between $^3P_0$ and $^3H_4$ is an electric dipole transition (3, 13) and this transition is allowed when a Pr^{+3} ion occupies a lattice site lacking a center of symmetry. The crystal structure of Y(Gd and La)$_2O_2S$ crystals belongs to the D_{3d} space group and the rare earth cation site symmetry is C_{3v}(3m) (14). The rare earth ion is coordinated with seven anions; four oxygens and three sulfurs, having different bonding lengths; 2.23 and 2.90Å. The Pr^{+3} ions are expected to occupy the cation sites in Y(Gd and La)$_2O_2S$ crystals, so that electric dipole transition which give rise strong emission is allowed.

Effect of host cation radius on the emission line wavelength.—It was observed that the positions of the emission lines of Pr^{+3} in Y, Gd, and La oxysulfide phosphors did change with wavelength with a change in host cation. Since these oxysulfides all have the La_2O_3 structure, the change in line position must be due to a change in the crystal field caused by the change in host cation. Figure 3 gives the relationship between the wavelength (in cm^{-1}) of several emis-

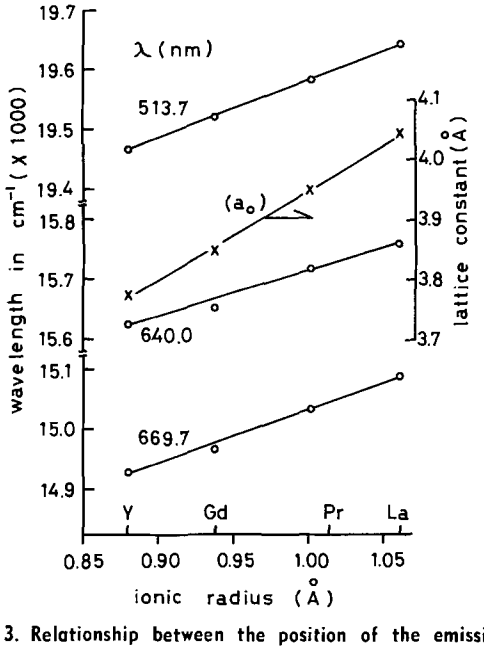

Fig. 3. Relationship between the position of the emission lines and ionic radius of rare earth cation in Y(Gd and La)$_2O_2S$. Lattice constant a_0 also indicated in the figure.

sion lines and the lattice constants as determined by x-ray analysis *vs.* the cation radius (15) of the host crystal. The wavelengths of the emission lines of Pr^{+3} in $(La_{0.5}Gd_{0.5})_2O_2S$ and its lattice constant are also plotted in Fig. 3.

All of the emission lines in the visible region shifted linearly to higher energies when the ionic radius of the rare earth cation increased, Fig. 3. The slope of the curves for 513.7 and 669.7 nm emission lines coincided with each other because the emitting level of all of these lines was the Pr^{+3} $^3P_0$ level. Because of their weak intensity, it was difficult to study the emission lines due to other emitting levels. From the slope of Fig. 3, the emission line shifted about 90 cm^{-1} when the cation radius changed by 0.1Å. The linear shift in spectral lines of Pr^{+3} in rare earth (Gd to La) trichlorides with cation radius have been reported by McLaughlin and Conway (16) and by Dieke (7). However, the shift in the rare earth trichlorides, about 50 cm^{-1} per 0.1Å change in radius is smaller than the shift observed in the rare earth oxysulfides.

The shift of emission with a change in host cation can be explained in the following way: Since the ionic radius of Pr^{+3} is 1.01Å and of La^{+3} is 1.06Å, Pr^{+3} ions substitute for La^{+3} in La_2O_2S crystal with little lattice distortion. On the other hand, in Gd_2O_2S and Y_2O_2S crystals, the Pr^{+3} ions would be incorporated with a perturbation because of the smaller radius of Gd^{+3} (0.99Å) and of Y^{+3} (0.88Å). The distortion of the Pr^{+3} center increases with a decrease in lattice constant. This distortion results in the lowering of the excited level $^3P_0$ of the Pr^{+3} ions.

The shift of the wavelength position of the emission lines of Eu^{+3} in Y(Gd and La)$_2O_2S$ with cation radius was also observed. However, the shift was half of that of Pr^{+3}. The small shift may be caused by the small difference in ionic radius between Eu^{+3} (0.95Å) and Y^{+3} and Gd^{+3}.

Excitation spectrum.—As already described in the section Assignment of lines of Pr^{+3}, the excitation spectrum of Pr^{+3} in Y_2O_2S crystals consisted of two strong broad bands centered at about 255 and 290 nm, respectively, and of many weak lines which were due to the direct excitation of the Pr^{+3} excited levels. These direct excitation lines were already described in the above mentioned section. This section discusses the origin of the broad excitation bands.

For this study, samples of $(Y_{1-x}Pr_x)_2O_2S$ were prepared in which x varied from 10^{-5} to 10^{-1}.

The broad excitation spectra obtained with representative samples are shown in Fig. 4. The relative number of quanta of each curve are comparable to each other. The 290 nm band increased with increasing praseodymium concentration, whereas the 255 nm band stayed relatively constant. The above results are more easily seen in the concentration

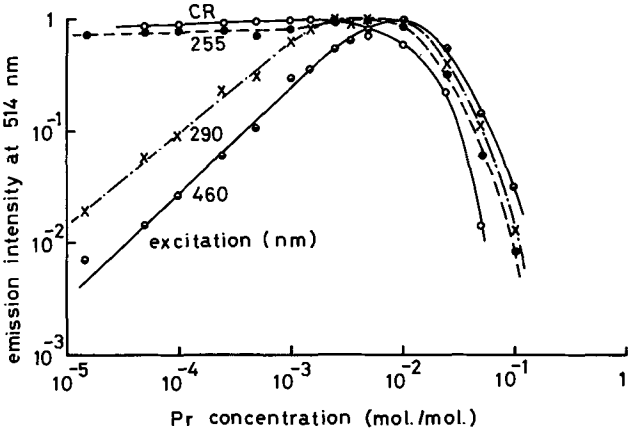

Fig. 5. Concentration dependence curves of $Y_2O_2S:Pr^{+3}$ phosphor under cathode-ray (CR), 255, 290, and 460 nm excitation.

dependence curves of the emission intensity of Y_2O_2S:Pr phosphors under various excitation modes, as shown in Fig. 5.

Since the emission intensity under 255 nm excitation was maintained at about constant level, the indication is that the amount of the energy absorbed by this excitation was independent of the activator concentration and that a constant portion of the absorbed energy was transferred to the Pr^{+3} activator ions. Therefore, it could be inferred that the 255 nm excitation band was due to the host excitation.

The emission intensity under 290 and 460 nm excitation increased linearly and with the same slope with an increase in praseodymium concentration when the praseodymium concentration was below about 1×10^{-3} mole Pr_2O_2S per mole of phosphor, Fig. 5. The 460 nm excitation is the direct Pr^{+3} ($4f^2$) excitation. Reflectance spectra of Y_2O_2S:Pr with various praseodymium concentration are shown in Fig. 6. When the praseodymium concentration increased, the reflectance at 290 nm decreased. From the above results, it was inferred that the 290 nm broad excitation band was due to the excitation associated with the Pr^{+3}.

Several lines superimposed on the broad excitation bands of Gd_2O_2S:Pr phosphors were observed at room temperature. The recorded uncorrected excitation spectrum of Gd_2O_2S:Pr (1×10^{-3} mole Pr_2O_2S) phosphor to give the 514 nm emission is given in Fig. 7. There are lines at 314, 307, 303, 282, 278, and 275 nm. These lines could be identified as the direct transitions from the ground level $^8S_{7/2}$ to the excited levels ^6P_J and ^6I_J of Gd^{+3} (17). The quantitative data on the energy transfer efficiency in mixed $(Y,Gd)_2O_2S$:Pr phosphors as a function of gadolinium concentrations were not obtained because of strong broad excitation

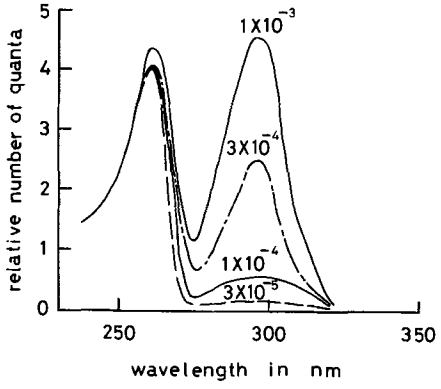

Fig. 4. Broad excitation spectra of $Y_2O_2S:Pr^{+3}$ phosphors having various activator concentrations.

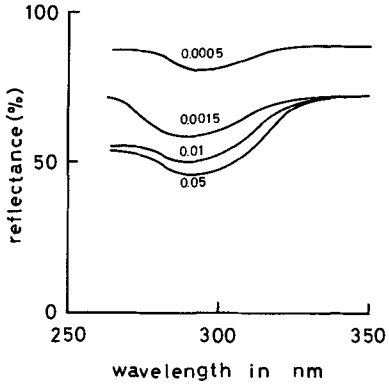

Fig. 6. Reflectance spectra in u.v. region of $Y_2O_2S:Pr^{+3}$ phosphor having various activator concentrations.

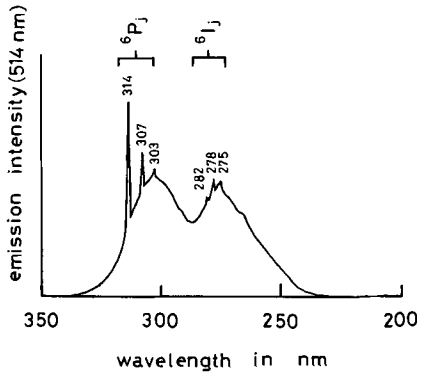

Fig. 7. Recorded excitation spectrum (uncorrected) of the green emission of $Gd_2O_2S:Pr^{+3}$ phosphor. Lines superimposed on the broad bands are believed due to absorption by paired gadolinium ions.

bands. However, there was evidence of the energy transfer from trivalent gadolinium to Pr^{+3} resulting in Pr^{+3} emission for the samples containing above 0.01 mole gadolinium, but there was no evidence of energy transfer below 0.005 mole gadolinium. This result is similar to that obtained with mixed $(Y,Gd)_2O_3$ phosphors activated with the rare earths where the energy transfer involved pairs of trivalent gadolinium ions (17). Therefore, it is deduced that the energy transfer from gadolinium to Pr^{+3} emission in $Gd_2O_2S:Pr$ may occur in a similar way.

Concentration dependence.—As already shown in Fig. 5, the optimum praseodymium concentration markedly changed with a change in the exciting modes: 0.25 m/o (mole per cent) under cathode rays, 0.3 m/o under 255 nm, 0.5 m/o under 290 nm, and 1.0 m/o under 460 nm.

Since the weighted number of nearest neighbor cation sites of Y_2O_2S crystal is twelve, the optimum activator concentration should be at 0.08 mole, if the concentration quenching is due to a decrease in the concentration of the isolated single activator ions (18). If so, an electrostatic multipolar interaction is involved in the concentration quenching (19).

When electrostatic multipolar interactions are involved in concentration quenching, the observed emission intensity I_{ob} as a function of the activator concentration is given by the following expression (20)

$$I_{ob} = KI_o\,[1 - \exp(-\alpha C)]\,[1 + \beta\,(C)^{\theta/3}]^{-1} \quad [1]$$

where I_o is intensity of the exciting light, α effective absorption coefficient for the exciting light, C activator concentration, β a constant for each interaction in a given structure, θ is 6, 8, or 10 for dipole-dipole, dipole-quadrupole, quadrupole-quadrupole interaction, respectively, and K is a constant. This expression indicates that the optimum activator concentration is not only a function of the luminescent centers but also of the absorption coefficient for exciting radiation. The experimental results agree qualitatively with the results predicted by expression [1]. Since it is difficult to determine the α value of powder phosphors, no quantitative analysis could be done. For the exciting radiation used here, Fig. 5, the absorption coefficient decreased with exciting wavelengths. For a weak absorbing exciting radiation, Eq. [1] becomes

$$I_{ob}/C = A\,[1 + \beta\,(C)^{\theta/3}]^{-1} \quad [2]$$

The value of θ for the green emission of Pr^{+3} (514 nm) in Y_2O_2S was 10.5 as indicated in Fig. 8. Therefore, quadrupole-quadrupole interaction ($\theta = 10$) was involved in the concentration quenching of the green emission of $Y_2O_2S:Pr$ phosphor. This result agrees closely with the result which quadrupole-quadrupole interaction predominantly involved in the concentration quenching of Pr^{+3} emission in LaF_3 (21). When the interaction of Pr^{+3} ions with each other increases as the praseodymium concentration increases, the excited electrons in the $^3P_0$ level of one Pr^{+3} ion relax to $^1D_2$. This relaxation energy $^3P_0 \rightarrow {}^1D_2$, 3800 cm^{-1}, is simultaneously transferred to other Pr^{+3} ions by the transition $^3H_4 \rightarrow {}^3H_6$, 4100 cm^{-1}. Because the ground level $^3H_4$ of Pr^{+3} in Y_2O_2S crystal is split into many levels (maximum of $2J + 1$) with energy difference of 450 cm^{-1}, the energy difference of 300 cm^{-1} is inconsequential and the energy transfer from $^3P_0 \rightarrow {}^1D_2$ to $^3H_4 \rightarrow {}^3H_6$ occurs readily.

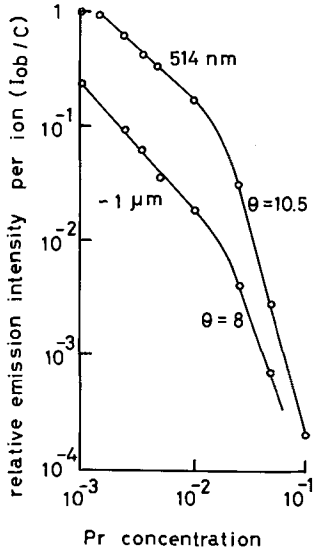

Fig. 8. Relative emission intensity from $^3P_0$ (514 nm) and from $^1D_2$ (~1 μm) per one Pr^{+3} ion (I_{ob}/C) of $Y_2O_2S:Pr^{+3}$ phosphor. θ values for 514 nm emission is 10.5 and for the 1 μm emission is 8. Concentration is mole Pr_2O_2S per mole phosphor.

When a multipolar interaction is involved in emission quenching, the decay time of the emission should vary according to the intensity of the multipolar interaction. Since the decay time of the green emission of $Y_2O_2S:Pr$ was very fast, several microseconds, the change of the lifetime due to multipolar interaction could not be detected in this study.

The optimum activator concentration of the emission from the lowest emitting levels of Eu^{+3} and of Tb^{+3} in Y_2O_2S is 0.08 mole fraction (20). However, the optimum activator concentration for the emission line from the lowest emitting level of Pr^{+3}, $^1D_2$, λ about 1 μm, was about 1×10^{-2} mole fraction. The slope of the (I_{ob}/C) curve was 8/3 as shown in Fig. 8. Thus dipole-quadrupole interaction was involved in the concentration quenching of the Pr^{+3} $^1D_2$ emission line. The transition responsible for this interaction is

$$^1D_2 \rightarrow {}^1G_4\ (6700\ cm^{-1});\ {}^3H_4 \rightarrow {}^3F_4\ (6600\ cm^{-1})$$

Under cathode-ray excitation, all of the excitation modes are involved in the excitation process. However, the host excitation may be dominant among these excitation modes. If so, then the concentration dependence curve for cathode-ray excitation of the phosphors which have a host excitation band should be similar to the concentration dependence curve under host excitation. As shown in Fig. 5, the concentration dependence curves obtained by cathode-ray excitation are indeed very similar to the concentration dependence curve obtained by 255 nm host excitation.

The green emission of $Y_2O_2S:Pr$ phosphor under cathode-ray excitation had good response to high current, *i.e.*, did not saturate at relatively low current densities like sulfide phosphors. Since the lifetime of the electrons remaining in the excited level $^3P_0$ is

very short, the saturation of the excited electrons in $^3P_0$ does not occur until very high beam current excitation. Therefore, the green emission of Y_2O_2S:Pr may be used as the green component in projection-type color TV picture tubes.

Conclusion

Y_2O_2S:Pr phosphors emit a green fluorescence under excitation by short u.v. and by cathode rays. The energy level assignment of the Pr^{+3} lines was made by the reference to the transitions within Pr^{+3} in YCl_3. In Y_2O_2S:Pr, all of the emission lines in the visible region are attributed to the transitions from $^3P_0$. The green emission lines around 514 nm are due to the transitions from $^3P_0$ to the ground level $^3H_4$ which is split into many levels with energy difference of about 450 cm^{-1}.

All of the emission lines of Pr^{+3} in Y(Gd and La)$_2O_2S$ shifted linearly to higher energy when the ionic radius of the rare earth host cation increased. This change was related to the distortion of the lattice caused by the change in size of the host cation.

The excitation spectrum consisted of two broad bands centered at 255 and 290 nm and of weak lines located around 480 nm. The latter is due to the direct excitation of Pr^{+3}. It is inferred that the 255 nm excitation band is due to host excitation and that the 290 nm excitation band is due to the excitation associated with an interaction of activator and host. The energy transfer from a pair of gadolinium ions to Pr^{+3} was observed. The optimum Pr^{+3} concentration in Y_2O_2S:Pr is around 1 x 10^{-2} mole Pr_2O_2S per mole of phosphor. Quadrupole-quadrupole interaction is involved in the concentration quenching of the green emission. The concentration dependence curve under cathode-ray excitation is almost identical to that obtained by host excitation indicating that the two process are similar.

Acknowledgment

The authors wish to thank Mrs. H. Stanczyk for her assistance in preparation of samples, Mr. L. Flemming for cathodoluminescent data, and Dr. G. Arai for x-ray data.

Calculation of the Ga-In-P Ternary Phase Diagram Using the Quasi-Chemical Equilibrium Model

G. B. Stringfellow

Hewlett-Packard Company, Palo Alto, California 94304

ABSTRACT

The Ga-In-P solid-liquid-vapor equilibrium phase diagram has been calculated based on the quasi-chemical equilibrium solution model. The calculated phase diagram, both isothermal liquidus and iso-(solid concentration) lines, and P_2 and P_4 vapor pressure curves, is found to be in agreement with recently published experimental data.

The thermodynamic properties of the III-V binary system In-As, Ga-As, and In-Sb have been calculated using the quasi-chemical equilibrium (QCE) treatment of the lattice solution model (1-2). A method of calculating a general III-V ternary phase diagram was also presented in ref. (2) and applied to the calculation of the In-As-Sb and Ga-In-As systems. Because of the lack of experimental data, the accuracy of the calculated ternary phase diagrams could not be adequately tested. The Ge-Si-Sn and Ge-Si-Pb phase diagrams, calculated using the QCE treatment, were found to be in excellent agreement with experimental phase diagram data (3).

Recently, experimental phase diagram data has been obtained for the system Ga-In-P (4-5). It is the purpose of this paper to compare the calculated phase diagram with the experimental data for the system Ga-In-P and thus test the accuracy of the QCE cal-

Key words: gallium-indium-phosphorus system, calculated phase diagram.

culation and present the entire Ga-In-P solid-liquid-vapor equilibrium phase diagram.

Calculation of Ga-In-P Phase Diagram

The calculation is based on the quasi-chemical equilibrium (QCE) model. The major assumptions on which this model is based are:

1. Each atom has Z nearest neighbors.
2. Nearest neighbors interact pairwise with the temperature and composition independent interaction parameter, Ω, defined as

$$\Omega_{AB} = Z[H_{AB} - \tfrac{1}{2}(H_{AA} + H_{BB})]$$

where H_{ij} is the energy of an i-j nearest neighbor pair.

3. Only the configurational free energy of mixing is considered, *i.e.*, the vibrational free energy of mixing is neglected.
4. The distribution of constituent atoms is calculated using a mass action-like expression

$$N_{ii}N_{jj}/(N_{ij})^2 = \tfrac{1}{4}\exp(2\Omega_{ij}/ZRT)$$

where i and j each represent either A, B, or C.

The equilibrium equations for the (ternary liquid)-(binary solid) equilibrium may be written

$$\ln(\gamma_{AC}X) = \ln\left(\frac{4\gamma_A\gamma_C N_A N_C}{\gamma^{s.l.}{}_A\gamma^{s.l.}{}_C}\right) + \Delta S^F{}_{AC}(T^F{}_{AC} - T)/RT \quad [1a]$$

$$\ln\gamma_{BC}(1-X) = \ln\left(\frac{4\gamma_B\gamma_C N_B N_C}{\gamma^{s.l.}{}_B\gamma^{s.l.}{}_C}\right) + \Delta S^F{}_{BC}(T^F{}_{BC} - T)/RT \quad [1b]$$

$$N_A + N_B + N_C = 1 \quad [1c]$$

The activity coefficients, γ_{ij}, in the ternary liquid phase cannot be expressed analytically but are computed numerically in terms of temperature and composition using the QCE model. The activity coefficients in the solid phase may be written

$$\gamma_{AC} = \left(\frac{\beta - 1 + 2X}{X(\beta+1)}\right)^{Z/2}$$

$$\gamma_{BC} = \left(\frac{\beta + 1 - 2X}{(1-X)(\beta+1)}\right)^{Z/2}$$

where

$$\beta = [1 + 4X(1-X)(\eta^2 - 1)]^{1/2}$$

$$X = N_{AC}/(N_{AC} + N_{BC}) \text{ and } \eta = \exp(\Omega_{AC-BC}/ZRT)$$

For the zinc blende lattice, where AC-BC interactions are considered, the appropriate value of Z is 12.

Using the activity coefficients calculated from the QCE model, Eq. [1a-c] can be solved numerically with N_A and N_C given to yield N_B, X, and T. A detailed description of the calculation is given in ref. (2).

The equilibrium P_2 and P_4 pressures over the liquidus surface were calculated from the following equilibrium equations

$$P_{P_4} = P^\circ{}_{P_4}(N_A\gamma_A)^4$$
$$P_{P_4}{}^2/P_{P_4} = K_P(T)$$

where $P^\circ{}_{P_4}$, the P_4 pressure over pure liquid phosphorus, and $K_P(T)$ may be calculated from data available in the JANAF Tables (6).

The parameters used in the calculation are listed in Table I. The In-Ga interaction parameter was determined by Macur, Edwards, and Wahlbeck (7). The In-P and Ga-P interaction parameters were obtained by making a least squares fit of the calculated binary phase diagrams to the experimental data (8-10) (see Fig. 1). The entropy (11) and temperature (11-14) of fusion for InP and GaP were extracted from the literature. The only parameter not available from binary data is the $InP_{(s)}$-$GaP_{(s)}$ interaction parameter. It was obtained by constraining the solid in equilibrium with a liquid composed of 35% Ga, 50% In, 15% P, to be 97.2% GaP, as per Panish's data (4). It was found that the liquid composition in equilibrium with a given solid near pure GaP is the variable most sensitive to the InP-GaP interaction parameter.

Table I. Parameters used in the QCE calculation of the Ga-In-P phase diagram

Parameter	Value used in the calculation
$T^F{}_{GaP}$	1740°K (11-13)
$T^F{}_{InP}$	1333°K (10)
$\Delta S^F{}_{GaP}$	16.25 eu* (10)
$\Delta S^F{}_{InP}$	14.7 eu* (10)
Ω_{Ga-P}	−3500 cal/mole
Ω_{In-P}	0 cal/mole
Ω_{In-Ga}	1066 cal/mole (6)
$\Omega_{InP-GaP}$	4000 cal/mole

* ΔS^F was calculated from the value of ΔH^F given by Sirota (10) and the values of T^F used in the calculation; $\Delta S^F = \Delta H^F/T^F$.

The calculated results are presented in Fig. 2-5. In Fig. 2, the calculated isothermal liquidus lines are presented for comparison with points obtained from interpolating between Panish's data points. No points from the extrapolation of his data are included since they are subject to large errors. The agreement between calculated and experimental liquidus compositions is within 2 a/o (atomic per cent). Low temperature liquidus isotherms in the In-rich corner of the phase diagram are the most useful for crystal growth information. This area of the phase diagram is expanded in Fig. 3. In Fig. 4, calculated iso-(solid composition) lines are plotted along with the experimental data. Each line represents the locus of liquid compositions in equilibrium with a given solid composition. Each data point is labeled with the mole fraction GaP in the solid in equilibrium with that particular liquid composition.

The agreement between calculated and experimental liquid composition in equilibrium with a particular

solid composition is generally good. There is a systematic deviation from Panish's data at the low GaP concentrations, even though the agreement with Foster's data is excellent. It should be pointed out that Panish's method of determining the solid composition in equilibrium with a given liquid by slowly cooling to 20° below the liquidus temperature leads to errors, especially when the mole fraction of GaP in the solid is low; because the equilibrium solid composition changes on cooling. For example, cooling from 1100°C by 20°C changes the equilibrium solid composition on the pseudobinary from 30 to 14% GaP. If error bars were extended from each of Panish's data points to the liquidus 20° below the original liquidus, Panish's data would be in agreement with the calculated results.

Calculated P_2 and P_4 pressures in equilibrium with the liquid composition on the liquidus surface are plotted in Fig. 5. The calculated curves are compared with data from the interpolation of Panish's data (4), and the data of Johnson (15) for pure GaP. The agreement is excellent for pure InP and GaP; and even though the agreement is good within the Ga-In-P ternary system, the calculated curves are systematically higher than the experimental data. The curves for 750°, 800°, and 850°C where there is no experimental pressure data are included because this information is useful for crystal growth experiments in this temperature range.

Discussion

To determine the usefulness of the QCE calculation, it is necessary to compare the calculated results with experimental results and with the results calculated using other model solutions. Panish compared his experimental results with liquidus curves calculated for an ideal solution and for a solution with $\gamma_{Ga} = \gamma_{In} = 1$ and γ_P determined from experimental results. Neither method gives satisfactory results. To further compare the QCE and ideal solution calculations, the ideal Ga-P liquidus curve is included in Fig. 1. The iso-(solid concentration) curves calculated for ideal solid and liquid solutions are compared with experimental data

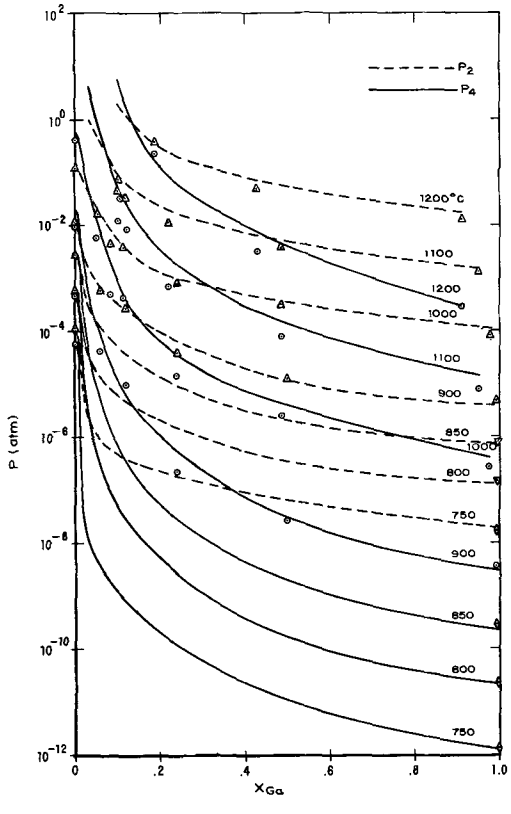

Fig. 5. P_2 and P_4 vapor pressures in equilibrium with the Ga-In-P liquidus surface. - - - - - - - - P_2; ——— P_4; △ Panish (4) P_2; ○ Panish (4) P_4; ◇ Johnson (15) P_4; ▽ Johnson (15) P_2.

in Fig. 6. These comparisons clearly show the QCE calculation to be a dramatic improvement over the ideal calculation, but there is a systematic deviation from the experimental results for liquidus, iso-(solid concentration) and vapor pressure curves. This deviation can be seen in the In-P, Ga-P, In-As, Ga-As, and In-Sb binary liquidus curves (2), so it is not entirely due to the inadequacy of the QCE model in describing the solid solution, where one would expect the largest deviations from any simple model.

There are two approaches which might be taken in attempting to improve the phase diagram calculation: (*i*) use the same model and allow the interaction parameters to be an arbitrary function of T and/or X; (*ii*) use a more sophisticated model which contains the elements necessary to better describe the real solution. The first approach is simply bending the model to fit the binary data, since Ω is constant for the simple QCE model. The second approach involves trying to determine the physical processes which might make the interatomic interactions change with temperature or composition and building them into the model solution.

Guggenheim (1) suggested that Ω could be taken as a linear function of T, $L(T)$, to improve the agreement between calculated properties of the QCE solution and experimental data. An attempt was made to improve the calculation of the Ga-In-P phase diagram using this procedure. By calculating Ω for each experimental point on the liquidus and determining the $L(T)$ which best fit the data, the In-P and Ga-P interaction parameters were determined to be

$$\Omega_{\text{In-P}} = 8220 - 7.57T \text{ and } \Omega_{\text{Ga-P}} = 4650 - 5.85T$$

The respective binary phas diagrams calculated using these interaction parameters are plotted in Fig. 1. As expected, allowing $\Omega = L(T)$ improves the fit to the experimental data.

The Ga-In-P phase diagram was calculated using these new temperature dependent interaction parameters, all other parameters remaining the same as for the regular QCE calculation. The isothermal liquidus curves are compared with the regular QCE results and the experimental results in Fig. 2. The iso-(solid concentration) curves are the same as those presented in Fig. 4. The phase diagram calculated using temperature dependent, interaction parameters is in substantially worse agreement with the experimental data. This result illustrates the danger of bending the model to fit the binary results. The ternary calculation is more than an extrapolation of binary data. It is based on finding a self-consistent solution model which contains the elements necessary to describe the binary systems and then calculating the ternary using the same conceptual basis. The appropriate method of improving the calculation is to use a more sophisticated model which includes the physical processes which make the interatomic interactions temperature and composition dependent.

Kleppa (16) classfied many binary metal systems according to whether they had symmetric ΔH_M *vs.* X curves, characteristics of ideal, regular, and QCE solutions. He found that only systems from the same group of the periodic table had symmetrical ΔH_M *vs.* X curves. This is consistent with the results of Stringfellow and Greene (3) where the Ge-Si, Ge-Sn, Ge-Pb, Si-Sn, and Si-Pb systems were found to behave as QCE solutions. It would be expected that III-V systems could be better described using a more sophisticated model giving the more general asymmetrical ΔH_M *vs.* X curves.

One approach to improving the model would be to retain the lattice model but improve the QCE assumptions: (*i*) nearest neighbors interact pairwise, (*ii*) only configurational free energy of mixing is important, *i.e.*, vibrational free energy of mixing is neglected. The surrounded atom model (17) is similar to the QCE model except the basic entity is an atom with all its nearest neighbors, rather than atom pairs. This is an example of building into the model the physical processes which make the interatomic interactions change with composition. It improves the QCE approximations above and gives the more general asymmetric ΔH_M *vs.* X, but involves 12 interaction parameters for the binary system and 84 for the ternary system. Approximations can be made to reduce the number of parameters, but a calculation of the ternary phase diagram based on the surrounded atom approach is still not practical.

Other, more sophisticated models such as cell models, hard sphere models, and conformal solution theory have been developed for nonpolar spherical molecules and sophisticated models have been developed for ionic solutions. Work is needed in the construction of more sophisticated models applicable to metallic solutions. One problem is that the basic interactions in metallic systems are not well understood. Only recently has progress been made in understanding the intermolecular potentials in liquid metals (18-20). Cell models using intermolecular potentials may be useful in better describing the thermodynamic properties of liquid metals, in particular in III-V systems.

Thus, the QCE model appears to be the best, presently available, practical basis for the calculation of III-V ternary phase diagrams.

Acknowledgments

The author gratefully acknowledges the kindness of M. Panish and M. Foster for allowing him to use their results prior to publication. The author also wishes to thank R. A. Burmeister for many helpful discussions.

Phase Diagram of the Zn-Cd-Te Ternary System

Jacques Steininger, Alan J. Strauss,* and Robert F. Brebrick*

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts 02173

ABSTRACT

The ternary Zn-Cd-Te liquidus surface and the pseudobinary CdTe-ZnTe solidus curve have been determined by thermal analysis of cooling and heating curves, respectively, of homogenized liquid and solid alloy samples. The binary Cd-Te and Zn-Te liquidus arrest temperatures are in good agreement with most of the previously published data and confirm the presence of well-defined inflections on the metal-rich and Te-rich sides of both liquidus curves. The binary interchange energy parameters calculated along each liquidus curve for the regular and quasi-chemical approximation solution models give essentially similar values for dilute solutions. Near equiatomic composition however, they show values respectively in excess of 200 kcal/mole and less than 40 kcal/mole. The pseudobinary CdTe-ZnTe liquidus and solidus curves exhibit monotonic and sublinear increases in temperature with increasing ZnTe content. The gap between the two curves remains less than 0.16 mole fraction and shows excellent agreement with the values calculated from the ideal liquidus-solidus thermodynamic relationship. The ternary liquidus temperatures form a smooth surface with a narrow ridge near the pseudobinary CdTe-ZnTe composition line and practically degenerate ternary eutectic and boundary lines.

The II-VI compounds CdTe and ZnTe form a complete series of solid solutions with cubic zincblende structure and with band gaps varying from 1.5 to 2.3 eV at room temperature. The alloys containing up to 85 m/o (mole per cent) ZnTe can be made both n- and p-type, and efficient visible electroluminescence at 77°K has been obtained with $Zn_xCd_{1-x}Te$ diodes prepared by diffusion of Zn and P into Al-doped CdTe single crystals (1). The samples prepared by this method however showed evidence of strain which became more severe with increasing x. Recently, alloy crystals have been grown directly from the liquid phase by the Bridgman and slow cooling techniques (2), but details on their crystallographic and optical quality were not reported.

Because of interest in the growth of alloy crystals from the melt and from Te-rich solutions (3), we have investigated the phase diagram of the ternary Zn-Cd-Te system by thermal analysis of homogenized liquid and solid alloy samples. Particular attention was paid to the CdTe-ZnTe subsystem, which was assumed to be pseudobinary, and to the Te-rich region of the ternary liquidus surface. The binary Cd-Te and Zn-Te liquidus curves were also re-investigated because of discrepancies in the published data. Finally, the metal-rich region of the ternary liquidus surface was selectively surveyed in order to present the first comprehensive set of data for thermodynamic analysis of ternary mixed II-VI systems.

Experimental

Thermal analyses were conducted in a vertical platinum-wound resistance furnace by slow cooling of homogenized liquid samples and slow heating of homogenized solid samples at temperatures up to 1265°C. A 10-15g charge of an accurately weighed mixture of 6-9's purity elements was placed in a 1 by 10 cm silica ampoule with a 2.5 cm re-entrant thermocouple well. The free space inside the ampoule was less than 5 cm^3, and the loss by evaporation of the most volatile component was estimated to be less than 0.1% by weight over the experimental range of temperatures. A similar ampoule containing about 8g of silicon was used as a reference. The ampoules were sealed under forepump vacuum (10^{-3} Torr) and placed in two symmetrical cavities drilled in a 5 by 12.5 cm nickel cylinder fitted with a nickel lid. A Pt-Pt 13% Rh thermocouple was inserted in each ampoule, and the two were connected for simultaneous recording of the sample temperature and of the temperature difference between sample and reference as a function of time. To increase the sensitivity of the temperature readings, the emf from the sample thermocouple was partially balanced out with a millivolt potentiometer. The outputs from the two channels were then amplified by d-c microvolt amplifiers and recorded on a two-pen recorder with 1 and 0.1 mV full scale deflection, respectively. Calibration with a gold sample (melting point 1063.0°C) gave melting and freezing arrests of 1063.0° ± 0.1°C and showed that no correction of the sample temperature readings was necessary.

The samples were slowly heated to reaction temperature, melted, and then equilibrated for at least 16 hr at 50°C above the estimated liquidus temperature. Because of apparently slow kinetics of dissolution of CdTe and ZnTe in liquid Te, shorter equilibration times produced erratic results which may explain some of the discrepancies observed in previously published data. Particular care was taken to approximate equilibrium conditions at the onset of freezing.

* Electrochemical Society Active Member.

Key words: ternary phase diagram, thermal analysis, zinc, cadmium, tellurium, alloy crystal growth, quasi-chemical interchange energy, liquidus-solidus thermodynamics.

This was achieved by cooling melts that were only slightly superheated (20°-25°C above the liquidus temperature) at sufficiently low rates (1°-2° C/min) to avoid appreciable supercooling. Under these conditions, there was usually no evidence of supercooling and the cooling curve showed a break that could be reproduced to within ± 1°C (Table I). When supercooling could not be prevented, the liquidus arrest temperature was taken to be the maximum in the recalescence curve. No attempts were made to obtain liquidus data from heating curves because the end of melting for noncongruently melting compositions is poorly defined and can be erroneously interpreted.

Solidus arrests for the pseudobinary CdTe-ZnTe system were obtained from slow heating curves (1°-2° C/min) of samples that had been melted as indicated above, resolidified and homogenized by annealing for at least 16 hr at about 20°C below the solidus temperature. X-ray powder analysis of samples annealed in this way showed no evidence of inhomogeneity and gave lattice parameters in agreement with published values. The temperature of each thermal arrest was obtained from the intersection of the nearly straight lines below and above the solidus break on the sample temperature recording. More prolonged annealing (up to 10 days) resulted in sharper breaks but did not cause any substantial displacement of the intersections. The reproducibility of the solidus arrests was about ± 3°C (Table I).

Because of the large thermal effects in this system, differential thermal recording was used only to confirm the arrests observed on the sample temperature recording. The over-all accuracy of both liquidus and solidus temperatures is estimated to vary from within ± 1°C near the compounds to within a few degrees at higher dilution in excess elements or in the middle of the pseudobinary composition range.

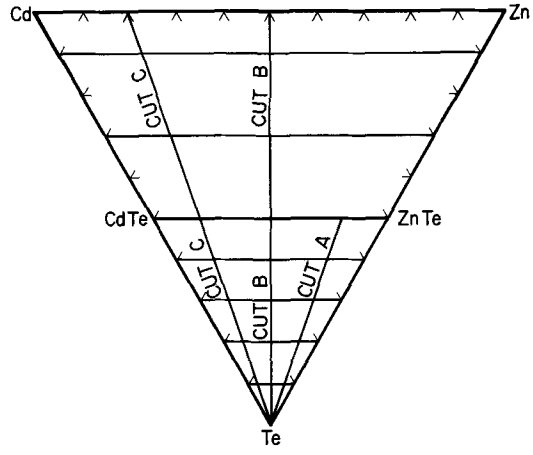

Fig. 1. Zn-Cd-Te ternary system

Results

The liquidus and solidus arrest temperatures, the amount of supercooling observed on the cooling curves, and the reproducibility of repeat runs are listed in Table I for the following subsystems (Fig. 1): Cd-Te binary liquidus; Zn-Te binary liquidus; CdTe-ZnTe pseudobinary liquidus and solidus; liquidus isopleths at constant Zn/Cd ratios of 4.0, 1.0, and 0.25 (Cuts A, B, C); and liquidus isopleths at constant Te concentrations of 0.10, 0.30, 0.60, 0.70, 0.80, and 0.90.

Binary Cd-Te *system (Fig. 2).*—The Cd-Te binary liquidus curve has been previously investigated by de Nobel (4) by visual observation of initial freezing, and by Lorenz (5) and Kulwicki (6) by DTA in sealed quartz ampoules. Their data show generally good agreement on the Cd-rich side, with the exception of the high-temperature data of de Nobel which is significantly lower, probably because of supercooling. On the Te-rich side, they also show good agreement except for the values of Kulwicki which are significantly higher in the 50 to 80 a/o (atomic per cent) Te region. Our arrest temperatures are listed in Table I and shown in Fig. 2 together with the values of Lorenz and Kulwicki. Melting and freezing arrests of 1092.0° ± 0.2°C were observed for CdTe in good agreement with the previously reported values of 1090° ± 2°C (de Nobel), 1092° ± 3°C (Lorenz), and 1091° ± 2°C (Kulwicki). Our liquidus arrests are in best agreement with the data of Lorenz, on both sides of the liquidus curve. Substantial supercooling, which might have explained the differences between the results of Lorenz and of Kulwicki on the Te-rich side, was not in evidence on our cooling curves (Table I). It is therefore suspected that the high temperatures observed by Kulwicki in both binary systems (see below) may have been caused by in-

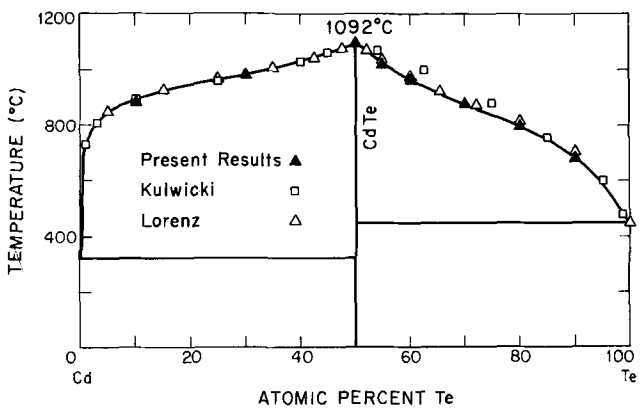

Fig. 2. Cd-Te binary liquidus curve

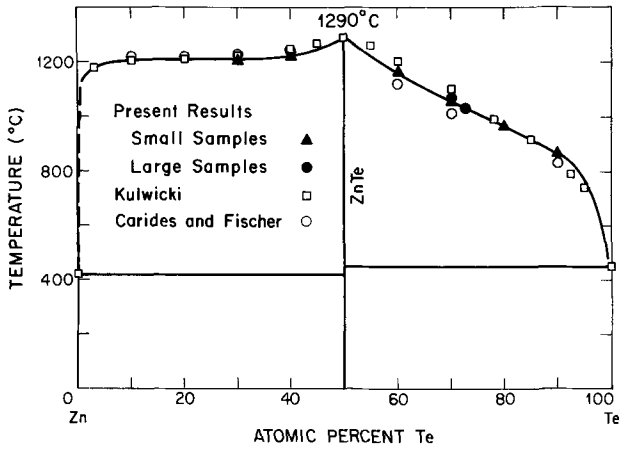

Fig. 3. Zn-Te binary liquidus curve

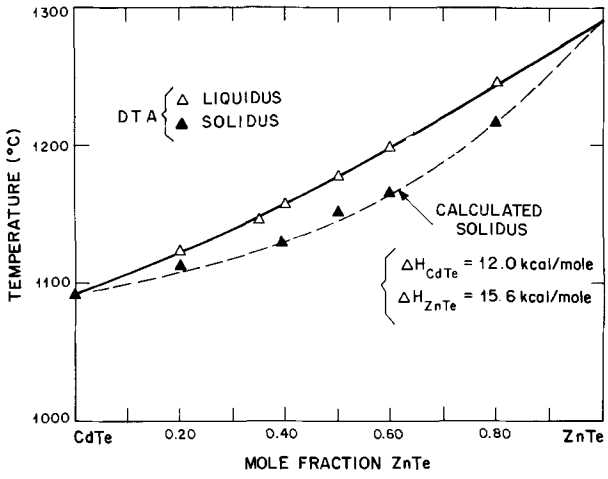

Fig. 4. CdTe-ZnTe pseudobinary liquidus and solidus curves

complete homogenization of the Te-rich liquid samples.

Binary Zn-Te *system (Fig. 3).*—The Zn-Te liquidus curve was investigated almost 60 years ago by Kobayashi (7) in an open system and more recently by Carides and Fischer (8) by thermal analysis in a high pressure autoclave and by Kulwicki (6) by DTA in sealed quartz ampoules. The data of the two more recent investigations are in generally good agreement except in the region between 50 and 80 a/o Te where the values of Kulwicki are almost 100°C above those of Carides and Fischer. Our arrest temperatures are listed in Table I and shown in Fig. 3 together with the data of Carides and Fischer and of Kulwicki. No attempt was made to redetermine the melting point of ZnTe because of its relatively high temperature, and we adopted the value of Kulwicki (1290° ± 2°C), which is in agreement with that of Carides and Fischer (1295° ± 20°C). On the Zn-rich side, our liquidus temperatures are in good agreement with the previously reported experimental curves, showing an almost horizontal inflection near 1210°C. From theoretical calculations of the activities in a regular associated solution model (see Discussion), Jordan (9) has recently suggested a miscibility gap in the liquid phase between 9 and 35 a/o Te. However, careful analysis of several of our cooling curves at 30 and 40 a/o Te did not reveal the monotectic arrest which he predicted near 1213°C. On the Te-rich side, our liquidus temperatures are intermediate between the low values of Carides and Fischer (probably due to supercooling) and the higher values of Kulwicki. Contrary to Kulwicki's diagram, our liquidus curve shows a well-defined inflection (near 1025°C and 70 a/o Te) which is comparable to that observed in the Cd-Te system in the same composition range.

Because of the discrepancies observed on the Te-rich side in both binary systems, two additional points were determined on the ZnTe-Te liquidus curve by slow cooling of large liquid samples (about 150g) in another, previously described (10), DTA apparatus. The arrest temperatures of 1070° and 1030°C for compositions of 70 and 72.5 a/o Te are in good agreement with the rest of our data (Fig. 3) and confirm the inflection on the liquidus curve.

Pseudobinary CdTe-ZnTe *system (Fig. 4).*—No previous investigation of the pseudobinary liquidus and solidus curves has been reported. X-ray diffraction data (11) show that the $Zn_x\ Cd_{1-x}Te$ alloys form a complete series of solid solutions and that the lattice parameter varies linearly with composition in agreement with Vegard's law.

Our liquidus and solidus arrest temperatures are listed in Table I and shown in Fig. 4. Both temperatures show a monotonic and sublinear variation with composition from the melting point of CdTe (1092°C) to that of ZnTe (1290°C). This type of variation suggests small and nearly comparable positive deviations from ideality in the liquid and solid phases (see Discussion) and is similarly observed in several other II-VI pseudobinary systems, such as HgTe-HgSe (12), ZnTe-ZnSe (13), and CdTe-CdSe (14). Of particular interest are the slow increase in liquidus temperatures and the relatively narrow gap between liquidus and solidus curves (less than 0.16 mole fraction). These are both favorable for the growth of alloy crystals from the melt in standard quartz ampoules up to relatively high values of Zn content.

Ternary liquidus surface (Fig. 5-8).—No previous study of the ternary liquidus surface has been reported.

The Te-rich ternary liquidus isopleths for constant Zn/Cd ratios (Fig. 5) show the same type of variation as the limiting CdTe-Te and ZnTe-Te binary liquidus curves, with an inflection near 70 a/o Te and a marked increase in temperature near the equiatomic composition. On the metal-rich side, there is a gradual transition from the smooth Cd-CdTe liquidus curve to the initially steep and then almost flat Zn-ZnTe curve. The inflections on both sides of the isopleths suggest a tendency for separation into different liquid phases. Such separations actually occur on the Se-rich side of other II-VI systems such as Hg-Se (10), Cd-Se (15), and probably Zn-Se (16). However, no monotectic arrests have been observed in the Zn-Cd-Te system.

Like the pseudobinary CdTe-ZnTe liquidus curve, the constant-Te isopleths exhibit slow, monotonic increases in temperature from the Cd-Te liquidus to

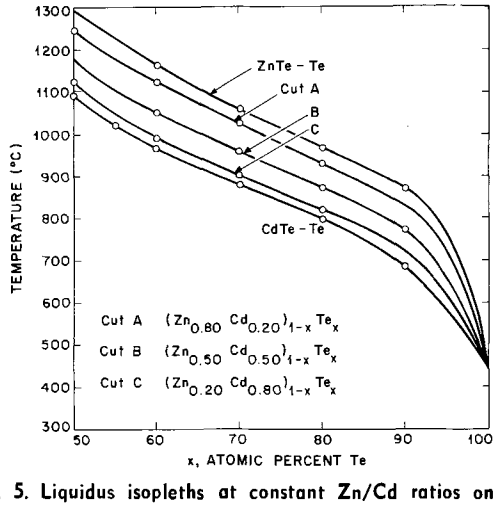

Fig. 5. Liquidus isopleths at constant Zn/Cd ratios on Te-rich side.

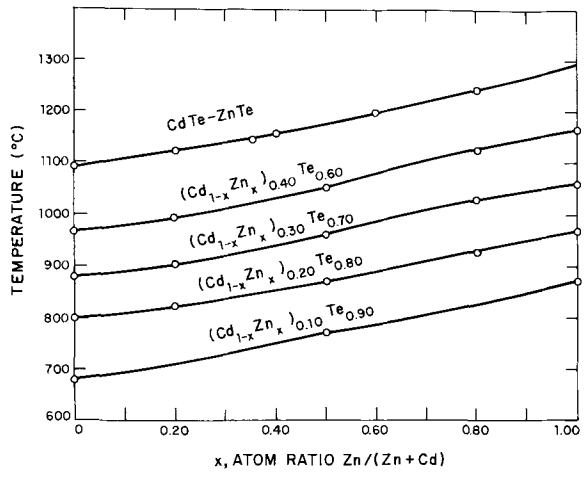

Fig. 6. Liquidus isopleths at constant Te concentrations on Te-rich side.

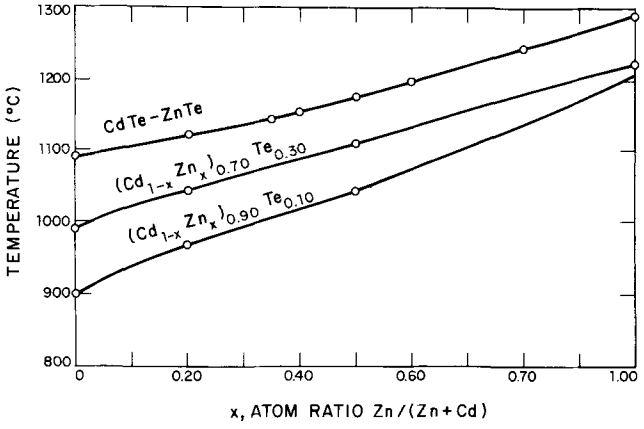

Fig. 7. Liquidus isopleths at constant Te concentrations on metal-rich side.

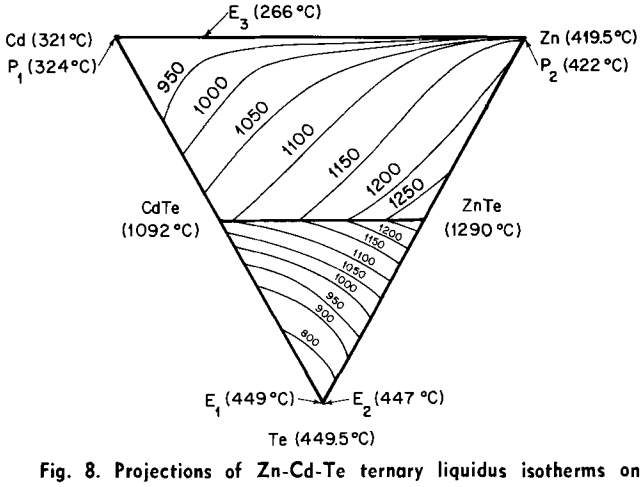

Fig. 8. Projections of Zn-Cd-Te ternary liquidus isotherms on composition plane.

the Zn-Te liquidus, both on the Te-rich side (Fig. 6) and on the metal-rich side (Fig. 7).

The projections of the ternary liquidus isotherms on the composition plane (Fig. 8) have been constructed by interpolation along the various liquidus curves. They vary smoothly between the binary Cd-Te and Zn-Te liquidus curves but show sharp peaks along the pseudobinary CdTe-ZnTe composition line which correspond to the marked increase in temperature as the composition approaches 50 a/o Te. The binary Cd-Zn system (17) shows a eutectic at 26.5 a/o Zn and 266°C. The binary Cd-Te and Zn-Te systems however show almost completely degenerate eutectics or peritectics, the thermal arrests being very close to the melting points of the pure elements (6). As a consequence, the ternary eutectic and boundary lines are also expected to be degenerate (Fig. 8).

Discussion

Liquidus surface.—Solution models of increasing complexity have been called upon to interpret the thermodynamic properties of III-V and II-VI binary and ternary systems. The relatively moderate deviations from ideality in the III-V systems led early investigators (18-20) to use expressions derived by Wagner (21) and Vieland (22) for a regular solution model with an interchange energy parameter varying linearly with temperature. Recently however, Stringfellow and Greene (23) have shown that the first-order quasi-chemical approximation of Guggenheim (24) with a temperature independent interchange energy parameter leads to satisfactory representation of the liquidus temperatures and of the activities in the III-V systems In-Sb, Ga-As, In-As, and the corresponding mixed ternary systems.

In the II-VI systems, the larger differences in electronegativity between metal and chalcogen atoms produce more ionic and stronger interactions between unlike atoms, as evidenced by the marked increase in temperature in the Zn-Cd-Te liquidus surface near the pseudobinary CdTe-ZnTe composition line (Fig. 8). As a result, the interchange energy parameter calculated along the liquidus curve from Vieland's regular solution expression exhibits a steep minimum (in excess of 200 kcal/mole) near the equiatomic composition (Fig. 9) instead of the approximately linear temperature dependence found in the III-V systems. This led Jordan (9) to propose the Regular Associated Solution model which postulates the existence of stable CdTe or ZnTe complexes in the liquid phase and effectively shows an interchange energy parameter that becomes very large at equiatomic composition.

This effect apparently stems from the failure of the regular solution model to account for the nonrandom distribution of atoms in the liquid phase. The quasi-chemical approximation, on the contrary, postulates a nonrandom distribution of pairs of atoms weighted exponentially in terms of the energy of interchange between pairs of unlike atoms and the corresponding pairs of like atoms (24).

Values of the quasi-chemical interchange energy parameter have been calculated in this study for experimental points along the Cd-Te and Zn-Te liquidus curves. A computer half-interval search method (25) was used to solve the liquidus equation derived by

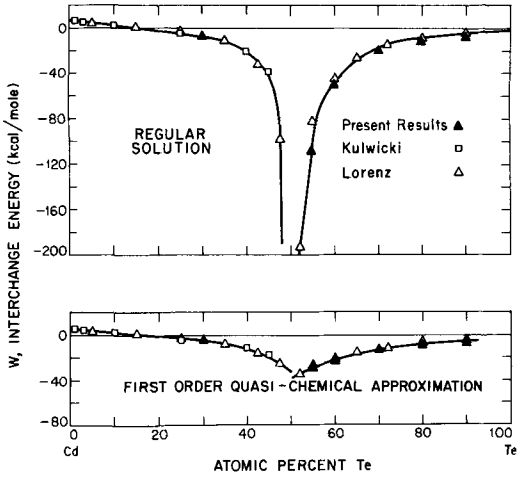

Fig. 9. Interchange energy parameter for regular and quasi-chemical approximations (Cd-Te binary system).

Stringfellow and Greene (23) from the general liquidus equation of Vieland (22) and the quasi-chemical activity coefficients of Guggenheim (24). (The values of Kulwicki (6) were used for the entropies of fusion of CdTe and ZnTe.) The variation of the interchange energy parameter for the Cd-Te system is shown in Fig. 9 for a coordination number of 4. Unlike the III-V systems investigated by Stringfellow and Greene, the II-VI systems show significant variations of the quasi-chemical parameter along the liquidus curve. The minimum near equiatomic composition however is much shallower than in the regular solution model and remains less than 30 and 35 kcal/mole on the Cd-rich and the Te-rich sides, respectively.

Both the regular and the quasi-chemical models are based on the assumption that the energy of the solution is a function solely of the number of pairs of unlike atoms and they fail to differentiate between metal-rich and chalcogen-rich solutions. The phase diagrams of the II-VI systems are highly unsymmetrical, because of the difference in energy of metal-metal and chalcogen-chalcogen bonds, and they cannot be adequately represented by either of these two models, unless they are arbitrarily separated into metal-rich and chalcogen-rich subsystems (6, 9). The more recent Non-Random Two-Liquid solution model of Renon (26) takes account of the differences in bond energy of the solvent atoms and offers the possibility of representing unsymmetrical phase diagrams with a single consistent set of parameters. Preliminary results indicate that it gives a better representation of the Ga-As liquidus curve and thermodynamic functions than the quasi-chemical model. Good fits to the Cd-Te and Zn-Te liquidus curves are also obtained, but some questions remain concerning the values of the temperature dependent bond energy parameters in these two systems.

Pseudobinary liquidus-solidus gap.— A general expression for the thermodynamic relationship between liquidus and solidus equilibrium compositions has recently been derived (27) for non-ideal but homogeneous and monotonic alloy systems (*i.e.*, systems showing complete liquid and solid mutual miscibility and monotonic variations of the liquidus and solidus curves). For a system of two components A and B with melting temperatures $T_A < T_B$, the molar fractions of A and B in the liquid and solid phases, X^l_A, X^l_B and X^s_A, X^s_B, in equilibrium at the intermediate temperature T such that $T_A < T < T_B$, are related by

$$RT\left(\ln\frac{X^s_A}{X^s_B}-\ln\frac{X^l_A}{X^l_B}\right)=\Delta H_A\left(1-\frac{T}{T_A}\right)-\Delta H_B\left(1-\frac{T}{T_B}\right)-D \quad [1]$$

where R is the ideal gas constant, ΔH_A and ΔH_B are the enthalpies of fusion of A and B, and D represents the difference between the partial excess free energies of mixing in the solid and liquid phases

$$D=\frac{\partial\Delta G^s_{e,m}}{\partial X^s_A}-\frac{\partial\Delta G^l_{e,m}}{\partial X^l_A} \quad [2]$$

If the liquid and solid solutions are ideal, the excess free energies of mixing are zero and $D = 0$. The ideal form cf Eq. [1] with $D = 0$ has also been found to fit the experimental data for a large number of binary and pseudobinary alloy systems (metallic, semiconducting, and ionic) in which the liquidus and solidus curves vary monotonically with composition (27). Although the liquid and solid phases in these systems are generally not ideal solutions, the ideal liquidus-solidus expression is applicable because the difference between the partial excess free energies of mixing is small enough to be neglected. The ideal expression can therefore be used to calculate one of the boundaries of the two-phase field when the other one and the enthalpies of fusion of the pure components are known. The solidus curve for the pseudobinary CdTe-ZnTe system in Fig. 4 has been calculated from our experimental liquidus data and from the enthalpies of fusion determined by Kulwicki (6). It shows excellent agreement with the solidus data (the root mean square of the difference between calculated and experimental temperatures for five points is 3.8°C), therefore confirming that the deviations from ideality in the two pseudobinary phases are small and nearly equal.

Growth Characteristics of Rutile Film by Chemical Vapor Deposition

R. N. Ghoshtagore and A. J. Noreika

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Thin film rutile has been grown by the chemical vapor deposition reaction of $TiCl_4$ and O_2 on silicon and a variety of oxide substrates over a range of temperatures (673°-1320°K) and reactant partial pressures ($p_{TiCl_4} = 2.9 \times 10^{-2}$ to 9.28×10^{-1} Torr, $p_{O_2} = 2.5 \times 10^{-1}$ to 760 Torr). At high oxygen partial pressures between 990° to 1100°K, the films have been found to contain the rutile modification of TiO_2 almost exclusively. Polycrystalline deposits on silicon, fused quartz, and amorphous silica (thermally grown or chemically vapor deposited) substrates displayed some preferred growth orientation (fiber texture). Epitaxial films were obtained on (001)-, (110)- and (111)-rutile, (100)-MgO, and (0001)-sapphire substrates at elevated temperatures.

The process of chemical vapor deposition (CVD) has recently attracted considerable attention as a method of depositing thin films of refractory materials on a variety of substrates (1). However, very few data are available on the nucleation and growth behavior in CVD systems. One such CVD process of potential importance is the growth of thin film ceramic oxides on semiconductors for use as insulators or dielectrics.

Among the simple oxides, titanium dioxide in rutile modification is known to have one of the highest dielectric constants (90 $\perp$ and 180 $\parallel$ c-axis) (2). Both physical and chemical deposition techniques have been reported for the preparation of titanium dioxide films. The former include the evaporation of titanium followed by oxidation, reactive sputtering of titanium in oxygen, and rf sputtering of titanium dioxide (3). The pyrolysis of titanium alcoholates (*e.g.*, tetraisopropyl titanate) (4), hydrolysis of titanium tetrachloride (5), and anodization of titanium films (6) are examples of chemical deposition of titanium dioxide. In this study, a new chemical vapor deposition process to form TiO_2 has been explored on a variety of substrates. Where practical, the growth characteristics, *i.e.*, crystal size and orientation, have been observed. Some relevant kinetic data regarding the formation of TiO_2 films on silicon have been reported elsewhere (7).

Experimental Technique

The experiments utilize the chemical reaction between titanium tetrachloride and oxygen on a heated substrate in a conventional horizontal quartz tube "silicon epitaxial" reactor at atmospheric pressure (8). Purified titanium tetrachloride (prepared by multiple distillation of 99.995% pure material) in thermostat-held quartz bottles is used as a titanium source bubbler through which a carrier gas of ultrapure argon or ultrapure oxygen (Matheson) is passed at a controlled rate. This gas (saturated with $TiCl_4$ vapor) is then mixed with additional ultrapure oxygen and/or argon through a set of calibrated flowmeters, liquid traps, and filters and the mixture reacted on a quartz encapsulated high purity graphite susceptor heated by rf induction. The over-all reaction can be described by

$$TiCl_4(g) + O_2(g) \rightleftarrows TiO_2(\text{rutile})\ (s) + 2Cl_2(g) \quad [1]$$

Free energy changes (ΔF) for this reaction, calculated from known thermochemical data (9), are −33.0, −30.3, −27.7, and −25.2 kcal/mole at 700°, 900°, 1100°, and 1300°K, respectively.

Single crystal silicon wafers (15-20 mils thick) of (111), (100), and (110) orientations, obtained from Texas Instruments, were lapped, polished in Linde B, and then chemically etched in 15:5:3 HNO_3:HAc:HF to a mirror finish by the supplier. Substrates for TiO_2 deposition were prepared by scribing 5 mm squares out of these wafers. The substrates were then degreased by boiling in trichloroethylene and acetone and chemically polished in 15:5:3 HNO_3:HAc:HF to remove about 5-10μ of surface layer. The substrates were then blown dry in dry nitrogen, mounted on the susceptor and baked for 20-30 min in ultrapure hydrogen at 1175°-1275°K to remove any residual oxide film (10).

The reactor atmosphere is then flushed with ultrapure argon and the substrate temperature is adjusted, the temperature being monitored with an optical pyrometer [corrected for absorption by the quartz tube wall, reactor atmosphere, and substrate emissivity (11)] and/or an infrared radiation pyrometer. Titanium tetrachloride vapor in the carrier gas is then passed into the reactor (after prolonged purging to vent), argon flow is discontinued, and mainline ultrapure oxygen is introduced at a predetermined flow rate. The deposits and substrates are then pushed off the susceptor at regular time intervals with a quartz push rod, and the deposition rate is determined from an average of 16 to 18 samples run for 8 to 9 different time periods. Film thicknesses were determined by reference to an ellipsometrically calibrated color chart (12). The temperature of titanium tetrachloride was maintained at 298° ± 0.5°K and that of the substrates to ± 5°K.

Similar experiments were performed using fused quartz and single crystal MgO, Al_2O_3, and TiO_2 (rutile) substrates, an exception to the previously described experimental procedure when using these substrates being the omission of the hydrogen anneal. The reported data on the fused quartz, MgO, and Al_2O_3 substrates were determined from the change in weight (to microgram accuracy) of several substrates of known surface area before and after depositing a 4000-6000Å thick rutile film. The theoretical density of 4.26 g/cm^3 (for bulk rutile) was used for thickness computation of the rutile film. Determinations of crystallite size and film orientation were made from transmission electron microscopy (TEM) and reflective electron diffraction (RED) studies, respectively. The Si substrates were particularly well suited for the TEM study since they lend themselves to a well-established chemical jet-etching technique (13). In this technique, selected areas of the substrates are dissolved in a chemical jet-etch solution, the remainder being retained as support for the TiO_2 membranes which span the etched areas.

Key words: rutile, film, epitaxy, nucleation, deposition, orientation, growth, dielectric.

Results and Discussion

Nucleation density and deposition rate.—Figure 1 shows Arrhenius plots relating the deposition rate of TiO_2 to substrate temperature at three constant partial pressures of titanium tetrachloride. Within the range of experimental error the rates are seen to be independent of both substrate composition and substrate orientation. Consequently, it can be inferred that the mechanism of TiO_2 film formation is identical on all the substrates studied and is that which has been elucidated by kinetic studies in the case of single crystal silicon substrates (7). Nucleation in the vapor phase by gas phase reaction becomes predominant around 1125°K in all cases, above which temperature the rates decline. The effects of vapor phase reaction and consequent reduction of the effective vapor pressure of the rate-limiting reactant $TiCl_4$ are also evident in Fig. 2, a plot of the number of embryo crystallites, *i.e.*, those formed during the first minute of deposition, as a function of temperature. At temperatures less than 1125°K, the count increases with temperature; above 1125°K, the crystallite density decreases.

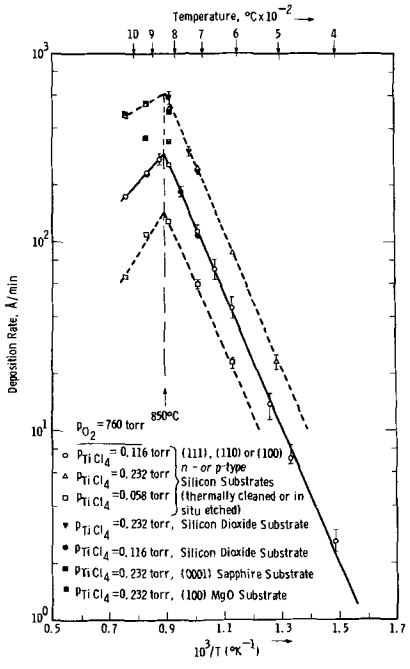

Fig. 1. Arrhenius plot of rutile thin film deposition rate

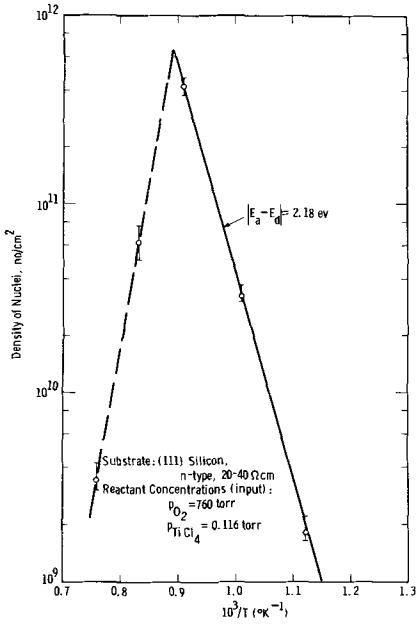

Fig. 2. Arrhenius plot of the density of TiO_2 nuclei on (111) silicon.

The trend of the data, *i.e.*, the exponential rise as a function of increasing substrate temperature, in both sets of curves (Fig. 1 and 2) below 1125°K is presumably due to two complementary effects, (*i*) an increase of the rate of reaction of component gases as the thermal energy supplied to the substrate is increased, *i.e.*, the exponential dependence of the surface reaction rate constant with temperature (7), and (*ii*) an almost negligible vapor pressure of the solid reaction product (TiO_2) in the temperature range of interest (9). The latter effect is equivalent to an "ideal" complete condensation of impinging product atoms or molecules as envisioned in physical vapor deposition systems. Coupling of the above two effects produces an effective supersaturation which also increases with temperature exponentially. Deposition rate and nucleation density, both strongly related to supersaturation, assume a similar temperature dependence. However, the activation energies of deposition and nucleation are quite different in magnitude because of the difference in the physicochemical processes involved in each phenomenon.

It is well known that when a solid surface catalyzes a hetereogeneous gas reaction, the energy of the reaction is decreased by the adsorption of one or more of the reactants. If E_H and E_s are the energies for uncatalyzed and catalyzed reactions, respectively, and E_i^A is that for the adsorption and/or desorption of the ith reaction species on the catalyst, then

$$E_H - \sum_1^n E_i^A = E_s \qquad [2]$$

where n is the number of species involved in the reaction.

E_H can be calculated from the available thermodynamic data (9) and is $\sim$ 1.25 eV whereas E_s can be obtained from Fig. 1 and is $\sim$ 0.8 eV. Since only the adsorption of atomic oxygen is involved in our CVD mechanism (7), $\sum_i^n E^{A}_{\text{atomic oxygen}} = E_o^A \cong 1.25 - 0.80$ eV $= 0.45$ eV.

Now, if ΔE_o is the enthalpy of activation for the reaction

$$\frac{1}{2} O_2 \rightleftarrows O \qquad [3]$$

and K is the equilibrium constant, then

$$K = \frac{p_O}{p_{O_2}^{1/2}} = \text{Exp} \frac{-\Delta E_o}{kT} \qquad [4]$$

or

$$p_O = p_{O_2}^{1/2} \text{Exp} \frac{-\Delta E_o}{kT} \qquad [5]$$

where p_O and p_{O_2} are the partial pressures of atomic and molecular oxygen, respectively.

Since TiO_2 is formed by the adsorption of atomic oxygen (charged or uncharged) (7) on the substrate, the saturation nucleation density of TiO_2 (N_s) is proportional to the density of adsorbed oxygen which, in turn is, proportional to the gas phase concentration of atomic oxygen produced by the reaction represented by Eq. [3]. Using Eq. [5], we obtain

$$N_s = C_1 p_O^{\text{adsorbed}} = C_1 C_2 p_O \text{Exp} \frac{E_o^A}{kT}$$

$$= C_1 C_2 p_{O_2}^{1/2} \text{Exp} \frac{-\Delta E_o + E_o^A}{kT} = C \exp \frac{-\Delta E_o + E_o^A}{kT}$$

$$= C \text{ Exp} - 2.14 \text{ eV}/kT \qquad [6]$$

where C_1, C_2, and C are constants, and $E_o^A \cong 0.45$ eV and $\Delta E_o = 2.58$ eV (14). The excellent agreement of the calculated activation energy of saturation nucleation density (Eq. [6]) with the experimental data (Fig. 2) also seems to validate earlier conclusions on the mechanism of the surface nucleation. Furthermore, the other possible mechanism of surface nucleation by the collection of the nuclei formed in the vapor phase seems to be ruled out by the experimental facts that (*i*) the nuclei do not have spherical morphology (see later), and (*ii*) the saturation nucleation density does not remain constant above 1125°K, when the gas phase reaction has overtaken the surface reaction.

When vapor phase reaction becomes predominant (above 1125°K, Fig. 1 and 2), the model described still applies although the curve appears to assume a positive slope. As the gas phase temperature is raised along with that of the substrates, nucleation in the vapor phase is enhanced, and the effective pressure of the rate-limiting reactant gas ($TiCl_4$) seen by the substrate diminishes. Since the rate of surface reaction and the supersaturation are also functions of this pressure, both deposition rate and nucleation density decrease. The data above 1125°K, in both Fig. 1 and 2, represent a sum of two competing physicochemical processes. Thus, above 1125°K, the nucleation density (N_s) can be described by Eq. [6] modified by an additional factor for the amount of unreacted $TiCl_4$ present. A similar adjustment can be made to describe the deposition rate above 1125°K.

Orientation behavior.—Some variations were observed in the crystallographic orientations adopted by TiO_2 films, on the several types of substrates used. On oriented Si wafers, for example, crystal orientation within the films was found to be independent of substrate orientation. These data obtained from RED observations are presented as functions of the substrate temperature (630°-1320°K) and orientation in Fig. 3. All Si substrates were of the low-index type, *i.e.*, (100), (110), and (111). Figure 3 indicates that with a change of substrate temperature, different crystal orientations are produced in the films. At temperatures below 630°K, the crystallites are oriented at random. A strong {110}-orientation occurs between 630° and 730°K. This is succeeded by a {101}-orientation between 730° and 990K, then by a {301}-orientation between 990° and 1125°K; and finally, by a strong {100} orientation at higher temperatures, at least to 1320°K. Deposition of TiO_2 on fused quartz substrates over a temperature range of 990°-1100°K produced films having orientations similar to those for TiO_2 on Si.

This similarity prompted additional experiments in which oxides of Si were deliberately formed on oriented Si surfaces. The oxide layers were either

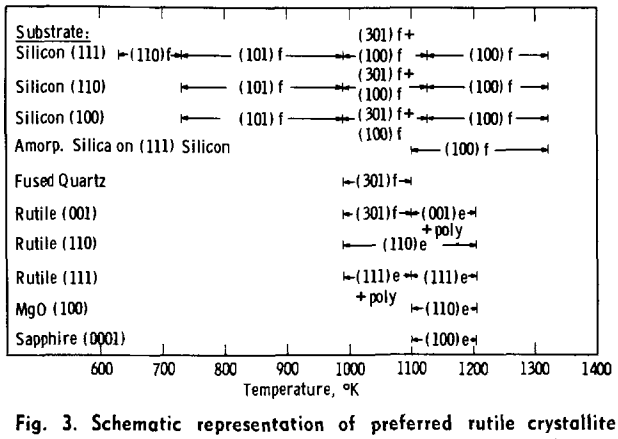

Fig. 3. Schematic representation of preferred rutile crystallite orientation in thin films (as a function of substrate material, temperature, and orientation) grown at $p_{O_2} \simeq 760$ Torr and $p_{TiCl_4} = 0.058$ to 0.232. Symbols f and e stand for fiber and epitaxial habits, respectively.

thermally grown or chemically vapor deposited (by the reaction of SiH_4 and O_2). When TiO_2 films were subsequently deposited, orientations were the same as those deposited on both the hydrogen annealed Si and the silica surfaces. In another experiment, *in situ* gaseous etching of Si substrates with HCl was performed prior to TiO_2 deposition. After 1-2 μm of the substrate surface had been removed, the reaction components were introduced, and films were deposited. Orientations altered slightly in this case, the onset of {100}-orientation occurred at a temperature of 1000°K, and the {301}-orientation was eliminated.

The evidence suggests that the observed TiO_2 orientations represent equilibrium orientations on both neutral and neutralized surfaces; the single crystal Si substrates being neutralized by exposure to oxygen. Moreover, the presence of neutralized surfaces is virtually inevitable since the adsorption of oxygen at the surface is a prime requirement in the reaction sequence. The cause of slight modification in the results for films etched *in situ* by HCl is, as yet, not well established. Since the etch was intended to remove the natural surface oxide, as was the hydrogen anneal, one assumes that the predeposition treatments of the substrate did not produce equivalent results and that the {301}-orientation, where it occurs, may be artificially stabilized.

Efforts to detect the presence of SiO_2 between substrate and film included infrared absorption measurements. Known thicknesses of SiO_2 in especially prepared Si-SiO_2-TiO_2 structures served as standards. Since infrared absorption was not observed for either the experimental films or for the standards in which SiO_2 thickness was less than 200Å, oxide films, if present, had not exceeded the absorption thickness limit.

Since oxygen neutralized surfaces may well be the rule on metallic and semiconductor single crystal substrates, single crystal oxide substrates appear to offer the most likely surfaces for the epitaxial growth of rutile. Deposits on cleaved and polished surfaces of rutile, MgO, and sapphire, in fact, showed varying degrees of epitaxy, Fig. 3, at temperatures between 990° and 1205°K.

Figure 3 also indicates that the best orientation match between the film and substrate occurs for (110)-oriented rutile substrates. Good epitaxial alignment is also evident on the (111)-oriented substrates at temperatures greater than 1100°K. Films deposited on (001)-oriented substrates showed a moderate degree of epitaxy at temperatures near 1200°K; orientations of deposits prepared at lower temperatures ranged from a {301}-fiber texture at 990°K to a badly twinned (001)-epitaxial layer near 1100°K. The degree of twinning was greatly reduced and often completely eliminated in all homoepitaxial growth experiments, *i.e.*, on (110), (100), and (111)-oriented rutile substrates, by *in situ* etching of the substrates in gaseous chlorine at 1320°K; 1000-1500Å of a substrate was so removed.

Films prepared on (100)-oriented MgO and (0001)-oriented sapphire substrates in a temperature range of 1100°-1205°K also exhibited strong epitaxial behavior. Some of their representative RED patterns are shown in Fig. 4. The orientation relationships between rutile films and substrates (where TiO_2 represents the rutile film and Al_2O_3 represents the sapphire substrate) were $(110)_{TiO_2} \parallel (100)_{MgO}$, $[001]_{TiO_2} \parallel [011]_{MgO}$ and $(100)_{TiO_2} \parallel (0001)_{Al_2O_3}$, $[010]_{TiO_2} \parallel [110]_{Al_2O_3}$, $[011]^*_{TiO_2} \parallel [110]_{Al_2O_3}$. ([ ]* = R.L. vector). Inspection of the orientation relationship observed for rutile films on (100)-oriented MgO substrates indicates that a continuous oxygen sublattice exists across the substrate-film interface with titanium atoms occupying unoccupied octahedral sites of MgO lattice. Since the respective oxygen ion densities for observed crystallographic planes are MgO(100) $= 1.13 \times 10^{15}/cm^2$ and rutile (110) $= 1.04 \times 10^{15}/cm^2$, some interfacial dis-

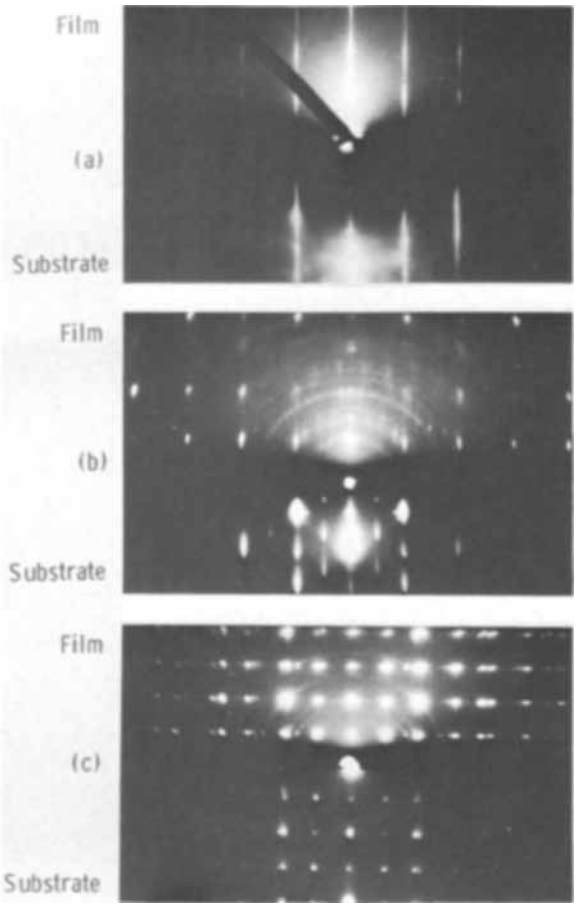

Fig. 4. Reflection electron diffraction (RED) patterns of epitaxial rutile films on (a) (110) rutile, (b) (100) MgO, and (c) (0001) sapphire. Corresponding RED patterns of substrates are shown on the bottom half of each photograph. Substrate temperature = 1100°K, $p_{O_2} \simeq 760$ Torr, $p_{TiCl_4} = 0.232$ Torr.

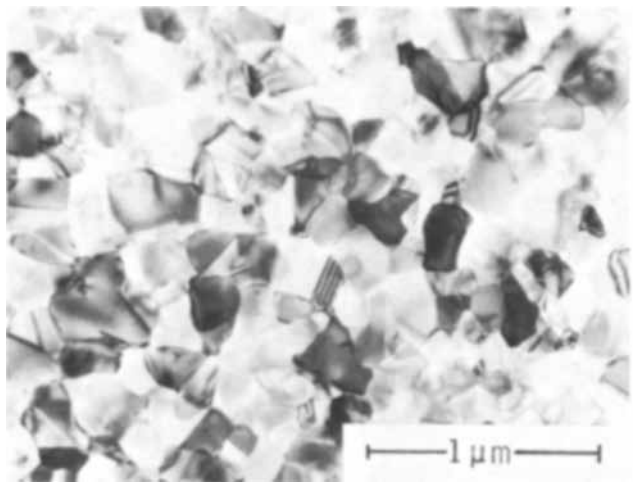

Fig. 5. Typical transmission electron micrograph of rutile film grown on silicon. $p_{O_2} \simeq 760$ Torr, $p_{TiCl_4} = 0.116$ Torr, $T = 1100°K$, $t \simeq 1500Å$.

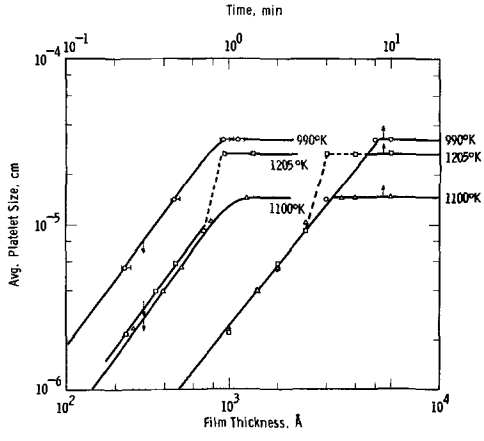

Fig. 6. Average lateral size of rutile crystallites in the thin films grown on (111) silicon single crystal substrates as functions of film thicknesses and growth times at 990°, 1100°, and 1205°K. $p_{TiCl_4} = 0.116$ Torr, $p_{O_2} \simeq 760$ Torr.

tortion is expected. A somewhat similar alignment occurs on (0001)-oriented sapphire crystals where the oxygen-filled substrate surface becomes common to both substrate and film. In this case, the respective oxygen ion densities are sapphire (0001) = 5.12 x 10^{14}/cm^2 and rutile (100) = 7.37 x 10^{14}/cm^2. In deposits on to single crystal rutile surfaces (homoepitaxy), the oxygen-titanium stacking becomes that of the substrate.

Growth behavior.—The growth behavior of TiO_2 films was most conveniently observed by transmission electron microscopy (TEM) of films deposited on Si substrates. The majority of films so investigated had mean thicknesses between 230 and 1500Å, were deposited in a fixed set of reactant partial pressures ($p_{TiCl_4} = 0.116$ Torr, $p_{O_2} \simeq 760$ Torr), and at one of three predetermined temperatures, 990°, 1100°, or 1205°K. All films on silicon showed a platelet morphology as shown in Fig. 5. The data obtained from such micrographs are given in Fig. 6 where the average platelet dimension is plotted both as functions of film thickness and equivalent growth time. The average platelet size was observed from the electron micrographs by linear analysis (error $\cong \pm 10\%$). Since average values did not change with annealing at the growth temperatures in oxygen ($p_{O_2} = 760$ Torr) (the annealing period was at least ten times the period of the deposition), they were considered to represent equilibrium dimensions. From the data in Fig. 6, deposits prepared between 990° and 1205°K show lateral extension of individual grains at almost a constant rate until a film thickness between 700 and 1000Å are reached. At these thicknesses, further lateral growth ceases. The ultimate lateral dimensions reflect the differences in nucleation densities observed earlier, i.e., deposits where nucleation density was greatest show crystallites of smallest lateral dimension and vice versa. Approximate dimensions (maximum) are 1470Å (1100°K), 2700Å (1205°K), and 3300Å (990°K). The data from films deposited at 1205°K indicate that at this temperature the rate of lateral extension is irregular in the thickness range 700-900Å. These growth results are regarded as uncertain at present and are indicated by a dashed line in Fig. 6. The size irregularities are likely related to the appearance of another TiO_2 phase during deposition [electron diffraction reveals the presence of TiO_2 (anatase) in deposits prepared above 1125°K]. The observed two-component multilayered film is likely to produce crystallites of various dimensions, the averaging of which could cause the observed discrepancy. The mechanism for formation of the second phase may well occur via a homogeneous reaction between $TiCl_4$ and O_2; such a reaction has been reported in a similar CVD reaction (4) although no structural data of the reaction product is available.

Effects of partial pressure ratio.—The effects of the variation of partial pressure ratio p_{O_2}/p_{TiCl_4} on the deposition rate of TiO_2 film is shown in Fig. 7 at two substrate temperatures. The slope of 1/2 is due to the fact that atomic oxygen is a reactant species at both these temperatures; this has been discussed in detail elsewhere (7). The pressure ratio at which TiO_2

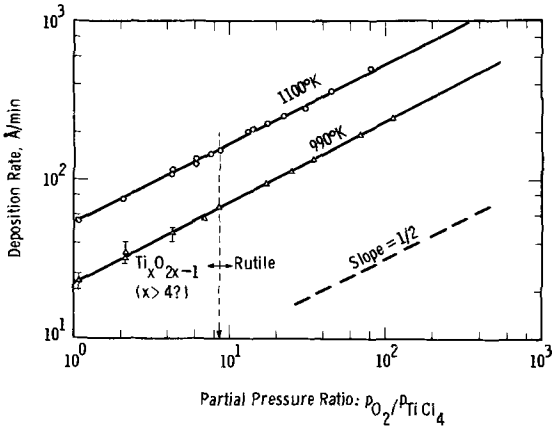

Fig. 7. TiO_2 thin film deposition rate as a function of the reactant partial pressure ratio (p_{TiCl_4} = 0.058 to 0.232 Torr, p_{O_2} = 0.25 to 25 Torr) at two substrate temperatures.

(rutile) formation is prominent is 8.62; below this ratio an unidentified reaction product is formed which is stable to the extent of complete resistance to further oxidation in pure oxygen (760 Torr) at temperatures up to 1320°K and at annealing durations of up to 8 hr. Thermodynamic calculations, using free energy change values from the JANAF thermochemical tables (9) and assuming equilibrium, *i.e.*

$$2p_{Cl_2} = p_{TiCl_4} \text{ and } p_{O_2}/p_{TiCl_4} = \tfrac{1}{4} Kp \qquad [7]$$

predict that the minimum p_{O_2}/p_{TiCl_4} ratio for rutile formation is 7.7 x 10^{-7} at 1100°K. This is orders of magnitude lower than the experimental value of 8.62 and is in the right direction for a reaction sequence controlled by the surface adsorption kinetics of atomic oxygen produced in the gas phase.

Refractive index data.—The refractive indices (n_D) and thicknesses of TiO_2 films on silicon were determined by ellipsometric methods (12). For films in the thickness range of 200-1500Å the average value of n_D was 2.83 ± 0.03. A few films thinner than ~ 500Å had a refractive index 5-8% lower than this average value. Such data are not uncommon in thin films, viz., indices of refraction of the oxides (Al_2O_3, Ta_2O_5, Nb_2O_5) are less in thin film form than in the bulk (15). The average refractve index of TiO_2 films (2.83 ± 0.03) produced for the present studies is greater than that obtained by a similar CVD process (n_D = 2.0) using tetrabutyl titanate and tetraisopropyl titanate (16) and compares favorably with the single crystal n_D values (17) (2.909 for the extraordinary ray and 2.613 for the ordinary ray). No reproducible behavior of change in n_D as a function of film thickness and/or deposition temperature could be detected.

Summary and Conclusions

The present study on the structure of chemically vapor deposited TiO_2 thin films on a variety of substrates has shown that (*a*) the crystallographic modification of TiO_2 produced by the reaction of $TiCl_4$ (g) and O_2(g) on all substrates studied is predominately rutile at and above a $p_{O_2}:p_{TiCl_4}$ ratio of 8.62; (*b*) the film is always polycrystalline on single crystal silicon between 0.001 to 30 ohm-cm, p- or n-type and low-index orientations and silica (amorphous or fused quartz) substrates and exhibits a particular fiber texture which is a function of only the temperature of deposition; (c) at temperatures below 1100°K, growth on (001) and (111) rutile substrates generates polycrystalline films and at relatively high deposition temperatures (> 1100°K) epitaxial films were produced on single crystal rutile, MgO and sapphire substrates; (*d*) *in situ* HCl etching of single crystal substrates produces preferred crystalline orientation at lower temperatures (in the case of silicon) and better quality epitaxial films (little or no twinning) on rutile substrates; (*e*) under a fixed set of experimental conditions comparable growth rates were obtained on all substrates; (*f*) between 990° and 1205°K the rutile crystallites grew laterally (on silicon) at about the same rate up to a film thickness of about 700Å; and (*g*) the density of TiO_2 nuclei (on silicon) increased exponentially with increasing temperature up to about 1125°K with an activation energy of 2.18 eV.

The energetics of the rutile crystallite formation process (on silicon) has been analyzed to support an earlier conclusion that the kinetics of the reaction $TiCl_4(g) + O_2(g) \rightarrow TiO_2$ (rutile) + $Cl_2(g)$ (on the silicon surface) involve adsorbed atomic oxygen and $TiCl_4$ molecular species (in the gas phase). Also, the epitaxial rutile thin film grown on low-index MgO, rutile, and sapphire substrates have easily understandable film-substrate structural relationships.

Technical Notes

Deposition of Silicon and Silicon Carbide by Film-Boiling

Raymond W. Conrad*

Physical Sciences Laboratory, U. S. Army Missile Command, Redstone Arsenal, Alabama 35809

When a substrate is immersed in a liquid and heated to a temperature much higher than the boiling point of the liquid, a sheath of vapor forms, separating the liquid from the substrate. This process is generally called "film boiling." If the liquid thermally decomposes or otherwise reacts to produce a substance which is nonvolatile at the temperature of the substrate, plating of this substance onto the substrate may occur. Basically, such a process is simply vapor deposition, at the high vapor concentration limit.

Recently Nieberlein (1) has used the film-boiling method to deposit polycrystalline silicon carbide onto tungsten filaments from mixtures of trimethylchlorosilane and cyclohexane at temperatures of ~900°C. Deposition rates of up to 100 μm/min were obtained. X-ray investigations (2) have not yet unraveled the crystal structure of the deposits. However, an extensive transition layer of tungsten carbide was identified.

This report presents the initial results of our attempts to adapt the film-boiling technique to the production of materials for electronics applications, particularly silicon carbide. Graphite and single-crystal silicon substrates were used in an attempt to eliminate transition layers. Several liquid systems were investigated.

Experiments and Results

The deposition system (Fig. 1) consisted of a pair of copper electrodes, with adjustable spacing, immersed in the liquid under study. The deposition cell was cooled with chilled acetone (~0°C) to minimize evaporation. The substrates were clamped between the electrodes by tightening the Teflon spacers and heated with a variable autotransformer. A current-limiting resistor was required when using silicon substrates. This consisted of a coil of resistance wire wound on a spiral-grooved ceramic core (total resistance, 15 ohm). Several intermediate taps were provided for lower resistances.

Temperature was monitored with an optical pyrometer. Sight-path effects introduced an uncertainty of ±50°C. The boiling, liquid sheath did not interfere with the temperature measurements during the early stages of deposition. However, the solutions eventually became turbid, making temperature measurements unreliable toward the end of deposition.

Graphite substrates, nominally 2 × 0.3 × 0.1 cm, were cut from disks of spectroscopic grade graphite (National Carbon, Grade CCH), lightly sanded with fine emery paper, rinsed with acetone and wiped dry. Silicon substrates, nominally 2 × 0.3 × 0.05 cm, were obtained by scribing and fracturing from 0.2 to 0.5 ohm-cm, (111), p-type silicon wafers. These were degreased in trichloroethylene and etched in $HF-HNO_3$ before use. Solutions for deposition were prepared from reagent grade materials without further purification. They were used only once because of the turbidity produced during deposition.

Graphite substrates.—Deposition from pure trimethylchlorosilane at ~1100°C produced thick, adherent layers of polycrystalline material which were identified by x-ray diffraction as the 6H polytype of α-silicon carbide. Deposition rates were ~350 μm/min for runs of up to 1½ min duration. Knoop microhardness values averaged 2200. No electrical evaluations have yet been made on these deposits, other than to note that they appeared to be n-type by thermal probe and to have relatively high resistivity.

Dilution of the trimethylchlorosilane with cyclohexane decreased the rate of deposition, but otherwise had no apparent effects on the gross characteristics of the deposits. Dilution with methanol, however, produced a rather dramatic effect. For mixtures with less than ~65 v/o (volume per cent) methanol, the deposits resembled those from pure trimethylchlorosilane. For mixtures with higher methanol concentrations, a black, lustrous deposit was obtained. Fracture surfaces of this material appeared glassy (see Fig. 2). Pro-

longed etching in $HF-HNO_3$ (4 days in a 50-50 mixture) revealed that some areas of the deposits were not single-phase. X-ray diffraction indicated the material was indeed noncrystalline. Knoop microhardness values averaged 1800. The chemical composition has not yet been determined. However, the material was observed to form a liquid phase when heated in an inert atmosphere to 1700°C. Microscopic examination of the surface after this treatment revealed that portions of the layer had been transformed into a colorless glassy material which we suspect is silica.

The preparation of a similar, black, glassy substance by the decomposition of methyltrimethoxysilane vapor on a hot tungsten filament was reported by Hough and Early (3). They reported the composition to be $\sim Si_{33}C_6O_{40}$.

Silicon substrates.—Deposition from pure trimethylchlorosilane at ~950°C produced thick, polycrystalline layers shown by x-ray diffraction to be silicon. Deposition rates were 200 μm/min for runs of up to 1½ min duration. The deposits appeared to have relatively high resistivity. Thermal probing indicated n-type conduction.

Dilution with cyclohexane not only decreased the deposition rate but materially improved the physical quality of the deposit. Figure 3 shows a 94 μm thick layer deposited in 4½ min from a mixture containing 20 v/o trimethylchlorosilane. Back reflection x-ray diffraction indicates that some areas of the deposit are (111) single crystal. Thermal probing showed the deposit to be n-type. The electrical characteristics of the p-n junction have not yet been investigated. No deposits could be obtained using trimethylchlorosilane and methanol mixtures because the conductivity of such solutions was higher than that of the substrate.

Discussion

The deposition of silicon onto silicon substrates from trimethylchlorosilane, both with and without cyclohexane, was an unexpected result in view of the results obtained using tungsten and graphite substrates. The influence of deposition temperature on the composition of the deposit, however, has yet to be determined. The results reported here were for a relatively low deposition temperature, and the formation of silicon carbide at higher temperatures cannot be ruled out. Different results might also be obtained by using a different silane or an organic diluent or both. Nevertheless, the effect of the substrate on the course of the reactions occurring is vividly illustrated.

The suitability of material prepared by film-boiling for device fabrication has yet to be demonstrated. The rather unsophisticated technique used here can certainly be improved upon. By using highly purified liquids and inert electrodes (*e.g.*, graphite), the purity of the deposits should be substantially improved. Actually, this technique should be inherently cleaner than solution epitaxy, since the container for the liquids is not heated. Should it prove to be detrimental, the turbidity of the liquids, produced during deposition, might be eliminated by using a liquid flow system in which the liquids are continuously pumped from the deposition chamber through a filter, thence back to the chamber. Dopants might also be thus introduced.

There are several characteristics of the film-boiling technique that may limit its usefulness for epitaxial deposition. For example, there is a very large temperature gradient along the substrate major axis. This might be reduced, however, by using very long, thin substrates. High resistivity substrates obviously could not be used. The inability to vapor etch might also be a disadvantage. However, some degree of etching might be obtained by heating the substrate to a relatively low temperature if the liquid easily decomposes to produce vapors of an etchant, *e.g.*, HCl. The tendency to deposit thick polycrystalline layers from concentrated solutions, although undesirable for epitaxy, may have applications to the technology of integrated circuit fabrication using dielectric isolation.

Gallium Diethyl Chloride: A New Substance in the Preparation of Epitaxial Gallium Arsenide

K.Lindeke, W. Sack, and J. J. Nickl

Forschungslaboratorium für Festkörperchemie am Institut für Anorganische Chemie der Universität München, München, Germany

Manasevit *et al.* (1, 2) and Rai-Choudhury (3) have reported on the use of alkyl-gallium compounds and arsine in the preparation of gallium arsenide epitaxial layers. However, these compounds are distinguished by a high reactivity (4) [$Ga(CH_3)_3$ ignites with O_2 even at −76°C, and a mixture of its vapor with air explodes at room temperature; $Ga(C_2H_5)_3$ ignites in air and explodes in O_2.] The use of trialkyl-gallium together with highly toxic arsine (threshold limit value 0.05 ppm) is extremely hazardous in case of any leakage.

Key words: materials, preparation, gas epitaxy, organic Ga source, arsine.

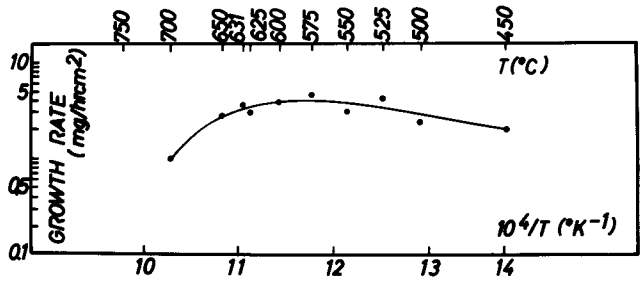

Fig. 1. Growth rate of (100) GaAs layers vs. $10^4/T$

The reaction between $Ga(CH_3)_3$ and Pyrex has also been reported (2). This causes difficulties during distillation for purification purposes. In a technical application it would be important to have a Ga-compound which is safer to handle even in large quantities.

Therefore, the comparable low reactive gallium diethyl chloride (GDC) has been used as the Ga source. This substance hydrolyzes slowly even in 0.1*N* NaOH. Although 1 mole of HCl is generated per mole GaAs, this should not have a negative influence on the layer quality because, in the Cl-transport system, layers of highest purity can also be produced (5, 6). In addition, gas-phase etching occurs in the reaction mixture just before growing the crystal by increasing the temperature to 750°C, which may be very helpful in preparing an absolutely clean surface.

GDC was obtained commercially and is used without further purification. The arsine (purity 99.5%) concentration was 5.5% in high-purity H_2. Semi-insulating Cr doped GaAs wafers of $(\bar{1}\bar{1}\bar{1})$ ("B" face), (110) and (100) orientation were etched in 10% Br_2/CH_3OH and washed in methyl alcohol just before use.

The experiments were performed in a vertical rf heated flow-type reactor designed to permit evacuation. Quartz, Pyrex, Teflon, and stainless steel have been used in constructing the system. This kind of CVD apparatus has also been used successfully in the preparation of elemental semiconductors such as Si and Ge (7, 9) and has many advantages. A thermocouple NiCr/Ni, calibrated at the freezing point of Al, was embedded in the graphite susceptor in close proximity to the GaAs wafer.[1] The susceptor was coated with pyrolytic carbon. A bubble-type vaporizer inserted into an oil bath at about 60°C contained the liquid gallium source. Three special bubblers containing H_2O, Br/H_2O, and 30% NaOH, are used downstream to destroy the waste products, especially AsH_3.

Before deposition takes place the wafers are heated to 900°C for 1 min to remove surface contaminations. In the early stage of the investigation the grown layers often showed holes; this could be prevented by this annealing step. Then the temperature is lowered to the growth temperature and the AsH_3-stream (0.7 l/hr) is started. After As deposits at the reactor walls the H_2 (3.5 l/hr) is bubbled through the GDC, and GaAs is formed on the substrate. The GaAs wafers were heated to growth temperature (450°-700°C) and after deposition cooled to room temperature in Pd-diffused H_2. It is recommended that the wafers not be cooled in the reaction mixture, since GaAs is formed down to 450°C (Fig. 1). Below growth temperature of 500°C the layers are of high resistivity and have rough surfaces. Single crystallinity as determined by reflection x-ray Laue pattern was obtained as low as 450°C. At 750°C gas-phase etching takes place, as observed by weight changes of the wafers before and after the process. The nature of this reaction is not known so far. We believe that 1 Cl from the GDC transports 1 Ga as GaCl from the surface and the other part of the GDC is evaporated as a alkyl subcompound Ga $(alkyl)_{1\text{ or }2}$ from the surface. However, no visible amount of metallic Ga could

[1] The influence of the rf was prevented by a capacitor shunted to the thermocouple.

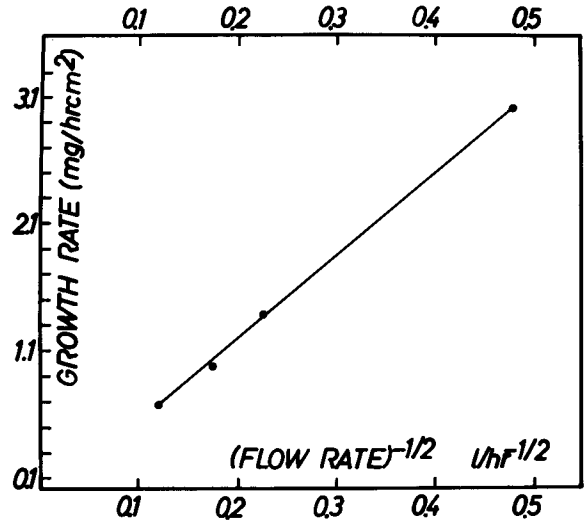

Fig. 2. Growth rate of (100) GaAs layers vs. (total flow rate)$^{-1/2}$ at constant GDC and AsH_3 flux.

be detected at the substrate or anywhere in the reaction chamber (by reaction 3 $GaR_1 \rightarrow GaR_3 + 2$ Ga).

Mirror smooth layers of epitaxial GaAs on (100), (110), $(\bar{1}\bar{1}\bar{1})$-surfaces were obtained, but the reported data are measured on layers with (100)-orientation. Layer thickness was determined by two methods: first by etching (10); second by the weight gain of the wafers. Growth rate was evaluated as function of substrate temperature (Fig. 1) and gas stream velocity at constant GDC and AsH_3 input values. Since the reaction is nearly independent of the temperature, we assume a mass transport phenomenon to be the rate-controlling step. This is supported by Fig. 2 which shows the growth rate increasing with the reciprocal square root of the gas stream velocity.

The electrical properties of the layers were assessed using the van der Pauw method (11). For this purpose contacts of Sn/In (48/52) were alloyed at about 250°C in a H_2, Ar, HCl (80/15/5) atmosphere. The ratio of the two van der Pauw resistivities $R_1:R_2$ was constant within 3% from 70° to 300°K. The Hall coefficient R_H and the resistivity ρ were measured in this temperature range. The mobility was calculated from the ratio R_H/ρ. The magnetic field was 4 kG. Plots of carrier concentrations as a function of reciprocal temperature are shown in Fig. 3. The mobility plots *vs.* temperature are shown in Fig. 4. The correlation between deposition temperature, layer thickness, the measured carrier concentration, and mobility are shown in Table I. The

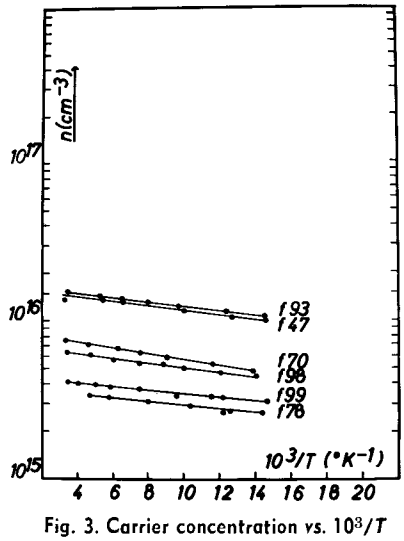

Fig. 3. Carrier concentration vs. $10^3/T$

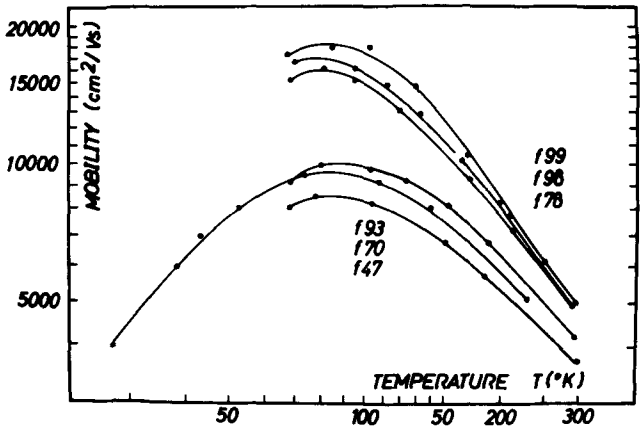

Fig. 4. Mobility vs. temperature

samples seem to have an impurity with an ionization energy of about 8 meV, calculated under the assumption of one single donor term, partly compensated by acceptor terms. The impurity has not yet been identified. No carbon could be detected in the reaction chamber or on the layers either by microanalytical methods or by x-ray investigations.

The results, listed in Table I, show that GDC is a suitable substance for the preparation of epitaxial GaAs layers. However, better results should be obtained when purer starting materials are used.

Acknowledgment

The authors are greatly indebted to Dr. Doetzer, Siemens AG. Erlangen, Germany, for supplying GDC. Thanks are given to Mrs. M. Betz for technical assistance.

Development of a Controlled Porosity Silver Electrode

G. W. Mao, D. S. Polcyn,* and R. E. Tieder

Gould Incorporated, Gould Laboratories, Energy Technology, Minneapolis, Minnesota 55414

ABSTRACT

Silver electrodes which require no supporting grid and have a porosity graded structure were fabricated by combining silver powder of uniform mesh size with a plasticizer and pore forming additives. The proportions of these materials are selected to give a uniform doughlike mixture which is rolled and then sintered. Porosity control is achieved by controlled decomposition of the plasticizer and pore forming additives. Multilayered graded porosity electrodes are assembled by a combination of sintering and compaction. Performance data based on cycling tests and coulombic efficiencies demonstrated that these electrodes are comparable to conventional silver electrodes and the absence of the grid is not a limiting factor.

Silver electrodes for electrochemical cells can be produced by various methods either from silver or silver oxide powders. Junger (1), Morrison (2), and Jirsa (3) have produced silver electrodes by various methods of pasting a silver grid. Moulton and Enters (4) describe producing a sintered porous silver mass by thermally decomposing a dried silver(I) oxide pasted grid. More recently, electrodes have been prepared by application of silver(II) oxide paste to a silver grid using methylcellulose or sodium carboxymethylcellulose as binders (5). Wilburn (6) and Wilburn *et al.* (7, 8) have described methods for producing electrodes by dry compaction of silver(II) oxide to silver grids. Additional methods for producing porous silver electrodes primarily for use in fuel cells have been described by Schroeder *et al.* (9) and Niedrach and Alford (10).

Even though several methods are available for producing silver electrodes, they are normally prepared from silver powder which has been compacted on a silver grid, sintered, and electroformed (6). In these processes little regard is given to available electrode porosity, a known control factor of battery electrode performance, other than pressing sintered silver powder to various densities. Experience has shown that this practice is used to increase the A-hr/g capacity rather than controlling porosity.

Since these electrodes may be rather dense, they must be kept relatively thin; otherwise the interior active material becomes electrolyte-starved during cycling because of restricted electrolyte flow. Production of an electrode with controlled porosity would make all portions of the electrode equally accessible to electrolyte and enables the use of relatively thick electrodes for high efficiency, primarily at low discharge rates. At high discharge rates, the zinc electrode is the limiting electrode rather than the silver electrode, so the silver electrode can be made thin. However, porosity control provides an additional advantage in controlling the over-all performance of the cell. Since a controlled porosity sintered silver electrode would oxidize uniformly during charge, a silver grid would not be required since a continuous network of silver during discharge should remain throughout the electrode, and act as a more efficient conductor than the conventional silver grid. Presumably the process of hot rolling a mixture of polyethylene and silver powder followed by heating to burn out the polyethylene (11) may well be used to control porosity. No data to this effect have been published.

This paper describes the fabrication and electrochemical behavior of sintered silver electrodes of uniform pore size, produced by sintering a rolled sheet of uniformly mixed wet silver and binder powders. High efficiency thick electrodes were produced by sintering electrode material of 60% and 78% accessible porosities into a porosity-graded layered structure. It is expected that the electrochemical behavior of these porosity layered electrodes may possess good performance in comparison to conventional pressed and sintered grid-containing silver electrodes.

The work of Bogenschutz *et al.* (12) interrelating porosity and sintering temperature showed that, over the porosity range 57-65%, the capacity varied 20%. These results were used in determining our optimum sintering temperature for gridless silver electrodes.

Electrode Processing Procedure

The first processing step for producing porosity controlled silver electrodes consists of rolling a doughy silver powder-methyl cellulose mixture into a continuous sheet. The mixture is composed of 93 parts −325 mesh silver powder (44μ diam) blended with 7 parts methyl cellulose. The components are mechanically shear mixed with 10 ml of 10% aerosol and approximately 35 ml of alcohol per 100g until "dough" consistency is achieved. After suitable mixing, the material is rolled to the desired thickness and allowed to air dry. Any scrap, prior to sintering, can be reprocessed with the appropriate liquid addition. The dry material is sintered in air by placing it into a 788°C furnace for 15 min. Sintering produces a porous structure by burning out the plasticizer and creates sufficient strength by joining adjacent silver particles.

The sintered sheet (0.05 cm thick) was cut into 3.8 cm squares, and a 0.32 cm wide silver strip current collector was attached to one edge. Several methods

* Electrochemical Society Active Member.

Key words. silver electrodes, porous electrodes, sintered electrodes, gridless, porosity graded.

for attaching the current collector were tried, but the most successful method was to first position the silver strip with a single spot weld along the edge of the square electrode. Then the electrode assembly was placed in a furnace at 780°C for 3 min. While in the furnace, the current collector section of the electrode was rolled at a pressure of about 0.07 g/m^2. This rolling process assured contact of the strip to the silver electrode over the entire collector-electrode contact area.

In comparing the structure of gridless electrodes with conventional pressed and sintered electrodes, it was apparent that the experimental process produces an evenly distributed, uniform pore size. Many of the silver particles of conventional electrodes are massively sintered together in the press and sinter technique resulting in poor contact between portions of the supporting grid and adjoining silver. This lack of contact indicates that the sintered silver structure may be the primary current conductor instead of the grid. In the case of the gridless electrode, the interconnected silver network which remains after oxidation of the silver should provide efficient current conduction because of its uniform distribution.

Porosity Control

Available porosity can be increased by blending pore-forming agents with the silver powder and methocel. Ground charcoal and wood flour were chosen as porosity controllers, since burn-out during sintering forms gases which produce interconnecting pores upon leaving the silver mass and minimizes residual contaminants. These additives were used to increase the accessible porosity from nominal 68-80% as seen in Fig. 1. Porosity was determined by comparison of the bulk density with the true density where:

$$\text{Total porosity} = 1 - \frac{\rho\text{Bulk}}{\rho\text{True}}$$

The relationship between the amount of pore agent and per cent void volume is not linear since, as porosity increases, the silver structure partially collapses during sintering. Therefore, 80% was determined to be the practical upper porosity limit. Chemical analysis shows that -100 $+140$ mesh ground charcoal was completely removed during sintering. With the other porosity controllers, a trace of carbonaceous material remained. Photomicrographs showed that the wood particles contain a greater volume per mesh size, because they are fibrous, while the charcoal is particulate. Therefore, it seems reasonable to assume that wood flour would result in less surface area per unit volume in comparison to an equal volume of charcoal because of the difference in particle shape and over-all size.

Available porosity can be decreased from the nominal 68% by adding additional silver to the basic batch mix. For example, an extra 50 parts silver decrease porosity to 60%. Larger additions were not evaluated, since producing a dense electrode with little interconnection between pores was not desirable.

Porosity Layered Electrode Fabrication

In preparing porosity gradient electrodes, the sintered material of 0.05 cm thickness and of 60% and 78% accessible porosity was cut into 3.8 cm squares and three-layered assemblies of 60-60-60%, 60-78-60%, 78-60-78%, and 78-78-78% porosity were made. These layered structures are designated as *DDD, DPD, PDP,* and *PPP,* respectively, where D=60% porosity and P=78% porosity.

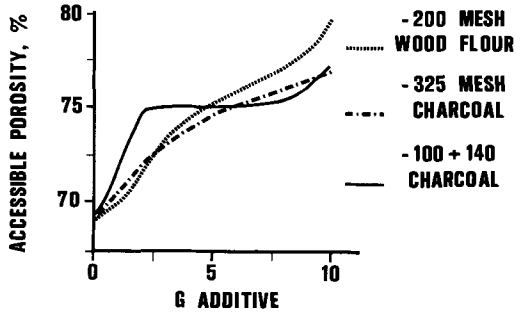

Fig. 1. Porosity effect of additives per 100g Ag-methocel

Material using -100 $+140$ mesh charcoal pore agent was used to produce these porosities, since it was completely removed during sintering. Furthermore, preliminary testing indicated higher capacity than with -100 $+140$ mesh wood flour or -325 mesh charcoal as pore-forming agents.

A 0.33 x 0.02 cm silver lead was positioned along the edge of an outside layer. Spot welding at a single point maintained alignment of the silver layers and lead. Each assembly was placed in a 788°C furnace for 3 min and hand rolled with a ceramic roller at a pressure not exceeding 0.07 g/m^2. The electrodes were immediately removed from the furnace to prevent densification. It was found that the rolling operation is necessary and sufficient to create sintered bonding between the layers.

Testing Procedure

Charge-discharge testing was done in open-top 5 x 6.2 x 1.8 cm cells so cycling characteristics of the electrodes could be observed. The silver electrode under test was placed between two nickel counterelectrodes (3.8 x 3.8 cm) in approximately 40 cc of 40% KOH. An Hg/HgO reference electrode which had a Luggin capillary probe was placed between the nickel and silver electrodes. During discharge, Ag/AgO, AgO_2//Hg/HgO potential was monitored to determine electrode discharge stability and capacity. This potential varied with distance between reference and silver electrode due to IR drop and nonuniform current distribution, but an attempt was made to minimize the variation by maintaining this distance constant. The use of nickel counterelectrodes prevented problems of zinc dendrites and corrosion that are associated with silver-zinc cells. Furthermore, the silver electrode performance here is much more favorable than would be expected in cells with separators and zinc anodes.

Experimental single-layer electrodes with 70% porous structure and a conventional silver electrode which was also 70% porous were charged and discharged at currents based on the silver weight. Porosity layered electrodes were cycled in two groups, one at charge and discharge currents determined by 70% conversion of silver weight to silver oxides, and another at a charge of 0.021 A/cm^2 for 8 hr, followed by alternate discharges at 2.21 A/cm^2 and 0.038 A/cm^2 to the hydrogen evolution potential. An example of the calculations based on the 70% conversion are included in the section titled Calculations.

Experimental Results

Charge/discharge of grid and gridless electrode.— Discharge curves for 0.05 cm sheet silver electrodes (3.50g, 70% accessible porosity) were measured in 40% KOH at the 5 hr, 1 hr, and ½ hr rate for a conventional grid structure and for a gridless structure. The discharge curves are shown in Fig. 2. Comparing the discharge curves at the 5 hr rate for the grid and gridless silver electrodes, the discharge times agree within 2.5%. At the 1 hr rate a difference of 1.3 min was observed, while at the ½ hr rate the conventional grid electrode discharged about 10% longer than the gridless electrode, but at a lower voltage level. Voltage decay of the conventional grid electrode is more rapid at each of the rates.

Considering voltage levels of the discharge curves, the voltage (*vs.* Hg/HgO) is lower for the grid electrode at the ½ hr and 1 hr rate, but is nearly identical at the 5 hr rate. This voltage difference may be due to lower resistivity of the gridless electrode, but there are not sufficient data to determine the variation exactly. Analysis of the two electrodes showed that

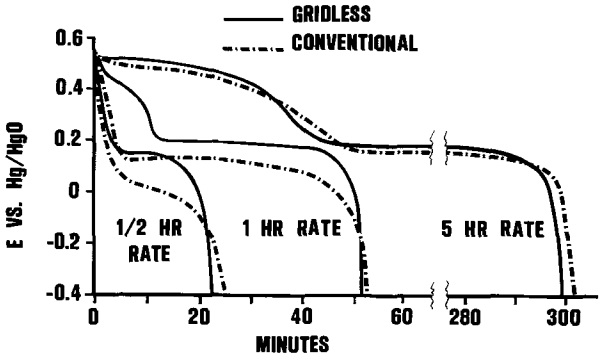

Fig. 2. Silver electrode discharge

the grid electrode contained 17.4% free silver, whereas the gridless electrode contained 14.1% silver. This slight difference in silver content is not sufficient to produce the observed voltage variations.

A characteristic of silver electrode discharge curves is the two-step voltage pattern. This two-step pattern results from the discharge of the divalent oxide to the monovalent oxide and then the monovalent oxide to the metal. Generally this two-step phenomenon is undesirable, either in battery charging or in its application as a power source. The presence or absence of this two-step discharge has been found to be dependent on the physical and electrochemical properties of silver electrodes.

Comparing discharge curves for the conventional and gridless electrodes, it is noted that at all discharge rates a two-step discharge occurred. At the ½ hr and 1 hr rate, the discharge time at the divalent oxide potential was less for the conventional electrode structure and nearly identical at the 5 hr rate.

Further evidence of the improved electrochemical behavior of these electrodes is that, after extended cycling, the cells maintained their performance at a high level. The cells were cycled over 100 times in an open-cell configuration without any significant decrease in performance. It is expected that cell life could be increased considerably by using a closed cell in which the electrodes maintain their physical shape due to tight packing.

During the test period no evidence of unusual charge acceptance, discharge behavior, or physical deterioration was noticed on visual examination of the electrodes. After cycling, both electrode structures, conventional and gridless, are quite brittle. With severe deformation, the gridless electrode fractures quite easily, breaking up into several small parts. The grid electrode is also brittle after cycling, but on deformation the electrode is held together by the grid. This should not be a problem in application since, in the cell assembly, the electrodes are tightly packed and breakage will be minimal.

On the basis of the experimental observations, the gridless electrode performs as well or better than the conventional electrode, indicating that the silver electrode is not limited by the absence of a supporting internal grid. Furthermore, comparing the voltage levels, discharge times, and capacities for the two structures, the gridless electrode is superior to the conventional electrode.

Electrochemical behavior of layered silver electrodes with constant current charge/discharge.—Four electrodes of graded porosity construction were tested. The 60% porous material is designated by *D* and the 78% by *P*. Four combinations of these abbreviations are used to refer to the different electrode structures. The data on physical properties are summarized in Table I.

These electrodes were charged for 8 hr at 0.21 A/cm² and then discharged at two different currents, alternately at 0.021 A/cm² and 0.038 A/cm². At this low rate of charge, the four different structures showed essentially the same charge rate on the basis of the amount of silver present. It is expected that at high-rate charging the more porous electrodes would have improved charge acceptance when compared with the dense structures.

Table I. Physical dimensions of graded porosity electrodes

Porosity layer, %	Electrode	Weight, g	Thickness, cm
60-60-60	*DDD*	7.87	0.152
60-78-60	*DPD*	6.48	0.147
78-60-78	*PDP*	5.27	0.142
78-78-78	*PPP*	4.14	0.142

The average A-hr/g capacity of four discharges was used as the basis for determining the average discharge curves of Fig. 3 and 4. Since the discharge time is proportional to the electrode weight and the weights of the various assemblies were different, a nondimensional time scale was chosen to allow direct comparison of the discharges. The time scale is $t/t_{\text{theoretical}}$, where $t_{\text{theoretical}}$ is the time for discharge assuming 100% utilization of the silver. In addition, the coulombic efficiency was found to be independent of the discharge rate.

From Fig. 3, at a discharge current of 100 mA/cm², the voltage levels and discharge times are similar for the mixed porous structures with *PDP* having the longest discharge time and *DPD* discharging at a higher voltage. The monoporous structures, *DDD* and *PPP*, have nearly identical discharge curves, indicating that the porosity or layered structure is not a controlling factor at this discharge current.

Figure 4 shows the discharges of these graded electrode structures at a current density of 20 mA/cm². The discharge times and voltage levels are similar for

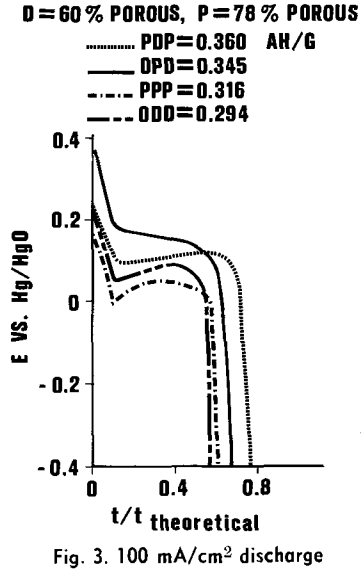

Fig. 3. 100 mA/cm² discharge

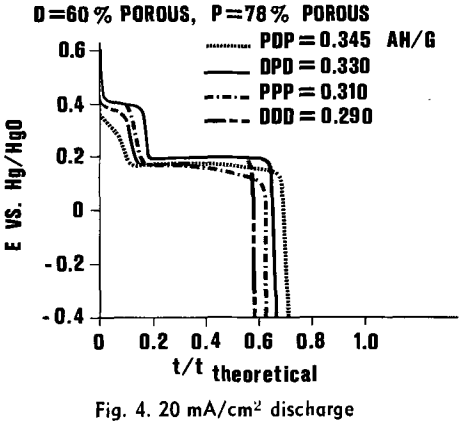

Fig. 4. 20 mA/cm² discharge

Table II. Charge-discharge rate based on electrode weight

Porosity layer, %	Electrode	Weight, g	Thickness, cm	Charge, A 5 hr	Charge, A 25 hr	Discharge, A ½ hr	Discharge, A 5 hr
60-60-60	*DDD*	8.32	0.154	0.582	0.116	5.82	0.582
60-78-60	*DPD*	6.92	0.149	0.484	0.097	4.84	0.484
78-60-78	*PDP*	5.39	0.142	0.377	0.075	3.77	0.377
78-78-78	*PPP*	4.15	0.142	0.290	0.058	2.90	0.290

the multiporous layered electrodes, *PDP* and *DPD*, and, as at the high rate, the DDD and PPP show nearly identical behavior. Discharge time at the divalent oxide potential is longest for the *DPD* structure and decreases in the order *PPP*, *DDD*, and *PDP*. However, no significant differences in the discharge curves are noted at this low rate which could be attributed to variations in the layered structure.

Electrochemical behavior of layered silver electrodes with charge discharge rate determined by electrode weight.—These electrodes were discharged alternately at the ½ hr and 5 hr rates for eight cycles, with the charging done in two steps: charge at a 5 hr rate until oxygen evolution occurs, followed by charging at a 25 hr rate until oxygen evolution again occurs. The experimental data for these electrodes are given in Table II.

The average ampere-hour/gram capacity of four discharges was used for determining the average ½ hr and 5 hr rate discharge curves of Fig. 5 and 6. The coulombic efficiency was found to depend directly on the electrode weight.

From Fig. 5, at the ½ hr discharge rate, the porous outside layers appear to control the discharge, since *PPP* and *PDP* both show higher discharge efficiency than electrodes with dense outer layers. Furthermore, the *PPP* electrode appears most efficient. This was expected, since a more porous electrode outperforms a dense electrode structure at relatively high rates because of the lower effective current density on the porous structure and accessibility of the active material for reaction. It appears that highly porous gridless electrodes have an optimal pore size for the ½ hr rate discharge, as evidenced by the similarity of the discharge voltage-time relationship and the efficiency data. However, the *DDD* structure shows a significant voltage drop at this discharge rate, indicating that only the surface layer is discharged and the discharge process is probably mass transport limited.

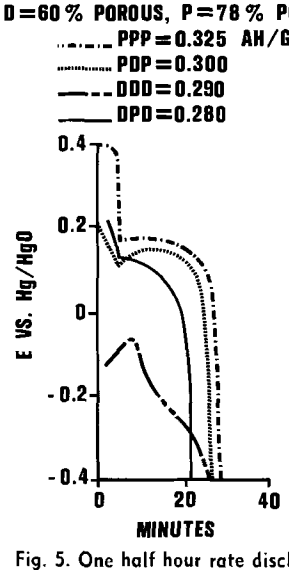

Fig. 5. One half hour rate discharge

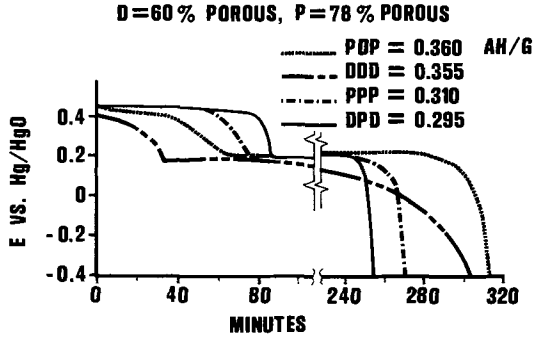

Fig. 6. Five hour rate discharge

Discharge curves at the 5 hr rate are shown in Fig. 6. Here the discharge is at a low enough current density so that the dense inside layer is also discharging and becomes the control layer. This is evidenced by *PDP* and *DDD* electrodes outperforming the electrodes with porous centers. However, the electrodes with porous outside layers outperform the electrodes with dense outside layers, regardless of center layer porosity. Even at low rates the porous layers control the discharge, especially at the divalent oxide potential.

The divalent oxide potential is markedly evident at the 5 hr rate, especially for the *DPD* structure where about one third the discharge time is at the higher potential. The other structures also discharge at this higher potential, but for much shorter times. Probably, explanations for the presence of the divalent oxide potential are weak metal contact between the layered structures, decreased conductivity, nonuniform current distribution due to the porous structure, and poor contact between the silver-to-silver bonds due to the semiconductor AgO in the electrode.

Since discharge time at the divalent oxide potential is greatest for the *DPD* structure and decreases in the order *PPP*, *PDP*, and *DDD*, it appears that the center porous layer may be a controlling factor. However, the manner in which the porous layers control the divalent potential for these electrodes has not been thoroughly investigated in this work, and will be considered in future studies.

Conclusions

The gridless electrode has been shown to have physical and electrochemical properties exceeding, or as good as, those of the conventional grid structured silver electrode. The manufacturing process is simple and economical. Considerable savings will be realized on the total amount of silver used by elimination of the grid. Furthermore, the process permits controlling the porosity of the silver electrode which is not realizable with the conventional silver electrode.

Comparing the electrochemical performance of the (0.05 cm thick) gridless and grid electrodes, the gridless electrode's performance was not limited by the absence of a conducting grid, as evidenced by the discharge data.

On extending the controlled porosity layer concept, to a multiporosity structure, the mixed porosity combinations performed significantly better than the monoporosity combinations. In fact the *PDP* structure was superior in three of the four tests, with the *DPD* closely approximating it. It also appears that, in the conventional Ag-Zn battery, several thin electrodes could be replaced by a single thick graded structure, if the separator and anode space requirements, as well as the discharge rate, are considered.

Although it has been demonstrated that the layered structure is feasible, no attempt has been made to determine the optimum pore size of the layered structure. This will be considered in further investigations of gridless electrodes. Further testing of these electrodes at higher rates is also under investigation, since the high discharge rate performance was not thoroughly studied.

CALCULATIONS

70% Conversion

As an example of charge/discharge cycling with currents determined by silver weight, consider the following example for a silver electrode weighing 2.8g.

From Faraday's law it can be shown that 1.0g of silver will theoretically require 0.5 A-hr to be produced from AgO. Therefore:

$$2.8g\ Ag = 1.4\ A\text{-}hr\ theoretical$$

Actual conversion based on AgO is 70% since some Ag^+ and Ag^o remain during charging to Ag^{++}. Therefore

$$1.4 \times 70\% = 0.98\ A\text{-}hr$$

is actually expected to force discharge 1.0g of fully charged silver. Testing commences by charging at a 5 hr rate until oxygen evolution. The charging current is decreased to 25 hr rate until oxygen evolution once again occurs.

Currents would be

$$\frac{0.98\ A\text{-}hr}{5\ hr} = 0.196A\text{—}5\ hr\ rate\ charge$$

$$\frac{0.98\ A\text{-}hr}{25\ hr} = 0.039A\text{—}25\ hr\ rate\ charge$$

Testing continues by discharging at a 1 hr rate until hydrogen evolution

$$\frac{0.98\ A\text{-}hr}{1\ hr} = 0.98A\ discharge$$

Note that the discharge time is such that, in 1 hr, 70% efficiency based on Ag^{++} would be achieved. Theoretically, the longest discharge would be

$$\frac{1.4\ A\text{-}hr}{0.98A} \times 60 = 85.8\ min\ at\ the\ 1\ hr\ rate$$

Study of Lithium-Lead Alloys as Grid Material for Lead-Acid Batteries

G. W. Mao, T. L. Wilson,* and J. G. Larson

Gould Incorporated, Research Division, Minneapolis, Minnesota 55414

ABSTRACT

Lithium-lead alloys with low contents of lithium were investigated for lead-acid battery grids. The metallographical alloy structures, mechanical properties, anodic corrosion resistance, cell performance, and castability were determined. Experimental data are interpreted and compared with the well-known antimony-lead and calcium-lead battery grid alloys. A useful lithium-lead alloy range is presented. The potential electrochemical superiority and economical feasibility are discussed.

Although the positive grid does not participate directly in primary discharge/charge processes, it is this member that often limits battery life and utility. A suitable positive grid must: (*a*) have sufficient mechanical strength to support its own weight and that of the active material, (*b*) conduct electrical current evenly and efficiently, (*c*) provide a low impedance electrical contact between grid and active material, (*d*) be relatively resistant to anodic corrosion, and (*e*) be easily formed.

Antimony-lead alloys in the range of 4.5-12 w/o (weight per cent) Sb are generally used as battery grids in lead-acid batteries; the presence of antimony, however, enhances self-discharge (1). In addition, stibine gas evolution excludes use of these alloys in confined areas.

Over 30 years ago, the advantages of using alloying elements electronegative to lead were outlined, and the properties of a 0.1 w/o Ca alloy were discussed (2, 3). Although similar compositions still serve as alloys for storage battery grids, poor cycling characteristics have limited their use in many applications. In addition, corrosive attack under anodic conditions can be selective, causing problems in dimensional stability (4).

Chemically, lithium resembles calcium in the free state, whereas it resembles antimony metallurgically (5). Lithium-lead binaries were thus selected for study as possible grid alloys with the expectation that they would possess some of the better properties of both the calcium- and antimony-lead alloys. The possibility of using alloys containing lithium as grid alloy has not gone without previous investigation (6). Earlier investigators, however, were probably concerned with alloys too rich in lithium.

This paper presents experimental results that are believed to have a bearing on the applicability of lithium-lead as a positive grid alloy. The mechanical strength, resistance to anodic corrosion, cell performance, and castability are compared with similar data for calcium- and antimony-lead alloys. A usable alloy

* Electrochemical Society Active Member.

Key words: battery grid, lithium-lead, lead-acid battery.

range is outlined and the characteristics of the lithium alloys are compared with grid alloys used at present.

Procedure

The alloys referred to in this paper were prepared from Tadanac lead of 99.998% purity (principal impurities were copper, silver, antimony, and bismuth) and 99.9+% lithium (Na 0.007-0.01%, Ca 0.02-0.05%, Fe 0.001-0.01%, Si 0.006-0.01%). Alloys were prepared either by adding lithium directly to a melt held at 650°F, or by adding a concentrated master alloy to lead in iron crucibles. The combination of reactivity of lithium in the melt, stirring, and a nominal holding time after the melt had stabilized appeared adequate to insure homogeneity of the alloy. Flame spectroscopy of nitric acid solutions of samples systematically selected during casting gave no indication that segregation had occurred.

All melting and casting was done under an inert atmosphere of argon. Except where noted, the melt temperature prior to pouring was maintained at 700°F and the mold temperature 350°F. The molds were coated with a layer of a silicate-cork dust slurry as standard practice. The alloy compositions referred to later represent the chemical analyses of gates taken from the castings and are generally the average of several such samples. Cast ¼ in. by 5 in. rods were used as the anodes for corrosion studies. Tensile specimens were cast to the shape prescribed for sheet lead samples, *i.e.* providing a gauge area of 2 x ½ x ⅛ in. The castability data were obtained using the method described in the literature (7).

Briefly, castability was determined by pouring the lead alloy into an inverted tree-type mold cavity at controlled melt and mold temperatures, and cast samples were compared. Casting was scored by assigning points to each portion of the inverted tree mold. The more difficult areas to fill were given higher values than the easier to fill areas. The highest possible index score was arbitrarily set at 100.

The metallographic techniques of sample preparation have been presented in detail in an earlier paper (8). Briefly, these comprised mounting the sample in a low-temperature setting plastic, polishing through successively finer lubricated abrasives to a final 0.1μ alumina slurry, and etching in a dilute citric acid-ammonium molybdate solution.

Alloy rods were corroded separately at constant potential (the potential being higher than the solvent decomposition voltage) or at constant current in 1.115 sp gr sulfuric acid at room temperature. Pure lead sheet cathodes with a surface area of 170 cm^2 were concentrically arranged at a distance of 3 cm from the anode (surface area of 17 cm^2). Current and voltage were recorded throughout the experiments, and weight losses due to corrosion were determined by stripping the corrosion product from the surface of the corroded rods in a hot alkaline mannitol solution. Duplicate alloy rods were corroded so one experiment could be interrupted to metallographically observe the progress and the morphology of the anodic corrosion.

Battery grids were cast under inert atmosphere using optimum mold and melt temperatures. Grids were hand pasted in a manner simulating commercial practice and formed accordingly. Cells constructed from these grids were discharged in deep cycle tests. Historically, cycle life tests have been proven indicative of a grid alloy's capability. Although pure, calcium-, and dispersion-strengthened-lead satisfy many of the requirements of grid alloys, they are characterized by an inability to maintain cyclic capacity (9-12). Lithium-lead alloys were therefore submitted to a comparison with commercial alloys in cycle life tests.

Five-plate, miniature cells were constructed with paste:grid weights resembling industrial conditions. Theoretical capacities were approximately 3 A-hr so that at 35% efficiency a reasonable charge:discharge cycle could be maintained daily with a 16 hr overcharge. Cells were discharged at a theoretical 4 hr rate (thus taking 1 hr at 25% efficiency) and charged back at a theoretical 20 hr rate (normally taking 6 hr). A particularly deep cycle (1.1V cutoff) was used to accelerate failure—as much paste as possible was used in each cycle without deliberate sulfation. It was commonly observed that nonantimony cells fell to one third their capacity under this test regime.

A 16 hr, 2.2V float cycle (64 hr on weekends) was incorporated into the test procedure. Earlier results had indicated that grain boundary corrosion was severe in two-phase, lithium-lead alloys. Despite the fact that cells normally spent 520 hr on overcharge compared to 20 on discharge, tests were invariably terminated because of paste, not grid, failures.

Experimental Results

Anodic corrosion.—Under conditions of exceeding the $PbO_2/PbSO_4$ potential, the net effect of making dilute additions of lithium to lead is to reduce the anodic corrosion rate, as shown in Fig. 1. Corrosion was carried out at 82 mA/cm^2 constant current density for a period of 4 weeks in 1.115 sp gr sulfuric acid.

Two composition-dependent types of corrosion morphology were found, and these areas are noted in Fig. 1. For dilute alloys (lithium content less than 0.02 w/o) attack was generally uniform, maintaining much the same characteristics as pure lead. For lithium contents between 0.02-0.03 w/o lithium, penetration was concentrated at grain boundaries. Examples of these morphologies are illustrated in Fig. 2.

The critical composition distinguishing these classes of alloys, based on anodic corrosion, essentially defines and restricts the maximum alloying addition that may be made to obtain a usable binary. Grids containing greater amounts of lithium would be expected to "grow" during service, and this penetration type of attack may lead to premature grid fracture.

In the accelerated corrosion tests of this study, the kinetics of corrosion appeared to be chemically controlled since the depth of grain boundary penetration exceeded the grain size in alloys containing more than

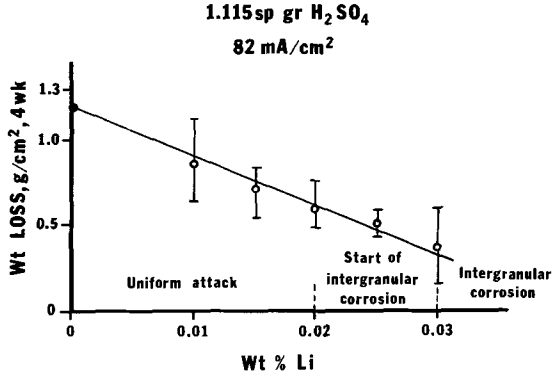

Fig. 1. Anodic corrosion of Li-Pb

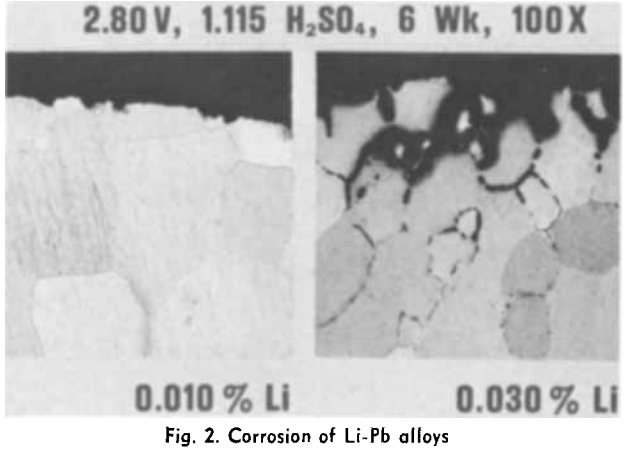

Fig. 2. Corrosion of Li-Pb alloys

0.03 w/o Li. This undoubtedly is a consequence of the dissolution of the LiPb intermetallic compound. Such chemical attack leads both to increasing the area exposed to corrosion and to locally increasing the alloy temperature. The latter factor could lead to catastrophic failure because it accelerates the rate of anodic attack and favors the kinetics of precipitation resulting in increased rate of precipitation.

On anodic corrosion, the deceptiveness of weight loss data cannot be overemphasized in interpreting corroded microstructures. The corrosion of lithium-lead alloys is a classic example of the necessity of microscopically studying the morphology of corrosion attack. The tendency for grain boundary attack increases with increasing lithium content, but catastrophic dissolution does not occur until alloy compositions in excess of 0.03 w/o Li are reached. Apparently, once started, the process of grain boundary consumption is one that propagates itself on a localized basis.

X-ray diffraction analyses of the oxide films stripped or brushed from the surface of the anodically corroded rods indicated that the corrosion products resulting from the conditions referred to above were largely αPbO_2. Both free lead and βPbO_2 patterns were observed but only in minor quantities. In a 0.03 w/o Li-Pb alloy, these phases were observed to constitute 5% free lead and 3% βPbO_2 of the total oxide film. The elemental lead is thought to result from complete grain boundary dissolution, thus mechanically freeing individual grains. The beta lead dioxide is also tentatively associated with the corrosion of the alloy-rich boundary layer. This latter conclusion was reached largely on the basis of a 3% shift in lattice parameter of the beta phase. The lattice parameter, a_o, for beta lead dioxide formed on lithium-lead differs from the value for beta lead dioxide formed from pure lead. It would appear from this latter observation that selective partitioning of lithium occurs between the oxides.

Chemical analysis of corroded rods proved that there was a slight decrease in lithium content. However, no lithium was found either in the cell electrolyte or the cell sludge. The other possible place where lithium could concentrate is in the adherent oxide layer. As the lithium contents were extremely low, x-ray diffraction did not detect its definite presence.

Comparisons of type of anodic attack were made with pure lead and representative calcium and antimony alloys. Corrosion was carried out at constant potential (2.8V) to get an indication of the alloy performance during overcharge conditions. Lithium-lead appeared to be very similar to pure lead both in degree of attack and corrosion morphology. Typical results of observed weight losses are reproduced in Table I and the general features of corrosion morphology are shown in Fig. 3.

Alloys corroded anodically above the decomposition potential of the electrolyte illustrate decisively the tendency for preferential grain boundary attack of the alloys. Even the cast 99.998% pure lead demonstrated a tendency toward preferential grain boundary penetration, presumably due to the segregation of elements to the boundary area. Westbrook and Aust have documented the propensity of solutes to segregate to grain boundaries in dilute lead alloys (13).

Mechanical strength and metallography.—Photomicrographs of cast structures of compositions ranging from 0.01 to 0.10 w/o Li are reproduced in Fig. 4. These figures reflect directly on the corrosion performance noted previously and the mechanical strength results presented in this section. As might be expected from the broad two-phase liquid plus solid field, the effects of coring in the lithium-lead system are quite evident. The first interdendritic type intermetallic compound is observed in alloys containing less than 0.04 w/o Li. In the 0.10 w/o alloy, the intermetallic is continuous and defines the grain size.

Table I. Anodic corrosion of lead alloys at constant voltage

Alloy composition (w/o)	2.8 V, 1.115 H_2SO_4, 4 weeks total time: Corrosion weight loss (mg/cm^2)
4.5 Sb-Pb	135.4
0.07 Ca-Pb	49.5
0.01 Li-Pb	46.8
0.02 Li-Pb	48.0
0.03 Li-Pb	63.1
Pure Pb	61.1

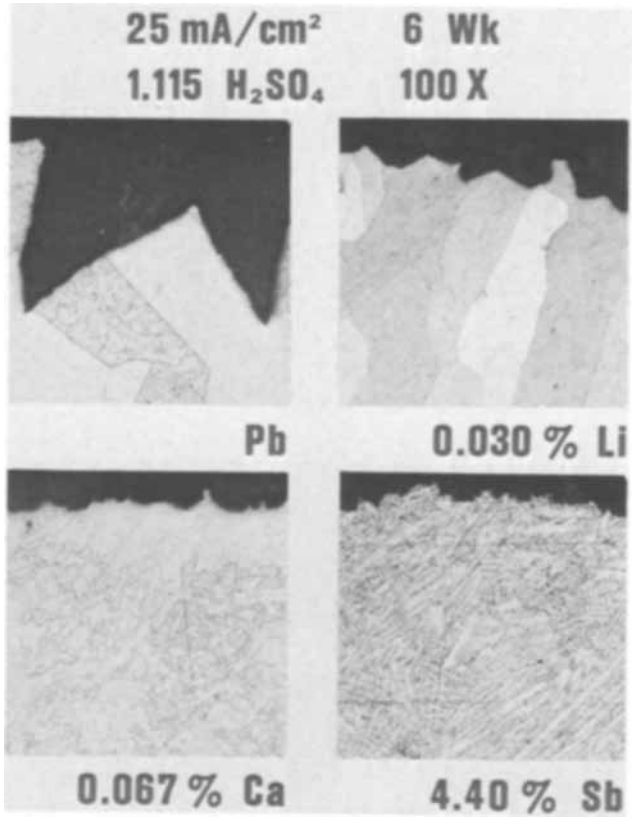

Fig. 3. Anodic corrosion of grid alloys

The kinetics of precipitation are reasonably rapid. At room temperature, the alpha solid solution grain boundaries of alloys containing 0.02 w/o Li are decorated with the intermetallic precipitates. Complete coverage ostensibly occurs in 0.04 w/o Li alloys. This heterogeneous precipitate morphology strongly affects the chemical reactivity of alloys in this system, as mentioned previously in corrosion studies.

The other effect that lithium has on the as-cast structure is a marked reduction in primary grain size. The 0.01 w/o Li alloy has a grain size approximately one fourth that of pure lead cast under identical conditions, and increasing the lithium content from 0.01 to 0.05 w/o reduces the grain size further by a factor of two. This observation of a decrease in grain size within the solid solution is in agreement with that reported by Greenwood (14). Although this grain size reduction has only a secondary effect on the chemical behavior of the alloys, it does contribute to its strength characteristics.

Tensile results are in general accord with an age-hardening system in which precipitation occurs from a supersaturated solution. Figure 5 shows a rapid increase in strength for alloys of less than 0.02 w/o Li and then a more gradual, linear increase for richer alloys. The rapid increase is primarily associated with solid solution strengthening, with the remaining 25% contribution from grain refinement. The linear portion of the strength increase is a consequence of the dispersion hardening influence of the intermetallic.

Tensile strength, yield strength, and per cent elongation varied only slightly with aging time for compositions up to 0.015 w/o Li. For compositions up to 0.025

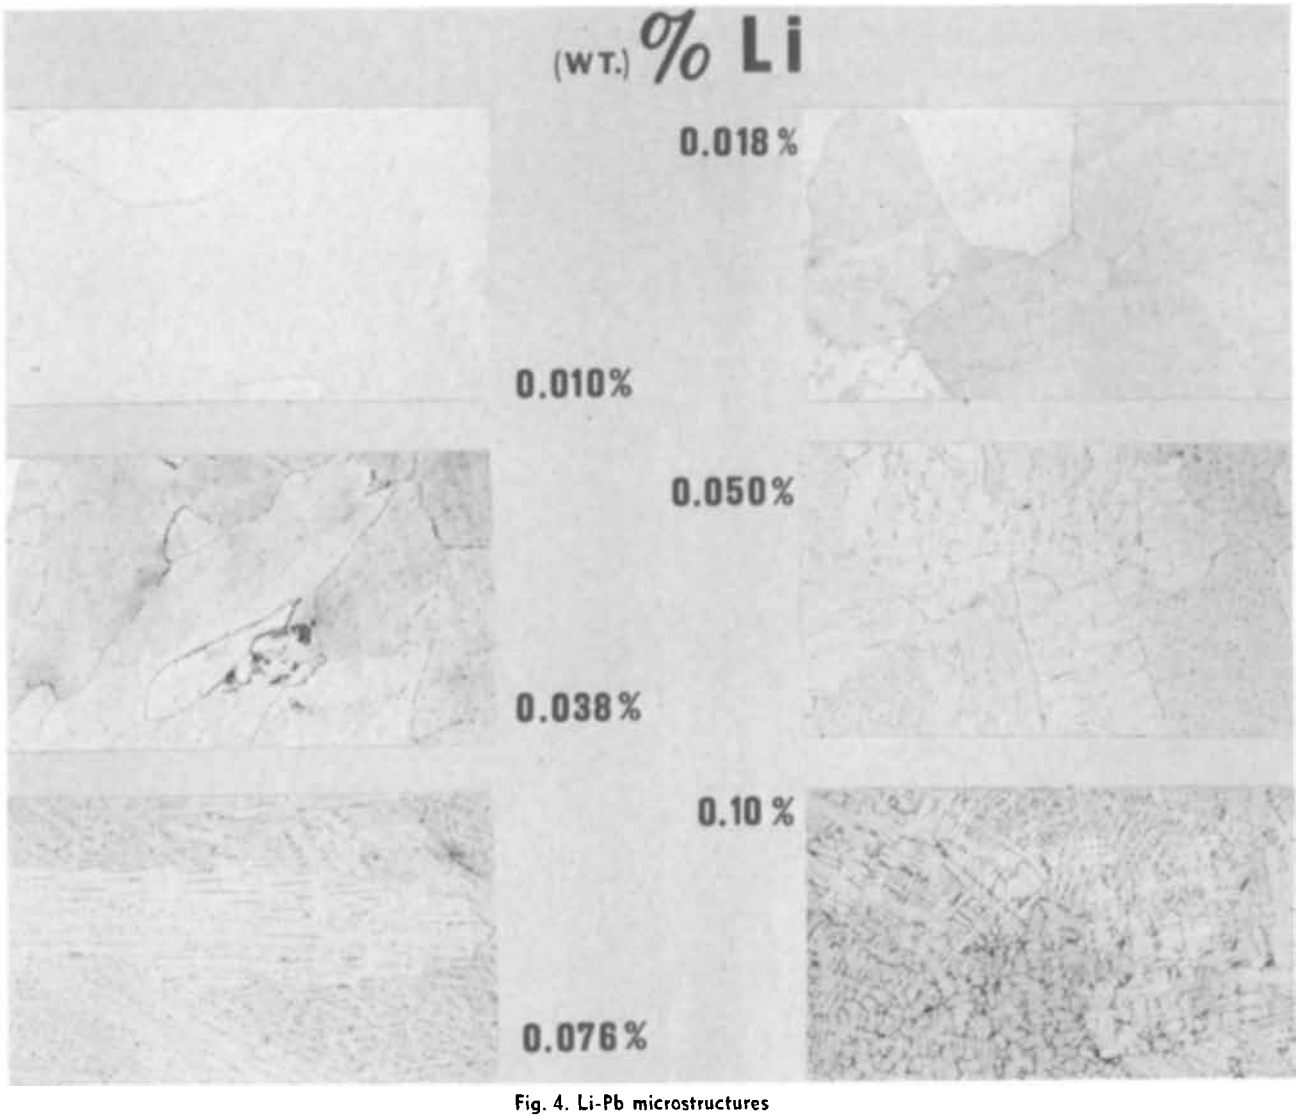

Fig. 4. Li-Pb microstructures

w/o, changes were noted largely in yield strength, whereas ultimate strength and elongation were relatively stable. An embrittlement associated with precipitation from the supersaturated solid solution existed above 0.025 w/o Li, however. The instability was the type where both the ultimate strength and elongation decreased, while the yield strength increased. In other age-hardening systems where this occurs, embrittlement is associated with overaging at grain boundaries, frequently with solute depleted regions (15).

Aging at room temperature apparently imparts a ripening process to the precipitate. Samples tested after a period of 4 weeks lost the dispersion hardening contribution to their tensile strength, whereas the ultimate tensile strength levels out to a value of about 5000 psi. The instability that exists in the richer alloys correlates qualitatively with the corrosion results. The corrosion as well as strength results indicate that

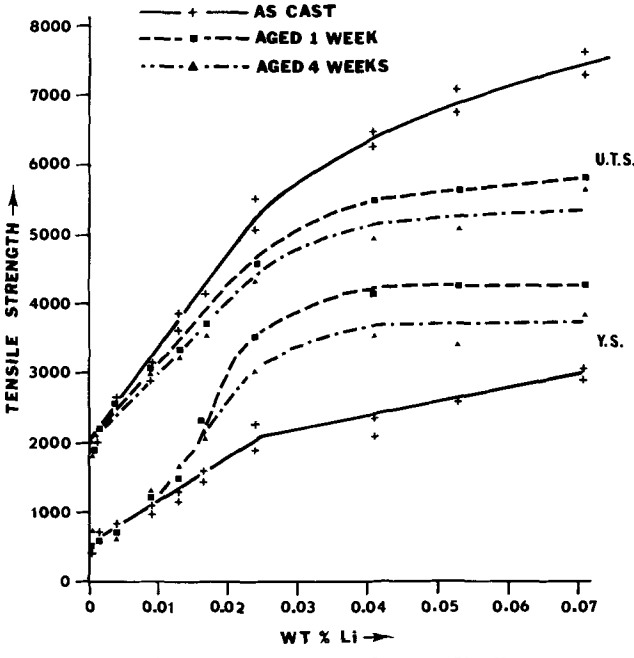

Fig. 5(a). Tensile properties of cast Li-Pb alloys

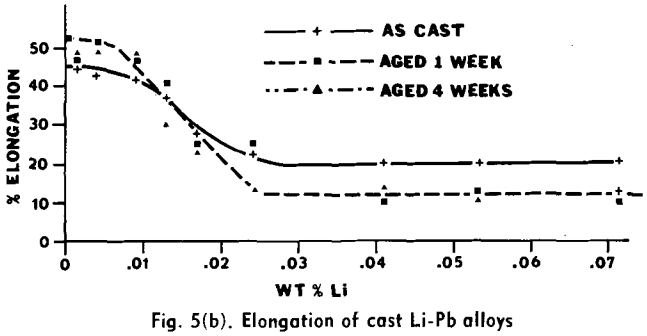

Fig. 5(b). Elongation of cast Li-Pb alloys

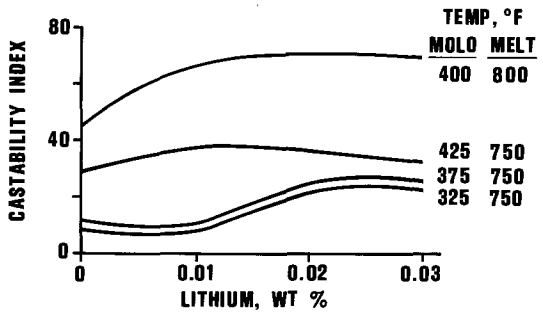

Fig. 6. Castability of dilute Li-Pb

ripening must proceed to a greater extent at grain boundaries. The aging data are included in Fig. 5.

For comparison, tensile strengths of calcium and antimony alloys are reproduced in Table II for two aging conditions that simulate conditions met during stripping, pasting, and use. Relatively dilute lithium alloys are comparable with the other two alloys.

Casting behavior of lithium-lead.—Inasmuch as the general grid fabrication process is one of casting, the casting behavior of any grid alloy is of primary concern. Both castability and the shrink associated with solidification were determined for standard casting practice for the alloys of concern. Castability data are illustrated in Fig. 6 and Table III. The internal shrink of alloy rods was determined by rolling samples into sheets and determining the change in density before and after rolling. The porosities (*i.e.*, per cent change in density values) for pure lead, 0.03 w/o Li-Pb, 0.07 w/o Ca-Pb, and 4.5 w/o Sb-Pb rods were 0.20, 0.08, 1.16, and 0.00%, respectively.

These casting parameters show antimony-lead is superior to the other alloys with which it was compared, since it solidifies with an eutectic phase present in the lead-rich matrix. Lithium-lead is a reasonably castable alloy in the useful grid composition range. Since the castability test essentially describes the ability to fill 1/16 in. diameter capillaries under various conditions (7), it is apparent that this may be done with little internal porosity with lithium alloys in the solid solution range. Grids of various shapes, and as thin as 0.06 in., are cast freely with lithium-lead.

Cell Performance.—Under the test regime used in this study, it was observed that nonantimony cells lost capacity from cycle to cycle. Antimony cells, on the other hand, regained and maintained their capacity after an initial loss. Both observations are in substantial agreement with earlier studies. The data gathered for the standards (7.0 antimony-, 0.07 calcium-, and unalloyed-lead) are reproduced in Fig. 7.

For comparison, the data for the lithium alloys are shown in Fig. 8. It appears that the performance of lithium-lead is composition-independent in the range studied and most similar to pure lead.

Table II. Ultimate tensile strength of lead alloys

Alloy composition (w/o)	As-cast, psi	Aged 1 week (room temp) psi
4.5 Sb-Pb	5100	5400
0.07 Ca-Pb	4200	5300
0.01 Li-Pb	3300	3100
0.02 Li-Pb	4700	4250
0.03 Li-Pb	5700	5000

Discussion

The useful composition range for lithium-lead binary alloys as battery grids is limited by anodic corrosion to lithium contents of less than 0.03 w/o. Lithium-lead binary alloys with lithium content higher than 0.03 w/o do not withstand high rate anodic corrosion. Below 0.03 w/o, the grid strength will be 4000-4500 psi and castability is midway between commercial antimony-lead and calcium-lead alloys. Total casting porosity should, however, be less than that generally obtained in the latter type grids. Under deep cycling, performance is similar to that obtained in pure lead grids.

If a general comparison is made with present alloys, it becomes immediately evident that lithium-lead alloys present the possibility for construction of low self-discharge grids at low material cost, due to the low alloy content. Balancing these merits are problems like the difficulty in maintaining lithium within the melt at high temperatures.

Positive grid elements of the three main classes of lead-acid batteries are constructed of particular alloys because of performance requirements. A review of these three classes is useful to place lithium-lead in perspective and to assess the merits of lithium-lead grids.

Automotive grids require frequent high-rate discharges, in which only a portion of the capacity is used, and reasonable life on overcharge. Strength and ease of casting are important because it is desirable to have the grids made as thin as possible (usually of 0.060 in. thickness). Lithium-lead, even with its pure lead type cycle behavior, might satisfy these requirements, but the castability of a hypoeutectic definitely surpasses that of a single-phase alloy. Competition with 4.5% antimony alloys would be enhanced if a different method of casting lithium-lead grids other than gravity casting is developed. On the other hand, if the industry is considering a maintenance-free, quasi-sealed, storage battery, then an alloy of the lithium-lead type would be a necessity.

Grids of industrial batteries where a long cycle (8 hr discharge rate) is desired are made of even richer antimony alloys (7.5-12 w/o). The chief requirement in the class is the cycle life and this parameter for Li-Pb appears to be an area open for improvement. In this respect, additives to the grid, paste, or electrolyte might be considered to obtain a flatter capacity: cycle

number curve. This general problem is something the whole lead-acid industry is considering due to the mounting price of antimony.

Finally, industrial standby cells utilize calcium-lead or pure lead grids because of low self-discharge requirements. Li-Pb alloys should perform adequately in this respect because they possess many of the properties necessary for this use. In addition, good welding and casting properties of lithium-lead should be a definite advantage.

The Effect of Several Electrode and Electrolyte Additives on the Corrosion and Polarization Behavior of the Alkaline Zinc Electrode

F. Mansfeld*,[1] and S. Gilman*

NASA/Electronics Research Center, Cambridge, Massachusetts 02139

ABSTRACT

The corrosion behavior of zinc in 6*N* KOH at 25°C was investigated through measurement of the rate of hydrogen evolution (r_{H_2}) at the corrosion potential. Anodic and cathodic potentiostatic polarization curves as a function of alloying and additions to the electrolyte were obtained. It was found that the corrosion and polarization behavior of 99.999% zinc can be explained by mixed-potential theory assuming that the reactions were $Zn + 4\,OH^- \rightleftharpoons Zn(OH)_4^{2-} + 2e^-$ and $H_2O + e^- \rightleftharpoons \frac{1}{2}H_2 + OH^-$. Good agreement between theoretical curves obtained by computer solution of the kinetic equations corresponding to the above reactions and actual polarization measurements was obtained in the absence and presence of zincate. Theoretical and experimental corrosion rates also agreed well. Binary Zn-Pb alloys [0.2-1.0 w/o (weight per cent)] and Zn-Al alloys (0.2-0.8 w/o) made up from high-purity metals had r_{H_2}-values which were lower than those for zinc, while r_{H_2}-values of commercial zinc alloys were much higher than those of zinc, most likely due to the presence of low overvoltage impurities such as Cu, Ni, or Fe. Addition of 10^{-3}M copper, tin, or lead ions to the electrolyte also influenced r_{H_2}, which in the presence of metal ions noble to zinc is no longer equivalent to the corrosion rate. The strong increase of r_{H_2} in the presence of Cu ions is explained by the low hydrogen overvoltage of Cu, while the decrease of r_{H_2} in the presence of Pb ions is explained by the high hydrogen overvoltage of Pb. Anions such as Cl^- or Br^- do not affect r_{H_2}. In the presence of thiourea, r_{H_2} increases steadily, while S^{2-} leads to severe corrosion.

The rate of hydrogen evolution on zinc in slightly acid and in concentrated alkaline solutions has been measured on zinc sheets, rods, powders, and on battery electrodes. Correlation of the few data obtained until now is very difficult. Dirkse and Timmer (1) found a decrease of the rate of hydrogen evolution (r_{H_2}) on zinc wire (99.999%) in 20-45% KOH with increasing concentration of KOH, saturation of the electrolyte with ZnO, or amalgamation of the wire. Oxley and Humphrey (2) observed that As, Co, and Cu ions increased r_{H_2} on zinc ribbon (99.99%) in 30% KOH at 60°C in measurements which extended over several days, while Sn, Cd, and Pb ions decreased r_{H_2}, Pb having the most pronounced effect. The effect of Pb was also observed at a practical zinc electrode, although to a somewhat smaller extent. Additions of zincate also lowered r_{H_2} as observed in (1). The effect of additions of metal ions to the electrolyte has been also studied by Era *et al.* (3) on zinc sheets (99.99%) in a solution of 25% NH_4Cl + 10% $ZnCl_2$ + HCl at pH = 5, 50°C. Additions of Pb decreased r_{H_2}, while Fe, Cu, Ni, As, and Sb increased r_{H_2} in tests which were conducted for 14 days. Krug and Borchers (4) found that alloying with Fe (up to 310 ppm) increased r_{H_2} in a solution of 1% NH_4Cl + 0.12% HCl (pH = 2) at 45°C; alloying with Pb up to 1% reduced this increase. Zinc alloys with small additions were studied earlier by Vondracek and Izak-Krizko (5) who found that, in 0.5*N* H_2SO_4, additions of Cd, As, Sn, Sb, Fe, and Cu increase r_{H_2}, while additions of Al, Pb, and Hg decrease r_{H_2}.

Key words: hydrogen evolution, electrode kinetics, zinc and zinc alloys, alkaline batteries.

It is difficult to arrive at mechanistic interpretations or even to derive general trends, based on the experiments cited above, since the data are scanty for the considerable number of experimental parameters being varied. The present study of the effect of Pb and other metal ions on corrosion and hydrogen evolution on zinc was made as a logical sequel to the authors' (6) previous studies of the effect of Pb ions on Zn dissolution and deposition. The topic is of additional interest from a theoretical standpoint since it was reported in (2) that current-voltage curves in 30% KOH at room temperature exhibited a higher hydrogen overvoltage on zinc than on all other metals studied in (2). The authors point out that the overvoltage characteristics of the metal added to the electrolyte alone cannot explain the observed behavior.

The corrosion potential of zinc in a solution of KOH is a mixed potential, the partial oxidation reaction being

$$Zn + 4\,OH^- = Zn(OH)_4^{2-} + 2e^- \qquad [1]$$

while the partial reduction mechanism is

$$H_2O + e^- = \tfrac{1}{2}H_2 + OH^- \qquad [2]$$

The relationship between current and potential for reaction [1] can be expressed as (7)

$$i_{Zn} = i_{Zn}^{o}\,\frac{\exp\left\{\frac{n\alpha_{Zn}\mathbf{F}}{RT}\Delta\phi_{Zn}\right\} - \exp\left\{-\frac{n(1-\alpha_{Zn})\mathbf{F}}{RT}\Delta\phi_{Zn}\right\}}{1 + \frac{i_{Zn}^{o}}{i_{Zn}^{L}}\exp\left\{\frac{-n(1-\alpha_{Zn})\mathbf{F}}{RT}\Delta\phi_{Zn}\right\}} \qquad [3]$$

where i_{Zn}^{o} is the exchange C.D. for reaction [1], $\Delta\phi_{Zn}$ the deviation from the reversible potential ϕ_{rev} of reaction [1] and i_{Zn}^{L} is the limiting C.D. for zinc deposition. The other symbols have their usual meaning. The form of Eq. [3] results from the fact that there is a limiting diffusion C.D. for metal deposition, but not for metal dissolution under ordinary corrosion conditions (7). If it is assumed that the concentration of zincate in the electrolyte is small (corroding zinc specimen in pure KOH) with a value of $C_{Zn(OH)_4^{2-}} = 10^{-5}$M, one obtains

$$i_{Zn}^{L} = 2\mathbf{F}DC/\delta = 1.4 \times 10^{-6}\ A/cm^2 \qquad [4]$$

by assuming a value for the diffusion coefficient D of 7×10^{-6} cm^2/sec (7) and a value of $\delta = 10^{-2}$ cm (unstirred solutions).

Theoretical polarization curves according to Eq. [3] have been calculated using an IBM 7094 computer for values of i_{Zn}^{o} from 10^{-1} to 10^{-6} A/cm^2 using $n = 2$, $\alpha = 0.5$, and $T = 298$°K (Fig. 1). ϕ_{Zn}^{rev} was calculated (8) as -532 mV with respect to a hydrogen electrode in the same solution,[2] pH = 14 and $C_{Zn(OH)_4^{2-}} = 10^{-5}$M.

The hydrogen-evolution reaction [2] can be expressed by the simple relationship

$$i_H = i_H^{o}\left[\exp\left\{\frac{(1-\beta_H)\mathbf{F}}{RT}\phi\right\} - \exp\left\{\frac{-\beta_H\mathbf{F}}{RT}\phi\right\}\right] \qquad [5]$$

Plots of ϕ *vs.* log i_H, assuming values of i_H^{o} from 10^{-10} to 10^{-8} A/cm^2 and $\beta_H = 0.5$ are also given in Fig. 1. Their intersection with the anodic part of the zinc curves gives the corrosion potentials and currents. It is evident that for the range of i_H^{o} values under consideration here, the value of i_{Zn}^{o} would have to be decreased drastically by additives to the electrode or electrolyte (to $<\sim 10^{-5}$ A/cm^2) from the literature value of 0.1 A/cm^2 (9) before there is an effect on the corrosion potential and corrosion current density. Significant effects on both these quantities will, however, always be produced by variations in i_H^{o}.

[2] All potentials cited in this paper are based on this electrode.

If the ion of a metal which is more noble than zinc (*e.g.*, Cu, Pb, Sn) is added to the electrolyte, an additional reduction process will occur and the corrosion current will increase, if the hydrogen overvoltage stays constant

$$i_{corr} = i_{Zn}^{ox} = i_H(\phi_{corr}) + i_{Me}^{red}(\phi_{corr}) \qquad [6]$$

where $i_H(\phi_{corr})$ and $i_{Me}^{red}(\phi_{corr})$ are the respective hydrogen and metal reduction currents at ϕ_{corr}. In this case a measurement of the rate of hydrogen evolution cannot give the exact value of the corrosion C.D., a fact which has been overlooked in previous work (2-5). Figure 2 shows this relationship for the same conditions as in Fig. 1 with the current-voltage curve for metal ions other than zinc added. It is assumed that ϕ_{rev}^{Me} of these metal ions is sufficiently noble to ϕ_{rev} of zinc; the reduction process is therefore completely under diffusion control. For the values of i_H assumed, $i_{Me}^{red}(\phi_{corr})$ is larger than $i_H(\phi_{corr})$ and

$$i_{corr} \approx i_{Me}^{red}(\phi_{corr}) \qquad [7]$$

For this case, corrosion potential and current are almost independent of the parameters of hydrogen evolution. Polarization curves in the anodic region are independent of i_H^{o} and i_{Zn}^{o} as long as $i_{Zn}^{o} > 10^{-3}$ A/cm^2.

In the present work the effect of addition of ions, neutral molecules, or metal cations to the electrolyte and alloying of small amounts of metals to zinc has been investigated and an attempt has been made to explain the results obtained by the mechanism outlined below.

Experimental

Zinc rod used for studies of hydrogen evolution was of 99.999% purity.[3] Alloys of Zn-Pb and Zn-Al were made by Ventron Electronics Corporation from Zn(99.999%), Pb(99.99%), and Al(99.98%). The content of Pb or Al was increased step-wise from 0.2 to 1.0 w/o. The commercial alloys Zamak 3, 5, and 7, and zinc alloy "955" were donated by Belmont Smelting and Refining Works, Incorporated, Brooklyn, New York. A typical analysis is given in Table I.

Solutions of 6*N* KOH were prepared using AR grade KOH pellets and triple-distilled water (quartz still).

[3] The effect of purity and temperature is reported in (18).

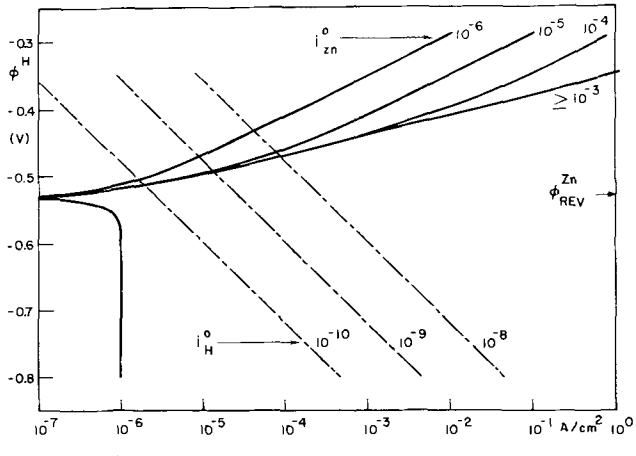

Fig. 1. Theoretical Tafel plots for the zinc dissolution-deposition and hydrogen evolution processes as a function of the exchange current density: ——— Eq. [3], — — — Eq. [6] (assuming $\alpha_{Zn} = \beta_H = 0.5$, $n = 2$, $\phi^{Zn}_{rev} = -0.532$V, $i_{Zn}^{L} = 10^{-6}$ A/cm^2, $T = 298$°K).

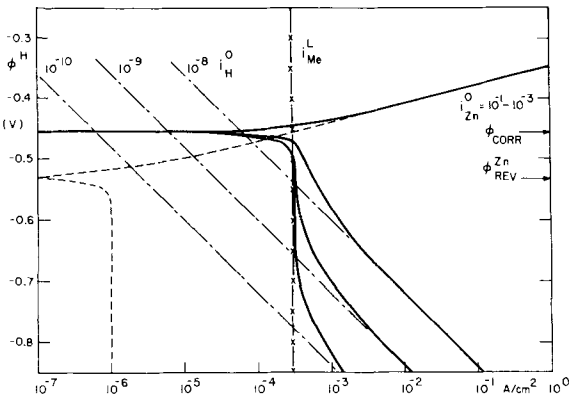

Fig. 2. Theoretical Tafel plots for reactions at a zinc electrode in the presence of added reducible metal ions: ——— Zn dissolution-deposition (Eq. [3], assuming $i_{Zn}^0 \geq 10^{-3}$ A/cm²); — — — — hydrogen evolution (Eq. [6]); x – x – deposition current, i_{Me}^L, for added metal ions; ——— Over-all reaction.

The rate of hydrogen evolution (r_{H_2}) was measured in cells as proposed in (3) or (10) in a water-thermostat at 25°C. Lead was added to the electrolyte as the acetate, tin and copper as chlorides. These, and all other additives, were of AR grade purity.

Zinc electrodes (zone refined) were degreased in benzene for 5 min at 80°C and then etched for 2 min in 10% $HClO_4$. Samples of Pb and Sn were etched in 5% HNO_3. The electrodes were then washed with distilled H_2O and immediately immersed in the electrolyte. Polishing with emery paper was avoided, since this led to irregular behavior in some cases.

Polarization curves were carried out in deaerated 6*N* KOH at room temperature (24° ± 1°C) using zinc rod counterelectrodes and a hydrogen electrode in the same solution as reference electrode. When polarization curves on Pb or Sn were measured, Pt counterelectrodes were used, since it was observed that small amounts of zincate produced while the working electrode was cathode diffused from the counterelectrodes to the Pb or Sn electrode and were reduced or oxidized during potential sweeps from the rest potential of Pb or Sn to H_2 evolution and back.

Potentiostatic polarization curves were obtained using a Tacussel potentiostat and function generator. Values of current were recorded on a Moseley strip chart or X-Y recorder and the potential was monitored on a Keithley electrometer. Runs were usually started at a potential of −900 mV. The potential was then increased step-wise in the noble direction and the current recorded after 1 min at each potential. To obtain a quick survey of the polarization behavior of zinc or the zinc alloys, cyclic voltammetry was carried out between −1.5 and +3.0V at sweep speeds of 4.5-45 mV/sec. When the effect of such additives to the electrolyte as Sn, Pb, Sn, and Cu ions was studied, runs were started at the corrosion potential and the potential was increased step-wise to more cathodic values.

Results

Corrosion tests.—The effect of metal ions in the electrolyte on r_{H_2} is shown in Fig. 3. While additions of

Table I. Typical analyses of Asarco die casting alloys

* No exact analysis for the alloy "955" was obtained.

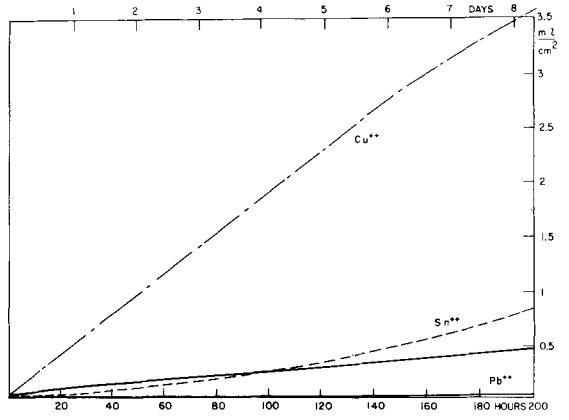

Fig. 3. Effect of 10^{-3}M of $CuCl_2$, $SnCl_2$, or PbAC on hydrogen evolution from zinc; 6*N* KOH, 25°C.

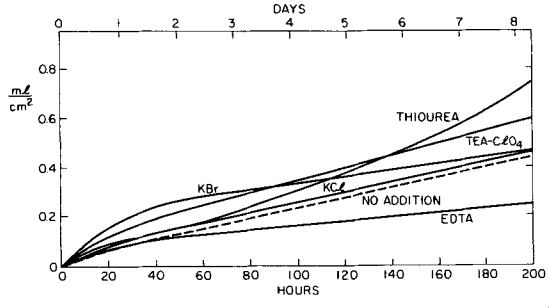

Fig. 4. Effect of 10^{-3}M of KCl, KBr, tetraethylammonium-ClO_4, thiourea and EDTA on hydrogen evolution from zinc; 6*N* KOH, 25°C.

10^{-3}M Cu markedly increase r_{H_2}, additions of 10^{-3}M Pb decrease r_{H_2}. The effect of 10^{-3}M Sn is the same as observed in 0.5*N* H_2SO_4 (5) for a Zn-1% Sn alloy. The curves of hydrogen evolution *vs.* time for pure Zn-Pb and Zn-Al alloys were similar in appearance to those of zinc. The r_{H_2} values are summarized in Table II, which also contains the values for the commercial die casting alloys. The rate of hydrogen evolution was lower for the Zn-Pb alloys than for zinc; it was also lower for the Zn-Al alloys except for the alloy with the highest Al content. The commercial zinc alloys have much higher r_{H_2} values, especially the alloy containing 1% Cu. Additions[4] of KCl apparently do not change r_{H_2} (Fig. 4), while the Br^- ions increase r_{H_2} in the initial stage of the experiments. Tetraethylammonium-perchlorate increases and EDTA lowers r_{H_2},

[4] The concentration of additions was 10^{-3}M.

while r_{H_2} increases steadily in the presence of thiourea. The S^{--} ion had a catastrophic effect on the zinc: after several hours r_{H_2} increased greatly, the specimen was full of holes and deep pits, while a white deposit (probably ZnS) covered the bottom of the test cell.

Polarization curves.—In order to obtain a better understanding of the effect of additives on the rate of hydrogen evolution and corrosion of zinc, polarization curves have been recorded for pure zinc (with or without additions to the electrolyte) and for zinc alloys. Figure 5 shows a polarization curve for zinc in 6*N* KOH, 25°C in the region of hydrogen evolution and active dissolution. Included for comparison is a theoretical curve using Eq. [3] and [5] for $i_H{}^o = 10^{-9}$ A/cm² and $i_{Zn}{}^o = 10^{-1}$ A/cm², $i_{Zn}{}^L = 10^{-6}$ A/cm², $\phi^{Zn}{}_{rev} = -532$ mV, $\alpha = \beta = 0.5$. The agreement is very good considering that only approximate values were chosen for these parameters. The corrosion potential obtained in this measurement was −505 mV, which agrees well with corrosion potentials extrapolated from measurements of Bartelt and Landsberg (11). The corrosion C.D. obtained by extrapolation from the anodic Tafel line to the corrosion potential was found to be 7 μA/cm² corresponding to a corrosion rate of 20 mdd, compared to a theoretical value of 13 μA/cm² obtained by the same extrapolation, *i.e.* 38 mdd. The initial rate of H_2 evolution in corrosion tests at 25°C was 0.065 ml/cm² day which corresponds to 10 mdd. The satisfactory agreement of two independent measurements (10 and 20 mdd) with theoretical value (38 mdd) shows that the corrosion behavior of zinc in 6*N* KOH in the absence of additives can be very well explained by the mechanisms in Eq. [3] and [5].

Polarization curves in the active and passive region for zinc and the commercial die-casting alloys were rather similar except for a lowering of oxygen overvoltage produced by the alloyed impurities. Curves for the pure Zn-Pb and Zn-Al alloys were very similar to those of pure zinc.

Figure 6 shows the effect of addition of ZnO to the electrolyte on the shape of the polarization curves. A plot of the limiting C.D. for zinc deposition in the concentration range of 10^{-3}M to 0.25M ZnO *vs.* concentration gave a value of $D/\delta = 2.9 \times 10^{-4}$ cm/sec. This value justifies the value for $i_{Zn}{}^L$ of 10^{-6} A/cm² used for the theoretical curves in Fig. 1, where it was assumed that a "pure" solution of KOH contains about 10^{-5}M of zincate (based on polarization curves measured in KOH equilibrated with Zn) due to the corrosion of zinc. Higher amounts of ZnO decrease the critical C.D. for passivation of zinc and lead to passivation at a more active potential. Theoretical corrosion rates as a function of ZnO concentration, have been calculated using values of $i_{Zn}{}^L$ based on the experimental value of $D/\delta = 2.9 \times 10^{-4}$ cm/sec, values of $\phi^{Zn}{}_{rev}$ from Ref. (8) and assuming no effect of zincate additions on $i_H{}^o$ which was again taken as 10^{-9} A/cm². Table III shows theoretical and experimental values for the corrosion potential and corrosion rates. Agreement is fair except at high ZnO concentration.

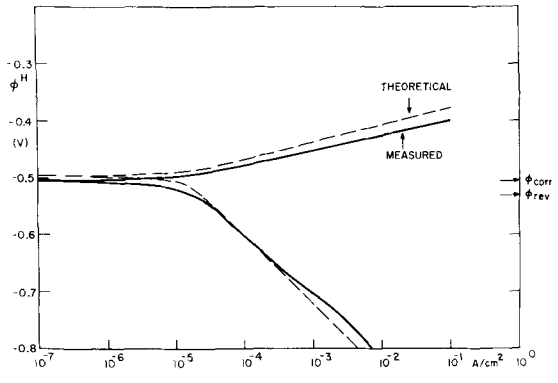

Fig. 5. Theoretical and measured polarization curves on zinc in 6*N* KOH, 25°C.

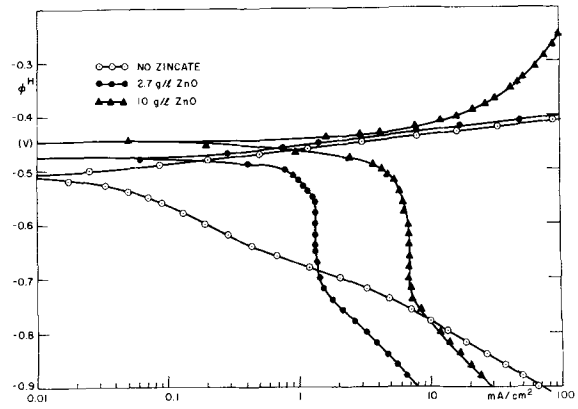

Fig. 6. Polarization curves for zinc with and without additions of ZnO, 6*N* KOH, 25°C.

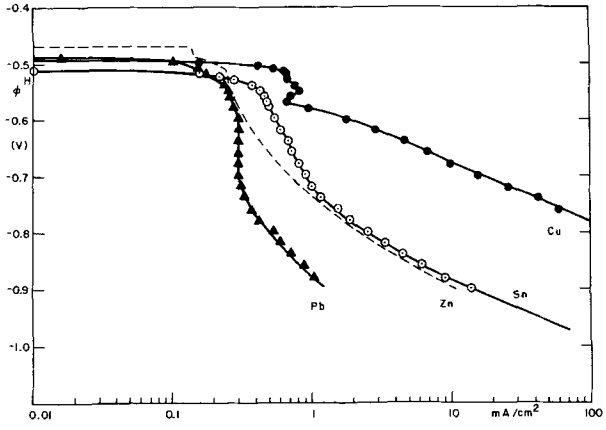

Fig. 7. Polarization curves for zinc in the presence of 10^{-3}M of ZnO, $CuCl_2$, $SnCl_2$, or PbAC; 6*N* KOH, 25°C.

The effect of additions of 10^{-3}M Cu, Sn, Pb, or Zn to the electrolyte on the polarization behavior of zinc in 6*N* KOH is shown in Fig. 7. Copper decreases hydrogen overvoltage markedly, Sn seems to have no effect compared to a solution containing equal amounts of zincate, while Pb increases overvoltage for hydrogen evolution markedly. The limiting C.D. for deposition of all these metals on zinc is near the value for Pb of 3×10^{-4} A/cm² which was used in Fig. 2. A comparison of Fig. 7 and Fig. 2 shows good agreement of theoretical and measured polarization curves in the regions of the limiting C.D. and hydrogen evolution. According to these curves, the exchange C.D. for the hydrogen evolution reaction on zinc in the presence of 10^{-3}M Cu would be between 10^{-8} and 10^{-7} A/cm², and between 10^{-11} and 10^{-10} A/cm² in the presence of 10^{-3}M Pb. Measurements of polarization curves on pure Sn or Pb in deaerated 6*N* KOH (Fig. 8) are not easy to interpret since Tafel behavior was not found, which is partly due to hydride formation observed at more negative potentials for both metals. In general it seems that the overvoltage for hydrogen evolution is somewhat higher for Pb than for Sn and that both metals have a higher hydrogen overvoltage than zinc, contrary to what was observed by Oxley and Humphrey (2).

0.25	−436	−401	0.8	6

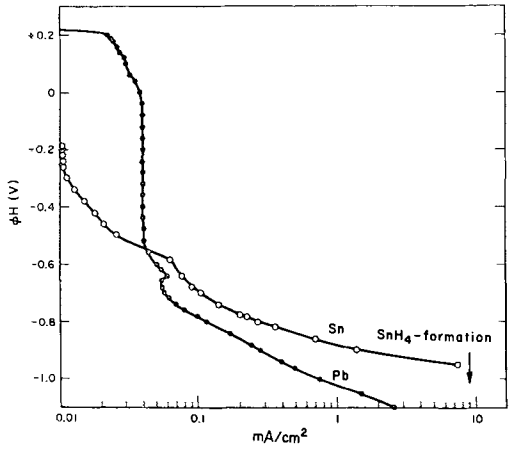

Fig. 8. Polarization curves for tin (AR) and lead (99.999%) in 6*N* KOH, 25°C.

Discussion

The good agreement between experimental and theoretical corrosion rates (Table III) and polarization curves (Fig. 5) confirms our assumption that the corrosion behavior of zinc in KOH can be readily explained by mixed potential theory; zinc metal is oxidized to the zincate ion, while water is reduced to hydrogen gas. It is not necessary to consider the rate of dissolution of interfacial ZnO or $Zn(OH)_2$ as rate controlling as done by Rüetschi (10) and partly by Dirkse and Timmer (1). The formation of ZnO or $Zn(OH)_2$ in 6*N* KOH at the rest potential seems unlikely, since the reversible potential for these reactions is more noble than the observed corrosion potential of zinc. An over-all reaction similar to the one assumed by Dirkse and Timmer (1)

$$Zn + 2H_2O \rightleftharpoons H_2 + Zn(OH)_2 \qquad [8]$$

with a reversible potential of $\phi_{rev} = -439$ mV (12) is not consistent with a corrosion potential of $\phi_{corr} = -497$ mV in 6*N* KOH, 25°C.

The effect of addition of the metal cations Cu, Sn, or Pb on hydrogen evolution rates and polarization behavior can be explained only on a qualitative basis since a third process (reduction of the metal ions) is added to the process of zincate formation and water reduction. In this case a measurement of r_{H_2} no longer gives the exact value of corrosion rates (Eq. [6]). It seems, however, still possible to explain the changes of r_{H_2} (Fig. 3) by assuming that the large increase of r_{H_2} upon additions of Cu results from a lowering of hydrogen overvoltage on the surface of the test specimen, while the decrease of r_{H_2} upon additions of Pb results mainly from an increase of hydrogen overvoltage. The high rate of hydrogen evolution of the commercial alloys (Table II) must result from low overvoltage impurities[5] and, characteristically, the alloy containing 1% Cu (Zamak 5) has the highest corrosion rate.

The effect of zincate (Table III) can be explained by mixed potential theory by considering the decrease in r_{H_2} and the shift of the polarization curve of zinc in the noble direction as zincate is added to the electrolyte (ϕ^{Zn}_{rev} becomes more noble). The fact that experimental corrosion rates are lower and experimental corrosion potentials more active than the theoretical values based on constant hydrogen overvoltage could be explained using the suggestion by Dirkse and Timmer (1) that dissolved zincate lowers the activity of water according to

$$ZnO + H_2O + 2\,OH^- \rightleftharpoons Zn(OH)_4^{2-} \qquad [9]$$

which thereby increases the hydrogen overvoltage slightly. Evidence for this can be found in Fig. 6 where increasing amounts of zincate increase hydrogen overvoltage at the most negative potentials.

From Eq. [3] it follows that for $i^o_{Zn} \geq 10^{-3}$ A/cm^2, variations in the value of i^o_{Zn} caused by additions to the electrolyte or the electrode would not influence the polarization curve for zinc oxidation. It is for these reasons not expected that anions which, through adsorption, affect the dissolution of other metals, as for example of Fe in H_2SO_4 (14), would have a similar effect for zinc in KOH. An effect of anions is unlikely also in view of the fact that the point of zero charge for zinc is approximately at +0.16V *vs.* hydrogen electrode at *p*H = 14 (15) and therefore noble to the corrosion potential of zinc by about 0.7V. In fact, as can be seen from Fig. 4, addition of KCl had no effect of r_{H_2}, while the effect of KBr is small. The small increase in r_{H_2} in the presence of tetraethylammonium ions is presumably due to the effect of specific adsorption on the kinetics of hydrogen evolution (16). The tremendous effect of the S^{2-} ion also observed by Merkulov and Flerov (17) might result from formation of ZnS, while the effect of thiourea (Fig. 4) which produced a constantly increasing corrosion rate might result from complex formation between the sulfur group and the zinc.

Conclusions

1. The polarization and corrosion behavior of zinc with and without additions of zincate is accounted for by mixed potential theory. In the presence of metal cations which are more noble than zinc and which therefore plate out on zinc at the rest potential, the rate of hydrogen evolution can increase or decrease, depending on the relative values of hydrogen overvoltage of zinc and the metal deposit on zinc.

2. The low corrosion rates of Zn-Pb alloys suggest that the rate of hydrogen evolution of zinc can be lowered if the impurity level of the electrode is carefully controlled. This and the beneficial effect of lead additions to the electrolyte on growth morphology reported by the authors (6) explain the beneficial action of lead in zinc batteries.

3. The expected absence of an effect of inorganic anions on gassing rates has been confirmed experimentally.

4. Compounds containing sulfur and especially the $S^=$ ion must be avoided since they increase hydrogen evolution rates to very high values.

Anodic Discharge of Chloride Ions on Pt-Ir Alloy Electrodes

G. Faita and G. Fiori

Laboratory of Electrochemistry and Metallurgy, University of Milan, Milan, Italy

and A. Nidola

Oronzio De Nora-Impianti Elettrochimici, Milan, Italy

ABSTRACT

The behavior of Ti-supported Pt-Ir alloys in the electrolysis of NaCl has been examined as a function of Ir content, NaCl concentration, and electrolysis time. Short-time experiments show that an iridium content as low as 0.5% is sufficient to eliminate almost completely the passivation effects (in 1M and saturated NaCl solution). Long-run experiments make clear that the minimum percentage of 5/10% Ir is necessary in order to have low potentials after thousands of hours; in such a case, however, complicating factors such as mechanical stability and chemical corrosion should be taken into account.

It is known that Pt electrodes undergo strong passivation (1) when used as anodes in brine electrolysis. A previous work (1) showed that Pt-Ir electrodes (30% Ir) do not passivate under similar experimental conditions. The aim of the present paper is to deal with the behavior of Pt-Ir electrodes as function of Ir content, NaCl concentration, and electrolysis time.

Experimental Methods

The measurements were carried out by means of a rotating disk electrode (2); this equipment allows the Cl_2 bubbles to be quickly removed from the surface. Consequently, currents and potentials are highly stable and their value can be read with sufficient precision and accuracy.

Pt, Pt-Ir alloys, and Ir coatings were obtained by a new thermal method (3): the titanium matrices were turned into a cylindrical shape (10 mm diameter) and were degreased, ground, and painted with a mixture containing $(NH_4)_2PtCl_6$ and $(NH_4)_2IrCl_6$ in the suitable ratio (see below). The painting was followed by decomposition at 500°C in air; the sequence, painting and decomposition, was repeated five times. Annealing at 550°C (2 hr) and air quenching completed the thermal treatment.

In the case of 30% Ir alloy, the following amount of mixture was applied to each square centimeter:

$(NH_4)_2PtCl_6$	6.4 mg
$(NH_4)_2IrCl_6$	2.8 mg
NH_4Cl	1-4 mg
$HCONH_2$	0.2-0.5 ml
Polyrad 1110/A (Hercules)	0.1-0.3 ml

The same amount of mixture was used in the preparation of the other alloys, the only difference being in the ratio of Pt and Ir salts.

Key words: chlorine electrochemistry, chlorine Pt/Ir electrodes, anode chlorine evolution.

Electrochemical measurements were carried out both in potentiostatic and galvanostatic conditions; electrode potentials were read by means of a 610B Keithley electrometer and were freed from ohmic drop contributions. These were determined by the usual current interruption technique, using a Tektronix mod. 531A oscilloscope and a transistor-driven mercury relay. Typical rise times were in the 1.5-2μs range. Before each experiment, the electrodes were brought to a reproducible state of activity by polarizing for 10 sec alternatively at 1.7V (NHE) and at −0.4V (NHE) for ten times. In addition, before each measurement the electrodes were held at −0.4V (NHE) for 3 sec: this treatment appeared to remove all oxides from the electrode surface. During each experiment, nitrogen containing 1% chlorine was bubbled through the NaCl solutions whose *pH* was held to a value of 3.

Results

Potentiostatic measurements.—In 0.1M NaCl (Fig. 1), all electrodes follow the Tafel law (slope: 0.03V/decade of current) up to 40 mA/cm^2; at higher current densities, Pt and Pt-Ir 0.5% show a kind of limiting current which can be attributed to a passivation process (see discussion below).

Ir, Pt-Ir 4%, Pt-Ir 2% show quite smaller deviations from the Tafel straight line at current densities above 90 mA/cm^2.

In 1M and saturated NaCl solution, the electrode behavior is qualitatively similar to that in 0.1M NaCl: again, the electrodes follow Tafel law with a slope of 0.03V/decade of current. Pt shows clearly a beginning of passivation (see discussion below) at 140 mA/cm^2 in 1M NaCl and 300 mA/cm^2 in saturated NaCl solution.

It must be mentioned that the potentiostatic measurement current values were always read after 15 sec.

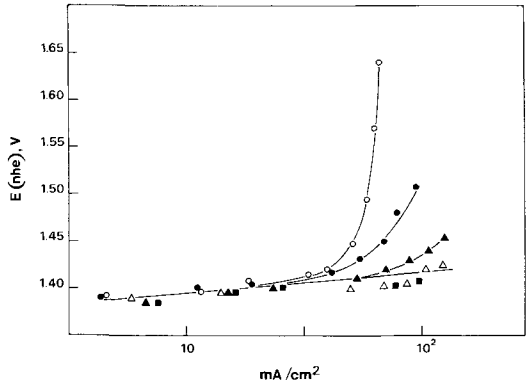

Fig. 1. Polarization curves in 0.1M NaCl, pH = 3, Cl_2 1%, T = 30°C, rotation speed = 2800 rpm. ○, Ti/Pt; ●, Ti/Pt-Ir (0.5%); △, Ti/Pt-Ir (2%); ▲, Ti/Pt-Ir (4%); ■, Ti/Ir.

Galvanostatic measurements.—Figure 4 shows the behavior in galvanostatic conditions (current density: 8 mA/cm²) in 0.1M NaCl: the increase in potential difference with respect to the value after 15 sec ($\Delta\eta$) has been plotted against time. This difference is time dependent and increases as Ir content decreases.

The Pt-Ir alloys (5, 10, 20, and 30%) were also tested under more drastic conditions: 1 A/cm² (constant current density), 70°C, 310 g/l NaCl. In this case, the coatings were deposited on the Ti network by the previously described procedure and the electrodes were used as anodes in pilot brine cells.

From Fig. 5 it can be seen that Pt-Ir 20% and 30% display a potential as low as 1.6V (NHE) after 8000 hr of electrolysis, whereas the potential of the Pt-Ir 5% and 10% is higher than 2V (NHE) after 1000 and 7000 hr, respectively.

Pt electrodes show a sufficiently low potential, about 1.5V (NHE), during the first few hours of electrolysis. After this time, quick passivation takes place; *i.e.*, the electrode potential jumps to values of about 2.5-3.0V (NHE) in the space of a few minutes.

Discussion

The different behavior between Pt and Ir electrodes can be explained by the different properties of chemisorbed oxygen.

The chemisorbed oxygen on Pt is characterized by some degree of irreversibility: capacitance measurements (4), for instance, show that the "oxide" amount is nearly constant when the electrode potential is decreased from 1.4V (NHE) to 0.9V (NHE). A similar conclusion can be drawn from the analysis of the current/potential curves obtained when a periodic triangular voltage is applied potentiostatically to the electrode (4).

In addition, it has been found (5) that the building up of the "oxide" layer on Pt starts at more anodic potentials in solutions containing halide ions; moreover, the amount of chemisorbed oxygen decreases when halide ion concentration increases. In the short-time experiments (5), the oxygen chemisorption disappears almost completely when chloride ion concentration is higher than 0.01M.

More likely, under these conditions oxygen adsorption has been considerably slowed down rather than completely prevented. Now from Fig. 1 to 3 it can be concluded that Cl^- ions are discharged at a Pt electrode at low potentials only when the surface is free from chemisorbed oxygen, whose formation rate is inversely proportional to Cl^- concentration and electrode potential. Clearly, the amount of chemisorbed oxygen is proportional to the electrolysis time; this means that under potentiostatic conditions the current values decrease with time, whereas under galvanostatic conditions the electrode potentials increase with electrolysis time (see Fig. 4).

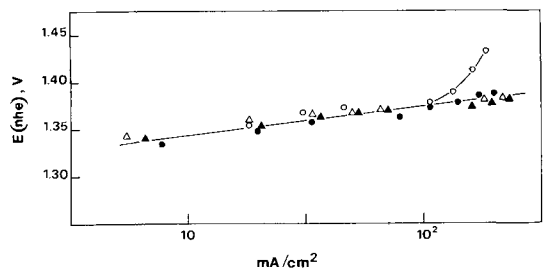

Fig. 2. Polarization curves in 1M NaCl, pH = 3, Cl_2 1%, T = 30°C, rotation speed = 2800 rpm. ○, Ti/Pt; ●, Ti/Pt-Ir (0.5%); △, Ti/Pt-Ir (2%); ▲, Ti/Pt-Ir (4%).

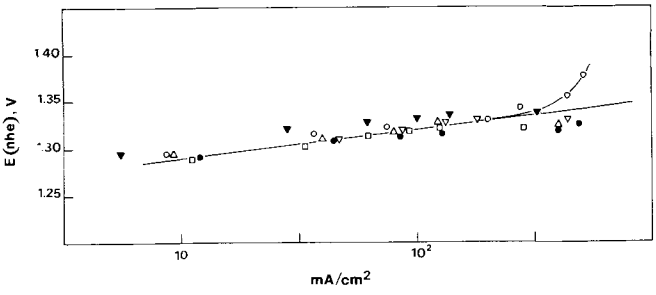

Fig. 3. Polarization curves in saturated NaCl, pH = 3, Cl_2 1%, T = 30°C, rotation speed = 2800 rpm. ○, Ti/Pt; ●; Ti/Pt-Ir (0.5%); △, Ti/Pt-Ir (2%); □, Ti/Pt-Ir (10%); ▽, Ti/Pt-Ir (20%); ▼, Ti/Pt-Ir (30%).

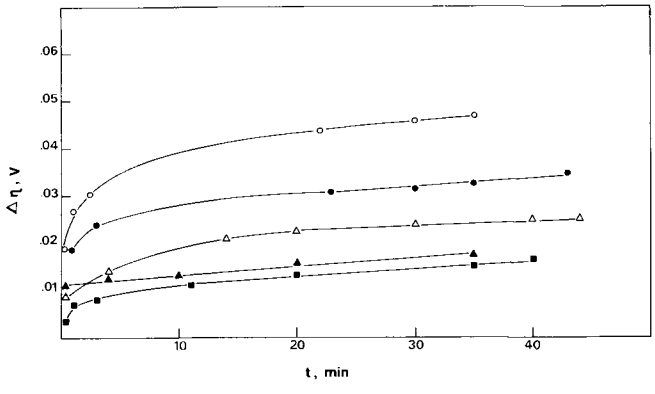

Fig. 4. Potential difference (with respect to the value after 15 sec) against time. Constant current density = 8 mA/cm². 0.1M NaCl, pH = 3, Cl_2 = 1%; T = 30°C, rotation speed = 2800 rpm. ○, Ti/Pt; ●, Ti/Pt-Ir (0.5%); △, Ti/Pt-Ir (2%); ▲, Ti/Pt-Ir (4%); ■, Ti/Ir.

Ir, on the contrary, shows a nearly reversible behavior with respect to the formation and removal of the chemisorbed oxygen (4). The breaking of the Ir-O bond is characterized by an absence of significant energy barrier; an irreversible passivation of the surface due to an "oxide" layer cannot take place (see Fig. 4).

As regards Pt-Ir alloys, the potentiostatic measurements (short-time experiments) in 1M and saturated NaCl solutions show that very low percentages (0.5%) of Ir are quite effective in decreasing the passivation effect (see Fig. 2 and 3). Long-run experiments (Fig. 5) show clearly that a minimum content of 5-10% in Ir is necessary in order to assure a lifetime of thousands of hours. In such a case, however, a number of phenomena must be taken into account, especially:

(*i*) mechanical stability related to gas evolution in the pores of the coating

(*ii*) chemical corrosion which can be brought about in the pores by the acidity due to some oxygen evolution.

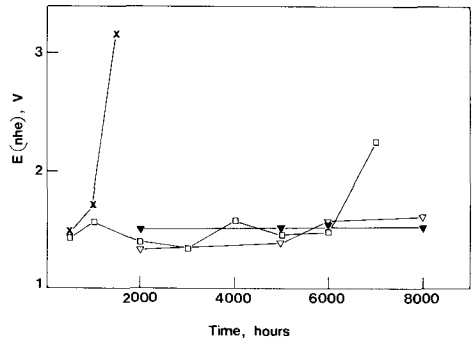

Fig. 5. Electrode potential as a function of electrolysis time. Constant current density = 1 A/cm^2. NaCl = 310 g/l, pH = 3, T = 70°C. ×, Ti/Pt-Ir (5%); □, Ti/Pt-Ir (10%); ▽, Ti/Pt-Ir (20%). ▼, Ti/Pt-Ir (30%).

It should be remembered that the lowest pH value where Pt is stable in the presence of the chlorine and chlorides is about 2. However, it is apparent that mechanical stability and chemical corrosion are negligible in short-time experiments where the catalytic properties of the electrode surface are predominant.

As regards the kinetics, it must be pointed out that all the electrodes show a Tafel b-coefficient equal to 0.03 V/decade of current; according to this low value, the electrode mechanism could be the following one

$$Cl^- \rightleftarrows Cl_{ads} + e$$
$$2Cl_{ads} \rightarrow Cl_2$$

The second step being rate determining.

Technical Note

Polarization Cell for Potentiostatic Crevice Corrosion Testing

E. A. Lizlovs*

Climax Molybdenum Company of Michigan, Research Laboratory, Ann Arbor, Michigan 48106

Several electrochemical methods, including potentiostatic techniques, have been proposed in recent years for the investigation of crevice corrosion (1-6). In general, two major problems are involved in designing a suitable electrode for crevice corrosion studies: elimination of unwanted crevices while maintaining a well-defined exposed electrode area, and introduction of a reproducible crevice. Considering that fissures involved in crevice corrosion of stainless steels are of the order of 10^{-3} in. or less, both of these problems are quite formidable. The present investigation was prompted by the observations of crevice attack during potentiodynamic polarization experiments with stainless steels in hydrochloric acid (7). It was envisioned at that time that, if an appropriate working electrode could be designed, the potentiostatic polarization current in the passive state could be utilized to measure the progress of crevice corrosion. In addition, if reproducible crevices could be introduced in electrode design, the relative resistance to crevice corrosion of a series of alloys could be determined by comparing the polarization current at some selected potential.

Experimental

Crevice corrosion cell.—The polarization cell for the crevice corrosion studies consisted of a 5 in. long, 3½ in. diameter glass tubing mounted between two rectangular polycarbonate blocks. The essential parts of the cell are shown in Fig. 1. The cell was equipped with two 10/30 and two 24/40 standard taper ground glass necks to accommodate the electrolytic bridge from the reference electrode, inlet and outlet tubes for purging gas, and auxiliary platinum electrode, which was separated from the bulk of the solution by a fritted glass disk. The glass tube was mounted to polycarbonate blocks by placing the tube on the blocks in a proper position and applying silicone rubber (G.E. RTV-12 adhesive) around it and allowing the adhesive

[a] Not analyzed but assumed to be approximately at indicated levels. See Ref. (9).

to solidify for a day. One of the end-blocks served as a working electrode holder. The design of the electrode holder was a modified version of the electrode holder described by France (8). The working electrode, which was a disk approximately ¾ in. in diameter, was pressed against a Teflon washer by a PVC[1] bolt. Electrical contact to the sample was established by a copper back-up disk and copper wire extending through the PVC bolt. The opposite end-block contained a threaded ½ in. diameter hole, concentric with the working electrode opening. This opening was fitted with a Teflon bolt with inserted glass rod with a smooth, approximately 4 mm diameter, glass bead at the end. A variable crevice was produced by advancing the bolt through the threaded hole until the bead was pressed against the surface of the working electrode. If the same glass bead is employed for all experiments, it can be assumed that crevices of equal geometries are produced. The crevice can be applied or removed as desired at any stage of the experiment by simply manipulating the Teflon bolt.

Materials.—Commercial stainless steels, Types 304 and 316, and high-purity laboratory alloys, 17% Cr, 17% Cr-3% Mo, 25% Cr and 25% Cr-3.5% Mo, were selected for the evaluation of the performance of the crevice corrosion cell and feasibility of the potentiostatic method for crevice corrosion tests. Chemical compositions of the steels are given in Table I.

Procedures.—All experiments were performed in N_2-saturated 1*N* NaCl at room temperature (24° ± 1°C). The working electrode was first polarized for 10 min at −1.00V (SCE), then the potentiostat was switched off for 10 min, and then switched on again. The potential of the working electrode was then carefully changed from −1.00 to −0.20V, and the electrode was passivated at this potential for 2 hr. Timing was started from the moment the polarization current fell down to 5 μA. After a 2 hr passivation, the potential was scanned from −0.20 to 0.00V at the rate of 0.15 mV/sec, and then the glass bead was pressed to the surface. The electrode with the "crevice applied" was kept at 0.00V for 1-3 hr, and then the crevice was removed. Polarization current and potential were recorded continuously throughout the above operations by a two-pen strip chart recorder.

After the experiment, the electrode was removed from the assembly and inspected for corrosion damage. Only those experiments were considered acceptable in which corrosion occurred under the glass bead and no place else.

Results and Discussion

A noticeable polarization current rise, indicating the onset of crevice corrosion, usually started almost immediately after the glass bead was pressed against the electrode surface. No critical potential for crevice corrosion was found and the attack could be initiated at potentials as low as −0.20V. Polarization current as a function of time for various stainless steel electrodes is shown in Fig. 2. Since the electrode area for samples was the same (1.26 cm^2) and the same glass bead was applied to the surface, the polarization current itself rather than current density may be used to compare the relative rates of crevice corrosion. Polarization current-time curves at 0.00V in the presence of a crevice were for the most part quite irregular and indicated a complex corrosion process. Comparison of the behavior of various grades of stainless steels and evaluation of the relative resistance to crevice corrosion, however, were possible. Type 304 and high-purity 25% Cr stainless steels showed about the same relative resistance to crevice corrosion and both materials repassivated immediately upon removal of the crevice. The high-purity 17% Cr alloy showed the highest polarization current of all materials over a 1 hr period and it did not repassivate immediately after removal of the crevice. Instead, the 17% Cr alloy continued to corrode at almost the same rate for at least 1 min after removal of the crevice, after which time the experiment was interrupted. Examination of the electrode showed that corrosion was localized under the glass bead. Apparently, for the 17% Cr alloy, a stable pit could be formed at 0 volt at the site of the crevice damage. Both Type 316 stainless steel and 17% Cr-3% Mo steel repassivated while the bead was still applied to the surface. The 17% Cr-3% Mo alloy repassivated within 30 min of the initiation of crevice corrosion, while Type 316 repassivated 90 min after crevice was applied. Apparently the potential of 0.00V was not sufficiently oxidizing to sustain corrosion under the bead for these alloys. Type 316 steel also showed higher polarization current than the 17% Cr-3% Mo alloy. No crevice corrosion could be initiated for the 25% Cr-3.5% Mo alloy either at 0 volt or at +0.80V. This alloy was also tested for crevice corrosion in 1*N* hydrochloric acid at room temperature. In this experiment, the electrode was first activated, then allowed to corrode for about 7 min, then the potentiostat with potential set at +0.80V was switched on. Immediately after the potential was applied to the electrode, the glass bead was brought against the electrode surface. The polarization behavior under these drastic conditions is shown in Fig. 3. The electrode completely passivated and no effect of the presence of a crevice on the electrode surface was discernible on the polarization current-time curve.

The results of the two successive applications of the crevice to two different points of the same 17% Cr-3% Mo alloy are shown in Fig. 4, which illustrates the kind of reproducibility expected in the operation of the crevice corrosion cell. Both curves were quite

[1] Polyvinyl chloride.

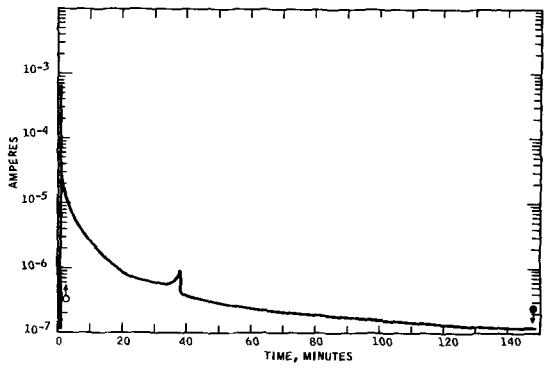

Fig. 3. Variation in polarization current with time at 0.80V for 25% Cr-3.5% Mo in 1N HCl (24° ± 1°C): ⇩, crevice applied to the electrode surface; ⇧, crevice removed from electrode surface.

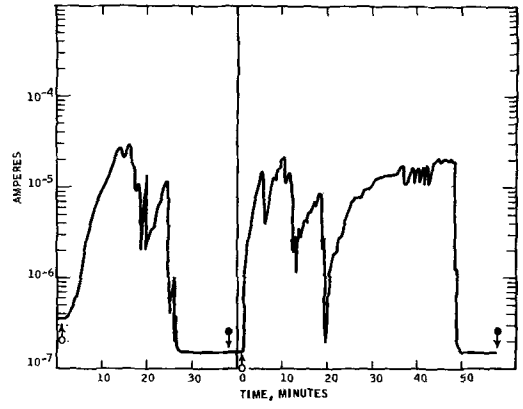

Fig. 4. Two successive polarization current-time curves at 0.00V (SCE) for 17% Cr-3% Mo alloy in 1N NaCl (24° ± 1°C): ⇩, crevice applied to the electrode surface; ⇧, crevice removed from electrode surface.

irregular and, in both, repassivation occurred before the removal of the crevice. In the first curve, repassivation occurred in about 25 min and in the second in about 50 min. Maximum current reached for both was about the same.

On the basis of the above observations, it can be concluded that the relative order of the resistance to crevice corrosion is 17% Cr (least resistant) <T304 = 25% Cr <T316 <17% Cr-3% Mo<<25% Cr-3.5% Mo (immune to crevice corrosion at room temperature in 1N Cl^-). In previous qualitative work, with 25% Cr alloys in acidified 10% Fe Cl_3 solution with crevice applied by means of a rubber band and Teflon disk, it was found that 25% Cr alloy did suffer crevice attack, while the 25% Cr-3.5% Mo alloy was immune to crevice as well as pitting corrosion. Earlier potentiostatic experiments in 1N HCl also indicated that 25% Cr-3.5% Mo alloy should be immune to crevice corrosion, while 25% Cr alloy would suffer crevice corrosion under the same conditions (9). Thus, these previous results with 25% Cr alloys are in agreement with the results from this investigation. Furthermore, all other stainless steels investigated here are known to suffer crevice corrosion in chloride media.

Conclusion

The crevice corrosion cell described in this paper makes it possible to obtain potentiostatic measurements with simple and easily prepared electrodes. Since the same crevice geometry is employed in every experiment, a relative resistance to crevice corrosion for a series of alloys can be deduced from comparison of polarization current-time curves at a given potential. Furthermore, the initiation and progress of the crevice attack can also be conveniently observed. Since the crevice can be applied or removed at will, many experiments which would not be possible with a fixed crevice can be performed.

Electron Microscope Study of Positive Lead-Acid Electrodes during Formation

W. O. Butler,* C. J. Venuto,* and D. V. Wisler

ESB Incorporated, Research Center, Yardley, Pennsylvania 19067

ABSTRACT

The formation process of positive lead-acid electrodes was studied using electron microscopy, and these results were correlated with those of x-ray diffraction and chemical analysis. Both the surface and the interior reactions taking place during active material formation were examined. The study showed the conversion of $PbSO_4$ crystals to β-PbO_2 and the subsequent growth of β-PbO_2 crystals to fully formed crystals. In addition, the crystal habits of $3PbO \cdot PbSO_4 \cdot H_2O$, $PbSO_4$, and β-PbO_2 in lead-acid electrodes were characterized.

Even though a number of years have elapsed since Planté presented his first storage battery to the French Academy of Sciences in 1860, the physical and chemical reactions taking place during electrode processing are still not fully understood. The literature abounds with publications on electrical and chemical studies of the system, and in recent years the more sophisticated techniques have been used to investigate these processes. X-ray diffraction, optical and electron microscopy, and electron microprobe analysis are now being used to study not only the physiochemical reactions taking place during electrode processing but also the reactions taking place during electrode cycling.

However, the work reported here is limited to a study of the formation process, that is, the anodization of fully cured electrodes to convert the electrode's active material from a mixture of $3PbO \cdot PbSO_4 \cdot H_2O$, PbO, and Pb to PbO_2.

Simon and Jones (1) used optical microscopy to great advantage in studying the formation process. Pierson (2) combined optical microscopy with x-ray diffraction and chemical analysis in his formation studies. An electron probe was used by Chiku and Nakajima (3) to study the formation process. Fully formed active material was studied using electron microscopy by Burbank and Ritchie (4, 5). To our knowledge, only Buskirk, Boyd, and Smith (6) used electron microscopy to study the active material during the different stages of formation. However, no correlation was made between the electron microscopy data and x-ray diffraction, optical microscopy, and chemical analysis.

This paper describes a study of both the surface and interior active material, examined *in situ* on Pb grids at various stages of formation. The electron microscopy data is closely correlated with x-ray diffraction data and with previous formation studies in our laboratory using optical microscopy and chemical analysis.

* Electrochemical Society Active Member.

Key words: electrode microstructure, electron microscopy, lead acid electron microscopy, and lead acid formation.

Experimental

Fully cured electrodes using Pb-5.75% Sb grids were formed at the rate of 160 A-hr/lb of active material for 1, 3, 7, 9, 11, 15, and 20 hr. The formation current was selected so that at 20 hr the electrodes received a full 160 A-hr/lb and were thus considered fully formed. The forming electrolyte was 1.060 sp gr H_2SO_4. After the desired formation time the electrodes were washed for 15 hr in distilled H_2O and then dried at 60°C in a mechanically pumped vacuum oven. Both the surface and the interior of the electrodes were examined. Single stage carbon replicas preshadowed with platinum-carbon pellets (7) were made of the surfaces of the different samples. The replicas were released using 25-50% HCl. The surface was also examined by x-ray diffraction.

The interiors of the sample electrodes were examined after scraping the surface parallel to the face of the electrode. A 1½ in. square was cut from the sample electrode. The surface was scraped with a clean razor blade until approximately one-half of the active material was removed. Prior to replication, the scraped surface was analyzed by x-ray diffraction. The carbon replicas of the surface and interior (scraped surface) were then examined in an RCA EMU-3G electron microscope. In addition, the active material, after it was removed from the Pb grid, of all seven formed samples was examined by x-ray diffraction. To characterize fully the crystal habits of the different compounds in lead-acid electrodes, plates consisting of only $PbSO_4$, $3PbO \cdot PbSO_4 \cdot H_2O$, tetragonal and orthorhombic phases of PbO, and the α and β phases of PbO_2 (confirmed by x-ray diffraction) were examined by electron microscopy. The crystal habits of $PbSO_4$, $3PbO \cdot PbSO_4 \cdot H_2O$, and β-PbO_2 were definitely characterized. Both β-PbO_2 and $PbSO_4$ have an equant crystal habit. Beta-PbO_2 usually exhibits a dipyramidal crystal form while $PbSO_4$ exhibits a combination of crystal forms with the prismatic and domal forms being more prevalent. $3PbO \cdot PbSO_4 \cdot H_2O$, as it appears in cured electrodes, is columnar in crystal habit.

Orthorhombic-PbO appeared as equidimensional grains and was difficult to distinguish from free Pb particles. Tetragonal-PbO has several crystal habits, one similar to orthorhombic-PbO and another tabular. Alpha-PbO_2 was particularly hard to characterize in that it is difficult to produce a pure standard and it seems to crystallize in a variety of crystal habits.

Observations

Surface examination.—A typical electron micrograph of the surface of a fully cured, unformed, positive electrode used in this study is shown in Fig. 1. The long columnar crystals are $3PbO \cdot PbSO_4 \cdot H_2O$, and the irregular grains are tetragonal or orthorhombic-PbO. X-ray diffraction indicates $3PbO \cdot PbSO_4 \cdot H_2O$ and orthorhombic and tetragonal-PbO to be present on the surface. No free Pb was detected by x-ray diffraction on the surface of the cured electrode.

The surface of an electrode formed for 1 hr is shown in Fig. 2. Both the large well-developed crystals and the smaller crystals are $PbSO_4$. No effect of the anodization process was noted at this time. X-ray diffraction did detect a little tetragonal and orthorhombic-PbO. No $3PbO \cdot PbSO_4 \cdot H_2O$ or PbO_2 was detected by x-ray diffraction.

Active material areas near grid members were converted to β-PbO_2 after 5 hr of formation. The β-PbO_2 crystals are initially rounded agglomerate crystal growths as shown in areas A of Fig. 3b. Beta-PbO_2 crystals next to the grid members, see Fig. 3a, are better formed since the formation reaction is initiated at the grid active material interface and then progresses toward the center of the active material pellets. The central portion of the active material pellets are still composed of unaltered $PbSO_4$ crystals as shown in Fig. 2.

After 9 hr of formation the β-PbO_2 crystals which make up the formed aggregates have become larger and their dipyramidal crystal form can be observed (Fig. 4). In addition, much more β-PbO_2 is present on the electrode surface.

At the end of 11 hr of formation the β-PbO_2 crystals have continued their development. At this state of formation the central portions of the pellet surface

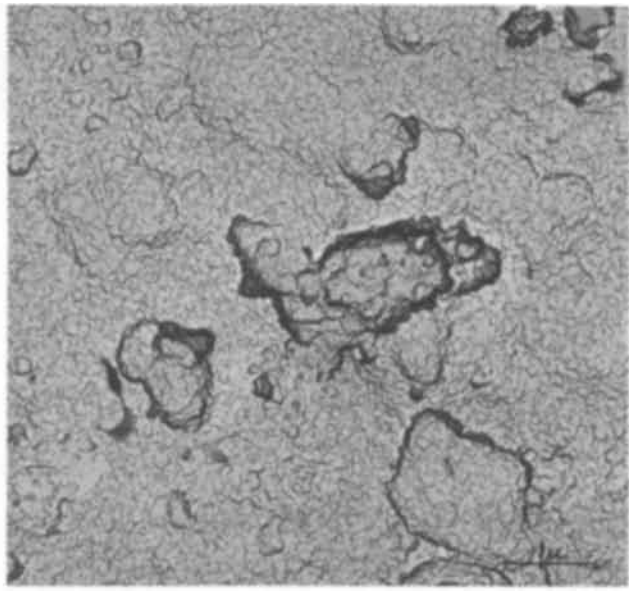

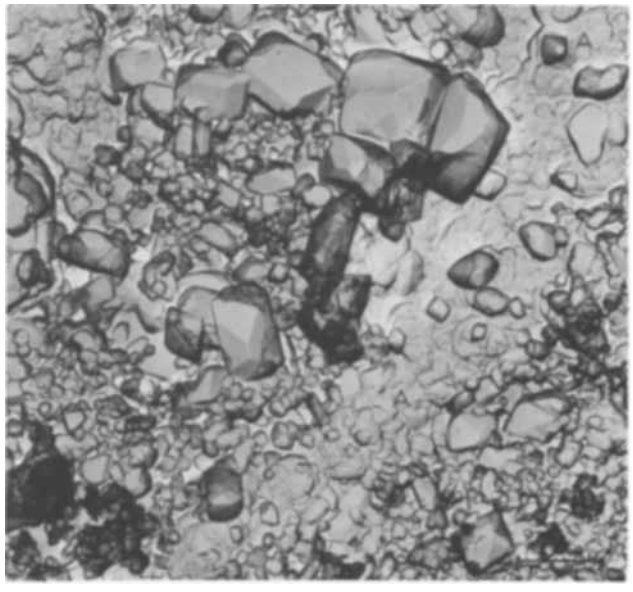

Fig. 3. Electrode surface after 5 hr of formation: (a, *top*) active material next to a grid member; small crystals are β-PbO_2; (b, *bottom*) active material further away from a grid member. Well developed crystals are $PbSO_4$. The initial appearance of β-PbO_2 occurs as rounded crystal agglomerates and appear in areas A of the electron micrograph.

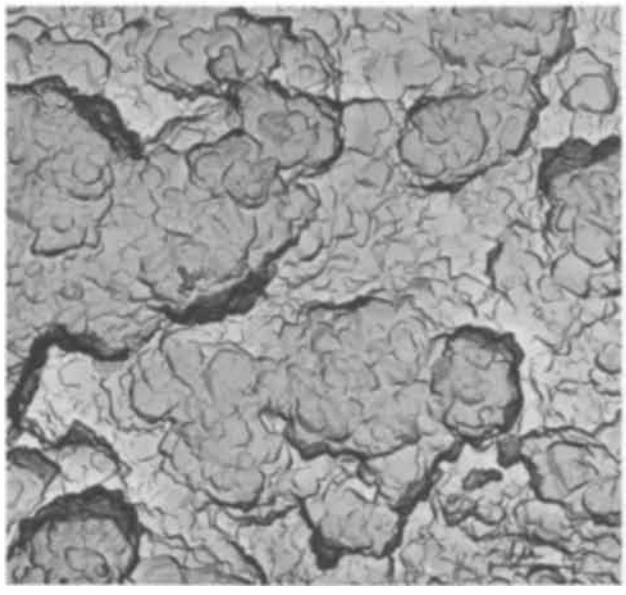

Fig. 4. Electrode surface after 9 hr of formation showing the development of the initial rounded crystal agglomerates of β-PbO_2 into larger well-defined crystal groups.

begin to form and appear similar to the areas shown in Fig. 3. These reactions continue throughout the remainder of the electrochemical formation. An electron micrograph of a fully formed surface observed in the central pellet area is shown in Fig. 5. The well-developed dipyramidal β-PbO_2 crystals are typical for a fully formed electrode. X-ray diffraction showed that the surface of the fully formed electrode consists of β-PbO_2 with trace amounts of the tetragonal and orthorhombic-PbO.

Interior examination.—The interior of the above electrodes were examined as above in order to determine if the same general sequence of formation reactions occurred in the interior as on the surface. X-ray diffraction examination of the fully cured active material indicated it is composed of mainly $3PbO \cdot PbSO_4 \cdot H_2O$ plus minor amounts of Pb and orthorhombic and tetragonal PbO.

The interior active material after 1 hr of formation (Fig. 6) is still essentially the same as for a fully cured electrode (unformed). It consists of $3PbO \cdot PbSO_4 \cdot H_2O$, tetragonal and orthorhombic-PbO, $PbSO_4$, and Pb.

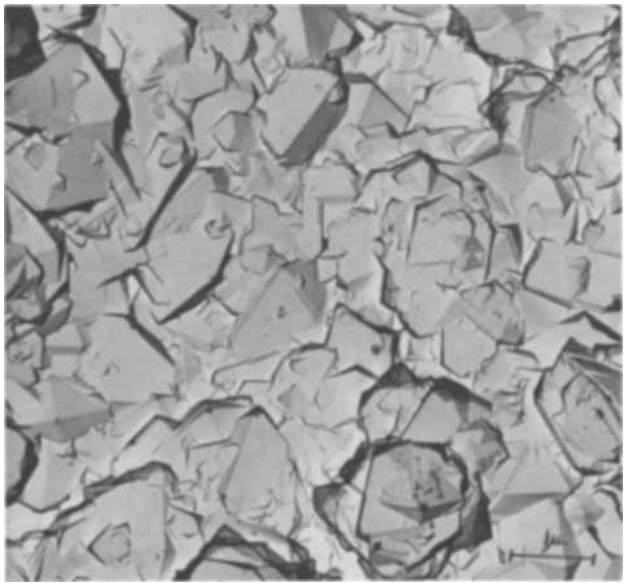

Fig. 5. Surface of a fully formed (20 hr) positive electrode. Shows well developed β-PbO_2 dipyramidal crystals.

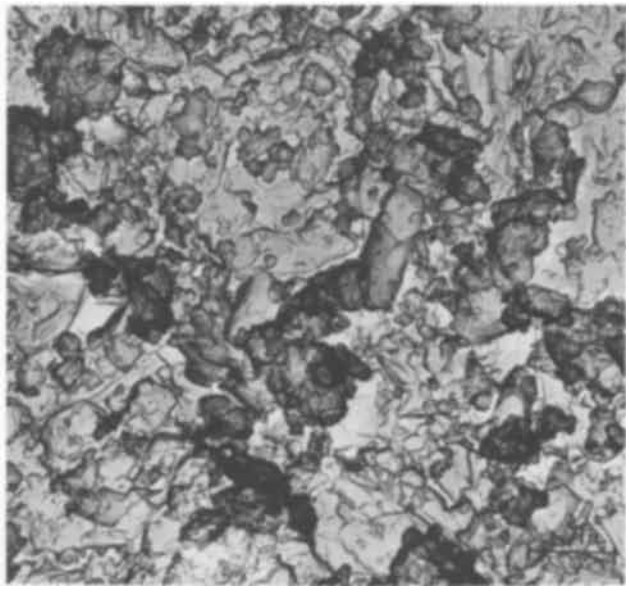

Fig. 6. Interior active material of a 1-hr formed electrode. Compounds present are $3PbO \cdot PbSO_4 \cdot H_2O$, $PbSO_4$, orthorhombic and tetragonal-PbO, and free Pb.

After 5 hr of formation, only a small amount of $3PbO \cdot PbSO_4 \cdot H_2O$ remains (Fig. 7). The interior is primarily composed of $PbSO_4$, β-PbO_2,, and tetragonal-PbO. A small amount of α-PbO_2 was also detected by x-ray diffraction.

The interior of an 11 hr formed electrode no longer contains any $3PbO \cdot PbSO_4 \cdot H_2O$ (Fig. 8). It is primarily composed of β-PbO_2, tetragonal-PbO, α-PbO_2, and $PbSO_4$. Figure 8 shows agglomerates of β-PbO_2 forming at the expense of large $PbSO_4$ crystals.

The reaction sequences are very similar to those observed on the electrode surfaces for the remainder of the formation time. X-ray diffraction shows that the fully formed interior active material is composed of α- and β-PbO_2 plus some tetragonal-PbO. Chemical analysis indicates the total (surface and interior) fully formed active material contains 81% PbO_2, 17% PbO, with the remaining 2% being Pb and $PbSO_4$.

An electron micrograph of a typical fully formed interior is shown in Fig. 9. The overgrowths on the

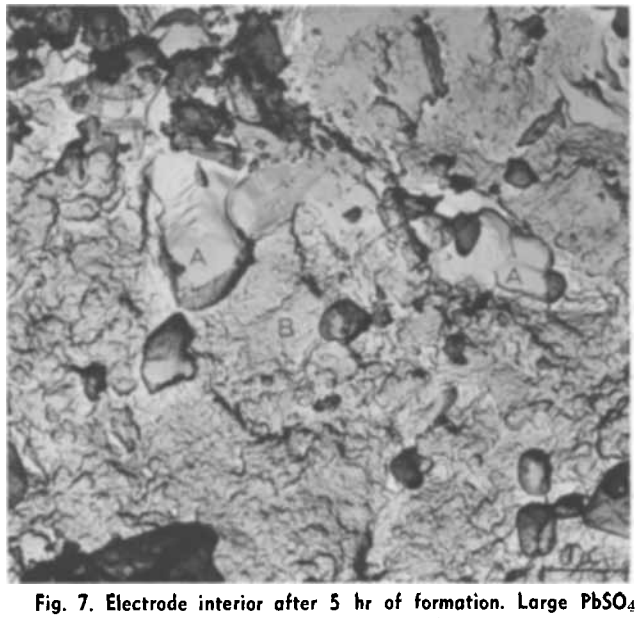

Fig. 7. Electrode interior after 5 hr of formation. Large $PbSO_4$ crystals (A), agglomerate crystalline mass of β-PbO_2 (B), and a small amount of tetragonal-PbO which is indistinguishable are shown.

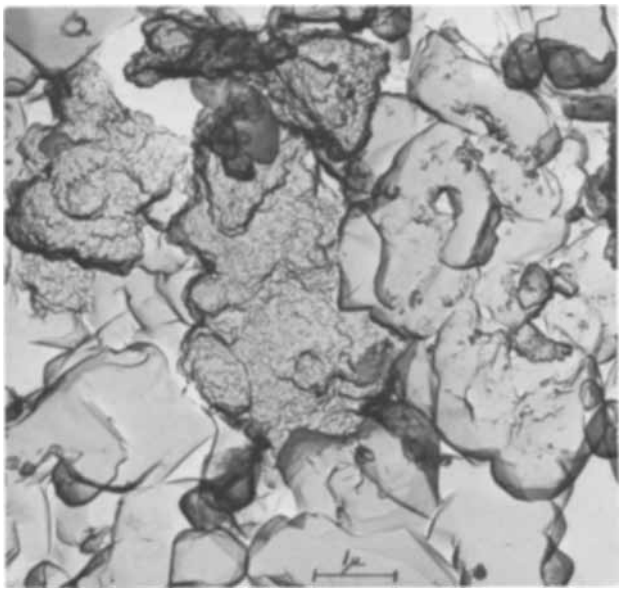

Fig. 8. Interior of positive electrode after 11 hr of formation showing large $PbSO_4$ crystals being converted to crystalline aggregates of β-PbO_2.

faces of the β-PbO_2 crystals in Fig. 9 were observed on crystals both on the surface and in the interior of the fully formed electrode. Once the β-PbO_2 crystals reach a definite size, growth of an individual crystal slows considerably or even ceases, and any further formation occurs as new crystals developing on the faces (presumably where imperfections are present) of the fully matured crystals. This phenomenon was naturally more prevalent in active material nearer grid members.

The sequence of reactions observed in the interior of the electrodes is very similar to those observed on the electrode surfaces. The main differences are (*i*) the presence of more $PbSO_4$ on the surface, especially during the initial formation period, and (*ii*) no α-PbO_2 was detected on the surfaces of the different formed electrodes. Crystals believed to be α-PbO_2 were observed in the active material interior near the grid members as shown in Fig. 10. However, these

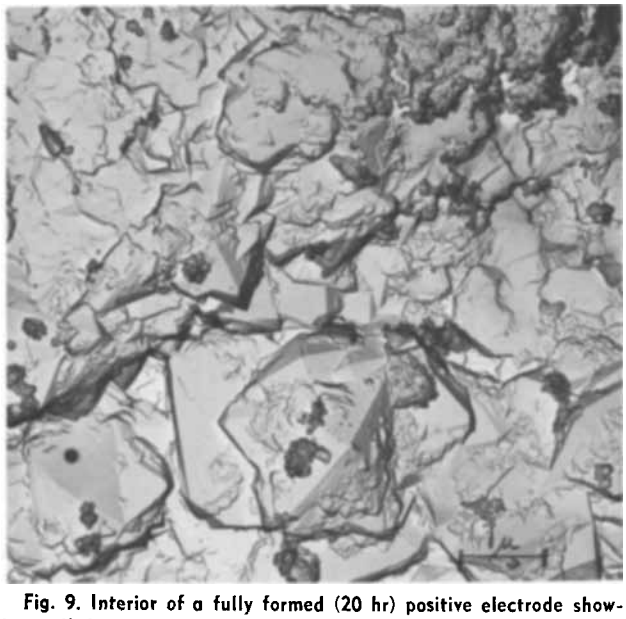

Fig. 9. Interior of a fully formed (20 hr) positive electrode showing well-developed β-PbO_2 dipyramidal crystals.

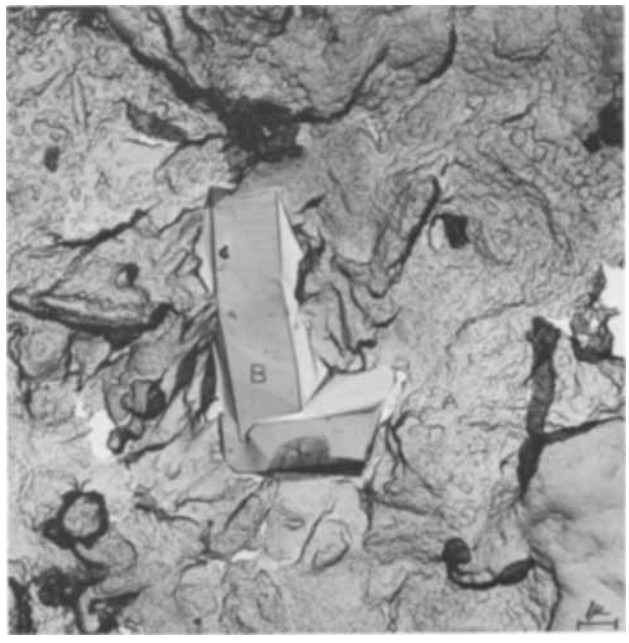

Fig. 10. Interior of active material after 15 hr of formation showing undeveloped crystalline masses (A) and large well-developed crystals believed to be α-PbO_2 (B). Active material area is very near a grid member. These and similar areas were observed in both 15- and 20-hr formed electrodes.

crystals could not be definitely characterized as α-PbO_2 with a standard as was done with the other lead compounds.

Concluding Remarks

This study established that the initial reactions taking place during formation are essentially chemical. These chemical reactions consist mainly of converting $3PbO \cdot PbSO_4 \cdot H_2O$ and orthorhombic-PbO to $PbSO_4$. Tetragonal-PbO is not as easily converted to $PbSO_4$. Second, the resulting $PbSO_4$ and PbO are then electrochemically converted to PbO_2. The interior and surface reactions are essentially the same. The one major difference is the absence of α-PbO_2 forming on the electrode's surface. Also, α-PbO_2 preferentially forms in the interior near the grid members and assumes a variety of crystal habits.

The crystal habits of $3PbO \cdot PbSO_4 \cdot H_2O$, $PbSO_4$, and β-PbO_2 in positive lead-acid electrodes were definitely established, and electron micrographs were obtained showing the conversion of $PbSO_4$ crystals to PbO_2 crystals and the subsequential growth of β-PbO_2 crystals to their full size as found in a fully formed electrode.

Electrochemical Properties of Polycrystalline Tin Oxide

D. Elliott, D. L. Zellmer,[1] and H. A. Laitinen*

Department of Chemistry, University of Illinois, Urbana, Illinois 61801

ABSTRACT

Some electrochemical properties of polycrystalline tin oxide in the form of thin films have been examined. For a variety of antimony-doped specimens the carrier concentration has been determined from the space charge capacity and compared with donor concentrations. Disparities between the two values have been found, and explanations have been sought in terms of structural defects as well as chloride impurity and nonstoichiometry. Analyses for the last two have been made. The kinetics of several reactions at highly doped specimens (5.9 x 10^{20} carriers/cc) indicate that the space charge region is completely transparent to electrons due to tunneling. With a series of samples of diminishing carrier concentration the increasing limitation of the tunneling process is demonstrated until it becomes the principal current controlling factor at about 3 x 10^{19} carriers/cc.

Polycrystalline tin dioxide, deposited as a thin conducting layer on glass or quartz, has recently come into some use as an electrode material with unique properties. Among these are transparency, resistance to oxidation, and the absence of adsorption by organic surfactants.[2] Extensive use of the first property, for example, has been made by Kuwana and co-workers (1), and also by others (2). The present investigation is part of a series aimed at characterizing the electrode surface (3, 4). The latter reference contains a fairly comprehensive list of references dealing with the electronic properties of tin oxide. A recent paper by others on the electrode properties has also appeared (5).

Tin oxide is a semiconducting material of large band-gap (3.7 eV). Its intrinsic resistivity is very high but may be decreased enormously by the introduction of appropriate doping agents. Minimum values down to about 2.5 x 10^{-4} ohm cm are reached with a few per cent antimony. Further increase in the antimony concentration causes the resistance to get larger again, probably caused by increasing lattice disorder (6, 7).

Experimental

Two types of electrode have been used in the study. The first was a commercially available tin oxide coated glass (here designated IRR).[3] This was analyzed[4] to contain 2.5 m/o (mole per cent) Sb. Also included under this heading are some special samples made by the same manufacturer to the author's specifications and containing varying percentages of antimony (Table I). The second type was prepared in the laboratory by hydrolysis of an atomized solution of acidified $SnCl_4$ containing various percentages of $SbCl_3$ on a hot substrate which was variously Pyrex, quartz, or polished platinum. In both cases the thickness ranged up to about 1 μm. The mounting technique has been described (3). Electrical contact was made via a flat silver ring of about ½-in. diameter which pressed against the surface concentric with the exposed working area of 5/32-in. diameter (0.1236 cm^2). This ensured that for tin oxide layers on nonconducting bases the series resistance was as low as possible to facilitate capacitance measurements up to 20 kHz. Such a contact also minimizes capacitance dispersion due to the distributed resistance of the thin film (Appendix). Capacitance measurements were made with base electrolyte only under conditions of cyclic linear potential scan at a rate of 0.5 V/min. Using a phase sensitive detector, Fig. 1, and with a Pt counterelectrode of about 24 cm^2 area, the reciprocal capacitance was recorded directly. No change in capacitance or background current was produced by deaeration of the electrolyte or shielding from daylight. With electroactive species present linear sweep voltammograms at the stationary electrode were recorded using a conventional three-electrode system. Thickness of the conducting layer was determined from the variation of the interference maxima and minima as a function of wavelength for a reflected light beam at 45° inci-

dence. Conductivity was determined by a four-point probe method. Reproducible results for the capacity and linear sweep base current were found only after specimens had been polished. Polishing was effected with 0.3 and 0.05 μm alumina abrasives and also with a polishing compound made of powdered tin oxide.[5] The electrodes were then boiled in water or cleaned in steam before use, and allowed to dry in air or heated in an air oven.

Results

Variation of capacity with various parameters.—Measurements made in the first minutes after contact with the electrolyte are about 5% lower than the values finally reached after several hours when equilibrium is attained. This may be associated with the slow adsorption of ions causing a shift in the flat band potential. A positive shift is indicated suggesting that a slow chemisorption of H^+ ions to the oxide ions of the lattice is the dominant factor. This is in accordance with the observation that the surface after contact with acid electrolyte is completely wetted whereas the initially prepared surface after polishing and boiling in water is strongly hydrophobic. Measurements of the contact angle in fact show large changes during the first hour of contact. This phenomenon together with an account of the adsorption of halide ions is discussed in ref. (4). The measurements of capacitance were made after several hours contact, and data were taken from the recorded graph after two or three cycles of the scanning voltage. Only a small difference ($\sim$1%) is noted in the capacitance values for the cathodic and anodic sweeps; likewise the difference between the first and successive cycles is less than 1% suggesting that the value recorded was at equilibrium. The background current varies between specimens but is generally between 0.1 and 0.05 μA for the area used (0.124 cm^2) in 1M acid. Such values are observed within the cathodic and anodic limits set by the decomposition of the electrolyte. The potential of H^+ reduction is near the reversible value especially after prolonged contact with the electrolyte. Oxidation, however, occurs with a large overvoltage which depends on the doping level; *e.g.*, for IRR this takes place at about +2V *vs.* SCE in 1M H_2SO_4.

In the absence of surface states the capacity of a semiconductor-electrolyte system may be subdivided into three series capacitances due to the semiconductor space charge, the compact double layer, and the diffuse double layer. The last two would be expected to be large in 1M electrolyte especially at the positive potentials used (up to +2.0V *vs.* SCE) so that the measured capacitance should closely approximate to the space charge value. The experimental justification for this is based on the application of the Mott-Schottky relationship (8, 9) valid for high carrier concentrations.

$$\frac{1}{C^2} = \frac{2}{qK\epsilon C_D}\left(V - \frac{RT}{F}\right)$$

where C = space charge capacitance
q = electronic charge
K = dielectric constant (mean value 12.7) (10)
ϵ = permittivity of vacuum
C_D = carrier concentration
V = potential with respect to the flat band potential V_B (zero charge potential)

It is implicit in the use of this relationship that the surface potential should remain constant while the potential of the bulk of the semiconductor is varied, thus approximating to the one sided step junction concept (9). Because of the adsorption of ions the surface potential differs from the bulk value even in concentrated electrolytes. For this difference to remain constant the net adsorbed charge must increase negatively as the electrode is positively changed. If these charges are not matched, the $1/C^2$ graph can be curved or have a slope other than that determined solely by the carrier concentration. Electrode roughness can also cause curvature of the characteristic since the effective area decreases as the depletion layer extends into the bulk of the electrode with increasing applied voltage. These considerations are particularly relevant for highly doped specimens where the depletion layer (9) is only a few tens of angstroms thick, *e.g.*, for IRR containing 5.9 x 10^{20} carriers/cm^3 the thickness is 16.9Å at 1.0V *vs.* SCE).

Effect of donor concentration and frequency.—Satisfactory linear graphs of $1/C^2$ *vs.* applied potential have been obtained for samples containing up to 13% antimony; an example is shown in Fig. 2.

Table I shows a comparison of computed carrier concentrations based on capacitance measurements (at 20 kHz except where noted) with the antimony concentrations of a series of samples coated on glass.

At low concentrations the carrier values are higher than those due to the antimony alone probably because of other carrier mechanisms, *e.g.*, oxygen deficiency and residual chloride. The two values agree at about 1.7% Sb which is not far from the value where the conductivity is a maximum. Samples containing more than this percentage are noticeably blue colored (the 13% sample is almost opaque). This behavior, together with the sharp increase in resistance, has been interpreted as being due to increasing lattice disorder (6, 7) causing scattering of the carriers. Such disorder could also involve appreciable segregation of the antimony in its stable oxidized form (Sb_2O_5) which would not then donate carriers. This accounts for the fall off in apparent carrier concentration with percentage of antimony. In addition, the finite value of the solution-side capacitance would cause the measured value to be lower than the true space charge capacitance causing the carrier concentration to appear lower.

These results are for polished samples in 2N H_2SO_4. Other strong acids give similar results. The effect of polishing is to reduce the measured capacity, possibly by reducing the surface area, and to eliminate surface states of the type described previously (3). Such surface states show up in the impedance characteristic as peaks in the capacity and resistance, particularly at

low frequencies. Surface states can also be produced by adsorbed impurities from the electrolyte. For example, some samples of KCl electrolyte at *p*H 2 gave a particularly marked enhancement in capacitance at −0.4V which persisted up to 20 kHz indicating very fast states. Peaks in the linear sweep voltammograms were also present. The behavior was finally traced by spectroscopic analysis of the KCl as being due to molybdenum impurity. In a separate experiment with "pure" NaCl at *p*H 2 as little as $2 \times 10^{-6}M$ molybdate produced a fourfold increase in capacitance. This surface property could not be removed even with boiling HCl. Surface states of some sort are probably responsible for the frequency dispersion observed even for polished specimens. Under the most favorable conditions, high doping and strong acid electrolytes, the capacity tends to a constant value with frequency at about 20 kHz whereas the value at 50 Hz is about 15% higher. The series resistance also tends to a constant value at 10-20 kHz being much higher at lower frequencies. Such dispersion is not predicted for a purely space-charge capacitance under depletion conditions although it would occur under so-called "inversion" conditions (8) where the minority carriers (holes) become predominant in the space charge region. This might occur if the applied potential with respect to the flat band value approaches the band gap (3.7V); however, it is not relevant in the present instance.

Frequency dispersion increases as the doping level diminishes. In such cases, as the potential increases positively, marked frequency dispersion is still present at 20 kHz and the $1/C^2$ values are not linear with voltage. The slope increases as the potential increases positively. This is not to be explained by the ionization of deep donors with increasing voltage which would cause a decrease in slope (8). For such samples the slope of the first part of the graph is used where the dispersion is small. Extrapolation of this part of the graph also provides an intercept, (V_B), in the region of those for the highly doped samples, and this would not be expected to change much with doping level. The less highly doped specimens have a higher resistance tending to cause "transmission sheet dispersion" (Appendix). Some samples were made by putting the test layer on top of a more highly doped layer, but because of the possibility of contamination a series of samples was made by deposition on a polished platinum disk at approximately 700°-800°C. The layer does not adhere so tenaciously as it does to glass or quartz and may be scratched off. However, it is quite coherent enough to withstand polishing and can be examined electrochemically provided the potential excursion on the cathodic side stops short of the hydrogen evolution region (~0V). Extension into this range causes the layer to be lifted off in patches possibly due to the evolution of gas underneath.

Table II shows the variation of carrier concentration with the spray concentration of donor. These results are for $1N$ H_2SO_4 at 20 kHz. The variation of apparent donor concentration with spray concentration bears a similar relationship to the variation of the analyzed antimony concentration in the case of the glass samples (Table I). Thus for the glass samples, the ratio Sb (analyzed)/Sb (spray) is about 2 over the range while the ratio Donor equiv./Sb (spray) for the platinum varies between 3 and 5. Direct determination of antimony has not yet been accomplished due to difficulty in removing the film in a form suitable for emission spectrographic analysis. Because of the above it is believed that the actual values approach the donor equivalents much more closely than in the case of the samples on glass. The much higher temperatures operative during the preparation on platinum (800°) compared with that for glass (~600°) should favor lower chloride retention, less oxygen deficiency, and less lattice disorder. Further studies are under way to test these conclusions. The greater concentration in the layer compared to the spray is qualitatively the same as indicated in one of the patents dealing with the material (7). With no doping, the carrier concentration drops to about 3×10^{19} which, being far above the intrinsic level, may be due to residual chloride or to oxide vacancies. Possible oxide deficiency (nonstoichiometry) was looked for in samples of IRR. The technique, which has been described (4), was to dissolve[6] the layer in a molten bead of LiClKCl eutectic at 450° in a stream of dry HCl causing the Sn(IV) component to volatilize and leaving the Sn(II) behind. The latter was determined by anodic stripping from a stationary mercury drop. The Sn(II) was found to vary between 0.02 and 0.3 m/o SnO for a series of samples of IRR. Analysis for chloride was conducted on specimens prepared by hydrolysis on an electrically heated gold wire and was determined by spark source mass spectrometry to be in the region of 0.1 to 0.2%.

Table II. Variation of carrier concentration

Spray Sb, m/o	Carrier conc./cm³	Donor conc. equiv. to carriers, m/o
2.5	$3.4_7 \times 10^{21}$	12.5
1.0	$1.1_9 \times 10^{21}$	4.3
0.25	$2.5_2 \times 10^{20}$	0.91
0.08	$7.0_2 \times 10^{19}$	0.25
0	3.2×10^{19}	0.11

Table III. Variation of properties of IRR

*p*H	−0.2	1.95	4.2	6.9	9	12
Carrier conc (10 kHz)	5.84	5.81	5.21	5.24	5.09	5.09×10^{20}
V_B (*vs.* SCE)	−0.25	−0.45	−0.61	−0.95	−1.42	−1.52

Effect of *p*H.—The variation of the properties of IRR in $2M$ Cl^- with *p*H is shown in Table III.

Frequency dispersion increases with increase in *p*H, and the apparent carrier concentration at 10 kHz decreases. Surface states due to adsorbed impurities could be responsible; slight peaks in the capacity curves are observed. Displacement of adsorbed chloride with hydroxyl could also affect the variation of net adsorbed anions with applied potential thus causing changes in the $1/C^2$ slope as discussed above. These factors make the extrapolation of high *p*H values very uncertain. At low *p*H values the trend is not far from 60 Mv/*p*H unit which is the value observed for ZnO (11) and generally expected for oxide electrodes (12, 13).

Reaction kinetics at the tin oxide electrode.—Reaction at highly doped specimens (IRR).—The techniques of chronopotentiometry and linear sweep voltammetry were used to examine the kinetics of a number of reactions.

Studies of the bromine-bromide couple showed highly irreversible behavior at the IRR electrodes, whereas this couple is reversible on platinum electrodes. Chronopotentiometric and linear sweep tests for adsorption or other complications indicated simple diffusion controlled irreversible charge transfer kinetics (4).

The kinetics of several other couples were studied to determine if the slow charge transfer rates could be attributed to depletion effects taking place at potentials far removed from the flat-band potential of tin oxide. Rate constants were measured using chronopotentiometry (14) or linear sweep voltammetry (15, 16); the results are given in Table IV.

Comparing these seven systems, there seems to be no correlation between the equilibrium potentials of

[6] The material is impervious to most normal reagents such as strong acids or oxidizing agents. It can, however, be brought into solution by electrolytic reduction or with acid chromous chloride solution.

the couples and their reversibility on tin oxide. Iron (II) o-phenanthroline is very nearly reversible at +0.87V *vs.* SCE, whereas HBr at 0.92V is highly irreversible on tin oxide. The reversibility of ferricyanide at 0.289V has been demonstrated at concentrations as high as 0.2*M* and current densities up to 6.61 mA/cm² (4). On the other hand, Fe(III) at 0.435V and chlorocomplexes of Cu(II)/Cu(I) at 0.205V show 10 to 100 times faster rates on platinum than on tin oxide.

Since semiconductor depletion effects do not account for the irreversibility of some couples on the highly doped IRR tin oxide, the explanation for the slow charge transfer kinetics observed may lie in interferences caused by the oxide nature of the surface. It may be significant that the couples which are reversible on tin oxide have bulky ligands which may prevent a surface interference effect.

Variation of reaction rate with doping level.—The specimens prepared on platinum and described in Table II were used with two redox couples, the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ and the $Fe(o\text{-phen})_3^{3+}/Fe(o\text{-phen})_3^{2+}$ systems where o-phen represents 1, 10, o-phenanthroline. Both were chosen for their substantial reversibility on highly doped specimens. Linear sweep voltammograms are shown in Fig. 3 and 4. In the case of $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ a transition to apparently irreversible behavior is observed as the donor concentration is lowered. The effect is more marked for the second redox system which has a reversible potential of 0.87V. The initially symmetric drop in rate constant is due to the diminishing density of states of the semiconductor according to the theory of Dogonadze and Chizmadzev (17, 18). At lower carrier concentrations asymmetry in the current characteristic is introduced because of limitation of the tunneling process through the depletion layer. For the lowest carrier concentration the anodic peak is suppressed completely and dependence on sweep rate is eliminated though there is a small difference in the current as the potential scan is reversed. This represents the condition when tunneling becomes current limiting. The corresponding potential diagram is shown in Fig. 5 where for simplification the variation of potential in the double layer is left out. E_o is the reversible potential of the couple which is considered to be a sufficiently large source of electrons that concentration polarization does not occur. The tunneling probability into the bulk of the semiconductor is governed by the shape of the energy barrier which in principle should follow the quadratic relationship (9).

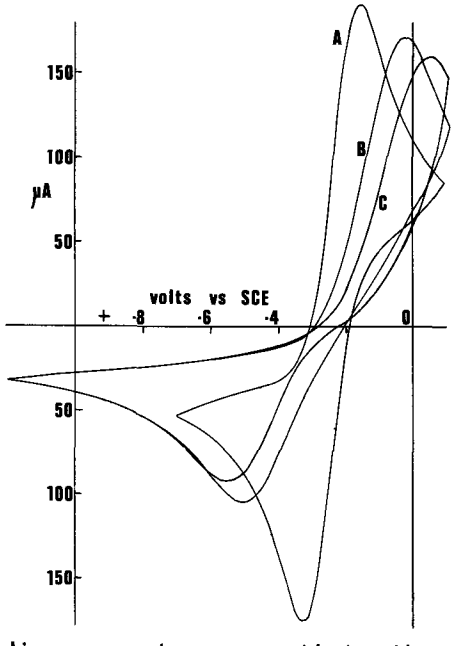

Fig. 3. Linear sweep voltammograms with tin oxide on platinum 1*N* Na_2SO_4, 0.1*N* H_2SO_4, 10 mM $K_3Fe(CN)_6$, 10 mM $K_4Fe(CN)_6$. Area = 0.124 cm²; sweep rate = 2 V/min. A, $2.5_2 \times 10^{20}$ carriers/cm³; B, $7.0_2 \times 10^{19}$ carriers/cm³; C, 3.2×10^{19} carriers/cm³.

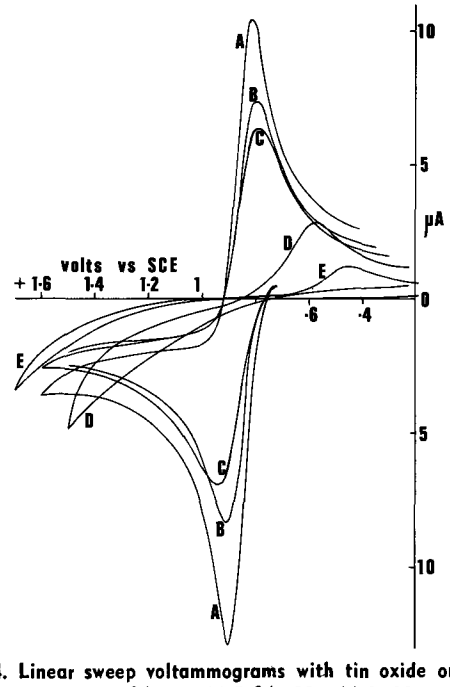

Fig. 4. Linear sweep voltammograms with tin oxide on platinum 1*N* Na_2SO_4, 1 mM Fe^{3+}, 1 mM Fe^{2+}, 33 mM 1, 10 o-phenanthroline; pH 2.5; area = 0.124 cm² sweep rate = 2 V/min. Fig. 5. Potential energy diagram at tin-oxide solution interface

$$\phi = x\sqrt{\frac{2qC_DV}{K\epsilon}} - \frac{qC_Dx^2}{2K\epsilon} \qquad [1]$$

where ϕ = potential in the space charge region and x = distance from the surface. The validity of the band model at such high fields as are necessary to promote tunneling is, however, suspect so that it is reasonable for ease of treatment to consider a linear barrier. As V becomes increasingly greater than $E_0 - V_B$ the linear approximation becomes more satisfactory because tunneling occurs across the gap AB or AB' (Fig. 5). In this region also, only the current in the direction $A \rightarrow B$, B' need be considered. Under these conditions the anodic current is given by (19, 20)

$$i = I \exp -\left[\frac{4\pi(8m^*)^{1/2}}{3h} \cdot (q[E_0 - V_B])^{1/2} l\right] \qquad [2]$$

where m^* is the effective mass, h = Planck's constant, $(E_0 - V_B)$ is the value (in volts) by which the potential barrier height exceeds the total energy of electrons incident on the barrier, l is the gap AB, and I is a factor depending on the rate and energy of electron collision at the barrier. Assuming I to be constant for a given reagent concentration, and expanding l (from Eq. [1]) in the form

$$l = \sqrt{\frac{K\epsilon}{2qC_DV}}(E_0 - V_B)\left[1 + 1/4\frac{E_0 - V_B}{V}\ldots\right]$$

one obtains

$$\text{Log } i = \text{Log } I - \frac{1}{2.303}\frac{4\pi}{3h}\left(\frac{8m^*K\epsilon}{2C_D}\right)^{1/2} (E_0 - V_B)^{3/2}\frac{1}{\sqrt{V}}\left[1 + 1/4\frac{E_0 - V_B}{V}\ldots\right]$$

The second order term is to some extent compensated for by the fact that the actual barrier slope is curved rather than flat causing the current to be larger than indicated in Eq. [2]. Consequently, by eliminating the second order term and putting $C_D = 3.2 \times 10^{19}$ carriers/cm^3 and $V_B = -0.1$V (for 1N $SO_4^=$) one obtains

$$\text{Log } i = \text{Log } I - 9.23\left(\frac{m^*}{m}\right)^{1/2} \cdot \frac{1}{\sqrt{V}}$$

Figure 6 shows a graph of Log i *vs.* $1/\sqrt{V}$ which gives a mean slope of 6.73 thus indicating a mass ratio of approximately 0.54. A range of values for this ratio for the bulk semiconductor has been given varying between 0.15 (6, 21) to 0.3 (10). It is not clear whether such bulk values are relevant to the present situation so that considering the drastic approximations applied, the experimental results can be considered reasonable.

For undoped specimens with approximately 3 x 10^{19} carrier/cm^3 it is concluded that tunneling probability is the principal current limiting factor. The carrier concentration and conductivity can be further reduced by prolonged heating, *e.g.*, at 800° for 12 hr and also by

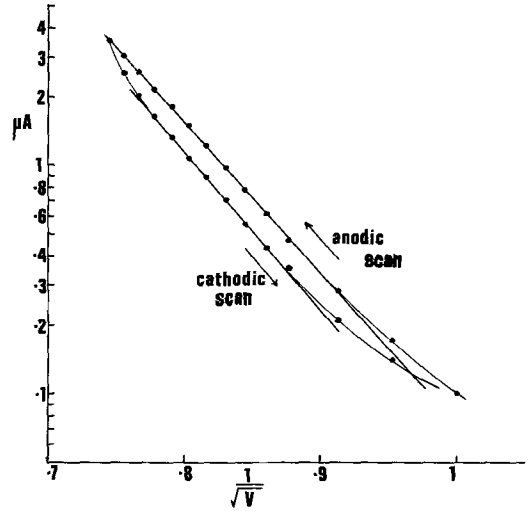

Fig. 6. Log$_{10}i$ vs. $1/\sqrt{V}$. Area = 0.124 cm^2; sweep rate = 2V/min; 3.2 x 10^{19} carrier/cm^3.

the addition of indium (5). Under these conditions it is expected that two other current generating mechanisms would become dominant. These are the space charge generation current which is proportional to the depletion layer thickness and the diffusion current which is independent of this thickness (9, 22). These currents depend on the characteristics of the semiconductor material, *e.g.*, number of defects, electron-hole pair generation, diffusion lifetime of carriers, etc., and are strongly influenced by temperature and illumination. These currents can become significant only when tunneling becomes negligible which happens as the carrier density drops still further below the lowest value encountered in the present study. It is suggested that the more highly resistive specimens investigated in reference (5) are operating in the nontunneling region since the currents reach limiting values as the voltage increases.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1971 JOURNAL.

APPENDIX

The finite resistance of the thin layer causes the potential to vary over the area that is exposed to the electrolyte. The equivalent circuit for the electrode only is a finite, two-dimensional, transmission line or transmission "sheet" with distributed resistance and capacitance. If the exposed area is circular and contact is made via a concentric ring, the distribution of potential follows a solution of the equation

$$\frac{\partial^2 v}{\partial r^2} + \frac{1}{r}\frac{\partial v}{\partial r} - \rho C\frac{\partial v}{\partial t} = 0$$

where v = voltage at distance r from the center
ρ = resistivity per square
C = capacitance per unit area

The solution of an equivalent problem (in heat conduction) with periodic boundary conditions, has been given (23). The result here is to cause frequency dis-

persion in the measured impedance. The measured capacity, C*, can be expressed in the form

$$\frac{1}{C^*} = \frac{1}{C}\left[1 + \frac{\rho^2\omega^2C^2a^4}{2^6\cdot3} - \frac{\rho^4\omega^4C^4a^8}{2^{10}\cdot3^2\cdot5} + \cdots\right]$$

where ω is the angular frequency and a is the radius of the area exposed to the solution. The correction is negligible at 20 kHz for samples of optimum conductivity (~10 ohms per square) but increases rapidly with decreasing conductivity.

Electrochemical Measurements on Austenitic Stainless Steels in Boiling Magnesium Chloride

J. A. Davis and B. E. Wilde*

Applied Research Laboratory, U. S. Steel Corporation, Monroeville, Pennsylvania 15146

ABSTRACT

Electrochemical polarization measurements have been made on AISI Type 304 and USS 18-18-2 stainless steels in magnesium chloride boiling at 150°C. Little difference in the cathodic Tafel constant was noted; the observed values being equal to that expected from a charge transfer rate-determining step. Steady-state corrosion currents increased in the order Type 304 > USS 18-18-2 for the unstressed and the stressed condition. Analysis of corrosion potential *vs.* time and cyclic polarization data indicates the presence of a film on the corroding surface, which affects the corrosion kinetics. The presence of two mixed potentials during cyclic polarization does not support the noble metal enrichment concept of crack propagation, but rather, the film rupture model.

The mechanism of stress corrosion cracking (SCC) in austenitic stainless steels exposed to chloride-containing media has been the subject of many publications (1-6) and has recently received an excellent review (7). It appears that two major theories have been proposed for crack propagation, both involving plastic deformation at the crack tip and the subsequent influence on the anodic dissolution kinetics.

The mechanochemical model proposed by Hoar and Hines (8) outlines the concept of stress- (or strain-) assisted anodic dissolution of the film-free metal at the tip of the crack.

The film rupture model suggested by Champion (9) and Logan (10) invokes the repetitive rupture of a passive film at the crack tip due to plastic deformation, allowing localized anodic dissolution to take place. This latter model has been criticized because it is not considered likely for passive films to form on austenitic stainless steels in magnesium chloride solutions (8, 11). To overcome this criticism, the concept of noble metal enrichment has been proposed by Latanision and Staehle (12), who suggest the formation of a nickel-rich film at the crack tip which is subsequently ruptured periodically by dislocation movement resulting from plastic flow.

The present work was conducted on both a resistant and a susceptible austenitic stainless steel to see if the different cracking behavior could be explained in terms of electrochemical parameters, and also to see if information could be gained to support either of the above mechanistic theories.

Materials and Experimental Work

The composition of the alloys studied are shown in Table I, and some pertinent mechanical properties determined at 150°C appear in Table II. Tests were conducted on wires having a diameter of 0.102 cm. The

wires were heat-treated at 1000°C in argon for 15 min and water-quenched. The annealed wires were abraded through 600-grit silicon carbide paper, degreased in a detergent in an ultrasonic cleaner, washed and dried in hot air. The corrodent was aqueous magnesium chloride boiling at 150°C prepared from reagent grade chemical and distilled water (6.3 megohm cm, at 25°C).

Potentiostatic and potentiodynamic polarization measurements were conducted by using the apparatus and procedure described elsewhere (13, 14). All potentials were measured against a saturated calomel electrode at 25°C, connected to the corrodent through a ground-glass stopper filled with solid $MgCl_2$. No attempt was made to correct for junction, thermal diffusion, or IR potentials.

The wires were mounted in a glass cell similar to that described elsewhere (11), such that stress was applied by uniaxial dead weight loading. The steady-state corrosion current, I_{corr}, was determined by extrapolating the linear activation controlled region of the polarization curve to steady-state corrosion potential, E_{corr}.

Reaction films formed on the alloys after 200 hr (3μ Al_2O_3 polished unstressed coupons 2.54 cm by 2.54 cm by 0.127 cm) in boiling $MgCl_2$ were stripped by treating the specimens with 10% iodine/methanol solution similar to that described previously (15).

Results and Discussion

A summary of the electrochemical parameters of the alloys determined potentiostatically in boiling $MgCl_2$ is given in Table III. All unstressed polarization measurements were made after the specimens had reached a steady-state E_{corr}. In the case of the stressed experiments, the stress was applied to the wire at steady-state E_{corr}, and the runs were commenced after 5 min of application of stress on Type 304 stainless steel and 1 hr on 18-18-2 stainless steel. The polarization parameters for the test alloys were very similar in the unstressed state. No reliable anodic data could be obtained due to the interference of pronounced pitting at potentials only 25 mV noble to E_{corr}.

With the application of stress (90% of the 150°C yield strength), a marked increase in I_{corr} was observed on Type 304 stainless steel while I_{corr} increased only slightly on 18-18-2 stainless steel. The application of stress also shifted E_{corr} of both steels in the active direction. While E_{corr} on 18-18-2 stainless steel returned to the unstressed E_{corr} in 30 to 40 min, the E_{corr} on Type 304 stainless steel only shifted to slightly more noble values with time.

Potentiostatic anodic polarization on stressed Type 304 specimens produced early cracking or failure due to pitting through the wire in approximately 5 to 15 min. On the basis of the data shown in Table III, it is not apparent why the silicon steel is superior to Type 304 stainless steel. It is possible, however, that the effect of stress on the E_{corr} reflects the tendency of surface films to rupture (in a manner similar to the scratching experiment), and in this light the films formed on USS 18-18-2 stainless steel may be more resistant to fracture.

The unstressed potential *vs.* time behavior of the two steels was recorded and is shown in Fig. 1. The character of the transient was similar to that reported by Hoar and Hines (16) for Type 304 stainless steel. They suggest that the shift in the noble direction was due to the formation of a protective film. Other workers (12), however, have described this type of transient to be the result of noble component enrichment on the corroding surface. When an unstressed specimen of Type 304 stainless steel was equilibrated to steady-state E_{corr} and scratched with a diamond stylus, the E_{corr} immediately decreased from —0.360 V_{SCE} to —0.415 V_{SCE}. This behavior was taken as confirmation that the establishment of the noble E_{corr} was the result of a surface reaction between the metal and the corrodent. Unfortunately, both of the above hypotheses for the shape of the transient could be invoked to explain the scratching experiment.

The time required for the potential to reach steady state (less than 5 mV shift in 15 min), was markedly different for the two test materials. Type 304 stainless steel achieved steady state after 2 to 10 min, compared with 50 to 100 min for USS 18-18-2. The shape of the potential-time transient observed in these experiments was reminiscent of that observed by other workers when studying the active to passive transition of stainless steels in aerated acidic media (17, 18). The similarity in these transients suggested that an analogous passivation process was occurring in boiling $MgCl_2$ but not necessarily by the same species as with steels in dilute acid.

The polarization behavior of the two materials under potentiodynamic conditions is of interest. Typical cyclic polarization curves are shown in Fig. 2, where an unstressed specimen of USS 18-18-2 stainless steel was polarized from the steady-state corrosion potential to —0.800V at a rate of 15 volts per hour in boiling $MgCl_2$. At —0.800V the sweep was reversed and continued to —0.200V, after which it was reversed again to —0.800V. It is clear from Fig. 2 that two steady-state mixed potentials exist at points *A* and *B*, similar to those reported on other materials in dilute acid (19, 20). The results for Type 304 stainless steel (Fig. 3) were practically the same.

Table III. Summary of potentiostatic electrochemical parameters in boiling $MgCl_2$

Material	Condition	β_c, V	β_a, V	E_{corr}, V_{SCE}	I_{corr}, $\mu A/cm^2$
Type 304 stainless steel	Unstressed	—0.162	0.069	—0.360**	260
USS 18-18-2	Unstressed	—0.170	0.062	—0.312**	210
Type 304 stainless steel	Stressed to 90% of yield	—0.100	N.D.*	—0.420†	900
USS 18-18-2	Stressed to 90% of yield	—0.175	N.D.	—0.312†	310

* N.D. = not determined.
** Steady-state value (see Fig. 1).
† Value attained within 5 min after applying the load to Type 304 stainless steel specimen. In the case of USS 18-18-2 stainless steel, the load was applied after 1 hr at the unstressed steady-state E_{corr}.

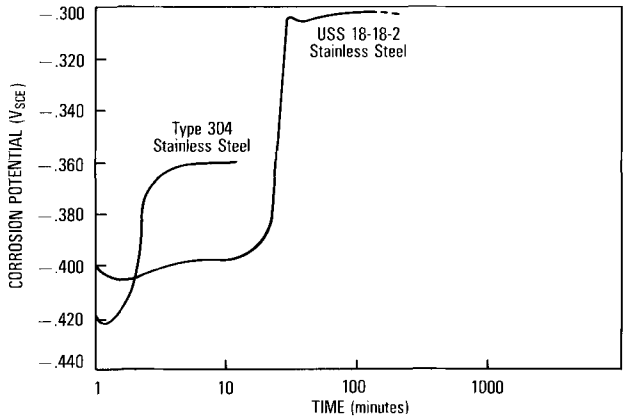

Fig. 1. Potential-time transients in boiling magnesium chloride

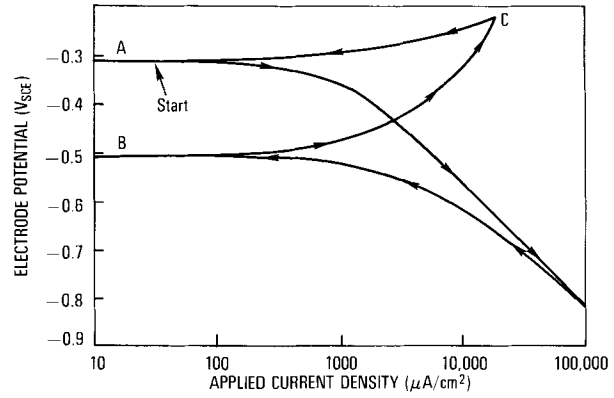

Fig. 2. Cyclic polarization curve for unstressed USS 18-18-2 stainless steel in boiling $MgCl_2$. (Sweep speed 15 V/hr.)

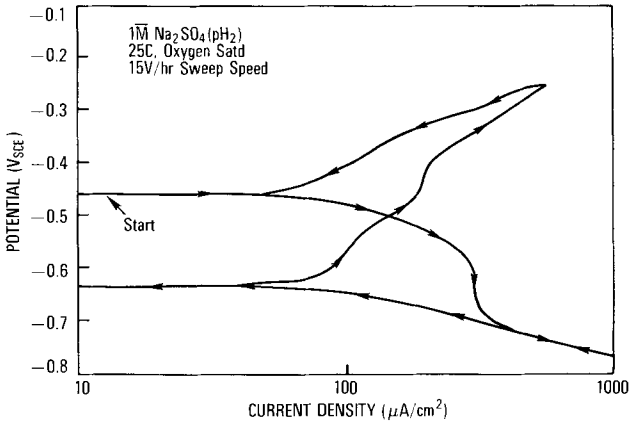

Fig. 3. Cyclic polarization curve for unstressed AISI Type 304 stainless steel in acidified Na_2SO_4. (Sweep speed 15 V/hr.)

To explain this behavior we suggest that E_{corr} at point *A* in Fig. 2 is the result of a reaction film covered surface after the specimen has come to steady state (see Fig. 1). When polarized in the active direction, hydrogen-ion reduction occurs and normal Tafel behavior is obtained down to −0.800V, during which process the film on the surface is reduced. Reversal of the sweep results initially in hydrogen-ion reduction at the same rate as with the active-going sweep. However, since the surface is now film-free, a new mixed potential is developed at *B*. Electrochemical oxidation of this surface results in anodic dissolution along *BC* and is not significantly affected by pitting because of the rather rapid sweep rate. Polarization in the cathodic direction from *C* results in the dissolution curve *AC*, which is similar to that obtained by anodic polarization of a steady-state surface from *A*.

If the above interpretation is correct, it should be possible to duplicate the cyclic response (Fig. 2) with a steel in an unambiguous state of stable passivity. In an attempt to demonstrate this behavior, a Type 304 stainless steel electrode was exposed to an oxygen-saturated solution of 1M Na_2SO_4, (where the *pH* was adjusted to 2.0 with H_2SO_4). Cyclic polarization of this electrode produced a similar type of curve to that in Fig. 2, as shown in Fig. 3. An active mixed potential was observed because the kinetics for the re-passivation of the surface following cathodic reduction are slower than the speed of the sweep. These data lend strong support to the theory of film formation and passivation-type electrode kinetic behavior of austenitic alloys in boiling $MgCl_2$.

Although the theory of noble metal enrichment could account for the phenomenon observed in both the unstressed potential-time behavior and the scratch experiment, it cannot in our opinion be reconciled with the presence of a new mixed potential following cathodic reduction.

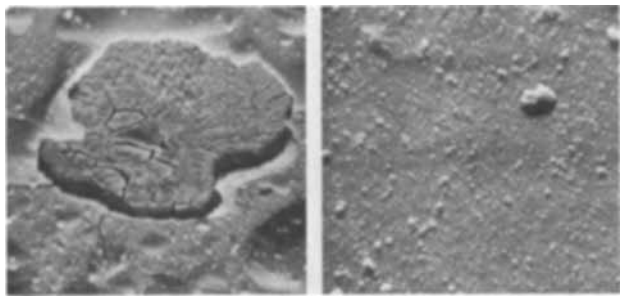

Fig. 4. Scanning electron micrographs of austenitic stainless steels exposed for 200 hr unstressed to boiling magnesium chloride (150°C) X 1000. (Left) AISI Type 304 stainless steel. (Right) USS 18-18-2 stainless steel.

Attempts to strip films off corroded surfaces were successful. Films of variable thickness were lifted from both steels after 200 hr exposure to boiling $MgCl_2$. Bulk electron diffraction studies produced an unidentified pattern, with diffuse Debye rings. It is worthy of note, however, that the patterns from both Type 304 and USS-18-18-2 stainless steel appeared to be identical. Small inclusions were observed in the films which gave diffraction patterns of a chromium nitride structure, which is isomorphous with NiO.

Emission spectrographic analysis of film residues indicated that the composition was the same for both steels, with magnesium as a major component. Scanning electron micrographs were obtained on corroded surfaces (after 3 hr at steady-state E_{corr}, as in Fig. 1) of two alloys and are shown in Fig. 4. A wide variation in surface structure was observed at 2000X. The Type 304 stainless steel sample evidenced pronounced spalling of the surface film while USS 18-18-2 stainless steel showed a rather featureless nonporous film.

Conclusions

The following conclusions can be drawn from the data presented:

1. The values of the cathodic Tafel constant for Types 304 and USS 18-18-2 stainless steel in boiling $MgCl_2$ are equal to that which would be expected for a charge transfer controlled discharge process.
2. No systematic relationship between electrochemical polarization parameters (stressed or unstressed) and the stress corrosion cracking behavior of the above two materials was observed.
3. Analysis of potential-time data and cyclic polarization curves has indicated the presence of a stable film on the metal surface, which can be reduced by cathodic hydrogen evolution.
4. The presence of two mixed potentials on a cyclic polarization plot cannot be rationalized on the basis of noble metal enrichment, but it can be explained by a passive type of behavior entirely analogous to that observed on Type 304 stainless steel in sodium sulfate solutions at room temperature.

Preparation of 2,3,4,5-Tetraphenyl-1,6-Hexanedioic Acid

S. Wawzonek,* A. R. Zigman, and G. R. Hansen

Department of Chemistry, University of Iowa, Iowa City, Iowa 52240

ABSTRACT

2,3,4,5-Tetraphenyl-1,6-hexanedioic acid has been prepared electrochemically by the reductive dimerization of α-phenylcinnamic acid and α-phenylcinnamonitrile. The latter gave a mixture of 1-amino-2,3,4,5-tetraphenyl-5-cyano-1-cyclopentene and 2,3,4,5-tetraphenyl-1,6-hexanedinitrile. Both the cyclopentene derivative and the dinitrile were converted chemically to the desired acid. Chemical methods based on condensation reactions of benzil were not successful for the preparation of this acid.

2,3,4,5-Tetraphenyl-1,6-hexanedioic acid (V) was required as a starting material for the preparation of 5,11-diphenyl-6,12-diketochrysene. This paper describes electrochemical and chemical studies of the preparation of this acid.

Experimental[1]

2,3,4,5-Tetraphenyl-1,6-hexanedioic acid (V).—The electrochemical reductive dimerization of α-phenylcinnamic acid (22.4g) in dimethylformamide (190 ml) containing 28% sulfuric acid (72 ml) was carried out at a mercury cathode using the directions given for cinnamic acid (1). The resulting solution was poured into water, and the oily layer was separated and taken up in benzene. Extraction with sodium hydroxide followed by acidification of the alkaline solution gave an oil which solidified. Treatment with benzene and chloroform gave 5.2g of a white solid melting at 275°-290°C. Two crystallizations from ethanol gave the desired acid (0.7g); mp 306°-308°C. The IR spectrum showed absorptions at 3.5-3.8 (OH) and 5.84, 6.04μ (COOH).

Anal. Calcd. for $C_{30}H_{26}O_4$: C, 79.91; H, 5.81; Found: 79.67; H, 5.81.

Electrolytic reduction of α-phenylcinnamonitrile.—A solution of α-phenylcinnamonitrile (20.5g) in dimethylformamide (300 ml) containing 150 ml of a 57% solution of tetraethylammonium *p*-toluenesulfonate in water was reduced at a mercury cathode (68 cm^2). The platinum anode was placed in a porous cup in a similar solution without the nitrile. The solution during the electrolysis was kept neutral by the addition of acetic acid. After the passage of a current of 1A for 3 hr the white solid (13.8g) formed was filtered and could be separated into two compounds with hot benzene. The soluble fraction (75%) was the cyanoamine (I) and the insoluble part was 2,3,4,5-diphenyl-1,6-hexanedinitrile (25%). Addition of water to the filtrate gave an additional 2.2g of the cyanoamine (I). This compound, 2,3,4,5-tetraphenyl-5-cyano-1-amino-1-cyclopentene (I), melted at 219°-225°C after one recrystallization from a mixture of benzene and ethanol; IR: 3.03 (NH_2), 4.54 (CN) and 6.15μ (C = C); NMR (CD_3CN) δ7.5 (s C_6H_5); 7-7.48 (m $3C_6H_5$), 5.04 (d 1 H J = 10 Hz), 4.02 (s 2 H) and 3.54 (d 1 H J = 10 Hz). In the presence of D_2O the broad singlet at 4.02 disappeared.

Anal. Calcd. for $C_{30}H_{24}N_2$: C, 87.37; H, 5.86; N, 6.79. Found: C, 87.70; H, 5.83; N, 6.57.

2,3,4,5-Tetraphenyl-1,6-hexanedinitrile after recrystallization from a large volume of benzene melted with sublimation at 348°-355°C. TGA indicated that the sublimation started at 240°C; IR 4.53μ (CN); mass spectral analysis gave a peak at 412.

Anal. Calcd. for $C_{30}H_{24}N_2$: C, 87.37; H, 5.86; N, 6.79. Found: C, 87.75; H, 5.85; N, 6.66.

2,3,4,5-Tetraphenyl-2-cyanocyclopentanone (II).—A solution of the cyanoamine (I) (1.2g) in dioxane (50 ml) was refluxed with 6*N* hydrochloric acid (15 ml) for 1 hr and poured into water. The cyanoketone (1.1g) melted at 178°-180°C after two crystallizations from ethanol. On solidification this compound would occasionally remelt at 190°-192°C. The IR and NMR spectra, however, were the same as those for the 178°-181°C compound; IR: 4.45 (CN) and 5.74μ(CO); NMR ($CDCl_3$): δ7.04-7.25 (m $4C_6H_5$); 3.92-4.21 (m 3 H).

Anal. Calcd. for $C_{30}H_{23}NO$: C, 87.14; H, 5.61; N, 3.39. Found: C, 87.30; H, 5.73; N, 3.28.

2,3,4,5-Tetraphenyl-5-cyanopentanoic acid (III).—The cyanoketone (II) (1g) was refluxed with potassium hydroxide (1g) in methanol (40 ml) for 15 hr. The resulting solution when poured into water and acidified gave a solid (1.0g) which was recrystallized

* Electrochemical Society Active Member.

Key words: hydrodimerization; 1-amino-2,3,4,5-tetraphenyl-5-cyano-1-cyclopentene; 2,3,4,5-tetraphenyl-1,6-hexanedinitrile.

[1] Melting points are not corrected. Infrared spectra were determined as nujol mulls on a Perkin-Elmer Infracord. NMR spectra were determined on a Varian A60 Spectrometer.

from benzene; yield, 0.35g; mp 235°-237°C. A second recrystallization from benzene gave a sample melting at 236°-237°C; IR: 3.5-3.9 (OH), 4.43 (CN) and 5.8μ (COOH). The more soluble fraction obtained in this reaction was not investigated further.

Anal. Calcd. for $C_{30}H_{25}O_2N$: C, 83.53; H, 5.80; N, 3.25. Found: C, 83.34; H, 5.94; N, 3.31.

2,3,4,5-Tetraphenyladipamic acid (IV).—The nitrile acid (III) (0.4g) was refluxed with 10 ml of 50% sulfuric acid in acetic acid (28 ml) for 28 hr and the resulting solution was poured into water. The solid (0.32g) obtained, when recrystallized from a large volume of benzene, melted at 292°-293°C; IR: 2.8-3.0 (NH_2), 3.5-9 (OH); 5.83 (COOH) and 6.01μ ($CONH_2$).

Anal. Calcd. for $C_{30}H_{27}O_3N$: C, 80.18; H, 6.01; N, 3.12. Found: C, 79.97; H, 6.14; N, 3.19.

2,3,4,5-Tetraphenyl-1,6-hexanedioic acid (V).—The amide acid (0.5g) in 10 ml of acetic acid containing 1 ml of concentrated hydrochloric acid was treated at 100°C with excess 20% sodium nitrite solution. The white solid (0.4g) on recrystallization from ethanol and water melted at 304°-307°C and gave an identical ir spectrum to that of the acid obtained by the dimerization of α-phenylcinnamic acid.

Hydrolysis of 2,3,4,5-tetraphenyl-1,6-hexanedinitrile.—The dinitrile (2.75g) was refluxed with 25 ml of 50% sulfuric acid in acetic acid (250 ml) until all the solid material had dissolved. This process required 11 days. The resulting solution was poured into water, and the white solid (3.0g) was filtered. Extractions with alkali gave a mixture of acids containing nitrogen. Deamination of a portion (0.8g) in acetic acid (10 ml) containing concentrated hydrochloric acid (1 ml) at 100° with 2 ml of 20% sodium nitrite gave 0.42g of an isomeric 2,3,4,5-tetraphenylhexanedioic acid. Recrystallization from benzene gave a sample melting at 291°-295°C. A mixture with the acid prepared from the cyanoketone method melted at 265°-280°C. IR: 3.5-4 (OH) and 5.88μ (COOH).

Anal. Calcd. for $C_{30}H_{26}O_4$: C, 79.91; H, 5.81. Found: C, 79.70; H, 5.94.

Cyclization of 2,3,4,5-tetraphenyl-1,6-hexanedinitrile.—The dinitrile (0.65g) was refluxed in benzene (150 ml) and absolute ethanol (50 ml) with sodium methoxide (0.3g) for 22 hr. Removal of the solvent gave a solid which was treated with water, filtered, and dried. The resulting solid was treated with cold benzene, and the insoluble starting material was separated; yield, 0.38g. The filtrate was treated with ethanol and on concentration gave a white crystalline solid (0.21g) melting at 239°-242°C; IR: 2.9 (NH_2), 4.45 (CN) and 6.10μ (C = C); NMR ($CDCl_3$) δ6.6-7.6 (m $4C_6H_5$), 4.63 (d 1H J = 8 Hz), 3.95 (d 1H J = 8 Hz) and 3.8 (broad s 2H). In the presence of D_2O the broad singlet at 3.8 disappeared. The NMR spectrum in CD_3CN in which the compound is much less soluble gave a similar coupling constant for the two doublets. A mixture with isomer I melted at 199°-220°C.

Anal. Calcd. for $C_{30}H_{24}N_2$: C, 87.37; H, 5.86; N, 6.79. Found: C, 86.99; H, 5.59; N, 6.45.

Reaction of benzil with benzyl cyanide.—A solution of benzil (15.7g) and benzyl cyanide (17.5g) in ethanol (250 ml) was treated at reflux with a solution of potassium hydroxide (3g) in ethanol (15 ml). The solution became purple and was refluxed for 30 min. Removal of the solvent was followed by acidification and extraction with ether. The ether layer after treatment with dilute alkali and acid gave an orange oil (28g). Addition of alcohol gave crystals of α-phenylcinnamonitrile (4.0g); mp 85°-88°C. Identification was made by comparison with an authentic sample (2).

Reaction of benzil with ethyl alpha-bromophenylacetate.—A stirred refluxing mixture of zinc dust (6.8g) in dry benzene (100 ml) was treated with a solution of benzil (11.56g) and ethyl α-bromophenylacetate (25.0g) in benzene (100 ml). After approximately 40 ml of this solution was added, reaction occurred, and the addition was completed dropwise with further heating. The resulting solution was refluxed an additional 12 hr, cooled, and treated with ice-cold 10% sulfuric acid. The benzene layer gave 16g of the monoadduct. Recrystallization from ethanol gave a sample melting at 121°-124°C; IR: 2.87 (OH), 5.80 ($COOC_2H_5$) and 5.91μ(CO).

Anal. Calcd. for $C_{24}H_{22}O_4$: C, 77.00; H, 5.92. Found: C, 76.51; H, 5.78.

Results

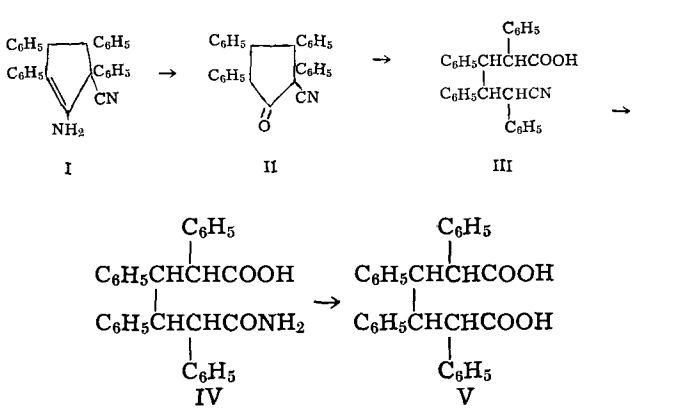
2,3,4,5-Tetraphenyl-1,6-hexanedioic acid (V) was prepared directly by the electrochemical reductive dimerization of α-phenylcinnamic acid using the procedure for dimerizing cinnamic acid (1). The amount of benzene soluble by-products formed was larger than that obtained with cinnamic acid. In view of the complexity reported for these products (1), the by-products were not studied further.

The low yield of acid obtained suggested a study of the electrochemical hydrodimerization of α-phenylcinnamonitrile as a source of this acid. This reduction actually behaved differently than expected and gave a mixture of 1-amino-2,3,4,5-tetraphenyl-5-cyano-1-cyclopentene(I) and 2,3,4,5-tetraphenyl-1,6-hexanedinitrile. The structure of the former was based on IR and NMR spectra and its chemical behavior.

The NMR spectrum showed two doublets centered at δ3.54 and 5.04 ppm for the 3- and 4-hydrogens and a broad singlet at δ4.02 integrating for two hydrogens which disappeared in the presence of deuterium oxide. This spectrum favors the designation of I exclusively as the enamine form. The presence of the imine isomer would be expected to shift the hydrogen absorptions to the same region shown by the ketone II.

The large splitting constant of 10 Hz indicates that the 3- and 4-hydrogens are cis and that the configuration is *meso* for this portion of the compound.

Hydrolysis with acid gave the ketonitrile(II) which could be cleaved with alkali to the cyano acid (III). This acid (III) when hydrolyzed with sulfuric acid gave the amide acid (IV) which was resistant to further hydrolysis with acid or alkali. Deamination with nitrous acid gave the same acid (V) as is obtained by the dimerization of α-phenylcinnamic acid.

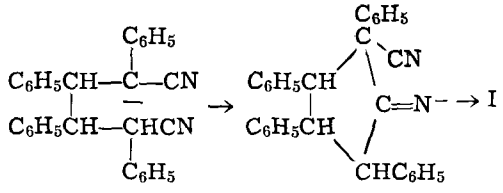


A similar cyclization has been observed in the electrochemical reductive dimerization of benzalacetophenone in dimethylformamide in the presence of carbon dioxide (3) and ethyl cinnamate in aqueous dimethylformamide (4).

The structure of 2,3,4,5-tetraphenyl-1,6-hexanedinitrile was based on its ir spectrum, mass spectral data, and chemical conversion to an isomeric 2,3,4,5-tetraphenylhexandioic acid (V) and an isomeric 1-amino-2,3,4,5-tetraphenyl-5-cyano-1-cyclopentene(I). The last compound gave an nmr spectrum which showed two

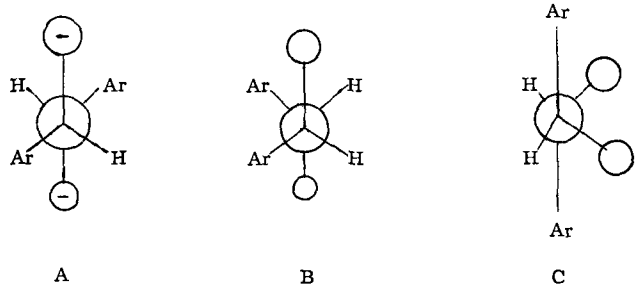
doublets centered at δ4.63 and 3.95 ppm for the 3 and 4-hydrogens and a broad singlet at δ3.8 for the two hydrogens of the amino group. A coupling constant of 8 Hz indicates that the 3- and 4-hydrogens are *trans* and that the configuration is *dl* for this portion of the molecule. Such an assignment is based on the Karplus rule (5).

The cyclopentene derivative I no doubt is formed from the anion of the expected hydrodimer (VI) by a Ziegler condensation even though the electrolyte was kept at the neutral point with acetic acid during the electrolysis.



This anomaly may be caused by the tetraethylammonium ions adsorbed on the electrode surface. Such an environment would be more anhydrous than that of the bulk of the solution and less susceptible to the addition of acid.

The higher ratio of *meso/dl* suggests that in the dimerization of the anion radical directly at the surface of the electrode, steric factors and repulsion of the negative charges would favor form A and would lead to the formation of the *meso* isomer which cyclizes to the cyclopentane derivative I.



A B C

The second method of forming the dimer is by dimerization of the radical formed by protonation of the anion radical. Such a dimerization would be governed only by the steric effects of the groups involved and could give forms B and C. This type of addition would be expected to predominate in the bulk of the solution and to give the *dl*-isomer of the dinitrile.

Similar factors may be involved in the high ratio of *meso/dl* pinacols observed in the reduction of benzaldehyde in the presence of tetraalkylammonium and iodide ions (6).

Chemical methods leading to the synthesis of 2,3,4,5-tetraphenyl-1,6-hexanedioic acid (V) based on the condensation reactions of benzil were not successful. The Reformatsky reaction with ethyl α-bromophenylacetate gave only the monoadduct, ethyl 2,3-diphenyl-3-benzoyl-3-hydroxypropionate.

The alkaline condensation of phenylacetonitrile with benzil gave α-phenylcinnamonitrile.

The Electrochemical Oxidation of N,N-Dimethylaniline

Rodney Hand and R. F. Nelson*

Department of Chemistry, Sacramento State College, Sacramento, California 95819

ABSTRACT

The electrochemical oxidation of N,N-dimethylaniline (DMA) has been investigated in nonaqueous media in some detail. The products formed were found to depend on DMA concentration and the time of electrolysis. At low concentrations (10^{-3}M), the main product formed is N,N,N′,N′-tetramethylbenzidine. At intermediate concentrations (10^{-2}M) the major product is 4,4′-methylenebis (N,N-dimethylaniline), and at higher concentrations, especially at longer electrolysis times, the dye crystal violet and its leuco form were produced in large amounts. The mechanism to form these products depends on the lability of the methyl groups on the amine nitrogen; when other N,N-dialkylanilines were electrolyzed under similar conditions, only the corresponding tetraalkylbenzidines could be isolated.

The oxidation of N,N-dimethylaniline (DMA), by both chemical and electrochemical means, has commanded a good deal of attention for a number of years. The amine exhibits a multitude of reactions, as evidenced by the large number of products generated under varying conditions. The products formed seems to depend upon a bewildering series of variables: the solvent medium, the oxidizing agent, temperature, and concentration of reactants, for example, (1-9) and references therein. In addition, electrochemical oxidation under proper conditions can lead to substitution in either the aromatic ring (10-12) or on the N-methyl groups (13, 14). Thus, upon oxidation one can expect the cation radical to decompose by one or more of several pathways.

* Electrochemical Society Active Member.

Key words: organic electrochemistry, mechanism, coulometry, cyclic voltammetry.

As part of a study involving the anodic oxidation pathways of aromatic amines, the electrochemistry of DMA was investigated in some detail. Previous work in both aqueous and nonaqueous media had shown N,N,N',N'-tetramethylbenzidine (TMB) to be the primary electrolysis product. However, upon inspection of cyclic voltammograms in acetonitrile, it was apparent that indeed TMB was being formed by oxidation of DMA at platinum, but the amount formed was not at all equivalent to the quantity of DMA present, *i.e.*, it appeared that other unidentified products were forming. Various electrochemical and spectroscopic techniques were employed and it was found that other products were formed, the identities and amounts of which depended markedly upon solution conditions. In addition, several other N,N-dialkylanilines were studied electrochemically and their behavior correlated with that of DMA.

Experimental Procedures

The electrochemical and spectroscopic instrumentation and techniques were as previously described (15). The NMR spectra were recorded in $CDCl_3$ using a Perkin-Elmer R-20 spectrometer.

The N,N-dimethylaniline was obtained commercially and purified according to a standard procedure (16). N,N-Diethylaniline, N,N-di-n-butylaniline, N,N-di-sec-butylaniline, and N,N-di-n-decylaniline were all obtained commercially and were not further purified. The tetramethylbenzidine and tetraethylbenzidine were prepared by methylation and ethylation, respectively, of benzidine using trialkyl phosphates and were purified by column chromatography and recrystallization. N,N,N',N'-Tetramethyl-2,2'-diaminobiphenyl (o-oTMB) and N,N,N'N'-tetramethyl-2,4'-diaminobiphenyl (o-pTMB) were prepared by catalytic hydrogenation of the dinitro compounds (17). The diamino compounds were then methylated and purified by chromatography and recrystallization. 4,4'-Methylenebis (N,N-dimethylaniline) (MBDMA) and 4,4',4"-methylidynetris (N,N-dimethylaniline) (LCV) were obtained commercially and purified by recrystallization. N-p-Dimethylaminobenzyl-N-methylaniline was prepared by a benzoyl peroxide oxidation of DMA (1).

The purification of acetonitrile and the preparation and purification of tetraethylammonium perchlorate (TEAP) have also been previously described (15). Benzonitrile was obtained commercially and used with no further purification.

Constant potential mass electrolyses were carried out using a Wenking 61RH potentiostat. A two-compartment cell with a fine frit was used for electrolyses. A platinum gauze electrode was used as the working electrode, and an SCE was used as the reference electrode. All oxidation potentials were set about 100 mV anodic of the primary oxidation waves of the dialkylanilines as determined from cyclic voltammograms. The electrolyses were carried to virtual completion, *i.e.*, to a point where the current was less than 1% of the value at initiation of the electrolysis. In addition, after exhaustive oxidation the solutions were electrolyzed at −0.6V in order to convert any species in the oxidized state to the neutral form and to reduce protons generated by the various coupling reactions involved. It was found that if these protons were not electrolyzed before product isolation appreciable amounts of starting material and electrolysis products were lost during work-up.

Constant current mass electrolyses were carried out using the Wenking potentiostat modified according to procedures set forth in the operation manual (18). The constant current electrolyses were stopped after proceeding for calculated time intervals corresponding to one-half, one, one and one-half, and two electron n-values for DMA.

Products were isolated by evaporation of the solvent from the electrolysis mixture and extraction with dichloromethane. The TEAP taken up was precipitated out by the addition of ether. The supernatant was taken to dryness and chromatographed on Woelm neutral alumina with benzene, then dichloromethane and, if necessary, ethanol; the products were then recrystallized from benzene-ethanol. Thin layer chromatography experiments were carried out on "Baker-flex" aluminum oxide grade 1B T.L.C. paper using mixtures of benzene and petroleum ether as solvents (the per cent composition was not critical). The chromatograms were developed with iodine.

Results and Discussion

When the possible products that could form by oxidation of DMA were considered, the most likely prospects seemed to be the isomeric benzidines, TMB, o-pTMB, and o-oTMB. This was based on intuition as well as tritium tracer experiments run on DMA suggesting some sort of *ortho*-coupling (6) taking place. Consequently, the electrochemical properties of the previously mentioned benzidines were studied, and their cyclic voltammograms matched up with the DMA system, as shown in Fig. 1. One can see that a fertile imagination could find any of the benzidines in the DMA cyclic upon careful inspection. Consequently, recourse was taken to other means of identification of products. Attempts were made to detect the benzidines using *in situ* electrolysis in a Cary 14 uv-visible spectrometer, but the TMB band was so broad and intense that it swamped out any o-pTMB or o-oTMB (both of which had weak bands in this region) that might be present. Results with thin-layer chromatography were somewhat more successful. Using benzene-petroleum ether as a solvent medium, solutions from electrolysis of 10^{-3}M DMA were spotted along with authentic samples of the three isomeric benzidines.

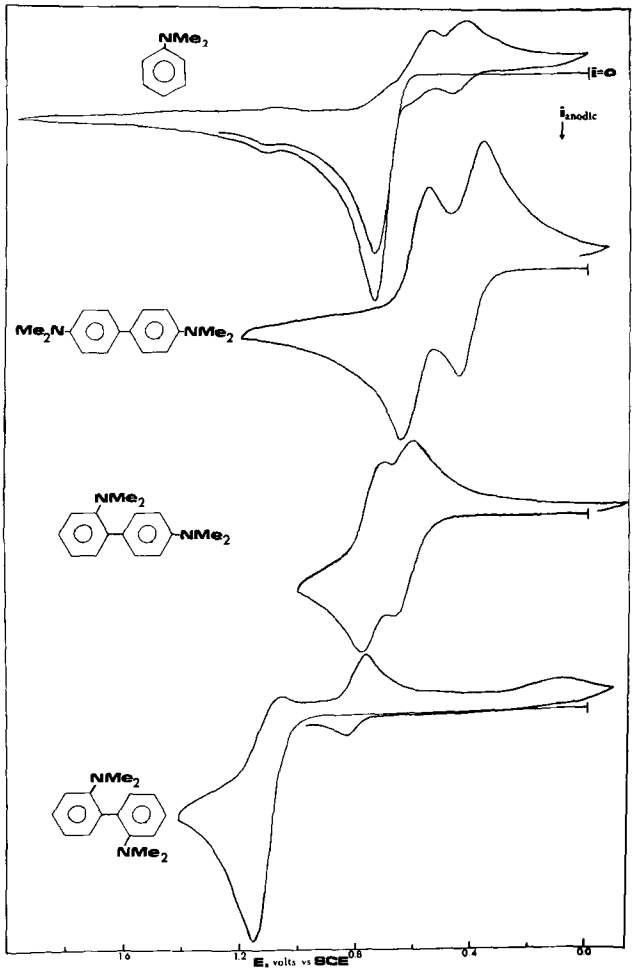

Fig. 1. Cyclic voltammograms of DMA and the isomeric benzidines in acetonitrile/0.1M TEAP.

TMB was definitely identified and another spot from the electrolysis solution matched up with either the o-pTMB or the o-oTMB. Since there is considerably less steric hindrance to *ortho-para*-coupling, it is believed that the other product formed in dilute solution is o-pTMB, in minor amounts.

Thus, in the region of milliformal concentration, the reaction mechanism seems to be relatively uncomplicated; DMA is oxidized to the cation radical; these then couple in one or more of several ring coupling fashions. As would be anticipated, the least sterically hindered pathway, *para-para*-coupling, predominates. One problem was finally solved after considerable consternation: on cyclic voltammograms it seemed that much less than quantitative amounts of TMB were forming from the oxidation of DMA. In addition, the electrochemical data gave an n-value of about one as opposed to the two electrons that would be expected for this classical ECE system (TMB is more easily oxidized than DMA). This is due to the fact that appreciable amounts of the DMA are protonated by protons released in the coupling reaction to form TMB. Since DMA is a moderately strong base, the degree of protonation, estimated at 40-50% when compared with aliphatic amines (19), is appreciable. This factor must be considered when one is working on the electrochemistry of organic bases in nonaqueous media.

As the concentration of DMA is increased from 10^{-3} to 10^{-1}M, the composition of the electrolysis products obtained changes markedly. At intermediate concentrations (10^{-3} to 10^{-2}M), relatively little TMB is obtained, and instead, another product resulted in fairly high yields (30-40%). This product eluded identification for some time until heed was paid to work that cited the formation of MBDMA from DMA via various chemical oxidation pathways (1, 2); small amounts had also been isolated from electrochemical oxidations in aqueous media (4). Once the product was acknowledged, identification was straightforward. Normally, cyclic voltammograms are not a reliable matching-up tool for suspected electrolysis products, but in this case the cyclic of the electrolysis product was found to be very similar to that of an authentic sample of MBDMA, as shown in Fig. 2. The electrolysis product was verified by melting point, its IR spectrum and its NMR spectrum, in each case compared with an authentic sample of MBDMA.

Since the MBDMA contains a methylene group inserted between two DMA segments, the question of the origin of the methylene group seemed pertinent. In the normal electrolysis situations, a methylene group could conceivably be abstracted from either the solvent (CH_3CN) or the ethyl groups of the supporting electrolyte, TEAP. Accordingly, a mass electrolysis of a 10^{-2}M solution of DMA in benzonitrile using 0.1M sodium perchlorate as supporting electrolyte was conducted. In this system, the only source of methyl groups would be from the DMA. Similar results were obtained compared to the acetonitrile/TEAP experiments (however, product yields were much lower due to problems in work-up from benzonitrile), so it seems safe to conclude that the electrochemical oxidation pathway involves abstraction of a methyl group from the dimethylamino portion of DMA to form the MBDMA. In addition, chemical oxidations of DMA to MBDMA have been carried out in solvents such as benzene and carbon tetrachloride using benzoyl peroxide as oxidant (1, 20).

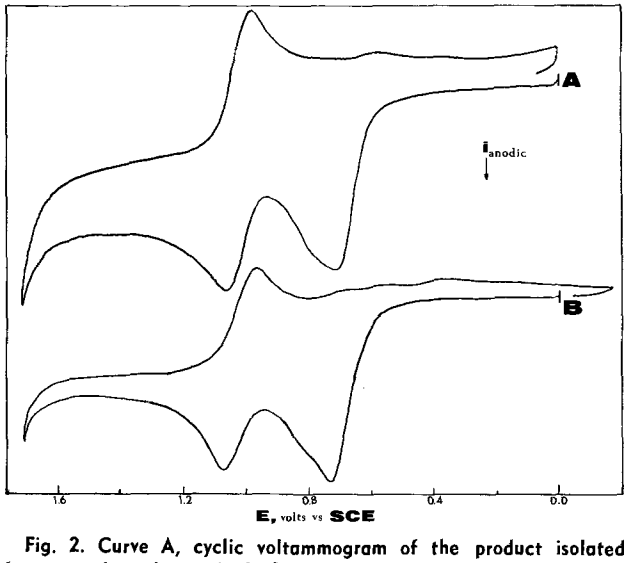

Fig. 2. Curve A, cyclic voltammogram of the product isolated from an electrolysis of 10^{-2}M DMA in acetonitrile/0.1M TEAP; curve B, cyclic voltammogram of an authentic sample of MBDMA in acetonitrile/0.1M TEAP.

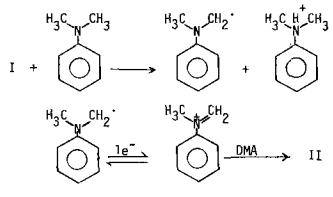
The most plausible mechanism for formation of MBDMA from DMA has been proposed as the reaction pathway followed in the benzoyl peroxide oxidation and gamma radiolysis of DMA (21, 22). This involves initial formation of a DMA cation radical, not an unreasonable assumption. It should be pointed out that no direct evidence for the existence of DMA cation radical was found in the present work or in any previous studies. However, based on other studies on aromatic amines in general and substituted DMA's in particular, it seems safe to assume that the DMA cation radical is the first intermediate formed (I). This radical can then attack a parent DMA molecule, the *para*-ring position of the cation attacking one of the methyl groups of the parent to form a substituted benzyl amine, N-p-dimethylaminobenzyl-N-methylaniline (II). This species is then protonated to form (III). This then breaks up to give (IV) and N-methylaniline. A molecule of DMA then reacts with (IV) to form MBDMA. Attack of (I) on MBDMA could then lead to a molecule of leuco crystal violet, LCV. Since LCV is more easily oxidized than DMA, formation of crystal violet dye from LCV ensues. In addition to all this, there is a parallel reaction pathway, the one classically cited, whereby TMB is formed by coupling of two DMA radicals. The over-all reaction pathway is shown in Fig. 3. Due to the coupling reactions occurring in these systems, protons are generated in substantial amounts; protonation of DMA and the various products certainly occurs, but this has not been shown for the sake of clarity.

Several alternative paths to this general mechanism are possible and should be mentioned, although they are difficult or impossible to verify. Reaction [3] in Fig. 3 may go by the pathway shown below[1] rather than by attack of (I) on the methyl group of a parent DMA molecule. The over-all result is identical in both cases, *i.e.*, formation of (II), but this alternative mechanism is certainly a possibility.



These mechanistic steps are consistent with the fact that MBDMA and crystal violet are formed only at intermediate and high DMA concentrations, where parent DMA molecules are available to act as bases toward DMA cation radicals. Deprotonation of the cation radical (I) has also been suggested from the results of chemical oxidation studies (23). This work is particularly pertinent since the oxidizing agents employed, chloranil and copper(II), are one-electron types and hence might furnish data more applicable to reactions of the DMA cation radical. In fact, the product distribution obtained in this study was markedly similar to that from the present electrochemical work.

[1] This alternative mechanism was suggested by a referee.

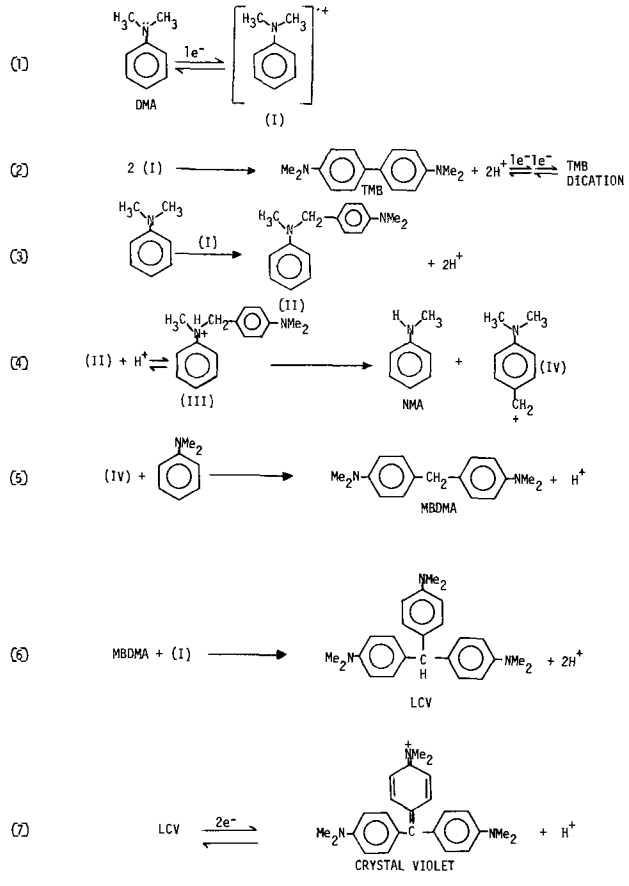


Fig. 3. Proposed reaction pathways for the anodic oxidation of N,N-dimethylaniline in acetonitrile.

Reaction [6] in Fig. 3 is also somewhat less than certain. It would seem just as likely that the formation of leuco crystal violet might occur via reaction between oxidized MBDMA and parent DMA, rather than by the opposite radical-parent route; this is so because the oxidation potentials of DMA and MBDMA are almost identical. Thus, it was not possible to carry out studies where one would be electrolyzed in the presence of the other to induce formation of leuco crystal violet. Again, the pathways are different, but the end product is identical; verification of the correct pathway must await more sensitive studies in order to differentiate.

Repeated attempts were made to isolate the substituted benzyl amine intermediate by terminating electrolyses well short of the calculated end point and attempting recovery by chemical means. These attempts were singularly unsuccessful probably due to the fact that this intermediate is quite unstable; the application of even moderate heat induces its conversion to MBDMA in the presence of any excess DMA.

It was felt that detection of N-methylaniline (NMA) in the electrolysis mixtures was essential to verifying the proposed mechanism, but this task was hampered by the fact that NMA is oxidized at about the same potentials as DMA, leading to unknown products. However, visible absorption spectra of electrolysis solutions of DMA and NMA show a common peak at about 550 mμ that cannot be ascribed to any of the DMA oxidation products previously mentioned. Likewise, a common spot is obtained on thin-layer chromatograms of the two solutions. Further work now under way on the oxidation of NMA may clarify this aspect of the work.

At higher DMA concentrations (10^{-1}M and higher), less MBDMA is found; as shown in the reaction scheme the next highest analog, leuco crystal violet, is formed in small amounts and a goodly portion of the yield is in the form of the dye crystal violet. This is an intensely colored dye and its presence was confirmed by comparison of the visible absorption spectra of a DMA electrolysis solution and an authentic sample of the dye; the match-up is striking. The gradual formation of the dye can be seen in the visible absorption spectra shown in Fig. 4. These spectra were recorded after various times of electrolysis of a 0.2M solution of DMA in acetonitrile. Note that even at this concentration it appears that TMB is formed initially. However, as the electrolysis proceeds the concentration of crystal violet increases and the TMB fades away in comparison. At the end of the electrolysis the only species giving rise to an absorption band in the visible region of the spectrum is the crystal violet dye. It is felt that parallel reaction pathways are operative to produce TMB and the other electrolysis products; fairly extensive studies on the electrochemical oxidation of TMB alone and in the presence of DMA, though complicated, have not shown evidence for formation of MBDMA or crystal violet (24). At first, the concept of crystal violet being formed from the oxidation of DMA is implausible at best, but again recourse to the literature shows that it is not unheard of. In fact, chemical oxidation of DMA by chloranil and copper(II) leads to appreciable yields of crystal violet (23, 25) (see above).

In order to verify that all the products cited are formed concurrently, a constant current electrolysis of a 1M DMA solution in MeCN was run and terminated well before completion ($n = 0.5$). The major products formed were MBDMA and LCV; small amounts of TMB and crystal violet were also detected. It would seem, then, that the formation of the various products depends markedly on DMA concentration. This is certainly true, but another variable was also found to be important, namely current density (or electrolysis duration). At low current densities (or long electrolysis times), more of the crystal violet and its leuco form were produced from DMA. This was confirmed with a series of constant current electrolyses at varying current densities, and it was found that solutions containing intermediate concentrations of DMA (10^{-2} to 10^{-1}M) yielded progressively larger amounts of the

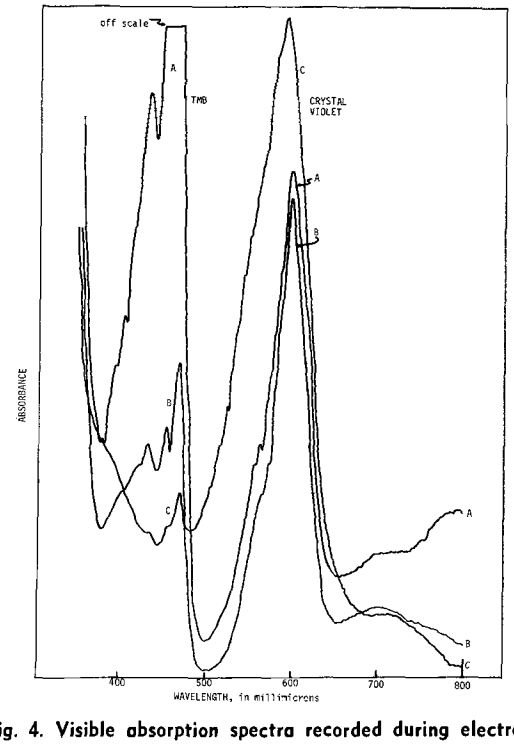

Fig. 4. Visible absorption spectra recorded during electrolysis of a DMA solution (0.2M) in acetonitrile/0.1M TEAP. Concentrations are not comparable (samples were diluted to various extents) from one curve to the next. Curve A, early in the electrolysis; curve B, middle electrolysis; curve C, late in the electrolysis.

dye with decreasing current density. This is reasonable in view of the deprotonation mechanism mentioned above. At low current densities, the ratio of parent DMA to cation radical is greater and deprotonation is more likely to occur.

Several other N,N-dialkylanilines were briefly investigated to determine whether the bulk and abstractability of the alkyl group would have an effect on the course of the electrochemical oxidation pathway. The electrochemical properties of DMA and these other N,N-dialkylanilines are shown in Table I. Over-all, the properties do not vary a great deal with the nature of the alkyl group; most of the variation can be ascribed to differences in diffusion coefficients. Electrochemical data for N,N-dimethyl-p-anisidine, a model one-electron, reversible system, are included for purposes of comparison. The *n*-value data obtained at varying concentrations confirm the relatively uncomplicated behavior at low concentrations, *i.e.*, formation of benzidines, and the complex nature of the electrode process at higher concentrations, especially for DMA. At low concentrations, one would anticipate a ratio of reverse to forward current of 0.5 if only benzidine formation were taking place, analogous to the triphenylaminetetraphenylbenzidine system (26). This is generally observed for all the dialkylanilines at low concentrations and for all but DMA at intermediate and higher concentrations. The very low value for DMA at 10^{-1}M is due to the fact that the major product formed by multiple electrochemical and chemical steps, crystal violet, is not re-reduced after the initial oxidation.

When exhaustive electrolyses were carried out on 10^{-1}M solutions of the ethyl and n-butyl derivatives, only the *para-para*-benzidines corresponding to the dialkylanilines were isolated, with some difficulty and in only moderate yields of 40-50%. The fact that the ethyl and n-butyl analogs of MBDMA and crystal violet were not detected is further evidence to confirm the origin of the central carbon of MBDMA and crystal violet as coming from DMA itself and not the solvent or supporting electrolyte. No other products could be isolated and identified in these systems, although the rather low yield of benzidines indicates further complications. This may be due, in fact, to follow-up reactions involving the benzidine dications. These systems, previously thought to consist only of reversible electron transfer steps, have been found to contain chemical complications as yet undefined (24).

From the foregoing data, it would seem that the products formed in the anodic oxidations of N,N-dialkylanilines depend on a number of factors, namely, concentration, length of electrolysis (or current density), and the nature of the alkyl groups attached to the amine nitrogen. The concentration dependence most likely stems from the relative concentrations of parent amine and radical cation near the electrode surface, the area in which the homogeneous chemical reactions take place. At low bulk concentrations of parent amine, the ratio of radical to parent near the electrode surface is high, hence radical-radical coupling occurs to form the benzidines. At higher bulk concentrations there is more parent amine near the electrode surface, and so the rather complicated series of homogeneous chemical reactions leading ultimately to crystal violet dye ensues. However, even at high DMA concentrations benzidine formation still occurs as a parallel reaction pathway.

It was not unexpected that the anodic oxidation pathways of the other N,N-dialkylanilines, as opposed to DMA, would be less complicated. In the former species, the alpha-carbon of the dialkylamino groups is much less susceptible to attack by incoming radicals; therefore, it is not surprising that benzidine formation predominates even at higher concentrations.

Preparation of N-Alkylacetamides by the Anodic Oxidation of Carboxylic Acid Salts

D. L. Muck* and E. R. Wilson

The Procter & Gamble Company, Miami Valley Laboratories, Cincinnati, Ohio 45239

ABSTRACT

The possibility of preparing N-alkylacetamides by the electrolytic oxidation of carboxylate ions at a carbon anode in the presence of acetonitrile has been investigated. A yield of substituted acetamide of about 50% was obtained with potassium valerate, but it gradually dropped to zero in favor of the Kolbe coupled product in going from potassium octanoate to potassium laurate. An explanation of this effect involving specific orientation of the adsorbed long chain carboxylates on the electrode surface is included. Products derived from intermediate carbonium ions were found, and a mechanism for their formation is proposed.

After a period of time when little work was done on the Kolbe electrosynthesis, the last few years have seen a definite surge of interest in the reaction. Most of this recent work has been directed toward the elucidation of the mode of electron transfer taking place at the electrode surface, but one very important feature which may have definite synthetic implications is the relatively recent discovery that carbonium ions are sometimes formed in the reaction (1-14). The important variables affecting carbonium ion formation are apparently the nature of the anode material and the structure of the carboxylate salt employed. In the case of an oxidation run under normal Kolbe conditions where platinum anodes are employed, carbonium ions are apparently formed only when the radical initially generated in the reaction has an electron impact ionization potential (I.P.) of less than 8 eV (3). However, Koehl (6) has shown that the use of a carbon anode promotes carbonium ion formation even with carboxylates derived from simple straight chain fatty acids, where the I.P. may be 8-10 eV. We have been very interested in this development, since it ideally presents a way to functionalize the alkyl chains derived from fatty acids.

In addition to the more common nucleophiles known to react with carbonium ions, acetonitrile has been shown to give nitrilium salts (7, 15) which can then react with water to give N-substituted acetamides. A precedent for

$$R^+ \xrightarrow{CH_3CN} R{-}N{=}\overset{+}{C}{-}CH_3 \xrightarrow{H_2O} RNHC(=O)CH_3 \quad [1]$$

the trapping of anodically generated carbonium ions with acetonitrile had previously been set by Eberson (7), so we also used acetonitrile and employed carbon anodes to promote carbonium ion formation. During the period of our work, the results of a similar study were published by Kornprobst and co-workers (12). In this case, however, the oxidations were carried out at platinum anodes, so that products derived from carbonium ions were isolated in yields of more than 20% only when branched chain carboxylates were employed (where the I.P. of the alkyl radical was less than 8 eV). In our work we have found that butyl cations react with acetonitrile and water to give two unexpected products, an N-acylvalerylamide and an N-butylvalerylamide in addition to the desired acetamide and other by-products. This work confirms and complements the results of Kornprobst and co-workers. We have also uncovered an intriguing phenomenon involving a gross variation in reaction products: longer chain fatty acid carboxylates give decreasing amounts of carbonium ions as the chain length increases, thereby yielding larger quantities of normal Kolbe coupled products. Explanations for this variation are discussed.

Key words: Kolbe electrosynthesis, n-alkylacetamides, carbon anodes, carbonium ions.

Experimental

Materials.—The acetonitrile employed was Matheson, Coleman, and Bell spectral grade. The carboxylic acids, the isomeric heptyl alcohols, and docosane used were all obtained commercially and were used without further purification.

Apparatus.—A d-c power supply capable of producing 5A current and potentials of up to 220V was employed. The electrolysis cell consisted of a resin pot with 3 ground glass joints in the lid through which the electrode leads and a cooling coil were sealed. The system was flushed with He before each reaction. The gases evolved during the reaction were passed through the tube of Drierite, a tared tube of Ascarite, and finally through a trap cooled in liq N_2. The electrodes were carbon rods 1 in. in diam and 2 in. long (A = 7.0 in.^{2}; 45.7 cm^2). Infrared spectra were obtained with a Perkin-Elmer Infracord spectrophotometer, while the NMR spectra were obtained on Varian T-60 and HA-100 spectrometers. Gas chromatographic separations were made on an F&M Model 700 equipped with a 6 ft x 0.25 in. column packed with 10% Apiezon L on 60-80 mesh Chromosorb W, acid washed and dimethyldichlorosilane treated. Mass spectra were obtained with an Atlas CH-4 instrument.

General electrolysis procedure.—A description of the oxidation of potassium valerate is given as being typical. Potassium valerate (140.0g, 0.10 mole) was dissolved in 22 cc of water and diluted with 200 cc of acetonitrile. A d-c voltage of about 20V was applied until a current of 2.0A flowed. The applied voltage was then held constant and the electrolysis was continued for a period equal to three times the half-life of the reaction (the half-life of each reaction was taken as the time required for the current to drop to 50% of its original value). The reaction solution was then removed from the cell, the cell was rinsed with a little water, and the rinse was combined with the bulk solution. The resulting solution was analyzed for octane and butyl alcohol by GLC, and then refluxed under a condenser connected to a liq N_2 trap to collect any remaining volatile hydrocarbons. The solvents were then removed from the reaction solution on a rotary evaporator, about 75 cc of water were added, and this solution was extracted with ether. The ether extracts were combined, dried over $MgSO_4$, and concentrated on a rotary evaporator to give about 5g of organic products. The aqueous layer was acidified with 6*N*

HCl, extracted continuously overnight with ether, and the resulting ether layer was dried over $MgSO_4$ before evaporation on a rotary evaporator to give 0.5-3g of unreacted valeric acid. The volatile hydrocarbons collected in both liq N_2 traps were warmed to dry ice-acetone temperature before being weighed, and were then analyzed by NMR and mass spectrometry. They were found to be essentially the same mixture of butenes and methyl cyclopropane as previously reported. The liquid organic products were isolated and purified by preparative scale GLC. The identities of the products were established by comparison of GLC retention times, *IR* spectra and NMR spectra with those obtained on samples prepared by independent methods.

Preparation of N-alkylacetamides.—Samples of the various N-alkylacetamides needed for comparison purposes were prepared by adding an ether solution of acetyl chloride drop-wise to an equimolar quantity of the appropriate amine in ether at room temperature. The resulting ether solution was filtered and the solvent removed from the filtrate on a rotary evaporator. The crude acetamides were then purified by preparative scale GLC.

N-(sec-butyl)-N-acetylvalerylamide.—To 4.8g (0.03 mole) of N-(sec-butyl)valerylamide which was prepared by reacting valeryl chloride with sec-butyl amine were added 100 ml of ether and 4.8g (0.06 mole) of pyridine. A solution of 2.4g (0.03 mole) of acetyl chloride in 20 ml of ether was added drop-wise, and the resulting solution was refluxed for 2 hr. More acetyl chloride (1.2g; 0.015 mole) was then added and the mixture was refluxed for 2 hr more. About 5 ml of ethanol were added, and the resulting solution was washed twice with dil HCl, 3 times with satd. $NaHCO_3$, and finally once with water before drying over anhyd $MgSO_4$. The solvents were removed with a rotary evaporator to give 1.0g (17%) of a clear oil with no N-H infrared absorption. Purification by preparative scale GLC gave a colorless liquid.

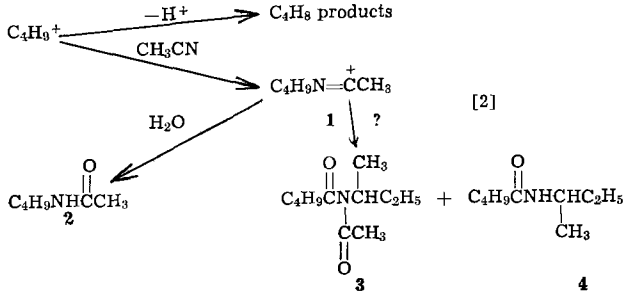
Anal Calc for $C_{11}H_{21}NO_2$: C, 66.33; H, 10.55; N, 7.04. Found: C, 66.50; H, 10.85; N, 7.32.

Stability of N-(sec-butyl)-N-acetylvalerylamide to reaction conditions.—The conditions for the electrolysis of potassium valerate as described above were repeated, except that 15% water in acetonitrile was used as the solvent, and 2.0g of N-(sec-butyl)-N-acetylvalerylamide were added. The electrolytic oxidation of the valerate was then carried out as before, and the products were isolated. Octane (0.1g; 0.0009 mole) and N-sec-butyl acetamide (1.8g; 0.016 mole) were obtained along with 4.8g of the above substituted valeryl amide. Subtracting out the amount of this latter material that was added to the initial reaction solution (2.0g), a yield of 2.8g (0.014 mole) was obtained, which is very close to the average of 2.4g obtained in three normal reactions.

Electrolysis of potassium octanoate in water.—Octanoic acid (14.4g; 0.10 mole) and 5.6g (0.10 mole) of potassium hydroxide were dissolved in 200 ml of water and electrolyzed according to the general procedure described before. The aqueous solution obtained was then extracted three times with ether, and the combined extracts were dried over anhydrous magnesium sulfate. The solvent was then removed on a rotary evaporator to give 0.8g of heptyl alcohols. This mixture was analyzed on capillary column GLC using known samples of the various isomeric heptyl alcohols as standards. The following amounts of each were found: 1-heptanol, 18.5%; 2-heptanol, 43.8%; 3-heptanol, 37.7%.

Results

Since long-chain compounds are often difficult to work with, potassium valerate was employed initially as the starting material. In every case, contrary to normal Kolbe reaction conditions, the valeric acid was completely neutralized, since it has previously been shown that high carboxylate concentrations favor carbonium ion formation (14). For anodes, we initially attempted to use the types of carbon used before by Koehl (6), but the acetonitrile dissolved the organic binders they contained and eroded the electrodes badly. A shift was then made to regular amorphous hard carbon rods, the apparent density of which varied in the range of 1.42-1.53 g/ml, and these anodes seemed to serve very well. A cylindrical perforated copper cathode was used, and the initial reactions were run in a 10% water in acetonitrile solvent mixture. We did obtain the desired acetamide **2** in a 26% yield, but we also isolated the unexpected products **3** and **4** as well as isomeric butenes and methyl cyclopropane arising from loss of a proton from the intermediate butyl cation.



In an effort to maximize the yield of the desired acetamide **2**, a study of the variation of products with an increase in the amount of water employed was made. Concentrations of water below 10% were not used because the starting material was not completely soluble. At least four runs were made for each set of conditions, and the average values of these are shown in Table I. The yields for each run were generally within 5% of the average value, but they sometimes varied as much as 15% from the average.

Since it was conceivable that products **2** or **4** could have resulted from a degradation of **3**, a sample of **3** prepared by an independent synthesis was added to a normal electrolytic reaction to check its stability to reaction conditions. The amount of **3** obtained from this reaction was greater than normal by essentially the amount added to the reaction, and the quantities of other products isolated were within their normal ranges. Therefore, **3** is stable to the reaction conditions and could not be a source of **2** or **4**.

In order to investigate the possible variations in the product distribution with changes in the type of carbon used for the anode, normal graphite as well as pyrolytic graphite anodes were also used. The characteristics of

C_8H_{18}	10	6	1	1	0	0	0
C_4H_9OH	0	0	0	0	43	22	48

these materials are shown in Table II, and the data on the product trends observed in a 15% water in acetonitrile solvent mixture are listed in Table III. The yields obtained on a platinum anode are included in Table III for the sake of comparison.

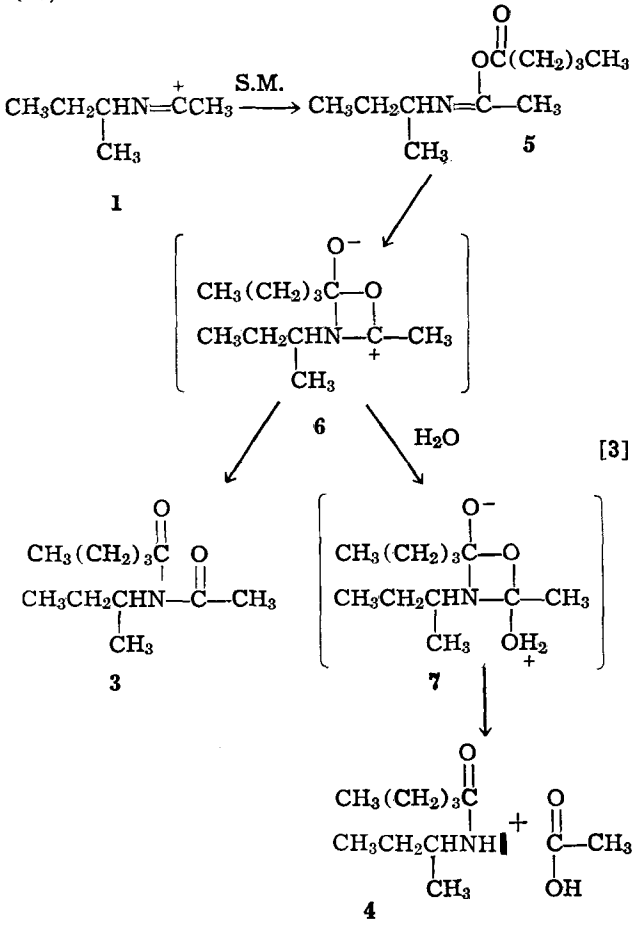
From Table I, one can see that the best yields of N-sec-butyl acetamide were obtained in 15-20% water in acetonitrile solvent mixtures. Therefore, the potassium salts of octanoic and lauric acids were electrolyzed under these conditions to verify that similar results could be obtained with longer chain fatty acids. Surprisingly however, the results differed with these salts. As the length of the carbon chain attached to the carboxy group increased, the amount of normal Kolbe coupled product increased markedly to the point at which only docosane, $C_{22}H_{46}$, was formed in the oxidation of potassium laurate. A summary of the data obtained from the oxidation of these salts is shown in Table IV.

Kornprobst and co-workers (12) observed a number of alkyl group rearrangements in their work. With potassium valerate we found the same isomerization of the C_4H_9 chain to give sec-butyl derivatives. In order to study the alkyl rearrangements in longer chain salts, we analyzed the alcohols obtained from the oxidation of potassium octanoate in a 50% water in acetonitrile solvent mixture by capillary column gas chromatographic comparison with known samples of the isomeric heptyl alcohols. The results showed 18.5% 1-heptanol, 43.8% 2-heptanol, and 37.7% 3-heptanol with no 4-heptanol found.

Discussion

Oxidation of valeric acid.—The products obtained from the oxidation of potassium valerate were generally those expected. It has previously been established that side reactions of the butyl cation give isomeric butenes as well as some methylcyclopropane (6). The fact that butyl alcohol was observed in these reactions is not unusual because its formation from a carbonium ion generated in the presence of water would certainly be predicted, but it does seem unreasonable that the amount of water would have to be greater than 25% for this reaction to take place. One can justify the result by assuming that adsorption of carboxylate ions and/or acetonitrile on the anode surface prevents the water from reaching the reactive carbonium ion generated on that surface.[1]

While the above products were generally expected, the formation of the N-acyl amide **3** and the valeryl amide **4** was somewhat unusual. In order to explain the formation of these products, the following is presented as a reasonable mechanism which is consistent with the observed results. The basic concept was substantiated by the report of Kornprobst and co-workers (12), who also explained the formation of the N-acyl amide **3** by rearrangement of **5**. The rearrangement of **5** to the products **3** and **4** is postulated in our mechanisms as proceeding *via* a 4-membered ring transition state which may or may not be a concerted process. The hypothetical intermediate **6** is shown to illustrate the rearrangement more clearly. A similar rearrangement involving a 1,3-acyl migration from carbon to nitrogen has been reported by Curtin and Richman (16).



The trends in the variation of these products as the concentration of water changes are generally consist-

[1] A referee has suggested that the anode potential in these reactions may be high enough that water is being oxidized, thereby depleting its concentration at the electrode surface. This could explain the high concentration of water required to form alcohol from the butyl cation. We cannot rule out this possibility but tend to discount it for the following reasons. Numerous electrochemical studies in the past have demonstrated that the electrolysis of water ceases in the Kolbe electrosynthesis when the potential becomes anodic enough to oxidize carboxylate ions. In addition, one would not expect the current to decrease in value with time as it does in these reactions if water were being electrolyzed because the amount of water is so great that its concentration would remain essentially constant during the time span involved.

ent with the scheme above. The yield of N-(sec-butyl)acetamide, **2**, increases sharply as the per cent of water changes from 10 to 15%, indicating that the concentration of water is such that it can effectively compete with the starting material for reaction with the nitrilium cation. The large molar excess of water required for this to happen may be the result of the carboxylate anion adsorbing on the positively polarized anode. The yield of substituted acetamide then begins to decrease with increasing water concentration due to increased side reactions of the butyl cation, initially to form olefins and later to react directly with the water to form alcohol. The drop in the amount of the N-acyl amide **3** formed with an increase in the amount of water present would be predicted. The over-all yield of N-(sec-butyl) valeryl amide formed was never high and, therefore, the small changes observed are not significant. The Kolbe product in this case is octane, and while about 10% was formed in the 10% water in acetonitrile solvent system, generally negligible quantities were observed in the solutions with greater amounts of water present.

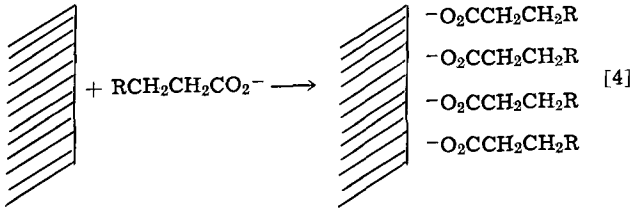
Although the data obtained in the above studies involving varying water concentrations were reproducible only to about ± 15%, there seems to be no obvious explanation. Each experiment was conducted with a new carbon anode, and while a third electrode for maintaining a controlled potential at the electrode surface was not employed, each reaction was initiated at a potential necessary to generate an initial current of 2A. The applied potential was then held constant throughout the reaction and the current allowed to decrease as the starting material was depleted. An attempt was made to use a third electrode for monitoring the potential near the surface of a rotating carbon rod, but the potentials observed were so high (3.5-5V *vs* SCE) that it was apparent that uncompensated *IR* drop was making the measurement meaningless. A factor which might have caused the inconsistency in the yields of products would be variation in the extent of reaction of the starting material. Most of the reactions were continued for a period of time equivalent to three half-lives of the reaction (as measured by the current drop). However, varying amounts of unreacted valeric acid were recovered from these reactions. When a series of oxidations was run to a degree of completeness where essentially equal amounts of valeric acid remained, a similar trend in product distribution was obtained. Since an accurate measure of the net potential at the electrode surface was not attainable, the nonreproducibility in yields observed may simply be due to a variation in the potential obtained at the surface of the anode. It has been suggested (13) that the potentials required for the oxidation of carboxylate ions and for the oxidation of alkyl radicals are significantly different to allow two distinct waves. Assuming that the oxidation of an alkyl radical to a carbonium ion takes place at a more anodic potential than the oxidation of a carboxylate ion, it is possible that some of the reactions described herein might have been carried out at potentials slightly more cathodic than that required for efficient oxidation of the alkyl radicals to carbonium ions. This would lead to differing rates of formation of carbonium ions, and thereby varying yields of products from these ions.

The results obtained from the electrolysis of potassium valerate at a number of different anodes (Table III) indicate that similar processes are taking place at amorphous carbon and normal graphite anodes. This agrees with the work of Koehl reported earlier (6). However, of the other carbons studied, pyrolytic graphite behaved atypically. This is not unreasonable since the surface structure of pyrolytic graphite is essentially voidless due to the layered platelet structure it possesses.

When platinum anodes were employed, much larger quantities of the normal Kolbe dimer were obtained, as would be expected. However, the amount of products derived from the butyl cation are higher than would be predicted. The N-(sec-butyl)acetamide formed in a 19% yield represents carbonium ion which has reacted with acetonitrile, while the 42% yield of C_4H_8 products indicates the amount of carbonium ion which lost a proton. Since the electron impact ionization potential of the n-butyl radical is higher (8.64 eV) than the 8 eV limit suggested as being the maximum value for promoting carbonium ion formation, this combined yield of 61% of ion is unreasonably high.

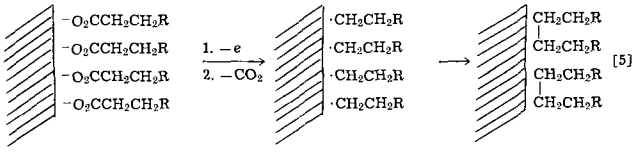
Oxidation of octanoic and lauric acids.—The observation that the yield of Kolbe coupled products increased with increasing chain length in the fatty acids studied was not anticipated. The yield of dimer obtained under normal Kolbe reaction conditions is generally constant as the chain length increases, except for propionic and butyric acids which give unusually low yields (17).

In considering an explanation of the phenomenon observed in this work, the most logical proposal to make is that attractive forces between the long chain alkyl radicals are keeping them from reaching the electrode surface where they would undergo further oxidation. A reasonable scheme based on this premise can be proposed if two assumptions are made. First, assume that as the carboxylate anions approach the electrode surface they will assume an orientation dependent on the chain length of the molecule involved. Short chain carboxylates (possibly up through C_6) will be adsorbed on the surface in a more or less random fashion. However, as the alkyl chains become longer, they will tend to adsorb in an orientation perpendicular to the electrode surface, with a subsequent stacking or layering effect becoming pronounced as more and more ions are adsorbed. This stacking effect



[4]

would be predicted to be enhanced by the Van der Waals attraction of the hydrophobic alkyl chains for each other, since they would constantly be searching for a more organic environment than the polar solvent surrounding them. Now also assume that the radicals generated in this reaction are separated from the electrode surface at the instant of formation by the width of the leaving CO_2 molecule (about 6Å), as has been previously postulated by Eberson (3, 10). The over-all net effect predicted then would be that the radicals would be generated in layers perpendicular to the electrode surface, and about 6Å away from the surface. Whether or not the intermolecular attractions these radicals experience would be enough noticeably to slow their migration through such a short distance is debatable, but it is certain that the stacked orientation described would be predicted to increase significantly the probability of radial coupling.



[5]

Since both the processes of radical-radical coupling and migration through a few angstroms of solution would be expected to be very fast, it would not take much of an effect to noticeably favor one or the other

of these processes. The simple slowing of the rate of migration of long chain alkyl radicals due to the increase in molecular weight might even be enough of a factor to cause the observed change in reaction.

The assumption made above that the radicals formed in the Kolbe reaction are separated from the electrode surface by the width of a molecule of carbon dioxide deserves further discussion. Eberson made this proposal after obtaining evidence that the radicals generated under similar conditions did not react stereospecifically as one would predict for reaction of an adsorbed radical. It now appears that the "long chain effect" observed in this work supports Eberson's postulation. If the radicals were generated in an adsorbed state and were never really "free," the only obvious way one could explain the observed increase in coupling with increasing chain length would be by assuming that there existed enough difference in the ionization potentials of the alkyl radicals to cause preferential oxidation of those with shorter chain lengths. However, this argument is unreasonable since the ionization potentials that have been measured for alkyl radicals decrease with increasing chain length, which would indicate that the long chain radicals would be more easily oxidized to carbonium ions.

Polarography in Acetone of Tris(Dithioacetylacetonato)-Complexes of Iron(III), Ruthenium(III), Osmium(III), and Rhodium(III)

A. M. Bond, G. A. Heath, and R. L. Martin

Department of Inorganic Chemistry, University of Melbourne, Parkville, 3052, Australia

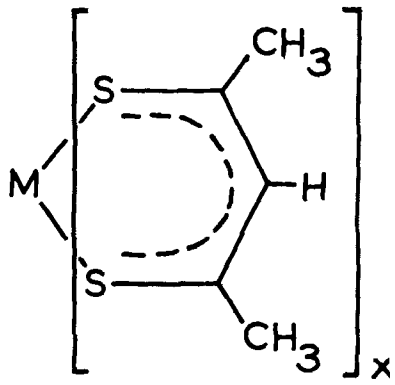
ABSTRACT

Polarographic studies have been carried out in acetone on the dithio(acetylacetonato)-complexes $[M(SacSac)_3]$ ($SacSac^- = CH_3{\cdot}CS{\cdot}CH{\cdot}CS{\cdot}CH_3^-$) where M = Fe(III), Ru(III), Os(III), (all d^5, low-spin) and Rh(III) (d^6, low-spin). The iron and osmium complexes are reversibly reduced at the DME, whereas the ruthenium complex undergoes a quasi-reversible reduction. For the d^5 systems the electrode reaction is believed to be $[M^{III}(SacSac)_3] + e^- \rightleftharpoons [M^{II}(SacSac)_3]^-$. However reduction of $[Rh(SacSac)_3]$ is highly irreversible and may involve adsorption or compound formation at the mercury surface. Millicoulometric studies indicate the electrode reaction is Rh(III) + $2e^- \rightarrow$ Rh(I). The half-wave potentials (Fe, −0.21; Ru, +0.04; Os, −0.05; Rh, 1.05V *vs.* Ag/AgCl) accord with the known chemistry and spectroscopic properties of the complexes. The development of polarographic techniques for use in acetone is described in detail.

Recently, considerable attention has been directed to transition metal derivatives of the sulfur-containing ligand dithioacetylacetone (1-17). Complexes of all the group VIII transition metals have been characterized although the parent ligand has not yet been isolated in the monomeric state. X-ray structural investigations confirm that the coordinated dithioacetylacetonato anion is planar and attached to the metal by both sulfur atoms as in (I). Table I summarizes the compounds $[M(SacSac)_x]$ (I) presently known.

Key words: polarography, tris(dithioacetylacetonato)-complexes, acetone.

(I)



Studies by various workers have employed the techniques of infrared, electronic, e.s.r., p.m.r., and mass spectroscopy. Magnetic susceptibility and magnetic anisotropy measurements have also been performed. However, until recently no electrochemical studies had been reported.

The polarographic method is capable of furnishing considerable thermodynamic and structural information on such compounds. It is also an effective means of identifying new species which are related to the known compounds by oxidation or reduction. In this way further synthetic and chemical investigations may be suggested.

Examination of Table I reveals that the complexes [Co(SacSac)$_3$] and [Co(SacSac)$_2$] provide the only instance where dithioacetylacetone derivatives have been characterized for two oxidation states of the one transition metal.

The reduction of [Fe(SacSac)$_3$] with sodium dithionite was reported to yield "auto-oxidizable" [Fe(SacSac)$_2$], but no further characterization was described (3). Attempts to repeat this work have been unsuccessful (18). A more recent report of [Fe(SacSac)$_2$] (12), based on a sulfur analysis only, has been questioned (14) and, in our hands, the published method reliably yields [Fe(SacSac)$_3$] with the expected analytical and physical properties (15). In these circumstances, we thought it worthwhile to make a detailed polarographic investigation of the redox behavior of [Fe(SacSac)$_3$].

The compounds [Fe(SacSac)$_3$], [Ru(SacSac)$_3$], and [Os(SacSac)$_3$] were thus chosen as a representative group for the initial polarographic studies of dithioacetylacetone complexes. Each of these low-spin $d\epsilon^5$ chelates was found to undergo a ready one-electron reduction which might be regarded as completing the metal $d\epsilon$ subshell. A convenient comparison was provided by the polarographic behavior of the low-spin $d\epsilon^6$ complex [Rh(SacSac)$_3$], in which the metal $d\epsilon$ subshell is fully occupied. These results, which have been briefly reported elsewhere (15), are now discussed in detail.

Recently, polarographic data for the analogous cobalt(II) and nickel(II) complexes were described in a note by Ouchi *et al.* (19). However, neither the compounds, the solvent system, nor the reference electrode are common to the studies described herein.

The dithioacetylacetone complexes are insoluble in water. Acetone was chosen as a suitable solvent since preliminary investigations showed that a stable Ag/AgCl reference electrode could be maintained in this solvent. Furthermore, acetone was known not to interact chemically with the compounds and was commercially available in sufficient purity. Polarographic techniques, suitable for use in acetone, have been developed and are described here. These techniques include conventional and rapid polarography with a dropping mercury electrode (DME), inverse polarography with a hanging drop mercury electrode (HDME), and the millicoulometric determination of n values with a DME.

So far as the present authors are aware, acetone has been used only occasionally as an electrolytic solvent (20), and rarely for polarography (21). One of the problems confronting its use is the need for a suitable reference electrode system. Aqueous calomel electrodes have been used (20), but are undesirable in otherwise nonaqueous media, particularly if junction potentials are to be minimized. A satisfactory Hg/Hg_2Cl_2, LiCl (acetone) system has been reported (22), but the Ag/AgCl/LiCl(acetone) electrodes described here commend themselves for stability and ease of construction.

Acetone is a versatile solvent for both organic and complex inorganic compounds; the development of this simple reference system may encourage its much wider use as a polarographic medium.

Experimental

Polarography.—Conventional d-c polarographic studies were carried out in B.D.H. Analar grade acetone with tetraethyl-ammonium perchlorate (0.1 mole/liter) as the supporting electrolyte. A Metrohm Polarecord, E 261, was used in conjunction with a Metrohm IR compensator, E 446, and a three-electrode system. The two reference electrodes were identical Metrohm Ag/AgCl EA 425 electrodes filled with a solution of LiCl in acetone (0.1 mole/liter). The glass capillary dropping mercury electrode (DME) had the following characteristics in acetone/0.1M Et_4NClO_4 (at open circuit and a mercury column height of 40 cm): flow rate of mercury, $m = 3.25$ mg sec^{-1}; drop time, $t = 2.70$ sec; $m^{2/3}t^{1/6} = 2.58$. In the rapid polarographic method, the short controlled drop times were achieved with a Metrohm Polarographie Stand, E 354. Hanging mercury drops used in this work were 0.52 mm in diameter with a surface area of 1.38 ± 0.04 mm^2 and were produced by a Metrohm BM 5-03 hanging drop mercury electrode (HDME).

Preliminary experiments showed that acetone/0.1M $LiClO_4$ gave a polarographically useful potential range of +0.8 to −1.6V at the DME *vs.* Ag/AgCl, whereas for acetone/0.1M Et_4NClO_4 the useful range was +0.8 to at least −2.0V. The latter supporting electrolyte was preferred because of the wider potential range. The reference electrodes were fitted with geometrically identical salt bridges containing acetone/0.1M Et_4NClO_4 to minimize LiCl leakage into the test solution. Potentials measured relative to a Ag/AgCl(acetone) reference electrode are qualitatively similar to those measured relative to Ag/AgCl(water). In acetone, $LiClO_4$ and $Co(ClO_4)_2$ reduction and Hg oxidation all occur at potentials about 0.4V more positive than the corresponding processes in water.

The very high resistance of acetone, even with a carrier electrolyte, makes compensation of the large ohmic potential (IR drop) essential. The three-electrode system provides a convenient means for achieving this. For optimum compensation, the measuring reference electrode should be positioned in the field shadow of the mercury electrode and the working reference electrode, *i.e.*, the three electrodes must be in one plane. Identical Ag/AgCl electrodes were thus employed and were symmetrically disposed in the test solution in relation to the mercury electrode. With only one reference electrode in circuit (*i.e.*, no IR com-

pensation), the ohmic potential drop rendered any polarographic wave unobservable (c.f. Fig. 4).

The reliability of the three-electrode system and the stability of the nonaqueous reference electrodes were checked throughout this work by frequent recording of the polarogram of [Rh(SacSac)$_3$] in acetone solution (among other tests). As reported below, this system has a well-defined wave with $E_{1/2} = -1.05$V *vs.* Ag/AgCl. Over three months duration, the reproducibility of this value was better than ±10 mV. Transposition of the functions of the two Ag/AgCl electrodes was regularly confirmed not to alter the polarogram in any respect.

Test solutions were degassed with argon which was previously passed through two acetone-filled wash bottles and a spray-trap. Twenty minutes was sufficient for effective deoxygenation. All solutions were thermostated in a water-jacketed cell at 20.0° ± 0.1°C, unless otherwise stated.

Millicoulometry.—The number of electrons involved in the reduction of [Rh(SacSac)$_3$] was determined by coulometric studies involving controlled-potential reduction at the DME. The decrease in concentration due to reduction was conveniently measured by the change in the polarographic diffusion current. The coulometric determination of n values with the DME employed a considerably smaller volume of solution than that used in conventional polarography. The small volume limits the time necessary for the reduction of the compound at controlled potential to cause a significant decrease in concentration. The polarographic cell was modified as in Fig. 1 and enabled volumes between 0.5 and 3 ml to be used. For [Rh(SacSac)$_3$], electrolysis times were between 30 min and 1 hr.

Each test solution was prepared by dissolving the compound in degassed acetone/0.1M Et_4NClO_4 in a 5-ml standard flask fitted with a rubber seal. By means of a micrometer syringe an accurately known volume was transferred directly to the inner coulometry cell, the whole apparatus having been previously flushed with argon. Throughout the electrolysis, the whole vessel was thermostated at 0°C to minimize evaporation, and acetone-saturated argon was gently bubbled through the acetone in the outer "moat". Blank runs, where no electrolysis occurred, showed that the concentration of the test solution did not alter measurably over 90 min.

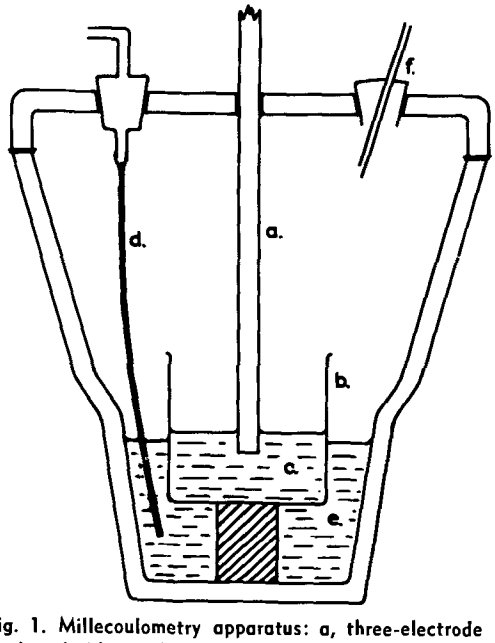

Fig. 1. Millecoulometry apparatus: a, three-electrode planar array, viewed side-on; b, inner cell; c, test solution; d, argon inlet; e, acetone moat; f, rubber seal, with argon outlet.

Materials.—Tetraethyl-ammonium perchlorate was prepared by admixture of aqueous solutions of Et_4NI and $NaClO_4$. The precipitated product was recrystallized three times from 95% alcohol and dried under vacuum. The pure compound was stored over silica gel until use. Solutions in dilute nitric acid gave no precipitate with silver nitrate.

The dithioacetylacetonato chelates [Fe(SacSac)$_3$] (14, 15), [Ru(SacSac)$_3$] (15), [Os(SacSac)$_3$] (15), and [Rh(SacSac)$_3$] (10) were prepared and purified as described elsewhere. The concentration of each compound in solution was checked spectrophotometrically by reference to the known optical spectrum (15).

Results and Discussion

[Fe(SacSac)$_3$], [Ru(SacSac)$_3$], [Os(SacSac)$_3$].—These complexes form a useful group for comparison since the first, second, and third row transition metals are all represented, and in each case the central metal atom formally has oxidation state III and d electron configuration d^5. The complexes each exhibit one extremely well-defined polarographic reduction wave at a potential near zero volt *vs.* Ag/AgCl. Figure 2 shows a typical [Os(SacSac)$_3$] polarogram. Polarograms of the other complexes have a similar appearance.

For each complex, graphical plots of diffusion current, i_d, *vs.* concentration are linear, and pass through the origin. Plots of i_d *vs.* the square root of the mercury column height, h, are linear. The waves are therefore diffusion controlled.

Plots of $E_{d.e.}$ *vs.* log $i/(i_d - i)$ are linear for [Fe(SacSac)$_3$] and [Os(SacSac)$_3$]. In each case the slope of this plot is 60 ± 2 mV, indicating that the electrode reaction is a reversible one-electron step. For [Ru(SacSac)$_3$], the log plot (Fig. 3) is slightly curved and the electrode reaction is quasi-reversible. The limiting slope, determined from potentials at the foot of the wave, is 62 mV in accord with a quasi-reversible one-electron reduction (23).

For the iron and osmium systems, the $(E_{1/4} - E_{3/4})$ values are independent of DME drop-time and equal to 58 ± 2 mV, providing further evidence for the reversible nature of the electrode reactions. In the case of [Ru(SacSac)$_3$], $(E_{1/4} - E_{3/4})$ values increase slightly with decreasing drop-time (Table II). The latter feature is consistent with the electrode possessing a high but not complete degree of reversibility, and confirms the quasi-reversible assignment.

The $E_{1/2}$ values for each complex (Fe, −0.21; Ru, +0.04; Os, −0.05V *vs.* Ag/AgCl/0.1M LiCl) are independent of drop-time; typical results for [Ru(SacSac)$_3$] are included in Table II.

In general, reversible half-wave potentials $E_{1/2}^r$, rather than measured $E_{1/2}$ values, have real thermodynamic significance as they are closely related to E° values. For the reversible iron and osmium electrode reactions, $E_{1/2}^r = E_{1/2}$. For the quasi-reversible [Ru(SacSac)$_3$] electrode process, $E_{1/2}^r$ may be calcu-

lated (23) from the limiting slope of the logarithmic analysis shown in Fig. 4 and is found to be +0.055V *vs.* Ag/AgCl. Comparison of the $E_{1/2}^r$ values shows that the standard free energy required for reduction of the complexes decreases in the order Fe > Os > Ru.

When a reversible electrode process is observed, it is implied that the charge transfer kinetics are rapid compared to the time scale of the polarographic experiment. It generally follows that the oxidized and reduced forms have the same molecular structure and differ only in their electronic populations. Therefore, in the present systems, the suggested electrode reaction is

$$[M(SacSac)_3] + e^- \rightleftharpoons [M^{II}(SacSac)_3]^-$$

The reduced form, $[M^{II}(SacSac)_3]^-$ should have essentially the same six-coordinate structure as the original $[M(SacSac)_3]$ species. If the reduction did involve gross structural change, such as the loss of a bidentate ligand, then this step would be unlikely to occur rapidly in terms of the polarographic time scale and a nonreversible electrode process should result. The kinetic inertness of low spin d^5 and d^6 systems is well known. That rapid, reversible, and complete ligand dissociation does not occur is indeed clear from the absence of subsequent polarographic steps which would be anticipated for the free divalent metal ions. The slight departure of the $Ru^{III} \rightarrow Ru^{II}$ wave from reversibility might result from a minor structural modification during the reduction; however, it is not clear why [Ru(SacSac)3] should behave differently from its congeners.

Several interesting features of the polarography of these complexes are apparent. First, all three compounds are reduced around 0V *vs.* Ag/AgCl, *i.e.*, reduction of the complexed metal ion to the divalent oxidation state is relatively easy. However no further reduction occurs in the useful potential range. The ready one-electron reduction corresponds to completion of the stabilized metal $d\epsilon$ subshell so that the reduced species $[M^{II}(SacSac)_3]^-$ would be isoelectronic with the neutral Co(III), Rh(III), and Ir(III) complexes. Further reduction would require electrons to be placed in the much higher energy $d\gamma$ level.

Second, these compounds are typified by rather low-frequency ligand-to-metal electronic charge transfer transitions as well as ready one-electron reduction waves (15). Both these properties are no doubt associated with the vacancy in the metal $d\epsilon$ subshell. The readier reduction of [Ru(SacSac)3] than either its first or third row congener, while unexpected in itself, correlates nicely with the observation that [Ru(SacSac)3] has the lowest frequency ligand-to-metal charge transfer absorption.

Finally, crystalline derivatives of the postulated $[M^{II}(SacSac)_3]^-$ complex anions are now being sought. The polarography suggests that the trivalent complexes should react readily with moderately strong reducing agents. Sodium dithionite has been reported to reduce [Fe(SacSac)3] to a species having no e.s.r. signal (3), however the suggested product, neutral $[Fe^{II}(SacSac)_2]$, is now questioned. It is, of course, possible that chemical reduction takes a different route from the polarographic electrode process, or that the complex anions are only stable during the life-time of the polarographic experiment.

[Rh(SacSac)3].—This complex shows one well-defined reduction wave at the DME with $E_{1/2} = -1.05$V *vs.* Ag/AgCl (Fig. 4).

The graph of i_d *vs.* concentration is linear, and the dependence of i_d on h is almost linear (Fig. 5). The electrode process therefore possesses a high degree of diffusion control. Table III shows that, as the drop-time increases, $E_{1/2}$ remains constant but $(E_{1/4} - E_{3/4})$ values increase markedly. Plots of $E_{d.e.}$ *vs.* log $i/i_d - i$ also vary greatly with drop-time. Such behavior indicates that the electrode reaction is highly irreversible.

In this case the number of electrons involved in the reduction, n, cannot be evaluated by the logarithmic analysis of the polarographic wave.

The current-voltage curve obtained with an HDME in unstirred solution (Fig. 6) was almost identical to the conventional d-c polarogram. A potential at half-wave height, $E_{p/2}$, of −1.00V *vs.* Ag/AgCl and a $(E_{p/4} - E_{3p/4})$ value of 80 mV were observed using a potential scan rate of 1 V/min. Such current-voltage curves were only obtained as the first scan on a new

mercury drop. Repeated scans using the same drop produced diminishing currents until no reduction was observable. When a fixed potential more negative than that required for reduction was maintained, the cathodic current decayed to zero within a few minutes. After such electrolysis at −1.45V *vs.* Ag/AgCl, inverse scanning in the positive direction revealed no anodic wave. The mercury drop was not affected by mere immersion, but became obviously tarnished during electrolysis.

Apparently, at sufficiently negative potentials, a reduced species or decomposition product becomes adsorbed on the HDME. The adsorbed substance eventually covers the entire surface of the drop preventing further reduction. Since inverse scans do not strip this species from the drop it must be tightly bound. Possibly mercury compound formation rather than adsorption occurs at the drop surface.

1.13	−1.052	104
0.32[a]	−1.050	120

[a] Drop-time of 0.32 sec by rapid polarographic method.

The interaction of [Rh(SacSac)$_3$] with the HDME indicated that coulometric evaluation of n would require a continually renewing mercury surface. A millecoulometric method at the DME was resorted to in the apparatus described above. A controlled potential of −1.45V *vs.* Ag/AgCl was employed, and the charge consumed by the electrode process was calculated by graphical integration of the current-time curves. Four independent determinations gave n values of 2.27, 2.09, 2.18, and 2.05.

The suggested electrode process is therefore Rh(III) + $2e^-$ → Rh(I). The electrode reaction is undoubtedly more complicated for [Rh(SacSac)$_3$] than for the previous complexes. It shows substantial diffusion control, irreversibility, and evidence for compound formation or adsorption at the mercury surface. A feasible product of the two-electron reduction of [Rh(SacSac)$_3$] would be [Rh(SacSac)$_2$]$^-$, isoelectronic with the well-characterized planar d^8 complex, [Pd(SacSac)$_2$]. However, the reduction product is not identified by these electrochemical studies.

It seems that, for [Rh(SacSac)$_3$], the completely filled metal d_ϵ subshell is associated with two properties; the highly negative $E_{1/2}$ value and the absence of low energy ligand-to-metal charge transfer. In comparison, one-electron reduction of the d^5 systems, [Fe(SacSac)$_3$], etc., occurs relatively easily to give complex anions isoelectronic with [Rh(SacSac)$_3$]; not surprisingly, no further reduction is observed.

Reduction of [Rh(SacSac)$_3$] has been attempted using zinc amalgam, sodium borohydride, and other strong chemical reductants without success. This is understandable in view of the polarographic data.

In conclusion, it appears that the polarographic results for the present complexes are consistent with their known chemical and spectroscopic properties. The existence of new stable entities has been indicated. Polarographic studies on other dithioacetylacetonato derivatives have been equally informative, and will be reported shortly.

Manuscript submitted May 25, 1970; revised manuscript received July 8, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1971 JOURNAL.

Oxygen Adsorption on Gold and the Ce(III)/Ce(IV) Reaction

R. A. Bonewitz*[1] and G. M. Schmid*

Department of Chemistry, University of Florida, Gainesville, Florida 32601

ABSTRACT

In 1*N* $HClO_4$ and in 2*N* H_2SO_4, "oxygen" uptake on Au electrodes begins at 1.25V *vs.* NHE. Using a roughness factor of 1.4, monolayer coverage (600 μcoul/cm^2) is reached at 1.45V; a second monolayer is completed at 1.75V. Oxygen, once adsorbed, is removed at approximately 1.3V. Thus, the kinetic parameters of the Ce(III)/Ce(IV) reaction in 1*N* $HClO_4$ and in 2*N* H_2SO_4 can be obtained at oxygen coverages $\theta = 1.5$-2.0 and $\theta = 0.7$-2.0, respectively. Apparent exchange current densities, i_o^a, were obtained from low overvoltage data ($\leq$10 mV). The charge transfer coefficient, $\alpha = 0.65 \pm 0.06$, was determined from the slope of plots of log i_o^a *vs.* equilibrium potential. It is independent of oxygen coverage in the range indicated. The apparent rate constant, k_o^a, was calculated from i_o^a and α to be $k_o^a \approx 3 \times 10^{-4}$ cm/sec in the range $1 \leq \theta \leq 2$ ($1.5 \leq \theta \leq 2.0$ in $HClO_4$). Extrapolation of the data to $\theta = 0$ yields $k_o^a \approx 12 \times 10^{-4}$ cm/sec. This change in k_o^a can be interpreted as a change in the potential across the inner double layer which appears as a change in ϕ_2, $\Delta\phi_2 = 7.9$ mV. It appears that up to $\theta = 1$, oxygen adsorbs uniformly and is an excellent electronic conductor which simply serves as an extension of the electrode surface. The constancy of k_o^a at $1 \leq \theta = 2$ indicates no changes in the over-all structure of the interface in this region.

The influence of noble metal surface "oxides" on redox reactions has been known for some time. Davis (1) noted an increase in the standard rate constant of the vanadium(IV)-vanadium(V) reaction on platinum electrodes in the presence of surface oxides followed by a decrease in the rate constant as the oxygen coverage increased. A similar effect was shown for the oxidation of oxalic acid and the reduction of iron(III). Baker and MacNevin (2) found that heavy platinum oxides decreased the electrolysis currents for iron(II) and arsenic(III) by approximately an order of magnitude. Greef and Aulich (3) have shown that the reduction of cerium(IV) is inhibited more by platinum oxides in perchloric than in sulfuric acid.

Anson (4, 5) has explained the increased reversibility of the iron(II)-iron(III) reaction and the iodate and vanadium(V) reduction by an increase in electrode surface area due to platinization upon oxide reduction. Müller, on the other hand, pointed out that the platinum oxides themselves can have a twofold effect. At low oxide coverage they exhibit a catalytic effect on the reduction of such molecules as hydrogen peroxide (6, 7), thiosulfate (8, 9), iodate (8), hypochlorate (10), nitrous acid and hydroxylamine (8). Here the oxide effects a catalytic heterogeneous dissociative adsorption breaking or weakening the X-O or X-OH bond (X represents the main portion of the molecule) allowing reduction to proceed more readily at more anodic potentials than might ordinarily be found. As the oxide coverage increases, however, the electrochemical charge transfer is inhibited and the reduction current decreases. On the other hand, reduction of such species as cobalt(III) (8, 11) and oxygen (6, 7) is inhibited only. Thus the presence of surface oxides may have a variety of effects on the reaction of an electroactive species.

Except for the work of Davis (1) no attempts have been made to determine quantitatively the influence of oxides on the standard rate constant of an electrochemical reaction. The present work was undertaken in view of the theoretical interest attached to the effect of adsorbed layers on reaction kinetics. The system cerium(III)-cerium(IV)-gold was chosen because the cerium(III)-cerium(IV) reaction is a relatively simple one and because gold is inert in acidic solution. In addition, oxygen shows considerable hysteresis in its adsorption on gold (12, 13) and the kinetics of a redox reaction can be studied for a variety of oxygen coverages for any given equilibrium potential of the particular electrochemical reaction.

Experimental Procedure

The all-Pyrex cell was of standard design with the reference electrode compartment separated from the main cell by two ground glass stopcocks to prevent chloride contamination of the test solution. It initially contained a cylindrical platinum gauze polarizing electrode (Engelhard Industries) of approximately 100 cm^2 apparent area. Use of this electrode apparently caused platinum plating at the test electrode. The gauze was therefore plated with gold from a cyanide bath prepared according to Rosebury (14). In measurements where rapid stirring was important the gauze was removed and replaced by a gold foil electrode. The reference electrode was a saturated calomel electrode. All potentials are reported with respect to the normal hydrogen electrode.

The test electrode was a gold disk 0.071 cm^2 in apparent (geometric) area. It was made by pressure sealing a gold rod (Engelhard Industries, Fine Gold) into a Teflon mount according to Breiter (15). The

Key words: oxygen coverage, gold, kinetics of redox reaction.

test electrode was prepared by grinding with No. 1 to No. 4/0 emery paper and then polishing the surface with 600 grit alumina (Buehler). Excess alumina was removed by polishing the electrode on a clean cloth using copious amounts of water. The electrode was cleaned with warm chromosulfuric cleaning solution and rinsed thoroughly with triply distilled water before being placed in the cell. Before use all test electrodes were electrochemically "aged" by holding the potential alternately at 1.65 and −0.25V for 10 min each. The cycle was repeated three times to bring the electrode to a reproducible state.

All solutions were prepared from water first distilled from alkaline permanganate and then twice more in a Heraeus quartz still. The supporting electrolyte was 1*N* perchloric or 2*N* sulfuric acid prepared from Baker reagent grade 70% perchloric or concentrated sulfuric acid. Ultrahigh-purity perchloric acid (E. Merck Suprapur), acid-washed charcoal, and acid treated with H_2O_2 according to Visscher and Devanathan (16) did not affect the results and were therefore not used.

Cerium sulfate solutions were prepared from G. F. Smith reagent grade cerous and ceric sulfate without further purification. The 0.1*N* stock solutions were standardized with ferrous ammonium sulfate using Ferroin as an indicator (17). Cerous solutions were first oxidized with ammonium persulfate. When ceric sulfate solutions were first oxidized and then standardized, their normality was increased by 7.5%, indicating the presence of cerous ions. Test solutions were prepared volumetrically from the standardized stock solutions taking the amount of cerous ion in the ceric sulfate into account. Solutions were made with either the cerous or ceric concentration constant at 0.01*N*, varying the other between 0.01 and 0.0008*N*.

Solutions were prepared, also, using cerous sulfate which had previously been recrystallized three times from triply distilled water. These solutions were electrolyzed between gold electrodes to obtain the correct ceric concentrations for the desired equilibrium potential. In all cases the cerous concentration was 0.01*N*. The concentrations were checked by the Brucine method (18).

Cerium perchlorate solutions were prepared using G. F. Smith reagent grade cerous perchlorate salt and ceric perchlorate solution. Because perchlorates interfere with the oxidation of cerous to ceric ion with ammonium persulfate (17), silver(II) oxide was used as the oxidant (19). When the ceric perchlorate solutions were first oxidized and then standardized, the normality increased by 3.5%, again indicating the presence of cerous ion. Because of the high equilibrium potentials, E_e, in perchlorate solutions (see below) and the danger of irreversible oxidation of the gold at potentials above 1.75V, only test solutions containing 0.01*N* cerous and from 0.001 to 0.0001*N* ceric ion were used.

The solutions were purged of oxygen with a constant stream of helium (99.99% pure). This gas was purified by passing it through a 12 cm column of Linde 5A molecular sieve pellets held at −78°C. All gas lines were made of Pyrex glass and 5/16-in. Teflon tubing connected with Teflon Swageloks.

The charge necessary to remove adsorbed oxygen was determined by constant current cathodic stripping. The potential from which stripping was initiated was set with a Wenking 61TRS potentiostat allowing the potentiostat to buck the current from a Hewlett Packard 881A power supply. After waiting 10 min for the oxygen coverage to come to steady state, the potentiostat was removed from the circuit with a Western Electric mercury wetted relay (total switching time 1 msec), and the potential time curve was observed on a Tektronix 549 storage oscilloscope. The constant current from the power supply was measured with a Keithley 602 electrometer. The current density was usually 1.27 mA/cm^2 referred to the geometric area. Going in the anodic direction the electrode was first held at potentials less than 0.5V where the surface was free of adsorbed oxygen. The potential was then set to a value in the range of 1.25 to 1.75V. After 10 min at this potential, the constant cathodic current was applied and the charge due to adsorbed oxygen was obtained from the potential-time curve. Going in the cathodic direction the potential was raised from a value less than 0.5V to between 1.40 and 1.75V. The potential was held there for 10 min and was then lowered to the desired value $\geq$1.25V for another 10 min. The electrode was then stripped, and the charge obtained as before.

In order to determine the influence of cerium in solution on the charge due to the adsorbed oxygen on gold, a linear cathodic potential sweep of 50 mV/sec was applied, and the current was recorded as a function of time with a Beckman Electroscan 30. The area under the reduction peak represents the charge necessary for removal of the adsorbed oxygen.

The apparent exchange current, i_o^a, for the cerium(III)-cerium(IV) reaction was obtained at various equilibrium potentials between 1.35 and 1.50V and electrode coverages with adsorbed oxygen between $\theta = 0.7$ and 2. First, the electrode was set for 10 min at the anodic potential giving the desired electrode coverage with a Wenking 61TRS potentiostat. The potential was then lowered to about 15 mV above E_e as estimated from the Nernst equation, and the current was measured at 5 mV intervals over a range of 30 mV through E_e. These potentials could be set to within 0.1 mV using a Keithley 660 guarded differential voltmeter. The current was determined by placing a standard resistor (±0.1%) across the recorder output of the potentiostat and measuring the potential drop across it with a Keithley 602 electrometer. The apparent exchange current was then calculated from the slope of the potential-current curve taking into account the proper correction for mass transfer.

Results and Discussion

Cathodic stripping.—In preliminary work in 1*N* perchloric acid on etched disk electrodes, two types of stripping curves were found, one with arrests at 1.25V and at 0.75V, and one with only one arrest at 1.25V (20). Several aspects of the electrodes with an arrest of 0.75V were observed: (A) the total charge on the electrode surface was the same whether one or two arrests were present; (B) the length of the second arrest was not dependent on the stirring rate, indicating that it was not due to bulk solution impurity; and (C) electrodes with an arrest at 0.75V showed higher H_2 evolution currents (order of magnitude) at −0.25V than did freshly prepared electrodes. The arrest at 0.75V appeared only on electrodes that were not repolished over a period of several weeks; then if they were polished, the arrest disappeared.

Because the tendency of platinum to dissolve under mild anodic conditions has been recently recognized (21-24), contamination of the test electrode with platinum from the auxiliary electrode seemed possible. Therefore, an electrode with only one potential arrest (at 1.25V) was cathodized in a 2% solution of platinum chloride in 2*N* HCl for 10 sec at 10^{-5} A/cm^2. After potentiostating for 10 min at 1.65V and at −0.25V each several times, the arrest at 0.75V became apparent. Simultaneously, the H_2 evolution current increased from 10 to 200 mA/cm^2 at −0.25V. This is in agreement with Breiter (25), who demonstrated that as gold is made richer in platinum the activity of the electrode towards the Volmer reaction increases. Thus it appears that the arrest at 0.75V found in this laboratory (13, 20) and by other workers (26) is due to platinum deposition on the test electrode. After the auxiliary electrode was goldplated, the arrest at 0.75V was never detected and H_2 evolution currents always stayed below 10 mA/cm^2 at −0.25V. The adsorbed

oxygen is removed during cathodic stripping with 1.27 mA/cm² during a single arrest at 1.25V.

Charge-potential curves for a freshly mounted and polished gold electrode (never used in the presence of platinum) are shown in Fig. 1. The charge due to oxygen adsorption differed from electrode to electrode by ±20%. Any one electrode could be reproduced to ±5%. Each point shown was done in triplicate in 1*N* perchloric and in 2*N* sulfuric acid. There were no differences in the two media, and the results were computed together.

The charge values found here agree well with the results of other work. For example, at 1.65V they are within 10% of the data shown by Laitinen and Chao (12), Vetter and Berndt (27), and Schmid and O'Brien (13), and within 25% of those of Brummer and Makrides (26). The values of Will and Knorr (28) are some 35% higher. The hysteresis between the charge found on electrodes cathodically pretreated and those which were anodically pretreated has previously been noted by Schmid (13) and by Laitinen and Chao (12). A break at 1.45V in the curve coming from cathodic potentials is apparent in Fig. 1 at 600 μcoulombs/cm². Hickling (29) has calculated the charge equivalent of a monolayer of divalent oxygen adsorbed on gold and found it to be about 450 μcoulombs/cm². Brummer and Makrides (26) considered the break at 1.45V to be the point at which a monolayer of divalent oxygen atoms are adsorbed on the surface. Adopting this interpretation leads to the conclusion that the electrodes used here had a roughness factor of about 1.4, a reasonable value for mechanically polished electrodes. Brummer and Makrides (26) found only 400 μcoulombs/cm² for monolayer coverage. However, they were using electropolished electrodes which might be expected to have a roughness factor very close to 1.0.

Various values have been given for the potential at which oxygen adsorption on gold goes to zero. The cathodic stripping data presented here show that this potential is 1.25V, *i.e.*, adsorption at this point is less than about 25 μcoulombs/cm², the smallest charge that could be clearly measured in the present work. Brummer and Makrides (26) concluded that the surface was essentially free of oxygen below 1.3V and Huq (30) found it free below 1.2V. Laitinen and Chao (12) find oxygen adsorption at potentials as low as 0.65V. However, if one linearly extrapolates the major portion of their charge curves to zero charge, one finds a value of 1.25V. This is also the actual potential of the arrest

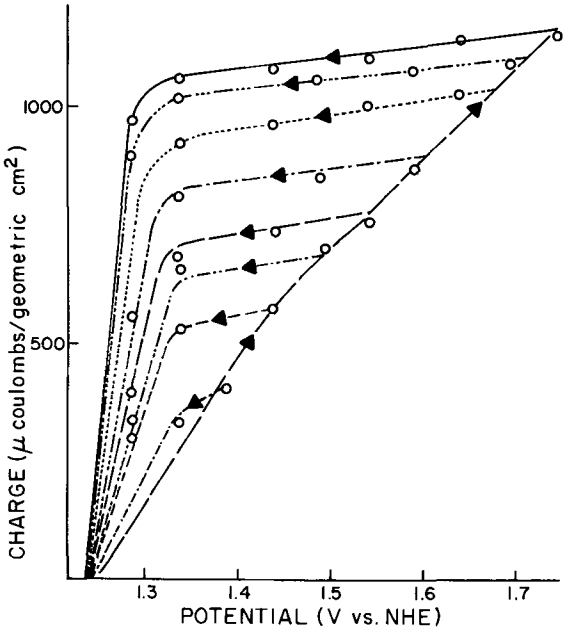

Fig. 1. Charge *vs.* potential for oxygen adsorption, Au in 1*N* $HClO_4$ and in 2*N* H_2SO_4.

in their stripping curves. The electrodes used by Laitinen and Chao were heated to 300°C. It has been noted by Clark, Dickenson, and Mair (31) that the potential arrest on annealed electrodes is followed by a region of slope much less steep than one usually associates with double layer charging. They suggest that this is due to impurities in the gold accumulated on the surface during heating. Apparently, Laitinen and Chao mistook this for oxygen adsorption. Thus, it appears that significant oxygen adsorption is absent at potentials below 1.20 to 1.30V.

The cerium(III)-cerium(IV) reaction.—The cerium redox couple shows different apparent standard potentials in solutions containing various electrolytes. Thus, in 2*N* sulfuric acid a formal potential of 1.44V is found (32). Here, cerium(IV) is complexed to $Ce(SO_4)^{++}$, $Ce(SO_4)_2$, and $Ce(SO_4)_3^{=}$, with stability constants of 3500, 200, and 20, respectively (32, 33). Therefore, virtually all the cerium(IV) is in the form of $Ce(SO_4)_3^{=}$ and the activity of the free cerium(IV) ion is considerably less than its formal concentration. Also, about half of the total cerium(III) in solution undergoes complexation to $Ce(SO_4)^{+}$ (32, 34). On the other hand, in 1*N* perchloric acid the formal potential is about 1.70V (32). This higher value is due to the fact that neither cerium(IV) nor cerium(III) forms complexes with the perchlorate ion. Instead cerium(IV) hydrolyzes to $Ce(OH)^{+3}$ which dimerizes to $CeOCe^{+6}$, the stability constant being 5.2 and 6.5, respectively (32, 35). Cerium(III) apparently does not undergo any reaction in perchloric acid (32). This difference in the formal potentials between a sulfuric acid and a perchloric acid solution makes reaction kinetic studies possible in various regions of oxygen coverage and was used to advantage in this study.

Effect of cerium ion on electrode coverage.—Results from potential sweep measurements showed an 11% reduction in the charge associated with the oxygen reduction peak in cerium-containing solutions as compared to blank acid solutions. This is within the error limits of the experimental procedure used in view of a 5% reproducibility in the charge on the electrode (stripping curve measurements), a 5% reproducibility in peak area measurements, and a 5% reproducibility of the Electroscan. It appears, then, that the oxygen coverage of the gold electrode is determined only by the potential pretreatment of the electrode and is independent of the cerium concentration in solution. Greef and Aulich (3) obtained an identical result on platinum. They concluded also that cerium had essentially no effect on oxygen adsorbed on their electrodes.

The apparent exchange current.—The polarization resistance, R_p, was obtained as the slope of the potential-current curves at zero overvoltage. It is thought to be composed of a charge transfer resistance, R_t, and a diffusion resistance, R_d, according to

$$R_p = R_t + R_d$$

$$= \frac{RT}{n\mathbf{F}}\left(\frac{1}{i_o{}^a}\right) + \frac{RT}{n\mathbf{F}}\sum^{j}\left|\frac{\nu_j}{i_{d,j}}\right|$$

where ν_j and $i_{d,j}$ are the stoichiometric factor and diffusion limiting current of species j. From this the apparent exchange current, $i_o{}^a$, was found as a function of oxygen coverage of the electrode by appropriate selection of the initial anodic potential of the electrode. As can be seen in Fig. 1, the coverage initially set at potentials >1.30V is retained down to 1.30V and, therefore, for a given E_e in the range from 1.75 to 1.40V various initial coverages could be chosen. All values for $i_o{}^a$ were averaged from three separate determinations.

The results of these experiments are shown in Fig. 2-4. All values are given in terms of the true area by using the roughness factor of 1.4 previously obtained. The reproducibility of $i_o{}^a$ in all sulfate solutions was

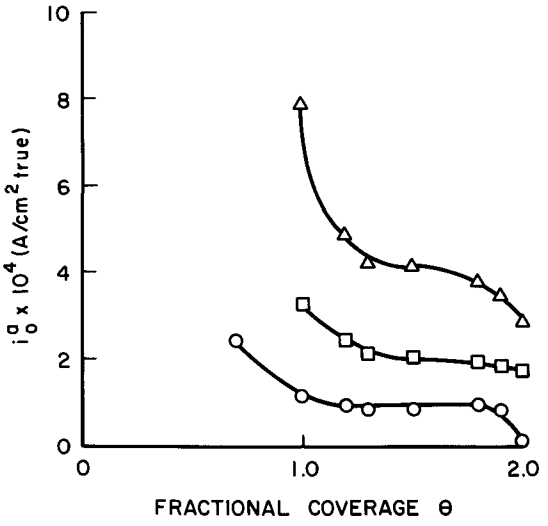

Fig. 2. Apparent exchange current, i_o^a, vs. coverage, Au in 2*N* H_2SO_4 with 0.01*N* Ce(III) and △: 1 x 10^{-2}, □: 5 x 10^{-3}, and ○: 1 x 10^{-3} *N* Ce(IV) sulfate (recrystallized).

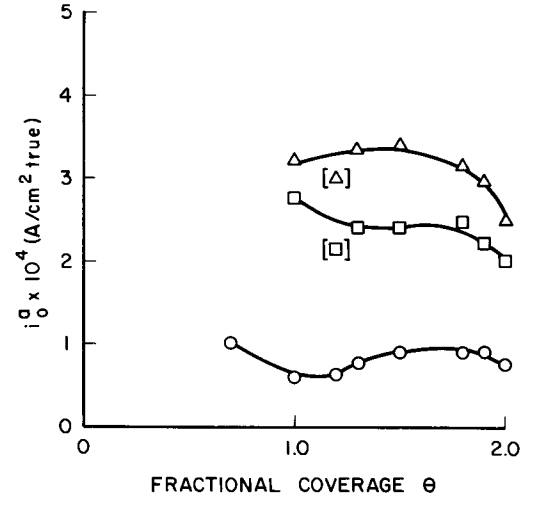

Fig. 3. Apparent exchange current, i_o^a, vs. coverage, Au in 2*N* H_2SO_4 with 0.01*N* Ce(III) and △: 1 x 10^{-2}, □: 5 x 10^{-3}, and ○: 1 x 10^{-3}*N* Ce (IV) sulfate.

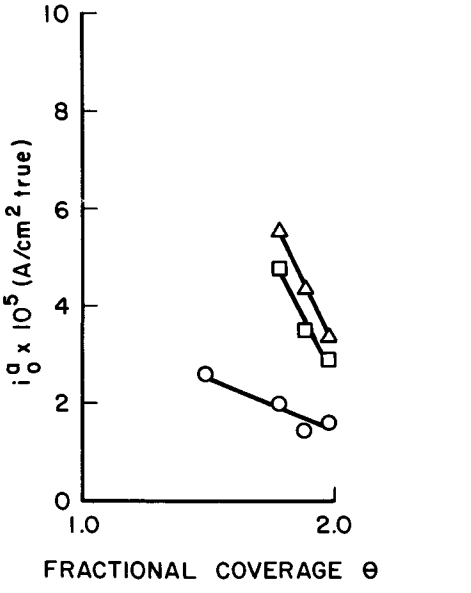

Fig. 4. Apparent exchange current, i_o^a, vs. coverage, Au in 1*N* $HClO_4$ with 0.01*N* Ce(III) and △: 1 x 10^{-3}, □: 3 x 10^{-4}, and ○: 1 x 10^{-4} *N* Ce(IV) perchlorate.

better than ±6%. Agreement between recrystallized and unrecrystallized salts was good. A slight depression which appears in the i_o^a for unrecrystallized salts (Fig. 3) at $\theta = 1.2$ is not significant and is probably due to the adsorption of impurities. The i_o^a with cerium(IV) = 0.01*N* is smaller by a factor of 0.8 in unrecrystallized salts as compared with the recrystallized ones. This is possibly due to the greater amounts of impurities introduced in unrecrystallized solutions. In perchlorate solutions, due to the large E_e potentials, the i_o^a could be obtained only for coverages of $\theta = 1.5$ to 2.0. The relative standard deviation there was less than ±5%

The charge transfer coefficient.—The anodic charge transfer coefficient, α, was obtained using the expressions (36)

$$(\partial \log i_o^a/\partial E_e)_{c_r} = \alpha \mathbf{F}/2.3RT$$

and

$$(\partial \log i_o^a/\partial E_e)_{c_o} = -(1-\alpha)\mathbf{F}/2.3RT$$

where c_o and c_r are the concentrations of the oxidized and the reduced species, respectively. Thus, α is obtained from the slope of plots of log (i_o^a) *vs.* E_e, keeping either c_r or c_o and the coverage with adsorbed oxygen constant. One such plot is shown in Fig. 5 for θ — 1.3, the coverage set at 1.55V. The slope was determined by a least squares analysis (37), assuming E_e to be known precisely. At a 70% confidence level $\alpha = 0.65 \pm 0.06$ for all values of θ between 0.7 and 2 in both sulfuric and perchloric acid.

Values of α for the cerium(III)-cerium(IV) reaction have been reported by other authors. Galus and Adams (38) determined α to be 0.79 and 0.72 on platinum and carbon paste electrodes, respectively. Vetter (39) determined α to be 0.75 on platinum. The charge transfer coefficient found here is somewhat less but not significantly so. This indicates that the mechanism of the cerium reaction is essentially independent of the electrode material.

The constancy of α with oxygen coverage found here is in agreement with the results obtained on other systems. Davis (1) found no change in α with the extent of oxygen coverage of a platinum electrode for either the vanadium(IV)-vanadium(V) or arsenic(III)-arsenic(V) couples. This same phenomenon has also been found with adsorption of organic species. Aramata and Delahay (40) found that α for the zinc(II) discharge on a zinc amalgam electrode was not affected by coverage with n-amyl alcohol. Biegler

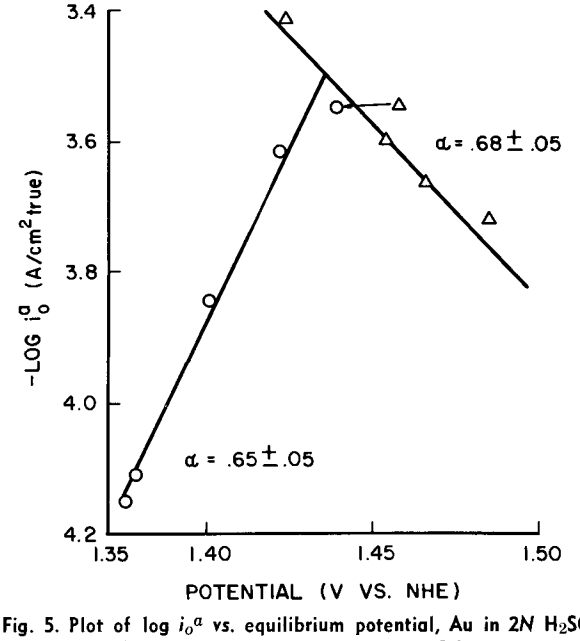

Fig. 5. Plot of log i_o^a vs. equilibrium potential, Au in 2*N* H_2SO_4 with Ce(III)/Ce(IV) sulfate, oxygen coverage $\theta = 1.3$.

and Laitinen (41) concluded that for the discharge of cadmium(II), α possibly decreased slightly on mercury, but this conclusion is not at all certain. On the other hand, Müller (10) found that for hypochlorate reduction on platinum α decreases with coverage.

The standard rate constant.—From the data for i_o^a and α, the standard rate constant, k_o^a, was calculated using the equation (36)

$$i_o^a = n\mathbf{F}k_o^a c_r^{(1-\alpha)} c_o^{\alpha}$$

with $\alpha = 0.65$. The concentrations c_r and c_o were taken as their bulk values since the diffusion-limiting currents (not shown) are the same in both sulfuric and perchloric acid and approximately of the magnitude expected from the analytical concentration of cerium(III) and cerium(IV) in solution. Thus, even though the equilibrium potential is dependent on the activity of free cerium, all the cerium is available when needed for reaction. This means that there is no limiting chemical reaction step and kinetic parameters may be calculated on the basis of bulk concentrations.

Values of k_o^a *vs.* oxygen coverage are given in Fig. 6. Each point on this curve was averaged from five values in sulfates and four values in recrystallized sulfates and perchlorates corresponding to the different cerium(III)-cerium(IV) ratios obtained for each coverage. The relative standard deviation was ±7% in unrecrystallized sulfates and ±17% in recrystallized sulfates and perchlorates.

It is seen that in sulfates k_o^a is approximately constant at 4 x 10^{-4} cm/sec above $\theta = 1.0$, *i.e.*, above monolayer coverage with oxygen. This can be compared to $k_o^a = 3.7 \times 10^{-4}$ cm/sec (38) and 4.8 x 10^{-4} cm/sec (39) found on platinum and $k_o^a = 3.8 \times 10^{-4}$ cm/sec (38) on carbon paste electrodes. The similarity between k_o^a found on different electrode surfaces indicates that the energy of activation is essentially independent of the electrode surface for the cerium(III)-cerium(IV) reaction. In perchlorates k_o^a appears to decrease from $\theta = 1.5$ to 2.0. However, this is still within experimental error and may not be significant. Further, the point at 1.5 is based on limited data so that speculation seems tentative.

The presence of adsorbed oxygen can have several effects on an electrochemical reaction. (*i*) It can cause a change in $\Delta\phi_c$, the potential drop across the compact double layer, and since the electrode potential is kept constant, this will result in a change in ϕ_2, the potential drop across the diffuse double layer. This changes the electric field and would directly affect k_o^a but not α. (*ii*) Alternatively, the presence of adsorbed oxygen could result in a change in the position of the effective plane at which the reaction occurs, leaving the electric field unchanged. This would lead to a change in the fraction of $\Delta\phi_c$ effective on the activation energy and would thus change α. (*iii*) It could cause a change in both $\Delta\phi_c$ and the effective plane of the reaction. This would cause a change in both α and k_o^a. Finally, (*iv*) a change in the reaction mechanism may lead to a change in α and k_o^a.

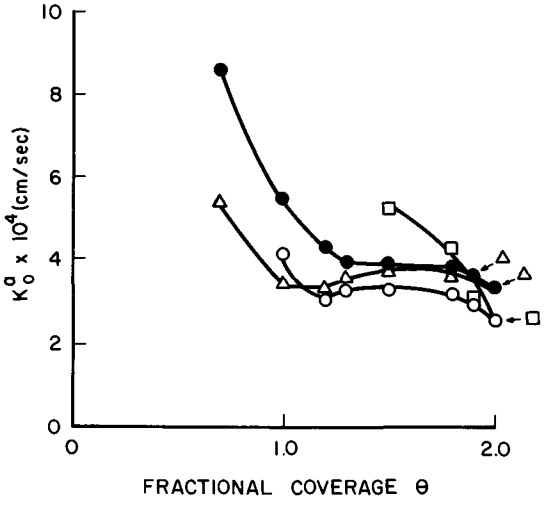

Fig. 6. Standard rate constant for the Ce(III)/Ce(IV) reaction on Au as a function of coverage with oxygen. ●: Recrystallized sulfates, Ce(III) = 0.01*N*, ○: sulfates, Ce(III) = 0.01*N*, △: sulfates, Ce(IV) = 0.01*N*, □: perchlorates, Ce(III) = 0.01*N*.

The results presented here indicate that α is independent of coverage, and possibilities *ii*, *iii*, and *iv* can therefore be discarded. This means, as a first order approximation, that there is no change in the reaction mechanism and that the plane of the reaction is not affected by the adsorbed oxygen, at least not with respect to the potential across the compact double layer. Because k_o^a does decrease, however, there must be a change in $\Delta\phi_c$ with a concomitant change in ϕ_2.

This change in ϕ_2 can be estimated from the following consideration. Assuming that there is an apparent standard rate constant for oxygen covered surfaces, k_o^a, and one for bare surfaces, $k_o^{a'}$, then the latter can be obtained to a first order approximation by linear extrapolation to $\theta = 0$ of the plot in Fig. 6. Thus, $k_o^{a'} \approx 12 \times 10^{-4}$ cm/sec. Then, writing

$$k_o^a = k_o^t \exp\left[-(z_r + \alpha)\mathbf{F}/RT\ \phi_2\right] \qquad (36)$$

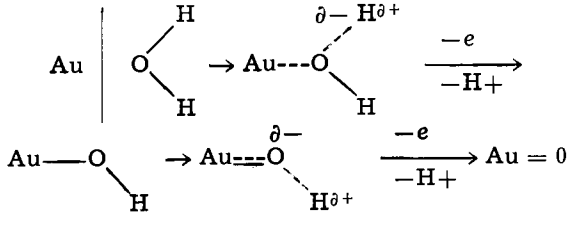
and

$$k_o^{a'} = k_o^t \exp\left[-(z_r + \alpha)\ \mathbf{F}/RT\ \phi_2'\right]$$

where k_o^t is the true standard rate constant and z_r is the charge of the reduced species, one obtains $\Delta\phi_2 = \phi_2 - \phi_2' = 7.9$ mV as the difference in $\Delta\phi_c$ between a bare surface and an oxygen-covered surface at any given potential E.

This small change in $\Delta\phi_c$ indicates that the adsorbed oxygen is a good electronic conductor which contributes only little to the potential drop in the compact double layer. The adsorbed oxygen then acts simply as an extension of the electrode surface, and the double layer forms outside the adsorbed oxygen atoms as usual. Thus, the over-all potential drop effective on the electrochemical reaction is the same as before, less a small potential drop of a few millivolts in the adsorbed oxygen layers.

The gradual decrease in k_o^a up to $\theta = 1.1$ indicates a uniform adsorption of oxygen over the gold surface. This occurs possibly by a continuous transition with increasing potential from adsorbed water to adsorbed oxygen, with little difference in the electron



exchange through adsorbed water, adsorbed hydroxyl radical and/or adsorbed oxygen.

The constancy of k_o^a at higher coverages where $\theta > 1$ indicates that once a monolayer is formed further adsorption has little effect on the reaction rate. This argues that there is little change in the over-all structure of the interface in this range.

Conclusion

The adsorption of oxygen on gold electrodes in 1*N* perchloric acid and in 2*N* sulfuric acid was measured as a function of potential and potential-prehistory using constant current cathodic stripping. Coming from potentials <1.20V, oxygen uptake begins at 1.25V. A slight inflection in the charge-potential curve at 600 μcoulombs/cm^2 (1.45V) is thought to indicate monolayer coverage and corresponds to an electrode roughness factor of 1.4. A coverage of $\theta = 2$ is reached at 1.75V. Coming from potentials ≧1.35V the cover-

age with adsorbed oxygen is essentially independent of potential down to 1.35V. The electrode is free of adsorbed oxygen at $\leq$ 1.20V. Potential arrests found in cathodic stripping curves below 1.20V are probably due to platinum deposition on the gold electrode, either from solution or from the interior of the electrode.

The kinetic parameters of the Ce(III)/Ce(IV) reaction on gold in 1*N* perchloric acid and in 2*N* sulfuric acid were obtained at coverages $\theta = 1.5$-2.0 and $\theta = 0.7$-2.0, respectively. Apparent exchange current densities, i_o^a, were calculated from potentiostatic low overvoltage data. The anodic charge transfer coefficient, α, was determined, at constant coverage, from the slope of plots of log i_o^a *vs.* the equilibrium potential at constant Ce(III) or Ce(IV) concentration. At the 70% confidence level $\alpha = 0.65 \pm 0.06$. Apparent standard rate constants, k_o^a, were calculated from i_o^a and α to $k_o^a \approx 4 \times 10^{-4}$ cm/sec, independent of coverage $1 \leq \theta \leq 2$. Extrapolation of the data to $\theta = 0$ yields $k_o^{a'} \approx 12 \times 10^{-4}$ cm/sec.

The slight change in k_o^a in going from $\theta = 0$ to $\theta = 1$ (at constant potential) is considered to be due to a change in the potential drop across the inner double layer caused by the adsorbed oxygen accompanied by a corresponding change in the potential across the diffuse double layer, ϕ_2. The latter can be calculated to 7.9 mV. Once monolayer coverage has been reached, further adsorption to $\theta = 2$ does not change the potential drop across the double layer.

It seems that the adsorbed oxygen on gold in acidic solution, as far as the Ce(III)/Ce(IV) reaction is concerned, is an excellent electronic conductor, contributes only little to the potential drop across the inner double layer, and simply serves as an extension of the electrode surface. There is little discernible change at $1 \leq \theta \leq 2$ and this suggests no change in the over-all structure of the interface in this region.

Correction

In the paper "Oxygen Reduction on Oxide-Free Platinum in 85% Orthophosphoric Acid: Temperature and Impurity Dependence" by A. J. Appleby which appeared on pp. 328-335 in the March 1970 JOURNAL, Vol. 117, No. 3, on p. 333, Eq. [1] should read

$$i_{\text{forward}} = \mathbf{F}\frac{kT}{h}(\theta^{\bullet})[\mathrm{H}^+]\left(\exp -\frac{[\Delta G^{\neq} + (1-\beta)(\Delta G_p - \Delta G_r)]}{RT}\right)\cdot\exp -\left(\frac{(1-\beta)\mathbf{F}V}{RT}\right) \quad [1]$$

Oxygen Reduction and Corrosion Kinetics on Phase-Oxide-Free Palladium and Silver Electrodes as a Function of Temperature in 85% Orthophosphoric Acid

A. J. Appleby*

Institute of Gas Technology, Chicago, Illinois 60616

ABSTRACT

Oxygen reduction on oxide-free palladium and silver surfaces has been studied as a function of temperature in purified 85% orthophosphoric acid. In each case, oxygen reduction is first order, and available evidence suggests that on both metals the reaction

$$O_2 + H_3O^+ + e^- \rightarrow (O_2H)$$

is the rate-determining step. Experimental activation energies, extrapolated to the reversible oxygen electrode potential, are 22.4 ± 2.0 kcal on palladium and about 26 kcal on silver. Activity of the palladium electrode is only slightly (< one decade) less than on platinum under the same conditions, whereas silver is even less active than gold. On palladium, as with platinum, the extrapolated activation energy includes a heat of adsorption term corresponding to the effect of Temkin-type equilibrium adsorption of —O species derived from water oxidation, which are present on the electrode under the experimental conditions. This term may be eliminated by considering activation energies extrapolated to potentials at which —O adsorption is small, where an activation energy difference between silver and palladium on the order of 9.8 kcal occurs. This suggests that the intermediate (O_2H) is relatively strongly adsorbed on palladium and only weakly on silver, and accounts for the rate difference on the two metals.

Rest potentials of the metals are corrosion mixed potentials and the metal dissolution reaction is fast in both cases so anodic processes are under Nernstian control. Palladium passivates at potentials greater than 900 mV HRE. No passivation of silver was observed.

Studies on oxygen reduction on silver and palladium electrodes in acid solution have been reported relatively infrequently in the literature.

On silver, Krasil'shchikov (1, 2) reported a *p*H-independent mechanism in neutral and acid solutions down to *p*H 2, and suggested that under these conditions the reaction

$$O_2 + e^- \rightarrow O_2^-$$

is rate-determining. Akopyan (3) reported the effect of temperature on the electrode reaction and Nikulin (4) showed the specific effect of single crystal faces on oxygen reduction. Bianchi *et al.* (5, 6) have shown that silver electrodes give Tafel slopes for oxygen reduction of 2 $RT/\mathbf{F}$ in 0.5M H_2SO_4 at overvoltages even higher than those for gold (7) under similar conditions. Again, *p*H-dependence was shown to be small (5) at least in the neutral *p*H range thus confirming Krasil'shchikov's mechanism (1, 2).

Palous and Buvet (8) also examined oxygen reduction on silver over a wide *p*H range. Their results show an H^+ dependence for the reaction in the *p*H range 0-2, with no *p*H dependence at higher *p*H. Hydrogen peroxide has been detected as a reaction product (1-3, 5).

In contrast with acid solution the amount of work reported on silver oxygen electrodes in alkaline solution is considerable and has been reviewed (9, 10).

Oxygen reduction on palladium electrodes was reported by Sawyer *et al.* (11, 12) to resemble that on platinum in acid solution. In oxygen-saturated 2*N* H_2SO_4 solution Hoare (13, 14) reported rest potentials of palladium electrodes of about 870 mV HRE and potentiostatic Tafel plots of slope 102 mV/decade (14) for oxygen reduction on electrodes that had been anodized, then reduced. Damjanovic *et al.* (15-17) indicated that Tafel behavior of oxide-free palladium and platinum in dilute $HClO_4$ was almost identical, although palladium electrodes were about 50 mV less active than corresponding platinum electrodes. This and other considerations, for instance, —O adsorption character (18), suggest similarity of rate-determining step, which is supported by ring-disk electrode experiments using the two metals (19).

In this paper, oxygen reduction on and corrosion behavior of phase-oxide-free palladium and silver electrodes are studied in 85% orthophosphoric acid as a function of temperature.

Experimental Techniques

The present series of experiments was conducted in an all-silica cell (20) using the same galvanostatic technique as in previous work (21). Temperatures were maintained to ± 0.2°C by means of an oil bath or a refrigerated bath, as appropriate.

The electrodes used were palladium and silver foils of 99.99% purity, with areas of approximately 1 cm^2. The palladium foils were welded to gold wires and were hung in the cell in Teflon sliding seals as described in previous experiments (20). The silver foils were similarly suspended in a separate series of experiments, although in this instance silver wires were used.

A gold counterelectrode was used in all experiments to avoid the possibility of contamination of working electrodes with electroactive deposits (as is the case if platinum is used). For the same reason, the electrolyte (85% orthophosphoric acid) was not given pre-electrolytic purification treatment before being used in the cell. Cleaning of the solution was done by refluxing several times with 5% hydrogen peroxide, followed by distillation of the excess water.

* Electrochemical Society Active Member.

Key words: oxygen reduction, corrosion, palladium, silver.

Oxygen or oxygen-nitrogen mixtures were supplied to the cell via presaturators from a capillary flowmeter gas mixing system and a purification train.

A dual isothermal bubbling hydrogen-85% phosphoric acid reference electrode was used, to which all potentials throughout this paper are referred (HRE potentials).

Results

Palladium electrodes.—Oxygen reduction data.—The palladium foil electrodes were degreased with organic solvents and washed with concentrated HCl, conductivity water, and the electrolyte itself before use. They were then potentiostated for a short time in oxygen-saturated electrolyte at 22.0°C at 350 mV HRE to reduce any residual oxide. After this preparation, electrodes took up rest potentials in the range 895-898 mV; these rest potentials fell by about 10 mV after 1-2 hr, thereafter remaining constant. A descending cathodic galvanostatic steady-state Tafel plot was then made on each electrode, allowing sufficient time (5-15 min) between points for a final potential to be set up at each applied current density that varied by less than 1 mV/min. This polarization study was followed by a similar ascending plot. These have been shown in Fig. 1 as "initial" Tafel plots. Results were very reproducible, and Tafel lines could be accurately retraced forward and backward.

Cathodic Tafel plots were also obtained by means of the pulsing technique used in previous work (21). Before each point was taken, the electrode was given a series of anodic and cathodic galvanostatic pulses to ensure that a surface in a reproducibly clean condition was present. Potentials were read after 2 min at each current density.

Pulses for palladium were restricted to +850-+200 mV HRE. At the high potential, some dissolution starts to occur. Below about +200 mV palladium starts to occlude large quantities of hydrogen. The plot for the palladium surface in this clean condition is shown in Fig. 1. The electrode is only slightly less active than platinum under the same conditions and has a similar Tafel slope ($\sim RT/\mathbf{F}$).

Corrosion behavior.—Corrosion behavior was tested by means of a steady-state anodic plot (Fig. 1). A Tafel plot was obtained with the low slope of $RT/2\mathbf{F}$ in the anodic direction. The slope led into what was apparently a diffusion current at about $i = 3.5 \times 10^{-6}$ A/cm². Corrosion currents were estimated by extrapolation of anodic and cathodic Tafel plots to their point of intersection (represented by dashed lines in Fig. 1).

The electrolyte in the cell was replaced after each series of anodic polarization studies on the electrode.

Temperature dependence.—Results were repeated at 52.0°, 76.0°, and −3.0°C. Although the freezing point of 85% orthophosphoric acid is normally quoted as being 21.1°C, it may be supercooled to a very viscous liquid at well below 0°C (22). Results obtained are shown in Fig. 2-4. In the anodic polarization experiments, no passivation was observed at 76.0°C, whereas at the other temperatures studied the onset of passivation occurred at a potential of about 900-930 mV. At −3.0°C no definite corrosion behavior was seen in the anodic plot, and anodic currents above 4.0×10^{-8} A/cm² resulted in passivation. Under these conditions, palladium exhibits a behavior like that of platinum.

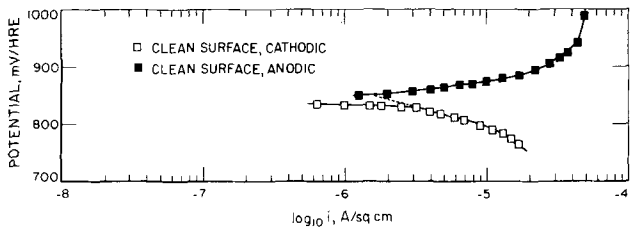

Fig. 2. Cathodic reduction of oxygen on palladium and anodic production of Pd^{++} at 52.1°C.

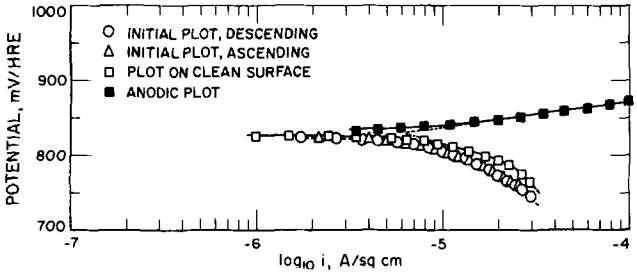

Fig. 3. Cathodic reduction of oxygen on palladium and anodic production of Pd^{++} at 76°C.

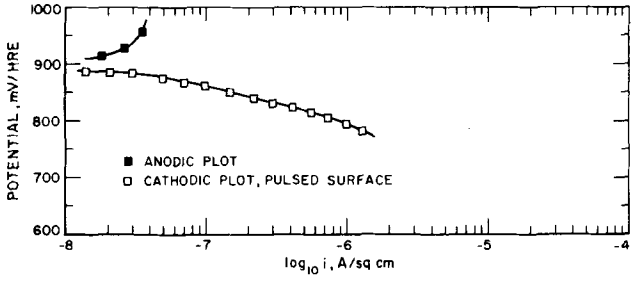

Fig. 4. Cathodic reduction of oxygen on palladium at −3.0°C

Tafel slopes and $1/\alpha$ values for the oxygen reduction reaction together with values of the exchange current obtained by extrapolation of the Tafel line to the reversible potential at each temperature are given in Table I. Similarly, data for the anodic dissolution reaction are given in Table II. The corrosion current and the corrosion potential are in each case obtained from the intersection of the extrapolated anodic and cathodic Tafel plots.

Order of reaction in oxygen reduction.—A series of experiments was carried out on the same palladium foil electrode using oxygen partial pressures of 1.0, 0.26, 0.080, and 0.025 atm at 22.0°C.

The pulsing procedure mentioned previously was used before each point to ensure that a reproducible

Table I. Oxygen reduction on palladium

−3.0	—	—	1.7×10^{-8}	905
22.0	31	0.53	1.7×10^{-7}	888
52.1	32	0.50	1.6×10^{-6}	849
76.0	35	0.51	6.3×10^{-6}	830

surface was present. Results obtained are shown in Fig. 5, which also includes an anodic plot obtained at 0.025 atm oxygen partial pressure.

Inspection of the data indicates that oxygen reduction approximates to first order at constant potential (Fig. 9).

Activation energy for oxygen reduction on palladium.—Figure 6 shows an Arrhenius plot of extrapolated i_0 values on oxide-free palladium, corrected to 1 atm oxygen partial pressure. Activation energy at the reversible potential is 22.4 ± 2.0 kcal, close to the values previously reported on oxide-free rhodium (22.0 kcal) and platinum (22.9 kcal).

Silver electrodes.—Silver foil electrodes were degreased, welded to silver wires, and mechanically polished using graded alumina powders. They were then washed in dilute nitric acid and lightly etched in a dilute hydrogen peroxide-ammonium hydroxide solution. Preliminary experiments established that electrodes prepared in this way gave high results when cathodically polarized, with nonstirring-dependent reduction currents that were in excess of the limiting current for the oxygen reduction in the electrolyte. These high currents were apparently due to the reduction of passivating silver oxides and oxygen dissolved in the silver foil; such electrodes exhibited rest potentials 100-200 mV higher than the eventual corrosion potentials. The electrodes showed a limiting behavior after cathodic polarization for 5-8 hr at 2.0 μA/cm^2, after which consistent cathodic oxygen reduction Tafel plots could be obtained. Under these conditions the rest potential (corrosion potential) of the silver electrode was 360-365 mV HRE at 22°C. An alternative preparation procedure, involving heating the etched electrode in a stream of hydrogen at 330°-400°C for 5-10 min followed by cooling under hydrogen, gave electrodes with the same properties as those that have been electrochemically reduced. The oxygen electrode and corrosion behavior reported here refer to electrodes that have been prepared by final treatment in hydrogen.

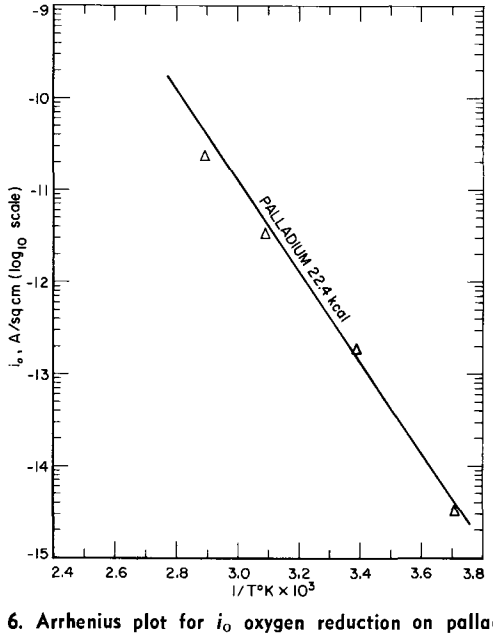

Fig. 6. Arrhenius plot for i_0 oxygen reduction on palladium in 85% orthophosphoric acid.

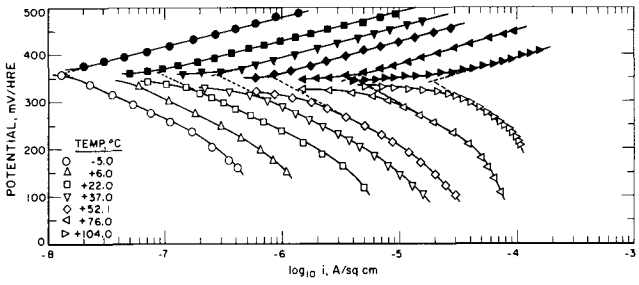

Fig. 7. Temperature dependence of cathodic reduction of oxygen and anodic production of Ag^+ on silver in 85% orthophosphoric acid.

Oxygen reduction data.—Hydrogen-reduced electrodes took up rest potentials of 340-345 mV HRE at 104.0°C to 362-365 mV HRE at −5.0°C in the oxygen-saturated electrolyte. A galvanostatic descending Tafel plot was started immediately on immersion. As in the case of the experiments on palladium electrodes, the silver electrodes were left for sufficient time (2-5 min at each applied current density) for stabilization of the potential to within 1 mV change in 1 min. These plots could be traced forward and backward several times with little hysteresis. Potentials, once established at any given current density, were very stable and showed no tendency to decay. Preliminary pulsing of the electrode galvanostatically between 50 mV HRE and open circuit caused no changes in the Tafel plot. Silver is thus insensitive to impurity deactivation when acting as an oxygen reduction surface in acid solution. Previous work has demonstrated that gold is also essentially unaffected by impurity adsorption (23).

Tafel plots on different silver electrodes were generally within 10 mV at the same current density, the differences between individual electrodes being temperature independent. A series of Tafel plots for a typical hydrogen-reduced electrode is shown in Fig. 7; kinetic data as a function of temperature are given in Table III.

Corrosion behavior of silver electrodes.—After completion of the oxygen reduction tests on the above electrode a series of plots was carried out to show the anodic behavior of the electrode as a function of temperature. Ascending galvanostatic Tafel plots were made at each temperature, starting from the open-circuit potentials of the electrode, using a freshly prepared electrolyte for each plot. At each applied current density a stable potential was very rapidly attained (within 30 sec. at the lowest current densities

104.0	72	0.96	2.0×10^{-5}	344

studied, within a few seconds at 10^{-5} A/cm²), and no sign of passivation was observed. Normally the electrolyte was gently stirred with oxygen at the rate of 20 ml/min, and it was noted that the potentials achieved at each current density were somewhat dependent on the rate of stirring, as was the case with palladium. Table IV gives data on the corrosion potential and corrosion current obtained by extrapolation of anodic and cathodic Tafel lines, together with anodic Tafel slopes and $1/\alpha$ values as a function of temperature.

Order of reaction for oxygen reduction.—Tafel plots were obtained on a silver electrode at oxygen partial pressures of 1.0, 0.26, 0.080, and 0.025 atm at 22.0°C. The plots obtained are shown in Fig. 8, which includes an anodic plot at the lowest oxygen partial pressure studied. The limiting current region of the plot at 0.025 atm merges with the plot for the hydrogen evolution reaction.

A log pO_2-log i plot at constant potential is given for the Tafel region of both palladium and silver electrodes in Fig. 9. In both cases the oxygen reaction order is close to unity.

Activation energy for oxygen reduction on silver.—Because of the difficulty of extrapolation over many decades of current density back to the theoretical reversible oxygen potential, activation energy for oxygen reduction has been estimated by plotting the current densities at an overpotential within the measurement range, at $\eta = 960$ mV (300 mV HRE at 22°C). Current densities have been corrected to 1 atm oxygen partial pressure.

An Arrhenius plot on this basis is shown in Fig. 10. Activation energy is 15.5 ± 0.8 kcal under these potential conditions. Tafel slopes for the oxygen electrode on silver have close to theoretical temperature dependence; the mean slope is 2.07 $RT/\mathbf{F}$. Consequently, assuming the same reaction is still rate determining at the reversible potential, we may expect that the activation energy at $\eta = 0$ to be $15.5 + \alpha\eta\mathbf{F}$ kcal.

For $\alpha = 1/2.07$ and $\eta = 0.96$V, $\alpha\eta\mathbf{F} \sim 10.7$. Thus the activation energy at the reversible potential should be about 26.7 kcal on silver for the primary charge transfer step. This is somewhat greater than the value previously determined (23) on gold electrodes (23.6 kcal).

Discussion

Corrosion of palladium and silver.—Tables II and IV indicate that the anodic log current-potential plots on palladium and silver have slopes of $RT/2\mathbf{F}$ and $RT/\mathbf{F}$, respectively.

Because of the stirring dependence of the plots and the fact that the dissolution reaction in silver has been shown by Gerischer and Tischer (24) to have an exchange current considerably in excess of the current range explored here, it is reasonable to suppose that the reactions on both metals are diffusion controlled.

In such a case we can write for the anodic process

$$E = E_0 + \frac{RT}{z\mathbf{F}} \ln [X^{z+}]$$

where E_0 is the standard potential of the electrode, and X^{z+} is the concentration of the ion of valence z produced in the double layer by anodic dissolution.

If the reaction is under diffusion control

$$X^{z+} = \frac{\delta}{DzF}(i_a + i'_c) = k\,(i_a + i'_c)$$

where i_a is the imposed anodic current at potential E, and i'_c is the current due to the cathodic process (oxygen reduction) under the same conditions. In this expression D is the diffusion coefficient of X^{z+} and δ is the thickness of the Nernst diffusion layer. The other symbols have their usual meanings. Thus

$$E - E_o = \frac{RT}{zF} \ln [k(i_a + i'_c)]$$

As

$$i'_c = i_c \exp - \frac{\alpha F}{RT}(E - E_o)$$

where α is the transfer coefficient for the oxygen reduction reaction, and i_c is the rate of the oxygen reduction reaction at potential E_o, we obtain

$$i_a = \frac{1}{k} \exp \frac{zF}{RT}(E - E_o) - i_c \exp - \frac{\alpha F}{RT}(E - E_o)$$

This expression has a similar form to the Butler-Volmer equation, and the right-hand term may be discarded at comparatively small values of $E - E_o$, when

$$\partial E/\partial \ln i_a = RT/zF$$

The experimental Tafel slopes are close to RT/F for silver and $RT/2F$ for palladium, indicating dissolution as Ag^+ and Pd^{++} ions or complexes with the same oxidation number. The passivation of Pd at about 900 mV appears to be due to the formation of a film of $Pd(OH)_2$ (25) or PdO. Corrosion of palladium under these conditions is a result of its lower lattice energy compared with that of platinum.

Oxygen reduction reaction.—Palladium.—Palladium has a low Tafel slope for oxygen reduction ($\sim RT/F$) and in this respect resembles platinum (21, 26) and rhodium (27). On all three oxide-free metals oxygen reduction has been determined to be first order at constant potential (21, 26, 27), implying that the stoichiometric number (υ) of the rate-determining step is unity. It has been shown previously that an RT/F Tafel slope with $\upsilon = 1$ is not explicable if Langmuirian adsorption of reaction intermediates is assumed. In the case of rhodium and platinum electrodes in the phase-oxide-free state, a mechanism has been proposed in which the heat of adsorption of the product of the rate-determining step (—O_2H) falls as the total coverage of —O and —OH radicals derived from water oxidation rises (26). The coverage of —O and —OH rises linearly with potential (26) and the experimental coverage potential data are explained in terms of an isotherm in which adsorbed molecules are considered immobile and in which interaction effects are accounted for in the second virial coefficient (Frumkin isotherm or in the coverage range $0.1 < \theta < 0.9$, the Temkin isotherm). When such an isotherm operates, it effects the heat of adsorption of all adsorbed species on the electrode (28). A similar explanation of the effect of adsorbed anions on the hydrogen evolution reaction, which assumes that the chemical potential of the activated complex in the charge-transfer reaction depends on the second virial coefficient for the adsorption of the adsorbed anion, was recently provided by Parsons (29).

On this basis it can be shown that the observed Tafel slope and oxygen reaction order, together with the pH dependence at constant ionic strength, are consistent with theory (21, 26, 27). In view of the resemblance of linear potential-scan oxygen pseudocapacitance data on platinum (30, 31) and rhodium (32) to that on palladium (32) in acid solution, all of which may be accounted for by Temkin behavior (31), it is reasonable to suppose that the reaction

$$O_2 + H_3O^+ + e^- \rightarrow (O_2H)_{ads}$$

is also rate-determining on palladium. This view is supported by the similar experimental activation energies at the reversible potential on palladium, 22.4 kcal (27), and platinum, 22.9 kcal (21), for the oxygen reduction reaction.

Silver.—On silver, —O and —OH equilibrium coverage (from water oxidation) in the potential range where experimental measurements were made may be expected to be low because the electrode potential under these conditions was ~850 mV lower than the reversible potential for oxide formation (33). In alkaline solution, silver and gold electrodes show almost indistinguishable cyclic voltammetric scans (34), so on this basis a generally similar —O adsorption behavior would be expected, with low coverage (Langmuir conditions) on both metals.

Experimental Tafel slopes on silver are approximately $2RT/F$, and again oxygen reduction is first order. As has been shown for gold and iridium (23), these data are consistent with a primary charge transfer under Langmuir adsorption conditions. Thus the two possible rate-determining steps on this metal are

Reaction A: $O_2 + H_3O^+ + e^- \rightarrow (O_2H)$

Reaction B: $O_2 + e^- \rightarrow O_2^-$

Reaction A, involving a superoxide ion, is improbable in strongly acid solution, although it has been postulated by Krasil'shchikov (1, 2) to explain his pH-independent results for oxygen reduction on silver at pH 2. However, rotating electrode results of Palous and Buvet (8) show $(\partial\eta/\partial pH)_i > RT/F$ at pH values between 0 and 2 [see also ref. (5)]. On this basis Reaction B, shown already to be the rate-determining step on gold electrodes, appears to be the most likely rate-determining step on silver. Both metals have similar Tafel slopes ($2RT/F$) and similar activation energies at the reversible oxygen potential (23.6 kcal on gold, 26.2 kcal on silver).

The cyclic voltammetric data (34) imply similar heats of adsorption for oxygenated species on gold and silver. As this quantity, to a first approximation, is the only factor that determines activation energy differences between electrode materials, the similar experimental heats of activation on gold and silver are thus accounted for.

Conclusions

The rate-determining step in oxygen reduction on palladium and silver in strongly acid solution is a primary charge transfer, in all probability involving a proton

$$O_2 + H_3O^+ + e^- \rightarrow —O_2H$$

Although both metals have similar activation energies at the reversible potential (22.4 kcal on palladium, 26.2 kcal on silver), the figure on palladium includes a heat of adsorption term that depends on the equilibrium coverage of —O and —OH derived from water oxidation adsorbed on the electrode (21, 26). This coverage is linearly potential dependent—that is, adsorption follows the Temkin isotherm. For this reason it is more legitimate to compare activation energies on the two metals at potentials where —O coverage is low. Under such conditions there is a marked difference in activation energy between palladium and silver. At a potential of 750 mV HRE, where both metals can be expected to show low oxygen coverage (Langmuir conditions of intermediate adsorption), the activation energy will be approximately

$$E_1 - E_2 + (\alpha_1 - \alpha_2)\,\eta F$$

where E and α are the respective reversible potential activation energies and transfer coefficients and η is the overpotential. Taking η to be −500 mV (+760 mV HRE at 25°C), with $\alpha_2 = 1.0$ (Pd), $\alpha_1 = 1/2.07$ (Ag), E silver-E palladium ~ 9.8 kcal.

Thus, the intrinsic heat of activation for oxygen reduction on phase-oxide-free palladium (in the absence of poisoning effects due to equilibrium —O and —OH coverage) is appreciably lower than on silver, which accounts for the much greater rate of the reaction on palladium electrodes. Palladium and platinum, both with d-band vacancy values of about 0.6 (18), show similar oxygen reduction rates (15), whereas gold and silver electrodes, both with filled d-bands, give rates some orders of magnitude lower. The difference in rates in acid and alkaline solution for the latter two metals is particularly striking.

The Ultraviolet Photovoltaic Effect in Evaporated Silver Bromide Conduction Cells

Joseph I. Masters

Technical Operations, Incorporated, Burlington, Massachusetts 01803

ABSTRACT

Ag/AgBr/Ag cells fabricated by a suitable masking of three overlapping evaporations exhibit a photovoltage when one semitransparent silver electrode is illuminated with 3650Å light and the AgBr electrolyte layer is much thicker than an absorption length for this radiation. Below a saturating illumination of approximately 1 mW/cm^2, a photocurrent proportional to the intensity of illumination flows in an external circuit. In this linear range the quantum yield is typically 40%; however, the energy conversion efficiency is only about 0.01%. In general, discoloration and gradual cell deterioration were observed as a result of photovoltaic operation. Conclusions are drawn from a comparison, using the same cell, of photoconduction and of dark conduction produced by an applied voltage. The former is characterized by a lower internal resistance.

We are concerned with the specific cell Ag/AgBr/Ag in which a current may be passed from one silver electrode to the other through an evaporated AgBr electrolyte film. The electrochemistry of solid electrolyte cells employing various types of electrodes was treated by Wagner (1, 2), and several authors (3-9) have studied mixed conduction in cells using electrolytes of compressed AgBr pellets or bulk AgBr crystals. Recently, reproducible miniature rechargeable batteries in the form of evaporated Ag/AgBr/Pt and Ag/AgI/Pt concentration cells were fabricated and studied (10).

On the other hand, photovoltaic activity from an AgBr electrolyte in contact with Ag is less well known.

Key words: Dember effect, photolysis, solid electrolyte, thin films, silver/silver bromide.

In 1929, Vanselow *et al.* (11) reported voltages in the millivolt range from the illumination of one electrode of an (Ag, AgBr)/liquid electrolyte/(AgBr, Ag) cell. Within the last decade, Eggert (12) investigated and described a photovoltaic effect caused by the illumination of an Ag/AgBr/Ag sandwich cell in which the AgBr layer was grown by brominating the surface of a bulk silver substrate rather than by the evaporation method employed here. The bromination method gave poor sample reproducibility. It was, nevertheless, possible to make observations of linearity in response, a high quantum yield, and a strong dependence on the wavelength of the illumination. By employing the evaporation method of deposition, reproducible cell samples can be fabricated more readily, allowing a convenient configuration for confirmation of earlier findings as well as a more detailed view and further study of the photovoltaic effect. The latter includes a comparison of the transient and steady photocurrent, believed characterized by both electronic and ionic diffusion, with the predominantly ionic dark current produced by application of a d-c voltage step.

Interest in the AgBr uv photovoltaic effect stems from a general interest in quantum detection, as well as from a parallel interest in evaporated AgBr as a photographic recording surface. The charge separation process associated with the effect almost certainly involves the diffusion and trapping of photolytic species, the basis of photographic sensitivity in AgBr systems. Generally speaking, successful deposition of reproducible silver halide layers by evaporation is a recent technology, and measurements of the type performed in the past using relatively thick AgBr materials have yet to be made on samples of thin evaporated AgBr films and cell structures.

Cell Fabrication

Pinhole-free Ag/AgBr/Ag overlapping sandwich cells were made by the successful evaporation procedure reported previously (10). Even in AgBr films of submicron thicknesses, continuous coatings of a contiguous domain structure are readily obtained, as shown in the Fig. 1 electron micrograph of a 0.5μ film. The sequence of evaporations for cell fabrication is shown in Fig. 2. The Ag and AgBr evaporations are best performed in separate vacuum systems to avoid bromination of the Ag electrodes by free bromine present when AgBr is evaporated. In the purification of AgBr used in this work, the prevalent impurities are silicon, iron, lead, and copper. Normally, the concentration of silicon is held to less than 25 ppm, and the remaining impurities to less than 5 ppm. Further purification results from deposition of the AgBr by evaporation.

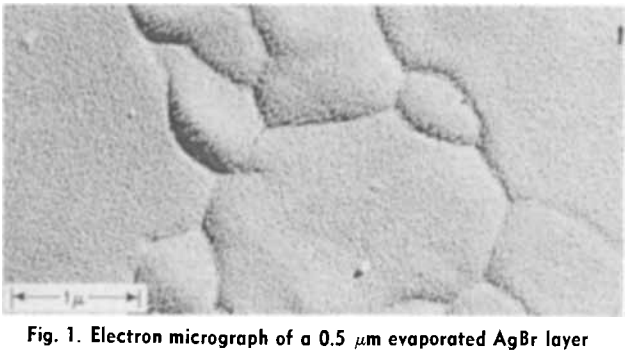

Fig. 1. Electron micrograph of a 0.5 μm evaporated AgBr layer

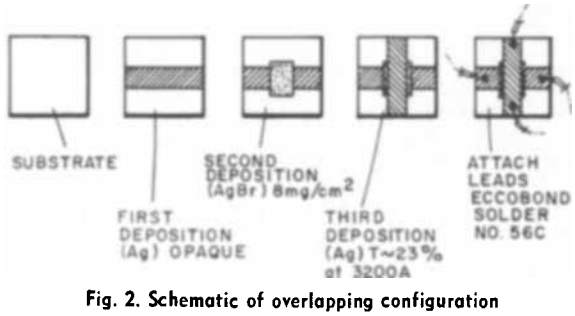

Fig. 2. Schematic of overlapping configuration

Ag/AgBr/Ag cells were made with an AgBr coverage of 8 mg/cm^2, and as a check on thickness dependence, two cells were covered with 3 mg/cm^2 of AgBr. Films in this thickness range approach a density equal to the bulk density of 6.5, yielding thicknesses estimated, respectively, of 13 and 5 μm. The bottom Ag electrodes were deposited to an arbitrarily opaque thickness on a glass substrate. The top electrodes were deposited to give about 20% transparency at 3200Å, the approximate peak of the uv window in silver.

After fabrication, the cells' electrolyte resistance was measured with a 1000 Hz a-c bridge and their open-circuit voltage with a high-impedance vacuum-tube voltmeter. The cells with a 3 mg/cm^2 layer of AgBr had an a-c resistance in the 21-25 ohm range, and the a-c resistance of cells with an 8 mg/cm^2 layer of AgBr was in the 42-46 ohm range.[1] The nonlinearity in the dependence of the measured values of electrolyte resistance with electrolyte thickness is an expected consequence of boundary effects (see following section). In general, measured values of AgBr thin film resistivity at room temperature are about 3 to 4 order of magnitude lower than bulk crystal values because the films are structure-sensitive and conduction along low resistance domain boundaries predominates.

Because of the chemical symmetry of the cells, they would be expected to have no open-circuit voltage. However, this was not the case. Cells produced by the method indicated in Fig. 2 had what appeared to be a random distribution of open-circuit voltage in the 0.0001 to 0.0005V range, with the top electrode always positive. The effect is believed to result from a difference in electrode potentials caused by a difference in the stress at the two electrodes, in turn caused by the shrinkage of the AgBr deposit in cooling to its substrate temperature. This suggests that the bottom Ag electrode remains under compression with respect to the top electrode. Support of this hypothesis is given by some related work on the deformation potential in solid-state cells (13).

In the measurements reported here, corrections for the deformation potential are made as required. However, measurements are normally under closed-circuit conditions, causing a relaxation of the open-circuit deformation potential to a much lower value.

Total Dark Conductivity

In an ionic semiconductor such as AgBr, conduction at room temperature is predominately by interstitial Ag^+ ions and silver ion vacancies, V^-. In addition, there is a small electronic contribution to the conductivity. The magnitude and type of the electronic portion of the total conduction (electrons or holes) depends on the AgBr sample's metal/nonmetal ratio. A silver excess, established by equilibration of AgBr with an Ag electrode, results in an electronic current predominately by conduction band electrons, and to detect it, the much greater ionic current must be suppressed by the use of a blocking or inert material such as carbon as the positive electrode (3). However, when a d-c voltage below the decomposition voltage is applied to an ideal Ag/AgBr/Ag cell, Ag^+ ion transport between the Ag electrodes is unblocked and ohmic, and the electronic contribution to the total conductivity is negligible. Nevertheless, in practice, the reactions that take place at the positive and negative silver electrodes are not reversible, and a significant amount of electrode resistance to Ag^+ ionic flow is encountered, generally much larger than the resistance within the thin electrolyte. This is especially noticeable if no attempt is made to fabricate graded or porous electrodes.

[1] Stated values of cell resistance, current, capacitance, etc., are for an effective cell area of 1 cm^2.

It is significant that R, the resistance to the ionic current at the electrodes, is caused by a capacitive pileup of ionic carriers unable to exchange charge with the electrodes freely. As a first order approximation, the polarization lends itself to a parallel R, C representation of the electrode interface impedance shown in the circuit analogue insert of Fig. 3. The build-up of cell voltage V to the steady state for this circuit is given by the exponential function

$$\frac{V}{V_0} = \frac{R}{R_L + R}\{1 - \exp[-(R_L + R)/R_L RC]t\} \quad [1]$$

in which V_0 is the applied voltage, R and C are constants, and where we have safely neglected the small contribution of the electrolyte resistance term $R_e << R$.

We may note here that the standard method of determining R_e is suggested by the circuit analogue, namely the substitution of d-c by an a-c voltage of frequency high enough (>0.1 kHz) to reduce the electrode impedance to a relatively low value of capacitive reactance. The a-c method, in which an impedance bridge is usually employed (10), yields upper bound values of R_e that may include a contribution from electrode resistance that is in effect not capacitively shunted.

From Eq. [1] the time constant of the equivalent circuit may be broken down as follows
when

$$R_L >> R, \ \tau \cong RC \quad [2a]$$

when

$$R >> R_L, \ \tau \cong R_L C \quad [2b]$$

and for the matching condition

$$R_L \cong R, \ \tau = RC/2 \quad [2c]$$

In an actual cell a dependence of R and C on cell voltage, as well as differences in conduction at the two electrodes, is expected. These factors are neglected in this simple model. Nevertheless, it is a guide in the evaluation of a typical cell's dark current response to a d-c voltage step.

By using an external circuit as shown inserted in Fig. 3, typical rise and decay curves of cell voltage were recorded for applied voltage steps from 0.003 to 0.03V. The electrode capacitance C derives from a very thin double layer and for cell voltages <0.015V, is in the order of 1000 μF/cm^2. Therefore, the use of load resistances smaller than a matching load was done in accord with Eq. [2b] at a sacrifice in accuracy to avoid a sluggish transient. Note that even in this low voltage range, the curves do not asymptotically approach a true steady state. Rather the room temperature mass transfer of silver from the positive to the negative electrode appears to cause a continuous increase in the value of R, which may be accompanied by some irreversible cell deterioration. Accordingly, cell parameters cannot generally be considered constant but depend on cell history.

To compare the dark current's slowly increasing R values with the smaller internal resistance encountered when the cell is operated as a photovoltaic element, it was necessary to assume the attainment of a quasi-steady dark current after an arbitrary 5 min time lapse, roughly the time allowed in the measurement of quasi-steady photocurrents. Thus, R is calculated from Eq. [1] for $t = \infty$, but using values of cell voltage obtained from the curves of Fig. 3, at time $t = 5$ min. The uncertainty of calculated effective internal resistance values (Fig. 4) includes variations caused by hysteresis observed as a result of reversing both the order of the measurements and the polarity of the applied voltage. We note, however, an indication of an increase in internal resistance with decreasing values of the cell voltage.

The Photovoltaic Effect

Theory.—The photovoltaic effect produces a potential difference between the electrodes of a symmetric Ag/AgBr/Ag cell. The phenomenon is observed if an asymmetry existis in the density of photolytic species as a result of the absorption of light close to a partially transparent electrode. If, for example, a 10^{-3} cm thick Ag/AgBr/Ag sandwich cell is illuminated with 4600Å light, for which the absorption coefficient is relatively low ($\alpha \cong 10^2$ cm^{-1}), then asymmetry in the distribution of photoelectrons and photoholes would be negligible, with no possibility of a detectable electrode potential difference. In such a thin cell, asymmetry is, however, assured by illuminating with light of wavelength below 4000Å, where the absorption coefficient in AgBr rises sharply with decreasing wavelength. At the wavelength of the convenient mercury 3650Å line, α is approximately 10^4 cm^{-1}, corresponding to an absorption depth of 1μ in the AgBr electrolyte.

Clearly, the effect must depend on certain properties well established in AgBr crystals at room temperature, namely, a sufficiently small recombination rate for photoelectrons and photoholes allowing their migration to trapping sites. The trapped photoelectrons

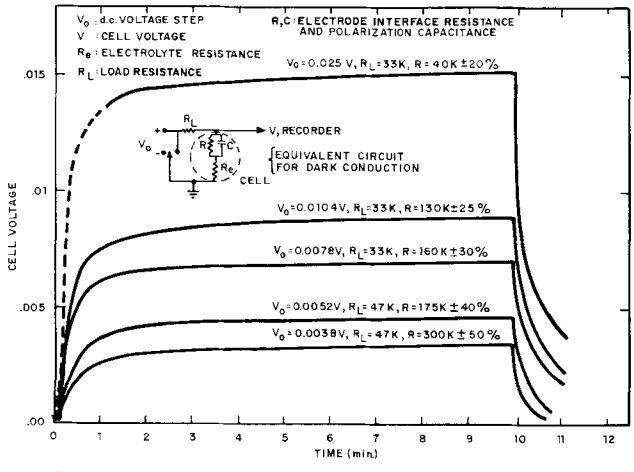

Fig. 3. Transient cell voltage, Ag/AgBr/Ag conduction cell

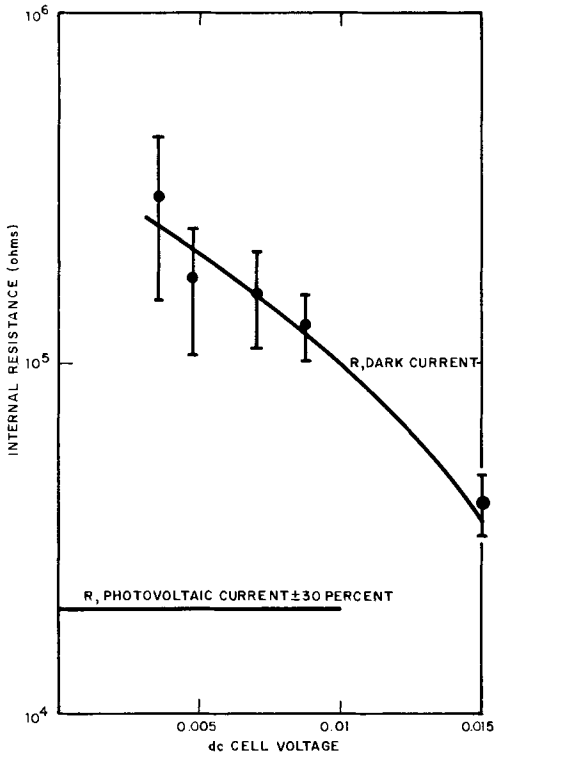

Fig. 4. Internal resistance. Ag/AgBr/Ag conduction cell dark current, photovoltaic current.

attract available interstitial Ag^+ ions, forming neutral silver atoms. A photohole can be trapped and neutralized by an existing negative silver ion vacancy V^-, or alternatively, by forcing a lattice Ag^+ ion into an interstitial site. A bound neutral bromine atom is thus formed.

Because of their much greater drift mobility (approximately 2 orders greater than the photohole mobility and with a diffusion length roughly half the thickness of a 13 μm cell), an appreciable fraction of the photoelectrons are trapped at depth in the AgBr layer, a small fraction possibly reaching the unlighted electrode. This leaves a net positive space charge near the lighted electrode due to the concentration of two relatively immobile species; the photoholes and the excess of interstitial Ag^+ ions resulting from the neutralization of trapped photoholes. In the absence of appreciable electrode charge transfer leading to an external photocurrent, this electrolyte polarization is expected to produce an induced or Dember effect photovoltage (14), measurable at the electrodes and with the lighted electrode positive. Of interest here, however, is the more complex photovoltaic effect that supports an external photocurrent of electrons from unlighted to lighted electrode and depends upon a charge transfer at both electrolyte-electrode interfaces.

The mechanism of negative charging of the unlighted electrode is postulated as follows: We assume that the aforementioned positive space charge prevents the lighted electrode from supplying Ag^+ ions to the electrolyte to make up for those that are neutralized by photoelectrons at trapping sites. Instead these ions are supplied primarily by the unlighted electrode giving this electrode a negative charge. The unlighted electrode is thus consumed by the flux of injected Ag^+ ions which numerically approaches the external photocurrent flux. A mechanism providing for the numerically equal charge transfer required at the lighted electrode is, however, less certain, as indicated by the variety of competitive reactions listed in Table I.

As a result of the photocurrent, the lighted electrode's silver mass is increased or decreased to the extent of plating or bromination as described in reactions of the type 3a or 3b (Table I). The photocurrent's quantum yield is less than unity to the extent of direct electron-hole recombination and noncontributory reactions of the type 3b. Departure from this optimum conversion would result from the arrival of some of the photoelectrons at the lighted electrode, the very unlikely arrival of the much shorter range photoholes at the unlighted electrode, or the lighted electrode acting as a donor of Ag^+ ions to replenish the electrolyte. These activities, assumed suppressed for cell thicknesses large compared to the illumination's absorption depth, cancel photovoltaic collected charges. In terms of quantum yield they are, therefore, twice as costly as recombination alone.

We must also account for a possible bromination (discoloration) of the lighted electrode. Bromination would require diffusion of normally bound neutral bromine atoms through the lattice toward a boundary. Although unlikely in a pure crystal, the outer layer of a thin AgBr film is a dislocation region which can support the diffusion of halogen atoms (15). This relates to experiments (16, 17) in the vacuum photolysis of thin silver halide films indicating that light absorbed close to the surface causes appreciable Br_2 evolution from the surface. The positive vacancy left by a diffusing neutral Br atom may be neutralized by a neighboring Ag^+ lattice ion jumping to an interstitial site (leading to reactions 3a or 3b, Table I), or by an electron (reaction 2b). Alternatively, a V^- vacancy may trap and thus neutralize a photohole, this neutral center then diffusing to the Ag/AgBr boundary (18). Note, the diffusion of bromine atoms toward the nearby lighted electrode, followed by electrode bromination (reaction 3b), is in itself a neutral process in the sense that it fails to charge the lighted electrode positively. However, to the extent that interstitial Ag^+ ions, generated in the aforementioned production of neutral Br atoms, are in turn neutralized at photoelectron trapping sites or serve to replenish those previously so neutralized, bromination represents a loss in the collection of photolytic charges and, from a quantum yield viewpoint, is equivalent to recombination.

Table I. Lighted electrode reactions

1. Charge transfer by photohole migration: $h + e \rightarrow Br^-$
2. Charge transfer by electrons from external photocurrent that neutralize h and Ag^+ in electrolyte:
   (a) $e + h \rightarrow Br^-$ (recombination)
   (b) $e + Ag^+ \rightarrow Ag^o$ (print out)
3. Results of Ag^+ and Br^o generated by trapped photoholes:
   (a) $Ag^+ + e \rightarrow Ag^o$ (charge transfer, with plating)
   (b) $Br^o + Ag^o \rightarrow AgBr$ (bromination, no charge transfer)

Response of photovoltaic cells.—The photovoltaic effect exists as an open-circuit cell voltage and does not require an external circuit. For a continuous uv illumination of the lighted electrode, the open-circuit voltage increases, but various loss phenomena cause the cell voltage to reach a quasi-steady value. Under closed-circuit conditions continuous uv illumination of the lighted electrode is partially converted, as discussed above, into a quasi-steady d-c photocurrent with the lighted electrode as the positive electrode.

The photovoltaic effect in the Ag/AgBr/Ag cell is a conversion process that alters, essentially irreversibly, the original structure. At best, the unlighted electrode is consumed and reappears as printout silver at trapping sites. This case might be approached with low current levels (low light intensity) and with small values of load resistance. On the other hand, the use of large light levels or a large load resistance appears to saturate the mechanism and to intensify the competitive processes of electrode bromination. In view of the dynamic nature of the irreversibility, defining a saturating radiant power level is difficult. For the cells tested, however, it was found that illumination exceeding $P = 1$ mW/cm^2 of 3650Å light caused indications of saturation, and therefore measurements were made at lower levels of illumination. Here we do not make the distinction between saturation in terms of nonlinear response, or intensification of cell deterioration, hysteresis effects, electrode discoloration, etc.

A study of the transient and steady behavior of the photocurrent generated by photovoltaic cells was carried out by illuminating the covering electrode of each cell with a spatially uniform light beam from a calibrated 3650Å source; *i.e.*, radiation in the 3650Å line from a stable mercury arc was isolated with suitable filters, and its radiant power measured with a thermopile. The intensity was varied using attenuators that were also calibrated at 3650Å. The photocurrent generated by a cell was recorded as the voltage common to both the cell and its parallel load resistor, which was varied in the $10^2 \rightarrow 10^5$ ohm range. Variation of the load provided data for calculating the effective internal resistance and for studying the dependence of response time on load resistance. The illumination of the cells was in the range from $P = 0.03$ mW/cm$^2 \rightarrow 1.0$ mW/cm^2, which allowed an observation of linearity and quantum yield.

Typical response curves for 13 μm thick cells under various loads are shown in Fig. 5 for cells illuminated with light at an intensity level of about 0.3 mW/cm^2. When $R_L << R$, the cell behaves as a current source and the quasi-steady current is nearly independent of the load. The transient is roughly exponential, and the rise time, which is the order of 1 sec for $R_L \sim 10^2$ ohms, increases with R_L.

The specific origin of the transient portion of the photocurrent is uncertain, because of the variation in the character of conduction throughout the electrolyte. However, some insight may be gained by satisfying charge conservation conditions. At the onset of illumi-

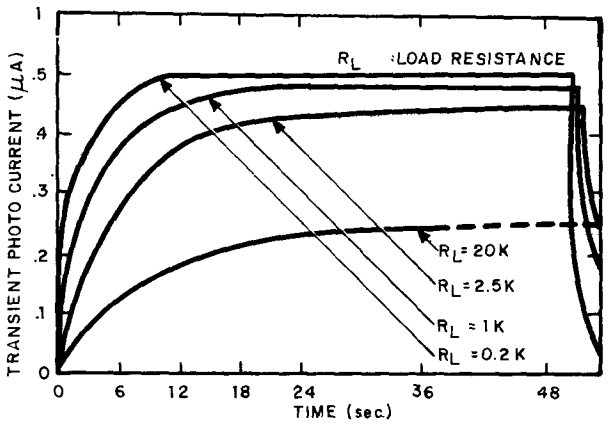

Fig. 5. Photovoltaic response of a 13 μm Ag/AgBr/Ag cell to 3650Å, 0.3 mW/cm² illumination.

nation, if the proximity of photolytic charge generation causes charge transfer to one electrode[2] charge neutrality of the cell is satisfied, not entirely by an equal and opposite charge on the other electrode, but partially by an excess of charges of opposite sign in the electrolyte. For example, if nearby photoholes first charge the lighted electrode positively (reaction 1, Table I), cell neutrality may result from a V^- excess created by a loss of Ag^+ interstitials to electron trapping sites, and from some yet unneutralized sites, rather than by a negatively charged unlighted electrode. The transient phase of the photocurrent then appears to be due to a sluggishness in the actual negative charging of the unlighted electrode by the suggested electrode reaction $Ag^o \rightarrow Ag^+ + e$. This reaction describes Ag^+ injection into the AgBr lattice that would be enhanced by the arrival at this electrode of the diffusing V^- species. The combination of low ion mobility and electrode impedance, the latter as described previously under dark conduction, are believed responsible for the sluggishness.

As in the case of dark ionic conduction (Fig. 3), a true steady photocurrent is not observed because the cells deteriorate slowly. Once the cell is illuminated, the transient response (as shown in Fig. 5) is followed by a plateau in photocurrent of several minutes duration, and then a gradual decay. For example, when a 13 μm thick evaporated cell connected to a 1 kohm load was illuminated for a prolonged period by a 3650Å beam for which $P = 1$ mW/cm², the photocurrent fell by 30% in 1 hr.

Plateau values of the photocurrent $i_1, i_2, \ldots$, obtained by using various load resistances $R_{L1}, R_{L2}, \ldots$, are in approximate agreement with the ratio

$$\frac{i_1}{i_2} = \frac{(R_{L2} + R)}{(R_{L1} + R)}$$

This formula applies in the case of an emf in series with an internal resistance R that is independent of the load, as in a battery. From this formula, R is defined as the effective internal resistance of an Ag/AgBr/Ag photovoltaic cell. Not only was the photovoltaic internal resistance found to be approximately independent of the load, but it was also nearly independent of P. The estimated over-all accuracy in determining the photovoltaic internal resistance is ±30%.

When a dark cell's internal resistance is compared to the same cell's internal resistance to a photocurrent the latter is, therefore, constant over the applicable photovoltaic cell voltage range (see Fig. 4). It is also much less than the voltage-dependent internal resistance of the dark current. For either type of cell operation we recall that $R >> R_e$, so that the origin of the difference in R lies in a comparison of electrode reactions. The unlighted electrode of an Ag/AgBr/Ag photovoltaic cell and the positive electrode of the same cell supporting dark conduction are assumed doner electrodes with similar roles, in the sense that they both supply Ag^+ ions to the electrolyte. The photovoltaic cell's lower resistance may be due in part to a larger V^- concentration at its doner electrode due to photolysis, or to dissimilarities at the acceptor electrodes of the two cell types. At the dark conduction cell's acceptor electrode plating occurs, reaction 3a, Table I; whereas the reflecting surface of the photovoltaic cell's lighted electrode, after prolonged uv exposure (cited above), shows discoloration attributed to bromination on an area strictly confined to the exposure region with no evidence of silver plating. These observations indicate that the electronic transport reactions 1 and/or 2, Table I, support the steady photocurrent whereas reaction 3b dominates over 3a and causes bromination. A technique to show the relative frequency of occurrence of reactions 1 and 2, which would give evidence of photohole diffusion length, does not seem possible in this type of experiment.

Quantum yield.—Determination of the quantum yield of the photovoltaic effect involves the use of the formula

$$Q = 3.2 \times 10^3 \, i/\beta P \quad \text{electrons/photon}$$

where i is the photocurrent in amperes for a 1 cm² cell, P is the intensity of the incident 3650Å illumination in mW/cm², and β is the fraction of these uv photons transmitted by the silver covering electrode (lighted) to the AgBr electrolyte. Values of the quasi-steady current i were obtained by measuring the voltage across the cell's load resistance with a precision digital voltmeter. The radiation intensity was measured with a calibrated thermopile. Unfortunately, because of the large uv absorption coefficient in AgBr, β was not measured directly. Instead the 3650Å transmission of the partially transparent electrode film was measured at a region off the cell where it was not backed by the AgBr layer. However, as a result of equilibration with evaporated AgBr or cell aging caused by photovoltaic operation, this technique leaves some doubt as to the transmission of the part of the silver film covering the cell surface. Since such factors would tend to reduce the effective silver thickness of the covering electrode film, and hence increase β, the calculated values of Q are taken to represent, at best, an upper bound approximation of the actual quantum yield. For $P < 1$ mW/cm², 13 μm thick cells, for which the measured value of $\beta = 0.017$ ±20%, produced calculated values of $Q = 0.4$ ±20%. This is in rough agreement with a similar determination by Eggert (12) for cells containing a 10 μm thick layer of AgBr fabricated by bromination of an Ag base. The photocurrent measurements reported here were performed on fresh cells and therefore represent a minimum of cell usage. The calculated value of Q decreases with prolonged use in proportion to the decrease in photocurrent. In the case of the thinner 5 μm cells the quantum yield was considerably less, namely, $Q = 0.1$ to 0.15, presumably a result of the aforementioned competitive phenomena arising from the proximity of the unlighted electrode.

The efficiency of converting radiant power into useful electrical power is

$$\eta = i^2 R_L 10^3/P \cong Q^2 \beta F R_L/10^4$$

where $F = \beta P$ is the radiant power in mW/cm² delivered to the electrolyte, and the condition $R_L = R$ is implied for optimizing η. For the configuration of the cells tested, in which β is the order of 0.01 and hence the saturation value of $F \cong 10^{-2}$ mW/cm², the conver-

[2] For a short duration after illumination (<0.1 sec) nearby photoelectrons may charge the lighted electrode negatively prior to dominant positive charging. This effect, which was not observed using the slow recording techniques of this experiment, has been reported (11, 12) in cases where positive hole migration was chemically suppressed using a halogen acceptor between electrode and electrolyte. The cell voltage resulting from such charging should endure for a time $\tau \sim R_L C_i$ where C_i is the relatively small interelectrode capacitance of the cell.

sion efficiency is very small, namley, $\eta \cong 0.0001$. It would appear that η should increase if β and P are increased. For instance, the efficiency of solar cells does not become large ($\eta = 0.1$) until the power input approaches the solar constant ($P = 100$ mW/cm^2). However, more than likely any increase in the value of F above the aforementioned estimated saturation limit will bring down the value of Q, and no increase in η will be realized. Relevant to this argument are some measurements by Eggert (12). Although his data are widely scattered, there is evidence of a decrease in Q as β is increased above the value of $\beta \cong 0.01$ employed in this investigation.

Manuscript submitted Dec. 3, 1969; revised manuscript received July 17, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1971 JOURNAL.

Steady-State Chemical Potential Profiles in Solid Electrolytes

N. S. Choudhury and J. W. Patterson

Department of Metallurgy and Engineering Research Institute, Iowa State University, Ames, Iowa 50010

ABSTRACT

Steady-state chemical potential profiles in a solid electrolyte under open-circuit and ion-blocking conditions, may be obtained by balancing the steady-state flux at points inside the electrolyte. Steady-state oxygen chemical potential profiles inside a scaling layer of thoria and inside yttria-doped thoria specimens under open-circuit and ion-blocking (d-c polarization) conditions are illustrated in special cases.

Wagner (1) has shown that the oxidation of metals may be treated quantitatively in cases where the tarnishing is rate limited by steady-state transport through the tarnishing layer. Many other problems may be considered which also conform to this type of irreversible thermodynamic steady-state treatment. A partial listing might include specific diffusion problems and thermal conduction problems as well as problems involving charge conduction through mixed conductors with various blocking electrodes. The important feature common to all such problems is that quantitative expressions for local internal transport fluxes may be integrated over the length of the transport medium. By this integration device, the steady-state flux may be written in terms of the boundary values of the driving force potential, *i.e.*, the limits of integration. To arrive at explicit relationships, however, one must know how the transport parameter (thermal conductivity, for example) depends on the magnitude of the potential (temperature or thermal energy, for example). Here we are concerned with the problem of deducing steady-state profiles for certain of these potentials inside transport media for which the required conductivity dependences are known functions.

In particular we are concerned with deducing the steady-state chemical potential profiles (μ_{X_2} or equivalently log P_{X_2} *vs.* x) inside M_aX_b mixed conductors subjected to selected boundary conditions and/or boundary values for log P_{X_2}. Applying the analysis to solid electrolytes allows interesting prediction regarding the emf generated by double electrolyte tablets placed in series in galvanic cell measurements (2-4). The same analysis may also be used to calculate the steady-state log P_{X_2} *vs.* x profile that prevails in a homogeneous solid electrolyte being employed in a typical solid electrolyte galvanic cell experiment. Actually the profile determination in solid electrolytes is a special case of the profile determination problem for general mixed conductors. This more general problem is solved below and then used to discuss the log P_{X_2} profile types that may occur in ionic and electronic conducting scaling layers. In addition to these open-circuit type problems, the method may be used to calculate the steady-state log P_{X_2} profiles induced in mixed conductor specimens subjected to applied emf's under selected ion-blocking conditions. In particular, log P_{X_2} *vs.* distance profiles corresponding to the Hebb-Wagner (5-7) d-c polarization technique are calculated and discussed below.

Key words: chemical potential, solid electrolytes, mixed conductors, d-c polarization, scaling, electronic conductivity, hole conductivity, ionic conductivity, ionic transference number, open circuit emf.

General Determination of Steady-State Profiles

Before proceeding to specific cases, we outline the general features of the method by considering a somewhat generalized transport medium. We consider the medium to be capable of supporting a flux transport I_η (where η may be mass, charge, heat, etc.). This flux results locally from a gradient in some variable V (where V may be a chemical potential, electrostatic potential, temperature, etc.). The local flux equation may be written as

$$I_\eta/A = J_\eta(x) = -\sigma_\eta(x)\nabla V \qquad [1]$$

where $J_\eta = I_\eta/A$ is the η flux or the amount of η transported per unit time and cross sectional area due to the local gradient ∇V of the potential V. Equation [1] is typical of conductive-type transport processes such as Fick's law of diffusion, Fourier's law of heat conduction, or Ohm's law of charge conduction. In such processes ∇V acts as the driving force for the transport process and the proportionality parameter σ_η is called the conductivity parameter for η and very often is found to be a function of V. Although more general geometries may be readily considered, we limit consideration to the case of linear conduction geometry for simplicity. In this case ∇V in Eq. [1] may be replaced by dV/dx so that the equation may be rearranged and integrated to give

$$\int_o^L \frac{I}{A}\eta\, dx = \int_{V(O)=V'}^{V(L)=V''} \sigma_\eta(V)\, dV \qquad [2]$$

Because we are considering the steady-state case, I_η is independent of x and because of the linear geometry, A is independent of x. Equation [2] may be recast as

$$J_\eta L = \Delta \qquad [3]$$

where I_η/A has been replaced by J_η

$$\Delta = \int_{V(O)=V'}^{V(L)=V''} \sigma_\eta(V)\,dV \qquad [4]$$

and L is the total specimen thickness measured in the direction of transport. Note that Δ may be evaluated explicitly in terms of the end point values $V(L) = V''$ and $V(O) = V'$ if the functional dependence of $\sigma_\eta(V)$ on V is known.

Applying these elementary results to the series composite medium depicted in Fig. 1 yields for medium L

$$x^I J_\eta' = \Delta' \qquad [5]$$

where

$$\Delta' = \int_{V(O)=V'}^{V(x^I)=V^I} \sigma_\eta'(V)\,dV \qquad [6]$$

and yields for medium R

$$(L - x^I) J_\eta'' = \Delta'' \qquad [7]$$

where

$$\Delta'' = \int_{V(x^I)=V^I}^{V(L)=V''} \sigma_\eta''(V)\,dV \qquad [8]$$

The primes and double primes denote quantities in the left and right hand medium, respectively. To be consistent with these steady-state expressions, however, we must also invoke the additional steady-state relation

$$I_\eta' = I_\eta'' \qquad [9]$$

For the linear transport geometry being considered, this result is equivalent to

$$J_\eta' = J_\eta'' \qquad [10]$$

which, together with expressions [5] and [7], yields

$$\frac{x^I}{L} = \frac{\Delta'}{\Delta' + \Delta''} \qquad [11]$$

where Δ' and Δ'' may be evaluated from the integrals in Eq. [6] and [8], respectively. Wagner used an alternative, equivalent approach to calculate the silver chemical potential at the interface between contacting Ag_2S and AgI specimens (8).

In cases where the left and right side portions of the transport medium are the same material, Eq. [11] gives a formula for deducing the V *vs.* x profile. This is done by merely picking values of V intermediate between V' and V'', evaluating the Δ' and Δ'' integrals from Eq. [6] and [8], and then calculating the x/L values to which these selected V values correspond. For example, in the analysis of oxide solid electrolyte galvanic cell applications or of oxidation processes, V' and V'' may be taken to be the end point log P_{O_2} values log P_{O_2}' and log P_{O_2}'', respectively. The Δ' and Δ'' expressions are then generated by the appropriate integration of Wagner's general expression (1) for the net flux of mobile ions through any compact M_aX_b scaling layer as discussed in more detail below.

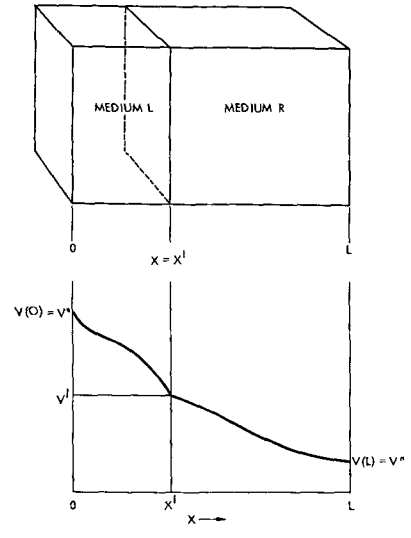

Fig. 1. Schematic steady-state potential distance profile inside two transport media in series contact.

In the cases where the composite medium is actually two different materials, the log P_{X_2} profiles inside each medium may be calculated individually according to the procedure outlined above with both contacting surfaces sharing the same μ_{X_2} value, *i.e.*, the interfacial value, log $P_{X_2}{}^I$. It is apparent from Eq. [6], [8], and [11] that when the conductivity parameters of both media are V independent, the V *vs.* x profiles reduce to two straight line segments connected at the point V^I, x^I. Much more interesting and less obvious profiles result when the conductivities exhibit a more or less complicated functional dependence on the driving force variable V.

Application to Mixed Conductors under Open-Circuit Conditions

Consider the case of a general mixed conductor specimen pressed between two reversible electrodes that establish the nonmetal chemical potential μ_{X_2} at the left and right hand faces of the specimen. According to Wagner's scaling rate theory (1), J_η for this case may be taken to be the electronic current J_e and the driving force variable is the electrochemical potential for electrons η_e. Under various assumptions involving local equilibria among various electronic, ionic, and atomic components and assumptions involving virtual stoichiometry constraints on the M_aX_b compound, Wagner's theory allows $\nabla\eta_e$ to be written in terms of $\nabla\mu_{X_2}$ so that the location-independent steady-state electronic current density $J_e = I_e/A$ may be written in terms of the alternative driving force variable μ_{X_2} as follows

$$J_e = [1/(2z_X\mathbf{F})]\, t_{ion} t_e \sigma\, d\mu_{X_2}/dx \qquad [12]$$

where z_X is the anion's valence, $\mathbf{F}$ is Faraday's constant, σ is the total electrical conductivity, and t_{ion} and t_e are the ionic and electronic transference numbers, respectively. Rearranging Eq. [12] and integrating from $x = 0$ to x^I and from x^I to L (*i.e.*, over two mixed conductors in series contact at x^I) yields

$$\Delta' = [1/(2z_X\mathbf{F})] \int_{\mu_{X_2}'}^{\mu_{X_2}{}^I} t_{ion}' t_e' \sigma'\, d\mu_{X_2} \qquad [13]$$

$$\Delta'' = [1/(2z_X\mathbf{F})] \int_{\mu_{X_2}{}^I}^{\mu_{X_2}''} t_{ion}'' t_e'' \sigma''\, d\mu_{X_2} \qquad [14]$$

These may be used in Eq. [11] to generate μ_{X_2} *vs.* x profiles in cases where the functional dependences of t_{ion}', t_e', σ' and t_{ion}'', t_e'', and σ'' on μ_{X_2} are known. For example, one may use Eq. [11], [13], and [14] to calculate the μ_{X_2} profile prevailing inside a scaling layer growing on an oxidizing metal. This is done by letting x^I be any arbitrary location inside the scale. In such cases, however, it is more conventional to use log P_{X_2} instead of μ_{X_2} as the variable V. Then, for the scaling layer example, P_{X_2}' is the P_{X_2} value established by equilibrium coexistence between the metal and the M_aX_b scale material and may be calculated from tabulated data for the standard free energy of formation ΔG° of the M_aX_b compound. P_{X_2}'', the ambient P_{X_2} of the "X-idizing" atmosphere, must be determined from the specified ambient conditions. In this example the interface at x^I separates two regions of the same material, hence the functional forms of t_{ion}, t_e, and σ are the same whether double or single primed. Figure 2 shows the results of such a log P_{O_2} *vs.* x/L profile inside a scaling layer of ThO_2 forming on thorium metal in O_2 gas at 1 atm pressure and at 1000°C. The necessary transport parameters ($P_\oplus$, $P_\ominus$, n and σ as discussed in detail below) were deduced from reported conductivity measurements on ThO_2 (9, 10) and also

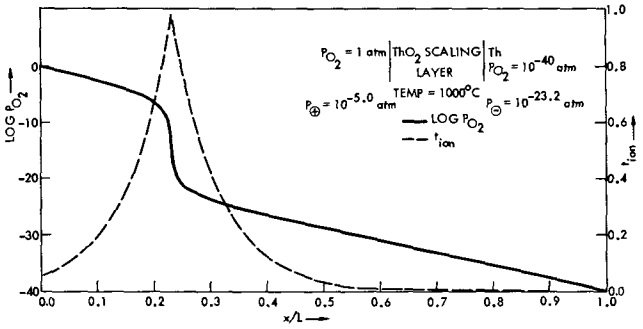

Fig. 2. Log P_{O_2} vs. x/L profile inside a ThO_2 scaling layer forming on Th metal at 1000°C in 1 atm P_{O_2}.

from as yet unpublished measurements on ThO_2 made in our laboratory.

To further illustrate the application of these ideas, let us specialize considerations to the class of mixed conductors known as solid electrolytes. For these materials, $t_{ion}\sigma \equiv \sigma_{ion}$ is known to be invariant over wide ranges of log P_{X_2} and may therefore be moved outside the integrals of Δ' and Δ'' in these ranges. Considering the entire medium between $x = 0$ and L to be comprised of the same solid electrolyte material, Eq. [11] reduces to

$$\frac{x^I}{L} = \frac{\log \left| \frac{P_{X_2}{}^I}{P_{X_2}{}'} \right| - \int_{\log P_{X_2}'}^{\log P_{X_2}{}^I} t_{ion}\, d \log P_{X_2}}{\log \left| \frac{P_{X_2}{}''}{P_{X_2}{}'} \right| - \int_{\log P_{X_2}'}^{\log P_{X_2}{}''} t_{ion}\, d \log P_{X_2}} \quad [15]$$

where we have changed the variable of integration from μ_{X_2} to log P_{X_2} through the relationship

$$\mu_{X_2} = \mu_{X_2}{}^{\circ} + 2.303RT \log P_{X_2} \quad [16]$$

According to an analysis by Schmalzried (11, 12) the integrals appearing in Eq. [15] may be evaluated by employing the formula

$$\int_{\log P_{X_2}(a)}^{\log P_{X_2}(b)} t_{ion}\, d \log P_{X_2} = [2.303n/\sqrt{w}] \log \left| \frac{2(P_{X_2}/P_{\oplus})^{1/n} + 1 - \sqrt{w}}{2(P_{X_2}/P_{\oplus})^{1/n} + 1 + \sqrt{w}} \right|_{P_{X_2}(a)}^{P_{X_2}(b)} \quad [17]$$

where

$$w = 1 - 4\left(\frac{P_{\ominus}}{P_{\oplus}}\right)^{1/n} \quad [18]$$

In Eq. [17] and [18], $P_{\ominus}$ is the P_{X_2} where $\sigma_{\ominus} = \sigma_{ion}$. $P_{\oplus}$ is the P_{X_2} where $\sigma_{\oplus} = \sigma_{ion}$, and $\ominus$ and $\oplus$ denote excess electron and positive hole carriers, respectively. The empirical parameter n characterizes Schmalzried's presumed dependence of the electronic conductivities $\sigma_{\ominus}$ and $\sigma_{\oplus}$ on $P_{X_2}{}^{-1/n}$ and $P_{X_2}{}^{+1/n}$, respectively. Thus the parameters $P_{\ominus}$, $P_{\oplus}$, and n must be known from independent experiments if quantitative results are to be obtained. A computer program with these parameters and P_{X_2}' and P_{X_2}'' as input is used to generate x^I/L values according to Eq. [15], [17], and [18] for an array of $P_{X_2}{}^I$ values between P_{X_2}' and P_{X_2}''. The resulting tabulation of x^I/L vs. $P_{X_2}{}^I$ values is then plotted to provide the desired profiles. All the profiles for open-circuit conditions, *i.e.*, Fig. 2-5 were generated in this fashion.

Figures 3-5 show the results of such an application for the oxide solid electrolyte YDT ($Th_{0.85}$ $Y_{0.15}$ $O_{1.925}$)

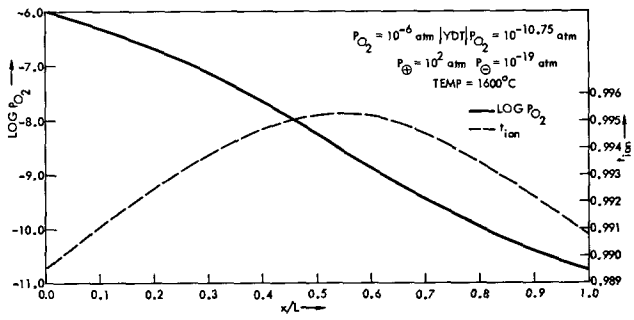

Fig. 3. Log P_{O_2} vs. x/L profile inside a yttria-doped thoria electrolyte for reversible electrode P_{O_2} values within the electrolytic domain at 1600°C.

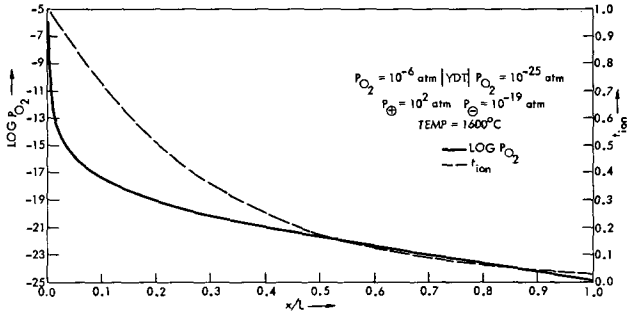

Fig. 4. Log P_{O_2} vs. x/L profile inside a yttria-doped thoria electrolyte for reversible electrode P_{O_2} values spanning the mixed conduction region between the electrolytic and excess electron conduction domains at 1600°C.

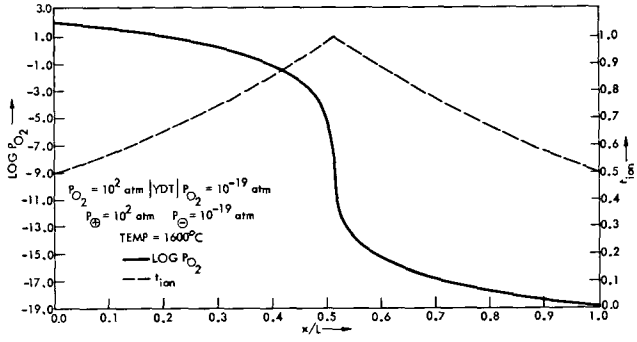

Fig. 5. Log P_{O_2} vs. x/L profile inside a yttria-doped thoria electrolyte for reversible electrode P_{O_2} values located at $P_{\ominus}$ and $P_{\oplus}$, respectively, at 1600°C.

at 1600°C. The values of $P_{\ominus}$, $P_{\oplus}$, and n at 1600°C were determined from an assessment of conductivity and galvanic cell data involving the electrolyte YDT. The values of P_{O_2}' and P_{O_2}'' were chosen so that three interesting cases could be demonstrated. Figure 3 shows the log P_{O_2} vs. x/L profile for the case where P_{O_2}' and P_{O_2}'' both lie within the electrolytic conduction domain[1] for YDT. The P_{O_2}' and P_{O_2}'' values for Fig. 4 span a mixed conduction region from the electrolytic domain down into the domain where excess electron conduction becomes predominant. Similarly the P_{O_2}' and P_{O_2}'' values for Fig. 5 were chosen well outside the domain where ionic conduction predominates. Thus in this case $P_{O_2}' = P_{\ominus}$ and $P_{O_2}'' = P_{\oplus}$ so that the entire electrolytic domain is spanned. In addition to giving the log P_{O_2} vs. x/L profile, each figure also shows the t_{ion} vs. x/L profile. The t_{ion} values were determined

[1] That is, the log P_{O_2}, $1/T$ domain where $t_{ion} > 0.99$ according to a recent paper (13) which also elucidates the details of electron hole and excess electron conduction domain on log P_{X_2}, $1/T$ diagrams.

for these log P_{O_2} profiles by evaluating

$$t_{ion} = [1 + P_{\oplus}^{-1/n} P_{O_2}^{1/n} + P_{\ominus}^{+1/n} P_{O_2}^{-1/n}]^{-1} \quad [19]$$

Note that the log P_{X_2} profiles show a steep gradient at the region where t_{ion} is a maximum, the region having predominantly ionic conduction. Wagner long ago (1) alluded to this feature of such chemical potential profiles inside mixed conductors but reported no quantitative calculations.

This procedure may be readily adapted to the determination of log $P_{X_2}{}^I$ values that prevail at the contacting interface between two different X (or M) ion conductors in series. In cases where two different oxide solid electrolytes are used in series for galvanic cell emf measurements, it is important that the log $P_{O_2}{}^I$ value prevailing at their contacting interface lie within the electrolytic domain for both electrolytes at all times. Otherwise the measured emf's will depart from the thermodynamic values by unknown amounts. However, by applying the above methods one may readily calculate the log $P_{O_2}{}^I$ values to be sure they do fall within the electrolytic domains. No example profiles for this type problem are offered in the present context, however, because others (4, 8) have already solved this class of problems by an alternate method.

Application to Mixed Conductors Subjected to Applied EMF's and Ion Blocking Conditions

Now let us consider the case of a mixed conductor between a reversible electrode and an ion-blocking electrode which are both capable of transporting electrons with negligible impedance. Let an emf E be applied across the mixed conductor, as in d-c polarization experiments (14-17). The situation is schematically illustrated in Fig. 6.

For ion-blocking conditions, Wagner (6, 7) has derived a general expression for the steady-state current due to electrons and holes in ionic crystals. Wagner's result is related to the quantity of Eq. 3 by the relation

$$\Delta = J_e L = -[1/(2z_X \mathbf{F})] \int_{\mu_{X_2}(O)}^{\mu_{X_2}(L)} \sigma_e \, d\mu_{X_2} \quad [20]$$

where

$$\mu_{X_2}(L) = \mu_{X_2}(O) - 2z_X \mathbf{F} E(L)$$
$$= \mu_{X_2}(O) + RT \ln [P_{X_2}(L)/P_{X_2}(O)] \quad [21]$$

and where $\sigma_e = \sigma_{\oplus} + \sigma_{\ominus}$ is the sum of the electron hole $\oplus$ and excess electron $\ominus$ conductivities inside the specimen.

For most ionic compounds capable of predominant ionic conduction we may assume the following transport parameter dependences

$$\sigma_{\oplus} = \sigma_{ion} P_{\oplus}^{-1/n} P_{X_2}^{1/n} \quad [22]$$

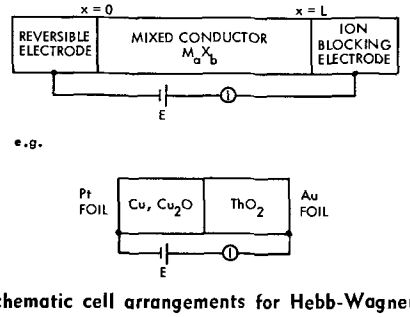

Fig. 6. Schematic cell arrangements for Hebb-Wagner d-c polarization experiments.

$$\sigma_{\ominus} = \sigma_{ion} P_{\ominus}^{1/n} P_{X_2}^{-1/n} \quad [23]$$

σ_{ion} is P_{X_2} independent where as before $\sigma_{\oplus} = \sigma_{ion}$ at $P_{X_2} = P_{\oplus}$ and $\sigma_{\ominus} = \sigma_{ion}$ at $P_{X_2} = P_{\ominus}$. Equations [11], [20], [21], [22], and [23] may be combined to yield

$$\frac{x}{L} = \frac{[P_{\oplus}^{-1/n} P_{X_2}^{1/n}(O) \{\exp(-2z_X \mathbf{F} E(x/L)/nRT) - 1\} + P_{\ominus}^{1/n} P_{X_2}^{-1/n} \{1 - \exp(2z_X \mathbf{F} E(x/L)/nRT\}]}{[P_{\oplus}^{-1/n} P_{X_2}^{1/n}(O) \{\exp(-2z_X \mathbf{F} E(L)/nRT) - 1\} + P_{\ominus}^{1/n} P_{X_2}^{-1/n} \{1 - \exp(2z_X \mathbf{F} E(L)/nRT\}]} \quad [24]$$

Equation [24] combined with Eq. [21] gives the log P_{X_2} profile within the mixed conductor under ion-blocking conditions.

Figures 7 and 8 show log P_{O_2} profiles induced in YDT under ion-blocking conditions at 1600°C. Figure 7 shows such a profile for both electrodes having P_{O_2} values inside the electrolytic domain. The P_{O_2} value at the reversible electrode is established by the presence of oxygen gas at 10^{-6} atm, whereas the effective P_{O_2} at the blocking electrode is established at $10^{-10.75}$ atm as a result of the imposed emf $E = -0.442$V. Figure 8 shows the effect of increasing the magnitude of the applied voltage. In this case the reversible electrode is presumed to be established at $P_{\oplus}$ so that the applied emf of $E = -1.951$V renders the effective P_{O_2} at the blocking electrode to be $P_{\ominus} = 10^{-19}$ atm at 1600°C.

Interestingly, an emf *vs.* x/L profile for Ag_2S has been obtained by Hebb (5). Unfortunately, his data cannot be correlated with Eq. [24] because no effort was made to establish the silver chemical potential with a reversible electrode in Hebb's experiment.

A comparison of Fig. 7 and 8 shows that, under blocking conditions at least, a significant region of an oxide conductor can be made substantially n-type by merely controlling the magnitude of the applied voltage. Theoretically reversing the voltage (under

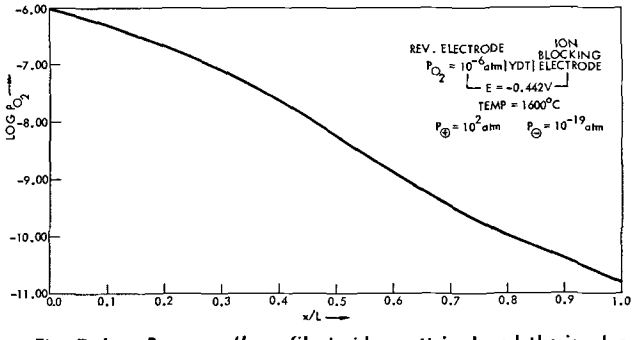

Fig. 7. Log P_{O_2} *vs.* x/L profile inside a yttria-doped thoria electrolyte with the reversible electrode P_{O_2} at 10^{-6} atm and the ion-blocking electrode at 0.442V negative polarity, $T = 1600$°C.

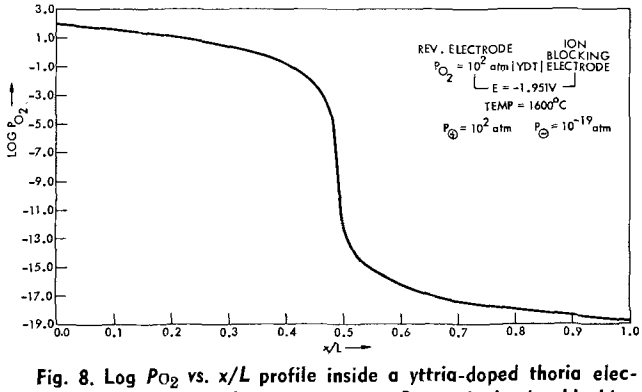

Fig. 8. Log P_{O_2} *vs.* x/L profile inside a yttria-doped thoria electrolyte with the reversible electrode at $P_{\oplus}$ and the ion-blocking electrode at a sufficient negative emf to induce an effective P_{O_2} equal to $P_{\ominus}$ at 1600°C.

blocking conditions) should induce a p-type region. This property could be important in catalysis engineering where the electronic nature of the catalyzing substrate is often vital, although the above calculations assume that there is no source of oxygen (the mobile species) other than at the reversible electrode. These calculations do suggest that some degree of control over the n- or p-type nature of an oxide lateral surfaces may be possible even if a limited amount of oxygen exchange between the oxide and the ambient is permitted.

APPENDIX

The Conductance of a Solid Electrolyte When Subjected to a Difference in the Nonmetal Chemical Potential at the Ends under Open-Circuit Condition

With reference to Fig. A-1, let us assume the mixed conductor of length L and uniform cross section A, subjected to nonmetal chemical potential $\mu_{X_2}(1)$ and μ_{X_2} (2) at its two ends.

The conductance is then given by

$$1/G = [1/A] \int_0^L [1/\sigma(l)]dl \qquad [25]$$

where G = total conductance and $\sigma(l)$ = the total conductivity at location l.

We can write Eq. [25] as

$$1/G = [1/A] \int_0^L [t_{ion}/\sigma_{ion}(l)]dl \qquad [26]$$

In the case of solid electrolyte σ_{ion} is a constant and is independent of l. Therefore

$$1/G = 1/(A\sigma_{ion}) \int_0^L t_{ion}(l)\,dl \qquad [27]$$

Since a plot of t_{ion} *vs.* x/L can be obtained, as discussed earlier, graphical integration of Eq. [27] is possible, yielding the value of G.

Experimental determination of the quantity G under open-circuit condition becomes difficult if an a-c bridge or any other instrument is connected across the ends of the specimen, because the open-circuit condition is violated. However, the cell assembly illustrated in Fig. A-2 allows determination of the conductance.

The total conductance G' of the double cell can be determined with an a-c bridge without violating the open-circuit conduction, because the nonmetal chemical potentials at the two ends are identical. The total conductance G' is then given by

$$1/G' = [1/(A\sigma_{ion})]\left\{\int_0^{L_1} t_{ion}(l)\,dl + \int_0^{L_2} t_{ion}(l)\,dl\right\} \qquad [28]$$

The quantities on the right can be determined as explained earlier and thus an experimental check may be obtained.

Fig. A-2. A symmetric double cell with solid electrolyte M_aX_b to determine the conductance when the solid electrolyte is subjected to a difference in the nonmetal chemical potential at its two ends.

LIST OF SYMBOLS

A	cross-sectional area
E	electrical potential difference
$E(L)$	electrical potential difference from O to L
$E(x/L)$	electrical potential difference from O to x
$\mathbf{F}$	Faraday's constant
G	total electrical conductance
I_η	current of species η
J_e	electronic current density
J_η	flux of species η
l	distance coordinate inside the specimen
L	total length of the specimen
n	empirical parameter characterizing presumed dependence of electronic conductivity
P_{X_2}	partial pressure of nonmetal gaseous dimer (X_2 gas)
$P_\oplus$	P_{X_2} at which $\sigma_\oplus = \sigma_{ion}$
$P_\ominus$	P_{X_2} at which $\sigma_\ominus = \sigma_{ion}$
R	gas constant
t_e	electronic transference number
t_{ion}	ionic transference number
T	temperature, °K
V	generalized potential
V'	potential at location O
V''	potential at location L
V^I	potential at location x^I
x	distance coordinate inside the specimen
z_X	valence of anion
η_e	electrochemical potential for electrons
μ_{X_2}	chemical potential/mole of nonmetal gaseous dimer (X_2 gas)
$\mu_{X_2}^o$	chemical potential for one mole of X_2 gas in the standard state
σ	total electrical conductivity
σ_e	total electronic conductivity
σ_{ion}	ionic conductivity
σ_η	conductivity parameter for species η
$\sigma_\oplus$	hole conductivity
$\sigma_\ominus$	excess electronic conductivity

Alkaline Earth Sulfide Phosphors Activated by Copper, Silver, and Gold

Willi Lehmann*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Emission spectra of cathodoluminescence of Cu, Ag, and Au in MgS, CaS, SrS, and BaS, at room temperature and near 80°K, are presented. The spectra depend very much on the coactivators used including the alkalies and the halides. The observations indicate the luminescence to be caused by centers containing both activator and coactivator.

Copper, silver, and gold are well known to be most effective activators in ZnS-type phosphors. They are probably incorporated as acceptors and, for charge compensation, require the simultaneous incorporation of a donor impurity, *e.g.*, a halide (except F) or a trivalent metal (*e.g.*, Al) as coactivator. Earlier workers have noted already, that the situation is quite different in alkaline earth sulfides where not Cl, Br, or I but F is the preferred halide and where even alkalies are effective coactivators (1, 2).

Investigations on alkaline earth sulfide phosphors activated by copper, silver, or gold are surprisingly rare, and the few publications are not always in agreement with each other. Lenard (1) reported three different emission bands, at 420, 512, and 600 nm, respectively, in CaS:Cu, but in view of the uncertain compositions of the materials of his days, the results may be questioned. More recently, and apparently working with better materials, Sorge (2) reports a single emission band in CaS:Cu,F, at 430 nm with 0.1% Cu and at 480 nm with 1% Cu. Gradual replacement of CaS by SrS and BaS shifts the copper emission to lower energies. Other reports on CaS:Cu include those by Avinor *et al.* (3) (one emission band at 460 nm) and by Wachtel (4) (two bands, at 435 and 500 nm). Reports on silver or gold activated alkaline earth sulfides do not seem to exist. Our investigations were made to clarify the reported contradictions on CaS:Cu and, more generally, to improve our knowledge of the entire alkaline earth sulfide phosphor system.

The compounds MgS, CaS, SrS, and BaS all crystallize in the cubic NaCl lattice. Some properties of interest are summarized in Table I. The optical absorption "edge" actually is the spectral position where, in a compound as pure as we could make, the optical absorption coefficient goes through the value of about 100 cm^{-1}. These points were determined by simple powder reflection measurement at room temperature; they are not necessarily identical to the true band gaps of the compounds which may be (and apparently are) obscured by various native defects, exciton absorptions, *etc*, and which may be slightly higher than the "edges" mentioned in Table I. The cationic radii are those reported by Pauling (5), and the next-neighbor distances are simply the sums of cationic and anionic radii (with 1.84Å for S^{--}). The interstitial radius is the maximum radius of a solid sphere which could be placed interstitially in the lattice without deformation of the latter.

Key words: magnesium sulfide, calcium sulfide, strontium sulfide, barium sulfide, alkaline earths, phosphors, luminescence, spectra, copper, silver, gold.

Table I. Some properties of alkaline earth sulfides

		MgS	CaS	SrS	BaS
Optical abs. edge	(eV)	~5.4	4.8	4.4	3.8
Cation radius	(Å)	0.65	0.99	1.13	1.35
Next-neighbor distance	(Å)	2.49	2.83	2.97	3.19
Interstitial radius	(Å)	0.32	0.61	0.73	0.93

Preparation

Alkaline earth sulfides of luminescence grade purity do not seem to be commercially available. We prepared CaS, SrS, and BaS by a method described by Sorge (2) and Wachtel (4). The purest available nitrates are dissolved in water and, for several hours, kept boiling in the presence of magnesium metal ribbon. Heavy metal impurities either deposit on the magnesium or are trapped in small amounts of hydroxide which, afterwards, is filtered out. The sulfates are then precipitated with H_2SO_4, briefly washed in water to remove excess acid, dried, and converted to the sulfides by firing in an atmosphere of H_2 and H_2S (4). The results are white, nonluminescent powders containing no spectroscopically detectable traces of Fe, Mn, Cu, etc. The major remaining impurity is silicon (usually about 100 ppm), probably from the quartz containers. Oxygen, due to unavoidable contact with atmospheric air, probably is also present but cannot be detected spectroscopically. We believe silicon to have no effect on the luminescence properties of the sulfides, and a possible effect of oxygen is minimized by the strongly sulfurizing atmosphere of the final firing step and by protection of the phosphors from air by an inert atmosphere (*e.g.*, argon) during storage. Only MgS cannot be prepared in this way ($MgSO_4$ is soluble in water). It was made by firing $MgCO_3$ (luminescence grade purity) in argon loaded with CS_2 (6). The conversion is quantitative but the resulting MgS has, at best, only the purity of the used $MgCO_3$.

Desired impurities were added to the prefired pure sulfides before the final firing step. It is considered to be an important point in these investigations that, whenever possible, only one activator element (here Cu, Ag, or Au) and one co-activator element were tested in any one of the samples, and that all other impurities were kept out as well as possible. Copper and silver were added as sulfides, gold as fine metal powder. Alkali metals, whose sulfides are too inconvenient to handle, were added as sulfates or carbonates. Halides were added as alkaline earth halides (*e.g.*, CaF_2 in case of CaS phosphors) or as ammonium halides, the latter react quickly with the host sulfides with liberation of small amounts of NH_3 and H_2S. The presence of traces of ammonium in this case, or of carbon in case of added carbonates, are not harmful since it was especially ascertained that both have no visible effect on the luminescence of the final phosphor. The presence of oxygen from decomposing sulfate or carbonate is somewhat more serious, but we believe to have reduced the influence to a negligibly low level by means of the sulfurizing atmo-

sphere during firing. All samples were fired in small amounts (a few grams) either in open quartz boats in flowing H_2S, or in capped quartz tubes containing, besides the phosphor, some free sulfur, and surrounded by argon[1] for one to two hours, MgS and CaS at 1200°C, SrS at 1000°C, and BaS at 800°C. Strontium sulfide and especially barium sulfide tend to form polysulfides if prepared in sulfurizing atmosphere. They were converted back to single sulfides by a brief refiring, at 700°C, in pure H_2.

Measurements

The emission spectra of luminescence were measured on thin powder layers excited in a demountable cathode-ray tube by 10 kV electrons at approximately 1 $\mu A/cm^2$ current density, either at room temperature or cooled to near 80°K. The luminescence was observed through a quartz window, with a quartz prism monochromator (Beckman DU) and a photomultiplier (1P28) in quartz glass. Spot tests showed the mode of excitation (electron beam or short wave ultraviolet) to have little or no effect on the spectra. All spectra presented here are corrected for monochromator transmission and photomultiplier response by means of a standard incandescence lamp supplied by the National Bureau of Standards, and given in terms of quantum intensity per unit energy interval as function of the quantum energy. The limit of spectral resolution is about 0.02 eV, or better, fairly independent of the spectral position. All spectra are normalized to equal peak height (= 100 units) irrespective of the emission intensities actually observed.

Experimental Results

The influence of the added copper concentration on the emission spectra of a series of CaS:Cu,Na (3%) phosphors is demonstrated in Fig. 1. The emission intensity increases with the copper concentration up to about 0.1% Cu and then decreases again. At low copper concentrations, the spectrum consists of two structureless bands about 0.28 to 0.30 eV apart. These two bands disappear at high copper concentrations (about 0.5% and more) and, instead, a very broad and irregularly shaped band with the peak at about 2.3 to 2.4 appears. We observe similar dependence on the activator concentration also within other alkaline earth sulfides activated by copper, silver, or gold. The spectra observed at low concentrations apparently are due to isolated luminescence centers and the broad bands, observed at high concentration, to interaction between adjacent centers. The following results are limited to materials with low activator concentrations, *i.e.*, about 0.1 mole % or less.

Various co-activators have an influence (reproducible) on the peak positions and the widths of the two emission bands of CaS:Cu and (less quantitatively reproducible) on their intensity ratio. Some representative spectra are shown in Fig. 2. The following observations may especially be mentioned:

(*a*) Even CaS:Cu containing only copper (no intentionally added coactivator) is well luminescent in two separate emission bands.

(*b*) The observed peak positions, as function of the added coactivator, scatter over a range clearly exceeding the unavoidable uncertainties in phosphor reproducibility (about ± 0.02 eV) and accuracy of measurements.

(*c*) The two emission bands resemble, in width and separation, very much the two emission bands observed in ZnS:Cu phosphors.

(*d*) The emission of CaS:Cu with Cl (similar also Br) as coactivator is weak. Its emission spectrum resembles the broad band observed, with other coactivators, only at high copper concentrations.

The influence of the coactivator on the emission spectrum is not limited to CaS:Cu but almost universally observable within all alkaline earth sulfides activated by Cu, Ag, or Au. It is very pronounced in some cases (*e.g.*, in SrS:Au, Fig. 3), weaker but still clearly visible in others (*e.g.*, in BaS:Cu, Fig. 4) but nearly always present. This is demonstrated also in Fig. 5 and 6 showing the peak positions of the

[1] The latter method is described by Wachtel (4).

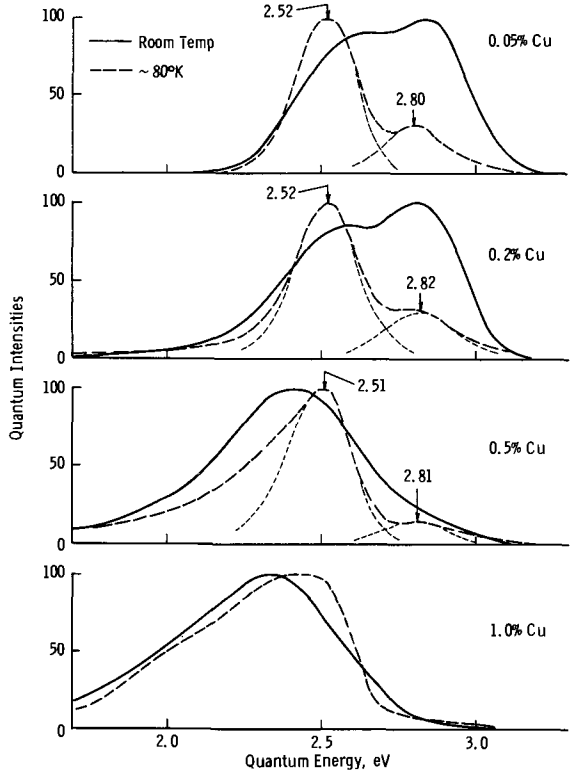

Fig. 1. Emission spectra of CaS:Cu,Na(3% added) phosphors of varied copper concentrations.

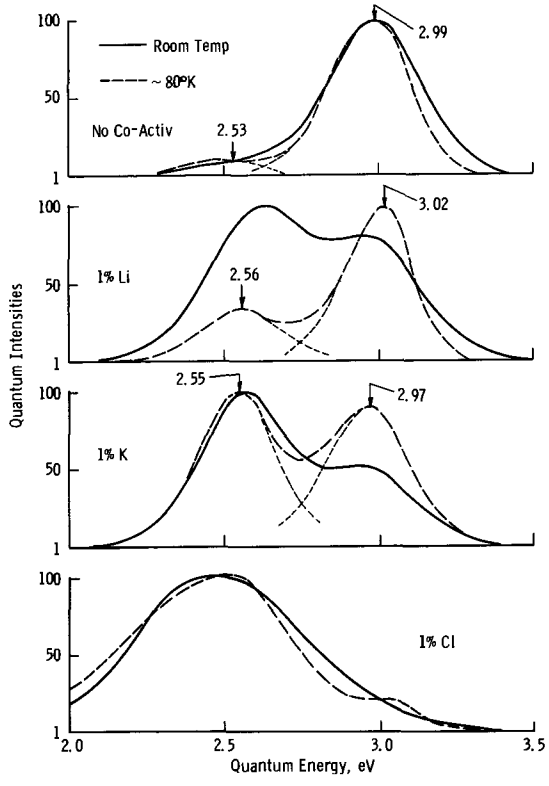

Fig. 2. Emission spectra of CaS:Cu(0.1%) with different coactivators (1% added).

emission bands of alkaline earth sulfides activated by Cu and by Au as function of the used co-activator. The length of each horizontal bar indicates approximately the accuracy of the determination of the peak positions. It is clear that the scatter due to variation of the coactivator by far exceeds the limit of accuracy in many cases. It may especially be stressed here that these variations are not accidental due to poor reproducibility of the materials; they are well reproducible.

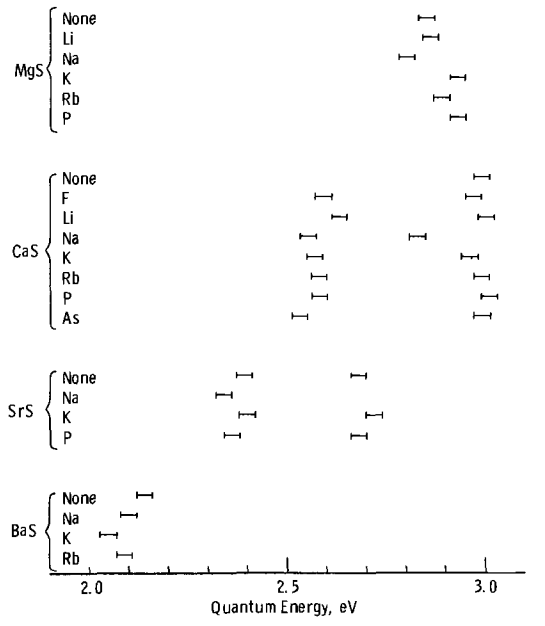

Fig. 5. Peak positions of alkaline earth sulfide phosphors all made with 0.1% of copper and 1% of various coactivators, measured at room temperature.

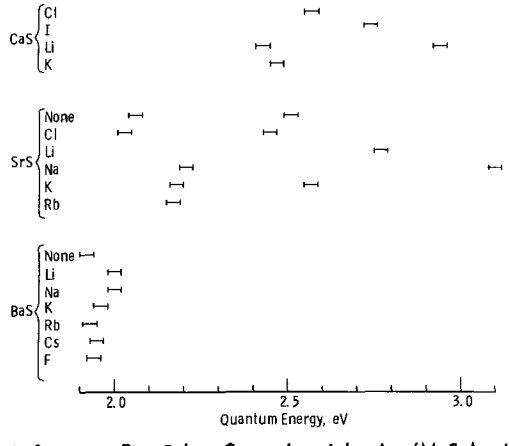

Fig. 6. Same as Fig. 5 but Cu replaced by Au (MgS:Au is nonluminescent).

In view of these complications it is not surprising that no simple "shift" of an emission spectrum to lower energies is observed if, with any activator-coactivator pair, the host crystal is varied from MgS to CaS to SrS to BaS. Some spectra demonstrating this are shown in Fig. 7-9. The closest resemblance to a simple spectral shift exists for copper (Fig. 7), but deviations appear here also. Any regular behavior is missing in cases of silver (Fig. 8) and gold (Fig. 9).

The following general remarks may be made to the efficiencies of copper, silver, and gold in alkaline earth sulfide phosphors:

Copper-activated alkaline earth sulfides normally are efficient phosphors, quantum efficiencies of photoluminescence of about 50% or more, and energy efficiencies of cathodoluminescence of 10 to 15%, can routinely be obtained. Exceptions are only materials containing Cl, Br, or I which perform very poorly.

Silver is an inefficient activator in any one of the alkaline earth sulfides and with any coactivator, efficiencies of photo- and of cathodo-luminescence rarely come to about 10% and 1%, respectively. Silver does enter the lattices, however, and produces emission spectra clearly different from those caused by copper or gold.

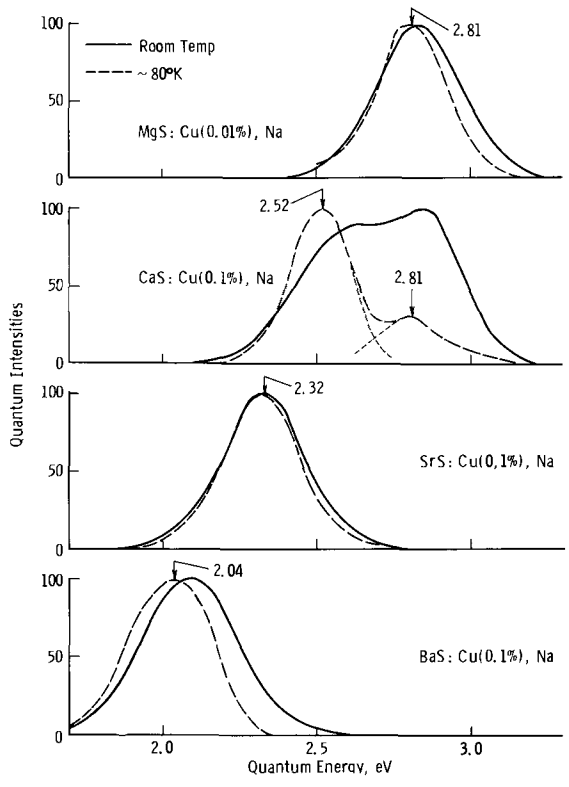

Fig. 7. Emission spectra of MgS, CaS, SrS, and BaS activated by copper and sodium (1% added).

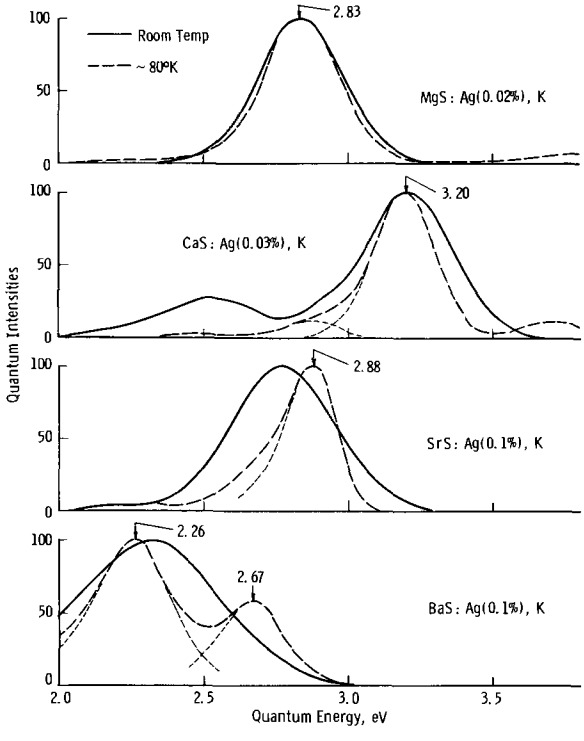

Fig. 8. Emission spectra of MgS, CaS, SrS, and BaS activated by silver and potassium (1% added).

Gold-activated alkaline earth sulfides containing Cl, Br, or I as coactivator are about as efficient in photo- and in cathodo-luminescence as Cu-activated materials containing halides. The alkalies perform somewhat poorer in combination with gold. Gold is completely ineffective in MgS, however. All attempts to make luminescent MgS:Au phosphors, without or with added coactivators (tested: F,Cl,Br,I,Li,Na,K, Rb,P) failed; the materials invariably were dead. It

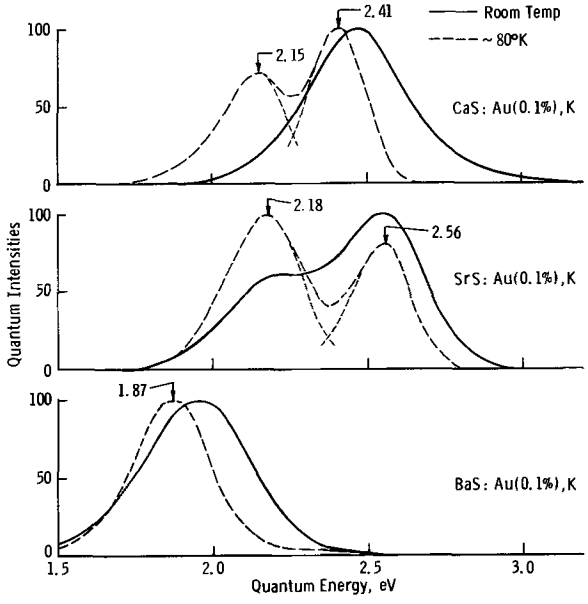

Fig. 9. Emission spectra of CaS, SrS, and BaS activated by gold and potassium (1% added). MgS:Au is nonluminescent.

may be that gold is too big (ionic radius = 1.37Å) to replace the small Mg^{2+} ion (0.65Å) in the lattice of MgS.

Discussion

The Schön-Klasens model of luminescence in ZnS-type phosphors assumes the emission to be due to an electron transition from the lower edge of the conduction band, or from a level very close to that edge, into a previously emptied level (caused by Cu^{+}, etc.) not too far above the valence band edge. This model certainly does not apply to alkaline earth sulfide phosphors because:

(*a*) It would require independence of the emission spectra on the used coactivator.

(*b*) It would require the emission spectra simply to shift to lower energies, parallel to the change of the width of the band gap, as the host crystal is varied from MgS to CaS to SrS to BaS.

Both predictions are in strong disagreement with the observations. The emission spectra do very definitely depend on the coactivator, and there is no spectral shift over a range corresponding to the change in band gap (compare Fig. 5-7 with data in Table I). The observations can only be understood on the basis of a Prener-Williams type of recombination (7, 8) in which both, activator and coactivator, are directly involved. Shionoya *et al.* (9) recently presented strong evidence that this type of recombination is responsible for all the main emission bands of copper and silver in ZnS-type phosphors.

No attempt shall be made here to present a model to explain quantitatively the observed variations in alkaline earth sulfide phosphors activated by copper, silver, or gold.

Liquid-Phase Epitaxy of $In_xGa_{1-x}As$

G. A. Antypas*

Central Research Laboratories, Varian Associates, Palo Alto, California 94303

ABSTRACT

$In_xGa_{1-x}As$ layers grown by liquid-phase epitaxy were obtained in the range of $0.0 < x < 0.23$, when grown on the (111 Ga) plane of GaAs. Attempts to grow alloys on the (110), (111 As), (100), and (112 As) planes resulted in polycrystalline layers. The alloy composition was determined by x-ray fluorescence and the band gap by infrared transmission. The ternary-phase diagram was calculated using Darken's quadratic formalism to describe the ternary liquid and assuming the solid solution in equilibrium with the liquid to be regular. It was found that the experimental results were in good agreement with the calculated phase diagrams. A number of liquidus isotherms were calculated in the temperature range of 700°-1200°C. Gallium arsenide isoconcentration curves are shown for 0.95, 0.90, 0.80, 0.50, and 0.30 GaAs mole fraction.

Early experimental investigation of the solid solutions of III-V compounds indicated that systems having a column V common element do not form continuous solid solutions, while systems having a common III element do. This observation was based on the report by Koster and Thoma (1) on GaSb-InSb, AlSb-InSb, and GaSb-AlSb, and the work of Folberth (2) on the InAs-InP and GaAs-GaP systems. Goryunova and Fedorova (3), however, reported that complete solid solutions were obtained in the InSb-GaSb system, and an almost complete solid solution was obtained for the InAs-GaAs system when the alloys were annealed at relatively high temperatures for extended periods of time. Since then, the InAs-GaAs system has received wide attention primarily due to its wide direct band gap range. Woolley and Smith (4) have obtained a series of alloy compositions by annealing compressed powders at 900°C. X-ray diffraction studies on these samples indicate that Vegard's law was obeyed. Abrahams *et al.* (5) studied the electrical, thermal, and optical properties of InGaAs alloys prepared either by gradient freezing or zone leveling techniques. Van Hook and Lenker (6), using the techniques described by Shafer and Weiser (7), obtained InGaAs alloys across the whole composition range. All of the mentioned techniques yielded polycrystalline material; furthermore, the mixed crystals were annealed or grown at temperatures close to the melting point of InAs (942°C).

Liquid-phase epitaxy as reported by Nelson (8) has been used previously in growing high-quality epitaxial layers with low native defect density (9). This technique was used by Antypas and James (10) in growing $GaAs_xSb_{1-x}$ epitaxial layers on GaAs substrates in the range $1.00 > x > 0.75$. Olsen *et al.* (11) reported the growth of InGaAs epitaxial layers on GaAs substrates in the temperature range of 750°-600°C. The author, however, was unable to obtain any more information on the growth characteristics and/or properties of the grown layers. Recently, Stringfellow and Greene (12) reported that Ewing grew InGaAs epitaxial layers across the alloy series on (111 As) InAs substrates by liquid-phase epitaxy. Their results were in excellent agreement with their calculated ternary-phase diagram based on the quasi-chemical theory.

* Electrochemical Society Active Member.

Key words: III-V alloy semiconductors, InGaAs ternary phase diagram.

The present investigation was oriented toward developing InGaAs epitaxial layers, preferably on GaAs substrates, to be used as high-efficiency, long-wavelength threshold semitransparent photoemitters. Similar investigations in our laboratory have led to the development of high-efficiency 1.06μ photoemitters based on $GaAs_xSb_{1-x}$ epitaxial layers.

Experimental Procedure

The epitaxial layers were grown using the horizontal technique initially described by Nelson (8). The In-Ga melts are prepared in a carbon boat, over which palladium-purified hydrogen is flowing, inside a quartz tube. A preweighed InAs crystal which is the source of As is also placed in the boat. The melts are heated to the starting growth temperature (sgt) for approximately 3 hr. After the equilibrium amount of InAs is dissolved, any further dissolution will result in the growth of a ternary layer of InGaAs on the seed, which will be in equilibrium with the melt. This would prevent any further dissolution of the substrate.[1]

Following saturation, the undissolved InAs is removed and reweighed, thus determining the composition of the melt. The saturation experiments are repeated for longer periods of time, and at 750°C (which is the temperature of interest in our investigation) weight losses between experiments of less than 1% were observed. This could be accounted for by both temperature fluctuations of the furnace and As evaporation. In any event, the loss of As as a source of error in determining the liquidus composition can be neglected at low temperatures.

Prior to growth, the substrate was placed at one end of the boat and a dendrite of GaAs was introduced in the melt so that it would prevent any etch-back from the substrate due to temperature fluctuations in the furnace or due to the loss of As from the melt. The furnace was then tilted about 10° from the horizontal position so that the melt would roll over the substrate, at which point a programmed cooling cycle was initiated. At the end of the growth cycle, the furnace was

[1] We attempted to identify this thin epitaxial layer on experiments performed on the GaAsSb system by monitoring the photoluminescence spectra of GaAs seeds that were used in saturating Ga-Sb melts. In all cases, only GaAs band gap radiation was observed. Apparently the layers present cannot be detected by this technique.

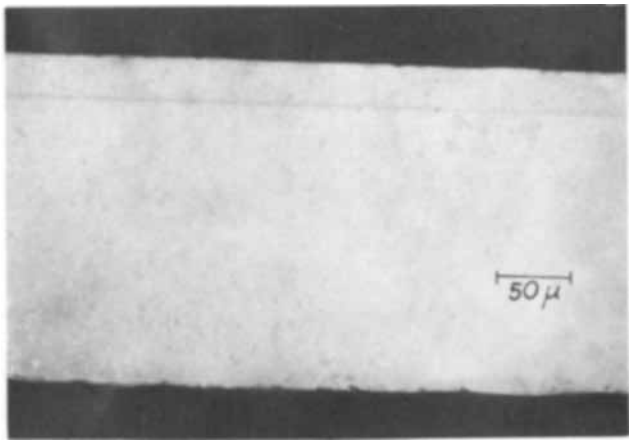

Fig. 1. Cross section on cleaved (110) plane showing an $In_{0.03}Ga_{0.97}As$ epitaxial layer grown on (100) oriented GaAs substrate.

tipped back to the horizontal position and the melt was removed from the substrate with the aid of a quartz hoe.

Experimental Results

During early experiments, it was observed that the distribution coefficient of GaAs when grown from In-Ga-As solutions is greater than unity. Similar behavior has been observed for GaAlAs when grown from Ga-Al-As melts (13). Thus, epitaxial layers of InGaAs will have to be grown from In-rich melts. Figure 1 shows an epitaxial layer (sample No. 4-5-B) of InGaAs grown on (100) Cr-doped GaAs substrates. The sample was cleaved and etched in a $H_2O:H_2O_2:HF$ (10:1:1) delineation etch for 10 sec. Details of melt composition, solid composition, and growth temperatures are given in Table I.

A representative epitaxial layer grown on (100) GaAs substrates from melts having higher In concentration than those from which sample No. 4-5-B was prepared is shown in Fig. 2. The layers were polycrystalline in nature, with a very rough surface which is the result of a great number of In-Ga inclusions. Further experimentation showed that it was impossible to grow high-quality InGaAs epitaxial layers having InAs concentrations greater than 5% on (100) GaAs substrates.

Growth of InGaAs layers on (110), (111 As), and (112 As) GaAs faces exhibited similar characteristics to those grown on (100) faces. However, when growing on the (111 Ga) plane, the layers have mirror-smooth surfaces and planar interfaces. Figure 3 represents an epitaxial layer of InGaAs (1.17 eV band gap) grown from In-rich melts, the details of which are shown in Table I. The (111 Ga) GaAs substrates were chemically polished in dilute NaOCl solutions. Epitaxial layers grown on the (112 Ga) plane of GaAs were of lower quality and did not have the mirror-smooth surface exhibited by the layers grown on the (111 Ga) plane.

The band gap of the epitaxial layers grown on GaAs substrates was determined by infrared transmission corrected for sample thickness. The absorption edge

Table I. Results and summary of the growth conditions of the InGaAs epitaxial layers

Sample No.	Melt composition in a/o In	Ga	As	Growth temp (°C)	Band gap (eV)	x_{GaAs}	Substrate orientation
4-5-B	55.5	40.5	4.0	740-690	1.35	0.97	(100)
9-15-A	61.5	33.5	5.0	740-700	1.30	0.94	(111 Ga)

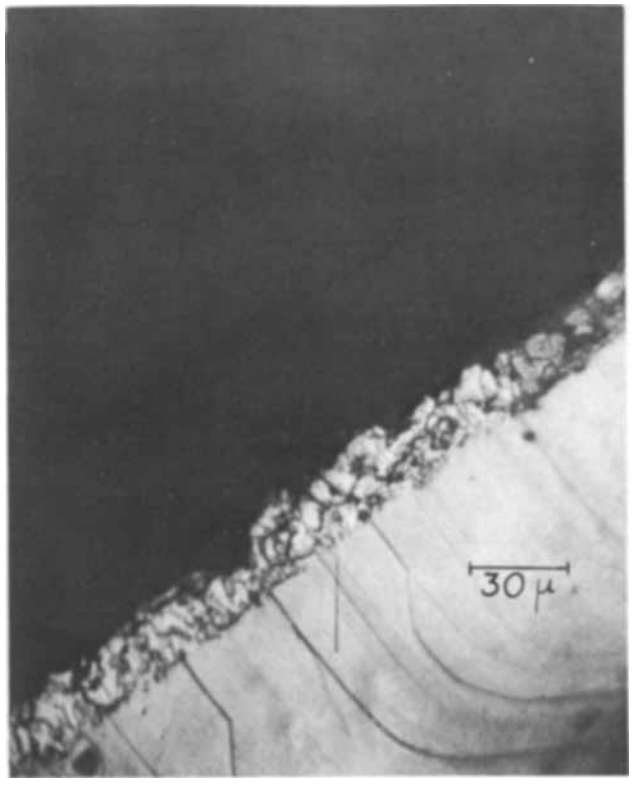

Fig. 2. Cross section of polycrystalline InGaAs epitaxial layer grown on the (100) plane of GaAs substrates. Similar layers have been obtained when InGaAs epitaxial layers are grown on the (110), (111 As), and (112 As) planes of GaAs from melts resulting in $x_{InAs} > 0.05$.

Fig. 3. Cross section of representative InGaAs epitaxial layers grown on the (111 Ga) plane of GaAs. Similar layers were obtained in the composition range of $0.77 < x_{GaAs} < 1.0$.

was very sharp, and the band gap was taken as the 10% transmission point. Figure 4 shows the band gap variation as a function of alloy composition. The band gap of InGaAs alloys reported by a number of investigators is also shown.

Epitaxial layers of InGaAs grown on (111 As) InAs substrates had mirror-smooth surfaces only when grown at temperatures around 650°C. At higher temperatures (~750°C), it was observed that on a number of occasions the layer substrate interface was completely obliterated and, in general, the layers appeared rougher than those grown at lower temperatures.

Phase Diagram Calculation

Phase diagram calculations for ternary III-V compounds have been reported by Stringfellow and Greene

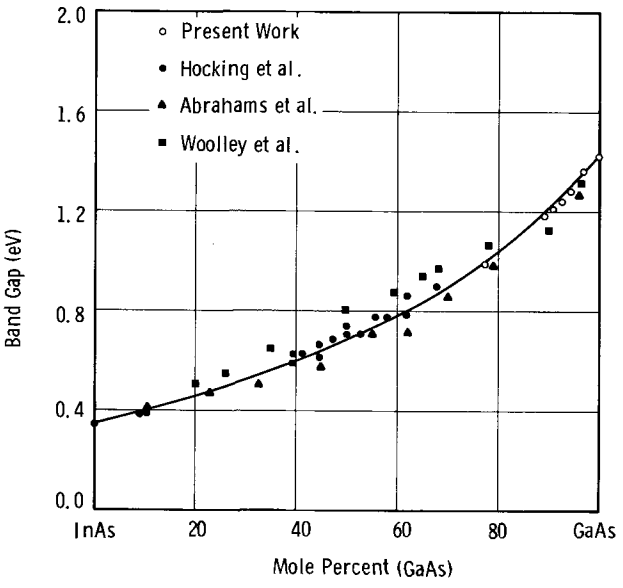

Fig. 4. Dependence of the band gap on the composition of InGaAs alloys prepared by a variety of techniques.

(12) who used the quasi-chemical approach to describe both the solid and liquid solutions, and by Ilegems and Pearson (13) who calculated the ternary-phase diagrams of $Ga_xAl_{1-x}As$ using the regular solution theory to describe the ternary liquid and ideal solution for the pseudobinary solid. Antypas and James (10) recently calculated the ternary-phase diagrams of $GaAs_xSb_{1-x}$, using Darken's (14) quadratic formalism to describe the liquid and assuming the pseudobinary solid to be described by a regular solution. They found it to be in good agreement with experiment. Antypas (15) has also calculated the ternary-phase diagram of GaAsP based on the same theory and found it to be in excellent agreement with available experimental data.

In computing the conditions for equilibrium between a ternary liquid solution A, B, C, (In,Ga,As) and a pseudobinary solid solution AC-BC (InAs-GaAs), Stringfellow and Greene (12) derived the following equations:

$$\ln \gamma_{AC}x = \ln 4N_AN_C + \ln (\gamma_A\gamma_C/\gamma_A^{STC}\gamma_C^{STC}) + \Delta S^F_{AC}(T^F_{AC} - T)/RT$$

$$\ln \gamma_{BC}(1-x) = \ln 4N_BN_C + \ln (\gamma_B\gamma_C/\gamma_B^{STC}\gamma_C^{STC}) + \Delta S^F_{BC}(T^F_{BC} - T)/RT \quad [1]$$

where γ_{AC} and γ_{BC} are the activity coefficients of AC and BC in the solid solution, x is the mole fraction of AC, N_i and γ_i ($i = A,B,C$) are the atom fraction and activity coefficient of i in the liquid solution, respectively, γ_i^{STC} is the activity coefficient of N_i at the stoichiometric composition, ΔS^F_{AC} is the entropy of fusion of AC, T^F_{AC} is the temperature of fusion of AC, R is the universal gas constant, and T is the temperature in °K.

Under the restriction

$$N_A + N_B + N_C = 1 \quad [2]$$

Eq. [1] can be solved numerically on a computer to yield two sets of curves, one describing the liquidus isotherms and the other describing the solidus isoconcentration curves of the system.

In previous investigations, the activity coefficients were determined by the quasi-chemical equilibrium (12) approach and by considering the ternary liquid as a strictly regular solution (13). In the present communication, however, the determination of the activity coefficient in the liquid phase is based on Darken's (16) quadratic representation, which for a binary liquid is

$$\ln \gamma_A = \alpha_{AC}N_C^2$$

$$\ln (\gamma_C/\gamma_C^0) = \alpha_{AC}(-2N_C + N_C^2) \quad [3]$$

where A is the solvent and C is the solute, γ_C^0 is the activity coefficient of C at infinite dilution, and α_{AC} is the interaction parameter of the system. Equation [2] reduces to that describing a regular solution if $\ln \gamma_C^0 = \alpha_{AC}$. This formalism has been satisfactorily applied by Darken (16) and Turkdogan and Darken (17) to a number of liquid metallic solutions for concentration of up to 60%. This formalism is consistent with the Gibbs-Duhem equation and satisfies Raoult's and Henry's laws as the limiting cases. The activity coefficients for a ternary liquid based on Darken's quadratic formalism are given by

$$\ln \gamma_A = \alpha_{AB}N_B^2 + \alpha_{AC}N_C^2 + (\alpha_{AB} + \alpha_{AC} - \alpha_{BC})N_BN_C$$

$$\ln (\gamma_B/\gamma_B^0) = -2\alpha_{AB}N_B + (\alpha_{BC} - \alpha_{AB} - \alpha_{AC})N_C + \alpha_{AB}N_B^2 + \alpha_{AC}N_C^2 + (\alpha_{AB} + \alpha_{AC} - \alpha_{BC})N_BN_C$$

$$\ln (\gamma_C/\gamma_C^0) = -2\alpha_{AC}N_C + (\alpha_{BC} - \alpha_{AB} - \alpha_{AC})N_B + \alpha_{AB}N_B^2 + \alpha_{AC}N_C^2 + (\alpha_{AB} + \alpha_{AC} - \alpha_{BC})N_BN_C \quad [4]$$

where component A is the solvent and components B and C are the solutes, γ_B^0 is the activity coefficient of component B at infinite dilution, and α_{i-j} are the interaction energies of the various binary systems. The above formalism is also consistent with the Gibbs-Duhem equation, and furthermore it reduced to the binary quadratic formalism as one of the solutes in the ternary approaches infinite dilution.

The solid solution in equilibrium with the ternary liquid was assumed to be regular, *i.e.* $\Delta F^{xs} = \alpha_{AC-BC}x(1-x)$, where α_{AC-BC} is the interaction energy and x is the mole fraction of one of the components in the solid. The activity coefficients are thus given by

$$\ln \gamma_{AC} = \alpha_{AC-BC}(1-x)^2$$

$$\ln \gamma_{BC} = \alpha_{AC-BC}x^2 \quad [5]$$

Substituting Eq. [4] and [5] in Eq. [1], the ternary-phase diagram can be calculated numerically to yield the liquidus and solid distribution curves.

The parameters necessary in calculating the ternary-phase diagram are the temperatures T^F and entropies ΔS^F of fusion of the III-V compounds and the interaction parameters α_{AB}, α_{AC}, α_{BC}, and α_{AC-BC}. T^F and ΔS^F for InAs and GaAs can be obtained directly from the literature and are shown in Table II. Vieland (18) has used regular solution theory to calculate the liquidus of III-V compounds. The interaction parameter obtained from such a treatment is

$$\alpha = \frac{\Delta S^F(T - T^F)[1 + R/\Delta S^F]\ln 1/4x(1-x)}{2(x-0.5)^2} \quad [6]$$

where x is the column V element in solution. For a regular solution, α should be independent of temperature and composition. Thurmond (19), however, demonstrated that for GaAs α is a linear function of temperature given by

$$\alpha_{GaAs} = 9960 - 11.15T \quad [7]$$

(When the interaction parameter, α, is divided by RT so that it will be thermodynamically consistent with Darken's formulation, it takes the form of

$$\omega = \frac{\mathcal{L}}{RT} - \frac{\delta}{R} \quad [8]$$

Table II. Parameters used in calculating the ternary-phase diagram

	InAs	GaAs	In-Ge	InAs-GaAs
α (cal/mole)	$-9.160\,T + 4300$	$-3.7\,T$	1000	2000
ΔS^F (eu)	14.52 [Ref. (24)]	16.64 [Ref. (24)]	—	—
T^F (°C)	942	1238	—	—

which is of the form derived by Turkdogan and Darken (17), where $\mathcal{L}$ and δ have the units of enthalpy and entropy, respectively.)

In calculating α_{GaAs}, Thurmond assumed a ΔS^F_{GaAs} value of 14.0 eu. Arthur (20) pointed out that, when a recently measured value for ΔS^F_{GaAs} of 16.64 eu is used, then

$$\alpha_{GaAs} = 5160 - 9.16T$$

Arthur has also calculated the activity coefficient of As from As vapor pressure measurements, and using a regular solution treatment found that the interaction parameter is accurately given by

$$\alpha_{GaAs} = -3.7T$$

A similar analysis performed on the InAs system based on the solubility data of Hall (21) and Liu and Peretti (22) resulted in an interaction parameter given by

$$\alpha_{InAs} = -9.160T + 4300$$

The interaction parameter for the In-Ga system was calculated to be 1000 cal/mole by fitting the liquidus curve to a regular solution model and comparing it to available experimental data (23). Similarly, the interaction parameter of the InAs-GaAs system was determined by fitting the solidus curve to published data of the InAs-GaAs pseudobinary. Calculations performed are in good agreement with experiment when $\alpha_{InAs\text{-}GaAs} = 2000$ cal/mole. In the ternary phase diagram calculations, the activity coefficient of Ga at infinite dilution, $\ln \gamma_{Ga}^{o}$, was varied between 0 and -1.8. The best fit to the experimental liquidus, and solidus, data for the 750° and 700°C isotherms were obtained when $\ln \gamma_{Ga}^{o} = -0.8$.

Figure 5 shows the calculated phase diagram where the solid lines represent the liquidus isotherms, while the dotted lines are the GaAs isoconcentration curves. A number of experimental points are also shown. The composition of the pseudobinary solid was determined by x-ray fluorescence. The pseudobinary diagram obtained from Fig. 5 is shown in Fig. 6. It is seen that the calculated phase diagram is in good agreement with available experimental data. For Fig. 7, we replotted a portion of the ternary-phase diagram in cartesian coordinates. It shows the calculated solidus isotherms for 700° and 800°C along with experimental results.

Conclusions

InGaAs layers have been grown on GaAs substrates. It has been observed that, when growing from In-rich melts, epitaxy of $In_xGa_{1-x}As$ layers on GaAs with $x > 0.05$ can be obtained only when growing on the (111 Ga) face. The In-Ga-As ternary-phase diagram was calculated using Darken's quadratic formalism to describe the ternary liquid while treating the solid as a regular solution; it was found to be in good agreement with experiment. The calculated pseudobinary phase diagram was in excellent agreement with available experimental data. The composition of the mixed crystals was determined by x-ray fluorescence techniques, and the band gap by infrared transmission, corrected for sample thickness. The variation of the band gap was plotted as a function of composition along with the data obtained by a number of investigations for InGaAs alloys prepared by a variety of techniques. Stringfellow and Greene (12) reported that Ewing obtained alloys of InGaAs grown on InAs substrates across the alloy series, from a starting growth temperature of as high as 780°C. Our experi-

ence is that high-quality epitaxial layers on InAs substrates could be grown only at lower temperatures.

Acknowledgments

The author wishes to thank L. Garbini who performed the x-ray fluorescence analysis of the samples, and S. Reita for his technical assistance.

Silicon Epitaxy from Mixtures of SiH_4 and HCl

J. Bloem*

Semiconductor Development Laboratory, N. V. Philips Gloeilampenfabrieken, Nijmegen, Holland

ABSTRACT

An investigation of the epitaxial growth of silicon from $SiCl_4$ in H_2 and from mixtures of SiH_4 and HCl in H_2 indicates that the gas phase reactions are slow and that equilibrium between solid and gas occurs at the interface. Kinetic data point to a diffusion controlled reaction rate, and it is shown that thermodiffusion in the stagnant gas layer on the silicon surface retards the growth rate of silicon and enhances the etching reaction.

In the epitaxial growth of silicon several studies of the thermodynamics and kinetics of the system have been published. Surveys are given in ref. (1) and (2).

At temperatures over 1100°C the reaction is considered to be diffusion controlled, with chemical equilibrium occurring at the solid-gas interface.

Recently Eversteyn *et al.* (2) introduced the concept of a stagnant gas layer of constant thickness over the substrates in a horizontal reactor. In the stagnant layer a steep temperature gradient (~1000°/cm) is present (2), and it is interesting to examine whether gas phase reactions occur in this boundary layer and whether the diffusion of species from and to the growing interface will be influenced by the presence of the temperature gradient.

In this investigation epitaxy from $SiCl_4$ in H_2 and from mixtures of SiH_4 and HCl in H_2 is studied because, if chemical equilibrium is attained in the gas phase, $SiCl_4$ in H_2 would be expected to give the same growth rate and the same temperature dependence of growth rate, as a mixture of $SiH_4 + 4HCl$ in H_2.

The calculations of Eversteyn *et al.* (2) on the growth rate have been extended to include the effect of thermodiffusion (3). The results of the extended calculation are applied here to the growth rate of Si from SiH_4 and to the etch rate of Si by HCl. The former reaction is governed by the diffusion of SiH_4 toward the reacting surface, the latter by the diffusion of the reaction products of the etching reaction, mainly $SiCl_2$ (1, 4) away from the interface.

Growth and Etch Rates

In a diffusion controlled reaction involving a stagnant layer of constant thickness, δ cm, the growth rate of silicon can be calculated from the material balance at the interface.

The flux of material toward the interface in moles/cm² sec, for a given position on the susceptor, is given by (5)

$$J_x = -D_i n \left[\frac{d \frac{n_i}{n}}{dy} \right] \qquad [1]$$

where D_i is the diffusion coefficient of the rate-determining species in cm²/sec, n is the total gas density (moles/cm³), n_i is the concentration of the diffusing species (moles/cm³), and y is the direction perpendicular to the growing interface.

In the Appendix the growth rate of silicon is calculated for the case where the diffusion of SiH_4 toward the surface is the rate-controlling step.

At temperatures around 1150°C HCl etching of silicon proceeds via the reaction.

$$Si + 2HCl \leftrightharpoons SiCl_2 + H_2 \qquad [2]$$

For $p_{H_2} = 1$

$$K_{SiCl_2} = \frac{p_{SiCl_2}}{(p_{HCl})^2} \qquad [3]$$

The value of K_{SiCl_2} at 1500°K is nearly unity (1, 4), which implies that with $p_{HCl} = 10^{-2}$ the maximum value of p_{SiCl_2} will be about 10^{-4} atm. For a diffusion

limited reaction the silicon etch rate will be slow, because the diffusion of $SiCl_2$ away from the surface constitutes the rate-controlling step in the steady-state condition, assuming that the diffusion coefficients of HCl and $SiCl_2$ in hydrogen do not differ markedly. The HCl partial pressure at the silicon interface will be nearly equal to the HCl partial pressure in the main gas ($\sim 10^{-2}$ atm).

Because the growth rate depends on diffusion toward the interface and the etch rate depends on diffusion away from the interface, the ratio of growth and etch rates may give information regarding second order effects in the transport processes, *i.e.*, thermodiffusion.

For a binary gas mixture in a temperature gradient a concentration gradient is produced, given by (3, 5, 6)

$$\frac{d\frac{n_1}{n}}{dy} = K_T \frac{d \ln T}{dy} \qquad [4]$$

where n_1 is the concentration of the heavier molecule in the gas (moles/cm^3), K_T is the thermodiffusion ratio, and T is the temperature with a gradient in the y-direction (°K).

The thermodiffusion ratio can also be expressed as

$$K_T = \alpha \frac{n_1}{n} \cdot \frac{n_2}{n} \qquad [5]$$

where α is the thermodiffusion factor, and n_2 is the concentration of the second component in the binary gas mixture.

Equations [4], [5], and [1] can be combined to give the expected growth and etch rates including the thermodiffusion effect. In the Appendix it is shown that the ratio of growth rate (G) and etch rate (E), neglecting thermodiffusion, is given by (13)

$$\frac{G}{E} = \frac{D_{SiH_4} \cdot p_{SiH_4}}{D_{SiCl_2} \cdot p_{SiCl_2}} = \frac{D_{SiH_4} \cdot p_{SiH_4}}{D_{SiCl_2} \cdot K_{SiCl_2} \cdot (p_{HCl})^2}$$

Including thermodiffusion for the simplified case that α_1 and α_2 are equal the expression [20] in the Appendix becomes

$$\frac{G}{E} = \frac{D_{SiH_4} \cdot p_{SiH_4}}{D_{SiCl_2} \cdot K_{SiCl_2} (p_{HCl})^2} \cdot \frac{T_g^{\alpha_1}}{T_s^{\alpha_2}}$$

where D_{SiH_4} and D_{SiCl_2} are the diffusion coefficients in H_2 of SiH_4 and $SiCl_2$, respectively (cm^2/sec), p_{SiH_4} is the partial pressure of SiH_4 in the main gas (atm), p_{SiCl_2} is the equilibrium pressure of $SiCl_2$ at the silicon surface (atm). T_g and T_s are the temperatures of the main gas and the substrate in °K, and α_1 and α_2 are the thermodiffusion factors of SiH_4 and $SiCl_2$, respectively.

The greater the values of α and the smaller the ratio T_g/T_s the greater will be the difference between growth and etch rates arising from the diffusion of SiH_4 toward the interface being hampered and the diffusion of $SiCl_2$ away from the interface being promoted. The value of α depends on the relative molecular diameters and relative masses of solute and solvent. For heavy molecules in a light gas, relatively high values of α can be expected, up to a value of about 3 for an extreme case (6, 7).

Taking reasonable values for the molecular diameters gives the following results

$$\alpha_{SiH_4-H_2} = 1.0; \quad \alpha_{SiCl_2-H_2} = 1.5; \quad \alpha_{SiCl_4-H_2} = 1.7$$

Not much is known about the temperature dependence of α, but a slight increase with temperature is to be expected (5).

Apart from thermodiffusion there are other factors that can cause growth and etch rates to differ from the values calculated. Two important ones are the temperature dependence of the diffusion coefficients and the value of the chemical equilibrium constant, K_{SiCl_2}. For the diffusion coefficients, the value of the exponent, m, in the expression for the temperature dependence $D = D_0(T/T_0)^m$, theoretically may vary from 1.5 to 2.0 (8); a smaller value of m being expected for SiH_4 than for $SiCl_2$. Analysis of the literature (9, 10) indicates a value of 1.0 ± 2.5 for the equilibrium constant K_{SiCl_2} at 1500°K. Moreover SiH_2Cl_2 and possibly $SiHCl_3$ also occur in concentrations that increase the etch rate, and an effective value of K_{SiCl_2} of 2.5 therefore is not unreasonable.

The experimental approach involves: (*a*) estimating the magnitude of the thermodiffusion effect for SiH_4, (*b*) selecting the temperature dependence of D_{SiH_4} to fit the experimental growth rate of silicon, (*c*) using the data of (*a*) and (*b*) to estimate reasonable values of α and m for $SiCl_2$, (*d*) obtaining an estimate of the magnitude of K_{SiCl_2} from the closeness of the fit between experimental and calculated rates, and from the ratio of growth and etch rates.

Experimental

The conventional horizontal RF heated epitaxial reactor employed an 80 cm long quartz tube with rectangular cross section (10 x 2.5 cm^2), in which a SiC coated graphite susceptor was placed (10 x 24 x 1.25 cm^3). The total hydrogen gas stream was kept at 75 l/min giving a stagnant layer thickness over the heated susceptor of about 0.30 cm at a mean gas temperature of 750°K (2).

The exhaust gas left the system via a water-cooled heat exchanger; the gas pressure in the system being 1 atm. Flow rates of SiH_4, $SiCl_4$, and HCl were controlled by calibrated flow meters. Ten silicon substrate slices of 38 mm diameter were placed on the susceptor in two rows. The slices were n-type, Sb-doped (0.007 ohm cm) with an orientation 3° from the (111) orientation in the direction of the nearest (110) (11). After slicing, the silicon substrates were lapped, etched and polished to a surface finish good enough to allow epitaxial growth, free of stacking faults without HCl etching prior to growth. By giving the susceptor a tilt of 1°30′ against the direction of gas flow the growth and etch rates over the length of the susceptor were kept constant to within ±5% excluding the first 4 cm of the susceptor. Prior to epitaxial growth the silicon slices were heated in H_2 at 1250°C for 15 min. Growth rates were obtained from measurements of epitaxial layer thickness by the infrared interference technique. A linear plot of layer thickness *vs.* growth time was found. In the thickness determination the ASTM correction for the phase shift at the interface between epitaxial layer and substrate was used (12). The temperature of the substrates were measured with an optical pyrometer, and the values were corrected for the emissivity of silicon and absorption of the quartz wall (13).

Results and Discussion

In Fig. 1 the growth rates from SiH_4 + 4HCl in H_2, $SiCl_4$ in H_2, and $SiHCl_3$ in H_2 are given as a function of temperature. In the literature conflicting data are presented on the temperature dependence of the growth rate, but the results given here agree with those of Shepherd (1), Charig (14), and Oldham *et al.* (15). It will be noted that, in order to reach a growth rate of 1 μ/min, concentrations of about 0.1% for SiH_4 (10^{-3} mole SiH_4/mole H_2), 0.2% for $SiHCl_3$, and 0.5% for $SiCl_4$ were required. In the high-temperature region the temperature dependence of the growth rates was small and the influence of concentration was great, as expected for a diffusion controlled reaction rate (Fig. 1, curves for $SiCl_4$ 0.1% and 0.5%). At lower temperatures the temperature dependence was much greater, with surface reactions controlling the rate and the concentration dependence being much smaller.

The difference between the behavior of SiH_4 + 4HCl and $SiCl_4$ indicates that equilibrium in the gas phase is not established, the differences in growth rate at the higher temperatures being of the order to be expected from the differences in diffusion coefficients of the re-

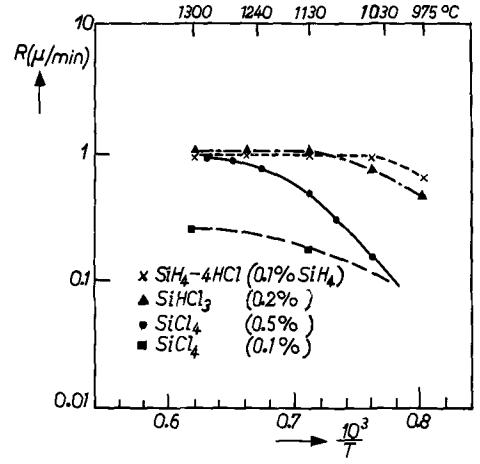

Fig. 1. Temperature dependence of the growth rate of epitaxial silicon layers from $SiCl_4$, $SiHCl_3$, and a mixture of SiH_4 + 4HCl in H_2. The concentrations indicated refer to mole percentages of the silicon compound in the gas phase.

acting silicon compounds. Gas phase reactions are expected to be nearly absent. This, however, does not exclude the possibility of equilibrium being reached at the solid-gas interface at the higher temperatures.

The temperature dependences of the reaction rates in the low-temperature region indicate that here the reaction rate was controlled by the rate at which surface reactions proceed, and not by mass transfer over the stagnant gas layer. The higher the chlorine content of the species the higher the temperature at which mass transfer became the dominant factor. For silicon growth from SiH_4 and for etching of silicon by HCl the temperature dependence of the reaction rates was small at temperatures from 1100° to 1300°C (16). This indicates that for both processes surface reactions are fast, and it can be assumed that in this range of temperatures equilibrium between solid and gas was reached. This means that for SiH_4 the surface concentration was practically zero and that for $SiCl_2$, the main reaction product in etching, a concentration as given by [3] was reached.

Figure 2 shows the growth rate of silicon at 1150°C from mixtures of SiH_4 and HCl, the HCl concentration varies up to an HCl/SiH_4 ratio greater than 15 where etching of the substrates occurs. Growth rates from mixtures with an HCl/SiH_4 ratio of 3 and 4, corresponding to the stoichiometry of $SiHCl_3$ and $SiCl_4$, respectively, are only 5-10% smaller than those for SiH_4. The growth rate decreases proportionally to $(p_{HCl})^2$ and can be described by[1]

$$G = 0.95 \times 10^3 p_{SiH_4} - 4.27 \times 10^3 (p_{HCl})^2 \ \mu/\text{min} \quad [6]$$

If gas phase reactions are absent, then SiH_4 and HCl are diffusing independently through the stagnant layer, transport of SiH_4 giving silicon growth, transport of HCl leading to the etching of silicon. The net result is the growth rate given in Eq. [6] and shown in Fig. 2. The etch rate of silicon deduced from [6] should have the same value as etching with HCl in H_2 without the presence of SiH_4. In Fig. 3 the etch rate given by [6] is plotted as a function of the partial pressure of HCl, together with the etch rates for pure HCl in H_2 found by Spakovskis (17) in a comparable reactor.[1]

The fit between the two curves is good; for low HCl concentrations the etch rate is proportional to $(p_{HCl})^2$, and for HCl partial pressures greater than 0.1 the etch

[1] Another set of experiments in a comparable reactor gave

$$G = 0.7 \times 10^3 p_{SiH_4} - 3 \times 10^3 (p_{HCl})^2 \ \mu/\text{min}$$

From these results it can be seen that small differences in reactor geometry, temperature distribution, gas flow pattern, and boundary layer thickness cause differences in the absolute values of the growth and etch rates; the ratio between the values remaining about the same.

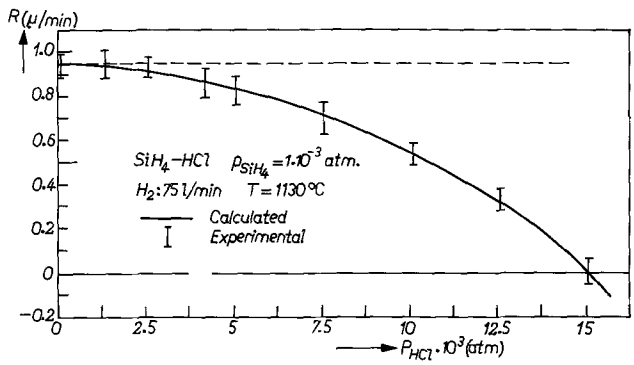

Fig. 2. Growth rate of silicon from mixtures of SiH_4 and HCl, the partial pressure of SiH_4 is kept constant at 1.10^{-3} (atm).

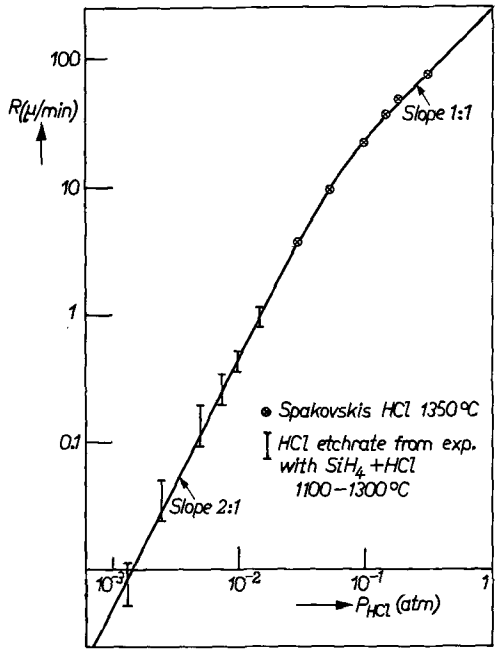

Fig. 3. Etch rate of silicon in HCl + H_2 as a function of the partial pressure of HCl. The low concentration values are from the present work, the high concentration values from Spakovskis (17). The curve gives a best fit of the experimental data to lines of slope 2:1 or 1:1 (see text).

rate is proportional to p_{HCl}. Here the assumption $p_{H_2} = 1$ in [3] is no longer valid, and the transport of HCl toward the interface is beginning to be rate controlling.

With Eq. [6], [11], and [12] it is possible to compare the experimental and the calculated results.

Introducing room temperature diffusion coefficients of SiH_4 and $SiCl_2$ of 0.60 cm^2/sec and 0.26 cm^2/sec, respectively (1), together with $\delta = 0.3$ cm, $T_s = 1500°K$; $T_g = 750°K$, $T_o = 273°K$, $R = 82$ cal/atm degree, and $K_{SiCl_2} = 1$ the calculated values of growth and etch rates are found to be

$$G = 2.57 \times 10^3 p_{SiH_4}$$

(experimental value $G = 0.95 \times 10^3 p_{SiH_4}$) [7]

$$E = 1.10 \times 10^3 (p_{HCl})^2$$

(experimental value $E = 4.2 \times 10^3 p_{SiH_4}$) [8]

The calculated growth rate is nearly a factor of three higher than the experimental one, and the calculated etch rate is more than a factor of 3 lower than that found experimentally.

The silicon growth rate including thermodiffusion effects corresponding to the estimated value $\alpha_{SiH_4} = 1$ gives, according to the calculation in the Appendix [18].

$$J = \frac{D_{SiH_4} \cdot p_{SiH_4}}{\delta R T_0^2} \cdot T_g \qquad [9]$$

This gives a decrease in growth rate by a factor 1.43 compared with [11]. In the expression for D_{SiH_4} the temperature dependence is taken to be $D = D_0(T/T_0)^2$. Experimental and calculated results are brought into agreement if the exponent is taken to be 1.6 instead of 2.0. For SiH_4, $\alpha_{SiH_4} = 1.0$ and $m = 1.6$ are selected, and for $SiCl_2$ $\alpha = 1.5$ and $m = 2$ are thought to be realistic values.

Introducing these quantities in the etch rate formula [17] gives an increase in etch rate by a factor of 1.64. To bring the experimental and calculated results into agreement an effective value of $K_{SiCl_2} = 2.4$ has to be taken, which is well within the possible limits.

In view of the accuracies involved it can be said that a reasonable fit is obtained and that the model used has been shown to yield a qualitative and semi-quantitative description of the epitaxial process.

Conclusion

Silicon growth rates from mixtures of SiH_4 and HCl can be interpreted in terms of a mutually independent growth of silicon from SiH_4 and an etching of silicon by HCl. Comparison of growth rates from mixtures of $SiCl_4$ in H_2 and SiH_4 + 4HCl in H_2 indicates that gas phase reactions are slow, and that equilibrium between solid silicon and the gas phase is established.

Growth and etch rates calculated on the basis of a diffusion controlled model differ somewhat from the experimental results, the growth rates being lower and the etch rates being higher than those calculated from the model. Three possibilities to explain the differences are discussed: (*i*) thermodiffusion in the steep temperature gradient over the silicon substrates; (*ii*) uncertainty in the temperature dependence of the diffusion coefficients giving rise to differences in the calculated growth rate by up to a factor of two; and (*iii*) uncertainty in the chemical equilibrium constant K_{SiCl_2} which gives the $SiCl_2$ concentration during HCl etching of silicon; K_{SiCl_2} at 1500°K = 1.0 ± 2.5.

It is shown that the growth and etch rates may be explained by taking account of these three factors.

APPENDIX

The mass transfer of silicon in the diffusion controlled model is given by

$$J = \frac{G \cdot \rho}{6.10^5 M} = -D_i n \left[\frac{d\frac{n_i}{n}}{dy} \right] \qquad [10]$$

G is the growth rate in μ/min, ρ is the density of Si in g/cm^3, and M is the molecular weight of Si. It will be assumed that the temperature dependence of the diffusion coefficients is given by $D = D_0(T/T_0)^2$, $T_0 = 273$°K. For an ideal gas the total gas density $n = p/RT$ moles/cm^3, and in the open tube reactor $p = 1$ atm, and thus $n = (RT)^{-1}$ and $n_i/n = p_i$ (atm).

Furthermore, in the stagnant layer over the susceptor a linear temperature gradient gives

$$T = T_s - \frac{\Delta T}{\delta} \cdot y$$

where T_s is the surface temperature of silicon, T_g is the temperature of the main gas, $\Delta T = T_s - T_g$, δ is the thickness of the stagnant layer (cm), and y is the distance from the surface (cm). For $p_{SiH_4} = 0$ at the solid-gas interface the growth rate is found to be

$$G = \frac{7.2 \times 10^6 D_{SiH_4} \cdot p_{SiH_4}}{\delta R T_0^2} \cdot \frac{\Delta T}{\ln (T_g/T_s)} \qquad [11]$$

The etch rate of Si by HCl, assumed to depend on the transport of $SiCl_2$ away from the substrate, gives

$$E = \frac{7.2 \times 10^6 \cdot D_{SiCl_2} \cdot p_{SiCl_2}}{\delta R T_0^2} \cdot \frac{\Delta T}{\ln (T_s/T_g)} \qquad [12]$$

From [11] and [12] the ratio of growth and etch rates is found to be

$$\frac{G}{E} = \frac{D_{SiH_4} \cdot p_{SiH_4}}{D_{SiCl_2} \cdot p_{SiCl_2}} \qquad [13]$$

Thermodiffusion gives an additional concentration gradient in the temperature gradient over the substrates

$$\frac{d\frac{n_1}{n}}{dy} = K_T \frac{d\ln T}{dy}$$

With $K_T = \alpha\, n_1/n \cdot n_2/n$, $n_2 \approx n$ and 1 atm total pressure, $n_1/n = p_1$ (atm), this gives for the extra concentration gradient

$$K_T \frac{d\ln T}{dy} = \frac{\alpha p_1}{T} \frac{dT}{dy} \qquad [14]$$

Equation [14] can be combined with [10] to include the effect of thermodiffusion in the calculation of growth and etch rates.

$$J = -Dn \left(\frac{d p_1}{dy} + \frac{\alpha p_1}{T} \frac{dT}{dy} \right) \qquad [15]$$

with

$$D = D_0 (T/T_0)^2 \text{ and } n = (RT)^{-1}$$

$$J = -\frac{D_0}{RT_0^2} (T dp_1 + \alpha p_1 dT)/dy$$

in the model

$$T = T_s - \frac{\Delta T}{\delta} \cdot y$$

then

$$J = -\frac{D_0}{RT_0^2} \left\{ \left(T_s - \frac{\Delta T}{\delta} \cdot y \right)^{\frac{dp}{dy}} - \alpha p_1 \frac{\Delta T}{\delta} \right\}$$

$$-\frac{JRT_0^2}{D_0} + \alpha p_1 \frac{\Delta T}{\delta} = \left(T_s - \frac{\Delta T}{\delta} \cdot y \right)^{\frac{dp}{dy}}$$

integration gives

$$\int \frac{dt_1}{-\frac{JRT_0^2}{D_0} + \alpha p_1 \frac{\Delta T}{\delta}} = \int \frac{dy}{T_s - \frac{\Delta T}{\delta} \cdot y}$$

and

$$\ln \left(-\frac{JRT_0^2}{D_0} + \alpha \frac{\Delta T}{\delta} \cdot p_1 \right) = \ln \left(T_s - \frac{\Delta T}{\delta} \cdot y \right)^{\alpha} + c$$

for Si growth: at $y = 0$, $p_1 = 0$, $T = T_s$

at $y = \delta$, $p_1 = p_{SiH_4}$, $T = T_g$

$$J = \frac{D_{SiH_4} p_{SiH_4} \cdot \Delta T}{\delta R T_0^2} \cdot \frac{\alpha_1 T_g^{\alpha_1}}{T_s^{\alpha_1} - T_g^{\alpha_1}} \qquad [16]$$

for Si etching: at $y = 0$, $p_1 = p_{SiCl_2}$, $T = T_s$

at $y = \delta$, $p_1 = 0$, $T = T_g$

$$J = \frac{D_{SiCl_2} \cdot p_{SiCl_2} \cdot \Delta T}{\delta R T_0^2} \cdot \frac{\alpha T_s^{\alpha_2}}{T_s^{\alpha_2} - T_g^{\alpha_2}} \qquad [17]$$

For $\alpha > 0$ the growth rate decreases and the etch rate increases. For SiH_4 the value of α is expected to be $\alpha_{SiH_4} = 1.0$ giving

$$J = \frac{D_{SiH_4} \cdot p_{SiH_4}}{\delta R T_0^2} \cdot T_g \qquad [18]$$

For etching $\alpha = 1$ gives

$$J = \frac{D_{SiCl_2} \cdot p_{SiCl_2}}{\delta R T_0^2} \cdot T_s \qquad [19]$$

For α values greater than 1 and $T_s >> T_g$, Eq. [19] approximates to

$$J = \frac{D_{SiCl_2} \cdot p_{SiCl_2}}{\delta R T_0^2} \cdot \Delta T \cdot \alpha_2$$

directly proportional to the values of α and the temperature gradient over the slices.

The ratio of growth and etch rates, including thermodiffusion, from [16] and [17] is found to be

$$\frac{G}{E} = \frac{D_{SiH_4} \cdot p_{SiH_4}}{D_{SiCl_2} \cdot p_{SiCl_2}} \cdot \frac{\alpha_1}{\alpha_2} \cdot \frac{T_g^{\alpha_1}}{T_s^{\alpha_2}} \left(\frac{T_s^{\alpha_2} - T_g^{\alpha_2}}{T_s^{\alpha_1} - T_g^{\alpha_1}} \right) \quad [20]$$

Anisotropy of Macrostep Motion and Pattern Edge-Displacements during Growth of Epitaxial Silicon on Silicon Near {100}

C. M. Drum and C. A. Clark

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania 18103

ABSTRACT

For growth of epitaxial silicon by the $SiCl_4/H_2$ process onto silicon surfaces oriented from 0° to 9° off {100}, data are reported on the lateral motion of fabricated macrosteps (~500Å high) and on the resultant displacement of shallow surface depressions bounded by the steps. The displacements ranged from less than a tenth of the layer thickness to greater than twice the layer thickness, depending on the surface orientation. The depressions mark the sites of localized n^+ diffused regions which become buried layers after epitaxy in the fabrication of integrated circuits. Step-broadening was found to be anomalously large for exact {100} surfaces for growth at 1215°C, whereas all orientations from 0° to 9° off {100} had similar step-broadening at 1240°C. At 1240°C, the displacement of the center of the depression relative to the center of the buried layer was a minimum for exact {100} surfaces. Both advancing and receding step-motion was found, and the symmetry of the step-motion was consistent with the crystal symmetry as previously reported for surfaces near {111}. A design graph is developed relating the necessary tolerance of substrate orientation near {100} to the desired epitaxial thickness and allowable alignment errors of masks during the fabrication of integrated circuits. For example, with an allowable 1 μm displacement and with $\leq$15 μm epitaxial thickness, the surface should be {100} within 10 min of arc, whereas up to 30 min off {100} is adequate for $\leq$2 μm displacement with a 7 μm epitaxial layer.

During the fabrication of p-n junction isolated integrated circuits with buried layers of n^+ material, epitaxial silicon is grown onto substrates whose surfaces contain an array of steps about 500Å high. These macrosteps mark the positions of the buried layers, whose function is to reduce the collector series resistance (1, 2). During epitaxy, the steps may be displaced laterally, which can lead to errors in the alignment of subsequent masking operations. The reason for this is that growth at steps can be anisotropic whereas volume diffusion (the buried layer) is isotropic. It was previously reported that the exact substrate orientation near {111} has a considerable influence on the displacement of the steps (3, 4). Here we present new data on this effect for substrates oriented up to 9° off {100}. One purpose of this work was to establish tolerances on the substrate orientation for the control of the displacement.

Key words: epitaxial silicon, buried layers, step motion, integrated circuits.

The motion of steps during crystal growth has previously been studied for a variety of systems, with the usual point of view being that lateral motion of steps can be a basic part of the growth mechanism. Theoretical treatment is given by Burton *et al.* (5) and by Schwoebel and Shipsey (6). The present case is somewhat different in that we are dealing with fabricated steps of height equal to several hundred monolayers. There is evidence that spreading of monolayer steps does occur during the growth of epitaxial silicon near {111}, both for the cases of epitaxy by sublimation-condensation (7) and by chemical reaction (8, 9). For {100} epitaxial silicon, similar observations have not been reported. It is generally believed that the ideal {100} surface is rather rough structurally, hence should be expected to grow without the necessity of step-motion. However, the present work shows that the macrosteps can move considerably, and the relationship between the motions of macrosteps and the monolayer steps is yet to be established.

Experimental

The fabrication of the steps during integrated circuit processing was described previously (4). Briefly, windows are opened in an oxide on a p-type substrate using standard photolithographic techniques. Then n^+ regions are formed by diffusion, and a subsequent thermal oxidation causes growth of about 1000Å of SiO_2 at the site of the diffusion. Removal of all the SiO_2 with HF leaves the silicon surface with an array of depressions bounded by steps which mark the sites of the n^+ regions. Then an epitaxial layer is grown, with thickness usually greater than a micron. The array of steps on the epitaxial surface will correctly identify the buried n^+ regions if the displacements of the steps during growth are taken into account. Epitaxial growth was by the $SiCl_4 + H_2$ process, with 1 m/o (mole per cent) of $SiCl_4$. Temperatures were near 1200°C (after correcting for emissivity) as indicated in the data. Surface orientations were measured with Laue x-ray photographs and with x-ray goniometry (10).

Definitions

Characterization of the step-motion involves many geometrical variables such as surface orientation, step-orientation, sense of the step, and also growth temperature. Cross-sectional drawings for the case of n-type and p-type epitaxial layers are shown in Fig. 1, along with a drawing of the steps and buried layers as observed by interference contrast of angle-lapped-stained sections. The coordinate system is chosen to be symmetrical, with origin at the center of the buried layer and with positive directions outward from the center. The displacements of the steps relative to the border of the stain are denoted X_R and X_L for the right- and left-hand steps, respectively; the detailed crystallographic meaning of these designations for the purposes of this paper is given by Fig. 2. For a deep (9 μm) diffused layer, X_R and X_L will each measure -9 μm prior to epitaxial growth. The most important quantity is the magnitude of the displacement of the center of the depression relative to the buried layer, given by

$$X_C = |(X_R - X_L)/2| \qquad [1]$$

For a rectangular depression X_C can be measured for two independent directions in the plane of the surface. Perfectly symmetrical pattern-edge motion would give $X_C = 0$ in each case. For good results on registry of the next mask, X_C should be smaller than 2.5 μm. The over-all measurement error can be nearly 1 μm, however, since X_C for a slice prior to epitaxy was measured to be 0.7 μm. This is due to the fact that there is a finite width to the surface step and some uncertainty about the exact position of the edge of the stain. So a value of $X_C \leq 1$ μm after epitaxy is about as low as one can expect to measure. The sensitivity of the measurement (200X photograph, comparator) is about 0.5 μm.

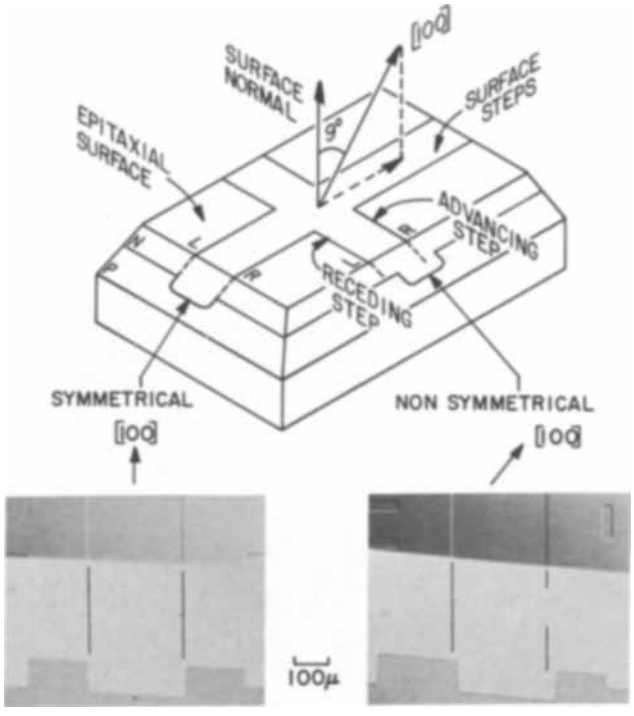

Fig. 2. Drawing of double-angle-lapped epitaxial layer, to illustrate orientation relationships used in this study.

The relationship of the steps to the crystal symmetry is important. We define the symmetrical case as that in which a mirror plane of symmetry in the lattice is normal to the surface and is also parallel to the macrosteps. This is illustrated by Fig. 3. Whatever crystal face is exposed by the left step, the same face will be exposed by the right step by symmetry. This is not true for the nonsymmetrical case illustrated in Fig. 3.

Results

One set of data on X_R, X_L, and X_C is plotted *vs.* substrate orientations from 0° to 9° off (100) toward

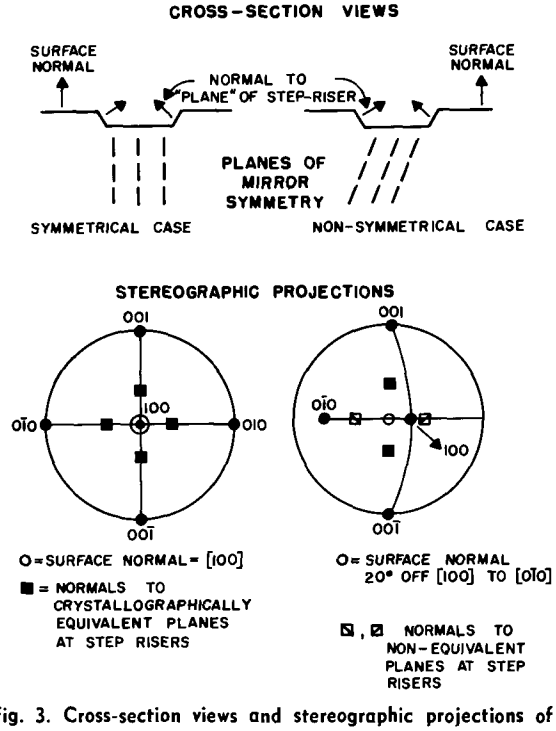

Fig. 3. Cross-section views and stereographic projections of the symmetrical case and the nonsymmetrical case.

a nearest {110}, in Fig. 4. For each surface with a pattern of rectangular depressions, data on the displacement were recorded for four edges of the depressions. We have deliberately oriented the surface and pattern so that one pair of these edges would always be the "symmetrical case" as in Fig. 3. For exact (100) surfaces, the other pair of edges would then also be the symmetrical case; the geometry is illustrated in Fig. 3 by a stereographic projection for surfaces 1° → 9° off (100), and the other pair of edges would be the nonsymmetrical case. The distinctions of symmetrical and nonsymmetrical are indicated in the data of Fig. 4. Four situations were studied, growth at 1215° and 1240°C, with and without HCl etching (1% HCl in H_2, 2 min at 1250°C). Complete data from one set are given in Fig. 4. Data from the other sets show essentially the same features. In each case there was a marked effect of crystal symmetry. Even at 9° of {100}, X_C is very small for the symmetrical part but large for the nonsymmetrical part as illustrated in Fig. 2. Both portions of the patterns were symmetrical on the exact {100} and exhibited very small X_C. It should be noted that the positive displacements of Fig. 4 correspond to receding step-motion, illustrated in Fig. 2.

Further data were recorded for slices 0°, 0.5°, and 1° off {100}, as shown in Fig. 5. Each point is the average of several measurements. In spite of the scatter, the trend of larger X_C with larger misorientation is evident.

Data on the observed step widths are given in Fig. 6. The lower temperature (1215°C) leads to a broadening of steps only on the 0° to 0.5° off {100} surfaces, whereas all orientations had similar step-widths after growth at 1240°C. Larger step-broadening is undesirable since it is associated with imprecise definition of the boundary of the surface depression. This effect is illustrated in Fig. 7.

Further information of interest is obtained by plotting X_C *vs.* epitaxial thickness; this is shown in Fig. 8. Taking X_C to be ideally zero at zero epitaxial thickness, the data show that the displacement of the center is greater with increasing film thickness, but it is still less than 2 μm at 15 μm thickness for exact (100) surfaces.

A design graph (Fig. 9) can be constructed, to select orientation tolerances when desired values of X_C and epitaxial thickness are known. This information can be

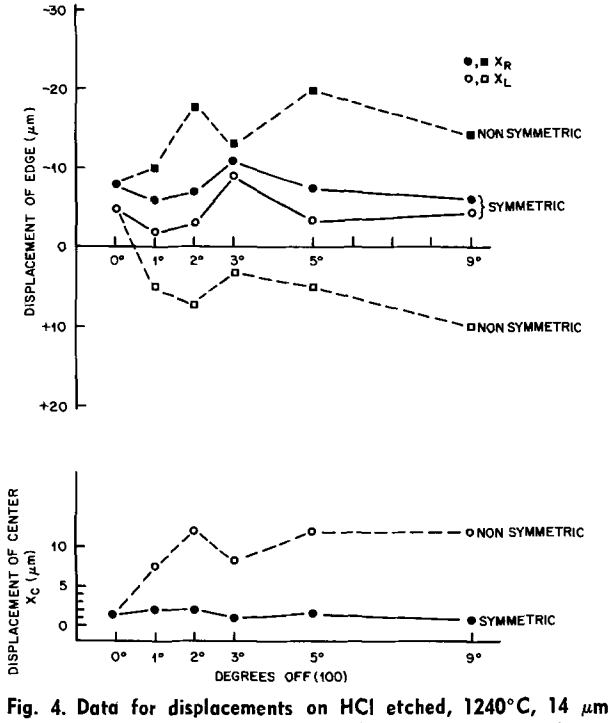

Fig. 4. Data for displacements on HCl etched, 1240°C, 14 μm n-type epitaxial layer. The direction of the misorientation is indicated in Fig. 2.

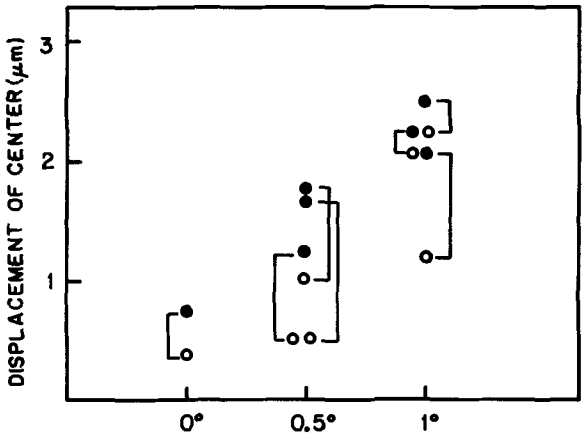

Fig. 5. Displacement data for surfaces 0°, 0.5°, 1° off {100}. Brackets indicate data from the same slice.

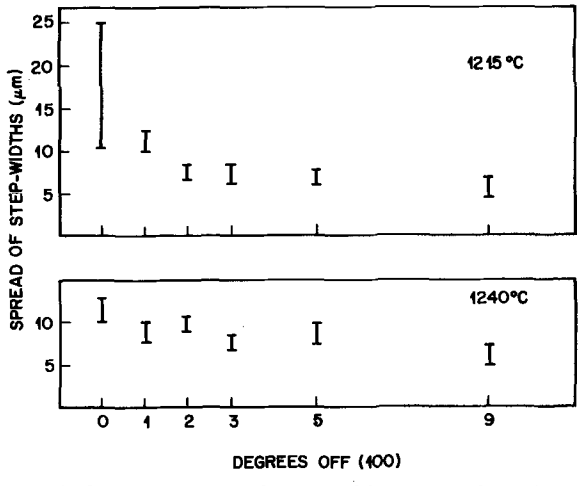

Fig. 6. Data on spread of step widths vs. angular orientation from (100), in direction indicated in Fig. 2.

important when large quantities of material are being considered. Data with the greatest displacement have been used to construct Fig. 9, to give the greatest design safety.

To use the graph, one chooses the epitaxial thickness t and center displacement X_C. Let t = 15 μm, X_C = 2.5 μm. Find the point on the t = 15 μm line with X_C = 2.5 μm, and note that the corresponding angle is 10 min off (100). This means that surfaces (100) ± 10 min would be required. For another example, let t = 7 μm. For X_C = 2.5 μm, then the maximum allowed angular misorientation is 35 min. So (100) ± 35 min would be adequate. To make this graph reasonably complete, interpolated lines for 9, 11, 13 μm thickness are drawn. Actual data are used for 7 and 15 μm thicknesses. It may be argued that a limitation of these design data is that only one type of misorientation from {100} was studied. However, the region of interest is clearly from 0° to 1° off {100}, and in this region the distinction between the various ways of misorienting a surface off {100} is difficult to determine in practice.

From the previous data, it is predicted that pattern displacement would be very small for thin epitaxial layers. This has been confirmed by the data in Table I for p-type epitaxial layers on p-type substrate with n+ buried layers.

Discussion

The data show that lateral motion of macrosteps can range from a negligibly small value up to several times the epitaxial layer thickness, depending on the orientations of the surface and of the steps. Also, the

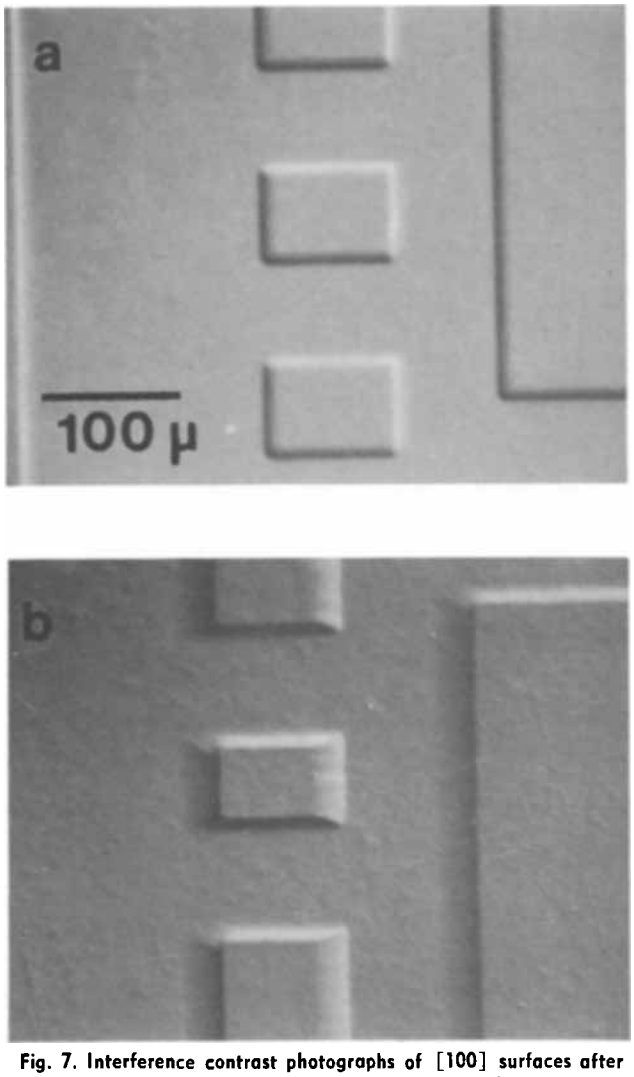

Fig. 7. Interference contrast photographs of [100] surfaces after epitaxy showing: *a*, sharp steps, growth at 1240°C; *b*, wide steps, growth at 1215°C.

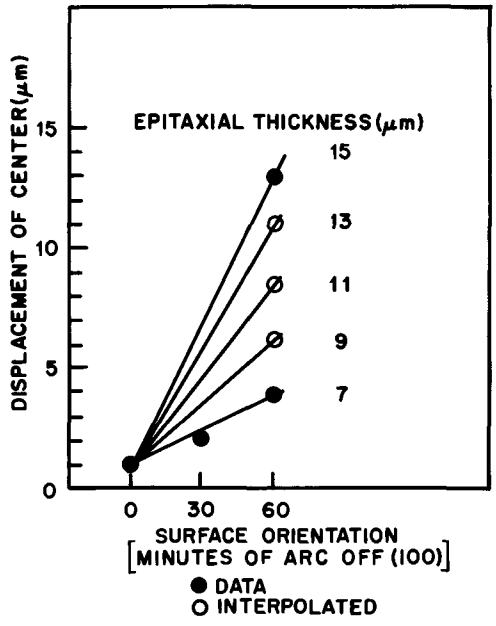

Fig. 9. Design graph for tolerance on surface orientation near {100}.

symmetry of the step-motion follows the symmetry of the lattice. In addition to the advance of steps across a surface, receding step-motion was also observed while at the same time vertical growth occurred on either side of the receding step. Each of the above results for {100} was also found previously for substrates near {111}, but with the opposite effect that greater displacements occurred nearer {111} whereas greater displacements occur farther from {100} according to the present data.

The results provide information on the orientation tolerances, as given in Fig. 9. Furthermore, the results raise some more fundamental questions about the growth mechanism. One can ask how these steps would move as a function of step-height. Very small steps should approach the behavior of monolayer steps which may be fundamental to growth. Very large steps (25 μm) have been studied by Runyan *et al.* (11), and the relationships between behavior of these various steps should be clarified. Very small steps can be fabricated by the present technique by reducing the oxide thickness, and 30Å steps can be observed optically with interference contrast (12), so it should be possible to obtain data on the behavior of steps covering a wide range of heights.

Information on the behavior of the steps during epitaxy by other techniques such as molecular beam (13), evaporation, and silane decomposition should be useful. The receding motion of steps is apparently an unexpected etching effect which may be associated with the inevitable HCl by-product in the $SiCl_4/H_2$ system. Other growth systems should be helpful in clarifying this phenomenon.

To interpret the macrostep motion, it is tempting to start with a macroscopic model which assumed that an appreciable facet exists at the step-riser as drawn in Fig. 3, and that the end result depends primarily on the growth rates of the various exposed crystallo-

Table I

Epitaxial thickness (μm)	Orientation	X_0 (for two directions) (μm)

2.9	180′ off {111}*	<1, <1

* Toward a nearest {110}.

graphic planes. This model is unsatisfactory, since it does not explain (*a*) why the displacement is generally greater for larger misorientation from {100}, (*b*) why the lower temperatures cause step-broadening at {100}, or (*c*) why some receding step-motion occurs. This model might be more plausible if the data on growth rate *vs.* orientation showed a definite minimum at {100}, but this was not the case with the present study. Bean and Gleim (14) on the other hand do report a lower growth rate for {100} as opposed to 1.5° off {100}; as pointed out by Runyan (15) data from various experimenters seldom seem to agree on the numerical values of the growth rate.

An alternate model of greater complexity would involve a consideration of the atomic structure at the steps; the rate at which atoms could be attached to the various structures would then determine the resultant displacement. Edge effects, *e.g.*, at the bottom of a step, would probably be important in this model, whereas the simpler macroscopic model would ignore what happens at such an edge. Either model is sufficient to explain the symmetry effect, since in each model the growth rate depends on the crystal structure. This implies that atoms are readily supplied to all possible growth centers by transport mechanisms, which may include surface diffusion as suggested by the work of Runyan *et al.* (11).

Manuscript submitted Feb. 2, 1970; revised manuscript received *ca.* July 9, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1971 JOURNAL.

Doped Oxides as Diffusion Sources

II. Phosphorus into Silicon

M. L. Barry*

Research and Development Laboratory,
Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

The diffusion of phosphorus from a deposited doped oxide into silicon has been found to be consistent with a previously derived model describing doped oxides as diffusion sources. Diffusion coefficients of phosphorus in both silicon and silicon dioxide have been measured in terms of this model over surface concentrations varying from 6×10^{17} to 2×10^{20} atoms/cm^3 at diffusion temperatures of 1000°, 1100°, and 1200°C.

The use of doped oxides which have been deposited at low temperatures as diffusion sources adds considerable flexibility to the processing of semiconductor devices. Perhaps the greatest advantage over standard gas-phase doping techniques is independent control of the surface concentration over several orders of magnitude. Other advantages include better process control, adaptability to low defect processing, and the ability to control the final oxide thickness independently of the diffusion conditions. In addition, it is possible to make certain device configurations, such as self-aligned-gate metal-oxide-semiconductor transistors, or complementary MOS integrated circuits, which are very difficult with standard technology.

In an earlier paper (1), a model describing the diffusion of a dopant into a semiconductor from a doped oxide was presented and shown to describe reasonably well the case of boron diffusing into silicon. The purpose of this paper is to extend this model to the case of phosphorus diffusing into silicon and to report measured values of the constants of the diffusion. Interpreting these constants in terms of atomistic descriptions of the diffusion mechanism is not within the scope of the present paper.

Diffusion from deposited doped oxides has been reported fairly extensively (2-13), including several descriptions of the diffusion of phosphorus into silicon. However, values of the appropriate diffusion coefficients have not been reported in these papers over the range of temperature and concentration covered in the present work. The literature treating the diffusion process itself of phosphorus into silicon is very extensive and cannot be reviewed here.

Theory

The general one-dimensional case for diffusion of a dopant from a uniformly doped oxide of thickness $x_o - x_B$ and initial concentration C_o into a silicon substrate is shown in Fig. 1. Inclusion of an undoped oxide of thickness x_B, which acts as a barrier to diffusion, allows the measurement of the diffusion parameters of the dopant in the oxide; in actual device

* Electrochemical Society Active Member.
Key words: solid-state diffusion, semiconductor processing.

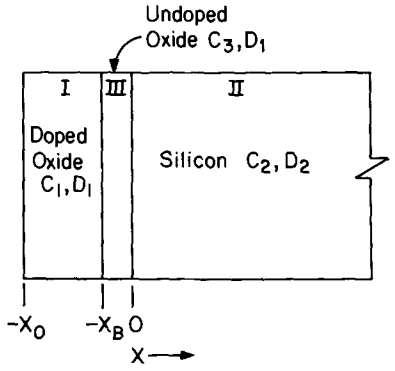

Fig. 1. Diffusion from a deposited doped oxide through a barrier oxide into a semiconductor substrate.

fabrication, this barrier oxide is normally reduced to a minimum. The diffusion equations in each region can be written

$$\frac{\partial C_i(x,t)}{\partial t} = D_i \frac{\partial^2 C_i(x,t)}{\partial x^2} \quad [1]$$

where the subscript i takes the value 1, 2, or 3 depending on the region. This formulation implicitly assumes that no field-aided diffusion terms are operating on ionized dopants and that ion-vacancy interactions can be ignored. The conditions under which these assumptions appear valid and the corrections to be made when they are not are discussed in a later section. The solution of Eq. [1] with the appropriate boundary conditions has been described in some detail in earlier work (1); suffice to say that when the thickness of the doped oxide is much greater than the diffusion length of the dopant in the oxide, the solution for the concentration in the silicon reduces to a simple form

$$C_2(x,t) = \frac{C_o\sqrt{D_1/D_2}}{(1+k)} \operatorname{erfc}\left[\frac{x_B + mkx}{2\sqrt{D_1 t}}\right] \quad [2]$$

where t is the diffusion time; m is the segregation coefficient, or the ratio of the concentration of dopant in the silicon to the concentration in the oxide at the silicon-oxide interface; and

$$k = \frac{1}{m}\sqrt{D_1/D_2} \quad [3]$$

Determination of D_2.—For the case of no undoped barrier oxide ($x_B = 0$), Eq. [2] reduces to the simple case of diffusion from a semi-infinite source into a semi-infinite sink, or a complementary-error-function diffusion with an equivalent surface concentration C_s

$$C_s = \frac{C_o\sqrt{D_1/D_2}}{(1+k)} \quad [4]$$

Thus, the surface concentration for this simple case is independent of time and depends on the initial concentration of dopant in the oxide, the square root of the ratio of the diffusion coefficients, and the segregation coefficient. Integration of Eq. [2] also leads to a simple expression for the sheet conductivity when $x_B = 0$ and the substrate resistivity is reasonably high (greater than 1 ohm-cm for this work)

$$I/V = 8.15 \times 10^{-23}\,\bar{\mu} C_s \sqrt{D_2 t} \quad [5]$$

where I/V is the inverse of the V/I commonly measured with a 4-point probe, $\bar{\mu}$ is the effective mean mobility of carriers, and the constant includes the electron charge, the spreading-current factor for the 4-point probe, and $2/\sqrt{\pi}$, a constant of the integration. It can also be shown for the case of no barrier oxide that the junction depth can be written

$$x_j = 2\sqrt{D_2 t}\ \text{argerfc}\left[\frac{C_b}{C_s}\right] \quad [6]$$

where C_b is the bulk concentration of the substrate.

From Eq. [5] and [6], the junction depth and sheet conductivity should be linear functions of the square root of the diffusion time, and the slopes of the corresponding straight lines are measures of the diffusivity of the dopant in silicon

$$\sqrt{D_2} = \frac{1.23 \times 10^{22}}{\bar{\mu} C_s} \frac{d(I/V)}{d(\sqrt{t})} \quad [7]$$

$$\sqrt{D_2} = \frac{\dfrac{d(x_j)}{d(\sqrt{t})}}{2\text{argerfc}\left[\dfrac{C_b}{C_s}\right]} \quad [8]$$

If the surface concentration is greater than about 1×10^{19} atoms/cm^3, it is possible to measure C_s by a plasma-frequency method; it is then possible to determine two independent values of D_2 from sheet conductivity and junction depth data. For low values of C_s, Eq. [7] and [8] can be combined, and self-consistent values of D_2 and C_s can be calculated.

Determination of D_1.—Inclusion of an undoped barrier oxide as shown in Fig. 1 allows the measurement of D_1, the diffusivity of the dopant in the oxide. If the subscript B refers to a wafer with a thin, undoped oxide of thickness x_B, and the subscript N refers to a wafer with no such barrier oxide, then Eq. [2] can be manipulated to show for a given C_o

$$\sqrt{D_1} = \frac{x_B}{2\sqrt{t}\ \text{argierfc}\left[\dfrac{\bar{\mu}_N (I/V)_B}{\bar{\mu}_B (I/V)_N \sqrt{\pi}}\right]} \quad [9]$$

$$\sqrt{D_1} = \frac{x_B}{2\sqrt{t}\ \text{argerfc}\left[\dfrac{(C_s)_B}{(C_s)_N}\right]} \quad [10]$$

$$\sqrt{D_1} = \frac{x_B\sqrt{D_2}}{(x_j)_N - (x_j)_B} \quad [11]$$

Thus, by measuring the differences in sheet conductivities, junction depths, and surface concentrations between wafers diffused with and without a barrier oxide, it is possible to determine D_1 by three independent measurements.

Determination of m.—In theory, the segregation coefficient can be determined from different variants of Eq. [2] once D_1 and D_2 are known and C_o, the concentration of the dopant in the oxide, is measured (1). Numerically, however, m is calculated as the reciprocal of a small difference between two large experimentally determined numbers, and for the case of phosphorus the resulting uncertainties are large enough to render its calculation meaningless. This will be enlarged upon in a later section.

Experimental

The substrates used in this study were (111) silicon wafers, sliced from Czochralski-grown crystals, lapped on both sides, and mechanically and chemically polished on one side. The phosphorus doped oxides were deposited by oxidation of silane and phosphine at a substrate temperature of 400°C, and the diffusions were performed in dry nitrogen ambients at within ±2°C of the nominal diffusion temperature. The thickness of the doped oxide normally was 0.6μ. The

phosphorus concentration in the films was determined by a spectrophotometric analysis using films deposited simultaneously with those used for diffusion (14). The sheet conductivity was measured with a 4-point probe, and junction depths were measured using the Nomarsky interference technique after grooving and staining. The mean mobilities were calculated as a function of surface concentration by numerical integration of Irvin's conductivity mobility data (15) assuming complete ionization. The junctions were delineated by staining with a nitric-hydrofluoric acid solution (0.1:50:50 by volume of 70% HNO_3:49% HF:H_2O). The surface concentration was determined from the minimum in the infrared reflection spectrum (plasma-frequency), using the curves of Gardner *et al.* (16) and corrected for shallow junctions by the method of Abe and Nishi (17). Ellipsometric methods were used to measure the thickness of the barrier oxides.

Results

Values of the diffusivity of phosphorus in silicon as determined by this technique are shown in Fig. 2 for surface concentrations ranging from 6×10^{17} to 2×10^{20} atoms/cm^3 and temperatures from 1000° to 1200°C. For surface concentrations of 1×10^{19} atoms/cm^3 and above, where C_s generally could be measured independently, the values of $\sqrt{D_2}$ measured by the sheet conductivity method are shown as closed points, while the values measured from the junction depth method are open points. For lower values of C_s, the calculated self-consistent values of $\sqrt{D_2}$ and C_s are shown as partially closed points. These data indicate that the diffusivity of phosphorus in silicon is relatively independent of C_s up to values of about 1×10^{19} atoms/cm^3 and that it then increases with increasing concentration.

The reliability of these values of $\sqrt{D_2}$ has been estimated by geometrically combining the standard deviations or uncertainties of each of the factors entering into the calculations. The estimated accuracy of $\sqrt{D_2}$ as measured by the sheet conductivity method includes a 20% uncertainty in the measurement of C_s, a 10% uncertainty in the mean mobility, and a 1% relative standard deviation in the slope of the $I/V - \sqrt{t}$ curve (from a least-squares fit assuming no uncertainty in the diffusion time). These combine to yield a total uncertainty of about 25%; however, at high surface concentrations (over 1×10^{20}) the uncertainty in C_s reduced to about 10%, and the total uncertainty drops to about 15%. In a similar fashion, the $\sqrt{D_2}$ as measured by the junction depth method has an estimated uncertainty of less than 10%, primarily because it is relatively insensitive to values of C_s. As Fig. 2 shows, there is generally excellent agreement between values determined by the two techniques, and agreement between duplicate measurements also is good.

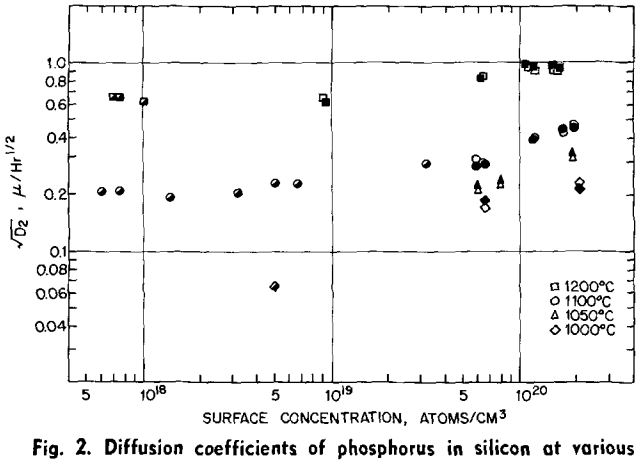

Fig. 2. Diffusion coefficients of phosphorus in silicon at various temperatures and surface concentrations.

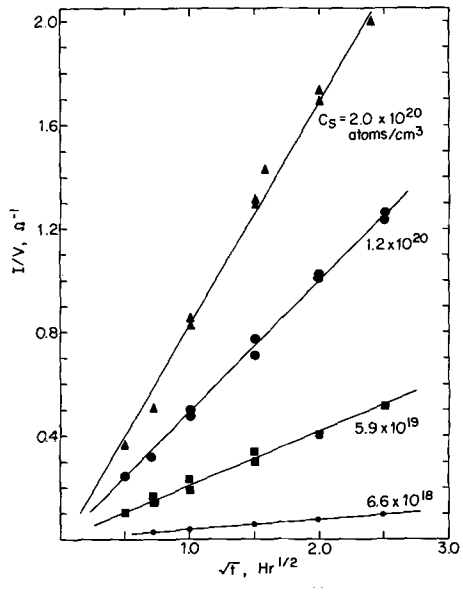

Fig. 3. Sheet conductivities resulting from diffusion of phosphorus into silicon at 1100°C from deposited oxides with different initial phosphorus concentrations.

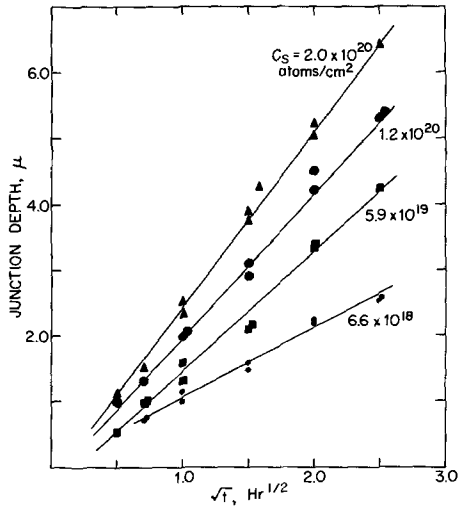

Fig. 4. Junction depths resulting from diffusion of phosphorus into silicon at 1100°C from deposited oxides with different initial phosphorus concentrations.

In the case of boron diffusing from a doped oxide at high surface concentrations ($C_s > 1 \times 10^{20}$ atoms/cm^3), the sheet conductivity was found to be anomalously high at short diffusion times (1). This behavior appears to be absent in the case of phosphorus, as indicated by Fig. 3 and 4. The sheet conductivity, as shown in Fig. 3, is a linear function of $\sqrt{t}$ at surface concentrations as high as 2×10^{20},[1] and it extrapolates properly back through the origin or to a very small intercept on the positive time axis. The junction depth is also linear in $\sqrt{t}$ over all concentration ranges utilized. In addition, the surface concentration remains independent of the diffusion time in all these studies, as predicted by Eq. [4]. The surface concentrations of phosphorus in the silicon for various initial concentrations of phosphorus in the oxide are shown in Fig. 5.

[1] The upper limit of C_s in these experiments is controlled by a phase change of the doped oxide. At high phosphorus concentrations, the oxide appears to liquefy at the diffusion temperature, increasing $\sqrt{D_1}$ to a high value and thereby increasing C_s, as indicated by Eq. [4]. This phase change corresponds quite well to the phase diagram for SiO_2-P_2O_5 proposed by Tien and Hummel (18).

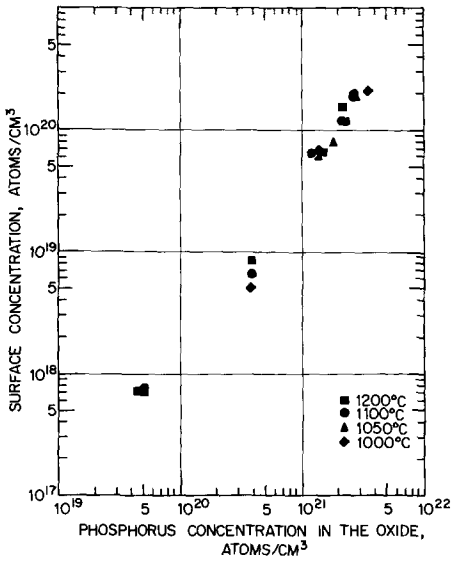

Fig. 5. Surface concentrations of phosphorus in silicon resulting from various concentrations of phosphorus in the deposited oxide.

Concentration profiles for diffusions from two different concentrations of doped oxide are shown in Fig. 6. These profiles were determined by measuring the sheet conductivity gradient normal to the wafer surface using the anodic oxidation technique of Tannenbaum (19). The deviation of the high surface concentration profile from the expected erfc relation is discussed in a later section.

The measurement of D_1, the diffusivity of phosphorus in the oxide, is slightly more complicated than in the case of boron. Glasses containing more than about 2×10^{21} phosphorus atoms/cm^3 dissolve the undoped barrier oxide at a finite rate at the diffusion temperatures, and this tends to obscure the diffusion process in the oxide. This case can be treated as diffusion from a moving boundary (20), but the experimental results do not justify the effort. This dissolution does not affect the measurement of $\sqrt{D_2}$, of course, wherein no barrier oxide is used. As a matter of fact, the dissolution of the very thin naturally occurring oxide on the silicon surface insures that the sheet conductivity and junction depth curves for high surface concentrations will pass through the origin rather than be shifted along the positive time axis, as may be the case for boron.

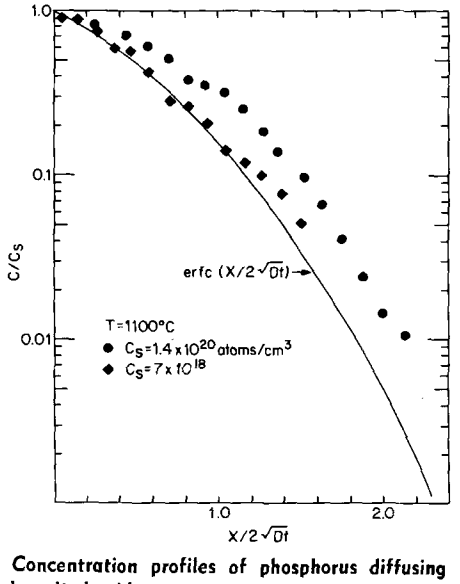

Fig. 6. Concentration profiles of phosphorus diffusing into silicon from deposited oxides.

For phosphorus concentrations below about 2×10^{21} atoms/cm^3 in the oxide, the dissolution of the barrier oxide is negligible, and the diffusion coefficient can be measured. Figure 7 shows values of $\sqrt{D_1}$ at temperatures from 1050° to 1200°C. Because of the required low concentrations, determination of D_1 by differences in C_s (Eq. [10]) is not possible, but there is good agreement between the other two techniques. Of these, the method using differences in junction depths (Eq. [11]) appears most reliable. The sheet conductivity technique (Eq. [9]) involves estimating the effective mean mobility, and electron mobilities change quite rapidly with surface concentration in the region where these measurements are made. In addition, for much of the data the surface concentrations are too low to be measured directly; in these cases calculation of C_s, $\bar{\mu}$, and D_1 must be done by a reiterative procedure. On the other hand, measurement of D_1 by the junction depth method can involve taking small differences between two large numbers. Estimated uncertainties in these measurements vary from 10% at 1100°C to about 25% at 1200°C, and must be combined with the uncertainties in $\sqrt{D_2}$, since this quantity enters directly into the calculation of D_1. As a result, values of $\sqrt{D_1}$ may be good only within ±30%. Typical data for this technique are shown in Fig. 8.

As mentioned earlier, values of the segregation coefficient, m, are not reported here. The equations for

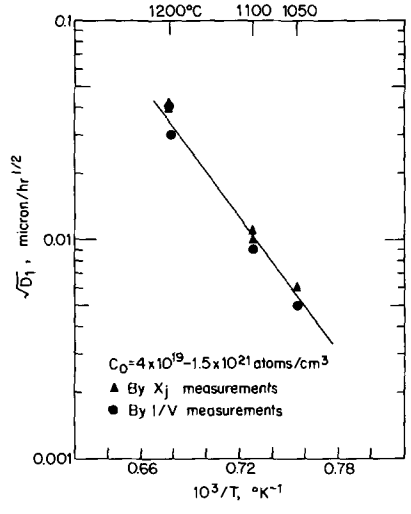

Fig. 7. Diffusion coefficients of phosphorus in SiO_2

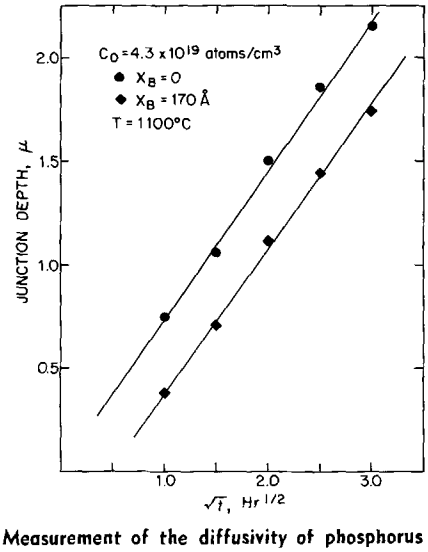

Fig. 8. Measurement of the diffusivity of phosphorus in oxide by the difference in junction depths after diffusion through a barrier oxide.

calculating m all have the form

$$m = \frac{1}{\frac{C_0}{C_s} - \sqrt{D_2/D_1}} \quad [12]$$

Since values of m are expected to be greater than unity (21), the denominator of Eq. [12] will be less than one. Since the ratios of C_0 to C_s and $\sqrt{D_2}$ to $\sqrt{D_1}$ are typically in the range twenty to fifty, with sizable uncertainties, small differences between these ratios cannot be considered significant.

Discussion of Results

At high surface concentrations the diffusivity of phosphorus in silicon is not strictly independent of concentration, as has been assumed in this simple model. As can be seen from Fig. 2, there is a one-and-a-half- to threefold increase in $\sqrt{D_2}$ as the surface concentration varies from below 1×10^{19} to 2×10^{20} atoms/cm^3, depending on the diffusion temperature. Effects that have been advanced to account for such an increase are the action of the self-induced field on the ionized impurities (22, 23) and an increase in the equilibrium lattice vacancy concentration (24-26). The first effect should result in a factor of 2 increase in D_2 as the dopant concentration becomes large compared to the intrinsic carrier concentration at the diffusion temperature. The vacancy mechanism should result in D_2 being nearly proportional to the dopant concentration at values well above the intrinsic carrier concentration.

Profiles for the low surface concentration diffusions agree within the accuracy of the profiling technique with the predicted complementary error function, as shown in Fig. 6. However, a higher surface concentration diffusion shows some deviation from the expected profile (the kinks in either curve are not significant experimentally). The non-normalized data for this second diffusion are plotted in Fig. 9 together with curves representing the expected behavior mentioned above, as interpolated from the curves of Hu and Schmidt (25). Curve A is the concentration profile predicted for this surface concentration if only field-aided diffusion terms are taken into account, while curve B shows the additional effect of the equilibrium vacancy terms. In both cases, the value of the intrinsic $\sqrt{D_2}$ has been taken as 0.20 $\mu/hr^{1/2}$, the apparent value of the low-C_s asymptote at 1100°C as shown in Fig. 2. As can be seen from Fig. 9, agreement of the data with either of these curves is worse than with the simple error function curve of Fig. 6. The curve that seems to fit the data best is that for field-aided diffusion using 0.40 $\mu/hr^{1/2}$, the value of $\sqrt{D_2}$ which was actually measured for this diffusion assuming a simple erfc relation.

The proper interpretation of the high surface concentration data is not obvious, and as mentioned in the introduction, it is beyond the scope of this paper to discuss mechanisms of diffusion in silicon. The deviations of the concentration profiles from the expected values are not large, but are significant. On the other hand, there is excellent agreement between the values of $\sqrt{D_2}$ measured independently from both sheet conductivity and junction depth data, and this should not be the case for large deviations from the erfc relation. The conclusion drawn is that the low surface concentration values of D_2 are valid intrinsic diffusivities of phosphorus in silicon, while the values at high surface concentrations are effective diffusivities (averaged over some range of concentration) which adequately describe the diffusion characteristics.

A comparison is made in Fig. 10 of some of these data with that reported by other investigators. The values of the diffusivity presented here for high surface concentrations are lower in general than those reported by Mackintosh (27), but higher than those of Fuller and Ditzenberger (28). The apparent activation energy is lower for the high surface concentration diffusion than for the low surface concentration (2.6 eV compared to 3.7 eV), as predicted by the vacancy mechanism, but the difference is larger than that suggested by Hu and Schmidt (25).

Conclusions

Diffusion of phosphorus from a deposited doped oxide source is an attractive technique for fabricating both emitter and base junctions in silicon transistors because of the independent control of surface concentration over a wide range. The diffusion appears describable by a simple model, although there are small discrepancies in the concentration profiles at surface concentrations near 1×10^{20} atoms/cm^3. Measurement of diffusivities of phosphorus in heavily doped oxides is complicated by the dissolution of the undoped barrier oxide used in this technique. However, values of the diffusivity of phosphorus in lightly doped oxides are measurable.

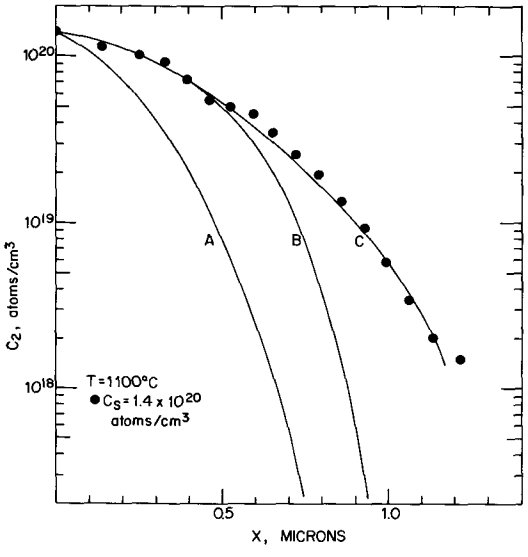

Fig. 9. Comparison of the concentration profile of phosphorus from a high surface concentration diffusion with profiles predicted for: curve A, field-aided diffusion only; curve B, field-aided plus equilibrium-vacancy diffusion; curve C, best fit by field-aided diffusion with $\sqrt{D_2} = 0.40$ $\mu/hr^{1/2}$.

Electrical Characteristics of the Silicon Nitride-Gallium Arsenide Interface

J. E. Foster and J. M. Swartz

The National Cash Register Company, Dayton, Ohio 45409
and The Ohio State University, Columbus, Ohio 43210, respectively

ABSTRACT

The results of an investigation of the electrical characteristics of the silicon nitride-gallium arsenide interface as determined by capacitance-voltage (C-V) curves is presented and discussed. The Si_3N_4 was pyrolytically deposited from SiH_4 and NH_3 in the range 650°-750°C on n- and p-type, <111>, GaAs. A hysteresis of the C-V curve is noted; the amount of curve shift is shown to be heavily process dependent. Times involved in curve shift both with and without applied bias are given. Surface state density for the best p sample is in the 10^{12} range.

In the rapid advance of the semiconductor industry over the last two decades, silicon has emerged as the most important material. Silicon can be purified to a very high degree by relatively simple methods so that high-purity material is readily available at low cost. In the 1960's, the III-V compounds have attracted increased attention. Of these materials, gallium-arsenide (GaAs) is the most serious competitor to silicon. The major advantages of GaAs over silicon as a transistor material are: (*a*) greater energy gap allowing operation at higher temperatures, (*b*) high electron mobility giving theoretically higher frequency response, and (c) a direct band gap providing much shorter recombination time. The materials technology of GaAs is, however, much more difficult than silicon. Because of the volatility of arsenic from the compound, refinement is much more difficult than for the elemental semiconductors. Only recently have such new technologies as liquid encapsulation (1) been developed. It is to be expected that, as research and development continue on this important material, high-purity, economical substrates will be achieved.

Key words: MOS, semiconductor, amorphous, pyrolysis.

In order to maximize drain current, transconductance, and operating frequency of an insulated gate field effect transistor (IGFET), it is desirable to have the largest possible value of effective channel conductance ($\bar{\mu}$) and also to use a gate insulator having a high dielectric constant (2). The value of $\bar{\mu}$ depends on the mobility, μ, of the substrate—$\bar{\mu}$ being typically one half that of μ. It has been widely recognized, therefore, that GaAs with its high electron mobility is potentially a better substrate material for FET's than silicon.

There has recently been a great deal of attention (3-35) focused on amorphous silicon nitride (Si_3N_4) as a passivating and masking film partly or fully replacing silicon dioxide. Silicon nitride is much more impervious to diffusants of all kinds than silicon dioxide. In addition, the use of silicon nitride as an insulator in a metal-nitride-semiconductor (MNS) FET increases the

transconductance and drain current compared to SiO_2 by 50% because of its higher dielectric constant.

A GaAs FET utilizing silicon nitride as the gate insulator would have considerable advantage over the silicon MOS-FET. Before such a GaAs metal-nitride-semiconductor (MNS) FET can be realized, however, a great deal of investigation into the Si_3N_4-GaAs interface must be made. This paper gives the results of an investigation of the Si_3N_4-GaAs interface with particular attention to those properties which would affect the achievability of a GaAs MNS-FET. The Si_3N_4 films were pyrolytically deposited from SiH_4 (silane) and NH_3. Major emphasis was placed on p-material since an n-channel enhancement-mode device would be desired to utilize the high electron mobliity of GaAs.

A hysteresis effect in the Si_3N_4-Si system has been reported (18). This effect is also present in the Si_3N_4-GaAs system as is shown.

The metal-insulator-semiconductor (MIS) capacitor was used as the principal device for this investigation. The theory of MIS capacitors has been presented by many authors (36-37) and hundreds of articles have been written on the metal-insulator-semiconductor system. An extensive bibliography has been given by Schlegel (38, 39).

Deposition and Measurement Techniques

Si_3N_4 deposition.—The vapor deposition of Si_3N_4 has been accomplished by the ammonolysis of both silicon tetrachloride and silane (7). The reaction between silane (SiH_4) and ammonia (NH_3) has been favored recently. Films deposited using SiH_4 and NH_3 are reported to be amorphous at deposition temperatures below 900°C (9) with deposition possible down to 650°C (11). The vapor pressure of As over GaAs is given for four-atom and two-atom molecules of arsenic vapor in the range 950°-1200°K by Drowart and Goldfinger (40). Using their results as a guide, it was anticipated that amorphous films of Si_3N_4 could be deposited at the low end of the SiH_4-NH_3 temperature range (*e.g.*, 650°-750°C) without appreciable loss of arsenic from the GaAs surface.

Semiconductor-grade nitrogen used as a carrier gas was purchased from the Mineweld Company. The SiH_4 diluted with nitrogen (96% N_2, 4% SiH_4) and the ultrahigh-purity (99.999%) NH_3 was purchased from Matheson.

A schematic of the deposition apparatus used is shown in Fig. 1. All tubing was Teflon; flow meters were stainless steel. A two-way valve allowed the NH_3 and SiH_4 to be turned from exhaust to the quartz reaction tube to start deposition. N_2 was allowed to flow to exhaust as well as through the quartz tube at all times when depositions were not being made. In this manner, the system did not have to be pumped down or otherwise purged.

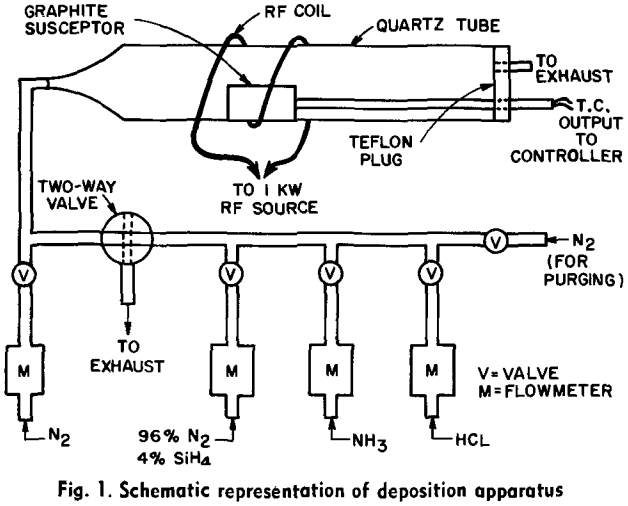

Fig. 1. Schematic representation of deposition apparatus

The quartz reaction tube was 30 mm ID. The susceptor was formed from a graphite cylinder 1 in. in diameter and ⅝ in. long. The cylinder was cut in half (lengthwise) to form a 1 in. x ⅝ in. horizontal surface upon which the sample was laid. A hollow quartz tube served as a handle for the graphite susceptor.

A thermocouple rod passed down the hollow quartz handle into the graphite susceptor. The leads from the thermocouple connected to a Research Inc., Thermac 6000 Temperature Controller. The controller output, by means of an interfacing circuit, controlled the d-c plate voltage of 1 kW, 475 kHz Ther-Monic induction heating unit.

Sample preparation.—The GaAs wafers used in this investigation were purchased from Bell and Howell Research Laboratories. Both n- and p-type wafers were 0.020 in. thick and <111> oriented. The n-type material was tellurium doped and showed an electron mobility of 6600 $cm^2/V\text{-}sec$ and a carrier concentration of $3.84 \cdot 10^{16}$ cm^{-3} as determined by Hall measurements. Carrier concentration of the zinc-doped p-material was 1.4×10^{17} cm^{-3}.

The wafers were hand lapped on an iron plate using 9μ aluminum oxide in an oil slurry to obtain a dull, smooth surface, then mounted on a polishing block and polished on a wheel covered with a polishing cloth (Buehler Ltd., No. 40-7618). A ½% solution of bromine in methanol was dripped onto the cloth to effect the chemical polishing. This method of polishing GaAs was first reported by Sullivan and Kolb (41). The wafers were polished to a mirror finish, scribed by a diamond scribe, and broken into chips approximately ¼ in. square.

Final preparation included ultrasonic cleaning in trichloroethylene and acetone, rinsing in methanol, then rinsing in deionized water having a resistivity greater than 15 meg and etching for 20 sec in an etch consisting of HCl, H_2O_2, and H_2O in volume ratio 3:1:1. The chips were again rinsed in the deionized water, blown dry with high-purity N_2, and put on the graphite susceptor in the quartz tube of the rf furnace. N_2 flowed through the tube until the deposition temperature was reached, at which time the SiH_4 and NH_3 gases were switched to the tube to begin the deposition. The color changes were clearly visible as the Si_3N_4 deposited. Nearly all samples tested had film thickness in the 850-1050Å range (dark blue to blue).

After deposition of the Si_3N_4, aluminum dots were evaporated onto the chip through a metal mask. The dots were nominally 10 and 20 mils in diameter. The aluminum was approximately 10,000Å thick.

Since C-V measurements were to be made on the MNS (metal-nitride-semiconductor) capacitors, a contact resistance at the substrate (*i.e.*, the back contact) of less than 100 ohms was adequate. Indium was applied to the back of n-type chips with a soldering iron. This gave a contact resistance of less than 10^{-3} $ohm\text{-}cm^2$. An alloy of 30% Ag-70% Ga was used on the back surface of p-type chips. This alloy could be applied to the chips with a soldering iron, and gave a contact resistance of 20-50 ohms.

C-V measuring techniques.—The chips were placed on the stage of a micromanipulator for making the C-V tests. The stage was gold plated and provided the electrical contact to the substrate. A 0.010 in. beryllium-copper wire probe made contact to the aluminum dot field plate.

Leads from the probe station were connected to the appropriate test instrument. Most measurements were made with a Boonton Electronics Model 75C Capacitance Bridge which has a frequency range of 5-500 kHz. Measurements at higher frequencies were made on a modified Boonton Type 250A RX Meter which has a frequency range from 0.5 to 250 MHz.

Experimental Results

An overview.—Table I gives the results of a preliminary test on several n-type samples at different

Table I. Etch rate, dielectric constant, and maximum field strength of Si_3N_4

Flow rate of NH_3 (cc/min)	Vol ratio NH_3 to SiH_4	Etch rate (Å/min)	ϵ_r	Max field strength (V/cm)
18	5:1	300-350	7.9	5×10^6
30	25:1	800-1000	6.3	9×10^6
60	62.5:1	800-1000	6.2	1.1×10^7
290	80:1	800-1000	6.1	2.9×10^7
290	121:1	800-1000	6.15	2.8×10^7

NH_3 to SiH_4 ratios. Deposition temperature was 725°C with an N_2 carrier flow of 5 ft^3/hr. The etch test was made in 49% HF acid at room temperature. The relative dielectric constant given in the table is the average of 3 to 5 samples.

Thickness was measured by interference fringes and by means of a Bausch and Lomb Spectrophotometer (Model 505). Only a slight difference is seen in the etch rate, dielectric constant, and maximum field strength for films deposited with NH_3 to SiH_4 ratios of 25 to 1 or greater. The relative dielectric constant appears to decrease somewhat and the field strength increases as the NH_3:SiH_4 ratio increases—both effects saturating at high ratios. The film deposited at 5:1, however, shows a distinct difference in all three parameters. Other workers (6, 7, 10, 31) have reported Si_3N_4 films deposited at 900°-1100°C on silicon to have etch rates of 150-300 Å/min in 49% HF. Their results also show higher etch rates for lower deposition temperatures. The etch rates of 800-1000 Å/min given here for a deposition temperature of 725°C are in good agreement with their findings. The relatively low etch rate of 300-350 Å/min for the 5:1 film suggests that this film contains excess silicon. This agrees also with the conclusion of Bean *et al.* (9) that a 5:1 ratio is silicon rich. It is interesting to note that Saxena and Thal (26) reported etch rates of 350 Å/min with films deposited at 400°C from NH_3 and SiH_4 in a glow discharge. The ratio of NH_3 to SiH_4 was not reported, however. The higher dielectric constant and lower field strength for the 5:1 film here also would seem to support the conclusion that the film is silicon rich.

The C-V curves obtained on p-substrates showed two prominent characteristics, presence of fast surface states and a field-induced hysteresis. The presence of fast surface states is indicated by the curves of Fig. 2. For this sample, a test frequency of 1.5 MHz was required to "freeze out" the fast states, frequencies above 1.5 meg yielding the same curve. Zaininger (42) has outlined a method of determining the effective density of surface states which can respond to frequencies up to that of the test signal. The intent here is to point out that the energy distribution and frequency response of these fast states is affected by the NH_3:SiH_4 ratio. The NH_3 to SiH_4 ratio for the sample of Fig. 2 was 25:1; at higher NH_3 to SiH_4 ratios, the frequency response of the fastest states decreased until at a ratio of 55:1 the surface states for good samples could not follow a 500 kHz signal (Fig. 3). A comparison of Fig. 2 and 3 shows, moreover, a difference in the energy position of those states which could respond to 100 kHz but not 500 kHz. In Fig. 2, the greatest difference between the 100 and 500 kHz curves is in the inversion region. In Fig. 3, however, the greatest difference between the 100 and 500 kHz curves lies in the accumulation and depletion regions. This indicates that, whereas the fastest states lie near or above midgap (the inversion position of the Fermi level) for the sample of Fig. 2, they lie in the lower half of the band gap (the depletion and accumulation position of the Fermi level) for the sample of Fig. 3. A frequency of 500 kHz was sufficiently high to freeze out all fast states for nearly all films deposited at NH_3 to SiH_4 ratios of 55:1 or greater. The curves of Fig. 3 are shifted toward more negative voltages than the curves of Fig. 2. This shift was found to be generally true as the NH_3 to SiH_4 ratio was increased.

Depositions on n-type substrates were made only at 700°C with NH_3:SiH_4 ratios ranging from 25 to 121 to 1. These samples also show a very large effect of fast surface states. Figure 4 shows a sample for which a frequency of 1.5 meg was required to "freeze out" the fast states. The flat band voltage is +20V. As in the case of p-type samples, depositions made at high NH_3 to SiH_4 ratios (62.5 and above) gave surface states that could not respond at 500 kHz. Figure 5 shows C-V curves for six representative samples taken at 1.5 MHz. There is considerable difference in samples deposited at the same NH_3 to SiH_4 ratio as for examples N30 and N33. N-type samples showed much poorer repeatability than p-type samples. Flat band voltages for most samples were greater than 22V—cor-

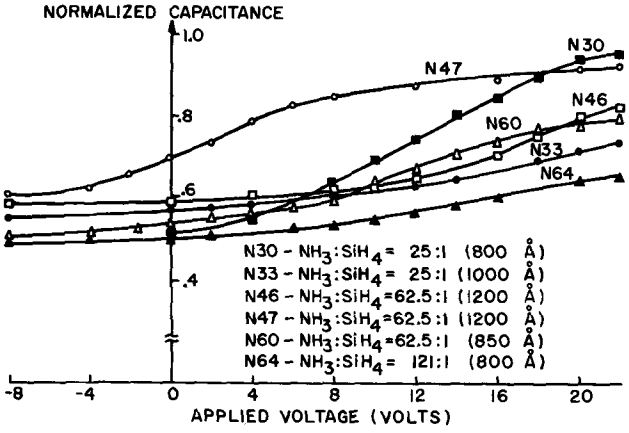

Fig. 5. Normalized C-V curves for samples on n-substrates

responding to field strengths greater than 2-3 x 10^6 V/cm.

The Fermi level for the p-substrates lies very close to the valence band (within 0.1 eV) so that at flat band most of the energy gap lies above the Fermi level. For the n-substrates, the Fermi level is about 0.125 eV below the conduction band, so that most of the energy gap is below the Fermi level at flat band. For n- and p-type samples processed in the same manner, the ionic contamination should be similar. Any significant difference in flat band voltage beyond that due to ϕ_{MS} (difference in metal, semiconductor work functions) should, therefore, reflect the nature of the surface states. The C-V curves for n-substrates are shifted to the right giving positive flat band voltages in contrast to negative flat band voltages for p-type samples. This strongly suggests that the surface states are negative when below the Fermi level, thus accounting for the difference between the curves on p- and n-substrates. The positive charge causing the shift of C-V curves on p-substrates must, then, be accounted for by traps that are positive when empty.

The hysteresis effect.—Figure 6 shows a C-V plot made on an x-y plotter. The voltage sweep was 5 V/sec so that both curves were swept out in about 15 sec. The curve swept from left to right lies some 8V to the left of the return sweep. This field-induced hysteresis has been reported in the case of Si_3N_4 deposited on Si (17, 18) and is also present for the Si_3N_4-GaAs system.

The displacement of the two curves indicates either a transfer of charge across the Si_3N_4-GaAs interface, or a movement of charge within the Si_3N_4. The direction of the curve shifting is, however, in the wrong direction to be explained by movement of charge within the Si_3N_4. It must be concluded that charge moves across the semiconductor-insulator interface and is trapped. The direction of the curve shifting as well as the recovery times involved can be explained, at least in a qualitative way, by such a trapping model. Herman and Warfield (43) have treated the effects of traps in the MOS structure. Ross and Wallmark (44) have dealt with trapping in the metal-Si_3N_4, SiO_2-silicon

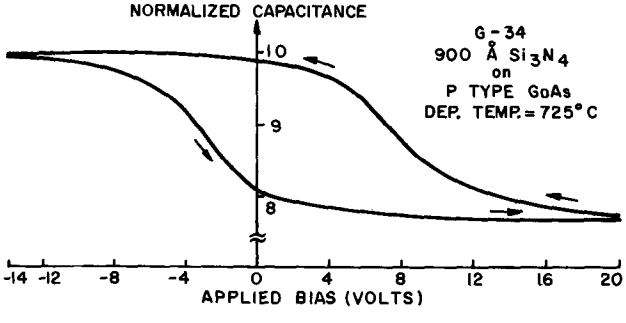

Fig. 6. C-V curves showing hysteresis

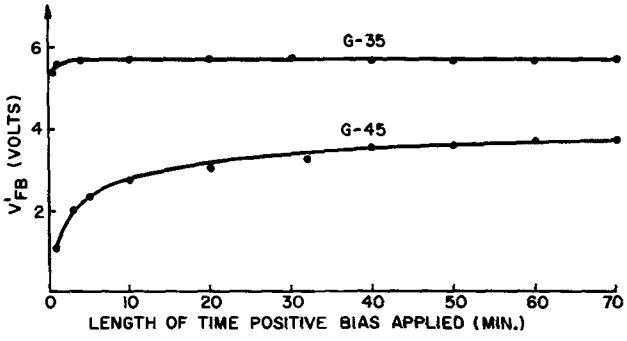

Fig. 7. Shift of flat band voltage by positive bias

system. The difficulty in obtaining a quantitative model lies in the fact that no method has yet been devised to determine both the spatial and energy distribution of the traps.

Figure 7 shows the "trap filling" response for two p-type samples having Si_3N_4 thicknesses of 850Å. A 20V bias was applied and the capacitance at flat band, which had previously been determined, was used as an indication of curve shift. The application of the bias was interrupted at each test point for about 10 sec in order to determine how much the flat band voltage (*i.e.*, the voltage required to yield flat band capacitance) had shifted. Whereas sample G-35 reached equilibrium in about 2 min with a shift of 5.7V, G-45 reached a shift of only 3.7V after an hour. G-35 was deposited at a NH_3:SiH_4 ratio of 49:1 at 725°C, whereas G-45 was deposited at a 62:1 ratio at 700°C. It can be concluded that, whereas G-35 has a relatively high density of traps near the interface (*i.e.*, within the tunneling distance) and/or the traps have a large electron capture cross section so that equilibrium is soon reached, G-45 has a lower density of states near the interface so that when equilibrium is finally reached the shift in flat band voltage is less.

The filling of traps involves electrons crossing the semiconductor-nitride interface and being captured by traps, which accounts for the right-most curve of Fig. 6. As the bias voltage sweeps out to +20V traps fill, so that the return path is displaced to the right indicating a net increase of negative charge at the interface.

The complementary part of the cycle is completed as the bias swings negative. The bias is then in a direction to raise the energy levels of the traps causing trapped electrons to tunnel back to the semiconductors. As the bias is swept negative to −20V, traps empty as electrons tunnel back to the semiconductor. The subsequent sweep from left to right is displaced to the left, indicating a net gain of positive charge.

In addition to the emptying of those traps which at flat band lie above the Fermi level, it is possible that some traps which are below the flat band Fermi level also empty as they are raised in energy by the negative bias. When the negative bias is released, these latter traps must fill before equilibrium is again achieved.

Establishing an equilibrium condition.—The discussion above has pointed out the nature of the hysteresis cycle—filling of traps with positive bias, emptying of traps with negative bias. Before quantitative measurements could be made on the samples, however, it was necessary to establish an equilibrium or reference condition. In particular, the "zero bias, equilibrium capacitance" (ZBEC) would be the value of capacitance at zero bias when the sample is in complete thermal equilibrium. Any procedure outlined for returning the sample to the ZBEC[1] should be repeatable. Such a procedure can be drawn up only after examination of the relaxation times involved in returning the sample to equilibrium.

[1] The term ZBEC will be used interchangeably to denote "zero bias equilibrium capacitance" and "zero bias equilibrium condition." The meaning should be clear from context.

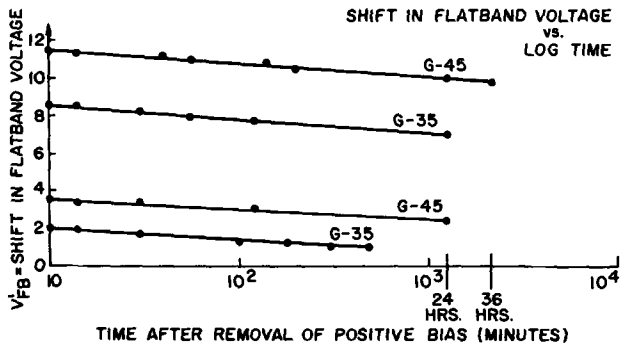

Fig. 8. Relaxation after filling of traps by positive bias

Figure 8 shows relaxation curves for two p-samples after removal of positive bias. The two curves for each sample result from a difference in the initial shift before relaxation. V'_{FB} represents the change in flat band voltage from its value prior to application of the positive bias.

It is apparent from the straight line plots of Fig. 8 that

$$\Delta V'_{FB} = -A \log t$$

with A in the range 0.5-0.7 for t in minutes. All samples tested showed similar relaxation curves. There was no apparent correlation between the NH_3:SiH_4 ratio and the value of A. The relaxation of filled traps is very slow. For an initial shift of 6V in flat band voltage, and using a value of 0.6 for A, 10^{10} min would be required for relaxation back to equilibrium. This is nearly 20,000 years.

In contrast to the extremely long time required for the traps to empty with no applied bias, they could be emptied in a short time by the application of a negative bias. A typical plot of this resetting of V'_{FB} as a function of time is shown in Fig. 9. Notice that V'_{FB} does not return to zero but goes to negative values. In terms of the C-V plot of Fig. 10, the following sequence has occurred:

1. Starting at "equilibrium" curve A, a positive bias is applied which shifts the curve to the position marked B as traps fill.

2. A negative bias is applied which moves the curve from B to C, overshooting the equilibrium position A.

In going from position B to C, not only have the traps that were filled by application of the positive bias been emptied, but also some traps which are filled in the equilibrium condition have been emptied. It is to be expected that these latter traps would fill exponentially, the dominant process being described by

$$\frac{dn_t}{dt} = A\, n(N_t - n_t)$$

where n_t is the density of filled traps, N_t is the total density of filled traps at equilibrium, n is the density of conduction band electrons, and A is a capture con-

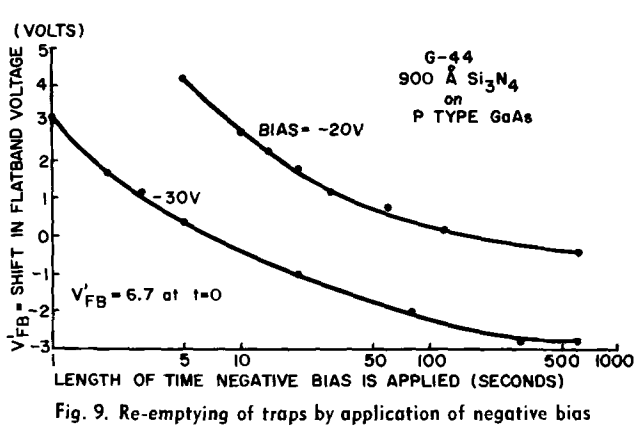

Fig. 9. Re-emptying of traps by application of negative bias

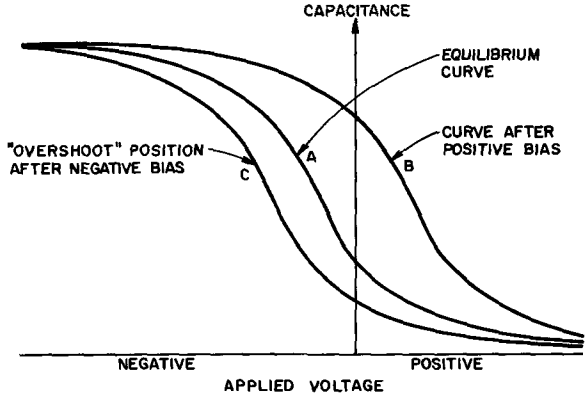

Fig. 10. Shift of C-V curve shift with positive and negative bias.

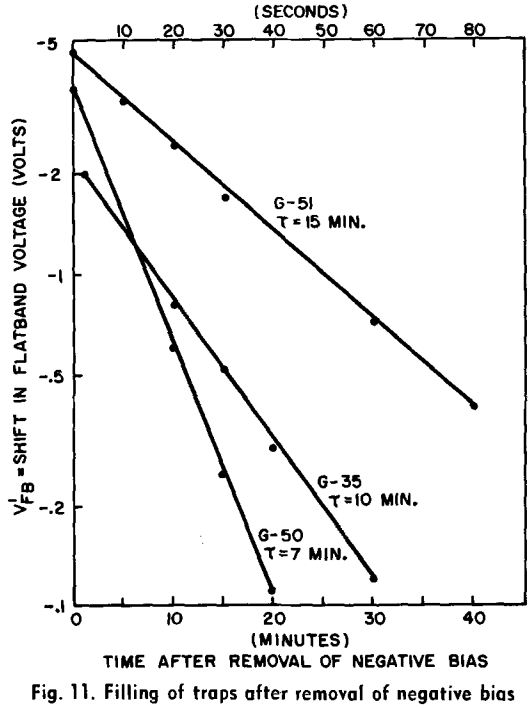

Fig. 11. Filling of traps after removal of negative bias

stant. Figure 11 shows this recovery for three samples. The shift in flat band voltage is given by

$$V'_{FB} = V_0\, e^{-t/\tau}$$

Typical values for τ are 5-15 min for the samples in the dark.

At this point a procedure for establishing a ZBEC can be given:

1. Apply a negative bias for 5 min. A bias of −30V for Si_3N_4 films in the 850-1000Å range is adequate. All traps above the flat band Fermi level will empty, as will some traps below the flat band Fermi level.

2. Remove all bias for 45 min to allow traps below the Fermi level to fill.

Effects of NH_3:SiH_4 *ratio on hysteresis.*—A detailed investigation was made to determine how the hysteresis varies as the NH_3:SiH_4 ratio is changed. Over a hundred samples were investigated. The zero bias equilibrium capacitance (ZBEC) was carefully established for each sample as outlined above. Using this capacitance as a reference, a positive bias was first applied to the sample and the voltage (V_0') required to again achieve the reference capacitance was noted. This cycle was repeated for a given positive bias until no further voltage shift was obtained. In this manner, the amount of shift in the C-V curve for a given bias was found. The flat band capacitance could have been

used as the reference point, but the ZBEC was more convenient since it could be found directly by measurement.

Figure 12 shows the shift in C-V plot, as determined by monitoring the voltage (V_o') required to obtain the ZBEC, as a function of bias for seven representative p-type samples. Film thickness for all samples was 900Å ± 10%. The samples can be divided into two groups, those deposited at NH_3:SiH_4 ratios above or below about 50:1. Samples deposited at ratios below 50:1 show a relatively large amount of shift at low bias with the rate of shift reducing at higher bias. Samples deposited at ratios above 60:1 show the reverse effect, *i.e.*, lower shift at low bias and a great deal of shift as the bias voltage was increased. A ratio of about 55:1 gave a nearly linear plot—intermediate to the two groups.

The above grouping was independent of deposition temperature over the temperature range 700°-725°C. It was found, however, that depositions at 725°C at ratios above 60:1 did not give good C-V plots. Little or no change in capacitance *vs.* bias was found, although the films had good physical appearance and good field strength (> 10^7 V/cm). Judging from the thickness of the films, the capacitances were always low. This indicated that the samples were so heavily inverted that it was impossible to achieve accumulation. Reducing the temperature to 700°C gave good curves at high ratios.

Looking at Fig. 12 in greater detail, it is clear that processing has a very pronounced affect on the density of traps as a function of distance from the insulator-semiconductor interface. Samples G-25, G-26, G-34, and G-35 exhibit 2-3 times as much shift as the other samples at a bias of 10V. Since the bias at each value was repeatedly applied until no more shift was obtained, it must be concluded that G-25, G-26, G-34, and G-35 have a much greater density of traps within the tunneling distance than do the other samples. This is also in agreement with the discussion relating to Fig. 7 above where it was concluded that G-35 had a much higher density of traps near the interface than G-45. At higher bias (> 25V), samples G-26, G-34, and G-35 show a decreasing amount of shift—indicating a decreasing density of traps.

Samples G-45, G-49, and G-50 show an increasing amount of shift with increasing bias. At high bias, the slopes of these curves approach unity. These samples appear to have a high density of traps at greater distance from the interface.

Depositions were made on p-substrates from 650° to 725°C at NH_3:SiH_4 ratios ranging from 25:1 to 300:1. Best results were obtained at a NH_3:SiH_4 ratio of about 60:1 at 700°C. These samples show low hysteresis at fields below 2-3 x 10^6 V/cm. Higher NH_3:SiH_4 ratios (up to at least 121:1) give about the same amount of hysteresis at low fields, but the C-V curves for these samples are increasingly shifted toward negative voltages. Figure 13 shows the improvement in hysteresis at low fields (< 3 x 10^6) for one of the best p-type samples (G-45) processed at 700°C at a NH_3:SiH_4 ratio 62:1 over the best sample (G-35) obtained at 725°C. Both curves were made at 100 kHz on an x-y plotter.

Although the C-V curves for n-type samples are quite different from those for p-type samples, the hysteresis effect is very similar. As for p-samples, the C-V curves for n-samples show the effect of trap filling and emptying. Application of positive bias results in a shift of the C-V curve toward more positive voltages. The relaxation (trap emptying) with no bias applied was again found to be logarithmic with time. A relaxation rate of 0.5-0.6 V/decade in excellent agreement with that of p-type samples was found. Again the traps could be emptied by the application of negative bias—a field of 2-3 x 10^6 V/cm for 2-5 min being sufficient.

Figure 14 shows the shift in ZBEC for several n-samples. As in the case of p-type samples, the shapes of the curves are quite dependent on the NH_3 to SiH_4 ratio. Samples deposited at low ratio show greatest shift at low fields, while samples having higher NH_3 to SiH_4 ratios (62.5:1 or greater) show the opposite effect. These results are in good agreement with those for p-type samples.

Density of surface states.—Because of the hysteresis effect in these samples, the concept of surface state density does not have its usual meaning. In the normal situation (*e.g.*, grown silicon dioxide on silicon) surface state density is a function of surface potential but is not dependent on the past history of the sample. The situation here is different, however, since the shape of the C-V curve is a function of the direction in which the voltage is varied. Figure 15 shows two curves for the p-type sample (G-45) exhibiting the least amount of hysteresis at low fields. Curve *A* was taken by varying the voltage in the negative and positive direction starting each time from zero volts in the equilibrium condition. This was the standard procedure used in taking C-V curves as discussed above. Curve *B* was taken by first adjusting the bias to +25V and then taking data as the voltage was decreased back through zero to negative voltages. The dotted curve in Fig. 15 is Curve *B* shifted next to Curve *A*. Curve *B* is somewhat steeper than Curve *A*.

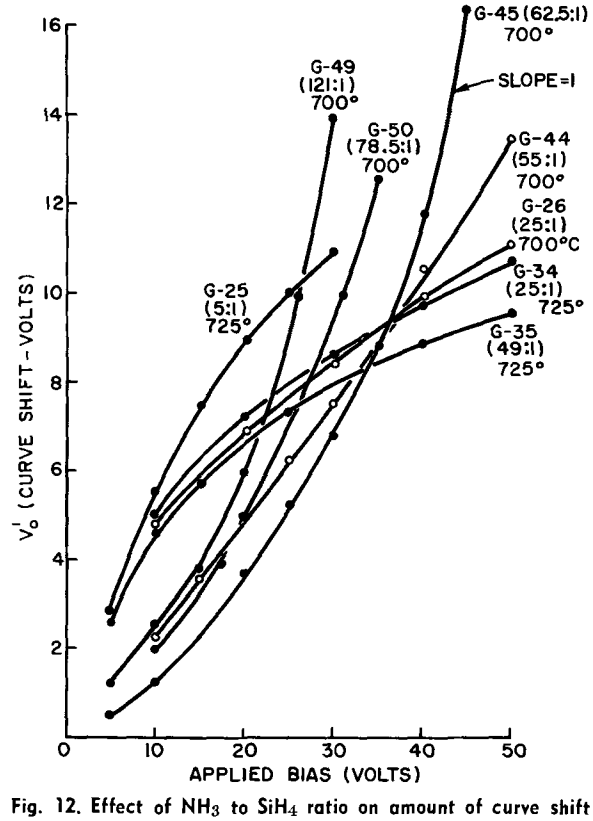

Fig. 12. Effect of NH_3 to SiH_4 ratio on amount of curve shift

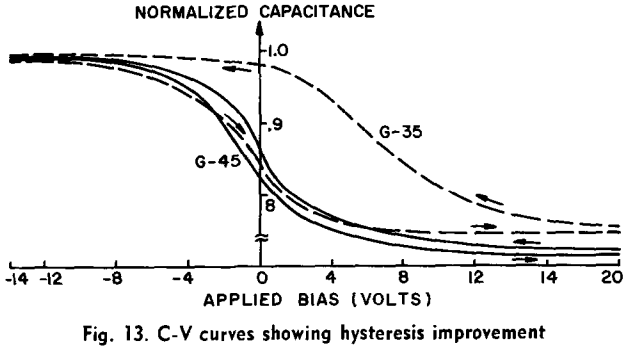

Fig. 13. C-V curves showing hysteresis improvement

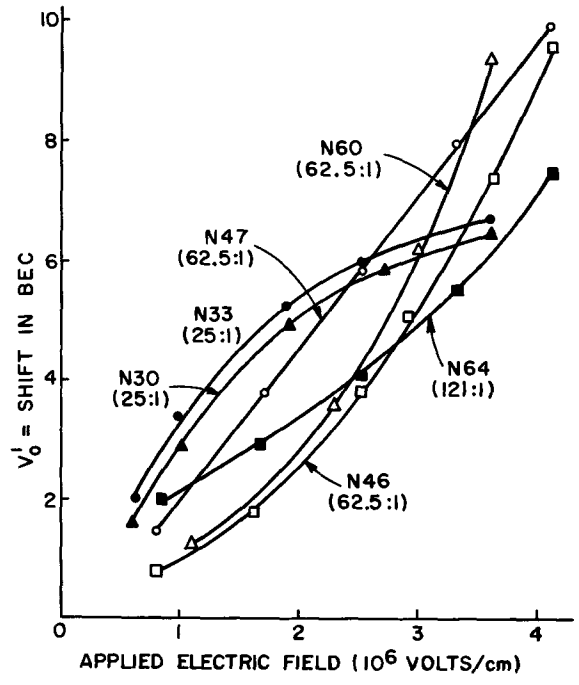

Fig. 14. Curve shift for n-type samples with positive applied voltage.

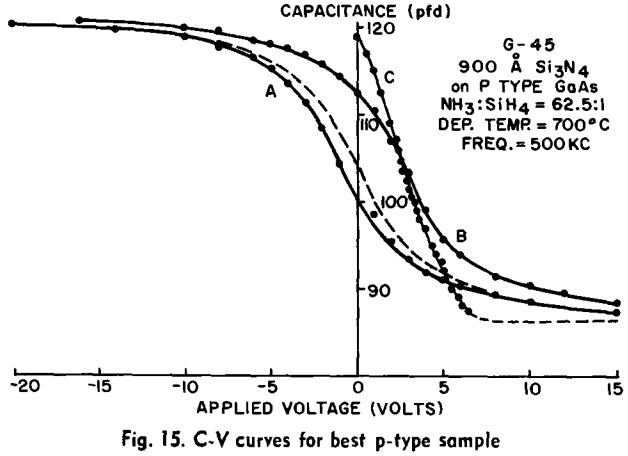

Fig. 15. C-V curves for best p-type sample

This is due to the fact that the traps were first filled before taking Curve *B*. Since the traps empty very slowly until negative voltages are reached, this curve gives the minimum effect of hysteresis as far as determining surface state density. The fact that the curve is shifted to the right of the equilibrium Curve *A* does not affect surface state density measurements. Such a shift is analogous to that produced by a non-zero ϕ_{MS} (metal-semiconductor work function difference) and has no effect on determination of surface state density.

Curve *C* in Fig. 15 is the calculated theoretical C-V curve (45) for values of surface potential, ψ_S, ranging from 0 to +1.1V. This corresponds to the Fermi level going from 0.1V above the valence band ($\psi_S = 0$) to 0.2V below the conduction band ($\psi_S = 1.1$). The surface state density was calculated from Curves *B* and *C* and is shown in Fig. 16. N_{SS} is the effective density of surface states per square centimeter per unit voltage. N_{SS} is in the 10^{12}-10^{13} range—being highest for low values of ψ_S. Values of ψ_S between 0 and 0.1V correspond to negative values of the applied voltage. The emptying of traps in this region could account for the large increase in N_{SS}. The lowest value of N_{SS} is 1 x 10^{12} for ψ_S of 0.4-0.5V.

Summary

The predominant characteristic of the Si_3N_4-GaAs interface is the presence of hysteresis due to the filling and emptying of traps in the Si_3N_4 near the interface. The spatial distribution of these traps from the interface is strongly dependent on the $NH_3:SiH_4$ ratio. The amount of this hysteresis was minimized to less than 2V for fields below 1.7 x 10^6 V/cm for the best p-type sample. Best results were obtained at a deposition temperature of 700°C and a $NH_3:SiH_4$ ratio of 62.5:1.

The relaxation (emptying) of filled traps with no applied bias is extremely slow and logarithmic in time. Recovery times as long as 20,000 years are indicated. The refilling of traps to equilibrium after removal of a negative bias is exponential in time with time constants of a few minutes in the dark. Surface states at the interface appear to be negative when below the Fermi level and account for the opposite polarity of flat band voltage for n- and p-samples.

A method was found for obtaining repeatable C-V measurements. This involved the establishing of a zero bias equilibrium condition—ZBEC. This condition could be achieved in a few minutes by relaxation after the application of a negative bias.

Surface state density for the best p-sample was in the 10^{12}-10^{13} range. Repeatability on p-type samples was good—apparently being primarily determined by repeatability of the processing. Repeatability for n-type samples was relatively poor for reasons not yet determined.

Some further reduction in the amount of hysteresis is needed before stable gates can be fabricated from GaAs-Si_3N_4 FET's.

The Orientation Dependence of Epitaxial $InAs_xP_{(1-x)}$ on GaAs

H. A. Allen*

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

The orientation dependence of the deposition of $InAs_xP_{1-x}$ epitaxial layers on GaAs using an AsH_3, PH_3, indium, and HCl vapor-deposition system was studied. The total flow rate and the ratio of Group III to total Group V components were held constant while deposits were made simultaneously on (100), (110), (111)A, and (111)B substrates. Similar deposits were made under the same conditions on spherical, single-crystal GaAs substrates. Growth on these spheres exhibited facets that correspond to slow growth and high-perfection orientations. The sphere surface morphologies were similar to the planar substrates over much of the composition range.

Many of the properties of the $InAs_xP_{(1-x)}$ alloy system have been known for some time. It has only been more recently that this material has been grown epitaxially by chemical-vapor deposition on InAs (1), GaAs, and GaP (2) substrates. The perfection of hetero-epitaxial layers is, generally, strongly dependent on the substrate orientation and in binary alloy systems, the preferred orientation can also be a function of alloy composition. In order to determine which is the preferred growth orientation for a given alloy, a systematic investigation under controlled growth conditions is necessary. The goal of this investigation is to define the preferred growth planes of the $InAs_xP_{(1-x)}$ alloy system on GaAs as a function of alloy composition.

Materials Preparation

An open-tube deposition system constructed of fused quartz was used in these studies (2) (Fig. 1). Purified hydrogen and high-purity AsH_3 and PH_3 each in hydrogen gas are mixed in a mixing chamber prior to introduction to the reactor. Anhydrous HCl gas (purchased from the Matheson Company) which has also been mixed with purified hydrogen, is passed through the heated indium reservoir and transports the volatile InCl to the deposition zone (1, 2). In these experiments 4% AsH_3 and 4% PH_3 each in hydrogen obtained from the Matheson Company, were sources. Elemental indium was six-nines pure and was purchased from Cominco American Incorporated. The composition of the deposited alloys was controlled by the relative flow rates of the AsH_3 and PH_3 gases and was reproducible to a standard deviation of 1% in alloy composition. The flow rates could be varied continuously from 0 to about 250 cc/min for AsH_3 and

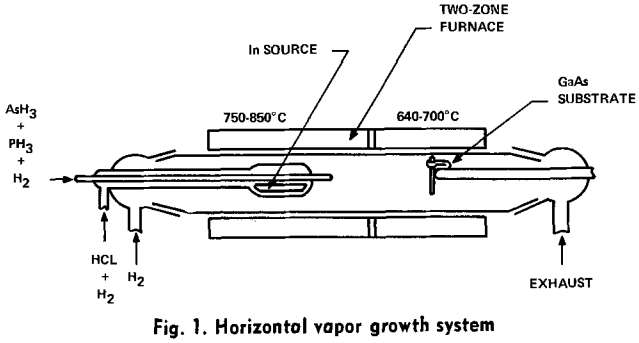

Fig. 1. Horizontal vapor growth system

* Electrochemical Society Active Member.

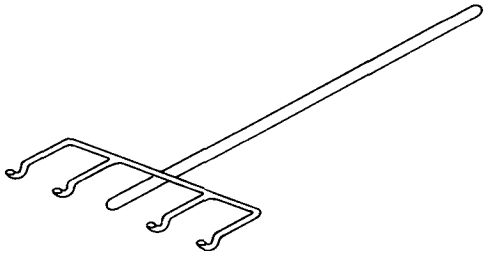

Fig. 2. Four-slice seed holder

PH_3 in hydrogen. The total flow rate was held constant at 300 cc/min. The Group III to Group V ratio was held constant at 5:4 with an anhydrous HCl flow of 14 cc/min and a total Group V flow of 11.3 cc/min.[1] The flow rates of AsH_3 and PH_3 relative to the alloy composition were determined in earlier studies (1, 2).

A two-zone resistance furnace provided temperature control of the indium reservoir and the GaAs substrates. The indium zone was controlled at 800°C and the substrate temperature was controlled at a temperature between 640° and 700°C; the seed temperature was increased from 640°C for InP to 700°C for InAs (2). The temperature gradient in the system was gradual within the indium reservoir and the seed being separated by 3-4 in. In most runs the seed or seeds were held normal to the direction of gaseous flow by quartz pins through a hole in the slice (Fig. 2). All temperatures were maintained at ± 2°C throughout a given run.

The GaAs substrates used in this investigation were from Czochralski-grown crystals that had been sawed in the (100), (110), (111)A, and (111)B planes and polished to about 20 mils in thickness. These substrates were sawed to within ± 0.5° of the given direction as evidenced by x-ray diffractometer readings of the slices. The substrates were chemically polished with 8:1:1(H_2SO_4:H_2O_2:H_2O) immediately prior to use. The GaAs spheres were mechanically ground from cubes which had been sawed from Czochralski-grown crystals. The spheres were between 0.063 and 0.125 cm in diameter. Immediately prior to use, the spheres were polished with the nonpreferential 40HCL:$4H_2O_2$:$1H_2O$ etch (3). The deposition times were 20 min for all substrates and 2-3 hr for the sphere deposits. Layer thicknesses varied between 8 and 20 μm and were determined by cleave or angle lap-and-stain techniques (2).

Large Area Deposits

The regular substrate deposits are referred to as large area as compared to the hypothetical point locations of each orientation on a sphere.

The (100), (110), (111)A, and (111)B substrates were suspended normal to the gas flow in the same run by use of a four-hooked fused silica seed holder (Fig. 2). Thus, in each run a nearly constant set of growth conditions was maintained. Very shiny deposits with smooth substrate-epitaxy interface could be grown reproducibly on the (111)A substrates from compositions consisting of pure InP up to about 80% InAs. The alloy deposits above 80% were generally polycrystalline in nature with the frequency of the poly layers increasing with the InAs concentration in alloy. Figure 3 is photomicrographs of representative (111)A deposits.

The (111)B deposits were erratic throughout the composition range and were generally polycrystalline in nature. The (110) deposits were similar in trend to the (111)A, but the frequency of poly layers was much higher above 75% and below 25% InAs. The deposits on (100) substrates, below 75% InAs, were practically all poly. The highest perfection InAs layers

[1] Assuming a 1:1 ratio of indium transported to HCl introduced.

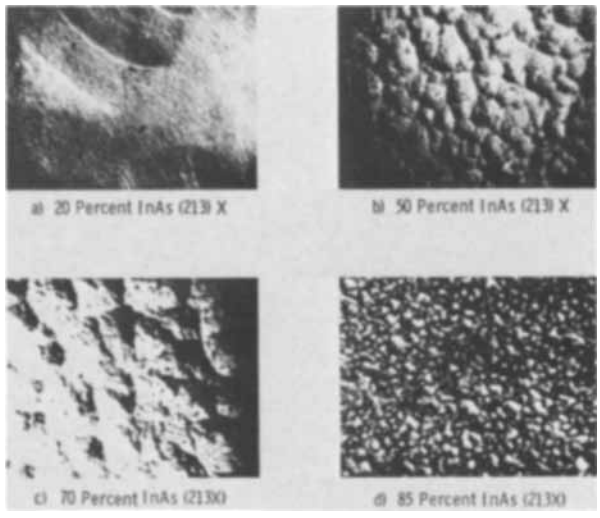

Fig. 3. Undoped $(InAs)_x$ $(InP)_{1-x}$ (III)A surfaces

were grown on this orientation. Representative photomicrographs of the (111)B, (110), and (100) surfaces are shown respectively in Fig. 4-6.

The compositions of the above samples were obtained by electron microprobe analysis and checked by x-ray diffraction techniques (4). The crystallinity was determined by x-ray diffraction and Laue backreflection techniques (5). Single crystals had well-defined Laue patterns as well as diffractometer peaks sharp enough to enable composition analysis to ± 2%. Table I gives the results of these measurements.

Sphere Deposits

Deposition on a sphere, ideally, makes it possible to have all orientations present at the same time. The

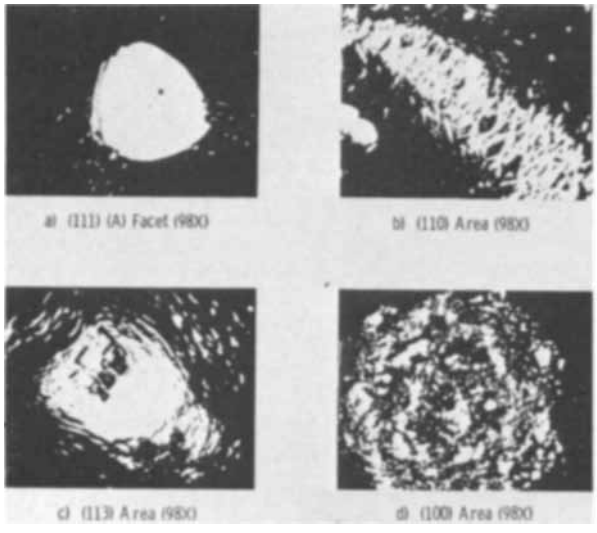

Fig. 7. InP sphere facets

faster growing planes will "grow out" leaving only the slower growing orientations as facets. In general, these facets represent optimum growth directions for high-perfection crystal growth. This proved to be the case with the epitaxial growth of InP on a GaAs sphere. The only true facet was a (111)A, with the (110) and (113) directions exhibiting shiny, shingled flats. The (100) and (111)B area could be located and were dull in appearance. The (111)A facet was distinguished by its surface similarity with control slices included in the run. Figure 7 is the facets observed on the InP deposited sphere.

Table I. Mole per cent InAs

Orientation	Run numbers								
	18	19	12	21	23	24	25	26	27
(111)A	0	17	25	50	77	80	79	89	93
(110)	0	17	24	52	66	83	82	87	95
(111)B	0	18	24	49	78	85	79	85	
(100)	0	22	30	55	80	87	85	84	94

Note: — denotes single crystallinity.

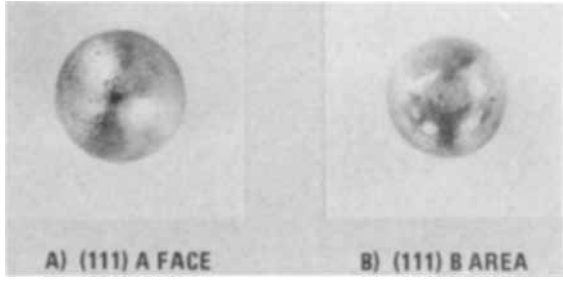

Fig. 8. $(InAs)_{0.50}$ $(InP)_{0.50}$ on GaAs sphere

Unfortunately, the InP deposited GaAs sphere was the only one which lent itself to such a straightforward explanation. Five more spheres were deposited with various compositions of the alloy between an InAs composition of 20 and 90 m/o (mole per cent). In all cases the only discernible facet was a (111)A with the (111)B direction identifiable by a triangular banded area 180° from each (111)A facet as shown in the (111)A and (111)B polar photographs in Fig. 8. No other identifiable facets were seen on these spheres.

Discussion

The composite of the large area and sphere deposits indicate that the (111)A direction of GaAs is the best plane for high-perfection epitaxial $InAs_xP_{(1-x)}$ alloy layers in the 0-80% InAs range. There is a pronounced orientation shift in large-area 85-100% InAs alloys to the (100) as the preferred growth. The above results were observed as the general rule through many depositions; it was occasionally possible to grow a high-perfection layer on an orientation which had previously given all poly deposits. Though no extensive experiments were conducted, the general trends stated in the test were seen on selected deposits with temperature conditions varied widely (± 75°C), on the seed and feed and with change in the Group III to Group V ratio between 0.5 and 3.0.

The fact that there were no identifiable facets on the alloy sphere deposits other than (111)A and in particular no (100) facets for alloy layers of greater than 85% InAs, is not well understood. It should be stressed that although one expects agreement, large-area and sphere deposits are very different. As was mentioned earlier, with a sphere each orientation is only a point on the sphere's surface and therefore, only slow-growing orientations tend to increase this point to a real geometrical area as growth occurs. Thus, it is possible that a preferred growth direction could be fast growing and not produce a facet on a sphere. Obviously, this would not be a problem with large-area deposit.

Phase Diagram of the CdTe-CdSe Pseudobinary System

Alan J. Strauss* and Jacques Steininger

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts 02173

ABSTRACT

The liquidus and solidus curves of the CdTe-CdSe pseudobinary system have been determined by thermal analysis of cooling and heating curves, respectively, for homogenized liquid and solid alloy samples. The phase diagram has a eutectic point at 1091° ± 1°C near 20 m/o (mole per cent) CdSe. Above the eutectic composition both liquidus and solidus temperatures increase monotonically and sublinearly with increasing CdSe content. In this region the experimental values of the liquidus-solidus gap do not exceed 11 m/o and are in excellent agreement with the ideal thermodynamic liquidus-solidus relationship. The phase diagram below the solidus has been investigated by x-ray diffraction measurements on alloy powders annealed between 770° and 1050°C and quenched. It consists of two broad single-phase regions, one of alloys with the zinc blende structure of CdTe and the other of alloys with the wurtzite structure of CdSe, separated by a two-phase region only about 3 m/o wide, whose boundaries shift toward increasing CdSe content with decreasing temperature. For compositions between 30 and 45 m/o CdSe, either structure could be obtained at room temperature, depending on annealing temperature and rate of cooling. In addition, a polytype of unknown structure, which appears to be a metastable intermediate in the wurtzite-to-zinc blende transformation, was observed in two melt-grown furnace-cooled ingots containing 45-50 m/o CdSe.

The II-VI compounds CdTe and CdSe have the cubic zinc blende and hexagonal wurtzite structures, respectively, when prepared by solidification of stoichiometric melts or nonstoichiometric Cd-Te or Cd-Se solutions. [Other methods of preparation can be used to obtain CdTe with wurtzite structure (1) or CdSe with zinc blende structure (2).] The phase diagram of the CdTe-CdSe system has not been determined previously but x-ray diffraction studies (3, 4) on a limited number of samples prepared by solidifying stoichiometric melts indicate that pseudobinary solid solutions are formed over the entire composition range. According to these studies, undoped alloys containing less than about 40 m/o CdSe have the zinc blende structure, those containing at least 70 m/o CdSe have the wurtzite structure, and those with intermediate compositions may have either structure.

In this investigation, the liquidus and solidus curves in the CdTe-CdSe pseudobinary system have been determined by thermal analysis measurements on homogenized liquid and solid alloy samples. The cubic-hexagonal transition in the solid phase has been studied by x-ray diffraction analysis of annealed and quenched alloy powders. The x-ray data show that the cubic and hexagonal phase fields are separated by a two-phase region about 3 m/o wide, whose boundaries shift toward increasing CdSe content with decreasing temperature. Therefore, within a certain composition range, alloys can be obtained with either cubic or hexagonal structure, as reported earlier (3, 4), depending on the annealing temperature and rate of cooling. In addition to these two phases, a previously unreported polytype of unknown structure can also be formed as shown by x-ray diffraction data for two melt-grown, furnace-cooled ingots containing 45-50 m/o CdSe.

Experimental Procedure

Alloys for thermal analysis and x-ray diffraction studies were prepared from CdTe and CdSe. The CdTe was synthesized by fusion of the elements (nominal purity 99.9999%) in forepump-evacuated and sealed fused silica ampoules coated with pyrolytic graphite. To prepare CdSe, the elements (same nominal purity) were combined in an open-tube fused silica reactor (5) heated to 1050°-1100°C under helium gas at 1 atm. The composition of the CdSe was then adjusted by sublimation in a dynamic vacuum in order to remove the excess of unreacted elements and reduce the vapor pressure during subsequent high temperature annealing.

To prepare each alloy for x-ray analysis, a 10g mixture of the two powdered compounds was sealed in a fused silica ampoule containing helium gas (pressure of about 400 Torr at room temperature), annealed at 950°C for 21 days or longer, and quenched by dropping the ampoule into water. Annealing was continued until x-ray diffraction measurements gave no evidence of inhomogeneity, and the measured lattice parameters were consistent with the nominal compositions.

Samples for thermal analysis were either alloy powders annealed in the manner described or unannealed mixtures of CdTe and CdSe powders. A sample weighing about 10g was sealed in an evacuated fused silica ampoule and placed in a DTA apparatus described previously (6), together with a similar ampoule containing about 8g of silicon used as a reference. The sample and reference temperatures were measured with Pt-Pt, 13% Rh thermocouples inserted into reentrant wells in the ampoules. Calibration with a gold sample (melting point 1063.0°C) gave melting and freezing arrests of 1063.0°C ± 0.1°C and showed that no correction of the sample temperature readings was necessary. Solidus temperatures were obtained from thermal arrests observed either during initial heating of the annealed powder samples or during heating of both types of samples after they had been melted, frozen, and then homogenized by annealing in the DTA apparatus for 16 hr at about 20°C below the solidus temperature. The two types of experiments gave solidus temperatures which agreed to within a fraction of a degree. The liquidus temperatures were obtained from the thermal arrests observed when the samples were cooled after homogenization in the DTA apparatus for 16 hr at about 50°C above the liquidus temperature. Liquidus temperatures reproducible to ±1°C were obtained from repeated runs on the same sample. Rates of 1°-2°C/min were used for both heating and cooling. Supercooling was observed during most of the cooling runs but was limited to only a few degrees (Table I). When supercooling occurred, the liquidus arrest temperature was taken to be the

maximum in the recalescence curve. Otherwise, both liquidus and solidus arrest temperatures were obtained from the intersection of the practically straight lines below and above the break in the sample temperature curve. Because of the large thermal effects in this system, differential temperature recording was used only as a confirmation of the arrests observed on the sample temperature curve. The over-all accuracy is estimated to vary from within ± 1°C near the terminal compounds to within a few degrees in the middle of the composition range.

To investigate the cubic-hexagonal transition below the solidus, pairs of homogenized alloy powders with the same composition, in the range 30-50 m/o CdSe, were preannealed so that one was initially cubic and the other initially hexagonal. Portions of the samples weighing 1-2g were then sealed in separate fused silica ampoules containing helium gas, annealed at temperatures between 770° and 1050°C, quenched by dropping the ampoules into water, and ground to minus 325 mesh. The phases present were determined from x-ray diffractometer patterns obtained with Cu Kα radiation. Annealing was repeated if necessary until both samples were either single-phase cubic, single-phase hexagonal, or two-phase. The total annealing times ranged from 16 hr at 1050°C to 30 days at 800°C. A sample was taken to be single-phase cubic if the noncoincident (111) hexagonal line in the vicinity of $2\theta = 23°$ was not detected, and single-phase hexagonal if the noncoincident (400) cubic line in the vicinity of $2\theta = 58°$ was not detected. [Use of these criteria gives a considerably lower detection limit for the hexagonal phase than for the cubic phase, since the (111) hexagonal line is 5-10 times more intense than the (400) cubic line.]

X-ray diffraction patterns were also obtained with a Debye-Scherrer camera for all the alloys following initial homogenization and for a number of samples after subsequent annealing. These patterns were used to calculate the cubic or hexagonal lattice parameters to an accuracy of ±0.001Å by a least-squares extrapolation method (7).

In addition to the alloys prepared by annealing mixtures of powdered CdTe and CdSe, a number of polycrystalline alloy ingots each weighing 150g were obtained by the Bridgman method of crystal growth. Stoichiometric melts containing up to 60 m/o CdSe, which were prepared from the elements in evacuated and sealed fused silica ampoules coated with pyrolytic graphite, were frozen directionally by lowering the ampoules at the rate of about 1 mm/hr out of a vertical resistance-heated furnace. One ingot, containing 35 m/o CdSe, was quenched by pulling the ampoule out of the furnace with part of the material still molten. The others were allowed to cool in the furnace after the power had been turned off. Portions of the ingots were analyzed with an electron microprobe (8) to determine their alloy composition, and a number of these and other portions were ground for x-ray diffraction analysis with the diffractometer and/or Debye-Scherrer camera.

Results

The phase diagram determined for the CdTe-CdSe system is shown in Fig. 1. The compositions plotted are the nominal compositions calculated from the weights of CdTe and CdSe used to prepare the alloys. The thermal analysis data are listed in Table I, which gives the liquidus and solidus arrest temperatures, the amount of supercooling observed during the liquidus determinations, and the reproducibility when repeated runs were made. Melting and freezing arrests of 1091.8° ± 0.2°C were obtained for CdTe, in good agreement with the literature values of 1090° ± 2°C [Ref. (9)], 1092° ± 3°C [Ref. (10)], and 1091° ± 2°C [Ref. (11)]. The liquidus and solidus temperatures for 10 and 20 m/o CdSe do not differ significantly from each other or from the melting point of CdTe and suggest the presence of a eutectic point at 1091° ± 1°C and near 20 m/o CdSe. (The separation between liquidus and solidus curves in this region is not shown in Fig. 1 because of the small scale of the diagram.) Above 20 m/o CdSe, both liquidus and solidus temperatures increase monotonically and sublinearly with increasing CdSe content. The liquidus-solidus gap in this region remains rather narrow, never exceeding 11 m/o. Melting and freezing arrests of 1252.5° ± 0.5°C were obtained for CdSe, in fair to good agreement with previously reported values of 1239° ± 3°C [Ref. (12)], 1250° ± 2°C [Ref. (11)], 1258° ± 3°C [Ref. (13)], 1259° ± 4°C [Ref. (14)], and 1264° ± 10°C [Ref. (15)].

The results of the x-ray diffractometer measurements on annealed and quenched powders are represented by circles in Fig. 1—closed circles for single-phase cubic samples, open circles for single-phase hexagonal samples, and half-closed circles for two-phase samples. (There was no evidence for ordering of the Te and Se atoms in either the cubic or hexagonal structure.) Over the limited composition range where the relationship between structure and temperature has been studied in detail, the cubic and hexagonal phase fields are separated by a two-phase region only about 3 m/o wide. The boundaries of this region are well represented by parallel straight lines, along which the temperature decreases with increasing CdSe content. According to these lines, the two-phase field extends from 26 to 29 m/o CdSe at 1000°C and from 46.5 to 49.5 m/o CdSe at 800°C. The composition range investigated was not extended to lower CdSe content because of the difficulty anticipated in retaining the hexagonal phase by quenching as the hexagonal-cubic transformation temperature increased. The range was not ex-

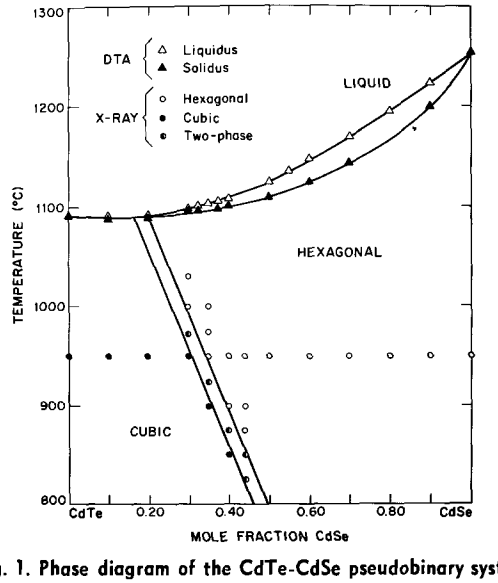

Fig. 1. Phase diagram of the CdTe-CdSe pseudobinary system

tended to higher CdSe content because the time required to attain equilibrium in the solid phase became inconveniently long as the transformation temperature decreased. (Some two-phase samples may have been incorrectly identified as single-phase because the quantity of the minor phase was too small to be detected by the x-ray diffraction method used. Errors of this kind would tend to make the width of the two-phase region shown in Fig. 1 somewhat less than the actual width.)

As shown in Fig. 1, when extrapolated linearly the lower and upper boundaries of the two-phase field intersect the solidus curve at 17 and 20 m/o CdSe, respectively, consistent with a eutectic point near 20 m/o CdSe. Linear extrapolation to lower temperatures gives an hexagonal-cubic transformation temperature around 250°C for pure CdSe, although such an extended extrapolation is obviously of limited significance. Partial transformation from cubic to hexagonal CdSe after annealing for 10 hr at 130°C has been reported (2).

The cubic (a_0) and hexagonal (a_0, c_0) lattice parameters measured for annealed single-phase alloy powders are listed in Table II, together with the values calculated from them for the unit cell volume (V) and for the c/a ratio of the hexagonal alloys. (Where duplicate results are given for the same composition, they were obtained for independent samples, not for aliquots of the same sample.) The c/a ratios range from 1.631 to 1.638, compared with the theoretical value of 1.633 for the wurtzite structure. For CdTe, the measured a_0 is 6.481Å, compared with literature values of 6.480-6.483Å [Ref. (3, 16-18)]. [The value of 6.423Å given by Litwin (4) is obviously incorrect.] For CdSe, a_0 = 4.301Å and c_0 = 7.016Å, compared with literature values of a_0 from 4.297 to 4.309Å, and values of c_0 from 7.007 to 7.034Å [Ref. (3, 4, 14, 19)]. Most of the lattice parameters reported previously (3, 4) for the alloys with cubic structure agree fairly well with the present ones, but there is greater disagreement among the parameters for the hexagonal alloys.

The values of a_0 for cubic samples, a_0 and c_0 for hexagonal samples, and V for all samples are plotted against nominal alloy composition (expressed in mole fraction CdSe, x) in Fig. 2, 3, and 4, respectively. The three lattice parameters vary linearly with composition, according to the following expressions which correspond to the straight lines in Fig. 2 and 3: a_0 (cubic) (Å) = 6.481-0.411x; a_0 (hexagonal) (Å) = 4.580-0.279x; c_0 (Å) = 7.502-0.486x. Except at the extremes of the composition range, the values of V fall slightly below the straight line joining the unit cell volumes of CdTe and CdSe. For the region ($0.3 \leq x \leq 0.45$) in which both cubic and hexagonal samples have been obtained, the values of V are generally somewhat lower for cubic samples than for hexagonal.

For the $CdTe_{1-x}Se_x$ ingots which were prepared by directional freezing of stoichiometric melts, the results of electron microprobe analysis of small sections close to the tip are qualitatively consistent with the liquidus-solidus relationships shown in Fig. 1. If solidification of an alloy occurs under equilibrium conditions, the first-to-freeze composition is the solidus composition corresponding to the liquidus composition given by the nominal ingot composition. For $CdTe_{1-x}Se_x$ ingots with nominal x up to 0.3, within the error of the microprobe (estimated to be ±3%) the measured compositions are the same as the nominal ingot compositions, presumably because the gap between liquidus and solidus compositions is quite small in this region. For 3 ingots with nominal x = 0.4, 0.4, and 0.5, the measured compositions were x = 0.41, 0.45, and 0.55, respectively, compared with the solidus compositions of x = 0.50, 0.50, and 0.61 given by the phase diagram. The measured compositions are all less than the corresponding

solidus compositions; these discrepancies are in the direction expected if the rate of solidification was too high for equilibrium to be established between the liquid and solid or if the samples analyzed were too far removed from the first-to-freeze region.

Although the x-ray diffractometer measurements made on the alloy ingots were not extensive, the data are sufficient to show that the phases present depend on ingot composition, the location of the sample in the ingot, and the method of cooling. Thus all samples from ingots with $x \leq 0.2$ are cubic, and all those from an ingot with $x = 0.6$ are hexagonal. (The compositions quoted in this discussion are nominal, and the ingots were furnace cooled unless otherwise specified.) The first-to-freeze portions of ingots with $x = 0.3$, 0.4, and 0.45 are either entirely cubic or contain a small amount of the hexagonal phase in addition to the cubic. A sample frozen later in one of the ingots with $x = 0.4$ contains a larger proportion of the hexagonal phase but is still primarily cubic. In contrast, samples from an ingot with x of only 0.35, which had been air quenched by removing the growth ampoule from the hot furnace, are entirely hexagonal.

For two ingots with $x = 0.45$ and 0.5, the first-to-freeze portions are single-phase cubic and hexagonal, respectively. However, a number of other samples from these ingots give diffractometer patterns which cannot be attributed to these two phases. Part of one such pattern is shown in Fig. 5, together with the same angle range ($20° \leq 2\theta \leq 28°$) from patterns for single-phase cubic and hexagonal samples of about the same composition. The unusual features of the new patterns are: (*a*) the appearance of new although poorly defined lines at 25.4° and 42.9°; (b) an increase in the relative intensity of the line at 24.6°, which cannot be attributed to the cubic phase because the characteristic cubic line at 58.8° is either weak or absent; and (*c*) a marked decrease in the relative intensities of the lines at 26.3°, 44.4°, and 76.5° which appear in the wurtzite pattern. We attribute these features to the presence of a polytype, like those observed for ZnS and SiC, whose structure is intermediate between the zinc blende structure (with entirely cubic close packing) and the wurtzite structure (with entirely hexagonal close packing). In the ingot with $x = 0.5$, the region containing the polytype is in the interior, completely surrounded by a thin outer shell of the wurtzite phase. The two regions are easily distinguished by visual observation of a lapped cross section.

In addition to the diffractometer patterns for ingot samples, Debye-Scherrer patterns were also obtained for a number of such samples which were powdered after they had been analyzed with the electron microprobe. The lattice parameters and unit cell volumes measured for single-phase cubic and hexagonal samples, which are plotted in Fig. 2-4 as a function of the measured composition, are the same within experimental error (including the error of the microprobe analysis) as those for annealed alloy powders.

Discussion

The qualitative features of the CdTe-CdSe phase diagram (Fig. 1) reflect the fact that the crystal structures of CdTe and CdSe are different but very closely related. Because of their difference in structure, the compounds cannot form a complete series of solid solutions along the solidus curve. Therefore the CdTe-CdSe diagram has the eutectic form, rather than the simple lens form of the II-VI pseudobinary CdTe-ZnTe [Ref. (6)] and HgTe-HgSe [Ref. (20)] diagrams. In each of the latter systems, involving two binary compounds with zinc blende structure which exhibit complete mutual solid solubility, both liquidus and solidus temperatures increase monotonically and sublinearly with increasing ZnTe or HgSe content across the entire diagram. Thus the liquidus and solidus curves in these systems resemble those for the hexagonal branch of the CdTe-CdSe diagram (*i.e.*, the region between about 20 m/o CdSe, the eutectic composition, and pure CdSe). Over this entire region $CdTe_{1-x}Se_x$, alloys with wurtzite structure are stable along the solidus curve, according to a linear extrapolation of the hexagonal phase boundary from lower temperatures.

Liquidus-solidus relationship.—For a binary alloy system of completely miscible components A and B, by expressing the equality of the partial free energies of mixing in the liquid and solid phases, it has been shown (21) that the liquidus and solidus compositions in equilibrium at temperature T are related by

$$RT\left(\ln\frac{X_A^s}{X_B^s}-\ln\frac{X_A^l}{X_B^l}\right)=\Delta H_A\left(1-\frac{T}{T_A}\right)-\Delta H_B\left(1-\frac{T}{T_B}\right)-D \quad [1]$$

with

$$D=\frac{\partial\Delta G_{e,m}^s}{\partial X_A^s}-\frac{\partial\Delta G_{e,m}^l}{\partial X_A^l}$$

where X_i^l and X_i^s are the mole fractions of component i in the liquid and solid phases, respectively, T_i and ΔH_i are the temperature and enthalpy of fusion of the pure component, and $\Delta G_{e,m}^s$ and $\Delta G_{e,m}^l$ are the excess molar free energies of mixing in the respective phases. Equation [1] is a general thermodynamic expression which is applicable to any system. If both liquid and solid solutions are ideal, the excess free energies of mixing are zero and $D = 0$. The ideal form of Eq. [1] with $D = 0$ has also been found to fit the experimental data for a large number of binary and pseudobinary alloy systems (metallic, semiconducting, and ionic) in which the liquidus and solidus temperatures vary monotonically with composition (21). Although in general the liquid and solid phases in these systems are not ideal solutions, the ideal liquidus-solidus expression is applicable because the deviations from ideality in the two phases are comparable, and therefore, the difference between the partial excess free energies of mixing is small enough to be neglected. (An excellent fit to Eq. [1] with $D = 0$ is obtained for the CdTe-ZnTe system but not for the HgTe-HgSe system. We believe that the deviations between experiment and calculation in the latter case are probably due to errors in the experimental determination of the solidus curve.)

The ideal form of Eq. [1] can be used to calculate one of the boundaries of the two-phase field when the other boundary and the enthalpies of fusion of the pure components are known. In the present study this expression has been used to calculate the solidus curve for the CdTe-CdSe system from the experimental liquidus data and the enthalpies of fusion of CdTe and CdSe determined by Kulwicki (11) (12.0 and 10.5 kcal/mole, respectively). As shown in Fig. 6, the calculated curve is in excellent agreement with the experimental solidus data for the hexagonal branch of the diagram. (The root mean square of the difference between calculated and experimental temperatures for 8 data points is 2.4°C.) The agreement indicates that over this composition range the deviations from ideality are comparable for the liquid and solid phases, as in systems where the liquidus and solidus temperatures vary monotonically over the whole range of composition. The agreement between calculation and experiment for the hexagonal branch also implies that the zinc blende and metastable wurtzite structures of CdTe do not differ greatly in free energy, since the temperature and enthalpy of fusion used in the calculations were measured for CdTe with zinc blende structure.

It should be noted that calculation of the solidus curve from our initially limited liquidus data facilitated the selection of temperatures close to the solidus for annealing the frozen alloy samples. Because homogenization was accelerated by the increased rates of diffusion, the heating curves for such samples annealed for only 16 hr at these high temperatures gave thermal arrests almost as sharp as those obtained with powder samples annealed at 950°C for 3 weeks or more.

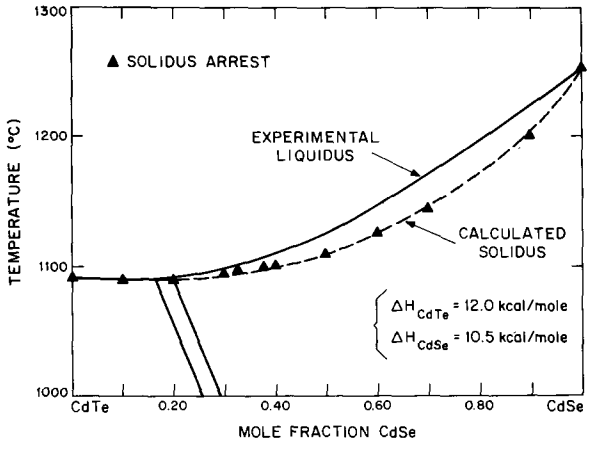

Fig. 6. Comparison of calculated solidus curve with experimental solidus data for CdTe-CdSe system.

Sub-solidus phases.—The zinc blende and wurtzite structures have the same primary coordination, with each cation surrounded by four nearest-neighbor anions in tetrahedral configuration, and *vice versa*. This close structural relationship, together with the chemical similarity between Te and Se, explains the broad range of mutual solid solubility exhibited by CdTe and CdSe. Within the temperature region where the boundaries of the cubic and hexagonal phases have been determined, the miscibility gap at a fixed temperature is only about 3 m/o, and its position shifts sufficiently with temperature to permit formation of solid solutions over the whole range of compositions.

According to the phase diagram of Fig. 1, for any composition up to 17 m/o CdSe the zinc blende structure is stable at all temperatures below the solidus curve. For any other composition, this structure is stable only up to a transition temperature which decreases quite rapidly with increasing CdSe content. Above this temperature there is an interval of about 15°C in which no solid solution of this composition is stable, and at still higher temperatures the wurtzite structure is stable. The same sequence of low-temperature zinc blende, intermediate two-phase, and high-temperature wurtzite regions has recently been observed by Shalimova *et al.* (19) for fixed compositions near 40 m/o CdSe in the pseudobinary system formed by CdSe and ZnSe, which like CdTe has the zinc blende structure. According to their results for annealing temperatures between 800° and 1200°C, the phase diagram below the solidus in this system is similar to that of the CdTe-CdSe system, since it too consists of cubic and hexagonal phase fields separated by a narrow two-phase region whose boundaries shift toward increasing CdSe content with decreasing temperature.

For ZnS, the prototype compound for both structures, the zinc blende structure is the low-temperature form and the wurtzite structure the high-temperature form, just as in the two alloy systems. The fact that in all three cases there is a temperature at which the two phases have the same free energy is another result of their close structural relationship. In each case, at constant composition the free energy of the zinc blende phase increases more rapidly with increasing temperature than that of the wurtzite phase. [For the alloys, the temperature of equal free energy lies in the region where neither structure is stable with respect to the formation of a mixture of two phases with different compositions. Shalimova *et al.* (19) claim that the zinc blende and wurtzite structures are both stable for any composition and temperature within the two-phase region of the CdSe-ZnSe system. This is thermodynamically impossible.]

Although the zinc blende and wurtzite structures have the same primary coordination, transformations from one to the other require the breaking of nearest-neighbor bonds (22). Such reconstructive transformations involve an appreciable activation energy, and their rates therefore depend approximately exponentially on temperature. It is this strong temperature dependence which makes it possible to establish equilibrium phase relations for elevated temperatures by means of phase determinations at room temperature on samples which have been annealed and quenched. The use of this method requires the transformation rates to be high enough at the annealing temperature for equilibrium to be achieved in a convenient time and low enough at any phase boundary for the high-temperature phase to be retained by quenching. In our investigation of the CdTe-CdSe system, these conditions were apparently satisfied for small powder samples with compositions between 30 and 44 m/o CdSe, corresponding to transition temperatures between about 950° and 800°C at the upper boundary of the cubic phase field. Within this range single-phase sam-

ples of a given composition were prepared with both wurtzite and zinc blende structures by annealing above or below the transition temperature, respectively. No attempt was made to prepare hexagonal samples containing less than 30 m/o CdSe, because of the difficulty anticipated in cooling rapidly enough to prevent conversion to the cubic phase at temperatures of 1000°C and above. Cubic samples containing more than 44 m/o CdSe were not prepared because it would have taken too long to transform them from the hexagonal phase at temperatures below 800°C.

In the two earlier investigations (3, 4) of the structure of CdTe-CdSe alloys, the samples studied were prepared by solidification from the melt. Those containing up to 30 m/o CdSe were entirely cubic. Stuckes and Farrell (3) found that samples containing 40 and 50 m/o CdSe were cubic with only a trace of the hexagonal phase, and Litwin (4) observed both phases for compositions of 36, 50, and 60 m/o CdSe. Only samples containing at least 70 m/o CdSe were entirely hexagonal. According to the phase diagram of Fig. 1, however, alloys containing more than about 20 m/o CdSe crystallize from the melt in the hexagonal structure. Therefore the presence of the cubic phase in samples containing 30-60 m/o CdSe must have resulted from the partial or complete transformation of the hexagonal phase during cooling, after the temperature had fallen below the hexagonal-to-cubic transition temperature. The cubic phase was not formed for compositions exceeding 60 m/o CdSe because of the decrease in the transition temperature with increasing CdSe content and the decrease in transformation rate with decreasing temperature. In this range, the cubic phase becomes stable at such low temperatures (less than about 700°C) that the transformation rate was never high enough for appreciable transformation to occur at the cooling rates used. Since cooling rates were not discussed in either paper, it can be assumed that they were neither extremely fast nor extremely slow, and that times of the order of hours were probably required to cool to room temperature. This indicates that the rates of the hexagonal-to-cubic transformation were much faster for solid samples than for the powdered samples annealed in our investigation at fixed temperatures, which required many days for complete transformation to the cubic phase even at 800°C.

Increased transformation rates in solid samples were also observed for ingots prepared in our investigation by directional solidification of stoichiometric melts. The hexagonal phase was retained without transformation in a 35 m/o CdSe ingot which was air quenched to room temperature from above the transition temperature, while transformation occurred in furnace-cooled ingots containing up to 45 m/o CdSe. In one such furnace-cooled ingot containing 30 m/o CdSe, cubic single-crystal regions up to about 1 cm on a side were identified by sandblasting, which reveals the grain boundaries in these alloys. Thus under suitable experimental conditions the transformation to the cubic phase can occur without introducing polycrystallinity. This is another consequence of the close relationship between the zinc blende and wurtzite structures.

This relationship is also reflected by the rather close agreement in unit cell volume measured at room temperature (Fig. 4) between alloys with the zinc blende and wurtzite structures. The volume difference for a given composition does not exceed 0.6% in the range ($0.3 \leq x \leq 0.45$) where both structures have been obtained. However, the significance of the comparison is limited because the wurtzite structure is metastable at room temperature in the overlapping range and also for compositions considerably richer in CdSe—quite possibly for CdSe itself. A valid comparison would require x-ray diffraction measurements at temperatures high enough for each structure to be stable over a wide composition range. Such high-temperature measurements would also be necessary to satisfactorily test the conformity of the CdTe-CdSe alloys to Vegard's law. According to the room temperature volume data, the alloys with zinc blende structure deviate by as much as 0.8% from the straight line shown in Fig. 4, while the wurtzite alloys generally exhibit smaller deviations.

As a final result of the zinc blende-wurtzite relationship, we note the formation of a polytype in two furnace-cooled ingots with nominal compositions of 45 and 50 m/o CdSe. A large number of polytypes with structures intermediate between zinc blende and wurtzite are known for ZnS and SiC, but to our knowledge none has been reported for a ternary alloy. No attempt has been made to identify the polytype by single-crystal x-ray diffraction analysis, but calculations of the powder diffraction patterns for the 4H, 6H, 8H, 12H, and 15R polytypes of $CdTe_{0.5}Se_{0.5}$ indicate that it is probably not one of these.

Apparently the polytype was formed as an intermediate stage in the hexagonal-to-cubic transformation because the rate of cooling was too slow to permit retention of the hexagonal phase but too fast to permit complete transformation to the cubic phase. (The first-to-freeze tip of the ingot containing 45 m/o CdSe was cubic, apparently because it reached the transition temperature and transformed before the furnace was shut off. In the ingot containing 50 m/o CdSe, a thin outer shell remained hexagonal because it cooled rapidly enough to prevent transformation, but the center was converted to the polytype because it cooled more slowly.) Our experiments do not give any evidence that the polytype is a thermodynamically stable phase rather than a metastable intermediate, since it was not observed in any of the powdered samples which were quenched after annealing. Polytype formation as an intermediate step in the cubic-to-hexagonal transformation of thin films of ZnS has recently been reported (23).

Phase Equilibria Relations in the Ternary System BaO-SrO-Nb_2O_5

J. R. Carruthers and M. Grasso

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Phase equilibria in the binary system SrO-Nb_2O_5 and the Nb_2O_5-rich region of the ternary system BaO-SrO-Nb_2O_5 were investigated by DTA, x-ray diffraction, strip heater, and Curie temperature measurement techniques. The ternary-phase fields of three tetragonal-tungsten-bronze type structures have been located. Only one of these structures is a ternary compound; it is located along the $SrNb_2O_6$-$BaNb_2O_6$ binary join, extending from 20 to 80 m/o $BaNb_2O_6$, and melts congruently near 50% $BaNb_2O_6$. The ternary solubility extends from about 4% excess (Ba + Sr) to about 1% excess Nb_2O_5. This phase possesses observable orthorhombic distortion in the $BaNb_2O_6$-rich region of the solid solution. The implications of the phase diagram for the crystal growth of these compounds are briefly discussed.

The existence of a ferroelectric compound $Ba_xSr_{(1-x)}Nb_2O_6$ (BSN) was independently reported in 1960 by Francombe (1) and Ismailzade (2). The structure was found to be closely related to the tetragonal tungsten bronze structure. The existence regions were found to be $0.30 \leq x \leq 0.80$ by Francombe and $0.35 \leq x \leq 0.75$ by Ismailzade. No indication of the extent of solid solution in the ternary region was given. Both workers reported that the tetragonal structure was distorted to orthorhombic over a part of the range; however, Francombe found the orthorhombic structure for $x < 0.45$, while Ismailzade found the values $x > 0.40$ corresponded to this structure. Both workers also reported that the Curie temperatures varied from 50°C at the high $SrNb_2O_6$ end of the solution to 200°-300°C at the high $BaNb_2O_6$ end. Ismailzade reported that the paraelectric phase was tetragonal over the entire solid solution range.

The first large BSN single crystals were grown in this system by Ballman and Brown (3) over a range of melt compositions $0.25 \leq x \leq 0.75$. Chemical analysis indicated that the solid compositions were quite similar to those of the melt. Also the Curie temperature was found to vary in a similar manner to that found for the ceramic specimens. These crystals have been used by Jamieson, Abrahams, and Bernstein (4) for structure determination as well as Glass (5, 6) for investigations of the electrical properties with special reference to the pyroelectric detection of infrared radiation. These crystals have also been shown to have interesting electro-optic properties (7).

The crystal structure was determined by Jamieson *et al.* (4) for the composition $x = 0.27$ (grown from a melt with $x = 0.25$). In agreement with Ismailzade, the structure was found to be tetragonal tungsten bronze and to belong to the space group P4bm. This structure consists of a framework of NbO_6 octahedra sharing corners so that there are three different types of interstitial sites, two of which may be occupied by Ba or Sr ions. There are five formula units per unit cell so that the five Ba/Sr ions can be distributed on six possible interstitial sites (two A1 sites with distorted tetragonal symmetry and four A2 sites with distorted trigonal symmetry). In addition, it was found, for $x = 0.27$, that only Sr ions were found in the two A1 sites with an occupancy factor of 82.2% and Sr and Ba ions in the four A2 sites with occupancy factors 50.3 and 34.4%, respectively. As Glass (6) points out, if the A1 site continues to be occupied only by Sr ions as the Sr/Ba ratio changes, then the entropy of distribution of the ions becomes a minimum when $x = 0.67$. At this composition, only Sr ions occupy the A1 sites and Ba ions occupy the A2 sites (for the same occupancy factors).

The electrical properties of BSN were investigated by Glass (6) over the solid-solution range and from 10°-500°K. His dielectric constant and electrical conductivity measurements showed a behavior at the Curie temperature which correlated with the degree of randomness in the Ba/Sr distribution. Glass also measured the field and frequency dependence of the dielectric properties and the specific heat and pyroelectric coefficients of BSN.

There have been no phase equilibria studies of the ternary BaO-SrO-Nb_2O_5 system or of the SrO-Nb_2O_5 system. The BaO-Nb_2O_5 system was reported by Roth and Waring (8). The ternary oxide system SrO-NbO_2-Nb_2O_5 has been reported by Ridgley and Ward (9). These studies showed that the compounds $SrNb_2O_6$ (SN) and $BaNb_2O_6$ (BN) existed and possessed a complex and an orthorhombic crystal structure, respectively. In addition, the compounds $3BaO.5Nb_2O_5$ (B_3N_5) and $BaO.3Nb_2O_5$ (BN_3) were observed with distorted tungsten-bronze-type structures. The structures of both SN and BN have been

Key words: phase equilibria, barium strontium niobate, nonlinear optical materials.

observed to be quite sensitive to the valence state of the Nb. Partial reduction of the Nb causes SN to become cubic perovskite with characteristics of the tungsten bronzes (8) while in the case of BN, less direct evidence suggests that a hexagonal phase is stabilized which is apparently an intermediary structure between orthorhombic BN and the tungsten-bronze type structures.

The present investigation was undertaken to complete the ternary BaO-SrO-Nb_2O_5 phase diagram around the tungsten-bronze structures in this system. We wished to establish the crystal-growth equilibria and existence regions for these compounds.

Experimental Procedure

Specimen preparation.—Specimens were prepared from dried $Ba(NO_3)_2$ and $Sr(NO_3)_2$ (Fisher reagent grade) and Nb_2O_5 (CIBA optical grade). Specimens were multiply ground, pelletized, and sintered in air at temperatures 50°C below solidus temperatures. The ternary region along the binary join SN-BN possessed some strange reactivity problems to be discussed later which required the use of a strip heater to obtain completely reacted samples.

Measurements.—DTA measurements were made on a DuPont 1600 Thermoanalyzer. X-ray diffraction measurements were performed on a Nonius-Guinier focusing camera using monochromatic $CuK\alpha$ radiation. Curie temperature (T_c) measurements were made on small ceramic pellets (~ 2 mm on a side) using a General Radio 1673A capacitance bridge at 1 kHz with platinum electrodes. Firm electrode pressure was essential for these measurements. Silver paste electrodes, although used on most specimen surfaces, were found not to be necessary. The Curie temperature was reported as the position of the capacitance maximum, although Glass (6) has shown that this does not exactly coincide with the actual Curie temperature. Nevertheless we are only interested in relative changes in the position of the peak with composition.

Experimental Results

SrO-Nb_2O_5 *system.*—The DTA and x-ray results are shown in Fig. 1. In addition to SN, three new compounds were observed, S_5N_2, S_2N, and S_2N_5. The *d*-spacings for the compounds SrO, S_5N_2, S_2N, and SN are shown in Table I. SrO has a simple cubic structure while S_5N_2 has a hexagonal structure which resembles its counterpart B_5N_2 in the BaO-Nb_2O_5 system (8). The structures of S_2N and SN are seen to be complex and will not be considered further. The structure of S_2N_5 is of the tungsten-bronze type and is identical to that of BN_3. This compound will be discussed later in more detail.

Liquidus temperatures in excess of 1500°C in Fig. 1 were determined by means of an optical pyrometer using SN as a calibration and an iridium strip as the heating source. This method minimized SrO volatilization for these compositions and also insured completion of the reaction. Sintering temperatures of 1400° were insufficient to achieve solid-state reaction over this composition range (0-30% Nb_2O_5).

$SrNb_2O_6$-$BaNb_2O_6$ *pseudobinary system.*—The DTA and x-ray results for the SN-BN binary join are shown in Fig. 2. The structure of $(BSN)_I$ is of the tetragonal tungsten bronze type and will be discussed later. At room temperature, compositions greater than $x = 0.55$ (where x = mole fraction $BaNb_2O_6$) showed orthorhombic splittings in agreement with the work of Ismailzade (2).

It is of some interest here to mention the reactivity problem encountered in this system. Attempts to

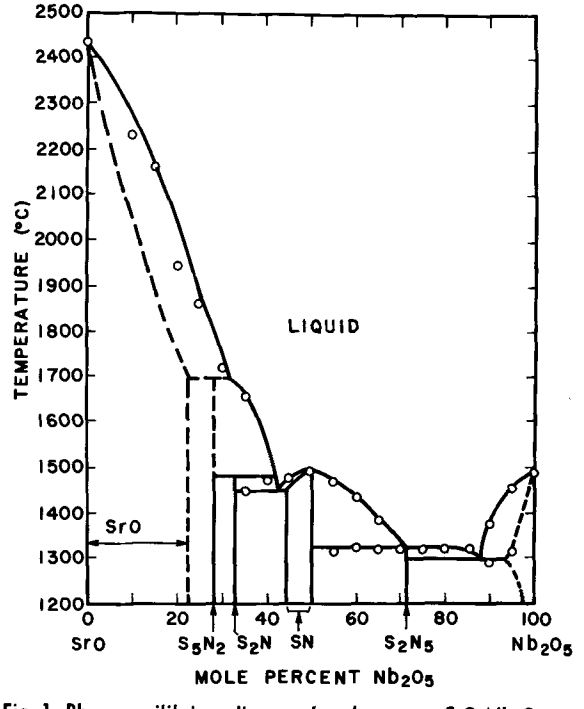

Fig. 1. Phase equilibrium diagram for the system SrO-Nb_2O_5

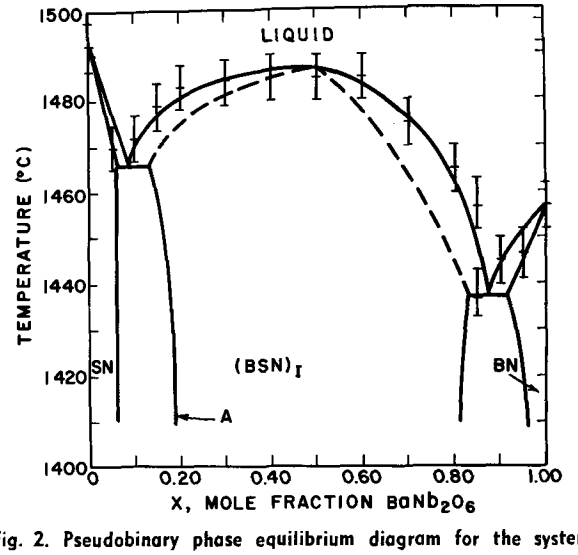

Fig. 2. Pseudobinary phase equilibrium diagram for the system $SrNb_2O_6$-$BaNb_2O_6$.

produce a single-phase BSN by sintering at 1000°C failed completely, even with ten regrindings and using a reducing ambient of 15% H_2-85% N_2 for 6 hr. As the sintering temperature was progressively raised by 100°C increments to 1400°C, the single-phase field opened up starting with the BN-rich end. The solvus line, A, in Fig. 2 moved to the left and was located at 35% BN after sintering at 1400°C. The final location of solvus line A at 20% BN was determined by melting these specimens on a platinum strip heater, slowly freezing under a microscope, and looking for second-phase SN lines with the Nonius-Guinier camera.

The liquidus shown in Fig. 2 is flat within experimental error over the composition range 20-60% BN. The location of the liquidus maximum and associated congruently melting composition was determined with the aid of T_c measurements described later. The solidus lines (shown as dashed lines) were located approximately using the composition shifts reported by Ballman and Brown (3) as guidelines and also the end-points of the eutectic arrest lines (which are observable by DTA).

BaO-SrO-Nb_2O_5 *ternary system.*—The compositions investigated in the ternary oxide region are shown in Table II together with the x-ray and DTA results. The room temperature existence regions are reproduced in Fig. 3 where the compounds $(BSN)_I$, $(BSN)_{II}$, $(BSN)_{III}$, and $(BSN)_{IV}$ have been identified. Data points have been omitted for clarity. These compounds all have tetragonal-tungsten-bronze type structures and the *d*-spacings are given in Table III. Compound I and its orthorhombic modification, II, is the compound shown in the binary join (Fig. 2) and was the subject of the introduction of this paper. Compound III corresponds to the ternary solid solution of B_3N_5, while compound IV corresponds to the ternary solid-solution range of the isomorphous S_2N_5-BN_3 series. Both III and IV show othorhombic splittings as can be seen in Table III.

The high-temperature phase equilibria for these ternary compounds may be seen from the isopleth taken at 25% BaO shown in Fig. 4. The DTA data points are shown as well as the solid-solution extent of the three bronze structures in this particular section. The solidus curves for $(BSN)_I$ are seen to be quite steep, especially in comparison to their behavior in the binary join of Fig. 2. This indicates that growth from melts with compositions off the binary SN-BN join will readily give rise to the usual types of compositional variations in the grown crystals. Compounds $(BSN)_{III}$ and $(BSN)_{IV}$ both melt peritectically in agreement with the behavior observed by Roth Waring (8) in the end members, B_3N_5 and BN_3, respectively.

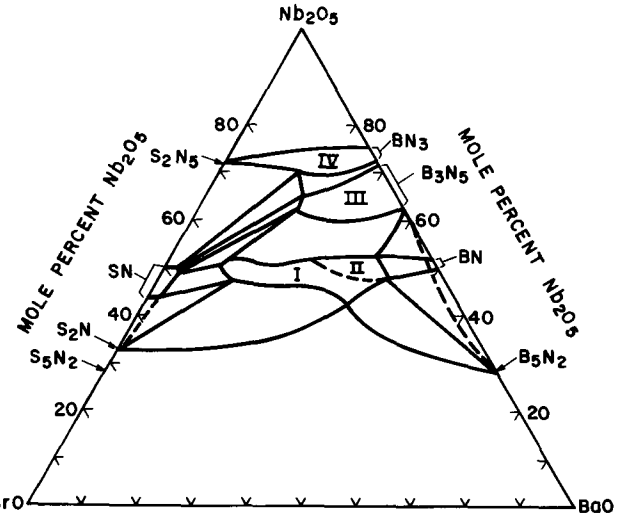

Fig. 3. Ternary phase relationships in the room-temperature isotherm of the system BaO-SrO-Nb_2O_5. Phases I, II, III, IV have tetragonal-tungsten-bronze type structures and the *d*-spacings shown in Table III.

crystals grown from the melt compositions (shown on the abscissa) as reported by Glass (6). Ceramic specimen results are given in terms of solid composition.

The results of Fig. 5(a) will be discussed first. The relationship between the Curie temperature of crystals and ceramics has been used in the binary lithium niobate (10) and lithium tantalate (11) systems to locate the congruently melting composition and establish liquidus-solidus tie lines. It is not strictly possible to use this procedure in ternary systems because the ternary tie lines move on three dimensional surfaces. Nevertheless the technique can be useful in pseudobinary regions such as the SN-BN join. A comparison of the slopes of the solidus curves of Fig. 2 and 4 suggests that melt compositions on the binary join freeze along the binary join. In fact the low values of T_c measured in the 48.0% Nb_2O_5 isopleth support this conclusion. These two observations do not agree with the composition shifts reported by Ballman and Brown (3) on the basis of chemical analysis. The error in the ceramic T_c measurements is quite large in the region 20-50% BN because of the very broad dielectric peaks in this region. This agrees with the results of Glass (6) on crystals in this composition range. We estimate the uncertainty in T_c as ± 8°C at 50% BN. Thus the location of the congruently melting composition is 54 ± 4% BN in the 50% Nb_2O_5 isopleth.

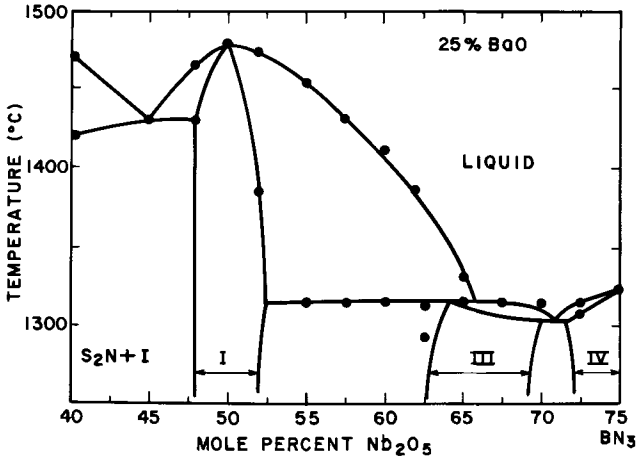

Fig. 4. High-temperature portion of 25% BaO isopleth shown as a function of Nb_2O_5 concentration.

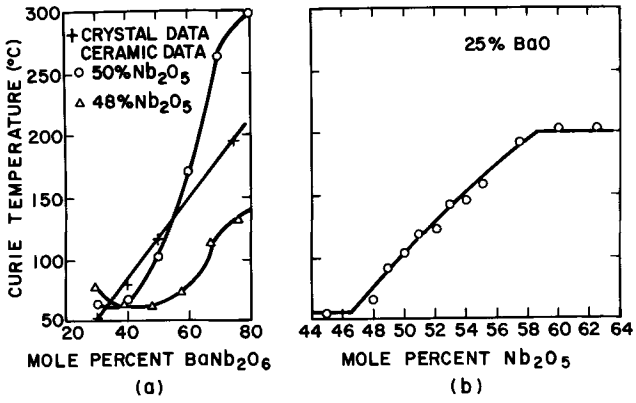

Fig. 5. Curie temperatures as a function of composition (a) along the binary join $SrNb_2O_6$-$BaNb_2O_6$ and (b) along the 25% BaO isopleth (ceramic specimens).

The variation of T_c with Nb_2O_5 concentration is shown for ceramic specimens in Fig. 5(b) along the 25% BaO isopleth. The composition range, 46-52% Nb_2O_5, represents the solid-solution range of $(BSN)_I$ traversed by this isopleth at room temperature. The composition range 52-60% Nb_2O_5 represents the two-phase region $(BSN)_I + (BSN)_{III}$, and the change in T_c corresponds to the change in composition of $(BSN)_I$ along this direction in the two-phase region. An internal check on the consistency of this data is provided by noting that the composition corresponding to the constant value of T_c = 200°C from Fig. 5(b) on the binary section [Fig. 5(a)] is 63% BN. If this point is joined by a straight line to pure Nb_2O_5 on Fig. 3, the line can be seen to pass through the coordinates (60% Nb_2O_5, 25% BaO) at the solid-solution boundary of $(BSN)_{III}$ as would be expected.

The dielectric properties of $(BSN)_{III}$ and $(BSN)_{IV}$ were not studied because the phase diagram indicates that these compounds melt incongruently and cannot be easily prepared as large single crystals. We did observe a capacitance peak at 287°C for specimen No. 150 (compound BN_3). However we observed no capacitance peak for $(BSN)_{III}$ specimens up to 400°C.

Some mention should be made of the early Curie temperature work of Francombe (1) where regions of constant T_c were observed in ceramic specimens across the binary join [phase $(BSN)_I$ and $(BSN)_{II}$]. Our observations in Fig. 5(a) show that T_c varies smoothly. However, very small variations in the (BaO + SrO)/Nb_2O_5 ratio cause large shifts in T_c, and it may be conceivable that Francombe's specimens possessed a variable ratio due to insufficient reaction and consequently scatter in the transition temperature. It is also possible that the disorder of Ba/Sr ions on the A1 and A2 sites may influence T_c in a fashion

similar to that reported by Burns and O'Kane (12) for barium sodium niobate. We observed no shift by fast air cooling from 1000°C. Since our specimens were all furnace cooled to 1000°C, it remained possible that the degree of cation ordering could be influenced by the cooling rate through the range 1300°-1000°C. Although Francombe did not report his preparation technique in detail, it is probable that his specimens were removed from the furnace at 1300°C and air cooled to room temperature in view of the short (1 hr) sintering times used. A check on several of our $(BSN)_I$ specimens with x near 0.5 showed that air cooling from the furnace at 1200°C did in fact decrease T_c by 20°-40°C. We were thus satisfied that the T_c measurements shown in Fig. 5 were made on specimens properly equilibrated with respect to both temperature and composition.

The crystal growth of ferroelectric compounds of controlled or uniform composition and properties requires a knowledge of the high-temperature phase equilibria for the particular system. Recent investigations have been undertaken for lithium niobate (13-15), barium sodium niobate (16-18), strontium potassium niobate (19), and potassium lithium niobate (20). These are all systems which exhibit a wide solid-solution range and a congruently melting composition which is substantially different from the "stoichiometric" composition. In practical crystal growth, we wish to operate as closely to a congruently melting composition as possible in order to avoid the problems associated with the redistribution of an excess component at the growing interface. However the desired properties, such as phase matching temperatures above room temperature, may be obtainable only at noncongruently melting compositions. Consequently, a system such as barium sodium niobate, where the congruently melting composition has desirable properties, is of more practical interest. In the present system, we can therefore eliminate compounds $(BSN)_{III}$ and $(BSN)_{IV}$ as being potential crystal growth candidates, since neither melts congruently at any point in the ternary solid-solution range. However the compound BSN [representing $(BSN)_I$ and $(BSN)_{II}$], which has been grown as large single crystals by Ballman and Brown (3), can be seen from Fig. 2 to melt congruently near 50% BN. Furthermore, the liquidus and solidus curves are very close together for this compound across the pseudobinary SN-BN section. This behavior is reminiscent of the SN-rich region of strontium potassium niobate (19) and the BN-rich region of barium sodium niobate (17, 18). Thus it is possible to prepare large crystals of reasonable optical perfection at compositions other than the congruent composition in this compound. This fact allowed Glass (5, 6) to use crystal compositions in the SN-rich region where there are large pyroelectric effects.

Summary

This investigation of the phase equilibria in the BaO-SrO-Nb_2O_5 system shows the existence of three tetragonal-tungsten-bronze type structures as well as the ternary phase fields. Only one of these structures is a ternary compound; it has the formula $Ba_xSr_{(1-x)}Nb_2O_6$ and has been estimated to melt congruently near $BaO:SrO:Nb_2O_5 = 0.27:0.23:0.50$. This phase possesses a large existence region along the binary $SrNb_2O_6$-$BaNb_2O_6$ join and some adjacent ternary solubility. This structure possesses observable orthorhombic distortion in the $BaNb_2O_6$-rich region.

Acknowledgments

We wish to thank A. A. Ballman and A. M. Glass for many discussions and for providing us with single crystals. We also thank R. A. Laudise for discussions and suggestions.

Thermodynamics of the Iron-Nickel-Oxygen System at 1000°C

A. D. Dalvi** and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

The isothermal section of the Fe-Ni-O system at 1000°C has been defined by determining the compositions and structures of the equilibrated solid phases. Wustite can coexist with Fe-Ni alloys containing up to 79.6 a/o (atomic per cent) Ni. The three-phase field wustite-spinel-alloy consists of wustite containing 0.51 a/o Ni, spinel containing 0.6 a/o Ni, and an alloy containing 79.6 a/o Ni. The three-phase field, spinel-nickel oxide-alloy, consists of nickel ferrite, nickel oxide containing 6.5 a/o Fe, and an alloy containing 99.5 a/o Ni. Tie lines in the spinel-alloy field were investigated in detail. Wustite-nickel oxide solid solutions exhibited nonideal behavior.

The properties of the Fe-Ni-O system at high temperatures where the iron-nickel alloys occur in the form of austenitic solid solution have not been intensively investigated. Brabers and Birchenall (1) determined the equilibrium compositions of wustite, spinel oxide, and alloys containing up to 60 w/o (weight per cent) Ni at 1050°C. The latest available results obtained for temperatures in the range 700°-1100°C are those reported by Viktorovich and Lisovskii (2) and Viktorovich *et al.* (3) for compositions within the wustite-alloy phase field including the limiting compositions of wustite and alloy coexisting with spinel. Values for the dissociation pressures of wustite containing nickel in solid solution have been reported for the temperature of 1000°C by Oriani (4) and Roeder and Smeltzer (5). Accordingly, the purpose of this work has been to obtain more complete knowledge of this ternary system at 1000°C by investigating the nickel-rich region of the phase diagram.

Experimental

Specimens were prepared by two methods. Mixtures of powders containing iron and nickel (99.99 w/o pure) in given proportions and one or more of the C.P. reagent grade oxides (99.6 w/o pure)—nickel oxide, hematite. and nickel ferrite—were compressed into tablets, 12.5 mm diameter and 2 mm thick, at a pressure of 6.5 tons/cm^2 by means of a hydraulic press. In the second method, alloy plates, 2 x 1 x 0.05 cm of various compositions ranging from 40 to 95% Ni were oxidized to desirable degrees in oxygen at 1000°C. The tablets and oxidized alloy specimens were sealed in quartz tubes containing argon [99.99 v/o (volume per cent) pure]. All encapsulated specimens were equilibrated at 1000° ± 2.5°C and then cooled to room temperature within 5 min by means of an air quench. Tablets were equilibrated for 30 days, while the oxidized alloy plates were equilibrated for periods up to 75 days. The phases in the quenched specimens were identified by x-ray techniques using a diffractometer equipped with a copper tube and nickel filter.
